Interactions of Aluminum with Biochars and Oxidized Biochars: Implications for the Biochar Aging Process

Linbo Qian and Baoliang Chen*

Department of Environmental Science and Zhejiang Provincial Key Laboratory of Organic Pollution Process and Control, Zhejiang University, Hangzhou, Zhejiang 310058, China

Supporting Information

ABSTRACT: Interactions of aluminum with primary and oxidized biochars were compared to understand the changes in the adsorption properties of aged biochars. The structural characteristics of rice straw-derived biochars, before and after oxidation by HNO_3/H_2SO_4, were analyzed by element composition, FTIR, and XPS. The adsorption of Al to primary biochars was dominated by binding to inorganic components (such as silicon particles) and surface complexation of oxygen-containing functional groups via esterification reactions. Oxidization (aging) introduced carboxylic functional groups on biochar surfaces, which served as additional binding sites for Al^{3+}. At pH 2.5−3.5, the Al^{3+} binding was significantly greater on oxidized biochars than primary biochars. After loading with Al, the −COOH groups anchored to biochar surfaces were transformed into COO^- groups, and the negative surface charge diminished, which indicated that Al^{3+} coordinated with COO^-. Biochar is suggested as a potential adsorbent for removing Al from acidic soils.

KEYWORDS: *oxidized biochar, carboxyl functional groups, aluminum, aging process, soil remediation*

INTRODUCTION

Biochar is a carbon-rich material produced during the pyrolysis of biomass, and its biogeochemical cycles have received much attention in recent years.[1,2] Following the amendment of contaminated soils or sediments with biochar, physical and biochemical processes (aging) can affect the biochar properties. Yao et al. reported that mineral elements (such as K, S, Ca, and P) were released from biochar during weathering.[3] The formation of carbonyl and carboxylic functional groups on the surface of aged biochar was also observed.[3] This trend was confirmed by long-term studies of the dynamics of black carbon in which the O/C ratios and carboxyl groups of aged biochar increased by over 133 and 192% after the first 10 and 30 years, respectively.[4] Mao et al. used quantitative ^{13}C NMR to show that Terra Preta soils (with char >800 years) consisted predominantly of char residues with about six fused aromatic rings with COO^- substituents.[5] Obviously, oxidation is an important process controlling the quality of biochars and black carbon in the environment.[4]

Typically, minerals (such as P and Si) and oxygen-containing groups in biochars control the mobility and bioavailability of toxic metals in soil amended with biochars.[6−10] Cao et al. reported that the precipitation of phosphorus-containing minerals dominated Pb adsorption.[7] Uchimiya et al. showed that carboxyl functional groups of biochar controlled heavy metal retention in soil, and biochar oxidized by HNO_3/H_2SO_4 (to simulate aging) can enhance this process.[6,11] Qian et al. demonstrated that biochar amendments effectively reduced aluminum (Al) phytotoxicity due to biochar's liming effect and adsorption properties, and the complexation of Al with organic hydroxyl and carboxyl groups and the surface adsorption and coprecipitation of Al with silicate particles both contributed to Al adsorption on biochars.[8,9] However, more studies of the interaction of Al with aged biochar are needed to understand the long-term effects of biochar on the remediation of soils that contain Al.

Aluminum is a major limitation on plant productivity in acidic soils in up to 30% of the world's total land area,[12] and this issue is receiving more attention because of increasing soil acidification trends.[13,14] Biochars can display variable physicochemical properties and, therefore, their interaction with aluminum can vary over the long term. To improve our knowledge of the long-term behavior of biochar in acidic soil, we simulated the oxidative aging of biochars with HNO_3/H_2SO_4 to gain insights into the mechanisms of interactions between biochar and aluminum. A series of biochars were produced from rice straw at different temperatures (350, 500, and 700 °C), and the corresponding oxidized samples were prepared. The structures of biochars before and after oxidation were analyzed by Fourier transform infrared spectra (FTIR) and X-ray photoelectron spectroscopy (XPS). The effect of pH on aluminum adsorption was investigated. To investigate binding mechanisms, the surface and structural changes of Al-loaded biochars were further characterized by FTIR and zeta potential.

MATERIALS AND METHODS

Biochar Preparation and Oxidation. Rice straw (RS) was chosen as a precursor for biochar. Rice straw was collected from the farm at the Zijingang campus of Zhejiang University, Hangzhou, China. Samples were air-dried for 2 days and subsequently oven-dried overnight at 70−80 °C, ground, and then passed through a 0.154 mm sieve to produce raw biomass material. Temperature is presumably a

key parameter affecting the structure of organic and inorganic components, and thus temperature was the controlled variable in this study. On the basis of multiple lots within a specific temperature, biochars were produced by pyrolyzing rice straw at 350, 500, and 700 °C under nitrogen using a modified method.[15,16] Briefly, the powdered rice straw (100 g) was packed tightly in a ceramic pot, covered with a fitted lid, and then pyrolyzed at different temperatures in a furnace (1100-40, Shanghai HAOYUE Instrument and Equipment Co. Ltd., China) under nitrogen atmosphere for 6 h to prevent calcination of the biomass in the presence of oxygen. The heating rate was controlled at 5 °C/min for slow pyrolysis to produce more solid residue (biochar). The charred solids were passed through a 0.154 mm sieve to produce the final biochar samples. Rice straw biochars were referred to as RS350, RS500, and RS700; these numbers refer to the pyrolysis temperatures.

A mixture of concentrated HNO_3 and H_2SO_4 was selected to oxidize these rice straw biochars and simulate the aging process in acidic environments (acid rain), because NO_3^- and SO_4^{2-} were the main anions in acid rain in China[17] and these acids were shown previously to significantly increase the carboxyl content of biochars.[6,18] Biochars were oxidized with an HNO_3/H_2SO_4 mixture (1:3 (v/v)) using a modified method.[6,18] Each biochar sample (5 g) was immersed in 400 mL of a different HNO_3/H_2SO_4 solution, 20, 40, or 60% (e.g., concentrated HNO_3 and H_2SO_4 were mixed at a ratio of 1/3 and then diluted to 20, 40%, or 60%). The other samples without acid oxidation were treated with deionized water instead. The reaction was highly exothermic, so the solution was maintained at 70 °C for 6 h. To remove residual acid, oxidized biochars were first drained through a 325 mesh sieve and then washed repeatedly with 1 L of deionized water for 1 h until the pH stabilized (Supporting Information Figure S1). Samples that were not treated with HNO_3/H_2SO_4 (NS0) were rinsed until the pH reached 7. The oxidized biochar samples are denoted RS350-NS0 (without the HNO_3/H_2SO_4 mixture), RS350-NS20 (oxidized with a 20% solution of the HNO_3/H_2SO_4 mixture), RS350-NS40, and RS350-NS60. After treatment, the RS500 and RS700 samples are denoted RS500-NS0 and RS500-NS60 and RS700-NS0 and RS700-NS60, respectively. The preparation of each biochar and treated biochar was replicated.

Sample Characterization. Elemental (C, H, N) analysis was conducted using an EA112 CHN elemental analyzer (Thermo Finnigan). The Na, K, Ca, and Mg contents in these biochars were extracted by digestion in HNO_3 for 24 h at 150 °C.[19] Elemental concentrations in the extraction solution were determined by inductively coupled plasma atomic emission spectroscopy (ICP-AES). The biochars were also examined using FTIR and XPS analysis. Biochar samples in KBr wafers (0.5%) were prepared for FTIR measurements. The FTIR spectra were recorded in the 4000−400 cm^{-1} region by a Nicolet FTIR spectrophotometer (model 7600, Thermo Scientific, USA) with a resolution of 1.0 cm^{-1}. For XPS analysis, RS350 and RS350-NS60 were tested. The chemical bonding state at the biochar surface was obtained by using an XPS (VG ESCALAB MARK II) with Mg Kα (1253.6 eV) radiation emitted from a double anode at 50 W.

Batch Adsorption Experiment. The adsorption experiment (run in duplicate) was conducted in 8 mL vials by mixing 4 mg of biochar with 8 mL of 0.5 mmol/L $CaCl_2$ (to simulate the soil interstitial water) as a background solution containing 500 μmol/L Al at an initial pH ranging from 2.0 to 4.5. The adsorption experiments including the blank and calibration control were performed in duplicate. The mixtures were agitated on a reciprocating shaker at 120 rpm for 24 h. A preliminary experiment showed that Al sorption reached equilibrium after 12 h. After 24 h, the solid and liquid phases were separated by centrifugation at 3000 rpm for 15 min, and the solution was filtered through a 0.22 μm Millipore filter. The filtrate was acidified immediately with 0.2% (v/v) HNO_3 for Al analysis. The total Al concentration in the supernatant fluid was determined using a Perkin-Elmer Analyst 700 (PE700, USA) atomic adsorption spectrometer equipped with an HGA-800 graphite furnace. The residual solid was vacuum-dried for FTIR analysis.

Zeta Potential Analysis. Surface charge properties of biochars were measured with the zeta potential. Biochar (0.25 g/L) was suspended in deionized water or 100 μmol/L Al solutions and adjusted to pH 1.0−9.0, and the zeta potential was measured with a Zetasizer (Malvern ZEN3690). The pH of the biochar suspensions was adjusted using 1 mol/L HCl or 1 mol/L NaOH. On the basis of the measured total aqueous Al concentration and the final pH value, the concentrations of various Al species, including Al^{3+}, $AlOH^{2+}$, $Al(OH)_2^+$, and $Al(OH)_3^0$, were calculated using the Visual MINTEQ model.[20]

RESULTS AND DISCUSSION

Structural Characterization of Biochars. The chemical properties of the rice straw-derived biochars processed over a range of temperatures and their oxidized derivatives are shown in Table 1. Elemental analysis showed the progressive decrease of the H/C and O/C ratios with increasing pyrolysis temperature, which was attributed mainly to the thermal conversion of organic matter to carbonized organic matter and indicative of the formation of structures containing condensed carbons such as aromatic rings.[16,21−23] After samples were washed with water, the O/C ratio decreased due to the release of soluble minerals. When samples were oxidized with HNO_3/H_2SO_4, the O/C ratio increased to 0.38, 0.29, and 0.21 for RS350-NS60, RS500-NS60, and RS700-NS60, respectively, indicating that oxygen-containing groups were introduced on biochar surfaces. An increase in the O/C ratios was also

dx.doi.org/10.1021/jf404624h | J. Agric. Food Chem. 2014, 62, 373−380

observed when soot and biochars were oxidized using HNO_3/H_2SO_4.[6,24] Meanwhile, the increase of the O/C ratio during the aging of biochars was also confirmed.[25] The nitrogen content in oxidized samples increased with the increasing concentration of HNO_3/H_2SO_4. The nitrogen content of RS350-NS60 was nearly 3-fold greater than that in RS350. This observation is attributed to the treatment with nitric acid.[26]

The FTIR spectra of these rice straw-derived biochars and their oxidized samples are presented in Figure 1. At higher

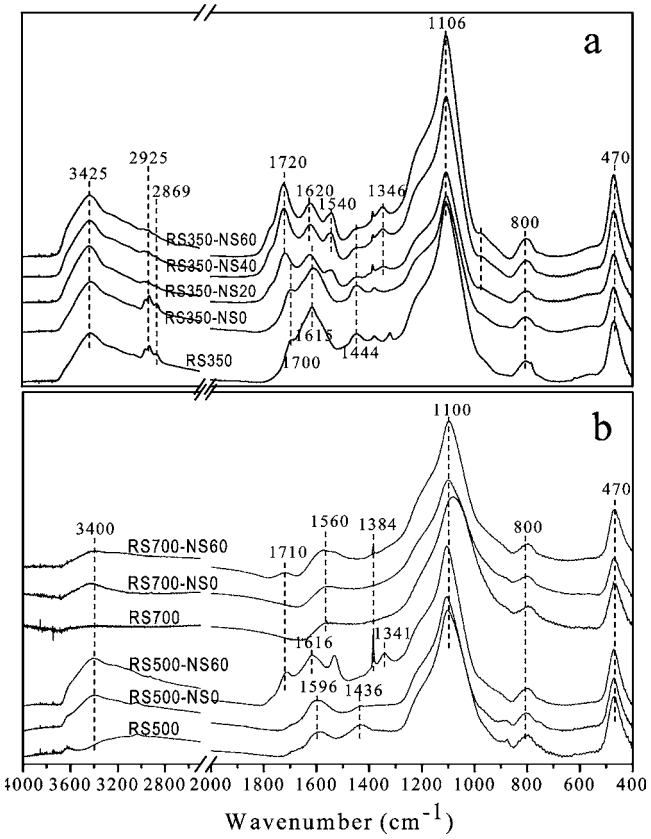

Figure 1. FTIR spectra of the rice straw-derived biochars before and after oxidation using HNO_3/H_2SO_4 (RS350 (a), RS500 and RS700 (b)). The numbers in the sample names represent the pyrolysis temperatures. NS, concentrated HNO_3/H_2SO_4 = 1/3; the following numbers refer to the percent of NS.

pyrolytic temperatures, the intense bands for aliphatic CH_2 groups (2925, 2869, and 1444 cm^{-1}) disappeared abruptly, and the intensity of the band at 1620 cm^{-1} (for aromatic C═C and C═O bonds) diminished for RS500 and RS700, which was attributed to a decrease in the nonpolar groups and the surface functional groups.[16,27] With oxidation by HNO_3/H_2SO_4, there is a large increase in the intensity of the band at 1720 cm^{-1} (the C═O stretching vibration), indicating the increase of carboxyl acid groups of RS350.[6,16,28] An increase in the level of oxygen-containing functionalities strongly suggests that substantial amounts of solid organic oxidation products are formed during the oxidation process (Table 1) and retained on the biochar surfaces. Additionally, the peaks at 1540 and 1346 cm^{-1} are assigned to asymmetric NO_2 and symmetric NO_2 vibration, respectively.[26] The nitric acid mixed with concentrated sulfuric acid formed nitronium ions, which then reacted via electrophilic substitution of the hydrogen ions in the carbon matrix.[24,29] Some studies of activated carbon oxidized by HNO_3 also revealed the presence of nitrate and nitro surface groups.[26,29,30] The oxidized samples of RS500 and RS700 enhanced peaks in these regions to a much lesser extent than RS350. Further analysis of the C and O bonding states was performed by XPS for both RS350 and RS350-NS60 to identify the change in C and O bonding states on biochar surfaces after oxidation by HNO_3/H_2SO_4 (Figure S-2 in the Supporting Information and Figure 2). Figure S-2 showed that the O 1s peak was

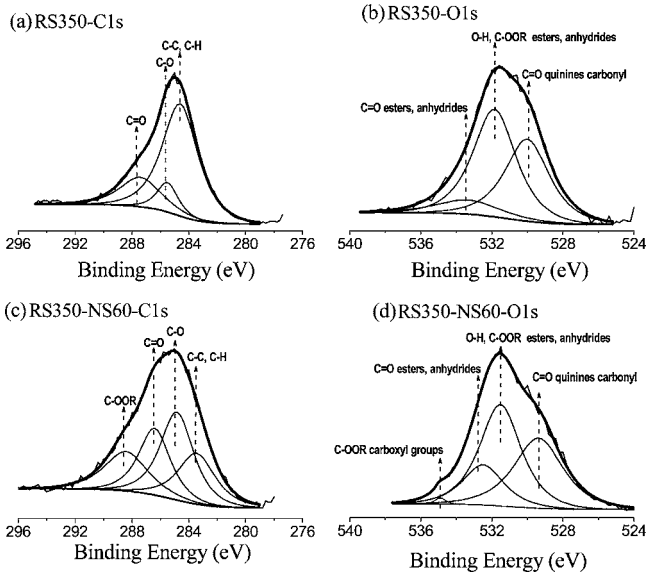

Figure 2. XPS C 1s (a and c) and O 1s (b and d) region scans and peak fitting for rice straw-derived biochars before (RS350, a and b) and after (RS350-NS60, c and d) oxidation using HNO_3/H_2SO_4. The numbers in the sample names represent the pyrolysis temperatures. NS, concentrated HNO_3/H_2SO_4 = 1/3, the following numbers refer to the percent of NS.

strengthened after oxidization. From Figure 2, a new peak appeared at the binding energy of 288.4 eV after HNO_3/H_2SO_4 treatment, which can be attributed to the carboxylic groups, esters, and lactones (−COOR). The new peak appearing at the binding energy of the O 1s spectra (534.9 eV) confirmed that carboxylic groups formed.[31] A previous study about mineral ash-rich biochar geochemical weathering in a modified Soxhlet reactor has also shown a considerable increase in carbonyl and carboxylic functional groups.[3]

The ash content and alkaline elements (Na, K, Mg, and Ca) in biochars increased with temperature (350−700 °C) (Table S-1). When treated with water, the ash content and alkaline elements decreased significantly. Because the alkaline elements were lost during water washing, the pH decreased to neutral (Supporting Information Figure S-1). In samples oxidized by HNO_3/H_2SO_4, the alkaline elements (K, Mg, and Ca) also showed a decreasing trend because these elements were released during oxidation. The release of alkaline elements is a typical process for biochars during geochemical weathering. Previous studies demonstrated that the alkaline elements were released from biochar during weathering or aging.[3] The release of such elements (Ca and Mg) supplies nutrients to plants, but this result also indicated that the liming effect of biochar may be a short-term effect. Unlike alkaline elements, the silicon content in biochar remained high (Figure 1). The bands at 1100−1000, 880−780, and 470 cm^{-1} were characteristic of Si−O−Si asymmetric stretching, symmetric stretching, and bending,

dx.doi.org/10.1021/jf404624h | J. Agric. Food Chem. 2014, 62, 373−380

respectively. All biochars and oxidized samples exhibited a relatively strong Si−O−Si stretching band, which corresponded to results for biochars with high silicon contents.[9] As the concentrations of HNO_3/H_2SO_4 increased, the intensity of the Si−O−Si stretching band became much stronger, indicating that the oxidation process concentrated Si-containing minerals. The XPS data confirmed this observation. After oxidation by HNO_3/H_2SO_4, the intensities of Si 2p and Si 2s were strengthened (Supporting Information Figure S-2). Remarkably, the soluble Si was decreased after water treatment and acid oxidation (Table 1). Notably, Si is common in grasses such as rice but uncommon in biochar from non-Poaceae plants.

Effect of pH on Aluminum Adsorption. The pH-dependent adsorption of Al from aqueous solution on biochar samples is shown in Figure 3. When the initial pH was below

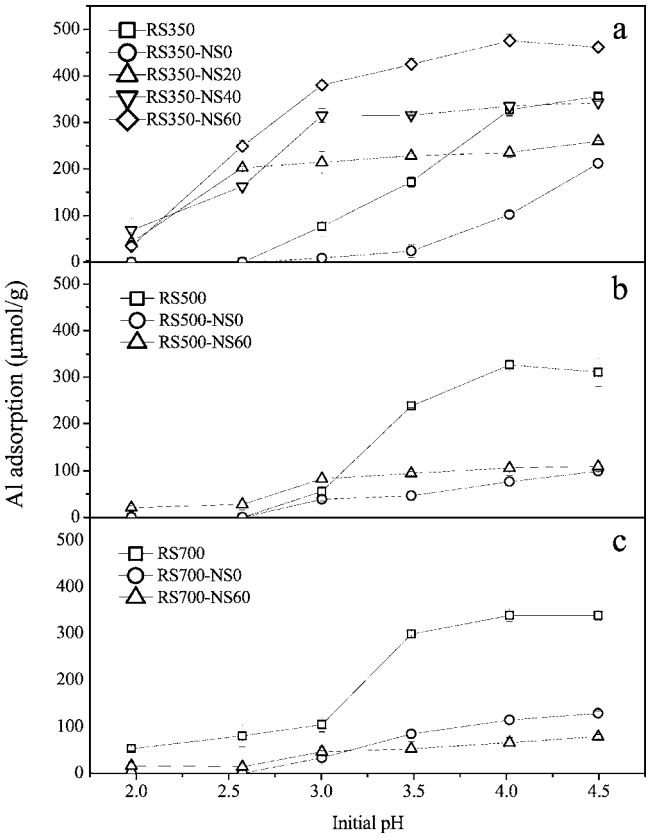

Figure 3. Effect of pH on Al adsorption by rice straw-derived biochars before and after oxidation using HNO_3/H_2SO_4 (RS350 (a), RS500 (b), and RS700 (c)). The numbers in the sample names represent the pyrolysis temperatures. NS, concentrated HNO_3/H_2SO_4 = 1/3, the following numbers refer to the percent of NS. Values are given as the mean ± SD, which are from duplicated experiments.

3.0, little Al adsorption by RS350 and RS350-NS0 was observed. The RS500, RS500-NS0, RS700, and RS700-NS0 samples displayed the same trend. The competition of H^+ led to little electrostatic bonding of Al to biochars. The Al adsorption by oxidized samples occurred at an initial pH of 2.5 and reached 203, 163, and 249 μmol/g for RS350-NS20, RS350-NS40, and RS350-NS60, respectively. This result is attributed primarily to the lower pK_a of oxidized samples. The lower pK_a of oxidized samples was mainly attributed to the nitro groups added to biochar surface (Figure 1 and Figure S-2) and the multicarbxylic groups.[32,33] Nitro groups can form an extended conjugated π-system with the benzene ring and exhibit strong enhancement of the acidity.[33] Additionally, oxidation may also increase the ionic strength of the linear charge density and, thus, lower the pK_a of the oxidized samples. For RS500 and RS700, as the pyrolytic temperature increased, the organic matter carbonized and formed condensed carbons; it is difficult to oxidize, and few carboxylic groups formed on RS500 and RS700 surfaces (Table 1 and Figure 1). Therefore, little Al adsorption by RS500-NS60 and RS700-NS60 occurred below pH 3.0. When the initial pH was increased to 3.5, enhanced adsorption of Al was observed for RS350 (172 μmol/g), RS500 (238 μmol/g), and RS700 (298 μmol/g). These observations may be attributed to the liming effect of primary biochar, and the final pH of RS350, RS500, and RS700 reached 4.14, 4.35, and 4.43, respectively (Figure 4). At these pH values,

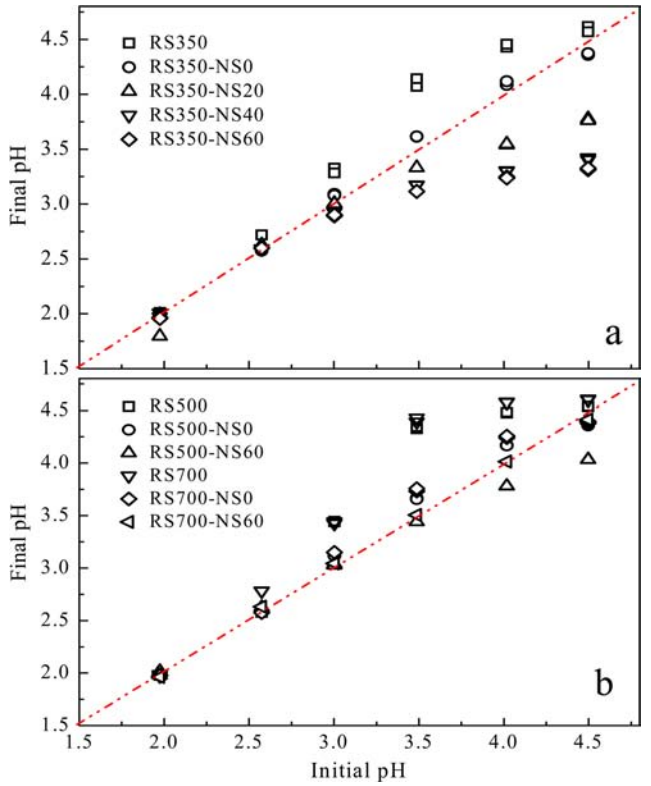

Figure 4. pH changes with Al adsorption by rice straw-derived biochars before and after oxidation using HNO_3/H_2SO_4 (RS350 (a), RS500 and RS700 (b)). The numbers in the sample names represent the pyrolysis temperatures. NS, concentrated HNO_3/H_2SO_4 = 1/3, the following numbers refer to the percent of NS.

some carboxylic groups started to dissociate. Below this pH value, it is possible that the Al hydrolysis reacted with dissociated carboxylic groups and silicon particle.[9,34]

Remarkably, the adsorption of Al by washed biochars (RS350-NS0, RS500-NS0, and RS700-NS0) was significantly lower than that by the corresponding primary biochars. As carboxyl groups formed on oxidized samples (RS350-NS20, RS350-NS40, and RS350-NS60), the adsorption of Al maintained a high level at pH 3.5. When the initial pH value increased to 4.0 and 4.5, Al adsorption by the oxidized samples reached a plateau at pH 4.0, which suggests that available binding sites are saturated by Al. In a comparison, Al adsorption by the primary samples (RS350, RS500, and RS700) increased progressively. This phenomenon may be

dx.doi.org/10.1021/jf404624h | J. Agric. Food Chem. 2014, 62, 373−380

related to the pH-dependent Al adsorption mechanism. At the final pH 4.0−4.5 for adsorption by primary samples, additional Al adsorption sites such as silica surfaces were introduced.[9]

FTIR Spectra of the Biochars before and after Loading with Al. The FTIR spectra of aluminum-loaded RS350 and RS350-NS60 at different pH values are shown in Figure 5. The

peaks at 1609 and 1444 cm^{-1} were assigned to asymmetric and symmetric COO^- stretching, respectively.[35] On the basis of Figure 5, as the initial pH increased, the peak at 1609 cm^{-1} shifted toward higher wavenumbers and the adsorbed aluminum increased. The difference in the calculated wavenumbers between the asymmetric and symmetric COO^- stretching regions increased as the initial pH increased, that is, 169, 169, 169, 170, 172, and 172 cm^{-1} for pH 2.0, 2.5, 3.0, 3.5, 4.0, and 4.5, respectively. The increase in the wavenumber difference between the asymmetric and symmetric COO^- stretching peaks suggested that the adsorption of Al was associated with carboxyl groups.[9,35] Surface complexation, the dominant adsorption mechanism between the carboxylate groups and Al, is attributed mainly to the esterification reactions of carboxylate groups and Al hydrolysis.[34] Furthermore, the band at 1100 cm^{-1} shifted or became broader, and the band at 1160−1200 cm^{-1} became narrower, which indicated that Al reacted with silicon.[9,36]

Increasing numbers of carboxyl functional groups and additional nitro groups were observed after oxidation by HNO_3/H_2SO_4 (Figure 1a), and the FTIR spectra of the aluminum-loaded samples showed more obvious variations (Figure 5b). The bands at 1720 and 1620 cm^{-1} were characteristic of C═O stretching vibrations of ester bonds and C═C or C═O stretching in aromatic rings, respectively.[16] The intensities of the bands at 1720 and 1620 cm^{-1} were reversed when associated with Al. Without added Al, the intensity of the band at 1720 cm^{-1} was stronger than that of the band at 1620 cm^{-1}. After Al was added, the band at 1620 cm^{-1} became more intense, whereas the band at 1720 cm^{-1} became less intense. This was evidence of the conversion of COOH groups to COO^- groups in the biochar.[37] Meanwhile, the changes in the bands at 1720 and 1620 cm^{-1} coincided with the Al adsorption by samples (Figure 3a). This result indicated that carboxyl groups were the adsorption sites of Al. In a previous investigation of the adsorption of Al onto biomaterials derived from the cell walls of *Datura inoxia*, ^{27}Al NMR spectroscopy revealed that carboxylate groups were responsible for Al^{3+} adsorption at pH 3.5.[38]

Zeta Potential of Biochar Particles with and without Al Loading. The results for zeta potential measurements of primary biochars and oxidized samples (with and without added Al) are illustrated in Figure 6 and Figure S-3 in the Supporting Information. Because biochars are amphoteric in nature due to the various functional groups on their surfaces, it is always important to evaluate their isoelectric point (IEP), which is the pH at which the zeta potential is zero. These results show a marked difference in the pH_{IEP} of the primary biochars and the oxidized samples. The pH_{IEP} values for primary biochars were approximately 3.0, 4.0, and 4.0 for RS350, RS500, and RS700, respectively. The organic components ($-COO^-$ and $-OH$) and the mineral fractions both potentially contribute to the biochar surface charge. Without oxidation, the concentrations of oxygen-containing functional groups (e.g., $-COO^-$ and $-OH$) decreased and eventually disappeared as the pyrolysis temperature increased (Figure 1). Crystalline minerals formed (e.g., calcite and albite), and thus RS500 and RS700 had less negative surface charges. In contrast, the pH_{IEP} decreased to approximately 1.0 for oxidized biochars. This sequence indicated that after treatment with HNO_3/H_2SO_4, the biochar surface fixed a larger number of oxygen complexes. The low pH_{IEP} values for oxidized samples are due to the presence of weakly acidic carboxylic functional groups and nitro groups.[29,32,33]

The negatively charged surfaces of the tested samples dramatically changed after they interacted with Al. However, these changes were sample dependent, which indicated that different mechanisms were involved. For RS350 and RS350-NS0, the pH−zeta potential curves before and after Al loading had the same trends when the pH values were below 3.0 (Figure 6a,b). In contrast, the negative surface charge of oxidized samples partially diminished after Al loading at pH 2.0−3.0 (Figure 6c−e). As the dominant Al species at pH 2−3 was Al^{3+}, the free energy of dehydration of Al^{3+} was too large for adsorption to occur on silica-like minerals.[39] The diminished negative surface charge was attributed mainly to the electrostatic attraction of Al^{3+} to biochars. Before oxidation, when the pH value was below 3, none of the primary biochars (except RS700) reacted with Al^{3+}, whereas after oxidation by HNO_3/H_2SO_4, adsorption occurred. This phenomenon demonstrated that Al may concentrate on biochar surfaces following aging processes even in strongly acidic environments.

Mechanisms of Aluminum Adsorption. For primary biochars, Al adsorption was dominated by binding to inorganic

matter (alkaline elements and silicon particles) and surface complexation to functional groups containing organic oxygen by esterification reactions. Qian and Chen found that the organic components and silicate particles within the biochars served as dual adsorptive sites for Al.[9] After aging with water, as the inorganic matter was leached by water, the Al adsorption sharply decreased. For the oxidized samples, the most likely mechanism for aluminum adsorption was the creation of oxygenated adsorption sites by HNO_3/H_2SO_4 oxidation, which was attributed mainly to the electrostatic interaction of Al^{3+} with the negative surfaces of oxidized biochars. This finding was consistent with the adsorption of Pb by mesoporous carbon foams oxidized by HNO_3.[40] It is important to reveal the interaction between the biochar aging process and Al, not only

dx.doi.org/10.1021/jf404624h | J. Agric. Food Chem. 2014, 62, 373–380

because the adsorption capacity increased following the aging process but also to respond to the trend of increasing soil acidity due to acid rain.[13] Furthermore, the existence of ancient, char-rich Terra Preta in the Amazon and similar char-rich soils elsewhere in the world provides important examples of the long-term carbon sequestration potential of anthropogenic amendment with charred organic matter. This long-term carbon stability serves as a durable structure for silica attachment, thus resisting geochemical weathering. Binding organic ligands with Al is likely to increase soil organic carbon storage.[41] Thus, the binding of biochar with Al may increase the stability of biochar. Carbonyl and carboxylic functional groups were formed on biochar surfaces by HNO_3/H_2SO_4 oxidation (simulation of aging processes). The carboxylic functional groups controlled Al adsorption at low pH values of 2.0−3.5 through electrostatic attractions. When pH values were above 3.5, Al adsorption primarily involved complexation with organic hydroxyl and carboxyl functional groups of biochars. Additional coprecipitation and surface adsorption on silica particle surfaces were confirmed by zeta potential measurements. The results indicated that Al concentrated on biochar surface during geochemical weathering. However, the effects of biochar aging should be addressed fully by considering additional processes such as the coating of biochar surfaces by minerals, organic matter, and silt components of soil. Our future studies on biochar biogeochemical samples as well as field trials will provide additional information for implementing large-scale biochar soil amendment.

ABSTRACT: Three series of novel azabridge neonicotinoid analogues were designed and synthesized, which were constructed by starting material **A**, glutaraldehyde, and primary amine hydrochlorides (aliphatic amines, phenylhydrazines, and anilines). Most of the eight-membered azabridge compounds presented higher insecticidal activities than oxabridged compound **B** against cowpea aphid (*Aphis craccivora*) and brown planthopper (*Nilaparvata lugens*). Compared with imidacloprid, some azabridged compounds exhibited excellent insecticidal activity against brown planthopper. The crystal structures and bioassay indicated that changing bridge atoms from O to N could lead to entirely different conformations, which might be the important influential factor of the bioactivities.

KEYWORDS: *oxabridge, azabridge, neonicotinoids, insecticide*

INTRODUCTION

Based on the natural alkaloid nicotine, imidacloprid, discovered by Kagabu et al.,[1] was the forerunner of neonicotinoid insecticides. Moreover, following the organophosphates, carbamates, and pyrethroids, neonicotinoids were regarded as fourth-generation insecticides in modern crop protection.[2] Experimental research indicated that the neonicotinoids act selectively as agonist of the insect nicotinic acetylcholine receptors (nAChRs), one of the most important insect targets in mediating rapid excitatory neurotransmission in the central nervous system (CNS) of piercing−sucking insects.[3−7]

The neonicotinoid compounds have the characteristics of high efficiency, low mammalian toxicity, no cross-resistance, and unique mode of action (MoA), which had showed great development in agriculture and animal health markets in the past 20 years.[8] Recently, Dow AgroSciences launched a neonicotinoid insecticide, Sulfoxaflor[9] (Figure 1), which is a new member of the neonicotinoids.[10]

In our previous work,[11] by introducing succinaldehyde and glutaraldehyde, two unexpected oxabridged compounds, **B** and cycloxaprid (Figure 2), were synthesized. Interestingly, according to the crystallographic diffraction analysis and biological tests, the two oxabridged compounds exhibited large differences in overall conformation and insecticidal activities (Figure 2), which implied that the molecular structure could significantly influence the bioactivities. Therefore, an effort to modify the structure was carried out, in which the oxabridge was converted to an azabridge, by replacing O with N, to increase the insecticidal activities of bridged compounds.

Owing to the difficulties of obtaining succinaldehyde, in this paper, the synthesis and insecticidal activities of three series of eight-membered azabridged neonicotinoids are first reported; these compounds were constructed by starting material **A**,

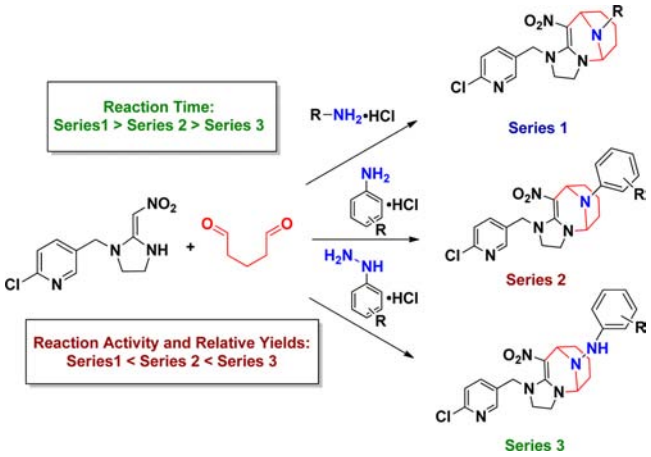
glutaraldehyde, and three kinds of primary amine hydrochlorides (Scheme 1).

Scheme 1. Reaction Route To Synthesize Three Series of Compounds



MATERIALS AND METHODS

Instruments and Chemicals. All melting points were obtained with a Büchi Melting Point B540 and are uncorrected. Nuclear magnetic resonance spectra were recorded on a Bruker AM-400 spectrometer with $CDCl_3$ or DMSO-d_6 as the solvent (^{1}H at 400 MHz and ^{13}C at 100 MHz) and TMS as the internal standard. Chemical shifts are reported in parts per million (δ). Coupling constants (J) are reported in hertz (Hz). High-resolution electron mass spectra (ESI-TOF) were performed on a Micromass LC-TOF spectrometer. Analytical thin-layer chromatography (TLC) was carried out on precoated plates (silica gel 60 F_{254}), and spots were visualized with ultraviolet (UV) light. All other solvents and reagents were obtained from commercial sources without further purification.

General Procedure for the Preparation of Aliphatic Amine Hydrochlorides. The corresponding aliphatic amine (20 mmol) was dissolved in diethyl ether (20 mL). With cooling and vigorous stirring, HCl gas was introduced into the mixture to yield an off-white precipitate. This was collected by filtration, washed with plenty of Et_2O, and used immediately.

General Procedure for the Preparation of Substituted Aniline Hydrochlorides. The corresponding aniline (20 mmol) in ethyl acetate (20 mL) was cooled to 0 °C. A solution of concentrated HCl was dropwise added and adjusted the pH value of the reaction mixture to 1−2. After the addition was completed, precipitate was filtered and washed with less concentrated HCl and ethyl acetate. After drying under vacuum, the obtained corresponding aniline hydrochloride could be used without further purification.

General Procedure for the Preparation of Substituted Phenylhydrazine Hydrochlorides. A suspension of the corresponding aniline (20 mmol) in concentrated HCl (40 mL) was cooled to −10 °C. A solution of $NaNO_2$ (20.2 mmol) in water (2 mL) was dropwise added, keeping the reaction temperature below 0 °C. After 30 min of stirring, a solution of $SnCl_2{\cdot}2H_2O$ (40.4 mmol) in concentrated HCl (15 mL) was slowly added. Amounts of precipitate were immediately formed. After the addition was completed, the mixture was stirred overnight and filtered. The precipitate was washed with less concentrated HCl and dichloromethane. After drying under vacuum, the obtained corresponding phenylhydrazine hydrochloride could be used without further purification.

General Procedure for the Preparation of Three Series. A mixture of starting material **A** (2 mmol), corresponding primary amine hydrochloride (2.5 mmol), and 50% mol NaH_2PO_4 (1 mmol) in acetonitrile (20 mL) was stirred at 0 °C. After 5 min of stirring, 25% glutaraldehyde aqueous solution (1 mL) was added slowly. Then the reaction mixture was stirred at 0 °C to room temperature and monitored by TLC. After completion, the pH value of the reaction mixture was adjusted to 7−8 by saturated aqueous $NaHCO_3$, and the solvent was removed under reduced pressure. The resulting mixture was extracted with dichloromethane (3 × 50 mL), and the organic layer was washed with brine, dried over anhydrous sodium sulfate, filtered, and concentrated. The residue was purified by silica gel column chromatography to afford the corresponding product.

Series 1: Compounds 1a−1d. *1-((6-Chloropyridin-3-yl)methyl)-11-methyl-10-nitro-1,2,3,5,6,7,8,9-octahydro-5,9-epiminoimidazo-[1,2-a]azocine (**1a**):* yield, 51.5%; mp, 165.6−166.2 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.37 (d, J = 1.6 Hz, 1H), 7.84 (dd, J = 8.0, 2.0 Hz, 1H), 7.52 (d, J = 8.0 Hz, 1H), 4.88 (d, J = 15.2 Hz, 1H), 4.74 (d, J = 15.2 Hz, 1H), 4.20 (s, 1H), 3.96 (s, 1H), 3.77−3.49 (m, 4H), 2.11 (s, 3H), 1.84−1.68 (m, 2H), 1.66−1.51 (m, 2H), 1.48−1.35 (m, 1H), 1.17−0.98 (m, 1H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 156.66, 149.78, 149.74, 139.91, 133.33, 124.48, 104.10, 72.83, 56.33, 51.63, 49.76, 49.06, 47.15, 29.41, 28.20, 15.45; HRMS (ES+) calcd for $C_{16}H_{20}{}^{35}ClN_5O_2Na$ $(M + Na)^+$ 372.1203; found, 372.1185; calcd for $C_{16}H_{20}{}^{37}ClN_5O_2Na$ $(M + Na)^+$ 374.1174; found, 374.1168.

*1-((6-Chloropyridin-3-yl)methyl)-11-ethyl-10-nitro-1,2,3,5,6,7,8,9-octahydro-5,9-epiminoimidazo[1,2-a]azocine (**1b**):* yield, 20%; mp, 130.4−131.1 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ 8.36 (d, J = 2.4 Hz, 1H), 7.83 (dd, J = 8.4, 2.4 Hz, 1H), 7.52 (d, J = 8.4 Hz, 1H), 4.86 (d, J = 15.6 Hz, 1H), 4.75 (d, J = 15.6 Hz, 1H), 4.32 (s, 1H), 4.10 (s, 1H), 3.76−3.50 (m, 4H), 2.37−2.20 (m, 1H), 2.19−2.06 (m, 1H), 1.84−1.72 (m, 2H), 1.66−1.50 (m, 2H), 1.50−1.40 (m, 1H), 1.20−1.04 (m, 1H), 0.95 (t, J = 7.2 Hz, 3H); ^{13}C NMR (100 MHz, DMSO-d_6) δ 157.34, 149.78, 149.73, 139.90, 133.01, 124.45, 104.84, 71.35, 53.86, 51.58, 49.82, 49.06, 47.17, 29.48, 28.41, 16.13, 13.18; HRMS (ES+) calcd for $C_{17}H_{23}{}^{35}ClN_5O_2$ $(M + H)^+$ 364.1540; found, 364.1535; calcd for $C_{17}H_{23}{}^{37}ClN_5O_2$ $(M + H)^+$ 366.1511; found, 366.1517.

X-ray Diffraction Analysis. Compound **2a** was recrystallized by slow evaporation from a mixture of acetone, dichloromethane, and cyclohexane to afford a suitable single crystal. Green blocks of **2a** (0.23 mm × 0.18 mm × 0.13 mm) were mounted on a quartz fiber. Cell dimensions and intensities were measured at 293 K on a Bruker SMART CCD area detector diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å); θ_{max} = 25.99°; 11673 measured reflections; 3763 independent reflections (R_{int} = 0.0277). Data were corrected for Lorentz and polarization effects and for absorption (t_{min} = 0.4568 and t_{max} = 1.0000). The structure was solved by direct methods using SHELXS-97;[12] all other calculations were performed with a Bruker SAINT System and Bruker SMART programs.[13] Full-matrix least-squares refinement based on F^2 using the weight of $1/[\sigma^2 (F_o^2) + (0.0613P)^2 + 0.0371P]$ gave final values of R = 0.0331, ωR = 0.0844, and GOF (F) = 1.035 for 263 variables and 3763 contributing reflections. Maximum shift/error = 0.000(3) and max/min residual electron density = 0.178/−0.156 e Å^{-3}. Hydrogen atoms were observed and refined with a fixed value of their isotropic displacement parameter.

Compound **3o** was recrystallized by slow evaporation from a mixture of acetone, dichloromethane, and cyclohexane to afford a suitable single crystal. Yellow blocks of **3o** (0.36 mm × 0.30 mm × 0.20 mm) were mounted on a quartz fiber. Cell dimensions and intensities were measured at 293 K on a Bruker SMART CCD area detector diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å); θ_{max} = 32.64°; 24369 measured reflections; 7970 independent reflections (R_{int} = 0.0222). Data were corrected for Lorentz and polarization effects and for absorption (t_{min} = 0.9203 and t_{max} = 0.9546). The structure was solved by direct methods using SHELXS-97; all other calculations were performed with a Bruker SAINT System and Bruker SMART programs. Full-matrix least-squares refinement based on F^2 using the weight of $1/[\sigma^2 (F_o^2) + (0.0613P)^2 + 0.0371P]$ gave final values of R = 0.0378, ωR = 0.1077, and GOF (F) = 1.033 for 325 variables and 7970 contributing reflections. Maximum shift/error = 0.000(3) and max/min residual electron density = 0.521/−0.639 e Å^{-3}. Hydrogen atoms were observed and refined with a fixed value of their isotropic displacement parameter.

Biological Assay. All bioassays were performed on representative test organisms reared in the laboratory. The bioassay was repeated at 25 ± 1 °C according to statistical requirements. All compounds were dissolved in *N*,*N*-dimethylformamide (AP, Shanghai Chemical Reagent Co., Ltd., Shanghai, China) and diluted with distilled water containing Triton X-100 (0.1 mg L^{-1}) to obtain series concentrations of 500, 100, and 4 mg L^{-1} and others for bioassays. For comparative purposes, imidacloprid, cycloxaprid and oxabridged compound **B** were tested under the same conditions.

Insecticidal Test. The insecticidal activities of the synthetic compounds against cowpea aphid (*Aphis craccivora*) and brown planthopper (*Nilaparvata lugens*) were tested according to our previously reported procedure.[11,14]

RESULTS AND DISCUSSION

Synthesis. Generally, the eight-membered nitrogen-containing rings (azocines) were constructed by intra- or intermolecular reactions.[15,16] Among these, Robinson−Schöpf reaction was regarded as a classical and efficient intermolecular methodology to synthesize azabridged bicyclic systems, which involved 1,3-dicarbonyl compounds, methylamine hydrochloride, and dialdehydes via double-Mannich condensation.[17] Thus, by comparing the 1,3-dicarbonyl derivatives and cyclic β-nitroenamines (starting material **A**), it was discovered that these two structures have very similar nucleophilic centers (Figure 3), which indicated the possibility of synthesizing eight-membered azabridge neonicotinoid analogues by reacting with various primary amine hydrochlorides and glutaraldehyde (Scheme 2).

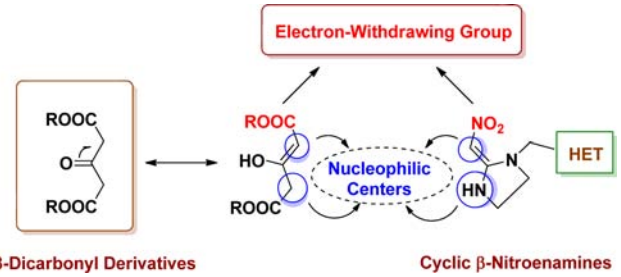

Figure 3. Structural comparison of the 1,3-dicarbonyl derivatives and cyclic β-nitroenamines.

When compound **1a** was synthesized, oxabridged compound **B** and a lot of unreacted starting material **A** were observed, which resulted in low yield (Table 1, entry 1). To optimize this reaction, several buffer salts and Lewis acids, such as $MgCl_2$, $NiCl_2$, $BF_3{\cdot}Et_2O$, $ZnCl_2$, $CoCl_2$, NH_4OAc, NaH_2PO_4, and Na_2HPO_4, were investigated (Table 1, entries 2−9). According to the screening of catalysts, NaH_2PO_4 presented higher yield. Furthermore, through adjusting the amounts of NaH_2PO_4, it was observed that 50 mol % was more appropriate to the reaction (Table 1, entry 10). Then, the influence of reaction temperature was studied. The results showed that increasing the reaction temperature led to decreasing yields. However, when the temperature was below 0 °C, the yield of **1a** was no longer improved (Table 1, entries 10 and 12−14). The effect of the solvent in the reaction was also investigated; various solvents such as acetonitrile, tetrahydrofuran (THF), H_2O,

[a]All reactions were performed with glutaraldehyde (1.2 equiv mol), methylamine hydrochloride (1.2 equiv mol), and starting material **A** (1 equiv mol). [b]All reaction time were 12 h. [c]Yields were determined by HPLC. [d]No reaction. [e]Trace.

acetone, EtOH, CH_2Cl_2, 1,2-dichloroethane, and dioxane were employed. According to the yields of HPLC, acetonitrile was more suitable to carry out the reaction (Table 1, entries 13 and 15−22).

On the basis of the optimizations above, various aliphatic amine hydrochlorides were introduced to obtain series **1** (compounds **1a**−**1d**). With the extension of the alkyl chains, it was found the R_f values of the corresponding compounds were very close to those of the unreacted starting material **A** or oxabridged compound **B**, which resulted in the difficulties of isolation. For studying the effects of substituents on the bridged nitrogen atom, other primary amine hydrochlorides such as aniline hydrochlorides (series **2**) and phenylhydrazine hydrochlorides (series **3**) were employed. Consequently, another two series of azabridged analogues were synthesized. Compared to series **1**, the compounds of series **2** and **3** could be obtained with higher yields and the reaction could finish in shorter reaction time because of the different reaction activities among the three primary amine hydrochlorides (Scheme 1). However, the oxabridged compound **B** was still observed in the mixtures, which led to the low yields.

Crystal Structure Analysis. Azabridged compounds **2a** and **3o** were recrystallized by slow evaporation from mixed solvent of dichloromethane and acetone (v/v = 1:1), and their single-crystal structures were determined by X-ray crystallography as illustrated in Figures 4 and 5.

In these two crystal structures, the pharmacophore nitro groups lay approximately in the same plane with the imidazole ring. Under the delocalization role of the lone pair electron on the amine and the electron-withdrawing effect of the nitro group, a coplanar olefin-amine extended π electron network was formed in these two compounds. It resulted in the corresponding bond lengths of C—N (Table 2, entries 3 and 4) being shorter than the typical C—N single bond (1.47 Å) but close to the length of C═N (1.33 Å).[18,19] The bond lengths of C═C in **2a** and **3o** were 1.408 and 1.401 Å, respecitvely, which were longer than the normal C═C (1.34 Å), and the C—NO_2 was shorter than the typical C—NO_2 (1.49 Å) (Table 2, entry 1). Whereas the pyridine ring and the bridged oxygen atom of oxabridged compound **B** were directed in same orientation,[11] the pyridine and benzene rings of **2a** pointed in opposite directions. For **3o**, the directions of the nitrogen atom in the pyridine plane and the bridged nitrogen atom were contrary. Obviously, from the crystal structures, it was exhibited that the changing of bridge atoms or the substituents of the bridged nitrogen atom could lead to entirely different conformations, which might be important influential factors of the bioactivities.

3	N(2)−C(7)	1.347	N(2)−C(9)	1.373
4	N(3)−C(7)	1.344	N(3)−C(9)	1.350

Insecticidal Activities. The insecticidal activities of series **1** are shown in Table 3. At the concentration of 100 mg L^{-1}, the mortality of all tested compounds reached 100% against cowpea aphid (*A. craccivora*) and brown planthopper (*N. lugens*). Compared with imidacloprid, compounds **1b** and **1c** exhibited excellent insecticidal activity against brown planthopper (Table 6).

Table 3. Insecticidal Activities of Series 1

		mortality (%)			
		Aphis craccivora		*Nilaparvata lugens*	
compd	R	100 mg L^{-1}	4 mg L^{-1}	100 mg L^{-1}	4 mg L^{-1}
1a	Me	100	20	100	10
1b	Et	100	0	100	100
1c	i-Pr	100	0	100	90
1d	n-Pr	100	50	100	20
B		0	0	100	0
cycloxaprid		100	100	100	100
imidacloprid		100	100	100	100

The insecticidal activities of series **2** are listed in Table 4. Most of the azabridged compounds showed 100% mortality at 500 mg L^{-1}, which were higher than the oxabridged compound **B** against cowpea aphid. Compared to the unsubstituted compound **2a**, introducing electron-withdrawing groups, electron-donating groups, or halogen atoms did not contribute to great improvement of the bioactivities of the corresponding compounds. Moreover, when a bromine atom was introduced into the phenyl ring, related compounds **2e**, **2i**, and **2l** showed lower insecticidal activity than oxabridged compound **B** against cowpea aphid, which indicated that a bromine atom on position 2 or 4 of the phenyl ring would decrease the insecticidal activity. Meanwhile, compounds **2c**, **2g**, **2h**, and **2n** with electron-donating groups or halogen atoms (except Br) on position 2 of the phenyl group showed relatively high mortality at 4 mg L^{-1} against cowpea aphid, which confirmed that position 2 was the key substitution site for structural derivation to obtain high-activity molecules.

The bioactivities of series **3** are shown in Table 5. At the concentration of 100 mg L^{-1}, the mortality of most tested compounds reached 100% against cowpea aphid and brown planthopper, which was much higher than that of oxabridged compound **B**. Introducing halogen atoms into position 2 (**3e**, **3t**, and **3u**) and position 4 (**3c**, **3f**, and **3g**) of the phenyl ring could increase the activity against brown planthopper. Furthermore, the compounds with electron-donating groups

on position 3 (**3j** and **3s**) also had higher insecticidal activity against brown planthopper compared with unsubstituted compound **3a**.

In conclusion, three series of eight-membered azabridged neonicotinoid analogues were designed and synthesized. All of the target compounds were obtained in optimized reaction conditions. The azabridged compounds constructed by aliphatic amine and phenylhydrazine hydrochlorides exhibited excellent insecticidal activities against cowpea aphid and brown planthopper among three series. On the basis of the LC_{50} values (Table 6), compounds **1b**, **1c**, **3c**, **3g**, **3j**, and **3r** showed higher bioactivity than imidacloprid against brown planthopper (Table 6). Most of the azabridged compounds presented higher bioactivities than eight-membered oxabridged compound **B** against cowpea aphid and brown planthopper, which indicated that the modification on the bridge atom was an effective strategy to discover new candidates as pesticides. However, the insecticidal activities against cowpea aphid and brown planthopper were lower than that of seven-membered oxabridged compound cycloxaprid. Therefore, the obtaining of seven-membered azabridges and study of their biological behavior are underway.

ABSTRACT: The aroma and aroma-active compounds of olive oils obtained from Nizip Yaglik (NY) and Kilis Yaglik (KY) cultivars and the effect of the geographical area (southern Anatolian and Aegean regions) on these compounds were analyzed by gas chromatography−mass spectrometry−olfactometry (GC-MS-O). For this purpose, two oil samples were obtained from their native geographical area including NY from Nizip province and KY from Kilis province (southern Anatolian region of Turkey). Another two oils of the same cultivar, NY-Bornova (NY-B) and KY-Bornova (KY-B), were obtained from the Olive Oil Research Center-Bornova, Izmir province (Aegean region of Turkey) to compare geographical effect on aroma and aroma-active compounds. Simultaneous distillation and extraction (SDE) with dichloromethane was used for extraction of volatile components. SDE gave a highly representative aromatic extract of the studied olive oil based on the sensory analysis. Totals of 61, 48, 59, and 48 aroma compounds were identified and quantified in olive oils obtained from NY, NY-B, KY, and KY-B cultivars, respectively. The results of principal component analysis (PCA) showed that the aroma profile of native region oils was discriminately different from those of Bornova region oils. Aldehydes and alcohols were qualitatively and quantitatively the most dominant volatiles in the oil samples. Aroma extract dilution analysis (AEDA) was used for the determination of aroma-active compounds of olive oils. The number of aroma-active compounds in native region oils was higher than in Bornova region oils. Within the compounds, aldehydes and alcohols were the largest aroma-active compounds in all olive oils.

KEYWORDS: *olive oil, olfactometry, aroma, aroma-active compounds, geographical effect*

INTRODUCTION

Olive oil is obtained from the olive (*Olea europaea*), a traditional tree crop of the Mediterranean area. It is almost unique among oils as it can be consumed in crude form without refining, possessing increased stability as well as nutritional and healthy features with respect to other vegetable oils.[1] According to olive oil production data released in 2012, Spain (992,000 tonnes), Italy (570,000 tonnes), Greece (351,800 tonnes), Turkey (206,300 tonnes), Syria (200,000 tonnes), and Tunisia (192,600 tonnes) are the leading production countries.[2]

Aroma compounds stimulate much more qualities and therefore are mainly responsible for the characteristic flavor of foods.[3] Olive oil aroma consists of a complex mixture of volatile compounds, which includes mainly aldehydes, alcohol, ketones, and esters. Enzymatic reactions and autoxidation play crucial roles in the occurrence of aroma substances. The formation of these compounds starts at the moment of cell disruption during crushing of olives and continues during the extraction process. Synthesis of the aroma compounds of virgin olive oil (VOO) occurs through the lipoxygenase (LOX) pathway comprising mainly the actuation of LOX and hydroperoxide-lyase enzymes. The volatile compounds found in virgin olive oil are mainly C-6 and C-5 compounds biogenerated from polyunsaturated fatty acids through the lipoxygenase pathway. These compounds are mainly responsible for the characteristic aroma of olive oil, which is of prime importance in the food industry, because it plays a significant role in consumer choice.[4−6]

More than 180 different aroma compounds have been found in olive oils.[6] However, it is well-accepted that only a small fraction on the large number of volatile compounds occurring in food actually contribute to the overall aroma. The technology of gas chromatography−olfactometry (GC-O) made it possible to divide identified volatiles into odor-active and non-odor-active compounds with regard to their existing concentration in the studied sample.[7,8] Limited numbers of researchers have analyzed the aroma-active compounds of olive oils: Guth and Grosch[9] determined potent odorants of different virgin olive oils using aroma extract dilution analysis (AEDA). They indicated that (*Z*)-3 hexenol, (*E*)-2-hexenal, and (*Z*)-3-hexenal were mainly responsible for the green odor notes of four different olive oils. Reiners and Grosch[10] studied the aroma-active compounds of virgin olive oils from Italy, Spain, and Morocco by AEDA and GC-O of headspace samples. Morales and Aparicio[7] investigated the best extraction conditions (temperature and time of malaxing) on the basis of odor-active compounds that are responsible for the unique

attributes of virgin olive oil. Collin et al.[11] determined the aroma-active compounds in extracts obtained by simultaneous extraction/distillation (SDE) of Moroccan black and green olives. In this study, odor-active compounds were identified by using the AEDA method and GC-O.

Cultivar is one of the most important factors that significantly influences volatile compound composition and sensorial characteristics of virgin olive oil. The same olive cultivar grown in different locations produces oils with different volatile profiles.[6] In addition to cultivar, the degree of fruit ripening, environment, growing season, traditional growing habits of various cultivars, extraction methods, processing techniques, and storage conditions affect the aroma profiles of olive oils.[12,13] It is well-known that VOO obtained from different cultivars, under identical growth conditions, harvested at roughly equal ripeness degree, and processed in the same manner, is characterized by more or less different composition and concentration of minor components.[8,14]

Up to now, there is no information on the identification of the main odorants in Turkish olive oils. NY and KY are economically important cultivars to olive production of the southern Anatolian region and used mainly for producing oil. Therefore, the aim of the present study was to investigate aroma and aroma-active compounds in two of the most important monovarietal olive oils (cvs. Nizip Yaglik (NY) and Kilis Yaglik (KY)) produced in two geographical areas of Turkey. Before the GC-MS-O analysis, the aromatic extract obtained from SDE was analyzed by sensory evaluation to assess its representativeness.

MATERIALS AND METHODS

Chemicals. The water used in the study was purified by a Millipore-Q system (Millipore Corp., Saint-Quentin, France). The reference aroma compounds were obtained from the following sources: Hexanal, (*E*)-2-pentenal, (*E*)-2-hexenal, (*Z*)-3-hexenal, nonanal, nonanol, (*E*)-2-heptenal, (*E*)-2-octenal, and (*E*)-2-decenal were obtained from Fluka (Buchs, Switzerland). 2-Methyl-1-propanol, 1-penten-3-ol, pentanol, 3-penten-2-ol, hexanol, (*E*)-3-hexenol, (*Z*)-3-hexenol, (*E*)-2-hexenol, 2-hexanol, heptanol, 2-ethyl-1-hexanol, (*Z*)-2-pentenol, phenol, hexyl acetate, (*Z*)-3-hexenyl acetate, ethyl salicylate, methyl palmitate, ethyl palmitate, limonene, linalool, (*Z*)-4-heptenal, 1-octen-3-ol, (*E*)-2-nonenal, benzaldehyde, (*E*,*E*)-2,4-heptadienal, (*E*,*E*)-2,4-decadienal, δ-octalactone, γ-nonalactone, γ-decalactone, δ-decalactone, δ-dodecalactone, and γ-dodecalactone were purchased from Sigma-Aldrich (Steinheim, Germany). Octanal, octanol, (*E*)-2-octenol, heptanal, benzyl alcohol, 2-phenylethanol, 6-methyl-5-hepten-2-one, β-pinene, α-copaene, α-farnesene, farnesol, acetic acid, octanoic acid, nonanoic acid, decanoic acid, hexanoic acid, dodecanoic acid, and guaiacol came from Merck (Darmstadt, Germany). Pentane, dichloromethane, 4-nonanol, sodium chloride, and sodium sulfate were also obtained from Merck (Darmstadt, Germany). Dichloromethane was freshly distilled prior to use. All chemicals used as standards and solvents were of GC grade having purity up to 99.0%.

Olives. Olive varieties (NY, KY, NY-B, and KY-B) averaging 50−70 kg were used in this study. Two olive samples were obtained from their native geographical area including NY from Nizip province and KY from Kilis province (southern Anatolian region of Turkey). To investigate geographical effect, the same olive cultivars were bought from the Olive Research Center located in Bornova-Izmir province (NY-B and KY-B; Aegean region of Turkey). Sound olives were harvested at the optimum maturity stage in 2011 seasons. The maturity indices were calculated according to the International Olive Oil Council method.[15]

Extraction of the Olive Oils. First, leaves were removed and then the healthy olives washed with water. Then, the cold-press with dual-phase centrifuge (Olio Mio Mini, Italy) was used for olive oil extraction. Cold-press has been a widely used method for many years to produce high-quality olive oils.[16] Olives in the mill after grinding for 30 min underwent malaxation (kneading). Then fractions were divided into decanters. These fractions were oil and wastewater plus oil cake. Fresh olive oils were put into glass bottles and were kept in a dark and cool place until analysis.

Standard Chemical Analysis. Moisture, oil content, percentage of free fatty acidity, and peroxide values of the samples were calculated following the methods described in the regulation of the European Economic Commission.[17] The color of the olive oil was measured in a colorimeter using a HunterLab Color QuestXE (Reston, VA, USA). Results for L^*, a^*, and b^* color system profile were recorded using CIE. Measurements were made at room temperature. Olive oils were placed in a sample cell (6 cm diameter), 2 cm deep, and the data were read.

Extraction of the Volatile Compounds. The volatile compounds of olive oils were extracted by SDE in a Likens-Nickerson apparatus (Neubert-Glas, Geschwenda, Germany). This method has already shown its reliability for the extraction of volatile components of olive oils.[18,19] For the extraction, 40 mL of olive oil, 100 mL of pure water, 25 mL of 30% NaCl, and 40 μg of 4-nonanol as the internal standard were put into a 500 mL distillation flask on one hand, and on the other 40 mL of dichloromethane solvent was pipetted into another (a 100 mL distillation flask). Both flasks were placed in a heater, and then extraction was performed for approximately 3 h. The temperatures of the sample mixture and the dichloromethane flasks were maintained by a water bath at 70 and 50 °C, respectively. After the dehydration by anhydrous sodium sulfate, the resulting organic extract was condensed to 5 mL in a Kuderna Danish concentrator (Sigma-Aldrich, St. Louis, MO, USA) and then to 200 μL under a gentle stream of pure nitrogen.[18] Olive oils were extracted in triplicate, and three independent extracts were obtained for each sample. The extracts were subsequently kept at −20 °C in a 2 mL glass vial before the analysis.

Representativeness Test of the Extract. *Sample Preparation and Presentation.* The panel was composed of seven assessors (two females and five males between 25 and 46 years old) from the Department of Food Engineering, University of Cukurova. The assessors were previously trained in odor recognition and sensory evaluation techniques and had experience in gas chromatography−olfactometry. In the present study, we used a cardboard smelling strip (reference 7140 BPSI, Granger-Veyron, Lyas, France) for checking the representativeness of the aromatic extract obtained by SDE. Smelling strips have already given good results for the representativeness test of orange juice[20] and Dwarf Cavendish banana extracts.[21] Two solvents (dichloromethane and pentane plus dichloromethane) were evaluated for the representativeness using SDE. First, 5 mL of olive oil was placed in a 25 mL brown coded flask as a reference for representativeness tests. Olive oil aromatic extracts obtained from two solvents were adsorbed onto a cardboard smelling strip. After 1 min (the time necessary for solvent evaporation), the extremities of the strips were cut off, and then they were placed in dark coded flasks (25 mL) and presented to the panel after 15 min. Dichloromethane and pentane/dichloromethane (2:1) are very volatile solvents. After evaporation, no panelists detected the odor of the solvents. Samples were assessed at room temperature (20 °C) and in neutral conditions.

Similarity and Intensity Tests. Similarity and intensity tests were performed to demonstrate the closeness between the odor of extracts and the olive oil. These test procedures were well documented in our previous studies.[20] Results were analyzed with an analysis of variance with Statgraphics Plus software (Manugistic, Inc., Rockville, MD, USA).

GC-FID, GC-MS, and GC-MS-O Analyses of Aroma Compounds. The GC system consisted of an Agilent 6890 chromatograph equipped with a flame ionization detector (FID) (Wilmington, DE, USA), an Agilent 5973-network-mass selective detector (MSD), and a Gerstel ODP-2 (Linthicum, MD, USA) sniffing port using deactivated capillary column (30 cm × 0.3 mm) heated at 240 °C and supplied with humidified air at 40 °C. This system allowed us to simultaneously obtain a FID signal for the quantification, an MS signal for the

identification, and the odor characteristics of each compound detected by sniffing port. GC effluent was split 1:1:1 among the FID, MSD, and sniffing mode via a Dean's switch. Aroma compounds were separated on the DB-WAX (30 m length × 0.25 mm i.d. × 0.5 μm thickness; J&W Scientific, Folsom, CA, USA) column. A total of 3 μL of extract was injected each time in pulsed splitless (40 psi; 0.5 min) mode. The injector and FID detectors were set at 270 and 280 °C, respectively. The flow rate of carrier gas (helium) was 1.5 mL/min. The oven temperature of the DB-WAX column was first increased from 50 to 200 °C at a rate of 5 °C/min and then to 260 °C at 8 °C/min with a final hold at 260 °C for 5 min. The same oven temperature programs were used for the MSD. The mass detector was operated in scan mode, with an electronic impact ionization energy of 70 eV. The GC-MS interface and ionization source temperatures were set at 250 and 180 °C, respectively. Identification and quantification were performed in full scan mode with a mass/charge range of 30−300 amu at 2.0 scan/s scan rate. The compounds were identified by comparing their retention index and Wiley 6 and NIST 98 mass spectral data libraries installed in the GC-MS and the instrument's internal library created from previous laboratory studies. Some of the identifications were confirmed by the injection of the chemical standards into the GC-MS system. Retention indices of the compounds were calculated by using the retention data of the linear alkane series. After identification, the concentrations of aroma compounds were calculated according to the internal standard.[20]

Aroma Extract Dilution Analysis. The original aroma extracts were analyzed by GC-MS-O using three experienced sniffers. For AEDA, the concentrated aromatic extract (200 μL) of olive oils was stepwise diluted 1:1 using dichloromethane as the solvent to obtain dilutions of 1:1, 1:2, 1:4, 1:8, 1:16, and up to 1:1024 of the original extracts.[22] Sniffing of dilutions was continued until no odor could be detected by GC-MS-O. Each odor was thus assigned a flavor dilution factor (FD factor) representing the last dilution in which the odor was still detectable. As the FD factor of aroma compounds increases, also the degree of flavor activity increases.[23,24] This method has been used in different foods such as green olives[25] and orange juices.[26]

Sensory Analysis of Olive Oils. Sensory analysis of olive oil samples was made by a group of 10 trained panelists according to the published methods of the International Olive Oil Council determining the terms of organoleptic assessment.[27] Olive oil samples (15 mL) were placed in tasting glasses coded with different four-digit numbers. The temperatures of samples were kept at 28 ± 2 °C. A profile sheet was used by tasters. Each panelist smelled and then tasted the oil in the tasting glass and detected the intensity of the positive (fruity, bitter, pungent) and negative attributes (fusty/muddy, musty/humid, winey-vinegar, metallic, and rancid) on a 10 cm scale.

Statistical Analyses. The findings of this study were subjected to analysis of variance using the SPSS 17 software package, and Duncan's multiple-comparison test was used to find significant differences.[28] On the other hand, principal component analysis (PCA) was carried out using XLStat-Pro7.5 (2007) for Windows (Addinsoft, New York, NY, USA).

RESULTS AND DISCUSSION

Chemical Composition of Olive Oils. General properties of the assayed samples are shown in Table 1. As can be seen in Table 1, maturity indices were found between 3.9 and 4.2. This is an important factor in determining the harvest time of olives and must be between 2.5 and 4.5 for processed olive oil.[29] Oil and moisture contents of olives were found between 21.80 and 30.50% and between 43.62 and 50.33%, respectively. Oil contents of olive samples grown in the native region were higher than in olives grown in the Bornova geographical area. In addition, a similar situation was observed in the moisture content of the samples. This finding agrees with previous studies[30,31] reporting that a significant difference of olive oil composition exists among the different growing regions.

The percentage of free fatty acidity, peroxide values, and color values are usually used for quality characteristics and depend on the quality of the olives and on possible enzymatic alteration of olive fruits.[32] The percentage of free fatty acidity values of all olive oils were not significantly different ($p < 0.05$) and under the limit of 0.8% established for extra virgin olive oil. Peroxide values also were below the limit of 20 mequiv oxygen/kg oil, which is accepted as the limit for extra quality of VOO (Table 1). Peroxide values of native area oils were lower than in oils obtained from the Bornova area. In a previous study, acidity and peroxide values of olive oils obtained from 12 olive samples grown on islands of Italy and France were measured within the ranges of 0.20−1.34% and 3.28−16.15 mequiv oxygen/kg of oil, respectively.[33] Color properties of olive oils influence consumer acceptance. Color values varied depending on the cultivar and growing region. The L^*, a^*, and b^* values of olive oils obtained from olives grown in the Bornova area were higher than those of olives grown in native areas.

Representativeness of the Extract. *Intensity and Similarity Evaluation.* The intensity scores of the aromatic extract obtained from dichloromethane and pentane/dichloromethane solvents on smelling strips were found to be 63.5 and 64.2 mm on a 100 mm unstructured scale, respectively. The intensity scores of both extracts were close to each other. The differences of intensity scores for the two tests were not found as statistically significant. With regard to similarity evaluation, this score of dichloromethane extract (75.7 mm on a 100 mm unstructured scale) was found to be better than that of pentane/dichloromethane (50.2 mm on a 100 mm unstructured scale). The similarity scores of two solvents were found to be significantly different ($p < 0.05$). The similarity score of the dichloromethane extract was found to be acceptable and quite high and also scored relatively more closely to the reference sample. On the basis of these results, we selected the dichloromethane solvent for extracting olive oil aroma

[a]Results are the means of three repetitions as μg/kg. Values with different letters in the same row are significant statistically ($p < 0.05$) [b]Linear retention index calculated on DB-WAX capillary column. [c]Methods of identification: LRI (linear retention index); MS tent., (tentatively identified by MS); std (chemical standard). When only MS or LRI is available for the identification of a compounds, it must be considered as an attempt of identification. Standard deviation of all aroma compounds was below 10%.

compounds. As previously stated, it is of great importance to assess the representativeness of the aromatic extracts in a matrix with characteristics similar to those of the original product.[34] When we compared other studies, the similarity score of the banana extracts was found to be 66.7 mm,[21] and that of rainbow trout (*Oncorhynchus mykiss*) was found to be 51.1 mm.[34] Briefly, the similarity and intensity results indicated that the representative aromatic extracts were achieved with the SDE method to determine the aroma-active compounds of olive oils. Similarly, the SDE technique has shown to be a reliable method for the determination of Moroccan black olive odor active compounds by Collin et al.[11] and hazelnut oils odorants by Pfnuer et al.[35]

Volatile Composition of Olive Oils. The volatile compounds identified in olive oils and linear retention index values on the DB-WAX column for these compounds are presented in Table 2. Mean values (μg/kg) of the GC analyses of triplicate extractions are reported. As can be seen in Table 2, a wide variety of volatile compounds was found in the VOO samples. Differences were observed in terms of the number of volatile compounds depending on growing regions. Totals of 61, 48, 59, and 48 compounds, including aldehydes, alcohols, ketones, esters, terpenes, lactones, carboxylic acids, and phenols, were identified and quantified in NY, NY-B, KY, and KY-B olive oils, respectively. The highest amount of volatiles was found in NY oil (31090 μg/kg), followed by KY (29837 μg/kg), KY-B (16802 μg/kg), and NY-B (16285 μg/kg). When the geographical effect was compared, the major difference observed was that the total amount of volatile compounds in the native region oils was approximately 2 times higher than that found in the Bornova region oils (Table 2). To evaluate the possibility of differentiating the oil samples taking into account the aromatic profile, we applied a multivariate statistical analysis using the total concentration of volatile in each of the eight chemical groups from Table 2. The variables were selected for the PCA, and the explained variance was 90.81% (factor 1, 54.32%; factor 2, 36.50%). Figure 1A represents the projection of the variables with regard to the single factor (PC1 or PC2) on the factor plane (PC1 × PC2). The application of the PCA algorithm showed two distinct groups (Figure 1B). The first group represents the results of NY and KY oils. The second one was characterized by KY-B and NY-B. The first group was positively associated with PC1 (lactones, alcohols, aldehydes, terpenes, and carboxylic acids), whereas the second group was negatively associated with PC1 (ketones and esters). It seems that each sample results in a different quarter of the PCA space: for example, KY-B has a higher quantity of ketones, NY-B is richer in esters, NY is characterized by a higher amount of lactones, and finally KY is characterized by terpenes and carboxylic acids. As previously stated, growing areas affected the aroma profiles of olive oils by different researchers. Issaoui et al.[36] studied the aroma profiles of virgin olive oils from the Tunisian Chemlali and Chétoui cultivars, grown in two different locations. They found significant differences of aroma profiles between the oils from both cultivars when grown in the different locations. In the results of their study, they stated that aroma profiles were influenced by the pedoclimatic conditions. Our data were also in accordance with the results obtained by Tura et al.[37] The authors investigated the geographical origin and cultivar effects on the typical volatile profile of extra virgin olive oils. They noted that the growing area and cultivars significantly affected the aroma profiling of oils. Most of the volatile compounds identified in the present study have already been identified in Italian, Spanish, and Greek olive oils.[16,18,31]

Aldehydes and alcohols quantitatively and qualitatively represent the main group of the volatile fraction in all olive oils compared to other volatile compounds. The main aldehyde compounds in oil samples were (*E*)-2-hexenal and hexanal (Table 2). The total concentration of these compounds in cv. NY (15678 μg/kg) was greater than those of the KY (15375 μg/kg), KY-B (9182.5 μg/kg), and NY-B (9157.4 μg/kg) oils.

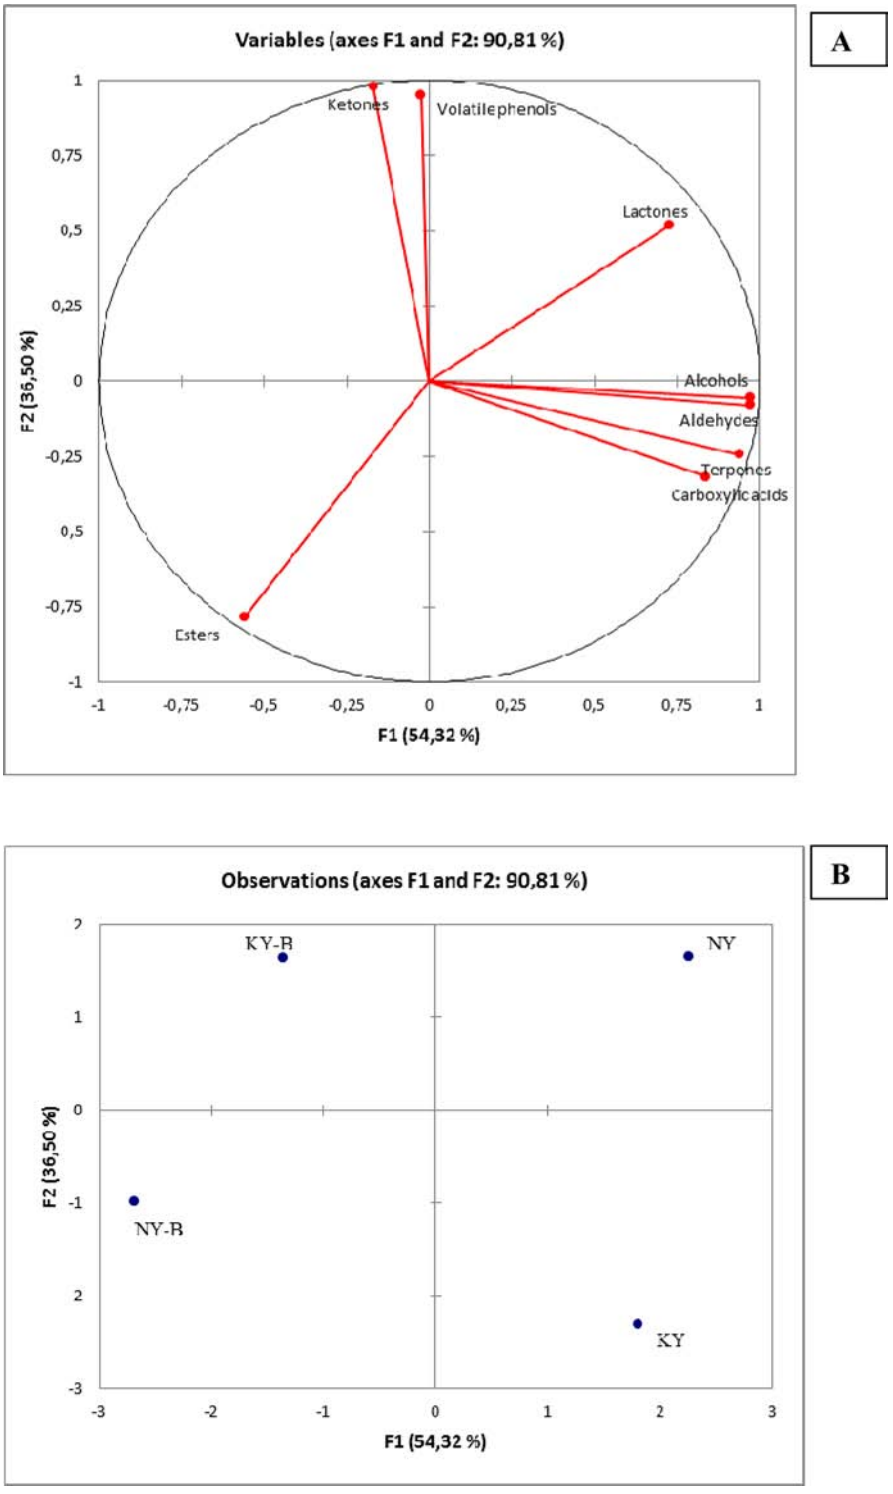

Figure 1. (A) Projection of the variables on the factor plane (PC1 × PC2) considering the aroma compounds quantified. (B) Score plot for the two principal components showing the two geographical origins studied.

Significant difference between the two growing areas was found for aldehydes, which were found in higher concentrations of the native region oils than the Bornova region oils. Kiralan et al.[38] also pointed out a significant difference in the composition of volatile components between the oils from the same cultivar and from different geographic regions. (*E*)-2-Hexenal and hexanal were present at the highest concentration in all oils, which accounted for between 13.82 and 21.42% and between 54.39 and 62.83% of total aldehyde compounds, respectively. The amounts of (*E*)-2-hexenal and hexanal in the native region oils reached higher levels than the Bornova region oils. Similarly, Aparicio et al.[39] reported that the major aroma compounds identified in most virgin olive oils from European countries are (*E*)-2-hexenal, hexanal, hexanol, and 3-methyl-butan-1-ol. (*E*)-2-Hexenal is produced by the enzymatic breakdown of the 13-hydroperoxide of linolenic acid in leaf homogenates, whereas hexanal is formed by the action of the enzyme aldehyde-lyase.[4,5] These aldehydes are widespread, as

[a]FD factor is the highest dilution of the extract at which an odorant is determined by aroma extract dilution analysis. [b]Linear retention index calculated on DB-WAX capillary column. [c]Odor description as perceived by panelists during olfactometry.

they have already been found in many other olive oils, such as Spanish cvs. Arbequina, Cornicabra, Morisca, Picolimon, Picudo, and Picual[40] and Tunisian cvs. Jemri Ben Gerdane, Chemlali Zarzis, and Zalmati.[41] Vichi et al.[42] studied the effect of different growing regions on the aroma profile of same cultivars. The authors noted that there were significant differences in the mean values of hexanal of the oils in relation to different regions. Among the aldehydes, the ratio hexanal/nonanal was found to be an appropriate way to detect the beginning of oxidation and its evolution,[19] and Morales et al.[43] proposed that, when the ratio of hexanal to nonanal was below 2, the oil should be considered as rancid. The ratios of these two aldehydes in NY, NY-B, KY, and KY-B olive oils were found to be 19.3, 6.1, 9.0, and 8.8, respectively.

Alcohols are produced by the action of ADH enzyme. It is widespread in the plant kingdom and is responsible for the

dx.doi.org/10.1021/jf4045167 | J. Agric. Food Chem. 2014, 62, 391−401

formation of volatile alcohols that contribute to the aroma of olive oils. The native region olive oils contained more alcohols than the Bornova region olive oils. The total amount of alcohols in the native region oils was approximately 2 times higher than the that of the Bornova region oils. The highest amount of alcohols was observed in NY oil (10534 μg/kg), probably related to higher activity of the alcohol dehydrogenase (ADH) enzyme, followed by KY (9333.6 μg/kg), KY-B (4751.4 μg/kg), and NY-B (4737.2 μg/kg) oils. Within the alcohols, C-6 alcohols such as hexanol, (*E*)-2-hexenol, and (*Z*)-3-hexenol were observed as high amounts in oil samples. When compared to other studies, a similar pattern of the three mentioned C-6 alcohols was identified in virgin olive oils from Spain,[40] Italy,[42] and Tunisia.[44] (*E*)-2-Hexenol predominated in NY (2658.1 μg/kg) and KY (2410.3 μg/kg) oil samples. Similarly, hexanol was observed in highest amount in the native region (NY = 1971.6 μg/kg and KY = 1877.4 μg/kg) oil samples. In previous studies, higher amounts of C-6 alcohols were determined in Tunisian and Italian olive oils, and the amount of hexanol and (*E*)-2-hexenol ranged between 50 and 2970 μg/kg and between 410 and 6920 μg/kg, respectively.[44]

GC-MS-O Results. The results of olfactometric analysis are given in Table 3. Application of the AEDA on the olive oil extracts revealed 29, 20, 30, and 27 aroma-active compounds in the NY, NY-B, KY, and KY-B oils, respectively. The differences in the number of aroma-active compounds of the oils are mainly caused by concentration differences of these compounds. As can be seen in Table 3, the native region oils contained more aroma-active compounds than the Bornova region oils. The FD factors of the compounds were detected to fall within the range of ≥8−1024 (Table 3). The compound having the highest FD factor (1024) was 1-penten-3-ol for NY oil, 2-ethenyl-2-butenal (FD = 512) for NY-B oil, (*E*)-2-hexenal and 2-ethenyl-2-butenal (FD = 512) for KY oil, and (*E*)-2-hexenal and (*Z*)-3-hexenol for KY-B oil.

Aldehydes were the largest class of aroma-active components of the olive oil extracts. Odor threshold values of these compounds are generally lower than those of volatile compounds; thus, they have important potential effect of the overall aroma of olive oils. A total of 14 aldehydes were identified in olive oils as key compounds (Table 3). Aldehydes are generally characterized by intense sensory description by panelists and are associated with green, cut grass, green plant, citrusy, fatty, and sweet notes. The total numbers of aroma-active aldehydes were 9, 5, 11, and 8 in NY, NY-B, KY, and KY-B oils, respectively. Among these compounds, hexanal, (*Z*)-3-hexenal, (*E*)-2-hexenal, and (*E*,*E*)-2,4-decadienal were common to all varieties. These aldehydes are widespread, as they have already been found in many other olive oils.[9,10] Within the aroma-active aldehydes, (*E*)-2-hexenal (FD = 512) for NY and KY oils and 2-ethenyl-2-butenal (FD = 512) for NY-B and KY oils were the most powerful aroma-active compounds to contribute to the aroma profile of oils. The first has a cut grass note, and the latter has a fruity, green note. The FD factor of (*E*)-2-hexenal was 256 for NY-B and KY-B. Solinas et al.[45] suggest that monovarietal virgin olive oils could be distinguished by the (*E*)-2-hexenal compound. This aldehyde is a well-known powerful odorant that contributes to the characteristic aromas of olive oils.[9] The other most important aldehydes, which have FD factors of 256, were 2-ethyl-(*E*)-2-butenal (grassy, floral) and octanal (citrus, lemon) for NY and KY, respectively. In a previous study, Dierkes et al.[46] stated that hexanal (green), (*E*)-2-hexenal (green, apple-like), nonanal (citrus-like), (*E*)-2-nonenal (paper-like, fatty), and (*E*,*E*)-2,4-decadienal (fatty, solvent) were potent aldehyde compounds in olive oils. Similarly, hexanal (fresh cut grass), (*E*)-2-hexenal (green), and heptanal (fatty, soapy) have been detected as aroma-active aldehyde compounds in Portuguese extra virgin olive oils from Galega Vulgar and Cobrançosa cultivars by Peres et al.[47]

Alcohols were the second largest class of odor-active compounds in the oil samples. A total of 11 aroma-active alcohol compounds were found in the samples. These were 1-penten-3-ol (grassy, green plant), 3-penten-2-ol (green, grassy), (*Z*)-2-pentenol (fatty), hexanol (floral, grassy), (*Z*)-3-hexenol (cut grass, herbal), (*E*)-2-hexenol (grassy, green plant, fruity), heptanol (margarine, fatty), octanol (floral, grassy), nonanol (citrus), (*E*)-2-nonenol (fruity, waxy), and 2-phenylethanol (rose). Within these, 1-penten-3-ol, 3-penten-2-ol, hexanol, (*Z*)-3-hexenol, and (*E*)-2-hexenol were common aroma-active alcohol compounds in all oil samples. The FD factors of these compounds varied depending on cultivar. Alcohols have less sensorily significant than aldehydes due to their higher odor threshold values. The most powerful aroma-active alcohol compound was 1-penten-3-ol to contribute to the aroma profile of the olive oils. The FD factor of these compounds was 1024 for NY. This compound was generated from polyunsaturated fatty acids (PUFA) by the influence of an enzyme such as lipoxygenase or hydroperoxidase.[48] (*Z*)-3-Hexenol (FD = 256 for KY and KY-B) was the second most important aroma-active alcohol compound in the oils. Most of the potent alcohols found in our samples have already been identified in olive oils by Luna et al.[8] and Dierkes et al.[46] and in green olives by Iraqi et al.[25] Among the alcohols, 2-phenylethanol was detected in NY, NY-B, and KY-B oils with FD factors of 128, 32, and 32, respectively, and described as a floral-rose odor. As stated previously, 2-phenylethanol has been cited as a major aroma-active compound in Moroccan black olives by Collin et al.[11] and in olive oils by Dierkes et al.,[46] providing a floral-fruity and sweet-winey odor, respectively.

β-Pinene (green plant, floral), limonene (light floral), *α*-copaene (sweet, fruity), linalool (lilac, lavender), *α*-terpinolene (floral, light), (*E*,*E*)-*α*-farnesene (floral, herb), and *α*-farnesene (floral, green plant) were detected as aroma-active terpene compounds in the olive oil extracts. The samples NY, KY, and KY-B contained four aroma-active terpene compounds, but NY-B only one. On the basis of GC-O, the most potent aroma-active terpenes were limonene and linalool, which have 128 FD factors. *β*-Pinene and *α*-farnesene were detected only in KY and KY-B oils. In addition, limonene was not sensed in oil obtained from the Bornova region. Among the terpenes, limonene, linalool, and *α*-farnesene were identified as being the key odorants in Moroccan green olives.[25]

Hexyl acetate (fruity, green), (*Z*)-3-hexenyl acetate (fruity, green), methyl palmitate (fruity), and ethyl palmitate (fruity) were detected in oil aromatic extracts as aroma-active compounds. Esters are the main volatile compounds found in most fruits and are responsible for the fruity notes.[20] Increasing the alcohol acetyl transferases (AAT) activity can enhance the production of volatile esters in olive oils.[42] Within the esters, ethyl palmitate had the highest FD factor (256) value detected by GC-O in KY oil.

Lactones contribute to the characteristic fruity odors of the olive oil samples. *γ*-Decalactone (fruity), *δ*-decalactone (fruity), and *γ*-dodecalactone (fruity) were identified as aroma-active lactone compounds. As summarized in Table 3, oil produced

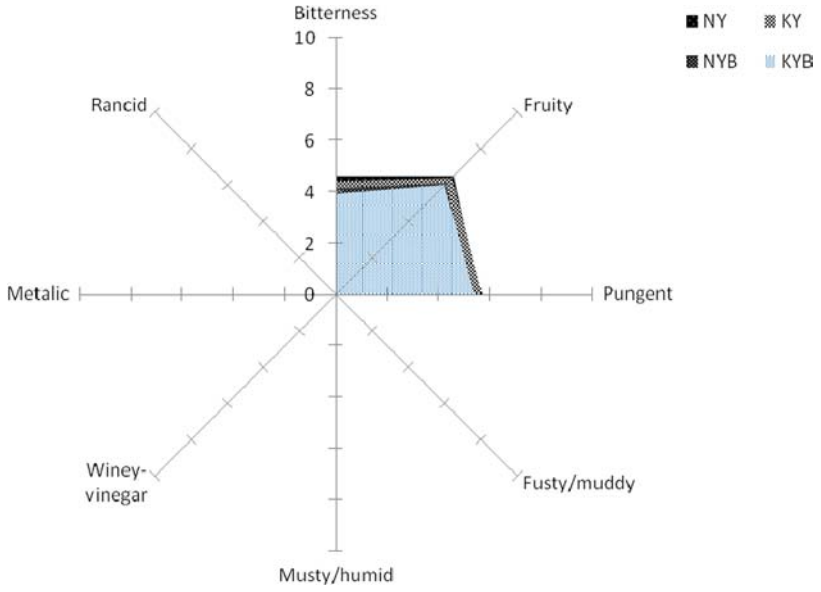

Figure 2. Sensory properties of olive oils.

from NY olives had a higher number and FD factors than the others. On the basis of the FD factor values, the most powerful aroma-active lactone compound was γ-dodecalactone in NY oil, qualified as having a fruity odor. The FD factor of this compound was 512. All of the potent lactones found in our samples have already been identified in black olives by Collin et al.[11]

The other aroma-active compound identified in the olive oils was guaiacol (olive paste, soapy). This compound was detected only in NY and NY-B oils. The FD factors of this volatile phenol were 32 and 16, respectively. This compound was also determined in Italian, Spanish, and Moroccan olive oils as the aroma-active compound. The highest FD value (128) of this compound was determined in Moroccan olive oils.[10]

A total of eight unknown compounds may contribute to the overall aroma of the olive oil samples. Among the unknowns, **14** (LRI = 1269) was found to be the pickled olive odor in KY and KY-B oils. Unknown **27** (LRI = 1544), with a sweet, floral note, was detected in only NY and NY-B oils. Unknowns **30** and **41** were found in oils obtained from the Bornova region, whereas unknown **43** was found in oils obtained from the native region.

Sensory Analysis of Olive Oils. The results of the positive and negative sensory attributes of the olive oils are given in Figure 2. Olive oils are classified as extra virgin olive oils if the median of defects is equal to zero and the median of fruity is more than zero.[27] The studied oils showed no defects in the sensory analysis, so they were considered extra virgin olive oils. The highest fruity median was found in NY oil (6.50). This value was quoted at 6.40, 6.10, and 6.0 for KY, NY-B, and KY-B oils, respectively. The bitterness values of olive oils were detected between 3.90 and 4.60. According to median value of positive attributes (fruity, bitterness, and pungent), oils from the native region had the higher values than those from the Bornova region. The highest value (5.70) of pungent property was detected in olive oil obtained from cv. KY. According to Regulation EEC/640/2008,[49] the term "medium" may be used when the median of the positive attribute concerned is between 3 and 6. In our research olive oil samples were characterized as medium for all criteria (fruity, bitter, and pungent). In a previous study, sensory properties of olive oils were evaluated by using the medians of defects and positive attributes.[50]

In conclusion, this first study revealed key aroma compounds of olive oils obtained from NY and KY cultivars and the effect of growing regions on these compounds. The results suggest that besides cultivars, growing area influences volatile formation in olive oil. The native region oils were distinguished from the Bornova region samples by their number and quantity of volatile compounds. Totals of 61, 48, 59, and 48 aroma compounds were identified and quantified in olive oils obtained from NY, NY-B, KY, and KY-B cultivars, respectively. Aldehydes were found as, qualitatively and quantitatively, the majority of aroma-active compounds in the oil samples. On the basis of sensory analysis, the olive oils studied in the present work were defined as extra virgin olive oils, and the highest fruity median was found in NY oil followed by KY, NY-B, and KY-B oils, respectively.

ABSTRACT: A rapid, sensitive, and direct method (without derivatization) was developed for the detection of reduced glutathione (GSH) in cultured hepatocytes (HepG2 cells) using high-performance liquid chromatography with electrochemical detection (HPLC-ECD). The method was validated according to the guidelines of the U.S. Food and Drug Administration in terms of linearity, lower limit of quantitation (LOQ), lower limit of detection (LOD), precision, accuracy, recovery, and stabilities of GSH standards and quality control samples. The total analysis time was 5 min, and the retention time of GSH was 1.78 min. Separation was carried out isocratically using 50 mM sodium phosphate (pH 3.0) as a mobile phase with a fused-core column. The detector response was linear between 0.01 and 80 μmol/L, and the regression coefficient (R^2) was >0.99. The LOD for GSH was 15 fmol, and the intra- and interday recoveries ranged between 100.7 and 104.6%. This method also enabled the rapid detection (in 4 min) of other compounds involved in GSH metabolism such as uric acid, ascorbic acid, and glutathione disulfite. The optimized and validated HPLC-ECD method was successfully applied for the determination of GSH levels in HepG2 cells treated with buthionine sulfoximine (BSO), an inhibitor, and α-lipoic acid (α-LA), an inducer of GSH synthesis. As expected, the amount of GSH concentration-dependently decreased with BSO and increased with α-LA treatments in HepG2 cells. This method could also be useful for the quantitation of GSH, uric acid, ascorbic acid, and glutathione disulfide in other biological matrices such as tissue homogenates and blood.

KEYWORDS: *glutathione, electrochemical detection, hepatocytes, method validation, buthionine sulfoximine*

INTRODUCTION

Glutathione (γ-L-glutamyl-L-cysteinglycine, GSH) is a tripeptide nonprotein thiol antioxidant molecule composed of cysteine, glutamic acid, and glycine. The thiol group of the cysteine residue is the biologically active site of GSH.[1,2] GSH has a number of important roles in human metabolism including scavenging of free radicals, detoxifying xenobiotics, maintaining cell homeostasis, protecting against oxidative stress, controlling gene expression, detoxifying heavy metals, and in-signal transduction.[2−6] GSH is also involved in regenerating antioxidants involved in the antioxidant network system, such as vitamin E and ascorbic acid.[2] GSH is present in all organs with particularly high levels in the liver.[1] Severe oxidative stress leads to oxidation of GSH and the formation of glutathione disulfide (GSSG).[7]

The identification and quantitation of GSH are of great interest due to its critical protective functions in the body. Furthermore, it may be a useful biomarker for oxidative stress, a common occurrence in many disease states. Various chemiluminescence,[8] spectrofluorometric,[9] and spectrophotometric[7] methods are available for the determination of GSH in biological samples. In addition, chromatographic methods with improved specificity and sensitivity have been developed using high-performance liquid chromatography (HPLC) coupled to ultraviolet,[10] fluorescence,[11] and coulometric electrochemical detections[12] as well as mass spectroscopy[13] and capillary electrophoresis.[14,15] Most of these methods require either precolumn or postcolumn derivatization of GSH with fluorogenic (monobromobimane, *o*-phthalaldehyde), and chromophoric (*N*-ethylmaleimide or iodoacetic acid) agents or reduction with reducing agents (tributylphosphine, tris(2-carboxyethyl)phosphine),[16] which is time-consuming.

Among the chromatographic techniques, coulometric electrochemical detection facilitates the resolution and accurate identification of trace amounts of electroactive compounds, including redox-reactive compounds such as thiols and disulfides.[17] Thus, HPLC coupled to electrochemical detection (HPLC-ECD) is a valuable tool for analyzing GSH with high specificity and sensitivity without the need of prior derivatization.[12,18] In addition, run time is an important aspect of any chromatographic method. The currently available methods for GSH analysis are often longer than 3 min.[12,19,20]

In this study, we aimed to develop a rapid and sensitive HPLC-ECD method for the analysis of GSH in HepG2 cells and to validate it according to FDA guidelines for bioanalytical method validation.[21] The measurement of GSH levels is crucial for determining the influence of treatments on the GSH−GSSG redox system. We therefore tested the application of this method by measuring changes in GSH levels in HepG2 cells treated with buthionine sulfoximine (BSO), an inhibitor, and α-lipoic acid (α-LA), an inducer of GSH synthesis.

MATERIALS AND METHODS

Chemicals. Standards of glutathione, ascorbic acid, α-lipoic acid, and sodium dihydrogen phosphate monohydrate were purchased from Sigma-Aldrich (Steinheim, Germany). Glutathione disulfide, dimethyl sulfoxide (DMSO), and metaphosphoric acid were from Carl Roth (Karlsruhe, Germany), and orthophosphoric acid was from Merck (Darmstadt, Germany). Uric acid and buthionine sulfoximine were from Fluka (Buchs, Switzerland). Reference standards of analyzed compounds had purities >98%. Water was of Milli-Q grade, purified by a Milli-Q UV purification system (Millipore, Bedford, MA, USA).

Preparation of Standard Solutions. A stock solution of GSH standard was prepared in 1% metaphosphoric acid at a concentration of 10 mM, and working standards were prepared daily from this stock solution by dilution in 1% metaphosphoric acid. It is recommended to prepare the standards daily as an effect of temperature and storage time was observed for GSH in our stability studies.

Cell Culture Conditions. HepG2 cells were obtained from Applied Cell Culture (IAZ, München, Germany). Dulbecco's modified Eagle's medium (DMEM), fetal calf serum (FCS), and penicillin/streptomycin were purchased from PAA (Coelbe, Germany). HepG2 cells were cultured in DMEM containing 10% FCS and 1% penicillin/streptomycin in a temperature- and humidity-controlled incubator (95% air, 5% CO_2) at 37 °C. Cells were grown in T75 flasks (Sarstedt, Nümbrecht, Germany) at a density of 8×10^6 cells in DMEM and subcultured twice a week when at 80% confluence. Confluent cells were harvested by trypsination.

Extraction of GSH from HepG2 Cells. Confluent cells were seeded at a density of 1.2×10^6 cells per well in 12-well plates (Corning Inc., NY, USA) and cultivated for 24 h. Cells were washed with cold PBS and then incubated with 500 μL of trypsin/EDTA per well for 10 min. Cells were suspended in 1 mL of DMEM and pelleted by centrifugation at 2000*g* for 5 min at 4 °C. Cell pellets were suspended in 300 μL of PBS and frozen at −80 °C. The cell suspension was then thawed and mixed with 600 μL of PBS. An equal volume of 1% metaphosphoric acid (900 μL) was added before homogenization with a Qiagen TissueLyser (Hilden, Germany) for 2 min. The cell suspension was then centrifuged at 13000*g* for 10 min at 4 °C, and the supernatants were transferred into HPLC vials for GSH analysis. GSH content was expressed as micromoles per liter.

Cytotoxicity Test for BSO and α-LA. The cytotoxicity of BSO and α-LA was determined using the neutral red (NR) assay.[22] Viable cells incorporate NR in lysosomes, which can then be photometrically measured at 540 nm. Cell viability was expressed as a percentage of solvent-only exposed control cells. HepG2 cells were incubated with BSO (prepared in distilled water) or with α-LA (prepared in DMSO and the final concentration of DMSO was <0.1%) at concentrations of 1−1000 μmol/L to establish the highest nontoxic concentration. In concentration−response experiments, HepG2 cells were exposed to increasing concentrations of BSO and α-LA ranging from 1 to 250 μmol/L for 24 h. For each treatment, three independent experiments were performed in duplicate ($n = 6$).

HPLC Analysis of GSH. HPLC analyses were carried out on a Jasco system (Jasco GmbH Deutschland, Gross-Umstadt, Germany) consisting of a pump (PU-2085) and autosampler (XLC-3059AS), whereas detection was carried out on a four-channel ESA 5600A CoulArray detector with an integrated column oven (ESA Inc., Chelmsford, MA, USA). For analyte detection, increasing potentials of 250, 400, 600, and 800 mV were applied. Separation of phenolics was achieved on a Kinetex C18 column (100 × 4.6 mm, 2.6 μm; Phenomenex, Aschaffenburg, Germany) using isocratic elution with 50 mM NaH_2PO_4. The pH of the aqueous eluent was adjusted to 3.0 with orthophosphoric acid, and the eluent was vacuum-filtered through a 0.2 μm hydrophilic polypropylene membrane filter (Pall Corp., MI, USA). The column temperature was maintained at 30 °C, the flow rate was set at 1.0 mL/min, and the injection volume was 10 μL. GSH was quantified against an external standard using the sum of peak heights.

Method Validation. The analytical method for the determination of GSH was validated according to the requirements of FDA guidelines for bioanalytical method validation in terms of linearity, limit of quantitation (LOQ), limit of detection (LOD), accuracy, precision, recovery, stock solution stability, short-term stability, freeze−thaw stability, and benchtop stability. All of the analyses were performed three times.

Linearity, Lower LOD, and Lower LOQ. The linear range of detection was determined using serial dilutions of the stock solution. Calibration curves were obtained by plotting the sum of the peak heights of GSH versus its concentration for eight different concentrations. Standard solutions corresponding to each point in the calibration curve were injected in triplicate and regression parameters calculated. The LOQ was defined as the lowest concentration that could be determined with a deviation from the actual concentration and a coefficient of variation of precision of <20%, respectively. The LOD was the lowest concentration of the analyte of interest that could be reliably discerned from the baseline (signal-to-noise ratio ≈ 3).

Precision and Accuracy. The precision and accuracy of the method were ascertained by measuring five replicates of control samples with known amounts of GSH (low, medium, and high concentrations) on three consecutive days. After thawing, 600 μL of 1% metaphosphoric acid or GSH (2, 10, or 40 μmol/L prepared in 1% metaphosphoric acid) was added to cell suspensions and treated according to the protocol outlined under Extraction of GSH from HepG2 Cells. These concentrations were determined according to the amount of GSH in HepG2 cells found in the literature. Also, lower limit of detection and upper limit of detection values of the method were taken into account. The calculated concentration of GSH extracted from the spiked cell suspensions was compared with the known concentration within the same day (intraday) and from day-to-day (interday). The precision is given as the intra- and interday coefficients of variation (% CV). The accuracy was expressed as the absolute percentage error and calculated as follows: accuracy (%) = [(mean of measured concentration − known added concentration)/known added concentration] × 100.

Recovery. The recovery of GSH was calculated by analyzing the peak heights of five replicate spiked cell suspensions (spiked cell sample − cell sample) for each GSH concentration (low, medium, and high) and comparing them with calibration standards of the same concentration. The recovery (in percent) was calculated as follows: recovery (%) = [(peak height of spiked cell sample − peak height of cell sample)/peak height of standard] × 100.

Stock Solution Stability. The stability of three concentrations (low, medium, and high) of stock solution was determined at room temperature and 4, −20, and −80 °C for 24 h. The sum of peak heights of GSH prestorage was compared to those poststorage, and the results were expressed as percent degradation.

Short- and Long-Term Stability. Five aliquots of spiked cell suspensions were prepared at two concentrations (low and high). The aliquots were initially analyzed, and the remaining samples were stored at room temperature and 4, −20, and −80 °C for 24 h to assess short-term stability and at −20 and −80 °C for 4 months to assess long-term stability. The initial values were compared with those obtained after storage and the results expressed as percent degradation.

Freeze−Thaw Stability. Three aliquots of spiked cell suspensions were prepared at two concentrations (low and high). The aliquots were initially analyzed, and remaining samples were frozen at −80 °C for 24 h, thawed at room temperature, and then frozen again for 12−24 h at −80 °C. The freeze−thaw cycle was repeated two additional times and the stability determined by comparing initial values to those obtained after repeated freeze−thaws. Results were expressed as percent degradation.

Benchtop Stability. Three aliquots of spiked cell suspensions were prepared at two concentrations (low and high), and the effect of length of time in the autosampler on sample stability was determined by injecting samples at 6 h intervals (6, 12, and 18 h). The samples were injected from the same HPLC vial, and the screw-caps were replaced after each injection to minimize solvent loss. The results were expressed as percent degradation.

Statistical Analysis. Statistical analysis was performed using SPSS version 16.0 (SPSS Inc., Chicago, IL, USA). Data were analyzed for

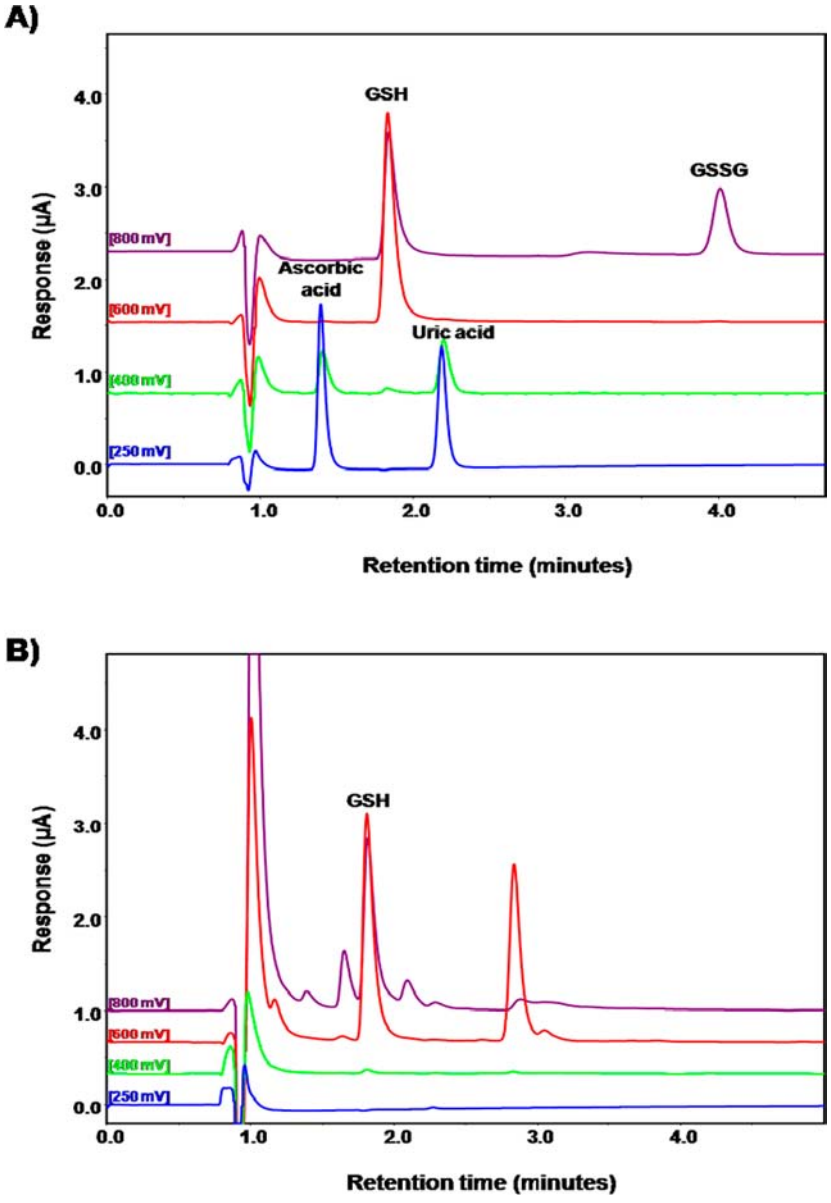

Figure 1. (A) Representative chromatogram of ascorbic acid, GSH, uric acid, and GSSG standards. The injection volume was 10 μL, and the concentrations of ascorbic acid, GSH, uric acid, and GSSG in the standard mixture were 5 μM. (B) GSH extracted from HepG2 cells resolved by isocratic elution on a Kinetex C18 fused-core column and detected by four-channel coulometric electrochemical detection. The retention times of the analytes (in minutes) are given in parentheses: 1, ascorbic acid (1.39); 2, GSH (1.78); 3, uric acid (2.19); 4, GSSG (4.00).

normality of distribution (Kolmogorow−Smirnov and Shapiro−Wik tests) and equality of variance (Levene test). For the comparison of group means, one-way ANOVA was performed with the Dunnet post hoc test. Results are expressed as mean values with standard deviation (SD). Differences were considered significant when the P value was $\leq$0.05.

RESULTS AND DISCUSSION

We developed and validated a method for the direct measurement of GSH in HepG2 cells without the requirement of prior derivatization. Cell extracts were acidified with metaphosphoric acid to facilitate protein precipitation and minimize oxidation of GSH. This newly developed and validated method enables the detection of GSH with a retention time of only 1.78 min (Figure 1) and a total run time of 5 min. Currently, we know of no other method for GSH analysis that has a shorter total run time. In addition, the method we describe herein also enables the detection of ascorbic acid, uric acid, and GSSG to be achieved within 4 min (Figure 1). However, validation according to FDA guidelines for bioanalytical method validation was applied only to GSH. The developed method is important because it can be used to efficiently detect and measure GSH as well as three other key molecules involved in GSH metabolism and its biological activity, namely, ascorbic acid, uric acid, and GSSG. GSH can regenerate the exogenous antioxidant ascorbic acid from its radical form, which results in the conversion of GSH to its oxidized form GSSG. However, one particular challenge in the analysis of GSSG with electrochemical detectors is that it requires the application of high voltages (>800 mV), which can cause detrimental effects to the detection system over time. Therefore, an amperometric boron-doped diamond electrode rather than a coulometric graphite electrode would be preferable if GSSG is analyzed with this method.[23] Uric acid

is a powerful antioxidant and has recently been reported to increase cysteine uptake and GSH synthesis in the brain[24] and liver.[25]

Linearity, Lower LOD, and Lower LOQ. The linearity of the detector response for GSH was evaluated by triplicate injection of standard solutions corresponding to each point on the standard curve on three different days. The detector response was linear between 0.01 and 80 μmol/L with a regression coefficient (R^2) >0.99. The LOQ and LOD of GSH were 50 and 15 fmol (given as total amount injected), respectively, which are lower than reported in the literature for most other studies (Table 1).

Precision, Accuracy, and Recovery. Precision, accuracy, and recovery were determined by adding low, medium, and high concentrations of the GSH standard to HepG2 cell suspensions (n = 5). Intra- and interday repeatability studies were carried out by analyzing five cell suspensions on three consecutive days. Intraday precision values were 3.75, 1.67, and 0.71%, and interday precision results were 5.27, 6.89, and 9.86% for low, medium, and high GSH concentrations, respectively (Table 2). These precision and accuracy values are within the limits prescribed by the FDA (≤20% for concentrations near the LOQ and ≤15% for other concentration levels). The intraday and interday recovery values of GSH in cell suspensions ranged from 100.7 to 104.6% (Table 2).

Table 2. Intra- and Interday Precision, Accuracy, and Recovery of GSH Added to Cell Suspensions of HepG2 Cells at Low, Medium, or High Concentrations and Determined in Five Replicate Analyses (n = 5)

concn (μmol/L)	calcd concn (μmol/L)	recovery (%)	accuracy (%)	precision (CV%)
		Intraday		
2	2.01	100.7	−0.71	3.75

Stability. The stability of analytes prior to injection is an important issue that is often neglected during method development. Therefore, in the present study, we determined both the stability of GSH stock solutions and GSH-spiked cell extracts. Aliquots of GSH stock solutions (low, medium, and high concentrations) were stored at room temperature and 4, −20, or −80 °C for 24 h. The concentrations after storage were compared with the prestorage values (Table 3). The low-concentration GSH stock solution showed the highest level of degradation (−7.60%) when stored at −20 °C for 24 h. No significant differences in 24 h stability were observed between temperatures. During long-term storage for 4 months, GSH was less stable when stored at −20 °C compared to −80 °C, with the highest level of degradation being observed for the low GSH (Table 3). These results indicate that, to optimize stability, long-term storage of GSH stock solutions and standards should be at −80 °C.

Table 3. Stock Solution Stability of GSH Standards at Low, Medium, or High Concentration after Storage at Room Temperature or 4, −20, or −80 °C for 24 h (Short-Term Stability) and at −20 or −80 °C for 4 Months (Long-Term Stability)

	degradation (%)					
	short-term stability				long-term stability	
concn (μmol/L)	room temp	4 °C	−20 °C	−80 °C	−20 °C	−80 °C
0.4	4.85	−5.48	−7.60	−5.54	27.29	1.93
4	2.23	0.08	0.66	−2.24	17.01	10.97
40	0.25	−2.40	−3.30	2.81	13.06	11.04

To assess short-term stability in cell extracts, HepG2 cells were spiked with GSH at two concentrations (low and high) and analyzed after storage at room temperature or 4, −20, or −80 °C for 24 h. The highest degradation was observed in samples with high concentrations of GSH at −20 °C (−3.68%). There were no clear differences in the stability of GSH between samples stored at room temperature or 4, −20, or −80 °C for 24 h (Table 4). To assess long-term stability, the GSH-spiked HepG2 cells were also stored at −20 or −80 °C for 4 months. Significant degradation was seen in the sample spiked with the high concentration of GSH at −20 °C (12.53%). As with the GSH stock solutions, −80 °C is preferable for long-term storage of cell extracts to protect GSH from degradation (0.13 and 1.16% for high and low concentrations, respectively).

The effect of repeated freezing and thawing on the stability of GSH-spiked cell extracts was also assessed. GSH degraded by 2.01% and by −1.87% at low and high concentrations, respectively, indicating that GSH withstands freeze−thawing in cell extracts (Table 4).

The stability of HepG2 cell extracts during the time in the autosampler was also investigated. The autosampler temper-

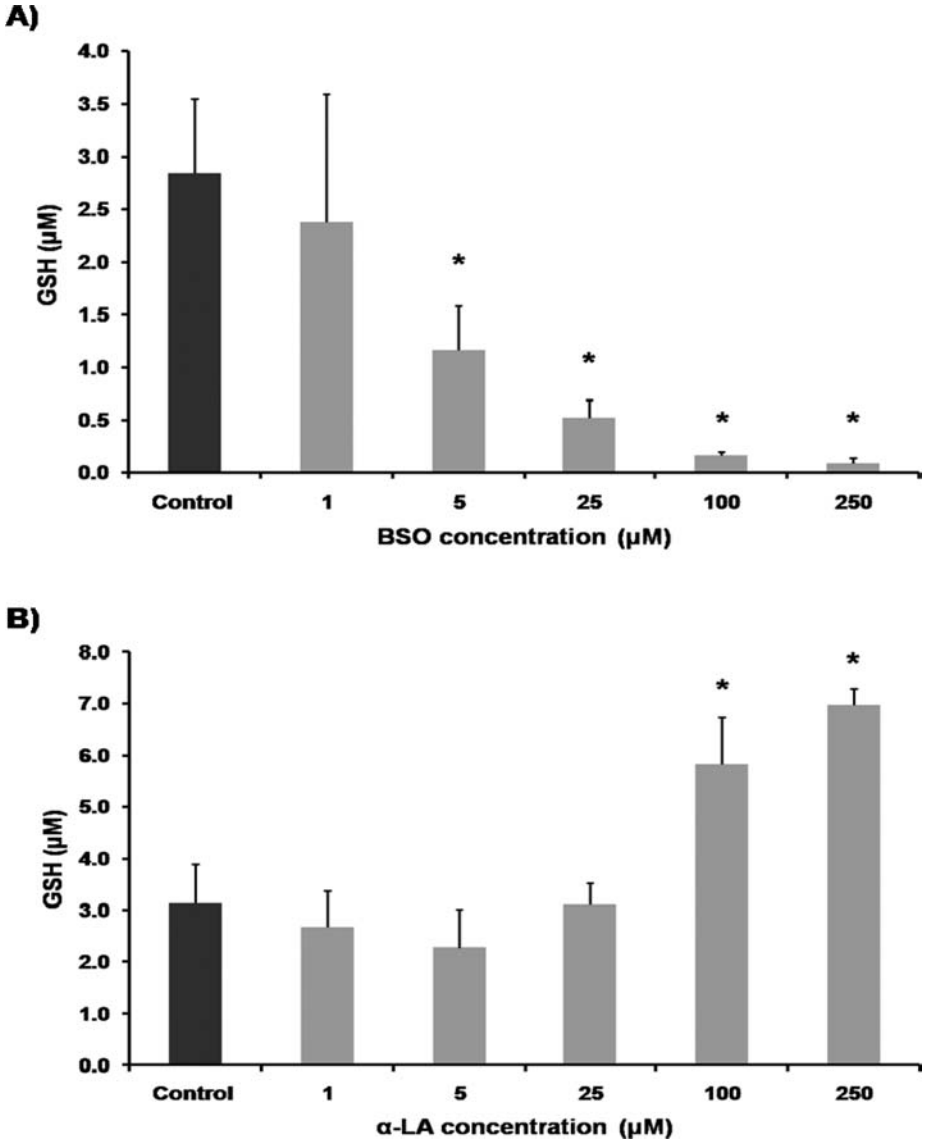

Figure 2. (A) Concentrations of GSH (μmol/L) in HepG2 cells treated with buthionine sulfoximine (BSO) or (B) α-lipoic acid (α-LA) at concentrations ranging between 1 and 250 μmol/L. Values are expressed as arithmetic means ± SD from three individual experiments performed in duplicate (n = 6). Comparison of mean values to control was performed by one-way ANOVA with the Dunnett post hoc test, and significant differences are indicated by asterisks: ∗, $P < 0.001$.

ature was maintained at 4 °C. Cell extracts containing high and low GSH concentrations were found to be stable for 18 h in the autosampler (Table 4). The highest degradation was observed after 18 h (−3.9%) in the high GSH-spiked samples.

Application of the Method for the Quantitation of GSH in HepG2 Cells Treated with BSO and α-LA. The measurement of GSH is useful in assessing the effectiveness of treatments that may affect synthesis of GSH. The developed and validated method was used to analyze the content of GSH in BSO- and α-LA-treated HepG2 cells. The sensitivity of the analytical method is an important issue when GSH is altered in cells by depleting agents, oxidative stress, or physical agents. BSO acts as an inhibitor of GSH synthesis and has been shown to be effective at lowering GSH levels in a number of cell types both in vitro and in vivo.[26,27] According to the results of the neutral red test, no toxic effect of either BSO or α-LA on HepG2 cells was detected at concentrations between 1 and 1000 μmol/L. HepG2 cells were concentration-dependently

dx.doi.org/10.1021/jf403857h | J. Agric. Food Chem. 2014, 62, 402−408

treated with 1−250 μmol/L of BSO, and significant GSH depletion was achieved even at a low concentration (5 μmol/L) (Figure 2A, $P < 0.001$). Conversely, treatment with the GSH inducer α-LA, when used at concentrations of 100 and 250 μmol/L, significantly increased cellular GSH (Figure 2B, $P < 0.001$).

In conclusion, we developed and validated a simple, fast, direct, sensitive, and specific HPLC-ECD method for the determination of GSH in HepG2 cells. This chromatographic method has a number of advantages, including a quick sample preparation, as it requires no derivatization step, a very good sensitivity with markedly lower LOD than for most other methods reported in the literature, and a very short retention time of GSH of only 1.78 min, which results in the fastest analysis time among the published HPLC methods for GSH. This method furthermore allows the elution of GSH as well as three other compounds involved in GSH metabolism (ascorbic acid, uric acid, and GSSG) in 4 min, resulting in a total analysis time of under 5 min. The method may thus be useful for the analysis of these compounds, too. The developed method was successfully applied to analyze GSH in HepG2 cells treated with BSO and α-LA. It needs to be established whether our method can also be applied for the analysis of GSH in other biological samples such as blood and tissues.

Quantification of Individual Phenolic Compounds' Contribution to Antioxidant Capacity in Apple: A Novel Analytical Tool Based on Liquid Chromatography with Diode Array, Electrochemical, and Charged Aerosol Detection

Merichel Plaza,*[,†] James Kariuki,[§] and Charlotta Turner[†]

[†]Department of Chemistry, Centre for Analysis and Synthesis, Lund University, P.O. Box 124, SE-221 00 Lund, Sweden

Supporting Information

ABSTRACT: Phenolics, particularly from apples, hold great interest because of their antioxidant properties. In the present study, the total antioxidant capacity of different apple extracts obtained by pressurized hot water extraction (PHWE) was determined by cyclic voltammetry (CV), which was compared with the conventional antioxidant assays. To measure the antioxidant capacity of individual antioxidants present in apple extracts, a novel method was developed based on high-performance liquid chromatography (HPLC) with photodiode array (DAD), electrochemical (ECD), and charged aerosol (CAD) detection. HPLC-DAD-ECD-CAD enabled rapid, qualitative, and quantitative determination of antioxidants in the apple extracts. The main advantage of using CAD was that this detector enabled quantification of a large number of phenolics using only a few standards. The results showed that phenolic acids and flavonols were mainly responsible for the total antioxidant capacity of apple extracts. In addition, protocatechuic acid, chlorogenic acid, hyperoside, an unidentified phenolic acid, and a quercetin derivative presented the highest antioxidant capacities.

KEYWORDS: *antioxidant capacity, charged aerosol detector, cyclic voltammetry, electrochemical detector, hyphenation, phenolic compounds*

INTRODUCTION

Flavonoids represent a highly diverse class of secondary plant metabolites with about 9000 structures.[1] Flavonoids are polyphenolic compounds derived from 2-phenylchromone, commonly found in many plants, vegetables, and flowers.[2] They have received considerable attention in the literature, specifically due to their biological and physiological importance. They are also known to have benefits to human health, including antioxidant activity,[3] metal chelation,[4] and anti-proliferative, anticarcinogenic, antibacterial, anti-inflammatory, antiallergenic, and antiviral effects.[5−7]

In this context, the apple is an interesting vegetable plant species due to its natural high content of polyphenols (500−2700 mg/kg) and its widespread popularity all over the world.[8] Thus, there is considerable research interest toward the production of polyphenols and their enriched extracts, for use as food supplements or active ingredients by the cosmetics and pharmaceutical industries. Due to this ongoing interest, in this work, various apple extracts were investigated as sources of natural antioxidants.

Pressurized hot water extraction (PHWE) has been successfully used at an analytical level for the quantitative recovery of target analytes.[9−13] For instance, in a previous study, PHWE was used to extract antioxidants from apple byproducts.[14] This study showed the optimum conditions to extract antioxidants while minimizing the formation of undesirable compounds, such as Maillard and caramelization reaction products, during the extraction. The extraction conditions used in the present work to extract phenolic compounds from different types of apples were based on that previous, study although slightly modified.

There is an increased interest in assessing the total antioxidant capacity of complex samples, that is, the total number of moles of a given free radical that is scavenged by the sample. The *antioxidant capacity* should be distinguished from the *antioxidant activity*, of which the latter corresponds to the rate constant of a reaction between a specific antioxidant and a specific oxidant.[15] Several methods to measure antioxidant properties have been proposed and were recently reviewed.[16,17] Among these, trolox equivalent antioxidant capacity (TEAC), scavenging of stable radical 2,2-diphenyl-1-picrylhydrazyl (DPPH), oxygen radical absorbance capacity (ORAC), total radical-trapping antioxidant parameter (TRAP), ferric reducing antioxidant power (FRAP), and cupric ions (Cu^{2+}) reducing power (Cuprac) were employed in foods.[16] These methods are related to the capacity of a sample to compete for and scavenge a specific reactive oxygen species (ROS).

Even though these methods provide useful information, they are not sufficient for the evaluation of the overall antioxidant profile of biological fluids, tissue homogenate, or plant extract. Besides, these procedures present some drawbacks because

they require the use of specific reagents and they are tedious and time-consuming. Furthermore, the DPPH$^{\bullet}$ and ABTS$^{\bullet+}$ radicals are not representative of biomolecules found in any biological system. In this context, cyclic voltammetry (CV) methodology allows a rapid production of the electrochemical profile of samples and is especially suitable for screening studies. It is based on the analysis of the anodic current (AC) waveform, which is a function of the reactive potential of a given compound in the sample or a mixture of compounds. The CV tracing indicates the ability of a compound to donate electrons at the potential of the anodic wave. A CV also provides information describing the integrated antioxidant capacity without the specific determination of the contribution of each individual component. Therefore, in the past couple of years, CV has been suggested as an instrumental methodology for the evaluation of the total antioxidant capacity of foods.[18−21] Therefore, we have used CV methodology to evaluate the antioxidant capacity of apple extracts and then compared it with the traditional methods such as DPPH and TEAC.

The main purpose of the current study was, however, to assess the contribution of individual components of apple extracts to the overall antioxidant capacity of the extracts. Recently, online HPLC methods for analyzing radical-scavenging activity have been developed.[22−24] Such methods require a stable model free radical system, such as DPPH$^{\bullet}$ and ABTS$^{\bullet+}$, with radical-scavenging activity assessed in comparison to the water-soluble synthetic vitamin E derivative 6-hydroxy-2,5,7,8-tetramethylchroma-2-carboxylic acid (trolox). Online assessment of antioxidant activity allows complex mixtures to be separated by HPLC and the antioxidant contribution of individual components to be evaluated. Instead, likewise to CV, electrochemical properties of the individual compounds can be used for quantifying their antioxidant capacity. In our previous work, we have developed a separation system useful for characterizing antioxidants in complex samples, which was based on the hyphenation of high-performance liquid chromatography with diode array, electrochemical, and mass spectrometry detection (HPLC-DAD-ECD-MS/MS).[25,26] However, a large drawback is that none of these detectors can give any information about the quantity of the analyzed compounds without their respective standards. Because chemical standards are rarely available for most flavonoids found in plants and herbs, and the available flavonoid standards are generally very expensive, the quantification of these compounds is a true challenge.

Recently, a novel detector has been suggested to overcome this drawback; the charged aerosol detector (CAD), which is based on a technique that adds charges to each particle containing analytes eluting from HPLC column. The size of the charge is not dependent on chemical properties of the analytes, which makes the CAD relatively generic, thereby requiring only a limited number of chemical standards to quantify a large number of analytes in complex samples.

The aim of this work was to develop a method to measure the total antioxidant capacity of apple extracts obtained by PHWE from different apple varieties and, additionally, to evaluate the contribution of individual compounds to the total antioxidant capacity of the extracts, as well as to quantify the compounds present. Hence, this paper presents for the first time the use of a hyphenated system, HPLC-DAD-ECD-CAD, to directly screen and characterize antioxidants in apples. This system shows great potential in all applications involving the analysis of antioxidants in complex samples.

MATERIALS AND METHODS

Chemicals and Reagents. All of the chemicals were of analytical grade. 2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) was purchased from Fluka (Buchs, Switzerland). Trolox, ammonium formate, potassium persulfate, chlorogenic acid, caffeic acid, protocatechuic acid, homovanillic acid, rutin, and phloridzin were supplied by Sigma-Aldrich (Steinheim, Germany). Formic acid was from Merck (Darmstadt, Germany). Methanol, LC-MS grade, was provided by Scharlau (Barcelona, Spain). The flavonoid standards were purchased from Extrasynthese (Lyon, France). Deagglomerated alumina (α-Al_2O_3) suspensions with grain size = 0.1 μm was provided by Struers (Ballerup, Denmark). The ultrapure water used was obtained from a Milli-Q (Millipore, Billerica, MA, USA) instrument.

Samples. The apple samples (Fuji, Golden Delicious, Granny Smith, Jonagold, Royal Gala, organic Golden Delicious, and organic Royal Gala, one of each) were obtained from a local market in Lund, Sweden. The apple samples were cut in small cubes (3 mm) composed of skin and flesh.

PHWE. Extractions were performed on a Dionex ASE 200 system (Thermo Fisher, Germering, Germany). At the beginning of the day, the water was sonicated for 40 min. Extractions were performed at 112 °C for 10 min on the basis of an experimental method used in a previous study.[14] Prior to each experiment, heating of an extraction cell was carried out for 6 min. Likewise, all extractions were performed in 11 mL extraction cells, containing 5 g of fresh sample. Samples were prepared in duplicate.

The dry weight of apple was calculated by subtracting water content from the total weight. The fresh apple was led to dryness in an oven at 125 °C for 24 h.[27] This process was carried out in triplicate. The water contents in the apples, Fuji, Golden Delicious, Granny Smith, Jonagold, Royal Gala, organic Golden Delicious, and organic Royal Gala, were 84.5 ± 0.3, 85.1 ± 0.2, 85.3 ± 0.1, 86.1 ± 0.1, 83.4 ± 0.2, 88.1 ± 0.1, and 84.5 ± 0.4%, respectively.

The extraction procedure was as follows: (i) the extraction cell was loaded into the oven; (ii) the cell was filled with solvent up to a pressure of 1500 psi; (iii) heating time was applied; (iv) a static extraction with all system valves closed was performed; (v) the cell was rinsed (with 60% cell volume using extraction solvent); (vi) solvent was purged from the cell with nitrogen gas; and (vii) depressurization took place. Between extractions, a rinse of the complete system was made to prevent any extract carry-over. The extracts obtained were protected from light, freeze-dried, and stored at −20 °C until analysis. To prepare the sample solutions, the freeze-dried extracts were redisolved in water at a concentration of 20 mg/mL.

Evaluation of Antioxidant Capacity. *TEAC Assay.* The TEAC assay described by Re et al.[28] with some modifications was used to measure the antioxidant capacity of the extracts. The ABTS radical cation (ABTS$^{\bullet+}$) was produced by reacting 7 mM ABTS with 2.45 mM potassium persulfate and allowing the mixture to stand in the dark at room temperature for 12−16 h before use. The aqueous ABTS$^{\bullet+}$ solution was diluted with 5 mM phosphate buffer (pH 7.4) to an absorbance of 0.70 (±0.02) at 734 nm. Ten microliters of sample solution (four different concentrations) was added to 1 mL of diluted ABTS$^{\bullet+}$ radical solution. After 50 min at 30 °C, 300 μL of the mixture was transferred into a well of the microplate, and the absorbance was measured at 734 nm in a microplate spectrophotometer reader (Multiskan GO, Thermo Fisher). Trolox was used as a reference standard, and results were expressed as TEAC values (mmol trolox/g extract). These values were obtained from at least four different concentrations of each extract tested in the assay giving a linear response between 20 and 80% of the initial absorbance. All analyses were done in triplicate for each extract.

DPPH Radical-Scavenging Assay. The antioxidant capacity of all the obtained extracts was measured using the DPPH radical-scavenging assay based on the protocol by Brand-Williams et al.[29] Briefly, a solution was prepared by dissolving 23.5 mg of DPPH in 100

mL of methanol. This stock solution was further diluted 1:10 with methanol. Both solutions were stored at 4 °C until use. Four different concentrations of extracts were tested. Twenty-five microliters of these solutions was added to 975 μL of DPPH diluted solution to complete the final reaction medium (1 mL). After 4 h at room temperature, 300 μL of the mixture was transferred into a well of the microplate, and the absorbance was measured at 516 nm in a microplate spectrophotometer reader (Multiskan GO, Thermo Fisher). A DPPH−methanol solution was used as a reference sample. The DPPH concentration remaining in the reaction medium was calculated from a calibration curve. The percentage of remaining DPPH against the extract concentration was then plotted to obtain the amount of antioxidant necessary to decrease the initial DPPH concentration by 50%, or EC_{50}. Therefore, the lower the EC_{50}, the higher the antioxidant capacity. To enhance the clarity of the results, the antioxidant capacity was determined as the inverse value of the efficient concentration EC_{50} (μg/mL), representing a comparable term for the effectiveness of antioxidant and radical-scavenging capacity ($1/EC_{50}$). The larger the antioxidant capacity, the more efficient the antioxidant. Measurements were done in triplicate for each extract.

Cyclic Voltammetry. Cyclic voltammetric experiments were performed in 50:50 (methanol/water, v/v) extracts mixed with sodium formate buffer (pH 3.0) at a 1:1 (v/v) ratio and 0.5 M $NaNO_3$ following the method of Zettersten et al.[26] The sodium formate buffer consisted of 200 mM NaHCOO/HCOOH in water. The sodium formate buffer and $NaNO_3$ served as supporting electrolytes for the voltammetric measurement.

Cyclic voltammetry measurements were performed in a sealed-bottom three-electrode cell in which the electrode area was defined by an elastomeric O-ring (area ∼ 0.5 cm^2) using a glassy carbon electrode. A platinum auxiliary electrode and a silver/silver chloride reference electrode were used. The glassy carbon electrode was slightly polished on a polishing cloth with Al_2O_3 before each voltammetric experiment. All voltammograms were obtained at a scan rate of 20 mV/s. The homemade three-electrode cell used had angled openings allowing the reference and the working electrodes to be placed as close as possible to each other. The cell was connected to a battery-powered potentiostat (PalmSens, Palm Instruments BV, Houten, The Netherlands). The potentiostat was controlled by an HP iPAQ Pocket PC (HP 2200 series, Hewlett-Packard Co.) using PalmScan software (vs 1.4.2, Palm Instruments BV). All apple extract solutions (concentration = 10 mg/mL) were purged for 5 min with nitrogen gas prior to use. Measurements were done in triplicate.

For the purpose of testing, the total anodic peak wave area (S) of the voltammogram was calculated.[30] This method is based on the correlation between the total anodic peak wave area of cyclic voltammograms and the antioxidant capacity of the sample and reference substance. For the reference, an 80% methanol solution of trolox within the concentration range of 0.05−2.50 mM was used, and the results were expressed as micromoles of Trolox per gram of dry extract.

HPLC with Hyphenated Diode Array, Electrochemical, and Charged Aerosol Detection. *Instrumentation.* The HPLC-DAD-ECD-CAD setup is described schematically in Figure 1. It consisted of an UltiMate-3000 HPLC system from Dionex (Thermo Fisher) with an online degasser, a quarternary solvent pump, and an autosampler with cooler, column oven, and photodiode array detector (DAD) with scanning capabilities, all controlled by Chromeleon 6.80 (Thermo Fisher) software. The detection wavelengths used were 200, 280, 350, 370, and 520 nm.

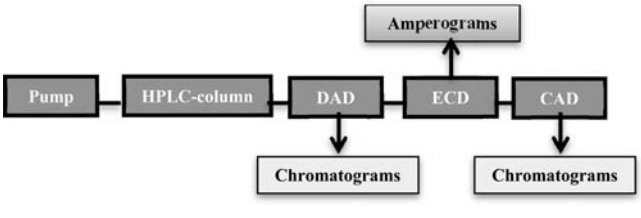

Figure 1. Employed online HPLC-DAD-ECD-CAD system.

An ECD instrument was attached just after the DAD. The online amperometric detection setup included a thin layer flow cell (Bioanalytical System Inc., West Lafayette, IN, USA) with a series dual glassy carbon disk electrodes (3 mm diameter) working electrode imbedded in a PEEK block (Bioanalytical System Inc.). A spacer gasket with a thickness of 16 μm (Bioanalytical System Inc.) was placed between the PEEK block comprising the working electrode and the stainless steel block serving as counter electrode. This resulted in a total cell volume of 1.0−1.2 μL. The reference electrode was fixed in a compartment in the stainless steel block. The ECD redox potential measured at +0.6 V vs Ag/AgCl was found to yield antioxidant capacity results comparable with those of the DPPH and ABTS assays. A battery-powered potentiostat (Palmsens, Palm Instrument BV) was connected to the flow cell and was controlled by an HP iPAQ Pocket PC (HP 2200 series, Hewlett-Packard Co.). PalmTime software (vs 2.3.0.0, Palmsens) was used to collect data.

A Corona CAD instrument from ESA Biosciences Inc. (part of Thermo Fisher) was placed in series after the ECD detector. Data processing was carried out with Chromeleon 6.8 software (Thermo Fisher). Nitrogen gas flow rate was regulated automatically and monitored by the CAD device regulated at 35 psi. Response range was set to 20 pA full scale. Medium filter was applied.

Chromatographic Separation. A porous-shell fused core Ascentis Express C18 (150 mm × 2.1 mm, 2.7 μm) from Supelco (Bellefonte, PA, USA) was used as an analytical column for LC separation. The mobile phases consisted of (A) ammonium formate buffer (pH 3.0), 60 mM (NH_4HCOO/HCOOH) in water; and (B) methanol with 0.2% of formic acid in a gradient elution analysis programmed as follows: 0 min, 5% (B); 0−5 min, 5% (B); 5−35 min, 40% (B); 35−40 min, 40% (B), with 10 min of post-time at a flow rate of 300 μL/min. The mobile phases were purged with nitrogen to remove oxygen. The column temperature was set at 50 °C, the injection volume was 2 μL, and the vial tray was held at 4 °C.

Statistical Analysis. The KaleidaGraph 4.03 (Synergy Software, Reading, PA, USA) program was employed for statistical analysis of the data with the level of significance set at 95%. Student's t test was used to assess significant differences between antioxidant assays.

RESULTS AND DISCUSSION

As mentioned in the Introduction, the aim of this work was mainly to develop a method that can be used to characterize and quantify antioxidants in complex samples. Hence, the focus was not to identify the different types of antioxidants found in apples.

Antioxidant Capacity of Apple Extracts Produced by PHWE. PHWE is an environmentally friendly technique that presents important advantages over traditional solvent extraction techniques, mainly achieving safe, green, and rapid extractions. Increasing the temperature decreases the dielectric constant of water, resulting in the possibility of tuning its solvent properties, as has been shown for aromatic plants.[11] In this work, PHWE was used to obtain a variety of extracts from seven different apples: Fuji, Golden Delicious, Granny Smith, Jonagold, Royal Gala, organic Golden Delicious, and organic Royal Gala. The extraction yield (percent dry weight) obtained from apple PHWE extraction was around 63% (Table 1), being maximum in Jonagold (67%) and minimum in organic Golden Delicious (60%).

In this study, we conducted a critical evaluation of a cyclic voltammetry method for the determination and rapid screening of antioxidant capacity of different apple type extracts compared with ABTS and DPPH assays. The representative cyclic voltammograms of the apple extracts (10 mg/mL concentration) were recorded from 0 to 700 mV at a scan rate of 20 mV/s (Figure 2). The obtained voltammograms

Table 1. Extraction Yield and DPPH, ABTS, and Cyclic Voltammetry Antioxidant Capacity Values Obtained for the Different Varieties of Apple Extracts after PHWE at 112 °C and 10 min[a]

	extraction yield		ABTS		DPPH		CV	
apple variety	% (dry wt)	RSD (%)	TEAC (mmol/g dry extract)	RSD (%)	$1/EC_{50}$ (μg/mL)	RSD (%)	mmol trolox/g dry extract	RSD (%)
Golden Delicious	60	1.7	0.12	4.0	3.4	1.7	7.9	3.0
Royal Gala	64	4.9	0.082	7.8	2.7	2.2	7.4	1.1
Fuji	64	5.5	0.050	8.0	1.5	2.0	5.1	6.1
Granny Smith	62	1.7	0.13	1.9	3.5	1.0	7.4	4.7
Jonagold	67	4.8	0.18	3.3	4.9	2.2	12	4.3
organic Golden Delicious	59	8.0	0.16	6.0	4.2	4.9	9.3	7.1
organic Royal Gala	63	2.4	0.10	4.0	2.9	2.3	6.7	8.7

[a]All measurements were done in triplicate for each extraction. The data are presented as the average of six measurements from two extracts (mean and relative standard deviation (RSD)).

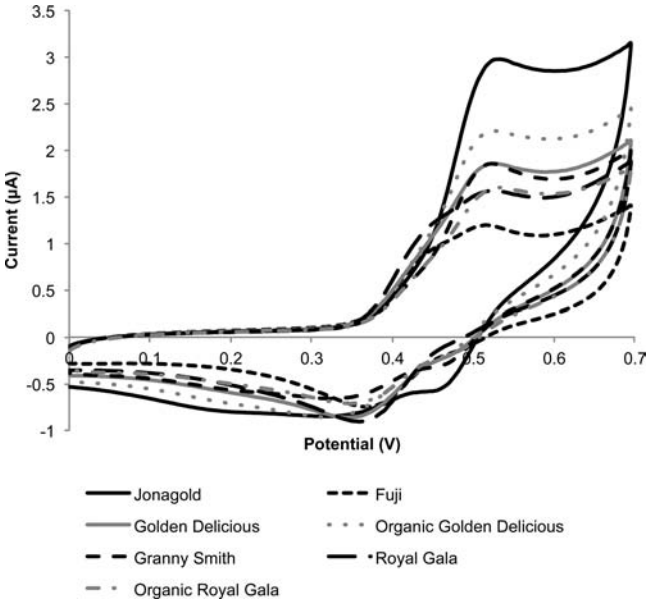

Figure 2. Cyclic voltammograms of PHWE extracts from different apple varieties. Operative conditions: concentration of each extract, 10 mg/mL; scan rate, 20 mV/s.

show that the different apple extracts exhibit well-defined oxidation and reduction votammetric peaks. The area of each voltammetric peak is related to the concentration of antioxidants.[31,32] A broad anodic peak between 0.4 and 0.6 V was observed. The peak is due to the response of several antioxidants with different oxidation potentials, which are mainly flavonoids and phenolic acids.[14] The results show that the samples contain multiple reducing agents in the respective extracts. Therefore, the area under the anodic current waveform (AUC) was taken to reflect the total antioxidant capacity of the samples compared to a set of trolox solutions, as suggested by Chevion et al.,[31] Martínez et al.,[32] and Zielinska et al.[30] This provides a marked advantage in some cases, particularly when the AUC wave represents more than a single component. Higher AUC area indicates a higher antioxidant capacity of the investigated extract.

Furthermore, the use of three different methods to measure the antioxidant capacity of different apple extracts allowed us to gain insight into their reaction mechanism. The results obtained are summarized in Table 1. All extracts were able to act against $ABTS^{\bullet+}$ and DPPH radicals and were susceptible to oxidation. Extracts from different apple varieties show significant differences in their antioxidant capacity, although the extraction yields are similar.

To correlate the CV data for different apple varieties with the ABTS and DPPH, the results in Figure 3 have been normalized so that the values range from 0 to 1, 1 being the maximum value of total antioxidant capacity in each method. The results from CV strongly correlate with those determined using well-known spectrophotometric methodologies such as DPPH and ABTS assays. There was no statistically significant difference between the different assays ($p > 0.05$). From the above results it follows that a good correlation exists between antioxidant capacity (obtained from the oxidation peak areas in CV) and antiradical power, indicating that the voltammetric method can be used for the determination of antioxidant capacity, in the same way as the DPPH and ABTS assays. At least this is true for water-soluble antioxidants in apples.

This means that the values of the oxidation potentials can be interpreted in the same way as the antiradical power values obtained from DPPH and ABTS, and the quality of the information obtained is the same in all cases. This result is in agreement with other studies, in which CV was shown to be an efficient instrumental tool for evaluating the antioxidant capacity of plant, food, and biological samples.[21,30,33,34] An advantage of the electrochemical measurement compared to the DPPH and ABTS methods is that it is fast. The CV measurement is carried out in <10 min; that is, it is less tedious. Moreover, there is no necessity to use expensive reagents that include free radicals, thus lowering the cost. In addition, the use of a small amount of organic solvent reduces the amount of organic waste produced.

Optimization of an Online HPLC-DAD-ECD-CAD Method. The separation of all phenolic compounds in the fruit extract using HPLC is a crucial and challenging task. Considerable effort was required to develop the HPLC conditions used in this paper. Apples are rich in flavonoids with similar skeleton structures. Because acidic conditions are known to create uncharged hydroxyl groups, the pH of the analytes should be kept below the pK_a of the flavonoids, thus achieving better separation for flavonoid derivatives by reducing the tailing of the peaks. This was achieved by adding acid into the mobile phase used in this work.[35,36] It was also necessary to use a mobile phase that could also serve as a supporting electrolyte in the EC cell. To meet these conditions, an ammonium formate buffer (pH 3) was used as the mobile phase and contained 60 mM $NH_4HCOO/HCOOH$ in water.[26] In the course of optimizing the conditions of separation, the system conditions including gradient program (gradient time, gradient shape, and initial composition of the mobile phase),

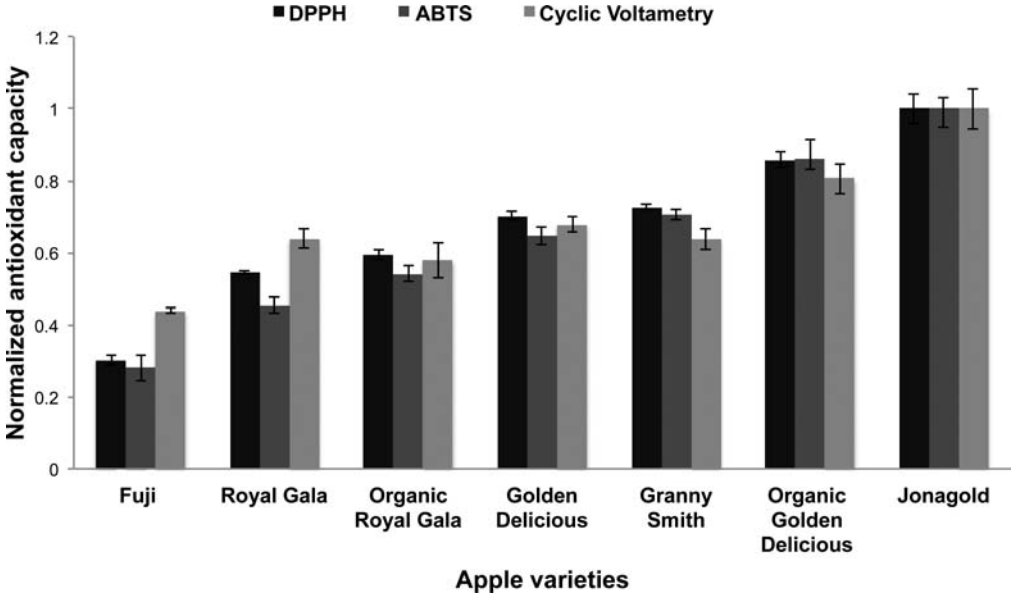

Figure 3. Normalized antioxidant capacity of DPPH, ABTS, and cyclic voltammetry values obtained for the different varieties of apple extracts after PHWE at 112 °C and 10 min. All measurements were done in triplicate for each extraction. The data are presented as the average of six measurements from two extracts.

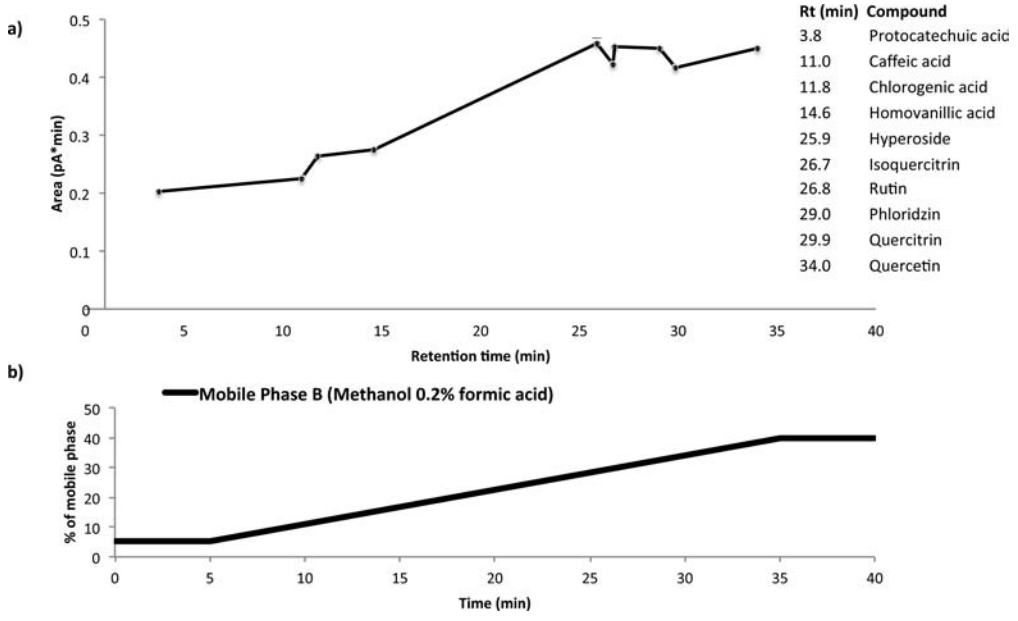

Figure 4. Charged aerosol detection response for a selection of phenolic compounds injected at the same concentration (0.1 mg/mL) (a) and a HPLC gradient of mobile phases employed for the analysis of these compounds (b). All measurements were done in triplicate.

column temperature (25−50 °C), flow rate (0.2−0.4 mL/min), injection volume (1−5 μL), and detection wavelength (200, 280, 350, 370, and 520 nm) were investigated. The final results showed that the best resolution and shortest analysis time were achieved when a gradient elution was composed of solvent (A) ammonium formate buffer (pH 3.0)−60 mM (NH_4HCOO/HCOOH) in water and solvent (B) methanol with 0.2% formic acid programmed as follows: 0 min, 5% B; 0−5 min, 5% B; 5−35 min, 40% B; 35−40 min, 40% B; and a 10 min post-time at final composition. The selected flow rate was 300 μL/min, the column temperature was 50 °C, and the injection volume was 2 μL. The vial tray was held at 4 °C.

The analytes were detected by a DAD, which was set to record chromatograms between 200 and 600 nm, with selected wavelengths of 280 nm (for identification of the phenolic acids and chalcones) and 350 nm (for flavonols and chlorogenic acid). The DAD allowed a preliminary characterization of the compounds based on their retention time and UV−vis spectra by comparison with standards, when available, or with data appearing in the literature.[37,38]

The DAD was coupled online to an ECD to estimate the antioxidant capacity of each compound and its contribution to the total antioxidant capacity of the apple extracts. The oxidation potential for the phenolic compounds from apples was determined on the basis of the cyclic voltammograms. The oxidation peak for the phenolic compounds from apples occurred at a potential of about 0.55 V. This peak is due to the oxidation of hydroxyl groups on the extracted phenolic

Table 2. Calibration Curves Using Various Standards of Phenolic Compounds in HPLC-CAD and the Error Obtained When Calibration Curves of Chlorogenic Acid (for Phenolic Acids) and Hyperoside (for Flavonols and Chalcones) Were Used Instead of Their Respective Standards To Carry Out the Quantification of These Standards[a]

RT (min)	compound	regression coefficient	R^2	LOD[b] (μg/mL)	LOQ[c] (μg/mL)	error (%)
3.76	protocatechuic acid	$2.097x + 0.003$	0.992	4.6	16.7	11.7
10.98	caffeic acid	$2.295x + 0.001$	0.998	4.4	14.4	7.3
11.80	chlorogenic acid	$2.655x - 0.006$	0.997	5.8	18.8	
14.61	homovanillic acid	$2.729x + 0.006$	0.998	7.5	30.4	1.4
25.87	hyperoside	$4.662x + 0.004$	0.998	1.5	5.4	
26.67	isoquercitrin	$4.184x - 0.0001$	0.999	1.6	5.9	5.4
26.81	rutin	$4.501x + 0.005$	0.999	1.5	5.2	1.7
29.04	phloridzin	$4.494x - 0.002$	0.999	1.3	5.4	1.8
29.88	quercitrin	$4.116x + 0.001$	0.999	1.8	6.2	6.2
34.04	quercetin	$4.594x - 0.002$	0.997	1.6	7.8	0.7

[a]All measurements were done in triplicate. [b]LOD, limit of detection. [c]LOQ, limit of quantification.

compounds and, unfortunately, cannot be used to identify individual antioxidants.[31] More in-depth information about oxidation of phenolic compounds is given by Yakovleva et al.[39] In conclusion, for the ECD experiments, we used a fixed potential of 0.60 V to ensure all of the phenolic compounds were oxidized.

To carry out the quantification of the phenolic compounds, the HPLC-DAD-ECD system was hyphenated online to a corona CAD detector. CAD is now established as a universal detector for HPLC applications, which has been shown to produce direct quantification of compounds relative to a known standard.[40,41] CAD involves first nebulizing the HPLC column eluent with nitrogen and then drying in a drift tube to produce analyte particles. A secondary flow of nitrogen becomes positively charged as it passes through a corona generated by high voltage. This charged nitrogen is then mixed with the stream of analyte particles where the charge migrates to the analyte.[42] Charged analyte particles proceed to a collector region, where a highly sensitive electrometer produces a signal that is proportional to the weight of sample present, independent of chemical structure.[43] This results in an equal response for equal mass amounts.[44]

To measure the detector response of the CAD, different phenolic compounds (flavonols, chalcones, and phenolic acids), which have been previously described in apples,[14,37] were injected in triplicate at the same concentration of 0.1 mg/mL (see Figure 4a). As can be seen in Figure 4a, the response obtained was different, dividing the compounds into two groups. The phenolic acids, protocatechuic, caffeic, chlorogenic, and homovanillic acids, which had shorter retention times, had similar response areas around 0.20−0.27 pA·min. On the other hand, the flavonols and chalcone, hyperoside, isoquercitrin, rutin, quercitrin, quercetin, and phloridzin, which had longer retention times, had similar response areas around 0.42−0.46 pA·min. The differences observed may have been due to mobile phase composition. As can be seen in Figure 4, it is evident that the response factors increased with increasing concentration of methanol in the mobile phase. As has been reported before, a weakness of all detectors employing a nebulization process is that the response is dependent on the composition of the mobile phase and increases with the organic solvent content.[45] A solution to this is to use a second gradient pump that applies a reverse gradient. We are currently carrying out experiments to test this hypothesis.

The data concerning the validation of the quantification of phenolic compounds method by HPLC-CAD are summarized in Table 2. The linearity of the detector response was determined by the square correlation coefficients of the calibration curves generated by three repeated injections of standard solutions at nine concentration levels (Table 2). Quercetin-3-*O*-galactoside (hyperoside), quercetin-3-*O*-glucoside (isoquercitrin), quercetin-3-*O*-rutinoside (rutin), phloretin-2′-*O*-glucoside (phloridzin), quercetin-3-*O*-rhamnoside (quercitrin), and quercetin were injected in concentrations from 1 to 100 μg/mL each; chlorogenic acid, protocatechuic acid, and caffeic acid were injected in concentrations from 2 to 200 μg/mL each; and homovanillic acid was injected in concentrations from 3 to 200 μg/mL.

The calibration curves were obtained by plotting peak area as a function of concentration (in micrograms per milliliter). Although it is known that Corona CAD response is nonlinear at a range of 4 orders of magnitude, its signal is nearly linear in the smaller ranges.[46] Responses obtained in the examined ranges were expressed by a linear equation, $y = ax \pm b$, with good r^2 determination coefficient values (Table 2). Estimations of the limit of detection (LOD) and limit of quantification (LOQ) of the phenolic compounds were determined on the basis of the signal-to noise ratio (S/N) of 3 and 10, respectively (Table 2). The analytical methodology revealed good linearity (Table 2). The regression coefficients using the CAD were very similar for the phenolic acids and for the flavonols and chalcones. In this sense, the calibration curve of one phenolic acid and one flavonol could be used to quantify other phenolic compounds present in the apple extracts. The calibration curves of chlorogenic acid and hyperoside were selected to quantify all of the phenolic compounds, because they are normally found in high concentration in the different apple extracts.[14] The error obtained by using the two selected standards (chlorogenic acid and hyperoside) instead of the corresponding standard for each sample was calculated at concentrations of LOQ. The data are given in Table 2. The maximum error obtained was <12%, and the average error was 5%. Our results suggest that CAD shows great promise as an appropriate universal detector for quantifying phenolics from apple extracts using only the calibration curves of one phenolic acid and one flavonoid. A disadvantage of CAD is its relatively low sensitivity compared to DAD. For instance, the obtained values for LOD and LOQ were 5.8 and 18.8 μg/mL for chlorogenic acid and 1.5 and 5.4 μg/mL for hyperoside, respectively (see Table 2), which are around 5−18 times higher than those described in the literature for these compounds and other flavonoids analyzed with a similar method but with DAD.[47−49]

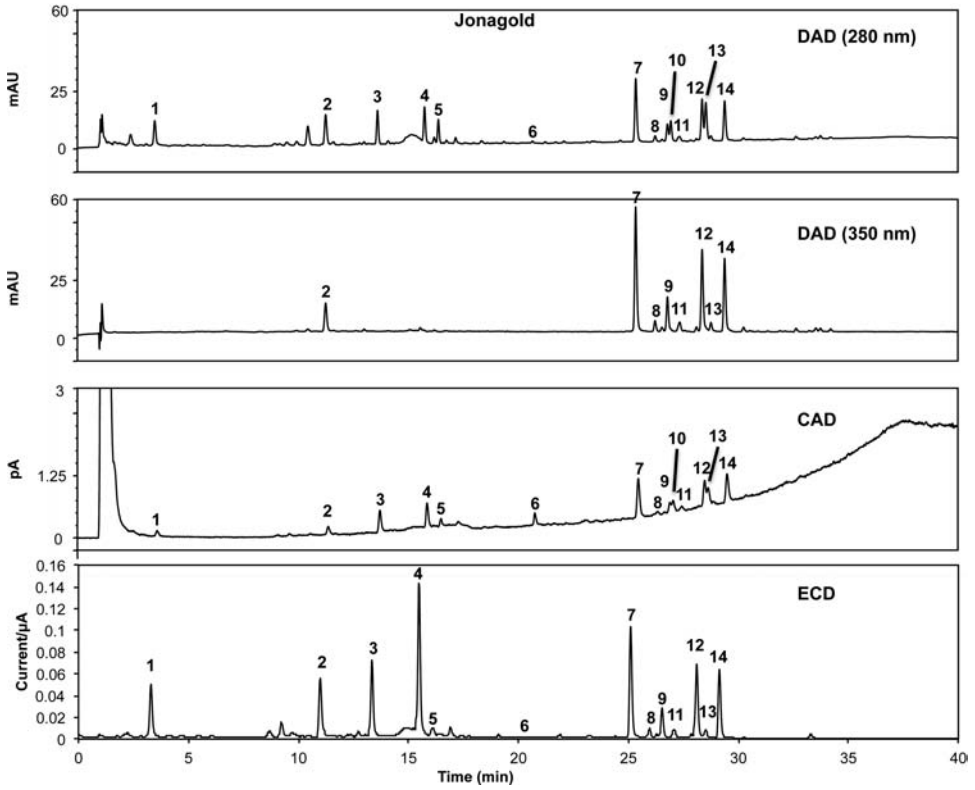

Figure 5. Chromatograms and amperogram corresponding to the HPLC-DAD-ECD-CAD analysis of Jonagold apple extract at 280 nm (a) and 350 nm (b), CAD chromatogram (c), and amperogram (d). Analytical conditions are given under Material and Methods. For peak identification, see Table 3.

Quantification and Tentative Identification of Phenolic Compounds in Apples. The developed online HPLC-DAD-ECD-CAD method was tested with the different apple extracts. Selected chromatograms and amperogram obtained from the Jonagold sample are shown in Figure 5. The data clearly demonstrate that several phenolic acids and polyphenols could be separated in an analysis time of around 40 min. As shown in Figure 5, the peak profile of the HPLC-ECD amperogram corresponded well with the chromatographic peaks in the DAD and CAD profiles. The careful analysis of the separated compounds, using the information provided by the DAD detector together with the information found in the literature[37,38] and from commercial standards (when available), allowed the tentative identification of 14 antioxidant compounds in the different apple extracts, which belong to the phenolic family (Table 3).

As discussed above, the quantification of phenolic compounds was carried out with a CAD detector using the calibration curve of chlorogenic acid for phenolic acids and hyperoside for flavonols and chalcones. This detector allowed the quantification of all of the separated phenolic compounds without their respective standards. All of the results for the quantification of phenolic compounds in apple varieties are shown in Table 1 of the Supporting Information.

Determination of Individual Phenolic Compound Contributions to the Total Antioxidant Capacity in Apples. The use of cyclic voltammetry for the determination of the antioxidant capacity has been reported. The intensity of the anodic peak current or the area under the anodic peak can be used as an indicator of the antioxidant capacity.[31] As a result, in this work, the ECD was used to study the oxidation of phenolic compounds to indicate the antioxidant capacity of each compound. To carry out the determination of the contribution of individual phenolic compounds to the total antioxidant capacity of the apple extracts, the concentration of each compound as determined by CAD and the peak areas obtained by ECD for each compound were correlated in scatter plots (Figure 6 and Table 3). The complete set of data is given in Table 1 of the Supporting Information.

Table 3. Linear Coefficient (R^2) and Slope of the Regression Line for a Side-by-Side Comparison between CAD Response (Concentration (Milligrams per Gram Dry Extract)) and ECD Response (Area (nA·s)) for Each Phenolic Compound Found in Seven Different Varieties of Apple Extracts Injected at a Concentration of 20 mg/mL[a]

peak	RT (min)	compound	R^2	slope ± 95% CI
1	3.6	protocatechuic acid	0.993	1269 ± 21

[a]The data are presented as the average of four measurements from two extracts. CI, confidence interval.

dx.doi.org/10.1021/jf404263k | J. Agric. Food Chem. 2014, 62, 409−418

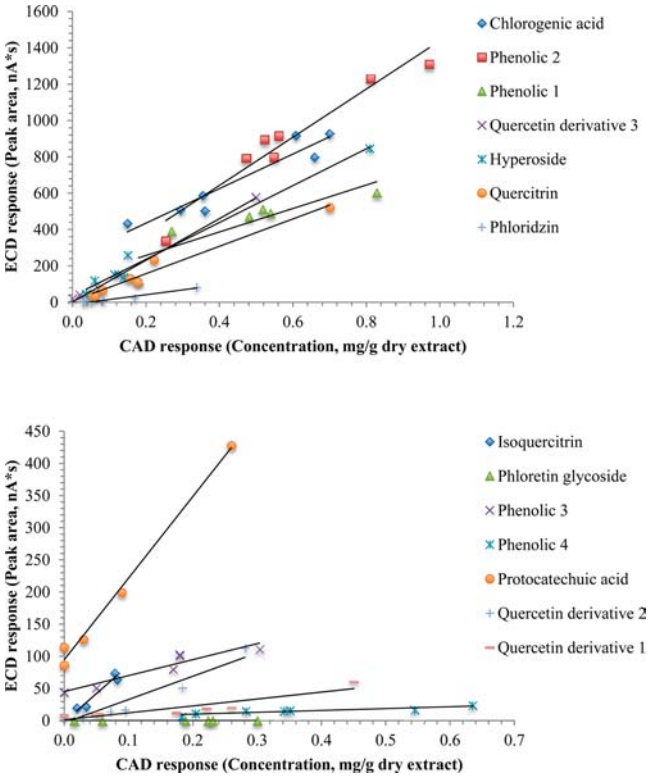

Figure 6. Scatterplots of ECD response (area (nA·s)) versus CAD response (concentration (mg/g dry extract)) for each phenolic compound found in seven different varieties of apple extracts injected at a concentration of 20 mg/mL. The data are presented as an average of four measurements from two extracts.

As shown in Table 3, the response between both detectors was fairly linear, with the R^2 of 14 compounds being ≥0.782. Using the slope, it was possible to calculate the antioxidant capacity and the contribution of each phenolic compound to the total antioxidant capacity of the apple extracts. The higher the slope, the higher the antioxidant capacity. The results revealed that phenolic 2 (not identified), protocatechuic acid, quercetin derivative 3 (not identified), hyperoside, and chlorogenic acid with slopes of 1320, 1269, 1145, 1013, and 948, respectively, were the phenolic compounds with higher antioxidant capacity. On the contrary, the phenolic compounds with lower antioxidant capacity were phenolic 4 (not identified), quercetin derivative 1 (not identified), phenolic 3 (not identified), and phloridzin, with slopes of 29, 107, 248, and 265, respectively. Phloretin glycoside was not possible to detect with ECD due to the low concentration present in the apple extracts. For this reason, it was not possible to calculate the R^2 and the slope for phloretin glycoside. This result suggests that this chalcone is not a significant contributor to the total antioxidant capacity of apple extracts. On the other hand, protocatechuic acid was present in concentrations lower than the detection limit of the CAD detector in several of the apple extracts, but showed high antioxidant capacity as observed with the ECD. In conclusion, phenolic 2, chlorogenic acid, phenolic 1, and hyperoside were found in high concentrations and also exhibited higher antioxidant capacity. Therefore, these compounds can be expected to contribute the most to the total antioxidant capacity of apple extracts (see Figure 6).

Figure 7 shows the sum of all peak areas obtained for each apple from the ECD voltammograms. The area represents the

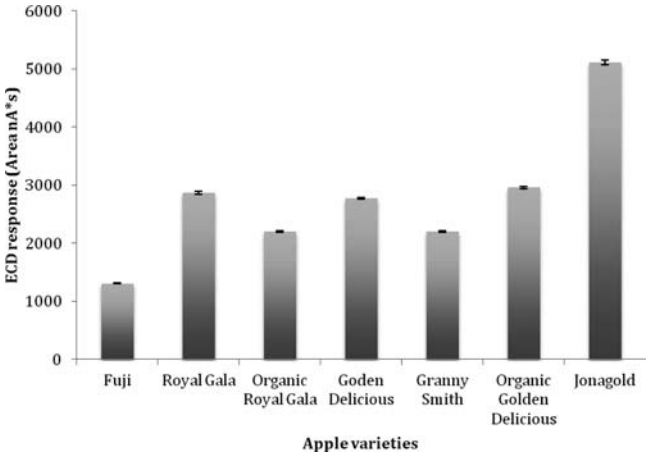

Figure 7. Total areas of phenolic compound peaks obtained by ECD for the different varieties of apple extracts. The data are presented as an average of four measurements from two extracts.

total antioxidant capacity of phenolic compounds found in the apple extracts. As can be seen in Figure 7, the highest antioxidant capacity was observed in Jonagold apple followed by organic Golden Delicious, Royal Gala, Golden Delicious, organic Royal Gala, Granny Smith, and Fuji. These results were similar to the data observed in Figure 3, which indicated that the total antioxidant capacity of apple extracts may be contributed mainly by phenolic compounds. However, in complex samples, synergism and antagonism reactions between different compounds may occur, and these reactions affect the total antioxidant capacity.[50−52]

In conclusion, a cyclic voltammetry assay was demonstrated to be an effective method for measuring the antioxidant capacity of apple extracts. It was comparable with conventional ABTS and DPPH antioxidant assays. Furthermore, for the first time, a HPLC-DAD-ECD-CAD method was developed for the determination and quantification of phenolic compounds in apple extracts. The main advantage of the developed hyphenated method is its selectivity, because it not only separates and detects polyphenols but also determines the compounds' potential functionality in terms of antioxidant capacity by utilizing ECD in combination with CAD responses.

Clearly, the advantage of online antioxidant measurement lies in its ability to distinguish the antioxidant capacity of compounds that can hardly be separated by fractionation. The relative importance of these compounds for antioxidant capacity is measured directly, without time-consuming techniques. Furthermore, an independent measurement of the quantity of antioxidant compounds is performed by CAD. This latter detector proved to enable quantification for different classes of compounds, relative to each other. This is particularly useful when no standards are available, as is usually the case for many flavonoids.

Supporting Information

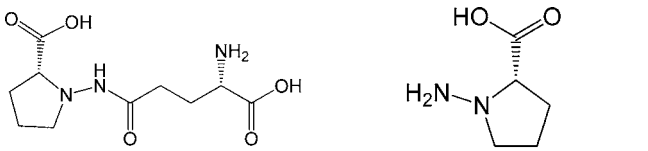
ABSTRACT: In the present study, the anti-pyridoxine compounds linatine (1-[(*n*-γ-L-glutamyl)amino]-D-proline) and 1-amino-D-proline (1ADP) were quantified following extraction from defatted flaxseed using aqueous isopropanol as a solvent, with extraction variables including time, temperature, and the solid/solvent ratio. Both linatine and 1ADP were identified, characterized, and quantified via UPLC/ESI-MS using authentic standards. To optimize the extraction conditions for these anti-pyridoxine compounds, a response surface methodology was applied using a second-order polynomial to describe the experimental data. The predicted model for the optimal extraction was significant ($P < 0.05$) with a R^2 of 0.82. A varietal analysis showed that the amount of anti-pyridoxine present in flaxseed ranged from 177 to 437 μg 1ADPE/g of whole seed. The current study establishes the content of specific anti-pyridoxine factors in flaxseed and positions the data for use in subsequent risk assessment modeling.

KEYWORDS: *anti-pyridoxine, linatine, 1-amino-D-proline, flaxseed*

INTRODUCTION

The seeds of the flax plant (*Linum usitatissimum* L.) contain several nutritionally relevant compounds. Flaxseeds contain 35–45% oil by weight, of which 52% is α-linolenic acid (ALA), an omega-3 fatty acid.[1] Dietary ALA supplementation lowers the production of inflammatory biomolecules such as interleukin-6 (IL-6) and C-reactive protein (CRP).[2,3] Flaxseed consumption suppressed the development of atherosclerosis by reducing plasma total cholesterol (TC), low-density lipoprotein (LDL), and triglycerides (TGs) in a rat model.[4] For humans, the dietary reference intake (DRI) process led to the establishment of adequate intakes of ALA in the amounts of 1.1 and 1.6 g/day for women and men, respectively.[5] Given its enriched status, flaxseed has been positioned as a good source of ALA for the human diet. Additionally, flaxseed also represents a good source of cyclolinopeptides,[6,7] fiber, and contains significant levels of lignans, especially isolariciresinol, pinoresinol, and secoisolariciresinol diglucoside (SDG).[8−10] The latter phytoestrogenic compounds possess putative antitumorigenic,[10,11] antioxidant,[12] and hypotensive properties.[13] Given the increased interest in the potential health-promoting aspects of whole flaxseed, its utilization in the commercial food supply has expanded. Whereas the positive attributes of flax consumption have been the focus of attention in recent years, it is important to recognize the potential antinutritive factors present in whole seeds.

Flaxseed contains several antinutritive compounds, including phytic acid,[14] cyanogenic glycosides,[5,15,16] and the dipeptide linatine.[17] Linatine (1-[(*n*-γ-L-glutamyl)amino]-D-proline), is a polar compound first identified by Kratzer[18] to possess anti-pyridoxine activity. Chicks fed a diet containing linseed meal established signs of vitamin B_6 deficiency.[19] Subsequent studies confirmed the structure of the compound as $C_{10}H_{17}N_3O_5$ with an observed molecular weight of 259.26. It is a dipeptide formed by 1-amino-D-proline (1ADP) bound to a glutamic acid by a peptide bond through the γ-carbonyl of the glutamic acid[17] (Figure 1). The potent anti-pyridoxine component of linatine is



Linatine 1-amino D-proline

Figure 1. Structures of anti-pyridoxines from flaxseed.

purported to be 1ADP, which has a molecular weight of 130.15. The latter compound acts as an asymmetrically substituted secondary hydrazine that is thus responsible for the in vivo hydrazone toxicity of the active pyridoxyl-5-phosphate (PLP), ultimately leading to the vitamin B_6 deficiency symptoms.[19] Numerous PLP-dependent enzymes, including glutamic amino-transferase, tryptophanase, tyrosine decarboxylase, and glutamic

decarboxylase, demonstrated marked activity inhibition when treated, in vitro, with 1ADP.[20] Additionally, the intraperitoneal injection of 1ADP greatly disturbed methionine metabolism, resulting in the accumulation of L-cystathionine and its derivatives.[21] Given the recognized potential for the presence of an anti-pyridoxine factor in the food supply, the establishment of an analytical technique for the measurement of linatine and 1ADP in flaxseed is required prior to any risk assessment analysis.

Previous research has relied upon the use of first-generation chromatography (paper, thin layer) techniques coupled with ninhydrin-based, spectrophotometric analysis for linatine and 1ADP analysis.[17,22−24] The present study was designed to develop an ultrahigh-performance liquid chromatography−mass spectrometry (UPLC-MS) technique for the measurement of linatine and 1ADP. Additionally, the objectives included the optimization of extraction conditions using response surface methodology (RSM) with four factors (solvent concentration, time, and temperature, and the liquid/solid ratio), each tested at three distinct levels. The final objective of this study was the determination of the content of the anti-pyridoxine components in selected varieties of commercial flaxseed.

MATERIALS AND METHODS

Materials. Flaxseed samples [a harvest composite sample made of flaxseed samples (150) harvested within one year in western Canada and nine different varieties] were provided by the Canadian International Grain Commission, Winnipeg, Canada. Isotopically labeled D-proline (2,5,5-d_3) was obtained from C/D/N Isotopes (QC, Canada), whereas 1-amino D-proline was purchased from Santa Cruz Biotech (Dallas, TX, USA). All solvents (analytical and HPLC grades) were purchased from Sigma-Aldrich (Oakville, ON, Canada). A bulk of composite flaxseed was defatted through the use of a Soxhlet apparatus, using hexane as solvent. After drying, it was reground using a commercial seed/bean grinder, passed through 50 mesh sieves to obtain a fine powder (particle size = 300 μm), and used for optimization experiments.

Ultrasound-Assisted Extraction of Anti-pyridoxine Factors from Flaxseed. Ultrasound-assisted extraction was performed in a VWR 250 HT ultrasonic cleaning bath (VWR International, AB, Canada). The flaxseed samples (500 mg) were accurately weighed in a 50 mL centrifuge tube, the required amount of extracting solvent was added, and the contents were homogenized at 13500 rpm for 1 min using an Ultra-Turrax T25 homogenizer (IKA-Labortechnik, Wilmington, NC, USA). The mixture was transferred into a 100 mL volumetric flask and sonicated for the designated times and at designated temperatures. Temperatures were controlled through the use of a circulating thermostatic water bath. The resultant flaxseed extracts were centrifuged at 5000*g* for 20 min at 4 °C and the supernatants collected. The extracts were concentrated using a rotary evaporator set to 35 °C. The concentrated extracts were diluted to a constant volume (10 mL) followed by centrifugation at 12000*g* for 20 min and filtered through a 0.2 μm filter before injection onto the UPLC-MS system. All extracted samples were freshly analyzed.

UPLC-MS Conditions. An Acquity UPLC system coupled with a Quattro Micro Atmospheric pressure ionization (API) tandem mass spectrometer (Waters Corp., Milford, MA, USA) was used for the analysis. Deionized water (18.2 MΩ) as solvent A and acetonitrile as solvent B, both containing 0.1% formic acid, were used as mobile phases, and the column was a Hypersil Gold C18 column, 150 × 3.0 mm, 3 μm (Thermo Scientific Inc., Waltham, MA, USA). The gradient elution was programmed at 0, 2, 3, 3.4, 3.5, and 8 min with 0, 20, 50, 50, 0, and 0% of solvent B, respectively, at a flow rate of 0.16 mL/min. The column was maintained at 35 °C, whereas the autosampler was maintained at a temperature of 4 °C. The tandem mass spectrometer was operated in positive electrospray ionization (ESI+) mode, with the conditions tuned on the basis of 1ADP. The main parameters of MS were as follows: capillary voltage, 3 kV; cone voltage, 20 V; source temperature, 120 °C; desolvation temperature, 500 °C; desolvation gas (N_2) flow, 600 L/h; and cone gas flow, 50 L/h. Multiple reaction monitoring (MRM) mode was set to monitor the mass transition of precursor ion to the product ion. The mass transition was monitored at 118.9 → 72.9 for d_3-D-proline (internal standard), at 131.0 → 85 for 1ADP, and at 259.9 → 85 for linatine. Data acquisition and processing were done using MassLynx V4.1 (Waters Corp.).

Purity Analysis and Validation of the Presence of Linatine in Flaxseed Extracts. The flaxseed extract was concentrated in a rotary evaporator to form a crude linatine extract. It was fractionated using a Varian 920LC high-performance liquid chromatography (HPLC) system, equipped with a UV- detector and fraction collection capabilities (Varian Inc., Palo Alto, CA, USA). Fractions of each 15 s were collected using a reverse phase Luna C18 $_{(2)}$ column (250 × 4.6 mm, 5 μm (Phenomenex, Torrance, CA, USA)) and solvent conditions as described above. The identification of linatine in the fraction was confirmed on the basis of the theoretical mass spectrum, using UPLC-MS. The final linatine fraction collected was lyophilized to obtain a white amorphous solid. The amorphous solid was dissolved in deionized water and scanned at 200−400 nm to identify λ_{max} using a DU 8000 spectrophotometer (Beckman Coulter Inc., Brea, CA, USA). The purity of the linatine in the solution was determined by normalizing the peak areas detected by the UV detector of the HPLC at λ_{max} using the same column and method mentioned above.

The amorphous linatine fraction at a concentration of 50 μg/mL was analyzed by an Agilent 6538 Q-TOF mass spectrometer coupled with a dual ESI source (Agilent Technologies, Santa Clara, CA, USA) in positive mode using a Poroshell C18 column (2.1 × 50 mm, 2.7 μm (Agilent Technologies, Santa Clara, CA, USA)) with a flow rate of 0.6 mL/min using the same solvent and the gradient system mentioned above for UPLC-MS method. For the mass spectrometry and MS/MS analyses, data were acquired for the fragment range of m/z 50−1200. ESI capillary voltage was set at fast switch polarity mode ESI± with 4000 V (±) ion mode with a fragmentor voltage of 60 V. A drying gas (N_2) at a temperature of 300 °C was supplied at a flow rate of 11 L/min. The reference masses used were 121.050873, 922.00978, and119.03632 (Agilent Technologies, Mississauga, ON, Canada). Find by auto and targeted MS/MS algorithms options within the Agilent MassHunter Qualitative Analysis B.05.00 were used to verify the presence of linatine in the sample using the Metlin database and library.

Furthermore, to confirm the presence of linatine in the amorphous solid, 1 mg of the sample was hydrolyzed in 1 M HCl for 2 h at 100 °C. The hydrolyzed solution was passed through a H^+-form resin column (Bio-Rad, Hercules, CA, USA). It was then washed with deionized water and the sample was eluted with 3 M NH_4OH solution. The eluate was dried under N_2 at 35 °C and reconstituted with deionized water to 5 mL. Verification was done by comparing the retention time and daughter ion mass spectrum as described above for the UPLC-MS/MS method.

Preparation of Calibration Curve and Quantification of Anti-pyridoxines. A calibration curve was prepared according to FDA guidelines.[25] Fifty milliliters of the sample extract was incubated at 70 °C in a water bath for 48 h until all of the 1ADP and linatine had been degraded. A calibration curve was prepared by spiking the resulting extract with known concentrations of the analyte, either 1ADP or linatine, into the same sample matrix. The concentrations of standards were chosen on the basis of the concentration range of the sample. A blank sample matrix was also run concurrently with the calibration curve. The concentrations of anti-pyridoxine factors in the samples were determined on the basis of the peak area response of 1ADP and linatine with respect to the internal standard (d_3-D-proline) at a concentration of 200 ng/mL. The total anti-pyridoxine content was expressed as 1-amino D-proline equivalents (1ADPE) using eq 1 given below. The limit of detection (LOD) and the lower limit of quantification (LLOQ) were also determined.

$$\text{total anti-pyridoxine (1ADPE } \mu\text{g/g)} = \frac{1}{2}(\text{linatine}) + \text{1ADP} \quad (1)$$

Experimental Design of Extraction Procedures. An isopropanol−water mixture was used as the extraction solvent.[17] Four factors, isopropanol concentration (A, % v/v), time (B, min), temperature (C,

°C) and liquid/solid ratio (D, mL/g), were selected as the primary influential parameters for extraction yield. The anti-pyridoxine compounds (1ADP and linatine) from flaxseed were first extracted on the basis of a single-factor experiment to determine the three levels of each factor. During the entire extraction process, the chosen temperature of the sonication bath was kept steady (within ±1.5 °C).

After examination of the test results obtained from single-factor extraction, a design based on a central composite model with three levels and four variables was used to find the best extraction parameter combination to optimize the recovery of anti-pyridoxines from flaxseed. The variables were generated according to the equation[26]

$$x_i = (X_i - X_0)/\Delta X \quad (2)$$

where x_i was the value of the independent variable X_i, X_0 was the value of X_i at the center point, and ΔX was the step change value.

Table 1 shows the four independent variables with their respective levels. The central composite design matrix and experimental extraction values are listed in Table 2. Of the three responses (1ADP, linatine, and total 1ADPE), extraction of total 1ADPE was considered as the response for the regression analysis. The model was fitted on the second-order polynomial function as[27]

$$Y = b_0 + \sum_{i=1}^{4} A_i X_i + \sum_{i=1}^{4} A_{ii} X_i^2 + \sum_{i=1}^{3} \sum_{j=i+1}^{4} A_{ij} X_i X_j \quad (3)$$

where Y is the predicted variable function and A_i, A_{ii}, and A_{ij} are the regression coefficients of linear, quadratic, and interaction terms of the independent variables X_i and X_j.

The experimental design and calculation of the predicted data were carried out using Design Expert 8.0.7.1 software to estimate the best response. The predicted model was verified by conducting three additional experiments. The final response was also compared with the samples extracted with either ethanol or methanol.

Varietal Analysis and Stability of Anti-pyridoxine on Storage. Nine flaxseed varieties, grown in different locations, were defatted with SER 148 solvent extractor (VELP Scientifica, Via Stazione, MB, Italy) using hexane as solvent according to the AOAC official method guidelines[28] to avoid the interference of oil during extraction procedures. Anti-pyridoxine contents of those samples were determined using the optimized extraction parameters. To check the storage stability of anti-pyridoxines, 1ADP and linatine in solution or in the sample extract were incubated at 3 and 37 °C for 48 h. Every 6 h, the samples were injected in UPLC-MS and the changes in peak area ratio were noted.

Statistical Analysis. The design of the experiment for the optimization of extraction using RSM was performed using Design Expert 8.0.7.1 software (Trial Version, State-Ease Inc., Minneapolis, MN, USA). Statistical analysis was performed using SigmaPlot 11.0 (Systat Software Inc., San Jose, CA, USA). All data were analyzed using one-way ANOVA with Bonferroni's multiple comparison, and $p < 0.05$ was set for all analyses to reflect statistically significant differences.

[a]Total 1ADPE = 1/2(linatine) + 1ADP.

RESULTS AND DISCUSSION

Identification and Characterization of Anti-pyridoxines in Flaxseed. The anti-pyridoxines were detected using an ESI+ mode in MRM mass chromatograms. These compounds were identified by comparing the retention times and daughter ion mass spectra of the authentic standards. 1ADP was eluted at 5.48 min, whereas linatine was eluted at 7.33 min (Figure 2). There was an increase in the peak area of 1ADP when the sample was spiked with synthetic standard. This confirmed the presence of free 1 ADP in flaxseed (Figure S1, Supporting Information). It was verified by comparing the mass spectra of the authentic standard parent ion at m/z 131 and base ion at m/z 85 (Figure 3).

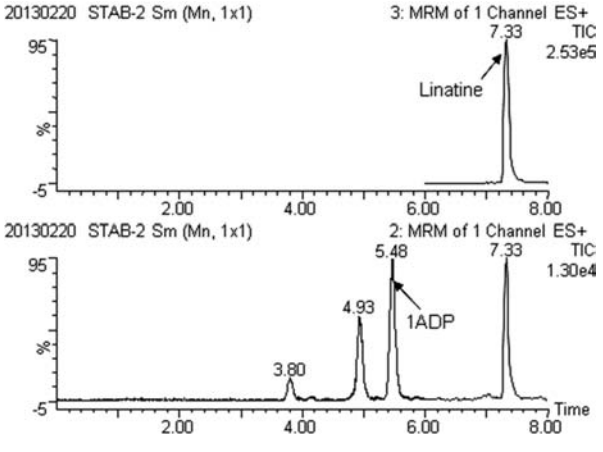

Figure 2. Chromatograms of linatine and 1-amino-D-proline (1ADP) from a flaxseed extract.

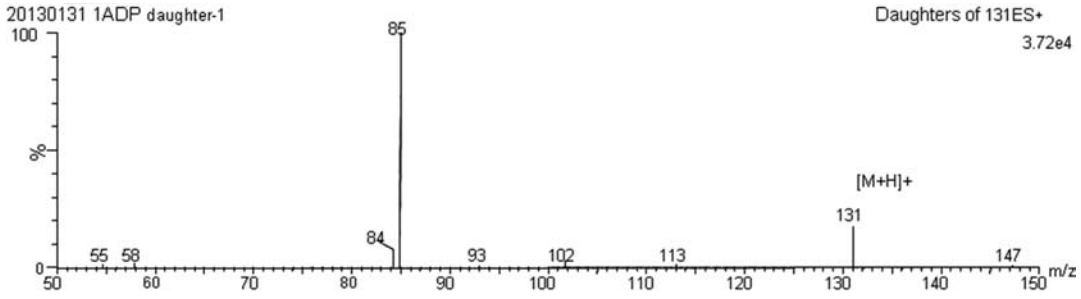

Figure 3. UPLC-mass spectrum of 1ADP: parent ion at m/z 131, $[M + H]^+$, and base ion m/z 85.

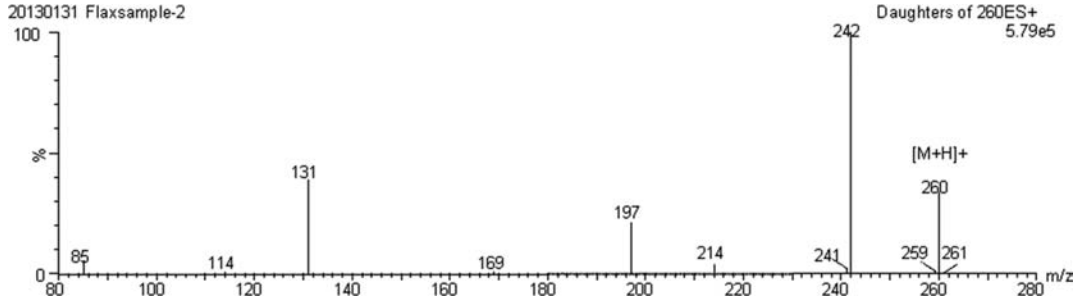

Figure 4. UPLC-mass spectrum of linatine in flaxseed extract: parent ion at m/z 260, $[M + H]^+$.

This was the first report indicating the presence of free 1ADP in flaxseed. Earlier, it was suggested that free 1ADP was not detected in the freshly prepared flaxseed extract when quantified using either the pyridoxal phosphate assay or an amino acid analyzer.[17] The latter results may be due to the lack of sensitivity of the methods and the instruments used at the time. In the current study, the limit of detection (S/N = 5) and lower limit of quantification (S/N = 10) for 1ADP were 10 and 15 ng/mL, respectively, showing the higher sensitivity of the new method.

Linatine was identified and characterized on the basis of its supposed mass spectral profile. We could not obtain a synthetic linatine standard as it was not commercially available. The mass spectrum of the chromatogram, obtained by scanning the flaxseed extract at m/z 260 $[M + H]^+$, was analyzed to validate the authenticity of linatine (Figure 4). Besides the parent ion, there were two major base peaks at m/z 242 $[M + H - 18]^+$ and m/z 131 $[M + H - 129]^+$. The first base peak was formed by losing a H_2O molecule (−18u), whereas the second base peak was formed by losing the glutamyl group (−129 u) as $[M + H - C_5H_7NO_3]^+$ to give the 1ADP spectrum. Apart from those two major base peaks, the minor peak obtained with m/z 197 $[M + H - 63]^+$ was due to the loss of a H_2O (−18 u) plus a COOH group (−63 u) as $[M + H - H_2O - COOH]^+$. The occurrence of common peaks at m/z 131 and 85 in both 1ADP and sample extract provided additional evidence supporting the presence of linatine in flaxseed.

Purity Analysis and Validation of the Presence of Linatine. The λ_{max} of a linatine solution prepared by dissolving the amorphous solid, obtained after the fractionation of crude flaxseed extract, into deionized water was found at 268 nm. The purity of linatine in the solution calculated after normalizing the peak area of three consecutive HPLC injections detected at $\lambda_{268\ nm}$ was 78%. The mass spectrum from Q-TOF (Figure S2, Supporting Information) showed a similar fragmentation of linatine as mentioned above in the case of UPLC-MS with a m/z value of 260.1217, $[M + H]^+$. Targeted MS/MS molecular feature analysis had provided a compatibility score of 99.15 of linatine compared to the database available in online Mass-Hunter software. This indicated a very high chance of the presence of linatine in the sample. Moreover, linatine was hydrolyzed into 1ADP, which was not found in the unhydrolyzed sample (Figure S3, Supporting Information). The appearance of the 1ADP peak in the chromatogram of the hydrolyzed sample also confirmed the presence of linatine in the amorphous solid fractionated from the crude extract. This amorphous solid was used as an authentic linatine standard for quantification.

Extraction Parameters. Ultrasound-assisted extraction of bioactive compounds from plant sources have been documented to be affected by extraction solvent, time, temperature, and ratio of liquid/solid.[22−24] The effects of the specific test parameters (isopropanol concentration, sonication time, temperature, and liquid/solid ratio) on the anti-pyridoxines extraction are displayed in Figure 5.

An isopropanol concentration of 30% resulted in the highest amount of 1ADP and linatine extraction. These results indicated that the efficiency of extraction was higher when the proportion of organic solvent was the lowest. Opportunities to use solvent concentrations lower than 30% were hampered by the increased extraction of water-soluble flax-derived gums and mucilages,[29−31] which created challenges during sample preparation (gelation). Therefore, the range for optimum isopropanol concentration was considered to be 30−50%. A similar trend was also observed in liquid/solid ratio, as the extraction efficiency was highest when the ratio was 50:1, indicating that higher water contents enhanced the extraction efficiency. The range for the liquid/solid ratio for extraction was selected as 30−50:1 (v/w). Similarly, ranges of sonication time and temperature were selected as 20−40 min and 25−45 °C, respectively. The above selected parameters were used for the RSM design.

Optimization of Extraction Conditions. On the basis of the values obtained from the single-factor experiments, the levels of independent variables chosen for the central composite design, that is, isopropanol concentration (A, % v/v), sonication time (B, min), sonication temperature (C, °C), and liquid/solid

dx.doi.org/10.1021/jf404786v | J. Agric. Food Chem. 2014, 62, 419−426

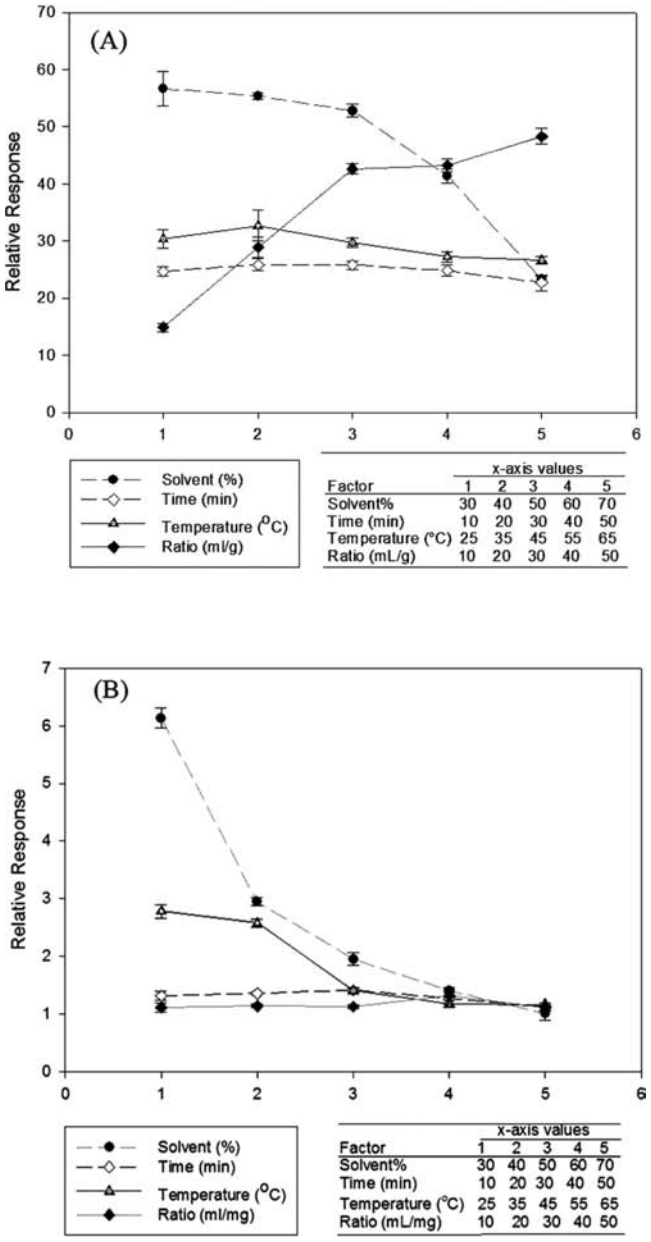

Figure 5. Effect of single-factor test on linatine (A) and 1ADP (B) extraction from flaxseed. Values on *x*-axis represent the five levels of each factor.

ratio (D, mL/g), were selected as design variables in the RSM (Table 1). Of the three anti-pyridoxine responses, that is, 1ADP, linatine, and total 1ADPE (Table 2), extraction of total 1ADPE was employed as the response value with four factors and three levels for the optimization using RSM design. Analysis of variance (ANOVA) for response surface of quadratic model analyses was chosen to test the significance and adequacy of the design. The value of "prob > F" of the model was significant with $p = 0.0082$, and the lack of fit was not significant ($p = 0.052$). This suggested that the model terms were precise and applicable (Table 3). The coefficient of determination (R^2) of the model was 0.82, and the regression equation after replacing experimental points was

Table 3. Analysis of Variance for the Fitted Quadratic Polynomial Model on Total 1ADPE

$$Y = -307.92 + 26.54A - 11.28B + 17.48C + 0.63D + 0.02AB + 0.27AC - 0.18AD + 0.1BC - 0.01BD - 0.003CD - 0.36A^2 + 0.12B^2 - 0.45C^2 + 0.15D^2 \quad (4)$$

Each 3D plot (Figure 6) represents the number of combinations of the two test variables. After carrying out optimization of all the parameters on the basis of the mathematical model, the points of prediction for maximum extraction of total anti-pyridoxine were as follows: isopropanol concentration, 35.97% (v/v); time, 24.89 min; temperature, 31.54 °C; liquid/solid ratio, 44.68:1 (mL/g). At these points the predicted values for linatine, 1ADP, and total anti-pyridoxine (as 1ADPE) were 916.5, 41.3, and 499.5 μg/g, respectively.

Verification of the Predicted Model. To validate the adequacy of the model equation, a verification experiment was carried out under the optimal condions. Extraction conditions were adjusted to the following: isopropanol concentration, 36%; sonication time, 25 min; temperature, 32 °C; and liquid/solid ratio, 45:1 (mL/g). The results showed that the anti-pyridoxine content values were linatine, 1030 ± 21.7 μg/g; 1ADP, 42 ± 1.0 μg/g; and total 1ADPE, 557.9 ± 10.8 μg/g (of defatted flaxseed, $n = 3$). These results provide evidence that the experimental values were not only consistent with the predicted values but also better than any single-factor experiment. Therefore, the extraction conditions obtained by response surface methodology were considered optimized and repeatable.

The efficiency of anti-pyridoxine extraction using different solvents at optimized conditions were also evaluated (Table 4). Isopropanol has significantly ($p < 0.001$) higher capacity to extract both linatine and 1ADP compared to ethanol and methanol. Ethanol was able to extract more 1ADP than methanol; however, linatine extraction efficiencies were not significantly different for either of the solvents.

Varietal Analysis and Stability of Anti-pyridoxines on Storage. The oil removed from the nine varieties of flaxseed ranged from 32 to 43%. The amount of anti-pyridoxine compounds present in the nine varieties was significantly different (Table 5). The total amount of anti-pyridoxine content (1ADPE) in the tested varieties ranged from 177 to 437 μg/g for whole seed. Of the nine varieties, Normandy had the highest amount of anti-pyridoxine (437 ± 10.8 μg/g), whereas Taurus had the lowest (177.3 ± 5 μg/g). These results may provide evidence of genotypic variation in the 1ADPE content of flaxseed, but this remains to be rigorously tested.

The stability of 1ADP and linatine during storage is shown in Figure S4 (Supporting Information). Standard 1ADP solution was stable for 48 h at 3 °C but, it was readily degraded in 3 h at 37 °C. The amount of 1ADP content in sample increased during storage at both temperatures up to 12 h of incubation. The slight degradation of linatine likely results in the release of 1ADP in the

sample solution. Linatine in the sample also degraded at both temperatures; however, the rate of degradation was faster at 37 °C as compared to 3 °C.

In conclusion, this study establishes a new method for assessing the anti-pyridoxine content of flaxseed in advance of risk assessment modeling for specific populations. Our method provided a better extraction of 1ADP and linatine from flaxseed by optimizing the extraction parameters using a RSM design. The UPLC-MS/MS method, which has higher specificity and sensitivity for those analytes, revealed that the amount of anti-pyridoxine content in flaxseed was up to 437 μg/g of whole seed, much higher than previously reported by Klosterman et al.[17] Furthermore, we have documented the presence of free 1ADP in flaxseed, which has never been reported before. Although varietal differences in 1ADP equivalents were apparent, further work is required to ascertain the impact of genotype by environment effects on the anti-pyridoxine content of flaxseed. Future work will assess the oral toxicity of anti-pyridoxines, especially 1ADP and linatine, as it will be important to assess the risk factors associated with the consumption of flaxseed and its related products.

Supporting Information

ABSTRACT: Canary grass is used as traditional food for diabetes and hypertension treatment. The aim of this work is to characterize the biological activity of encrypted peptides released after gastrointestinal digestion of canary seed proteins. Canary peptides showed 43.5% inhibition of dipeptidyl peptidase IV (DPPIV) and 73.5% inhibition of angiotensin-converting enzyme (ACE) activity. An isolated perfused rat heart system was used to evaluate the canary seed vasoactive effect. Nitric oxide (NO), a major vasodilator agent, was evaluated in the venous effluent from isolated perfused rat heart. Canary seed peptides (1 μg/mL) were able to induce the production of NO (12.24 μM) in amounts similar to those induced by captopril (CPT) and bradykinin (BK). These results show that encrypted peptides in canary seed have inhibitory activity against DPPIV and ACE, enzymes that are targets for diabetes and hypertension treatments.

KEYWORDS: *angiotensin-converting enzyme, canary seed, dipeptidyl peptidase IV, encrypted peptides, nitric oxide*

INTRODUCTION

The canary seed (*Phalaris canariensis* L.) belongs to the Graminea family with production practices and life cycle similar to those of other winter cereal crops such as wheat and oats.[1,2] The grain is cultivated in many areas of the temperate climates and, currently, its production is concentrated in the southwestern provinces of Canada and, on a smaller scale, in Argentina, Thailand, and Australia.[3−5] Its main use is as food for birds, alone or mixed with other grains such as millet, sunflower seeds, and flaxseeds.[3,4]

Due to its good nutritional value, interest in canary seed has increased as an alternative nongluten cereal.[1,2] Compared to common cereals, canary seed contains high levels of protein (21%), although more deficient in both lysine and threonine than wheat proteins. Canary seed is very rich in cysteine, tryptophan, and phenylalanine.[6] The groats contain 61% starch, which are composed by small polygonal granules with diameters of 1.5−3.5 μm with lower amylose contents than wheat and high pasting temperatures forming rigid and highly stable gels when cooked or frozen.[7] Canary seed groats are rich in crude fat (8.7%), which is mainly composed of linoleic (55%), oleic (29%), palmitic (11%), and linolenic acids (2.5%).[8] The sterol and triterpene alcohol esters of caffeic acid are the major effective antioxidant components in the crude oil of a canary seed.[9] The major carotenoid compounds identified in canary seed are lutein, zeaxanthin, and β-carotene.[10]

Traditionally, canary seeds are also used as a "folk medicine" for diabetes and hypertension treatments; however, there is no scientific information about the possible bioactives responsible for such effects. Type 2 diabetes mellitus is a metabolic disorder characterized by a hyperglycemic chronic state due to several fundamental defects such as insulin resistance in muscles and liver and an impaired insulin secretion by pancreatic β-cells.[11] The incretin-based therapy is actually used as diabetic treatment. Incretins are responsible for >50% of postprandial insulin secretion, especially the hormone glucagon-like peptide 1 (GLP-1).[12] However, the half-life of incretins is very short due to the cleavage and inactivation of these proteins by dipeptidyl peptidase IV (DPPIV).[13] Hence, DPPIV inhibitors are the actual therapies that have shown promising results as antidiabetic agents.[14] Hypertension is about twice as common in a diabetic as in nondiabetics and has become the most common public health problem worldwide.[15] Hypertension treatments are based on inhibition of the angiotensin converting enzyme (ACE). ACE is a peptidylpeptidase hydrolase that plays an important physiological role in the regulation of blood pressure. ACE catalyzes the conversion of the inactive decapaptide angiotensin I into a powerful vasoconstrictor octapeptide, angiotensin II.[16] ACE also catalyzes the inactivation of the vasodilator bradykinin (BK) that regulates different biological processes including vascular endothelial nitric oxide (NO) release mediated by the activation of eNOS. NO exert its effects on the vascular smooth muscles, promoting vascular relaxation.[17]

Peptides with inhibitory activity of DPPIV and ACE have been found in several food proteins,[18,19] but there are no reports about the presence of these peptides encrypted in canary seed proteins that could be responsible for its claimed health benefits. Thus, the aim of this work was to test the

hydrolysis conditions to release the canary seed peptides and to evaluate the inhibitory activity of these peptides against DPPIV and ACE. In addition, the antihypertensive function of canary seed peptides was tested on isolated perfused rat heart system.

MATERIALS AND METHODS

Biological Material. Canary seed (Birdseed "Marabu") and commercial canary seed flour ("more Lait"), used as folk medicine, were purchased in local markets. Seeds were ground in a mill (Krup Coffe, Medford, MA, USA) and passed through 80 mesh. Defatted flours were obtained according to a reported protocol.[20] Canary seeds were placed in water (1:5 w/v, flour/water) overnight at room temperature. The soaking water was removed, the seeds were dried and milled, and the resultant flour was named canary seed milk.

Seed Storage Protein Fractionation. Proteins from (a) canary seed flours, (b) commercial flour "more Lait", and (c) canary seed milk were fractionated on the basis of their solubility.[20,21] The albumin fraction was solubilized with distilled water, and the suspension of flour/water (1:10 w/v) was under agitation for 1 h and centrifuged at 20000*g* for 30 min. The resulting pellet was resuspended in 0.1 M NaCl, 0.01 M KH_2PO_4, and 1 mM EDTA, pH 7.5, agitated and centrifuged as above, and the soluble protein was named 7S globulins. The pellet was resuspended in 0.8 M NaCl solution, 0.01 M KH_2PO_4, and 1 mM EDTA, pH 7.5, to obtain the 11S globulin fraction. Prolamins were extracted from the resulting pellet with 70% ethanol, and the final pellet was extracted with 0.1 M NaOH to obtain the glutelins fraction. Total proteins were extracted from canary seed flours (1 g) with 10 mL of buffer containing 7.5 M urea, 63 mM CHAPS, 2.2 M thiourea, 22 mM Tris-HCl, 17.3 mM trizma base, and 0.25% (v/v) Triton X-100, pH 3.1; the suspension was mixed with vortex and centrifuged for 10 min at 20000*g*, and the supernatant was named total protein. All extractions were performed in triplicate.

Tryptic Digestion of Canary Seed Proteins. Total protein extracts were used for protein digestion using trypsin from porcine pancreas (Sigma-Aldrich, St. Louis, MO, USA) at a ratio of enzyme/substrate 1:5 (w/w). Hydrolysis was carried out in a 100 mM Tris buffer, pH 8, at 37 °C for 6 h. The reaction was stopped by freezing, and the enzyme was removed by ultrafiltration using 10 kDa MWCO filters (Millipore, Billerica, MA, USA).

Simulation of Gastrointestinal Digestion Method. The protein hydrolysis of canary seed samples was also performed using the simulated gastrointestinal method.[19] Flour (1 g) was resuspended in 20 mL of 0.03 M NaCl, pH 2, heated in a water bath at 80 °C for 5 min, and allowed to cool to room temperature. Porcine pepsin (Sigma-Aldrich) previously dissolved in 0.03 M NaCl, pH 2.0, was added in a 1:40 ratio (w/w enzyme to substrate). The samples were digested at a constant pH for 3 h at 37 °C under constant agitation. Next, the pH was adjusted to 7.5, and a mixture of trypsin/pancreatin from porcine pancreas (Sigma-Aldrich) was added at a ratio of 1:1 w/w; enzymes were previously dissolved in 0.1 N $NaHCO_3$ at a ratio of 1:5000 (w/w enzyme/substrate). Samples were incubated at a constant pH for 3 h. Digestion was stopped by heating the samples at 75 °C for 20 min; the samples were allowed to cool and centrifuged at 20000*g* for 30 min. To remove the enzymes, the digests were ultrafiltered using 10 kDa MWCO membranes (Millipore).

Protein Quantification. Canary seed protein fractions were quantified using the kit Pierce BCA Protein Assay (Thermo Scientific, Rockford, IL, USA). The concentration of peptides released by the tryptic and gastrointestinal digestion methods was determined using the Lowry-based DC Protein Assay (Bio-Rad, Hercules, CA, USA). Bovine serum albumin was used as a standard.

Electrophoresis. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) was carried out according to the method of Laemmli.[22] Protein samples (5 μg) were dissolved in 0.1 M Tris-HCl, pH 6.8, and 2% SDS. Electrophoresis was conducted at a constant current of 20 mA per gel for 2–3 h. After electrophoresis, the gel was stained with Phast Gel Blue R-350 (GE Healthcare Bio-Science AB, Uppsala, Sweden) in a final concentration of 0.02%. Destaining was accomplished by washing the gel with a solution of 30% methanol, 10% acetic acid, and water. Gels were digitalized in a Gel-Doc XR (Bio-Rad).

Assay for Inhibitory Activity of Dipeptidyl Peptidase IV. The assay for in vitro activity of DPPIV was carried out as reported previously.[19] The chromogenic substrate Gly-Pro-pNA (500 μM) and 100 ng/mL dipeptidyl peptidase IV isolated from a porcine kidney (Sigma) were used. Different concentrations (0, 200, 400, 600, 800, 1000, 1200, and 1400 μg/mL) of canary seed peptides were tested. The reaction was carried out for 1 h at 37 °C, and the absorbance of *p*-nitroaniline (pNA) released was read at 415 nm in a microplate reader (Bio-Rad). Diprotin A (Ile-Pro-Ile) was used as positive control of inhibition. All assays were performed in triplicate.

Assay for Inhibitory Activity of Angiotensin Converting Enzyme. The ACE inhibition assay was conducted following the protocol described previously.[18] The reaction was performed at 37 °C for 30 min in 100 μL of 0.1 M potassium phosphate buffer, pH 8.3, containing 0.3 M NaCl, 5 mM hippuryl-histidyl-leucine, 2 mU of ACE, and 25 μL of canary seed peptides at different concentrations (0, 83, 166, 249, 332, 415, 498, and 581 μg/mL). The reaction was stopped with the addition of 100 μL of 1 M HCl. The hippuric acid that formed was extracted with 1 mL of ethyl acetate, evaporated, and dissolved in 1 mL of distilled water; the hippuric acid absorbance was measured at 228 nm. The activity of each sample was tested in triplicate. Captopril (CPT) was used as a positive control. The IC_{50} value was defined as the peptide concentration (μg/mL) needed to inhibit 50% ACE activity, calculated by the ACE inhibition (%) versus log peptide concentration (μg/mL) linear regression.

Bioassay of Isolated Perfused Rat Heart (Langendorff Perfusion System). To evaluate the effect of vasoactive canary seed peptides, the Langendorff method was used.[23−25] Briefly stated, male Wistar rats (300−350 g) were euthanized with 50 mg/kg sodium pentobarbital intraperitoneally and 500 IU of heparin following the Animal Care Protocols (UASLP, Mexico). The rats' heart were removed and cannulated via the ascending aorta in a retrograde perfusion system (IsoHearth-SR Harvard Apparatus, Holliston, MS, USA) and were maintained at a constant flow rate of 10 mL/min. The perfusion medium was Krebs–Henseleit solution, pH 7.4,[21] equilibrated with 95% O_2 and 5% CO_2 at 37 °C. Increasing concentrations (0.01, 0.1, and 1 μg/mL) of canary seed peptides were administered intracoronary. BK at 10 μM and CPT at 50 μM were used as controls of vasodilation. Angiotensin I (ANG I) and/or angiotensin II (ANG II) at 1 μM were used as controls of vasoconstriction.

Quantification of Nitric Oxide in the Venous Effluent of Isolated Perfused Rat Heart. The concentration of NO, as nitrite and nitrate, was determined by using the Griess method.[18] Venous effluents from isolated hearts (100 μL) were collected and incubated at 37 °C for 30 min in the presence of 80 μL of vanadium chloride (VCl_3) followed by the addition of 20 μL of Griess reagent (1% sulfanilamide, 0.1% of naphthylethylenediamine in 2.5% phosphoric acid). Absorbance was read at 540 nm, and sodium nitrate ($NaNO_3$) was used as a standard.

Statistical Analysis. All experiments were carried out in triplicates, and results are reported as the mean values ± standard deviation. Statistical analyses were performed using GradphPad Prism 5 software (GraphPad Software Inc., La Jolla, CA, USA). One-way ANOVA and Tukey's test ($P < 0.05$) were performed to detect statistical differences.

RESULTS AND DISCUSSION

Extraction and Quantification of Canary Seed Storage Proteins. As shown in Figure 1, no differences were observed in protein fractions among canary seed flour (white bars), commercial flour "more Lait" (gray bars), and canary seed milk (black bars). The main fraction of canary seed storage proteins was prolamins with values ranging from 31 to 36% and glutelins (35−39%). Albumins fraction represented around 16%, and globulins were found in low concentrations (6%). The protein fraction values were similar to those in previous studies;[7] however, the electrophoretic profile has not been reported, and

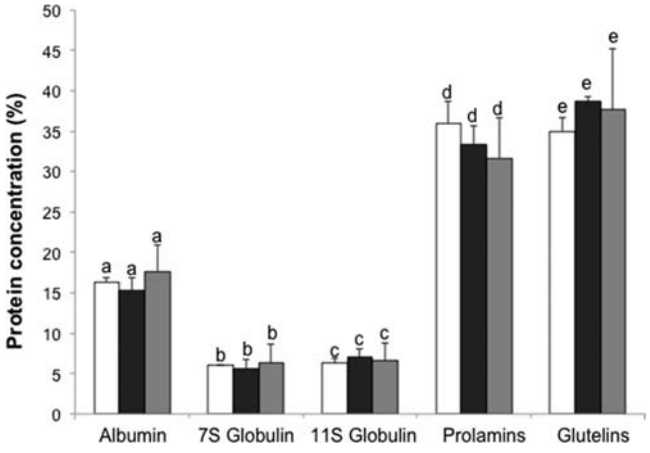

Figure 1. Distribution of canary seed storage proteins fractions expressed in percentage: canary seed flour (white bars); flour obtained from soaked seeds in water (black bars); commercial flour "more Lait" (gray bars). In each case the bar is the average of three replicates and standard deviation is indicated. The same letters mean no significant differences at $P < 0.05$ in the same fraction.

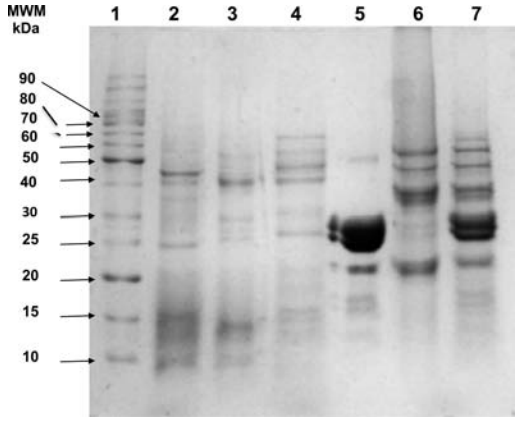

Figure 2. Electrophoretic profile of canary seed storage proteins. Canary seed storage proteins from commercial flour "more Lait" were extracted according to their solubility in different solvents. Lanes: 1, molecular weight marker (MW); 2, albumins; 3, 7S globulins; 4, 11S globulins; 5, prolamins; 6, glutelins; 7, total seeds proteins.

then we proceeded to characterize the protein profile of the canary seed storage protein fractions.

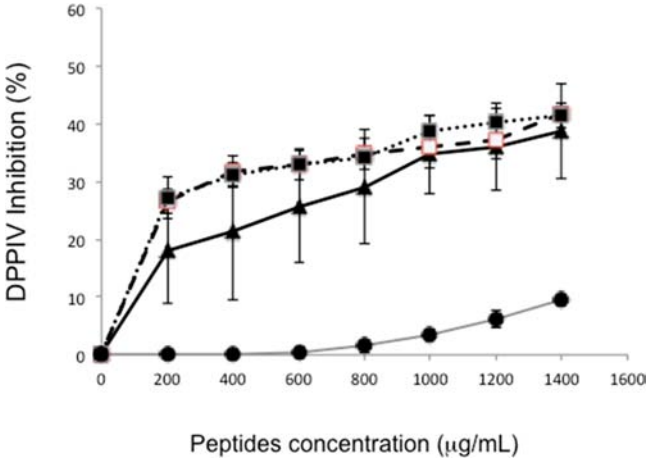

Figure 4. Inhibitory function of canary seed peptides against DPPIV activity. Canary seed proteins were digested by gastrointestinal digestion method, and fragments smaller than 10 kDa, obtained by ultrafiltration, were tested. The percentage of DPPIV inhibition was measured in the presence of increasing concentrations of canary seed peptides from canary seed flour (solid triangles), canary seed milk (open squares), and commercial canary seed flour "more Lait" (solid squares). Negative control used was nondigested canary seed proteins (solid circles). Error bars ± SD ($N = 3$).

Electrophoretic Profile of Canary Seed Storage Proteins. The electrophoretic profile under denaturing conditions of canary seed fractions obtained from commercial flour "more Lait" is shown in Figure 2. This pattern was similar to canary seed flour and canary seed milk (Supporting Information Figure 1S). Canary seed albumins pattern showed bands of molecular masses of 9.8, 12.8, 15.8, 19.3 23.4, 25.9, 39.2, and 43.4 kDa similar to the components of oat albumin (14−17, 20−27, and 36−47 kDa).[23] The 7S globulins profile was similar to that of albumin with the addition of another band of 37.8 kDa; 11S globulins showed bands at 62.8, 57.1, 46.5, 39.2, 25.8, 15.3, and 12.8 40 kDa. Prolamins patterns in canary seed showed a broad band containing at least two bands of 26.6 and 24.9 kDa. Prolamins patterns were similar to those of the oat (17−34 kDa), barley (15−20 kDa), and the zeins or prolamins from corn (23−24 and 26.5−27 kDa).[26,27] Glutelins main bands were located at 53.3, 41.5, 34.7, and 31.9 kDa, which are within a range similar to that of barley glutelins (35 and 42−46 kDa).[28] These results suggest that the electrophoretic profile of the canary seed storage proteins is

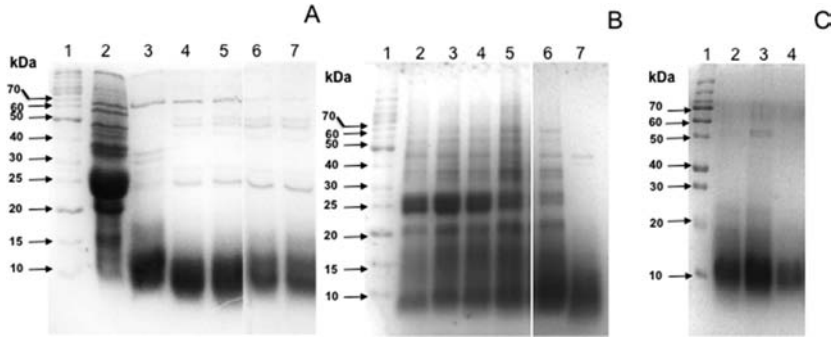

Figure 3. Digestion profile of total soluble proteins extracted from canary seed commercial flour "more Lait": (A) tryptic digestion; (B) gastrointestinal digestion. Lanes: 1, molecular weight marker; 2, nondigested canary seed proteins; 3−7, digestions at 0.1, 0.5, 1, 5, and 6 h, respectively. (C) Lanes: 1, molecular weight marker; 2−4, 10 kDa ultrafiltrates obtained from commercial flour "more Lait", canary seed flour, canary seed milk, respectively.

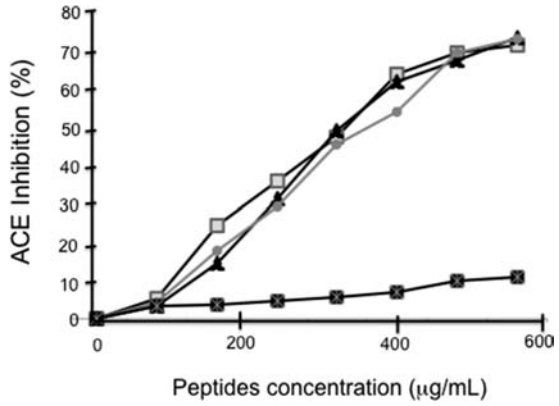

Figure 5. Inhibitory function of canary seed peptides against ACE activity. Canary seed proteins were digested by gastrointestinal digestion method, and fragments smaller than 10 kDa, obtained by ultrafiltration, were tested. The percentage of ACE inhibition was measured in the presence of increasing concentrations of canary seed peptides from canary seed flour (light-dotted dark squares), canary seed milk (solid triangles), and commercial canary seed flour "more Lait (gray circles). Nondigested canary seed proteins were used as negative control (gray-crossed black squares).

characteristic of the subfamily Pooideae cereals such as barley and oats and cereal family Poaceae (grass) such as corn.

Digestion of Canary Seed Proteins. The tryptic and gastrointestinal digestion (Figure 3) hydrolysis patterns of canary seed flour "more Lait" were similar to those of canary seed flour and canary seed milk patterns (Supporting Information Figure 2S). It was observed that at 6 h of gastrointestinal digestion, the bands of high molecular mass disappeared with the concomitant increasing of a smear below 10 kDa (Figure 3A). At this time, with tryptic digestion, bands of high molecular mass are still undigested (Figure 3B). Large protein fragments were removed by ultrafiltration using membranes of 10 kDa MWCO (Figure 3C), and eluted peptides were used for enzyme inhibition assays.

Characterization of Canary Seed Peptides Inhibitory Function against DPPIV Activity. Canary seed peptides obtained by gastrointestinal digestion showed an inhibition of DPPIV activity in a dose-dependent manner, where the highest inhibition of 43.4% was obtained at the higher peptide concentration (1.4 mg/mL). This behavior was similar among the three samples of canary seed under study (Figure 4). Nondigested canary seed proteins showed very low inhibition (9.3%). The tryptic digests (Supporting Information Figure 3S) had a lower percentage of inhibition (23%), and from this observation followed experiments that were evaluated using peptides obtained from gastrointestinal digestion. Diprotin A (Ile-Pro-Ile), the inhibition control for DPPIV, had an IC_{50} of 2 μg/mL

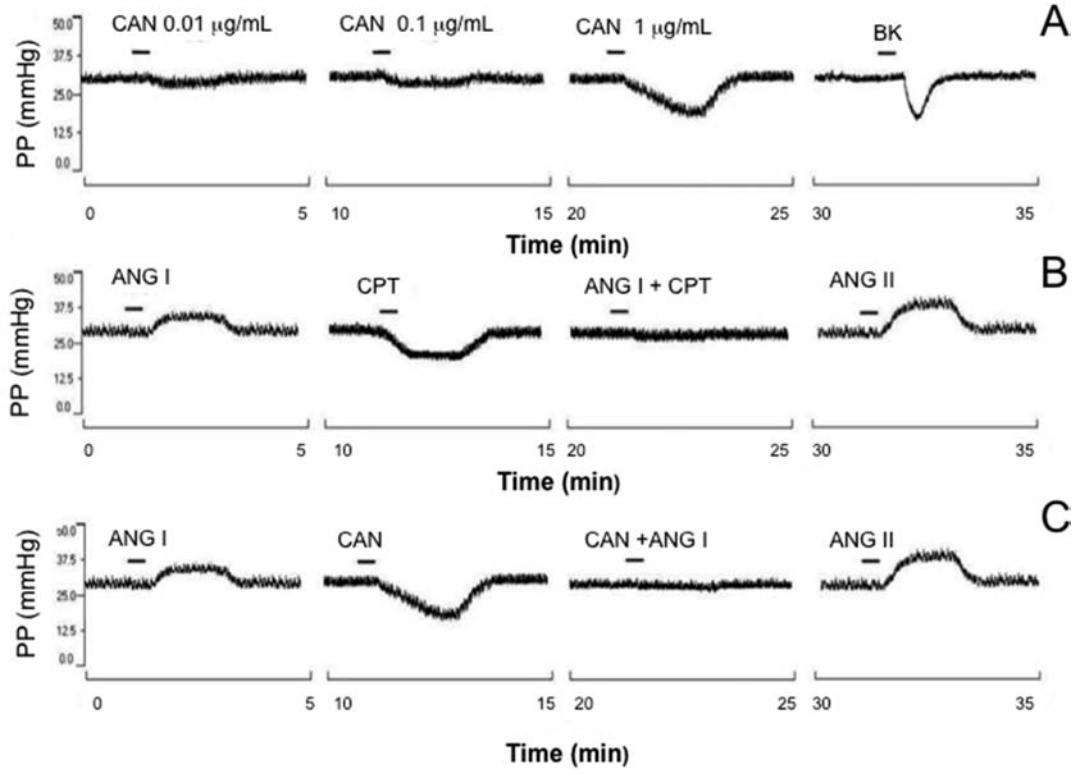

Figure 6. Representative trace recordings of the vasodilator effect induced by canary seed peptides in Langendorff system. Perfusion pressure (PP) was taken as an index of vascular tone (vasodilation/vasoconstriction) recorded from isolated perfused rat heart. PP representative trace recordings were in response to (A) increasing and independent administrations of canary seed peptides obtained by gastrointestinal digestion (CAN, 0.01, 0.1, and 1 μg/mL). Bradykinin (BK, 10 μM) was infused as control of vasodilation. (B) Vascular tone controls: Angiotensin I (ANG I; 1 μM), the precursor of the formation of ANG II. ANG II (1 μM) was administered as control of vasoconstriction, and captopril (CPT, 50 μM), an ACE inhibitor, was administered as control of vasodilation. The administration of ANG I in the presence of CPT blocked the vasoconstriction induced by ANG I. (C) ANG (1 μM) was administered as control of vasoconstriction, and the vasodilation action of CAN (1 mg/mL) was measured. ANG I in the presence of CAN blocked the vasoconstriction induced by ANG I. ANG II was infused as control of vasoconstriction. Canary seed peptides and controls were administered in all cases after washout periods. All experiments were carried out in triplicates.

dx.doi.org/10.1021/jf404539y | J. Agric. Food Chem. 2014, 62, 427−433

(Supporting Information Figure 4SA), this value being similar to values reported in the literature.[29,30]

Characterization of Canary Seed Peptide Inhibitory Function against ACE Activity. The antihypertensive action of canary seed peptides was evaluated as the capacity to inhibit ACE activity. Increasing concentrations of the gastrointestinal digestion derived peptides (0−581 μg/mL) were evaluated. The highest inhibition value was 73.5% (Figure 5), a value similar to that reported for the bovine whey peptides.[31] The IC_{50} of canary seed peptides was 332 μg/mL, similar to the IC_{50} value of the peptides of chickpea,[32] pea,[32] soybean,[33] wheat gliadin,[34] and sardine muscle.[35] All canary seed presentations had the same inhibition pattern. Nondigested samples reached only 10.7% inhibition at its highest concentration. Captopril, used as a positive control of ACE inhibition, showed an IC_{50} value of 4.074 μg/mL (Supporting Information Figure 4SB), similar to that reported in the literature.[37]

Assessment of the Vascular Tone Induced by Canary Seed Peptides in Isolated Perfused Rat Heart. In the Langendorff system, the perfusion pressure (PP) was taken as an index of vascular tone (vasodilation/vasoconstriction).[17] Three different concentrations (0.01, 0.1, and 1 μg/mL) of canary seed peptides were tested. The vasodilator effect was observed in a dose-dependent manner, where the lowest pressure was observed at 1 μg/mL, similar to the vasodilation induced by BK (10 μM) (Figure 6A). It has been reported that ANG I causes vasoconstriction in biological systems in perfusion[36−39] and is blocked by ACE inhibitors;[37,40−42] then ANG I and ANG II (1 μM) were tested as vasoconstriction controls, and CPT (50 μM) was used as vasodilation control and blocker of ACE (Figure 6B). In Figure 6C canary seed peptides (1 μg/mL) were used instead of CPT. It was observed that both CPT (Figure 6B) and canary seed peptides (Figure 6C) counteract the vasoconstrictor effect induced by ANG I. Vasodilation by canary seed peptides (1 μg/mL) was 82.7% compared to the 100% vasodilation induced with CPT and BK (Figure 7A). Figure 7B shows the percentage of vasoconstriction of ANG I (72%) and ANG II (100%), and it was observed that both CPT and canary seed peptides completely block the ANG I-induced vasoconstriction, suggesting the endogenous activity of ACE in the coronary vessels of the isolated and perfused rat hearts. Thereby, it was proposed that canary seed peptides are potential candidates as inhibitors of ACE activity (Figure 7B).

Nitric Oxide in the Venous Effluent Isolated Perfused Rat Heart. To determine whether the vasodilator effect of the canary seed peptides was also associated with NO production, NO was determined in venous effluent from the isolated perfused rat heart. The highest amount of NO produced by canary seed peptides at 1 μg/mL was 12.24 μM, whereas CPT induced the production of 20.27 μM and BK 19.24 μM (Figure 8). These data suggest an important function of canary seed peptides in the regulation of vascular tone through NO production. The NO produced in the inner layer of the blood vessel diffuses at the cardiac cell, blocking the release of calcium needed for muscle contraction, and therefore promotes a state of relaxation.[18,43] ACE inhibitors induce vasodilation due the formation of a BK−NO-dependent pathway.[18] Then, canary seed peptides are ACE type inhibitors stimulating NO production by this route.

In conclusion, the protein profile of canary seed protein fractions is more similar to those of cereals such as oats and maize and is farther from wheat electrophoretic patterns. Canary seed proteins contain encrypted peptides with

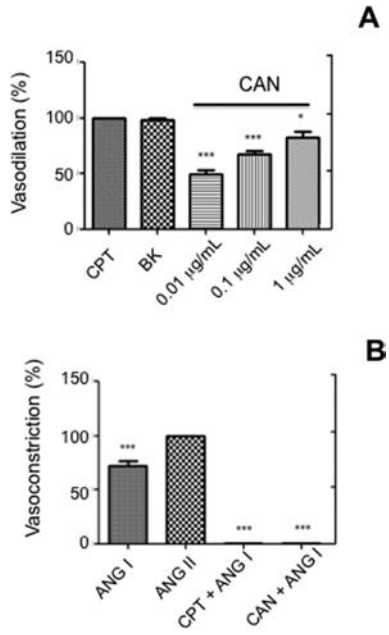

Figure 7. Vasodilation/vasoconstriction exerted by canary seed peptides (CAN) obtained by gastrointestinal digestion. (A) Vasodilation induced by different CAN concentrations (0.01, 0.1, 1 μg/mL). Vasodilation controls: captopril (CPT, 50 μM) and bradykinin (BK, 10 μM). (B) Vasoconstriction effect of CPT in the presence of angiotensin I (ANG I) or CAN in the presence of ANG I. Vasoconstriction controls (1 μM ANG I or ANG II). Values are expressed as the mean of three independent experiments. Asterisks indicate statistical differences at $P < 0.05$.

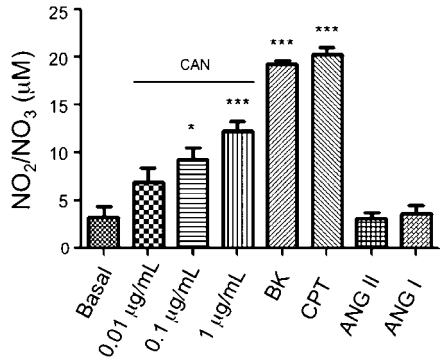

Figure 8. Induction of nitric oxide (NO) production by different concentrations of canary seed peptides (CAN; 0.01, 0.1, 1 μg/mL) obtained by gastrointestinal digestion. The NO (NO_2/NO_3) was measured in the venous effluent of the heart of rat isolated perfused. Results are representative of three independent experiments. Values are expressed as the mean ± standard error (SE). Asterisks indicate statistical differences at $P < 0.05$ versus basal.

inhibitory activity against DPPIV and ACE. The inhibition of DPPIV is the basis of modern antidiabetic therapy, whereas inhibition of ACE is the drug therapy against hypertension. In addition we have demonstrated that canary seed peptides are able to induce the production of NO, a potent vasodilator, at levels similar to those produced by CPT and BK.

Supporting Information

ABSTRACT: The inhibitory effect of betulinic acid (BA) on hepatic glucose production was examined in HepG2 cells and high fat diet (HFD)-fed ICR mice. BA significantly inhibited the hepatic glucose production (HGP) and gene expression levels of PGC-1α, PEPCK, and G6Pase. BA activated AMPK and suppressed the expression level of phosphorylated CREB. These effects were all abolished in the presence of compound C (an AMPK inhibitor). Moreover, inhibition of AMPK by overexpression of dominant negative AMPK prevented BA from suppression of HGP, indicating that the inhibitory effect of BA on HGP is AMPK-dependent. In addition, BA markedly phosphorylated CAMKK, and phosphorylation of AMPK and ACC, and suppression of HGP were all reversed in the presence of STO-609 (a CAMKK inhibitor), suggesting that CAMKK is an upstream kinase for AMPK. In an animal study, HFD-fed ICR mice were orally administered with 5 or 10 mg of BA per kg (B5 and B10) for three weeks. Plasma glucose, triglyceride, and the insulin resistance index of the B10 group were decreased by 34%, 59%, and 38%, respectively. In a pyruvate tolerance test, pyruvate-induced glucose excursion was decreased by 27% when mice were pretreated with 10 mg/kg of BA. In summary, BA effectively ameliorates hyperglycemia through inhibition of hepatic gluconeogenesis via modulating the CAMKK-AMPK-CREB signaling pathway.

KEYWORDS: *AMPK, betulinic acid, CREB, hepatic glucose production, type 2 diabetes*

INTRODUCTION

Type 2 diabetes mellitus (T2DM), characterized by insulin resistance and β-cell dysfunction, is one of the leading causes of death and disability. Despite the great advances that have been made in the understanding and management of this complex, multifactorial disease, T2DM has become a worldwide epidemic in the 21st century.[1] Because of the variable and progressive pathophysiological changes associated with T2DM, pharmacological compounds acting on multiple targets are needed at different stages of the disease to complement the benefits of lifestyle changes, which can be effective but difficult to maintain.[2] Antidiabetic agents, however, have some limitations, including no sustainability of efficacy because of continued β-cell dysfunction and having side effects such as hypoglycemia, weight gain, gastrointestinal disturbances, peripheral edema, and potential cardiovascular effects.[3,4] Therefore, new therapeutic agents need to be developed that will sustain glycemic control, reverse or halt the decline in β-cell function, assist with weight loss, improve insulin action, avoid hypoglycemia, and have a favorable effect on cardiovascular disease. There is an increasing demand for the use of natural products with antidiabetic activity. In this context, phytochemicals derived from natural sources, including foods, are of worth to examine their beneficial effects on chronic diseases such as T2DM.

As part of the search for biologically active antidiabetic agents, more than 200 phytochemicals were evaluated, and betulinic acid (BA) was found to be one of the active ingredients that ameliorate hyperglycemia. BA is a pentacyclic triterpene isolated from the bark of *Albizia Julibrissin*. BA has been reported to show a wide spectrum of biological and pharmacological activities, such as anti-inflammation,[5,6] anticancer,[7−9] antimalaria,[10] anti-AIDS,[11] antifatty liver,[12] antidiabetes,[13,14] and antidepression[15] effects. However, whether BA exerts a suppressive effect on hepatic glucose production is unknown yet. In this study, we investigated whether BA inhibits hepatic gluconeogenesis in human hepatoma HepG2 cells and in high fat diet (HFD)-fed ICR mice, and underlying mechanisms. These studies reveal that suppression of the hepatic glucose production by BA as an AMP-activated protein kinase (AMPK) activator is of key therapeutic importance for T2DM.

MATERIALS AND METHODS

Chemicals. BA was kindly provided by Prof. N. I. Baek (Institute of Life Sciences and Resources, Kyung Hee University) and dissolved in DMSO. Antibodies against AMPK, phospho-AMPK, acetyl-CoA carboxylase (ACC), phospho-ACC, cAMP response element-binding protein (CREB), phospho-CREB, CREB-regulated transcription coactivator 2 (CRTC2), and IgG were from Cell Signaling Technology (Beverly, MA, USA), and actin was from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Ca^{2+}-calmodulin dependent protein kinase kinase (CAMKK) and phospho-Ser/Thr antibodies were from BD Biosciences (San Jose, CA, USA). Reverse transcriptase, Taq polymerase, and cell proliferation assay kits were supplied by Promega (Madison, WI, USA), and SYBR premix Ex Taq was from Takara Bio Inc. (Dalian, China). Compound C (AMPK inhibitor)[16] and STO-609 (CAMKK inhibitor)[17] were from Calbiochem (Darmstadt, Germany). Protein

extraction, easy-BLUE total-RNA extraction, and enhanced chemiluminescence (ECL) reagent were from Invitron Biotechnology Inc. (Beverly, MA, USA). Jet-PEI Hepatocyte DNA transfection reagent was from Polyplus transfection Inc. (San Marcos, CA, USA), and the glucose production assay kit was from Roche Applied Sciences (Indianapolis, IN, USA). Regular diet (RD) and HFD (Table 1) were purchased from Research Diets, Inc. (New Brunswick, NJ, USA). The other reagents and chemicals were of the highest grade commercially available.

Cell Culture and Viability Assay. The human hepatoma cell line HepG2 was purchased from the American Type Culture Collection (Rockville, MD, USA). HepG2 cells were grown in high glucose DMEM (Gibco BL, Grand Island, NY, USA), supplemented with 10% fetal bovine serum (FBS) and antibiotics (100 unit/mL penicillin and 100 μg/mL streptomycin). Cells were maintained at subconfluent conditions in a humidified incubator at 37 °C with ambient oxygen and 5% CO_2. The cytotoxicity of BA was determined by a Cell Titer 96 AQueous One solution Cell Proliferation Assay kit. In brief, cells were seeded at 3×10^4 cells/well in a 96-well plate and treated with BA as indicated for 24 h. After one day of treatment, 20 μL of 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) solution was added and incubated at 37 °C for 30 min, and the absorbance was recorded at 490 nm using an ELISA plate reader (Thermo LabSystem, Helsinki, Finland).

Stable Transfection. Expression plasmids for the Myc-tagged AMPKα1 wild type (WT) and dominant negative (DN) form, in which Asp157 was replaced with Ala, were generously provided by Prof. Ha (Department of Biochemistry, School of Medicine of Kyung Hee University). The HepG2 cells were seeded in 6-well plates and grown to 60% confluences, and the pdDNA3-AMPK α1-WT or -DN vectors were transfected into HepG2 cells using a jet-PEI transfection reagent. Briefly, each 1 μg of DNA vector was diluted to a volume of 100 μL with FBS-free and antibiotic-free DMEM, and then incubated with 10 μL of transfection reagent at room temperature for 15 min. Antibiotic-free DMEM containing 10% FBS was then added to a final volume of 1.5 mL before addition to the cells in a 6-well plate. Cells were incubated with the recombinant complexes for 48 h and then replaced with the selective medium containing 5 mg/mL G418. The stably expressed clones were screened through limiting dilution and Western blot analysis.

Glucose Production Assay. Cells were cultured in a 12-well plate at the density 3×10^5 cells/well, attached for 12 h, and then maintained in serum-free DMEM with or without BA for 3 h. Cells were washed twice with phosphate buffered saline (PBS) to remove glucose and incubated for 3 h in glucose production assay medium (glucose- and phenol red-free DMEM supplemented with 2 mM sodium pyruvate and 20 mM sodium lactate). Glucose in the media was quantified using an Amplex Red Glucose/Glucose Oxidase Assay Kit (Invitrogen, CA, USA) and normalized to the cellular protein concentration measured with a Bio-Rad protein assay kit (Hercules, CA, USA). The total glucose production is derived from glycogenolysis and gluconeogenesis in the liver. The glucose production from glycogenolysis was measured in the absence of gluconeogenic substrates. Thereafter, the glucose production via gluconeogenesis can be measured by the difference between the total glucose production and the glucose derived from glycogenolysis.

Animal Study. Five-week-old ICR mice were purchased from Orient Bio Inc. (Seongnam, Korea). The animal experiment protocol was reviewed and approved by the Institutional Animal Ethics Committee of Kyung Hee University (permission number: KHP-2010-12-9). Mice were housed in environmentally controlled conditions with a 12 h light/12 h dark cycle, and given free access to food and water under constant room temperature (22 ± 2 °C) and humidity (50 ± 5%). After 1 week acclimation, a pyruvate tolerance test (PTT) was performed using fasted 6-week-old ICR mice to examine the effect of a single administration of BA on hepatic glucose production. Ten mg/kg of BA (dissolved in 0.5% CMC) was orally administered to the ICR mice, and after 2 h, mice were intraperitoneally injected with 2 g/kg of pyruvate and blood glucose was obtained from the tail vein every 30 min until the 3 h period. Glucose levels were measured using an Accu-chek Advantage glucometer (Roche Diagnostics, Indianapolis, IN, USA). Next, to evaluate the effect of chronic administration of BA on blood glucose and lipid levels, mice were randomly divided into four groups (n = 8 for each group): regular diet fed group (RD), high fat diet fed group (HFD); HFD plus BA at 5 mg/kg body weight (BA5); and HFD plus BA at 10 mg/kg (BA10). Mice were orally administered with BA once a day for 3 weeks. Upon completion of treatment, mice were anesthetized by diethyl ether inhalation after overnight fasting. Blood was collected by cardiac puncture, and liver was dissected and snap-frozen in liquid nitrogen for further experiments.

Blood Chemistry Analysis. The plasma concentrations of glucose and triglyceride were determined using commercial kits (Stanbio Laboratory, Boerne, TX, USA) and an automatic analyzer (SMART-TLAB, Mannheim, Germany). The plasma insulin concentration was determined using a Bio-Plex Pro Mouse Diabetes Assay Kit (Bio-Rad, Hercules, CA, USA).

Immunoprecipitation and Western Blot Analysis. To detect proteins in whole cell lysates, cells were washed with ice-cold PBS and lysed using a protein extraction kit. Insoluble protein was removed by centrifugation at 13,000 rpm for 20 min. The protein concentration of the cell lysates was measured using a Bio-Rad protein assay kit. To determine protein expression in livers, the livers were removed and homogenized for 30 s, and then the protein concentration was measured as described above. For immunoprecipitation, 300 μg of cell lysate was cleared with 20 μL of protein G-sepharose beads (Santa Cruz, CA, USA) and 1 μg of antibody (anti-CAMKK or anti-CRTC2) was used. After the addition of 20 μL of G-Sepharose beads, incubation was continued for an additional 2 h at 4 °C. The beads were then collected by centrifugation and washed three times with PBS, the supernatant was removed, 30 μL of 2× loading buffer was added, and samples were run on a 8% SDS-polyacrylamide electrophoresis gel (SDA-PAGE). For Western blot assays, equal amounts of protein (40 μg/lane) were resolved by 8% SDS-PAGE and transferred to polyvinylidene difluoride membranes (Millipore, Bedford, MA, USA). Levels of protein and actin were detected with a 1:1000 dilution of each antibody in a nonfat dry milk solution (Tris-buffered saline with 5% nonfat dry milk and 0.1% Tween 20), followed by incubation with a horseradish peroxidase-

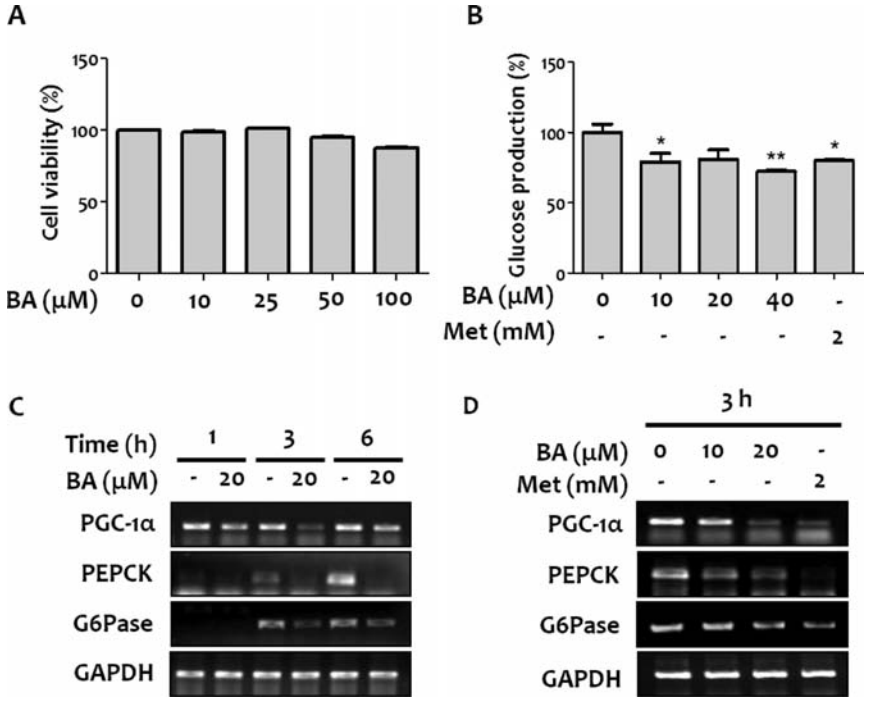

Figure 1. Effects of BA on glucose production and mRNA expression of gluconeogenic proteins in HepG2 cells. (A) HepG2 cells were treated with different concentrations (10, 25, 50, and 100 μM) of BA for 24 h, and cell viability was determined by MTS assay. (B) Cells were cultured in a 12-well plate, attached for 12 h, and then maintained in serum-free DMEM with or without BA at indicated concentrations for 3 h. Cells were washed twice with PBS to remove glucose and incubated for 3 h in glucose production assay medium (glucose and phenol red-free DMEM supplemented with 2 mM sodium pyruvate and 20 mM sodium lactate). The glucose concentration was determined using a glucose assay kit and normalized to cellular protein concentration. (C) Cells were treated with 20 μM BA for up to 6 h or (D) cells were treated with 10 or 20 μM BA for 3 h, and mRNA expression levels of PGC-1α, PEPCK, and G6Pase were analyzed by RT-PCR. Data are represented as the mean ± SE: *$p < 0.05$, **$p < 0.01$ compared to control cells.

conjugated secondary antibody (diluted 1:2000) for 2 h at room temperature. Protein bands were detected using an ECL Western blot detection kit.

RT- and Real Time-PCR. To determine the levels of gene expression of phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase (G6Pase), and peroxisome proliferation-activated receptor γ coactivator-1α (PGC-1α), total RNA was isolated from cultured HepG2 cells and liver tissue using an easy-BLUE total-RNA extraction kit according to the manufacturer's protocol. Five micrograms of extracted RNA was used to synthesize single-strand cDNA with oligo (15) dT primers and reverse transcriptase in a reaction volume of 50 μL. PCR reactions were performed in a total volume of 20 μL comprising 2 μL of cDNA product, 0.2 mM of each dNTP, 20 pmol of each primer, and 0.8 unit of Taq polymerase. PCR was performed at 95 °C for 30 s, followed by an annealing procedure for 30 s, and incubated at 72 °C for 1 min. The final extension was done at 72 °C for 10 min. The RT-PCR products were electrophoresed in 1% agarose gels under 100 V and were stained with 0.5 g/mL ethidium bromide. Levels of the house-keeping genes GAPDH and actin were used to correct for differences in RNA isolation, RNA degradation, and the efficiency of the reverse transcription reaction. To determine gene expression levels of PEPCK and G6Pase in a more accurate way, quantitative PCR was performed using 1 μg of cDNA in a 20 μL reaction volume with the LightCycler real-time PCR System (Roche Applied Science, Indianapolis, IN, USA). A relative gene expression quantification method was used to calculate the fold change of mRNA expression according to the comparative threshold cycle method using house-keeping gene as an endogenous control. The primers and annealing temperatures for both procedures are shown in Table 2.

Statistical Analysis. The results were shown as the mean ± standard error mean (SEM) of triplicate experiments. Comparisons between groups were made using ANOVA, and the significance was determined by Tukey's Test. Differences of $p < 0.05$ were considered to be statistically significant.

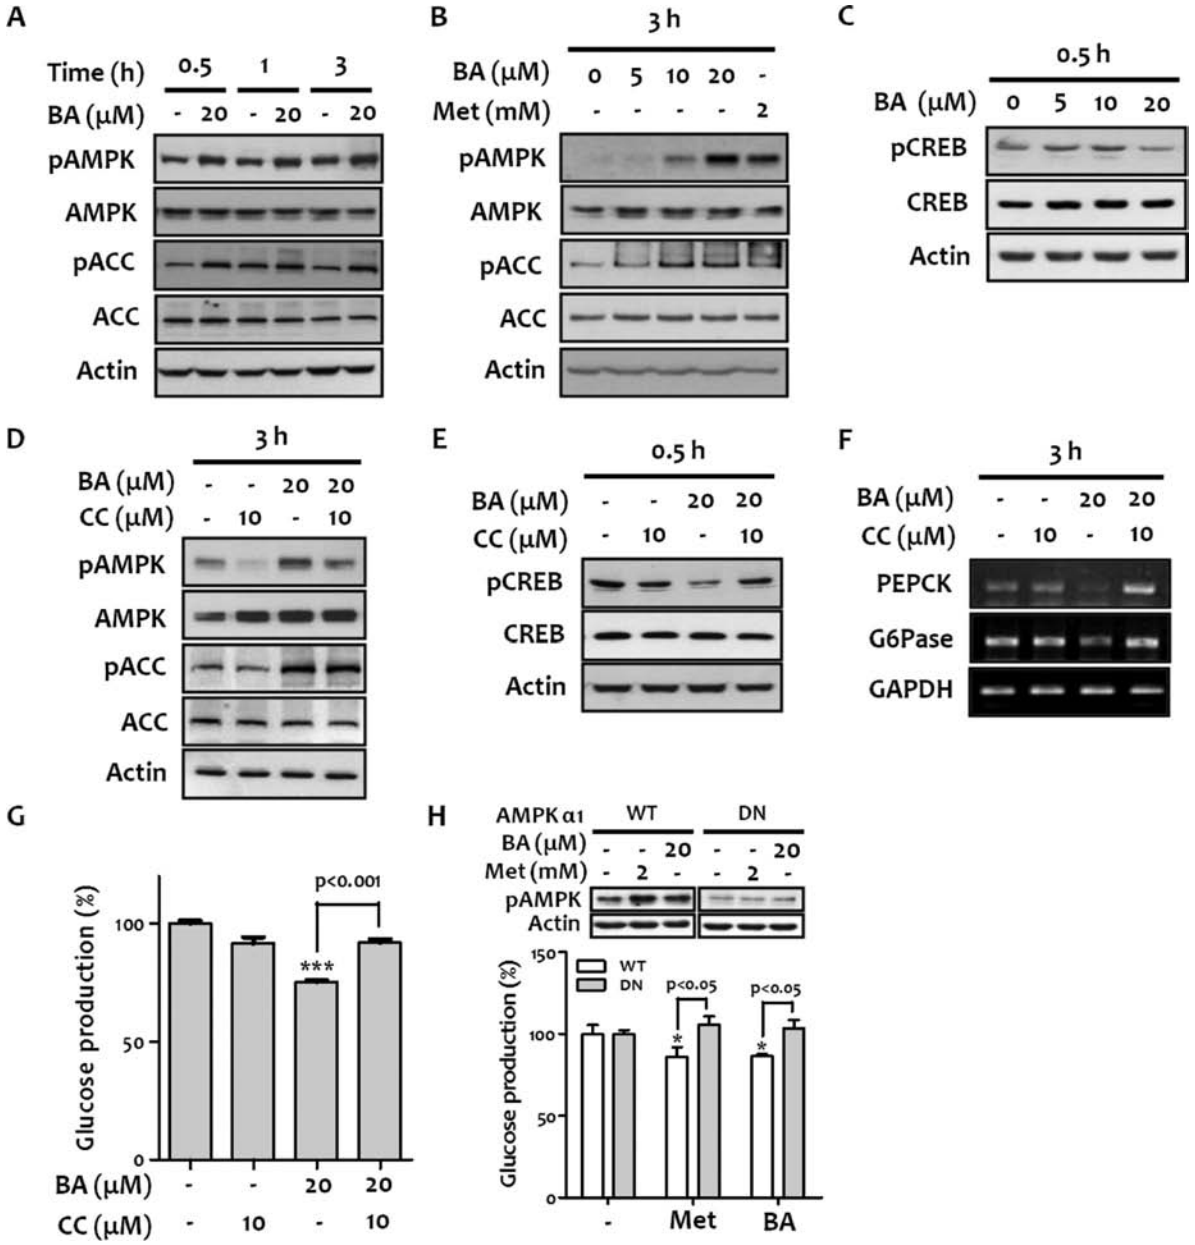

Figure 2. Effects of compound C (a chemical AMPK inhibitor) and AMPKα1-DN on BA-induced suppression of glucose production and the AMPK signaling pathway in Hep2 cells. (A) Cells were treated with 20 μM BA for up to 3 h or (B) cells were treated with 5−20 μM BA for 3 h, and phosphorylated forms of AMPK and ACC were determined by Western blot. (C) Cells were treated with 5−20 μM BA for 30 min, and the phosphorylated form of CREB was determined by Western blot. (D, E) Cells were pretreated with 10 μM compound C for 2 h and incubated with 20 μM BA for 3 h or 30 min, and phosphorylated forms of AMPK, ACC, and CREB were determined by Western blot. (F). Cells were pretreated with 10 μM compound C for 2 h and incubated with 20 μM BA for 3 h, and mRNA expression levels of PEPCK and G6pase were analyzed by RT-PCR. (G) Cells were pretreated with 10 μM compound C and incubated with 20 μM BA for 3 h in serum-free DMEM containing gluconeogenic substrates, and glucose production was determined. (H) HepG2 cells transfected with AMPKα1-WT or -DN were treated with 20 μM BA or 2 mM metformin for 3 h, and the protein expression level of phosphorylated AMPK was analyzed by Western blot. Under the same conditions, glucose production was also determined. Data are represented as the mean ± SE: *p < 0.05, ***p < 0.001 compared to control cells.

RESULTS

BA Inhibits Hepatic Glucose Production via Suppression of mRNA Expression of Gluconeogenic Proteins. First, we investigated the effect of BA on the viability of HepG2 cells using the MTS assay. The growth profile observed over one day of culture in the presence of BA at up to 50 μM was similar to that of the control (Figure 1A), but concentrations of BA greater than 50 μM resulted in cytotoxicity in HepG2 cells. Therefore, less than 50 μM BA was used in the following study. To examine the inhibitory effect of BA on hepatic glucose production, liver cells were treated with the indicated concentrations of BA for 6 h. The glucose contents were decreased in a concentration-dependent manner (Figure 1B). To elucidate the underlying mechanism of BA, the mRNA expression levels of PGC-1α, PEPCK, and G6Pase were examined using RT-PCR (Figure 1C and D). Gene expression levels of these proteins in 20 μM BA-treated cells were comparable to those in 2 mM metformin-treated cells (Figure 1D). Treatment with BA suppressed the gene expression of gluconeogenic proteins in HepG2 cells, and

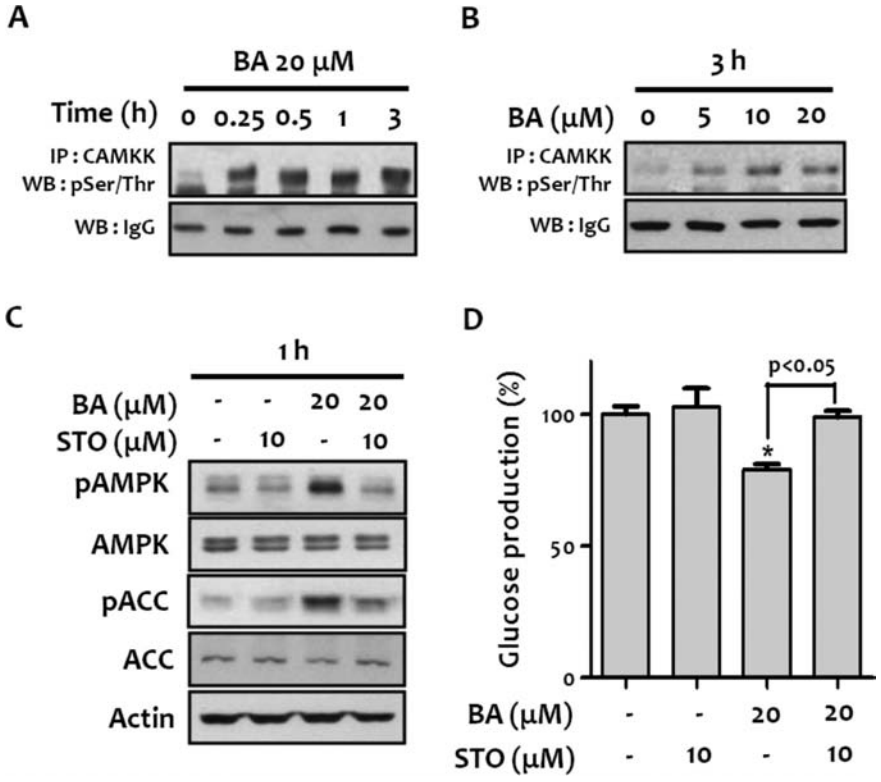

Figure 3. Effect of STO-609, a specific inhibitor of CAMKK, on BA-induced AMPK phosphorylation in HepG2 cells. (A) Cells were treated with 20 μM BA for up to 3 h or (B) cells were treated with BA at indicated concentrations for 3 h, and cell lysates were immunoprecipitated with an antibody against CAMKK, and then phospho-Ser/Thr was analyzed by Western blot. (C) Cells were pretreated with 10 μM STO-609 for 2 h and incubated with 20 μM BA for 3 h, and the protein expression levels of AMPK and ACC were analyzed by Western blot. (D) Cells were pretreated with 10 μM STO-609 for 2 h and incubated with 20 μM BA for 2 h in serum-free DMEM containing gluconeogenic substrates, and glucose production was determined. Data are represented as the mean ± SE: *$p < 0.05$ compared to control cells.

these results were parallel to the reduction of hepatic glucose production, as shown in Figure 1B.

BA Inhibits Hepatic Glucose Production via Activation of the AMPK Signaling Pathway. We examined whether BA stimulates the phosphorylation of AMPK in HepG2 cells because activated AMPK is known to generate ATP by increasing fatty acid oxidation and reducing ATP hydrolysis through decreased lipogenesis and gluconeogenesis.[18] When HepG2 cells were treated with BA, BA markedly phosphorylated AMPK and ACC, an immediate substrate of AMPK, in a concentration-dependent manner (Figure 2B). Next, downstream of the AMPK signaling pathway, including CREB, was examined, because phosphorylated CREB acts as a scaffold for coregulators such as CBP, p300, and CRTC2 that activate gluconeogenesis genes.[19] The expression of the phosphorylated form of CREB was significantly suppressed in 20 μM BA-treated cells (Figure 2C). To confirm whether the glucose-suppressive effect of BA was associated with AMPK, a chemical inhibitor of AMPK (compound C) and the dominant negative (DN) AMPK expression vector were employed. HepG2 cells were pretreated with 10 μM compound C for 2 h and then incubated with 20 μM BA for up to 3 h. The increases in AMPK and ACC phosphorylation, the decrease in the phosphorylation of CREB, the decreases in PEPCK and G6Pase gene expression, and the decrease in hepatic glucose production in 20 μM BA-treated cells were all completely reversed in the presence of compound C (Figure 2D−G). Next, HepG2 cells were transfected with either AMPKα1-WT or -DN and the phosphorylated form of AMPK was determined. As shown in Figure 2H, BA and metformin could not induce phosphorylation of AMPK in AMPKα1-DN transfected cells when compared to those in AMPKα1-WT transfected cells. Moreover, AMPKα1-DN transfected HepG2 cells could not suppress hepatic glucose production (Figure 2G) when these cells were treated with BA or metformin, indicating that the AMPK signaling pathway is positively associated with a suppressive effect of BA on hepatic glucose production.

CAMKK Is an Upstream Kinase that Acts on AMPK. Next, to identify the upstream kinase that acts on AMPK, liver kinase B1 (LKB1) and CAMKK were examined in BA-treated HepG2 cells. As shown in Figure 3A and B, CAMKK was significantly phosphorylated in time- and concentration-dependent manners when the cells were treated with BA, but not LKB1 (data not shown). To confirm whether CAMKK acts as a kinase for AMPK, the protein expression levels of phosphorylated AMPK and ACC were measured in the presence of a specific CAMKK inhibitor (STO-609). BA-induced AMPK and ACC phosphorylation and suppression of hepatic glucose production were markedly reversed when the cells were pretreated with 10 μM STO-609 (Figure 3C and D).

BA Improves Pyruvate Tolerance and Insulin Resistance. Having *in vitro* experimental results, we tested whether BA has a beneficial effect on hyperglycemia through suppression of hepatic glucose production. To directly assess the effect of BA on hepatic glucose production, mice were challenged with the gluconeogenic precursor pyruvate in which 10 mg/kg of BA was orally administered to ICR mice prior to intraperitoneal injection of pyruvate. Single administration of BA improved pyruvate tolerance, as represented by significant reduction in AUC of 27%

dx.doi.org/10.1021/jf4030739 | J. Agric. Food Chem. 2014, 62, 434−442

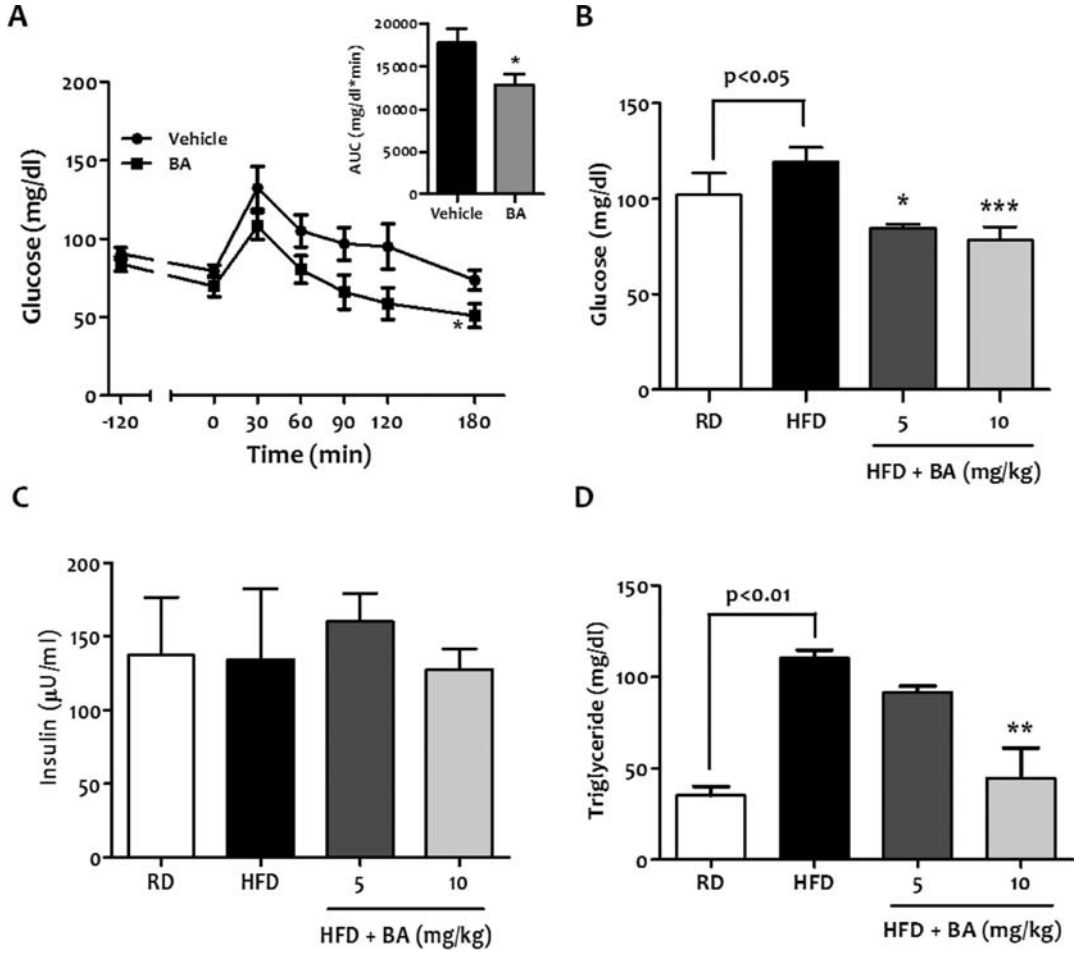

Figure 4. Effects of BA on pyruvate tolerance and the plasma levels of glucose, insulin, and triglyceride in ICR mice. (A) 10 mg/kg of BA was orally administered to the ICR mice, and after 2 h, mice were intraperitoneally injected with 2 g/kg of pyruvate and blood glucose was obtained from the tail vein every 30 min until the 3 h period. (B) Mice were fed either a regular diet (RD) or high fat diet (HFD) for 3 weeks with 5 or 10 mg/kg of BA. At the end of the treatment, plasma levels of fasting glucose (B), insulin (C), and triglyceride (D) were determined as described in the Materials and Methods. Data are represented as the mean ± SE: $*p < 0.05$; $**p < 0.01$; $***p < 0.001$ compared to the HFD group.

compared to that in vehicle-treated mice (Figure 4A). To affirm the results from *in vitro* and pyruvate tolerance test, ICR mice were treated with either 5 or 10 mg/kg of BA for a 3 week period. Plasma glucose, insulin, and triglyceride levels were determined in the blood at the end of the treatment. The results showed that BA5- and BA10-treated groups decreased the plasma glucose level by 29% and 34% (Figure 4B) and decreased plasma triglyceride levels by 17% and 59% (Figure 4D), respectively, when compared to those in the HFD-fed control group. However, no significant changes were observed in plasma insulin level after BA treatment (Figure 4C). In order to evaluate the improving effect of BA on insulin resistance, which was induced by HFD feeding to ICR mice, homeostasis model assessment (HOMA)-insulin resistance (IR) was used to calculate an index of insulin resistance as insulin (μU/mL) × glucose (mM)/22.5.[20] HOMA-IR of the HFD control group was increased to 40 from 35 of the RD control group, and this value was decreased to 34 and 25 in the BA5- and BA10-treated groups, respectively. When 5 and 10 mg/kg of BA were administered to HFD-fed mice for a 3-week period, HOMA-IR values for these groups were decreased by 15% and 38%, respectively, compared to that in the HFD-fed control group.

BA Suppresses Hepatic Glucose Production via Modulation of a CAMKK-AMPK-CREB Signaling Pathway in the HFD-Fed ICR Mice. Six-week-old ICR mice were fed a HFD with BA for 3 weeks, after which they were sacrificed and their liver tissues removed. Liver protein and mRNA were extracted to examine levels of CAMKK, AMPK, CREB, the CRTC2·CREB complex, PGC-1α, PEPCK, and G6Pase. The protein expression levels of activated CAMKK, AMPK, and ACC were increased, but the protein expression levels of pCREB and the CRTC2·CREB complex were decreased in a dose-dependent manner in the liver tissues of BA-treated mice when compared to those in HFD-fed control mice (Figure 5A), mimicking the effects observed *in vitro*. To determine the functional consequences of AMPK activation, the mRNA expression levels of key target proteins were assessed by RT- and real time-PCR (Figure 5B). The mRNA expression levels of gluconeogenic proteins were markedly enhanced in the HFD control group compared to mice fed a RD, whereas BA treatment significantly reduced the mRNA expression of all of these proteins in a dose-dependent manner.

DISCUSSION

Hepatic glucose production (HGP) is a key physiological process that becomes altered in diabetic patients[21] and represents the main target of the antihyperglycemic agents such as metformin.[22] Metformin reduces cellular respiration in hepatocytes by

dx.doi.org/10.1021/jf4030739 | J. Agric. Food Chem. 2014, 62, 434−442

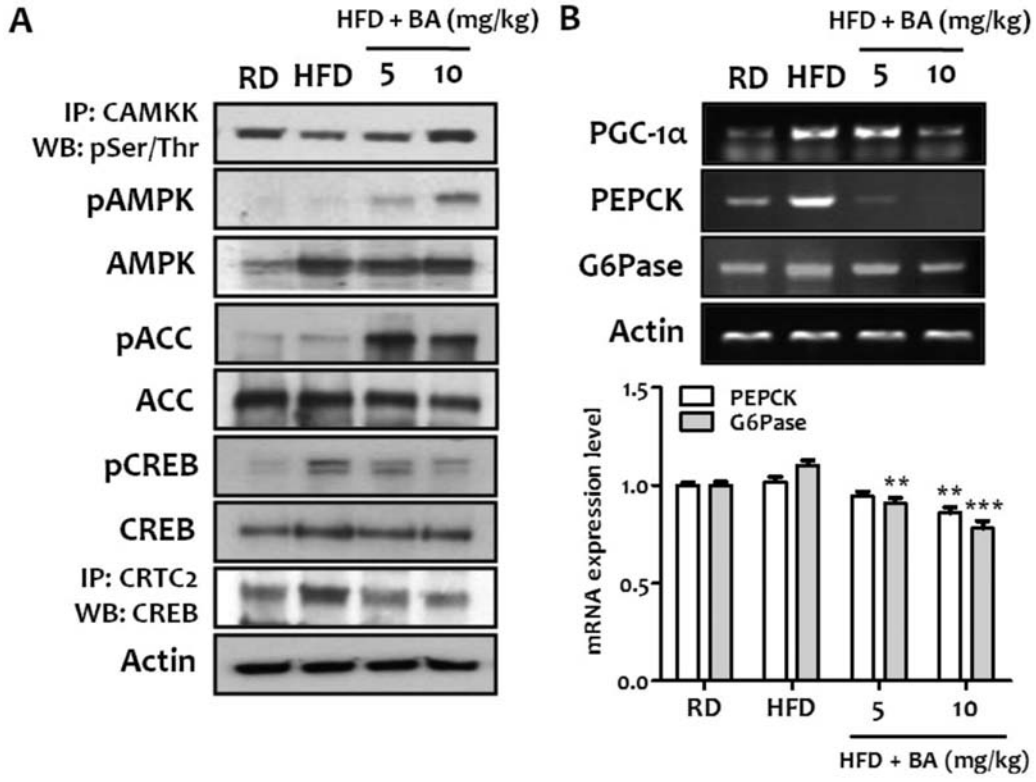

Figure 5. Effects of BA on protein and mRNA expression levels in the liver of HFD-fed ICR mice. (A) Protein expression levels of AMPK, ACC and CREB were analyzed by Western blot. The CAMKK and CRTC2●CREB complex were determined using immunoprecipitation followed by Western blot. (B) Gene expression levels of PGC-1α, PEPCK and G6Pase were estimated by RT-PCR and real time-PCR.

inhibiting the mitochondrial respiratory chain complex[23] and might thus blunt gluconeogenesis by reducing intracellular ATP. Although metformin is likely to be the main therapy due to its efficacy and tolerability, its use in diabetic patients is limited because of side effects such as lactic acidosis. There is a need for safer hypoglycemic agents that act on HGP. Dietary intake from plant food and their ingredients could be a more effective strategy for the management of T2DM because they act on multiple target sites and are relatively low cost. Recently, aloe vera phytosterols and decaffeinated green coffee extract (Svetol) were reported to show antidiabetic activity, primarily due to suppression of HGP.[24,25]

In this study, human hepatoma HepG2 cells and ICR mice fed HFD were used to examine the antihyperglycemic activity of BA and its underlying mechanisms, because the antidiabetic activity of BA has not been thoroughly studied yet. Based upon *in vitro* and pyruvate tolerance tests, we assumed that the antihyperglycemic activity of BA is mainly ascribed to suppression of hepatic glucose production. Therefore, we attempted to elucidate the underlying mechanisms that regulate the production of glucose by the liver, focusing on modulation of the AMPK signaling pathway by BA treatment.

In the cell studies using HepG2, hepatic glucose production and mRNA expression levels of PGC-1α and rate-limiting enzymes for gluconeogenesis (PEPCK and G6Pase) were all suppressed compared to those in vehicle-treated cells when the cells were treated with BA at indicated time and concentrations (Figure 1). Next, we examined whether BA activates the AMPK signaling pathway, because AMPK has been implicated in the control of hepatic glucose and lipid homeostasis by many additional effects, both on genes and on the short-term regulation of specific enzymes.[26] In vitro and in vivo studies showed that BA administration caused enhanced phosphorylation of AMPK and ACC (Figures 2A, 2B, and 5A) but inhibited phosphorylation of CREB, a scaffold for coregulators such as CBP, p300, and CRTC2 (Figures 2C and 5A). However, the protein expression of pAMPK, pACC, and pCREB, the mRNA expression of PEPCK and G6Pase, and HGP were all completely reversed when the cells were exposed to 10 μM compound C (an AMPK inhibitor) before treatment with BA (Figure 2D−G). In addition, HepG2 cells transfected with negative dominant AMPKα1 could not induce phosphorylation of AMPK and suppress glucose production when the cells were treated with BA or metformin compared to those in wild type AMPKα1 (Figure 2H), indicating that AMPK is strongly associated with the suppressive effect of BA on HGP.

Recently, as a molecular mechanism underlying AMPK-mediated PEPCK gene suppression, the phosphorylation of CRTC2, a coactivator of CREB protein, by AMPK was reported.[27] Phosphorylation of CRTC2 at Ser171 by AMPK confers binding of the protein 14-3-3 and sequestration of CRTC2 out of the nucleus, resulting in the inhibition of gluconeogenic gene expression.[28] In response to fasting, CRTC2 controls the gluconeogenic program in the liver via its nuclear translocation and association with the CREB, driving the expression of the PGC1α coactivator. Expression of the coactivator PGC-1α in turn drives the transcription of key gluconeogenic enzymes such as PEPCK and G6Pase. With this notion, HFD-fed mice seem to stimulate HGP through the induction of CREB phosphorylation, CRTC2·CREB interaction, and the expression of gluconeogenic enzymes. When ICR mice were treated with BA for 3 weeks, CREB phosphorylation, the CRTC2·CREB complex, and mRNA expression levels of PGC-1α, PEPCK, and G6Pase were all suppressed in a dose-

dx.doi.org/10.1021/jf4030739 | J. Agric. Food Chem. 2014, 62, 434−442

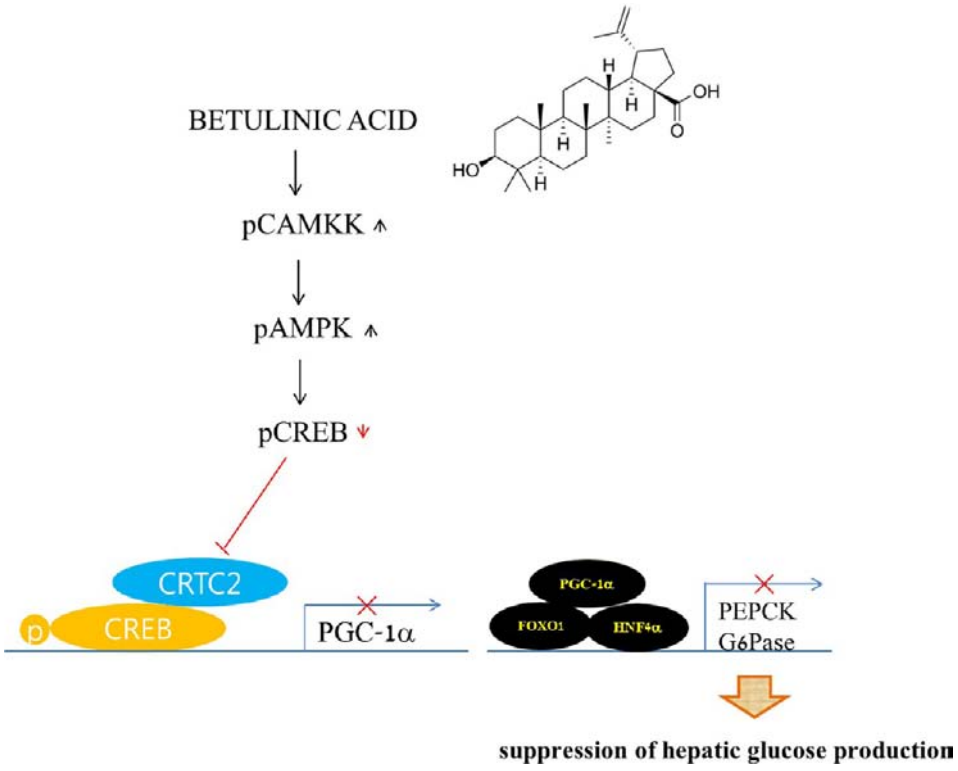

Figure 6. Schematic diagram illustrating the proposed mechanism by which betulinic acid inhibits hepatic gluconeogenesis. Inhibition of hepatic gluconeogenesis by betulinic acid may result from the activation of the CAMKK-AMPK-CREB signaling pathway.

dependent manner (Figure 5A and B), indicating that the inhibitory effect of BA on HGP is mediated through the AMPK-CREB-PGC-1α signaling pathway. Finally, to identify the upstream kinase that acts on AMPK, LKB1 and CAMKK were examined in BA-treated HepG2 cells, and BA activates AMPK by increasing its phosphorylation by CAMKK in HepG2 cells (Figure 3A and B) and liver tissues of ICR mice fed a HFD (Figure 5A). The fact that CAMKK acts as an upstream kinase for AMPK was verified by pretreatment with the STO-609, a specific inhibitor of CAMKK (Figure 3C and D). At this time, we do not know exactly how BA activates AMPK in HepG2 cells and liver tissue of HFD-fed ICR mice, although a calcium-dependent pathway involving phosphorylation of AMPK by CAMKK is evidently provided in this study. As alternative or additional explanations, mechanisms involving either inhibition of mitochondrial ATP synthesis or an SIRT1-dependent pathway via increase in NAD^+ levels should be tested to elucidate further how BA activates AMPK in hepatocytes.

ACC is an important rate-controlling enzyme for the synthesis of malonyl-CoA, which is a critical precursor for biosynthesis of fatty acids and a potent inhibitor of mitochondrial fatty acid oxidation. Phosphorylation of ACC by AMPK lead to a fall in malonyl-CoA content and a subsequent decrease in triglyceride synthesis concomitant with an increase in β-oxidation.[29] This was evidenced by the decrease in plasma triglyceride levels after BA treatment in HFD-fed ICR mice (Figure 4D). In addition, insulin resistance was also significantly reduced in BA-treated mice compared to that in HFD control mice even though there are no significant differences in plasma insulin levels among groups (HOMA-IR was decreased by 15% and 38% in BA5 and BA10 groups, respectively). Significant reduction of triglyceride levels in the plasma and the liver tissue may partly contribute to improvement of insulin resistance. Based upon *in vitro* and *in vivo* studies, an action mechanism of antihyperglycemic activity of BA might be due to the suppression of HGP, and this plausible mechanism was verified by a pyruvate tolerance test in which BA administration significantly reduced the AUC by 27% compared to that in vehicle-treated mice (Figure 4A).

In conclusion, BA has beneficial effects on hyperglycemia and insulin resistance by modulating the CAMKK-AMPK-CREB signaling pathway (Figure 6), and BA itself or BA-containing medicinal plants could represent a promising therapeutic agent to prevent type 2 diabetes.

ABSTRACT: The consumption of wine and spirits, traditionally aged in oak barrels, exposes humans to roburin ingestion. These molecules belong to a class of ellagitannins (ETs), and their only known source is oak wood. Very little is currently known about roburin bioavailability and biological activity. We reported for the first time human absorption of roburins from a French oak wood (*Quercus robur*) water extract (Robuvit) by measuring the increase of total phenols (from 0.63 ± 0.06 to 1.26 ± 0.18 μg GAE equiv/mL plasma) and the appearance of roburin metabolites (three different glucoronidate urolithins and ellagic acid), in plasma, after 5 days of supplementation. Robuvit supplementation induced also the increase of plasma antioxidant capacity from 1.8 ± 0.05 to 1.9 ± 0.01 nmol Trolox equiv/mL plasma. Moreover, utilizing a combined ex vivo cell culture approach, we assessed the effect of *Q. robur* metabolites (present in human serum after supplementation) on gene expression modulation, utilizing an Affymetrix array matrix, in endothelial, neuronal, and keratinocyte cell lines. The functional analysis reveals that Robuvit metabolites affect ribosome, cell cycle, and spliceosome pathways

KEYWORDS: *ellagitannins, roburins, Quercus robur, human study, gene array*

INTRODUCTION

In the past decades, epidemiological surveys pointed out the association between a significantly lower risk for cardiovascular, metabolic, and cancer diseases, cognitive decline, and neurodegeneration and the consumption of diets rich in plant polyphenols.[1,2] The beneficial role of polyphenols was initially attributed to a "nonspecific" antioxidant capacity. After a first enthusiasm, it became apparent that health contributions of polyphenols were not (only) associated with cellular protection from oxidation but are due to a more complex mechanism involving the induction of cellular response to potentially harmful stimuli finally resulting in a number of specific adaptive and defensive responses. Despite a consensus about this "hormetic" (*para*-hormetic) activity,[3] comprehensive knowledge about the absorption, metabolism, and specific biological activities of the different classes of polyphenols is still scarce.

Tannins are a specific family of polyphenols having a relatively large molecular structure. Tannins are considered to be "secondary" compounds of plant physiology, not functioning in "primary" metabolism such as biosynthesis or energy conversions, although they serve biological purposes such as protecting plants from herbivores and microbial infections. Tannins are divided into two groups on the basis of their structural characteristics: hydrolyzable and condensed tannins. In the hydrolyzable tannins, a carbohydrate is partially or totally esterified with phenolic groups such as gallic acid (gallotannins, GTs) or ellagic acid (ellagitannins, ETs). These compounds are present in significant amounts in many berries, nuts, pomegranates, muscadine grapes, and edible dark-colored fruits.[4,5]

The French oak water extract Robuvit is a registered proprietary water extract obtained from fresh *Quercus robur* wood, standardized to provide a specific profile of tannins and in particular a mixture of ≥20% roburins (A−E) including grandinin. The main ETs in *Q. robur* are two diastereoisomers, vescalagin and castalagin, which were originally isolated and described by Mayer et al.[6] Sugar derivatives of vescalagin with aldopentoses xylose and lyxose are defined as roburin E and grandinin, respectively (Figure 1).[7] Roburins A−D are dimers, with roburin D consisting of vescalagin and castalagin and roburin A of two vescalagin subunits. Roburins B and C resemble the structure of roburin A with additional xylose (roburin C) or lyxose (roburin B) bound to one vescalagin unit (Figure 2). Further to the roburins, Robuvit contains monomeric vescalagin and castalagin, as well as ellagic acid (EA) and gallic acid (GA). Oak wood is currently the only known source of roburins, and according to this specificity, the major source of roburins in human diets results from the consumption of wine and spirits (cognac and whiskey) traditionally matured, aged, and stored in oak barrels. In fact, oak wood constituents contribute to the improvement of the aroma, taste, and color and to the building up of the sensation of "mouth-fullness". As a result of this technological practice, humans have been exposed to roburins for centuries. In wines and spirits, roburins (including grandinin and the monomers

castalagin and vescalagin) have been found to range between 1.2 mg/L (bourbon whiskey) and 9.4 mg/L (red wines).[8] A number of indications suggest that, similarly to other polyphenols, ETs and their metabolites may exert beneficial effects on human health.[9] Despite the traditional consumption of roburins with wine and spirits, very little is currently known about their bioavailability in humans. In general, ET from berries, pomegranate, walnuts, pecans, and pistachios are known to require the involvement of the colonic microflora to be metabolized into dibenzopyranone species (urolithins).[10] The consumption of oak-aged red wine was found to result in only trace amounts of urolithin-B aglycone and glucuronide in urine.[11] Furthermore, several kinds of grapes have been found to contain EA, and therefore excreted urolithins may not necessarily be attributed to oak constituents extracted following wine aging in barrels. The aim of our study is to investigate the absorption and metabolism of Robuvit extract in healthy volunteers and to evaluate the effect of Robuvit consumption on gene expression in cultured endothelial, neuronal, and keratinocyte cells to obtain a solid background for further studies addressing the understanding of possible beneficial effects of this family of molecules on human health.

MATERIALS AND METHODS

Chemicals. MeOH, HOCOOH, gallic acid, ellagic acid, Trolox, fluorescein, perchloric acid, and 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH) were purchased from Sigma-Aldrich (Milano, Italy); randomly methylated *β*-cyclodextrin (RMCD) was purchased from Cyclolab (Budapest, Hungary).

In Vivo Study. *Experimental Design.* Three healthy, nonsmoker, volunteers participated in this study, which was approved by the CRA-NUT ethical committee. The investigation conforms to the principles outlined in the Declaration of Helsinki and its amendments. None of subjects was taking any medication or vitamin supplementation for the 2 weeks before the beginning of the experiment. The day before the experiment subjects abstained from drinking coffee, tea, wine, and beer, and they ate no chocolate, fruits, and vegetables. The first day of the in vivo experimental protocol, blood was withdrawn in fasting

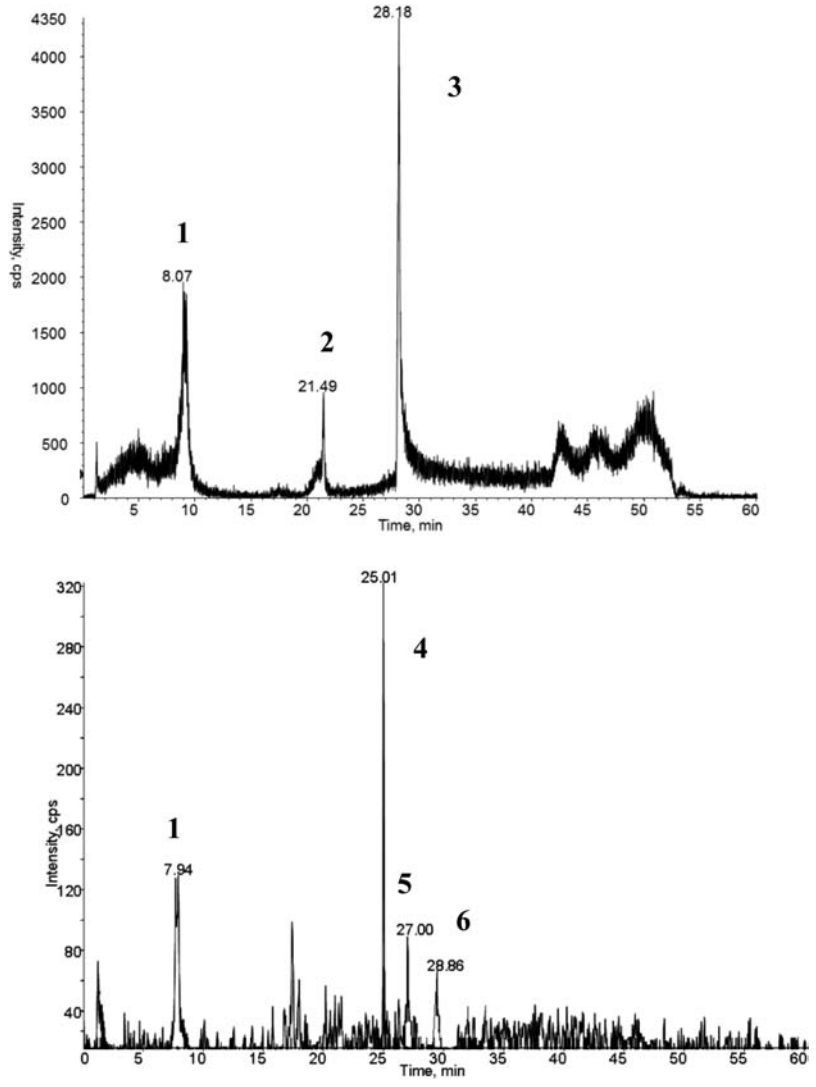

Figure 3. LC-MS total ion current (TIC) chromatograms of standards (top) and a representative plasma sample (bottom). Peaks: 1, gallic acid; 2, methyl gallate; 3, ellagic acid; 4, urolithin C diglucuronide; 5, urolithin A glucuronide; 6, urolithin B glucuronide.

condition and serum isolated and stored at −80 °C until its utilization. Volunteers were then supplemented with one capsule of Robuvit (containing 100 mg of *Q. robur* extract) three times a day for 5 days. During the 5 days of the supplementation, the subjects were encouraged to reduce as much as possible the consumption of polyphenol-rich foods. The last day of the supplementation, subjects were administered 300 mg of Robuvit in fasting condition, about 1 h before blood withdrawal, and serum was collected and isolated again as described above.

Q. robur Capsule Analyses. Robuvit capsule was extracted with 50 mL of MeOH/H_2O 80:20 (v/v) in a shaking bath overnight in reduced light and temperature conditions. Subsequently, the extract was centrifuged for 10 min at 2000*g* and 4 °C. The supernatant was filtered through a 0.20 mm PVDF filter (Whatman, USA) and diluted 1:1 with methanol before the analyses.

Plasma Sample Preparation. Plasma samples were acidified immediately to pH 3 with 1 N HCl immediately after blood withdrawal and stored at −80 °C. Once thawed, samples were mixed with acetonitrile 1:4 (v/v) to precipitate plasma proteins and then centrifuged for 10 min at 25000 rpm and 4 °C. The supernatant was recovered, dried under nitrogen (N_2), and reconstituted with 0.5 mL of H_2O acidified with 0.1% HCOOH. Extraction of metabolites was performed using solid-phase extraction (SPE) OASIS HLB 1 cm^3 (30 mg) extraction cartridges (Waters, Milford, MA, USA). The SPE procedure consisted of the following steps: activation of SPE cartridges with 1 mL of MeOH acidified with 0.1% HCOOH, conditioning with 1 mL of H_2O acidified with 0.1% HCOOH, loading of the sample, washing with H_2O acidified with 0.1% HCOOH (2 mL) and with water/methanol (95:5) (2 mL), and finally elution of metabolites with MeOH acidified with 0.1% HCOOH (2 mL). The eluted fraction was evaporated under nitrogen, and the residue was reconstituted with mobile phase to 0.3 mL and filtered through a 0.2 mm PVDF filter (Whatman) into a vial insert for LC-MS/MS analyses. We determined only the principal compounds that were extracted in MeOH/H_2O. However, several ETs are insoluble and should be measured after hydrolysis (by detection of the produced EA). Moreover, our MS has a maximum limit of m/z 1500; therefore, ETs that have higher molecular weights (such as roburin dimers) cannot be measured.

ESI-MS, ESI-MS/MS, LC-ESI-MS, and LC-ESI- MS/MS Analyses. Quantitative online HPLC-ESI-MS/MS analysis of the capsule extract and plasma sample were performed using a Perkin-Elmer series 200 HPLC system interfaced to an Applied Biosystems (Foster City, CA, USA) API 3200 instrument equipped with a Turbo ionspray source. A gradient elution was performed by using a mobile phase A represented by water acidified with formic acid (0.1%) and a mobile phase B represented by acetonitrile acidified with formic acid (0.1%). The gradient started from 0% of eluent B, remained at 0% of B for 10 min, then rose from 0 to 60% B in 40 min and subsequently to 100% B in 25 min. The flow (0.300 mL min^{-1}) generated by chromatographic separation was directly injected into the electrospray ion source. The

dx.doi.org/10.1021/jf403493a | *J. Agric. Food Chem.* 2014, 62, 443−453

chromatographic separation was carried out using a Restek Ultra C18 column (100 × 2.1 mm, 3 μm).

The API 3200 ES source was tuned by infusing standard solutions of EA, GA, and methylgallate (1 mg/mL in methanol) into the source at a flow rate of 0.01 mL/min. The mass spectrometer was operated in the negative ion mode under the following conditions: declustering potential, −75 eV; entrance potential, −6.2 eV; collision energy, −45 eV; and collision cell exit potential, −23.3 eV for EA; declustering potential, −40 eV; entrance potential, −4.2 eV; collision energy, −20 eV; and collision cell exit potential, −18.4 eV for GA; declustering potential, −40 eV; entrance potential, −4.2 eV; collision energy, −35 eV; and collision cell exit potential, −19 eV for methyl gallate. MS and MS-MS daughter spectra were measured from m/z 150 to 500 for plasma sample and from m/z 150 to 1500 for *Q. robur* capsule. The spectrometer was used in the MS/MS mode with multiple reaction monitoring (MRM) of fragmentation reactions selected for each compound. Volume injection for capsule extract was 0.01 mL and that for plasma samples, 0.03 mL. Because of the absence of commercially available standards for metabolites, the same MS/MS conditions of EA were used for other compounds. For calibration curves, stock solutions of EA (1 mg 5 mL^{-1}) and GA standards were prepared by dissolving each compound in MeOH. Eight different solutions, containing, respectively, 0.1, 0.5, 1, 5, 10, 25, 50, and 100 mg mL^{-1} of each compound (external standards), were prepared in MeOH and used for method development. A volume of 0.01 mL was injected in the chromatographic system. The calibration curves for each standard were made by linear regression by a graph reporting the area ratio of external standard against the known concentration of external standard. The result represents the average of curves performed by three injection of each concentration. All quantitative data were elaborated with the aid of Analyst software (Applied Biosystems). ETs and ET metabolites were identified according to their ion mass spectra, retention times, and MS-MS fragments.[12] For quantification purposes data were collected in MRM tracking the transition of parent and product ions specific for each compound. Because of the absence of commercially available standards for metabolites, quantification was calculated on the basis of EA calibration curve. In Figure 3 the HPLC-TIC-MS chromatograms of standards and a representative post-supplementation plasma sample are shown.

Plasmatic Total Phenols. Folin−Ciocalteu colorimetry was used to measure the total phenolic amount in plasma isolated from the three subjects before and after *Q. robur* supplementation. To remove plasmatic protein interference, 0.5 M perchloric acid (1:1) was used, whereas the hydrolysis of the conjugated forms of polyphenols was performed according to Serafini.[13] Results are expressed as micrograms of GA equivalent (GAE) per milliliter of plasma. This assay was also carried out on *Q. robur* capsule after extraction with 80% MeOH.

Antioxidant Capacity Analysis. The total antioxidant capacity has been evaluated using the oxygen radical absorbance capacity (ORAC) assay. Plasma was treated according to the method of Prior[14] to obtain the hydrophilic and lipophilic components of the plasma and to remove the interference of protein fraction. Briefly, 100 μL of plasma was mixed with 200 μL of ethanol and 100 μL of water. Then 400 μL of hexane was added twice. The hexane layers were removed, combined, and dried under nitrogen. For the lipophilic antioxidant assay, the dried hexane extract was dissolved in 250 μL of acetone and then diluted with a 7% randomly methylated β-cyclodextrin (RMCD) solution as a solubility enhancer. For the hydrophilic antioxidant assay, the residual aqueous plasma sample was treated with 400 μL of 0.5 M perchloric acid to precipitate proteins and then dissolved in phosphate buffer. ORAC assay was performed in a microplate fluorescence reader (TECAN) according to the method of Huang et al.[15] Briefly, ORAC is a method that utilizes the peroxyl radical generator 2,2-azobis(2-amidinopropane) dihydrochloride (AAPH) and fluorescein as an oxidizable substrate. AAPH induces oxidative damage to the substrate, which is inhibited by the presence of reductants. The inhibition measured is related to the antioxidant capacity of the reductants under analysis. Results are expressed as nanomoles of Trolox equivalent per milliliter of plasma.

Ex Vivo Study. Serum isolated before and after the supplementation of Robuvit from the three healthy subjects was used to enrich the medium of different cell cultures, that is, a permanent human endothelial cell, obtained by cell fusion of HUVEC, primary human endothelial cells, and immortalized human alveolar epithelial cells (EA.hy 926), human keratinocytes (HaCaT), and human neuroblastoma cells (SH-SY5Y). Cells were cultured in the absence of bovine serum in culture media supplemented with 10% (v/v) of the isolated human serum for 3 h.

RNA Extraction and Gene Array. At the end of the incubation, RNA was isolated using an RNAeasy Plus Mini kit (Qiagen). The concentration, purity, and integrity were analyzed using the Agilent 2100 bioanalyzer, before gene expression analysis was performed. Two micrograms of each isolated RNA samples was sent to the FIRC Institute of Molecular Oncology Foundation (IFOM), Milano, Italy, to be processed and hybridized on Gene 1.0 ST array chips according to the Affymetrix protocol. These arrays allow the assessment of the expression level of 28869 genes represented by approximately 26 probes spread across the full length of the gene, providing a more complete and accurate picture of gene expression than the classical 3′ -based expression array designs. Cell intensity files for each Gene 1.0 ST chip processed were generated utilizing Command Console software. Microarray statistical analysis was performed utilizing the OneChannelGUI R package.[16] Raw signal intensities were normalized utilizing the gene-chip robust multiarray average (GCRMA) method employing the empirical Bayes approach for background correction followed by quantile normalization. Differentially expressed genes were identified using the "limma package", applying linear models and moderated t statistics that implement empirical Bayes regularization of standard errors. Differences in expression values were expressed by means of $\log_2$ fold change (FC). A minimum difference threshold of FC ± 0.5 with a p value ≤0.05 was selected as gene differentially expressed in cells incubated with serum isolated after the supplementation with respect to cells incubated with serum isolated before the supplementation. To highlight small variations on a quantitative scale, we decided to decrease the threshold of FC. The lists of significantly differentially expressed genes in association with the administration of Robuvit-enriched serum were analyzed by using DAVID[17] and FIDEA[18] Web servers to identify statistically over-represented biological processes annotated in gene ontology (GO). Enriched GO biological processes (level 5) and Kegg pathways were identified according to p value threshold <0.05.

Both tools produced overlapping lists of enriched terms, and over-represented biological processes highlighted by DAVID were further clustered utilizing the functional annotation clustering utility included in the Web server. Most representative terms were selected and are listed under Results.

Statistical Analysis. Data obtained by total phenol analysis and antioxidant capacity analysis were analyzed using a paired, two-tailed, Student's t test. The threshold for significance was set at $p < 0.05$.

RESULTS

Phenolic Composition of *Q. robur* Capsules. Each Robuvit capsule contains a total phenol amount equivalent to 59.91 ± 14.67 mg of GA equivalents (GAE). On the basis of these data, each volunteer ingested approximately 179 mg of total phenols per day, expressed as GAE, for 5 days. The content of the principal soluble ETs in Robuvit capsule is presented in Table 1. The capsule contains EA and GA and peculiar ETs, such as vescalagin, castalagin, castalin or vescalin, and grandinin or roburin E. The soluble ETs were about 1.8 mg/capsule.

Plasmatic Total Phenols and ET Metabolites. Five days of Robuvit supplementation are associated with doubling of total plasmatic phenolic concentration up to 1.26 μg GAE/mL (Table 2). Table 3 shows the identification and relative quantification of six ET metabolites obtained by HPLC-MS^2 analysis of plasma isolated after supplementation. EA, GA, and

four EA-derived metabolites, conjugated with glucuronic acid, namely, urolithin B-glucuronide, urolithin A-glucuronide, urolithin C-diglucuronide, and EA methyl ether glucuronide, were detected. The total concentration of metabolites in plasma was in the order of 0.2 μM. With the exception of EA, none of these metabolites was present in plasma collected before Robuvit supplementation. No sulfate derivatives were detected in our analysis. The interindividual variability observed among the volunteers was quite high.

Antioxidant Capacity Analysis. To assess if the administration of Robuvit resulted in an increase of plasmatic antioxidant capacity, we performed a classical "antioxidant capacity test", according to the ORAC assay. Five days of Robuvit supplementation was associated with a significant increase of the ORAC value related to the hydrophilic plasmatic component, but not to the lipohilic fraction (Table 4). When the assay was directly performed on a Robuvit capsule, an ORAC value equal to 648 nmol Trolox eq/mg *Q. robur* was obtained.

Microarray Results. As mentioned under Materials and Methods, human serum isolated before and after 5 days of Robuvit supplementation was used to enrich the culture medium of cells at a concentration of 10% v/v.

Microarray results show that, in this experimental condition, the presence of Robuvit metabolites induces a differential expression of a limited number of genes. In HaCaT (stabilized human keratinocites), only one gene (PRPF8, a component of the spliceosome that removes introns from a transcribed pre-RNA) was modulated with a FC ≥ 1, and 13 genes were modulated with a FC between ±1 and ±0.5 (Table 5).

after supplementation	1.9 ± 0.01[b]	1.2 ± 0.06

[a]Data are expressed as nmol Trolox equiv/mL plasma and measured before and after supplementation. [b]Significantly different $p < 0.05$.

In EA.hy.926 (permanent human endothelial cells), the genes RPL30 and RPL24 (60S ribosomal proteins) have been found to be up-regulated with a FC > 1 and 12 genes up-regulated with a FC between 0.5 and 1. Eight genes were down-regulated with a FC between −0.5 and −1 (Table 6).

In SHSY5Y cells (human bone marrow neuroblastoma), two genes (SMNDC1, a component of the spliceosome that removes introns from a transcribed pre-RNA, and FAU, involved in translation) were down-regulated with a FC ≤ 1 and 12 genes were up-regulated with a FC number between 0.5 and 1. Conversely, 23 genes have been found to be down-regulated with a FC between −0.5 and −1 (Table 7). Despite these cell-specific differences, the genes modulated by Robuvit supplementation are mainly involved in translation, cell cycle, RNA splicing, and ribosome biogenesis in all cell types, according to the statistical pathway enrichment analysis.

On the basis of the evidence of a non-negligible interindividual difference of *Q. robur* metabolite profile we considered that the effect of Robivit supplementation on gene expression modulation could be flattened out. We therefore assessed the effect of sera isolated from each subject (1,2 or 3) separately on the different cell lines. Table 8 shows the total number of genes modulated within a FC≤ ≥1. However, because most of the genes regulated are pseudogenes, not mapped in any GO term, the pathway analysis is only able to capture a percentage ranging from 30 to 50% of the total number of the modulated genes measured (shown in the second column). Moreover, the table shows the list of the genes, up- and down-regulated by each serum, that were used by the software to enrich the GO pathways and the resulting over-represented pathway in the three cell lines: ribosome, aminoacyl tRNA biosynthesis, and spliceosome. These results show that, independently of the individual profile metabolites resulting by Robuvit supplementation, the over-represented pathways associated with the three sera are similar in the three cell lines considered in the study.

DISCUSSION

This study represents the first investigation on standardized French oak wood extract, Robuvit, absorption/metabolism and on the effect of Robuvit metabolites on gene expression modulation, by utilizing a combined ex vivo cell culture approach.[19] To the best of our knowledge we have reported for the first time absorption of ETs from *Q. robur* in humans; in fact, to date, metabolites resulting from human consumption of oak wood constituents remained unknown.

The HPLC-MS^2 analysis of Robuvit capsule shows that it is mainly composed of GA and EA and of several ETs such as castalagin, vescalagin, and roburin E. Our data show that the consumption of about 180 mg of total phenols per day (three capsules a day of Robuvit) resulted in a significant increase of GA and EA in plasma. GA is generally rapidly absorbed and has a good bioavailability,[20,21] whereas ETs are hydrolyzed in vivo to EA, which is further metabolized by gut microbiota mostly to produce the derivative urolithins. Similarly to isoflavone metabolism, where there is a quite clear-cut separation between equol and nonequol producers,[22] it has been proposed that humans can be divided into high and low urolithin producers due to their microbiota, supporting the large variability in the metabolism of ETs.[23,24] The appearance of *three* glucuronated urolithin (urolithin B-glucuronide, urolithin A-glucuronide, urolithin C-diglucuronide) moieties in plasma isolated after the supplementation, absent at baseline, suggests that oak wood ETs are bioavailable. Although glucuronidated urolithin A was present in all three subjects, only one subject showed high urolithin B (about 0.1 μg/mL) but not detectable urolithin C levels. ET bioavailability has been already studied addressing the consumption of different foods and beverages.[11] EA and urolithin glucoronides were detected in human plasma at 6 h from pomegranate juice (PJ) administration (providing 318 mg of punicalagins and 12 mg of free EA)[9,25] or pomegranate

extract (providing 330 mg of punicalagin and 21 mg of EA).[26] Glucuronides were the only urolithin metabolites found in plasma of subjects supplemented for 5 weeks with PJ consumption.[27] Urolithin glucuronides and EA derivatives were detected after 3 days of walnut consumption.[28] Stoner and co-workers found EA in human plasma at 2 h after the administration of 45 g of freeze-dried black rasberries (containing 13.5 mg of EA).[29] However, neither EA nor any of ET metabolites have been found in detectable quantities in human plasma over a 24 h period after 300 g of rasberry consumption.[12] According to the authors, this negative result is not a real proof of absence as it could be due to the high detection limit of the method used in the study. In agreement with our data, no sulfate metabolites have been found in humans after ET-rich food supplementation.[10]

EA structure presents two *o*-dihydroxy groups, and it may therefore be transformed by the activity of catechol-*O*-methyltransferase (COMT) (in the liver) in mono- and/or dimethyl ether of EA. These metabolites can be further metabolized by enzymatic glucuronic acid derivatization. In fact, dimethylellagic acid glucuronide has been found in the urine[9] and plasma[28] of subjects supplemented with PJ and in the plasma of rats supplemented with 6% punicalagin.[30] In the present study, we detected a low amount of methylellagic glucuronide in plasma isolated after the supplementation in only one of three subjects. Also in agreement with our study, a high interindividual variability of metabolic profile has been already frequently reported.[9,24,27,28]

Moreover, as expected, the total plasma polyphenol amount increased significantly by on average 100% in all volunteers. The consumption of the aqueous oak wood extract Robuvit led, also, to a statistically significant increase of hydrophilic blood oxygen radical absorbance capacity (ORAC) in healthy volunteers, even if the small change observed may not have a biological relevance.

The methodologies utilized to assess plasma polyphenol concentration and plasma antioxidant capacity are known to be non specific. In fact, it has been reported that the Folin assay provides polyphenol estimation consistently 2−4 times greater than that obtained by HPLC methods,[31] because it measures the reducing capacity of phenolic components by detecting nonspecific hydroxyl groups. GA and EA contain three and four

hydroxyl groups, respectively, and they strongly contribute to Folin and possess high antioxidant properties. However, in our results the extent of the increase of plasmatic GA and EA, after the supplementation, is not sufficient to explain the observed increase of ORAC and Folin. It is known that urolithins exhibited a significant antioxidant action correlated with the number of hydroxyl groups,[32] whereas no antioxidant activity has been reported for the glucuronide derivative forms.[24,33] Therefore, we have to hypothesize that a synergic activity of all *Q. robur* metabolites occurs.

Dietary EA and its metabolites, either independently or synergistically, are good candidates to be among the most active molecules responsible for a wide spectrum of molecular effects. In vivo and in vitro studies have shown that EA and urolithins have antiproliferative effects in human bladder cancer cells and antitumoral properties in several lines of cultured human cancer cells,[34,35] in hamster buccal carcinoma[36] and anti-inflammatory properties in colon fibroblasts,[4] and in human primary endothelial cells.[37] EA and urolithin A have been demonstrated to down-regulate the expression of COX-2 and iNOS and other inflammatory markers and to modulate the expression of genes involved in cell cycle in colonic mucosa in a colitis rat model.[4] Moreover, CaCo2 cells exposed to concentrations of EA and urolithins achievable in the colon from the diet arrested cell growth at the S and G_2/M phases. Transcriptional profiling obtained by microarray and functional analysis revealed significant changes in the expression levels genes involved in MAPK signaling such as growth factor receptors (*FGFR2*, *EGFR*), oncogenes (*K-Ras*, *c-Myc*), and tumor suppressors (*DUSP6*, *Fos*) as well as the modulation of genes involved in cell cycle (*CCNB1*,*CCNB1IP1*).[38] Similarly, GA has been shown to inhibit carcinogenesis in animal models and in vitro cancerous cell lines. The inhibitory effect of GA on cancer cell growth has been reported to be mediated by the modulation of the expression of genes encoding for proteins involved in cell cycle, metastasis, angiogenesis, and apoptosis.[39,40] Upstream to gene expression, GA has been reported to inhibit activation of NF-κB and Akt signaling pathways along with the activity of COX and inflammatory cytokines.[41,42]

The present study provides an original background to the understanding of possible effects of *Q. robur* extract metabolites on the modulation of gene expression in endothelial, neuronal, and keratinocyte cell lines. Our methodological approach allows the assessment of the effects of *Q. robur* metabolites at concentrations physiologically achievable in vivo and in a profile prevailing in humans. The transcriptome of each cell line was identified utilizing an Affymetrix customized array that recognizes a total number of 28869 genes.

Subsequent, functional analysis revealed that culturing cells in serum obtained from subjects administered *Q. robur* extract results in a moderate although significant modulation of the expression of genes related to specific GO categories, namely, cell cycle, ribosome biogenesis, and RNA processing pathways in HaCaT (stabilized human keratinocytes) cells; cell cycle, M phase mitotic cycle in Ea.Hy.926 cells (a permanent human endothelial cells); translation, RNA splicing, and ribosome pathways in SHSY5Y cells (human bone marrow neuroblastoma). Obviously, changes of gene expression at the level of mRNA do not necessarily imply that corresponding changes occur at the level of protein. Nonetheless, an understanding of the effect of dietary bioactive molecules at the transcriptional level is important to the building up of a conceptual background to be exploited in future studies addressing the putative effect of these botanical extracts in human health and disease.

Specific interindividual differences in the metabolization of *Q. robur* extract components may have differently influenced the final outcome in terms of the single gene expression. However, surprisingly, the functional analysis reveals that the three sera, independently of the individual profile metabolites, modulate similar pathways, ribosome, aminoacyl tRNA biosynthesis, and spliceosome, suggesting that the ET metabolites display a uniform behavior, in a cell-type independent way. However, the small differences in FC of most of the genes do not let us assign to the modulated pathways either a positive or a negative health concern. Moreover, it is important to note that the rate of cell proliferation was not affected by serum containing *Q. robur* metabolites compared to control sera (data not shown).

In conclusion, we demonstrate that Robuvit, a proprietary patented extract from *Q. robur*, is (at least in part) bioavailable to humans and that despite the very low concentration of the metabolite in serum, its consumption is associated with a statistically significant increase of the antioxidant capacity and to specific changes of gene expression profile.

Acidolysis of *p*-Coumaric Acid with Omega-3 Oils and Antioxidant Activity of Phenolipid Products in in vitro and Biological Model Systems

Jiankang Wang[†] and Fereidoon Shahidi*[,†,‡]

[†]Departments of Biology and [‡]Biochemistry, Memorial University of Newfoundland, St. John's, Newfoundland and Labrador A1B 3 × 9, Canada

ABSTRACT: Lipase-catalyzed acidolysis of *p*-coumaric acid with seal blubber oil (SBO) and menhaden oil (MHO) was carried out, followed by identification of major phenolipids in the resultant acidolysis mixture using high-performance liquid chromatography/mass spectrometry. Separation of phenolipid components from the resultant acidolysis mixture was achieved using flash column chromatography. The antioxidant activities of the phenolipids were examined in in vitro assays and biological model systems. The major phenolipids identified from acidolysis mixtures with both SBO and MHO included eight phenolic monoacylglycerols and eight phenolic diacylglycerols. Phenolipids derived from SBO and MHO generally showed good antioxidant potential in the systems tested. The prepared phenolipids exhibited high scavenging capacity toward 1,1-diphenyl-2-picrylhydrazyl (DPPH) and peroxyl radicals and displayed reducing power, strong inhibitory effect on bleaching of *β*-carotene, human low-density lipoprotein (LDL) cholesterol oxidation, as well as radical-induced DNA cleavage, thus suggesting that phenolipids derived from omega-3 oils may be used as potential stable products for health promotion and disease risk reduction.

KEYWORDS: *lipase-catalyzed acidolysis, p-coumaric acid, seal blubber oil, menhaden oil, phenolipid, DPPH radical scavenging activity, oxygen radical absorbance capacity, reducing power, β-carotene−linoleate, human LDL cholesterol, DNA*

INTRODUCTION

The omega-3 oils from marine origin, especially those from fish such as menhaden and from marine mammals such as seal blubber, are commonly used as supplements due to their high content of omega-3 fatty acids, such as eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA).[1] The beneficial effects of omega-3 fatty acids have been associated with their ability to lower triacylglycerol levels in the circulatory system and in the treatment and/or prevention of hypertension, arrhythmia, arthritis, and inflammatory, immune, as well as mental disorders.[2−4] For instance, DHA is believed to be essential for normal development of the central nervous system and visual acuity in humans.[5] However, the high degree of unsaturation of these oils decreases their oxidative stability. Synthetic antioxidants such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and *tert*-butylhydroquinone (TBHQ), as well as natural antioxidants such as mixed tocopherols are often added to edible oils and foods in order to enhance their stability.[6] However, synthetic antioxidants have fallen out of favor due to concerns about their safety when used in high doses in animals.[7−9] Furthermore, effectiveness of tocopherols as antioxidants can be compromised by the presence of metal ions, including those of iron and copper, which are commonly present in marine oils.[2,3] Therefore, studies on the potential use of other forms of naturally occurring antioxidants to stabilize edible oils have been pursued.

Investigations on the search for natural antioxidants such as phenolics in foods and food processing byproducts have been widely reported, and most of them have proven to reduce the extent of lipid oxidation as well as rendering health benefits by reducing oxidative stress and the risk of associated diseases. For instance, *p*-coumaric acid occurs in various food sources and beverages, including tomatoes, carrots, garlics, as well as wines and vinegars.[10] Its strong antioxidant and anticancer effects have been reported in a number of studies.[11,12]

Modifying the structure of triacylglycerols can be used as a strategy and an effective means to improve nutritional and health benefits of highly unsaturated oils. Acidolysis is a modification process, which incorporates desired fatty acids or other forms of organic acids, such as phenolic acids, into triacylglycerols using enzyme catalysts.[13] For example, acidolysis of phenolic acids and triacylglycerols has been successfully conducted and reported in several studies.[14,15] Synthesis of phenolipids using *p*-coumaric acid and triolein was successfully conducted in our laboratory (unpublished work). The purified lipid derivatives of *p*-coumaric acid, monooleyl and dioleyl *p*-coumarates, demonstrated great antioxidant activity in a number of model systems, which may be explained by changes of lipophilicity and the steric conformation of modified lipids. In this study, acidolysis of *p*-coumaric acid with seal blubber oil (SBO) and menhaden oil (MHO) was conducted, and the phenolipids produced were purified from the resultant mixture using column chromatography and identified by using high-performance liquid chromatography/mass spectrometry (HPLC-MS). Antioxidant activity of synthesized phenolipids was also tested in several in vitro

assays, including 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical scavenging activity, oxygen radical absorbance capacity (ORAC), and reducing power evaluations. In addition, antioxidant activity of synthesized phenolipids was further examined in a β-carotene−linoleate model system. The efficacy of the phenolipids so obtained in reducing the extent of oxidation of human low-density lipoprotein (LDL) cholesterol and prevention of DNA scission was also examined in order to obtain a better understanding of their antioxidant capacity and their potential use in food and supplements for health promotion.

MATERIALS AND METHODS

Novozyme 435 and *p*-coumaric acid were obtained from Sigma−Aldrich Canada Ltd. (Oakville, ON, Canada). Trolox was purchased from Acros Organics (Fair Lawn, NJ, USA). Human LDL cholesterol and supercoiled plasmid pBR322 DNA were purchased from Sigma−Aldrich Canada Ltd. (Oakville, ON, Canada). SYBR safe gel stain was obtained from Invitrogen Corporation (Carlsbad, CA, USA). All solvents used were of HPLC grade and purchased from Fisher Scientific (Nepean, ON, Canada).

Methods. *Lipase-Catalyzed Acidolysis of p-Coumaric Acid with SBO and MHO.* Lipase-catalyzed acidolysis of *p*-coumaric acid with SBO and MHO was carried out according to the method employed in the synthesis of phenolipids using *p*-coumaric acid and triolein (unpublished study). A stock solution of *p*-coumaric acid (10 mM) was freshly prepared in 2-butanone, and stock solutions of the oils (53.36 mM; the average molecular weight of the oils was calculated from the weight of the oil sample used and the amount of base used for its saponification.) were prepared in hexane. A 30 mL amount of the *p*-coumaric acid stock solution and 90 mL of each oil stock solution were transferred to a 250 mL round-bottom flask followed by addition of 645 mg of immobilized Novozyme 435 (15%, w/w of substrates). The final reaction solutions contained 2.5 mM of *p*-coumaric acid and 40 mM (calculated based on the average molecular weight of SBO and MHO) of SBO or MHO. Flasks were flushed with a stream of nitrogen and sealed properly. The acidolysis reaction was performed in an orbital shaking water bath at 50 °C and 170 rpm. Reaction mixtures were removed from the water bath after 12 days. The reaction mixture (0.1 mL) was transferred to a 4 mL vial, and the solvent was removed under a stream of nitrogen. The sample was redissolved in 2 mL of methanol/acetonitrile (41:59, v/v) for HPLC-MS analysis.

HPLC-MS Analysis of Synthesized Products. Phenolipids derived from SBO and MHO in the final acidolysis mixture were identified using reversed-phase HPLC-MS according to Sabally et al.[14] with minor modifications. An Agilent 1100 HPLC unit (Agilent Technologies, Palo Alto, CA, USA) with a UV−diode array detector (UV-DAD) was used. Separation was achieved on a C-18 column (4.6 mm × 250 mm coupled with a guard column; Agilent) by gradient elution using a methanol/acetonitrile/isopropanol mobile phase at a flow of 0.8 mL/min; fractions were detected at both 215 and 300 nm. The mobile phase used initially was methanol/acetonitrile/isopropanol (41:59:0, v/v/v), which was maintained for 15 min, but then gradually changed to 16.5:23.5:60 (v/v/v) from 15 to 25 min, then allowed to reach 100% isopropanol from 25 to 35 min, and kept there for 10 min. The mobile phase was changed to its initial components, methanol/acetonitrile/isopropanol (41:59:0, v/v/v) in the next 5 min and was subsequently maintained for 10 min in order to recondition the column. LC flow was further analyzed online by a mass spectrometric detector (LC-MSD-Trap-SL, Agilent) with atmospheric pressure chemical ionization (APCI) at alternative mode for identification of each fraction. The operating conditions used were 121 V for the fragmentor voltage, a drying temperature of 350 °C, an APCI temperature of 400 °C, a nebulizer pressure of 60 psi, and a drying gas flow of 7 L/min.

Purification and Identification of Derivatives of p-Coumaric Acid. Separation of phenolipid components from the final acidolysis mixture was achieved using flash column chromatography in order to investigate the antioxidant activity of produced phenolipids in test systems. The mixture was eluted from a column (40 cm × 5 cm i.d.) packed with silica gel (Selecto Scientific, Suwannee, GA, USA) with a series of solvent mixtures consisting of 350 mL of hexane, 100 mL of hexane/ethyl acetate/formic acid (95:5:2, v/v/v), 400 mL of hexane/ethyl acetate/formic acid (85:15:2, v/v/v), 400 mL of hexane/ethyl acetate/formic acid (75:25:2, v/v/v), and 400 mL of hexane/ethyl acetate/formic acid (65:35:2, v/v/v), in the order stated. Fractions corresponding to each component were collected, and then, solvents were removed using a rotary evaporator.

Antioxidant Activity Tests. DPPH Radical Scavenging Activity. The effect of phenolipid mixtures obtained from SBO (PSBO) and phenolipid mixtures obtained from MHO (PMHO) on the scavenging of DPPH radicals was determined according to the method described by Madhujith and Shahidi[16] with slight modifications. *p*-Coumaric acid was used as a reference in this study. *p*-Coumaric acid, PSBO, and PMHO were dissolved in ethanol in order to attain a concentration of 2.5 mM, which was followed by the addition of 2 mL of ethanolic solution of DPPH (0.18 mM). Contents of each test solution were thoroughly mixed and injected to the sample cavity of a Bruker E-scan electron paramagnetic resonance (EPR) spectrometer (Bruker Biospin Co., Billercia, MA, USA), and the spectrum was recorded after 10 min. Ethanol was used as the control in place of the test compounds. Meanwhile, trolox solutions (12.5−200 mM) were prepared for constructing a standard curve. The operating parameters of the Bruker E-scan were set as follows: 5.02 × 102 receiver gain, 1.86 G modulation amplitude, 2.621 s sweep time, 8 scans, 100.00 G sweep width, 3495.53 G center field, 5.12 ms time constant, 9.795 GHz microwave frequency, and 86.00 kHz modulation frequency. DPPH radical scavenging capacities of test compounds were calculated using the equation shown below:

$$\text{DPPH radical scavenging capacity}(\%) = 100 \times (1 - \text{signal intensity}_{\text{sample}}/\text{signal intensity}_{\text{control}})$$

where the control contained no trolox or test compounds. The DPPH radical scavenging capacities of the test compounds were expressed as millimolar trolox equivalents (TE) per millimolar sample.

ORAC Assay. The determination of ORAC was carried out using a Fluostar optima plate reader (BMG Labtech, Durham, NC, USA) equipped with an incubator and two injector pumps as described by Madhujith and Shahidi.[17] Fluorescein and 2,2′-azobis(2-amino-propane) dihydrochloride (AAPH) were used as the probe and radical generator, respectively. Solutions of *p*-coumaric acid (5 mM), PSBO (5 mM), PMHO (5 mM), and trolox standards (6.25−100 μM) were prepared in 7% (w/v, in H_2O) randomly methylated β-cyclodextrin (RMCD). An aliquot of each solution (20 μL) was injected into a 96-well Costar black plate (Corning Incorporated, Corning, NY, USA), followed by the addition of 75 μL of AAPH (17.2 mg/mL) in phosphate-buffered saline (PBS) (75 mM, pH 7.0). The RMCD solution without antioxidant was used as a blank. Samples were incubated at 37 °C for 10 min prior to the autoinjection of 75 μL of AAPH (17.2 mg/mL in PBS) to each sample. The operating conditions were set as follows: 0.3 s position delay, 8 s orbital shaking before each cycle with 4 mm width, 210 s cycle time, and 48 cycles. Fluorescence was measured at excitation and emission wavelengths of 485 and 520 nm, respectively. A standard curve was constructed from the trolox standards, and the results were expressed as millimolar trolox per millimolar sample.

Determination of Reducing Power. Reducing power of *p*-coumaric acid, PSBO, and PMHO was measured according to Duh et al.[18] with minor modifications. A 1 mL amount of the test compounds (1 mM in 95% ethanol) was transferred to centrifuge tubes containing 2.5 mL of PBS (0.2 M, pH 6.6) and 2.5 mL of potassium ferricyanide solution. The mixture was incubated at 50 °C for 20 min, which was followed by addition of 2.5 mL of trichloroacetic acid (TCA) (10%, w/v), and then, the content was centrifuged at 3000*g* for 10 min. After incubation, a portion (2.5 mL) of the supernatant was transferred to

dx.doi.org/10.1021/jf404140v | J. Agric. Food Chem. 2014, 62, 454−461

the test tube containing 2.5 mL of distilled water and 0.5 mL of ferric chloride (0.1%). The contents were thoroughly mixed, and the absorbance was read at 234 nm using a Hewlett−Packard model 845LA diode array spectrophotometer (Agilent, Palo Alto, CA, USA). Increased absorbance of the reaction mixture indicated increased reducing power. A series of ascorbic acid solutions (1−6 mM in 95% ethanol) were prepared for use in order to construct a standard curve.

Antioxidant Activity in a β-Carotene−Linoleate Model System. Antioxidant activity of *p*-coumaric acid, PSBO, and PMHO was assessed using the β-carotene bleaching assay according to Amarowicz and Shahidi[19] with minor modifications. β-Carotene (10 mg) was dissolved in chloroform (10 mL), and an aliquot (1.0 mL) of this solution was transferred into a 150 mL round-bottom flask containing linoleic acid (20 mg) and Tween 40 (200 mg). A blank without β-carotene was also prepared (20 mg of linoleic acid and 200 mg of Tween 40). After removal of chloroform under a stream of nitrogen, 50 mL of aerated distilled water was added to each flask, and the contents were then thoroughly mixed using a magnetic stirrer. Test compounds (30 μL, 1 mM in ethanol) and the control, ethanol, were injected into the Costar 96-well white plates (Corning Incorporated, Corning, NY, USA). The β-carotene−linoleic acid emulsion and the blank emulsion were injected to the test vials by the built-in injector pump. The absorbance was read immediately after the addition of emulsion to samples at 450 nm by using a Fluostar optima (BMG LABTECH Inc., Durham, NC, USA) plate reader. The operating parameters of the Fluostar optima were set as follows: 24 cycle no., 420 s cycle time, 4 s shaking time, 5 mm orbital width, and 310 μL/s injection speed.

Antioxidant activity of test compounds in protecting β-carotene-linoleic acid against oxidation was calculated using the following equation.

$$\text{Inhibition}(\%) = 100 \times [1 - (A_{s0} - A_{st})/(A_{c0} - A_{ct})]$$

where $A_{s0} - A_{st}$ are corrected absorbance values for test samples measured at zero time and after incubation, respectively; while $A_{c0} - A_{ct}$ are corrected absorbance values for control at zero time and after incubation, respectively.

Inhibition Effect on Copper-Induced LDL Cholesterol Oxidation. The inhibitory activity of *p*-coumaric acid, PSBO, and PMHO against copper-induced LDL cholesterol oxidation was assessed according to Lebeau et al.[20] with minor modifications. Human LDL cholesterol solution was dialyzed in PBS (10 mM, 0.15 M NaCl, pH 7.4) at 4 °C under a nitrogen blanket for 12 h. Sample solutions were prepared by dissolving the test compounds in ethanol at 1.0 mM. Sample solutions (10 μL) were transferred into Eppendorf tubes, and the solvent was removed under a stream of nitrogen. To each tube, 100 μL of PBS was added, followed by vortexing for 1 min. An aliquot (0.8 mL of the dialyzed and diluted LDL cholesterol solution (0.125 mg/mL)) was added to each tube; the contents were mixed well and incubated at 37 °C for 15 min. The induced oxidation reaction was initiated by the addition of 100 μL of $CuSO_4$ solution (20 μM, previously incubated at 37 °C). A blank containing only the sample without LDL or $CuSO_4$ was prepared for each test compound. After incubation of the reaction mixture at 37 °C for 22 h, the conjugated dienes formed were measured spectrophotometrically at 234 nm using a Hewlett−Packard model 8452A diode array spectrophotometer. Antioxidant activities of test compounds were expressed as percentage inhibition of conjugated dienes formation, as calculated according to the following equation:

$$\text{Inhibition } (\%) = 100 \times (A_{\text{control}} - A_{\text{sample}})/(A_{\text{control}} - A_{\text{native LDL}})$$

where the control contained LDL cholesterol and $CuSO_4$ without antioxidants and native LDL cholesterol contained LDL cholesterol only. All absorbance values for samples were blank-corrected.

Inhibition Effect on Radical-Induced DNA Scission. Antioxidant activity of *p*-coumaric acid, PSBO, and PMHO against radical-induced DNA scission was determined as described by Zhong and Shahidi[21] with slight modifications. Oxidation and nicking of DNA strands was induced by hydroxyl and peroxyl radicals and monitored by gel electrophoresis, respectively. For hydroxyl radical induced DNA oxidation, 2 μL of ethanolic solution (15 μM) of test compounds was added into a 0.5 mL Eppendorf tube, and the solvent was then removed under a stream of nitrogen. To the tube, 2 μL of PBS (0.5 M, pH 7.4) was added followed by thorough vortexing for 1 min. The following reagents were subsequently added to the tube in the order stated: 2 μL of PBS (0.5 M, pH 7.4), 4 μL of supercoiled pBR322 DNA (20 μg/mL in PBS), 2 μL of H_2O_2 (0.5 mM), and 2 μL of Fe_2SO_4 (0.5 mM). The mixture was then incubated at 37 °C for 1 h. For peroxyl radical induced DNA oxidation, a higher concentration (50 μM) of samples was used, and H_2O_2 and Fe_2SO_4 were replaced with 4 μL of AAPH (9 mM). A blank (containing only DNA) and a control (containing DNA and one of the radicals) were also prepared for both assays.

Upon completion of the incubation, l μL of loading dye (0.25% bromophenol blue/0.25% xylene cyanol/50% glycerol) was added, and the whole mixture was centrifuged and loaded onto an agarose gel, which was prepared by dissolving 0.7% (w/v) agarose in Tris−acetic acid−ethylenediaminetetraacetic acid (EDTA) buffer (TAE, pH 8.5) and stained with SYBR safe gel stain (1:10 000, v/v). Gel electrophoresis was performed at 80 V for 80 min in TAE buffer using a horizontal submarine gel electrophoresis apparatus (Sigma−Aldrich Canada Ltd., Oakville, ON, Canada). The DNA bands were visualized under ultraviolet light. Images were photographed by a GelDoc apparatus equipped with a Sony digital camera and analyzed using AlphaEase stand-alone software (Alpha Innotech Co., San Leandro, CA, USA). The intensity of the bands (obtained from a densitometer) was used as an indicator of the concentration of the supercoiled and nicked DNA fractions. Antioxidant activity was calculated as percent retention of DNA according to the following equation:

$$\text{Retention } (\%) = 100 \times (\text{intensity of supercoiled DNA}_{\text{sample}}/\text{intensity of supercoiled DNA}_{\text{blank}})$$

RESULTS AND DISCUSSION

Identification of Phenolipids. The HLPC profiles of samples were monitored by a UV detector at both 215 and 300 nm. Each compound was identified by comparing its retention time with that of its corresponding standard and/or the characterization of the molecular ion so generated from mass spectrometry. The major phenolipid compounds derived from *p*-coumaric acid are listed in Table 1, which include eight phenolic monoacylglycerols and eight phenolic diacylglycerols. The mass spectra of the representative identified ions and their corresponding chemical structures are shown in Figure 1. Although esterification of the hydroxyl group of *p*-coumaric acid with the released fatty acid is possible, formation of such products was not evident.

DPPH Radical Scavenging Activity. The DPPH radical scavenging assay is frequently used for examining antioxidant activity because of the relatively short analysis time required.[22] Phenolic compounds may act as free radical scavengers by virtue of their hydrogen atom donating ability.[23] The strong DPPH radical scavenging capacity of *p*-coumaric acid has been reported by Fukumoto and Mazza.[24]

The results of the DPPH radical scavenging assay on test compounds are summarized in Figure 2. The signal intensity in the EPR spectra of the DPPH radical as affected by the test compounds decreased significantly, which revealed the scavenging capacity of *p*-coumaric acid and its lipid derivatives on DPPH radicals. All test compounds exhibited effective DPPH radical scavenging activity. When comparing the scavenging capacity of *p*-coumaric acid and its derivatives, *p*-coumaric acid demonstrated a significantly lower ($P < 0.05$) capacity as trolox equivalents than both PSBO and PMHO.

Table 1. Lipid Derivatives of *p*-Coumaric Acid Identified in Both Acidolysis Mixtures of *p*-Coumaric Acid with SBO and MHO

phenolipid	fragmentation pattern	*m/z*
Phenolic Monoacylglycerol		
monomyristyl *p*-coumarate[b]	$[M + H - H_2O]^+$	431.3
monocetyl *p*-coumarate[c]	$[M + H - H_2O]^+$	459.3
monopalmitoleyl *p*-coumarate[c]	$[M + H - H_2O]^+$	457.3
monostearyl *p*-coumarate[c]	$[M + H - H_2O]^+$	487.3
monooleyl *p*-coumarate[c]	$[M + H - H_2O]^+$	485.3
monolinoleyl *p*-coumarate[b]	$[M + H - H_2O]^+$	483.3
monoeicosenyl *p*-coumarate[c]	$[M + H - H_2O]^+$	513.3
monoeicosapentaenyl *p*-coumarate[c]	$[M]^+$	523.5
Phenolic Diacylglycerol		
dimyristyl *p*-coumarate[c]	$[M]^+$	661.5
myristyl myristeyl *p*-coumarate[b]	$[M + H - H_2O]^+$	639.5
myristeyl cetyl *p*-coumarate[a]	$[M + H - H_2O]^+$	667.5
myristyl cetyl *p*-coumarate[b]	$[M + H - H_2O]^+$	669.5
cetyl palmitoleyl *p*-coumarate[a]	$[M + H - H_2O]^+$	695.5
myristeyl elaidolinolenyl *p*-coumarate[b]	$[M + H - H_2O]^+$	689.5
myristeyl stearidonyl *p*-coumarate[a]	$[M + H - H_2O]^+$	687.5
myristeyl eicosapentaenyl *p*-coumarate[b]	$[M + H - H_2O]^+$	713.5

[a]Indicates phenolipid compounds derived only from SBO. [b]Indicates phenolipid compounds derived only from MHO. [c]Indicates phenolipid compounds derived from both SBO and MHO; $[M + H - H_2O]^+$ resulting from the loss of a molecule of H_2O and addition of a proton; and $[M]^+$ resulting from the loss of an electron.

Meanwhile, PMHO showed superior DPPH radical scavenging activity compared to PSBO. Lipophilicity of phenolic compounds plays an important role in their antioxidant activity in certain systems; higher lipophilicity of phenolic compounds may lead to greater antioxidant activity.[25] In this case, esterification of *p*-couamric acid improved its lipophilicity, and thus, its lipid derivatives showed higher DPPH radical scavenging capacity. Although the improved lipophilicity of PSBO and PMHO may extend their application in more lipophilic environments, further investigation is required to obtain a better understanding of their antioxidant efficacy in different model systems and test media.

ORAC. *p*-Coumaric acid and its derivatives PSBO and PMHO demonstrated strong activity in the DPPH radical scavenging assay. However, the results obtained from the DPPH assay may not well reflect the antioxidant capacity of these compounds in the real food and biological systems, where the lifetime of their radicals are much shorter than the stable and artificial DPPH radical.[26] Therefore, the radical scavenging efficacy of *p*-coumaric acid and its derivatives was further evaluated by an oxygen radical (peroxyl radical) absorbance capacity assay, which uses a biologically relevant radical source.[21]

Dávalos et al.[27] reported that the ORAC value of *p*-coumaric acid was 4.5 fold that of trolox, which was 2 times higher than that of BHA. The ORAC values of *p*-coumaric acid and its lipid derivatives are summarized in Figure 2. All test compounds exhibited strong peroxyl radical scavenging activity. Both PSBO and PMHO showed significantly higher ($P < 0.05$) ORAC values than *p*-coumaric acid, and the trend of the results was correlated with the result of the DPPH radical scavenging assay. The improved antioxidant activity of PSBO and PMHO may be caused by changes of chemical and physical characteristics of the lipid derivatives, such as lipophilicity, electron distribution, and steric effect. For instance, the improved lipophilicity may have a positive effect on radical scavenging activity as higher lipophilicity of phenolic compounds may lead to improved antioxidant activity.[25] However, the weak electron-donating ester group may compromise the hydrogen-donation activity of *p*-coumaric acid, which leads to lower antioxidant activity.[28] It appears that the weaker hydrogen atom donating ability caused by the ester group was overwhelmed by the effect of improved lipophilicity, and thus, a postitive effect of esterification on peroxyl radical scavenging capacity became evident.

Reducing Power. The ferric reducing antioxidant power assay is frequently employed to assess the efficiency of antioxidants for their electron transfer capacity. The reducing power of antioxidants and its measurement is based on the reduction of Fe^{3+} to Fe^{2+} by antioxidants in an acidic environment.[28,29]

p-Coumaric acid demonstrated strong reducing power in the study conducted by Medina et al.[30] In this work, the results summarized in Figure 3 show effective reducing power of *p*-coumaric acid and its derivatives. Compared to *p*-coumaric acid, PSBO did not show significant difference ($P > 0.05$), and PMHO showed significantly higher ($P < 0.05$) reducing power. This phenomenon may be caused by the decrease of the ionization potential of *p*-coumaric acid when it was esterified to bulky acylglycerol substituents[31] as decreased ionization potential facilitates the electron transfer in PMHO and PSBO. The results of the reducing power of PSBO and PMHO are correlated with those of both DPPH radical scavenging and ORAC assays as shown in Figure 2. However, the reducing power of PSBO is not significantly different from that of *p*-coumaric acid, which may partially be due to the decreased hydrophilicity of *p*-coumaric acid after esterification in the aqueous test system. In the reducing power assay, the capacity of an antioxidant is strongly solvent-dependent as the solvent facilitates the stability of charged ions.[28] The reducing power of derivatives might be compromised under the hydrophilic test environment; however, such an effect was overwhelmed by the effect of decreased ionization potential.

Antioxidant Activity in a β-Carotene−Linoleate Model System. High surface-to-volume ratio of oil-in-water emulsions normally occurs in food systems. Therefore, it is essential to investigate the effectiveness of antioxidants in oil-in-water emulsions to achieve a comprehensive assessment of their antioxidant activity prior to their application in food systems.[25]

Gadow et al.[32] studied the antioxidant activity of *p*-coumaric acid in the β-carotene−linoleic acid model system and reported its strong inhibitory effect on β-carotene bleaching. In this work, the results (Figure 4) indicated that PSBO inhibited the bleaching of β-carotene by 50.1% over the entire incubation period, followed by PMHO (12.2%) and *p*-coumaric acid (8.35%). On the basis of the "polar paradox" theory, nonpolar antioxidants exhibit higher efficacy than that of polar ones in emulsion systems, which implies that the derivatives with improved lipophilicity may exhibit a higher inhibitory effect on β-carotene bleaching than *p*-coumaric acid.[21] However, the efficacy of an antioxidant is also determined by its hydrogen-donation capacity. In this case, esterification of *p*-coumaric acid may have changed the surrounding molecular structure of its hydroxyl group on the aromatic ring as well as the bond dissociation enthalpy of the O−H bond. The steric hindrance to the hydroxyl group and the changed bond dissociation enthalpy of the O−H bond may decrease the hydrogen atom donation capacity and lead to compromised antioxidant activity

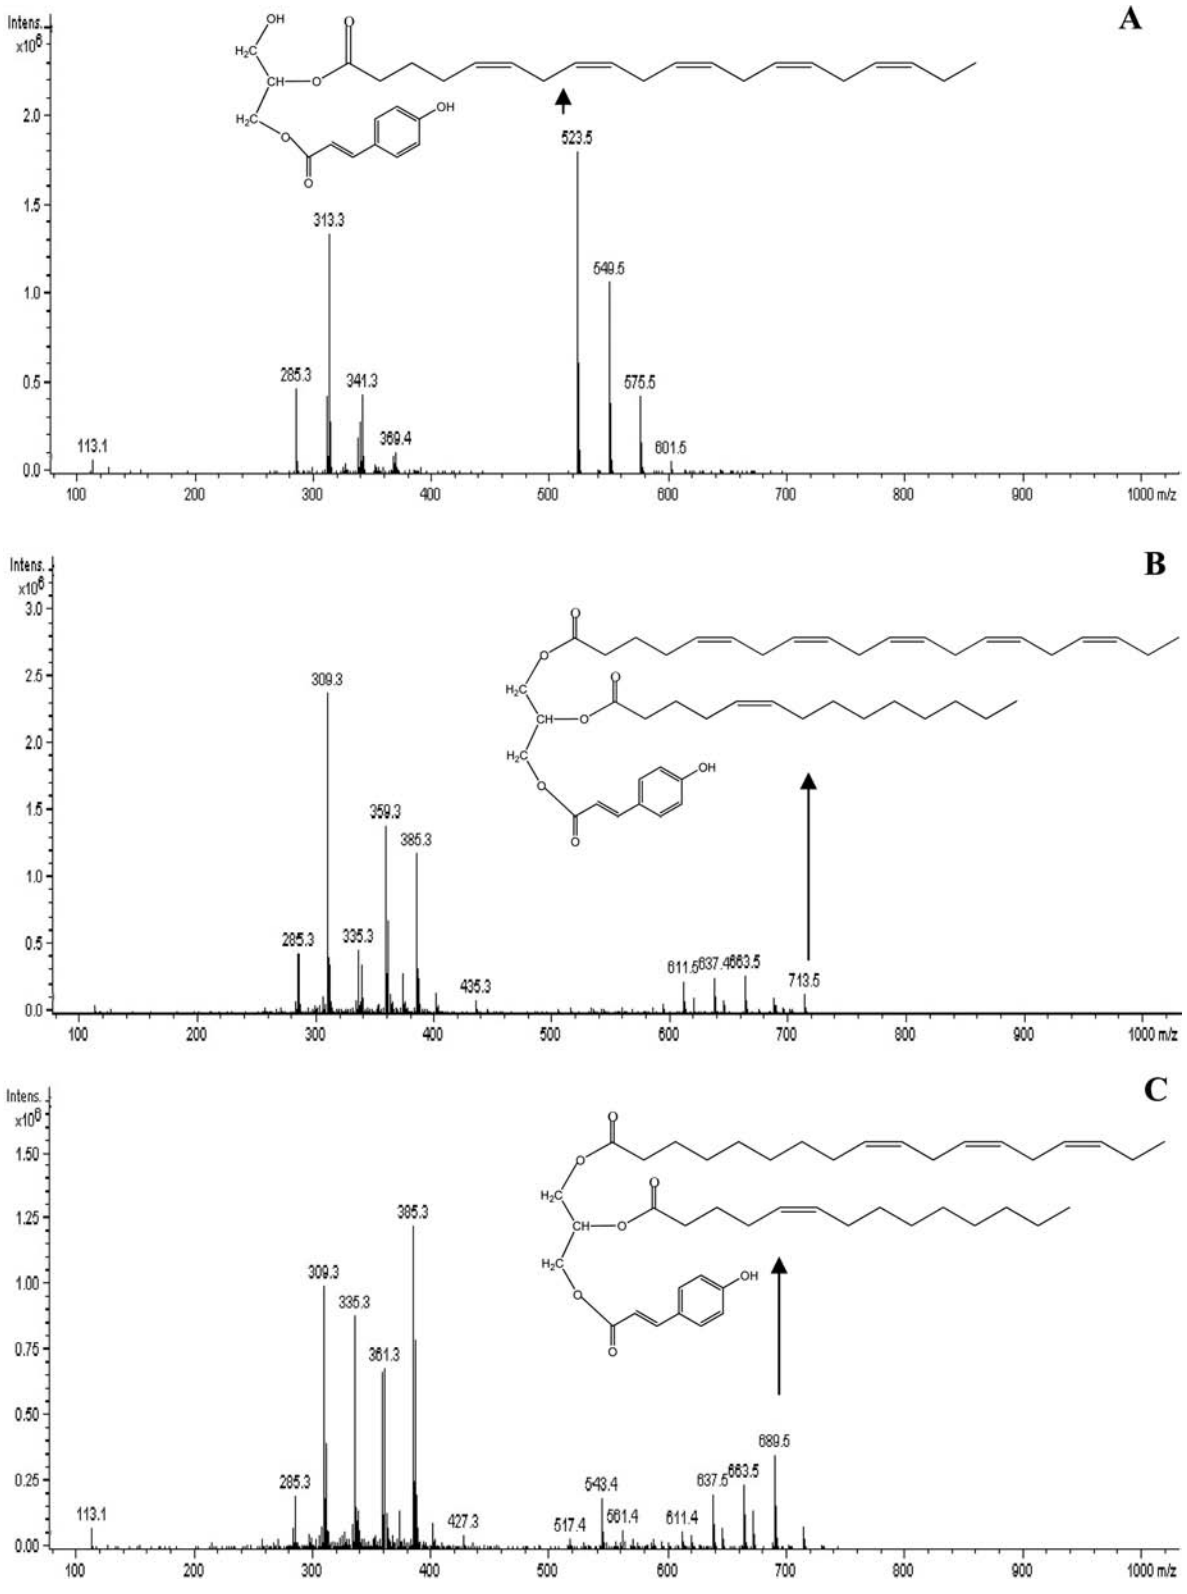

Figure 1. Chemical structures and mass spectrometric data of (A) monoeicosapentaenyl *p*-coumarate, (B) myristeyl eicosapentaenyl *p*-coumarate, and (C) myristeyl elaidolinolenyl *p*-coumarate.

of the test lipid derivatives. This may partially explain that the inhibitory activity of PMHO on β-carotene bleaching did not show any significant difference ($P > 0.05$) compared to that of *p*-coumaric acid.

Inhibitory Effect on Human LDL Cholesterol Oxidation. LDL cholesterol is one of the five major cholesterol carriers in the blood. It has been proven that the risk of atherosclerosis is positively associated with the increased plasma level of LDL.[33] The oxidized products of LDL have

dx.doi.org/10.1021/jf404140v | J. Agric. Food Chem. 2014, 62, 454−461

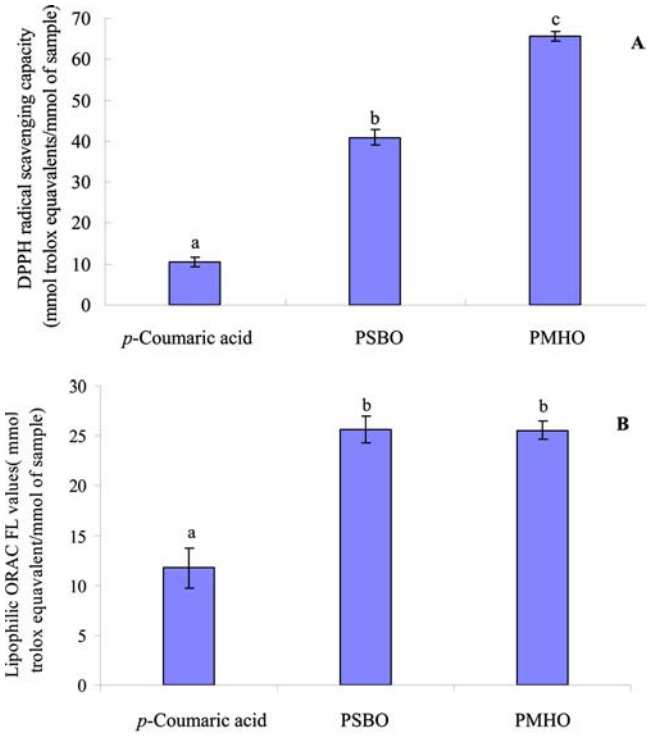

Figure 2. (A) DPPH radical scavenging capacity and (B) oxygen radical absorbance capacity of *p*-coumaric acid, PSBO (phenolipids mixture obtained from SBO), and PMHO (phenolipids mixture obtained from MHO) as trolox equivalents (TE); bars with different letters are significantly different ($P < 0.05$).

been recognized as contributors to the formation of atherosclerotic plaques in arteries, hence providing incentive for preventing LDL oxidation.[34] Dietary antioxidants such as phenolic acids are believed to be effective inhibitors of LDL oxidation caused by free radical attack.[35−37]

In this work, the inhibitory effects of *p*-coumaric acid, PSBO, and PMHO on Cu^{2+}-induced LDL cholesterol oxidation were evaluated, and the results are summarized in Figure 5. LDL cholesterol was oxidized to different levels at the end of a 22 h incubation period, which depended on the type of antioxidant added to the samples. All test compounds showed high inhibitory capacity on LDL cholesterol oxidation. Inhibition percentage of LDL cholesterol upon addition of *p*-coumaric acid was 37.3%, which is much higher than the value reported by Andreasen et al.[35] due to the higher concentration of *p*-

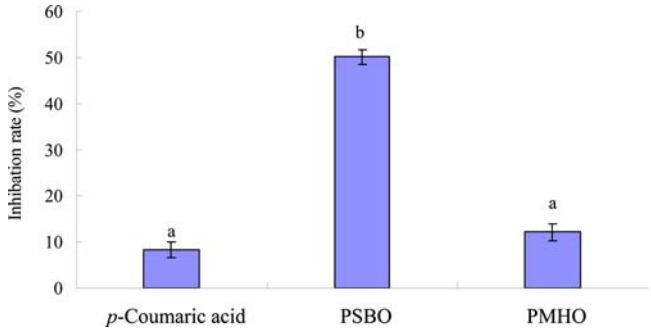

Figure 4. Inhibitory effects of *p*-coumaric acid, PSBO (phenolipids mixture obtained from SBO), and PMHO (phenolipids mixture obtained from MHO) against β-carotene bleaching; bars with different letters are significantly different ($P < 0.05$).

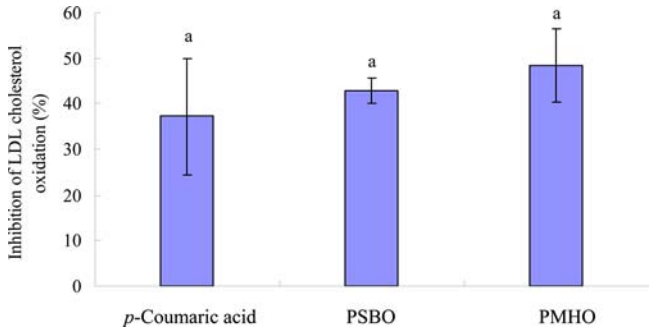

Figure 5. Inhibitory effect of *p*-coumaric acid, PSBO (phenolipids mixture obtained from SBO), and PMHO (phenolipids mixture obtained from MHO) on LDL cholesterol oxidation; bars with different letters are significantly different ($P < 0.05$).

coumaric acid employed in this work. Meanwhile, the inhibition percentages shown by derivatives of *p*-coumaric acid PSBO and PMHO were 42.8% and 48.4%, respectively, which are not significantly higher than that of *p*-coumaric acid ($P > 0.05$). The slightly improved inhibitory capacity of PSBO and PMHO against LDL cholesterol oxidation may be due to their improved lipophilicity as the higher lipophilicity allowed these lipid derivatives to have greater affinity to the major components on the surface of LDL cholesterol, that is, the phospholipids. Moreover, hydrophilic *p*-coumaric acid and a lipophilic fatty acid chain may lead to better amphiphilicity of the lipid derivatives, which further allowed them to exert their antioxidant activities within the LDL particles and/or on the surface of LDL cholesterol.[21] Thus, the potential use of PSBO and PMHO as antiatherosclerosis agents is supported by their high inhibitory activity on LDL cholesterol oxidation.

DNA Scission Assay. Oxidative stress in cells caused by reactive oxygen species such as hydroxyl and peroxyl radicals leads to DNA damage. Hydroxyl and peroxyl radicals react with DNA by possible addition to double bonds of DNA bases or abstraction of a hydrogen atom from the methyl group of thymine, among others.[38] Therefore, oxidative damage of DNA may occur at both the nucleotide bases and the phosphate backbone resulting in strand breakage and sister chromatid exchange, DNA−DNA and DNA−protein cross-linking, and base modification.[39] A background level of oxidative DNA damage is an inevitable consequence of cellular metabolism and can be repaired in normal tissues. However, the oxidative stress caused by excess free radicals may lead to severe DNA damage, which is implicated in mutagenesis, carcinogenesis, and

dx.doi.org/10.1021/jf404140v | J. Agric. Food Chem. 2014, 62, 454−461

cytostasis. Thus, the effect of various antioxidants such as phenolic acids on DNA oxidation inhibitory activity has been widely studied.[40,41]

In this study, the inhibitory activity of *p*-coumaric acid, PSBO, and PMHO on hydroxyl and peroxyl radical induced supercoiled DNA strand oxidation was evaluated, and the results are shown in Figures 6 and 7. The oxidative damage

caused by hydroxyl and peroxyl radicals led to supercoiled plasmid DNA strand nicking and formation of a nicked open circular form as a result of single strand cleavage. At higher concentrations, the free radicals can even cause double-bond breakage and convert the supercoiled plasmid DNA strand to a linear form of DNA. However, no linear form of DNA was observed due to the modest concentration of radicals employed in the test. The results from Figure 7 showed effective DNA retention in all test compounds in hydroxyl radical induced DNA tests due to their high radical scavenging capacity and for eliminating hydroxyl radicals generated from H_2O_2 through the Fenton reaction.[42] Of these, the lipid derivatives PSBO showed a slightly higher retention percentage than *p*-coumaric acid at an insignificant level ($P > 0.05$); meanwhile, PMHO exhibited a significantly ($P < 0.05$) higher retention percentage than *p*-coumaric acid. The trend of retention percentage of *p*-coumaric acid and its lipid derivatives in hydroxyl radical induced DNA nicking is positively correlated to that of the inhibitory effect of these compounds in the LDL cholesterol oxidation assay, which may result from the greater amphiphilic nature of these lipid derivatives.

The oxidation of supercoiled DNA was also successfully induced by peroxyl radical and resulted in the occurrence of nicked open circular DNA at the end of incubation, but no linear DNA was observed (Figure 6). All test compounds showed high retention of DNA. The derivatives, PSBO and PMHO, exhibited a slightly higher inhibitory capacity compared to *p*-coumaric acid although this was statistically insignificant ($P > 0.05$) (Figure 7). The different performance of test compounds on DNA retention between hydroxyl and peroxyl radical induced DNA oxidation may be due to the better stability of the peroxyl radical compared to the hydroxyl radical that helps it reach specific targets before being degraded or eliminated.

Derivatives of *p*-coumaric acid PSBO and PMHO showed variable levels of antioxidant capacity due to different antioxidant mechanisms involved in different testing systems employed. The improved lipophilicity and the decreased ionization potential of the lipid derivatives are the major factors that lead to the changes of antioxidant efficacy of *p*-coumaric acid. The good antioxidant activity of the phenolipids obtained from the acidolysis of *p*-coumaric acid with SBO and MHO, displayed in different assays employed, suggests that the phenolipids so produced may be used as potential ingredients in functional foods, supplements, or cosmetics for health promotion and disease risk reduction.

ABSTRACT: The Japanese herb, Ashitaba (*Angelica keiskei* Koidzumi), contains two prenylated chalcones, 4-hydroxyderricin and xanthoangelol, which are considered to be the major active compounds of Ashitaba. However, their effects on inflammatory responses are poorly understood. In the present study, we investigated the effects and underlying molecular mechanisms of 4-hydroxyderricin and xanthoangelol on lipopolysaccharide (LPS)-induced inflammatory responses in RAW264 mouse macrophages. LPS-mediated production of nitric oxide (NO) was markedly reduced by 4-hydroxyderricin (10 μM) and xanthoangelol (5 μM) compared with their parent compound, chalcone (25 μM). They also inhibited LPS-induced secretion of tumor necrosis factor-alpha (TNF-α) and expression of inducible NO synthase (iNOS) and cyclooxygenase-2 (COX-2). Although chalcone decreased the DNA-binding activity of both activator protein-1 (AP-1) and nuclear factor-kappa B (NF-κB), 4-hydroxyderricin and xanthoangelol suppressed only AP-1 and had no effect on NF-κB. On the other hand, all of the tested chalcones reduced the phosphorylation (at serine 536) level of the p65 subunit of NF-κB. 4-Hydroxyderricin and xanthoangelol may be promising for the prevention of inflammatory diseases.

KEYWORDS: *4-hydroxyderrin, xanthoangelol, Angelica keiskei Koidzumi (Ashitaba), anti-inflammation, NF-κB, AP-1*

INTRODUCTION

Chronic inflammation plays a critical role in the development of several diseases, including asthma, rheumatoid arthritis, atherosclerosis, inflammatory bowel diseases, and various human cancers.[1] Infection or injury stimulates inflammatory cells to produce proinflammatory mediators, such as NO, reactive oxygen species, prostaglandins, and cytokines.[2] AP-1 and NF-κB are well-known to be an important regulator of the expression of iNOS, COX-2, and TNF-α.[3−5]

Natural dietary sources, such as fruits, vegetables, herbs, and spices, have been reported to provide beneficial effects for human health,[1,2,4] thus drawing attention for their prevention against various diseases. Many types of compounds, including 1′-acetoxychavicol acetate (a phenylpropanoid derived from ginger),[6] nobiletin (a citrus polymethoxyflavonoid),[6] and xanthohumol (a prenylated chalcone contained in hop),[7] exhibit anti-inflammatory activity and decrease the transcriptional activity of AP-1 and NF-κB in inflammatory cells.

The Japanese herb, Ashitaba (*Angelica keiskei* Koidzumi, Apiaceae), is a perennial plant grown along the Pacific coast of Japan (Izu islands and the Izu, Bouso, and Miura peninsulas). Ashitaba is enriched with numerous active compounds such as coumarins, flavanones, and chalcones. Among these compounds, prenylated chalcones 4-hydroxyderricin and xanthoangelol (Figure 1) are more abundant and exhibit anti-bacterial,[8] anti-cancer,[9−11] and anti-diabetic actions.[12,13] However, the anti-inflammatory activity of 4-hydroxyderricin and xanthoangelol remains unclear. Although the *n*-hexane extract of Ashitaba has been found to suppress inflammatory responses in LPS-treated macrophages, active compounds were not identified.[14] Sugii et al. (2005)[15] have reported that xanthoangelol D, a xanthoangelol derivative, suppresses TNF-α-induced NF-κB activation in cultured porcine aortic endothelial cells. Also, Ohkura et al. (2011)[16] have found that xanthoangelol B and D reduced plasminogen activator

inhibitor-1 production in TNF-α-stimulated human umbilical vein endothelial cells. To our knowledge, there have been no reports evaluating an anti-inflammatory action of 4-hydroxyderricin and xanthoangelol. In the current study, we investigated the effects and underlying mechanisms of 4-hydroxyderricin, xanthoangelol, and their parent compound chalcone (1,3-diphenyl-prop-2-en-1-one framework)[17] on LPS-induced inflammatory responses in the murine macrophage RAW264 cell line.

MATERIALS AND METHODS

Chemicals. 4-Hydroxyderricin and xanthoangelol were purified as described previously.[13] Their purity (>90%) were confirmed by high-performance liquid chromatography. Nobiletin and 1′-acetoxychavicol acetate were kindly donated by Dr. Akira Murakami (Kyoto University, Japan). The anti-iNOS and COX-2 antibodies were purchased from Cayman Chemical Company (Ann Arbor, MI, USA). The anti-p65, phospho-p65 (Ser536), c-jun N-terminal kinase (JNK), phospho-JNK (Thr183/Tyr185), and lamin B1 antibodies were from Cell Signaling Technology (Beverly, MA, USA). Horseradish peroxidase-conjugated anti-rabbit IgG and anti-goat IgG antibodies were obtained from Calbiochem (San Diego, CA, USA) and Sigma (St. Louis, MO, USA), respectively. Anti-β-actin antibody was purchased from Santa Cruz Biotechnology. Can Get Signal immunoreaction enhancer solution was obtained from Toyobo (Osaka, Japan). All other chemicals were purchased from Wako Pure Chemicals (Osaka, Japan) unless specified otherwise.

Cell Culture. RAW264 mouse macrophages (RCB0535; RIKEN Bio Resource Center, Tsukuba, Japan) were grown in Dulbecco's Modified Eagle Medium (DMEM, Sigma) supplemented with 10% (v/v) heat-inactivated fetal bovine serum (FBS, Thermo Fisher Scientific, Waltham, MA, USA), penicillin (100 U/mL), and streptomycin (100 μg/mL). L929 mouse fibroblast cells (RCB1422, RIKEN Bio Resource Center) were cultured in Roswell Park Memorial Institute (RPMI) medium 1640 containing 10% heat-inactivated FBS, penicillin (100 U/mL), and streptomycin (100 μg/mL). Cells were grown at 37 °C under a humidified atmosphere of 95% air and 5% CO_2. RAW264 cells (2.5×10^5 cells/mL) and L929 cells (2.3×10^5 cells/mL) were seeded (in culture medium) on 96-well plates (for NO and TNF-α measurements), 48-well plates (for western immunoblotting), 12-well plates (for real-time reverse transcription-polymerase chain reaction (RT-PCR)), or 60 mm dishes (for electrophoretic mobility shift assay) in the culture medium. After 24 h incubation, cells were used for their respective assay. The final concentration of LPS was 100 ng/mL.

Determination of the Production of NO. NO production was determined via the Griess reaction,[18] which is based on the amount of nitrite, a stable end-product of NO. Briefly, RAW264 cells were treated with the tested compounds (4-hydroxyderricin (10 μM), xanthoangelol (5 μM), chalcone, (25 μM), nobiletin (50 μM), or 1′-acetoxychavicol acetate (6 μM)), which were dissolved in dimethyl sulfoxide (DMSO) in serum-free DMEM for 30 min and then exposed to LPS for a further 24 h. The supernatants (0.1 mL) were mixed with 0.1 mL of Griess reagent 1% (w/v) sulfanilamide and 0.1% (w/v) *N*-(1-naphthyl) ethylenediamine dihydrochloride in 2.5% (v/v) phosphoric acid) in 96-well plates. Absorbance was measured at 543 nm using the SPECTRAmax 190 (Molecular Devices, Sunnyvale, CA, USA). The half-maximal inhibitory concentration (IC_{50}) was defined as the concentration of each compound that inhibited NO production by 50%.

Measurement of Cell Viability. Cell viability was measured via crystal violet staining. RAW264 cells were fixed and stained with crystal violet solution (0.2% (w/v) in 2% (v/v) ethanol) for 10 min. The stained cells were then extracted with sodium dodecyl sulfate (SDS) solution (0.5% (w/v) in 50% (v/v) ethanol). The optical density was measured at 570 nm with a reference wavelength of 630 nm using the SPECTRAmax 190. The positive control (DMSO + LPS-treated cells) was taken as 100% cell viability.

Measurement of TNF-α Production. TNF-α was measured using the L929 fibroblast killing assay with some modifications.[19] Briefly, RAW264 macrophages were treated with DMSO, 4-hydroxyderricin (10 μM), xanthoangelol (5 μM), chalcone (25 μM), or nobiletin (50 μM) in the presence of LPS as described above. The culture supernatant was collected at 1, 3, 6, 12, and 24 h and diluted (500-fold) with RPMI1640 containing 10% FBS, which were used as the sample for the Killing assay. L929 cells were exposed to 2 μg/mL actinomycin D-containing medium and the sample for 20 h. Viability of L929 cells was measured by the crystal violet staining as described above. TNF-α levels in the supernatants were calculated from a standard curve that was constructed using the viability of L929 cells and the concentration of recombinant mouse TNF-α.

Real-Time RT-PCR. RAW264 macrophages were incubated for 30 min in serum-free DMEM containing DMSO or the tested compounds (4-hydroxyderricin (10 μM), xanthoangelol (5 μM), chalcone, (25 μM), nobiletin (50 μM), or 1′-acetoxychavicol acetate (6 μM)). After a further 4 h incubation with LPS, total RNA was isolated from the cells using TRIzol reagent (Invitrogen, Carlsbad, CA, USA), followed by cDNA synthesis from 20 ng of total RNA using PrimeScript RT reagent kit with gDNA Eraser (Takara, Shiga, Japan). Thermal cycling was performed on a Thermal Cycler Dice real-time system TP860 (Takara) using SYBR Premix Ex *Taq*II (Takara). The primers used were purchased from Takara (for primers: *β-actin* and *iNOS*) and Rikaken (Nagoya, Japan) (for primer: *COX-2*). Primer sequences were as follows: *β-actin* as a control (5′- CATCCGTAAAGACCTCTATGCCAAC-3′ and 5′-ATGGAGCCACCGATCCACA-3′), *iNOS* (5′-TAGGCAGAGATTGGAGGCCTTG-3′ and 5′-GGGTTGTTGCTGAACTTCCAGTC-3′), *COX-2* (5′-CCCCCACAGTCAAAGACACT-3′ and 5′-AGTTGCTCATCACCCCACTC-3′).

Western Immunoblot Analysis. RAW264 cells were incubated with DMEM containing DMSO or the tested compounds (4-hydroxyderricin (10 μM), xanthoangelol (5 μM), chalcone, (25 μM), nobiletin (50 μM), or 1′-acetoxychavicol acetate (6 μM)) for 30 min and then treated with LPS for a further 2 and 24 h. Whole cell lysates (for iNOS, COX-2, and β-actin, 24 h) and nuclear and cytoplasmic extracts (for p65, lamin B1, and JNK, 2 h) were made with RIPA buffer and the NE-PER nuclear and cytoplasmic extraction reagents kit (Pierce Biotechnology, Rockford, IL, USA), respectively. The cells were lysed with RIPA buffer (50 mM Tris, pH 8.0, 150 mM sodium chloride, 0.5% (w/v) sodium deoxycholate, 0.1% (w/v) SDS, and 1 mM 1,4-dithiothreitol) containing the protease inhibitor cocktail, Complete (Roche, Mannheim, Germany), and the phosphatase inhibitor cocktail, PhosSTOP (Roche). Cell lysates were centrifuged (15000*g* for 5 min at 4 °C), and the supernatant was used as the whole cell lysate. Nuclear and cytoplasmic extraction was performed according to the manufacturer's instruction. Protein concentrations were determined via the BioRad protein assay (BioRad Laboratories, Hercules, CA, USA) against the standard curve of γ-globulin. Equal amounts (10 μg) of protein were separated by 10% SDS polyacrylamide gel electrophoresis for 60 min at 120 V and transferred to polyvinylidene difluoride membranes (Millipore, Billerica, MA, USA) for 60 min at 100 V using the Mini Trans-Blot electrophoretic transfer cell (Bio-Rad Laboratories). After blocking with Blocking One or Blocking One-P (Nacalai Tesque, Kyoto, Japan), the membranes were treated with the primary antibodies diluted in Tris buffer (0.1 M Tris, pH 7.5, 0.15 M NaCl, 0.1% (v/v) Tween 20) containing 5% (v/v) Blocking One (for anti-iNOS (1:2000), anti-COX-2 (1:8000), or β-actin (1:500)) or Can Get Signal solution 1 (for total and phospho-p65 (both 1:4000), total and phospho-JNK (both 1:4000), or Lamin B1 (1:2000)) overnight at 4 °C. Corresponding horseradish peroxidase-conjugated secondary antibodies were diluted in Tris buffer (0.1 M Tris, pH 7.5, 0.15 M NaCl, 0.1% (v/v) Tween 20) containing 5% (v/v) Blocking One (for rabbit IgG (1:4000) or goat IgG, (1:2000)) or Can Get Signal solution 2 (for rabbit IgG (1:10000)) and added to the membranes for 1 h at room temperature. The blots were detected by enhanced chemiluminescence using ImmunoStar LD and developed by the LAS4000 mini (Fujifilm, Tokyo, Japan).

Electrophoretic Mobility Shift Assay. RAW264 macrophages were treated with DMSO or the tested compounds (4-hydroxyderricin (10 μM), xanthoangelol (5 μM), chalcone, (25 μM), nobiletin (50 μM), or 1′-acetoxychavicol acetate (6 μM)) in DMEM for 30 min followed by the exposure to LPS for a further 2 h. Nuclear extracts and protein concentration determination were performed as described above. Equal amounts (7 μg) of protein were subjected to the LightShift chemiluminescent EMSA kit (Thermo Fisher scientific, Waltham, MA, USA) according to the manufacturer's instructions. The 3′-biotin-labeled oligonucleotide sequences for *NF-κB* were 5′-AGTTGAGGGGACTTTCCCAGGC-3′ and 5′-GCCTGGGAAAGTCCCCTCAACT-3′ and for *AP-1* were 5′-CGCTTGATGACTCACCGGAA-3′ and 5′-TTCCGGCTGAGTCATCAAGCG-3′ (STAR Oligo; Rikaken, Nagoya, Japan).

Statistical Analysis. All data are expressed as the mean ± standard deviation from at least three independent experiments. Each treatment for the NO and TNF-α assays was performed in triplicate from at least three independent experiments. Comparisons between groups were analyzed by the Dunnett test. Statistical analysis was performed by SPSS 16.0J (SPSS Inc., Chicago, IL, USA). Significance was reached at values of $P < 0.05$.

RESULTS

4-Hydroxyderricin and Xanthoangelol Down-Regulated LPS-Mediated Production of NO in Mouse Macrophages. We first determined the effect of 4-hydroxyderricin and xanthoangelol on LPS-induced NO production (Figure 2A). NO production was induced in RAW264 macrophage cells exposed to LPS for 24 h (Figure 2A), and 6 μM 1′-acetoxychavicol acetate or 50 μM nobiletin, which are anti-

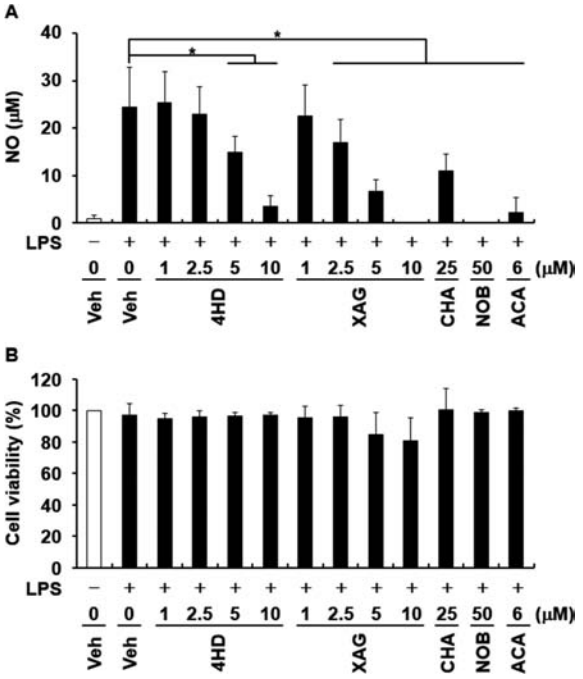

Figure 2. 4-Hydroxyderricin and xanthoangelol decrease NO production in LPS-treated RAW264 macrophages. RAW264 cells were incubated with 4-hydroxyderricin (4HD, 1−10 μM), xanthoangelol (XAG, 1−10 μM), chalcone (CHA, 25 μM), nobiletin (NOB, 50 μM), 1′-acetoxychavicol acetate (ACA, 6 μM), or DMSO (vehicle, Veh) for 30 min and then treated with or without LPS (100 ng/mL) for 24 h. The cell culture supernatant was collected and (A) NO production was determined. (B) Quantification of cells stained with crystal violet to estimate the cytotoxicity of the tested phytochemicals. *$p < 0.05$.

inflammatory dietary factors[6] and were used as the positive controls, significantly suppressed this response (Figure 2A). Furthermore, 4-hydroxyderricin (5 and 10 μM) and xanthoangelol (2.5−10 μM) significantly inhibited LPS-induced NO production in a concentration-dependent manner, with IC_{50} values of 5.0 ± 1.2 and 2.9 ± 0.4 μM, respectively. At 10 μM, 4-hydroxyderricin and xanthoangelol suppressed the production of NO by 90% and 100%, and both compounds had negligible effects on cell viability at this concentration (Figure 2B). Chalcone (25 μM) significantly reduced NO production. Treatment with each phytochemical alone did not affect the production of NO (data not shown).

4-Hydroxyderricin and Xanthoangelol Suppressed LPS-Induced Production of TNF-α in Mouse Macrophages. We next evaluated the effects of 4-hydroxyderricin and xanthoangelol on the production of TNF-α. LPS-stimulated RAW264 cells secreted TNF-α into the culture medium in a time-dependent manner (Figure 3). Xanthoange-

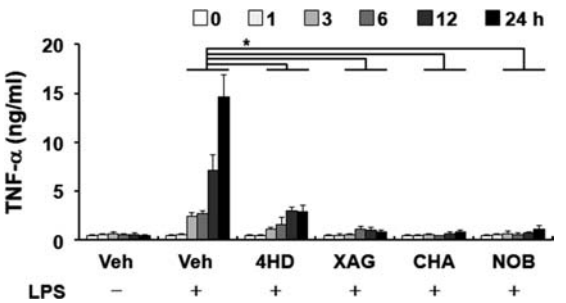

Figure 3. 4-Hydroxyderricin and xanthoangelol inhibit LPS-mediated secretion of TNF-α from RAW264 macrophages. RAW264 cells were treated with 4-hydroxyderricin (4HD, 10 μM), xanthoangelol (XAG, 5 μM), chalcone (CHA, 25 μM), nobiletin (NOB, 50 μM), or DMSO (vehicle, Veh) for 30 min and then stimulated with LPS. The TNF-α level in the culture supernatant at the various time-points was measured using L929 Killing assay as described in Materials and Methods. *$p < 0.05$.

lol, chalcone, and nobiletin strongly decreased the secretion of TNF-α from 3 to 24 h by 57−94% ($P < 0.05$), respectively, and 4-hydroxyderricin suppressed it by 40−80% ($P < 0.05$), respectively (Figure 3).

4-Hydroxyderricin and Xanthoangelol Inhibited LPS-Induced Expression of iNOS and COX-2. To assess whether the suppression of NO production by 4-hydroxyderricin or xanthoangelol is due to the reduction in the expression of iNOS, western immunoblots and RT-PCR were performed for iNOS. RAW264 cells treated with LPS for 24 h significantly induced the expression of iNOS protein and mRNA (parts A and B of Figure 4, respectively). All of the tested compounds down-regulated the expression of iNOS protein and mRNA (parts A and B of Figure 4, respectively). Similar responses were found with COX-2 (Figure 4A,B). These data indicate that the prenylated chalcones may attenuate LPS-induced NO production via the suppression of iNOS at the transcriptional level.

4-Hydroxyderricin and Xanthoangelol Reduced the DNA-Binding Activity of AP-1 and Inhibited the Phosphorylation of NF-κB but Not Its DNA-Binding Activity. We then investigated the effects of the prenylated chalcones on transcription factors, AP-1 and NF-κB. 4-Hydroxyderricin showed partial inhibition of AP-1 DNA-binding activity, while xanthoangelol and other compounds

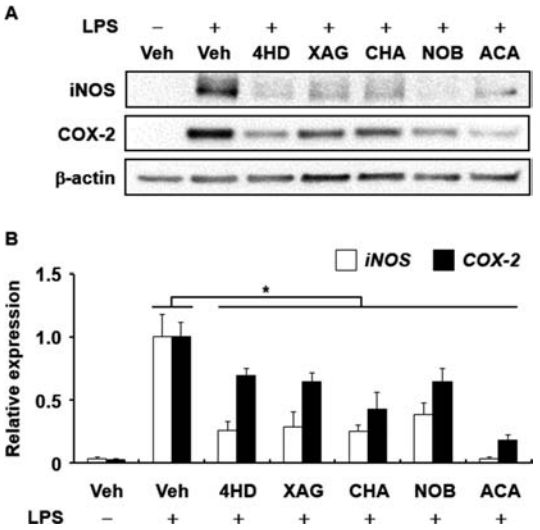

Figure 4. 4-Hydroxyderricin and xanthoangelol reduce the expression levels of iNOS and COX-2 in LPS-treated RAW264 macrophages. RAW264 cells were treated with 4-hydroxyderricin (4HD, 10 μM), xanthoangelol (XAG, 5 μM), chalcone (CHA, 25 μM), nobiletin (NOB, 50 μM), 1′-acetoxychavicol acetate (ACA, 6 μM), or DMSO (vehicle, Veh) for 30 min and then treated with LPS (100 ng/mL) for 24 h for (A) western immunoblots and for 4 h for (B) reverse-transcription-polymerase chain reaction. *β-Actin* and *gapdh* were used as the internal standard for (A) and (B), respectively. Results shown are representative of three independent experiments. *$p < 0.05$.

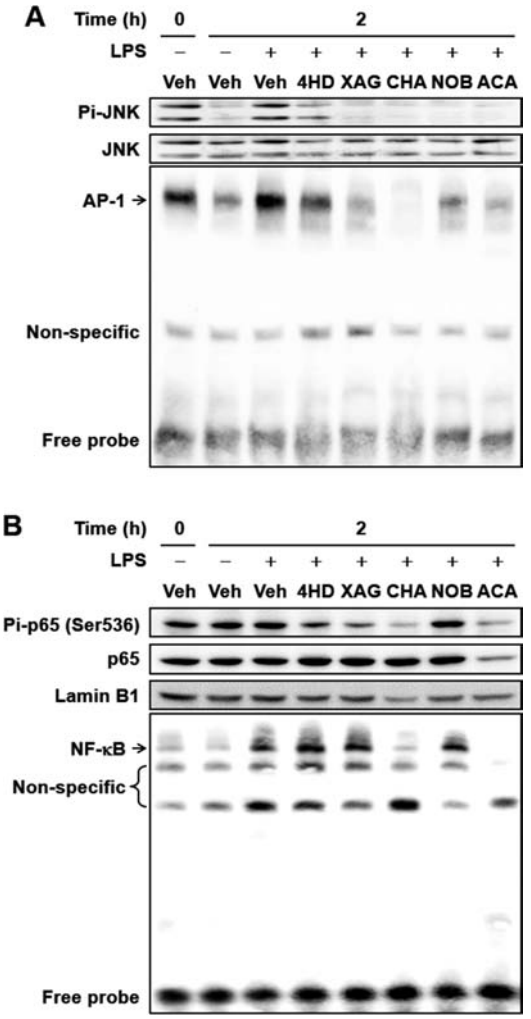

Figure 5. Effects of 4-hydroxyderricin and xanthoangelol on the activation of AP-1 and NF-κB. Nuclear and cytoplasmic extraction, western immunoblotting, and an electrophoretic mobility shift assay were performed on RAW264 cells treated with 4-hydroxyderricin (4HD, 10 μM), xanthoangelol (XAG, 5 μM), chalcone (CHA, 25 μM), nobiletin (NOB, 50 μM), 1′-acetoxychavicol acetate (ACA, 6 μM), or DMSO (vehicle, Veh) for 30 min and followed by LPS (100 ng/mL) for 2 h. The nuclear and cytoplasmic extracts prepared from cells immediately after the preincubation was set as 0 h. (A) JNK phosphorylation and AP-1 DNA-binding activity, (B) p65 phosphorylation and NF-κB-DNA binding activity. The NF-κB complex (indicated by the arrow) was confirmed by a supershift assay using the anti-p65 antibody (data not shown). Lamin B1 was used as the internal standard. Results shown are representative of three independent experiments.

completely abolished it (Figure 5A). A similar pattern of inhibition was observed in the phosphorylation level of JNK (Figure 5A). On the other hand, the prenylated chalcones did not affect the DNA-binding activity of NF-κB (Figure 5B). Interestingly, however, 4-hydroxyderricin and xanthoangelol decreased LPS-induced p65 phosphorylation at Ser536 (Figure 5B). In contrast, chalcone suppressed p65 phosphorylation and reduced its activity (Figure 5B). 1′-Acetoxychavicol acetate decreased the phosphorylation, nuclear translocation, and DNA-binding activity of p65 (Figure 5B). However, nobiletin had no effect on the phosphorylation and the activity of p65 (Figure 5B).

DISCUSSION

Proinflammatory mediators play important roles in chronic inflammation, which is associated with the development of obesity, cancer, cardiovascular diseases, and diabetes mellitus.[1,3,4] In the current study, we investigated the anti-inflammatory activities of 4-hydroxyderricin and xanthoangelol under in vitro conditions. Our findings reveal that these two compounds significantly decrease the production of NO and TNF-α in LPS-treated RAW264 mouse macrophages. Furthermore, the expression of iNOS and COX-2 genes are reduced. These findings are the first to report that 4-hydroxyderricin and xanthoangelol attenuate LPS-mediated inflammatory responses in macrophages. Their parent compound chalcone also display similar effects but at concentrations 5- to 10-fold higher than those of the prenylated chalcones. In addition, xanthoangelol, which has the geranyl group (two isoprene units), showed more strong activity (2-fold) than 4-hydroxyderricin, which has the dimethylallyl group (one isoprene unit). This may be because that the prenylation increases hydrophobicity and thus the uptake ratio into the cells. In other types of prenylated chalcones, both xanthohumol containing the dimethylally group at 3′ position and licochalcone A containing 2-methyl-3-buten-2-yl group at 4 position are known to have an anti-inflammatory activity,[7,20] suggesting the position of a prenyl group may be not important for exhibiting an anti-inflammatory activity. 1′-Acetoxychavicol acetate and nobiletin are widely accepted as the potent anti-inflammatory and cancer chemopreventive agents.[6,21−24] 4-Hydroxyderricin and xanthoangelol showed the anti-inflammatory activity at a concentration below that of nobiletin and lower toxicity to macrophages compared with 1′-acetoxychavicol acetate because toxic concentrations of the prenylated chalcones and 1′-acetoxychavicol acetate were above 25 and 10 μM, respectively (data not shown). Taken together, 4-

dx.doi.org/10.1021/jf404175t | J. Agric. Food Chem. 2014, 62, 462−467

hydroxyderricin and xanthoangelol with increased hydrophobicity by the prenyl group may effectively accumulate and work in the cells and hence be more potent than compounds with no prenyl group.

The expression of several proinflammatory mediators, including iNOS, COX-2, and TNF-α, are regulated by the transcription factors AP-1 and NF-κB.[5] Inflammatory stimuli, such as LPS, activate the pathways of mitogen-activated protein kinase (MAPK) and inhibitor of κB kinase (IKK), which then induce the nuclear translocation and increase the transcriptional activity of AP-1 and NF-κB, respectively. Nobiletin and 1′-acetoxychavicol acetate are known to exhibit anti-inflammatory activity via the inhibition of the activation of these transcription factors.[6] Like them, 4-hydroxyderricin, xanthoangelol, and chalcone reduced the DNA-binding activity of AP-1 and suppressed the activation of upstream kinase JNK. On the other hand, they reduced the phosphorylation of the p65 subunit of NF-κB, whereas only chalcone completely abolishes the DNA-binding activity of NF-κB. Moreover, all of the tested chalcones do not affect p65 nuclear translocation. In the present study, because the actions of the prenylated chalcones on NF-κB were distinct from those of chalcone, prenylation may have thus affected these mechanisms and bioavailability in macrophages. In the report by Murakami et al. (2005),[6] 1′-acetoxychavicol acetate inhibited gene transcription of COX-2 via reducing the activation of MAPKs, the translocation of p65, and the transcriptional activity of NF-κB, while nobiletin suppressed the COX-2 expression via reducing NF-κB transcriptional activity without affecting MAPK activation and p65 translocation. They showed nearly the same results in our study (though nobiletin suppressed the phosphorylation of JNK). The inhibition patterns of NF-κB by chalcone and the prenylated chalcones are similar to 1′-acetoxychavicol acetate and nobiletin, respectively. However, other prenylated chalcone xanthohumols have shown the chalcone-like action mechanism, namely the reduction of both p65 phosphorylation at Ser536 and NF-κB DNA-binding acivity.[7] Murakami et al. (2005)[6] supposed that nobiletin may disrupt binding of NF-κB with transcription coactivators such as p300. Buss et al. (2004)[25] have suggested that Ser536 phosphorylation disrupts the hydrogen bond between Ser536 and Asp533, thus leading to a lower and higher affinity of p65 for transcription corepressors and coactivators, respectively. IKKβ is considered to be an essential kinase in LPS-induced p65 phosphorylation at Ser536.[26] In addition, LPS-mediated and cAMP-independent activation of the catalytic subunit of protein kinase A increases the transcriptional activity of NF-κB through the phosphorylation of p65 at Ser276.[27] Licochalcone A suppressed the expression of inflammatory mediators including TNF-α without affecting nuclear translocation and DNA-binding activity of NF-κB.[20] This compound inhibited LPS-induced phosphorylation of p65 at Ser276, but not Ser536, resulting in reduced association with coactivator p300.[20] Furthermore, the acetylation of NF-κB affects the DNA-binding activity.[28,29] Therefore, 4-hydroxyderricin and xanthoangelol may regulate the interaction of NF-κB with transcriptional cofactors by inhibiting phosphorylation at Ser536 and at other sites (e.g., Ser276) and chalcone may suppress the NF-κB activation through the control of phosphorylation and acetylation statuses.

4-Hydroxyderricin and xanthoangelol have been found to suppress adipocyte differentiation by reducing the expression of adipocyte-specific transcription factors.[30] Furthermore, enhanced glucose uptake activity by the prenylated chalcones in muscle cells and adipocytes in vitro has been shown to occur via the activation of glucose transporter 4.[12,13] Anti-diabetic activities of 4-hydroxyderricin in KK-A^y mice was also reported.[12] Nakamura et al. (2012)[31] have demonstrated that 4-hydroxyderricin and xanthoangelol are distributed as both aglycone and conjugated forms to various tissues, such as liver, muscle, and fat, when mice are orally administered with Ashitaba extract. Generally, flavonoids are rapidly metabolized via glucuronidation, methoxylation, and/or sulfation and then circulate throughout the body. Interestingly, however, 4-hydroxyderricin and xanthoangelol are more abundant as aglycones than glucuronides in plasma and tissues.[31] 4-Hydroxyderricin and xanthoangelol predominantly accumulate in mesenteric fat tissue as aglycones,[31] possibly because of the hydrophobicity by the prenyloxy group. Chronic inflammation accompanying hypertrophy of mesenteric fat is known to cause insulin resistance, resulting in abnormal control of blood glucose by skeletal muscle tissue.[32] Taken together, 4-hydroxyderricin and xanthoangelol may be promising dietary factors for the prevention and improvement of metabolic syndromes.

Various components from Ashitaba inhibit inflammatory responses. For example, the coumarin derivative, selinidin, suppresses allergic inflammatory responses in mast cells.[33] Xanthoangelol B and D was shown to inhibit TNF-α-induced inflammatory responses in cultured endothelial cells.[15,16] Therefore, the Japanese herb, Ashitaba, which is rich in prenylated chalcones, may thus be a promising food source for the prevention of chronic inflammatory diseases

In conclusion, our study reveals that 4-hydroxyderricin and xanthoangelol are potent suppressors of inflammatory responses and may have distinct mechanisms of action than the parent compound, chalcone. We will address the investigation of the contribution of prenyl groups to their bioavailability and the elucidation of more details of their action mechanisms in the near future.

Supporting Information

ABSTRACT: High-value coproducts can greatly improve the feasibility of utilizing plant feedstocks for biorefining and biofuel production. Plant polyphenolics have potential application in the pharmaceutical and cosmetic industries. Orchard grass varieties have been noted for accumulation of polyphenolic compounds, and the current study determined the soluble phenol profile and content in the orchard grass variety 'Abertop'. Hydroxycinnamates and flavonoids were monitored during the transition from vegetative to flowering stage at maximum crop yield. Caffeic acid derivatives, related to bioactives in the Asian medicinal herb *Salvia miltiorrhiza*, and novel hydroxycinnamate−flavone conjugates were also identified in extracts. Harvest yields of hydroxycinnamates and flavonoids ranged from 2.6 to 4.0 kg/ha and from 2.1 to 5.1 kg/ha, respectively. Abundant compounds showed high levels of antioxidant activity comparable with that of trolox. Minimal changes in soluble phenol content and composition were observed after ensiling with the exception of increases in caffeic acid, a caffeic acid derivative, and a caffeic acid breakdown product, dihydroxystyrene.

KEYWORDS: *Dactylis glomerata, orchard grass, phenolic acid esters, flavonoid glycosides, caffeic acid derivatives*

INTRODUCTION

Orchard grass (*Dactylis glomerata*) is a relatively coarse, tussock-forming grass that is native to Europe, temperate Asia, and North Africa.[1] It has been introduced as a forage grass into most temperate countries in the world and is one of the most important sown species in Australia and New Zealand.[2] Plants are either diploid ($2n = 14$) or, more commonly, autotetraploid ($2n = 28$), and subspecies are morphologically distinguishable according to area of origin. For example, plants of the Eurasian (or Northern) group are typically large with broad leaves and winter-dormant, whereas plants from the Mediterranean region are relatively small, narrow-leaved, and summer-dormant. Although this species has a lower nutritional value compared to other forage species such as perennial ryegrass, it is more tolerant to heat and drought, resulting in higher production during summer dry periods.

Phenolic compounds are generally abundant in orchard grass compared with other temperate grass species. The presence of phenolic compounds in this species was first reported in 1926 by Landsborough-Thompson,[3] who described the isolation of a flavone glycoside and a free flavone from plant extracts. More recently, Parveen et al.[4] identified a number of hydroxcinnamate esters in a commercial variety of orchard grass (*D. glomerata*). There is a strong tendency for chemotaxonomically related plants to produce similar types of flavonoids,[5] and a number of studies have reported characteristic variation in the flavonoid profile of different populations of orchard grass.[6,7]

Although temperate grasses have a fundamental role in ruminant nutrition, recent studies have focused on their potential as feedstocks for biorefining.[8−10] Increased recovery of components with a marketable value can improve the feasibility of grasses as biorefining feedstocks. Valuable components can be recovered from the liquid fractions of ensiled grass biomass including lactic acid and amino acids,[11] whereas the residual presscake has potential as a combustible feedstock.[12] Alternatively, residual biomass may be used to produce bioethanol[9] or biogas.[13] Polyphenols have been identified as potential high value coproducts in a biorefinery, and processes have been developed for their recovery from olive mill wastewater.[14] These classes of compounds are of interest to the pharmaceutical, cosmetics, and nutraceutical sectors, and there is an increasing body of evidence demonstrating the health benefits of plant phenols.[15] Orchard grass is reported to be a traditional remedy for tumors, kidney, and bladder ailments.[16]

Here we report on the identification and quantitative analysis of flavonoids/phenolic compounds in a commercial variety of orchard grass, 'Abertop'. This variety has been developed to provide a high-yielding conservation cut and good ground cover. We monitor the phenol profile during the transition from vegetative stage to flowering stage, which corresponds with maximum yield. We also present data on changes in soluble phenol profile following a short period of ensiling.

MATERIALS AND METHODS

Chemicals. HPLC grade methanol was obtained from Fisher Scientific (Loughborough, UK), and commercial standards for phenolic acids and flavone aglycones were from Sigma-Aldrich (Gillingham, UK) and PhytoLab (Vestenbergsgreuth, Germany).

Plant Material. *D. glomerata* cv. Abertop was established in 1.2 m^2 plots (replicated × 4) at Aberystwyth University, Gogerddan, Aberystwyth (52°19′22″ N, 3°56′54″ W). Plots were harvested with a Haldrop plot harvester at regular intervals during May 2010. Plant yields were recorded during harvesting. Following harvesting, plant material was transported to the laboratory within a period of 1 h and stored at −20 °C for subsequent analysis.

Ensiling. Plant material was harvested from plots on May 8, 2010. Leaf material was chopped into 1 in. lengths and packed into three silage tubes (approximately 200 mL size) and capped with silo air traps. Tubes were incubated at 25 °C and opened after 2 weeks. Freshly sampled material was extracted for phenols, and remaining material was frozen at −20 °C for further chemical analysis. Samples were analyzed for dry matter content, pH, volatile fatty acids, and water-soluble carbohydrates.

Extraction and Analysis of Water-Soluble Carbohydrates and Organic Acids. Fresh and ensiled material was extracted by immersing 2.5 g in 10 mL of water. Samples were homogenized and centrifuged at 3000*g* for 15 min. The supernatant was recovered and the pellet discarded. Fifty microliters of extract was added to 950 μL of a buffer comprising 5 μM H_2SO_4, containing 5 μM crotonic acid as an internal standard. These samples were analyzed with a Jasco HPLC system (Jasco Ltd., Great Dunmow, Essex, UK), and the column used was a 150 mm × 7.8 mm Rezex ROA-Organic Acid (Phenomenex, Macclesfield, UK) with a mobile phase of 5 μM H_2SO_4 at 0.6 mL/min. Peaks were detected with a refractive index detector, identified using Jasco EZChrom Elite HPLC software (Jasco Ltd., Essex, UK), and quantitated by comparison with standard samples of fructan, sucrose, glucose, fructose, lactic acid, and acetic acid.

Phenol Extraction. Plant material was chopped and immersed in 70% methanol at 80 °C for 5 min to inactivate polyphenol oxidases (typically 1 g FW of sample was extracted for monitoring variation over a growing season, and a bulk sample of approximately 6 g was extracted for detailed profiling of phenolic compounds). The supernatant was decanted, and the pellet was extracted with methanol/water (8:2) and centrifuged for 20 min at 3000*g*. The fractions were then combined to give a total soluble phenol extract. Methanol was removed from the extracts by rotary evaporation, and extracts were then partially purified on a 500 mg Sep-Pak C_{18} 3 cc Vac RC cartridge (Waters Ltd., Elstree, UK). Cartridges were prepared with 4 mL of methanol (100%) followed by 4 mL of 5% acetic acid. Samples were then loaded, washed with 2.5 mL of water, and subsequently eluted with 4 mL of methanol (100%), dried down at 50 °C under nitrogen, and redissolved in 70% MeOH.

HPLC. Flavonoid and phenolic end products were analyzed by reverse-phase HPLC with online photodiode array detection with and without electrospray ionization−ion trap mass spectrometry.

HPLC analysis was carried out on a Waters system with a 996 photodiode array detector (PDA) and a 8 mm × 100 mm i.d., 4 μm, C_{18} Nova-Pak radial compression column (Waters), equilibrated with 100% solvent A (5% acetic acid) at a flow rate of 2 mL/min.

Compounds were eluted by linear gradient to 100% solvent B (100% methanol) over 50 min and monitored from 240 to 400 nm. Compounds were quantitated by comparison to calibration curves for appropriate standards.

HPLC−ion trap mass spetrometry (HPLC-MS^n) analysis was performed on a Thermo Finnigan LC-MS system (Thermo Electron Corp., Waltham, MA, USA) comprising a Finnigan Surveyor PDA Plus detector and a Finnigan LTQ linear ion trap with ESI source, and the column used was a 3.9 mm × 100 mm i.d., 4 μm, C_{18} Nova-Pak (Waters). The autosampler tray temperature was maintained at 5 °C and the column temperature at 30 °C. Sample injection volume was typically 10 μL, the detection wavelength was set to 240−400 nm, and the flow rate was 1 mL/min, with 100 μL/min going to the mass spectrometer. The mobile phase consisted of water/formic acid (A; 100:0.1, v/v) and MeOH/formic acid (B; 100:0.1, v/v). The column was equilibrated with 95% solvent A, and the percentage of B increased linearly to 60% over 65 min.

Ionization parameters were optimized by infusion of chlorogenic acid standard at a constant rate into the LC flow. Mass spectra were acquired in negative ionization mode with the following interface and MS parameters: nitrogen sheath gas, 30 arbitrary units; nitrogen auxiliary gas, 15 units; spray voltage, 4 kV; capillary temperature, 320 °C; capillary voltage, −1 V; and tube lens offset, −68 V. MS/MS fragmentation was carried out at a normalized collision energy of 35% and isolation width m/z 2.0.

Purification of Selected Compounds and Acid Hydrolysis. Abundant phenolic compounds were purified by reverse-phase chromatography with the Waters system described above. Fractions were concentrated by rotary evaporation, and a portion was retained for acid and alkali hydrolysis. Acid hydrolysis was performed by combining a volume of purified compound with an equal volume of 2 M HCl. The solution was heated to 90 °C for 1 h, and the pH was then adjusted to 4−5 with NaOH. Alkali hydrolysis was performed by combining a volume of purified compound with an equal volume of 2 M NaOH. The solution was incubated for 16 h under N_2, and the pH was then adjusted to 4−5 with HCl. Purified compounds and neutralized hydrolysates were partially purified on a 500 mg Sep-Pak C_{18} 3 cc Vac RC cartridge (Waters Ltd.) as described above, dried down at 50 °C under nitrogen, and redissolved in 70% MeOH.

Antioxidant Assays. Antioxidant activity was expressed as trolox equivalents (TE) by comparison of tested compounds to trolox calibration curves in the range of 5−50 μmol/L. The diphenylpicrylhydrazyl (DPPH) radical scavanging assay was carried out according to the method of Brand-Williams et al.[17] A 140 μM solution of DPPH was prepared in 50:50 methanol/water. This was combined with an equal volume of sample in a 1.5 mL cuvette, with 50:50 methanol/water as a control. Mixtures were left to stand for 30 min at room temperature, after which time absorbance at 517 nm was determined. A range of sample concentrations were tested to identify the range giving partial reduction of the DPPH in the reaction mixture.

A second radical-scavanging assay based on the positive radical ion, $ABTS^{\bullet+}$, was carried out according to the protocol of Re et al.[18] The radical form was prepared by adding potassium persulfate to a 7 mM stock solution of ABTS to give a final concentration of 2.45 mM and allowing the mixture to stand for 16 h at room temperature in the dark. At the time of assay, the $ABTS^{\bullet+}$ solution was diluted with water to give an absorbance of 0.700 (±0.2) at 743 nm. Sample volumes of 25 μL were added to 1475 μL of reagent in a 1.5 mL cuvette, and absorbance was measured after 6 min. A range of sample concentrations were tested to identify the range giving partial reduction of the $ABTS^{\bullet+}$ in the reaction mixture.

The ferric reducing capacity of samples was measured by the FRAP assay, which detects reduction of the ferric ion (Fe^{3+}) to the ferrous ion (Fe^{2+}).[19] The assay reagent was prepared by combining 10 mM TPTZ, 20 mM ferric chloride, and 300 mM sodium acetate buffer (pH 3.6) in the ratio of 1:1:10. Sample volumes of 25 μL were added to 1475 μL of reagent in a 1.5 mL cuvette, and absorbance was measured at 593 nm after 10 min.

RESULTS AND DISCUSSION

Phenol Profile. Figure 1 shows a typical profile of soluble phenols extracted from 'Abertop'. Analysis by LC ESI-MS with PDA detection revealed approximately 50 compounds that could be easily distinguished (Table 1). Several compounds were readily identified by comparison of retention times and fragmentation patterns with known standards. Others were tentatively identified by the similarity of UV absorbance characteristics and fragmentation patterns with known standards and compounds reported in the literature.[5,20,21] Representative structures are shown in Figure 2.

Compounds identified by LC-MS include hydroxycinnamoyl esters, flavone glycosides, salvianolic acids, and hydroxycinnamoyl flavone conjugates. Relatively abundant hydroxycinnamate esters, which have been previously reported by Parveen et al.[4] in orchard grass, were identified in extracts including 5-caffeoyl quinate (chlorogenic acid), 2-*O*-caffeoylisocitrate, and 2-*O*-caffeoylisocitrate 6-methyl ester (compounds **5**, **9**, and **18a** as shown in Table 1).

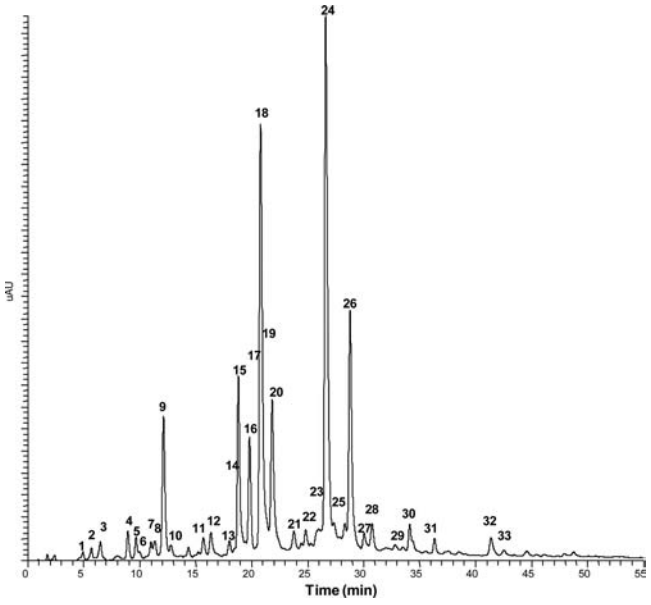

Figure 1. HPLC chromatogram showing separation of soluble phenolic compounds in extracts of orchard grass detected by photodiode array at 340 nm. Peak numbering corresponds with Table 1.

Hydroxycinnamate Esters. A number of hydroxycinnamate esters that have not previously been reported in orchard grass were detected in 'Abertop' extracts. Compound **7** with M_r 268 Da at t_R 11 min showed characteristics consistent with a caffeoyl/feruloyl ester with UV maxima at 303sh and 326 nm. MS^2 of m/z 267 in negative mode produced a base peak at m/z 161 $[\text{caffeic acid} - H_2O - H^+]^-$ and a secondary peak at m/z 105 $[\text{glyceric acid} - H^+]^-$. Further fragmentation of the m/z 105 ion produced a base peak at m/z 75 $[\text{glyceric acid} - \text{HCOH} - H^+]^-$ and corresponded with the fragmentation pattern observed for glyceric acid. This compound is identified as caffeoylglycerate. 2-Caffeoylglycerate has previously been identified in extracts of the medicinal plant, *Mercurialis perennis* L.[22]

A second hydroxycinnamoyl ester (M_R 352 Da), compound **22a**, was detected at t_R 24.8 min, showing maximal UV absorbance at 315 nm. This compound produced an MS^2 base peak at m/z 163 $[\text{coumaric acid} - H^+]^-$ and secondary ions at m/z 169 $[\text{methylisocitric acid} - 2 \times H_2O - H^+]^-$, 205 $[\text{methylisocitric acid} - H^+]^-$, and 119 $[\text{coumaric acid} - CO_2 - H^+]^-$. Further fragmentation of the 205 ion in MS^3 produced a base peak at m/z 173 $[\text{methylisocitric acid} - CH_3OH - H^+]^-$ and secondary ions at m/z 111 $[\text{methylisocitric acid} - CH_3OH - CO_2 - H_2O - H^+]^-$ and 155 $[\text{methylisocitric acid} - CH_3OH - H_2O - H^+]^-$. Caffeoylisocitrate methyl ester has been previously identified in orchard grass,[4] and this compounded yielded an ion at m/z 205 in MS^2 with an equivalent fragmentation pattern in MS^3 to the 205 ion reported here. On this basis this compound is identified as coumaroylisocitrate methyl ester.

Compound **8** with M_r 430 Da showed a fragmentation pattern related to that of compound **7** and was detected at t_R 11.4 min. This compound also showed a UV profile consistent with a caffeoyl/feruloyl ester with UV maxima at 300sh and 324 nm. It produced an MS^2 base peak in negative mode at m/z 267 corresponding to the neutral loss of 162 Da and secondary peaks at m/z 179 and 411 $[M - H_2O - H^+]^-$. The 179 ion was confirmed as $[\text{caffeic acid} - H^+]^-$ in MS^3. Further fragmentation of the 267 ion in MS^3 yielded a base peak at m/z 249 $[267 - H_2O - H^+]^-$ and secondary peaks at m/z 113, 175, 85, 87, and 205, and the 249 ion in MS^4 yielded a base peak at 113 and secondary peaks at 205, 157, 87, and 85. This indicates that the 157 ion yielded in MS^4 is released from the 175 ion yielded in MS^3. These fragments are consistent with neutral losses of CO_2 (−44 Da), dehydrophenoxy radical (−92 Da), dehydrophenoxy radical and CO_2 (−136 Da), and dehydrophenoxy radical, CO_2, and C_2H_2/C_2H_4 (−162/−164 Da). These fragments may be accounted for by whole or partial loss of a coumaroyl moiety, and the ion at m/z 87 is consistent with a dehydro-glycerate moiety. On this basis it is proposed that compound **8** is caffeoylglycerate conjugated with coumaric acid formed via an oxidative radical coupling reaction.

Caffeic Acid Derivatives. Antioxidant, antithrombotic, antitumor, and antiviral properties of the popular Asian medicinal herb, danshen (*Salvia miltiorrhiza*), have been attributed to constituent caffeic acid derivatives known as salvianolic and lithospermic acids.[23] A number of compounds with structural properties consistent with these caffeic acid derivatives were detected in orchard grass extracts. These included compounds **15**, **19a**, **19b**, **22b**, **23c**, **23d**, **25a**, and **25b** with M_r 360, 492, 538, 556, and 736 Da. ESI MS^n spectra of negative ions showed characteristic fragmentation patterns of lithospermic and salvianolic acids with products derived from neutral losses of 198, 180, 162, 110, and 44 Da corresponding to losses of 3,4-dihydroxyphenyl-lactic acid (danshensu), caffeic acid, caffeic acid dehydrate, catechol, and CO_2 moieties, respectively. They also yielded characteristic fragment ions of salvianolic acids at m/z 537, 493, 383, 339, 313, 295, 197, and 179.[24]

Compound **25b** with M_r 360 Da shows retention time, UV absorption profile (maxima at 276 and 331 nm), and fragmentation pattern consistent with those of rosmarinic acid (MS^2 fragments at m/z 161, 179, and 197). The remaining members of the group have been identified on the basis of their MS and UV spectra where detected.

Compound **23d** with M_r 492 Da at t_r 26.0 min shows characteristic features of caffeic acid derivatives. This compound showed a base peak in negative mode at m/z 339 and a secondary peak at m/z 447 corresponding to neutral losses of 152 and 44 Da. The fragmentation pattern suggests a molecular structure consistent with lithospermic acid less CHOOH. The loss of 152 Da is equivalent to the loss of 198 Da observed during fragmentation of lithospermic acid in negative mode resulting from a cleavage of the ester bond between the carboxyl oxygen and second oxygen atom, yielding a negative ion at m/z 339 as observed here. Other fragments in common with those yielded by lithospermic acid include negative ions at m/z 295 and 185. Other fragments observed include ions at 447 and 337, which may correspond with ions observed at m/z 493 and 383 in lithospermic MS spectra (447 + CHOOH and 337 + CHOOH, respectively).

Compounds **19b** and **25a** with M_r 556 and 736 Da at t_r 21.6 and 27.3 min, respectively, yielded fragment ions in negative MS at m/z 537 and 717, respectively, corresponding with lithospermic acid and lithospermic acid B. Similar compounds with equivalent masses have been reported in sage tea.[25] A 736 Da isomer gave rise to a base peak at m/z 537 (198 Da loss), which in MS^3 yielded fragment ions typical of lithospermic acid as reported by Zeng et al.[24]

Caffeic acid derivatives, including rosmarinic, lithospermic, and salvianolic acids, have potent radical-scavenging activity related to the number of catechol moieties contained in the

structure and are reported to have a range of protective and antimicrobial properties.[26,27]

Hydroxycinnamate Esters and Flavone Glycoside Conjugates. UV combined with MS analysis revealed a novel group of compounds in *D. glomerata* extracts with distinctive fragmentation patterns in negative mode MS. These compounds show neutral losses consistent with cleavage of ester-linked organic acids and, where detected, UV absorption maxima at 269−270 and 349 nm. UV profiles were typical of the profile produced by orientin (luteolin-8-*C*-glucoside) standard. Compound **24** with M_r 800 Da eluted at t_R 26.6 min and in negative mode produced a mass spectrum with a base peak at m/z 581 and further peaks at m/z 607 and 625. This corresponds to neutral losses of 218, 192, and 174 Da, respectively. Interestingly, full MS

Table 2. Variation in Composition and Yield of Orchard Grass during the Transition from Vegatative to Flowering Stage

	May 8	May 13	May 18	May 23	May 29
crude protein (g/kg DM)	166.6	161.3	129.1	126.9	106.9
WSC (g/kg DM)	152.7	114.3	165.4	150.9	130.6
NDF (g/kg DM)	430.9	480.0	465.1	469.1	522.4
ADF (g/kg DM)	206.0	236.2	230.8	234.7	264.0
DMD (g/kg DM)	759.6	722.4	744.8	720.2	692.1
yield (t/ha)	2.58	3.05	3.68	3.87	6.36

in positive mode revealed major ions at m/z 801 and 627 at t_R 26.6, whereas only one ion was observed in negative mode, suggesting a neutral fragment of 174 Da is readily lost in positive mode. Losses of 192 and 174 Da correspond to cleavage of an isocitrate or quinate moiety on either side of the ether linkage in an ester bond. The neutral loss of 218 Da could be accounted for by cleavage at the far side of the carbonyl group (174 + 44 Da). Further fragmentation of the 581 ion in MS^3 yielded ions at m/z 461 and 491, which correspond to neutral losses of 120 and 90 Da, typical of C-linked flavonoid hexosides.[28] Additional fragments at m/z 471 and 351 correspond to neutral losses of 110 and 230 Da. These may be accounted for by loss of a catechol moiety (110 Da) and a catechol moiety combined with a C-linked hexoside fragment (110 and 120 Da). Spectra in MS^4 of the ions at m/z 491 and 461 showed base peaks at m/z 381 and 351, respectively, corresponding to the loss of a catechol moiety. Compound **24** was purified by reverse phase chromatography and incubated with 1 M HCl with heat or with 1 M NaOH at room temperature to hydrolyze ester and O-glycosidic linkages. Major products of acid and alkali hydrolysis experiments included compounds with M_r 626, 582, and 472 Da. These compounds yielded identical fragment ions in MS^2 corresponding to fragment ions described above and may be accounted for by hydrolysis of ester linkages, acid-catalyzed decarboxylation, and release of pyrocatechol by decomposition. Minor products included compounds with M_r 192, 354, and 447 Da. These compounds showed fragmentation patterns identical to those of isocitric acid, 2-*O*-caffeoylisocitrate, and orientin.

On the basis of this evidence, this molecule is composed of 2-*O*-caffeoylisocitrate and orientin residues. The fragmentation patterns observed in MS^n experiments including the release of isocitrate and catechol moieties and CO_2 indicate that this compound is formed by a condensation reaction with bonds formed between C2 and C3 on the alkyl side chain of the caffeoyl moiety and the luteolin B-ring. Similar condensation products include naturally occurring oxyneolignans, americanin A[29] and eusiderin,[30] and the coumarinolignoid, daphneticin.[31] Other related compounds include a hydroxcinnamate−mandelonitrile conjugate, which has been reported in *Miscanthus* × *giganteus* stem extracts.[32] These compounds are postulated to be formed by oxidative coupling mechanisms, and conjugates identified in orchard grass extracts may be formed by similar pathways. Activity of plant oxidative enzymes during the extraction process could potentially catalyze formation of these products. To eliminate this possibility, we repeated the extraction procedure including 50 mM ascorbic acid in the extraction solvent. An identical profile of phenolic compounds was obtained by this method (data not presented), indicating that these conjugates were not formed during the extraction procedure.

dx.doi.org/10.1021/jf4040749 | J. Agric. Food Chem. 2014, 62, 468−475

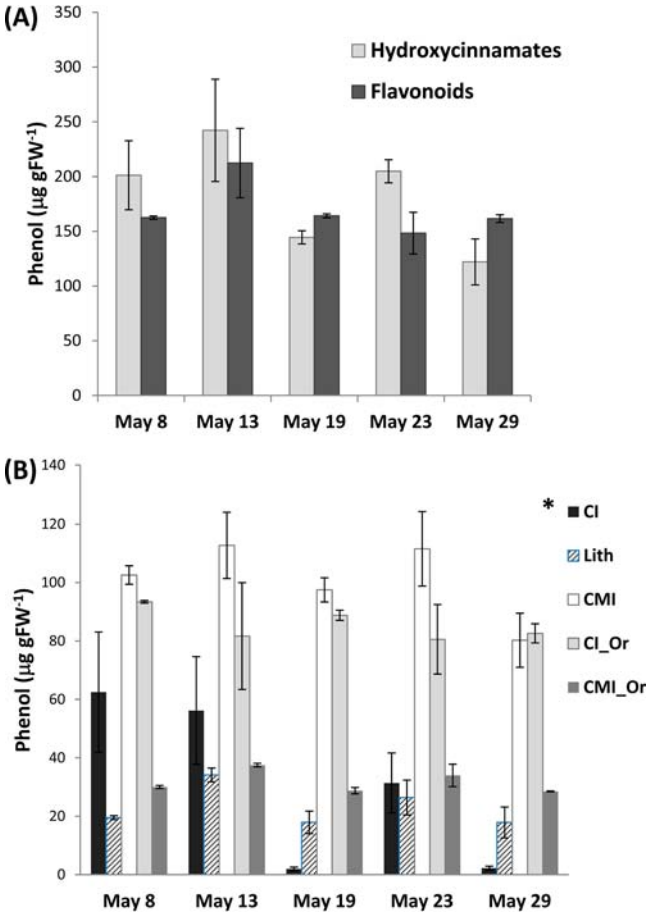

Figure 4. Variation in phenolic composition of orchard grass during the transition from vegetative to flowering stage: (A) changes in total flavonoids and hydroxycinnamates; (B) changes in abundant phenolic compounds. CI, 2-*O*-caffeoylisocitrate, **9**; Lith, lithospermic, **15**; CMI, 2-*O*-caffeoylisocitrate 6-methyl ester, **18a**; CI-Or, 2-*O*-caffeoylisocitrate orientin conjugate, **26**; CMI-Or, 2-*O*-caffeoylisocitrate methyl ester orientin conjugate, **28**.

Other compounds assigned to this group on the basis of fragmentation patterns include compounds **23a**, **23b**, **26**, **28**, and **29** with M_r 744, 714, 814, 814, and 828 Da. Common fragments detected in negative mode ESI MS^n spectra include ions at m/z 625, 607, 581, 491, 487, and 461 Da. Compounds with M_r 714, 744, and 814 Da have been tentatively identified as conjugates of orientin with caffeoylthreonate, caffeoylglycerate, and caffeoylisocitrate methyl ester, respectively (Figure 3), and a compound with M_r 828 Da has a fragmentation pattern consistent with a conjugate of hispidulin-*C*-glycoside with caffeoylisocitrate methyl ester.

Variation in Phenolic Profiles during Transition from Vegetative to Flowering Stage. Orchard grass production was monitored during transition from vegetative to flowering stage, which corresponds with maximum yield of biomass. Table 2 shows changes in composition in harvested material. Changes in composition reflect the alteration in morphology that occurs during flowering, that is, increasing proportion of stem tissue with a corresponding decrease in leaf tissue. Neutral detergent fiber (NDF) and acid detergent fiber (ADF) show an increasing trend, whereas the opposite pattern is observed with dry matter digestibility and crude protein, which generally decrease with plant maturity. Biomass yield showed a steady increase during this period. Figure 4A shows changes in total hydroxycinnamate and flavonoid content during flowering. Levels remained high throughout this period, with potential yields of hydroxycinnamates and flavonoids ranging from 2.6 to 4.0 kg/ha and from 2.1 to 5.1 kg/ha, respectively. Levels of the most abundant phenolic compounds are shown in Figure 4B. These included compounds 2-*O*-caffeoylisocitrate, **9**; 2-*O*-caffeoylisocitrate methyl ester, **18a**; lithospermic acid isomer, **19**; 2-*O*-caffeoylisocitrate orientin conjugate, **24**; and 2-*O*-caffeoylisocitrate methyl ester orientin conjugate, **26**. Some variation in content was observed with 2-*O*-caffeoylisocitrate concentrations decreasing over time. Analysis of the antioxidant activity of these compounds by a range of assays, including DPPH, ABTS, and FRAP, showed levels of activity comparable with that of trolox (Table 3) and indicate that the lithospermic isomer is the most potent antioxidant of the compounds tested.

Table 4. Composition of Fresh and Ensiled 'Abertop' Plant Material

	fresh	ensiled
DM (g/kg fw)	22.00	19.13
pH	6.40	5.95
WSC (g/kg dm)	167.41	147.59
lactic acid (g/kg dm)		23.86
acetic acid (g/kg dm)		14.31

Ensiling. Orchard grass was ensiled in laboratory silos for 14 days to investigate the effect of conservation on the phenol profile of the plant material. The composition of the silage is shown in Table 4. Limited fermentation occurred during this period with reduced production of fermentation acids, minimal depletion of WSC content, and little change in pH.

Analysis of phenolic compounds in ensiled orchard grass showed that many of these compounds persisted during the ensiling period (Figure 5). Whereas all compounds were not fully resolved in these extracts, differences in compound abundance were verified by total ion counts. There was evidence of hydrolysis of caffeoyl esters with accumulation of free caffeic acid, **4a**. There was also evidence of further catabolism of caffeic acid with accumulation of dihydroxystyrene (X, Figure 5). 2-*O*-Caffeoylisocitrate, **9**, showed a decrease, while an increase in the lithospermic acid isomer, **15**, was also evident. It is noteworthy

that dramatic increases in levels of the compound salvianolic acid B, which is a bioactive component in the medicinal herb danshen (*Salvia miltiorrhiza*), were observed during postharvest drying of the herbal material.[33] This observation may be significant as this component is potentially of therapeutic value.

This study suggests that restricted silage fermentation may be advantageous from a biorefining perspective. Limited degradation of metabolites offers increased scope for recovery of high-value components, and a high WSC content provides a fermentable substrate in extracted juice for the production of ethanol or lactic acid.

In summary, there is currently much interest in developing biorefineries based on grass feedstocks, and ensilage is the preferred method for stabilizing harvested biomass for biorefining and biofuel production. Processes have been developed at pilot scale for the extraction of amino acids and lactic acid from silage juice.[10] Recovery of other potential high-value components such as soluble phenolic compounds with bioactive properties can improve the economic feasibility of these biorefineries. It is noteworthy that we have demonstrated in previous experiments that compounds identified in orchard grass can also be extracted with ethanol, a solvent compatible with the production of nutraceuticals. Moreover, biorefining can enable recovery of these compounds on a large scale as coproducts when profit margins would prohibit an operation based solely on these molecules.

Supporting Information

ABSTRACT: Prothrin, a synthetic pyrethroid insecticide, was synthesized from the biomass-derived platform chemical 5-(chloromethyl)furfural in six steps and overall 65% yield. Two structural analogues of prothrin were also prepared following the same synthetic approach. Preliminary testing of these furan-based pyrethroids against the yellow fever mosquito *Aedes aegypti* indicates promising insecticidal activities.

KEYWORDS: *biomass, furans, pyrethroids, synthesis, 5-(chloromethyl)furfural*

INTRODUCTION

Previously, we have described the synthesis of the natural herbicide δ-aminolevulinic acid (**2**)[1] and the anti-ulcer drug ranitidine (Zantac) (**3**)[2] from the renewable platform chemical 5-(chloromethyl)furfural (CMF) (**1**), which can be derived in a single step from either sugars, cellulose, or raw biomass in isolated yields between 80 and 90%.[3] In a continuing effort to expand the derivative markets of CMF (**1**), we now report a simple, six-step approach to the furan-based pyrethroid insecticide prothrin (**4**) alongside five-step routes to analogues **5** and **6**.

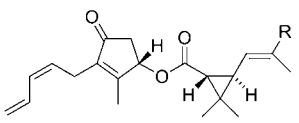
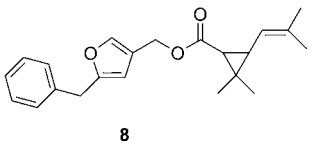
6 R=OPh

The naturally occurring insecticide pyrethrum, isolated from flowers of *Chrysanthemum* sp., has been in commercial use for over 100 years.[4] Elucidation of the chemical structure of its active constituents [i.e., pyrethrins (**7**)] in 1924 ultimately led to the production of several synthetic pyrethroids.[5] As a result of extensive structure−activity studies, the insecticidal and toxicological properties of these compounds typically surpass those of the natural products. Prothrin (**4**) is a member of the synthetic furan-based pyrethroids,[6] which class also includes resmethrin (**8**), a high-volume commercial insecticide.[7]



7a R= Me
7b R= CO_2Me



8

Pyrethroids are generally well-suited for agricultural and household uses because of their biodegradability and low mammalian toxicity, and demand for these products has increased in the past decade with the declining use of organophosphates. However, all United States Environmental Protection Agency (U.S. EPA)-registered pesticides are regularly submitted to a process by which they are systematically reviewed to establish that they can still perform their intended function without unreasonable adverse effects on human health or the environment, and this process applies constant pressure on the development of new generations of products that are even more selective in their mode of action.

The synthesis of prothrin (**4**) was first reported in 1969 and is always completed by esterification of 5-propargylfurfuryl alcohol (**10**) with chrysanthemic acid chloride.[6] Because chrysanthemic acid is commercially available as a synthetic version of the natural product,[8] the actual target of prothrin syntheses becomes compound **10**, and most approaches to this molecule have centered around either the reaction of a metalated derivative of furfuryl alcohol (**9**) with a propargyl electrophile[9] or a metalated acetylene with a 5-methyl-substituted furfuryl alcohol derivative incorporating a leaving group (**11**) (Scheme 1).[10,11] Looking to the structures of both compound **10** and CMF (**1**), it becomes apparent that a concise route connecting them should be achievable, and we

[a]Reagents: *a*, 1-butanol, concentrated HCl (catalyst), 98%; *b*, TMS−acetylene, CuI, K_2CO_3, CH_3CN, 55 °C, 88%; *c*, 1 M aqueous HCl, 97%; *d*, $NaBH_4$, MeOH, 0 °C, 98%; *e*, chrysanthemic acid chloride, benzene, reflux, 95%; and *f*, Bu_4NF, THF, −20 °C, 84%.

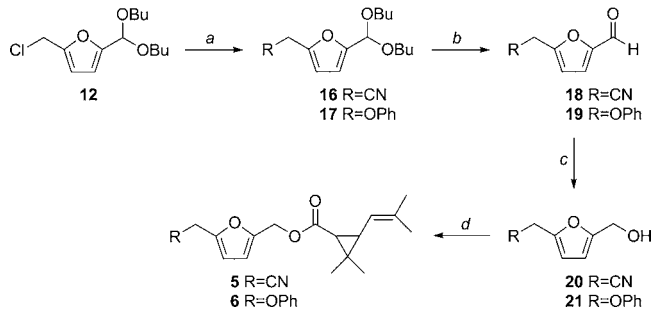
were naturally attracted to published methods that involved CMF (**1**) as a precursor to structure **11**[10] but considered the use of organometallics a serious drawback to any industrial application of this synthetic approach. We proposed that the installation of the propargyl group could instead be achieved by copper(I)-mediated coupling of the chloromethyl functionality to an acetylene derivative.[12] The synthesis is shown in Scheme 2.

Attempts to couple compound **1** and trimethylsilyl (TMS) acetylene in the presence of the aldehyde group were unsuccessful; thus, CMF (**1**) was protected as the dibutyl acetal (**12**). Coupling of the alkyne to compound **12** proceeded to give compound **13** in good yield, which was hydrolyzed to the furfural derivative (**14**). Reduction of compound **14** with sodium borohydride gave alcohol **15**. Compound **15** is essentially a protected form of compound **10**, but to complete the synthesis of prothrin (**4**), we esterified compound **15** with chrysanthemic acid chloride and, finally, desilylated with tetrabutylammonium fluoride. It was necessary to retain the TMS protecting group until the end of the synthesis, because any attempt to remove it at an earlier stage resulted in gradual isomerization of the triple bond to the allene.

The above-described route to prothrin (**4**) does not necessitate the synthesis of a 5-methylfurfuryl precursor to compound **10** but rather derives it directly from biomass. It also involves no organometallic reagents, requires no chromatographic separations until the final step, and proceeds in an overall 65% yield. The efficiency of this approach and the ready availability of CMF (**1**) presented an attractive opportunity to carry out analoging studies on the prothrin framework.

A highly apparent analogue to prothrin (**4**) is the cyanomethylfuran derivative (**5**), and this was targeted for synthesis along with the known resmethrin-like aryloxymethyl analogue (**6**).[13] Thus, in the approach to analogues **5** and **6**, the acetylene nucleophile is exchanged for cyanide and phenoxide, respectively. We had initially supposed that conversion of CMF (**1**) into acetal **12** would not be necessary in these cases, because compound **1** is known to be effectively substituted with nucleophiles, such as alcohols[3a] and azide anion.[1] However, attempts to directly substitute the chloromethyl group in compound **1** with either phenol or cyanide were unsuccessful. From substituted acetals **16** and **17**, the syntheses proceeded as for compound **4** but are one step shorter, because no deprotection is required at the end (Scheme 3). The overall yields of analogues **5** and **6** from CMF (**1**) were 51 and 70%, respectively.

Scheme 3. [a]



[a]Reagents: *a*, for compound **16**, NaCN, DMSO, 85 °C, 78%; for compound **17**, phenol, K_2CO_3, DMSO, 50 °C, 87%; *b*, 1 M aqueous HCl; *c*, $NaBH_4$, $MeOH/CH_2Cl_2$, 0 °C; and *d*, chrysanthemic acid chloride, benzene, reflux.

MATERIALS AND METHODS

2-(Chloromethyl)-5-(dibutoxymethyl)furan (12).[14] CMF (**1**) (2.00 g, 13.8 mmol) was dissolved in 1-butanol (40 mL), and concentrated HCl (0.1 mL) was added. The solvent was then removed using a rotary evaporator under high vacuum (0.1 mmHg) while cooling the evaporating flask in an ice−water bath. The product **12** was obtained as a yellow oil (3.721 g, 98%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.32 (s, 1H), 6.29 (s, 1H), 5.47 (s, 1H), 4.53 (s, 2H), 3.51 (m, 4H), 1.52 (m, 4H), 1.35 (m, 4H), 0.88 (t, 7.3 Hz, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 153.1, 150.1, 110.4, 109.4, 96.5, 65.7, 37.7, 31.9, 19.5, 14.0. HRMS: $(M - OBu)^+$, $C_{10}H_{14}O_2Cl$ calculated, 201.0682; found, 201.0678.

2-(Dibutoxymethyl)-5-[3-(trimethylsilyl)prop-2-yn-1-yl]furan (13). Copper(I) iodide (0.269 g, 1.41 mmol), potassium carbonate (0.328 g, 2.37 mmol), and (trimethylsilyl)acetylene (0.21 mL, 0.15 g, 1.5 mmol) were added to a solution of compound **12** (0.328 g, 1.19

dx.doi.org/10.1021/jf4045843 | J. Agric. Food Chem. 2014, 62, 476−480

mmol) in anhydrous acetonitrile (10 mL) under argon. The suspension was heated to 55 °C and stirred overnight. Saturated aqueous $NaHCO_3$ (50 mL) was added and the layers were separated. The aqueous layer was extracted with dichloromethane, the organic layers were combined and dried over sodium sulfate, and the solvent was evaporated to give compound **13** as a yellow oil (0.353 g, 88%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.31 (d, 3.1 Hz, 1H), 6.17 (d, 3.1 Hz, 1H), 5.45 (s, 1H), 3.61 (s, 2H), 3.56−3.44 (m, 4H), 1.59−1.52 (m, 4H), 1.40−1.32 (m, 4H), 0.90 (t, 7.5 Hz, 6H), 0.16 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 151.0, 150.1, 109.0, 106.7, 101.0, 96.5, 86.5, 65.4, 31.8, 20.1, 19.4, 13.9, 0.0. HRMS: $(M - OBu)^+$, $C_{15}H_{23}O_2Si$ calculated, 263.1462; found, 263.1469.

5-[3-(Trimethylsilyl)prop-2-yn-1-yl]furfural (14). A mixture of compound **13** (0.210 g, 0.624 mmol) and 1 M HCl (10 mL) was stirred for 2 h and then extracted with dichloromethane. The combined organic layers were dried over sodium sulfate and the solvent was evaporated to give compound **14** as a yellow solid (0.125 g, 97%) with a melting point (mp) of 46 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.55 (s, 1H), 7.19 (d, 3.6 Hz, 1H), 6.49 (d, 3.6 Hz, 1H), 3.72 (s, 2H), 0.18 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 177.2, 157.5, 152.5, 123.1, 109.9, 98.9, 88.1, 20.5, −0.1. HRMS: $(M + H)^+$, $C_{11}H_{15}O_2Si$ calculated, 207.0835; found, 207.0833.

2-(Hydroxymethyl)-5-[3-(trimethylsilyl)prop-2-yn-1-yl]furan (15). Sodium borohydride (0.0720 g, 1.90 mmol) was added to a solution of compound **14** (0.391 g, 1.90 mmol) in methanol (10 mL) at 0 °C. The mixture was allowed to come to room temperature over 2 h with stirring. The solvent was evaporated and the residue was taken up in dichloromethane (25 mL), which was washed with saturated aqueous NH_4Cl solution. The aqueous layer was back-extracted with dichloromethane, the organic layers were combined and dried over sodium sulfate, and the solvent was evaporated to give compound **15** as a pale yellow oil (0.388 g, 98%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.21 (d, 3.0 Hz, 1H), 6.16 (d, 3.0 Hz, 1H), 4.56 (s, 2H), 3.62 (s, 2H), 1.73 (s, 1H), 0.17 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 153.4, 150.2, 108.8, 107.1, 101.1, 86.6, 57.3, 20.0, 0.0. HRMS: $(M + H)^+$, $C_{11}H_{17}O_2Si$ calculated, 209.0992; found, 209.0987.

Mixture of (±)-*cis*- and (±)-*trans*-{5-[3-(Trimethylsilyl)prop-2-yn-1-yl]furan-2-yl}methyl-2,2-dimethyl-3-(2-methylprop-1-en-1-yl)cyclopropane-1-carboxylate. Compound **15** (0.157 g, 0.754 mmol) was dissolved in dry benzene (25 mL) under argon. A mixture of (±)-*cis*- and (±)-*trans*-chrysanthemic acid chloride (0.156 g, 0.836 mmol) was added and the solution was heated at reflux for 5 h. The reaction was allowed to cool to room temperature and the solvent was evaporated. Excess chrysanthemic acid chloride was removed under high vacuum (0.1 mmHg) to give the product as a brown oil (0.257 g, 95%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.32 (m, 1H, H_d and $H_{d'}$), 6.19 (m, 1H, H_c and $H_{c'}$), 5.38 (d, 8.5 Hz, 0.4H, H_j), 5.09−4.90 (m, 2H, H_e and $H_{e'}$), 4.88 (d, 7.7 Hz, 0.6H, $H_{j'}$), 3.62 (s, 2H, H_b and $H_{b'}$), 2.06 (dd, 7.7 Hz, 5.5 Hz, 0.6H, $H_{i'}$), 1.88 (t, 8.5 Hz, 0.4H, H_i), 1.75−1.65 (m, 6H, H_k, $H_{k'}$, H_l, and $H_{l'}$), 1.41 (d, 5.5 Hz, 0.6 H, $H_{f'}$), 1.25−1.11 (m, 6H, H_g, $H_{g'}$, H_h, and $H_{h'}$), 0.18 (s, 9H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 172.2, 170.7, 151.1, 151.0, 149.2, 149.1, 135.6, 134.9, 121.2, 118.1, 111.6, 111.4, 107.4, 100.8, 86.7, 58.1, 57.7, 34.7, 33.1, 32.6, 31.1, 29.0, 28.9, 26.8, 26.0, 25.7, 22.2, 20.5, 20.1, 18.6, 18.4, 14.8, 0.1. HRMS: $(M + H)^+$, $C_{21}H_{31}O_3Si$ calculated, 359.2037; found, 359.1999.

Mixture of (±)-*cis*- and (±)-*trans*-Prothrin (4). A mixture of (±)-*cis*- and (±)-*trans*-{5-[3-(trimethylsilyl)prop-2-yn-1-yl]furan-2-yl}methyl-2,2-dimethyl-3-(2-methylprop-1-en-1-yl)cyclopropane-1-carboxylate (0.143 g, 0.399 mmol) was dissolved in tetrahydrofuran (THF) (10 mL) and the solution was cooled to −20 °C in a dry-ice/ethylene glycol bath. A solution of tetrabutylammonium fluoride in THF (1.0 M, 0.44 mL, 0.44 mmol) was added dropwise with stirring. After 15 min at −20 °C, saturated ammonium chloride (50 mL) was added and the aqueous layer was separated and extracted with ethyl acetate. The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated. The residue was purified by flash column chromatography on silica gel (20:1 hexanes/ethyl acetate) to give compound **4** as a pale yellow oil (0.095 g, 84%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.30 (t, 3.0 Hz, 1H, H_d and $H_{d'}$), 6.18 (d, 3.0 Hz, 1H, H_c and $H_{c'}$), 5.35 (d, 8.4 Hz, 0.4H, H_j), 5.04−4.90 (m, 2H, H_e and $H_{e'}$), 4.85 (d, 7.9 Hz, 0.6H, $H_{j'}$), 3.56 (d, 2.4 Hz, 2H, H_b and $H_{b'}$), 2.13 (t, 2.4 Hz, 1H, H_a and $H_{a'}$), 2.05 (dd, 7.9 Hz, 5.4 Hz, 0.6H, $H_{i'}$), 1.87 (t, 8.4 Hz, 0.4H, H_i), 1.72−1.65 (m, 6H, H_k, $H_{k'}$, H_l, and $H_{l'}$), 1.40 (d, 5.4 Hz, 0.6H, $H_{f'}$), 1.24−1.09 (m, 6H, H_g, $H_{g'}$, H_h, and $H_{h'}$). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 171.9, 170.5, 150.5, 150.4, 149.2, 149.1, 135.4, 134.6, 121.1, 118.1, 111.4, 111.3, 107.3, 78.6, 70.3, 57.9, 57.5, 34.5, 32.9, 32.4, 30.9, 28.8, 28.7, 26.6, 25.9, 25.5, 22.1, 20.3, 18.5, 18.4, 18.2, 14.7. HRMS: $(M + H)^+$, $C_{18}H_{23}O_3$ calculated, 287.1642; found, 287.1639.

2-(Cyanomethyl)-5-(dibutoxymethyl)furan (16). Sodium cyanide (0.174 g, 3.55 mmol) was added to a solution of compound **12** (0.811 g, 2.95 mmol) in dimethyl sulfoxide (DMSO) (6 mL) and the mixture was stirred at 90 °C under argon for 3 h. Saturated aqueous $NaHCO_3$ (50 mL) was added and the mixture was extracted with hexanes. The combined organic layers were washed with saturated aqueous $NaHCO_3$, dried over sodium sulfate, and decolorized with charcoal. The solvent was evaporated to give compound **16** as a light yellow oil (0.608 g, 78%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.34 (s, 1H), 6.28 (s, 1H), 5.44 (s, 2H), 3.60−3.42 (m, 4H), 1.65−1.47 (m, 4H), 1.45−1.27 (m, 4H), 0.90 (t, 7.5 Hz, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 152.8, 143.1, 115.6, 109.4, 109.2, 96.5, 65.9, 31.9, 19.5, 17.8, 14.1. HRMS: $(M - OBu)^+$, $C_{11}H_{14}NO_2$ calculated, 192.1019; found, 192.1019.

5-(Cyanomethyl)furfural (18). A mixture of compound **16** (0.224 g, 0.844 mmol) and 1 M HCl (10 mL) was stirred for 2 h and then extracted with dichloromethane. The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated to give compound **18** as a brown oil (0.109 g, 95%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.55 (s, 1H), 7.20 (d, 3.0 Hz, 1H), 6.56 (d, 3.0 Hz, 1H), 3.88 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 177.6, 153.2, 149.9, 122.7, 114.6, 111.7, 18.2. HRMS: $(M + H)^+$, $C_7H_6NO_2$ calculated, 136.0393; found, 136.0389.

2-(Cyanomethyl)-5-(hydroxymethyl)furan (20). Sodium borohydride (0.0560 g, 1.47 mmol) was added to a solution of compound **18** (0.155 g, 1.15 mmol) in methanol (10 mL) at 0 °C. The reaction was allowed to stir for 2 h at 0 °C. Saturated aqueous NH_4Cl (25 mL) was added and the mixture was extracted with dichloromethane. The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated to give compound **20** as a brown liquid (0.142 g, 90%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.22 (d, 3.0 Hz, 1H), 6.20 (d, 3.0 Hz, 1H), 4.48 (s, 2H), 3.72 (s, 2H), 3.16 (br, 1H, OH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 154.9, 142.8, 115.7, 109.3, 108.9, 56.9, 17.5. HRMS: $(M - OH)^+$, C_7H_6NO calculated, 120.0444; found, 120.0435.

Mixture of (±)-*cis*- and (±)-*trans*-[5-(Cyanomethyl)furan-2-yl]methyl-2,2-dimethyl-3-(2-methylprop-1-en-1-yl)-cyclopropane-1-carboxylate (5). Compound **20** (0.152 g, 1.11 mmol) was dissolved in dry benzene (25 mL) under argon. A mixture of (±)-*cis*- and (±)-*trans*-chrysanthemic acid chloride (0.247 g, 1.32 mmol) was added and the solution was heated at reflux for 2 h. The reaction was allowed to cool to room temperature and the solvent was evaporated. The residue was taken up in dichloromethane (20 mL), which was then washed with brine. The aqueous layer was back-extracted with dichloromethane. The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated. The crude product was purified by flash column chromatography on silica gel (10:1 hexanes/ethyl acetate) to give compound **5** as a light yellow oil (0.244 g, 77%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.28 (s, 1H, H_d and $H_{d'}$), 6.22 (s, 1H, H_c and $H_{c'}$), 5.28 (d, 8.3 Hz, 0.4H, H_j), 5.01−4.84 (m, 2H, H_e and $H_{e'}$), 4.80 (d, 7.0 Hz, $H_{j'}$), 3.70 (s, 2H, H_b and $H_{b'}$), 1.99 (t, 7.0 Hz, 0.6H, $H_{i'}$), 1.83 (t, 8.3 Hz, 0.4H, H_i), 1.68−1.56 (m, 6H, H_k, $H_{k'}$, H_l, and $H_{l'}$), 1.33 (d, 5.4 Hz, 0.6H, $H_{f'}$), 1.20−1.00 (m, 6H, H_g, $H_{g'}$, H_h, and $H_{h'}$). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 172.0, 170.6, 150.9, 150.8, 144.0, 144.0, 135.7, 135.0, 121.1, 118.1, 115.6, 111.8, 111.7, 109.6, 57.8, 57.4, 34.6, 33.2, 32.7, 31.0, 29.1, 28.8, 26.9, 26.0, 25.7, 22.2, 20.5, 18.6, 18.5, 17.6, 14.9. HRMS: $(M + H)^+$, $C_{17}H_{22}NO_3$ calculated, 288.1600; found, 288.1612.

2-(Dibutoxymethyl)-5-(phenoxymethyl)furan (17). Phenol (0.232 g, 2.47 mmol) and potassium carbonate (0.360 g, 2.61

dx.doi.org/10.1021/jf4045843 | J. Agric. Food Chem. 2014, 62, 476−480

mmol) were added to a solution of compound **12** (0.564 g, 2.05 mmol) in DMSO (5 mL), and the mixture was stirred at 50 °C under argon for 5 h. Saturated aqueous $NaHCO_3$ (50 mL) was added and the mixture was extracted with hexanes. The organic layers were combined, washed with saturated aqueous $NaHCO_3$, and dried over sodium sulfate. The solvent was evaporated to give compound **17** as a pale yellow oil (0.592 g, 87%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.34−7.25 (m, 2H), 7.02−6.93 (m, 3H), 6.42 (d, 3.3 Hz, 1H), 6.40 (d, 3.3 Hz, 1H), 5.55 (s, 1H), 4.99 (s, 2H), 3.65−3.49 (m, 4H), 1.70−1.55 (m, 4H), 1.51−1.35 (m, 4H), 0.95 (t, 7.2 Hz, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.3, 152.4, 150.2, 129.4, 121.2, 114.9, 110.3, 109.0, 96.5, 65.5, 62.4, 31.8, 19.4, 13.9. HRMS: $(M - OBu)^+$, $C_{16}H_{19}O_3$ calculated, 259.1329; found, 259.1331.

5-(Phenoxymethyl)furfural (19).[15] A mixture of compound **17** (0.322 g, 0.970 mmol) and 1 M HCl (10 mL) was stirred for 2 h and then extracted with dichloromethane (20 mL). The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated to give compound **19** as a yellow solid (0.194 g, 99%), with a mp of 84 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 9.64 (s, 1H), 7.36−7.20 (m, 3H), 7.05−6.91 (m, 3H), 6.61 (d, 3.3 Hz, 1H), 5.10 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 178.0, 158.1, 157.0, 152.9, 129.9, 122.4, 122.0, 115.0, 111.9, 62.7. HRMS: $(M + H)^+$, $C_{12}H_{11}O_3$ calculated, 203.0703; found, 203.0706.

2-(Hydoxymethyl)-5-(phenoxymethyl)furan (21).[13] Sodium borohydride (0.269 g, 7.08 mmol) was added to a solution of compound **19** (1.196 g, 5.915 mmol) in a 1:1 mixture of methanol and dichloromethane (20 mL) at 0 °C. The reaction was allowed to come to room temperature over 2 h with stirring. The solvent was evaporated, and the residue was taken up in dichloromethane (20 mL) and washed with brine. The aqueous layer was back-extracted with dichloromethane. The organic layers were combined, dried over sodium sulfate, and evaporated to give compound **21** as a pale yellow liquid (1.156 g, 96%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.36−7.25 (m, 2H), 7.04−6.94 (m, 3H), 6.37 (d, 2.7 Hz, 1H), 6.26 (d, 2.7 Hz, 1H), 4.96 (s, 2H), 4.56 (s, 2H), 2.91 (s, 1H, OH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.5, 155.0, 150.3, 129.8, 121.6, 115.1, 111.1, 108.9, 62.6, 57.6. HRMS: $(M + H)^+$, $C_{12}H_{13}O_3$ calculated, 205.0859; found, 205.0861.

Mixture of (±)-*cis*- and (±)-*trans*-[5-(Phenoxymethyl)furan-2-yl]methyl-2,2-dimethyl-3-(2-methylprop-1-en-1-yl)-cyclopropane-1-carboxylate (6).[13] Compound **21** (0.331 g, 1.62 mmol) was dissolved in dry benzene (25 mL) under argon. A mixture of (±)-*cis*- and (±)-*trans*-chrysanthemic acid chloride (0.364 g, 1.95 mmol) was added and the solution was heated at reflux for 3 h. The reaction was allowed to cool to room temperature and the solvent was evaporated. The residue was taken up in dichloromethane (25 mL), which was then washed with brine. The aqueous layer was back-extracted with dichloromethane. The organic layers were combined and dried over sodium sulfate, and the solvent was evaporated. The crude product was purified by flash column chromatography on silica gel (15:1 hexanes/ethyl acetate) to give compound **6** as a colorless oil (0.484 g, 85%). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.35−7.24 (m, 2H), 7.03−6.93 (m, 3H), 6.39 (s, 2H, H_c, $H_{c'}$, H_d, and $H_{d'}$), 5.37 (d, 8.3 Hz, 0.15H, H_j), 5.13−4.95 (m, 4H, H_b, $H_{b'}$, H_e, and $H_{e'}$), 4.88 (d, 7.5 Hz, 0.85H, $H_{j'}$), 2.08 (t, 7.5 Hz, 0.85H, $H_{i'}$), 1.90 (t, 8.3 Hz, 0.15H, H_i), 1.81−1.65 (m, 6H, H_k, $H_{k'}$, H_l, and $H_{l'}$), 1.43 (d, 5.1 Hz, 0.85H, H_f), 1.30−1.08 (m, 6H, H_g, $H_{g'}$, H_h, and $H_{h'}$). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 172.3, 170.9, 158.5, 151.1, 151.1, 150.8, 150.6, 135.8, 135.1, 129.7, 121.5, 121.3, 118.3, 115.1, 111.6, 111.5, 111.1, 62.6, 58.2, 57.9, 34.8, 33.3, 32.8, 31.3, 29.2, 29.0, 27.0, 26.2, 25.8, 22.4, 20.6, 18.8, 18.6, 15.0. HRMS: $(M + H)^+$, $C_{22}H_{27}O_4$ calculated, 355.1909; found, 355.1925.

Entomological Studies. *Mosquitoes.* The Orlando strain of *Aedes aegypti* (established 1952) was reared in the insectary of the Mosquito and Fly Research Unit at the Center for Medical, Agricultural, and Veterinary Entomology (CMAVE), Agricultural Research Service (ARS), United States Department of Agriculture (USDA), according to the procedures described by Pridgeon et al.[16] Briefly, eggs were hatched in a flask with deionized water, left overnight, and transferred to a plastic tray containing distilled water. A powdered diet (2:1 pot belly pig chow/brewer's yeast) was added to each tray. Mosquitoes were reared in an environmental chamber at 28 °C, 80% relative humidity, and a photoperiod of 14 h/10 h (light/dark). Adults were held in a screened cage and provided 10% sucrose *ad libitum*. Female adults were used for all bioassays.

Adult Topical Bioassays. To determine the toxicity of each compound against female *A. aegypti*, samples were initially diluted to a 10% solution in DMSO. This solution was then serially diluted 1:10 in acetone and then topically applied to individual mosquitoes. Each addition of diluent and stock solution was weighed to allow for accurate concentration calculations and to account for pipetting variability because of the volatility of acetone. Prior to application, 5−7-day-old females were cold-anaesthetized and placed on a 4 °C chill table (BioQuip Products, Rancho Dominguez, CA). A 0.5 μL droplet of chemical solution was applied to the thorax using a 700 series gastight syringe and a PB 600 repeating dispenser (Hamilton, Reno, NV). Control treatments with 0.5 μL of acetone alone gave control mortality of less than 10%. After treatment, mosquitoes were kept in plastic cups and supplied with 10% sucrose solution for 24 h before mortality was recorded. Temperature and relative humidity were maintained at 26−27 °C and 80%, respectively. Cohorts of 20−30 mosquitoes were treated at each dose. Bioassays were replicated 3 times. Technical-grade permethrin (Chemservice, West Chester, PA), a combination of 46.1% *cis* and 53.2% *trans* isomers, was used as the positive control in all assays and diluted in the same manner as the test compounds. This system reliably results in a LD_{50} for permethrin of around 0.1 ng per mosquito.

RESULTS AND DISCUSSION

Preliminary entomological testing of pyrethroids **5** and **6** was conducted against prothrin (**4**) and the commercial insecticide permethrin as standards using the "Orlando" strain of the pesticide-susceptible mosquito *A. aegypti*, as described above. Mortality was recorded at 24 h post-application, and three replicates were performed. Averaged mortality counts are included in Table S1 of the Supporting Information, and the estimated LD_{50} values are given in Table 1. The activities of analogues **5** and **6** are thus within about a log of that of prothrin (**4**), which itself is more active than the natural pyrethrins.[17] Further testing will determine whether these derivatives show any useful selectivity in their action.

Table 1. Estimated LD_{50} Values (ng/Mosquito) of Analogues 5 and 6 with Prothrin (4) and Permethin Standards against *A. aegypti* "Orlando" Strain Mosquitos

toxicant	LD_{50}
permethrin	0.07
prothrin (**4**)	0.50
5	7.0
6	3.3

In conclusion, CMF (**1**), a biomass-derived platform chemical, is an attractive starting material for the high-yield synthesis of prothrin (**4**) and analogues **5** and **6**. This scalable synthetic approach could be generalized toward the renewable-sourced production of a variety of furan-based pyrethroids, which will enable further structure−activity studies and potential commercial development of this important family of insecticides.

ABSTRACT: Cacao (*Theobroma cacao* L.), the source of cocoa, is an economically important tropical crop. One problem with the premium cacao market is contamination with off-types adulterating raw premium material. Accurate determination of the genetic identity of single cacao beans is essential for ensuring cocoa authentication. Using nanofluidic single nucleotide polymorphism (SNP) genotyping with 48 SNP markers, we generated SNP fingerprints for small quantities of DNA extracted from the seed coat of single cacao beans. On the basis of the SNP profiles, we identified an assumed adulterant variety, which was unambiguously distinguished from the authentic beans by multilocus matching. Assignment tests based on both Bayesian clustering analysis and allele frequency clearly separated all 30 authentic samples from the non-authentic samples. Distance-based principle coordinate analysis further supported these results. The nanofluidic SNP protocol, together with forensic statistical tools, is sufficiently robust to establish authentication and to verify gourmet cacao varieties. This method shows significant potential for practical application.

INTRODUCTION

Cacao (*Theobroma cacao* L.) is an important tropical crop because it is the source of cocoa butter and powder for the confectionery industry. This species comprises a large number of highly morphologically variable populations, which can all be crossed with one another.[1,2] The upper Amazon, including parts of Ecuador, Peru, Brazil, and Colombia, is generally believed to be the center of origin of cacao, because of the high morphological and genetic diversity observed in this region.[1,3,4] Cacao was domesticated by the Mayas and Aztecs,[5,6] and this crop was widely grown in Mexico and Central America in pre-Columbian times.[7,8]

Production and marketing of differentiated (or specialty) high-value cocoa provides socioeconomic opportunities for cacao growers, the chocolate industry, and especially for consumers. From the conservation perspective, the higher farm-gate revenues from this premium market can provide strong economic incentives for demand-driven, *in situ*/on-farm conservation of cacao genetic diversity. However, among premium cacao varieties, adulteration is common and can happen at different steps of the cocoa chain, from farm to port. Cacao varietal authentication, therefore, is of considerable interest to the various stakeholders in the chocolate value chain.

DNA-based authentication has been widely investigated in various crop species.[9−12] Examples of these methods include identifying different varieties of cereals,[13,14] fruits,[15] olives,[16,17] tea,[18] and coffee.[19] Thus far, microsatellite markers have been used in the majority of the published research.[12] Microsatellite markers have been commonly used in cacao breeding, germplasm management, and propagation of planting materials.[20,21] However, comparisons of microsatellite genotyping results from different laboratories have not been straightforward. Data generated from different genotyping platforms are often difficult to compare to one another because the same allele may be binned differently, which can lead to false conclusions. Moreover, an additional challenge for cocoa anthentication is that the DNA profile needs to be established for a single bean (seed) rather than leaves or other tissues. This is because, during fermentation, drying, or packaging, cacao beans from different varieties may be mixed into a lot being sold to traders. Adulteration may be intentional or unintentional at any of these steps.

A cacao bean is a botanical seed. The integument of the matured ovule develops into the seed coat, which thus shares the same diploid genotype with the mother tree. The seed coat is, therefore, ideal for tracing the genetic identity of the mother tree, which provides strong evidence for the authentication of a cacao variety. Nevertheless, there has thus far been no research on molecular authentication in cacao, partially because of the

difficulty in extracting sufficient DNA from beans that has acceptable quality for DNA fingerprinting.

Recent progress in the development of cacao genomics has led to the use of single nucleotide polymorphism (SNP) markers in cacao DNA fingerprinting. SNPs are the most abundant class of polymorphisms in plant genomes.[22] In comparison to simple sequence repeat (SSR) markers, accurate identification of SNPs can be performed without requiring DNA separation by size and can, therefore, be automated in an assay array format or on microchips. The diallelic nature of SNPs offers a much lower error rate in allele calling than with SSRs, and genotyping can be multiplexed and performed very quickly at lower costs. TaqMan-based SNP assays have been developed for cacao genotyping under field conditions.[23,24] SNP genotyping through the Sequenom genotyping platform has been applied to molecular identification of farmer varieties of cacao in Nicaragua and Honduras.[25] However, the application of SNP markers for cacao authentication has not been investigated. The objective of this work was to develop a SNP-based analysis enabling authentication of a fine-flavor cacao variety from northern Peru. The SNP-based DNA fingerprints were compared to other cacao varieties that were cultivated in the same region, including the most commonly used adulterant variety.

MATERIALS AND METHODS

Cacao Bean Samples. Dried cacao bean samples of the fine-flavor variety "Fortunato No. 4" were provided by Marañón Chocolate, San Diego, CA. These cacao beans, from a single source in northern Peru, are from an indigenous variety enjoying premium market price. On the basis of their relative cultivation area in Cajamarca province of Peru,[26] five other varieties were chosen for testing as the "adulterant varieties". These varieties included the most widely cultivated variety in Peru "CCN-51", which is considered an inferior variety in terms of flavor and quality. In addition, DNA samples of 18 international clones were included in this experiment as reference clones (Table 1). The genetic identities of these clones are known through an international initiative for DNA fingerprinting of the cacao germplasm.[27−29] The majority of the accessions were maintained in the international genebanks in Trinidad.

Extraction and Treatment of DNA from Cacao Seed Coat Samples. DNA was extracted from seed coats of single fermented and dried cacao beans with the DNeasy Plant Mini Kit Tissue Kit (Qiagen, Inc., Valencia, CA), which is based on the use of silica as an affinity matrix. The thin seed coat was carefully separated from the seed, and 30 mg of this dry tissue was placed in a 2 mL microcentrifuge tube with one $^1/_4$ in. ceramic sphere and 0.15 g of garnet matrix (Lysing Matrix A, MP Biomedicals, Solon, OH). The seed coat samples were disrupted by high-speed shaking in a TissueLyser II (Qiagen) at 30 Hz for 1 min, followed by an additional 1 min, with a 1 min rest between disruptions. Lysis solution (buffer AP1 containing 25 mg/mL polyvinylpolypyrrolidone), along with ribonuclease I or ribonucleate 3′-pyrimidinooligonucleotidohydrolase (RNase A), was added to the powdered seed coat, and the mixture was incubated at 65 °C, as specified in the kit instructions. The remainder of the extraction method followed the suggestions of the manufacturer. DNA was eluted from the silica column with two washes of 50 μL of buffer AE, which were pooled, resulting in 100 μL of DNA solution. Using a NanoDrop spectrophotometer (Thermo Scientific, Wilmington, DE), the DNA concentration was determined by absorbance at 260 nm. DNA purity was estimated by the 260/280 ratio and the 260/230 ratio.

Over a total of 51 extractions, the DNA concentration ranged from 3.4 to 21.7 ng/μL; 260/280 ratios were from 1.06 to 2.08; and 260/230 ratios were from 0.20 to 1.01. To mitigate possible problems of low concentration or quality in DNA samples during polymerase chain reaction (PCR), each DNA was first subjected to a multiplex specific target amplification (STA) procedure using primer pools provided by Fluidigm Corp. (South San Francisco, CA), Qiagen 2× Multiplex PCR Master Mix (PN 206143), and the protocol recommended in the Fluidigm SNP Genotyping User Guide.[30]

SNP Markers and Genotyping. The 48 cacao SNP markers were selected from 1560 candidate SNPs that were developed from cDNA sequences from a wide range of cacao tissues (Boccara, personal communication).[31−33] The selection of SNPs was based on the level of polymorphism and their distribution across the 10 chromosomes in cacao. The chosen 48 markers were used to design and manufacture primers for a SNPtype genotyping panel (Fluidigm Corp.). Genotyping was performed on the high-throughput Fluidigm EP1 system, using the Fluidigm SNPtype Genotyping Reagent Kit according to the instructions of the manufacturer and a nanofluidic 48.48 Dynamic Array integrated fluidic circuit (IFC, Fluidigm Corp.). This chip automatically assembles PCR reactions, enabling simultaneous testing of up to 48 samples with 48 SNP markers.

Fluorescent intensity was measured with the EP1 reader and plotted in two axes. Genotypic calls were made using the Fluidigm SNP Genotyping Analysis program.[30]

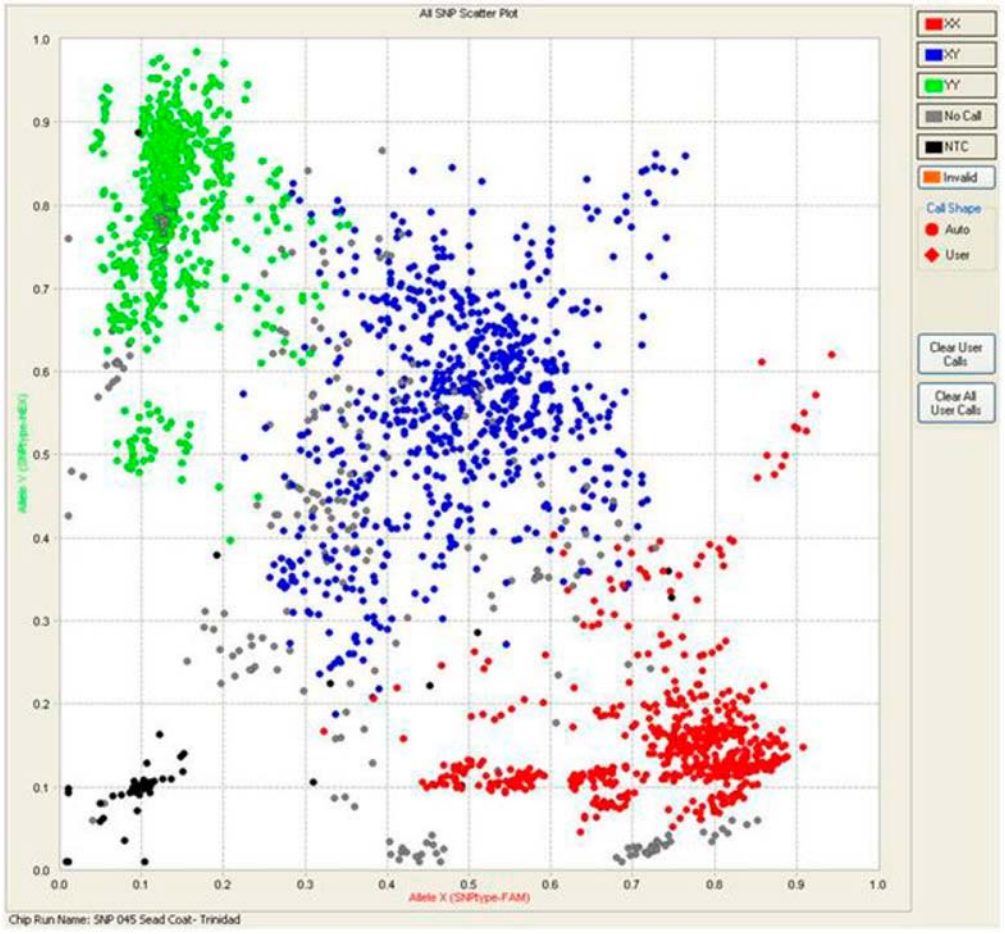

Figure 1. Cluster plots for the 48 SNP assays and 48 cacao DNA samples obtained from Fluidigm Dynamic Array IFCs.

Data Analysis. Key descriptive statistics for measuring the informativeness of these SNP markers were calculated, including minor allele frequency, observed heterozygosity, expected heterozygosity, Shannon's information index, and probability of identity.[34,35] The program GenAlEx 6.2[36,37] was used for computation.

Two approaches were taken to identify the adulterant varieties in the tested samples. Initially, SNP profiles of the authentic variety and the putative adulterant variety were compared at every locus using a pairwise multilocus matching procedure, as implemented in the computer program GenAlEx 6.2.[36,37] To assess the differentiation power of the SNP markers, we calculated the probability of identity (PID).[35] We computed the probability of identity among siblings (PID-sib), which was defined as the probability that two sibling individuals drawn at random from a population have the same multilocus genotype.[34]

The second approach employed assignment tests to check if all of the cacao beans claimed as "Fortunato No. 4" were truly from the "home population". An exclusion test,[38] as implemented in the program GeneClass,[39] was used to identify if there was a presence of the adulterant variety in the tested samples. Both Bayesian assignment test and classical frequency-based assignment were applied. In both cases, the resampling algorithm of Cornuet et al.[39] was used and the minimum number of simulated individuals was set at 10 000. The "type I error" was set at 0.01.

To understand and visualize the relationship among the authentic and adulterant varieties, we also computed the genetic distances for each possible pair of tested individuals. Principle coordinate analysis (PCoA), implemented in GenAlEx 6.2,[36,37] was used for computation.

RESULTS

Summary Information of SNP Fingerprints and Multilocus Matching. From the 48 SNPs tested, 46 primer pairs generated polymorphic fingerprints (Figures 1 and 2). Locus 226, 836 and locus 1038, 1114 had more than 20% no call, and they were therefore excluded from subsequent analyses. At the remaining 44 marker loci, two alleles were detected for each locus in the 45 DNA samples. The average polymorphism information content (PIC) was 0.60, ranging from 0.356 to 0.692. The mean observed heterozygosity was 0.284, ranging from 0.043 to 0.563, whereas the mean expected heterozygosity was 0.412, ranging from 0.203 to 0.499 (Table 2). Repeated tests, using three independently extracted DNAs from the same seed, showed that the genotyping result was highly consistent. The five repeatedly genotyped beans (each with three replications) always generated the same SNP profiles.

Individual genotype matching (pairwise comparisons) based on multilocus SNP profiles showed that there were no matched pairs, either within the 30 putative "Fortunato No. 4" samples or between the "Fortunato No. 4" samples and CCN 51, the targeted adulterant variety. The 30 "Fortunato No. 4" samples differed by at least three loci, showing that each bean came from a different mother tree. The "Fortunato No. 4" samples differed from CCN-51 by at least six loci, thus demonstrating no mixture of CCN-51 in the examined "Fortunato No. 4" samples. The probability that two unrelated accessions will have

dx.doi.org/10.1021/jf404402v | J. Agric. Food Chem. 2014, 62, 481−487

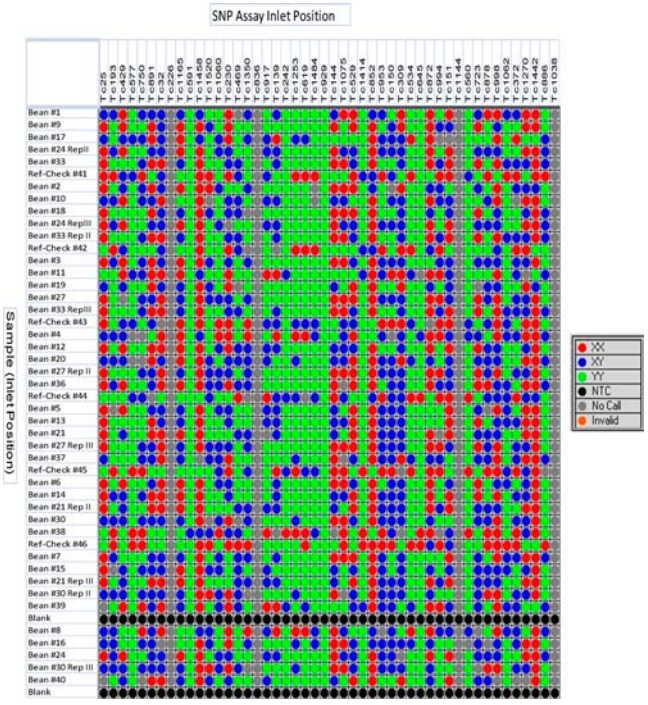

Figure 2. Call map view shows the overall calls for the Dynamic Array IFC, displaying 2304 data points at one time. The 48 accessions include 30 DNA samples extracted from fermented/dry beans from a single source provider in northern Peru, six reference clones, and two blank used as checks.

the same genotype at the 44 SNP loci is approximately 1 in 100 000 for the tested samples.

Assignment Test. The result of assignment by the exclusion−simulation method[39] showed that the 30 "Fortunato No. 4" samples should be assigned into one genetic cluster if the threshold probability of >0.50 was taken. Because CCN 51 and the other 17 international clones had an assignment probability ranging from <0.001 to 0.012, they were categorized as the putative adulterant variety (Table 3). When the algorithm was changed from Bayesian clustering analysis to frequency-based assignment, the overall result remain unchanged (Table 3).

PCoA. The genetic relationships among the tested varieties/clones were shown by PCoA (Figure 3). The plane of the first three main principle coordinate (PCO) axes accounted for 53.7, 14.2, and 11.2% of total variation, respectively. In the plane of coordinate 1 versus 2 (Figure 1), the 30 accessions of the authentic variety "Fortunato No. 4" formed a relatively homogeneous group, whereas the assumed adulterant variety "CCN-51" was clearly separated from the authentic group, indicating its "non-resident" status. All of the other reference accessions were well-differentiated from "Fortunato No. 4" as well. The result of distance-based multivariate analysis is fully compatible with the Bayesian method as well as the frequency-based assignment test.

DISCUSSION

Rapid segmentation in the chocolate market has resulted in a strong demand for sustainably and responsibly produced cocoa products. To meet this demand, scientific tools for verification of cacao genetic identity is essential to provide authentication in the value chain. A DNA fingerprint from a single fermented

cacao bean is essential for cocoa authentication. Thus far, it is not possible to distinguish the genetic identity of cacao beans from their morphological characteristics. The only available method to assess the authentication of cacao bean is for an experienced sensory panel to taste the cocoa liquor. This practice is not practical when dealing with large number of samples because there is a limit to the number of samples a sensory panel can evaluate before losing its accuracy. Plus, the

evaluation result of the sensory panel is difficult for statistical analysis. Moreover, it cannot be performed on a single bean basis. In the present study, we demonstrated a DNA fingerprinting method that uses a small set of SNP markers to verify the genetic identity of a single cacao bean. This method can handle a large amount of samples in a short period of time, and the result is highly robust and repeatable.

Our results showed that single bean genotyping using the nanofluidic array of SNP markers is particularly suitable for this purpose. The STA protocol, performed before genotyping, is a multiplex PCR reaction using primers for all loci of interest, but without targeting the specific alleles, thus proportionally increasing the copies of these loci.[40] This procedure has been demonstrated to significantly improve call rates for SNPs[41] and solved our problem of the low concentration of DNA obtained from a single seed coat. Cacao seed coat, similar to the cacao leaves, contains a high level of polyphenolic compounds and other PCR inhibitory compounds, and in addition, the seed coat is encrusted in a dried plant and microorganism residue that is a direct result of the fermentation and drying processes. The STA protocol efficiently dealt with problems of the DNA quality extracted from cacao.

Results from the repeatedly genotyped five beans (three independent DNA extractions were performed from the same seed coat of each bean) showed 100% concordance. SNP profiles of CCN 51 as well as of the 17 other reference clones fully matched their established genotypes, determined by previous independent methodology, suggesting that the nanofluidic system is a reliable platform for generating cacao DNA fingerprints with high accuracy.

The present study used CCN 51 as the targeted adulterant variety because this variety is the most widely cultivated bulk cocoa variety in Peru. According to the report from the Peruvian Ministry of Agriculture,[26] CCN 51 accounted for 50% of the production in the region where the authentic variety ("Fortunato No. 4") is grown. CCN 51 is also the number one bulk cocoa variety in Ecuador, where the fine flavor Nacional cacao is produced. Knowing the targeted adulterant variety (e.g., CCN 51 in Ecuador and Peru) made the identification straightforward. A conclusion can be reached by multilocus matching the SNP profiles without any ambiguity. Nevertheless, in this situation, the effectiveness of individual identification via SNP fingerprints depends upon the number of loci used for genotyping. An important statistical parameter for determining the number of loci required to identify all distinct individuals with a needed confidence level is the probability of identity (PID). Multilocus PID values can be obtained by multiplying together single-locus PID values, assuming independence of loci. A stringent PID value is needed for domesticated crop species, because they often share similar ancestors. Therefore, PID calculated for sibs would provide a highly conservative boundary for domesticated crop species. The present result shows that, using 44 SNP loci, the chance of sampling identical genotypes from a random mating population would be 1 out of 100 000. It thus predicts the high statistical power of using this set of SNPs for cacao genotype verification.

When the adulterant varieties are unknown, direct multilocus matching cannot be applied; therefore, the DNA fingerprints need to be used with an assignment test to single out unknown adulterant varieties, as well as to confirm the authentic variety. Among the different kinds of assignment tests, an exclusion test is the most suitable for cacao beans because it can be used even if only one variety (i.e., the authentic variety) has been sampled. In reality, this is the case for most of the authentication issues in the cocoa trade. For example, the fine-flavor varieties produced in Peru and Ecuador were often mixed with other high-yielding varieties of bulk cocoa, such as CCN 51. This situation is equivalent to a small number of "non-resident" individuals mixed into the resident population in typical population genetics. Using self-assignment test, such as the one

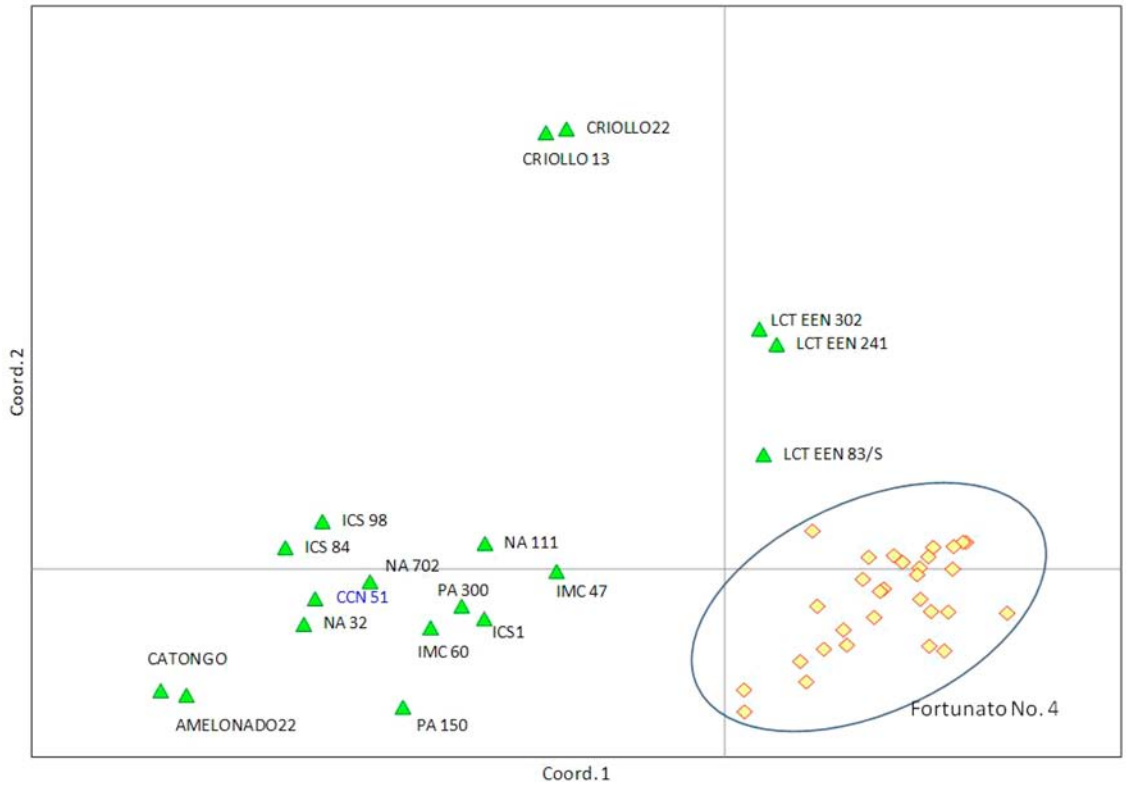

Figure 3. PCoA plot of 45 cacao accessions, including 30 DNA samples extracted from fermented/dry beans from a single source provider in northern Peru, 1 putative adulterant clone (CCN 51), and 17 international clones serving as reference samples. The plane of the first three main PCO axes accounted for 89.6% of total variation. First axis = 53.7% of the total information; second axis = 14.2% of the total information; and third axis = 11.2% of the total information.

implemented in GeneClass2,[39] one could calculate the observed allele frequencies in the resident group, simulate a distribution of random multilocus genotypes that are expected to occur in the resident group (on the basis of the observed allele frequencies), and exclude the resident group (the authentic variety) as the origin of the cacao bean if its multilocus genotype lies outside the distribution of the simulated genotypes. As demonstrated in the present study, the non-resident cacao genotypes, including some Forastero-type clones indigenous to Peru, all received low assignment probability (<0.0001−0.02 for the Bayesian method and <0.0001−0.037 for the allele frequency method). In contrast, all 30 samples in the resident group received high assignment probability (>0.50). The genetic relationship among the analyzed samples was further visualized by distance-based PCoA (Figure 3). The concordant results of the assignment test and distance-based PCoA suggest that the protocol for authentication testing is robust and accurate.

In conclusion, we conducted a pilot study on verification of authentication for cacao. We applied single bean genotyping using a nanofluidic array and SNP markers. This technology enabled us to generate high-quality SNP-profile-based DNA extracted from a single seed coat. Together with forensic statistical tools, the single-bean-based DNA fingerprints allowed for an unambiguous identification of the targeted adulterant variety. It also enabled the assignment test to authenticate and exclude adulterated samples. To our knowledge, this is the first authentication study in cacao using molecular makers. This approach is robust for authentication verification of gourmet cacao varieties and, thus, has significant potential for practical application.

[‡]National Center for Natural Products Research, and Department of Pharmacognosy, Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, Mississippi 38677, United States

Supporting Information

ABSTRACT: Five new triterpenoid saponins, **1**−**5**, together with 10 known ones, **6**−**15** were isolated from the aerial parts of *Ilex cornuta*. The structures of compounds **1**−**5** were determined as 3*β*-*O*-*α*-L-arabinopyranosyl-19*α*,23-dihydroxy-20*α*-urs-12-en-28-oic acid 28-*O*-*β*-D-glucopyranosyl ester, **1**; 3*β*-*O*-*β*-D-glucopyranosyl-(1→2)-*α*-L-arabinopyranosyl-19-hydroxy-20*α*-urs-12-en-28-oic acid 28-*O*-*β*-D-glucopyranosyl ester, **2**; 19*α*,23-dihydroxyurs-12-en-28-oic acid 3*β*-*O*-*β*-D-glucuronopyranoside-6-*O*-methyl ester, **3**; 19*α*,23-dihydroxyurs-12-en-28-oic acid 3*β*-*O*-[*β*-D-glucuronopyranoside-6-*O*-methyl ester]-28-*O*-*β*-D-glucopyranosyl ester, **4**; and 3*β*-*O*-[*α*-L-arabinopyranosyl-(1→2)-*β*-D-glucuronic acid]-oleanolic acid 28-*O*-*β*-D-glucopyranosyl ester, **5**, on the basis of spectroscopic analyses (IR, ESI-MS, HR-ESI-MS, 1D and 2D NMR) and chemical reactions. Protective effects of compounds **1**−**15** were tested against H_2O_2-induced H9c2 cardiomyocyte injury, and the data showed that compounds **1**, **4**, **6**, and **13** had significant cell-protective effects. No significant DPPH radical scavenging activity was observed for compounds **1**−**15**.

KEYWORDS: *Ilex cornuta, Aquifoliaceae, triterpenoid saponins, structure identification, cardiomyocyte oxidative injury, DPPH radical scavenging activity*

INTRODUCTION

Ilex cornuta Lindl. et Paxt. (Aquifoliaceae family) is an evergreen shrub with dense foliage. Its leaves are the major source of "Ku-Ding-Cha", a popular herbal tea consumed in China and other countries.[1] The tea is widely used for its health benefits, such as relief of sore throat and weight loss.[2] According to the Traditional Chinese Medicine theory, the leaves of *I. cornuta*, which are bitter and cool-natured, can invigorate the liver and kidney and can expel "wind" and "heat". It has been used to cure weakness of waist, knees, arthrodynia, head-wind, acute conjunctivitis, toothache, and urticaria.[3] The results from modern pharmacology research showed that the plant had many therapeutic effects, such as increase of coronary blood flow[4] and anticancer[5] and antibacterial properties.[6] Previous phytochemical investigation on the *Ilex* genus led to the isolation of triterpenes, triterpenoid saponins,[7] flavones, flavonoid glycosides,[8] polyphenols,[9] and fatty acids.[10]

Cardiovascular disease is one of the major causes of deaths worldwide. Oxidative stress is considered as a causative factor in the pathogenesis of cardiomyocyte ischemic injury. Activation of oxidative stress leads to a variety of intracellular signaling events that ultimately cause dysfunction of the endothelium, proliferation of vascular smooth muscle cells, expression of pro-inflammatory genes, and reconstruction of the extracellular matrix.[11] Growing evidence has suggested that the intake of foods rich in antioxidants can result in a lower risk of cardiovascular disease.[12] In our effort to develop the extract of *I. cornuta* as a herbal dietary supplement for the prevention of coronary artery disease, a phytochemical investigation of its aerial parts was undertaken, which led to the isolation of 5 new triterpenoid saponins, **1**−**5** (Figure 1), along with 10 known ones. In this paper, we report the isolation and structural elucidation of the new compounds, as well as the protective effects of the isolates against cardiomyocyte injury induced by H_2O_2. In addition, their radical scavenging activity was evaluated by DPPH assay.

MATERIALS AND METHODS

General. The specific optical rotation values were determined with a Perkin-Elmer model 241 polarimeter (Perkin-Elmer Inc., Waltham, MA, USA). IR spectra were determined on a Perkin-Elmer 983 G spectrometer. ^{1}H and ^{13}C NMR and 2D NMR spectra were recorded on a Varian Inova 500 spectrometer (Varian Inc., Palo Alto, CA, USA) in C_5D_5N using tetramethylsilane (TMS) as the internal standard. HR-ESI-MS spectra were determined on a Micromass Q-TOF2 spectrometer (Micromass Corp., London, UK).

Chromatography. HPLC analysis and purification were performed with an Agilent Zorbax SB-C18 semipreparative HPLC column (250 × 9.4 mm i.d., 5 *μ*m, Agilent Corp., Palo Alto, CA, USA) on a Shimadzu HPLC system composed of an LC-20AT pump with an SPD-20A detector (Shimadzu Corp., Kyoto, Japan), and the wavelength for detection was 203 nm. Medium-pressure liquid chromatography (MPLC) purification was performed on a Büchi flash chromatography system composed of a C-650 pump and a flash column (460 × 26 mm i.d., Büchi Corp., Flawil, Switzerland). Silica gel (60−100 mesh) used for column chromatography and precoated silica gel for TLC plates were purchased from Qingdao Marine Chemical

Factory (Qingdao, China). A 10% sulfuric acid alcohol solution was used for TLC colorization. Sephadex LH-20 for column chromatography was purchased from GE Corp. (Piscataway, NJ, USA). D101 macroporous resin for column chromatography was purchased from Xi'an Sunresin New Materials Co. Ltd. (Xi'an, China). GC analyses were conducted on a GC-14C (Shimadzu Corp.) instrument with a flame ionization detector (FID), and the analytical conditions were as follows: DB-5 column (i.d. = 0.25 μm, length = 30 m, Suzhou Huitong Chromatography Technology Co., Ltd., Suzhou, China); column temperature at 210 °C; injector temperature at 270 °C; detector temperature at 300 °C.

Materials. The aerial parts of *I. cornuta* were collected from Liuan City of Anhui province, in April 2011, and were authenticated by Professor Xiao-ran Li. A voucher specimen (04-21-01-11) was deposited in the herbarium of the College of Pharmaceutical Science, Soochow University.

Extraction and Isolation. The dried plant material (10 kg) was crushed into powder and extracted twice with 50% EtOH at 80 °C under reflux. The solvent was subsequently removed under reduced pressure to yield a residue (325 g), which was then dissolved in 30 L of distilled water and passed through D101 macroporous resin column (200 × 30 cm i.d.), eluted with a gradient of aqueous EtOH (EtOH/H_2O 0, 30, 60, 90%). The 90% EtOH eluate (30 g) was further vacuum chromatographed on a silica gel (60−100 mesh) column (30 × 18 cm i.d.), eluted with a gradient of $CHCl_3$/MeOH (90:10, 80:20, 70:30, 60:40, 50:50, 40:60, 30:70, 0:100, each 6.0 L). The $CHCl_3$/MeOH (90:10) eluate (1.5 g) was then separated by MPLC over an ODS column, eluted with MeOH/H_2O (60:40, 70:30, 80:20, 90:10, 100:0, each 500 mL) to afford five fractions. Fraction 2 (125 mg) was separated by semipreparative HPLC to yield compounds **7** (25 mg, t_R 35.27 min), **8** (8 mg, t_R 38.28 min), and **9** (33 mg, t_R 41.32 min). The $CHCl_3$/MeOH (80:20) eluate (4.9 g) yielded five fractions after separation by MPLC. Fraction 3 (90 mg) was further separated by using semipreparative HPLC to yield compounds **1** (9 mg, t_R 60.27 min) and **10** (19 mg, t_R 63.19 min). From fraction 4 (1500−2000 mL, 180 mg) compounds **3** (40 mg, t_R 70.15 min) and **4** (8 mg, t_R 73.23 min) were obtained after it was subjected to the semipreparative HPLC separation. In a similar way, the $CHCl_3$/MeOH (70:30) eluate (6.7 g) from the vacuum chromatography was first separated into six fractions by MPLC over the ODS column, and then these fractions were further separated by using semipreparative HPLC to yield compounds **6** (20 mg), **12** (55 mg), **13** (10 mg), **14** (9 mg), and **15** (14 mg). Moreover, compounds **2** (10 mg), **5** (17 mg), and **11** (36 mg) were obtained from the $CHCl_3$/MeOH (60:40) eluate (4.8 g) after MPLC and semipreparative HPLC separations as described above.

Acid Hydrolysis of Compounds 1−5. A solution of each compound (4 mg) dissolved in 1 N HCl (dioxane/H_2O, 1:1, 2.0 mL) was heated to 90 °C for 2 h. After cooling, the reaction mixture was neutralized with silver carbonate (10 mg), and the solvent was evaporated to dryness under N_2 and then extracted with $CHCl_3$ and H_2O. The aqueous layer was concentrated to dryness, the residue was dissolved in dry pyridine (0.2 mL), and then L-cysteine methyl ester hydrochloride in dry pyridine (0.06 M, 0.2 mL) was added. The mixture was reacted at 60 °C for 2 h, and 0.2 mL of (trimethylsilyl)-imidazole dissolved in dry pyridine was added. After being held at 60 °C for another 2 h, the reactant was partitioned with *n*-hexane and H_2O (0.1 mL, each). The *n*-hexane fraction was subjected to gas chromatographic analysis. The sugar residues in compounds **1−5** were identified by comparison with the standard references: D-glucose (t_R 10.49 min), L-glucose (t_R 11.10 min), D-glucuronic acid (t_R 9.21 min), L-glucuronic acid (t_R 9.66 min), D-arabinose (t_R 8.52 min), and L-arabinose (t_R 8.33 min).[13]

Assay for Testing the Protective Effects against Myocardial Cell Injury Induced by H_2O_2. H9c2 cells (1×10^5/well; Cell Bank of the Chinese Academy of Sciences Shanghai, China) were seeded into 96-well plates. After incubation with different concentrations of compounds **1−15** (12.5−200 μM) for 12 h, the cells were treated with 200 μM H_2O_2 for 24 h.[14,15] The cells in the control groups were treated with the same volume of phosphate-buffered saline (PBS). Cell viability was evaluated by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, which is based on the reduction of MTT by the mitochondrial dehydrogenase of intact cells to a purple formazan product. The quantity of formazan was determined by measuring the absorbance at 540 nm using an ELISA plate reader. The percentage cell viability was calculated as a ratio of the optical density (OD) value of the sample to the OD value of the control.[16] All experiments were done three times.

DPPH Radical Scavenging Capacity Assay. DPPH free radical scavenging activity of fractions and compounds was determined in

[a]Data in parentheses are J values (in hertz). Ara refers to arabinose, GlcA refers to gluconic acid, and Glc refers to glucose.

triplicate according to the method proposed by Hatano.[17] In brief, 100 μL of tested fraction or compound at final concentrations (5−200 μM) in methanol was added to 100 μL of a 0.5 mM DPPH radical solution in methanol. The mixture was shaken vigorously and allowed to stand for 30 min in the dark. Vitamin E was considered as a positive control. A freshly prepared DPPH solution exhibits a deep purple color with absorption maximum at 517 nm with a spectrophotometer. The radical scavenging rate of free radical DPPH in percent (I%) was calculated in the following way:

$$I\% = (100 \times [1 - (A_{sample} - A_{blank})/A_{control}]$$

$A_{control}$ is the absorbance of the control reaction (containing all reagents except the test compound), A_{sample} is the absorbance of the test compound, and A_{blank} is the absorbance of blank sample.

Statistical Analysis. Data were expressed as the mean ± SD and evaluated using one-way ANOVA. The post hoc test was done with Student's Dunnett test. $p < 0.05$ was considered statistically significant. Calculations were performed using the SPSS 16.0 statistical package.

RESULTS AND DISCUSSION

The 50% EtOH extract of the aerial parts of *I. cornuta* was separated by repeated D101 resin CC and ODS CC to afford 5 new triterpenoid saponins, **1**−**5**, as well as 10 known ones, which were identified as 19α-hydroxyurs-12-en-28-oic acid 3β-*O*-α-L-arabinopyranosyl-(1→2)-β-D-glucuronopyranoside-6-*O*-methylester, **6**;[18] siaresinolic acid, **7**;[19] hederagenin-28-β-D-glucopyranoside, **8**;[20] hederacolchiside A, **9**;[21] ilexolic acid A, **10**;[22] 3β,23-dihydroxyurs-12-en-28-oic acid 28-*O*-β-D-glucopyranosyl ester, **11**;[23] cynarasaponin E, **12**;[24] cynarasaponin E methyl ester, **13**;[24] mateside, **14**;[25] and ilekudinoside D, **15**,[26] (Figure 1).

Compound **1** was obtained as a white powder. The molecular formula of $C_{41}H_{66}O_{14}$ was determined on the basis of its HR-ESI-MS $[M + Na]^+$ ion peak at m/z 805.4303 (calcd 805.4350). The ^{1}H NMR spectrum showed singlet resonances of five methyl groups at δ 1.72 (3H, s, Me-27), 1.45 (3H, s, Me-29), 1.30 (3H, s, Me-26), 1.08 (3H, s, Me-25), 1.02 (3H, s, Me-24) and one doublet methyl signal at δ 1.05 (3H, d, J = 7.5 Hz, Me-30), an olefinic proton signal at δ 5.58 (1H, m, H-12), and signals of a hydroxymethylene group at δ 4.34 (1H, m, H-23) and 3.78 (1H, d, J = 11.5 Hz, H-23), as well as a signal at δ 4.34 (1H, m, H-3). The ^{13}C NMR data, the downfield shift of C-3, and the upfield shift of C-28 suggested the presence of a bisdesmosidic saponin aglycone. The ^{1}H NMR data also indicated the presence of two sugar residues, which was inferred by the two anomeric proton signals at δ 5.06 (1H, d, J = 7.0 Hz, H-1 of arabinose) and δ 6.43 (1H, d, J = 8.0 Hz, H-1 of glucose), which correlated with δ_C 106.9 (C-1 of arabinose), 95.9 (C-1 of glucose), respectively, in the HSQC spectrum (Table 2). The types of sugar residues obtained from the acid hydrolysis of **1** were identified as L-arabinose and D-glucose by the GC analysis. The glycosidic side chain was located at C-28 of the aglycone, revealed by the HMBC correlation between δ_H 6.43 (H-1 of glucose) and δ_C 177.2 (C-28 of aglycone) (Figure 2). The β configuration of the glucopyranosyl group was confirmed on the basis of the large $^3J_{H\text{-}1,H\text{-}2}$ coupling constant. The location of another glycosidic unit, α-L-arabinopyranosyl, was determined to be attached at C-3, evidenced by the HMBC correlation between δ_H 4.34 (H-3 of aglycone) and δ_C 106.9 (C-1 of arabinose), as well as correlation between δ_H 5.06 (H-1 of arabinose) and δ_C 82.0 (C-3 of aglycone). The configuration of the arabinopyranosyl group was assigned as α on the basis of

dx.doi.org/10.1021/jf4046667 | J. Agric. Food Chem. 2014, 62, 488−496

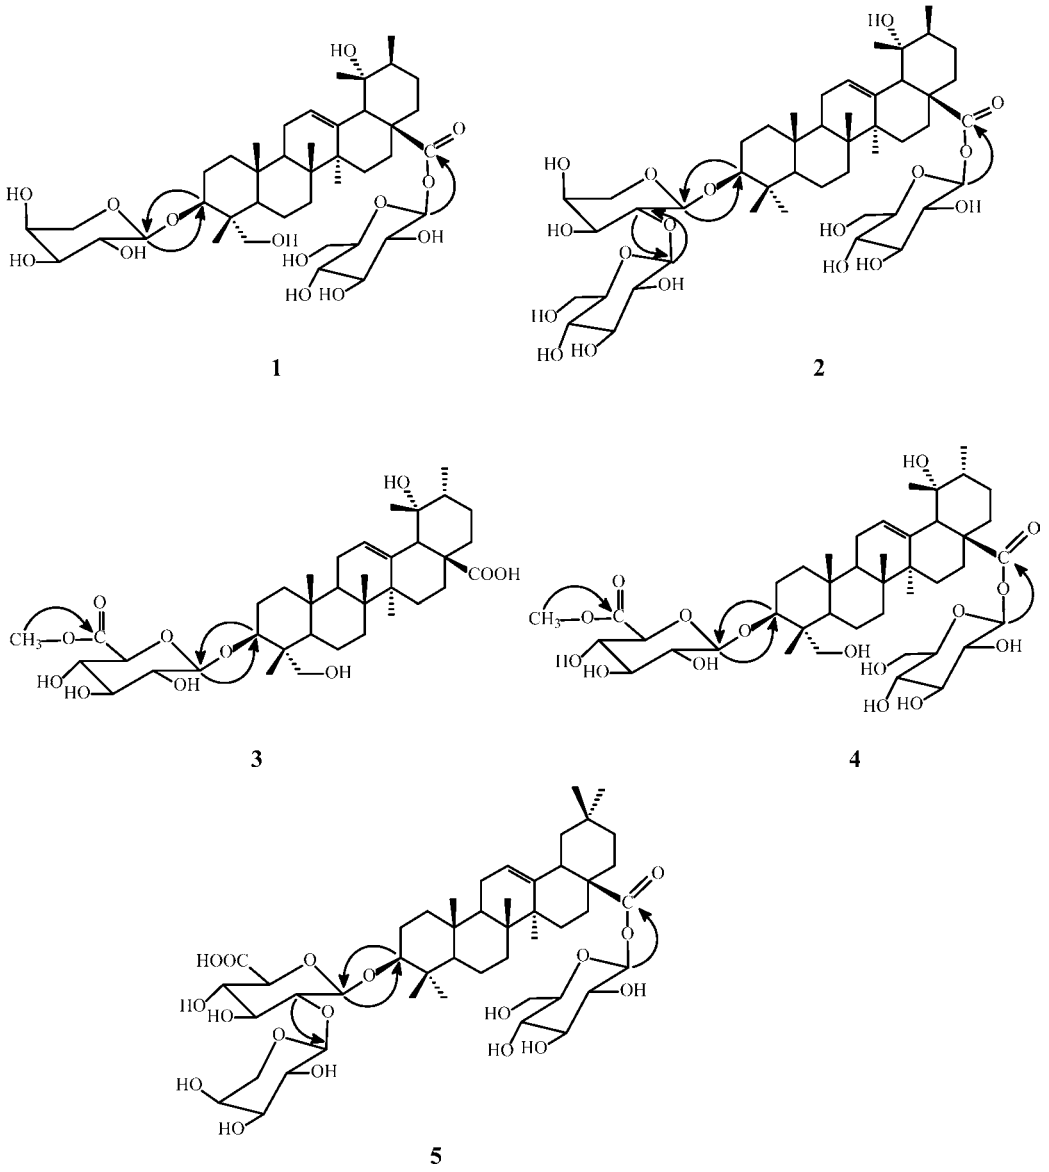

Figure 2. Key HMBC correlations for **1**−**5**.

the NOESY correlations between δ 5.06 (H-1 of arabinose) and δ 4.14 (H-3 of arabinose), 4.32 (H-4 of arabinose) (Figure 3). The ^{1}H and ^{13}C NMR spectral data of **1** were similar to those of 3β-*O*-α-L-arabinopyranosyl-19α,23-dihydroxyurs-12-en-28-oic acid 28-*O*-β-D-glucopyranosyl ester,[26] but showed differences for C-18 and C-22. Significant upfield shifts of the C-18 signal (−7.2 ppm) at δ 47.3 and C-22 signal (−5.9 ppm) at δ 32.0 were observed for compound **1**, which could be explained as the results of the γ-effect of the 30-β (axial) methyl group instead of a 30-*a* (equatorial) methyl group in the 3β,23-dihydroxyurs-12-en-28-oic acid moiety.[27] The β orientation of Me-30 was also confirmed by the NOESY correlations of Me-30 (δ_H 1.05) to both Me-29 (δ_H 1.45) and H-18 (δ_H 3.26) (Figure 3). The orientation of H-20 was determined to be α on the basis of the NOE information. Thus, compound **1** was identified as 3β-*O*-α-L-arabinopyranosyl-19α,23-dihydroxy-20α-urs-12-en-28-oic acid 28-*O*-β-D-glucopyranosyl ester.

Compound **2** was obtained as a white powder. The molecular formula was determined as $C_{47}H_{76}O_{18}$ on the basis of its HR-ESI-MS $[M + Na]^+$ ion peak at *m*/*z* 951.4887 (calcd 951.4929). The ^{1}H NMR spectrum showed singlet resonances of six tertiary methyl groups at δ 1.78 (3H, s, Me-27), 1.47 (3H, s, Me-29), 1.28 (3H, s, Me-26), 1.28 (3H, s, Me-23), 1.13 (3H, s, Me-24), and 0.99 (3H, s, Me-25), a doublet methyl signal at δ 1.07 (3H, d, J = 10.0 Hz, Me-30), and an olefinic proton signal at δ 5.59 (1H, m, H-12), as well as a signal at δ 3.27 (1H, dd, J = 15.0, 5.0 Hz, H-3). The ^{13}C NMR data and the downfield shift of C-3 and the upfield shift of C-28 indicated the presence of a bisdesmosidic saponin aglycone. The ^{1}H NMR spectroscopic data also indicated the presence of three sugar residues, which was inferred by three anomeric proton signals at δ 5.03 (1H, d, J = 7.0 Hz, H-1 of arabinose), δ 5.26 (1H, d, J = 9.5 Hz, H-1′ of glucose 1′), and δ 6.43 (1H, d, J = 10.0 Hz, H-1 of glucose 1), correlated with δ_C 104.9 (C-1 of arabinose), 106.1 (C-1′ of glucose 1′), and 95.9 (C-1 of glucose 1), respectively, in the HSQC spectrum (Table 2). The sugar residues were identified as L-arabinose and D-glucose by the GC analysis. The ^{1}H and ^{13}C NMR data of **2** were similar to those of brevicuspisaponin 3[28] except for the presence of additional signals attributed to one glucose moiety. The location of this

dx.doi.org/10.1021/jf4046667 | J. Agric. Food Chem. 2014, 62, 488−496

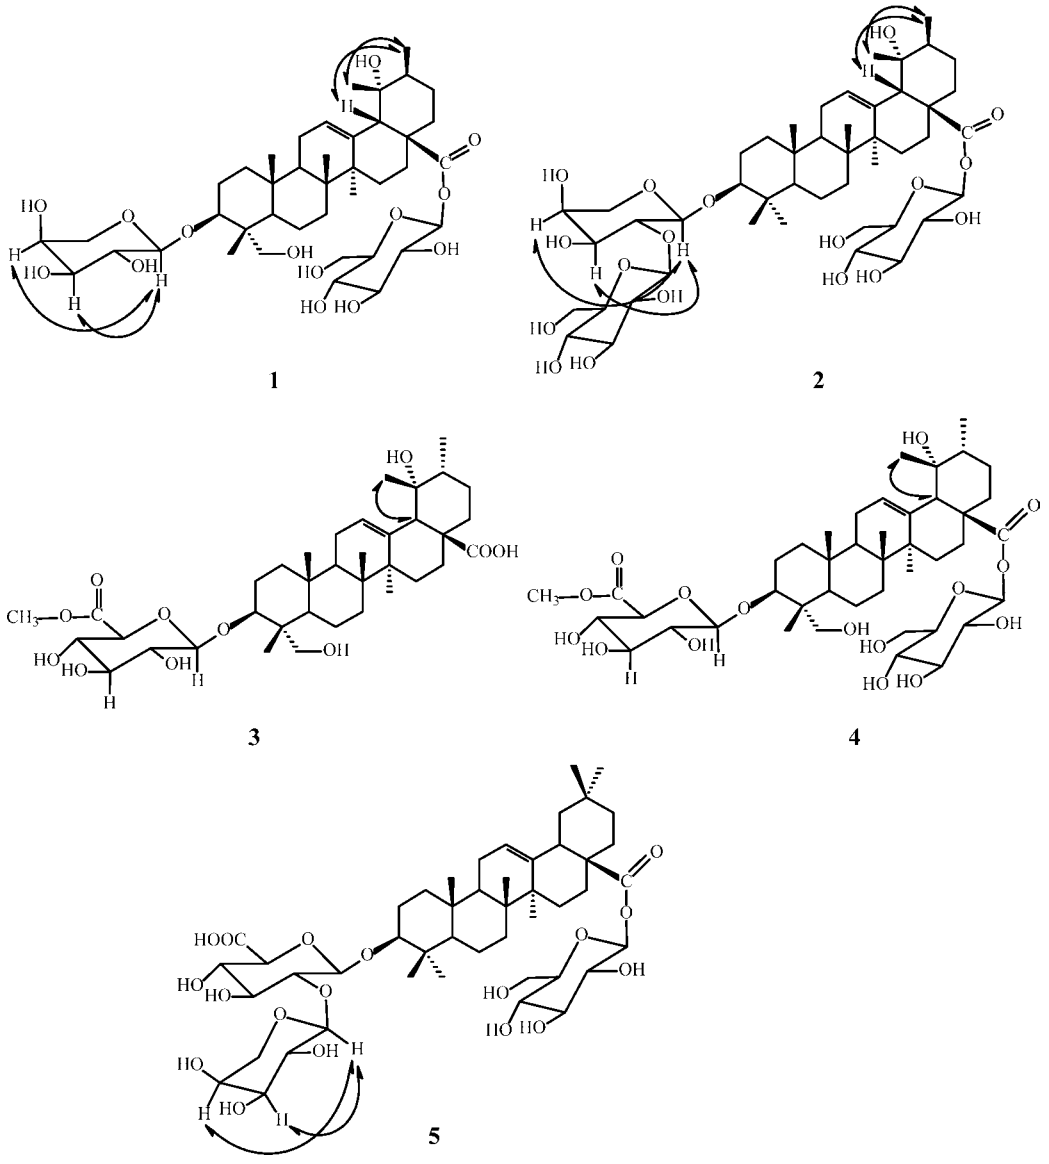

Figure 3. Key NOESY correlations for **1**−**5**.

glucose residue was determined at C-2 of the arabinose moiety, inferred by the downfield shift of C-2 of arabinose and HMBC correlation between δ_H 5.26 (H-1′ of glucose 1′) and δ_C 81.1 (C-2 of arabinose). Thus, the structure of compound **2** was established as 3*β*-*O*-*β*-D-glucopyranosyl-(1→2)-*α*-L-arabinopyranosyl-19-hydroxy-20*α*-urs-12-en-28-oic acid 28-*O*-*β*-D-glucopyranosyl ester.

Compound **3** was obtained as a white powder. The negative HR-ESI-MS of **3** showed a quasi-molecular ion peak at *m*/*z* 677.3869 ($[M - H]^-$, calcd 677.3901), indicating the molecular formula of $C_{37}H_{58}O_{11}$. The ^{1}H NMR spectrum showing singlet resonances of five tertiary methyl groups at δ 1.77 (3H, s, Me-27), 1.50 (3H, s, Me-29), 1.17 (3H, s, Me-26), 1.01 (3H, s, Me-24), 0.98 (3H, s, Me-25), a doublet methyl signal at δ 1.19 (3H, d, J = 6.5 Hz) corresponding to Me-30, an olefinic proton at δ 5.66 (1H, m, H-12), and hydroxymethylene group signals at δ 4.39, 3.78 (2H, m, H-23), as well as a proton signal at δ 4.36 (1H, m, H-3), suggested it contained an aglycone as 19*α*,23-dihydroxyurs-12-en-28-oic acid.[29] An anomeric proton was observed at δ_H 5.31 (1H, d, J = 8.0 Hz, H-1 of glucuronic acid), which showed HSQC correlation to the anomeric carbon at δ_C 106.6 (C-1 of glucuronic acid), indicating the presence of a sugar unit in the structure of compound **3**. The sugar residue obtained from the acid hydrolysis of **3** was identified as D-glucuronic acid by the GC analysis. The ^{1}H and ^{13}C NMR data of **3** were very similar to those of ilexasoside A,[30] except that it had an additional hydroxyl group. The downfield shift of C-23 signal (+36.3 ppm) at δ_C 64.4 suggested that the additional hydroxyl group was located at C-23, which was confirmed by the HMBC correlations of C-23 (δ_C 64.4) to Me-24 (δ_H 1.01) and H-3 (δ_H 4.36). Thus, compound **3** was identified as 19*α*,23-dihydroxyurs-12-en-28-oic acid 3*β*-*O*-*β*-D-glucuronopyranoside-6-*O*-methyl ester.

Compound **4** had a molecular formula of $C_{43}H_{68}O_{16}$, which showed a quasi-molecular ion peak ($[M + Na]^+$) at *m*/*z* 863.4405 (calcd 863.4405). The signals of two anomeric protons at δ_H 5.31 (1H, d, J = 10.0 Hz, H-1 of glucuronic acid) and 6.39 (1H, d, J = 10.0 Hz, H-1 of glucose), which correlated to the two anomeric carbon signals at δ_C 106.5 (C-1 of glucuronic acid) and δ_C 96.0 (C-1 of glucose), respectively, in the HSQC spectrum, suggested the presence of two sugar residues. The sugar residues were identified as D-glucuronic acid

13	21.43 ± 2.73
14	23.58 ± 3.18
15	11.86 ± 3.32
vitamin E	92.74 ± 0.70

[a]For compounds **1**−**15**, the test concentrations ranged from 5 to 200 μM; for vitamin E, the test concentration was 200 μM.

and D-glucose by the hydrolysis and GC analysis. The ^1H and ^{13}C NMR data of **4** were similar to those of **3** except for the presence of the additional signals corresponding to one glucose group. This glucose unit was attached to C-28 of the aglycone, evidenced by the downfield shift of C-28 and the HMBC correlation between δ_H 6.39 (H-1 of glucose) and δ_C 177.1 (C-28 of aglycone) (Figure 2). Both the glucopyranosyl and glucuronopyranosyl units existed in the form of β anomeric configuration, based on the observation of the large $^3J_{H\text{-}1,\ H\text{-}2}$ coupling constants. Thus, compound **4** was identified as 19α,23-dihydroxyurs-12-en-28-oic acid 3β-*O*-[β-D-glucuronopyranoside-6-*O*-methyl ester]-28-*O*-β-D-glucopyranosyl ester.

Compound **5** had a molecular formula of $C_{47}H_{74}O_{18}$ on the basis of its HR-ESI-MS $[M + Na]^+$ ion peak at m/z 949.4729 (calcd 949.4772). The ^1H and ^{13}C NMR data of **5** were similar to those of silphioside G[31] except for the presence of additional signals corresponding to one arabinose group. Compound **5** contained three sugar residues, which were identified as L-arabinose, D-glucuronic acid, and D-glucose by GC analysis. The arabinose group was located at the C-2 of the glucuronic acid unit, evidenced by the HMBC correlation between δ_H 5.28 (H-1 of arabinose) and δ_C 83.7 (C-2 of glucuronic acid). The β anomeric configuration of the glucopyranosyl unit was established on the basis of the observation of the large $^3J_{H\text{-}1,\ H\text{-}2}$ coupling constant. The anomeric configuration of the arabinopyranosyl unit was assigned to be α, deduced from the NOESY correlations among the signals at δ_H 5.28 (H-1 of arabinose), δ_H 4.28 (H-3 of arabinose), and δ_H 4.39 (H-4 of arabinose) (Figure 3). Therefore, compound **5** was identified as 3β-*O*-[α-L-arabinopyranosyl-(1→2)-β-D-glucuronic acid]-oleanolic acid 28-*O*-β-D-glucopyranosyl ester.

Protective Effects of the Isolates against H_2O_2-Induced Myocardial Cell Injury. Cardiovascular diseases may be caused by intracellular oxidative damage to biomolecules via reactive oxygen species (ROS).[32] A number of studies showed that antioxidants reduced oxidative stress-mediated cellular injury.[33] Among ROS, H_2O_2 readily crosses cellular membranes and gives rise to the highly reactive hydroxyl radical, which is the most reactive and induces severe damage to adjacent biomolecules.[34] The H_2O_2-mediated oxidative injury resulted in a significant decrease of mitochondrial respiration, glutathione, and protein thiol content and in an increased level of GSSG.[35] H_2O_2 has been used frequently in models of oxidative stress in H9c2 cardiomyocytes to investigate protective function.[36,37] The *I. cornuta* extract was reported to have the protective effect on myocardial ischemia.[38] In this study, the protective effects of compounds **1**−**15** against H_2O_2-induced myocardial cell injury were tested. As shown in Table 3, compounds **1**, **4**, **6**, and **13** (12.5−200 μM) significantly increased the viability of H9c2 induced by H_2O_2 in a dose-dependent manner, ranging from the concentrations at 12.5 to 200 μM. Compound **4** was shown to be the most efficient among the isolates. It increased the cell viability at a low concentration of 25 μM and was more efficient than vitamin E, which was used as the positive control. Compounds **1**, **6**, and **13** showed moderate protective effects. They significantly improved cell viability at a concentration of 200 μM. Previous studies have indicated that vitamin E inhibits peroxidative damage associated with ischemia and reperfu-

dx.doi.org/10.1021/jf4046667 | J. Agric. Food Chem. 2014, 62, 488−496

sion.[39,40] The triterpenoid saponins contained in *I. cornuta* might play a similar preventive role. Further studies are warranted to explore their potential.

DPPH Radical Scavenging Capacity Assay. The antioxidant activity bioassay of compounds **1**−**15** was tested by DPPH radical scavenging capacity assay. The maximal scavenging rates of compounds **1**−**15** are shown in Table 4; the scavenging rates of compounds **1**−**15** were <30% at a concentration of 200 μM. In other words, compounds **1**−**15** had no significant DPPH radical scavenging capacity over the concentration range from 5 to 200 μM. Combined with H_2O_2-induced myocardial cell injury experiment, these results indicated that the protective effects of the compounds against myocardial cell injury were not directly associated with their radical scavenging capacity. The mechanisms of the protective effects of the compounds on myocardial cell injury need to be further investigated.

Assessment of Multi-mycotoxin Adsorption Efficacy of Grape Pomace

Giuseppina Avantaggiato,* Donato Greco, Anna Damascelli, Michele Solfrizzo, and Angelo Visconti

Institute of Sciences of Food Production (ISPA), National Research Council (CNR), Via Amendola 122/O, 70126 Bari, Italy

ABSTRACT: Grape pomace (pulp and skins) was investigated as a new biosorbent for removing mycotoxins from liquid media. In vitro adsorption experiments showed that the pomace obtained from Primitivo grapes is able to sequester rapidly and simultaneously different mycotoxins. Aflatoxin B_1 (AFB_1) was the most adsorbed mycotoxin followed by zearalenone (ZEA), ochratoxin A (OTA), and fumonisin B_1 (FB_1), whereas the adsorption of deoxynivalenol (DON) was negligible. AFB_1 and ZEA adsorptions were not affected by changing pH values in the pH 3−8 range, whereas OTA and FB_1 adsorptions were significantly affected by pH. Equilibrium adsorption isotherms obtained at different temperatures (5−70 °C) and pH values (3 and 7) were modeled and evaluated using the Freundlich, Langmuir, Sips, and Hill models. The goodness of the fits and the parameters involved in the adsorption mechanism were calculated by the nonlinear regression analysis method. The best-fitting models to describe AFB_1, ZEA, and OTA adsorption by grape pomace were the Sips, Langmuir, and Freundlich models, respectively. The Langmuir and Sips models were the best models for FB_1 adsorption at pH 7 and 3, respectively. The theoretical maximum adsorption capacities (mmol/kg dried pomace) calculated at pH 7 and 3 decreased in the following order: AFB_1 (15.0 and 15.1) > ZEA (8.6 and 8.3) > OTA (6.3−6.9) > FB_1 (2.2 and 0.4). Single- and multi-mycotoxin adsorption isotherms showed that toxin adsorption is not affected by the simultaneous presence of different mycotoxins in the liquid medium. The profiles of adsorption isotherms obtained at different temperatures and pH and the thermodynamic parameters ($\Delta G°$, $\Delta H°$, $\Delta S°$) suggest that mycotoxin adsorption is an exothermic and spontaneous process, which involves physisorption weak associations. Hydrophobic interactions may be associated with AFB_1 and ZEA adsorption, whereas polar noncovalent interactions may be associated with OTA and FB_1 adsorption. In conclusion, this study suggests that biosorption of mycotoxins onto grape pomace may be a reasonably low-cost decontamination method.

INTRODUCTION

Winemaking generates waste in the form of grape pomace that remains after grape has been pressed. On the basis of some estimates, approximately 20% of the grape total weight is waste, which translates to >8 million tons worldwide of grape pomace.[1] Removal of grape pomace is costly, and if it is not treated effectively, it poses a serious environmental problem.[2] Several processes have been suggested for utilization of pomace, including extraction of anthocyanins, citric acid, ethanol, and grape seed oil.[3] At present, grape pomace is mainly used for soil conditioning or as low-cost raw material for animal feed, especially for herbivores and in the dry season when pastures are scarce.[4,5] Grape pomace represents a potentially valuable source of phenolic antioxidants, which can have technological applications as feed additives and possible nutritional and health benefits.[6] The content of tannins in grape pomace reduces ruminal crude protein degradability, which may prevent bloat when cows are fed high-concentrate diets.[7] Dietary polyphenol-rich grape products were found effective in broiler chicks and piglets in improving the physiology and biochemistry of the gut, thus leading to better nutrient absorption and increased disease resistance.[8,9] The supplementation of human food with grape pomace and its use during some food-processing processes have been also attempted. In the form of dried, milled flour, grape pomace has been incorporated into bakery products to make cookies, cakes, or specialty breads, which showed higher contents of dietary fiber and phenolic compounds and enhanced antioxidant properties.[10,11]

Recently, an innovative winemaking procedure involving the use of grape pomace has been suggested as a corrective measure to reduce ochratoxin A (OTA) levels in must and wine.[12] The procedure proposed the repassage of contaminated musts or wines over grape pomaces having no or little OTA contamination, and it removed up to 65% of OTA within 24 h.[12] These findings supported the hypothesis that grape pomace has affinity for OTA adsorption.[12] The work did not study the mechanism for OTA adsorption by grape pomace or explore its effectiveness in adsorbing mycotoxins other than OTA, such as aflatoxin B_1 (AFB_1), zearalenone (ZEA), fumonisin B_1 (FB_1), and deoxynivalenol (DON). These fungal metabolites are the most commonly occurring mycotoxins, which can be found worldwide in food and feed. They can cause a variety of diseases (mycotoxicoses) in a wide range of susceptible animal species including humans.[13,14] They often co-occur, depending on the environmental and substrate conditions, and can lead to toxicological interactions (synergistic effects).[15] So far, only activated carbon has been found effective in adsorbing in vitro these mycotoxins.[16−19] However,

it is probably more suited to be used as an antidote for severe intoxication. The great variability in the results of long-term exposure experiments and its potential for also sequestering important nutrients diminishes its overall practical effectiveness for routine dietary inclusion.[18] Except for activated carbon, most substances (clays) used as mycotoxin binders to decontaminate mycotoxin-contaminated feeds fail in sequestering structurally different mycotoxins.[16,18] They appear to bind to only a limited group of mycotoxins (mainly aflatoxins) while showing very little or no binding to others. Therefore, feed additives acting as multi-mycotoxin binders are sought.

Due to the potential ability of grape pomace in binding OTA and its well-known health benefits, the objective of the present work was to explore the feasibility of using grape pomace as a low-cost biosorbent for mycotoxin decontamination. For the first time, this study examined the ability of grape pomace to adsorb simultaneously different mycotoxins from liquid media at physiological pH. The pomace obtained from a red grape variety (cv. Primitivo) was used for the adsorption study.

MATERIALS AND METHODS

Reagents and Samples. Mycotoxin standards (purity > 99%) were supplied by Sigma-Aldrich (Milan, Italy). All chemicals used were of analytical grade unless otherwise stated. All solvents (HPLC grade) were purchased from J. T. Baker (Deventer, The Netherlands). Water was of Milli-Q quality (Millipore, Bedford, MA, USA). Mycotoxin adsorption was studied at different pH values using different media (1 mmol/L), such as citrate buffers at pH 3, 4, and 5 and phosphate buffers at pH 6, 7, 8, and 9. Mycotoxin stock solutions of AFB_1, OTA, ZEA, and DON (1 mg/mL each) were prepared by dissolving solid commercial toxins in acetonitrile (HPLC grade). FB_1 stock solution (1 mg/mL) was prepared in acetonitrile/water (50:50, v/v). Stock solutions were stored in the dark at 4 °C. A multi-mycotoxin standard solution containing 200 μg/mL of each toxin (AFB_1, ZEA, FB_1, OTA, and DON) was prepared by mixing equal volumes of mycotoxin stock solutions. This solution or the mycotoxin stock solutions were properly diluted with buffers at different pH values to prepare the mycotoxin working solutions for adsorption experiments and calibrants.

Fermented grape pomace was obtained by manually processing grapes of a red grape variety (Primitivo) grown and harvested in Conversano (Apulia, Italy). Seeds and stems were manually separated and discarded, and the peel and pulp were oven-dried at 50 °C until constant weight. The dried material was ground into fine powder by a microfine grinder drive, MF10 Basic model (IKA-Werke GmbH & Co., KG/Germany), provided with a 0.5 mm interchangeable sieve (MF 0.5 model) for particle size filtering. OTA analysis of grape pomace was performed according to the method of Solfrizzo et al.[20] and showed the absence of toxin.

LC Analysis of Mycotoxins. DON, AFB_1, ZEA, and OTA were analyzed according to a UPLC method, which allowed the simultaneous determination of the toxins. The UPLC apparatus consisted of a Waters Acquity UPLC system (Milford, MA, USA). Data acquisition and instrument control were performed by Empower 2 software (Waters). The column used was a 100 mm × 2.1 mm i.d., 1.7 μm, Acquity UPLC BEH RP-18, with an Acquity UPLC column in-line filter (0.2 μm). Chromatographic separation of DON, AFB_1, ZEA, and OTA was achieved through a 13.5 min gradient delivery of a mixture of A (water/acetonitrile 85:15 v/v) and B (methanol/acetonitrile 50:50 v/v, containing 0.5% acetic acid) at a flow rate of 0.4 mL/min. The temperatures of the column and sample compartment were maintained at 40 and 15 °C, respectively. The injected volume was 5 μL in a partial loop with needle overfill mode. The UV absorption spectra of DON and AFB_1 were recorded in the range of 190−400 nm. UV absorbance data were collected with a bandwidth of 1.2 nm and without digital filtering, at wavelengths of 220 nm for DON and 350 nm for AFB_1. A LC UV chromatogram was acquired at 220 nm absorbance wavelength for the first 3 min and then at 350 nm. Fluorescence detection of AFB_1, ZEA, and OTA was carried out using a wavelength program with, respectively, excitation and emission wavelengths of 333 and 460 nm until 7.5 min for AFB_1 detection, then of 274 and 440 nm from 7.5 to 8.5 min for ZEA, and of 333 and 460 nm from 8.5 to 13.5 min for OTA. AFB_1 was detected by both UV and fluorometric detectors without postcolumn derivatization.

FB_1 was analyzed according to a HPLC method. The HPLC-FLD apparatus was an Agilent 1100 series (Agilent, Waldbronn, Germany) equipped with a binary pump, autosampler, column thermostat set at 30 °C, and spectrofluorometric detector with excitation and emission wavelengths set at 335 and 440 nm, respectively. The column was a 100 × 4.6 mm i.d., 2.6 μm, Kinetex core−shell particle with pentafluorophenyl stationary phase (Phenomenex, Torrance, CA, USA). The isocratic mobile phase consisted of the mixture water/methanol/acetonitrile (50:25:25, v/v/v) containing acetic acid (1%) and eluted at an 0.8 mL/min flow rate for 20 min. Prior to HPLC analysis, FB_1 samples were precolumn derivatized with *o*-phthaldialdehyde reagent, according to the method described by De Girolamo et al.[21]

LC methods were linear in the concentration range of 0.07−1.0 μg/mL (five mycotoxin levels) for DON; 0.007−1.0 μg/mL (seven mycotoxin levels) for AFB_1, ZEA, and OTA; and 0.05−5.0 μg/mL (eight mycotoxin levels) for FB_1. Calibrants were prepared in buffer at pH 3 and 7 and analyzed in triplicate. The coefficients of determination (R^2) were ≥0.996. The limits of quantitation were 70 ng/mL for DON, 7 ng/mL for ZEA, 0.7 ng/mL for OTA and AFB_1, and 50 ng/mL for FB_1 (S/N ratio = 10). These limits were 2−4 orders of magnitude below toxin concentration of the working solutions used for adsorption tests and safeguarded the ability to perform accurate LC measurements even when strong mycotoxin adsorption occurred (>90%).

Mycotoxin Adsorption Experiments. Grape pomace (pulp and skins) was weighed in a 4 mL silanized amber glass vial and suspended with an appropriate volume of (multi-)mycotoxin working solution in buffer. The suspension was vigorously mixed by vortex for a few seconds and then shaken in a thermostatically controlled shaker at constant temperature and 250 rpm speed. Adsorption studies were carried out for 90 min to ensure complete adsorption of mycotoxins. After the incubation period, the sample was allowed to settle, and 1 mL of suspension was transferred into an Eppendorf tube and centrifuged for 20 min at 18000*g* and 25 °C. Supernatant sample was split into two aliquots and analyzed for the residual mycotoxin content by HPLC for FB_1 and by UPLC for AFB_1, ZEA, OTA, and DON. Samples analyzed by UPLC were properly diluted by mixing 700 μL of the sample (in citrate or phosphate buffer solution) with 300 μL of a mixture of acetonitrile/methanol (1:2, v/v) containing acetic acid 1% and then filtered by microspin filter tubes 0.2 μm, RC/G (Grace Davison Discovery Science, Deerfield, IL, USA). A blank control was prepared using the mycotoxin working solution in buffer without grape pomace. This was subjected to the same test procedure and served as background control during the analysis to investigate the stability of toxins in the buffer solutions or any possible nonspecific adsorption. Chemical precipitation and losses of mycotoxins due to nonspecific adsorption were not detected.

Preliminary adsorption experiments were performed at constant temperature (37 °C) to determine the effect of various parameters (particle size, contact time, medium pH, and pomace dosage) on the adsorption of mycotoxins. Mycotoxin concentration was 1 μg/mL in all cases.

To study the effect of particle size on mycotoxin adsorption, five fractions of grape pomace were tested by quintuplicate independent adsorption experiments, at pH 7 and 0.5% w/v (5 mg/mL) dosage. The fractions (>500, 500−300, 300−100, 100−60, <60 μm) were obtained by sieving the dried ground material (>500 μm) and using woven wire test sieves (Endecotts, London, UK) with different nominal sizes of apertures placed in sequence.

To investigate the effect of contact time on the adsorption process, the grape pomace was tested at pH 7 and 0.1% w/v (1 mg/mL) dosage (triplicate independent experiments). Samples were withdrawn

eq 2	Freundlich	$Q_{eq} = K_f C_{eq}^{1/n}$	K_f = constant related to capacity of the adsorbent for the mycotoxin n = adsorption intensity
eq 3	Langmuir	$Q_{eq} = Q_{max}[(K_L C_{eq})/(1 + K_L C_{eq})]$	Q_{max} = constant related to maximum mycotoxin uptake K_L = constant related to the energy of adsorption and affinity of the adsorbent
eq 4	Langmuir separation factor (R_L)[a]	$R_L = 1/(1 + K_L C_0)$	K_L = Langmuir constant C_0 = adsorbate initial concentration
eq 5	Sips	$Q_{eq} = (q_m a_s C_{eq}^{1/n})/(1 + a_s C_{eq}^{1/n})$	q_m = constant related to maximum mycotoxin uptake a_s = constant related to energy (affinity) of adsorption $1/n$ = index for the heterogeneity of binding sites[b]
eq 6	Hill	$Q_{eq} = (Q_{max} C_{eq}^{nH})/(K_D + C_{eq}^{nH})$	Q_{max} = constant related to maximum mycotoxin uptake K_D = Hill constant nH = Hill cooperativity coefficient of the binding interaction[c]

[a] R_L value indicates the adsorption nature: $R_L > 1$, unfavorable; $R_L = 1$, linear; $0 < R_L < 1$, favorable; $R_L = 0$, irreversible. [b] $1/n$ value indicates the heterogeneity of the adsorption sites ($0 < 1/n < 1$): $1/n < 1$, heterogeneous system; $1/n = 1$ material with relatively homogeneous binding sites. [c] $nH > 1$, positive cooperativity; $nH = 1$, no cooperativity; $nH < 1$, negative cooperativity.

at appropriate time intervals (1−120 min). Supernatant liquid portions were filtered by 0.2 μm syringe filter tubes (Sartorius Stedim Biotech, Goettingen, Germany) and analyzed for residual mycotoxin content.

To study the effect of pH on toxin adsorption, quintuplicate independent experiments were performed at different pH values (3−9), using 0.5% w/v (5 mg/mL) dosage. To investigate the desorption capacity of mycotoxins from grape pomace due to pH change, 10 mg of pomace was weighed into a 2 mL screw-cap test tube and mixed with 1 mL of mycotoxin working solution (pH 3), containing 1 μg/mL of each toxin (AFB_1, ZEA, OTA, FB_1, and DON) (1% w/v adsorbent dosage). Samples were incubated at 37 °C for 90 min in a rotary shaker (250 rpm). Then, they were centrifuged, and the supernatants were completely removed and analyzed for residual mycotoxin content to calculate mycotoxin adsorption. The adsorbent pellets were washed with 1 mL of buffer at pH 7 (30 min shaking), and then they were centrifuged and the supernatants analyzed to assess mycotoxin desorption. Desorption studies were performed in triplicate. Values for mycotoxin adsorption (pH 3) and desorption (pH 7) were calculated for each toxin and expressed in percent.

The effect of pomace dosage on toxin adsorption was investigated by equilibrium isotherms. Adsorption experiments were performed in triplicate, at constant pH (7 and 3), testing a fixed amount of toxins with different pomace dosages (0.05−3% w/v corresponding to 0.5−30 mg/mL). Adsorption data were expressed as percentage of mycotoxin adsorbed and plotted as a function of grape pomace dosage. Mycotoxin adsorption plots were fitted by the Langmuir model (Table 1).

Equilibrium Adsorption Isotherms. Three sets of adsorption isotherms were carried out at constant temperature and pH by testing a fixed amount of grape pomace with buffered solutions of mycotoxins at different toxin concentrations (0.05−5 μg/mL). Equilibrium isotherms were set up according to the results of preliminary adsorption experiments, using 90 min of contact time, a <500 μm particle size fraction, a 0.1% w/v (1 mg/mL) pomace dosage for AFB_1 and ZEA adsorption, and a 0.2% w/v (2 mg/mL) pomace dosage for OTA and FB_1 adsorption. Due to the inefficacy of grape pomace in adsorbing DON from liquid media, DON was excluded from this study. Isotherms consisted of 10 or more experimental points and were carried out in triplicate. The first set of isotherms (single-mycotoxin system) was conducted at constant temperature (37.0 ± 0.5 °C) and different pH values (3 and 7). These isotherms were used to calculate the parameters (maximum adsorption capacity, adsorption affinity, and heterogeneity of the adsorption process) related to the adsorptions of AFB_1, ZEA, OTA, and FB_1 onto grape pomace and the effect of pH on the adsorption. The second set of isotherms was conducted at constant pH (7) and different temperatures (5.0 ± 0.5, 37.0 ± 0.5, 50.0 ± 0.5, and 70.0 ± 0.5 °C). These isotherms allowed investigation of the influence of temperature change on the uptake of mycotoxins and calculation of the thermodynamic parameters ($\Delta G°$, $\Delta H°$, and $\Delta S°$) related to the mycotoxin adsorption. The third set of isotherms (multi-mycotoxin system) was carried out at constant temperature (37.0 ± 0.5 °C) and pH 7 using mycotoxin working solutions containing a pool of five mycotoxins, in the 0.05−5 μg/mL concentration range and in the 1:1 ratio. These multiple adsorption isotherms were performed to verify if the simultaneous presence of AFB_1, ZEA, OTA, FB_1, and DON can interfere with the adsorption process related to each toxin. The change for adsorption values due to the simultaneous presence of mycotoxins was evaluated by comparing adsorption isotherms and related parameters obtained by single- and multi-mycotoxin adsorption experiments carried out in the same experimental conditions.

Data Calculation and Curve Fitting. The amount of adsorbed mycotoxin was calculated as the difference between the amount of mycotoxin in the supernatant of the blank tubes with no grape pomace and the amount found in the supernatant of the experimental tubes with the pomace. This amount was related then to the quantity present in the supernatant of the blank tubes and expressed in percent. The amount of bound mycotoxin per unit mass of pomace was calculated using eq 1:

$$Q_{eq} = [(C_0 - C_{eq})V]/m \quad (1)$$

Q_{eq} = quantity of mycotoxin adsorbed per milligram of grape pomace (μg/mg); C_0 = concentration of mycotoxin in the supernatants of the blank tubes with no grape pomace (μg/mL); C_{eq} = residual mycotoxin concentration in the supernatant of the experimental tubes with grape pomace at equilibrium (μg/mL); V = volume of solution (mL); and m = mass of grape pomace (mg).

Adsorption isotherms were obtained by plotting the amount of mycotoxin adsorbed per unit of mass of adsorbent (Q_{eq}) against the concentration of the toxin in the external phase (C_{eq}), under equilibrium conditions ($Q_{eq} = f(C_{eq})$. These data were transferred to SigmaPlot (Systat.com, version 12.3) and fitted by the Langmuir, Freundlich, Sips, and Hill isotherm models (Table 1).[22−27] A dimensionless constant known as the separation factor (R_L) derived from the Langmuir equation (Table 1) was used to assess the favorability of adsorption.[25] The Gibbs free energy change ($\Delta G°$, kJ/mol), the standard enthalpy ($\Delta H°$, kJ/mol), and the standard entropy ($\Delta S°$, kJ/mol·K) were calculated according to the study performed by Ringot et al.[28] The SigmaPlot nonlinear regression method, which uses the Marquardt−Levenberg algorithm, was used as a viable tool to define the best-fitting relationship between a set of experimental data and the proposed isotherm models. Statistical analysis was performed using a factorial ANOVA with concentration (C_{eq}) or pomace dosage as categorical predictor variable and quantity of mycotoxin adsorbed (Q_{eq}) as dependent variable. The normality test (Kolmogorov−Smirnov test), the constant variance test (Spearman rank correlation), and the Durbin−Watson statistic test were used to test, respectively, for normally distributed population, constant variance assumption, and correlation between residuals. The threshold for significance level for normality and constant variance test was set at $p < 0.05$. The expected

[a]Values labeled with the same letters in a column are not significantly different (p < 0.05).

value of the Durbin−Watson statistic for random, independent, normally distributed residuals was 2. The coefficient of determination (R^2), the standard errors of the estimate (s_{ylx}), the residual sum of squares (SS_{res}), and the predicted residual error sum of squares (PRESS) were calculated to assess the fitness/suitability of the regression models. The isotherm models that provided the lowest SS_{res}, s_{ylx}, and PRESS and the highest R^2 were considered to give the closest fit.

RESULTS AND DISCUSSION

Effect of Particle Size. The effect of particle size on the mycotoxin adsorption process was studied using fractions with particle size ranging from >500 to <60 μm (Table 2). All fractions adsorbed significant amounts of AFB_1, ZEA, OTA, and FB_1, whereas DON adsorption was negligible. For most toxins, the coarse fraction yielded significantly lower adsorption values (75% AFB_1, 63% ZEA, 50% OTA, and 26% FB_1). These values slightly increased by decreasing particle size (<500 μm) and were constant in the range from 500 to <60 μm. Maximum adsorptions recorded in this range were 82% AFB_1, 70% ZEA, 61% OTA, and 28% FB_1. Therefore, the grape pomace fraction <500 μm was used for subsequent adsorption experiments.

Effect of Contact Time. The effect of contact time for the adsorption of mycotoxins by grape pomace was studied for a period of 2 h (Figure 1). From the kinetic experiments, the plot of mycotoxin adsorption versus time showed that the rate of AFB_1, ZEA, OTA, and FB_1 adsorption by grape pomace is fast at the initial stages of the contact period and then becomes slower near equilibrium. Half of the total adsorption occurred in <3 min, and maximum adsorption was reached in 15 min. No further changes in the adsorption were noted beyond the 15 min period up to 2 h (Figure 1). This finding is of significant importance in the toxin reduction by adsorption. A rapid uptake of toxins and establishment of equilibrium in a short period imply the efficacy of pomace for its use in reduction of toxin bioaccessibility in the gastrointestinal (GI) tract.

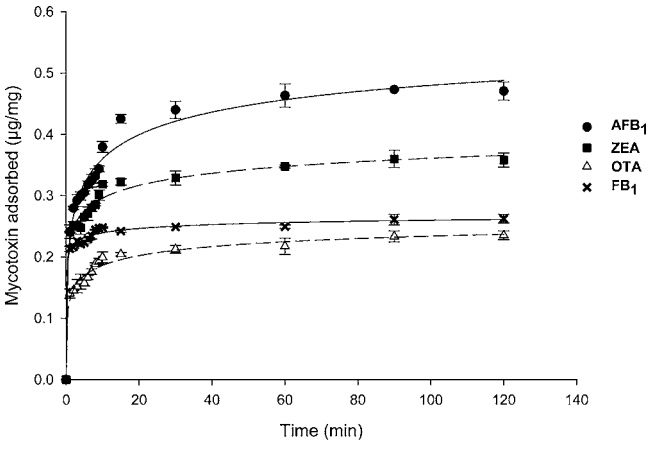

Figure 1. Effect of contact time on adsorption rate of AFB_1, ZEA, OTA, and FB_1 by grape pomace. Adsorption experiments were performed at constant pH (7) and temperature (37 °C), using 0.1% w/v pomace dosage and 1 μg/mL mycotoxin concentration.

Effect of pH. The removal of mycotoxins from aqueous medium through an adsorption process is, in most cases, highly dependent on the pH. Medium pH can affect the surface charge of adsorbents as well as the degree of ionization of toxins, and subsequently it can lead to a shift in reaction kinetics and equilibrium characteristics of the adsorption process. This is more important when the adsorption process involves electrostatic interactions. In general, the charge of the toxin depends on its pK_a. The toxin is mainly in protonated form at pH < pK_a and in deprotonated form at pH > pK_a. The effect of pH on AFB_1, ZEA, OTA, and FB_1 adsorption by grape pomace was different according to the degree of ionization of molecules (Table 3). AFB_1 is a non-ionizable molecule (Figure 2), and the

[a]Values labeled with the same letters in a column are not significantly different (p < 0.05).

pK_a in water is not applicable. Therefore, a change of pH should not affect AFB_1 adsorption. Accordingly, grape pomace sequestered AFB_1 to the same extent in all pH ranges assayed in the study (Table 3). ZEA is a diphenolic compound with an estimated pK_a of 7.6,[29] so some amount of phenolate anion can be present in water near pH 7. ZEA adsorption was unaffected by pH in the range of 3−8 and slightly decreased at pH 9 (p < 0.05). OTA consists of a dihydroisocoumarin moiety linked through its 7-carboxyl group by an amide linkage to L-phenylalanine (Figure 2). The pK_a values are in the ranges of 4.2−4.4 and 7.0−7.3, respectively, for the carboxyl group of the phenylalanine moiety and the phenolic hydroxyl group of the isocoumarin part.[30] This indicates that, in aqueous solutions near pH 7, both the monoanion (OTA^-) and the dianion (OTA^{2-}) are present, whereas the protonated and uncharged toxin is present in acid solutions (pH <4). OTA adsorptions recorded at pH ≤4 were constant and significantly higher than those recorded at pH ≥5 (p < 0.05) (Table 3). This result

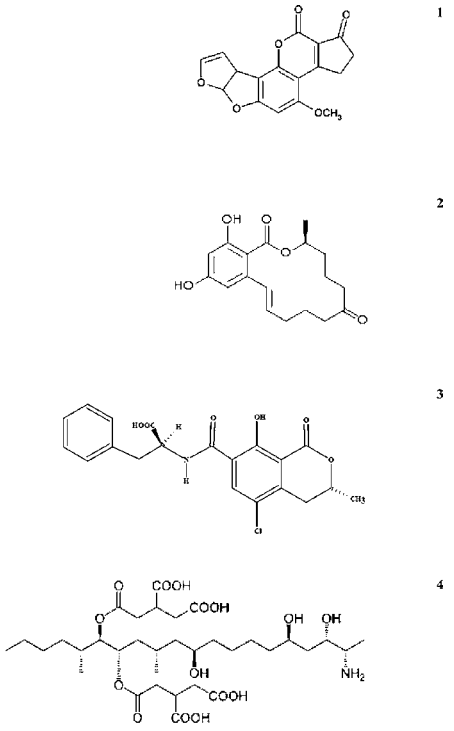

Figure 2. Structures of mycotoxins: **1**, AFB_1; **2**, ZEA; **3**, OTA; **4**, FB_1.

suggests that OTA adsorption is higher when it is in the uncharged form and slightly decreases when it is in the anionic form. Contrary to AFB_1, ZEA, and OTA, FB_1 is a more polar and water-soluble toxin, containing carboxylic, hydroxyl, and amino functional groups (Figure 2). No report concerning the pK_a of FB_1 is available in the literature.[31] The pK_a values for tricarballylic acid are 3.5, 4.6, and 5.8, and the aliphatic amine group should have a pK_a >9. Therefore, at pH between 6 and 9, FB_1 could be in the anionic form because of deprotonation of carboxylic groups, whereas it could be in the cationic form at pH <6 due to protonation of the amine group. FB_1 adsorption by grape pomace recorded at pH ≥6 was significantly higher than that recorded at pH ≤5 ($p < 0.05$) (Table 3). It seems that the anionic form of FB_1 contributes to adsorption by grape pomace, whereas the cationic form decreases such adsorption. During digestion, the pH of the food bolus is not constant but, depending on GI compartments, changes to a large extent. In monogastric animals, it ranges from 1.5−2.5 in the stomach to 5.5−6.0 in the intestinal lumen. Taking into account the findings of this study, it can be supposed that AFB_1 and ZEA adsorptions by grape pomace are stable within the pH range that can be found in the GI tract of monogastric animals, whereas pH change could affect FB_1 and OTA adsorptions to some extent. Hence, a desorption study was performed to assess if change of pH can cause release of the sequestered toxins. Mycotoxins were first adsorbed onto grape pomace at pH 3, and then the pellet containing the adsorbed mycotoxins was washed with a medium at pH 7. Adsorption and desorption values were, respectively, 94 and 4% for AFB_1; 87 and 10% for ZEA; 84 and 14% for OTA; and 16 and 45% for FB_1. These results suggest that grape pomace has high efficacy in adsorbing AFB_1, ZEA, and OTA at acid pH, and it is able to retain the adsorbed toxins when the pH rises to neutral values. FB_1 is sequestered poorly at pH 3, and almost half of the adsorbed toxin can be released when the pH of the medium changes from 3 to 7.

Effect of Adsorbent Dosage. AFB_1, ZEA, OTA, and FB_1 adsorption was significantly affected by the adsorbent dosage, and the percentage of mycotoxins removed from neutral or acid buffer solutions increased with increasing dosages of grape pomace (Figure 3). The Langmuir model provided good correlations for isotherm adsorption plots ($R^2 > 0.990$). AFB_1, ZEA, and OTA isotherms obtained at different pH values were comparable (Figure 3). Experimental values for AFB_1, ZEA, and OTA adsorption were in the ranges of 28−98, 21−94, and 6−94%, respectively. FB_1 adsorptions were significantly higher at pH 7 (17−44%) than at pH 3 (11−31%) (Figure 3). The Langmuir model allowed the calculation of the theoretically estimated maximum adsorption (Ads_{max}) and the C_{50},[32] which is the theoretically estimated adsorbent dosage to achieve a 50% reduction of the absorbable toxin (Table 4). The C_{50} could not be calculated for FB_1 at pH 3. For all toxins, Ads_{max} and C_{50} values were in accordance with the experimental values for mycotoxin adsorption shown in Figure 3. With these findings taken into account, it is not useful to increase the dosage of grape pomace beyond 4 mg/mL to sequester AFB_1, ZEA, and OTA from a 1 μg/mL or higher mycotoxin solutions. Therefore, for all of the subsequent isotherm experiments, grape pomace dosage was fixed at 1 mg/mL for AFB_1 and ZEA and at 2 mg/mL for OTA and FB_1.

Adsorption Isotherms (Single-Mycotoxin System). The adsorption isotherm is an invaluable curve describing the phenomenon governing the retention (or release) or mobility of a substance from the aquatic environments to a solid phase at a constant temperature and pH.[33] Its physicochemical parameters together with the underlying thermodynamic assumptions provide insight into the adsorption mechanism and surface properties as well as the degree of affinity of the adsorbents.[33] Several equations have been published to study the isotherm adsorption of mycotoxins to organic and inorganic adsorbent materials.[22,34] In this study, four adsorption models often reported in the literature were used to provide the best description of mycotoxin adsorption by grape pomace (Table 1). The nonlinear regression analysis method,[35] instead of the linear regression with transformed variables, was applied to assess the goodness of the fits and to calculate the parameters involved in the adsorption mechanism (Table 5). All adsorption models provided a good fit line to experimental adsorption data (small variance and $R^2 \geq 0.979$) (Table 5). The amount of mycotoxin adsorbed per unit mass of grape pomace increased gradually by increasing mycotoxin molecules in the working solution; thus, isotherms showed an exponential relationship and a typical L-1 (Langmuir) shape (Figure 4). This suggests that, in the experimental conditions of this study, the plateau was not reached and part of the capacity of the absorbent was occupied by the mycotoxins.

AFB_1 Adsorption Isotherms. AFB_1 adsorption by grape pomace yielded similar equilibrium isotherms at pH 3 and 7 (Figure 4). Experimental values for AFB_1 adsorption in percent varied in the range of 57−30%. The experimental values for maximum adsorption capacity recorded at pH 3 and 7 were, respectively, 1.53 ± 0.04 μg/mg (4.89 ± 0.12 mmol/kg) and 1.54 ± 0.05 μg/mg (4.94 ± 0.16 mmol/kg) (Figure 4). Among the tested isotherm equations, the better representation of the experimental results of the AFB_1 adsorption isotherms was obtained using the Sips and Hill models ($R^2 > 0.998$ and low error values) (Table 5). These equations are often found to be

AFB_1	103.9 ± 0.5	103.2 ± 0.3	1.4	1.2
ZEA	101.9 ± 0.5	100.7 ± 0.7	2.5	2.5
OTA	100.3 ± 0.9	100.2 ± 2.2	2.5	4.0
FB_1	22.8 ± 0.5	45.5 ± 0.4	nd	30.0

[a] Ads_{max} and C_{50} were calculated by fitting the adsorption isotherms in Figure 3 with the Langmuir isotherm model.

superior to either the Freundlich or Langmuir equation in correlations, as they were developed for adsorption on heterogeneous solids. The Sips isotherm (Table 1) is a combined form of the Langmuir and Freundlich expressions deduced for predicting the heterogeneous adsorption systems and circumventing the limitation of the rising adsorbate concentration associated with the Freundlich isotherm model.[26] At low adsorbate concentrations, it reduces to the Freundlich isotherm, whereas at high concentrations, it predicts a monolayer adsorption capacity characteristic of the Langmuir isotherm. The Hill model (Table 1) assumes that adsorption is a cooperative phenomenon, with the ligand binding ability at one site on the macromolecule, and may influence different binding sites on the same macromolecule.[27] The Sips and Hill models are mathematically equivalent[36] and provide same error values and coefficients of determination (Table 5). The $1/n$ exponent in the Sips model is analogous to the nH exponent in the Hill model. However, they have different meanings, $1/n$ being the heterogeneity factor of the adsorption and nH the cooperativity coefficient of the binding interaction. According to the Sips and Hill models, the theoretical maximum AFB_1 adsorption capacity was 4.73 ± 0.77 μg/mg (15.15 ± 2.47 mmol/kg) and 4.69 ± 0.55 μg/mg (15.02 ± 1.76 mmol/kg) at pH 3 and 7, respectively (Table 5). The constant a_s in the Sips equation is related to the energy and affinity of adsorption. The values for the a_s parameter in the Sips model were 0.17 ± 0.03 and 0.16 ± 0.02 mL/μg at pH 3 and 7, respectively (Table 5). The Sips exponent ($1/n$) was <1 in all cases, suggesting heterogeneous binding sites. Similarly, the Hill cooperativity coefficient (nH) was <1, indicating a negative cooperativity of the binding interaction. In conclusion, these findings suggest that the AFB_1 adsorption mechanism is heterogeneous and occurs at a finite (fixed) number of definite localized sites, which are nonequivalent, with lateral interaction (negative interaction) and steric hindrance between the AFB_1 adsorbed molecules.

[a]The Sips and Hill models are mathematically equivalent and provide the same error values and adsorption parameters. [b]Does not converge.

ZEA Adsorption Isotherms. Isothermal adsorption of ZEA by grape pomace was not affected by pH (Figure 4). The experimental values for ZEA adsorption recorded at pH 3 and 7 were comparable and ranged from 38 to 20%. The experimental values for maximum adsorption capacity were 1.25 ± 0.03 μg/mg (3.91 ± 0.09 mmol/kg) and 1.12 ± 0.09 μg/mg (3.51 ± 0.27 mmol/kg) at pH 3 and 7, respectively. The Langmuir equation was found to be the best fitting isotherm model for ZEA adsorption (Table 5). At both pH values, the correlations obtained by this model were in excellent agreement with the experimental adsorption data and yielded comparable adsorption parameters (Table 5). The predicted maximum ZEA adsorption capacity was 2.65 ± 0.14 μg/mg (8.32 ± 0.44 mmol/kg) and 2.73 ± 0.20 μg/mg (8.58 ± 0.63 mmol/kg) at pH 3 and 7, respectively. The Langmuir K_L parameter, which is related to the free energy of adsorption, was 0.20 ± 0.01 and 0.19 ± 0.02 mL/μg at pH 3 and 7, respectively. These values suggest favorable ZEA adsorption by grape pomace. The favorability of ZEA adsorption was confirmed by the essential features of the Langmuir isotherm model, called the separation factor, R_L (Table 1).[25] At both pH values, this dimensionless factor ranged from 1.00 to 0.50 for the initial ZEA concentration values of 0.05−5.00 μg/mL. At all ZEA concentrations, R_L values were in the range of 0−1, which is indicative of favorable adsorption. In addition, the R^2 and error values demonstrate that the Sips and Hill models can also adequately fit ZEA adsorption data (Table 5). The Hill cooperativity coefficient (nH) was approximately 1, indicating no cooperativity of the binding interaction. Similarly, the heterogeneity factor ($1/n$) of the Sips isotherm equation was almost equal to 1. This implies that the Sips isotherm equation reduces to the Langmuir equation, and ZEA adsorption data are more of the Langmuir form rather than of the Freundlich form. In conclusion, these results are all indicative of a homogeneous adsorption process for ZEA by grape pomace.

OTA Adsorption Isotherms. Unlike AFB_1 and ZEA adsorptions, OTA adsorption was slightly affected by pH. The experimental values for OTA adsorption were 54−33% at pH 3 and 33−26% at pH 7. The related experimental values for maximum adsorption capacity were, respectively, 0.82 ± 0.08 μg/mg (2.04 ± 0.20 mmol/kg) and 0.64 ± 0.09 μg/mg (1.58 ± 0.22 mmol/kg) (Figure 4). At both pH values tested in the study, the Freundlich and Langmuir models provided a good fit line to experimental data (small variance and R^2 values >0.993), whereas the Hill and Sips models did not converge (Table 5). The latter models, exceeding the maximum number of repeated fit attempts before failure (200 iterations), provided inaccurate parameters. Maximum adsorption capacities were calculated by the Langmuir model and comparable at pH 3 and 7, being 2.79 ± 0.21 μg/mg (6.91 ± 0.52 mmol/kg) and 2.54 ± 0.47 μg/mg (6.29 ± 1.16 mmol/kg), respectively. Between the biparametric models, the Freundlich model was superior to the Langmuir model in fitting adsorption data. This may be explained by the binding process occurring under conditions outside the assumptions of the Langmuir model, and it suggests a heterogeneous binding mechanism. The Freundlich isotherm is the earliest known relationship describing the nonideal and reversible adsorption, not restricted to the formation of monolayer.[23] This empirical model can be applied to multilayer adsorption, with nonuniform distribution of adsorption heat and affinities over the heterogeneous surface. The Freundlich model provides no information on the monolayer adsorption capacity, in contrast to the Langmuir model. The heterogeneity index in the Freundlich model, $1/n$, gives information on the population of the binding sites and the adsorption intensity and is associated with the favorability of the binding process. A value of $1/n = 1$ suggests that the population of binding sites is homogeneous, whereas a value below unity implies favorability of the adsorption. At acid and neutral pH, the values computed for the Freundlich parameter $1/n$ were 0.77 ± 0.01 and 0.87 ± 0.02, respectively. These values were <1 and indicate

dx.doi.org/10.1021/jf404179h | J. Agric. Food Chem. 2014, 62, 497−507

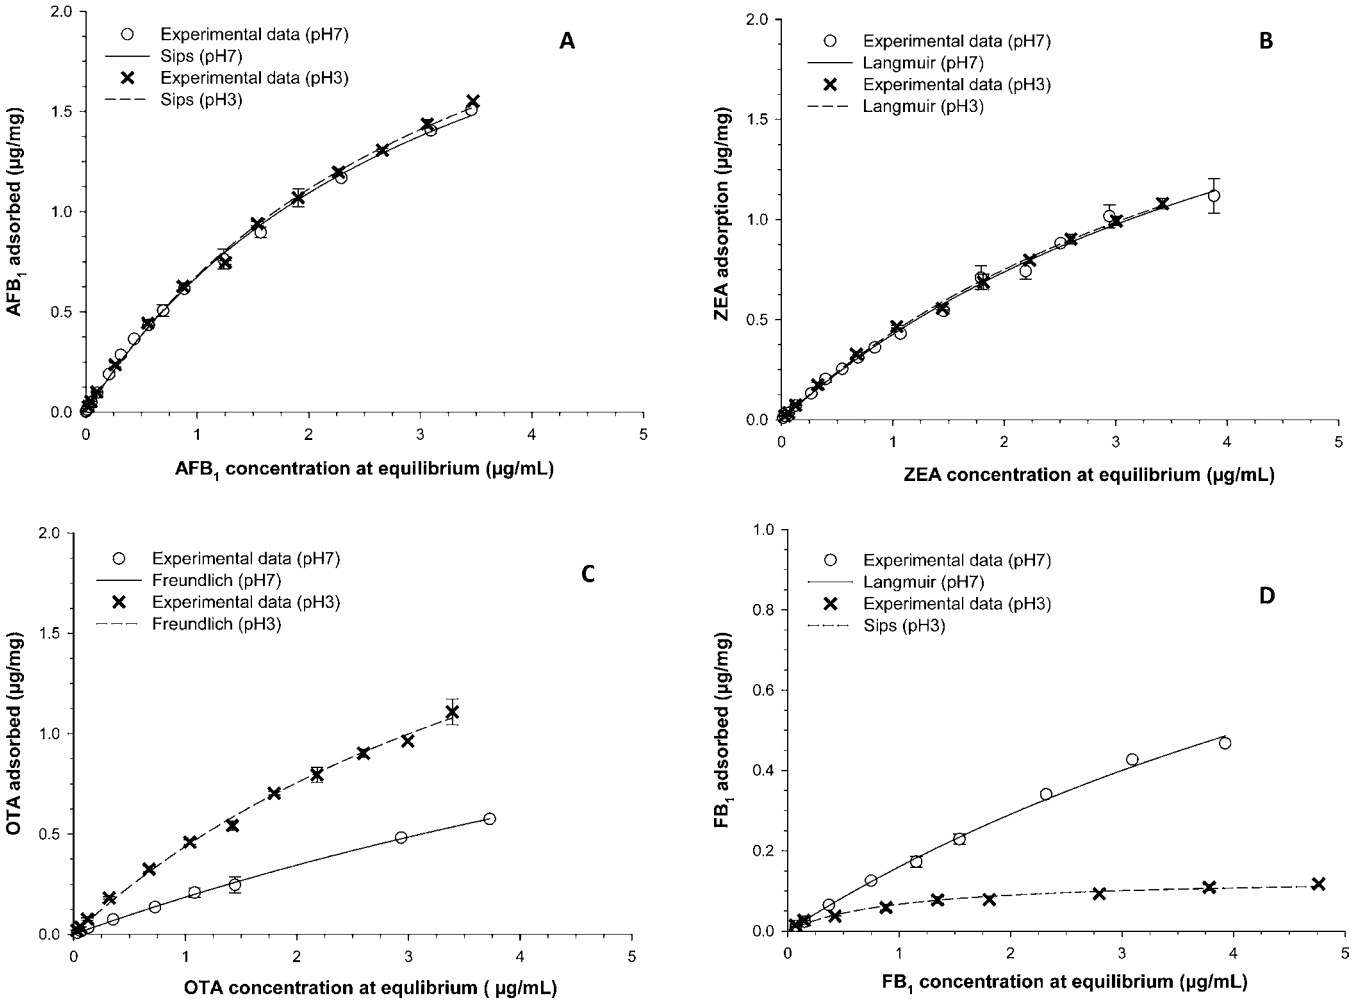

Figure 4. Effect of mycotoxin concentration on (A) AFB_1, (B) ZEA, (C) OTA, and (D) FB_1 adsorption by grape pomace. Equilibrium adsorption isotherms were obtained at constant temperature (37 °C) and pH (3 and 7) by testing a fixed amount of grape pomace with increasing toxin concentrations (0.05−5 μg/mL).

favorability for the OTA adsorption process. However, the $1/n$ parameter being estimated at pH 3 lower than at pH 7, it can be assumed that more binding sites or higher adsorption intensity can be found at acid pH than at neutral pH. Accordingly, the K_f Freundlich constant, which is attributed to affinity of the adsorbent, was 2-fold higher at pH 3 than at pH 7 (Table 5). In conclusion, increase of medium pH from 3 to 7 reduces the affinity of adsorption. The decreased affinity for OTA adsorption by grape pomace at pH 7 may be induced by the presence of an anionic form of the toxin, which probably leads to the repulsion between OTA molecules and negative charges that could be found on the adsorption surface. In agreement with these findings, OTA adsorption by negative charged surfaces (such as zeolites) has been found significantly higher at pH 3 than at pH 7 and 9.[30] The existence of a heterogeneous adsorption in the case of OTA suggests that different types of interaction can occur, such as hydrophobic and ionic forces.

FB_1 Adsorption Isotherms. Similarly to OTA adsorption, different mechanisms may be involved in FB_1 adsorption depending on pH and then on the degree of ionization of molecules. Highest adsorption was achieved at pH 7 (Figure 4). The experimental values for FB_1 adsorption were 30−5% at pH 3 and 25−22% at pH 7. The experimental values for maximum adsorption capacity recorded at these pH values were, respectively, 0.12 ± 0.01 μg/mg (0.16 ± 0.01 mmol/kg) and 0.54 ± 0.06 μg/mg (0.74 ± 0.08 mmol/kg) (Figure 4). With error and R^2 values reported in Table 5 taken into account, it was determined that the Langmuir model is the best isotherm model to fit the adsorption data at pH 7, whereas the Sips and Hill models produce better correlations at pH 3. The applicability of these isotherm models to the FB_1−grape pomace system implies that FB_1 adsorption is complex, and it confirms that more than one mechanism can be involved. In particular, monolayer adsorption (homogeneous adsorption) may exist at pH 7, whereas heterogeneous and lower adsorption can occur at pH 3. The predicted maximum adsorption capacities calculated by the Langmuir model at pH 7 and by the Sips/Hill models at pH 3 were 1.60 ± 0.19 μg/mg (2.22 ± 0.26 mmol/kg) and 0.28 ± 0.11 μg/mg (0.39 ± 0.15 mmol/kg), respectively (Table 5). In addition, at pH 7 the exponents in the Sips and Hill models were equal to 1. This suggests that the Sips model reduces to the Langmuir equation and the material holds relatively homogeneous binding sites. Moreover, no cooperativity in the binding interactions occurs when the adsorption system is at neutral pH, that is, when FB_1 has negative charges. At pH 3, FB_1 should be in the cationic form. Likely, the positive charge in the adsorbable molecules reduces the capacity and affinity of the adsorption and results in

dx.doi.org/10.1021/jf404179h | J. Agric. Food Chem. 2014, 62, 497−507

negative cooperativity of the binding process. Thus, it can be concluded that in aqueous solutions near the physiological pH (pH 7), FB_1 adsorption onto grape pomace is favored and occurs mainly by polar noncovalent interactions, such as electrostatic interactions or hydrogen bonds involving the carboxylic functional groups.

Multi-mycotoxin Adsorption Isotherms. In general, adsorbate−surface interactions complicate the adsorption in multicomponent systems.[37] Multi-mycotoxin systems have received less attention than single-mycotoxin systems, and multi-mycotoxin adsorption isotherms have never been described in the literature. Therefore, the adsorption of AFB_1, ZEA, OTA, and FB_1 by grape pomace was also studied by equilibrium adsorption isotherms using a five-component system. This system contained simultaneously AFB_1, ZEA, OTA, FB_1, and DON in equal ratios. Of course, these ratios are not reflected in the real world of natural contamination in which aflatoxin and fumonisin occur orders of magnitude apart. Multi-mycotoxin adsorption isotherms were obtained as in the single-mycotoxin adsorption system, testing the toxins at pH 7 and 37 °C. The adsorption parameters calculated for each toxin in the presence (five-mycotoxin system) and absence (single-mycotoxin system) of other mycotoxins are presented in Table 6. AFB_1 adsorption isotherm plots were fitted by the Sips/Hill models, because they produced better goodness of fit. ZEA, OTA, and FB_1 adsorption isotherms were well fitted by the Langmuir equation. For all mycotoxins considered in the study, the experimental values for mycotoxin adsorption obtained in the single- and multi-mycotoxin adsorption systems were comparable. Similarly, the predicted isotherm adsorption parameters calculated by these systems did not differ (Table 6). The effect of mycotoxin interactions on adsorption may be represented by the ratio of the adsorption capacity for one mycotoxin in the presence of the other mycotoxins, Q^{mix}, to the adsorption capacity for the same mycotoxin when it is present alone in the solution, Q^0. When $(Q^{mix}/Q^0) > 1$, adsorption is promoted by the presence of other mycotoxins; when $(Q^{mix}/Q^0) = 1$, there is no net interaction; and when $(Q^{mix}/Q^0) < 1$, adsorption is suppressed by other mycotoxins. As shown in Table 6, the values of Q^{mix}/Q^0 were all almost equal to 1. Therefore, it can be supposed that mycotoxin adsorption by grape pomace is not suppressed or enhanced by the presence of other mycotoxins in the experimental conditions. In conclusion, for the first time, this study proves that grape pomace can adsorb simultaneously AFB_1, ZEA, OTA, and FB_1 and that these mycotoxins did not compete for adsorption. Grape pomace shows the potential to be used as a broad-spectrum adsorbent material.

Table 6. Mycotoxin Adsorption Parameters Calculated for Mycotoxin Adsorption Isotherms Obtained by Single- and Multi-mycotoxin Adsorption Systems (37 °C, pH 7)

mycotoxin	parameter	single-mycotoxin system	multi-mycotoxin system	Q^{mix}/Q^{0a}

[a] Q^{mix} = adsorption capacity for one mycotoxin in the presence of other mycotoxins; Q^0 = adsorption capacity for one mycotoxin when it is present alone in the solution. [b] Sips parameter related to maximum adsorption capacity (μg/mg). [c] Sips parameter related to energy (affinity) of adsorption. [d] Sips index for the heterogeneity of binding sites. [e] Langmuir parameter related to maximum adsorption capacity (μg/mg). [f] Langmuir parameter related to the energy of adsorption and affinity of the adsorbent.

Thermodynamic Studies. In adsorption studies, both energy and entropy factors must be considered to determine what processes will occur spontaneously.[28] The Gibbs free energy change, $\Delta G°$ (kJ/mol), is the fundamental criterion of spontaneity. Reactions occur spontaneously at a given temperature if ΔG is a negative quantity. Thermodynamic parameters for AFB_1, ZEA, OTA, and FB_1 adsorption by grape pomace were calculated at pH 7 and at different temperatures (5, 37, 50, and 70 °C). For all toxins, experimental adsorption data and predicted maximum adsorption capacities calculated according to isotherm models decreased with an increase in temperature, indicating an exothermic process. Accordingly, the values for the equilibrium constant K^0 for the adsorption reaction decreased as the temperature rose (Table 7). This may be due to a tendency for the mycotoxin molecules to escape from the solid phase with an increase in temperature of the solution. The K^0 was used to calculate the standard Gibbs free energy of adsorption, $\Delta G°$.[28] The negative values of $\Delta G°$ in Table 7 are indicative of a spontaneous adsorption process with a high affinity of the mycotoxins to the surface of the grape pomace. Thermodynamic parameters ($\Delta H°$ and $\Delta S°$) were calculated according to the van't Hoff equation and were determined from the slope and intercept of the plots of ln K^0 versus $1/T$.[28] The plots obtained for all mycotoxins at four different temperatures gave good correlation ($R^2 \geq 0.985$) (data not shown). The values of $\Delta H°$ and $\Delta S°$ are presented in Table 7. $\Delta H°$ values for mycotoxin adsorption are negative, confirming the exothermic nature of the phenomenon. The magnitude of the $\Delta H°$ value gives an indication of the type of adsorption, which can be either physical or chemical.[38] Physisorption involves weak associations, which include hydrogen bonds, van der Waals, dipole−dipole, and induced dipole. Chemisorption implies a chemical reaction or sharing of electrons between the adsorbent and the adsorbate, such as covalent bonds. Physisorption is described as having an enthalpy of <20 kJ/mol, whereas chemisorption is generally >20 kJ/mol.[34] For all mycotoxins the value of enthalpy was <20 kJ/mol, indicating a physical adsorption phenomenon (Table 7). Physical adsorption requiring small energy allows the equilibrium to be attained rapidly and the process to be easily reversible. Interestingly, $\Delta S°$ values were positive for AFB_1 and ZEA adsorptions, but negative for OTA and FB_1 adsorptions (Table 7). The negative values of $\Delta S°$ for OTA and FB_1 adsorption may be understood in terms of restriction of the movement of the molecules on the surface (two dimensions), as compared to the bulk solution (three dimensions). The binding of OTA and FB_1 on grape pomace is thus only enthalpically driven. Generally, this situation corresponds to polar noncovalent interactions (benefit in enthalpy associated to a cost in entropy), such as electrostatic interactions or hydrogen bonds. At the pH value of this study (7.0 ± 0.5), OTA and

FB_1 are in the anionic form; thus, they may be involved in polar noncovalent interactions. On the contrary, positive $\Delta S°$ values for AFB_1 and ZEA adsorption process reflect an increase in the randomness at the solid/liquid interface and suggest hydrophobic interaction between the adsorbent and the adsorbate.[39−41] The positive entropy change may also be caused by the decrease in the number of water molecules surrounding both the adsorbent and the adsorbate molecules involved in the hydrophobic interaction. Generally, hydrophobic interactions are associated with a cost in enthalpy. In conclusion, the thermodynamic parameters calculated for adsorption of mycotoxins onto grape pomace give information about the type of the interaction involved in the adsorption process. At pH 7, hydrophobic interactions could be associated with AFB_1 and ZEA adsorption (small $\Delta H°$ and positive $\Delta S°$ values). Electrostatic interactions could explain the higher $\Delta H°$ and the negative $\Delta S°$ values calculated for OTA and FB_1 adsorption.

The present work shows that grape pomace can be used as a low-cost and healthy biosorbent for removing mycotoxins from liquid media. This is the first time that grape pomace has been tested as a multi-mycotoxin adsorbent. These findings show that a grape pomace prepared from a red grape variety (cv. Primitivo) is able to sequester, in different adsorption systems, AFB_1, ZEA, OTA, and FB_1. Contact time curves showed that the adsorption of mycotoxins by grape pomace is rapid, which is of significant importance in the toxin reduction by adsorption. Adsorption/desorption studies performed at physiological pH showed that mycotoxin adsorption by grape pomace is stable within the pH ranges that can be found in the GI tract of monogastric animals. For the first time, multi-mycotoxin adsorption isotherms were used to study the mechanism of mycotoxin adsorption by grape pomace and to calculate the adsorption and thermodynamic parameters. This work did not study the mycotoxin adsorption efficacy of pomaces obtained from different grape cultivars or different grape byproducts (such as stalks and seeds). Further studies are required to assess if the mycotoxin adsorption efficacy of grape pomace can be affected by the grape cultivar used to make wine, as well to understand which components are the active compounds for the adsorption process by grape pomace.

In conclusion, grape pomace is a sustainable source of bioactive compounds that may have a wide range of technological applications as biosorbent to decontaminate mycotoxin-contaminated foodstuffs. The use of grape pomace as a supplement in the formulation of food/feed products does not guarantee efficacy in sequestering mycotoxins, unless proper digestion or feeding experiments are performed. In addition to must, wine, and grape juice, grape pomace could be used to decontaminate mycotoxin-contaminated liquid foods, such as fruit juice. It is not expected to affect relevant quality parameters of the final products, apart from the color intensity and the enrichment in health-promoting phenolic content.

Subcellular Distribution and Chemical Forms of Cadmium in Two Hot Pepper Cultivars Differing in Cadmium Accumulation

Junliang Xin and Baifei Huang*

Department of Safety and Environmental Engineering, Hunan Institute of Technology, Hengyang 421002, China

ABSTRACT: A greenhouse experiment was conducted to compare the subcellular distribution and chemical forms of cadmium (Cd) in roots, stems, leaves, and fruits between a low-Cd cultivar (Yeshengchaotianjiao, YCT) and a high-Cd cultivar (Jinfuzaohuangjiao, JFZ) of hot pepper (*Capsicum annuum* L.). The Cd concentrations in the root's subcellular fractions, and in all chemical forms in roots, were 1.85−4.88- and 1.84−4.90-fold higher, respectively, in YCT than in JFZ. Compared with JFZ, YCT had significantly lower Cd concentrations in the subcellular fractions (1.10−2.42-fold) of stems and leaves and in almost all chemical forms (1.17−2.97-fold) in the stems and leaves. Also, in fruits, the concentrations of Cd in the cell wall and soluble fractions were 1.18−2.24-fold significantly lower in YCT than in JFZ, and there were lower Cd concentrations (1.36−2.08-fold) in the chemical forms in YCT than in JFZ.

KEYWORDS: *hot pepper (Capsicum annuum L.), cadmium (Cd), subcellular distribution, chemical form, low-Cd cultivar*

INTRODUCTION

Cadmium (Cd) accumulation in agricultural soils as a result of industrial and agricultural activities has become a worldwide environmental problem.[1] Cadmium is readily taken up by the roots of crop plants and transported to edible plant parts because of its high mobility and bioavailability. Consequently, Cd-contaminated foodstuffs have become the major source of Cd intake by humans.[2] There are a variety of serious health risks associated with Cd intake, including lung cancer, osteoporosis, cardiovascular disease, and renal dysfunction.[3]

The accumulation of Cd in crops varies greatly not only among crop species but also among cultivars or genotypes within the same species.[4−6] Therefore, many researchers have suggested that the production of low-Cd cultivars could be useful tools in reducing the amount of Cd entering the human food chain.[2,7−9] However, the reasons for the variations in Cd uptake and accumulation among cultivars are still poorly understood.

There is some evidence that the subcellular distribution and chemical forms of Cd greatly affect the concentrations of free Cd ions in plant cells. Therefore, these factors can explain some of the differences in uptake and translocation of Cd among cultivars or genotypes.[10,11] Qiu et al. reported that the proportion of Cd bound to the cell walls was higher in a low-Cd cultivar than in a high-Cd cultivar of Chinese flowering cabbage (*Brassica parachinensis* L.).[12] However, the proportions of Cd bound to cell walls in the stems and young leaves were similar in low-Cd and high-Cd cultivars of water spinach (*Ipomoea aquatica* Forsk.).[13] Zhou et al. compared the chemical forms of Cd between low- and high-Cd genotypes of amaranth (*Amaranthus* spp.) and found that only the low-Cd genotype's stems had a lower proportion of Cd integrated into pectates and proteins.[14] In contrast, the shoots and roots of a low-Cd cultivar of Chinese flowering cabbage had higher proportions of Cd in the pectate/protein-integrated form, and lower proportions of Cd in the inorganic and other water-soluble forms, compared with a high-Cd cultivar.[12] Such studies have not yet provided consistent results regarding the differences in Cd uptake and storage among cultivars/species. Furthermore, these previous studies mainly focused on the roots, stems, and leaves of plants; there is little information available on other plant organs, including fruits, grains, or flowers.

Hot pepper (*Capsicum annuum* L.) is one of the most important vegetable crops worldwide. In China, hot pepper is cultivated on approximately 1.3 million hm^2 annually, producing 27 million tons of pepper.[15] It was reported that pepper has a medium tolerance to Cd, and accumulates Cd more readily in its fruits, when compared with the other two crops from the Solanaceae family, tomato (*Lycopersicon esculentum*) and aubergine (*Solanum melongena*).[16] Furthermore, the shoot portion of chili peppers maintained higher Cd uptake levels than the roots,[17] which is beneficial to the movement of Cd into fruits. Therefore, to minimize Cd accumulation in hot pepper fruits, it is extremely important to screen for low-Cd cultivars and elucidate the mechanisms for lower Cd accumulation. In our previous study, we identified some typical low- and high-Cd cultivars of hot pepper and found that the difference in fruit Cd concentrations between the low- and high-Cd cultivars was due to differences in Cd translocation rather than differences in Cd uptake by the roots.[18] However, the mechanisms of Cd translocation via the xylem or phloem to fruits, which are responsible for the differences in fruit Cd concentrations between low- and high-Cd cultivars, remained unclear. To study these mechanisms, we conducted a greenhouse pot experiment to investigate the subcellular distribution and chemical forms of Cd in the roots, stems, leaves, and fruits of two cultivars of hot pepper with different Cd accumulation characteristics.

The objectives of this study were to analyze the subcellular distribution, chemical forms, and amounts of Cd in various organs of a low-Cd cultivar and a high-Cd cultivar of hot pepper. We hypothesized that the subcellular distribution and chemical forms of Cd differ significantly among different tissues as well as between the low-Cd and high-Cd cultivars.

MATERIALS AND METHODS

Plant Materials. Two cultivars, Yeshengchaotianjiao (YCT) and Jinfuzaohuangjiao (JFZ), were selected from 30 hot pepper cultivars used in our previous study. The fruit Cd concentration in JFZ (0.19−3.22 mg kg^{-1} dry weight, DW) was 2.1−2.7-fold higher than that in YCT (0.07−1.54 mg kg^{-1}, DW) when grown in Cd-contaminated soils (0.28−2.69 mg kg^{-1}, DW).[18] Therefore, YCT and JFZ were identified as low-Cd and high-Cd cultivars, respectively.

Chemicals and Reagents. In the present study, 2-(*N*-morpholino)ethanesulfonic acid (MES), tris(hydroxymethyl)-aminomethane (Tris), and 1,4-dithioerythritol ($C_4H_{10}O_2S_2$, DTE) were purchased from Sigma (St. Louis, MO, USA). All other chemicals and reagents, except deionized water (d-H_2O), were of analytical grade and purchased from Guangzhou Chemical Regent Factory (Guangzhou, China).

Experimental Site and Soil. We conducted the pot experiment at the experimental garden of Hunan Institute of Technology (112°41′ E, 26°52′ N), Hunan Province, China. The experimental soil was collected from nearby farmland and was air-dried and ground to pass through a sieve with a 5 mm mesh size. The soil was a sandy loam, and its main physical and chemical properties were determined using the analytical methods described by Lu.[19] The soil pH, organic matter content, cation exchange capacity, total nitrogen, available P, available K, and total Cd were 6.42 g kg^{-1}, 19.3 g kg^{-1}, 91.0 mmol kg^{-1}, 1.6 g kg^{-1}, 103 mg kg^{-1}, 129 mg kg^{-1}, and 1.22 mg kg^{-1}, respectively. According to the Farmland Environmental Quality Evaluation Standards for Edible Agricultural Products (HJ 332-2006), the maximum level (ML) for Cd in soil is 0.3 mg kg^{-1}; therefore, the tested soil is considered as Cd-contaminated and served as a treatment (T1) without additional Cd^{2+} in this experiment. Two other Cd treatments (T2 and T3) consisted of soil with target Cd concentrations of 2.0 and 3.0 mg kg^{-1}, respectively, which were created by mixing T1 soil with appropriate amounts of Cd in the form of $Cd(NO_3)_2{\cdot}4H_2O$. Each of the T2 and T3 soils was placed in a large basin, watered, and left to equilibrate outdoors under a waterproof tarpaulin for approximately 6 months. This long period allowed for the equilibration of the various sorption mechanisms in the soils. For T2 and T3 treatments, the final soil total Cd concentrations were 2.02 and 3.26 mg kg^{-1}, respectively.

Experimental Design. The pot experiment was conducted in a greenhouse with an air temperature of 28−35 °C. Plastic pots (top diameter, 18 cm; bottom diameter, 13 cm; height, 15 cm) were filled with 3.0 kg (DW) of prepared soil. For each treatment, three pots (n = 3) were planted for each cultivar. The seeds were sown in the soil in the pots on March 10, 2013, and watered daily with tap water. The experiment was arranged in a completely randomized design. Within 15 days after germination, the seedlings were thinned to one per pot. A solid compound fertilizer (N/P/K = 15:15:15) was applied to the soil at the rate of 3.0 g pot^{-1} every 2 weeks. After the 120 day growth period, the plants were harvested. Fruits, leaves, stems, and roots were separately rinsed with tap water, and roots were desorbed for 15 min in ice-cold 5 mM $CaCl_2$ solution (5 mM MES-Tris, pH 6.0). All samples were thoroughly washed with deionized water, and the fresh weights were recorded. The fresh plant samples were divided into two portions: one for the analysis of the subcellular distribution of Cd and the other for the analysis of the chemical forms of Cd. Each portion was weighed (approximately 5 g), then immediately frozen in liquid N_2, and kept frozen until analyzed.

Separation of Tissue Fractions. Frozen plant samples were pretreated according to the method of Lozano-Rordriguez et al.[20] Each sample was homogenized in precooled extraction buffer (50 mM Tris-HCl, 250 mM sucrose, and 1.0 mM DTE, pH 7.5) with a chilled mortar and pestle.[21] The homogenate was sieved through nylon cloth (80 μm), and the liquid was squeezed from the residue. The residue on the cloth was washed twice with homogenization buffer and was designated fraction I (FI); it contained mainly cell walls and cell wall debris. The filtrate was centrifuged (Beckman JA-25.50 rotor, Fullerton, CA, USA) at 20000g for 45 min. The supernatant solution was referred to as the soluble fraction (including the vacuoles) and was designated fraction II (FII). The deposit was treated as the organelles (excluding the vacuoles) and was designated fraction III (FIII). All steps were performed at 4 °C. The subcellular fractions were dried at 70 °C to a constant weight and then digested at 145 °C for 24 h with an oxidative acid mixture of $HNO_3/HClO_4$ (2:1, v/v).

Extraction of Chemical forms of Cd. The chemical forms of Cd were determined using the method described by Wu et al.[10] Cd in different chemical forms was extracted by the specific solutions, in the following order: (1) 80% ethanol, which extracts inorganic Cd, giving priority to nitrate/nitrite, chloride, and aminophenol forms of Cd; (2) d-H_2O (Milli-Q, Millipore, Bedford, MA, USA), which extracts water-soluble Cd−organic acid complexes and $Cd(H_2PO_4)_2$; (3) 1 M NaCl, which extracts pectate- and protein-integrated Cd; (4) 2% acetic acid (HAc), which extracts undissolved Cd phosphates including $CdHPO_4$, $Cd_3(PO_4)_2$, and other Cd−phosphate complexes; and (5) 0.6 M HCl, which extracts Cd oxalate. Cd was not detected in residues because of its low concentration in the samples.

Frozen tissues were homogenized in extraction solution with a mortar and pestle, diluted at the ratio of 1:10 (w/v), and shaken for 22 h at 25 °C. Then, the homogenate was centrifuged at 5000g for 10 min, and the first supernatant was removed and transferred to a conical beaker. The sediment was resuspended twice in the same extraction solution, shaken for 2 h at 25 °C, and centrifuged at 5000g for 10 min, and the supernatant was collected. The three supernatants were pooled. The extraction procedure was the same for each of the five extraction solutions. Each of the pooled supernatant solutions was then evaporated on an electric plate at 70 °C to a constant weight and digested at 145 °C with an oxidative acid mixture of $HNO_3/HClO_4$ (2:1, v/v).

Chemical Analysis. The Cd concentrations in the digests were determined with an atomic absorption spectrophotometer (Shimadzu AA-6300C, Kyoto, Japan). A Certified Reference Material (CRM) of plant GBW07605 (provided by the National Research Center for CRM, China) was used for quality assurance and quality control (QA/QC) of the Cd analytical procedure.

Statistical Analysis. All Cd concentrations were calculated on the basis of the fresh weights of samples before separation or extraction. Data were statistically analyzed with the independent samples t test and least significant difference (LSD) test based on one-way ANOVA using Excel 2003 and SPSS 13.0. The data were checked for heteroscedasticity using Levene's test before the ANOVA was performed and showed no heteroscedasticity.

RESULTS

Effect of Soil Cd Concentrations on Plant Biomass. For both cultivars, there were no significant differences ($p > 0.05$) among the treatments in terms of the biomasses of roots, stems, and leaves (Table 1). However, the fruit biomass of JFZ in the T2 and T3 treatments was higher than that in the T1 treatment, and the fruit biomass of JFZ in the T2 treatment was significantly higher ($p < 0.05$) than that in the T1 treatment (Table 1). There was no significant difference ($p > 0.05$) in the fruit biomass of YCT among the three treatments (Table 1).

Subcellular Distribution of Cd. The subcellular distribution of Cd in fruits, leaves, stems, and roots of YCT (low-Cd cultivar) and JFZ (high-Cd cultivar) was analyzed by determining the Cd concentration in each of the different tissues. The Cd concentrations in the subcellular fractions of various tissues increased with increasing concentrations of Cd in the soil (Table 2). The concentrations of FI-Cd and FII-Cd in fruits were always significantly higher ($p < 0.01$ or $p < 0.05$)

Table 1. Biomass of Two Hot Pepper (*Capsicum annuum* L.) Cultivars, YCT and JFZ, under Different Cadmium (Cd) Treatments (T1−T3)

		biomass[a] (g FW)		
organ	cultivar	T1	T2	T3
fruit	YCT	10.9 ± 2.0	10.6 ± 1.2	9.2 ± 0.7
	JFZ	23.7 ± 6.7b	38.4 ± 7.6a	32.4 ± 7.0ab
leaf	YCT	41.2 ± 1.2	41.2 ± 1.6	39.6 ± 0.7
	JFZ	33.7 ± 1.4	31.0 ± 4.0	31.3 ± 3.0
stem	YCT	32.8 ± 2.7	35.1 ± 0.4	33.1 ± 0.6
	JFZ	19.1 ± 0.5	19.8 ± 1.6	19.2 ± 2.5
root	YCT	35.6 ± 4.3	39.6 ± 3.6	37.4 ± 2.8
	JFZ	36.2 ± 4.0	31.6 ± 1.7	31.6 ± 1.7

[a]Values are the mean ± SD (n = 3). Different letters in a row indicate significant difference at $p < 0.05$.

in JFZ than in YCT (Table 2). However, there were no significant differences ($p > 0.05$) in the concentrations of FIII-Cd in fruits between the two cultivars in all treatments (Table 2). In each treatment, the concentrations of FI-Cd, FII-Cd, and FIII-Cd in the leaves and stems of JFZ were significantly higher ($p < 0.01$ or $p < 0.05$) than those of their counterparts in the leaves and stems of YCT (Table 2). In contrast, the concentrations of FI-Cd, FII-Cd, and FIII-Cd in roots were always lower ($p < 0.01$) in JFZ than in YCT (Table 2).

In fruits, the majority of Cd was associated with FI, followed by FII and then FIII (Figure 1A). The proportions of FI-Cd in YCT fruit (46−51%) were lower than those in JFZ fruit (57−63%), but the proportions of FII-Cd and FIII-Cd in YCT fruit (27−30 and 22−24%, respectively) were slightly higher than those in JFZ fruit (22−26 and 15−18%, respectively). In leaves, most of the Cd was in FI (57−63% for YCT and 56−64% for JFZ), followed by FIII (20−28% for YCT and 23−24% for JFZ), and the smallest proportion of Cd was in FII (14−18% for YCT and 13−20% for JFZ) (Figure 1B).

In the stems, there were higher proportions of FI-Cd in YCT (71−75%) than in JFZ (63−70%) and lower proportions of FIII-Cd (13−15%) in YCT than in JFZ (18−21%) (Figure 1C). Furthermore, with increasing soil Cd concentrations, the proportions of FI-Cd decreased in both YCT (from 75 to 71%) and JFZ (from 70 to 63%), but the proportions of FII-Cd increased in both YCT (from 10 to 15%) and JFZ (from 10 to 19%). The proportions of FIII-Cd remained fairly constant (Figure 1C).

In roots, the largest proportion of Cd (77−82% for YCT and 82−87% for JFZ) was stored in FII, and the proportions of FII-Cd slightly increased as the soil Cd concentration increased in both cultivars (Figure 1D). In both cultivars, only small proportions of Cd (12−17% for YCT and 8−10% for JFZ) were bound to the cell wall, and even smaller proportions of Cd were partitioned into the organelles (5−6% for YCT and 4−8% for JFZ) (Figure 1D).

Chemical Forms of Cd. Overall, the concentrations of Cd in different chemical forms in various organs of hot pepper increased with increasing soil Cd concentrations (Table 3). In fruits, the concentrations of Cd in all chemical forms were consistently and significantly higher in JFZ ($p < 0.01$ or $p < 0.05$) than in YCT (Table 3), except there was no significant difference in the level of Cd extracted by 2% HAc between the two cultivars in the T2 treatment (Table 3). In addition, the Cd form extracted by 0.6 M HCl was not detected in fruits of either cultivar.

In leaves, the concentration of Cd extracted by 80% ethanol was higher in JFZ ($p < 0.05$) than in YCT in the T1 and T3

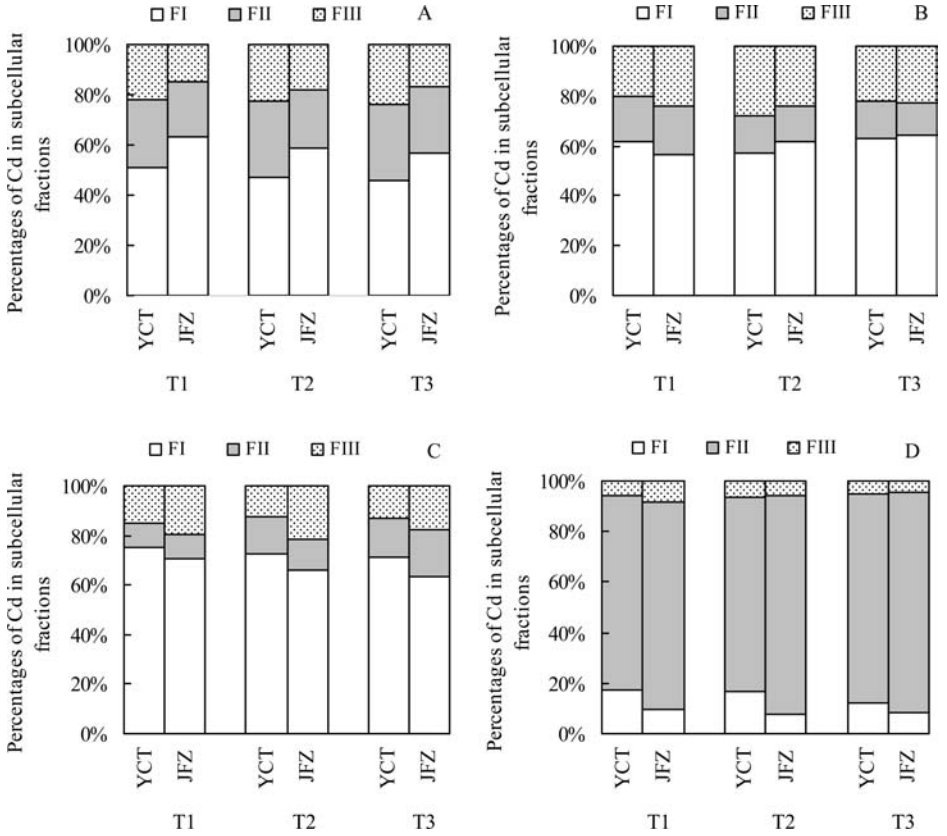

Figure 1. Percentages of cadmium (Cd) in subcellular fractions of fruits (A), leaves (B), stems (C), and roots (D) of hot pepper (*Capsicum annuum* L.) grown in soil with three different Cd concentrations. Cd percentage (%) = Cd concentration in fraction/(sum of Cd concentrations in all fractions) × 100.

treatments, but there was no significant difference ($p > 0.05$) between the two cultivars in the T2 treatment (Table 3). Also, the concentrations of Cd in other forms were always significantly higher in JFZ ($p < 0.05$ or $p < 0.01$) than in YCT (Table 3). In stems, the concentrations of Cd in all chemical forms were significantly higher in JFZ ($p < 0.05$ or $p < 0.01$) than in YCT, except for the chemical form extracted by d-H_2O in the T1 treatment (Table 3). In roots, the Cd concentration of each chemical form was significantly lower in JFZ ($p < 0.05$ or $p < 0.01$) than in YCT (Table 3).

In terms of the distribution of the different chemical forms of Cd, the Cd form extracted by 1 M NaCl accounted for the largest proportion of Cd in fruits, leaves, and stems, but the form extracted by 80% ethanol was the predominant form in roots (Figure 2). In addition, with increasing soil Cd concentrations, the proportion of the Cd form extracted by 1 M NaCl decreased in the leaves, stems, and roots, whereas those of the forms extracted by 0.6 M HCl, 2% HAc, and 80% ethanol markedly increased in the leaves, stems, and roots, respectively (Figure 2B–D). The proportions of each Cd form in the fruits were similar between YCT and JFZ (Figure 2A). However, in leaves, the proportions of the Cd form extracted by 80% ethanol were slightly higher in YCT (11–14%) than in JFZ (7–10%) in all treatments, but the proportions of the Cd form extracted by 1 M NaCl were lower in YCT than in JFZ in the T2 and T3 treatments (Figure 2B). In the stems and roots, the proportion of the Cd form extracted by 1 M NaCl was higher in YCT than in JFZ, whereas the proportion of the Cd form extracted by 80% ethanol was lower in YCT than in JFZ (Figure 2C). In most cases, the proportions of other forms of Cd extracted by d-H_2O, 2% HAc, or 0.6 M HCl in the stems, leaves, and roots were similar between YCT and JFZ.

DISCUSSION

The subcellular distribution of Cd has extremely important effects on the accumulation, migration, and detoxification of Cd in different species or cultivars.[12,13] In this study, most of the Cd (77–87%) in hot pepper roots was stored in the soluble fraction. The vacuole is a dynamic organelle that occupies as much as 90% of the total cell volume in some cell types.[22] Our results imply that the vacuole is the predominant sink for Cd in hot pepper. Similarly, Vázquez et al. reported that Cd was primarily associated with the vacuoles of bean roots, and no Cd was detected in the cell walls.[23] Wu et al.[10] reported that 51% of total Cd was present in the soluble fraction in barley roots, and a similar proportion of Cd was associated with the soluble fraction in rice roots, as reported by Yu et al.[11] Sequestration of Cd into the vacuole would greatly decrease its concentration in the cytosol, thereby preventing damage not only to organelles but also to many physiological and biochemical processes in the cells.

Plant cell walls, which are the first barrier protecting the protoplast against Cd toxicity, are mainly composed of polyose (including cellulose, hemicellulose, and pectin) and proteins, which provide functional groups, such as carboxyl, hydroxyl, amino, and aldehyde groups, on their surfaces to bind Cd ions and restrict their transport across the cell membrane.[1] Wang et al. reported that a large proportion of Cd (48.2–57.6%) in *Bechmeria nivea* (L.) Gaud. roots was bound to the cell walls.[24] However, in the present study, only a small proportion (8–

		JFZ	ND	1.29 ± 0.16	0.17 ± 0.02	0.03 ± 0.00

[a]Values shown are the mean ± SD (n = 3). ND, not detected. ns, *, and ** indicate that the difference between the two cultivars in the same treatment is not significant, significant at $p < 0.05$, and significant at $p < 0.01$, respectively.

17%) of Cd was bound to the cell wall fraction in the roots of hot pepper. These conflicting results presumably reflect differences in experimental conditions and differences among species that have specific mechanisms and characteristics of Cd tolerance, uptake, translocation, and compartmentalization.

There was a higher Cd concentration in YCT's roots than in JFZ's roots, indicating that the low-Cd cultivar could retain more Cd in the root tissues. This may be associated with protection mechanisms by which excessive accumulation of a toxic substance will alleviate further uptake of that substance, such as NH_4-N in N-fixing symbiotic associations.[25] Similarly, a low-Cd water spinach cultivar accumulated more Cd in the roots than did a high-Cd cultivar.[13] However, Yu et al. reported that the root Cd concentration in a low-Cd rice cultivar was significantly lower than that in a high-Cd cultivar.[11] Therefore, the low Cd translocation from roots to aboveground parts in the low-Cd hot pepper cultivar, YCT, might be an additional mechanism to decrease uptake of Cd from the soil. Further research is needed to clarify this point.

When Cd is translocated from roots to aerial parts, the stem acts as a cation exchange column and, thus, it effectively reduces the amount of Cd that accumulates in leaves.[26] In the present study, a large proportion of Cd (63−75%) in stems was bound to the cell wall fraction. This could effectively reduce Cd accumulation in the cytoplasm and, hence, decrease the amount of Cd transported to the leaves. In addition, 56−64% of the total Cd in leaves was in the cell wall fraction. Therefore, large amounts of Cd were immobilized by the cell walls in stem and leaf tissues, thus decreasing the amount of Cd translocated to fruits. In the subcellular distribution of Cd between the two cultivars, YCT consistently had lower Cd concentrations in all three fractions of the stems and leaves and had a higher or similar proportion of Cd in FI, which contributed to the decrease of Cd mobility into the fruits from the stems and leaves. These attributes met the characteristics of a low-Cd cultivar. A high Cd concentration in the soluble fraction of rice leaves facilitates Cd translocation from leaves to grains.[11] Therefore, the reason for the high concentrations of Cd in fruits of JFZ might be that it has high concentrations of Cd in the FII of stem and leaf tissues.

A decrease in the concentration of free Cd in the cytosol of plants is one of the defense strategies against Cd toxicity and is achieved via various mechanisms.[10] The plant cell decreases the amount of Cd in the cytosol by sequestering Cd in subcellular

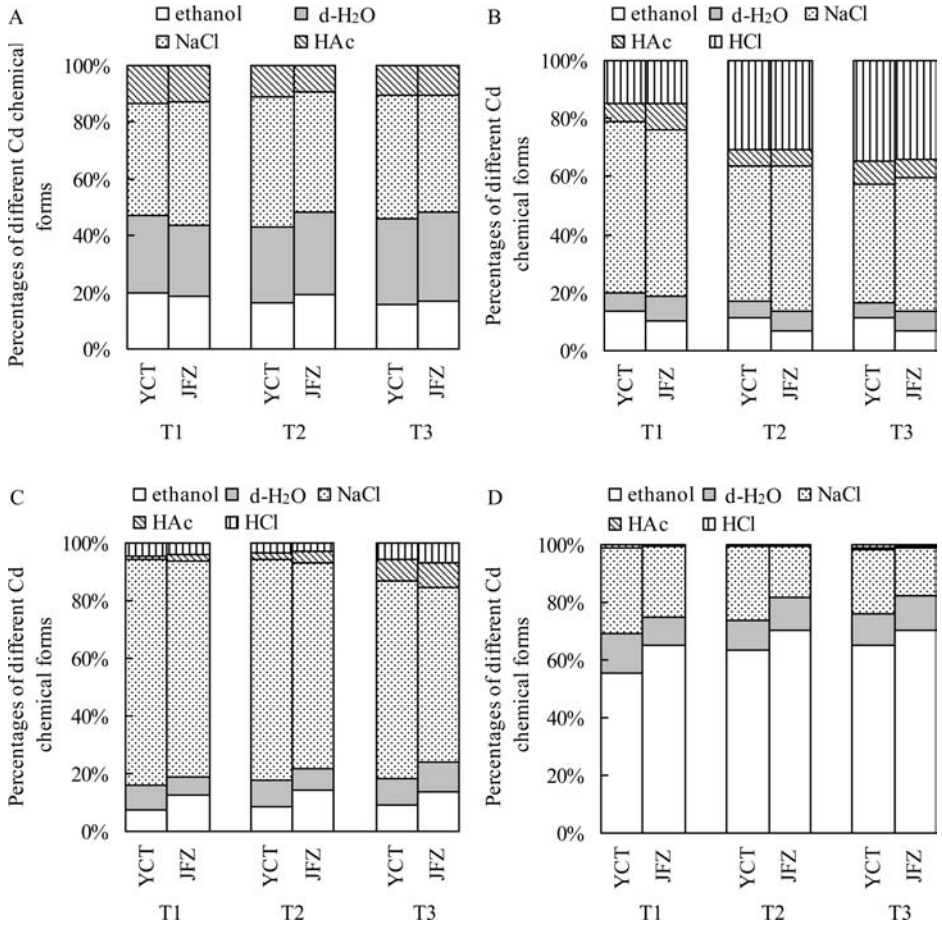

Figure 2. Percentages of different chemical forms of cadmium (Cd) in fruits (A), leaves (B), stems (C), and roots (D) of hot pepper (*Capsicum annuum* L.) grown in soil with three different Cd concentrations. Cd percentage (%) = Cd concentration in fraction/(sum of Cd concentrations in all fractions) × 100.

compartments. Our results showed that compared with YCT, JFZ accumulated a greater proportion of Cd in FI of fruits, thus reducing the proportion of Cd stored in FII. As a consequence, JFZ and YCT had similar concentrations of Cd in FIII of fruits. Also, the Cd concentrations in FIII of the stems and leaves were significantly higher in JFZ than in YCT, but the Cd concentrations in FIII of roots were significantly lower in JFZ than in YCT. However, the biomasses of stems, leaves, and roots did not decrease with increasing soil Cd concentrations in either cultivar. These results suggest that both cultivars are tolerant to Cd at the levels used in this experiment and that the Cd toxicity may be alleviated by sequestering Cd in cell walls. However, it is necessary to state that not all hot pepper cultivars have the same tolerance to Cd. León et al. reported that there were significant differences in tolerances to Cd^{2+} ions among pepper cultivars, and the tolerance to Cd is mainly dependent on the availability of nicotinamide adenine dinucleotide phosphate (NADPH) in pepper plants.[27] It was noteworthy that the highest proportion of Cd associated with organelles was generally in leaves, followed by fruits and then stems, and the lowest was in roots for both cultivars in all treatments. This may be because of the preferential accumulation of Cd in chloroplasts.[28]

The biological activity of Cd in plants is also dependent on its chemical forms, which can be extracted with various extractants.[10] For example, water-soluble Cd in inorganic forms (extracted by 80% ethanol) and organic forms (extracted by d-H_2O) migrate more readily than other forms and have strong negative effects on plant cells. Other forms of Cd, such as pectate/protein-integrated Cd (extracted by 1 M NaCl), insoluble cadmium phosphate (extracted by 2% HAc), and cadmium oxalate (extracted by 0.6 M HCl) are the least mobile and the least toxic to plant cells.[24] The largest proportion of Cd in roots of hot pepper was in the inorganic form, which is consistent with the highest proportion of Cd in FII. In root cells, Cd ions can induce phytochelatins (PCs) synthesis in the cytosol.[29,30] The PC−Cd complexes are sequestered into vacuoles by ATP-binding cassette transporters and can also be transported into vacuoles by heavy metal ATPases (e.g., HMA3) and proton/cation exchange transporters.[28] Thus, the amount of Cd^{2+} in the cytosol that can be loaded into the xylem by HMA2 and HMA4 and then translocated from root to shoot[31,32] is greatly decreased. In this sense, compartmentalization into the vacuoles may be crucial for Cd detoxification. Therefore, we can assume that more of the water-soluble Cd, extracted by 80% ethanol and d-H_2O from the roots, could be sequestered into vacuoles in YCT compared with that in JFZ. Also, the Cd concentration in the cytosol of root cells might not be higher in YCT than in JFZ. Further research is required to explore this point in detail. More importantly, HMA2 and HMA4 have been identified as key transporters mediating root-to-shoot Cd translocation via the xylem in rice.[31] Therefore, the Cd concentrations in aerial parts in the two hot pepper cultivars

dx.doi.org/10.1021/jf4044524 | J. Agric. Food Chem. 2014, 62, 508−515

might be strongly associated with that of the xylem sap, rather than that of the root's water-soluble form.

In the stems of YCT and JFZ, most of the Cd was integrated into pectates/proteins, and the Cd proportion in this form was higher in YCT than in JFZ; this might be partly related to the lower concentration of water-soluble Cd in the stem tissues of YCT. As a result, less Cd was translocated to leaves from the stem via the xylem in YCT than in JFZ. In leaves, most of the Cd was integrated with pectates/proteins, but the proportion of cadmium oxalate dramatically increased with higher soil Cd concentrations. The higher Cd concentrations in leaves might induce an increase in the production of oxalate to immobilize Cd and, thus, reduce Cd translocation to fruits via the phloem. Phloem-mediated transport might play a key role in delivering Cd to hot pepper fruits, and xylem-mediated Cd transport due to the transpiration of the fruits might also play an important role. Physiological experiments revealed that Cd is transported into seeds of grains mainly via the phloem in wheat and rice plants.[33,34] Analyses of different plant species have shown that the main Cd-ligand molecules in phloem sap are glutathione (GSH) and PCs.[35,36] Thus, it is assumed that in JFZ, which had higher Cd concentrations in fruits, a greater level of Cd translocation from the roots to aboveground parts via the xylem leads to higher levels of Cd in the stems and leaves (source organs). Subsequently, more Cd is available for transport from the source organs to sink organs (fruits) via the phloem, leading to higher Cd concentrations in fruits of JFZ than in fruits of YCT. Certainly, it is also possible that the greater Cd concentration in the xylem is transported directly into fruits after the xylem−phloem transfer, which may also cause more Cd accumulation in fruits.

The concentrations of all forms of Cd in fruits were lower in YCT than in JFZ, but the proportions of Cd in each form were similar in the two cultivars. Wu et al. reported that a Cd-sensitive barley genotype had higher Cd concentrations in inorganic and water-soluble forms, but lower concentrations of Cd in pectate/protein-integrated forms as compared with the Cd-resistant genotypes.[10] Because there were no differences in the proportions of Cd in each chemical form between YCT and JFZ and because the fruit biomass of the two cultivars did not decrease with increasing soil Cd concentrations, we assumed that the fruits of both hot pepper cultivars had a high tolerance to Cd at the levels used in these experiments.

In conclusion, our data support the hypothesis that there is a significant difference in the subcellular distribution and chemical forms of Cd among different tissues between the low-Cd and high-Cd hot pepper cultivars. Although most of the Cd is stored in the soluble fraction in roots of the two cultivars, the difference in the ability to translocate Cd from the roots to the stems is the main reason for the genotypic difference in Cd accumulation. In the stems, leaves, and fruits of both cultivars, the cell wall is the most crucial subcellular fraction for immobilization of Cd. Compared with the high-Cd cultivar, the low-Cd cultivar had lower concentrations of inorganic Cd (extracted by 80% ethanol), water-soluble Cd (extracted by d-H_2O), and pectate/protein-integrated Cd (extracted by 1 M NaCl) in both the stems and leaves; this resulted in less Cd being translocated from the stems and leaves to fruits via the phloem.

Supporting Information

ABSTRACT: A new analytical strategy based on liquid chromatography−tandem mass spectrometry (LC-MS/MS) combined with accurate mass high-resolution Orbitrap mass spectrometry (HR-Orbitrap MS) was performed for high-throughput screening, confirmation, and quantification of 22 banned or unauthorized veterinary drugs in feedstuffs according to Bulletin 235 of the Ministry of Agriculture, China. Feed samples were extracted with acidified acetonitrile, followed by cleanup using solid-phase extraction cartridge. The extracts were first screened by LC-MS/MS in a single selected reaction monitoring mode. The suspected positive samples were subjected to a specific pretreatment for confirmation and quantification of analyte of interest with LC-MS/MS and HR-Orbitrap MS. Mean recoveries for all target analytes (except for carbofuran and chlordimeform, which were about 35 and 45%, respectively) ranged from 52.2 to 90.4%, and the relative standard deviations were <15% except for 20% for carbofuran. The decision limits (CCαs) for target analytes in formulated feed were between 2.6 and 23 μg/kg, and the detection capabilities (CCβs) were between 4.2 and 34 μg/kg. The method was successfully applied to screening of real samples obtained from local feed markets and confirmation of the suspected target analytes. It provides a high-throughput, sensitive, and reliable screening, identification, and quantification of banned veterinary drugs in routine monitoring programs of feedstuffs.

KEYWORDS: *screening, banned drugs, liquid chromatography-tandem mass spectrometry, confirmation, Orbitrap mass spectrometry, feedstuff*

INTRODUCTION

During the past decade, a large number of veterinary drugs have been widely used in the treatment of disease infection besides their use as growth promoters in farm animals. However, the increasing trend of abuse and illegal use of veterinary drugs as premixes and feed additives raises the risk of contamination of animal food and causes public panic. Therefore, in the European Community (EC), a series of regulations and directives have been issued to stringently regulate the appropriate use of veterinary drugs.[1] In Bulletin 235 of the Ministry of Agriculture (MOA), China, maximum residue limits (MRLs) of 96 veterinary drugs have also been laid down, 9 veterinary drugs without being detected in edible animal tissues, and 33 banned drugs in food-producing animals are regulated.[2] Great attention has been paid to the development and validation of various sensitive, specific, and reproducible analytical methods for simultaneously determining those registered veterinary drugs and banned drugs in various matrices such as edible animal tissues[3−5] and feedstuffs.[6,7]

Tandem mass spectrometry (MS/MS), using triple-quadrupole analyzer with electrospray ion (ESI) source, operated in selected reaction monitoring (SRM) mode, can provide accurate quantitative results, reliable identification, and confirmation. Thus, high-performance liquid chromatography coupled to triple-quadrupole mass spectrometry (LC-MS/MS) has become the predominant analysis technique in the detection of veterinary drug residues.[8−10] However, for a method to be deemed confirmatory in accordance with Commission Decision 2002/657/EC, identification of a target compound must meet the tolerances for the retention times, identification points (IPs), and relative ion ratios of the selected SRM transitions.[11] As for the latter, the relative intensities of the qualifier transition of some compounds (only limited fragment ions) are very weak no matter whether a standard or matrix is analyzed. As a result, the structural confirmation (the ion ratio of qualifier transition to quantifier transition) required in the system of IPs is unavailable in trace level of the target analyte. For example, in our routine monitoring of banned drugs in animal-derived foods and feeds, it has been observed that the intensity of a second "transition" (pair m/z parent > m/z product) is not strong enough in low level of a few compounds including but not limited to testosterone propionate, ronidazole, methaqualone, and trenbolone; higher 3:1 of signal-to-noise ratio (S/N) for the qualifier transition is difficult if the concentration of the analyte is below 1 ng/mL, so that the IPs rules defined in the Decision 2002/657/EC cannot be accomplished. More importantly, as for the routine monitoring of banned and illegal drugs in feeds and animal drinking water, the positive samples in fact are commonly very little. However, in cases when positive results are detected, the sample is required to be reanalyzed including a specific sample preparation (mandated in China). This implies that the two

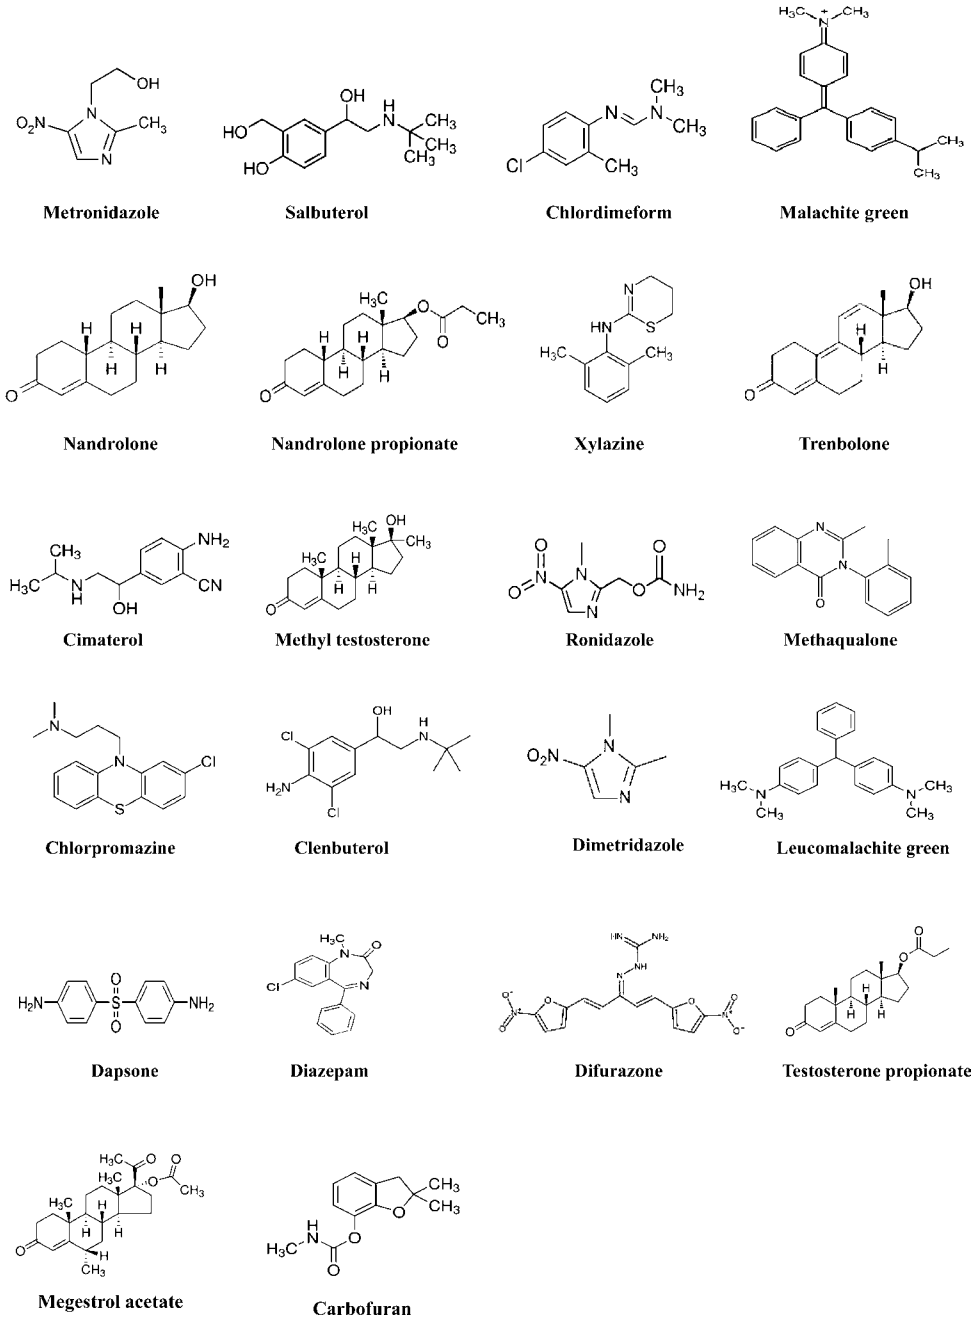

Figure 1. Chemical structures of 22 target compounds.

monitored transitions (in SRM mode) for each analyte are not necessary during multiresidue screening analysis by LC-MS/MS (only one transition). Thus, the acquired parameter settings are a simplification, and the number of monitoring analytes of interest may be double in a single selected reaction monitoring (S-SRM, a single ion pair monitoring) mode.

On the basis of the literature[12−15] and the descriptions above, a new idea for multiclass multiresidue analysis of veterinary drugs and banned substances in feedstuffs, animal drinking water, and animal-derived food is suggested. That is, one transition (the most abundant transition) in S-SRM mode is first adopted for high-throughput screening of target analytes in complex matrices. Then the suspected positive sample is subjected to a specific pretreatment for confirmation and quantification of the analyte of interest with LC-MS/MS and HR-Orbitrap MS in accordance with the accurate mass of precursor ion of target compound acquired in full scan mode. As an example, the present work aims at building up a high-throughput, sensitive, and efficient multiclass multiresidue approach for the screening and confirmation of 22 "no-tolerance" substances listed in Bulletin 235 of MOA, China, including metronidazole, salbutamol, chlordimeform, malachite green, nandrolone, nandrolone propionate, xylazine, trenbolone, cimaterol, methyl testosterone, ronidazole, methaqualone, chlorpromazine, clenbuterol, dimetridazole, leucomalachite green, dapsone, diazepam, difurazone, testosterone propionate, megestrol acetate, and carbofuran (Figure 1).

MATERIALS AND METHODS

Chemicals. Methanol, acetonitrile, and formic acid (HPLC grade) were supplied by Fisher Scientific (Fair Lawn, NJ, USA). Ultrapure water was obtained by a Milli-Q Millipore system (Bedford, MA, USA). Acetone, ethyl acetate, and acetic acid, etc. (analytical reagent), were purchased from Guangzhou Chemical Reagent Factory. Solid phase extraction (SPE) cartridges including Oasis-HLB and Oasis-WCX (3 mL, 60 mg, Waters, Milford, MA, USA), SUPERCLEAN LC-18 cartridge (3 mL, 500 mg, Supelco, Bellefonte, PA, USA), HYPERSEP SCX (3 mL, 500 mg, Thermo Scientific and Technologies), and Poly-Sery MCX SPE (3 mL, 60 mg, CNW, Germany) were supplied from Shanghai ANPEL Scientific Instrument Co.

Preparation of Standards. The veterinary drug reference substances listed in Table 1 were of the highest available purity and were bought from Dr. Ehrenstorfer GmbH (Augsburg, Germany), China Institute of Veterinary Drugs Control (Beijing, China), and the National Institute of Control of Pharmaceutical and Biological Products (Beijing, China).

Individual stock standard solution (100−1000 μg/mL) was prepared by weighing each compound and then dissolving it in methanol, except for methaqualone and carbofuran standard solutions (100 μg/mL) purchased from Dr. Ehrenstorfer GmbH. They were stored in the dark at −20 °C for a maximum of 6 months. Multianalyte intermediate standard solution (0.050, 0.100, 0.500, 1.00, 5.00, 10.0, and 20.0 μg/mL) was prepared by pipetting appropriate individual standard solution and then diluting with methanol, respectively. Mixed standard working solution was prepared by diluting the multianalyte intermediate standard solution with a mixture of methanol/0.1% formic acid aqueous solution (10:90, v/v). The concentration of target analytes in the working standard solution ranged from 1.00 to 1000 ng/mL on the basis of the targeted concentration of the compound when added to the blank feed sample. Reconstitution solution was always prepared to dilute working standard solution and make a matrix-matched calibration curve.

Sample Collection. All kinds of feeds for pig, chicken, cattle, and aquatic product were collected from the local feedstuff markets and Quality Control and Inspection Center for Domestic Animal Product, MOA (Guangzhou, China). Prior to usage, feed samples were ground and passed through a 1 mm size sieve (16 mesh) and then stored at 4 °C. A previous analysis was conducted to ensure that they contained none of the studied analytes.

Sample Extract and Cleanup. Two grams of feed sample was accurately weighed into a 50 mL polypropylene centrifuge tube. For a spiked blank feed, the desired concentration levels (0.05, 0.25, 0.5, and 1.0 mg/kg for salbutamol, cimaterol, clenbuterol, and xylazine; 0.1, 0.5, 1.0, and 2.0 mg/kg for metronidazole, dimetridazole, difurazone, carbofuran, dapsone, methaqualone, diazepam, chlorpromazine, nandrolone 17-propionate, megestrol acetate, malachite green, and leucomalachite green; 0.2, 1.0, 2.0, and 4.0 mg/kg for ronidazole, chlordimeform, trenbolone, nandrolone, methyl testosterone, and testosterone propionate) were prepared, respectively, and these spiked samples were allowed to stand at room temperature in the dark for about 30 min before proceeding.

Twenty-four milliliters of acetonitrile and 1 mL of formic acid were added into the tube. The extraction was performed with an ultrasonic bath at 60 °C for 15 min and then centrifuged at 8000 rpm for 10 min at 4 °C. The supernatant was carefully decanted into another 50 mL tube, and the residue was re-extracted with 24 mL of acetontrile and 1 mL of formic acid. The mixture was then centrifuged at 8000 rpm for 10 min at 4 °C, the supernatant was decanted into the tube, and all of the organic

dx.doi.org/10.1021/jf404501j | J. Agric. Food Chem. 2014, 62, 516−527

extracts were combined into a 50 mL volumetric flask and diluted to the mark with 2% formic acid. Finally, 1 mL of sample extract solution was pipetted into a 10 mL tube and diluted with 2% formic acid to 5 mL for cleanup.

Five types of solid-phase extraction cartridges including Oasis HLB, WCX, LC-18, SCX, and MCX were evaluated. The cartridge was preconditioned with 3 mL of methanol, followed by 3 mL of water (WCX and SCX cartridge were further conditioned with 3 mL of 2% formic acid). Then, the sample extraction solution was loaded onto the cartridge and washed with 3 mL of 10% methanol aqueous solution. After the cartridge had been dried for 5 min under low vacuum, the analytes were eluted with 5 mL of methanol containing 5% ammonia (v/v), and the eluates were evaporated to near dryness under a gentle stream of nitrogen at 40 °C. The residues were reconstituted in 10% methanol in water containing 0.1% formic acid and filtered through a 0.22 μm filter before LC-MS/MS analysis.

LC-MS/MS Conditions. The chromatographic system was composed of an Agilent 1200 series high-performance liquid chromatography (LC) system, including a quaternary pump and an autosampler (Milford, MA, USA). The mass system included an Applied Biosystems API 4000 triple-quadrupole mass spectrometer with electrospray ionization interface and Analyst 1.5 software (Foster City, CA, USA).

The samples were analyzed using an Agilent ZORBAX SB-Aq (150 mm × 2.1 mm i.d., 3.5 μm) reversed-phase column (Torrance, CA, USA). The column temperature was kept at 35 °C. The mobile phase consisted of 0.1% formic acid aqueous solution (A) and acetonitrile (B). The detailed gradient elution program was as follows: 0−8.0 min, 4−55% B; 8.0−11 min, 55−95% B; 11−15 min, 95% B; 15−16 min, 4% B; 16−22 min, 4% B. An injection volume of 5 μL and a flow rate of 0.2 mL/min were used in LC-MS/MS analysis.

The mass analyses were performed using an ESI source in positive ionization mode. The operation conditions were as follows: ionspray voltage, 5.0 kV; source temperature, 550 °C; curtain gas (nitrogen), 20 psi; ion source gas 1, gas 2, and collision gas (nitrogen), 50, 55, and 6 psi, respectively. One SRM transition mode (for screening) and further SRM mode (for confirmation of the suspected positive findings) were carried out. The optimization of the main mass spectrometry parameters including collision energy (CE), declustering potential (DP), entrance potential (EP) and cell exit potential (CXP) values were optimized by flow injection analysis (FIA) for each compound. Table 1 shows the optimized parameter values and the single SRM transition used for screening and quantification of the 22 compounds.

LC-LTQ-Orbitrap MS Conditions. The LC system consisted of a Finnigan Surveyor LC system with a built-in degasser, autosampler, and pump (San Jose, CA, USA). The separation was performed on a Thermo Scientific Hypersil Gold (100 mm × 2.1 mm i.d., 3.5 μm) C_{18} column (Waltham, MA, USA), and the cartridge temperature was set at 35 °C. The same mobile phase composition and linear gradient program as for the LC-MS/MS analysis were used. The injection volume was 10 μL, and the flow rate was 0.25 mL/min.

Mass spectra were analyzed on a Finnigan LTQ-Orbitrap XL instrument with an ESI source (Thermo Electron, Bremen, Germany). Nitrogen was used as sheath gas (30 arbitrary units) and auxiliary gas (5 arbitrary units); helium served as the collision gas. Values of tube lens voltage and capillary voltage were set to 70 and 200 V, respectively. The scan event cycle used a full scan mass spectrum at a resolution of 30000 full width at half-maximum (fwhm at m/z 400). An external calibration for mass accuracy was performed using a mixture of caffeine, MRFA peptide, and Ultramark 1600 (Thermo Fisher Scientific Corp.) on the day of analysis. The mass spectrometric data were collected from m/z 65 to 500 in positive ion mode.

MetWorks 1.2 software (Waltham, MA, USA) was set to automatically identify target analytes by comparing the sample with the control. The mass tolerance and baseline window were set to 5 ppm and 40 s, respectively. An intensity ratio threshold of 5× and match threshold of 0.8 were set as limits to perform on the component-detected subtraction. LTQ-Orbitrap MS parameters and all of the analytes' elemental composition, theoretical mass (Da), experimental mass (Da), and characteristic fragment ions of precursor ion are shown in Table 1.

Validation Process. On the basis of the 2002/657/EC guidelines and the proposed new idea, in brief, the validation includes the high-throughput screening by LC-MS/MS and then the confirmation and quantification of the positive finding with LC-MS/MS and HR-Orbitrap MS. The performance characteristics of the developed LC-MS/MS method including specificity, decision limit (CCα) and detection capability (CCβ), recovery and precision, calibration curve, and stability were determined for validation purposes. The confirmation analysis of the suspected positive finding by HR-Orbitrap MS was also demonstrated.

Specificity. The specificity of the method was checked by analyzing 50 blank feed (30 formulated feeds and 20 premixes) samples from different species including pig, chicken, cattle, and fish to evaluate possible endogenous interferences.

CCα and CCβ. CCα is the lowest concentration at which a method can discriminate with a statistical certainty of $1 - \alpha$ that the analyte is present. In this case, CCα was established by the following: 20 blank matrix samples of feed (pig, chicken, cattle, and fish) were analyzed, and the S/N was calculated at the time window in which the analyte is expected. CCα values were defined as 3 times the S/N.

CCβ is the concentration at which the method is able to detect truly contaminated samples with a statistical certainty of $1 - \beta$. CCβ was calculated by analyzing 20 blank feed (pig, chicken, cattle, and fish) samples spiked with the analytes at CCα, and then the CCα value plus 1.64 times the corresponding standard derivation is equal to CCβ (β = 5%).

Recovery and Precision. Recovery and intraday precision (repeatability) were performed by the determination of the spiked blank feeds such as pig, chicken, cattle, and fish at the four concentration levels (six replicates at each level), respectively. For evaluation of interday precision (reproducibility), various blank feed samples were fortified with the same concentration levels during the three consecutive days. The final concentration of the spiked sample was determined by means of matrix-match standard curve. The recovery was calculated by the ratio of the concentration measured versus the concentration spiked in blank feed sample, whereas the precision was expressed as the relative standard deviation (RSD).

Calibration Curve. The matrix-matched calibration curves were prepared and used for quantification and testing the linearity of the developed method. Various blank feeds (pig, chicken, cattle, and fish) were pretreated according to the optimized extraction and cleanup procedures described above. The eluates from blank feeds were used to prepare a series of concentrations from 0.5 to 1000 ng/mL. The matrix-matched calibration curves were generated by using the peak area of analyte versus the corresponding concentration in the matrix solution. The acceptance criterion was that the coefficient of correlation (r^2) must be >0.99.

Stability. Instability of the analytes in stock solution or working standard solution may result in significant deviations of the detected results and thus exerts some influence on the accurate determination and confirmation of the target analytes. The stability of the 22 target analytes in the neat standard solution (10 μg/L) and the matrix-matched standard solution (10 μg/kg) at room temperature and 4 °C was assessed within 1 week. The measured values were compared to those of freshly prepared standard solutions.

RESULTS AND DISCUSSION

Optimization of Instrumental Conditions. The chromatographic conditions were investigated to gain overall optimum peak shape and resolution for the 22 analytes. Because the target compounds cover a wide diversity of polarities including polar compounds such as β-agonists, nitroimidazoles, and nonpolar compounds such as anabolic hormone esters, the mobile phase composition should be optimized to obtain higher sensitivity and resolution for major analytes. Numerous chromatographic runs were performed to test different mobile phases consisting of methanol or acetonitrile (as organic phase) and water with different percentages of formic acid (0.05, 0.1, and 0.2%, v/v). It

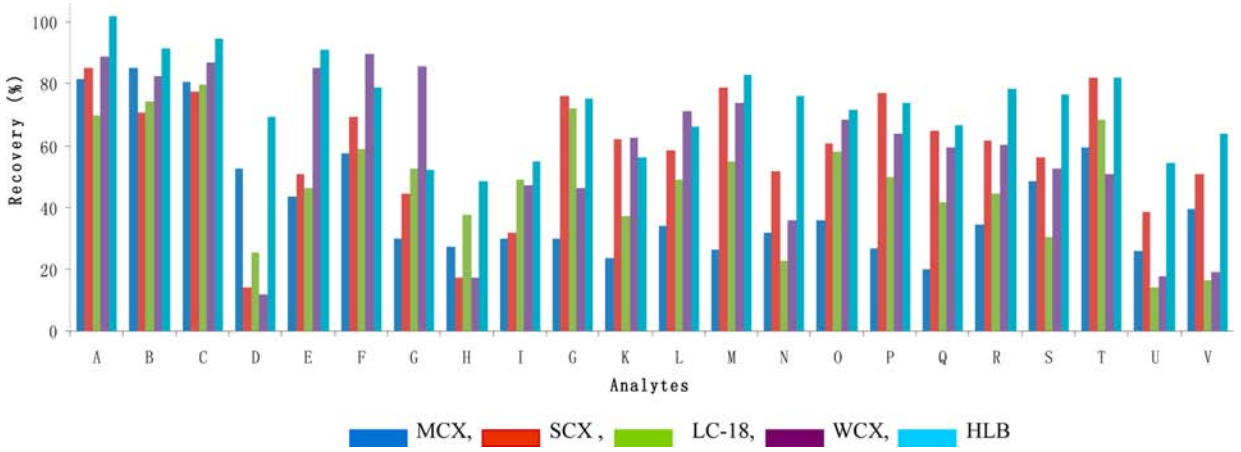

Figure 2. Recoveries of 22 analytes in the spiked formulated feed (0.5 mg/kg each) purified by different cartridges. Metronidazole (A), salbutamol (B), chlordimeform (C), malachite green (D), nandrolone (E), nandrolone propionate (F), xylazine (G), trenbolone (H), cimaterol (I), methyl testosterone (J), ronidazole (K), methaqualone (L), chlorpromazine (M), clenbuterol (N), dimetridazole (O), leucomalachite green (P), dapsone (Q), diazepam (R), difurazone (S), testosterone propionate (T), megestrol acetate (U), carbofuran (V).

was experimentally shown that acetonitrile provided better peak shape than methanol, and 0.1% formic acid in water gave the best overall peak sensitivity. Therefore, the system of acetonitrile and 0.1% formic acid aqueous solution was selected as the final mobile phase.

Four chromatographic columns (Thermo Hybrid golden C_{18}, CNW Athena C_{18}-WP (150 mm × 2.1 mm i.d., 3 μm), Agilent ZORBAX SB-Aq, and Phenomenex Luna C_{18} (150 mm × 2.0 mm i.d., 5 μm)) were used to evaluate their retention capabilities to the 22 target analytes. Under the optimized conditions, the separation of the analytes was performed on the Thermo Hybrid golden C_{18} chromatographic column, providing ideal analyte retention from 4 to 17 min, especially for those compounds with a similar polarity.

It should be mentioned that the properties of reconstitution solution before injection into the LC-MS/MS system were very important. Several different reconstitution solutions such as methanol, 10, 20, 30, 40, and 50% (v/v) methanol in water with 0.1% formic acid, and 10 mmol/L ammonium acetate solution were used to reconstitute the final extracts and dilute the mixed standard solution to prepare working standard solution. The results showed that the purified extracts reconstituted with methanol or 20, 30, 40 and 50% methanol aqueous solution containing 0.1% formic acid obtained broad and tailing peak shape and gave the drift of retention times. Conversely, not only good peak shape and constant retention time were obtained, but target analytes were also more stable when 10% methanol aqueous solution containing 0.1% formic acid was used as reconstitution solution.

Optimization of the main mass spectrometry parameters was achieved by FIA for each compound (0.5−10 μg/mL). The electrospray ion source operated in positive mode and a transition providing the highest signal was selected for each compound. The other optimized MS parameter values for screening and quantification are shown in Table 1.

For the confirmation of target analytes in the LTQ Orbitrap analyzer, the theoretical mass of each adduct ($[M + H]^+$) was previously calculated according to the elemental composition. The measurement of accurate mass obtained in full scan mode coupled to the characteristic ion fragmentations of precursor ion was used to confirm the presence of the target analyte and its molecular formula in suspected positive sample. A database including the elemental composition, the polarity of data acquisition, and expected adducts was established, and a high mass accuracy (below 5 ppm) was set as one of the identification criteria.

Extraction and Cleanup. The present work mainly aims at realizing a simultaneous detection for multiclass multiresidue target compounds. The performance of several generic extraction solvents and SPE cleanup cartridges has been evaluated. In the field of veterinary drug residue analysis, an extraction using acetonitrile followed by an SPE cleanup procedure is commonly used for multiple subclasses of veterinary drugs in feed,[16] meat,[17] milk,[18] and honey.[19] On the basis of these publications, methanol and acetonitrile were first used to extract the 22 target analytes from various feed matrices, and poor recoveries were obtained for the majority of the analytes. Therefore, organic solvent acidified with formic acid was used as extractive solvent.[6] The results show that acetonitrile acidified with formic acid could obtain extraction recoveries of >70% for all 22 analytes in feeds, especially >90% for β-agonists and nitroimidazoles; however, slightly lower recoveries for most analytes were obtained when methanol acidified with formic acid was used. To enhance the extraction yield of anabolic hormones while keeping the other recoveries within an acceptable range, a mixed solvent of acetonitrile, ethyl acetate, and formic acid (30:20:1, v/v/v) was further investigated. Regrettably, although much cleaner feed extracts and higher extraction recoveries for anabolic hormones were obtained, the recoveries of the other analytes were slightly decreased. Thus, acetonitrile acidified with formic acid was chosen as the final extraction solvent in the following experiments.

As far as the complex feed matrix is concerned, an additional cleanup step is generally required. Five SPE cartridges of HLB, WCX, LC-18, SCX, and MCX were used to purify and enrich the 22 analytes in feed extracts under their corresponding optimized conditions, respectively. High overall recoveries (>70%) for three β-agonists (salbutamol, cimaterol, and clenbuterol) in various feeds were obtained on the five types of cartridges, and slightly lower recoveries (>40%) for most analytes (except for metronidazole and chlordimeform, <20%) were obtained on Oasis HLB and WCX SPE cartridges. For most analytes poor recoveries (<40%) were obtained on the LC-18 and SCX SPE cartridges. Acceptable recoveries (>65% for 80% the compounds,

>50% for all 22 target analytes except for carbofuran and chlordimeform) were obtained on the Anpel MCX SPE cartridge. The recoveries of analytes of interest in spiking formulated feed purified by the five SPE cartridges are shown in Figure 2, demonstrating the higher absorptive capability of the MCX SPE cartridge relative to that of the other four SPE cartridges. Therefore, the MCX cartridge was selected for the following experiments. Further optimization of the loading, washing, and eluting solution for the MCX SPE cartridge was performed.

Because the acetontrile extraction solution was directly loaded on the MCX SPE cartridge, anabolic hormones were not well retained on the cartridge. When acetonitrile extracts were diluted with 2% formic acid before loading, good recoveries were obtained for most target analytes. In the washing step, methanol was first used, and some drugs were rinsed off. Finally, 10%

methanol aqueous solution was selected as a proper washing solution. The selection of eluting solution was conducted between methanol and acetonitrile with different percentages of ammonium hydroxide. It was shown that 5% ammonium hydroxide in methanol could efficiently elute all target analytes on the cartridge and obtain fewer interferences.

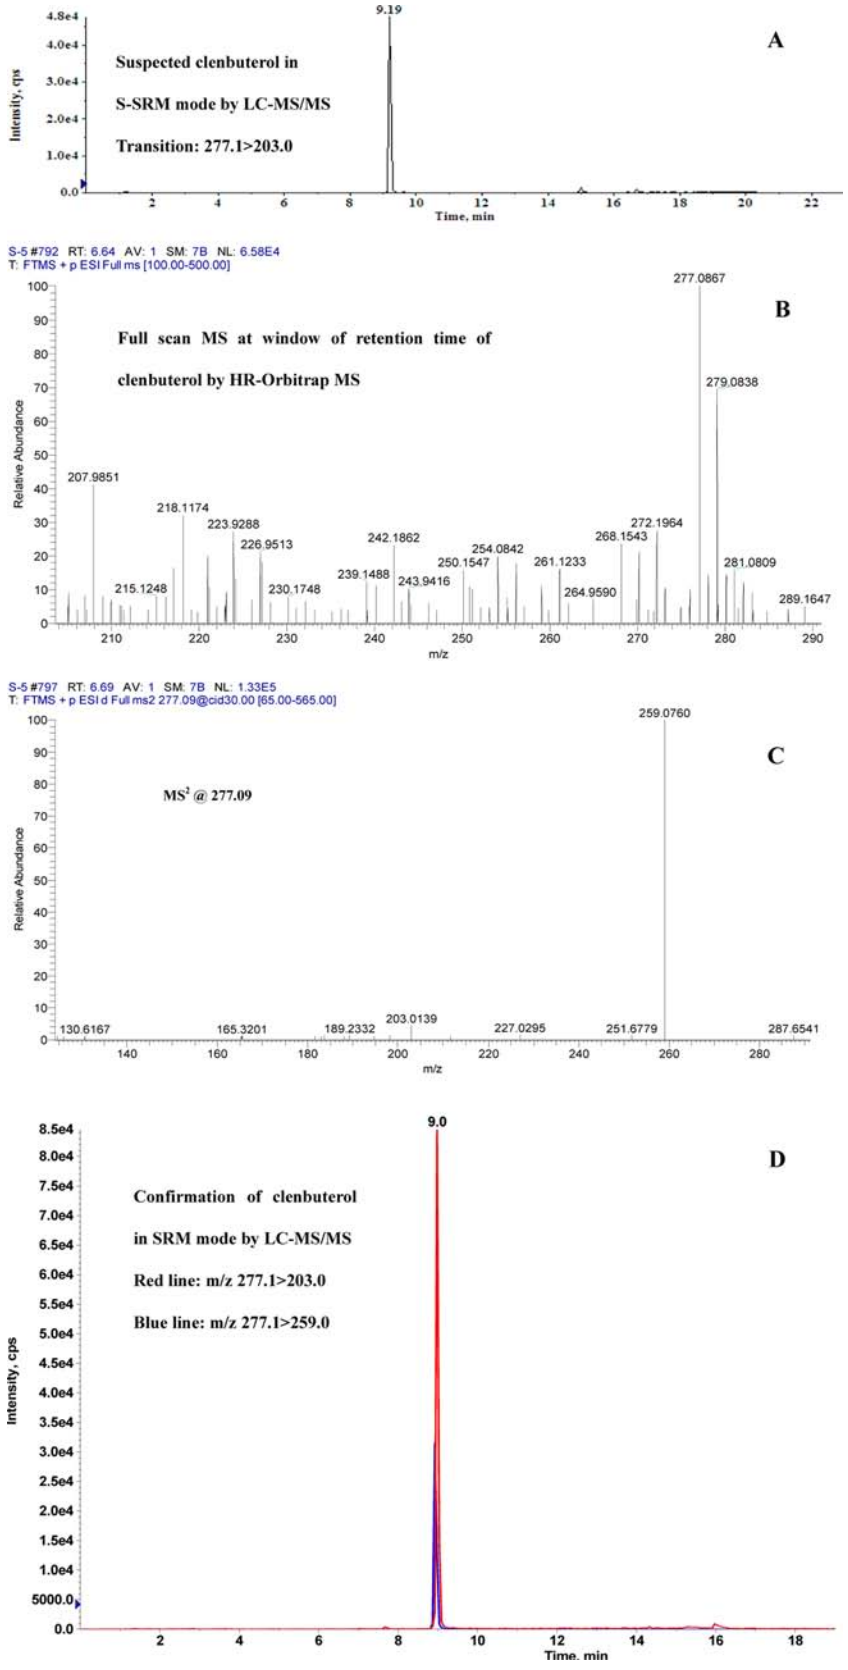

Figure 5. Demomstration of screening by LC-MS/MS and confirmation with LC-LTQ-Orbitrap MS in the cattle feed sample incurred by clenbuterol.

Method Validation. In accordance with Commission Decision 2002/657/EC, the performance characteristics of the proposed method based on LC-MS/MS analysis were validated as follows.

The selectivity was investigated by analyzing 50 blank pig, chicken, cattle, and fish feed samples to verify the absence of interfering substances. The results demonstrate that no interfering peaks within the 2.5% margin of the relative retention

dx.doi.org/10.1021/jf404501j | J. Agric. Food Chem. 2014, 62, 516−527

time of the 22 target analytes are detected in the single SRM chromatograms (Supporting Information, Figure S1).

As forbidden drugs used in feeds, the value of the limit should be as low as possible, as required by the Chinese government. To reveal weak intensity of qualifier transition of a certain compound in multiclass drugs analysis by LC-MS/MS in SRM mode, the ion abundance ratios of qualifier transition to quantifier transition of the studied analytes are shown in Table 2. The relative abundance ratios of testosterone propionate, methyl testosterone, and methaqualone were <15%, and those of metronidazole, chlorpromazine, and diazepam were about 20%. For obtaining 3 times the S/N ratio for confirmation transition of the compounds above, their corresponding concentration should be >1 μg/L. Thus, it is possible that the structural confirmation based on the relative abundance ratio in SRM mode is unavailable for certain compounds in the concentration levels required by the government. Under the conditions optimized in the proposed method, the values of CCα for the 22 compounds in various feeds ranged from 2.6 to 23 μg/kg, and the values of CCβ ranged from 4.2 to 34 μg/kg, suggesting the confirmation of these substances including but not limited to testosterone propionate, ronidazole, methaqualone, and trenbolone at <10 μg/kg in feeds is difficult by LC-MS/MS in SRM mode.

Accuracy (recovery) and precision (repeatability and within-laboratory reproducibility) were determined by processing independently the spiked feed samples at four different levels in three days (Table 3). The results show that the intraday recoveries for all target analytes were above 50% except chlordimeform and carbofuran (below 50 and 40%, respectively), and the intraday RSDs were all below 13%. The interday recoveries for most analytes were above 60%, and the interday RSDs were below 15% except for 19% carbofuran. The typical single SRM chromatograms of the spiked formulated feed sample are shown in Figure 3.

The linearity of the chromatographic response was evaluated with matrix-matched calibration curves at six concentration levels. The matrix-matched standard calibration curves showed good linearity in the ranges of 0.5−250 μg/mL for salbutamol, cimaterol, clenbuterol, and xylazine, 1.0−500 μg/mL for metronidazole, dimetridazole, difurazone, carbofuran, dapsone, methaqualone, diazepam, chlorpromazine, nandrolone 17-propionate, megestrol acetate, malachite green, and leucomalachite green, and 2.0−1000 μg/mL for trenbolone, nandrolone, methyltestosterone, testosterone propionate, ronidazole, and chlordimeform. The linear regression coefficients (r^2) of all the matrix-matched standard calibration curves were >0.99 (regression equations omitted).

Confirmation with LC-LTQ-Orbitrap MS. Because the confirmation of certain compounds using LC-MS/MS in SRM mode was unavailable according to Decision 2002/657/EC, the selectivity, sensitivity, and high-resolution mass behavior of the 22 target compounds using LC-LTQ-Orbitrap MS in full scan mode were evaluated. The blank feed matrices and spiked blank feeds in LC-MS/MS analysis were also subjected to analyses with LC-LTQ-Orbitrap MS. On the basis of the relative retention times, the 22 compounds in the spiked sample were identified efficiently in accordance with accurate mass provided by HR-Orbitrap MS, and no interfering peaks within the 2.5% margin of the relative retention time of the target analytes were detected. The typical extracted ion chromatograms of blank formulated feed are shown in Figure S2 (Supporting Information). The mean values of the mass measurements were all within 2 ppm of their theoretical m/z values at a mass resolving power of 30000 fwhm (Table 1). The results demonstrate that the confirmation of the spiked feed sample by HR-Orbitrap MS is reliable and feasible. The typical extracted ion chromatograms of the spiked formulated feed are shown in Figure 4.

The stability experiments revealed that the response factor of each compound remained almost constant in feed matrices for 2 days (room temperature) and 4 days (4 °C) and remained constant in neat solvent for 3 days (room temperature) and 6 days (4 °C), respectively. Therefore, the prepared samples should be injected within 2 days for good quantification. In addition, the mix standard stock solution should be used completely within 3 weeks.

Application to Real Samples. To evaluate the applicability of the proposed method, the analytical procedures described above were used to extract and determine 22 target analytes in 300 feed (including piglet, swine, poultry, cattle, and fish) samples collected from local feed markets. The real feed samples were first screened using LC-MS/MS in single SRM positive mode. The screening results showed that clenbuterol might be found in several cattle feed samples. These suspected positive samples were further confirmed by LC-MS/MS in SRM mode and also by means of accurate mass confirmation methodology of LC-LTQ-Orbitrap MS in full scan mode. Screening, confirmation, and quantification of clenbuterol in the incurred cattle feed based on this novel method are demonstrated in Figure 5. The screening analysis of the extracts of feed sample was carried out with LC-MS/MS in a single selected reaction monitoring mode. As shown in Figure 5A, the peak at a retention time of 9.2 min is detected in the channel of m/z 277.1/203.0. This suggested that there might be clenbuterol in this feed sample, so the extracts were subjected to further analysis by accurate mass HR-Orbitrap MS in full scan mode. In Figure 5B, the accurate monoisotopic mass of the $[M + H]^+$ ion of m/z 277.0868 is confirmed as clenbuterol, and in Figure 5C, clenbuterol is further proved by m/z 259.0760 and 203.0134 of specific fragment ions of m/z 277.0868. Finally, this positive cattle feed sample containing clenbuterol was reprepared with a specific procedure.[20] Briefly, after cleanup of extracts with the SCX cartridge, the eluates were evaporated to near dryness at 55 °C under a mild stream of nitrogen, dissolved in 10% methanol in water containing 0.1% formic acid, and filtered through a 0.22 μm filter. Then confirmation and quantification (simultaneously) by LC-MS/MS in selected reaction monitoring mode were carried out (Figure 5D). The identified result in accordance with the ratio of the qualifier transition to quantifier transition in LC-MS/MS analysis is consistent with the result of accurate mass confirmation by LC-LTQ-Orbitrap MS analysis. However, the HR-Orbitrap MS instrument is not cheap and can not be widely used in routine analytical laboratories registered with the government in China. Therefore, the high-throughput screening of multiclass drugs based on LC-MS/MS operated in a single SRM mode is feasible and recommendable in routine regulatory analysis. The suspected positive sample might be further identified by HR-Orbitrap MS for obtaining more reliable analysis if the confirmation with LC-MS/MS is poor.

In conclusion, a high-throughput, sensitive, and reliable screening and confirmative method using LC-MS/MS combined with accurate mass LC-LTQ-Orbitrap MS was first developed and validated for 22 banned and illicit drugs in feed matrices (Bulletin 235 of MOA, China). The multiclass screening analysis by LC-MS/MS operated in a single selected reaction monitoring mode is not only an intuitive and less time-consuming data process, but the number of monitoring analytes is also doubled

(in the same dwell time). For several suspected positive findings, accurate mass confirmation using LC-LTQ-Orbitrap MS can be an effective additional means of confirmation based on the ratios by LC-MS/MS in SRM mode.

Composition and Biological Activities of Hydrolyzable Tannins of Fruits of *Phyllanthus emblica*

Baoru Yang* and Pengzhan Liu

Food Chemistry and Food Development, Department of Biochemistry, University of Turku, FI-20014 Turku, Finland

ABSTRACT: Fruits of emblic leafflower have been used as food and traditional medicine in Asia. A wide range of biological activities have been shown in modern research suggesting potential of the fruits as healthy food and raw material for bioactive ingredients of food. Hydrolyzable tannins are among the major bioactive components of the fruits. Mucic acid gallate, mucic acid lactone gallate, monogalloylglucose, gallic acid, digalloylglucose, putranjivain A, galloyl-HHDP-glucose, elaeocarpusin, and chebulagic acid are the most abundant hydrolyzable tannins. The compositional profiles of tannins in the fruits vary depending on the cultivars as well as ripening stages. Fruits and tannin-rich extracts of fruits have shown antidiabetic, antimicrobial, anti-inflammatory, and immune-regulating activities in vitro and in animal studies. The fruits and fruit extracts have manifested protective effects on organs/tissues from damages induced by chemicals, stresses, and aging in animal models. The fruits and fruit extracts have potential in inhibiting the growth of cancer cells and reducing DNA damage induced by chemicals and radiation. Antioxidative activities are likely among the mechanisms of the biological activities and physiological effects. Human intervention/clinical studies are needed to investigate the bioavailability and metabolism of the tannins and to substantiate the health benefits in humans. Emblic leafflower may be a potential raw material for natural food preservatives.

KEYWORDS: *emblic leafflower, hydrolyzable tannins, elaeocarpusin, chebulagic acid, bioactive ingredients, nutraceuticals*

INTRODUCTION

The importance of food and diet in maintaining health and reducing the risk of chronic diseases is increasingly recognized. There is a fast-growing trend in the demand for foods with targeted health-promoting properties. The food industry is searching for new raw materials as sources of bioactive ingredients for foods and nutraceuticals.

Hydrolyzable tannins are derived by gallic acid (3,4,5-trihydroxybenzoic acid) being esterified to a core polyol, and the galloyl groups may be further esterified or cross-linked through dehydration to yield more complex hydrolyzable tannins.[1] Hydrolyzable tannins cover a wide group of compounds belonging to ellagitannins (esters of ellagic acid) and gallotannins (esters of gallic acid) that are present in many plant families. These compounds are gaining increasing attention of researchers in the areas of food and medicine because they are found to have a number of biological properties, including antioxidant, anticancer, antiatherosclerotic, antihepatotoxic, antibacterial, and anti-HIV replication activities.[2,3]

Emblic leafflower (*Phyllanthus emblica*) is a tropical fruit-bearing tree commonly planted in southern China, India, and other Asian countries. The fruits are consumed fresh and are also processed into food products in these regions. The fruits have been used in traditional medicines to treat various illnesses in Siddha, Sri Lanka, India, and China.[4] Recently, there has been increasing interest in the fruits as a raw material for food and nutraceuticals as well as bioactive ingredients of food and personal care products because of the traditional use and the biological activities shown in modern research. A wide array of biological activities and potential health benefits have been reported for emblic leafflower, including antioxidative, antidiabetic, antibacterial, hypolipidemic, anticancer, immunomodulatory, anti-inflammatory, and antiatherogenic properties as well as protective effects on the liver, gastric mucosa, and cardiovascular and nervous systems.[5−10] The materials studied are fresh fruits, fruit juice, and dried fruits, as well as extracts prepared with various solvents. The protocols applied in the studies carried out so far are mostly in vitro studies and animal experiments. Most of the studies have suggested that the phenolic compounds consisting of primarily hydrolyzable tannins of the fruits are the key bioactive components contributing to the beneficial effects. Several research groups have investigated the tannins of emblic leafflower fruits. This review summarizes the current literature on the compositional profile and the biological activities of hydrolyzable tannins of emblic leafflower fruits, juices, and various extracts of the fruits. The aim is to provide guidance for future research and application of this fruit as a source of bioactive ingredients of food.

HYDROLYZABLE TANNINS IN FRUITS OF *PHYLLANTHUS EMBLICA*

Hydrolyzable tannins are the dominating phenolic compounds of the fruits of *P. emblica*.[11,12] The tannin content is reported to be 4% of fresh weight in fruit[13] and 35% in dried fruit powder.[14] The highest content of tannins is found at the early development stage of the fruits.[15]

Tannins have been investigated in freeze-dried juice,[16] aqueous acetone (60%) extract of juice powder,[17,18] enzyme-aided water extract of fruits,[19] water extract of fresh fruits,[16]

target and method of study	fruits and extracts	dose	result	ref
DPPH, $O_2^{\bullet -}$, $OH^{\bullet}$, and NO radicals, in vitro	methanol extract of PE fruit		methanol extract of PE fruit exhibited the highest scavenging activity against DPPH, $O_2^{\bullet -}$, $OH^{\bullet}$, and NO radicals; the extract also significantly inhibited the oxidation of low-density lipoprotein (LDL) in vitro	7
$DPPH^{\bullet}$ radical, in vitro	gallic acid, ellagic acids, emblicanins A and B		all compounds showed activities in scavenging of $DPPH^{\bullet}$ radicals; emblicanins A and B showed highest activities	23
NO radicals, in vitro	methanolic extract of PE fruit		ethyl acetate fraction of methanolic extract of PE fruit showed strong NO-scavenging activity in vitro; gallic acid was found to be a major compound in the ethyl acetate fraction, and geraniin showed the highest NO-scavenging activity among the isolated compounds from the ethyl acetate fraction	24
oxidation of DNA, in vitro	free and bound phenolics of PE fruit		positive correlation between antioxidant activity and phenolic content was found ($R = 0.74$); gallic acid and tannic acid were identified as the major antioxidant components in phenolic fractions of PE; the extracts of PE also exhibited significant protection to DNA against oxidative damage	25
alcohol-induced oxidative changes in rats, in vivo	PE fruit extract (an aqueous fruit extract dry powder, including 49.5% tannins)	250 mg kg^{-1} BW per day for 60 days	PE fruit extract showed ameliorative effects against alcohol-induced oxidative changes in different organs of rats (erythrocyte membrane, plasma, liver, brain); the tannins present in PE fruit extract with antioxidant as well as NO-scavenging properties were suggested to contribute to these effects	26−30
ochratoxin-induced LPO in the kidney and liver of mice, in vivo	PE fruit aqueous extract	2 mg per animal per day for 45 days	significant reduction in the ochratoxin-induced LPO in liver and kidney of mouse were found	31
oxidative stress during aging process in rats, in vivo	SunAmla/ethyl acetate extract of PE fruit	40/10 mg kg^{-1} BW per day for 100 days	extract of PE fruit could attenuate age-related renal dysfunction and prevent age-related hyperlipidemia through attenuating oxidative stress in the aging process	19, 32

dx.doi.org/10.1021/jf404703k | J. Agric. Food Chem. 2014, 62, 529−541

lactone 3-*O*-gallate,[19] mucic acid 1,4-lactone 5-*O*-gallate,[16] and mucic acid 1,4-lactone 3,5-di-*O*-gallate.[17] Mucic acid 2-*O*-gallate, mucic acid 1,4-lactone 2-*O*-gallate, and mucic acid 1,4-lactone 5-*O*-gallate are found to be the major compounds of this group in juice powder.[17] 3-Ethylgallic acid was also isolated from the fruits.[20] Two isomers of mucic acid gallate and several isomers of mucic acid digallate, mucic acid lactone gallate, and mucic acid lactone digallate have been detected in the methanol extract of dried fruits of emblic leafflower.[12] Different isomers of mucic acid gallates, mucic acid digallates, and mucic acid lactone digallates tend to reach equilibrium in water solution, indicating the possible impact of sample handling and analytical procedures on the ratios between different isomers.[19] Methyl esters of mucic acid gallates, mucic acid 1,4-lactone gallates, and mucic acid 1,4-lactone-digallates have been identified in the fruit juice powder[17] and methanol extracts of whole fruits.[12] Examples of these compounds are mucic acid dimethyl ester 2-*O*-gallate, mucic acid 1-methyl ester 2-*O*-gallate, mucic acid 6-methyl ester 2-*O*-gallate, mucic acid 1,4-lactone 6-methyl ester 2-*O*-gallate, and mucic acid 1,4-lactone 6-methyl ester 5-*O*-gallate.[19] It has been suggested that most of the methyl esters found may have been artifacts generated during the separation process of multiple stages of column chromatography, although a small amount of methyl esters has been detected in an aqueous acetone extract of the juice powder.[19]

Figure 2 presents the structure of major gallotannins and ellagitannins found in the fruit and juice of emblic leafflower. Complex tannins have been investigated in an aqueous acetone extract of fruit juice powder.[18] 1(*β*)-*O*-, 1(*β*),6-di-*O*-, and 1(*β*),2,3,6-tetra-*O*-galloylglucose, corilagin, chebulanin, chebulagic acid, elaeocarpusin, punicafolin, tercatain, mallonin, putranjivain A, and phyllanemblinin A have been identified on the basis of mass spectrometric (MS) and nuclear magnetic resonance spectroscopic (NMR) spectra. In the same study, five other compounds named phyllanemblinins B, C, D, E, and F have been isolated and identified from leaves and branches, but not in the fruits, of *P. emblica*.[18] Isostrictinin is found in the aqueous acetone (70%) extract of dried fruit powder.[20]

In the study of Yang et al., the phenolic compounds in a methanol extract of dried fruits of *P. emblica* have been studied systematically by HPLC-DAD and HPLC-ESI(−)-MS combined with column chromatography.[12] A mucic acid gallate, three mucic acid lactone gallate isomers, a galloylglucose, gallic acid, a digalloylglucose, putranjivain A, a galloyl-HHDP-glucose, elaeocarpusin, and chebulagic acid are the most abundant compounds in the crude methanol extract of the fruits. In addition, 130 peaks are detected, of which 63 are identified/tentatively identified as simple gallic acid derivatives and derivatives of chebulic acid and chebuloylglucose, as well as ellagitannins and flavonoids. Neochebulagic acid, isomers of neochebuloyl galloylglucose (phyllanemblinins D, E, and F), punicalagin, geraniinic acid, ellagic acid glycosides, and quercetin glycosides are reported.[12]

Many hydrolyzable tannins have been reported in the fruits of *P. emblica*,[12] which remain to be identified by future research. In addition, some contradictory results have been reported concerning the identification of some hydrolyzable tannins in the fruits. For instance, according to Ghosal et al., the fruits of *P. emblica* contain two hydrolyzable tannins, emblicanin A (2,3-di-*O*-galloyl-4,6-(*S*)-hexahydroxydiphenoyl-2-ketogluconolactone) and emblicanin B (2,3,4,6-bis(*S*)-hexahydroxydiphenoyl-2-ketogluconolactone) (Figure 2).[11] However, Majeed et al. have suggested that the compounds identified as emblicanins A and B by Ghosal et al. are 1(*β*)-*O*-galloylglucose and mucic acid 1,4-lactone 5-*O*-gallate, respectively, according to the NMR spectra.[16] Thus, the presence of emblicanin A and emblicanin B needs confirmation by further studies. Both the origin of the samples and methods of sample preparation could influence the content and profile of hydrolyzable tannins. Corilagin, geraniin, chebulagic acid, and ellagic acid are found to be the major ellagitannins in both an enzyme-aided water extract and an ethyl acetate extract of fresh fruits of *P. emblica*.[19] Eleaocarpusin, a major compound in the water extract, is not detected in the ethyl acetate extract of the fruits. Furosin is more abundant in the ethyl acetate extract than in the enzyme-aided water extract.[19]

A recent study has shown clear differences in both the content and profile of tannins in the fruits of emblic leafflower of different origins in southern China.[12] Fruits of two cultivars from Guangxi province are richer sources of tannins than those of Tian Chuan emblic leafflower from Fujian province.[12] The fruits from Guangxi differ from those from Fujian also by higher proportions of ellagitannins and derivatives of chebulic acid and chebuloylglucose.[12]

HEALTH EFFECTS OF HYDROLYZABLE TANNINS OF *PHYLLANTHUS EMBLICA* FRUITS

Many studies have demonstrated that the *P. emblica* fruits and its extracts have beneficial effects on the health of human beings. Several studies have tested the compounds of purified hydrolyzable tannins; others used whole berries and extracts of different solvents. However, the hydrolyzable tannins were considered as the major bioactive compounds in the materials tested in most of the studies.

Antioxidant, Radical-Scavenging, and Antiaging Activities. An excess generation of free radicals is linked to many human diseases and early aging. Reactive oxygen species [ROS; superoxide anion radicals ($O_2^{\bullet -}$), hydroxyl radicals ($OH^{\bullet}$), and hydrogen peroxide (H_2O_2)] and reactive nitrogen species [RNS; nitric oxide (NO) and peroxynitrite ($ONOO^-$)] cause oxidation of lipids, proteins, and DNA, damage the structures and functions of cells, and lead to aging and development of diseases.[22]

Table 1 summarizes the literature on the antioxidative and radical-scavenging activities of *P. emblica* fruit or its extracts.

The free radical-scavenging activity of extracts and individual compounds of *P. emblica* fruits have been evaluated in vitro.[7,23−25] Methanol and aqueous extracts of the fruits have exhibited scavenging activity against 2,2-diphenylpicrylhydrazyl radical ($DPPH^{\bullet}$), $O_2^{\bullet -}$, $OH^{\bullet}$, and NO radicals[7,24] and inhibited the oxidation of low-density lipoprotein (LDL)[6] and DNA.[25] Emblicanins A and B are reported to have $DPPH^{\bullet}$-scavenging activity close to 10 times that of ascorbic acid and twice of that of gallic acid.[23] Geraniin has been identified as the compound with the highest NO-scavenging activity in an aqueous extract of *P. emblica* fruit.[24] Gallic acid and tannic acid are the major antioxidant components in phenolic fractions of *P. emblica* fruits according to both $DPPH^{\bullet}$-scavenging and reducing power assays.[25]

A series of studies have shown the ameliorative effects of a *P. emblica* fruit extract (a dried powder of aqueous fruit extract with a total content of tannins of 49.5% dry weight) against alcohol-induced oxidative changes in rats, suggesting tannins to be the major antioxidants in the extract.[26−30] Administration of the extract [250 mg kg^{-1} body weight (BW) per day] resulted in a significant ($p < 0.05$) reduction in NO levels, lipid

target and method of study	fruits and extracts	dose	result	ref
streptozotocin (STZ)-induced type 2 diabetes rats, in vivo	ethanolic extract of PE fruit	200 mg kg^{-1} BW for 45 days	significant reduction in blood glucose and significant increase in plasma insulin in diabetic rats	33
normal and diabetic human volunteers, clinical trial	PE fruit	1, 2, or 3 g PE fruit powder per day	decrease ($p < 0.05$) was found in fasting and 2 h postprandial blood glucose levels in both normal and diabetic subjects receiving PE powder; significant ($p < 0.05$) decreases were observed in TC and triglycerides in both normal and diabetic volunteers that were given either 2 or 3 g PE powder per day; the diabetic volunteers receiving 3 g of PE powder per day exhibited a significant ($p < 0.05$) decrease in total lipids; both normal and diabetic volunteers receiving 2 or 3 g of PE powder showed significant ($p < 0.05$) improvement in cholesterol levels	35
α-amylase and α-glucosidase, in vitro	extract of PE fruit		extract of PE fruit was able to inhibit α-amylase and α-glucosidase (IC_{50} value = 1.0 and 94.3 μg mL^{-1}, respectively)	7
fructose-induced metabolic syndrome in rat model	ethyl acetate extract of PE fruit	10 or 20 mg kg^{-1} BW per day for 2 weeks	ethyl acetate extract of PE fruit ameliorated the high fructose diet-induced hypertriacylglycerolemia and hypercholesterolemia	41
diabetic cataract, in vitro	PE fruit and an enriched fraction of PE fruit tannins		aqueous extract of PE fruit inhibited aldose reductase (AR) of rat lens and recombinant human AR with IC_{50} values of 0.72 and 0.88 mg mL^{-1}, respectively,	36
STZ-induced diabetic cataract in rats, in vivo	PE fruit and an enriched fraction of PE fruit tannins	0.2% diet	supplements of PE fruit and PE fruit tannins delayed cataract progression	37
diabetic neuropathy in rats, in vivo	aqueous extract of PE	250−1000 mg kg^{-1} per day	insulin in combination with PE extract not only attenuated the diabetic condition but also reduced neuropathic pain through modulation of oxidative−nitrosative stress in diabetic rats	38
diabetic-uremic patients, clinical trial	1:1 mixture of epigallocatechin-3-gallate and PE extract	100 mg of EGCG and 100 mg of PE extract 3 times per day	the mixture significantly improved antioxidant defense as well as diabetic and atherogenic indices in uremic patients with diabetes	39

dx.doi.org/10.1021/jf404703k | J. Agric. Food Chem. 2014, 62, 529−541

peroxidation (LPO), and the activities of Na^+/K^+- and Mg^{2+}-ATPases in erythrocyte membranes in alcohol-treated rats.[24] The extract showed hepatoprotective effects, reduced the contents of lipid peroxide and protein carbonyls, and restored the levels of enzymatic and nonenzymatic antioxidants in the liver[27,29] and the brain[30] of alcohol-treated rats. An ameliorative effect of a *P. emblica* aqueous extract on ochratoxin-induced LPO in the kidney and liver of mice is reported.[31]

Both an enzyme-aided water extract and a polyphenol-rich ethyl acetate extract of *P. emblica* fruits attenuated age-related renal dysfunction and prevented age-related hyperlipidemia by attenuating oxidative stress in the aging process of rats.[19,32] Oral administration of the fruit extract also significantly increased the hepatic peroxisome proliferator activated receptor α (PPARα) protein level and inhibited the levels of thiobarbituric acid-reactive substances (TBARS) in the serum, hepatic mitochondria, and kidney in aged rats.[19,32]

Effects on Sugar Metabolism, Diabetes, and Diabetic Complications. The antidiabetic activities of *P. emblica* fruits and fruit extracts have been studied in animal models and in humans (Table 2). Oral administration of an ethanol extract of the fruits (200 mg kg^{-1} BW for 45 days) resulted in a significant reduction in the plasma level of glucose and a significant increase in the plasma level of insulin in streptozotocin (STZ)-induced type 2 diabetic rats.[33] In addition, administration of the extract reduced total cholesterol (TC), VLDL-C, LDL-C, free fatty acid (FFA), and phospholipid (PL) levels in blood and increased the level of high-density lipoprotein (HDL) cholesterol.[33] Oral administration of an aqueous extract of *P. emblica* seeds reduced fasting glucose level and improved glucose tolerance in normal as well as subdiabetic and mildly diabetic rats.[34] Daily supplementation with 1, 2 or 3 g of *P. emblica* fruit powder for a period of 3 weeks significantly decreased ($p < 0.05$) fasting and 2 h postprandial levels of blood glucose as well as plasma lipid levels from baseline values in both normal subjects and diabetic patients.[33] The antidiabetic properties of *P. emblica* fruits and extracts are likely to be related to the inhibition of the activities of α-glucosidase and α-amylase, enzymes crucial for the digestion and absorption of dietary starch.[7]

Prolonged exposure to uncontrolled chronic hyperglycemia in diabetes results in complications including various microvascular and macrovascular diseases. Microvascular complications include neuropathy, nephropathy, and vision disorders. Macrovascular complications include heart disease, stroke, and peripheral vascular disease. Studies have shown that *P. emblica* and its tannins have beneficial effects on cataracts,[36,37] neuropathy,[38] and uremia[39] as complications of diabetes.

The studies of Suryanarayana's group have suggested that *P. emblica* fruits and the tannins of the fruits might be effective in delaying the development of diabetic cataracts in rats.[36,37] An aqueous extract of *P. emblica* fruit and a fraction rich in tannins of the fruits prevented activation of aldose reductase (AR) and also inhibited sugar-induced osmotic changes in the cultured lens of rat.[36] Neither *P. emblica* fruit nor its tannins showed any preventive effects on STZ-induced hyperglycemia as assessed by blood glucose and insulin levels in rats.[37] However, slit lamp microscopic observation indicated that these supplements delayed cataract progression. *P. emblica* fruit also prevented the aggregation and precipitation of lens proteins caused by hyperglycemia.[37]

Diabetic neuropathy is one of the most common microvascular complications, affecting >50% of diabetic patients. Tiwari et al. found that *P. emblica* fruits could correct functional, biochemical, and molecular defects in experimental diabetic neuropathy by targeting the inflammatory cascade mediated by oxido-nitrosative stress.[38] Treatment with an aqueous extract of the fruits (250−1000 mg kg^{-1} per day) significantly attenuated oxidative stress and the levels of nitrite and cytokines [tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and transforming growth factor- β1 (TGF-β1)] both in the serum and in the sciatic nerve in a dose-dependent manner in diabetic rats.[38] Oral administration of a mixture of epigallocatechin-3-gallate and *P. emblica* fruit extract for 3 months significantly improved the antioxidative defenses as well as the diabetic and atherogenic indices in uremic patients with diabetes.[39]

Metabolic syndrome is characterized by insulin resistance, dyslipidemia, and hypertension and is associated with increased morbidity and mortality from several prevalent diseases, such as diabetes, cancer, myocardial infarction, and stroke.[40] An ethyl acetate extract (polyphenol-rich fraction) of *P. emblica* fruit ameliorated the high fructose diet-induced hypertriacylglycerolemia and hypercholesterolemia in rats.[41]

Effects on Cardiovascular Health. Fruits and extracts of *P. emblica* have shown beneficial effects on different cardiovascular diseases (Table 3). Oxygen-derived free radicals play an important role in the initiation and progression of all clinical manifestations of ischemic heart disease. Myocardial cellular injury occurring during reperfusion of ischemic cells, known as ischemia-reperfusion injury, is primarily due to oxidative stress.[42] Studies have shown that antioxidants exert a protective effect against cardiac ischemia-reperfusion injury (IRI).[43,44]

Studies by Bhattcharya et al. and Rajak et al. have shown that tannin-rich extracts of *P. emblica* fruit can ameliorate the oxidative stress induced by IRI.[45,46] Oral administration of a *P. emblica* fruit extract enriched with emblicanins A and B (50 and 100 mg kg^{-1} BW twice per day for 14 days) significantly reversed the effects of IRI on superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx), and LPO activities.[45] Similar results have been found in a study by Rajak et al.[46] Fresh *P. emblica* fruit homogenate (250−750 mg kg^{-1} per day) and saline were administered orally to Wistar albino rats for 30 days. There was a reduction in basal myocardial LPO, as evidenced by decreased TBARS levels, and an augmentation of myocardial endogenous antioxidants in the *P. emblica*-treated rats compared to those in the saline group. The results indicate that long-term *P. emblica* fruit administration improves myocardial adaptation by augmenting endogenous antioxidants and protecting the rat heart from oxidative stress associated with IRI.[46]

Anila and Vijayalakshmi separated flavonoids from *P. emblica* fruit by solvent extractions and silica gel column chromatography.[47] The ethyl acetate/methanol (50:50) fraction provided the maximum yield of flavonoids (789.4 mg from 1.9 kg of fresh fruit). The flavonoids were administered orally (10 mg kg^{-1} BW per day) to male albino rats fed a high-fat diet (coconut oil 15% and cholesterol 2%). After 90 days of treatment, significant decreases in lipid levels in serum and tissues were observed when compared with the control group.[47] Duan et al. studied the antiatherogenic effects of two soluble tannins, corilagin and its analogue Dgg16 (1,6-di-*O*-galloyl-β-D-glucose), isolated from *P. emblica* fruit. The results suggested that the two compounds are effective in inhibiting the progress of atherosclerosis by alleviating oxidation injury and by inhibiting

Table 3. Effects on Cardiovascular Health of *P. emblica* (PE) Fruits and Fruit Extracts

target and method of study	fruits and extracts	dose	result	ref
cardiac ischemia-reperfusion injury (IRI) in rats	emblicanin A and B enriched PE extract (prepared by eluting fresh PE juice though a Sephadex LH-20 column)	50 mg and 100 mg kg^{-1} BW twice per day for 14 days	the PE extract (50 mg and 100 mg kg^{-1} BW) significantly reversed the effects of IRI on SOD, CAT, GPx, and LPO activities	45
cardiac ischemia-reperfusion injury (IRI) in rats	fresh PE fruit homogenate	250−750 mg kg^{-1} per day for 30 days	PE administration improves myocardial adaptation by augmenting endogenous antioxidants and protects rat hearts from oxidative stress associated with IRI	46
rats fed a high-fat diet	flavonoids separated from PE fruit	10 mg kg^{-1} BW per day for 90 days	significant decreases in total cholesterol, triacylglycerol, phospholipids, and free fatty acid levels in serum and tissues were observed when compared with the control group	47
human umbilical vein endothelial cells, ECV-304, incubated with ox-LDL (50 mg/L), in vitro	tannins (corilagin/Dgg16) isolated from PE fruit	0.0001−0.1 mmol L^{-1}	corilagin and Dgg16 are effective in inhibiting the progress of atherosclerosis by alleviating oxidation injury and by inhibiting ox-LDL-induced VSMC proliferation	48
deoxycorticosterone acetate/1% NaCl high salt (DOCA/HS)-induced hypertension model rat	extract of PE	75−300 mg kg^{-1} BW per day for 5 weeks	extract of PE reduces oxidative stress, prevents development and progression of hypertension as well as cardiac and renal hypertrophy in DOCA/HS-induced hypertension via activation of endothelial nitric oxide synthase (eNOS) and endogenous antioxidants as well as regulation of serum NO and electrolyte levels	49

oxidized LDL-induced proliferation of vascular smooth muscle cell.[48]

Bhatia et al. investigated the antihypertensive effect of *P. emblica* fruit extract in a deoxycorticosterone acetate/1% NaCl high salt (DOCA/HS)-induced hypertension model in rat.[49] Hypertension was induced in rats by the DOCA/HS (20 mg kg^{-1}, sc) and, at the same time, these rats received cotreatment with different doses of an extract of *P. emblica* fruit with tannin content of 9.4% (75−300 mg kg^{-1} BW per day) for 5 weeks. The extract significantly decreased arterial blood pressure and heart rate as well as cardiac and renal hypertrophy in a dose-dependent fashion as compared to control rats treated with DOCA alone. Increased TBARS and decreased endogenous antioxidants activity in serum, heart, and kidney tissues of hypertensive rats were also normalized. These results demonstrate that the extract of *P. emblica* can prevent the development and progression of hypertension as well as cardiac and renal hypertrophy in DOCA/HS-induced hypertension via the activation of endothelial nitric oxide synthase (eNOS) and endogenous antioxidants as well as regulation of serum NO and electrolyte levels.[49]

Inflammation is involved in multiple aspects of the development of cardiovascular diseases.[50] Anti-inflammatory effects of PE fruits and extracts are among the mechanisms supporting vascular health.

Anticancer Activities. The anticancer effects of *P. emblica* fruit have been recently reviewed by Baliga and Dsouza.[9] They summarized that *P. emblica* fruit and its extracts can be used as (1) antineoplastic agents,[51,52] (2) radio-protective agents,[53,54] and (3) chemopreventive and chemomodulatory agents[55−59] to reduce the risk of cancers. The mechanism of the anticancer effects includes the following aspects: *P. emblica* fruit or its extracts (1) are scavengers of free radicals and decrease oxidation of lipids and other biomolecules; (2) can decrease the hepatic levels of phase I enzymes; (3) can increase the levels of glutathione *S*-transferase (GST), a phase II enzyme; (4) can decrease levels of ornithine decarboxylase; (5) can increase the levels of antioxidant enzymes; (6) have antimutagenic effects; (7) possess immunomodulatory effects; (8) can modulate the levels of proteins important in cell cycle progression; (9) can induce apoptosis of neoplastic cells; and (10) can prevent metastasis. Table 4 presents a list of studies related to the anticancer effects of *P. emblica* fruits and fruit extracts. Readers are referred to the paper recently published by Baliga and Dsouza for a thorough review on the topic.[9] A few points are worth noticing here. First, the inhibitory efficacy of *P. emblica* fruit extracts may differ between different cancer cell lines.[51] Second, the fruit extracts may work synergistically with some therapeutic cytotoxic agents (doxorubicin and cisplatin) inhibiting the growth of cancer cells.[51,52] Third, some short-term inhibitory effect has been recognized of aqueous extracts of *P. emblica* fruits on the growth of noncancer cells in vitro.[60]

Immune-Modulating and Anti-inflammatory Activities. Immune activation is an effective as well as protective approach against infectious diseases. Studies have shown that *P. emblica* fruits and fruit extracts have immune-modulating and anti-inflammatory activities (Table 5). A 90% ethanol extract of dry *P. emblica* fruits counter-acted the immune-suppressive effects of chromium(VI) compounds on lymphocytes[61] and macrophages[62] in vitro. The extract reduced the apoptosis and DNA fragmentation induced by chromium and relieved the suppressive effects of chromium on cell proliferation and production of IL-2 and γ-interferon (γ-IFN) of lymphocytes.[61]

Table 4. Cytotoxic Effects, Protective Effects against Clastogenicity, and Anticancer Activities of *P. emblica* (PE) Fruits and Fruit Extracts

subject and method of study	plant parts	dose	result	ref
human hepatocellular carcinoma (HepG2) and lung cancer cells (A549), in vitro	aqueous extract of PE fruit	4−48 μg mL^{-1} for A549/25−200 μg mL^{-1} for HepG2	PE extract demonstrated growth inhibitory activity, with a certain degree of selectivity between the two cancer cell lines tested; synergistic effects (CI < 1) between PE and doxorubicin as well as between PE and cisplatin were demonstrated on A549 and HepG2 cells at different dose levels	51
Vero cell line, in vitro; *Plasmodium falciparum* infected mice, in vivo	aqueous extract of PE	250 mg kg^{-1} BW per day (in vivo)	extract of PE exhibited interesting in vitro and in vivo antiplasmodial activity with good selectivity	52
Chinese hamster ovary (CHO) cell line	aqueous extract of PE fruit	50 μg mL^{-1}	aqueous extract of PE fruit caused 42% growth inhibition on CHO cells; aqueous extract of PE fruit did not significantly alter the colony-forming efficiency of CHO cells	60
chromosome aberrations (CA) on bone marrow cells induced by CsCl in mice	aqueous extract of PE fruit	685 mg kg^{-1} BW per day for 7 days	significantly reduced the frequency of CA on bone marrow cells induced by CsCl (125, 250, and 500 mg kg^{-1} BW) in Swiss albino mice	55
CA on bone marrow cells induced by nickel chloride in mice	aqueous extract of PE fruit	685 mg kg^{-1} BW per day for 7 days	significantly reduced the frequency of CA on bone marrow cells induced by nickel chloride in mice	56
CA on bone marrow cells induced by lead nitrate in mice	aqueous extract of PE fruit	685 mg kg^{-1} BW per day for 7 days	significantly reduced the frequency of CA on bone marrow cells induced by lead nitrate in mice	57
CA on bone marrow cells induced by aluminum sulfate in mice	aqueous extract of PE fruit	685 mg kg^{-1} BW per day for 7 days	significantly reduced the frequency of CA on bone marrow cells induced by aluminum sulfate in mice	58
mice exposed to 9 Gy of γ-radiation	aqueous extract of PE fruit	50−800 mg kg^{-1} BW per day for 7−30 days	the extract had radioprotective effects; the optimum dose was 100 mg kg^{-1} BW	54
mice exposed to 7 Gy of γ-radiation	fruit pulp of PE	2.5 g kg^{-1} BW for 10 days	administration of PE significantly increased the total leukocyte count, bone marrow viability, and level of hemoglobin; administration of PE significantly enhanced the activity of the various antioxidant enzymes and GST as well as glutathione system in the blood, and treatment with PE suppressed the elevation in lipid peroxides in the serum	53
hepatocarcinogenesis induced by NDEA in rats	aqueous extract of PE fruit	50−250 mg kg^{-1} BW per day for 20 weeks	extract of PE significantly inhibited hepatocarcinogenesis induced by NDEA in a dose-dependent manner	59

Table 5. Anti-inflammatory and Immunomodulating Activities of *P. emblica* (PE) Fruits and Fruit Extracts

subject and method	plant parts	dose	result	ref
L-arginine induced acute pancreatitis in rats	PE fruit extract	100 mg kg^{-1} BW per day for 3, 7, 14, and 28 days	PE treatment was found to be beneficial for treating acute pancreatitis	65
carrageenan and cotton pellet induced acute and chronic inflammatory in rat paw	free and bound phenolic compounds from PE fruit (70% ethanol extract)	20 and 40 mg kg^{-1} BW for 6 days	in both acute and chronic inflammation, both free and bound phenolics of PE reduced inflammation	66
lymphocytes, in vitro	90% ethanol extract of PE dry fruit	10 μg^{-1} mg mL^{-1}	PE extract also inhibited apoptosis and DNA fragmentation induced by Cr, relieved immunosuppressive effects of Cr on lymphocyte proliferation, and restored IL-2 and γ-IFN production considerably; the results showed the fruit extract of PE had cytoprotective and immunomodulatory properties	61
chromium(VI) induced oxidative injury in murine macrophages, in vitro	70% ethanol extract of PE dry fruit	250 μg mL^{-1}	the presence of the PE extract enhanced cell survival, decreased free radical production, and maintained antioxidant levels close to those of the control cells; furthermore, chromium(VI) treatment resulted in decreased phagocytosis and γ-IFN production, which were restored by the PE extract	62
mice bearing Dalton's lymphoma ascites (DLA) tumor	PE fruit powder	20 mg kg^{-1} BW per day	PE enhanced natural killer (NK) cell activity and antibody-dependent cellular cytotoxicity (ADCC) in syngeneic BALB/c mice bearing DLA tumors	63
adjuvant induced arthritic (AIA) rat model	crude extract of PE	6.25−100 mg kg^{-1} BW	PE extract can cause immunosuppression in AIA rats	64

Treatment with *P. emblica* fruit extract increased the survival of cells and restored the phagocytosis and production of cytokines of murine macrophages treated with chromium(VI).[62] The cytoprotective and immune-modulating properties of the *P. emblica* extract were related to protection from oxidative damages induced by chromium treatment by scavenging the free radicals and by maintaining the antioxidative status as well as the levels of antioxidants and antioxidative enzymes.[61,62] Intake of *P. emblica* fruit powder enhanced natural killer (NK) cell activity and antibody-dependent cellular cytotoxicity (ADCC) in syngeneic BALB/c mice bearing Dalton's lymphoma ascites (DLA) tumors.[63] Adjuvant-induced arthritis (AIA) has been widely used as a model for rheumatoid arthritis (RA) and reactive arthritis. Crude water extracts of *P. emblica* fruit suppressed the immune response in AIA model in rats.[64]

The anti-inflammatory activities of *P. emblica* fruits or fruit extracts have been studied in animal models.[65,66] Acute pancreatitis is a rapidly developing inflammatory disease of the pancreas. A *P. emblica* fruit extract (tannin content $\geq$ 30% weight) has been reported to be effective in the treatment of arginine-induced acute pancreatitis in rats.[65] The administration of the extract lowered the serum levels of lipase and interleukin-10 in the arginine-treated rats. The nucleic acid content and rate of DNA synthesis in pancreatic tissue, pancreatic proteins, and pancreatic amylase content were significantly improved.[65] Muthuraman et al. studied the anti-inflammatory effects of extracts of free and bound phenolic compounds from *P. emblica* fruits in carrageenan- and cotton pellet-induced models of acute and chronic inflammation in rats at dose levels of 20 and 40 mg extract kg^{-1} body weight.[66] In both acute and chronic inflammation, both the free and bound phenolics of *P. emblica* reduced inflammation; at high doses, the effects of both fractions were comparable to treatment with diclofenac.[66] In this study, free phenolic compounds were extracted with 70% aqueous ethanol, acidified, and further extracted with ethyl acetate. The extract of bound phenolic compounds was prepared by extraction of fruits with sodium hydroxide (1 M) containing sodium borohydride (0.5%), followed by acidification with hydrochloride acid to pH 1.5.[66]

Ethanolic extract from *P. emblica* fruit and pyrogallol isolated from the extract were equally effective in inhibiting *Pseudomonas aeruginosa*-induced expression of the pro-inflammatory genes in bronchial epithelial cells in vitro. These results suggest that pyrogallol is a major bioactive compound responsible for the anti-inflammatory effect of the extracts of *P. emblica* fruit.[67]

Antimicrobial and Antidiarrheal Activity. The antimicrobial and cytotoxic activities of *P. emblica* fruits and fruit extracts have been studied by several research groups.[68−70] The antibacterial activity of the fruit extracts against 345 bacterial isolates belonging to 6 different genera of Gram-negative bacteria isolated from urine specimens was evaluated by Saeed and Tariq.[69] Aqueous infusion and decoction of *P. emblica* fruits exhibited potent antibacterial activity against *Escherichia coli*, *Klebsiella pneumoniae*, *Klebsiella ozaenae*, *Proteus mirabilis*, *Pseudomonas aeruginosa*, *Salmonella typhi*, *Salmonella paratyphi* A, *Salmonella paratyphi* B, and *Serratia marcescens*.[69] Saini et al. studied the protective effect of *P. emblica* fruit against *Klebsiella pneumoniae*-induced pneumonia in mice. The effect of short- (15 days) and long-term (30 days) feeding of *P. emblica* fruit powder in mice over the course of *K. pneumoniae* ATCC43816 infection in the lungs was studied in terms of bacterial colonization, macrophage activity, malondialdehyde (MDA)

and nitrite production in the bronchoalveolar lavage fluid.[70] TNF-α level in serum was also assessed. The results in the long-term feeding experimental model suggested that supplementation with *P. emblica* fruits might reduce bacterial colonization in the lung.[70] In addition to tannins, alkaloids were suggested to be among the antimicrobial compounds of *P. emblica* fruits.[71]

The methanol extract of *P. emblica* fruit showed a significant inhibitory effect on diarrhea in Wistar albino rats induced by castor oil and magnesium sulfate.[70] Oral administration of the extract (50−150 mg kg^{-1} BW) produced a significant dose-related reduction in gastrointestinal motility in charcoal meal tests in rats. The treatment also significantly inhibited the production of prostaglandin E_2 (PGE_2)-induced enteropooling.[72] The potential of *P. emblica* for the treatment of diarrhea has been investigated in mice and in isolated rabbit jejunum and guinea pig ileum.[73] Oral administration of 70% ethanol crude extract of *P. emblica* fruits inhibited castor oil-induced diarrhea and intestinal fluid accumulation in mice at 500−700 mg kg^{-1} BW. The results of the in vitro studies indicate that the *P. emblica* fruit extract possesses antidiarrheal and spasmolytic activities, possibly through the blockade of muscarinic receptors and Ca^{2+} channels.[73]

Hepato- and Gastroprotective Activities. *P. emblica* fruit and its extract have been shown to have potential in protecting the liver[74−77] and the gastric mucosa[10,78,79] from injuries induced by chemical agents in experimental models. Moreover, fruit of *P. emblica* may reverse CCl_4- and TAA-induced fibrosis in the liver in rat.[80,81]

Supplementation of *P. emblica* fruits decreased nitrosodiethylamine (NDEA)-induced hepatic apoptosis and autophagy via down-regulation of the Bax/Bcl-2 ratio and Beclin-1 expression.[74] Administration of an aqueous extract (2 mg/animal/day) of *P. emblica* fruits for 45 days along with ochratoxin significantly ameliorated ochratoxin-induced reduction in the content of DNA, RNA, and protein in the livers and kidneys in mice.[75] Oral administration with an extract of fresh *P. emblica* fruits (obtained by extraction with 50% ethanol) at a single dose of 25, 50, or 75 mg kg^{-1}, 4 h before ethanol treatment, enhanced liver cell recovery from the damage by ethanol and suppressed the ethanol-induced elevation in the levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and IL-1β in rats.[76]

A hydroalcoholic (50%) extract of *P. emblica* fruit reversed fibrogenic events in the liver in rats[80] and showed a protective effect against antituberculosis (anti-TB) drug-induced liver toxicity in hepatocytes in vitro and in vivo.[77] In another study, *P. emblica* fruit reversed CCl_4- and TAA-induced prefibrogenic events in rat liver.[81]

Protective and healing properties of *P. emblica* fruit and its extracts against gastric ulceration have been studied mostly in animal models.[10,78,79]

Pretreatment with the butanol fraction of an aqueous extract of *P. emblica* fruit at a dose of 100 mg kg^{-1} BW per day, via oral administration to rats for 10 consecutive days, enhanced the secretion of gastric mucus and hexosamine ($p < 0.001$) in the context of indomethacin-induced ulceration in rats.[79] The morphological observation also suggested a protective effect of the extract on the stomach wall. Indomethacin treatment increased SOD and MDA levels in gastric tissue of rats but hardly affected the MDA or SOD levels in animals pretreated with the *P. emblica* fruit extract.[79] A methanolic extract of *P. emblica* fruits had significant gastroprotective and ulcer-healing effects, which might be due to its effects on both offensive and defensive mucosal factors.[78] A 95% ethanol extract of sun-dried *P. emblica* fruit (oral administration, 100 mg kg^{-1} per day) accelerated the healing process of indomethacin-induced ulcers in rats.[10] Biphasic activities were reported of an ethanolic extract of *P. emblica* fruits on gastric ulcers induced by nonsteroidal anti-inflammatory drug (NSAID) in mice, healing effects being observed at low dose but adverse effects at high dose.[82]

The hepato- and gastroprotective activities of *P. emblica* fruits and extracts are suggested to be related to the antioxidative and membrane-stabilizing activities.[77] Treatment with *P. emblica* fruit and extracts significantly preserved the expression of SOD and CAT and decreased the expression of inducible nitric oxide synthase (iNOS) and cytochrome P450 2E1 (CYP2E1) proteins in the liver of rats.[74,77] Antioxidant properties of *P. emblica* fruits and fruit extracts appeared to be among the primary factors responsible for the healing effects of the *P. emblica* extract on gastric ulcer.[78,79]

Analgesic and Antipyretic Activities and Effects on Nervous System and Skin. *P. emblica* fruits are traditionally used to treat disorders in the central nervous system (CNS).[83] Pretreatment with a hydroalcoholic extract of *P. emblica* fruits (500 and 700 mg kg^{-1} ip) increased the latency of seizures and reduced the cognitive deficits induced by kainic acid.[83] The extract suppressed the increase in TBARS and TNF-α levels and the decrease in reduced glutathione (GSH) level in the brain in kainic acid-treated rats, suggesting a possible role of antioxidant and anti-inflammatory activities in the neuroprotective effects of *P. emblica* fruit.[83] A memory-enhancing activity of orally adminstered *P. emblica* fruit was shown in mice.[84] The elevated plus maze and passive avoidance apparatus served as the exteroceptive behavioral models for testing memory. Diazepam-, scopolamine- and aging-induced amnesia served as the interoceptive behavioral models. *P. emblica* produced a dose-dependent improvement in memory scores in young and aged mice and reversed amnesia induced by scopolamine and diazepam and reduced cholinesterase activity in the brain.[84]

Some studies also suggest that *P. emblica* fruits possess antipyretic and analgesic activity, skin protective effects, and wound-healing effects.[83−88] A single oral dose of ethanol or aqueous extracts of *P. emblica* fruit (500 mg kg^{-1} BW, ip) led to a significant reduction in brewer's yeast-induced hyperthermia in rats.[85] Oral administration with the extracts also elicited inhibitory effects on the acetic acid-induced writhing response in mice, suggesting analgesic activity of the extracts.[85] *P. emblica* fruit effectively inhibited UVB-induced photoaging in human skin fibroblasts in vitro likely because of its strong ROS-scavenging ability.[86] Topical application of a 90% ethanol extract of dried fruit powder speded wound healing through the up-regulation of collagen expression and extracellular signal-regulated kinase (ERK1/2) signaling.[88]

Bioavailability of Hydrolyzable Tannins. The bioavailability of hydrolyzable tannins from various sources has been reviewed.[2,89] Most human studies have focused on pomegranate juice with punicalin and punicalagin being the major ellagitannins. Also, the ellagitannins of raspberries, strawberries, walnuts, and oak-aged wines have been studied. Dietary ellagitannins are hydrolyzed, releasing free ellagic acid, which is partly absorbed directly in the stomach and the proximal small intestine. After consumption of pomegranate juice by volunteers, the concentration of ellagic acid reached the maximum 33 ng/mL plasma 1 h after intake.[2] Ellagitanins

and free ellagic acid are metabolized to urolithins by the action of the microbiota in the distal part of the small intestine and the colon. After absorption, urolithins are converted to various derivatives of urolithin-3-*O*-glucuronide by the action of phase II enzymes.[89] The amount of urolithin A 3-*O*-glucuronide excreted in the urine corresponded to 3−17% of the intake of ellagitannins, depending on the sources.[89] Significant variations among individuals have been observed, mostly likely due to differences in the colonic microbiota. Some evidence obtained in Iberian pigs fed oak acorns suggested significant hepatic metabolism of urolithins and enterohepatic circulation of urolithin metabolites.[89] The tannins of emblic leafflower are a mixture of ellagitannins and gallotannins. The bioavailability and metabolism of tannins in emblic leafflower have not been reported. Further studies on these aspects would provide useful data for substantiating the physiological effects of these compounds in humans.

PERSPECTS FOR FUTURE RESEARCH

From a compositional point of view, the hydrolyzable tannins of emblic leafflower are a very complex mixture of over 100 compounds. Many compounds are either preliminarily identified or unidentified. Some contradictory identifications have been reported. Further research is necessary to provide a detailed characterization of the compounds in the tannin fraction of emblic leafflower. Most of the biological activities and physiological effects of the fruit and fruit extracts have been shown by in vitro studies or in animal models. The data from clinical and human intervention studies are extremely scanty. Ellagitannins and ellagic acid in food have been suggested to have low bioavailability due to the low absorption rate in the small intestine. Most of the dietary ellagitannins are metabolized to urolithins by the microbiota in the colon.[1] Urolithins are weaker antioxidants than ellagitannins. They are absorbed to the circulation and may accumulate in certain tissues as various derivatives with estrogenic or antiestrogenic activities. Therefore, it is also worth investigating the estrogenic and antiestrogenic effects of dietary supplementation of the tannin fraction of emblic leafflower in humans. Whereas many studies suggested that antioxidative activities are associated with most of the beneficial effects observed for the fruits and fruit extracts, the molecular biological mechanisms of the biological activities and physiological effects need further study. Extracts of emblic leafflower (*P. emblica*) fruits and hydrolyzable tannins isolated from some plant materials have been demonstrated to have effects on the expression of some genes related to various aspects of the biological activities. The approach of nutragenomic and metabolomic research shall be applied to investigate the effects of the fruits and extracts of *P. emblica* on the expression of genes and the metabolomes in humans of different genetic backgrounds and baseline metabolomic profiles. The current literature suggests strong antioxidative and antimicrobial activities of tannin-rich extracts of emblic leafflower fruits. Research shall be carried out to explore the potential of emblic leafflower fruit as a raw material for natural food preservatives.

ABSTRACT: Licorice is an herbal plant named for its unique sweet flavor. It is widely used in the food and tobacco industries as a sweetener. Licorice is also used in traditional Chinese medicine (TCM) and complementary medicine. Because the use of licorice has long been a part of TCM, the details of its therapeutic applications have been thoroughly established. In modern science, licorice is of interest because of its broad range of applications. Extracts of and compounds isolated from licorice have been well studied and biologically characterized. In this review, we discuss the nutraceutical and functional activities of licorice as well as those of the extracts of and the isolated compounds from licorice, including agents with anti-inflammatory activity, cell-protective abilities, and chemopreventive effects. The side effects of licorice are also enumerated. A comparison of the activities of licorice described by modern science and TCM is also presented, revealing the correspondence of certain characteristics.

KEYWORDS: *licorice, glycyrrhizic acid, 18β-glycyrrhetinic acid, biological function, safety*

INTRODUCTION

Licorice, also called liquorice, is the root or stem of *Glycyrrhiza glabra* (*G. glabra*), which has a sweet flavor. In China, licorice is called "gan cao". The ancient Greek physician Pedanius Dioscorides named licorice *γλυκύρριζα* (glukurrhiza), meaning "sweet root"; the first part of the word, "*γλυκύς*", (glukus) means "sweet", and the last part of the word "*ρίζα*" (rhiza) means "root" (Perseus digital library, http://www.perseus.tufts.edu/hopper/). Three plants are identified as licorice, *Glycyrrhiza glabra* (*G. glabra*), *Glycyrrhiza uralensis* Fisch. (*G. uralensis*), and *Glycyrrhiza inflata* Bat. (*G. inflata*).

Because of its sweet favor, licorice is used in a number of foods, most prominently condiments and confectionery. Condiments such as soy sauce and sweet chili sauce contain licorice powder to add a unique sweet flavor that might be referred to as mellow in English. Confectionery flavored with an extract of the roots of the licorice plant is also called licorice. Candies such as Red Vines and London drops are flavored with licorice. Tobacco manufacturers use a considerable amount of licorice in their products. Licorice block, powder, and extract can be used in tobacco for multiple purposes. According to Carmines et al.,[1] licorice is added to tobacco to enhance and harmonize the smoke flavor, reduce dryness in the mouth and throat, improve the moisture-holding characteristics of the tobacco to increase its stability and shelf life, act as a surface-active agent during the spraying process of the casing ingredients, improve the uniformity of the absorption of flavors, and minimize the rough smoke character by balancing the overall flavor profile of the tobacco smoke. Licorice is generally recognized as safe (GRAS, Report No. 28, Conclusion 2), which indicates that it does not represent a hazard to the public when used at typical levels and in a typical manner. Licorice is also a common and useful ingredient in cosmetics. In a clinical study, topical treatment with a gel containing 2% licorice extract led to a significant improvement in erythema, edema, and pruritus.[2] Licorice extracts are also used as skin depigmenting agents and are effective in the treatment of postinflammatory hyperpigmentation, including that caused by chemical peeling and laser therapy.[3] Licorice extract inhibits the rate-limiting first step of the oxidation of tyrosinase,[4] making it an effective treatment for melasma.[5] Furthermore, licorice extract is very useful in the treatment of aphthous ulcers;[6] even the deglycyrrhizinated form of licorice (DLG) has a similar positive effect.[7]

The application of licorice is not restricted to food, tobacco, and cosmetic use; this plant is also used in medicine. Licorice is considered to be an herbal remedy for many disorders. Nassiri et al.[8] characterized some of the traditional uses of licorice, including the treatment of wounds, diabetes, cough, and tuberculosis. In traditional Chinese medicine (TCM), licorice is one of the most frequently used herbs. Licorice is commonly used in herbal formulas to harmonize other ingredients and to carry the formula to the 12 regular meridians in TCM.[9] The compendium of Materia Medica (Bencao Gangmu) states that licorice can act as an effective antidote, a detoxicant, a beneficial agent in the development of bone and muscle, and a remedy for throat disorders and cough.[9] Licorice is also found in many TCM formulas for treating liver disease. Sho-saiko-to (TJ-9) is frequently used in Japan for liver disorders (e.g., chronic active hepatitis),[10] although this formula is from Xiao Chai Hu Tang (Minor Bupleurum Formula) in Shang Han Lun of TCM.[11]

Modern studies have demonstrated that the uses of licorice in TCM are viable. For example, Ma Huang Tang, a classic Chinese formula composed of Ephedra, Cassia twig, bitter apricot kernel, and prepared licorice, has recently been confirmed to be an effective remedy for pulmonary disorders such as colds, influenza, acute bronchitis, and bronchial asthma. The He group demonstrated that the direct effects of bitter apricot kernel

and prepared licorice on the integral potency of the formula are nonsignificant. However, these two drugs have a significant synergetic effect when administered with Ephedra or Cassia twigs.[12] That study provides evidence that licorice can harmonize with the other ingredients in the formula, even though it may not be a primary effective ingredient. A gargle containing licorice has been shown to be an effective method for attenuating both the incidence and severity of postoperative sore throat,[13] providing scientific evidence corroborating the TCM-described effect of licorice. Because some of the healing effects described in TCM have been confirmed by modern medicine, an important question arises: which compound(s) in licorice mediate these effects?

BIOACTIVE COMPOUNDS IN LICORICE AND THEIR BIOLOGICAL FUNCTIONS

Glycyrrhizic Acid and 18β-Glycyrrhetinic Acid. The sweetness of licorice is derived from glycyrrhizic acid, also called glycyrrhizin (Figure 1A). Glycyrrhizic acid is a triterpenoid saponin glycoside and is 30−50 times as sweet as sucrose because glycyrrhizic acid can induce impulses from sugar receptor-containing cells at a concentration (3.0 mM) that is much lower than that of sucrose.[14] Furthermore, unlike the sugar substitute aspartame, glycyrrhizin maintains its sweetness after heating. Both sugar and glycyrrhizic acid taste sweet, but glycyrrhizic acid induces a lower onset sweet flavor than sugar, and its sweetness remains in the mouth for a longer period of time. Glycyrrhetinic acid (18α-glycyrrhetinic acid and 18β-glycyrrhetinic acid) is another triterpenoid in licorice (Figure 1A). Glycyrrhetinic acid can be obtained from the hydrolysis of glycyrrhizic acid. This process can be completed by presystemic metabolism by intestinal bacteria that perform glycolysis.[15] Human intestinal bacteria metabolize glycyrrhizic acid through the action of the glucuronidases of *Bacteroides* J-37 and *Eubacterium* sp. to yield 18β-glycyrrhetinic acid (18βGA).[16] Processing (Chinese Materia Medica) licorice by dry-roasting or honey-roasting[18] to obtain licorice preparata accelerates the hydrolysis of the sugar chains in the saponin and glycosidic flavonoid constituents.[17] Raw licorice and licorice preparata are both important agents in TCM, and each has a different function. Recent studies indicate that the anti-inflammatory activities[19] and neuroprotective effects[20] of roasted licorice may be more potent than those of raw licorice, in contrast to the characteristics described by TCM. Bencao Gangmu suggests that raw licorice can be used to treat the syndrome known as inflammation in modern medicine (Xie Huo in Chinese), and roasted licorice can be used for reinforcement (Bu Zhong in Chinese).[9] For example, roasted licorice is used in Buzhong Yiqi Tang instead of raw licorice, which suggests that glycyrrhizic acid and 18β-glycyrrhetinic acid may have distinct biological properties.

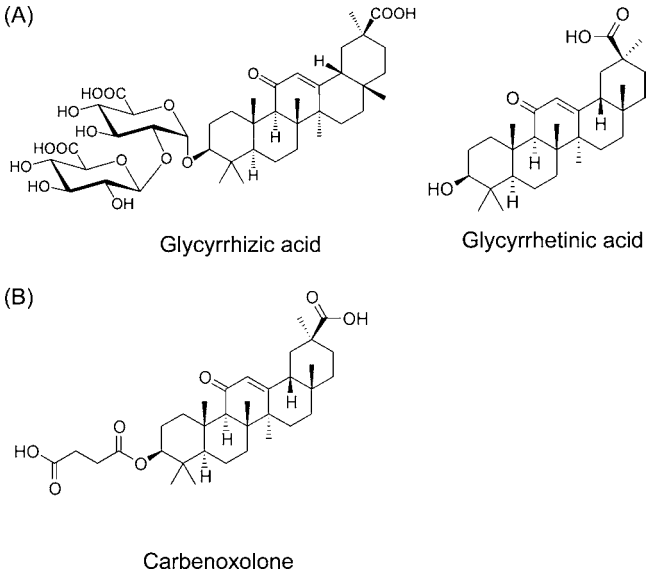

Figure 1. Chemical structures of glycyrrhizic acid and glycyrrhetinic acid (A) and the derivative of glycyrrhetinic acid; carbenoxolone (B) in licorice.

Because licorice has been used alone and as a component in many formulas to treat liver diseases, multiple mechanisms have been proposed for the hepatoprotective effects of glycyrrhizic acid and 18β-glycyrrhetinic acid. Both glycyrrhizic acid and 18β-glycyrrhetinic acid can protect rat hepatocytes from bile acid-induced cytotoxicity.[21] Recently, a beneficial effect of glycyrrhizic acid on hepatitis was demonstrated; the intravenous administration of glycyrrhizic acid decreases serum alanine transaminase (ALT) and necro-inflammation and fibrosis in the liver.[22] Many mechanisms are involved in the protective effects of glycyrrhizic acid and 18β-glycyrrhetinic acid. These mechanisms likely involve reduced AST (aspartate transaminase, also called GOT) and ALT (also called GPT) activities. The pregnane X receptor (PXR), as well as the cytochrome P450 family 3 subfamily A (CYP3A), can also be modulated by glycyrrhizic acid to protect against lithocholic acid-induced injury.[23] Both glycyrrhizic acid and 18β-glycyrrhetinic acid treatments can inhibit liver fibrosis,[24] which may lead to cancer.

In addition to liver protection, glycyrrhizic acid and 18β-glycyrrhetinic acid may be effective in the protection of other organs. Both glycyrrhizic acid and 18β-glycyrrhetinic acid have positive effects on brain damage induced by ischemia and 6-hydroxydopamine.[25] A recently study demonstrated that glycyrrhizic acid and 18β-glycyrrhetinic acid can penetrate the blood-brain barrier (BBB).[26] These findings indicate that glycyrrhizic acid and 18β-glycyrrhetinic acid are potent agents for the treatment of neural diseases, ischemic brain diseases, and Parkinson's disease. Glycyrrhizic acid also exhibits protective effects in the kidney; studies have demonstrated that glycyrrhizic acid protects against cisplatin-induced genotoxicity and nephrotoxicity.[27] Protective effects have also been observed with a renal hypoxia-reoxygenation model. However, 18β-glycyrrhetinic acid does not exhibit the same potential.[28] Glycyrrhizic acid seems to be effective against ischemic damage, including damage to the spinal cord,[28] myocardium,[29] liver,[30] and gut.[31]

Glycyrrhizic acid and 18β-glycyrrhetinic acid are considered inhibitors of inflammation induced by both bacterial and viral infection. Because inflammation is frequently triggered by bacteria or viral infection, antibacterial and antiviral activities are possible anti-inflammatory strategies. Glycyrrhizic acid can inhibit the replication of and infection by various viruses,[32] including severe acute respiratory syndrome (SARS)-associated coronavirus,[33] human immunodeficiency virus (HIV),[34] hepatitis A virus (HAV),[35] hepatitis B virus (HBV),[36] hepatitis C virus (HCV),[37] herpesviridae (varicella zoster virus, VZV),[38] herpes simplex virus 1 (HSV-1),[39] Epstein−Barr virus (EBV),[40] cytomegalovirus (CMV),[41] and influenza viruses, including H1N1[42] and H5N1.[43] Studies also indicate that glycyrrhizic acid inhibits the growth of *Helicobacter pylori*, and thus, this agent can be used in the treatment of gastric ulcers.[44] 18βGA has also been shown to be effective against clarithromycin-resistant

dx.doi.org/10.1021/jf404939f | J. Agric. Food Chem. 2014, 62, 542−553

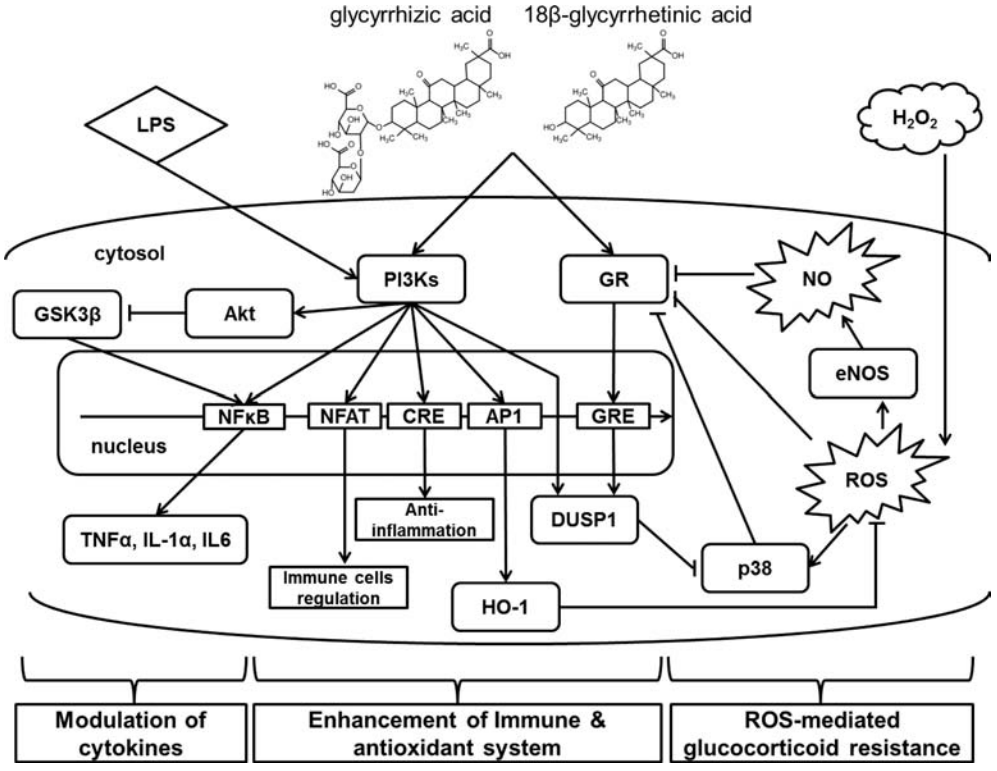

Figure 2. The proposed anti-inflammatory mechanism of glycyrrhizic acid and 18β-glycyrrhetinic acid. Glycyrrhizic acid and 18β-glycyrrhetinic acid can modulate PI3K signaling to upregulate the antioxidant system, leading to reduced intracellular ROS. Therefore, PI3K signaling also enhances GR signaling and modulates cytokines.[47,50]

strains of *H. pylori*.[45] Further studies have revealed that glycyrrhizic acid and 18β-glycyrrhetinic acid can modulate inflammation-related mechanisms. TCM often incorporates licorice to enhance the effect of other formulas that act as anti-inflammatory agents. Glycyrrhizic acid enhances the anti-inflammatory effect of licorice extract without glycyrrhizic acid.[46] Michaelis et al.[43] also demonstrated that glycyrrhizic acid can inhibit H5N1-induced pro-inflammatory gene expression without affecting the cytolytic activity of natural killer cells. These results indicate that glycyrrhizic acid might modulate inflammation by two methods of regulation, the inhibition of proinflammatory cytokines and the promotion of immune function. PI3K may play a role in this regulation. Glucocorticoids and the glucocorticoid receptor modulate inflammation very effectively, and glucocorticoids (e.g., dexamethasone) are used extensively in clinical treatment. There are several potential mechanisms for the involvement of glycyrrhizic acid and 18β-glycyrrhetinic acid in the induction of cortisone activity. Glycyrrhizic acid and 18β-glycyrrhetinic acid can activate glucocorticoid receptor (GR) signaling by binding to the GR[47] and inhibiting the activity of corticosteroid 11β-dehydrogenase isozyme 2 (11β-HSD2), which converts active cortisol into inactive cortisone.[48,49] Glycyrrhizic acid and 18β-glycyrrhetinic acid may also enhance GR signaling by eliminating intracellular oxidative stress.[50] Although glycyrrhizic acid can enhance glucocorticoid activity, it does not seem to increase glucocorticoid-induced side effects. For example, excessive glucocorticoid levels exert diverse effects on bone microstructure, integrity, and mineral metabolism.[51] Ramli et al.[52] demonstrated that glycyrrhizic acid has the potential to be used as an agent to protect bone against glucocorticoid-induced osteoporosis. High-mobility group box 1 (HMGB1), a nuclear component that functions extracellularly as a signaling molecule in acute and chronic inflammation, is inhibited by binding to glycyrrhizic acid.[53] Glycyrrhizic acid and 18β-glycyrrhetinic acid can modulate PI3K signaling to alleviate inflammation (Figure 2).[50] Altogether, these results suggest that glycyrrhizic acid and 18β-glycyrrhetinic acid have considerable potential for development as novel inflammation-modulating agents.

Glycyrrhizic acid and 18β-glycyrrhetinic acid also affect the biological mechanism of cancer formation. Glycyrrhizic acid may inhibit angiogenesis by targeting ERK signaling.[54] Glycyrrhizic acid also protects against UVB-induced carcinogenesis in the epidermis of SKH-1 hairless mice.[55] Because GA is effective against HCV-induced liver disorders, it also prevents hepatocarcinogenesis associated with hepatitis.[56,57] Glycyrrhetinic acid has a more potent anticarcinogenesis effect than glycyrrhizic acid. 18β-Glycyrrhetinic acid not only induces apoptotic cell death but also exhibits a synergistic toxic effect with antibiotics and anticancer drugs (e.g., camptothecin, mitomycin c, and doxorubicin).[58] Glycyrrhetinic acid, oleanolic acid, and ursolic acid have similar chemical structures and potent antiulcer activities.[59] Compounds whose chemical structures are similar to that of glycyrrhetinic acid also provide a satisfactory anticarcinogenesis outcome.[60] Many cancer cells are sensitive to treatment with glycyrrhetinic acid and its derivatives, including the human epithelial ovarian carcinoma cell lines OVCAR-3 and SK-OV-3,[61,62] the human prostate cancer cell lines DU145[63,64] and PC3, the human breast cancer cell line MCF7,[65,66] the human bladder cancer cell line NTUB1,[67] the human leukemia cell line HL60,[68] the human erythromyeloblastoid leukemia cell line K562,[69] the human colon cancer cell lines RKO and SW480,[70] the pancreatic cancer cell lines Panc1 and Panc28,[71] and many other cell lines. 18β-Glycyrrhetinic acid is more toxic than glycyrrhizic acid;

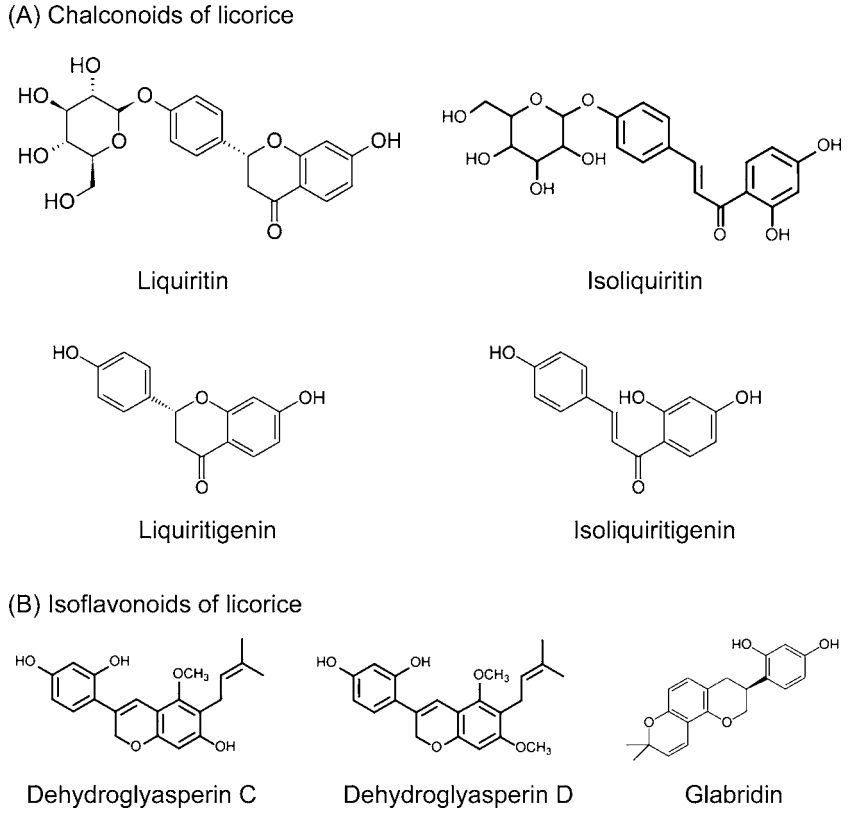

Figure 3. Chemical structures of the chalconoids (A) and the isoflavonoids (B) in licorice.

glycyrrhizic acid displays no obvious cell toxicity, even at 200 μM.[25,47,50]

Glycyrrhizic acid and glycyrrhetinic acid can bind to DNA[72] and RNA.[73] This behavior implies that glycyrrhizic acid and glycyrrhetinic acid may directly interfere with the pattern of transcription factors, the targeting of gene expression, and the interactions of DNA and RNA. This issue might be a promising research topic for understanding the biological functions of glycyrrhizic acid and glycyrrhetinic acid. On the basis of the above evidence, glycyrrhizic acid and 18β-glycyrrhetinic acid have distinct biological functions, which may be due to the differences in their chemical structures.

Liquiritin, Isoliquiritin, Liquiritigenin, and Isoliquiritigenin. Liquiritigenin and isoliquiritigenin are chalconoids of licorice; liquiritin and isoliquiritin are the glycone forms of liquiritigenin and isoliquiritigenin, respectively (Figure 3A). Although studies of the antioxidant abilities of liquiritin, isoliquiritin, liquiritigenin, and isoliquiritigenin are limited, these compounds are considered to be potent protective agents against cancer. These four compounds may have a potent antispasmodic effect.[74] Mai Men Dong Tang is a widely used licorice-containing TCM formula that is used to achieve tussive relief. Researchers believe that these four compounds play an important role in licorice's healing effects.[75] Because the chemical structures of these compounds are similar, the simultaneous study of all four compounds may facilitate the elucidation of the relationship between their biological effects and structure.

The biological functions of liquiritin are similar to those of glycyrrhizic acid. Liquiritin promotes neurite outgrowth in PC12 cells with nerve growth factor treatment,[76] suggesting its potential as a remedy for neurodegenerative diseases such as Alzheimer's disease or Parkinson's disease. Furthermore, liquiritin may exhibit an antidepressant-like effect in chronic variable stress-induced depression model rats by modulating oxidative stress.[77] Liquiritin also attenuates the induction of the RAGE/NFκB pathway in human umbilical vein endothelial cells (HUVECs) by advanced glycation end products (AGE), which may benefit patients with diabetes mellitus.[78] Liquiritin and glycyrrhizic acid can also stimulate immune responses,[79] enhance antioxidant enzymes such as superoxide dismutases (SOD), catalase, and glutathione peroxidase in mice focal cerebrum,[80] and might act as protective agents against epithelial injury in chronic obstructive pulmonary disease (COPD).[81] As with glycyrrhizic acid, liquiritin may bind to DNA.[82] Liquiritin may directly affect gene expression or other DNA-related mechanisms. Both liquiritin and glycyrrhizic acid are glycones or glycosides, functional groups that may be important for DNA binding, although this characterization has yet to be confirmed.

There are few studies of isoliquiritin listed in the PubMed database, and most are concerned with its isolation and identification. Isoliquiritin is thought to prevent angiogenesis and tube formation in granulomas[83] and may also have a potent antitussive effect.[84] Another possible application of isoliquiritin is skin depigmentation due to tyrosinase inhibition.[85] Research on isoliquiritin may be limited because of its lack of commercial availability.

Liquiritigenin is a well-known selective estrogen receptor β agonist[86] that has been implicated in the weight-reducing effects of licorice oil.[87] Liquiritigenin may facilitate the recovery of learning and memory deficits induced by amyloid beta Aβ(25−35)[88] and also help to enhance osteoblast function.[89] Both liquiritigenin and isoliquiritigenin are able to inhibit xanthine oxidase,[90] a promoting factor in many disorders. The IC_{50} values of these compounds are similar, 49.3 μM for liquiritigenin and 55.8 μM for isoliquiritigenin. Both liquiritigenin and isoliquir-

dx.doi.org/10.1021/jf404939f | J. Agric. Food Chem. 2014, 62, 542−553

itigenin display potential PPARγ activating activity,[91] suggesting their potential for use in recovery from metabolic syndrome. Isoliquiritigenin is also an inhibitor of aldose reductase, which suggests that it might be effective in treating diabetic complications.[92] In addition, both liquiritigenin and isoliquiritigenin are effective anti-inflammatory agents. Liquiritigenin inhibits iNOS and proinflammatory cytokines by blocking NFκB,[93] while isoliquiritigenin can influence the intercellular adhesion molecule-1 (ICAM-1) and the vascular cell adhesion molecule-1 (VCAM-1) to modulate inflammation.[94] In many cells and organs, liquiritigenin has a protective role against a number of injuries, including acetaminophen-induced rat liver damage,[95] cadmium-induced rat hepatoma Reuber H35 cell (H4IIE) damage,[96] D-galactosamine/lipopolysaccharide- or CCl_4-mediated rat hepatitis,[97] Aβ(25−35)-induced injury of rat hippocampal neurons,[98] and infection by *Candida albicans*.[99] Isoliquiritigenin also protects many cells and organs by inhibiting cisplatin-induced rat anorexia,[100] the hyperaggregability of platelets induced by diabetes,[101] and the accumulation of cyclic AMP in rat ventricular heart muscle[102] and by potently promoting neuronal health by inhibiting monoamine oxidase A and B,[103] among other mechanisms. In the liver, liquiritigenin can enhance bile secretion via a choleretic effect and can enhance the activity of transporters and phase II enzymes in the liver.[104] This effect is thought to be related to the antidote ability of licorice. In addition to increasing bile secretion, liquiritigenin might increase the rate of hepatic blood flow.[105] Liquiritigenin may also exhibit chemopreventive activity in liver cancer[106,107] and lung cancer.[108] The mechanisms by which liquiritigenin modulates chemoprevention might involve apoptotic molecular targets, such as cytochrome c, caspases,[109] matrix metalloproteinases (MMPs), PI3K, Akt,[110] and vascularization.[111] Notably, C8-prenylation of a flavonoid such as liquiritigenin may enhance the induction of H4IIE and C6 glioma cell apoptosis without affecting its antioxidative properties.[112] Isoliquiritigenin has been reported to inhibit lipoxygenase and prostaglandin E2 (PEG2),[113] induce cell cycle arrest in the human prostate cancer cell lines DU145 and LNCaP cells,[114] induce cell death in the human breast cancer cell line MCF7 at high concentration,[115] suppress pulmonary metastasis of mouse renal cell carcinoma,[116] inhibit human lung cancer cell growth,[117] inhibit colon cancer in ddY mice,[118,119] induce apoptosis in human MGC803 gastric cancer cells,[120] and activate the apoptosis in hepatoma cells[121,122] among other effects in cancer cell. Thus, liquiritigenin is a potent protectant in cells and organs, whereas isoliquiritigenin exhibits greater potential in cancer chemoprevention.

Liquiritigenin and isoliquiritigenin have also been applied in the treatment of cocaine addiction. Although the results are preliminary, liquiritigenin improved the selective molecular and behavioral disorders associated with cocaine use,[123] and isoliquiritigenin inhibited the dopamine release induced by cocaine.[124] This research has high practical value and is worth further study.

Dehydroglyasperin C and Dehydroglyasperin D. Dehydroglyasperin is an isoflavonoid isolated from licorice that has two isoforms, dehydroglyasperin C (DGC) and dehydroglyasperin D (DGD) (Figure 3B).[125] DGC and DGD are also classified as phenylflavonoids[126] and are strong antioxidants, although the potency of DGC is greater. Another phenylflavonoid, isoangustone A, was identified by Lee et al.[125] The antioxidant activity of isoangustone A is lower than that of DGD.[126]

DGC and DGD are potent ligands of peroxisome proliferator-activated receptor γ (PPARγ), which is thought to play a role in metabolic syndrome. Treatment with an ethanolic extract of licorice containing DGC and DGD prevents and ameliorates metabolic syndrome in diabetic KK-A^y and obese C57BL mice.[127] DGC is not only a ligand of PPARγ but also an activating factor of Nrf2 and detoxifying enzymes.[128] PI3K/Akt and Nrf2-Keap1 are also modulated by DGC to protect against glutamate-induced neuronal cell damage.[129] While DGC and DGD exhibit various potent activities, they are relatively newly isolated compounds in licorice, and further study of their biology and toxicity is needed.

Glabridin. Glabridin (Figure 3B) is a licorice isoflavonoid with antimicrobial[130] and antioxidant properties.[131] Because of its well-described antioxidant capabilities, glabridin is frequently used in studies of oxidative stress, including LDL oxidation.[132] The structure of glabridin is similar to that of estradiol-17β, and studies have shown that glabridin might modulate bone disorders in postmenopausal women[133] and increases in osteoblastic cell function.[134] Although glabridin is a potent antioxidant, brain penetration of glabridin through the BBB is altered by P-glycoprotein, which might limit the application of glabridin in central nervous system (CNS) diseases.[135]

The main application of glabridin might be cosmetics. The antioxidant ability of glabridin might help modulate anti-inflammatory mechanisms in skin tissue. Although clinical studies are lacking, some commercial formulations contain licorice extract and claim that glabridin is useful for skin depigmentation.[136] Glabridin and its derivatives[137] inhibit tyrosinase, and there have been reports of a reduction in UVB-induced pigmentation and erythema in brownish guinea pigs when glabridin was administered for three weeks after UVB irradiation.[138] As part of its potent anti-inflammatory activity, glabridin can inhibit inducible nitric oxide synthase (iNOS) expression[139] and upregulate manganese SOD, catalase, and paraoxonase 2 expression.[140]

Increasing evidence indicates that glabridin may be beneficial in the treatment of diabetes mellitus and related diseases. Licorice flavonoid oil (LFO, also called Kaneka glavonoid rich oil) contains glabridin as the bioactive flavonoid and suppresses abdominal fat accumulation and blood glucose levels in KK-A^y mice.[141] LFO can activate AMP-activated protein kinase (AMPK) and ameliorate the increases in fatty liver and in the triglyceride and cholesterol plasma levels induced by obesity.[142] LFO administered daily up to 1200 mg/day is considering safe in humans.[143] On the basis of this finding, LFO might be safe as a functional food. Glabridin also works as a cancer preventive agent. It blocks FAK/rho signaling in human nonsmall cell lung cancer A549 cells and inhibits the migration, invasion, and angiogenesis of A549 cells.[144] On the basis of these studies, uses of glabridin beyond cosmetics should be explored.

Carbenoxolone. Sodium carbenoxolone (also called carbenoxolone or CBX) is the 3-hemisuccinate of glycyrrhetinic acid and may be the best-known derivative of glycyrrhetinic acid (Figure 1B). As the disodium salt of the 3-*o*-hydrogen succinate, carbenoxolone is freely soluble in water.[145] The chemical structure of carbenoxolone is similar to that of glucocorticoids, and CBX can be used as an anti-inflammatory agent and an inhibitor of 11β-hydroxysteroid dehydrogenase type 1.[146] Sterol regulation is a very important characteristic of carbenoxolone, which is related to its effectiveness in the prevention of fatty liver.[147] Because of the regulatory ability of glucocorticoids, carbenoxolone might have a nootropic effect by improving verbal

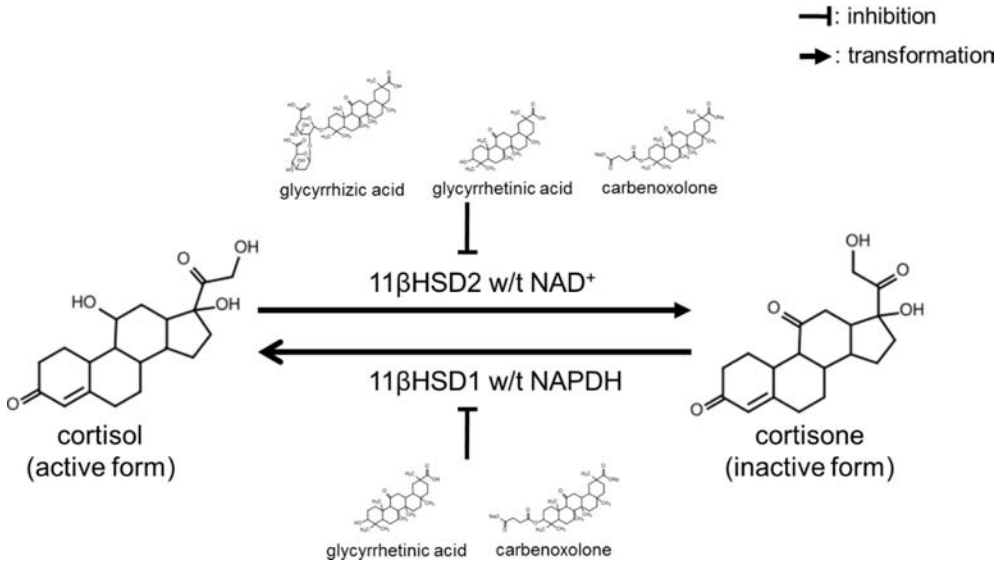

Figure 4. 11β-Hydroxysteroid dehydrogenase inhibition caused by glycyrrhizic acid, glycyrrhetinic acid, and carbenoxolone. There are two isoforms in humans, 11βHSD1 and 11βHSD2. 11βHSD2 converts biologically active cortisol into inactive cortisone, whereas 11βHSD1 converts inactive cortisone into active cortisol. Studies have shown that both glycyrrhizic acid and glycyrrhetinic acid can inhibit 11βHSD2, as can carbenoxolone. For 11βHSD1 inhibition, glycyrrhetinic acid and its derivative, carbenoxolone, may have greater potency than glycyrrhizic acid.

fluency and verbal memory in humans.[148] In TCM, Bencao Gangmu has been quoted as stating that licorice consumption may enhance memory. The best-known modern application of carbenoxolone is gastric ulcer treatment, which is based on the spironolactone,[149] and has good outcome in aphthous ulcers.[150]

Carbenoxolone is also a well-known gap junction inhibitor and is widely used in neuroscience research.[151] Gap junctions are also important in glutamate-induced neurotoxicity, and carbenoxolone can decrease the toxic effects of glutamate.[152] Carbenoxolone also protects against ischemic injury in skeletal muscle and the hippocampus resulting from gap junction inhibition.[153] Gap junctions are also related to pain control because the spinal cord glia exhibit extensive gap junctional connectivity, which is involved in the contralateral spread of excitation that results in mirror image pain.[154] Because carbenoxolone is an inhibitor of gap junctions, its application in pain relief is not unreasonable. Connexin gap junction proteins (Cx43 and Cx26) initiate brain metastatic lesion formation in association with the vasculature. Carbenoxolone can prevent tumor cell extravasation and blood vessel involvement.[155] Carbenoxolone is frequently used in cancer research to probe the relationship between gap junctions and cancer formation, such as in the study of the relationship between gap function and breast cancer metastasis or melanoma brain colonization.[155] Carbenoxolone is a useful agent for many research fields and is widely applied in clinical treatments.

SAFETY OF LICORICE

Although licorice is considered to be a nontoxic herb in TCM, some health concerns may be associated with the use of licorice. Clinical studies show that licorice may cause edema and apparent mineralocorticoid excess syndrome because glycyrrhizic acid and glycyrrhetinic acid can inhibit the activity of 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2),[48,49] which converts biologically active cortisol into the inactive compound cortisone, thereby preventing the overstimulation of the mineralocorticoid receptor by cortisol.[156] Mineralocorticoid overdose can lead to excessive sodium ion levels and the excretion of potassium ions, which may cause water retention and lead to hypertension. Excessive daily supplementation with licorice may cause low potassium levels due to licorice-induced hyperaldosteronism and may lead to hypertension and heart disease.[157] Licorice-induced hypertension can be reversed by stopping the intake of licorice-based products.[157] 11β-Hydroxysteroid dehydrogenase type 2 is inhibited by licorice, and licorice constituents can cause hypertonia and hypokalemia because of the associated change in potassium levels in the blood. Similar concerns are associated with the intake of carbenoxolone because it is a more potent inhibitor of 11βHSD2 (IC_{50}: 20−50 nM) than 11βHSD1 (IC_{50}: 1.8 μM)[49] (Figure 4). Potassium levels are also affected by digoxin,[158] which might act synergically with licorice intake. Some products use deglycyrrhizinated licorice (DGL) instead of raw licorice extract, which may reduce glycyrrhizic acid and glycyrrhetinic acid-induced side effects.

Excessive licorice intake may also influence the effects of other medicines. Glabridin may inhibit human cytochrome P450,[159] an important enzyme in drug metabolism and bioactivation.[160] Cytochrome P450 metabolizes warfarin (coumadin), an anticoagulant agent, into its inactive form,[161] and thus, licorice may increase warfarin clearance.[162] If treatment with warfarin is required, consulting a physician is strongly advised before consuming foods containing licorice.

Pregnant women should consider limiting their intake of licorice. Little research has examined the teratogenicity of licorice, but a single study has indicated that licorice may aggravate cyclophosphamide-induced body weight loss and malformations of fetuses by upregulating cytochrome P450 type 2B.[163] However, a study conducted in Korea indicated that women taking licorice for cough and cold control did not have an increased risk of stillbirths.[164] Licorice also increases estrogen levels in humans[165] and may increase the risk of estrogen-mediated cancer.[166] Licorice can potentially cause an antiandrogenic effect,[167,168] which may lead to erectile dysfunction. To avoid these side effects, careful intake of licorice-related food is highly advised.

antispasmodic	rat	muscle contraction ↓	74
antitussive	guinea pig	cough ↓	75
antidiabetes	rat	aldose reductase activity ↓	92
antianorexia	rat	5-HT2B antagonist	100
antiplatelet	platelet	cyclooxygenase activity ↓, lipoxygenase activity ↓, peroxidase activity ↓, acts as aldose reductase inhibitor	101
cardiotonic	rat	cyclic AMP ↑	102
antidepression	rat, mice	monoamine oxidase A and B ↓	103
anticarcinogenesis	mice	PGE2 ↓, platelet 12-lipoxygenase and 5-lipoxygenase ↓, immune ↑, direct cytotoxicity, iNOS ↓, preneoplastic aberrant crypt foci ↓, aberrant crypt focus formation ↓	113, 116, 118, 119
anticocaine addiction	rat	extracellular dopamine level ↓, GABA(B) receptor modulation	124
		Dehydroglyasperin C/Dehydroglyasperin D	
antidiabetes	mice	PPARγ ligand, spontaneously hypertension ↓	127
		Glabridin	
antiosteoporosis	rat	structure similar to estradiol-17β	133
antidiabetes	mice	body weight (gain) ↓, abdominal adipose tissues ↓, blood glucose level ↓, PPARγ ↑	141
antiobesity	rat	AMPK ↑	142
depigmentation	guinea pig	T1 and T3 tyrosinases ↓, ROS ↓, COX ↓	138
anti-inflammation	mice	NFκB ↓, ROS ↓	139

CONCLUSION

Licorice is extensively used in the TCM and appears as a component herb in about 60% of all TCM prescriptions. Numerous *in vitro* and *in vivo* studies have suggested healthful properties of licorice and its bioactive constituents such as glycyrrhizic acid, 18β-glycyrrhetinic acid, carbenoxolone, dehydroglyasperin C, and dehydroglyasperin D as well as some unique compounds such as glabridin, licoricidin, licorisoflavan A, and licochalcone A have potential beneficial effects in human diseases. These effects have been associated with the anti-inflammatory, antioxidative, antimicrobial, antivirus, and antidote properties of the compounds as summarized in Table 1.

dx.doi.org/10.1021/jf404939f | J. Agric. Food Chem. 2014, 62, 542−553

Although licorice intake may have some side effects in humans, all of these side effects should be reversible. With proper control of licorice intake, its health benefits outweigh its side effects. It is highly recommended that before beginning the regular intake of any food or medicine containing licorice and its related compounds, one should consult a traditional Chinese physician. In our opinion, licorice and the compounds isolated from this plant can be used as a complement to aid current medicines to reduce/eliminate side effects and improve the healing efficacy and outcome.

Does "Best Before" Date Embody Extra-Virgin Olive Oil Freshness?

ABSTRACT: Virgin olive oil (VOO) decays in quality properties during aging, so aged VOOs may have detectable undesirable sensory descriptors in comparison with oils recently extracted. For that reason, freshness has become a parameter of paramount importance to maintain the highest standard levels within the period indicated in the "best before" date. However, it is important to note that freshness of VOOs is not necessarily related to its sensory quality. Pigments have been suggested for tracing aging of VOO, and pyropheophytin *a* (PPP) seems to be the most promising molecule for this task. A predictive model has been used to estimate %PPP in VOO stored at different worldwide locations characterized with different temperatures. The recorded average temperatures, on a monthly basis, were inputs of the predictive model. The results show the influence of temperature in %PPP and how this molecule could serve as a better monitor of the storage period of VOOs. The initial value of %PPP in the oil could help to carry out the storage traceability. This information would be of interest for producers, sellers, and inspection agencies.

KEYWORDS: *virgin olive oil, freshness, pyropheophytin, storage*

Virgin olive oil (VOO), unlike red wines, decays in quality properties during aging due to oxidative processes, which decisively influences the consumer's preferences. Thus, an aged VOO may have detectable undesirable sensory descriptors in comparison with an olive oil recently extracted as long as both oils are produced from healthy and sound olives harvested at their optimum ripeness. These undesirable descriptors are mostly rancid notes, which are the result of a long and/or inadequate storage. However, sometimes VOOs are not produced entirely from healthy olives, but the batch of olives contains damaged olives that would be responsible for undesirable descriptors as those resulting from alcoholic and butyric fermentations of the olives. In this latter case, VOO may be characterized with sensory defects (e.g., fusty, musty, winey-vinegary) even if the oil is recently extracted.[1] As a consequence, sometimes aged oils from healthy olives may be of better quality than fresh oils obtained from damaged olives. This hypothetical comparison of oils illustrates how the relationship between freshness and quality is misleading because they are independent concepts. Thereby, freshness and sensory quality should not be mixed up as is commonly done by retailers and consumers. In fact, several compounds change in their concentration during VOO shelf life, but not all necessarily imply decay in aroma or taste properties.

It is unquestionable that freshness has become a parameter of paramount importance to maintain the highest standard levels, although freshness is not necessarily related to VOO sensory quality. Therefore, there is high interest in measuring freshness by chemical and objective methods to establish an appropriate "best before" date.

The methodologies to assess the freshness of oils should be separated from those evaluating sensory quality, for example, the sensory assessment or the profiles of volatile and phenolic compounds. Thus, the concept of freshness, which is intuitively associated with the time since olive oil processing, should be measured with chemical compounds that do not mislead to VOO underestimations or overestimations.[2]

Pigments have been suggested for tracing aging of VOOs[3] because their degradation process (e.g., pheophytinization of chlorophylls[4]) starts at the malaxation process of crushed olives and increases during olive oil storage.[5] Thus, pyropheophytin *a* (PPP) is formed from pheophytin *a* due to the loss of the carbomethoxy group in the C13 of the isocyclic ring of the chlorophyll structure.[5] The former compound, which is not quantified in VOOs produced under good manufacturing practices, has been revealed as a useful parameter for monitoring VOO degradation[4] as a consequence of inadequate temperatures during the storage of VOOs. This finding has awakened an interest in studying its kinetic performance with the aim of establishing a prediction model[3] for determining the "best before" date of VOOs by taking into account the temperature of the place of sale.

Although researchers have tried to demonstrate the usefulness of pigments for the assessment of the freshness,[6] these compounds actually have a merely casual relationship to the product age[2] because their concentration values are strongly influenced by the inadequate conditions of temperature during storage of any VOO in addition to the storage time. To increase the confusion, the only current regulation does not demand that the estimation for the "best before" date is calculated on the basis of the harvesting time of the olives (or the olive oil processing) but the bottling time,[7] although it is suggested that olive oil should be under "adequate storage condition" before bottling.

The term "adequate storage conditions" is relevant because, as previously mentioned, the percentage of PPPs increases after olives are crushed, and it depends on temperature. As a consequence, VOOs stored in a warm place would reach the limit (17% PPP) proposed in regulatory bodies of some countries[8−10] earlier than if they were stored in a cold place. Thus, the scientific support explaining the association of %PPP with freshness may have flaws because of the high dependence on temperature. Nevertheless, the determination of PPPs[11] can contribute to harmonize the parameter "best before" with the intuitive perception that consumers have for the freshness of VOOs.

A predictive mathematical model (Know-How, Utility model, MIT_TO-0022272) has been used to estimate %PPP in VOOs stored at any given temperature in darkness and with lack of oxygen.[3] The mathematical model has resulted from isokinetic

[a]%PPP was determined by means of a mathematical model.[3]

studies of the formation and degradation of pigments at different temperatures, ranging from 15 to 120 °C, with various cultivars.[5] The predictive model can be used to estimate the trend of the percentages of pyropheophytin *a* in a given time−temperature frame.

Table 1 shows the results of applying the mathematical model expressed as %PPP during two years for the particular case of VOO var. Arbequina, which is the most globally distributed cultivar, in places where VOOs are usually sold. Thus, VOO was produced in Estepa (Spain) and its hypothetical sale places were Sacramento (USA) and Frankfurt (Germany) in the northern hemisphere and Adelaide (Australia) and Johannesburg (South Africa) in the southern hemisphere. The recorded average temperatures were considered for the application of the predictive model, which admits information in monthly, daily, and even hourly bases. All of the temperature values were collected from The Weather Channel.

Thus, VOO stored at a daily basis of average temperature of Sacramento would reach 17% PPP after 21 months, but this percentage would be reached sooner (at month 7) using the maximum average temperature. These results show that, in this case, VOO should be fully controlled and protected from daily temperatures if considering the limit of 17% PPP for freshness, although the oil can still be qualified as VOO according to IOC trade standards.[12] A very different situation is the hypothetical storage of the same VOO sample in Frankfurt, with the same monthly basis of average temperature, where winters and summers are much cooler, and VOO would be "fresh", in terms of %PPP, for more than 3 years and for around a year using the maximum average temperature. The behavior is similar in hypothetical places of the southern hemisphere (Adelaide and Johannesburg), although with the well-known change in the sequence of the seasons.

The main conclusion is that the initial value of %PPP should be supplied for a better monitoring of the storage period of VOOs. Several advantages would result from this information. Consumers would benefit from a better knowledge of the initial freshness of the olive oil (from the olive harvesting instead of the olive oil bottling). Producers and sellers would gain knowledge for selecting the best place of sale for each VOO,

dx.doi.org/10.1021/jf405220d | J. Agric. Food Chem. 2014, 62, 554−556

according to its initial %PPP and its predicted evolution. Finally, initial values of %PPP would also allow inspection agencies to carry out backward traceability of the storage conditions of VOOs by checking %PPP with the "best before" date at any moment.

ABSTRACT: Pepper (*Capsicum annuum* L.) is an economically important agricultural crop and an excellent dietary source of natural colors and antioxidant compounds. The levels of these compounds can vary according to agricultural practices, like inoculation with plant growth-promoting rhizobacteria. In this work we evaluated for the first time the effect of the inoculation of two *Rhizobium* strains on *C. annuum* metabolites and bioactivity. The results revealed a decrease of organic acids and no effect on phenolics and capsaicinoids of leaves from inoculated plants. In the fruits from inoculated plants organic acids and phenolic compounds decreased, showing that fruits from inoculated plants present a higher ripeness stage than those from uninoculated ones. In general, the inoculation with *Rhizobium* did not improve the antioxidant activity of pepper fruits and leaves. Considering the positive effect on fruit ripening, the inoculation of *C. annuum* with *Rhizobium* is a beneficious agricultural practice for this nonlegume.

KEYWORDS: *Rhizobium spp., Capsicum annuum L., maturation, metabolites profile, bioactivity*

INTRODUCTION

Pepper (*Capsicum annuum* L.) is a member of the Solanaceae family, and its fruit is important as a vegetable food and spice.[1] It is a good source of vitamins C and E, provitamin A, carotenoids, tocopherols, flavonoids, and phenolic acids, compounds with well-known antioxidant properties.[1−3]

Although flavonoids and phenolic acids are considered separately from capsaicinoids, which provide pungency or "heat" to hot peppers,[4] it is known that the phenylpropanoid and capsaicinoid biosynthetic pathways may converge during pepper maturation.[5] The intake of these compounds is an important health-protecting factor, since they have been considered as beneficial for the prevention of widespread human diseases, including cancer and cardiovascular diseases, when taken daily in adequate amounts.[6]

Pepper fruits are recognized for their economic importance and nutritional value, being the second most consumed vegetable worldwide. Nevertheless, information concerning byproducts resulting from its production, namely, leaves, is scarce. This material may also be an interesting source of bioactive phytochemicals.

The increase of quality demanded by consumers requires specific agricultural practices, such as fertilization with products containing microorganisms.[7] The inoculation with plant growth-promoting rhizobacteria (PGPR) reducing the chemicals added to crops can improve not only the growth but also the quality of plants, since these microorganisms can mobilize nutrients to the plants, influence the plant hormonal balance, or produce microbial inhibitory compounds that preclude the growth of phytopathogens.[8] In the case of pepper, some bacteria have been reported as PGPR for different plants, as occurs with *Pseudomonas* and *Pantoea*.[9] Nevertheless, not all bacterial species can be used in biofertilization schemes when the fruits are raw consumed, those used for decades as plant biofertilizers being preferred. Within them, *Rhizobium*, widely known for its ability to establish symbiotic relationships with legume plants,[10] also has different plant growth-promoting mechanisms, being able to promote the development of nonlegumes.[8,11,12]

Some *Rhizobium* strains have a positive effect on pepper growth, since fruits from plants inoculated with them exhibited significantly higher fresh weight.[12] Moreover, the number of mature fruits in inoculated plants was higher than that in noninoculated ones, which could suggest that these fruits reach the maturation stage earlier. This is an important factor for the composition of fruits, since several biochemical, physiological, and structural modifications occur during fruit ripening and these changes determine the attributes of the fruit.[13] For example, a decline in phenolic compounds during maturation of *Capsicum* fruits has been reported.[14] These losses during fruit maturation may reflect the metabolic conversion to secondary phenolic compounds and degradation *via* enzyme action and

may indicate diversion of phenolic precursors from flavonoids to capsaicinoids.[15] Organic acids also contribute to fruit maturation, since the concentration of individual acids changed in pepper contributing to pepper fruit flavor.[16]

Although some work has been carried out about the changes in the chemical composition of pepper fruits after PGPR inoculation,[17] as far as we know there are no studies about the effect of rhizobial inoculation in the chemical composition of leaves and fruits of *C. annuum*, nor in their biological properties. Therefore the objectives of the present work were to compare the accumulation of bioactive compounds indicative of maturation, namely, phenolics and organic acids, in pepper leaves and fruits obtained after the inoculation with two PGPR *Rhizobium* strains with that of noninoculated material and its impact on their bioactivity.

MATERIALS AND METHODS

Standards and Reagents. All chemicals used were of analytical grade. The standard compounds were purchased from various suppliers. 5-*O*-Caffeoylquinic acid, quercetin-3-*O*-rutinoside, quercetin-3-*O*-rhamnoside, luteolin-7-*O*-glucoside, myricetin-3-*O*-rhamnoside, and apigenin-7-*O*-glucoside were from Extrasynthese (Genay, France). Caffeic, ferulic, sinapic, oxalic, malic, quinic, succinic, fumaric, acetic, citric, and aconitic acids, capsaicin, and dihydrocapsaicin were obtained from Sigma-Aldrich (St. Louis, MO, USA). 1,1-Diphenyl-2-picrylhydrazyl (DPPH$^{\bullet}$), β-nicotinamide adenine dinucleotide (NADH), phenazine methosulfate (PMS), nitrotetrazolium blue chloride (NBT), 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), sulfanilamide, acetylcholinesterase (AChE) from electric eel (type VI-s, lyophilized powder), acetylthiocholine iodide (ATCI), sodium nitroprusside dehydrate (SNP), and methanol were purchased from Sigma-Aldrich (St. Louis, MO, USA). N-(1-Naphthyl)ethylenediamine dihydrochloride and sulfuric acid were obtained from Merck (Darmstadt, Germany). Water was deionized using a Milli-Q water purification system (Millipore, Bedford, MA).

Plant Samples and Bacterial Strains. Samples of leaves and fruits used in this study were obtained from pepper var. "sweet Italian" plants inoculated with two fast-growing rhizobial strains, PETP01 and TVP08, and from uninoculated plants. These strains were isolated from *Trifolium pratense* and *Phaseolus vulgaris* nodules, respectively, presenting effective nodulation in their respective hosts.[12] PETP01 and TVP08 strains were identified in a previous work as *Rhizobium leguminosarum*, and they belong to different subphyla within this species following the analysis of the core *recA* and *atpD* genes and of two different symbiovars (trifolii and phaseoli, respectively), according to the analysis of the symbiotic *nodC* gene.[12]

Inoculation assays were performed as was previously described:[12] for plant inoculation, nonsterilized seeds were germinated in peat following the steps commonly used in the commercial process of seedling production and were irrigated from a bottom reservoir with water every 48 h and with commercial Hoagland's solution (Sigma Co., USA) every 8 days. Once placed on peat, each seed was inoculated with 1 mL of a suspension (2×10^8 cells/mL) of 5-day-old *Rhizobium* strains TPV08 and PETP01 grown on yeast-mannitol agar (YMA). Then, they were covered with vermiculite and germinated in darkness in a growth chamber at 24 °C, for seven days. Afterward, they were maintained in a plant growth chamber with mixed incandescent and fluorescent lighting (400 microeinsteins m^{-2} s^{-1}; 400 to 700 nm), programmed for a 16 h photoperiod, day−night cycle, with a constant temperature varying from 25 to 27 °C and 50−60% relative humidity. Uninoculated controls were kept under the same conditions.

After four weeks, 25 plants *per* treatment were used for a microcosm experiment, which was performed in a clayey soil collected at Salamanca (Spain), with neutral pH, 1.5−1.8% of organic matter, and 0.09−0.1 of N content. The seedling roots were flooded in bacterial suspensions containing 2×10^8 cells/mL during 4 h. Each plant was transplanted to a pot containing 2 kg of soil. Plants were irrigated from a bottom reservoir with water every 48 h and with commercial Hoagland's solution every 8 days. The plants were maintained during 10 weeks in a greenhouse illuminated with natural light in summer (night temperature ranging from 15 to 20 °C and day temperature ranging from 25 to 35 °C) with humidity control. At the end of the experiment, flowers and fruits were counted, fruits were harvested, and their fresh weight was measured.

Data related to the precocity of the pepper plants not published before are included in the present work.

Five plants *per* treatment were randomly selected and used for the chemical and biological analysis. They were frozen, lyophilized, and powdered (mean particle size lower than 910 μm), being divided into three aliquots, extracted, and analyzed separately for chemical composition and biological activity.

Phenolic Compounds. *Extraction.* *C. annuum* leaves and fruits (3 g) were extracted with 600 mL of boiling water during 15 min. The resulting extracts were filtered through a Büchner funnel, frozen, and lyophilized. The yield of extractions was 45.0 and 33.9% for fruits and leaves, respectively. The extracts were kept in a desiccator, in the dark, until analysis. Aqueous lyophilized extracts were redissolved in methanol and filtered through a PTFE membrane (0.45 μm).

Analysis by HPLC-DAD. The phenolic compounds were analyzed using a previously described procedure.[18] Briefly, each extract was analyzed on an analytical HPLC unit (Gilson), using a Spherisorb ODS2 (25.0 × 0.46 cm; 5 μm, particle size; Waters, Milford, MA) column. The solvent system used was a gradient of water:formic acid (19:1) (A) and methanol (B), starting with 5% methanol and installing a gradient to obtain 15% B at 3 min, 25% B at 13 min, 30% B at 25 min, 35% B at 35 min, 45% B at 39 min, 45% B at 42 min, 50% B at 44 min, 55% B at 47 min, 70% B at 50 min, 75% B at 56 min, and 80% B at 60 min, at a solvent flow rate of 0.9 mL/min. Detection was achieved with a Gilson diode array detector (DAD). Chromatograms were recorded at 280, 320, and 350 nm. The data were processed on Unipoint System software (Gilson Medical Electronics, Villiers-le-Bel, France). The compounds in each extract were identified by comparing their retention times and UV−vis spectra with those of authentic standards. Because standard was not commercially available, luteolin-7-*O*-(2-apiosyl-6-malonyl)-glucoside was quantified as luteolin-7-*O*-glucoside. Phenolic acids were determined at 320 nm and flavonoids at 350 nm. This procedure was performed in triplicate.

Capsaicinoids. *Extraction.* The method described by Estrada et al.[19] was used, with some modifications: 1.0 g of fruits and leaves was extracted with 10 mL of acetonitrile at 80 °C, for 4 h. The extract obtained was centrifuged at 4000 rpm for 5 min, and the supernatant was filtered. A 20 μL aliquot was used for each HPLC-DAD injection.

Analysis by HPLC-DAD. The samples were analyzed using an ACE3 C-18-AR column (150 × 4.6 mm, 3 μm particle size, Advanced Chromatography Technologies, Aberdeen, Scotland). The elution solvent was acetonitrile:water (60:40) at isocratic mode, flow rate of 1.0 mL/min, and a 35 min run.

Detection was achieved with a Gilson DAD, and chromatograms were registered at 280 nm. Spectral data from peaks were accumulated in the 200−400 nm range. The data were processed on Unipoint System software (Gilson Medical Electronics, Villiers-le-Bel, France). The compounds in each extract were identified by comparing their retention times and UV−vis spectra with those of external authentic standards (capsaicin and dihydrocapsaicin). Capsaicinoids quantification was achieved by measuring the absorbance at 280 nm in the chromatograms relative to external standards. This procedure was performed in triplicate.

Organic Acids. *Extraction.* Extraction of organic acids was performed according to a described procedure:[18] 0.1 and 1.0 g of lyophilized fruits and leaves, respectively, were mixed with 50 mL of H_2SO_4 0.01 N for 30 min under stirring (300 rpm). The obtained extracts were then filtered, evaporated to dryness under reduced pressure (40 °C), and redissolved in H_2SO_4 0.01 N.

HPLC−UV Analysis. The separation and quantification of organic acids were carried out according to the procedure described by Silva et al.[18] in an analytical HPLC unit (Gilson), using an ion exclusion Nucleogel Ion 300 OA (300 × 7.7 mm; Macherey-Nagel, Düren, Germany) column. Elution was performed in isocratic mode with

H_2SO_4 (0.01 N), at a flow rate of 0.2 mL/min. Detection was achieved with a UV detector set at 214 nm. Quantification of organic acids was achieved by measuring the absorbance recorded in the chromatograms relative to external standards. This procedure was performed in triplicate.

Antioxidant Activity. The aqueous lyophilized extracts prepared for phenolic compounds determination were used in the screening of the antioxidant activity. All determinations were made in a Multiskan Ascent plate reader (Thermo Electron Corporation).

DPPH• Assay. For each extract, a dilution series (five different concentrations) was prepared in a 96-well plate. The reaction mixtures in the sample wells consisted of 25 μL of extract (redissolved in methanol) and 200 μL of 150 mM methanolic DPPH•. The plate was incubated for 30 min at room temperature after addition of DPPH• solution, and the absorbance was determined at 515 nm.[20] Three experiments were performed in triplicate.

Nitric Oxide Assay. Antiradical activity was determined spectrophotometrically in a 96-wells plate reader. The reaction mixtures in each well consisted on 100 μL of extract dissolved in buffer (KH_2PO_4 100 mM, pH 7.4) and 100 μL of SNP (20 mM). The plates were incubated at room temperature for 60 min, under light. Griess reagent (1% sulfanilamide and 0.1% naphthylethylenediamine in 2% H_3PO_4) (100 μL) was then added, and 10 min later the absorbance of the chromophore formed during the diazotization of nitrite with sulfanilamide and subsequent coupling with naphthylethylenediamine was determined at 562 nm.[20] Three experiments were performed in triplicate.

Superoxide Radical Assay. Superoxide was generated by the NADH/PMS system, according to a described procedure: PMS reduced by NADH reacts with oxygen to produce $O_2^{\bullet-}$; this radical then reduces NBT to a formazan blue dye, which has an absorption maximum at 560 nm. [20] The reaction mixtures in the wells consisted on 50 μL of extract dissolved in buffer (KH_2PO_4 19 mM, pH 7.4), 50 μL of NADH (166 μM), 150 μL of NBT (43 μM), and 50 μL of PMS (2.7 μM). The rate of the reaction was assessed at 560 nm, during 2 min after PMS addition.[20] Three experiments were performed in triplicate.

AChE Inhibitory Activity. The aqueous lyophilized extracts were also used to assess AChE inhibition properties. Spectrophotometric determinations at 405 nm were performed in a Multiskan Ascent plate reader (Thermo Electron Corporation), based on Ellman's method, as previously described.[20] In each well the mixture consisted of 25 μL of ATCI (15 mM), 125 μL of DTNB (3 mM), 50 μL of buffer (50 mM Tris-HCl, pH 8, containing 0.1% BSA), and 25 μL of sample dissolved in buffer with 10% of methanol. The absorbance was read at 405 nm during 2 min. After this step, 25 μL of AChE (0.44 U/mL) was added and the absorbance was read again. The rates of reactions were calculated by Ascent Software version 2.6 (Thermo Labsystems Oy). The rate of the reaction before adding the enzyme was subtracted from that obtained after adding the enzyme in order to correct eventual spontaneous hydrolysis of substrate. [20] Three experiments were performed in triplicate.

Statistical Analysis. All data were recorded as mean ± standard deviation of triplicate determinations. Mean values were compared using one-way analysis of variance (one-way ANOVA) (Graph Pad Prism Version 5.00, GraphPad Software, Inc., San Diego, CA). Differences were considered significant for $p < 0.05$.

RESULTS AND DISCUSSION

Effect of *Rhizobium* Strains in the Growth of Pepper Plants. The inoculated plants were more precocious than noninoculated ones, displaying more rapid flowering and fruiting when they were inoculated with the two *Rhizobium* strains. In this way, the percentage of plants with flowers three weeks after transplanting was 80 and 100%, for the plants inoculated with strains TVP08 and PETP01, respectively, whereas only 60% of the noninoculated plants had flowers at this time. Also, seven weeks after transplanting, the percentage of plants with fruits was 50 and 60% for the plants inoculated with strains TVP08 and PETP01, respectively, whereas only 35% of the noninoculated plants had fruits at this time. These results showed that the inoculation with *Rhizobium* increased the precocity of pepper plants since the fruit production began earlier in inoculated plants. Therefore, pepper plants inoculated with *Rhizobium* strains TVP08 and PETP01 not only yielded more fruits, which have higher weight, than noninoculated plants, as was described before,[12] but also they are produced earlier. These results suggest that the inoculation has a direct effect on pepper fruit ripening, this being the first report about the ability of rhizobia to advance the fruit production of a nonlegume.

Phenolic Compounds. Phenolic compounds are plant secondary metabolites, which are synthesized by plants as a result of their adaptation to biotic and abiotic stress conditions.[1] They include flavonoids with antioxidant activity that may be beneficial for human health.[21,22]

The analysis of the aqueous extracts by HPLC-DAD allowed the identification of several phenolic compounds (Table 1). To evaluate the recovery of phenolic compounds, aliquots of known concentration of luteolin-7-*O*-glucoside standard solution were added to the samples and a recovery of 98% (±0.3) and 92% (±1.3) was obtained for leaves and fruits, respectively.

In pepper leaves hydroxycinnamic acids (5-*O*-caffeoylquinic, caffeic, and ferulic acids) and flavonoids (luteolin-7-*O*-gluco-

dx.doi.org/10.1021/jf4046649 | J. Agric. Food Chem. 2014, 62, 557−564

side, quercetin-3-*O*-rutinoside, and apigenin-7-*O*-glucoside) were identified (Table 1 and Figure 1A). These flavonoids have already been described in pepper leaves by Reigosa et al.[23] Several studies have already reported the fundamental role of luteolin and apigenin derivatives in the protection of cells (membranes, chlorophyll, and fragile organelles) from the damage caused by UV radiation.[1]

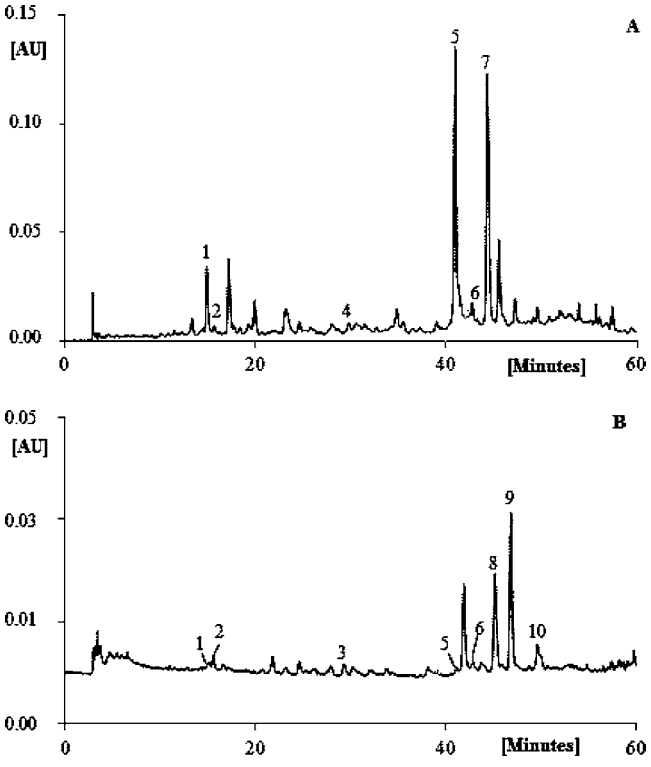

Figure 1. HPLC phenolic profile of *Capsicum annuum* (A) leaf control and (B) fruit control. Detection at 320 nm. Peaks: (1) 5-*O*-caffeoylquinic acid; (2) caffeic acid; (3) sinapic acid; (4) ferulic acid; (5) luteolin-7-*O*-glucoside; (6) quercetin-3-*O*-rutinoside; (7) apigenin-7-*O*-glucoside; (8) myricetin-3-*O*-rhamnoside; (9) quercetin-3-*O*-rhamnoside; (10) luteolin-7-*O*-(2-apiosyl-6-malonyl)-glucoside.

Pepper fruits showed a distinct phenolic profile, eight compounds being determined: 5-*O*-caffeoylquinic, caffeic, and sinapic acids, luteolin-7-*O*-glucoside, quercetin-3-*O*-rutinoside, myricetin-3-*O*-rhamnoside, quercetin-3-*O*-rhamnoside, and luteolin-7-*O*-(2-apiosyl-6-malonyl)-glucoside (Table 1 and Figure 1B). From these, only 5-*O*-caffeoylquinic acid and myricetin-3-*O*-rhamnoside were not previously described in pepper fruits.[1,2,15,24]

Quantitatively, the sum of the identified phenolic compounds in the three leaves samples was similar (Table 1). The major compound was apigenin-7-*O*-glucoside, corresponding to ca. 49, 52, and 54% of the total content in control sample and in the samples inoculated with strains PETP01 and TVP08, respectively. However, inoculation led to a significant increase of caffeic acid. Ferulic acid also increased significantly, but just in plants inoculated with the strain PETP01. On the contrary, the amounts of 5-*O*-caffeoylquinic acid and luteolin-7-*O*-glucoside were significantly higher in control leaves than in inoculated ones.

Regarding the fruits, the phenolic content decreased with the inoculation of both *Rhizobium* strains, especially with strain TVP08 (Table 1). Quercetin-3-*O*-rhamnoside was the main phenolic compound in all fruits. Although the inoculation with *Rhizobium* strains led to a significant decrease of the amounts of this compound, its relative content was higher in fruits from plants inoculated with strains PETP01 (about 60%) and TVP08 (almost 40%) than in control leaves, in which it represented 34% of total phenolics.

Several authors reported a decrease of phenolic compounds during ripening of several pepper varieties[15,25,26] due to their enzymatic degradation in secondary metabolism[15] and by the involvement in the structure of cell walls.[1] The decrease of phenolics in the fruits of plants inoculated with *Rhizobium* strains supports that the ripeness of these fruits is higher when the plants were inoculated with *Rhizobium* strains, mainly when the strain TVP08 was used. This result contrasts with that obtained by Amor et al.,[17] who did not find a decrease of phenolic compounds in pepper inoculated with *Azospirillum* and *Pantoea,* two bacteria considered as PGPR. Therefore, to our knowledge, this is the first report of a positive influence on fruit ripeness of the inoculation with *Rhizobium* PGPR strains of a nonlegume.

Capsaicinoids. Capsaicinoids are a group of alkaloids responsible for the pungent sensation caused by pepper fruits, capsaicin and dihydrocapsaicin being responsible for about 90% of the spiciness.[13]

HPLC-DAD analysis allowed the identification of two capsaicinoids (Table 2). To evaluate the recovery of capsaicinoids, aliquots of known concentration of capsaicin standard solution were added to the samples, a recovery of 80% (±7.3) and 77% (±3.0) being obtained for fruits and leaves, respectively.

In pepper leaves only capsaicin was detected (Table 2), ranging between 75.3 and 78.3 mg/kg. This contrasts with the results of Estrada et al.,[19] who also detected dyhidrocapsaicin in the leaves of other varieties of pepper in which the content of capsaicin was lower, ranging from 1 to 20 μg/g. No significant differences were found in the amounts of capsaicin of leaves from uninoculated and inoculated plants.

Besides capsaicin, dyhidrocapsaicin was also detected in the fruits. The total content of these capsaicinoids ranged between 275.2 and 309.2 mg/kg, capsaicin representing ca. 88.0% and dyhidrocapsaicin ca. 12.0%. As expected, these values are lower

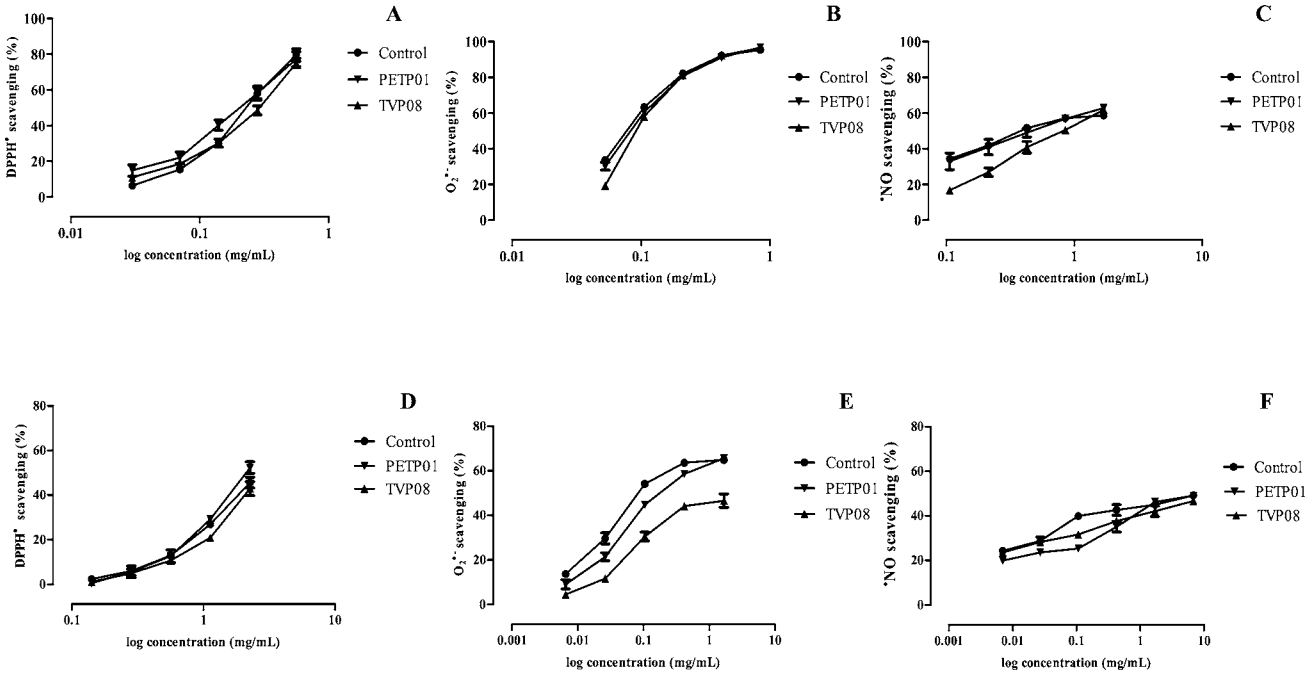

Figure 2. Effect of aqueous extracts of *C. annuum* leaves and fruits against (A, D) DPPH•, (B, E) superoxide radical ($O_2^{\bullet-}$), and (C, F) nitric oxide (•NO), respectively. Values show mean ± SE of three experiments performed in triplicate.

than those found on mature fruits from the spicy variety Jalapeño, in which levels of capsaicin and dyhidrocapsaicin ranging from 499−899 mg/kg to 540−989 mg/kg of dried material, respectively, were reported.[27]

Menichini et al.[13] observed that capsaicinoid amounts increase with ripening in *Capsicum chinense* Jacq. var. habanero, which is one of the most spicy varieties of pepper. In this study we also found a slight increase of capsaicin in peppers inoculated with *Rhizobium*. Nevertheless, the differences were not significant with respect to noninoculated ones, and in the case of dyhidrocapsaicin a decrease was even found. This was expected taking into account that a sweet variety ("sweet Italian") was analyzed in this study. This is the first study about the effect on content of capsaicinoids in leaves and fruits of *C. annuum* after the inoculation with *Rhizobium* spp. showing that it has not a significant effect in sweet peppers.

Organic Acids. Organic acids are primary metabolites, which can be found in great amounts in all plants, especially in fruits. Citric, malic, and tartaric acids are commonly found in fruits and berries, while oxalic acid is present in higher amounts in green leaves.[28]

The analysis of *C. annuum* fruits and leaves by HPLC−UV revealed a similar profile, composed of oxalic, malic, quinic, succinic, fumaric, citric, acetic, and aconitic acids (Table 3). To evaluate the recovery of organic acids, aliquots of a standard solution of fumaric acid with known concentration were added to the samples, 89 ± 0.9 and 81 ± 1.2% being recovered from fruits and leaves, respectively.

The total amount of organic acids in the leaves from control plants was lower than those from plants inoculated with PETP01 strain, but higher than in those from plants inoculated with TVP08 strain (Table 3).

In pepper leaves from all treatments oxalic acid was the main compound representing ca. 45, 48, and 28% from the total of the determined organic acids, in leaves of control, plants inoculated with strain PETP01, and those inoculated with strain TVP08, respectively (Table 3). The amounts of this acid together with quinic, citric, and acetic acids were significantly increased after the inoculation with strain PETP01, whereas it significantly decreased malic, succinic, fumaric, and aconitic acids. In the case of leaves from plants inoculated with strain TVP08 significant increases of malic, succinic, fumaric, and

acetic acids were observed, while the content of oxalic, quinic, and citric acids was significantly reduced. Therefore, both strains had the same effect just in what concerns acetic acid content, which was significantly increased (Table 3).

The increased levels of malic acid in leaves from plants inoculated with TVP08 strain are in agreement with the results found for rice leaves inoculated with the PGPR bacterium *Herbaspirillum seropedicae* by Curzi et al.[29] This is the first report about the effect of the inoculation of *Rhizobium* in the organic acids composition of *C. annuum* leaves.

The organic acids qualitative profile of *C. annuum* fruits was similar to that of the leaves (Table 3), citric acid being the major organic acid in all samples, representing ca. 28% in control fruits and 45 and 40% in fruits from plants inoculated with strains PETP01 and TVP08, respectively. Succinic, acetic, and aconitic acids are described for the first time in this matrix, while all the others were already reported.[30] The inoculation with both *Rhizobium* strains led to the decrease of most of the organic acids in fruits, except citric acid; additionally, acetic and quinic acids increased when PETP01 and TVP08 strains were inoculated, respectively. These results are in agreement with those obtained with soybean, a legume, after the inoculation of *Bradyrhizobium*[31] and in pepper fruits after inoculation with other PGPR bacteria, such as *Azospirillum* sp. and *Pantoea* sp.[17] The concentrations of organic acids in sweet peppers change notably during ripening, a decrease of their total amounts being reported.[6,15,16] These authors reported that the concentration of malic acid decreases while that of citric acid increases considerably during the ripeness process. The same results were found in our study when the plants were inoculated with the two *Rhizobium*, strengthen the results obtained for phenolic compounds and showing a more advanced degree of ripeness in peppers from plants inoculated with *Rhizobium* strains.

Antioxidant Activity. Peppers are a good source of antioxidant compounds that can reduce harmful oxidation reactions in the human body, thus preventing various diseases associated with free radical oxidation, such as cardiovascular and neurological disorders and cancer.[2]

The antioxidant activity of the aqueous lyophilized extracts from *C. annuum* fruits and leaves was tested against DPPH•, superoxide ($O_2^{\bullet-}$), and nitric oxide (•NO) radicals. A concentration-dependent potential was observed in all assays (Figure 2).

As far we know, this is the first study about the antioxidant capacity of *C. annuum* leaves. The extract of leaves from plants inoculated with PETP01 strain revealed a tendency to be the most active against DPPH• radical (Table 4). In the assays against •NO and $O_2^{\bullet-}$ radicals the best results were obtained with the extract of leaves from control plants (Table 4). This result is in agreement with the phenolic composition of leaves, in which luteolin-7-*O*-glucoside and 5-*O*-caffeoylquinic acid (chlorogenic acid), two compounds with antioxidant potential,[32,33] were found in significant higher amounts in control leaves (Table 1). Although the contribution of other bioactive compounds not determined in the extracts cannot be discarded, the presence of higher amounts of luteolin-7-*O*-glucoside and 5-*O*-caffeoylquinic acid in control leaves may be linked to the higher antioxidant activities found in them. Comparing the results of the three assays performed, we can observe that the leaves' extracts were more active against superoxide radical. The scavenging of this reactive oxygen species is of great importance due to its potential to originate other reactive species that could be extremely deleterious to the cells.[34]

The extracts obtained from fruits followed the same pattern as those from the leaves. The extract of fruits from plants inoculated with PETP01 strain was the most active against DPPH• radical and that of fruits from plants inoculated with TVP08 strain the less effective, the differences being significant when compared to control (Figure 2D, Table 4). The extract from control fruits also showed a tendency to be the most active against •NO and $O_2^{\bullet-}$ (Table 4).

Conforti et al.[25] observed that more immature pepper fruits showed better antioxidant activity, due to the presence of higher amounts of phenolic compounds. Since the inoculation of pepper with *Rhizobium* anticipated the fruit ripening, a decrease in the antioxidant activity of fruits inoculated with *Rhizobium* was expected. Nevertheless, the inoculation with the PETP01 strain significantly increased the activity against DPPH•, decreasing only with the inoculation of the strain TVP08, which was the strain that more significantly advanced the ripening of pepper fruits. The inoculation does not significantly affect the activity against •NO and $O_2^{\bullet-}$ radicals.

Acetylcholinesterase (AChE) Inhibitory Activity. The search for natural matrices with capacity to inhibit AChE has increased due to their benefits in the treatment of Alzheimer's disease and other forms of dementia.[35]

In this study the inhibitory activity of aqueous extracts of *C. annuum* leaves was evaluated against AChE and a concentration-dependent activity was obtained (data not shown). Extract from control leaves was the most active (Table 4), and this result can be explained by the presence of various bioactive compounds, namely, flavonoids.[36]

The capacity of fruits' aqueous extracts to inhibit AChE was also assessed, but no effect was found for the tested concentrations. Despite the different composition, the same kind of phenolic compounds was found in both fruit and leaf extracts. As such, the absence of effect on AChE observed with the extracts prepared from fruits seems to suggest the interference of other nondetermined bioactive compounds.

In summary, the most relevant result obtained in this study is a positive effect on fruit ripening of pepper plants inoculated with two *Rhizobium* strains. The fruits from inoculated plants

had lower total levels of organic acids and phenolic compounds, pointing to a higher ripening stage than those from uninoculated ones. Data suggest that the application of nodulating rhizobacteria is a beneficial agricultural practice for this nonlegume, ensureing that they are optimal bacteria for biofertilization, with positive effects on production and fruit ripening, contributing to an increase in the consumption of this fruit, either as fruit or dietary supplement.

ABSTRACT: Peppers (*Capsicum* spp.) are consumed worldwide, imparting flavor, aroma, and color to foods, additionally containing high concentrations of biofunctional compounds. This is the first report about the effect of the inoculation of two *Rhizobium* strains on sterols, triterpenes, fatty acids, and volatile compounds of leaves and fruits of pepper (*Capsicum annuum* L.) plants. Generally, inoculation with strain TVP08 led to the major changes, being observed a decrease of sterols and triterpenes and an increase of fatty acids, which are related to higher biomass, growth, and ripening of pepper fruits. The increase of volatile compounds may reflect the elicitation of plant defense after inoculation, since the content on methyl salicylate was significantly increased in inoculated material. The findings suggest that inoculation with *Rhizobium* strains may be employed to manipulate the content of interesting metabolites in pepper leaves and fruits, increasing potential health benefits and defense abilities of inoculated plants.

KEYWORDS: *Capsicum annuum L., plant-growth-promoting rhizobacteria, sterols, triterpenes, fatty acids, volatile compounds*

INTRODUCTION

The genus *Capsicum* belongs to the Solanaceae family and includes many species distributed by both sweet cultivars, mainly eaten as vegetables, and hot ones, often used as spice.[1] There is a plethora of dishes, pastas, and sauces to which peppers impart their particular color and flavor. Furthermore, peppers can be utilized at both ripe and unripe stages, although the former is preferred by European consumers.[2]

The increased production of peppers has created an economic and environmental burden that has led to the discarding of stems and leaves, even with nutraceutical potential. However, little information is available concerning specific phytochemicals or their functional value.

Within *Capsicum* genus, the most genetically diverse and economically important species corresponds to the common pepper (*Capsicum annuum* L.), whose varieties are cultivated worldwide. This species has become popular not only because of its morphological and genetic diversity, flavor, and aroma but also due to its beneficial properties for human health.[3] Actually, it is recognized for its excellent nutritional composition, containing proteins, fatty acids, and sugars, high levels of α- and β-carotene, β-cryptoxanthine, and other carotenoids, vitamin C, tocopherols, and phenolic compounds, mainly flavonoids like quercetin and luteolin derivatives.[3,4]

In plant tissues, the most abundant saturated fatty acids are palmitic and stearic, oleic, linoleic, and linolenic being the most common unsaturated ones.[5] The diet contains a mixture of different types of saturated (SFA), monounsaturated (MUFA), and ω-6 and ω-3 polyunsaturated (PUFA) fatty acids. Some fatty acids are primarily used for energy or storage (SFA and MUFA), and others, especially long-chain PUFAs, are used in cell membrane phospholipids and synthesis of lipid-derived mediators and as regulators of a number of cellular functions, including gene transcription.[6] PUFAs from the ω-6 family have important biological properties and are the biosynthetic precursors of eicosanoids (i.e., prostaglandins), having effects on cardiovascular diseases, triglyceride levels, and arthritis.[7]

Plant sterols are bioactive components of all vegetable foods. Phytosterols are cholesterol-like molecules found in most plant foods, with the highest concentrations occurring in vegetable oils. Plant materials contain free and esterified sterols that can be acylated, β-sitosterol, campesterol, and stigmasterol being the more abundant ones in nature. They are recognized to lower blood cholesterol, may provide protection against certain types of cancer, and present an immune-modulating activity.[8] The addition of plant sterols to the diet is suggested by health experts as a safe and effective way to reduce the risk of coronary heart disease,[9] and the short-term use of food supplements rich in these compounds is a safe and effective strategy, with or without statin therapy, among the majority of dyslipidemic patients with need for additional lipid-lowering (reviewed by Gupta et al.[10]).

Volatile compounds are released from leaves, flowers, and fruits into the atmosphere and from roots into the soil. The primary functions of volatile compounds are to defend plants against herbivores and pathogens, to attract pollinators, seed dispersers, and other beneficial animals and microorganisms, and to serve as signals in plant−plant communication.[11]

Currently the consumers demand high quality for raw consumed vegetables, such as pepper, and this implies a reduction of chemicals added to the crops that can be substituted by biological agents like fungi[12] and plant growth-promoting rhizobacteria (PGPR). These bacteria can enhance the plant growth by diverse mechanisms, such as mobilization of nutrients, production of siderophores that chelate iron and make it available to the plant roots, and synthesis of phytohormones.[13,14]

Rhizobia are generally regarded as microbial symbiotic partners of legumes and are mainly known for their role in the formation of nitrogen-fixing nodules.[15] Some of these bacteria have been explored with respect to their effect in the production of bioactive compounds in legumes.[16] Nevertheless, there are no data about the effect of rhizobia inoculation on the bioactive metabolites of nonlegumes. Part 1 of this study concerned the influence of the inoculation of two *Rhizobium* strains on the phenolic compounds, organic acids, capsaicinoids, and bioactivity of leaves and fruits of *C. annuum*.[17] Therefore, the aim of this second part was to evaluate the influence of the same strains on sterols, triterpenes, fatty acids, and volatiles composition.

MATERIALS AND METHODS

Standards and Reagents. All chemicals used were of analytical grade. The standard compounds were purchased from various suppliers: (*E*)-2-hexenal, camphene, α-pinene, linalool, camphor, β-caryophyllene, β-cyclocitral, (*Z*)-4-heptenal, (*E*,*Z*)-2,6-nonadienal, methyl salicylate, eugenol, hexanal, 1-octen-3-ol, benzyl alcohol, 6-methyl-5-hepten-2-one, 2-isobutyl-3-methoxypyrazine, benzaldehyde, *o*-guaiacol, β-sitosterol, campesterol, betulin, and stigmasterol were obtained from Sigma-Aldrich (St. Louis, MO, USA); fatty acid methyl esters kit were purchased from Supelco (Bellafonte, PA, USA), methyl jasmonate (internal standard), β-ionone, α-ionone, (*E*)-2-octenal, 2-methylbutanal, 3-methylbutanal, and heptanal from SAFC (St. Louis, MO, USA), and menthol and limonene from Fluka (Buchs, Switzerland). Methanol and acetonitrile were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sodium sulfate anhydrous and isooctane were purchased from Panreac Química SA (Barcelona, Spain). Potassium hydroxide was from Pronalab (Lisboa, Portugal) and boron trifluoride (BF_3) 10% methanol solution from Supelco (Bellafonte, PA, USA). Water was deionized using a Milli-Q water purification system (Millipore, Bedford, MA).

Plant Samples and Bacterial Strains. The leaves and fruits of pepper were obtained in a previous experiment.[18] Nonsterilized seeds of peper var. "sweet italian" were germinated in peat, according to the steps usually applied in the commercial process of seedling production, and were irrigated from a bottom reservoir with water every 48 h and with commercial Hoagland's solution (Sigma Co., USA) every 8 days. Each seed was inoculated with 1 mL of a suspension (2×10^8 cells/mL) of 5-day-old *Rhizobium* strains TPV08 and PETP01 grown on yeast-mannitol agar (YMA). Then they were covered with vermiculite and germinated in the dark, in a growth chamber at 24 °C, for seven days. Afterward they were maintained in a growth chamber with fluorescent lighting 400−700 nm and 400 microeinsteins/m^2/s, set to a photoperiod of 16 h/day with temperature varying from 25 to 27 °C and 50−60% relative humidity. Uninoculated controls were kept under the same conditions.

After four weeks, 25 plants/treatment were used for a microcosm experiment, developed in a clayey soil (neutral pH, 1.5−1.8% of organic matter and 0.09−0.1 of N content). The seedling roots were flooded in bacterial suspensions containing 2×10^8 cells/mL during 4 h. Each plant was transplanted to a pot containing 2 kg of soil. Plants were irrigated from a bottom reservoir with water every 48 h and with commercial Hoagland's solution every 8 days. The plants were kept in a greenhouse illuminated with natural light (night temperature ranging from 15 to 20 °C and day temperature ranging from 25 to 35 °C) and humidity control, for 10 weeks. At the end of the experiment, flowers and fruits were counted, fruits were harvested, and their fresh weight was measured.

Five plants per treatment were then randomly selected. They were frozen, lyophilized, and powdered (mean particle size lower than 910 μm), being divided into three aliquots and analyzed separately.

Analysis of Sterols and Triterpenes. *Extraction and Alkaline Hydrolysis.* Alkaline hydrolysis was performed to obtain the free forms following the procedure described by Silva et al.[19] with some modifications. Briefly, 0.50 g of lyophilized fruits and 0.25 g of lyophilized leaves were saponified by refluxing with 20 mL of 0.5 M ethanolic KOH for 1 h at constant temperature (80 °C). The mixture was then centrifuged at 4000 rpm for 3 min, decanted, and transferred to a separation funnel to extract the unsaponifiable fraction with *n*-hexane (3 × 10 mL). The organic phase was evaporated to dryness in a rotary evaporator. The residue was dissolved in 1 mL of methanol and then filtered through a 0.45 μm PTFE membrane. This procedure was performed in triplicate.

HPLC-DAD Analysis. Compounds were determined using the method described by Silva et al.[19] The extracts were analyzed on an analytical HPLC unit (Gilson) coupled to a diode array detector (Gilson). The compounds in each extract were identified by comparing their retention times and UV spectra with those of authentic standards. Quantification was achieved by measuring the absorbance recorded at 205 nm relative to external standards. This procedure was performed in triplicate.

Analysis of Fatty Acids. *Extraction and Derivatization.* The extraction and derivatization procedures were performed according to Silva et al.[19] Briefly, esterified fatty acids in 40 and 100 mg of lyophilized fruits and leaves, respectively, were hydrolyzed with methanolic KOH and derivatized to their methyl ester forms with BF_3 (10%) methanolic solution. The methyl ester derivatives were extracted with isooctane, and anhydrous sodium sulfate was added to ensure the total absence of water. The resulting extract was evaporated to dryness under a stream of nitrogen and redissolved in 400 μL of isooctane. All assays were performed in triplicate.

GC−IT/MS Analysis. Quantification of fatty acids followed the work by Silva et al.[19] The thermal desorption was performed in a Varian CP-3800 gas chromatograph (USA) coupled to a VARIAN Saturn 4000 mass selective detector (USA), and a Saturn GC/MS workstation software version 6.8. A VF-5 ms (30 m × 0.25 mm × 0.25 μm, FactorFour) column from VARIAN was used in the analysis. The injector port was heated to 250 °C, and injections were performed in split mode with a ratio of 1:40. The carrier gas was helium C-60 (Gasin, Portugal), at a constant flow of 1 mL/min. The oven temperature was set at 40 °C for 1 min, then increased 5 °C/min to 250 °C, 3 °C/min to 300 °C, and held for 15 min. 1 μL of the extracts was analyzed in Full Scan mode. The components were identified according to their retention indices relative to C_8−C_{20} *n*-alkanes and mass spectra, which were compared with those of the NIST 05MS Library Database (Match and R. Match >80%), pure standards analyzed under the same conditions and the NIST Chemistry WebBook. The amounts of fatty acid methyl esters (FAMEs) present in the extract were calculated from the calibration curve of the respective FAME standard. The FAME values were then converted to the respective fatty acid contents. The assays were performed in triplicate.

Volatile Compounds Analysis. *Headspace Solid Phase Microextraction (HS-SPME).* HS-SPME was performed according to Silva et al.[19] Briefly, fruits (100 mg) and leaves (150 mg) of *C. annuum* were stirred (500 rpm) with 5 mL of water and 2 g of NaCl at 45 °C, for 5 min. A divinylbenzene/polydimethylsiloxane (DVB/PDMS) 65 μm fiber was then exposed to the headspace for 10 min, with agitation (250 rpm) at 45 °C.

[a]Values are expressed as mean ± standard deviation of three assays. RT, retention time. Different letters in the same material and same row mean statistically significant differences ($p < 0.05$).

GC–IT/MS Analysis. The analysis of volatiles was performed as described by Silva et al.[19] The injector port was heated to 220 °C, and injections were performed in splitless mode. The carrier gas was helium C-60 (Gasin, Portugal), at a constant flow of 1 mL/min. Oven temperature was set at 40 °C (for 1 min), then increased 2 °C/min to 98 °C. All mass spectra were acquired in electron impact (EI) mode. Transfer line, manifold, and trap temperatures of the ion trap detector were set at 280, 50, and 180 °C, respectively. The emission current was 50 μA, and the electron multiplier was set in relative mode to auto tune procedure. The maximum ionization time was 25,000 μs, with an ionization storage level of 35–350 *m/z*. The analysis was performed in Full Scan mode. Compounds were identified according to their retention indices relative to C_8–C_{20} *n*-alkanes and mass spectra, which were compared with those of the NIST 05MS Library Database (Match and R. Match >80%), pure standards analyzed under the same conditions, NIST Chemistry Web-Book, and bibliography.[20−23] Each sample was analyzed in triplicate.

Statistical Analysis. All data were recorded as mean ± standard deviation of triplicate determinations. Mean values were compared by one-way analysis of variance (one-way ANOVA) (Graph Pad Prism Version 5.00, GraphPad Software, Inc., San Diego, CA). Differences were considered significant for $p < 0.05$.

Principal component analysis (PCA) was carried out using XLSTAT 2012 software. The PCA method shows similarities between samples projected on a plane and makes it possible to identify which variables determine these similarities and in what way.

RESULTS AND DISCUSSION

Profile of Sterols and Triterpenes. The analysis of the alkaline hydrolysis extracts by HPLC-DAD revealed a similar profile among *C. annuum* leaves, one triterpene (betulin) and three sterols (stigmasterol, campesterol, and β-sitosterol) being identified (Table 1). According to the literature, this is the first study about the sterols and triterpenes in *C. annuum* leaves. To evaluate the recovery of compounds, aliquots of betulin standard solution with known concentration were added to the samples, recoveries of 97% (±0.04) and 93% (±0.47) being obtained for fruits and leaves, respectively.

The total amounts of sterols and triterpenes in the leaves from all treatments ranged between 760.5 and 1025.6 mg/kg (Table 1). Concerning the effect of inoculation, we can observe a decrease of total compounds in the leaves from plants inoculated with strain TVP08, whereas those inoculated with strain PETP01 showed a total content higher than control. The decrease observed in leaves inoculated with TVP08 can be justified by higher use of these compounds (compared with PEPT01) in the synthesis of brassinosteroids during plant growth producing an increase in biomass.[24] Garcia-Freile et al.[18] reported a higher increase of plant weight with TVP08 than with PETP01.

Betulin was the main compound in the leaves of both inoculated and uninoculated plants, representing 64, 50, and 60% of the total content for control, PETP01, and TVP08, respectively (Table 1). A significant decrease of this compound was found in the leaves from plants inoculated with the strain TVP08 (Table 1), but no differences were found between the control leaves and those from plants inoculated with strain PETP01. The amounts of β-sitosterol and stigmasterol in leaves from plants inoculated with strain TVP08 were not affected, but campesterol content in these leaves was significantly higher. These three sterols significantly increased in leaves inoculated with strain PETP01.

The same four metabolites were found in the fruits of *C. annuum* (Table 1). As far as we know, with the exception of betulin, all compounds were already described in *C. annuum* fruits.[25,26] Besides these, Piironen et al.[25] reported the presence in *C. annuum* fruits of small amounts of brassicasterol, which was not found in the peppers analyzed in this study.

The amounts of sterols and triterpenes found in the fruits varied between 175.5 and 211.3 mg/kg (Table 1). As occurred in leaves, the total content increased when the plants were inoculated with the strain PETP01 and decreased when the strain TVP08 was used. Nevertheless, the amounts of stigmasterol were higher in fruits of inoculated plants.

Betulin was also the main compound in pepper fruits, representing 59, 58, and 63% of the identified metabolites in control fruits and in those inoculated with strains PETP01 and TVP08, respectively. As occurred in leaves, inoculation with strain TVP08 produced a significant decrease of betulin in pepper fruits. The amounts of stigmasterol increased significantly in both treatments. This is the first time that changes in the sterol content of *C. annuum* fruits is observed after *Rhizobium* inoculation. Nevertheless, differences were observed depending on the strain used for inoculation that can be related to the efficiency of each strain as PGPR, since strain TVP08 showed better characteristics (flower number, plant weight, and fruit size) in pepper production than PETP01.[18]

PGPR increase the vegetal growth through the synthesis of growth hormones, including brassinosteroids.[27] Indeed, the decrease of betulin and of some sterols (β-sitosterol and campesterol) in fruits from plants inoculated with the strain TVP08 can be justified because sterols are precursors and/or substrates of other biosynthetic pathways, such as the synthesis of brassinosteroids, involved in pepper production with an increase in the number of fruits.[24] As was previously reported, the pepper plants inoculated with the strain TVP08 presented higher fruit number[18] and these fruits were in a more advanced ripening stage than those from the other treatment (see part 1 of this work[17]).

Fatty Acids Profile. The fatty acids were determined by GC–IT/MS, which allowed the identification of 16 fatty acids in the fruits and leaves of *C. annuum* (Table 2). To evaluate the

[b]RT, retention time (min). [c]Results are expressed as mean ± standard deviation of three determinations (mg/kg). Different letters in the same material and same row mean statistically significant differences compared with control sample ($p < 0.05$); nd, not detected.

fatty acids recovery, aliquots of oleic acid standard solution with known concentration were added to the samples, recovering 99% (±0.7) and 81% (±1.7) for fruits and leaves, respectively.

Whitaker[28] described the lipid composition of leaves from several species of the Solanaceae family, reporting the presence of five fatty acids in *C. annuum* leaves: palmitic (C16:0), palmitoleic (C16:1), stearic (C18:0), oleic (C18:1c), and linoleic (C18:2). The remaining fatty acids are being described in leaves for the first time.

The control leaves exhibited the highest total fatty acids content (5929.4 mg/kg). In inoculated samples, the concentrations corresponded to 1973.0 and 3263.1 mg/kg for leaves from plants inoculated with strains PETP01 and TVP08, respectively (Table 2). Stearic acid (C18:0) was the major one in control leaves (37% of total fatty acids), and oleic acid (C18:1c) was the main one in leaves inoculated with PETP01 (43%) and TVP08 strains (38%).

SFAs represent 43 to 77% of the total fatty acids contents (Table 2), stearic acid (C18:0) being the major one. Concerning unsaturated fatty acids, samples were richer in MUFAs (Table 2). Within this class, the main compound is oleic acid, ranging between 93 and 99% of MUFAs. In general, the inoculation with *Rhizobium* produced significant decreases in fatty acids content. However, significant increases of linoleic acid (C18:2) were observed in all inoculated treatments, of palmitoleic (C16:1) and oleic (C18:1c) acids in leaves inoculated with strain TVP08, and of heneicosanoic acid (C21:0) in those inoculated with strain PETP01.

In fruits of *C. annuum* 14 fatty acids were determined (Table 2). Pentadecanoic (C15:0), elaidic (C18:1t), heneicosanoic

(C21:0), tricosanoic (C23:0), and lignoceric (C24:0) acids are described here for the first time in this matrix. The remaining fatty acids were already previously reported in fruits of *C. annuum*, palmitic (C16:0), stearic (C18:0), oleic (C18:1c), and linoleic (C18:2) acids being confirmed as the main ones.[28−30]

The total contents of fatty acids found in the analyzed fruits varied between 7617.3 and 22638.0 mg/kg (Table 2). The fatty acid profiles are mainly composed of SFAs, showing values that ranged between 67 and 89% of total compounds. Within the class of unsaturated fatty acids, control and fruits inoculated with TVP08 strain are richer in MUFAs, especially oleic acid (C18:1c), whereas the fruits inoculated with strain PETP01 are richer in PUFAs, linoleic acid being the only PUFA found.

In agreement with the results obtained by other authors,[28,30,31] palmitic (C16:0) and stearic (C18:0) acids were the main fatty acids in the fruits from all treatments: the first represented 27, 30, and 35% and the second 23, 31, and 27% of total amounts of fatty acids quantified in control and inoculated samples with strains TVP08 and PETP01, respectively.

The inoculated fruits showed a higher total content of fatty acids, those inoculated with the strain TVP08 having contents three times higher than controls (Table 2). Individually, the

inoculation produced significant increases in several fatty acids, like pentadecanoic (C15:0), palmitic (C16:0), stearic (C18:0), and arachidic (C20:0), some of them with antimicrobial properties.[32] This effect is probably related to the maturation of the fruit since the highest increase was found in pepper fruits from plants inoculated with strain TVP08, with the higher potential in advancing fruit ripening (see part 1 of this work[17]). The fatty acids contents obtained in this work are similar to those found in peppers var. "green italian".[30] The increase of fatty acid contents, such as those of myristic (C14:0), palmitic (C16:0), stearic (C18:0), arachidic (C20:0), and behenic (C22:0) acids, has been reported in other fruits during ripening.[33]

Volatiles Profile. Although the volatile compounds in pepper fruits have already been studied, as far as we know, this is the first study on the volatile profile of the leaves, in which 26 compounds from several chemical classes were identified (Table 3).

The results showed that the leaves of plants inoculated with the two strains of *Rhizobium* (PETP01 and TVP08) are richer in these compounds than control material. All inoculated leaves showed higher levels of esters, namely, of methyl salicylate, which is the major volatile compound. Aldehydes are the second main class in control and in the material inoculated with PETP01 strain, (*E*,*E*)-2,4-heptadienal being the most abundant compound. Norisoprenoids were the second main class of

compounds in leaves inoculated with TVP08, β-ionone being the major volatile.

Leaves from plants inoculated with both strains PETP01 and TVP08 also exhibited increases of monoterpenes and miscellaneous compounds.

In *C. annuum* fruits 24 volatiles were characterized (Table 4), methyl salicylate and 2-isobutyl-3-methoxypyrazine being the main compounds in all analyzed samples. The identified compounds have been previously reported in pepper fruits,[34−39] with the exception of camphor and longifolene, which are described for the first time in fruits of *C. annuum*. Camphor, heptanal, and camphene were detected only in the fruits from inoculated plants (Table 4).

As occurred in leaves, the fruits from inoculated plants exhibited increased levels of aldehydes and esters; however, unlike the leaves, a decrease of monoterpenes, norisoprenoids, and 2-isobutyl-3-methoxypyrazine was observed (Table 4). Individually, all aldehydes increased with inoculation, except 3-methylbutanal, 2-methylbutanal, and benzaldehyde in the fruits from plants inoculated with TVP08 strain. The increase of volatiles like (*E*)-2-hexenal, (*E*)-2-octenal, and (*E*)-2-nonenal in fruits from inoculated plants can be associated with their intervention in plant defense, since these compounds are described as antimicrobials.[40] Concerning esters, the inoculated fruits showed significantly increased levels of methyl salicylate, a derivative of salicylic acid that may be accumulated at high levels in plants. Salicylic acid has been related, together with jasmonic acid, with systemic resistance (SAR) in plants,[14] and recently it has been reported that methyl salicylate is involved in long-distance communication and signal amplification in SAR.[41] Therefore, our results suggest that *Rhizobium* could elicit a long-distance systemic response *via* methyl salicylate, which is an unknown mechanism in PGPR to date.

PCA Analysis. The results obtained for volatiles, sterols, triterpenes, and fatty acids were analyzed by PCA to assess the influence of inoculation in their contents of the fruits and leaves more thoroughly. Figure 1 shows the projection of variables, grouped by chemical classes obtained for the three fruits and three leaves in the plane composed by principal axes F1 and F2, containing 84.5% of the total variance (Figure 1).

Fruits and leaves are clearly separated into the F1 axis; fruits are disposed in the negative section and leaves in the positive one. Leaves showed higher amounts in aldehydes, alcohols, ketones, norisoprenoids, triterpenes, esters, monoterpenes, sesquiterpenes, and sterols; on the other hand, fruits showed higher levels of miscellaneous compounds and fatty acids (Figure 1, Tables 1−4).

Control and fruits from plants inoculated with TVP08 are closely related due to their higher amounts of MUFA and miscellaneous compounds. Both samples are projected in the plane formed by negative F1 and positive F2 axes, 2-isobutyl-3-methoxypyrazine and oleic acid (C18:1c) being the main compounds (Figure 1, Tables 2 and 4).

The projection of fruit samples from plants inoculated with strain PETP01 is related to higher contents of PUFA, due to the higher linoleic acid (C18:2) content (Figure 1, Table 2).

The leaf samples from inoculated plants are projected in the plane formed by the F1 and F2 positive axes, while control leaves are projected into the plane formed by F1 positive and F2 negative axes (Figure 1). This separation may be due to the richness in SFA and ketones and lower contents of esters, monoterpenes, sesquiterpenes, and miscellaneous compounds in control sample (Tables 1 and 3).

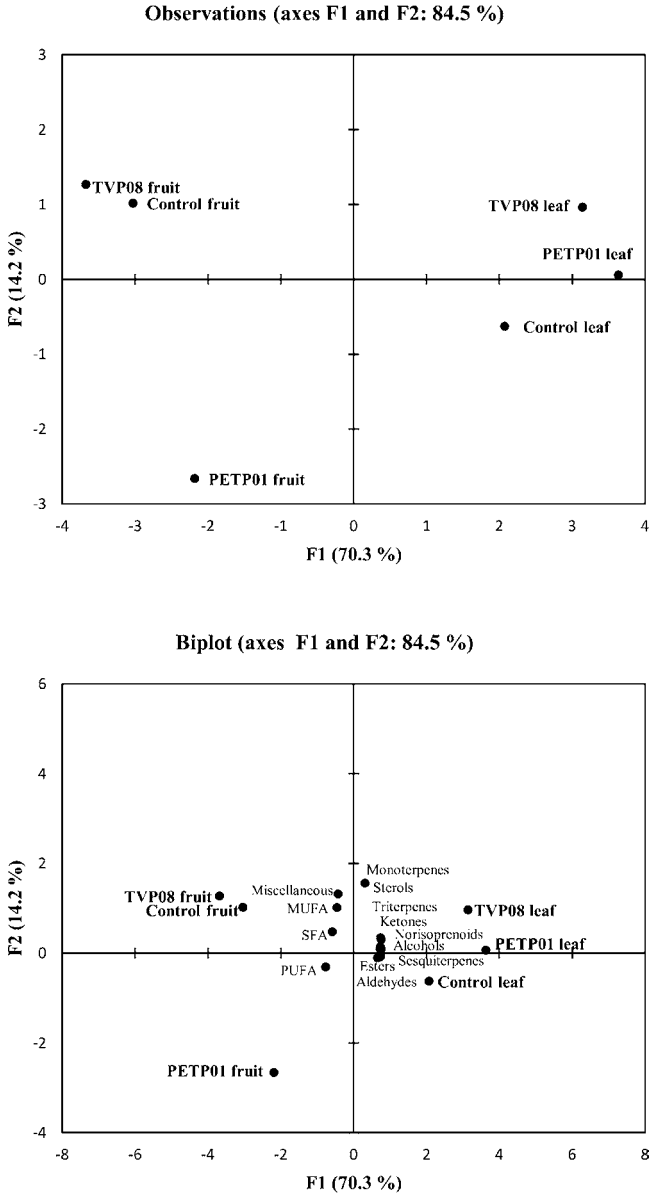

Figure 1. PCA of volatile compounds, sterols, triterpenes, and fatty acids in fruits and leaves of *C. annuum*: projection of volatile compounds (variables: total of monoterpenes, sesquiterpenes, aldehydes, ketones, alcohols, esters, norisoprenoids, miscellaneous compounds, sterols, triterpenes, and saturated (SFA), monounsaturated (MUFA), and polyunsaturated (PUFA) fatty acids; control leaf, PETP01 leaf, TVP08 leaf, control fruit, PETP01 fruit, and TVP08 fruit) in the plane composed by the principal axes F1 and F2.

In summary, the data obtained from sterol and fatty acids contents confirmed those obtained in part 1 of this work,[17] showing that the inoculation of *Rhizobium* has a positive effect on pepper fruit ripening. The increase of some primary and secondary metabolites in *C. annuum* materials by inoculation of PGPR may be beneficial to the plant, improving its nutritional value, which might contribute to an increase in the consumption of pepper. Moreover, the increase of content of volatile compounds, some of them involved in plant defense, was clearly demonstrated. Overall, the results of this work suggest that the inoculation with PGPR *Rhizobium* strains may be employed to manipulate the content of interesting

metabolites in pepper leaves and fruits, increasing the health benefits and the defense abilities of the plants.

ABSTRACT: Phenolic products are highly demanded by the food and cosmetics industries and consumers due to their high antioxidant activities. To evaluate the potential of crabapples (*Malus* wild species) in preparing phenolic extracts, fruits of 10 crabapples grown in China were separately extracted with 80% (v/v) ethanol and ethyl acetate and the phenolic profiles, polyphenol (PC) and flavonoid contents (FC), and antioxidant activities of the extracts were analyzed. Chlorogenic acid, (−)-epicatechin, rutin, hyperin, and phlorizin appeared as the major phenolic compounds in all phenolic extracts. Ethanol extracts had PC of 302.83−1265.94 mg GAE/100g and FC of 352.45−2351.74 mg RE/100g, being 4.17 and 4.49 times those obtained in ethyl acetate extracts and much higher than those previously reported in apples. *Malus* wild species appeared as rich sources of phenolic compounds with high antioxidant activity, especially when high chlorogenic acid and rutin contents are emphasized.

KEYWORDS: *wild apple, polyphenol, flavonoid, antioxidant activity*

INTRODUCTION

Phenolic compounds are of particular interest to food processors and consumers because they play a key role in preventing oxidation processes in human.[1,2] They are also highly valued as they possess high antioxidant activities.[3,4] Phenolic extracts are in high demand in the cosmetics and food industries due to their many functions promoting health benefits and preventing human diseases, such as reducing the occurrence of cancer,[5] anti-inflammation,[6−8] decreasing blood pressure,[9] resisting neurodegenerative disorders,[10] modulating gut microbial composition,[11] preventing obesity,[12] and protecting against acute oxidative damage.[13] Polyphenols derived from natural plants are used in edible oil, ham, cakes, chocolate, and other foods to prevent spoilage caused by oxidation and inhibit the generation of nitrosamines in these foods. Apple pomace is currently developed as a major source of phenolic compounds due to its high phenolic content and widespread occurrence in the world. To make apple trees more resistant to disease and suitable for diverse environments, *Malus* wild species are widely used as rootstocks in apple breeding besides being of importance in ecological diversity and use as an ornamental and economic *Malus* germplasm resource.[14]

Phenolic extracts are usually prepared using different solvents according to the solubility of the major phenolic compounds in the materials. Agourram et al. found 80% (v/v) aqueous acetone was more effective than 80% (v/v) aqueous methanol and 80% (v/v) aqueous ethanol in preparing phenolic extracts from fruit and vegetable byproducts.[15] However, Seo et al. found ethanol was more efficient in producing phenolic extracts from *Smilax china* L. leaf with higher antioxidant activity and total phenolic content than methanol, acetone, or water,[16] whereas Katalinić et al.[17] reported 80% (v/v) aqueous ethanol was efficient in the extraction of phenolic compounds from many plant materials. Eighty percent (v/v) aqueous methanol,[18] 80% (v/v) aqueous ethanol,[19] and 70% (v/v) aqueous acetone[20] have also been used to extract phenolic compounds from apples (*Malus*) and resulted in high phenolic containing extracts. From the toxicological point of view, ethanol and water are safer than methanol and other organic solvents.[21] However, it should be mentioned that ethyl acetate is normally used to prepare the phenolic extracts in the assays of obtaining phenolic profiles using high-performance liquid chromatography (RP-HPLC).[22−25] Furthermore, ethyl acetate is more efficacious with respect to aqueous ethanol in extracting carotenoids, and apples are known to be rich in this class of compounds. More importantly, these extraction solvents can be easily removed from the obtained phenolic extracts by evaporation, and thus there is opportunity to use these solvents to extract polyphenols for food, pharmaceutical, or cosmetics application.[26] In addition, the diversity in obtained phenolic profiles is theoretically expected when different extraction solvents are used in the preparation of phenolic extracts. However, this has not been comprehensively investigated before.

[a]Means of 3 replicates ± standard errors or standard deviation.

Phenolic profiles of apple fruits have been extensively studied. Apple is found to be abundant in vitamin C,[27] flavonoids,[9] and polyphenols and has high antioxidant capacity.[4,28,29] Apple juice has been reported to have strong inhibitory activity on the proliferation of HL-60 human leukemia cells.[30] Belonging to *Malus* species, crabapples are supposed to possess similar nutrients, particularly phenolic compounds, as apples. However, no information of phenolic content and phenolic profiles of crabapples has been found in the literature.

To characterize the phenolic profile, phenolic contents, and antioxidant activity of different *Malus* wild species and to evaluate the potential of these species in producing phenolic extracts, 10 different crabapples grown in China were collected and analyzed. Ethanol and ethyl acetate were both used in aspects of the above characteristics to compare which is better in preparing phenolic extracts with high phenolic content and antioxidant activities.

MATERIALS AND METHODS

Chemicals. Folin−Ciocalteu reagent, 2,2-diphenyl-1-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzenothiazoline-6-sulfonic) (ABTS), 2,4,6-tri(2-pyridyl)-*s*-triazine (TPTZ), 6-hydroxy-2,5,7,8-teramethyl-chroman-2-carboxylic acid (Trolox), methanol, and phosphoric acid (HPLC grade) were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Gallic acid, protocatechuic acid, (+)-catechin, chlorogenic acid, caffeic acid, (−)-epicatechin, *p*-coumaric acid, ferulic acid, rutin, hyperin, phlorizin, and quercetin (>98%) were purchased from Shanghai Winherb Medical Science Co., Ltd. (Shanghai, China). Ethanol, ethyl acetate, Na_2CO_3, $NaNO_2$, $AlCl_3$, NaOH, $K_2S_2O_8$, CH_3COONa, CH_3COOH, HCl, and $FeCl_3$ were from local reagent shops in Xi'an, China. All chemicals were of analytical grade. Water was prepared by purification with a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Fruit of Crabapples. Fruits of 10 wild *Malus* species were collected from the garden of germplasm resources in Institute of Pomology, Chinese Academy of Agricultural Sciences (Xingcheng, Liaoning provionce). No manual protection was carried out during the whole growing season. All fruits were picked by hand at their ripeness season in September 2012 and immediately cooled and stored at −20 °C before the extraction and measurement were carried out within 1 month. The cross-sectional diameter of the fruits was measured using a vernier caliper (Xigong, Jiangsu, China). The main features of the analyzed fruits are reported in Table 1.

Blanching of Crabapple Fruits. The fruits of different wild *Malus* species were treated according to the method previously reported by McGhie et al.[19] and Lin et al.[31] with slight modification. In brief, 100 g of fruit was cut into slices in approximately 3 mm thickness. The slices were subjected to steam blanching for 1 min and then immediately taken out and placed in a refrigerator (Haier, Qingdao, China) for cooling.

Preparation of Phenolic Extracts. Eighty percent aqueous ethanol and ethyl acetate were separately used to extract the cooled crabapple slices according to the methods reported by Zhao et al.[32] and Kong et al.[33] with slight modification. Briefly, sliced and blanched crabapples were ground to a fine jam using a blender (Media, Foshan, China). A 5 g jam sample was weighed and then separately extracted with 25 mL of 80% aqueous ethanol and ethyl acetate. The extraction was conducted for 30 min at 20 °C in a Unique-1400A ultrasonic bath (Shumei, Kunshan, China) at a power of 250 W. After the extraction, centrifugation at 8000*g* was carried out for 10 min. The supernatant was collected, and the residue was extracted and centrifuged again two more times. The supernatants of each extraction solvent were combined and evaporated to dry powder using an R-210 vacuum rotary evaporator (Büchi, Flawil, Switzerland) at 40 °C. The dry residues were dissolved in 10 mL of 50% aqueous methanol and stored at −20 °C for measurements of polyphenol content, flavonoid content, antioxidant activity, and phenolic profiles by high-performance liquid chromatography (HPLC).

Measurement of Polyphenol and Flavonoid Contents. Measurement of polyphenol content (PC) was carried out using a modified colorimetric Folin−Ciocalteu method at 765 nm.[34] In summary, 0.2 mL of extract was mixed with 1.0 mL of deionized water and 1.0 mL of freshly prepared Folin−Ciocalteu reagent (diluted 10-fold in water). The mixing process was performed for 5 min before 0.8 mL of 7.5% (w/v) Na_2CO_3 solution was added. The above mixture was incubated at 25 °C in darkness for 30 min. Absorbance was obtained using a UVmini-1240 spectrophotometer (Shimadzu, Tokyo, Japan). A standard curve was created using gallic acid. Additional dilution was carried out when the measured absorbance value outranged the linear range of the standard curve. Results were expressed as milligrams of gallic acid equivalent per 100 g of fresh weight (mg GAE/100 g).

Flavonoid content (FC) was determined using the colorimetric method at 510 nm according to the method of Wolfe et al.[35] with slight modification. In brief, a 0.5 mL extract sample was mixed with 1.0 mL of deionized water and 0.15 mL of a 50 g/L $NaNO_2$ solution. After 5 min, 0.3 mL of $AlCl_3$ (100 g/L) was added. The mixture was incubated at 25 °C for 6 min, followed by the addition of 1.0 mL 1 mol/L NaOH before absorbance reading. A standard curve was made using rutin. Additional dilution was carried out when the measured absorbance value outranged the linear range of the standard curve. Results were expressed as milligrams of rutin equivalents per 100 g of fresh weight (mg RE/100 g).

Antioxidant Activity Assays. The DPPH assay was performed according to the method reported by Ma et al.[36] with minor modifications. A 50 μL extract was mixed with 2.0 mL of a 6.0×10^{-5} mol/L ethanol solution containing DPPH. After incubation at 25 °C for 30 min, the absorbance at 517 nm was read. A standard solution of Trolox was used to prepare a calibration curve. Results were expressed as micromoles of Trolox equivalent antioxidant capacity per 100 g ± SD fresh weight (μmol TE/100 g).

The ABTS assay was carried out according to the method described by Tai et al.[37] with slight modification. ABTS radical cation ($ABTS^{\bullet+}$)

was produced by reacting a 7 mmol/L ABTS solution with 140 mmol/L $K_2S_2O_8$, and the mixture was kept in the dark at room temperature for 12−16 h before use. For each assay, the above stored solution was freshly diluted with ethanol until the absorbance at 734 nm reached 0.700 ± 0.05. In the measurement, 25 μL of phenolic extract was allowed to react with 3.0 mL of $ABTS^{\bullet+}$ solution at 25 °C for 30 min. Then the absorbance was taken at 734 nm. Results wee reported as micromoles of Trolox equivalent antioxidant capacity per 100 g ± SD fresh weight (μmol TE/100 g).

The FRAP assay was performed according to the method described by Ma et al.[36] with slight modification. The stock solutions included 300 mmol/L acetate buffer (pH 3.6), 10 mmol/L TPTZ in 40 mmol/L HCl, and 20 mmol/L $FeCl_3$. A fresh working FRAP solution was prepared using the above stock solution in ratio of 25 mL of acetate buffer, 2.5 mL of TPTZ solution, and 2.5 mL of $FeCl_3$ solution. Twenty-five microliters of phenolic extract was allowed to react with 3.0 mL of fresh FRAP solution for 10 min at 37 °C. Readings of the colored product were taken at 593 nm. Results are reported as micromoles of Trolox equivalent antioxidant capacity per 100 g ± SD fresh weight (μmol TE/100 g).

Analysis of Phenolic Profiles. The phenolic profiles of phenolic extracts were measured using HPLC after a filtration through a 0.45 μm filter. The HPLC analysis was carried out using a Waters 600E HPLC system (Waters, Milford, MA, USA) equipped with a Waters 2487UV detector and a Waters Symmetry C18 reversed-phase column (250 × 4.6 mm, 5 μm). The mobile phase consisted of solvent A (methanol) and solvent B [water−phosphoric acid (pH 2.6)] using the following gradient program: 0−15 min, 15−25% solvent A; 15−25 min, 25% solvent A; 25−65 min, 25−75% solvent A; 65−70 min, 75−15% solvent A. All of the polyphenol and flavonoid standards were prepared in 50% methanol solution. The flow rate was kept constant at 1.0 mL/min throughout the measurement. The column temperature was set at 30 °C, and the injection volume was 5 μL. The UV detection wavelength was monitored at 280 nm because the phenolic extracts had obvious absorption peaks at 280 nm, but not at 320 and 350 nm. In addition, solely reading at 280 nm was also performed in phenolic analysis by Bhaskar et al.,[38] Łata et al.,[39] and Du et al.[40] Individual phenols and flavonoids in the sample were identified on the basis of comparison of their UV−vis spectra and retention times with the corresponding standards.

RESULTS AND DISCUSSION

Polyphenol and Flavonoid Contents. The PC and FC values obtained from ethanol extracts were significantly ($P < 0.01$) higher than those from ethyl acetate extracts (Figure 1). For wild *Malus* species of Xiaojin (*Malus xiaojinensis* Cheng et Jiang), the FC value obtained from ethanol extract was nearly 14-fold that obtained from ethyl acetate extract. A similar trend was also found by NurulMarian et al.[41] for *Barrington racemosa* leaves. Theoretically, different extraction solvents are greatly diverse in polarity, and therefore extracting abilities of different compounds are different.[33,42,43] Polyphenol and flavonoid are both polar due to their polyhydroxyl groups. Normally, the less polar solvents (ether, benzene, and chloroform) are effective in extracting aglycone flavonoids and more polar solvents (acetone, ethyl acetate, alcohol, and water) are effective in extracting glycoside flavonoids.[44] Also, phenolic compounds have higher solubility in higher polarity solvents,[45,46] such as ethanol. Ethyl acetate is comparatively more efficacious than aqueous ethanol in extracting carotenoids.[33] The higher values of PC and FC obtained in ethanol extracts than in ethyl acetate extracts illustrated that the phenolic and flavonoid compounds in crabapples are of high polarity.

In detail, PC values ranged from 302.83 to 1265.94 mg GAE/100 g (Figure 1A) with an average of 566.58 mg GAE/100 g (Table 2) for the ethanol extracts and from 62.96 to 215.21 mg GAE/100 g (Figure 1A) with an average of 135.97 mg GAE/100 g (Table 2) for ethyl acetate extracts. FC values ranged from 352.45 to 2351.74 mg RE/100 g (Figure 1B) with an average of 965.05 mg RE/100 g (Table 2) for ethanol extracts and from 83.77 to 369.21 mg RE/100 g (Figure 1B) with an average of 214.90 mg RE/100 g (Table 2) for ethyl acetate extracts. The average values of PC and FC in all ethanol extracts were 4.17- and 4.49-fold, respectively, of those in ethyl acetate extracts. Lijiang-shanjingzi (*Malus rockii* Rehder) had the highest values of PC and FC in both ethanol and ethyl acetate extracts, whereas Huaguan (*Malus coronaria* (L.) Mill.) had the lowest ones.

In addition, the HPLC data of total polyphenols were much lower than those obtained in Folin−Ciocalteu analysis. This is because the total amount of phenolic content was under-

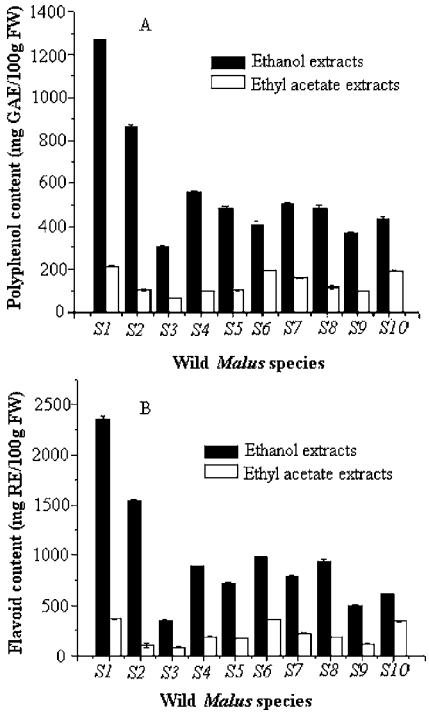

Figure 1. Polyphenol content (A) and flavonoid content (B) of 10 wild *Malus* species. Data are the means of three replicates ± standard deviation.

Table 2. Comparison of Polyphenol Contents and Antioxidant Activities of All *Malus* Wild Species Obtained in Different Solvent Extracts

	ethanol extracts[a]	ethyl acetate extracts[b]	ratio[c]

estimated in HPLC analysis at 280 nm and Folin−Ciocalteu data were increased due to the interference caused from other chemical components existing in the extracts, such as sugars and ascorbic acid.[47] Also, the Folin−Ciocalteu method gives different results in the semiquantification of polyphenols depending on the kind of prevalent classes of polyphenols present in the extracts.[48,49] However, the Folin−Ciocalteu procedure still provides a rapid and useful overall evaluation of the phenolic content of extracts.[50]

It should be mentioned that the PC values in ethanol extracts of the tested wild *Malus* species in the study were much higher than those reported for cultivated apple varieties, such as Fuji (167.11 mg GAE/100 g), EpagriCOOP24 (180.39 mg GAE/100 g), and EpagriF5P283 (233.57 mg GAE/100 g).[28] This is easy to understand because different varieties accumulate different quantities of polyphenols. However, the influence of environment may be another important contributor to the high value of phenolic contents in various *Malus* species. Environmental factors, such as climatic factors of soil type, sun exposure, rainfall, agronomic factors of biological culture, hydroponic culture, and fruit yield per tree, and the degree of ripeness affect the concentrations and proportions of different polyphenols in fruits.[51] The influence of agronomic factors can be verified by using principal component analysis (PCA) in the analysis of polyphenol indices in apple juice[52] and apple fruits.[53] Exposure to fungal infection is also an important role for the high accumulation of phenolic compounds in plants, such as resveratrol, to promote disease resistance.[54,55] Wild *Malus* species grow in various environments without any manual protection. Exposure to harsh environments and fungal infection might be another important reason for the high value of phenolic compounds in the wild *Malus* fruits used. In any case, it can be concluded that wild *Malus* species are good materials to prepare phenolic extracts.

Antioxidant Activity. *Radical-Scavenging Activity (DPPH and ABTS Assays).* Panels A and B of Figure 2 present the results of DPPH and ABTS assays, respectively. Consistent with that found in PC and FC, ethanol extracts had nearly 6-fold higher DPPH values and 5-fold higher ABTS values than ethyl acetate extracts on average. The higher values of DPPH and ABTS in ethanol extracts than in ethyl acetate extracts were also true for each wild *Malus* species. Also, similar to PC and FC, Lijiang-shanjingzi (*Malus rockii* Rehder) possessed the highest values of DPPH (3789.25 μmol TE/100 g) and ABTS (13056.68 μmol TE/100 g).

Ferric Reducing Antioxidant Power (FRAP Assay). Figure 2C shows that the FRAP values of ethanol extracts were significantly ($P < 0.01$) higher than those of ethyl acetate extracts. Particularly, the average FRAP value of ethanol extracts was almost 6 times higher than that in ethyl acetate extracts. For Xiaojin (*Malus xiaojinensis* Cheng et Jiang), the FRAP value of ethanol extract (6671.79 μmol TE/100 g) was nearly 54 times higher than that of ethyl acetate extract. Lijiang-shanjingzi (*Malus rockii* Rehder) still had the highest FRAP values in both ethanol extract (9356.14 μmol TE/100 g) and ethyl acetate extract (1181.94 mg GAE/100 g).

The antioxidant activity values obtained for most wild *Malus* species were significantly higher than that obtained in apple peel, from 1004.00 to 3877.73 μmol TE/100 g in DPPH assay, from 1225.53 to 4144.97 μmol TE/100 g in ABTS assay, and from 520.71 to 1160.58 μmol TE/100 g in FRAP assay,[4] even though apple peel had significantly higher antioxidant activity values than other parts of apple fruits.[4,19,50] In the present study, the antioxidant activity of whole fruits of wild *Malus* species, particularly Lijiang-shanjingzi (*Malus rockii* Rehder), was much higher than the reported value of apple peel, indicating *Malus* fruits are rich sources for preparing extracts with high antioxidant activities.

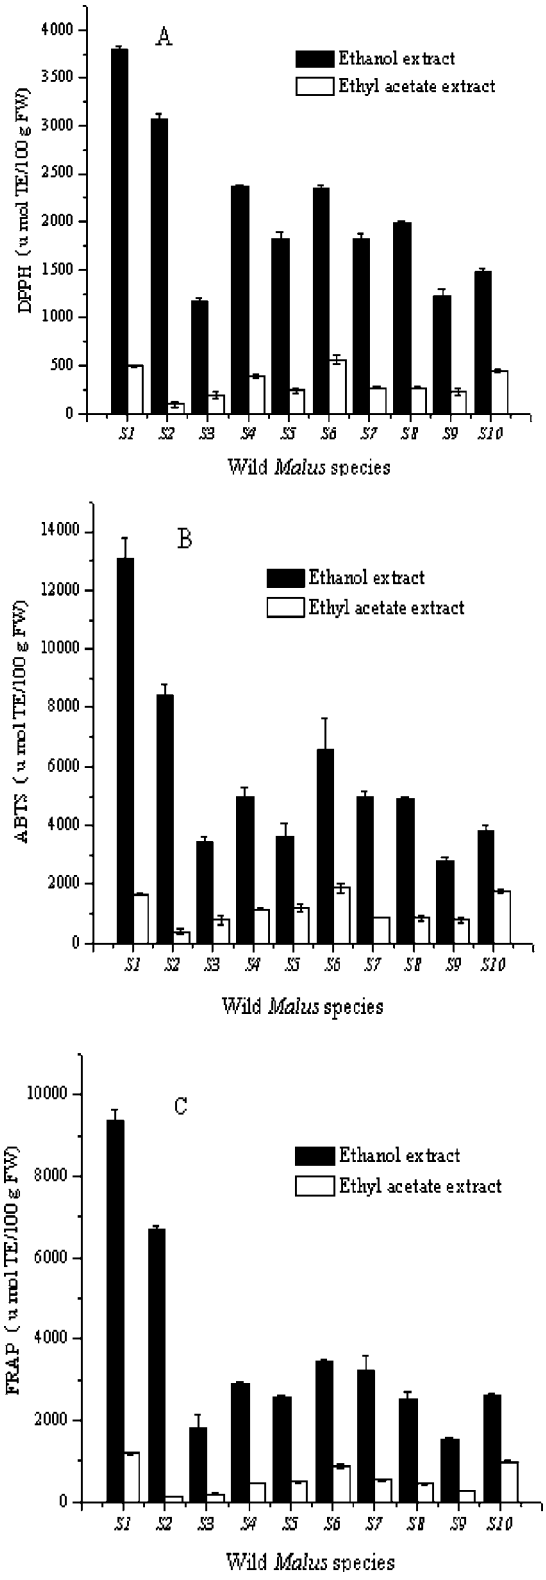

Figure 2. Antioxidant activities of 10 wild *Malus* species measured by DPPH (A), ABTS (B), and FRAP (C) assays. Data are the means of three replicates ± standard deviation.

Correlation Analysis. A correlation analysis was performed to investigate the relationship among PC, FC, DPPH, ABTS, and FRAP. The linear correlation coefficients are shown in Table 3. The results of PC and FC from ethanol extracts and ethyl acetate extracts were significantly and positively correlated with the antioxidant activity analysis values, including DPPH, ABTS, and FRAP. PC and FC were also significantly correlated with DPPH, ABTS, and FRAP for each used extraction solvent. Comparatively, the correlation between PC and antioxidant activity (DPPH, ABTS, and FRAP assays) was more significant (0.927, 0.944, and 0.975) in ethanol extracts, indicating more active polyphenols and flavonoids were extracted using ethanol. Although ethyl acetate is more efficacious than aqueous ethanol in extracting carotenoids, carotenoid content was reported to be negatively related to all of the antioxidant assays.[33] Therefore, aqueous ethanol is more efficacious for preparing phenolic extracts with high antioxidant activities than ethyl acetate.

Phenolic Profiles. Figure 3 shows the HPLC profiles at 280 nm of phenolic compounds of standards and of ethanol extract and ethyl acetate extract of Lijiang-shanjingzi (*Malus rockii* Rehder). Table 4 shows the obtained data of each phenol detected. It can be seen that the phenolic profiles differed when different extraction solvents were used. Chlorogenic acid, (−)-epicatechin, rutin, hyperin, and phlorizin were detected in both ethanol and ethyl acetate extracts of all tested wild *Malus* species. Caffeic acid, *p*-coumaric acid, and ferulic acid were detected in only some species. The occurrence of protocatechuic acid, (+)-catechin, and quercetin in the two different extracts was not consistent in some samples. Even for the same wild *Malus* species, the obtained phenolic profiles were different, which depends upon the extraction solvents used. For all tested species, the contents of chlorogenic acid and rutin were much higher in ethanol extracts than in ethyl acetate extracts.

It should be mentioned that phenolic profiles in HPLC analysis are not only related to the extraction solvents used but also depend on the wavelength used for measurement. Measurement of absorption at 280 nm is totally appropriate for monomeric and oligomeric proanthocyanidins, such as (+)-catechin and (−)-epicatechin, but not for the other individual compounds that have maximum absorbance at 369 nm (quercetin) and 320−340 nm (caffeic, *p*-coumaric acid, and ferulic acid). Valavanidis et al.[56] performed readings at 280, 320, and 350 nm and found that chlorogenic acid, catechin, procyanidins B1 and B2, and phloridzin were important polyphenol compounds in both organic and conventional apples. In the current study, reading was performed only at 280 nm using the external standard methods reported by Bhasker et al. in dietary fiber measurement,[38] Łata et al. in apple,[39] and Du et al. in jujubes.[40] The obtained data of caffeic acid, *p*-coumaric acid, and ferulic acid may be underestimated because 280 nm is

not the maximum wavelength of these compounds. This might be one reason these phenolic compounds were occasionally and rarely detected in tested crabapples. For more precise analysis, readings should be performed at different wavelengths.

The obtained results were comparable with those reported by Łata et al.,[39] who performed HPLC analysis at 280 nm, the same as used in this study. They reported that chlorogenic acid, flavan-3-ols, rutin, and phloridzin presented the greatest amounts of phenolic compounds detected in whole apple fruits. Phloridzin is a dihydrochalcone and has been reported as the typical phenol in bark, leaves of apple trees, and apple fruits.[7,57] The similarity of the occurrence of phloridzin in apple and wild *Malus* species may be because they belong to the rose family known as Rosaceae. The obtained high content of chlorogenic acid in all wild *Malus* species was also consistent with previous results.[58] Comparatively, the chlorogenic acid, rutin, and phlorizin contents in all tested wild *Malus* species were higher than those reported in apples.

Inconsistent occurrence and low contents of caffeic acid, *p*-coumaric acid, and ferulic acidin in ethanol and ethyl acetate extracts of the tested wild *Malus* species might be because these compounds were not major phenolic compounds in Rosaceae, although they were abundant in wheat,[59] oat,[60−62] and rice.[63] This may be caused by the different regulations of phenolic metabolism in the plant family and grass family.

On the basis of the above results, it is concluded that fruits of wild *Malus* species are good sources for preparing phenolic extracts having high contents of chlorogenic acid, rutin, and phlorizin and having high antioxidant activity, indicating great potential in replacing apple pomace in producing phenolic extracts. In addition, extraction solvents had significant influence on the quality of phenolic extracts, and 80% ethanol was more effective than ethyl acetate in extracting phenolic compounds from wild *Malus* species.

ABSTRACT: The anodic oxidation of mercury in the presence of hydrogen peroxide in differential pulse voltammetry (DPV) was used to determine the antioxidant (AO) character of radical scavengers. Hydroperoxide radical is formed at the potentials of the oxidation peak on mercury electrodes, such radical reacting with the antioxidants in different extension. The parameter C_{10} (antioxidant concentration at which the peak area decreases by 10%) is used to measure the scavenging activity of the individual antioxidants. To establish the scavenging activity of antioxidant mixtures as a whole, the parameter, μ_{10} as the reverse of V_{10}, V_{10} being the volume necessary to decrease the peak area in DPV by 10%, was selected. Higher μ_{10} values correspond to higher scavenging activity. The studies have been extended to aqueous extracts of some species. The results may be useful in explaining the effect of spices in vitro and in vivo studies.

KEYWORDS: *hydroperoxide radical, radical scavengers, antioxidant activity, spices, cinnamon, clove, numteg, oregano, thyme*

INTRODUCTION

Oxidative stress is defined as the excessive production of reactive oxygen species (ROS) and/or deficiency of the antioxidant cellular defense system. The ROS play a major role in causing antioxidant stress and damage to DNA, proteins, and lipids.[1] Free radical mediated cell damage has been implicated in the pathology of various human chronic diseases such as Alzheimer's, Parkinson's, Crohn's, and certain cancers.[2,3] In addition to endogenous antioxidant systems, a diet rich in antioxidant food products also protects DNA and increases resistance against oxidative stress. Spices may offer many health benefits and have been proven to counteract oxidative stress over in vitro and in vivo systems.[4,5]

Primary antioxidants (pro-oxidants) prevent the formation of free radicals,[6] particularly ROS. Secondary antioxidants (antioxidants with radical scavenging activity) interrupt the propagation of free radicals, inhibit the generation of ROS, and prevent the metabolic activation of carcinogens.[7,8] Tertiary antioxidants repair the damage from free radicals or eliminate damaged molecules.[9,10]

Direct and indirect methods have been proposed to evaluate the antioxidant activity of natural products.[11] Electrochemical measurements are a rapid proof to test the antioxidant capacity of many organic molecules[12,13] and to study the interaction between the antioxidant and ROS, as was observed for dihydropyridines and electrogenerated superoxide radical.[14,15]

Oxidation potentials of the peaks appearing in cyclic voltammetry have been used for comparison of the antioxidant action of compounds such as phenolic acids, flavonoids, and cinnamic acids.[16−18] The electrode more used was the glassy carbon electrode (GCE). Similarly, cyclic voltammetric measurements have been applied to the determination of the antioxidant capacity of wines.[17,18] The variation of the oxidation potential with the pH values can be provided, and measurements made at different pH values can be compared. Concentration is critical to the success of the technique. The area under the first voltammetric peak is a good estimate of phenol concentration with low oxidation potential and can be related to the antioxidant activity of the sample of wine. Other advantages are as follows: there is no need to measure the antioxidant capacity specific to each component, the sample preparation is simple and fast, and the sensitivity of the technique is sufficient for determination at physiological concentrations of antioxidants. Low oxidation potentials are associated with a greater facility of a given molecule for electrodonation, that is, acting as an antioxidant, with good correlation with other techniques such as the scavenging of the DPPH$^{\bullet}$ radical.[19]

The radical scavenging ability given by the DPPH$^{\bullet}$ assay was related to the reduction potential of DPPH$^{\bullet}$. Radicals such as ROO$^{\bullet}$ and OH$^{\bullet}$ exhibit much higher formal potentials than DPPH$^{\bullet}$ and can react with species with high oxidation potentials for which it is not possible to determine the antioxidant activity by the DPPH assay. There are some accepted methods for ROS, such as fluorometric assay for hydrogen peroxide,[20] ESR/EPR method, and so on.[20−24]

The anodic oxidation reaction of hydrogen peroxide was used in pioneering research to determine the antioxidant character of compounds in foods,[25−29] but some experimental problems led

to a revision of this method.[30] Recently, Gorjanovic et al. and Potkonjak et al.[31−33] have developed polarographic criteria for antioxidant activity.

Sužnjević and co-workers[25] assessed that the anodic wave of H_2O_2 observed on mercury electrodes is due to the oxidation of Hg to Hg^{2+} and the subsequent formation of a mixed complex with HO_2^- and OH^- ions, as previously reported by Kikuchi and Murayama.[34] This led to the revision of the approach made in ref 30.

On the other hand, spices are commonly used to enrich flavor and aroma in cooking and to preserve food and also as components of a healthy diet. They are traditionally thought to have beneficial effects on health, and specific spices are used in traditional medicine as part of therapeutic formulations. Pharmacological studies on spices revealed a wide range of biological activities, including antioxidant, anti-inflammatory, antitumor, immunomodulatory, and antiradical activities.[35−37] Their antioxidant constituents are identified as responsible for the health-promoting properties of spices, such as antiatherosclerotic, anticancer, and anti-inflammatory activities.[38]

The aim of this work was, first, to revise the DPV method in light of the oxidation mechanism on mercury electrodes; second, to apply the studies to potential food antioxidants, namely, a number of bioactive compounds found in spices and condiments; and, third, to extend these studies to mixtures of antioxidants and to aqueous extracts of some species.

The compounds studied are mainly active principles of spices, seasonings, or drugs, belonging to the family of low molecular weight antioxidants, being aromatic phenolics and nonphenolics or cyclic and acyclic nonaromatic compounds: eugenol, carvacrol, cinnamaldehyde, thymol, sesamol, 3-hydroxycoumarin, salicylaldehyde, limonene, geraniol, vanillin, cinnamic acid, α- and β-pinene, 2,4- and 2,5-dihydroxybenzaldehydes, and gallic acid. The spices studied contain one or more of the above compounds.

MATERIALS AND METHODS

Materials. 3-Hydroxycoumarin, carvacrol, vanillin, and gallic acid were purchased from Aldrich (or Sigma-Aldrich), and the rest of chemicals were Merck analytical grade reagents. All of the reactants were used without further purification. Thyme, cinnamon, oregano, clove, and nutmeg were purchased in a grocery store and were of the Mercadona S.A. trademark.

Solutions of 0.1 M in both sodium carbonate and phosphoric acid at pH 10.5 were used as supporting electrolytes. The aqueous solutions were prepared with ultrapure water type I (resistivity = 18.2 MΩ·cm at 25 °C) obtained from a Millipore Simplicity system. The ionic strength was adjusted to 0.5 M with solid KNO_3, and the pH was adjusted with solid NaOH. Antioxidants were dissolved in ethanol, and the stock solution concentrations were 5×10^{-3} M. These solutions were stored in darkness at 277 K to avoid decomposition.

Aqueous extracts of thyme, cinnamon, oregano, clove, and nutmeg were obtained by adding 250 mg of the spice to 100 mL of deionized water, heating for 5 min at 95 °C, and filtering at room temperature. The DPPH assays of these filtrates were made directly, but they were 10-fold diluted for the H_2O_2 experiments. In this last case, the data reflected under Results and Discussion show the results corrected for the dilution.

Methods. *Electrochemical Measurements.* The concentration of hydrogen peroxide in the cell was 5×10^{-4} M, and the percentage of ethanol in the cell was 30%. Because the change in the ethanol content modifies the DPV peak area,[30] solutions were prepared with a fixed amount (6.9 mL) of supporting electrolyte, 100 μL of 5×10^{-2} M H_2O_2, variable volumes, V_{AO}, of the stock solution of antioxidant in ethanol, and the total volume was completed with $(3-V_{AO})$ mL of pure ethanol. Therefore, it was necessary to prepare a separate solution for each concentration of antioxidant, and the samples were not gradually added to the solution because of the undesirable decrease produced by the presence of ethanol, which depends on the ethanol content. One hundred microliters of H_2O_2 was added after the solutions were purged with purified nitrogen. For the experiments made with the aqueous extracts of spices, no ethanol was added, the overall volume being completed with water, and the measurements being referred to the signal obtained for H_2O_2 in the absence of ethanol.

Measurements were made on a CHI650A electrochemical workstation from IJCambria coupled to an EF-1400 controlled growth mercury electrode from BAS instruments, in the HMDE mode. The Hg drop area was 6.70×10^{-3} cm^2. The temperature was kept at 298 ± 0.1 K. All potentials were measured against an Ag|AgCl|KCl_{sat} electrode (BAS MF-2052). A platinum counter electrode, BAS MW-1034, was used. The parameters selected in the differential pulse voltammetry (DPV) were as follows: pulse amplitude, 0.05 V; pulse width, 0.05 s; and pulse period, 0.2 s.

The reproducibility of the measurements was ensured by repeating the experiments, and the standard deviations of the data were <5%.

Spectrophotometric Measurements. DPPH$^\bullet$ Radical Scavenging Assay. The maximum wavelength of the UV−visible absorption band of the DPPH$^\bullet$ is 515 nm, and the action of an AO causes the decrease of this band or its eventual disappearance through the reactions to give DPPH and AO$^\bullet$. The amount of antioxidant required to decrease the initial concentration of DPPH$^\bullet$ to 50% (efficient concentration or EC_{50}) is a measurement of the antioxidant activity. The reverse value, namely, antiradical power, ARP = $1/EC_{50}$, should be higher as the antioxidant is more efficient.

UV measurements were made on a Genesys 10 UV spectrophotometer from Thermo Electron Corp. with quartz cuvettes of 1.0 cm path length.

Different concentrations of antioxidants were added to DPPH$^\bullet$ methanolic solution. The initial DPPH$^\bullet$ concentration was 6×10^{-5} M. The DPPH$^\bullet$ concentration in the reaction medium was calculated from a calibration curve with the equation

$$\mathrm{Abs}_{515nm} = 12.195 c_{DPPH} - 0.0137$$

as determined by linear regression.

For the aqueous extracts of the spices, the ARP was referred to the weight of antioxidant required to decrease the initial concentration of DPPH$^\bullet$ to 50%, W_{50}, expressed in mg, the ARP value being ARP = $1/W_{50}$, in mg^{-1}.

RESULTS AND DISCUSSION

Kikuchi and Murayama[34] proposed that the anodic wave of H_2O_2 observed on mercury electrodes is due to the oxidation of Hg to Hg^{2+} and the subsequent formation of a mixed complex with HO_2^- and OH^- ions:

$$Hg \rightleftharpoons Hg^{2+} + 2e^-$$

$$Hg^{2+} + HO_2^- + HO^- \rightleftharpoons Hg(HO_2)(OH)$$

The formation of this complex was assessed by Sužnjević and co-workers[25] by titration of H_2O_2 with $HgCl_2$ in basic solutions. However, if the reactions shown in the above scheme were the only processes occurring at the electrode, no effect of the addition of antioxidants on the oxidation wave could be observed, because the antioxidants do not react with the mercury ions in the absence of hydrogen peroxide, at least under the experimental conditions of polarographic and voltammetric experiments.[39]

It could be claimed that antioxidants act by reacting with the dissociated hydrogen peroxide and thus decreasing the concentration of the complex, this producing a decrease in the polarographic limiting current (or in the DPV peak current) that can be related to the antioxidant activity. However, this implies that the antioxidant must react with H_2O_2 in the solution.

Experiments were made to check this possibility. As can be seen in Figure 1, linear sweep cyclic voltammograms of solutions of

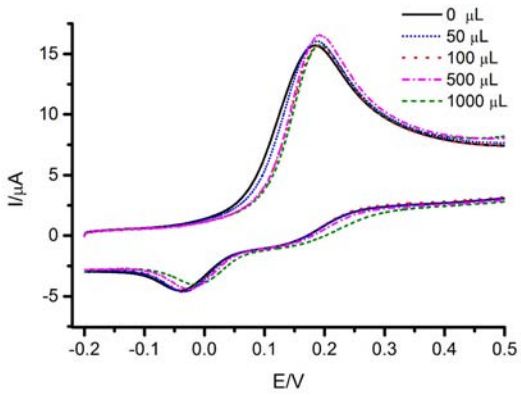

Figure 1. Linear sweep cyclic voltammograms on a glassy carbon electrode (IJCambria 38.5 mm^2) of 1 mM sesamol at pH 10.5 and different amounts of 5×10^{-2} M H_2O_2 solution added to a 10 mL final volume in the cell.

0.5 mM of the antioxidant sesamol were recorded at pH 10.5 in the absence and in the presence of increasing concentrations of hydrogen peroxide.

No effects on the oxidation wave were observed even at H_2O_2 concentrations 10 times higher than sesamol. In addition, the peak current of the oxidation peak of sesamol remained constant during 30 min, even at the maximum peroxide concentration used. Therefore, no reaction occurs involving these two reactants and, in conclusion, additional reactions must be considered.

Because the presence of radicals is needed to give an interaction with the antioxidants, the only possibility is that in the range of potentials of the oxidation peak on mercury electrodes such radicals are formed. It is evident that the electrode must play an important role in the electro-oxidation. This role could be viewed as the occurrence of adsorbed species on the electrode, the Gibbs energy of the adsorption processes decreasing the oxidation potential of hydrogen peroxide. In consequence, the simplified reaction scheme given in ref 30 must involve adsorbed species.

Another approach to the problem is to assume that radicals are produced after the formation of the mercury complex, probably through intramolecular electron transfers:

$$Hg \rightleftharpoons Hg^{2+} + 2e^-$$

$$Hg^{2+} + HO_2^- + HO^- \rightleftharpoons Hg(HO_2)(OH)$$

$$Hg(HO_2)(OH) \rightleftharpoons Hg + HO_2^{\bullet} + HO^{\bullet}$$

In this scheme, the last reaction must occur at trace levels in the absence of radical scavengers. The addition of increasing amounts of antioxidants must cause a shifting to the right of the last step by reaction with the radicals, and, consequently, the shifting to the right of the overall process. In this case, the addition of antioxidants must increase the limiting current of the dc wave (or the peak current of the DPV peak), in contradiction with the experimental findings.

It is known from decades ago[40] that the anodic oxidation of mercury involves both Hg(II) and Hg(I) ions in equilibrium with the complexes formed with chloride or bromide ions present in the solution. This takes place at potentials 0.1−0.2 V more positive than the peak here analyzed. This behavior is common to the redox processes of metal ions; that is, the electron transfers are one-electron, and the redox state of the ions increase, or decrease, in one unity.[41] Therefore, it seems reasonable to think that the Hg(I) ions are formed after the first one-electron transfer, and the following reactions could take place:

$$Hg \rightleftharpoons \frac{1}{2}Hg_2^{2+} + e^- \quad (1)$$

$$\frac{1}{2}Hg_2^{2+} \xrightarrow{e^-} Hg^{2+} \quad (2)$$

$$\frac{1}{2}Hg_2^{2+} \xrightarrow[+HO_2^-]{} Hg + HO_2^{\bullet} \quad (2')$$

$$Hg^{2+} + HO_2^- + HO^- \rightleftharpoons Hg(HO_2)(OH) \quad (3)$$

In the absence of AO, reaction 2′ takes place only at trace levels. When a radical scavenger is added, this species reacts with the hydroperoxide radical produced in reaction 2′ and decreases the available concentration of Hg(I) ion to give the Hg(II) ion and, consequently, the oxidation current. This scheme explains all of the experimental results obtained. First, the DPV peak area decreases as the antioxidant concentration increases from the value corresponding to a two-electron transfer (Hg oxidation to mercuric ions through mercurous ions followed by the complex formation) to the value corresponding to an EC one-electron transfer (Hg oxidation to mercurous ions followed by hydroperoxide radical and subsequent reaction with AO), that is, to a value not less than 50% of the original area. Second, the half-width of the DPV peak changes from the value corresponding to a two-electron process to the value corresponding to an EC one-electron process, as was experimentally found.[30]

The I-E relationships for the above-described process can be obtained by using the convective diffusion approximation and the steady-state conditions and the Nernst diffusion-layer approximation, but the equations for the limiting currents as a function of the AO concentration and the equilibrium and rate constants of reaction 2′ are complex and cannot be linearized. It is evident that the rate of such reaction must increase as the rate constant increases, and the decrease in limiting current (or in the area of DPV peak) must be higher at lower AO concentrations.

Therefore, the approach of Gorjanovic et al. and Potkonjak et al.[31−33] seems appropriate for the evaluation of the scavenging activity of antioxidants. In these papers, the slope of the linear part of the curve obtained by plotting the percentage of decrease of polarographic current versus the amount of individual compounds or volume of complex samples was used to express AO activity. This slope was found to be the most relevant and accurate way to express AO activity of samples with large differences in activity and was finally chosen as AO activity criteria. High correlations were reported between the slope and the content of total phenolics and AO activity determined by standard spectrophotometric assay such as FRAP, ABTS, and DPPH.

DPV is a differential technique, this implying that the parameter proportional to the concentration of the species that is oxidized or reduced at the electrode is the peak area.[40] Conversely, as the polarographic limiting current, the peak

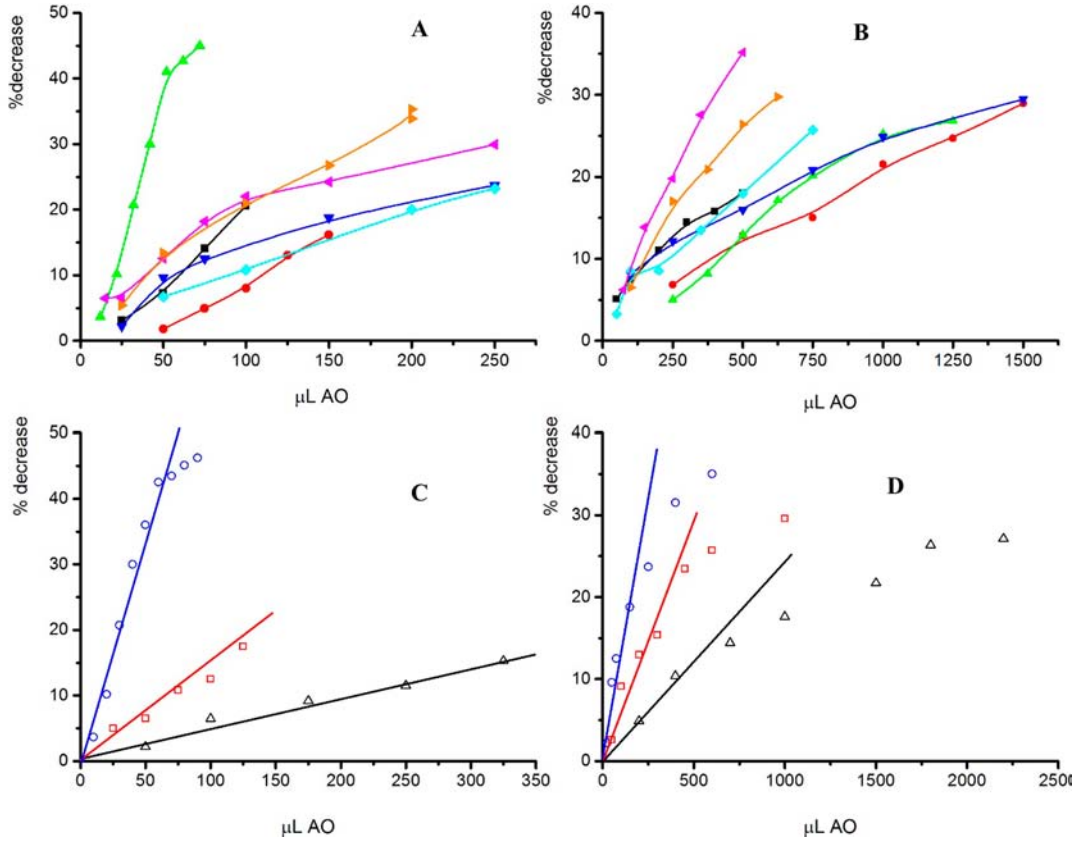

Figure 2. Dependencies of the DPV area of 5×10^{-4} M H_2O_2 after the addition of increasing amounts of antioxidants, relative to the area of the peak in the absence of antioxidant. (A) AO concentration = 5 mM: (green triangles) gallic acid; (magenta triangles) eugenol; (yellow triangles) 3-hydroxycoumarin; (black squares) 2,4-dihydroxybenzaldehyde; (purple triangles) carvacrol; (blue diamonds) cinnamaldehyde; (red circles) 2,5-dihydroxybenzaldehyde. (B) AO concentration = 5 mM: (magenta triangles) thymol; (yellow triangles) vanillin; (black squares) cinnamic acid; (purple triangles) salicylaldehyde; (blue diamonds) sesamol; (green triangles) limonene; (red circles) geraniol. (C) Gallic acid concentrations = (open triangles) 1 mM, (red outline squares) 3 mM, and (open circles) 5 mM. (D) Carvacrol concentrations = (open triangles) 1 mM, (red outline squares) 3 mM, and (open circles) 5 mM.

current depends on the reaction mechanism, at the same concentration, pH, temperature, and ionic strength. The half-width of the DPV peak changes with the AO addition, implying that there is a change in the oxidation mechanism and, so, the change of intensity reflects not only the dependence with the AO concentration but also this change in half-width. Therefore, the parameter to be tested is the DPV peak area.

Panels A and B of Figure 2 show the decrease of the peak area of the DP voltammograms of the DPV oxidation peak obtained for H_2O_2 in mercury electrodes after the addition of increasing amounts of several antioxidants.

Panels C and D of Figure 2 show the decrease of the peak area as a function of the added volume for two selected antioxidants and starting from different concentrations of antioxidant, to study the dependence on this parameter. From these graphs, it follows that the dependence of the decrease with the added volume is roughly linear at low percentages of decrease and is proportional to the initial antioxidant concentration. Therefore, this slope can be used as an AO activity criterion in the same way as in refs 31−33. The calculated slopes are given in Table 1.

To perform the experiments, different concentrations of antioxidants were used, because the more active antioxidants decrease the current below 10% at very low volumes added. Therefore, if this is the case, the essays were repeated after dilution of the antioxidant, allowing the addition of higher volumes and thus permitting a more accurate determination of the C_{10}, that is, the antioxidant concentration at which the area of the H_2O_2 oxidation peak decreases by 10%. The 10% decrease falls in the linear range of the plots shown in Figure 2.

As stated in a previous work,[30] the results obtained by using $1/C_{10}$, ARP, or voltammetric oxidation potentials (E_p) are quite different. Table 1 illustrates this. In this table, the ARP values of the previously essayed compounds have been taken from ref 30 (α- and β-pinene have been tested for this work), and the EP values were determined again for this work, being the same as found previously,[30] as expected.

From Table 1 it follows that there are compounds that do not exhibit measurable ARP or E_p values, but their scavenging activity can be evaluated using $1/C_{10}$. A part of these compounds consists of antioxidants of low scavenging activities. Other compounds such as 3-hydroxycoumarin, 2,4-dihydroxybenzaldehyde, or cinnamaldehyde showed very low ARP values and high oxidation potentials, but the corresponding $1/C_{10}$ values are high, indicating a high scavenging activity. In other cases such as carvacrol and vanillin or eugenol and sesamol, the ARP and the oxidation potentials have similar values, but the $1/C_{10}$ values are quite different. In fact, no evident correlation between ARP and $1/C_{10}$ or between E_p and $1/C_{10}$ has been found.

geraniol	0.026	5.383			4.050
limonene	0.021	5.233			2.330

[a] ±1% = average of slope confidence interval. [b] ±0.5% = average of ARP confidence interval. [c] Confidence interval for E_p values was always < ±4 mV. [d] μ_{10} values at concentrations of 5 mM.

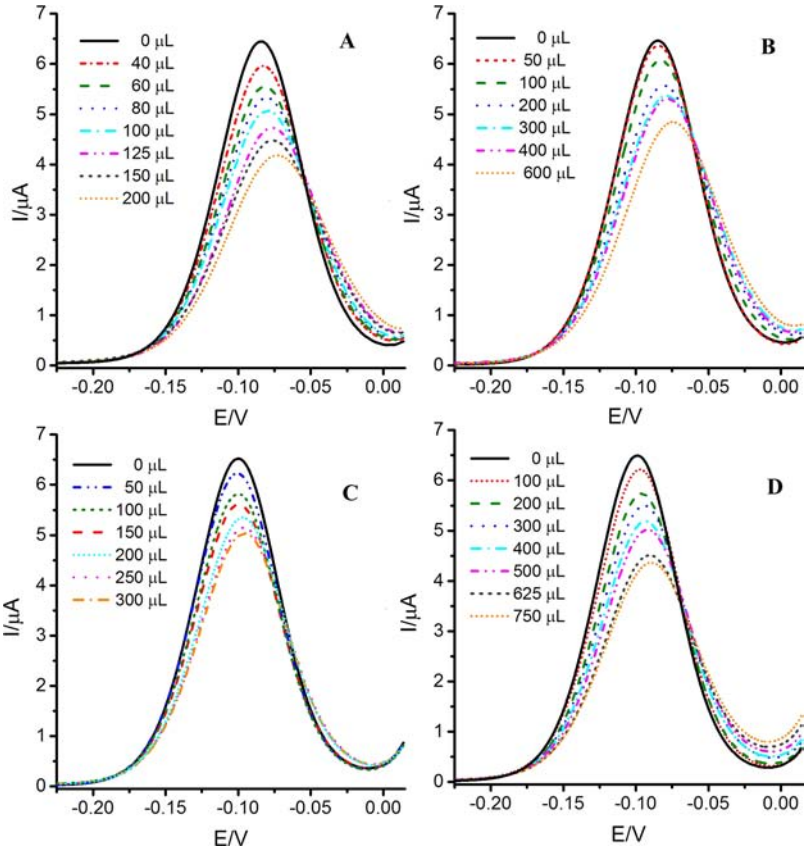

Figure 3. DPV voltammograms of 5×10^{-4} M H_2O_2 and different amounts of antioxidant mixture solution. pH 10.50. 30% ethanol in the medium. AO mixtures: (A) 2.5 mM eugenol + 2.5 mM limonene; (B) 0.5 mM eugenol + 0.75 mM thymol + 0.75 mM sesamol; (C) 0.5 mM eugenol + 0.75 mM thymol + 2 mM limonene; (D) 2.5 mM sesamol + 2.5 mM limonene.

It is known[19] that both ARP and oxidation potentials measure the capacity of a given compound to react with the DPPH• radical. The $1/C_{10}$ parameter is related to the interaction of the antioxidant with the ROS (hydroperoxide radicals).

The method can be easily extended to mixtures of n antioxidants because in this case reaction 2′ will consist of n parallel reactions. In this case, the goal is to establish the scavenging activity of the mixture as a whole, not the individual antioxidant activities. Because the added volume is proportional to the concentrations, the volume necessary to decrease the area of the H_2O_2 oxidation peak by 10%, V_{10}, must be related with the scavenging activity (more precisely,

dx.doi.org/10.1021/jf404578a | J. Agric. Food Chem. 2014, 62, 582−589

the reverse of V_{10}), equivalent to C_{10}. In this work $\mu_{10} = 1/V_{10}$ (expressed in mL^{-1}) is selected to express the antioxidant activity. In this way, higher μ_{10} values indicate higher scavenging activity. This parameter can be also used with individual antioxidants. Table 1 also lists the μ_{10} values corresponding to the antioxidants in the experiments made at concentrations of 5 mM.

Figure 3 shows the DP voltammograms of the H_2O_2 oxidation before and after the addition of increasing volumes of four antioxidant mixtures. Binary and ternary mixtures of antioxidants of high, medium, and low μ_{10} have been investigated. The concentrations were chosen to cover different proportions of compounds having low and high AO activities. As the volume added was increased, the DP peak decreases, and at a high enough volume of mixture added, the area of the peak becomes half of the original area (data not shown).

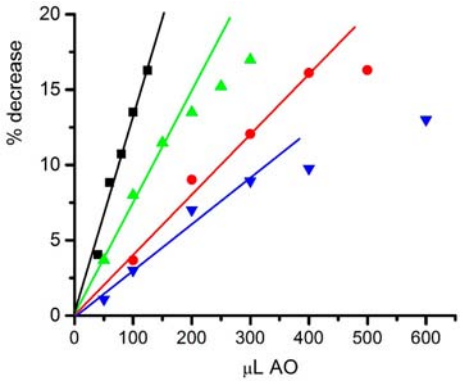

Figure 4. Dependencies of the DPV area of 5×10^{-4} M H_2O_2 after the addition of increasing amounts of antioxidant mixture solution, relative to the area of the peak in the absence of antioxidant. AO mixtures: (black squares) 2.5 mM eugenol + 2.5 mM limonene; (green triangles) 0.5 mM eugenol + 0.75 mM thymol + 2 mM limonene; (red circles) 2.5 mM sesamol + 2.5 mM limonene; (purple triangles) 0.5 mM eugenol + 0.75 mM thymol + 0.75 mM sesamol.

Figure 4 shows the dependence of the peak area of the DP voltammograms of the H_2O_2 oxidation after the addition of increasing volumes of antioxidant mixtures, relative to the area of the peak in the absence of antioxidant, for the same mixtures as in Figure 3.

From these data, the μ_{10} values can be obtained. Table 2 shows these values for a collection of mixtures of four antioxidants, mainly binary combinations.

The scavenging activities of the mixtures must be related, evidently, to the scavenging activities of the antioxidants used. Therefore, an antioxidant having high scavenging activity but in low concentration could contribute to the overall activity of the mixture in less grade than other antioxidants having lower activity, but present in greater concentration. Because the assumption in this work is that μ_{10} values are related with the scavenging activity, "expected" μ_{10} values have been calculated for each mixture from the individual μ_{10} values given in Table 1 and taking into account the concentration of each compound. The results of such calculations are given in Figure 5. The graph shows a correlation between experimental and calculated values. More precisely, there is a proportionality between both values, the slope obtained from the correlation being 1.06, that is, close to unity. This indicates that the μ_{10} parameter is a measure of the scavenging activity, being additive; that is, the overall μ_{10} value of a mixture is constituted by the sum of the μ_{10} values of the individual antioxidants.

Moreover, the proportionality shown in Figure 5 indicates that there are not synergistic effects in the mixtures, at least for the investigated mixtures, but this conclusion must be checked with a wider range of antioxidant mixtures.

The measurements were extended to the aqueous extracts of five spices. Figure 6 and Table 3 summarize the results. As can

Table 2. μ_{10} Values for Mixtures of Antioxidants[a]

Table 3. V_{10} and μ_{10} Values, ARP, and Antioxidants Found in the Extracts for Aqueous Extracts of Spices[40]

spice	V_{10} (μL)	μ_{10} (mL^{-1})	ARP (mg^{-1})	main antioxidants	
oregano	23.10	43.29	5.25	*p*-cymene	12%
				thymol	5%
				carvacrol	49%
clove	32.40	30.86	16.23	*β*-caryophyllene	7%
				eugenol	83%
				acetyleugenol	8%
thyme	51.70	19.34	21.81	p-cymene	27%
				linalool	6%
				thymol	46%
cinnamon	56.80	17.61	16.02	*β*-caryophyllene	5%
				cinnamaldehyde	68%
				eugenol	7%
numteg	219.20	4.56	10.40	*α*-pinene	21%
				β-pinene	15%
				sabinene	19%
				terpinen-4-ol	4%

be seen, at low values of decrease, the plot shown in Figure 6 is roughly linear. From these experiments, μ_{10} values have been calculated for each extract and have been gathered in Table 3. In the table are also given the ARP values obtained from the DPPH$^{\bullet}$ experiments but not the oxidation potentials, because the voltammograms were complex and showed more than one oxidation peak.

In general, the sequence of μ_{10} values is related to the contents in antioxidants of the different spices, but it is important to note that such contents correspond to essential oils, not to aqueous extracts,[42] and the proportions must vary from one extraction mode to another. Nevertheless, when the spices are used as food condiments, they act essentially as aqueous extracts rather than nonaqueous essential oils.

New Method for the Extraction of Volatile Lipid Oxidation Products from Shrimp by Headspace−Solid-Phase Microextraction−Gas Chromatography−Mass Spectrometry and Evaluation of the Effect of Salting and Drying

Hugo A. L. Souza and Neura Bragagnolo*

Department of Food Science, Faculty of Food Engineering, University of Campinas, 13083-862 São Paulo, Brazil

Supporting Information

ABSTRACT: A new method based on headspace−solid-phase microextraction (HS−SPME) and gas chromatography−mass spectrometry (GC−MS) was developed, aimed at evaluating the formation of volatile lipid oxidation products (VLOPs) in shrimp during the salting and drying process. Of the four fibers evaluated, the fiber coated with divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) was the most adequate for the quantification of the VLOPs. The best analytical conditions were obtained by homogenization in an ultraturrax followed by extraction at 40 °C for 30 min. The optimized method allowed for the rapid and simple extraction of the VLOPs, with low detection (≤0.15 ng g^{-1}) and quantification (≤0.50 ng g^{-1}) limits and satisfactory precision (≤12.67%) and extraction efficiency (≥94.28%). The salting and drying negatively affected shrimp quality, reducing the fatty acid content and increasing the VLOPs, especially hexanal.

INTRODUCTION

Shrimp represents about 15% of the fisheries commercialized throughout the world, being the most economically important international fishing and aquiculture product.[1] However, shrimp deteriorates easily; thus, it must be submitted to some kind of preservation method to increase its shelf life.[2] Among the preservation methods, salting followed by drying stands out because it allows for storage of the shrimp at room temperature for various days.[3]

Drying or dehydration is one of the oldest and most important unit operations in the food industry, which, by decreasing the water activity, reduces microbial growth and the speed of chemical and enzymatic reactions.[4] However, the addition of salt and application of heat can accelerate lipid oxidation, with the formation of products with off-flavors, and cause the loss of some nutritional properties.[5]

Despite its low lipid content (0.70−1.16 g/100 g), the lipid fraction of shrimp is rich in polyunsaturated fatty acids (PUFA), such as eicosapentaenoic acid (EPA, 20:5ω-3), docosahexaenoic acid (DHA, 22:6ω-3), and arachidonic acid (ARA, 20:4ω-6), making it highly susceptible to lipid oxidation.[6−8]

Various compounds are formed during lipid oxidation, and of these, those with the greatest impact on the sensory quality of foods are the short-chain volatile products formed from the β-cleavage of hydroperoxides.[9] In addition, analysis of these secondary lipid oxidation products presented good correlation with the more traditional analyses, such as the peroxide index (PI), the 2-thiobarbituric acid reactive substances (TBARS) test,[10,11] and the sensory analysis.[12]

Headspace−solid-phase microextraction (HS−SPME) is widely used in the analysis of volatile compounds in foods[13] and consists of the use of a fiber with a very small diameter covered by a stationary phase, which, upon being exposed to the headspace of a sample, adsorbs the volatile analytes, which are thermally desorbed directly in the gas chromatograph (GC) injector.[14,15] Among the advantages of SPME, short analysis time, absence of solvents, and high sensitivity and selectivity stand out, in relation to traditional techniques.[13]

Exhaustive extraction of the analytes does not occur during SPME, but equilibrium is formed between the sample and the stationary phase of the fiber. Various factors can affect this equilibrium, such as the type of stationary phase and the extraction time and temperature, and therefore, a careful study is required to establish a SPME method.[10,16]

Thus, the objective of the present work was to establish a headspace−solid-phase microextraction−gas chromatography−mass spectrometry (HS−SPME−GC−MS) method to quantify the volatile lipid oxidation products (VLOPs) in shrimp and, with the aid of this technique, evaluate the effect of processing on the lipid fraction of salted and salted, dried shrimp.

MATERIALS AND METHODS

Reagents and Materials. The alkane series (C_5−C_{24}) used to calculate the retention index was obtained from Polyscience (New Haven, CT). The standards used to identify and quantify the volatile compounds were pentanal, 2-methylpentanal [internal standard (IS)], hexanal, 1-penten-3-ol, heptanal, 2-pentylfuran, 1-pentanol, octanal, 1-hexanal, nonanal, 1-octen-3-ol, 1-heptanol, decanal, 1-octanol, and 2-octen-1-ol from Sigma Aldrich (St. Louis, MO). The purity of

standards varied from 95 to 99%. The fibers carboxen/polydimethylsiloxane (CAR/PDMS), divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS), polyacrylate (PA), and polydimethylsiloxane/divinylbenzene (PDMS/DVB) were acquired from Supelco (Bellefonte, PA). A total of 37 saturated, monounsaturated, and polyunsaturated fatty acid methyl ester standards (C_4−C_{24}, Sulpeco 37-Component FAME Mix, catalog number 18919-1) were used to identify the fatty acids, and methyl undecanoate and methyl tricosanoate (Sigma Aldrich) were used to quantify the fatty acids. The reagents and solvents used were of analytical grade (Synth, Diadema, São Paulo, Brazil) or high-performance liquid chromatography (HPLC) grade (Fisher, Fair Lawn, NJ), and the water was purified by the Millipore Milli-Q system (Billerica, MA).

Samples. The volatile compound extraction method was optimized using salted and dried pacific white shrimp (*Litopenaeus vannamei*). The fresh and whole shrimp (1.0 kg with head and shell) was obtained from the local market in Campinas (São Paulo, Brazil) and was submitted to salting in boiling water (30% NaCl for 10 min) and drying in an air-circulating oven at 60 °C for 4 h. A new sample was prepared with fresh shrimp for each step of optimization.

To evaluate the effects of processing on the shrimp lipids, two new batches, each of 1.5 kg of fresh shrimp, were acquired from the same place with an interval of 1 week. Again, each batch was separated into three parts (500 g each, ∼25 shrimps), one fresh, another just salted, and the third salted and dried. The shrimp processing was identical to that used in the method optimization step. The moisture content was carried out according to the Association of Official Analytical Chemists (AOAC) method 950.46.[25] The moisture content of fresh samples was 75.75 ± 0.22 g/100 g at batch 1 and 76.41 ± 0.16 g/100 g at batch 2; the moisture content of salted shrimp was 63.68 ± 0.11 g/100 g at batch 1 and 62.34 ± 0.38 g/100 g at batch 2; and the moisture content of salted, dried shrimp was 50.84 ± 0.18 g/100 g at batch 1 and 47.57 ± 0.15 g/100 g at batch 2.

Optimization of the Analysis of the Volatiles by HS−SPME−GC−MS. To establish the method used to extract the volatile compounds by SPME, three factors that affect the extraction performance were evaluated in sequence: the type of stationary phase used to coat the fiber, the sample preparation method, and the extraction time/temperature binomial, using the best condition obtained in the previous step for the subsequent step.

Fibers coated with four different materials were tested to choose the best fiber for the above purpose: CAR/PDMS, DVB/CAR/PDMS, PA, and PDMS/DVB. The fibers were first conditioned according to the instructions of the manufacturer. The extraction procedure was carried out in the same way for all of the fibers (n = 6). The salted, dried shrimp (100 g) was peeled and ground, and 1 g of ground sample was placed in a vial [20 mL with a screw top and polytetrafluoroethylene (PTFE) septum, Supelco, Bellefonte, PA]. The vial was then incubated for 15 min at 40 °C, and then the fiber was exposed for 30 min to headspace (HS), followed by desorption directly in the injector for 1 min at 250 °C. After each desorption, the fibers were reconditioned for 10 min at 250 °C in a flow of He. The whole extraction step was carried out using an AOC-5000 autoinjector (Shimadzu, Kyoto, Japan).

Three sample preparation procedures were tested: in the first, 1 g of shrimp was sealed in a vial; in the second, 3 mL of ultrapure water was added to the shrimp (1 g), which was then sealed and homogenized in a vortex (Phoenix Luferco, São Paulo, Brazil) for 1 min; and in the third, 30 mL of ultrapure water was added to 10 g of sample in a beaker and homogenized in a high-speed ultraturrax (Jankel and Kunkel GmbH, Staufen, Germany) for 1 min at 12 000 rpm and 4 g of this mixture was placed in a vial and sealed. In the three cases, the volatiles were extracted in the same condition as that employed in the selection of the fiber (n = 3).

To evaluate the influence of time and temperature on the extraction of the volatile compounds by HS−SPME, analyses were carried out at 40, 60, and 80 °C for 15, 30, 60, and 120 min in random, independent trials using the fiber and sample preparation mode that gave the best results (n = 3).

GC−MS. The chromatographic analysis was carried out in GC coupled to mass spectrometer (MS, GCMS-QP2010 Ultra Shimadzu, Kyoto, Japan), equipped with a splitless injector at 250 °C, RTX-Wax capillary column (30 m × 0.25 mm inner diameter, 0.20 μm thick stationary phase, polyethylene glycol, Restek, Bellefonte, PA), workstation (GCMSSolution, Shimadzu, Kyoto, Japan), and ion source in the electron ionization (EI) mode at 70 eV and 250 °C, cutting the solvent after 1.1 min. The mass/charge (m/z) analyzer was quadrupole, operating in the scanning mode (SCAN = m/z 35−350) to identify the compounds and in the selected ion monitoring (SIM) mode for quantification. Helium was used as the carrier gas in the linear flow control mode with a constant column flow of 1.22 mL/min. The oven temperature program started at 30 °C for 5 min, followed by heating at 10 °C/min to 115 °C, maintaining at this temperature for 1 min, then heating at 30 °C/min to 220 °C, and maintaining at this temperature for 12 min, giving a total time of 30 min. The temperature program of the oven was based on the study by Shahidi and Pegg,[17] with changes in the initial and final temperatures.

The volatile compounds were identified by comparison of the mass spectra obtained for the samples to the mass spectra of the analytical standards under the same experimental conditions and those from the mass spectra library (Wiley9). In addition, an alkane series (C_5−C_{24}) was used to calculate the retention index (RI) for each compound with the RTX-Wax column[18] and compared to those found in the literature for columns with the same polarity.[19,20] The compounds that presented mass spectra similar to those in the library but differed from the literature with respect to the RI were considered to be tentatively identified.[21]

The VLOPs were quantified using analytical curves obtained with the respective standards added to the sample, using 2-methylpentanal as the IS in the SIM mode and the fragments that gave the best signal/noise ratio for each compound (Table 1).

Table 1. Standard RIs and Fragments Used To Quantify the VLOPs

[a]RI = retention index. [b]IS = internal standard.

Validation. The optimized method for extracting the VLOPs (DVB/CAR/PDMS, ultraturrax, at 40 °C for 30 min) was submitted to validation by way of the following criteria: linearity, detection and quantification limits, repeatability, and recovery. Samples of salted, dried shrimp prepared on the same day as the analysis were used for validation.

The analytical curve was elaborated by the addition of external standards to the sample in the concentration range from 1 to 80 ng g^{-1} with the addition of 100 ng g^{-1} of 2-methylpentanal as the IS. The detection and quantification limits were calculated on the basis of the signal-to-noise ratio (S/N) with S/N = 3 and 10, respectively. Repeatability was expressed as the relative standard deviation (% RSD; n = 6). To calculate the recovery, samples were fortified with standards

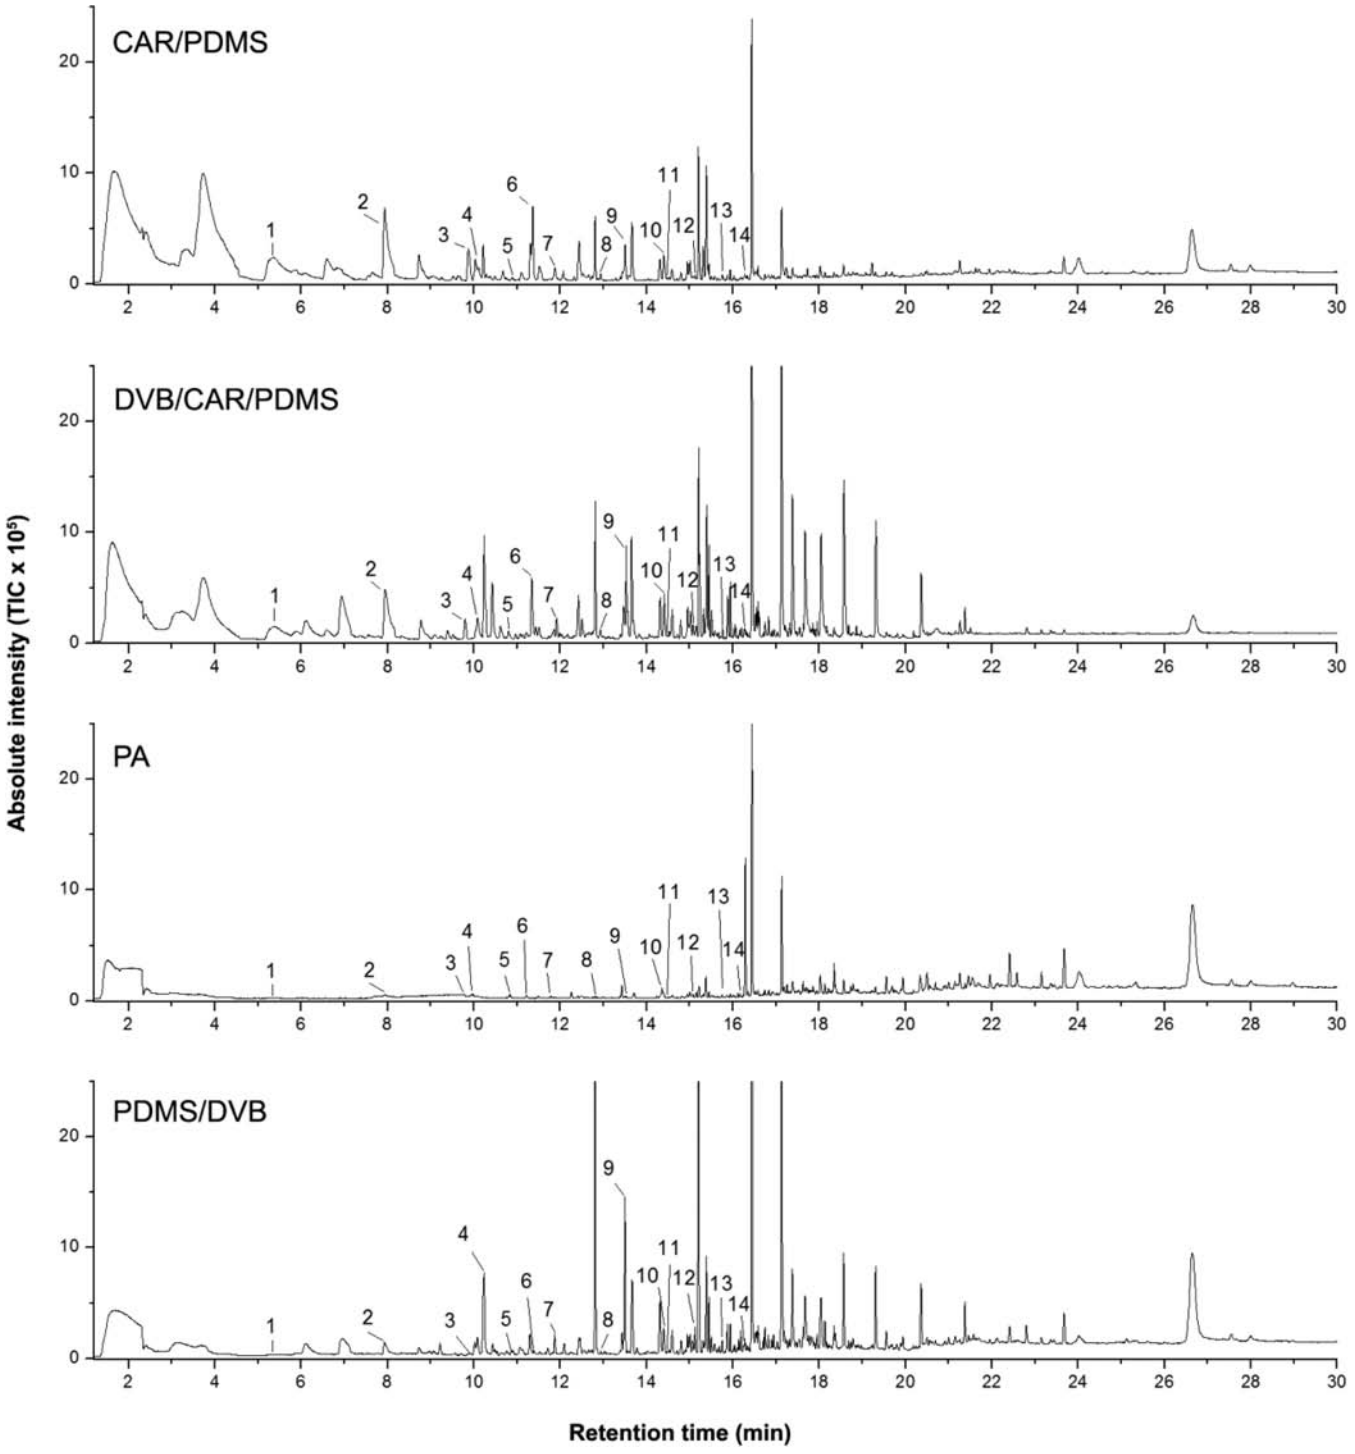

Figure 1. Chromatograms of the volatile compounds obtained from salted, dried shrimp by HS−SPME−GC−MS (scan m/z 35−350) according to the fiber used. Compounds are numbered according to Table 1.

in two levels (5 and 20 ng g^{-1}) and the response was subtracted from the mean result of not fortified samples (n = 6).

Fatty Acid Composition of the Shrimp Lipids. For the three samples of the two batches, the lipids were obtained according to the study by Folch et al.,[22] with the analyses being carried out in triplicate (n = 3). After extraction, the lipids (25 ± 1 mg) were converted into FAME according to Joseph and Ackman[23] and injected into GC using the hot needle technique for 5 s. The chromatograph used was the GC-2010 (Shimadzu, Kyoto, Japan) equipped with a split injector ($^1/_{50}$) at 250 °C, fused silica CP-SIL 88 capillary column (100 m × 0.25 mm inner diameter, 0.20 μm thick stationary phase, cyanopropyl, Chromopack, Middleburg, Netherlands), flame ionization detector at 260 °C, and workstation (GCSolution, Shimadzu, Kyoto, Japan). The temperature was programmed according to the study by Sancho et al.,[24] with H_2 as the carrier gas at a linear velocity of 34 cm/s and N_2 as the makeup gas at 30 mL/min. The fatty acids were identified by comparison of the retention times to those of the standards. Quantification was performed by internal standardization (11:0 and 23:0). The fatty acid concentrations were calculated according to the AOAC method,[25] and the results were expressed as milligrams of fatty acid per gram of lipid.

Statistical Analysis. The results were compared using the one-way analysis of variance (ANOVA) followed by Tukey's test in the case of

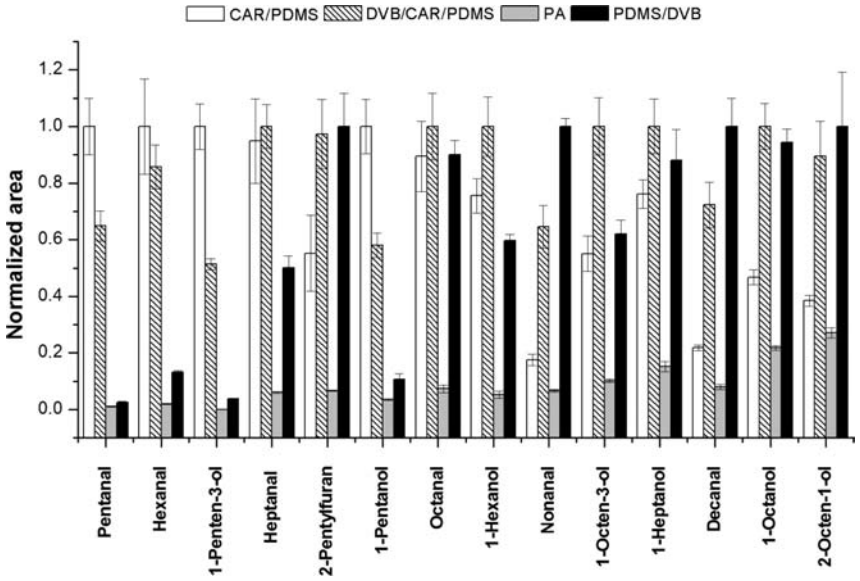

Figure 2. Effect of fiber coating in the extraction of VLOPs from salted, dried shrimp (obtained in the SIM mode; $n = 6$). Compounds are placed in order of increasing RI from left to right.

significant differences ($p < 0.05$). The ANOVA and the fit of the analytical curves were carried out with the aid of the Statistica 5.0 software (Statsoft, Tulsa, OK).

RESULTS AND DISCUSSION

Optimization of the HS–SPME Method. A total of 123 volatile compounds were found in the salted, dried shrimp (65 with the CAR/PDMS fiber, 64 with DVB/CAR/PDMS, 67 with PA, and 81 with PDMS/DVB; see Table S1 of the Supporting Information). Of those compounds, 14 (7 alcohols, 6 aldehydes, and 1 furan) could be classified as VLOPs (Table 1 and Figure 1).[26−28] Hexanal, heptanal, and 1-octen-3-ol were also found in cooked lobsters.[29,30] Dried shrimp of the species *Acetes chinensis* presented 1-penten-3-ol, 1-pentanol, 1-hexanol, and 1-octen-3-ol among their volatiles.[31]

The fiber coated with CAR/PDMS showed the best results for the VLOPs with the lowest RI values (Figure 2), whereas the fiber coated with PDMS/DVB presented the best results for the compounds with higher RI values, and the fiber coated with PA presented smaller areas for all of the compounds. However, the fiber coated with DVB/CAR/PDMS presented good results in a broader range of RI than the other fibers. Similar results were reported by Garcia-Esteban et al.,[32] where the CAR/PDMS fiber gave the best results for compounds with RI values below 980 and the DVB/CAR/PDMS fiber was better for compounds with higher RI values.

Thus, the DVB/CAR/PDMS fiber was considered to be the most adequate for the extraction of VLOPs from salted, dried shrimp. A total of 49 compounds were identified, and 15 were tentatively identified with this fiber, which are listed with their respective RI values in Table 2.

Sample preparation before SPME also influences the extraction yield of VLOP (Figure 3). Vortex homogenization with water resulted in the smallest area values and the highest RSD values (19.22% on average). The shrimp without water addition presented the largest areas for 2-pentylfuran, octanal, and 1-hexanol, whereas the shrimp homogenized with water in the ultraturrax showed the largest areas for 1-heptanol, 1-octanol, and 2-octen-1-ol. In these cases, no difference was observed for the areas between the other VLOPs. Nevertheless, the sample without water addition presented a mean RSD higher (8.47%) than that of the sample homogenized with water in the ultraturrax (2.34%). The difference in the results of the sample homogenized in the vortex and the ultraturrax can be attributed to the fact that, after a few minutes, the sample homogenized with vortex separated in two layers (liquid phase at the top and solid phase at the bottom). Probably, the liquid phase containing water hampered the volatile compounds to migrate to the headspace, leading to lower extraction; however, a homogeneous slurry was formed when the ultraturrax was used.

Both the temperature and the exposition time of the fiber in the HS of the sample significantly influenced the quantity of volatiles extracted. All of the VLOPs showed similar behavior to hexanal with the exception of pentanal, 1-penten-3-ol, and 1-pentanol. The increase in the temperature and extraction time provoked an increase in the area (Figure 4A). The five-carbon VLOPs (pentanal, 1-penten-3-ol, and 1-pentanol) probably did not interact with the fiber coating in the same way as the compounds with higher molecular masses, although their extraction was also affected by the time and temperature (see Figure S2 of the Supporting Information). The extraction time was not sufficient to reach equilibrium, which could take more than 5 h for the fiber used (DVB/CAR/PDMS). Moreover, long extraction times could cause the formation of a high amount of VLOPs, such as hexanal and nonanal,[33] while shorter extraction times make the analysis more acceptable for practical ends.[32]

After 30 min of extraction (Figure 4B), the RSD was lower, principally for the extractions at 40 and 80 °C, and no improvement in repeatability was achieved after this extraction time. Although the use of higher temperatures allowed for greater extraction of the volatile compounds, lower temperatures avoided the formation of VLOPs during extraction.[34,35] The use of lower temperatures (<50 °C) also allowed for better correlation with the sensory profile.[9]

Validation. The method (using DVB/CAR/PDMS fiber, homogenization with water using ultraturrax, and extraction at 40 °C for 30 min) showed good linearity for all of the VLOPs (the coefficient of determination varied from 0.9637 to 0.9978; Table 3). The detection limits varied from 0.03 to 0.15 ng g^{-1},

and the quantification limits varied from 0.11 to 0.50 ng g^{-1}. The method showed satisfactory precision (RSD $\leq$ 12.67%) and efficiency (recovery $\geq$ 94.28%). The analytical curve was developed with low initial values (1 ng g^{-1}), because the VLOPs found in the salted, dried shrimp, according to the study by Buttery et al.,[36] have low thresholds (0.7−15 ng g^{-1}) but a great impact on the sensory characteristics, especially the aldehydes.

Effect of Processing on the Shrimp Fatty Acids. The ω-3 fatty acids represented the majority among the PUFAs of fresh shrimp (Table 4), and the fatty acids profiles were similar in both batches, with little differences in the eicosadienoic acid (20:2ω-6) and behenic acid (22:0). The predominant fatty acids in the shrimp lipids were palmitic acid (16:0), oleic acid (18:1ω-9), stearic acid (18:0), linoleic acid (18:2ω-6), DHA, and EPA.

Salting caused a reduction in five fatty acids in batch 1, whereas only four fatty acids were reduced in batch 2, but only the contents of ARA and DHA were reduced in both batches. After drying, the reduction in pentadecanoic acid (15:0), margaric acid (17:0), stearic acid (18:0), and EPA became significant for both batches in comparison to the fresh shrimp. In addition, processing reduced the total fatty acid content of the lipid fraction. A reduction in the fatty acid content after cooking was also observed in fish[24,37] and crab.[38]

According to Maulvault et al.,[38] the reduction in PUFAs during heat processing occurs because of their great susceptibility to oxidation at high temperatures. Although less frequent, a decrease in the SFA content can also occur during cooking.[24] The loss of PUFAs occurs mainly because of lipid oxidation and can be accelerated by both an increase in the temperature and the addition of salt (NaCl).[39] The main contribution of the increase in the temperature to fatty acid oxidation is due to the increase in the reaction rate.[40] The pro-oxidant effect of NaCl is attributed to an increase in the non-heme iron content in meats after cooking,[41] although this increase is mainly due to the liquid retention capacity of NaCl, because when cooked without salt, the non-heme iron is carried out because of liquid loss.[42] Another pro-oxidant mechanism of NaCl is due to the reduction in activity of the antioxidant enzymes.[43]

ARA, EPA, and DHA are fatty acids of great importance to human health and can be generated metabolically from essential fatty acids (linoleic and linolenic acids), although the conversion

[a]Values expressed as the mean ± standard deviation (n = 3). Different letters in the same line indicate significant difference between the values (p < 0.05). [b]ND = not detected (below the detection limits, 0.04 ng g^{-1}). [c]Below the quantification limit.

rate is very low, indicating the need for exogenous sources of these lipids.[44,45] Thus, the processing of shrimp negatively affected the nutritional value because it reduced the contents of these fatty acids in up to 29% for ARA, 23% for EPA, and 16% for DHA.

In comparison of the lipids of salted shrimp to those of salted, dried shrimp, there was no difference between them for any fatty acid simultaneously in both batches, indicating that the drying process did not significantly affect the lipids. In general, these results are in agreement with those by Ortiz et al.,[46] who observed that drying at 60 °C had little influence on the fish lipid profile, generating low oxidation indices.

Effect of Processing on Shrimp VLOPs. The two batches of fresh shrimp showed the same VLOP composition (Table 5), differing only with respect to 2-octen-1-ol. The only aldehydes with quantifiable contents in the fresh shrimp were nonanal and decanal. The main VLOP produced during processing was hexanal, as also verified by Shahidi and Pegg.[17] The salting process caused an increase in all of the aldehydes, as compared to the fresh shrimp, in addition to a reduction in 1-octanol and 2-octen-1-ol in both

batches as well as the contents of 1-pentanol and 2-pentylfuran in batch 1 but not in batch 2.

Drying caused an increase in hexanal and 1-penten-3-ol in both batches, plus an increase in 2-octen-1-ol just in batch 1. The formation of volatiles presented a behavior similar to the degradation of the fatty acids, where the salting process presented a greater oxidative effect than the drying process.

Of the VLOPs found in shrimp, only 1-penten-3-ol originated from the oxidation of ω-3 fatty acids, with pentanal, hexanal, 1-pentanol, 2-pentylfuran, 1-hexanol, 1-octen-3-ol, and 2-octen-1-ol being formed as from ω-6 fatty acids. Heptanal can be formed from both ω-6 and ω-9 fatty acids, and the other VLOPs are formed from ω-9 fatty acids.[26−28]

Despite a significant increase, 1-penten-3-ol was below its threshold, and hence, the oxidation of ω-3 fatty acids, despite forming VLOPs, was not sufficient to alter the sensory properties of the shrimp. However, the formation of hexanal, 1-octen-3-ol, octanal, nonanal, and decanal could have a negative impact on the aroma of the final product, because the contents of these compounds were above their respective thresholds.[36] Thus, the oxidation of ω-6 fatty acids showed a greater influence on the sensory quality of the shrimp than the oxidation of ω-3 fatty acids.

In conclusion, the type of fiber, sample preparation mode, and the time/temperature binomial during extraction all presented an influence on the extraction by HS−SPME. The best conditions to extract VLOPs from shrimp by HS−SPME consisted of homogenizing 1 g of sample in 3 mL of water using an ultraturrax and extracting the volatiles at 40 °C for 30 min with the fiber DVB/CAR/PDMS. This method was quick and practical and showed good repeatability, sensitivity, and efficiency. Heat processing and mainly the salting process caused a reduction in the content of fatty acids of the shrimp, especially in ARA, DHA, and EPA, as well as forming some VLOPs above their threshold values, showing an impact on the nutritional and sensory characteristics of the final product.

Supporting Information

ABSTRACT: A previously developed method for measurement of oleocanthal and oleacein in olive oil by quantitative ^{1}H NMR was expanded to include the measurement of the monoaldehydic forms of oleuropein and ligstroside aglycons. The method was validated and applied to the study of 340 monovarietal Greek and Californian olive oils from 23 varieties and for a 3-year period. A wide variation concerning the concentrations of all four secoiridoids was recorded. The concentration of each one ranged from nondetectable to 711 mg/kg and the sum of the four major secoiridoids (named as D3) ranged from nondetectable to 1534 mg/kg. Examination of the NMR profile of the olive oil extract before and after contact with normal or reversed stationary chromatography phase proved the artificial formation of the 5*S*,8*S*,9*S* aldehydic forms of oleuropein and ligstroside aglycon isomers during chromatography. Finally, methyl elenolate was identified for the first time as a minor constituent of olive oil.

KEYWORDS: *extra virgin olive oil, secoiridoids, oleuropein aglycon, ligstroside aglycon, quantitative NMR*

INTRODUCTION

Olive oil is a fundamental constituent of the traditional Mediterranean diet which is continuously attracting the interest of the scientific community for its health-protecting activities.[1−3] Among the numerous constituents of olive oil, the secoiridoid derivatives present an increasing potential for health protection, which tends to place olive oil in the interface between food and drugs.[4] A very important change in the European Union legislation with potentially very significant impact on the field of olive oil marketing and labeling is the recent recognition by EFSA of specific health claims related to the levels of specific phenolic compounds found in olive oil.[5] More specifically, hydroxytyrosol, tyrosol, and their derivatives have been correlated with protection from LDL oxidation, creating thus a new need for the accurate measurement of the levels of those compounds in olive oil. It is noteworthy that up to today there is no internationally accepted regulation concerning the method for their measurement because of several technical difficulties. It is well-known that the concentration of free hydroxytyrosol and tyrosol in olive oil is very low while their esterified derivatives are much more abundant.[6] Hydroxytyrosol is mainly present in the form of oleacein (3,4-DHPEA-EDA) and the monoaldehydic form of oleuropein aglycon (3,4-DHPEA-EA), while tyrosol is mainly present in the form of oleocanthal (*p*-HPEA-EDA) and the monoaldehydic form of ligstroside aglycon (*p*-HPEA-EA). All those four secoridoid derivatives possess significant biological activities, as previously summarized.[7] Especially oleocanthal and oleuropein aglycon have been very recently correlated with protection against Alzheimer's disease,[8,9] giving a new potential field for medical applications of olive oil. Although there are several works concerning the chromatographic analysis of those compounds (HPLC−UV or LCMS)[10−13] we have recently described[7] the reactivity of oleocanthal and oleacein with methanol and water, which are commonly and officially used for the extraction of polyphenols[14] and as constituents of the mobile phase during their analysis, leading to the formation of several artifacts and making the analysis very difficult. To overcome these problems that make the chromatographic analysis complicated and questionable, we recently developed a simple and rapid method using quantitative NMR (qNMR) and avoiding any interacting solvents as well as the need of chemically pure standards.[7] In the present work we have expanded the previous method to include all four major secoiridoid derivatives of hydroxytyrosol and tyrosol. Interestingly, during this study we recognized the instability of oleuropein and ligstroside aglycon when they come in contact with common normal or reversed stationery phases, leading to the artificial formation of isomers. In addition, during the isolation of olive oil constituents we identified a compound that is for the first time reported from a natural source. The qNMR method was applied to 340 olive oil samples, and the varieties presenting the highest concentrations of the studied compounds were recognized.

MATERIALS AND METHODS

Extra Virgin Olive Oil Samples. The commercial extra virgin olive oil (EVOO) samples used in the study were obtained from olives (*Olea europaea* L.) harvested and extracted in three seasons:

November 2010−February 2011, October 2011−February 2012, and October 2012−February 2013. A total of 320 monovarietal commercial samples were obtained from Greece and 20 from California. In total, samples of 23 different varieties were included in the study. The olive oil production was performed in either two-phase or three-phase mills. All samples were provided by small-scale producers that could guarantee their monovarietal origin.

Olive Oil Extraction and Sample Preparation for NMR Analysis. Olive oil (5.0 g) was mixed with cyclohexane (20 mL) and acetonitrile (25 mL). The mixture was homogenized using a vortex mixer for 30 s and centrifuged at 4000 rpm for 5 min. A part of the acetonitrile phase (25 mL) was collected, mixed with 1.0 mL of a syringaldehyde (4-hydroxy-3,5-dimethoxybenzaldehyde) solution (0.5 mg/mL) in acetonitrile, and evaporated under reduced pressure using a rotary evaporator (Buchi, Switzerland).

Reference Compounds. Oleuropein aglycon and ligstroside aglycon were isolated from an olive oil extract prepared using the extraction method similar to that described above for sample preparation. The obtained extract was first fractionated using column chromatography, and then the fractions containing the two aglycons were purified with preparative TLC until maximum purity was achieved. In both cases, the mobile phase was prepared using mixtures of cyclohexane with ethyl acetate and silica gel as stationary phase. Details of the purification procedure are provided as Supporting Information. Each aglycon was obtained as an inseparable mixture of the 5*S*,8*R*,9*S* and 5*S*,8*S*,9*S* diastereomers in a ratio 3:1 and 4:1 for oleuropein and ligstroside aglycons, respectively. The ^{1}H NMR purity of both compounds (as a total of the two diastereomers in each case) was >98%. The identity of both compounds was undoubtedly defined by extensive 2D NMR study and comparison with literature data.[15−19] Syringaldehyde (98% purity) used as internal standard (IS) was purchased from Sigma-Aldrich (Steinheim, Germany). IS solution was prepared in acetonitrile at a concentration of 0.5 mg/mL and kept in a refrigerator. Prior to use the IS solution was left to come to room temperature. All NMR solvents used throughout the experiments were obtained by Sigma-Aldrich.

NMR Spectral Analysis. The residue of the above procedure was dissolved in $CDCl_3$ (750 μL) and an accurately measured volume of the solution (550 μL) was transferred to a 5 mm NMR tube. ^{1}H NMR spectra were recorded at 600 MHz (Bruker Avance600) or 400 MHz (Bruker DRX400). Typically, 50 scans were collected into 32K data points over a spectral width of 0−16 ppm with a relaxation delay of 1 s and an acquisition time of 1.7 s. Prior to Fourier transformation (FT) an exponential weighing factor corresponding to a line broadening of 0.3 Hz was applied. The spectra were phased corrected and integrated automatically using TopSpin software (Bruker). Where necessary, accurate integration was performed manually for the peaks of interest.

Calibration Curves and Quantitation. Calibration curves were prepared by addition of known quantities of isolated oleuropein aglycon or ligstroside aglycon to a selected olive oil, from cv. Adramytini, which is naturally free of secoiridoid derivatives, and following the above-described extraction and measurement method. The quantitation was based on the integration ratio between the aldehydic proton signal of syringaldehyde at 9.81 ppm and the aldehydic protons of oleuropein aglycon at 9.51 and 9.58 ppm and ligstroside aglycon at 9.49 and 9.55 ppm, respectively, for each pair of diastereomers.

Standard and Spiked Solutions. Stock standard solutions of oleuropein aglycon and ligstroside aglycon were prepared in acetonitrile at the 0.5 mg/mL level and were kept under refrigeration. Prior to use the stock solutions were allowed to come to room temperature. Spiked olive oil samples were prepared to give concentrations of both aglycons of 10, 20, 40, 80, 160, and 320 mg/kg by mixing appropriate volumes of the stock standard solutions with 5.0 g of olive oil of the variety Adramytini. The mixture was homogenized using a vortex mixer for 30 s and then extracted with cyclohexane (20 mL) and acetonitrile (as much as needed to become a total of 25 mL) as described above. A sample of Adramytini variety was selected as a blank because it was found that it did not contain oleuropein and ligstroside aglycons in detectable quantities and it did not give any interfering peaks at the chemical shift of the analytes.

Method Validation. The method was checked for the linearity, precision [calculated as the relative percent standard deviation (RSD %)], accuracy [evaluated as the relative percentage error (Er%), defined as (assayed concentration − nominal concentration)/(nominal concentration) × 100], and sensitivity [evaluated as the limits of detection (LOD) and quantitation (LOQ)].

Linearity. Spiked olive oil samples were prepared to give concentrations of oleuropein aglycon and ligstroside aglycon at 10, 20, 40, 80, 160, and 320 mg/kg and were analyzed for the determination of the linearity. The relationship of the integration ratio of the analytes versus the internal standard and the corresponding concentration of the spiked olive standards was determined by linear regression analysis.

Precision. The intraday precision was determined by analyzing five replicates of spiked olive oil samples at two concentration levels of both aglycons (80 and 160 mg/kg). The interday precision was assessed by analyzing spiked olive oil samples at two concentration levels, namely, 80 and 160 mg/kg levels, on five consecutive days.

Accuracy. Spiked olive oil samples at three concentration levels of both aglycons, 10, 80, and 160 mg/kg, were analyzed in order to determine the accuracy of the method.

Recovery. For the calculation of the recovery, spiked olive oil samples with concentrations of both analytes at the 160 mg/kg level (n = 5 for each analyte) were analyzed by employing the proposed extraction procedure. The recovery was calculated as the ratio of the response of both compounds in the spiked olive oil samples against that of the standards at the same levels and was expressed as the mean ± SD (standard deviation).

Limits of Detection and Quantitation. The LOD and LOQ were determined by running six blank samples of Adramytini olive oil and measuring the background response at the chemical shift of each analyte. Signal-to-noise (S/N) ratios of 3:1 and 10:1 were used for the calculation of the LOD and LOQ, respectively.

Isolation and Spectroscopic Identification of Methyl Elenolate. Methyl elenolate was isolated using column chromatography during the purification of the reference compounds as described above and in more details in the Supporting Information. The complete NMR data of methyl elenolate (^{1}H NMR, ^{13}C NMR) as well as the original 1D and 2D NMR spectra are provided in Supporting Information and were in accordance with literature data.[19,20]

RESULTS AND DISCUSSION

Purification of Oleuropein and Ligstroside Aglycons. In order to set up the qNMR method for the measurement of oleuropein and ligstroside aglycons it was necessary to obtain the target compounds in the maximum possible purity to be used as standards for the construction of the calibration curve. For this purpose usual chromatographic methodologies were followed either using normal or reversed stationary phases. In a first step the olive oil was extracted with acetonitrile and the ^{1}H NMR spectrum of the extract was recorded to ensure that the target compounds had been successfully extracted. Then the extract was submitted to column chromatography using silica gel as stationary phase and mixtures of cyclohexane with ethyl acetate as mobile phase. When both compounds were isolated, the ^{1}H NMR spectrum showed that each one contained 20−25% of the 5*S*,8*S*,9*S* isomer and 75−80% of the 5*S*,8*R*,9*S* isomer, identified by comparison with literature data.[17−19] However, when the spectra of the purified compounds were compared with the spectrum of the initial extract, surprisingly, we observed that the peaks corresponding to the 5*S*,8*S*,9*S* isomers were almost absent (Figure 1). The 5*S*,8*R*,9*R* isomer reported by Perez-Trujillo et al.[17] was not observed neither before nor after purification (and probably this is related with differences in olive variety or the followed extraction

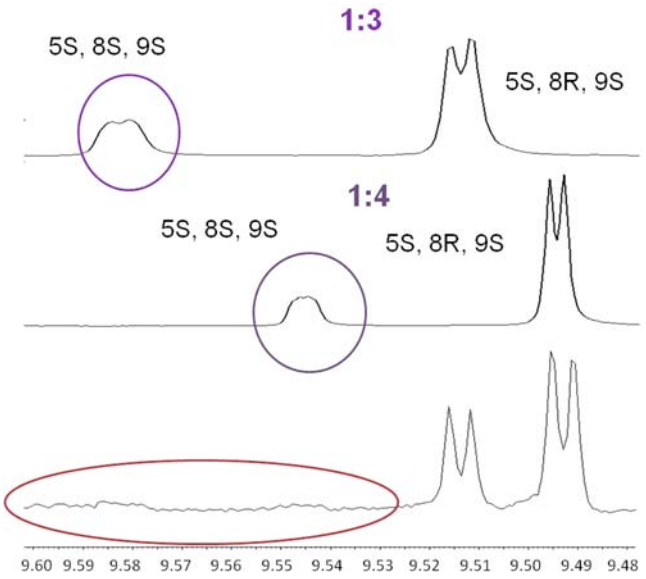

Figure 1. NMR region from 9.48 to 9.60 ppm showing the aldehyde protons of oleuropein and ligstroside aglycons. Top: Oleuropein aglycon after purification with normal-phase silica gel. Middle: Ligstroside aglycon after purification with normal phase silica gel. Bottom: Olive oil extract before submission to purification. The peaks of the 5*S*,8*S*,9*S* isomers of both aglycons are almost absent.

procedure). This observation led us to suppose the artificial formation of the minor isomers. Interestingly, the same was observed when the extract from another olive oil sample was submitted to reversed chromatography using RP-18 silica and a mixture of acetonitrile and water as mobile phase. In that case, the 5*S*,8*S*,9*S* isomers were observable before purification, but after purification, the ratio between the two isomers changed to 1:2 or 1:1 for ligstroside and oleuropein aglycons, respectively (Figure 2a,b).

To further study the role of the stationary phase in this isomerization, the following experiment was performed: A quantity of olive oil extract was diluted in a solvent (dichloromethane, cyclohexane, ethyl acetate, or mixtures of them) and added to a quantity of normal stationary phase and allowed to stand for 2 h. The same was performed with acetonitrile and water and reversed stationary phase. At the end, the mixture was filtered and evaporated and the residue was studied by NMR using $CDCl_3$. The comparison of the NMR profile of the treated and untreated olive oil extract showed that in all cases the percentage of the 5*S*,8*S*,9*S* isomers was significantly increased (Figure 3). The only combination that left the ratio unchanged was acetonitrile 100% with RP-18 silica. However, this combination was not useful for the purification of the target compounds. Although one previous work reports the purification of each isomer using Si 60 stationary phase,[19] in our hands it was obvious that it was not possible to purify oleuropein and ligstroside aglycons without isomerization using silica-based chromatography. Moreover, as it has been previously shown by LC−NMR, the two compounds are inseparable by HPLC.[17,18]

On the basis of the above observations, it is obvious that when oleuropein and ligstroside aglycons are needed for biological testing their diastereomeric purity cannot be safely determined by liquid chromatography methods. Any characterization of bioactivity should be accompanied by the isomer ratio as measured by NMR.

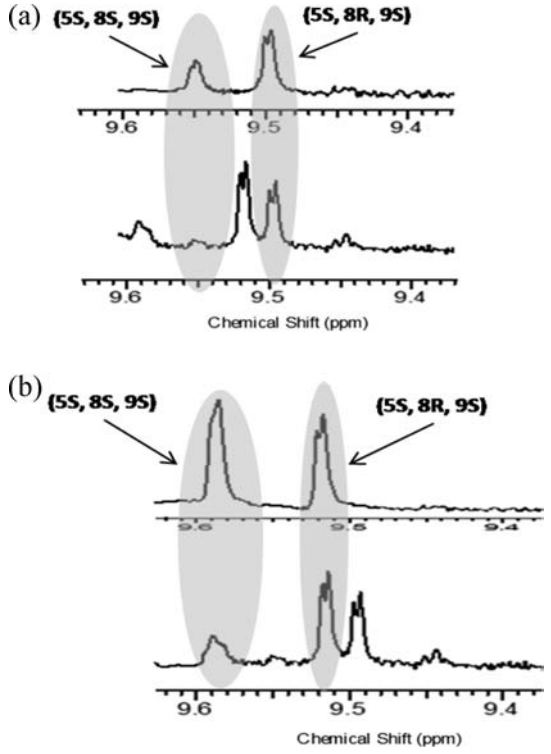

Figure 2. (a) Top: Ligstroside aglycon after purification with RP-18 and acetonitrile/water. Bottom: Olive oil extract before purification. (b) Top: Oleuropein aglycon after purification with RP-18 and acetonitrile/water. Bottom: Olive oil extract before purification.

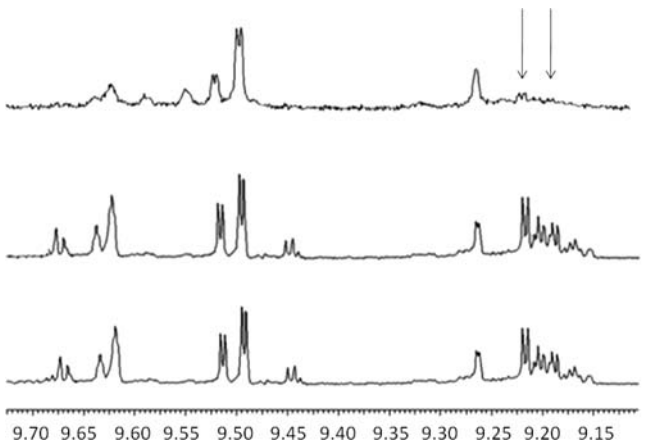

Figure 3. Oleocanthal and oleacein decomposition after contact with normal-phase silica gel. Top: NMR profile of the aldehydic region after contact with normal-phase silica gel. Middle: NMR profile of the aldehydic region after contact with reversed-phase silica gel and acetonitrile 100%. Bottom: NMR profile of the aldehydic region before contact with any stationary phase. The arrows show the strong reduction of the signals of oleocanthal and oleacein after contact with normal-phase silica gel. The signals of oleuropein and ligstroside aglycons are also reduced and new peaks corresponding to their isomers appear.

One additional observation based on the comparison of the NMR spectra of the olive oil extract before and after contact with normal phase silica (Figure 3) is that there is a significant percentage of decomposition of both oleocanthal and oleacein. This is a reasonable explanation for the low reported yield of both compounds when they are isolated by column

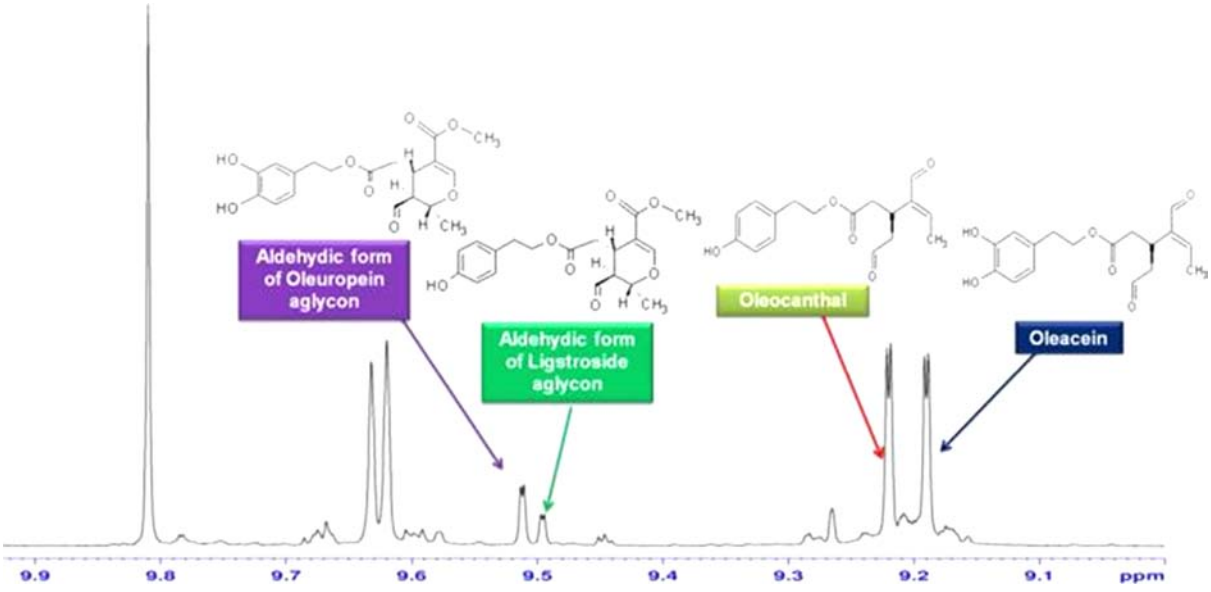

Figure 4. Typical NMR spectrum showing the peaks used for integration for each analyte.

chromatography. The mechanism of decomposition and the decomposition products were not studied.

Method Development. *Selection of Extraction Solvent.* The selection of acetonitrile as solvent for extraction of olive oil was based on the observation that it does not react with the two aglycons, as also described previously for the case of oleocanthal and oleacein.[7] It should be emphasized that methanol and/or water, which are commonly[17,18] and officialy[14] used for the extraction of phenolics from olive oil, react immediately with the dialdehydic form of oleocanthal or oleacein, leading to the corresponding acetals or hemiacetals.[7] A large number of compounds identified in HPLC−UV or LCMS chromatograms of olive oil extracts are obviously artifacts produced by that type of reaction. All those artifacts make the chromatograms much more complex and less reproducible and need to be reconsidered. For example, a recent study[13] quantified oleocanthal and oleacein with LC−MS/MS using external calibration curves prepared by dilution of standards in acetonitrile, although the analyzed olive oil extract was prepared using methanol. The proved reactivity of both compounds with methanol poses serious question about the reliability of such measurements. All hemiacetals or acetals produced during the extraction with methanol (and water) are not measured if the calibration is based on the MS/MS fragmentation of the dialdehydic forms and thus only a small part of unreacted oleocanthal or oleacein is finally measured, leading to questionable conclusions.

The two aglycons do not present such reactivity and this is possibly an explanation why they are often measured in higher levels than oleocanthal and oleacein. Moreover, one extraction with acetonitrile was sufficient for more than 85% recovery of all studied compounds. A second extraction achieved quantitative recovery but it was avoided to simplify the procedure. However, it should be noted that the exact percentage of recovery was not used for the calculations, because the final concentrations of the studied compounds in olive oil were calculated using calibration curves prepared by addition of pure compounds in olive oil originally free of both compounds.

Selection of Internal Standard and NMR Solvent. The choice of syringaldehyde as internal standard and of $CDCl_3$ as solvent for the NMR measurement was based on reasons explained previously.[7]

NMR Spectral Analysis of Target Compounds in Extra Virgin Olive Oil. The qNMR method was based on the observation that the ^1H NMR spectrum of olive oil acetonitrile extracts when recorded in $CDCl_3$ presented a very well resolved set of peaks corresponding to the aldehydic protons of the studied compounds between 9.1 and 9.8 ppm (Figure 4). This spectrum region in all the studied samples was clearly resolved, making feasible the integration of the corresponding peaks and their comparison with the peak of the internal standard. Oleuropein aglycon (3,4-DHPEA-EA) and ligstroside aglycon (*p*-HPEA-EA) were quantified by integrating doublets at 9.51and 9.49 ppm, respectively. Oleocanthal and oleacein were measured at 9.23 and 9.19 ppm, respectively, as previously described.[7]

The peaks of both aglycons did not present any overlapping in any studied sample recorded at 600 MHz or even at 400 MHz. The target peak of oleocanthal also did not present any overlapping at 600 MHz, but in some cases there was some overlapping observed at 400 MHz. The problem of overlapping was more significant for oleacein at 400 MHz but only in a few cases at 600 MHz (<3%). Even in those cases for the partially overlapped oleacein a good estimation of its quantity could be obtained. The overlapping problem can be overridden by 2D qNMR, which is currently under investigation.

Development of Calibration Curve. Since in our hands it was not possible to isolate oleuropein and ligstroside aglycons without the 5*S*,8*S*,9*S* isomer, it was obligatory to construct the calibration curve using the mixture of both isomers at a standard ratio. Since their difference is only one asymmetry center, it is reasonable to expect that their behavior during extraction will be similar and that the integration of the aldehyde proton of each isomer in the NMR spectrum in comparison with the internal standard will be the same. Under these conditions, the calibration curve was constructed by the addition of known quantities in a specifically selected olive oil sample which did not contain oleuropein or ligstroside

dx.doi.org/10.1021/jf404421p | J. Agric. Food Chem. 2014, 62, 600−607

aglycons. The sum of the integration of the two peaks corresponding to the aldehyde protons of each isomer of each compound was used as the response. The method was validated for accuracy, precision, and sensititvity.

Linearity. Good linearity was achieved for both analytes, as indicated by the equations listed in Table 1, for a concentration ranging from 10 to 320 mg/kg, with satisfactory correlation coefficients, r^2 (0.9991 and 0.991 for oleuropein and ligstroside aglycons, respectively.

Table 1. Linearity of the Oleuropein and Ligstroside Aglycons Determination in Olive Oil Samples

ratio	regression eq	correlation coeff, r^2
oleuropein aglycon/IS	$y = 336.5x - 8.66$	0.9991
ligstroside aglycon/IS	$y = 324.0x - 0.78$	0.991

Precision. The intraday precision, expressed as the relative standard deviation (RSD) ranged from 3.3 to 4.9% for the two analytes, as shown in Table 2. The interday precision ranged between 3.7 and 4.8% (Table 2). The RSD values are adequate and indicate the suitability of the method.

Table 2. Precision Data of the Oleuropein and Ligstroside Aglycons for Olive Oil Samples

	intraday precision (RSD%)		interday precision (RSD%)	
ratio	80 mg/L	160 mg/kg	80 mg/kg	160 mg/kg
oleuropein aglycon/IS	4.7	3.5	4.8	4.3
ligstroside aglycon/IS	4.9	3.3	4.8	3.7

Accuracy. The results for the accuracy are listed in Table 3 and are expressed as the relative percentage error (Er%). The estimated accuracy values with the proposed method are within acceptable levels for the two analytes. The obtained data indicate that the method could be considered as accurate.

Table 3. Accuracy Data of the Oleuropein and Ligstroside Aglycons Determination in Olive Oil Samples

	accuracy (Er%)		
ratio	10 mg/kg	80 mg/kg	160 mg/kg
oleuropein aglycon/IS	3.3	−2.9	0.70
ligstroside aglycon/IS	−9.3	−6.9	4.9

Recovery. The recoveries were found to be 85.5% (±3.5) and 85.8% (±3.1) for the 160 mg/kg levels for oleuropein and ligstroside aglycon, respectively, indicating acceptable recovery.

Sensitivity. The sensitivity of the method as presented by its limit of detection (LOD) and the limit of quantification (LOQ) were found to be 1 and 10 mg/kg, respectively, for both compounds, similarly with oleocanthal and oleacein as previously described.[7]

Isolation of Methyl Elenolate. During the isolation procedure of the four major secoiridoids, one additional minor constituent was also isolated and characterized. The ^{1}H NMR spectrum showed that it was a secoridoid derivative without a phenolic moiety. Examination of 1D and 2D NMR and MS data and comparison with literature data showed that it was the methyl ester of elenolic acid.[19,20] As in the case of oleuropein and ligstroside aglycons, methyl elenolate was isolated as a mixture of two diastereomers in a 1:4 ratio. The major one was identified as the 5*S*,8*R*,9*S* isomer by comparison with a synthetic methylated derivative of *epi*-elenolic acid.[20] The coupling constants of the major isomer were also in accordance with those described for the 5*S*,8*R*,9*S* isomer of oleuropein aglycon.[17] The main difference was the absence of the hydroxytyrosol moiety and its replacement by the methyl group. The minor diastereomer was identified as the 5*S*,8*S*,9*S* diastereomer of methyl elenolate described by Gariboldi et al.[19] as a synthetic product. As in the case of oleuropein and ligstroside aglycons, the formation of the minor isomer is most probably artificial (or artificially enhanced) due to the contact with the stationary phase during the chromatographic purification. This compound has been reported only as a synthetic derivative[19,20] and herein is reported for the first time as a constituent of olive oil.

Method Application. The developed method was applied to 340 samples of olive oil. The quantification results for each compound together with data about variety, geographic origin, and harvest time are provided as Supporting Information. The sum of the concentrations of the four compounds (named as D3) showed wide variation ranging from <1 to 1534 mg/kg (Figure 5). The highest recorded concentration of oleocanthal reached 711 mg/kg from cv. Koroneiki, while the concentration of oleacein was in almost all studied cases lower than that of oleocanthal (the highest recorded concentration for oleacein was 588 mg/kg). In total, among the Greek samples the highest concentration of the four secoiridoids were recorded in cv. Koroneiki from Aegean Islands (Paros, Antiparos), Messinia, Zakynthos, and Crete, and in cv. Throuba from Thassos Island (Table 4 and Supplementary Table 1, Supporting Information). Very interesting seems to be the case of olive oil samples from wild trees (Magnesia, Crete, Lakonia) showing very high oleocanthal content (Table 4 and Supplementary Table 1, Supporting Information). A map showing the main olive producing regions of Greece with the major variety in each region and the mean values of D3 has been constructed (Figure 6).

Concerning the two aglycons, their concentration in most studied cases was lower than that of oleocanthal and oleacein, and the previously described D1 index (sum of oleocanthal and oleacein) seems to have a dominating role in the total concentration of the secoiridoid derivatives. The concentration of the two aglycons in the Greek olive oil samples ranged from not detectable to 257 and 228 mg/kg for oleuropein and ligstroside aglycons, respectively. As shown in Figure 6, the sum of the four compounds is very well correlated with D1 as well as oleocanthal alone (supplementary Figure 9, Supporting Information), revealing the role of oleocanthal as the dominating factor at least among the Greek studied varieties. The highest recorded concentration of oleuropein aglycon (342 mg/kg) was recorded in a sample from cv. Mission from California, produced from green olives under stressed irrigation and low-temperature milling. The cv. Mission from California seems to be highly interesting, since in all studied samples the major secoiridoid was oleuropein aglycon. Moreover, in all Mission samples the concentration of oleocanthal and oleacein was lower than that of oleuropein and ligstroside aglycons, revealing that there are two distinct biosynthetic pathways leading to the domination of each group of compounds. It is apparent that regarding the phenolic secoiridoids of olive oil there are at least three different chemotypes: one with the domination of decarboxymethyl dialdehydic forms (oleocanthal,oleacein) (e.g., cv. Koroneiki, cv. Throuba, cv. Athenolia),

[a]Oleacein + oleocanthal. [b]Oleacein/oleocanthal. [c]Sum of four secoiridoids. [d]Bottled samples.

one with the domination of monoaldehyde aglycons (e.g., cv. Mission), and one with the absence (or significantly reduced content) of both categories (e.g., cv. Adramytini, cv. Megaritiki) (supplementary Figure S1A–C, Supporting Information). However, we have also observed a number of samples with a different pattern presenting aldehyde peaks with significant intensity corresponding to not yet measured derivatives like oleuropein and ligstroside aglycon dialdehyde forms (supplementary Figure S1D, Supporting Information). The existence of varieties with other major secoiridoid derivatives makes necessary their exact identification and measurement. This is currently in progress as well as the expansion of the chemical database to other important varieties.

Although according to the European union legislation[21] all the studied samples were considered as extra virgin olive oils, the observed significant variation of the concentration of the bioactive polyphenolic secoiridoids confirms our previous conclusion[7] that there is need of a new type of classification of EVOO, especially related to possible health claims of those compounds.

Another observation that was further confirmed is that the ratio between oleocanthal and oleacein (index D2 = oleacein/oleocanthal) seems to be dependent on the olive tree variety, probably due to genetic reasons and independent of the olive mill procedure. Expanding our database[7] and including more samples (from 30 to 56 samples) coming only from cv.

dx.doi.org/10.1021/jf404421p | J. Agric. Food Chem. 2014, 62, 600–607

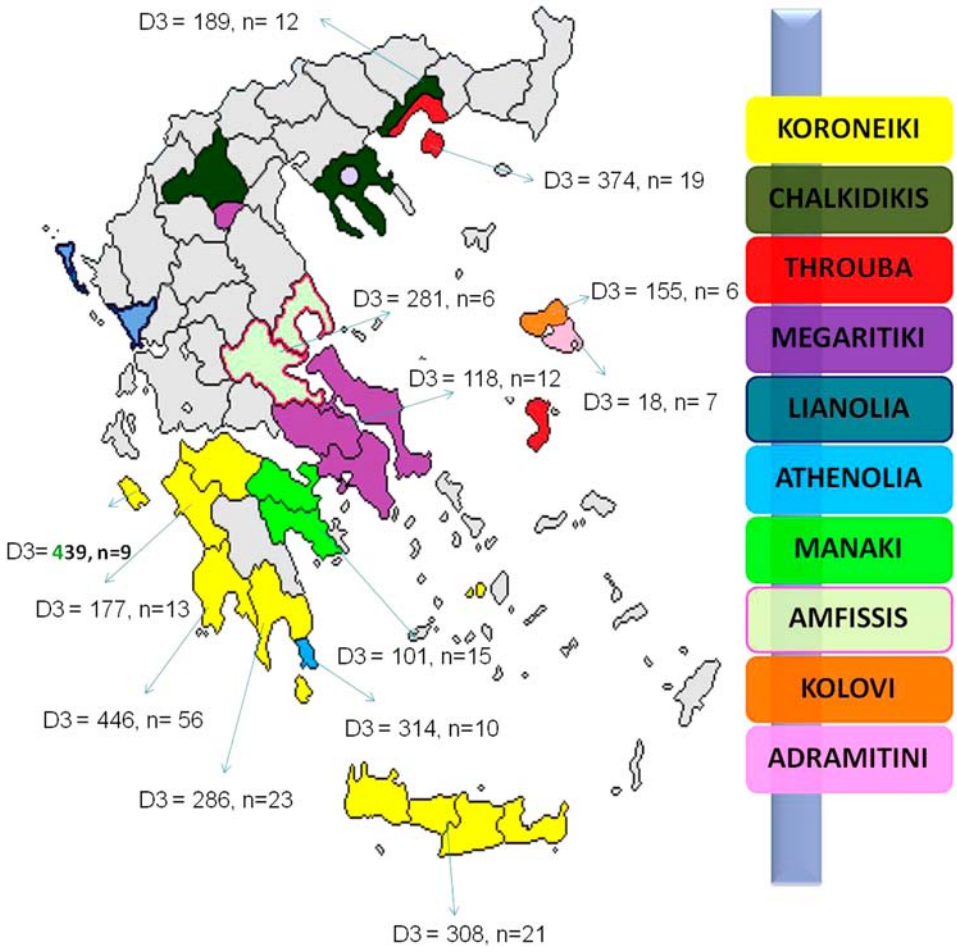

Figure 6. Map of the major olive oil producing regions of Greece showing the main variety cultivated/studied in each region and the mean D3 index for each region, *n* = number of studied samples.

Koroneiki from a narrow geographic region (Messinia) we observed that despite the variability of D1 (due to differences in harvest time or milling procedures), the correlation between oleocanthal and oleacein concentration was almost linear (R^2 = 0.71) and the mean D2 value was 0.50 ± 0.22 (supplementary Figure S8, Supporting Information). In contrast, in other varieties, for example Throuba Thassos (25 samples), the mean D2 value was significantly lower (0.29 ± 0.15) or, for Athenolia (20 samples, D2 = 0.31 ± 0.20), showed that the ratio between olacein and oleocanthal is mainly influenced by the tree variety.

Moreover, as previously reported for oleocanthal and oleacein, the highest levels of the two aglycons were also recorded in samples coming from early harvest showing again the positive correlation of the secoiridoid levels in olive oil with the low maturity index of the olive fruit.

As a final remark and based on the above observations, we would like to propose one more supplementary index, D3, as an addition to the previously described D1 and D2 indexes. Those indexes can be used for the support of health claims, since they are directly related with the European Union regulation[5] about the derivatives of hydroxytyrosol and tyrosol in olive oil. D1 and D3 are more accurate and specific than the commonly used total polyphenols index (expressed as gallic acid equivalent) and could become a new standard for the characterization of olive oil healthfulness.

White Tea as a Promising Antioxidant Medium Additive for Sperm Storage at Room Temperature: A Comparative Study with Green Tea

Tânia R. Dias, Marco G. Alves, Gonçalo D. Tomás, Sílvia Socorro, Branca M. Silva,* and Pedro F. Oliveira*

CICS − UBI − Health Sciences Research Centre, University of Beira Interior, 6201-506 Covilhã, Portugal

ABSTRACT: Storage of sperm under refrigeration reduces its viability, due to oxidative unbalance. Unfermented teas present high levels of catechin derivatives, known to reduce oxidative stress. This study investigated the effect of white tea (WTEA) on epididymal spermatozoa survival at room temperature (RT), using green tea (GTEA) for comparative purposes. The chemical profiles of WTEA and GTEA aqueous extracts were evaluated by ^{1}H NMR. (−)-Epigallocatechin-3-gallate was the most abundant catechin, being twice as abundant in WTEA extract. The antioxidant power of storage media was evaluated. Spermatozoa antioxidant potential, lipid peroxidation, and viability were assessed. The media antioxidant potential increased the most with WTEA supplementation, which was concomitant with the highest increase in sperm antioxidant potential and lipid peroxidation decrease. WTEA supplementation restored spermatozoa viability to values similar to those obtained at collection time. These findings provide evidence that WTEA extract is an excellent media additive for RT sperm storage, to facilitate transport and avoid the deleterious effects of refrigeration.

KEYWORDS: *sperm, Camellia sinensis, white tea, green tea, epigallocatechin-3-gallate, reactive oxygen species, antioxidants*

INTRODUCTION

Tea (*Camellia sinensis* (L.)) is one of the world's most widely consumed beverages, and its medicinal properties have been widely explored.[1] It can be classified in three types: unfermented (green and white teas), partially fermented (oolong tea), and completely fermented (black tea).[2] To produce green tea (GTEA), freshly harvested leaves are steamed to inactivate polyphenol oxidase enzyme and then rolled and dried. Its chemical composition is very similar to that of the fresh tea leaf.[1] White tea (WTEA) is exclusively prepared from young tea leaves or buds, harvested before being fully opened. The tea materials are picked and immediately sent to be steamed and dried to prevent oxidation, frequently followed by polymerization.[3] Unfermented teas are known to have high polyphenolic content, mainly catechin derivatives, (−)-epigallocatechin 3-gallate (EGCG) being the most abundant and powerful antioxidant.[4] With respect to processing, there are very little differences between green and white teas, although several papers suggest that WTEA presents higher levels of antioxidants than GTEA.[5] Recently, antioxidant components have aroused great interest due to their ability to minimize the deleterious effects of reactive oxygen species (ROS) on a number of biological and pathological processes.[6] ROS are necessary for the normal physiological function of sperm,[7] although their concentration must be kept under strict control to avoid deleterious effects, such as damage to cell structures: lipids and membranes, proteins, and DNA.[8] It has been reported that ROS overproduction results in oxidative stress (OS), which is related to several problems that may end up in male subfertility or infertility.[9] In fact, spermatozoa are particularly vulnerable to such stress because ROS readily attack the polyunsaturated fatty acids (PUFA) of the cells membrane, initiating a self-propagating chain reaction. End-products of these lipid peroxidation reactions, such as malondialdehyde (MDA), are especially dangerous for cell viability.[10] Therefore, there is a growing interest in enlightening the role of ROS formation in sperm as they are responsible for lower sperm quality in freshly collected semen and poor quality of sperm after processing for usage in reproductive technologies, such as artificial insemination (AI), in vitro fertilization (IVF), or cryopreservation.[11]

The maintenance of mammalian sperm at room temperature (RT) for short-term periods is advantageous as the storage of sperm in a refrigerated environment induces a rapid decline in its viability.[12] Establishment of optimal composition for sperm storage is of extreme relevance, as these cells are highly dependent on the supply of exogenous substrates and, due to their high metabolic rates, produce elevated amounts of ROS.[12] The addition of GTEA polyphenols has proven to be of great significance on frozen−thawed spermatozoa motility.[13] Here, we aimed to investigate the possible protective effect of WTEA extract on epididymal spermatozoa survival at RT, using GTEA as a comparison reference.[14] For that purpose, the chemical profiles of WTEA and GTEA aqueous extracts were determined by using ^{1}H NMR as well as the antioxidant potential of storage media containing these extracts. Furthermore, the effect of both extracts on epididymal spermatozoa maintenance at RT during 24, 48, and 72 h was evaluated by determining the spermatozoa antioxidant potential, lipid peroxidation, and viability during that time frame.

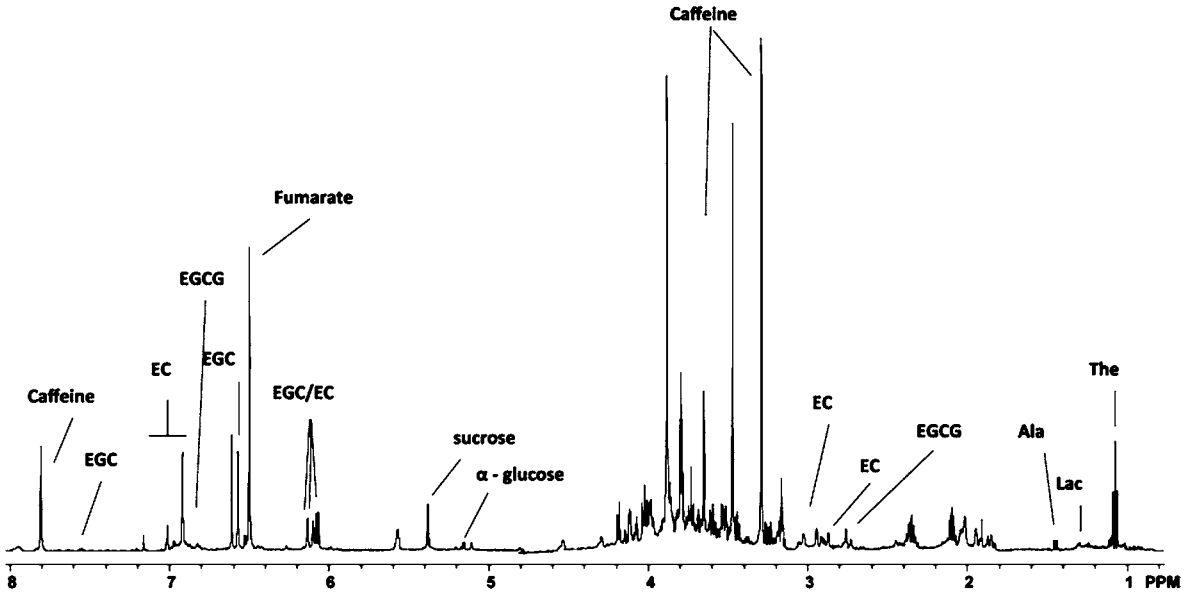

Figure 1. Representative ^{1}H NMR spectrum of WTEA extract showing the phytocomponent peak assignments: (EC) (−)-epicatechin; (EGC) (−)-epigallocatechin; (EGCG) (−)-epigallocatechin 3-gallate; (Ala) alanine; (The) theanine; (Lac) lactate.

MATERIALS AND METHODS

Chemicals. All chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA) unless specifically stated otherwise.

Tea Extracts. WTEA and GTEA were purchased on the Portuguese market (Diese, Bestlife - Comércio e Distribuição Lda., Portugal). Samples (n = 5) were subjected to infusion (1 g/100 mL distilled water; pH 5.5) at 100 °C during 3 min, according to the manufacturer's instructions. The resulting infusions were filtered with qualitative filter papers (catalog no. 516-0819, VWR, Leuven, France) in a vacuum system and freeze-dried overnight in a ScanVacCoolSafe Freeze-Dryer (Labogene, Lynge, Denmark). The mean extraction yields (g of lyophilized extract per 100 g of dried teas leaves) were 25% (for WTEA) and 20% (for GTEA). The lyophilized extracts were kept in a desiccator, protected from light, until analysis.

Proton Nuclear Magnetic Resonance (^{1}H NMR). ^{1}H NMR spectra were acquired as previously described.[15] Briefly, ^{1}H NMR spectra of WTEA and GTEA aqueous extracts dissolved in D_2O were acquired at 14.1 T, 25 °C, using a Bruker Avance 600 MHz spectrometer equipped with a 5 mm QXI probe and a z-gradient. ^{1}H NMR spectra were acquired with solvent suppression and a sweep width of 6 kHz, using a delay of 14 s, a water presaturation of 3 s, a pulse angle of 45°, an acquisition time of 3.5 s, and at least 128 scans. Sodium fumarate was added to the samples for quantification purposes (in a final concentration of 1 mM), because it does not exist in our tea extracts and was used as a reference (6.50 ppm), as routinely done in our laboratory,[16,17] to quantify the extract compounds whenever present in solution. The following coupling patterns, available in the literature,[18−23] were used to quantify the identifiable extract compounds (multiplet, ppm): L-theanine (triplet, 1.08); lactate (doublet, 1.33); alanine (doublet, 1.45); EGCG (doublet, 2.7); caffeine (singlet, 3.29); H1-α-glucose (doublet, 5.22); sucrose (doublet, 5.4); (−)-epigallocatechin (EGC) (singlet, 6.6); (−)-epicatechin (EC) (singlet, 7.0) (for a representative image see Figure 1). The relative areas of ^{1}H NMR resonances were quantified using the curve-fitting routine supplied with the NUTSproTM NMR spectral analysis program (Acorn, NMR Inc., Fremont, CA, USA).

Isolation of Epididymal Spermatozoa. The present study used six male 3-month-old Wistar rats, obtained from our accredited animal colony (Health Sciences Research Centre, University of Beira Interior) and maintained on ad libitum food and water in a constant room temperature (20 ± 2 °C) on a 12 h cycle of artificial lighting. Rats were fed a standard chow diet (4RF21 certificate, Mucedola, Italy). All animal experiments were performed according to the *Guide for the Care and Use of Laboratory Animals* published by the U.S. National Institutes of Health (NIH Publication 85-23, revised 1996) and the European directives for the care and handling of laboratory animals (Directive 86/609/EEC), after approbation by the National Ethics Committee of Animal Welfare.

Animals were anesthetized, by intraperitoneal injection of a mixture of 90 mg/kg of ketamine and 10 mg/kg of xylazine, and euthanized by cervical displacement. Cauda epididymis were isolated and immediately placed separately in 3 mL of a prewarmed (37 °C) Krebs−Ringer bicarbonate (TYH) medium (in mM: NaCl, 118.8; KCl, 4.78; $CaCl_2$, 1.71; KH_2PO_4, 1.19; $MgSO_4$, 1.19; $NaHCO_3$, 25; glucose, 5.56; sodium pyruvate, 1.01; sodium lactate, 29.2; plus 4.00 mg/mL BSA, 0.06 mg/mL potassium penicillin G and 0.05 mg/mL streptomycin sulfate), prepared on the day of the experiment, as described by Toyoda.[24] The two cauda epididymis of each animal were minced together with a scalpel blade, to allow sperm to disperse into the medium, and the suspension was then incubated for 1.5 h at 37 °C. The number of spermatozoa was determined using a hemocytometer, and 8×10^5 spermatozoa were placed in 300 μL of a control medium (in mM: NaCl, 96.66; KCl, 4.78; $CaCl_2$, 1.71; KH_2PO_4, 1.19; $MgSO_4$, 1.19; $NaHCO_3$, 4.15; D-glucose, 5.56; sodium pyruvate, 0.33; sodium lactate, 23.28; HEPES, 20.85; plus 4.00 mg/mL BSA, 0.06 mg/mL potassium penicillin G, 0.05 mg/mL streptomycin sulfate) as previously described.[25] Moreover, the same amount of spermatozoa was placed in four other media, with the same composition of the control group but containing additional concentrations of freeze-dried WTEA or GTEA aqueous extracts to a final concentration of 0.5 or 1 mg/mL. Subsequently, sperm suspensions were kept at acclimatized RT (22−23 °C) during 24, 48, and 72 h. These sperm suspensions were used for the FRAP, TBARS, and sperm viability assays, after being processed as described in each section.

Protein Quantification. After the 72 h of incubation, spermatozoa were separated from the storage media through centrifugation at 5000g for 15 min at 4 °C. Then, sperm pellets were washed with 100 μL of phosphate-buffered saline (PBS) solution (in mM: NaCl, 137; KCl, 2.7; Na_2HPO_4, 4.3; KH_2PO_4, 1.47; pH 7.4) and centrifuged again at 5000g for 15 min at 4 °C. Total proteins were isolated from the spermatozoa by the addition of an adequate amount of PBS, followed by a sonication for 15 min at 4 °C. Protein concentration was determined by Bio-Rad (Hemel Hempstead, UK) Bradford microassay according to the manufacturer's instructions. Sperm suspensions were used in FRAP and TBARS assays.

Ferric Reducing Antioxidant Power (FRAP) assay. The ferric reducing antioxidant power (FRAP) of the media samples and

dx.doi.org/10.1021/jf4049462 | J. Agric. Food Chem. 2014, 62, 608−617

spermatozoa pellets was performed according to the colorimetric method described by Benzie and Strain.[26] Briefly, working FRAP reagent was prepared by mixing acetate buffer (300 mM, pH 3.6), 2,4,6-tripyridyl-s-triazine (TPTZ) (10 mM in 40 mM HCl), and $FeCl_3$ (20 mM) in a 10:1:1 ratio (v/v/v); 180 μL of this reagent was mixed with 6 μL of each sample. The reduction of the Fe^{3+}−TPTZ complex to a colored Fe^{2+}−TPTZ complex by the samples was monitored immediately after addition of the sample and 40 min later, by measuring the absorbance at 595 nm using an Anthos 2010 microplate reader (Biochrom, Berlin, Germany). The antioxidant potential of the samples was determined against standards of ascorbic acid, which were processed in the same manner as the samples. Absorbance results were corrected by using a blank, with water instead of sample. The changes in absorbance values of test reaction mixtures were used to calculate FRAP values as described elsewhere.[26]

Thiobarbituric Acid Reactive Substances (TBARS) Assay. TBARS are formed as a byproduct of lipid peroxidation, which can be detected by the TBARS assay using thiobarbituric acid (TBA) as a reagent. This peroxidation reaction produces MDA, which reacts with TBA in conditions of high temperature and low pH, generating a pink complex that absorbs at 532 nm.[27] The TBARS assay was carried out according to the method described by Iqbal et al.,[28] with slight adaptations. Briefly, the reaction mixture in a total volume of 0.1 mL contained 0.01 mL of the sample, 0.01 mL of Tris-HCl buffer (150 mM, pH 7.1), 0.01 mL of ferrous sulfate (1.0 mM), 0.01 mL of ascorbic acid (1.5 mM), and 0.06 mL of H_2O. This mixture was incubated at 37 °C for 15 min. The reaction was stopped by the addition of 0.1 mL of trichloroacetic acid (10% w/v). Subsequently, 0.2 mL of thiobarbituric acid (0.375% w/v) was added, and all samples were incubated for 15 min at 100 °C. Finally, samples were subjected to centrifugation at 3000*g* for 10 min at 4 °C. The amount of MDA formed in each of the samples was estimated by measuring the optical density at 532 nm using a UV−vis spectrophotometer (Shimadzu, Kyoto, Japan) against a blank. The results were expressed as nanomoles of TBARS per milligram of protein.

Sperm Viability Evaluation. To assess sperm viability, an eosin/nigrosin staining was used because it is effective, simple, and, in addition to allowing sperm to be readily visualized, permits assessment of sperm membrane integrity. This method was performed with slight modifications of a method previously described.[29] A total of 5 μL of the sperm suspensions obtained as described above (see Isolation of Epididymal Spermatozoa) was mixed with 10 μL of 0.5% eosin/nigrosin stain and placed on a prewarmed glass microscope slide. Samples were analyzed at 0, 24, 48, and 72 h of the experiment. The number of viable and nonviable spermatozoa was determined by counting a total of 333 spermatozoa per slide in continuous random fields under a light microscope, with oil immersion (×1000 magnification), to determine the percentage of viable sperm, as previously described.[16] Live sperm remained white, whereas dead sperm stained pink, because the integrity of their plasma membrane was compromised, causing an increase in membrane permeability, which led to the uptake of the dye (Figure 5A).

Statistical Analysis. Statistical significance was assessed by two-way ANOVA, followed by Bonferroni post-test using GraphPad Prism 5 (GraphPad Software, San Diego, CA, USA). All data are presented as the mean ± SEM. Differences with $p < 0.05$ were considered statistically significant. Further analysis of the statistical power (SP) of differences of experimental data was evaluated with a one-tailed test assuming an α value of 0.05, which corresponds to a 0.95 confidence interval, as described by Levin,[30] using the software provided by http://www.dssresearch.com/KnowledgeCenter/toolkitcalculators/statisticalpowercalculators.aspx.

RESULTS

White Tea Extract Presents the Highest Content in Catechin Derivatives, Especially EGCG. Tea has been characterized by its high content in flavonoids,[31] such as catechin derivatives and other polyphenols,[32] which have biological and pharmaceutical properties that have been linked to beneficial effects on human health.[33]

The ^{1}H NMR data obtained from the aqueous extracts allowed the assignment of the following phytochemicals: three catechin derivatives, EC, EGC, and EGCG; one methylxanthine, caffeine; two free amino acids, L-theanine and alanine; two carbohydrates, glucose and sucrose; and one organic acid, lactate (for a representative image see Figure 1). As expected, the most abundant class of phytochemicals was the catechin family, representing 133 ± 14 and 91 ± 7 g/kg of WTEA and GTEA extracts, respectively. Among catechins, EGCG was the one present in the highest amount in both tea extracts, although in WTEA extract the quantity of this compound (82 ± 7 g/kg of WTEA extract) was nearly twice that verified in GTEA extract (42 ± 2 g/kg of GTEA extract). Concerning caffeine and sucrose, WTEA extract also demonstrated a larger amount (71 ± 8 and 60 ± 4 g/kg of WTEA extract, respectively) in comparison with GTEA (21 ± 3 and 26 ± 2 g/kg of GTEA extract, correspondingly). L-Theanine, alanine, and glucose were also present in considerable amounts, accounting for 19 ± 2, 0.7 ± 0.1, and 6 ± 1 g/kg of WTEA extract and 22 ± 1, 0.20 ± 0.04, and 11 ± 2 g/kg of GTEA extract, respectively (Table 1).

Table 1. White (WTEA) and Green Tea (GTEA) Extract Phytochemical Profiles As Determined by ^{1}H NMR Spectroscopy

	content[a] (g of compd/kg of tea extract)	
compound	WTEA	GTEA
glucose	6 ± 1.00	11 ± 2.00
sucrose	60 ± 4.00	26 ± 2.00
lactate	0.40 ± 0.01	0.46 ± 0.02
alanine	0.7 ± 0.10	0.20 ± 0.04
caffeine	71 ± 8.00	21 ± 3.00

In fact, (−)-epicatechin 3-gallate (ECG), (−)-catechin (C), and (−)-gallocatechin-3-gallate (GCG) were absent in our extracts. Generally, these polyphenols are minor tea components but sometimes are absent in tea extracts. For instance, Carvalho et al.[34] and Rusak et al.[35] have not found GCG and C, respectively, in tea extracts. Hence, the white and green tea qualitative phytochemical profiles obtained using ^{1}H NMR (Table 1) are in accordance with the phenolic and methylxanthine profiles obtained by HPLC-UV, HPLC-DAD, or HPLC-MS previously reported by Carvalho et al.,[34] Rusak et al.,[35] and Unachukwu et al.[36] The observed differences in the quantitative profile may be mainly due to the use of different extraction conditions (solvents, temperatures, times of extraction, and ratio leaves/water). Also, the natural variability of plants caused by edapho-climatic factors, harvesting techniques, or agricultural practices may contribute to these differences.

Storage Media Supplemented with White Tea Extract Have the Highest Antioxidant Potential. As the aqueous extracts of WTEA and GTEA demonstrated to be rich in

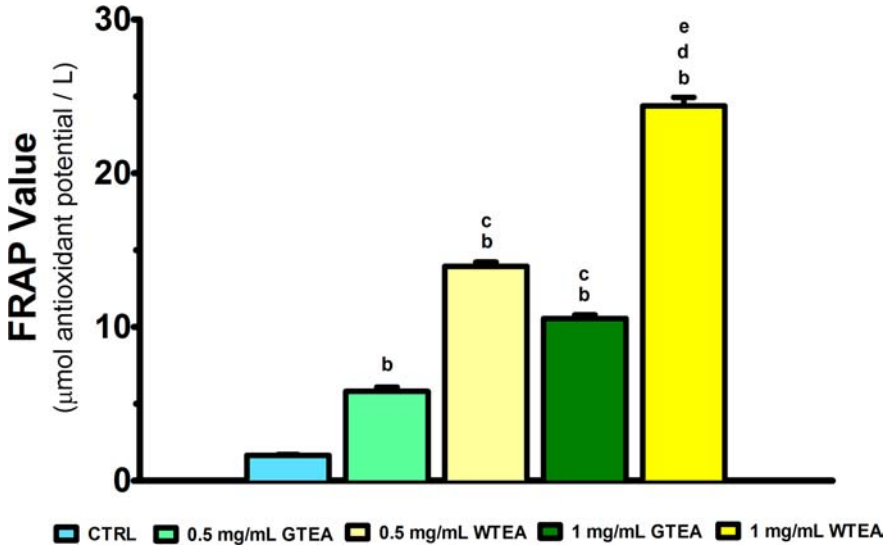

Figure 2. Ferric reducing antioxidant power (FRAP) of the epididymal spermatozoa storage media, control medium (CTRL), and media supplemented with freeze-dried WTEA or GTEA aqueous extracts to a final concentration of 0.5 or 1 mg/mL. The antioxidant power is expressed by the FRAP value (μmol of antioxidant potential/L). Results are presented as the mean ± SEM (n = 6). Significant results (p < 0.05) are indicated: b, versus CTRL; c, versus GTEA, 0.5 mg of GTEA extract/mL; d, versus WTEA, 0.5 mg of WTEA extract/mL; e, versus GTEA, 1 mg of GTEA extract/mL.

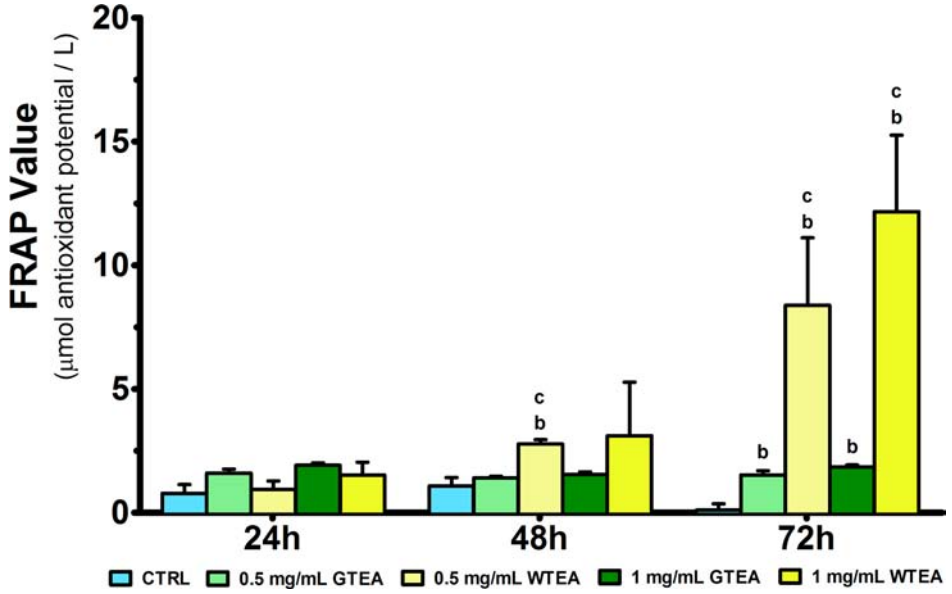

Figure 3. Ferric reducing antioxidant power (FRAP) of the epididymal spermatozoa stored in control medium (CTRL) and media supplemented with freeze-dried WTEA or GTEA aqueous extracts to a final concentration of 0.5 or 1 mg/mL, during the 24, 48, and 72 h of the experiment. The antioxidant power is expressed by the FRAP value in μmol of antioxidant potential/μg of protein and is presented as the mean ± SEM (n = 6). Significant results (p < 0.05) are indicated: b, versus CTRL; c, versus GTEA, 0.5 mg of GTEA extract/mL.

catechin derivatives, namely, EGCG, we performed a FRAP assay to evaluate the antioxidant potential of all experimental media supplemented with these extracts in comparison with the control media. The FRAP assay measures the potential of an antioxidant to reduce ferric(III) to ferrous(II) in a redox-linked colorimetric reaction that involves single electron transfer.[37] The reducing power of a compound/extract serves as a significant indicator of its potential antioxidant activity (FRAP value). The control medium showed a FRAP value of 1.64 ± 0.05 μmol of antioxidant potential/L (Figure 2). On the other hand, the FRAP value of the media supplemented with WTEA and GTEA revealed a dose-dependent reducing power (Figure 2), with significantly higher FRAP values relative to the control group during all of the experiments (SP = 100%). Comparing GTEA supplementation, the medium with 1 mg/mL of GTEA extract presented a significantly higher antioxidant potential compared to the medium with 0.5 mg of GTEA extract/mL (11 ± 0.2 vs 6 ± 0.3 μmol of antioxidant potential/L) (SP = 100%). In relation to WTEA, the FRAP value of the medium supplemented with 0.5 mg/mL of WTEA extract was 14 ± 0.3 μmol of antioxidant potential/L, which was significantly higher compared to the medium with the same concentration of GTEA extract (SP = 100%). Moreover, the medium containing 1 mg/mL of WTEA presented a significantly higher antioxidant potential of 24 ± 0.6 μmol of antioxidant potential/L in comparison with the medium supplemented with 0.5 mg/

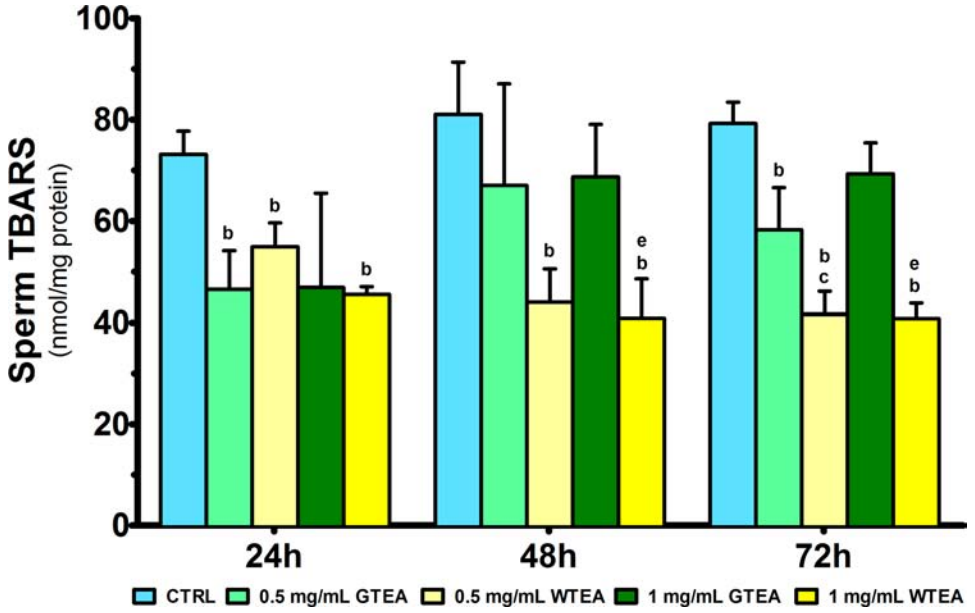

Figure 4. Sperm TBARS values produced in epididymal spermatozoa stored in control medium (CTRL) and media supplemented with freeze-dried WTEA or GTEA aqueous extracts to a final concentration of 0.5 or 1 mg/mL, during the 24, 48, and 72 h of the experiment. Results are expressed in nmol/mg of protein and are presented as the mean ± SEM ($n = 6$). Significant results ($p < 0.05$) are indicated: b, versus CTRL; c, versus GTEA, 0.5 mg of GTEA extract/mL; e, versus GTEA, 1 mg of GTEA extract/mL.

mL of WTEA extract and 1 mg/mL of GTEA extract (SP = 100%).

White Tea Extract Considerably Increases the Antioxidant Potential of Spermatozoa. Because the media supplemented with WTEA extract proved to have the highest antioxidant potential, we expected to verify the same profile in the antioxidant potential of the spermatozoa. Therefore, we also measured the antioxidant potential of the spermatozoa pellets at 24, 48, and 72 h with the FRAP assay. Accordingly, spermatozoa kept in control medium had always a lower antioxidant potential than spermatozoa stored in the media supplemented with WTEA and GTEA extracts, although these differences were statistically significant only after 48 and 72 h of storage, respectively (Figure 3). Indeed, at 48 h the spermatozoa stored in the medium with 0.5 mg of WTEA extract/mL presented a FRAP value of 2.8 ± 0.2 μmol of antioxidant potential/μg of protein, significantly higher than that of spermatozoa maintained in the control medium (1.1 ± 0.3) and in medium supplemented with 0.5 mg of GTEA extract/mL (1.4 ± 0.1) (SP = 100%). At 72 h, the FRAP values of spermatozoa maintained in media with 0.5 and 1 mg of GTEA extract/mL were 1.5 ± 0.2 (SP = 84%) and 1.8 ± 0.1 (SP = 100%) μmol of antioxidant potential/μg of protein, respectively, being significantly higher than that verified in the control group. At this time of incubation, the FRAP value determined for spermatozoa kept in the control medium was significantly lower than that at 48 h, reaching a value of 0.1 ± 0.3 μmol of antioxidant potential/μg of protein (SP = 100%) (Figure 3). In contrast, the antioxidant potentials of spermatozoa stored in the media supplemented with WTEA extract (0.5 and 1.0 mg of WTEA extract/mL) were remarkably higher than those observed at 48 h (8.4 ± 2.7 (SP = 99.9%) and 12.2 ± 3.1 (SP = 100%) μmol of antioxidant potential/μg of protein, respectively) and also than the FRAP value of the control group. Moreover, at 72 h there were no significant differences between both concentrations of the same extract.

Spermatozoa Lipid Peroxidation Is Significantly Reduced by White Tea Supplementation. During spermatozoa storage, ROS production is known to induce several deleterious effects[38] such as lipid peroxidation. Because spermatozoa antioxidant potential was increased after incubation with the tea extracts, we hypothesized that it could also decrease ROS production, thus decreasing lipid peroxidation. Therefore, we performed the TBARS assay to determine the levels of lipid peroxidation that occurred in spermatozoa during storage in the different media. Because ROS have extremely short half-lives, they are difficult to measure directly. Instead, several products induced by OS, such as TBARS, can be measured and used as an accurate indicator of OS.[39] Using the TBARS assay, it was possible to detect a significant decrease in lipid peroxidation in spermatozoa stored in media supplemented with WTEA and GTEA extracts. At 24 h, there was a significant decrease in lipid peroxidation from spermatozoa stored in the control medium (73 ± 4 nmol TBARS/mg protein) relative to the media containing 0.5 mg/mL of GTEA (47 ± 7 nmol TBARS/mg protein) and 0.5 and 1 mg/mL of WTEA (54.8 ± 4.7 and 46 ± 2 nmol TBARS/mg protein, respectively) (Figure 4) (SP = 100%). After 48 h, the lipid peroxidation significantly decreased from 81 ± 10 nmol TBARS/mg protein in the control group to 44 ± 6 and 41 ± 8 nmol TBARS/mg protein (SP = 100%) in the spermatozoa stored in the media supplemented with 0.5 and 1 mg of WTEA extract/mL, respectively (Figure 4). Moreover, the spermatozoa stored in the medium with 1 mg of WTEA extract/mL also presented significantly less lipid peroxidation than the spermatozoa maintained in the medium with 1 mg of GTEA extract/mL, which presented a value of 69 ± 10 nmol TBARS/mg protein (SP = 99.9%). At the end of the experiment (72 h), the control group presented a lipid peroxidation of 79 ± 4 nmol TBARS/mg protein that significantly decreased to 58 ± 8, 42 ± 5, and 41 ± 3 nmol TBARS/mg protein (SP = 100%) after storage in the media supplemented with 0.5 mg of GTEA extract/mL and 0.5 and 1 mg of WTEA extract/mL,

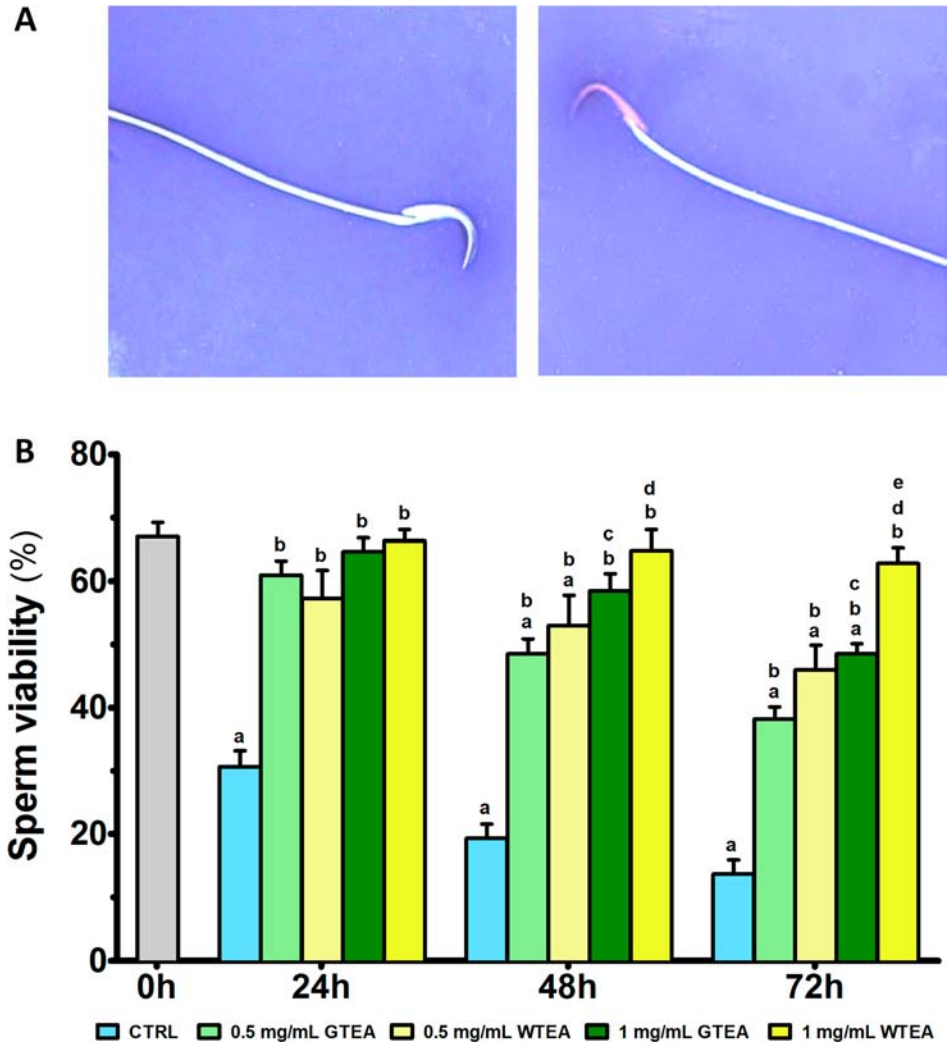

Figure 5. (A) Spermatozoa staining using eosin/nigrosin showing a viable (left) and a nonviable (right) cell. (B) Spermatozoa viability at collection time (0 h) and during the 3 day storage in control medium (CTRL) and media supplemented with freeze-dried WTEA or GTEA aqueous extracts to a final concentration of 0.5 or 1 mg/mL. Results are presented as the mean ± SEM (n = 6). Significant results (p < 0.05) are indicated: a, versus 0 h; b, versus CTRL; c, versus GTEA, 0.5 mg of GTEA extract/mL; d, versus WTEA, 0.5 mg of WTEA extract/mL; e, versus GTEA, 1 mg of GTEA extract/mL.

respectively. Additionally, lipid peroxidation in spermatozoa kept in the media with 0.5 and 1 mg of WTEA extract/mL were significantly lower than in spermatozoa stored in the media supplemented with 0.5 (SP = 99.5%) and 1 mg of GTEA extract/mL (SP = 100%), correspondingly.

White Tea Supplementation Increases Spermatozoa Viability after Room Temperature Storage. Sperm viability is one of the most important parameters to assess sperm quality.[40] Once the WTEA and GTEA supplementation significantly increased the antioxidant potential of storage media and spermatozoa and decreased spermatozoa lipid peroxidation, we hypothesized that sperm viability could be improved by these extracts. Therefore, we evaluated the sperm viability at the time of epididymal collection (0 h) and at 24, 48, and 72 h. At collection, sperm viability averaged 67 ± 2%. During spermatozoa storage at RT in control medium we observed that viability was continuously decreasing, presenting values of 31 ± 2, 19 ± 2, and 14 ± 1% at 24, 48, and 72 h, respectively (Figure 5B) and being significantly lower compared to viability at collection time (SP = 100%). There was a dose-dependent significant increase in viability, during the 3 day storage, in spermatozoa stored in media supplemented with both tea extracts when compared with the control. At 24 h, viability of spermatozoa kept in the media supplemented with any of the tea extracts was very similar to that observed at 0 h. At 48 h, viability of spermatozoa kept in the media with 0.5 mg/mL of GTEA or WTEA significantly decreased (49 ± 2 and 53 ± 5%, respectively) in comparison with that observed, 67 ± 2%, at the collection time (SP = 100%). Conversely, viability corresponding to the spermatozoa stored in the media with 1 mg/mL of GTEA or WTEA (59 ± 3 (SP = 100%) and 65 ± 3% (SP = 99.5%), respectively) was significantly higher than the viability verified in the media containing half the concentration of these extracts. The same profile was verified at 72 h of storage with the only exception that spermatozoa kept in 1 mg of WTEA extract/mL medium exhibited significantly higher viability of 63 ± 3% in relation to the spermatozoa kept in the medium with 1 mg of GTEA extract/mL, which was 49 ± 2% (SP = 100%), being in its turn significantly lower compared to the viability at 0 h (SP = 100%). Remarkably, spermatozoa maintained in the medium with 1 mg of WTEA extract/mL averaged a viability of 65%

dx.doi.org/10.1021/jf4049462 | J. Agric. Food Chem. 2014, 62, 608−617

throughout the experiment, a very similar value relative to viability at 0 h (Figure 5B).

DISCUSSION

Despite the similarities between GTEA and WTEA, the number of investigations studying the health benefits of WTEA is negligible compared to GTEA. Recently, WTEA aroused great interest among investigators due to its higher concentrations of tea polyphenols when compared to GTEA.[41] Thus, WTEA has been proven to have higher antioxidant activity than any other type of tea.[2,5] As expected, the WTEA extract we obtained was richer in this class of flavonoids than the GTEA extract, predominantly in EGCG (82 ± 7 g/kg of WTEA extract vs 42 ± 2 g/kg of GTEA extract), which is known as one of the most powerful antioxidants and the most pharmacologically active catechin derivative.[42] There are several pieces of evidence that EGCG has a positive impact in a variety of human diseases that is dependent on its concentration.[2,43,44] EGCG has been proven to have protective action against several deleterious effects of diseases by minimizing OS.[45]

Recently, it was reported that EGCG therapy protects against testicular ischemia-reperfusion injury through its antioxidant activity.[46] Importantly, it has been reported that for human spermatozoa maintained at 37 °C during 30 min, motility and viability can be improved by the addition of EGCG to the extracellular media at low concentrations.[47] In fact, our results showed that WTEA is very rich in EGCG, which represents 61.7% of the total catechin content, and the lower content in EGCG of GTEA may be reflected in the antioxidant properties of the extract.[41] In addition, caffeine content is also known to be higher in WTEA,[41] and our extract presented a remarkably high caffeine content (71 ± 8 g/kg of WTEA extract) when compared with the results obtained by other authors.[48] This phytochemical content difference, as well as the variation found between our GTEA extract composition and the ones verified by other authors,[34] could be due to the natural variability of the plants (caused by the influence of geographical origin, climate, and/or agricultural practices) and to differences in the extraction procedures (solvents, temperatures, times of extraction, and ratio of leaves to water) and analytical techniques.[35,49,50] Our WTEA extract also presented higher caffeine content compared to our GTEA extract (21 ± 3 g/kg of GTEA extract). This should be due to differences in leaf processing (e.g., the collection date and/or the type of leaves) to produce WTEA or GTEA, which have already been proven to influence the tea chemical composition.[41] Nevertheless, caffeine is described to stimulate lipolysis and interfere with glucose and fatty acid metabolism, thus having an important role in cellular metabolism.[51] The WTEA extract was also richer in the content of total sugars, which are known to be important substrates to cellular metabolism. Overall, our ^{1}H NMR results concerning WTEA and GTEA are in accordance with the phenolic and methylxanthine profiles obtained by HPLC-UV, HPLC-DAD, or HPLC-MS previously reported by Carvalho et al.,[34] Rusak et al.,[35] and Unachukwu et al.[36] Possible differences found in our quantitative profile compared to previous ones are certainly due to the reasons above-mentioned.

Spermatozoa present high metabolic rates that are in close association with elevated amounts of OS,[52] which is known as one of most relevant factors responsible for poor semen quality.[53] OS is associated with uncontrolled ROS production that, when it exceeds spermatozoa antioxidant capacity, becomes harmful, inducing membrane lipid peroxidation, compromising spermatozoa survival and fertilizing capacity.[54] Epididymal spermatozoa survival and maintenance are crucial for both natural and assisted reproduction.[55] The mammalian epididymis creates a unique microenvironment that helps in testicular spermatozoa maturation from an immotile immature state to fully fertile competent cells. Besides, it stores the fertile and viable spermatozoa in cauda epididymis until ejaculation. For that reason, spermatozoa from cauda epididymis are often used in assisted reproductive technologies. In fact, cryopreservation and refrigeration of spermatozoa have been highly debated, and it has been proposed that the maintenance of spermatozoa at RT for short-term periods can be an effective alternative to avoid the rapid decline of sperm viability after storage in a refrigerated environment.[12,56] Hence, there is a growing interest in the establishment of an optimal composition medium for RT sperm storage. Several media intended to improve spermatozoa survival at RT have been developed, but spermatozoa viability after storage in those media is still very low and far from the ideal.[12,57−60] A study using mouse sperm evaluated the effect of RT storage in various bicarbonate and phosphate-based media used for IVF or embryo culture, reporting that the low bicarbonate- and HEPES-containing media were able to better preserve spermatozoa in vitro.[12] The addition of substrates, such as glucose, further enhanced sperm survival, although the authors concluded that further tests concerning the addition of preserving agents are still required.[12,60] Studies using sperm from different mammalian origins preserved at RT in a saline-buffered storage medium also showed that supplementation with serum or egg yolk could greatly increase sperm survival and function.[57−59] At the same time those authors concluded that there was still a crucial requirement in controlling the ROS, which are more likely to be generated in an ambient temperature system, in the media in which the spermatozoa are suspended. Indeed, some studies have been made to assess the effect of tea catechins, which are known antioxidant agents, on sperm viability and survival.[13,47] In one of those studies, several concentrations of EGCG (1, 50, and 100 μM) were tested as a supplement of the storage media, and although the authors obtained encouraging results in the sperm fertilization ability of frozen−thawed sperm, they did not verify a significant increase in sperm survival after storage.[13]

Therefore, we hypothesized that WTEA extract could modulate some important functions such as antioxidant capacity and lipid peroxidation of spermatozoa, thus improving spermatozoa viability during RT storage. Using the FRAP assay, we verified that the media containing WTEA extract presented a higher antioxidant potential value, in a dose-dependent manner, than the media with GTEA extract, evidencing that the antioxidant potential is greatly increased by the addition of WTEA extract. The higher increase in the antioxidant potential of sperm after storage was verified in media with WTEA extract, and this is concomitant with the alteration measured for the media antioxidant potential. Indeed, the sperm antioxidant potential showed an increase over time with storage in WTEA supplemented media that is surely due to incorporation of antioxidant compounds present in the extract. The same profile was verified in sperm stored with GTEA extract in a much smaller extent, evidencing that WTEA extract is the one giving the best antioxidative potential.

One of the most important deleterious effects caused by OS is lipid peroxidation because mammalian spermatozoa are rich in PUFA that are highly vulnerable to OS.[10] When subjected to

high levels of OS, spermatozoa lipid membranes are oxidized, and the end-product of these reactions, MDA, can be measured by the TBARS assay. Our results showed that during the 3 day sperm storage at RT, WTEA extract was the most effective in decreasing the lipid peroxidation in spermatozoa. As WTEA extract presented a higher concentration of polyphenols, which are known to decrease lipid peroxidation in cells, it was expected that the media with WTEA extract presented a higher antioxidant potential and, consequently, a higher capacity to prevent lipid peroxidation. However, at 24 h, although there was a significant decrease in lipid peroxidation relative to the control group, there were no significant differences between storage with WTEA or GTEA. This is concordant with the sperm FRAP assay at 24 h that also showed no differences in the antioxidant potential of sperm stored with both tea extracts. This could be explained by ROS production, which is expected to increase over time and needs to be accompanied by the antioxidant defenses increase to control the amount of ROS. After 48 and 72 h, lipid peroxidation of sperm stored in the media supplemented with WTEA extract remained constant and similar to that observed at 24 h, whereas in sperm stored in the media containing GTEA extract the lipid peroxidation increased over time.

As our WTEA and GTEA extracts presented EGCG contents of 82 ± 7 g/kg of WTEA extract and 42 ± 2 g/kg of GTEA extract, these amounts reflect EGCG concentrations in the ranges of about 90−180 μM for WTEA and 45−90 μM for GTEA supplemented sperm storage media. Therefore, as our EGCG concentrations are in the same order of magnitude of those used in the study of Kaedei et al.[13] and, conversely to the data reported by those authors who were not able to verify a significant increase in the survival of sperm kept in the EGCG supplemented media, our results showed that tea supplementation highly improved spermatozoa survival, and this supports our idea that the synergistic effect between the tea components may be responsible for the positive effects observed in sperm viability. Additionally, our results support the effectiveness of WTEA extract in detriment to GTEA extract.

Male infertility is relatively common and affects about 50% of couples with fertility problems.[61] In most male patients with subfertility or infertility, the condition is due to loss of sperm function rather than the number of spermatozoa.[62] Therefore, spermatozoa viability is an essential parameter to evaluate sperm quality and male factor infertility. Supplementation of the storage media with tea extracts significantly increased sperm viability in a dose-dependent manner. OS is known to play a crucial role in the loss of functional competence, and when ROS production is significantly elevated, dysfunctional spermatozoa are produced.[63] A negative correlation between ROS production and sperm movement, evidencing the importance of ROS control in spermatozoa function, has also been reported.[64] High ROS levels are reported to be detrimental to fertility potential in natural and assisted conception,[65] and sperm capacitation is also known to be lost in the presence of high OS levels.[66] Therefore, the higher increase of sperm viability in spermatozoa stored in WTEA-supplemented media compared to spermatozoa stored in GTEA-supplemented media is certainly due to the higher polyphenolic content in WTEA extract and, consequently, to its higher antioxidant potential. Moreover, because the viability improvement was more effective with the highest dose of WTEA extract (1 mg/mL), we suggest that the best protection attained with the highest dose of WTEA extract may be responsible for the overall better results observed with this concentration.

In conclusion, WTEA is richer in antioxidants than other teas (black, oolong, and green teas),[2] and the addition of WTEA aqueous extract to the media can be a good, simple, and inexpensive strategy for sperm storage at RT. Our results strongly indicate that WTEA extract improves spermatozoa viability by increasing the spermatozoa and storage media antioxidant potential and decreasing spermatozoa lipid peroxidation. Moreover, the first hours of sperm preservation is crucial and marked by an increase in OS that can be counteracted by WTEA polyphenols. More studies will be needed to fully disclose the molecular mechanisms behind the results now reported. Nevertheless, the addition of WTEA aqueous extract to the standard sperm storage medium proved to be an excellent strategy for sperm storage at RT, which can reduce or even eliminate the limitations of the in vitro spermatozoa storage in a refrigerated environment and enable sperm transport for IVF or AI use.

Supporting Information

ABSTRACT: Tumor necrosis factor-alpha (TNF-α) is a crucial inflammatory cytokine when hepatocytes are damaged. *Glycyrrhiza uralensis* Fisch. (Chinese licorice) has been widely used in Chinese herbal prescriptions for the treatment of liver diseases and as a food additive. Nuclear factor-kappa B (NF-κB) reporter gene assay in TNF-α-induced HepG2 was used as a screening platform. IκBα phosphorylation and p65 translocation were measured by Western blotting, and nitric oxide (NO) production and inducible nitric oxide synthase (*iNOS*) gene expression were further confirmed in rat primary hepatocytes. Results showed that TNF-α enhanced NF-κB activity was significantly attenuated by glycyrrhetinic acid in a concentration-dependent manner in the NF-κB reporter gene assay. Glycyrrhetinic acid decreased the gene expression of *iNOS* through inhibited IκBα phosphorylation and p65 translocation in protein level. Furthermore, NO production and *iNOS* expression were reduced by glycyrrhetinic acid in TNF-α-induced rat primary hepatocytes. These results suggest that glycyrrhetinic acid may provide hepatoprotection against chronic liver inflammation through attenuating NF-κB activation to alleviate the inflammation.

KEYWORDS: *TNF-α, hepatocytes, Glycyrrhiza uralensis, NF-κB, glycyrrhetinic acid*

INTRODUCTION

Chronic liver injury, resulting from viral infection, alcohol consumption, chemical substances, drugs, autoimmune diseases, and so on, induces liver fibrogenesis that can lead to the onset of cirrhosis or even hepatocellular carcinoma. When a liver is damaged, hepatocytes live in an inflammatory microenvironment. Liver inflammation can be induced by xenobiotic toxicity (such as alcohol and chemicals) or endogenous stimulation (such as LPS and cytokines). TNF-α, which is mainly released by Kupffer cells in the liver, has emerged as a key cytokine in various liver diseases.[1] TNF-α production is one of the earliest events in many types of liver injury, triggering the production of other cytokines that together recruit inflammatory cells, inducing hepatocyte apoptosis and initiating hepatic wound-healing response, including fibrogenesis. The involvement of TNF-α has been demonstrated in both acute and chronic alcoholic hepatitis[2] and in type B and C virus hepatitis.[3] Liver injury and fibrosis are reduced in TNF-$\alpha^{-/-}$ mice[4] and TNF receptor (TNFR)$1^{-/-}$ mice,[5] and liver fibrosis induced by carbon tetrachloride (CCl_4) is also alleviated in TNFR$1^{-/-}$ mice.[6] Therefore, TNF-α has been considered as a crucial inflammatory cytokine for liver injury and subsequent liver fibrosis. NF-κB, a major downstream of TNF-α, is permissive to α1(I) collagen expression and prevents apoptosis in activated hepatic stellate cells, which are key players in liver fibrosis. On the basis of this knowledge, inhibition of NF-κB is one important target for the therapeutic blockade of fibrogenesis.[7] NF-κB is a family of heterodimeric proteins including a proteolytic processing the p50 subunit as well as p65 subunit. NF-κB is ordinarily inactivated in a latent cytoplasmic form by association with various inhibitors such as IκBα. Dissociation of p65 from IκBα, through phosphorylation of IκBα followed by proteolysis via ubiquitination, is a prerequisite for p65 translocation.[8] NF-κB is a redox-sensitive transcription factor that regulates many genes related to inflammation, such as *iNOS*, interleukin-8 (*IL-8*), and cyclooxygenase-2 (*COX-2*) at the transcription level.[9]

The dried root of *Glycyrrhiza uralensis* Fisch. (Chinese licorice or *Gan-Cao* in Chinese) is widely used in traditional Chinese prescriptions[10] and as a flavoring additive in the food industry. Triterpenes such as glycyrrhizin (glycyrrhizic acid) and glycyrrhetinic acid, as well as flavonoids, such as neoliquiritin, liquiritigenin, and liquiritin, are two kinds of its major constituents.[11] Longyin decoction[12] and Sho-saiko-to[13] are famous Chinese prescriptions containing licorice for hepatoprotective effects. Glycyrrhizin, the major sweetening component, has been reported to exhibit hepatoprotective effects in different chemical-induced liver injury models. Tsuruoka et al. reported that glycyrrhizin (10.5 mg/kg, ip) suppresses increases in AST and ALT, inhibiting *iNOS* mRNA expression and protein, cell infiltration, and the degeneration of hepatocytes in the liver of concanavalin A-treated mice.[14] Lee et al. reported that glycyrrhizin (200 mg/kg, ip) alleviates CCl_4-induced liver injury by diminishing free radical toxic properties and down-regulating pro-inflammatory mediators.[15] Both glycyrrhizin and glycyrrhetinic acid exhibit protective effects on retrorsine-induced liver damage in rats,[16] inhibit Smad3-

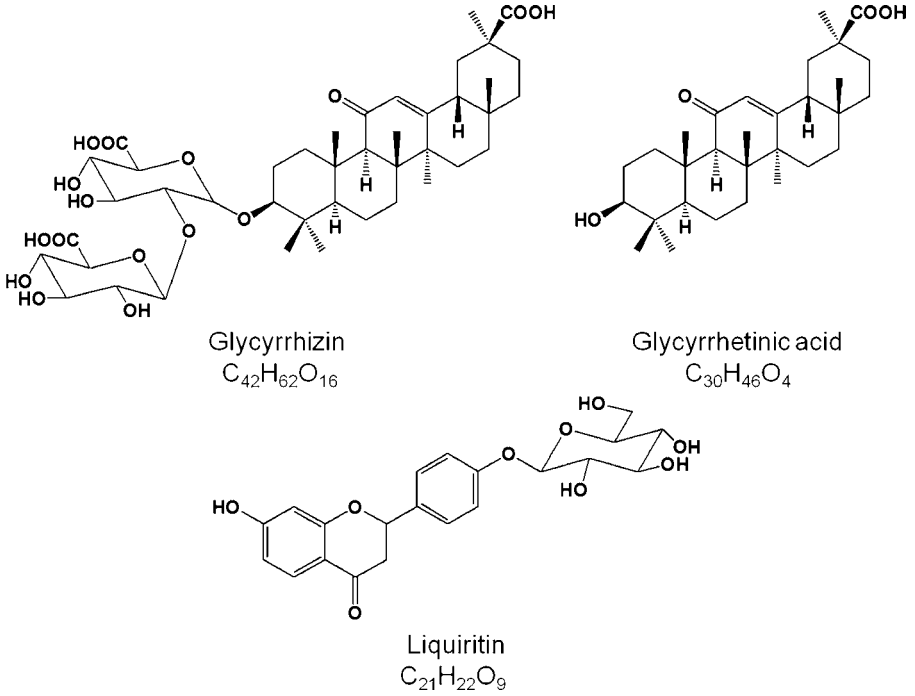

Figure 1. Structures of three major isolated pure compounds from *G. uralensis*.

mediated type I collagen gene transcription, and suppress experimental murine liver fibrosis.[17] Flavonoids from licorice have been reported to exhibit potent radical-scavenging activity.[18] A CO_2-supercritical licorice extract exhibited potent anti-inflammatory properties in LPS-induced IL-1β, -6, and -8 and TNF-α responses of macrophages.[19] Furthermore, two isoflavans, licoricidin and licorisoflavan A, isolated from the above supercritical licorice extract were potent inhibitors of the pro-inflammatory cytokine in the ex vivo human whole blood model, suggesting that these two isoflavans could be potential candidates for the development of a new therapy to prevent and/or treat periodontitis-associated tissue destruction.[20] However, the effects of licorice against endogenous stimulation such as TNF-α in hepatocytes are not clear.

The TNF-α-activated HepG2 cell model has been used for evaluating the translocation of the p65 of NF-κB subunits mediated by its inhibitor (IκBα) proteolysis.[21] The hepatoprotective effects of *G. uralensis* in TNF-α-induced HepG2 and rat primary hepatocyte inflammation were investigated in this study.

MATERIALS AND METHODS

Materials and Equipment. Silica gel (230−400 mesh) and Sephadex LH-20 (Amersham Biosciences, Uppsala, Sweden) were used for column chromatography. Solvents (analytical grade) were purchased from Merck (Darmstadt, Germany). Nuclear magnetic resonance (NMR) spectra were run in methanol-d_4 (Sigma-Aldrich Co., St. Louis, MO, USA) on a Varian unity INOVA-500 or VNMRS 600 (Varian, Palo Alto, CA, USA) using standard pulse sequences. Mass spectra (ESIMS) were recorded on a Finnigan MAT LCQ ion trap mass spectrometer system (Thermoquest, San Jose, CA, USA). Dulbecco's modified Eagle's medium (DMEM) and nonessential amino acids (NEAA) were purchased from Gibco BRL (Carlsbad, CA, USA). Fetal bovine serum (FBS) was purchased from Gibco BRL (Gaithersburg, MD, USA). pNF-κB-Luc was purchased from Stratagene (La Jolla, CA, USA). pCMV-β-gal was purchased from Life Technologies (Grand Island, NY, USA). Antiphospho-IκBα, antiphospho-IKKα/β, anti-p65, anti-lamin A/C, and anti-α-tubulin monoclonal antibodies were purchased from Cell Signaling (Danvers, MA, USA). HRP conjugated secondary antibodies were used. Pyrrolidine dithiocarbamate (PDTC) was purchased from Merck. All other chemicals used were of analytical grade and purchased from a commercial supplier (Sigma-Aldrich Co.).

Preparation of *G. uralensis* Extract and Isolation of Pure Compounds. *G. uralensis* was purchased from an herbal retailer in Taipei. A voucher herbarium specimen has been deposited at the Herbarium of National Research Institute of Chinese Medicine (NRICM) (NHP00917) and was identified by Dr. I-Jung Lee, herbarium leader of NRICM. The dried slices of *G. uralensis* (3 kg) were extracted at 60 °C by aqueous ethanol (80% ethanol/H_2O) overnight three times. The extract was concentrated with a vacuum rotary evaporator under reduced pressure and dried in a vacuum oven (491 g). The dried sample (GUE, about 16.4% yield based on dry raw materials) was sequentially partitioned with ethyl acetate (EtOAc) and *n*-butanol (BuOH) to give ethyl acetate- (GUE-EtOAc, 87.8 g, 2.93% of raw materials), *n*-butanol- (GUE-BuOH, 125.2 g, 4.17% of raw materials), and water- (GUE-H_2O, 265.3 g, 8.84% of raw materials) soluble fractions. The bioactive fraction, GUE-EtOAc, was chromatographed by silica gel column (5.5 × 60 cm) and eluted with an *n*-hexane/EtOAc gradient. The active fraction of 30−50% EtOAc elute was further purified over Sephadex LH-20 (3.8 × 40 cm, 50% EtOAc/MeOH elution) and then silica gel columns (2.8 × 30 cm, 30 or 40% EtOAc/*n*-hexane) to give glycyrrhetinic acid (0.024 g). The other two major components, glycyrrhizin (1.03 g) and liquiritin (1.35 g), were isolated from the BuOH subfraction by repeated Sephadex LH-20 column chromatography (Figure 1). All of the isolated compounds were mainly identified by 1D- and 2D-NMR and MS and further compared with an authentic sample, respectively (see the Supporting Information). For bioassay, the extracts and isolated pure compounds were all dissolved in dimethyl sulfoxide (DMSO) and diluted with a medium to give a final DMSO concentration of <0.1%. The vehicle control group contained 0.1% DMSO. Curcumin, a bioactive phenol compound from the Zingiberaceae family, was used as a positive control.[22,23]

Cell Culture. HepG2 cells were obtained from the Bioresource Collection and Research Center (BCRC, Food Industry Research and Development Institute, Hsinchu, Taiwan, no. 60025) and were cultured with DMEM containing 10% heat-inactivated FBS, 2% NEAA, and 2% glutamine in a 5% CO_2 incubator at 37 °C. Cells were

dx.doi.org/10.1021/jf405352g | J. Agric. Food Chem. 2014, 62, 618−625

detached with trypsin−EDTA solution. After washing, the cells were resuspended in fresh medium and used for subsequent experiments.

Cytotoxicity Assay. The assay of reduction of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) was performed to evaluate the cytotoxicity of crude extract, subfractions, and isolated pure compounds. All test samples mentioned above were dissolved in DMSO, and the final concentration of DMSO was <0.1%; 0.1% DMSO was used as the control group.

Transfection and Reporter Assay. Transient transfection was conducted with Genejuice (Merck) according to the instructions of the manufacturer. HepG2 cells were seeded into 24-well plates at a density of 1×10^5 cells/well and cotransfected with the pNF-κB-Luc (0.2 μg/well) and pCMV-β-gal (0.02 μg/well). The total DNA amount was normalized with empty vectors in the transfection mixture. After transfection (24 h), the cells were cultured in FBS-free DMEM for the treatment of the test sample for 30 min and then incubated in TNF-α (10 ng/mL) for another 6 h. The total cells were harvested for luciferase assay. The luciferase assay was conducted using a 96-well luminometer with the dual luciferase substrate system (Promega, Madison, WI, USA). Relative luciferase activity was normalized to the β-gal assay and presented as the ratio of cells with and without TNF-α treatment. Each experiment was repeated at least three times.

mRNA Expression of *iNOS*, *COX-2*, and *IL-8* by Real-Time Polymerase Chain Reaction (PCR). HepG2 cells were seeded into 6-well plates at a density of 5×10^5 cells/well. After incubation overnight, cells were washed with PBS, and the medium was replaced with FBS-free DMEM. After 24 h of starvation, cells were pretreated with test samples for 6 h and then stimulated with TNF-α (10 ng/mL) for another 3 h. After washing with cold phosphate-buffered saline (PBS), the total RNA was prepared by TriPure isolation reagent (Roche, Mannheim, Germany) following the manufacturer's directions. After that, cDNA preparation and PCR were performed by a RevertAid First Strand cDNA synthesis kit (Fermentas, USA) according to the manufacturer's protocol. For real-time PCR, the amplification was carried out in a total volume of 20 μL containing 0.5 μM of each primer, 4 mM $MgCl_2$, 10 μL of SYBR Green Master (Roche), and 10 μL of 1:10 diluted cDNA. Real-time PCR was performed using the LightCycler480 (Roche), and PCR reactions were performed in duplicate and heated to 95 °C for 5 min, followed by 45 cycles of denaturation at 95 °C for 10 s, annealing at 55 °C for 10 s, and extension at 72 °C for 12 s. The sequences of primers for real-time PCR are listed in Table S1 (Supporting Information). Data are represented as the fold induction of inflammatory-related genes by TNF-α-induced compared to the spontaneous group. PDTC, a specific NF-κB inhibitor, was used as a positive control.[24]

Protein Preparation and Western Blotting. HepG2 cells were seeded into a 10 cm culture plate at a density of 2×10^6. After incubation overnight, cells were washed with PBS and the medium was replaced with FBS-free DMEM. After 24 h of starvation, cells were pretreated with test samples for 6 h and then stimulated with TNF-α (10 ng/mL) for another 30 min. The cells were washed twice with ice-cold PBS and then lysed in RIPA lysis buffer (20 mM Tris-HCl, 2 mM EDTA, 500 μM sodium orthovanadate, 10 μg/mL aprotinin, 10 mM NaF, 1% Triton X-100, and 0.1% SDS, pH 7.4) on ice for 20 min. The total cell lysates were clarified by centrifugation at 10000*g* for 30 min at 4 °C. The supernatants were collected for phosphor-IκBα assay.

For nuclear p65 assay, nuclear extraction was performed by a nuclear extraction kit (Millipore, Billerica, MA, USA). Briefly, HepG2 cells were lysed in ice-cold cytoplasmic lysis buffer and incubated on ice for 15 min. After centrifugation at 10000*g* for 5 min at 4 °C, the supernatants were discarded and the cell pellets resuspended with ice-cold cytoplasmic lysis buffer. After cytoplasma extraction by syringing with a 27 gauge needle, the supernatants were removed, and the remaining pellet consisted of the nuclear portion of the cell lysates. The nuclear pellet was suspended in ice-cold nuclear extraction buffer and incubated for 1 h. Nuclear proteins were harvested in the supernatant after centrifugation at 10000*g* for 10 min at 4 °C.

The protein contents of the supernatants were measured with the Bio-Rad Protein Assay Kit. Equal amounts (50 μg) of the samples were subjected to SDS-PAGE using 10% running gels and then transferred onto a PVDF membrane. The membrane was blocked with 5% nonfat milk in TBS-Tween buffer (25 mM Tris, 190 mM NaCl, and 0.5% Tween-20, pH 7.5) for 1 h at room temperature and subsequently incubated overnight at 4 °C with appropriate primary antibodies. After hybridization with the primary antibodies, the membrane was incubated with an HRP-labeled secondary antibody for 1 h. Following washing with TBS-Tween buffer, the membrane was developed with enhanced chemiluminescence (ECL) Western blotting reagents (Amersham Pharmacia Biotech). Immunoblot images were analyzed by ImageJ (NIH, USA).

Isolation and Culture of Primary Rat Hepatocytes. Isolation of rat hepatocytes from Sprague−Dawley (SD) rats was performed using the two-step collagenase perfusion method outlined in a previous study.[25] The isolated hepatocytes were cultured in Leibovitz L-15 medium supplemented with 10% FBS, 45 μg/mL penicillin G, and 50 μg/mL streptomycin in collagen-precoated 24-well plates (1×10^5 cells/mL) and incubated under 5% CO_2 in air at 37 °C.

Assay of NO Release. An NO release assay was carried out according to the method described by Chen et al.[26] Briefly, rat primary hepatocytes were seeded at 1×10^5 cells/well in a 96-well plate. After a washing with PBS, cells were pretreated with glycyrrhetinic acid (40 μM) for 6 h and then incubated with 10 ng/mL TNF-α for another 24 h. The supernatant (100 μL) was mixed with the same volume of Griess reagent (1% sulfanilamide in 5% phosphoric acid and 0.1% *N*-(1-naphthyl)ethylenediamine dihydrochloride in water) and incubated for 15 min in the dark. The absorbance of the water-soluble purplish-red product was read at 570 nm with an enzyme-linked immunosorbent assay (ELISA) reader. The amount of NO was calculated by a calibration curve established with 1.5−100 μM $NaNO_2$.

Statistical Analysis. Results are expressed as the mean ± standard deviation (SD) for three independent experiments. Differences between specific means were analyzed by one-way analysis of variance (ANOVA) using the SPSS system, vers. 11.0 (SPSS, Chicago, IL, USA). Group means were compared using one-way ANOVA followed by S−N−K test. p values of <0.05 were considered significant.

RESULTS

Extracts and Isolated Compounds of *G. uralensis* Attenuated the NF-κB Activation in TNF-α-Induced HepG2 Cells. The cytotoxicity of the extracts of *G. uralensis* were measured by MTT assay. Results showed that the ethanolic crude extract (GUE) and its subfractions have no direct cytotoxicity to HepG2 cells at the working concentrations (5−25 μg/mL) (Figure S1 in the Supporting Information). To determine the effect of *G. uralensis* on TNF-α-induced NF-κB activation, HepG2 cells were transfected with NF-κB *cis*-reporter plasmid, pNF-κB-Luc, which contains five repeats of NF-κB binding element GGGGACTTTCC in the enhancer element of the plasmid. Thereafter, cells were pretreated with or without 30 min GUE and its subfractions and then incubated with TNF-α (10 ng/mL) for 6 h. As shown in Figure 2, TNF-α significantly increased the NF-κB activation by a factor of 2.1 over the spontaneous control. GUE (25 μg/mL) treatment clearly attenuated the NF-κB activation induced by TNF-α with an $IC_{50} = 18.1 \pm 2.8$ μg/mL. In addition, GUE-EtOAc suppressed the activation of NF-κB at a lower concentration (10 μg/mL), but not in other subfractions. This result may imply that bioactive compounds exist in the EtOAc subfraction of GUE.

Under activity-guided fractionation to investigate the bioactive components in *G. uralensis*, glycyrrhetinic acid was isolated from GUE-EtOAc as an active compound. Two other major pure compounds were isolated from GUE-BuOH, named glycyrrhizin and liquiritin, for comparison. Figure 3 shows that glycyrrhetinic acid significantly decreased the activation of NF-

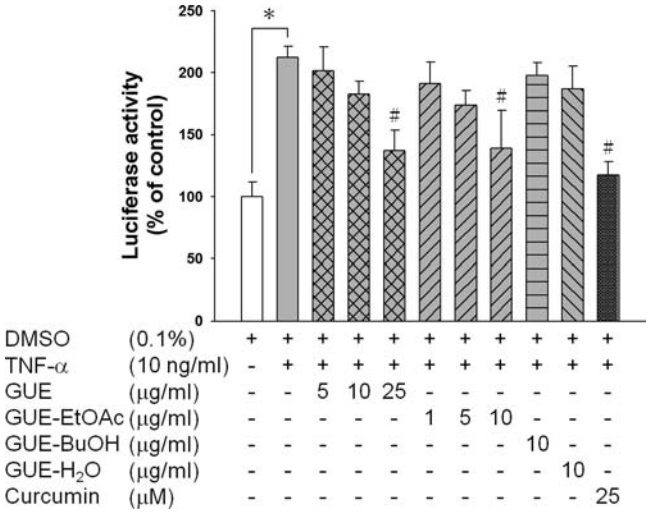

Figure 2. Effect of extracts of *G. uralensis* on the TNF-α-induced NF-κB activation in HepG2 cells. HepG2 cells were transiently cotransfected with pNF-κB-Luc and pCMV-β-gal for 24 h. The transfected cells were pretreated with or without test samples for 30 min, prior to 6 h of treatment with TNF-α (10 ng/mL). Spontaneous HepG2 cells acted as a negative control. Cells were then harvested, and luciferase activities were assessed with normalization by β-gal assay. Curcumin was used as a positive control. Data are presented as the mean ± SD of three independent experiments. *, $p < 0.05$, compared with the spontaneous control. #, $p < 0.05$, compared with the TNF-α-induced group.

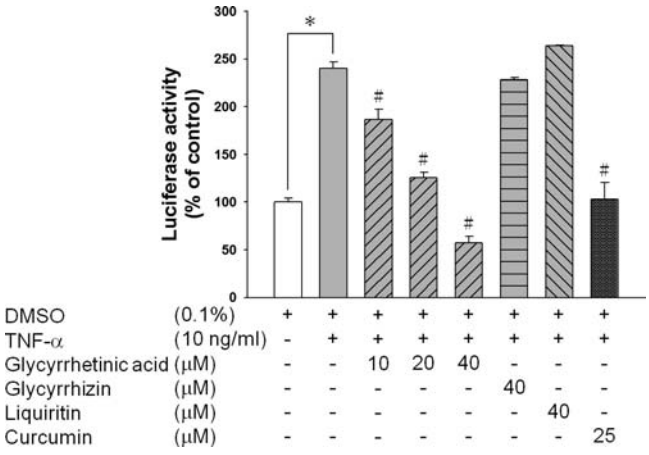

Figure 3. Effect of pure compounds isolated from *G. uralensis* on the activation of NF-κB in TNF-α-induced HepG2 cells. HepG2 cells were cotransfected with pNFκB-Luc and pCMV-β-gal for 24 h. The transfected cells were pretreated with or without various concentrations of pure compounds isolated from GUE for 30 min followed by TNF-α (10 ng/mL). After 6 h of incubation, the luciferase and β-gal activity assays were performed. The efficiency of transfection was normalized by β-gal activity. Curcumin was used as a positive control. Data are presented as the mean ± SD of three independent experiments. *, $p < 0.05$, compared with the spontaneous control. #, $p < 0.05$, compared with the TNF-α-induced group.

κB in a concentration-dependent manner (10−40 μM, $R = 0.898$, $p < 0.05$). However, glycyrrhizin and liquiritin have no effects in this NF-κB reporter gene assay even at a concentration of 40 μM. For a positive control, curcumin has an anti-inflammatory effect, as shown in the inhibition of NF-κB activation at 25 μM.

Glycyrrhetinic Acid Suppressed the Gene Expression of *iNOS* and *COX-2* but Not *IL-8* in TNF-α-Induced HepG2 Cells. To evaluate the expression of inflammatory genes in TNF-α-induced HepG2 cells, quantitative real-time PCR was performed. After prescreening of the gene expressions in TNF-α-induced HepG2 cells, *iNOS*, *COX-2*, and *IL-8* were selected as indicators for further experiments. As shown in Figure 4, HepG2 cells were stimulated with TNF-α (10 ng/mL) for 3 h, and the mRNA expressions of *iNOS*, *COX-2*, and *IL-8* were significantly enhanced compared with the spontaneous control (2.3-, 3.1-, and 4.3-fold, respectively). Glycyrrhetinic acid (40 μM) dramatically suppressed the mRNA expression of *iNOS* and *COX-2* by 57 and 53%, respectively. However, the mRNA expression of *IL-8* showed no significant changes in either glycyrrhetinic acid or curcumin in TNF-α-induced HepG2 cells.

Glycyrrhetinic Acid Suppressed the TNF-α-Induced Activation of NF-κB via Decreased Phosphorylation of IκBα and Translocation of p65. To explore whether glycyrrhetinic acid inhibition of *iNOS* expression is mediated by blocking the IκBα/NF-κB pathway, the protein levels of phospho-IκBα in cytosol and NF-κB p65 in the nucleus were analyzed by Western blotting. With or without pretreatment of glycyrrhetinic acid (40 μM) for 6 h, HepG2 cells were stimulated with TNF-α for 30 min. After TNF-α treatment, phosphorylation of IκBα in cytosol was apparently increased, because IκBα was degraded by ubiquitination. Thereby, NF-κB was activated (Figure 5A). Moreover, the translocation of p65 from cytosol into the nucleus revealed that the transcription factor, NF-κB, was activated in the nucleus (Figure 5B). Glycyrrhetinic acid suppressed the phosphorylation of Akt, inhibited the activation of IKK-α/β, and decreased the phosphorylation of IκBα, thereby inactivating NF-κB activity. PDTC, a specific inhibitor of NF-κB activation, inhibited the nuclear translocation of the NF-κB p65 subunit by reducing IκBα degradation and served as a positive control.

Glycyrrhetinic Acid Has an Anti-inflammatory Effect on TNF-α-Induced Rat Primary Hepatocytes. To clarify the anti-inflammatory effect on the liver ex vivo, the rat primary hepatocytes were stimulated by TNF-α and all samples were tested at noncytotoxic concentration as shown in Figure S2 (Supporting Information). NO is a molecular mediator of many physiological processes, including inflammation. After 24 h of rat primary hepatocyte stimulation by TNF-α, the nitrite concentration in the culture medium was measured as an indicator of NO production according to the Griess reaction. TNF-α (10 ng/mL) caused distinct increase of NO production compared to the spontaneous control (18.1 vs 10.7 μM, $p < 0.05$). As shown in Figure 6A, glycyrrhetinic acid significantly decreased NO production. Moreover, the biosynthesis gene, *iNOS*, was investigated at the transcription level by quantifying the mRNA level. TNF-α-induced *iNOS* expression was significantly reduced by 62% by glycyrrhetinic acid (Figure 6B). Curcumin served as the positive control showing anti-inflammatory effects in both NO production and *iNOS* expression.

DISCUSSION

In the present study, the NF-κB reporter gene assay was performed to evaluate the hepatoprotective qualities of *G. uralensis*. We demonstrated that glycyrrhetinic acid (a) attenuated the activation of NF-κB in a concentration-dependent manner (10−40 μM); (b) decreased the mRNA

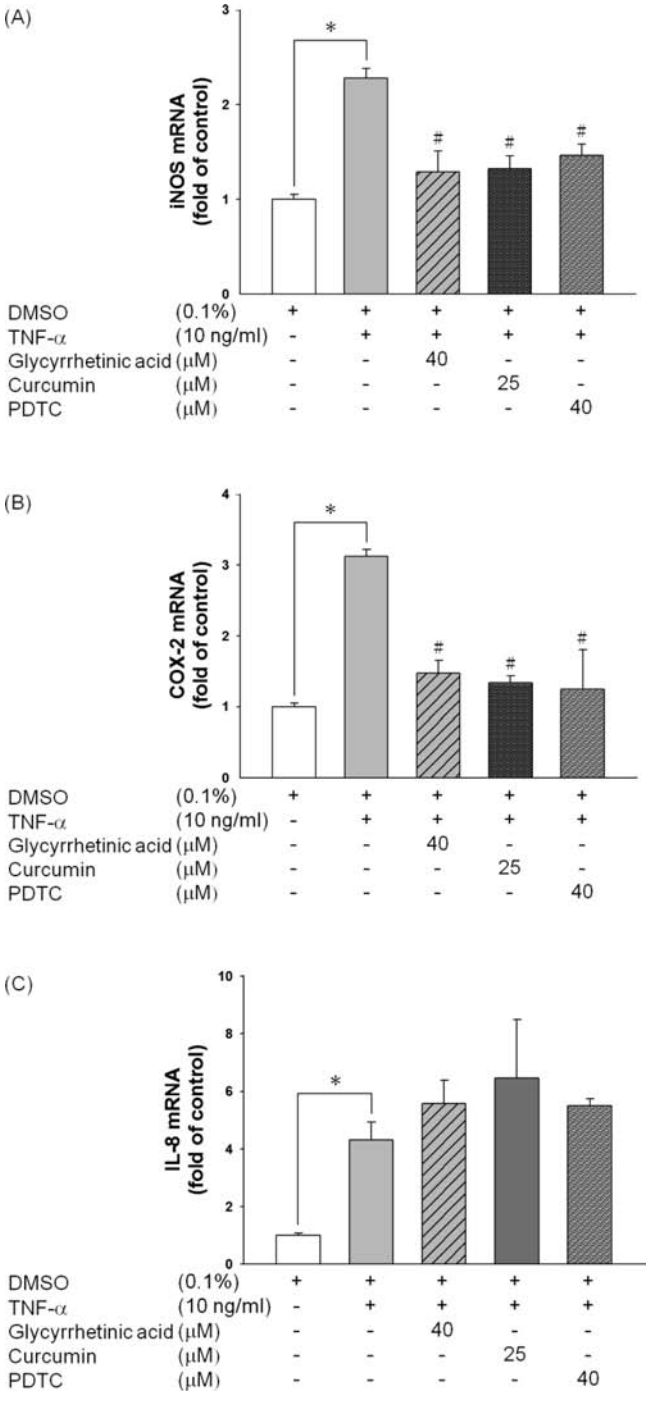

Figure 4. Effect of glycyrrhetinic acid on the mRNA expression of *iNOS* (A), *COX-2* (B), and *IL-8* (C) in TNF-α-induced HepG2 cells. HepG2 cells were pretreated with glycyrrhetinic acid (40 μM) for 6 h, followed by treatment with TNF-α (10 ng/mL) for 3 h. The expression of *iNOS*, *COX-2*, or *IL-8* mRNA was analyzed by quantitative real-time PCR. The level of *iNOS*, *COX-2*, or *IL-8* mRNA expression was normalized to *GAPDH*. Curcumin and PDTC were used as positive controls. Data are presented as the mean ± SD of three independent experiments. ∗, $p < 0.05$, compared with the spontaneous control. #, $p < 0.05$, compared with the TNF-α-induced group.

levels of *iNOS* and *COX-2*; (c) significantly inhibited the phosphorylation of IκBα and nuclear translocation of p65 in TNF-α-induced HepG2 cells; and (d) reduced NO production via suppression of *iNOS* expression in TNF-α-induced rat primary hepatocytes.

TNF-α is a pleiotropic cytokine triggering pro-inflammatory effects via NF-κB related pathways in various liver injuries. Therefore, therapeutic intervention in TNF-α/NF-κB signaling is technically feasible and could be of potential benefit in inflammatory liver disease.[27] Wu et al. reported that a *n*-hexane/ethanol (9:1; v/v) nonpolar extract of licorice inhibited LPS-induced nitrate oxide production in RAW 264.7 cells and also showed Nrf2-dependent transcriptionally active Nrf2-mediated antioxidant and induced phase II detoxifying agents genes in the Nrf2 knocked out mice.[28] Recently, Chen et al. reported that glycyrrhetinic acid (25 mg/kg, ig) protects the liver from CCl_4-induced oxidative stress through activation of the Nrf2 signaling, thereby reserving its hepatoprotective effect.[29] Furthermore, with chemical acute toxicity, endogenous factors, such as TNF-α and LPS, stimulate hepatocytes, causing chronic liver inflammation.[1,30] Ngan et al. reported that *Ginkgo biloba* revealed anti-inflammatory effects via activation of the PPARs transcriptional activity in TNF-α-induced HepG2 cell.[31] In our study, we focused on the role of *G. uralensis* in TNF-α-induced chronic liver inflammation. GUE and GUE-EtOAc attenuated the activation of NF-κB induced by TNF-α in a concentration-dependent manner with IC_{50} values of 18.1 ± 2.8 and 8.5 ± 3.2 μg/mL, respectively. Glycyrrhetinic acid, the bioactive compound isolated from GUE-EtOAc, showed suppression effects on NF-κB activation with an IC_{50} value of 14.3 ± 1.1 μM (~6.73 μg/mL) by reporter gene assay. A previous study demonstrated that glycyrrhetinic acid inhibited NF-κB activation in TNF-α-activated HUVEC cells.[32] Our findings provide evidence that glycyrrhetinic acid protects the liver from inflammation via inactivation of NF-κB signaling. Curcumin, as a positive control, has also been reported with hepatoprotective and anti-inflammatory effects via suppression of NF-κB activation both in vivo[22] and in vitro.[23]

The transcription factor NF-κB is important for the regulation of various genes involved in immune and acute phase inflammatory responses.[8] Most anti-inflammatory functional foods, such as mulberry leaf,[33] *Dunaliella salina* alga,[34] and *Magnolia officinalis*,[35], have been shown to suppress the expression of pro-inflammatory genes by inhibiting the NF-κB activation pathway. The NF-κB signal transduction pathway is directly engaged by the TNFR/Akt/IKK pathway with TNF-α stimulation.[36] Our study showed that glycyrrhetinic acid markedly suppressed NF-κB activation through the suppression of Akt phosphorylation and inhibition of IκBα phosphorylation, thereby inhibiting p65 translocation (Figures 3 and 5). These results are coincident with the effect of curcumin on NF-κB signaling.[37] The pro-inflammatory-related genes, inducible *iNOS*, *COX-2*, and *IL-8*, are downstream from NF-κB and are related to liver diseases. When a liver is damaged, *iNOS* is induced, followed by increased NO production, thereby decreasing the liver's detoxification ability and resulting in fibrosis or hepatitis.[38] COX-2 is a pro-inflammatory mediator that is correlated with chronic hepatitis, liver cirrhosis, and hepatocarcinogenesis.[39] IL-8, which is produced in response to stimulation by TNF-α, is a potent chemokine that may be implicated in infiltration of neutrophils causing acute hepatitis.[40] Our results showed that the mRNA expressions of *iNOS*, *COX-2*, and *IL-8* were significantly enhanced after being stimulated with TNF-α for 3 h in HepG2 cells. Glycyrrhetinic acid effectively suppressed mRNA expression of *iNOS* and *COX-2*, but not that of *IL-8* (Figure 4). Various transcription

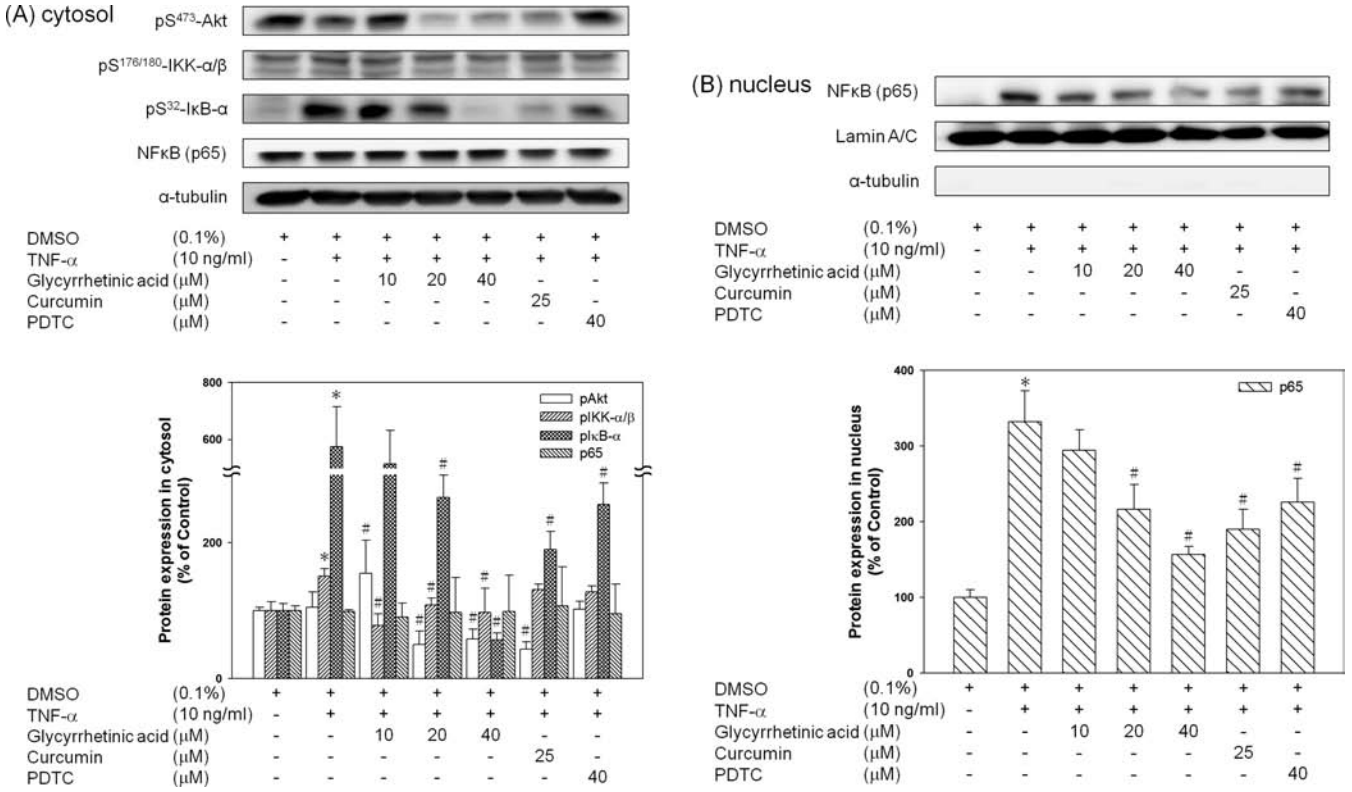

Figure 5. Effect of glycyrrhetinic acid on (A) TNFR/Akt/NF-κB signaling and (B) p65 translocation in TNF-α-induced HepG2 cells. HepG2 cells were pretreated glycyrrhetinic acid (40 μM) for 6 h, followed by treatment with TNF-α (10 ng/mL) for 30 min. The total cell lysate was collected to detect the levels of phospho-Akt, -IKKα/β, and -IκBα, and the nucleus lysate was collected to detect the level of p65 by Western blotting. Curcumin and PDTC were used as positive controls. Data are presented as the mean ± SD of three independent experiments. ∗, $p < 0.05$, compared with the spontaneous control. #, $p < 0.05$, compared with the TNF-α-induced group.

factors induced by TNF-α such as NF-κB and AP-1 modulate *IL-8* expression.[41] The effect of glycyrrhetinic acid on the regulation of AP-1 in TNF-α-induced hepatocytes is not clear and remains to be further investigated.

Although HepG2 is frequently used to replace primary human hepatocytes in in vitro models for various experiments, cell lines still have some restriction such as lack of phase I enzymes and thereby cannot reflect real organisms.[42] Therefore, we further isolated primary rat hepatocytes to confirm the effects of glycyrrhetinic acid on TNF-α-induced inflammation. Modulation of *iNOS* gene expression and suppression of NO production are important targets for anti-inflammatory properties in screening natural compounds.[43] Our results showed that glycyrrhetinic acid inhibited NO production and concomitantly suppressed *iNOS* expression at the mRNA level in primary hepatocytes (Figure 6). These results were also supported by the hepatoprotective property of *G. uralensis* in animal models.[44]

Glycyrrhizin and glycyrrhetinic acid are two major bioactive components in *G. uralensis*.[45] Glycyrrhizin, a glucuronide of glycyrrhetinic acid, is much more polar. It may hydrolyze in vivo to glycyrrhetinic acid, which is responsible for most of its pharmacological properties. Lin et al. reported that a 3 day pretreatment with either glycyrrhizin (200 mg/kg, ip) or glycyrrhetinic acid (10 mg/kg, ip) exhibited protective effects on retrorsine-induced liver damage in rats.[16] However, glycyrrhizin may have too high of a polarity to pass through the cell membrane. Therefore, it has not shown an effect on NF-κB activation in the in vitro study (Figure 3). Nonetheless, Wang et al. reported that both glycyrrhizin and glycyrrhetinic acid attenuate the generation of excessive NO, by suppressing the expression of pro-inflammatory genes via inhibition of NF-κB in a LPS-induced RAW 264.7 cell model.[46] This result may imply that glycyrrhizin cannot competitively inhibit the TNF receptor to inactive the NF-κB. Therefore, the suppression of NF-κB activation by glycyrrhizin may go through other pathways, such as the PI3K/Akt/GSK3β pathway.[47] Furthermore, roasted licorice extract inhibits acute inflammation more potently than raw licorice extract, and the glycyrrhetinic acid levels in licorice are increased after roasting.[48] Our results support this finding and suggest that glycyrrhetinic acid, an aglycone triterpene, may be a more potent inflammatory inhibitor than its glycoside, glycyrrhizin. Likewise, liquiritin, a glycoside of liquiritigenin with *O*-glucopyranosyl at C-4′ of the B-ring, has no effect in the reporter gene assay.

Our results suggest that glycyrrhetinic acid in *G. uralensis* contributed, at least partially, to its anti-inflammatory effect by inactivating NF-κB through decreasing phosphorylation of IκB and thereby inhibiting the translocation of p65. To our knowledge, this is the first study related to the inhibitory effect of TNF-α/NF-κB signaling in hepatocytes demonstrating the anti-inflammatory ability of glycyrrhetinic acid. These findings provide the molecular mechanisms for the hepatoprotective action of glycyrrhetinic acid against TNF-α-induced chronic inflammation and may be beneficial to the prevention of chronic liver injury.

ABSTRACT: A novel amphiphilic chitosan derivative of *N*,*N*-dimethylhexadecyl carboxymethyl chitosan (DCMCs) was synthesized. The structure of DCMCs was confirmed via FT-IR and ^{1}H NMR, and the critical micelle concentration (CMC) was investigated by fluorescence spectroscopy. The results indicated that DCMCs has hydrophilic carboxyl and hydrophobic methylene groups and the CMC value was 23.00 mg·L^{-1}. The polymeric liposomes (DCMCs/cholesterol liposomes, DC-Ls) were developed, and its properties were evaluated. The DC-Ls exhibited multilamellar spheres with positive charge (+73.30 mV), narrow size distribution (PDI = 0.277), and good crystal properties. Salidroside was first to encapsulate into DC-Ls. Compared with traditional liposomes (phosphatidylcholine/cholesterol liposome, PC-Ls), DC-Ls showed higher encapsulation efficiency (82.46%) and slower sustained release rate. The in vitro salidroside release from DC-Ls was governed by two distinct stages (i.e., burst release and sustained release) and was dependent on the pH of the release medium. The case II transport and case I Fichian diffusion were the main release mechanisms for the entire release procedure. These results indicated that DC-Ls may be a potential carrier system for the production of functional foods that contain salidroside or other bioactive food ingredients.

KEYWORDS: *amphiphilic chitosan, liposomes, salidroside, sustained release, release mechanism*

INTRODUCTION

Because of a lipophilic and a hydrophilic group on the same molecules, polar lipids can be self-assembled and form self-organized traditional liposomes after interaction with water.[1] As an active agent's carrier, traditional liposomes have advantages, including biocompatible and biodegradable properties and targeting and protection of entrapped agents.[2] In addition, traditional liposomes are capable of entrapping both hydrophilic and hydrophobic agents.[3] Recently, traditional liposomes have been widely applied in pharmaceutical,[4] cosmetic,[5] nutrition, and food industries.[1,6,7] However, traditional liposomes exhibit notable defects on short circulation half-life in vitro, instability of the lipid, and a few certain chemical groups on the liposome surface. Hence, many efforts have been exerted to design sufficiently stable polymeric liposomes, which may be a promising carrier with good physical and thermal stability, excellent solubility, and high encapsulation efficiency.[8,9] For promoting the application of polymeric liposomes in the food industry, choosing the optimal food-grade biopolymers is a critical factor.

Chitosan (CS) is a natural polymer composed of randomly distributed β-(1−4)-linked D-glucosamine (deacetylated unit) and *N*-acetyl-D-glucosamine (acetylated unit).[10] CS has been widely used in several areas such as biomedical, pharmaceutical, and biotechnological fields as well as in the food industry because of its good properties such as nontoxicity, good biodegradability, and biocompatibility.[11−13] Among various food biopolymers for encapsulation and delivery systems, CS is one of the most popular polymers and has also been extensively investigated for its potential using in delivery of various nutrients.[14] However, CS is only soluble in aqueous acidic solutions below pH 6.5 but insoluble in neutral pH and physiological environments. Therefore, different chemical agents have been used to improve the CS solubility, and the formation of micelles has been confirmed. However, only a small section of the hydrophobic segment can conjugate to the CS backbone (substitution degree, DS < 10%) because of the limited solubility property.[15] Hence, the loading capacities of the micelles for hydrophobic bioactive agents are very low. Thus, CS derivatives were synthesized using the soluble CS (such as carboxymethyl chitosan, CMCs) as a necessary backbone.

Among these CS derivatives, amphiphilic CS derivatives with hydrophilic and lipophilic blocks have received extensive study.[15−17] The characteristics of amphiphilic CS derivatives are quite similar to that of polar lipids and surfactant complexes, which can form micelles via intra- or intermolecular association between hydrophobic moieties, and this process primarily minimizes interfacial free energy in contact with aqueous solvents.[13] Evidence has shown that amphiphilic CS derivatives have been applied to develop liposomes for drugs and genes delivery[8,9] because such polymeric liposomes exhibit higher stability in vivo/vitro and encapsulation efficiency.

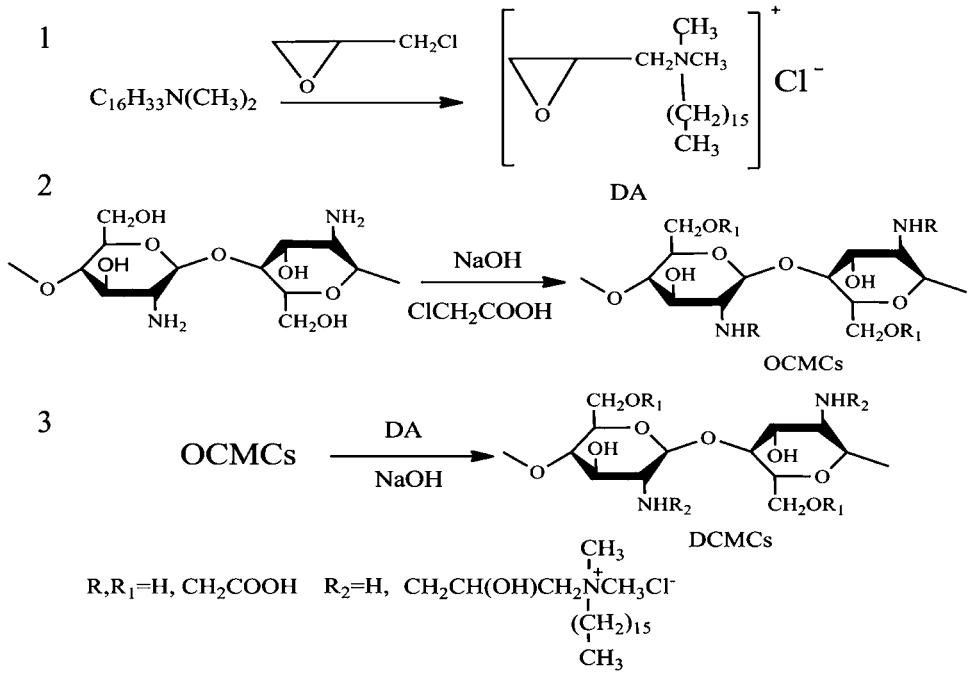

Figure 1. Schematic illustration of the synthesis process of DCMCs: (1) DA was synthesized using epoxychloropane and *N,N*-dimethylhexadecylamine; (2) OCMCs were synthesized using CS and monochloroacetic acid in an alkali environment; (3) DCMCs were then synthesized using OCMCs and DA in 2-propanol aqueous solution in an alkali environment.

However, to the best of our knowledge, the application of amphiphilic CS derivatives liposome in the food industry is rarely reported.

Salidroside has been widely used as a functional food for the various pharmacological actions such as antiaging, antioxidative, anticancer, and antidepressant activities.[18−20] Salidroside was widely applied in functional food industries in oral solution, powder, and capsule forms. The application of these forms has been significantly restricted because of the fluctuation of its concentration in blood, very high intake frequency, and poor oral bioavailability.[21,22] To overcome these drawbacks, traditional liposomes (phosphatidylcholine/cholesterol liposomes, PC-Ls) were developed to encapsulate salidroside.[21,22] However, PC-Ls suffer from various disadvantages such as instability in vivo/vitro environments and leaking of entrapped salidroside. On the basis of the advantages of amphiphilic CS derivatives, formulating a polymeric liposome by using amphiphilic CS derivatives for salidroside encapsulation may be an effective approach to overcome the above-mentioned problems.

In this study, the amphiphilic CS derivative (DCMCs) was synthesized. DCMCs were then used to develop liposomes with cholesterol (DC-Ls). As a functional food agent, salidroside was encapsulated first into DC-Ls. The physicochemical properties of DCMCs and DC-Ls were studied. Meanwhile, the encapsulation capacity and in vitro release properties of DC-Ls were also investigated.

EXPERIMENTAL PROCEDURES

Reagents and Materials. Salidroside (with 98.00% purity) was purchased from Dingsheng Pharmaceutical Technology Co., Ltd. (Hunan, China). Chitosan (CS) (300 KDa molecular weight, 90% deacetylation degree) was obtained from Lanji Technology Co., Ltd. (Shanghai, China). Epoxychloropane was purchased from Aladdin Chemistry Co., Ltd. (Shanghai, China). *N,N*-Dimethylhexadecylamine was purchased from Aoke Industrial Co., Ltd. (Shanghai, China). Cholesterol (Chol) and pyrene (with 99.00% purity) were purchased from Aladdin Chemistry Co., Ltd. (Shanghai, China). All other chemical agents used were of analytical grade.

Preparation of DCMCs. Figure 1 illustrates the synthesis procedure of DCMCs. Epoxychloropane (10 mg) and *N,N*-dimethylhexadecylamine (4 mg) were added into a flask and were reacted at 60 °C for 2 h with stirring. The residual epoxychloropane was then removed via reduced pressure distillation. The hexadecyl dimethylammonium chloride (DA) production was recrystallized using acetone and was washed with ether. CS (5 g) was subjected to swelling by using NaOH solutions (75 mL, 50 wt %) for 24 h in a flask. Monochloroacetic acid (5 g, 53 mmol) was dissolved in 25 mL of 2-propanol and then added dropwise into the flask containing CS for reaction of 24 h at room temperature. The pH of the reacted systems was adjusted to 7 using HCl (2.5 M). The product of *O*-carboxymethyl chitosan (OCMCs) was filtered and washed with ethanol. The production was then dialyzed for 3 days and was subsequently freeze-dried. OCMCs (5 g) were dissolved in an 2-propanol aqueous solution (100 mL, 2-propanol/deionized water = 1/3, V/V). In addition, DA was added slowly. The mixture was trickled with 10 mL of NaOH solution (42%, w/w) and reacted at 50 °C for 24 h with stirring. Finally, the solution was dialyzed for 3 days and lyophilized and the DCMCs were then obtained.

Structure Characterizations of DCMCs. The structure of DCMCs was determined via FT-IR and ^{1}H NMR. The FT-IR spectra of CS, OCMCs, and DCMCs were obtained using KBr pellets on a spectrophotometer (Nicolet 5700, Thermo Electron Corporation, Waltham, MA, USA) in the region of 400−4000 cm^{-1}. The ^{1}H NMR spectra of DCMCs were obtained using a spectrometer operated at 500 MHz (Bruker DPX300, Bruker Corporation, Karlsruhe, Germany) with D_2O as the solvent.

Substitution Degree (SD) of OCMCs. The SD of OCMCs was measured via the conductometric method.[23] OCMCs (0.1 g) was dissolved in an HCl solution (100 mL, 0.05 M) with mild stirring. The pH was adjusted to 2.0−2.2 by adding NaOH solution (0.1 M). The OCMCs solution was then titrated with NaOH solution (0.1 M) to pH 11.0−12.0. The typical titration curve was calculated, and the SD of OCMCs was measured based on the following equation:

$$SD = (V_2 - V_1) \times DD/(V_3 - V_2) \quad (1)$$

dx.doi.org/10.1021/jf4039925 | J. Agric. Food Chem. 2014, 62, 626−633

where SD is the OCMCs substitution degree and DD is the deacetylation degree of original CS. V_1, V_2, and V_3 are the consumed volume of NaOH in different linear sections of the titration curve.

Critical Micelle Concentration (CMC) of DCMCs. The CMC of DCMCs was investigated via fluorescence spectroscopy by using pyrene as a hydrophobic probe. A known volume of pyrene in acetone (6.0×10^{-6} M, 1 mL) was added to each of a series of 10 mL vials. Then 10 mL of various concentration of DCMCs (1.0×10^{-4}, 1.0×10^{-3}, 2.0×10^{-3}, 5.0×10^{-2}, 1.0×10^{-1}, and 1.0 mg·mL^{-1}) were added into each vial after acetone evaporation was complete. The fluorescence emission spectra were obtained using a fluorometer (F-4500, Hitachi, Tokyo, Japan) at an excitation wavelength of 339 nm, and the emission wavelength was 360−t450 nm for excitation spectra.

Preparation of DC-Ls. The DC-Ls were developed via thin-layer evaporation method.[9] DCMCs and cholesterol (Chol) (weight ratio 1/0.81, total lipids 90 mg) were dissolved in ethanol (15 mL) in a round-bottomed flask. The mixture was dried under reduced pressure by using an Eyela rotary evaporator (model N-1000; Eyela, Tokyo, Japan) at 40 °C under condition of N_2 environment to form a thin lipid film. The trace solvent was then removed by holding the lipid film at high vacuum overnight. The thin lipid film was hydrated by using deionized water (15 mL, with salidroside of 0.5 mg·mL^{-1}) and was then ultrasonicated using an ultrasonic processor (KQ-600B, Kun Shan Ultrasonic Instruments Co., Ltd., Jiangshu, China) at 25 °C for 30 min at 45 W to produce multilamellar liposomes (DC-Ls). For comparison, traditional PC-Ls were also prepared via the same procedures and conditions except egg yolk phosphatidylcholine (PC) replaced the DCMCs.

For verifying that DC-Ls have the capacity of forming multilamellar film structure, 25 mg of OA-Fe_3O_4 was also dissolved in ethanol (15 mL) with DCMCs and Chol, and other procedures were the same as that in the preparation of DC-Ls. The physical mixtures of DCMCs/Chol were prepared as follows: DCMCs/Chol (weight ratio 1/0.81) was mixed with chloroform, and the chloroform was then evaporated to obtain the dried physical mixtures of DCMCs/Chol.

Physicochemical Properties of DC-Ls. Transmission electron microscopy (TEM) images were obtained using JEOL (JEM-2010HR, Hitachi, Tokyo, Japan) with an operating voltage of 200 kV. X-ray diffraction (XRD) patterns were recorded using an XRD analyzer (D/max 2400, Rigaku Corporation, Tokyo, Japan) with a scattering angle range of 3−45°. DSC was performed using DSC equipment (Perkin-Elmer, Waltham, MA, USA) with a heating rate of 10 °C·min^{-1}. The average particle size was determined by a dynamic light scattering Zetasizer (Nano ZS90, Malvern Instruments, Worcester, UK). The ζ potential was measured using the Nano ZS90 zetasizer (DTS1060, Malvern Instruments) at 25 °C. The vibrating specimen magnetometer (VSM) (model 7407, Lakeshore, Westerville, OH, USA) was used to examine the magnetic properties of the DC-Ls.

Encapsulation Efficiency (EE) of DC-Ls. The Sephadex G_{25} column method was used to determine the salidroside EE in DC-Ls. A predetermined aliquot of salidroside loaded DC-Ls were first eluted through the Sephadex G_{25} column to remove free salidroside. The DC-Ls was dissolved in chloroform to destroy the liposomes structure. The trapped salidroside was extracted with deionized water and was then determined with high performance liquid chromatography (HPLC) (1100 series, Agilent Technologies Co., Ltd., Palo Alto, CA, USA) at a wavelength of 480 nm. The analytical column was a C_{18} column (5 μm, 4.6 mm × 150 mm, Waters Company, Milford, MA, USA). The mobile phase was a mixture of methanol/water (20:80, v/v) at a flow rate of 1.0 mL min^{-1}, and the injection volume was 20 μL at 25 °C. The EE of DC-Ls was determined using the equation below. EE test were performed in triplicate with data reported as the mean values.

$$\mathrm{EE}(\%) = (\text{salidroside loaded in DC-Ls/total salidroside added}) \times 100 \quad (2)$$

In Vitro Release of DC-Ls. First, 5 mL of salidroside loaded DC-Ls suspension were placed in dialysis bags and were suspended in 30 mL of simulated gastric fluid (SGF, pH 1.2), phosphate buffer saline (PBS, pH 7.0), and simulated intestinal fluid (SIF, pH 7.4), respectively. The release media was incubated at 37 ± 0.1 °C with stirring. At specified time intervals, 1 mL of the sample was taken and the same volume of fresh media was added to maintain a constant volume. The amount of salidroside release from DC-Ls was estimated via HPLC. All release tests were performed in triplicate, and the mean values were reported. The ingredients of simulated fluids were as follows:[24]

SGF (pH 1.2): NaCl (0.2 g), HCl (7 mL), and pepsin (3.2 g), pH was adjusted by NaOH to 1.2 ± 0.5.

SIF (pH 7.4): KH_2PO_4 (6.8 g), 0.2 N NaOH (190 mL), and pancreatin (10.0 g).

PBS (pH 7.0): 0.2 M KH_2PO_4 (250 mL), 0.2 M NaOH (145.5 mL), and H_2O (604.5 mL).

Release Mechanism of DC-Ls. The first-order, Higuchi, and Peppas models were used to fit the release data of salidroside from DC-Ls and were then used to investigate potential release mechanisms.

$$\text{first-order model: } \ln(1 - M_t/M_\infty) = -k_t \quad (3)$$

$$\text{Higuchi model: } M_t/M_\infty = k_t^{1/2} \quad (4)$$

$$\text{Peppas model: } \ln(M_t/M_\infty) = n \ln t + \ln k \quad (5)$$

where M_t/M_∞ is the fractional active agents release at time t, k is a constant incorporating the properties, and n gives an indication of the release mechanism. The correlation coefficient (R^2) is the linear relationship between salidroside release and time.

RESULTS AND DISCUSSION

Synthesis and Structural Characterization of DCMCs. A novel amphiphilically modified CS molecule with hydrophilic carboxyl and long hydrophobic methylene chains were synthesized. Detailed schemes for the DCMCs preparation are shown in Figure 1. FT-IR and ^{1}H NMR were performed to confirm the structural properties of DCMCs. The FT-IR spectra of CS, OCMCs, and DCMCs are shown in Figure 2A. In the FT-IR spectra of CS, the stretching vibrations at 3444.62 and 2927.73 cm^{-1} were attributed to the −OH and C−H groups, respectively. Meanwhile, the stretching vibration of C−O was found at 1092.96 cm^{-1}.[25] In the FT-IR spectra of OCMCs, the vibration absorption peaks were observed at 1575.94 and 1419.22 cm^{-1}, which indicates that carboxylate groups were successfully conjugated into CS.[26] In the FT-IR spectra of DCMCs, the characteristic stretching vibration absorption of long methylene chain was found at 2921.31 and 2853.49 cm^{-1}. Additionally, the appearance of new stretching vibration absorption at 721.55 cm^{-1} corresponds to the methylene planar rocking vibration. These results showed that the quaternary ammonium salt group was grafted into DCMCs. The DCMCs structure was further confirmed by the ^{1}H NMR spectra. In the ^{1}H NMR spectra of DCMCs (Figure 2B), the signal at δ 4.78, 1.72, 3.67, 3.65, 3.60, and 3.37 ppm were attributed to H-1, H-2, H-3, H-4, H-5, and H-6 of the D-glucosamine unit of DCMCs, respectively. The new signals at δ 0.91, 1.32−1.40, 3.25, 3.27, and 3.90 ppm were attributed to H-e, H-d, H-b, H-a, and H-c, which correspond to the proton assignment of long-chain alkyl of quaternary ammonium salt. The results of FT-IR and ^{1}H NMR confirmed that DCMCs were successfully synthesized, which was consistent with the previous report of Liang at el.[27]

Substitution Degree (SD) of OCMCs. A typical conductometric titration curve of OCMCs that consists of four linear branches is shown Figure 3. The excess HCl was neutralized using the volume of NaOH ($0-V_1$). (V_1-V_2) corresponds to the volume of NaOH that reacted with the

dx.doi.org/10.1021/jf4039925 | J. Agric. Food Chem. 2014, 62, 626−633

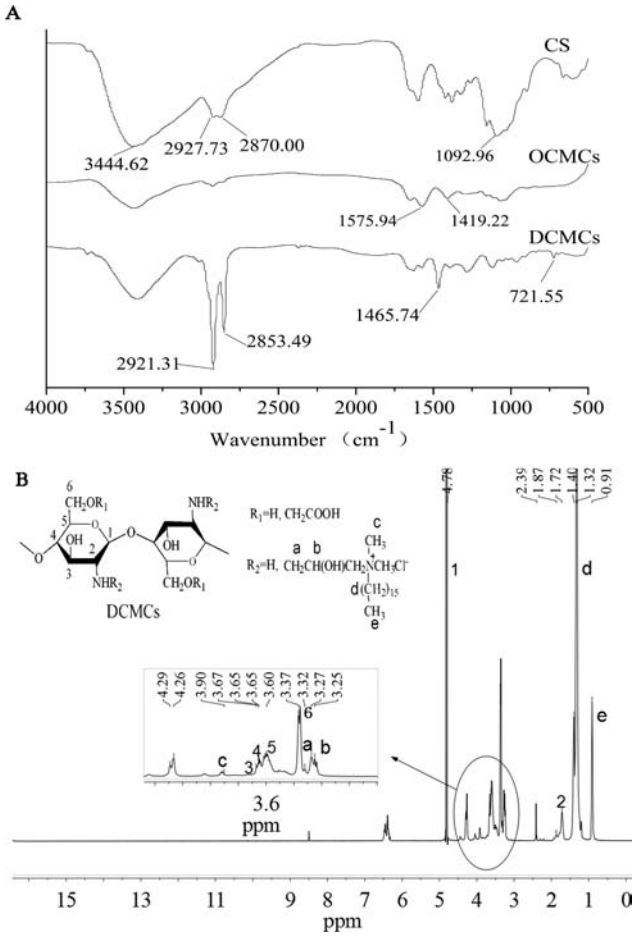

Figure 2. FT-IR spectra (A) of CS, OCMCs and DCMCs, and ^{1}H NMR spectra (B) of DCMCs.

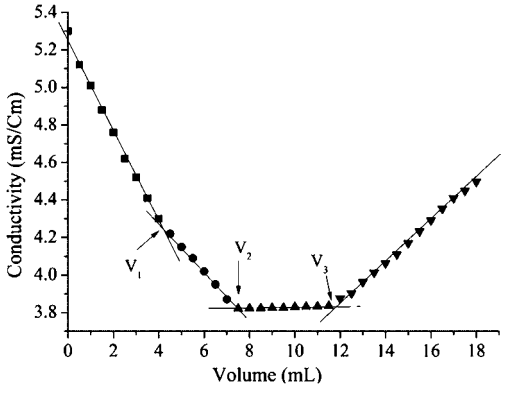

Figure 3. Conductimetric titration curve of OCMCs.

carboxymethyl groups of OCMCs. (V_2−V_3) represents the volume added to react with NH_3^+ of CS. The final volume (from V_3 to the end) indicated the excess amount of NaOH in the solution. The SD of OCMCs was determined according to eq 1, and the SD value was 70.00%. The results obtained in the current study was higher than that of the previous study.[23]

Critical Micelle Concentration (CMC) of DCMCs. For evaluation of the aggregation properties of DCMCs, the probe fluorescence technique was applied to determine the CMC by using pyrene as the fluorescence probe. Pyrene has a strong hydrophobic character with a very low solubility in water and tends to solubilize into the hydrophobic region of the micelles, thereby resulting in the fluorescence emission changes. Figure 4A shows the fluorescence emission spectra of pyrene in

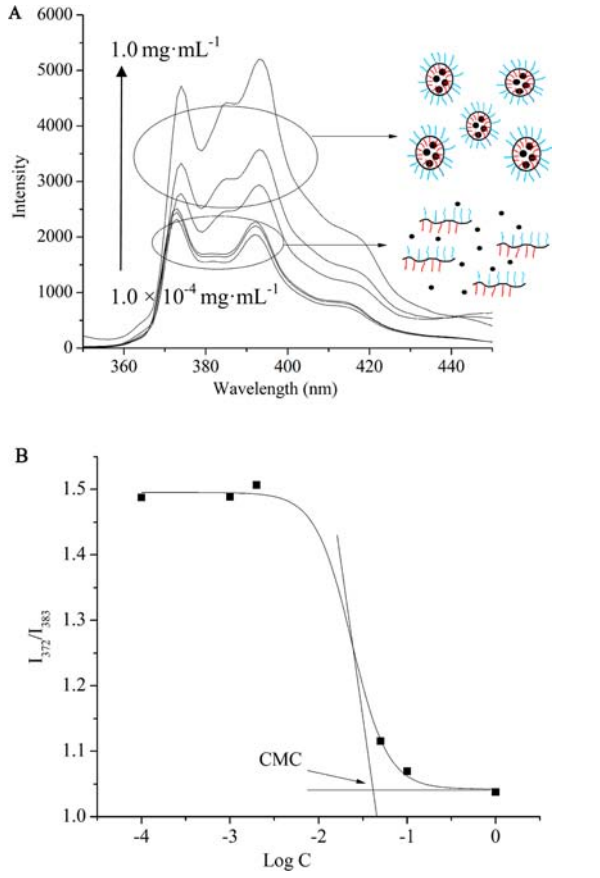

Figure 4. Fluorescence spectra of pyrene in different DCMCs concentrations (1.0×10^{-4}, 1.0×10^{-3}, 2.0×10^{-3}, 5.0×10^{-2}, 1.0×10^{-1}, and 1.0 mg·mL^{-1}) (A), and intensity ratio (I_{372}/I_{383}) versus the DCMCs concentration (B).

DCMCs solution with concentrations varying from 1.0×10^{-4} to 1.0 mg·mL^{-1}. The results indicated that the fluorescence intensity increased with increasing the concentration of DCMCs. The pyrene solubility in water is extremely low, and its dissolved fraction produces negligible fluorescence. When the concentration is above CMC, the hydrophobic phase (micelle core) was formed, which solubilizes pyrene and results in increased solution fluorescence. Plots of pyrene I_1 (372 nm /I_3 (383 nm) ratio versus logarithm of DCMCs concentration are shown in Figure. 4B. The scatters are fitted by using a Boltzmann function, which is expressed as following:

$$y = 1.29 + 0.52/[1 + e^{(x+1.88)/\Delta x}] \quad (6)$$

where y and x is the pyrene I_1/I_3 ratio and the DCMCs concentration logarithm, respectively. A common tangent can be obtained by determining the midpoint, which is obtained by using the second derivative of y ($y'' = 0$), and the CMC was defined as the crossover point of common tangent and flat tangent.[28] The CMC value of DCMCs was determined as approximately 23.00 mg·L^{-1}, which was lower than other similar CMCs-based micelle systems such as deoxycholic acid-*O*-carboxymethylated chitosan−folic acid conjugates and acylated CMCs.[29,30] These results indicated that DCMCs are capable of forming self-organized liposomes easily and are also

dx.doi.org/10.1021/jf4039925 | J. Agric. Food Chem. 2014, 62, 626−633

capable of maintaining their integrity even upon strong dilution.

Formulation of DC-Ls. Figure 5 illustrats the preparation processes of DC-Ls via the thin-layer evaporation method.

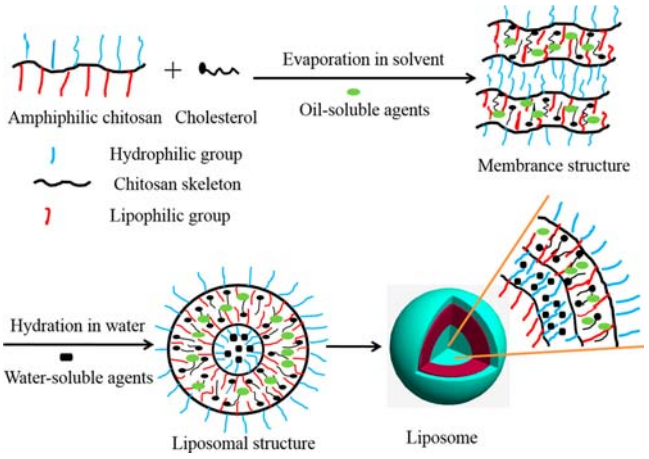

Figure 5. Schematic illustration of the formation process of DC-Ls. DCMCs and Chol (or with poorly water-soluble agents) were dissolved in an organic solvent, which was then completely removed, and the thin film was obtained. The thin film was hydrated using deionized water (or with water-soluble agents) and sonicated to obtain the liposomes. As a soluble agent, salidroside was dissolved in deionized water and used to hydrate the thin film and thus obtained the salidroside-load DC-Ls.

DCMCs and Chol were dissolved in organic solvents, and a thin film was obtained after removing the solvent via evaporation. The DC-Ls solution was obtained after hydration of thin film by adding an aqueous phase. The cross section of DC-Ls (Figure 5) showed that the hydrophilic heads of the DCMCs are oriented toward the water compartment, whereas the lipophilic tails are directed toward the center of the vesicle. Thus, the hydrophilic and lipophilic bioactive agents can be loaded into the water compartment and lipid section of DC-Ls, respectively.

Characterization of DC-Ls. The morphology and bilayer structure of DC-Ls were observed by TEM (Figure 6). The results indicated that DC-Ls exhibit a nearly spherical bubble with slight aggregation (Figure 6A,B). For verifying OA-Fe_3O_4 incorporated into DC-Ls, VSM was employed to study the magnetic properties of the DC-Ls@OA-Fe_3O_4. From the magnetic hysteresis loop of OA-Fe_3O_4 and DC-Ls@OA-Fe_3O_4 (Figure 7), it was found that the saturation magnetization of OA-Fe_3O_4 and DC-Ls@OA-Fe_3O_4 was 66.45 and 23.45 em$\mu\cdot g^{-1}$, respectively. These results (Figures 6C and 7) indicated that OA-Fe_3O_4 was encapsulated into DC-Ls with properties of core (OA-Fe_3O_4) and shell (DCMCs films) structure. Meanwhile, the multilamellar film structure was also found on the surface of OA-Fe_3O_4 nanoparticles (Figure 6D).

The particle size and ζ potential of DC-Ls were determined and are shown in Figure 8. The average size of DC-Ls was 32.21 nm with a narrow distribution (PDI = 0.277 < 0.5), and the ζ potential was approximately +73.30 mV. A previous study reported that the average size, PDI and ζ potential of the traditional liposomes (PC-Ls) were 604.00 nm, 0.36, and +7.50 mV,[21] respectively. These results indicated that DC-Ls has better properties than PC-Ls. Evidence has shown that nanocarriers with a small particle size (<200 nm) and positive

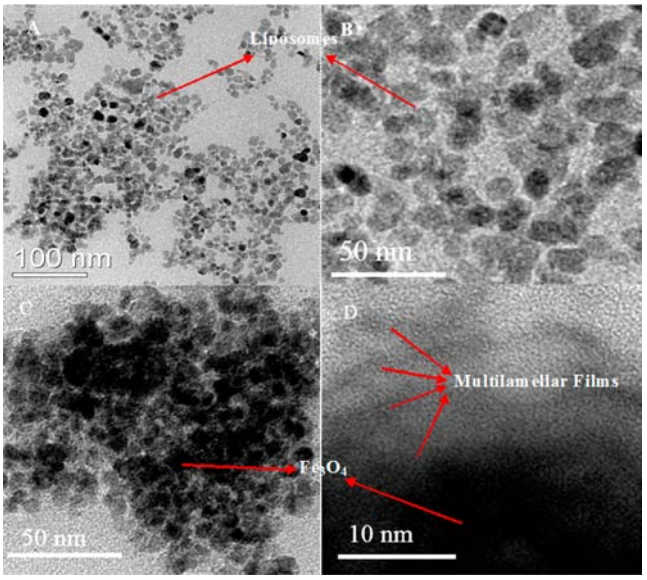

Figure 6. TEM images of DC-Ls and DC-Ls@OA-Fe_3O_4. DC-Ls exhibit a nearly spherical bubble shape with slight aggregation (A,B), DC-Ls@OA-Fe_3O_4 exhibit property of core (OA-Fe_3O_4) and shell (DMCMs films) structure (C,D), and multilamellar films can be seen on the surface of OA-Fe_3O_4 (D).

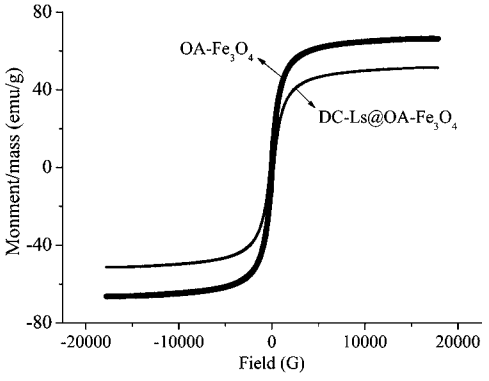

Figure 7. Magnetic hysteresis loop of OA-Fe_3O_4 and DC-Ls@OA-Fe_3O_4.

charge were not captured by the reticuloendothelial cell systems but were easily absorbed by the negatively charge cellular membrane.[31] Consequently, the bioavailability of bioactive agents can be improved after encapsulation into DC-Ls.

The XRD of DCMCs, Chol, DC-Ls, and DCMCs/Chol physical mixture were investigated, and the results are shown in Figure 9A. CS has the property of the crystal form II at 2θ = 20.5°. However, the crystal peaks of DCMCs at 2θ were sharply changed with shifting from 20.5° to 21.6°, and a new peak at 2θ of 5° appeared. These results indicated that DCMCs molecules have good crystal properties with a billayered lamellar structure.[32] The DCMCs peak of 21.6° and all Chol peaks disappeared for DCMCs/Chol physical mixture, which indicated that the interaction (i.e., hydrogen bonding and hydrophobic interactions) between DCMCs and Chol was occurred.[9] However, the peak at 20.9° appeared for DC-Ls after hydration, which suggested that DC-Ls can form lamellar-like structures as lipid.

The lipid physical state can change from an ordered gel phase to a disordered liquid-crystalline phase when temperature is

dx.doi.org/10.1021/jf4039925 | J. Agric. Food Chem. 2014, 62, 626−633

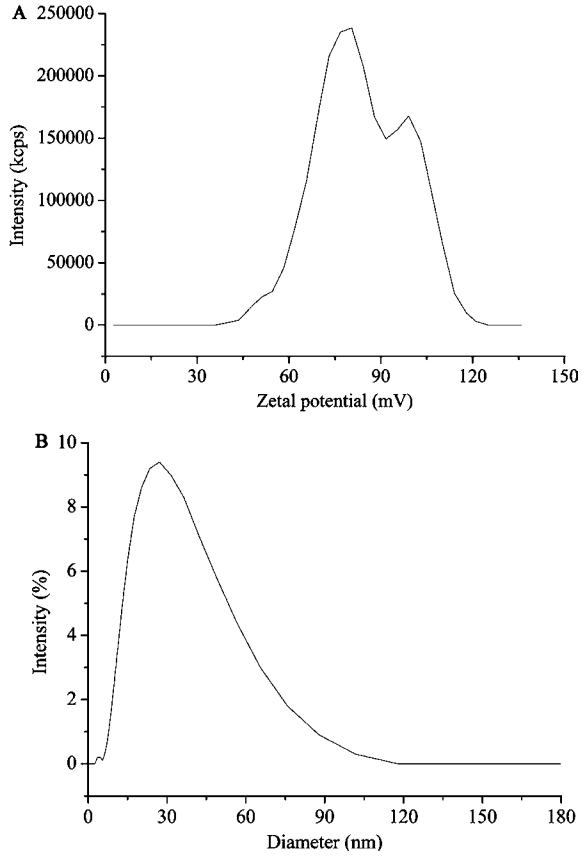

Figure 8. Size distribution (A) and ζ potential (B) of DC-Ls.

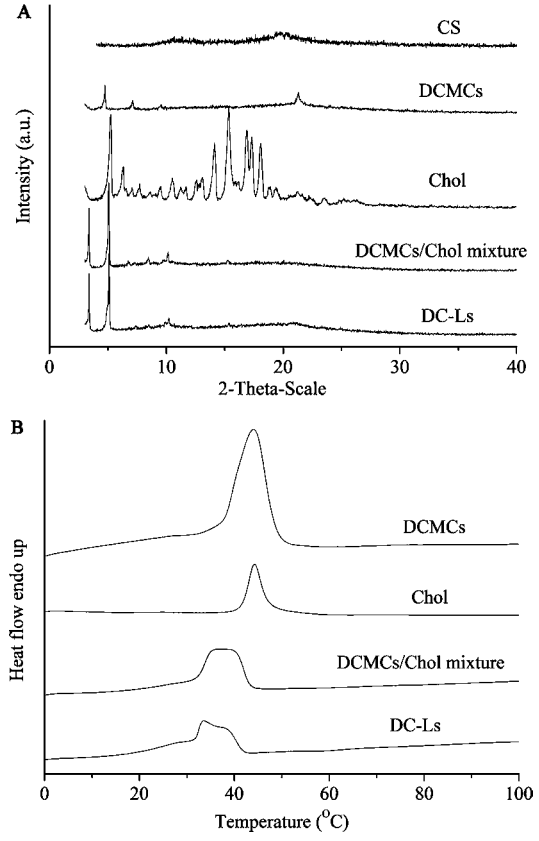

Figure 9. XRD (A) and DSC (B) spectra of DCMCs, Chol, DCMCs/Chol physical mixture, and DC-Ls.

changed. This change was defined as phase transition temperature (T_m). The DSC of DCMCs, DC-Ls, Chol, and DCMCs/Chol physical mixture was investigated and is shown in Figure 9B. The T_m values of Chol and DCMCs were 44.43 and 44.29 °C, respectively. However, the T_m of DCMCs/Chol physical mixture and DC-Ls decreased and the values were 37.50 and 33.61 °C, respectively. The results indicated that the structure of DCMCs was rearranged and interacted with Chol. The Chol interaction with DCMCs would increase the rigidity of the "fluid state" liposomal bilayers of DC-Ls, which results in good thermal stabilization.[33] The XRD and DSC results suggested that DC-Ls have the same physiochemical properties as that of PC-Ls.

Encapsulation Efficiency (EE) of DC-Ls. Compared with DC-Ls, PC-Ls of salidroside loading was also developed and the EE was only about 54.72%. Previous studies have also reported that the EE of salidroside loading in PC-Ls was lower than 60.00%.[21,22] Fortunately, the EE of salidroside in DC-Ls increased to 82.46%. The high EE (82.46%) may be attributed to the multilamellar structure of DC-Ls, which favored the formation of a high inner volume.[15] EE depends on the inner volume of liposomes for water-soluble compounds, thus, a large inner volume of DC-Ls results in a high EE.

Release of Salidroside from DC-Ls. The release of salidroside from salidroside solution (control sample), PC-Ls, and DC-Ls was investigated in PBS solutions (pH 7.0) (Figure 10A). The release of salidroside from the control solution occurred rapidly with a release rate of 86.44% after 6 h. As expected, the salidroside release from liposomes was slower than that in the control solution. The release rates were only about 38.38% and 30.77% for PC-Ls and DC-Ls after 6 h,

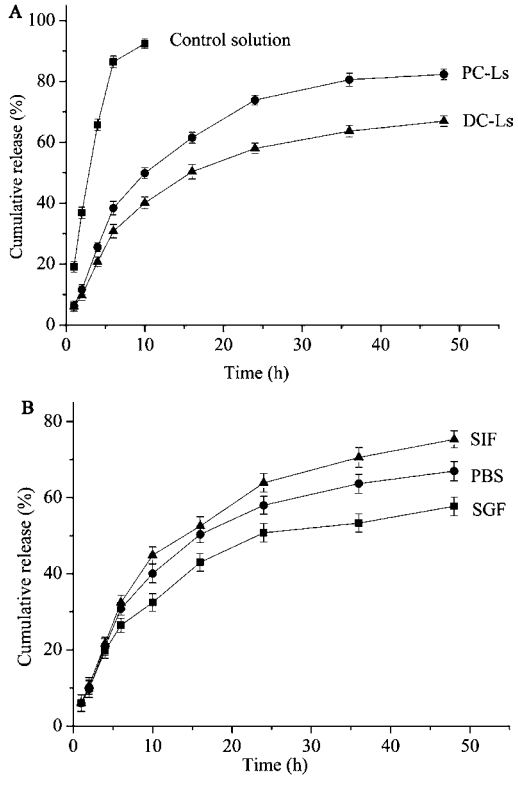

Figure 10. In vitro release of salidroside from control solution, PC-Ls, and DC-Ls in PBS solutions (A), and from DC-Ls in SGF, PBS, and SIF solutions (B), respectively. Data represent the mean ± SD (n = 3).

Table 1. Correlation Coefficients (R^2) and Release Exponent (n) of Different Models in SGF, PBS, and SIF Solution, Respectively[a]

		SGF solution		PBS solution		SIF solution	
model		stage 1	stage 2	stage 1	stage 2	stage 1	stage 2
First model	R^2	0.939	0.897	0.975	0.941	0.993	0.943
Higuchi model	R^2	0977	0908	0.984	0.951	0.989	0.933
Peppas model	R^2	0.983	0.948	0.987	0.979	0.995	0.964
	n	0.767	0.252	0.870	0.259	0.901	0.322

[a]Stage 1 and 2 is the burst (0−10 h) and sustained release (10−48 h) process, respectively.

respectively, and more interestingly, the release rate was 66.98% and 82.33% for DC-Ls and PC-Ls after 50 h, respectively. These results indicated that DC-Ls had a relatively longer release time than PC-Ls, which may be due to the high molar mass of DCMCs. Thus, DC-Ls can be used for sustained release of salidroside.

To further investigate the effect of gastrointestinal environment on salidroside release from DC-Ls, the solutions of SGF (pH 1.2), PBS (pH 7.0), and SIF (pH 7.4) were used as release media (Figure 10B). The results suggested that the release rate of salidroside from DC-Ls decreased with decreasing pH value. In the SGF solution, the H-bond between −COOH and −OH caused the aggregation of salidroside in the inner portion of DC-Ls. Moreover, the repulsive force between H^+ and the positive charge of liposomal surface made DC-Ls more stable. Consequently, the release rate of salidroside from DC-Ls was lower in the SGF solution. On the other hand, the positive charge on the surface of DC-Ls was partially neutralized with OH^- in the SIF solution, which leads to the destruction of DC-Ls and an improvement in the release rate of salidroside.

Release Mechanism of DC-Ls. Figure 10B shows that two stages were observed for the release of salidroside from DC-Ls. The first stage of release was initially rapid and was considered the burst release, which may be due to the unbound excess of salidroside on the DC-Ls surfaces. The second stage was a sustained release process. The burst release of salidroside may help to reach the effective concentration rapidly in plasma, whereas the sustained release would maintain the effective concentration in plasma for a long time. Thus, the bioavailability and biological half-life time of salidroside can be improved after loading into DC-Ls.

The amphiphilic CS derivatives have been used to develop liposome for drugs and genes delivery. However, the release mechanism is rarely reported. Thus, different kinetic models of first-order, Higuchi, and Peppas were used to fit the two release stages for further investigation of the probable DC-Ls release mechanism, and the results are shown in Table 1. It can be seen that the R^2 of Peppas model was highest among models. This finding indicated that Peppas is the most suitable model for describing the release kinetic of salidroside from DC-Ls. The value n of the Peppas model is characteristic for the release mechanism such as $n \leq 0.43$ for Case I Fichian diffusion, $0.43 < n < 0.85$ for anomalous behavior or non-Fickian transport, and $n \geq 0.85$ for case II transport.[34] The n values of DC-Ls were determined and are shown in Table 1. The results suggested that case II transport was the main release mechanism for stage 1 and case I Fichian diffusion for stage 2.

In conclusion, amphiphilic CS derivatives of DCMCs were successfully synthesized and the structure was confirmed via FT-IR and ^{1}H NMR. DCMCs have a self-assembling property with low CMC as the traditional lipid. DCMCs were used to develop liposomes with Chol (DC-Ls), which exhibits multilamellar structure with positive charge and narrow size distribution. Compared with traditional liposomes, DC-Ls have higher thermal stabilization and encapsulation efficiency. The release of salidroside from DC-Ls was initially burst release, followed by sustained release. Furthermore, the case II transport and case I Fichian diffusion were the main release mechanisms for the whole release process. In conclusion, DC-Ls may be a promising carrier system for the production of functional foods that contain salidroside or other bioactive food ingredients. However, further in vivo investigation is required to demonstrate the efficacy and safety of DC-Ls.

ABSTRACT: (1,3)-β-D-Glucans with (1,6)-β-D-glucosyl branches are bioactive polysaccharides in fruiting bodies and mycelia of *Ganoderma lucidum*, a mushroom used in traditional Chinese medicine. Submerged cultivation of mycelium is one of the more efficient means of generating polysaccharides from this fungus. Twelve mycelium samples examined in this study demonstrated the quantitative and qualitative molecular characteristics of soluble (1,3;1,6)-β-D-glucans. It was observed that the concentration of soluble (1,3;1,6)-β-D-glucan varied substantially from 1.3 to 79.9 mg/dL. (1,3;1,6)-β-D-Glucans also preserved their molecular characteristics with degrees of branching (DB) of 0.21−0.36 and molecular masses of 10^5−10^6 g/mol for those samples with substantial quantities of β-D-glucan. Using the high aggregating tendency of these molecules, (1,3;1,6)-β-D-glucans were successfully purified via fractional precipitation with 35% (v/v) ethanol. (1,3;1,6)-β-D-Glucan was proposed as a putative bioactive marker for immunomodulation because it was the most abundant polysaccharide in *G. lucidum* mycelium products to stimulate macrophage RAW 264.7 cells to release TNF-α.

KEYWORDS: *(1,3;1,6)-β-D-glucans, Ganoderma lucidum, degree of branching, molecular weight*

INTRODUCTION

Ganoderma lucidum, commonly known as Ling-Zhi and Reishi, is a medicinal mushroom that has long been a component of Oriental medicine. Polysaccharides are associated with the attributes of immunomodulating and antitumor activities of *Ganoderma*. Submerged fermentation of mycelium culture is one of the efficient means for producing *Ganoderma* polysaccharides.[1−3] Recently, as fermentation strategies have improved (e.g., fed-batch, pH-shift, or dissolved oxygen tension-shift), the maximum production of soluble (extracellular) polysaccharide has risen to higher yields from the range of 10−200 mg/dL[2−4] to reported yields of 259 mg/dL[5] and 1500 mg/dL.[6] However, not all *Ganoderma* polysaccharides are associated with immunoactivities. Therefore, using well-known bioactive polysaccharides as a quality marker during production is a more suitable strategy.

The β-D-glucans isolated from *G. lucidum* displayed high growth-inhibition activities against Sarcoma 180 solid tumors in mice[7] and enhanced regeneration of mouse bone marrow by protecting stem cells from irradiation damage.[8] Our previous study also confirmed that (1,3;1,6)-β-D-glucan was the major active polysaccharide from *G. lucidum* and showed significant tumor necrosis factor-α (TNF-α) releasing stimulation activity from human mononuclear cells (MNC).[9]

(1,3;1,6)-β-D-Glucans have been recognized as potent bioactive polysaccharides in mushrooms and fungi.[10−12] Several (1,3;1,6)-β-D-glucans and their conjugates have been commercialized for the clinical treatment of patients undergoing cancer therapy, such as those treated with schizophyllan, lentinan, grifolan, and Krestin (PSK, polysaccharide−protein complex).[13,14] In Japan, lentinan is prescribed to patients with gastric cancer, showing encouraging results in enhancing survival rates of patients.[15] (1,3)-β-D-Glucans are components of the fungal cell wall,[16,17] which can be recognized by specific cell-surface receptors, for example, dectin-1 in animal immunocytes[18,19] due to its pathogen-associated molecular pattern.[20] The interaction of (1,3)-β-D-glucans with immune cell receptors triggers a variety of immunological responses, leading to immunomodulation and antitumor activity. The distinct chemical structures of β-D-glucans provide various affinities toward these receptors.[21−23] It has been reported that the presence of (1,6)-linked side-chain branches on (1,3)-β-D-glucan increases the affinity of pattern recognition receptors[23] and dectin-1.[21] The activity plateau of these (1,3;1,6)-β-D-glucans showed a degree of branching (DB) ranging from 0.2 to 0.33.[10,24,25] Moreover, glucans with larger molecular weight may be required to cross-link spatially separated receptors and alter immunocyte function.[26]

There is limited information concerning the quantitative and qualitative molecular characteristics of soluble (1,3;1,6)-β-D-

glucans in submerged cultivation products of *G. lucidum*. Our preliminary study indicated that the concentration of soluble (1,3;1,6)-β-D-glucans varied substantially even under the same cultivating parameters. Twelve samples with different concentrations of (1,3;1,6)-β-D-glucans were selected to demonstrate this variance, and their DB and molecular weight data were also examined to understand their molecular characteristics.

MATERIALS AND METHODS

Submerged Cultivation Products of *Ganoderma lucidum* Mycelium. Twelve *G. lucidum* mycelium culture products from BCRC 36123 (Bioresource Collection and Research Center, Taiwan) kindly provided by Professor B. H. Chiang, Graduate Institute of Food Science and Technology, National Taiwan University, were used as samples in this study. The whole fermentation cultures were autoclaved and the mycelia removed by centrifugation. Only broth was used for analysis and coded S1−S2 and C1−C10, according to (1,3;1,6)-β-D-glucan concentration (in descending order). Samples S1 and S2 were products of static mycelium culturing with synthetic chemically defined medium (200 mL of medium consisted of 3% glucose, 2% malt extract, and 0.1% peptone with 10% mycelium inoculation) cultivated in customized 600 mL glass flasks (the inside diameters both of the bottom and of the broth surface were 14 cm) in a 28 °C incubator without aeration, illumination, and shaking. The harvest time was set when the mycelium mat fully covered the broth surface, which were 22 and 17 days for S1 and S2, respectively. Broth from three flasks was pooled for each sample. For comparison of the concentration variation of (1,3;1,6)-β-D-glucans in different samples, we designated S1 and S2 as references because they were cultured at the conditions (medium and temperature) suggested by BCRC and the cultivating conditions can be easily controlled. Samples C1−C10 were products from a commercial fermentor with leguminous composite medium [consisting of 2% glucose, 5% soybean (*Glycine max* L.), and 2% *Astragalus membranaceus*]. The fermentation was conducted in the dark, and the aeration rate, agitation speed, and inoculum size were 0.75 vvm, 50 rpm, and 10%, respectively, for 12 days. The fermentation temperature was at 30 °C for all of the C-samples except C6 and C7, for which 24 °C was used. Samples C1, C2, C6, and C7 were products of a 200 L customized pilot-scale manufacture fermentor (Grape King Inc., Taoyuan County, Taiwan) and others were of a 5 L fermentor (FB-6S, Firstek Scientific Co., Ltd., New Taipei City, Taiwan). No culture medium contained a detectable amount of (1.,3;1,6)-β-D-glucan (data not shown).

Preparation and Fractionation of Polysaccharides. The polysaccharides in the samples were obtained by precipitating polysaccharides in 4 volumes of 95% ethanol (Taiwan Tobacco and Wine Corp., Taipei, Taiwan) in a fermentation broth.

In this study, C2 was used to isolate (1,3;1,6)-β-D-glucans by using repeating fractional precipitation with ethanol. The polysaccharides of C2 were further separated into two fractions: (1,3;1,6)-β-D-glucans and C2-GRF (glucan-removed fraction). Ethanol was dripped into 3% (w/v) C2 polysaccharide aqueous solution with stirring; ethanol concentrations required for (1,3;1,6)-β-D-glucans and C2-GRF precipitation were 35 and 76% (v/v), respectively. After settling in a refrigerator overnight, the polysaccharide-precipitated fractions were collected by centrifugation (1500*g* for 15 min). The (1,3;1,6)-β-D-glucan fraction was precipitated three times to increase its purity.

Analytical Methods. *Content of Polysaccharides.* Polysaccharides were dispersed in 0.5 M NaOH and stirred at ambient temperature overnight until completely dissolved. The polysaccharide content of the sample was determined using a phenol−sulfuric acid method,[27] and glucose (Sigma Chemicals, St. Louis, MO, USA) was used as a standard (10−100 μg/mL).

Sugar Composition of Polysaccharides. The hydrolysis procedure used consisted of a combination of methanolysis and trifluoroacetic acid (TFA) hydrolysis. The polysaccharide sample (1−5 mg) was methanolyzed under vacuum in 1 mL of anhydrous 2 M HCl in absolute methanol in a sealed hydrolytic tube at 80 °C for 12 h. Next, the reagent was removed by evaporation, and the methyl glycosides generated during methanolysis were further hydrolyzed with 2 M TFA at 100 °C for 1.5 h. After removal of TFA by repeated evaporation under vacuum with HPLC grade distilled water, the sugars in the hydrolysate were analyzed by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD). The HPAEC-PAD consisted of a Bioscan 817 Metrohm IC system (Metrohm, Herisau, Switzerland) including an IC pump 709, injection valve unit 812 with a 20 μL loop, and an electrochemical detector with a gold working electrode (E1 = 0.05 V, 0.48 s; E2 = 0.80 V, 0.18 s; E3 = −0.30 V, 0.36 s). A CarboPac PA1 (4 mm × 250 mm) analytical column (Dionex Corp., Sunnyvale, CA, USA) with a guard column (4 mm × 50 mm) was used. For separation of neutral monosaccharides, the eluent consisted of 19 mM NaOH containing 1 mM barium acetate applied at a flow rate of 0.5 mL/min. For separation of acidic monosaccharides (galacturonic acid and glucuronic acid), the eluent consisted of 75 mM NaOH, 150 mM sodium acetate, and 1 mM barium acetate applied at a flow rate of 1 mL/min. Data were collected and analyzed using Metrodata IC Net 2.1 software (Metrohm).

Concentration and Degree of Branching of (1,3;1,6)-β-D-Glucans. The concentration and the ratio of (1,6)-β-D-glucosyl branches of (1,3;1,6)-β-D-glucans were determined according to an enzymatic HPAEC-PAD method developed by Chang.[28] Samples (5 mg) were dissolved in 0.5 M NaOH and stirred at ambient temperature overnight. After addition of arabinose (Sigma) as an internal standard, the pH of the sample solution was adjusted to 4.5 by the addition of 1 M HCl, and the volume was filled to 5 mL with 50 mM sodium acetate buffer (pH 4.5) for use as the stock for enzymatic hydrolysis. A 1 mL sample aliquot was reacted with exo-(1,3)-β-D-glucanase (1 U; Megazyme, Wicklow, Ireland) and endo-(1,3)-β-D-glucanase (0.1 U, Megazyme) for 3 h at 40 °C, followed by boiling in water for 15 min to stop the enzymatic reaction. A 4 mL volume of ethanol (95%, v/v) was added to precipitate undigested polysaccharides. The supernatant was dried by vacuum evaporation and redissolved in distilled water. The glucose and gentiobiose released from the enzyme digestion were quantified by using HPAEC-PAD. The system conditions applied were identical to those described in identifying the sugar composition of polysaccharides above, except that isocratic elution was performed at 1 mL/min with 10 mM NaOH eluent containing 2 mM barium acetate.

The concentration and the DB of (1,3;1,6)-β-D-glucan in sample were calculated as follows:

$$\text{content of (1,3;1,6)-β-D-glucan in polysaccharide (mg/mg)} = (\text{Wt-Glc} \times 0.9 + \text{Wt-Gen} \times 0.95)/\text{Wt-Poly}$$

Wt-Glc and Wt-Gen are the calculated weights of glucose and gentiobiose in samples, respectively; 0.9 and 0.95 are factors to account for differences in molecular weight of a glucosyl monomer and gentiobiosyl (a dimer) bound in a polysaccharide, respectively, compared to the free form; and Wt-Poly is the weight of polysaccharide present in the stock solution for enzymatic hydrolysis. The weight of polysaccharide was determined by phenol−sulfuric acid.

$$\text{Wt-Glc} = \text{PA-Glc}/\text{PA-Is} \times \text{RF}_{\text{Glc}} \times \text{Wt-Is}$$

$$\text{Wt-Gen} = \text{PA-Gen}/\text{PA-Is} \times \text{RF}_{\text{Gen}} \times \text{Wt-Is}$$

PA-Glc, PA-Gen, and PA-Is denote peak areas of glucose, gentiobiose, and internal standard, respectively; RF_{Glc} and RF_{Gen} denote response factor of glucose and gentiobiose in chromatography, respectively; Wt-Is denotes the weight of internal standard present in the stock solution for enzymatic hydrolysis.

$$\text{DB (degree of branching)} = \text{Gen}/(\text{Glc} + \text{Gen})$$

Gen denotes mmol of gentiobiose = Wt-Gen/342.3, and Glc denotes mmol of glucose = Wt-Glc/180.2 (both denominators denote the formula for the weight of the compound).

[a]Assays were performed in triplicate. Values are expressed as the mean ± SD. Data in the same column with different letters are significantly different ($p < 0.05$) by Duncan's test. [b]Determined by endo-, and exo-(1,3)-β-D-glucanase digestion and high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD).

performed on Toyopearl HW-65F gel (packing volume i.d. 2.6 cm × 90 cm; Tosoh, Tokyo, Japan), where 5 mL of sample was eluted with degassed eluent consisting of 100 mM NaOH and 50 mM NaCl (pH 13.0) at a flow rate of 0.5 mL/min. Fractions were collected in 4 mL volumes. The concentrations of polysaccharides and (1,3)-β-D-glucans in each fraction were determined.

The concentration of polysaccharides in each fraction was determined by using the phenol–sulfuric acid method. (1,3)-β-D-Glucan was measured by aniline blue fluorescence stain method, and the isolated (1,3;1,6)-β-D-glucans were used as a standard (5–30 μg/mL). The method described by Wood and Flucher[29] and Young and Jacobs[30] was adapted with some modifications.[28] Each 1 mL fraction aliquot was pipetted into a new tube. The pH of the solution was subsequently adjusted to 11.5 ± 0.1 by adding 2 M HCl, and the volume was filled to 2 mL by Na_2HPO_4–NaOH buffer (pH 11.5, containing 1 M NaCl). The sample aliquot was incubated with 0.2 mL of 0.1% (w/v) aniline blue (Ferak, Berlin, Germany) for 2 h at ambient temperature. The absorbance of the sample was measured on a Hitachi F4500 fluorescence spectrophotometer (Tokyo, Japan), with excitation and emission wavelengths set at 395 and 495 nm, respectively.

The molecular weight standards used for calibration were pullulans (Shodex, Standard P-82, Showa Denko, Kawasaki, Japan), with molecular weights of 5.9, 11.8, 47.3, 112, 212, 404, and 788 kDa. Additionally, blue dextran (Sigma) with an average molecular weight of 2000 kDa and glucose were used to determine the void volume and total permeation volume of the column, respectively.

TNF-α Release Activity. The murine macrophage cell line RAW 264.7 (Bioresource Collection and Research Center) was cultured in Dulbecco's modified Eagle's medium (Invitrogen, Grand Island, NY, USA) supplemented with 10% heat-inactivated fetal bovine serum (Invitrogen), high glucose (4.5 g/L), and 2 mM glutamine at 37 °C under 5% CO_2. Cells were seeded into 96-well culture plates (Nunc, Roskilde, Denmark) at a density of 1×10^4 cells/well and left to adhere for 3 h. After removal of the medium, cells were subsequently incubated in media containing each polysaccharide sample for 48 h. The concentrations of TNF-α in the cultured supernatants were assayed by DuoSet ELISA Development Systems (R&D Systems, Minneapolis, MN, USA) following the manufacturer's protocol.

Statistical Analysis. Statistical analysis was conducted by using SAS 9.3 software (SAS Institute, Cary, NC, USA). Data were determined to be significantly different ($p < 0.05$) by Duncan's test.

RESULTS AND DISCUSSION

Concentration Variation of Soluble (1,3;1,6)-β-D-Glucans. We developed an enzymatic HPAEC chromatographic method for (1,3;1,6)-β-D-glucan determination that can simultaneously measure the concentration and DB of the glucan in a *G. lucidum* fermentation broth with complicated composition. The concentration variation of soluble (1,3;1,6)-β-D-glucan in the broth was as large as the variance of the polysaccharide, a common quality index of broth (Table 1). The highest concentration (79.9 mg/dL) of soluble (1,3;1,6)-β-D-glucan was found in sample C1, which was 61 times the quantity found in sample C10 (1.3 mg/dL), although all samples were prepared by the same strain BCRC 36123. The results also showed that the mycelium of *G. lucidum* does not always generate substantial amounts of soluble (1,3;1,6)-β-D-glucans. Although (1,3)-β-D-glucans are the major class of structural polysaccharide found in the fungal cell wall and are required for normal development of fungi,[16,17,31] they are not always soluble and can be released into the broth, a common material for the food industry to produce *Ganoderma* products. In mature fungal cells, (1,3)-β-D-glucan is insoluble due to covalent linkages to chitin.[31] In response to environmental changes, such as medium composition, temperature, shaking speed, and cultivating volume, the fungal mycelia may alter its synthetic patterns to generate a more soluble component for greater water retention and cell wall flexibility. Despite a lack of data about (1,3;1,6)-β-D-glucans, many studies on *Ganoderma* spp. have indicated that small pellet size and short mycelium increased the production of extracellular *Ganoderma* polysaccharide.[32−36] In contrast to the morphology of mycelia, the amount of mycelia was not a major factor contributing to *Ganoderma* polysaccharide productivity.[32,37,38] We did not find a correlation between the concentration of (1.3;1,6)-β-D-glucans and the cultivating parameters (data not shown) in this study. This is worth further investigating in the future.

(1,3;1,6)-β-D-Glucan Percentage and Sugar Composition of Soluble Polysaccharides. To understand the relationship between yield of (1,3;1,6)-β-D-glucan and polysaccharides, the common marker for *Ganoderma* product

[a]The tested polysaccharide samples did not contain significant amounts of glucuronic acid. ND, not determined; trace, ratio was <1%.

quality, we analyzed the concentration of soluble polysaccharides and calculated its (1,3;1,6)-β-D-glucan percentage. The soluble polysaccharide concentration of samples from the composite (C) medium group ranged between 70.4 and 322.6 mg/dL with 4.6 times difference. By comparison, the reference groups S1 and S2 possessed far lower polysaccharide contents (26.4 and 24.2 mg/dL, respectively; Table 1) but much higher (1,3;1,6)-β-D-glucan percentage, revealing 48.4 and 33.9%, respectively, than that from samples fermented in the C medium group. The results demonstrate that samples with high polysaccharide concentration did not represent a high quantity of (1,3;1,6)-β-D-glucan. The lack of association between the yield of polysaccharide and (1,3;1,6)-β-D-glucan might come from the fact that the composite medium is also a source of soluble polysaccharide in *G. lucidum* mycelium products.

To confirm the assumption, we further analyzed the sugar composition profile of the soluble polysaccharide samples (Table 2). The results revealed that the glucose content of soluble polysaccharides of S1 and S2 reference groups accounted for 81.0 and 84.9%, respectively, with smaller amounts of galactose, mannose, and xylose and trace amounts of arabinose and fucose. Similar findings were also reported by Sone et al.[7] and Wagner et al.,[34] as glucose was universally observed as the dominant species in *Ganoderma* extracellular polysaccharide. For an alternate 10 samples from the C group, the molar ratio of glucose was in the range of 5.3 and 33.2%, far less than the corresponding ratios in S1 and S2. The ratios of galactose and galacturonic acid were substantially higher in the C group than in the reference group. This sugar composition ratio may be considered as an index of the presence of hemicellulose and pectic polysaccharides from higher plants. *Ganoderma* spp. are white-rot fungi and express several wood-degrading enzymes, for example, cellulases, lignin peroxidases, proteinase, and xylanase,[39] which hydrolyze composite media for mycelium growth. The partially degraded polysaccharides of leguminous plants used in the medium must be dissolved into the fermentation broth. A trend in the use of composite media, such as the use of food industrial waste material in *G. lucidum* mycelium culture, is reported in the literature;[40,41] therefore, adulteration of polysaccharide from the cultivating medium is inevitable. Therefore, the content of polysaccharide, a common index for mycelium quality, may not solely represent mycelium growth and the production of fungal polysaccharides.

Additionally, we also observed the content of glucan was not equal to the content of (1,3;1,6)-β-D-glucans in *Ganoderma* polysaccharides. For S1 and S2, the glucose contents of soluble polysaccharides (81.0 and 84.9%, respectively; Table 2) were higher than the contents of (1,3;1,6)-β-D-glucans (Table 1, 48.4 and 33.9%, respectively). This result indicated that *G. lucidum* generates different types of glucans aside from those with a β-(1,3)-linked backbone such as (1,3)-α-D-glucans,[42] β-D-galactoglucan with (1,4)-linked α-D-glucopyranosyl residues, highly branched mannoglucan with (1,3)-, (1,4)-, (1,6)-linked β-D-glucopyranosyl residues,[43] and (1,4)-α-D-glucans.[44] Therefore, specific methods for (1,3;1,6)-β-D-glucan determination are demanded for quality control, such as the one presented in this study or the one described by Danielson et al.[45]

Molecular Characteristics of Soluble (1,3;1,6)-β-D-Glucans. It has been reported that the molecular characteristics of soluble (1,3;1,6)-β-D-glucans are important to its biological function. We thus characterized several molecular characteristics. As shown in Table 1, DBs of soluble (1,3;1,6)-β-D-glucans in the majority of samples were in the range of 0.21−0.36, indicating that every 3−5 β-D-glucosyl residues in the (1,3)-linked backbone have a (1,6)-linked β-D-glucopyranosyl branch. The result was in accordance with the results reported by Sone et al.[7] showing that the DB of (1,3;1,6)-β-D-glucan from submerged fermentation of *G. lucidum* was approximately 0.31 (5/16), whereas that obtained from fruit body cold/hot water extraction had a DB in the range of 0.32−0.33. DBs of our samples also existed in the most bioactive DB range of (1,3;1,6)-β-D-glucans proposed by Bohn and BeMiller (i.e., 0.2−0.33).[10] Lentinan, a (1,3;1,6)-β-D-glucan with a DB of 0.2−0.3 from shiitake mushroom (*Lentinus edodes*), has been successfully administered as an antitumor adjuvant.[46]

The molecular weight of (1,3;1,6)-β-D-glucans reflect their solubility, stability in water, and rheological properties, concomitant with biological activity, although the structure−bioactivity relationship remains inconclusive.[12,47] The molecular mass of soluble (1,3;1,6)-β-D-glucans in samples with substantial quantities of β-D-glucan concentrated in the large molecular size range with M_n (number-average molecular weight) and M_w (weight-average molecular weight) of (11.0−

dx.doi.org/10.1021/jf404533b | J. Agric. Food Chem. 2014, 62, 634−641

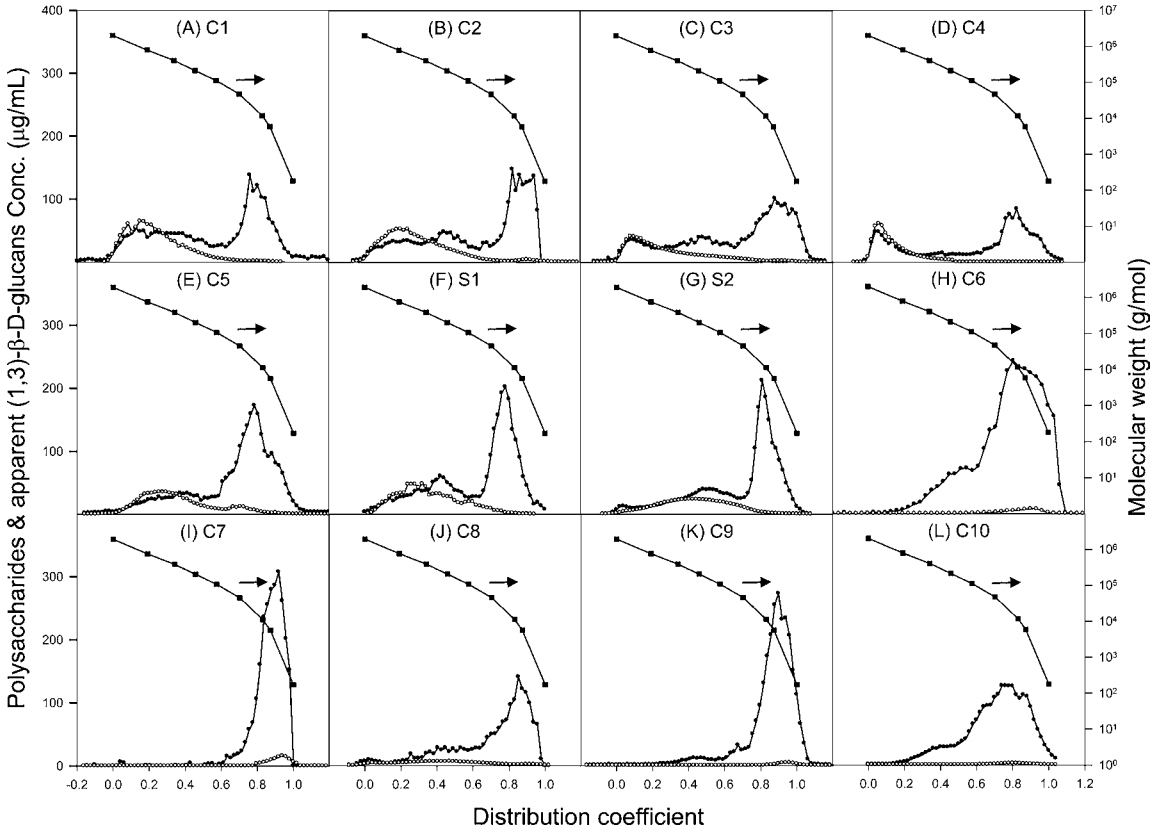

Figure 1. Chromatograms of molecular weight distribution of soluble polysaccharides (●) and (1,3)-*β*-D-glucans (○) from submerged cultivation products of *Ganoderma lucidum* mycelium. Pullulan standards and glucose were used to construct a standard curve (■) for molecular weight determination.

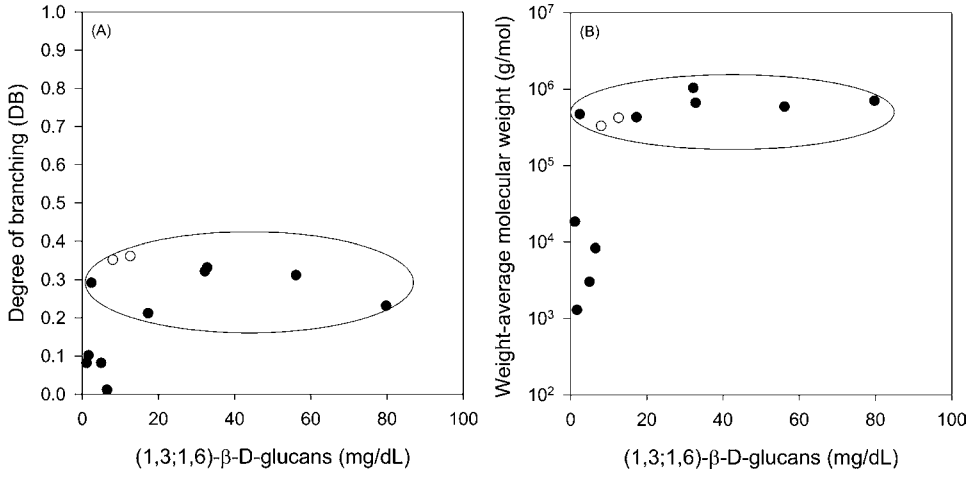

Figure 2. Scatter plot of the concentration versus degree of branching (A) and concentration versus molecular weight (B) of soluble (1,3;1,6)-*β*-D-glucans in submerged cultivation products of *Ganoderma lucidum* mycelium: (○) samples cultivated in synthetic chemically defined medium, including S1 and S2; (●) samples cultivated in composite medium containing polysaccharide matrix, including C1−C10.

79.1) × 10^4 and (32.3−101.8) × 10^4 g/mol, respectively (Table 1; Figure 1). The polydispersity (M_w/M_n), an index of the molecular weight distribution of polymers, of soluble (1,3;1,6)-*β*-D-glucans was in the range of 1.1−3.9. The molecular mass was consistent with the results from our previous study (2.08 × 10^6 g/mol)[9] as well as the previously reported value from fruiting bodies (6.3 × 10^4 g/mol).[43] Interesting, we also observed the molecular sizes of (1,3;1,6)-*β*-D-glucans were higher than the other types of polysaccharides in samples (Figure 1A−G), which could be considered useful information for isolating (1,3;1,6)-*β*-D-glucans from other polysaccharides in samples.

Subsequently, we plotted the relationship between concentration versus DB and molecular weight of (1,3;1,6)-*β*-D-glucans by using the collected data set. As shown in Figure 2, instead of spreading, both the DB and molecular weight distributions were consistently and similarly preserved for those samples with substantial quantities of (1,3;1,6)-*β*-D-glucan. This observation suggested that although the production of (1,3;1,6)-*β*-D-glucans could be altered by cultivation, the

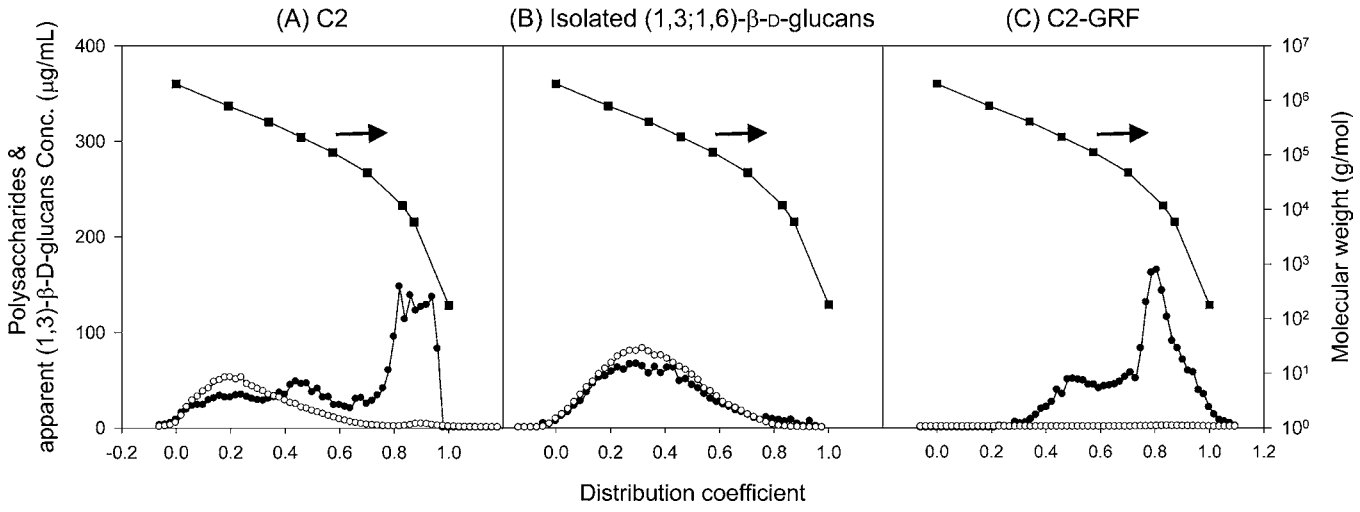

Figure 3. Chromatograms of molecular weight distribution of soluble polysaccharides (●) and (1,3)-β-D-glucans (○) from C2, a submerged cultivation product of *Ganoderma lucidum* mycelium (A), and its fraction after fractional precipitation with ethanol, isolated (1,3;1,6)-β-D-glucans (B) and C2-GRF [glucan-removed fraction (C)]. Pullulan standards and glucose were used to construct a standard curve (■) for molecular weight determination.

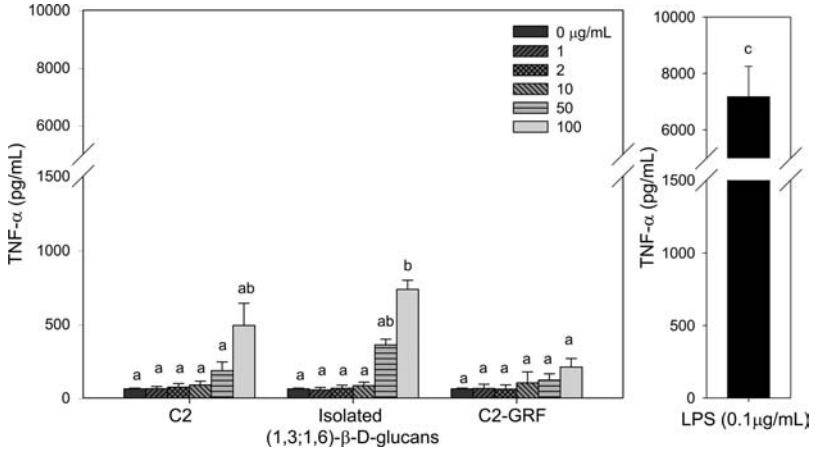

Figure 4. TNF-α releasing of RAW 264.7 treated with soluble polysaccharides from cultivation product of *Ganoderma lucidum* mycelium sample C2 and its isolated (1,3; 1,6)-β-D-glucans and glucan-removed fraction (C2-GRF). The error bars in the figure indicate standard deviation from three replicates. Data with different letters are determined to be significantly different ($p < 0.05$) by Duncan's test.

molecular structures of (1,3;1,6)-β-D-glucans displayed similar profiles. Therefore, we suggested this may be due to physiological homeostasis, which might be controlled by some metabolic pathways of *G. lucidum*. By contrast, (1,3)-β-D-glucans with lower DB (~0.1) and low molecular mass ($<10^4$ g/mol) were present in samples C6, C7, C9, and C10, which contained little (1,3;1,6)-β-D-glucan. It is known that linear (1,3)-β-D-glucans without branches are less soluble in water than those with branches. Sone et al. generated low-DB (0.06 and 0.04) glucans through alkali extraction from fruiting bodies of *G. lucidum*.[7] We surmise that most linear (1,3)-β-glucans are tightly attached to additional cell wall components and that autoclaving used in this study allowed for the collection of only a small portion of linear (1,3)-β-D-glucan. The concurrence of low molecular weight distribution and low DB may support the belief that glucans in samples C6, C7, C9, and C10 were fragments of the fungal cell wall caused by the autoclaving process.

Isolation and Immunoactivity Verification of (1,3;1,6)-β-D-Glucans. To further confirm the bioactivity and establish a method to purify (1,3;1,6)-β-D-glucans, fractional precipitation with ethanol was used whereby high molecular weight polysaccharides are precipitated by low concentrations of ethanol. Our results indicated that (1,3;1,6)-β-D-glucans could be isolated from a C2 sample by using 35% (v/v, final concentration) ethanol repeating precipitation. The purity of isolated (1,3;1,6)-β-D-glucans was 99.42 ± 4.82%, as determined by the enzymatic HPAEC method. The remaining polysaccharides in the 35% ethanol solution were collected by adding more ethanol to allow the concentration of ethanol to reach 76%. The percentage of (1,3;1,6)-β-D-glucans in the C2-GRF (glucan-removed fraction) was <1% on a carbohydrate basis. The high efficiency of (1,3;1,6)-β-D-glucan separation was a result of the high aggregation tendency of (1,3)-β-D-glucans,[47] although (1,3;1,6)-β-D-glucans and C2-GRF in the original polysaccharide solution overlapped with one another between the distribution coefficient range of 0.3−0.7 (Figure 3). A similar operation had been successfully performed for the isolation of (1,3;1,6)-β-D-glucans from fruiting bodies of *G. lucidum* in our previous study.[9]

On the basis of previous studies of the immunomodulating activities of (1,3;1,6)-β-D-glucans, the murine macrophage

dx.doi.org/10.1021/jf404533b | J. Agric. Food Chem. 2014, 62, 634−641

RAW 264.7 cell line was selected as a model for testing the TNF-α-stimulating activity of the polysaccharides. The original soluble polysaccharide of C2 and its fractions (1,3;1,6)-β-D-glucans and C2-GRF all displayed a trend in stimulating TNF-α release in RAW 264.7 cells (Figure 4). Isolated (1,3;1,6)-β-D-glucans displayed substantial stimulating activity in a dose-dependent manner at concentrations of 10, 50, and 100 μg/mL. The TNF-α stimulating activity was markedly less than that induced by lipopolysaccharide (LPS), suggesting a potentially beneficial effect for cytokine induction on innate immunity. Stimulating activities of (1,3;1,6)-β-D-glucans from *G. lucidum* and other distinct biological sources that trigger cytokine release from macrophage have been reported in the literature.[4,48−50] Therefore, (1,3;1,6)-β-D-glucans, rather than total polysaccharides, may be a more appropriate biological activity marker for the cultivation products of *G. lucidum* mycelium.

In conclusion, we reported quantitative data of concentration, degree of branching, and molecular weight distribution of soluble (1,3;1,6)-β-D-glucans in cultivation products of *G. lucidum* mycelium. (1,3;1,6)-β-D-Glucan was proposed to function as a biomarker because it was the most abundant polysaccharide in the stimulation of macrophage RAW 264.7 cell to release TNF-α in *G. lucidum* mycelium products. Indirect evidence was also provided demonstrating that polysaccharides from composite medium for submerged fermentation were included in the final mycelium products. The polysaccharide content was not well represented during the production of fungal polysaccharides. The large molecular size and degree of branching of the (1,3;1,6)-β-D-glucans were reserved for the mycelium products examined, as long as substantial quantities of the glucan were being produced. The cultivating factors that affected the production of soluble (1,3;1,6)-β-D-glucans should be further investigated. An understanding of the mechanisms of the fungal cell wall synthesis and related enzyme activities with the characteristics of soluble (1,3;1,6)-β-D-glucans may lead to improved design of optimum cultivation conditions necessary for efficient production.

ABSTRACT: Nonsteroidal anti-inflammatory drugs, such as ketoprofen, are generally used to treat pain and inflammation and as pyretic agents in clinical medicine. However, the usage of these drugs may lead to oxidative injury to the gastrointestinal mucosa. Camellia oil (*Camellia oleifera* Abel.) is commonly used in Taiwan and China as cooking oil. Traditional remedies containing this oil exert beneficial health effects on the bowel, stomach, liver, and lungs. However, the effects of camellia oil on ketoprofen-induced oxidative gastrointestinal mucosal lesions remain unknown. The objective of this study was to evaluate the effect of camellia oil on ketoprofen-induced acute gastrointestinal ulcers. The results showed that treatment of Int-407 cells with camellia oil (50−75 μg/mL) not only increased the levels of heme oxygenase-1 (HO-1), glutathione peroxidase (GPx), and superoxide dismutase (SOD) mRNA expression but also increased vascular endothelial growth factor (VEGF) and prostaglandin E_2 (PGE_2) protein secretion, which served as a mucosal barrier against gastrointestinal oxidative injury. Moreover, Sprague−Dawley (SD) rats treated with camellia oil (2 mL/kg/day) prior to the administration of ketoprofen (50 mg/kg/day) successfully inhibited COX-2 protein expression, inhibited the production of interleukin-6 (IL-6) and nitrite oxide (NO), reversed the impairment of the antioxidant system, and decreased oxidative damage in the gastrointestinal mucosa. More importantly, pretreatment of SD rats with camellia oil strongly inhibited gastrointestinal mucosal injury induced by ketoprofen, which was proved by the histopathological staining of gastrointestinal tissues. Our data suggest that camellia oil exerts potent antiulcer effects against oxidative damage in the stomach and intestine induced by ketoprofen.

KEYWORDS: *gastrointestinal ulcer, ketoprofen, camellia oil, antioxidant enzyme, VEGF, HO-1*

1. INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ketoprofen and indomethacin, are generally used to alleviate swelling and pain of rheumatoid arthritis and other inflammatory diseases in clinical medicine. Despite their benefits as anti-inflammatory agents, these drugs may cause peptic ulcers.[1,2] Currently, peptic ulcers caused by mucosal damage are a common digestive disease in the United States and it affects approximately 500000 individuals per year.[3] The major causes of peptic ulcers include gastric acid, pepsin, bile salts, consumption of alcohol and tobacco, *Helicobacter pylori* infection, and NSAIDs. Musumba et al.[4] indicated that NSAID users have a higher risk of peptic ulcers than those with *Helicobacter pylori* infection. Thus, it is imperative to search for novel compounds that may help to prevent ulceration of the gastrointestinal tract.

Digestive diseases, including peptic ulcers, are associated with mucosal lipid peroxidation and oxidative damage.[5] Proton pump inhibitors (PPIs), such as lansoprazole, are usually used to cure gastric and duodenal ulcers.[6,7] Some reports have indicated that lansoprazole can also reverse the effects of diclofenac, indomethacin, ketoprofen, and piroxicam on the mucosal content of lipid peroxidation products (malondialdehyde, MDA), glutathione (GSH), and myeloperoxidase (MPO).[6−8] Therefore, the up-regulated activity of antioxidant enzymes may play an important role against oxidative stress in gastrointestinal mucosa.[9,10] Recent evidence indicates that heme oxygenase-1 (HO-1) breaks down heme to biliverdin and carbon monoxide, which has antioxidative effects in addition to mitigating inflammation, controlling cell growth, and eliminating cell death.[11] Guo et al.[12] suggested that the upregulation of HO-1 expression may reduce inflammation and tissue injury caused by reactive oxygen species (ROS) in the gastrointestinal tract. We recently found that catechin effectively inhibits ketoprofen-induced oxidative damage by upregulating HO-1 in Int-407 cells, which might play a key role in the prevention of NSAIDs-induced gastrointestinal injury.[13] These results suggest that HO-1 expression induced by pharmacological modulators may be a novel means of increasing gastrointestinal protection.

Ketoprofen is one of the most common NSAIDs. Some reports have indicated that photodegradation products of ketoprofen by sunlight or UV-irradiated are associated with oxidative stress-induced peptic ulcer.[2,14] de la Lastra et al.[14] reported that the gastrointestinal toxicity of ketoprofen in rats

was due to stimulation of cyclooxygenase-2 (COX-2) enzyme production and nitric oxide (NO) synthase in gastric mucosal lesions. Liu et al.[2] indicated that pro-inflammatory mediators, such as NO and interleukin-6 (IL-6), were generated by upregulation of COX-2 expression following ketoprofen treatment in Sprague−Dawley (SD) rats. Therefore, reduction of excess NO and IL-6 production as well as inhibition of COX-2 enzyme expression may be associated with the prevention and treatment of ketoprofen-induced inflammatory disease in the gastrointestinal mucosa.

Camellia oil (obtained from tea seed, *Camellia oleifera* Abel.) is generally used as cooking oil in Taiwan and China and usually consists of an abundance of unsaturated fatty acids, vitamins, and various antioxidant factors. The naturally occurring active compounds in tea seeds are different from those in other types of oil seeds.[15,16] Camellia oil is also traditionally used as a remedy for bowel, stomach, and burn injuries in China. Chen et al.[17] indicated that the saponin in tea seed could lower the triglyceride, cholesterol, and low density-lipoprotein levels in the blood of rats. Our previous study indicated that administration of camellia oil strongly prevented the liver injuries induced by carbon tetrachloride (CCl_4).[18] However, the role of camellia oil on acute gastrointestinal ulcers induced by ketoprofen remains unknown. The objective of this study was to evaluate the effects of camellia oil on the activities of antioxidant enzymes and on ketoprofen-induced acute gastrointestinal oxidative damage.

2. MATERIALS AND METHODS

2.1. Materials. *S*(+)-Ketoprofen and 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Basal Medium Eagle (BME/EBSS), bovine serum, trypsin-EDTA (T/E), L-glutamine, and penicillin/streptomycin (PS) were purchased from Gibco (Grand Island, NY, USA). The Trizol RNA isolation kit was purchased from Life Technologies (Rockville, MD, USA). Primers, dNTPs, reverse transcriptase, and Taq polymerase for RT-PCR were purchased from Gibco BRL (Cergy Pontoise, France). All chemicals and solvents used were of the highest purity available. The camellia oil was obtained from the Hsin-I Country Farmer'S Association (Nantou, Taiwan).

2.2. Cell Culture and Treatment. The human intestinal Int-407 cell line (BCRC 60022) was obtained from the Bioresource Collection and Research Center (BCRC) of the Food Industry Research and Development Institute (Hsinchu, Taiwan). The cells were cultured in complete medium (90% BME/EBSS, 10% bovine serum, and 1% penicillin/streptomycin) at 37 °C, under humidified 5% CO_2 incubator. The cells were detached with T/E (0.1% trypsin, 10 mM EDTA) solution and split weekly. The solution of camellia oil was prepared in DMSO, and according to the method described by Jang et al.,[19] The control group received DMSO only and the concentration of DMSO used for the experiments was lower than in 0.1% (v/v).

2.3. Wound Scratch Assay. The human Int-407 cells were cultured to 90% confluence in 6-well tissue culture plates. A wound phenomenon was made by scratching the cells with a sterile 200 μL pipet tip and removing floating cells with PBS. Next, camellia oil (prepared in DMSO) was added to the complete medium at 25, 50, and 75 μg/mL (final concentrations) for 24 h. Cell migration was monitored and recorded under a phase contrast microscope. The cell migration ability was calculated using the following equation: migration area = [migration area $_{(treated)}$/migration area $_{(control)}$].

2.4. Animal Treatment Procedures. Six-week-old (175−200 g) male SD rats were obtained from BioLASCO Co. (Taipei, Taiwan). Each rat was raised at 22 ± 2 °C, under 65−70% relative humidity on a 12/12 h light/dark cycles. The animals were fed a LabDiet 5001 Rodent Diet (24% protein, 5% fat, 5% fiber) (Nestle Purina, St. Louis, MO). All animal trial protocols were based on the National Institutes of Health (NIH) guidelines. These experiments were approved by the Institutional Animal Care and Use Committee (IACUC) of the National Chung Hsing University (approval no. 100-21). The compounds were orally administered as in the previous methods.[13,20] Briefly, the animals received an oral administration of camellia oil (1, 2, and 4 mL/kg/day) for 3 weeks. The control group received soybean oil (Sigma, St. Louis, MO, USA) only. On the 21st day, all animals were orally administrated with ketoprofen (50 mg/kg) and were sacrificed using CO_2 after 24 h.

2.5. Preparation of Gastrointestinal Mucosal Homogenate. Extraction of the gastrointestinal mucosa was carried out according to a previously reported method with some modifications.[21] Briefly, gastrointestinal mucosa was homogenized in 1.15% potassium chloride (KCl) buffer. The tissue samples were centrifuged at 10000g for 10 min (4 °C) to obtain a homogenate of gastrointestinal mucosa. Finally, aliquots of the homogenate were collected and preserved at −80 °C for the subsequent assay.

2.6. Measurement of Antioxidant Enzymes. The activities of GSH peroxidase (GPx), glutathione reductase (GRd), catalase, and GSH S-transferase (GST) antioxidant enzymes were assayed according to previously reported methods.[18,22] The GSH and the GSH/GSSG ratio were measured using a commercial kit (Cayman Chemical Co., Ann Arbor, MI, USA). SOD activity was assayed using a SOD assay kit-WST (Dojindo Molecular Technologies Inc., Gaithersburg, MD, USA) as specified by the manufacturer.

2.7. Measurement of Nitric Oxide (NO). The levels of NO were assayed according to a previously reported method.[23] Briefly, a gastrointestinal mucosal homogenate solution was mixed with the same volume of Griess reagent (5% phosphoric acid, 1% sulfanilamide, and 0.1% naphthyl ethylenediamine dihydrochloride) and incubated at room temperature for 10 min. The concentration of nitrite was measured by determining the optical density (OD) at 550 nm and calculated with a standard curve generated by Sodium nitrite.

2.8. Enzyme-Linked Immunosorbent Assay (ELISA). Int-407 cells were grown to 90% confluence in 6-well tissue culture plates and then added to the complete medium with camellia oil (prepared in DMSO) at 25, 50, and 75 μg/mL (final concentrations) for 24 h. The supernatants of Int-407 cells grown in conditioned medium and rat gastrointestinal mucosa protein samples was then harvested to be assayed for PGE_2 (Cayman Chemical Company, Ann Arbor, MI, USA), VEGF (Invitrogen, Carlsbad, CA, USA), and IL-6 (eBioscience, San Diego, CA, USA) secretion using a specific ELISA kit as indicated by the manufacturer's instructions.

2.9. RNA Extraction and Reverse Transcription-Polymerase Chain Reaction (RT-PCR). The mRNA expression levels of GPx, HO-1, and SOD were determined by RT-PCR. Total RNA was prepared using the TRIzol method (Life Technologies, Rockville, MD) following the manufacturer's instructions. The following sense and antisense primer sequences used for RT-PCR analysis were: GPx, 5′-GCA GAG CCG GGG ACA AGA GAA-3′ (forward) and 5′-CTG CTC TTT CTC TCC ATT GAC′-3 (reverse); HO-1, 5′-AAG ATT GCC CAG AAA GCC CTG GAC-3′ (forward) and 5′-AAC TGT CGC CAC CAG AAA GCT GAG-3′ (reverse); SOD, 5′-TAC ACC CAG ATG AAC GAG C-3′ (forward) and 5′-AGG AAC TTC TCA AAG TTC CAG GA-3′ (reverse); 18S, 5′-TTG GAG GGC AAG TCT GGT G-3′ (forward) and 5′-CCG TCC CAA GAT CCA ACT A-3′ (reverse). The amplification products were determined by electrophoresis on a 1.8% agarose gel containing 0.06 mg/L ethidium bromide. The gel was then photographed under UV transillumination. The results are expressed as ratios after normalization of the gene signal to the corresponding 18S or β-actin signal in each sample.

2.10. Pathological Histology Studies. The gastrointestinal tissues were fixed in formaldehyde (10%) and processed for histopathological studies according to the standard method and stained by hematoxylin/eosin (H&E) solutions. The pathological features of the gastrointestinal inner surface were scored as described by de la Lastra et al.[24] as follows: score 0 = no lesions; score 1 = vasodilatation or erythema; score 2 = 1−10 scattered small ulcers (<5 mm); score 3 = more than 10 scattered small ulcers (<5 mm); score 4 = 1−10 scattered medium ulcers (5−10 mm); score 5 = more than 10 scattered medium ulcers (5−10 mm); score 6 = 1−5 longitudinal ulcers (>10 mm); score 7 = more than five longitudinal ulcers (>10 mm).

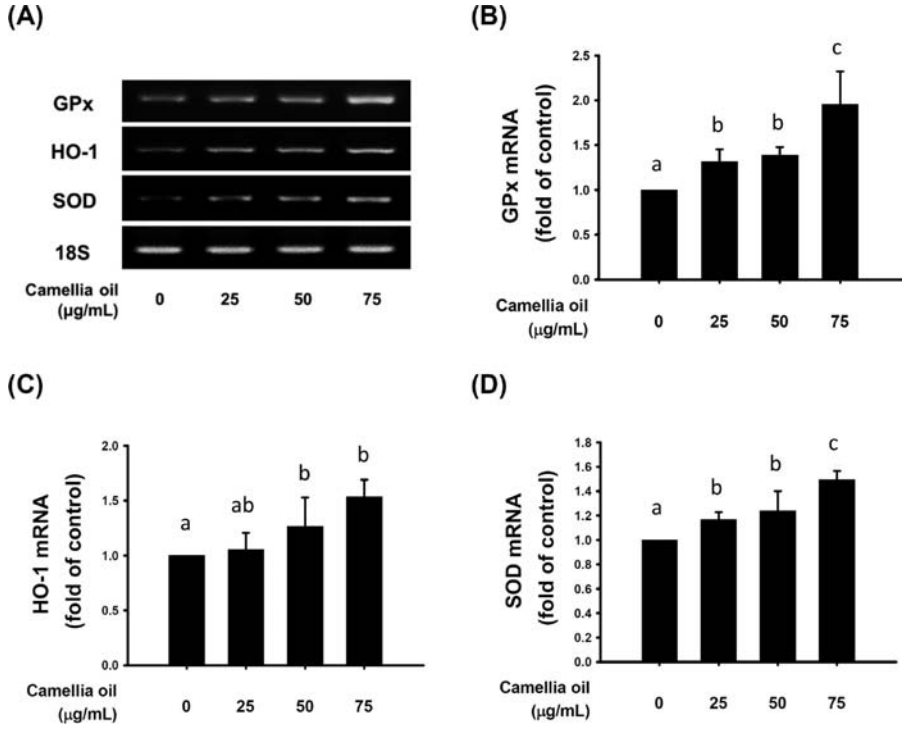

Figure 1. Effect of camellia oil on GPx, HO-1, and SOD mRNA expression in Int-407 cells. The cells were treated with camellia oil at 25, 50, and 75 μg/mL for 12 h, and the levels of GPx, HO-1, and SOD mRNA expression were analyzed by RT-PCR. The results are presented as the mean ± SD for $n = 3$. Each group with different letter subscripts is significantly different ($p < 0.05$).

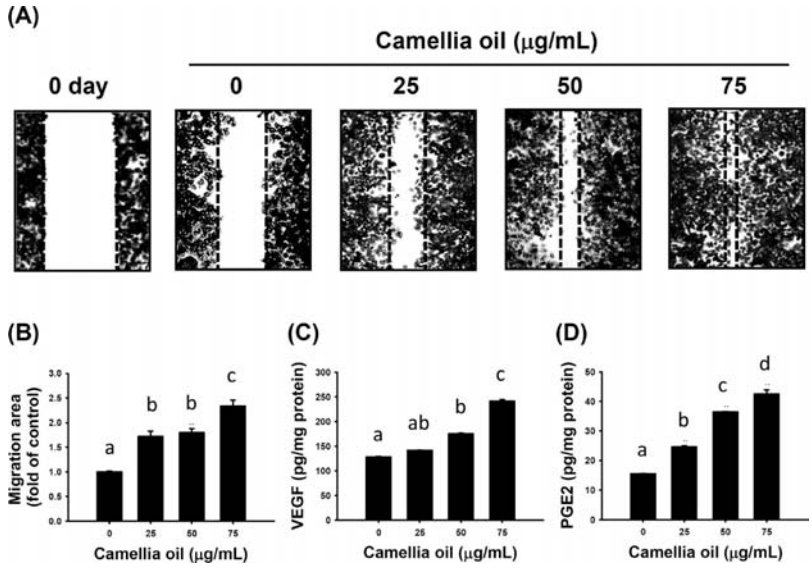

Figure 2. Effect of camellia oil on wound healing in Int-407 cells. (A) The cells were treated with camellia oil (25, 50, and 75 μg/mL) for 24 h, and a migration assay was performed to evaluate the wound-healing effects of camellia oil in Int-407 cells. (B) Graphical representation of cell migration ability. (C,D) Cells were treated with camellia oil at 25, 50, and 75 μg/mL for 24 h, and the production of VEGF and PGE_2 was analyzed by ELISA. The results are presented as the mean ± SD for $n = 3$. Each group with different letter subscripts is significantly different ($p < 0.05$).

2.11. Immunohistochemical (IHC) Staining. For IHC staining of VEGF and HO-1 was determined following a previously reported method.[25] Briefly, the tissue sections were blocked with StartingBlock blocking buffers prior to incubation with an anti-VEGF or anti-HO-1 antibody. Finally, the tissue sections were incubated with Envision-labeled polymer reagent containing peroxidase-conjugated anti-IgG at room temperature, followed by detection with a 3,3-diaminobenzidine tetrahydrochloride solution and hematoxylin.

2.12. Statistical Analysis. The statistical analysis was carried out using analysis of variance (ANOVA) according to the SAS User's Guide. Duncan's multiple range test was used to determine the significant differences ($p < 0.05$) between the means.

3. RESULTS

3.1. Effects of Camellia Oil on GPx, HO-1, and SOD mRNA Expression in Int-407 Cells. It has been suggested that upregulation of antioxidant enzyme activities may play an important role on cytoprotection against oxidative stress. In the present study, the induction effect of camellia oil on the activity

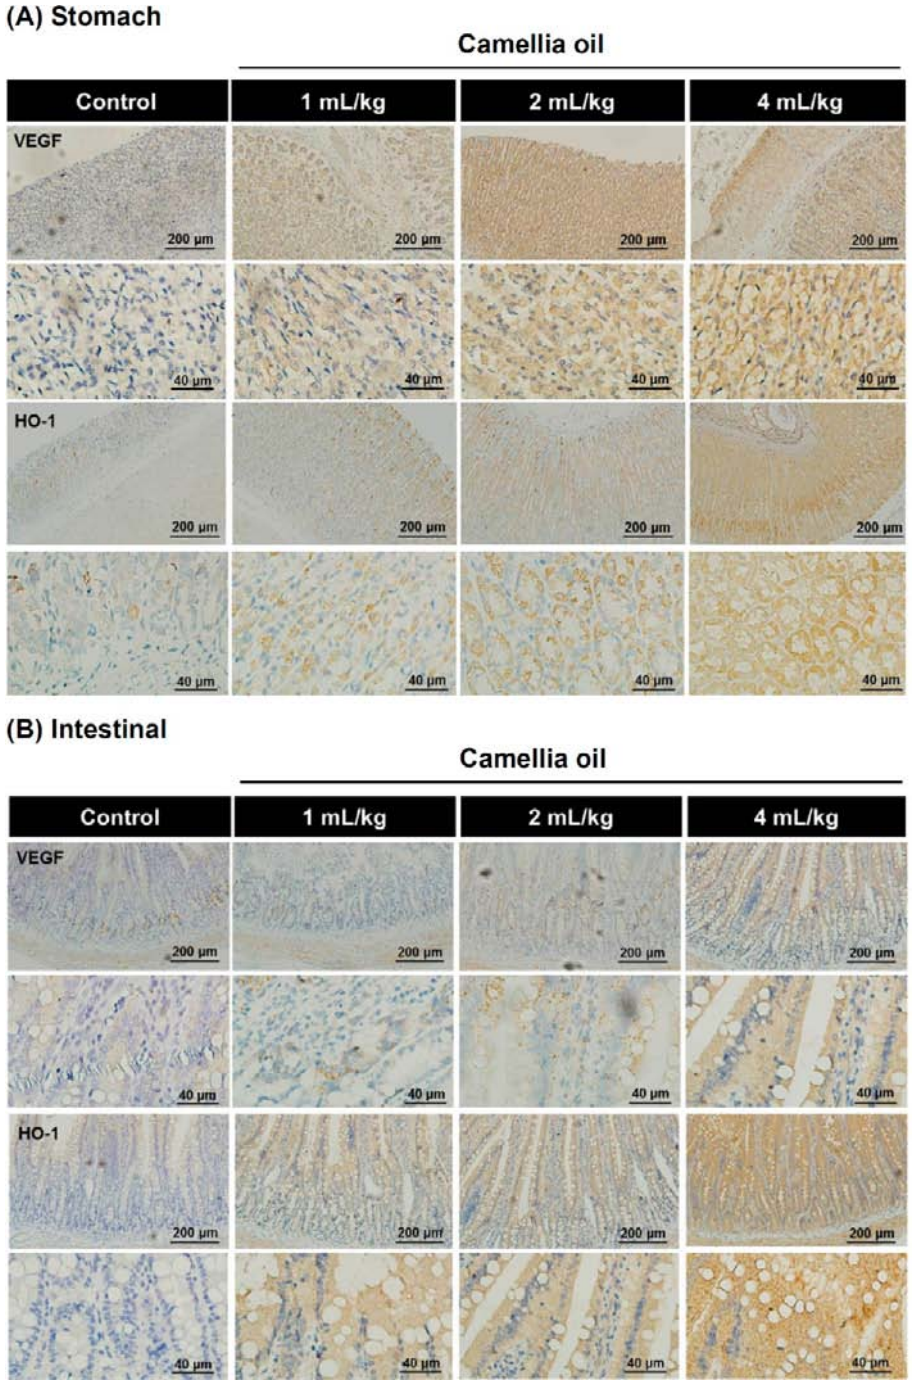

Figure 3. Immunohistochemical analysis of VEGF and HO-1 in the gastrointestinal mucosa induced by oral administration of camellia oil. SD rats were orally administered camellia oil (1, 2, and 4 mL/kg/day) for 21 days, and VEGF and HO-1 expression levels were examined by immunohistochemical analysis. VEGF and HO-1 protein expression in the gastrointestinal mucosa is represented by brown color.

of antioxidant enzymes was evaluated, including GPx, HO-1, and SOD. Int-407 cells treated with camellia oil at 25, 50, and 75 μg/mL for 12 h showed a dose-dependent increase in the mRNA expression of the antioxidant enzymes GPx, HO-1, and SOD, which reached a maximum at 75 μg/mL. Moreover, in the cells treated with camellia oil at 75 μg/mL for 12 h, the mRNA expression levels of GPx, HO-1, and SOD were increased by 1.80, 1.53, and 1.49-fold, respectively, compared with the control group (Figure 1, $p < 0.05$). These results suggest that camellia oil may potentially prevent oxidative stress-induced gastrointestinal injury.

3.2. Effect of Camellia Oil on Wound Healing in Vitro and in Vivo. In the wound-healing assay, Int-407 cells were treated with various concentrations (25, 50, and 75 μg/mL) of camellia oil for 24 h. As shown in Figure 2A,B, the 75 μg/mL concentration exhibited the greatest effect on cell motility after 24 h of incubation relative to the control group ($p < 0.05$). VEGF (vascular endothelial growth factor) and prostaglandins play key roles in maintaining gastrointestinal mucosal integrity.[26,27] As shown in Figure 2C,D, treatment of the cells with camellia oil at 25, 50, and 75 μg/mL for 24 h led to a dose-dependent increase in VEGF and PGE_2 production. Moreover, some reports have

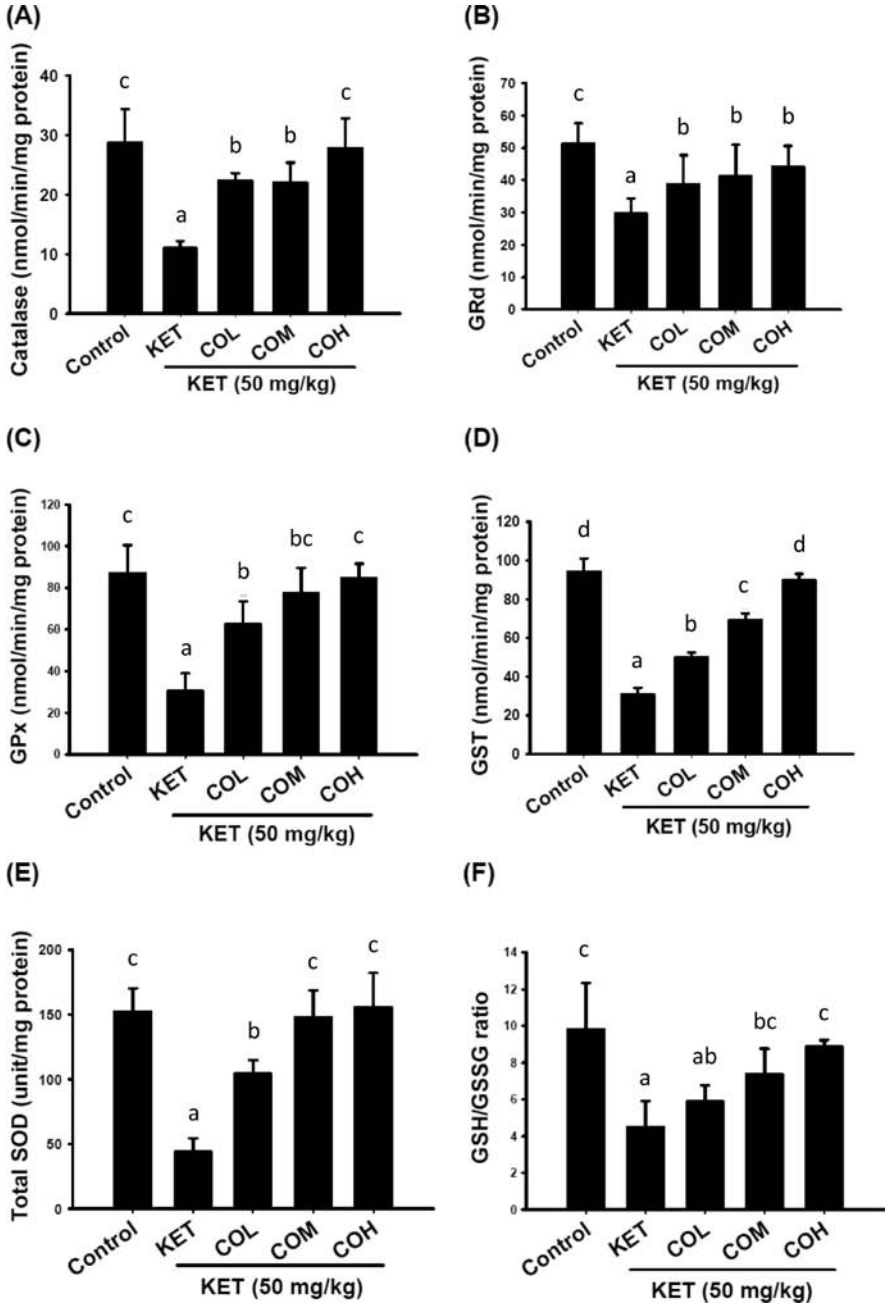

Figure 4. Effect of camellia oil on ketoprofen-induced changes in the activity levels of (A) catalase, (B) GRd, (C) GPx, (D) GST, (E) SOD, and the ratio of (F) GSH/GSSG in the gastrointestinal mucosa of SD rats. The animals were orally administered camellia oil (1, 2, and 4 mL/kg/day) for 21 consecutive days, and ketoprofen was then orally administered to all animals for 1 day. The data are presented as the mean ± SD for $n = 6$. Each group with different letter subscripts is significantly different ($p < 0.05$). KET, 50 mg ketoprofen/kg BW; COL, 1 mL camellia oil/kg BW; COM, 2 mL camellia oil/kg BW; COH, 4 mL camellia oil/kg B.W.

suggested that VEGF might prevent gastric mucosal injury by upregulation of HO-1 expression.[27,28] In vitro, Int-407 cells treated with camellia oil at 25, 50, and 75 μg/mL exhibited a dose-dependent increase in HO-1 mRNA expression as well as VEGF production (Figures 1C and 2C). More importantly, the administration of camellia oil to animals at 1, 2, and 4 mL/kg for 21 days had significant effects on VEGF and HO-1 protein expression in the stomach (Figure 3A) and intestinal (Figure 3B) mucosa, as determined by immunohistochemical analysis. These results suggest that the induction of VEGF and HO-1 by camellia oil might play a key role in the regulation of wound healing.

3.3. Effect of Camellia Oil on Ketoprofen-Induced Changes in Catalase, GRd, GPx, GST, and SOD Activities As Well as the GSH/GSSG Ratio in Gastrointestinal Mucosa. As shown in Figure 4, the treatment of SD rats with ketoprofen (50 mg/kg) resulted in a significant ($p < 0.05$) reduction in the activity of catalase, GRd, GPx, GST, and SOD as well as a reduction in the GSH/GSSH ratio in the gastrointestinal mucosa. However, oral administration of camellia oil (1, 2, and 4 mL/kg/day) exhibited a significant dose-dependent reversal of the impairment of the antioxidant enzyme system in the gastrointestinal mucosa compared with the ketoprofen-induced group ($p < 0.05$). The results indicate that camellia oil could

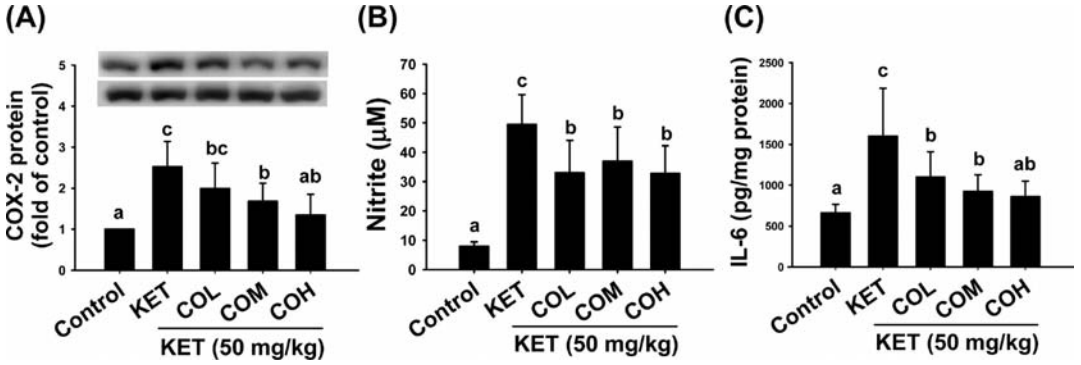

Figure 5. Effect of camellia oil on ketoprofen-induced changes in the levels of COX-2, NO, and IL-6 expression in rat gastrointestinal mucosal tissue. The animals were orally administered camellia oil (1, 2, and 4 mL/kg) for 21 consecutive days, and ketoprofen was then orally administered to all animals for 1 day. The data are presented as the mean ± SD for $n = 6$. Each group with different letter subscripts is significantly different ($p < 0.05$). KET, 50 mg ketoprofen/kg BW; COL, 1 mL camellia oil/kg BW; COM, 2 mL camellia oil/kg BW; COH, 4 mL camellia oil/kg BW.

reverse the impairment of the antioxidant system induced by ketoprofen in the gastrointestinal mucosa of SD rats.

3.4. Effect of Camellia Oil on Ketoprofen-Induced Changes in COX-2, NO, and IL-6 Expression Levels in the Gastrointestinal Mucosa. As shown in Figure 5A, treatment of rats with ketoprofen showed a significant ($p < 0.05$) increase in the level of COX-2 protein expression that was partly reduced by pretreatment with camellia oil (1, 2, and 4 mL/kg/day). NO and IL-6 are potent mediators of gastrointestinal mucosal inflammation caused by a wide variety of inflammatory stimuli such as toxic chemicals, viruses, and drugs. As shown in Figure 5B, NO production was abrogated by camellia oil in ketoprofen-treated SD rats ($p < 0.05$). As shown in Figure 5C, IL-6 production in animals treated with camellia oil (1, 2, and 4 mL/kg/day) was significantly inhibitory ($p < 0.05$), compared with the ketoprofen-induced group. However, no significant ($p < 0.05$) difference was found between any of dose-dependent manner. These results indicate that camellia oil might have the potential to protect patients with inflammation-associated gastrointestinal ulcers.

3.5. Pathological Histology of the Gastrointestinal Tract. The protective effects of camellia oil against oxidative injury to the gastrointestinal mucosa were investigated by hematoxylin/eosin staining. As shown in Figure 6, treatment of animals with ketoprofen at 50 mg/kg/day caused acute gastrointestinal injury as well as concavity of the gastrointestinal surface. The gastrointestinal tissues showed cloudy, swelled areas of variable size as well as necrosis and lymphocyte infiltration in the central zone and midzone. However, animals pretreated with camellia oil at 1, 2, and 4 mL/kg/day for 3 weeks prior to the administration of ketoprofen (50 mg/kg/day) showed decreased incidence of gastrointestinal mucosal injury.

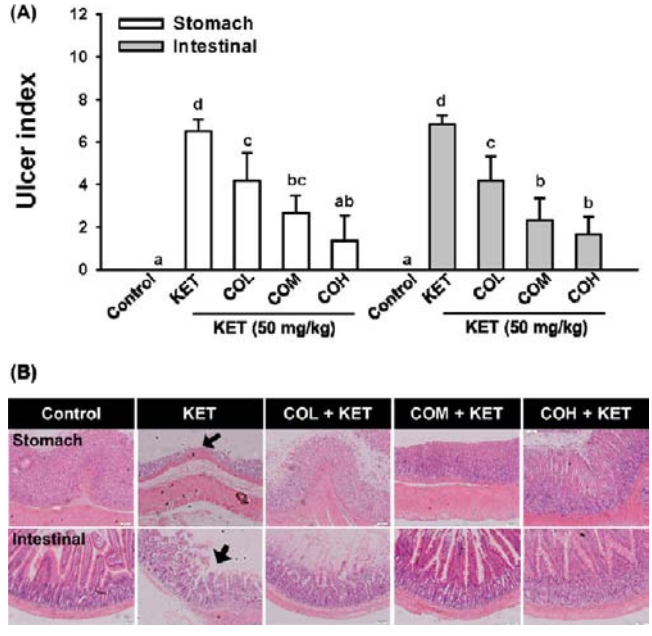

Figure 6. Effect of camellia oil on ketoprofen-induced gastrointestinal mucosal damage in SD rats. (A) Histological injury score of the gastrointestinal mucosa after different doses of camellia oil in rats treated with ketoprofen. (B) The morphology of ketoprofen-induced gastrointestinal ulcers in SD rats pretreated with or without camellia oil for 21 d. Gastrointestinal damage is indicated with an arrow. The data are presented as the mean ± SD for $n = 6$. Each group with different letter subscripts is significantly different ($p < 0.05$). KET, 50 mg ketoprofen/kg BW; COL, 1 mL camellia oil/kg BW; COM, 2 mL camellia oil/kg BW; COH, 4 mL camellia oil/kg BW. Hematoxylin/eosin staining, 100×.

4. DISCUSSION

Camellia oil has been reported to have positive health effects and is used as a traditional remedy for stomachache. Several studies have suggested that vegetable oils (corn, olive, and sunflower oils) strongly inhibit gastrointestinal injuries induced by NSAID.[20] Similar to olive oil, camellia oil is rich in oleic acid, which plays a key role in protection against ulcerogenesis.[18] In the preliminary test (data not shown), our data found that methanol extract of camellia oil revealed the highest antioxidant activity (127.48 μM trolox/g extract) as determined by trolox equivalent antioxidant capacity (TEAC). The similar antioxidant activity was also obtained by the oxygen radical absorbance capacity (ORAC) assay; it was the equal of 1.27 mM trolox/g extract. Moreover, methanol extract of camellia oil had the highest α-tocopherol (303.09 μg/g oil) and total phenolics (12.61 mg gallic acid/g extract) content as compare to soybean oil at concentrations of 24.27 (μg/g oil) and 1.72 (mg gallic acid/g extract), respectively. Chen et al.[17] have demonstrated that administration of camellia oil could lower triglyceride, cholesterol, and low density-lipoprotein levels in the blood of rats. Moreover, we reported that two major active compounds in camellia oil, sesamin, and novel compound B (2,5-bis-benzo[1,3] dioxol-5-yl-tetrahydro-furo[3,4-*d*][1,3]dioxine) could effectively prevent carbon tetrachloride (CCl_4)-induced liver oxidative

dx.doi.org/10.1021/jf404614k | J. Agric. Food Chem. 2014, 62, 642−650

damage in rats.[18] However, the protective effect of camellia oil against injury of the gastrointestinal mucosa induced by ketoprofen remains unknown. Thus, the objective of this study was designed to study the effects of camellia oil on the activities of antioxidant enzymes against ketoprofen-induced acute gastrointestinal damage.

NSAIDs such as ketoprofen are commonly used to treat inflammatory pain and as pyretic agents in clinical medicine. Despite their benefits, these drugs may cause peptic ulcer.[2] Our previous study indicated that ketoprofen causes gastrointestinal ulcers through a variety of mechanisms, including increased mucosal lipid peroxidation and oxidative damage as well as decreased gastric mucus secretion in rats.[13] Therefore, reducing oxidative stress and/or upregulating antioxidant enzymes may be effective approaches for preventing and treating gastrointestinal ulcers induced by ketoprofen. GPx, SOD, and, HO-1 are important antioxidant enzymes in the human body that have been shown to act as metal ion chelators and effective scavengers for ROS and reactive carbonyl species (RCS).[11,12,29] As shown in Figure 1, camellia oil (75 μg/mL) strongly increased GPx, SOD, and HO-1 mRNA expression in Int-407 cells. Some reports have indicated that gastrointestinal isoenzyme-GPx is the mainly important gastric enzyme because it serves as a barrier against hydroperoxide formed during xenobiotic metabolism.[30] Kirkby and Adin[11] indicated that HO-1 breaks down heme to biliverdin and carbon monoxide, which can protect gastrointestinal cell against oxidative damage. Guo et al.[12] reported that the upregulation of of HO-1 expression may reduce inflammation and tissue injury caused by ROS in the stomach and intestine. Our previous study showed that catechin effectively prevented injury of Int-407 cells induced by ketoprofen with upregulating HO-1 expression through the Nrf2 pathway.[13] These results suggest that camellia oil inhibits oxidative injury of the gastrointestinal mucosa induced by ketoprofen through upregulating antioxidant enzymes, especially HO-1.

Another approach for protection against ketoprofen-induced gastrointestinal mucosal damage may involve the upregulation of neovascularization in the gastrointestinal mucosal tissue. Neovascularization, which is the generation of new capillaries by sprouting of pre-existing microvessels, is under stringent control and normally occurs during embryonic and postembryonic development, the reproductive cycle, and wound repair.[27,28] Taupin and Podolsky[31] also indicated that enhanced stomach epithelial cell migration may be an effective approach for the treatment of stomach ulcers. VEGF is one of the most important factors for gastrointestinal mucosal reconstruction, mucosal defense, and ulcer healing.[27] Sofalcone is used to treat gastrointestinal ulcers and protects the gastric mucosa. Shibuya et al.[28] indicated that sofalcone might prevent gastric mucosal injury through the upregulation of VEGF production mediated via the Nrf2/HO-1 pathways. Similar to VEGF, prostaglandins play an important role in maintaining gastrointestinal mucosal integrity, which controls most gastric mucosa defense, and resolving inflammation.[26,27] Megias et al.[32] indicated that HO-1 modulated PGE_2 production in osteoarthritic chondrocytes. Similarly, our results showed that treatment with camellia oil (25−75 μg/mL) not only increased the levels of HO-1, VEGF, and PGE_2 expression but also enhanced the migration of human Int-407 cells (Figures 1C and 2). Furthermore, the VEGF and HO-1 protein levels in the stomach and intestinal mucosa of animals pretreated with camellia oil at 1, 2, and 4 mL/kg for 21 days were upregulated as evidenced by immunohistochemical analysis (Figure 3). These results indicate that camellia oil may serve as barrier against ketoprofen-induced gastrointestinal mucosal injury, which may aid mucosal repair.

Proton pump inhibitors (PPIs), such as lansoprazole, are usually used to treat gastric and duodenal ulcers.[6,7] Many studies have suggested that administration of lansoprazole can reverse the effects of diclofena, ketoprofen, indomethacin, and piroxicam on the mucosal content of GSH, MDA, and myeloperoxidase (MPO).[6−8] Similarly, our results indicated that camellia oil caused a significant ($p < 0.05$) dose-dependent reversal of the impairment of the antioxidant system during ketoprofen-induced gastrointestinal mucosal injury (Figure 4). To further investigate the protective effects of camellia oil against gastrointestinal injury in vivo induced by ketoproten in relation to antioxidant systems, SD rats were orally administered lansoprazole followed by gavage with ketoprofen. Our results showed that administration of lansoprazole (30 mg/kg) inhibited lipid peroxidation and reversed the reduction in the activities of GRd, GPx, GSH, and the GSH/GSSG ratio induced by ketoprofen (data not shown). These results suggest that camellia oil could reverse the impairment of the antioxidant enzymes activity in the gastrointestinal mucosa of SD rats induced by ketoprofen.

On the other hand, numerous studies have indicated that the gastrointestinal toxicity of *S*(+)-ketoprofen in rats is due to stimulation of the production of COX-2 and NO synthase in gastric mucosal lesions.[2,33,34] Pawlik et al.[35] suggested that proinflammatory mediators, such as IL-6 and NO, are produced by COX-2. Erkan et al.[36] indicated that COX-2 plays a key role in the stepwise process that ultimately causes gastric cancer. Blandizzi et al.[8] reported that administration of lansoprazole prevented gastric mucosal injury caused by indomethacin, piroxicam, or ketoprofen by reducing COX-2 mRNA expression in SD rats. As shown in Figure 5, the administration of camellia oil to animals at 2 mL/kg/day reduced COX-2 protein expression as well as the production of NO and IL-6 in SD rats treated with ketoprofen. Moreover, the camellia oil group was no difference ($p < 0.05$) in food, water intake, and body weight compared with the levels in the control group and the ketoprofen-treated group (data not shown). More importantly, we found that administration of camellia oil (2 mL/kg/day) strongly prevented the ketoprofen-induced gastrointestinal mucosal damage, as demonstrated by the histopathological (H&E) staining of gastrointestinal tissues (Figure 6). Odabasoglu et al.[20] indicated that animals treated with vegetable oils (corn, olive, and sunflower oils) at 2 mL/kg strongly inhibited indomethacin-induced gastric injuries in vivo. Furthermore, the animal dose of camellia oil was further extrapolated to a human equivalent dose following the calculated of Freireich et al.[37] The result suggests that oral administration of camellia oil at 2 mL/kg is approximately equivalent in human dose to 0.3 mL/kg. Overall, these data indicate that camellia oil may offer a potential therapeutic approach for inflammation-associated disorders such as gastrointestinal ulcers.

In conclusion, we demonstrated that intestinal epithelial cells treated with camellia oil (50−75 μg/mL) not only exhibited increased levels of GPx, HO-1, and SOD mRNA expression but also exhibited increased VEGF and PGE_2 protein expression, which might serve as barrier against gastrointestinal mucosal oxidative injury. Moreover, the administration of camellia oil at 2 mL/kg/day strongly inhibited the ketoprofen-induced gastrointestinal mucosal damage in SD rats. These results confirm the health-promoting effects of camellia oil, which exhibits potent antiulcer effects against oxidative damage in the stomach and intestine induced by ketoprofen.

Synthesis of All Stereoisomers of 3,3′-Dimethoxy-7,7′-epoxylignane-4,4′-diol and Their Plant Growth Inhibitory Activity

Hisashi Nishiwaki, Kumiko Nakayama, Yoshihiro Shuto, and Satoshi Yamauchi*

Faculty of Agriculture, Ehime University, 3-5-7 Tarumi, Matsuyama, Ehime 790-8566, Japan

Supporting Information

ABSTRACT: All stereoisomers of 3,3′-dimethoxy-7,7′-epoxylignane-4,4′-diol were synthesized to examine the effect of stereochemistry on their plant growth inhibitory activity using lettuce and Italian ryegrass. The effect of structural modifications such as dehydroxylation, methoxylation and hydroxylation at the 9- and 9′-positions of the lignans on the activity was also studied. Most of the epoxylignanes showed higher plant growth inhibitory potency against ryegrass than against lettuce, and the inhibitory activity varied depending on the configurations of each position of the tetrahydrofuran ring (7-, 7′-, 8-, and 8′-positions of the epoxylignanes). Among the 9,9′-position-modified derivatives, the dehydroxy derivatives showed the highest potency. These results suggested that the plant growth inhibitory activity should be influenced by the structure of the epoxylignanes.

KEYWORDS: *3,3′-dimethoxy-7,7′-epoxylignane-4,4′-diol, lignan, plant growth inhibitory activity, lettuce, Italian ryegrass*

INTRODUCTION

Lignans widely distributed in plants exert various biological activities such as anticancer and antioxidant activities.[1] Lariciresinol, which is a trisubstituted tetrahydrofuran lignan, has also interesting biological activities including phytotoxic activity. Our previous study of the effect of the stereochemistry of lariciresinol on plant growth regulatory activity against lettuce (*Lactuca sativa* L.) and Italian ryegrass (*Lolium multiflorum* Lam.) demonstrated that the phytotoxic activity of lariciresinol depended on its stereochemistry, that is, the importance of both the 8*S* absolute configuration and the 7,8′-*trans* relative configuration for high activity.[2] It is undoubted that lignans other than lariciresinol should also show potent phytotoxic activity, as reported for diayangambin and dihydrodiconiferyl alcohol,[3,4] and that the structural modification as well as the absolute structure of lignans should influence their phytotoxicity, but data regarding the phytotoxicity of lignans, especially in-depth discussion of the relationship between their stereochemistry and activity, are less available.

Herein we focused on the relationship between the stereochemistry of 3,3′-dimethoxy-7,7′-epoxylignane-4,4′-diol compounds, which are tetrasubstituted tetrahydrofuran lignans (Figure 1), and their plant growth regulatory activity. In addition, the effect of the structural modifications at the 9- and 9′-positions such as dehydroxylation, methoxylation and hydroxylation on the activity was also studied. Some of these lignans have been isolated and named as follows: (−)-verrucosin, **1** (**1-H**, (−)-odoratisol);[5,6] (+)-verrucosin, **4** (**2-H**);[7] (+)-fragransin A2, **7** (**3-H**);[7] (+)-*neo*-olivil, **9** (**3-OH**);[8] (+)-saucernetin diol, **13** (**5-H**);[9,10] (−)-*neo*-olivil, **18** (**6-OH**);[11] (−)-machilin-I, **22** (**8-H**);[12] nectandrin B, **25** (**9-H**);[7] and tetrahydrofuroguaiacin B, **28** (**10-H**).[10] The syntheses of **1**,[13] **7**,[13] and **13**[14,15] have been achieved, and the conversion from glucoside to **27** (**9-OH**) has been reported.[16] The other stereoisomers were synthesized for the first time in this project. In our previous studies, the constructions of all stereochemistries of 7,7′-epoxylignane have been established,[17−19] and these synthetic methods were modified to provide the stereoisomers of 3,3′-dimethoxy-7,7′-epoxylignane-4,4′-diol. This research would contribute to the collation of stereoisomer libraries of natural products.

MATERIALS AND METHODS

Chemicals. The synthetic scheme is shown in Figure 2. Reagents used for the syntheses were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan), Nacalai Tesque, Inc. (Kyoto, Japan), Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan), and Aldrich Chemical Co (Milwaukee, WI, USA). Melting points were uncorrected. Optical rotations were measured on a SEPA-200 instrument (Horiba Ltd., Kyoto, Japan). NMR data were obtained using a Bruker AVANCE III 500 spectrometer (Bruker BioSpin K.K., Kanagawa, Japan). EIMS data were measured with a JMS-MS700 V spectrometer (JEOL Ltd., Tokyo, Japan). The silica gel used was Wakogel C-300 (Wako, 200−300 mesh). The numbering of compounds follows the nomenclature of lignans.[20] Information for compounds **1**, **4**, **7**, **9**, **10**, **12**, **13**, **15**, **16**, **18**, **19**, **22**, **25**, **27**, and **28** (**1-H**−**10-H**, **3-OH**, **4-OH**, **5-OH**, **6-OH**, and **9-OH**), which has been published,[5−8,10,11,13,14,16,21] was placed in the Supporting Information.

(7S,7′R,8S,8′S)-4,4′-Dibenzyloxy-3,3′-dimethoxy-7,7′-epoxylignane-9,9′-diol, ***31****:* colorless oil; $[\alpha]^{20}_{D}$ −18 (*c* 1.2, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 2.23 (1H, m, H-8′), 2.55 (1H, m, H-8), 2.65−3.00 (1H, br, OH), 3.08 (1H, dd, *J* = 10.3, 9.9 Hz, H-9a), 3.18−3.48 (1H, br, OH), 3.30 (1H, dd, *J* = 10.3, 4.7 Hz, H-9b), 3.55 (1H, dd, *J* = 9.6, 9.0 Hz, H-9′a), 3.72 (1H, dd, *J* = 9.6, 3.4 Hz, H-9′b), 3.84 (3H, s, 3-OCH_3), 3.88 (3H, s, 3′-OCH_3), 4.47 (1H, d, *J* = 9.4 Hz, H-7′), 5.09 (1H, d, *J* = 8.7 Hz, H-7), 5.11 (2H, s, CH_2OPh), 5.14 (2H, s, CH_2OPh), 6.82 (2H, s, H-5, H-6), 6.84 (1H, d, *J* = 8.3 Hz, H-5′), 6.89 (1H, s, H-2), 6.92 (1H, dd, *J* = 8.3, 1.9 Hz, H-6′), 7.04 (1H, d, *J* = 1.9 Hz, H-2′), 7.27−7.30 (2H, m, BnO), 7.33−7.37 (4H, m, BnO), 7.40−7.43 (4H, m, BnO); ^{13}C NMR (125 MHz, $CDCl_3$) δ 50.9 (C-8), 54.9 (C-8′), 56.0 (C-9′), 56.1 (C-9), 63.0 (OCH_3), 63.7 (OCH_3), 71.10 (OCH_2Ph), 71.13 (OCH_2Ph), 81.2 (C-7), 82.5 (C-7′), 110.4 (C-2′), 110.8 (C-2), 113.9 (C-5), 114.0 (C-5′), 118.7 (C-6′), 119.0 (C-6),

Evaluation of Plant Growth Inhibitory Activity. For all of the synthesized epoxylignane derivatives, their plant growth inhibitory activities were evaluated using lettuce (*L. sativa* L., green-wave (Takii Seed Co. Ltd., Kyoto, Japan)) and Italian ryegrass (*L. multiflorum* Lam., wase-fudo (Takii Seed Co. Ltd., Kyoto, Japan)), according to our earlier paper.[2] Briefly, 30 seeds of each plant were placed on a filter paper (in a 90 mm Petri dish) moisturized with 3 mL of water

dx.doi.org/10.1021/jf4046396 | J. Agric. Food Chem. 2014, 62, 651−659

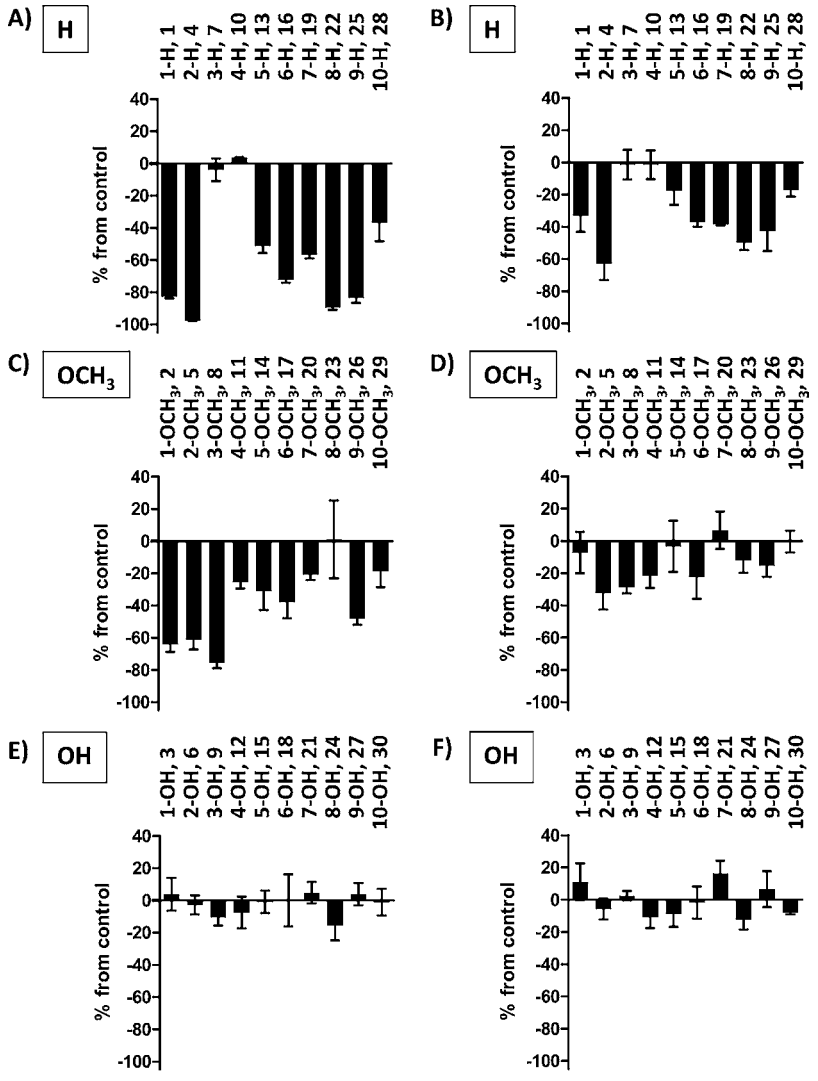

Figure 5. Plant growth inhibitory activity (percent from control) of test chemicals against root (A, C, E) and shoot (B, D, F) of ryegrass when applied at the concentration of 1×10^{-3} M. Data are presented as the mean ± standard error of the mean.

containing each sample at the concentration of 1.0 mM. After they were incubated in the dark at 20 °C for 3 and 5 days for lettuce and grass, respectively, the lengths of their roots and shoots were measured using a ruler. Experiments were performed in triplicate, and statistical analyses were conducted by one-way ANOVA followed by Tukey's multiple-comparison test using PRISM software (Graphpad Software, San Diego, CA, USA).

For compounds **1-H** and **2-H**, the germination rates of lettuce and grass seeds were recorded 3 days after seeding.

■ RESULTS AND DISCUSSION

The intermediates **31**−**34** and **39** were synthesized according to the previously described method with modification.[17−19] The mesylation of the two hydroxyl groups, followed by reduction, gave dimethyl compounds. To obtain **1-H**, **2-H**, **3-H**, and **4-H**, $NaBH_4$ in hexamethylphosphoramide (HMPA) was employed for the corresponding mesylates. On the other hand, lithium triethylborohydride (superhydride) was used for reduction of mesylate from the intermediate **39**, giving **9-H**. To prepare the intermediates **35** and **37**, compound **33** was selected as a starting compound. After conversion of **33** to the corresponding conjugated diene by elimination, hydroboration was tried to give two stereoisomers **35** and **37**. By the same procedure, **36** and **38** were obtained from diol **34**. The intermediate **40** was obtained by the isomerization of **39** using elimination followed by hydroboration. The intermediates **35**−**38** and **40** were subjected to mesylations followed by superhydride reductions, giving **5-H**, **6-H**, **7-H**, **8-H**, and **10-H**, respectively.

Among 10 stereoisomers of **H**-type epoxylignane (**1-H**−**10-H**), the compounds with the configurations of 7*S*,7′*R*,8*R*,8′*R* (**1-H**) and 7*R*,7′*S*,8*R*,8′*S* (**9-H**) suppressed the growth of lettuce root to −94 and −69%, respectively, whereas the other stereoisomers showed less activity (from −25 to +7.5%) (Figure 3A). Against the lettuce shoot (Figure 3B), −60 and −52% inhibitions relative to the control were observed for **1-H** and **2-H**, respectively. On the other hand, **5-H**, **6-H**, **7-H**, **8-H**, and **9-H** suppressed the shoot growth moderately (from −20 to −40%), but statistically insignificant relative to the control. The application of **3-H**, **4-H**, and **10-H** did not influence the lettuce shoot growth. With these results taken together, **1-H** showed the highest potency against lettuce. Introduction of the methoxy and hydroxyl groups to the 9 and 9′ carbon atoms (**1-OCH_3**−**10-OCH_3** and **1-OH**−**10-OH**) induced the absolute values of the growth rate below 25% (Figure 3C−F), demonstrating that the modification of the 9 and 9′ carbon atoms with the methoxy and hydroxyl groups influences the

dx.doi.org/10.1021/jf4046396 | J. Agric. Food Chem. 2014, 62, 651−659

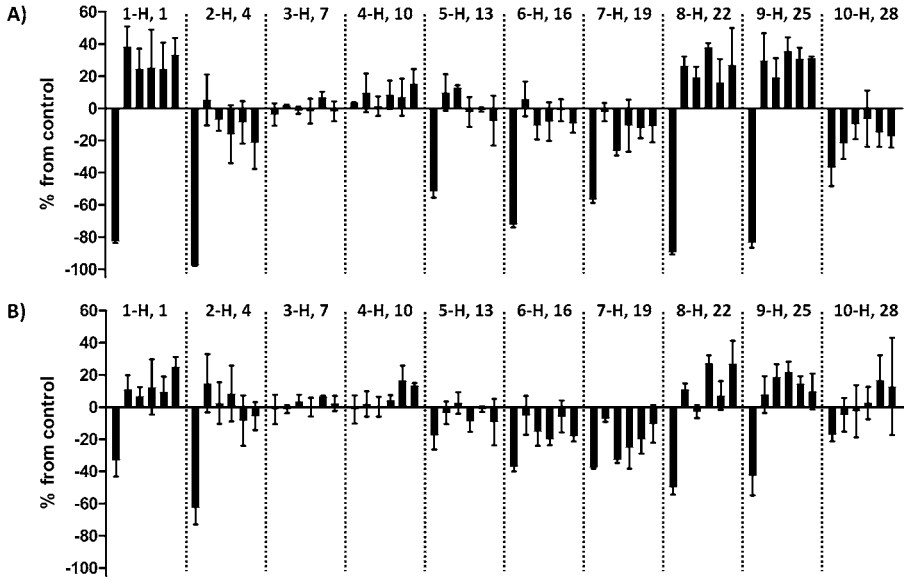

Figure 6. Plant growth inhibitory activity (precent from control) of **1-H**−**10-H** against root (A) and shoot (B) of ryegrass when applied at concentrations from 1×10^{-3} to 1×10^{-8} M (from left to right for each compound). The plant growth activity of the commercial herbicide, diuron, was as follows: for root (1×10^{-3}−1×10^{-8} M), −78.2 ± 3.79%, −49.8 ± 2.47%, −21.8 ± 8.69%, −4.83 ± 1.29%, −0.02 ± 6.1%3, and −9.70 ± 8.83%; for shoot (1×10^{-3}−1×10^{-8} M), −66.7 ± 8.15%, −32.9 ± 6.29%, −24.1 ± 8.59%, −21.9 ± 3.19%, −15.8 ± 5.54%, and −25.4 ± 5.52%. Data are presented as the mean ± standard error of the mean.

activity adversely. At the dose-dependent assay for evaluating the influence on the lettuce growth of the **H**-type epoxylignane compounds, the compounds did not influence the root growth at the diluted concentrations (Figure 4A). The inhibitory activity of **2-H** against the lettuce shoot decreased depending on the dilution of the concentration, but no significant activity was observed for the other compounds at the tested concentrations (Figure 4B).

Ryegrass root was found to be more sensitive to the epoxylignanes than lettuce root (Figure 5). Among the **H**-type epoxylignanes, not only the compounds **1-H** and **9H**, which were active to the lettuce root, but also **2-H**, **5-H**, **6-H**, **7-H**, and **8-H** suppressed the growth of the grass root below −50%, whereas **3-H** and its enantiomer **4-H**, which have the configuration of all *R* and all *S*, respectively, did not show any inhibitory activity (Figure 5A). Among these epoxylignanes, compound **2-H** with the 7*R*,7′*S*,8*S*,8′*S* configuration was the most potent compound, which could suppress the growth of the root almost completely at 1×10^{-3} M. The order of the sensitivity of the grass shoot to the **H**-type epoxylignanes was likely to be similar to that of the sensitivity of the grass root, although the sensitivity of the shoot was relatively less than that of the root (Figure 5A vs 5B). Introduction of the methoxy group induced less activity except the compounds with the configuration of all *R* and all *S*; especially the inhibitory activity of the all *R* configuration compound **3-H**, which showed no activity to the grass shoot, was strengthened up to −76% from control by attaching the methoxy group (**3-OCH$_3$**, Figure 5C). The inhibitory activity against the grass shoot of the compounds having the methoxy group was weak (Figure 5D). The compounds having the hydroxyl group did not influence the growth of grass root as well as shoot (Figure 5E,F). At the dose-dependent assay for evaluating the influence on the grass of the **H**-type epoxylignane compounds, compounds **1-H**, **8-H**, and **9-H** showed a promotive effect on the growth of grass root at diluted concentrations (Figure 6).

The phytotoxicity of all stereoisomers of lariciresinol has been evaluated in our previous paper,[2] in which (−)-lariciresinol and its 7*S*,8*S*,8′*R* stereoisomer have been found to inhibit the growth of Italian ryegrass as well as suppress the germination of the ryegrass seed to some extent. The most potent compound in the present study, **2-H**, inhibited the root growth of ryegrass almost completely, demonstrating that lariciresinol, which suppressed the growth of ryegrass root to around 50%, was less potent than **2-H**. Lariciresinol has the hydroxyl group at the 9-position, and all of the **OH**-type epoxylignanes in the present study were slightly potent, suggesting that hydrophilic features of the compounds having a hydroxyl group at the 9-position should be adverse to the root growth of ryegrass. Because the substitution patterns on the epoxylignanes synthesized in this study are basically different from that of lariciresinol, the effects of the conformations of each compound on the phytotoxicity were not compared.

The germination rate of the lettuce seed applied by **1-H**, which showed the highest inhibitory activity against the lettuce root (Figure 3), was 92.5 ± 1.12% (mean ± SEM, $n = 3$), which was almost the same as the control (95.7 ± 2.15%, $n = 3$). Also, the germination rate of the ryegrass seed applied by **2-H**, which almost completely suppressed the growth of the ryegrass root (Figure 5), was 87.3 ± 2.07% ($n = 3$), which was a little smaller than that of the control (94.7 ± 2.78%, $n = 3$), suggesting that these potent epoxylignanes should not suppress the germination process of the seed, unlike lariciresinol,[2] but influence the development and growth process other than germination. Because the inhibitory effects of the compounds on the shoot of both lettuce and grass were similar (in Figures 3B and 5B, **3-H** and **4-H** were ineffective, but the others suppressed the growth to some degree), the target sites would be the same in both species, although the mode of action of these compounds remains unknown.

Among the epoxylignanes that have been isolated in the previous studies, the antifungal activity[5] and disruption of ion homeostasis of (−)-verrucosin (**1-H**)[22] have been reported.

dx.doi.org/10.1021/jf4046396 | J. Agric. Food Chem. 2014, 62, 651−659

Nectandrin B (**9-H**) was found to activate AMP-activated protein kinase[10,23] and endothelial nitric-oxide synthase phosphorylation,[24] to show neuroprotective effects,[25,26] antifungal,[27] and glucocorticoid receptor binding activity,[28] and to inhibit proliferation,[29,30] hydroxysteroid dehydrogenase,[30] aromatase,[30] topoisomerase,[31] melanin biosynthesis,[32] prostaglandin,[33] and platelet aggregation induction.[34] Tetrahydrofuroguaiacin B (**10-H**) also activated AMP-activated protein kinase.[10] The target sites in the plants of the epoxylignanes synthesized in the present study are still unclear, but the targets should strictly recognize the stereochemistry of the compounds, and the affinity to the target sites may be different among the stereoisomers, because these stereoisomers should have the same physicochemical properties such as hydrophobicity (Clog P) and acidity (pK_a), indicating that the potency of the systemic translocation to the target site would be similar.

In summary, stereoisomers of tetrasubstituted tetrahydrofuran type epoxylignanes were synthesized to evaluate their plant growth inhibitory activity, and it was suggested that the structures of these epoxylignanes should be strictly recognized by the targets in the plants. As seen in the recent reviews for lignans,[35,36] studies on the effect of its fine chemical structure of lignans on their biological activities should be performed routinely. To retrieve the information of the target sites of the epoxylignanes, the structure−activity relationship results in the present study should be useful, and the probe compound will be designed on the basis of the stereochemical structure of the highest potency compound in the future.

Isolation of Megaritolactones and Other Bioactive Metabolites from 'Megaritiki' Table Olives and Debittering Water

Evgenia Mousouri, Eleni Melliou, and Prokopios Magiatis*

Department of Pharmacognosy and Natural Products Chemistry, Faculty of Pharmacy, University of Athens, Panepistimiopolis Zografou, GR-15771 Athens, Greece

Supporting Information

ABSTRACT: 'Megaritiki' is an olive cultivar widely used in Greece for the production of low polyphenol olive oil and table olives. To investigate possible metabolic differentiation in comparison with other varieties, the composition of 'Megaritiki' olive fruits and wastewaters from the debittering procedure was studied. Moreover, the recovery of bioactive metabolites from wastewater using adsorption resin was studied to exploit this byproduct. Metabolites in fruits and wastewaters were monitored using NMR spectroscopy. The major constituents of wastewater were hydroxytyrosol-4-*O*-glucoside, 11-methyl-oleoside, hydroxytyrosol, and tyrosol but not oleuropein. Furthermore, wastewater afforded rengyoxide and rengyoside B, which are for the first time isolated from olives. The final edible olives, besides hydroxytyrosol and tyrosol, contained rengyoxide and cleroindicin C, which are the first isolated from the species, haleridone for the first time isolated from edible olives, and four metabolites, which are the first reported as natural products, megaritodilactone, megaritolactonic acid, methyl ester of megaritolactonic acid B, and megaritolactonol.

KEYWORDS: *Olea europaea, 'Megaritiki', table olives, iridoid, qNMR*

INTRODUCTION

Table olives are used as a typical part of the Mediterranean diet since antiquity. They contain a large number of minor constituents[1] with interesting bioactivities, which are mainly dependent on the olive variety and the followed debittering process.[2,3] In general, olive fruits undergo a debittering procedure that removes totally or partially the natural bitterness that is mainly due to oleuropein, **1**. A few years ago, we performed a screening of the major table olive varieties found in the Greek market, and we identified varieties with high oleuropein, **1**, and/or hydroxytyrosol, **2**, content in the final edible product.[3] Both compounds have important antioxidant activities, and they have been correlated with protection from LDL oxidation.[4] The role of hydroxytyrosol and oleuropein derivatives has been recently recognized by the European Union for olive oil but not yet for edible olives. A significant observation[3] concerning the olive debittering method was that the use of dry salt and not brine can lead to table olives with high oleuropein content and potentially increased health protecting properties. However, one of the varieties that had been included in the previous study and that had been treated with dry salt without giving high oleuropein content was cv. 'Megaritiki'. This fact had been initially attributed to a possible metabolic differentiation of that specific variety without further study.

Meanwhile, we studied extensively the olive oil produced by the major olive oil producing varieties in Greece, and again we found that the olive oil from cv. 'Megaritiki' presented very low concentration of secoiridoid derivatives (oleocanthal, oleacein, oleuropein aglycone, and ligstroside aglycone).[5] This specific variety is widely cultivated in regions like Attica for the production of both table olives and olive oil (dual use variety). The olive oil of that cultivar is known in the market as a low bitterness oil, which is in accordance with the low recorded content of the usual secoiridoid derivatives responsible for pungency and bitterness. Moreover, the table olives from that variety belong to a group of cultivars that require traditionally little processing to debitter, indicating that oleuropein levels in the untreated fruit of this variety are lower comparatively to others. A simple method, known since antiquity for the debittering of this variety, is crushing and placement for a few days in water. The olives produced with this method are traditionally known as "klastades".

All of the above observations led us to investigate that specific variety for possible metabolic differentiation. For this purpose, we studied the initial metabolic profile of the untreated olive fruits for the presence of oleuropein, and in a next step we studied the major compounds recovered from the debittering wastewater, and finally we studied the chemical constituents of the final edible product (Figure 1).

MATERIALS AND METHODS

General Experimental Procedures. NMR spectra were recorded on Avance 600 (with cryoprobe) and DRX400 spectrometers (Bruker, Rheinstetten, Germany); chemical shifts are expressed in ppm downfield from TMS. Column chromatography was performed on columns containing Si gel 60 (40−63 μm) (Merck, Darmstadt, Germany). Thin layer chromatography (TLC) was performed on plates coated with Si gel 60 F_{254} Merck, 0.25 mm. For HPLC−MS analysis, the column used was a 150 mm × 2.0 mm i.d., 5 μm, PolymerX RP-1 (Phenomenex, Torrance, CA). Samples (5 μL) were dissolved in methanol and injected onto HPLC−MS. A standard

reverse phase linear gradient with acidified water (0.1% formic acid) and acetonitrile was run over 30 min at a flow rate of 250 μL/min, and the eluent was monitored for negative anions by a LTQ Orbitrap (Thermo Fisher Scientific, Waltham, MA) operated in the centroided mode. Source parameters were 5.5 kV spray voltage, capillary temperature of 275 °C, and nitrogen sheath gas setting of 20 mL/min. Data were acquired at a resolution setting of 60 000 fwhm with the lockmass feature, which typically results in a mass accuracy <2 ppm.

Preparation of Table Olives. Olives of the 'Megaritiki' cultivar used in this study were collected in August, October, and November 2011 from Salamina island. The olives collected in November were water-cured according to a traditional method of debittering as follows: olive fruits (3 kg) were soaked in water (3 L) for 1 day, and the second day each olive was removed, incised, and subsequently added to water (3 L). The water was replaced daily for 5 days. At the end of the sixth day, water-cured olives were placed in brine (salt solution of 10% NaCl) and stored until further analysis. Debittering wastewaters were stored separately for each day at −20 °C until analysis.

Sample Preparation for NMR Analysis. The fruits were collected and analyzed in the same day. The fruits were first washed with water, and then the stone and the flesh were separated and mashed using a laboratory blender. The olive flesh (10 g) was extracted with 25 mL of a MeOH/H_2O mixture (4:1) in a supersonic bath for 45 min. The supernatant was separated from the flesh by centrifugation at 3400*g* for 10 min. Next, 25 mL of hexane was added for oil removal, agitated for 30 s, and then the methanol extract was separated by subsequent centrifugation at 3400*g* for 3 min. The volume of the methanol phase was measured, and 1/20 of the extract was used for NMR analysis. The appropriate volume of methanol extract was mixed with 0.5 mL of the internal standard solution (0.5 mg of syringaldehyde/mL in acetonitrile) and evaporated under reduced pressure at 40 °C.

Quantitative NMR Analysis of Oleuropein Content. The dry extract was dissolved in 600 μL of CD_3OD. ^{1}H NMR spectra were recorded at 400 MHz. 32 scans were collected, and the spectra were phased corrected and integrated automatically using TopSpin software (Bruker). The quantitation was based on the integration ratio between the aldehydic proton signal of syringaldehyde at 9.75 ppm and the proton of oleuropein appearing at 5.91 ppm. Calibration curve of oleuropein was prepared at seven different concentrations ranging between 70 and 4500 μg in tube. The solutions for the construction of the calibration curve were prepared by mixing appropriate volumes of a stock solution of pure oleuropein (Extrasynthese, Genay, France) (1 mg/mL in MeOH) with 0.5 mL of the internal standard solution (0.5 mg of syringaldehyde/mL in acetonitrile) and evaporation under reduced pressure at 40 °C. The equation used for the quantitation of oleuropein in tube was $y = 0.512x + 0.0904$, with $r^2 = 0.995$.

Study of the Debittering Wastewaters. *Treatment with Resins.* After filtration through filter paper, wastewater from each day was separately passed through a column containing adsorption resin. A column of 3.5 cm diameter filled with 250 g of Amberlite XAD-4 resin (Rohm and Haas, Philadelphia, PA) (BV = 375 mL), was used. The feeding flow rate was 750 mL/h (2 BV/h). The resin total feeding duration was 2 h. The procedure above refers to 1.5 L of wastewater. After the adsorption, the subsequent regenerating procedure consisted of three steps. The first one included resin wash by water until the water effluent was colorless. Afterward, the resin was regenerated by eluting the metabolites with methanol (500 mL). The methanol extract was evaporated to dryness and was used for subsequent analysis. Finally, the resin was washed again by water (500 mL). After these three steps, the resin was ready to be used again.

Monitoring. The debittering procedure was monitored using thin layer chromatography (TLC) and ^{1}H NMR spectroscopy. More specifically, 20 mg of the dry methanol extract from each day of the debittering procedure was dissolved in 600 μL of CD_3OD, and ^{1}H NMR spectra were recorded at 400 MHz. The appearance, increase, or decrease from day to day of characteristic peaks corresponding to 11-methyl oleoside, **3** (5.95 ppm), hydroxytyrosol-4-*O*-β-D-glucoside, **4** (7.09 ppm), hydroxytyrosol, **2** (6.53 ppm), and tyrosol, **5** (7.02 ppm), were monitored.

Isolation. The extracts were combined, and low pressure column chromatography was performed on them leading to the isolation of five compounds. Three of them were already known, and the other two were for the first time isolated from olives. The structures of the already known compounds were identified using NMR spectroscopy, and the structure elucidation of the other two compounds was achieved both with NMR spectroscopy and with MS spectrometry.

A part (2.30 g) of the total extract (7.78 g) was placed into a 5 cm diameter column filled with silica gel 60 Merck (40−63 μm) up to 20 cm height. The eluent flowed through the column under low pressure. The column was eluted collecting fractions of 20 mL according to the following gradient: 1% (25 fractions), 2% (55 fractions), 3% (57

dx.doi.org/10.1021/jf404685h | J. Agric. Food Chem. 2014, 62, 660−667

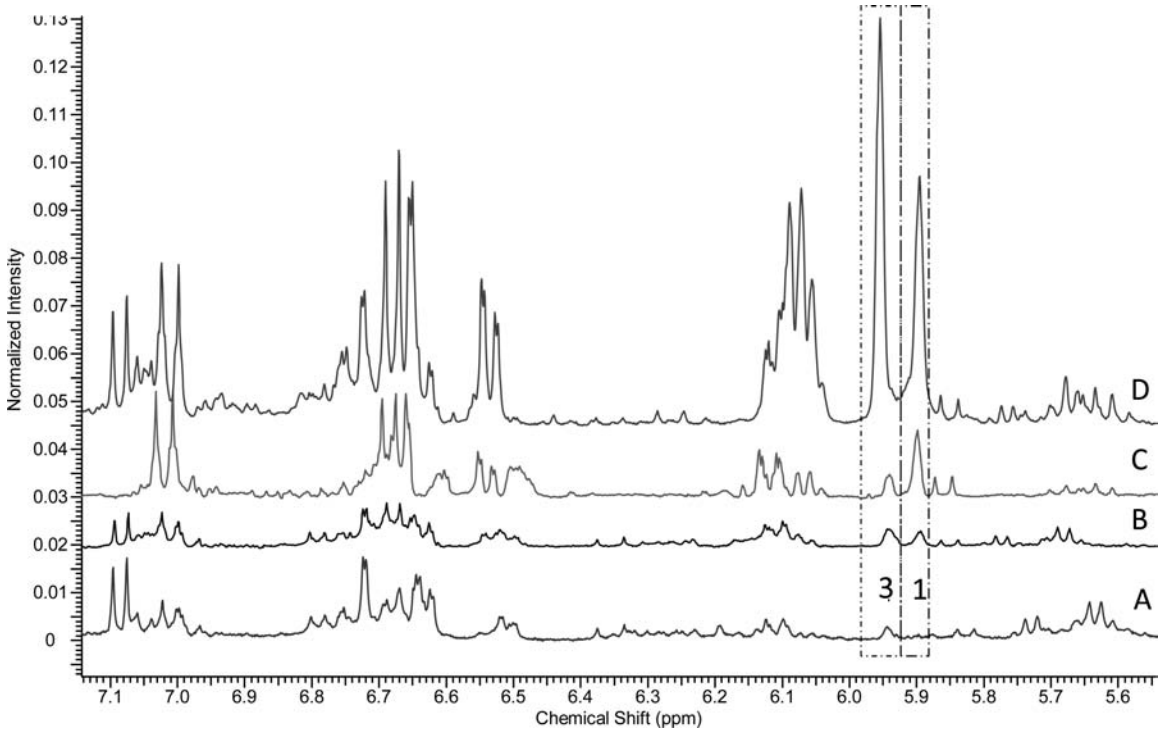

Figure 2. Monitoring of oleuropein in unprocessed olives of cv. 'Megaritiki' by quantitative ^{1}H NMR. (A) 'Megaritiki', November; (B) 'Megaritiki', October; (C) 'Megaritiki', August; (D) 'Throuba Thassos', November. **1**, oleuropein; **3**, 11-methyl oleoside. Spectra are normalized according to the contained internal standard peak (not shown).

fractions), 4% (19 fractions), 5% (21 fractions), 6% (29 fractions), 7% (26 fractions), 8% (63 fractions), 10% (45 fractions), 20% (20 fractions), and 50% (25 fractions) MeOH in CH_2Cl_2. The obtained fractions were pooled using TLC (migration solvent 90:10 CH_2Cl_2:MeOH) to give 32 final fractions. Fractions 8 and 9−14 afforded rengyoxide, **6**[6] (29.9 mg), and hydroxytyrosol, **2**[7] (43.6 mg), respectively. Fraction 19 was rechromatographed on a preparative TLC plate Merck (migration system 80:20 CH_2Cl_2/MeOH) to give rengyoside B, **7**[8] (6.8 mg), hydroxytyrosol-4-*O*-*β*-D-glucoside, **4**[9] (12.4 mg), and 11-methyl oleoside, **3** (14 mg).[10] Other fractions containing the above compounds were extensively rechromatographed leading to a total yield of hydroxytyrosol (30 mg/g of total extract), hydroxytyrosol-4-*O*-*β*-D-glucoside (82 mg/g), and 11-methyl oleoside (25 mg/g).

Study of the Olive Flesh. *Extraction and Resin Treatment.* Six months after the brine addition, 1 kg of the debittered olives was extracted at room temperature with water (2 × 0.5 L) in a supersonic bath for 1 h. The water extract (1 L) was treated in the same way as the wastewater above to lead to an enriched extract. It was passed through a column of 3.5 cm diameter filled with 250 g of XAD-4 resin (BV = 375 mL). The feeding flow rate was 750 mL/h (2 BV/h). The resin total feeding duration was 1.3 h. The procedure above refers to 1.0 L of wastewater. The resin regeneration procedure was exactly the same as the corresponding for the case of the wastewater treatment described above. The MeOH eluent was evaporated under reduced pressure at 40 °C.

Isolation. The enriched extract of the olive flesh was fractionated with low pressure column chromatography, and this separation procedure led to the identification of nine compounds. Two of the isolated compounds were already known, three were for the first time isolated from table olives, and the other four are for the first time reported as natural compounds. The dry MeOH extract (1.98 g) was chromatographed under low pressure on a column similar to that above filled with silica gel 60 Merck (40−63 μm) up to 20 cm height. The volume of the collected fractions was 20 mL, and the solvent gradient was 1% (40 fractions), 2% (66 fractions), 3% (28 fractions), 4% (60 fractions), 5% (15 fractions), 6% (25 fractions), 7% (30 fractions), 8% (13 fractions), 10% (25 fractions), 20% (25 fractions), and 50% (25 fractions) MeOH in CH_2Cl_2. The obtained fractions were merged using TLC (migration solvent 90:10 CH_2Cl_2/MeOH) to afford 27 final fractions. From fractions 4, 5, 6, and 8 were isolated the four new compounds, megaritodilactone, **8** (1.2 mg), megaritolactonic acid, **9** (2 mg), megaritolactonic acid B methyl ester, **10** (3 mg), and megaritolactonol, **11** (3 mg) respectively, after rechromatography on preparative TLC (migration systems 10:50:40 CH_2Cl_2/hexane/EtOAc, 80:20 EtOAc/cyclohexane, 96.5:3.5 CH_2Cl_2/MeOH, and 96:4 CH_2Cl_2/MeOH, respectively). Fraction 12 was purified using preparative TLC to give tyrosol, **5**[7] (30 mg), and two compounds first isolated from olives: halleridone (rengyolone), **12**[6] (9.7 mg), and cleroindicin C, **13**[11] (16.1 mg). Finally, fraction 15 was rechromatographed on silica gel 60 Merck (40−63 μm) with CH_2Cl_2/MeOH (from 100:0 to 95:5 gradient) leading to the isolation of hydroxytyrosol, **2** (119 mg), and rengyoxide, **6** (78.4 mg).

RESULTS AND DISCUSSION

Oleuropein Monitoring in Untreated Olives. The initial target was to monitor the presence of oleuropein, **1**, in the untreated olive fruit of cv. 'Megaritiki'. For this purpose, a simple method for the measurement of oleuropein was developed using quantitative ^{1}H NMR. Using the integration ratio between the internal standard and the characteristic peak of oleuropein at 5.91 ppm, we constructed a calibration curve, which was used to measure quantitatively the levels of oleuropein in the olive fruit. The method was applied in the untreated fruits of cv. 'Megaritiki' at three different stages of ripeness as well as in cv. 'Throuba Thassos' well-known[3] for producing oleuropein at harvest time. As it is presented in Figure 2, the peak of oleuropein in the case of cv. 'Megaritiki' at usual harvest time (mid November, half green-half violet color) was almost absent corresponding to a concentration lower than 0.15 mg/g. In contrast, cv. 'Throuba Thassos' at the same harvest time and maturity stage presented significantly higher concentration of 9.1 mg/g, which is comparable with the usually measured levels of oleuropein in untreated olives.[12] When the cv. 'Megaritiki' olives were studied in August (fully unripe), oleuropein was present in higher levels (3.2 mg/g) than in November as expected, showing that the variety has the capability to biosynthesize oleuropein. In early October, the oleuropein level had been already reduced to 0.55 mg/g, showing a gradual but early oleuropein catabolism. In contrast with oleuropein, the peak of 11-methyl oleoside, **3**, was higher at harvest time than that of oleuropein showing that in the case of cv. 'Megaritiki', the hydrolysis of oleuropein is activated much earlier than in other varieties, leading to a fruit that at harvest time has very low content of oleuropein. The peak of methyl oleoside at 5.95 ppm was clearly distinguished from that of oleuropein and was used for its monitoring. Several other characteristic compounds (such as hydroxytyrosol, **2**, hydroxytyrosol-4-*O*-glucoside, **4**, tyrosol, **5**, maslinic acid, etc.) could be simultaneously quantitated by combination of 1D and 2D qNMR, but this is a subject of a separate work. The characteristic peak for the measurement of oleuropein was not overlapping with signals from other major constituents as confirmed by extensive 2D NMR experiments. The observation of the very low content in untreated 'Megaritiki' olives offers an explanation why the debittered olives with dry salt did not contain oleuropein in contrast with cv. 'Throuba Thassos', which after debittering with the same method contained high amounts of oleuropein.[3] Moreover, this finding shows that specific cultivars like 'Megaritiki' present technological advantages concerning the removal of bitterness because oleuropein is already naturally hydrolyzed and the main bitter compound needing to be removed is 11-methyl oleoside. This compound is very soluble in water and can be easily dissolved out of the olive flesh simply by contact with water as explained below. A similar case of an olive cultivar in which the oleuropein level is very low at harvest time due to earlier activation of glucosidase and esterase has also been reported in cv. Dhokar from Tunisia,[12] but most probably there are also many other cultivars with similar behavior.

Study of the Debittering Process with Water. To study the evolution of the debittering process, table olives were prepared, according to a traditional water-curing method for 6 days, and the composition of the wastewater resulting from the

dx.doi.org/10.1021/jf404685h | J. Agric. Food Chem. 2014, 62, 660−667

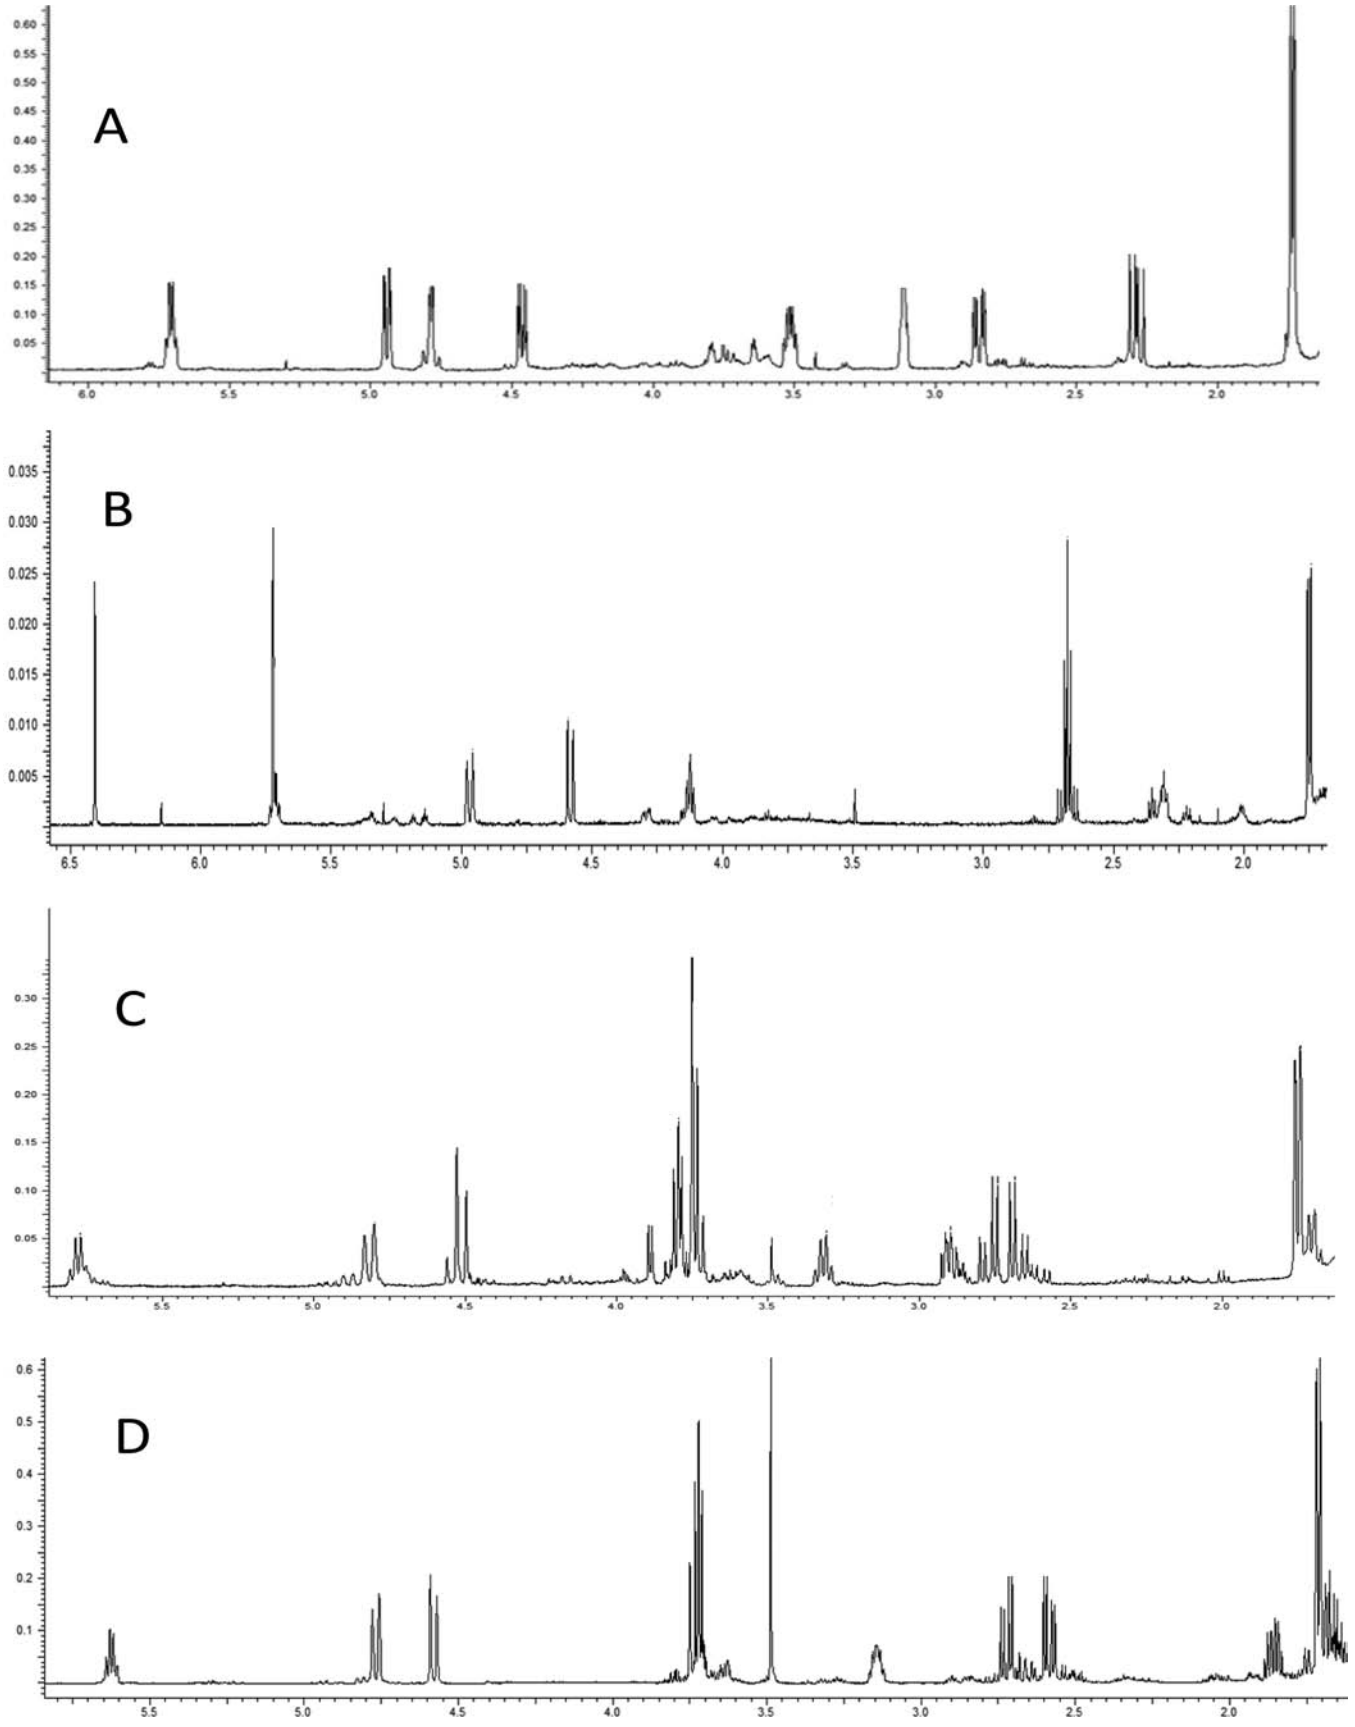

Figure 4. ^{1}H NMR spectra of compounds **8**–**11**. (A) **8**, (B) **9**, (C) **10**, (D) **11**.

debittering procedure as well as that of the final edible olive fruits was determined. To facilitate this study, we applied a method for the recovery of metabolites from wastewater and then we monitored them using NMR spectroscopy. More

dx.doi.org/10.1021/jf404685h | J. Agric. Food Chem. 2014, 62, 660–667

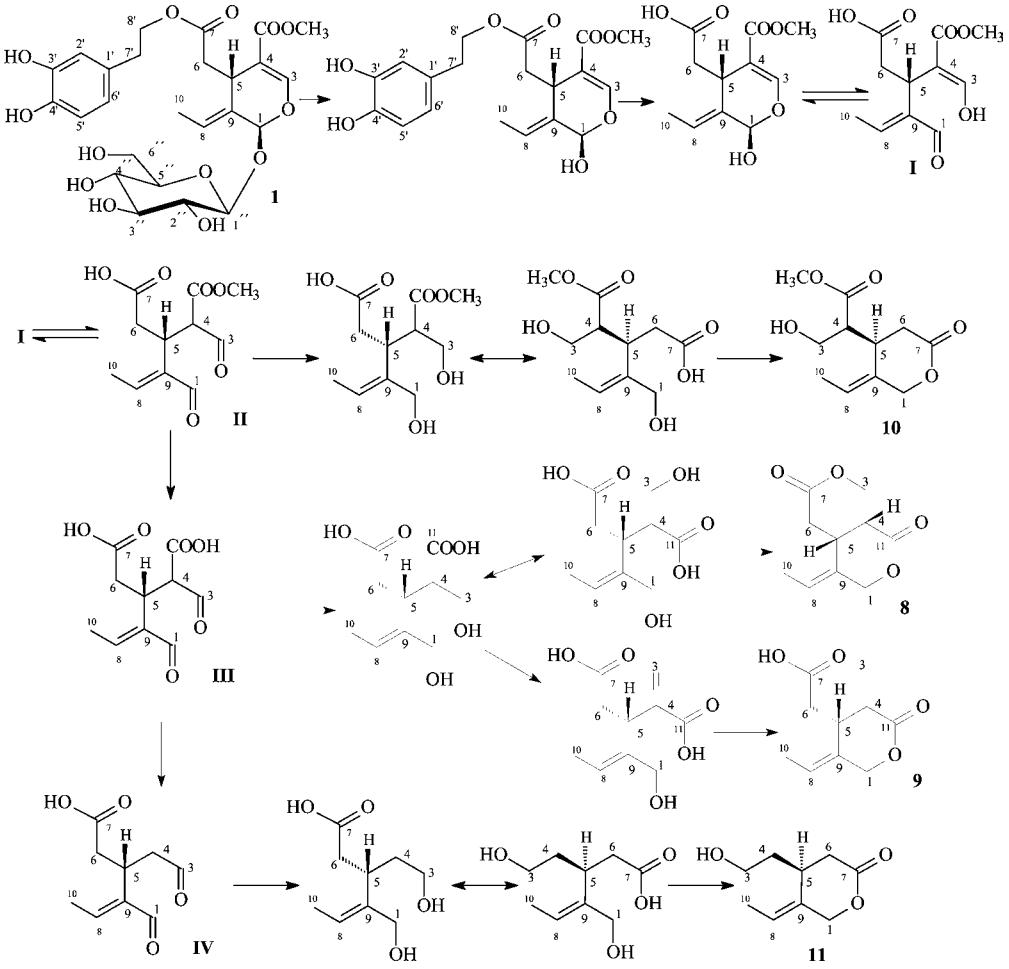

Figure 5. Proposed biosynthetic pathway of compounds **8**−**11**.

specifically, we used a method similar to that developed a few years ago for the recovery of bioactive compounds from the olive mill wastewater.[13] In the current case, the debittering water was treated with adsorption resin XAD-4, and the adsorbed compounds were desorbed using a polar solvent such as methanol. The methanol extract was analyzed by TLC chromatography and NMR. This study showed that the major components of this specific wastewater are the bioactive metabolites: hydroxytyrosol, **2**, 11-methyl oleoside, **3**, hydroxytyrosol-4-*O*-glucoside, **4**, and tyrosol, **5**, but not oleuropein, **1**. It is very interesting that the diffusion of each compound from the flesh to the debittering water was very different (Figure 3). Characteristically, 11-methyl oleoside was almost completely removed after the first two days, while hydroxytyrosol started to appear only after the third day. Additionally, the chemical analysis of the wastewater afforded two metabolites, rengyoxide, **6**, and rengyoside B, **7**, which are for the first time isolated from olives. Rengyoxide has been previously isolated from plants of the families Oleaceae (*Forsythia suspensa*),[6] Bignoniaceae,[14] Verbenaceae (*Clerodendrum indicum*),[11] Scrophulariaceae,[15] and Plantaginaceae.[16] Rengyoside B has been previously isolated from several Bignoniaceae (e.g., *Markhamia stipulata*)[17] and from *Forsythia suspensa* (Oleaceae).[8]

Study of Metabolites Identified in the Final Treated Product. The early hydrolysis of oleuropein in cv. 'Megaritiki' led us to assume that the olive flesh should be rich in compounds deriving from the breakdown of the oleuropein secoiridoid skeleton. In particular, the less hydrophilic derivatives should stay in the flesh until the stage of the final edible product. Indeed, the water extract of the final olive flesh after enrichment with adsorption on XAD4 resin and several chromatographic purification steps led to the isolation of: two metabolites that are for the first time isolated from this species, rengyoxide, **6**, and cleroindicin C, **13**, one that is for the first time isolated from the edible fruit (rengyolone, **12**) and four new natural products. The new natural products are all lactone derivatives coming from the skeleton of oleuropein after hydrolysis of the hydroxytyrosol moiety, cleavage of the glycosidic bond, removal or not of the carbomethoxy group, and subsequent reactions of reduction and/or dehydration and final lactonization. Their common characteristics prompted us to name them as megaritolactones. Currently, it is not known if they are common or not in other edible olive varieties.

Structure Elucidation of New Compounds. Megaritolactonol, **11**, was isolated as an amorphous solid with molecular formula corresponding to $C_9H_{14}O_3$. The ^{1}H NMR profile (Figure 4A) was very closely related to that of (5-ethylidene-2-oxo-tetrahydropyran-4-yl) acetic acid, **14**, which had been described as a semisynthetic derivative[18] and isolated[13] in significant quantities from olive mill wastewater as a breakdown product of the secoiridoid skeleton of oleuropein after hydrolysis of the glycosidic bond and removal of the hydroxytyrosol moiety. The most characteristic signal revealing the similarity with lactone **14** is the methyl group observed as a

dx.doi.org/10.1021/jf404685h | J. Agric. Food Chem. 2014, 62, 660−667

doublet at 1.74 ppm, which is attached to the exocyclic double bond observed as a quadruplet at 5.62 ppm. Moreover, two pairs of geminal protons H-1a,b and H-6a,b at 4.77/4.58 and 2.72/2.58, respectively, and one methine at 3.14 ppm (H-5) comprised the six-membered lactone ring, similar to lactone **14**. The presence of the lactone was confirmed by the carbonyl observed at 172.5 ppm. The main difference from lactone **14** is the side chain attached at position 5. While in the case of lactone **14** the side chain was ethanoic acid, in the case of compound **11** the side chain consisted of one oxygenated methylene at 3.72 ppm and one aliphatic methylene observed as two multiplets at 1.65 and 1.86 ppm. Sequential COSY correlations between H-6a,b/H-5, H-5/H-4a,b, H-4a,b/H-3 confirmed the positioning and the structure of the side chain. The structure was confirmed by the HMBC spectrum where the most important correlations were between H-1a,b and carbonyl C-7 and between H-5 with both the double bond carbon C-8 and the carbonyl C-7. The NOE correlation between H-8 and H-1 revealed the orientation of the methyl group of the double bond as depicted in Figure 1. On the basis of the above description, it was clear the compound **11** was a δ-lactone with one ethylidene and one ethanol side chain for which we propose the name megaritolactonol. The absolute stereochemistry was deduced from the biosynthetic pathway (Figure 5).

Compound **10** was isolated as an amorphous solid with molecular formula $C_{11}H_{16}O_5$. The ^{1}H NMR profile of **9** (Figure 4B) showed many similarities with **11**, making it obvious that it was also a δ-lactone with one ethylidene group. The methyl group on the exocyclic double bond, two pairs of geminal protons, and one methine (3.32 ppm, H-5) bearing a side chain in combination with the carbonyl at 171.5 ppm made clear that **10** belonged to the same family of megaritolactones. The main difference from **11** was the size and the substitution pattern of the side chain. The side chain of **10** contained an oxygenated methylene H-3a,b at 3.73/3.80 ppm, one methine at 2.90 ppm (H-4), and a carbomethoxy group. In the COSY spectrum, H-3a,b was correlated with the methine at 2.90 ppm, and this methine (H-4) was correlated with the second methine at 3.32 ppm (H-5) belonging to the lactone ring. In the HMBC spectrum, both H-3, H-5 and the methoxy group were correlated with the carbonyl at 173.7 ppm, showing that the side chain of **10** consisted of a 2-yl-3-hydroxypropanoic acid methyl ester. The side chain was attached at the same position as in the case of **11**. The NOE spectrum showed also the same orientation for the methyl group of the ethylidene moiety. The absolute stereochemistry was also based on the biosynthetic pathway starting from the oleuropein secoiridoid skeleton as discussed below. Compound **10** was named as the methyl ester of megaritolactonic acid B.

Compound **9** was also obtained as a white amorphous solid with molecular formula $C_{10}H_{12}O_4$. Compound **9** showed also significant similarities with lactone **14** as well as **10** and **11** (Figure 4C). In comparison with **14**, the main difference was the presence of an exomethylene double bond observed as two singlets at 6.41 and 5.72 ppm and the absence of one pair of geminal protons. On the other hand, all of the other signals of the ethylidene group, the ethanoic acid side chain, and the oxygenated methylene of the lactone group were observed as expected. The third member of the megaritolactone family was also a product coming from the breakdown of oleuropein skeleton after hydrolysis, reduction, dehydration, and lactonization as explained in the biosynthetic pathway scheme (Figure 5). The exact placement of the exomethylene group was determined through the HMBC spectrum where the geminal protons of the double bond showed a ^3J correlation with conjugated lactone carbonyl at 165 ppm and the methine carbon C-5 at 36.3 ppm. H-5 showed also critical correlations with both the lactone and the carboxylic carbonyls as well as the ethylidene double bond and the oxygenated methylene of the lactone ring. The lactone carbonyl was clearly discriminated from the carboxylic carbonyl through its correlation with the oxygenated methylene H-1a,b. The orientation of the methyl group was also the same as in **10** and **11**, highlighting their common biosynthetic origin. The orientation of the ethanoic acid side chain was opposite in comparison with **10** and **11** because the lactonization occurred between C-11 and C1 and not between C-1 and C-7 as in the case of **10** and **11**. In the case of **11**, C-11 is not present due to decarboxylation, while in the case of **10** C-11 is blocked as a methyl ester and cannot participate in the formation of the lactone. Compound **9** was named megaritolactonic acid.

The corresponding compound coming from the lactonization between C1 and C7 can be obtained in the case where C-11 is blocked as a methyl ester. It could be considered as a dehydration derivative of **10** leading to an exomethylene double bond on the side chain and not on the ring. This compound has been originally isolated from 'Throuba Thassos' table olives.[19] Although it has not yet been isolated from 'Megaritiki' olives, its existence is reported herein to strengthen the discussion about the biosynthesis of the olive lactones and the possible occurrence of similar compounds in other table olives cultivars.

The last member of the megaritolactones family **9** had a molecular formula $C_{10}H_{12}O_4$. It was a compound closely related to megaritolactonic acid with the difference that the alcohol at position 3 was not dehydrated as in the case of **9** but lactonized with the carboxyl at C-7. This compound contained two δ-lactone rings, and for this reason was named megaritodilactone. It presented all of the expected HMBC correlations, and more significantly the oxygenated methylene H-3 was correlated not only with C-11 and C-5 (as in **9**) but also with C-7 due to the formation of the second lactone ring. As in all of the previous compounds, the orientation of the methyl group was the same. Concerning the fusion between the two rings, it was found to be cis based on the small coupling constants of H-4 with H-5, H-3a, and H-3b, 6.4, 3.1, and 4.6 Hz, respectively. H-5 has clearly an axial orientation based on the large coupling constant with H-6b (12.1 Hz), and consequently H-4 has an equatorial orientation leading to a cis fusion between the two lactone rings (Figure 4D).

The proposed biosynthetic pathway (Figure 5) leading to megaritolactones starts from oleuropein (or ligstroside) first by hydrolysis of the glycosidic bond and then by hydrolysis of the ester at position 7. The obtained form I through keto−enol tautomerism leads to the key compound II. Reduction of aldehydes at positions 1 and 3 and subsequent lactonization between alcohol at position 1 and carboxyl at position 7 leads to **10**. Compound II after hydrolysis of the methyl ester at position 11 gives compound III from which starts the biosynthesis of **9** and **8**. Reduction of aldehydes at positions 1 and 3, dehydration of alcohol 3 to double bond, and lactonization between positions 1 and 11 leads to **9**. In the case of **8**, the biosynthesis occurs through double lactonization, between positions 1 and 11 and between 3 and 7. Compound III after decarboxylation leads to compound IV, which after reduction of the two aldehydes at positions 1 and 3 and

dx.doi.org/10.1021/jf404685h | J. Agric. Food Chem. 2014, 62, 660−667

subsequent lactonization between positions 1 and 7 leads to **11**. In all cases, the absolute configuration at position 5 is already determined by the configuration of the corresponding carbon of oleuropein, which remains unchanged.

In conclusion, 'Megaritiki' table olives and debittering wastewater are useful sources of polyphenols and secoiridoids with unique structural characteristics. Quantitative NMR is a very useful tool for the rapid and easy measurement of key compounds in complex mixtures such as the olive extracts.

Supporting Information

ABSTRACT: Feruloylated oligosaccharides (FOs) were prepared by autoclaving corn bran in oxalic acid (0.6%) solution, and their protection effects against oxidative stress in pheochromocytoma cells (PC 12) cells were investigated. The FOs samples, which comprised a mixture of feruloylated mono- and dipentoses with 4.88% bound ferulic acid (FA), as well as xylose, arabinose, galactose, and glucose amounting to 46.43, 40.46, 3.76, and 8.68% of the total sugars, respectively, were prepared by autoclaving the pretreated corn bran in 0.6% oxalic acid and then further separated. Antioxidant activity was tested by 1,1-diphenyl-2-picrylhydrazyl radical 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazyl (DPPH) scavenging and oxygen radical absorbance capacity (ORAC) methods. Oxidative stress was induced by H_2O_2 in PC 12 neuronal cell culture model. The results showed that FOs exhibited higher antioxidant activity than free ferulic acid, with an IC_{50} value of 11 versus 128 μM for DPPH and an ORAC value of 4.77 versus 2.62 μmol Trolox/μmol. Tetrazolium blue assay showed that the addition of FOs with an FA concentration >50 μM significantly increased cell viability after treatment with H_2O_2. Flow cytometry analysis showed that the addition of FOs at concentrations of 800, 200, and 50 μM significantly decreased the apoptosis rate at the sub-G0 phase from 37.5 to 12.7, 16.2, and 20.9% ($P < 0.01$), respectively. FOs also significantly decreased the malonic dialdehyde content and lactate dehydrogenase (LDH) activity, but increased superoxide dismutase activity in PC 12 cells treated with H_2O_2 and prevented the damage of cellular membranes by decreasing the release of LDH to the cultures. The addition of FA at 800 μM showed an effect similar to that of FOs at 200 μM. Therefore, the FOs prepared from corn bran are potential functional ingredients for protection against oxidative stress.

KEYWORDS: *feruloylated oligosaccharides, corn bran, antioxidative stress, PC 12 cells*

INTRODUCTION

Oxidative stress is caused by an imbalance between the production of reactive species (peroxides and oxygen radicals) and the scavenging ability of the organism to destroy these species.[1] Oxidative stress can damage the macromolecules in cells and tissues, resulting in membrane damage, fragmentation, or random cross-linking of molecules, such as DNA, enzymes, and structural proteins, and can even lead to cell death induced by DNA fragmentation and lipid peroxidation. Thus, oxidative stress has a crucial role in the development of cancer, neurodegenerative disorders, cardiovascular diseases, Alzheimer's disease, diabetes, and autoimmune disorders.[2,3]

Ferulic acid, an antioxidant ubiquitously existing in plant tissues,[4] protects DNA against Cu^{2+}/GSH-induced oxidation,[5] has therapeutic effects on hydrogen peroxide-induced oxidative stress in nucleus pulposus cells,[6] and restores activity at the antioxidant level in alloxan-induced mice.[7] Corn (*Zea mays*) ranks first among the crops in the world. Corn bran, produced at a yield of 60−70 g/kg after milling, contains the highest content of ferulic acid (28−31 g/kg of ferulic acid) among fiber sources.[8] However, ferulic acid in corn bran is only slightly bioavailable in rats.[9] Zhao et al. fed rats a diet containing 5% refined corn bran for 10 days and found that only 0.4−0.5% of the ingested ferulic acid was recovered in rat urine, whereas 81% of the ingested ferulic acid was excreted through the rat feces within 3 days after ingestion.[9] Thus, the ferulic acid of corn bran would show very low bioavailability in humans when corn bran is eaten unprocessed.

Feruloylated oligosaccharides (FOs), which comprise a bound form of ferulic acid and oligosaccharides, possess the physiological functions of both ferulic acid and oligosaccharides. The ferulic acid in FOs acts as a novel antioxidant, whereas oligosaccharides increase water solubility, and their combination may result in the synergistic antioxidant activities of FOs[10,11] and may act as a new potential antioxidant for the prevention of oxidative stress. Corn bran contains a high amount of ferulic acid and hemicellulose (approximately 700 g/kg) but <10 g/kg level of lignin.[8] These characteristics make corn bran an ideal source for the preparation of FOs compared with other brans.

FOs prepared from corn bran have good antioxidant activity in the lipid oxidation of rapeseed−fish oil-in-water emulsions[12] and human low-density lipoprotein (LDL) autoxidation system by $CuSO_4$[13] and showed stronger antioxidant activity than free ferulic acid.[14] However, studies on the protective effect against oxidative stress in cells by FOs are lacking.

In this research, FOs were prepared from corn bran by autoclaving in a 0.6% oxalic acid solution for 30 min and were tested for their prevention of oxidative stress in H_2O_2-injured pheochromocytoma cells (PC 12).

MATERIALS AND METHODS

Materials and Chemicals. Corn bran and PC 12 cells were provided by Shandong Xiwang Group Co. Ltd. (Zouping, Shandong, China) and the College of Medicine, Jinan University, Guangzhou, China, respectively. Dulbecco's modified Eagle medium (DMEM) with horse serum, fetal bovine serum, and trypsin were purchased from Gibco BRL (Grand Island, NY, USA). Tetrazolium blue (MTT), RNase A, nitrotetrazolium blue chloride, 1,1-diphenyl-2-picrylhydrazyl radical 2,2-diphenyl-1-(2,4,6-trinitrophenyl)hydrazyl (DPPH), monosaccharides, and Trolox [(±)-6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid] were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). 2,2′-Azobis(2-methylpropionamidine) dihydrochloride (AAPH) and fluorescein (FL) sodium were purchased from Wako Pure Chemical Industries, Ltd. (Japan). Amberlite XAD-2 was from Beijing North Real Science and Technology Development Co. Ltd. (Beijing, China). Test kits for the determination of malonic dialdehyde (MDA), lactate dehydrogenase (LDH), and superoxide dismutase (SOD) were from Nanjing Jiancheng Biological Engineering Research Center (Nanjing, China). Heat-stable α-amylase (EC 3.2.1.1, from *Bacillus licheniformis*, 120,000 units/g), alcalase (EC 3.4.21.62, from *B. licheniformis*, 2.4 units/g), and amyloglucosidase (EC 3.2.1.3, from *Aspergillus niger*, 300 units/g) were purchased from Novo Nordisk (Bagsvaerd, Denmark).

All other reagents were of analytical grade.

Preparation of FOs from Corn Bran. Corn bran was oven-dried at 105 °C for 6 h and then ground to pass a 45-mesh sieve. The dried corn bran (2000 g) was then destarched and deproteinized in a 30 L biological reactor (Zhenjiang East Bioengineering Co., Zhenjiang, Jiangsu Province, China) by heat-stable α-amylase, amyloglucosidase, and protease, sequentially, and the water-insoluble dietary fiber was separated by a basket centrifuge as pretreated corn bran.[15]

FOs were prepared according to our previous method.[16] The pretreated corn bran was suspended in 10 volumes of oxalic acid (0.6%) solution, autoclaved at 120 °C for 30 min, cooled, and filtered using 200-mesh nylon cloth and further ultrafiltered at 5 kDa using a Pellicon XL 50 cassette and a Labscale TFF system. The filtrate was loaded on an Amberlite XAD-2 (filtrate/resin, 2:1) column and eluted with 10 volumes of deionized water to remove the oxalic acid and some non-FOs; 5 volumes of ethanol at 50% was used to elute the FOs. The eluents then were vacuum-concentrated to approximately 70% moisture content.

The bound ferulic acid content and relative contents of different FOs were determined by HPLC, and the species of FOs were identified by HPLC-MS or MS alone. The average degree of polymerization (DP) was calculated as the total content of sugars divided by the content of reducing sugars, and the monosaccharides in FOs were determined using an ion chromatograph.

Oxygen Radical Absorbance Capacity (ORAC)-FL Assay. The assay was conducted in three replicates using the procedure described by Davalos et al.[17] with some modifications. Phosphate-buffered saline (PBS) at 75 mM (pH 7.4, 20 μL), FOs (26.8 μM based on ferulic acid, 20 μL), and FL at 20 μL (63 nM, final concentration) were placed in the microplate well. The mixture was then pre-incubated for 15 min at 37 °C. The AAPH solution at 140 μL (12.8 mM, final concentration) was added rapidly using a multichannel pipet. The microplate was immediately placed in the reader, and an automated ORAC assay was then performed on a Labsystems Fluoroskan Ascent plate reader (Labsystems Co.) with fluorescent filters (Infinite F200, excitation wavelength, 485 nm; emission wavelength, 527 nm) described in our previous study.[18] Trolox (20 μM) was used as a standard, and ferulic acid (50.29 μM) was used as a control. The final results were calculated on the basis of the difference in the area under the fluorescein decay curve between the AAPH control and the samples.

DPPH Assay. A 0.5 mM solution of DPPH in ethanol was prepared. Subsequently, 2 mL of this solution was mixed with different concentrations of FOs or ferulic acid in a test tube and incubated for 30 min at room temperature (in three replicates). The residual DPPH was determined by absorbance at 517 nm. The DPPH radical scavenging activity (%) was calculated as $[(A_0 - A_1/A_0) \times 100]$, where A_0 is the absorbance of the control and A_1 is the absorbance of the FOs or ferulic acid.

Cell Culture. The PC 12 cell line was cultivated in DMEM supplemented with 10% heat-inactivated fetal bovine serum, 5% fetal bovine serum, and 1% antibiotic mixture comprising penicillin and streptomycin, in a 5% CO_2 humidified atmosphere at 37 °C. Growth medium was replaced once every 2−3 days. PC 12 cells were seeded in flat-bottom 96-well plates (100 μL/plate) at a density of 6×10^4 cells/mL and then incubated in a Forma MIP-332 CO_2 incubator (Sanyo Electric Medica System, Tokyo, Japan) overnight, until all cells adhered to the wall.

Effect of Hydrogen Peroxide on the Viability of PC 12 Cells. The cell culture media were replaced with 100 μL/plate DMEM complete media, which contained H_2O_2 at concentrations of 0, 0.25, 0.4, 0.5, 0.8, 1.0, 1.6, and 2.0 mM, and incubated at 37 °C in a humidified atmosphere of 5% CO_2/95% air for 4 h. The culture media were removed, the cells were washed once with DMEM and incubated in DMEM (100 μL/plate). The MTT reagent (10 μL) was then added to the cells with continuous shaking for 2 min, followed by 4 h of incubation at 37 °C. The liquid was then carefully removed by pipets, 100 μL of dimethyl sulfoxide was added to dissolve the formazan crystal, and the absorbance at 570 nm was measured with a Safire 2 microplate reader (Tecan, Switzerland). The absorbance of the control cells was assumed to be 100%, and the results were expressed as the percentages of reduced MTT, in that

$$\text{cell viability (\%)} = (1 - A_{570}\ \text{of}\ H_2O_2\ \text{treatment}/A_{570}\ \text{of the control}) \times 100\%$$

Protective Effects of FOs against Oxidative Stress in PC 12 Cells. The cell culture medium was replaced with 100 μL/plate DMEM complete media, which contained 0, 25, 50, 100, 200, 400, 800, and1600 μM FOs (based on ferulic acid), and incubated at 37 °C in a humidified atmosphere of 5% CO_2/95% air for 12 h. Subsequently, 10 μL of H_2O_2 was added after pre-incubation with FOs for different times to reach a final concentration 0.8 mM, after which culturing was performed for another 4 h. PBS at 10 μL was added then to the treatment without the addition of H_2O_2 and FOs as a control.

Cell viability was determined with six replicates using the MTT method, as previously mentioned. In the following research, the low, middle, and high levels of FOs at 50, 200, and 800 μM, respectively, were used for determining the apoptosis rate by flow cytometry method, the contents of MDA, and the activities of SOD and LDH using the test kits. Morphological observation was conducted using a Leica DM IRBE inverted microscope (Heidelberg, Germany).

Flow Cytometry Method. The cells were centrifuged at 10000*g* for 5 min and thoroughly washed with PBS at room temperature. Cells were collected and fixed overnight using 70% ethanol at −4 °C. Cells were subsequently washed and resuspended in DNA staining solution, which contained propidium iodide (100 μg/mL) and RNase A (250 IU/mL), for 30 min. Analysis of cells was done by flow cytometry using a BD FACSAria flow cytometer. The data were analyzed with BD FACS Diva software (all from BD Biosciences, Franklin Lakes, NJ, USA). The apoptosis rate and percentage of the cells at different phases were also calculated.

Effect of FOs on MDA Content and the Activities of SOD and LDH in H_2O_2-Injured PC 12 Cells. Cells were suspended in PBS at 0 °C at the end of the culture and then completely crushed using a Scientz-IID Ultrasonic cell crusher (Ningbo Scientz Biotechnology Polytron Technologies Inc., Zhejiang province, China) until no intact cells were observed under the microscope. MDA content and the activities of LDH and SOD in cells and cultures were determined using

dx.doi.org/10.1021/jf404841c | J. Agric. Food Chem. 2014, 62, 668−674

commercially available kits from Nanjing Jiancheng Bioengineering Co. (Nanjing, China), as previously described.[15]

Determination of Ferulic Acid, Reducing Sugars, Total Sugars, and Monosaccharide Composition in FOs. FOs were hydrolyzed using 10 volumes of NaOH (1.0 M) as previously described.[19] Reducing sugars were determined using the DNS method, and total sugars were determined using the DNS method after the FOs were acid-hydrolyzed by 1 M H_2SO_4 at 100 °C for 3 h according to the method used by Van den Borne et al.[20] Monosaccharides in the acid hydrolysates were determined using an ICS-2500 model (Sunnyvale, CA, USA) ion chromatogram equipped with an ED50A pulsed amperometric detector. The column used was a Dionex PA 10 (250 mm, 5 μm) and kept at 30 °C. The samples at 10 μL were injected and eluted using 10.0 mol/L NaOH at a flow rate of 0.25 mL/min. A mixture of monosaccharides at a concentration of 8 μmol/L was used as a standard.

Identification of FOs in Oxalic Acid Hydrolysates. The analysis of FOs was performed in an Agilent 1100 HPLC equipped with quaternary pumps, a 4000Q TRAP mass spectrometer (Applied Biosystem Sciex), and an electrospray ionization source (ESI, Thermo Scientific) or an atmospheric pressure chemical ionization (APCI) ion source. Samples (10 μL) were separated on an Agilent Eclipse XDB-C_{18} column (2.1 mm × 150 mm, 5 μm) using 0.01% formic acid (A) and methanol (B) as mobile phase for the following stepwise gradient elution time scale: at 0−5 min, A:B = 90:10 (v/v); 5.1−20 min, A:B = 75:25; 20.1−25 min, A:B = 68:32; and 25.1−35 min, A:B = 90:10. The flow rate was 0.3 mL/min, and the column temperature was set at 23 °C. ESI-positive or -negative ions (H^+) were used to determine the molecular weight of the components in the hydrolysates. Full-scan MS was conducted using APCI-MS.

Statistical Analysis. Data were analyzed using SPSS 13.0 software.

RESULTS

Chemical Composition of Oxalic Acid Hydrolysates. Ferulic acid, reducing sugars, and total sugars (based on dry pretreated corn bran) at 15.6, 158.3, and 532.2 mg/g, respectively, were recovered in the hydrolysates after autoclaving the pretreated corn bran in 0.6% oxalic acid for 30 min. When the hydrolysates were separated and purified sequentially by ultrafiltration and Amberlite XAD-2, 204.8 mg/kg solids was obtained, of which the contents of total sugars, reducing sugars, and bound ferulic acid were 959.4, 315.2, and 48.8 mg/kg, respectively. Therefore, the average DP of the purified product, which was used as FOs in the following study, was approximately 3.0 (959.4/315.2). The monosaccharides existing in FOs include xylose, arabinose, galactose, and glucose, which amount to 46.43, 40.46, 3.76, and 8.68% of the total sugars, respectively.

Two main FOs, compounds **1** and **2** (at a concentration of 9:1 according to their peak areas in HPLC), were separated by HPLC at 314 nm. The results of APCI-MS and LC-MS indicated that the molecular weight of compound **1** is 326, with an m/z 327.3 $[M + H^+]$ and an m/z 325.4 $[M - H^+]$. Compound **1** can be tentatively regarded as feruloylated arabinose (MW = 194 + 150 − 18) according to the linkage type reported previously in corn bran.[10] Compound **2** has an m/z 459.5 $[M + H^+]$ and an m/z 457.6 $[M - H^+]$ in APCI-MS, indicating that its molecular weight is 458. Thus, compound **2** is supposed to be an FO comprising two molecules of pentose, and the linkage type would be (5-*O*-ferulic acid-α-L-arabinose)-1,3-xylose according to the structure of polysaccharide in corn bran.[10] A trace amount of ferulic acid was also detected, but no other species of FOs were detected after oxalic acid hydrolysis and purification using Amberlite XAD-2 resin.

The FOs we prepared from corn bran have the same structure as thaose prepared from wheat bran. The latter have been approved by U.S. FDA as wheat bran extract (GRAS Notice 000343),[21] which has an average DP 3−8 and bound ferulic acid content of 1−3%, suggesting that the samples we prepared following this standard, but with higher ferulic acid content. In the next research, the samples (mixture of FOs and oligosaccharides) were used for testing the antioxidant activity in vitro and in an in vitro cell culture (PC 12) study.

Scavenging Capacity of FOs against DPPH Free Radical and Their ORAC. The scavenging capacity of FOs and free ferulic acid against DPPH free radical was investigated at concentrations of 0, 25, 50, 100, 200, 400, 800, and 1600 μM (based on ferulic acid). FOs showed higher scavenging capacity for DPPH free radical than free ferulic acid at all tested concentrations (Figure 1), especially at concentrations <400

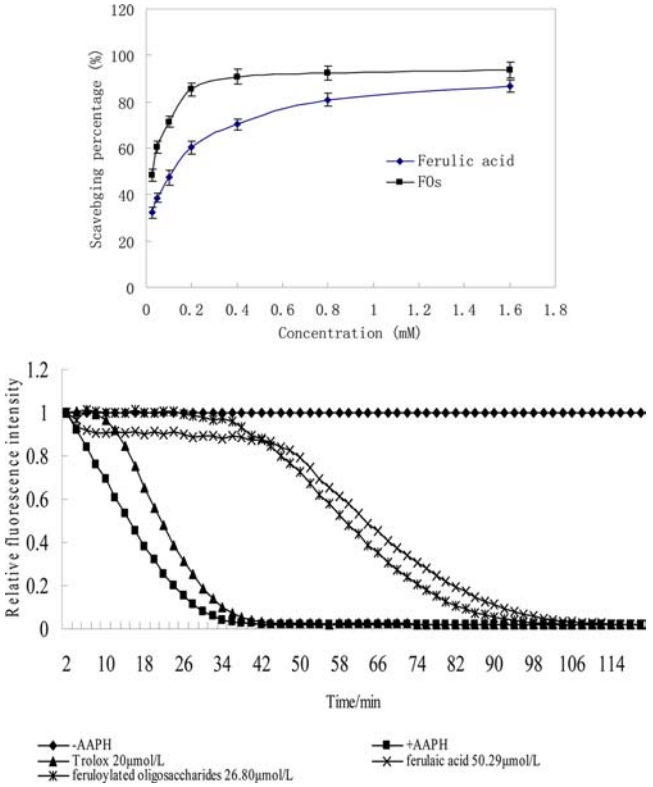

Figure 1. Scavenging capacity of FOs for DPPH free radicals (top) and their fluorescence extinction curves (bottom).

μM. At 1.6 mM, the DPPH free radical scavenging capacity of FOs was 93.80%. The IC_{50} values (the concentration for scavenging 50% of DPPH free radical) of FOs and free ferulic acid were 0.011 and 0.128 mM, by the extrapolated method.

The extent of the antioxidant capability of FOs was also evaluated by the ORAC method. Both FOs and ferulic acid showed the capacity to postpone the fluorescence extinction. The ORAC value was calculated as the ratio of the area under the fluorescence decay curve, with 20 μM Trolox as a standard. The ORAC value for FOs is 4.77 μmol Trolox/μmol, which was 1.8 times higher than that of ferulic acid (2.62 μmol Trolox/μmol). These findings are in accordance with previously reported results, which indicated that FOs exhibit higher antioxidant activity than ferulic acid in vitro.[10]

Effect of FOs on the Viability and Apoptosis of PC 12 Cells. H_2O_2 injured the PC 12 cells in a dose-dependent manner (Table 1), and probit analysis using the SPSS 13.0

program showed that the IC_{50} value was 0.8 mM. In the following study, 0.8 mM H_2O_2 was used on PC 12 cells to test the protective effect of FOs against oxidative stress.

The MTT assay showed a significant protection in PC 12 cells when the cells were pretreated with FOs ($P < 0.05$ at 50 μM and $P < 0.01$ at ≥100 μM). The protective effect was dose dependent. The viability of the PC 12 cells significantly ($P < 0.05$) increased after the addition of FOs at concentrations of 50 μM ($P < 0.05$) or higher ($P < 0.01$, Table 2). When the concentration reached 800 μM, the cell viability increased from 53.91% (without the addition of FOs) to 81.91% (Table 2).

Table 2. Effects of Feruloylated Oligosaccharides Added 12 h before Injury by 0.8 mM H_2O_2 on Cell Viability of PC 12 Cells

FO concn (FA; μM)	A[a]	cell viability (%)
0	0.356 ± 0.006	53.91 ± 0.58
1600	0.475 ± 0.007[c]	78.69 ± 2.34[c]
800	0.493 ± 0.003[c]	81.91 ± 1.57[c]
400	0.441 ± 0.004[c]	70.46 ± 1.12[c]
200	0.407 ± 0.006[c]	65.82 ± 1.04[c]
100	0.383 ± 0.005[c]	60.44 ± 1.68[c]
50	0.336 ± 0.004[b]	55.73 ± 0.68[b]
25	0.325 ± 0.010	53.80 ± 1.46

[a]Means ± SD (n = 6). [b]$P < 0.05$ vs 0.8 mM H_2O_2 treatment alone. [c]$P < 0.01$ vs 0.8 mM H_2O_2 treatment alone.

Obvious morphological changes of the cells were observed after H_2O_2 treatment. Cells in the control (without H_2O_2 treatment) grew well with regular shapes (fusiform), uniform sizes, and clear borders (Figure 2). After treatment with 0.8 mM H_2O_2, the cells became round and distorted, the synapse shortened, and the cell border remained clear. When the H_2O_2 concentration reached 1.6 mM, cell distortion became apparent and the cell borders became obscure. After the addition of FOs into the cell culture with H_2O_2 treatment, cells grew better, the number of adhered cells increased, the number of round cells decreased, and cell synapse recovered normally. The addition of 800 μM ferulic acid improved the growth of PC 12 cells in a manner similar to that obtained with the addition of FOs at 200 μM (Figure 2).

The administration time of FOs also affected the viability of the PC 12 cells. Cells were pre-incubated with different concentrations of FOs and ferulic acid before treatment with H_2O_2, and cell viability was determined after culturing for another 4 h after H_2O_2 treatment. Increasing the time difference between the addition of FOs and hydrogen peroxide increased the cell viability in all of the treatments, including treatments involving FOs and ferulic acid (Table 3). FOs were

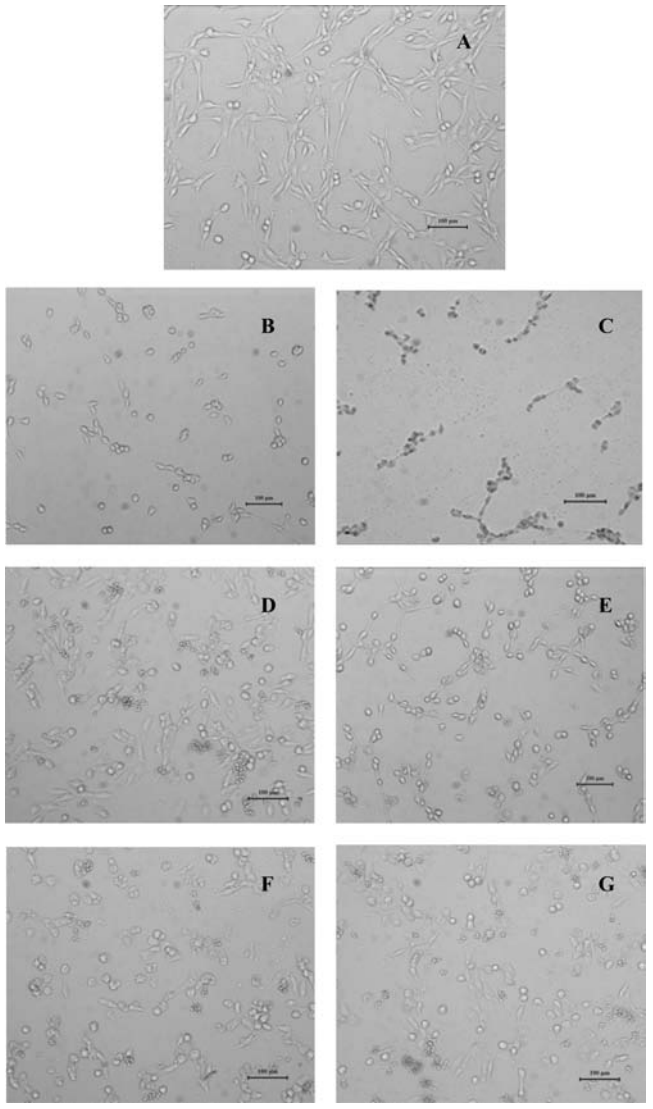

Figure 2. Effect of H_2O_2 treatment on the morphology of PC 12 cells under reverse-phase microscope: (A) control; (B, C) treatment with H_2O_2 at 0.8 and 1.6 mM; (D−F) addition of FOs at 800, 200, and 50 μM (on the basis of FA) to the treatment with 0.8 mM H_2O_2; (G) addition of ferulic acid at 800 μM to the treatment with 0.8 mM H_2O_2.

more efficient for preventing oxidative stress and have restoring capacity for antioxidant activity, resulting in an increase in the viability of the PC 12 cells after H_2O_2 treatment (Tables 2 and 3).

The effect of H_2O_2 treatment on apoptosis (Figure 3) was investigated using the flow cytometry method. After incubation with H_2O_2 at concentrations of 0.4, 0.8, and 1.6 mM for 4 h, apoptosis peaks were observed at the sub-G0 phase, and the apoptosis rates were 19.6 ± 0.6, 37.5 ± 1.1, and 46.2 ± 1.3%, respectively (n = 6), which were significantly higher ($P < 0.01$) than the control (8.2 ± 0.2%). Moreover, the rate of cells in G0/G1 phase was significantly reduced to 61.2% ($P < 0.05$), 59.6% ($P < 0.01$), and 58.1% ($P < 0.01$), at concentrations of 0.4, 0.8, and 1.6 mM, respectively, compared with 67.5% in the control. The rate of the cells in the S phase significantly increased to 35.8, 37.3, and 38.2% ($P < 0.01$) at concentrations of 0.4, 0.8, and 1.6 mM, respectively, compared with the control (31.2%). After the addition of FOs at 800, 200, and 50 μM, the apoptosis rates at sub-G0 phase decreased to 12.7 ± 0. 3, 16.2

control	205.36 ± 7.17	350.08 ± 45.68	0.14 ± 0.02
0.8 mM H_2O_2	98.75 ± 6.92[b]	1343.01 ± 133.37[b]	1.22 ± 0.10[b]
0.8 mM H_2O_2 + 800 μM FOs	180.98 ± 3.04[d]	573.71 ± 36.34[d]	0.27 ± 0.02[d]
0.8 mM H_2O_2 + 200 μM FOs	147.46 ± 3.95[d]	923.95 ± 42.44[d]	0.70 ± 0.04[d]
0.8 mM H_2O_2 + 50 μM FOs	119.34 ± 6.25[d]	1218.21 ± 77.34[c]	1.08 ± 0.07[c]
0.8 mM H_2O_2 + 800 μM FA	158.61 ± 3.74[d]	1023.84 ± 40.36[d]	0.58 ± 0.04[d]

[a]Means ± SD (n = 3). [b]P < 0.01 vs control group. [c]P < 0.05 vs H_2O_2 injury group. [d]P < 0.01 vs H_2O_2 injury group.

± 0.6, and 20.9 ± 0.8%, significantly lower (P < 0.01) than that obtained from treatment with 0.8 mM H_2O_2 alone (Table 3). The addition of 800 μM ferulic acid showed an effect similar to that of 200 μM FO (Table 4).

Effect of FOs on MDA Content and Activities of SOD and LDH of PC 12 Cells after Injury by H_2O_2. H_2O_2 treatment significantly (P < 0.01) increased the activities of LDH and MDA contents in PC 12 cells by 3.84 and 8.71 times, respectively, compared with cells in the control (Table 5), whereas H_2O_2 significantly decreased the activity of SOD by 2.05 times. The addition of FOs significantly decreased the MDA content and LDH activity, but significantly increased SOD activity compared with the group treated with H_2O_2 alone (Table 5). FOs at 800 μM resulted in an MDA content and LDH activity of only 1.9 and 1.6 times higher than the control, and the SOD activity was restored to 88.2% of the activity in normal cells (calculated from Table 5). Ferulic acid at the 800 μM level also decreased MDA content and LDH activity and increased SOD activity, compared with the group treated with hydrogen peroxide alone. However, ferulic acid showed antioxidant activity in PC 12 cells only at a concentration equivalent to 200 μM FOs (Table 5).

DISCUSSION

Corn bran contains high amounts of ferulic acid and hemicellulose, which makes it a suitable source for the preparation of FOs. However, our previous research indicated that enzymatic hydrolysis is not an efficient way to prepare FOs from corn bran. When a mixture of enzymes containing Viscozyme L and xylanase was used to hydrolyze the pretreated corn bran at pH 5.5 and 45 °C for 24 h, only 25.4% of ferulic acid (including bound and free) and 30.0% of sugars were released.[22] In the current study, autoclaving the pretreating corn bran in 0.6% oxalic acid for 30 min can release nearly 50% of ferulic acid and reducing sugars. Approximately 20% of the target products (FOs), which contain 4.88% bound ferulic acid, were obtained. The composition and structures of FOs were similar to those in wheat bran extract,[21] which indicates that corn bran FOs can be a commercially functional ingredient.

PC 12 cells, a rat pheochromocytoma cell line, have been extensively used as a tool for studying the functions of

neurotrophic factors and neuronal differentiation.[23] H_2O_2 can induce apoptosis in many different cell types and has been extensively used as an inducer of oxidative stress in in vitro models. The injury of PC 12 cells by H_2O_2 has been often used to screen neuroprotective drugs.[24,25] In this study, LDH and SOD activities and MDA content were used to evaluate the protective effects of FOs against oxidative stress in PC 12 cells induced by H_2O_2. LDH is a stable cytoplasmic enzyme present in all cells, and the release of intracellular enzymes can be used to evaluate the release of cellular contents into the plasma and the damage to cellular membranes.[26] Peroxidative damage has often been expressed in terms of MDA content, and SOD was considered an enzyme for protection against oxidative damage.[15]

The results showed that FOs prepared from corn bran can significantly decrease the content of MDA and the LDH activity, but significantly increase SOD activity in PC 12 cells injured by H_2O_2. Thus, cell growth is restored. An increase in the number of dead or plasma membrane-damaged cells results in an increase in LDH activity in the culture.[24] FOs can also decrease the release of LDH to the medium (Table 6), suggesting that FOs can mitigate the cell membrane damage induced by H_2O_2.

Table 6. Effects of FOs on the Activities of SOD and LDH and the Content of MDA in the Cultures

group	SOD (IU/mg)	LDH (IU/L)	MDA (nmol/mL)
control	29.01 ± 1.15	311.64 ± 15.43	1.15 ± 0.16
0.8 mM H_2O_2	12.39 ± 0.88[a]	1372.35 ± 70.84[a]	2.40 ± 0.18[a]
0.8 mM H_2O_2 + 800 μM (FA) FOs	25.91 ± 0.67[c]	510.83 ± 38.97[c]	1.35 ± 0.13[c]
0.8 mM H_2O_2 + 200 μM (FA) FOs	18.91 ± 1.14[c]	895.59 ± 41.18[c]	1.78 ± 0.14[c]
0.8 mM H_2O_2 + 50 μM (FA) FOs	14.66 ± 0.51[b]	1128.19 ± 78.35[c]	2.07 ± 0.12[b]
0.8 mM H_2O_2 + 800 μM FA	21.31 ± 1.04[c]	874.53 ± 40.24[c]	1.64 ± 0.12[c]

[a] $P < 0.01$ vs control group. [b] $P < 0.05$ vs H_2O_2 injury group. [c] $P < 0.01$ vs H_2O_2 injury group.

PC 12 cells can be induced to differentiate to neuron-like cells by nerve growth factor and other factors,[23] and, thus, whether or not FOs can act as neuroprotective agents to prevent or mitigate neurodegenerative disorders should be investigated.

In summary, FOs with structure similar to that of the wheat bran extracts can be prepared from corn bran by autoclaving in 0.6% oxalic acid for 30 min. FOs showed higher capacity than ferulic acid for protection against oxidative stress, which involves scavenging free radicals, and decreasing the apoptosis rate and membrane damage induced by H_2O_2 in PC 12 cells.

ABSTRACT: The present study examined the cholesterol-lowering activity of sterol extract (SE) derived from alga *Schizochytrium* sp. and its interaction with gene expression of transporters, receptors, and enzymes involved in cholesterol absorption and metabolism. GC-MS analyses found that SE was a mixture of various sterols including lathosterol, ergosterol, stigmasterol, 24-ethylcholesta-5,7,22-trienol, stigmasta-7,24(24[1])-dien-3β-ol, and cholesterol. Results showed that SE at doses of 0.06 and 0.30 g/kg diet were able to decrease plasma cholesterol concentration by 19.5 and 34%, respectively, compared with the control, in hamsters maintained on a 0.1% high-cholesterol diet. SE at a dose of 0.30 g/kg diet was as effective as β-sitosterol in reducing plasma total cholesterol (TC). SE-induced reduction in plasma TC was accompanied by down-regulation of intestinal acyl-CoA:cholesterol acyltransferase 2 (ACAT2) and hepatic 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase and up-regulation of hepatic low-density lipoprotein (LDL) receptor. Addition of SE to the diet increased the excretion of total fecal sterols. It was concluded that SE possessed the same cholesterol-lowering activity as β-sitosterol and the underlying mechanisms were mediated by increasing sterol excretion and decreasing cholesterol absorption and synthesis.

KEYWORDS: *algal sterol, β-sitosterol, cholesterol, ACAT2, LDL receptor, HMG-CoA-reductase*

INTRODUCTION

Cardiovascular disease is the major cause of human mortality. It has been shown that total plasma cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) are positively, whereas high-density lipoprotein cholesterol (HDL-C) is negatively, correlated with coronary heart disease. The three basic principles associated with cholesterol-lowering functional foods are to reduce cholesterol absorption, decrease cholesterol synthesis, and increase cholesterol catabolism by converting cholesterol to bile acids for elimination via the bile duct. Cholesterol absorption is mediated by actions of intestinal Niemann-Pick C1 like 1 (NPC1L1), acyl-CoA:cholesterol acyltransferase (ACAT-2), microsomal triglyceride protein (MTP), and ATP-binding cassette transporters (ABCG5/8).[1] Cholesterol synthesis is regulated by 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, whereas low-density lipoprotein (LDL) receptor mediates cholesterol removal from the circulation. Elimination of excessive cholesterol in the liver is mediated by cholesterol-7a-hydroxylase CYP7A1, which converts cholesterol to bile acids.[2] In this connection, cholesterol homeostasis is maintained by sterol-responsive element-binding protein 2 (SREBP2) and hepatic liver X receptor-α (LXRα) with the former regulating the gene expression of LDL receptor and HMG-CoA reductase and the latter governing the gene expression of CYP7A1.[1,2]

Microalgae are a new source of functional foods because they are rich in lipids, proteins, chlorophyll, carotenoids, vitamins, minerals, and pigments as well sterols. It is known that plant sterols cannot be absorbed and are capable of reducing plasma TC concentration by inhibiting cholesterol absorption.[3−7] However, no study has addressed the effect of algal sterols on plasma TC. We have previously examined the cholesterol-lowering activity of the lipid extracts of alga *Schizochytrium* sp., finding algal lipids were capable of lowering plasma TC and LDL-C; the two fatty acids, namely, docosahexaenoic acid (22:6n-3, DHA) and docosapentaenoic acid (22:5n-3, DPA), in the lipid extract were partially accountable for such activity.[8,9] We herewith speculate that sterols in the algal lipid extract are also possible cholesterol-lowering active ingredients. The present study was therefore the first time (i) to characterize the sterol profile of alga *Schizochytrium* sp; (ii) to compare the cholesterol-lowing activity of algal sterols with that of β-sitosterol; and (iii) to investigate its cholesterol-lowering activity as well as its interaction with gene expression of sterol transporters, proteins, and receptors involved in cholesterol metabolism.

MATERIALS AND METHODS

Preparation of Algal Sterol Extract (SE). Algal total lipids were prepared as we previously described.[8] Algal lipid (50 g) was weighed in a 1 L round-bottom flask followed by the addition of 500 mL of 1 M

NaOH in 90% ethanol. The sample was subjected to saponification by refluxing under a gentle stream of N_2 for 2 h at 90 °C. After the mixture was cooled to the room temperature, 200 mL of double-distilled H_2O was added. The total sterols were extracted into 200 mL of cyclohexane followed by centrifugation at 2500 rpm for 10 min. The process was repeated three times. The cyclohexane layer was pooled and evaporated using a rotary evaporator at 40 °C. The resultant SE was weighed and saved for the animal feeding study described below.[8]

GC-MS Analysis of SE. Sterol-TMS derivatives were prepared, and GC-MS analysis was performed in a fused silica capillary column (SACTM-5, 30 m × 0.25 mm, i.d.; Supelco, Inc., Bellefonte, PA, USA) fitting in a 6890N gas−liquid chromatograph coupled with a 7683B injector and an Agilent 5975 inert mass selective detector (Agilent Technologies Inc., Palo Alto, CA, USA) with a full scan mode (m/z 50−550). Helium was used as a carrier gas at a flow rate of 1 mL/min. The column temperature was set at 290 °C and held for 10 min followed by programming to 300 °C at the rate of 5 °C/min and being held for 20 min. MS interface temperature was set at 280 °C, and the ion source was set at 230 °C. The electron ionization energy was 70 eV. A typical GC chromatogram of SE is shown in Figure 1. Individual TMS sterols were identified according to their retention times of authentic standards and specific characteristics of mass spectra as previously published.[10−13] The characteristic spectrum of each sterol was shown in Supplementary Figure 1.

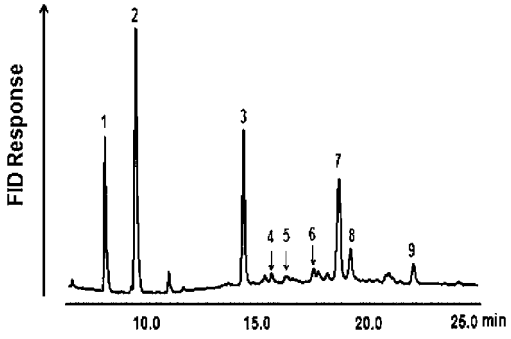

Figure 1. Gas−liquid chromatogram profiles of algal sterol extract (SE). Peaks: 1, squalene; 2, 5α-cholestane (internal standard); 3, cholesterol; 4, lathosterol; 5, ergosterol; 6, stigmasterol; 7, 24-ethylcholesta-5,7,22-trienol; 8, stigmasta-7,24(24^1)-dien-3β-ol; 9, unknown.

Diets. The four diets were prepared as previously described.[8] Casein, mineral mix, and vitamin mix were purchased from Harlan Teklad (Madison, WI, USA), and lard was purchased from the local market. DL-Methionine and cholesterol were purchased from Sigma Chemical (St. Louis, MO, USA). The control diet (CTL) was formulated by mixing 508 g of cornstarch, 242 g of casein, 50 of lard, 119 g of sucrose, 40 g of mineral mix, 20 g of vitamin mix, 1 g of DL-methionine, and 1 g of cholesterol. The other three experimental diets were prepared by adding 0.06 g of SE derived from 10 g of algal lipids (SE1), 0.30 g of SE derived from 50 g of algal lipids (SE5), and 0.30 g of β-sitosterol (ST), respectively, into 1 kg of basal diet (Table 1). The powered diets were gelatinized with a gelatin solution (20 g/L) in a ratio of 200 g of diet per liter and were cut into 10 g cubes and stored frozen at −20 °C before the hamsters were fed.

Hamsters. Male golden hamsters (*Mesocricetus auratus*; body weights = 110−130 g) were randomly divided into four groups (n = 10/group) and fed one of the four diets for 5 weeks. Diets and water were given ad libitum. Body weights were recorded, and the fecal samples per cage were collected weekly. Blood (0.5 mL) was obtained from the retro-orbital sinus into a heparinized capillary tube at the end of weeks 0, 3, and 5 following food deprivation for 14 h overnight and light anesthesia, using a mixture of ketamine, xylazine, and saline (v/v/v, 4:1:5).[14] Following the last blood sample collection at week 5, all of the hamsters were sacrificed by carbon dioxide suffocation. The liver, heart, kidney, testis, epididymal and perirenal adipose tissue, and aorta were removed, washed in saline, and weighed. The first 10 cm of duodenum was discarded, and the next 30 cm of the small intestine was kept. All tissue samples were flash frozen in liquid nitrogen and stored at −80 °C until analysis. The entire experimental procedure was approved by the Animal Experimental Ethical Committee, Chinese University of Hong Kong.

Measurement of Plasma Lipoproteins. Plasma TC, HDL-C, non-HDL-C, and triacylglycerols (TG) were measured using the commercially available enzymatic kits from Infinity (Waltham, MA, USA) and Stanbio Laboratories (Boerne, TX, USA), respectively.[14] To quantify plasma HDL-C, very low-density lipoprotein (VLDL) and LDL were first precipitated using a commercial kit containing phosphotungstic acid and magnesium chloride (Stanbio Laboratories). HDL-C in the supernatant was measured similarly as done for TC. Non-HDL-C was calculated by deducting HDL-C from TC. The apparent cholesterol absorption was calculated by the equation [cholesterol intake − (excretion of cholesterol + microbial neutral and acidic sterols)]/cholesterol intake].

Quantification of Organ Cholesterol. Cholesterol in the liver was determined as we previously described.[15,16] The 300 mg liver sample was homogenized with 5α-cholestane being added as an internal standard. The total liver lipids were extracted into a solvent mixture of methanol/chloroform (2:1, v/v). After evaporation of the solvent, the total lipid extract was mildly saponified. The free cholesterol in the extract was converted to its trimethylsilyl ether (TMS) derivative before the GC analysis.

Fecal Sterol Analysis. Fecal sterols were analyzed as we described previously.[14] The total fecal output from each hamster was collected, freeze-dried, and then ground into powder. The fecal powder sample of about 300 mg was weighed with the addition of 5α-cholestane and hyodeoxycholic acid as internal standards for quantification of fecal neutral and acidic sterols, respectively. Total fecal neutral sterols were extracted into cyclohexane and then converted to their TMS derivatives. The total acidic sterols in aqueous phase were saponified, extracted, and converted to their corresponding TMS derivatives. Both neutral and acidic sterol TMS derivatives were run in a fused silica capillary column (SAC-5, 30 m × 0.25 mm, i.d.; Supelco, Bellefonte, PA, USA) using a Shimadzu GC-14 B gas−liquid chromatograph equipped with a flame

Table 2. Sterol Composition of Algal Lipids Derived from *Schizochytrium* sp.

sterol	% total sterol extract
squalene	20.69
cholesterol	27.67
lathosterol	1.23

ionization detector (Kyoto, Japan). Total neutral sterols were the sum of cholesterol and its microbial metabolites, namely, coprostanol, coprostanone, and dihydrocholesterol, whereas fecal total acidic sterols were the sum of primary and secondary bile acids including cholic, chenodeoxycholic, lithocholic, deoxycholic, and ursocholic acids.

Real-Time PCR Analysis. mRNA of liver SREBP-2, LDL receptor, HMG-CoA reductase, LXRα, CYP7A1, and intestinal NPC1L1, ABCG5/8, ACAT2, and MTP was measured as we described previously.[14] In brief, total RNA was extracted and then converted to its complementary DNA. Real-time PCR analysis was carried out on a Fast Real-time PCR System 7500 (Applied Biosystems). Primers and TaqMan probes were used for real-time PCR analysis of liver GAPDH, CYP7A1, HMG-CoA reductase, LDL receptor, SREBP-2, LXRα[14] and intestinal NPC1L1, ABCG5, ABCG8, ACAT2, MTP, and 18S with SYBR green being used as fluorophore.[17−19]

Statistics. All data are presented as the mean ± standard deviation (SD). The significance of difference was assessed using ANOVA. Differences were considered significant when the P value was <0.05. The post hoc LSD test was carried out to detect any significant difference between the two group means using SigmaStat Advisory Statistical Software.

RESULTS

SE Composition. Dry powder of alga *Schizochytrium* sp. was rich in lipids (49.80%).[8] It was found that algal lipids contained 0.66% SE by weight. The GC-MS analysis demonstrated that SE was a mixture of squalene, cholesterol, lathosterol, ergosterol, stigmasterol, 24-ethylcholesta-5,7,22-trienol, and stigmasta-7,24-(24^1)-dien-3β-ol with 24-ethylcholesta-5,7,22-trienol accounting for 32.62% and squalene accounting for 20.69% with cholesterol being about 27.67% (Table 2).

Food Intake and Body and Organ Weights. The food intake among the four groups was in the range of 10.14−11.00 g daily. The SE1 group had lesser food intake than the control

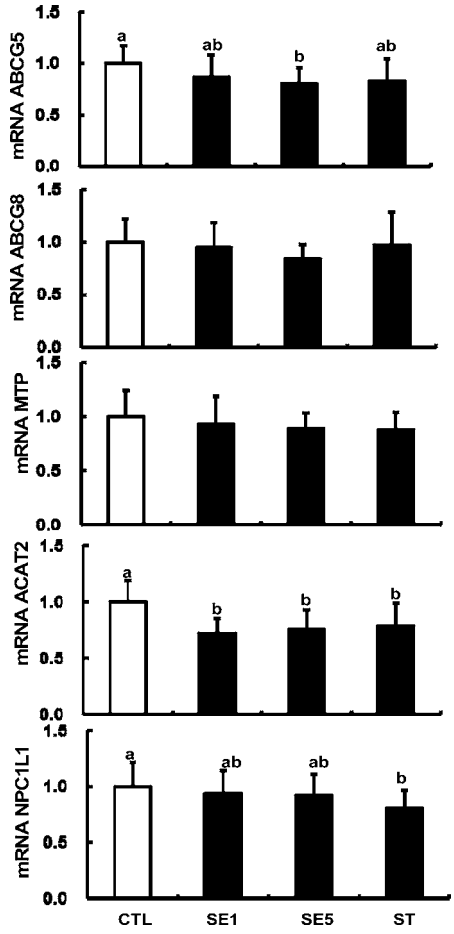

Figure 2. Effect of 0.06 g of sterol extract (SE1), 0.30 g of sterol extract (SE5), and 0.30 g of β-sitosterol (ST) per kilogram diet on intestinal Niemann-Pick C1 like 1 (NPC1L1), acyl coenzyme A:cholesterol acyltransferase 2 (ACAT2), microsomal triacylglycerol transport protein (MTP), and ATP binding cassette transporters (ABCG5 and ABCG8) in hamsters fed a high-cholesterol diet. Data are normalized with cyclophilin. Values are expressed as means ± SD (n = 10) with those for the control group being arbitrarily taken as one. Means with different letters differ significantly, $P < 0.05$.

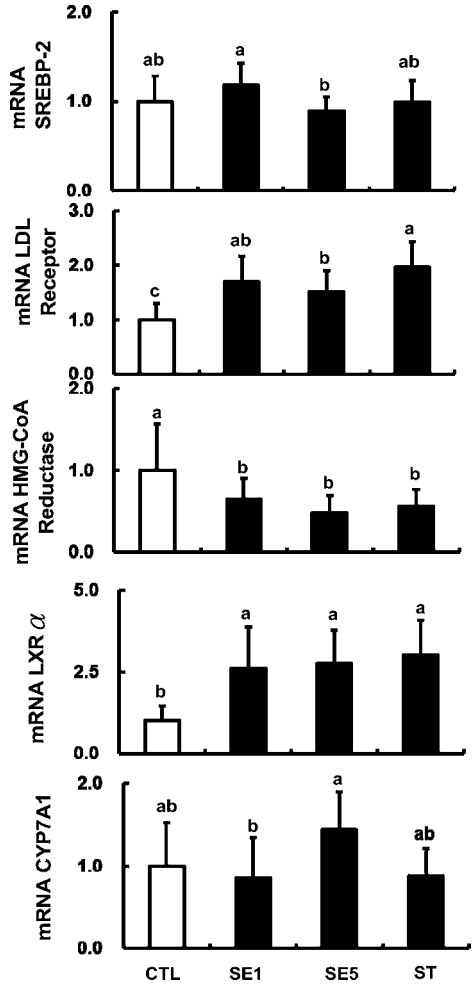

Figure 3. Effect of 0.06 g of sterol extract (SE1), 0.30 g of sterol extract (SE5), and 0.30 g of β-sitosterol (ST) per kilogram diet on mRNA levels of hepatic sterol regulatory element-binding protein-2 (SREBP-2), liver X receptor (LXRα), 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase, LDL receptor, and cholesterol-7α-hydroxylase (CYP7A1) in hamsters fed a high-cholesterol diet. Data are normalized with GAPDH. Values are expressed as means ± SD (n = 10) with those for the control group being arbitrarily taken as one. Means with different letters differ significantly, $P < 0.05$.

hamsters. The SE1 group had lighter initial and final body weights compared with the ST hamsters (Table 3). However, no significant differences were seen among the other three groups. The sizes of liver, heart, and testis in the ST group were smaller compared with the control group. No significant differences in the kidney and epididymal fat pad were seen among the four groups. The SE1 group had a smaller perirenal fat pad compared with the control (Table 3).

Plasma Lipid Profile. There was no difference in plasma lipoprotein profiles among the four groups at week 0 (Table 4). At the end of week 3, plasma TC in group SE5 was significantly decreased compared with the other three groups (SE5, 205.28 mg/dL; CTL, 260.43 mg/dL; SE1, 233.54 mg/dL; ST, 248.28 mg/dL). Plasma TG in groups SE1 and SE5 was significantly lower compared with that in the other two groups. Non-HDL-C concentration in the SE5 group was significantly decreased compared with the SE1 group, whereas HDL-C concentration was lower in groups SE1 and SE5 compared with that in the control and ST groups (Table 4). At the end of week 5, plasma TC in SE1, SE5, and ST was significantly lower than that in the control (SE5, 194.42 mg/dL; CTL, 292.98 mg/dL; SE1, 235.95 mg/dL; ST, 204.91 mg/dL). Among the three experimental groups, SE5 had the lowest plasma TC concentration followed by the ST group. With regard to non-HDL-C, addition of SE and ST to the diet significantly reduced its concentration compared with the control hamsters. Both SE5 and ST groups had HDL-C concentration lower than the control group.

Liver Cholesterol. No significant differences in hepatic cholesterol concentrations were seen among the four groups (data not shown).

mRNA Analyses of Intestinal ABCG5, ABCG8, NPC1L1, MTP, and ACAT2. Real-time PCR analyses demonstrated that dietary SE and β-sitosterol had no effect on the gene expression of ABCG8 and MTP (Figure 2). With regard to intestinal ABCG5, only the SE5 group demonstrated down-regulation compared with the control. In contrast, addition of SE and ST to diets could down-regulate the mRNA of intestinal ACAT2. ST also down-regulated the mRNA of intestinal NPC1L1. Although SE1 and SE5 showed a trend of down-regulation of intestinal NPC1L1, no significant difference was seen compared with the control (Figure 2).

mRNA Analysis of SREBP-2, HMG-CoA Reductase, LDL Receptor, LXRα, and CYP7A1. The real-time PCR analyses demonstrated that SE1, SE5, and β-sitosterol had no effect on

mRNA level of SREBP-2 and CYP7A1. However, SE1, SE5, and β-sitosterol all up-regulated LDL receptor and mRNA LXRα, whereas they all down-regulated HMG-CoA reductase (Figure 3).

Cholesterol Balance and Excretion of Fecal Neutral and Acidic Sterols. The individual neutral and acidic sterols in the feces at weeks 1 and 5 were quantified (Tables 5 and 6). In week 1, group SE5 had significantly higher fecal excretion of cholesterol and its major microbial metabolite coprostanol as well as total fecal neutral sterols. SE5 hamsters also excreted greater cholic acid than other three groups. In week 5, SE5 excreted a greater amount of cholesterol compared with the other three groups. Excretions of total fecal neutral sterols in both SE5 and ST groups were greater than those of the control hamsters. SE and ST groups had an increasing trend in the excretion of fecal total acidic sterols; however, no significant difference between the control and the three experimental groups was seen.

Total intake of cholesterol was compared with its excretion of neutral and acidic sterols (Table 7). Net cholesterol equivalent retained was calculated by difference between the intake and excretion of cholesterol and both its neutral and acidic metabolites. It was clear that at week 1, SE and ST demonstrated a trend of decreasing the apparent cholesterol absorption. At the end of week 5, the inhibition of the apparent cholesterol absorption by both SE and ST became more significant compared with that of the control group.

DISCUSSION

The present study clearly demonstrated that SE of alga *Schizochytrium* sp. possessed cholesterol-lowering activity. Addition of 0.06 and 0.30 g of SE to 1 kg of diet was able to decrease plasma TC concentration by 19.5 and 34%, respectively, in hamsters fed a 0.1% high-cholesterol diet. The reason for choosing 0.06 g/kg diet as the first dose was that it was equivalent to the amount present in 1% algal lipids, which was added to the diet and showed a cholesterol-lowering activity in a previous study.[8] The rationale for choosing 0.30 g SE/kg diet as the second dose was that this dose was used in most research studies on phytosterols. It was clear that SE reduced plasma cholesterol concentration in a dose-dependent manner. The present result supports the hypothesis that, in addition to DPA n-3 and DHA, SE in alga *Schizochytrium* sp. may also be the active ingredient accountable for the cholesterol-lowering activity of algal lipid extract observed in the previous studies.[8,9]

The hypocholesterolemia effect of SE was comparable to that of β-sitosterol (Table 4), which is commonly used as a cholesterol-lowering functional plant sterol added to foods such as margarine and vegetable oil.[5] As a health supplement, phytosterols including β-sitosterol can lower blood cholesterol concentration and reduce the risk of heart diseases.[20,21] The cholesterol-lowering activity of phytosterols is mediated by their inhibition of cholesterol absorption in the digestive tract through its competition with cholesterol for transporter NPL1L1.[22−26] Additionally, numerous studies have investigated the potential applications of β-sitosterol as blood cholesterol-lowering agents not only for pharmaceutical formulations but also for use as a food ingredient, and their effectiveness and safety have also been demonstrated.[27] The present results clearly demonstrated that algal sterols were as effective as β-sitosterol in reducing plasma cholesterol concentration, most likely mediated by decreasing cholesterol absorption (Tables 4−7). GC-MS analyses found that SE was a mixture of several sterols, lathosterol, ergosterol, stigmasterol, 24-ethylcholesta-5,7,22-trienol, and stigmasta-7,24-(24[1])-dien-3β-ol. In this connection, two questions remain unanswered. First, it is unknown which sterol species is responsible for SE's cholesterol-lowering activity. Second, if two or more sterol species are the active ingredients, it will be interesting to know whether they have any synergistic effect on plasma TC.

The real-time PCR analyses demonstrated that SE could affect the gene expression of intestinal ACAT2. On the one hand, SE behaved like β-sitosterol, which could down-regulate the ACAT2 mRNA level. ACAT2 is an essential enzyme in intestinal cholesterol absorption because it catalyzes the reaction of converting cholesterol to cholesteryl ester before cholesterol can be packed into chylomicrons via lymphatic system to blood. Previous studies found that β-sitosterol was poorly esterified by ACAT2.[28,29] On the other hand, SE did not behave like β-sitosterol as it did not significantly affect, whereas β-sitosterol could down-regulate, the mRNA of intestinal NPC1L1. Cholesterol absorption in the intestine is a very complex process and requires several transporters. NPC1L1 is responsible for carrying free cholesterol in the lumen to enterocytes.[30] As SE contained cholesterol, it was therefore speculated that SE had two confronting factors. The cholesterol in SE could up-regulate, whereas the other sterols could down-regulate, the gene expression of intestinal NPC1L1, and therefore no effect of SE on the gene expression of intestinal NPC1L1 was seen.

The real-time PCR analyses demonstrated that SE could down-regulate the gene expression of HMG-CoA reductase, whereas it could up-regulate that of hepatic LDL receptor. This was consistent with the observation in the previous study that algal lipids down-regulated the mRNA of HMG-CoA reductase.[8] As expected, SE behaved like β-sitosterol to modulate these genes as they are structurally similar. It is known that HMG-CoA reductase is a key enzyme involved in cholesterol synthesis, whereas LDL receptor is responsible for the removal of LDL-cholesterol from circulation. The present results clearly suggest that algal sterols are one of the active ingredients also partially accountable for the cholesterol-lowering activity of alga *Schizochytrium* sp., possibly mediated by down-regulation of HMG-CoA reductase and up-regulation of LDL receptor in addition to down-regulation of intestinal ACAT2.

In conclusion, the present study was the first time to demonstrate that algal SE had a cholesterol-lowering activity comparable to that of β-sitosterol. Cholesterol-lowering activity of algal SE was mediated by down-regulation of intestinal ACAT2 and hepatic HMG-CoA reductase but up-regulation of LDL receptor. Acting like β-sitosterol, SE increased the excretion of total sterols and decreased cholesterol absorption. Together with the results in our previous study,[9] it was concluded that DPA n-3, DHA, and sterols were all active ingredients accountable for the cholesterol-lowering activity of alga *Schizochytrium* sp. The whole investigation clearly showed that alga *Schizochytrium* sp. could be further explored as a cholesterol-lowering functional food.

ABSTRACT: The preparation of xylan-*graft*-poly(ε-caprolactone) (xylan-*g*-PCL) copolymers was investigated by homogeneous ring-opening polymerization (ROP) in a dual-component system containing Lewis base LiCl and strong polar aprotic solvent dimethyl sulfoxide (DMSO). DMSO/LiCl acted as solvent, base, and catalyst for the ROP reaction. The effects of the parameters, including the reaction temperature, molar ratio of ε-caprolactone (ε-CL) to anhydroxylose units (AXU) in xylan, and reaction time, on the degree of substitution (DS) and weight percent of PCL side chain (W_{PCL}) were investigated. The results showed that xylan-*g*-PCL copolymers with low DS in the range of 0.03−0.39 were obtained under the given conditions. The Fourier transform infrared spectroscopy (FTIR), ^{1}H nuclear magnetic resonance (NMR), ^{13}C NMR, ^{1}H−^{1}H correlation spectroscopy (COSY), and ^{1}H−^{13}C correlation two-dimensional (2D) NMR [heteronuclear single-quantum coherence (HSQC)] characterization provided more evidence of the attachment of side chains onto xylan. Only one ε-CL was confirmed to be attached onto xylan with each side chain. Integration of resonances assigned to the substituted C_2 and C_3 in the HSQC spectrum also indicated 69.23 and 30.77% of PCL side chains attached to AXU at C_3 and C_2 positions, respectively. Although the attachment of PCL onto xylan led to the decreased thermal stability of xylan, the loss of unrecovered xylan fractions with low molecular weight because of the high solubility of xylan in DMSO/LiCl resulted in the increased thermal stability of the samples. This kind of xylan derivative has potential application in environmentally friendly and biodegradable materials considering the good biodegradability of xylan and PCL.

KEYWORDS: *xylan, ε-caprolactone, DMSO/LiCl, ring-opening polymerization*

INTRODUCTION

Hemicelluloses, the second most abundant class of renewable and biodegradable polysaccharides found in nature after cellulose, account for on average about 20−35% of most plant materials.[1,2] Because of the easy availability, good biodegradability, biocompatibility, and renewability, low price, and good mechanical properties, much attention has been paid to the use of hemicelluloses to produce performance biomaterials, biofuels, and platform biochemicals with increased environmental awareness and the development of green chemistry.[3,4]

Xylan-type hemicelluloses are the main hemicellulosic components of cell walls of hardwoods and grasses. As heterogeneous polymers with low molecular weight, they possess backbone chains of β-(1 → 4)-D-xylopyranose units and are branched by short carbohydrate chains.[5] Besides xylose, xylans may also contain arabinose, glucuronic acid or its 4-*O*-methyl ether, and acetic, ferulic, and *p*-coumaric acids. Usually, mostly the α-L-arabinofuranosyl residue may attach to some of the C_3 positions of the xylan backbone as the principal substituent and also carry minor amounts of 4-*O*-methlglucuronic or α-1,2-linked glucuronic acid residues, which are mainly linked to the C_2 positions of the xylan backbone.[6] In addition, there can be *O*-acetyl substitution on the backbone.[1]

Recently, much attention has been focused on the use of lignocellulosic biomass and its components.[7] In comparison to cellulose and lignin, the exploiting of hemicelluloses was paid little attention until the last decade. Because of their inherent low molecular weight and heterogeneous structure, chemical modification of hemicelluloses becomes an important way to prepare material with the desired properties.[8,9] In comparison to heterogeneous functionalization, homogeneous functionalization is simple and the degree of substitution (DS) of the products can be easily controlled and reproduced.[10−12] Because of the excellent biodegradability, biocompatibility, and permeability, considerable efforts have been paid to aliphatic polyesters,[13] among which poly(ε-caprolactone) (PCL) is one of the most important polyesters. PCL is a tough, flexible, and crystalline polymer with a low glass transition temperature (about −60 °C) and melting point (60 °C).[14−17] Ring-opening polymerization (ROP) of ε-caprolactone (ε-CL) is the most common way to prepare PCL, which can be accomplished in melt or in solution, catalyzed with 4-dimethylaminopyridine (DMAP), stannous octoate [$Sn(Oct)_2$], LiCl, or other catalysts.[18−20] However, because of the cytotoxicity and difficulties in the removal of the catalyst from the resulting polymers, the use of $Sn(Oct)_2$ and DMAP has been limited in many cases. LiCl, a very economic and

almost nontoxic chemical, could effectively catalyze the ROP reaction.[19]

The novel dissolution systems for lignocelluloses and their components received much attention because of the complexity of the plant cell walls. Dimethyl sulfoxide (DMSO)/LiCl was proposed as a novel dual-component system containing a Lewis base and strong polar aprotic solvent for the dissolution and pretreatment of plant materials.[21,22] In the present study, the DMSO/LiCl system was investigated as the reaction medium for the ROP reaction of ε-CL onto xylan. The physicochemical properties of xylan derivatives were characterized with Fourier transform infrared spectroscopy (FTIR), ^{1}H nuclear magnetic resonance (NMR), ^{13}C NMR, ^{1}H−^{1}H correlation spectroscopy (COSY), ^{1}H−^{13}C correlation two-dimensional (2D) NMR [heteronuclear single-quantum coherence (HSQC)], scanning electron microscopy (SEM), and thermal analysis.

MATERIALS AND METHODS

Materials. Xylan with a xylose content of over 85% was purchased from Yuan-Ye Biological Technology Co., Ltd. (Shanghai, China). LiCl with a purity of 97% was provided by Kermel Chemical Reagent Co., Ltd. (Tianjin, China). DMSO with 99.5% purity and ε-CL with 99% purity were supplied by Aladdin Reagent Co. (Shanghai, China). All chemicals were of analytical reagent grade and directly used without further purification.

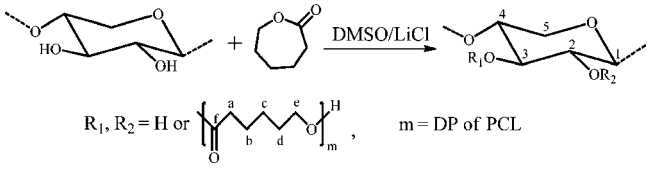
Preparation of Xylan-*g*-PCL Copolymers in DMSO/LiCl. A series of xylan-*g*-PCL copolymers were prepared in dual-component system DMSO/LiCl under the conditions in Table 1. Dry xylan (0.33 g, 0.005 mol of hydroxyl group in xylan) was added to 20 mL of DMSO/LiCl (6 wt % LiCl) in a 50 mL dried three-neck flask. The mixture was agitated with magnetic stirring at 80 °C for about 2 h under the protection of nitrogen to achieve a homogeneous solution. Then, the required quantities of ε-CL [the molar ratio of ε-CL to anhydroxylose units (AXU) in xylan were 1:1, 4:1, 8:1, 12:1, and 20:1] were added at 80, 90, 100, 110, and 120 °C, respectively. The reaction was carried out under the protection of nitrogen with magnetic stirring for 3, 6, 12, 24, and 48 h, respectively. After the required time, the resulting solution was cooled to room temperature. The solid residues after precipitation into 150 mL of ethanol were filtered out, washed thoroughly with ethanol and dichloromethane to eliminate DMSO, LiCl, ε-CL, and byproducts, and then dried in vacuum for 48 h at 50 °C.

Table 1. Detailed Structural Factors of Xylan-*g*-PCL Copolymers Obtained under Various Conditions in DMSO/LiCl

sample	temperature (°C)	time (h)	ε-CL/AXU	DS	W_{PCL} (%)
1	80	24	4:1		
2	90	24	4:1	0.04	3.34
3	100	24	4:1	0.20	14.73
4	110	24	4:1	0.18	13.45
5	120	24	4:1	0.09	7.21
6	100	24	1:1	0.04	3.34
7	100	24	8:1	0.21	15.35
8	100	24	12:1	0.23	16.57
9	100	24	20:1	0.39	25.20
10	100	3	8:1	0.03	2.53
11	100	6	8:1	0.07	5.70
12	100	12	8:1	0.15	11.47
13	100	48	8:1	0.21	15.35

Film Preparation and Physical Property Determination. The xylan-*g*-PCL copolymer sample (0.3 g) was dissolved in 10 mL of deionized water. The solution was poured onto a polystyrene dish (9 × 9 cm) and allowed to dry at ambient temperature to obtain xylan-*g*-PCL film. The film thickness was measured using a micrometer (Lorentzen and Wettre; precision = 1 μm) at five different locations, and the mean value was used for the measurements of stress strength, tensile strain, and elasticity modulus on a universal tensile machine (DRK101).

Scheme 1. Grafting Copolymerization of PCL onto the Xylan Backbone in DMSO/LiCl



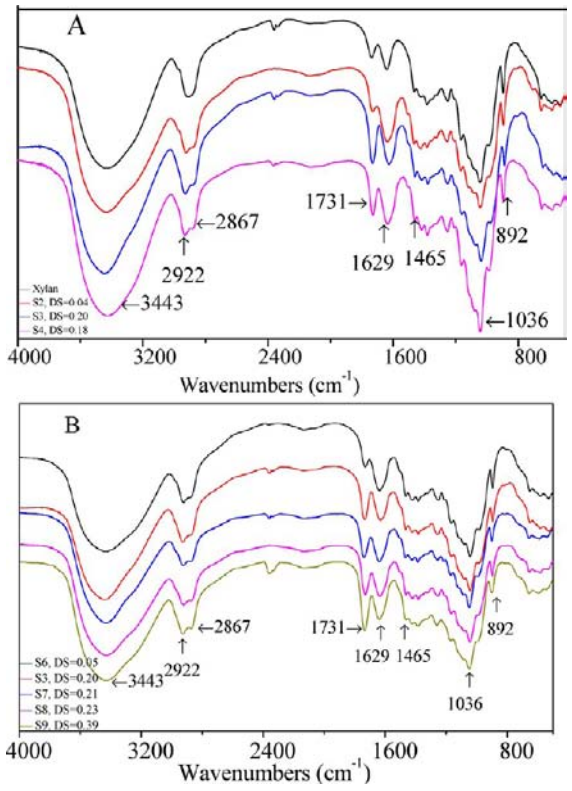


Figure 1. FTIR spectra of unmodified xylan and xylan-*g*-PCL copolymers obtained with an increased reaction temperature (A) from 90 °C (sample 2) to 100 °C (sample 3) and 110 °C (sample 4) and increased molar ratio of ε-CL to AXU (B) from 1:1 (sample 6), 4:1 (sample 3), 8:1 (sample 7), 12:1 (sample 8), and 20:1 (sample 9).

Detailed Physicochemical Characterization. FTIR spectra of the unmodified xylan and xylan-*g*-PCL copolymers were recorded on a Bruker spectrophotometer (TENSOR 27, Switzerland) from finely ground samples (1%) in KBr pellets in the range of 4000−500 cm^{-1}. The ^{1}H NMR, ^{13}C NMR, ^{1}H−^{1}H COSY, and HSQC spectra of unmodified xylan and xylan-*g*-PCL copolymers were recorded from 40 mg samples in 0.5 mL of DMSO-d_6 on a Bruker Avance III 400 M spectrometer (Germany) with a 5 mm multinuclear probe. For the ^{1}H NMR analysis, the detailed collecting and processing parameters were listed as follows: number of scans, 11; receiver gain, 62; acquisition time, 4.0894 s; relaxation delay, 1.0 s; pulse width, 11.0 s; spectrometer frequency, 400.13 MHz; and spectral width, 8012.8 Hz. For the ^{13}C NMR analysis, the detailed collecting and processing parameters were listed as follows: number of scans, 1932; receiver gain, 1440; acquisition time, 1.2583 s; relaxation delay, 1.5 s; pulse width, 12.0 s; spectrometer frequency, 100.61 MHz; and spectral width, 26 041.7 Hz. For the ^{1}H−^{1}H COSY analysis, the detailed collecting and processing parameters were listed as follows: number of scans, 16; receiver gain, 355; acquisition time, 0.4588 s; relaxation delay, 2.0 s; pulse width, 8.5 s;

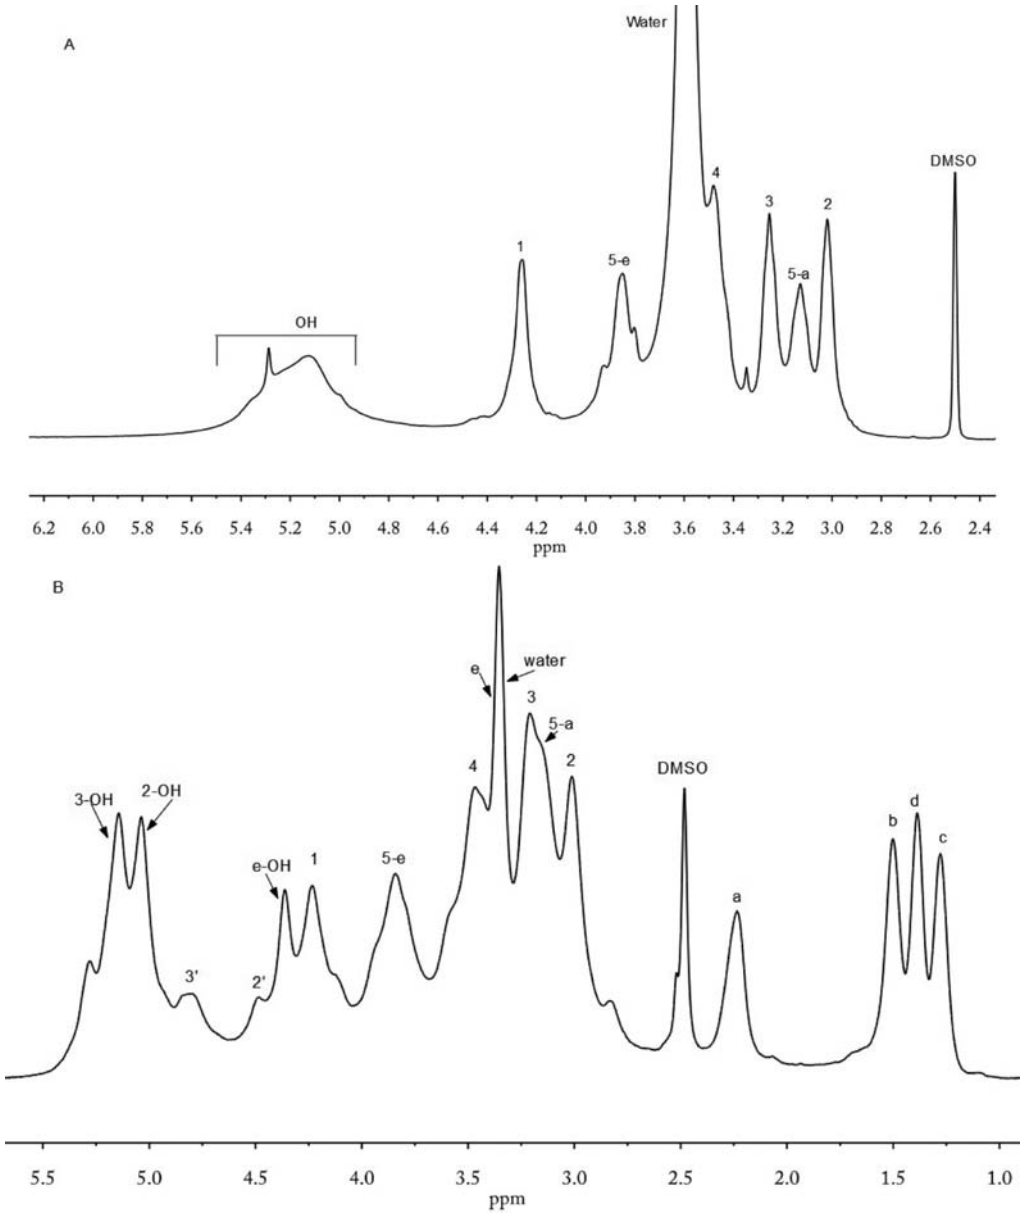

Figure 2. ^{1}H NMR spectra of unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B).

spectrometer frequency, 400.13/400.13 MHz; and spectral width, 2231.1/2231.1 Hz. For the ^{1}H−^{13}C HSQC analysis, the detailed collecting and processing parameters were listed as follows: number of scans, 20; receiver gain, 879; acquisition time, 0.1645 s; relaxation delay, 2.0 s; pulse width, 8.5 s; spectrometer frequency, 400.13/100.61 MHz; and spectral width, 3113.3/22 727.3 Hz. The detailed structural factors of xylan-*g*-PCL copolymers, including DS and weight percent of PCL side chains (W_{PCL}), were calculated from the integral area of the resonances assigned to the characteristic protons from AXU (H_1) and the attached PCL (the methylene protons). The thermal stability of the samples was performed using thermogravimetric analysis (TGA) and derivative thermogravimetry (DTG) using a Q500 theromgravimetric analyzer (TA Instruments, New Castle, DE). The apparatus was continually flushed with nitrogen. The sample between 9 and 11 mg was heated from 30 to 600 °C at a heating rate of 10 °C/min. The surface morphology was examined by SEM on a field emission scanning electron microscope (LEO 1530 VP, LEO, Germany). The samples for SEM were prepared by casting a few solids onto a mica sheet followed by gold plating.

RESULTS AND DISCUSSION

Effects of Reaction Conditions on the DS of Xylan-*g*-PCL Copolymers. Xylan-*g*-PCL copolymers were synthesized via homogeneous ROP of *ε*-CL onto xylan in DMSO/LiCl. Scheme 1 illustrates the ROP reaction of *ε*-CL with the hydroxyl groups of AXU in xylan in DMSO/LiCl. The preparation conditions and the detailed structural factors of xylan-*g*-PCL copolymers are shown in Table 1. The ROP reaction was easily achieved in DMSO/LiCl at 100 °C, and the xylan derivatives with DS of 0.20 were obtained within 24 h. However, the reaction occurred much more difficultly at higher or lower temperatures and even did not occur at 80 °C. The optimum reaction temperature for the ROP reaction in DMSO/LiCl was 100 °C. Clearly, the increase of the derivatizing reagent dosage and reaction time had favorable effects on the ROP reaction because of the increased molecule collisions of *ε*-CL with reactive hydroxyl groups. An enhancement of the molar ratio of *ε*-CL to AXU in xylan from 1:1 to 20:1 resulted in an increase in DS from

dx.doi.org/10.1021/jf4036047 | J. Agric. Food Chem. 2014, 62, 682−690

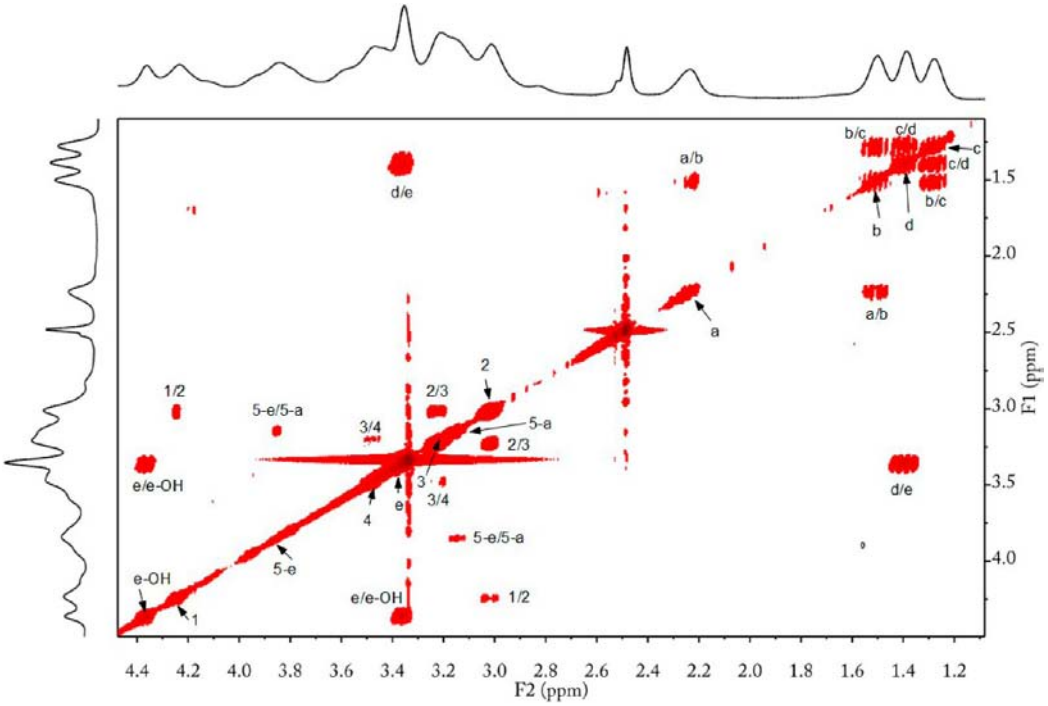

Figure 3. $^{1}H-^{1}H$ COSY spectrum of xylan-*g*-PCL copolymer sample 9.

0.04 to 0.39, and an increasing reaction time from 3 to 48 h led to an improvement of DS from 0.03 to 0.21. The similar results of the ROP reaction of ε-CL onto cellulose were reported in ionic liquid 1-*N*-butyl-3-methylimidazolium chloride ([Bmim]Cl) with DMAP and $Sn(Oct)_2$ as catalysts at 130 °C.[18] The higher DS of cellulose-*g*-PCL (0.09−2.41) was probably due to the higher temperature in [Bmim]Cl and more hydroxyl groups available in cellulose. Because the ROP reaction of ε-CL onto xylan is acid- or base-catalyzed, in the present study, the favorable effect of Lewis base LiCl in strong polar aprotic solvent DMSO resulted in the occurrence of the ROP reaction of ε-CL with the hydroxyl groups in xylan at relatively low temperatures. This dual-component system acted as a solvent, base, and catalyst in the preparation of xylan-*g*-PCL copolymers. Similarly, the dissolution of the plant whole cell wall was reported in this system, because of the favorable effects on the destruction of hydrogen bonds extensively present in the cell wall.[23,24]

FTIR. Figure 1 illustrated the FTIR spectra of unmodified xylan and xylan-*g*-PCL copolymers obtained with an increased reaction temperature (A) and molar ratio of ε-CL to AXU (B). The absorbances at 3443, 2922, 1731, 1629, 1465, 1036, and 892 cm^{-1} in the spectrum of unmodified xylan are previously reported.[23] In comparison, the spectra of xylan-*g*-PCL copolymers provided evidence for the ROP reaction by showing changes of two important bands at 2867 cm^{-1} for CH_2 stretching and 1731 cm^{-1} for C═O stretching.[24] The intensities of these two bands increased with the increment of the reaction temperature and the molar ratio of ε-CL to AXU, corresponding to the slight changes of DS in Table 1.

^{1}H NMR, $^{1}H-^{1}H$ COSY, ^{13}C NMR, and HSQC. Figure 2 illustrates the ^{1}H NMR spectra of unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B; DS of 0.39). In spectrum A, the proton signals at 4.90−5.50 ppm originated from the hydroxyl groups in AXU.[25] The strong signals at 3.59 and 2.50 ppm relate to water and DMSO, respectively. The signals at 4.26, 3.02, 3.25, 3.48, 3.85, and 3.13 ppm originated from the protons at H_1, H_2, H_3, H_4, H_{5e}, and H_{5a} of AXU, respectively.[26] In comparison, spectrum B provided evidence of the attachment of PCL side chains onto xylan. The methylene proton signals of the attached PCL could be observed at 3.36 ppm (−C$\underline{H}_2$OH, e, end unit), 2.24 ppm (−COC$\underline{H}_2$−, a), 1.50 ppm (−C$\underline{H}_2$−, b), 1.38 ppm (−C$\underline{H}_2$−, d), and 1.28 ppm (−C$\underline{H}_2$−, c).[18] The signal for the hydroxyl group at the end of PCL side chains (−CH_2O$\underline{H}$, e−OH) after the ROP reaction was present at 4.36 ppm. Unexpectedly, there was no signal for the methylene proton at the e position in the repeating unit of PCL (−C$\underline{H}_2$−O−, e), indicating probably only one ε-CL attached onto xylan with each side chain. As expected, no carboxyl proton was found in spectrum B, suggesting the absence of homopolymers of ε-CL and the formation of xylan−PCL ester. To confirm the correct assignment of the primary signals, the $^{1}H-^{1}H$ COSY spectrum of xylan-*g*-PCL copolymer sample 9 was collected, as illustrated in Figure 3. To avoid the overlapping of the primary signals, the COSY spectrum is shown at higher contour levels to provide the well-resolved correlations. As shown in Figure 3, the moderate cross-correlations in the lower left corner for H_1/H_2, H_2/H_3, H_3/H_4, and H_{5e}/H_{5a} were clearly observed. More importantly, the strong cross-correlations for PCL side chains in the upper right corner for a/b, b/c, c/d, and d/e and that in the lower left corner for e/e−OH provided the primary proton signals in PCL. Beside the cross-correlation at δ_H/δ_H of 3.36/1.38 ppm, there were no other cross-correlations of the methylene proton at the d position, indicating the absence of the PCL repeating unit. This result was consistent with ^{1}H NMR analysis, confirming that only one ε-CL was attached onto xylan with each side chain; that is, the degree of polymerization (DP) of the side chain was only 1.

On the basis of the typical proton signals from PCL side chains and AXU in xylan, the DS and weight percent of PCL side chains in Table 1 were calculated with the integral area of the resonances of the corresponding protons according to the following equations:

dx.doi.org/10.1021/jf4036047 | J. Agric. Food Chem. 2014, 62, 682−690

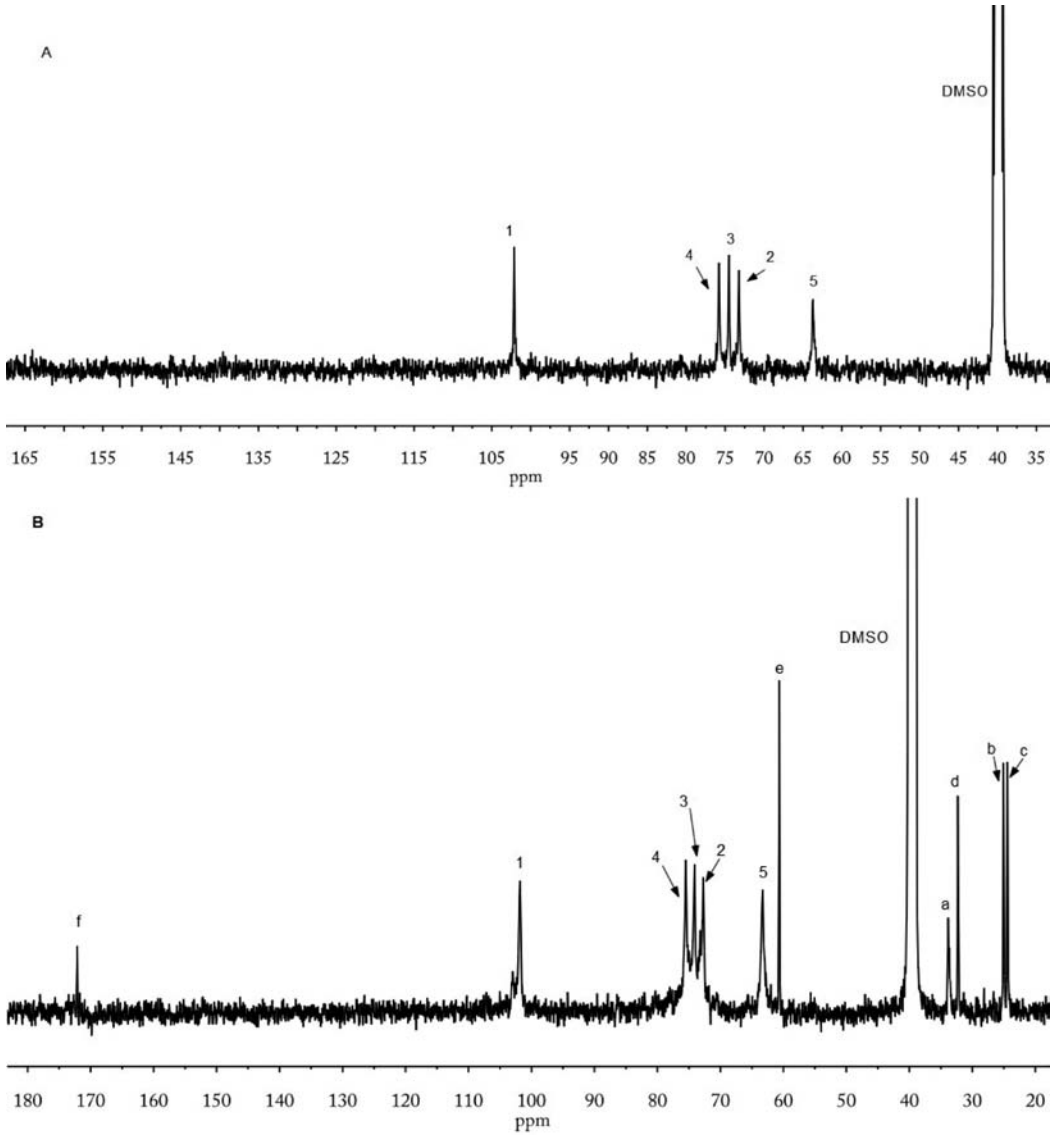

Figure 4. ^{13}C NMR spectra of unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B).

$$\mathrm{DS} = \frac{\text{terminal CL}}{\text{AXU}} = \frac{Ia/2}{I_{H_1}} \quad (1)$$

$$W_{\mathrm{PCL}} = \frac{114\mathrm{DS}}{132 + 114\mathrm{DS}} \times 100\% \quad (2)$$

where DS is the degree of substitution of PCL, W_{PCL} is the weight percent of PCL side chains, AXU is anhydroxylose unit, 114 g/mol is the molar mass of ε-CL, and 132 g/mol is the molar mass of an AXU.

As shown in Table 1, the data calculated from ^{1}H NMR confirmed the attachment of PCL onto xylan. However, the length of PCL side chains was only 1, which was less than that (2.29−3.05) attached onto cellulose in ionic liquid [Bmim]Cl.[18] The differences of the ROP reaction of ε-CL onto xylan and cellulose were probably due to the different chemistries of xylan and cellulose. Cellulose is a linear chain polymer with three reactive hydroxyls on each anhydroglucose unit (AGU), while xylan is heterpolysaccharide with two reactive hydroxyls on each AXU of the backbone and branched with different groups. Cellulose comparatively allows for slightly longer side chains than xylan, resulting in the high DP of PCL attached.

Figure 4 shows the ^{13}C NMR spectra of the unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B; DS of 0.39). The five major signals at 102.1, 75.8, 74.5, 73.2, and 63.7 ppm are attributed to C_1, C_4, C_3, C_2, and C_5, respectively, of AXU in xylan.[25] The signal at 172.1 ppm observed in spectrum B is assigned to the carbonyl group (f position in PCL), indicating the successful attachment of PCL onto xylan, corresponding to the results from FTIR analysis. Moreover, the signals at 33.7 ppm (a), 32.3 ppm (d), 25.0 ppm (b), 24.4 ppm (c), and 60.6 ppm (e) correspond to the methylene carbons of the attached PCL side chains,[18] suggesting that the ROP reaction of ε-CL onto xylan does occur in DMSO/LiCl.

Two-dimensional ^{1}H−^{13}C HSQC is a powerful tool for qualitative and quantitative analyses of chemical structures. It could provide more detailed information of signals overlapped in ^{1}H and ^{13}C NMR spectra. In the present study, unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B; DS of 0.39) were characterized with HSQC spectroscopy to better understand the xylan-*g*-PCL structure and further confirm the attachment of PCL on xylan. The HSQC spectra are illustrated in Figure 5 at a relatively low contour level to exhibit the primary

dx.doi.org/10.1021/jf4036047 | J. Agric. Food Chem. 2014, 62, 682−690

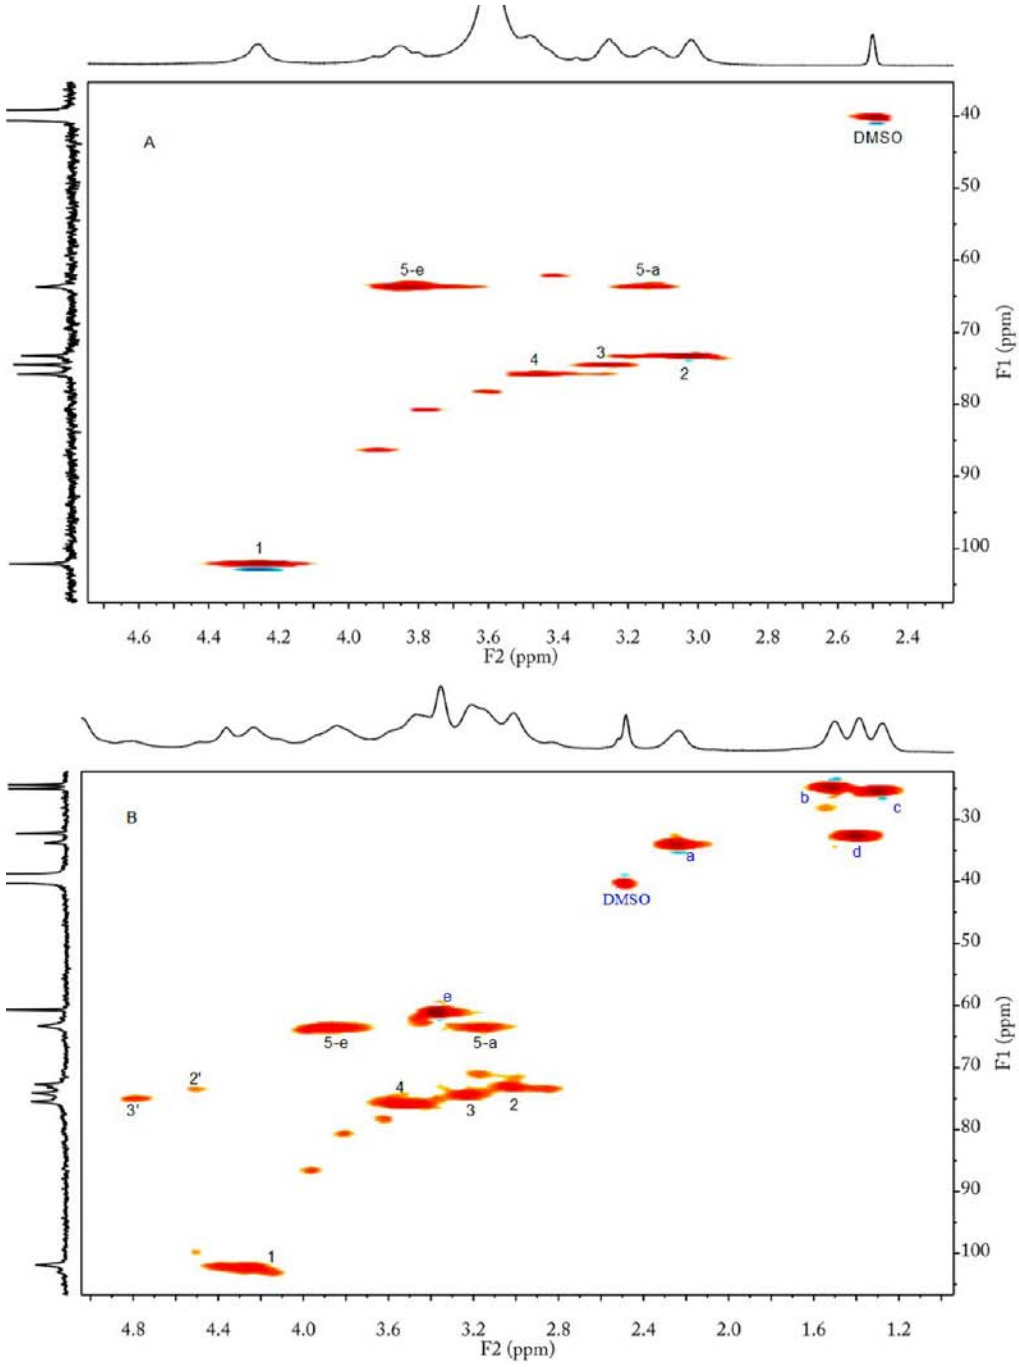

Figure 5. HSQC spectra of unmodified xylan (A) and xylan-*g*-PCL copolymer sample 9 (B).

signals, both substituted and unsubstituted. In spectrum A, the six strong correlations at δ_H/δ_C of 4.26/102.1, 3.02/73.2, 3.25/74.5, 3.48/75.8, 3.85/63.7, and 3.13/63.7 ppm are related to C_1-H_1, C_2-H_2, C_3-H_3, C_4-H_4, $C_{5e}-H_{5e}$, and $C_{5a}-H_{5a}$, respectively, in xylan. The weak correlations at δ_H/δ_C of 3.78/80.8, 3.60/78.3, 3.91/86.4, and 3.41/62.2 ppm are attributed to C_2-H_2, C_3-H_3, C_4-H_4, and C_5-H_5 in α-L-arabinofuranosyl residues.[26] Typically, methylene signals in the PCL side chain are shown in the aliphatic region as strong $^1H-^{13}C$ correlations. The strong correlations at δ_H/δ_C of 2.24/33.7, 1.50/25.0, 1.28/24.4, 1.38/32.3, and 3.36/60.6 ppm in spectrum B are assigned to the methylene group at a, b, c, d and e positions of PCL, respectively. The presence of these strong correlations indicated that the PCL side chains were successfully introduced into xylan. More importantly, the changes of the correlations belonging to the polysaccharides indicated the detailed ROP reaction on AXU. The strong signals, especially C_2 and C_3, indicated that most of xylan was unsubstituted, corresponding to the relatively low DS (0.39). The two important weak correlations at δ_H/δ_C of 4.49/73.6 and 4.79/75.0 ppm are due to substituted C_2 and C_3,[27] respectively, indicating that the attachment of PCL occurred at C_2 and C_3 positions of AXU. Clearly, more PCL side chains were attached to C_3 than to C_2. The resonances assigned to substituted and unsubstituted C_2 and C_3 were integrated to quantitatively compare the ROP reactivity of hydroxyl groups at C_2 and C_3 in DMSO/LiCl, and the results indicated that 69.23 and 30.77% of PCL side chains were attached to C_3 and C_2 positions of AXU, respectively.

dx.doi.org/10.1021/jf4036047 | J. Agric. Food Chem. 2014, 62, 682−690

In addition, the HSQC spectrum indicated that the proton signal at C_1 was not overlapped with other signals after the ROP reaction, whereas that at C_4 was overlapped with methylene at the e position from PCL, C_3 and C_5 from AXU, and C_3 from arabinofuranose. Similarly, the proton signal at the a position had less overlapped signals than other positions. Therefore, H_1 and methylene at the a position were selected as the typical proton signals in the DS calculation in the present study.

Thermal Analysis. The thermal properties of unmodified xylan and xylan-*g*-PCL copolymers were investigated using TGA and DTG, and the TGA/DTG curves are illustrated in Figure 6.

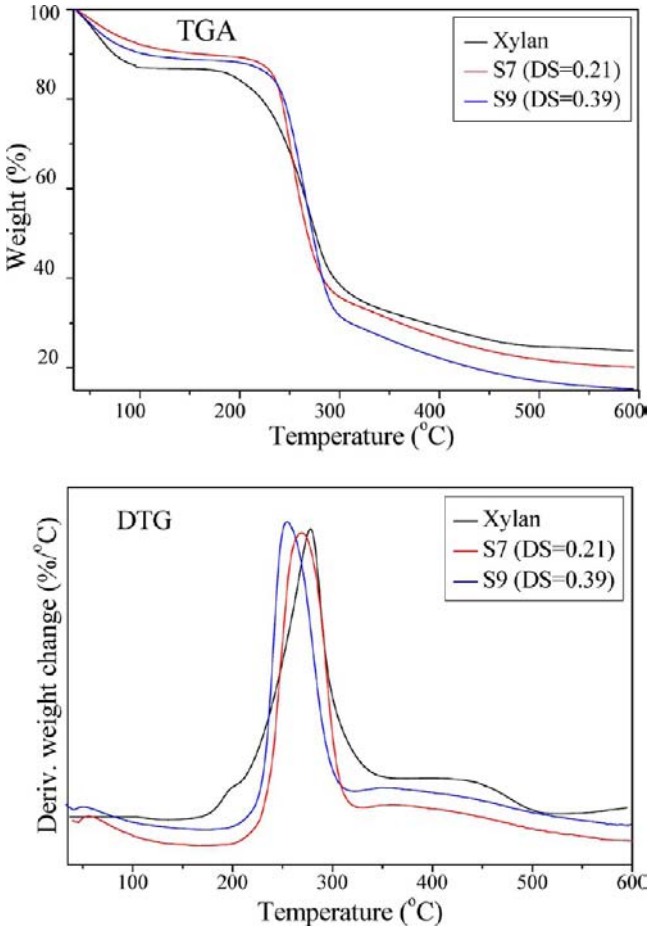

Figure 6. TGA/DTG curves of xylan and xylan-*g*-PCL copolymer samples 7 and 9.

In TGA curves, unmodified xylan began to decompose at 180 °C, while xylan-*g*-PCL copolymer samples 7 (DS of 0.17) and 9 (DS of 0.39) began to decompose at 220 and 235 °C, respectively. At 50% weight loss, the decomposition temperature occurred at 270 °C for unmodified xylan, 275 °C for sample 7, and 278 °C for sample 9. These data implied that the thermal stability of xylan increased after the ROP reaction in DMSO/LiCl. It is interesting that the pyrolysis residues at 600 °C for unmodified xylan and samples 7 and 9 were 28, 24, and 16%, respectively, indicating the decreased contents of inorganic salts in the samples after modification in DMSO/LiCl under the selected conditions, which was really different from that of cellulose regenerated from ionic liquids.[28] DTG means the degradation rate and can be used to compare the thermal stability between the samples.[29] In DTG curves, the small peak at about 185 °C in unmodified xylan disappeared after modification, indicating that the low-molecular-weight xylan was not recovered after the ROP reaction under the selected conditions, which was probably due to the high solubility of the dual-component system containing a strong polar aprotic solvent and Lewis base. The primary peak in DTG curves showed the maximum degradation rate at 270 °C for unmodified xylan, 260 °C for sample 7, and 255 °C for sample 9. These data suggested that the attachment of PCL onto xylan led to the decrease of thermal stability of xylan, especially with the increased DS of xylan-*g*-PCL copolymers, which implied that the increased thermal stability of xylan after modification was probably due to the loss of unrecovered low-molecular-weight fractions in xylan. The TGA/DTG curves of unmodified xylan and xylan-*g*-PCL copolymers indicated that the ROP reaction actually led to the reduction in thermal stability of xylan.

SEM and Physical Properties. The surface morphologies of unmodified xylan and the dried xylan-*g*-PCL copolymer samples 6 (DS of 0.04), 7 (DS of 0.17), 8 (DS of 0.23), and 9 (DS of 0.39) were examined by SEM, as shown in Figure 7. Unmodified xylan exhibited a rough and irregular surface with different sizes of agglomerates and blocks. The dissolution, modification, and regeneration of xylan destroyed the blocks, and the morphology of xylan-*g*-PCL copolymer samples changed from an irregular surface with blocks to relatively less rough surface. With the increased DS, the surface of the xylan derivatives gradually became regular and homogeneous, resulting in a more compact structure with decreased agglomerates, which was probably due to the attached PCL side chains on the xylan backbone. In addition, hemicelluloses from plant biomass are known to be non-film-forming polymers.[30] The rough and irregular surface with different sizes of agglomerates and blocks of unmodified xylan was probably responsible for the cracks and shrinkage during the failed film forming. Unexpectedly, the easily film-forming capability of xylan-*g*-PCL copolymers was found in comparison to that of unmodified xylan. The film from xylan-*g*-PCL copolymer sample 9 exhibited a flat and smooth surface. In addition, the film with a thickness ranging from 20 to 30 μm exhibited a relatively low tensile strength, and the stress strength, tensile strain, and elasticity modulus were 17.8 MPa, 5.33%, and 532.8 MPa, respectively.

In conclusion, the xylan-*g*-PCL copolymers were successfully prepared by the homogeneous ROP reaction in DMSO/LiCl under the given mild conditions. The dual-component system, containing a Lewis base LiCl and strong polar aprotic solvent DMSO, acted as a solvent, base, and catalyst for the ROP reaction. The results showed xylan-*g*-PCL copolymers with a low DS in the range of 0.03−0.39 were obtained under the given conditions. The FTIR and NMR characterization provided more evidence of the occurrence of the ROP reaction and the attachment of PCL side chains onto xylan. The results also indicated that only one ε-CL was confirmed to be attached onto xylan with each side chain. A total of 69.23 and 30.77% of PCL side chains were attached to C_3 and C_2 positions of AXU, respectively. Thermal analysis indicated that the attachment of PCL onto xylan led to the decreased thermal stability of xylan; however, the loss of unrecovered xylan fractions with a low molecular weight resulted in the increased thermal stability of the samples. The smooth surface of derivatived xylan was obtained with increased DS. Considering the good biodegradability of xylan and PCL, this kind of xylan derivative has potential application in environmentally friendly and biodegradable materials, such as edible food packaging film.

Treatment and Biotransformation of Highly Polluted Agro-industrial Wastewater from a Palm Oil Mill into Vermicompost Using Earthworms

Su Lin Lim,[†] Ta Yeong Wu,*[,†] and Charles Clarke[‡]

[†]Chemical Engineering Discipline, School of Engineering and [‡]School of Science, Monash University, Jalan Lagoon Selatan, Bandar Sunway, 46150, Selangor Darul Ehsan, Malaysia

ABSTRACT: In this laboratory-scale study, earthworms were introduced as biodegraders of palm oil mill effluent (POME), which is a wastewater produced from the wet process of palm oil milling. POME was absorbed into amendments (soil or rice straw) in different ratios as feedstocks for the earthworm, *Eudrilus eugeniae*. The presence of earthworms led to significant increases in pH, electrical conductivity, and nutrient content but decreases in the C/N ratio (0.687−75.8%), soluble chemical oxygen demand (19.7−87.9%), and volatile solids (0.687−52.7%). However, earthworm growth was reduced in all treatments by the end of the treatment process. Rice straw was a better amendment/absorbent relative to soil, with a higher nutrient content and greater reduction in soluble chemical oxygen demand with a lower C/N ratio in the vermicompost. Among all treatments investigated, the treatment with 1 part rice straw and 3 parts POME (w/v) (RS1:3) produced the best quality vermicompost with high nutritional status.

KEYWORDS: *cleaner production, rice straw, soil, wastewater treatment, organic fertilizer, Eudrilus eugeniae, palm oil mill effluent (POME), vermicomposting*

INTRODUCTION

Agro-industries play a major role in the global economy, especially in developing countries. Developing nations often rely on a combination of subsistence farming and formal and/or informal agro-industries for income generation, yet associated health risks and environmental pollution can have a great impact on these nations. Due to the unsafe disposal of untreated agro-industry wastes in the form of solid wastes or effluents, clean water supplies are polluted, productive potential is exhausted, and health risks around the region are gravely increased.

Malaysia is one of the leading global producers and exporters of palm oil. The Malaysian palm oil industry is growing rapidly and is quickly becoming a significant agricultural industry in this country. However, the production of large amounts of crude palm oil leads to the generation of a greater amount of agro-industrial wastewater or palm oil mill effluent (POME). The wet process of palm oil milling consumes a large amount of water. It is estimated that POME is generated at nearly 3 times the rate of crude palm oil.[1] In Malaysia, approximately 44 million tonnes of POME was generated during oil palm processing in 2008. As the Malaysian palm oil industry continues to grow, the amount of POME generated is expected to increase annually.[2] POME is a brown slurry, containing 95−96% water, 0.6−0.7% residual oil, and 4−5% solids (mainly organic). POME is characterized by a high biochemical oxygen demand (BOD) (25000 mg/L) and chemical oxygen demand (COD) (53630 mg/L) and contains 8370 mg/L oil and grease, 43635 mg/L total solids, 19020 mg/L suspended solids, and a high concentration of organic nitrogen.[3] One of the disposal options for POME is a ponding system, which is used by >85% of palm oil mills in Malaysia. This treatment method is proven to be economically viable, but it accumulates large amounts of sludge, causes uncontrollable release of greenhouse gases, and requires large areas of land. Furthermore, it was reported that this disposal option allows the lowest utilization of renewable resources.[2] Other conventional POME treatment processes are aerobic and anaerobic digestions, physiochemical treatments, and membrane treatments. However, biological processes such as aerobic and anaerobic digestion are inefficient ways to treat POME due to its colloidal nature (suspended solids), low pH, and high BOD and COD loadings.[3]

In many countries, waste management systems are undergoing changes due to the threat of global climate change and other environmental issues.[4] Waste management systems are also influenced by socio-economic, political, and environmental factors, including population growth, consumption patterns, and technological development of waste systems.[5] Recently, numerous studies have examined the "zero waste" concept. Waste treatment technologies such as composting give rise to opportunities for resource recovery and production of nutrient-rich organic fertilizer and soil conditioner from the waste.[6] Thus, vermicomposting could be used as an alternative treatment method for managing POME. In this process, earthworms and micro-organisms convert organic wastes into a useful product known as vermicompost.[7] Earthworms affect the soil biological activity through organic matter decomposition and nutrient mineralization. They are the important drivers for substrate conditioning, whereas microbes are responsible for the biochemical degradation of organic matter. Among all of the different species of earthworms, epigeic earthworms are the most suitable for the vermicomposting process. Epigeic earthworms

are litter dwellers and live in or near the soil surface. These species feed on decaying organic matter and have high reproduction rates. Examples of epigeic earthworms are *Eisenia fetida*, *Eisenia andrei*, *Eudrilus eugeniae*, and *Perionyx excavatus*.[8,9] Epigeic earthworms are also less susceptible to toxicity than endogeic or anecic earthworms.[10] In the reported study, *E. eugeniae* was used because it is able to decompose organic wastes rapidly and it is a suitable species for vermicomposting in tropical countries.[8] Compared to compost, vermicompost is produced in less time and has greater fertilizer value with a higher humus content and less phytotoxicity.[7] A study conducted by Coria-Cayupán et al.[11] showed that vermicompost application increased the yield of lettuce without significant loss in food nutritional value. Additionally, vermicompost can be used for soil remediation purposes, such as degradation of pesticides.[12] According to Hait and Tare,[13] vermicomposting is a cost-effective, energy-saving, and zero-discharge process. However, several factors such as moisture content, pH, temperature, and aeration need to be monitored closely during the vermicomposting process because earthworms are involved. The surrounding conditions need to be favorable for the earthworms to break down organic wastes.[9] Nevertheless, the utilization of earthworms to stabilize solid wastes has been well documented. Vermicomposting of wastes such as animal manure, sewage sludge, agricultural wastes, and industrial wastes showed that it is an efficient technology for waste management.[9,14] This process can also be performed at any scale, from small-scale household vermicomposting to community or pilot-scale vermicomposting.[9] Pilot-scale vermicomposting has been attempted on paper mill and dairy industry sludges and on pineapple wastes by Elvira et al.[15] and Mainoo et al.,[16] respectively. Both studies showed that the pilot-scale vermicomposting process is feasible. However, there were differences between the end products produced at the laboratory scale and the pilot scale. For example, Elvira et al. found that the pilot-scale trials yielded better quality vermicompost than the laboratory-scale trials.[15]

Thus far, no studies have been conducted on the vermicomposting of POME because vermicomposting is generally used in solid waste management. Wastewaters (for example, swine and urban wastewaters) are usually treated using a vermifiltration process, which is adapted from a traditional vermicomposting system.[17,18] However, the present study shows that it is possible to treat POME if it is mixed with an appropriate ratio of amendments, which act as absorbents of wastewater. In this study, rice straw and soil were used as amendments to achieve a conducive physical and chemical environment in which the earthworms could thrive. POME was absorbed into the amendments to produce a suitable solid feedstock for the growth and reproduction of the earthworms. The addition of amendments also improved the C/N ratio of the initial organic wastes, making the POME more suitable for decomposition by the earthworms.[19] Therefore, the aim of this study was to assess the potential of using *E. eugeniae* to treat and biotransform POME into organic fertilizer after absorption of wastewater into amendments.

MATERIALS AND METHODS

Epigeic Earthworms and Collection of Organic Waste. *E. eugeniae* worms were obtained from ESI Agrotech, Malaysia. Stock earthworms were cultured and developed in the laboratory under ambient temperature on partially decomposed papaya and cow dung. POME was obtained from Hulu Langat Palm Oil Mill, Selangor, Malaysia, and kept in the refrigerator (at 4 °C) before being used as a feedstock in vermicomposting. As mentioned earlier, rice straw and soil were used as amendments. The rice straw was obtained from a paddy field in Sekinchan, Selangor, Malaysia, and experimental soil was a locally mixed peat moss soil obtained from Peat Organic (M) Sdn Bhd, Selangor, Malaysia. The initial chemical characteristics of POME, rice straw, and soil are given in Table 1.

Table 1. Chemical Characteristics of POME, Rice Straw, and Soil (Means ± SD, n = 3)

parameter	POME	rice straw	soil
pH	4.51 ± 0.01	7.17 ± 0.03	4.65 ± 0.04

volatile solids (g/kg dry wt)		751.6 ± 13.5	806.8 ± 23.8
COD (mg/L)	65667 ± 1803		

Experimental Design. Rice straw or soil amendments (200 g) were mixed with POME in three different ratios, namely, 1:1, 1:2, and 1:3 w/v (amendment:POME) (Table 2). The initial chemical characteristics of all treatments are given in Table 3. The amendments with different volumes of POME were then placed in rectangular plastic containers (17 cm × 14 cm × 12 cm). A 1:4 (w/v) treatment ratio was not attempted because earthworm mortality was observed at the initial stage of vermicomposting. Furthermore, the POME was not absorbed fully into the amendments (especially soil) in the 1:4 (w/v) treatment. Control bins (without earthworms) were also set up for all ratios investigated. Waste mixtures were turned periodically for 2 weeks to eliminate anaerobic conditions and remove any volatile gases potentially toxic to earthworms.[20] After 2 weeks, 10 nonclitellate *E. eugeniae* (~0.60 g each) were selected from the stock culture and released into each experimental container. The experimental containers were kept in triplicate for each treatment. Periodic sprinkling with water maintained moisture content at approximately 75% throughout the vermicomposting process. Experimental containers were placed in a dark laboratory at a temperature of 25 ± 2 °C.

Table 2. Description of the Different Treatments Used for the Vermicomposting Experiment

treatment in w/v	treatment description
RS1:1	1 part rice straw:1 part POME
RS1:2	1 part rice straw:2 parts POME
RS1:3	1 part rice straw:3 parts POME
S1:1	1 part soil:1 part POME
S1:2	1 part soil:2 parts POME
S1:3	1 part soil:3 parts POME

The vermicomposting process was conducted for 6 weeks. In each experimental container, the changes in earthworm biomass were measured at the beginning and the end of vermicomposting process to reduce the stress on the earthworms due to changing environmental conditions.[21] Earthworms were hand-sorted and then washed with distilled water to remove any adhering materials from their bodies. The live weights of the earthworms were measured, and no correction for gut content was applied to any of the data.

Approximately 10 g of homogenized wet substrates (free from earthworms, hatchlings, and cocoons) was collected for analysis on the first and final days of vermicomposting. The samples were oven-dried at 60 °C for 48 h, ground in a blender, and stored in polythene bags (at 4 °C) for further chemical analysis.

[a]Mean value followed by different letters is statistically different (ANOVA; Tukey's test, $P < 0.05$). Statistical analysis was carried out separately for initial, vermicompost and control values.

Vermicompost Analysis. The electrical conductivity (EC) and pH of the vermicompost in 1:10 (w/v) aqueous solution (deionized water) were measured using digital conductivity and pH meters, respectively.[22] Total organic carbon (TOC) was determined using the partial oxidation method.[23] Total Kjeldahl nitrogen (TKN) was measured using the micro-Kjeldahl method.[24] Total calcium, magnesium, and potassium were measured with the ignition method using an atomic absorption spectrophotometer following sample digestion with concentrated H_2SO_4 and concentrated H_2O_2.[25] Total phosphorus was determined using the colorimetric method following sample digestion with concentrated HNO_3 and concentrated HCl.[26] The soluble COD (sCOD) was analyzed in 1:10 (w/v) aqueous solution using the reactor digestion method (Hach method 8000).[1] The volatile solids (VS) content (loss on ignition) was obtained by combusting the dried samples in a furnace at 550 °C for 2 h.[13] The microstructures of the vermicompost were determined using a variable-pressure scanning electron microscope (VP-SEM), Hitachi S3400N-II, from Japan.

Statistical Analysis. One-way ANOVA was used to analyze the differences within vermicomposting and control treatments. Tukey's b test was also performed to identify the homogeneous type of treatments for the various parameters. IBM SPSS Statistics (version 20) was used for data analysis. All results reported in this study are significant at the $P < 0.05$ level.

RESULTS AND DISCUSSION

sCOD and VS of Vermicompost. sCOD is an important indicator of wastewater organic load. More sCOD was removed in treatments inoculated with earthworms than in those without earthworms (controls) (Table 4). The results suggest that, by feeding on the solid fractions of the POME, earthworms were responsible for the removal of the organic load in wastewater.[17] Earthworms secrete gut enzymes that help to reduce the chemical compounds in wastewater that cannot be decomposed by microbes alone.[27] In fact, Zhao et al.[28] suggested that, with the help of microorganisms, earthworms could accelerate the decomposition of organic wastes by favoring the breakdown of excreted polysaccharides. There was also a significant difference in sCOD removal when different amendments were used. The ranges of sCOD removal for earthworm treatments amended with rice straw and soil were 56.9−87.9 and 19.7−27.1%, respectively. The higher percentages of sCOD removal in treatments amended with rice straw can be explained by the higher decomposition rate of organic matter by the earthworms and microorganisms.[17] Khwairakpam and Bhargava[22] reported that COD was reduced by 29−73% during vermicomposting of sewage sludge. In comparison, conventional POME treatment using aerobic and anaerobic digestion is usually able to reduce the COD of POME by >95%.[2] Although the vermicomposting process could not remove the same amount of COD as the conventional biological method, it managed to transform POME into an organic fertilizer for agricultural purposes (Table 5). The sCOD removal was highest in the RS1:3 treatment, which was statistically different from the other treatments ($P < 0.05$).

Figure 1 shows a linear relationship between sCOD and VS for treatments amended with rice straw and soil. The sCOD and VS of the initial feedstocks and final vermicomposts were represented well by linear equations, with R^2 values of 0.8826 and 0.7414 for treatments amended with rice straw and soil, respectively. As shown in Figure 1, the slope of the equation demonstrates large differences between the two amendments. The slope for treatments amended with soil was higher, as there was a minimal decrease in VS content relative to the treatments amended with rice straw during vermicomposting process. Similar to sCOD removal, higher VS reduction was observed in treatments amended with rice straw relative to those amended with soil. In general, more VS reduction was also observed in the vermicomposts relative to controls for all treatments (Table 4). The decrease in VS is an indication of decomposition, substrate mineralization, and compost maturity.[13] VS reduction in the vermicomposts in treatments amended with rice straw (44.4−52.7%) and soil (0.7−4.1%) was also statistically different ($P < 0.05$). Hait and Tare[29] also showed decreases in volatile solids in waste-activated sludge during the vermicomposting process. The higher rate of VS reduction in POME treatments amended with rice straw showed that the

[a]Mean values followed by different letters are statistically different for each parameter (ANOVA; Tukey's test, $P < 0.05$). Statistical analysis was carried out separately for vermicompost and control values.

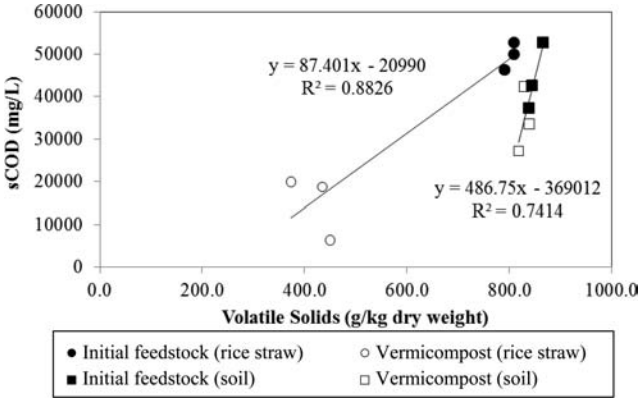

Figure 1. sCOD content (mg/L) against volatile solids (g/kg dry wt) of the treatments amended with rice straw and soil.

earthworms were consuming and breaking down these wastes at a much higher rate.[22]

pH of Vermicompost. The pH shifted toward alkaline conditions except in treatment S1:1, which showed no significant difference from the initial sampling (Tables 3 and 5). The shift in pH could be attributed to degradation of short-chain fatty acids and intensive mineralization of nitrogen by microbes.[25] A similar increase in pH was also observed by Shak et al.[30] and Tognetti et al.[31] Final pH ranged between 5.08 and 5.79 for treatments using soil as an amendment, but the final pH in the rice straw treatments ranged between 7.98 and 8.46. There was a significant difference between the rice straw and the soil treatments ($P < 0.05$). According to Singh and Suthar,[32] the difference in pH when different amendments were used was mainly due to variation in amendment quality, which affected the mineralization process and the intermediate species produced during the vermicomposting process.

Electrical Conductivity of Vermicompost. EC describes the soluble salt level in an organic amendment and is a good indicator of the applicability of vermicompost for agricultural purposes.[33] In this study, EC increased significantly in all vermicomposts. Control treatments also had higher final EC values, except in the RS1:1 treatment as compared to initial feedstocks (Tables 3 and 5). The loss of organic matter and release of minerals in the form of cations during vermicomposting are the main reasons for the EC increase.[20,34] Cations such as potassium, magnesium, and calcium are contributors to EC in vermicomposts,[35] which explains the higher EC in all treatments. The percentage of increase in EC also depends on the extent of organic matter mineralization under favorable experimental conditions.[29] The EC of the final vermicomposts did not exceed the threshold value of 3000 μS/cm, indicating that they can be safely applied as agronomic fertilizers.[33]

C/N Ratio of Vermicompost. The C/N ratio is used as an indicator of stabilization and mineralization of organic waste during the vermicomposting process.[36] The C/N ratio decreased for both the controls and the vermicomposts when POME was absorbed into rice straw. The treatments with earthworms showed a larger reduction in the C/N ratio relative to the treatments without earthworms (control) (Tables 3 and 5). Decreases in the C/N ratios in vermicomposts and controls using rice straw as an amendment ranged from 54.1 to 75.8% and from 35.6 to 55.4%, respectively. The greater reduction in the vermicompost C/N ratio relative to the control was due to the mineralization process caused by both the earthworms and microorganisms.[19] This is because earthworms release carbon as CO_2

during respiration and produce mucus and nitrogen excrements, thus increasing the nitrogen content.[37] Additionally, during a successful vermicomposting process, organic wastes are generally transformed into more stable, complex organic forms that resemble humic substances through the activity of microbial populations and earthworms.[9] However, there were no significant differences between initial and final products in the POME amended with soil treatment (Tables 3 and 5). Soil consumption rates are dependent on the earthworm species, the organic matter content of the feedstock, and the quality of the soil.[38] *E. eugeniae* is an epigeic earthworm that feeds on biodegradable waste; thus, *E. eugeniae* prefers fresh organic materials to soil.[9] Additionally, rice straw is rich in cellulose, which could increase the carbon mineralization rate during vermicomposting due to colonization by cellulose-decomposing fungi, contributing to the lower C/N ratio as compared to soil. The presence of earthworms is known to increase cellulolytic fungal populations and cellulase activity.[39] The lowest C/N ratio was observed in RS1:3 (9.64), followed by RS1:1 (11.34) and RS1:2 (16.37). There were no statistical differences between the treatments amended with rice straw. However, the C/N ratios were significantly different between the rice straw and soil amendments ($P < 0.05$). A final C/N ratio of approximately 10−15 is often taken as an indication of humic material formation and enhanced stability of treated organic wastes.[40] Thus, it is possible for the vermicomposts derived from rice straw and POME to be used as organic fertilizers.

Phosphorus, Potassium, Calcium, and Magnesium in Vermicompost. After 6 weeks of vermicomposting, all vermicomposts had higher phosphorus contents (43.7−308%), with the exception of the S1:2 treatment. Control treatments (except S1:1) also showed increases in phosphorus content, but the percentage increases were generally lower than those observed in vermicomposts (Tables 3 and 5). Similarly, there was a significant increase in potassium for all vermicomposts except in treatment of S1:3. Potassium content was highest in RS1:3 (21.35 g/kg) and lowest in S1:3 (5.38 g/kg) (Table 5). Higher percentage increases were observed in vermicomposts containing rice straw relative to those containing soil. The phosphorus and potassium contents in the rice straw and the soil treatments were statistically different ($P < 0.05$). Both Hait and Tare[29] and John Paul et al.[19] reported similar results during vermicomposting of waste-activated sludge and municipal solid waste, respectively.

Increases in calcium in the vermicomposts were observed in RS1:1 (342%), as well as RS1:3 (117%) and RS1:2 (77.6%) (Tables 3 and 5). A significant increase in calcium was also reported by other researchers using the earthworm *E. eugeniae* in a vermicomposting process.[22,41] However, the opposite was found in treatments using soil as an amendment, in which calcium increased more in the control relative to the vermicomposts. There are contradicting reports regarding the final calcium content obtained from different feedstocks. For example, Liu and Price[42] also reported a greater increase in calcium content for composts (30.8−171.4%) as compared to vermicomposts (10.3−53.8%) when spent coffee grounds were used as a feedstock. In contrast, Raphael and Velmourougane[41] reported a greater increase in calcium content in vermicomposts relative to composts with coffee pulp as a feedstock. The richness of organic wastes used is important in determining the final calcium level in vermicomposts.[43]

Magnesium content was higher in all vermicomposts and controls than in initial feedstocks, except S1:3 treatment for control. Generally, the increase in magnesium was more prominent in vermicomposts than controls (Tables 3 and 5). The maximum increase in magnesium content in vermicomposts occurred in the treatments RS1:1 (161%), RS1:3 (97.7%), RS1:2 (66.3%), S1:2 (63.7%), S1:1 (9.17%), and S1:3 (8.47%). Other researchers have reported an increase in magnesium content during the vermicomposting process. For example, Raphael and Velmourougane[41] reported an increase in magnesium (210%) during vermicomposting of coffee pulp amended with farmyard manure. Similarly, Liu and Price[42] reported a 50% increase in magnesium during vermicomposting of spent coffee grounds. Currently, there is no known contribution of earthworms to magnesium metabolism. Therefore, it is postulated that fungal and microalgal hyphae, which easily colonize freshly deposited earthworm casts, contribute to magnesium content in the vermicomposts.[43] Statistically, only treatment S1:1 was significantly different ($P < 0.05$) from the S1:2 treatment.

In general, the overall increase in nutrient contents (phosphorus, potassium, calcium, and magnesium) in the vermicompost can be explained by the reduction in weight of the feedstock material during the vermicomposting process.[21,44] According to Garg et al.,[34] the concentration effect was caused by the degradation of organic matter, which reduced the volume of feedstock due to the release of CO_2. In addition, the total nutrient contents in the vermicompost were generally higher than in the control, implying that the earthworms accelerated the decomposition of organic matter.

Earthworm Biomass. The biomass of earthworms in all treatments had decreased by the end of the vermicomposting process (Figure 2). There were no significant differences

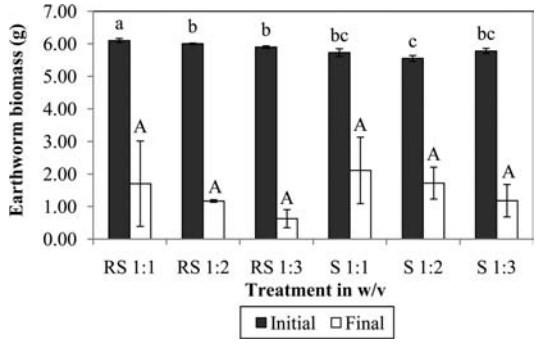

Figure 2. Initial and final earthworm biomass (g) of different treatments. Lower and uppper case letters indicate significant difference ($P < 0.05$) between initial and final earthworm biomass, respectively.

in total earthworm biomass among the different treatments ($P < 0.05$). The number of earthworms also decreased in all treatments. The highest sCOD removal rates (Table 4) and lowest C/N ratios in final vermicomposts (Table 5) were observed in the treatments amended with rice straw, indicating the possibility of food shortage after 6 weeks of the vermicomposting process. Food shortage caused the earthworms to lose weight, leading to the observed reduction in biomass and to earthworm fatality. Moreover, earthworms lost weight at a rate that depended on the quantity and nature of their indigestible substrates.[20] Degradation of the feedstock during vermicomposting could also result in environmental changes that would increase earthworm mortality. For example, a breakdown of polysaccharides could alter the structure of the feedstock, reducing the water retention capacity.[14] Additionally, Liu and Price[42] reported that high EC, low oxygen availability,

dx.doi.org/10.1021/jf404265f | J. Agric. Food Chem. 2014, 62, 691−698

and high levels of harmful organic compounds during vermicomposting were the reasons for poor earthworm survival rates. On the other hand, treatments amended with soil showed only a marginal reduction in sCOD and no significant decrease in the C/N ratio in final vermicomposts, indicating low organic matter ingestion rates by the earthworms. This was also corroborated by the higher levels of VS in treatments amended with soil. Thus, the decrease in earthworm biomass in treatments amended with soil was most likely due to the feedstock quality and its palatability.[38] In general, different amendments exhibit different chemical profiles that affect earthworm growth patterns differently. Therefore, the use of rice straw as an amendment provides a more conducive environment (i.e., easily metabolized organic matter and lower concentrations of growth-retarding substances for earthworms) relative to soil.[14] Shak et al.[30] also came to the conclusion that growth of *E. eugeniae* was closely associated with feed quality.

Physical Structure of Waste Mixture and Vermicompost. As a comparison of initial waste mixture (Figure 3a)

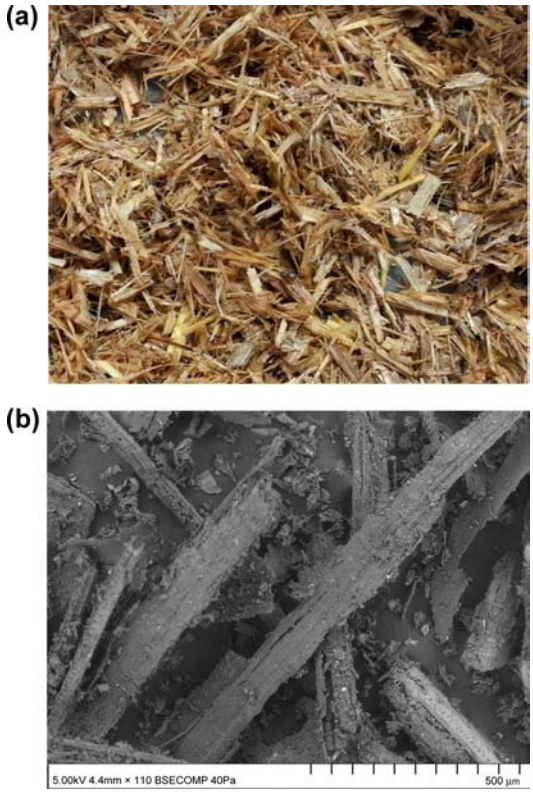

Figure 3. Photography (a) and scanning electron microscopy (b) images of waste mixture of RS1:3 treatment.

and the vermicompost obtained from RS1:3 (Figure 4a), the latter had finer granular structure and was darker in color. The vermicompost was also odorless after 6 weeks of vermicomposting. These observations were similar to those in previous studies conducted by Lim et al.[25] and Yadav and Garg.[45] However, some rice straw residues could still be observed in the final vermicompost (Figure 4a), suggesting that the initial waste mixture was not completely digested by the earthworms. Thus, the duration of the vermicomposting process could be extended to ensure complete biotransformation of rice straw into organic fertilizer.

Scanning electron microscopy (SEM) images of the initial waste mixture and final vermicompost in treatment RS 1:3

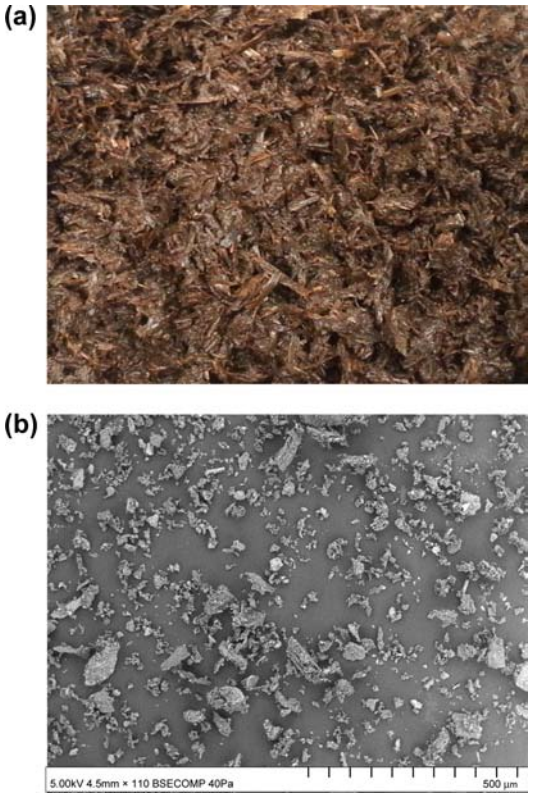

Figure 4. Photography (a) and scanning electron microscopy (b) images of vermicompost of RS1:3 treatment after 6 weeks of vermicomposting process.

are shown in Figures 3b and 4b, respectively. The SEM image revealed that the initial waste mixture was characterized by long fibers (Figure 3b). After the vermicomposting process, the vermicompost exhibited a distinct physical appearance that was more fragmented and porous (Figure 4b). The observations indicate that the long fibers of the rice straw present in the initial state were digested and fragmented by the earthworms, leading to a larger surface area in the vermicompost.[28]

Conclusions. This study demonstrates that vermicomposting enables the treatment and biotransformation of POME (and amendment) into mature organic fertilizer with higher nutrient contents than feedstock materials. Rice straw was proven to be a better absorbent for POME relative to soil because vermicomposts that were produced from the POME amended with rice straw had higher nutrient contents and sCOD removal rates but lower VS contents and C/N ratios. Among all of the waste mixtures, RS1:3 had the greatest reduction in sCOD (87.9%) and produced superior quality vermicompost with the lowest C/N ratio (9.64), but considerably high levels of phosphorus (6.29 g/kg), potassium (21.35 g/kg), calcium (24.25 g/kg), and magnesium (6.88 g/kg). The present results suggest that the vermicomposting process can be considered a viable waste treatment technology for POME that is amended with rice straw. This process utilized organic wastes to produce organic fertilizer or vermicompost, suitable for agronomic application. The vermicompost produced could also be used for soil remediation purposes.

Effect of Oxidation of Dietary Proteins with Performic Acid on True Ileal Amino Acid Digestibility As Determined in the Growing Rat

Shane M. Rutherfurd,* Carlos A. Montoya, and Paul J. Moughan

Riddet Institute, Massey University, Palmerston North, New Zealand

ABSTRACT: The study examined the impact of oxidation with performic acid on the true ileal amino acid digestibility (TIAAD) of seven dietary protein sources. TIAAD of both the unoxidized and oxidized protein sources was determined in the growing rat and compared. After oxidation, TIAAD was 30 and 58% higher across amino acids ($P < 0.001$) for the more poorly digestible protein sources, zein and blood meal respectively, 6−16% lower ($P < 0.05$) for the more highly digestible protein sources (casein, soy protein isolate, and beef muscle protein), and generally unchanged (<2% difference) for the more moderately digested protein sources (lactalbumin and gelatin). Overall, the change in TIAAD after oxidation was negatively correlated ($P < 0.001$, $r = -0.90$) with the TIAAD prior to oxidation, most likely as a result of the balance between two processes, protein denaturation resulting in increased digestion and indigestible limit peptide formation resulting in decreased digestion.

KEYWORDS: *performic acid, oxidation, digestibility, protein, ileal*

INTRODUCTION

During the processing or prolonged storage of foods, dietary nutrients are susceptible to oxidative damage. The oxidation of dietary lipids has been studied extensively, and protein oxidation in the context of age-related diseases has also received some attention.[1,2] However, oxidation as it pertains to dietary proteins has been largely ignored by the scientific community.[3] Several different oxidative reactions in proteins are believed to occur during food processing, which include the formation of carbonyl groups and the oxidation of thiol groups to sulfenic acids, sulfinic acids, and disulfides. As an example, it has been reported that in processed foods, even those that undergo relatively mild processing such as infant formulas, soy protein isolate (SPI), and egg white powder, between 23 and 64% of the methionine present may be oxidized to methionine sulfoxide or methionine sulfone.[4,5] In addition, cross-linking can also occur via the formation of disulfide bonds and dityrosine bonds[6,7] and reactions of the side chains of several amino acids (for example, lysine, histidine, methionine, and phenylalanine) with the products of lipid peroxidation.[8]

Studies on the oxidation of food proteins have largely focused on the presence of oxidized derivatives such as carbonyl, sulfhydryl, and dityrosine groups and the effect these derivatives have on protein functionality. However, given that it is well-known that the chemical modification of proteins during processing can greatly affect their subsequent digestion in the gastrointestinal tract (for example, the Maillard reaction with lysine)[9] and because dietary protein sources can be substantially oxidized during processing,[4−8] it is important to have an understanding of the impact of protein oxidative damage on protein digestion in the gastrointestinal tract. However, to date, little published work has focused on the impact of oxidation on the digestion of dietary proteins, and of those studies that have been published, all have used in vitro digestion models[10−13] where the in vitro digestion findings are often extrapolated to digestion in the gastrointestinal tract. However, given that in vitro digestion models are simplistic and provide only approximations of gastrointestinal digestion, such extrapolations must be viewed with caution. Ideally, the impact of oxidation on protein digestion should be evaluated using animal or human models. To the authors' knowledge, no such in vivo studies have been reported in the literature. Consequently, the aim of the present study was to conduct a preliminary examination of the impact of oxidation on the true ileal amino acid digestibility of dietary protein sources using both highly and poorly digestible dietary protein sources. To that end, performic acid was used to oxidize the proteins, and true ileal amino acid digestibility determined in the growing rat was used as a measure of the extent of digestion. True ileal amino acid digestibility is measured as the difference between the amino acid content of the diet and the amino acid content of digesta collected from the end of the small intestine (terminal ileum), corrected for the presence of endogenous amino acids (amino acids derived from nondietary proteins present in the gut lumen, for example, mucins, digestive enzymes, microbial protein). Performic acid is a powerful oxidizing agent and was used to allow investigation at the boundaries of the extent of oxidation likely to occur during food manufacture.

MATERIALS AND METHODS

Chemicals. Soy protein isolate (SPI, Supro 670) was obtained from Columbit NZ Ltd., Auckland, New Zealand, zein from Sigma-Aldrich Chemicals (St Louis, MO), gelatin (GB25 standard) from Gelita NZ Ltd., Christchurch, New Zealand, and blood meal from Denver Stockfeeds, Palmerston North, New Zealand. Casein and lactalbumin were obtained from Fonterra Group Ltd., New Zealand, and for beef muscle protein, lean ground beef was obtained from a

local supermarket. All of the original protein sources (unoxidized) were also ground and freeze-dried prior to inclusion in the diets. Vitamin and mineral mixes for the rat diets were obtained from Plant and Food Research Ltd., Palmerston North, New Zealand. Laboratory rats were obtained from the Small Animal Production Unit, Massey University, Palmerston North, New Zealand.

Oxidized Protein Sources and Diets. The unoxidized protein sources were used as controls. They contained no detectable methionine sulfone, methionine sulfoxide, or cysteic acid and underwent no form of oxidation treatment. The latter controls, which were effectively "untreated", were designated "unoxidized" protein sources. Each protein source was oxidized using performic acid.[14] Performic acid was prepared by adding one part hydrogen peroxide (30%) to nine parts formic acid (98%). The solution was then mixed and left at room temperature for 30 min before being cooled to 0 °C. Approximately 200 g of each protein source was incubated in 1.5 L of performic acid at 0 °C overnight. Hydrogen bromide (450 mL) was then very slowly added to the protein−performic acid mixture on ice to reduce the performic acid to formic acid. The pH of each protein solution was then slowly adjusted with sodium hydroxide until the protein precipitated. The precipitated protein was filtered and washed with water using a Buchner funnel to remove any residual formic acid. The washed precipitate was then freeze-dried and finely ground, ready for chemical analysis and incorporation into the experimental diets.

Fourteen semisynthetic powdered diets were formulated containing one of the seven protein sources (casein, SPI, beef muscle protein, gelatin, blood meal, lactalbumin, or zein) or their oxidized counterparts. Each experimental diet was formulated to contain 100 g/kg crude protein. The diets also contained 50 g/kg purified cellulose, 50 g/kg soybean oil, 100 g/kg sucrose, 50 g/kg vitamin mix, and 50 g/kg mineral mix. The vitamin and mineral mixes were proprietary mixes formulated to meet the requirements of the growing rat for vitamins and minerals in the final diets.[15] All diets met the nutritional requirements of the growing rat for all nutrients except protein.[15] Titanium dioxide (3 g/kg) was included in each diet as an indigestible marker. Wheat starch was used to make each diet up to its total weight of 1 kg.

Animal Trial. Ethics approval for the animal trial was obtained from the Animal Ethics Committee, Massey University, Palmerston North, New Zealand.

Two hundred and twenty-four Sprague−Dawley male rats (204 ± 1.3 g, mean ± standard error, body weight) were housed individually in stainless steel wire-bottom cages in a room maintained at 22 ± 2 °C, with a 12 h light/dark cycle. For the first 13 days of the trial, the rats received the diets containing the unoxidized protein sources only, such that there were 32 rats allocated to each unoxidized protein source. The rats were fed using a frequent (hourly) feeding regimen as described by Rutherfurd and Moughan,[16] and water was available at all times. On the final day of the study, the rats were reallocated to the diets such that half the rats in each treatment group (i.e., receiving one of the unoxidized protein sources during the first 13 days of the study) received the diet containing the corresponding oxidized protein source. The diets containing the oxidized protein sources were fed only on the final day as the amount of oxidized protein source material was limited. Approximately 5 h after the first meal, the rats were killed by asphyxiation with carbon dioxide gas followed by cervical dislocation and digesta carefully sampled from the terminal ileum as described by Rutherfurd and Moughan.[16] To ensure there was sufficient digesta material for all of the chemical analyses, digesta samples were pooled across randomly selected pairs of rats within each treatment group, to give eight samples each per oxidized and unoxidized protein source and then freeze-dried and stored at −20 °C ready for chemical analysis.

Chemical Analysis. The crude protein content of the unoxidized and oxidized protein sources was determined as the total nitrogen content multiplied by 6.25. Total nitrogen was determined using the Dumas method on a LECO analyzer (LECO Corp., St. Joseph, MI, USA).

Amino acid contents were determined as described by Rutherfurd et al.[17] Briefly, amino acids in the ileal digesta and diets were hydrolyzed using 6 M glass-distilled HCl containing 0.1% phenol for 24 h at 110 ± 2 °C in evacuated sealed tubes before undergoing C18 reversed-phase HPLC (Agilent 1200 HPLC system) with precolumn derivatization with *o*-phthalaldehyde and detection by fluorescence (excitation λ 338 nm; emission λ 450 nm). Norvaline was used as an internal standard. Tryptophan in the protein sources was determined by alkali hydrolysis (4.5 M NaOH containing 5% (w/v) of maltodextrin at 110 °C for 20 h), followed by neutralization and C18 reversed-phase HPLC on an Agilent 1100 HPLC system and detected using absorbance at 280 nm. For the tryptophan analysis, 5-methyltryptophan was used as an internal standard, and tryptophan concentration values were corrected for the recovery of the internal standard. Cysteine is most commonly determined as cysteic acid using amino acid analysis following performic acid oxidation. Therefore, bcause cysteic acid was present in the oxidized protein sources and would consequently interfere with the determination of cysteine in the corresponding diets and digesta, cysteine was not determined as part of the present study. When appropriate, the weight of each amino acid was calculated using free amino acid molecular weights.

The titanium dioxide content of the diets and digesta samples was determined following the method of Short et al.[18] Briefly, samples were ashed at 500 °C in a muffle furnace before being digested in 60% (v/v) sulfuric acid. The mixture was then incubated with 30% hydrogen peroxide and the absorbance read at 405 nm.

Data Analysis. Ileal amino acid flows were calculated using the following equation:

$$\begin{aligned}&\text{ileal amino acid flow (mg/kg dry matter intake (DMI))}\\&\quad=\text{ileal amino acid content (mg/kg DM)}\\&\qquad\times\frac{\text{diet titanium (mg/kg DM)}}{\text{ileal titanium (mg/kg DM)}}\end{aligned}\tag{1}$$

True ileal amino acid digestibility (TIAAD) was calculated using the following equation (units are mg/kg DMI):

$$\begin{aligned}\text{TIAAD (\%)}=[&\text{dietary AA intake}-(\text{ileal AA flow}\\&-\text{endogenous AA flow})]/\text{dietary AA intake}\times 100\end{aligned}\tag{2}$$

Endogenous AA flow is based on average endogenous amino acid flows for growing rats of a similar age and body weight as those used in the present work and as reported by Rutherfurd and Moughan[19] determined using the enzyme hydrolyzed protein (casein)/ultrafiltration method.[20,21]

The percentage difference in true ileal amino acid digestibility after oxidation was calculated as follows (units are %):

$$\begin{aligned}\text{difference (\%)}=\Big[&(\text{TIAAD}_{\text{oxidized protein source}}\\&-\text{TIAAD}_{\text{unoxidized protein source}})\\&/\text{TIAAD}_{\text{unoxidized protein source}}\Big]\times 100\end{aligned}\tag{3}$$

Statistical Analysis. The true ileal amino acid digestibilities of the unoxidized and oxidized protein sources were compared statistically using one-way ANOVA (GLM procedure)[22] for each protein source separately. The correlation between the percentage difference in true ileal amino acid digestibility before and after oxidation and the true ileal amino acid digestibility of the unoxidized protein sources was analyzed by simple correlation using the CORR procedure of SAS.[22]

RESULTS

The mean daily food intakes of the rats consuming the diets containing the unoxidized protein sources on the penultimate day of the study were 6.5 ± 0.15, 15.3 ± 0.61, 12.6 ± 0.62, 19.0 ± 0.65, 19.7 ± 0.36, 6.3 ± 0.65, and 9.7 ± 0.31 g for the rats receiving the zein-, SPI-, lactalbumin-, beef muscle protein-,

casein-, blood meal-, and gelatin-based basal diets, respectively. The mean daily weight gains of the rats over the last 7 days of the study were −0.5 ± 0.09, 2.6 ± 0.28, 5.9 ± 0.31, 4.5 ± 0.45, 4.2 ± 0.19, −0.1 ± 0.15, and −0.5 ± 0.12 g for the rats allocated to the zein-, SPI-, lactalbumin-, beef muscle protein-, casein-, blood meal-, and gelatin-based basal diets, respectively. One rat allocated to the oxidized blood meal-based diet died during the study, but all the remaining rats appeared to be healthy throughout the study. The rats fed the zein-, blood meal-, and gelatin-based diets lost weight over the last 7 days of the study, and this likely reflects the poor amino acid balance and relatively lower feed intake for the rats on the latter diets compared to the animals receiving the diets containing SPI, lactalbumin, beef muscle protein, or casein. Although it has been reported that feed intake can affect true ileal amino acid digestibility, at least in piglets,[23] the extent of the latter effect is reported to be small (<3% over a feed intake range of 30−60 g/kg bodyweight). Consequently, in light of the latter finding and also because the dietary treatments were compared only within protein source (oxidized vs unoxidized), any impact on true ileal amino acid digestibility due to the lower feed intakes for the rats receiving the unoxidized and oxidized zein-, blood meal-, and gelatin-based diets was deemed to be insignificant in the context of the present study.

The amino acid compositions of the unoxidized and oxidized protein sources are presented in Table 1. The main observation was that the concentrations of methionine, tyrosine, and tryptophan in the seven protein sources after performic acid treatment were 0−0.5, 0−0.7, and 0 g/kg protein, respectively, indicating that the latter amino acids were almost completely chemically modified. Given that performic acid is a powerful oxidizing agent, it was assumed that any reduction in the

[e]Mean true ileal amino acid digestibility across all examined amino acids.

amount of the determined amino acids present in the protein sources after performic acid treatment was due to the oxidation of those amino acids. Oxidation appeared to be incomplete for methionine in beef muscle protein (2.1% of the original methionine was present after oxidation) and for tyrosine in beef muscle protein, blood meal, lactalbumin, and zein (1.2−2.4% of the original tyrosine was present after oxidation). The recovery of histidine after performic acid oxidation was also low for beef muscle protein, gelatin, blood meal, lactalbumin, and zein with recoveries of 27, 65, 59, 31, and 13%, respectively. The recoveries of all of the remaining determined amino acids were virtually complete, suggesting that no modification of the latter amino acids occurred during performic acid oxidation, although it is possible that oxidized amino acids were present but that any altered amino acids reverted back to their parent form during HCl hydrolysis.

True ileal amino acid digestibility was determined for both the unoxidized and oxidized protein sources, and these data are presented in Tables 2−8. Digestibility values for glycine were omitted because the enzyme-hydrolyzed protein (casein)/ultrafiltration method used to determine endogenous ileal amino acids flows, which are in turn used to calculate true ileal amino acid digestibility, underestimates endogenous ileal flows for glycine because a significant amount of the endogenous glycine in the gastrointestinal tract is conjugated to bile salts, the latter of which are excluded from the endogenous protein fraction during ultrafiltration of the digesta.[16] For almost all of the amino acids examined in lactalbumin (Table 2) and gelatin (Table 3), histidine being the exception for gelatin and aspartic acid being the exception for lactalbumin, there was no difference ($P > 0.05$) between true ileal amino acid digestibility of the protein sources prior to and after treatment with performic acid. However, for the oxidized lactalbumin, the true ileal amino acid digestibility values obtained for one replicate were quite different from the others within the treatment group. The digestibility values for the latter replicate, which were not outliers based on the Grubb test and were therefore not excluded from the statistical analysis, may explain why large

mean digestibility[e]	92.6	78.0			

[a]Methionine, cysteine, tyrosine, and tryptophan were not included in the analysis because they were destroyed during the oxidation process. [b]Overall standard error of the unoxidized and oxidized beef muscle protein. [c]***, $P < 0.001$. [d]Difference was calculated according to eq 3. [e]Mean true ileal amino acid digestibility across all examined amino acids.

numerical differences observed between the true ileal amino acid digestibility for the unoxidized and oxidized lactalbumin were not statistically significant. For blood meal (Table 4) and zein (Table 5), true ileal amino acid digestibility was higher ($P > 0.05$) after treatment with performic acid for all of the amino acids for blood meal and for all of the amino acids except alanine and histidine for zein. For beef muscle protein (Table 6), SPI (Table 7), and casein (Table 8), true ileal amino acid digestibility was lower ($P > 0.001$) after treatment with performic acid for all of the amino acids examined, with the exception of serine for casein. Overall, treatment with performic acid led to an increase in the mean true ileal amino acid digestibility across amino acids of 63% for zein (Table 5) and 29% for blood meal (Table 4), a decrease in the mean true ileal amino acid digestibility across amino acids of 16% for beef muscle protein (Table 6), 15% for SPI (Table 7), and 6% for casein (Table 8) and had little effect on the mean true ileal amino acid digestibility of lactalbumin (Table 2) and gelatin (Table 3).

A correlation analysis was also conducted comparing true ileal amino acid digestibility prior to performic acid treatment and the percentage change in true ileal amino acid digestibility after performic acid treatment across the seven protein sources for each of the amino acids individually and across all amino acids collectively. A negative correlation ($P < 0.01$, $r = -0.90$ to -0.98) was observed for each of the amino acids individually and also for the amino acids collectively. True ileal amino acid digestibility prior to performic acid treatment and the percentage change in true ileal amino acid digestibility after performic acid treatment were plotted for all of the amino acids collectively, and a quadratic model fitted the data well ($P < 0.001$, adjusted $R^2 = 0.90$; Figure 1).

DISCUSSION

Performic acid is a powerful oxidizing agent and was chosen in the present study to provide conditions that would lead to extensive, but defined, modifications of selected amino acids, namely, cysteine, methionine, tyrosine, and tryptophan.[24] In the

presence of performic acid, cysteine is oxidized to cysteic aci [25] and any disulfide bonds present will be inevitably broken, which will in turn cause the affected proteins to unfold.[26] Methionine is quantitatively oxidized to methionine sulfone in the presence of performic acid,[25,27] tyrosine undergoes halogenation, and the indole ring of tryptophan is destroyed.[28] In the present study, the oxidation of methionine, tyrosine, and tryptophan was evaluated on the basis of the disappearance of the original amino acids after performic acid treatment rather than quantitation of the modified amino acids themselves. The negligible recoveries of methionine, tyrosine, and tryptophan after performic acid treatment, as determined using conventional amino acid analysis, suggest that the latter amino acids were almost completely modified. In addition, the poor recoveries of histidine suggest that this amino acid also was modified, at least to some degree. The concentrations of cysteine in the unoxidized and oxidized protein sources were not determined because cysteine is commonly determined following performic acid oxidation of the protein, and any unoxidized cysteine oxidized to cysteic acid as part of the amino acid analysis procedure would not be distinguishable from cysteic acid present due to the original performic acid treatment used to chemically modify the dietary protein sources. However, given that cysteine is particularly sensitive to oxidation, it is likely that performic acid treatment would have resulted in the complete oxidation of cysteine to cysteic acid in the oxidized protein sources.[29]

The protein sources used in the present study were chosen to represent both poorly and highly digestible protein sources. Zein and blood meal were poorly digestible (mean digestibility across amino acids was 53 and 65% for zein and blood meal, respectively), lactalbumin and gelatin were digested to an intermediate degree (mean digestibility across amino acids was 85 and 88% for lactalbumin and gelatin, respectively), and casein, beef muscle protein, and SPI were the most digestible proteins (mean digestibility across amino acids ranged from 92

dx.doi.org/10.1021/jf403146u | J. Agric. Food Chem. 2014, 62, 699−707

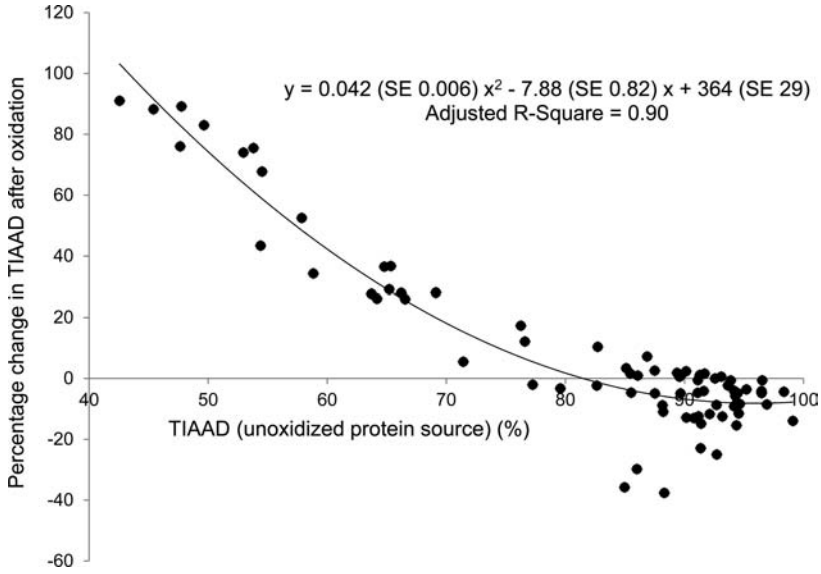

Figure 1. Relationship between the true ileal amino acid digestibility (TIAAD) of the seven protein sources prior to oxidation and the percentage change in TIAAD after oxidation. Methionine, cysteine, tyrosine, tryptophan, and histidine were not included in the analysis because they were destroyed (or partially destroyed in the case of histidine) during the oxidation process. Percentage change (%) was calculated according to eq 3. The differences within individual amino acids for each protein source are presented in Tables 2−8.

to 93% for the latter three protein sources). Interestingly, for the poorly digested protein sources, performic acid treatment led to a quantitatively large increase in the overall true ileal amino acid digestibility, whereas for the moderately digested proteins performic acid treatment had little impact on true ileal amino acid digestibility and for the highly digested protein sources true ileal amino acid digestibility generally decreased after performic acid treatment.

The rate and extent to which dietary proteins are digested in the gastrointestinal tract are dependent on many factors including the structure of the dietary protein, the presence of antinutritional factors, digesta viscosity, and enzyme to substrate ratio within the gastrointestinal tract. In the context of the present study protein structure is likely to have had the greatest impact on the extent of protein digestion. Proteins possess primary (the amino acid sequence), secondary (α-helix and β-sheet), and tertiary (the three-dimensional folding of the protein chain) structures, all of which can affect the efficacy of proteases in the digestive tract. Given the range of cleavage site specificities of the proteases in the gastrointestinal tract, it is expected that primary structure would have only a relatively minor influence on the overall extent of protein digestion in the small intestine. In contrast, the presence of secondary and tertiary structures in dietary proteins may be of greater significance for digestion. Deshpande and Damodaran[30] demonstrated that by changing the tertiary structure, but not the secondary structure, using heat treatment, the in vitro digestion of phaseolin was markedly increased. Samadi et al.[31] reported a strong correlation between the ratio of α-helix to β-sheet structures in heated canola meal proteins and the digestion of protein in the bovine rumen and intestine. Moreover, Carbonaro et al.[32] reported a strong inverse correlation between in vitro digestibility and the relative amount of β-sheets across a range of unprocessed and processed protein-containing foods. The latter workers suggested that the β-sheet structure present in the unprocessed foods and the intermolecular β-sheet aggregates induced by processing negatively affected digestibility and indeed were major factors in this regard.

In the present study, the performic acid oxidation would be expected to denature the proteins, leading to an increase in the digestibility of the protein source overall. However, for highly digestible proteins such as those present in casein and SPI, any increase in digestibility due to denaturation will be small. While for poorly digested proteins, the increase in digestibility will be much greater. In the present study, performic acid oxidation led to a marked increase in the true ileal amino acid digestibility of zein and blood meal, both of which were poorly digested prior to oxidation.

The proteolytic endopeptidases such as pepsin, trypsin, and chymotrypsin do not cleave proteins at random but rather cleave peptides adjacent to specific amino acids. For example, pepsin has a preference for large uncharged residues, whereas trypsin is specific for arginine and lysine and chymotrypsin has a preference for hydrophobic, preferably aromatic, residues.[33] When amino acids within a protein source are chemically modified, proteases present in the gastrointestinal tract are often less effective, leading to the presence of relatively large indigestible peptides (limit peptides) at the terminal ileum, which would in turn lead to lower true ileal amino acid digestibility.[34]

Although denaturation of the dietary proteins may explain the increase in true ileal amino acid digestibility for zein and blood meal, it does not explain the decrease in the true ileal amino acid digestibility of casein, SPI, and beef muscle protein. Conversely, although the formation of limit peptides may explain the decrease in the true ileal amino acid digestibility of casein, SPI, and beef muscle protein, it does not explain the increase in true ileal amino acid digestibility for zein and blood meal. Consequently, it is hypothesized that the change in true ileal amino acid digestibility of the dietary protein sources after performic acid oxidation observed in the present study was due to the relative contribution of the two opposing processes: (1) increased digestion due to the denaturation of the proteins and (2) decreased digestibility due to the formation of indigestible

limit peptides. It is hypothesized that denaturation was the predominant factor for zein and blood meal and that the presence of limit peptides was the predominant factor for casein, SPI, and beef muscle protein. For lactalbumin and gelatin, it is conjectured that the relative contributions of the two opposing factors were similar. Although the analysis of digesta material for the presence of limit peptides can be carried out using LC-MS, the latter analysis is not trivial and therefore was not done as part of this preliminary study. However, more work in this area is warranted.

It is also possible that oxidation of the dietary protein sources affected the endogenous protein secretion into the gastrointestinal tract, which could in turn affect the determination of true ileal amino acid digestibility given that endogenous ileal amino acid flows were used to correct apparent ileal amino acid digestibility values to true values. However, in the present study, modulation of the endogenous ileal amino acid flows due to alimentation with oxidized versus unoxidized protein sources did not appear to be a factor. The evidence for this is given below. Zein contains negligible amounts of lysine and tryptophan, and as such the total ileal flows of the latter two amino acids for the rats given the unoxidized and oxidized zein-based diets were equivalent to endogenous ileal flows. The endogenous ileal lysine and tryptophan flows were not different ($P > 0.05$) between the unoxidized and oxidized zein (313 ± 30.1 and 327 ± 35.1 mg/kg DMI for lysine in the unoxidized and oxidized zein, respectively, and 171 ± 16.7 and 203 ± 13.4 mg/kg DMI for tryptophan in the unoxidized and oxidized zein, respectively). Similarly for gelatin, which is almost completely devoid of tryptophan, the endogenous ileal tryptophan flows were not different between the unoxidized (321 ± 15.6 mg/kg DMI) and oxidized (299 ± 19.7 mg/kg DMI) gelatins.

The present study represents a preliminary investigation into the impact of oxidation of proteins on protein digestion using an in vivo (rat) model. Only the net effects of oxidation on true ileal amino acid digestibility were examined, and as a result the mechanisms by which performic acid oxidation altered protein digestion can only be surmised. Nevertheless, the results suggest that protein oxidation affected protein digestion in the gastrointestinal tract, possibly by more than one mechanism, most likely (1) denaturation of the protein and (2) formation of limit peptides, and that the overall effect of oxidation on digestibility as a whole is a result of the balance of these individual effects. The study provides insights as to how oxidation affects the digestion of proteins in the gastrointestinal tract, and further studies elucidating the structural changes that take place in proteins in relation to true ileal amino acid digestibility and using oxidation conditions relevant to those used for the processing of food proteins are warranted.

Supporting Information

ABSTRACT: This study aimed to determine differences among wheat cultivars in the distribution and speciation of Fe and Zn in grain milling fractions. Cultivars with higher Fe and Zn concentrations in the wholemeal flour were found to contain higher concentrations in the white flour. Soluble Fe and Zn were extracted and analyzed by size exclusion−inductively coupled plasma mass spectrometry. Fe speciation varied between milling fractions with a low molecular weight (LMW) complex likely to be Fe−deoxymugenic acid/nicotianamine being the predominant extractable Fe species in white flour, accounting for approximately 85% of the extractable Fe. Bran fractions had a lower amount of LMW-Fe form but more as soluble Fe−phytate and an unidentified high molecular weight peak. In the white flour fraction soluble Zn was found to be present mainly as a LMW peak likely to be Zn−nicotianamine complex. Soluble Fe−phytate was found in the white flour fraction of a high-Fe cultivar but not in a low-Fe cultivar.

KEYWORDS: *wheat, iron, zinc, speciation, phytic acid, nicotianamine, deoxymugenic acid*

INTRODUCTION

Iron (Fe) and zinc (Zn) deficiencies are associated with increased mortality and morbidity. Populations in developing countries are at a disproportional risk, in part due to a greater reliance on less nutrient dense foods such as cereals.[1] One proposed approach to reducing Fe and Zn deficiencies is through biofortification, including the breeding of cereals with higher concentrations of Fe and Zn.[2,3] However, essential minerals are under tight homeostatic control within the grain as they are required at an adequate level for germination without causing toxicity.[4] Therefore, a greater understanding of how Fe and Zn are distributed within the grain is required.

The majority of wheat products consumed in the diet are produced after milling of the grain to yield white flour. This consists almost entirely of the starchy endosperm, while the bran, which contains the aleurone layer, embryo, and outer layers of the grain (pericarp and testa), is largely discarded.[5] However, the concentrations of Fe and Zn in the endosperm are much lower than those in the bran.[6] It is therefore important that biofortification strategies also consider the localization of minerals within the grain if the end products are to have increased nutritional benefits.

Variation in the concentrations of total Fe and Zn in whole grain of wheat genotypes has been widely reported. For example, a recent study of 130 cultivars grown on the same site showed that the concentrations of Fe and Zn ranged from 28 to 51 and from 13 to 35 mg/kg, respectively.[7] Other studies have shown even greater variation; analyses of lines grown in France showed variation of 19−58 and 14−35 mg/kg for Fe and Zn, respectively,[8] while in Asian wheat varieties the concentration of Fe ranged from 23 to 49 mg/kg [9] and of Zn from 25 to 56 mg/kg.[10] Variation from 4 to 16 mg/kg of Fe and from 5 to 16 mg/kg of Zn has also been reported for white flour of Chinese wheat cultivars.[11] Although this range of genotypic variation is encouraging from a plant breeding perspective, it is not clear whether the variation is consistent between different fractions of the grain and, in particular, whether the variation reported for whole grain is reflected in white flour from the same genotypes.

In addition to concentration and localization, the speciation of Fe and Zn is also an important factor in determining grain nutritional quality. Fe and Zn are present in plants as various chemical species, which may vary in their bioavailability. The nonprotein amino acid nicotianamine [2(*S*),3′(*S*),3″(*S*)-*N*-[*N*-(3-amino-3-carboxypropyl)-3-amino-3-carboxypropyl]-azetidine-2-carboxylic acid, NA] complexes both Fe and Zn [12] and is involved in the transport of these minerals via the phloem and subsequent loading into the seed, as well as in the detoxification of free minerals.[13] Recently 2′-deoxymugineic acid (DMA), which is biosynthesized from NA, has also been shown to play a role in the phloem transport of Fe and is thought to be the predominant Fe chelator in the phloem sap of rice.[14,15] Complexes of Fe and Zn with NA and DMA are present in rice grain,[15] especially in the transgenic lines overexpressing NA synthase (NAS) genes,[16] indicating that

they may also play a role in Fe and Zn storage. Elevated levels of NA in rice seed have also been shown to improve Fe and Zn bioavailability using both mouse and Caco-2 cell models.[12,17,18] However, to date there is no report of NA- or DMA-bound Fe or Zn in wheat grain.

Most of the Fe, Zn, and other minerals in cereal grain are complexed by phytic acid [inositol hexakisphosphate (IP_6)], resulting in salts known as phytates, which may be insoluble or soluble depending on the degree of metal bonding to phosphate groups.[19,20] However, it has recently been reported that Zn may not be complexed by phytate in barley embryos and is instead associated with S (as a proxy for thiol groups) and therefore likely to be bound to proteins.[21] There is also evidence that some of the soluble Fe in cereal grains is bound to inositol pentaphosphate (IP_5), a partially dephosphorylated soluble form of IP_6.[21,22] Since nonruminant animals (including humans) lack phytases, minerals complexed with IP_6 are unavailable for uptake.[23] Phytate has therefore been regarded as an "anti-nutrient". However, soluble forms of phytate-complexed Fe such as monoferric phytate (Fe−IP_6) and Fe−IP_5 have been suggested to have some degree of bioavailability.[19,22] By contrast, Zn bound to phytates is thought to be insoluble, being made up of heterometal salts and/or Zn_5IP_6 and therefore not bioavailable.[20]

Identifying and quantifying Fe and Zn species in cereals remains a technical challenge. Size-exclusion chromatography coupled with inductively coupled plasma mass spectrometry (SEC−ICP-MS) has been used to identify a soluble form of Fe complexed with phytate in barley embryos [21] and Fe and Zn complexed with NA and/or DMA in rice endosperm.[12,18] The presence of NA−Zn and DMA−Zn complexes in the low molecular weight (LMW) peak eluded from SEC was further confirmed by electrospray ionization mass spectrometry.[18] However, little is known about Fe and Zn speciation within wheat grain. The objective of this study was therefore to determine genotypic differences in the total concentrations and speciation of extractable Fe and Zn in different milling fractions of wheat, particularly white flour.

MATERIALS AND METHODS

Grain Materials. Analyses were initially performed on grain samples of six wheat cultivars selected on the basis of previous results which showed high Fe concentrations in three cultivars (Rialto, San Pastore, Tiger) and low Fe concentrations in the other three cultivars (Crousty, Rialto, Riband).[7] The six cultivars were grown at three European sites (Martonvásár, Hungary; Saxham, UK; Choryn, Poland) in 2007, as described by Shewry et al.[24] Climate and soil conditions of all three sites are reported by Shewry et al.[24] Grain samples from replicated plots at each site were pooled for each cultivar, giving rise to a total of 18 grain samples (6 cultivars grown at 3 sites). In addition, Rialto (a high-Fe cultivar) and Riband (a low-Fe cultivar) were grown in a field trial on a farm of Rothamsted Research, U.K., in 2010, in three replicated plots (1.8 × 10 m) in a completely randomized block design. Standard farm practices and fertilization (176 kg N/ha split into two applications) were followed. All grain samples were stored in a cold room at 4 °C prior to analysis.

Milling. Grain was dried at ambient temperature and the water content was raised to 15% before milling. Wholemeal samples were produced using a Perten Laboratory Mill 3100 (Des Plaines, IL) (with 0.5 mm sieve). White flour and bran fractions were prepared using a Brabender Quadrumat Junior Mill (Duisburg, Germany). The flour samples from the Brabender mill were sieved (150 μm mesh) to remove contaminating bran. Grain from the replicated field plots of Riband and Rialto was combined and 2.5 kg sample each was milled using a Bühler MLU-202 mill (Urzwil, Switzerland) to produce 10 milling fractions. These comprised six white flour fractions: three breaks (B1−B3) which are obtained sequentially and three reductions (R1−R3). These vary in purity, with the first break (B1) and reduction (R1) corresponding to the purest starchy endosperm tissue and the third break (B3) and reduction (R3) the least pure. The remaining four fractions are the bran fractions, which are then separated into offal flour, bran flour, coarse offal, and coarse bran.

Total Mineral Analysis. Mineral concentrations were determined using inductively coupled plasma optical emission spectrometry (ICP-OES, Perkin-Elmer Optima 7500 DV, Waltham, MA). A 500 mg portion (oven-dried at 80 °C for 4 h) of each sample was digested in ultrapure HNO_3 and $HClO_4$ (87:13% v/v) in triplicate using digestion blocks (200 °C, 12 h) (Eurotherm MBB151, Durrington, UK). Working conditions for ICP-OES wereas follows: RF power 1.5 kW, auxilary gas (Ar) flow rate 0.2 L/min, carrier gas (Ar) flow 0.85 L/min. Blank and certified reference materials (CRM, BCR-189, wheat wholemeal flour and NIST1568a, rice flour) were included in each batch of analyses, and the values for the CRM were within <5% of the certified values for Fe and Zn. Signal drift was corrected by measuring a standard solution every 10−20 samples.

Extraction of Soluble Fe and Zn. All samples were extracted in a Tris-HCl buffer solution as described by Persson et al.[21] with some modifications. Preliminary experiments showed that grinding with quartz sand using a pestle and mortar, as reported by Persson et al.,[21] released contaminating Fe which bound to the samples; therefore, the grinding step was omitted in our study. To enhance extraction a longer extraction at an elevated temperature was used (18 h, 37 °C). This longer extraction was used because preliminary tests showed a higher extraction rate for Fe and Zn in endosperm compared with the 1 h extraction used by Persson et al.[21] However, it is possible that this longer extraction could result in a higher degree of digestion of phytate by phytase activity in the aleurone layer. Briefly, 140 mg of flour fractions or 70 mg of bran fractions was extracted with 7 mL of Tris-HCl buffer (50 mM, pH 7.5) in sterile vials with gentle shaking (120 rpm). Samples were then centrifuged (21 000*g*, 10 min) to remove the solid phase before being filtered through 0.2 μm sterile filters (Minisart). Total concentrations of Fe and Zn in the extracts were determined using inductively coupled plasma mass spectrometry (ICP-MS; Agilent 7500ce, Agilent Technologies, Palo Alto, CA) with the following conditions: RF power 1.5 kW, carrier gas 0.85 L/min, nebulizer pump speed 0.2 L/min, H_2 gas 6 mL/min. All samples were measured with three technical replicates. A standard of 10 μg/L Fe and Zn and a blank were used to monitor signal stability.

Iron and Zinc Speciation. All analyses were performed on an HPLC (Agilent 1100 Series, Agilent Technologies, Waltham, MA) coupled to ICP-MS (Agilent 7500ce, Agilent Technologies, Waltham, MA). A Superdex 75 10/300 GL size exclusion column (glass, 10 × 300 mm, 13 μm cross-linked agarose/dextran, Amersham Biosciences) was used with an optimum separation range between 0.7 and 70 kDa. The mobile phase was Tris-HCl buffer (50 mM, pH 7.5), pumped through the column isocratically at 0.47 mL/min at a controlled temperature of 18 °C. The sample injection volume was 100 μL. After HPLC molecular size exclusion separation, the solution was measured sequentially by a UV detector at the wavelength of 214 nm and then by ICP-MS. ICP-MS was set up with the following conditions: RF power 1.5 kW, carrier gas 0.85 L/min, nebulizer pump speed 0.2 L/min, and collision/reaction gas H_2 3 mL/min and He 2 mL/min. Due to the low levels of Fe in the white flour samples the analyses were performed on ^{56}Fe, which is the most abundant isotope (91.8 atom %). H_2 and He were used as the collision/reaction gas as this prevented any polyatomic inference on this isotope. Molecular size calibration was achieved using a range of standard compounds varying in molecular size, including apoprotein (6.6 kDa), cytochrome *c* (12.4 kDa), vitamin B_{12} (1.35 kDa), triglycine (0.19 kDa), and glycine (0.075 kDa) (all from Sigma-Aldrich). The UV absorption was first measured. For cytochrome *c* and vitamin B_{12}, Fe and Co, respectively, were also measured by ICP-MS following UV detection. The delay in the retention time from the UV absorption peak to the ICP-MS signal peak was 0.6 min. A log−linear regression curve was derived from the plot of molecular size versus retention time (based on the ICP-MS

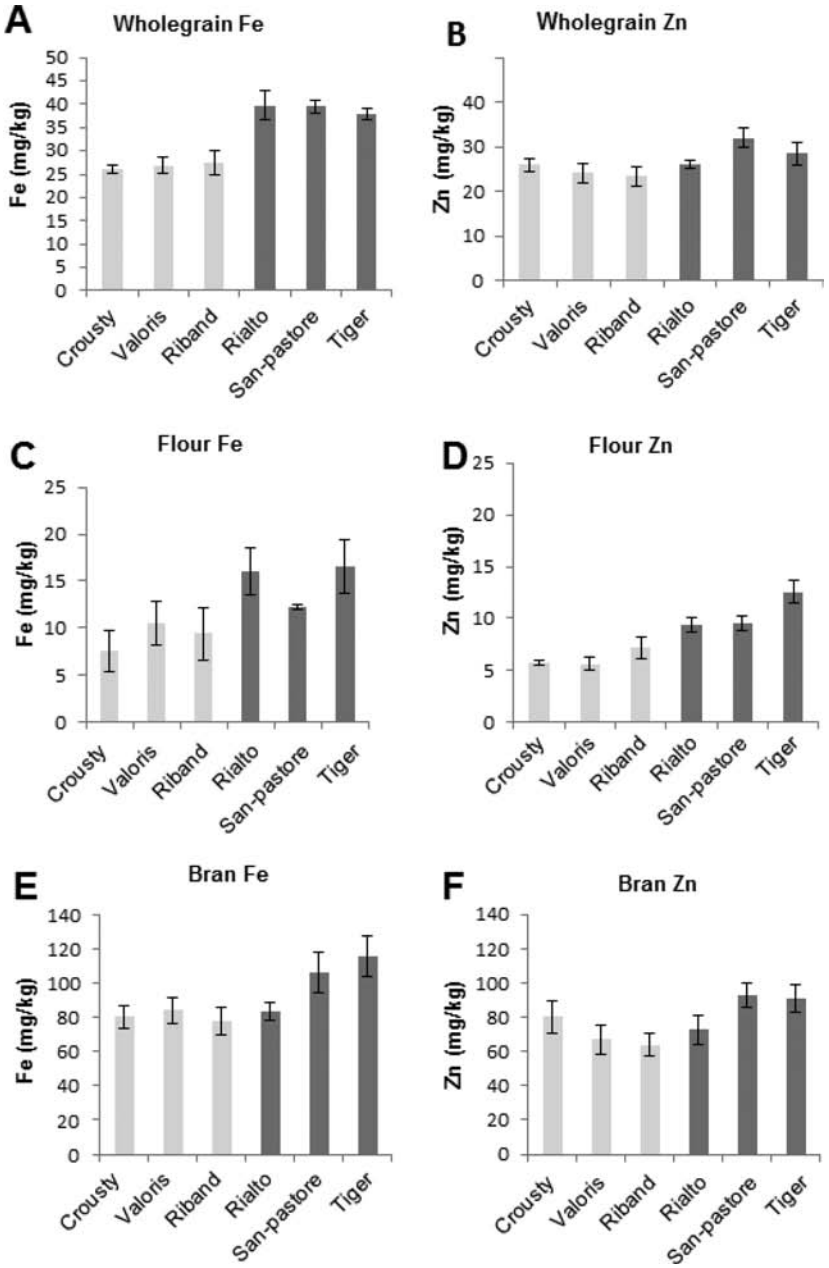

Figure 1. The concentrations of Fe and Zn in wholemeal, bran and white flour fractions of six wheat cultivars. Data are means (mg/kg dm ± SE) of materials grown in field trials at three sites (Hungary, Poland, UK) in 2007.

signal peak). A 100 μL aliquot of 20 mM EDTA/50 mM Tris-HCl buffer (pH 7.5) was injected between flour samples to remove residual metals adsorbed to the column. This wash was repeated twice after bran fractions due to the higher levels of Fe and Zn in the samples. A more thorough wash with 100 μL of pepsin (1 mg/mL), phytase (2 mg/mL), NaCl (0.5 M), and acetic acid (10%) (all from Sigma-Aldrich), at a flow rate of 0.2 mL/min at 36 °C, was performed between batches of samples. Finally, 10 mM EDTA/50 mM Tris-HCl buffer (pH 7.5) was run through the column for 40 min each day to remove any residual metals retained by the column. All speciation analysis was performed within 6 months of milling, as longer term storage may have an effect on phytate levels and therefore speciation.[23]

Ash Content. Ash contents of milling fractions were determined using the AACC-approved Method 08-12.[25]

Phytic Acid Content. Phytic acid analysis was performed using a commercially available kit (K-PHYT 12/12 Megazyme) as per the manufacturer's instructions.

Statistical Analysis. For the Rothamsted trial comparing the cultivars Rialto and Riband, one-way analysis of variance (ANOVA) was performed using GenStat (13th ed.; VSN, Hemel Hempstead, UK). For the multisite trials comparing six cultivars, ANOVA was not performed because replicated samples were bulked. Instead, correlation analyses between the Fe and Zn concentrations in the wholemeal and white flour samples were performed.

RESULTS

Concentrations of Fe and Zn in Whole Grain, Bran and Flour Fractions. Figure 1 shows the concentrations of Fe and Zn in the white flour and bran samples of six wheat cultivars grown on three European sites (in Hungary, Poland, UK). It was observed that cultivar differences were generally consistent across the three sites, and therefore, only the mean data (±SE across the three sites) are presented in Figure 1. Cultivars Rialto, San Pastore, and Tiger contained higher

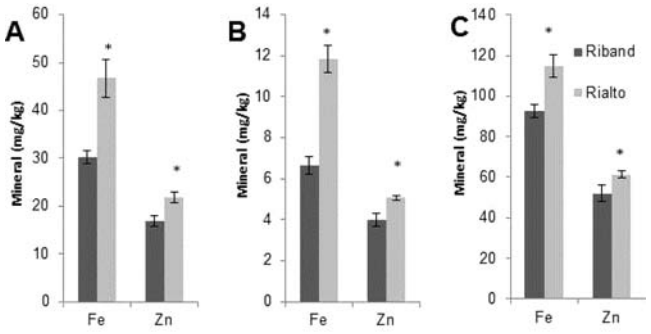

Figure 2. The concentrations of Fe and Zn in (A) wholemeal, (B) white flour, and (C) bran fractions of the cultivars Rialto and Riband grown at Rothamsted in 2010. Data are means ± SE of three biological replicates, and * represents significant difference at $p < 0.05$ according to ANOVA.

concentrations of Fe in the wholemeal than cultivars Crousty, Valoris, and Riband. This cultivar difference was generally maintained for the concentrations of Fe in both bran and white flour. Notably, the mean concentrations of Fe were 43% higher in the wholemeal samples and 43% higher in the white flour of the high-Fe cultivars when compared to the low-Fe cultivars. Similarly, the mean concentrations of Zn were 16% higher in the wholemeal samples and 58% higher in the white flour of the high-Fe cultivars when compared to the low-Fe cultivars. Among the six cultivars across the three sites, the concentrations of Fe and Zn of white flour were found to correlate significantly with those of the wholemeal ($r = 0.54$ and 0.48 for Fe and Zn, respectively; $p < 0.05$). There were also significant correlations between Fe and Zn concentrations in the wholemeal ($r = 0.60$, $p < 0.01$), bran ($r = 0.49$, $p < 0.05$), and white flour ($r = 0.61$, $p < 0.01$).

Figure 2 shows the concentrations of Fe and Zn in grain of Rialto and Riband grown at Rothamsted in 2010. Rialto had significantly ($p < 0.05$) higher concentrations of Fe and Zn than Riband, in wholemeal (by 54% and 29%, respectively), bran (by 24% and 18%), and white flour (by 80% and 26%). It is notable that the difference in the concentration of Fe was greatest in the white flour fraction. These differences were broadly similar to the data from the multisite trials (Figure 1).

Speciation of Fe and Zn in the Soluble Extracts from White Flour. Figures 3 and 4 show SEC−ICP-MS analyses of the Fe and Zn species in the Tris-HCl extractable fraction of white flour from the samples of Riband (low Fe) and Rialto (high Fe) grown at Rothamsted in 2010. The flour extracts of both cultivars showed two unidentified high molecular weight (HMW) forms of Fe (at 20 ± 0.4 and >70 kDa, respectively). A medium molecular weight (MMW, 5.0 ± 0.1 kDa) peak of Fe was identified in the extracts of Rialto, but not in Riband. Further analysis of this peak using He and O_2 as the collision/reaction gases and measuring P as ^{47}PO and Fe as ^{57}Fe showed that the 5 kDa ^{57}Fe peak coeluted with ^{47}PO (Supplementary

Figure 1, Supporting Information). We therefore tentatively consider this peak to be soluble Fe−phytate (possibly Fe−IP_6 and/or Fe−IP_5), as it has a similar composition to a peak identified as a soluble Fe−phytate oligomer in the extracts of barley embryo.[21]

The extracts of Riband and Rialto contained similar amounts of a low molecular weight (LMW, 1.5 ± 0.1 kDa) peak of Fe, which has no coelution of P (Supplementary Figure 1, Supporting Information). This LMW peak eluted at the same time as a standard of Fe−DMA; however, the retention time was also very similar to that of Fe−NA (Supplementary Figure 2, Supporting Information). Similarly, previous studies[12,18] using SEC−ICP-MS and ES-MS have shown that the LMW peak in the extract of rice endosperm contains both Fe−DMA and Fe−NA. For comparison, a rice endosperm sample was extracted and analyzed with the same method, and the LMW peak identical to that in wheat flour extracts was found (Supplementary Figure 2, Supporting Information). In contrast, Fe−citrate can be ruled out as the possible Fe−chelate form for the LMW peak, as it eluted at a much smaller size (Supplementary Figure 2, Supporting Information). On the basis of retention time matching and the similarity to previous studies on rice,[12,18] we tentatively consider the LMW peak to represent a mixture of Fe−DMA and Fe−NA.

SEC−ICP-MS also identified a LMW Zn complex (1.9 ± 0.2 kDa) in the extracts of white flour (Figure 4a) that was of a similar size to a peak identified in rice using SEC−ICP-MS.[18] On the basis of this report and on comparison with Zn−NA and Zn−DMA standards, which eluted at 1.9 and 2.5 kDa respectively (Supplementary Figure 3, Supporting Information), we tentatively identified the LMW peak as Zn−NA, although further investigation is needed to determine its exact identity.

The concentrations of soluble Fe differed significantly between the two cultivars ($p < 0.05$), with Rialto having 23% more soluble Fe than Riband (Figure 3B), but the total concentrations of soluble Zn (sum of both LMW Zn and Zn associated with HMW compounds) were not significantly different (Figure, 4B). Most of the soluble Fe and Zn were bound to LMW complexes and the total amounts of LMW Fe and LMW Zn did not differ significantly between the two cultivars (Figures 3C and 4C).

As a percentage, insoluble Fe made up the majority of the total Fe in the white flour, accounting for 74.6% in Rialto and 62.5% in Riband (Figure 3B). Fe−NA/DMA was the largest soluble fraction of Fe, making up 19.3% of the total Fe in Rialto and 32.1% in Riband. Soluble Fe−phytate accounted for 2% of the total Fe in Rialto, while HMW peaks accounted for 4.1% in Rialto and 5.8% in Riband. Insoluble Zn also made up the majority of the total Zn in the white flour, accounting for 60.7% in Rialto and 52.5% in Riband (Figure 4B). Zn−NA was the largest soluble fraction of Zn, accounting for 31.8% of the total Zn in Rialto and 40% in Riband, while HMW Zn peaks accounted for 7.3% in Rialto and 7.4% in Riband.

Fe Speciation in Milling Fractions. Figure 5 shows the speciation of Fe in soluble extracts of 10 milling fractions from Bühler mill for both Riband (low Fe) and Rialto (high Fe) grown in the Rothamsted trial. The break fractions B1−B3 and

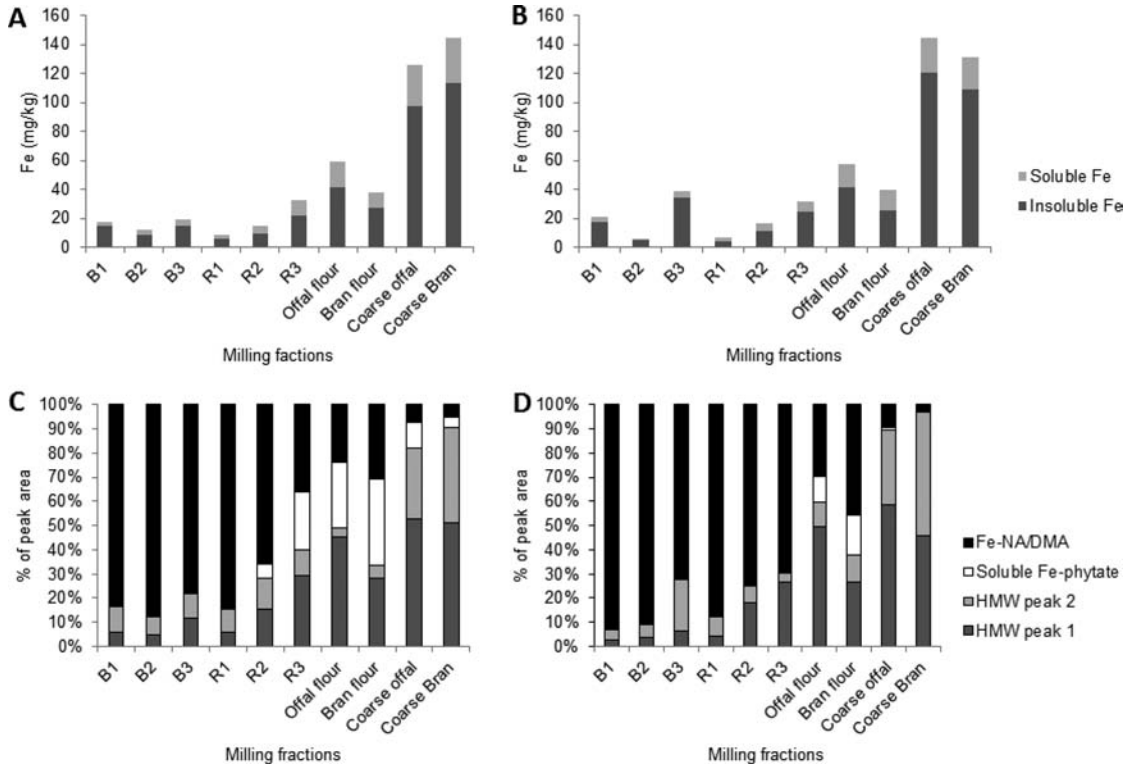

Figure 5. Quantification of the Fe forms in different milling fractions of Rialto (A, C) and Riband (B, D) from the Rothamsted trial. Parts A and B show the concentrations of different Fe forms and parts C and D the relative proportions of soluble Fe species in the total soluble Fe. Results are means of two technical replicates. The standard deviation of the method was less than 0.5% by analysis of five replicate samples of bran flour from Rialto.

Table 1. Extraction Yield, Ash Content, and Phytic Acid Content of 10 Milling Fractions from Bühler Mill

[a]Mean of three replicates.

the reduction fractions R1−R3 correspond to white flour, with R1 accounting for 47.6% and 42.1% of the total mass in Rialto and Riband, respectively (Table 1). The R1 and B1 fractions have very low ash and phytate contents (Table 1) and are therefore considered to represent the purest starchy endosperm fraction derived from the central part of the grain.[26] Ash content, an indicator of bran contamination, decreases closer to the center of the grain. A similar effect is observed with phytic acid content (Table 1).

The total concentrations of Fe (Figure 5A,B) varied greatly between the six flour fractions (R1, R2, R3, B1, B2, and B3), from 9 to 32 mg/kg in Rialto and 5 to 35 mg/kg in Riband, respectively. The differences were even greater between the six flour and four bran/offal (offal flour, bran flour, coarse offal and coarse bran) fractions, with a 26-fold difference in Fe concentration between the R1 and coarse offal fractions from Riband. The speciation of Fe in soluble extracts also differed between the flour fractions and bran/offal fractions, with LMW complexes being the predominant soluble form of Fe in flour (Figure 5C,D). By contrast, Fe bound to HMW components was the predominant form in bran/offal.

The main difference observed between the milling fractions from the two cultivars was in the amount of soluble Fe−phytate (Figures 5C,D). These results agree with the data in Figure 3A, showing that soluble Fe−phytate was present in the white flour extracts of Rialto but not of Riband. In addition, more soluble Fe−phytate was present in the bran fractions, especially the offal fractions, of Rialto compared to Riband.

The calculated amounts of soluble Fe species in whole grains of Rialto and Riband are given in Table 2, based on the yields of the milling fractions and the SEC−ICP-MS analyses. This shows that the concentration of soluble Fe−phytate was over 5-fold higher in Rialto than in Riband, although this form still represents only a small percentage of the total grain Fe (1.6%). The contents of LMW Fe (likely to be Fe−NA and/or Fe−DMA) were similar in the two cultivars but it represented a

Table 2. Quantification of Forms of Fe in Grain of Rialto and Riband, Based on Analyses of Milling Fractions and Whole Grain

	Fe species in whole grain[a]						
	Fe-HMW1	Fe-HMW2	soluble Fe−phytate	Fe−NA/DMA	insoluble Fe	sum	total Fe determined by ICP-OES[b]
Rialto (mg/kg)	4.1	2.9	0.7	2.3	33.1	43.1	46.7
%	9.6	6.7	1.6	5.3	76.7		
Riband (mg/kg)	3.8	3.3	0.12	2.5	24.2	33.8	30.3
%	11.2	9.6	0.38	7.3	71.4		
technical error (%)[c]	0.5	0.5	0.2	0.4			

[a]The total concentrations and percentages of each form of Fe were calculated on the basis of the peak relative area on SEC−ICP-MS and total soluble Fe determined by ICP-MS for each milling fraction and the proportions of the milling fractions (Table 1). [b]Total Fe determined by ICP-OES of whole grain. [c]Technical error was determined by analyzing five replicate samples of Rialto bran.

higher percentage of the total Fe in Riband. The concentration of insoluble Fe in Rialto was 36% higher than that in Riband (Table 2).

DISCUSSION

The initial aim of our study was to establish if there was a relationship between the total concentrations of Fe and Zn in whole grain and in white flour of wheat. There is evidence that the loading of minerals, such as Fe and Zn, into the starchy endosperm is highly regulated and occurs independently of loading into the outer layers that constitute the bran.[27,28] Consequently, the concentrations of minerals in the white flour may not reflect those in whole grain, which is dominated by the minerals stored in the outer layers (especially the aleurone) and the embryo. Our results (Figures 1 and 2) show that cultivars with higher concentrations of Fe and Zn in whole grain also tend to have higher concentrations of these minerals in the white flour, although the concentrations in the white flour are much lower than those in the whole grain. Therefore, for biofortification purposes, the rankings of wholegrain and white flour Fe and Zn concentrations among wheat cultivars are likely to be reasonably consistent.

The second aim of our study was to determine Fe and Zn speciation in the soluble extracts of wheat flour and to investigate if they differ between a high-Fe (Rialto) and a low-Fe (Riband) cultivar. Tris-HCl buffer-soluble Fe accounted for 25−37% and 23−29%, respectively, of the total Fe in white flour (Figure 3) and whole grain (Table 2). The high-Fe cultivar (Rialto) had a larger concentration of soluble Fe than the low-Fe cultivar Riband; however, when this concentration was expressed as a percentage of the total Fe, the cultivar difference was the reverse. Compared to Fe, Zn appeared to be more soluble in white flour, accounting for 39−48% of the total Zn (Figure 4).

SEC−ICP-MS analyses showed the presence of HMW, MMW, and LMW peaks of Fe and Zn (Figures 3 and 4). The LMW Fe in wheat is likely to be a mixture of Fe−NA and Fe−DMA, whereas Zn−NA appears to be the only form of soluble Zn in the endosperm in both rice and wheat (Supplementary Figures 2 and 3, Supporting Information). This is in agreement with other studies which have shown that Zn binds more favorably with NA [29] and Zn−NA was the only Zn−chelate in the phloem sap of rice.[14] Proportionally, LMW Fe increased from the bran to the endosperm fraction and was quantitatively the most important species in the soluble extracts of white flour, suggesting that NA/DMA may also play an important role in the storage of Fe in the endosperm of wheat. However, there was no significant difference in the proportion of this Fe form between the two cultivars. Zn−NA was also the most important soluble Zn species in the white flour extracts, with no significant difference between the two cultivars being observed.

The most notable difference between the two cultivars was the presence of Fe bound to soluble phytate, which appeared as MMW complexes in the white flour of the high-Fe cultivar (Rialto) but not of the low-Fe cultivar (Riband) (Figure 3). The highest concentrations of soluble Fe−phytate were found in the offal and bran flour fractions, with Rialto having higher concentrations than Riband (Figure 5). One explanation for the difference between the two cultivars could be premature sprouting of Rialto, which is known to be prone to prematurity amylase production. This is supported by the determination of the Hagberg falling number (HFN), which was lower for Rialto than for Riband (112.3 ± 10.0 compared to 217.0 ± 23.3, $p < 0.05$). Although HFN measures the activity of amylase on starch, the synthesis of phytase also occurs during germination.[30] Increased phytase activity could therefore be responsible for the higher soluble phytate in Rialto. We found no evidence of soluble forms of phytate−Zn in white flour (Figure 4) or other milling fractions (data not shown), which is in agreement with analyses of barley embryos.[21] Another factor which needs to be considered is how each cultivar responds to shear forces during the milling process, as milling of hard (e.g., Rialto) and soft (e.g. Riband) wheat may result in different amounts of aleurone tissue being present in the white flour fractions, especially the late break and reduction fractions (i.e., B3, R3). In particular, white flour from hard wheat cultivars contains more aleurone material, especially the break fractions (B1−B3).[26] The degree to which this would affect our data is not known, but the observation that the R2 and R3 fractions of the hard wheat Rialto contained more ash, phytate, and soluble Fe−phytate (Table 1, Figure 5) is consistent with the presence of aleurone tissue.

In addition to the complexes with soluble phytate and NA/DMA, Fe and Zn are also bound to HMW compounds (Figures 3−5, Table 2). The identification of these peaks is challenging. HMW1 is excluded from the size exclusion column, suggesting that it is in excess of 70 kDa in size and could represent any complexes above this size. HMW2 also elutes very close to HMW1. The Fe storage protein ferritin may contribute to these peaks as it is a soluble complex of subunits of mass 40−44 kDa.[31] However, ferritin is present in low abundance in cereals (1−3% of total Fe).[32,33] Therefore, it is possible that these peaks are also made up of other large Fe-containing complexes (e.g., soluble proteins). Previous studies using high resolution secondary ion mass spectroscopy (NanoSIMS) have shown the presence of Fe in the cytoplasm surrounding the starch granules in starchy endosperm cells of wheat grain, suggesting a possible association of Fe with proteins.[34] Our results also show that these HMW forms are present in higher concentrations in bran

fractions than in the white flour; the former are more protein rich than the latter.[26]

Very little is known about the insoluble forms of Fe and Zn in wheat, which in the case of Fe make up 76.7% in Rialto and 71.4% in Riband of the total amount under our extraction conditions. In the outer fractions at least part of this is probably bound to insoluble phytate,[35] while another proportion may be bound to tannic acid, which is present in the outer layers of the grain and forms both soluble and insoluble complexes with Fe.[19]

The results from this study demonstrate the usefulness of SEC−ICP-MS in the speciation of Fe and Zn in wheat flour. This information is likely to be important for understanding the factors that influence the bioavailability of the minerals and will allow for more targeted breeding strategies for improved mineral content and speciation in wheat grain.

Type and Amount of Lipids Influence the Molecular and Textural Properties of a Soy Soft Pretzel

Supporting Information

ABSTRACT: Altering baked goods by the addition of nutrient-rich ingredients, such as soy and ground almonds, affects the water and lipid distribution of the product and, subsequently, its final quality. Here, we studied how three lipid sources, shortening, canola oil, and ground almonds, affected texture and water distribution in a baked soy pretzel and the molecular mobility in the dough. Pretzel crumb from all formulations exhibited 40−43% moisture with a little more than half present as "freezable" water. Firmness and chewiness decreased with increased shortening and canola oil, whereas firmness and chewiness increased with additional almonds. In contrast, neither springiness nor cohesiveness was affected by the lipid quantity or source. Finally, magnetic resonance imaging of the soy pretzel dough revealed two or three populations of dough components that have distinct molecular mobilities. With increased lipid content, the mobility of each population increased in magnitude and heterogeneity. Interestingly, almonds had the smallest effect on the molecular mobility of the dough but had the largest effect on textural properties. These results provide quantitative insight into the mechanisms by which the lipid source can influence molecular properties that have textural implications for bakery products.

KEYWORDS: *soy, lipid, almond, physical properties, bread, magnetic resonance, pretzel*

INTRODUCTION

In order to deliver bioactive compounds in soy bread and related bakery products,[1−3] we must understand the interactions between the macromolecular constituents. Herein, we focus on the key plasticizing components in a soy soft pretzel,[4] water and lipids, and their influence on the texture of dough and the final product.

Lipids serve an essential structural role in the production of bakery products, such as soft pretzels. The amphipathic properties of lipids lubricate the gluten strands and adsorb to the gas−lipid interface of gas cells, allowing for the bubbles to develop and be evenly distributed in the crumb.[5] Solid fat (traditionally lard, now more commonly shortening) promotes a lighter, more homogeneous crumb than liquid oil (for a review, see the study by Pareyt et al.[6]). Oil does not adhere to the surface of gas cells as well as solid fat, and therefore, oil promotes a less consistent distribution of gas cells and gluten in the dough. An unrefined lipid source, for example, ground nuts, is unique in that it is composed of mostly unsaturated oils but is present in a solid matrix. It was hypothesized that oil from ground nuts can participate in molecular interactions that promote the growth of gas cells and serve the essential role of lipids in the developing crumb.

As a representative unrefined lipid source for use in these studies, ground almonds were selected. Almonds were chosen because of their natural β-glucosidase activity driving the conversion of soy isoflavones to aglycones and, thereby, potentially promoting the absorption of these phytochemicals.[4,8] Accordingly, the soy soft pretzel formulation used in these experiments contained about 25 mg of soy isoflavone aglycone equivalents per 59 g of pretzel, and a soy pretzel made with 5.5% ground, raw almonds doubled the amount of aglycones in the pretzel (more than 25% aglycones).[4] It was hypothesized that ground almonds could be substituted for shortening in a soy pretzel while maintaining favorable crumb texture. As a comparison, in addition to using shortening and almond lipid sources, canola oil was selected as a commonly used, refined, pure lipid source with a similar triglyceride profile as almonds.[7]

Several prior studies have examined the effects of the type and amount of lipid on the crumb texture of bread. A reciprocal relationship has been established between consumer acceptability and crumb firmness, since increased crumb firmness is an indicator of bread staling.[9] Because of the role of shortening in facilitated gas formation and structural support of the gas cells in bakery products,[6] it was hypothesized that its incorporation would result in the softest crumb compared to pretzel rolls made with canola oil or ground almonds. Describing the state of the water and its interaction within the matrix will help

elucidate the mechanisms by which the type, amount, and source of lipid modulate physical properties of the crumb.

Using thermogravimetric analysis (TGA), the total quantity of water in the crumb as well as the relative binding strength of the water to the macromolecules in the matrix can help determine the locational and functional relationship between the lipid and the matrix, as well as how the lipid ingredients modulate the interactions between the water and macromolecule.[10] Additionally, differential scanning calorimetry (DSC) reveals the compartmentalization of water into "freezable" water (FW) and "unfreezable" water (UFW), which is useful in determining the susceptibility of the products to staling and frozen storage shelf life.[11,12] In a prior study using magnetic resonance imaging (MRI), Lodi et al. did not observe large differences in the water states between soy bread and soy bread containing almonds,[13] but it is unknown how the different lipid components affect the water properties in the dough or the physical attributes of the baked product.

Only two studies, to our knowledge, have investigated the use of nuts as the lipid source in bread. Oliete et al.[29] and Gómez et al.[33] produced bread with almond, hazelnut, peanut, or walnut pastes at 5, 10, and 15% in the absence of other added lipid. They demonstrated that different types and amounts of nut pastes discretely affect dough rheology,[33] as well as the firmness, chewiness, cohesiveness, and resilience of the bread.[29] However, it is unknown how ground almonds would affect texture in a soy bread matrix or the mechanisms by which the lipids participate in intermolecular interactions with water.

To assess the physiochemical effects of lipid constituents on a soy soft pretzel, pretzel rolls were prepared with 0, 2.9, or 6.0% lipid from shortening, canola oil, or ground almonds. To study the dough, pretzel dough was prepared with 2.9 or 10% of shortening, canola oil, or ground almonds. The crumb was subsequently assessed for texture and water distribution, and dough was assessed for water mobility. We hypothesized that the addition of ground almonds would attenuate the negative effects of the crumb texture that are associated with oil because of the differences in the distributions of water and lipid in the pretzel roll.

MATERIALS AND METHODS

Pretzel Preparation. Soft pretzel rolls with 16.2% soy ingredients (dry weight) were produced on the basis of the protocol by Simmons et al.[1,4] and soy bread patent[14] with the ingredients in Table S1 of the Supporting Information. Formulations included 0, 2.9, or 6.0% lipid from shortening, ground almonds, or canola oil; none of the formulations included more than one of these lipid sources. Almonds contain approximately 50% fat by weight,[7] and therefore, to achieve the traditional lipid amount, 2.9% lipid, a soy bakery product required 5.5% ground almonds (w/w). The pretzel inherently contained 1.9 ± 0.2% endogenous lipid from the other ingredients.[4]

To make the sponge, activated yeast, 43% of the total wheat flour, the wheat gluten, and the dough conditioner were combined with 45% of the total water in a standing mixer (Kitchen Aid, St. Joseph, MI) on a low setting with the beater attachment. The sponge was proofed at about 43 °C at 100% humidity (CM2000 Combination Module, InterMetro Industries Corp, Wilkes-Barre, PA). The remaining ingredients, except lipid, were added, and the dough was stirred with the dough hook attachment, first on low until ingredients were moistened and then on medium–high. After about 5 min, the lipid source was added. The dough was then stirred until it sheeted (about 5 min more). Pretzel rolls were formed by rolling 71.0 g of dough into slightly oblong balls (pretzel rolls were formed instead of the traditional twisted shape to produce congruent samples of crumb for textural analysis). Stickier formulations were dusted lightly with wheat flour to facilitate roll formation. Balls were submerged in 1.0% sodium hydroxide solution at 60–65 °C for 60 s and placed in the center of a lightly greased mini loaf pan. Rolls were proofed for 25 min (43 °C and 100% humidity) and then baked at 149 °C for 16 min in a convection oven (Jet-Air oven, JA14, Doyon, Linière, Québec, Canada). Rolls were cooled on wire racks, stored in plastic bags overnight, and analyzed the following day. At least four pretzel rolls were prepared and analyzed per batch. Analysis of all of the parameters of pretzel rolls made from 2.9% shortening from two different batches prepared on 2 different days showed that the variability between samples of different batches was similar to the variability between samples of the same batch. Therefore, one batch was prepared for each of the other variables.

Quantification of Total Water, FW, and UFW. The moisture content and water desorption patterns were assessed using TGA (Thermogravimetric Analyzer Q5000, TA Instruments, New Castle, DE). Samples of pretzel crumb (15–20 mg) were subjected to a linear heat ramp from room temperature to 200 °C at 10 °C/min. Under the assumption that weight loss resulted solely from water evaporation,[15] the weight of the sample at 150 °C was subtracted from the initial weight to yield the moisture content. The derivative of the thermogravimetric analysis curve (dTG) was calculated by Advantage for the Q Series, version 2.8.0.394 (TA Instruments–Waters LLC, New Castle, DE).

The amount of FW was quantified using DSC. Pretzel crumb (10–15 mg) was placed in a hermetically sealed stainless-steel pan with an O-ring (PerkinElmer, Waltham, MA). The temperature was lowered to −50 °C, held isothermally for 2 min, and then increased linearly at 5 °C/min to 150 °C. The peak near 0 °C was integrated to yield the change of enthalpy (ΔH) associated with the phase transition from ice to water. The latent heat of fusion of water (333 J/g) was used to quantify the amount of FW in the dough sample.[16,17] Subsequently, the amount of FW was subtracted from the amount of total water to yield UFW.

Textural Profile Analysis (TPA). Pretzel rolls were sliced into two adjacent 2.5 cm cubes that included pretzel crumb free of crust (electric carving knife, Toastmaster, St. Louis, MO). Each cube of pretzel crumb was subjected to a double compression test to 40% compression at a crosshead speed of 100 mm/min (Instron Universal Texture Analyzer 5542, Instron, Norwood, MA). Firmness, springiness, chewiness, and cohesiveness of the pretzel crumb were calculated using Bluehill 2 software, version 2.17 (Instron, Norwood, MA).[18] Firmness was reported as the maximum force at the first compression. Cohesiveness was calculated as the ratio of the energy to maximum load during the second compression to that at the first compression. At least five samples were analyzed per treatment.

Dough Preparation for MRI. Dough was prepared by combining 189.6 g of wheat flour, 57.6 g of soy flour, 19.2 g of soy milk powder, 4.6 g of wheat gluten, 0.6 g of dough conditioner, 5.0 g of salt, 20.0 g of sugar, and 188.5 g of water (yeast was omitted to avoid changes in the sample during image acquisition). The dough was then divided into 6 × 75 g portions to ensure that the only difference between dough samples was the added lipid. Subsequently, lipid was added to produce six formulations: 1.6 g for 2.9% shortening or canola oil, 5.1 g for 10.0% shortening or canola oil, 3.3 g for 2.9% ground almonds, or 10.4 g for 10.0% ground almonds. Lipid was incorporated by kneading by hand, and then dough was placed in 6 g glass vials. Vials were capped and then sealed with Parafilm M (Bemis Co., Neenah, WI) to prevent moisture equilibration.

Proton Intensity and T_2-Weighed Images. MRI scans were performed the same day that the dough was prepared. The experiments were performed at ambient temperature on a 4.7 T/40 cm magnet controlled by a Bruker Avance Console (Bruker Biospin, Billerica, MA). The instrument was equipped with a 260 mm inner diameter gradient coil and a 200 mm inner diameter proton volume radio-frequency coil. For an intensity reference, a phantom was prepared by combining water and deuterated water at a proportion that resulted in an intensity similar to that of an average dough sample. Both the dough sample and the phantom were placed inside the coil.

For all images acquired, the voxel size was 234.375 × 234.375 μm with a 5 mm slice thickness (i.e., 0.275 mm^3 per voxel). Each of five slices used 256 × 128 voxels for a 60.0 × 30.0 mm field of view. The proton intensity images were T_1-weighed, using a multi-slice FLASH pulse sequence with two averages (Bruker, Billerica, MA); there was a 0.5 s repetition time (TR), a 2.6 ms echo time (TE), and a 32° flip angle. The T_2 images were acquired using a multi-slice, multi-echo (MSME) Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence (Bruker, Billerica, MA) with a 90° flip angle and a 5 s TR, with TE of 10, 20, 35, 55, 75, 95, 115, 135, 150, and 160 ms. The set of 10 images in the echo series were used to estimate T_2 values for each voxel by fitting intensity(TE) = amp × exp(−TE/T_2) + offset, where intensity(TE) is the observed intensity of the voxel in the image with echo time TE, amp is the amplitude of the T_2 decay curve, T_2 is the T_2 of the decay curve, and offset is the intensity at infinite TE (the magnitude of the noise). These fits yielded T_2 maps for each formulation and were the focus of additional analyses.

The program ImageJ (version 1.46r; http://rsbweb.nih.gov/ij) was used to prepare T_2 histograms using a region of interest analysis of the T_2 spatial maps. For each formulation, a circular region of interest was drawn within the edges of the dough image in each slice to avoid edge effects. Each T_2 histogram contained 200 bins between 0 and 50 ms (0.25 ms per bin) with 3228 voxels per five slices, for a total of 16 140 voxels per formulation.

T_2 histograms were analyzed using a deconvolution analysis programmed in MATLAB (The Mathworks, Natick, MA). In this analysis, the T_2 histogram of each formulation was fit to a sum of one, two, or three Gaussian curves to quantify distinct populations of T_2 values in the sample. Each Gaussian curve was modeled as counts(T_2) = amp × exp(−((T_2 − μ)^2)/(2σ^2))/($\sigma\sqrt{(2\pi)}$), where counts(T_2) is the number of counts in the T_2 histogram, amp is the amplitude of the Gaussian curve, μ is the mean T_2 value for the population, and σ is the standard deviation in T_2 value for the population. The fitted parameters were amp, μ, and σ. For the two-population deconvolution analysis, the observed data, counts$_{obs}$(T_2), were fit to the simulated curve counts$_{tot}$(T_2) = counts$_A$(T_2, amp$_A$, μ_A, σ_A) + counts$_B$(T_2, amp$_B$, μ_B, σ_B). For the three-population deconvolution analysis, observed data were fit to counts$_{tot}$(T_2) = counts$_A$(T_2, amp$_A$, μ_A, σ_A) + counts$_B$(T_2, amp$_B$, μ_B, σ_B) + counts$_C$(T_2, amp$_C$, μ_C, σ_C). Population fractions were calculated using numerical integrals of fitted counts(T_2) curve of each population compared to the numerical integral of the observed data curve counts$_{obs}$(T_2). Confidence intervals for each fitted parameter (amp, μ, and σ for each population) and for the population fractions were estimated using 1000 iterations of Monte Carlo bootstrapping from residuals.[19]

Statistical Analysis. For quantity of total moisture, FW, and UFW as well as texture properties, statistical analysis was performed to fit the model Y = lipid type + lipid amount + (lipid type × lipid amount), where Y is the parameter at hand, lipid type is shortening, almonds, or canola oil, lipid amount is 2.9 or 6.0%, and lipid type × lipid amount is the interaction between the two variables. Analysis of variance and least-squares means for the (lipid type × lipid amount) interaction were calculated using SAS 9.1 (SAS Institute, Cary, NC). Statistical significance was evaluated with an α of 0.05; the Bonferroni correction was used where appropriate. Average ± standard deviation is reported throughout the text.

RESULTS AND DISCUSSION

Moisture Content, FW, and UFW. Soy soft pretzel rolls were produced with lipid from shortening, canola oil, and ground almonds at two different levels and assessed for total moisture content, percent FW, and percent UFW. All pretzels contained 41.9 ± 4.3% total moisture, while FW comprised 58.7 ± 2.6% of the total water. There were no statistical differences in total moisture content or percent FW or UFW between the formulations (p > 0.09). Because the same amount of water was added to all of the soy pretzel formulations and almonds have only about 5% moisture,[7] this observation suggests that there were little to no differences in water migration, distribution between the crust and crumb, or evaporation from the crust during baking.

Water desorption as determined by TGA occurred in a biphasic manner for the shortening and almond samples and a monophasic manner in canola oil samples and samples without added lipid (Figure 1 and Table 1). The absence of the peak at

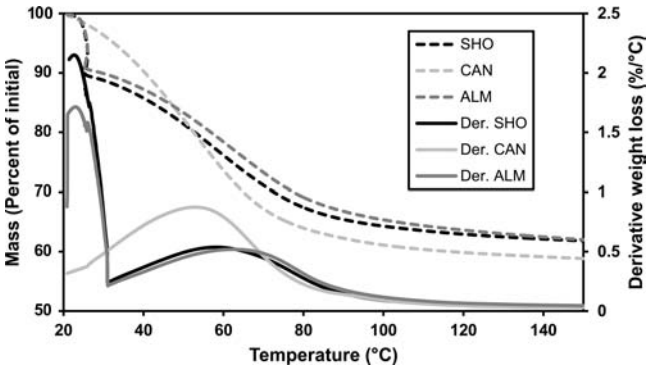

Figure 1. Example water desorption patterns from samples with 6.0% added lipid measured using TGA. Black lines represent samples made with shortening; dark gray lines represent samples made with ground almonds; and light gray lines represent samples made with canola oil. Dashed lines show the mass of the sample as a function of the temperature, whereas solid lines show the derivative of the weight loss curve. SHO, shortening; CAN, canola oil; and ALM, ground almonds.

Table 1. Peak Rate of Water Loss during Heating of Soy Pretzel Crumb

type of lipid	amount added (%)	dTG1 (°C)	dTG2 (°C)
no added lipid	0.0	N/A	64.2 ± 7.9 b
shortening	2.9	23.7 ± 1.5 a	64.1 ± 2.5 b
shortening	6.0	23.8 ± 2.1 a	63.5 ± 4.8 b
almond	2.9	23.1 ± 0.2 a	63.3 ± 2.5 b
almond	6.0	25.8 ± 4.9 a	65.1 ± 2.7 b
canola oil	2.9	N/A	55.7 ± 3.6 c
canola oil	6.0	N/A	53.8 ± 2.5 c

the lower temperature range (23−40 °C) in the canola oil samples and samples without added lipid suggests that (1) water loosely bound to the matrix exhibited a vaporization temperature lower than room temperature and quickly evaporated during sample preparation and/or (2) water did not exist in the fraction that was more easily removed. Also, in the water desorption thermograms, there was a peak near 60 °C that represented the majority of the water evaporation for all formulations (Figure 1 and Table 1). The temperature of this peak was similar for the shortening samples, almond samples, and samples without added lipid (approximately 60−68 °C) but was lower for the canola oil samples (51−59 °C; p < 0.05 when comparing canola oil samples to other samples; differences in peak temperatures between 2.9% canola oil and 6.0% canola oil samples were not statistically significant). Because the water evaporated at different temperatures, this suggests that canola oil caused different interactions between the water and macromolecular structures, such as starch, lipids, and proteins, as observed historically (Pareyt et al.,[6] and references within).

Both the physical state of the lipid and the chemical composition of the lipids likely contributed to the disparity in water desorption patterns observed in the samples with canola

oil. Specifically, the melting points of the individual triglycerides within each lipid ingredient can dictate both lipid−lipid interactions (such as the size and distribution of fat crystals[20]) and interactions between the lipid and other macromolecules. Shortening is about 19% saturated fat and forms solid lipid crystals that reduce surface tension at the oil−water interface and promote air incorporation and gas cell stabilization during baking.[6] On the other hand, canola oil is less than 10% saturated fat and liquid at room temperature, thereby contributing a much more uniform triglyceride profile and very little emulsification properties; it is expected that water would be associated with fewer microenvironments within the matrix.

Almond as a lipid source differs drastically from shortening and canola oil in that part of the lipid provided by ground almonds is bound in the nut matrix and not involved in macromolecular interactions with the other ingredients. For example, more mastication of almonds led to a greater *in vivo* bioaccessibility of lipid and less lipid in the feces;[21] therefore, it is expected that the lipid bound in the almonds within the food matrix is also inaccessible to its surrounding environment. It is interesting to note that ground almonds also promoted the diphasic water desorption pattern, despite the low percentage of saturated fat (about 7% compared to shortening at about 19%[7]). Almonds contain polysaccharide-rich cell wall material[22] that likely promoted water−lipid−protein interaction during proofing and baking, although the extent of the endogenous emulsifying properties of almond has yet to be explored.

This is the first study, to our knowledge, showing that different sources and amounts of lipid did not lead to differences in the partitioning of water into FW and UFW compartments in the pretzel formulations studied. Consistent with these results, Matuda et al. did not observe a change in UFW in dough with and without shortening when investigating the effects of vegetable shortening and different dough conditioners in French bread dough.[23] These results are also consistent with findings by Lodi and Vodovotz that showed that the addition of almond to soy bread (both formulations contained shortening) led to only small temperature differences in the peak rates of water loss in a similar TGA experiment.[24] Together, these results demonstrate that the soy matrix can accommodate ground almonds with or without shortening but not canola oil without drastically altering water content, water state, or water desorption patterns.

Texture Analysis. This soy pretzel formulation contained 16.2% soy ingredients (dry weight; see Table S1 of the Supporting Information) and, consequently, less gluten, more protein, more fiber, and more water (for optimal workability[2]) compared to a wheat pretzel without soy. The changes in the macromolecular composition and microscale ingredient interactions led to changes in texture when comparing bakery products made with or without soy ingredients, including firmness and chewiness.[25,26] However, the role of the lipid component in modulating textural properties of a soy-based bakery product had not been explored.

In Figure 2, the firmness, chewiness, and cohesiveness of the pretzel rolls are illustrated relative to the properties of the 2.9% shortening product. The values for the 2.9% shortening product were firmness, 9.37 ± 1.63 N; chewiness, 57.8 ± 9.6 N; and cohesiveness, 0.62 ± 0.03 (ratio). The springiness values were 7.83 ± 0.66 mm, with no difference between formulations ($p > 0.05$). Although it was expected that the canola oil products would be firmer and chewier than the shortening products

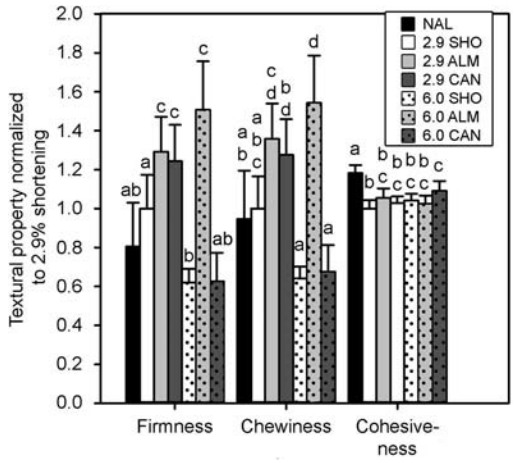

Figure 2. Textural properties of the pretzel rolls, including firmness, springiness, chewiness, and cohesiveness. The actual values were normalized to the 2.9% shortening pretzel roll (the traditional formulation; i.e., values obtained for the 2.9% shortening formulation were set to 1.0). Formulations with no added lipid (NAL) are black bars; formulations with 2.9% added lipid are solid white or gray bars; and formulations with 6.0% shortening have black dots. Shortening (SHO) samples are white; almond (ALM) samples are light gray; and canola oil (CAN) samples are dark gray. Different letters above the bars indicate statistical significance for each property. Error bars are standard deviations across five independent measurements.

because of their inability to promote gas cell development,[6] less than a 25% increase in firmness was observed when ground almonds or canola oil was used in place of 2.9% shortening (Figure 2). The presence of polar lipids (e.g., soy lecithin) in the soy ingredients perhaps attenuated changes in gas cell formation[27] compared to crumb of a wheat product without soy. An increase in the lipid content to 6.0% lipid caused a 40% decrease in firmness for both the shortening and, unexpectedly, the canola oil products. Baldwin et al. proposed that shortening melts during proofing and baking, thereby providing a constant source of lubrication for bubble formation and strengthening for air retention; perhaps the high amount of lipid in the 6.0% canola pretzel roll provided ample lipid for coating growing gas cells during proofing, while the soy ingredients aided in gas cell stabilization.[28] Additionally, large, inhomogeneous gas cells would also exhibit low degrees of firmness. The gas cell size was not quantified here but may be important in future studies. The higher amount of almond did not soften the crumb, corroborating TGA and water mobility data and suggesting that the lipid in the almond is bound within the nut matrix. Similarly, although the lipid is more accessible in an almond paste compared to ground almonds, an increase in firmness and chewiness was also observed with the addition of different kinds of nut pastes to wheat bread likely because of other components of the nut.[29]

The springiness and cohesiveness of the crumb were similar between all formulations (Figure 2). Similarly, no practical changes were observed in springiness when comparing wheat and soy bread,[25] suggesting that springiness is very resilient to such changes in bread formulation. The cohesiveness values were similar to what has been reported previously in soy, and these values were greater than wheat bread.[25] Similar to the trends observed with firmness, chewiness was increased slightly in formulations with ground almonds and canola oil at 2.9% (Figure 2). Moreover, at 6.0% added lipid, pretzels made with

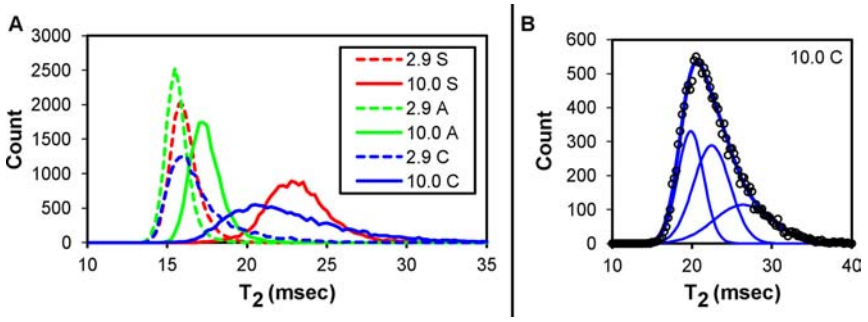

Figure 3. T_2 histograms from each formulation reveal that each formulation has a different magnitude and heterogeneity of T_2 values, reflecting different molecular level mobilities of the dough. (A) Each formulation is shown overlaid. (B) Deconvolution analysis quantifies the population fraction, mean T_2, and heterogeneity in T_2 for each of 2−3 subpopulations in each formulation. The results for the 10.0% canola oil formulation are shown here. Results for all formulations are listed in Table 2. Figures for the other formulations are in Figures S4−S6 of the Supporting Information.

shortening and canola oil exhibited a slight although not statistically significant decrease in chewiness, likely because of a more airy structure. In contrast, pretzels made with 6.0% lipid from ground almonds were chewier than all other formulations (89.2 ± 14.1 N versus 78.5 ± 10.5 N or less). Collectively, these data show that (1) both 2.9% canola oil and increasing amounts of ground almonds led a greater force requirement to deform the product and, because deformations are equally reversible with all formulations, more total force would be required to chew the product, (2) addition of more than twice the traditional amount of shortening provides a softer, less chewy crumb, and, interestingly, (3) addition of greater amounts of canola oil, for example 6.0%, reversed the increase in firmness and chewiness seen at 2.9% canola oil, perhaps because of very large air bubbles.

Proton Intensity and T_2-Weighted Images of Pretzel Dough. MRI allows for the spatial resolution of water content and water mobility within a sample[13,30] and can provide insight into the molecular properties and interactions between ingredients. Proton density-weighed images minimize the effects of T_2 relaxation and correlate with the water content of the dough at each voxel. Because the dough samples had equal amounts of added water, it was expected that these images would be similar, as was observed (see Figure S1 of the Supporting Information). In all samples, the water appeared to be evenly distributed in the dough on a centimeter scale. However, the mottled appearance indicates that the water content of each voxel is slightly different from neighboring voxels. This mirrors what was seen previously in MRI images of non-yeasted wheat and soy dough.[30]

T_2-weighed images reported the mobilities of protons from water, lipids, carbohydrates, and proteins in the dough. T_2 histograms revealed that each formulation had a different magnitude and heterogeneity of T_2 values, reflecting different molecular level mobilities of the dough (Figure 3A). There are several noteworthy features of these results. First, the T_2 values in all three 2.9% lipid formulations (shortening, canola oil, and ground almonds) exhibited similar T_2 values, suggesting that their proton mobilities were similar. However, when more lipid was used (i.e., the 10% lipid formulations), the mean T_2 increased, which implies that the protons were more mobile, the deviation in T_2 increased, which implies that there were greater differences in the mobilities of the protons in the sample, and the samples appeared increasingly different from one another. Moreover, samples with canola oil and shortening exhibited much greater shifts in average and standard deviation T_2 upon higher lipid addition compared to the almond samples. This is likely due to the inaccessibility of the almond lipid to the dough matrix environment, as was observed in TGA. Mechanistically, one possible explanation for the observation that adding more lipid increased the molecular mobility of the dough is that water droplets became larger (i.e., more like mobile bulk water than less mobile bound water) because of the immiscibility between the water and lipid.

Moreover, the T_2 histogram from each formulation suggests that there were several populations of T_2 values, which were quantified using a deconvolution analysis (Figure 3B and Table 2). From this analysis, the shortening and almond formulations each revealed two populations of T_2 values, whereas the canola oil formulations both revealed three populations of T_2 values. Each population is likely important because it made up a significant fraction of the observed protons (i.e., the smallest population was 25%). Unfortunately, assigning the molecular identity of these populations (e.g., water, lipid, or carbohydrate) could not be accomplished with these data alone. However, on the basis of the changes of the proton relaxometry during baking of bread dough, Engelsen et al. labeled the two proton populations with the longest relaxation times as starch-bound water and protons that are diffusing between starch, protein, and water.[31] In contrast, Lodi et al. observed a peak from not just water protons but also lipid protons in MRI images of baked soy bread.[13] Careful assignment of these populations may be important in future studies. In any event, the range of T_2 values observed here was more broad than those in soy and soy−almond bread,[24] indicating that molecular mobilities of this dough were much less homogeneous than the molecular mobilities of baked bread.

Taken together, these MRI data support that, with increased lipid content, the average proton mobility both increased and became more heterogeneous across voxels. This is consistent with increasing size of the components (e.g., water and fat) within each 0.275 mm^3 voxel, such that with greater lipid content, some voxels were more water or more lipid than when there was a smaller percentage of fat.

These MRI experiments have several limitations. First, the T_2 values presented here result from fitting a mono-exponential function to the T_2 decay curve at each voxel. However, each voxel likely contained a mixture of molecules with different T_2 values, and thus, the T_2 decay curve is best described by a multi-exponential function. Unfortunately, these multiple T_2 values cannot be determined using these data because the temporal resolution was too low to trust the fitted parameters from a multi-exponential function. Thus, the T_2 values reported here are influenced by all of the molecules within each voxel, and the

distributions shown here reflect deviations in the molecular composition of the voxels. Second, small air bubbles in the samples could have an effect on the results in a manner that depends upon the magnetic susceptibility difference between the air in the bubble and the surrounding medium, the size of the bubble, and the read-out gradient strength.[33] To minimize bubble formation, yeast was not added to the samples for MRI experiments, yet it is possible that different formulations led to discernible differences in the size and distribution of air bubbles in the sample. Further experiments are required to quantify potential artifacts because of air bubbles and how these potential artifacts may differ across samples. Third, images based on magnitude data were used to calculate T_2 values; fitting magnitude data to a decay curve can result in an overestimate of the decay time.[34] With that in mind, these results must be analyzed relatively and not absolutely.

Molecular insight into textural properties has been achieved with nuclear magnetic resonance (NMR) and MRI on baked bread, including work by Engelsen et al.,[31] Seow and Teo,[32] Lodi et al.,[13] and Bosmans et al.[35,36] However, quantitative analyses have not yet been performed to predict the texture of the bread from molecular properties of the dough. Dough made with high amounts of shortening or canola oil exhibited the longest T_2 relaxation times, and pretzel rolls baked from similar formulations also exhibited the lowest degrees of firmness and chewiness. Similarly, upon increasing levels of ground almonds, both T_2 relaxation times and textural properties exhibited only relatively small changes compared to changes induced by added shortening or added canola oil. Future experiments can shed light on the role of relaxometry of the protons (especially water) and the textural consequences of the baked product. Engelsen et al. developed a model to predict the degree of staling in bread from T_2 relaxation behavior of protons in freshly baked bread.[31] It is theoretically possible to adapt this model to dough to identify formulations that have favorable shelf stability.

In conclusion, the substitution of 100% oil for shortening has historically led to a decrease in the quality of bread crumb;[6] however, a denser and chewier crumb is an asset for soft pretzels. The pretzel matrix can easily accommodate a significant amount of soy while still remaining consumer-acceptable,[1] and this work has shown that pretzels can accommodate different types and levels of lipids, although a sensory evaluation is needed to confirm consumer acceptability (and is planned as part of a future study). The different types (shortening, canola oil, and ground almonds) and levels (2.9 and 6.0%) of added lipid did not affect the total moisture content or compartmentalization of FW and UFW. However, the water in samples with higher lipid exhibited greater proton mobility, as seen with MRI. The lipid in the ground almond appeared to be bound in the solid nut matrix, thereby attenuating added-lipid-induced changes in water mobility, firmness, and chewiness of the crumb compared the observed changes in these properties with increased shortening and canola oil. These findings emphasize that the source of the lipid can influence molecular properties and have consequential textural implications. The details of these relationships can aid functional food development in baked goods.

ABSTRACT: Capsaicin o/w nanoemulsions with enhanced skin permeation were successfully prepared by controlling the ratios of the surfactant mixtures, oleoresin capsicum as the oil phase, and aqueous phase. Oleoresin capsicum contains 22.67 mg/g of capsaicin, which is an active and oil-soluble ingredient. Nonionic surfactants, Tween 80 and Span 80, were used to optimize the weight ratio of surfactant mixtures (85.98:14.02) by calculating the hydrophile−lipophile balance (HLB) value. The optimal processing conditions for stable nanoemulsions were investigated by using a ternary phase diagram. The mean droplet size of nanoemulsions ranged from 20 to 62 nm. Skin permeation studies were performed using a Franz diffusion cell. The permeation profiles and confocal laser scanning microscopy (CLSM) images supported that capsaicin nanoemulsion could well permeate all skin layers from the stratum corneum to the dermis. The selected nanoemulsions showed great potential as transdermal delivery carriers for enhancing the permeation of core materials.

KEYWORDS: *nanoemulsion, capsaicin, skin penetration, confocal microscopy, HLB value*

INTRODUCTION

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide), the primary active ingredient of chili pepper, is a pungent and lipid soluble compound.[1] Capsaicin has been extensively used as a therapeutic agent for various diseases such as cancer, inflammation, cardiovascular disease, stroke, neurodegenerative disorder, and dermatological disease due to its excellent pharmacological activity.[2−6] However, capsaicin has shown two contradictory physiological effects. First, capsaicin stimulates the nervous system and induces intense pain in mammalian tissues, but its strong pungency has limited its clinical applications. Second, capsaicin has great antinociceptive and anti-inflammatory effects even if it excites the desensitization of nociceptors by depleting the neurotransmitter substance P and other sensory neuropeptides.[7]

Especially, transdermal delivery system of capsaicin has received considerable attention in the pharmaceutical and medical fields due to the antinociceptive and anti-inflammatory functions of capsaicin.[8,9] Compared to an oral drug delivery system, a transdermal delivery system provides various advantages such as avoidance of hepatic first-pass metabolism, reduction of side effects, and improvement in drug solubility.[10] The challenge of skin penetration is to overcome the stratum corneum, (SC) which is highly hydrophobic and rich in proteins. Hydrophobic drugs, however, are not favorable to hydrophilic viable epidermis and dermis layer in deeper stage.[11] To date, various transdermal delivery systems have been investigated for improving transdermal transport through the epidermal barrier. In order to enhance the skin penetration of drugs, nanocarrier delivery systems have been extensively investigated in various formulations such as nanoparticles, solid lipid nanoparticle (SLN), nanostructured lipid carrier (NLC), liposomes, microemulsions, and noisomes.[12−18] For improved transdermal delivery, carrier materials should be biocompatible, biodegradable, and easily excreted from the body as well as capable of sustaining the active core ingredient until reaching the target site without causing skin irritation during skin penetration.

As an effective transdermal carrier systems, nanoemulsion appears an attractive and competitive system due to many benefits such as easy manufacturing, small droplet size (20−200 nm), high thermodynamic stability, and enhanced solubilization for hydrophobic ingredients.[10,11] It has been shown that the active ingredients in an emulsion can enhance skin penetration through the large surface area of the emulsion system, the low surface tension of the whole system, and the low interfacial tension of the o/w droplets.[19] Because of their small size (less than 100 nm), nanoemulsions can easily penetrate the skin surface.[10]

The aim of this study is to investigate the optimum condition of capsaicin-loaded nanoemulsion formulations for topical application. In order to compare the quantitative permeability of the capsaicin nanoemulsion with that of a capsaicin-free ethanol solution, skin permeation studies were conducted using a synthetic membrane similar to human skin. In addition, ex vivo permeation study was performed using pig skins to demonstrate that capsaicin can penetrate through the whole pig skin layers, which consist of the stratum corneum, epidermis,

and dermis. Confocal laser scanning microscopy (CLSM) images were examined to verify that the capsaicin-loaded nanoemulsion fully penetrated the whole skin layers in both in vitro and ex vivo permeation studies.

MATERIALS AND METHODS

Chemicals. Span 80 and Tween 80, used as surfactant, were purchased from Samchun Pure Chemical (Seoul, Korea). Oleoresin capsicum was purchased in pungency ratings of 500,000 Scoville Heat Units (SHU) from EVESA (Madrid, Spain). Since oleoresin capsicum is an oil extraction from a fruit of *Capsicum* species and consists of mainly capsaicin, oleoresin capsicum was used as the oil phase. Strat-M membrane was purchased from Merck KGaA (Darmstadt, Germany), and Nile red was purchased from Sigma-Aldrich (St. Louis, MO, USA). HPLC-grade methanol and acetonitrile were used for HPLC analysis.

Skin. The flank area of a pig skin sample (700 μm thick as measured using dermatome) was obtained from Micropig (Medi Kinetics Co. Ltd., Pyeongtaek, Korea). All skin samples were prepared less than 1 mm thick to allow following confocal microscope study. The skin samples prepared were carefully washed with a phosphate buffered saline (PBS) solution, stored at −20 °C, and used within 1 week for the ex vivo skin permeation experiments.

Capsaicin Contents in Oleoresin Capsicum. Oleoresin capsicum is an extract of chili pepper that contains capsaicin as a primary active ingredient. The accurate amount of capsaicin in the nanoemulsion was determined by measuring the capsaicin contents in oleoresin capsicum by high performance liquid chromatography (HPLC) consisting of a pump (model 2690, Waters, Milford, MA, USA), a photodiode array detector (model 996, Waters), and a Kromasil C18 column (250 mm × 4.6 mm; EKA Chemicals AB, Bohus, Sweden). The mobile phase was a mixture of isocratic methanol−water (70:30 v/v), and the flow rate was 1 mL/min at room temperature. The injection volume was 10 μL, and the column effluent was monitored at a wavelength of 280 nm for capsaicin.

Preparation of Capsaicin Nanoemulsion. Capsaicin nanoemulsion was prepared using hot homogenization and high pressure homogenization. Tween 80 and Span 80 were mixed in various ratios, and the surfactant mixture was added to distilled water with magnetic stirring at 75 °C for 30 min. The surfactant and water mixing solution was added into oleoresin capsicum, which was preheated to 75 °C. The mixture of surfactant, water, and oil was homogenized using an Ultra-Turrax T 25 basic homogenizer (IKA-Werke, Staufen, Germany) at 12,000 rpm for 5 min, followed by size reduction using high pressure homogenization (model: M-110P Microfluidizer, Microfluidics, Newton, MA, USA) under 1,000 bar pressure.

Screening of Hydrophile−Lipophile balance (HLB) Value. The HLB value of surfactant was screened to determine the best ratio of surfactant mixture.[20] As nonionic surfactant, Span 80 (sorbitan monooleate, HLB value of 4.3) and Tween 80 (polyoxyethylene sorbitan monooleate, HLB value of 15) were chosen, and various mixtures of Span 80 and Tween 80 were prepared to determine the optimum ratio. The HLB values of the surfactant mixtures (HLB_{mix}) were calculated using the weight fraction of Tween 80 and Span 80 according to the following equation:

$$HLB_{mix} = f_A\ HLB_A + f_B\ HLB_B \quad (1)$$

where HLB_A and HLB_B are the HLB values for Tween 80 and Span 80, respectively, and f_A and f_B are the weight fractions of Tween 80 and Span 80, respectively. Phase separation and size distribution of the nanoemulsions were considered to determine the optimum condition.

Ternary Phase Diagrams. To delineate ternary phase diagrams, the stability of the prepared formulations was monitored at room temperature for 1 month. The formulations, in which no phase separation, flocculation, and sedimentation were observed, were selected as stable nanoemulsions. In the selected formulations, the droplet size of nanoemulsions was not changed significantly over one month and the PDI value was also maintained less than 0.3. The formulations were found to maintain isotropic, transparent properties during the observation period.

Measurement of Droplet Size, Polydispersity Index (PDI), and Zeta Potential. The mean droplet size, PDI, and zeta potential of nanoemulsions were measured using nano size analyzer (Malvern Zetasizer Nano ZS; Malvern Instruments, Malvern, U.K.). Three milliliters of capsaicin nanoemulsion diluted in 40 times Milli-Q water was added to polystyrene latex cells, and the mean droplet size, PDI, and zeta potential were measured at 25 °C with a detector angle of 90°, and wavelength of 633 nm. Each sample was measured at least three times, and the average values were used.

Morphology of Nanoemulsions. The morphology of the nanoemulsions was investigated using a TECNAI G2 F30 transmission electron microscope (Philips-FEI, Eindhoven, Holland). For transmission electron microscopy (TEM) sample preparation, approximately 10 μL of the nanoemulsion was dropped onto carbon-coated grids for 30 s and the excess was drawn off with membrane filter paper. This step was performed three times. The grid was stained with uranyl acetate and dried overnight at room temperature. The images were obtained using TEM in the high angle annular dark field (HAADF) micrograph mode.

Skin Penetration Experiments. A synthetic membrane (Strat-M) was used to mimic human skin. The skin penetration studies were performed using a vertical modified amber glass Franz diffusion cell (Daihan Labtech, Gyeonggi-do, South Korea) with an effective diffusion area of 2.27 cm^2 and a receptor volume of 15.9 mL. The skin sample was sandwiched between the donor and receiver compartments, which were then securely fastened with a clip. The receiver compartment was filled with 20% ethanol in PBS solution and continuously stirred at 600 rpm at 37 ± 1 °C for 1 h to equilibrate the skin. After equilibration, 1 mL of the nanoemulsion or the capsaicin in a 40% ethanol aqueous solution (control) was dropped slowly on the donor compartment to cover the nanoemulsions on the skin surface. The receptor medium (1 mL) was withdrawn at fixed intervals (1, 2, 3, 6, 9, 12, and 24 h) and analyzed by HPLC to evaluate skin penetration. To fill the withdrawn amount, 1 mL of hydro ethanolic solution was added to the receptor medium.

HPLC Analysis of the Cumulative Amount of the Nanoemulsion Penetrating the Skin. The capsaicin content was analyzed by reversed phase HPLC using the more sensitive fluorometric detector rather than the photodiode detector so that even a trace of capsaicin permeating the skin into the receptor solution could be detected.[21] For capsaicin, the excitation wavelength was 270 nm and the emission wavelength was 330 nm. The HPLC system consisted of a model 2690 pump (Waters, Milford, MA, USA), a model 717 auto sampler (Waters), a fluorescence detector (Waters), and a Symmetry C18 column (100 Å, 5 μm, 4.6 mm × 150 mm, Waters). The mobile phase was an isocratic acetonitrile−water mixture (70:30 v/v), and the flow rate was 1 mL/min at room temperature.

Permeation Data Analysis. The cumulative amount of capsaicin permeation per unit of skin surface area (Q_t/S) was calculated using eq 2:[22,23]

$$Q_t = V_r C_t + \sum_{i=0}^{t-1} V_s C_i \quad (2)$$

where C_t and C_i are the capsaicin concentrations of the receiver solution at each sampling time and for the ith sample, respectively, while V_r and V_s are the volumes of the receiver solution and the sample, respectively.

The flux of capsaicin permeation at steady state (J_{ss}) was calculated from the slope of the linear portion of the graph plotted between cumulative capsaicin permeation per unit of skin surface area (Q_t/S) and time (t) as follows (eq 3):

$$J_{ss} = \frac{\Delta Q_t}{\Delta t \times S} \quad (3)$$

The permeability coefficient (K_p) was calculated by dividing J_{ss} by the initial concentration of capsaicin in the donor compartment (C_0) as follows (eq 4):

$$K_p = \frac{J_{ss}}{C_0} \quad (4)$$

Enhancement ratio (E_r) was calculated by dividing the J_{ss} of the respective formulation with the J_{ss} of the control formulation as follows (eq 5):

$$E_r = \frac{J_{ss} \text{ of formulation}}{J_{ss} \text{ of control}} \quad (5)$$

CLSM Studies for Optical Images of ex Vivo Skin Penetration. Fluorescent dye (Nile red, 0.1% w/w) was incorporated in the selected nanoemulsions to study skin penetration using CLSM. Nile red could be mixed well with capsaicin due to its similar lipophilicity to capsaicin.[32] The skin from the flank area of the pig was used for ex vivo skin permeation studies. The skin samples were thawed at room temperature and rehydrated in PBS solution for 30 min before the experiments. The skin permeation studies were performed for 24 h by using a vertical modified amber glass Franz diffusion cell as described above. After the ex vivo skin permeation experiments, the skin surface was gently rinsed with 50% ethanol and wiped. The skin was placed between a slide glass and a coverslip and examined using CLSM (LSM 5 Exciter, Carl Zeiss, Jena, Germany). The skin sample was scanned from the skin surface (0 μm) to a depth of 32 at 1 μm intervals. The skin was inspected under a 20× objective lens (EC Plan-NEOFLUAR 20x/0.50 M27). The detecting wavelength was 543 nm. CLSM images were recorded and further processed using LSM Image Browser software, version 4.2.0.121 (CarlZeiss Microimaging, Gottingen, GMBH).

CLSM Images from Cryotome-Sectioned Skin. After the final sampling interval of 24 h for the ex vivo skin permeation experiments, the skin was washed with 50% ethanol and stored at −20 °C. The skin samples were cut into small pieces and sectioned vertically to a thickness of 30 μm by using a cryotome (Leica Cryostat CM 3505S, Wetzlar, Germany). The permeation of the fluorescence dye incorporated into the capsaicin nanoemulsion was qualitatively observed using CLSM (LSM 5 Exciter, Carl Zeiss, Jena, Germany). The skin was inspected under a 10× objective lens (EC Plan-NEOFLUAR 10x/0.30 M27). The images were obtained in differential interference contrast (DIC) mode, fluorescence mode, and merge mode.

Statistical Analysis. All data were statistically analyzed using analysis of variance (ANOVA). Statistical Package for the Social Science (SPSS, Version 20.0, SPSS Inc., Chicago, IL, USA) was used for this analysis. Duncan's multiple range tests were used to determine the statistical significance among the means at 95% significant level.

RESULTS AND DISCUSSION

Screening of Optimal Surfactant Mixtures. Before the screening of surfactant mixtures, the concentration of capsaicin in oleoresin capsicum was measured by HPLC. Oleoresin capsicum contains 22.67 mg/g of capsaicin (data not shown). The selection of the best emulsifier is really crucial to enhance the emulsion stability. The ratios of nonionic surfactant mixtures were studied to determine the most stable and size controllable nanoemulsion with a droplet size optimal for efficient topical delivery of capsaicin. In this experiment, various ratios of Span 80 (HLB value 4.3) and Tween 80 (HLB value 15) were selected to prepare the nonionic surfactant mixtures. The optimal HLB_{mix} was determined when the nanoemulsion with a surfactant mixture having an appropriate HLB value also showed the smallest droplet size and a low PDI (less than 0.3). The droplet size distribution and phase separation were also considered. Results from a previous study suggested that surfactants with higher HBL values formed more stable o/w emulsion than surfactants with lower HLB values; thus, HLB values ranging from 9 to 15 were chosen to screen the optimum condition. We selected an HLB value of 13.5 for oleoresin capsicum because the nanoemulsion showed the smallest droplet size with the lowest PDI as shown in Figure 1. Nanoemulsions using higher hydrophilic surfactant showed smaller particle sizes than those using lower hydrophilic surfactant. According to our screening of the HLB value for oleoresin capsicum, the weight ratio of Tween 80 to Span 80 was fixed at 85.98:14.02.

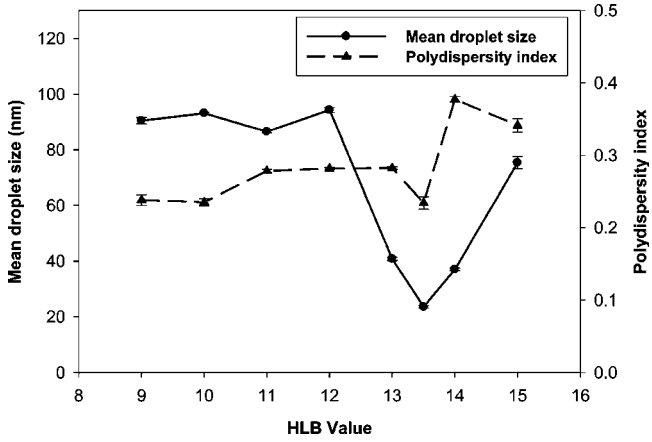

Figure 1. Droplet size and polydispersity index of nanoemulsions depending on the surfactant HLB value. Data are plotted as the mean ± standard deviation (n = 3).

Ternary Phase Diagram. To determine the best formulation of capsaicin-loaded nanoemulsion, we constructed a ternary phase diagram that consisted of various ratios of water, oleoresin capsicum, and a fixed surfactant mixture of Tween 80 and Span 80 at a weight ratio of 85.98:14.02 ($surfactant_{mix}$), respectively. In Figure 2, the area I indicates the optimal process conditions for fine and uniform sized nanoemulsions. The droplet size and zeta potential of nanoemulsions ranged from 20.26 to 62.98 nm and from −19.9 to −8.8 mV, respectively. Any phase separation was not observed until 30 days of storage for this region. Table 1 showed the formulations and characteristics such as droplet size, PDI, and zeta potential of nanoemulsions indicated in the area I. The droplet size of nanoemulsions was dependent on the ratio of oil to surfactant. In most case, droplet size of nanoemulsions decreased with lower oil to surfactant ratio. When the ratio of oil to surfactant was 1:1, the droplet size was around 63 to 64 nm and not statistically significant ($P < 0.05$) while the droplet size was around 20 nm when the ratio of oil to surfactant was 1:3. In contrast, area II nanoemulsions were not formed homogeneously and showed high PDI values (>0.3). For the remainder of the regions, immediate phase separation was obserbed. Our observations indicated that nanoemulsion regions were not identified when the aqueous phase was below 50%. The optimal nanoemulsion formulations were found to be in the range of more than 50% of water, less than 18% of oleoresin capsicum, and 15.4%−33.3% of $surfactant_{mix}$ with treatment of a high pressure homogenization.

Optimal Formulation and Stability Study of the Nanoemulsions. Based on the HLB value and the phase study, the nanoemulsion formulations that had oil/$surfactant_{mix}$ ratios of 1:1, 1:1.3, 1:1.5, 1:2, and 1:3 were selected for the following penetration studies. Figure 3 represents the profile for the change in droplet size and PDI value of nanoemulsion formulations (NE-1 to NE-13) in which the oil and $surfactant_{mix}$ ratio ranged from 1:1 to 1:3. The formulations of the selected nanoemulsions were stable and showed a controlled droplet size ranging from 20.26 to 62.98 nm. As the surfactant concentration increased, the droplet size tended to become smaller, but PDI

and zeta potential were not correlated with the amount of surfactant. A smaller droplet size might have a larger the surface area, so that more surfactant would be required to cover particles.[24] When we fixed the ratio of oil and surfactant, the droplet size of nanoemulsion was decreased by adding more aqueous phase.

Morphology of Capsaicin-Loaded Nanoemulsions. Figure 4 shows the TEM images of the nanoemulsions (NE-13). The droplet size of NE-13 was approximately 20 nm in TEM images, and this was consistent with our previous results obtained by using a size analyzer. The droplets were spherical and showed a uniform emulsion droplet distribution.

Penetration Profiles of Different Formulation of Nanoemulsion. One of the main barriers for skin penetration is the lipophilic stratum corneum (SC) layer. It is well-known that it is difficult for hydrophilic substances and high molecular weight vesicles to penetrate the SC. On the other hand, hydrophobic substances easily get into the SC layer but they also have some limitation to penetrate the next epidermis layer which has a hydrophilic feature.[25] Therefore, it needs to be delivered in both hydrophilic and hydrophobic barriers with special formulation vesicles to penetrate all layers of the skin. The effect of different compositions of nanoemulsions on skin permeation was investigated using the synthetic membrane that is considered the standard model for in vitro transdermal diffusion studies replacing human or animal skin. Reproducibility of results is enhanced by using this synthetic membrane as compared with using animal skin. Figure 5 shows the permeation profiles of capsaicin-loaded nanoemulsions and a control sample. The concentration of capsaicin in nanoemulsion ranged from 2.08 to 3.45 mg/g whereas the capsaicin concentration of control was 2.64 mg/g. All nanoemulsion samples continuously

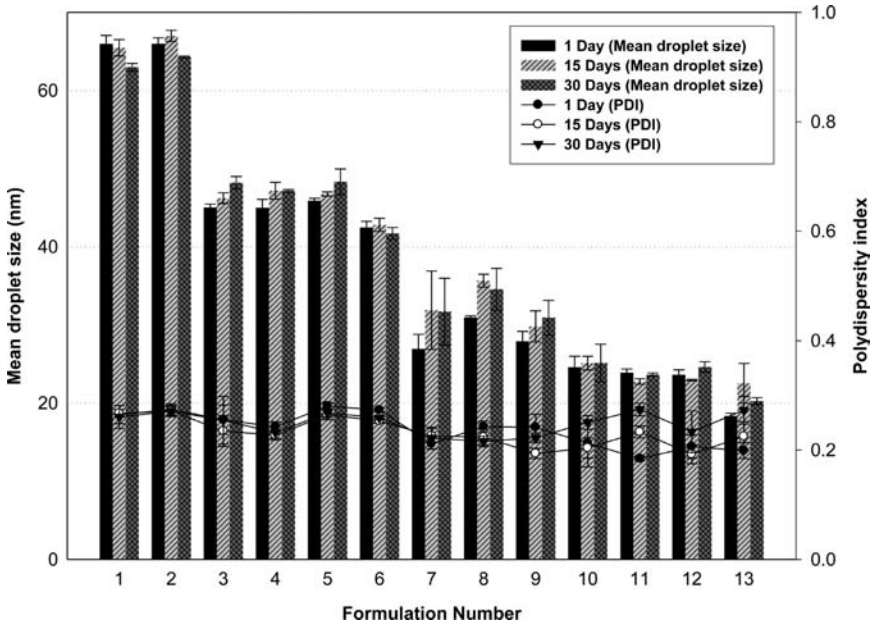

Figure 3. Droplet size profiles of nanoemulsion formulations for 30 days. Data are plotted as the mean ± standard deviation (n = 3).

permeated the membrane over time. NE-1 showed the highest cumulative capsaicin permeated amounts whereas NE-13 showed the lowest permeated amounts, which were not statistically significant ($P > 0.05$) with those of the control at the all sampling time as shown in Figure 5. Cumulative capsaicin permeated amounts of NE-4 and NE-9 were not statistically significant ($P > 0.05$) until 8 h and were significantly ($P < 0.05$) higher at 12 and 24 h compared to the control. Only NE-1 showed statistical significance ($P < 0.05$) in the capsaicin permeated amounts with other formulations including the control throughout all the time. Cumulative permeation of NE-1 was steeply increased for the initial time (until 6 h) and was slowly increased over time. This phenomenon could be explained by capsaicin-incorporated nanoemulsion being highly accumulated in the receptor fluid, which could affect the permeation flux and delay the capsaicin penetration since the sink condition limit might have been reached. However, many factors may affect the diffusion phenomenon for skin membrane permeation such as sink condition, sampling frequency, experiment duration, type of membrane sample, or membrane materials.[24] It has been reported that infrequent sampling increases drug concentration in the receptor chamber and sink condition (<10%) could rise over the limited state.[26] Thus, in our case, the sampling frequency and experimental duration of 24 h could also account for the slower cumulative permeation observed after 12 h.

The permeation parameters such as permeation flux (J_{ss}), permeability coefficient (K_p), and enhancement ratio (E_r) are summarized in Table 2. The permeation flux of the nanoemulsions ranged from 10.597 μg/cm^2 h to 21.251 μg/cm^2 h. The highest permeation flux was obtained in NE-1, while the lowest permeation flux was observed in NE-13. Except for NE-13, the permeation flux of the nanoemulsions was higher than that of control (12.864 μg/cm^2 h) by about 30% to 65%. However, the permeation flux and permeability coefficient of most of the nanoemulsion formulations were not statistically significant ($P > 0.05$) compared to those of the control except NE-1 as shown in Table 2. The enhancement ratio (E_r) of the nanoemulsions ranged from 0.849 for NE-13 to 1.658 for NE-1. The enhancement ratio of the nanoemulsions was statistically significant ($P < 0.05$) compared to that of the control except NE-13. The enhancement ratios of the nanoemulsions were also higher than that of the control sample, except for NE-13. It has been reported that the manner of skin penetration depends on various physiological properties including size, composition, and surface charge of the vesicles, the HLB value, and the type of surfactant, as well as the presence of a penetration enhancer.[27] In general, the skin penetration should be fast and higher with smaller droplet size. However, the highest penetration flux was obtained with NE-1 containing larger mean droplet size of 62.98 nm and the lowest penetration flux was obtained with NE-13 containing smaller droplet size of 20.26 nm. The skin penetration might be highly dependent on the amount of surfactant because thermodynamic activity of core in nanoemulsion increased at the lower concentration of surfactant.[28] NE-1 contains the least amount of surfactant in the formulations and showed the highest penetration flux. Based on the permeation profiles, NE-1 showed the best nanoemulsion

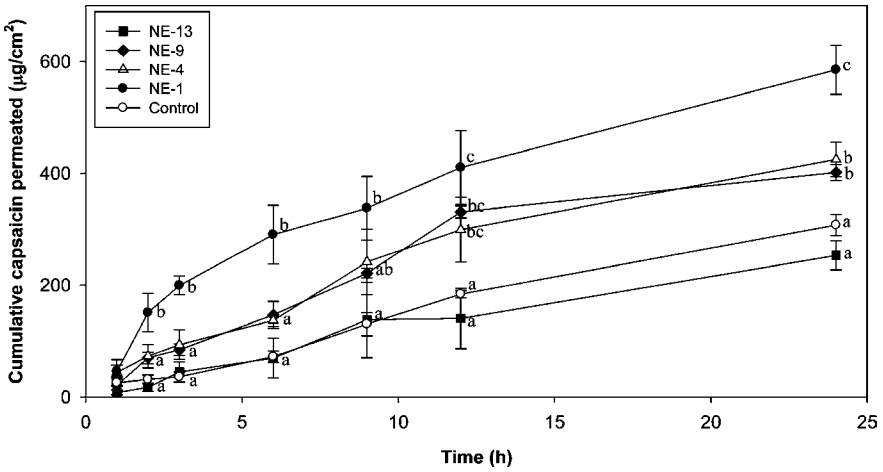

Figure 5. Permeation profiles of capsaicin from capsaicin-loaded nanoemulsion formulations through a synthetic membrane similar to human skin. The control sample was a 40% ethanol solution of capsaicin (mean ± SD, n = 3). Different letters at the same time indicate a significant difference at $P < 0.05$ by Duncan's multiple range test.

formulation for improved skin penetration and was, therefore, selected for optical image observation using CLSM.

CLSM. Images derived from CLSM were used to show the permeation pathway of active compounds through the skin layer. This method provides multidepth images that parallel the skin surface without any physical sectioning.[29] While the conventional method of studying skin penetration relies on classical sectioning processes that can destroy the skin membrane structures, CLSM is noninvasive and allows the observation of the skin penetration pathways of active compounds without

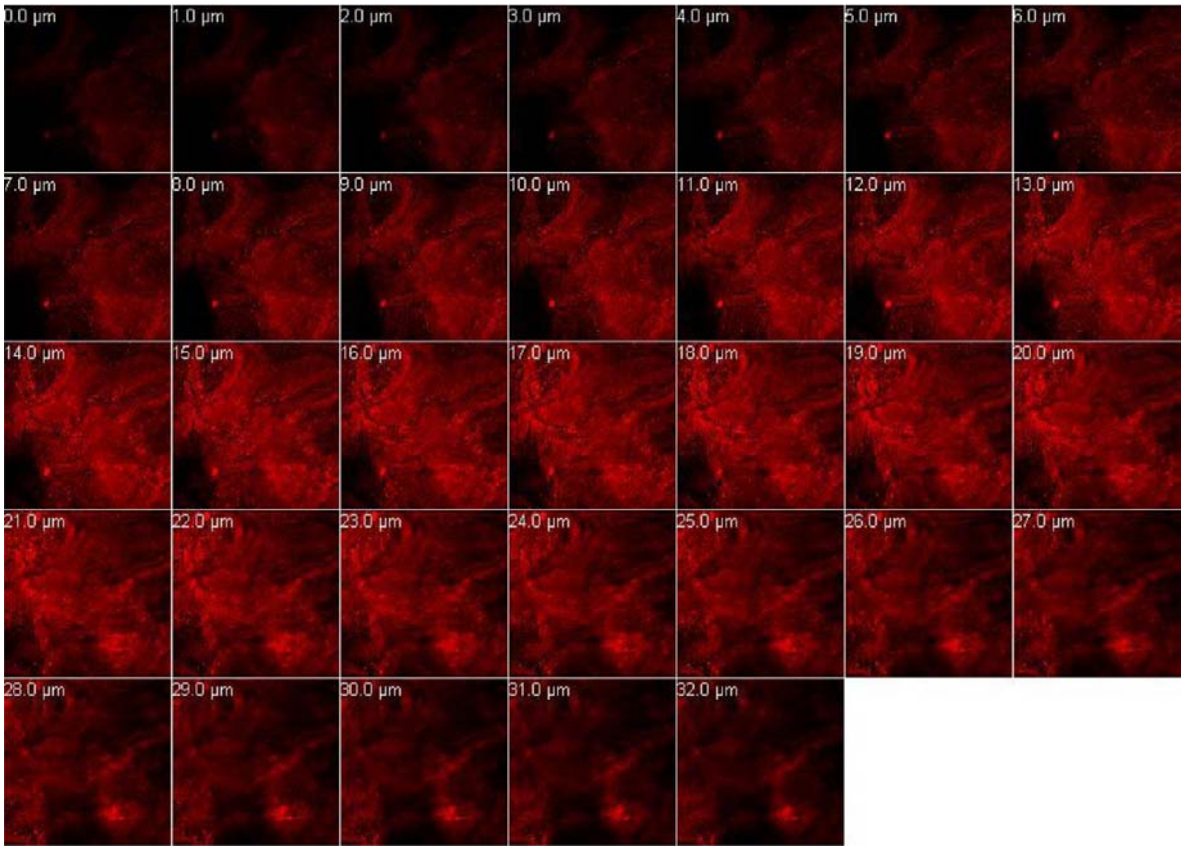

Figure 6. Confocal laser scanning microscopy (CLSM) images for penetration of capsaicin-loaded nanoemulsion (NE-1) into the pig skin. Nile red (0.1% w/w) was used as a fluorescence dye, and the detection wavelength was 543 nm.

inflicting tissue damage.[30,31] To obtain images using CLSM, the skin thickness was not more than 700 μm from SC to dermis so that the laser could penetrate all skin layers. The fluorescence dye, Nile red (0.1% w/w), was used as model compound for observation of capsaicin-loaded NE-1 permeation pathway. Nile red has the ability to emit strong fluorescence, and its lipophilicity (log P = 3.10) is similar to capsaicin (log P = 3.81).[32] The fluorescence intensity indirectly indicates the amount of permeated capsaicin. Figure 6 shows 32 fluorescence images that parallel the skin surface (z direction images). The first skin surface image did not show strong fluorescence intensity compared with other images because of rinsing the skin sample with 50% ethanol in sample preparation. However, we could observe a clear fluorescence image of penetrated capsaicin nanoemulsion until 32 μm depth in other images. The strongest fluorescent spot was observed near the hair follicles. Capsaicin nanoemulsion can penetrate and accumulate in the skin well through the hair follicles as shown in Figure 6. Because the thickness of the stratum corneum is 10−20 μm, these images indicated that capsaicin-loaded NE-1 permeated stratum corneum and epidermis.

CLSM Images of Cryotome-Sectioned Skin. Vertical sectioning of pig skin using the cryotome was performed to ensure and visualize the permeation profile through the skin layers. Figure 7 shows CLSM images of Nile red in 40% ethanol

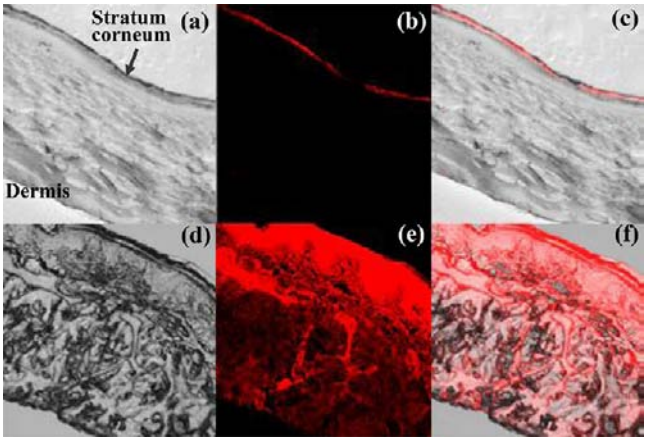

Figure 7. Confocal laser scanning microscopy (CLSM) images of cryotome-sectioned pig skin of (a, b, c) Nile red in 40% ethanol and (d, e, f) capsaicin-loaded nanoemulsion (NE-1) permeation in differential interference contrast mode (a, d), fluorescence mode (b, e), and merge mode (c, f). Sample thickness is 700 μm. Images of the same area were obtained in fluorescence mode (420−720 nm and 580−720 nm).

(control) and capsaicin-loaded nanoemulsion (NE-1) permeating into pig skin layers consisting of stratum corneum, epidermis, and dermis. Nile red in 40% ethanol could not permeate even the stratum corneum layer, and any fluorescence intensity was not observed in Figure 7a. However, capsaicin-loaded nanoemulsion (NE-1) could successfully penetrate the skin layers, and strong fluorescence intensity was observed through the whole skin layers from stratum corneum to dermis. The stratum corneum layer (10−20 μm thick) shows the strongest fluorescence intensity while the dermis layer shows less fluorescence intensity. Although it gradually decreased from stratum corneum to dermis, the red fluorescence intensity was observed through all skin layers up to 700 μm thick. This result indicates that capsaicin-loaded nanoemulsions have a great potential as a transdermal delivery carrier for the effective penetration through all skin layers.

Supporting Information

ABSTRACT: Processing beverages containing high concentrations of globular proteins represents a technological challenge due to their instability during heating caused by protein aggregation and gelation. Aggregation of whey protein mixtures was investigated in aqueous model systems at pH 3.5, 4.0, and 4.5 at heating conditions resembling conventional industrial treatment (90 °C for 30 s). The extent of aggregation progressively decreased moving away from the p*I*. Protein aggregates became smaller and had a more open structure compared to higher pH values. Significant loss of protein dispersibility occurred at pH 4.0 and 4.5 above the denaturation *T* of whey protein (~70 °C), at which aggregation was caused by intermolecular hydrophobic interactions. Accessible thiol groups were detected in the heat-treated systems, with a higher intensity at higher pH and increasing extent of aggregation. Intermolecular −S−S− bonding played only a minor role in the aggregation at all conditions studied.

KEYWORDS: *whey protein, aggregation, thiol reactivity, surface hydrophobicity*

INTRODUCTION

The use of whey proteins in beverages represents an important opportunity due to their high nutritive and biological values,[1] which can fulfill the dietary requirements of various categories of individuals (e.g., the elderly and the frail).[2] However, the production of stable whey protein-based nutritional beverages is a great technological challenge. Processing (i.e., thermal treatment to ensure microbial safety) and product formulation affect protein solubility, which can lead to turbidity and/or sedimentation[3,4] or compromise manufacturing due to fouling of the heating equipment during pasteurization/sterilization processes.[5] To reduce the effect of the heat load the whey protein undergoes, whey-based beverages can be formulated at acidic pH (below pH 4.6) as, for their microbial safety, a milder thermal treatment compared to pH-neutral recipes is possible.[6]

Whey protein of bovine milk is a mix of globular proteins (*β*-lactoglobulin, *β*-LG, 50%; *α*-lactalbumin, *α*-LA, 20%; bovine serum albumin, BSA, 5%; immunoglobulins, IGs, 10%; lactoferrin, LF, 2.5%; lactoperoxidase, LP, 0.5%) with a high level of secondary, tertiary, and in some cases quaternary structure.[7] Far from their isoelectric point (p*I*), proteins have a net charge that leads to electrostatic repulsion, resulting in stable protein solutions.[8,9] At the p*I* (*β*-LG, p*I* = 5.1; *α*-LA, p*I* = 4.3; BSA, p*I* = 4.1) where the net charge of the proteins equals zero, the electrostatic repulsive forces are minimal, and intermolecular interactions, such as hydrophobic interaction and hydrogen bonds, may lead to aggregation.[9−11]

The solubility of whey proteins is highly dependent on the modification of the protein structure caused by heat treatment. Native globular proteins unfold upon heating and, depending on the balance of attractive and repulsive interactions, can form aggregates or gels with various structures (i.e., opaque particulates or transparent filaments).[9,12,13] When whey proteins are heated in an aqueous solution, the globular structure progressively unfolds, exposing hydrophobic groups and free thiol groups (when present, as in the case of *β*-LG and BSA) which are normally buried in the interior of the native protein molecule away from the protein−water interface. The exposed hydrophobic domains are driven toward their association, thereby leading to noncovalent protein aggregation (physical aggregation). At the same time, reactive −SH groups can lead to intermolecular covalent cross-linking (chemical aggregation) via oxidation or, as thiolate groups $-S^-$, via sulfhydryl/disulfide interchange reactions. The −S−S− bridges can also rearrange within the same molecule via an intraprotein thiol−disulfide exchange reaction (i.e., disulfide bond shuffling).[14,15] As Ako et al.[16] pointed out, aggregation and gelation of denatured whey proteins can even occur at conditions of strong electrostatic repulsion.

The mechanism of heat-induced aggregation and gelation of whey proteins has been extensively studied for model systems at neutral pH[4,17−20] or at high acidity (pH ~2), where fine-stranded fibrillar structures are formed.[12,21,22] At intermediate pH values, near the p*I*, the structural characteristics of particulate *β*-LG gels have been studied. It was found that between pH 4.05 and 5.55, *β*-LG heated at 60 °C for 24 h formed particulate aggregates without evidence for fibrillar structures. However, near the p*I*, spherical crystalline structures, called spherulites, can be formed by fibrillar structures growing radially from a central amorphous nucleus.[13] Recently, *β*-LG close to the p*I* was thoroughly investigated as a way to obtain

stable dispersions of spherical protein particles, called microgels.[23,24] Furthermore, micrometer-size highly-dense spherical whey protein particles were prepared[25,26] by heat-induced gelation of whey protein solutions dispersed as droplets in water-in-oil emulsions.

Although the literature has provided an in-depth characterization of the structures formed when β-LG is heated in aqueous solutions around the p*I*, the mechanism of aggregation of whey protein mixtures at moderately acidic conditions (3.5 < pH < 4.5) has received less attention.

Therefore, in this study we chose to focus on whey protein aggregation and dispersibility at heating conditions resembling the manufacturing of acidic beverages. The relevance of intermolecular disulfide bonds and hydrophobic interactions on the heat-induced aggregation of whey protein isolate in aqueous solutions at pH 3.5, 4.0, and 4.5 was investigated. The microstructure of the systems was also characterized. The results of this study contribute to a better understanding of the mechanism leading to whey protein instability at acidic pH and can be used to develop novel strategies for improving the stability and processability of concentrated whey protein aqueous formulations.

MATERIALS AND METHODS

Materials. A commercial whey protein isolate (BiPRO, Davisco Foods International Inc., Le Sueur, MN, USA) was used. The protein content was 92.84% (w/w) (all percentages used are w/w, unless stated otherwise) protein on a wet basis (N × 6.25), as measured by Dumas nitrogen analysis (Thermo Fisher Scientific Inc., Flash 4000 N/Protein Analyzer, Waltham, MA, USA).

All salts and reagents used for the thiol reactivity and the hydrophobicity study were of reagent grade. HPLC grade chemicals were used for ζ-potential measurements, transmission electron microscopy (TEM), and electrophoresis experiments.

Preparation of Protein Solutions. Protein solutions were freshly prepared for each set of experiments, similar to methods reported in the literature.[16,27] Protein powder was dispersed in demineralized water to obtain a homogeneous stock solution of 25%. The concentrated protein solution was stirred at room temperature for 3 h and stored overnight to allow for complete hydration of the protein. The next day, the 25% solution (approximately 400 mL) was transferred into a 3.5 kDa cutoff dialysis tubing (35 mm dry SnakeSkin, Thermo Scientific, Rockford, IL, USA) and dialyzed against 10 L of demineralized water for 2 h. After washing with demineralized water, the dialysis tubing was transferred into 10 L containing 3% of 12 kg mol^{-1} polyethylene glycol (PEG) (Sigma-Aldrich, Steinheim, Germany) solution, and the dialysis was continued for 24 h. The overall preparation was performed at 4 °C, and after dialysis no sign of bacterial growth was observed. Addition of PEG was necessary to compensate for osmotic pressure, thereby avoiding bursting of the dialysis tube. After dialysis, the concentration of the protein in the dialyzed solution was determined by the UV absorbance at 280 nm (kinetics spectrophotometer, LKB Biochron, Ultrospec K 4053, Cambridge, UK) using calibration curves prepared by dissolving known amounts of whey protein. At the dialysis conditions used in this study, the final protein concentration was approximately 14%. This stock solution was divided into various aliquots, and the pH was adjusted to pH 3.5, 4.0, and 4.5 using 2 N HCl. Finally, the solutions were diluted to the different protein concentrations (1, 5, and 10%).

Mineral and Lactose Contents. The concentrations of Ca, Cl, P, K, Mg, Mn, Na, and lactose were measured in the nondialyzed and dialyzed solutions with the same protein concentration. Minerals were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-OES) (iCAP 6300, Thermo Fisher Scientific Inc.), whereas lactose was determined by high-performance anion-exchange chromatography (HPAEC) and pulsed electrochemical detection (PED) (Dionex ICS-5000, Thermo Scientific, Sunnyvale, CA, USA).

Protein Dispersibility after Heat Treatment. Whey protein dispersibility before and after heat treatment was measured in 1, 5, and 10% protein solutions at pH 3.5, 4.0, and 4.5. Solutions with a volume of 15 mL were transferred into sealed screw-capped glass test tubes and heated in a water bath at 92 °C. The temperature increase of the sample was monitored with a thermocouple inserted in a reference tube containing 15 mL of deionized water.

The initial temperature of the sample was 20 °C, and heat treatment was immediately stopped when the sample temperature had reached 50, 60, 70, 80, or 90 °C. All of these temperatures were reached within 5 min. One of the samples was held at 90 °C for 30 s (this latter heat treatment is indicated as 90* °C). After heat treatment, the test tubes were cooled to room temperature using running tap water. This heating protocol was chosen to mimic temperature treatments of acidic formulations on liquid processing lines. At the end of the heat treatment protein aggregates were removed by centrifuging the samples at 3500*g* for 30 min using a refrigerated centrifuge (Biofuge Fresco, Heraeus Sepatech GmbH, Osterode, Germany).

The supernatant was filtered through a 0.2 μm pore size syringe filter (Minisart; Sartorius Stedim Biotech GmbH, Goettingen, Germany), and the protein concentration was analyzed by Dumas.

The dispersibility was expressed as the percentage of the protein concentration in the supernatant, relative to the initial total protein concentration of the solution. The heat treatment was repeated in three replicate experiments, and values were reported as an average and standard deviation.

Accessibility of Thiol Groups. The accessibility of the free thiol groups in protein was determined by their reactivity with 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB; Sigma-Aldrich, Inc., St. Louis, MO, USA) according to the method described by Ellman,[28] adapted for the composition of the system.[19]

A 0.1 M sodium citrate at pH 3.5, 4.0, and 4.5 buffer containing 1 mM ethylenediaminetetraacetic acid (EDTA; Sigma-Aldrich, Inc.) was prepared and diluted 1:1 with demineralized water. Ellman's reagent was prepared by dissolving 8 mg of DTNB (Sigma-Aldrich, Inc.) in 2 mL of buffer. The reaction mix for the analysis of accessible reactive thiol groups was prepared by adding 2.5 mL of reaction buffer to 50 μL of Ellman's reagent solution and 250 mL of protein solution (or protein gels) and was left to react overnight. After complete reaction, solutions were spun at 16000*g* for 100 min at 20 °C (Biofuge Fresco, Heraeus Sepatech GmbH, Osterode, Germany) to remove the aggregates. The supernatant was collected, and the reactive thiol concentration was measured spectrophotometrically at 412 nm and determined using an extinction coefficient of 13600 M^{-1} cm^{-1}.[4,28−30] This method is based on the quantification of *p*-nitrothiophenol derived from the equimolar reaction between DTNB and −SH. Blank samples were prepared by replacing 250 μL of protein solutions with 250 μL of reaction buffer. The heat treatment was repeated in three replicated experiments, and values were reported as an average and standard deviation.

Surface Hydrophobicity. Surface hydrophobicity was determined using the fluorescent probe 1-(anilino)-naphthalene-8-sulfonate (ANS) (Sigma-Aldrich, Inc.), according to the method described by Monahan, German, and Kinsella.[4] Protein solutions of 1, 5, and 10% at pH 3.5, 4.0, and 4.5 were heat treated as described above and centrifuged at 3500*g* for 30 min at 20 °C, and the protein concentration in the supernatant was measured by Dumas.

ANS [10% (w/v)] was dissolved in dimethyl sulfoxide (DMSO) (Sigma-Aldrich, Inc.) and diluted in 30 mM citrate buffer (pH 4.0) to obtain a stock solution containing 0.5% (w/v) ANS; 0.2 mL of the 0.5% (w/v) ANS solution was added to 0.3 mL of supernatant and diluted with 30 mM citrate buffer (pH 4.0) to a final volume of 3 mL. Samples were analyzed by a fluorescence spectrometer (LS50B; Perkin-Elmer, Norwalk, CT, USA), with an emission wavelength from 400 to 580 nm, an excitation wavelength at 350 nm, and both slits widths (emission and excitation) at 4 nm, as described in the literature.[31] Surface hydrophobicity was expressed as the value at the maximum emission wavelength (475 nm) and normalized relative to protein concentration. The background signal as caused by the presence of dispersed aggregates in systems with no added ANS was

found to be negligible relative to the signal when ANS was added (<1%).

Microscopy. The microstructure of 10% whey protein systems was observed by transmission electron microscopy (TEM) (JEM-1011/100 kV, JEOL, Tokyo, Japan), using the negative staining method. Systems at pH 3.5, 4.0, and 4.5 were diluted 100-fold with the appropriate buffer (citrate buffer, pH 3.5, 4.0, and 4.5) for the control samples (no heat treatment) and 1000-fold for the heat-treated samples (90* °C for pH 3.5 and 4.5 and 70 °C for pH 4.0, where a gel was formed at 90* °C).

A drop of diluted protein solution was deposited on a 400-mesh Formvar/carbon-coated copper grid (Electron Microscopy Sciences, Washington, PA, USA) and dried with filter paper. After 2 min, the sample was stained for 15 s with one drop of 2% uranyl acetate (Merck) and then dried with filter paper. The grid was left to dry completely for 15 min before analysis.

Electrophoresis. After heat treatment at 20, 50, 60, 70, 80, 90, and 90* °C, the 10% whey protein solutions were analyzed by polyacrylamide gel electrophoresis (Midi Criterion system, Bio-Rad Laboratories B.V., Veenendaal, The Netherlands). Native PAGE and SDS-PAGE experiments under reducing and nonreducing conditions were performed using stain-free precast 8−16% gradient gels (Criterion TGX, Bio-Rad Laboratories B.V.).

Care was taken to avoid overloading of the gels; therefore, 15 μg of protein was loaded on each well. The running buffer was prepared from 10× premixed Tris/glycine electrophoresis buffer (25 mM Tris, 192 mM glycine, pH 8.3, Bio-Rad) or from 10× Tris/glycine/SDS (25 mM Tris, 192 mM glycine, 0.1% SDS, pH 8.3, Bio-Rad) according to procedures described by the manufacturer.

To investigate the mechanisms of protein aggregation and the composition of protein aggregates[32] the following experimental approach was used:

- Native-PAGE was used as a control.
- For native-PAGE under reducing conditions, 10 mM dithiothreitol (DTT) solution was added to the sample buffer to investigate the presence of intermolecular disulfide bridges in the aggregates.
- In SDS-PAGE, SDS disrupts aggregates connected by noncovalent interactions; therefore, this method was used to determine the influence of noncovalent interactions on aggregation.
- For SDS-PAGE under reducing conditions, DTT (10 mM) was added to the SDS sample buffer to determine the influence of both intermolecular −S−S− bridging and noncovalent interactions on aggregation.

Gels were stained with 10 mL of Coomassie (Brilliant) Blue R-250 (Bio-Rad) for 30 min and destained in a solution of 40% (w/v) methanol, 10% (w/v) acetic acid, and 50% (w/v) demineralized water. Gels were scanned with a ChemiDoc XRS system (Bio-Rad), and the protein bands were quantified using Quantity One 4.6.5 software (Bio-Rad). Values were normalized for each protein fraction by using α-LA (>85% purity, Sigma-Aldrich), β-LG (>90% purity, Sigma-Aldrich), and BSA (>98% purity, Sigma-Aldrich) standards. Protein concentrations were obtained using

$$C_U = (C_S/I_S)I_U$$

where, C_U and C_S are the concentrations, whereas I_S and I_U are the measured intensities of the unknown sample (U) and reference (S), respectively. The heat treatment of each system was performed in duplicate, and the heat-treated samples were run on two different lanes in the same gel. The average values of band intensity calculated from all of the previous were then quantified with a calibration curve obtained on a different gel (five concentrations in three replicates) and corrected according to the band intensity of an internal standard.

The concentrations of α-LA, β-LG, and BSA in the WPI were obtained by analyzing unheated aqueous solutions containing whey protein by SDS-PAGE. The relative concentrations of α-LA, β-LG, and BSA derived from a calibration curve were 24.0 ± 0.3, 68.0 ± 1.0, and 3.0 ± 0.2%, respectively.

RESULTS AND DISCUSSION

Effect of Dialysis on Minerals and Lactose. The data for nondialyzed and dialyzed protein dispersions obtained by ICP-OES (for minerals) and HPAEC-PED (for lactose) are compared in Table 1. Nondialyzed protein solutions contained only residual amounts of lactose and minerals. At the conditions used in the present study, dialysis did not lead to a significant loss of minerals, but reduced the lactose content 10-fold. This shows that most of the ions are present as counterions or associated with the protein structure (e.g., Ca^{2+} in α-LA).

Table 1. Compositional Data for 10% (w/w) Whey Protein Solutions before and after Dialysis through a 3.5 kDa Cutoff Membrane

element	control	3.5 kDa dialyzed system	unit
Ca	9	9	mg/100 g
Cl	1	0	mg/100 g
P	5	5	mg/100 g
K	3	2	mg/100 g
lactose	5.43	0.55	μg/mL
Mg	1	1	mg/100 g
Mn	0.005	0.003	mg/100 g
Na	54	50	mg/100 g

ζ-Potential and Visual Appearance. The ζ-potential of dialyzed whey protein solutions was measured upon titration with 1 M HCl from pH 7 to 2 using Zetasizer Nano cells (DTS1060, Malvern Instruments Inc., Worcestershire, UK), and the p*I* of the whey protein mix was determined. p*I* was reached around pH 4.8 (Supporting Information, Figure S1).

The whey protein solutions showed an increased turbidity as the pH was close to the p*I*. The visual appearance of the 5 and 10% freshly prepared whey protein samples at pH 4.5, 4.0, or 3.5 are shown in Figure 1. After 2 h at room temperature (Figure 1), the 5% whey protein samples at pH 4.5 phase-separated into an opaque protein-rich white sediment and a (protein-depleted) clear top layer. Less extensive separation was observed in the 10% whey protein samples at pH 4.5. No macroscopic phase separation was observed at pH 4.0 or 3.5, showing a cloudy or translucent appearance, respectively. At pH 4.5, close to the isoelectric point, the whey protein molecules form (reversible upon pH change) aggregates that

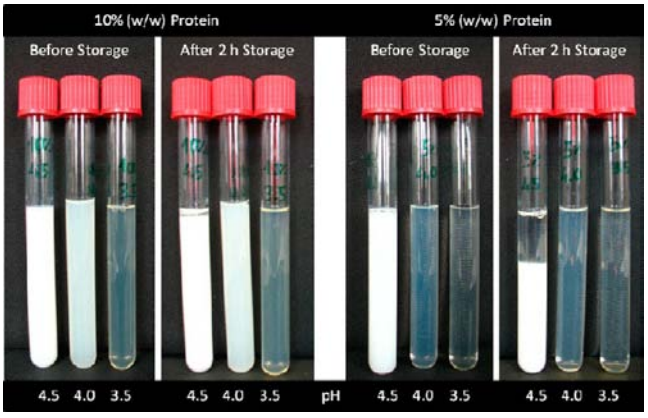

Figure 1. Whey protein solutions, 10 and 5% (w/w), at pH 4.5, 4.0, and 3.5, before and after 2 h of storage at room temperature.

dx.doi.org/10.1021/jf404456q | J. Agric. Food Chem. 2014, 62, 733−741

are large enough to be prone to sedimentation. This is often ascribed to the interactions between non-native protein fractions present in the whey protein isolate powders.[33,34]

Whey Protein Dispersibility. The results obtained for the protein dispersibility on systems containing 1, 5, and 10% protein are shown in Figure 2. In line with previous work,[8] a limited dispersibility of unheated whey protein at pH 4.5 was found. Dispersibility in the non-heat-treated systems was 93.88 ± 0.71, 93.22 ± 3.79, and 90.15 ± 1.26% at 1, 5, and 10% protein, respectively. This loss of dispersibility is in line with the visual observations described in the previous section.

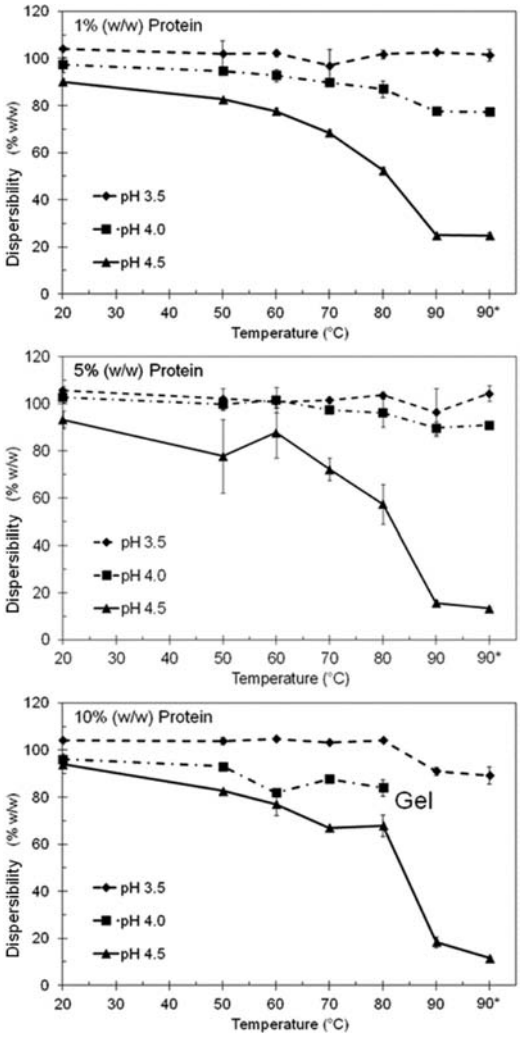

Figure 2. Dispersibility of 1, 5, and 10% (w/w) whey protein solutions at pH 4.5, 4.0, and 3.5 as a function of heat treatment.

At increasing temperature, the protein dispersibility progressively decreased until a sharp decrease occurred above 70 °C. This temperature is close to the peak of whey protein denaturation curve as measured by differential scanning calorimetry by Potes et al.[35]

According to the pathway suggested by Lumry,[36] upon heating, native proteins undergo structural changes, which can be followed by (irreversible) non-native protein association to form aggregates. Aggregation affects protein dispersibility so that protein clusters precipitate as they exceed a critical size[37] or are able to form a stable microgel.

The lower pH values investigated gave significantly higher dispersibility. The 1 and 5% protein systems at pH 3.5 did not lead to any significant dispersibility loss when heated from 20 °C to 90* °C. At higher protein concentration (10% protein), however, a limited loss in dispersibility (∼10%) was observed. A similar trend was observed for systems at pH 4.0. In this latter case 10% protein systems showed a lower dispersibility between 50 and 80 °C (dispersibility of ∼80%) and formed a gel at 90 °C.

At pH values between pH 3.5 and 4.5 a significant effect of the pH of the system on protein dispersibility was found. At all protein concentrations and heat treatments studied, the protein dispersibility increased progressively as the pH was decreasing below the p*I*. This is due to the higher net positive charge on the protein surface at low pH (Supporting Information, Figure S1), which leads to a stronger intermolecular electrostatic repulsion.

Accessibility of Thiol Groups. During the heating of whey protein, the formation of intermolecular disulfide bridges has been found to occur as a result of thiol−disulfide exchange reactions or oxidation. As explained by Visschers and de Jongh[15] and De Wit,[38] this process is driven by free sulfhydryl groups located on the cysteine of β-LG and BSA and is regulated by its pK_a (≈8.3), with the thiolate ion ($-S^-$) being the reactive species. Moreover, reactive thiols should be free from steric hindrance and be exposed and accessible to complete the reaction.[39]

In this study, the concentration of accessible thiol groups was monitored in 10% whey protein systems at pH 3.5, 4.0, and 4.5 during heating from 20 to 90 °C. To evaluate the accessibility of thiol groups, the reaction mixes in which the DTNB was allowed to react with proteins were buffered at pH 4.0 for all three systems (Figure 3A) and at pH 3.5, 4.0, 4.5 (Figure 3B). As shown in Figure 3A, the concentration of accessible thiol groups in the three different systems followed the same trend. No thiol groups were accessible to react with DTNB below 80 °C. As the proteins formed aggregates above the denaturation temperature, molecular rearrangement might have led to the exposure of the thiol groups to the solvent or to an open structure that allowed diffusion of DTNB (as already postulated by McGuffey et al.[19]). This implies the presence of accessible thiol groups. The experiment conducted in the three different buffer mixes (Figure 3B) revealed a pH-dependent accessibility of thiols on the protein aggregates. Again, reactive free thiol goups were detected with DTNB, and systems at pH 4.5 showed higher residual thiol group reactivity than systems at pH 4.0 and 3.5 (0.425 ± 0.003, 0.953 ± 0.014, and 4.134 ± 0.019 nmol/mg protein, in systems heated at 90* °C at pH 3.5, 4.0, and 4.5, respectively). As this might be due both to the increased reactivity of thiols to DTNB with increasing pH and to the different structural reorganization of the aggregates resuspended in different buffers, an additional experiment was performed. Solutions at the same concentration of free cysteine (0.4 mM) in citrate buffers at pH 3.5, 4.0, and 4.5 were tested with DTNB. Results showed values of absorbance that increased with increasing pH 3.5 < pH 4.0 < pH 4.5 (Supporting Information, Figure S2). However, the increased absorbance due to the sole effect of pH was significantly lower than the combined effect of pH and structural rearrangement observed for heat-treated (aggregated) whey proteins.

Therefore, it can be concluded that free thiol groups were accessible to DTNB only above 80 °C, when protein unfolding and aggregation occurred. Furthermore, the thiol accessibility

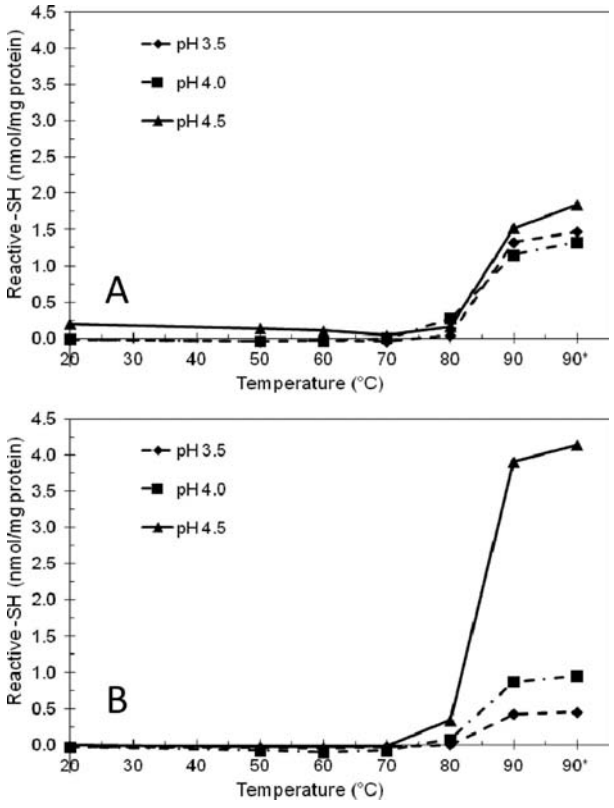

Figure 3. Temperature-dependent thiol group concentration of 10% whey protein solutions at pH 4.5, 4.0, and 3.5: (A) reaction with DTNB performed in citrate buffer, pH 4.0; (B) reaction with DTNB performed in citrate buffer, pH 3.5, 4.0, and 4.5.

increased rapidly with increasing pH from pH 3.5 to 4.5, whereas their reactivity was only slightly enhanced by increasing the pH from pH 3.5 to 4.5. This in agreement with earlier results[30,40] where the presence of exposed reactive of thiol groups was observed at acidic pH, in acid-induced cold-set gels of whey proteins. However, Alting et al.[41] observed a decrease of detectable thiol groups when aggregation was caused by a long heating period (>6 h). A long heat treatment might induce a compacting of the aggregate structure, which was not detected during the short heating time used in this study.

Surface Hydrophobicity. Heating globular proteins (such as whey proteins) causes conformational changes (denaturation), which can lead to the exposure of hydrophobic sites that are buried inside the native structure of the protein and are inaccessible to the surrounding.[42] Hydrophobicity is one of the major factors controlling intermolecular association of proteins, which results in the formation of (soluble or insoluble) aggregates.[43] Hence, studying the evolution of exposed hydrophobicity as a function of heating can provide useful information on the mechanism regulating whey protein aggregation and the impact on dispersibility. Here we assume that even if large aggregates are present, a discussion of the hydrophobicity on a molecular level is still meaningful.

The effect of pH and heating on whey protein hydrophobicity in 1, 5, and 10% protein solutions, as determined using the aromatic probe ANS, is reported in Figure 4. Independent of protein concentration, systems at pH 4.5 showed the lowest fluorescence intensity (<100 AU). The limited accessibility of hydrophobic patches at this pH might be

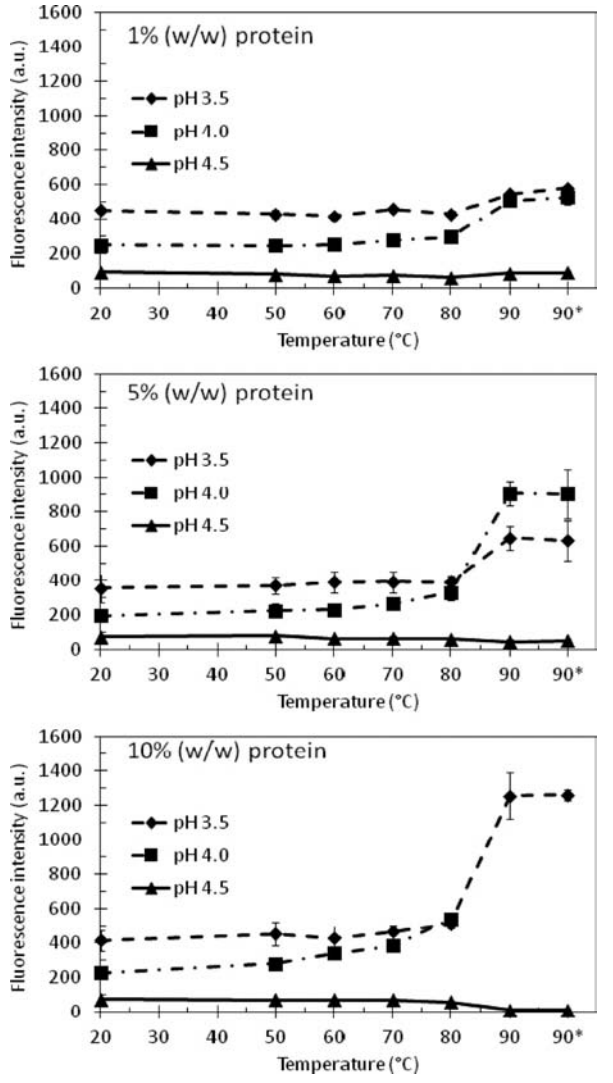

Figure 4. Heat-induced surface hydrophobicity change in whey protein systems. Surface hydrophobicity was expressed as the fluorescence value at the maximum emission wavelength (475 nm) per gram of protein.

explained with the formation of native octamers of β-LG[44] and compact structure of calcium binding (holo) α-LA, which hindered the interaction between hydrophobic sites and ANS.

Surface hydrophobicity progressively increased by decreasing the pH. Non-heat-treated systems at pH 3.5 showed an initial hydrophobicity (20 °C) equal to 451.65 ± 19.27, 354.25 ± 79.89, and 413.70 ± 57.37 au, whereas systems at pH 4.0 showed an initial hydrophobicity equal to 254.54 ± 16.72, 197.33 ± 11.18, and 228.67 ± 6.64 au, respectively, at 1, 5, and 10% protein concentrations. These different values might be explained with the partial dissociation of native β-LG octamers to form monomers with a higher accessibility of hydrophobic patches, and the loose structure of (apo) α-LA (decreasing pH below p*I*, α-LA reversibly loses its structure-stabilizing Ca^{2+}).[45]

The hydrophobicity of protein solutions at pH 3.5 and 4.0 increased more than linearly with protein concentrations at temperatures >70 °C. The 10% WPI solutions at pH 4.0 showed gelation at 90 °C, making the measurement of the hydrophobicity impossible. The increasing hydrophobicity with increasing heat treatment was also observed by Moro et al.[42] in

dx.doi.org/10.1021/jf404456q | J. Agric. Food Chem. 2014, 62, 733−741

a similar study on interactions between WPC and ANS in aqueous systems treated at 85 °C for periods from 0 to 60 min.

The change of surface hydrophobicity in the various systems closely followed the behavior observed for dispersibility. As pointed out earlier,[43] a low hydrophobicity leads to a higher dispersibility in an aqueous environment. Accordingly, the present study showed that the loss of dispersibility can be explained with the increasing surface hydrophobicity, which resulted in the formation of insoluble whey protein aggregates.

Microstructure. TEM images showed significant differences in the microstructure of 10% whey protein solutions at pH 3.5, 4.0, and 4.5 both before and after heat treatment (Figure 5). Aggregates were present in the samples before heat

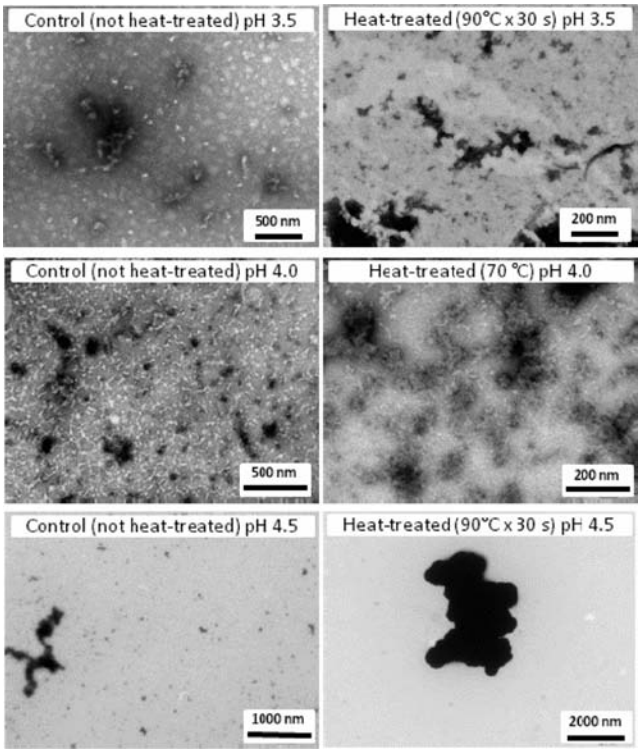

Figure 5. TEM micrographs showing untreated 10% (w/w) whey protein solutions at pH 3.5, 4.0, and 4.5 (left) and after heat treatment (right).

treatment. This was expected for systems at pH 4.0 and 4.5 due to their turbid appearance and reduced dispersibility. At pH 3.5, further away from the p*I*, unheated samples were translucent and the dispersibility was high (~100%); however, still some large aggregates were present. These can be attributed to the structural changes (i.e., denaturation) occurring during the production of the whey protein powder. In Figure 5, the three different morphologies of the systems are shown. At pH 4.0 the size and the distribution of the aggregates were more homogeneous than at pH 3.5 and 4.5. The pH 3.5 system showed that larger aggregates coexist with smaller aggregates, whereas at pH 4.5, larger aggregates (~1000 nm) could be observed. The larger aggregates seem to result from the aggregation of smaller spherical particles and are surrounded by numerous smaller (<100 nm) aggregates.

After heat treatment at 90* °C, the pH 3.5 systems showed an increased number of aggregates compared to the nonheated system. As shown in Figure 5, a few large aggregates (~200−400 nm) are surrounded by a number of smaller aggregates (~10−50 nm). This particle size distribution can explain the dispersibility value for the heat-treated pH 3.5 system (89.29 ± 3.66%). Whereas small aggregates (~10−50 nm) remained dispersed, large aggregates (~200−400 nm) precipitated, causing a ~10% dispersibility loss.

Heat-treated systems at pH 4.0 could be analyzed by TEM only before reaching the gelation temperature. Figure 5 shows the TEM results for pH 4.0 systems heated at 70 °C. The TEM picture gives an impression of the structure immediately before the formation of a gel network, with the presence of spherical particles with a radius of ~50 nm.

Heat-induced (90* °C) aggregation of systems at pH 4.5 resulted in the formation of large aggregates (size ~2000 × 4000 nm), which seem to result from the association of spherical smaller aggregates. No indication for the presence of single smaller aggregates was found. Similar structures were described by Jung et al.[46] for β-LG systems at pH 5.8 and by Sullivan et al.[47] using TEM and SEM, respectively.

PAGE. To investigate the mechanism leading to heat-induced aggregation and the relative contribution of the α-LA, β-LG, and BSA to aggregation, the water dispersible fractions of thermally treated 10% whey protein solutions were analyzed by native PAGE, native PAGE under reducing conditions (DTT), SDS-PAGE, and SDS-PAGE under reducing conditions (SDS + DTT) (Figure 6). The three major protein bands (α-LA, β-LG, and BSA) were observed after electrophoresis. The gels were scanned and the protein concentrations quantified on the basis of the intensity of the bands. Results of the intensity analysis are summarized in Figure 7.

Analysis of gels showed that the aggregation of α-LA, β-LG, and BSA was negligible in all of the systems heated to 80 °C. Samples heat-treated at 90 and 90* °C showed significant differences depending on pH and type of electrophoresis used. As observed in Figure 7 the concentration (%) of α-LA, β-LG, and BSA on native PAGE was reduced compared to the control at all pH values (pH 3.5: α-LA = 28.35 ± 8.50, 19.05 ± 8.52; β-LG = 38.13 ± 14.58, 27.86 ± 12.01; BSA = 46.79 ± 27.36, 22.07 ± 5.01. pH 4.0: α-LA = 23.44 ± 0.31, 21.22 ± 6.01; β-LG = 38.26 ± 0.15, 34.56 ± 12.13; BSA = 53.87 ± 12.04, 50.20 ± 1.57. pH 4.5: α-LA = 16.27 ± 1.50, 9.65 ± 2.13; β-LG = 22.02 ± 1.15, 13.40 ± 0.73; BSA = 101.32 ± 20.52, 57.91 ± 18.13, at 90 and 90* °C, respectively). This set of data shows that the amount of aggregated protein increased with increasing heating time and at pH 4.5, thus implying a more extensive aggregation close to the p*I* (in line with the results for dispersibility). The contributions of the various whey protein fractions in the formation of aggregates were proportional to their concentrations in the initial solution. By analyzing the data from native PAGE (Figure 7), in the aggregation at the three different pH values, α-LA, β-LG, and BSA participated in the following proportions at 90 °C: 28.50 ± 1.15, 69.89 ± 2.37, 1.60 ± 1.45. α-LA, β-LG, and BSA participated in the following proportions at 90*: 27.69 ± 1.33, 69.93 ± 1.79, 2.38 ± 0.88. At these temperatures, systems at pH 3.5 also aggregated into small clusters (SA band on the top of the gel in Figure 6). The SA band progressively reduced with increasing pH due to the larger size of the aggregates, which hindered their transport through the gel.

Unfortunately, the relevance of intermolecular disulfide bonds on aggregation and the relative contributions of α-LA, β-LG, and BSA could not be quantitatively determined on DTT-PAGE for systems at pH 4.0 and 4.5. This was due to the presence of a smeared band between 70 and 30 kDa, which

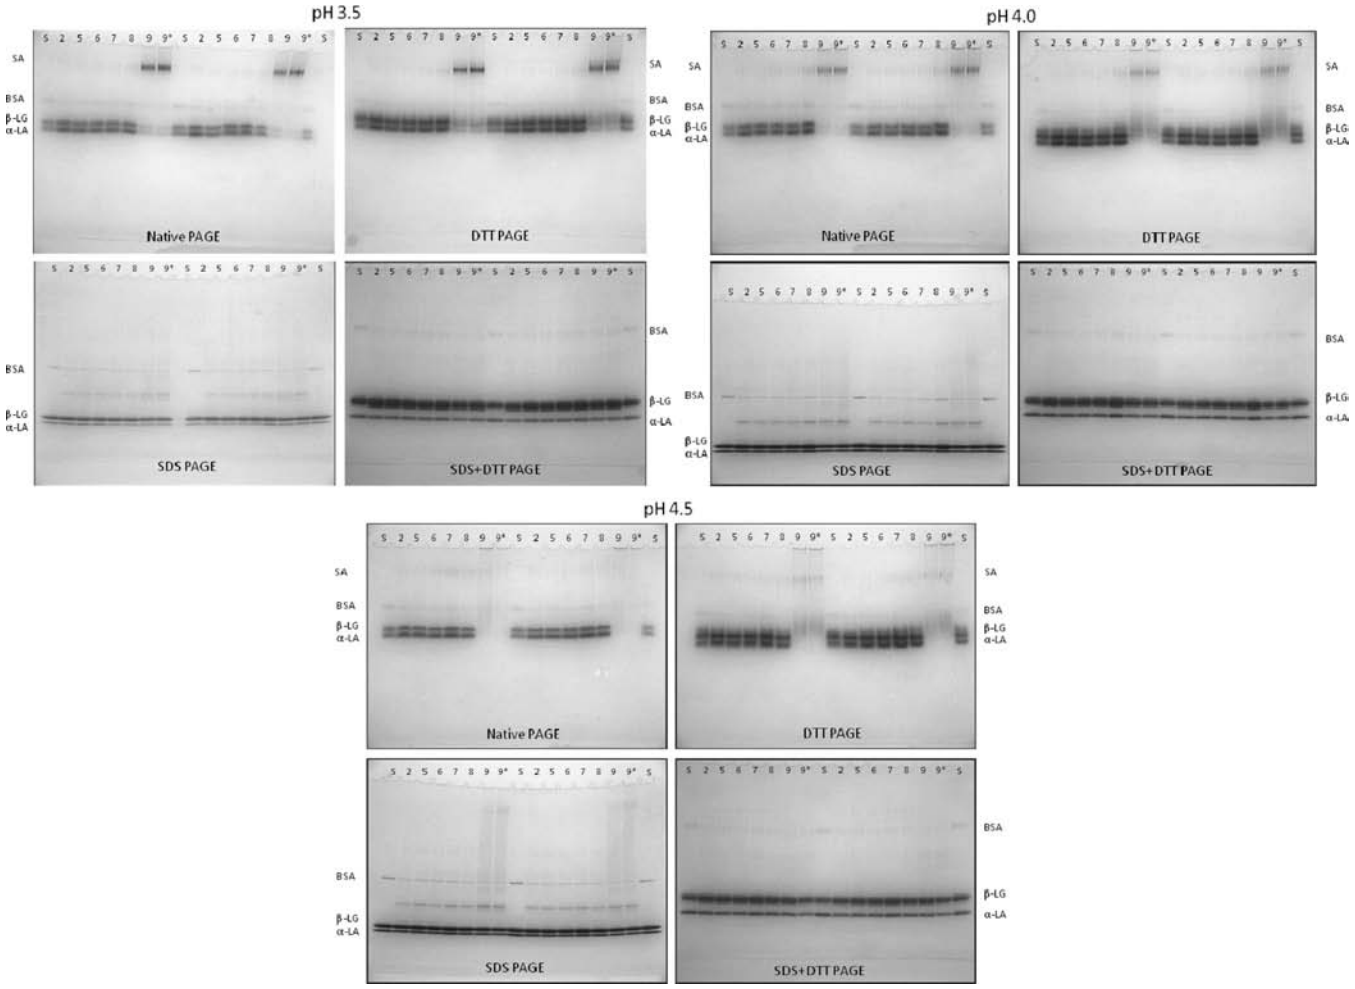

Figure 6. PAGE of dispersed fractions obtained from 10% (w/w) protein solutions. Electrophoresis was performed under native, reducing (DTT), denaturing (SDS), and denaturing and reducing (SDS + DTT) conditions. Lanes: S, standard; 2–9*, heat-treated samples (20, 50, 60, 70, 80, and 90 °C and 90 °C × 30 s).

could not be appropriately analyzed by the imaging software. However, the DTT-PAGE gels revealed that reducing the intermolecular S–S– bridges minimally affected the breakdown of aggregates into the various whey protein fractions. Interestingly, the smeared band visible between 70 and 30 kDa in systems heated at 90 and 90* °C suggests the presence of small aggregates derived from the breakdown of larger aggregates due to the reduction of –S–S– bridges caused by DTT.

SDS-PAGE and SDS-PAGE + DTT highlighted a complete recovery of all the protein fractions when hydrophobic bonds were disrupted. The only exception was BSA, which was partially lost as aggregates. Thus, hydrophobic interactions seem to be the dominating aggregation mechanism. Conversely, the covalent aggregation due to disulfide bonding was negligible; only DTT-PAGE seemed to indicate association of small aggregates via –S–S– bridges.

This result confirms the trend observed by Hoffmann and van Mil,[18] who postulated an increasing importance of noncovalent interactions in heat-treated (65 °C for various time periods) β-LG systems when the pH was closer to the p*I* (the pH range studied was 8–6). Moreover, Surroca et al.[48] excluded the formation of intermolecular –S–S– bridges in β-LG systems at pH 4.6 in the early stages of heat-induced aggregation (68.5 °C). However, despite the reduced reactivity of thiol groups at acidic pH, the formation of intermolecular disulfide bonds in acid-induced gels of heat-denatured whey proteins was observed earlier.[30,40,41,49] These authors postulated that the disulfide bond formation was favored by the effective concentration of thiol groups, which were placed in close proximity upon the physical aggregation of the protein. Accordingly, association driven by hydrophobic interactions was observed by Galani[50] for β-LG at pH 6.7, where intermolecular –S–S– bonds were also detected. In the same study, the noncovalent association was reported to be temperature dependent and maximal at 90–100 °C. Lupano, Renzi, and Romera[27] reported the lack of intermolecular –S–S– bonds in WPC gels obtained by heating (87 °C for 45 min) 10% protein solutions at pH 3.5 and 4.0. However, the same authors highlighted the presence of –S–S– bonds in gels obtained at pH 4.25.

The PAGE confirmed the limited contribution of covalent disulfide bridging in heat-induced whey protein aggregates at moderately acidic conditions and clearly highlighted the hydrophobic interactions as the driving mechanism behind the aggregation effect as the predominant association force. However, residual activity of free thiols was responsible for the association of intermediate-size whey protein clusters at pH 4.0 and 4.5.

dx.doi.org/10.1021/jf404456q | J. Agric. Food Chem. 2014, 62, 733–741

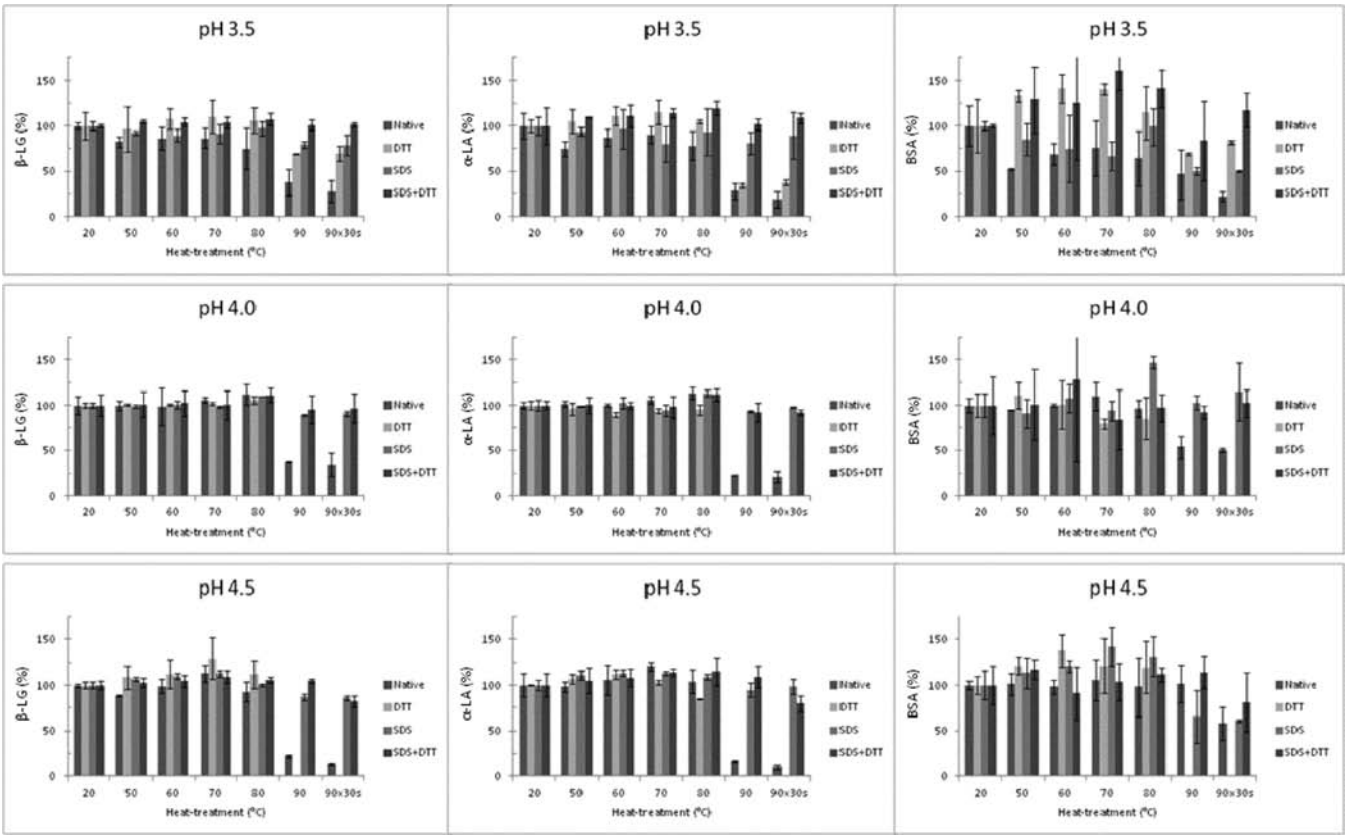

Figure 7. Concentration (%, w/w) of α-LA, β-LG, and BSA after heat treatment (20, 50, 60, 70, 80, and 90 °C and 90 °C × 30 s) in 10% (w/w) whey protein systems determined by native, DTT, SDS, and SDS + DTT electrophoresis. Data of DTT PAGE are missing for pH 4.0 and 4.5 systems treated at 90 and 90 °C × 30 s.

In conclusion, the association of whey protein isolate solutions is controlled by complicated mechanisms that are influenced by both pH and heat treatment. Close to the p*I*, the reduced intermolecular electrostatic repulsions facilitated the association of protein molecules, which caused a loss of protein dispersibility. Unfolding of the globular whey protein structure upon heating in aqueous systems between pH 3.5 and 4.5 showed that noncovalent hydrophobic interactions were the driving mechanism for aggregation, whereas intermolecular disulfide bridging contributed only in a limited way to the aggregation mechanism.

Microscopic and macroscopic observations revealed that the extent of aggregation was limited further away from the p*I* (i.e., pH 3.5), where aggregates were small and had a more open structure.

Preparation and Physicochemical Properties of Whole-Bean Soymilk

Hsin-Yu Kuo,[†] Shih-Hsin Chen,[‡] and An-I Yeh*[,†]

[†]Graduate Institute of Food Science and Technology, National Taiwan University, 1 Roosevelt Road, Section 4, Taipei 10617, Taiwan

[‡]Department of Food Science, National Ilan University, Ilan, 1 Shen-Lung Road, Section 1I-Lan 260, Taiwan

ABSTRACT: Whole-bean soymilk has been prepared by using media-milling. Some characteristics of media-milled soymilk have been determined and compared with filtered soymilk (similar to commercial ones) and whole-bean soymilk prepared by blending. There existed particles in the nano/submicrometer scale in both media-milled and filtered soymilk. The particles in blended soymilk were greater than 1 μm. Media-milled soymilk was the most stable among three samples, even after autoclaving. Solid recovery (98.44 ± 0.16%), viscosity (160.59 ± 4.26 cps), dietary fiber (22.68 ± 0.97% on dry basis), total polyphenol recovery (95.15 ± 7.09%), and isoflavone content (4.42 ± 0.03 mg/g dry solid) of media-milled samples were greater than those of filtered ones. Aglycones, the most bioactive form of isoflavone, in autoclaved media-milled soymilk were more than 2-fold those in autoclaved filtered soymilk. With almost no okara generated, the media-milled soymilk retained fiber in soybeans which would be beneficial to human health.

KEYWORDS: *soymilk, media milling, isoflavone, whole bean*

INTRODUCTION

Soymilk, an aqueous extract of soybeans, is a traditional beverage consumed for centuries in Asia. Soymilk provides high-quality proteins and essential fatty acids containing no cholesterol, gluten, and lactose. Thus, it is a good dietary protein source for general consumers or vegetarians and is a suitable substitute of cow's milk for lactose-intolerant populations.[1] In addition, there exist various biologically active phytochemicals such as isoflavones, polyphenols, phytate, saponins, lecithin, phytosteroids, and tocopherol.[2] Isoflavones, a plant derived phytoestrogen, have caught considerable attention due to its biological activities including antioxidation and prevention of cardiovascular diseases, type 2 diabetes, cancers, osteoporosis, as well as relief of menopausal syndromes.[3−8] Isoflavones can be divided into three types, daidzein, genistein, and glycitein, and each type consists of four different chemical forms which are β-glucoside, 6″-*O*-acetyl-β-glucoside, 6″-*O*-malonyl-β-glucoside, and aglycone.[9] During soymilk production, some processes such as soaking, grinding, filtering, and heating result in loss of isoflavones to different degrees.[10,11] These processes generally result in high loss of glucoside and malonylglucoside but increase in aglycone.[11−13]

Via traditional methods, soymilk is produced after soaked soybeans are ground and filtered.[14] To process 1 kg soybean for soymilk manufacture, about 8−10 kg water are added and about 0.3 kg of okara (dry basis) is generated.[15,16] Okara is rich in protein (25.4−28.4%), oil (9.3−10.9%), dietary fiber (52.8−58.1%), and isoflavone (0.14%).[17,18] Jackson et al.[11] have found that the proportion of aglycone in okara is greater than that in soymilk. However, okara is generally considered as waste. It putrefies very quickly due to high water activity, which results in an issue of plant management for commercial production. Whole-bean soymilk can retain original nutrients and is environmentally friendly.

A media mill is derived from a stirred ball mill which is utilized to produce nano/submicrometer particles via a top-down concept and has been applied in paint and pharmaceutical industries. During media-milling, material is comminuted among the stirring media, the grinding chamber wall, and the material itself by friction, impact, compression, and shearing forces.[19] Yeh et al.[20] have revealed that media-milling can significantly decrease crystallinity and average particle size (to submicrometer scale) and effectively enhance the enzymatic hydrolysis of microcrystalline cotton cellulose. Nano/submicrometer corn starch has been prepared by using media-milling and exhibits unique pasting properties.[21] Media-milling appears to be an attractive method for utilizing whole edible materials.

The objectives of this study were to explore the feasibility of preparing whole-bean soymilk by using media-milling and to understand the physicochemical properties of media-milled soymilk.

MATERIALS AND METHODS

Samples. Soybean (Kaohsiung no. 1 cultivar, moisture content 9.24 ± 0.13%) was provided by the Kaohsiung District Agricultural Research and Extension Station and was stored at 4 °C until use.

Soybean Flour Preparation. Soybeans were milled in a commercial pulverizing machine (RT-04, Hsin An Instrument Co. Ltd., Taipei, Taiwan) for 1−2 min through a 20-mesh sieve.

Soymilk Preparation. Soybeans (60 g) were soaked in deionized water (440 g) overnight at 4 °C and then ground by using a laboratory blender (MX-7012S, Waring Laboratory Science, New Hartford, CT, USA) for 3−4 min. The soybean slurry was used to prepare filtered, blended, and media-milled soymilk.

Filtered Soymilk (FS). The soybean slurry was filtered through a double-layered cheese cloth. The filtrate was designated as filtered soymilk, which was similar to the commercial products in Taiwan. The pulp was considered as okara.

Blended Soymilk (BS). The soybean slurry was further minced by using a high-speed blender (PT 3100, Kinematica, Lucerne, Switzerland) at 2000 rpm for 10 min to obtain the blended soymilk. As no okara was produced, its composition was similar to whole soybeans.

Media-Milled Soymilk (MS). The media-milled soymilk was prepared by using a media mill (Minipur, Netzsch-Feinmahltechnik GmbH, Germany) with a driving motor of 0.94 kW. Media (0.8 mm, yttria-stabilized tetragonal zirconia, YTZ) at 70% v/v filling ratio was loaded in the milling chamber (200 mL). The soybean slurry was loaded into a jacket-cooling tank and then fed at a flow rate of 350 mL/min into the milling chamber by a circulating pump. The agitation speed was set at 3000 rpm, and the milling was conducted for 60 min. During milling, particles smaller than the gap (0.30 mm) of the media separator were driven back to the stirred tank for cooling by the circulation system. The temperature of the soymilk was maintained below 30 °C during milling.

Generally, soymilk is cooked or autoclaved before consumption. To minimize the effect of concentration, the solid contents of three soymilks were adjusted to 7% (w/w) and then heated by an autoclave (TM-325, Tomin Medical Equipment Co. Ltd., Taipei, Taiwan) at 121 °C for 3 min.[22] The effects of heating on pH, viscosity, and stability of soymilk were explored.

Particle Size Distribution (PSD). Particle size distribution of samples was measured by using a laser diffraction particle size analyzer (LS 230, Beckman Coulter, Fullerton, CA) with a detection range of 0.04−2000 μm. The instrument was calibrated with deionized water. All samples were diluted 10-fold with deionized water and vortexed for 10 s. Average diameters of particles were obtained using the following equations.

by volume

$$D_V = \sum_i \frac{n_i d_i^4}{n_i d_i^3}$$

by number

$$D_N = \sum_i \frac{n_i d_i}{n_i}$$

where n_i was the number of i particle with diameter of d_i. All of the measurements were done in triplicate, and the average data were reported.

Morphology. Morphology of suspended particles in soymilk was examined by optical microscope (OM) (model TS100, Nikon Co., Tokyo, Japan) and scanning electron microscope (SEM) (Hitachi S-800, Hitachi Co. Ltd., Tokyo, Japan). Diluted samples (1%, w/w) were used for OM observation. For SEM, critical-point drying was used to prepare samples. Ten-fold diluted soymilk (FS, BS, or MS, 1 mL) was mixed with 9 mL of acetone and then evaporated to 1 mL at 60 mmHg. After repeating the replacement process in triplicate, solids were suspended in 5 mL of acetone. The suspension was further dried using liquid CO_2 in a critical-point drying apparatus (Hitachi HCP-2, Hitachi Co. Ltd., Tokyo, Japan) at 31.1 °C and 73.9 bar. After being dried, the sample was attached on a SEM stub using double-backed cellophane tape. The stub and sample were coated with gold−palladium and then were examined and photographed at 20 kV.

Viscosity. A rheometer (AR 2000ex, TA Instruments, New Castle, NJ, USA) was employed to measure the viscosity of soymilk. Soymilk (30 mL) was transferred into a concentric cylinder system with a procedure of FLOW. The viscosity of soymilk was measured at 25 °C using steady mode with a shear rate at 100 s^{-1}. In addition, the solid content of MS was adjusted to 7, 8, 9, and 10% (w/w) for understanding the effect of solid content on the viscosity of MS.

pH. The pH of sample was determined by using a pH meter (SP-2200, Suntex Instrument Co., Ltd., Taipei, Taiwan).

Stability. The stability of soymilk was determined by using a demixing tester (LUMiCheck, L.U.M. GmbH, Berlin, Germany). About 3 mL of sample was loaded into the sample cell. The intensity of light (870 nm) backscattered from the tilted bottom of the cell was detected every 5 min for 12 h. The stability was expressed by the difference (ΔI_{t-0}) in the light intensity at time of t (I_t) and initial state (0 min) (I_0) along with time. A positive ΔI_{t-0} indicates the occurrence of precipitation. Once floating or foaming occurred, ΔI_{t-0} drops with time. For a stable suspension, ΔI_{t-0} does not change significantly with time.

Composition Analysis. After freeze-drying, the lyophilized powder of soymilk was used for composition analysis. The contents of moisture, ash, crude fat, crude protein, and dietary fiber (including soluble, insoluble, and total fiber) were determined according to the methods of the Association of Official Analytical Chemists (AOAC).[23]

Total Polyphenol Content. The content of total polyphenol was determined according to the method of Xu and Chang.[24] Soybean flour and lyophilized soymilk powders (0.5 g) were extracted with 5 mL of acetone/water (50/50, v/v), and the mixture was stirred at 300 rpm for 3 h. After centrifuging at 3000 rpm for 10 min, the supernatant was collected. The precipitate was extracted again via the procedures described above. Both supernatants were combined and added with 50% acetone to be 10 mL and stored at 4 °C in the dark until analysis.

The total polyphenol content was determined by a Folin−Ciocalteu assay[25] using gallic acid as a standard.[26] The mixture of 50 μL sample solution, 3 mL of distilled water, 250 μL of Folin−Ciocalteu's reagents solution, and 750 μL of 7% sodium carbonate (Na_2CO_3) were vortexed and incubated for 8 min in the dark at 25 °C. Then, 950 μL of distilled water was added. The mixture was left in the dark for reaction for 2 h at 25 °C. The absorbance was measured at 765 nm. The total polyphenol content was obtained against the calibration curve of gallic acid and expressed as gallic acid equivalents (mg of GAE/g of dry sample or mg of gallic acid/100 g undiluted soymilk). The calibration curve of gallic acid was established with concentration of 12.5−1000 μg/mL.

Isoflavone Content. *Isoflavone Extraction.* The extraction procedure was conducted according to the method described by Murphy et al.[27] Soymilk samples were freeze-dried and sieved through a 60-mesh (for FS and MS) or 20-mesh (for BS) sifter. Lyophilized powder (1.0 g) was extracted with 10 mL of acetonitrile, 7 mL of deionized water, and 2 mL of 0.1 N HCl by stirring (400 rpm) at room temperature for 2 h and then filtered through Whatman no. 1 filter paper. The filtrate was evaporated to remove solvent at vacuum conditions and then was dissolved in 2 mL of 80% methanol. The solution was seeped through a 0.45 μm nylon syringe filter. Fluorescein (1000 μg/mL) was added into filtrate as an internal standard with a ratio of fluorescein solution to a sample solution of 1:9 (v/v). After being analyzed by using HPLC, the content of isoflavone was calculated using an internal standard method reported by Kao and Chen.[28] A calibration curve is required to quantitatively determine the concentration of isoflavone by utilizing the internal standard method. To establish calibration curves, each individual isoflavone compound was dissolved in 80% methanol at a concentration of 1000 μg/mL, which was further diluted at different concentrations (3.125, 6.25, 12.5, 25, 50, 100, 200 μg/mL) as standard solutions. Filtration and addition of fluorescein solution were conducted as described above for HPLC analysis.
