[a]Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. The double vertical line indicates the ANOVA analysis was assessed without the control group. Data are means ± SEM (n = 7−12). Statistics: within normal-fat conditions, a ≠ b, LSD post hoc analysis; within high-fat conditions, y ≠ x, LSD post hoc analysis. Key: #, different from their respective ad-libitum-fed group ($p <$ 0.05. paired t test); *, different from their respective NF-diet-fed group ($p < 0.05$. Student's t test); ↑/↓, different versus the control ($p < 0.05$, Student's t test).

dx.doi.org/10.1021/jf405161e | J. Agric. Food Chem. 2014, 62, 1590−1601

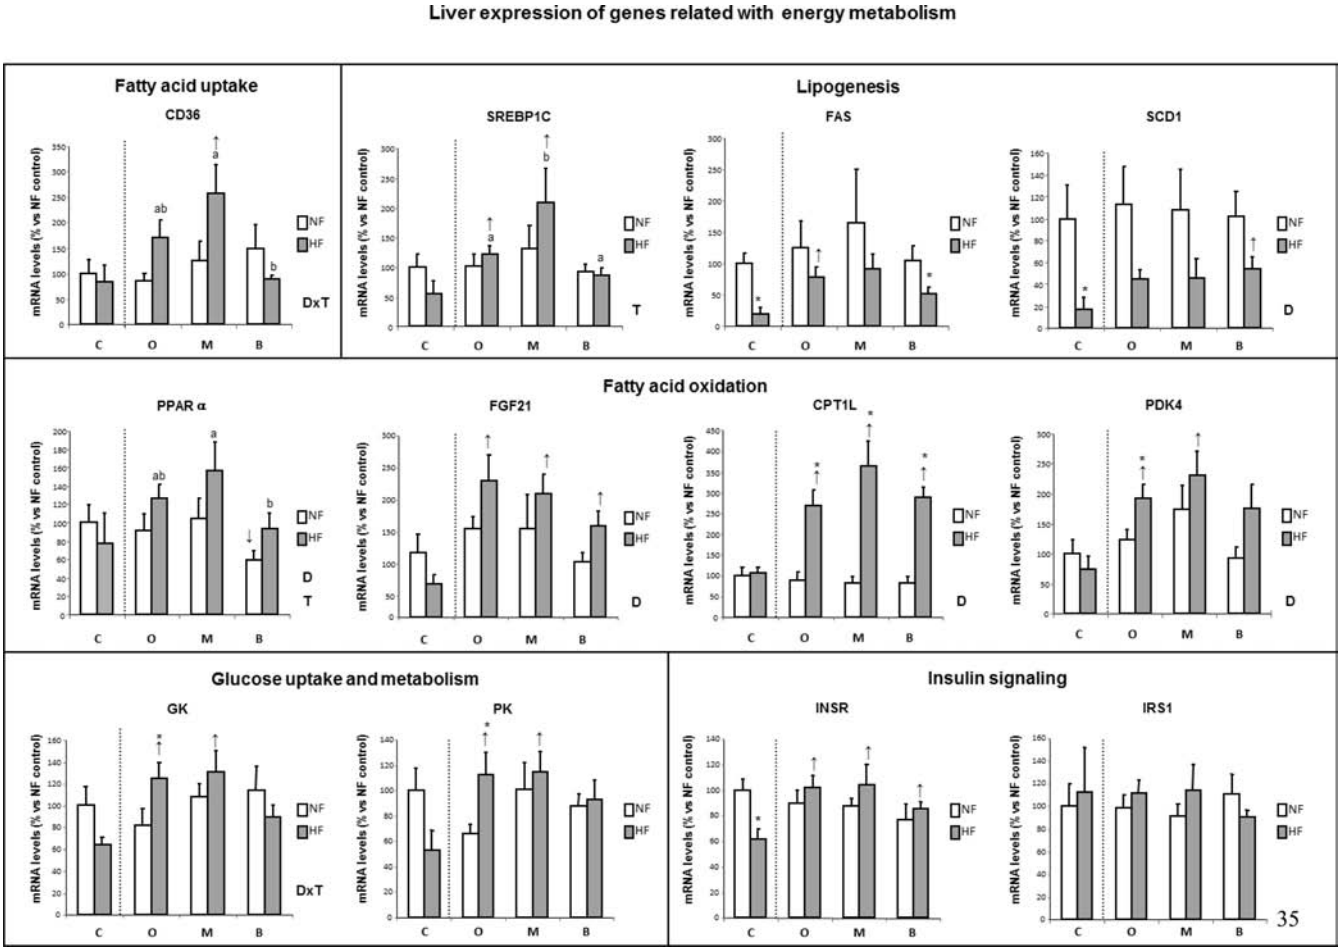

Figure 2. Expression of genes related to energy metabolism (FA uptake and oxidation, lipogenesis, glucose uptake and metabolism, and insulin signaling) in liver of 6 month old male offspring of dams supplemented with 30% of the normal caloric intake with different fat sources (olive oil, margarine, or butter) during late pregnancy and lactation. C = control, O = olive oil, M = margarine, and B = butter. Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. The dotted line indicates that the ANOVA analysis was assessed without the control group. Data are means ± SEM (n = 7−12). Genes determined were CD36, sterol regulatory element binding protein 1c (SREBP1c), fatty acid synthase (FAS), stearoyl coenzyme A desaturase 1 (SCD1), peroxisome proliferator activated receptor α (PPARα), fibroblast growth factor 21 (FGF21), liver carnitine palmitoyltransferase 1a (CPT1L), pyruvate dehydrogenase kinase 4 (PDK4), glucokinase (GK), pyruvate kinase 4 (PK), insulin receptor (INSR), and insulin receptor substrate 1 (IRS1). Statistics: D, effect of diet (NF or HF); T, effect of maternal supplementation; D×T, interaction between diet and maternal supplementation ($p < 0.05$, two-way ANOVA). a ≠ b, LSD post hoc analysis. Key: *, different from their respective NF-diet-fed group ($p < 0.05$, Student's t test); ↑, different versus the control ($p < 0.05$, Student's t test).

the different groups of animals at the age of 6 months, depending on maternal fat supplementation, under either an NF or an HF diet (Table 2). As expected, the body mass of animals under an HF diet was higher than that of animals under an NF diet ($p < 0.05$, two-way ANOVA), the difference being higher and significant by Student's t test in the olive oil group. Animals exposed to an HF diet presented higher body fat content, higher adiposity index (calculated as the percentage of the sum of the four fat depots measured—inguinal, mesenteric, retroperitoneal, and epididymal—divided by the mass of the animal), and greater mass of the individual fat depots ($p < 0.05$, two-way ANOVA). Nevertheless, the body fat content and mass of the inguinal WAT in the margarine group under an HF diet were not different compared to their NF-diet-fed counterparts (by Student's t test), and the values were significantly lower than those of the butter group. The offspring of all fat-supplemented groups displayed greater mass of the inguinal WAT under NF diet conditions compared to the control group ($p < 0.05$, Student's t test), but no differences were found under the HF diet. No differences between groups were found in liver mass, under either the NF or HF diet.

Figure 1A shows the hepatic lipid content in the different groups of animals. Animals exposed to the HF diet presented higher hepatic lipid content compared to animals maintained under the NF diet ($p < 0.05$, Student's t test), with the exception of animals in the margarine group. Notably, within animals exposed to the HF diet, animals in the margarine group presented lower hepatic lipid content compared to the controls ($p < 0.05$, Student's t test). Moreover, the margarine groups (NF and HF analyzed together) showed lower hepatic lipid content compared to the butter groups ($p < 0.05$, LSD post hoc).

Histological analysis of the liver (Figure 1B,C) revealed evidence of NAFLD in animals exposed to the HF diet, especially in the olive oil and butter groups. The control and margarine groups showed a lower incidence of steatosis. In addition, although the control and margarine groups did not show evidence of hepatic steatosis under NF diet conditions,

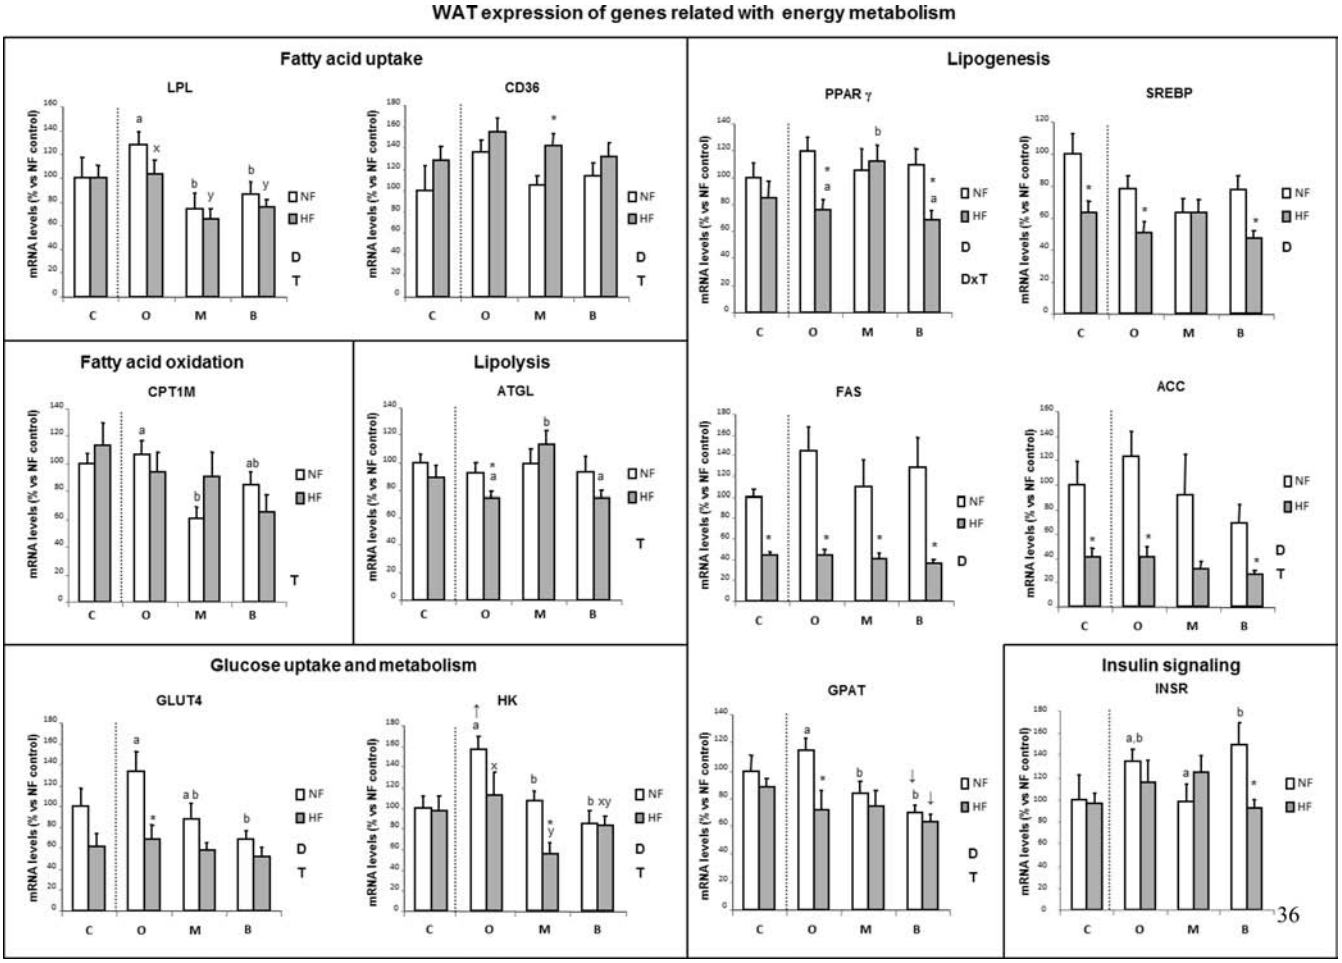

Figure 3. Expression of genes related to energy metabolism (FA uptake and oxidation, lipolysis, glucose uptake and metabolism, lipogenesis, and insulin signaling) in the retroperitoneal white adipose tissue (rpWAT) of 6 month old male offspring of dams supplemented with 30% of the normal caloric intake with different fat sources (olive oil, margarine, or butter) during late pregnancy and lactation. C = control, O = olive oil, M = margarine, and B = butter. Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. The dotted line indicates that the ANOVA analysis was assessed without the control group. Data are means ± SEM (n = 7−12). Genes determined were lipoprotein lipase (LPL), CD36, muscle carnitine palmitoyltransferase 1a (CPT1m), adipose triglyceride lipase (ATGL), glucose transporter 4 (GLUT4), hexoquinase II (HK), peroxisome proliferator activated receptor γ 2 (PPARγ2), sterol regulatory element binding protein 1c (SREBP1c), fatty acid synthase (FAS), acetyl coenzyme A carboxylase (ACC), glycerol-3-phosphate acyltransferase (GPAT), and insulin receptor (INSR). Statistics: D, effect of diet (NF or HF); T, effect of maternal supplementation; D×T, interaction between diet and maternal supplementation (p < 0.05, two-way ANOVA). a ≠ b, x ≠ y, LSD post hoc analysis. Key: *, different from their respective NF-diet-fed group (p < 0.05, Student's t test); ↑/↓, different versus control (p < 0.05, Student's t test).

some evidence of steatosis was already seen at this age in the olive oil group and particularly in the butter group.

Glucose, Insulin, NEFA, TG, and β-Hydroxybutyrate Circulating Levels. Table 3 shows circulating parameters in the different groups of animals fed an NF or HF diet and under ad libitum and 12 h fasting conditions. As expected, the glucose and insulin levels decreased with fasting in all groups (p < 0.05, repeated measures analysis and pair t test). No differences were observed in the glucose and insulin levels as an effect of maternal fat supplementation, under either the NF or HF diet. Notably, animals in the butter group exposed to an HF diet presented higher glucose levels under ad libitum feeding conditions compared to their NF-diet-fed counterparts (p < 0.05, Student's t test). No significant differences were found in HOMA-IR.

Regarding circulating NEFA, no significant differences were found under ad libitum feeding conditions between the different groups of animals. In all of them, circulating levels were higher under the HF diet conditions compared to those under the NF diet conditions (p < 0.05, Student's t test). In addition, in animals exposed to the NF diet, an increase in NEFA levels was observed as an effect of fasting (p < 0.05, pair t test), except in the margarine group, where differences did not reach statistical significance; however, under the HF diet, NEFA levels remained unchanged with fasting, with the exception of the animals in the margarine group, which showed lower levels under fasting conditions compared to the feeding state (p < 0.05, pair t test).

Concerning TGs, all groups showed increased triglyceridemia under the HF diet compared to the NF diet (p < 0.05, Student's t test), with the exception of the margarine group, where differences did not reach statistical significance. Fasting produced a decrease in TG levels in the margarine group, similar to the controls, under both NF and HF diet conditions (p < 0.05, pair t test); however, this decrease was not observed in the olive oil and butter groups fed the NF diet. Animals in

dx.doi.org/10.1021/jf405161e | J. Agric. Food Chem. 2014, 62, 1590−1601

the margarine group, under either the NF or HF diet, displayed lower fasting TG levels compared to the olive oil and butter groups ($p < 0.05$, one-way ANOVA).

Regarding ketone bodies, NF-diet-fed animals in the margarine and butter groups showed higher β-hydroxybutyrate (BHB) levels than the olive oil group (one-way ANOVA), under ad-libitum-fed conditions; the margarine group also presented higher levels than the controls, under both fed and fasting conditions ($p < 0.05$, Student's t test). Under fed conditions, the HF-diet-fed olive oil and butter groups showed increased BHB levels compared to their NF-diet-fed counterparts ($p < 0.05$, Student's t test). Fasting produced a significant increase in BHB levels in HF-diet-fed animals in the olive oil group and in the margarine group, under both NF and HF diet conditions ($p < 0.05$, pair t test), but no changes were found in the other groups.

Expression of Genes Related to Energy Metabolism in the Liver. Results showing the expression of selected genes involved in nutrient handling and metabolism in the liver are summarized in Figure 2. HF diet feeding differently affected CD36 expression levels in the distinct fat-supplemented groups (interactive effect between diet and maternal treatment, $p < 0.05$, two-way ANOVA). Whereas levels tended to increase in the olive oil and margarine groups as an effect of the HF diet (with levels in the latter being higher compared to those of the control and butter groups), they tended to decrease in the butter group. Concerning lipogenesis-related genes, HF-diet-fed animals in the margarine group showed higher mRNA levels of SREBP1c than the olive oil and butter groups, and both the olive oil and margarine groups also showed higher levels than the controls. FAS and SCD1 mRNA expression levels were decreased in control animals under HF diet conditions, but only SCD1 showed a significant decrease in the fat-supplemented groups, and the decrease was not as marked as in the control group. Compared to the controls, HF-diet-fed animals in the olive oil group and in the butter group showed higher mRNA levels of FAS and SCD1, respectively.

The expression levels of genes related to fatty acid oxidation (PPARα, FGF21, CPT1L, and PDK4) increased in the fat-supplemented groups as an effect of the HF diet but not in the control animals ($p < 0.05$, two-way ANOVA). Therefore, under the HF diet, all fat-supplemented groups revealed a greater expression of FGF21, CPT1L, and PDK4 compared to the controls (with the exception of the butter group for the latter gene). The increase in gene expression as an effect of HF diet feeding was particularly remarkable for CPT1L, and especially in the margarine group, which showed a 2.45-fold increase. Under the HF diet, animals in the margarine group also showed higher mRNA levels of PPARα compared to the butter group ($p < 0.05$, one-way ANOVA). Under the NF diet, animals in the butter group displayed lower expression levels of PPARα compared to the controls ($p = 0.06$, Student's t test).

GK and PK mRNA expression levels followed a similar pattern in the different groups of animals. Compared to the controls, the HF-diet-fed olive oil and margarine groups presented higher GK and PK mRNA levels ($p < 0.05$, Student's t test). These animals, together with the HF-diet-fed animals of the butter group, also showed higher INSR mRNA levels than the controls ($p < 0.05$, Student's t test). No significant changes were found concerning IRS1 between the different groups of animals

Expression of Genes Related to Energy Metabolism in WAT. The retroperitoneal fat pad was chosen as representative of WAT because it is a major internal fat pad present in rats and is involved in the development of insulin resistance and type 2 diabetes.[27] Results showing the expression of selected genes involved in nutrient handling and metabolism in this fat depot are summarized in Figure 3.

Animals in the olive oil group showed higher LPL mRNA levels compared to the other fat-supplemented groups, under both NF and HF diets ($p < 0.05$, one-way ANOVA). Concerning CD36, their mRNA levels were higher in the fat-supplemented groups under the HF diet compared to their NF diet counterparts ($p < 0.05$; two-way ANOVA), with higher significant differences by Student's t test in the margarine group. Concerning lipolysis and fatty acid oxidation genes, under HF diet conditions, animals in the margarine group showed higher ATGL mRNA expression levels than the olive oil and butter groups, whereas, under the NF diet, they presented lower CPT1M mRNA levels compared to animals in the olive oil group ($p < 0.05$, one-way ANOVA). Regarding ATGL, differences similar to those of the mRNA levels were also found in their protein levels, although in this case differences did not reach statistical significance (Figure 4).

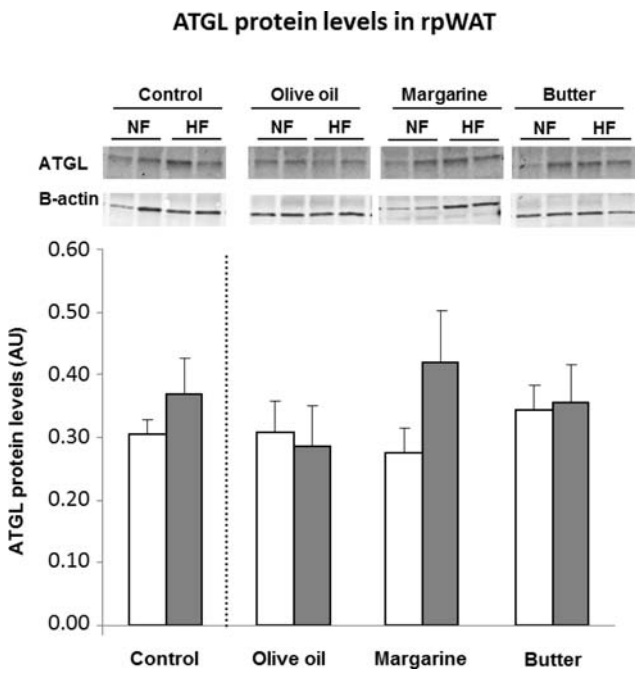

Figure 4. ATGL protein levels (measured by Western blotting) in retroperitoneal white adipose tissue (rpWAT) of 6 month old male offspring of dams supplemented with 30% of the normal caloric intake with different fat sources (olive oil, margarine, or butter) during late pregnancy and lactation. Animals were fed a standard NF diet until the age of 4 months and then an NF or HF diet until the age of 6 months. The dotted line indicates that the ANOVA analysis was assessed without the control group. Representative results are shown in the top panels. In the bottom panels, results represent the mean ± SEM (n = 7−12) expressed in arbitrary units (AU).

Animals of the fat-supplemented groups showed lower GLUT4 and HK mRNA levels under the HF diet compared to their NF-diet-fed counterparts ($p < 0.05$, two-way ANOVA), with a higher significant difference by Student's t test in the olive oil group (for both genes) and in the margarine group (for the latter gene). No significant changes were found in the control group as an effect of HF diet feeding, although a

B) The score plot of PC1 versus PC2

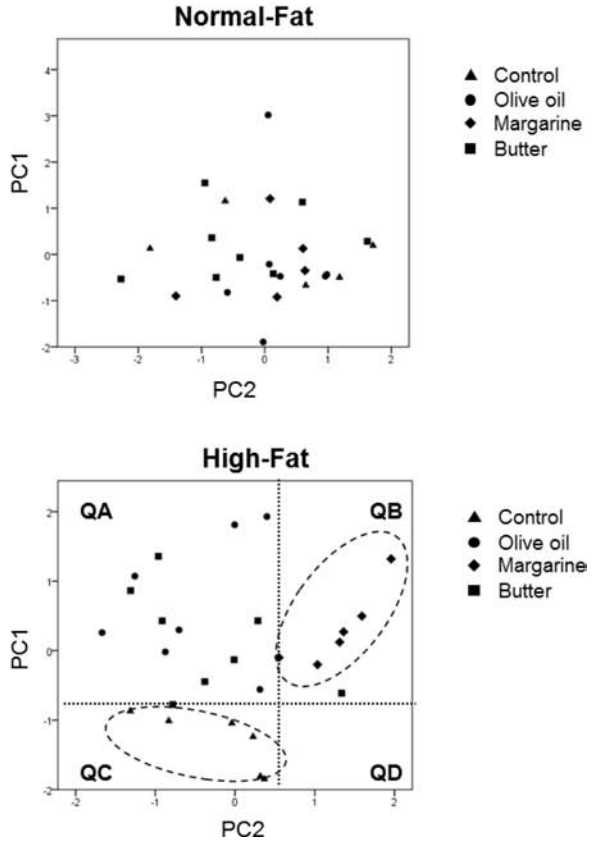

Figure 5. (A) Principal component loadings for the first two principal components (PCs). Data were spread by diet to assess possible relationships between gene expression in the tissues studied (liver and rpWAT) and the adiposity index and the hepatic lipid content under both dietary conditions (NF and HF diets). The most significant loadings are indicated with an asterisk. (B) Score plot representation.

tendency to lower levels was found concerning GLUT4. Notably, animals in the olive oil group displayed the highest mRNA levels of these genes under NF diet conditions, and these levels were significantly higher compared to those of the butter group (for GLUT4) and those of both the margarine and butter groups (for HK).

Under an HF diet, animals of the fat-supplemented groups showed lower mRNA expression levels of the adipogenic factor SREBP1c and of genes related to the synthesis of fatty acids (ACC1 and FAS) and TG (GPAT) with respect to those found under an NF diet ($p < 0.05$, two-way ANOVA), with some differences between groups. Specifically, HF-diet-fed animals in the margarine group did not show significant differences (by Student's t test) compared to their NF-diet-fed counterparts concerning SREBP1c, ACC, and GPAT mRNA levels, as also occurred for the latter in the animals in the butter group. A pattern similar to that of the SREBP1c gene was found for the other adipogenic factor, PPARγ. HF-diet-fed animals in the olive oil and butter groups showed lower mRNA levels compared to their NF-diet-fed counterparts ($p < 0.05$, Student's t test), while no changes were found in the margarine group as an effect of the HF diet. Control animals also showed a significant decrease in the expression levels of SREBP1c, ACC, and FAS under the HF diet, but no changes were observed concerning PPARγ and GPAT ($p < 0.05$, Student's t test), compared to their NF-diet-fed counterparts. Animals in the olive oil group fed an NF diet showed higher mRNA levels of GPAT with respect to animals in the margarine and butter groups ($p < 0.05$, one-way ANOVA).

Concerning the insulin receptor, animals in the butter group presented higher mRNA levels than animals in the margarine group under the NF diet ($p < 0.05$, one-way ANOVA), but their expression levels were decreased when these animals were fed the HF diet ($p < 0.05$, Student's t test). No significant changes were found in the other groups of animals as an effect of HF diet feeding.

Principal Component Analyses. The results of principal component analysis (PCA) of 27 variables are shown in Figure 5A. The data were spread by diet to assess possible relationships between gene expression in the studied tissues (liver and WAT) and the adiposity index and the hepatic lipid content under both dietary conditions (NF and HF diets). The first and second components were responsible for over 40% of the total variance in both conditions (43% in samples under the NF diet and 47% in those under the HF diet). Under NF diet conditions, PC1 was mainly characterized by liver transcripts related to glycolysis and lipogenesis, such as PK (0.895), SREBP1c (0.801), SCD1 (0.788), and FAS (0.767). Under the HF diet, the same transcripts mentioned above were important in the PC1, but other liver transcripts related to fat oxidation such as FGF21 (0.765), CPT1L (0.627), and PDK4 (0.626) were also of great importance. Concerning PC2, under the NF diet, the variables with higher loadings were liver transcripts related to fat oxidation [FGF21 (0.809), CPT1L (0.714), PDK4 (0.653), PPARα (0.635)] and insulin signaling [INSR

(0.627)] and WAT transcripts related to fat uptake [CD36 (0.745) and LPL (0.734)]. Under the HF diet, PC2 was mainly characterized by hepatic lipid content (−0.631), adiposity index (−0.532), and WAT transcripts, such as ATGL (0.898), PPARγ (0.857), INSR (0.730), and SREBP (0.613).

The score plots of PC1 versus PC2 of all the samples in both dietary conditions are shown in Figure 5B. As can be seen, no discriminant model was found for animals of the different groups under an NF diet. In contrast, under an HF diet, control animals were separated from the animals of the fat-supplemented groups and were located in quadrant C, with the lowest scores for PC1. Animals in the margarine group were located in quadrant B, completely separate from the control animals. The olive oil and butter groups were mainly located in quadrant A, and no discrimination between these two groups was achieved.

DISCUSSION

Maternal intake of excess fat during pregnancy and lactation in rodents has been reported to be associated with negative outcomes on metabolic health in offspring, increasing the susceptibility to develop obesity and other related metabolic diseases.[8] Studies performed in this respect are generally based on saturated fat sources. However, we previously described that maternal supplementation with excess fat during late pregnancy and lactation may have different outcomes in offspring depending on the source of fat. In particular, margarine, compared to other fats such as olive oil and butter, was shown to program the offspring for increased leptin sensitivity and a lower preference for fat food in adulthood.[19] Here, by using the same cohort of animals, we also aimed to assess whether maternal lipid oversupply (with margarine, olive oil, or butter) during late pregnancy and lactation may also differently affect the metabolic health of offspring and hence the risk of obesity-related metabolic diseases, particularly the development of hepatic steatosis.

We show here that although maternal supplementation with the different fat sources did not result in significant differences regarding body mass in the adult offspring, margarine supplementation conferred partial protection against the increase in body fat content, particularly subcutaneous fat, observed in the other groups when exposed to an HF diet. This protection was not seen under NF diet conditions, where the three fat-supplemented groups showed higher subcutaneous fat content than the control group. Concerning hepatic lipid content, HF-diet-fed animals from the different groups showed increased lipid accumulation compared to their NF-diet-fed counterparts with the exception of animals in the margarine group, which seemed to present a certain protection against lipid accumulation in the liver. Histological analyses of liver samples essentially confirmed the results obtained from lipid quantification, but showed little incidence of hepatic steatosis signs in HF-diet-fed control animals, which was similar to that of animals in the margarine group under the HF diet. On the other hand, although animals in the olive oil and butter groups under the HF diet presented hepatic lipid levels similar to those of the control animals, histological analysis unveiled that these animals presented a more advanced form of the disease, particularly the animals in the butter group. Indeed, even under an NF diet, some animals in the olive oil group and more acutely in the butter group presented histological signs of NAFLD, suggesting that maternal olive oil and particularly butter oversupply during critical periods of development may affect offspring susceptibility to develop this disease, with different degrees of severity depending on the type of diet they are exposed to in adulthood.

HF diet conditions in adulthood have been previously described to lead to increased hepatic content of lipids.[28] However, perinatal conditions have also been proved to be determinant. In fact, Bruce et al. showed that HF diet exposure during both development and postweaning periods was worse than HF diet exposure in the postweaning period alone,[16] and a maternal HF diet led to the development of NAFLD later in life, even if a control diet was given in the postweaning period.[16,17] Thus, maternal HF diet during early periods of development may increase susceptibility to hepatic steatosis and inflammation in adult offspring, which may result in a more severe form when animals are also exposed to adult nutritional insults.[16] Interestingly, we show here that this effect depends not only on the ingestion of fat per se but also on the maternal source of fat during the early stage of life.

To ascertain which metabolic pathway could be responsible for the observed effects of maternal supplementation with different fat sources, we analyzed the expression levels of selected genes involved in energy metabolism in liver and WAT of adult animals, under both NF and HF diet conditions. The results revealed that differences between the groups were made particularly evident when animals were exposed to HF diet conditions in adulthood. Under an HF diet, we observed increased hepatic expression levels of β-oxidation-related genes, such as PPARα, FGF21, CPT1L, and PDK4, in the offspring of all fat-supplemented groups, and the increase for most of them was more marked in the margarine group. HF-diet-fed animals in the margarine group also presented higher expression levels of CD36 compared to animals in the butter group and the controls, which suggests increased hepatic uptake of fatty acids. An increase in the fatty acid influx to the liver has been related to the development of hepatic steatosis;[28] however, this does not appear to be the case in these conditions, suggesting that fatty acids taken up by the liver may be efficiently oxidized, in accordance with the increased levels in ketone bodies found in the margarine group compared to the other groups, particularly animals in the olive oil and control groups. This assumed increase in the uptake and oxidation of fatty acids by the liver in animals in the margarine group could be a mechanism to avoid increased circulating levels of NEFA, which has been related to insulin resistance progression.[29] In fact, animals in the margarine group seemed to be protected against the increased triglyceridemia observed in the other groups under an HF diet and showed lower circulating levels of NEFA than the other groups under these conditions. This could be indicative of lower WAT lipolytic capacity, but contrasts with the presence in this tissue of higher mRNA levels (and to some extent also of the protein) of the key rate-limiting enzyme for lipolysis, ATGL, compared to those of the other fat-supplemented groups. Therefore, it is plausible that although WAT in these animals appears to have a greater capacity to release NEFA under fasting conditions, other tissues, as seen for the liver, could be more efficient in removing them from circulation. All in all, these results suggest that animals in the margarine group are programmed to be more efficient in the processing and handling of lipids under HF diet conditions, in relation to a better lipid clearance from circulation, and hence are protected against the ectopic accumulation of fat in tissues other than adipose tissue.

According to previous results,[28,30] exposure of control animals to HF diet conditions brings about a decrease in the expression of lipogenic genes (FAS and SCD1) in the liver; however, this decrease was diminished in the offspring of all fat-supplemented groups. This lower downregulation could be related to the increased mRNA levels of INSR, suggesting higher insulin signaling, and to higher mRNA levels of the transcription factor SREBP1c, also occurring in these animals with the exception of those in the butter group. SREBP1c mediates the effects of insulin on the expression of different lipogenic genes, such as GK, ACC, FAS, ELOVL6, SCD1, and GPAT.[18] In fact, HF-diet-fed animals in the olive oil and margarine groups showed increased expression levels of hepatic GK and PK compared to the controls. This may suggest a higher rate of fatty acid synthesis from glucose. Hence, lower downregulation of de novo lipogenesis under HF diet conditions may lead to higher hepatic accumulation of TG, as found in animals in the olive oil and butter groups. Animals in the margarine group, despite having increased lipogenesis capacity compared to the controls, appear to be more efficient in burning this excess fat supply and would better respond against hepatic steatosis under an HF diet. Therefore, increased β-oxidation capacity in spite of the higher capacity of de novo fatty acid synthesis appears to be responsible for the protection against hepatic steatosis in animals in the margarine group under HF diet conditions. This response seems to be different from that occurring in control animals under these obesogenic conditions, because they did not show increased lipogenic capacity in the liver, but in turn fatty acid oxidation capacity was not activated.

Differences in the expression of lipogenic genes, depending on maternal fat supplementation, were also observed in WAT. PPARγ is a master transcriptional regulator of adipogenesis. Animals in the margarine group did not show the down-regulation in the expression levels of PPARγ and SREBP occurring in the other groups of animals under HF diet conditions. This indicate that these animals may have a greater lipogenesis capacity in the WAT than the other fat-supplemented groups, but this could be counterbalanced with the increased ATGL mRNA expression levels in WAT of these animals compared to the other fat-supplemented groups under HF diet conditions.

Hepatic steatosis has been associated with insulin resistance, and several rodent models have shown that a decrease in the hepatic TG pool correlates with improved insulin sensitivity.[31,32] Here we did not find clear evidence of insulin resistance (in terms of serum parameters and HOMA-IR) in any group of animals, not even in those presenting signs of hepatic steatosis. Nevertheless, it should be mentioned that animals in the butter group fed an HF diet presented decreased expression levels of INSR in WAT compared to their NF-diet-fed counterparts, suggesting that these animals, which also presented the more advanced form of NAFLD, may be more prone to developing insulin resistance. Conversely, animals in the olive oil group, particularly under NF diet conditions, appear to be more efficient in the glucose clearance from circulation, since they showed the highest mRNA levels of GLUT4 and HK in WAT. This might indicate that animals in the olive oil group are metabolically better programmed for a correct glucose metabolism when under an NF diet. However, with the challenge of an HF diet, these animals do not seem to be that metabolically flexible and hence displayed a higher increase in body fat content than animals in the margarine group and presented signs of liver steatosis. The predictive adaptative response hypothesis proposes that the degree of mismatch between the pre- and postnatal environments is an important determinant of subsequent diseases.[8] Notably, we previously described that the intake of excess olive oil by dams during late pregnancy and lactation was associated with decreased adipogenesis and increased thermogenic capacity in weaned animals, affecting body mass gain and body fat during the suckling period.[20] According to the mentioned hypothesis, later effects of this type of fat during the perinatal period appear to be dependent on postweaning diet and conditions.

To figure out what changes in gene expression patterns (in the liver and WAT) were more related with two parameters related to metabolic health, such as adiposity and hepatic lipid content, a PCA was performed. This analysis showed that, under an HF diet, adiposity and lipid content in the liver were highly associated (in a negative way) with transcript levels in WAT related to lipolysis (ATGL) and to insulin sensitivity and adipogenesis (INSR, PPARγ, and SERBP). Thus, it can be interpreted that increased expression levels of these genes under an HF diet may be relevant to avoid excessive adiposity and TG accumulation in tissues other than WAT, particularly the liver. Interestingly, these variables were characteristic of principal component 2, and the margarine group was the one with the highest values of this component. In addition, PCA also showed the significance of the liver transcripts related to energy uptake and adipogenesis (GH, PK, and FAS) and also to fat oxidation (CPT1L, PDK4, and FGF21), all these transcripts with high scores in PC1 (in both dietary conditions). Curiously, control animals under an HF diet presented low values of this component compared to all the other groups. Therefore, although the distribution of animals under the NF diet was disperse, among HF-diet-fed animals, the control and the margarine groups were clearly distinguished between each other and from the olive oil and butter groups.

The specific factors underlying the effects of maternal supplementation with different fat sources are not known. Differences described in milk fatty acid composition depending on the type of maternal fat during lactation [20] could influence the different outcomes. In addition, the putative involvement of the leptin protein in the beneficial effects of margarine oversupply compared to other fat sources may be considered, taking into account that margarine-supplemented dams (in the same cohort of dams) were described to present higher milk leptin concentration compared to olive oil dams at day 12 of lactation.[19] Leptin is present in maternal milk,[33] and its intake during the suckling period has been described to exert protecting effects against the development of later obesity and related metabolic pathologies, such as hepatic steatosis, under obesogenic conditions.[25,34] It could be speculated that the greater supply of milk-borne leptin to animals in the margarine group could account for some of the beneficial effects found in this group of animals compared to the other fat-supplemented groups. However, further studies need to be done to confirm the involvement of milk-borne leptin and to ascertain whether other factors may be involved.

In conclusion, maternal HF diet feeding during pregnancy and lactation affects offspring susceptibility to metabolic diseases, but the consequences depend not only on the intake of fat per se but also on the type of fat supplied. That is, maternal supplementation with excess fat from margarine during late gestation and lactation, in comparison with other types of fat, appears to program the offspring for healthier lipid

partitioning and handling and in turn prevents, to some extent, hepatic steatosis under obesogenic conditions. This effect seems to be associated with an activation of the metabolic pathways related to adipogenesis and lipolysis in WAT, as well as with increased fatty acid oxidation in the liver. Conversely, butter oversupply during this critical period of development may promote hepatic steatosis in the offspring, even when animals are fed a balanced diet after weaning.

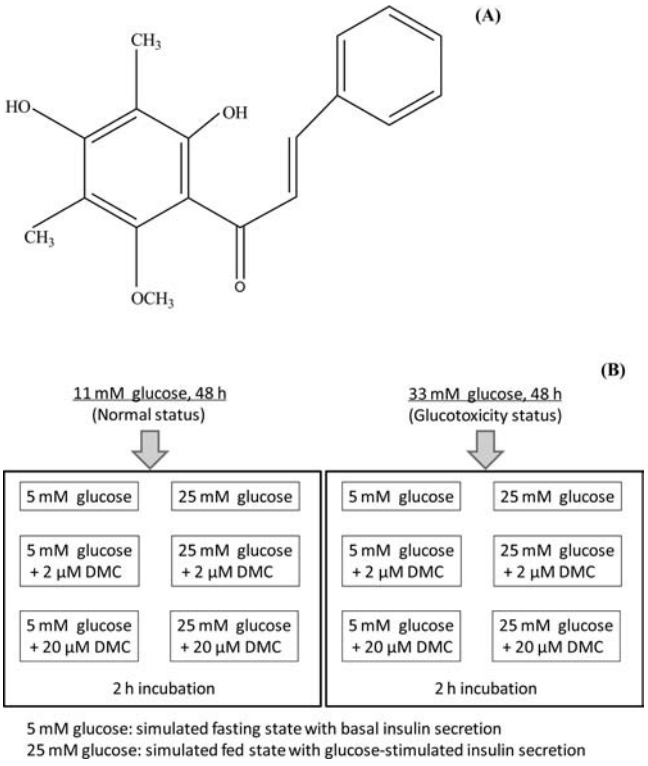

Figure 1. (A) Chemical structure of DMC. (B) Experiment design of insulin stimulation assay.

Although the hypoglycemic effects of *Cleistocalyx operculatus* flower bud aqueous extracts and DMC have been demonstrated in in vitro and animal models in the literature, and the mechanism of insulin enhancement has been illustrated in H_2O_2-damaged pancreatic cells, the effects and underlying mechanism of DMC against more physiologically relevant glucotoxicity conditions remains unclear. In this study, the effects of DMC on glucotoxicity induced insulin secretion impairment of RIN-5F cells and its corresponding mechanism were investigated.

MATERIALS AND METHODS

Reagents. DMC was isolated from the dried flower buds of *Cleistocalyx operculatus* as previous described.[16] Cell counting kit 8 (CCK-8) was purchased from Dojindo Molecular Technologies, Inc. (Tabaru, Japan), and dimethyl sulfoxide (DMSO) from Merck (Gibbstown, NJ, USA). All the primers were synthesized by Life Technologies (Carlsbad, CA, USA). Cell culture reagents were acquired from Life Technologies as well. All other chemicals were analytical reagent grade acquired from Sigma Aldrich (St. Louis, MO, USA).

Cell Culture. RIN-5F cells derived from rat pancreatic β-cells were purchased from American Type Culture Collection (ATCC, Manassas, VA). RIN-5F cells were maintained in RPMI-1640 containing 11 mM glucose, supplemented with 10% fetal bovine serum (FBS), and 1% penicillin/streptomycin under a condition of saturated humidity atmosphere containing 5% CO_2 at 37 °C. The medium was renewed every 3 days.

Measurements of Insulin Secretion and Cell Viability. RIN-5F cells (from 8 to 13 passages) were seeded in 24-well plates at a density of 2×10^5 cells/well. After 2 days, the cells were preincubated in RPMI-1640 medium at either a maintenance glucose condition (11 mM) or a high glucose condition (33 mM) for 48 h, and then the cells were used for insulin stimulation experiment. In detail, RIN-5F cells were washed twice with Krebs−Ringer bicarbonate buffer (KRB buffer, pH 7.4) containing 25 mM HEPES, 115 mM NaCl, 24 mM $NaHCO_3$, 5 mM KCl, 2.5 mM $CaCl_2$, and 1 mM $MgCl_2$ supplemented with 0.1% bovine serum albumin (BSA). Subsequently, the medium was replaced by 0.5 mL of KRB containing 5 mM glucose (simulated fasting state with basal insulin secretion) or 25 mM glucose (simulated fed state with glucose-stimulated insulin secretion) with or without DMC (2 μM and 20 μM), and the cells were incubated for 2 h at 37 °C as indicated respectively (Figure 1B). The supernatant was collected for measurement of secreted insulin using a high range rat insulin ELISA kit (Mercodia Inc., Uppsala, Sweden), and the attached cells were used for viability test by CCK-8 according to the manufacturer's instructions.

RNA Isolation and Quantitative RT-PCR. Total RNA from each well was extracted from RIN-5F cells using the RNeasy mini kit (Qiagen NV, Venlo, The Netherlands), and complementary DNAs (cDNAs) were synthesized using PrimeScript first strand DNA synthesis kit (TaKaRa Biotech, Japan) according to the manufacturer's instructions. Quantitative reverse transcription PCR (qRT-PCR) was done using SYBR Premix ExTaq kit (Takara Biotech, Dalian, China) and the ABI Prism 7500 sequence detection system (Applied Biosystems, Foster City, CA, USA) to determine the gene expression level. Each PCR was performed in a 20 μL solution containing 0.8 μL (10 μM) of each pair of forward and reverse primers, 10 μL of Premix Ex Taq DNA polymerase, 0.4 μL of ROX reference dye, 6 μL of dH_2O, and 2 μL of reverse transcription reaction products. The qRT-PCR primers used in the experiment are shown in Table 1. All experiments were done in triplicate. Relative expression was determined by the $2^{-\Delta Ct}$ method using GAPDH as the internal control, and fold change was calculated in comparison with the corresponding control group.

Determination of PDX-1 Protein Expression by Western Blotting. Pancreatic duodenum homeobox-1 (PDX-1) protein expression in RIN-5F cells was examined using Western blotting. Cells were seeded in 12-well plates at a density of 4×10^5 cells/well. Following the treatment with 11 and 33 mM glucose, with or without DMC (at 2 μM and 20 μM) for 48 h, cells were washed with ice-cold PBS before lysis in 200 μL of CelLytic-M cell lysis reagents (Sigma Aldrich). Then, samples were centrifuged at 14000 *g* for 15 min at 4

Table 1. Primer Sequences of the Selected Genes Involved in Key Pathways of Insulin Secretion in Rat Pancreatic β-Cells RIN-5F

		primer	
gene	full name	forward	reverse
GAPDH	glyceraldehyde-3-phosphate dehydrogenase	GGCAAGTTCAATGGCACAGT	TGGTGAAGACGCCAGTAGACTC
PRE-INS	preinsulin	TCTTCTACACACCCATGTCCC	GGTGCAGCACTGATCCAC
GLP-1R	glucagon-like peptide-1 receptor	GGGTCTCTGGCTACATAAGGACAAC	AAGGATGGCTGAAGCGATGAC
GLUT2	glucose transporter type 2	TTAGCAACTGGGTCTGCAAT	GGTGTAGTCCTACACTCATG
PDX-1	pancreatic duodenum homeobox-1	AAACGCCACACACCAAGGAGAA	AGACCTGGCGGTTCACATG
GCK	glucokinase	GCTTTTGAGACCCGTTTCGT	CGCACAATGTCGCAGTCG
iNOS	inducible nitric oxide synthase	CACCTTGGAGTTCACCCAGT	ACCACTCGTACTTGGGATGC
MCP-1	monocyte chemoattractant protein-1	GCAATCAATGCCCCAGTCA	GCCTCTGCACTGAGATCTTCCT

°C, the supernatant was collected, and the total protein was determined using a BCA assay (Pierce, Rockford, IL, USA). For Western blotting, equal amounts of total cellular protein (8 μg) were resolved by SDS−PAGE and transferred onto polyvinylidene difluoride (PVDF) membranes (Bio-Rad, Hercules, CA, USA) with a Bio-Rad Transblot apparatus, and probed with a primary antibody against PDX-1 overnight at 4 °C, followed by incubation with a horseradish peroxidase (HRP)-conjugated secondary antibody (all antibodies were from Cell Signaling Technologies, Beverly, MA, USA) for 1 h. The immune complexes of bound antibody were visualized with an enhanced chemiluminescence (ECL) system according to the manufacturer's instructions (GE Healthcare, Piscataway, NJ, USA). Equal loading was confirmed by analysis of the internal control of GAPDH, and bands were quantified using densitometry by the Image J Software (NIH, Bethesda, MD, USA).

Measurement of NO Release by Griess Assay. The quantity of NO produced during the experiment was estimated spectrophotometrically as formed nitrite (NO_2^-). After the 48 h treatment with 11 and 33 mM glucose, with or without DMC (at 2 μM and 20 μM), culture medium was collected for NO measurement. In brief, 50 μL of the culture medium and 50 μL of the sulfanilamide solution reagent (1% sulfanilamide in 5% phosphoric acid) were sequentially added to a 96-well microplate (Corning, Corning, NY, USA) in triplicate. After 10 min of incubation at room temperature, 50 μL of the NED solution (0.1% *N*-1-naphthylethylenediamine dihydrochloride in water) was added to all wells for another 10 min of incubation. Then, the optical density (OD) of the reaction mixture was determined by a Safire 2 microplate reader (Tecan, Mannedorf, Switzerland) at 540 nm. The nitrite content was calculated based on a standard curve constructed with sodium nitrite (Promega, Madison, WI, USA).

Statistics. Results were expressed as mean ± SEM. The data were analyzed by one-way analysis of variance (ANOVA) followed by Tukey's or Dunnett's post hoc comparisons to determine the significant differences between groups. Differences with $P < 0.05$ were considered statistically significant.

RESULTS

Glucose-Stimulated Insulin Secretion and Cell Viability of RIN-5F Cells. RIN-5F cells were exposed to 33 mM glucose for a sustained period of 48 h to induce impaired glucose-stimulated insulin secretion (GSIS). As shown in Figure 2A, high glucose-exposed RIN-5F cells had a blunted insulin secretory response when glucose was raised from 5 to 25 mM, with a 1.2-fold increase of insulin secretion compared with a 1.6-fold increase in normal control RIN-5F cells maintained in 11 mM glucose. Culturing RIN-5F cells at high glucose concentration of 33 mM decreased insulin content (3.05 vs 7.57 ng/mL insulin for RIN-5F cells cultured at 33 and 11 mM glucose, respectively; $P < 0.05$) when stimulated with 25 mM glucose. And, DMC improved the impaired insulin secretion (33 mM glucose for 48 h) with glucose stimulation (25 mM glucose for 2 h) in a concentration-dependent manner ($P < 0.05$ vs control group); it increased insulin secretion by 1.94 and 4.38 ng/mL (63 and 143%, respectively) at the concentration of 2 and 20 μM, respectively. However, DMC did not show significant insulin secretion enhancing effect at basal insulin secretion condition under 5 mM glucose. Under the condition of normal status of 11 mM glucose, the addition of DMC did not increase insulin secretion without glucose stimulation. When responding to an acute stimulation of 25 mM glucose, the insulin secretion rose from 7.57 to 9.30 and 9.94 ng/mL with the treatment of 2 and 20 μM DMC, respectively ($P < 0.05$). Thus, DMC maintained the GSIS potential of RIN-5F cells chronically exposed to high glucose levels.

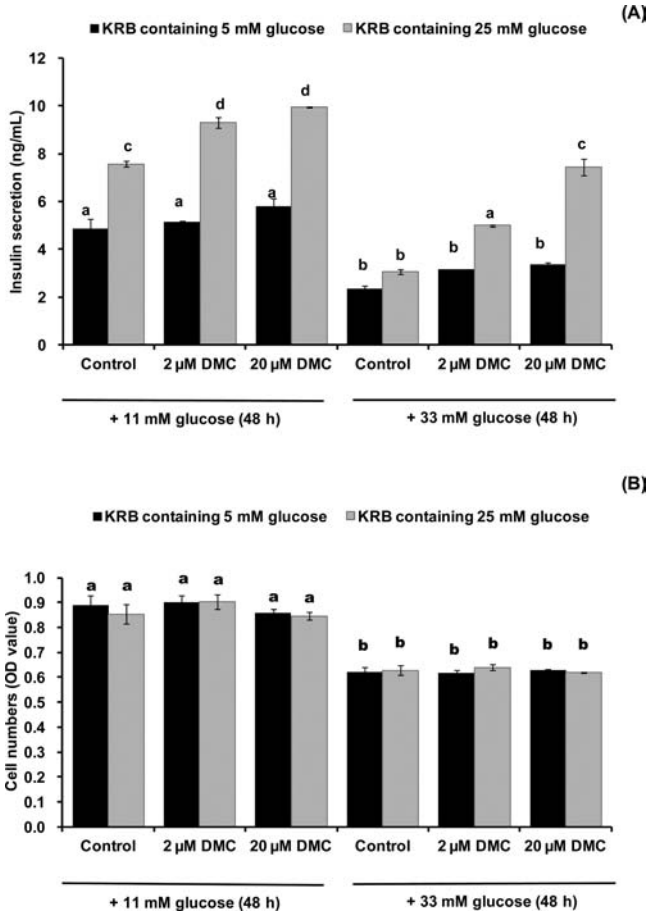

Figure 2. The effect of DMC on basal (5 mM glucose) and glucose-stimulated (25 mM glucose) (A) insulin secretion and (B) cell viability under maintenance glucose (11 mM) and glucotoxicity (33 mM) status. Values are presented as mean ± SEM ($n = 6$), duplicate by means of three independent experiments. The data values were analyzed by one-way ANOVA followed by Tukey's post hoc multiple comparison tests, and significant differences between groups are indicated by the lack of common letter annotations of a, b, c, d at $P < 0.05$.

To test the effects of high glucose and various concentrations of DMC on the viability of RIN-5F cells, CCK-8 assay was performed after the glucose stimulated insulin secretion assay. The results showed that the viability of RIN-5F cells treated with 33 mM glucose was reduced by 28% when compared with that of the control group with 11 mM glucose (Figure 2B). DMC, applied at different concentrations, did not affect the viability of RIN-5F cells compared with the corresponding controls (Figure 2B).

DMC Regulated β-Cell Function via GLP-1R, PDX-1, PRE-INS, GLUT2, and GCK at Gene Expression Level. In order to determine which step, from glucose sensing to insulin exocytosis, is impaired in glucotoxicity status in RIN-5F cells and the effect of DMC on glucotoxicity, we compared the gene expression levels of a series of regulators of insulin secretion process in pancreatic β-cells. The mRNA levels of glucagon-like peptide-1 receptor (GLP-1R), insulin transcription factor PDX-1, preinsulin (PRE-INS), glucose transport 2 (GLUT2), and glucokinase (GCK) were determined by qPCR. As shown in Figure 3, semiquantitative RT-PCR analysis showed that 33 mM glucose significantly downregulated the transcription levels of the tested genes compared with the normal glucose level of

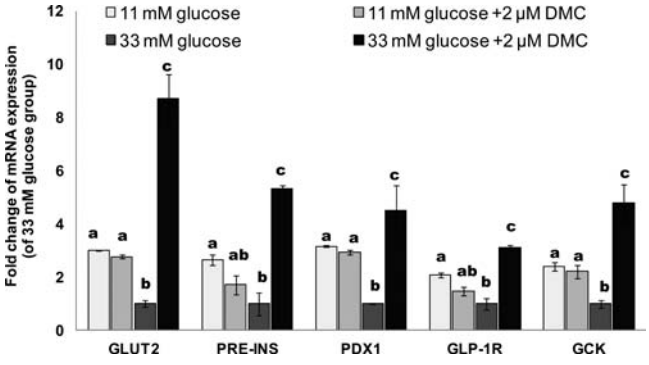

Figure 3. Relative mRNA expression of GLUT2, PRE-INS, PDX-1, GLP-1R, and GCK at glucose dose of 11 and 33 mM with or without the treatment of 2 μM DMC, fold change compared with 33 mM glucose control group. Values are shown as mean ± SEM (n = 3), triplicate by means of three independent experiments. The data values were analyzed by one-way ANOVA followed by Tukey's post hoc multiple comparison tests, and significant differences between groups are indicated by different letters of a, b, c at $P < 0.05$.

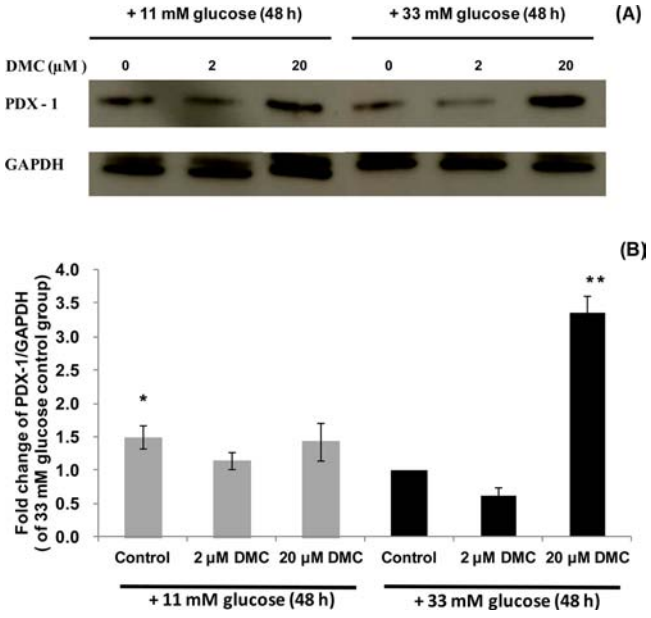

Figure 4. Effect of DMC on the glucose induced PDX-1 expression in RIN-5F cells. (A) A representative image of protein expression of GAPDH and PDX-1 measured by Western blot. (B) Quantification of PDX-1 protein expression. The level of PDX-1 expression was normalized against GAPDH, and the results were expressed as relative fold change compare to 33 mM glucose control. Values are shown as mean ± SEM (n = 3) by means of three independent experiments. The data values were analyzed by one-way ANOVA followed by Dunnett's post hoc: compare all columns vs 33 mM glucose control column tests, and significant differences between groups are indicated by * at $P < 0.05$ and ** at $P < 0.01$.

11 mM ($P < 0.05$). Under the treatment of 11 mM glucose, none of the tested target gene expression was statistically altered by 2 μM DMC. Under the condition of 33 mM glucose, 2 μM DMC significantly increased the expression levels of GLP-1R, PDX-1, PRE-INS, GLUT2, and GCK ($P < 0.05$) to a level beyond those at 11 mM glucose status (Figure 3).

PDX-1 Was Involved in Insulin Release at Protein Level. PDX-1 is involved in β-cell differentiation and functional maintenance and regulates the transcription of insulin and other insulin secretion related genes.[49] To confirm whether DMC stimulates the expression of PDX-1 at the protein level based on the results of mRNA investigation, Western blotting analysis was employed upon RIN-5F cells cultured at 11 and 33 mM glucose for 48 h. The high glucose control (33 mM) reduced the protein expression of PDX-1 compared with the maintenance glucose (11 mM) condition ($P < 0.05$). Application of 20 μM DMC effectively reversed the suppression of PDX-1 after prolonged high glucose incubation (Figure 4A,B) ($P < 0.01$), and resulted in ~3.3-fold enhancement in PDX-1 expression which was even stronger than that under maintenance glucose condition, whereas, 2 μM of DMC was not effective in regulating PDX-1 expression at the protein level, but it significantly increased its gene expression level; the possible reason was that 2 μM DMC induced PDX-1 mRNA changes were not strong enough to alter its protein expression level or needed more time to see the alteration.

DMC Inhibited NO Release under Glucotoxicity Condition. Since the half-life of NO is very short, the concentration of nitrite was measured using Griess reagents. As shown in Figure 5A, 33 mM glucose treatment significantly enhanced nitrite content compared with the treatment of maintenance glucose concentration of 11 mM ($P < 0.05$). Under the condition of glucotoxicity (33 mM glucose), DMC remarkably suppressed the increase of nitrite content dose-dependently ($P < 0.05$). Meanwhile, there was no significant difference among control and DMC treatment groups under the 11 mM glucose maintenance level. The results indicated that DMC could protect β-cells from damage caused by overproduction of NO.

DMC Suppressed the Expression of iNOS and MCP-1 at mRNA Level. As shown in Figure 5B, under conditions of glucotoxicity (33 mM glucose), the mRNA levels of iNOS and MCP-1 reached 2- and 2.8-fold of the maintenance level. At the glucotoxicity state, treatment with DMC at 2 and 20 μM decreased the mRNA level of iNOS by 86 and 88%, respectively ($P < 0.05$ vs control group), but did not show significant difference between these two concentrations ($P > 0.05$). With the concentration of 2 and 20 μM DMC, the mRNA levels of MCP-1 were decreased by 77 and 96%, respectively ($P < 0.05$ vs control group). While at the maintenance condition of 11 mM glucose, treatment with DMC at 2 and 20 μM did not cause a significant reduction of the mRNA level of iNOS and MCP-1.

■ DISCUSSION

Pancreatic islet cells are more susceptible to oxidative stress than cells in other tissue as they produce less antioxidant enzymes.[5] Damage of pancreatic islets leads to decreased insulin secretion, resulting in hyperglycemic condition and continuous generation of additional oxidative stress, forming a vicious cycle. Pretreatment of aqueous extract of *Cleistocalyx operculatus* flower buds has been demonstrated to restore the pancreatic islets insulin secretion injury of streptozotocin-induced diabetic rats.[14] Also, pretreatment of DMC was shown to protect the damage of H_2O_2-induced glucose responded insulin secretion of MIN6 cells[47] by conferring antioxidant and antiapoptotic effects through improved mitochondrial function in our previous work.[48] In the present study, we investigated the effect of DMC on RIN-5F cells under glucotoxicity condition and its underlying mechanism. Induction of glucotoxicity was achieved by incubating cells with 33 mM glucose for a duration of time, as previously reported.[50] Our

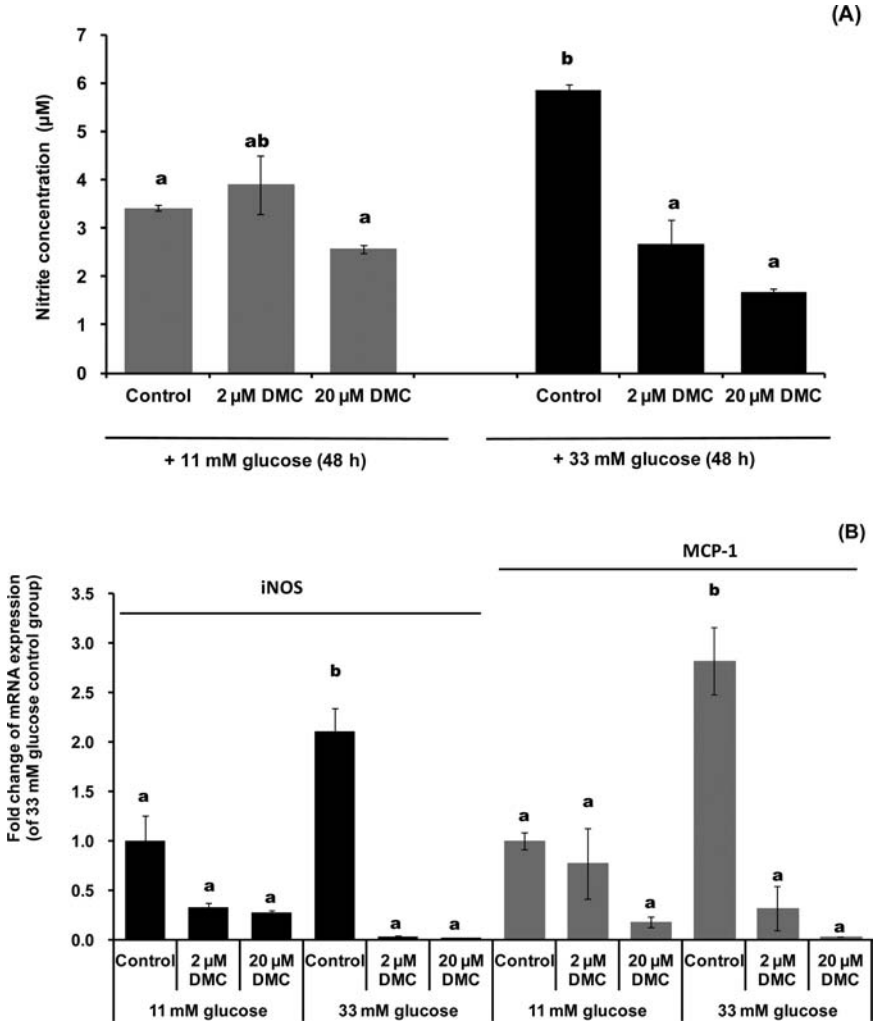

Figure 5. Effect of various concentrations of DMC on (A) NO release and (B) relative mRNA expression of iNOS and MCP-1 in RIN-5F cells under the maintenance and glucotoxicity conditions. Values are expressed as mean ± SEM (n = 3), triplicate by means of three independent experiments. The data values were analyzed by one-way ANOVA followed by Tukey's post hoc multiple comparison tests, and significant differences between groups are indicated by different letters of a, b at $P < 0.05$.

current study showed that incubation with 33 mM glucose for 48 h significantly impaired the basal and glucose-induced insulin secretion in RIN-5F cells. Treatment with DMC (2 and 20 μM) caused a significant increase of glucose-induced insulin secretion in a dose-dependent manner compared with control under conditions of glucotoxicity. As no impact on cell viability was observed, such effect could, at least in part, be attributed to the enhanced insulin secretion capacity.

There are two main signaling pathways impacting insulin secretion. In the first pathway glucose is transported into pancreatic β-cells by GLUT2, and then metabolized by GCK to glucose-6-phosphate, resulting in ATP production, which in turn induces Ca^{2+} influx, followed by the release of insulin (Figure 6).[51] Under simulated chronic glucotoxicity, the expression of GLUT2 and GCK in RIN-5F cells was decreased in the present study, accompanied with a reduction of insulin secretion, an observation which was in line with the existing literature.[52] In the present study, DMC was observed to reverse the decrease in glucose-stimulated insulin secretion by RIN-5F cells under glucotoxic conditions and to boost glucose-stimulated insulin secretion under normal conditions. At the same time, the mRNA levels of GLUT2 and GCK were

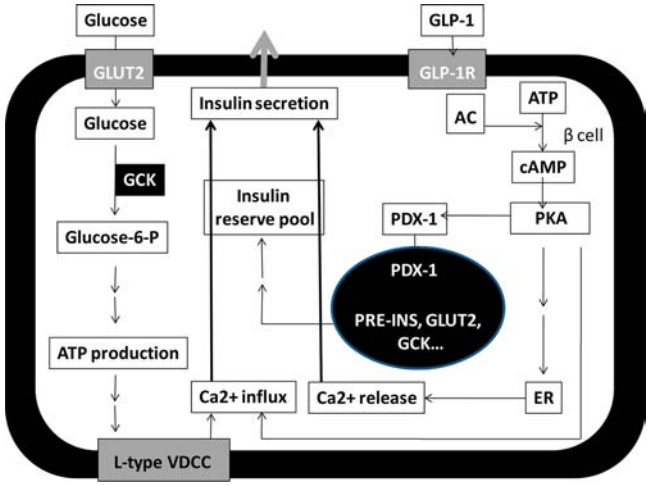

Figure 6. Schematic representation of the major intracellular steps that lead to insulin secretion. The signal pathways include glucose-induced and GLP-1-induced insulin secretion. The targets written in white color were tested in the present study.

dx.doi.org/10.1021/jf405365d | J. Agric. Food Chem. 2014, 62, 1602−1608

elevated by DMC, suggesting that the entire glucose-stimulated insulin release pathway was affected.

The second recognized signaling route affecting insulin secretion is mediated by GLP-1. GLP-1 is produced in the intestine and binds to a specific receptor (GLP-1R) located on the membrane of pancreatic β-cells. The interaction between GLP-1 and GLP-1R leads to activation of adenylate cyclase (AC) and production of cAMP as a secondary messenger. Followed by protein kinase A (PKA) activation and PDX-1 translocation to the nucleus, PRE-INS expression is induced (Figure 6).[51] In our study, DMC enhanced the gene expression of GLP-1R compared with control in the glucotoxicity assay. Thus, we concluded that DMC might mimic the effect of GLP-1, enhance the expression of GLP-1R, and promote insulin secretion. As GLP-1 stimulates the expression of GLUT2 and GCK to help to confer glucose sensitivity to β-cells,[53] DMC may mimic GLP-1 and stimulate GLP-1R to increase the expression of GLUT2 and GCK.

The gene expression levels of GLP-1R, PDX-1, PRE-INS, GLUT2, and GCK were only significantly elevated by DMC under glucotoxic conditions in the study, but not at normal conditions, suggesting that pancreatic cells might only be susceptible to DMC under the condition of elevated glucose (33 mM in this study). The upregulation of multiple genes by DMC may indicate potentiated glucose stimulation of multiple elements of the insulin secretion pathway. PDX-1 is recognized as a key regulation factor in the cascade regulating insulin secretion[49] (Figure 6); therefore, we quantified the impact of DMC on increasing the protein expression via Western blotting analysis, with results showing increased PDX-1 level as well. Since PDX-1 is a transcription factor that acts by translocation into the nucleus, we hypothesized that increased amount of PDX-1 would also enable stronger downstream gene expression activation.

We addressed the potential protective effect of DMC against oxidative and inflammatory damage induced by glucotoxicity. The incubation of RIN-5F cells with 33 mM glucose led to elevated levels of NO production and MCP-1 expression, contributing to oxidative stress and inflammatory damage. DMC treatment dramatically alleviated such impact, which could partially explain the restored insulin secretion ability observed in RIN-5F cells.

In conclusion, the present study provided evidence that DMC could ameliorate glucotoxicity-induced impairment of insulin secretion by RIN-5F cells. The mechanism was likely to involve potentiating GLP-1R mediated PDX-1 translocation, the elevated expression of GLUT2 and GCK, and protection against detrimental oxidative and inflammatory damage by DMC.

some other antihypertensive peptides are expected to be identified and isolated still from LF hydrolyzates.[12]

In a previous work, proteolytic yeast strains of *Debaryomyces hansenii*, *Kluyveromyces lactis* and *K. marxianus* isolated from cheeses[13] were screened for their ability to grow in media with LF as the sole nitrogen source and to produce LF hydrolyzates containing ACE-inhibitory peptides. *K. marxianus* Km2 strain grown on LF produced the most potent hydrolyzate which, when orally administered to SHRs, exerted antihypertensive effect.[14]

The objective of the present study was to identify the LF-derived peptides produced by *K. marxianus* Km2 and characterize their antihypertensive effects. For this purpose, a *K. marxianus* LF permeate enriched in peptides of molecular weight lower than 3 kDa (pLFH) was fractionated and the main peptides present in the ACE-inhibitory fractions were identified by using an ion trap mass spectrometer. Selected peptides were evaluated for their inhibitory effects on ACE activity, their antihypertensive effects in SHRs and their stability against simulated gastrointestinal digestion. Finally the *in vivo* effect of peptides on SHRs blood ACE activity as well as angiotensin II and aldosterone levels are discussed.

MATERIALS AND METHODS

Materials. Bovine LF was provided by FrieslandCampina Domo (Zwolle, The Netherlands). ACE from porcine kidney, captopril, and bicinchoninic acid protein assay kit were purchased from Sigma (St. Louis, MO). Glucose was obtained from Panreac (Barcelona, Spain), bacteriological peptone was purchased from Cultimed (Barcelona, Spain) and yeast extract and agar were acquired from Pronadisa (Madrid, Spain). ACE substrate *o*-aminobenzoylglycyl-*p*-nitrophenylalanylproline was provided by Bachem Feinchemikalien (Bubendorf, Switzerland). Corolase PP (porcine pancreatic extract) was from AB enzymes (Darmstadt, Germany). Diazepam and ketamine were purchased from Roche Farma (Madrid, Spain) and Parke-Davis (Alcobendas, Madrid, Spain), respectively. An ACE colorimetric kit was acquired from Bühlmann Laboratories (Schönenbuch, Switzerland). An AssayMax Angiotensin II ELISA kit was from AssayPro (Saint Charles, MI) and a Coat-A-Count Aldosterone ^{125}I RIA kit was provided by Siemens Medical Solutions Diagnostics (Los Angeles, CA).

Preparation of *K. marxianus* Lactoferrin Permeate (pLFH) and Fractionation by Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC). *K. marxianus* LF hydrolyzate was prepared as previously described, and it was subjected to ultrafiltration through a VivaFlow 50 3 kDa cutoff polyethersulfone membrane (Vivascience, Sartorius Stedim Biotech, Aubagne, France). Resulting permeate (pLFH), enriched in peptides of molecular weight lower than 3 kDa, showed an IC_{50} value of 50.2 ± 2.7 μg/mL. [14]

Fractionation of pLFH was carried out by RP-HPLC using a Waters system (Waters Corporation, Milford, MA) equipped with a 1525 Binary HPLC pump, a 2996 Photodiode Array Detector and a 717 plus Autosampler in combination with a Fraction Collector III. For this purpose, pLFH was applied to a Prep Nova-Pak HR C18, 60 Å, 6 μm, 7.8 × 300 mm column (Waters). The column was developed at a flow rate of 4 mL/min. Elution was performed with a linear gradient of solvent B (acetonitrile with 0.05% TFA) in solvent A (water with 0.05% TFA) from 0 to 20% B in 70 min. Samples of the whole permeate and the fractions (20 mL) were freeze-dried and kept at −20 °C until reconstitution with distilled water for determination of the protein content and *in vitro* ACE-inhibitory effect, as explained below.

Peptide Sequencing by Reversed-Phase High-Performance Liquid Chromatography Tandem Mass Spectrometry (RP-HPLC-MS/MS). RP-HPLC-MS/MS analysis of pLFH fractions was performed as described by Sánchez-Rivera et al.[15] with minor changes. The flow rate was 0.2 mL/min and the injection volume 50 μL. Peptides were eluted using a linear gradient from 0 to 45% of solvent B (acetonitrile:formic acid; 1000:0.1, v/v) and 55% of solvent A (water:formic acid; 1000:0.1% v/v) in 120 min. Data Analysis (version 4.0; Bruker Daltoniks) was used to process and transform spectra to representing mass values. BioTools (version 3.2; Bruker Daltoniks) was used to process the MSn spectra, to perform peptide sequencing and to calculate theoretical masses.

Main peptides identified in the pLFH were ordered at >90% purity from GenScript Corporation (Piscataway, NJ) wherein they were synthesized by solid phase methods using *N*-(9-fluorenyl) methoxycarbonyl (Fmoc) chemistry.

***In vitro* Assay of ACE-Inhibitory Activity.** *In vitro* ACE-inhibitory activity of pLFH fractions and synthetic peptides was measured using the fluorescent method described by Sentandreu and Toldrá[16] based on the hydrolysis of the internally quenched fluorescent substrate *o*-aminobenzoylglycyl-*p*-nitrophenylalanylproline by the action of ACE. Protein content of peptide fractions was estimated by the bicinchoninic acid method (BCA) using bovine serum albumin as standard.[7] Synthetic peptide concentration was based on the dry weight of the peptides.

The IC_{50} value was defined as the protein/peptide concentration required to inhibit 50% of the ACE activity, and the value for each experiment was estimated by nonlinear regression of the experimental data to a four-parameter logistic curve using the software package SigmaPlot v 10.0 (SPSS Inc., Chicago, IL).

***In vivo* Assay of Antihypertensive Effect in SHRs.** Experimental procedures were conducted in accordance with the Spanish legislation on 'Protection of Animals used for Experimental and other Scientific Purposes' and to the Directives of the European Community on this subject. The study was approved by the 'Ethics Committee for Animal Welfare' of 'La Fe' Hospital to be carried out in its accredited animal research facility.

Male SHRs weighing 230−330 g (Charles River Laboratories, Barcelona, Spain) were housed in temperature-controlled rooms (23 °C) with 12 h light/dark cycles and consumed tap water and standard diets *ad libitum*. To minimize the impact of light cycle and feeding on circadian rhythms of blood pressure,[17] the experiments always started at the same time in the morning (9:00 a.m.) in fasted rats. Indirect measurement of systolic blood pressure (SBP) was carried out in 18 awake restrained rats by the noninvasive tail-cuff method using computer-assisted Non-Invasive Blood Pressure equipment (LE5001 unit with LE5160R cuff and transducer, Panlab Harvard Apparatus, Cornellá, Barcelona, Spain). Peptides (up to 10 mg/kg) were orally administered by gastric intubation in 650 μL of physiological saline. Before the measurements, rats were kept at 37 °C during 15 min to make the pulsations of the tail artery detectable. The SBP was measured before peptide intake (zero time) and 1, 2, 3, 4, and 24 h after intake. Physiological saline (650 μL) and captopril (50 mg/kg) served as negative and positive controls, respectively. Each value of SBP was obtained by averaging at least three consecutive and successful measurements without disturbance of the signal. Changes in SBP were calculated as the absolute difference (in mm Hg) with respect to the basal values of measurements obtained just before peptide administration.

***In vitro* Simulated Gastrointestinal Digestion and Analysis of Digests by RP-HPLC.** Peptides were subjected to a two-stage simulated gastrointestinal digestion process as previously described.[10] Briefly, pepsin (0.2 mg) was added to aqueous solutions of peptides (10 mL; 1 mM) adjusted at pH 2.0 using 1 N HCl and incubated at 37 °C. After 90 min, the pH was adjusted to 7.5 adding 10 mL of 0.4 M sodium phosphate buffer at pH 7.5. Corolase PP, a proteolytic enzyme preparation that contains trypsin, chymotrypsin, and amino and carboxypeptidase activities, was added (0.2 mg), and the sample was further incubated at 37 °C for 150 min. The reaction was stopped by heating at 80 °C for 10 min in a water bath, followed by cooling at room temperature. Each sample was stored at −20 °C until further analysis by RP-HPLC.

Analysis of gastrointestinal digests was performed in the same RP-HPLC system specified above using a Symmetry C18 column (4.6 × 150 mm, 5 μm, Waters) kept at 40 °C. The column was developed at a flow rate of 1 mL/min. Peptides were eluted with a linear gradient of

[a]Fractions are termed as in Figure 1. [b]Charge of precursor ion: 1. [c]Calculated monoisotopic mass. [d]Chemically synthesized peptides are labeled in bold.

solvent B (acetonitrile with 0.1% TFA) in solvent A (water with 0.1% TFA) from 0 to 40% in 20 min and detected at 214 nm. Peptides LRP and KLRP were quantified in gastrointestinal digests of DPYKLRP, PYKLRP and YKLRP in accordance to standard curves in water.

Determination of Blood Components of the Renin-Angiotensin System. Twenty-two rats were anaesthetized by intraperitoneal injection of 5 mg/kg diazepam and 100 mg/kg ketamine. Blood samples were collected to obtain both serum and plasma which were kept frozen at −80 °C until the determination of ACE activity, angiotensin II and aldosterone levels.

Direct quantitative *in vitro* determination of ACE activity was carried out by using the Bühlmann ACE colorimetric kit according to the manufacturer's instructions. Briefly, it is a kinetic enzymatic assay in which ACE catalyzes the cleavage of the synthetic substrate (FAPGG) into an amino acid derivative and a dipeptide. The kinetic of this cleavage reaction is measured by recording the decrease in absorbance at 340 nm.

Quantitative *in vitro* measurement of angiotensin II was carried out by using the AssayMax Angiotensin II ELISA kit according to the manufacturer's instructions. Briefly, this assay employs a quantitative sandwich enzyme immunoassay technique in which a polyclonal antibody specific for angiotensin II is precoated onto a microplate. The angiotensin II in standards and samples is sandwiched by the immobilized antibody and biotinylated polyclonal antibody specific for angiotensin II, which is recognized by a streptavidin-peroxidase conjugate. A peroxidase enzyme substrate is added and intensity of developed color is measured.

Quantitative *in vitro* measurement of aldosterone was carried out by using the Coat-A-Count Aldosterone ^{125}I RIA kit according to the manufacturer's instructions. Briefly, it is a solid-phase radioimmunoassay, based on aldosterone-specific antibody immobilized to the wall of the assay tube. ^{125}I-labeled aldosterone competes for a fixed time with aldosterone in the sample for antibody sites.

RESULTS

Fractionation of *K. marxianus* pLFH: ACE-Inhibitory Activity of Resulting Fractions and Identification of Major Peptides. *K. marxianus* pLFH was subjected to semipreparative RP-HPLC and the total chromatogram was divided into 11 fractions which showed IC_{50} values ranging from 49 to 288 μg/mL. The three most active fractions (F6, F7 and F11) with IC_{50} values of 68, 74, and 49 μg/mL, respectively, were analyzed by HPLC-MS/MS, and the major peptide components were sequenced (35 peptides on total, Table 1).

Table 2. Inhibitory Potency of Selected LF-Derived Peptides on ACE Activity

peptide	IC_{50} (μM)[a]
DPYKLRP	30.5 ± 1.4 (c)
PYKLRP	10.2 ± 1.2 (b)
YKLRP	16.5 ± 0.7 (b)
KLRP	91.6 ± 4.0 (d)
LRP	0.35 ± 0.03 (a)
GILRP	90.7 ± 5.0 (d)

[a]Inhibitory potency is expressed as IC_{50} and data are mean ± SEM of at least 3 independent experiments. Data with the same letter are not significantly different, $P > 0.05$ (one way ANOVA followed by Student−Newman−Keuls test).

ACE-Inhibitory Activity of LF-Derived Peptides. A total of 6 peptides (labeled in Table 1) from those identified in fractions F6, F7 and F11 were chemically synthesized. These included four sequences (DGKEDL, ESPQTHY, YKLRP and DPYKLRP) that, being among the most abundant in each fraction, also fulfilled the common structural features described for many ACE-inhibitory peptides derived from food proteins.[18] Since the role of specifically C-terminal P residue in enhancing inhibition has been highlighted in most effective antihypertensive sequences derived from milk proteins,[1] the peptides PYKLRP and GILRP identified in the most active fraction (F11) were also included in the study despite not being abundant. Interestingly, the yeast proteolytic system produced the set of sequences DPYKLRP, PYKLRP and YKLRP differing in the amino acidic residue at the N-terminal end. With the aim of establishing sequence-inhibitory potency relationships, the peptides KLRP and LRP were also synthesized.

Only the six peptides having a P residue at the C-terminal end showed detectable inhibitory activity at 20 μM under our *in vitro* assay conditions. Further concentration response curves allowed the determination of IC_{50} values (Table 2) which varied over a 200-fold range. The higher potency as indicated by lower IC_{50} value corresponded to the tripeptide LRP.

Antihypertensive Effect of LF-Derived Peptides. The antihypertensive effect of the six ACE-inhibitory peptide sequences was characterized in SHRs. Average SBP, measured by the tail-cuff method in awake SHRs, was 200 ± 1 mmHg (n = 58). Oral administration of the six LF-derived peptides at 10 mg/kg induced significant reductions in SBP as shown in Figure 1, together with the lack of effect of oral saline and the antihypertensive effect of captopril (50 mg/kg). Similar to the effect caused by captopril, the antihypertensive effect of sequences DPYKLRP, GILRP and LRP remained significant up to 24 h post administration. Antihypertensive effects ranged from −26.8 mmHg for both DPYKLRP and LRP until −13.2 mmHg for KLRP. Reductions in SBP caused by DPYKLRP (−26.8 ± 2.4 mmHg; 1 h post administration) and LRP (−26.8 ± 1.3 mmHg; 2 h) were comparable to that of the captopril control (−27.9 ± 2.1 mmHg; 1 h) (one-way ANOVA; $P > 0.05$).

The heptapeptide DPYKLRP and the tripeptide LRP were further studied for dose-dependent antihypertensive effects. Both peptides induced significant dose-dependent (3, 7, and 10 mg/kg) reductions in SBP at each time point from 1 to 24 h after oral administration (Figure 2).

Resistance of LF-Derived Peptides to Gastrointestinal Enzymes. The six antihypertensive peptides were subjected to a hydrolysis process which simulates gastrointestinal digestion due to the action of gastric and pancreatic enzymes. The

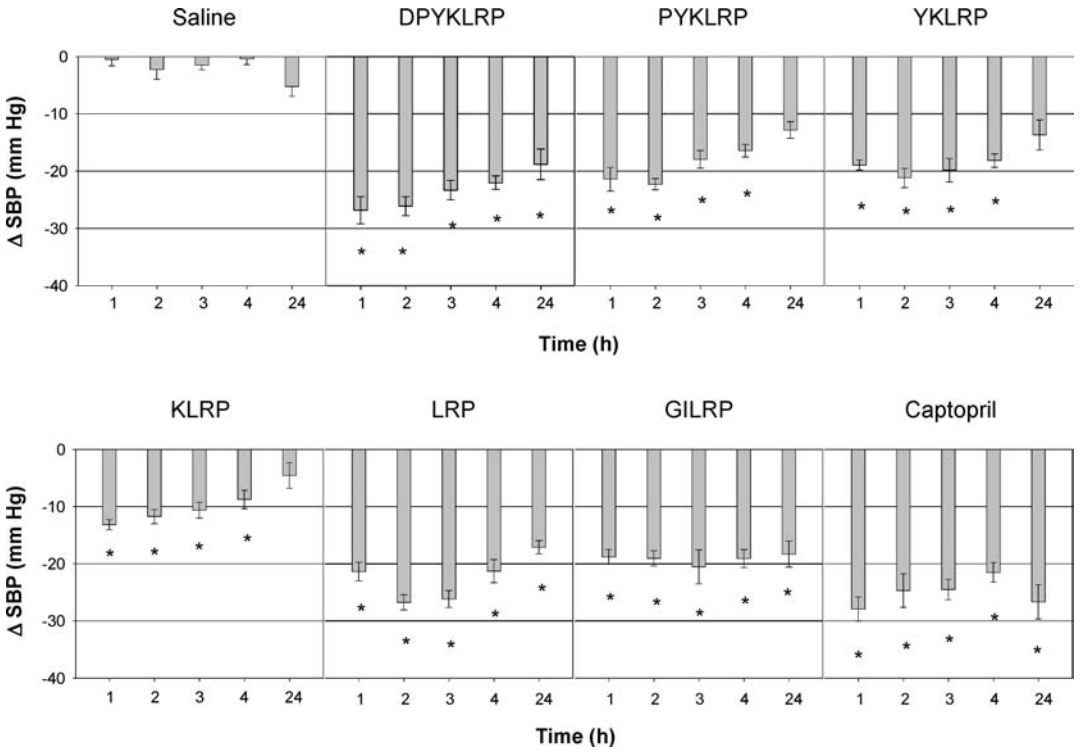

Figure 1. Time course of systolic blood pressure (SBP) changes after oral administration of physiological saline, captopril (50 mg/kg) and LF-derived peptides (10 mg/kg) to SHRs. Pressure changes (ΔSBP) are expressed in absolute values (mm Hg) and data are expressed as mean ± SEM from 6 to 7 determinations. *$P < 0.01$ versus control saline group (one-way ANOVA followed by Dunnett multiple comparison tests).

dx.doi.org/10.1021/jf4053868 | J. Agric. Food Chem. 2014, 62, 1609−1616

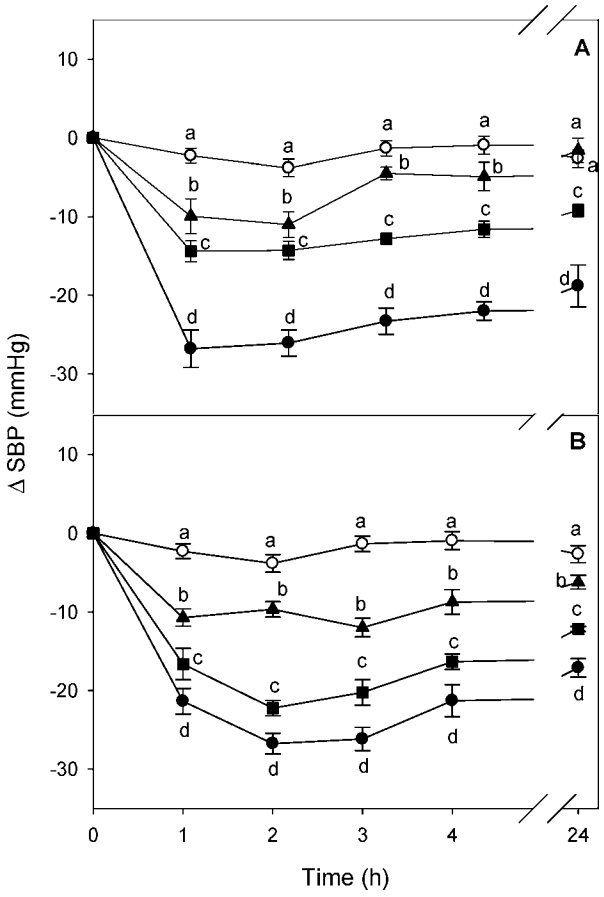

Figure 2. Time course of systolic blood pressure (SBP) changes after oral administration of increasing doses of (A) DPYKLRP and (B) LRP to SHRs. Physiological saline (○), 3 mg/kg (▲), 7 mg/kg (■), 10 mg/kg (●). Pressure changes are expressed in absolute values (mm Hg) and data are expressed as mean ± SEM from 5 to 8 determinations. Different letters indicate significant differences among doses at each time point (one-way ANOVA followed by Student−Newman−Keuls multiple comparison tests, $P < 0.05$).

analysis of digests by RP-HPLC (Figure 3) showed that the longer sequences, DPYKLRP and PYKLRP, were completely hydrolyzed releasing several fragments. A partial hydrolysis was observed for the pentapeptide YKLRP (approximately 60% of the initial concentration of the input peptide). In the conditions tested, sequences KLRP and GILRP were slightly hydrolyzed (approximately 6 and 12% decrease from the initial concentrations) whereas LRP was resistant to gastrointestinal enzymes. Noteworthy, in the gastrointestinal digests of the hydrolyzed peptides, the sequences LRP and KLRP were detected among others. LRP at concentrations of 525, 600 and 465 μM were detected in the digests of DPYKLRP, PYKLRP and YKLRP, respectively. Also, a minor quantity of LRP (3 μM) was detected in the KLRP digest. In the conditions tested, the sequence LRP was not detected in the GILRP digest. With respect to KLRP, concentrations of 550 and 140 μM were detected in the digests of DPYKLRP and PYKLRP. Also the sequence KLRP was detected at a concentration of 17 μM in the YKLRP digest.

Effects of LF-Derived Peptides on Blood Components of the Renin-Angiotensin System. The effects of DPYKLRP and LRP (10 mg/kg) on serum ACE activity and angiotensin II levels, and on plasma aldosterone levels were studied in SHRs. Captopril (50 mg/kg) was also included as a positive control.

The average serum ACE activity for all measurements carried out in the three experimental groups before treatment intake was 111.4 ± 1.8 U/L (n = 22). As shown in Figure 4A, ACE activity was significantly reduced in SHRs treated with DPYKLRP, LRP and captopril at 1 and 4 h post administration, and reverted to initial values after 24 h. At 1 h postadministration, when maximum effects were observed, the reduction in ACE activity induced by DPYKLRP (48.1 ± 2.5%) was similar to that caused by captopril (43.4 ± 3.1%) and significantly higher than the reduction induced by LRP (19.1 ± 2.7%) in SHRs (one way ANOVA followed by Student−Newman−Keuls test).

SHRs showed an average serum angiotensin II level of 71.2 ± 1.3 pg/mL (n = 22) before treatment intake. Angiotensin II levels in SHRs were significantly reduced by the three treatments at 1 h post administration (Figure 4B). The effect of LRP reverted at 4 h post administration whereas the reductions caused by the heptapeptide and captopril reverted at 24 h. When maximum effects were observed (1 h), the effects caused by DPYKLRP (27.1 ± 0.6% reduction in angiotensin II levels) and captopril (33.2 ± 1.3%) were similar and higher than that provoked by LRP treatment to SHRs (14.8 ± 1.9%; one way ANOVA followed by Student−Newman−Keuls test).

By contrast to that observed in serum ACE activity and angiotensin II levels, plasma aldosterone level of SHRs (244.7 ± 1.9 pg/mL; n = 22) was not significantly affected by any of the treatments (data not shown).

DISCUSSION

Yeast products have been used for many years as ingredients and additives in food processing, although their potential bioactivity has been less investigated.[19] *K. marxianus*, considered a GRAS (Generally Recognized As Safe) microorganism, has been isolated from a great variety of habitats, which results in a high metabolic diversity. Therefore, different biotechnological applications of this yeast including production of enzymes, of single cell-protein, and of aroma compounds as well as production of bioingredients from cheese-whey have been described.[20] Moreover, the beneficial properties of *K. marxianus* as a human probiotic have been recently assessed.[21]

In this study, we have identified four novel LF-derived peptides which are reported as ACE-inhibitory and antihypertensive sequences for the first time. To the best of our knowledge, DPYKLRP, PYKLRP, YKLRP and GILRP produced by the proteolytic system of *K. marxianus* Km2 strain when grown in LF as sole nitrogen source, are the first peptides with antihypertensive effects after oral administration to SHRs produced by a food-isolated yeast strain. Novel sequences identified here could at least in part contribute to the ACE inhibiting and antihypertensive effects of *K. marxianus* pLFH.[14]

The four *K. marxianus* ACE-inhibitory peptides have a C-terminal P residue. It has been described that the rigid structure of this amino acid may lock the carboxyl group into a conformation favorable for interaction with the positively charged residue at the active site of the enzyme.[22] Also the four sequences share the C-terminal tripeptide LRP. Interestingly LRP, which can be found in three different regions of LF sequence, was pointed out as the sequence responsible of the *in silico* high ACE-inhibitory activity of different peptide sequences in LF, and in accordance with our results, an IC_{50}

dx.doi.org/10.1021/jf4053868 | J. Agric. Food Chem. 2014, 62, 1609−1616

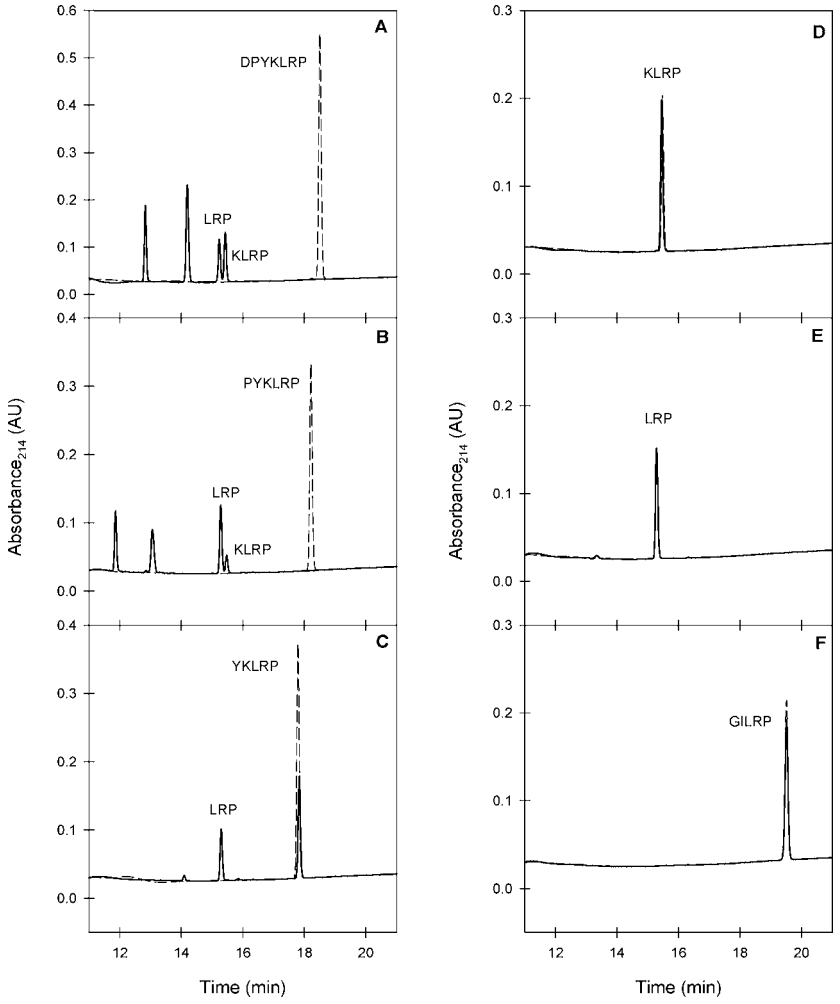

Figure 3. RP-HPLC chromatograms of peptides before (dashed line) and after (solid line) being submitted to a simulated gastrointestinal digestion. (A) DPYKLRP, (B) PYKLRP, (C) YKLRP, (D) KLRP, (E) LRP, (F) GILRP.

value of 0.27 μM was described for the tripeptide.[12] The sequence LIWKL was the most potent LF-derived peptide described so far (IC_{50} = 0.47 ± 0.01 μM).[8] Here, LRP was the most potent sequence with an IC_{50} value (IC_{50} = 0.35 ± 0.03 μM) slightly lower than that of LIWKL. Our results suggest that N-terminal elongations decrease *in vitro* inhibitory potency, although it might not result in lower antihypertensive effects (see below). Moreover, elongations at the C-terminal end of the tripeptide also provoked a decrease of inhibitory potency since an IC_{50} value of 4.14 μM was described for the sequence LRPVAA.[23]

Our results in SHRs show a complex relationship between the *in vitro* ACE-inhibitory potency and the *in vivo* antihypertensive effects after oral administration suggesting a role for gastrointestinal digestion in the formation and degradation of antihypertensive peptides. When subjected to hydrolysis with gastrointestinal enzymes all of the peptides tested in this study were hydrolyzed to different degrees with the exception of LRP. Remarkably this sequence was found in most of the digests suggesting that the tripeptide might contribute to the *in vivo* effects of parental peptides. Further work will be needed to clarify the physiological relevance of LRP as well as of the other digestion fragments that could also contribute to the blood pressure-lowering effects of parental peptides.

Although the IC_{50} values of LF-derived peptides were by far higher than that of ACE-inhibitory drug captopril (0.022 μM),[24] in the conditions tested, oral administration of DPYKLRP and LRP resulted in a significant decrease in SBP (13.4% reduction from baseline) similar to that of captopril (14% reduction). These results are also in agreement with the previously reported antihypertensive effect of the LF-derived peptide LIWKL (12.1% reduction).[8] It has been reported that food-derived ACE-inhibitory peptides might possess higher *in vivo* effects than expected from *in vitro* inhibitory potencies due to their higher affinity to target tissues and their slower elimination.[25]

It has been also postulated that other mechanisms of action apart from ACE inhibition might underlie *in vivo* antihypertensive effect of ACE-inhibitory peptides, including short-term vasoactive mechanisms as well as long-term-antioxidant and anti-inflammatory mechanisms.[26] In this context the sequence GILRP isolated here is part of the sequences GILRPY and GILRPYL identified in a proteinase K LF hydrolyzate which exerted *in vivo* antihypertensive effect. Both the hydrolyzate and GILRPY showed significant endothelin converting enzyme (ECE)-inhibitory effects.[9] ECE is a key peptidase in the endothelin system that cleaves precursor inactive big endothelin-1 to produce active endothelin-1 which has powerful vasoconstrictor and pressor properties.[27] The

dx.doi.org/10.1021/jf4053868 | J. Agric. Food Chem. 2014, 62, 1609−1616

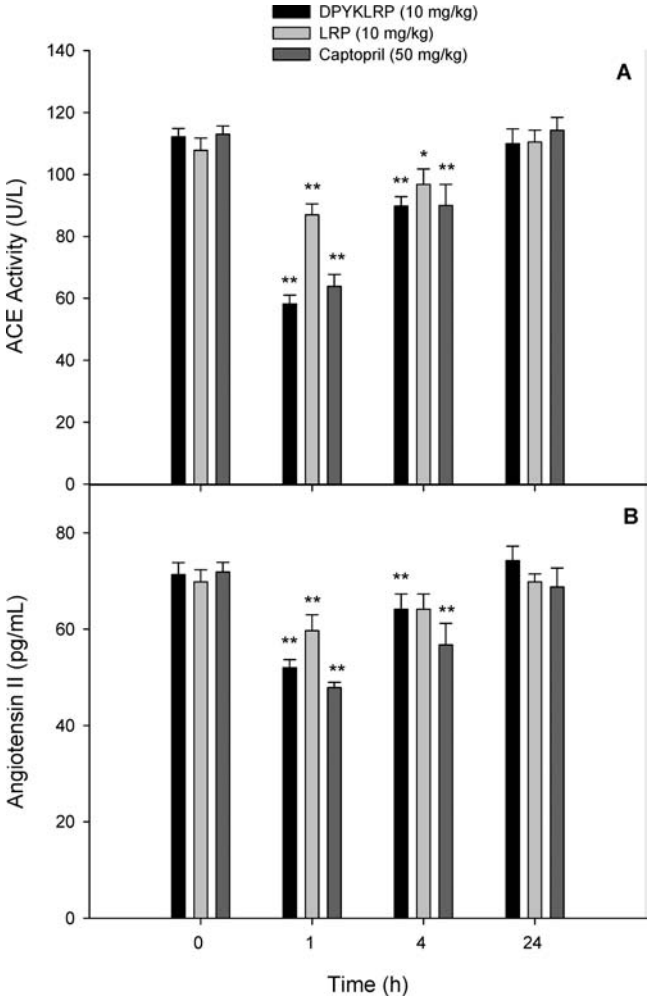

Figure 4. Time course of changes produced in the levels of blood components of the renin-angiotensin system after oral administration of DPYKLRP (10 mg/kg), LRP (10 mg/kg) and captopril (50 mg/kg) to SHRs. (A) Serum angiotensin I-converting enzyme (ACE) activity. (B) Serum angiotensin II levels. Data are mean ± SEM from 4 to 10 determinations. *P < 0.05 versus baseline values at time 0 h, **P < 0.01 versus baseline values at time 0 h (one-way ANOVA followed by Dunnett multiple comparison tests).

endothelin system has an increasingly recognized role in blood pressure regulation and has also been targeted for hypertension drug treatment. Moreover, we described a set of peptides derived from LF which showed inhibitory effects on ACE and ECE activities.[28] Also the ACE-inhibitory peptide lactokinin can modulate endothelin-1 release by endothelial cells.[29] Whether the antihypertensive effect showed by GILRP in this study might be also due to ECE inhibition deserves further studies.

Dose-dependent antihypertensive effects of DPYKLRP and LRP prompted us to look for a mechanism of action responsible for the graded *in vivo* responses of the LF-derived peptides. Determinations of blood RAS components support ACE inhibition as an *in vivo* antihypertensive mechanism in SHRs. *In vivo* ACE-inhibitory effect can be assessed by measuring tissue membrane-anchored or soluble, circulating ACE activities, and confirmed by measuring circulating levels of angiotensin II.[30] Our results show that serum ACE activity is reduced in SHRs after oral administration of both peptides. Moreover, inhibition of ACE was confirmed in peptide treated SHRs by the reduction in angiotensin II level. We have previously reported that long-term administration to SHRs of an antihypertensive bovine LF pepsin hydrolyzate enriched in low molecular weight peptides reduced circulating ACE activity, angiotensin II and aldosterone levels.[10] By contrast, in the present study, the level of serum aldosterone, the adrenal endocrine component downstream angiotensin II in the renin-angiotensin axis,[2] was not affected by single-dose treatments with DPYKLRP and LRP. *In vivo* ACE inhibition has been also pointed out as the mechanism underlying the blood pressure reduction of the tripeptide IQP derived from the blue algae *Spirulina platensis* since serum ACE and angiotensin II levels were significantly reduced in SHRs after one-week treatment.[31] Nonetheless, the identification of other *in vivo* mechanisms beyond ACE inhibition underlying antihypertensive effects of the LF-derived peptides identified in this study should be further investigated.

Our results point out *K. marxianus* as a feasible GRAS microorganism for the production of novel LF-derived peptides with ACE-inhibitory and antihypertensive effects. The LF-derived peptides produced by *K. marxianus*, DPYKLRP, PYKLRP, YKLRP and GILRP, effectively decreased arterial blood pressure in SHRs and could, at least in part, be responsible for the antihypertensive properties previously described for *K. marxianus* LF hydrolyzate. Also, data reported here suggest ACE inhibition as an *in vivo* mechanism for the antihypertensive effects of the sequences DPYKLRP and LRP in particular, although other mechanisms cannot be discarded.

promising host for heterologous gene expression, was already successfully used for the production of β-galactosidase from *Lactobacillus delbrueckii*[21] and chitinase from *Bacillus licheniformis*.[22] Available inducible expression systems[23] are based on quorum-sensing mechanisms involved in the production of sakacins A and P.[24−26] More recently, the erythromycin antibiotic resistance gene (*erm*) was replaced by the homologous alanine racemase gene (*alr*), and an alanine racemase-deficient host strain was constructed that obviates the undesirable fermentation in the presence of antibiotics and is suitable for applications in the food industry.[19]

In this study we present the heterologous expression of the L-AI and D-XI-encoding genes from the food grade microorganism *L. reuteri* in *E. coli*, the most commonly used organism for heterologous protein production, and the characterization of these novel enzymes.[27] *L. reuteri*, a heterofermentative and symbiotic species, is well adapted to colonize human and animal gastrointestinal tracts. Among probiotic microorganisms *L. reuteri* is unique due to its ability to produce and secrete the antimicrobial substance reuterin.[28] Furthermore, we coexpressed the genes in the food grade host *L. plantarum* using two different expression systems and performed comprehensive studies on the conversion of D-glucose and D-galactose, respectively.

MATERIALS AND METHODS

Chemicals and Enzymes. All chemicals were of the highest purity available and purchased from Sigma-Aldrich (St. Louis, MO, USA), unless otherwise stated. Restriction endonucleases, T4 DNA ligase, and Phusion High-Fidelity DNA polymerase were obtained from Thermo Fisher Scientific Biosciences (St. Leon-Rot, Germany), whereas GoTaq DNA polymerase was from Promega (Madison, WI, USA). Phenylmethanesulfonyl fluoride (PMSF) was obtained from Fluka (Buchs, Switzerland), and chromatographic materials were obtained from GE Healthcare (Chalfont St. Giles, UK).

Bacterial Strains and Culture Conditions. The bacterial strains and plasmids used in this study are listed in Table 1. *Lactobacillus reuteri* DSMZ 17509 (strain designation 100-23) was obtained from the German Collection of Microorganisms and Cell Cultures (DSMZ, Braunschweig, Germany). *Lactobacillus* strains were cultivated in deMan−Rogosa−Sharpe (MRS) medium at 30 °C without agitation. *E. coli* strain NEB5α (New England Biolabs, Ipswich, MA, USA), MB2159 (D-alanine auxotrophe), and BL21 Star (DE3) (Invitrogen, Carlsbad, CA, USA) were grown in Luria−Bertani (LB) medium at 37 °C with shaking at 125 rpm. When needed, media were supplemented with ampicillin at a concentration of 100 μg/mL and erythromycin at concentrations of 5 and 200 μg/mL for *L. plantarum* and *E. coli*, respectively. *E. coli* MB2159 and *L. plantarum* strain TLG02 were cultivated by adding 200 μg/mL D-alanine to the respective media. Solid media were prepared by adding 1.5% agar to the respective media.

DNA Amplification and Subcloning. DNA amplification was performed with Phusion High-Fidelity DNA Polymerase according to the manufacturer's instructions. The oligonucleotide primers were obtained from VBC Biotech (Vienna, Austria) and are listed in Table 2. PCR products and restriction enzyme digested DNA were purified with GFX PCR DNA and a Gel Band Purification Kit (GE Healthcare) as recommended by the supplier. When needed, the PCR fragments were subcloned into the pJET1.2 vector (CloneJET PCR cloning kit, Thermo Fisher Scientific Biosciences), and *E. coli* was used as host for plasmid propagation before transformation into *Lactobacillus*. The amplified sequences were verified by a commercial sequencing service (LGC Genomics, Berlin, Germany).

The *araA* gene (NCBI reference sequence for the genome: NZ_AAPZ02000002.1) was amplified by colony-PCR using the primers araA_LbReu_fwd1 and araA_LbReu_rev1. The *xylA* gene was amplified with the primer pair xylA_LbReu_fwd1 and xylA_LbReu_rev1. Each PCR product was ligated into the pJET1.2 vector as recommended by the supplier, resulting in plasmids pPW116 and pPW114, respectively. Each plasmid was transformed into chemically competent *E. coli* NEB5α cells according to the manufacturer's instructions.

Table 1. Strains and Plasmids Used in This Work[a]

strain or plasmid	relevant characteristics	ref
strains		
L. reuteri		
DSMZ 17509	source for L-AI and D-XI encoding genes	DSMZ
L. plantarum		
WCFS1	wild type	49
TLG02	Δalr, D-alanine auxotroph	19
E. coli		
MB2159	D-alanine auxotroph, cloning host	50
NEB5α	cloning host	New England Biolabs
BL21 Star (DE3)	expression host	Invitrogen
plasmids		
pET-21a(+)	Amp^r, T7 promoter, C-terminal His-Tag	Novagen
pSIP409	Erm^r, pSIP401 derivative, P_{sppQ}	25

pPS2	L-AI and D-XI from *L. reuteri* in pPS1	this work
pPS3	L-AI and D-XI from *L. reuteri* in pPW-015	this work
pPW116	L-AI from *L. reuteri* in pJET1.2	this work
pPW114	D-XI from *L. reuteri* in pJET1.2	this work

[a]Amp^r, ampicillin resistance; Erm^r, erythromycin resistance; *alr*, alanine racemase encoding gene; *erm*, erythromycin resistance gene.

Plasmid Construction and Expression in *E. coli*. The *araA* and *xylA* genes were amplified using the primer pairs AraReu*Nhe*I_fwd1/AraReu*Eco*RI_His6 and XylReuNheI_fwd1/XylReu*Eco*RI_His6 as well as pPW116 and pPW114 as templates, respectively. The resulting PCR fragments were cut with the restriction enzymes *Nhe*I and *Eco*RI and ligated into the equally treated expression vector pET21-a(+) (Novagen, Darmstadt, Germany) in frame with the C-terminal His_6-tag encoded by the vector. The resulting plasmids pPW002 and pPW004 were transformed into electrocompetent *E. coli* BL21 Star (DE3) according to the method of Inoue et al.[29]

Plasmid Construction and Expression in *L. plantarum*. The *Nco*I restriction site on the pSIP609 and pSIP409 vector, respectively, was replaced by a *Nhe*I restriction site by site-directed mutagenesis.[30] A PCR was peformed using the primer pair pSIP_SD_NheI_fwd1 and pSIP409_SD_NheI_rev1. Subsequent digestion with *Dpn*I and transformation into *E. coli* resulted in the plasmids pPS1 (pSIP609 derivative) and pPW015 (pSIP409 derivative), respectively.[30] The fusion of the *araA* and the *xylA* genes was performed according to the overlap extension method.[31] PCR reactions were done with the primer pairs XylReu_OE_fwd1/XylReu_OE_rev1 (pPW114 as template) and AraReuNheI_fwd1/AraReu_OE_rev1 (pPW116 as template). The resulting PCR products were purified and used as templates for a third reaction with the primers AraReu*Nhe*I_fwd1 and XylReu_OE_rev1. The resulting amplicon was digested with *Nhe*I and *Eco*RI and

ligated into the equally treated vectors pPS1 and pPW-015, resulting in plasmids pPS2 and pPS3, respectively. These plasmids were transformed into *E. coli* MB2159 and NEB5α, respectively, for plasmid propagation. Competent cells of *E. coli* MB2159 were prepared and transformed according to the method of Inoue et al.[29] The isolated plasmids were transformed into electrocompetent *L. plantarum* TLG02 and WCFS1 cells, respectively, according to the method of Josson et al.[32]

Sequence Analysis. The translated amino acid sequences were analyzed using the programs Translate and Compute pI/MW at http://www.expasy.org/.[33]

Expression in *E. coli*. *E. coli* BL21 Star (DE3) carrying the plasmids pPW002 and pPW004, respectively, was grown overnight at 37 °C and 125 rpm in 3 mL of LB medium containing 100 μg/mL ampicillin. Two hundred milliliters of Terrific-Broth (TB) medium supplemented with 100 μg/mL in 1 L baffled shaking flasks were inoculated with 1 mL of the starter culture. The cells were incubated at 37 °C until an optical density at 600 nm (OD_{600}) between 0.4 and 0.6 was reached. Lactose in a final concentration of 5 g/L was added to the culture for induction of the heterologous expression, and the cultures were incubated further at 25 °C for 20 h. Cells were then harvested by centrifugation (4000*g*, 20 min, 4 °C), resuspended in buffer A (50 mM sodium phosphate buffer, 500 mM NaCl, 5 mM imidazole, pH 6.0) supplemented with 5.7 mM PMSF, and disrupted by using a French press (Aminco, Silver Spring, MD, USA). Cell debris was removed by centrifugation (30000*g*, 30 min, 4 °C), and the supernatant was recovered as crude extract.

Expression in *L. plantarum*. *L. plantarum* carrying the plasmids pPS2 and pPS3, respectively, was grown overnight at 37 °C in 10 mL of MRS medium containing 5 μg/mL erythromycin in the case of the latter. These starter cultures were used to inoculate 1 L of the same media. The cultures were incubated at 30 °C until an OD_{600} between 0.3 and 0.4 was reached. Heterologous expression was induced by adding 25 ng/mL of the peptide pheromone IP-673 (supplied by the Molecular Biology Unit, University of Newcastle-upon-Tyne, UK). The cultures were incubated further at 30 °C for 20 h. Cells were washed twice by buffer A, and the cell pellet was resuspended in the same buffer containing 5.7 mM PMSF. The cells were homogenized by using a French press, and the cell debris was removed by centrifugation to obtain the crude extract.

Protein Purification. The crude extract was purified by one-step immobilized metal affinity chromatography (IMAC) on a prepacked 20 mL HisPrep FF 16/10 column (GE Healthcare). The column was pre-equilibrated with buffer A (see above), and the crude extract was applied at a rate of 2.5 mL/min. After an additional washing step (3 column volumes), the enzyme was eluted at the same rate by using a linear gradient of 5 mM−1 M imidazole in 10 column volumes. Active fractions were pooled, desalted, and concentrated in 50 mM sodium phosphate buffer (pH 6.0) using Amicon Ultra-15 centrifugal filter units (30 kDa cutoff; Millipore, Billerica, MA, USA) and stored at 4 °C. D-XI containing fractions were concentrated in 50 mM sodium acetate buffer (pH 5.0).

Protein Quantification, Electrophoresis, and Molecular Mass Determination. Protein concentration was determined according to the method of Bradford[34] using a BSA standard curve and a prefabricated assay solution (Bio-Rad). SDS-PAGE was carried out using Mini-PROTEAN TGX precast gradient gels (4−15%) and Precision Plus Protein Unstained Standard. Bio-Safe Coomassie was used for visualization of the protein bands (Bio-Rad). The theoretical mass was derived from the ExPASy ProtParam tool (http://web.expasy.org/protparam/) and confirmed by size exclusion chromatography (SEC) using a 190 mL Sephacryl S300 column (GE Healthcare) equilibrated with 50 mM potassium phosphate buffer (pH 7.0) containing 150 mM NaCl and the molecular weight marker kit for gel filtration (Sigma-Aldrich).

Enzyme Assays and HPLC Analysis. L-AI activity was measured by determing the amount of formed L-ribulose or D-tagatose. The reaction mixture contained 50 mM L-arabinose or D-galactose, 1 mM $CoCl_2$, 0.5 mM $MnCl_2$, 50 μL of 0.5−1.0 mg/mL enzyme preparation, and 50 mM sodium phosphate buffer (pH 6.0) to bring the final volume to 0.5 mL. The reaction mixture was incubated at 65 °C for 10 min followed by heating the mixture to 95 °C for 5 min to stop the reaction. The amount of L-ribulose or D-tagatose was determined either by HPLC analysis or colorimetrically using the cysteine−carbazole−sulfuric-acid method[35] with slight modifications. Fifty microliters of freshly prepared 1.5% (w/v) L-cysteine−HCl was added to 250 μL of reaction mixture (in a suitable dilution), 1.5 mL of ≈70% sulfuric acid and 50 μL of 0.12% (w/v) carbazole in ethanol were added, and the absorbance at 560 nm was measured after 1 h of incubation at room temperature. HPLC analysis was performed on a Dionex Summit HPLC system (Thermo Fisher Scientific) fitted with a Shodex RI-101 refractive index detector (Shoko Scientific, Yokohama, Japan) using an Aminex HPX 87-K column (Bio-Rad) with a guard column. Samples and standards were eluted at 80 °C with 1 g/L boric acid (pH 8.5, 0.5 mL/min). For calculation of the reaction product(s) L-arabinose, D-galactose, L-ribulose, and D-tagatose standards were included in the run. One unit of L-arabinose isomerase activity is defined as the amount of enzyme needed to produce 1 μmol of L-ribulose or D-tagatose per minute under the assay conditions.

D-XI activity was measured by the determination of the amount of formed D-xylulose (or D-fructose). The reaction mixture contained 50 mM D-xylose, 0.5 mM $CoCl_2$, 0.5 mM $MnCl_2$, 50 μL of 1 mg/mL enzyme preparation, and 50 mM sodium acetate buffer (pH 5.0) to bring the final volume to 0.5 mL. The reaction mixture was incubated at 65 °C for 10 min, and the reaction was stopped by heating the mixture at 95 °C for 5 min. For assaying the glucose isomerase activity, the reaction mixture contained 400 mM D-glucose, 5 mM $CoCl_2$, 5 mM $MnCl_2$, 5 mM $MgSO_4$, 50 μL of 5 mg/mL enzyme preparation, and 50 mM sodium acetate buffer (pH 5.0) to bring the final volume to 0.5 mL. The reaction mixture was incubated at 60 °C for 10 min.

The amount of D-xylulose or D-fructose was determined either by HPLC analysis or using the cysteine−carbazole−sulfuric-acid method[35] with slight modifications (see above). For HPLC analysis and calculation of the reaction products D-xylose, D-glucose, D-xylulose, and D-fructose standards were included in the run. One unit of D-xylose isomerase activity is defined as the amount of enzyme needed to produce 1 μmol of D-xylulose or D-fructose per minute under the assay conditions.

Effect of Temperature, pH, and Divalent Metal Ions on Enzyme Activity. The temperature optimum was measured by assaying the enzyme samples over the range of 30−90 °C, at pH 5 (D-XI) and pH 6 (L-AI). Three buffer systems (sodium acetate/sodium phosphate/Tris-HCl) were used for measuring the pH optimum of enzyme activity at 65 °C with D-xylose (D-XI) and L-arabinose (L-AI) as substrate. The effects of various metal ions were determined by the addition of 1 mM $MgSO_4$, $CoCl_2$, or $MnCl_2$ (or more than one in various concentrations) and assaying D-XI and L-AI activity, respectively, under standard conditions without 0.5 mM $MnCl_2$ and 0.5 mM $CoCl_2$ (D-XI) and without 0.5 mM $MnCl_2$ and 1 mM $CoCl_2$ (L-AI).

Determination of Kinetic Parameters. The kinetic paramters of L-AI were determined in 50 mM sodium phosphate buffer (pH 6.0) containing 0.5 mM $MnCl_2$ and 1 mM $CoCl_2$ and 5−800 mM L-arabinose (10−800 mM D-galactose). The reaction mixtures were incubated for 10 min at 65 °C. The kinetic parameters of D-XI were determined in 50 mM sodium acetate buffer (pH 5.0) containing 0.5 mM $MnCl_2$, 0.5 mM $CoCl_2$ (5 mM $CoCl_2$, 5 mM $MnCl_2$, 5 mM $MgSO_4$), and 1−500 mM D-xylose (25−1500 mM D-glucose). The reaction mixtures were incubated for 10 min at 65 °C (60 °C). The observed data were fitted to the Michaelis−Menten equation, and kinetic constants were calculated by nonlinear least-squares regression. Using the molecular mass, turnover numbers (k_{cat}) and catalytic efficiencies (k_{cat}/K_m) were calculated.

Enzymatic Conversion of D-Galactose to D-Tagatose. The conversion was carried out at 60 °C with 0.8 and 1.4 U of purified enzyme (i.e., 1.0 mg of L-AI produced in *E. coli* and 0.9 mg of L-AI expressed in *L. plantarum*), respectively, in a total volume of 1 mL. The conversion medium contained 500 mM D-galactose, 1 mM $CoCl_2$, and 0.5 mM $MnCl_2$ in 50 mM sodium phosphate buffer (pH 6.0). Samples were taken regularly for the analysis of D-galactose and D-tagatose by HPLC. The conversion rate represents the ratio between the formed D-tagatose and the initial D-galactose.

Enzymatic Conversion of D-Glucose to D-Fructose. The conversion was carried out at 60 °C with 2.1 and 1.1 U of purified enzyme (i.e., 1.9 mg of D-XI produced in *E. coli* and 0.9 mg of D-XI expressed in *L. plantarum*), respectively, in a total volume of 1 mL. The conversion media contained 500 mM D-glucose, 5 mM $CoCl_2$, 5 mM $MnCl_2$, and 5 mM $MgSO_4$ in 50 mM sodium acetate buffer (pH 5.0). Samples were taken regularly for the analysis of D-glucose and D-fructose by HPLC. The conversion rate represents the ratio between the formed D-fructose and the initial D-glucose.

RESULTS AND DISCUSSION

Heterologous Expression of the L-AI and D-XI Encoding Gene in *E. coli*. The L-AI encoding gene from *L. reuteri* DSMZ 17509 was successfully expressed in *E. coli* BL21(DE3). The nucleotide sequence contains an open reading frame of 1422 bp encoding a polypeptide of 473 amino acids. On the basis of the DNA sequence, two modified oligonucleotide primers containing restriction sites for in-frame ligation into the pET21-a(+) were designed and used to reamplify the *araA* sequence and to construct the expression vector pPW002. The L-AI encoding sequence was fused in frame with the C-terminal His_6-tag encoded by the vector, and the construct was expressed under the control of the lactose- or IPTG-inducible T7 promoter. Approximately 137.9 U of L-AI activity/L fermentation medium was produced under the described conditions with a volumetric activity of 1.6 U/mL and a specific activity of 0.18 U/mg using D-galactose as substrate. The D-XI encoding gene from *L. reuteri* DSM 17509 contains an open reading frame of 1350 bp encoding a polypeptide of 449 amino acids. The *xylA* sequence was fused in frame with the C-terminal His_6-tag encoded by the vector, and the heterologous expression resulted in approximately 780.5 U of D-XI activity/L fermentation medium with a volumetric activity of 8.9 U/mL and a specific activity of 0.57 U/mg using D-glucose as substrate.

Due to the use of an ampicillin resistance marker, the potential of the pET21-a(+) expression system is limited to food applications. Furthermore, the use of *E. coli* strains is not permitted in the food industry in most countries,[36] due to possible endotoxin production.[37]

Coexpression of L-AI and D-XI Encoding Gene(s) in *L. plantarum*. The resulting expression vector contains the *araA* gene fused with a C-terminal His_6-tag (CAC_6) and a stop-codon (TAG). The following ribosomal binding site (RBS)[38] was flanked downstream (5′) with TTC (three nucleotides downstream from the RBS) and upstream with the nucleotides ATTTTA (six nucleotides upstream of the RBS).[26,39] The *xylA* gene was also fused with a His_6-tag followed by the stop-codon (TAA). Approximately 28.6 U (18.3 U) of L-AI activity/L fermentation medium with a volumetric activity of 0.8 U/mL (0.5 U/mL) and a specific activity of 0.15 U/mg (0.08 U/mg) with D-galactose as substrate was produced in *L. plantarum* using the pSIP609 (pSIP409) vector. The coexpression of the *xylA* gene allowed production of approximately 32.3 U (55.9 U) of GI activity/L fermentation medium with a volumetric activity of 0.9 U/mL (1.6 U/mL) and a specific activity of 0.17 U/mg (0.23 U/mg) using the pSIP609 (pSIP409) expression system.

A food grade LAB strain was chosen as expression host as demonstrated by Rhimi et al.[40] and Salonen et al.[3] Although expression yields in *E. coli* are much higher, the combination of the (homologous) alanine racemase gene (*alr*) as selection marker and the safe cell factory *L. plantarum* has considerable potential for the production of ingredients and additives for the food industry.[19] Compared to the erythromycin-dependent expression system pSIP409, the expression yield of the (first) *araA* gene was higher; in the case of the (second) *xylA* gene, the induction/expression worked less efficiently. However, the antibiotic-independent expression system pSIP609 allowed the successful coexpression of the genes *araA* and *xylA* from *L. reuteri* DSMZ 17509. The slightly higher yields with the pSIP609 system (alanine racemase as selection marker in combination with a suitable deficient host strain) are in agreement with previous data and can be explained by the avoidance of antibiotic detoxification and subsequently reduced plasmid loss.[19]

Purification of Recombinant L-AI and D-XI. The recombinant enzymes were purified to apparent homogeneity from cell extracts by a single-step purification protocol using immobilized metal affinity chromatography (Figure 1).

The specific activities of the purified enzymes were 0.9 U/mg for L-AI and 1.1 U/mg for D-XI with *E. coli* as expression host and D-galactose and D-glucose, respectively, as substrate. The use of *L. plantarum* as expression host resulted in 1.6 U/mg (in the case of pSIP609 and 409) for L-AI and 1.2 U/mg (pSIP609) and 1.8 (pSIP409) for D-XI after purification. Although the coexpressed genes contained the same affinity tag, the resulting proteins are separated successfully and elute in different fractions.

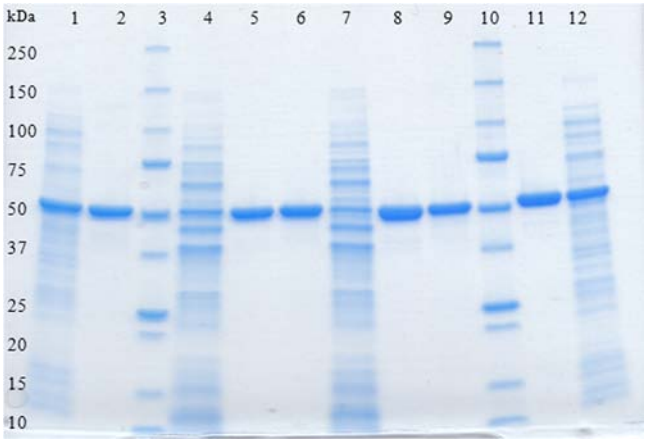

Figure 1. SDS-PAGE analysis of recombinant L-AI and D-XI from *L. reuteri*. Lanes: 1, L-AI-containing crude extract from *E. coli*; 2, purified L-AI (*E. coli*); 3, Precision Protein standard (Bio-Rad); 4, L-AI-containing crude extract from *L. plantarum* (pSIP609); 5, purified L-AI (pSIP609); 6, purified D-XI (pSIP609); 7, D-XI-containing crude extract from *L. plantarum* (pSIP409); 8, purified L-AI (pSIP409); 9, purified D-XI (pSIP409); 10, Precision Protein standard (Bio-Rad); 11, purified D-XI (*E. coli*); 12, D-XI-containing crude extract from *E. coli*.

Molecular masses of approximately 300 kDa (L-AI) and 190 kDa (D-XI) were determined using size exclusion chromatography. Considering the calculated molecular masses of 53.6 kDa (L-AI) and 51.04 kDa (D-XI), these data suggest that L-AI is naturally active as a homohexamer and D-XI is a tetramer. The hexameric quaternary structure of the L-AI from *L. reuteri* is also observed in the enzymes from *E. coli*[41] and *L. plantarum* NC8,[42] whereas many other L-AIs exhibit tetrameric structures.[9,42] The tetrameric quaternary structure of the D-XI from *L. reuteri* is the most common form of D-XIs,[43] but dimeric and trimeric forms are also described.[11]

Effect of Temperature, pH, and Divalent Metal Ions on Enzyme Activity. The temperature profile of purified L-AI and D-XI (expressed in *E. coli*), respectively, was determined from 30 to 90 °C using the standard assay according to Dische and Borenfreund.[35] L-AI exhibited maximum activity at 65 °C, with 90 and 97% activity at 60 and 70 °C, respectively (Figure 2). The enzyme D-XI exhibited the same temperature optimum (65 °C) and retained 85% of its maximum activity at 60 and 70 °C, respectively (Figure 2). For industrial production of D-tagatose and D-fructose, respectively, an isomerization at elevated temperature of 60−65 °C resulted in higher conversion yields, better sugar solubility, and lower risk of microbial contamination. Higher temperatures above 70 °C resulted in the formation of undesired byproducts and browning effects.[1,44]

The standard assay was performed using different buffers with pH ranging from 4 to 10. The pH optimum of L-AI and D-XI was found in the slightly acidic pH range (6.0 and 5.0, respectively) (Figure 3). Acidic conditions avoid the formation of undesired byproducts, a great advantage for industrial purposes.[3,44]

The L-AI enzyme activity was assayed at 65 °C and pH 6.0 in the presence of various cations and D-galactose as substrate (Table 3). The activity was increased by the addition of 1 mM Co^{2+} (3.7-fold) and 1 mM Mn^{2+} (1.4-fold). A mixture of 1 mM Co^{2+} and 0.5 mM Mn^{2+} increased the enzyme activity 3.9-fold. The D-XI enzyme activity was assayed at 65 °C and pH 5.0 in the presence of various cations and D-xylose as substrate (Table 3). The activity was increased by the addition of 1 mM Co^{2+} (1.9-fold) and 1 mM Mn^{2+} (2.9-fold). A mixture of 0.5 mM Co^{2+} and 0.5 mM Mn^{2+} increased the enzyme activity 3.2-fold. Glucose isomerase activity was assayed at 60 °C and pH 5.0 and was maximally enhanced by the addition of 5 mM Co^{2+}, 5 mM Mn^{2+}, and 5 mM Mg^{2+} (data not shown).

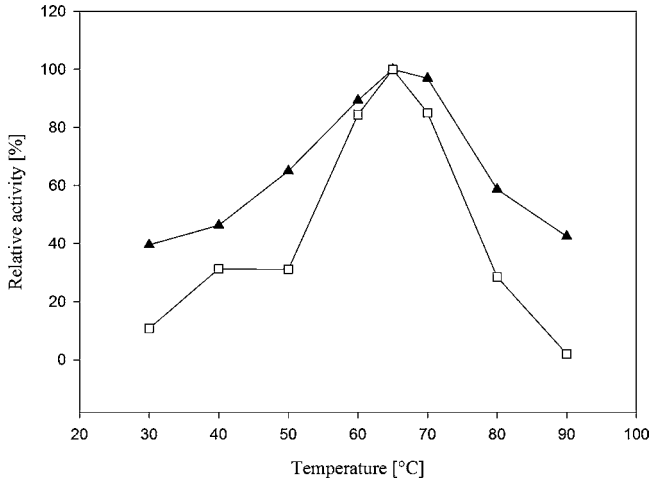

Figure 2. Effect of temperature on L-AI (solid triangles) and D-XI (open squares) activity. Relative activities are presented as functions of temperature with L-arabinose and D-xylose, respectively, as substrate. The reaction mixtures were incubated for 10 min.

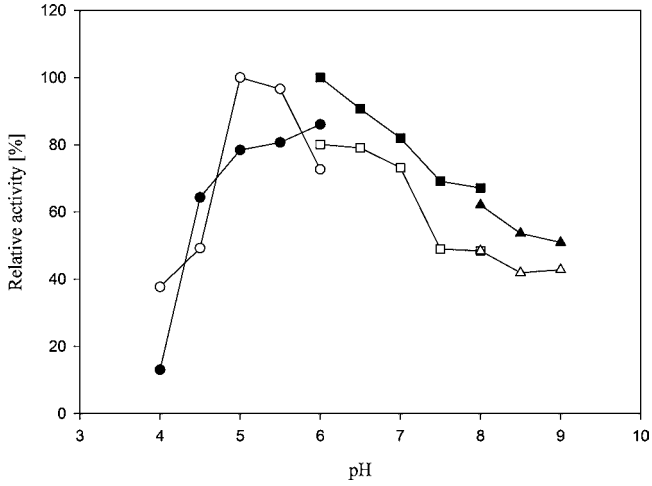

Figure 3. Effect of pH on L-AI (solid symbols) and D-XI (open symbols) activity. Relative activities are presented as functions of pH with L-arabinose and D-xylose, respectively, as substrate. The reaction mixtures were incubated for 10 min. The buffers used were acetate (circles), phosphate (squares), and tris (triangles).

Table 3. Effect of Metal Ions on L-AI and D-XI Activity[a]

metal ion	L-AI relative activity (%)	D-XI relative activity (%)
none	26	32
Co^{2+}	94	62
Mg^{2+}	25	36
Mn^{2+}	41	93
Co^{2+} + Mn^{2+}	100	100

[a] $CoCl_2$, $MgSO_4$, and $MnCl_2$ were added to the enzyme reaction mixture at a final concentration of 1 mM. The mixture of $CoCl_2$ and $MnCl_2$ was added at a final concentration of 1 or 0.5 mM (in the case of L-AI) and 0.5 or 0.5 mM (in the case of D-XI), respectively.

dx.doi.org/10.1021/jf404785m | J. Agric. Food Chem. 2014, 62, 1617−1624

A number of L-arabinose and D-xylose isomerases require metal ions for (maximal) activity (and stability).[4,11] The use of metal cofactors, especially Co^{2+}, increases downstream processing costs as they have to be removed from the final product.[9] For industrial purposes, independence from or a very low requirement for metal ions is advantageous.[3]

Kinetic Parameters/Properties. The apparent K_m, V_{max}, k_{cat}, and catalytic efficiency (k_{cat}/K_m) of L-AI using D-galactose as substrate were 647 ± 109 mM, 11 ± 1 U/mg, 59 ± 5 s^{-1}, and 0.09 mM^{-1} s^{-1}, respectively. For L-arabinose the apparent K_m, V_{max}, k_{cat}, and catalytic efficiency (k_{cat}/K_m) were estimated to be 633 ± 69 mM, 179 ± 10 U/mg, 959 ± 55 s^{-1}, and 1.5 mM^{-1} s^{-1}, respectively.

The high K_m value for D-galactose is comparable with that of the enzyme from *Bifidobacterium longum*[3] and *L. pentosus*,[7,45] whereas enzymes from other *Lactobacillus* strains exhibit up to 10 times lower K_m values.[1,9,42] The low affinity for L-arabinose is comparable with the enzyme from *Pediococcus pentosaceus* PC-5, which shows no activity for this substrate.[10]

The apparent K_m, V_{max}, k_{cat}, and catalytic efficiency (k_{cat}/K_m) of D-XI using D-glucose as substrate were 1099 ± 98 mM, 4.6 ± 0.2 U/mg, 15.5 ± 0.8 s^{-1}, and 0.014 mM^{-1} s^{-1}, respectively. For D-xylose the apparent K_m, V_{max}, k_{cat}, and catalytic efficiency (k_{cat}/K_m) were estimated to be 177.4 ± 5.6 mM, 43.1 ± 0.6 U/mg, 146.6 ± 1.9 s^{-1}, and 0.83 mM^{-1} s^{-1}, respectively.

The lower K_m value for D-xylose than for D-glucose is in agreement with the natural function of the D-XI to produce xylulose for the pentose phosphate or phosphoketolase pathway.[46] The high K_m value for D-glucose is compareable to that from *L. brevis*.[47]

Conversion Experiments. L-AI converted D-galactose to D-tagatose at a conversion ratio of approximately 35% after 25 h of incubation at 60 °C (Figure 4). The use of L-AI (120 U) from the related organism *L. plantarum* SK-2 resulted in a conversion rate of 39% after 96 h at 35 °C,[45] whereas the enzyme from strain NC8 showed a yield of 30% after 6 h at 60 °C. A similar equilibrium was observed by using D-AI from *L. sakei* as biocatalyst (36% after 7 h at 40 °C),[9] whereas a higher conversion yield (55% after 96 h at 65 °C) can be obtained by using the enzyme (9.98 U) from *L. fermentum* CGMCC2921 and 50 mM substrate.[1]

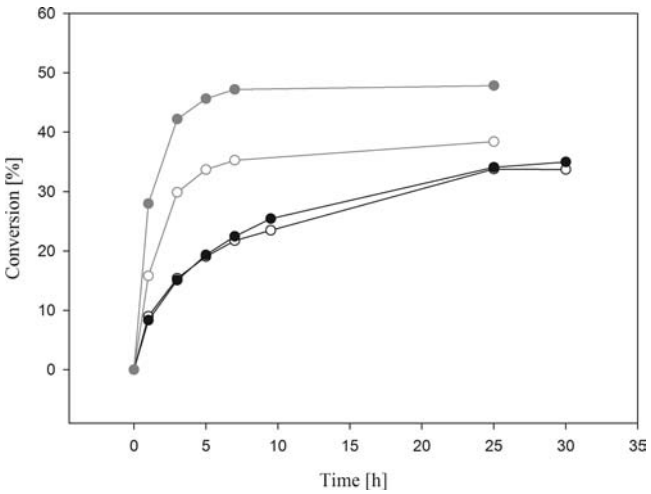

Figure 4. Time course of D-tagatose (black symbols) and D-fructose (gray symbols) production during L-AI- and D-XI-catalyzed isomerization of D-galactose and D-glucose, respectively: black, open circle) conversion curve at 60 °C performed with 0.9 mg of L-AI (expressed in pSIP609 *L. plantarum*); (black, solid circle) conversion curve at 60 °C performed with 1.0 mg of L-AI (expressed in pET21-a(+) *E. coli*); (gray, open circle) conversion curve at 60 °C performed with 0.9 mg of D-XI (expressed in pSIP609 *L. plantarum*); (gray, solid circle) conversion curve at 60 °C performed with 1.9 mg of D-XI (expressed in pET21-a(+) *E. coli*).

The conversion of D-glucose resulted in approximately 48% D-fructose after 25 h of incubation and the use of D-XI produced in the expression host *E. coli* (Figure 4). Using D-XI produced in *L. plantarum* resulted in approximately 38% D-fructose after 25 h of incubation (Figure 4) when approximately 1 unit (approximately 1 mg) of purified protein was used for the conversion experiment. After an incubation of 3 h, conversion rates of approximately 42% (*E. coli*) and 30% (*L. plantarum*) were obtained; thus, the reaction reached its equilibrium after 3 h. A reaction temperature at 40 °C for 3 h resulted in conversion rates of approximately 30 and 9% (data not shown). For industrial purposes an operating temperature of 60 °C is favorable due to the reasons mentioned above (i.e., limited color formation and byproduct formation). HPLC analysis revealed that no byproducts were formed, either in the conversion of D-galactose or in the case of D-glucose (data not shown).

In summary, this study demonstrates the successful expression of the L-arabinose isomerase and D-xylose isomerase encoding genes from *L. reuteri* in *E. coli* as well as the coexpression of both genes in the food grade microorganism *L. plantarum*. Small-scale conversion experiments demonstrate the principal suitability of both enzymes for isomerization of D-galactose and D-glucose, the hydrolysis products of lactose, under preferred industrial conditions (acidic pH and 60 °C). Neither enzyme is ideally suited for the envisaged application due to their rather unfavorable K_m values as well as their dependence on divalent metal cations. However, enzymes with more favorable properties can be screened from a large number of organisms that are considered safe, or an improvement of these properties by enzyme engineering methods[48] may be an alternative. The expression system based on the pSIP vector series is suitable for other lactic acid bacteria as well, and construction of alanine racemase-deficient strains containing no foreign DNA has been shown to be straightforward for organisms that are amenable to transformation.[19] Higher yields can be achieved by expression in *E. coli* and presumably also by expression of the single genes; however, the presented coexpression of two enzymes in a food grade host−vector system offers the possibility of cost-efficient production of enzyme preparations for the conversion of mixed substrates.

surfactants are relatively stable to droplet growth when the storage temperature is 25−70 °C below the PIT. On the other hand, O/W emulsions stored close to the PIT are highly prone to coalescence, which has been attributed to the ultralow interfacial tension.[16] It is therefore postulated that the storage stability of emulsions that are susceptible to coalescence can be improved by increasing the cloud point or PIT. Studies have shown that the cloud point of nonionic surfactant solutions increases with addition of ionic surfactants[17−20] which was attributed to the generation of electrostatic repulsion between the mixed micelles formed.[20] Addition of ionic surfactants to emulsions stabilized by nonionic surfactants has also been reported to increase their stability to droplet growth.[15,21−23] The purpose of this study was therefore to examine the influence of cosurfactant addition (nonionic, anionic, or cationic) on the thermal and storage stability of nanoemulsions formed in the presence of cosurfactants, and to determine the dominant instability mechanisms.

Previous studies, suggest that there are two main instability mechanisms contributing to the breakdown of vitamin E acetate nanoemulsions (VE-nanoemulsions) containing nonionic surfactants and cosolvents: Ostwald ripening and coalescence.[8,9] We therefore investigated the influence of posthomogenization cosurfactant addition on the stability on VE-nanoemulsions. Recently, it has been shown that this approach can improve the stability of oil-in-water nanoemulsions formed by the PIT method to droplet growth.[15] Cosurfactants may improve nanoemulsion stability by altering the spontaneous curvature of the surfactant monolayer and/or by generating repulsive interactions between droplets (Figure 1). The results of this study should be useful for designing vitamin-enriched delivery systems for utilization in foods, beverages, or pharmaceuticals.

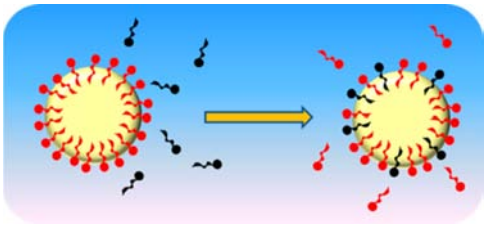

Figure 1. Schematic representation of the surfactant displacement approach: A nanoemulsion is created with one kind of surfactant, and then this is partially displaced by mixing it with another surfactant.

MATERIALS AND METHODS

Materials. Vitamin E acetate (VE, >96% purity) was kindly donated by BASF (Ludwigshafen, Germany). Nonionic surfactants (Tween 80 and 20) and sodium dodecyl sulfate (SDS, 99% purity) were purchased from Sigma-Aldrich Co. (St. Louis, MO). Lauric arginate (LAE) was obtained from Vedeqsa (Vedeqsa Inc., New York, NY). Citric acid and sodium benzoate were provided by PepsiCo (Valhalla, NY). Ethanol (99%) was purchased from Fisher Scientific Co. (Springfield, NJ). Double distilled water was used in the preparation of all solutions and nanoemulsions. All concentrations are expressed as a mass percentage (w/w %) of whole emulsion.

Nanoemulsion Preparation. Nanoemulsion formation was carried out using a method based on a spontaneous emulsification procedure described in the previous study.[9] In brief, spontaneous emulsification was performed by addition of an organic phase to an aqueous phase while magnetically stirring (600 rpm) the system at 25 °C. The organic phase consisted of different amounts of VE and surfactant, while the aqueous phase was a buffer solution (pH 3.0, 0.8% citric acid, 0.08% sodium benzoate) that contained ethanol. The initial nanoemulsions were prepared with the following composition: 10% vitamin E acetate, 10% Tween 80, 20% ethanol, and 60% buffer solution (pH 3). In these samples, the oil (10 g) and surfactant (10 g) were first mixed together and then the mixture was slowly poured into 80 g of aqueous phase over a 15-min period with continuous stirring.

Surfactant Displacement. Surfactant displacement was carried out using a method described previously[15] with a slight modification. Vitamin E nanoemulsions were prepared using the spontaneous emulsification method as described above and then diluted 2-fold using solutions of either nonionic (Tween 20) or ionic (SDS and/or lauric arginate) cosurfactants containing different cosurfactant concentrations.

Particle Size and Charge Measurements. Particle size distributions were measured using a dynamic light scattering instrument (Zetasizer Nano ZS, Malvern Instruments, Malvern, UK). This instrument determines the particle size from intensity−time fluctuations of a laser beam (633 nm) scattered from a sample at an angle of 173°. Each individual measurement was an average of 13 runs. To avoid multiple scattering effects, samples were diluted (× 500) before the particle size measurements using buffer solution (pH 3.0). The mean droplet radius (Z-average) was calculated from the particle size distribution. All measurements were conducted at ambient temperature.

The ζ-potential of the droplets in the emulsions was measured using a particle electrophoresis instrument (NanoZS, Malvern Instruments, Malvern, UK). This instrument calculates the ζ-potential of the particles from measurements of the direction and velocity that the droplets moved in the applied electric field. Conversion of electrophoretic mobility measurements into ζ-potential values was conducted by the software using the Smoluchowsky model. To avoid the multiple scattering, nanoemulsion was diluted before the particle charge measurement using buffer solution (pH 3.0, 0.8% citric acid, 0.08% sodium benzoate).

Turbidity Measurements and Cloud Point Calculation. The influence of temperature on nanoemulsion turbidity was determined using a UV−visible spectrophotometer with temperature scanning capabilities (Evolution Array, Thermo Scientific). The absorbance (A) at 600 nm was measured as the temperature was increased from 20 to 90 °C at 1 °C per minute. The *turbidity increase* was calculated as $A(T) - A(T_0)$, where $A(T)$ is the turbidity at temperature T and $A(T_0)$ is the turbidity at the starting temperature, T_0 (20 °C). The cloud point was determined by fitting the turbidity increase versus temperature data using graphical software (SigmaPlot, Systat Software Inc.). The cloud point was defined as the temperature at which the turbidity increase first reached 1 cm^{-1}.

Statistical Analysis. All experiments were carried out two or three times using two freshly prepared samples, and the results are reported as the calculated mean and standard deviation of these measurements. Statistical analysis was performed through subjection of data to analysis of variance (ANOVA) using statistics software (version 12.0; SPSS, Inc., Chicago, IL). Means were subjected to Duncan's test and a P-value of <0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Effect of Cosurfactants on Thermal Stability. Knowledge of the thermal stability of a nanoemulsion-based delivery system is of particular importance as they are often exposed to elevated temperatures during their manufacture, storage, and utilization. Thermal stability measurements may also be useful as an accelerated test for predicting the stability of nanoemulsions during long-term storage.[9] Therefore, oil-in-water nanoemulsions containing 10% vitamin E acetate (VE), 10% Tween 80, 20% ethanol, and 60% aqueous phase were prepared using the spontaneous emulsification method, and then diluted 2-fold using buffer solutions containing different concentrations of cationic (lauric arginate), ionic (SDS), or nonionic (Tween

20) cosurfactants. This led to nanoemulsions with a final composition of 5% VE, 5% Tween 80, 10% ethanol, and 0−1% cosurfactant.

The dependence of the turbidity on temperature for buffer solution containing 5% (w/w) Tween 80 and 10% (w/w) ethanol and nanoemulsions containing a similar amount of Tween 80 and ethanol and different types and amounts of cosurfactants were determined during heating from 20 to 90 °C. The results for the buffer solution containing Tween 80 and ethanol and nanoemulsions containing different levels of lauric arginate are shown in Figure 2a and b, respectively. Similar

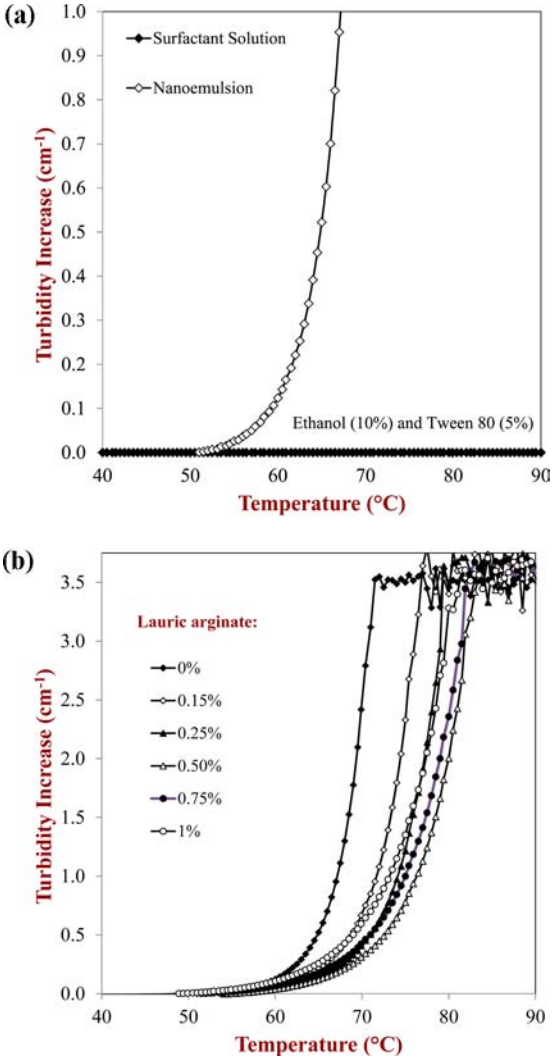

Figure 2. (a) Effect of temperature on the turbidity of surfactant solution containing 5% surfactant, 10% ethanol (pH 3.0) and nanoemulsion containing 5% vitamin E acetate, 5% surfactant, 10% ethanol, and 80% buffer solution (pH 3.0). (b) Effect of lauric arginate on the temperature dependence of the turbidity of nanoemulsions containing 5% oil phase (vitamin E acetate), 5% surfactant (Tween 80), 10% cosolvent (ethanol), and 80% buffer solution (pH 3).

results were also obtained for the nanoemulsions containing SDS or Tween 20 (data not shown). In general, the turbidity of the VE-nanoemulsions was relatively small at low temperatures, increased steeply above a particular temperature (the "cloud point"), and then remained high upon further heating (Figure 2b). Initially, we compared the cloud points of the nanoemulsion and the buffer solution both containing 5% Tween 80 and 10% ethanol (Figure 2a). The turbidity of the buffer solution containing Tween 80 and ethanol did not change over the temperature range of 20−90 °C, suggesting that the cloud point was higher than the range of temperatures studied. However, a steep increase in turbidity was observed at 65 °C for the nanoemulsion (containing no cosurfactant). This result suggests that the presence of the oil phase appreciably decreased the cloud point, presumably by altering the optimum curvature of the system. The presence of the cosurfactants in the nanoemulsions also altered their cloud points, with steep increases in turbidity occurring at 66−74, 71−83, and 75−89 °C for Tween 20, lauric arginate, and SDS, respectively. The observed increase in *turbidity* upon heating can be related to the progressive dehydration of the polar head groups of the nonionic surfactant molecules with increasing temperature.[24,25] The dehydration of the polar head groups of the nonionic surfactants alters their packing parameter ($p = A_T/A_H$), and thereby changes the optimum curvature of the surfactant monolayer. Here, A_T and A_H are the effective cross-sectional areas of the surfactant tail group and headgroup, respectively. At low temperatures, the packing parameter favors the formation of stable oil-in-water nanoemulsions ($A_H > A_T$). As the temperature increases, the headgroup becomes dehydrated (lower A_H) and so the packing parameter moves toward unity, which leads to an ultralow interfacial tension and accelerated droplet coalescence.[26] In addition, surfactant dehydration decreases the steric repulsion between the oil droplets thereby allowing the droplets to come closer together and coalesce. The turbidity increase versus temperature profiles were used to determine the *cloud points* of the nanoemulsions so that we could establish the influence of cosurfactant type and concentration on their thermal behavior.

We defined the cloud point practically as the temperature at which the *turbidity increase* during heating first exceeded 1 cm^{-1}. In general, the cloud point initially increased with increasing cosurfactant concentration, but then it decreased once a particular cosurfactant concentration was exceeded (Figure 3). The highest cloud points obtained for the three cosurfactants were ∼81, 76, and 69 °C at 0.5% SDS, 0.5% lauric arginate, and 0.25% Tween 20, respectively, which compared to a value of ∼67 °C measured in the absence of cosurfactant.

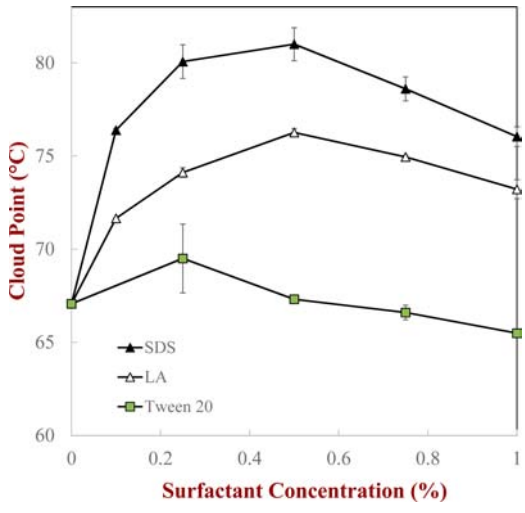

Figure 3. Effect of cosurfactants on the cloud point of nanoemulsions containing 5% oil phase (vitamin E acetate), 5% surfactant (Tween 80), 10% cosolvent (ethanol), and 80% buffer solution (pH 3).

dx.doi.org/10.1021/jf404182b | J. Agric. Food Chem. 2014, 62, 1625−1633

Significantly ($p < 0.05$) higher cloud points were observed in the presence of ionic cosurfactants than in the presence of the nonionic one.

The addition of 0.25% Tween 20 to the VE-nanoemulsions slightly increased the cloud point, but the addition of higher amounts of this cosurfactant caused a slight decrease (Figure 3). Previous studies have reported that Tween 20 has a lower cloud point (~ 79 °C) than Tween 80 (~ 95 °C),[27] which would account for the observed reduction in cloud point at higher Tween 20 levels. Tween 80 and Tween 20 both have similar polar head groups, but the nonpolar tail-groups are different. Tween 20 has a 12-carbon fully saturated hydrocarbon chain ($C_{12:0}$) that would be expected to be linear, whereas Tween 80 has an 18-carbon unsaturated hydrocarbon chain ($C_{18:1}$) that would be expected to be kinked. Consequently, adsorption of Tween 20 to the surfaces of oil droplets initially stabilized by Tween 80 may have changed the optimum curvature of the surfactant monolayer, and thereby altered the PIT and cloud point of the nanoemulsions.

The addition of ionic surfactants (SDS or lauric arginate) to the VE-nanoemulsions also caused an appreciable increase in the cloud point at relatively low levels (0–0.5%), but then caused an appreciable decrease at higher levels (Figure 3). This effect can be attributed to the ability of the ionic surfactants to adsorb to the droplet surfaces and alter the optimum curvature of the surfactant monolayer, as well as increasing the electrostatic repulsion between the oil droplets.

Effect of Cosurfactants on Droplet Charge. Information about the ability of the cosurfactants to adsorb to oil droplet surfaces can be established using droplet charge measurements. In addition, droplet charge plays a key role in determining the stability of nanoemulsions to aggregation: if the droplet charge is sufficiently high, the droplets are prevented from aggregation due to electrostatic repulsion.[28] We therefore measured the droplet charge of VE-nanoemulsions containing different concentrations of ionic and nonionic cosurfactants (Figure 4). The initial nanoemulsions stabilized by Tween 80 had a ζ-potential that was slightly negative (~ −0.8 mV). As expected, addition of different concentrations of nonionic cosurfactant (Tween 20) caused little change in droplet charge (~ −0.8 to −1.1 mV). The small negative charge on the droplet surfaces stabilized by the nonionic surfactants can be attributed to the presence of impurities such as free fatty acids in the surfactant or oil, or preferential adsorption of anions (such as hydroxyl ions) from the water.[29] Addition of increasing amounts of cationic surfactant (lauric arginate) to the VE-nanoemulsions increased the positive charge on the droplets until the ζ-potential reached a relatively constant value (~ +9 mV). Conversely, adding increasing amounts of an anionic surfactant (SDS) to the VE-nanoemulsions increased the negative charge on the droplets until the ζ-potential reached a relatively constant value (~ −11 mV). These results suggested that the ionic surfactants adsorbed to the surfaces of the droplets in the VE-nanoemulsions and altered their electrical characteristics, which would help account for the observed influence of ionic cosurfactants on the thermal stability of the nanoemulsions (Figure 3).

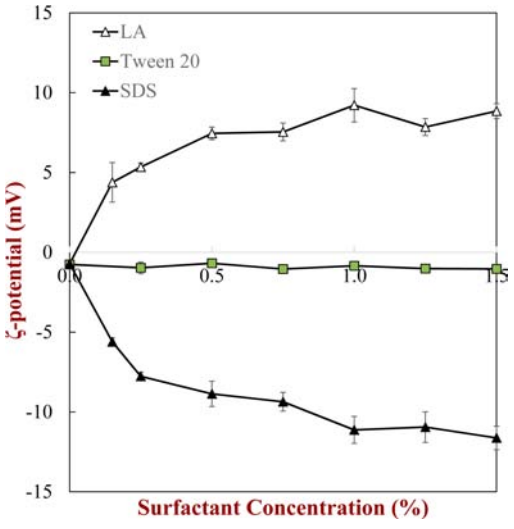

Figure 4. Effect of cosurfactant on the zeta potential of oil droplets in nanoemulsion containing 5% oil phase (vitamin E acetate), 5% surfactant (Tween 80), 10% cosolvent (ethanol), and 80% buffer solution (pH 3).

Effect of Cosurfactants on Storage Stability. Commercial food and beverage products containing emulsion-based delivery systems are required to have good long-term stability during storage, transport, and utilization. Nanoemulsions are thermodynamically unstable systems that may undergo a variety of breakdown processes, including flocculation, coalescence, Ostwald ripening, and gravitational separation.[1,10,28] As mentioned earlier, the two main instability mechanisms in VE-nanoemulsions containing cosolvents are droplet coalescence and Ostwald ripening.[8,9] We therefore examined the possibility of using a surfactant displacement approach for increasing the storage stability of VE-nanoemulsions (containing 20% cosolvent) against droplet growth through these mechanisms. In this approach, VE-nanoemulsions were formed using 10% Tween 80 and 20% ethanol and then diluted (1:1) with aqueous solutions containing different cosurfactants. Three different VE-nanoemulsions were prepared with final concentrations of 5% VE, 5% Tween 80, 10% ethanol, 0.5% cosurfactant, and 79.5% buffer solution. This cosurfactant concentration was selected because it was close to the level where the highest cloud points were observed in the thermal stability studies for the two ionic surfactants (Figure 3). The influence of storage time and holding temperature on their mean droplet sizes was then measured (Figure 5).

In the absence of cosurfactants (control), there was only a slight increase in the mean droplet radius over time for VE-nanoemulsions stored at 5 °C for 1 month, but there was an appreciable increase for those stored at 20 and 37 °C (Figure 5): r increasing from ~22 nm initially to ~25 nm at 5 °C (about 9% increase), ~30 nm at 20 °C (about 30% increase), and ~48 nm at 37 °C (about 112% increase). The droplet size distribution of the VE-nanoemulsions containing no cosurfactant remained monomodal at all storage temperatures, but the peak maximum occurred at larger droplets sizes with increasing storage temperature (Figure 6a). These results indicate that the droplet growth rate increased with increasing holding temperature. Droplet growth may have occurred due to droplet coalescence (merging together of two or more droplets) or Ostwald ripening (diffusion of oil molecules between droplets), which is discussed in Potential Physicochemical Mechanisms.

We found that the addition of the cosurfactants to the VE-nanoemulsions did not improve their isothermal storage stability (Figure 5), even those that appreciably increased the cloud points (Figure 3). Indeed, some of the cosurfactants actually decreased the isothermal stability of the nanoemulsions

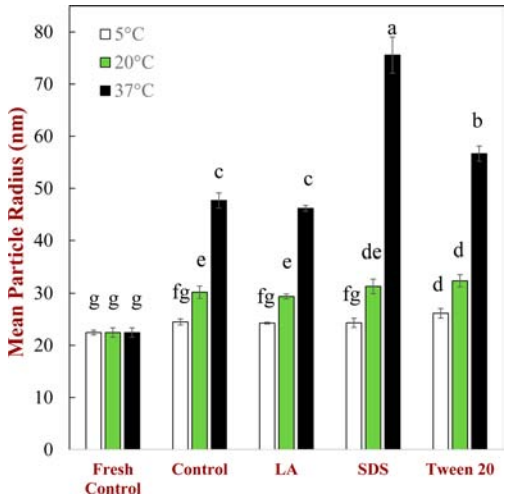

Figure 5. Effect of cosurfactant on mean particle diameter of nanoemulsions (5% vitamin E acetate), 5% surfactant (Tween 80), 10% cosolvent (ethanol), 0.5% cosurfactant, and 79.5% buffer solution) after storage at different holding temperatures for one month. Results are compared with controls (containing no cosurfactant) after 0 days ("fresh") and one month storage. Means with different superscripts are significantly ($P < 0.05$) different.

at elevated holding temperatures, e.g., droplet growth was faster in the nanoemulsions containing SDS than in the control at 37 °C. Like the controls, the particle size distributions of the VE-nanoemulsions in the presence of all three cosurfactants were monomodal at all storage temperatures and times, but with an increase in the location of the maximum at higher storage temperatures (e.g., see Figure 6b for nanoemulsions containing SDS).

Potential Physicochemical Mechanisms. There are a number of possible mechanisms that might be responsible for the observed increase in mean particle size in the nanoemulsions during storage, including flocculation, coalescence, and Ostwald ripening.[2,6,30] We do not believe that flocculation was important in the nanoemulsions used in this study since flocculated droplets were not observed in the systems using an optical microscope. In general, the growth of the individual droplets within a nanoemulsion may occur through either coalescence and/or Ostwald ripening mechanisms.[31] In practice, it is often difficult to distinguish between these two mechanisms, and to precisely establish the relative importance of each mechanism in particular systems. In this section, we present a brief overview of the mechanisms underlying Ostwald ripening and coalescence, and discuss how they may be influenced by cosurfactant addition.

Ostwald Ripening. Ostwald ripening (OR) is the process whereby larger droplets grow at the expense of smaller droplets due to diffusion of disperse phase molecules through the intervening continuous phase.[32] The driving force for this mechanism is the higher chemical potential of the disperse phase within the smaller droplets due to their higher curvature.[33] OR can be divided into two regimes that can be distinguished by the nature of the evolution of the particle size distribution (PSD) during storage: *transient* and *steady state* regimes.[33] Initially, the shape of the PSD depends on the method used to prepare the nanoemulsion. In the transient regime, the shape of the PSD changes over time due to diffusion of oil molecules from the small to the large droplets. Eventually, the PSD attains a characteristic shape (determined

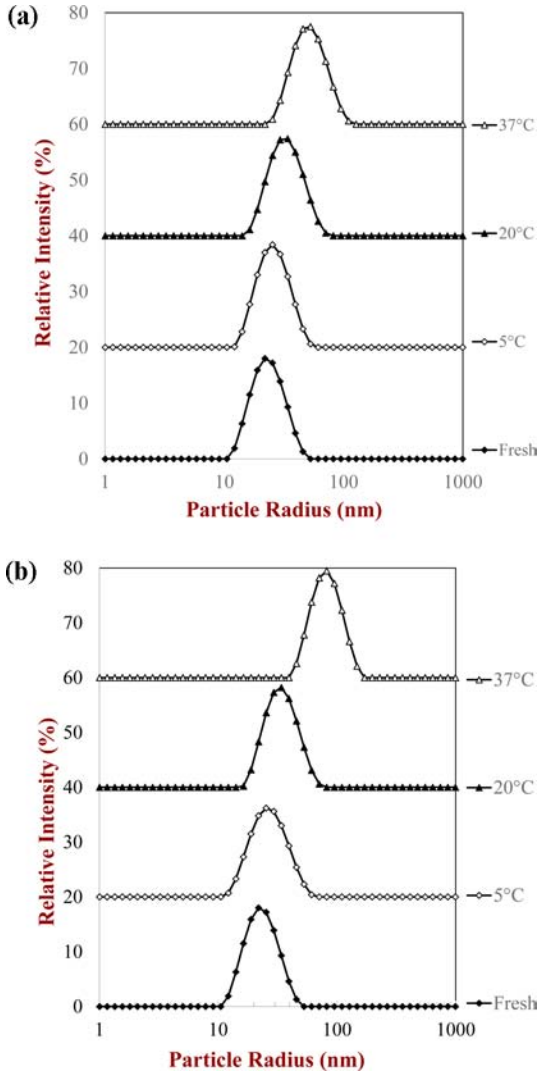

Figure 6. (a) Influence of storage temperature on particle size distribution of nanoemulsions produced using 5% oil phase (vitamin E), 5% surfactant phase (Tween 80), 10% ethanol, and 80% buffer solution immediately after formation ("Fresh") and after storage at different temperatures for one month. (b) Influence of storage temperature on particle size distribution of nanoemulsions produced using 5% oil phase (vitamin E), 5% surfactant phase (Tween 80), 10% ethanol, 0.5% cosurfactant (SDS) and 79.5% buffer solution immediately after formation ("Fresh") and after storage at different temperatures for one month.

by the size-dependence of droplet dissolution and growth processes), which signifies the beginning of the steady-state regime.[33] The PSD then retains this characteristic shape over time, but it moves up the particle size axis as the average size of the droplets continues to increase. In the steady-state regime, the mean droplet radius (r) should vary with time (t) according to the following expression:[33]

$$r^3 - r_0^3 = \omega_{OR} t = \frac{8\gamma V_m^2 c_\infty D}{9RT} t \quad (1)$$

Here, r_0 is the initial droplet radius, ω_{OR} is the Ostwald ripening rate, γ is the oil–water interfacial tension, V_m is the molar volume of the oil, c_∞ is the solubility of the oil in the aqueous phase, D is the diffusion coefficient of the oil molecules through the aqueous phase, R is the gas constant, and T is the

dx.doi.org/10.1021/jf404182b | J. Agric. Food Chem. 2014, 62, 1625–1633

absolute temperature. This theory suggests that the OR rate should increase as the water-solubility of the oil increases, the interfacial tension increases, or the diffusion coefficient increases. Equation 1 indicates that the cube of the mean droplet radius (r^3) should increase linearly with time for nanoemulsions undergoing Ostwald ripening. We therefore calculated r^3 versus time profiles for nanoemulsions at different storage temperatures, e.g., the data at 20 and 37 °C are shown in Figure 7. At 5 °C, we saw little change in the particle size with time, and therefore this data is not shown. The droplet growth rate (ω) for each of the nanoemulsions was calculated from the slope of r^3 versus time by linear regression analysis (Table 1).

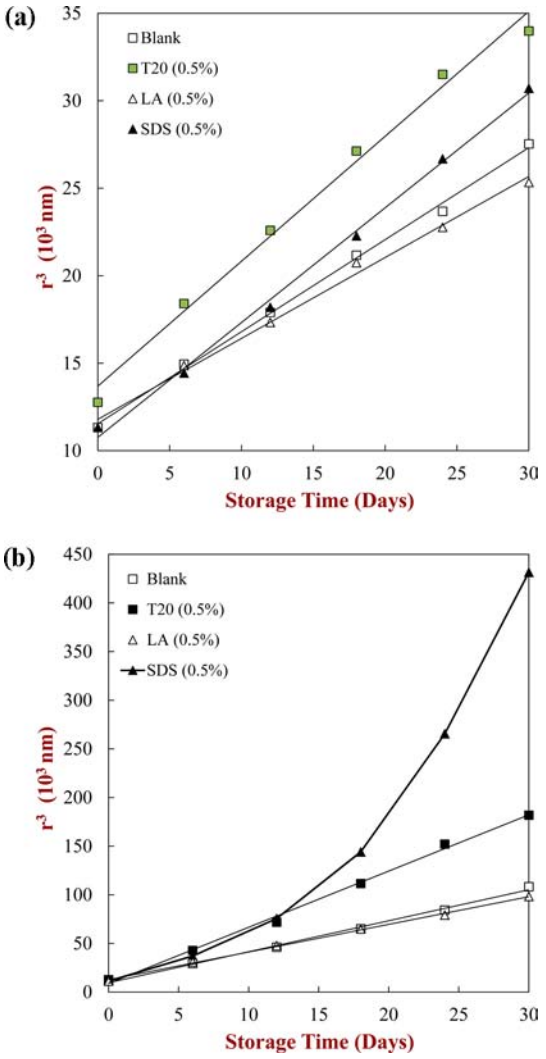

Figure 7. Effect of cosurfactant and storage time on droplet radius cubed of nanoemulsion containing 5% oil phase (vitamin E), 5% surfactant phase (Tween 80), 10% cosolvent (ethanol), 0.5% cosurfactant, and 79.5% buffer solution at storage temperatures of 20 °C (a) and 37 °C (b).

There were linear relationships between r^3 and time for VE-nanoemulsions that contained no cosurfactant, lauric arginate, and Tween 20 at all storage temperatures, and for the VE-nanoemulsions containing SDS at 5 and 20 °C. However, the relationship was not linear for the VE-nanoemulsions containing SDS at 37 °C (Figure 7). It is often assumed that a linear relationship between r^3 and time and a time-invariant particle size distribution is indicative of OR, but this is not generally the case.[31] Theoretical studies have shown that for certain types of coalescence mechanisms the PSD may also reach a constant shape at longer times, and that the cube of the droplet radius may also increase linearly with time, such as Brownian-motion induced coalescence, e.g., see Coalescence section below.[34] At relatively high surfactant concentration (10% Tween 80) in the VE-nanoemulsions studied there may have been appreciable amounts of free surfactant micelles present that could transfer oil molecules between droplets through an Ostwald ripening mechanism[35]or promote droplet aggregation through a depletion mechanism.[36] Further, we experimentally observed that the droplet growth rate increased with increasing temperature, and depended somewhat on cosurfactant addition (Table 1).

A number of physical properties of the system may influence the OR rate as the temperature increases. First, the aqueous phase viscosity decreases with increasing temperature (and therefore D increases), which would increase the OR rate. However, this effect would be expected to be fairly small since the shear viscosity of water only changes from about 1.5 to 0.69 mPa s when the temperature is increased from 5 to 37 °C (CRC Handbook of Chemistry and Physics). Second, the interfacial tension of nonionic surfactant monolayers decreases with increasing temperature due to progressive dehydration of the surfactant head groups,[37] which should decrease the OR rate. The change in interfacial tension with temperature may be appreciable, particularly near the phase inversion temperature (PIT) where the interfacial tension becomes ultralow, and therefore one would expect this effect to play an important role. Third, the solubility of the vitamin E acetate in the aqueous phase is likely to change with temperature. To our knowledge there are no published data on the solubility of vitamin E acetate in aqueous 20% ethanol solutions at different temperatures. We tried to measure this parameter by mixing excess vitamin E acetate with aqueous 20% ethanol solutions and storing the resulting systems at 5, 20, and 37 °C for 72 h. We then used UV−visible spectrophotometry to try to measure the concentration of vitamin E acetate present in the resulting solutions at saturation, using the published wavelength maximum (λ = 292 nm) and extinction coefficient (ε = 3260 M^{-1} cm^{-1}) of this compound.[38] However, the levels of vitamin

Table 1. Calculated Growth Rates of Nanoemulsions Containing Different Cosurfactants (0.5%) at Various Storage Temperatures (Correlation Coefficients Are Shown in Brackets)

	growth rates (nm^3 per day)

37 °C	3190 (0.998)	2840 (0.999)	13600 (0.948)	5780 (0.999)

dx.doi.org/10.1021/jf404182b | J. Agric. Food Chem. 2014, 62, 1625−1633

E acetate present were so small that we could not measure them, i.e., no maximum was observed at the expected wavelength and the UV-signal was close to the baseline.

The solubility of vitamin E acetate in pure water reported in a chemical database (www.scifinder.com) was therefore used to provide a rough prediction of the expected rate of Ostwald ripening in the system: $c_\infty = 2 \times 10^{-6}$ kg m^{-3} or 4.64×10^{-6} mol m^{-3} at 25 °C. The other parameters needed to calculate the OR rate using eq 1 were also taken from this database or measured in our laboratory: $V_m = 0.431$ kg mol^{-1}, $D = 3.9 \times 10^{-10}$ m^2 s^{-1}, $\gamma = 30$ mJ m^{-2}, $R = 8.31$ J K^{-1} mol^{-1}, and $T = 298.1$ K. The droplet growth rate was estimated to be around 4.2×10^5 nm^3/day, which is appreciably higher than the measured droplet growth rates particularly at the higher storage temperatures (Table 1). In addition, the above calculations have ignored the influence of ethanol on the predicted growth rate, and studies have shown that the solubility of vitamin E (α-tocopherol) increases over 5-fold when the ethanol concentration is increased from 0 to 20% in aqueous ethanol solutions.[39] There therefore seems to be a contradiction between the experimental measurements and the theoretical predictions made using the OR theory. There are a number of possible reasons for this discrepancy. First, some of the physicochemical parameters used in the calculations may have been incorrect. In particular, the solubility of the vitamin E acetate in the aqueous phase was predicted using a mathematical model from a chemical database, which may have been incorrect. Second, the influence of surfactant molecules adsorbed to the oil−water interface on the OR rate was ignored. Surfactants are known to decrease the interfacial tension (particularly near the PIT), which would reduce the OR rate considerably.[40] Third, there may have been some highly hydrophobic impurities within the vitamin E acetate preparation used in this study that acted as ripening inhibitors.[32,40]

Coalescence. Coalescence is the process whereby two or more droplets come into close contact and then merge together.[16,26] The rate at which this process occurs depends on the frequency and duration of encounters between droplets, as well as the colloidal and hydrodynamic interactions between them. The following expression has been derived to describe the increase in mean droplet radius with time due to Brownian-motion induced coalescence:[34]

$$r^3 - r_0^3 = \omega_C t = \frac{4.258 r_0^3 N_0 kT(\hat{\mu} + 1)E}{\mu(3\hat{\mu} + 2)} t \approx \frac{\varphi kT(\hat{\mu} + 1)E}{\mu(3\hat{\mu} + 2)} t \quad (2)$$

Here, ω_C is the coalescence droplet growth rate, N_0 is the total number density of droplets in the initial system, ϕ is the disperse phase volume fraction, μ is the viscosity of the continuous phase, $\hat{\mu}$ is the dispersed-to-continuous phase viscosity ratio (μ'/μ), k is Boltzmann's constant, and E is the collision efficiency. The collision efficiency depends on the nature of the colloidal and hydrodynamic interactions between the droplets and typically has a value <1.0. This theory suggests that the coalescence rate (ω_C) should increase as the droplet concentration and collision efficiency increases. Like the OR theory, it predicts that the droplet growth rate should increase linearly with the cube of the droplet radius. For certain initial particle size distributions, this theory also predicts that the PSD should maintain a constant shape at longer storage times, and should just move up the particle size axis with time.[34] The fact that changes in the mean particle size and PSD with time may be similar for OR and coalescence means that it is often difficult to distinguish between these two different growth mechanisms. To estimate the potential contribution of coalescence in the nanoemulsions we calculated the droplet growth rate using eq 2 and the physicochemical properties of the system ($\phi = 0.05$: $\eta = 0.001$ Pa s; $\eta' = 2.95$ Pa s) and assumed that every collision led to coalescence ($E = 1$). We estimated a droplet growth rate of 2400 nm^3/day using eq 2, which is fairly close to the values measured at the higher temperatures. The relatively low growth rates measured at lower temperatures may have been because the collision efficiency was much less than unity, due to the presence of repulsion colloidal interactions operating between the droplets in the nanoemulsions (such as steric or electrostatic repulsion).[24] These calculations suggest that coalescence may play an important role in determining the overall rate of droplet growth in the nanoemulsions during storage, particularly at elevated temperatures near the cloud point.

Experimentally, we observed that the rate of droplet growth increased appreciably with temperature and depended somewhat on cosurfactant addition (Figure 7, Table 1). Previous studies have shown that the rate of droplet coalescence increases as the temperature moves toward the PIT of the system due to changes in the optimum curvature of the surfactant monolayer at the droplet surfaces.[16] When the optimum curvature is close to unity the interfacial tension is very low, which leads to rapid droplet coalescence.[26] For example, Shinoda and Saito[14] showed that O/W emulsions stabilized by nonionic surfactants were relatively stable to droplet growth at storage temperatures well below the PIT, but were highly prone to coalescence at temperatures near the PIT. One might therefore expect that cosurfactants that increase the PIT would improve the coalescence stability of nanoemulsions at elevated temperatures. In addition, one would expect that cosurfactants that increased the repulsive interactions between droplets (decreased the collision efficiency) would reduce the coalescence rate.[34] Nevertheless, we did not find any correlation between increasing effects of cosurfactant on the cloud point (and thereby PIT) and the corresponding storage stability. The origin of this phenomenon is currently unknown, and it would be useful in future studies to identify its molecular basis. In particular, it would be useful to establish the physicochemical origin of the differences in the impact of the different surfactants on the droplet growth rates.

In this study, we investigated the effect of cosurfactants on the thermal and isothermal stability of VE-nanoemulsions (containing ethanol as cosolvent). These systems were highly unstable to droplet growth, which was attributed to droplet coalescence and/or Ostwald ripening. Addition of a nonionic cosurfactant (0.5% Tween 20) has little influence on the cloud point of VE-nanoemulsions, however addition of ionic surfactants (0.5% lauric alginate or SDS) caused an appreciable increase in the cloud point. On the other hand, addition of cosurfactants did not increase the long-term stability of VE-nanoemulsions under isothermal conditions, particularly at elevated temperatures. Theoretical calculations suggested that both coalescence and Ostwald ripening may be important, with coalescence being particularly important at high storage

temperatures. Overall, this study indicated that addition of nonionic or ionic surfactants did not have a major impact on the isothermal storage stability of nanoemulsions, but did alter their phase inversion temperatures.

tension. After adjustment to the same protein concentration, the heated SPI was used to prepare emulsions using a high-shear homogenizer. We examined the effects of homogenizer rotating speed and ionic strength on soy protein aggregates' adsorption. Results of the study could provide more information as to the effects of heating conditions on the emulsifying properties of soy proteins.

MATERIALS AND METHODS

Materials. Low-denatured, defatted soy flakes were kindly provided by Shandong Gushen Industrial & Commercial Co., Ltd. (Dongying, Shandong, China). For the preparation of the emulsions, soybean oil was obtained from a local supermarket and purified with Florisil (60−100 mesh, Sigma-Aldrich) to remove surface-active impurities. All other reagents and chemicals were of analytical grade.

Preparation of Soy Proteins. The defatted soy flakes were dispersed in 15-fold distilled water and adjusted to pH 7.0 with 2 M NaOH. After stirring for 1 h, the suspension was centrifuged at 15500*g* for 30 min at 4 °C, and then the supernatant was subjected to isoelectric precipitation by adjusting the pH to 4.5 with 2 M HCl and centrifuged at 4 °C for 1 h. The protein precipitate was washed twice with distilled water and then adjusted to pH 7.0 by 2 M NaOH. This protein suspension was centrifuged at 15500*g* for 30 min at 4 °C (CR-21G, Hitachi, Japan), and the supernatant was then freeze-dried and ground to yield soy proteins. Protein content of the prepared soy protein was 90.6% (w/w) as determined by using the micro-Kjeldahl method with a nitrogen conversion factor of 6.25.

Native soy protein (NSP) solution with concentrations of 1, 3, and 5% (w/v) were prepared by dissolving soy proteins prepared as above in 10 mM sodium phosphate buffer and stored at 4 °C overnight. The final pH was adjusted to 7.0 by adding 1 M NaOH or 1 M HCl. The protein dispersions were filtered to remove the insoluble particles through 0.45 μm filters (Φ50 mm × 0.45 μm, low protein binding, Sinopharm Chemical Reagent Co., Ltd.), using a sand core filter device by vacuum extraction filtering method. The filtrates were heated in a 95 °C water bath for 30 min and cooled to room temperature in an ice bath to obtain H1, H3, and H5, which was heated at protein concentrations 1, 3, and 5%, respectively. The protein concentration of the final solutions was checked by using the Lowry method.[14] In our experiment, high-purity native soy protein was used as a protein standard. The high-purity native soy protein was prepared in this laboratory and has a protein content of 99.0% as determined by the micro-Kjeldahl method.

High-Performance Size Exclusion Chromatography (HPSEC). The molecular weight distribution was determined according to the method of Wu et al.[15] Native and heated soy protein solutions were filtered through a cellulose acetate membrane with a pore size of 0.45 μm (Sartorius Co., Ltd., Gottingen, Germany). A Waters 2690 liquid chromatograph system (Waters Chromatography Division, Milford, MA, USA) equipped with a Shodex protein KW-804 column (Shodex Separation and HPLC Group, Tokyo, Japan) was used. The elution was performed with 50 mM phosphate buffer (pH 7.0, including 0.3 M NaCl) at a flow rate of 1.0 mL/min. About 20 μL of protein solutions was injected into the column, and the fluent was monitored at 280 nm. The relative amount of the aggregates was expressed as the percentage of its peak areas (PA) as related to the total area (TA) (eq 1). The content of non-aggregated fraction was calculated by taking the difference in relative protein content reading in the whole solution and the aggregates (eq 2).

$$C_{\text{aggregates}} = \frac{\text{PA}_{\text{aggregates}}}{\text{TA}} \times C_{\text{solution}} \quad (1)$$

$$C_{\text{non-aggregates}} = C_{\text{solution}} - C_{\text{aggregates}} \quad (2)$$

Dynamic Light Scattering. Apparent hydrodynamic radius (Rh) was determined according to method of Wang et al.[6] To avoid multiple particle effects, protein samples were diluted to 1.0 mg/mL with 10 mM phosphate buffer (pH 7.0), and the native proteins were filtered through a 0.45 μm filter. The appropriate viscosity and refractive index parameters for each solution were set. DLS analysis was carried out at a fixed angle of 173° using a Zetasizer Nano-ZS instrument (Malvern Instruments, British) at 25 °C. All measurements were performed in at least duplicate at room temperature, and the results reported are averaged over three readings.

Surface Hydrophobicity. Surface hydrophobicity of protein samples was determined according to the method of Wang et al.[6] The aliquots (1.0 mL) of protein solutions (0.2 mg/mL) were placed in the cell of an F7000 fluorescence spectrophotometer (Hitachi Co., Japan), and aliquots (10 μL) of 1-anilino-8-naphthalenesulfonate (ANS; 5 mM in 10 mM phosphate buffer, pH 7.0) were titrated to reach a final concentration of 50 μM. The molar coefficient (5000 M^{-1} cm^{-1} at 350 nm) was used to calculate ANS concentration. The relative fluorescence intensity (F) was measured at 390 nm (excitation; slit width, 5 nm) and 470 nm (emission; slit width, 5 nm). Data were elaborated using the Lineweaver−Burk equation (eq 3)

$$1/F = 1/F_{\max} + (K_d/L_0)(1/F_{\max}) \quad (3)$$

where L_0 is the fluorescent probe concentration (μM), $F_{\max}$ is the maximum fluorescence intensity of the ANS probe (at saturating probe concentration), and K_d is the apparent dissociation constant of a supposedly monomolecular protein/ANS complex. $F_{\max}$ can be calculated by standard linear regression fitting procedures.

Interfacial Tension. The interfacial tensions between soybean oil and 10 mM phosphate buffer or the protein solutions were measured according to the Wilhelmy plate method,[16] using a dynamic contact angle meter and tensiometer (DCAT21, Dataphysics, Germany), at 25 °C. The aqueous phase was water or SPI solution (0.3%, w/v) in water, pH adjusted to 7.0.

Emulsion Preparation. Two different series of emulsions were prepared. In the first series, the pH (7.0) and the salt addition level (0 M) were kept constant, whereas the homogenizer rotating speed was varied between 10000 and 22000 rpm. In the second series, the homogenizer rotating speed (16000 rpm) and the pH (7.0) were kept constant, whereas the salt addition level was adjusted to 0, 0.1, 0.2, 0.3, and 0.4 M, respectively. All protein samples were diluted to 0.3% (w/v) using 10 mM sodium phosphate buffer, pH 7.0, containing 0.02% sodium azide as an antimicrobial agent. Emulsions were prepared by mixing 10% soybean oil with 90% SPI solution and emulsified using a high-shear homogenizer (FA25 model, Fluko Equipment Co., Ltd., Shanghai, China) for 2 min at room temperature. Each emulsion was prepared at least three times to check for processing repeatability and stored at 4 °C for further analysis (within 2 h).

Mean Particle Size of Emulsion. The particle size distribution of the emulsion was determined using a Mastersizer 2000 laser particle-size analyzer (Malvern Instruments, Malvern, U.K.). The refractive indices of soybean oil and phosphate buffer were taken as 1.472 and 1.330, respectively; absorption index, 0.001; obscuration value, 15%. Half a milliliter of fresh emulsion was taken and diluted in 10 mL of 1% SDS solution (1% SDS in 10 mM phosphate buffer). The particle sizes measured are reported as the area-weighted mean diameter, d_{32}.

Determination of Protein Concentration at the O/W Interface. The concentration of protein adsorbed at the O/W interface was determined according to the method described by Keerati-u-rai et al.[1] with some modifications. Emulsions were centrifuged twice at 15500*g* at 4 °C for 45 min. The serum phase (unadsorbed protein) was withdrawn carefully using a syringe, and the protein concentration was determined according to the method of Lowry et al.[14]

The aggregates (A) or non-aggregates (NA) remaining in serum phase were determined using high-performance size exclusion chromatography (HPSEC).[15] The serum phase was concentrated by ultrafiltration tubes to about 3 mg/mL before the HPSEC experiment.

The surface load (Γ) was obtained by relating the adsorbed amount to the specific surface area of the emulsion.[13,17] Equation 4 was used to calculate the surface load (Γ) in this study:[13]

$$\Gamma\ (\text{mg/m}^2) = \frac{d_{32}(C_{\text{INI}} - C_{\text{SER}})(1 - \Phi)}{6\Phi} \quad (4)$$

dx.doi.org/10.1021/jf404464z | J. Agric. Food Chem. 2014, 62, 1634−1642

C_{INI} and C_{SER} are the protein concentration in the initial solution (prior to emulsification) and the concentration in the aqueous phase after the centrifugation procedure, respectively. Φ is the volume fraction of oil phase.

Statistical Analysis. Experiment data were analyzed by analysis of variance (ANOVA) using the SAS 9.1 package (SAS 2005). A least significant difference (LSD) test with a confidence interval of 95% was used to compare the means. All treatments were run in triplicate. Data were expressed as the mean ± SD (n = 3).

RESULTS AND DISCUSSION

Characterization of Soy Proteins. Heat treatment above the denaturation temperature caused protein unfolding and subsequent protein aggregation. As shown in Figure 1, native soy proteins (NSP) resulted in two peaks at 9−10 and 11−12 min, corresponding to molecular weights of 150 kDa (20−630 kDa) and 14.1 kDa (2−20 kDa). Elution profiles for heated soy proteins revealed that protein aggregates' peak emerged at about 6 min, and heating at higher protein concentration resulted in more aggregates. Protein aggregates' content increased from 0 to 1.92 mg/mL for H5, whereas the non-aggregated protein decreased from 2.78 to 0.857 mg/mL. Ratios of non-aggregated proteins to protein aggregates were approximately 1:2, 1:1, and 2:1 for H1, H3, and H5, respectively. At the same time, R_h values also increased with the heating concentration of proteins (Table1). These findings are well in agreement with previous studies.[8,18,19]

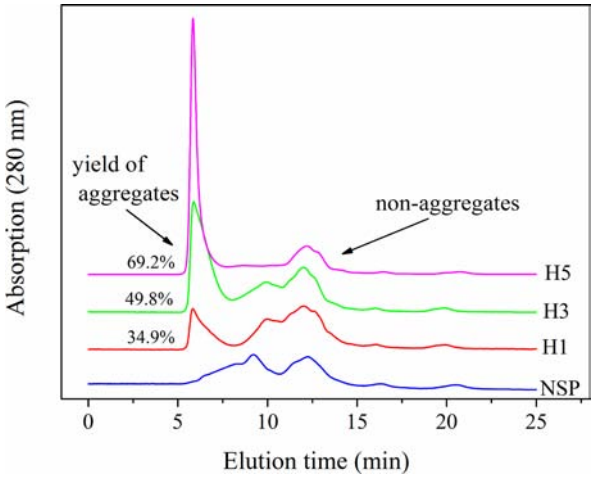

Figure 1. HPSEC profiles of native and heat-denatured soy proteins.

Surface hydrophobicity of protein has long been used to characterize the structural changes and recognized as a related factor controlling surface activity of protein. Table 1 summarizes the surface hydrophobicity data of native and heated soy proteins. The surface hydrophobicity of all heated proteins was significantly (p < 0.05) higher than that of NSP. Several previous studies had also reported that heat-treated soy protein possessed higher surface hydrophobicity than the native protein.[20,21] These changes might be induced by a modification of the native structure of soy proteins during heat treatment: more hydrophobic group clusters in the interior of molecule transferred to protein's surface as a consequence of heat-induced protein unfolding.[22] Furthermore, the heated proteins that were heated at higher concentration possessed more surface hydrophobicity. This may seem surprising because aggregation of heat-denatured proteins was thought to take place through hydrophobic interactions between nonpolar groups; thus, more aggregates mean fewer exposed hydrophobic groups. Semisotnov et al.[23] pointed out that protein−ANS binding was not only affected by accessibility of hydrophobic area but also influenced by the protein structure. Most probably, soy proteins heated at higher concentrations were more "molten globule" like and had higher β-structure, both of which displayed a higher affinity to ANS. The interfacial tension of the soybean oil−phosphate buffer (10 mM) was 18.1 mN/m. When soy protein (0.3%) was added to the aqueous phase, the interfacial tension of the O/W interface substantially decreased. However, heat treatment induced only a slight decrease in interfacial tension of soy proteins (Table 1). Possibly in addition to hydrophobicity, the interfacial tension is also related to properties such as molecular size and flexibility.[24,25]

Table 1. Surface Hydrophobicity (F_{max}), Interfacial Tension (σ), and Hydrodynamic Radius (R_h) of NSP or Heat-Denatured Soy Proteins[a]

sample	F_{max}	σ (mN m^{-1})	R_h (nm)
NSP	299.2c	12.1a	7.45d
H1	680.1b	11.1b	14.0c
H3	714.3b	10.9b	18.1b
H5	759.2a	11.7a	23.0a

Adsorption of Soy Protein at the O/W Interface As Affected by Homogenizer Rotating Speed. *Droplet Size Distribution of the Emulsions.* As shown in Figure 2, homogenizer rotating speed was a major factor determining the droplet size of emulsions. According to Walstra,[26] the size of an emulsion's drops depended mainly on the average power density in the emulsification chamber. This could explain why droplet sizes of emulsions stabilized by different proteins decreased in almost the same pattern. Heat treatment of soy proteins also affected droplet size of emulsions. For every rotating speed, NSP-stabilized emulsions possessed larger droplet sizes than emulsions stabilized by heated proteins. Li et al.[5] reported that heated soy proteins yielded smaller droplet

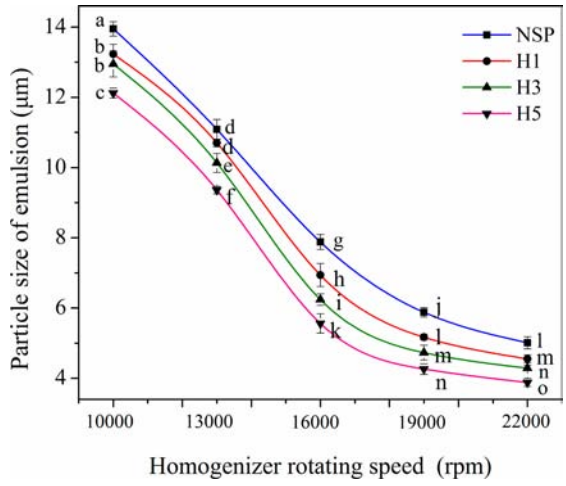

Figure 2. Mean particle size of emulsion (μm) at various homogenizer rotating speeds and zero salt addition. Letters (a−o) following each point indicate significant differences at the 0.05 level (n = 3).

sizes, whereas Keerati-u-rai et al.[1] found that heated soy proteins resulted in larger sized droplets. Li-Chan et al.[27] considered that emulsifying and fat-binding properties of heated proteins were improved under the conditions favoring combinations of high solubility and hydrophobicity. Because surface hydrophobicity of heated soy proteins increased substantially and protein solubility remained unchanged in this experiment, it was found that heated proteins displayed better emulsifying property than NSP. This was in agreement with previous studies, which have reported that increasing the heat-induced aggregate concentration resulted in the formation of emulsions with smaller droplet size.[3] The marked difference in emulsifying behavior among H1, H3, and H5 could not be solely explained by the surface hydrophobicity. Instead, a difference in the content of protein aggregates was found to parallel the changes in droplet size of emulsions (Figure 2). Different adsorption behaviors for aggregates and non-aggregates are considered in the following parts.

Adsorption of Total Proteins at the O/W Interface. Protein surface loads obtained in this study (Figure 3) were much

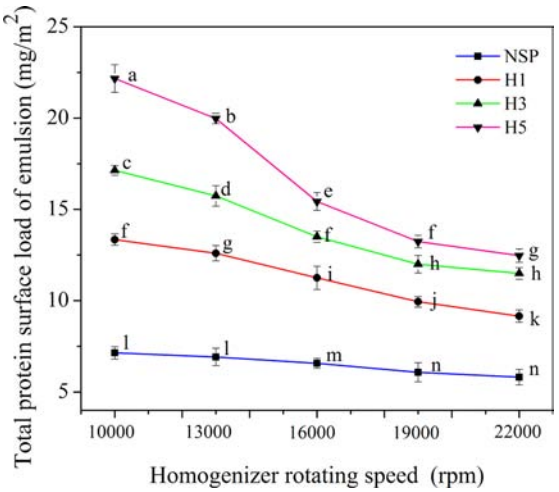

Figure 3. Total protein surface load (mg/m^2) of emulsion at various homogenizer rotating speeds and zero salt addition. Letters (a–n) following each point indicate significant differences at the 0.05 level (n = 3).

higher than the typical globular protein monolayer (about 1–3 mg/m^2).[16] The values of all heated samples were >9.16 mg/m^2. High protein surface load values were also reported by Puppo et al.[28] (>9.0 mg/m^2) and Waninge et al.[29] (4–5 mg/m^2) on emulsifying properties of soy protein and milk protein, respectively. As shown in Figure 3, heat treatment enhanced the surface load of soy protein; the protein surface load of H5 (22.2 mg/m^2) was almost doubled compared to that of H1 (13.3 mg/m^2) at the homogenizer rotating speed of 10000 rpm. Nilsson and Bergenståhl[30] considered that diffusional transport of polymers to the interface became less important; instead, convective transport would dominate during homogenization conditions. In the homogenization shear field, transportation to the O/W interface of large molecules was favored over small ones, leading to higher surface loads by causing jamming at the interface. Tcholakova et al.[13] attributed the much higher protein surface load at the O/W interface to the presence of aggregates in their study. From Figure 3, it could also be noted that the increasing rotating speed decreased the surface protein loads of all emulsions to various degrees. The protein adsorption at the O/W interface would be expected to increase at higher homogenizer rotating speed if there were enough proteins in the system. In the present systems, however, increase of rotating speed resulted in emulsions with small droplet size (larger interface area), at the expense of surface protein load.

Good linear relationships were found when protein surface loads (Γ) were plotted against concentrations of unadsorbed proteins in the aqueous phase (C_{SER}) under the respective homogenizer rotating speed (Figure 4). Thus, adsorption of soy

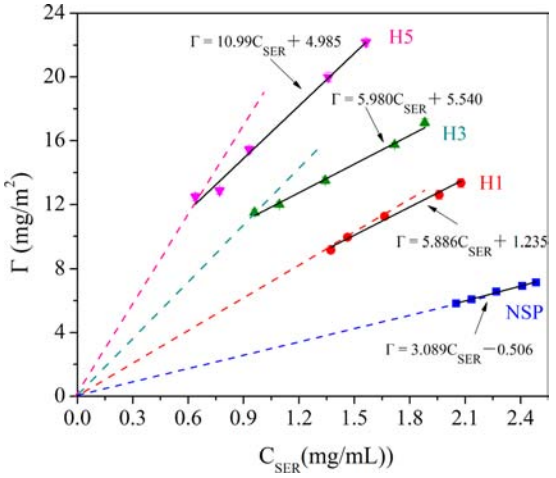

Figure 4. Linear relationships of protein surface loads (Γ) and unadsorbed proteins in the aqueous phase (C_{SER}) at various homogenizer rotating speeds.

proteins at the O/W interface could be described by a simple linear equation. Tcholakova et al.[13] also used an empirical equation to describe protein adsorption behavior at the O/W interface after an unsuccessful attempt of fitting data with those well-known adsorption isotherms. Unfortunately, there were no data describing adsorption behavior when the protein concentration approached 0. To simplify discussion, a linear adsorption isotherm was also assumed in this range (as represented by dashed lines in Figure 4).

In the linear Henry isotherm equation (eq 5)

$$\Gamma = kc \tag{5}$$

The amount of surface adsorbate was proportional to the unadsorbed protein concentrations in the aqueous phase. Therefore, a two-stage Henry isotherm was proposed to describe the adsorption of soy proteins at the O/W interface. The first stage, starting from the origin and ending at the point obtained at a homogenizer rotating speed of 22000 rpm, was assumed to be the adsorption of insufficient proteins relative to large interface area. The second stage, represented by the original fitted line, was the adsorption of excess proteins relative to small interface area. The Henry isotherm constant (k) was the adsorbed protein quantity corresponding to unit concentration of unadsorbed proteins and revealed the affinity of the adsorbate to the adsorbent. For both adsorption stages, k values changed according to the order H5 > H3 > H1 > NSP, again suggesting that proteins heated at higher concentration were prone to be adsorbed at the O/W interface. If k values of different adsorption stages were compared, we could find that for heated proteins, k values of the first stage were higher than those of the second stage. For NSP, however, k values for the

[a]Letters (a−u) following each value indicate significant differences at the 0.05 level (n = 3).

two stages were not remarkably different. Due to the much higher surface protein load than the monolayer adsorption, multilayer adsorption was expected for all emulsions. The different k values between stages 1 and 2 suggested that the adsorption behavior of NSP toward the oil surface was not substantially different from that toward the adsorbed protein layer. On the contrary, heated soy proteins, especially those heated at higher concentrations, showed much stronger affinity toward the oil surface than that toward the adsorbed protein layer.

Adsorption of Aggregates and Non-aggregates at the O/W Interface. The adsorption behavior of aggregated and non-aggregated proteins in heated soy proteins was studied. It was found that protein aggregates had higher adsorption percentages than non-aggregated proteins (Table 2). Furthermore, aggregates formed at higher concentrations had higher possibility to be adsorbed at the O/W interface (H5 > H3 > H1). However, non-aggregates formed by heating in lower concentrations were more extensively adsorbed by the O/W interface (H1 > H3 > H5).

Higher adsorption percentage for aggregates than for non-aggregates could be related to their difference in structure. As revealed in previous studies, heat-induced aggregation of soy proteins was a consequence of several steps, including dissociation, unfolding, reassociation, and aggregation.[10] Unfolding of heat-dissociated polypeptides from glycinin and conglycinin resulted in the loss of α-helical structure, whereas much of the β-sheet structure remained. Because the transition of structure and the exposure extent of hydrophobic sites for the protein molecules were closely related, the surface hydrophobicity increased.[10] Specific associations between basic polypeptides or between basic polypeptides and β-subunits through disulfide bonds or noncovalent bonds have been reported.[9] When soy proteins were heated at gradually increased concentrations, aggregation of unfolded polypeptides and reassociated oligomers would have more chances to occur and, as a result, those proteins with more hydrophilic nature would be left as non-aggregates. In addition to hydrophobicity, electric charge frequency and molecular flexibility[31] were important for protein function at an interface.

With the increase of homogenizer rotating speed, adsorption percentages for both aggregated and non-aggregated proteins rose. For aggregated proteins of H5, adsorption percentage increased from 58.5% at 10000 rpm to nearly 100% at 22000 rpm. However, under no circumstance did adsorption percentages of non-aggregated proteins exceed 40.8%. The low adsorption percentages suggested the low affinity of non-aggregated proteins toward the oil phase. On the other hand, the adsorption of larger sized protein aggregates was limited by the diffusion rate at low rotating speed, but effectively enhanced at higher speed. Nilsson et al.[32] reported that the high molar mass components in the polymer were selectively adsorbed in dynamic homogenization condition, which favored transport to the interface of the high molar mass polymers in the sample.

Next, surface protein loads for aggregated and non-aggregated soy proteins were studied (Figure 5) as a function of concentration of the corresponding unadsorbed protein species in the aqueous phases (Figure 6). Intriguingly, the behavior for aggregates in both H3 and H5 resulted in downward convex curves, whereas that for non-aggregates in both H1 and H3 showed upward concave curves. The adsorption energy of the convex type adsorption isotherm decreases as surface load increases, whereas that of concave type increases as surface load increases. Thus, the adsorbed aggregates expelled the adsorbing aggregates, possibly due to the steric effects, whereas the adsorbed non-aggregates attracted the adsorbing non-aggregates, probably because of the hydrophobic interactions between unfolded polypeptides. The adsorption behavior of H1 aggregates and H5 non-aggregates was abnormal because the Γ_A for H1 in the high C_{SER} region decreased, whereas Γ_N for H5 was exceptionally low. This phenomenon could be a demonstration of the interaction between two protein fractions: for H1, the adsorption of aggregates was suppressed by non-aggregates, but for H5 the reverse may be the case.

Adsorption of Soy Proteins at the O/W Interface As Affected by Ionic Strength. *Particle Size and Total Protein Surface Load of the Emulsions.* Soy protein stabilized emulsions were prepared with different levels of NaCl addition. Variation in oil droplet sizes and protein surface loads for heated and unheated soy protein stabilized emulsions followed the same pattern with the increase of NaCl concentration, although the effects differed quantitatively. At low salt concentration (<0.1 M), the addition of salt reduced droplet sizes. A gradual increase in droplet sizes was noted between NaCl concentrations of 0.1 and 0.3 M and then leveled off (Figure 7A). Some studies reported different ranges of emulsion droplet size as a function of salt concentrations. Dickinson[33] and Onsaard[34] found that the initial average droplet sizes and creaming behavior for emulsions stabilized by milk protein remained relatively stable at NaCl concentrations ≤0.1 M. Tcholakova et al.[35] observed that mean drop sizes remained almost constant (about 40 μm) in the electrolyte concentration range of 5−1000 mM (pH 6.2.). However, other studies[36−38] reported that droplet sizes of dairy protein stabilized emulsions increased at a much lower ionic concentration. In addition, emulsifying activities of some vegetable protein stabilized emulsions were reported to increase in the ionic strength range of 0−0.2 M,[39] some even in 0−0.4 M,[39,40] but reduced afterward with further increase in NaCl concentration. The lower sizes of emulsions at 0.1 M NaCl in this study might be partially because low ionic strength

encouraged unfolding of protein molecules and subsequent increase in protein solubility. Lawal et al.[39] considered that such an increase in protein solubility enhanced a rapid migration to the O/W interface and improved the emulsifying activity of the protein. With further increase in ionic strength (>0.1 M), screening of the surface charges increased and this encouraged protein–protein interaction but reduced protein–oil interaction.

Protein surface loads were also influenced markedly by increasing ionic strength (Figure 7B). More proteins, whether heated or unheated, were found to be adsorbed at the O/W interface with increasing of NaCl concentration. Tcholakova et al.[35] also found that the protein surface loads of emulsions stabilized by β-lactoglobulin (0.02 or 0.1%, w/v) increased with increasing NaCl concentration (5–1000 mM, pH 6.2.) In this study, the enhanced Γ was probably due to the electrostatic screening, which reduced electrostatic repulsion with increasing concentration of NaCl and facilitated the adsorption of soy proteins at the interface.

Adsorption of Aggregated and Non-aggregated Proteins at the O/W Interface at Different Ionic Strengths. Addition of salt was very effective in enhancing the adsorption of aggregated proteins. In fact, >95% of aggregated proteins were found to transfer to the O/W interface at a salt concentration of ≥0.2 M. Adsorptions of non-aggregated proteins as well as the unheated soy proteins displayed similar increasing trends, but the maximum adsorption percentage was much lower than that of aggregates. In contrast to the effect of homogenizer rotating speed, salt enhanced adsorption percentages of non-aggregates of H5 more effectively than other proteins (Table 3). It seems that adsorption of non-aggregates of H5 was more severely hindered by electrical repulsion, and the screening of electric charges on proteins resulted in a more remarkable increase in adsorption percentage. It was clear that aggregate/non-aggregate profiles on the O/W interfaces did not change substantially as a result of increasing salt concentration (Figure 8). With the elevation of salt concentration, aggregates in H5 remained as predominantly adsorbed components but both protein fractions contributed to the adsorbed layer for H1- and H3-stabilized emulsions. On the other hand, increase in NaCl concentration effected a marked decrease of Γ_A/Γ_N for H5 emulsions, from 8.21 to 3.66, whereas Γ_A/Γ_N was observed to increase from 0.76 to 1.17 for H1-stabilized emulsion.

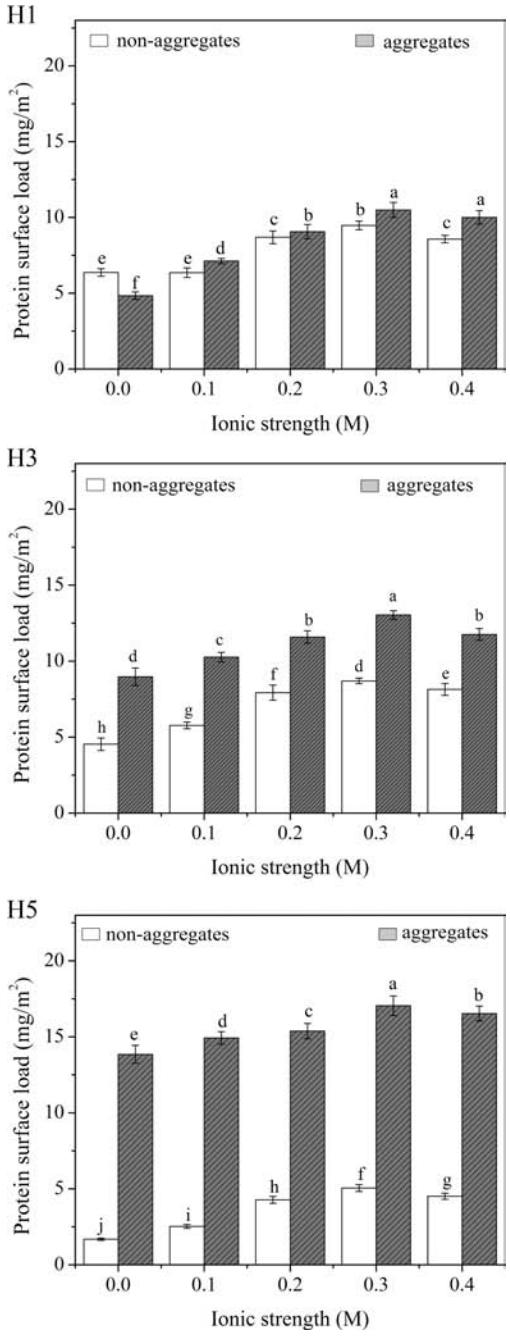

Figure 8. Protein surface load of aggregates and non-aggregates in emulsions at various ionic strengths and constant homogenizer rotating speed of 16000 rpm. Letters (a–j) above each column indicate significant differences at the 0.05 level (n = 3).

In summary, the present study showed that not only the heat treatment but also the heating concentration affected the emulsifying properties of soy proteins. Better emulsifying properties, as judged from droplet size, adsorption percentage, and surface load, could be obtained by heating soy proteins at higher concentrations. Levels of protein aggregates in heated samples were more important than other variables in affecting adsorption properties of proteins at the O/W interface. Adsorption properties of total proteins at the O/W interface as a function of homogenizer rotating speed or salt concentration seem to follow a similar trend, regardless of the use or not of heating and the heating concentrations. However, if aggregated and non-aggregated proteins were

considered separately, different adsorption behaviors that depended on heating concentrations could be observed. Thus, the adsorption of soy proteins at the O/W interface could not be considered as the sum of the independent adsorption of aggregates and non-aggregates.

to 300 °C, and baking time varied between 5 and 30 min.[8−15] Under these baking kinetics, a variety of complex physical and chemical phenomena would happen, including the important nonenzymatic browning reaction resulting in brown color and bakery flavor development. During cookie baking, α-dicarbonyls may be produced via caramelization, Maillard reaction, and lipid peroxidation. Their high reactivity with protein poses health risks associated with pathological events and carcinogenicity.[10] Cookies are also rich sources of dietary AGEs, which can be produced with α-dicarbonyls as precursors and are implicated in the development of oxidative stress and inflammation-associated diseases. On the basis of the above discussions, cookies would be suitable food models to examine the antioxidant and antiglycation activities of dietary polyphenols under thermal processing.

The current study prepared cookies fortified with five representative dietary polyphenols (naringenin, quercetin, epicatechin, chlorogenic acid, and rosmarinic acid), respectively. Examination of the antioxidant capacity of fortified cookies would allow characterization of how thermal treatment affected phenolics' antioxidant activity in the cookie system. The antiglycation potential of polyphenols in cookie was also assessed with reference to the formation of both total fluorescent AGEs and their important precursors, the reactive carbonyl intermediates. Finally, the practicality of polyphenol fortification was evaluated on the basis of the influence of phenolic addition on the color and other quality attributes of cookies.

MATERIALS AND METHODS

Reagents and Chemicals. Epicatechin was purchased from Biopurify Phytochemicals Ltd. (Chengdu, China). Naringenin, quercetin, chlorogenic acid, rosmarinic acid, sodium chloride, sodium carbonate, sodium bicarbonate, trolox, ABTS [2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid)], potassium peroxosulfate, OPD (*o*-phenylenediamine), quinoxaline, 2-methylquinoxaline, Tween-20, SDS (sodium dodecyl sulfate), Tris, and β-mercaptoethanol were all purchased from Sigma-Aldrich (St. Louis, MO, USA). The ingredients for cookie preparation including salt, sugar, baking powder, canola oil, and white flour were purchased at a local supermarket. All solvents and acids used were of analytical or HPLC grade and obtained from BDH Laboratory Supplies (Poole, UK).

Cookie Model. The cookie recipe consisted of double-deionized water (1.5 mL), salt (0.1 g), baking powder (0.12 g), sugar (3.5 g), canola oil (1.5 mL), and white flour (7.5 g). The ingredients were thoroughly mixed with 0.25% (w/w) of individual phenolic compound (naringenin, quercetin, epicatechin, chlorogenic acid, and rosmarinic acid). Dough was rolled and baked in an electronic baking oven (Kenwood, China) at 200 °C for 10 min. After baking, the cookie samples were cooled to room temperature and kept at −20 °C until further analysis.

Measurement of Color, Texture, Moisture, and pH of Cookie Samples. The three chromatic coordinates L^*, a^*, and b^* of ground cookie were measured by a colorimeter (CR-400, Konica Minolta, Japan). The coordinate L^* indicates the lightness of color ($L^* = 0$ yields black and $L^* = 100$ means diffuse white); a^* characterizes the position between red and green (negative values indicate green, and positive values indicate red); b^* suggests the position between yellow and blue (negative values indicate blue, and positive values indicate yellow). Chroma value was calculated as $(a^{*2} + b^{*2})^{1/2}$; E index was calculated as $(L^{*2} + a^{*2} + b^{*2})^{1/2}$.

The textural analysis was conducted by a texture analyzer (TA-XT2, stable micro system, Surrey, UK) equipped with a cylindrical probe of 20 mm in diameter. The mode was set as "measure force in compression", and the compression distance was 1 mm. Hardness of the cookies was estimated by the maximum force (g). The moisture content of cookie was measured by a moisture analyzer (HB43-S, Mettler Toledo, USA). Around 3 g of ground cookie was heated at 120 °C until stable weight, and the moisture content was calculated according to the weight loss. For measurement of pH, 0.4 g of ground cookie was vortexed in 20 mL of water for 3 min and then held for 1 h at room temperature. The pH of the supernatant layer was taken by a pH meter (pHI510, Beckman Coulter, USA).

Measurement of Antioxidant Capacity. The antioxidant capacity was quantified by Trolox equivalent antioxidant capacity (TEAC) assay.[16] The stock radical solution was prepared by reacting 7 mM ABTS solution with 2.45 mM potassium peroxosulfate in the dark for 16 h at room temperature. Working radical solution was freshly prepared by diluting stock radical solution with Milli-Q water to have an absorbance of 0.7 ± 0.05 at 734 nm. Ground cookie was dispersed in water and 30, 50, and 70% ethanol with a final concentration of 100 mg/mL. The samples were extracted by sonication for 30 min and then centrifuged at 5100*g* for 20 min. Fifty microliters of supernatant or Trolox standard was mixed with 1.9 mL of working radical solution, and absorbance at 734 nm was read by a spectrophotometer (UV-1206, Shimadzu, Japan) after 6 min of incubation. The results were expressed as nanomoles of Trolox per milligram of cookie.

Investigation of Thermal Products of Quercetin after Cookie Baking Process. Ten grams of ground cookie was weighed in a 100 mL volumetric flask, and extraction was conducted by 70% methanol under sonication for 1 h. The extract was filtered, and the filtrate was analyzed by HPLC-DAD and LC-MS/MS. The Shimadzu HPLC system is composed of a separation module (LC-20AT), an autosampler (SIL-20A), a degasser (DGU-20A3), and a photodiode array detector (SPD-M20A). The separation of reaction products was achieved on a YMC-pack Pro column (5 μm, i.d. 2.1 × 150 mm). The mobile phases were water with 0.1% formic acid (A) and acetonitrile (B), and gradient flow was as follows: 0 min, 3% B; 5 min, 3% B; 45 min, 50% B; 55 min, 80% B; 60 min, 90% B; back to 3% B in 1 min and held for 14 min. The total run time was 75 min, and flow rate was 0.2 mL/min. The injection volume was 10 μL. UV detection wavelength for quercetin was 366 nm.

The LC-MS/MS instrument was equipped with an electrospray ionization (ESI) source interfaced to a 3200 Qtrap mass spectrometer (AB Sciex, Canada). Liquid chromatography was performed on an Agilent 1290 UHPLC system with a binary pump (G4420A) and a thermostated autosampler (G4226A). The separation of the reaction products was performed in the same conditions as described above. The MS parameters were as follows: negative ion mode; spray voltage, −4300 V; scan range, 100−1000 Da; temperature, 450 °C; declustering potential (DP), −65 V; collision energy (CE), −30 eV.

Determination of Glyoxal (GO) and Methylglyoxal (MGO). The two typical representatives of reactive carbonyls, GO and MGO, were quantified by a derivatization HPLC-DAD method.[10] Two grams of ground cookie was extracted by 20 mL of 50% methanol under sonication for 1 h. After centrifugation, the supernatant was filtered, and 15 mL of filtrate was concentrated by rotary evaporation. The extract was redissolved in 2 mL of 50% methanol. Derivatization was conducted by mixing 600 μL of cookie extract with 200 μL of OPD (10 mM) and afterward incubating the solutions for 3 h at 70 °C in an oven. After cooling, 200 μL of acetic acid was added to the derivatized mixture. The samples were then filtered by a 0.45 μm membrane before HPLC-DAD analysis.

After derivatization with OPD, GO and MGO could be measured as quinoxaline (Q) and 2-methylquinoxaline (2-MQ) correspondingly detectable by UV absorbance at 315 nm. The same Shimadzu HPLC system is used as described above. Separation was conducted on an ACE C18 column (5 μm, 250 × 4.6 mm, Advanced Chromatography Technologies, Aberdeen, UK). Elution was performed with a mixture of (A) 0.5% (v/v) acetic acid in water and (B) methanol, and gradient flow was as follows: 0 min, 16% B; 2 min, 16% B; 22 min, 32% B; 37 min, 80% B; 42 min, 80% B; 43 min, 16% B; 53 min, 16% B. Flow rate was 0.8 mL/min, and injection volume equaled 10 μL. Quantitative interpolation was facilitated by calibration curves constructed by Q and 2-MQ standard.

Table 1. Impacts of Dietary Polyphenols on the Color of Cookies[a]

	L^*	a^*	b^*	chroma value	E index

[a]"a" marks values significantly higher than control value, whereas "b" marks values significantly lower than control value ($P < 0.05$).

Measurement of Fluorescent AGEs. To extract the protein from cookie samples, 250 mg of ground cookie was extracted by 4.75 mL of extraction buffer (0.05% Tween-20, 1% SDS, 5% β-mercaptoethanol, 50 mM Tris-HCl at pH 7.4).[14] Extraction was performed overnight at room temperature under gentle agitation. The supernatant containing extracted protein was collected after centrifugation. One hundred microliters of extracted protein solution from cookies was pippeted to each well of a 96-well plate, and fluorescent AGEs were indicated by fluorescence with excitation wavelength of 355/40 nm and emission wavelength of 405/10 nm (Victor X4 Multilabel Plate Reader, PerkinElmer, USA).

Statistical Analysis. Statistical analyses were carried out by Graphpad Prism 5 software package (GraphPad Software, Inc., La Jolla, CA, USA). Data are expressed as the mean ± standard error of triplicate determinations, and differences with $P < 0.05$ were considered to be statistically significant.

RESULTS AND DISCUSSION

Polyphenol Addition Alters Selected Quality Attributes. One key consideration in the utilization of dietary polyphenols as functional food ingredients is whether the polyphenols will adversely influence the appearance, flavor, taste, and other sensory or quality attributes of fortified foods. Green tea and grape seed extract fortification have been illustrated to alter the color of baked bread on the basis of instrumental analysis.[4,17] In this study, the potential of polyphenol addition to cause colorimetric changes of cookie was examined. As shown in Table 1, cookies prepared with 0.25% (w/w) quercetin, chlorogenic acid, and rosmarinic acid showed decreased redness and increased yellowness; epicatechin or naringenin could induce a positive shift in the redness or yellowness of cookies, respectively. For a comprehensive analysis combining lightness, redness, and yellowness values, the chroma value of cookies fortified with naringenin, quercetin, chlorogenic acid, and rosmarinic acid was significantly higher than control, whereas no obvious effects were observed on the E index. The above observed colorimetric changes might be attributed to colorants originated from thermal transformation of polyphenols or newly formed unknown colorants from reactions between polyphenol and the nutritional components in cookies.

Table 2 summarizes the influence of dietary polyphenol addition on three commonly used quality descriptive indices. In textural analysis, phenolics were found to cause no significant change in cookie hardness at the specific addition level used in the study. A 0.1−0.7 decrease in pH value, however, was recorded as a result of polyphenol addition, which is probably a result of acidic compound formation. Tested polyphenols resulted in 0.1−0.4% fluctuation in cookies' moisture content, and the decrease in the moisture content induced by epicatechin or rosmarinic acid fortification might favor the shelf life of cookies.[18]

Table 2. Impacts of Dietary Polyphenols on the Selected Quality Attributes of Cookies[a]

	hardness (g)	pH	moisture (%)
control	11613 ± 3448.6	9.62 ± 0.038	2.20 ± 0.065
naringenin	8270 ± 1407.3	9.49 ± 0.015b	2.25 ± 0.072
quercetin	6273 ± 1257.8	9.02 ± 0.017b	2.64 ± 0.061a

Polyphenol Fortification Enhances Antioxidant Capacity, but Primary Compounds Are Thermally Converted to Other Products. As shown in Figure 1, the antioxidant capacity of cookie extract, which was prepared by extraction with solvents of different polarity, was significantly elevated with phenolics fortification. The increase in the antioxidant capacity, however, was much lower than that carried by the quantity of polyphenol originally added to the cookie recipe (denoted polyphenol equivalent in Figure 1), especially in the cases of quercetin and epicatechin fortification. This observation was consistent with early findings that quercetin and epicatechin were relatively sensitive to thermal processing and suffered from obvious thermal loss of their antioxidant activity.[2] Naringenin and quercetin were selected for further quantitative analysis (70% methanol extraction followed by HPLC/DAD quantification) of remaining primary polyphenol compound after baking process. Surprisingly, results showed that even after a 10 min short baking time, a >30% decrease in naringenin amount was found, and in quercetin's case, there was around an 88% loss of detectable UV absorption signal of

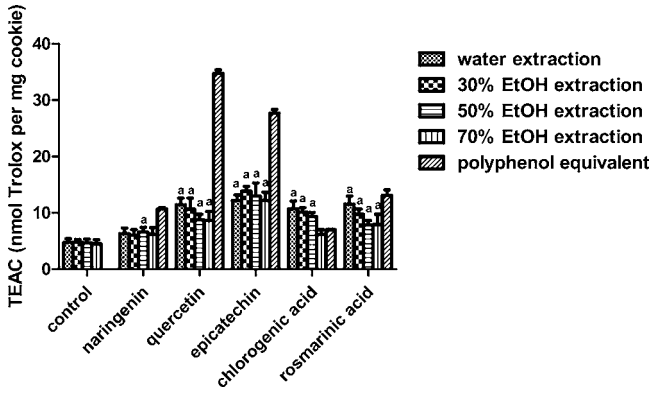

Figure 1. Antioxidant capacity of cookie extracts with or without addition of polyphenols and polyphenol equivalents. Extract with antioxidant capacity significantly higher than control is marked with "a" ($P < 0.05$).

primary compound. Quercetin has been previously reported to be thermally unstable after long heating: heating quercetin at 100 °C in aqueous solution caused a 25% decrease after 300 min at pH 5, whereas an alkalinic pH of 8 resulted in much more severe thermal loss that left no quercetin after 240 min of heating.[19] Our results indicate that in a low-moisture environment with heating temperature elevated to 200 °C, it took a very short time for quercetin to transform to other compounds.

Further investigation was made into the thermal transformation of quercetin. On the basis of the total ion chromatogram comparison of cookie extract without or with quercetin, three major additional peaks were identified in quercetin-fortified cookie extract, the information of which is summarized in Table 3. Remaining primary quercetin (m/z 301) was eluted at 28.7 min. Compound **I** (retention time = 20.2 min) showed UV λ_{max} at 290 nm and two main ions at m/z 349 and 331 during enhanced mass spectrometry (EMS) analysis, indicating easy loss of one molecule of water. Enhanced product ion (EPI) analysis of the ion at m/z 331 further elucidated a product ion at m/z 299, which may be the $[M - H]^-$ ion of oxidized quercetin, and the neutral loss was likely a molecule of methanol (32 Da).[20] Neutral loss of 28 Da from the ion at m/z 299, probably corresponding to a CO, gave rise to a product ion at m/z 271, whereas the same loss of CO from quercetin produced an ion at m/z 273. The product ion spectrum of both quercetin and its deprotonated ion at m/z 299 showed two ions at m/z 179 and 151. On the basis of the agreements on the UV absorption and LC-MS/MS data, compound **I** is likely to be 2-(3,4-dihydroxyphenyl)-3,3,5,7-tetrahydroxy-2-methoxy-2,3-dihydrochromen-4-one, which was identified by LC-MS/MS and NMR as the reaction product of quercetin and 2,2-diphenyl-1-picrylhydrazyl (DPPH) in methanol.[20] The compound has also been reported by Buchner et al.[19] to be present in the methanol solution of thermally processed quercetin at 100 °C.

Table 3. LC-MS/MS Data of Three Major Additional Compounds in Quercetin-Fortified Cookie Extract

peak	retention time (min)	m/z $[M - H]^-$	MS/MS	suggested structure
1	20.2	349, 331	299, 271, 179, 151	2-(3,4-dihydroxyphenyl)-3,3,5,7-tetrahydroxy-2-methoxy-2,3-dihydrochromen-4-one
2	24.4	363, 331	299, 271, 179, 151	2-(3,4-dihydroxyphenyl)-3,5,7-trihydroxy-2,3-dimethoxy-2,3-dihydrochromen-4-one
3	28.7	301	273, 179, 151, 107	quercetin

The maximum UV absorption wavelength of compound **II** (retention time = 24.4 min) is 293 nm, and the main ions found from the mass spectrum were at m/z 363, 331, and 299. The base ion at m/z 363 was of low abundance and may be unstable to readily lose a molecule of methanol (32 Da) to m/z 331. The neutral loss from m/z 331 to 299 could represent a second molecule of methanol. The following fragmentation pattern was analogous to that of compound **I**, giving rise to product ions at m/z 271, 179, and 151. Therefore, compound **II** might be the reaction product of oxidized quercetin incorporating two molecules of methanol, namely, 2-(3,4-dihydroxyphenyl)-3,5,7-trihydroxy-2,3-dimethoxy-2,3-dihydrochromen-4-one as previously identified by Hvattum et al.[20] In all, during the high-temperature baking process, quercetin was possibly degraded to very small molecules beyond detection of current LC/MS-MS methodology or transformed to unstable oxidized compounds, which readily react with methanol during extraction, forming compounds **I** and **II**.

In addition to degradation or oxidation loss of primary polyphenol structure carrying antioxidant activity, thermal processing likely favors reaction of phenolics with other nutritional components in cookie recipes, such as sugar fragments originated from caramelization and Maillard reaction, and thereafter affects the antioxidants' content.[2,21] Therefore, it seems to be necessary to consider the phenolics' thermal stability and reactivity in the food matrix when the food product is fortified with phenolics for the purpose of increasing the level of health-beneficial antioxidants.

Polyphenols Inhibit the Formation of Glycation Intermediates and Endproducts. The α-dicarbonyl compounds are important intermediate products originated from either sugar/lipid oxidation or thermal degradation of Schiff base or Amadori rearrangement products. GO and MGO are two major α-dicarbonyls that can react with amino groups on the protein backbone and contribute to the formation of AGEs.[10,22] The GO and MGO levels in model cookie control were 12.6 and 16.9 mg/kg, respectively, which are comparable to the values reported for commercial cookies.[10] Selected polyphenols, including tea catechins and theaflavins, chalcones represented by phloretin and phloridzin, stilbenes, and genistein, have been reported to trap these two reactive carbonyls in physiological conditions.[23] Our results suggested that under baking conditions, all five tested polyphenols were effective in reducing the amount of GO but not MGO in cookies (Figure 2). Furthermore, the inhibitory activity against glyoxal formation was positively correlated with polyphenols' antioxidant activity (R^2 = 0.975). This phenomenon led to a hypothesis that the inhibitory activity of tested phenolics against glyoxal formation during cookie baking might be attributable to the phenolics' free radical scavenging capability. Quercetin was most effective against fluorescent AGEs formation (>80% inhibition), followed by naringenin, rosmarinic acid, and epicatechin (Figure 2). Chlorogenic acid showed no significant inhibition.

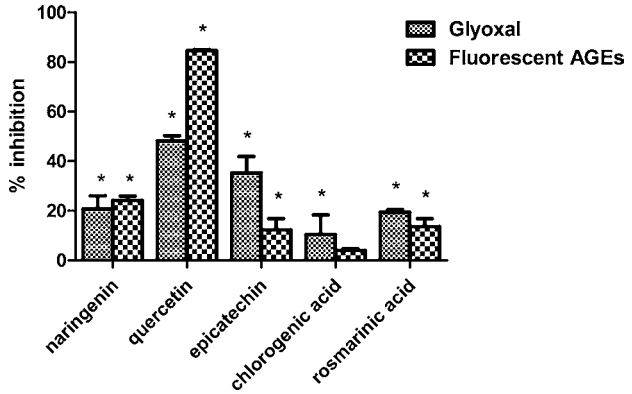

Figure 2. Inhibitory activity of polyphenols on the formation of glyoxal and fluorescent AGEs in a cookie model. Bars with an asterisk indicate significant difference from control ($P < 0.05$).

It has been suggested that the food ingredient profile has substantial effects on AGE formation and, compared with

sucrose, the lipid composition might play a more important role in AGE production in sponge cake.[7] The model cookie was rich in canola oil, which is a kind of edible oil containing a high proportion of unsaturated fatty acids including oleic acid, linoleic acid, and α-linolenic acid. Glyoxal is a prominent product of lipid peroxidation, and phenolics are able to inhibit lipid peroxidation via free radical scavenging capability. Therefore, it is likely that the tested dietary polyphenols reduced glyoxal generation by inhibiting lipid peroxidation. In agreement with earlier studies' viewpoints, the antiglycation effect of dietary polyphenols possibly relied on their free radical scavenging activity in the oxidative stage of glycation, when reactive carbonyl species are produced from sugar/lipid/Amadori product oxidation.[4,7]

In this paper, the antioxidant and antiglycation activities of five selected dietary polyphenols in a cookie model were discussed. Further to their potential to induce changes in cookies' color, pH, and moisture content, polyphenols were capable of increasing the health-beneficial antioxidants content in fortified cookies. The antiglycation activity of dietary polyphenols during cookie baking was indicated by lower levels of glyoxal and total fluorescent AGEs, which might be attributed to phenolics' free radical scavenging capacity. Compared with other tested polyphenols at the same mass-based fortification level, quercetin is suggested to be the most promising functional cookie additive given its significant promotion of antioxidant capacity together with strong inhibition against glycation toxicants formation.

The fate of dietary polyphenols during thermal food processing is of high research significance because the thermal conversion of chemical structure, which is associated with destruction of some primary compounds and introduction of many new compounds, would lead to alterations in foods' organoleptic properties and, more importantly, biological activities. The suggested reaction products of oxidized quercetin, for example, might be potential antioxidative and chemopreventive agents or in contrast be harmful to human health, which need further investigations. The current work suggests that during future functional food development by means of dietary polyphenol fortification before food processing, cautious measures are required to efficiently retain the primary chemical structure and the structure-associated health-beneficial bioactivities of polyphenols during thermal treatment; on the other hand, research efforts are expected elucidating the complex array of chemical conversions taking place during heating and characterizing the structure and bioactivity of reaction products formed.

Table 1. Composition of Mixtures Prepared from Milk and 10 mg/mL NaCas−Thymol Dispersions Used in Anti-Listerial Experiments

	volume of constituents (mL)			fat content of mixture (%)	overall thymol concentration (mg/mL)
	milk volume and type	thymol dispersion	sterile water		
A	9, skim	1		<0.05	1
B	5.5, 2% reduced-fat	4.5		~1.14	4.5
C	4, full fat	4.5	1.5	~1.33	4.5
D	4.5, full fat	4.5	1	~1.49	4.5
E	5.5, full fat	4.5		~1.83	4.5
control	same volume and type of milk as in A−E		10 minus milk volume		

and milk. Milk with different fat contents was studied as model food systems to investigate the impacts of binding with proteins and lipids on antilisterial properties of thymol. To further understand the binding between thymol and milk components, the second objective was to characterize thymol content in the milk serum to correlate antimicrobial properties observed in growth media and milk.

MATERIALS AND METHODS

Chemicals. NaCas was purchased from Sigma-Aldrich Corp. (St Louis, MO). The product had a purity of over 90% w/w according to the vendor. Thymol (>99% purity), pyrene, and sodium azide were purchased from Sigma-Aldrich Corp. SSPS was a commercial product from Fuji Oil Corp. (Osaka, Japan). Ultrahigh temperature-processed skim milk, 2% reduced-fat milk, and full (3.3%) fat milk were products of Simple Truth Organic (San Diego, CA).

Encapsulation. NaCas was hydrated at 5% w/w in deionized water overnight at room temperature (21 °C). The pH of the solution was 6.8. Thymol was mixed in the NaCas solution at 0, 5, 10, 15, and 20 mg/mL. The mixture was homogenized at 15000 rpm for 2 min using a Cyclone I.Q. microprocessor homogenizer (VirTis Co., Gardiner, NY).

Determination of Encapsulation Efficiency in Transparent Dispersions. The concentration of thymol encapsulated by NaCas was determined by UV−vis. spectroscopy. The dispersions as prepared above were centrifuged at 6000*g* for 10 min (Minispin plus, Eppendorff, Hamburg, Germany). The upper transparent supernatant was transferred and diluted 100 (for dispersions prepared with 5 and 10 mg/mL thymol) or 200 (for dispersions prepared with 15 and 20 mg/mL thymol) times in volume using hexane. After vortexing for 5 min, the mixture was allowed to stand until two separate transparent phases formed. The upper organic phase was taken to measure the absorbance at 275 nm to determine thymol concentration based on a calibration curve established previously using standard solutions with 0.01−0.1 mg/mL thymol dissolved in hexane. Three independent emulsion replicates were measured. The encapsulation efficiency was calculated based on the total thymol (g) used in encapsulation, the mass in the transparent dispersion, and the amount truly dissolved (eq 1). To quantify the amount of thymol truly dissolved in water (not encapsulated in casein nanoparticles), the dispersion prepared with 10 mg/mL thymol was acidified to pH 4.6 using 6 M HCl to precipitate casein nanoparticles (with encapsulated thymol) and was centrifuged at 10000*g* for 5 min. The supernatant was filtered through a 0.22 μm polyvinyl difluoride filter (Fisher Scientific, Co., Pittsburgh, PA), then 300 μL of the permeate was mixed with 1.5 mL of hexane and the thymol concentration determined as above.

$$\text{encapsulation efficiency \%} = \frac{\text{dispersed thymol} - \text{dissolved thymol}}{\text{total thymol} - \text{dissolved thymol}} \times 100\% \quad (1)$$

Particle Size and ζ Potential. The hydrodynamic diameter (D_h) was measured using a Delsa Nano analyzer (Beckman Coulter, Atlanta, GA). Samples were diluted 30 times with 10 mM phosphate buffer at pH 7.0. The scattering angle was fixed at 165°. The ζ potential of thymol dispersion, SSPS, and their mixture at pH 3.0−7.0 was also measured using the Delsa Nano analyzer. The dispersion, prepared with 10 mg/mL thymol, was diluted 100 times to a casein concentration of 0.05% using deionized water and adjusted to pH 3.0−7.0 using 1 and 0.25 M HCl. Solutions with 0.05% w/v SSPS and the mixture of the thymol dispersion and SSPS with same biopolymer concentrations at pH 3.0−7.0 were prepared similarly for ζ potential measurements.

Atomic Force Microscopy (AFM). The topography of NaCas nanoparticles before and after encapsulation of thymol was characterized using AFM. A 5% w/w NaCas dispersion and the dispersion prepared with 10 mg/mL thymol were diluted to a NaCas concentration of 10 mg/L using deionized water. Then 10 μL of each diluted sample was spread evenly onto a freshly cleaved mica sheet mounted on a sample disk (Bruker Corp., Santa Barbara, CA). A rectangular cantilever having an aluminum reflective coating on the backside and a quoted force constant of 2.80 N/m (FESPA, Bruker Corp.) were used on a Multimode VIII microscope (Bruker AXS, Billerica, MA). The tapping mode was used to scan the sample, and topography images were generated with a preset scan area of 2.0 μm × 2.0 μm at a scanning speed of 1 Hz.

Storage Stability. The storage stability of dispersions prepared with 0, 5, and 10 mg/mL thymol was determined by measuring the D_h during storage at room temperature (21 °C) for 30 d. The dispersion without thymol was added with 0.02% w/w sodium azide to prevent microbial spoilage.

Stabilization of Dispersions at pH 4.6 Using SSPS. The dispersion prepared with 5% NaCas and 10 mg/mL thymol was diluted to a NaCas concentration of 0.25% and mixed with 0−0.5% SSPS. The pH was adjusted to 4.6 with 0.25 M HCl. Samples were heated at 88 °C for 2 min, and the absorbance was measured at 400 nm as an indicator of turbidity before and after heating, with deionized water as the blank.

Fluorescence Spectroscopy. The interactions between thymol and NaCas were studied by fluorescence spectroscopy using a spectrofluorometer (model RF-1501, Shimadzu Corp., Kyoto, Japan). Briefly, thymol stock solution was prepared at 1.0% w/v in 95% aqueous ethanol and was diluted to 0−7.5 mg/L (10−50 μM) in 0.01 mg/mL aqueous NaCas (pH 7.0) and incubated at room temperature (21 °C) for at least 2 h before measurement. Fluorescent spectroscopy was carried out with excitation wavelength of 280 or 295 nm and emission spectra were recorded from 290 to 550 nm. The slit width for excitation and emission was set at 10 nm. The fluorescence intensity of thymol dissolved in 10% aqueous ethanol was used as background fluorescence for calibrating the spectra. Three replicates were performed at each condition.

Minimum Inhibitory Concentration (MIC) and Minimum Bactericidal Concentration (MBC) of Encapsulated Thymol. An antimicrobial microbroth dilution assay in 96-well microtiter plates was used to determine the MIC and MBC of encapsulated and free thymol against *L. monocytogenes* Scott A.[15,16] *L. monocytogenes* strain was from the culture collection of the Department of Food Science and Technology at the University of Tennessee. The stock *L. monocytogenes* culture, stored in glycerol at −20 °C, was transferred in tryptic soy broth (TSB) at 32 °C for two consecutive days to activate bacteria. *L. monocytogenes* was grown for 18 h in TSB at the

dx.doi.org/10.1021/jf4055402 | J. Agric. Food Chem. 2014, 62, 1649−1657

same temperature before use and diluted in TSB to ca. 7 log CFU/mL as a working culture. Free thymol stock solution was prepared in 95% ethanol at a concentration of 100 mg/mL, which was then diluted to 4 mg/mL with TSB as the working solution. The 4 mg/mL working solution was further diluted in TSB to 0.1−2 mg/mL thymol with 0.1 mg/mL increments. Thymol (10 mg/mL) encapsulated in NaCas was prepared and diluted to the same range as free thymol. The diluted thymol or thymol−NaCas samples (120 μL) were mixed with 120 μL of the working culture in the 300 μL wells of the microtiter plate, resulting in overall thymol concentrations of 0.05−1 mg/mL. Microtiter plates were then incubated at 32 or 21 °C for 24 h. The MIC was determined as the lowest thymol concentration that produced no visible growth.[15,16] To determine the MBC, 20 μL of the culture broth from each well showing no visible growth was transferred onto tryptic soy agar plates and incubated for another 48 h at 32 or 21 °C. The lowest concentration of thymol corresponding to the complete absence of *L. monocytogenes* growth on the agar surface was defined as the MBC. Experiments were performed in triplicate using three independent fresh working cultures.

Antilisterial Activity of Thymol in Milk with Different Fat Levels. Fat content is a dominant parameter impacting the effectiveness of lipophilic antimicrobials in milk.[17] Skim, 2% reduced fat, or whole milk were mixed with different volumes of the 10 mg/mL aqueous NaCas−thymol dispersion and sterile water to a total volume of 10 mL to obtain different fat levels (Table 1) so that the findings can be applied not only in fluid milk but also other dairy and relevant products with varying fat contents. Because liquid thymol dispersion was used to mix milk, it was not possible to simulate full fat (3.3%) milk. The overall concentration of thymol was 1 mg/mL in skim milk and 4.5 mg/mL in other milk treatments. These two concentrations were chosen because preliminary experiments showed complete inhibition of *L. monocytogenes* in skim milk within 4 h by 4.5 mg/mL of both free and encapsulated thymol, with no recovery in 7 days, while 1 mg/mL thymol in milk with 1% or higher fat corresponded to no inhibition of *L. monocytogenes*. For free thymol, thymol crystals were weighed and added directly into the milk at the same concentrations as the encapsulated thymol (Table 1). Sterile water was used to make up the total volume of 10 mL, followed by mixing using an end-to-end shaker for 30 min at room temperature. The 100 μL working culture with ca. 8 log CFU/mL *L. monocytogenes* was inoculated in the final milk mixture to an overall population of ca. 6 log CFU/mL using the method described previously.[18] After incubation at room temperature (~21 °C) for up to 7 d, *L. monocytogenes* was enumerated using the tryptic soy agar pour plating method with a detection limit of 1 log CFU/mL. Experiments were performed in triplicate using three independent fresh working cultures.

Quantification of Thymol Dissolved in the Aqueous Phase of Milk. The amount of thymol dissolved in the aqueous phase of milk was quantified as follows. Free thymol and encapsulated thymol samples were prepared in milk as described above except that the 0.1 mL of bacterial culture was replaced with 0.1 mL of deionized water. After incubation at room temperature (21 °C) for 0 and 48 h, samples were adjusted to pH 4.6 using 6 M HCl to precipitate caseins, followed by centrifugation at 10,000*g* for 5 min and filtration of the supernatant through a 0.22 μm polyvinyl difluoride membrane filter. The 300 μL of permeate was mixed with 1.5 mL of hexane to determine thymol concentration using the procedures described previously. Duplicate samples were measured.

Solubility of Thymol in Water at Room Temperature. The solubility of thymol in water was measured by adding an excess amount of thymol crystals to deionized water (2 mg/mL). After stirring overnight at room temperature (21 °C), the aqueous phase with dissolved thymol was mixed with hexane to determine thymol concentration, as described above. Two independent sample replicates were tested.

Statistical Analysis. Statistical analyses were performed using the JMP program (JMP Statistical Software, SAS Institute, Cary, NC). One-way analysis of variance was carried out. Differences between means were determined using a Fisher's least significant difference test. The significance level was set at 0.05.

RESULTS AND DISCUSSION

Encapsulation Efficiency. Transparent samples were observed after homogenizing thymol at overall concentrations of 5 and 10 mg/mL, which was well above its water solubility at 21 °C (0.75 mg/mL). Conversely, thymol crystals were visible after homogenization at overall thymol concentrations of 15 and 20 mg/mL (not shown), which indicated that 5% w/v NaCas reached its encapsulation capacity under the conditions studied. The dissolved thymol concentration determined in the transparent dispersion with 10 mg/mL thymol was 0.74 mg/mL, similar to the water solubility of thymol crystals. The efficiency of encapsulating thymol in transparent dispersions was determined according to eq 1 and listed in Table 2. There was no significant difference between samples with 5 and 10 mg/mL thymol, with encapsulation efficiency of 89% and 92.3%. The encapsulation efficiency as determined decreased to around 72% when thymol was emulsified at overall concentrations of 15 and 20 mg/mL.

Table 2. Encapsulation Efficiency of Dispersions Prepared with 5% w/v NaCas and Different Thymol Concentrations

overall thymol concentration (mg/mL)	encapsulation efficiency (%)[a]
5	89.0 ± 3.1[a]
10	92.3 ± 2.2[a]
15	72.1 ± 1.4[b]
20	72.4 ± 1.3[b]

[a]Numbers are mean ± standard deviation from triplicate samples. Different superscripts indicate differences in the means ($P < 0.05$).

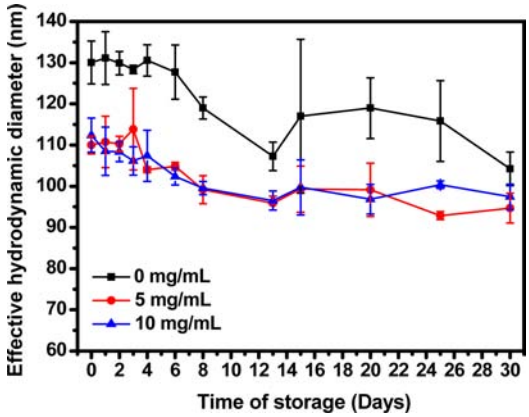

Figure 1. Effective hydrodynamic diameter of 5% w/v sodium caseinate dispersions homogenized with 0, 5, and 10 mg/mL thymol during storage at room temperature (21 °C).

Physical Properties of Transparent Dispersions. Because thymol was not completely encapsulated at an overall concentration of 15 and 20 mg/mL, only samples with 5 and 10 mg/mL thymol were characterized for storage stability. The D_h of transparent dispersions prepared with 5 and 10 mg/mL thymol during storage at room temperature for 30 days is shown in Figure 1. There was no significant increase of D_h during storage. The D_h of NaCas, also sheared at homogenization conditions, was around 130 nm, and the dispersion after encapsulating 5 or 10 mg/mL thymol had a D_h of about 110 nm. The smaller dimension of casein particles after encapsulation was also observed in AFM (Figure 2). The smaller dimension of particles measured in AFM than D_h may be the result of drying of particles during sample preparation

dx.doi.org/10.1021/jf4055402 | J. Agric. Food Chem. 2014, 62, 1649−1657

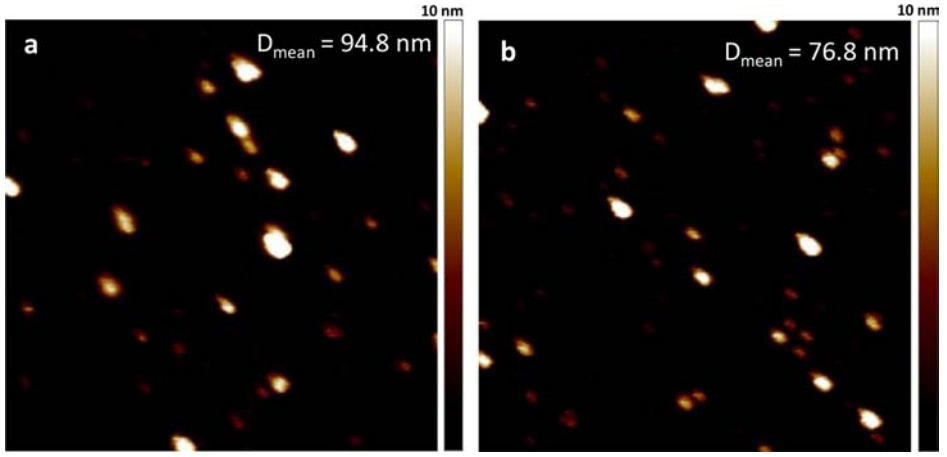

Figure 2. AFM topography images of NaCas (a) without or (b) with thymol. The dispersion was prepared with 10 mg/mL thymol and 5% NaCas before dilution for AFM. The NaCas only dispersion was also homogenized before dilution for AFM. Mean diameter of the particles was measured using the instrument software. Image dimension is 2 μm × 2 μm. The scale on the right is for particle height.

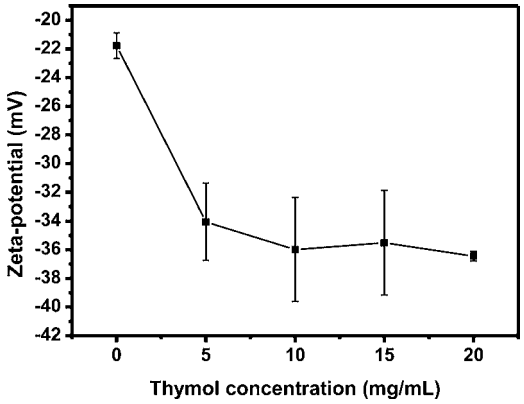

Figure 3. ζ potential of the dispersions prepared with 5% NaCas and different concentrations of thymol at pH 7.0. The dispersions were centrifuged, and the supernatant was collected and diluted before measurement.

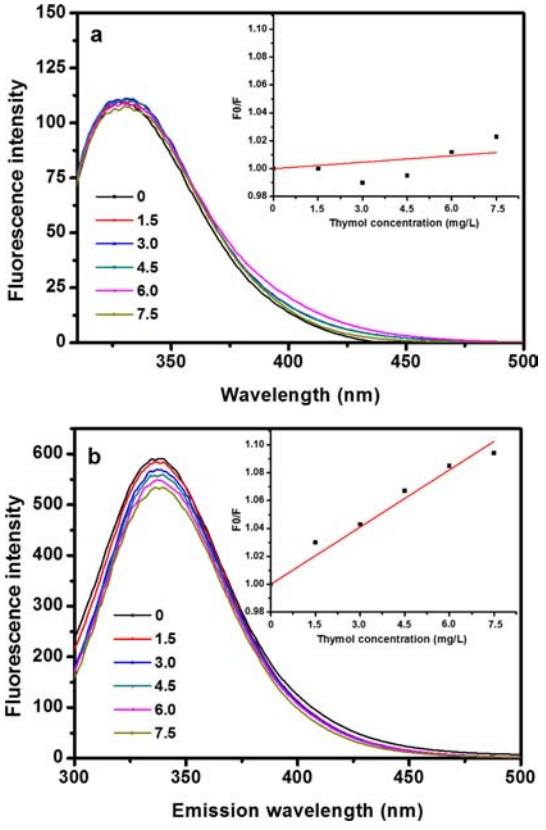

Figure 4. Fluorescence emission spectra of NaCas at excitation wavelength of (a) 295 nm and (b) 280 nm in 10 mM phosphate buffer at pH 7.0, after interacting with 0−7.5 mg/L (0−50 μM) thymol. The plot of F_0/F versus thymol concentration is shown in the inset, with the lines showing the linear fit of data with an intercept of 1.

for AFM. The reduction of casein nanoparticle dimension after encapsulation with thymol may be the result of enhanced packing of casein molecules due to hydrophobic attraction by thymol. Furthermore, the stable D_h during storage indicates the insignificance of Ostwald ripening as has been observed by others for dispersions prepared with small-molecule surfactants like Tween 80.[19]

NaCas dispersions with thymol had a much higher magnitude of ζ potential when compared with NaCas alone, and the thymol concentration did not affect the ζ potential significantly (Figure 3). The p*I*s of α_{s1}-, α_{s2}-, β-, and κ-casein are 4.94, 5.23, 5.14, and 5.90, respectively, with respective net charges of −21.9, −17.1, −13.3, and −2.0 at pH 6.6. [20] Theoretically, a more negative ζ potential is expected for smaller casein particles because of a smaller quantity of κ-casein per particle. The ζ potential results in Figure 3 therefore agree with this expectation based on particle dimension (Figures 1 and 2). The high magnitude of ζ potential can prevent particle aggregation during storage (Figure 1).

Interactions between Thymol and NaCas. Binding between proteins and small molecules in aqueous solutions can be conveniently studied using intrinsic fluorescence properties of proteins.[13] Figure 4 shows the emission spectra of NaCas with different concentrations of thymol. Figure 4a shows little change of the fluorescence intensity of NaCas after interacting with various amounts of thymol at the excitation wavelength of 295 nm, which reflects the binding near tryptophan (Trp) residues.[21] Conversely, the fluorescence intensity of NaCas excited at 280 nm, due to both Trp and tyrosine (Tyr) residues,[21] decreased with an increase in thymol concentration (Figure 4b). Therefore, thymol binds with caseins at Tyr or other residues away from Trp of caseins, effectively quenching the fluorescence excited at 280 nm.

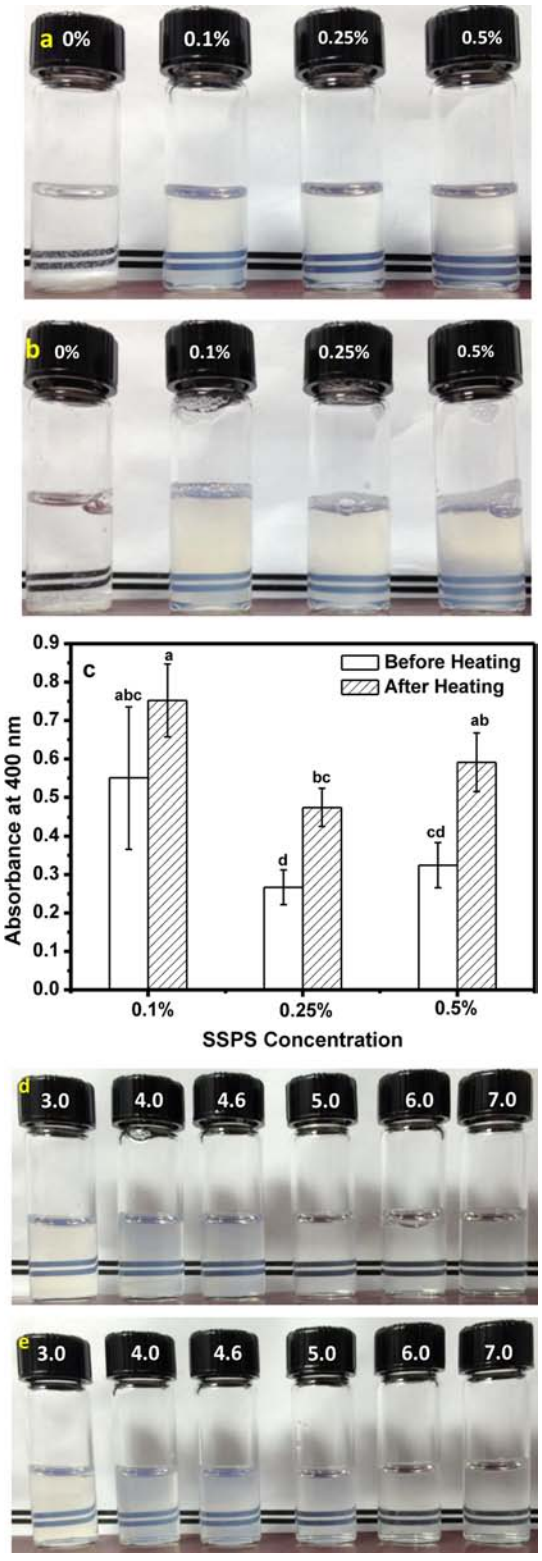

Figure 5. Appearance of thymol-containing dispersions containing 0.25% NaCas, diluted from the dispersion prepared with 5% NaCas and 10 mg/mL thymol, with 0%, 0.1%, 0.25%, and 0.5% SSPS (as labeled on vial caps) at pH 4.6, (a) before and (b) after being heated at 88 °C for 2 min. The absorbance at 400 nm is shown in panel (c), where different letters above bars indicate significant difference ($P < 0.05$) in the mean. Photos (d) and (e) show the respective samples, with 0.25% NaCas and 0.25% SSPS adjusted to pH 3.0–7.0 before and after heating at 88 °C for 2 min.

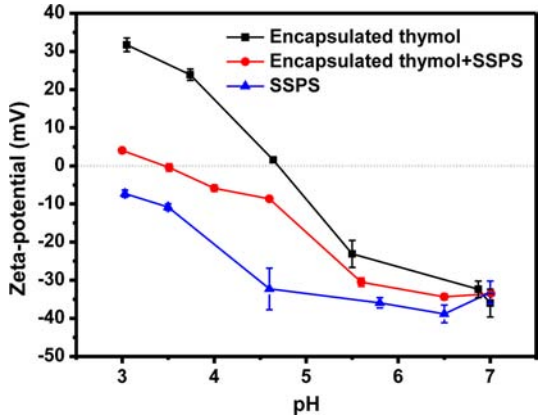

Figure 6. ζ potential of thymol dispersion, SSPS, and their mixture (with equal mass of NaCas and SSPS) at pH 3.0–7.0.

The intrinsic fluorescence was further analyzed using the Stern–Volmer equation[22]

$$F_0/F = 1 + k_q \times \tau_0 \times [Q] = 1 + K_{sv} \times [\text{thymol}] \quad (2)$$

where F_0 and F are fluorescence intensities in the absence and presence of a quencher, [Thymol] is the concentration of thymol (M), k_q is the fluorescence quenching rate constant, τ_0 is the lifetime of fluorophore fluorescence in absence of quenchers and equals 10^{-8} s, and K_{sv} is the Stern–Volmer quenching constant which can be determined by linear fit of F_0/F plot against [Thymol].[23] The linear plots of F_0/F as a function of [Thymol] excited at 295 and 280 nm are given in the inset of parts a and b of Figure 4, respectively. The good linear fit of data to eq 2 ($R^2 > 0.99$) showed the applicability of the Stern–Volmer model, and the obtained K_{sv} values were 100 ± 212 M^{-1} and 1900 ± 141 M^{-1} at the excitation wavelength of 295 and 280 nm, respectively. The K_{sv} at excitation wavelength of 295 nm is not statistically different from 0 ($P > 0.05$), which indicates no interactions between thymol and Trp. Fluorescence quenching can result from collision (dynamic quenching) or complex formation (static quenching) between biopolymers and quenchers.[22] The k_q at excitation wavelength of 280 nm is 1.9×10^{11} M^{-1} s^{-1}, which is about 10-fold higher than the maximum dynamic quenching constant (2×10^{10} M^{-1} s^{-1}) for quenchers interacting with biopolymers.[24] The results suggest the fluorescence quenching is static, and therefore complexes are formed when thymol binds with caseins at low NaCas concentrations.

Stabilization of Thymol Dispersions at pH 4.6 Using SSPS. The dispersion prepared with 10 mg/mL thymol was diluted to an overall NaCas concentration of 0.25% w/v and mixed with 0–0.5%w/v SSPS. After adjusting to pH 4.6, samples were heated at 88 °C for 2 min, equivalent thermal processing conditions for acidic beverages (pH < 4.6),[25] and the absorbance at 400 nm before and after heating was measured to indicate turbidity (presented in Figure 5). Without SSPS, the dispersion showed precipitation both before and after heating. With 0.1–0.5% SSPS, dispersions were stable before and after heating. The dispersion with 0.1% SSPS had higher absorbance than the other two SSPS treatments (Figure 5c), possibly because of insufficient SSPS to prevent particle aggregation. There is no significant difference ($P > 0.05$) between the dispersions with 0.25% and 0.5% SSPS, which indicates SSPS is able to stabilize equal mass of NaCas at pH 4.6.

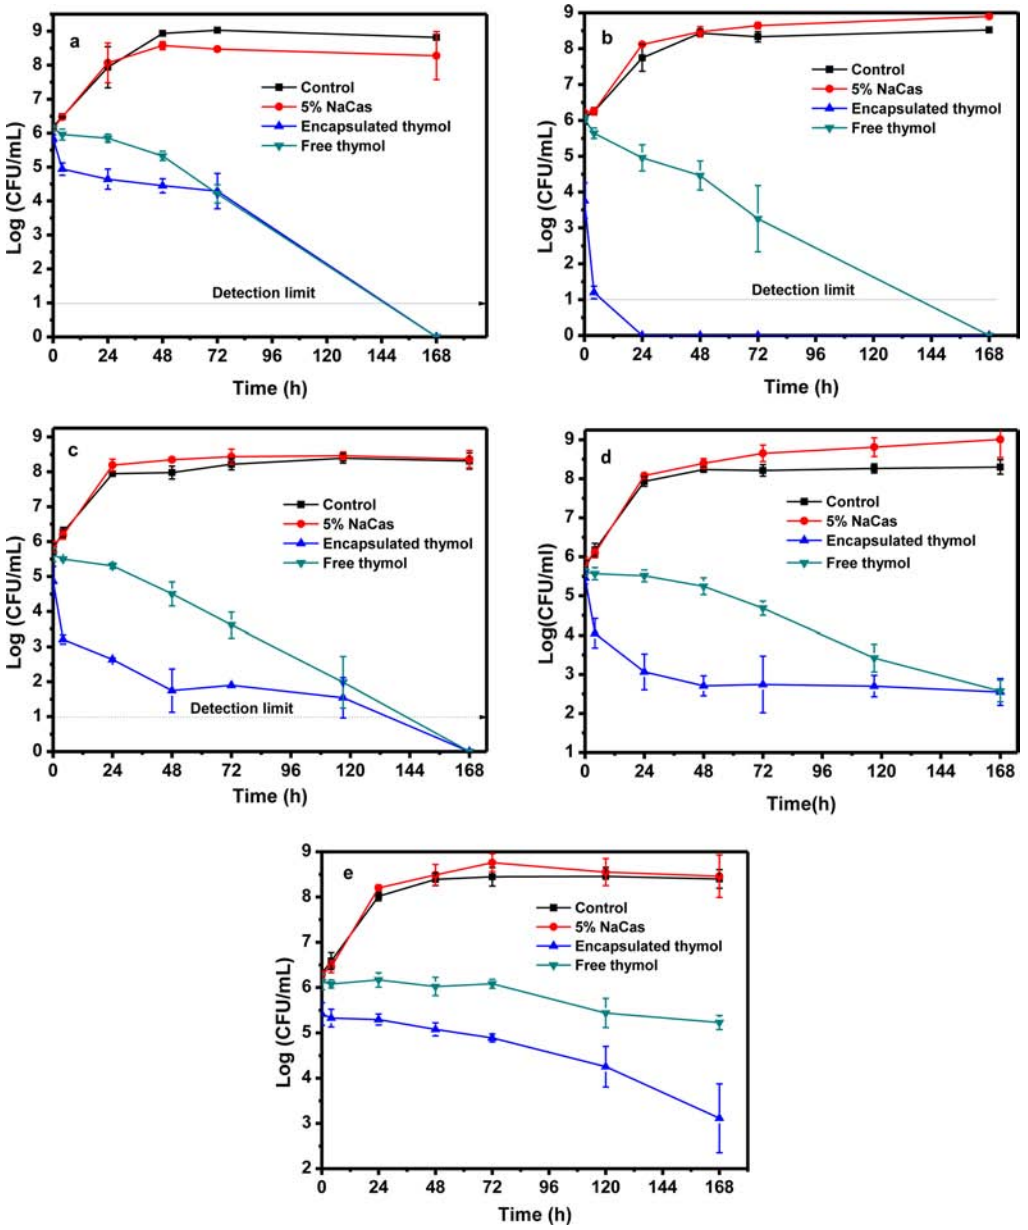

Figure 7. Growth of *Listeria monocytogenes* Scott A in milk prepared to different fat levels at room temperature (~21 °C) treated by different concentrations of free or capsulated thymol: (a) 1 mg/mL thymol in skim milk; 4.5 mg/mL thymol in milk with (b) 1.14%, (c) 1.33%, (d) 1.49%, and (e) 1.83% fat. Milk compositions are listed in Table 1. The control was the treatment with milk added with sterile water and culture only. The 5% NaCas treatment was conducted by adding 5% NaCas solution at the same volume as encapsulated thymol into milk. Error bars are standard deviations (n = 3).

The forces stabilizing colloidal particles from aggregation include electrostatic and steric repulsions.[12,26] At neutral pH, caseins are highly negatively charged and electrostatic repulsion itself is strong enough to prevent particle aggregation, as indicated in Figure 1 for stable D_h during storage. To understand the stabilization of dispersions by SSPS at pH 4.6, the ζ potential of SSPS, the thymol dispersion, and their mixture at pH 3.0−7.0 was measured and is presented in Figure 6. The lowest ζ potential magnitude of thymol dispersion was observed at around pH 4.6, the pI of caseins and the weakened electrostatic repulsion caused the aggregation and precipitation of casein capsules, as discussed above. The ζ potential of SSPS alone was negative at pH 3.0−7.0, with a smaller magnitude at a lower pH. After mixing thymol dispersion with SSPS, the ζ potentials were in between the individual components, with the magnitude being close to zero at pH 3.5, suggesting complex formation between SSPS and casein particles.[14] Because dispersions were stable at pH 3.0−7.0, even after heating at 88 °C for 2 min (Figures 5d and 5e), both electrostatic and steric interactions contributed to the stability of mixture system, with steric interactions being dominant at acidity near the pI of caseins. Therefore, SSPS stabilized thymol dispersions similarly to acidified milk by providing steric repulsion after adsorbing on free casein or casein-coated thymol particles,[14] as discussed previously. This enables the application of casein-based encapsulation systems in various acidic conditions.

Antilisterial Properties and Correlation to Solubility. The MICs and MBCs of free and encapsulated thymol against *L. monocytogenes* were 0.2 and 0.3 mg/L, respectively, at both 21 and 32 °C. These concentrations are below the water

dx.doi.org/10.1021/jf4055402 | J. Agric. Food Chem. 2014, 62, 1649−1657

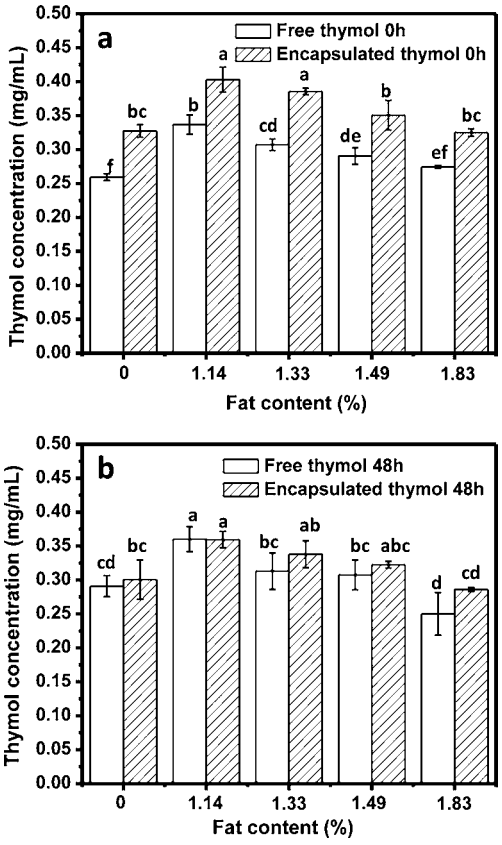

Figure 8. Concentration of thymol in the continuous phase of model milk systems with different fat contents after (a) 0 h and (b) 48 h at room temperature (21 °C). Different letters above bars indicate significant difference ($P < 0.05$) in the mean.

solubility limit of 0.75 mg/mL, and the similar MIC and MBC of encapsulated and free thymol suggest that the binding between thymol and caseins does not affect the activity of thymol interacting with bacteria. Similar results were previously reported for thymol against *Staphylococcus aureus* ATCC 25923 and *Escherichia coli* ATCC 25922 after encapsulation in methylcellulose/ethylcellulose.[27]

Figure 7 presents the growth activity of *L. monocytogenes* in milk with different fat levels in the presence of free and encapsulated thymol. The *L. monocytogenes* growth curves were similar for the control (no treatment) and NaCas control, indicating that NaCas alone has no antimicrobial activity. In skim milk (Figure 7a), encapsulated thymol has slightly better antilisterial activity (ca. 1 log CFU/ml) than free thymol in the first 48 h, while no difference was observed at 72 or 168 h. The concentration of thymol in the aqueous phase of milk at 0 h was significantly higher for encapsulated thymol than for free thymol (Figure 8a). The delay in antilisterial activity of free thymol may be due to the slow dissolution process of thymol from crystals compared to the encapsulated form that enabled faster distribution into the milk matrix.[28] The concentration of thymol (1 mg/mL) required to inhibit *L. monocytogenes* in skim milk is higher than the MIC and MBC of free and encapsulated thymol in TSB. Furthermore, the respective thymol concentration in the aqueous phase of skim milk at 0 h was 0.26 to 0.33 mg/mL for free and encapsulated thymol, which was much lower than the water solubility of 0.75 mg/mL, and reduced after 48 h (Figure 8a). This suggests that the reduced thymol activity in skim milk is due to binding by proteins and fat globules (<0.5% in skim milk).

To study effects of fat content on antilisterial properties, 4.5 mg/mL thymol was added to milk adjusted to 1.1−1.8% fat (Table 1). As shown in Figure 7b−e, the inactivation of *L. monocytogenes* was slower at a higher fat level and the encapsulated thymol consistently reduced the *L. monocytogenes* population to a lower level in a shorter time than free thymol. With 1.14% (Figure 7b) and 1.33% (Figure 7c) fat, both free and encapsulated thymol reduced *L. monocytogenes* to below the detection limit of 1 log CFU/mL in 168 h. With 1.49% fat (Figure 7d), *L. monocytogenes* was reduced to about 2.5 log CFU/mL in 168 h by free and encapsulated thymol. The greater than 3 log reduction after 48 h in milk with 1.14−1.49% fat is in agreement with thymol concentrations in the milk serum higher than the MBC (0.3 mg/mL) at both 0 and 48 h (Figure 8). At 1.83% fat (Figure 7e), the encapsulated and free thymol used at an overall concentration of 4.5 mg/mL was detected at 0.28 and 0.25 mg/mL in the aqueous phase of milk (Figure 8b), respectively, at 48 h. Because these concentrations were above the MIC (0.2 mg/mL) but below the MBC (0.3 mg/mL), inactivation of *L. monocytogenes* to a lesser extent was observed than in milk with lower fat levels, with the encapsulated thymol being more effective (Figure 7e).

Figures 7 and 8 indicate the significant effects of fat on the activity of hydrophobic antimicrobials like thymol. The antimicrobial activity of hydrophobic essential oil components is enabled after dissolution in phospholipids of the bacterial cell membrane to a sufficient quantity to result in substantial changes in membrane structures and cell metabolism.[29] The cell membrane of bacteria is covered by structures including peptidoglycan that can prevent the direct access of caseins and thymol enclosed in nanocapsules. Therefore, only the truly dissolved thymol may be able to diffuse into the cell membrane. For thymol binding with/encapsulated in caseins, the partitioning to the continuous water phase is expected, which is expected to further partition with bacterial cells. Because bacterial cells have phospholipids that are more hydrophobic than water-soluble caseins, the partitioning of lipophilic thymol to bacteria may be more favorable than binding with caseins and may become irreversible because of the much higher polarity of the continuous water phase. This may have resulted in the same MIC (0.2 mg/mL) and MBC (0.3 mg/mL) of free and encapsulated thymol, both of which are well below the water solubility of thymol (0.75 mg/mL). For the dispersion with 10 mg/mL thymol, the amount of truly dissolved thymol (after precipitation of casein capsules at pH 4.6, eq 1) is 0.74 mg/mL, which is close to the water solubility, while the rest is being dissolved/dispersed in casein nanocapsules. When the thymol dispersion is mixed with milk, the truly dissolved thymol is expected to decrease and the encapsulated thymol is again expected to be partitioning with the continuous water phase. The dissolved thymol also can diffuse into porous casein micelles[30] and bind with fat globules in milk. Analogous to bacterial cells, fat globules in milk are covered by membranes composed of phospholipids and proteins,[31] may be more favorable than caseins and water phase, and therefore reduce the amount of thymol that can potentially be dissolved in the continuous water phase and subsequently the bacterial membrane. For skim milk (with <0.5% fat), the impacts of binding by fat globules are not as significant, as 1 mg/mL thymol, ∼3 times higher than the MBC (0.3 mg/mL), is sufficient to inhibit *L. monocytogenes* (Figure 7a). As fat

concentration increases in milk, the binding by fat globules becomes more and more significant, reducing the amount of truly dissolved thymol (Figure 8) and therefore antilisterial activity (Figure 7) despite the higher overall thymol usage level (4.5 mg/mL). Findings from the present study agree with the speculations based on physics and mass transport.[28,32]

In conclusion, 5%w/v NaCas enabled the encapsulation of 1% w/v thymol as transparent dispersions that were stable at neutral pH during 30-day storage at room temperature. The encapsulation reduced the dimension of NaCas and increased the ζ potential. Thymol selectively binds with Tyr and possibly other amino acids not close to Trp of NaCas based on fluorescence spectroscopy. Under acidic conditions, the adsorption of SSPS on thymol-loaded casein particles provided steric repulsion and effectively prevented the aggregation and precipitation of casein capsules, even at pH 4.6. Lastly, encapsulation of thymol in casein nanocapsules enabled the fast and even distribution and increased the solubility and antilisterial activity of lipophilic antimicrobials in milk with different fat levels. Findings from the present study indicate the potential of the studied antimicrobial delivery system to improve the microbiological safety of complex food matrices such as Spanish cheeses.

Bacterial Cultures and Materials. *S. thermophilus* NBRC 13957 (National Institute of Technology and Evaluation Biological Resource Center, Chiba, Japan) and the commercially available lactic acid bacteria starter culture, YO-MIX505, from Danisco USA Inc. (Wilmington, DE, USA) were used in this study. The starter culture, which consisted of *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*, was freeze-dried and stored at −20 °C and was used according to the manufacturer's description. *S. thermophilus* NBRC 13957 was stored at −80 °C in an MRS broth with 30% (v/v) sterile glycerol and was cultured in an MRS broth for 16−24 h at 37 °C. The bacterial cells of *S. thermophilus* NBRC 13957 were washed twice with saline and were used for subsequent experiments. Commercially available pasteurized milk (Meiji Holdings Co., Ltd., Tokyo, Japan) and commercially available sterilized unprepared soymilk (Kikkoman Corporation, Tokyo, Japan) were used to produce fermented milk and soymilk, respectively. Soymilk whey solution was obtained from sterilized soymilk using a microfiltration module with a pore size of 1.0 μm (Asahi Kasei Chemicals Corp., Tokyo, Japan).

Fermentation Conditions. The commercially available starter culture, YO-MIX505, and *S. thermophilus* NBRC 13957 were cultured at 37 °C for 16 h in all the samples that were used in this study. A total of 128 mg of powdered YO-MIX505 starter was suspended in 5 mL of sterile water, and the 0.05% (v/v) of the starter solution was then inoculated into each sample. Casamino acids were sterilized as a 10% solution and then aseptically added to soymilk whey (final concentrations of 0.05%, 0.1%, and 0.5% (v/v)) before fermentation. Each amino acid solution (100 mM) was sterilized with filtration using 0.2 μm pore size membrane filter unit (Toyo Roshi Kaisha, Ltd., Tokyo, Japan) and then added to the soymilk whey to create a final concentration of 1.0 mM before fermentation.

Gas Chromatography and Mass Spectrometry Analysis. Ten grams of fermented soymilk whey samples were weighed into headspace vials, and 5.0 g of fermented soymilk was diluted with 5.0 g of sterile water and added to the headspace vials. Volatiles of each of the fermented products were equilibrated in the vials by heating for 20 min at 60 °C under strong agitation, and they were then injected onto a gas chromatography (GC) column with G1888 Network headspace sampler (Agilent Technologies, Inc., Santa Clara, CA, USA). The concentrations of diacetyl, acetoin, and acetoaldehyde in the fermented samples were quantified with the standard addition method with a HP 5973 mass spectrometry (MS) detector (Hewlett-Packard Company, Palo Alto, CA, USA). Briefly, four samples were prepared in the vials separately; next, each authentic preparation was added to each sample to result in the concentrations of 0, 1, 5, 10, and 20 ppm (v/v). The standard curve was prepared within the relative peak area against the concentration.

Isolation and Purification of Bacterial RNA. One milliliter of cultured soymilk whey with *S. thermophilus* NBRC 13957 was obtained in the middle of the logarithmic growth phase, and 2.0 mL of RNAprotect bacteria reagent (QIAGEN KK, Tokyo, Japan) was added. The cell pellets from the mixture of the cultured soymilk whey and the RNAprotect bacteria reagent were obtained by centrifugation at 8000*g* and 4 °C for 10 min, and the cell pellets were stored at −20 °C until RNA isolation. The cell pellets were lysed with lysozyme and proteinase K using an RNeasy Kit (QIAGEN KK) as per the manufacturer's instructions. Subsequently, RNA was isolated by phenol-chloroform extraction using TRIzol reagent (Life Technologies Corporation, Grand Island, NY, USA) in accordance with the manufacturer's instructions. The quantity and quality of isolated RNA were checked using a ND-1000 photospectrometer (Nanodrop Products, Wilmington, DE, USA), and RNA samples with an A260/A280 ratio over 1.8 and a clear two-peak (16S and 23S rRNA) pattern were included in the real-time quantitative polymerase chain reaction (RT-qPCR) analysis.

cDNA Synthesis and Real-Time Quantitative PCR. A total of 0.5 μg of total RNA was reverse transcribed into cDNA using a PrimeScript RT Reagent Kit (Takara Bio Inc., Shiga, Japan). Briefly, reverse transcription was performed in the Mastercycler gradient (Eppendorf AG, Hamburg, Germany) as follows: 37 °C for 15 min and 85 °C for 5 s in one cycle. The primers for the RT-qPCR were designed using the Primer 3 software (http://primer3plus.com) and are listed in Table 1. RT-qPCR was performed as per the following program: initial denaturation at 95 °C for 10 s, which was followed by 40 cycles of amplification at 95 °C for 5 s and at 60 °C for 20 s. The reaction mixture contained 2 μL of the reverse transcription product, 12.5 μL of SYBR *Premix Ex Taq* II (2×), 0.5 μL of ROX Reference Dye II (Takara Bio Inc.), 0.4 μL of forward primer (10 μM), 0.4 μL of reverse primer (10 μM), and 9.2 μL of RNase-free water. The reverse transcription product was replaced with RNase-free water for negative controls. Individual RT-qPCR was performed in triplicate for each gene.

Sensory Evaluation of Fermented Soymilk with Lactic Acid Bacteria. The sensory properties of fermented soymilk were evaluated with a method described previously.[14] Briefly, for the triangle difference test, a series of three samples were presented to nine untrained panelists. One sample was fermented soymilk alone; the other two samples were fermented soymilk with 1.0 mM L-valine. For the preference test, two samples with and without 1.0 mM of L-valine were prepared, and 30 untrained assessors selected the preferred sample. In each test, the panelists selected a sample based on sniffing alone. All samples were fermented with *S. thermophilus* NBRC 13957 at 37 °C for 16 h and were kept at approximately 10 °C. Each fermented soymilk sample was coded with three random digit numbers.

Statistical Analysis. The statistical significance of the differences between the experimental groups was determined with a two-tailed Student's *t*-test for unpaired data, with *P* values less than 0.05 considered significant.

RESULTS AND DISCUSSION

Comparison of the Flavor Components in Fermented Milk and Fermented Soymilk with Commercially Available Starter Culture. *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* are defined as yogurt starter strains by Codex Alimentarius. In milk, *S. thermophilus* grows and produces formic acid, folic acid, and carbon dioxide. *L. delbrueckii* subsp. *bulgaricus*, which has high proteolytic activity, grows simultaneously by consuming these organic acids and digests casein to produce peptides and amino acids, which are advantageous for the further growth of *S. thermophilus*.[15,16] These species establish a symbiotic relationship in milk and usually produce flavorful yogurt. However, in soymilk, only *S. thermophilus* can grow because *L. delbrueckii* subsp. *bulgaricus* cannot utilize sucrose, the main carbon source in soymilk. In other words, the mutual stimulation between these species does not occur during fermentation in soymilk.

To analyze the flavor difference between fermented milk and fermented soymilk, a commercially available starter culture, which contained only *S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*, was inoculated in crude unprepared ultrahigh

temperature treated milk and sterilized unprepared soymilk with the same fermentation conditions (37 °C, 16 h). The total ion chromatograms of fermented milk and fermented soymilk were obtained with the headspace sampler and GC-MS, as described in the Materials and Methods (Figure 1). Most of the

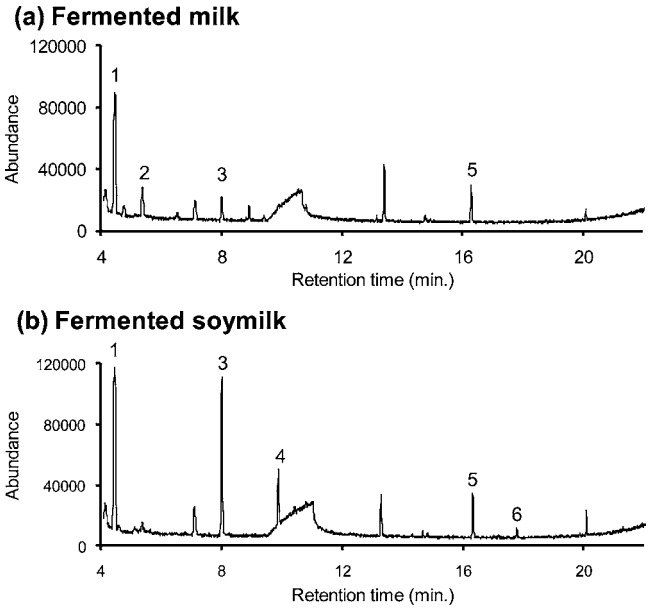

Figure 1. Total ion chromatograms of (a) fermented milk and (b) fermented soymilk with commercially available starter culture (*S. thermophilus* and *L. delbrueckii* subsp. *bulgaricus*) obtained from headspace gas chromatography−mass spectrometry. The fermentation conditions were the same (37 °C, 16 h). Each number in TIC indicates the following: (1) acetaldehyde, (2) acetone, (3) diacetyl, (4) 2,3-pentanedione, (5) acetoin, and (6) 1-hexanol.

flavors extracted, such as acetaldehyde, diacetyl, and acetoin, were qualitatively similar between fermented milk and fermented soymilk. However, the concentration of diacetyl was higher in fermented soymilk than in fermented milk, and 2,3-pentanedione was detected only in fermented soymilk. These compounds are vicinal diketones, and it is known that diacetyl has a much lower odor threshold than 2,3-pentanedione. Although these compounds are responsible for key aromas of dairy products,[17,18] the sensory test of this study suggested that the addition of a standard preparation of diacetyl, and not that of 2,3-pentanedione, contributed an unpleasant odor to fermented soymilk. In addition, it was suggested that the balance of the flavor compounds collapsed due to excess diacetyl production in fermented soymilk. In alcoholic beverages such as wine, beer, and Japanese sake, vicinal diketones, particularly diacetyl, contribute to off-flavors above a certain concentration.[19−22] We demonstrated that excess diacetyl could be one of the major off-flavors generated with *S. thermophilus* in fermented soymilk.

Influence of the Different Carbon Sources and Nitrogen Sources on Diacetyl Levels after Fermentation by *S. thermophilus* NBRC 13957 in Milk and Soymilk. To produce flavorful fermented soymilk, we first attempted to determine how diacetyl was excessively produced by *S. thermophilus* in soymilk. The main carbon sources of milk and soymilk are lactose and sucrose, respectively. Excess diacetyl was not detected in fermented milk. Thus, sucrose may have induced the generation of diacetyl by *S. thermophilus*. We measured the concentration of diacetyl was produced in a chemically defined medium whose carbon source was sucrose or lactose. The approximate amount of diacetyl generated was detected in both media (data not shown). Therefore, it was suggested that the diacetyl levels generated by *S. thermophilus* did not depend on the carbon source. Next, we focused on the differences in the nitrogen source between soymilk and milk. Previous reports have shown that *S. thermophilus* grows in milk by utilizing the peptides and amino acids derived from the proteolysis of casein by *L. delbrueckii* subsp. *bulgaricus*. However, the proteolytic activity of *L. delbrueckii* subsp. *bulgaricus* would be restricted in soymilk because it has no capability of growing in soymilk due to the carbon source. Therefore, it was hypothesized that free amino acids formed in the hydrolysis of casein are important for regulating the generation of diacetyl by *S. thermophilus*. On the basis of this hypothesis, we investigated the effects of casamino acid supplementation on the generation of diacetyl. In this experiment, we used soymilk whey instead of soymilk itself because we found that *S. thermophilus* could grow in soymilk whey and that it generated approximately the same amount of diacetyl compared to that in soymilk itself (data not shown). Therefore, it was suggested that insoluble soy proteins, such as 7S globulin and 11S globulin, were not implicated in the production of diacetyl by *S. thermophilus*. Ten percent of casamino acid solution was supplemented in the soymilk whey to produce a final concentration of 0.05%, 0.1%, and 0.5%, and diacetyl levels were then investigated in the cultured soymilk whey with *S. thermophilus*. As a result, the concentration of diacetyl in fermented soymilk whey with 0.05% casamino acids added was significantly decreased compared with that in fermented soymilk alone. In addition, fermented soymilk whey with 0.5% casamino acids had significantly lower diacetyl levels than the others (Figure 2). These results indicated that casamino acids had an effect on diacetyl production during fermentation by *S. thermophilus* although they were not sources of carbon.

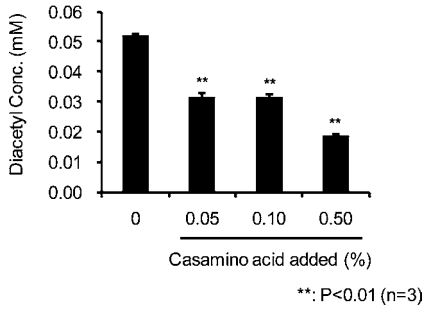

Figure 2. Evaluation of the diacetyl concentrations in fermented soymilk whey with each concentration of casamino acid added. The error bars indicate the standard deviations (SD) of the triplicate samples of the experiments. The statistical significance comparing the results from each concentration of casamino acid added to no casamino acid added is indicated (**$P < 0.01$). The error bars indicate the SD of the triplicate samples of experiments.

Influence of the 20 Essential Amino Acids on Diacetyl Levels after Lactic Acid Fermentation by *S. thermophilus*. The addition of casamino acids in soymilk whey had some impact on decreasing the diacetyl levels during fermentation. Therefore, to understand which amino acid mainly regulated diacetyl levels, each of the 20 essential amino acids was

separately added to soymilk whey to produce a concentration of 1.0 mM. Of the 20 amino acids added, L-valine had a strong effect on decreasing the diacetyl levels in fermented soymilk whey (Figure 3). L-Cysteine, L-threonine, L-tryptophan, L-

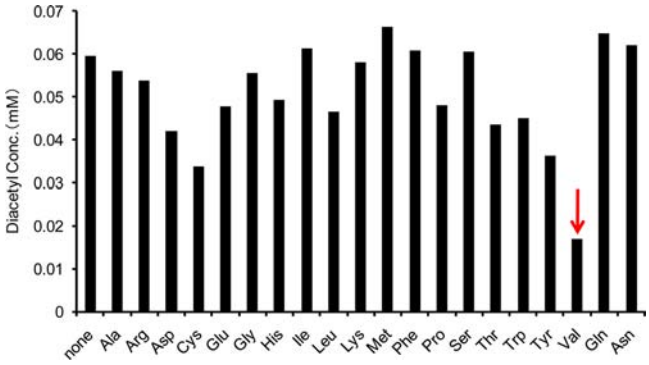

Figure 3. Concentration of diacetyl (mM) in soymilk whey fermented with *S. thermophilus* in the presence of 1.0 mM of each amino acid.

leucine, and L-tyrosine also had small effects on reducing diacetyl. The other amino acids did not any influence diacetyl levels. In previous studies, it has been reported that the supplementation of L-valine regulates the production of diacetyl due to the inhibition of 2-acetolactate synthase and the activation of acetolactate decarboxylase in *Escherichia coli*.[23,24] In addition, Ott et al. suggested an interconnection between the metabolism of L-valine and diacetyl in lactic acid bacteria.[25] The results of this study supported the findings of these reports.

Gene Expression Analysis of Metabolic Enzymes Related to the L-Valine Metabolic Pathway. Next, to investigate the effects of L-valine on the decline of diacetyl levels in fermented soymilk whey, the levels of expression of the *als*, *aldB*, and *ilvC* genes of *S. thermophilus* NBRC 13957 were examined with and without L-valine added in the middle of the exponential growth phase. The proposed schematic of the metabolic pathways involved in the biosynthesis of L-valine and diacetyl is shown in Figure 4. First, pyruvate is converted to α-acetolactate, which is an unstable compound. Then α-acetolactate is decarboxylated to diacetyl in the presence of oxygen without any enzymatic activity. With the addition of 1.0 mM of L-valine, the levels of expression of the *als* and *aldB* genes were significantly increased (Figure 5A,B), whereas the levels of expression of the *ilvC* gene were significantly repressed

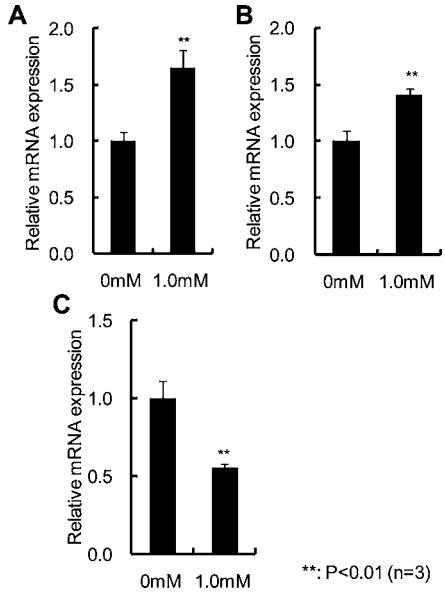

Figure 5. Comparison of the levels of expression of the *als* (A), *aldB* (B), and *ilvC* (C) genes that are involved in the biosynthesis of L-valine, diacetyl, and acetoin in the presence of 1.0 mM of L-valine. The error bars indicate the SD of triplicate samples of the experiments. The statistical significance of the comparisons of the results for each concentration of L-valine added compared with no L-valine added is indicated (**$P < 0.01$). The error bars indicate the SD of the triplicate samples of the experiments.

(Figure 5C). Acetolactate decarboxylase (*aldB*) catalyzes the conversion of α-acetolactate to acetoin, and acetohydroxy acid isomeroreductase (*ilvC*) catalyzes the conversion of α-acetolactate to the precursor of valine, 2,3-dihydroxy isovalerate.[25] Goupil et al. have shown that diacetyl is accumulated in fermented milk by a *Lactococcus lactis aldB* mutant, whose acetolactate decarboxylase activity was suppressed, more than that in the wild type.[26] On the basis of these results, it was suggested that supplementing L-valine into soymilk whey shifted the metabolic flux to produce more acetoin from α-acetolactate rather than the nonenzymatic oxidation from α-acetolactate to diacetyl in *S. thermophilus*.

Quantification of the Flavor Compounds of Acetaldehyde, Diacetyl, and Acetoin Produced by *S. thermophilus* with the Supplementation of L-Valine into Soymilk. The expression analysis of this study suggested that the

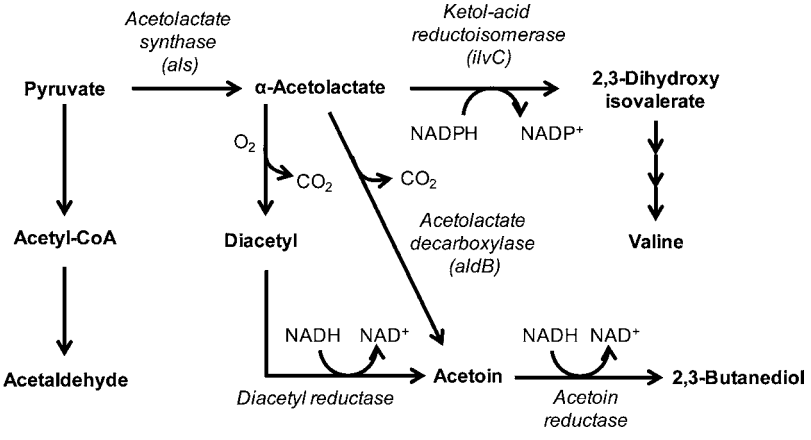

Figure 4. Proposed schematic of the metabolic pathways involved in the biosynthesis of L-valine and diacetyl from pyruvate.

dx.doi.org/10.1021/jf404567e | J. Agric. Food Chem. 2014, 62, 1658−1663

metabolic flux might shift from the biosynthesis of L-valine to acetoin by the addition of L-valine. In addition, according to the database of the complete genome sequence, *S. thermophilus* lacks metabolic enzymes of both diacetyl reductase and acetoin reductase, which catalyze the conversion of diacetyl to acetoin and acetoin to 2,3-butanediol, respectively. Therefore, it was hypothesized that acetoin would accumulate in fermented soymilk in response to the addition of L-valine instead of the decline of diacetyl concentration. In addition to acetoin and diacetyl, the concentration of acetaldehyde, which is one of the important flavor compounds in yogurt, was determined in fermented soymilk in response to the addition of L-valine because acetaldehyde is also produced from pyruvate by acetyl-coA. Figure 6 shows the concentration of acetaldehyde, diacetyl, and acetoin in fermented soymilk with *S. thermophilus* in the presence of increasing amounts of L-valine (0.0, 0.5, 1.0, and 5.0 mM). In the presence of L-valine, the concentration of diacetyl was decreased, whereas acetoin accumulated in fermented soymilk. The concentration of acetaldehyde stayed constant with the addition of L-valine. Chaves et al. have previously shown that the supplementation of the growth medium with L-threonine led to an increase in acetaldehyde production and that the differences in acetaldehyde formation were correlated with the differences in threonine aldolase activity.[27] Acetaldehyde is also generated by *S. thermophilus* through other metabolic pathways from citrate, which is already contained in soymilk itself. These findings suggested that the addition of L-valine had no effect on acetaldehyde production in soymilk. Like diacetyl, acetoin is characterized as having a butter-like aroma and it is important for the flavor of cheese. However, the odor threshold of acetoin is much higher than that of diacetyl. Therefore, fermented soymilk with L-valine added was expected to have fewer off-flavors than the one without L-valine supplementation.

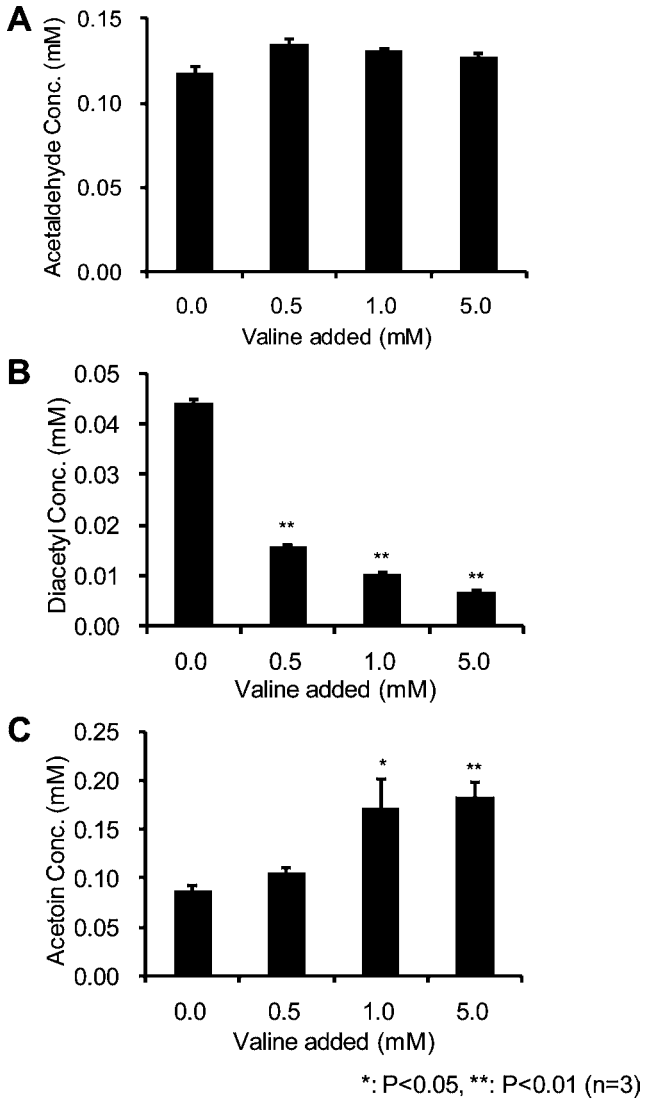

Figure 6. The concentrations of acetaldehyde (A), diacetyl (B), and acetoin (C) in fermented soymilk with *S. thermophilus* in the presence of increasing amounts of L-valine (0.0, 0.5, 1.0, and 5.0 mM). The statistical significance of the comparisons of the results for each concentration of L-valine added compared with no L-valine added is indicated (*$P < 0.05$, **$P < 0.01$). The error bars indicate the SD of the triplicate samples of the experiments.

Sensory Evaluation. The sensory properties of fermented soymilk were evaluated by an untrained panel of nine assessors with a triangle difference test and 30 assessors with a preference test. The experimental design was outlined in the Materials and Methods. As a result, six of the nine assessors could identify the flavor difference between fermented soymilk with and without L-valine supplementation. This result suggested that these two samples were significantly different. In the preference test, 27 of 30 assessors preferred fermented soymilk with L-valine added for its decreased off-flavor compared to the one without L-valine added.

On the basis of the results that were obtained in this study, we suggest that some natural ingredients consisting of highly concentrated branched-chain amino acids, such as powdered sugar beets, could be used for the enrichment of L-valine in soymilk instead of directly adding L-valine. In addition, the supplementation of a little protease (or peptidase)-treated soymilk could have enough L-valine to regulate diacetyl generation by *S. thermophilus*. Although it is well-known that a small amount of diacetyl is necessary for flavorful dairy yogurt, this study is the first to indicate that diacetyl could contribute an off-flavor in the case of fermented soymilk. Moreover, the present study showed that some metabolisms of lactic acid bacteria were controllable by modifying the amino acid compositions without the use of genetically modified lactic acid bacteria strains.

chloroform for chromatographic analysis of the lipid fraction. The acetone-extracted sample was then extracted with hot water (100 mL, 3 h at 100 °C) to determine the water-soluble material. Klason lignin content was estimated as the residue after sulphuric acid hydrolysis of the pre-extracted material, corrected for ash and protein content, according to the TAPPI method T222 om-88.[16] The acid-soluble lignin was determined, after the insoluble lignin was filtered off (Duran filter crucible 4; nominal pore size max. 10−16 μm), by UV-spectroscopic determination at 205 nm wavelength using 110 L cm^{-1} g^{-1} as the extinction coefficient. Holocellulose was isolated from the pre-extracted fibers by delignification for 4 h using the acid chlorite method.[17] The α-cellulose content was determined by removing the hemicelluloses from the holocellulose by alkali extraction.[17] Ash content was estimated as the residue after 6 h of heating at 575 °C according to the TAPPI method T211 om-02.[16] Three replicates were used for each sample.

Table 1. Abundance of the Main Constituents (% Dry-Weight) of Wheat Bran

constituent	content[a]
water-soluble extractives	2.4 ± 0.1
lipids	2.0 ± 0.1
Klason lignin[b]	12.1 ± 0.8
acid-soluble lignin	8.5 ± 1.0
carbohydrates	64.0 ± 1.0
(α-cellulose)	(30 ± 1.0)
proteins[c]	9.9 ± 1.0
ash	1.1 ± 0.1

[a]Average of three replicates. [b]Corrected for proteins and ash. [c]Determined indirectly by subtracting the other components to 100%.

GC and GC-MS Analyses. The lipophilic extractives (0.8 mg) were silylated with 0.250 mL bis(trimethylsilyl)trifluoroacetamide (BSTFA, from Supelco) in the presence of 0.050 mL pyridine at 70 °C for 2 h before GC and GC-MS analyses. An HP 5890 gas chromatograph (Hewlett-Packard, Hoofddorp, Netherlands) equipped with a split−splitless injector and a flame ionization detector (FID) was used for GC analyses. The injector and the detector temperatures were set at 300 and 350 °C, respectively. Samples were injected in the splitless mode at a concentration of 7.5 mg/mL. Helium was used as the carrier gas. The capillary column used was a high temperature, polyimide coated fused silica tubing DB5-HT (5 m x 0.25 mm I.D., 0.1 μm film thickness; J&W Scientific). The oven was temperature-programmed from 100 °C (1 min) to 350 °C (3 min) at 15 °C min^{-1}. Peaks were quantified by area, and a mixture of different standards, such as octadecane (Sigma-Aldrich, 99%), palmitic acid (Sigma-Aldrich, 99%), sitosterol (Calbiochem, 98%), cholesteryl stearate (Sigma-Aldrich, 99%), sitosteryl 3β-D-glucopyranoside (Matreya LLC, a mixture of three steryl glucosides of 98% purity, of which 56% correspond to sitosteryl glucoside) and triheptadecanoin (Sigma-Aldrich, 99%), with a concentration range between 0.1 and 1 mg/mL, was used to elaborate calibration curves. The correlation coefficient was higher than 0.99 in all cases. Quantification was obtained using response factors of the same or similar compounds (in the case of alkylresorcinols, they were quantified against sitosterol). The data from the three replicates were averaged. In all cases, the standard deviations from replicates were below 10% of the mean values. The total amounts of the different lipid families were determined by adding up the amounts of their constituent compounds.

The GC-MS analyses were performed on a Varian Star 3400 gas chromatograph (Varian, Walnut Creek, CA) coupled with an ion-trap detector (Varian Saturn 400) equipped with a high-temperature capillary column (DB-5HT, 15 m × 0.25 mm i.d., 0.1 μm film

thickness; J&W Scientific). Helium was used as carrier gas at a rate of 2 mL/min. The samples, at concentrations of 2.5 mg/mL, were injected with an autoinjector (Varian 8200) directly onto the column using a SPI (septum-equipped programmable injector) system. The temperature of the injector during the injection was 60 °C, and 0.1 min after injection was programmed to 380 °C at a rate of 200 °C min^{-1} and held for 10 min. The oven was heated from 120 °C (1 min) to 380 °C (5 min) at 10 °C min^{-1}. The temperature of the transfer line was set at 300 °C. Compounds were identified by comparing their retention times and mass spectra with authentic standards, except for alkylresorcinols and sterol ferulates, which were tentatively identified by comparing their mass spectra with those reported in the literature. Single ion chromatographic profiles were used to estimate compound abundances when two peaks partially overlapped.

RESULTS AND DISCUSSION

Lipid Composition of Wheat Bran. The destarched wheat bran sample selected for this study is mostly composed of carbohydrates (64.0% of the whole material, among which 30% corresponds to α-cellulose), lignin (20.6%), and proteins (9.9%), as seen in Table 1. Minor amounts of water-soluble extractives (2.4%), lipids (2.0%), and ash (1.1%) were also present in this sample. The detailed analysis of the chemical composition of the lipids was accomplished by GC and GC-MS (after preparation of the trimethylsilyl (TMS)-ether derivatives) according to the method previously described.[15] The chromatographic conditions used for the analyses, by using short- and medium-length high-temperature capillary columns with thin

films, allow for the elution of a wide range of compounds, from low molecular weight free fatty acids and sterols to intact high molecular weight lipids such as sterol esters, sterol glycosides, or triglycerides, that are usually biased in more standard GC conditions.

Figure 1 shows the GC-MS chromatogram of the lipids (as their TMS-ether derivatives) extracted from wheat bran. A large number of compounds were identified and quantified. The identities and abundances (mg/kg fiber, dry, ash-free basis) of the main lipid compounds identified in the extracts of wheat bran are listed in Table 2. Structures representative of the main lipid families identified in wheat bran, including aliphatic and steroid compounds, are shown in Figure 2 and Figure 3. The results demonstrated that the predominant lipids identified among the extracts of this wheat bran sample were series of free fatty acids, accounting for around 40% of all identified compounds, followed by series of acylglycerols (40% in total), that included mono-, di- and triglycerides. Important amounts of alkylresorcinols (13% of all identified compounds) were also found among the lipids of wheat bran. Alkylresorcinols have been the most widely reported lipids in wheat bran.[9,11−13] Steroid compounds (including hydrocarbons, ketones, free sterols, sterol glycosides, sterol esters, and sterol ferulates) were also present among the lipids of wheat bran in important amounts (7% of all identified lipids). Only free sterols and sterol ferulates were previously reported among the lipids of wheat bran.[9,12,18] Lower amounts of other aliphatic series such as *n*-alkanes, were also observed. The distributions of the main aliphatic series (fatty acids, *n*-alkanes, monoglycerides, and *n*-alkylresorcinols) are represented in the histograms of Figure 4.

Aliphatic Series. Free fatty acids (6620 mg/kg) were the most abundant family of identified lipids. The series of free fatty acids was found in the range from tetradecanoic acid (C_{14}) to tetratriacontanoic acid (C_{34}), with a predominance of the even

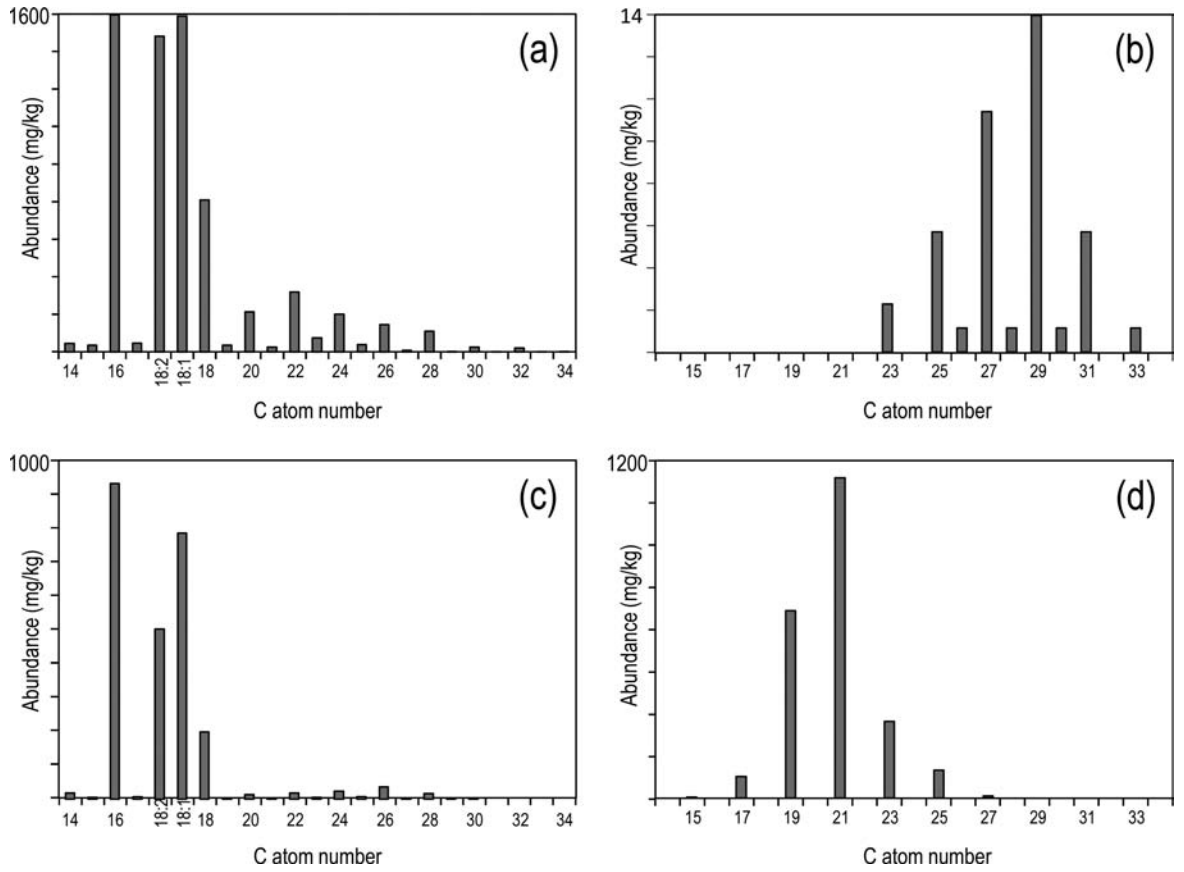

Figure 4. Distribution of the main aliphatic series identified in the extracts of wheat bran. (a) *n*-Fatty acids; (b) *n*-alkanes; (c) monoglycerides; and (d) *n*-alkylresorcinols. The histograms are scaled up to the abundance of the major compound in the series.

carbon atom number homologues. Hexadecanoic acid (palmitic acid, **I**) was the most abundant free fatty acid (1595 mg/kg), together with the unsaturated *cis*-9-octadecenoic acid (oleic acid, **II**) (1590 mg/kg) and *cis*,*cis*-9,12-octadecadienoic acid (linoleic acid, **III**) (1500 mg/kg). High amounts of the saturated octadecanoic acid (stearic acid) (720 mg/kg) were also found, while the rest of fatty acids were present in minor amounts. Despite the high abundance of fatty acids identified in wheat bran, a detailed analysis of their occurrence has not been performed so far, and there is a substantial gap in the information reported in the literature. The major free fatty acids previously reported in wheat bran were linolenic ($C_{18:3}$) and linoleic ($C_{18:2}$) acids,[9] which substantially differ from our results.

Acylglycerols (including mono-, di-, and triglycerides) were also found among the lipids of wheat bran in important amounts, accounting for a total of 6490 mg/kg, with monoglycerides being the predominant ones. However, and despite this abundance, the detailed analyses of their components have not been performed so far, and only the occurrence of the diglyceride dilinoleoylglycerol was previously reported.[9] Monoglycerides in wheat bran accounted for 2580 mg/kg, and were identified in the range from 2,3-dihydroxypropyl tetradecanoate (C_{14}) to 2,3-dihydroxypropyl triacontanoate (C_{30}), with a strong predominance of the even carbon atom number homologues. 1-Monopalmitin (**IV**) was the most abundant monoglyceride (930 mg/kg), followed by the unsaturated 1-monoolein (**V**, 785 mg/kg) and 1-monolinolein (**VI**, 500 mg/kg), and the saturated 1-monostearin (200 mg/kg). To our knowledge, this is the first time that the series of monoglycerides has been reported in wheat bran. The distribution of esterified fatty acids occurring as monoglycerides roughly matches that of the free fatty acids, as seen in the histograms of Figure 4. Diglycerides were also found in important amounts (2150 mg/kg) among the lipids in wheat bran. The most abundant diglycerides identified were 1,2-palmitoyl olein (**VII**) (210 mg/kg) and 1,3-palmitoyl olein (**VIII**) (280 mg/kg), with a predominance of the 1,3-isomers, as also occurs in other grasses.[19,20] Palmitic and linoleic acids were the most important esterified fatty acids occurring as diglycerides, as also occurred in the case of monoglycerides. A previous work only identified dilineoylglycerol (although it did not report the substitution pattern), but these compounds are minor components in our study. Triglycerides were also identified in high amounts among the lipids of wheat bran, accounting for 1960 mg/kg, (Table 2) and, although their occurrence was previously reported,[9] this is the first time that the identification of individual triglycerides was achieved by GC-MS. Dilinoleoyl palmitin (**IX**) was the most abundant triglyceride in the wheat bran sample (480 mg/kg) followed by dilinoleoyl olein (400 mg/kg), linoleyloleyl palmitin (300 mg/kg), and trilinolein (250 mg/kg). Palmitic and linoleic acids were the most abundant esterified fatty acids present as triglycerides, as also occurred in the case of mono- and diglycerides.

A series of *n*-alkanes could also be identified among the lipids of wheat bran, although in lower amounts (40 mg/kg). The series of *n*-alkanes was found in the range from *n*-tricosane (C_{23}) to *n*-tritriacontane (C_{31}), with a strong odd-over-even atom carbon number predominance. Nonacosane (**X**) was the main compound of this series, accounting for 14 mg/kg, followed by

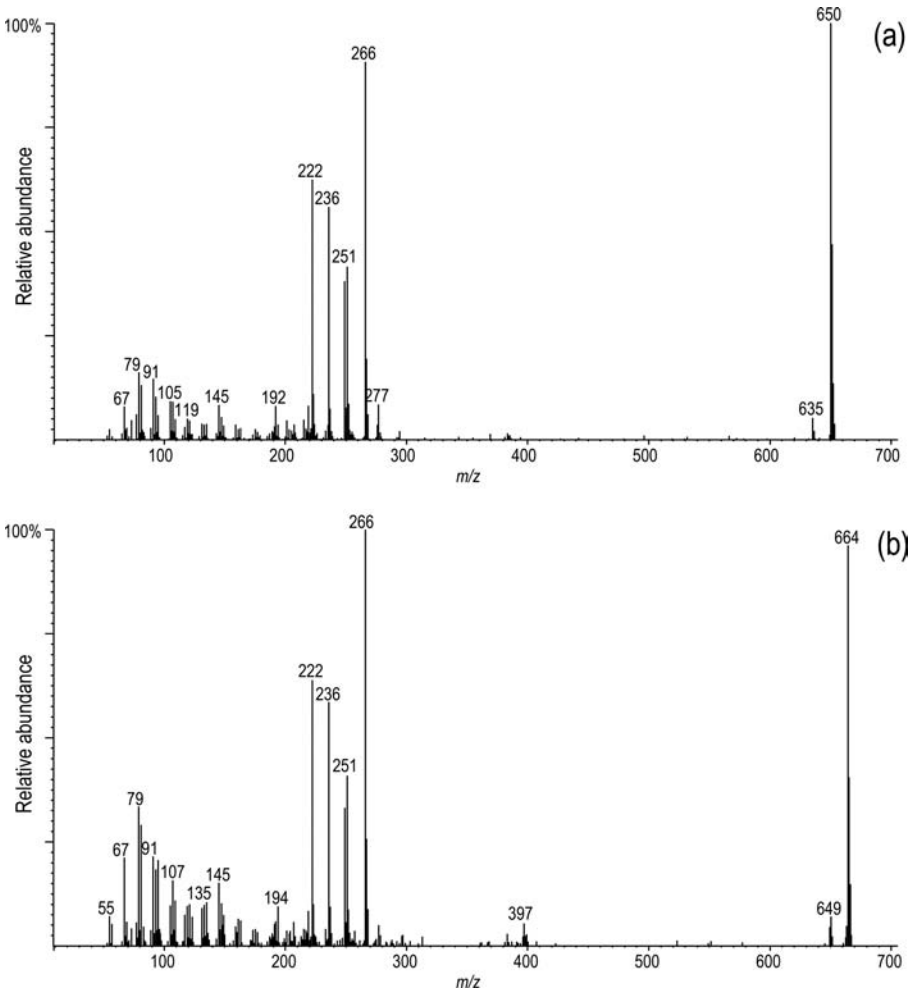

Figure 5. Mass spectra of (a) campestanyl ferulate, and (b) stigmastanyl ferulate, (as TMS ethers).

heptacosane (10 mg/kg). The rest of the alkanes were identified in very minor amounts.

Steroid Compounds. Different families of steroid compounds were identified among the lipids in wheat bran, including steroid hydrocarbons, steroid ketones, free sterols, sterol glycosides, sterol esters, and sterol ferulates. Free sterols, accounting for 510 mg/kg, were the major family of steroid compounds present in wheat bran, with sitosterol (**XII**) occurring at the highest level (290 mg/kg), followed by campesterol (**XIII**) (120 mg/kg). In addition, lower amounts of stigmasterol (**XIV**) and the saturated campestanol (**XV**) and stigmastanol (**XVI**) were also identified. Sterols conjugated with carbohydrates forming sterol glycosides or with long chain fatty acids or ferulic acid forming sterol esters were also identified. Important amounts of sterol glycosides (135 mg/kg) were identified among the lipids of wheat bran by comparison with the mass spectra and relative retention times of authentic standards.[21] As far as we know, this is the first time that sterol glycosides are reported as constituents of wheat bran lipids. Sitosteryl 3β-D-glucopyranoside (**XVII**) was the most predominant sterol glycoside in wheat bran (85 mg/kg) with lower amounts of campesteryl and stigmasteryl 3β-D-glucopyranosides, as usually observed in other grasses.[19,20] Sterol esters of long chain fatty acids corresponding to campesterol, campestanol, stigmasterol, sitosterol, and stigmastanol esterified with different fatty acids were also found (240 mg/kg). Each sterol ester series identified showed two major peaks due to the esterification with the C_{16} (palmitic acid) and with the unsaturated linoleic acid.

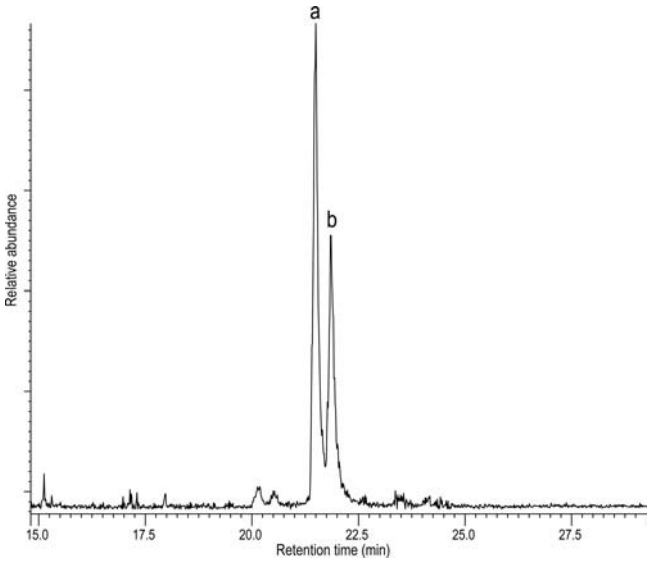

Figure 6. Single ion chromatogram (m/z 266) showing the distribution of sterol ferulates (as TMS ethers) identified in the extracts of wheat bran. (a) Campestenyl ferulate; and (b) stigmastanyl ferulate.

Sitosteryl linoleate (**XVIII**) was the most predominant (70 mg/kg) sterol ester in wheat bran, followed by sitosteryl hexadecanoate (60 mg/kg), as also occurs in other cereals.[22]

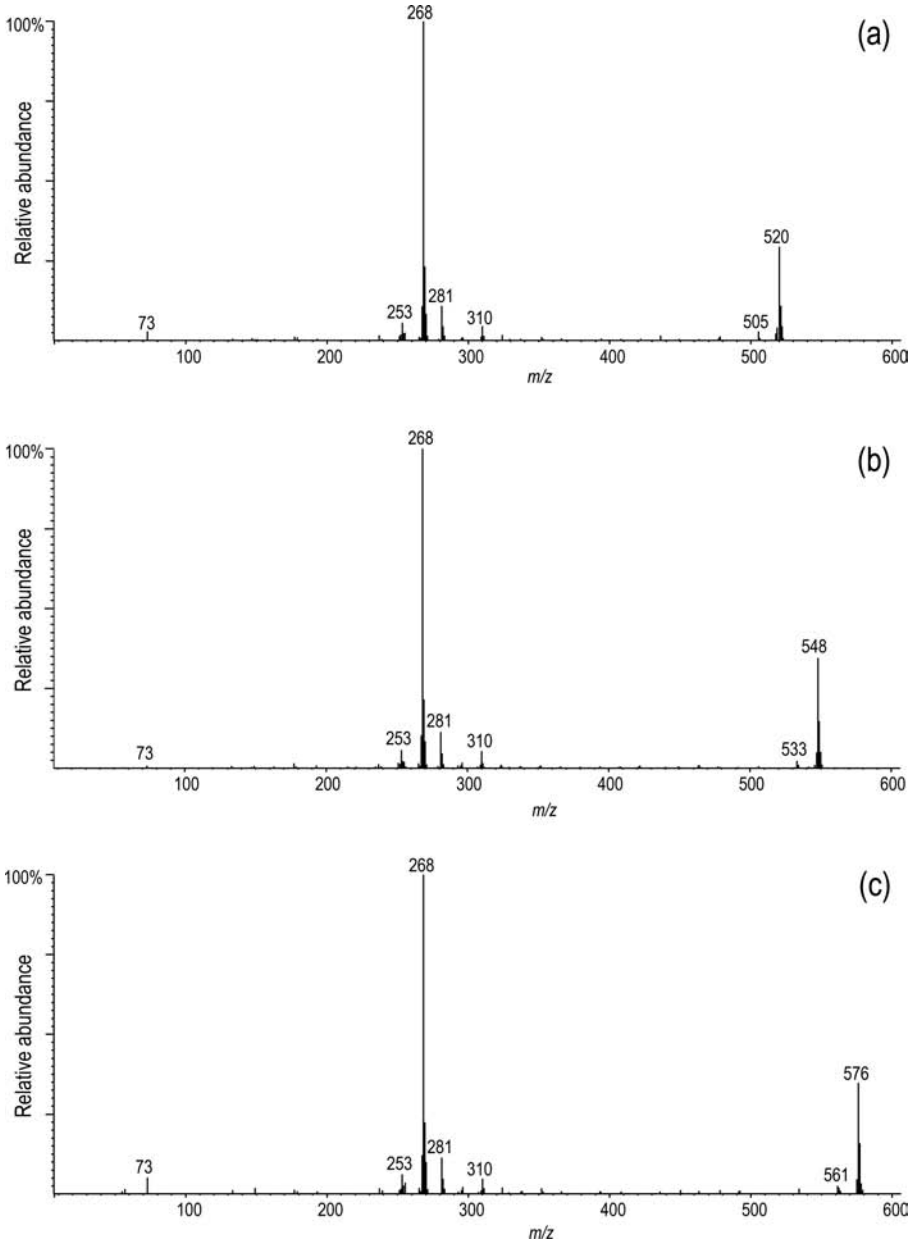

Figure 7. Mass spectra of selected alkylresorcinols (as TMS ethers): (a) 5-*n*-nonadecylresorcinol, (b) 5-*n*-heneicosylresorcinol, and (c) 5-*n*-tricosylresorcinol.

Sterol ferulates were also identified among the lipids of wheat bran (105 mg/kg), and consisted exclusively of the saturated campestanyl ferulate (**XIX**) and sitostanyl ferulate (**XX**). The identification of sterol ferulates was obtained from the mass spectra of their TMS ethers that show a characteristic base peak ion at *m*/*z* 266, typical of these molecules, together with the molecular ions at *m*/*z* 650 and *m*/*z* 664 for campestanyl and stigmastanyl ferulates, respectively.[23] The mass spectra of these sterol ferulates are shown in Figure 5, whereas Figure 6 displays the single ion chromatogram (*m*/*z* 266) showing the distribution of the series of sterol ferulates present among the lipids of wheat bran. The identification of these compounds is consistent with previous observations in several cereal bran oils.[12] Different steroid ketones, namely stigmast-3,5-dien-7-one (**XXI**), stigmasta-4,22-dien-3-one (**XXII**) and stigmast-4-en-3-one (**XXIII**), were also identified in lower amounts (80 mg/kg) among the lipids of wheat bran. Steroid hydrocarbons were also found, albeit in low amounts (60 mg/kg), and included stigmasta-3,5,22-triene (**XXIV**) and stigmasta-3,5-diene (**XXV**). The important amounts of steroid compounds present in wheat bran, and particularly the high content of free and conjugated sterols, makes wheat bran a good source of valuable phytosterols.

Alkylresorcinols. A series of 5-*n*-alkylresorcinos was identified among the lipids of wheat bran in important amounts (2250 mg/kg). The identification of 5-*n*-alkylresorcinols was achieved from their mass spectra that show a base peak due to the McLafferty rearrangement at *m*/*z* 268, characteristic of these molecules.[14,24] The mass spectra of three representative 5-*n*-alkylresorcinols are shown in Figure 7, with the characteristic base peak at *m*/*z* 268 and the molecular ions at *m*/*z* 520, *m*/*z* 548, and *m*/*z* 576 for the TMS ether derivatives of 5-*n*-nonadecyl-, 5-*n*-heneicosyl-, and 5-*n*-tricosylresorcinols, respectively. Figure 8 displays the single ion chromatogram (*m*/*z* 268) showing the distribution of the series of

dx.doi.org/10.1021/jf404772b | J. Agric. Food Chem. 2014, 62, 1664−1673

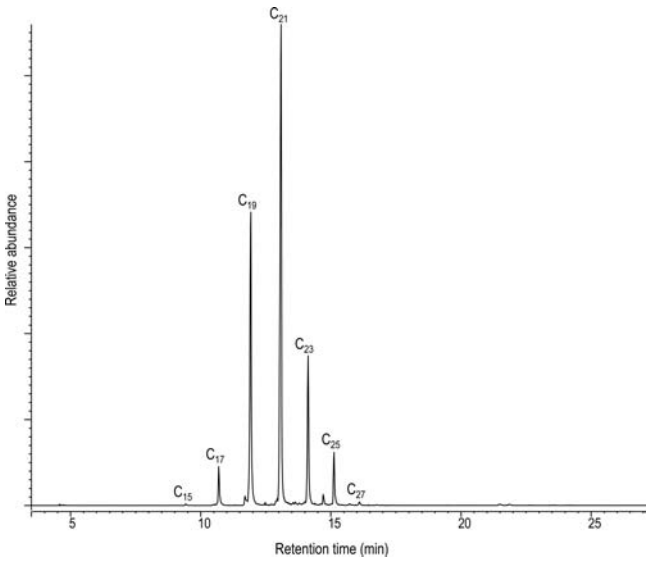

Figure 8. Single ion chromatogram (m/z 268) showing the distribution of the series of *n*-alkylresorcinols (as TMS ethers) identified in the extracts of wheat bran. C_n indicates the carbon length of the alkyl chain.

5-*n*-alkylresorcinols present among the lipids of wheat bran. The 5-*n*-alkylresorcinols ranged from 5-*n*-pentadecyl (C_{15}) to 5-*n*-heptacosylresorcinol (C_{27}), with the sole occurrence of the odd carbon atom-numbered homologues, and with 5-*n*-heneicosylresorcinol (C_{21}, **XI**) being the most abundant one (1140 mg/kg), followed by 5-*n*-nonadecylresorcinol (660 mg/kg). Alkylresorcinols are known to occur in cereal grains and their occurrence in wheat bran has been widely reported.[9,11−14,25] The distribution of alkylresorcinols identified is similar to that found in previous works,[9,11−14,25] although in the present work we have extended the series of identified alkylresorcinols up to C_{27}.

Possible Uses and Benefits of Wheat Bran Lipids. The study shown here indicates that wheat bran is a promising source of phytochemicals, such as fatty acids, triglycerides, phytosterols, and alkylresorcinols. These compounds have a wide range of nutraceutical, pharmaceutical, and cosmetic properties and are also of interest for other industrial sectors. The particularly high content of free fatty acids (40%) and acylglycerols (40%) in wheat bran extracts makes this material an interesting feedstock for biodiesel production, which is nowadays essentially produced from oil seed crops.[26] The potential use of cereal brans, such as rice bran, as useful feedstocks for biodiesel production, has recently being reported,[27] although there could be some considerations if the material used in animal diets are diverted to fuel production. Among the fatty acids, wheat bran also contains important amounts of linoleic acid, an essential unsaturated omega-6 fatty acid that must be consumed for proper health and is of interest for the food industry. Moreover, linoleic acid is also used in pharmaceutical and cosmetic products and is considered to influence the metabolic processes in the skin and to promote the activity of vitamins A and E and recovery barrier properties of stratum corneum.[28] On the other hand, phytosterols, which are also present in important amounts in wheat bran, when used as functional ingredients in foods, reduce blood cholesterol levels by interfering with intestinal cholesterol absorption.[29,30] The efficacy of phytosterols as cholesterol-lowering agents have been shown when incorporated into fat spreads as well as other food matrices. In addition, phytosterols have been combined with other beneficial dietary components to enhance their effect on risk factors of cardiovascular disease. Phytosterols appear not only to play an important role in the regulation of cardiovascular disease, but also to exhibit anticancer properties.[30] Hence, phytosterols, especially sitosterol, are suggested to have a protective effect against the most common cancers in the developed countries including colon, prostate, and breast.[12] In addition, sterol ferulates present anti-inflammatory effects and are also effective antitumor-promoters.[31] Finally, the important amounts of alkylresorcinols present in wheat bran are of special value since they are involved in multiple biological activities, including antimicrobial,[32] antiparasitic,[33,34] antioxidant,[13,14,35] and antimutagenic activities.[9,11,12,36]

In conclusion, we report a comprehensive description of the chemical composition of lipids in wheat bran that opens up new possibilities for a more complete industrial utilization of this side-stream in the context of a wheat bran biorefinery. Due to the large amounts produced annually worldwide, wheat bran can be viewed as an unexploited and promising source of highly valuable phytochemicals with potential health benefits and biological activities. Variations in the chemical composition of the lipids, however, can be expected to occur among different wheat bran samples from differences in wheat cultivars and milling procedures; the screening and analysis of additional wheat bran samples are therefore needed in order to evaluate the divergences in the composition and content of lipids among samples from different sources.

and pears were found to contain twice the amount of total phenolics as found in the peeled fruits.[5,23]

Major advances have been achieved in recent years in understanding the absorption and metabolism of most other classes of phenolic compounds. These studies have focused on anthocyanins, flavanones, catechins, proanthocyanidins, and the hydroxybenzoic and hydroxycinnamic acids.[24]

Some additives that can preserve the natural properties of foods are simple sugars. A number of mechanisms have been suggested for the explanation of sugar's effectiveness on preservation. These include sugar's ability to form glass, to lock in compounds, to mimic the hydrogen-bonding character of water, to increase the surface tension of the bulk solvent, to prevent thermotropic phase separations in lipid bilayers, and to prevent the fusion of membranes.[25,26]

The objective of this study was to investigate the influence of several simple sugar additions at levels of 1 and 5% on the polyphenol content and antioxidative activity of apple purée processed by freezing and freeze-drying and stored for 6 months.

MATERIALS AND METHODS

Chemicals. Folin−Ciocalteu reagent was purchased from Kemika (Zagreb, Croatia); 2,6-dichlorophenol indophenols, phloretin, catechin, epicatechin, rutin, quercetin, chlorogenic acid, caffeic acid were obtained from Sigma Chemical Co. (St. Louis, MO, USA); 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonate), 2,2-diphenyl-1-picrylhydrazyl, and procyanidin B2 were from Fluka (St. Louis, MO, USA); phlorizin was from Aldrich (St. Louis, MO, USA); and methanol (HPLC grade) and orthophosphoric acid (85%) were obatined from Panareac (Barcelona, Spain).

Apple Cultivars Used for Experiment. Actual apple cultivars 'Idared' and 'Fuji' were purchased from the Agricultural Institute (Osijek, Croatia). Both apple varieties were stored under regular atmosphere (RA) at 2−6 °C before they were purchased for study. During apple purée preparation the core area was removed and two opposite cuts of each fruit were pureed and mixed with simple sugars (S, sucrose; G, glucose; F, fructose; and T, trehalose). Sixteen variants of mixed purees were prepared: 1 and 5% of each sugar were mixed with both apple cultivars. Prepared samples were used for processing, freezing, and freeze-drying.

Physical and Chemical Analysis. Apples were held at room temperatures for ca. 1 h before preparation for analysis. Before the apple fruits were disintegrated using a Braun Multiquick Professional 600 W Turbo for the analysis, the core was removed. The content of soluble solids of apples was measured with a tabletop Abbe refractometer and given in Brix (°Brix). Acids were measured by titration with 0.1 M NaOH and phenolphthalein as an indicator and given as grams per 100 g of malic acid. Reducing and total sugars were determined by Luff Schoorl's method,[27] and vitamin C (L-ascorbic acid) was determined by a volumetric method: titration using dichlorophenol indophenol (DCPIP).[28]

Freezing and Freeze-Drying. Apple purée samples used for freezing were placed in plastic bags and frozen in a laboratory freezer. Samples were maintained at −18 °C. Apple purée samples used for freeze-drying were placed into plastic bags and frozen at −18 °C for 12 h before freeze-drying in a laboratory freeze-dryer (Christ Freeze-Dryer, Gamma 2-20, Germany). Drying conditions were as follows: freezing temperature, −55 °C; temperature of sublimation, −35 to 0 °C; vacuum level, 0.220 mbar. The temperature of isothermal desorption varied from 0 to 22 °C under the vacuum of 0.060 mbar. Freeze-drying lasted until the total solids content was 94−98%, which was about 48 h.

Extraction of Phenolics. The extraction of polyphenols for the determination of TPC and AOA was performed as follows: disintegrated apple parts (peel, peel + flesh, flesh), freeze-dried, and frozen apple purée were homogenized with methanol containing hydrochloric acid (1% v/v) (1 g of sample in 10 mL of 1% HCl methanol). The samples were held at ambient temperature for 1 h. After 1 h, the mixture was filtered through pleated Whatman no. 2 filter paper (Whatman International Limited, Kent, UK), and permeates were used for analysis. Before the identification of polyphenols, fresh and frozen samples were freeze-dried as described earlier. Phenolics were extracted from freeze-dried samples using 80% aqueous methanol. The mixture was sonicated for 15 min and centrifuged at room temperature for 15 min. Extracted samples were filtered through a 0.45 Rm poly(tetrafluoroethylene) syringe-tip filter (Chromafil Xtra, Macherey-Nagel GmbH & Co. KG), and extracts were used for HPLC analysis. The amount of phenolics was expressed as milligrams per 100 g of fresh weight (FW).

[a] n, number of fruits under study.

Determination of Total Polyphenol Content. The total phenols content was determined according to the modified colorimetric Folin−Ciocalteu method.[29] A 0.2 mL of apple extract and 1.8 mL of deionizer water were added to a 23 mL test tube. Ten milliliters of Folin−Ciocalteu reagent (1:10) was added to the solution, and finally 8 mL of 7.5% sodium carbonate (Na_2CO_3) solution was transferred into the test tubes. The color was developed in 120 min, and the absorbance was read at 765 nm by a spectrophotometer (Jenway 6300, Bibby Scientific, UK). The measurements were performed in triplicates for each sample, and the average value was interpolated on a gallic acid calibration curve and expressed as grams of gallic acid per kilogram of sample equivalents (g GAE/kg).

Antioxidant Activity Determination. The ABTS assay followed the method of Arnao et al. with some modifications.[30] The results were expressed as millimoles of trolox equivalents (TE) per 100 mL of sample. Additional dilution was needed if the measured ABTS value was over the linear range of the standard curve. For the DPPH assay 0.2 mL of the apple extract was diluted with methanol (2 mL), and 1 mL of DPPH solution (0.5 mM) was added. After 15 min, the absorbance was measured at 517 nm.[31] The results were expressed as

Table 2. Polyphenol Compounds in 'Idared' and 'Fuji' Apple Varieties (Milligrams per 100 g FW)[a]

[a]Each value is expressed as the mean ± standard deviation (n = 3). Within the same row, means followed by different letters are significantly different at $p \leq 0.05$ (ANOVA, Fisher's LSD). [b]nd, not detectable. [c]Quercetin glycosides retention times (min): peaks of quercetin-3-glucoside, galactoside, arabinoside, xyloside, and rhamnoside.

millimoles of trolox equivalents (TE) per 100 mL of sample. Additional dilution was needed if the measured DPPH value was over the linear range of the standard curve.

Identification of Phenolics. The analytical HPLC system employed consisted of a Varian LC system (Agilent, Avondale, PA, USA) equipped with a ProStar 230 solvent delivery module and a ProStar 330 PDA detector. Phenolic compound separation was done with an OmniSpher C18 column (250 × 4.6 mm inner diameter, 5 μm, Agilent, USA) protected with a guard column (ChromSep 1 cm × 3 mm, Varian, USA). The data were collected and analyzed on an IBM computing system equipped with Star Chromatography Workstation software (version 5.52). The same solvents and gradient elution program were used in the determination of phenolic acids and flavonols. Solvent A was 0.1% phosphoric acid, and solvent B was 100% HPLC grade methanol. The elution conditions were as follows: 0−30 min from 5 to 80% B; 30−33 min, 80% B; 33−35 min, from 80 to 5% B; with a flow rate = 0.8 mL/min.[32] Phenolic standards were used to generate characteristic UV−vis spectra and calibration curves. Individual phenolics in the sample were tentatively identified by comparison of their UV−vis spectra and retention times with spiked input of polyphenolic standard. Three replicated HPLC analyses were performed for each sample.

Color Measurement. The color of the apple purée was determined by using a colorimeter (Minolta CR-300) prior to the chemical analysis. Color values, for each fruit, were calculated using the averaging mode with five replications. The color measurements were made using the $L^*a^*b^*$ system. L^* measures lightness and varies from 100 for perfect white to zero for black, approximately as the eye would evaluate it. The a^* parameter measures redness when positive and greenness when negative, and b^* measures yellowness when positive and blueness when negative.

Statistical Analysis. All measurements were done in triplicate, and data were expressed as the mean ± standard deviation. The experimental data were subjected to a one-way analysis of variance (ANOVA), and Fisher's LSD values were calculated to detect significant differences ($p \leq 0.05$) between mean values. Statistical analyses were performed with the statistical program MS Excel (Microsoft Office 2007 Professional).

RESULTS AND DISCUSSION

The physicochemical parameters of both apple varieties are shown in Table 1. The water content of the total fresh weight of both apple varieties was ca. 84%, and the content of soluble solids ca. 13 °Brix. pH value differed from 3.4 ± 0.006 ('Idared') to 3.8 ± 0.017 ('Fuji'). 'Idared' apples had a higher acidity (0.3 ± 0.020 g 100 g^{-1} of malic acid) than 'Fuji' apples (0.2 ± 0.001 g 100 g^{-1} of malic acid), whereas the amount of ascorbic acid was higher in 'Fuji' apples (8.4 mg 100 g^{-1}). Mean values of ascorbic acid and soluble solids content were at a range of those reported for other commercial apple cultivars.[33] The total sugar content ranged from 11.6 mg ('Idared') to 12.4 mg ('Fuji') (Table 1). The total sugar contents were slightly lower than those obtained in studies on apple cultivars grown in, for example, Slovenia and Brazil.[34,35] Color parameters of 'Fuji' apples indicated that the flesh was lighter green (a^* parameter was negative) and the coordinate b^* indicates a slight yellow color, whereas 'Idared' apples had a light red flesh (a^* parameter was positive).

In both apple varieties, TPC was highest in the peel, followed by the flesh + peel and the flesh, which is in accordance with the results of other researchers.[36,37] However, 'Idared' apple peel had a higher TPC than 'Fuji' (5.7 ± 0.182 and 3.3 ± 0.082 g GAE/kg of peel, respectively).

[a]Each value is expressed as the mean ± standard deviation (n = 3). Within the same row, means followed by different letters are significantly different at $p \leq 0.05$ (ANOVA, Fisher's LSD).

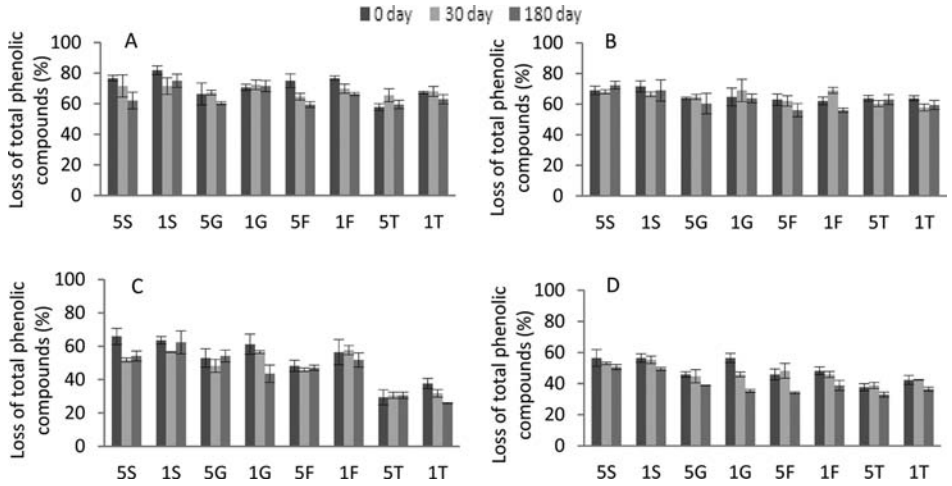

Figure 1. Loss of total polyphenols (%) in frozen (A, 'Idared'; C, 'Fuji') and freeze-dried (B, 'Idared'; D, 'Fuji') apple purée, prepared with an addition of sugars (S, sucrose; G, glucose; F, fructose; T, trehalose; 5, 5%; 1, 1%): black bars, immediately after preparation; light gray bars, after 3 months of storage; dark gray bars, after 6 months of storage. Error bars represent standard deviations of each data (n = 3).

Antioxidant activity in both ABTS and DPPH assays was positively correlated with TPC in the peel, flesh + peel, and flesh. Ki Won et al. found that quercetin, epicatechin, and procyanidin B2 significantly contribute to the total antioxidant activity of apples.[37] As shown in Table 2 the phenolics in apple flesh consisted of four main compounds, procyanidin B2, phloridzin, (−)-epicatchin, and chlorogenic acid. The apple peels contained additional quercetin glycoside such as glucoside, galactoside, xyloside, arabinoside, rhamnoside, and rutinoside. The main quercetin glycoside in the peel of both apple varieties was quercetin rutinoside (rutin). Mean values of phenolic compounds presented in Table 2 were at the range of those reported by Carbone et al. and Ceymann et al. for other commercial apple cultivars.[38,39] Differences in extraction procedures or quantification methods could explain the different results for the same cultivar as could be influenced by pre- and postharvest factors.[40] A difference in the levels of TPC between fresh and processed apple purées was detected, as shown in Table 3. The content of TPC in unprocessed apple fruit ranged from 0.9 g GAE/kg ('Fuji' apples) to 1.2 g GAE/kg ('Idared' apples). The highest retention of TPC in processed frozen samples was observed in (unprocessed 100% TPC) 'Fuji' apple purée: 29.4, 43.5, and 38.3% on days 0, 30, and 180 respectively. Retention of TPC in (unprocessed 100% TPC) 'Idared' apples purée was slightly lower at 23.3, 25.9, and 23.9% on days 0, 30, and 180, respectively. In freeze-dried samples, retention of TPC was 37.7, 37.7, and 40.0% for 'Fuji' apple purée and 25.9, 29.3, and 27.6 for 'Idared' apple purée on days 0, 30, and 180, respectively. In general, the highest levels of polyphenols were lost in the apple flesh (without peel) followed by flesh + peel, and peel (data not shown).

Significant losses during processing can be explained by the oxidation of phenolic compounds during the slow freezing process achieved in a laboratory freezer (−18 °C). These losses were detected also in freeze-dried samples. In some samples an increase of polyphenols during storage occurred. The higher amount of polyphenols during storage in frozen apple purée (peel + flesh) may be attributed to better extraction efficiency of polyphenols from frozen apple purée than from fresh apple fruit (purée) because of cellular disruption during freezing and thawing.[41]

It is known that AOA is influenced not only by the content of the polyphenols but also by phenolic compositions. The results of antioxidant activity (Table 3) obtained with the use of the $ABTS^{\cdot+}$ radical were higher compared to the results of assays performed using the DPPH radical (Table 3), which is in accordance with ref 1. The results obtained by the DPPH method (Table 3) indicate a decrease of AOA during storage of the samples of both apple varieties. This was not the case with AOA measured with the ABTS method. The AOA determined with the ABTS method increased during storage. This can be explained by the nature of the two radicals applied. Like $ABTS^{\bullet+}$, DPPH reacts with both electron and hydrogen donors, although more slowly, and as result of that, the DPPH radical can

underestimate fast reactors. DPPH is also more selective than $ABTS^{\bullet+}$ in the reaction with H-donors. For instance, the inhibition coefficient *f* for a series of tea catechins was found to be almost equal to the number of active OH-groups inherent in catechol and pyrogallol fragments.[42] In contrast to $ABTS^{\bullet+}$, DPPH does not react with flavonoids, which contain no OH-groups in the B-ring as well as with aromatic acids containing only one OH-group.[43,44] With regard to $ABTS^{\bullet+}$, nonspecific side reactions are common and could cause an overestimation of antioxidant activity. $ABTS^{\bullet+}$ reacts with any hydroxylated aromatics independently of their real antioxidative potential.[44] Some examples may verify this statement. The AOA of resorcinol determined with microsomal model was found to be less than that of catechol and *p*-hydroquinone by 150- and 10-fold, respectively. At the same time, AOA measured with the ABTS method for resorcinol (2.49) was significantly superior to those for catechol (1.43) and *p*-hydroquinone (1.33).[45]

In more recent years research on the influence of sugars upon polyphenols has focused on anthocyanins and color stability of fruit and vegetable products. Numerous studies have been performed to elucidate such effects, however, revealing contradictory results. Increased loss of anthocyanin color or uninfluenced anthocyanin color in the presence of saccharides was reported by Malien-Aubert et al., Dyrby et al., and Hubbermann et al.[46−48] In contrast, improved pigment stability upon sugar addition was reported by Kopjar et al., Ścibisz and Mitek, and Kopjar et al.[26,49,50]

In our research, the loss of TPC in all apple samples, determined immediately after sugar addition and after processing, was smaller compared to the findings in the samples without sugar addition (Figure 1).

The apple polyphenol profile was mostly preserved in the freeze-dried samples with sugar addition during 6 months of storage (Table 4). In the 'Idared' apple samples we observed a reduction of quercetin aglycon and an increase of quercetin glycosides, which is observed in all 'Idared' samples with added sugars.

In the freeze-dried apple samples the highest impact on (+)-catechin preservation had S 5% ('Idared') and G 5% ('Fuji') 4.6 and 2.7 mg/100 g FW, respectively. The highest impact on (−)-epicatechin preservation had T 1% ('Idared') and G 5% ('Fuji') 1.1 and 1.3 mg/100 g FW, respectively, whereas that on the phenolic acids (chlorogenic acid and caffeic acid) had T 1% ('Idared') and T 5% ('Fuji'). Addition of T 1% had the highest impact on flavonol preservation in both apple cultivars. Flavonols were present in the ranges from 6.0 to 10.2 mg/100 g FW and from 1.2 to 12.5 mg/100 g FW in 'Idared' and 'Fuji' apple samples, respectively. Rutin accounted for most of the flavonols, 4.6−8.0 and 0.4−11.0 mg/100 g FW in 'Idared' and 'Fuji' apple samples, respectively. Results obtained by an HPLC method showed that the samples in which T 1% was added had the highest levels of polyphenols in both apple cultivars 'Idared' and 'Fuji' (16.3 and 13.7 mg/100 g FW, respectively).

In the frozen samples after 6 months of storage, a different polyphenolic profile was identified (Table 5). It consists only of quercetin glycosides, of which rutin had the largest share. It can be seen that samples of both apple varieties, 'Idared' and 'Fuji', had the highest proportion of quercetin glycosides with addition of T 5% (12.2 and 16.7 mg/100 g FW, respectively) detected by HPLC.

As in the case of apple samples without sugars, there was an increase of AOA measured with the ABTS method during storage in all 'Idared' apple samples, whereas in 'Fuji' apple samples the increase of AOA during storage was noted in

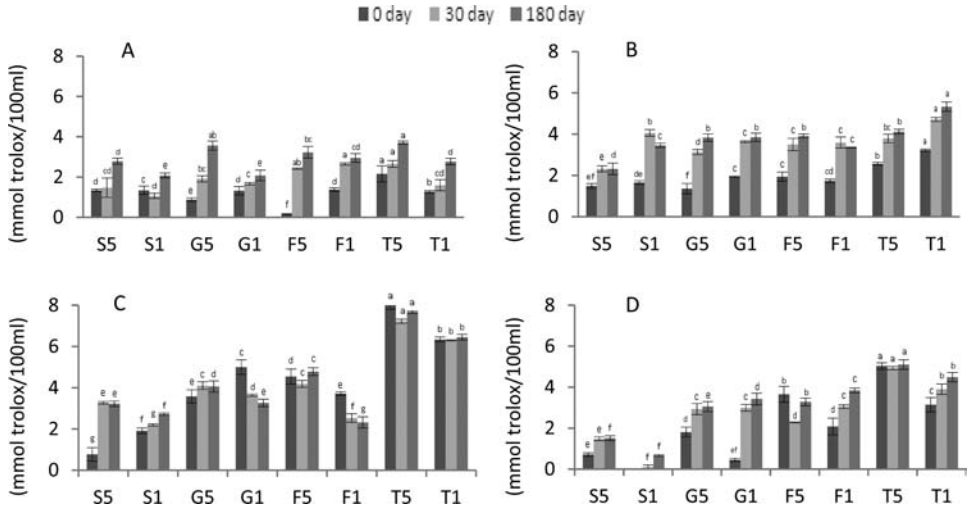

Figure 2. Antioxidative activity measured with ABTS method (mmol trolox/100 mL) for 'Idared' frozen (A) and freeze-dried (B) and 'Fuji' frozen (C) and freeze-dried (D) (S, sucrose; G, glucose; F, fructose; T, trehalose; 5, 5%; 1, 1%): black bars, immediately after preparation; light gray bars, after 3 months of storage; dark gray bars, after 6 months of storage. Each value is expressed as the mean ± standard deviation (n = 3). Among the different sugars within the same period of storage, different letters are significantly different at $p \leq 0.05$ (ANOVA, Fisher's LSD).

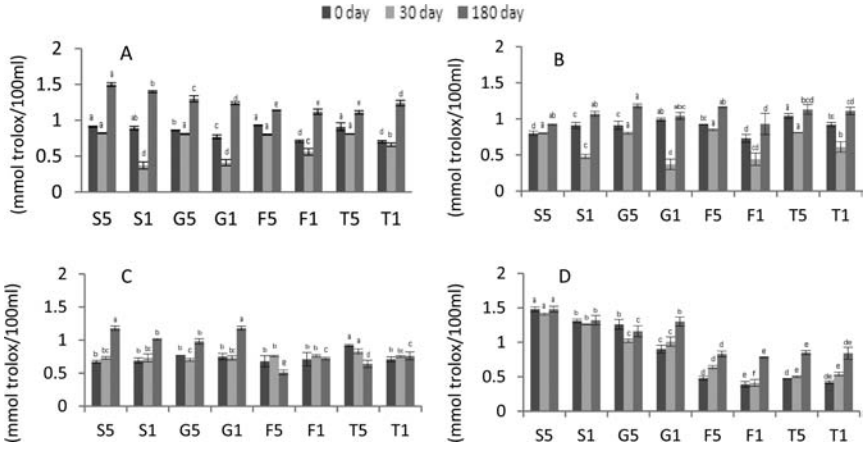

Figure 3. Antioxidative activity measured with DPPH method (mmol trolox/100 mL) for 'Idared' frozen (A) and freeze-dried (B) and 'Fuji' frozen (C) and freeze-dried (D) (S, sucrose; G, glucose; F, fructose; T, trehalose; 5, 5%; 1, 1%): black bars, immediately after preparation; light gray bars, after 3 months of storage; dark gray bars, after 6 months of storage. Each value is expressed as the mean ± standard deviation (n = 3). Among the different sugars within the same period of storage, different letters are significantly different at $p \leq 0.05$ (ANOVA, Fisher's LSD).

samples with addition of S 5%, S 1%, and G 5%. In frozen 'Idared' apple purée, antioxidative activity was the highest in the samples with an addition of T 5% and in freeze-dried samples with an addition of T 1% (3.71 and 5.33 mmol trolox/100 mL, respectively). Those results are equivalent to polyphenol content measured by HPLC.[51] The highest antioxidative activities measured in 'Fuji' apple purée with the addition of T 5%, in both frozen and freeze-dried samples, were 6.7 and 5.1 mmol trolox/100 mL, respectively. With addition of sucrose the AOA in freeze-dried 'Fuji' apple samples decreased (Figure 2).

During the first 30 days of frozen and freeze-dried 'Idared' apple purée storage, high AOA preservation after addition of S 5%, G 5%, F 5%, and T 5% was noted. In frozen 'Fuji' apple purée during the first 30 days of storage the highest preservation of AOA was noted in samples with added T 5%. However, in freeze-dried 'Fuji' apple purée during the first 30 days of storage the highest preservation ability of AOA was noted in samples with added S 5%. After the storage, the highest AOA in both frozen and freeze-dried 'Fuji' and 'Idared' apple purées was with addition of S 5% and G 5%, respectively (Figure 3).

In this study, the highest effect on polyphenol retention in freeze-dried apple purées was observed in the samples with addition of T 1%, whereas in frozen samples higher preservation of polyphenols was in samples with addition of T 5%.

The difference in the extent of the effect of sugars on TPC and AOA preservation in the particular apple variety could also depend on the complex apple matrix. In such complex natural systems, in which the presence of other compounds can lead to numerous reactions, the stability of the system will be limited by the extent to which physicochemical reactions can occur. Because the degradation mechanisms of polyphenols in the presence of sugars are still unknown, further investigations on processing (in this case freezing and freeze-drying) that induce degradation of polyphenols and the effect of different sugars on its preservation are needed.

oil−water interface plays an important role in the stability of the resultant emulsion.[18] The pH-shifting process, namely, subjecting the protein solution to an extreme acidic or alkaline pH condition and then to a neutral pH environment, allows the protein to undergo partial unfolding and then refolding to assume a molten globule conformation that has unique surface properties.[19] In our previous investigation, we applied the pH-shifting process to modify the structure of soy globulins for improved functionality. We showed that glycinin and β-conglycinin globulins subjected to such treatments lose much of their tertiary structure but retain considerable amounts of α-helical structure, embodying a molten globule state.[18,20] Typically, flexible polymers often assume "train", "loop", and "tail" configurations at the oil−water interface.[21] The tails and loops have the propensity to protrude into the aqueous phase, and the segments in the train configuration anchor into the lipid phase.[22] Both β-conglycinin (7S) and glycinin (11S) after the pH-shifting treatment appear to resume such an interfacial configuration.[23] The shear force during emulsion preparation is another important factor affecting protein load to the oil−water interface.[24] By varying the operating pressure and the geometry of the pressure cell, a certain shear force is generated to produce emulsion droplets with different sizes, thereby allowing the investigation of interfacial distribution of proteins and their possible role as antioxidants.

Pea protein, an emerging agricultural product, has great potential as a functional ingredient in the food industry.[25] Pea protein is relatively low in sulfur-containing amino acids but otherwise has an amino acid profile similar to that of other commonly consumed legumes.[26,27] According to Aluko et al.,[28] pea protein is a better emulsifier and foaming agent than soy protein at neutral pH. Proteins forming the interfacial membrane may act as a physical barrier that separates lipid molecules from pro-oxidants in the aqueous phase. Hence, the structure of adsorbed proteins and the droplet size influence the rate of lipid oxidation. On the other hand, the chemical nature of the antioxidant mechanism, including neutralization of radicals and chelation of metal ions by reactive amino acid residue side-chain groups, would further complement the physical effect and enhance the overall antioxidant activity of proteins.

The purpose of the present study was to test the hypothesis that structural modification aimed at improving protein interfacial adsorption and biophysical behavior can give rise to an O/W emulsion that is less prone to oxidation. Because pea protein having a molten globule structure induced by pH-shifting treatment is able to adsorb efficiently at the oil−water interface, it was used as the model protein surfactant. Here, we describe the evidence that physical barriers formed around oil droplets contribute to the overall oxidative stability of O/W emulsions.

MATERIALS AND METHODS

Materials. Pea protein isolate (PPI) was prepared from yellow field pea seeds (*Pisum sativum*) purchased from a local supermarket. Peas were milled and protein was extracted from the milled flour in 10 volumes (v/w) of a pH 8.0 solution and then precipitated by adjusting the pH to 4.5 as described previously.[23] The isoelectrically precipitated protein was redissolved by bringing the solution pH to 7.0 and lyophilized. All chemicals used were reagent or higher grade purchased from Sigma Chemicals (St. Louis, MO) or Fisher Scientific (Pittsburgh, PA).

pH-Shifting Treatment. Structurally modified protein was prepared by alkaline pH treatment as described previously.[23] Briefly, PPI (20 mg/mL, pH 7.0) solution was titrated to pH 12 with 2 M NaOH at 20 °C, held at this pH for 1 h to induce partial unfolding, and then titrated back to 7.0 with 2 N HCl to allow refolding. The residual salt was negligible (<0.03 in ionic strength) and therefore was not removed before lyophilization. This alkaline pH-treated sample was referred to as "APP", and the untreated (native) protein was defined as "NPP".

Evaluation of Antioxidant Activity. The prepared APP and NPP as comparison were subjected to the ABTS [2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid)] assay[29] to establish radical-quenching capability and the TBARS (thiobarbituric acid-reactive substances) analysis to validate the efficacy in a liposome system. The liposome was prepared from 0.2 mg/mL soybean phosphatidylcholine by sonication.[30] Prepared liposome was mixed with 3 mg/mL APP and NPP, stored in the dark at 37 °C, and analyzed for TBARS production during storage using the colorimetric thiobarbituric acid−malonaldehyde adduct assay.[31]

In addition, transmission electron microscopy (TEM) was applied to delineate the structural feature of liposome that might indicate the physical protective action of proteins under oxidative stress. Accordingly, one drop of liposome solution and one drop of staining solution (2% phosphotungstic acid) were applied onto a copper grid with 200 mesh and allowed to stabilize for 10 min. Images were captured using an ES500W Erlangshen charge-coupled device (CCD) camera (Gatan, Inc., Pleasanton, CA) mounted to a JEM-2100 electron microscope (JEOL, Tokyo, Japan).

Emulsion Preparation. Oil-in-water (O/W) emulsions were prepared from the mixture of 25% (v/v) sunflower oil and 75% (v/v) 10 mg/mL PPI (pH adjusted to 7.0 by titration) by initial dispersion with an Ultra-Turrax blender (Ika T18 Basic, Staufen, Germany) at 13 500 rpm for three bursts of 40 s each and then by homogenization twice with a high-pressure homogenizer at three pressure levels (30, 70, and 120 MPa) (AH2010, ATS Engineering, Inc., Shanghai, China). To prevent microbial growth, sodium azide (3 mM) was added to all samples.

Microstructure of Emulsion Droplets. Confocal laser scanning microscopy (CLSM) was applied to visualize the microstructure of emulsions and evidence the formation of protein coating around lipid droplets.[32] The oil phase in the emulsions was stained with Nile Red dye (0.1%), and the protein was stained with fluorescein isothiocyanate dye (0.1%). The dye-treated samples were placed in small cylindrical containers (10 μL) and kept in the dark for 20 min. Fluorescence was produced by excitation with a blue light (488 nm) and emission in the green region (514 nm) using a model LSM 710 CLSM machine (Carl Zeiss AG, Dresden, Germany).

Distribution and Characteristics of Interfacial Proteins. Emulsions were centrifuged at 15 000*g* for 30 min. After the removal of the cream phase (upper), the subnatant (serum) was collected and filtered through 0.22 μm pores (Stericup-GV, Minipore) to analyze the unadsorbed protein. The amount of protein present in the original cream phase and that in the serum were measured using Lowry's method. The distribution coefficient was calculated from the equation $[1 - (W_a/W_t)] \times 100\%$, where W_a is the protein (mg) in the aqueous phase and W_t is the total amount of protein (mg) in the emulsion. The cream phase was suspended in deionized water (equivalent in volume to the original serum phase) by gently stirring and then centrifuged under the same condition as described previously to recover the interfacial proteins.

The washed cream was then spread onto a Whatman No. 50 filter to dewater. The dehydrated cream containing membrane (adsorbed) proteins, as well as the serum proteins collected, were submitted to sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) to identify the composition of adsorbed proteins in the emulsions according to Laemmli using a 3% acrylamide stacking gel and 10% acrylamide separation gel.[33] Both the serum and cream samples were dissolved in an equal volume of SDS−PAGE sample buffer; the protein concentration was not standardized so that the relative distribution of polypeptides between the samples can be compared.

Emulsion Droplet Stability. Because the O/W emulsions made with APP and NPP under different pressure conditions would have different particle sizes, they might vary in flocculation behavior during storage and affect the oxidative stability. To test the tendency to flocculate, emulsion samples were placed in test tubes (22 mm diameter × 43 mm height) sealed with Teflon-coated caps and kept in the dark in a 37 °C incubator to track the formation of the cream layer during storage up to 14 days. The droplet size (d_{32}) of the emulsion samples taken at different times, after 10-fold dilution with deionized water, was measured using a Mastersizer Nano-ZS instrument (Malvern Instruments, Worcestershire, U.K.).

Whipped Cream Characterization. Whipped creams are products commonly prepared from tempered O/W emulsions. To investigate the influence of the type of protein surfactants (APP versus NPP) on the physical characteristics of such products, cream-type emulsions were prepared from the mixture of 18% hydrogenated palm oil, 16% corn syrup, 1% sodium caseinate, 0.2% xanthan, 0.1% guar gums, and 2% pea protein. The mixture was homogenized at 30 MPa as previously described, and the resultant emulsions were quickly frozen (−18 °C), thawed at 4 °C, and then blended with a KitchenAid to produce whipped creams.

For microstructural evaluation, the procedure described by Chang and Hartel was followed.[34] Briefly, samples of whipped creams placed in specimen capsules were quickly frozen by immersion in liquid nitrogen (−198 °C) and then fractured with a knife. Sublimation of ice crystals occurred under high vacuum at −115 °C. The cryo-etched samples were sputter-coated with gold and then observed in a model S-4800 Hitachi cryo-scanning electron microscope (SEM) (Tokyo, Japan).

Emulsion Oxidative Stability. We have previously shown that alkaline pH-treated soy protein, which has a markedly increased surface hydrophobicity, adsorbs more efficiently than native soy protein to the oil−water interface.[18] The peptide segments showing strong hydrophobicity have a propensity to stabilize radicals.[35] Therefore, we surmised that APP would contribute to the oxidative stability of emulsions and tested the hypothesis on stored emulsion samples. Freshly prepared emulsions were placed in Teflon-capped test tubes and incubated in the dark at 37 °C for different time periods up to 14 days. The primary and secondary products of lipid oxidation were measured as peroxides (POV) and TBARS using the procedures of AOCS[36] and Mei et al.,[31] respectively.

Statistical Analysis. The experiment was replicated 3 times (n = 3) as independent trials each with triplicate sample analyses. Data were subjected to analysis of variance using the linear model procedure of the Statistix software 9.0 (Analytical Software, Tallahassee, FL). Significant differences (P < 0.05) between means were identified by Tukey HSD all-pairwise multiple comparisons.

RESULTS AND DISCUSSION

Evidence of Antioxidative Activity of APP. When exposed to varying pH conditions, proteins undergo conformational and spectroscopic changes, a process referred to as the Tanford transition.[37] For example, shifting the pH by as little as 2 units can alter ligand-binding (and -releasing) efficiency of β-lactoglobulin due to protein structural change.[38] Upon the extreme alkaline pH (12) process, the surface hydrophobicity of resulting pea protein (APP) increased by 62% (result not shown), indicating the exposure of nonpolar amino acid residue side-chains and the attainment of a molten globule state.[18] According to Pownall et al.,[35] hydrophobic amino acids account for 40.6% of total pea protein content, and the peptide segments rich in hydrophobic and aromatic amino acids (i.e., Pro, Val, Leu, Ile, and Phe) have particularly strong radical-scavenging and metal-chelating activities. For intact proteins, His, Arg, Lys, Pro, Met, and Cys are the most common targets of oxidants due to their easy accessibility.[39] Yet, once unfolded, newly exposed hydrophobic amino acids could readily react with radicals, and, by virtue of stabilizing radicals, they accomplish the role as sacrificing antioxidants. Indeed, based on the ABTS$^{\bullet+}$ scavenging assay, antiradical activity of APP is 60% greater than that of NPP (Figure 1, lower panel). In

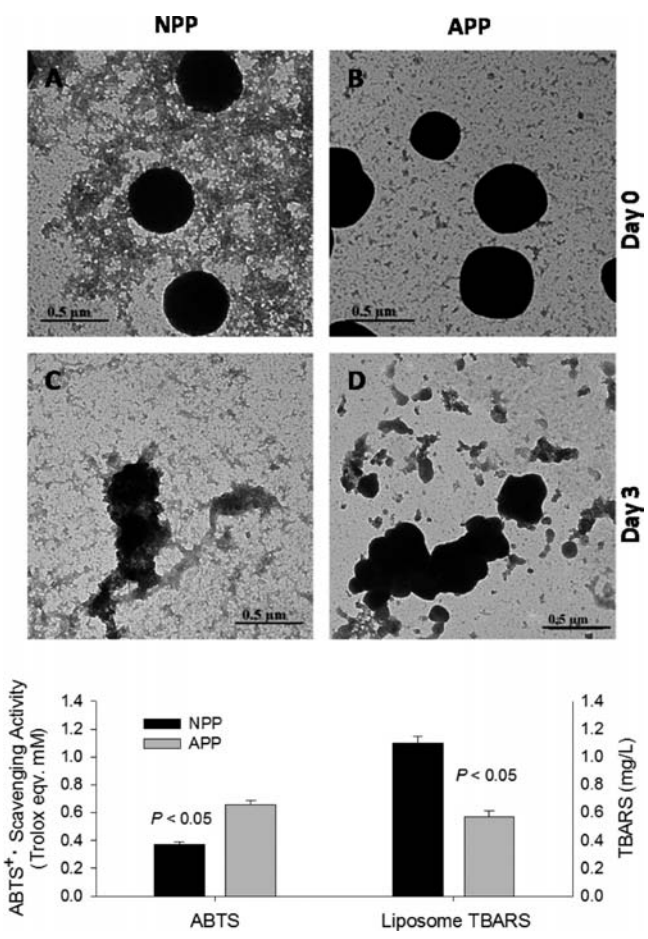

Figure 1. Transmission electron microscopic images of liposomes with native (NPP) and alkali-treated (APP) pea protein at different storage times (upper panel). Evidence of radical-scavenging activity (ABTS$^{+\bullet}$) and inhibition TBARS formation in liposome solution is shown in the lower panel.

agreement, in the oxidizing liposome model system, APP is nearly twice as effective as NPP in inhibiting the TBARS formation. Therefore, the results confirm APP as a more favorable chemical antioxidant than NPP. The stronger efficacy when compared with NPP is attributed to the protein conformational changes that expose proton/electron donors of specific hydrophobic groups.

Electron microscopy of liposome solution suggests possible physical effects of pea protein as well. Pea protein is a large globular polypeptide composed of multiple subunits.[18,35] Variations in protein−protein interaction and the effect on liposomal membrane under oxidative stress can be viewed (Figure 1, upper panel). In the process of pH-shifting, legume protein subunits are dissociated[40] and well-dispersed in aqueous solutions.[23] Therefore, proteins are largely invisible in the liposome system with APP (Figure 1B). In contrast, with their relatively intact quaternary and tertiary structures, NPP molecules in the continuous phase appear to form an interactive network surrounding liposomes (Figure 1A). The main driving force involved in the interaction between globally

dx.doi.org/10.1021/jf405190h | J. Agric. Food Chem. 2014, 62, 1683−1691

anionic liposomes and protein is believed to be electrostatic compensation, but hydrophobic contribution is also present.[41,42] In the liposome, the phosphatidylcholine head group contains a positively charged choline moiety and a negatively charged phosphate group. At pH 7.0, pea protein carries a net negative charge, and the dominant anionic groups can form charge pairing with the choline group so as to enable protein adsorption on liposomes via ionic forces. Moreover, due to the alkali-induced exposure of more nonpolar residues, hydrophobic interactions between nonpolar segments of pea polypeptides and liposome could be improved, leading to an enhanced physical protection of liposome particles against oxidation.

Because of the discrepant protein−phospholipid interaction, there are significant morphological differences between liposome particles with the presence of APP and those with NPP as well as their susceptibility to oxidation. The surface of fresh liposome particles in the NPP solution appears to be slightly rough when compared with that of liposomes dispersed in the APP solution. Liposome particles with NPP are very sensitive to oxidation, and the spherical structure is totally destroyed, forming clusters and fusion in an elongated manner, reminiscent of fibrillar aggregates (Figure 1C). While oxidized liposomes in the presence of APP also form aggregates with shrunk vesicles, some of the original structure, i.e., globes, appears to be partially preserved (Figure 1D).

Emulsion Oxidative Stability. The efficacy of APP to protect emulsions from autoxidative processes through serving as an oil droplet coating was assessed by monitoring the formation of primary (peroxides) and secondary (TBARS) products from oxidized lipids during storage. The relationship between POV (y) and storage time (x) is successfully fitted to the power-law model, $y = a(1 + x)^b$ (Figure 2, upper panel). While the a value is fairly constant, the power-law index, b, is significantly larger for emulsions prepared with NPP when compared with APP emulsions, indicating not only a greater rate but also a higher extent of autoxidation. The production of TBARS over time follows a sigmoidal curve pattern, and the most rapid accumulation of TBARS appears to occur between day 4 and day 10. Similar to the POV evolution, APP provides a stronger protection of the O/W emulsions than NPP. However, for emulsions prepared with NPP, the results are best fitted to a sigmoidal−logistic model, differing from the emulsions with APP that is perfectly fitted in a sigmoidal−Chapman equation. The subtle difference in curve fitting indicates that the mode of stabilization against oxidation has shifted and is dependent upon the protein surfactants used.

The influence of homogenization pressure on the emulsion oxidative stability cannot be ignored. In general, the most extensive autoxidation is induced at 120 MPa, whereas the difference between 30 and 70 MPa is variable and small (Figure 2). Because under the same pressure the NPP emulsion is always more susceptible to oxidation than the APP emulsion, the structure of parent proteins (i.e., before high-pressure homogenization) is an important controlling factor.[10] Aside from the elicited radical-scavenging power (Figure 1), physical shielding through increased adsorption and interfacial distribution (results described later) of the alkali-treated protein appears to impart a steric mechanism to the protection of the emulsion during storage.

As reported by Desrumaux and Marcand,[24] from 60 to 100 MPa, the viscosity and the amount of adsorbed protein in an O/W emulsion increases as the average droplet size decreases.

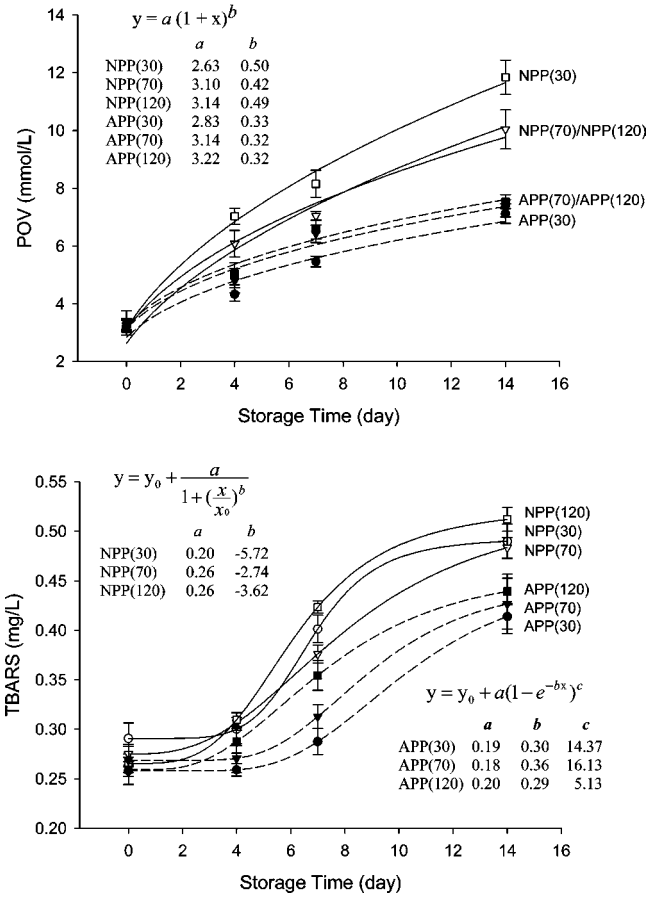

Figure 2. Oxidative stability (POV, TBARS) of O/W emulsions prepared under different pressures (values in parentheses, MPa) with native (NPP) and alkali-treated (APP) pea protein during storage (37 °C). The curves were fitted to the power-law model for POV (upper panel) and the sigmoidal−logistic/Chapman model for TBARS (lower panel).

At above 100 and up to about 210 MPa, d_{32} increases and then reaches a plateau, manifestating an "overprocessing" phenomenon. The total surface area increase due to particle size reductions leads to a rapid increase of the fraction of adsorbed proteins, i.e., a higher protein-to-lipid ratio. This also explains why the oxidative stability is improved in the presence of APP. Nakaya et al.[43] studied the oxidation of O/W emulsions with TAG and sucrose lauryl ester as the emulsifier, noting that fine-particle emulsions were more resistant to oxidation than large-particle emulsions.

CLSM. To elucidate the structural role of APP in the oxidative stability of emulsions, a series of morphological and physical analyses were performed. The CLSM image of pea protein-stabilized emulsions illuminated with two different fluorescent dyes demonstrates the coverage of oil droplets by proteins (dyed red). The microstructure of the emulsion containing NPP (Figure 3A) is very inhomogeneous. This emulsion has a broad droplet size distribution with a larger mean droplet diameter up to ~4 μm (data not shown). After 3 days of storage, many droplets form clusters with small droplets being attached to the surface of the larger ones, and some clusters appear to loosely connect with each other (Figure 3C). However, there is no apparent fusion or coalescence of the emulsion particles. In comparison, a different morphological image is observed for emulsions stabilized with APP where not

dx.doi.org/10.1021/jf405190h | J. Agric. Food Chem. 2014, 62, 1683−1691

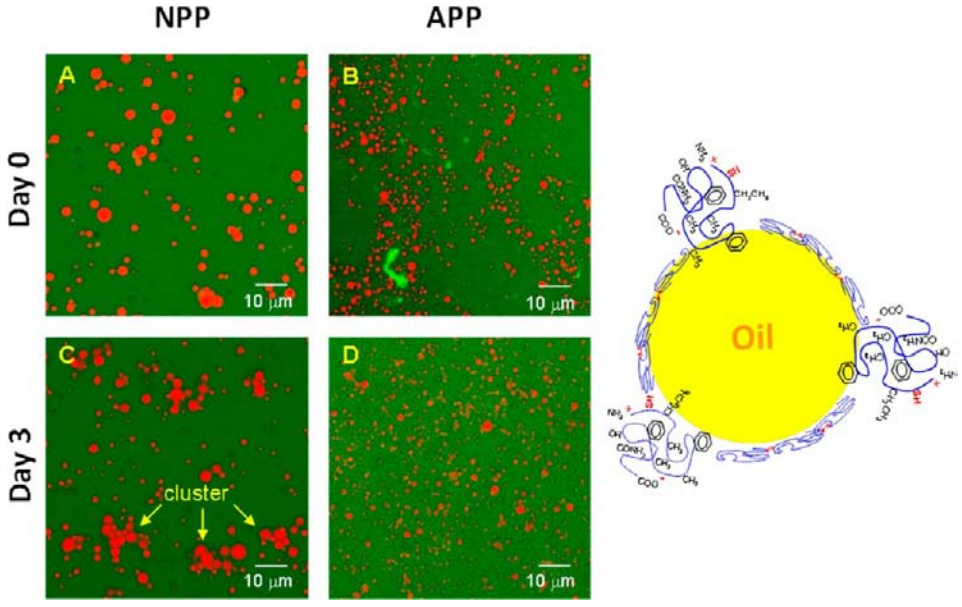

Figure 3. Representative confocal image of O/W emulsions prepared under 30 MPa with native (NPP) and alkali-treated (APP) pea protein at different storage times. The drawing on the right depicts hypothetical oil droplets with a protein membrane.

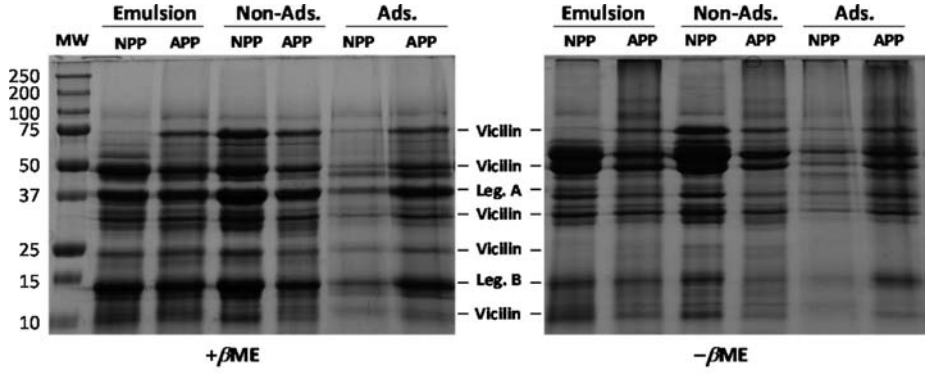

Emulsifier	Total protein (mg/mL)	Aqueous phase (%)	Cream phase (%)	Distribution coefficient
NPP	7.5	56.1	43.9	0.44
APP	7.5	33.3	66.7	0.67

Figure 4. Protein distribution in the aqueous and cream phases (lower panel) and the compositional profiles of nonadsorbed (Non-Ads.) and adsorbed (Ads.) proteins (upper panel) for O/W emulsions prepared under 30 MPa with native (NPP) and alkali-treated (APP) pea protein. MW, molecular weight (kDa); βME, β-mercaptoethanol. In each lane 30 μL of sample was loaded.

only are the oil droplets much smaller but also they are more homogeneous and uniform (Figure 3B). The result indicates a greater coating efficiency of alkali-treated (pH-shifting) protein on the oil droplets due to higher emulsifying activity, which would contribute to the oxidative stability of the O/W emulsion systems.

Furthermore, the emulsion with APP appears to be very stable, and the spherical droplets remain well-separated, showing no apparent flocculation after 3 days (Figure 3D). On the basis of our preliminary study on soy globulins, pH-shifting treatment induces a molten globular structure that has an improved surface activity and thus more efficient loading at the oil−water interface.[18] In the present case, partially unfolded pea polypeptides are more easily adsorbed to the surfaces of oil droplets through hydrophobic interactions, forming a multilayered thicker protein membrane capable of withstanding emulsion droplet coalescence when compared with the emulsion created with NPP. This would explain the improved oxidative stability of APP emulsions. Although in the present study the thickness of adsorbed protein layers is not known, Delahaije et al.,[44] using a β-lactoglobulin film model, have estimated that a film with an equilibrium thickness of ∼40 nm can form at the interface in the absence of salt. At the emulsion pH (7.0), pea legumin and vicilin carry net negative charges[45] and, therefore, will repel each other, counteracting the van der Waals attraction between membrane nonpolar groups. The greater thickness of the charged protein layer surrounding oil droplets would also compensate for the interparticle hydrophobic attraction, thereby contributing to the emulsion stability based on the DLVO theory.[46] As illustrated in the drawn diagram in Figure 3, for emulsion droplets coated with APP, the larger hydrodynamic volume of membrane molten globular

dx.doi.org/10.1021/jf405190h | J. Agric. Food Chem. 2014, 62, 1683−1691

protein molecules would impart steric hindrances to prevent particle aggregation.

Identification of Interfacial Proteins. In the process of homogenizing fat in an aqueous solution in the presence of amphiphilic molecules like proteins, a membrane quickly forms around the fat globule. This membrane acts to lower the interfacial tension (surface free energy) between oil and water and, depending on the amount of surfactant adsorbed, can increase the density of the fat globule.[10] In the emulsion prepared with NPP, 44% of the protein is distributed in the cream phase, compared to 67% for the emulsion prepared with APP (Figure 4, lower panel). The greater interfacial distribution for APP is attributed to the increased amphiphilicity of pea polypeptides as well as increased structural flexibility as a result of pH-induced structural change, similar to that observed on soy protein.[18] It must be noted, however, that the larger total surface area due to smaller droplet size for the APP emulsion should account for the greater interfacial distribution of protein.

To determine the specific polypeptides adsorbed on the fat globules, the cream phase was washed to remove unbound proteins, and the bound proteins were then desorbed and subjected to SDS−PAGE. In comparison with NPP-stabilized emulsions, significantly higher amounts (band intensity) of proteins are recovered from the membrane of APP-stabilized emulsions (Figure 4, upper panel), in agreement with the above distribution data. The more effective coverage of the fat globule by APP results in, reciprocally, lesser amounts of polypeptides in the nonadsorbed protein fraction. Because of the reduction of particle size as shown in Figure 3B, the interfacial area in APP-stabilized emulsions is larger; therefore, the protein load at the interface is higher.

An advantage of SDS−PAGE analysis is that it is possible to monitor the preferential adsorption of native and pH-treated proteins. Indeed, a detailed comparison of the electrophoretic patterns indicates discrepant protein subunit adsorptions of NPP and APP. Legumin, a hexameric protein, consists of acidic (Leg. A, 38−40 kDa) and basic (Leg. B, 19−22 kDa) peptides linked by S−S bonds.[47] Because disulfide bonds are mostly cleaved during alkaline pH treatments,[20] the dissociated legumin subunits with increased structural mobility are able to diffuse and subsequently adsorb more efficiently to the fat globule surface. A number of studies have shown that free cysteine groups participate in intra- and interdroplet sulfhydryl−disulfide interchanges during emulsification.[48,22] Comparison of the lanes of adsorbed APP (pH 12) samples shows a significant recovery of the legumin basic subunit (Leg. B) after the sample is treated with βME, suggesting that newly formed legumin polymers in APP contribute to the emulsion formation and its stability. This phenomeon is largely absent in NPP emulsions. Furthermore, the protein samples recovered from washed fat globules noticeably contain higher amounts of legumin (A and B) when compared with nonadsorbed protein, which is comprised of abundant vicilin subunits (Figure 4, $-\beta$ME). The differential adsorption is obviously promoted by pH-induced structural changes in legumin, which is a more efficient surfactant having a superior emulsifying activity over vicilin.[49]

Particle Size and Stability. The pressure applied to prepare O/W emulsions was varied to produce emulsions with different droplet sizes to enable the investigation of the influence of the protein-to-fat ratio in a given oil droplet on emulsion properties. As shown in Figure 5, while the average particle size (Sauter d_{32}) of freshly prepared emulsions is

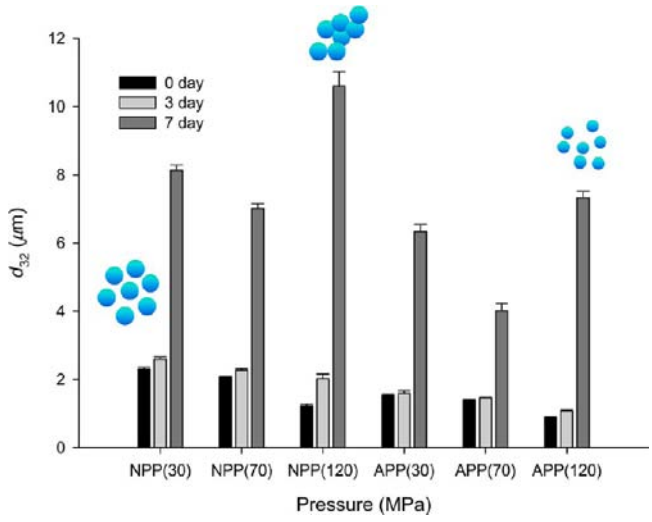

Figure 5. Average particle size (d_{32}) and storage-induced changes of O/W emulsions prepared with native (NPP) and alkali-treated (APP) pea protein under different pressures (30, 70, and 120 MPa).

reduced with increasing homogenization pressure (30 → 70 → 120 MPa), the pH treatment allows the pea protein to perform more effectively to disrupt oil into smaller droplets when compared with native protein. A smaller droplet size is obtained with a more efficient protein adsorption at the interface, and the result confirms the particle size variation observed under CLSM (Figure 3). By considering the protein distribution in the cream phase (Figure 4) and the average emulsion droplet size (Figure 5), it can be calculated that there are at least three times as many droplets (1.34×10^{10} vs 3.92×10^{9}) per mL in fresh APP emulsions (d_{32} = 1.53 μm) as in NPP emulsions (d_{32} = 2.30 μm) prepared at 30 MPa. Although the derived interfacial protein coverage based on the calculation is essentially identical (51.0 mg/m^2 for APP compared to 50.1 mg/m^2 for NPP), the substantially larger protein load per volume of an oil droplet for APP emulsions (1.99×10^{8} mg/m^3) compared to that for NPP emulsions (1.32×10^{8} mg/m^3) due to the particle size disparity would clearly favor the APP emulsion stability.

Although the mean particle size difference between freshly prepared APP and NPP emulsions is well within 1 μm, the NPP emulsion particles becomes noticeably larger during storage and the size increases 4−9-fold after 7 days, depending on the homogenization pressure. In comparison, the accretion of the APP emulsion particles is slower and the final size (by day 7) grows much less. Hydrophobic agglomeration of protein-coated oil droplets rather than fusion is responsible for the droplet size increases during storage (Figure 3). As reported by Floury et al.,[50] from 20 to 100 MPa, the diameter of whey protein-stabilized emulsion particles decreased, and, when the pressure exceeded 100 MPa, the viscosity of adsorbed protein rose significantly. The average particle sizes of the emulsions prepared with native and pH-treated pea protein at 120 MPa both increase remarkably after 7 days, ostensibly resulting from the association of the oil droplets through viscous membrane proteins.

Consequent to particle aggregation, O/W emulsions during storage are gradually separated into two phases: the cream phase (supernatant) and the serum phase (subnatant) (Figure 6). The emulsion with NPP begins showing signs of phase boundary after 1 day storage. Over the observation period, the

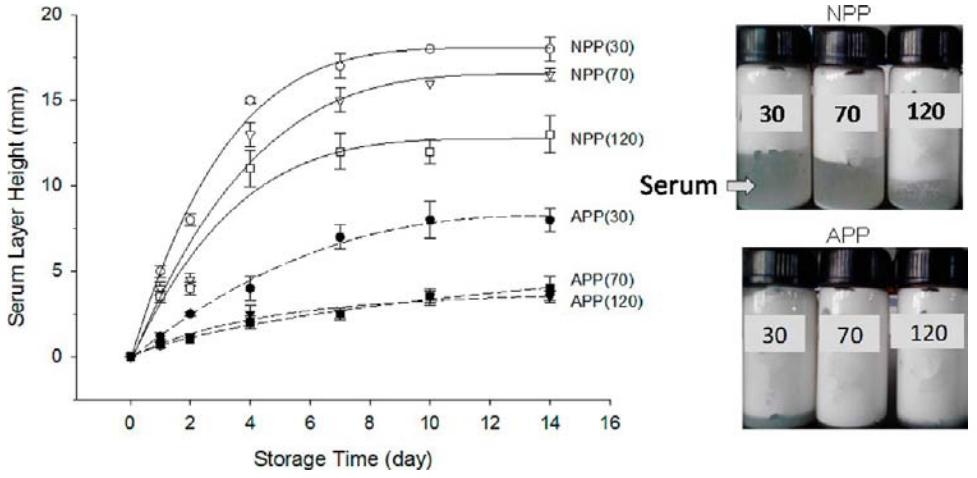

Figure 6. Storage-induced phase separation (right picture, 14 days) and resulting serum layer height (left plots) of O/W emulsions prepared with native (NPP) and alkali-treated (APP) pea protein under different pressures (30, 70, and 120 MPa).

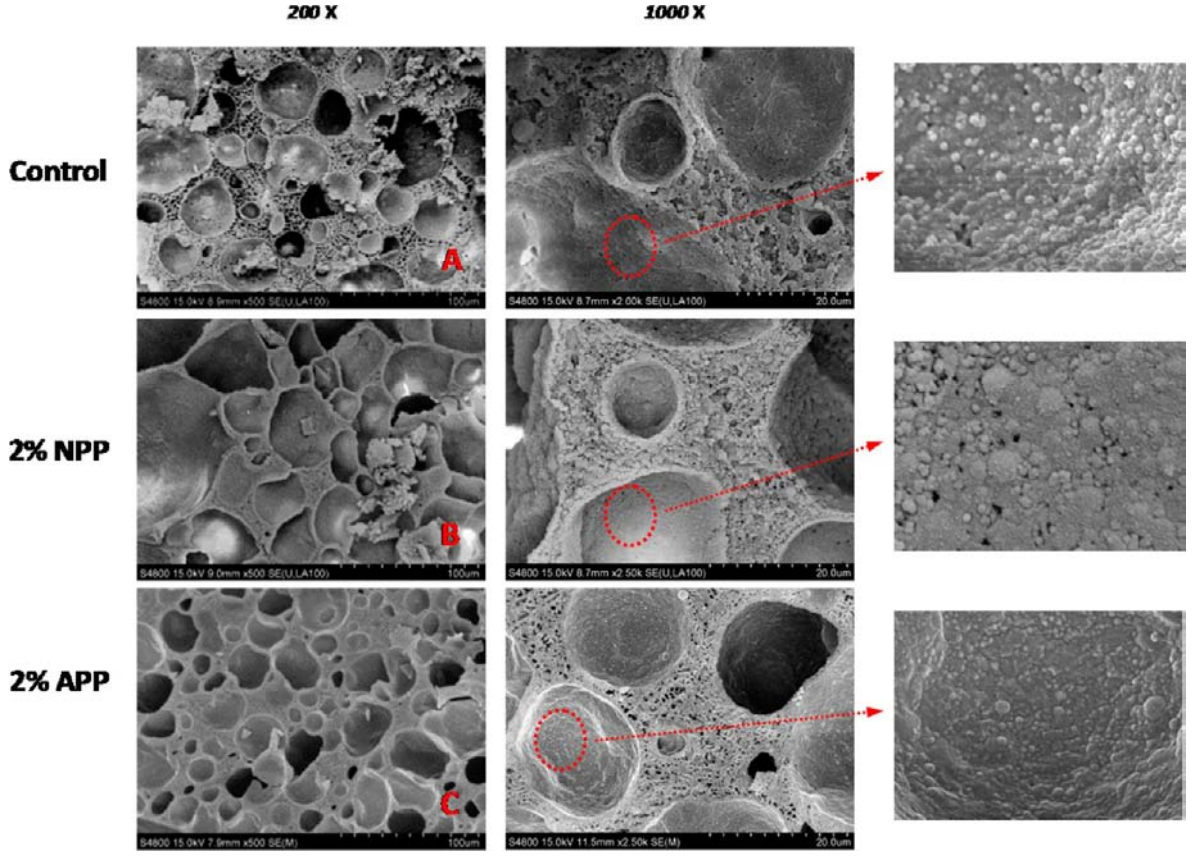

Figure 7. Cryo-scanning electron micrograph of the structure of whipped creams prepared with 18% fat without pea protein (Control); 18% fat with 2% native pea protein (NPP); and 18% fat with 2% alkali-treated pea protein (APP).

boundary line gradually becomes clearer and the height of the serum phase grows substantially within 7 days, while there is no appreciable further change between 7 and 14 days. In contrast, the emulsion with APP shows a remarkable storage stability, and the serum layer maintains a relatively low level except for samples prepared at 30 MPa, where it grows significantly taller ($P < 0.05$) after 14 days. The physical stability of a protein-based emulsion is largely attributed to the properties of the protein membrane. The fact that with APP there is a more efficient interfacial protein coverage than with NPP (Figure 4), allowing the formation of finer (Figure 5), less creaming-prone (Figure 6) and less oxidizable (Figure 2) emulsion particles, underscores the steric role of pea protein in the emulsion oxidative stability.

As also illustrated in Figure 6, the emulsion stability increases with the homogenization pressure, corresponding to the particle size reduction (Figure 5). This occurs in spite of the more rapid particle size growth in emulsions prepared at 120 MPa than in those prepared at other pressures after 7 days (Figure 5). It seems that, during storage, charge and steric repulsions are maintained between emulsion aggregates and clusters to prevent coalescence. For APP-stabilized emulsions,

dx.doi.org/10.1021/jf405190h | J. Agric. Food Chem. 2014, 62, 1683−1691

the stability is independent of the homogenization pressure at 70 and 120 MPa, suggesting that the increased particle size at 120 MPa after 7 days (Figure 5) is due to emulsion droplet flocculation. As a result of flocculation, there is an increased opportunity for the oil droplets (which ascend to the surface of the container) to be in contact with molecular oxygen. This would explain why, in the emulsion formed with NPP at 120 MPa, which consists of large particles or aggregates, there are more abundant peroxides and secondary aldehydes being produced during storage than in other emulsions (Figure 2).

Microstructure of Whipped Creams. The steric effect of pea protein at the interface was also tested in a whipped cream model system where two types of interfaces, i.e., oil−water and air−water, coexist and can influence each other. The fat content of a typical commercial whipped cream is ∼25−40% to necessitate the foam stability.[51] Foaming properties could be compromised if the fat content is reduced. In our study, we prepared whipped creams with 18% oil (which are more foamy than with a higher amount of fat) to investigate the structural role of pH-treated pea protein. Prepared emulsions after the aging, freezing, hardening, and thawing processes were blended to build a complex foam texture.

The matrix structures of three types of whipped creams (containing no added pea protein or containing 2% NPP or 2% APP) are presented in Figure 7. Each microstructure displays vivid air cells immobilized within a network consisting of protein and tiny fat globules. The control cream with 18% fat still maintains some degree of structure, but the foam stability is poor. The incorporation of NPP slightly improves the appearance of the whipped cream, but it still exhibits broad and flat large surface areas instead of regular-shaped air pockets, which are basically fracture planes along the largest dimension of the air cell. In contrast, with the presence of APP, the cream displays a uniform texture filled with air cells that are small and regular in shape. Moreover, the intricate underside of the "dome" of the air cells (pointed to by an arrow) in the APP-stabilized cream exhibits a somewhat fused layer of fat droplets immobilized with a continuous protein coating. The formation of such fat globule clusters and agglomerates in whipped creams has been described as "partial coalescence", which is responsible for surrounding and stabilizing air cells and creating a semicontinuous network or matrix of fat throughout the product.[52] Although weakening of the fat globule membrane through tempering and whipping is a necessary process for the creation of an agglomerated structure, partially coalesced fat globules with APP still maintain a superior aggregated network throughout the volume. Consequently, the air cells within the APP-fortified whipped cream are uniformly distributed and effectively entrapped. In comparison, the relatively weak adsorption of NPP at the oil−water interface seems to render the emulsion vulnerable to extensive coalescence during whipping, which is evidenced by the presence of large and discrete fat globules, resulting in a less stable cream product with numerous pinholes.

In conclusion, the properties of O/W emulsions formulated with sunflower oil and pea protein are significantly affected by the protein surfactant and the homogenization procedure that employs different pressures. The emulsions prepared with structurally modified pea protein by the alkaline pH-shifting process (APP) are distinctly more stable against coalescence and resistant to oxidation than emulsions formed with native pea protein (NPP). Evidence from confocal microscopy and electrophoresis suggests that increased adsorptions of APP molecules, particularly legumin, onto the fat globules and their accumulation at the oil−water interface are the primary mechanism for the physicochemical stability of the emulsions. High-pressure homogenization up to 70 MPa disrupts oil into fine droplets that are then stabilized by an interfacial protein coating capable of minimizing the interfacial tension and free energy. Attributed to steric repulsions, fine and small emulsion droplets with a viscoelastic membrane made up of structurally flexible APP are more resistant to lipid oxidation than large emulsion droplets formed with NPP. However, the lack of reliable correlations between particle size and oxidation rates suggests that the nature and properties of the interfacial protein rather than the particle size are a more important determinant of the oxidative stability of oil emulsions. Hence, it is entirely possible, through modifying the conformation of a protein surfactant (e.g., pH-shifting for pea protein as in the present case), to produce an O/W emulsion with desirable surface properties and oxidative stability thereby allowing the emulsion droplets to function as carriers for nutrients, bioactive compounds, and other food or pharmaceutical additives.

the membrane disturbance assumed to explain the proven activity of lysozyme against some Gram-negative strains.[15−17]

Molecules that provoke bacterial membrane disruption are mostly positively charged, amphipathic, and hydrophobic.[4] Lysozyme possesses these physicochemical criteria at physiological pH. However, lysozyme activity against Gram-negative bacteria remains limited, but when lysozyme is modified by fusion with a chemical moiety,[18−23] heat denaturation,[24−26] or enzymatic hydrolysis,[27,28] its antimicrobial activity is enhanced. One relevant question is then to investigate the antibacterial activity against Gram-negative bacteria of lysozyme modified to increase its positive charge and/or amphipathicity and/or hydrophobicity. Dry-heating of lysozyme has been described as an easy process resulting in different lysozyme isoforms, some of them being especially more positive and more hydrophobic than native hen egg white lysozyme.[29] This modified lysozyme could then be an opportunity to create a new efficient antimicrobial, simply using a safe physical treatment.

MATERIALS AND METHODS

Materials. Native lysozyme powder (pH 3.2) was obtained from Liot (Annezin, 62-France); it was heated for 7 days at 80 °C in hermetically closed glass tubes to obtain dry-heated lysozyme. *Micrococcus lysodeikticus*, ATCC no. 4698, Trisma base, potassium phosphate monobasic, potassium phosphate dibasic, potassium chloride, ampicillin, chloramphenicol, (*o*-nitrophenyl)galactoside (ONPG), 3,3′-dipropylthiadicarbocyanine iodide ($DiSC_3$), 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), and glucose were obtained from Sigma-Aldrich (Saint-Quentin, France).

Nitrocefin, a standard solution of potassium (1000 mg/L), casein peptone, and yeast extract were obtained from Merck Chemicals (Darmstadt, Germany). Tryptic soy broth (TSB) was from AES (Bruz, France).

Bacterial Strains. Three different *E. coli* strains have been used (Table 1). *E. coli* K12 was obtained from the Institut Pasteur (Paris, France). *E. coli* MG1655 *ivy*::*Cm* was kindly provided by C. Michiels (Centre of Food and Microbial Technology, KU Leuven, Belgium); this bacterial strain no longer expresses the lysozyme inhibitor Ivy. The bacterial strain *E. coli* ML-35p (*LacI*$^-$ *LacY*$^-$ *LacZ*$^+$, plasmid pBR322) was kindly provided by R. Lehrer (Department of Medicine, University of California, Los Angeles) and transmitted to our laboratory by D. Destoumieux-Garzon (UMR 5119, Ecologie des systèmes marins côtiers, University of Montpellier, France). *E. coli* ML-35p lacks lactose permease and expresses *β*-lactamase and *β*-galactosidase in the periplasm and cytoplasm, respectively.

Table 1. Presence (+) or Absence (−) of Ivy, *β*-Lactamase, *β*-Galactosidase, and Lactose Permease in the Different Bacterial Strains Used for the Present Study

	Ivy	*β*-lactamase	*β*-galactosidase	Lactose permease
E. coli K12	+	−	+	+
E. coli ML-35p	+	+	+	−
E. coli MG1655 *ivy*::*Cm*	−	−	+	+

Growth Assays with *E. coli* K12 and *E. coli* MG1655 *ivy*::*Cm*. The bacterial culture *E. coli* K12 or *E. coli* MG1655 *ivy*::*Cm* was grown overnight (18 h) at 37 °C under stirring (130 rpm) in TSB containing 50 *μ*g/mL ampicillin or 30 *μ*g/mL chloramphenicol, respectively. After the incubation period, the cultures contained about 10^9 CFU/mL *E. coli*, from which 10^5 CFU/mL bacterial suspensions were prepared by performing four 10-fold serial dilutions in LB05 (Luria broth containing 10 g/L peptone of casein, 5 g/L yeast extract, and 0.5 g/L NaCl). After solubilization in demineralized water, lysozyme (native or dry-heated) was added at 0.25 or 3.7 g/L to the bacterial suspension, before incubation at 37 °C under stirring (130 rpm) for 24 h; 3.7 g/L is the natural concentration of lysozyme in hen egg white. Cell enumeration was performed by colony count after 2, 4, 6, and 24 h as previously described by Baron et al.[30] The results for cell counts are based on nine replicates (three biological replicates, each with three technical replicates).

Outer and Inner Membrane Permeability Measurements. Outer and inner membrane permeability was measured using the Lehrer method,[31] modified as described by Derde et al.[32] The *E. coli* ML-35p culture was grown overnight (18 h) in TSB containing 50 *μ*g/mL ampicillin at 37 °C under stirring (130 rpm). The bacterial culture was washed twice in 50 mM Tris−HCl buffer, pH 7.0 (5000*g*, 10 min), and diluted to obtain about 10^7 CFU/mL in solutions containing 0.25 or 3.7 g/L native or dry-heated lysozyme.

To test outer membrane permeability, 0.015 mg/mL nitrocefin (substrate of *β*-lactamase) was added to the sample solutions. When the outer membrane was permeabilized, the periplasmic *β*-lactamase hydrolyzed nitrocefin into the hydrolysis product of nitrocefin (HP-nitrocefin). HP-nitrocefin absorbance was measured at 486 nm (Spectramax M2, Molecular Devices, United Kingdom), at 37 °C under stirring.

To test inner membrane permeability, 0.7 mg/mL ONPG (substrate of *β*-galactosidase) was added to the sample solutions. When the inner membrane was permeabilized, the cytoplasmic *β*-galactosidase hydrolyzed ONPG into *o*-nitrophenol (ONP). ONP absorbance was measured at 420 nm (Spectramax M2, Molecular Devices, United Kingdom), at 37 °C under stirring.

Two parameters could then be determined: maximal slope and lag time. The maximal slope determined the maximal velocity of the enzymatic reaction of either *β*-lactamase or *β*-galactosidase. The maximal velocity is directly related to the concentration of accessible enzyme and thus to the permeability of the outer or inner membrane, respectively. The lag time was the time between outer and inner membrane permeabilization, estimated by the delay between both enzymatic reactions.

The results of lysozyme activity on membrane permeability are based on three replicates. The results were corrected for reference absorbance, i.e., the absorbance of the microplate and of the buffer solution.

Detection of *β*-Lactamase and *β*-Galactosidase Leakage out of Bacterial Cells. After overnight growth (18 h) in TSB containing 50 *μ*g/mL ampicillin at 37 °C under stirring (130 rpm), the *E. coli* ML-35p culture was washed twice with 50 mM Tris−HCl buffer, pH 7.0 (5000*g*, 10 min), and diluted to obtain 10^7 CFU/mL bacterial suspensions. These suspensions were added with lysozyme (0.25 or 3.7 g/L, native or dry-heated lysozyme) and incubated for 5 h at 37 °C under stirring, before centrifugation at 5000*g* for 10 min. *β*-Lactamase and *β*-galactosidase activities were then tested in the supernatants by adding 0.05 g/L nitrocefin and 1 g/L ONPG, respectively. The initial reaction rates of both enzymatic reactions (v_0 = ΔAU/min) were determined at 25 °C from absorbance curves (Multiskan Go, Thermo Fisher Scientific, Illkirch, France) at 486 and 420 nm, respectively.

Measurement of the Bacterial Membrane Potential Disruption. The disruption of the bacterial membrane potential was measured according to the method proposed by Wu et al.[33] The *E. coli* K12 culture was grown for 3.5 h in TSB at 37 °C under stirring (130 rpm) to reach a midlog phase. The culture was washed twice with 5 mM HEPES buffer at pH 7.2 containing 5 mM glucose (5000*g*, 10 min) and diluted to obtain an absorbance of around 0.06 at 620 nm. A 1 *μ*M concentration of $DiSC_3$ and 100 mM KCl were added to the diluted bacterial suspension, before incubation for 1 h at 30 °C in the dark. Then lysozyme (0.25 or 3.7 g/L, native or dry-heated) was added to the bacterial cells, and the samples were incubated for 30 min at 30 °C in the dark. Fluorescence was then measured at 670 nm with a fluorimeter, Perkin-Elmer LS55 (Perkin-Elmer, Courtaboeuf, France), after excitation at 622 nm; the slit width was 2.5 nm/2.5 nm, and the integration time was 6.2 s. The results are based on nine replicates (three biological replicates, each with three technical replicates).

Potassium Leakage Measurement. The measurement of potassium leakage was performed according to the method described by Orlov et al.[34] After overnight growth (18 h) in TSB at 37 °C under stirring (130 rpm), the *E. coli* K12 culture was washed twice with 10 mM Tris−acetate buffer, pH 7.0, containing 100 mM NaCl (5000*g*, 10 min), and diluted to obtain 10^8 CFU/mL bacterial suspensions. Lysozyme (0.25 or 3.7 g/L, native or dry-heated) was added to the bacterial solutions, and then the samples were incubated for 3 h at 37 °C under stirring, centrifugated (5000*g* for 10 min), and filtered with 0.22 μm filters. The K^+ concentration was measured in the filtrates using a potassium-selective electrode (DX239-K) coupled to an S50 SevenMulti meter (Mettler Toledo, Viroflay, France) and recorded with an ISE meter previously calibrated with six standard solutions containing 5.15, 10.3, 77.6, 103, 1330, and 11700 μM potassium, respectively. Calibration and measurements were performed at 25 °C.

Optical Microscopy and Atomic Force Microscopy (AFM). The *E. coli* K12 culture was grown overnight (18 h) in TSB at 37 °C under stirring (130 rpm). After the incubation period, the culture contained about 10^9 CFU/mL *E. coli*, from which 10^5 CFU/mL bacterial suspensions were prepared by performing four 10-fold serial dilutions in LB05. Then lysozyme (0.25 or 3.7 g/L, native or dry-heated) was added to the bacterial suspension before incubation at 37 °C under stirring (130 rpm) for 24 h. Samples were washed in a 0.85% NaCl solution (3000*g*, 10 min) before optical microscopy and AFM were performed.

Optical microscopy observations were performed with an Olympus BX51 (enlargement 100×). Images were taken with a digital camera, Olympus Camedia C-5050.

Samples were deposited on freshly cleaved mica. To avoid accumulation of bacteria, a dipper (Nima Technology, Cambridge, U.K.) was used to gently remove the mica from the sample solution at 2 mm/min while the solution was being stirred. The mica plate was then dried at room temperature, and shortly after that, AFM imaging was performed. Images were recorded with a Pico-plus atomic force microscope (Molecular Imaging, Phoenix, AZ) operating in tapping mode. A scanner of 100 μm was used for the measurements. Topographic and phase images, illustrating cell topography and cell heterogeneity,[35] were acquired simultaneously using silicon nitride tips (AppNano, Silicon Valley, CA) with a resonance frequency of 145−230 kHz and a nominal spring constant of 20−95 mN/m. Transversal cross sections of the bacteria were performed to illustrate height and surface roughness. The images presented in the present study are representative of several samples.

Statistical Analysis. All experiments were performed at least in triplicate. Statistical analysis was performed with R 2.15.2. Significance levels were at least 95%. Data from the normal distribution and with equal variances were treated with parametric tests. In this case, for the comparison of means the Student *t* test was used. Data from other distributions or with unequal variances were treated with non-parametric tests. In this case, for the comparison of means the Wilcoxon rank sum test was used.

RESULTS

Growth of *E. coli* in the Presence of Lysozyme. The growth of *E. coli* K12 is disturbed in the presence of both native (N-L) and dry-heated (DH-L) lysozyme during the first hours of growth (Figure 1A), but after 24 h of incubation at 37 °C, no significant difference is observed between the samples with or without lysozyme. The growth of *E. coli* K12 shows the same pattern when N-L is added, whatever the concentration (0.25 or 3.7 g/L), and when DH-L is added at low concentration (0.25 g/L): the bacterial growth is inhibited for 2 h, before it recovers, and cell counts similar to those in the control sample (without lysozyme) are finally reached. On the contrary, the addition of 3.7 g/L DH-L induces a different pattern of the *E. coli* K12 growth: 1 log reduction of the bacterial cells is observed after 2 h of incubation, after which the growth rate recovers; with up to 6 h of incubation, the *E. coli* K12 population remains lower than in the other samples (control sample and samples with N-L or low-concentration DH-L).

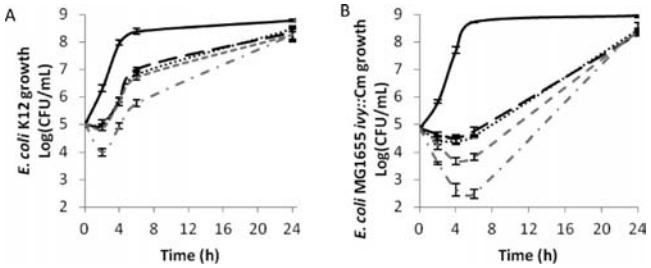

Figure 1. Growth curves of *E. coli* K12 (A) and of *E. coli* MG1655 *ivy*::*Cm* (B) in LB05 medium in the absence of lysozyme (—) or in the presence of 0.25 g/L N-L (− − −), 0.25 g/L DH-L (···), 3.7 g/L N-L (---,) or 3.7 g/L DH-L (-·-). The results are based on nine replicates.

When the same tests are performed on the *E. coli* MG1655 *Ivy*::*Cm* strain, which lacks the periplasmic lysozyme inhibitor Ivy, the impact of lysozyme on the bacterial growth pattern is stronger as compared to that for *E. coli* K12, for both N-L and DH-L and both concentrations (0.25 and 3.7 g/L) (Figure 1B). The modification of the growth pattern is dose-dependent: the higher the N-L or DH-L concentration, the higher the population decrease observed in the first hours of incubation. At high concentration (3.7 g/L), DH-L causes a population decrease which is 1.3 log higher than that of N-L, whereas no difference is observed between both types of lysozyme at low concentrations (0.25 g/L). However, the number of bacterial cells suitable for growth is the same after 24 h of incubation with N-L and DH-L.

Membrane State of *E. coli* in the Presence of Lysozyme. N-L and DH-L induce similar overall permeabilization of the outer membrane whatever the concentration, as measured by the total β-lactamase activity (Figure 2A), but externalized β-lactamase activity, i.e., activity in the supernatant resulting from centrifugation of the bacterial culture incubated with lysozyme, is higher with DH-L than with N-L at both lysozyme concentrations (Figure 2B). Moreover, it is noticeable

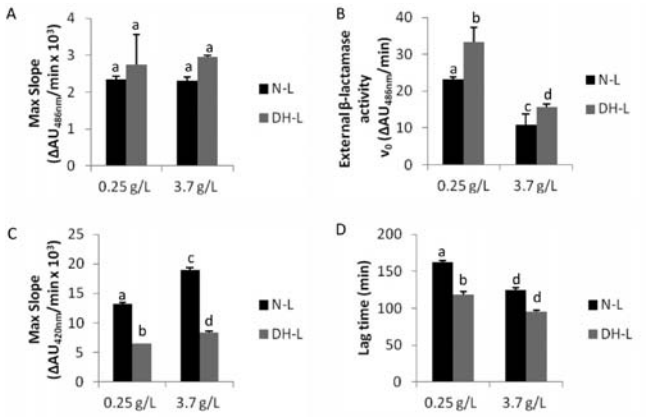

Figure 2. Comparison of the permeabilization of *E. coli* ML-35p outer (A, B) and inner (C, D) membranes by native (N-L) or dry-heated (DH-L) lysozyme as evidenced by β-lactamase and β-galactosidase activity, respectively. Different letters (a, b, c, d) indicate significant difference obtained from the Student *t* test (A, C, D) ($p < 0.01$) or Wilcoxon rank sum test (B) ($p < 0.01$).

that a high concentration (3.7 g/L) of N-L and DH-L causes lower externalized β-lactamase activity than a low concentration (0.25 g/L) (Figure 2B).

Figure 2C shows that permeabilization of the inner membrane is stronger with N-L than with DH-L at either 0.25 or 3.7 g/L. On the other hand, the lag time before detection of the inner membrane permeabilization is shorter with DH-L than with N-L at both concentrations (Figure 2D). The intensity of inner membrane permeabilization and lag time are lysozyme concentration-dependent for both N-L and DH-L.

Disturbance of the inner membrane has also been investigated by measurement of changes of the membrane potential. N-L and DH-L similarly disturb the membrane potential of *E. coli* when added at 0.25 g/L in the bacterial culture. On the contrary, at higher concentration (3.7 g/L lysozyme), DH-L causes a stronger disruption of the membrane potential than N-L, as indicated by the 2-fold higher relative fluorescence of $DiSC_3$ (Figure 3A). For both N-L and DH-L, a dose−response effect is observed.

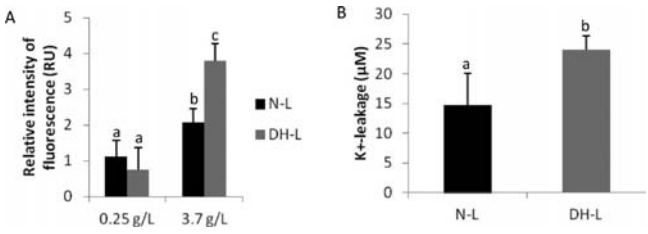

Figure 3. (A) Disruption of the membrane potential of *E. coli* K12 caused by native (N-L) or dry-heated (DH-L) lysozyme at 0.25 and 3.7 g/L. Different letters (a, b, c) indicate significant difference obtained from the Student *t* test ($p < 0.01$). Results are based on nine replicates. (B) K^+ leakage of *E. coli* K12 in the presence of 3.7 g/L N-L or DH-L after 3 h of incubation. Different letters (a, b) indicate significant difference obtained from the Student *t* test ($p < 0.01$). Results are based on six replicates.

Finally, the measurement of intracellular K^+ leakage has been used as an indicator of inner membrane disruption. K^+ leakage is not detectable in *E. coli* cultures containing 0.25 g/L N-L or DH-L (data not shown), but significant K^+ leakage is measured in the presence of 3.7 g/L lysozyme. The extent of the K^+ leakage is 75% higher with DH-L than with N-L (Figure 3B).

Morphology of *E. coli* K12 in the Presence of Lysozyme. *E. coli* K12 incubated for 24 h in the presence of 0.25 g/L lysozyme exhibits differences in cell morphology in comparison to the control sample, as shown by optical microscopy images (Figure 4). Abnormally elongated bacterial cells are observed after treatment with lysozyme; such modified bacteria are present in a larger number when DH-L is added as compared to N-L (Figure 4B,C). These elongated cells could not be observed at high concentration (3.7 g/L) of N-L and DH-L (data not shown).

Topographic AFM enables determination of the size and characterization of the shape and the surface topology of bacteria. Nontreated bacteria are about 2 μm long, with a diameter of 500 nm; the surface is smooth and regular, and flagella are observed (Figure 5A). When bacteria are treated with N-L, the size is not modified (Figure 5B,D), whereas abnormally elongated cells without a visible septum are observed when the bacteria are treated with 0.25 g/L DH-L (Figure 5C). With high-concentration N-L treatment (Figure 5D), depressions can be observed on the bacterial cells, but the bacterial morphology is more strongly disturbed when the bacteria are treated with DH-L (Figure 5C,E), with an especially irregular cell surface and depressions; the depth and the diameter of these depressions increase when the DH-L concentration increases: around 15 nm depth at 0.25 g/L DH-L versus around 26 nm at 3.7 g/L and around 128 nm diameter versus 160 nm. When the bacteria are treated with either 3.7 g/L N-L or both concentrations of DH-L, cell debris is also observed (data not shown).

Phase AFM enables visualization of homogeneity or heterogeneity of the cell surface composition.[35] Thus, the nontreated bacteria appear homogeneous (Figure 6A), whereas heterogeneity can be observed with all the treated samples, with either N-L or DH-L, and at both concentrations (Figure 6B−E). However, higher heterogeneity is observed when the bacteria are treated with DH-L as compared to N-L.

DISCUSSION

The capability of native hen egg white lysozyme to permeabilize the outer and inner membranes of *E. coli* has been previously established by Derde et al.[32] Moreover, some structural modifications of lysozyme proved to be efficient to enhance the antibacterial activity of this protein.[8] Modifying lysozyme to design a novel antimicrobial with enhanced membrane activity and thus improved antibacterial activity against *E. coli* then seems relevant. Because membrane activity of antimicrobial proteins or peptides is highly dependent on the physicochemical properties of the molecules, dry-heating could be an interesting process for lysozyme design. Indeed, dry-heated lysozyme is more hydrophobic and more surface-active, and it contains isoforms that are more positively charged than native lysozyme.[29] To test the hypothesis that dry-heated lysozyme is more active than native lysozyme against *E. coli*, because of an increased membrane activity, a comparative study is proposed.

Native Lysozyme Causes *E. coli* K12 Growth Latency. In the presence of low and high concentrations of N-L, the inhibition of *E. coli* K12 growth is observed for 2 h (Figure 1A). Lysozyme is undoubtedly the cause of this phenomenon, regarding the fact that the control sample (without lysozyme) does not induce any lag time before bacterial growth starts (Figure 1A). However, the N-L effect is rather short, and bacterial growth resumes. A bacterial concentration similar to that in the control sample is reached after 24 h of incubation (Figure 1A). This could be explained by several hypotheses: damage repair by the bacteria, activation of adaptation and defense mechanisms, and/or depletion of lysozyme in the growth medium by irreversible interaction with the bacteria.

The first possibility is that N-L causes minor damage to the bacterial cells. This damage does not lead to cell death, but the bacterial cell needs to repair the obtained cell structures. For these repair mechanisms, energy is needed and cell growth is thus retarded.

E. coli also have several defense mechanisms. The first defense mechanism of Gram-negative bacteria is the outer membrane. However, lysozyme has been shown to cross this hurdle.[32] Another present defense mechanism in *E. coli* is the lysozyme inhibitor Ivy, which neutralizes N-L in the periplasm.[36] When N-L reaches the periplasm of *E. coli*, Ivy binds to N-L. This makes N-L harmless for the *E. coli* cells (Figure 1). Enterobacteriaceae are also known for the presence of proteases on their outer membrane. *E. coli* K12 carries a protease, OmpT, which combines characteristics of serine and aspartate proteases. The OmpT of *E. coli* K12 has been

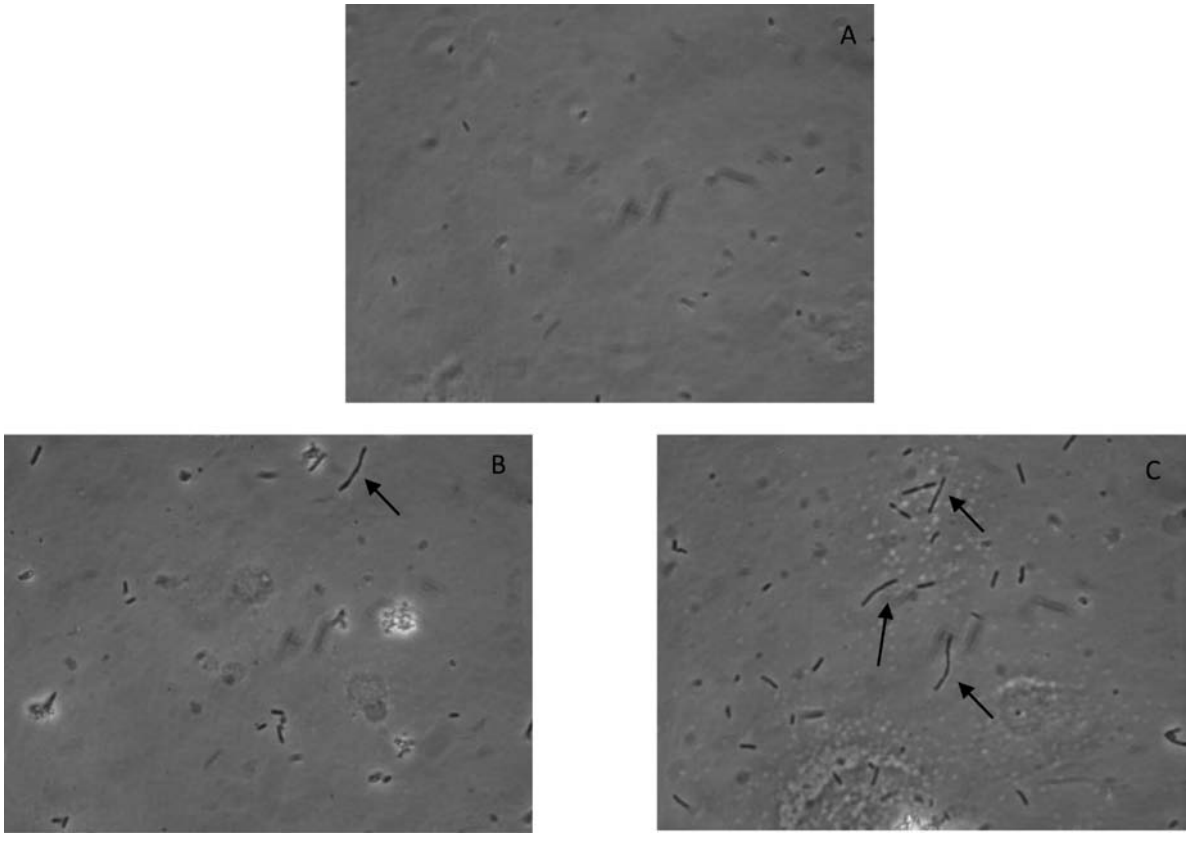

Figure 4. Observations of *E. coli* K12 with optical microscopy after 24 h of incubation in the absence of lysozyme (A) and in the presence of 0.25 g/L native lysozyme (N-L) (B) and dry-heated lysozyme (DH-L) (C).

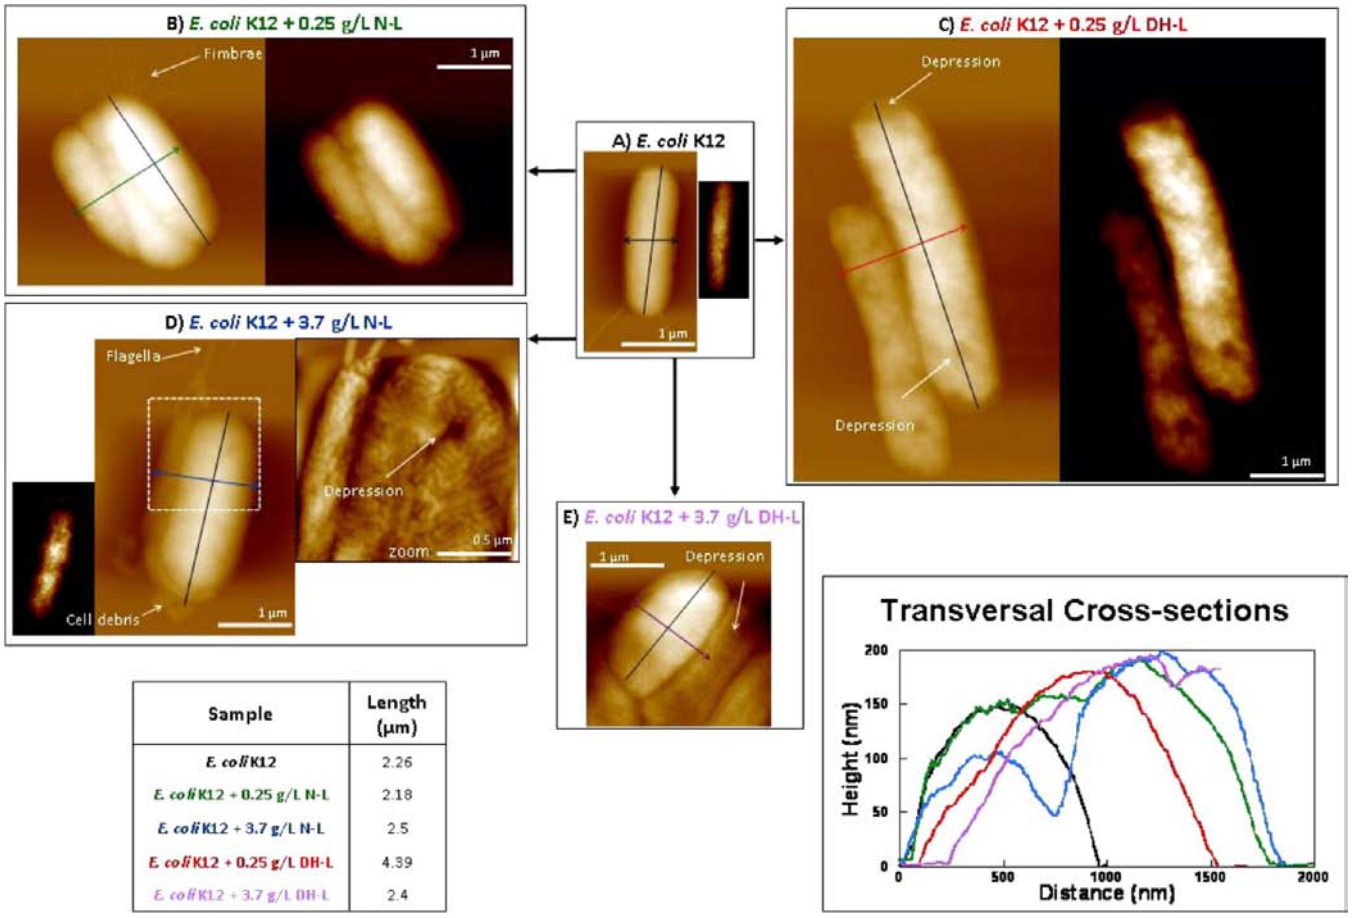
reported to degrade the antimicrobial peptide protamine.[37] It is thus possible that OmpT also hydrolyzes lysozyme molecules. Besides the above-mentioned defense mechanisms, *E. coli* is also able to modify the lipopolysaccharides of the outer membrane, protecting the outer membrane from permeabilization and neutralizing negative charges of the lipid A moiety.[37] Finally, all these defense mechanisms could protect *E. coli* from N-L and would delay the bacterial growth in the first moments after N-L addition.

Another assumption is that lysozyme concentration in the culture medium progressively decreases until it drops below a critical concentration, because of irreversible interaction between the protein and the bacterial cell membranes.[32] Because of its amphiphilic nature, and its surface-active properties, N-L could insert itself into the outer bacterial membrane, in which it could be irreversebly entrapped, causing depletion of N-L in the medium. Moreover, regarding the N-L molecules that could pass the outer membrane, binding to the peptidoglycan and/or to the inner membrane could decrease the lysozyme concentration in the culture medium. When this decrease results in a lysozyme concentration lower than the lowest active concentration, bacterial growth will resume.

Dry-Heated Lysozyme at High Concentration (3.7 g/L) Causes an Early-Stage Population Decrease. At low concentration (0.25 g/L), DH-L acts similarly to N-L at low and high concentrations: *E. coli* growth is inhibited whether Ivy is present or not (Figure 1), but bacterial growth resumes afterward, and the same bacterial levels as in the control sample are attained after 24 h. As suggested above, three assumptions can be proposed: damage repair by the bacteria, activation of defense and adaptation mechanisms, and/or depletion of lysozyme in the growth medium by irreversible interaction with bacteria.

On the contrary, high-concentration DH-L (3.7 g/L) causes a population decrease (~1 log) in the early stages of growth. Thus, it is noticeable that whereas the presence of the Ivy inhibitor completely removes the population decrease observed when *E. coli* is treated with 3.7 g/L N-L, a slight decrease is still observed in the presence of the Ivy inhibitor when *E. coli* is treated with 3.7 g/L DH-L, even when the muramidase activity of DH-L is 22% lower than that of N-L (data not shown). This indicates that the Ivy inhibitor is not enough to defend *E. coli* cells against the effect of DH-L and that DH-L undoubtedly acts in different way compared to N-L. The physicochemical differences between both lysozymes could be responsible for such different activities. Especially, DH-L has been described more surface-active, more positively charged, and more hydrophobic than N-L.[29] This indicates that DH-L is more membrane active than N-L. To confirm this hypothesis, the *E. coli* membrane state has been tested in the presence of either DH-L or N-L.

Membrane Disruption Differs between Native and Dry-Heated Lysozyme. Both N-L and DH-L pass the outer bacterial membrane and reach the periplasm, consistently with the increased lysozyme effect in the absence of the lysozyme inhibitor Ivy (Figure 1B). Actually, the passage of N-L through the outer bacterial membrane has already been described.[32] In the present study, it is demonstrated that N-L and DH-L permeabilize the outer membrane (Figure 2A), but when *E. coli* is treated with DH-L, more β-lactamase is released from the bacterial cell than when it is treated with N-L (Figure 2B),



Sample	Length (µm)
E. coli K12	2.26
E. coli K12 + 0.25 g/L N-L	2.18
E. coli K12 + 3.7 g/L N-L	2.5
E. coli K12 + 0.25 g/L DH-L	4.39
E. coli K12 + 3.7 g/L DH-L	2.4

Figure 5. Topographical AFM observations: nontreated *E. coli* K12 cells (A); cells treated with native lysozyme at 0.25 g/L (B) or 3.7 g/L (D); cells treated with dry-heated lysozyme at 0.25 g/L (C) or 3.7 g/L (E). Topographical AFM images have a *z*-range from 0 to 400 nm for full-scale images and from 0 to 15 nm for the 3.7 g/L N-L zoom. Bacterial lengths and cross sections are measured as indicated by full lines on the AFM images. AFM images shown here are representative of the whole sample.

meaning that DH-L causes either larger pores or more pores in the outer membrane as compared to N-L.

Outer membrane permeabilization intensity is independent of the concentration of N-L or DH-L administered to the bacteria (Figure 2A), but higher concentrations of N-L or DH-L (3.7 g/L) cause less β-lactamase leakage in the medium (Figure 2B). This could result from a large insertion of lysozyme molecules into the outer membrane and/or surrounding of the bacteria in high-concentration conditions, causing more difficult diffusion of β-lactamase.

The permeabilization of the inner membrane by DH-L is less intense as compared to that by N-L when measured by the maximal rate of β-galactosidase activity (Figure 2C), but permeabilization occurs faster with DH-L than with N-L (Figure 2D). In both cases, β-galactosidase activity could not be observed in the medium (data not shown), meaning that neither N-L nor DH-L causes pores large enough in the inner membrane to release this cytoplasmic enzyme. High-concentration DH-L also causes higher membrane potential disturbance and K^+ leakage than N-L (Figure 3). Inner membrane disruption is also dose-dependent: the higher the lysozyme concentration, the more severe (Figures 2C and 3) and the faster (Figure 2D) the inner membrane disruption.

It thus seems that, at high concentration, the DH-L activity on *E. coli* could be related to its enhanced activity on the outer and inner membranes. DH-L forms large and/or a lot of pores in the outer membrane; afterward it penetrates into the periplasm where it could either hydrolyze the peptidoglycan layer or diffuse through this layer to finally reach the inner membrane. Once it has arrived at the inner membrane, DH-L causes severe membrane potential disturbance and cytosol leakage (K^+ leakage). These latter phenomena suggest ion channel formation, which has already been reported for native lysozyme and lysozyme-derived peptides by Kimelberg and Papahadjopoulos[38] and Ibrahim et al., respectively.[28] The presented study thus suggests that DH-L forms more ion channels in the cytoplasm membrane than N-L. Moreover, membrane potential disturbance is known to cause cellular division disturbance.[39] In combination with the pore formation, this could explain the morphological modifications observed here.

The Impact of DH-L on the Membrane Integrity of *E. coli* Is Confirmed by Severe Morphological Modifications Observed in Vivo. Not only can the effect of lysozyme, and especially of DH-L, on the membrane integrity of *E. coli* be shown in vitro as described above, it can also be highlighted in vivo. DH-L causes severe disruptions of cellular division observed by optical and atomic force microscopy: elongated cells of about 4.5 μm long could be observed without any sign of septum formation (Figures 4 and 5), as well as depressions which could be pores in the outer membrane and lateral depression which can be related to the activity of an

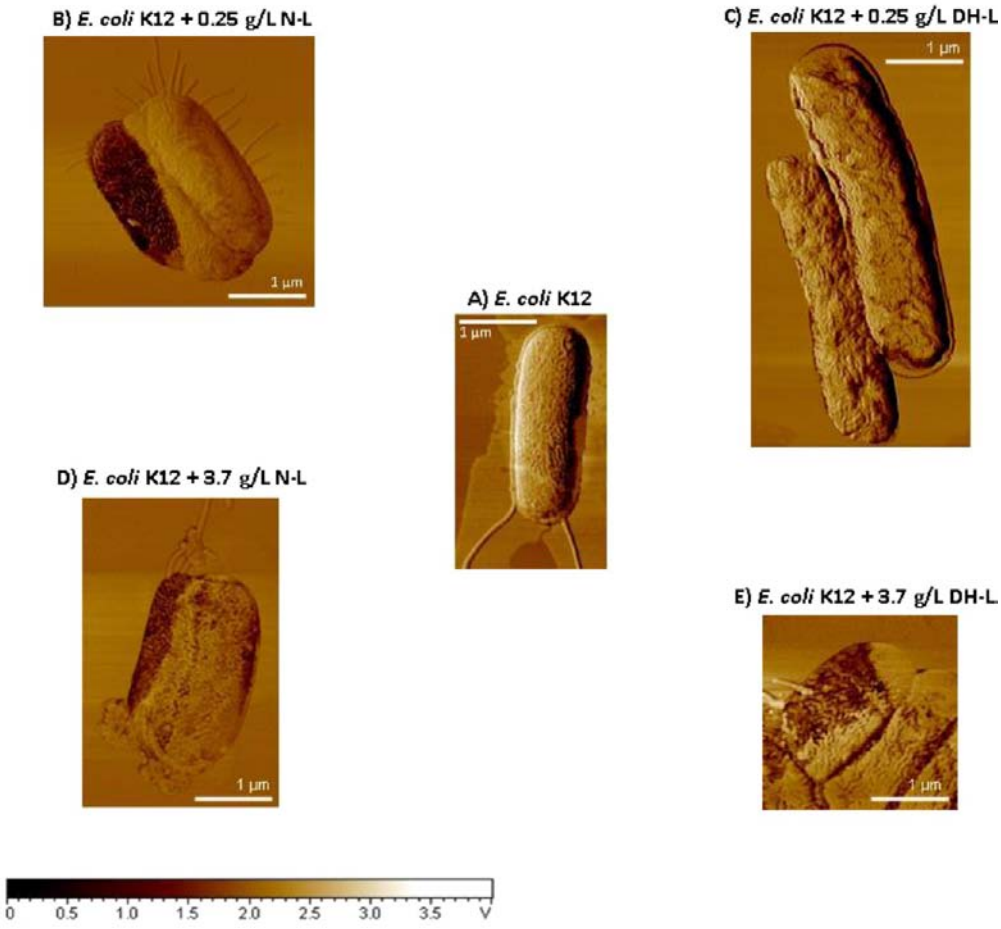

Figure 6. AFM phase imaging: nontreated *E. coli* K12 cells (A); cells treated with native lysozyme at 0.25 g/L (B) or 3.7 g/L (D); cells treated with dry-heated lysozyme at 0.25 g/L (C) or 3.7 g/L (E). The *z*-range is from 0 to 4 V. AFM images shown here are representative of the whole sample.

antimicrobial as reported by Meincken et al.[40] and Li et al.[41] (Figure 5). DH-L also homogenizes the ribs present on the bacterial cell surface at high concentrations (3.7 g/L), which could be the result of protein insertion into the bacterial cell wall as seen for *E. coli* cells treated with PGLa.[40] Then cell division and cell morphology are known to depend on the proton motive force, which itself depends on the bacterial membrane integrity.[39] In Figure 6, it is also noticeable that N-L or DH-L (0.25 and 3.7 g/L) alters the bacterial surface heterogeneity, resulting in the appearance of more rigid zones.[35,40]

These morphological modifications are consistent with the membrane integrity disturbances. Thus, the depressions formed in the presence of DH-L (Figure 5) are consistent with the higher leakage of β-lactamase, as compared to that in bacterial cells treated with N-L (Figure 2B). Perturbated cell division (Figures 4 and 5) is consistent with membrane potential disruption (Figure 3A), as recently reported by Strahl et al.[39]

To explain the differences observed between N-L and DH-L against *E. coli* membrane integrity, some assumptions can be proposed. Especially, the physicochemical modifications induced by dry-heating, and previously described by Desfougères et al.,[29] could be responsible for higher affinity of DH-L with outer and inner membranes and/or for more severe membrane disruptions. Because DH-L is more positively charged than N-L, interactions with LPS could be increased. Moreover, the higher hydrophobicity of DH-L could make it easier to interact with the lipid parts of bacterial membranes, and its higher flexibility could improve lysozyme insertion into the membranes. At last, the higher positive charge of DH-L could modify the membrane potential to a larger extent than N-L, when adsorbed on the inner membrane. However, more research has to be performed to identify the prevalent parameters responsible for the improved antibacterial activity of DH-L as compared to N-L. This is in progress by studying the behavior of DH-L at 2D model interfaces mimicking bacterial membranes.

in aged red wine as a result of ethanol oxidation. In summary, from a mechanistic point of view, the two key parameters leading to the formation of pyranoanthocyanins in red wine are the acidity, which controls the addition of ethanal on flavanols or procyanidins, as well as the cycloaddition of a vinyl group on the anthocyanin skeleton, and the oxygen level for the oxidative aromatization of pyranic ring D.

Pyranoanthocyanins linked directly to flavanol monomers and dimers have been detected and identified in different aged Port wine (i.e., from 2 to 6 year-old). In those wines pyranoanthocyanin−procyanidin dimers appear to be more abundant and more stable than pyranoanthocyanin−flavanol monomers.[22]

Thus the aim of this work was to estimate the impact of acidity and oxygen level in dry red wine on the formation of pyranomalvidin-3-*O*-glucoside-procyanidin dimers. For this purpose, the pH of a dry red wine has been adjusted at 3, 3.5, and 4, and each pH has been submitted to four different levels of oxygen (i.e., 0, 2, 8, and 20 mg/L). The occurrence in dry red wine of these two pyranomalvidin−procyanidin dimers, as well as their kinetics of formation, has been followed by HPLC-UV-MS.

MATERIALS AND METHODS

General. Distilled water was obtained from an ELGA system, and Milli-Q (Millipore) water used for HPLC-UV-MS separation and analysis was prepared using a Sartorius-arium 611 system. Acetonitrile (HPLC grade quality, > 99.8%) was purchased from VWR (Strasbourg, France).

Wine Sample. The wine used was a Merlot vintage 2011 from the "Entre deux mers" region of Bordeaux. The chemical characteristics of the red wine were as follows: a total polyphenolic index (TPI) of 61, a pH of 3.78, a total condensed tannins (i.e., estimated by Ribereau-Gayon and Stonestreet procedure) of 3.22 ± 0.25 g/L, total anthocyanins (i.e., determined using the SO_2 bleaching method) of 603 ± 1.2 mg/L, molecular anthocyanins content (i.e., anthocyanins quantified by HPLC-UV at 520 nm) of 347 ± 11.9 mg/L, and a condensed tannins mean degree of polymerization (mDP; i.e., determined by phloroglucinolysis method) of 4.38 ± 0.04. All of these parameters were determined using similar procedure as described in Chira et al.[23]

Experimental Conditions. The wine was placed in 5 L glass containers, which were closed as tightly as possible, using proper stoppers (i.e., silicone stopper with small septum in order to collect the sample and add oxygen without opening the containers), with addition of vacuum grease around the caps. Each 5 L glass container was flushed with N_2 prior to red wine filling in order to exclude incorporation of oxygen during filling. The wine was split in three pH groups: pH 3, pH 3.5, and pH 4. The pH was adjusted with NaOH (5 M) and/or sulphuric acid (99%). For each pH group, four quantities of oxygen were added: 0, 2, 8, and 20 mg/L. The oxygen was added into the bottles with a syringe filled with pure oxygen. As red wine consumes oxygen quite fast, oxygen was readjusted to 0, 2, 8, and 20 mg/L each week in order to keep constant levels during the four months. Each modality was performed in triplicate.

After four months, 1 mL of each separate sample was filtrated on a 0.45 μm membrane and then injected in the HPLC-UV-MS for identification and quantification. For the quantitative analyses, 900 μL of sample was mixed with 100 μL of chlorogenic acid (500 mg/L) used as internal standard.

Identification of the Pyranoanthocyanin−Procyanidin Dimers by HPLC-UV-MS/MS. These analyses were performed on two different systems. The first one was a Thermo-Finnigan Surveyor HPLC-UV system composed of a UV−vis detector (Surveyor PDA Plus), an autosampler (Surveyor autosampler Plus), and a quaternary pump system (Surveyor LC pump Plus) and controlled by a Xcalibur data treatment system. These analyses were carried out on a 250 × 4.6 mm, 5 μm Lichrospher 100 RP 18 column. The solvents used for the gradient were as follows: solvent A, water with 0.5% of formic acid, and solvent B, acetonitrile with 0.5% formic acid. The gradient used was as follows: from 100 to 85% of A in 5 min, from 85 to 70% of A in 30 min, from 70 to 0% of A in 1 min, then 0% of A during 4 min. The flow rate was set at 1 mL/min, and the tray temperature was fixed at 12 °C. The wavelengths used were 280 and 520 nm. This HPLC-UV system was also coupled to a Thermo-Finnigan LCQ Advantage spectrometer equipped with an electrospray ionization source and an ion trap mass analyzer. The electrospray ionization mass spectrometry detection was performed in positive mode with the following optimized parameters: capillary temperature 300 °C, capillary voltage 5 V, nebulizer gas flow 1.75 L/min, desolvation gas flow 1 L/min, and spray voltage 5 kV. The collision energy was set at 30% for the MS^2 analyses on the ion [M] = 1093 and MS^3 on the ion [M] = 931. The pyranoanthocyanin-procyanidin dimers were identified according to their mass spectra and fragmentation.

The molecular formula of the molecular ion [M] = 1093 as well as the fragment detected during MS/MS analyses with the ion trap were confirmed by injection on a high resolution Q-TOF mass spectrometer. The UHPLC system used was an Agilent 1290 Infinity Series which consisted of a quaternary pump, a solvent degasser, an autosampler, and a diode-array detector. These analyses were carried out on 2.1 × 100 mm, 1.8 μm Eclipse Plus C18. The solvents used for the gradient were: solvent A, water with 0.1% formic acid, and solvent B methanol with 0.1% formic acid at a flow rate of 400 μL/min. The gradient was as follows: 94% of A during 30 s; 94 to 5% of A during 13.5 min; 5% of A during 3 min. This UHPLC system was coupled to an ESI-Q-TOF-MS Agilent 6530 Series Accurate with an electrospray ion source with Agilent Jet Stream Technology. The mass spectrometer was operated in extended dynamic range of 2 GHz with the mass range up to 1700 Th, with a drying gas flow and temperature respectively set at 9 L/min and 300 °C. The nebulizer pressure was set at 25 psi, and the sheath gas flow and temperature were respectively set at 11 L/min and 350 °C. The capillary voltage was of 4 kV. The collision energy was set at 5, 15, and 30% for MS^2 analysis. The fragmentation voltage was set at 150 V. The reference masses used were $[M+H]^+$ = 121.050873, 322.048121, and 1221.990637. The software used for the determination of the exact molecular formula of the pyranoanthocyanin-procyanidin dimers molecular ions, as well as their fragments was MassHunter Qualitative Analysis.

Quantification of the Pyranoanthocyanin−Procyanidin Dimers by HPLC-UV-MS. The quantification of the pyranoanthocyanin−procyanidin dimers was performed by HPLC-UV-MS using the same HPLC Thermo Finnigan Surveyor system coupled to the ion-trap mass apparatus as described above. The pigment has been quantified using pure malvidin-3-*O*-glucoside as standard and chlorogenic acid as internal standard. The calibration curve was accomplished by injecting solutions with increasing concentrations of malvidin-3-*O*-glucoside ranging from 1 to 256 mg/L and containing 50 mg/L of chlorogenic acid. The response factor was established by plotting the concentrations ratios versus the peak-area ratios of malvidin-3-*O*-glucoside ion (i.e., m/z 493) to the internal standard ion (i.e., m/z 355). The R^2 obtained was 0.9998. The quantification of the pyranoanthocyanin-procyanidin dimers was realized using their molecular ion $[M]^+$ = 1093.

RESULTS AND DISCUSSION

The first part of our study was to identify pyranoanthocyanin−procyanidin dimers in Merlot red wine since these pigments have only been detected in aged Port red wine which is a sweet red wine.[22] This identification has been realized by HPLC-UV-MS using both low and high resolution HPLC-MS analysis. During the investigation on Merlot red wine, two peaks with a molecular ion of $[M]^+$ = 1093 have been detected which could be the two pyranomalvidin-3-*O*-glucoside-procyanidin dimers as previously described in aged Port wine.[11,22,24,25] MS^n analysis

with an ion trap mass spectrometer has been conducted to confirm this assignation. Fragmentation pattern in MS^2 of the molecular ion m/z 1093 leads to the formation of a single ion at m/z 931 which can result of the loss of a glucose moiety (i.e., loss of 162 amu). Then, a MS^3 analysis performed on the m/z 931 ion led to the formation of three main fragments at m/z 779, 641, and 623 (Figure 1). The fragment at m/z 641

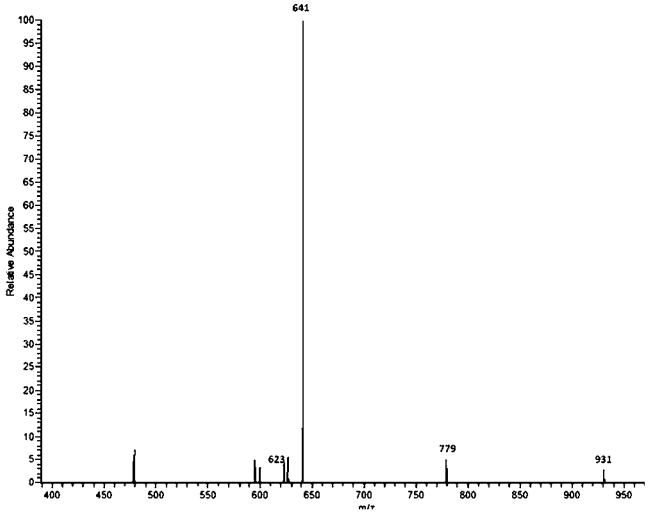

Figure 1. MS^3 fragmentation of the $[M]^+$ = 1093 compound.

resulted from the direct cleavage of the interflavanoid linkage from the pyranomalvidin-procyanidin-dimer aglycone (i.e., m/z 931). This fragment m/z 641 can then undergo a water elimination to form a new fragment at m/z 623. Another important fragmentation pattern of the ion at m/z 931 was attributable to the RDA (Retro-Diels–Alder) ring fission of the C-ring of the upper flavanol unit leading to an ion at m/z 779. This RDA ring fission was a key fragmentation for the structure elucidation, proving the presence of the procyanidin moieties in the molecule. Such fragmentation patterns (Figure 2) are in accordance with the fragmentation pattern of the pyranomalvidin–procyanidin dimer detected in Port wine.[22]

To confirm this assignation of both the molecular ion as well as the observed fragments, HPLC-UV-MS analysis using a high resolution Q-TOF mass spectrometer has been performed (Figure 3). This analysis clearly showed that the molecular ion of both peaks had a chemical formula of $C_{55}H_{49}O_{24}$ with a very high identity score and an extremely low difference (i.e., 0.34 ppm) between the measured mass and the calculated one (Table 1). Similarly, the identification and chemical formulas of the fragments have also been confirmed by high resolution mass analysis since the mass differences between the measured and the calculated masses were around 5 ppm. These investigations in HPLC-UV-MS confirmed the identification in dry red wine of two pyranomalvidin–3-*O*-glucoside-procyanidin dimers.

Following this first identification in dry red wine, a quantification method by HPLC-UV-MS using chlorogenic acid as internal standard has been developed and used to estimate the impact of acidity and oxygen levels in wine on the formation of these two pyranomalvidin–3-*O*-glucoside-procyanidin dimers. As shown in Figure 4, the quantification of both pyranomalvidin–procyanidin dimers showed similar trends among the different studied modalities (i.e., three pH 3, 3.5, and 4 as well as four different level oxygen 0, 2, 8, and 20 mg/L). Among the same pH, it clearly appeared that the amounts of the quantified compounds constantly increased from 0 to 20 mg/L of oxygen. In the modality without oxygen at pH 3, these compounds were present at the lowest concentration (i.e., around 2 mg/L), while in the modalities with 2, 8, and 20 mg/L of oxygen, the concentrations were respectively of 5.5, 14.5, and 19.7 mg/L. Following a similar trend, for a same quantity of oxygen, the amounts of the pyranomalvidin–procyanidin dimers increased along with the acidity of the red wine. Indeed, for the modality with the highest oxygen concentration, the amounts were 19.7, 12.5, and 4.6 mg/L from pH 3 to pH 4. However, for all studied pH, the lowest level was observed for the modality without oxygen, with concentrations of 2.0, 1.7, and 1.9 mg/L for the pH 3, 3.5, and 4, respectively. A similar trend has been previously observed from pyranomanthocyanins deriving from a vinyl cycloaddition mechanism in red wine with a single oxygen level and with three different pH.[26]

The observed formation trends according to pH and oxygen levels were of interest and confirmed these key parameters in the mechanism leading to the formation of pyranomalvidin–procyanidin dimers in red wine. Indeed, without oxygen the lowest level of pyranomalvidin–procyanidin dimers were similar for each pH which confirmed that oxygen is absolutely needed for the oxidative aromatization of the newly formed pyranic ring D of the pyranoanthocyanins. Similarly, the acidity of the red wine also appeared to be an important feature since the highest concentrations of pyranomalvidin–procyanidin dimers were observed for the lowest pH in the presence of oxygen.

Table 1. Accurate Mass Analyses of the Fragments

fragment $[M]^+$	chemical formula	mass difference (ppm)	score[b]	corresponding fragment
1093.2607	$C_{55}H_{49}O_{24}$	0.34	99.11	pyranomalvidin−procyanidin dimer
931.2026	$C_{49}H_{39}O_{19}$	5.82	X	glucose
779.1569	$C_{41}H_{31}O_{16}$	4.88	X	RDA ring fission[a]
641.1256	$C_{34}H_{25}O_{13}$	5.28	X	glucose, catechin

[a]RDA: (Retro-Diels−Alder) ring fission of the C-ring of the upper flavanol. [b]Score represent a percentage of identity between the calculate molecular formula and the analyzed mass taking in too account the obtained mass as well as the isotopic abondances.

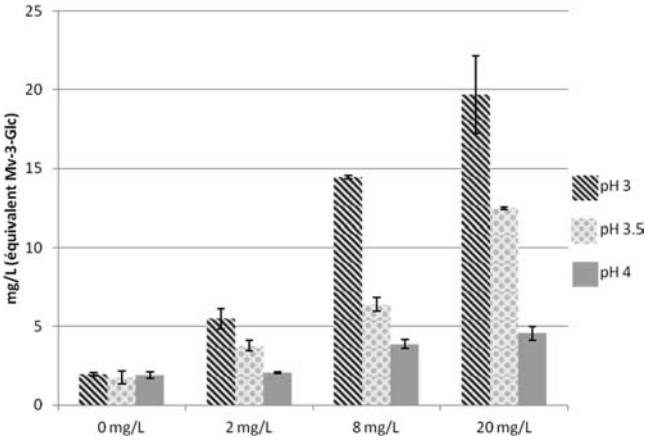

Figure 4. Evolution of the pyranomalvidin−-3-*O*-glucoside-procyanidin dimer content in red wine according to pH and oxygen level.

From an oenological point of view, the key involvement of red wine acidity in the formation of pyranoanthocyanins is an important parameter for red wine color stabilization since over the last two decades, red wine acidity tends to decrease due to the global warming. Such decrease in wine acidity might result in a diminution of pyranoanthocyanins contents, which are an important contributor to red wine color stability. Further studies on the impact of pH and oxygen levels on the formation of the other pyranoanthocyanins are actually under investigation.

The leaf EOs of the cinnamaldehyde-type *C.o.* have been proved to have excellent bioactivities, such as antifungal,[16] antibacterial,[17] antipathogenic,[18] anti-inflammatory,[19] antihyperuricemia,[20] antidyslipidemic,[21] and mosquito larvicidal activities.[22] Although there are so many bioactivities in the cinnamaldehyde-type *C.o.*, the information related to the coumarin contents of this species is very limited. To seek an alternative source for safe cinnamons without harvesting trees, the leaves of the cinnamaldehyde-type *C.o.* might have a great potential for this purpose. The objective of this study was to identify the coumarin level of this indigenous cinnamon. Samples from different geographical regions in Taiwan were collected, and the major constituents of essential oils from these samples were compared. Cassia cinnamon samples from local markets were also included in the comparison.

MATERIALS AND METHODS

Plant Materials. Leaves of *Cinnamomum osmophloeum* ct. cinnamaldehyde (*C.o.*) from sixteen individual clones were collected from six different geographic sites in Taiwan in 2006 and 2010, and the trees were about 20 years old when harvested. All samples were identified by Sheng-Yu Lu and Yen-Ray Hsui, Taiwan Forestry Research Institute. Voucher specimens were deposited with the Laboratory of Wood Chemistry (School of Forestry and Resource Conservation, National Taiwan University). Table 1 lists the detailed information of the *C.o.* leaf samples. The sites where these *C.o.* leaves harvested are also indicated in Figure 1. To compare the differences of flavoring constituents between Cassia cinnamon and *C.o.*, three additional bark samples of *Cinnamomum cassia* (*C.c.*), commonly sold in the local markets, were used for comparison. Two *C.c.* leaf samples were also collected for comparison (Table 1). All samples were air-dried at ambient temperature (23 °C) and stored at 4 °C for further experiments.

[a]Please refer to Figure 1 for the geographic sites. [b]Samples were collected between October and November.

Chemicals. The authentic compounds used to verify the flavoring constituents in current study, including *trans*-cinnamaldehyde, *trans*-cinnamyl acetate, *trans*-cinnamic acid, coumarin, and eugenol, are from TCI (Japan), Acros (Belgium), or Sigma-Aldrich (USA). The purities of these compounds are more than 95%.

Distillation of Essential Oils. About 200 g of air-dried samples with 1000 mL of water were hydrodistilled for 6 h in a Clevenger-type apparatus. The essential oils were stored in airtight brown bottles at 4 °C before further GC or GC−MS analyses.

Figure 1. Geographic sites of *Cinnamomum osmophloeum* ct. cinnamaldehyde (*C.o.*) and *Cinnamomum cassia* (*C.c.*) samplings. A: Fushan. B: Lileng. C: Hualian. D: Changhua. E: Lugu. F: Puli. G: Sinsian.

Instrumentation. A Thermo Trace GC Ultra system (Thermo Scientific, Waltham, MA, USA) was used to quantify the major flavoring constituents of different samples. GC was performed on a 30 m DB-5 ms column (J&W Scientific, Folsom, CA, USA) with 0.25 μm film thickness and 0.25 mm inner diameter. The injection port was set to 250 °C, and the flame ionization detector (FID) was set to 300 °C. The helium flow was 1 mL/min, and the splitting ratio was 10:1. After a 1 min isothermal heating at 60 °C, the oven temperature was programmed at 4 °C/min to 220 °C, held for 2 min, increased at 20 °C/min to 250 °C, and held isocratic for 2 min. The peak areas of the target compounds were used to quantify the absolute contents (mg/kg of EO) compared to that of calibration samples with known concentrations.

The same Thermo Trace GC Ultra system with a PolarisQ MSD mass spectrometer (Thermo Scientific, Waltham, MA, USA) was used for the compound authentication. The column and method used for GC−MS analysis were the same as those in the GC analysis, except the ion source was adjusted to 230 °C. Mass spectra were recorded from m/z 50 to 400 with an electron ionization of 70 eV. The compound authentication was achieved by the search results from NIST Mass Spectral Search Program V. 2.0 (National Institute of Standards and Technology, USA) and Wiley 7.0 mass database. Coinjection of the authentic compounds and calculation of the Kovats indices (KI)[23] were also used for the compound authentication.

Statistics. Different groups were compared all together by multiple means comparisons (Tukey HSD test, $\alpha = 0.05$) to test for significant differences among groups (SAS 9.3, SAS Institute Inc., USA). All data are expressed as mean ± SE ($n = 3$).

RESULTS AND DISCUSSION

Comparison of Main Compounds from the Essential Oils of *C.o.* Leaves and *C.c.* Samples. To know whether the

essential oils of *C.o.* leaves contain high levels of coumarin, *C.o.* leaves from five individual trees in one location (site A, Figure 1) were collected and the major compounds of their essential oils were compared with that of the essential oils from *C.c.* samples. The typical chromatograms of the essential oils from *C.o.* leaves, *C.c.* bark, and *C.c.* leaves are shown in Figure 2. The

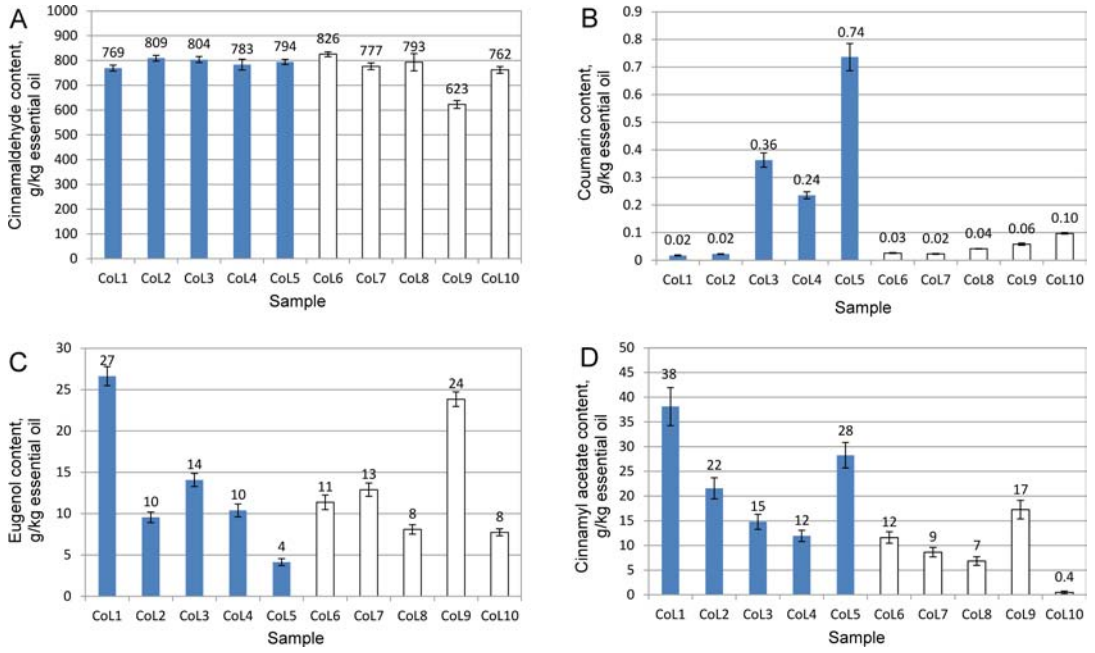

Figure 4. Variations of the main compounds from the essential oils of *C.o.* leaves in the same site. Solid bar: site A. Open bar: site B. (A) Cinnamaldehyde. (B) Coumarin. (C) Eugenol. (D) Cinnamyl acetate. All data are mean ± SE (n = 3). Please refer to Table 1 for the sample ID and site.

major compounds of essential oils from *C.o.* leaves (CoL1−CoL5 in Figure 3) detected by GC−MS are cinnamaldehyde, coumarin, eugenol, and cinnamyl acetate. About 80% (w/w) of the *C.o.* leaf EOs are composed of cinnamaldehyde (Figure 3A), and these values ranged from 769 to 809 g/kg of EOs, which correspond to about 8.9−26.1 g/kg of sample. The cinnamaldehyde contents from *C.o.* leaf EOs are rather comparable to that from *C.c.* bark EOs, ranging from 564 g/kg of EO for the *C.c.* stem bark (CcSB in Figure 3A) to 855 g/kg of EO for the *C.c.* bark powder (CcBP in Figure 3A). These values would be 23.6−33.8 g/kg based on sample weights. Woehrlin et al. reported that the cinnamaldehyde contents of *C.c.* powders were 12.0−42.6 g/kg of sample and that those of *C.c.* sticks were 8.93−54.3 g/kg of sample.[6] Similar cinnamaldehyde contents (15.4−22.3 g/kg) were also reported by Wang et al. when they analyzed *C.c.* bark samples.[4] Both results are consistent with our measurements. The cinnamaldehyde contents of the *C.c.* leaf EOs (CcL1 and CcL2 in Figure 3A) are 325 g/kg of EO and 176 g/kg of EO, respectively. Both are much lower than the cinnamaldehyde contents of the *C.o.* leaf EOs and the *C.c.* bark EOs, indicating that *C.c.* leaves are not a good source for cinnamaldehyde flavoring materials. Researchers have pointed out that a good quality cinnamon would contain 60−90% of cinnamaldehyde as the major constituent in its volatile oil.[3] *C.o.* leaf EOs contain about 80% of cinnamaldehyde as the major constituent, and hence *C.o.* leaves can be considered a good quality and also a great potential cinnamon substitute source to replace commercial bark cinnamons.

The coumarin contents of the *C.o.* leaf EOs are about 0.02−0.74 g/kg of EOs (Figure 3B), which correspond to 0.29−13.99 mg/kg leaf samples. The coumarin contents of the *C.c.* bark EOs are 6.69−9.46 g/kg of EOs (Figure 3B) and correspond to 94.1−374.6 mg/kg bark samples. The coumarin contents of the *C.c.* leaf EOs are 16.75−34.78 g/kg of EOs, however these values correspond to 26.8−97.4 mg/kg leaf samples due to very low EO yields of the *C.c.* leaf samples. Cassia cinnamon bark is known to contain a certain amount of coumarin,[4−7,24] and the amounts vary by research ranging from 40 to 12180 mg/kg of sample. These amounts of coumarin far exceed 2 mg/kg of sample, the maximum limits of coumarin for food in general set by the Council of European Communities in 1988.[11] Our results also confirmed that the *C.c.* bark samples contain high level of coumarin, whereas the *C.o.* leaf samples contain rather low levels of coumarin. Furthermore, the coumarin contents of the two *C.o.* leaf samples, CoL1 and CoL2, are remarkably lower than 2 mg/kg of sample, and they are 0.29 and 0.72 mg/kg of sample, respectively. Identifying *C.o.* clones with low-coumarin and high-cinnamaldehyde contents in their leaves as a potential source for bark cinnamon substitution would be very beneficial for reducing the coumarin-induced hepatotoxicity to certain groups of the populations.

Eugenol (Figure 3C) constitutes about 4−27 g per kg of the *C.o.* leaf EOs (i.e., 118−455 mg/kg leaf sample), but was not detected for all *C.c.* samples tested. Cassia cinnamon was often reported to be without eugenol.[4,6] Eugenol, the principal ingredient of cloves and their products, is widely used in agricultural industries as a food additive to protect foods from microbes during storage, and it is also routinely used in dental clinics as an antiseptic and analgesic.[25] Although eugenol appears to induce cytotoxicity at levels far greater than those occurring in foods,[26] when it is used as a food additive, it is listed as "generally recognized as safe (GRAS)" by the US Food and Drug Administration.[27] Yeh et al. reported that *C.o.* leaf EOs containing eugenol have a longer shelf life and thermostability compared to those without eugenol.[28] Bevilacqua et al. also pointed out that the combination of eugenol and cinnamaldehyde has excellent antimicrobial activity and is good for food product preservation.[29] This indicates that the shelf life of *C.o.* leaf samples could be longer than that of *C.c.* bark samples due to the existence of both eugenol and cinnamaldehyde within *C.o.* leaf EOs.

dx.doi.org/10.1021/jf405312q | J. Agric. Food Chem. 2014, 62, 1706−1712

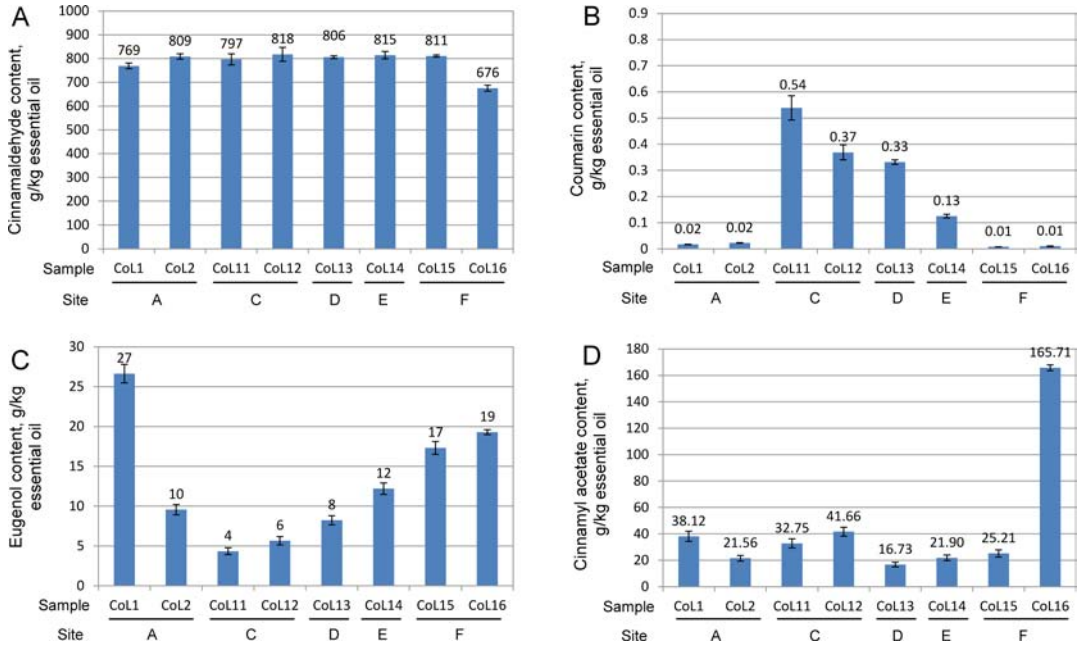

Figure 5. Variations of the main compounds from the essential oils of *C.o.* leaves from different geographic sites. (A) Cinnamaldehyde. (B) Coumarin. (C) Eugenol. (D) Cinnamyl acetate. All data are mean ± SE (n = 3). Please refer to Table 1 for the sample ID and site.

Cinnamyl acetate (Figure 3D) constitutes about 12−38 g/kg of EOs of the *C.o.* leaves (i.e., 136−694 mg/kg of *C.o.* leaf samples). The *C.c.* stem bark sample contains cinnamyl acetate in the level of about 7 g/kg of bark EO (i.e., 290 mg/kg of *C.c.* stem bark sample), and this level is higher in the *C.c.* leaf samples, about 122−288 g/kg of leaf EOs (i.e., 195−807 mg/kg of *C.c.* leaf samples). We did not detect any cinnamic acid (data not show) in the *C.o.* leaves' EOs, however, we did detect cinnamic acid of 88 and 132 g/kg of EOs (i.e., 960 and 5506 mg/kg of sample) from the *C.c.* twig bark and stem bark samples.

Clonal Variations of Essential Oils in *C.o.* Leaves from the Same Site. To know the clonal variations of the essential oils in *C.o.* leaves from the same geographic region, 5 additional *C.o.* clone samples from the second site (site B) were compared and the compositions of their leaf EOs were analyzed (Figure 4). The results showed that the cinnamaldehyde contents of the *C.o.* leaves within the same site, either site A or site B, are quite similar (Tukey HSD test, α = 0.05). They are all about 80% (w/w) of EOs in Figure 4A, except for that of CoL9 sample in site B. Although the cinnamaldehyde content of CoL9 sample is in the margin of 62.3% EO, it is still more than 60% of EO, which can also be considered as a good quality cinnamon source.

The clonal variations of the coumarin contents in *C.o.* leaves showed significant difference within site A (Tukey HSD test, α = 0.05), except for CoL1 and CoL2 samples (Figure 4B), whereas this big variation was less significant between different samples from site B (0.03−0.10 g/kg of EOs), indicating that the coumarin contents of the *C.o.* clones in site B are generally low-coumarin clones compared to that from site A. If *C.o.* clones from site A will be selected for future massive propagation for commercial purposes, a further coumarin screening for individual clones will be needed to ensure low-coumarin *C.o.* clones are selected for propagation to reduce the potential risk of coumarin-induced toxicity.

The clonal variations of eugenol and cinnamyl acetate contents from either site A or site B show differences within the same site (Tukey HSD test, α = 0.05). The eugenol content variations of the *C.o.* clones in site A range between 4 and 27 g/kg of EOs, and those of clones in site B range between 8 and 24 g/kg of EOs (Figure 4C). The *C.o.* leaves from site A contain 12−38 g of cinnamyl acetate per kg of EOs, however, those from site B contain 0.4−17 g of cinnamyl acetate per kg of EOs (Figure 4C). Franz pointed out that composition variation within a species seems to be the principle in essential oil crops,[30] and hence the variation seen within site A or site B is likely under the individual genetic variability of the *C.o.* plant itself.

Variations of Main Compounds from the EOs of *C.o.* Leaves from Different Geographic Sites. Additional samples from 4 different geographic sites were collected and compared with the low-coumarin clones (CoL1 and CoL2) from site A. The results showed that the cinnamaldehyde contents in the *C.o.* leaves from different sites were no different under Tukey HSD test at α = 0.05 level (Figure 5A), indicating that cinnamaldehyde contents of the *C.o.* leaves were quite consistent and stable between different geographic sites. The cinnamaldehyde contents of the *C.o.* leaves from different sites were all above 60% EO, which meets the criterion as a good quality cinnamon source indicated by Poole and Poole.[3]

The *C.o.* leaves from sites C, D, and E show relatively higher level of coumarin contents compared to those from sites A (CoL1 and CoL2) and F (CoL15 and CoL16) (Figure 5B). The coumarin contents of the *C.o.* leaves do vary by different geographic sites (Tukey HSD test, α = 0.05). The coumarin contents of the *C.o.* leaves from sites A (CoL1 and CoL2) and F (CoL15 and CoL16) were all around 0.01−0.02 g/kg of EOs. If we calculate them on the basis of leaf sample weight, they are all significantly lower than 2 mg/kg of sample, and are 0.29, 0.72, 0.13, and 0.15 mg/kg of leaf samples, respectively. The coumarin contents of many cinnamon species including *C. cassia*, *C. verum*, *C. burmannii*, *C. loureiroi*, *Cinnamomum*

dx.doi.org/10.1021/jf405312q | J. Agric. Food Chem. 2014, 62, 1706−1712

wilsonii, and *Cinnamomum japonicum* have been reported by many researchers,[3,4,6,7] and only *C. verum* samples (Ceylon cinnamon) might contain coumarin lower than 2 mg/kg of sample. All other samples were reported to exceed the 2 mg of coumarin per kg of sample regulation.[3,4,6,7] Our samples show that specific *C.o.* clones from some areas did show very low coumarin contents (lower than 2 mg/kg of sample).

The eugenol contents of the *C.o.* leaves from different geographic regions were from 4 to 27 g/kg of EOs (Figure 5C), and showed no significant difference between different sites except that from site C (Tukey HSD test, $\alpha = 0.05$). However the eugenol contents from all *C.o.* leaf samples were higher than those from the *C.c.* samples (Figure 3C), indicating that the shelf life of the *C.o.* leaf samples could be longer compared to that of the *C.c.* samples. The cinnamyl acetate contents of the *C.o.* leaves from different geographic sites showed no significant difference between different sites (Tukey HSD test, $\alpha = 0.05$) (Figure 5D).

Our results clearly suggested that leaves of *Cinnamomum osmophloeum* ct. cinnamaldehyde could be a potential renewable source for a better cinnamon substitute due to its low coumarin content. It will be worth selecting the high-cinnamaldehyde, low-coumarin, and eugenol-containing clones from the specific sites, and conducting further field tests using clonal propagations in different sites to test if these high-cinnamaldehyde, low-coumarin, and eugenol-containing clones are stable over different geographic regions and seasons. This will promote these special clones for further commercial purposes.

MS). Also, the modification effects of the enzyme on the wheat proteins were investigated in the current work.

MATERIALS AND METHODS

Materials. Three wheat varieties (Annong0950, Yang13, and Yang15) bred in China were used in this study. These cultivars were milled into flour using a Brabender experimental mill (Brabender, Duisburg, Germany) according to AACC approved method 26-21A. The flours were stored at 4 °C until further use.

High-purity α-[4-pyridyl 1-oxide]-*N*-*tert*-butyl nitrone (POBN) and high-quality linoleic acid (LA), linolenic acid (ALA), arachidonic acid (AA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) were purchased from Sigma Chemical Co. Ethanol, acetonitrile (ACN), and tetrahydrofuran (THF) were of HPLC grade. Purified ana-rLOX (activity = 30000 IU/mg) was prepared in our laboratory.

Measurement of Radical Formation with ESR. Enzyme reactions were performed in 1 mL of 50 mM Tris-HCl buffer (pH 8). The reaction mixture containing 1 mM linoleic acid (linolenic acid, arachidonic acid, eicosapentaenoic acid, and docosahexaenoic acid), 20 mM POBN, and 8×10^3 IU/mL ana-rLOX was incubated at 16 °C without light. After 30 min, the reaction product was injected for ESR to detect the peroxidation radical.

ESR spectra were obtained with a Bruker ElexSys E500 spectrometer equipped with a super high Q cavity operating at 9.78 GHz and room temperature. The ESR spectrometer settings were as follow: modulation frequency, 100 kHz; modulation amplitude, 1.0 G; microwave power, 20 mW; receiver gain, 10^6; time constant, 0.6 s; and magnetic field scan, 70 G.

Determination of Radical Species from ana-rLOX with MS. The above mixture of enzyme reaction was terminated by ACN after 30 min, and the reaction products were separated with a centrifuge (Thermo, USA) at 10^4 rpm. The supernatant was kept and concentrated by evaporation. Finally, the concentrated sample was filtered by using a 0.45 μL membrane filter and injected for MS analysis.

MS detection of lipid peroxidation radicals was carried out with a Finnigan LCQ ion trap mass spectrometer (Thermo, USA) using an electrospray ionization (ESI) and Finnigan X calibur software (version 1.2). ESI in positive ion mode was employed. The conditions were as follows: sheath gas flow, 35 arbitrary units; capillary temperature, 80 °C; capillary voltage, 17 V; and spray voltage, 4.5 kV. Samples were infused into the mass spectrometer at 5 μL/min.

Separation of Wheat Proteins and Their Modification with ana-rLOX/LA. Wheat protein (albumin, globulin, and gluten) was extracted from wheat flour using a classical Osborne procedure based on protein solubility with modification.[22] The protein extracts were further purified through dialysis and lyophilization and stored at 4 °C for further use. Protein content was assayed according to the colorimetric Bradford method using BSA as a standard.[23]

Wheat proteins modified with ana-rLOX were dissolved in 1% protein solution (w/v) containing 0.05% LA in 200 mL at 16 °C, with thermostatic shaking at 180 rpm for 2 h. The wheat proteins after enzyme reaction were extracted with acetone, and the extracts were dried through vacuum evaporation.

Determination of Functional Properties, Particle Size Distribution, and Morphological Observation of Wheat Proteins Modified with ana-rLOX/LA. Functional properties such as the foam capacity (FC) and foam stability (FS) of wheat proteins prepared were determined according to the following Makri method.[24] FC was measured in terms of volume increase on whipping expressed as percentage of original volume of the liquid. FS was expressed as percentage of foam volume remaining in relation to initial foam volume at room temperature after 0, 5, 10, 20, and 30 min. The emulsifying activity index (EAI), and emulsifying stability index (ESI) were tested according to Dipak's method.[25] The mixture of 140 mL modified protein and 60 mL oil was homogenized at 10000 rpm for 1 min, room temperature A sample of 0.02 mL of the emulsion was respectively taken out from the bottom of the vessel at 0 and 20 min, then diluted with 1 mL of 0.1% SDS solution. The light absorption of the emulsions at 500 nm was measured in a spectrophotometer with blank of 0.1% SDS solution.

Average particle size and specific surface area of proteins (albumin-, globulin-, gluten-soluble proteins) before and after ana-rLOX/LA enzymatic reaction, were measured by an integrated-laser light scattering instrument (Mastersizer 2000, Malvern Instruments Co. Ltd., Worcestershire, UK). Relative refractive index and absorption were set at 1.414 and 0.001, respectively. The particle size and specific surface area of proteins were analyzed using Malvern Mastersizer software (version 5.12c, Malvern Instruments Co. Ltd.).

The protein was frozen and lyophilized according to the same method as previously described. Protein texture was observed by using a scanning electron microscope (SEM). The images were taken by using the SEM with a 6 kV acceleration voltage. The micrographs were taken using the same magnification.

Effect of ana-rLOX on Texture of Wheat Flours. The ana-rLOX was added into 300 g of three kinds of wheat flours (Annong0950, Yang13, and Yang15), reaching final enzyme activities of 10, 20, 30, and 40 IU/g flour, respectively. Then, they were mixed in a Brabender Farinograph (mixer bowl 300 g, Brabender OHG, Duisburg, Germany) at 63 rpm and 30 °C for 10 min. Texture parameters including springiness (SP), gumminess (GU), cohesiveness (CO), and resilience (RE) of dough were evaluated using a textural analyzer (TA-XT plus, Stable Micro System Ltd., UK) equipped with a cylindrical probe of P20 (20 mm in diameter). The tested parameters for the instrument were set as follows: pretest speed, 2.0 mm/s; crosshead speed, 1 mm/s; post-test speed, 10.0 mm/s; rupture test distance, 1%; distance, 50%; and time, 5.00 s. The loaves were cut into slices of 15 mm, and the ends were discarded. All tests were conducted in triplicate

Statistical Analysis. Data were reported as means ± standard deviations (SD) for triplicate treatments. One-way analysis of variance (ANOVA) and orthogonal design were performed using SPSS (SPSS for Windows, version 10.0.5, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Radical Formation of PUFA Peroxidation by ana-rLOX. LOX-catalyzed PUFA peroxidation is a complex biochemical event that generate a series of free radicals.[6,7] However, there is limited direct evidence about the reactive and short-lived PUFA-derived free radicals due to the lack of an appropriate methodology. An ESR spectroscopy approach, with spin trapping, was taken here to investigate the dynamic behavior of fatty acids catalyzed by ana-rLOX with POBN. To

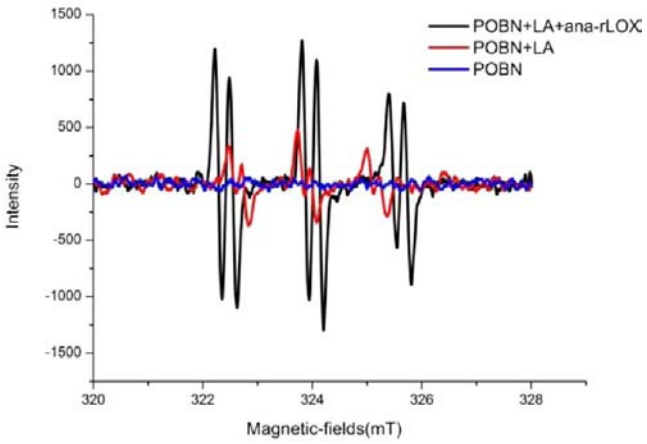

Figure 1. ESR spectra of POBN radical adducts from ana-rLOX/LA oxidation. The reaction mixture contained 20 mM POBN, 0.1 M LA, and 8×10^3 IU/mL ana-rLOX.

facilitate comparison, all samples were tested at the same condition (a^N = 15.7G and a^H = 2.8G). In Figure 1, six peaks of the radical species in the ESR spectrum are displayed in the reaction system by adding ana-rLOX with LA and POBN or LA with POBN, indicating that the free radical of lipid oxidation and POBN adducts existed. The POBN was used to trap free radicals during the reaction. It could be assumed that the oxidation of the LA fatty acid promoted the formation of transient unpaired-spin-density species, after reacting with POBN, generating the stable radicals displayed in the ESR spectrum.[26] A similar six peaks were found in soybean LOX.[27]

In addition, it was found that the spectrum of adding ana-rLOX was significantly different from that of nonenzyme, and the intensity of the peak with ana-rLOX was markedly increased. In comparison, the intensity of the peak without ana-rLOX was much lower, which indicated that ana-rLOX promoted the formation of LA peroxidation free radicals (Figure 1). Lipid peroxyl radicals resulted from the peroxidation of polyunsaturated fatty acids by soybean lipoxygenase.[28] The increase of the intensity of the peak with ana-rLOX might be because ana-rLOX promoted more free radicals during the lipid peroxidation.

Identification of the Oxygenated Position and Peroxidation Species Catalyzed by ana-rLOX. ESR alone cannot provide molecular structures and identities from hyperfine coupling constants, particularly those from spin adducts. Here, the combination with spin trapping and mass spectrometry (MS) was utilized to characterize PUFA-derived peroxidation radicals generated by ana-rLOX and to provide direct proof of the formation of PUFA peroxidation.

The position oxygenated and the radical species formed on five PUFA (LA, ALA, AA, EPA, and DHA) are shown in Table 1. By the ESI/MS analysis of oxidation ion fragments, the

dx.doi.org/10.1021/jf405425c | J. Agric. Food Chem. 2014, 62, 1713−1719

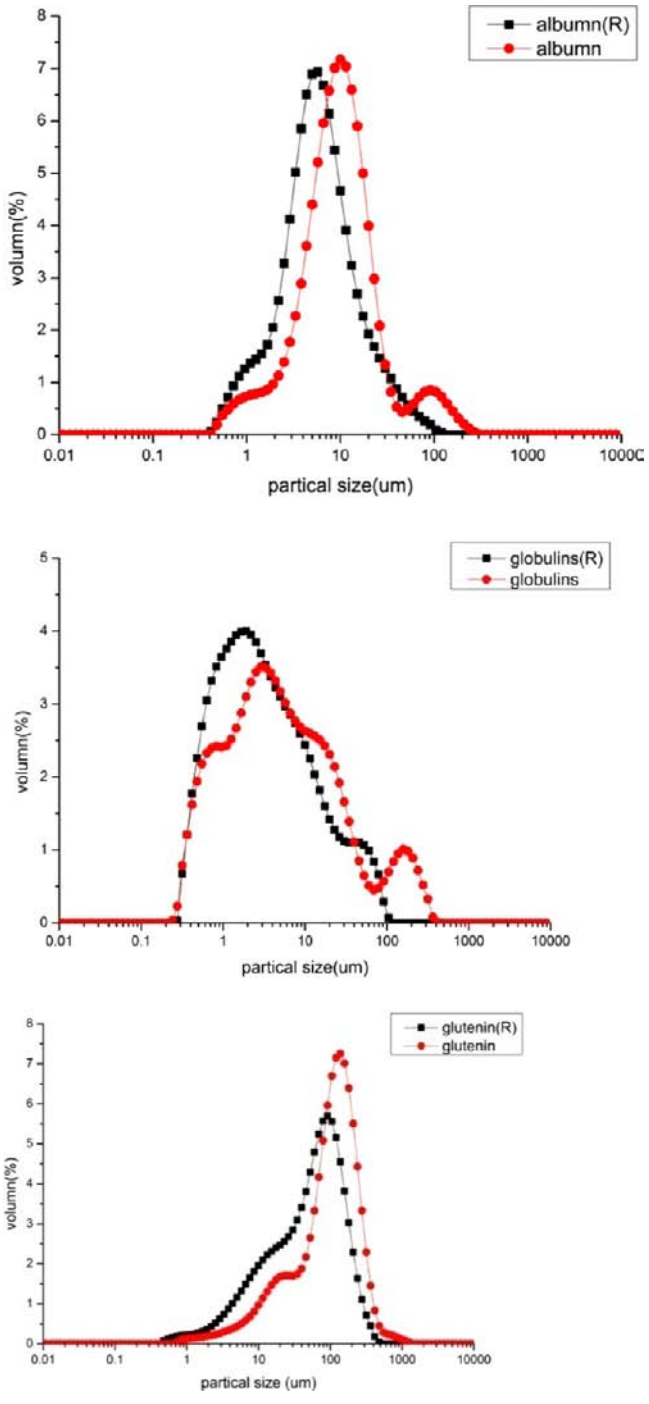

Figure 2. Effect of ana-rLOX on particle size distribution of wheat protein. (R), with ana-rLOX/LA.

oxygenation position on LA was C-13; C-13 and C-16 on ALA; C-9, C-13 and C-15 on AA; C-12, C-15 and C-18 on EPA; C-14 and C-16 on DHA, respectively. These results indicated that the positions oxygenated by ana-rLOX could vary with different PUFA. LA, as a substrate molecular oxygen, can be introduced either at carbon 9 (9-LOX) or at carbon 13 (13-LOX) of the hydrocarbon backbone, which led to the formation of 9-hydroperoxy and 13-hydroperoxy derivatives of LA (9- and 13-HPODE), respectively.[29]

In mammals, LOXs are similarly classified according to their positional specificity of arachidonic acid oxygenation, which can take place either at position C-5, C-8, C-9, C-11, C-12, or C-15.[30] The ana-rLOX did not oxygenate on the sites C-5, C-8, and C-11, but did on sites C-14, C-16, and C-18, which were not reported in latest published papers, neither from animals nor from plants or bacteria. We should note that the different positions LOXs acted on would create different novel compounds; this result may have a special application in the food and clinical fields.

globulin (R)	9.14	1.75	3.43
gluten	136.34	31.74	0.19
gluten (R)	79.12	15.62	0.38

[a]Volume mean diameter ($D[4,3]$); surface area mean diameter ($D[3,2]$); specific surface area (SSA) of protein. (R), adding ana-rLOX/LA.

In the radical adducts and their m/z of PUFA with ana-rLOX, totals of 7, 14, 30, 28, and 18 radical adducts for LA, ALA, AA, EPA, and DHA were respectively identified by ESI/MS. LOX-catalyzed PUFA peroxidation is a well-known free radical chain reaction. Peroxyl radical is generated from the reaction of oxygen and can also be converted into other types of free radicals through H abstraction; Fe^{2+} converted into Fe^{3+} through electron transfer.[31] As the result of chain reaction with peroxyl radical, many secondary radicals were produced and further induced more reactions. These new radicals can be metabolized to form new leukotrienes, lipoxins, jasmonic acids, green leaf volatiles, and lactones.[32]

Effect of ana-rLOX/LA on Funtional Properties of Wheat Protein. The use of soybean flour for commercial production of white bread has been well documented, and its main uses include bleaching flour, improving dough rheology, and increasing loaf volume. However, the effect of ana-rLOX/LA on wheat protein has not been well reported. Table 2 presents FC and FS of wheat proteins as albumin, globulin, and gluten with or without ana-rLOX/LA.

By adding ana-rLOX/LA in wheat proteins, FC and FS were significantly increased. The FC of albumin, globulin, and gluten solution respectively increased from 320, 292, and 360 mL before the enzymatic reaction to 360, 310, and 385 mL, and the FS of albumin, globulin, and gluten solution respectively increased from 149, 170, and 120 mL before the enzymatic reaction to 189, 188, and 190 mL, which suggested that the structural modification of wheat proteins had occurred and the physical properties had been changed during ana-rLOX enzymatic reaction. The proteins might generate two disulfide bonds through thiol oxidation with radicals initialized from ana-rLOX/LA, from which protein aggregation was produced, and finally the FC and FS increased.

As shown in Table 2, the EAI and ESI of wheat proteins were significantly enhanced with the ana-rLOX/LA reaction system. The EAI of albumin and globulin solution respectively increased from 4948 and 5838 to 5838 and 6019 m^2 g^{-1}, but there was no significant change in the EAI for gluten. The ESI of albumin, globulin, and gluten solution increased from 22, 26, and 25 to 26, 30, and 34 min, respectively. The increase of EAI and ESI may result in the change of hydrophilic groups and hydrophobic groups related to emulsibility of protein. In the

work, the conformation of wheat protein was changed in the oxidation process, caused by enzymatic reaction, and hydrophobic groups were exposed, which improved the lipophilicity of protein. Therefore, the emulsifying properties of proteins were improved. Through increasing EAI and ESI of wheat protein, the original dough of incompatibility of dispersed phase system becomes more homogeneous, and all kinds of materials in the dough were mixed evenly. Therefore, the quality of products is even and stable.[33]

Effect of ana-rLOX/LA on Particle Size and Surface Structure of Wheat Proteins. The particle size of wheat proteins in solution ranged broadly from 1 to 1000 μm (Figure 2). It was found that there were significant differences in the volume mean diameter ($D[4,3]$), the surface area mean diameter ($D[3,2]$), and the specific surface area (SSA) by addition of ana-rLOX/LA in protein solutions. The average particle size $D[3,2]$ of albumin, globulin, and gluten solution decreased from 5.79, 2.10, and 31.74 to 3.92, 1.75, and 15.62 μm after the enzymatic reaction, respectively (Table 3). These results might be attributed to the modified reaction that was caused by ana-rLOX/LA, which made the protein structure more compact and led to the decrease of average particle size of wheat proteins. In addition, lipid peroxidation radicals could also induce S−S bond formation. The results indicated that all kinds of wheat protein were cross-linked by lipid peroxidation radicals.

To confirm the above explanation, wheat proteins with or without ana-rLOX/LA were observed by scanning electron microscopy (SEM). The outer topography and inner structure of protein modified with or without ana-rLOX/LA are presented in Figure 3. Proteins modified by enzymatic reaction were in regular shape with a denser and tighter surface in comparison with nonenzymatic reaction. The wheat albumin, globulin, and gluten appeared to be tighter network structures, and wheat albumin presented the membrane-like structure by cross-linking of the radicals reaction after the addition of ana-rLOX/LA. The results indicated that the structure of wheat proteins became tighter and more compact due to the oxidation of proteins after the addition of ana-rLOX/LA. Therefore, the particle size of wheat proteins became smaller. All of the above changes of wheat proteins showed that the free radical yielded from the lipid oxidation affect the formation of the network of wheat protein. These results suggested that ana-rLOX might be useful in food industries to improve textural and leavening characteristics of bread, cakes, or toppings and confectionery products in which foaming properties are important, similar to that reported by Mirsaeedghazi.[34]

Modification Effect of ana-rLOX on Different Wheat Flours. It has been reported that LOX increases mixing tolerance and generally enhances dough rheological properties,[35] suggesting that LOX could be utilized as a natural food improver. In this study, three wheat flours, Annong0950, Yang13, and Yang15, which are weak-, medium-, and strong-gluten wheat flours, were used to determine whether ana-rLOX could effectively improve dough quality.

Table 4 shows that the dough processing characteristics of the three wheat flours, such as springiness (SP), cohesiveness (CO), gumminess (GU), and resilience (RE), were improved after the addition of ana-rLOX in flours.

The ana-rLOX had a positive impact on SP for three doughs. SP of three doughs with 30 IU/g ana-rLOX increased significantly by 8.4, 9.9, and 13.1%, respectively. A similar trend was shown in weak-, medium-, and strong-gluten flours (Table 4).

The ana-rLOX positively affected CO in three doughs, too (Table 4). For weak-gluten flour, the dough's CO increased by 13.3% at 30 IU/g of ana-rLOX and then decreased after the addition of more ana-rLOX. The same trend was also shown in medium-gluten flour with a maximum of 26.7% increase at 20 IU/g ana-rLOX. However, the dough's CO of strong-gluten flour increased with more addition of ana-rLOX, and the maximum value of 37.7% was observed at 40 U/g ana-rLOX.

ana-rLOX enhanced the dough's GU in three flours. For weak-gluten flour, the dough's GU increased by 63.1% at 30 IU/g of ana-LOX, followed by a decrease after additional ana-LOX. The same trend was also shown in medium-gluten flour with a maximum of 101% increase at 20 IU/g ana-LOX. For strong-gluten flour, dough GU increased with more addition of ana-LOX, and the maximum of 100% increase was observed at 40 IU/g ana-rLOX (Table 4).

Table 4 also shows different effects of ana-LOX on the dough's RE among three flours. The dough's RE of weak-gluten flour significantly decreased by 13.7% at 40 IU/g ana-rLOX as ana-rLOX increased. For medium-gluten flour, RE increased by 29.5% at 20 IU/g, but decreased thereafter. For strong-gluten flour, the maximum of the dough's RE is 55.7% increase at 30 IU/g ana-rLOX. The results supported that ana-LOX-treated bread volume improved by 16.8%, the loaf height increased by 10.3%, and the specific volume increased by 18.2%.

When LOX was added into dough, the increased number of formed disulfide bonds enhanced the ability of dough to retain gas.[36] In American baking practices, the main purpose for adding enzyme-active soy flour into wheat flour is to improve dough properties.[37] Overall, the additional ana-rLOX in the flours was able to improve wheat dough's processing characteristics including SP, CO, GU, and RE to different degrees except RE for low-gluten flour. Although the activity of adding ana-rLOX for reaching the best effect of improving dough quality was different, these results provided clear evidence that ana-rLOX from *Anabaena* sp. PCC7120 could effectively improve the quality of wheat flour and explained why the enzyme increased loaf height, bread volume, and specific volume,[22] suggesting that it could be not only applied to baking practices but also used as a natural flour improver for wheat-based food.

One of the main advantages of nanoemulsions over microemulsions is that they require considerably less surfactant to form them. Food-grade nanoemulsions can be formed by high-energy methods (such as high-pressure homogenization or sonication) or low-energy methods (such as phase inversion temperature, spontaneous emulsification, or emulsion phase inversion).[23,26] In this study, we examined the utilization of spontaneous emulsification for forming food-grade ω-3 fatty acid delivery systems suitable for utilization in transparent foods and beverages. This method involves simply injecting an oily phase (typically consisting of a hydrophilic surfactant, a carrier oil, and a lipophilic bioactive) into an aqueous phase (typically consisting of water and cosolvent) with continuous stirring.[27] We have recently shown that this method can be used to successfully encapsulate vitamin E in nanoemulsion-based delivery systems.[27−30] An advantage of using low-energy methods to form nanoemulsions is that no expensive processing equipment (such as a high-pressure homogenizer or sonicator) is required.

MATERIALS AND METHODS

Materials. Fish oil (Denomega 100) was kindly donated by Denofa (Brighton, CO, USA). Lemon oil (SC 020207, lot 2894308) was kindly donated by International Flavors and Fragrances (Union Beach, NJ, USA). The supplier reported that this oil contained ≈60% limonene, <18% citral + citral acetate, and <15% γ-terpinene. Medium-chain triglyceride (MCT) oil (*MIGLYOL* 812) was purchased from Warner Graham Co. (Sasol Germany GmbH). Nonionic surfactant (Tween 80), citric acid, sodium benzoate, and propylene glycol were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Glycerol was purchased from Fisher Scientific (Pittsburgh, PA, USA). Ethanol was purchased from Pharmco−Aaper (Brookfield, CT, USA). Double-distilled water was used in the preparation of all solutions and emulsions.

Sample Preparation. Nanoemulsions were prepared by spontaneous emulsification using the method described previously.[27] In brief, an organic phase was added by a micropipet in an aqueous phase with continuous stirring of the system at 25 °C and 500 rpm using a magnetic stirrer (PC-410 D, Corning Instruments, Corning, NY, USA). The organic phase consisted of a mixture of different amounts of fish oil (0−10 wt %), MCT or lemon oil (0−10 wt %), and nonionic surfactant (2.5−10 wt %), whereas the aqueous phase was a buffer solution (pH 3.0, 0.8% citric acid, 0.08% sodium benzoate) mixed with different amounts of propylene glycol, glycerol, or ethanol (0−50 wt %). The low pH of the buffer was designed to imitate the aqueous phase of commercial beverage products. An organic phase was prepared by mixing oils and surfactant together for 30 min (750 rpm), and then 20 g of this organic phase was slowly injected into 80 g of aqueous phase over a 15 min period using a micropipet with continuous stirring (500 rpm).

Particle Size Measurements. The particle size distributions of nanoemulsions and emulsions produced by spontaneous emulsification were measured using either a dynamic light-scattering instrument (Zetasizer Nano ZS, Malvern Instruments, Malvern, UK) or a static light-scattering instrument (Mastersizer 2000, Malvern Instruments). Dynamic light scattering was used for samples with relatively small particle diameters (d < 3000 nm), whereas static light sattering was used for samples with larger droplets.

Dynamic Light Scattering. The particle size distribution was determined by measuring the frequency shift of a laser beam (633 nm) scattered from a sample at an angle of 173°.[27] To avoid multiple scattering effects, all of the samples were diluted before the measurements (×500) with citric buffer. The mean particle diameter (Z-average) and polydispersity index (PDI) were calculated from the particle size distribution. The PDI provides a measure of the narrowness of the particle size distribution, with values ≤0.1 indicating a very narrow distribution.

Static Light Scattering. The particle size distribution was determined by measuring the angular dependence of the intensity of light scattered from the emulsions. Mean particle diameters (d_{32}) were calculated from the particle size distribution. All samples were diluted with citric buffer prior to making the measurements to avoid multiple scattering effects. This was achieved by adding a few drops of nanoemulsions into approximately 125 mL of citric buffer in the sample chamber of the instrument until an obscuration of 11−15% was obtained.

Turbidity Measurements. The influence of temperature on the turbidity of the nanoemulsions was determined using a UV−visible spectrophotometer with temperature-scanning capabilities (Evolution Array, Thermo Scientific, Madison, WI, USA). The turbidity was measured at 600 nm as the temperature was increased form 20 to 90 °C at 1 °C/min and then decreased back to 20 °C.

Statistical Analysis. All experiments were carried out twice with two samples being analyzed for each trial. The results are reported as the calculated mean and standard deviation of these measurements.

RESULTS AND DISCUSSION

The overall aim of this study was to identify optimum conditions to prepare stable ω-3-enriched nanoemulsions that were optically transparent. We therefore systematically examined the influence of a number of factors on the formation and stability of the nanoemulsions.

Influence of Carrier Oil. Preliminary experiments indicated that nanoemulsions with small droplets could not be formed using fish oil alone as the oil phase. We therefore examined the influence of mixing fish oil with a carrier oil (either MCT or lemon oil). Previous studies with vitamin E have shown that this approach can be used to produce nanoemulsions containing small droplets.[27] In this series of experiments, the composition of the oil phase was varied, whereas the total oil (10%), surfactant (10%), and buffer (80%) contents were kept constant.

Static light scattering (SLS) was used for these experiments because many of the samples formed after spontaneous emulsification had relatively large particle sizes (d > 1000 nm). The influence of carrier oil type and oil phase composition on the particle size of the systems formed by spontaneous emulsification is shown in Figures 1 and 2. The mean particle diameter was relatively small (d < 200 nm) for both carrier oils when the fish oil concentration in the oil phase remained relatively low (≤40% for MCT and ≤50% for lemon oil). On the other hand, there was a steep increase in the mean particle diameter when the fish oil concentration was higher than these values (Figure 1). At low fish oil concentrations, the nanoemulsions had relatively narrow monomodal particle size distributions for both lemon oil and MCT.

Ideally, one would like to have small droplet sizes but also a high loading capacity, that is, a relatively high concentration of fish oil within the oil phase. The nanoemulsions prepared using the lemon oil were more suitable for this purpose, because they still had relatively small droplet diameters at relatively high fish oil contents. For example, when the oil phase contained 50% lemon oil and 50% fish oil, the mean droplet diameter was 112 ± 3 nm when measured by static light scattering. This value was close to the mean droplet diameter of 106.0 ± 0.5 nm determined by dynamic light scattering on the sample. We therefore decided to utilize lemon oil as the carrier oil in the remainder of the study. Another advantage of using lemon oil is that it can mask any off-flavors associated with fish oil.

Influence of Surfactant Concentration. Previous studies have shown that the size of the droplets produced by low-

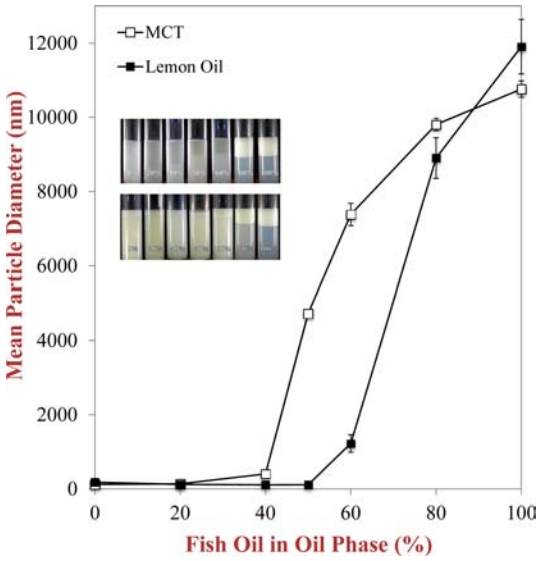

Figure 1. Influence of oil phase composition on the mean particle diameter. The oil phase contained different amounts of fish oil and carrier oil (MCT or lemon oil). (Inset) Photographs of the emulsions. Measurements were made after 24 h of storage at ambient temperature.

energy methods, such as the spontaneous emulsification and emulsion phase inversion methods, depends on the surfactant-to-oil ratio (SOR).[27,28,31,32] We therefore examined the influence of SOR on the size of the droplets produced in this study. The total oil content was maintained constant (10%) while the ratio of surfactant to buffer solution was varied. Polyoxyethylene-20-sorbitan-monooleate (Tween 80) was used as a food-grade hydrophilic nonionic surfactant (hydrophile–lipophile balance = 15). A 50% fish oil and 50% lemon oil mixture was used as the oil phase because this value gave small droplets with a high ω-3 acid content (see previous section).

As shown in Figure 3, the mean particle diameter was large (d > 1000 nm) at relatively low surfactant levels (SOR < 0.75), but small (<200 nm) at higher surfactant levels (SOR ≥ 0.75). Dynamic light scattering (DLS) measurements could not be carried out on emulsions at low SOR because they were out of the range of the instrument. However, there was excellent agreement between the mean particle diameters measured by DLS and SLS at higher SOR values (Figure 3). For example, at a SOR of 1 the mean droplet diameter was ≈108 ± 8 nm for DLS and ≈114 ± 2 nm for SLS. The particle size distrutions were monomodal at this SOR value (data not shown), with a narrow polydispersity index (PDI ≈ 0.18).

The physicochemical origin of the dependence of particle size on SOR may be related to the amount of surfactant required to cover the droplet surfaces formed. The minimum concentration of surfactant (C) required to cover all of the droplet surfaces in an emulsion is given by the relationship[33]

$$C = \frac{6\varphi\Gamma_S}{d_{32}} \quad (1)$$

where ϕ is the disperse phase volume fraction, d_{32} is the surface-weighted mean droplet diameter, and Γ_S is the surface load.[34] The surface load of Tween 80 has previously been reported to be about 3.1 mg m^{-2}.[35] Assuming ϕ = 0.1, d_{32} = 100 nm, and Γ_S = 3.1 mg m^{-2}, a surfactant concentration of around 1.9 wt % was calculated to be required to cover all of

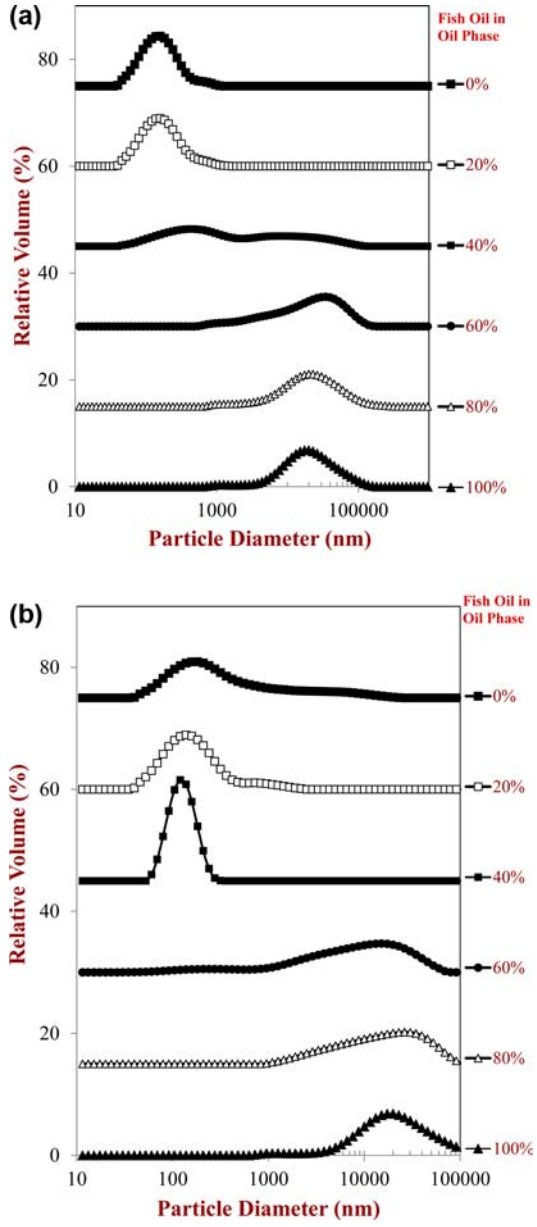

Figure 2. Particle size distributions of nanoemulsions and emulsions formed by spontaneous emulsification using oil phases with different compositions (a, MCT and fish oil; b, lemon oil and fish oil).

the droplets formed, which corresponds to an SOR of about 0.2. The experimental measurements show that a much higher SOR is required to form nanoemulsions with this droplet diameter (Figure 3), which suggests that the particle size is not limited by the amount of surfactant present. Instead, it must be related to the physicochemical events that occur at the boundary between the oil/surfactant and aqueous phases when they are brought into contact.

Influence of Cosolvent Type and Concentration. To produce optically transparent nanoemulsions, it is improtant that the droplet diameter is as small as possible. We therefore examined the influence of cosolvent type and concentration on the particle size of the droplets produced by spontaneous emulsification. Three short-chain alcohols (ethanol, propylene glycol, and glycerol) were used as water-soluble cosolvents in this study. The total oil content (10%) and surfactant content (10%) were kept constant in this study, with 50% fish oil/50%

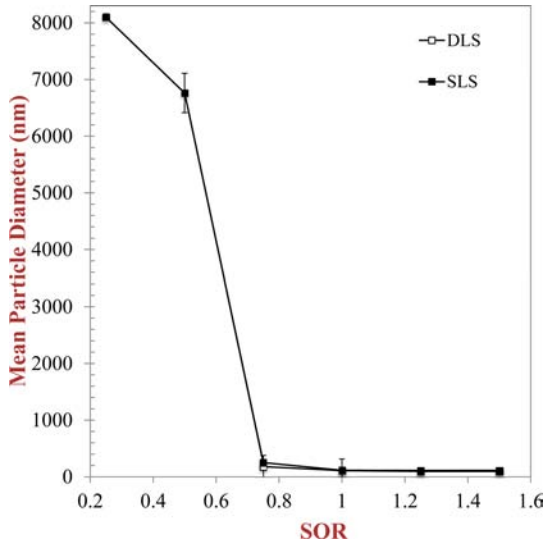

Figure 3. Influence of surfactant-to-oil ratio (SOR) on the mean particle diameter produced by spontaneous emulsification. All systems had the same total oil phase content (10%), which consisted of 50% fish oil and 50% lemon oil. Particle sizes were measured after 24 h of storage at ambient temperature.

lemon oil being used as the oil phase and Tween 80 being used as the surfactant. The amount of the different cosolvents in the aqueous buffer solution was systematically varied.

Incorporation of ethanol (10−50%) into the aqueous phase led to an increase in mean particle size and the formation of emulsions that were highly unstable to phase separation, and so this cosolvent was not studied further. Incorporation of propylene glycol (PG) into the aqueous phase led to a complex dependence of the particle size on cosolvent concentration. There was an increase in mean particle diameter with increasing PG concentration from 0 to 35%, but then a decrease from 35 to 40%, and then a steep increase from 35 to 45% (Figure 4a). The smallest droplets were formed in the systems containing 40% PG: $d \approx 99 \pm 2$ nm; PDI $\approx 0.22 \pm 0.01$. The physicochemical origin of this effect is currently unknown, but is presumably due to the nature of the structures formed at the boundary between the surfactant/oil and aqueous phases at particular cosolvent concentrations. Incorporation of glycerol into the aqueous phase could be used to cause an appreciable decrease in the mean droplet size of the nanoemulsions produced by spontaneous emulsification. The droplet size remained relatively constant from 0 to 20% glycerol, but decreased appreciably from 20 to 40% glycerol (Figure 4b). The smallest droplets were formed in the systems containing 40% glycerol: $d \approx 51 \pm 4$ nm; PDI $\approx 0.15 \pm 0.03$. In addition, these nanoemulsions appeared optically transparent in their nondiluted form (Figure 4b, inset). Optical transparency may have been due to the fact that glycerol addition reduced the refractive index contrast between the oil droplets and the surrounding aqueous phase or because it reduced the droplet size.[18] The DLS measurements were made after the nanoemulsions had been highly diluted with an aqueous solution containing no glycerol, and so the optical clarity of these systems can be at least partly attributed to their reduced light-scattering efficiency of the smaller droplets.

Presumably, the presence of the glycerol molecules in the aqueous phase altered the nature of the colloidal structures formed at the oil/surfactant and aqueous phase boundary when

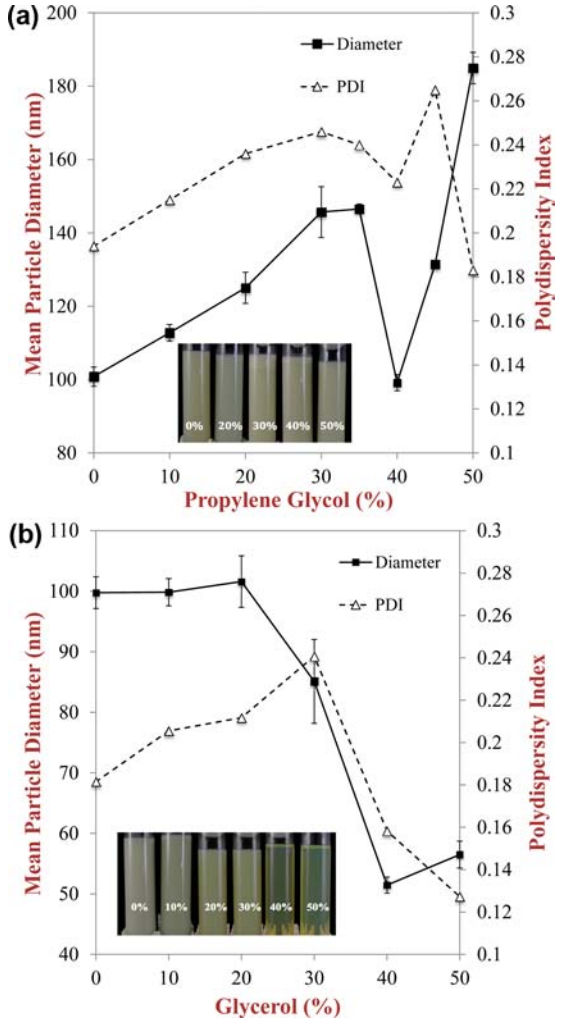

Figure 4. Influence of (a) propylene glycol content and (b) glycerol content in the aqueous phase on the mean particle diameter produced by spontaneous emulsification. All systems contained 10% oil phase (50% fish oil/50% lemon oil) and 10% surfactant (Tween 80). Particle sizes were measured after 24 h of storage at ambient temperature.

the two phases were brought into contact. For example, they may have been able to penetrate into the surfactant monolayer and alter its optimum curvature and flexibility.[36] As a result, the spontaneous formation of ultrafine droplets at the boundary may have been facilitated.

Thermal Stability. Nanoemulsions stabilized by nonionic surfactants are often unstable to coalescence when they are heated close to their phase inversion temperatures, and so we examined the influence of heating on nanoemulsion stability. A nanoemulsion was initially prepared by spontaneous emulsification that contained 10% oil phase (50% fish oil/50% lemon oil), 10% surfactant (Tween 80), and 80% aqueous phase (40% glycerol in citrate buffer). The turbidity of this nanoemulsion was then measured as the sample was heated from 20 to 90 °C (Figure 5).

The turbidity of the nanoemulsions remained relatively small from around 20 to 50 °C, indicating that they were relatively stable to droplet growth in this temperature range. However, there was a steep increase in turbidity from around 50 to 68 °C, which can be attributed to droplet growth due to coalescence. The turbidity of the samples then decreased steeply from 68 to 70 °C and remained relatively low until around 74 °C. Visual

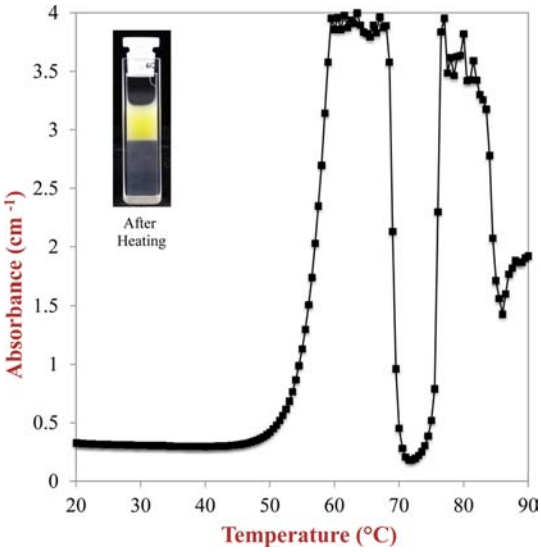

Figure 5. Influence of heating on the turbidity of nanoemulsions produced by spontaneous emulsification. All systems contained 10% oil (50% fish oil/50% lemon oil), 10% surfactant (Tween 80), and 80% aqueous phase (40% glycerol in citrate buffer solution). (Inset) Photograph of the sample after heating.

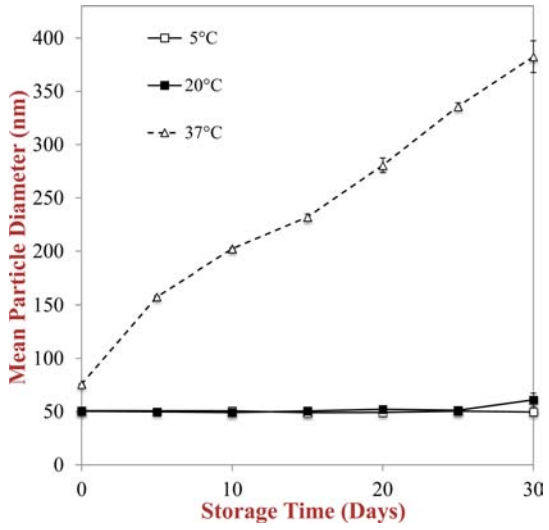

Figure 6. Influence of storage temperature on the mean particle diameter of nanoemulsions. All systems contained 10% oil (50% fish oil/50% lemon oil), 10% surfactant (Tween 80), and 80% aqueous phase (40% glycerol in citrate buffer solution).

observation of these samples showed that they were homogeneous and optically transparent. We propose that a single isotropic microemulsion phase was formed in this narrow temperature range, corresponding to the phase inversion temperature. When the samples were further heated, there was a steep increase in turbidity, which can be attributed to the formation of a water-in-oil emulsion and the corresponding increase in particle size. The reason that the emulsions go from an oil-in-water system at low temperatures to a microemulsion at intermediate temperatures to a water-in-oil system at high temperatures can be attributed to surfactant dehydration.[37,38] When the samples were cooled to ambient temperature inside the instrument (which occurred relatively slowly), they underwent phase separation (Figure 5, inset).

Isothermal Stability. For commercial applications, it is important that nanoemulsion-based delivery systems remain physically stable during storage. Nanoemulsions become physically unstable through numerous physicochemical processes, including flocculation, coalescence, Ostwald ripening, and gravitational separation.[23] We therefore examined the influence of isothermal storage on the stabilty of the nanoemulsions to droplet growth and phase separation. As before, nanoemulsions were prepared using the spontaneous emulsification method that contained 10% oil phase (50% fish oil/50% lemon oil), 10% surfactant (Tween 80), and 80% aqueous phase (40% glycerol in citrate buffer). These samples were then diluted in buffer solution, and their mean particle diameter and appearance were measured after they were stored at three storage temperatures for different times (Figure 6).

The nanoemulsions stored at 5 and 20 °C appeared to be stable to droplet growth with no change in mean particle diameter or appearance during 30 days of storage. On the other hand, the nanoemulsions stored at 37 °C showed an appreciable increase in mean particle diameter during storage and became cloudy in appearance. Indeed, after 30 days, they phase separated into a white cream layer on top of a clear serum layer. Presumably, droplet growth occurred due to enhanced coalescence when the nanoemulsions were held at temperatures close to their phase inversion temperature. Around these temperatures, there is a decrease in interfacial tension, which makes the surfactant monolayers more flexible and more prone to coalescence.[23]

This study has shown that stable transparent nanoemulsions containing relatively high levels of fish oil can be formed using a low-energy method (spontaneous emulsification). The size of the droplets in these nanoemulsions can be controlled by manipulating the surfactant-to-oil ratio, oil composition, and aqueous phase composition. A major advantage of the spontaneous emulsification method is that no sophisticated or expensive equipment is required to form the nanoemulsions. On the other hand, a major disadvantage of the method is that a relatively high surfactant concentration is required to form them. For example, about 250 mg of surfactant would be required to incorporate around 250 mg of fish oil into a commercial product. This level of surfactant may cause problems due to economic, flavor, or regulatory considerations. For example, the U.S. Food and Drug Administration puts legal limits on the use of Tween 80 in various food applications, for example, < 475 mg/day in fat-soluble vitamin preparations (www.fda.gov).

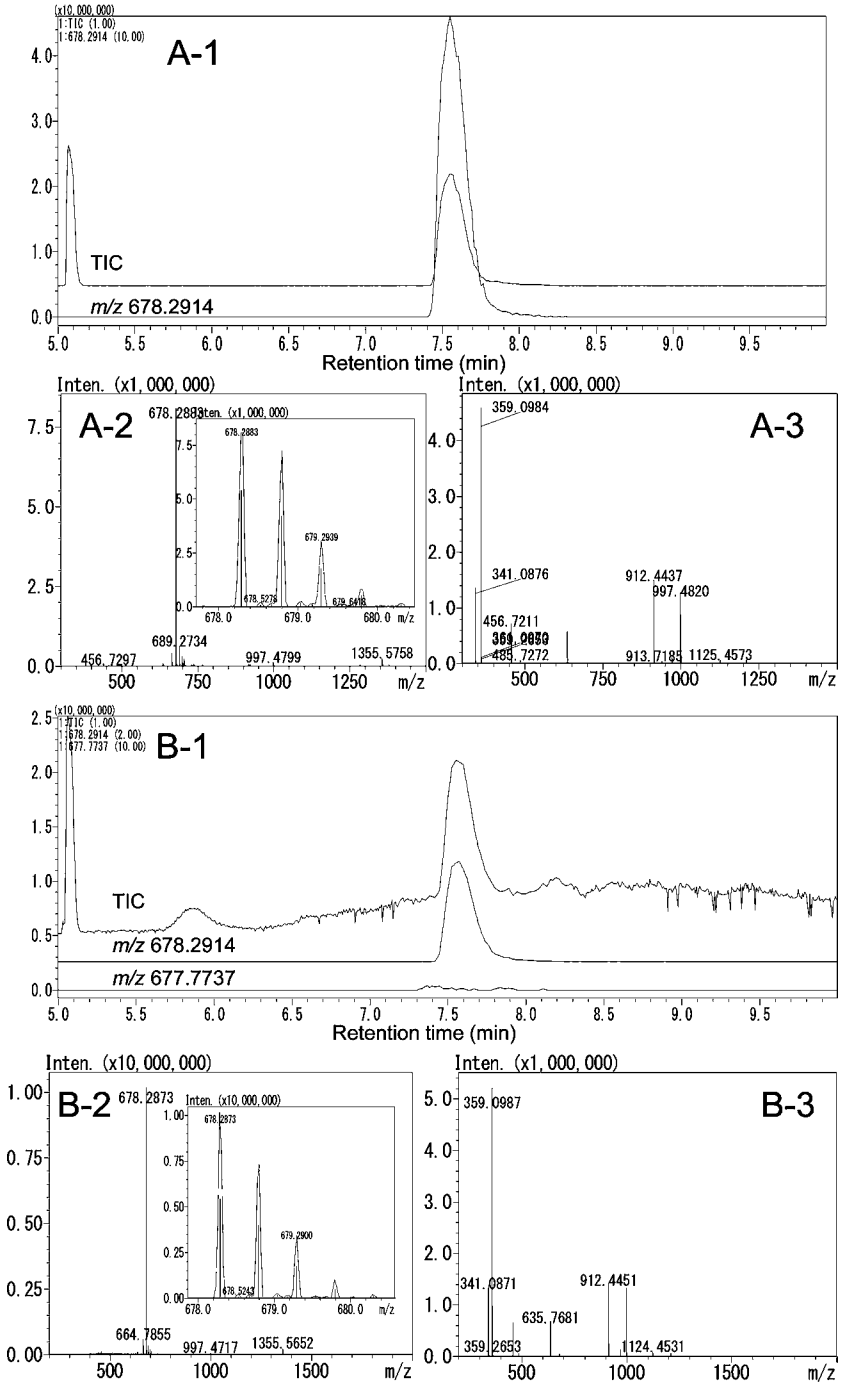

Figure 1. LC/ESI–MS/MS chromatograms of authentic B_{12} and the B_{12} compounds purified from the lion's mane mushroom sample G. B_{12} was analyzed using an LCMS-IT-TOF system (Shimadzu), as described in the text. Panels A-1 and B-1 show the total ion chromatograms (TICs) and the chromatograms (*m/z* 678.2914) of authentic B_{12} and the purified B_{12} compounds from lion's mane mushroom sample G, respectively. The mass spectra of authentic B_{12} and the B_{12} compounds purified from mushroom sample G at 7.55 min are shown in panels A-2 and B-2, respectively (the magnified spectrum range from *m/z* 678 to *m/z* 680 is shown as an insert in each panel). The MS/MS spectra for *m/z* 678.2883 peak of authentic B_{12} and the B_{12} compounds purified from the mushroom sample G are shown in panels A-3 and B-3, respectively.

known as alkali-resistant factors. Because *L. delbrueckii* ATCC 7830 can utilize both deoxyribosides and deoxyribonucleotides (alkali-resistant factors) as well as B_{12}, the amount of B_{12} was calculated by subtracting the values of the alkali-resistant factor from the values of total B_{12}. The B_{12} assay was performed in triplicate.

In the case of B_{12} assay using vitamin B_{12}-dependent *Escherichia coli* 215, each B_{12} compound was spotted onto a filter paper (circle, 6 mm), which was placed on 1.5% (w/v) agar containing a basal medium of *E. coli* 215 and incubated at 30 °C for approximately 20 h.[9] The gel plate was sprayed with a methanol solution containing 2,3,5-triphenyltetrazolium salt to enable visualization of the B_{12} compounds, indicating *E. coli* growth.

Identification of Mushroom B_{12} Compounds by LC/ESI–MS/MS. *H. erinaceus* fruiting body samples (each 50 g dry weight) were homogenized in a mixer (TML160; Tokyo, Japan). Each homogenate was added to 500 mL of distilled water, 50 mL of 0.57 mol/L acetic buffer, pH 4.5, with 0.77 mmol KCN, and boiled for 30 min to extract B_{12} compounds. The extraction procedures were performed in a draft chamber (Dalton Co., Tokyo, Japan). The boiled suspension was filtered with a cotton cloth, and the filtrate was centrifuged at 10 000*g*

for 10 min. Aliquots (approximately 200 mL) of the supernatant were placed in Sep-Pak Vac 20-cc (5-g) C18 cartridges (Waters Corp.), which had been washed with 75% (v/v) ethanol and equilibrated with distilled water. The C18 cartridges were washed with 30 mL of distilled water, and B_{12} compounds were eluted using 30 mL of 75% (v/v) ethanol. The remaining supernatant was treated in a similar manner. The combined eluates were evaporated to dryness under reduced pressure and the residual fraction was dissolved in 5 mL of distilled water and centrifuged at 10 000*g* for 10 min to remove any insoluble material. The supernatant fraction was loaded onto an immunoaffinity column (EASI-EXTRACT B_{12} Immunoaffinity Column (P80) R-Biopharm AG, Darmstadt, Germany), and B_{12} compounds were purified according to the manufacturer's protocol. The purified mushroom B_{12} compounds and authentic B_{12} were dissolved in 0.1% (v/v) acetic acid and filtered using a Nanosep MF centrifuge device (0.4 μm; Pall Corp., Tokyo, Japan) to remove small particles. We analyzed an aliquot (2 μL) of the filtrate using an LCMS-IT-TOF system coupled to an Ultra-Fast LC system (Shimadzu, Kyoto, Japan). Each purified sample was injected into an InertSustain column (3 μm, 2.0 × 100 mm; GL Science, Tokyo, Japan) and equilibrated with 85% solvent A (0.1% (v/v) acetic acid) and 15% solvent B (100% methanol) at 40 °C. B_{12} compounds were eluted using a linear gradient of methanol (15% solvent B for 0−5 min, 15−90% solvent B for 5−11 min, and 90−15% solvent B for 11−15 min). The flow rate was 0.2 mL/min. The electrospray ion (ESI) conditions were determined by injecting authentic B_{12} into the MS detector to identify the optimum parameters for detecting the parent and daughter ions of the B_{12} compound. ESI−MS was operated in the positive ion mode using argon as the collision gas. The identification of B_{12} (*m/z*

678.2914) representing $[M + 2H]^{2+}$was confirmed by comparing the observed molecular ions and their retention times.

Preparation of B_{12}[c-lactone]. B_{12}[*c*-lactone] was synthesized according to the method of Pathare et al.[10] In brief, B_{12}(cyanocobalamin, 0.5 g), was dissolved in 150 mL of distilled water, and 7.5 mL of acetic acid was added. Sodium iodide (50 mg) and *N*-chlorosuccinimide (90 mg) were then added, and the reaction mixture was stirred at 25 °C for 16 h in the dark. After the reaction mixture was desalted using Sep-Pak Vac 20-cc (5-g) C18 cartridges, the desalted solution was evaporated to dryness under reduced pressure and then dissolved in a small amount of distilled water. The solution was further purified using a reversed-phase HPLC column (Wakosil-II 5C18RS, 4.6 × 150 mm; 5-μm particle size; Wako Pure Chemical Industries, Osaka, Japan). B_{12}[*c*-lactone] was isocratically eluted with 20% (v/v) methanol solution containing 1% (v/v) acetic acid at 40 °C and monitored by measuring the absorbance at 280 nm. The flow rate was 1 mL/min. A main peak with a retention time of 12.2 min was recovered and treated as B_{12}[*c*-lactone] in the experiments. B_{12}[*c*-lactone] concentration was determined using the molar extinction coefficient ($\varepsilon = 2.63 \times 10^4$) at an absorbance of 359 nm as described previously.[10]

Analytical TLC and HPLC. Concentrated solutions of prepared B_{12}[*c*-lactone] and authentic B_{12} were spotted onto the silica gel 60 TLC sheet and developed at 25 °C in the dark using 2-propanol/NH_4OH (28%)/water (7:1:2 v/v) and 1-butanol/2-propanol/water (10:7:10 v/v) as solvents I and II, respectively. After drying the TLC sheet, the R_f values of the red spots were measured. In HPLC analysis, prepared B_{12}[*c*-lactone], authentic B_{12}, or a reaction mixture was analyzed using a reversed-phase HPLC column (Wakosil-II 5C18RS, 4.6 × 150 mm; 5-μm particle size; Wako Pure Chemical Industries, Osaka, Japan). Corrinoids were isocratically eluted with 20% (v/v) methanol solution containing 1% (v/v) acetic acid at 40 °C and monitored by measuring the absorbance at 361 nm. The flow rate was 1 mL/min. The retention times of authentic B_{12} and prepared B_{12}[*c*-lactone] were 8.4 and 12.2 min, respectively.

Conversion of B_{12} to B_{12}[c-lactone] by Chloramine-T. The reaction mixture contained 10 μmol/L B_{12} (cyanocobalamin), 10 μmol/L chloramine-T, and 100 mmol/L citrate buffer (pH range 3.0−6.0), 2-(*N*-morpholino)ethane sulfonic acid buffer (pH range 5.0−8.0), 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid buffer (pH range 7.0−9.0), or borate buffer (pH range 8.0−10.0). After leaving the reaction mixture for 24 h at 25 °C in the dark, each mixture was immediately analyzed using the reversed-phase HPLC system, as described above. The relative concentrations of B_{12} and B_{12}[*c*-lactone] were calculated based on the peak areas with the identical retention times of B_{12} and B_{12}[*c*-lactone], respectively. B_{12}[*c*-lactone] formation was represented as the percentage of B_{12}[*c*-lactone] versus the sum of B_{12} and B_{12}[*c*-lactone].

RESULTS AND DISCUSSION

The B_{12} contents were determined in seven samples of dried lion's mane mushroom (*H. erinaceus*) fruiting body using a microbiological assay method based on *L. delbrueckii* ATCC 7830 (Table 1). Trace levels (0.04−0.36 μg/100 g dry weight) of B_{12} were found in most samples (A, B, D, E, and F), and samples C and G contained 0.56 and 1.04 μg/100 g dry weight of B_{12}, respectively. As these cultured and dried lion's mane mushroom fruiting body samples were obtained from different manufacturers as food items, precise strains of the tested lion's mane mushrooms, culture conditions, and postharvest processing methods (probably heat-drying and then storage at an ambient temperature) of their fruiting bodies are not available. Thus, we have little information on why such differences in B_{12} contents occurred among these dried fruiting bodies.

L. delbrueckii ATCC 7830 can utilize deoxyribosides and deoxyribonucleotides (known as alkali-resistant factors) as well as B_{12}. High levels (0.51−4.03 μg as B_{12} equivalent/100 g dry weight) of the alkali-resistant factor were found in all mushroom fruiting body samples.

Corrinoids were purified from the extracts of dried lion's mane mushroom fruiting bodies using an immunoaffinity column and identified by LC/ESI−MS/MS (Figure 1). Authentic B_{12} was eluted as a peak with a retention time of 7.55 min (Figure 1A-1). The mass spectrum of authentic B_{12} mainly contained a doubly charged ion with an m/z of 678.2883 $[M + 2H]^{2+}$ (Figure 1A-1 and A-2). Its exact mass was calculated from its formula ($C_{63}H_{88}CoN_{14}O_{14}P$), i.e. 1354.5674, and the isotope distribution data showed that B_{12} mainly existed as a doubly charged ion under LC/ESI−MS conditions. The MS/MS spectrum of B_{12} indicated that a monovalent ion with an m/z of 359.0984 predominated, which was mainly attributable to the nucleotide moiety of B_{12} (Figure 1A-3). The compounds purified from dried lion's mane

dx.doi.org/10.1021/jf404463v | J. Agric. Food Chem. 2014, 62, 1726−1732

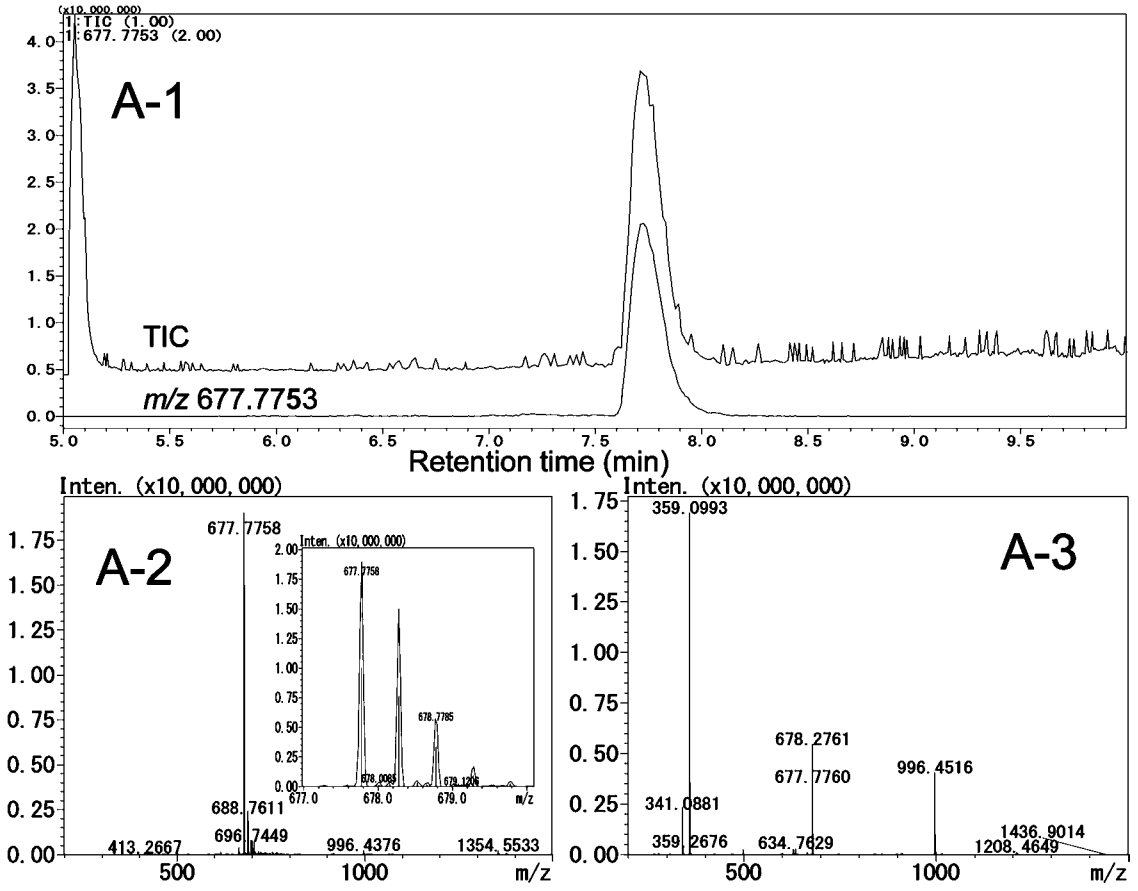

Figure 4. LC/ESI–MS/MS chromatograms of prepared B_{12}[*c*-lactone]. Panel A-1 shows the total ion chromatograms (TICs) and the chromatogram (*m*/*z* 677.7753) of prepared B_{12}[*c*-lactone]. The mass spectrum of prepared B_{12}[*c*-lactone] at 7.7 min is shown in panel A-2 (the magnified spectrum range from *m*/*z* 678 to *m*/*z* 680 is shown as an insert in each panel). The MS/MS spectra for the *m*/*z* 677.7758 peak of prepared B_{12}[*c*-lactone] is shown in panel A-3.

mushroom sample G were eluted as several ion peaks, which indicated that impurities were still present. The mass spectrum of the main peak had a retention time of 7.55 min in the purified sample (Figure 1B-1), where the B_{12} doubly charged ions had an *m*/*z* value of 678.2873 (Figure 1B-2). The MS/MS spectrum of the compound was identical to that of B_{12} (Figure 1B-3). These results indicated that dried lion's mane mushroom sample G contained B_{12} but not inactive corrinoid compounds. Similar LC/ESI–MS/MS chromatograms were obtained for the samples B, D, and F. No spectrum was obtained for mushroom sample A because it only had a trace level of B_{12}.

However, the compounds purified from mushroom sample C were eluted as two ion peaks in the chromatogram of *m*/*z* values of 678.2914 (Figure 2A-1). The mass spectrum of the minor ion peak had a retention time of 7.45 min in the purified compounds, where the B_{12} doubly charged ions had *m*/*z* values of 678.2877 (Figure 2A-2). The MS/MS spectrum of the compound was identical to that of B_{12} (Figure 2A-3). The mass spectrum of the major ion peak had a retention time of 7.7 min in the purified compounds (Figure 2A-1). The mass spectrum of the major peak had a doubly charged ion with an *m*/*z* of 677.7748 $[M + 2H]^{2+}$ (Figure 2A-4). The MS/MS spectrum of the major peak indicated that a monovalent ion with an *m*/*z* of 359.0974 (the nucleotide moiety of B_{12}) predominated (Figure 2A-5). The identical spectra were also obtained with sample E. These results indicated that dried lion's mane mushroom samples C and E contained another B_{12} compound as well as B_{12}.

Chloramine-T, an antimicrobial agent, has widespread uses in medical, dental, veterinary, food processing, and agricultural fields because of its low cytotoxicity.[11] Bonnett et al.[12] reported that chloramine-T is a source of electrophilic chlorine and it reacts with B_{12} to form B_{12}[*c*-lactone], which contains no halogen, at pH 4.0 (Figure 3). Thus, B_{12}[*c*-lactone] was synthesized according to the method of Pathare et al.[10] and then analyzed using the silica gel 60TLC and reversed-phase HPLC (Table 2). Although B_{12} and B_{12}[*c*-lactone] showed similar R_f values on TLC, B_{12}[*c*-lactone] was eluted as a single peak with different retention time of B_{12} during HPLC.

To identify the mushroom B_{12} compound with a doubly charged ion with an *m*/*z* of 677.7748 $[M + 2H]^{2+}$, B_{12}[*c*-lactone] was prepared and analyzed by LC/ESI–MS/MS (Figure 4). The prepared B_{12}[*c*-lactone] was eluted as a peak with a retention time of 7.7 min (Figure 4A-1). The mass spectrum of B_{12}[*c*-lactone] mainly had a doubly charged ion with an *m*/*z* of 677.7758 $[M + 2H]^{2+}$ (Figure 4A-1 and A-2). Its exact mass was calculated from its formula ($C_{63}H_{87}CoN_{14}O_{14}P$), i.e. 1353.5674. The MS/MS spectra of B_{12}[*c*-lactone] indicated that a monovalent ion with an *m*/*z* of 359.0993 predominated (the nucleotide moiety of B_{12}) (Figure 4A-3). These data were identical to those of the unidentified B_{12} compound found in mushroom C, which indicated that mushroom samples C and E contained an unnatural B_{12} compound, B_{12}[*c*-lactone]. To the best of our knowledge, this is the first report on the occurrence of B_{12}[*c*-lactone] in food.

We have no information on precise strains of the tested lion's mane mushrooms and their culture conditions and postharvest

dx.doi.org/10.1021/jf404463v | J. Agric. Food Chem. 2014, 62, 1726–1732

processes because the tested fruiting body samples were obtained as food items. Therefore, the reasons for such differences in B_{12} contents and occurrence of B_{12}[*c*-lactone] among the individual dried fruiting bodies is unclear. Previously, we demonstrated that the dried fruiting bodies of wild mushrooms (black trumpet and golden chanterelle) contained higher amounts (1.09−2.65 μg/100 g dry weight) of B_{12} than those of the cultured lion's mane mushrooms,[7] but B_{12}[*c*-lactone] was not detected in these dried wild mushroom fruiting bodies.

It is known that mushrooms neither have the ability to synthesize B_{12} *de novo* nor contain any B_{12}-dependent enzymes. Thus, mushroom B_{12} was probably derived from B_{12} sources outside the mushrooms, probably sawdust substrate (but no evidence of any B_{12}-containing substrates), or it was derived from B_{12} synthesized by bacteria living on the surfaces of the mushroom fruiting body. It is unclear at the present time whether such B_{12}-synthesizing bacteria can grow symbiotically with the mushroom during growth of its fruiting body or they are contaminated during preparation and storage of the dried mushroom fruiting body. However, occurrence of B_{12}[*c*-lactone] suggests that the antimicrobial agent chloramine-T was used during postharvest processing of the mushroom fruiting body.

Figure 5 shows the effects of varying pH on the conversion of B_{12} to B_{12}[*c*-lactone]. The formation of B_{12}[*c*-lactone] was

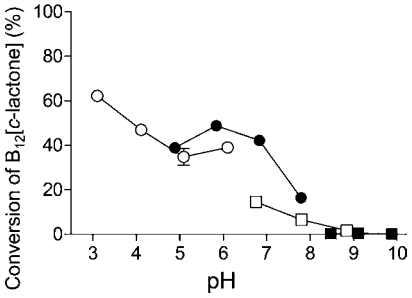

Figure 5. Effects of varying pH on the conversion of B_{12} to B_{12}[*c*-lactone]. B_{12}[*c*-lactone] formation is represented as the percentage of B_{12}[*c*-lactone] versus the sum of B_{12} and B_{12}[*c*-lactone]. Citrate buffer (○), 2-(*N*-morpholino)ethane sulfonic acid buffer (●), 4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid buffer (□), or borate buffer (■). The values represent the mean ± SD from three independent experiments.

highest at pH 3.0 in the experimental conditions, but considerable (approximately 40−50%) B_{12}[*c*-lactone] was also produced at neutral pH values (pH 6.0−7.0). These results indicate that B_{12}[*c*-lactone] is simple to be produced by incubating B_{12} with chloramine-T at a varying pH values (3.0−7.0).

We investigated whether B_{12}[*c*-lactone] exhibited any B_{12} activity in two B_{12}-dependent bacteria, which are used in microbiological B_{12} assays. B_{12}[*c*-lactone] was completely inactive in *E. coli* 215 (Figure 6A) and *L. delbrueckii* ATCC 7830 (Figure 6B). These results suggest that the lower B_{12} contents of mushroom samples C and E (Table 1) were due to the presence of B_{12}[*c*-lactone]. Stabler et al.[13] demonstrated that hydroxo (OH)-B_{12}[*c*-lactone] binds very weakly to the most specific B_{12}-binding protein, intrinsic factor. When OH-B_{12}[*c*-lactone] was injected into a rat blood vessel using an osmotic pomp, the indices of B_{12} deficiency (the serum methylmalonic acid and homocysteine levels) significantly increased because methylmalonyl-CoA mutase and methionine synthase were strongly inhibited by the addition of OH-B_{12}[*c*-lactone].

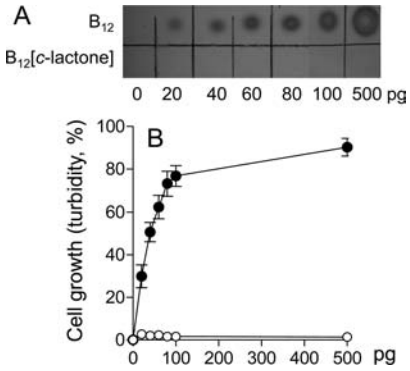

Figure 6. Effects of B_{12}[*c*-lactone] on two B_{12}-dependent bacteria used in microbiological B_{12} assay methods. (A) *E. coli* 215 and (B) *L. delbrueckii* ATCC 7830: Authentic B_{12} (○) and prepared B_{12}[*c*-lactone] (●). The values represent the mean ± SD from three independent experiments.

This study indicates that the use of the antimicrobial agent chloramine-T in food processing and agricultural fields readily promotes the formation of B_{12}[*c*-lactone] in food materials. Because nutritional values of foods treated with chloramine-T are reduced significantly, it would be necessary to make a detailed survey on the occurrence of B_{12}[*c*-lactone] in various foods.

The consumption of approximately 240 g of dried mushroom (even dried lion's mane mushroom sample G; 1.04 μg/100g dry weight) could provide the recommended dietary allowance for adults (2.4 μg/day),[14] although they would not be able to ingest such large amounts of this dried mushroom daily. Thus, dried lion's mane mushroom is not suitable for use as a B_{12} source by vegetarians because of its low B_{12} contents and the occasional presence of B_{12}[*c*-lactone] which is inactive in humans.

methods for TCC residue detection and screening in routine assays is still a research demand.

Immunochemical assays could be an alternative to meet all those requirements, as detection of low concentrations of TCC residues in many samples in a short time and in some cases avoiding long and tedious sample pretreatment steps may be possible. In fact, several approaches of competitive ELISA format assays have been already developed for the analysis of TCCs, being applied in most of the cases to milk samples.[1,15−17] Assuming that a majority of samples analyzed may not be contaminated by any of the TCCs, sample screening methods providing a reliable "yes/no" binary response related to a preset concentration threshold are of increasing interest in food control. Screening systems give mainly qualitative or semiquantitative information as they are focused on identifying and selecting a group of samples that contain one or more analytes above a preset concentration or threshold level.[18,19] In this context, the high selectivity and sensitivity typically provided by immunological methods are particularly suitable for the development of such screening strategies.

The use of quantum dots (QDs) as fluorescent labels in bioassays has been increasing due to their advantageous features, including excellent photostability and chemical stability, long fluorescence lifetimes, intense and narrow emission spectra, and size- and composition-tunable properties.[20] Furthermore, the possibility of attaching QDs to biomolecules keeping their functionality has allowed development of different formats of immunoassays such as microarrays[21] or Western blotting[22] as well as luminescent sensors for the analysis of health-risk environmental pollutants (e.g., based on molecular imprinted polymers[23]). However, the development of fluorescent immunoassay can report an additional benefit over the ELISA immunoassays, that is, saving time and costs in avoiding the final step of enzymatic reaction.

In this context, a QD-based immunoassay for direct screening of four TCCs in bovine muscle tissue is here described. The fluorescent probe consists of QDs bioconjugated to oxytetracycline−BSA conjugate (Oxy−BSA−QD), prepared following the carbodiimide chemistry. Due to the small size of the TCCs (haptens with only one site for binding to the antibody), the immunoassay design is restricted to a competitive format. So, competition for antibody binding sites between free antigen of the sample (unlabeled TCC) and the bioconjugates (Oxy−BSA−QD) is established.

MATERIALS AND METHODS

Reagents, materials, and instrumentation used through the work are available in the Supporting Information.

Characterization of Oxy−BSA conjugates. The synthesis and purification of Oxy−BSA conjugates are based on a commercial kit, and a detailed description about the procedure is collected in the Supporting Information. Once Oxy−BSA conjugates are obtained, an exhaustive characterization step is mandatory. A Bradford test[24] was used to determine the BSA concentration in the Oxy−BSA conjugate. The test correlates the ratio between absorbance of the samples measured at 465 and 595 nm (595/465) with the BSA (protein) concentration. According to a linear regression, BSA concentration in the conjugate was then calculated.

Molecular weight and stoichiometry of the conjugate were evaluated by MALDI-MS. A solution of 5 mg/mL of sinapinic acid in 30% of acetonitrile, containing 0.1% of trifluoroacetic acid, was prepared. An amount of 1−10 pmol of protein in the sample was needed, being 2.42 pmol in this case. As the sample has to be ideally clean of salts and the Oxy−BSA conjugate was stored in a 28 mM Na_3PO_4, 300 mM NaCl, and 33 mM sorbitol buffer (PBS), a previous cleanup step was carried out (sample desalting by Zip Tips). A solution of 1 mg/mL of BSA standard in water was used as reference. The MALDI plate was loaded with standards, matrix, and/or samples, and when the spots had been dried (at least after 30 min), the MALDI-MS analysis was performed.

Finally, following a strategy previously developed in our lab[25] based on the combination of the information provided by the Bradford test and the MALDI analysis, the final concentration of Oxy in the conjugate can be calculated. Such information is necessary to further optimize the bioconjugation of Oxy−BSA to QDs.

Synthesis and Characterization of the Immunoprobe: Oxy−BSA−QD Bioconjugate. The fluorescent labels used for labeling the Oxy−BSA conjugate giving rise to the tracer of the immunoassay are the CdSe/ZnS QDs. A brief description about their synthesis and solubilization are presented in the Supporting Information. The bioconjugation strategy used to synthesize the fluorescent tracer was based on a coupling procedure between −COOH groups from outer polymeric layers of QDs and $-NH_2$ groups from the BSA of the Oxy−BSA conjugate owing to the catalytic activity of EDC.[26] After stirring of the mixture of reagents during 2 h at room temperature, a purification step is needed to separate the bioconjugate from the rest of undesirable products (e.g., excess of reagents). The purification step is based on differences in molecular weights between the Oxy−BSA conjugate (71.2 kDa) and the Oxy−BSA−QD bioconjugate (>150 kDa). So, it can be carried out by ultrafiltration (UHF) using a 100 kDa membrane filter. Experimental conditions used for UHF were 3000 g, 5 min, making 3 washes with 100 mM PBS buffer at pH 7.4 at 4 °C.

The characterization of this bioconjugate consists on the evaluation of the fluorescent properties of QDs after the reaction and the stability in time of the tracer. These studies were carried out using fluorescent measurements.

Competitive Immunoassay Protocol. In a conventional immunoassay analysis the following experimental procedure was performed. First, the microtiter plate is coated with 100 μL/well of a 1 μg/mL antibody solution and is incubated at 37 °C for 2 h. In this step the antibody is immobilized on the microtiter plate wells by absorption over the surface of the support of polystyrene. Antibody solution is then removed and a blocking step is performed by adding 200 μL/well of 3% casein solution in water, in order to minimize further unspecific bindings. The microtiter plate is then incubated overnight at 4 °C. In a further step, the microtiter plate is washed three times using a washing solution (200 μL/well of 10 mM PBS pH 7.4 + 0.05% Tween20) to remove the excess of reagents. Then, the competition is established by the addition of a mixture of the standard (or the sample) and a known amount of the tracer (Oxy−BSA−QD) in a total volume of 150 μL/well. The reaction is incubated at 37 °C for 2 h. After the corresponding washing step, the fluorescence emission of the QDs from the Oxy−BSA−QD recognized by the antibody is measured.

Cross Reactivity Calculation. Cross reactivity (CR) is generally defined as the necessary amount of mass or concentration of interference able to produce an equal signal as when the analyte is assayed to provoke a signal inhibition of 50%.[27] Therefore, in this work CR rates, in terms of percentage (%), were calculated according to the expression (eq 1)

$$CR = [(IC_{50}(\text{analyte})/IC_{50}(\text{interference}))] \times 100 \quad (1)$$

where IC_{50} is the necessary concentration of species (analyte or interference) to induce a signal inhibition of 50%.

Screening Theory and Determination of the Unreliability Region. A screening system provides mainly qualitative or semiquantitative information. In this type of analysis it is not possible to express uncertainty in the same way as in quantitative analysis. For that reason it is necessary to define new concepts that characterize screening methods. Thus, "reliability" of a screening test is defined as the "proportion of correct yes/no responses from a large number of tests carried out on 'n' aliquots of the same sample". On the other hand, the term "uncertainty" should be replaced by "unreliability", that is the concentration range of the analyte around the limit where false

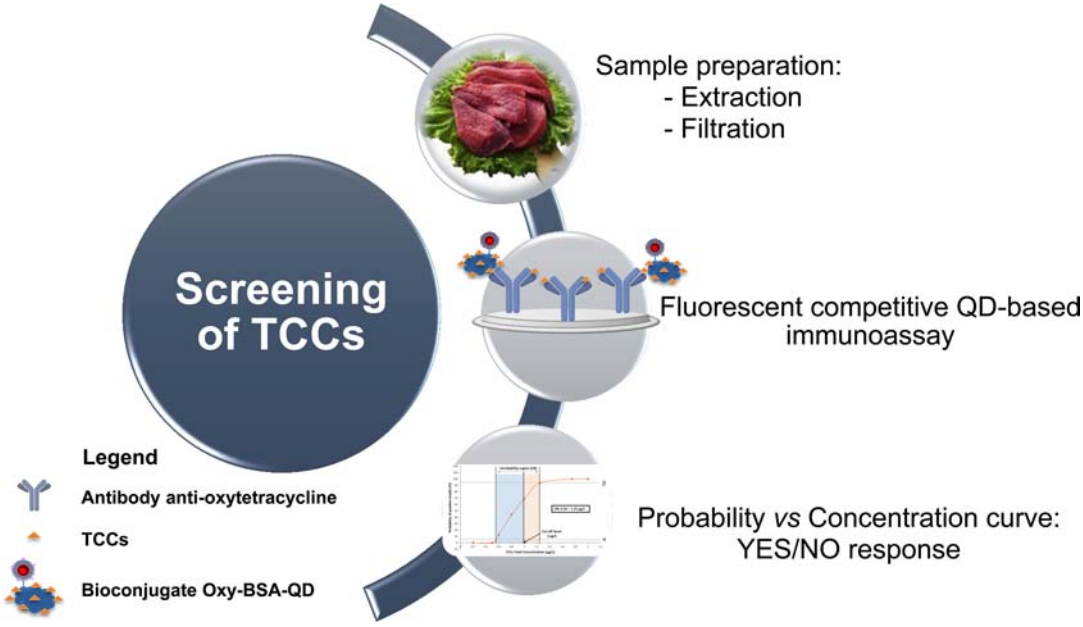

Figure 2. Work-flow diagram of the TCC screening in bovine muscle samples by fluorescent competitive QD-based immunoassay.

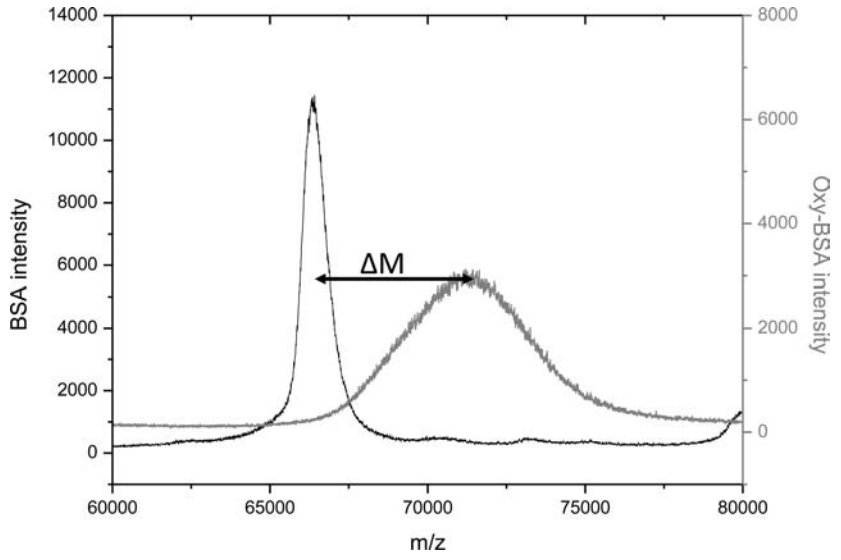

Figure 3. MALDI-MS characterization of the synthesized Oxy−BSA conjugate. The mass spectra were obtained using sinapic acid as matrix. BSA standard (black line) and Oxy−BSA conjugate (gray line) mass spectra are represented, showing clearly the mass shift between both (ΔM).

positives, false negatives, and dubious results are obtained.[18,28] In order to determine the unreliability region (UR) in the screening procedures, the cutoff level must be defined. The UR is finally calculated from the probability−concentration curve established for the screening test. In this work the limits defining the UR were determined as the levels of false positives (probability that a negative sample is classified as positive, also called α error) and false negatives (probability that a positive sample is classified as negative, also called β error).[29]

In this work, to obtain the probability vs concentration graph, 20 assays (random samples containing variable concentrations of the individual TCC but ensuring the same total antibiotic concentration) were carried out for each point of the curve, and the relative proportion (in terms of percentage) of "yes/no" answers was determined. In all cases, the binary "yes/no" response was obtained from the analytical signal (fluorescent intensity measured at the final step of the immunoassay) and was classified as "negative" or "positive" after its comparison with the fluorescence intensity signal registered for the corresponding cutoff concentration (I_0).

Analysis of Bovine Muscle Samples. Bovine muscle samples from noncontaminated cows were extracted following the Oka et al. procedure,[30] blending successively the meat samples (5 g) with three successive portions of 20, 20, and 10 mL of 0.1 M Na_2EDTA-McIlvaine buffer pH 4.0, centrifuging the mixture (at 850*g* for 5 min), and collecting and combining the supernatants by decanting. As no detectable levels of TCC residues were found in the meat samples, 5 g of chopped meat was spiked with the appropriate amount of TCC mixtures (see Table S1 in the Supporting Information for details of the concentrations of each TCC) and carefully stirred manually during 5 min. The samples were kept at 4 °C for 1 h. Afterward, the McIlvaine buffer was added and the Oka et al. procedure[30] was then followed. However, additional ultrafiltration steps were needed to remove the color that remains in the extract, which can interfere in the fluorescence measurements. For that reason, ultrafiltration with Amicon membrane filter of 10 kDa followed by ultrafiltration with Amicon membrane filter of 3 kDa (centrifuged at 12000*g* for 15 min in both cases) was performed, collecting the filtered solution. Two-hundred microliter aliquots of such solution were then used in the

immunoassays. A work-flow diagram of the complete process for the analysis of TCCs in bovine muscle samples is shown in Figure 2.

RESULTS AND DISCUSSION

Characterization of the Oxy−BSA Conjugate. As it is not possible to purchase commercial Oxy−BSA conjugate, it is necessary to synthesize it as described in Materials and Methods. A complete characterization of synthesized Oxy−BSA conjugate was performed following the strategy developed by Trapiella-Alfonso et al.[25] The molecular weight of the conjugate, the stoichiometry, and the concentration of Oxy and BSA in the conjugate are obtained.

Based on results obtained from a Bradford assay, BSA concentration was calculated to 335 ± 9 μg/mL. Molecular weight and stoichiometry were investigated by MALDI-MS. Results from MALDI experiments were used to calculate the molecular weight of the conjugate, being 71223 ± 99 Da (n = 15). Comparing the mass spectrum of BSA standard with the Oxy−BSA spectrum (see Figure 3), a mass shift (ΔM) is noticed, and this can only be attributed to the incorporation of the Oxy in the BSA structure.

If Oxy molecular weight is considered as 460.434 Da, dividing the ΔM observed by the Oxy molecular weight, the number of Oxy per BSA can be estimated. For this case, the found value was close to 10, leading to a ratio of Oxy:BSA of 10:1. Finally, applying eq 2 the final concentration of Oxy in the conjugate can be estimated.[25]

$$C_{Oxy} = 10C_{BSA}(MW_{Oxy}/MW_{BSA}) \quad (2)$$

where C_{Oxy} is the concentration of oxytetracycline in the conjugate, 10 is the Oxy:BSA ratio, C_{BSA} is the concentration of BSA in the conjugate obtained by the Bradford test, and MW_{Oxy} and MW_{BSA} are the molecular weights of oxytetracycline and BSA respectively.

Synthesis and Characterization of Oxy−BSA−QD Bioconjugate. The molar ratios used to carry out the bioconjugation reaction were optimized by varying the ratios QDs:Oxy−BSA from 1:1 to 3:1 (always with an excess of EDC in a ratio of 1500 mol per mol of biomolecule to ensure that bioconjugation is completed). Optimum molar ratio values were observed for 2:1:1500 (QDs:Oxy−BSA:EDC) attending to the highest fluorescence intensity signals measured, indicating a high efficiency on the labeling of the Oxy−BSA conjugate with the nanoparticles. According to Trapiella-Alfonso et al.[31] the concentration of Oxy and BSA in the tracer and the bioconjugation yield can be calculated.

In order to characterize the purified bioconjugate, fluorescence measurements were performed to check that QD emission is not interfered with the bioconjugation reaction. As can be seen in Figure 4, the Oxy−BSA−QD bioconjugate does not modify significantly QD emission wavelength or fluorescence intensity; therefore, it is possible to develop a fluorescent immunoassay with this tracer.

Finally, the stability of the immunoprobe (utility valid period of the tracer for immunoassays) was evaluated attending to the stability of the fluorescence emission and the ability of the antibody to recognize the tracer. It was observed that 10 days was established as the maximum period where the Oxy−BSA−QD is stable and suitable for immunosensing, being stored at 4 °C. In the Supporting Information, Figure S1 shows data from a stability study. It is observed that the fluorescence emission of the immunoprobe is reduced more than 50% after 10 days, limiting its utility in the immunoassay.

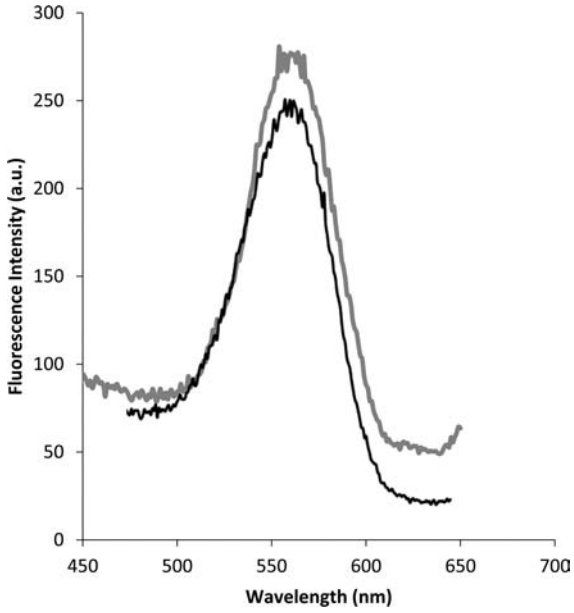

Figure 4. QDs (gray line) and Oxy−BSA−QD bioconjugate (black line) fluorescence emission spectra in buffer 10 mM PBS (pH = 7.4).

Development of the Competitive Fluorescent Immunoassay and Analytical Performance Characteristics. The immunoassay format consists of a competitive fluorescent immunoassay where nanoparticles are used as antigen labels. In this format, sample antigen and tracer (Oxy−BSA−QD) compete for the limited binding sites of the immobilized antibody.

First, the concentration of anti-Oxy antibody used for coating the well-plate and immunoprobe concentration added in the competition step were optimized for the development of the immunoassay. Optimum conditions (referring to the highest fluorescence intensity, the lowest signal deviation, and the best inhibition curve) were achieved with 1 μg/mL of the antibody solution and 10 μg/mL of the tracer (Oxy−BSA−QD) solution, ensuring a 1:1 volume ratio between the sample and the immunoprobe involved in the competition (see Table 1).

Table 1. Optimized Experimental Conditions of the Immunoassay Based on QDs

step/condition	optimized value
coating	100 μL/well Ab_{oxy} (1 μg/mL)
blocking	200 μL/well 3% casein
[Oxy] in the bioconjugate	10 μg/mL
sample:bioconjugate ratio	1:1

The analytical performance characteristics are assessed by the analysis of a series of Oxy standard solutions at different concentration levels, using the optimized QD-based immunoassay. The corresponding inhibition curve was fitted using a four-parameter equation with SOFTmax Pro software (see Figure 5). The principal parameters (see Table 2) are defined by different inhibitory concentration (IC) values calculated from the inhibition curve. Thus, a linear relationship was achieved ranging from 0.26 to 3.53 μg/L (IC_{20}−IC_{80}) enabling Oxy trace determination in bovine muscle. The detection limit (IC_{10}) was 0.12 μg/L of Oxy and the sensitivity of the assay (IC_{50}) was 0.96 μg/L of Oxy in aqueous media.

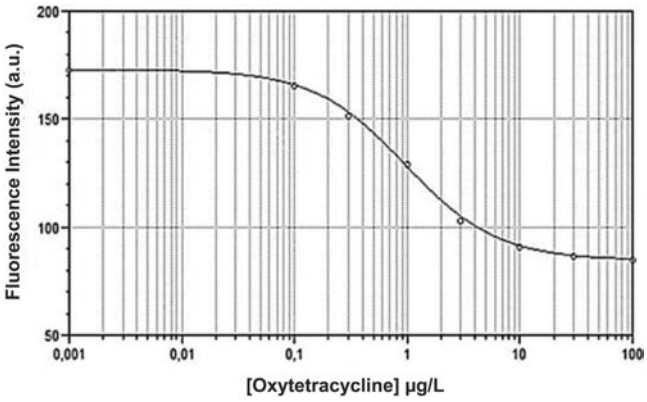

Figure 5. Fluorescent inhibition curve obtained for the analysis of TCCs in bovine muscle samples using oxytetracycline labeled with QDs as tracer in the competitive immunoassay. All the points that plot the curve exhibit a RSD < 5%.

Table 2. Analytical Characteristics of the Inhibition Curve for the Analysis of TCCs in Bovine Muscle

analytical parameter	obtained value
limit of detection (IC_{10})	0.12 μg/L
limit of quantification (IC_{20})	0.26 μg/L
linear range (IC_{20}–IC_{80})	0.26–3.53 μg/L
sensitivity (IC_{50})	0.96 μg/L
R^2	0.999

The here developed competitive QD-based fluoroimmunoassay shows some attractive features that make it advantageous over the established conventional immunoassays for the analysis of TCCs in bovine meat (in general competitive ELISA formats). Such advantages include a lower detection limit (<1.5 μg/kg), less time consumption (avoiding some steps required in the enzyme-linked immunosorbent assay), and low-cost assays (due to the smaller number of reagents used).[1,15,17,32] In addition, comparing with other analysis techniques, such as chromatographic methods, immunochemical techniques have the advantage that up to 96 samples can be analyzed within 2 h (in the best of the cases up to 24 samples can be analyzed by LC–MS[33]).

Cross Reactivity Test. A study of the cross reactivity was evaluated in order to test the performance of the antibody anti-Oxy rabbit IgG reaction with the other selected members of the TCC family under scrutiny (TC, Chlor, and Doxy). The selection of these TCCs was based on EU Commission Regulation[7] on pharmacologically active substances and their classification regarding maximum residue limits in foodstuffs of animal origin.

Different inhibition curves (corresponding to the different selected TCCs) were registered, employing the same optimized conditions as those used in the case of the Oxy determinations, and deviations from the standard curve were investigated. IC_{50} values for each analyte were determined and the cross reactivity rates were calculated applying the eq 1 given in Materials and Methods. Results obtained are collected in Table 3. Considering the high values observed for the four analytes, it is confirmed that anti-Oxy could be an appropriate antibody for the design of a screening test able to detect the presence of any of the four selected TCCs.

Additivity Studies. The immunoassay based screening system under development aims at recognizing the presence of total TCCs in the samples over a preset concentration level (e.g., the maximum residue level authorized for such family of antibiotics). Therefore, fluorescence signals from the different TCCs that could be present in the sample should be expected as additive.

Table 3. Cross Reactivity Test Using as Antibody Rabbit Anti-Oxytetracycline IgG

antigens assayed (TCC family)	CR (%)
tetracycline	89
chlortetracycline	90
doxytetracycline	82

To evaluate whether the analytical signals from the TCCs are additive, sets of aqueous samples containing only a single type of tetracyclines, as well as binary, ternary, and quaternary mixtures of the TCCs under study, were prepared and analyzed by the QD-based immunoassay. In all cases solutions contained 2 μg/L of TCC total concentration. The samples were analyzed according to the general procedure described above, and results are shown in Figure 6. A good agreement between experimental concentrations extracted from immunoassay fluorescence measurements and expected concentrations were observed. This is a proof of the analytical potential of the immunochemical method proposed for the development of the intended screening system of TCCs.

Characterization of the Screening System for TCC Detection. In order to characterize the here-developed screening test, and thus obtain the UR region, a screening curve for TCC detection was designed and characterized in aqueous media. For this purpose, a probability versus concentration graph was elaborated selecting a cutoff level of 1 μg/L total concentration of TCCs, according to the maximum sensitivity reached by the immunoassay methodology (IC_{50} factor extracted from the inhibition curve was 0.96 μg/L). The limits defining the UR of our method were determined by calculating the concentrations of TCCs that produce a probability of 5% to obtain a false positive and a probability of having a 95% of positive response (α, β errors) as it is explained in Materials and Methods. According to these patterns, the experimental unreliability region obtained was in the range between 0.56 and 1.25 μg/L total TCC concentration (see Figure 7).

This means that the presence of TCCs in aqueous media can be confirmed reliably by the proposed screening system for concentrations higher than 1.25 μg/L and, on the other hand, samples giving total concentration of TCCs below 0.56 μg/L can be reliably considered as noncontaminated.

Application to Bovine Muscle Samples. The applicability of this QD-based immunochemical method for the screening of TCC residues in contaminated bovine meat samples was finally evaluated. As no TCCs were detected by immunoassay in the scrutinized samples, they were spiked with known amounts of TCCs and then screened following the general procedure above-described.

In order to get a validation of the used methodology for the extraction of analytes from bovine muscle, a high-performance liquid chromatography (HPLC) with spectrophotometric detection for the determination of TCCs in bovine tissues was carried out. Bovine meat samples were extracted and then analyzed following the Cinquina et al. procedure.[34] The analyses were performed using a mobile phase of 0.01 M oxalic acid:acetonitrile:methanol (60:25:15 in volume) on a

dx.doi.org/10.1021/jf500118x | J. Agric. Food Chem. 2014, 62, 1733–1740

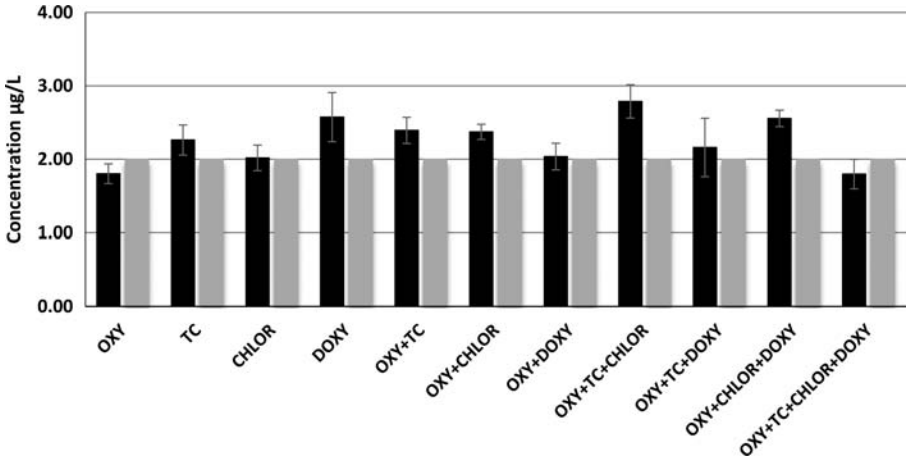

Figure 6. Additive study. In the graphic are represented the fluorescent signal intensities from different TCC mixtures (bars in black) compared with the expected signal for the concentration assayed (2 μg/L; bars in gray). As can be seen the results are in agreement.

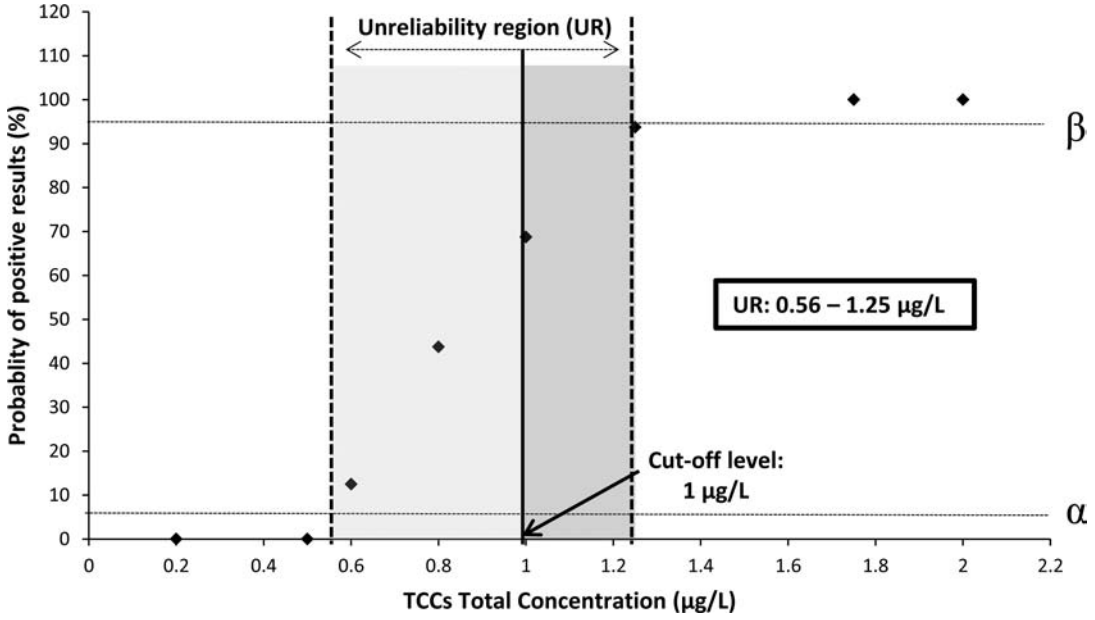

Figure 7. Experimental probability–concentration graph for the screening of TCCs in aqueous solution for a cutoff concentration value of 1 μg/L.

reversed-phase C_8 column. The recoveries were obtained by spiking bovine muscle samples at three different concentrations (50, 100, and 150 μg/kg) of the TCC quaternary mixture and then by analyzing the samples with reference to the blank. Good recoveries (average recoveries were higher than 95%) were observed in all cases, validating the selected sample pretreatment strategy here used.

A 1 μg/L total concentration of TCCs was set out as cutoff level considering the analyzed bovine muscle sample amount taken and the dilution carried out eventually before analysis, corresponding to 10 μg/kg in the bovine muscle. Results obtained for the screening in the bovine muscle samples using the proposed QD-based immunoassay are collected in Table 4. Results were classified as positive or negative, depending on their values in comparison to the cutoff one. Good agreement between expected and experimental results was obtained. This confirms that the immunoassay developed is suitable for TCC screening of bovine meat samples. Moreover, the here-developed screening methodology may provide rigorous and reliable analytical results in the case that legislation on these contaminants turns stricter in the future due to the lowest detection limit (10-fold lower than the current MRL given by European Legislation) and the selectivity achieved by this method for the TCC family compared to those developed up to now for similar purposes.[18,33] In addition, compared with other TCC screening luminescent approaches recently proposed[18]

Table 4. Screening of Bovine Muscle Samples Spiked with TCCs

[TCCs] μg/kg	screening result	expected screening result

and HPLC methodologies,[14] the QD-based immunoassay presents some benefits including the possibility of analyzing a high number of samples simultaneously in a short time (up to 96 samples/plate in 2 h), as well as the nonexistence of some problems related to phosphorescent labels (e.g., deoxygenation). The drawback of the proposed methodology is the need to carry out a sample preparation step in order to extract the analyte from the bovine muscle and make the sample colorless (filtration step) because the coloration can interfere in the final fluorescence emission of QDs. Nevertheless, the designed procedure is simple and up 10 samples can be prepared in 30 min.

Table 1. Abbreviation, Source, and Mass Spectral Tag[a]

volatile compound	abbreviation	mass spectral tag (retention index, target ion)	standard source
1-butanol	1-butanol	661.1, 56	Sigma-Aldrich
1-hexanol	1-hexanol	877.3, 56	Sigma-Aldrich
1-pentanol	1-pentanol	760.5, 55	Sigma-Aldrich
1-propanol	1-propanol	559.6, 31	J.T. Baker
2-ethyl-1-hexanol	2-eth 1-hex	1027.2, 57	Sigma-Aldrich
2-methyl-1-butanol	2-meth 1-but	743.2, 57	Sigma-Aldrich
2-methyl-1-propanol	2-meth 1-pro	622.9, 43	Sigma-Aldrich
2-methylbutyl acetate	2-MB ace	881.8, 43	Sigma-Aldrich
2-methylbutyl butanoate	2-MB but	1056.5, 71	synthesized
2-methylbutyl propanoate	2-MB Prop	971.1, 57	synthesized
2-methylpropyl acetate	2-MP ace	775.1, 56	Sigma-Aldrich
4-allylanisole	estragole	1198.8, 148	Sigma-Aldrich
6-methyl-5-hepten-2-ol	6M5H2Ol	992, 95	Sigma-Aldrich
6-methyl-5-hepten-2-one	6M5H2One	983.6, 108	Sigma-Aldrich
acetaldehyde	acet	462.4, 29	Sigma-Aldrich
acetone	acetone	508.8, 43	Sigma-Aldrich
benzaldehyde	benz	963.1, 106	Sigma-Aldrich
butyl 2-methylbutyrate	but 2-MB	1039.8, 103	Sigma-Aldrich
butyl acetate	but ace	818.2, 43	Sigma-Aldrich
butyl butyrate	but but	993.8, 71	Sigma-Aldrich
butyl hexanoate	but hex	1186.1, 117	Sigma-Aldrich
butyl propanoate	but pro	908, 57	Sigma-Aldrich
butyric acid	butyric	837.9, 60	Sigma-Aldrich
decanal	decanal	1203.2, 57	Sigma-Aldrich
ethanol	ethanol	516.7, 31	Decon
ethyl 2-methylbutyrate	eth 2-MB	852.8, 102	Sigma-Aldrich
ethyl acetate	eth ace	613.9, 43	Fischer
ethyl butyrate	eth but	805.2, 71	Sigma-Aldrich
ethyl hexanoate	eth hex	996, 88	Sigma-Aldrich
ethyl octanoate	eth oct	1190.8, 88	Sigma-Aldrich
ethyl pentanoate	eth pen	900.4, 101	synthesized
ethyl propionate	eth pro	711.9, 57	Sigma-Aldrich
heptanal	heptanal	899.6, 70	Sigma-Aldrich
hexanal	hexanal	799.6, 56	Sigma-Aldrich
hexyl 2-methylbutyrate	hex 2-MB	1231.6, 103	Sigma-Aldrich
hexyl acetate	hex ace	1011, 56	Sigma-Aldrich
hexyl butyrate	hex but	1187.9, 89	Sigma-Aldrich
hexyl propanoate	hex pro	1100.6, 57	Sigma-Aldrich
methyl 2-methylbutyrate	meth 2-MB	777.2, 88	Sigma-Aldrich
methyl acetate	meth ace	531.6, 74	Sigma-Aldrich
methyl butyrate	meth but	721.8, 74	Sigma-Aldrich
methyl hexanoate	meth hex	924, 74	Sigma-Aldrich
nonanal	nonanal	1102.3, 57	Sigma-Aldrich
octanal	octanal	1000, 84	Sigma-Aldrich
pentanal	pentanal	701.1, 44	Sigma-Aldrich
pentyl acetate	pen ace	913.8, 43	Sigma-Aldrich
propyl 2-methylbutanoate	prop 2-MB	945.8, 103	synthesized
propyl acetate	pro ace	714, 61	Sigma-Aldrich
propyl butyrate	pro but	898.1, 71	Sigma-Aldrich
propyl hexanoate	pro hex	1091.1, 99	Sigma-Aldrich
propyl propanoate	pro pro	811.9, 57	Sigma-Aldrich

[a]Synthesized volatiles produced using modification of methods in Fischer et al., 1895.[31]

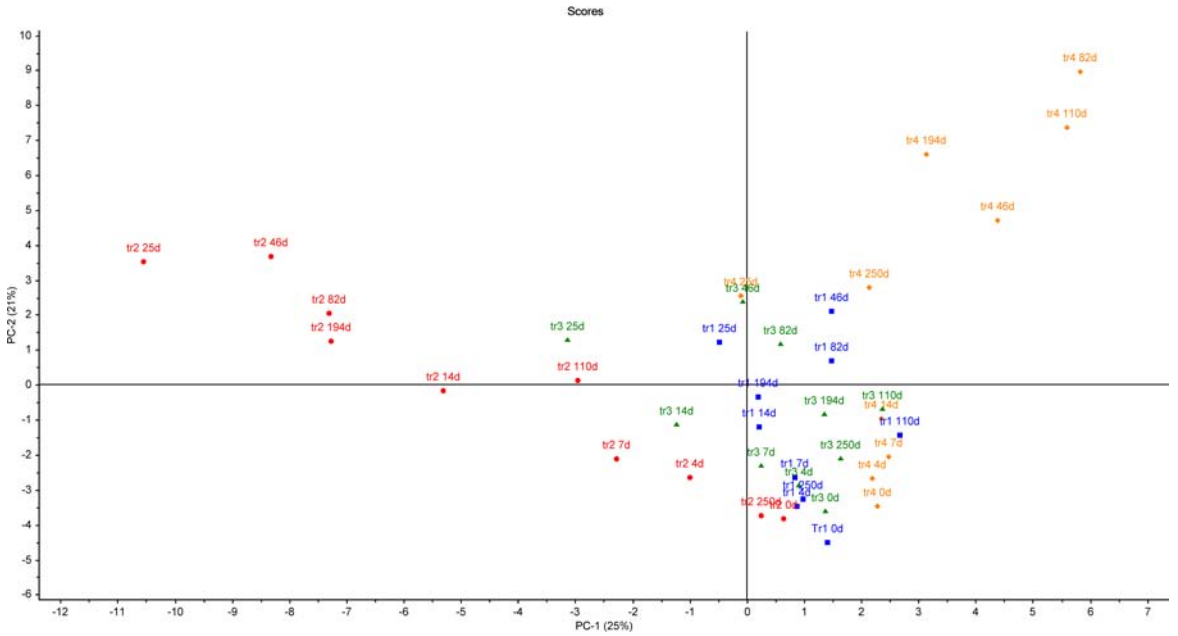

Figure 1. Principal Components Analysis plot of headspace volatile compounds collected during storage of 'Scarlett Spur Red Delicious' apple fruit. Gas samples collected from 3 replicate storage chambers for each atmosphere were analyzed by GC-MS. Red: 0.3 kPa O_2. Green: 0.8 kPa O_2. Blue: 1.6 kPa O_2. Orange: air. CO_2 in all low O_2 atmospheres was 1 kPa. All fruit stored at 0.5 °C.

(Hewlett-Packard, Avondale, PA) equipped with a 50 cm long × 0.32 cm internal diameter glass column packed with 80−100 mesh Porapak Q (Supelco, Bellafonte, PA). The injector, oven, and detector temperatures were 100 °C, 130 °C, and 200 °C, respectively. Gas flows for air, N_2 carrier, and H_2 were 5.0, 0.5, and 0.5 mL s^{-1}, respectively. Firmness was analyzed with a Mohr Digitest 1.25 penetrometer (Mohr and Associates, Richland, WA) equipped with an 11 mm tip. Starch hydrolysis was visually assessed on a full width tissue slice cut from the fruit equator using a 1−6 scale (1 = no hydrolysis, all tissue black, 6 = hydrolysis complete, tissue unstained) after staining with a 0.024 M I−KI solution.[28] Fresh juice prepared using a Champion juicer (Plastaket Mfg., Lodi, CA) was used to measure SSC with a

dx.doi.org/10.1021/jf405267b | J. Agric. Food Chem. 2014, 62, 1741−1754

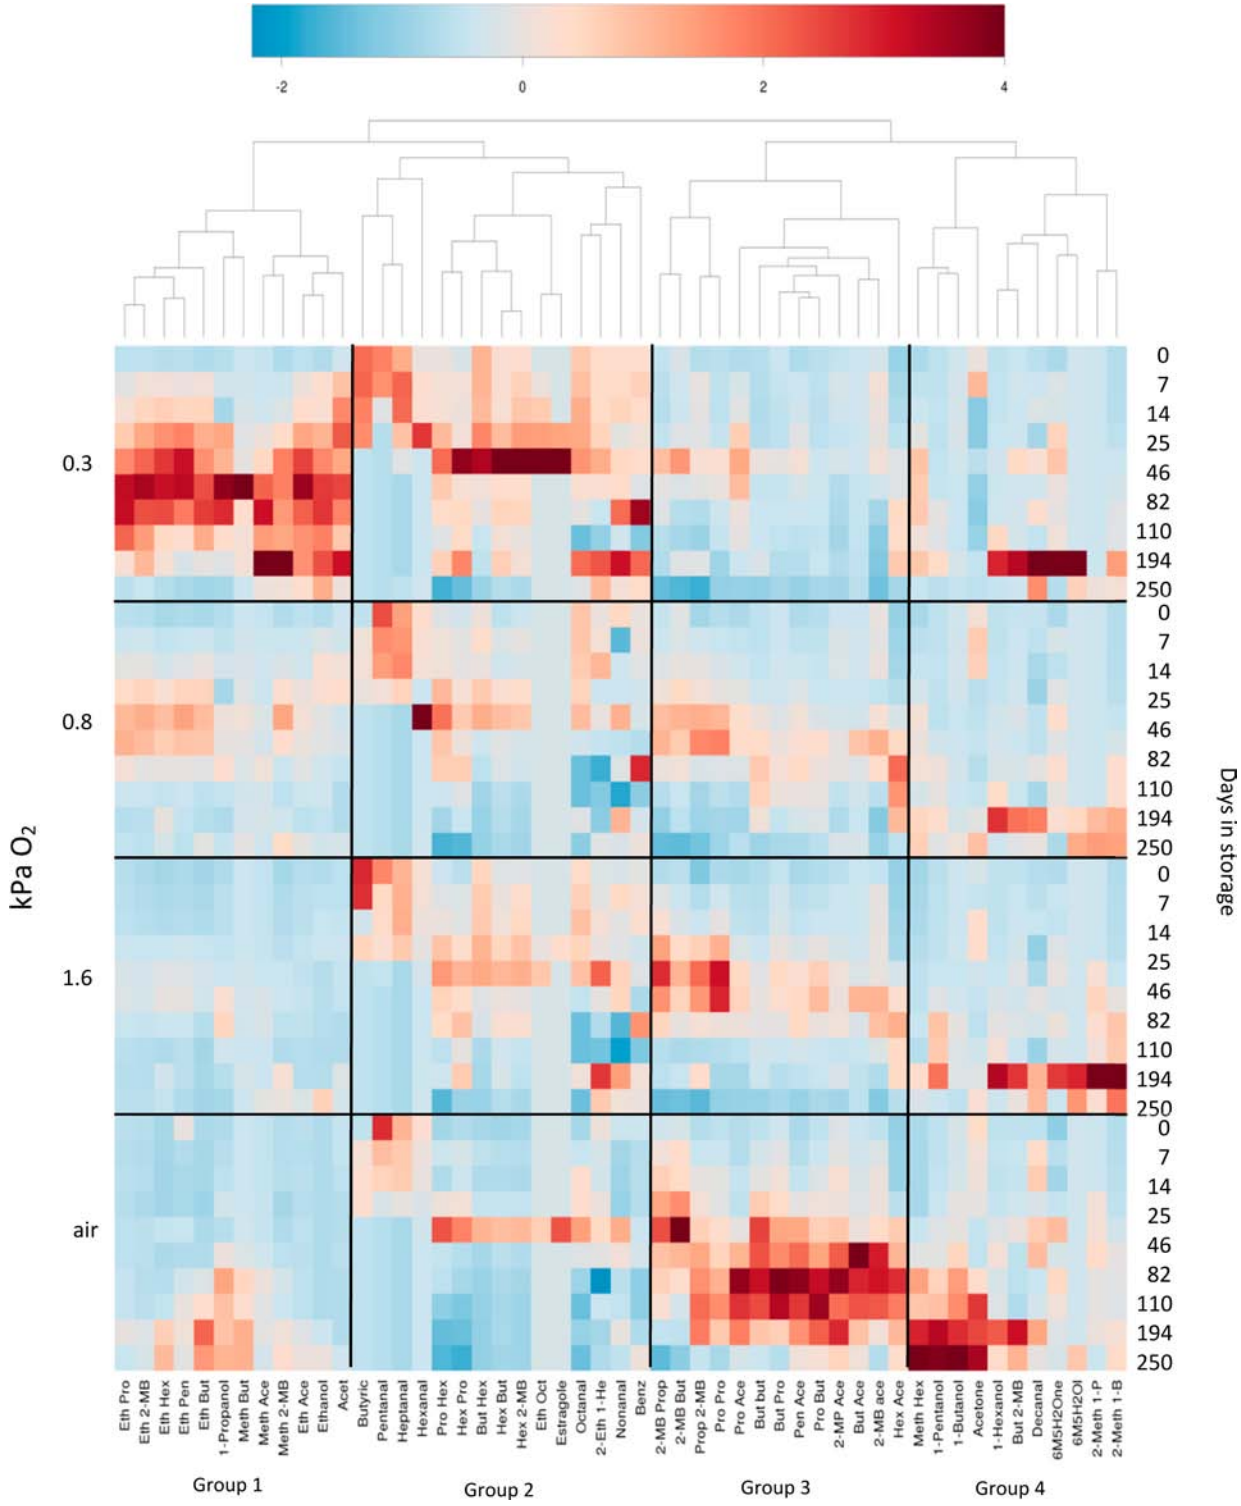

Figure 2. Heatmap of 'Scarlett Spur Red Delicious' volatile accumulation during cold storage. Gas samples collected from three replicate storage chambers for each atmosphere were analyzed by GC-MS. Storage temperature was 0.5 °C and storage chamber atmospheres were air or 0.3, 0.8, or 1.6 kPa O_2 with 1 kPa CO_2. Volatile compounds were hierarchically clustered using Pearson's correlation and Ward's linkage algorithm. Atmosphere treatment indicated on the left *y*-axis by colored bars, storage duration (days) indicated on the right *y*-axis. Compound concentration increases with blue to red color change. Compound abbreviations presented in Table 1.

hand-held refractometer (ATAGO, Tokyo), and TA by titrating 10 mL juice with 0.1 M KOH to pH 8.2 using an autotitrator (TIM850, Radiometer Analytical, Copenhagen, Denmark).

Fruit (18 fruit/pressed paper tray) were stored in air for 3 days at 0.5 °C before being weighed and placed into 0.145 m^3 stainless steel CA chambers with Plexiglas doors, four trays per chamber. CA chamber atmospheres were established over two days using compressed air and CO_2 plus N_2 from a membrane generator (Permea, St. Louis, MO). Chamber gas composition was analyzed every 90 min and automatically corrected as necessary (Techni-Systems, Chelan, WA); therefore, chamber atmospheres were static except when adjustments were conducted.[29] Fruit chlorophyll fluorescence measured with the

[a]Headspace gas samples collected from 3 replicate storage chambers for each atmosphere were analyzed by GC-MS. Chambers were maintained at 0.3, 0.8, or 1.6 kPa CO_2 with 1 kPa O_2 or air. All fruit was stored at 0.5 °C. Storage duration and atmosphere differences are denoted by upper and lowercase letters, respectively, and values with the same letter are not significantly different ($P \leq 0.05$, Tukey's HSD).

HarvestWatch system (Satlantic Inc., Halifax, NS) was used to determine the lowest pO_2 set-point based on changes in fruit chlorophyll fluorescence as pO_2 decreased.[30] Fruit were stored at 0.5 °C in air or CA (0.3, 0.8, or 1.6 kPa O_2, 1 kPa CO_2) with four chambers for each atmosphere: three for sampling volatile compounds (volatile chambers) and one from which fruit were periodically removed and assessed for quality (quality chambers).

After 1, 2, 4, and 8 months in storage, one tray was removed from each quality chamber. Fruit were examined for external disorders and then held at 20 °C in air for 7 days. On day 7, the rate of ethylene evolution was determined. Evolved ethylene was analyzed in gas samples collected from 4 replicates, 4 fruit each, from each storage atmosphere placed into 3.79 L glass jars with Teflon lids (Berghof/America, Coral Springs, FL) fitted with Tygon and Teflon tubing. Compressed air was passed through Purafil (Purafil Inc., Atlanta), calcium hydroxide, a carbon filter (Agilent Technologies, Santa Clara, CA), and Tenax TA (80−100 mesh, Alltech Associates, Deerfield, IL) before flowing through the jars. The purified air was passed through the jars for 60 min, then a 1 mL gas sample was collected at the outlet from each jar and 0.5 mL injected into the 5880A GC-FID (Hewlett-Packard, Avondale, PA) described previously. The incidence of internal and external disorders (superficial scald, decay, internal browning) was also recorded. Chamber ethylene concentration was determined by collecting a gas sample from each storage chamber into a 1 L Tedlar bag (SKC Inc., Eighty Four, PA). Ethylene in a 0.5 mL sample from each bag was analyzed using the 5880A GC-FID previously described. After 9 months storage plus 7 days at 20 °C, apples from the volatile chambers were assessed for internal and external disorders.

Volatile compounds were collected directly from each storage chamber 0, 4, 7, 14, 25, 46, 82, 110, 194, and 250 d after chambers were sealed. Tygon tubing was attached to an outlet gas port on the side of each chamber and gas samples (0.25−1 L) were drawn through a 17.8 cm Tenax TA Glass TD Tube (Supelco, Bellefonte, PA) containing 60 mm/180 mg Tenax using a pump and volume was measured using a digital flow meter. Traps were thermally desorbed (TDS3 and TDSA2, Gerstel, Linthicum, MD) using a temperature program of 20 °C for 30 s, increased at 1 °C s^{-1} to 250 °C and held for 360 s. Desorbed compounds were cryogenically trapped at −130 °C (CIS-3, Gerstel) using the Gerstel Maestro Global Analytical System. Following the transfer of desorbed compounds from the TDS, the cryotrap temperature was increased 10 °C s^{-1} to 250 °C and held for 120 s as compounds were transferred to a Hewlett-Packard 5890A-5971A GC-MSD system (Hewlett-Packard, Palo Alto, CA) equipped with a DB-5MS column (Agilent Technologies, Santa Clara, CA) 30 m long × 0.25 mm internal diameter with 0.25 μm film thickness. The oven initial temperature (35 °C) was held 600 s, increased at 0.17 °C s^{-1} to 250 °C, then held 180 s. Linear gas velocity of the He carrier gas was 33.9 cm s^{-1}. Mass spectra were recorded with a Hewlett-Packard Enhanced Chemstation (G1701BA Version B.01.00; Agilent Technologies, Santa Clara, CA). Using MSD Chemstation Data Analysis (Agilent Technologies, Santa Clara, CA), AMDIS GC/MS Analysis, and NIST MS Search 2.0 (NIST, Gaithersburg, MD), compounds were identified by comparing sample retention times and spectra with those of standards (Table 1). Sample compounds were quantified by comparing base peak abundances of selected ions with those for standards of known concentration. Standards were obtained from Sigma-Aldrich (Milwaukee, WI) except 1-propanol (J.T. Baker, Center Valley, PA), ethyl acetate (Fischer Scientific, Pittsburgh, PA), and ethanol (Decon Laboratories, King of Prussia, PA). Esters synthesized[31] included 2-methylbutyl butyrate, 2-methylbutyl propanoate, ethyl pentanoate, and propyl 2-methylbutryate. For each compound, synthesis was performed using 5 g of the organic acid and excess alcohol (at least two times the molar equivalent of the organic acid) refluxed for 1 h with 3 mL of concentrated sulfuric acid at the boiling point of the alcohol. The resulting mixture was partitioned against 50 mL water three times; then, the nonaqueous phase was purified by distillation. Purity was assessed using the GC-MS method previously described.

Chromatographic data was mean centered and scaled according to the standard deviation. MetaboAnalyst[32] was used to generate

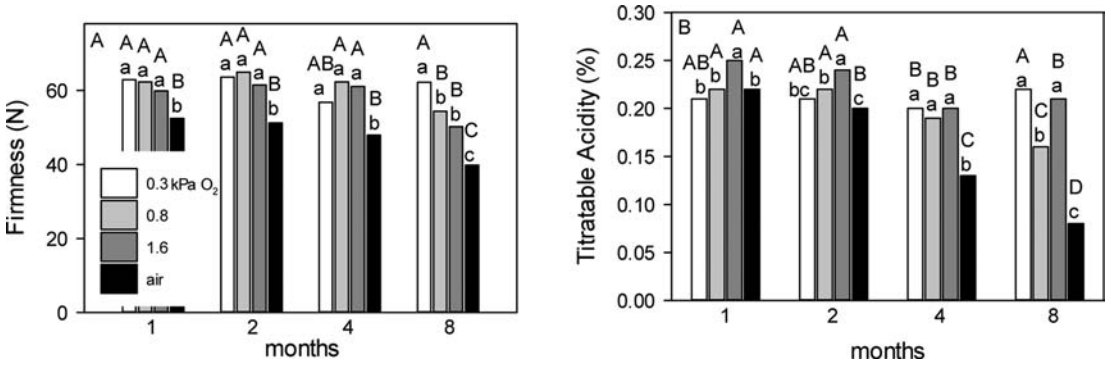

Figure 3. 'Scarlett Spur Red Delicious' apple firmness (A), and titratable acidity (B) of fruit previously stored in a controlled atmosphere (CA) or air at 0.5 °C. CA kPa O_2 concentrations were 0.3, 0.8, or 1.6, all with 1 kPa CO_2. Apples were removed from storage and analyzed after 7 days at 20 °C. Values are means of 18 individual fruit. Storage duration and atmosphere differences are denoted by upper and lowercase letters, respectively, and values with the same letter are not significantly different ($P \leq 0.05$, Tukey's HSD).

heatmaps from the normalized data analyzed by hierarchical clustering analysis using Pearson's correlation and Ward's linkage algorithm. Principal Components Analyses were performed using UnscramblerX 10.1 (CAMO Software, Woodbridge, NJ). The predictive models were created using cross-validation and outliers were removed. Statistical analyses were conducted using SAS 9.3 (SAS Institute, Cary, NC). Fruit quality data was analyzed by ANOVA, and means were separated using Tukey's HSD ($P < 0.05$). Non-normalized volatile compound data was analyzed using a GLM with storage duration as a repeated measure, and means were separated using Tukey's HSD ($P < 0.05$).

RESULTS AND DISCUSSION

Values for fruit maturity and quality at harvest were weight 223 ± 7 g, firmness 70.3 ± 0.9 N, internal ethylene 0.91 ± 0.33 μL L^{-1}, starch index 2.2 ± 0.2, SSC 11.9 ± 0.2%, and TA 0.278 ± 0.007%.

Principal Components Analysis (PCA) generated a model with principal components accounting for 25, 21, 17, and 10% (total: 72%) of the variance (Figure 1). The model identified storage duration and storage atmosphere effects on sample variation, with atmospheres diverging during the first 2 weeks storage. Volatile compound accumulation among storage atmospheres was the most similar during the first two and final 20 weeks storage. Atmosphere treatment differences were greatest on days 25, 46, and 82. The lack of significant atmosphere treatment effects at the end of storage suggests fruit volatile production was similar metabolically, possibly due to decreased metabolic rates and/or a lack of substrate for volatile production.[11,33] At 250 days, chamber volatile content was lower compared to previous dates for all atmospheres (Figure 2) indicating analysis of volatile accumulation in storage after 6 months may not be useful for monitoring anaerobic oxygen conditions imposed early in storage.

The hierarchical clustering procedure identified four main groups of volatile compounds. Volatiles in group 1, including many that are products of fermentation, were significantly highest from day 4 through day 194 in chambers where O_2 was 0.3 kPa (Table 2). The PCA loading plot (not shown) also associated fermentative volatiles with the 0.3 kPa O_2 atmosphere. The increase in fermentative compounds indicates the 0.3 kPa O_2 atmosphere induced oxygen stress and anaerobic metabolism.[7] Ethanol was the most abundant compound accumulating at 0.3 kPa O_2 followed by ethyl acetate. Ethanol accumulation was higher in 0.3 and 0.8 kPa O_2 chambers compared with 1.6 kPa O_2 and air chambers. The increase in ethanol likely provided substrate for ethyl ester production[34] and was accompanied by decreased butyl and hexyl ester content, consistent with previous reports.[10,13] Day 14 ethanol concentrations were significantly different among atmospheres, and ethanol increased with decreased pO_2. Ethyl esters also accumulated in chambers held at 0.8 kPa O_2, but concentrations in these chambers were significantly lower (ethyl propanoate, days 46–194; ethyl acetate, days 4–194; ethyl 2-methylbutyrate, days 4–14 and 46–194; ethyl hexanoate, days 4–14, 82 and 110; ethyl pentanoate, days 4,7, and 46–110; ethyl butyrate, days 46–110) compared with chambers held at 0.3 kPa O_2. Several volatiles began accumulating in significantly higher concentrations in the air chambers during the latter storage period (days 84–250) including ethyl hexanoate, ethyl pentanoate, ethyl butyrate, and methyl butyrate. The air stored fruit was riper compared with CA fruit during this period and had begun to senesce based on firmness, titratable acidity, and internal breakdown incidence in air stored fruit (Figures 3, 4) resulting in the production of volatiles typical of overripe fruit.[35,36]

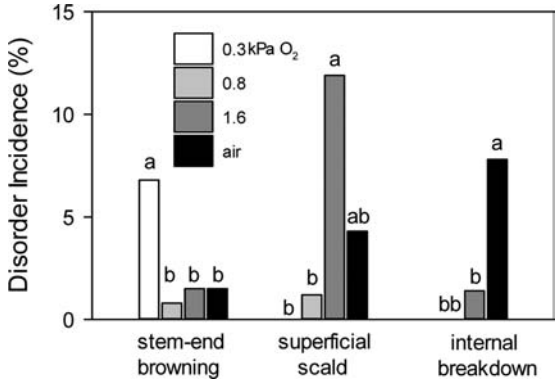

Figure 4. 'Scarlett Spur Red Delicious' apple physiological disorders after 9 months storage in a controlled atmosphere (CA) or air at 0.5 °C. CA kPa O_2 concentrations were 0.3, 0.8, or 1.6, all with 1 kPa CO_2. Fruit were evaluated after removal from cold storage plus 7 days at 20 °C. Values are means of 216 fruit for each storage treatment. Within each disorder, columns with the same letters are not significantly different ($P \leq 0.05$, Tukey's HSD).

Comparing days within storage atmospheres, most volatiles in group 1 were significantly highest during days 25–110. Ethanol concentration, however, did not significantly decrease in chambers held at 0.3 kPa O_2. This lack of change may indicate that the rates of fruit ethanol production and its metabolism to

[a]Headspace gas samples collected from 3 replicate storage chambers for each atmosphere were analyzed by GC-MS. Chambers were maintained at 0.3, 0.8, or 1.6 kPa O_2 with 1 kPa CO_2 or air. All fruit was stored at 0.5 °C. Storage duration and atmosphere differences are denoted by upper and lowercase letters, respectively, and values with the same letter are not significantly different ($P \leq 0.05$, Tukey's HSD).

esters and other compounds was similar during this period in storage. Acetaldehyde, also a product of fermentative metabolism, is metabolized first to ethanol and then to ethyl esters.[10,37] Low oxygen CA storage reduces fruit metabolic rate including activity of the terminal enzyme in ester synthesis alcohol acyltransferase[8] such that ester production decreases as storage duration increases.[5,11,12,25,26,28,29,37] Methyl acetate, methyl 2-methylbutyrate, and acetaldehyde were all significantly highest at day 194. Although methanol was not detected, the presence of methyl esters indicates methanol was likely present as a substrate for ester synthesis.[34]

The group 1 volatiles associated with fermentative metabolism in 'Delicious' may be useful indicators for monitoring the occurrence of anaerobic conditions during CA storage. An ideal indicator would have a marked concentration change soon after low oxygen conditions occur, and many of the group 1 volatiles are significantly highest in the 0.3 kPa O_2 chambers by day 4. The increase in ethanol concentration during the days after 0.3 kPa O_2 was established may indicate its utility as an early indicator of low O_2 stress due to the higher rate of increase between ultralow oxygen and more typical (1.6 kPa) O_2 CA conditions. The increase in ethanol at 0.8 kPa O_2 for which low oxygen injury development was similar to that occurring in fruit stored at 1.6 kPa O_2 or in air indicates a threshold concentration associated with injury risk may need to be identified to enable ethanol monitoring in storage room headspace as an indicator of low O_2 injury risk.

Amounts of the group 2 compounds butyl hexanoate, hexyl butyrate, and hexyl 2-methylbutyrate were significantly highest in 0.3 and 1.6 kPa O_2 through day 82 and at 0.3 kPa O_2 on days 110 and 194 (Table 3). On the same dates, the concentrations of these compounds were lowest in air chambers. Hexyl propanoate (days 82−194), benzaldehyde (days 4−25, 194), and heptanal (days 4, 14) were highest in 0.3 kPa O_2 and lowest in air. Amounts of butyric acid, pentanal, hexanal, ethyl octanoate, estragole, octanal, 2-ethyl-1-hexanol, nonanal, and propyl hexanoate were unaffected by storage conditions. Within atmospheres, butyric acid, pentanal, heptanal, and hexanal accumulated during the first 7 days of storage then significantly decreased during days 14−25. Aldehydes present in preclimacteric fruit are responsible for the 'green/unripe' aroma and, as ripening occurs, the volatile profile shifts to esters and a 'fruity' aroma.[34,38] Many group 2 volatiles were significantly highest on day 25 and significantly decreased by day 82 including propyl hexanoate, hexyl propanoate, butyl hexanoate, hexyl butyrate, hexyl 2-methylbutyrate, and octanal. This pattern indicates high production of these compounds occurred relatively early in the ripening process. Amounts of ethyl octanoate, estragole, 2-ethyl 1-hexanol, nonanal, and benzaldehyde did not change with storage duration. Lack of atmosphere treatment differences for these compounds indicates production was unaffected by storage atmospheres and ripening metabolism, while volatiles unaffected by storage duration were unrelated to the progression of ripening.

Group 3 volatiles accumulated in significantly higher concentrations in air chambers, while fruit stored in 0.3 kPa O_2 produced the lowest amounts of these compounds (Table 4). These volatiles, including propyl acetate, butyl butyrate, butyl propanoate, pentyl acetate, propyl butyrate, 2-methylpropyl acetate, butyl acetate, and 2-methylbutyl acetate, are compounds produced during typical climacteric ripening of 'Delicious' apples.[10] Due to fermentative metabolism in the 0.3 and 0.8 kPa O_2 stored fruit, ethanol accumulation provided substrate to favor

Table 5. Group 4 'Scarlett Spur Red Delicious' Volatile Accumulation (ηmol L^{-1}) During Controlled Atmosphere or Air Storage[a]

[a]Headspace gas samples collected from 3 replicate storage chambers for each atmosphere were analyzed by GC-MS. Chambers were maintained at 0.3, 0.8, or 1.6 kPa O_2 with 1 kPa CO_2 or air. All fruit was stored at 0.5 °C. Storage duration and atmosphere differences are denoted by upper and lowercase letters, respectively, and values with the same letter are not significantly different ($P \leq 0.05$, Tukey's HSD).

ethyl-ester synthesis and decreased butyl and hexyl ester production, consistent with previous reports.[10,13] Amounts of these compounds increased regardless of storage atmosphere from 25 to 82 days, however, these compounds continued to accumulate in air chambers until 194 days storage and had significantly higher levels compared with the CA chambers from 82 days until the end of storage. Amounts of propyl 2-methylbutyrate and propyl propanoate were significantly higher in air chambers compared with some or all CA treatments from 82 to 194 days storage. Within atmospheres, all group 3 volatiles were significantly higher on day 25 and/or day 46 compared to other sampling dates. High amounts of group 3 compounds in the air chambers and relatively lower levels in CA chambers indicates reduced ester production occurs during as well as following CA storage compared to fruit stored in air.[39,11,4]

Group 4 compounds methyl hexanoate, 1-butanol, and acetone were significantly higher in air compared to CA chambers (Table 5), and amounts increased for the entire storage duration. 2-Methyl-1-butanol concentration was significantly higher in chambers held at 1.6 kPa O_2 on days 82 and 194 compared with amounts in air or 0.3 kPa O_2 chambers. Accumulation of 2-methyl-1-butanol may have been lower in air storage due to its metabolism to 2-methylbutyl acetate.[40] No consistent atmosphere treatment effects were observed for 1-pentanol, 1-hexanol, butyl 2-methylbutyrate, 2-methyl-1-propanol, decanal, 6-methyl-5-hepten-2-one, and 6-methyl-5-hepten-2-ol. Amounts of all group 4 compounds except 1-butanol were higher on day 250 and/or day 194 compared with most/all other days for most atmospheres. As stated previously, alcohols are substrates for ester production and are actively converted to esters. However, by the end of storage, ester production decreases as ripening progresses and alcohols that could serve as substrates for ester synthesis (1-propanol, 1-butanol, 2-methyl-1-butanol, and 1-pentanol) accumulate.

Atmosphere−day interactions were significant for 31 of 51 volatiles detected. 1-Propanol, methyl butyrate, pentanal, propyl hexanoate, hexyl propanoate, butyl hexanoate, hexyl butanoate, hexyl 2-methylbutyrate, estragole, octanal, 2-ethyl-1-hexanol, nonanal, benzaldehyde, 2-methylbutyl propanoate, 2-methylbutyl butyrate, propyl 2-methylbutyrate, hexyl acetate, 1-hexanol, butyl 2-methylbutyrate, and decanal did not have a significant atmosphere−day interaction. Several of these volatiles (estragole, octanal, 2-ethyl-1-hexanol, nonanal, benzaldehyde, 1-hexanol, butyl 2-methylbutyrate, and decanal) were not affected by storage conditions, implying that their production is also unrelated to the progression of fruit ripening.

Dynamics of apple fruit volatile production following storage have been characterized[25,26] but information regarding production dynamics during storage is lacking. Argenta et al. (2004)[7] reported 'Fuji' apple volatile production 24 h after removal from 8 months in 0.5 kPa O_2 storage was less than that of fruit previously stored in air. Production of 1-butanol, 1-pentanol, and 1-hexanol and the corresponding esters for each alcohol was reduced following low oxygen storage, while amounts of ethanol, ethyl acetate, and ethyl esters increased. Higher oxygen CA storage also results in reduced poststorage alcohol, hexyl- and butyl ester emission with increased ethanol, ethyl acetate and acetaldehyde compared with fruit stored in air.[11,41] Diminution of post-storage volatile emission also increases with increasing storage duration and decreased CA oxygen content.[11] Imposition of anaerobic storage conditions following 4−5 months CA storage also results in enhanced

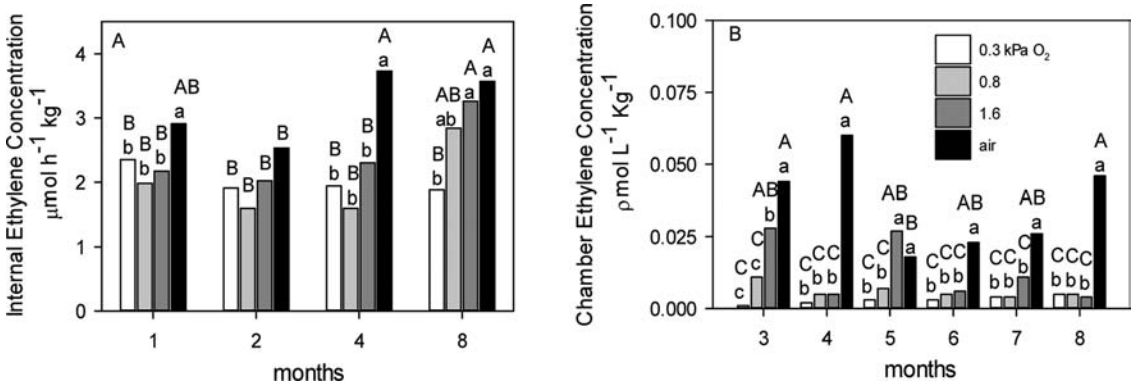

Figure 5. 'Scarlett Spur Red Delicious' fruit internal ethylene (A) and storage chamber ethylene concentration (B). All fruit stored at 0.5 °C. Controlled atmosphere kPa O_2 concentrations were 0.3, 0.8, or 1.6, all with 1 kPa CO_2. Internal ethylene values are means (n = 4) of apples (~ 1 kg) for each storage atmosphere, measured after removal from cold storage plus 7 days at 20 °C. Storage chamber ethylene was measured in gas samples removed from storage chambers (n = 3 per atmosphere) containing 72 fruit each. Time and treatment differences are denoted by upper or lowercase letters, respectively. Within each month or treatment, columns with the same letter are not significantly different (P < 0.05, Tukey's HSD).

acetaldehyde, ethanol, and ethyl ester production with reduced hexyl and butyl ester production.[10]

The current results indicate accumulation of many alcohols and esters is also reduced during low oxygen CA storage compared to fruit stored in air. Hexyl ester accumulation, however, was not affected by low O_2 storage conditions in this study. Fermentative volatile accumulation during storage was similar to that reported for fruit held in air after removal from CA.

Fruit ethylene production after storage increased relative to values at harvest regardless of storage atmosphere (Figure 5), and fruit stored in air consistently had the highest ethylene production. Ethylene production by fruit previously stored in 0.3 kPa O_2 did not change with storage duration but fruit stored in air, 0.8 kPa O_2, or 1.6 kPa O_2 significantly increased by months 4 and/or 8 compared to month 2. Ethylene content was significantly higher in storage chambers maintained with air compared to chambers with 0.3 or 0.8 kPa O_2 at 6, 7, and 8 months and 1.6 kPa O_2 chambers at 6 and 8 months. However, within atmospheres, storage duration did not significantly impact ethylene content with only 1.6 kPa O_2 having significant differences in ethylene content between 5 and 8 months.

The increase in ethylene production from harvest to month 1 indicates climacteric ripening was ongoing. Apple volatile production during storage increased in the first 3 months, also consistent with apple ripening. CA gas composition appeared to have no effect on the timing of ripening but did impact the amounts of ethylene and volatile production. Volatile accumulation among atmospheres was the most different during 1−3 months storage, confirming that gas composition had a large effect on the metabolic rates of ripening processes that impact volatile production. In addition, anaerobic conditions caused further changes in volatile production during the first 3 months in storage as indicated by the increased distance between the 0.3 kPa O_2 and the 0.8 and 1.6 kPa O_2 results in Figure 1. As expected, the rise in ethylene and volatile production was also accompanied by a gradual decrease in firmness and titratable acidity[42] (Figure 3). The lower ethylene levels in all CA treatments accompanying decreased losses in firmness and titratable acidity reflects the requirement for ethylene to promote ripening during cold storage.

At 9 months, internal breakdown incidence was significantly higher in air than in all CA treatments (Figure 4). The higher cortex browning and internal breakdown in air stored apples indicates that those fruit had become senescent. Consistent with previous studies, superficial scald levels were significantly higher in 1.6 kPa O_2 than in 0.3 or 0.8 kPa O_2 stored fruit. This indicates ultralow O_2 storage was able to reduce scald incidence.[15−17] However, 0.3 kPa O_2 stored fruit was negatively affected by the anaerobic conditions, resulting in significantly higher levels of stem browning and fermentative volatiles.

In summary, storage duration and O_2 concentration quantitatively impacted volatile production during long-term storage. Differences due to storage atmosphere were greatest during the first 6 months, and volatile production measured during CA storage was similar to measuring production after storage. Butyl and propyl ester production was inhibited by CA storage conditions and anaerobic oxygen storage promoted fermentative volatile production. CA storage prolonged storage life by reducing ethylene production, disorder incidence, and losses in firmness, and titratable acidity.

The rate of ethanol production increased with decreasing kPa O_2 and could be useful in monitoring for low O_2 stress during storage. Monitoring production of other fermentative volatiles such as acetaldehyde and ethyl acetate could also have potential as stress indicators. Fermentative volatile production was significantly different among atmospheres as early as day 4, so monitoring can begin early in storage.

The object of this work was to prepare biodegradable films using potato starch, PVA, and AsA as a plasticizer and a casting method. We also evaluated the effect of AsA content and heat curing time and temperature on the optical and physical properties of the prepared films such as tensile strength, elongation at break, water resistance, and water vapor absorption, thermal properties, and biodegradability in soil.

EXPERIMENTAL SECTION

Materials. Potato starch (PS) was purchased from Samyang Genex Co. Polyvinyl alcohol (PVA), ascorbic acid (AsA), glycerol (GL), and xylitol (XL) were purchased from Aldrich Chemical Co., Inc. (Milwaukee, WI). PVA was 99% hydrolyzed with an average molecular weight of 89000−98000. Distilled water (DW) was used in all experiments.

Preparation of Cross-Linked PS/PVA Blend Films. Cross-linked PS/PVA blend films were obtained by the casting method. At first, a PVA solution was prepared by dissolving PVA in hot water (90 °C). PS and plasticizers (GL, XL, and AsA) were mixed together with water using a KitchenAid mixer (Anymix, Hyun-woo Star, Seoul, Korea) for 15 min. Formulations contained 10, 20, 30, 40, and 50 wt % GL, XL, and AsA. The PVA solution and PS/plasticizer mix were kept at 95 °C for 10 min. Then, the mixture was blended to form a homogeneously gel-like solution with a mechanical stirrer (600 rpm) at room temperature for 60 min. Bubbles, the byproduct of preparation, were removed by using an aspirator. The mixing composition is shown in Table 1. The gel-like solution thus prepared

Table 1. Compositions of Gel-like Solutions Used To Prepare PS/PVA Blend Films

was poured onto a prewarmed (60 °C) Teflon mold (200 mm × 200 mm × 1 mm). Water was evaporated from the molds in a ventilated oven at 50 °C for 24 h. Dried films were put in open polyethylene bags and stored at 25 °C and 53% relative humidity (RH) for 1 week. The prepared films were then cured in a vacuum oven at 95 ± 2, 120 ± 2, 140 ± 2, or 160 ± 2 °C for 30, 60, 90, 120, 180, 240, and 300 min at atmospheric pressure. After being heat cured, films were conditioned again at 53% RH and 25 °C for 1 week before the measurements were taken. The surfaces of the prepared films with and without heat curing were investigated via scanning electron microscopy (SEM) (S-4700, Hitachi, Tokyo, Japan), at an acceleration voltage of 5 kV.

Mechanical Properties of Biodegradable Films. Tensile strength (TS) and elongation at break (%E) were evaluated for each film using an Instron 6012 testing machine. Five dumbbell-shaped specimens with a width of 15 mm (ASTM D-421) were cut from each film. Each piece was measured for thickness in three places along the test length using a mechanical scanner (digital thickness gauge "Mitutoyo") at 15 random positions around the film. The specimen's average thickness was ~0.12 ± 0.003 mm. The gauge length and grip distance were both 50.0 mm. The crosshead speed was 20 mm/min, and the load cell was 250 kg_f. The tests were conducted at constant values of 25 °C and 53% RH.

Fourier Transform Infrared (FT-IR). The FT-IR spectra of the noncured films and cured films with and without AsA were recorded on an FT-IR spectrometer (JASCO FT/IR-430). The samples were thoroughly dried in a vacuum oven at 50 °C, and 16 scans were taken for each sample.

Dynamic Thermogravimetric Measurements. Thermogravimetric measurements were taken on a Mettler-Toledo (Zurich, Switzerland) TGA/SDTA 851e thermal system from 25 to 600 °C in a N_2 environment (flow rate, 20 mL/min) at a heating rate of 10 °C/min. The sample size was between 10 and 12 mg.

Optical Properties. Each film specimen was cut into a rectangle piece and placed directly into a UV−visible spectrophotometer (Optizen 2120UV, Mecasys Co., Ltd.) test cell. All measurements were performed using air as the reference. A spectrum of each film was obtained at wavelengths between 200 and 800 nm. The transparency at 600 nm (T_{600}) was calculated with eq 1:[26]

$$T_{600} = -\log T_{600}/x \text{ or } A_{600}/x \quad (1)$$

where %T is percentage transmittance and x is the film thickness (millimeters).

The opacity of the films was obtained using eq 2 according to the method of Gontard and Guilbert.[27]

$$\text{opacity} = \text{absorbance at 500 nm} \times \text{film thickness (mm)} \quad (2)$$

Degree of Swelling and Solubility of Films. The degree of swelling (DS) and solubility (S) of the films were measured by applying the following method. The dried films were immersed in distilled water at room temperature (25 °C). After equilibrium had been reached (24 h), moisture on the surface of the film was removed, and the weight of the films was measured. DS in films was calculated as

$$\text{DS} = \frac{W_e - W_0}{W_0} \quad (3)$$

where W_e is the weight of the film at the adsorbing equilibrium and W_0 is the first dry weight of the film.

The swollen films were dried again for 24 h at 60 °C, and their solubility (S) was calculated with eq 4:

$$S = \frac{W_0 - W_d}{W_d} \quad (4)$$

where W_0 is the first dry weight of the film and W_d is the dry weight of the swelled film.

Water Vapor Absorption. The pieces of prepared films were cut into small pieces (5 cm × 5 cm), and the weights of pieces were measured immediately. They were then dried in an oven at 60 °C overnight and weighed. The water content (k) of starch/PVA composite films was calculated with eq 5

$$k = \frac{W_f - W_0}{W_0} \quad (5)$$

where W_0 is the mass of the dried sample and W_f is the mass of the sample before it had been dried. Water vapor adsorption of the films were evaluated after being stored in desiccator chambers over the salt solution of $MgCl_2$ (54% RH) and $Mg(NO_3)_2$[28] for 10 days at 25 °C.

The nitrogen adsorption and desorption isotherms at 77 K were measured in the relative pressure range of 10^{-5} to 0.99, using the volumetric adsorption analyzer (Micromeritics, ASAP 2020) to characterize the geometrical structures of the films with and without heat curing. Prior to the measurement, ~0.2 g of the sample was outgassed at 373 K under vacuum for 24 h to remove the moisture content as well as the impurities. The textural properties such as the specific surface area [Brunauer−Emmett−Teller (BET)] and pore volume [total pore volume at P/P_0 = 0.99 and Barrett−Joyner−

dx.doi.org/10.1021/jf4024855 | J. Agric. Food Chem. 2014, 62, 1755−1764

Halenda (BJH) for the mesopore size distribution] were calculated from the nitrogen adsorption isotherm data. AFM was also employed to assess the topography and roughness value of the surface of the films. AFM imaging was performed with a Multimode IV instrument (Veeco), and the images were scanned in tapping mode (noncontact mode) using silicon cantilevers. All measurements were taken under atmospheric conditions and at room temperature.

Soil Burial Degradation Test. Soil burial degradation was conducted as described by Devi et al.[29] and in our previous work[30] with a slight modification. Garden pots with an approximate volume of 10 L were filled with soil taken from a culture field in Gangjin Gun, Korea. The samples were cut into 3 cm × 3 cm pieces and buried in the soil at a depth of 10 cm. The pots were placed in an uncovered gazebo. The soil was kept moist by being sprinkled with water at a regular time interval to maintain 30−50% humidity. The excess water drained through the hole at the bottom of the pot. The degradation of the specimen was determined at a regular time interval (15 days) by taking the specimen carefully from the soil and washing it gently with distilled water to remove the soil. The specimen was dried in an oven until a constant weight was obtained. The loss of weight of the specimen with time was used to indicate the degradation rate in the soil burial test.

RESULTS AND DISCUSSION

Mechanical Properties of Films. The measurement of mechanical properties such as tensile strength (TS) and elongation at break (%*E*) of biodegradable films plays an important role in various fields for application and modification. In addition, curing has a significant effect on mechanical properties. The methods of curing are gamma and electron beam irradiation,[31,32] UV irradiation,[33−35] and heat curing.[36,37] The mechanical properties and water resistance for the films are improved by the use of these methods.

Figure 1a shows the FT-IR spectra obtained for noncured films and cured films with and without AsA at different curing times. The strong peaks observed at 990−998, 1015−1020, and 1080 cm^{-1} are characteristic of the anhydroglucose ring like that found in starch. The broad band at 3265−3280 cm^{-1} was due to hydrogen-bonded hydroxyl groups (O−H). This band is of great importance because it indicates the presence of hydrogen bonding in the polymer. Higher-frequency shifts were observed when the heat curing time increased (~3280 cm^{-1}). This result is closely related to an increase in the level of hydrogen bonding among PS, PVA, and AsA hydroxyl groups, provoking an improvement in the mechanical properties and a decrease in the water solubility of the blended films.[38] AsA is easily hydrolyzed by heat or light. To verify hydrolysis of AsA, the AsA was boiled in the DW at 90 °C, which was the same preparation condition used for the films. Figure 1b clearly shows the results of the FT-IR spectra before and after the AsA treatment. The results indicate that the hydrolysis of AsA did not occur under the synthesis conditions of the films. As shown in Figure 2b for the typical FT-IR spectrum of AsA, the spectra of C═O, C−O−C, and O−H groups appeared at 1757, 1678, and 2920−3525 cm^{-1}, respectively.

Figure 2 shows the effect of heat curing time and temperature on the TS and %*E* of a nonplasticizer film and an AsA-added film. As shown in Figure 2a, TS slightly increased with increasing heat curing time whereas %*E* decreased until 120 min. However, when the curing time exceeded 150 min, TS increased and %*E* decreased rapidly because the films were discolored and oxidized. TS and %*E* of films with heat curing temperature are shown in Figure 2b. With an increasing curing temperature, TS slightly increased and %*E* drastically decreased. When heat curing was conducted at 120 °C, discoloration of

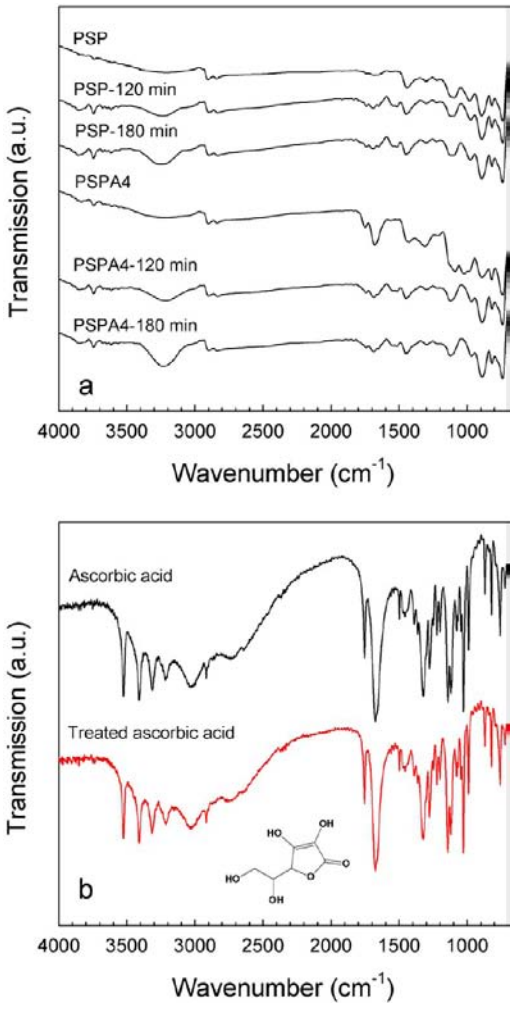

Figure 1. (a) FT-IR spectra of noncured and cured films with and without ascorbic acid (AsA). (b) FT-IR spectra of AsA and AsA treated with heat curing.

films occurred when heat curing lasted more than 150 min. When heat curing was performed for 120 min, discoloration of the film occurred after the temperature had reached ≥140 °C. Taking these results into consideration, we prepared the cross-linked PS/PVA blend films by heat curing at 120 °C for 120 min using glycerol (GL), xylitol (XL), and AsA as plasticizers. In addition, the results of the effects on heat curing revealed that TS of cured films was improved ~1.5 times compared with that of films without heat curing.

Panels a and b of Figure 3 show TS and %*E* for cured films with plasticizers (GL, XL, and AsA). Each plasticizer is added from 0 to 50 wt % on a mass percent ratio to total CS and PVA weight basis. As the content of GL, XL, and AsA increased, TS decreased and %*E* increased. A comparison of functional groups of plasticizers indicated that TS of a film with added XL with five hydroxyl groups was higher than that of a film with added GL with three hydroxyl groups. However, TS of a film with added AsA with four hydroxyl groups was highest of all the films because AsA has not only four hydroxyl groups but also one ether and one ketone. In other words, TS of an AsA-added film was improved because of the existence of the functional groups, i.e., hydroxyl, ether, and ketone groups, which can combine with starch and PVA molecules. In addition, the %*E* values indicated that GL-added films have higher values than

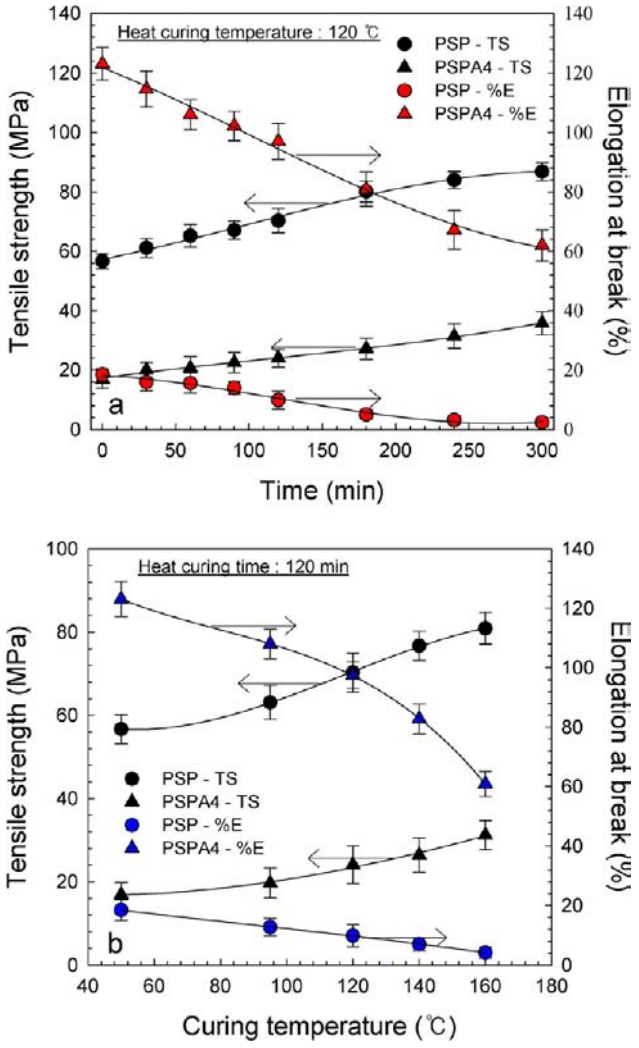

Figure 2. Tensile strength (TS) and elongation at break (%*E*) for a nonplasticizer film and an AsA-added film vs heat curing time (a) and temperature (b).

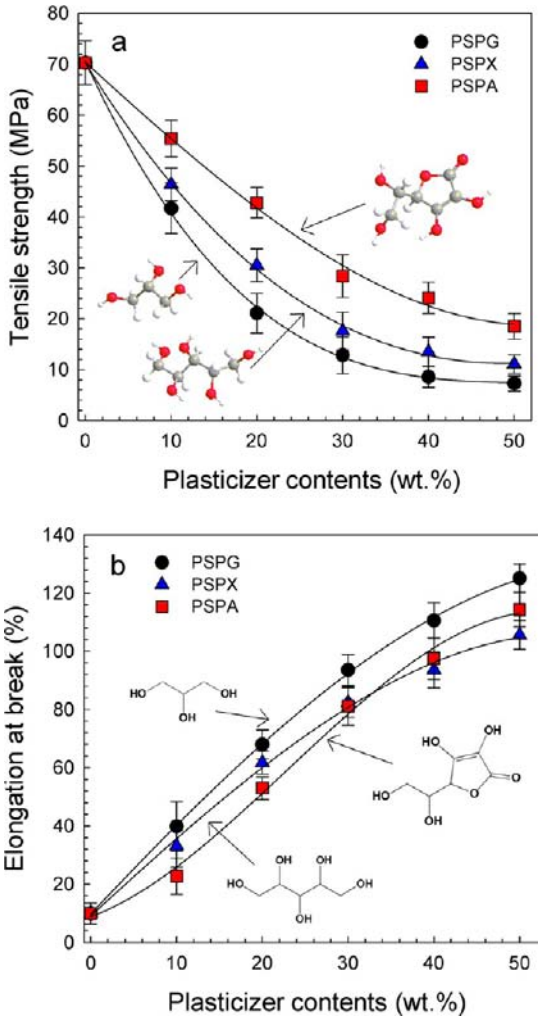

Figure 3. (a) Tensile strength (TS) and (b) elongation at break (%*E*) vs cured film glycerol (GL), xylitol (XL), and ascorbic acid (AsA) content.

XL-added films or AsA-added films. The %*E* values of XL-added films were higher than those of AsA-added films when <30 wt % plasticizers were added. However, when >30 wt % plasticizers were added, the %*E* values of AsA-added films were higher than those of XL-added films. A possible explanation of this phenomenon is that when >30 wt % AsA was added, the effect of inter-intramolecular reaction of one ether and one ketone as functional groups of AsA takes place between the components of PS, PVA, and plasticizer films.

Figure 4 presents the effect of heat curing on the SEM images of the surface of films to which 40 wt % plasticizers had been added. The surface of the noncured film without plasticizers appeared to be quite homogeneous and smooth (Figure 4a). However, as shown in panels c, e, and g of Figure 4, the noncured films to which 40 wt % plasticizers (GL, XL, and AsA) had been added appeared to be somewhat rough and agglomerated because of the combination of PS, PVA, and plasticizers for the formation of blended films. SEM images of the surface of the cured films with and without added plasticizers showed no agglomeration, cracks, or pores (Figure 4b,d,f,h).

Thermal Analysis of Films. Figure 5 shows the results of thermogravimetric analysis (TGA) of noncured and cured films with and without plasticizers. The effects of heat curing on the film without a plasticizer and the AsA-added film are shown in Figure 5a. Physical properties such as tensile properties, water resistance, and thermal stability are generally improved via the use of heat curing.[32] As shown in Figure 5a, the TGA curve of the cured films with and without AsA shifted toward the high-temperature region. It means that the thermal properties of cured films are improved by heat curing, which improved the mutual reaction of inter-intramolecular combinations. In other words, heat curing treatment of the film slightly decreased the degree of thermal decomposition. This may be due to the cross-linking of the films, which increases the resistance to thermal decomposition. The thermal properties are closely related to mechanical properties. Comparison of the noncured films and cured films showed that the TS value of the film without a plasticizer increased from 55.6 to 69.2 MPa, and at the same time, the thermal stability was also improved. The TS value of the noncured AsA-added film increased from 15.6 to 20.1 MPa when the film was treated with heat curing. The degree of thermal decomposition of the cured film without AsA was higher than that of the cured AsA-added films because the strong interaction between PS and PVA was weakened by addition of AsA as the plasticizer. Because PS and plasticizers (GL, XL, and AsA) are especially sensitive to thermal

decomposition, the incorporation of plasticizers into a PS/PVA blend film intensifies its thermal decomposition. Panels b and c of Figure 5 show the TGA curves for the cured films with added 20, 40, and 50 wt % AsA and the cured films with added 40 wt % GL, XL, and AsA. As shown in Figure 5b, the degree of thermal decomposition increased but TS decreased (see Figure 3a) because the mobility between the components of the films is increased by the addition of AsA as the plasticizer. Furthermore, the flexibility of AsA-added films also increased. Figure 5c shows the TGA curves of the cured films with the same ratio of GL, XL, and AsA added (40 wt %). The changes in the rate of thermal decomposition in the cured films indicate that the thermal stability of the AsA-added film is superior to those of other GL- or XL-added films. In addition, the reversed phenomenon is observed above 350 °C because strong interactions among PS, PVA, and plasticizer are formed by the heat curing process and the addition of plasticizers.

Degree of Swelling and Solubility of Films. The evaluation of the degree of swelling (DS) and solubility (*S*) of the prepared films plays an important role in the characterization of the degree of incorporation and cross-

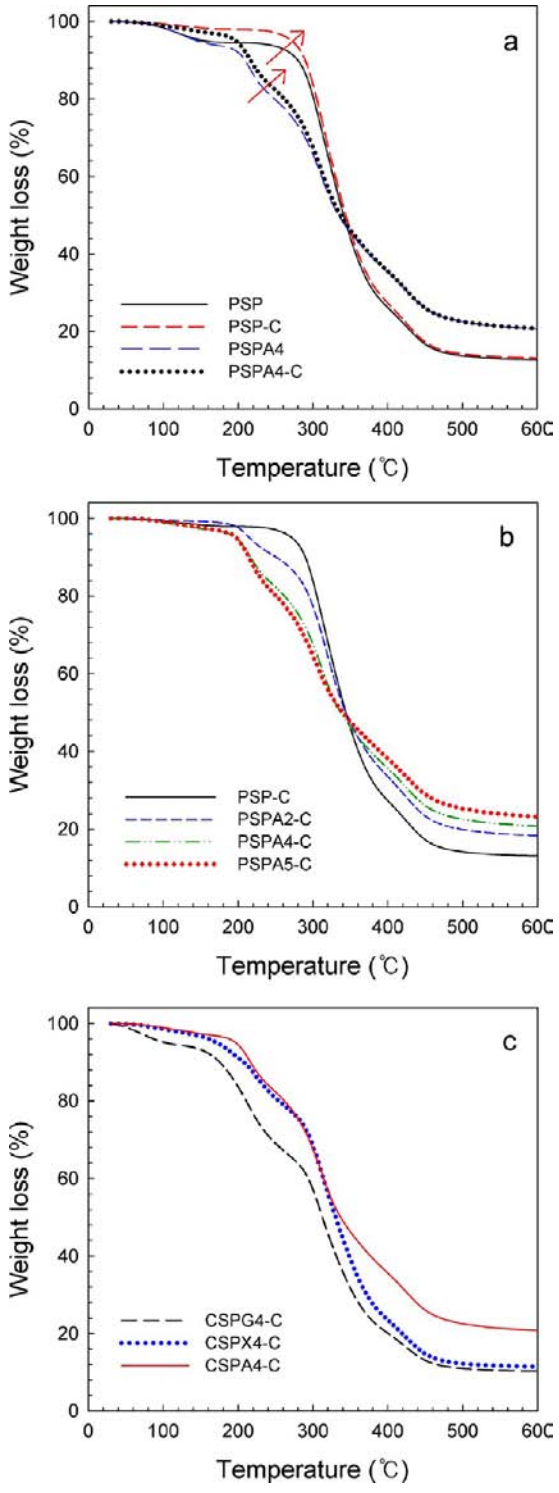

Figure 5. Thermogravimetric analysis (TGA) of noncured and cured films with and without plasticizers. (a) TGA curves of noncured and cured films with and without added AsA. (b) TGA curves of cured films with 20, 40, and 50 wt % AsA. (c) TGA curves of cured films with added 40 wt % GL, XL, and AsA.

linking between the constituents of films as well as water resistance.[39] Figure 6 shows the effect of heat curing time and temperature on the DS and *S* of the film without a plasticizer and those of the AsA-added film. As shown in Figure 6a, with an increasing heat curing time, DS values of the film without a plasticizer gradually decreased for 300 min until the end of

experiment but the *S* values drastically decreased until 120 min and increased again when the film was cured for >150 min. In the AsA-added film, DS and *S* values decreased rapidly until the sample had been cured for 120 min, but after curing had been conducted for ≥150 min, DS values slowly decreased and *S* values increased. These results indicate that the inter-intra-molecular interaction among PS, PVA, and plasticizer is improved until the sample is cured for 120 min, but when the sample had been heat cured for >150 min, the properties of the film markedly deteriorated, with discoloration and oxidation of the film. As for the effects of heat curing temperature, DS values gradually decreased until the final heat curing stage of 160 °C, but *S* values decreased rapidly up to 120 °C and then increased up to 160 °C (Figure 6b). These results suggest that these combinations between the constituents of films were

destroyed by high temperatures. From the results, the changes in DS and *S* indicate that the water resistance was improved by heat curing.

Table 2 lists DS and *S* values of cured films to which various plasticizers (GL, XL, and AsA) had been added. As the plasticizer content increased, DS values decreased but *S* values increased. DS values increased in the following order: GL-added film < XL-added film < AsA-added film. *S* values increased in the following order: AsA-added film < XL-added film < GL-added film. The GL-added films had the lowest DS value and the highest *S* value. This means that the GL-added film has a relatively weak bond strength. In contrast, the AsA-added films showed the highest DS value and the lowest *S* value, which indicates that the degree of combination among PS, PVA, and AsA is stronger than in the films with added GL or XL.

Optical Properties. One of the demands of biodegradable polymers such as edible and packing materials is that they should protect materials from the effects of light, i.e., ultraviolet radiation. Figure 7 shows the light transmission characterization of noncured and cured films with various added plasticizers. Cured films had lower transmittance (percent) than noncured films, suggesting that cured films had improved light barrier properties as a result of heat curing. In addition, films with added AsA had the lowest transmittance (percent) compared with those of the films with added GL, XL, and AsA. It means that AsA-added films have a good barrier to ultraviolet light. The opacity and transparency of noncured and cured films with GL, XL, and AsA are listed in Table 3. The results indicate that the opacity and transparency values had a tendency to increase because of the improvement of the inter-intramolecular adhesion among PS, PVA, and plasticizers by heat curing. It could confirm that the opacity and transparency values of prepared films in this study are lower compared with the reported values of synthetic films. The results obtained seem to indicate that the AsA-added films are clear enough to be used as packaging or coating materials when their values are compared with values reported by Shiku et al.[40]

Water Vapor Absorption. The water absorption property of starch-based polymers is one of their notable defects. Enhancement of water resistance is also an important issue. Therefore, we investigated the water contents of the noncured films and cured films to which GL, XL, and AsA had been added as a plasticizer. The influence of humidity on the prepared films was also evaluated because PS/PVA blend films are highly sensitive to humidity. Figure 8 shows the effect of water content on noncured films and cured films to which 40 wt % plasticizers had been added. The measurements of water content for the noncured films and the cured films with and without various plasticizers were taken at the same 55% RH. The water contents are highly dependent on the plasticizers regardless of their treatment conditions. The equilibrium water contents of noncured films were in the following order: GL-added film (0.1044) > XL-added film (0.0937) > AsA-added film (0.0788) > the film without a plasticizer (0.0714) (Figure

dx.doi.org/10.1021/jf4024855 | J. Agric. Food Chem. 2014, 62, 1755−1764

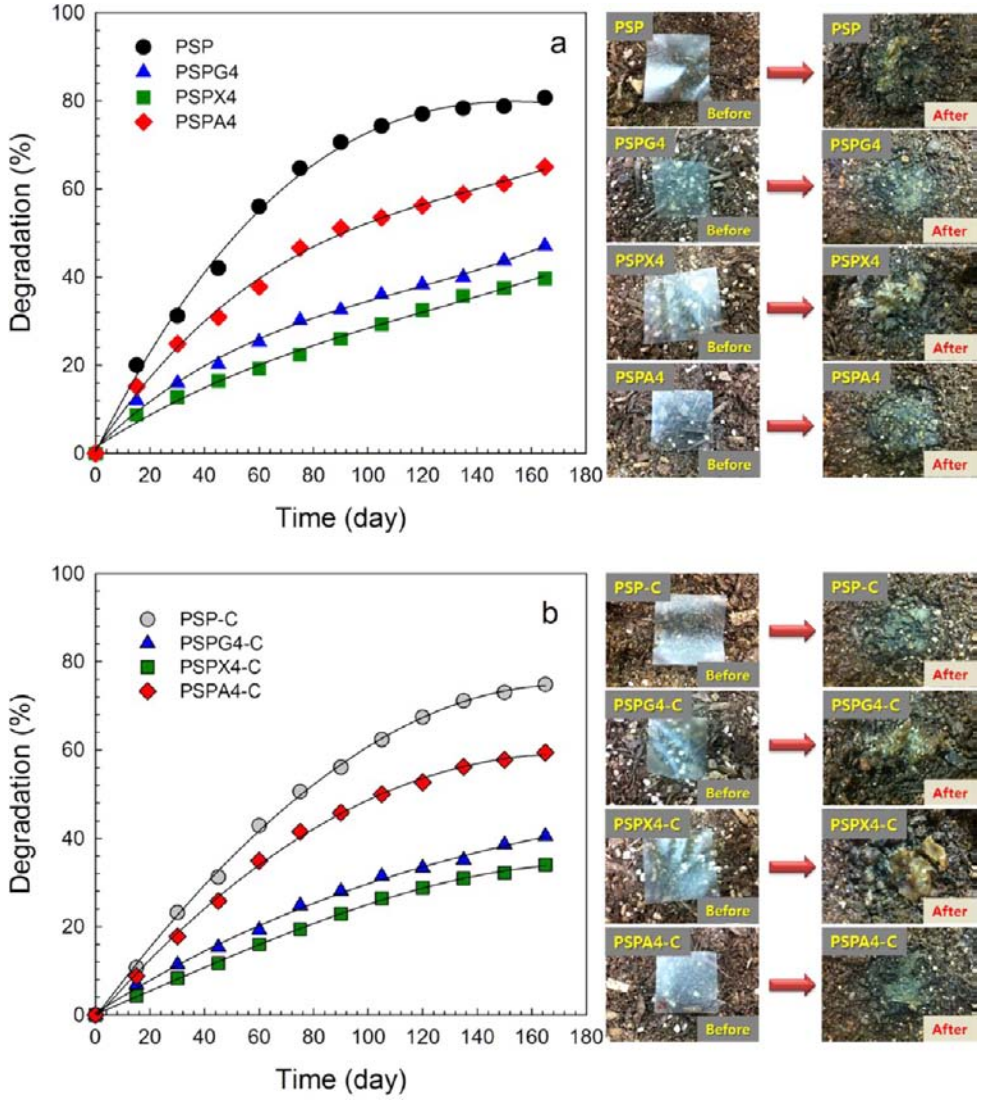

Figure 10. Biodegradation of non-cured and cured films with/without added 40 wt.% GL, XL, and AsA. (a) Biodegradation of non-cured films with/without added 40 wt.% GL, XL, and AsA. (b) Biodegradation of cured films with/without added 40 wt.% GL, XL, and AsA.

8a). However, as shown in Figure 8b, the water contents of the cured films, which were greater than those of the noncured films, were 0.1222 (GL-added film), 0.1147 (XL-added film), 0.0903 (AsA-added film), and 0.0990 (none plasticizer). The water content of the cured films was higher than that of noncured films. The hydrophilic properties of plasticizers are closely connected to the water resistance of starch-based blend films.[20] From these results, the water content of the GL-added film and the XL-added film was higher than that of the AsA-added film, which shows that GL and XL are more hydrophilic than AsA. The results of water vapor absorption in the prepared films indicated that the water resistance of the AsA-added film was better than that of the GL-added film and XL-added film.

It is important to note that the water content of the cured films is higher than that of noncured films. To confirm this phenomenon, we conducted a BET experiment and AFM analysis on the specific surface area, pore volume, and topography of both the noncured film and the cured films to which 40 wt % AsA had been added. Figure 9 shows the nitrogen adsorption and desorption isotherms and AFM images of the films. The nitrogen adsorption and desorption isotherms of the prepared films seemed to belong to type V according to the IUPAC classification. The adsorption behaviors of the prepared films were similar to each other. However, the adsorbed amount of the cured film was larger than that of the noncured film. The detailed properties of the films such as the surface area, pore volume, and average pore size are listed in Table 4. The results of AFM analysis also confirmed that the surface roughness of the cured film is decreased by heat curing, and pores that can absorb H_2O molecules are formed.

Soil Burial Degradation. The biodegradability of the noncured films and the cured films to which 40 wt % GL, XL, and AsA had been added as plasticizers was estimated by using a soil burial method. As shown in panels a and b of Figure 10, the degree of biodegradation of the films was investigated by the loss of weight of the films with time. In all the films, a rapid degradation occurred in the initial 60 days, followed by a slow degradation until the end of the experiment (165 days). The degree of biodegradation of the cured films was slightly lower than that of the noncured films because of the influence of cross-linking by the treatment of heat curing. In addition, different plasticizers showed different degrees of biodegradability. The degree of biodegradation of the AsA-added films was higher than that of the GL-added films and XL-added films.

dx.doi.org/10.1021/jf4024855 | J. Agric. Food Chem. 2014, 62, 1755−1764

The biodegradability of the GL-added films and XL-added films is low because GL and XL as plasticizers play a role as antibacterial agents.

Conclusions. Biodegradable films were successfully prepared by using potato starch, PVA, and ascorbic acid (AsA) as plasticizers and by heat curing treatment. The tensile strength (TS), elongation at break (%*E*), degree of swelling (DS), solubility (*S*), optical properties, water vapor absorption, thermal characteristics, and biodegradability of the prepared films were investigated. The results of the evaluation of the physical properties of noncured films and cured films indicated that the TS, %*E*, thermal properties, and water resistance of cured films were improved up to 65−295% by the use of heat curing. In addition, the optical properties of cured films were lower than those of noncared films. In particular, the optical properties of AsA-added films were superior to those of the other films. The water vapor absorption of cured films was slightly higher than that of noncured films. To verify this phenomenon, we investigated the specific surface area, pore volume, and topography of films with and without heat curing by using the BET experiment and AFM analysis. The results indicated that the nitrogen adsorption−desorption behavior of the prepared films was similar. However, the adsorbed amount of the cured film was larger than that of the noncured film. The results of AFM analysis verified that the surface roughness of the cured film was decreased by the heat curing process and that pores that can absorb H_2O molecules are formed. Compared to the properties of the films with various plasticizers (GL, XL, and AsA), the mechanical, thermal, and water barrier properties of a film with added AsA with four hydroxyl groups, one ether, and ketone groups were superior to those of the other films with added GL and XL with only hydroxyl groups.

The soil burial biodegradation test showed that the prepared films were degraded by ∼35−80% after 165 days. The degree of biodegradation of cured films, however, was lower than that of noncured films. In addition, the biodegradability was different with different plasticizers. The degree of biodegradation of AsA-added films was higher than that of GL-added films and XL-added films. Using the results of this study, we found that AsA could be used as an alternative plasticizer of biodegradable polymers.

EXPERIMENTAL SECTION

Materials. SPSR and AN were acquired from Henan Shizhong Shuye Ltd. (Henan, China) and Tianjin Fu Chen Chemical Reagents (Tianjin, China), respectively. Methanol, hydroxylamine hydrochloride, VC, and DMF were obtained from Tianjin Chemical Reagents (Tianjin, China). HMTA, bromoacetyl bromide, dimethylacetamide (DMAc), pyridine, LiCl, and La(0) powder were purchased from Aladdin Chemistry.

Methods. Infrared spectra (IR) were collected on a Perkin-Elmer Spectrum 2000 FTIR. The surface morphologies were studied using a scanning electron microscope, JSF5600LV, JEOL, Japan.

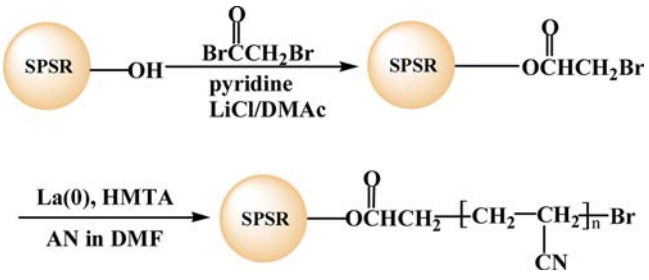
Preparation of AO BSPS-*g*-PAN. SPSR was bromoactylated using the method described in the literature[33] to prepare the bromoactylated sweet potato starch (BSPS). SI-SET-LRP of AN on the modified BSPS surface was achieved in DMF in the presence of VC with La(0) powder as catalyst and HMTA as ligand. The graft polymer BSPS-*g*-PAN was obtained. The modified resin (AO BSPS-*g*-PAN) was prepared by the reaction of BSPS-*g*-PAN with hydroxylamine hydrochloride ($NH_2OH{\cdot}HCl$).

Adsorption Characteristics of AO BSPS-*g*-PAN for Hg(II). The concentration of Hg(II) was determined by atomic adsorption spectroscopy. AO BSPS-*g*-PAN adsorbent was added to a buffered Hg(II) solution of certain pH to discuss adsorption behavior. Adsorption efficiency under situations mimicking real conditions was studied with the initial concentration of Hg(II) at 1.7×10^{-5} mol·L^{-1}, which was close to the levels found in industrial wastewater samples.[34]

RESULTS AND DISCUSSION

Surface-Initiated SET-LRP on the Bromoactylated Sweet Potato Starch Surface. Polymerization of AN via SI-SET-LRP initiated by BSPS was carried out in DMF with La(0) powder as the catalyst in the presence of VC at 65 °C (Scheme 1). The novel catalyst system based on La(0)/HMTA

Scheme 1. Modification of BSPS Macroinitiator and Polymerization of AN on BSPS Surface by SI-SET-LRP



had been developed by our laboratory, and proven to be superior to the traditional catalyst system.[35] In addition, we had also reported that the addition of a small amount of VC to the reaction mixture significantly increased the reaction rate and the controllability of the polymer.[36] The monomer conversion (C%) increased reaching about 23% within 24 h. Figure 1 shows kinetic plots of $\ln([M]_0/[M])$ versus reaction time. The apparent rate constant for SET-LRP of AN was calculated to be 2.9×10^{-6} s^{-1}. The linearity of the plot indicated that the polymerization was approximately first-order with respect to the monomer concentration.

Characterization. Figure 2 shows the infrared spectra of the (a) SPSR, (b) macroinitiator, (c) BSPS-*g*-PAN, and (d) AO BSPS-*g*-PAN. As shown in Figure 2c, the spectrum of the modified resins exhibits two absorption peaks at 1636 and 920 cm^{-1}, corresponding to the stretching vibrations of C−N and N−O bonds of AO groups, respectively. In Figure 2d, the band at 2244 cm^{-1} related to the CN group is absent. Compared

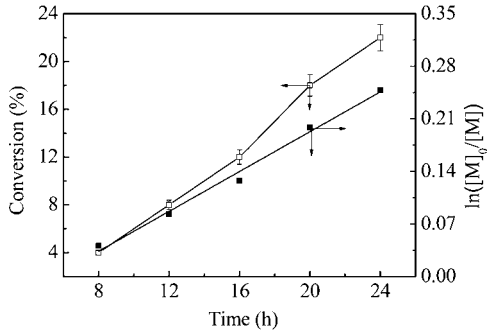


Figure 1. First-order kinetic plots for the SI-SET-LRP of AN.

with SPSR (Figure 2a), the FT-IR spectrum of BSPS (Figure 2b) shows a very sharp absorption band at 1749 cm^{-1} attributable to the carbonyl groups after esterification. A sharp peak at 2244 cm^{-1}, corresponding to the stretching of the CN bond, is present in Figure 2c but absent in Figure 2b. This indicates that PAN has been grafted onto BSPS using SET-LRP.

The SEM images of (a) SPS, (b) macroinitiator, (c) BSPS-*g*-PAN, and (d) AO BSPS-*g*-PAN are shown in Figure 3. Significant changes in morphology can be seen from PAN-*g*-BSPS (Figure 3c) to AO BSPS-*g*-PAN (Figure 3d), indicating successful modification. Moreover, the surface of BSPS changed significantly after the esterification reaction, which demonstrated the success of the grafting reaction. Compared with the macroinitiator, the surface of BSPS-*g*-PAN is rougher, confirming that organic moieties were anchored successfully on the surface. All these results indicated that PAN adsorbent was successfully prepared.

Adsorption Properties. *Effect of pH on Adsorption.* Figure 4 shows the effect of pH on the adsorption of Hg(II) by AO BSPS-*g*-PAN. With increasing pH of the adsorption medium, the uptake value increased and then decreased. When the pH was at 4.0, the uptake value reached a maximum of 4.03 mmol·g^{-1}. This maximum Hg(II) adsorption capacity value is higher than that for sulfur-containing Hg(II)-imprinted thiol-functionalized mesoporous sorbent (0.39 mmol·g^{-1})[37] and that for silica gel supported amidoxime adsorbents (1.28 mmol·g^{-1}).[38] The decrease of the uptake in the acidic media may be attributed to the protonation of nitrogen, hindering the complex formation. When the pH reached about 5 or higher, this condition is often not optimal. It was doubtful to attribute this decrease to the formation of metal hydroxide species.[39]

Adsorption Kinetics. As shown in Figure 5, the kinetic curves at four different temperatures follow an ascending trend with time, especially at the beginning. Then the increase becomes gentle and finally reaches equilibrium at around 4 h. In the temperature range from 15 to 45 °C, higher temperature corresponds to higher adsorption. This suggests that the adsorption was an endothermic process.

Adsorption Efficiency under Situations Mimicking Real Conditions. As shown in Figure 6, the adsorption of Hg(II) per unit weight of adsorbent decreases with increasing adsorbent load. When the amount of adsorbent reached 0.10 g, the percent adsorption maximized at approximately 100%.

The pseudo-first- and -second-order models were used to describe the adsorption process of Hg(II) on AO BSPS-*g*-PAN, as expressed in eq 1 and eq 2.

$$\ln \frac{(q_e - q_t)}{q_e} = - k_1 t \quad (1)$$

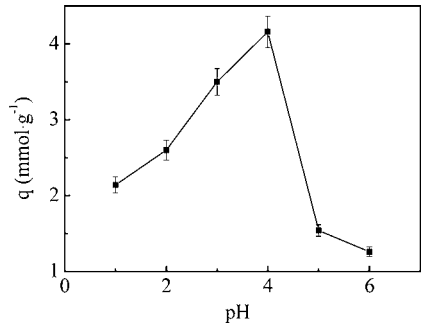

Figure 4. Effect of pH on the adsorption of AO BSPS-*g*-PAN for Hg(II).

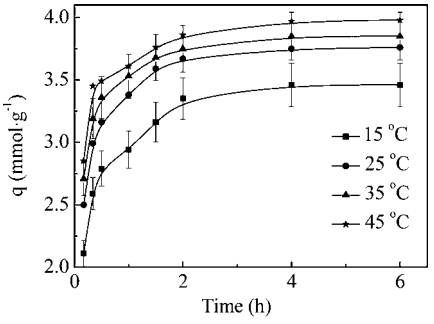

Figure 5. Adsorption kinetics of Hg(II) on AO BSPS-*g*-PAN.

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^{\,2}} + \frac{t}{q_e} \quad (2)$$

where k_1 and k_2 are the pseudo-first-order and the pseudo-second-order rate constants (min^{-1}), respectively; q_e and q_t ($mmol \cdot g^{-1}$) are the amounts of Hg(II) adsorbed at equilibrium and time t (min), respectively. The value of $\ln(q_e - q_t)$ was calculated from the experimental results and plotted against t (min). The slope and intercept of the linear plot t/q_t versus t yielded the values of q_e and k_2.

The pseudo-first-order kinetic plots and pseudo-second-order kinetic plots for the adsorption of Hg(II) onto AO PAN-*g*-BSPS are shown in Figures 7 and 8, respectively, and the fitting results are summarized in Table 1. Results suggest that

dx.doi.org/10.1021/jf4048397 | J. Agric. Food Chem. 2014, 62, 1765−1770

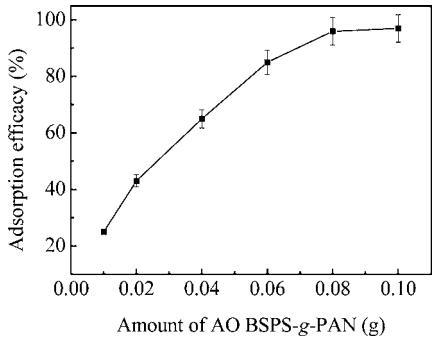

Figure 6. Effect of the amount of adsorbent on percent adsorption of Hg(II) ions.

the pseudo-second-order model was more suitable to describe the adsorption process.

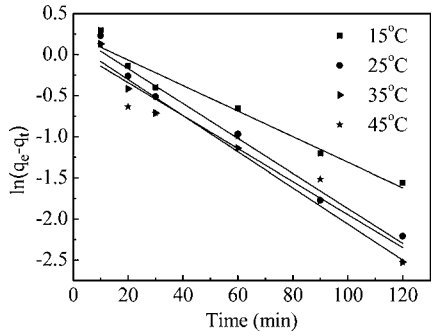

Figure 7. Pseudo-first-order kinetic plots for the adsorption of Hg(II) onto AO BSPS-*g*-PAN.

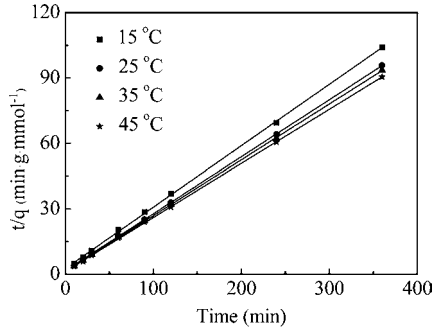

Figure 8. Pseudo-second-order kinetic plots for the adsorption of Hg(II) onto AO BSPS-*g*-PAN.

Adsorption isotherms. The adsorption experimental data were analyzed by Langmuir model (eq 3) and Freundlich model (eq 4), respectively.

$$\frac{Ce}{q_e} = \frac{Ce}{q_0} + \frac{1}{q_0 K_L} \quad (3)$$

$$\ln q_e = \ln K_F + \frac{1}{n} \ln Ce \quad (4)$$

where q_e is the adsorption capacity, mmol·g^{-1}; Ce is the equilibrium concentration of Hg(II), mol·cm^{-3}; q_0 is the adsorption capacity, mmol·g^{-1}; K_L is an empirical parameter; K_F is the binding energy constant reflecting the affinity of the adsorbents to Hg(II); and n is the Freundlich exponent related to adsorption intensity.

The adsorption isotherms of AO BSPS-*g*-PAN for Hg(II) in the temperature range from 15 to 45 °C are presented in Figure 9. The figures and parameters of the Langmuir and Freundlich

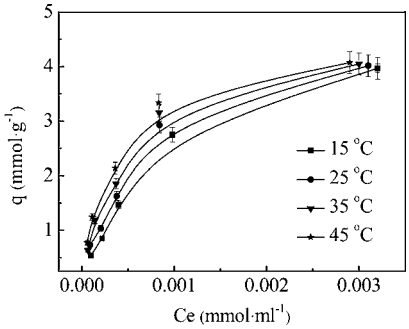

Figure 9. Adsorption isotherms of AO BSPS-*g*-PAN beads for Hg(II).

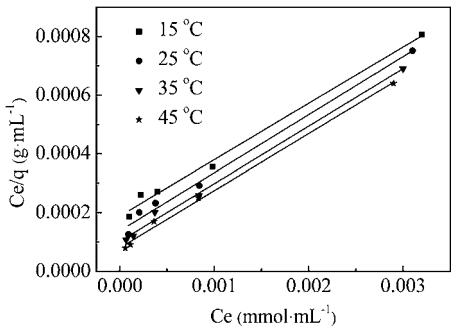

Figure 10. Langmuir isotherms of Hg(II) adsorbed on AO BSPS-*g*-PAN at different temperatures.

models are shown in Figure 10, Figure 11, and Table 2. The Langmuir model fits the experimental results better than Freundlich model as the values of R_L^2 are higher than those of R_F^2. The uptake of metal ions is applicable to homogeneous adsorption, where each molecule of adsorbate on the surface has equal adsorption activation energy. Thus, the adsorptions of

Hg(II) on AO BSPS-*g*-PAN follow the mechanism of monolayer adsorption.

Adsorption Selectivity. A series of representative binary metal ions of Hg(II)−Ag(I), Hg(II)−Pb(II), and Hg(II)−Ni(II) systems were chosen to investigate the adsorption selectivity of AO PAN-*g*-BSPS for Hg(II), and the results are shown in Table 3. As shown in Table 3, Hg(II) can be readily

Table 3. The Adsorption Selectivity of AO BSPS-*g*-PAN for Hg(II) in Binary Ions Systems at 25 °C

system	metal ion	adsorption capacity (mmol·g^{-1})
Hg(II)−Ag(I)	Hg(II)	4.02
	Ag(I)	0.41
Hg(II)−Pb(II)	Hg(II)	4.07
	Pb(II)	0.45
Hg(II)−Ni(II)	Hg(II)	3.99
	Ni(II)	0.36

adsorbed by AO BSPS-*g*-PAN in the binary systems of Hg(II)−Ag(I), Hg(II)−Pb(II), and Hg(II)−Ni(II). The percent adsorptions for Hg(II) are more than 98%, indicating that AO BSPS-*g*-PAN exhibited good selectivity for Hg(II).

to be different depending on the plant species. *rac*-Glufosinate and L-glufosinate were metabolized in nontransgenic and transgenic plant cell cultures, whereas D-glufosinate was not metabolized. Furthermore, the absorption rate of D-glufosinate was substantially lower than that of *rac*- or L-glufosinate in sugar beet.[24,25] Thus, considering the effect of chiral pesticides on the environment, enantioselectivity is an important factor that should not be ignored.[26,27]

Some methods for the achiral analysis and residue determination of dufulin in various matrices have been reported. However, information related to the degradation of dufulin enantiomers is limited. To evaluate the enantioselective degradation of dufulin enantiomers in the environment, it is necessary to understand dufulin enantiomer degradation in different soils under agricultural cultivation. Therefore, we investigated the enantioselective degradation of *rac*-dufulin and its two enantiomers in four types of soil.

MATERIALS AND METHODS

Chemicals and Reagents. *rac*-Dufulin (purity > 99%) was synthesized in pure form. The products were unequivocally characterized by nuclear magnetic resonance spectral and elemental analyses. Enantiopure enantiomers of dufulin were prepared on an Agilent HPLC system with a semipreparative chiral column. The purity of both enantiomers was >99%. Water was purified using a Milli-Q system. All other chemicals and solvents were analytical reagents or of HPLC grade and were obtained from common commercial sources. The chiral analytical column amylose tris(3,5-dimethylphenylcarbamate) (Chiralpak IA, 4.6 mm × 250 mm i.d., 5 μm) was purchased from Daicel (Tokyo, Japan).

Electronic Circular Dichroism (ECD) Spectroscopy. ECD spectroscopy was carried out using a Jasco-J810 spectropolarimeter at room temperature. The spectra were obtained from 200 to 330 nm at a scan speed of 50 nm/min.

ECD Calculations. The optimized geometry of the two dufulin enantiomers was obtained by Gaussian 09 with density functional theory (DFT) at the B3LYP/6-31G* level. ECD calculations of the two enantiomers of dufulin were obtained by Gaussian 09 with time-dependent density functional theory (TDDFT) methods at the B3LYP/6-311++G (2d, 2p) level following reported protocols.[28,29]

Soil Samples. Four types of soil were collected using a 0−20 cm plow layer from geographically distinct agricultural regions of China. The level of dufulin in these soil samples was lower than the limit of detection (LOD). All samples were air-dried at room temperature, homogenized, passed through a 2 mm sieve, and stored in the dark for several days until use. More details on soil sites and specific physicochemical characteristics are presented in Table 1.

Incubation of Dufulin in Soils under Nonsterile Conditions. Separate incubation experiments with pure (better biological activity)[30] *S*-(+)-dufulin and *R*-(−)-dufulin and with racemic compounds in soils were conducted in 50 mL polypropylene centrifuge tubes covered with aluminum foil. Approximately 5.0 g of soil (dry weight equivalent) was fortified with 30 μg (50 μL of 600 μg/mL stock solution in acetone) of *S*-(+)- or *R*-(−)-dufulin or 60 μg of *rac*-dufulin (*S*:*R* = 1:1), and they were set to air-dry for 5 min before thorough homogenization. The soil samples were then rehydrated by adding 1.2 mL of purified water (about 60% of the field holding capacity (w/w)) and incubated at 25 °C in the dark. To compensate for water loss throughout the experiments, the samples were weighed regularly and purified water was added. Triplicate samples were removed from each treatment at different time intervals (0, 1, 3, 5, 7, 10, 14, 21, 28, 49, 63, and 91 days) and immediately transferred to a freezer (−40 °C).

Incubation of Dufulin in Soils under Sterile Conditions. To determine if enantioselective degradation was a result of microbe-mediated transformations, portions of 5.0 g of soil set in 50 mL polypropylene centrifuge tubes were subjected to sterilization treatment, which was achieved by autoclaving the samples twice at 121 °C for 40 min 24 h apart. On a clean bench, the sterilized samples were treated with 30 μg of *S*-(+)- or *R*-(−)-dufulin or 60 μg of *rac*-dufulin (*S*:*R* = 1:1), and sterile water was added. The samples were then covered with glass paper to maintain sterile conditions.

Extraction of Soil Samples. Samples were thawed at room temperature, and 10 mL of water was added to each polypropylene centrifuge tube containing 5.0 g of soil. To extract the dufulin residues, 25 mL of acetonitrile, 1.5 g of NaCl, and 6 g of anhydrous $MgSO_4$ were added to the samples. Then the tube was stirred on a vortex shaker for 3 min, ultrasonically extracted for 10 min, and centrifuged at 6000 rpm for 5 min. A portion of 20 mL of supernatant was transferred and concentrated using a rotary evaporator and a nitrogen blow-dry instrument. The residue was dissolved in 1.0 mL of methanol for analysis.

Chromatographic Measurements. Analytical HPLC was performed using an Agilent 1200 series apparatus consisting of a quaternary pump, an autosampler, a diode array detector, a vacuum degasser, a column oven, and Agilent Chemstation software. After filtration, 5 μL of the sample was injected into a Daicel Chiralpak IA column. The temperature of the column was adjusted to 25 °C. The flow rate of the mobile phase, *n*-hexane/ethanol (90:10 by volume), was 1 mL/min.

Method Validation. For this study, a series of dufulin standard working solutions (12−1200 μg/mL) were prepared for determining the linearity of the two enantiomers by HPLC analysis. Calibration curves were generated by plotting the peak area versus concentration for each enantiomer. Linear regression analysis was performed using Microsoft Excel 2010. The LODs and the limits of quantitation (LOQs) were defined as signal-to-noise (S/N) ratios of 3:1 and 10:1, respectively.

Precision and accuracy of the methods were evaluated by recovery studies using spiked samples at three concentration levels (0.6, 1.2, and 6.0 μg/g for each dufulin enantiomer based on five replicates). For method recovery studies, samples without residue (5.0 g) were spiked prior to extraction by the addition of appropriate volumes of the pesticide standard solution in acetone. The treated samples were analyzed following the described procedure, and the recoveries were calculated. The method precision was assessed by determining repeatability and reproducibility, and both were expressed as relative standard deviation (RSD). Repeatability (RSD_r) was measured by comparing the SD of the recovery percentage of spiked samples run on the same day. Reproducibility (RSD_R) was determined by analyzing spiked samples from three different days.

Kinetic Analysis and Calculation. For all treatment conditions, data were assumed to follow the first-order kinetics model. The corresponding rate constant *k* for (+)-enantiomer and (−)-enantiomer was calculated on the basis of eq 1 by regression analysis. The starting

point was the maximum value of the concentration, which declined in subsequent days. The half-life ($t_{1/2}$, days) was determined on the basis of eq 2:

$$C_t = C_0 \times e^{-kt} \quad (1)$$

$$t_{1/2} = \ln 2/k \quad (2)$$

C_t and C_0 refer to the concentration of the *S*-(+)- or *R*-(−)-enantiomer at time t and time 0, respectively.

The enantiomer fraction (EF) was used to express enantioselectivity as defined by the equation EF = peak area of the (+)-enantiomer/[(+)-enantiomer + (−)-enantiomer]. EF values ranged from 0 to 1, with an EF value of 0.5 indicating racemic mixture.[31,32]

RESULTS AND DISCUSSION

Optical Isomerism Characteristics of Dufulin. The individual enantiomers of dufulin were stereochemically analyzed by ECD spectroscopy, and almost mirror-image ECD curves were obtained. The overall curves of ECD obtained by TDDFT calculations (Figure 2a) and experimental

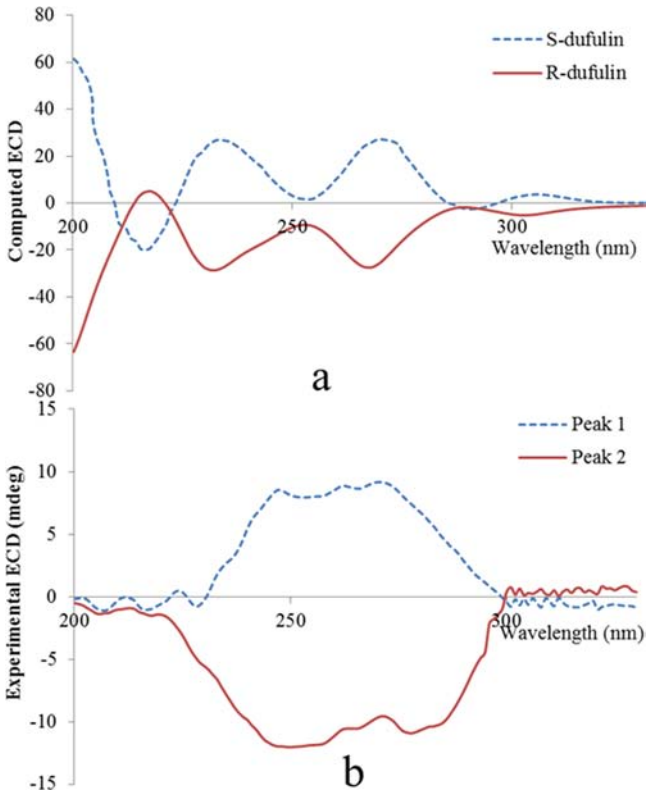

Figure 2. Calculation (a) and experimental measurement (b) of the ECD spectra of dufulin enantiomers in methanol (12 μg/mL).

ECD (Figure 2b) are similar. By comparison of the absolute configurations from computed ECD, the configurations of dufulin enantiomers eluted from the columns could be correctly assigned. As shown in Figure 2a, enantiomers with peaks 1 and 2 in Figure 2b are assigned to *S*-(+)-dufulin and *R*-(−)-dufulin, respectively.

Method Validation. Calibration curves were obtained over a concentration range of 12−1200 μg/mL (n = 7) for the *S*-(+)-enantiomer (y = 12.1432x + 12.8549, R^2 = 1.0000) and *R*-(−)-enantiomer (y = 12.0948x + 16.1483, R^2 = 0.9999) of *rac*-dufulin. The chromatogram of *rac*-dufulin in the standard solution is shown in Figure 3a. The precision data for *S*-(+)-

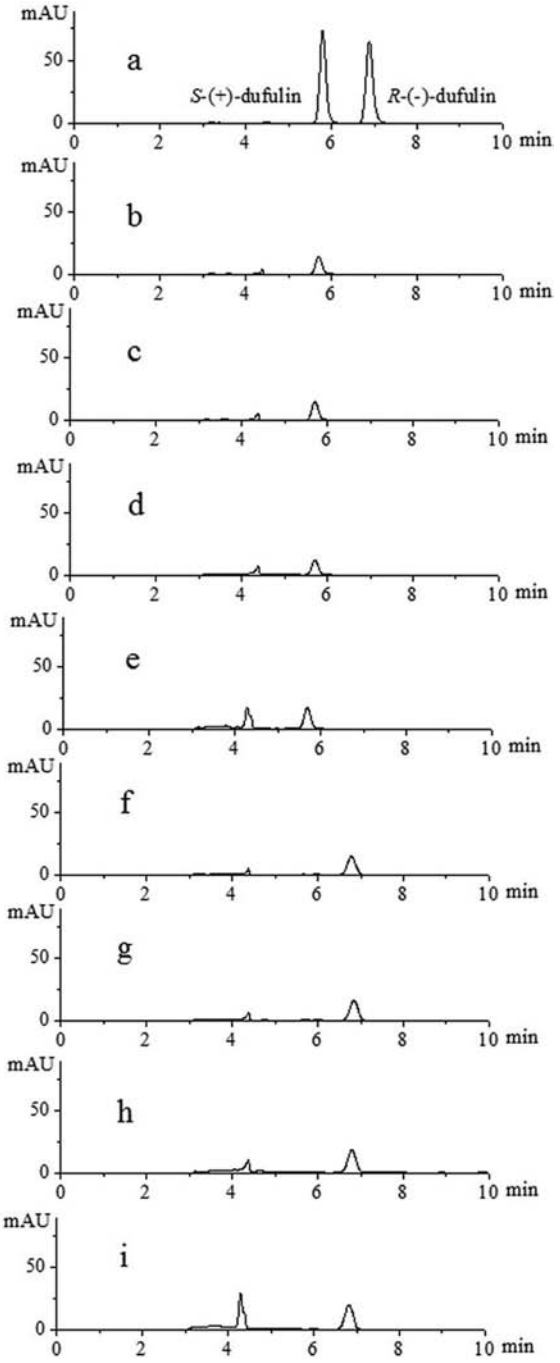

Figure 3. Chromatograms of the *S*-(+)- and *R*-(−)-dufulin enantiomers in the standard solution (a) and degradation experiments with the *S*-(+)-isomer for (b) Guiyang, (c) Nanning, (d) Hefei, and (e) Harbin soils and with *R*-(−)-isomer for (f) Guiyang, (g) Nanning, (h) Hefei, and (i) Harbin soils after 21 days of incubation under nonsterile condition.

and *R*-(−)-enantiomers of *rac*-dufulin are summarized in Table S1 in the Supporting Information. For both enantiomers, the recoveries obtained were in the acceptable range of 77.21−109.95%, whereas repeatability (RSD_r) ranged from 2.13 to 13.09% and reproducibility (RSD_R) ranged from 2.19 to 10.57% (Supporting Information Table S2). The LODs were 0.004 μg/g and the LOQs were 0.013 μg/g for both dufulin enantiomers.

Degradation of Racemic Dufulin, Enantiopure *S*-(+)-Dufulin, and *R*-(−)-Dufulin in Four Soil Types under Sterile Conditions. No significant difference in enantioselectivity was found for *rac*-dufulin degradation in four soils under sterile conditions. The concentrations of the two enantiomers of dufulin in sterile soils were determined. The EF values of dufulin in four sterile soils were approximately 0.5 after treatment (Supporting Information Figure S2f). Degradation of each enantiomer in the four soil types generally fit a first-order kinetics decay model (Table 2). Data from experiments involving sterilized soils are plotted in Figure S2c,d in the Supporting Information. Half-life ($t_{1/2}$) values of dufulin in the four sterile soils (Guiyang, Nanning, Hefei, and Harbin) were about 77.9, 64.2, 63.3, and 56.2 days, respectively.

Table 2. Degradation Rate Constant (k), Half-Life ($t_{1/2}$), and Correlation Coefficient (R^2) Values for the Degradation of *rac*-Dufulin in Four Types of Soil

condition	incubated compound	dufulin enantiomer	k (day^{-1})	$t_{1/2}$ (days)	R^2

		R	0.0112	61.89	0.9955
Heilongjiang Harbin Soil					
nonsterile	*rac*-dufulin	*S*	0.0259	26.76	0.9746
		R	0.0268	25.86	0.9724
sterile	*rac*-dufulin	*S*	0.0127	54.58	0.9950
		R	0.0120	57.76	0.9965

The degradation rates of enantiopure *S*-(+)-dufulin and *R*-(−)-dufulin were also similar (Supporting Information Figure S3c,d). No interversion between the two enantiomers was observed. Rate constants (k), half-lives ($t_{1/2}$), and correlation coefficients (R^2) were calculated (Table 3). Half-life ($t_{1/2}$) values in the four sterile soils (Guiyang, Nanning, Hefei, and Harbin) were about 82.52, 78.68, 60.27, and 50.97 days for *S*-(+)-dufulin and 83.51, 79.67, 59.24, and 51.73 days for *R*-(−)-dufulin, respectively.

Soil pH may play an important role in the degradation of various compounds in sterile soils.[33] Higher overall microbial activity in the soil with a high pH, high organic matter (OM), and high cation exchange capacity (CEC) was also the main reason for the fast degradation. Consistent with this theory we found that degradation $t_{1/2}$ of *rac*-dufulin in Harbin soil with the highest pH (8.5), OM (4.348%), and CEC (24.3%) was 56.2 days, which was shorter compared to those in Hefei, Nanning, and Guiyang soils (Table 2). Therefore, dufulin possibly degrades more efficiently in an alkaline soil with high CEC and high OM.

Table 3. Degradation Rate Constant (k), Half-Life ($t_{1/2}$), and Correlation Coefficient (R^2) Values for the Degradation of *S*-(+)- and *R*-(−)-Dufulin in Four Types of Soil

	R-(−)-dufulin	0.0134	51.73	0.9987

Degradation of Racemic Dufulin, Enantiopure *S*-(+)-Dufulin, and *R*-(−)-Dufulin in Four Soil Types under Nonsterile Conditions. The plots of concentration of *rac*-dufulin from nonsterile experiments versus incubation time (t) are shown in Figure S2a,b in the Supporting Information. The half-life ($t_{1/2}$) values of *S*-(+)-enantiomer were 38.30, 34.48, 32.54, and 26.76 days in Guiyang, Nanning, Hefei, and Harbin soils, respectively. The half-life ($t_{1/2}$) values of *R*-(−)-enantiomer were 38.09, 33.98, 34.66, and 25.86 days in Guiyang, Nanning, Hefei, and Harbin soils, respectively. Thus, degradation of dufulin was faster in Harbin soil, which had the highest organic carbon content and alkalinity, compared to the other three soils.

Our results revealed that degradation of dufulin under sterile conditions is much slower than under nonsterile conditions. In addition, besides abiotic degradation, dufulin degradation can also be attributed to microbial community activity in agricultural soils. Microorganisms in the soil may play important roles in the enantioselective metabolism of many chiral compounds. The enantioselective degradation behavior could be conducted by comparing the half-life ($t_{1/2}$) of each enantiomer. However, the half-life ($t_{1/2}$) of each enantiomer of dufulin was found to be approximately the same in the four soils from nonsterile conditions in our study. Moreover, EF values for *rac*-dufulin degradation in the four soils from nonsterile conditions were calculated to be approximately 0.5 after treatment (Supporting Information Figure S2e). This indicated that there was no significant enantioselectivity during degradation, which was the same as the degradation of *rac*-malathion in Nanchang soil,[20] but differed from other chiral pesticides.[21,32] Some studies suggested that soil properties such as texture, pH, and OM content could have major impacts on the activity of the soil microbial community and then could influence chiral signatures in soils.[12,20,21,34] Therefore, the activity of the microbial community might be distinguished in the four tested soils which had differing textures, pH values, and OM contents (Table 1). The degradation of *rac*-dufulin should

dx.doi.org/10.1021/jf404130d | J. Agric. Food Chem. 2014, 62, 1771−1776

be enantioselective in one or more soils, but the actual degradations of *rac*-dufulin in all tested soils were non-enantioselective. This result assumed that the microorganisms could not conduct the enantioselective degradation of *rac*-dufulin in soil. This phenomenon is possibly due to some interactions between the two enantiomers in *rac*-dufulin such as the mutual promotion effects, which led to the similar degradation rates of two dufulin enantiomers in soils.

During the degradation of enantiopure *S*-(+)- or *R*-(−)-enantiomer in nonsterile soils, no interconversion of *S*-(+)- to *R*-(−)-enantiomer or vice versa was detected. This indicated that the enantiomer was configurationally stable in these four soil types. The chromatograms of *S*-(+)-dufulin and *R*-(−)-dufulin after 21 days of incubation in the four soil types we tested are shown in Figure 3. We plotted data from the degradation of enantiopure *S*-(+)-dufulin and *R*-(−)-dufulin in four nonsterile soils (Supporting Information Figure S3a,b). Unlike the degradation study in sterile soils, the difference in degradation rate between enantiopure *S*-(+)-dufulin and *R*-(−)-dufulin was obvious. The half-life ($t_{1/2}$) values of *S*-(+)-dufulin and *R*-(−)-dufulin were 28.29 and 57.76 days, 26.36 and 50.97 days, 23.98 and 40.30 days, and 20.45 and 34.48 days in Guiyang, Nanning, Hefei, and Harbin soils, respectively (Table 3). Degradation rates for the enantiomers in the incubation with the single pure enantiomers were higher than in the incubations with the raceme; this phenomenon was consistent with the results reported by Zipper.[35] The degradation rate of *S*-(+)-dufulin incubations with single pure enantiomers was approximately 1.68−2.04 times higher than that of its antipode in the four types of soils tested. This result was also consistent with the results reported by Sun that enantiopure *R*-malathion degraded more rapidly than enantiopure *S*-malathion in Nanchang soil.[20] However, no enantiomerization was observed. These results differed from the degradation study of enantiopure malathion that converted between *R*-(+)-malathion and *S*-(−)-malathion in different soils.[20] No interaction between enantiomers existed during the degradation process of enantiopure dufulin in soil. This suggests that the microbial community in agricultural soils may decompose enantiopure *S*-(+)-dufulin more efficiently than *R*-(−)-dufulin, but not lead to the enantiomerization of the two dufulin enantiomers.

In conclusion, we investigated the enantioselective degradation of *rac*-dufulin and its two enantiopure enantiomers in four types of soil. We initially determined the absolute configuration of dufulin enantiomers on the basis of a combination of calculated and experimental ECD spectra. We found no significant enantioselectivity in the degradation of *rac*-dufulin in the four soil types tested under sterile and nonsterile conditions. However, enantiopure *S*-(+)-dufulin degraded much more quickly than its antipode *R*-(−)-dufulin in all nonsterile soils, which suggests that microorganisms degrade enantiopure *S*-(+)-dufulin more efficiently than they do *R*-(−)-dufulin.

Future studies should aim to identify the primary metabolites and metabolic processes of dufulin in soil and water to adequately assess the environmental risk associated with dufulin use.

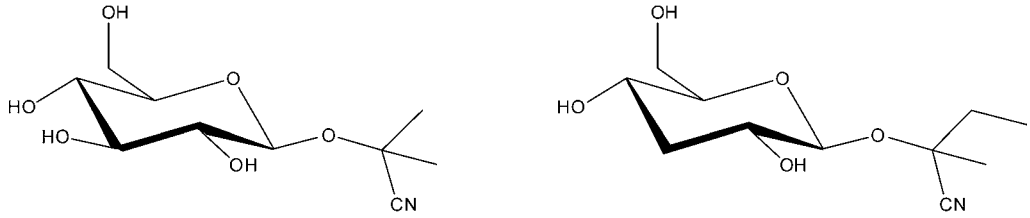

Figure 1. Structures of standards, linamarin (**1**) and lotaustralin (**2**), isolated from *Trifolium repens* aerial parts.

and they were harvested on July 8 (23 species), 18 (25 species), and 29 (14 species) and August 18th (26 species). A list of examined *Trifolium* species, their origins, and voucher specimens is reported in Table 1.

Extraction and Purification. Powdered aerial parts of *Trifolium* species were defatted with chloroform in Soxhlet apparatus. After removal of chlorophyll the samples (100 mg each) were extracted in an automated accelerated solvent extractor ASE 200 (Dionex, Sunnyvale, CA) using 80% aqueous MeOH (23 mL) at 40 °C and 1500 psi working pressure. Extracts were evaporated to dryness (at 40 °C). Residues were dissolved in Milli-Q water and purified by solid-phase extraction (SPE) using water preconditioned 1 mL, 360 mg C18 Sep-Pak cartridges (Waters Corp., Milford, MA). After loading the samples, cartridges were washed with water (1 mL) to remove carbohydrates; cyanogenic glycosides were eluted with 20% (v/v) MeOH (6 mL). Fractions were concentrated under reduced pressure and dissolved in 1 mL of 20% (v/v) MeOH for analyses. Three independent extraction and purification procedures were performed for each species, and data were presented as mean values with standard deviations (Table 2).

Isolation of Standards. Linamarin, **1**, and lotaustralin, **2** (Figure 1), used as standards for analysis, were isolated from *T. repens* L. cultivar 'Haifa'. The specimen (Voucher number 7/2010) has been deposited at the Department of Biochemistry and Crop Quality, Institute of Soil Science and Plant Cultivation, State Research Institute, Pulawy, Poland.

Plant material was defatted with chloroform and extracted three times with 75% (v/v) MeOH at room temperature for 24 h using an ultrasonic bath. Extracts were concentrated under reduced pressure and lyophilized. Then they were dissolved in water and loaded onto a 100 × 60 mm LiChroprep RP-18, 40−63 μm vacuum liquid chromatography column (Merck, Darmstadt, Germany). The column was washed with water, and cyanogenic glycosides were eluted with 20% (v/v) MeOH. Cyanogenic glycosides fraction was chromatographed with a semipreparative high-performance chromatograph Gilson HPLC equipped with a PrepELS II evaporative light-scattering detector and RP-18 column (10 × 250 mm; 5 μm; Kromasil C18, Eka Chemicals AB, Sweeden) at a flow rate of 5.0 mL/min using a 0.5% (v/v) HOAc−MeCN gradient as the mobile phase. Fractions containing pure compounds were precipitated in ethyl acetate. Single compounds were identified by NMR analysis, which was consistent with reported data. Purity of the standards linamarin, **1**, and lotaustralin, **2**, was 99.0 and 99.8%, respectively.

UPLC-MS/MS Analysis. A Waters ACQUITY UPLC system equipped with a binary solvent manager and coupled to a Waters ACQUITY TQD (tandem quadruple mass detector) with an electrospray ionization (ESI) source was used for quantitation. All data were acquired and processed using Waters MassLynx 4.1 and QuanLynx software. A Waters BEH C18 column (1 × 100 mm, 1.7 μm particles) was used to separate analytes. The elution program used for chromatographic separation consisted of solvents A (Milli-Q water containing 0.1% (v/v) HCOOH) and B (MeCN containing 0.1% (v/v) HCOOH) delivered as follows: 0.0−0.5 min (7% B), 8.0 min (25% B), 11.5 min (60% B), 12.0 min (80% B), 13.0 min (80% B), 13.1 min (7% B), and finished at 15.0 min. The flow rate was 0.15 mL/min, and the column temperature was 50 °C. The injection wash solvents were MeCN/H_2O (5:95, v/v) and MeOH/H_2O (5:95, v/v) for weak (900 μL) and strong wash (300 μL), respectively. A 1 μL sample was injected for analysis. For MS detection, negative ESI was used as the ionization mode. Nitrogen was used as the desolvation and cone gas with a flow rate of 800 and 80 L/h, respectively. Argon was used as the collision gas at a flow rate of 0.2 mL/min. The optimal MS parameters were as follows: capillary, 3.0 kV; extractor and radiofrequency voltage were fixed to 3.0 and 0.1 V, respectively; source temperature, 140 °C; desolvation temperature, 350 °C; cone voltage varied from 19 to 23 V; collision energies varied from 13 to 15 eV. Quantitation was performed using the selected reaction monitoring (SRM) mode; parent > daughter transitions were m/z 292 > 161 and m/z 306 > 161 for linamarin and lotaustralin, respectively.

Statistical Analysis. Statistical and cluster analyses (K-means clustering) were performed using the XLSTAT 2012 program.

RESULTS AND DISCUSSION

Analysis of cyanogenic glucosides in plant material creates some analytical problems. Older methods of analysis were based on sodium picrate or Feigl-Anger reagent.[16] Both tests depended on the release of HCN by enzymatic or nonenzymatic hydrolysis of cyanogenic glucosides. They were very sensitive but not always proper due to the fact that some other plant components (glucosinolates) could produce misleading information. Improvement in cyanogenic glucosides analysis was the application of high-performance liquid chromatography with refractive index detection.[15] The method provided more objective data, but its sensitivity was low, and some plants with trace amounts of compounds could be classified as non-cyanogenic. In the present research HPLC combined with the mass detector was applied in selected reaction monitoring (SRM) mode. This gave high sensitivity and precision of analysis, and both compounds could be detected even at very low concentration in plants (Figure 2).

Analysis of 88 species, originating from different parts of the globe but grown at the same site, provided interesting results. All analyzed species with respect to the content of cyanogenic glycosides could be grouped in five clusters (Table 2). As a criteria for clustering the presence of linamarin and lotaustralin and the linamarin/lotaustralin ratio were considered. The majority of 37 species belonged to cluster C1, which was characterized by the absence of cyanogenic glucosides. The second cluster C2 of 22 species grouped those, which contained only lotaustralin as a sole cyanogenic glucoside ranging from trace amounts of 0.85 (*T. alexandrinum*) to 121.47 μg/g (*T. incarnatum*) of dry weight. The third cluster C3 of 14 species was characterized by the presence of both linamarin and lotaustralin, but the linamarin occurred at a very low level; the linamarin/lotaustralin ratio ranged from 0.01 to 0.08, and the total concentration ranged from 13.26 (*T. ochroleucon* Huds.) to 424.77 μg/g (*T. resupinatum* L. var. *majus* Boiss.).

Similarly, the fourth cluster C4 of 13 species also contained both linamarin and lotaustralin, but the ratio of linamarin/lotaustralin ranged from 0.11 to 0.61, and the total

concentration varied from 4.97 (*T. repens* L.) to 1877.33 μg/g (*T. montanum* L.). Finally, the fifth cluster C5 contained only two species: *T. repens* L. and *T. repens* L. *giganteum* Lagr.-Foss with a relatively low total concentration of both cyanogenic glucosides (27.73 and 68.27 μg/g, respectively), but in these plants linamarin was the dominating compound and the linamarin/lotaustralin ratio was 3.25 and 3.75, respectively.

Considering the total concentration of cyanogenic glucosides it should be noticed that all samples were collected at the beginning of flowering, the period when most of the secondary metabolites are most intensively biosynthesized.[17] On the other hand, plants were harvested during the summer period (July–August) when, as shown with white clover varieties, cyanogenic glucoside content was the lowest,[13] which corresponded with the general view that cyanogen concentration increases at low temperatures.[18] For white clover in Europe the Swiss cultivar 'Milkanova' was accepted as a reference variety as regards the cyanogen content to be safe for grazing animals. This cultivar in Swiss conditions synthesizes about 370 mg of HCN/kg of dry matter. In these circumstances the concentration of cyanogens

[a]In cluster C1 (species 3, 7, 8, 17, 19, 21, 24, 27, 28, 31, 32, 33, 34, 36, 37, 41, 42, 50, 59, 62, 64, 65, 66, 68, 70, 76, 77, 78, 79, 80, 81, 82, 84, 85, 86, 88), no linamarin, **1**, or lotaustralin, **2**, was detected. [b]ND – not detected.

in plants of clusters C2, C3, and C5 should be considered as rather low. Cluster C4 contained species with concentrations comparable to cited 'Milkanova' cultivar. Only two species, *T. repens* var. *biasoletti* (Stend & Hochst.) Asch. & Graebn. and *T. montanum* showed extremely high cyanogen concentration (1505.30 and 1877.30 μg/g of dry matter, respectively). This has a concentration comparable to the content of linamarin and lotaustralin in cassava tubers where they accumulate up to 1.5 g/kg dry weight.[19,20] However, in cassava tubers the linamarin/lotaustralin ratio was approximately 97:3, whereas in most of the *Trifolium* species lotaustralin has been the dominant glucoside.

There was no regularity observed regarding the genus-dependent occurrence of cyanogenic glucosides. For these genera, which were represented by several species or subspecies of different origin, their distribution between different clusters was observed. Out of the six samples of widely cultivated red clover (*T. pratense*), four were free of cyanogenic glucosides, one had only lotaustralin, and one possessed both linamarin and lotaustralin. It is interesting to notice that *T. pretense* originating from Belgium (66) was free of cyanogens, while the same species originating from Netherlands (67) contained both linamarin and lotaustralin. White clover (*T. repens*) was also represented by six samples of different origin, and five of them contained both linamarin and lotaustralin. The total cyanogen concentration in these samples ranged between 6.37 and 1503.30 μg/g. The highest concentration was observed for samples originating from France: 342.83 (74) and 1503.30 μg/g (72). This finding correlates with previous reports, showing that in the Mediterranean region the frequency of cyanogenesis in white clover populations was 100%, while in other European regions it was decreasing when moving to the northeast, and in Central Russia the populations were noncyanogenic.[21] This was correlated with the mean temperature of January and preferential grazing of noncyanogenic plantlets by snails. Only the sample originating from Poland (70) was free of cyanogens. This finding confirmed previous data showing that old Polish cultivar 'Podkowa' bred from local population was non-cyanogenic.[14]

Similar trends were observed in the case of *T. incarnatum*. Three of the five samples were free of cyanogens, one (38) contained only lotaustralin, and one (39) contained both linamarin and lotaustralin. In contrast, white clover *T. incarnatum* originating from France was free of cyanogens, while the sample originating from Poland had the highest content of these glycosides.

In the case of *T. hybridum*, out of six samples five did not contain cyanogens and only the sample originating from Norway (35) possessed linamarin and lotaustralin at a relatively low level of 38.70 μg/g of dry matter.

The species *T. resupinatum* were differentiated in cyanogen content as well. Out of six tested samples five were noncyanogenic and one originating from the United States contained both linamarin and lotaustralin at a relatively high level of 424.77 μg/g.

dx.doi.org/10.1021/jf4056659 | J. Agric. Food Chem. 2014, 62, 1777−1782

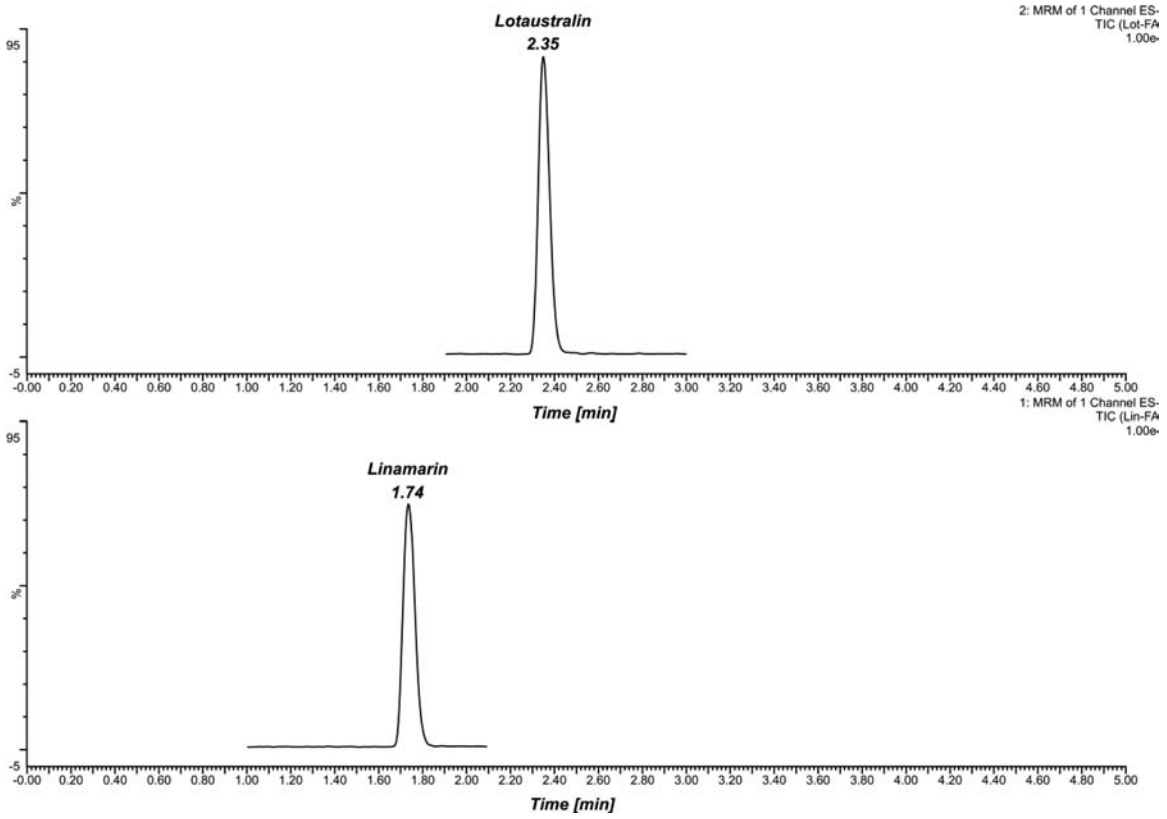

Figure 2. UPLC ESI-MS/MS ion chromatograms of linamarin (**1**) and lotaustralin (**2**) quantified in *T. repens* var. *biasoletti* (Steud. & Hochst.) Asch. & Graebn. were obtained with selected reaction monitoring (SRM).

The presence or absence of both glycosides is regulated by alleles of a single gene, designated Ac, whereas the presence or absence of the enzyme *linamarase* is governed by alleles or another, independently inherited gene (Li). Only plants possessing dominant functional alleles of both genes liberate HCN when damaged.[13,22] Biosynthesis of linamarin, **1**, and lotaustralin, **2**, the valine and isoleucine-derived cyanogenic glucosides has been recently extensively studied. The biosynthetic pathway that includes enzymes and corresponding genes has been fully identified in *Sorghum bicolor*, synthesizing aromatic cyanogenic glucoside dhurrin.[23] The CYP79 enzymes converting amino acids into oximes have been known in several plant species. For some species (great millet and cassava) the enzymes converting oximes to cyanohydrins have also been identified.[24−26] In particular, identification of *CYP71E1* and *CYP71E7* in cassava synthetizing aliphatic cyanogenic glucoside may aid as a probe for isolation of their paralogs in *Trifolium* species. Our present findings may help in selection of species/subspecies for these studies. The full recognition of the enzymes involved in biosynthesis, transport, and degradation of these compounds has been of crucial value for breeding purposes.

It is experimentally demonstrated that the acyanogenic plants have a competitive advantage over the cyanogenic ones (the relative fitness, i.e., biomass production and the number of flowers per plant are higher).[13] Screening, which was carried out, revealed the cyanogenic and acyanogenic species. Obtained data can be used for their future safe nutritive use or clover-breeding programs, and they can have a chemotaxonomic significance.

strategies reducing malnutrition in developing countries.[16] It has been reported that inoculation of bacteria (*Providencia sp.* PW5) resulted in a significant increase of Fe, Mn, and Cu in wheat grain.[16]

Recently, endophytic bacteria colonizing the internal tissues of metal hyperaccumulator or accumulator plants have been gaining increasing attention.[17] Endophytic bacteria promoted plant growth, increased heavy metal accumulation, and available heavy metal in the rhizosphere soil. Inoculation of plants with endophytes, which were isolated from metal-resistant or hyperaccumator plant species, is extensively used for phytoremediation of metalliferous soils.[18−20] However, there are few reports on whether the bacteria isolated from hyperaccumulator could survive in a crop system and their potential use in biofortification of micronutrients in crop plants. In the present study, five endophytic strains, *Burkholderia sp.* SaZR4, *Burkholderia sp.* SaMR10, *Sphingomonas sp.* SaMR12, *Variovorax sp.* SaNR1, and *Enterobacter sp.* SaCS20, were isolated from *Sedum alfredii* Hance, a Zn hyperaccumulator native to China.[21,22] Our previous studies showed that inoculation of the isolated endophytic bacterial strains back to sterilized plants of the hyperaccumulator *S. alfredii* resulted in elevated biomass and Zn concentrations in both shoots and roots.[23] The endophytic microbia were also harmless to crops according to pathogenic detection of tobacco leaf.[23] The objective of the study is to investigate the possibility of Zn biofortification in rice grains by inoculation with the endophytic strains isolated from *S. alfredii*.

MATERIALS AND METHODS

Bacteria, Plasmids, and Plants. Five single bacterial strains (SaZR4, SaMR10, SaNR1, SaMR12, and SaCS20) used in this study were isolated from *S. alfredii* as described by Zhang et al.[24] The bacterial strains were identified as *Burkholderia sp.* SaZR4, *Burkholderia sp.* SaMR10, *Sphingomonas sp.* SaMR12, *Variovorax sp.* SaNR1, and *Enterobacter sp.* SaCS20 based on their 16S rRNA gene sequences and carbon source utilization profiles determined using Biolog GN2 microplates (Biolog Inc., Hayward, CA, USA). SaZR4, SaMR12, SaNR1, and SaCS20 transconjugants constitutively expressing green fluorescent protein (GFP) were obtained by triparental mating with the vector plasmid pHC60 and helper phage pRK2013.[23] Bacterial physiology including indole-3-acetic acid (IAA) and siderophore production and phosphate solubilization (except SaNR1) was determined according to Lin et al.[25]

Japonica rice (*Oryza sativa* L.) variety Nipponbare obtained from Zhejiang Academy of Agricultural Sciences was used for this study. Surface-sterilized rice seeds were germinated at 30 °C in the dark. After germination, plantlets were sown in a sterile pot that was filled with sterilized quartz sand in a growth chamber. Uniform seedlings at three-leaf stage were transplanted to a 2.5 L black plastic pot with nutrient solution containing (in mM) NH_4NO_3, 1.43; $CaCl_2{\cdot}2H_2O$, 1.00; $MgSO_4{\cdot}7H_2O$, 1.64; $NaH_2PO_4{\cdot}2H_2O$, 0.32; and K_2SO_4, 1.32; and (in μM) $MnCl_2{\cdot}4H_2O$, 5.0; $CuSO_4{\cdot}5H_2O$, 0.2; $(NH4)_6Mo_7O_{24}{\cdot}4H_2O$, 0.075; H_3BO_3, 1.90; Fe-EDTA, 20.0; and $ZnSO_4{\cdot}7H_2O$, 2.0.[26] The nutrient solutions were replaced every 3 days and adjusted to pH 5.5 ± 0.1 every day. Plants were grown in a growth chamber under a photo flux density of 400 μmol m^{-2} s^{-1}, a light/dark period of 16/8 h, day/night temperatures of 30/25 °C, and day/night relative humidities of 75%/85%.

Inoculation with Endophytic Microbia under Hydroponic Conditions. The five isolated endophytic strains were used in the hydroponic experiment. A single bacterial strain was grown in liquid Luria broth (LB) medium for 48 h at 30 °C on a rotating shaker. Cells were harvested by centrifugation, washed twice with phosphate buffered saline (PBS), and suspended in biological saline (0.85% NaCl), then the inoculum density was adjusted to 10^8 colony-forming units mL^{-1}, and the resulting suspensions were used for inoculation.

Roots of rice seedling at five-leaf stage were surface sterilized with 3% chloride for 2 min and four washes with sterile water. A total of 5 mL of bacterial inocula were carefully introduced into 2.5 L of nutrient solution using a pipet avoiding contamination of the above-ground rice tissues. Plants were grown in a growth chamber, and treatments were arranged randomly with four replications. Rice plants were harvested at 30 d after inoculation (DAI).

Inoculation with Endophytic Microbia under Soil Conditions. In a separate experiment, the effects of the endophytic strains on rice growth and grain Zn accumulation were further investigated under soil conditions in a greenhouse. Two strains (SaMR12 and SaCS20) selected from the hydroponic experiment were used in the pot experiment. The silty loam soil used in this experiment was collected from the experimental field of Zhejiang University, Zhejiang Province, China. The physical−chemical properties of the experimental soil were pH 6.5, available N, P, and K of 67.7, 37.6, and 62.5 mg kg^{-1}, respectively, DTPA-extractable Zn 4.33 mg kg^{-1}. Soil was air-dried, sieved to 5 mm, and homogenized before filling the pot, each of which contained 8.0 kg of dry soil. Recommended levels of NPK fertilizers were supplied (in mg per kg of dry soil) to each pot at a rate of 160 mg of N (70% as basal and 30% at panicle initiation), 50 mg of P_2O_5, and 90 mg of K_2O before transplanting.

Roots of rice seedlings at five-leaf stage were sterilized as described above, and every six seedlings were inoculated by soaking the roots in 500 mL of single bacterial suspension (10^8 colony-forming units mL^{-1}) for 2 h and then transplanted to each pot. Rice was additionally treated with 20 mL of the bacterial cell suspensions (10^8 colony-forming units mL^{-1}) by spraying on the plant rhizosphere soil at tillering stage and flowering stage, respectively. The same volume of sterilized deionized water was used as control. Treatments were arranged randomly with four replications. Water content of each pot was maintained at 75% (w/w) with deionized water daily. Plants were grown in greenhouse with day/night temperatures of 30 ± 2 °C/23 ± 2 °C under natural light conditions from June to Oct., 2012, at Zhejiang Province, China.

Laser Scanning Confocal Microscopy (LSCM). For hydroponic experiments, rice roots for LSCM were excised from plants at 2, 4, and 6 DAI, and a random sample of root system was assessed for microbial colonization. For pot experiments, rice roots and root with less rhizosphere soil were excised at 3 and 7 DAI for LSCM. LSCM was performed according to Lin et al.[25]

Root Morphology and Root System Formation. Roots of harvest plants were analyzed with a root automatism scan apparatus (MIN MAC STDI600+, Tokyo, Japan) equipped with the WinRHIZO software (Regent instruments Inc., Quebec, Canada).[20] Root system formation of the rice was observed by using a stereomicroscope (Leica MZ9.5) with a DCF300 camera. Individual root was sampled randomly and cut into 10 mm fragments from root tips. Images were captured with a Leica application suite (LAS) software (Leica, Bannockburn, IL).

Elemental Determination. At 30 DAI under hydroponic conditions, roots of rice cultured hydroponically were submerged into a 1.0 L bath containing 1.0 mM $LaCl_3$ and 0.05 mM $CaCl_2$ for 10 min to remove apoplastic Zn.[27] Plants were separated into roots, stems, and leaves and cleaned with ultrapure water (resistivity ≥ 18.2 MΩ cm^{-2}). Rice plants cultured under soil conditions were harvested at maturity and separated into grains, flag leaves, leaves, and stems. All plant samples were rinsed thoroughly with ultrapure water, oven-dried at 65 °C for 72 h, weighed, and ground with an MM301 (Retsch, Germany) with agate ball and internal wall. Samples were digested in a diacid mixture of HNO_3−$HClO_4$ (v/v, 4:1), and the digest was transferred to a 50 mL volumetric flask, made up to volume, and filtered. Samples were digested in triplicate, and Zn concentration was determined using an inductively coupled-plasma mass spectrometer (ICP-MS, Agilent 7500a, CA, USA). DTPA-extractable Zn in the rhizosphere soil was analyzed by ICP-MS (Agilent 7500a, CA), and soil pH was measured in a soil slurry (soil/water ratio = 1:2.5).[28]

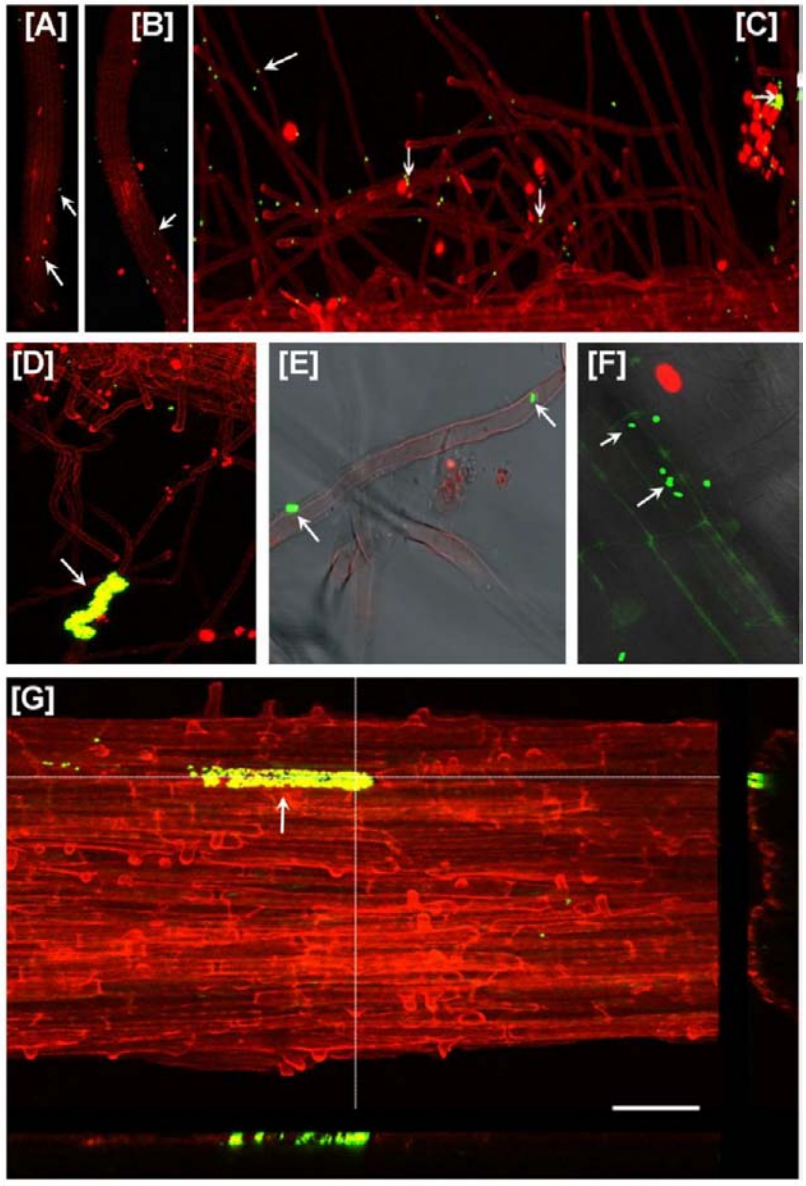

Figure 1. GFP-tagged *Burkholderia sp*. SaMR12 strain colonized on and in the roots of rice. LSCM images present bacterial GFP fluorescence in green and root autofluorescence in red. SaMR12 cells colonized on root cap (A), lateral root (B), and root hairs (C) at 2 DAI. SaMR12 cells colonized at root hairs (D), entered root hair cells (E) and cortical intercellular spaces (F) at 4 DAI. SaMR12 invaded vascular tissues of the primary root (G) at 7 DAI, and arrowhead points to bacterial aggregates. The *xy* crosshairs present the positions for orthogonal sectioning through the *z*-strack. The top right orthogonal view presents the *yz* section of the *z*-stack; the bottom orthogonal view presents the *xz* section of the *z*-strack. Bars: 50 μm in panels A–D and G and 5 μm in panels E and F. DAI, days after inoculation.

SRXRF Analysis. Micro-X-ray fluorescence imaging of Zn in rice root and rhizosphere soil was carried out on beamline BL15U at the Shanghai Synchrotron Radiation Facility (SSRF), Shanghai, China. At 30 DAI, root together with its adjacent rhizosphere soil (0.20 cm) was carefully cut with a razor blade. *In situ* micro-XRF mapping of Zn was analyzed according to Lu et al.[29] The electron energy in the storage ring was 3.5 GeV with a current range from 200 to 300(5) mA. The brilliance of the beam in BL15U was 0.5×10^{12} photons s^{-1} mm^{-2} $mrad^{-2}$ $(0.1\%\ BW)^{-1}$. The microfocused beam of 3.5 μm was provided by a Kirkpatrick–Baez mirror pair (Xradia Inc.) with the sample at 45° to the incident X-ray beam. The fluorescence yield was detected using a seven-element Si (Li) solid state detector, positioned at 90° to the beamline. Dwell time per point was 0.5 s. The step size was set to 10 μm. Scanning areas of the samples were selected and observed using a microscope. BL15U saves full XRF spectrum data at each pixel. Elemental distributions are achieved by windowing on the elements of interest in the XRF spectra. The windows can be applied during data collection or during data analysis since the full XRF spectrum is saved for each pixel. The beam energy was set to 13 keV during mapping. The fluorescence energy windows for this investigation were Zn, Fe, K, Ca, and Mn. The fluorescence data are presented as color maps, and pixel brightness is displayed in RGB, with the brightest spots corresponding to the highest element fluorescence.

Statistical Analysis. All data were statistically analyzed using the SPSS package (version 11.0). Analysis of variance (ANOVA) was performed on the data sets, and the mean and SE of each treatment as well as LSD ($P < 0.05$ and $P < 0.01$) for each set of corresponding data were calculated. The figures were made using the software Origin 8.0.

RESULTS

Root Colonization Patterns of GFP-Tagged Endophytic Bacteria. The GFP-tagged endophytic bacteria were inoculated as the treatment of endophytic inoculation for

determination of bacterial populations at different days after inoculation (DAI) under hydroponic conditions. Root colonization patterns of other GFP-tagged endophytic bacteria were quite similar to that of SaMR12, which is shown in Figure 1. At 2 DAI, GFP-tagged SaMR12 had successfully colonized the surface of lateral roots (Figure 1A) and primary roots from root caps (Figure 1B) to root hairs (Figure 1C). From 2 to 4 DAI, SaMR12 cells formed biofilm-like structures on the root surface (Figure 1D) and entered into root hair cells and cortical intercellular spaces (Figure 1E,F). By 7 DAI, SaMR12 had invaded vascular tissues of the primary root (Figure 1G). The GFP-tagged SaMR12 heavily colonized the roots of rice after 2 weeks of inoculation (data not shown). There was no fluorescent bacteria observed on or in the uninoculated roots of rice.

Plant Growth, Root Morphology, and Zn Uptake of Rice Modulated by Endophytic Bacteria. Modulation of plant growth, root morphology, and Zn uptake of rice plants by endophytic bacteria were investigated hydroponically. Five endophytic strains (SaZR4, SaMR10, SaMR12, SaNR1, and SaCS20) isolated from *S. alfredii* were inoculated in the rice roots of Nipponbare under hydroponic condition for 30 d. As shown in Figure 2, inoculation with endophytic bacteria, especially SaMR12 and SaCS20, significantly improved the rice growth. Both root and shoot biomass increased markedly with inoculation with each individual endophytic strain, by 29.4−70.6% in root and 21.1−53.3% in shoot. Among the five

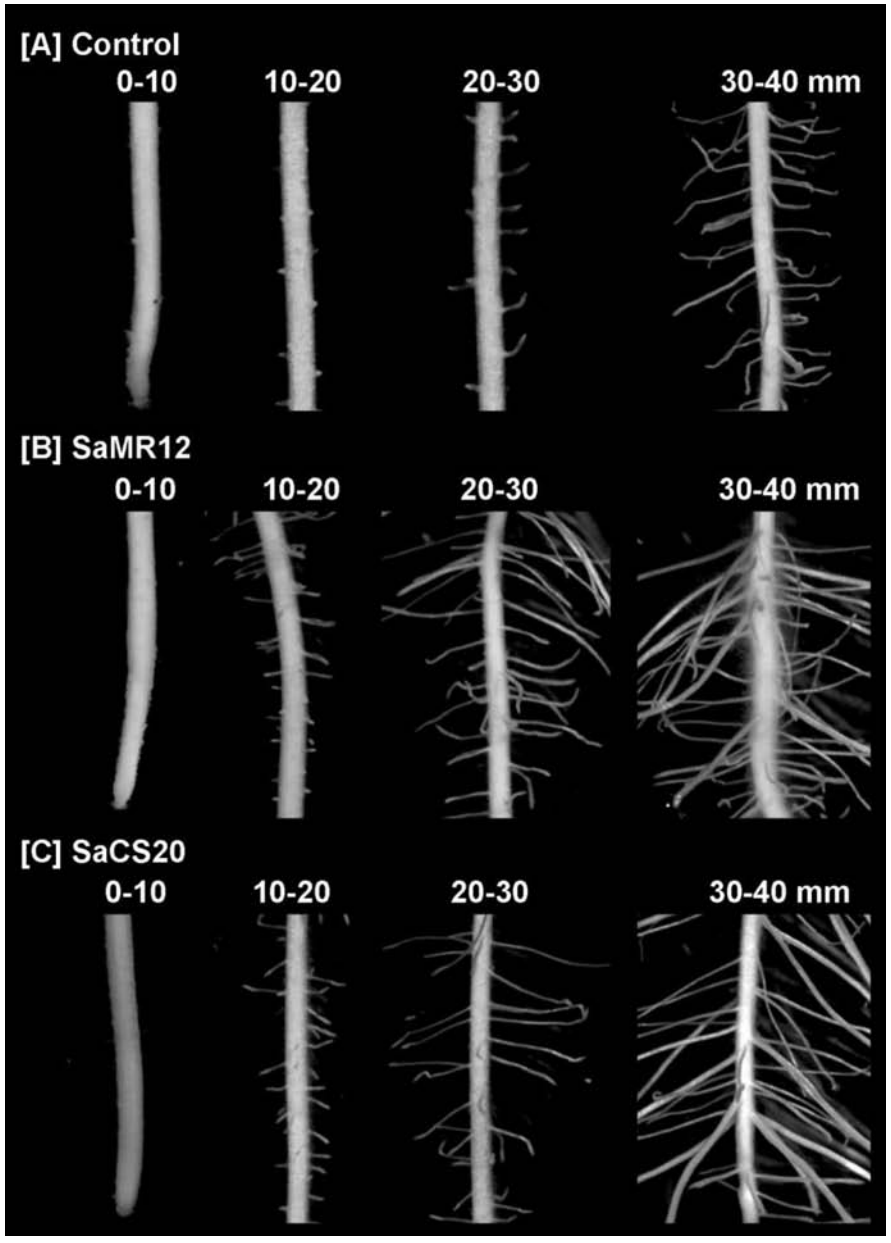

Figure 3. Root tips of rice after 30 days inoculation without (A) or with different endophytic bacteria, SaMR12 (B) and SaCS20 (C), isolated from *S. alfredii*.

endophytic strains, the most pronounced effect of inoculation on growth promotion was observed with SaMR12, followed by SaCS20.

Significant variation of root morphology was observed for rice plants with endophytic inoculation, especially by SaMR12 and SaCS20 (Table 1). Root length and diameter of inoculated seedlings significantly increased by 11.5−16.4% and 23.9−35.2%, respectively, compared with the controls, although no differences were recorded among the five strains. After inoculation with individual bacterial strain, root tips significantly increased by 11.3% and 14.7% at the presence of SaMR12 and SaCS20, although no significant difference of root forks was noted. Significantly increased (22.5%) root surface area was also observed with SaCS20 inoculation. Stereomicroscope imaging of single roots showed that endophytic inoculation of SaMR12 and SaCS20 significantly stimulated root hair production, especially at the 30−40 mm fragment, compared with the controls (Figure 3).

Elevated Zn uptake by rice was observed after inoculation with the five individual endophytic strains, among which the effects of SaMR12 and SaCS20 were mostly pronounced (Figure 4). Inoculation with SaMR12 and SaCS20 raised shoot Zn concentration of rice by 44.4% and 51.1%, respectively, compared with the controls (Figure 4A), and also increased Zn concentration in roots by 73.6% and 83.4%, respectively (Figure 4B). Root Zn concentration increased up to 48.1 and 50.8 $\mu g\ g^{-1}$, respectively, after SaMR12 and SaCS20 inoculation. Calculated from the biomass and Zn concentration, Zn accumulation in shoots and roots of rice increased by approximately 100% and 200%, respectively, in the presence of either SaMR12 or SaCS20.

Improved Grain Yield and Zn Accumulation by SaMR12/SaCS20 Inoculation. Since SaMR12 and SaCS20

dx.doi.org/10.1021/jf404152u | J. Agric. Food Chem. 2014, 62, 1783−1791

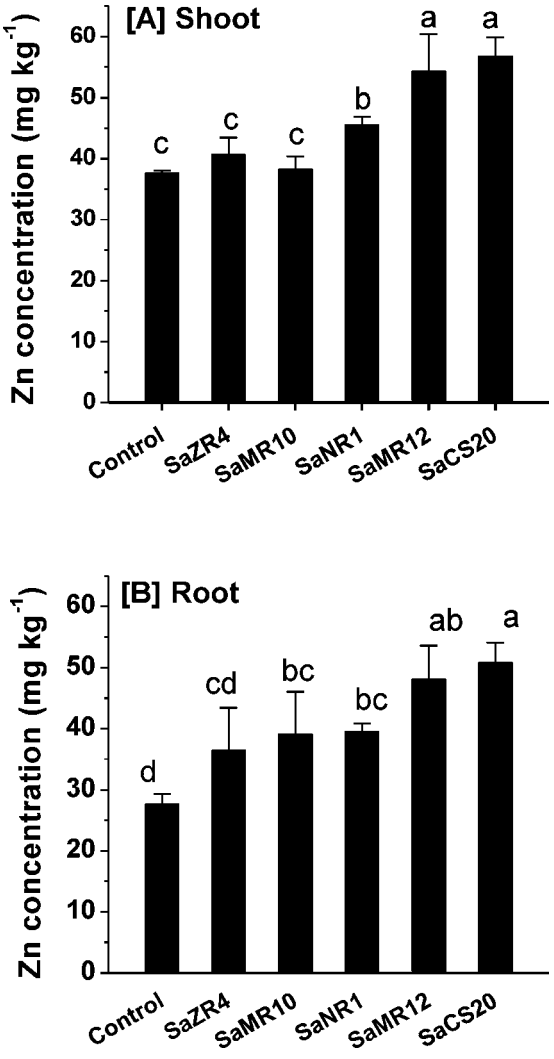

Figure 4. Zn concentrations in shoots (A) and roots (B) of rice after 30 days inoculation with different endophytic bacteria isolated from *S. alfredii*. Different letters indicate statistically significant difference ($P < 0.05$) among treatments. Error bars indicate standard deviations of three replicate determinations.

were of most effective for promotion of plant growth, root morphology, and Zn uptake of rice in solution, their impacts on grain yield and Zn accumulation in rice were further investigated under soil conditions. As shown in Figure 5, SaMR12 began to colonize root rhizosphere soil and root surface at 3 DAI and entered into root cortical intercellular spaces at 7 DAI. SaCS20 showed a similar colonization pattern to that of SaMR12 (data not shown).

Endophytic inoculation with SaMR12 and SaCS20 significantly affected the values of yield components and improved grain yields (Table 2). Although no variation of thousand-grain weight (TGW) and grain setting rate was observed, among all the treatments, significant elevation of panicles and grain per spike was noted by inoculation with the endophytes. When compared with the controls, grain yields increased by 25.5% and 26.9%, respectively, after endophytic inoculation with SaMR12 and SaCS20.

Inoculation with either SaMR12 or SaCS20 also resulted in significant increase of Zn densities in both brown rice and polished rice (Table 3). For instance, Zn concentrations in brown rice reached up to 30 mg kg^{-1} with SaMR12 and

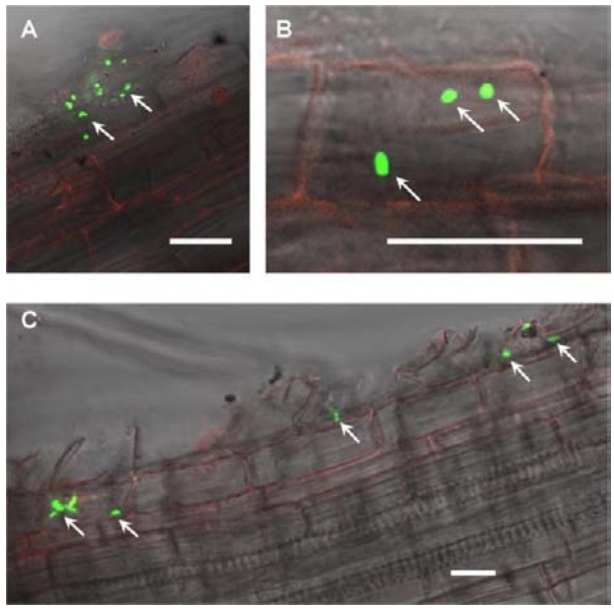

Figure 5. GFP-tagged *Burkholderia sp*. SaMR12 strain colonized in the roots of rice in soil. LSCM images present bacterial GFP fluorescence in green and root autofluorescence in red. SaMR12 cells colonized on root surface (A) and root cells (B, C) at 3 DAI. Bars: 10 μm.

SaCS20 inoculation. Accordingly, the total Zn accumulation in both brown rice and polished rice increased by 50.9−54.4% and 39.4−41.8%, as the result of endophytic inoculation of SaMR12 and SaCS20, respectively. Due to the elevated biomass, Zn accumulation in plant tissues (stems, leaves, flag leaf) was also significantly improved by inoculation with the two endophytic strains, although no variation of Zn concentrations was observed for leaves and stems (Table 3).

Alteration of Rhizosphere Zn by SaMR12/SaCS20 Inoculation. The impacts of SaMR12 and SaCS20 on soil pH and rhizosphere Zn were analyzed for rice cultured in pot experiments. Bacterial inoculation did not change soil pH in the rhizosphere zone cultured with rice plants (Figure 6A). However, in the presence of SaMR12 or SaCS20, rhizosphere soils contained a higher concentration of DTPA-Zn by 10.4−20.6% compared with the controls (Figure 6B).

To further investigate the impacts of endophytic bacterial inoculation on rhizosphere Zn of rice, microscanning XRF mapping of elemental distributions was performed on rice roots and rhizosphere soil nearby with or without SaMR12 inoculation. The integrated intensity for Zn was calculated from the spectrum and normalized by the intensity of the Compton scattering peak. Elemental mapping for the measurement area was obtained from the normalized intensity for the element. The elemental distribution maps of Zn in the scanned area of rhizosphere zone are presented in Figure 7, together with photographs taken using an optical microscope. The XRF maps indicate the relative distribution of Zn, and the normalized X-ray fluorescence intensities are scaled from red (maximum, 1000 counts s^{-1}) to purple (minimum, 0 counts s^{-1}). The XRF image of the controls (Figure 7A) revealed that Zn intensities were very low in the rhizosphere zone nearby the rice roots, while higher intensities of Zn were observed in both roots of rice and their adjacent rhizosphere zone with inoculation with SaMR12 at 30 DAI (Figure 7B). On the basis of the intensity of Zn signal (Figure 7B), the concentration of Zn in the rhizosphere zone in presence of

SaMR12 was likely to be many times higher than that of the controls.

DISCUSSION

Plant growth-promoting rhizobacteria (PGPR) are beneficial bacteria that colonize the rhizosphere and contribute to enhanced plant growth and yield of crop plants.[30] The most important characteristic of PGPR is the ability to colonize the roots of host plants.[31] Different plant hosts have different ability for the stains to be colonized.[32] The present study clearly showed successful colonization of endophytic microbial isolates from the Zn hyperaccumulator *S. alfredii*,[23] resulting in significantly plant growth promotion of rice plants (Figures 1 and 2). It has been reported that the survival of PGPR in soil was greatly influenced by external parameters including water content, pH, soil type, composition of root exudates, and other microorganisms;[33] their survival and colonization in soils are still doubtful even if the microbe could colonize the host plants in hydroponic conditions. Here we also clarified by pot experiments that the isolated endophytic strains from *S. alfredii* could succeed in surviving in paddy soils and colonize rice root cortical intercellular spaces (Figure 5). These results suggested that these endophytic microbial strains isolated from *S. alfredii* had a significant effect on plant growth promotion either under hydroponic or soil conditions.

Recent investigation on PGPR suggests its promotion of growth by a wide variety of mechanisms, including phytohormone production, rhizosphere engineering, phosphate solubilization, etc.[13,16] The main characteristic of PGPR is to promote the growth of plant roots, and this is confirmed by the bacteria-improved root morphology and enhanced root hair production in this study (Figure 2; Table 1). Most commonly, endophytic bacteria synthesize IAA to promote root growth and root length.[34] Zhang et al.[23] suggested that bacterial IAA production was likely involved in the plant-promoting effects on *S. alfredii* in hydroponic culture. IAA production of the endophytic microbes ranged from 0.51 to 82.99 μg mL^{-1},[24] with higher IAA production observed for SaMR12 and SaCS20. Although not determined in this study, it is possible that IAA production may be responsible for the enhanced plant growth of rice induced by SaMR12 and SaCS20 inoculation.

Distiguished from normal PGPR, endophytic microbial strains applied in this study were isolated from a Zn hyperaccumualtor *S. alfredii*, which has an extraordinary ability to take up Zn from soils and accumulate large amounts of Zn in its aerial parts.[21,22] The endophytic microbial strains were able to increase Zn accumulation in plants of their original host *S. alfredii*.[23] It is therefore not surprising that inoculation of the endophytic microbial strains (SaMR12 and SaCS20) to rice plants not only resulted in promotion of plant growth and grain yields (Table 2) but also elevated Zn densities in rice grains (Table 3). Reduced yield and low harvest index resulting from increased mineral concentrations in the edible parts is a general problem for micronutrient biofortification of crops.[35] The positive responses of both rice grains yields and Zn densities

dx.doi.org/10.1021/jf404152u | J. Agric. Food Chem. 2014, 62, 1783−1791

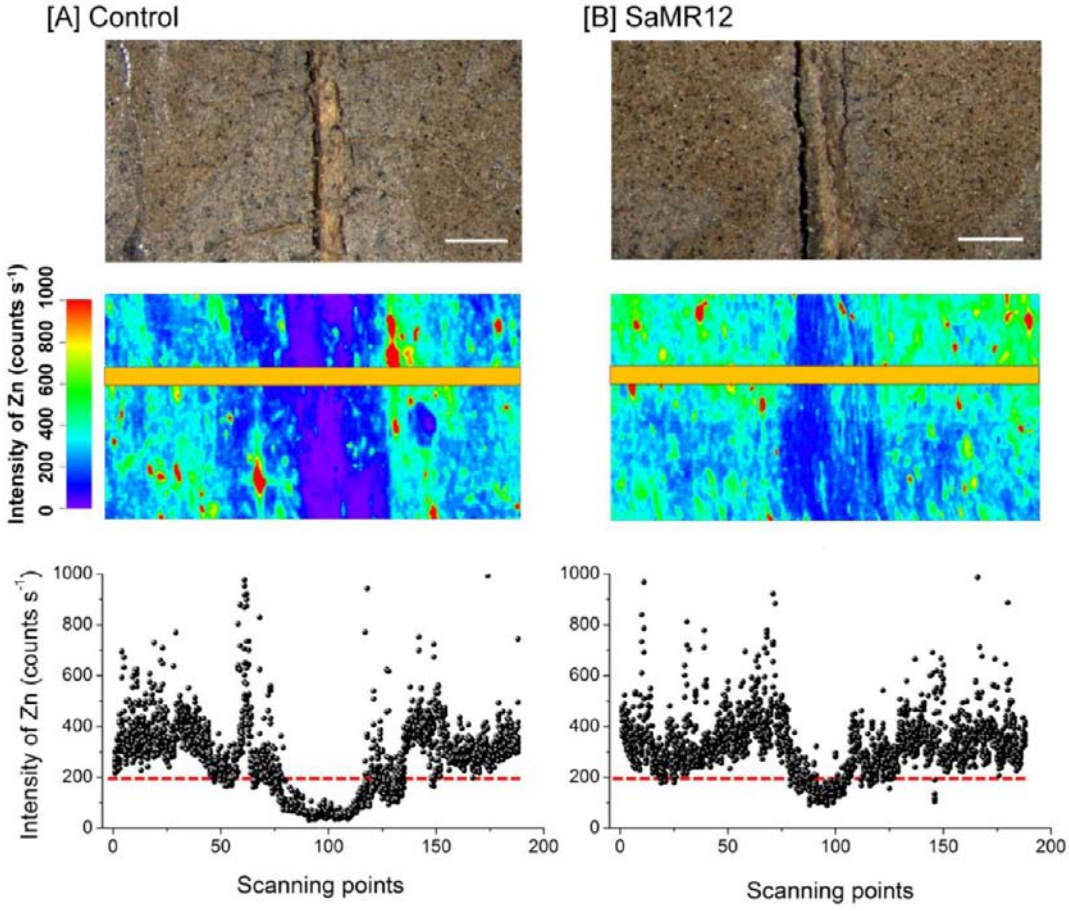

Figure 7. μ-XRF elemental maps for Zn of rice root and rhizosphere soil treated with control (A) and SaMR12 strain inoculation (B) for 30 DAI.

with SaMR12 and SaCS20 inoculation suggested that application of the endophytes could be an efficient strategy for Zn biofortification in rice grains. Millions of hectares of cropland are affected by Zn deficiency, and approximately one-third of the human population suffers from an inadequate intake of Zn.[36] To the best of our knowledge, the present study for the first time reported the potential use of endophytes isolated from hyperaccumulators on Zn biofortification of rice plants.

The possible mechanisms involved in the enhanced Zn accumulation in rice by endophytic inoculation, however, are not well-known. The results in the present study suggested modulation of root morphology might be one of the strategies involved in endophyte-enhanced metal uptake and accumulation in rice plants. In nutrient efficiency conditions, roots play the most important role in nutrient acquisition;[37] root morphology (length, surface, volume, and diameter) are of key importance for acquisition of nutrients. In hydroponic experiments, in the presence of endophytic bacteria, root length, surface, volume, and diameter of rice roots were significantly increased (Table 1; Figure 3). The enhancement of root morphology with endophytic inoculation might result in higher Zn uptake by rice plants. Another possible mechanism for enhanced Zn accumulation in rice plants is the alteration of rhizosphere Zn under soil conditions. Biofortification of Zn for food crops is largely dependent on the size of plant-available Zn pools in soil.[7] DTPA-Zn is regarded as a mixture of both mobile and potentially mobilizable species and represented the pool of bioavailable Zn in soils. The inoculation of endophytic bacteria increased the root surface area (Table 1) and DTPA-Zn content in the rhizosphere soil (Figure 6), the same as reported by Orhan et al.,[38] further facilitating Zn acquisition by the plants (Table 3). The XRF images (Figure7) further confirmed higher intensities of Zn observed in both roots of rice and their adjacent rhizosphere zone after inoculation of SaMR12 for 30 DAI, compared with the controls. The alteration of rhizosphere Zn was not due to the soil acidification since soil pH did not changed with inoculation of the endophytes.

In conclusion, the present study suggest that colonization with the endophytic microbial isolates from hyperaccumulators to rice plants could result in improved root morphology and plant growth, increased Zn bioavailability in rhizosphere soils, and elevated grain yields and Zn densities in both brown rice and polished rice, thus providing a potential strategy for Zn biofortification of rice grains.

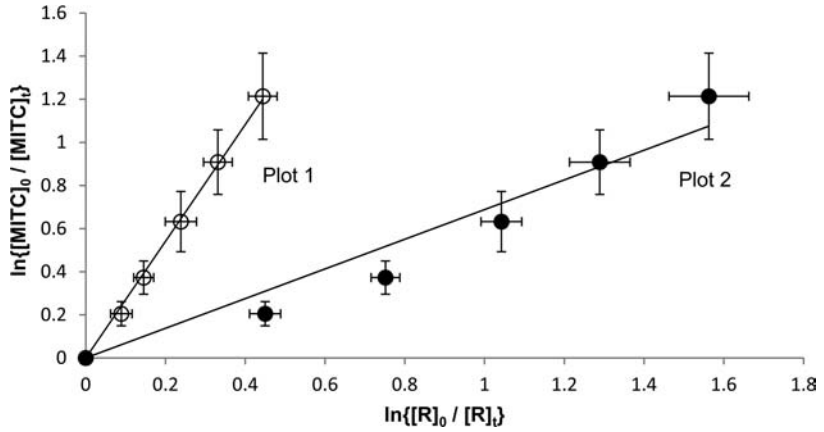

Figure 1. Plots of eq 5 for MITC using toluene (plot 1) and *m*-xylene (plot 2) as reference chemicals.

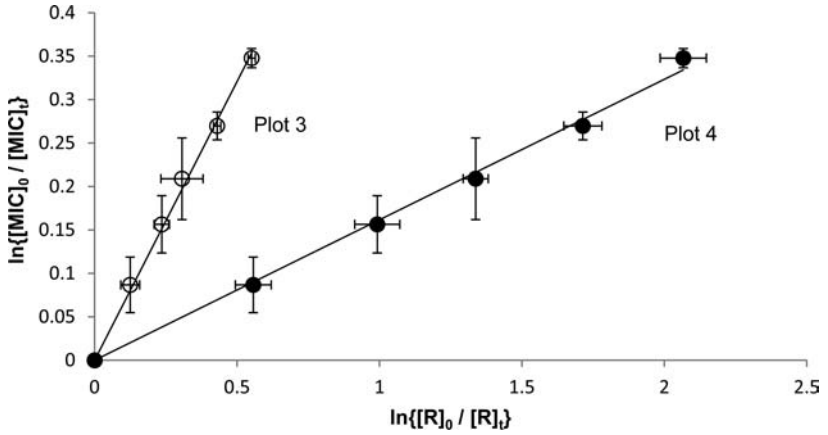

Figure 2. Plots of eq 5 for MIC using toluene (plot 3) and *m*-xylene (plot 4) as reference chemicals.

$$-\frac{d[T]}{dt} = k_1[OH][T] \quad (1)$$

$$-\frac{d[R]}{dt} = k_2[OH][R] \quad (2)$$

where k_1 and k_2 refer to the OH radical rate constants of the test compound and the reference chemical, respectively. Integrations can be made to both sides of eqs 1 and 2:

$$\int_0^c \left\{\frac{d[T]}{[T]}\right\} = -k_1[OH]\int_0^t dt \quad (3)$$

$$\int_0^c \left\{\frac{d[R]}{[R]}\right\} = -k_2[OH]\int_0^t dt \quad (4)$$

Finally, eq 5 is derived from the combination of eqs 3 and 4:

$$\ln\left\{\frac{[T]_0}{[T]_t}\right\} = \frac{k_1}{k_2}\ln\left\{\frac{[R]_0}{[R]_t}\right\} \quad (5)$$

where $[T]_0$ and $[R]_0$ refer to the concentrations of the test compound and the reference chemical at the beginning time of the experiment, t = 0, respectively; $[T]_t$ and $[R]_t$ are their concentrations measured at each time point as the experiment proceeds. A plot of $\ln\{[T]_0/[T]_t\}$ versus $\ln\{[R]_0/[R]_t\}$ will yield a straight line with a slope of k_1/k_2, assuming that there are no other reactions occurring.

Rate Constant Determination. The test procedures were performed in a 100 L Tedlar bag (SKC, Inc., Eighty Four, PA) with the irradiation of 9 Q-PANEL UVA-351 lamps (Q-LAB, Co., Westlake, OH). A fan was used to provide a stream of air to eliminate heating caused by the irradiation, and a temperature of 293 ± 2 K was measured around the bag. Carbon tetrachloride (CCl_4) was added as a stable tracer to demonstrate that the OH radical reaction is the predominant reaction causing the loss of the reactants in the bag. Certain amounts of CH_3ONO, CCl_4, MITC or MIC, toluene, and *m*-xylene were first injected into a glass gas sampling tube using a gastight syringe. The contents of the gas sampling tube were then passed into the Tedlar bag using a constant stream of air, which carried the volatile compounds into the bag until 90 L of air was added. The initial concentrations of each component in the bag were as follows: CH_3ONO, ∼400 ppm; MITC or MIC, ∼20 ppm; CCl_4, ∼20 ppm, toluene and *m*-xylene, ∼20 ppm.

The bag was first placed in the dark irradiation chamber for 1 h, which allowed each volatile compound to mix thoroughly. The loss of each substance in the irradiated bag was determined by sampling the bag every 10 min using a Supelco solid-phase microextraction (SPME) fiber (75 μm CAR/PDMS, Sigma−Aldrich Co. LLC.). The SPME sampling was performed for 30 s followed by 10 s desorption onto the inlet of a Hewlett−Packard 6890-5972 gas chromatography−mass spectrometry (GC-MS) system (Agilent Technologies, Inc., Santa Clara, CA) equipped with a 30 m × 0.25 mm DB-624 capillary column (Agilent Technologies). The oven temperature of the gas chromatograph was first held at 70 °C for 0.5 min; then, the temperature ramped from 70 to 150 °C at a rate of 15 °C/min. The mass spectrometer was operated in the selected ion monitoring (SIM) mode to screen mass-to-charge ratios (m/z) of 72 for MITC, 57 for MIC, 91 for toluene, 106 for *m*-xylene, and 117 for CCl_4. The MITC−OH and MIC−OH reaction experiments were replicated three times, respectively.

Conversion of MITC to MIC. A solution was prepared by dissolving the same mass of MITC and MIC in *o*-xylene. The solution was then analyzed by GC-MS to yield the peak area ratio of MITC to MIC.

dx.doi.org/10.1021/jf404526t | J. Agric. Food Chem. 2014, 62, 1792−1795

RESULTS AND DISCUSSION

OH Radical Reaction Rate Constants of MITC and MIC. Samples taken and analyzed using GC-MS every 15 min for 1 h in the dark indicated that there was no significant loss of either the test compound or the reference chemicals in the Tedlar bag during this period.

When the lamps were turned on, about 50% of the initial concentration of *m*-xylene was observed to be lost within 10 min, consistent with an observation of Biermann and co-workers.[11] As discussed in this previous study, a series of complex photoreactions induced by a small amount of impurity in CH_3ONO added could be one possible reason accounting for this phenomenon.[11] Thus, for these experiments, the samples taken at 10 min after turning on the lamps were used as the time 0 samples, since samples taken earlier showed a high level of inconsistency.

Concentrations of the test compound and the reference chemicals obtained from each sampling time point during the 1 h irradiation period were plotted based on eq 5 with standard deviations from three replications (Figures 1 and 2). Relevant index of the plots is shown in Table 1.

Table 1. Index of MITC and MIC OH Radical Reaction Data Plots

plots of eq 5	reference chemical	equation	R^2
plot 1	toluene	$y = 2.71x$	0.998
plot 2	*m*-xylene	$y = 0.688x$	0.943
plot 3	toluene	$y = 0.641x$	0.996
plot 4	*m*-xylene	$y = 0.162x$	0.996

A consistent, but small curvilinear response was observed for MITC, but not for MIC, when *m*-xylene was used as the reference chemical (see Figure 1), suggesting that some additional mechanism for loss of MITC exists, in addition to reaction with OH radicals. Previous research has indicated that MITC does undergo direct photolysis, although the photochemical reaction is slower than the OH radical reaction.[12] The reason for the observed lack of linearity may be due to a small contribution from direct photolysis, since while the lamps have a maximum emission at 351 nm, this is a broad band emission and emits light of shorter wavelengths. The relatively greater loss of MITC in those plots is consistent with this suggestion.

OH radical rate constants of 5.48×10^{-12} cm^3 molecule^{-1} s^{-1} for toluene and 23.0×10^{-12} cm^3 molecule^{-1} s^{-1} for *m*-xylene reported by Atkinson were used in this study.[13] Thus, according to eq 5, multiplying the slope of a linear plot by the rate constant of its corresponding reference chemical gives the OH radical rate constant of MITC and/or MIC (Table 2).

For determining the rate of loss of chemicals in the atmosphere from OH radical reactions, the concentration of OH radicals is required. Since the OH radical concentration varies at different times in a day, an average concentration of 8.0×10^5 molecules cm^{-3} is commonly utilized for estimating the rate of OH radical reactions.[5] The calculated half-lives of MITC and MIC using this average concentration are shown in Table 3.

Photolysis is also observed when MITC is exposed to midsummer sunlight, with a half-life on the order of 30 h of continuous exposure (including nighttime).[12] While direct comparisons using these results are only approximate, the results of the previous study on photolysis of MITC and the present study indicate that OH radical reactions are about twice as important as direct photolysis for transformation of MITC. MIC was also observed during the photolysis reactions, although it presumably went through a photochemically produced intermediate, methyl isocyanide, which was then oxidized to MIC.[14] The possibility that the OH radical was created during the direct photolysis studies also cannot be excluded.

Table 2. OH Radical Reaction Rate Constants of MITC and MIC

test compd	reference chemical	k_1/k_2[a]	k_1 ($\times 10^{-12}$ cm^3 molecule^{-1} s^{-1})	k_1 ($\times 10^{-12}$ cm^3 molecule^{-1} s^{-1})[b]

test compd	half-life (h)[a]
MITC	15.6
MIC	66.5

[a]Half-lives calculated by using the average OH radical rate constants in Table 2 and an average OH radical concentration of 8.0×10^5 molecules cm^{-3}.

Molar Conversion Ratio of MITC to MIC. At the same weight per volume concentration, the GC peak area ratio of MITC to MIC was determined to be 1.98 to 1. The calculated disappearance rate of MIC in the first 30 min of the irradiation of the MIC−OH reaction was approximately 14%. Since the MIC formed in the MITC−OH reaction also reacts with OH radicals to degrade at the same time, a correction of 14% should be made to the increased peak area of MIC measured during the first 30 min irradiation period of MITC−OH reaction. Thus, molar conversion ratio of MITC to MIC can be calculated by combining their peak area ratio, molecular weights (M_r) and the changed peak area (ΔA_{peak}) of MITC and MIC obtained in the first 30 min of the irradiation, respectively:

$$\text{Molar conversion ratio} = \frac{\Delta A_{peak(MIC)} \times (1 + 14\%) \times 1.98}{\Delta A_{peak(MITC)}} \cdot \frac{M_{r(MITC)}}{M_{r(MIC)}} \quad (6)$$

Finally, a molar conversion ratio of MITC to MIC during the first 30 min irradiation period of the MITC−OH reaction is estimated to be 67% ± 8% based on eq 6, indicating that MIC is a primary product of MITC in the OH radical reaction.

OH radical reaction rate constants measured in this work are 15.36×10^{-12} cm^3 molecule^{-1} s^{-1} for MITC and 3.62×10^{-12} cm^3 molecule^{-1} s^{-1} for MIC. The result of MITC is comparable to that of the former work done by Sommerlade, employing a smog chamber−mass spectrometer system.[5] Results obtained in this work demonstrate that MIC is a primary transformation product of MITC and it disappears approximately 4 times slower than MITC in the presence of OH radicals. Due to the large consumption of metam sodium in U.S. agriculture[1] and the important health concern of MIC,[9] this study will provide useful information for the exposure assessments for use of the

dx.doi.org/10.1021/jf404526t | J. Agric. Food Chem. 2014, 62, 1792−1795

fumigant metam sodium and other pesticides in which MITC serves as the active fumigant.

deaminates cytosine in single-stranded DNA are known to restrict HIV infection through deamination induced mutational inactivation.[16] A similar enzyme APOBEC3C (A3C) is known to restrict herpes viruses in mammalian cells.[17] APOBEC1 is known to initiate diversity in gene expression by deaminating dC to dU on single-stranded DNA and RNA.[18]

There are very limited reports on DCDs of terrestrial plants available so far and therefore in order to find out the prospective of their application, it is important to characterize the biochemical and functional properties of plant DCDs as studied in their mammalian counterpart. In this study, recombinant BoDCD was cloned and expressed in an *Escherichia coli* host system and the ability of the recombinant BoDCD to confer host resistance against cytarabine, a dC analog, was determined. The enzyme was further purified to homogeneity and characterized for their kinetic and physiological properties. Characteristics of BoDCD gives a novel insight on the functions of plant DCDs as it is the only resistance related DCD in plants reported and characterized so far.

MATERIALS AND METHODS

All the chemicals were purchased from Sigma-Aldrich (St. Louis, MO) unless stated otherwise.

Bacterial Strain and Growth Media. The *E. coli* Rosetta DE3 (provided by Dr. Ruey-Yi Chang, National Dong Hwa University, Taiwan) cells with recombinant and nonrecombinant PCR 2.1 plasmid were cultured in Luria−Bertani media containing 50 mg mL^{-1} kanamycin sulfate.

Cloning of BoDCD mRNA. The BoDCD was induced in *B. oleracea* plants and the BoDCD cDNA was amplified as described previously.[10] The primers used were 5′-GAATTCATGGAAGAA-GCTAAAGTGGAAGCA-3′ (sense) and 5′-CTCGAGGTATAA-ACGGAACTTCTCCTTGGT-3′ (antisense). The primers were designed from the nucleotide sequence of BoDCD (GenBank accession no. AEX58668). The sense primer contained the recognition sequences for *Eco*RI restriction endonuclease and N-terminal region of the BoDCD, and the antisense primer contained the recognition sequences for *Xho*I restriction endonuclease and the coding sequences of the C-terminal region of BoDCD. The amplified cDNAs were ligated into a PCR 2.1 vector by using the TOPO TA cloning kit (Invitrogen, Carlsbad, CA, USA) and transferred into $CaCl_2$-mediated competent *E. coli* TOP10 cells according to the manufacturer's instructions. The positive BoDCD transformants were screened by PCR, and the PCR 2.1-BoDCD plasmids from them were isolated and sequenced by using the commercial sequencing service from Protech Technology Enterprise Co., Ltd., Taipei, Taiwan (Republic of China).

Construction of Recombinant Expression Vector pET28a-BoDCD. The BoDCD insert from the PCR 2.1-BoDCD vector was collected by double digestion with *Eco*RI and *Xho*I restriction enzymes. The BoDCD fragments obtained (558 + 11 bp) were analyzed with 1.5% agarose gel electrophoresis and recovered with the Qiaquick gel extraction kit (Qiagen, Valencia, CA, USA). Similarly, the expression vector pET28a (+) (5369 bp) was also digested with *Eco*RI and *Xho*I (Promega, Madison, WI, USA), and the linear plasmid was recovered and purified after separating by electrophoresis in a 1% agarose gel. The digested pET28a vector and the BoDCD insert were constructed as a pET28a-BoDCD expression vector by ligating them with T4 DNA ligase (Promega, Annandale, NSW, Australia). The recombinant expression vector construct was transformed into *E. coli* DH5α host, and the positive recombinant clones were further detected by PCR and verified by DNA sequencing.

Induction and Expression of the Recombinant BoDCD. The recombinant BoDCD was overexpressed in *E. coli* Rosetta cells that provide suitable eukaryotic codons to facilitate universal translation. Specifically, screened single colonies of pET28a-BoDCD transformant *E. coli* cells were used for overexpression, and the transformant cells with pET28a plasmid without BoDCD insert were used as a control.

One milliliter of cultured cell suspension was inoculated into a culture flask with 100 mL of LB−kanamycin medium and incubated at 37 °C at 200 rpm until the OD_{600} reached 0.6−0.8. The cells were induced by adding100 μL of 1 M isopropyl-β-D-thiogalactopyranoside (IPTG) and incubated at 28 °C and 150 rpm for 7 h. The cell suspension was then centrifuged at 12000*g* for 10 min to pellet the cells, and the pellet was washed twice with pH 7.4 phosphate-buffered saline (PBS) buffer. The cells were then suspended in 100 μL of protein extraction buffer [50 mM Tris-HCl (pH 7.4), 0.1% (v/v) Tween 20, 1 mM phenylmethanesulfonyl fluoride (PMSF), and 10% glycerol (v/v)] and sonicated on ice using the Microson XL2000 sonicator (Misonix, Farmingdale, NY, USA) at 5 W for 5 min with an intermittent 30 s interval every 30 s. The lysate was then centrifuged for 10 min at 12000*g*, and the soluble and insoluble proteins were respectively isolated from the supernatant and the pellet. The supernatant was loaded to a HisTrap HP 1 mL column (GE Healthcare, Little Chalfont, UK) and purified using an ATKA prime plus FPLC system (GE Healthcare) by eluting with an imidazole linear gradient of 20−500 mM. The eluted protein was desalted by a HiTrap desalting column (GE Healthcare). Purified BoDCD was visualized by Coomassie-stained 12% SDS-PAGE analysis and protein concentration determined using a Bradford Protein Assay Kit (Bio-Rad).

Antibacterial Activity. The agar disk diffusion method was performed to determine the resistance exerted by the BoDCD transformants to cytarabine.[19] One milliliter of culture with 1×10^7 colony-forming units (CFUs) of *E. coli* was plated on the Luria−Bertani agar on which filter papers of 8 mm diameter, blotted with various concentrations of 50 μL of cytarabine, were placed on the middle of the cultured plates. Kanamycin sulfate (50 μg mL^{-1}) disks served as a positive control. After incubation at 30 °C for 24 h, the zone of inhibition around each disk was measured. Experiment was done with triplicates.

DCD Assays. Enzymatic activity was determined spectrophotometrically at 27 °C by following the decrease in absorption at 282 nm.[20] The reaction was performed in 300 μL of 50 mM Tris-HCl, pH 7.5, 50 mM NaCl, 0.2 mM substrate, and the BoDCD enzyme. One enzyme unit is defined as the amount of enzyme that catalyzes the deamination of 1 μM of dC per minute at 27 °C.

Enzyme Characterization. The protein concentration was determined according to the bicinchoninic acid (BCA) method using bovine serum albumin (BSA) as the standard.[21] Optimal temperature (T_{opt}) of the purified BoDCD (1 U) was determined by measuring the activity at different temperatures (from 15 to 45 °C). To determine the optimal pH (pH_{opt}) for the enzyme activity, the activity was measured in 0.5 M phosphate buffer, pH 5−9. K_m and V_{max} values of BoDCD for different substrates (dC, cytidine, and cytarbine) were determined from the initial velocities and substrate concentration. To evaluate the effects of different metal ions, the DCD activity of the purified enzyme was determined in the presence of 1 mM concentrations of different metal ions ($CaCl_2$, $MnCl_2$, $MgCl_2$, $HgCl_2$, $CoCl_2$, $CuCl_2$, $FeCl_3$, KCl, Na-EDTA) in 0.5 M phosphate buffer (pH 7.5).

RESULTS AND DISCUSSION

Enhancement of Resistance to Cytarabine in Transformant *E. coli* Cells. Like the mammalian DCDs, BoDCD also can potentially convert toxic dC analogues into relatively less toxic uridine derivatives and therefore provide resistance to infection-related hypersensitivity in plants.[10,22] To investigate this functional property, BoDCD was characterized for its ability to detoxify cytarabine, a cytosine base with an arabinose sugar, which is known to interfere with DNA synthesis.[23,24] Cytarabine is rapidly converted to cytarabine triphosphate, which damages DNA by incorporating into the DNA during the S phase. Cytarabine also inhibits both polymerase enzymes

and nucleotide reductase enzymes that are essential for DNA synthesis.[24,25]

The ability of an *E. coli* BoDCD transformant to resist cytarabine toxicity was comparatively assessed to find the potential of the recombinant BoDCD to neutralize cytidine analogues (Figure 1). Cytarabine inhibited the growth of

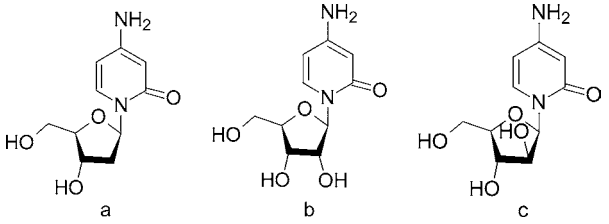

Figure 1. Structures of three substrates of BoDCD: 2′-deoxycytidine (a); cytidine (b); cytarabine (c).

control *E. coli* cells at all tested concentrations. The inhibition was found to increase with increasing concentration, but the transformed colonies were found to be resistant and were protected from the cytarabine toxicity. However, at a higher concentration of 2 μM cytarabine, the BoDCD transformants showed a slight inhibition (Figure 2).

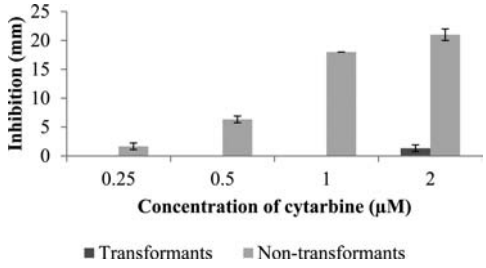

Figure 2. BoDCD mediated resistance to cytarabine toxicity and bacteriostatic effect of cytarabine on the BoDCD transformant and the control *E. coli*. Error bars indicate standard error of the mean (n = 3).

Catalytic Activity of the Recombinant BoDCD. To find the substrate specificity of BoDCD, the enzyme was overexpressed and purified as a C-terminal His-tagged soluble fusion protein, and its catalytic properties were determined. The size of the fusion protein (191 amino acid length) was determined as 20.8 kDa on the basis of 10% SDS-PAGE analysis (Figure 3). The theoretical mass of the native BoDCD without the His-tag was calculated as 20.01 kDa. The specific activity of BoDCD in the soluble portion of the total extract for its natural substrate dC was 54.6 U mg^{-1}, and that of the purified enzyme (96.6% yield) was 61 U mg^{-1} (Table 1).

Kinetic Parameters and Catalytic Properties of BoDCD. Although there are only a few reports on the characterization of plant DCDs so far, reports on plant cytidine deaminase (EC 3.5.4.5, CDA), an enzyme with a similar biochemical function, are available. The kinetic parameters of plant CDAs have been determined and reported previously. K_m and V_{max} of a previously known *Arabidopsis thaliana* CDA for dC have been reported as 49.3 and 24.4 μM, respectively.[26] CDA also deaminates known cytidine analogues such as cytarabine, 5-azacytidine, and 5-methylcytidine that are formed as a product of lipoxidation and targets nucleosides and dsDNA, causing severe damage to the DNA.[20] The substrate specificity and the kinetic properties show that BoDCD is

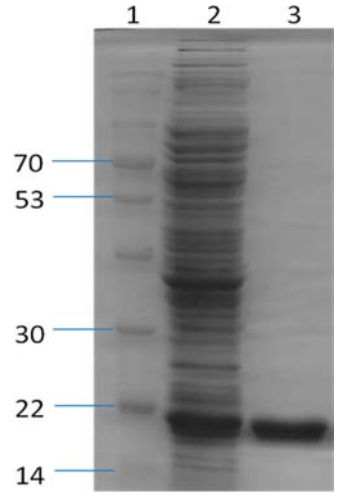

Figure 3. SDS-PAGE analysis of the overexpressed and purified recombinant BoDCD. An aliquot of sample containing 20 μg of protein was loaded for separation. Lanes: 1, molecular weight markers; 2, total soluble proteins from bacterial lysate after overexpression; 3, purified recombinant BoDCD.

Table 1. Purification of Recombinant *B. oleracea* Deoxycytidine Deaminase

purification step	total protein (mg)	total activity (U)[a]	specific activity (U mg^{-1})[a]	yield (%)
soluble lysate	30	1639	54.6	100
affinity column	26	1583.5	61	96.6%

[a]One enzyme unit (U) is defined as the amount of enzyme that catalyzes the deamination of 1 μM 2′-deoxycytidine (dC) min^{-1} at 27 °C.

functionally more active in metabolizing dC adducts such as cytarabine and comparatively less effective in deaminating dC to dU in nuclei acids and metabolizing cytidine to uridine for the pyrimidine pool. The conserved functional DCD domain (AA 27−AA 105) of BoDCD is a zinc binding region, which plays a central role in the proposed catalytic mechanism by activating a water molecule to form a hydroxide ion that performs a nucleophilic attack on the substrate. As three-dimensional structures of similar DCDs have not been determined so far, the specific characteristics of the catalytic domain that are responsible for the difference in substrate specificity were not established. However, upon analysis of the structures of all three substrates used, the difference in the functional group at the 2′ carbon and their spatial configurations appear to determine the enzyme−substrate binding and activity.

The K_m and the V_{max} of BoDCD for the substrate dC were detrermined as 91.3 μM and 1.475 mM, respectively; for cytidine the values were 368 μM and 0.599 mM, and for cytarabine the values were 63 μM and 2.072 mM (Table 2). The K_m of cytidine was >3-fold higher and the V_{max} was almost 1.5-fold lower than those of dC, whereas the K_m of cytarabine was almost 0.45 times lower and the V_{max} was 0.4-fold higher than those of dC (Table 2). On the basis of their respective k_{cat}/K_m values, the BoDCD was relatively more active when cytarabine was used as a substrate and was less active with cytidine as the substrate (Table 2). The higher BoDCD activity to cytarabine and dC can be attributed to the close structural

Table 2. Kinetic Parameters and Substrate Specificity of the Recombinant *B. oleracea* Deoxycytidine Deaminase

substrate	K_m (μM)	V_{max} (mM min^{-1})	k_{cat}/K_m (μM S^{-1})
2′-deoxycytidine	91.3 ± 5.6	1.475 ± 0.3	0.342
cytidine	368 ± 18.2	0.599	0.034
cytarabin	63 ± 12.2	2.072 ± 0.2	0.697

similarity of these two substrates. The k_{cat}/K_m values of BoDCD were 0.342, 0.034, and 0.697 μM S^{-1} for dC, cytidine, and cytarabine, respectively. The higher affinity and higher reaction rate of BoDCD to cytarabine, according to the kinetic parameters, suggest that the enzyme binds and metabolizes cytarabine comparatively more swiftly than it binds and metabolizes cytosine. This can be also theoretically interpreted that BoDCD potentially neutralizes cytarabine in less concentration during the early stages of cytarabine accumulation but maintains a higher threshold level before dC and cytidine metabolism. Therefore, BoDCD is more sensitive and active in the detoxification mechanism than dC and cytidine metabolism. Furthermore, although BoDCD can metabolize dC and cytidine, a function contributing to DNA synthesis and expression, the fact that they are known to be induced only during three-way interaction shows that they contribute more during cytotoxic challenges and potentially provide protection by neutralizing dC analogues to protect macromolecules from adducts.[10]

Optimal Conditions for BoDCD Activity. Optimal conditions for the activity of plant CDAs have been determined previously, and their T_{opt} and pH_{opt} ranges were found to vary greatly. At-cda1, a CDA from *A. thaliana*, is found to be active between pH 3.0 and 10.5, beyond which the enzyme was inactive irreversibly.[20] A CDA from *A. thaliana* was found to be active between pH 6 and 11 with a slight maximum at pH 7.5−8. The enzyme was inactive at pH 4.[27] The optimal temperature of the BoDCD was determined as 27 °C. The enzyme activity was found to be inhibited below 25 °C and above 30 °C (Figure 4). BoDCD was highly active at pH 7.5, and the activity

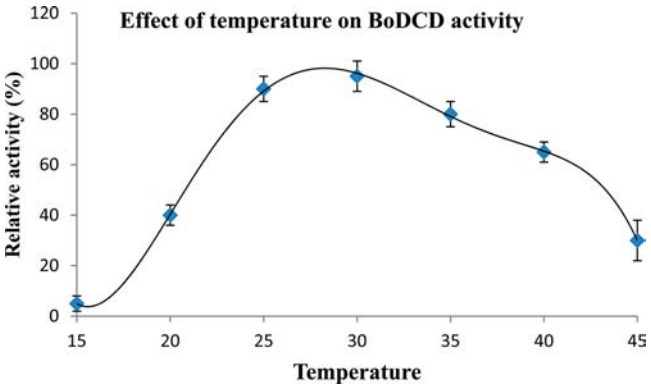

Figure 4. Influence of temperature on the activity of the recombinant BoDCD.

dropped significantly beyond this range (Figure 5). As the normal pH in the cytoplasm of most higher plants is slightly alkaline (7.4−7.5), the pH_{opt} of BoDCD suggests that they are potentially active during normal cytoplasm conditions without proton fluxes.[28] The ability of dC deamination by BoDCD was strongly inhibited in the presence of 1 mM Hg^{2+} and substantially inhibited in the presence of Cu^{2+} and Fe^{3+} ions.

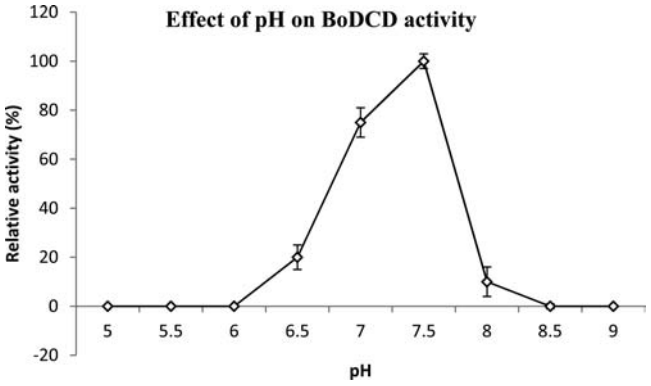

Figure 5. Influence of pH on the activity of the recombinant BoDCD.

This may be due to the presence of thiol groups in amino acids C90, C101, C107, C110, M112, and C113 located in the catalytic motif. All other metal ions relatively inhibited BoDCD activity by 5−30% (Table 3).

Table 3. Effect of Metal Ions on the *B. oleracea* Deoxycytidine Deaminase Activity

metal ion[a]	relative activity (%)	metal ion[a]	relative activity (%)
none	100	EDTA	80
$MnCl_2$	70	KCl	98
$CoCl_2$	85	$MgCl_2$	95
$CuCl_2$	15	$HgCl_2$	0
$CaCl_2$	88	$FeCl_3$	15

[a]Final concentration of the various agents was 1 mM.

The biochemical and physiological functions of plant DCDs were so far not characterized and were considered as the enzymes for pyrimidine metabolism and gene expression diversity. The deduced biochemical property of BoDCD justifies previous evidence on the role of DCD in plant resistance.[10] Enhancement of systemic resistance in plants to pathogens occurs due to two different mechanisms. The systemic acquired resistance (SAR) is mediated by a salicylic acid-dependent pathway and involves the role of pathogenesis-related proteins. SAR develops either locally or systemically according to the pathogen challenged, as a result of a successful infection or a hypersensitive response. The induced systemic resistance (ISR) is a response to colonization of plant roots by certain rhizosphere microorganisms. They are mediated by jasmonic acid/ethylene pathways. The biocontrol agent, *Trichoderma*, is commonly known as an inducer of ISR by root colonization.[29] As BoDCD is an enzyme induced during three-way interaction between *B. oleracea*, *T. harzianum* ETS 323, and *R. solani* that also involves hypersensitivity, the possibility of BoDCD being a cross talk between SAR and ISR is evident.

The functional properties of BoDCD, apart from revealing the antimicrobial potential of BoDCD, show that BoDCD can be used in other possible applications such as in ameliorating the adverse effect of dC analogues during chemotherapy. Normal intestinal florae help to maintain intestinal structure, function, and defense. Cytotoxic chemotherapeutic drugs such as cytarabine are detrimental to such protective florae. When the ecological balance of the intestine is damaged, a lot of bacteria and endotoxin enter into the circulation by the portal system and cause intestinal endotoxemia; under certain

dx.doi.org/10.1021/jf4048513 | J. Agric. Food Chem. 2014, 62, 1796−1801

conditions it can also stimulate a chain reaction of the cytokines and other inflammatory mediators and cause systemic organ damage.[30−34] The DCD enzymes can be effectively used to neutralize the side effects of cytotoxic cytidine adducts that are employed as drugs. As the affinity of BoDCD to cytarabine is greater than to its natural substrate DCD, the enzyme can be potentially considered for providing resistance to intestinal florae against cytidine analogues. Engineered microbes with BoDCD expression can be used as probiotics to counter the effects of cytarabine.[35] Further exploration on BoDCD will reveal interesting insights and applications.

chemical reagents were obtained from Sigma-Aldrich (Milwaukee, WI, USA) with the highest purity available.

Biochar Production. Feedstock property and pyrolysis conditions were described in detail previously.[13,17] Briefly, cottonseed hull (CH25) was used as received from Planters Cotton Oil Mill (Pine Bluff, AK, USA).[13] Broiler litter (BL25) was obtained from a USDA-ARS facility (Starkville, MS, USA) and was milled and pelletized.[17] Feedstock was pyrolyzed at 350, 500, 650, and 800 °C under 1600 mL min^{-1} N_2 flow rate for 1 h (for BL25) or 4 h (for CH25) using a laboratory-scale box furnace (22 L void volume) with a retort (Lindberg, type 51662-HR, Watertown, WI, USA). Biochar products were allowed to cool to room temperature overnight under N_2 atmosphere. Biochars are hereby denoted by the feedstock abbreviation and pyrolysis temperature, for example, cottonseed hull feedstock (CH25) and biochars produced at 350 (CH350) and 500 °C (CH500).

Extraction Procedures. To understand the solubility of different phosphorus species, each biochar sample was exposed to increasingly more rigorous extraction procedures (abbreviations in parentheses will be used throughout the text): DDW (water), Mehlich 3 (M3), basic EDTA (NaOH−EDTA), acidic ammonium oxalate (oxalate), and microwave digestion (total). Each extraction was performed independently, rather than sequentially. At the end of each extraction procedure, filtrate was acidified to 4 vol % nitric acid (trace metal grade, Sigma-Aldrich) for the determination of soluble P, K, Ca, Mg, Al, Fe, and Na concentrations using inductively coupled plasma atomic emission spectrometer (ICP-AES; Profile Plus, Teledyne/Leeman Laboratories, Hudson, NH, USA). Blanks, blank spikes, and matrix spikes were included for the quality assurance and control for the ICP-AES analysis.[18]

Except for sizing, all biochars were extracted without modifications. For M3, oxalate, and water extractions, biochars were ground and sieved to <2 mm. Total and NaOH−EDTA extractions employed 44 μm (325 mesh) sized biochars corresponding to the silt fraction (0.002−0.05 mm) having higher surface area and reactivity than the larger fractions.[2]

Water extracts were obtained by shaking 0.5 g of biochar in 30 mL of DDW end-over-end for 16 h at room temperature. The suspension was then centrifuged at 10000*g* for 15 min and vacuum filtered (0.45 μm Millipore filter paper; Millipore, Billerica, MA, USA). Mehlich 3 extraction followed the literature protocol.[19] Briefly, 2.5 mL of 2 mm sieved sample was extracted in 25 mL of 1 mM EDTA extraction fluid at pH 2.5 (0.2 M acetic acid + 0.25 M ammonium nitrate + 0.015 M ammonium fluoride + 0.13 M nitric acid + 0.001 M EDTA) for 5 min and then filtered through Whatman no. 2 filter paper. The Mehlich 3 method[19] determines extractable P on the sample volume, rather than the weight basis. To convert P concentration to units of milligrams per gram biochar, the density of biochar was determined by weighing dry biochar sample packed in a 2.5 mL volumetric flask. Acid ammonium oxalate extraction followed the literature procedure.[20] Briefly, 0.5 g of sample was shaken in 25 mL of 0.2 M ammonium oxalate at pH 3.5 for 4 h in the dark and then centrifuged and 0.45 μm filtered. Total P contents of cottonseed hull feedstock and biochars were determined by microwave-assisted (Ethos EZ microwave digester, Milestone, Inc., Shelton, CT, USA) digestion (concentrated HNO_3/HCl + 30% H_2O_2) following U.S. EPA method 3052;[21] values for broiler litter samples were obtained from the literature.[14] Electric conductivity (EC), pH, and total organic carbon (TOC) of 16 h hot (80 °C) water extracts[12] and proximate analysis[13,14] results were obtained from the literature.

^{31}P NMR Analysis. For each feedstock and biochar, 5 g of sample was shaken in 250 mM NaOH + 5 mM EDTA for 16 h and then centrifuged at 900*g* for 30 min and filtered through Whatman no. 42 filter paper.[22] An aliquot was kept for P concentration measurement by ICP-AES. To concentrate samples for the ^{31}P NMR analysis,[22] remaining filtrate was freeze-dried. The NMR sample was obtained by dissolving 100 mg of freeze-dried sample in 0.6 mL of 1 M NaOH in 10% D_2O. As described in detail previously,[7] ^{31}P NMR spectra were obtained using an Alpha 600 FT NMR spectrometer (JEOL, Tokyo, Japan) with a 5 mm probe. Spectra were recorded at 242.85 MHz using a pulse width of 10.00 μs (90°), an acquisition time of 0.4522 s, and broadband proton decoupling at 30 °C. The pulse delay time of 2 s was employed.[23] Each spectrum was scanned 30000 times, and a broadening factor of 5.00 Hz was used in the Fourier transform procedure. Chemical shifts (ppm) were determined with respect to 85% H_3PO_4 solution (0 ppm). The total signal intensity and the fraction contributed by each P compound were calculated by integration of the spectral signals using Alice 2 for Windows version 5.1.1 (JEOL).

RESULTS AND DISCUSSION

Soluble Phosphorus Content of Plant and Manure Biochars. To highlight the contrasting properties of plant (cottonseed hull; CH) and manure (broiler litter; BL) biochars employed in this study, Table 1 presents the pH, electric conductivity (EC), and total organic carbon (TOC) of 16 h hot (80 °C) water extracts at biochar/DDW (w/w) = 1:10;[12] ash, fixed carbon, volatile matter (VM), and moisture contents;[13,14] and density of feedstocks (CH25 and BL25) and biochars pyrolyzed at 350, 500, 650, and 800 °C. Manure biochars contained higher water-soluble inorganic salts (EC) as well as organic carbon (TOC) than plant biochars. Table 1 also presents total (microwave digestion in concentrated HNO_3/HCl + 30% H_2O_2), NaOH−EDTA (250 mM NaOH + 5 mM EDTA for 16 h), oxalate (200 mM oxalate at pH 3.5 for 4 h), M3 (1 mM EDTA at pH 2.5 for 5 min), and water-extractable (16 h at room temperature) P concentrations in milligrams per kilogram biochar on a dry weight basis. Values in parentheses provide percent extractable P (relative to total by microwave digestion) in NaOH−EDTA, oxalate, M3, and water extracts. Phosphorus-containing compounds vaporize near 760 °C.[24] Progressive increase in total P content of BL and CH biochars (Table 1) indicates that temperature-induced condensation of P on the solid biochar product outweighed the volatilization loss at pyrolysis temperatures as high as 800 °C. The "ash" component of biochar is a complex mixture of amorphous, semicrystalline, and crystalline inorganic phases as well as organic (char) components.[25] These ash components may be originally present in the manure feedstock or thermochemically produced. Common phosphorus minerals in biomass are calicum, iron, potassium, and magnesium phosphates.[26] Thermal treatment of biomass produces silicates, carbonates, halides, phosphates, sulfates, oxides, and hydroxides.[27] The organic carbon fraction of biochar likely stabilizes these inorganic phases by various organomineral interactions, for example, by serving as a template for the formation of nanocrystals during pyrolysis.[28] Limited solubility of P and Ca in 500 °C manure and food waste biochars was attributed to whitlockite ($(Ca,Mg)_3(PO_4)_2$).[29] More soluble struvite ($MgNH_4PO_4{\cdot}6H_2O$) was observed by XRD analysis of biochars produced from a mixture of cattle manure and wood chips.[30]

In Table 1, compared to the total (microwave digestible) P, percent extractable P of plant (CH) biochars increased in the following order (except for disproportionately high oxalate-extractable P of CH25): M3 < oxalate ≈ water < NaOH−EDTA. The following order was observed for manure (BL) biochars: water < M3 < NaOH−EDTA < oxalate. Of five extraction methods, total, oxalate, and M3 employed strongly acidic conditions (pH ≤3.5), whereas NaOH−EDTA solution was strongly basic. The pH of water extracts depended on the pH of biochar (Table 1). Especially for BL biochars, negligible P in water extract at ≥650 °C likely resulted from high pH in the absence of chelating agents. For the M3 extracts, low P concentrations likely resulted from the short (5 min) extraction

[a]Soluble phosphorus concentrations determined by different extraction procedures: total (by microwave digestion), NaOH-EDTA, oxalate, Mehlich 3 (M3), and water; values in parentheses are % extractable P (relative to total by microwave digestion) in NaOH-EDTA, oxalate, M3, and water extracts. [b]References 13 and 14. [c]Refereence 12. [d]Mean for triplicate (SD < 0.09 g L^{-1}). [e]Reference 14 for BL samples. [f]Mean for duplicate.

period, as observed previously.[31] For different extraction procedures, a greater degree of carbonization often leads to lower concentrations of labile P species. For example, Mehlich I (50 mM HCl + 12.5 mM H_2SO_4 for 5 min) P values were similar for 400 and 500 °C poultry litter biochars and decreased after steam activation of these biochars.[32] Pyrolysis at 450 °C decreased the water-soluble P fraction of sewage sludge from >60 to <20%.[8] Calcium-bound P phases (HCl-extractable) increased to >30% in the char fraction, whereas Fe/Al-bound fractions (NaOH extractable) did not change significantly.[8] In a separate study, nearly an order of magnitude greater Colwell (8.5 sodium bicarbonate) P content was observed in 450 °C poultry litter biochar than in the steam-activated 550 °C biochar.[33]

Distinctive feedstock and temperature dependence was observable for oxalate and NaOH−EDTA extractions in Table 1. Especially at ≥650 °C, oxalate was nearly as effective as microwave digestion for extracting P from manure biochars, but not from plant biochars. On the other hand, NaOH−EDTA was particularly effective for dissolving P in 350−500 °C plant biochars (Table 1). Table S1 of the Supporting Information provides stability constants for the 1:1 complex of oxalate, EDTA, and phosphate with Ca^{2+}, Fe^{3+}, and other selected cations.[34] EDTA has far greater stability constants for Ca^{2+}, Fe^{3+}, and other phosphate-binding metals than oxalate (Table S1). Greater P solubility of 350−500 °C plant biochars in NaOH−EDTA indicates the dominance of P species that are strongly interacting with the organic C fraction of biochar and/or associated with iron/aluminum hydroxides and other mineral surfaces and are resistant to acid dissolution. For manure biochars, greater P dissolution in acidic media containing weaker ligand (oxalate) suggests the acid dissolution of calcium phosphate phases. Oxalate is able to release P from calcium phosphate phases by forming insoluble calcium oxalate[35] having the solubility product constant (K_{SO}) of $10^{-8.75}$.[34] For both manure and plant biochars, Ca concentration in NaOH−EDTA was consistently higher than in oxalate extracts (Table S2, Supporting Information). Lower Ca concentration in the oxalate extract was set by the K_{SO} of calcium oxalate.

^{31}P NMR Analysis of Plant and Manure Biochar Extracts. To understand the individual P species contributing to extractable P concentrations in Table 1, NaOH−EDTA extracts were analyzed using solution-phase ^{31}P NMR. This extraction fluid (0.25 M NaOH + 0.05 M Na_2EDTA) is widely utilized to enhance P extraction from soil while minimizing the hydrolysis of organic P to inorganic P.[1] EDTA is used to release P from paramagnetic ions (see stability constant for Fe in Table S1), thereby decreasing line broadening.[2] To our knowledge, no prior liquid-phase ^{31}P NMR study systematically investigated the feedstock and pyrolysis temperature dependence. Figure 1 presents ^{31}P NMR spectra for manure (left) and plant (right) feedstocks and biochars pyrolyzed at 350, 500, 650, and 800 °C. Spectra for manure biochars (left) indicate the dominance of inorganic orthophosphate (PO_4^{3-} at 6.2 ppm) especially at higher temperatures. In contrast, pyrophosphate ($P_2O_7^{4-}$ at −4.1 ppm) persisted in plant biochars (Figure 1, right). Pyrophosphate is produced by heating orthophosphate above 300 °C.[36]

Figure 2 presents Figure 1 with an expanded *x*-axis to visualize the monoester region (3−7 ppm). Both cottonseed hull and broiler litter feedstocks showed four peaks corresponding to phytate: 5.9 ppm (attributable to the P_2

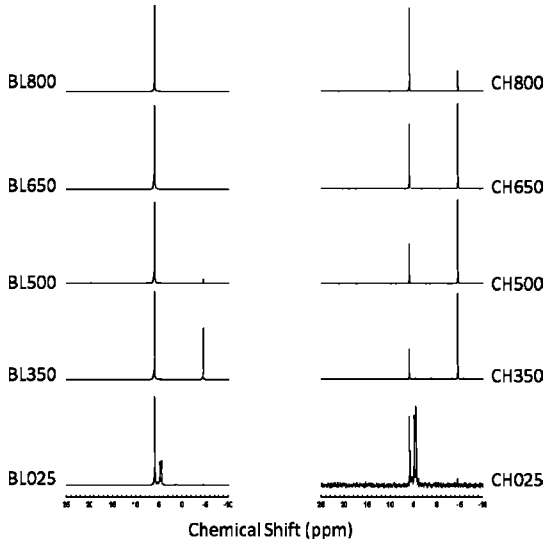

Figure 1. ^{31}P NMR spectra of broiler litter (BL25, left) and cottonseed hull (CH25, right) feedstock and biochar (pyrolyzed at 350, 500, 650, and 800 °C) extracts. Extraction method: 5 g of sample was shaken in 250 mM NaOH + 5 mM EDTA for 16 h. Chemical shifts (ppm) were determined with respect to 85% H_3PO_4 solution (0 ppm).

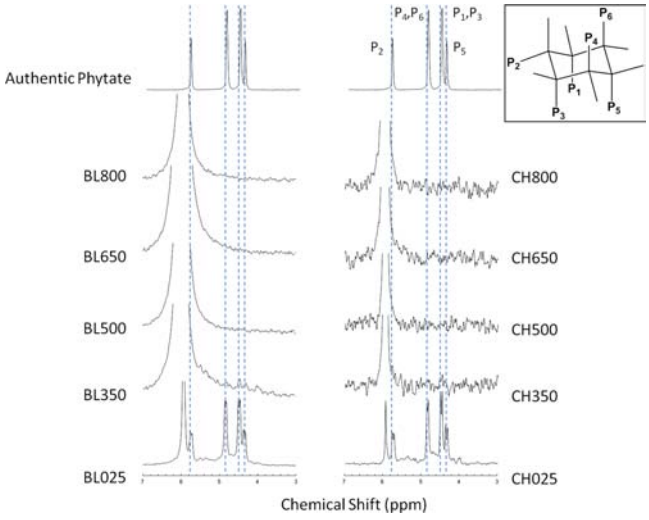

Figure 2. Figure 1 with expanded *x*-axis to visualize the monoester region (3−7 ppm). Top spectra show authentic phytate having 5.9 ppm (attributable to the P_2 position of phytate structure shown), 4.9 ppm (P_4 and P_6), 4.6 ppm (P_1 and P_3), and 4.4 ppm (P_5) peaks.

position of phytate structure in Figure 2), 4.9 ppm (P_4 and P_6), 4.6 ppm (P_1 and P_3), and 4.4 ppm (P_5).[2] An authentic spectrum of phytate is shown in Figure 2 (top) for comparison. Above pH 9.5, phytate exists in a sterically hindered form having one equatorial (P_2 in Figure 2) and five axial positions[37] as shown in Figure 2. The majority of the phytate peaks disappeared upon pyrolysis at ≥350 °C (Figure 2). Additional minor peaks in manure feedstock (BL25) are attributable to diesters: alkali-stable phospholipids and teichoic acid at 0.3−2.1 ppm and DNA at −1.5 to −0.13 ppm in Figure 1.[22,38] Polyphosphate (−20 ppm)[2] was not observable in the spectra showing the entire −30 to 30 ppm region (Figure S1, Supporting Information).

Table 2 presents ^{31}P NMR peak integration results for inorganic (orthophosphate, pyrophosphate, and total inorganic P) and organic P species (phytate, lipids, DNA, and total organic P), based on Figures 1, 2, and S1. The monoester region was integrated as a whole because of well-documented signal overlap at 3−7 ppm.[39] Absolute values in Table 2 are given in milligrams per kilogram biochar on a dry weight basis. These values were calculated by multiplying the fraction of integrated area (with respect to the total area) by total NaOH−EDTA extractable P in Table 1. Values in parentheses represent percent contribution of each P species to the total P extracted by NaOH−EDTA (Table 1). Broiler litter feedstock was dominated by phytate (58%) followed by inorganic orthophosphate (39%). Pyrolysis of broiler litter at 350 °C decreased phytate to 1%, and inorganic orthophosphate (63%) and pyrophosphate (36%) became dominant. Orthophosphate was the only species observable in 500, 650, and 800 °C broiler litter biochars (except for 3% pyrophosphate in BL500). In summary, pyrolysis of broiler litter transformed organic P dominance to inorganic P, and orthophosphate was the sole species at ≥500 °C. Cottonseed hull biochars showed a distinctively different temperature trend from the broiler litter biochars. Cottonseed hull feedstock was primarily (87%) phytate with lower orthophosphate fraction (12%) than BL25. At 350 °C, phytate decreased to zero, and pyrophosphate became the dominant species (71%); orthophosphate (27%) was much lower than BL350. The dominance of pyrophosphate continued until 650 °C: 68% pyrophosphate and 32% orthophosphate at 500 °C; 54% pyrophosphate and 46% orthophosphate at 650 °C (Table 2). Orthophosphate became the dominant species only at the highest temperature (800 °C): 81% orthophosphate and 19% pyrophosphate. In conclusion, EDTA was required to sufficiently dissolve P of plant biochar (Table 1) that was predominantly pyrophosphate (Table 2). The results suggest that pyrophosphate was stabilized by forming complexes with ash components (see stability constants in Table S1) or by interacting with organic C by electrostatic and hydrogen bonding interactions[40] and other organomineral interactions.[28] In contrast, orthophosphate was the dominant soluble P species of manure biochars (Table 2) and almost completely dissolved in acidic ammonium oxalate (Table 1). This observation suggests that soluble P of manure biochar consists of amorphous calcium phosphate, rather than the stable minerals such as apatite.

Literature reviews on the XRD analyses of manure, biochar, and ash indicated the presence of apatite in ashed[41] and gasified[42] manures, but not in the slow-pyrolysis manure biochars[29,30] containing as much as >40% C on a dry weight basis. Removal of organic matter by combustion is likely necessary to thermally form crystalline hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$; OH may be replaced by F or Cl) and other stable calcium phosphate minerals. Calcination (heating in air) and other high-temperature processing are commonly employed to produce crystalline apatite, especially for the synthesis of biomaterials.[43] Thermal stability of apatite is controlled by the Ca/P ratio, degree of substitution by carbonate and other ions, and heating atmosphere.[43] In addition, pyrolysis produces reactive nanometer-sized precipitates on the biochar surface.[42,44] These nanosized crystals can contain P and other nutrient elements that may be released into the aqueous phase in a more controlled fashion.[45,46] Such nanomaterials are reactive sorbents for inorganic (e.g., heavy metals) and organic (e.g., agrochemicals) solutes[44] and will add further complexity to the chemical interactions within rhizospheres that will ultimately influence crop growth.

[a]Separate correlation was observed between the phosphorus species and total, NaOH−EDTA, and water-extractable P concentrations.

Observed predominance of phytate in both plant and manure feedstocks and decomposition at ≥350 °C (Table 2) are in agreement with the reported properties of phytate. Phytic acid forms during ripening of seeds and cereal grains and composes 60−80% of total P in cereals, oilseeds, and legumes.[47] Poorly digestible phytate composes >60% P in swine and poultry (nonruminant) feed.[47] Phytate can hydrolyze in water[1] but is stabilized by forming complexes with metal cations.[48] Compared to phosphate monoesters, diesters are more mobile because of lower charge.[1] Mononucleotides and other monophosphate esters degrade within hours of release, whereas inositol phosphate is stabilized by interacting with iron/aluminum oxides and becomes the major organic P in soil.[49] However, phytate nonenzymatically decomposes at ≥150 °C within an hour.[50] Phytic acid visually darkened at 150 °C and lost C and H at 380 °C.[50]

Orthophosphate can be formed by hydrolysis and thermal degradation of phytate.[24,51] In general, more condensed P in a polyphosphate mixture reacts with water to form less condensed P, for example, from pyrophosphate to orthophosphate.[52] Thermal treatment of orthophosphate in turn forms less soluble polyphosphate species;[51] pyrophosphate is an intermediate species in this process. The 350−650 °C plant biochars were primarily composed of pyrophosphate (Table 2), and polyphosphate was not observed (Figure S1). Subsequent discussions aim to elucidate the mechanisms favoring the formation of pyrophosphate from phytate or orthophosphate during pyrolysis of cottonseed hulls (Table 2).

Polyphosphate is a food additive for meat and dairy products, partly to sequester Ca.[53] When triphosphate-treated cheese spread was cooked, the product became enriched with pyrophosphate.[54] In addition, pyrophosphate was more resistant to hydrolysis than triphosphate.[53] The authors hypothesized that after heat-induced hydrolysis of triphosphate, pyrophosphate product became stabilized by forming complexes with Ca as well as protein in cheese.[54] Similar enrichment of pyrophosphate product was observed when commercial polyphosphate was hydrolyzed by heating without

	total inorganic			X									X

[a]Separate correlation was observed between (i) orthophosphate or total inorganic P in NaOH−EDTA extracts by ^{31}P NMR and (ii) Fe, Ca, Mg, Al, K, or Na in different extracts.

a food product.[53] In addition to pyrophosphate, the formation of trimetaphosphate ring product was catalyzed by Ca^{2+} when commercial polyphosphate was heated at >120 °C.[53]

Pyrophosphate (P_2) can form nonenzymatically at neutral and alkaline pH and room temperature via coupled exergonic hydrolysis of polyphosphate (P_3) and endergonic condensation of orthophosphate (P): $P_3 + P = 2P_2$;[55] this reaction can be catalyzed by Ca^{2+} and other cations. Surface catalysis lowers the temperature at which high-energy phosphoanyhydride bonds can form nonenzymatically between orthophosphate to produce pyrophosphate.[56] Orthophosphate was converted to pyrophosphate on dry SiO_2 and $CaPO_4$ surfaces at 70 °C.[56] Similarly, the surface of cottonseed hull biochars may catalyze the formation of pyrophosphate from orthophosphate (Table 2).

Because water is the product of condensation reaction to form the phosphoric anhydride (P−O−P) bond,[57] drying alone can alter the P speciation.[38,56] Air-drying decreased water-extractable (labile) P in feed by 13−61%, primarily by decreasing orthophosphate.[38] In contrast, drying increased NaOH−EDTA extractable P by as much as 48%[38] In summary, thermal degradation of phytate produces orthophosphate, which thermally converts to pyrophosphate. Pyrophosphate was likely stabilized by forming complexes on the biochar surface and did not convert to polyphosphate. It must be noted that pyrophosphate has an order of magnitude higher water solubility (0.5 M) than phytate (0.07 M; both Na salts) (SciFinder Scholar).

Pearson's Correlation between P Species and Bulk Properties of Biochar. To understand the feedstock- and temperature-dependent origins of different P species, Pearson's correlation was conducted between P species (Table 2) and bulk parameters of biochar samples (Table 1). Table 3 presents parameters that showed positive correlation ($r > 0.878$ for $N = 5$, $p = 0.05$) with orthophosphate, pyrophosphate, total inorganic P, phytate, or total organic P determined by the ^{31}P NMR method: EC, ash, TOC, VM, and moisture. For the plant biochars, (i) orthophosphate correlated with EC; (ii) total inorganic P correlated with EC and ash; and (iii) total organic P correlated with TOC and VM. For the manure biochars, (i) total inorganic P correlated with EC, similarly to the plant biochars; and (ii) both phytate and total organic P correlated with TOC as well as the moisture content. In summary, bulk property for the inorganic component (EC and ash) correlated with inorganic P species. Bulk property for organic carbon (TOC and VM) correlated with organic P species. Hydrophilicity (moisture content) of manure biochars may contribute to the release of organic P species in NaOH−EDTA.

Table 3 shows a separate correlation between (i) the same series of P species in NaOH−EDTA extracts and (ii) total, NaOH−EDTA, and water-extractable P concentrations of plant and manure biochars. Interestingly, most labile (water-extractable) P fraction correlated with the signature P species in each feedstock category: pyrophosphate for plant biochars; phytate and total organic P for manure biochars (Table 3; note that water-extractable P was zero for BL350, 650, and 800 in Table 1). Total P (determined by the most rigorous microwave digestion method) correlated with orthophosphate for both plant and manure biochars. Plant biochars also showed a correlation between the total inorganic P and NaOH−EDTA extractable P (Table 3).

Pearson's Correlation between P and Other Extractable Elements. Phosphorus species are stabilized in aqueous systems by binding Al, Ca, Mg, Fe, and K (Table S1); these elements often dissolve together during extraction procedures.[7] For example, Mg^{2+} may dissolve together with orthophosphate from struvite ($MgNH_4PO_4{\cdot}6H_2O$) in poultry litter.[3] Alum (aluminum sulfate), lime, and iron sulfate are often intentionally added to poultry litter to decrease P runoff.[4] The Ca stability constant for a 1:1 complex increases from 2.66 for orthophosphate, to 8.1 for triphosphate, to approximately 22 for phytate (25 °C and zero ionic strength).[34] In contrast, the stability constant for Ca is similar for different phosphorus species containing one phosphate group: orthophosphate (2.66), $CH_3-O-PO_3^{2-}$ (1.47), and phenyl−O−PO_3^{2-} (1.45) (Table S1).

Table 4 presents observed correlation ($r > 0.878$ for $N = 5$, $p = 0.05$) between P and Fe, Ca, Mg, Al, K, or Na in total, NaOH−EDTA, and oxalate extracts. Overall, total P of broiler litter biochars correlated with total Fe, Ca, Mg, Al, K, and Na. Similarly, oxalate-extractable P correlated with oxalate-extractable Mg, Al, K, and Na of broiler litter biochars. In contrast, no

dx.doi.org/10.1021/jf4053385 | J. Agric. Food Chem. 2014, 62, 1802−1809

correlation was observed between EDTA-extractable P and these elements. Table 4 also shows observed correlations between (i) Fe, Ca, Mg, Al, K, and Na in different extracts and (ii) orthophosphate or total inorganic P in NaOH−EDTA extracts determined by ^{31}P NMR. Orthophosphate correlated with oxalate-extractable Mg, K, and Na for broiler litter biochars and Ca, K and Na for cottonseed hull biochars. Of different elements composing biochar ash, alkali metals (Na, K) dissolve in water most readily.[10] Alkaline earth metals (Ca, Mg) exist as sulfate, phosphate, and carbonate phases and dissolved in acidic oxalate solution (Table 4). At respective pyrolysis temperature, manure biochar contained >2-fold greater total Ca (by microwave digestion) than the plant biochar (Table S2). The persistence of pyrophosphate in cottonseed hull (but not broiler litter, Table 2) biochar having lower Ca (compared to manure biochars, Table S2) suggests the interaction of pyrophosphate with the organic C fraction of plant biochars. Strong chelating agent EDTA at elevated pH (Table 2) was necessary to compete with this interaction to release pyrophosphate from the biochar surface.

elucidation of the geographic origin of volatile compounds should lead to a better understanding of factors causing aroma differences between teas. To effectively organize and explain the results from the volatile component, some chemometric tools [such as cluster analysis (CA) and principal component analysis (PCA)] provide more objective interpretations. CA and PCA can be used to explain similarities and differences in data and discover natural groupings of samples.[13] Recently, on the basis of CA and PCA, many food products have been successfully discriminated according to variety and geographical origin.[14,15] For tea, quality control data obtained by the volatile component have been used to discriminate the different types,[16,17] different fermentation degrees,[18] and different grades of tea[19,20] by using CA and PCA. However, no studies have been reported for the determination of the aroma characteristics and discrimination model between Pu-erh and Fuzhuan teas based on their volatile components through using CA and PCA.

Previously developed methods for extracting the volatile compounds of tea mainly used simultaneous distillation extraction (SDE).[21−24] However, this approach is a lengthy process (e.g., 3−5 h) and consumes large amounts of both samples (e.g., 50−200 g) and organic solvents. Because headspace−solid phase microextraction (HS-SPME) is a simple, fast, and solvent-free analytical technology, it can help consumers to understand the authentic aroma components of tea.[12] Many studies have proved that HS-SPME has many enormous advantages compared with SDE;[25] HS-SPME coupled with GC-MS also has been successfully used to analyze volatile compounds of different tea samples.[18,26,27]

In our previous studies, fully automatic HS-SPME was investigated for the determination of aroma components from Pu-erh ripe tea and black tea, showing good repeatability, sensitivity, and selectivity.[28,29] However, these studies compared the aroma components of only a limited number of tea samples and did not use multivariate statistical methods, so the obtained results were not representative and persuasive. In this work, we report for the first time the discrimination or classification of Pu-erh and Fuzhuan teas, through their comprehensive volatile compound profiling by fully automatic HS-SPME combined with GC-MS analysis; multivariate statistical analysis such as PCA and CA was employed. To our knowledge, this is the first attempt of classification and differentiation of CDTs in accordance with production area through CA and PCA.

MATERIALS AND METHODS

Tea Samples. Thirteen Pu-erh tea samples, numbered from YP1 to YP13, were collected from five representative Pu-erh tea geographical protection areas (Puer, Xishuangbanna, Lincang, Dali, and Baoshan) in Yunnan province, and 13 Fuzhuan tea samples, numbered from HF1 to HF13, were collected from a local market in Anhua country of Hunan province and produced by Yiqingyuan Tea Ltd., Inc. All 26 dark teas were processed in 2012 and stored in a dry place.

HS-SPME Analysis. A 100 μm polydimethylsiloxane (PDMS) fiber, a 65 μm polydimethylsiloxane/divinylbenzene (PDMS/DVB) fiber, and a 75 μm carboxen/polydimethylsiloxane (CAR/PDMS) fiber were used in this work (Supelco, Bellefonte, PA, USA). The fiber used for analysis was previously kept in the GC-MS injection port for 30 min at 250 °C and used immediately to prevent subsequent contamination.

The 26 dark tea samples were ground into fine powder and passed through a 30−60 mesh. The ground tea sample (2.0 g) was introduced into a 20 mL sealed headspace bottle and infused with 5 mL of boiling water; the temperature of the headspace bottle was kept at 80 °C with a hot plate. A 65 μm PDMS/DVB fiber was then exposed to the sample headspace while the tea powder was continuously stirred (250 rpm) for 60 min. All of the volatile components absorbed on the SPME fiber were desorbed at the GC-MS injection port (250 °C for 3.5 min) and subsequently analyzed by GC-MS, separately.

GC-MS Analysis. An Agilent 7890A GC system, coupled with an Agilent 5975C MSD mass spectrometer (Agilent, Santa Clara, CA, USA), was used to identify volatile compounds of all tea samples. An Agilent HP-5MS capillary column (30 m × 0.25 mm i.d. × 0.25 μm film thickness) was employed, helium (purity > 99.999%) was used as the carrier gas, and the flow rate was 1 mL/min. The injector temperature was 250 °C, and injection mode was performed in splitless. The GC oven temperature was held at 50 °C for 5 min, then increased to 210 °C at a rate of 3 °C/min, maintained at 210 °C for 3 min, and finally increased to 230 °C at a rate of 15 °C/min. The mass spectrometer conditions were as follows: ionization energy, 70 eV; ion source temperature, 230 °C; quadrupole temperature, 150 °C; quadrupole mass spectrometer scan range, 30−500 atomic mass units (amu); solvent delay time, 2.8 min.

Data Analysis. Identifications of the peaks were made by searching the National Institute of Standards and Technology (NIST) 08.L GC-MS database, and the retention indices (RI) were compared with the published data.[30−33] The relative contents of the aroma compounds were calculated by peak area normalization. The GC Kovats RI for each compound was determined by using 1 μL of *n*-alkanes (C8−C40; Sigma-Aldrich, St. Louis, MO, USA) under the identical GC-MS experimental conditions. Significant differences between Pu-erh and Fuzhuan teas for each of the volatile compounds were determined by independent samples *t*-test analysis using the SPSS statistical package (version 17.0 for Windows, SPSS, Inc., Chicago, IL, USA). CA and PCA were performed using SIMCA-P12 software (Umetrics, Umea, Sweden).

RESULTS AND DISCUSSION

Optimization of HS-SPME Parameters. In this work, three key experimental parameters (type of fiber, extraction temperature, and extraction time) for fully automatic HS-SPME were examined. Pu-erh tea sample YP-1 was used as optimized sample under different conditions. In general, the effective SPME fibers included three polymeric materials: a liquid PDMS for the less polar components and two solid DVB and CAR for the more polar components. First, three types of fiber (100 μm PDMS, 65 μm PDMS/DVB, and 75 μm CAR/PDMS) were studied for the extraction of volatile compounds from the YP-1 sample. Each fiber can absorb volatile components under the same temperature and time. The SPME fiber adsorption yield was evaluated in terms of total amount of volatile components from the YP-1 sample. Results showed the 65 μm PDMS/DVB fiber can absorb 71 volatile components and obtain maximum peak area, whereas the 100 μm PDMS and 75 μm CAR/PDMS fibers can absorb only 49 and 60 volatile components, respectively. Therefore, the 65 μm PDMS/DVB fiber was used as the most optimal fiber for the HS-SPME method. Second, the extraction temperature and extraction time of SPME were investigated by varying the extraction temperature (50, 60, 70, 80, 90, and 100 °C) and time (30, 40, 50, 60, 70, and 80 min) when the SPME fiber was set as 65 μm PDMS/DVB. Figure 1 shows the sum of total peak area in the extraction temperature and time studied. As shown in Figure 1A, the total peak area of the YP-1 sample was gradually increased from 50 to 80 °C but slightly decreased above 80 °C. For extraction time, the total peak area of the YP-1 sample was gradually increased from 30 to 60 min. However, as the extraction time was extended, the total peak area of the YP-1 sample showed little change (Figure 1B). Because the extraction time was 60 min, the adsorption of aroma components by SPME fiber reached a dynamic equilibrium.

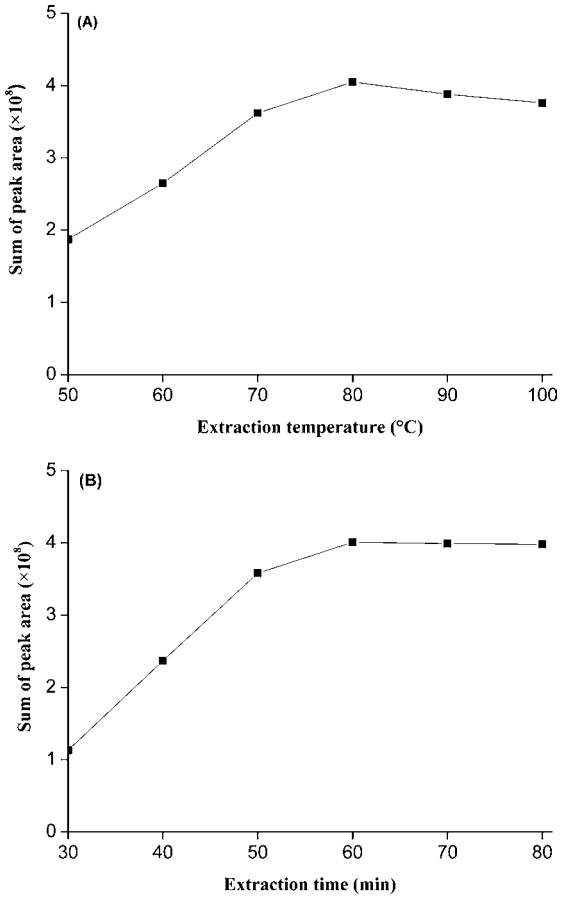

Figure 1. Effect of extraction temperature (A) and time (B) on extraction of volatile compounds from the YP-1 sample according to the sum of the total peak area.

Therefore, in this work, extraction temperature and extraction time were selected at 80 °C and 60 min, respectively.

Analysis of Volatile Compounds. Twenty-six samples of Pu-erh and Fuzhuan teas were analyzed by the fully automatic headspace GC-MS method. TICs are presented in Figure 2. The identified components and their relative percentage contents (%) are summarized in Table 1. The relative percentage contents of these identified aroma components were presented as "% average (range)". A total of 93 aroma components, including 23 hydrocarbons, 21 alcohols, 14 ketones, 11 methoxyphenolic compounds, 7 esters, 7 aldehydes, 4 furans, 2 nitrogen compounds, 2 lactones, 1 acid, and 1 phenol compound, were identified in 26 dark tea samples. Among these identified volatiles, methoxyphenolic compounds (31.77%), alcohols (15.50%), and hydrocarbons (14.63%) were the major volatile components in 13 Pu-erh teas, whereas ketones (25.42%), alcohols (19.14%), and hydrocarbons (15.58%) were the major volatile components in 13 Fuzhuan teas. The most abundant compounds in Pu-erh teas were 1,2,3-trimethoxybenzene, hexadecanoic acid, 1,2,4-trimethoxybenzene, and dihydroactinidiolide, whereas the most abundant compounds in Fuzhuan teas were caffeine, β-ionone, geranyl acetone, and dihydroactinidiolide.

A total of 23 hydrocarbon compounds were identified in 26 dark teas. There were no significant differences ($P > 0.05$) in the content of hydrocarbon compounds in these two kinds of dark tea samples. However, these identified volatile components were mostly saturated hydrocarbons, such as hexadecane,

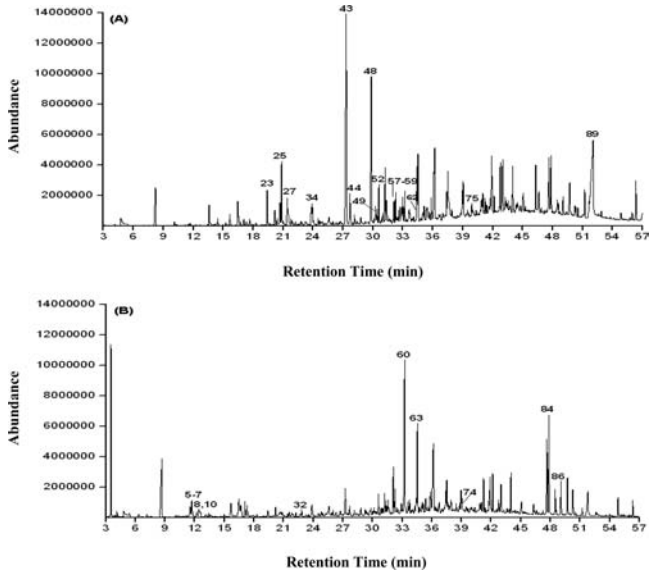

Figure 2. TIC of Pu-erh tea (A, sample YP-1) and Fuzhuan tea (B, sample HF-1). Twenty-six volatile compounds with significant differences ($P < 0.01$) in Pu-erh and Fuzhuan teas are denoted by the numbers shown in Table 1.

heptadecane, 2,6,10,14-tetramethylpentadecane, and 2,6,10,14-tetramethyhexadecane. Only five kinds of unsaturated hydrocarbons were identified, and the average contents of these compounds in Pu-erh and Fuzhuan teas were only 1.77 and 3.16%, respectively. Saturated hydrocarbons generally have no effect on flavor, whereas unsaturated hydrocarbons play an important role in giving the tea flavor.[34,35] In our results, limonene was present at a relatively high level in Fuzhuan teas, whereas β-guaiene was present at a relatively high level in Pu-erh teas. Qiao et al.[31] found limonene at the greatest concentrations (90.85%) in fruit juice but it did not exhibit the strongest aroma activity, although it had an orange odor in gas chromatography−olafactometry (GC-O). β-Guaiene was considered to be an important feature of aroma compounds and endowed with a unique woody scent for Pu-erh tea.[33] In short, the unsaturated hydrocarbons generally having a woody and fruit fragrance in Fuzhuan teas were in higher proportion than in Pu-erh teas, which may have special contribution to the flavor of Fuzhuan teas.

A total of 21 alcohol compounds were identified in 26 dark tea samples. Among them, 10 alcohols were common to all of the tea samples. Linalool oxides were the most abundant alcohols in Pu-erh teas (5.39%) and Fuzhuan teas (3.77%), followed by phytol and isophytol. As shown in Table 1, linalool, reported as an abundant volatile constituent in various green teas,[32] oolong teas,[23] and black teas,[36] was present at a relatively low level in Pu-erh teas (0.72%) and Fuzhuan teas (1.85%), but the content of linalool oxides increased sharply. This indicated that linalool underwent a significant oxygenation effect during the postfermentation process with microbial activity. The level of α-terpineol in Pu-erh teas (1.60%) had a significant difference ($P < 0.001$) compared to Fuzhuan teas (0.32%). Similar to our results, many studies have shown linalool oxides and α-terpineol, which have a unique floral and sweet odor, were the most abundant alcohol constituents in Pu-erh tea, and their formation may be mostly related to the postfermentation process with the microbial activity.[37] Phytol and isophytol, with a camphoraceous odor, were present at a relatively high content

[a]Twenty-six volatile compounds with significant differences ($P < 0.01$) in Pu-erh and Fuzhuan teas are indicated in bold type. [b]RI, retention indices as determined on HP-5MS column using the homologous series of *n*-alkanes (C_8−C_{40}). [c]Compounds are listed in order of retention time. [d]Method of identification: MS, identified by comparison with mass spectra; RI, identified by retention indices. [e]Two-sample *t*-test significant values at a level of 0.05. [f]The same letter in the same row indicates no significant difference ($P < 0.05$).

in both Pu-erh and Fuzhuan teas and are considered common among plant volatiles, because they are hydrolysis products of the alcohol moiety of chlorophyll;[38] their aroma activity and contribution to tea flavor needed to be further elucidated. These results indicated that these alcohol compounds contributed unique flavor for each kind of dark tea with different concentrations, and the concentration differences of these compounds were often determined by different production processes.

A total of 11 methoxyphenolic compounds were identified in 26 dark tea samples. Among them, 3,4-dimethoxytoluene, 3,5-dimethoxytoluene, 4-ethyl-1,2-dimethoxybenzene, 1,2,4-trimethoxybenzene, 1-methoxynaphthalene, and 2-methoxynaphthalene were detected only in Pu-erh teas, and 1-methoxynaphthalene and 2-methoxynaphthalene were reported here for the first time as volatiles of Pu-erh tea. It was worth noting that the level of methoxyphenolic compounds was significantly higher ($P < 0.001$) among Pu-erh teas (31.77%) than among Fuzhuan teas (3.53%). These methoxyphenolic compounds with a higher level appear to be the unique characteristic volatile compounds in Pu-erh teas. Our results are consistent with those of other studies for the high level of methoxyphenolic compounds coexisting in Pu-erh teas, mainly including 1,2,3-trimethoxybenzene and 1,2,4-trimethoxybenzene, and these methoxyphenolic compounds had an important effect in the unique "stale" flavor of Pu-erh tea.[27,33] Meanwhile, some studies have reported that *Aspergillus niger* was the major microorganism responsible for the formation of Pu-erh special flavor through the methylation effect of phenolic hydroxyl compounds.[39] Therefore, we conclude that the formation of these methoxyphenolic compounds may have great relation to *A. niger* activity in the postfermentation process. The degradation and hydrolysis of tannins and (−)-epigallocatechin gallate (EGCG) by microbial enzymes were considered to be related to these results.[40]

A total of 14 ketone compounds were identified in 26 dark tea samples. There were significant differences ($P < 0.001$) in the content of ketones between Pu-erh teas (12.57%) and Fuzhuan teas (25.42%). Among these ketones, *β*-ionone, geranyl acetone, farnesyl acetone, and 6-methyl-5-hepten-2-

one were the most abundant compounds in the Fuzhuan teas and had very significant differences compared with Pu-erh teas ($P < 0.001$). It is well-known that these ketone compounds are very important volatile compounds in various teas, providing a special floral and woody odor, and appear to be the unique volatile compounds in Fuzhuan teas. In particular, β-ionone, with low human odor perception thresholds, significantly contributes to the flavor of tea.[11] These ketone compounds were probably derived from the oxidation and condensation of carotenoids (phytoene or phytofluene) and oxidative breakdown products of β-carotene,[41] which may greatly dependent on *Eurotium* spp. activity in the postfermentation process of Fuzhuan tea.[42] The carotenoid degradation pathway also was considered to be a key route for the formation of aroma compounds in many plants and plant products.[43] A possible formation mechanism of these volatile components is shown in Figure 3. In short, the contents of these carotenoid degradation products in Fuzhuan teas were relatively higher than in Pu-erh teas.

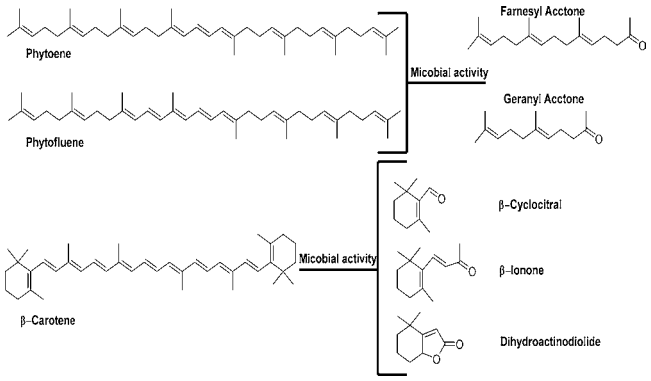

Figure 3. Carotenoids (left) are possibly degraded into some volatile compounds (right) in dark tea.

A total of 7 aldehydes and 7 esters were identified in 26 dark tea samples. The contents of aldehyde compounds were relatively low in Fuzhuan teas (1.00%) and Pu-erh teas (1.67%), mainly including β-cyclocitral, safranal, and benzaldehyde. Among them, β-cyclocitral had a very significant difference in these two kinds of dark teas ($P < 0.001$). Our results have some differences with the previous investigations; that is, Lv et al.[33] found 3,4,5-trimethoxybenzaldehyde was the dominant compound in Pu-erh teas, and Xu et al.[44] found aldehyde compounds were dominant and represented 51% of the identified volatile components in postfermented Fuzhuan dark tea. These differences could be accounted for by the difference of tea samples and extraction methods used in the analysis. The contents of ester compounds in Fuzhuan teas (4.68%) were relatively higher than in Pu-erh teas (1.45%). Among them, methyl jasmonate was detected only in Fuzhuan teas (0.99%), providing a special sweet floral, tenacious jasmine-like odor for black tea.[45] Methyl salicylate and isopropyl salicylate, which had a holly oil herbal fragrance, also were detected with a relatively high level in Fuzhuan teas compared Pu-erh teas. These compounds may give a unique contribution to the flavor of the Fuzhuan tea. In addition, hexadecanoic acid methyl ester, methyl linoleate, and methyl linolenate were formed from higher fatty acid and lower alcohol, in which these ester components had poor volatility, and thus, had no effect on the flavor of the tea.[46]

As for the rest of the identified compounds, hexadecanoic acid and caffeine were found at high levels in both Pu-erh and Fuzhuan teas. These compounds also were previously reported in other teas, but their aroma activities and contribution to tea flavor were not described.[47−49] In addition, dihydroactinidiolide existed at a high level in both Pu-erh and Fuzhuan teas in the present study and was found to be an important aroma compound, likely having a special contribution to the woody flavor of tea.[33] 2-Pentylfuran and *cis*-2-(2-pentenyl)furan with a burnt and sweet odor were found at a high level in Fuzhuan teas compared to Pu-erh teas ($P < 0.001$), and their formation may related to amino acids and sugars through Maillard and Strecker degradation reactions,[34] which is probably responsible for a special contribution to the flavor of Fuzhuan tea.

Although the microbial fermentation leads to a significant change of volatile flavor components in dark tea, very little is known about the microorganism group involved in the pile fermentation process and its effects on the chemical and biological transformation of the tea leaf ingredients. For this reason, the formation mechanism of volatile aroma components during the postfermentation process is urgently needed to be studied for explaining the dynamic process by microbial enzymes in subsequent studies. In addition, the distinct aroma of dark tea is a reflection of hundreds of chemicals, rather than a single flavor-active compound; thus, the odor threshold of identified compounds was not considered in this study. In future studies, novel analytical investigations will focus on determining the interactions between tea volatile matrices and flavor-active compounds and the human influence on odorant perception.

Cluster Analysis. In the present study, all percentage quantitative data of 93 volatile compounds were used for CA model. Objects will be gathered in terms of their nearness or

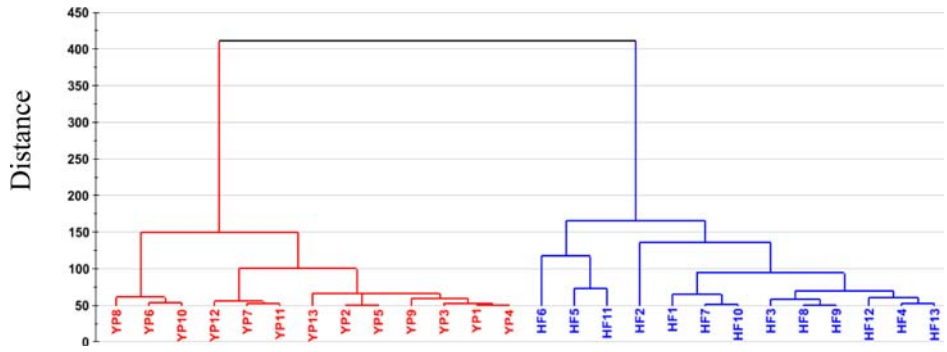

Figure 4. CA dendrogram of 26 dark tea samples.

dx.doi.org/10.1021/jf405237u | J. Agric. Food Chem. 2014, 62, 1810−1818

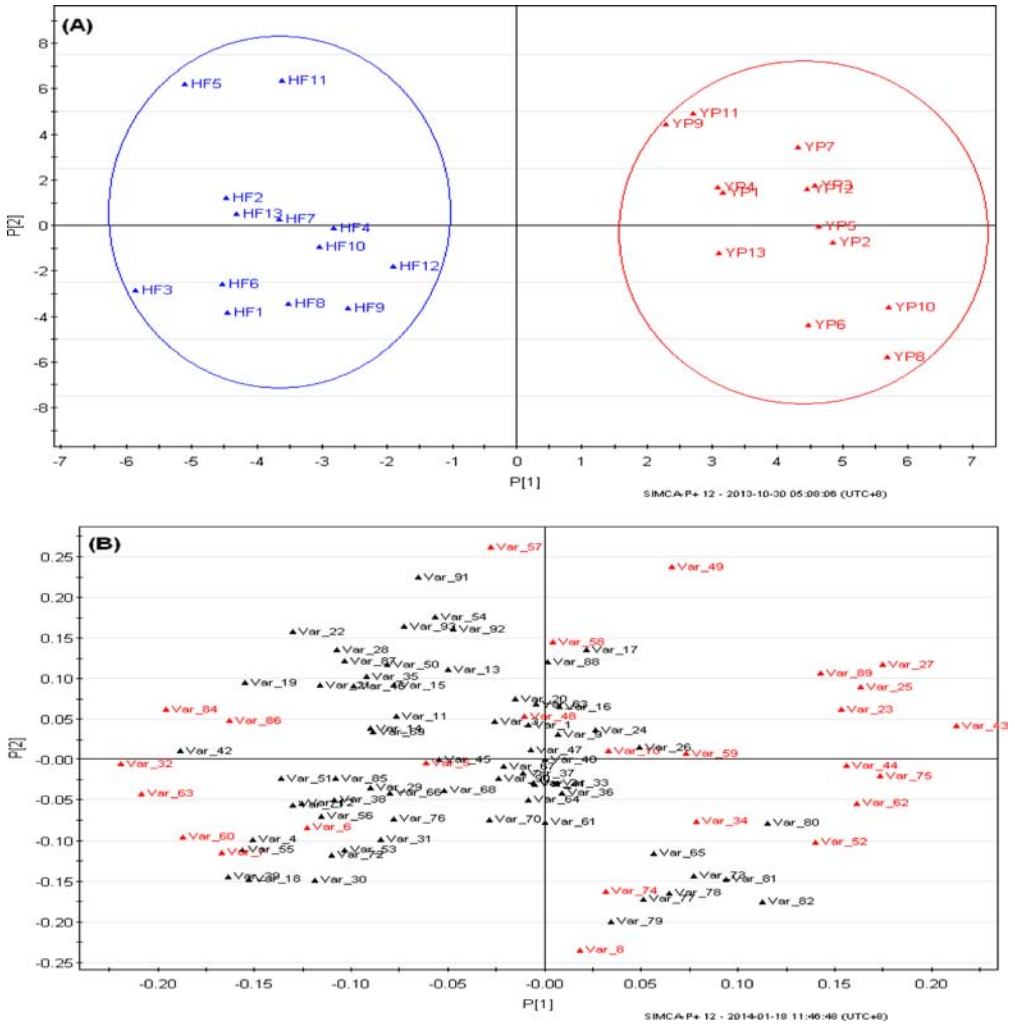

Figure 5. PCA score (A) and loading (B) plots derived from 93 volatile compounds of 26 dark tea samples: (A) YP indicated by red color represents Pu-erh tea from Yunnan province and HF indicated by blue color indicates Fuzhuan tea from Hunan province; (B) red color represents 26 volatile compounds with significant differences ($P < 0.01$) in Pu-erh and Fuzhuan teas based on the results given in Table 1.

similarity, and the objects with minimum variance were clustered preferentially. In this work, sample similarities were calculated on the basis of the Euclidean distance and Ward's method was used as an amalgamation rule.[50] As shown in Figure 4, there was a clear division between dark tea samples according to their respective production areas, and two clusters were observed: the first one was composed of 13 Yunnan Pu-erh teas, and the second main cluster was constituted by 13 Hunan Fuzhuan teas.

Principal Component Analysis. PCA is an unsupervised statistical method used to investigate the differences between sample groups by reduction of the dimension of principal components and has become a hot research field in recent years.[14,51,52] The score plot shows the differences/similarities between various tea samples, which is based on comprehensive volatile compounds. The loading scatter plot shows which volatile compounds contribute to the differences/similarities. PCA (Figure 5) was determined using the same data as used in the CA model. Figure 5A shows the score plot on the two first principal components (PC1 and PC2), representing 73.62% of the total variability. Figure 5B shows the loading scatter plot that established the relative importance of each variable, and it was useful for the study of relationships between variables and tea samples. As shown in Figure 5A, 13 Pu-erh teas were clearly distinguished from 13 Fuzhuan teas in the PCA model. As can be seen from Figure 5B, some variables that explained maximum variance in the data were given higher loading values and were considered as important for discrimination samples (corresponding with score plot and not close to the origin). These variables including 1,2-dimethoxybenzene (V23), linalool oxide IV (V25), α-terpineol (V27), 1,2,3-trimethoxybenzene (V43), 4-ethyl-1,2-dimethoxybenzene (V44), 1,2,3-trimethoxy-5-methylbenzene (V52), 4-(2,6,6-trimethylcyclohexa-1,3-dienyl)-but-3-en-2-one (V62), α-cadinol (V75), and hexadecanoic acid (V89) had high positive values on PC1 and mainly affected the discrimination of Pu-erh tea samples from dark tea samples. Other variables including β-cyclocitral (V32), isopropyl salicylate (V42), geranyl acetone (V60), β-ionone (V63), caffeine (V64), and farnesyl acetone (V86) had high negative values on PC1 and mainly were considered as important compounds for the discrimination of Fuzhuan teas from Pu-erh teas. In addition, *cis*-2-(2-pentenyl) furan (V8, having high negative values on PC2) was detected only in Fuzhuan teas, and β-guaiene (V49) and 1-methoxynaphthalene (V57), having high positive values on PC2, were present at higher contents in Pu-erh teas. These results in PCA were almost consistent with the significant result given in Table 1. PCA provided similar classification of Pu-erh and Fuzhuan

teas, showing that the volatile chemical compounds of teas analyzed by fully automatic HS-SPME can be used for quality evaluation based on chemometric and statistical methods using CA or PCA models.

In addition, we found that PCA results also showed some differences among the same types of tea samples. Because tea aroma is a complex colligation character, this may relate to the raw material selection, cultivation measures, and environment factors of tea. However, this result is a feasibility study because the number of dark tea samples is relatively small for classification. To improve the reliability of the clustering model, the increased variables by collecting various analytical data and extended number by adding dark tea samples are recommended.

In conclusion, this study reported for the first time an attempt to compare and differentiate dark tea samples from different production areas. The result obtained from the HS-SPME/GC-MS combined with CA and PCA has shown that this method can be useful to discriminate dark samples from Yunnan and Hunan. The HS-SPME coupled with GC-MS method showed obvious differences between Pu-erh tea and Fuzhuan tea with regard to volatile constituents. The abundant methoxyphenolic compounds existing in Pu-erh teas and the abundant ketone compounds existing in Fuzhuan teas represent their special characteristic aroma components. Combined with chemometric analysis, this HS-SPME/GC-MS technology can successfully differentiate different production areas of dark teas by their volatile compounds.

that are concentrated just before the detector using an external electromagnet device. The introduction into the flow system of the surfactant Triton X-100, together with ALP, gives rise to the lysis of the liposomes, the "in-situ" development of the enzymatic reaction, and the fluorometric detection of the substrate product.

The new method for ALP determination has been applied to the analysis of raw and commercial milk samples. The results have been compared with those obtained using a method based on the same enzymatic reaction, but involving the retention of the reaction product on a resin placed in the cell flow.[23] Although several methods have been described for the determination of ALP activity in milk samples,[24−26] the above-mentioned method was chosen because it also involves the use of MUP and a flow system, which enables an effective assessment of the MLs on the system. The usefulness of the method has been also checked by its application to study the milk pasteurization process by monitoring the degradation of ALP.

MATERIALS AND METHODS

Apparatus and Instruments. A Cary Eclipse Varian spectrofluorometer (Walnut Creek, CA, USA; http://www.varianinc.com) was used. A desktop laboratory MPW-350R centrifuge (MPW Med. Instrument, Warsaw, Poland) with a cooled rotating chamber and equipped with an angle rotor HSL-11199 (45°, 12 × 12 × 1.5 mL, maximum speed = 18000 rpm, 24088 RCF, and $r_{min/max}$ = 3.5/6.25) was used. A VorTemp 56 LA-S2056 shaking incubator (Labnet International, Woodbrige, NJ, USA) and an ultrasound bath were used. A Büchi rotavapor R-205 (Flawil, Switzerland) was used to evaporate the organic solvent and form the liposomes.

The characterization of the synthesized nanomaterials was performed by conventional and both transmission (TEM) and scanning (SEM) electron microscopy. Images were acquired in the first case using a bright-field UIS2 optical system microscope (Olympus, Hamburg, Germany; http://www.olympus.de/microscopy/, BX51, model U MDOB3) equipped with a DP20 digital camera, which provided high-precision images of 2 megapixels in UXGA (1600 × 1200), operating at 15 frames per second. TEM images were obtained using a CM-10 Philips microscope (Philips Research, Eindhoven, The Netherlands; http://www.research.philips.com) with 0.5 × 0.34 nm resolution and equipped with a digital megaview III camera. Copper grids (200C-FC) coated with a Formvar carbon film 200 mesh supplied by Aname (Madrid, Spain; http://www.aname.es) were used as support in TEM experiments. The XPS measurements of Fe_3O_4@AuNPs-DT were carried out using a Specs Phoibos 150 MCD instrument equipped with a monochromatized AlK (12 kV). The morphology and elemental composition of these NPs were studied by SEM, using a microscope (JEOL JSM 6300) operating at 20 kV, which was also equipped with an energy dispersive detector (EDX).

Reagents. All chemicals used were of analytical grade. 1,2-Diacyl-*sn*-glycerol-3-phosphatidylcholine (DSPC), 3-*sn*-phosphatidylethanolamine (DOPE) (type II-S from sheep brain), cholesterol (CH), tetrachloroauric acid ($HAuCl_4$) trihydrate, 1-dodecanethiol (DT), Triton X-100, 4-methylumbelliferyl-phosphate disodium salt (MUP), alkaline phosphatase (ALP), and sodium hydroxide were purchased from Sigma-Aldrich (Steinheim, Germany). Trisodium citrate dihydrate, iron(II) chloride, and other common reagents were also purchased from Merck, and iron(III) chloride was from Panreac. A buffer solution containing 50 mM tris(hydroxymethyl)aminomethane hydrochloride (Tris) (Merck) and adjusted to a pH of 9.8 was used. Methanol and chloroform were used for preparing the liposomes. Aqueous solutions were prepared using deionized water purified with a Milli-Q system (Millipore, Bedford, MA, USA).

Synthesis and Characterization of the Nanomaterial. Hydrophobic NPs (Fe_3O_4@AuNPs-DT) were prepared using a procedure previously reported,[27] which was modified to introduce the DT. Briefly, 25 mL of an aqueous solution containing 0.8 M iron(III) chloride, 0.4 M iron(II) chloride, and 40 mM hydrochloric acid was dropwise added into 250 mL of 1.5 M sodium hydroxide solution under vigorous stirring using a nonmagnetic stirrer. Black-brown Fe_3O_4NPs were immediately formed, which were separated using a commercial neodymium magnet (NdFeB) and washed three times with deionized water. The Fe_3O_4 NPs were collected by centrifugation at 5352.80*g* for 15 min and dispersed again in 100 mL of deionized water. The NPs concentration of this solution was about 100 mM,[18] which was stored refrigerated at 4 °C for further use.

The preparation of Fe_3O_4@AuNPs-DT was carried out by adding 2.2 mL of $HAuCl_4 \cdot 3\ H_2O$ (2.0 mg mL^{-1}) to 22.5 mL of deionized water and heated to boiling for 5 min. Then, 2 mL of the above prepared Fe_3O_4 NPs solution was added to the reaction mixture followed by the addition of 0.5 mL of sodium citrate (80 mM) and 5 mL of DT, and the mixture was vigorously mixed under stirring. The color of the solution gradually changed from brown to burgundy. The reaction mixture was boiled under stirring for 40 min.

TEM images were obtained by dropping the resulting Fe_3O_4@AuNPs-DT on a carbon-coated copper grid and setting a completely dried drop by the oven. XPS spectra were also obtained to identify the presence of a particular element and distinguish the different forms in the NPs. Also, SEM-EDX measurements were made to determine the elemental composition of the NPs.

Preparation, Separation, and Characterization of Magneto-liposomes. Liposomes containing MNPs and the enzyme substrate MUP were prepared using the rapid solvent evaporation (RSE) method.[28] Briefly, 100 μL of a lipid mixture containing DSPC, DOPE, and CH (75:12.5:12.5) was diluted to 1.0 mL with a chloroform/methanol (880:120) mixture and was put into a 50 mL round-bottom flask. Then, a mixture containing 3 mL of an about 7 mM Fe_3O_4@AuNPs-DT suspension, 2.5 mL of 40 mM MUP solution, and 3.5 mL of deionized water was carefully added along the flask wall. The organic solvent was removed in the rotary evaporator at 40 °C and 300 rpm under vacuum pressure. After 20 min, a pale brown opalescent fluid was obtained, which contained a wide variety of liposomes. The liposome population was homogenized by using two physical treatments, mechanical shaking and sonication. A volume (10 mL) of the liposome suspension was shaken in a shaking incubator at 40 °C, which is close to the transition temperature, and at 250 rpm for 30 min, stopping each 10 min for 2 min. After this treatment, the liposomes were resized by sonication. This liposome suspension was partially submerged in a bath sonicator and treated for a period of 10 min, stopping each 2 min for 10 s. The suspension changed in its appearance from milky to a clear suspension.

The separation of filled liposomes from empty liposomes, phospholipid residues, and untrapped magnetic NPs was carried out using conventional centrifugation at 20073*g* for 30 min. Filled liposomes, which showed a brown appearance, were located in the intermediate zone, whereas empty liposomes and untrapped NPs appeared in the top and bottom zones, respectively. After separation, filled liposomes were washed four times with deionized water. These liposomes were stable for at least 30 days.

Procedure for the Determination of ALP Activity. Figure 1 depicts the hydrodynamic arrangement used for the determination of ALP activity (A) and the process time schedule (B). A suspension of MLs containing MUP, prepared in Tris buffer solution (50 mM, pH 9.8), was injected through the injection valve IV_1 at a flow rate of 0.4 mL min^{-1}. The liposomes were retained before the detector, using an electromagnet device, for a time (retention time, Δt_1) of 200 s. A solution containing Triton X-100 and ALP standard or diluted milk sample solution, with an ALP activity in the range of the calibration graph, was then injected using the injection valve IV_2. The surfactant provided the liposome lyse and the release of the enzyme substrate, which was hydrolyzed by ALP, obtaining a transitory fluorescence signal that was monitored at λ_{ex} 365 nm and λ_{em} 449 nm, using a 10/5 slit ratio and a detector gain of 600 V. As Figure 1B shows, the system takes about 120 s (release time, Δt_2) to achieve the baseline. Each standard or sample solution was assayed in triplicate.

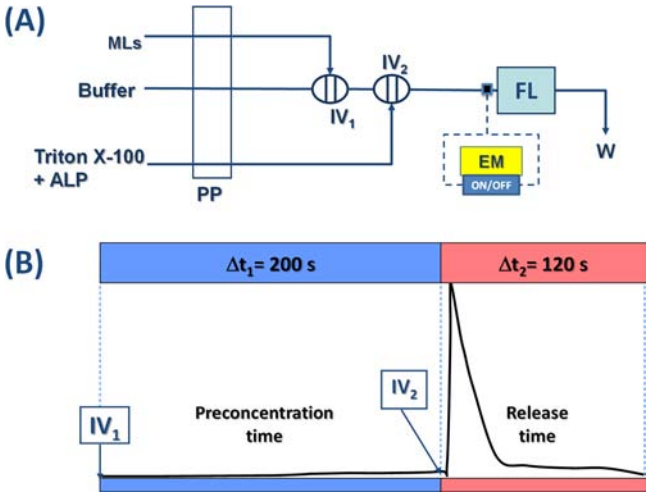

Figure 1. (A) Scheme of the flow injection system used for the determination of ALP activity. (B) Time schedule of the process. PP, peristaltic pump; IV_1 and IV_2, sample and reagent injection valves, respectively; EM, electromagnet device; FL, fluorescence detector; W, waste.

The same enzymatic reaction was assayed using a flow injection system in the absence of liposomes, with the aim of comparing the features of both methods. For this purpose, a solution containing 10 mM MUP prepared in Tris buffer solution (50 mM, pH 9.8) was pumped at a flow rate of 0.4 mL min^{-1} and mixed with the same buffer solution in which the ALP solution was injected. A transitory fluorescence signal (λ_{ex} 365 nm, λ_{em} 449 nm, 10/5 slit ratio, detector gain of 600 V) was obtained when the mixed reaction plug passed through the detector. The area of the peak was used as the analytical parameter.

Analysis of Food Samples. Several raw and commercial milk samples were processed to determine ALP activity. The raw samples were treated with bronopol as preservative and stored at −15 °C until use. The samples were adequately diluted using 50 mM Tris buffer solution (pH 9.8) and analyzed as described above.

Comparison Method. The results obtained by applying the new method to the analysis of milk samples were compared with those obtained using a flow-through method previously described.[23] This method involves the hydrolysis of MUP (0.4 mM) in the presence of ALP, the transient immobilization of the reaction product on a resin (Dowex-1 strongly basic anion exchange resin) packed in the flow cell, and the use of the fluorescence intensity as the analytical parameter. A solution containing EDTA (100 mM) and sodium chloride (150 mM) is used to remove the product of the reaction from the support. This method reaches a detection limit of 0.05 U L^{-1} ALP.

Statistical Analysis. All experiments were replicated three times. Statistical analyses were performed with Statgraphics Plus 5.1 software (Statistical Graphics Corp.). The paired *t* test was used to compare the results obtained for the analysis of milk samples using both the new method and the previously reported method.[23]

RESULTS AND DISCUSSION

Study of the Features of Hydrophobic Magnetic Nanoparticles. As indicated above, several methods have been described to protect the surface of Fe_3O_4 NPs against oxidation and corrosion and to improve their reactivity. The use of gold to coat magnetic NPs is frequently chosen because these core/shell NPs show adequate magnetic properties and chemical stability, and their surface can be easily modified using the well-developed Au−S chemistry.[15,16] After the synthesis of Fe_3O_4@-AuNPs, their surface was covered with DT to obtain hydrophobic MNPs and facilitate their entrapment into the internal medium of the liposomes. These Fe_3O_4@AuNPs-DT, characterized by TEM (Figure 2A), exhibited spherical structures with an average diameter of 30 ± 10 nm. Also, it was checked that they can be easily separated from the solution when an external magnetic field is applied.

The chemical composition of the hydrophobic magnetic NPs was studied using XPS and SEM-EDX. The XPS spectrum (Figure 2B) indicates the presence of Fe, Au, C, S, and O in the NPs. As can be seen in this figure, Fe(2p) electrons show binding energy (BE) at 725 and 712 eV, respectively, whereas the Au(4f) electrons BE correspond to 84 and 89 eV, respectively, which also indicate the presence of iron and gold in the Fe_3O_4@AuNPs-DT nanocomposites. In addition, the small peaks at 162 and 164 eV correspond to the S(2p3/2) and S(2p1/2) electrons, whereas the strongest peak obtained at 532 eV corresponds to the O(1s) electron.

Figure 2C depicts the image acquired using SEM-EDX, the results of which indicate the presence of Fe, Au, and S in the

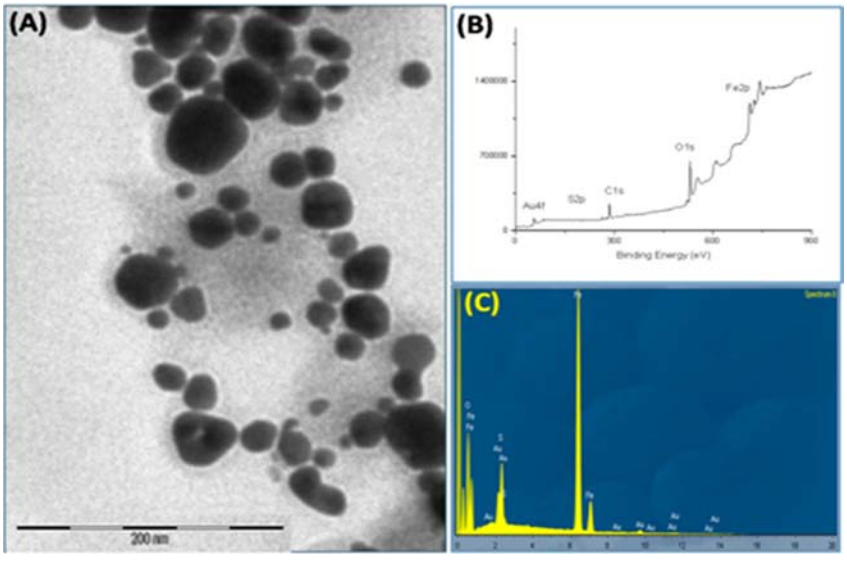

Figure 2. (A) TEM image, (B) XPS and (C) SEM-EDX measurements obtained for Fe_3O_4@AuNPs-DT nanocomposites.

Fe_3O_4@AuNPs-DT nanocomposites. The EDX diagram also provides a semiquantitative chemical composition of 64:8:6 from the Fe/Au/S distribution that confirms the composition of the hydrophobic MNPs. The absorption spectrum obtained for these NPs showed the typical band at 530−550 nm corresponding to the surface plasmon resonance of AuNPs.

Optimization of Variables. The variables affecting the synthesis of MLs containing MUP and those involved in the development of the method for ALP determination were studied using the univariate method. Tables 1 and 2 summarize the variables studied, the ranges assayed, and the values chosen.

Table 1. Optimization of Variables Affecting the Magnetoliposomes Synthesis

type of variable	variable	range studied	optimal value
hydrophobic MNP formation	$HAuCl_4$, mM	0.23−2.27	1.13

Variables Affecting the Synthesis of Magnetoliposomes Containing the Enzymatic Substrate. The optimization study was carried out to obtain adequate structural features (size, shape, and magnetic efficiency) of the hydrophobic MNPs[27] and maximum encapsulation efficiency for the synthesis of the liposomes.[28]

The synthesis of Fe_3O_4@AuNPs was carried out using $HAuCl_4$ and sodium citrate,[16] and the surface of these NPs was modified with DT to improve their hydrophobicity and the efficiency of their encapsulation into liposomes. The experimental conditions used to obtain these NPs are summarized in Table 1.

Liposomes containing hydrophobic MNPs and MUP were prepared using the RSE method and homogenized by shake/ultrasound treatments. A method previously described,[11] which was modified with respect to the type of phospholipids and the internalized material, was used to obtain these liposomes. The composition of the phospholipid mixture and the chloroform and methanol volume ratio are critical variables in the synthesis process. As Table 1 shows, the best results were obtained using a phospholipid mixture (100 μL) composed by DSPC, DOPE, and CH (75:12.5:12.5), which was diluted to 1 mL with a chloroform/methanol (880:120) mixture. This solution was mixed with a solution containing 3 mL of about 7 mM hydrophobic MNPs, 2.5 mL of 40 mM MUP, and 3.5 mL of deionized water.

The influence of the temperature in the RSE method was studied in the range of 30−60 °C, which covered the transition temperature of the phospholipids used. The percentage of liposomes increased up to a temperature of 40 °C, remaining constant at higher temperature values. The study of the stability of the liposome suspension showed that it increased when the suspension was refrigerated at 4 °C.

The purification of the liposome suspension, to separate filled liposomes from empty liposomes, phospholipid residues, and untrapped MNPs, was carried out using conventional centrifugation, in which the suspension (10 mL) was treated at different centrifugation speeds, between 2007.3*g* and 20073*g* at 4 °C, assaying also variable centrifugation times, between 15 and 30 min. A centrifugation of 20073*g* for 30 min provided the best results. Filled liposomes, which showed a brown appearance, were located in the intermediate zone, whereas empty liposomes and untrapped NPs appeared in the top and bottom zones, respectively. The liposomes were washed by 100 mL of deionized water four times.

Variables Affecting the Enzymatic Reaction. The method was developed by using a flow injection system in which a Tris buffer solution was used as the carrier to transport, first, the MLs containing the enzymatic substrate and, second, the ALP and Triton X-100 mixture. Hydrodynamic, instrumental, and chemical variables were optimized, as shown in Table 2, which includes the ranges assayed and the values chosen for each variable. All of the assays were carried out at 25 °C to avoid degradation of the liposomes.

The injection volumes chosen to introduce MLs (IV_1) and ALP (IV_2) solutions into the system were 1.3 mL and 150 μL, respectively, using a flow rate of 0.4 mL min^{-1}. The influence of the MLs retention and release times on the system is shown in Figure 3A, selecting 200 and 120 s, respectively, as the optimal values. A pH of 9.8 was chosen, which was adjusted using 50 mM Tris buffer solution. Figure 3B shows the influence of Triton X-100 concentration on the analytical signal, in which it can be seen that a 10 mM concentration is suitable to obtain the maximum peak area value. The influence of the enzymatic substrate on the system was studied by assaying different MLs synthesized in the presence of solutions containing different MUP concentrations. As Figure 3C shows, a maximum signal

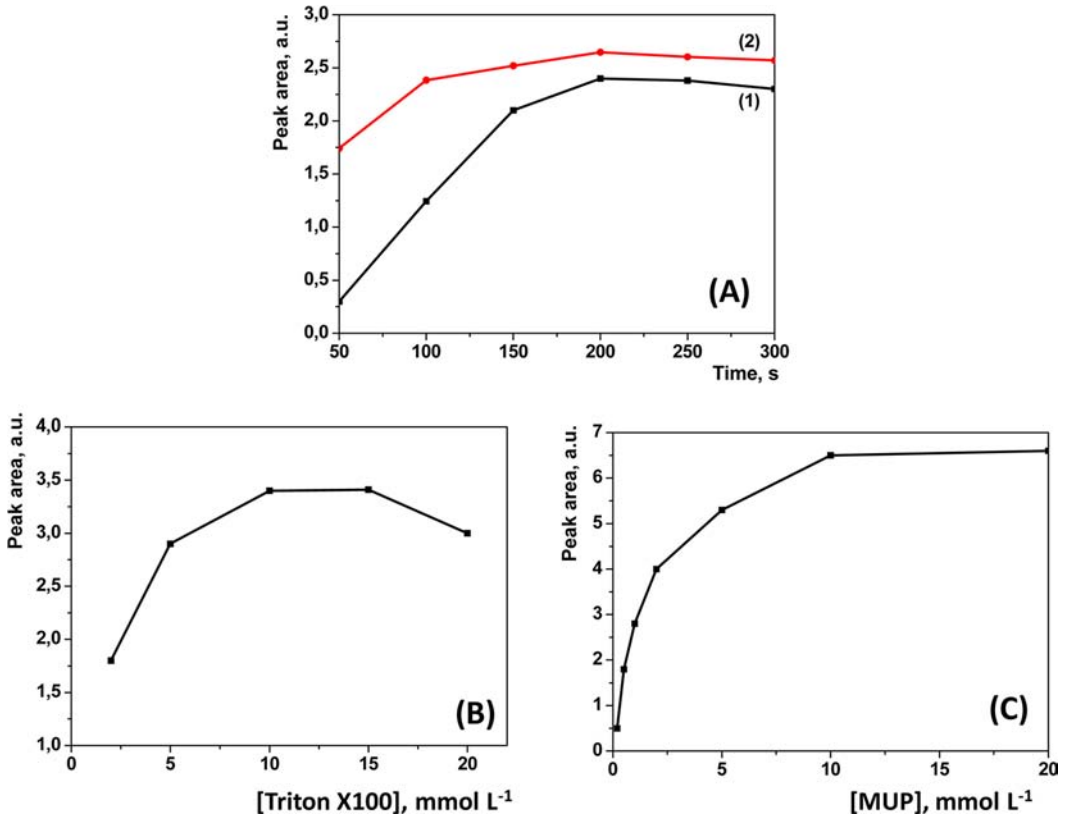

Figure 3. Influence of experimental variables on the flow system: (A) retention time of the MLs by the magnet (1) integration time of the analytical signal (2); (B) Triton X-100 and (C) MUP concentrations. pH 9.8; [ALP] = 50 mU L^{-1}; [MUP] = 2 mM in (A) and (B); [Triton X-100] = 3 mM in (A) and 10 mM in (C).

was obtained when the MUP concentration was 10 mM MUP, remaining constant for higher substrate concentrations.

Features of the Method. The area of the peak obtained in the flow injection scheme depicted in Figure 1A was used as the analytical parameter to obtain the figures of merit of the method. The same system was studied in the absence of MLs with the aim of checking the positive effect of the use of MLs on the ALP determination. Table 3 summarizes the features of both approaches. As can be seen, the dynamic range of the calibration graph in the presence of MLs is 6.4×10^{-3}–0.250 U L^{-1} ALP, and the limit of detection (LOD)[29] is 1.9×10^{-3} U L^{-1}, which is 58 times lower than that obtained in the absence of MLs (0.11 U L^{-1}). Also, the LOD is 26 times lower that that reached by retaining the product of the enzymatic reaction in a resin placed in the flow cell (0.05 U L^{-1}).[23] Table 3 also shows the repeatability ($n = 7$, $r = 3$) and reproducibility ($n = 5$, $r = 3$) data, expressed as RSD%, obtained in the presence and absence of liposomes. As can be seen, the precision values are better in the first case.

Application of the Method. The ALP activity in milk samples from farms and commercial local markets was determined using the new method, and the results were evaluated by comparison with the flow method involving the retention of the enzymatic reaction product above-described.[23] The standard addition method was used to carry out the analysis. Table 4 lists the content found in the samples using both methods. The paired t test was applied to the results at a 5% significance level. It was found that there were not significant differences in the results provided by both methods, which confirms the practical utility of the new method to the analysis of these samples. A recovery study was carried out by adding two different amounts of ALP to each sample and subtracting the results obtained from similarly treated unspiked samples. Table 4 shows the recovery percentages, which ranged from 87.5 to 104.6%. This internal validation also confirms the usefulness of the developed MLs method for the analysis of real samples.

The utility of the new method was also checked for milk pasteurization verification, in which ALP is used as a thermal

marker.[22] U.S. and EU regulations specify that pasteurized dairy products may contain <350 mU L^{-1} ALP.[30,31] The thermal degradation of the ALP activity in goat's and cow's milk samples after heating at 59 °C for different times was studied. Figure 4 shows the evolution of the degradation process studied

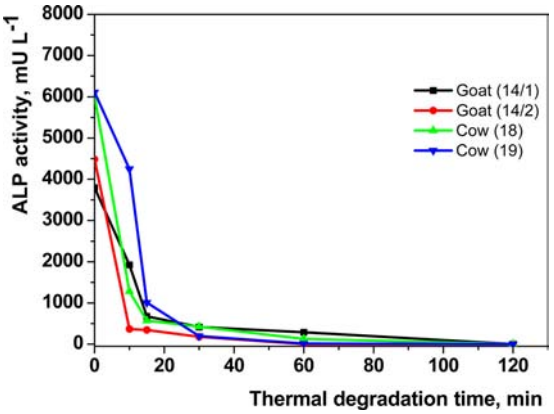

Figure 4. Study of the thermal degradation of milk samples.

using two samples of each milk type. As can be seen, the degradation process is slightly lower for cow's milk samples, which agrees with the results previously described using a similar thermal treatment.[32]

The results obtained show the practical usefulness of MLs containing the enzymatic substrate MUP as enhancement reagents for the determination of ALP activity in milk samples. The positive effect of the retention of the MLs before the detection system, using an external magnet, is mainly shown by the improvement of the LOD and the precision. Also, the flow system allows the automation of the method, obtaining analytical results in only a few minutes.

Apparatus. Cell culture plates and 96-well polystyrene microtiter plates were purchased from Costar (Corning, NY, USA). A direct heat CO_2 incubator, an automated plate washer (Wellwash 4 MK2), and a microplate reader were purchased from Thermo (Franklin, MA, USA). An electric heating constant-temperature incubator was purchased from Tianjin Zhonghuan Experiment Electric Stove Co. Ltd. An ultrasonic cleaner (KH-500E, Jiangsu, China) was purchased from Kunshan Hechuang Ultrasonic Apparatus Co. Ltd. Syringe filters (25 mm, 0.2 μm, and 0.45 μm pore size, Acrodisc) and filter unit (Acrocap) were purchased from Pall (Ann Arbor, MI, USA).

Medium. DMEM containing 10−20% (v/v) FBS was supplemented with 0.2 M glutamine, 50000 units/L penicillin, and 50 mg/L streptomycin. The standard medium was used for growing of myeloma and hybridoma cells.

Buffers and Solutions. Buffers and solutions included the following: (1) coating buffer (0.05 M carbonate buffer, pH 9.6); (2) phosphate-buffered saline (PBS) (0.1 M phosphate buffer containing 0.9% NaCl, pH 7.5); (3) PBS with 0.1% (v/v) Tween-20 (PBST); (4) PBST containing 0.5% (w/v) gelatin (PBSTG); (5) PBSTG containing 10% (w/v) methanol; (6) citrate−phosphate buffer (0.01 M citric acid and 0.03 M Na_2HPO_4, pH 5.5); (7) substrate solution (4 μL of 30% H_2O_2 added to 10 mL of citrate−phosphate buffer containing 2 mg/mL OPD); (8) stop solution (2 M H_2SO_4).

Myeloma Cell Line. The HAT-sensitive BALB/c mouse myeloma cell line SP2/0-Ag14 obtained from the Chinese Institute of Veterinary Drug Control (Beijing, China) was used in fusion experiments.

Synthesis of Hapten−Protein Conjugate. The synthetic route of the immunogen and coating antigen is presented in Figure 1. The

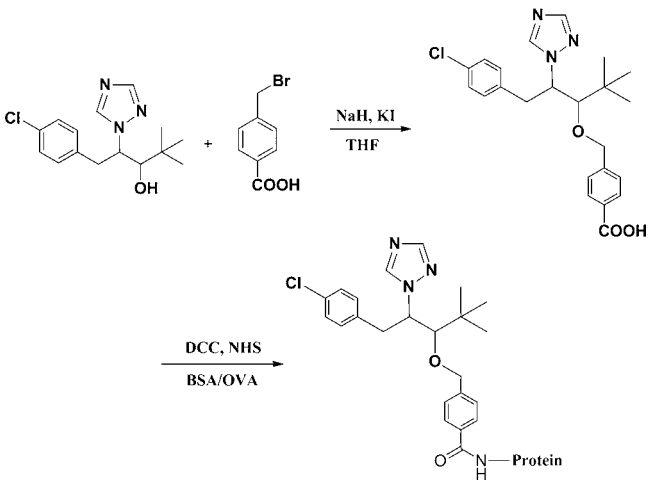

Figure 1. A general synthesis schematic and chemical structure of immunogen and coating antigen.

hapten, 4-(((1-(4-chlorophenyl)-4,4-dimethyl-2-(1*H*-1,2,4-triazol-1-yl)pentan-3-yl)oxy)methyl)benzoic acid, was synthesized through substitution reaction at the hydrogen group of PBZ. Briefly, 1.0 g (3.4 mmol) of PBZ and 0.73 g (3.4 mmol) of 4-(bromomethyl)-benzoic acid were dissolved in 20 mL of distilled tetrahydrofuran (THF) at 0 °C. The solution was stirred on an ice bath for 30 min after 0.3 g of NaH was added. After stirring at room temperature for an additional 30 min, 0.056 g of KI (0.34 mmol) was added. The solution was then heated to reflux overnight. The reaction solution was cooled to room temperature and quenched slowly by addition of 10 mL of distilled water. The mixture was acidified to pH 5 with 2 M HCl; and most THF was removed by rotary evaporation, followed by extraction of the organic layer three times with 20 mL of ethyl acetate. After the ethyl acetate extract had been dried over anhydrous Na_2SO_4, the solvent was evaporated. The residual product was eluted with a mixture of petroleum ether (boiling range: 60−90 °C)/ethyl acetate (4:1 v/v) from a silica gel column (30 g, 25 cm). The eluent was concentrated to give 0.70 g of hapten, in 48% yield. HRMS (ESI) calculated for $C_{23}H_{27}ClN_3O_3$: 428.17355, found m/z 428.17338 [M^+ + H] by Bruker Apex IV FTMS. ^{1}H NMR (300 MHz, $CDCl_3$): δ 0.89 (s, 9, *tert*-butyl), 3.16−3.34 (m, 2, Ar-CH_2CH), 3.44 (d, 1, J = 2.7 Hz, CHC*H*C(CH_3)), 4.69 (s, 2, OCH_2-Ar), 4.84−4.91(m, 1, CH_2C*H*CH), 6.97 (d, 2, J = 8.3 Hz Ar-H_a), 7.19 (d, 2, J = 8.3 Hz Ar-H_b), 7.43 (d, 2, J = 8.2 Hz Ar-H_c), 7.86 (s, 1, Ar-H_e), 8.12 (d, 2, J = 8.2 Hz Ar-H_d), 8.53 (s, 1, Ar-H_f), 10.54 (s, 1, COOH). ^{14}C NMR ($CDCl_3$, 75 MHz): δ 26.5, 36.5, 40.4, 63.7, 76.3, 87.3, 126.8, 128.9, 129.9, 130.0, 130.4, 133.0, 135.0, 142.8, 144.2, 149.2, 169.4.

The hapten (54.5 mg), NHS (10.3 mg), and DCC (14.8 mg) were dissolved in 1 mL of dimethylformamide. The activation reaction was carried out for 1 h at ambient temperature and then 18 h at 4 °C. After centrifugation, the supernatant was divided into two equal aliquots and added dropwise to protein solution (130.0 mg of BSA or 88.0 mg of OVA in 10.0 mL of carbonate buffer, 50 mM, pH 9.6). The reaction mixtures were stirred overnight at 4 °C followed by dialysis against PBS with five changes in 3 days. The dialyzed conjugate solutions were lyophilized, and then the powders were stored at −20 °C. The conjugates of hapten−OVA and hapten−BSA were used as a coating and immunogen antigen, respectively. The molar ratios of hapten-to-BSA and hapten-to-OVA were 10:1 and 9:1, respectively, which were determined through the UV−vis method.[15]

Immunization Protocol, Monoclonal Antibody Production, Purification, and Characterization. Six female BALB/c mice, 8 weeks old, were immunized with the immunogen (hapten−BSA) .The protocols of immunization, fusion, antibody production, and purification were the same as described previously.[16] All the experiments were approved by Beijing Experimental Animal Management Office and performed in compliance with the regulation of Animals Welfare Act of the U.S. Department of Agriculture.

icELISAs. The procedure of icELISA was applied in the screening of the best-performance sera, positive clones, and assay condition. First, a microplate was coated with the coating antigen (100 μL per well in coating buffer), at 37 °C for 3 h. After four washes with PBS, each well was blocked with 200 μL of 3% nonfat dry milk in PBS for 30 min at 37 °C. After the plate was washed with PBST, to each well was pipetted 50 μL of analytes which were diluted in PBSTG containing 10% (w/v) methanol and 50 μL of antisera, supernatant, or mAbs, which were diluted in PBSTG; this was followed by incubation for 30 min at 37 °C. The plate was washed with PBST four times. An aliquot of 100 μL per well of goat anti-mouse IgG−HRP conjugate diluted in PBSTG was added. Likewise, after being incubated at 37 °C for 30 min, the plate was washed four times. To each well was added 100 μL of substrate solution for color development. Finally, the reaction was terminated with 50 μL of 2 M H_2SO_4. The absorbance was read at 492 nm on the microplate reader. The calibration curve data were imported into OriginPro 8.5 (OriginLab) and fit to a sigmoidal logistical equation.

Preparation and Extraction of Samples. PBZ (300.0 mg/L, a recommended use concentration of the commercial product) aqueous solution was sprayed on wheat seedlings which were cultivated in an outdoor experimental field of China Agricultural University. On the harvest day, sixty days after PBZ spraying, eight kernel samples were randomly collected at multiple sites in the experimental field and PBZ-free wheat kernels for recovery study were collected from the unsprayed control field. All kernel samples were stored under an ambient dry condition prior to test.

PBZ was fortified at varying concentrations in PBZ-free kernel samples (10.0 g) for recovery studies. The fortified samples (10.0 g) in triplicate were finely powdered in liquid nitrogen. After crushing, to 10.0 g of finely powered kernel was added 0, 0.4, 1, 2, 5, 10, 20, and 50 μL of 50.0 μg/mL PBZ standard solution in HPLC grade methanol to obtain fortification levels of 0, 2.0, 5.0, 10.0, 25.0, 50.0, 100.0, and 250.0 ng/g, respectively. The spiked samples were allowed to stand at room temperature overnight prior to extraction. The samples were then extracted with 20 mL of methanol under sonication (5 min, room temperature, ultrasonic frequency 40 Hz, ultrasonic power 500 W) followed by centrifugation at 10000g for 5 min. The extraction and centrifugation were repeated three more times. Solids were removed by filtration through filter paper. All supernatants were combined in a 100 mL triangular flask. Five grams of anhydrous Na_2SO_4 was added

to remove H_2O in the supernatants. After filtration through a filter paper the solution was evaporated to near dryness in a 40 °C water bath. The rest of the supernatants were then diluted in 4 mL of HPLC grade methanol and transferred to a 10 mL volume centrifuge tube. After storage at −40 °C for 30 min the supernatants were centrifuged at 10000*g* for 1 min at 4 °C to separate out most of the lipids. The supernatants were transferred to a 5 mL volume centrifuge tube and further dried under a gentle nitrogen stream. The residues reconstituted in 1 mL of PBSTG containing 10% methanol through vigorous vortexing for 2 min. The solution was further diluted 10-fold in PBSTG containing 10% methanol and then was analyzed with the icELISA.

The extraction procedure of kernel samples from PBZ-sprayed seedlings was the same as the recovery study. The residue dried under nitrogen was dissolved in 4 mL of HPLC grade methanol. The solution was divided into two equal aliquots. One aliquot was passed through a 0.22 μm Xiboshi cellulose filter (Envta, Beijing, China) prior to direct injection into the LC−electrospray ionization (ESI)-MS system. The other aliquot was dried with a gentle nitrogen stream and reconstituted in 1 mL of PBSTG containing 10% methanol for icELISA anlaysis.

LC−ESI-MS. PBZ in extracts was also analyzed on a Waters Acquity UPLC H-class bio system (Waters, MA, USA) interfaced to a Thermo Scientific Q-Exactive hybrid quadrupole-Orbitrap mass spectrometer (Thermo Fisher, Franklin, MA, USA) at the State Key Laboratory of Plant Physiology and Biochemistry of China Agricultural University. PBZ in extracts was separated on an Inspire C18 column (100 mm × 2.1 mm i.d., 3 μm) (Dikma, Beijing, China) by gradient elution. The mobile phase was started with 40% acetonitrile in distilled water containing 0.1% formic acid and gradually increased to 95% acetonitrile in 4 min. After 4 min at 95% acetonitrile, acetonitrile percentage was decreased to 40% in 6 s and remained at 40% acetonitrile for 4 min prior to the next sample injection. The flow rate was 300 μL/min. The sample injection volume was 5 μL. The retention time of PBZ was at 3.8 min.

RESULTS AND DISCUSSION

Characteristics of Monoclonal Antibody. Six monoclonal hybridomas which were positive to PBZ were obtained, and mAb6H73C9 was the best in sensitivity and selectivity (data not shown). The titer (the maximum serum dilution that gave an absorbance of 1.0 at the noncompetitive assay conditions) of the ascites was $2-4 \times 10^4$. The dissociation constant (K_d) of the mAb was determined with the method of Zhang et al.[15] The K_d value was 2.8×10^{-10} M. The mAb is IgG1 isotype that has κ light chains.

Optimization of icELISA. Organic solvents, ionic strengths, and pH values are the most frequently studied factors that affect the ELISA performance.[17−19] High concentrations of organic solvent were often used to assist the hydrophobic analytes to dissolve in ELISA sample buffer,[19] while 20% methanol in sample buffer, for example, can cause a decrease in sensitivity due to the nonspecific binding and higher background.[20] We assessed effects of methanol, acetone, and DMSO as described previously.[17] The result demonstrated that over 20% acetone caused measurement errors and severe sensitivity decrease and 10% DMSO led to serious antibody deactivation. Sensitivity was notably decreased as concentrations of methanol in PBSTG increased from 5%, 10%, to 20%, which IC_{50} values increased around 2-fold (data not shown). Similar tests were carried out to examine effects of ionic strengths (0.1−0.4 M Na^+), pH (4.5−9.5), and assay buffer concentrations (0.01−0.4 M PBSTG contain 0.14 M Na^+), respectively, and no significant effects were observed. Consequently, the optimal assay solution used in the study was 0.01 M PBSTG buffer containing 0.14 M sodium chloride (pH 7.4) and 10% methanol. MAb6H73C9 was characterized by icELISA using a two-dimensional checkerboard method. The optimum working dilutions for the coating antigen (1.0 mg/mL), purified mAb (1.0 mg/mL), and IgG−HRP conjugate (1.0 mg/mL) were at a ratio of 1:16,000, 1:32,000, and 1:1,000, respectively. Figure 2 shows the standard sigmoidal inhibition curve of PBZ using the optimum reagent dilutions. The calibration curve showed good linearity with a correlation coefficient ≥0.999. The IC_{50} value and quantification detection range (between 80% and 20% B/B_0) were 8.7 ng/mL and 2.0−50.4 ng/mL, respectively. The IC_{50} value was lower than the reported LOD of GC−MS (10 ng/mL).[21]

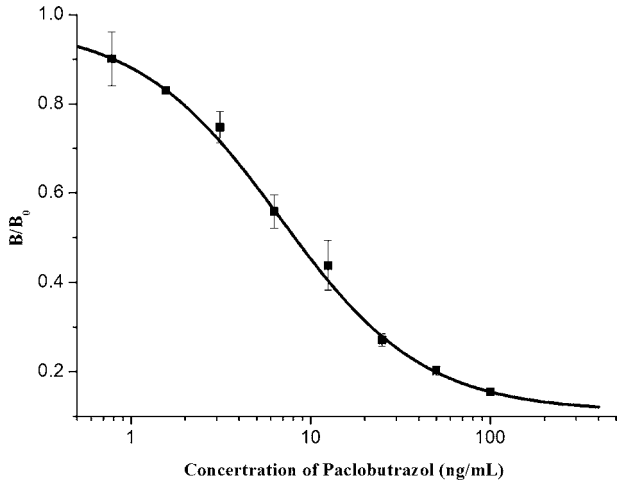

Figure 2. Standard inhibition curve of paclobutrazol by icELISA, obtained under optimized conditions. B_0 and B were absorbance in the absence and presence of competitors, respectively. Concentrations causing 20% and 50% inhibition by paclobutrazol were 2.0 and 8.7 ng/mL, respectively. Each value represents the mean of three replicates.

Cross-Reactivity Studies. The choice and design of the hapten are critical for the production of highly selective antibodies. The strategy to link PBZ with a carrier protein through the hydroxyl group by O-alkylation or O-succinylation as described previously[22] failed, probably due to steric hindrance of the hydroxyl group. Table 1 shows the IC_{50} values and cross-reactivity of 12 triazole compounds. Although most triazoles share the same moieties: a 1,2,4-triazolyl group, a mono- or dichlorinated phenyl group, the cross reactivity of mAb6H73C9 with uniconazole and triadimefon was approximately 0.7% or less. No inhibition was observed up to 4,000 ng/mL of the other 9 analytes. The cross-reactivity result suggested good specificity of mAb6H73C9 to PBZ.

Analyses of Paclobutrazol in Spiked Kernel Samples. Table 2 shows the average recoveries of PBZ fortified in PBZ-free wheat kernels. The matrix interference was almost inevitable for ELISA analysis.[23] The quantitation of hydrophobic compounds such as triazoles requires minimizing matrix interference, which is often a bottleneck in foodstuff analysis by ELISA.[19,22,24] A common method to minimize matrix interference was dilution or appropriate sample pretreatment. In the present study, most lipids were separated out in a small volume of methanol at low temperature, and the −40 °C treatment of concentrated extract solution and centrifugation have most effectively decreased the matrix interference in the optimized icELISA. It is noteworthy that Szekacs et al.[25] studied further cleanup to minimize the interference effects, but

Table 1. Cross-Reactivity of Paclobutrazol and Other Triazole Compounds

Analyte	Structure	IC_{50} (ng/mL)	Cross-reactivity[a] (%)
Paclobutrazol		8.7 ± 0.6[b]	100 ± 6.9
Uniconazole		1,252 ± 14	0.7 ± 0.005
Triadimenol		> 4,000	< 0.2
Triadimefon		NI[c]	0
Difenoconazole		NI	0
Flutriafol		NI	0
Hexaconazole		NI	0
Tebuconazole		NI	0
Cyproconazole		NI	0
Epoxiconazole		NI	0
Propiconazole		NI	0
Tricyclazole		NI	0

[a]Cross-reactivity (%) = (IC_{50} of paclotrabuzol/IC_{50} of other compound) × 100. [b]Values were mean of triplicate determinations ± SD (standard deviation). [c]No inhibition was observed up to 4,000 ng/mL of the analytes.

the average recoveries of the target analytes were not significantly improved. Therefore, the sample extracts were not further cleaned up in the present study. The average recoveries were between 84.3% and 118.9% and the standard deviations were between 3.9 and 14.2% for the seven concentrations. Based on the quantification detection range of icELISA and the recovery study, the LOD of the assay was 2.0 ng/g, which was below the MRLs set by China (500 ng/g) and EU (20 ng/g).

dx.doi.org/10.1021/jf404905w | J. Agric. Food Chem. 2014, 62, 1826−1831

Table 2. Average Recoveries of Paclobutrazol from Wheat Kernels

spiked concns (ng/g)	mean recoveries (%, n = 3)[a]
0	0 ± 0[b]
2.0	118.9 ± 6.3
5.0	114.3 ± 6.3
10.0	101.3 ± 10.5
25.0	118.2 ± 6.2
50.0	99.2 ± 14.2
100.0	89.2 ± 3.9
250.0	84.3 ± 9.2

[a]Data were the means of triplicate samples. Each extract was diluted 10-fold in PBSTG containing 10% methanol before detection. [b]Not detected.

Analyses of Paclobutrazol Residues in Wheat Kernel Samples. The icELISA was applied to monitor PBZ residues in wheat kernels (Table 3). PBZ residues were detectable in all eight kernel samples of which the seedlings were sprayed with PBZ, indicating that PBZ could be transferred from vegetable organs to kernels. The results by icELISA agreed well with those by LC−ESI-MS. The PBZ concentration in the kernel samples varied from 1.5 to 7.3 ng/g, which may be due to uneven sprays of PBZ solution, different efficiencies of absorption and transportation, and metabolic rate in PBZ treated wheat seedlings.

Table 3. Comparison between icELISA and LC−MS Analyses for Paclobutrazol Residues in Wheat Kernels

	concns of PBZ residues (ng/g)	
samples	icELISA	LC−MS
1	7.4 ± 1.1[a]	7.3 ± 0.7
2	5.7 ± 0.8	5.6 ± 0.4
3	3.2 ± 0.7	3.4 ± 0.5
4	2.8 ± 0.4	3.1 ± 0.3
5	2.6 ± 0.7	2.7 ± 0.6
6	2.4 ± 0.8	2.3 ± 0.3
7	<2.0[b]	1.6 ± 0.1
8	<2.0	1.5 ± 0.2

[a]Data were means of triplicate samples. [b]Data were below the LOD of 2.0 ng/g.

We also analyzed PBZ residues with the developed icELISA in commercially available wheat flour samples purchased from different provinces of China including Beijing, Shandong, Shanxi, Anhui, Hebei, and Inner Mongolia. All residues were below the icELISA LOD level or not detected in these 20 samples (Figure 3). ELISA methods have advantages of high throughput and low costs, making it possible to analyze a large number of samples, and the assay we developed can be applied in routine analysis for screening of residue levels in large numbers of wheat flour samples. Samples that appear to exceed the MRL would then be subjected to a confirmatory analysis by HPLC−MS/MS methods.

According to the US Environmental Protection Agency (EPA) memorandum of Paclobutrazol Human Health Risk Assessment, PBZ is allowed for uses on nonfood crops and fruits, while in China, PBZ is widely used on crops or fruits such as wheat, rice, rape, soybean, peanut, orange, longan, litchi, and mango due to its obvious advantages on seedling height decrease while yield increases. Therefore, there is an urgent need to screen PBZ residues in agricultural produce. Our study proved that the developed icELISA could satisfactorily measure PBZ residues in wheat kernels and the LOD was 10-fold below the EU MRL.

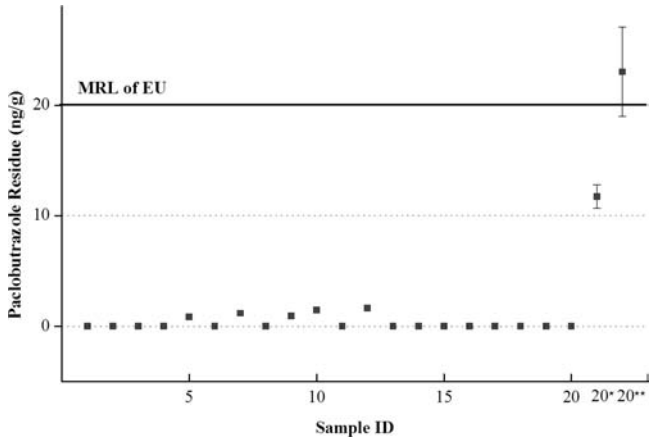

Figure 3. Result of paclobutrazol detection in twenty commercial wheat flour samples by icELISA. Samples 5, 7, 10, 12, and 19 contained paclobutrazol less than 2 ng/g. Residues were not detected in the other samples. Samples 20* and 20** represents sample 20 spiked with 10 ng/g and 20 ng/g paclobutrazol, respectively. Each value represents the mean of three replicates.

Early quantitation of water using gas chromatography consisted of methods using packed molecular sieve columns, and these methods used direct detection with thermal conductivity detectors (TCD)[33−35,37,39] and indirect detection methods (acetylene produced from water reacting with calcium carbide) with a flame ionization detector.[31] These methods yielded poor peak symmetry, poor sensitivity, and poor efficiency due to the strong adsorption of water to the stationary phase. To improve peak symmetry, capillary GC columns were used;[36] however, virtually all GC stationary phases are degraded by water, although bonded and cross-linked varieties are somewhat more stable.[50]

The aim of this work is to develop a method for the simultaneous quantitation of ethanol and water that is simple, accurate, precise, rapid, and cost-effective. This is done by using the response of water or ethanol to normalize reproducibility from injection to injection instead of using an internal standard. The use of water in the gas chromatographic quantitation of commercial products that contain both water and ethanol has been ignored mainly due to the high concentrations of water present in most samples. The concentration of water can exceed the linearity of the detectors, and it can be observed by only a few detectors.[51]

Gas chromatography detectors suitable for water detection are thermal conductivity detectors and ionization detectors that can produce energies higher than 12.6 eV (the ionization energy of water). Helium ionization detectors[52] and barrier discharge ionization detectors (BID)[53] are examples of GC ionization detectors. The detectors used in this study were the thermal conductivity detector and a new barrier discharged ionization detector. The TCD is widely used and available. The BID is chosen because of its high sensitivity to water and because it is optimally designed to reduce baseline fluctuation.[53] It was reported that the BID is 100 times more sensitive to water than the TCD.[54] It is known that TCDs are nonlinear at high concentrations of water and ethanol.[51] The degree of linearity of the BID response to water and ethanol has not been reported.

Column considerations for water analysis consist of column stability, peak efficiency and symmetry, and selectivity between water and ethanol. Armstrong et al. showed that new ionic liquid (IL) based GC capillary columns have far superior selectivity and stability toward water in all solvents tested as compared to traditional commercial columns.[55−62] In addition, the IL column containing bis(3-hydroxyalkylimidazolium)-polyethylene glycol triflate (SLB-IL107) is shown to have good peak shape and symmetry for water.[55]

Herein we outline an effective and accurate method for the quantitation of both ethanol and water at any/all levels in commercial products. Typical run times are just over 3 min. This paper examines the determination of ethanol and water in commercial products using their individual responses rather than an internal standard to improve method precision. Examination of the responses of water and ethanol over a broad range of concentrations with the TCD and BID GC detectors is performed. To our knowledge this is the first study that uses (a) the responses of both water and ethanol to maintain method precision, (b) a nonlinear-based calibration, (c) IL-based GC capillary columns, and (d) a BID in the simultaneous determination of ethanol and water in a variety of commercial products.

MATERIALS AND METHODS

Materials. *Chemicals.* Anhydrous 200 proof ethanol was purchased from Sigma-Aldrich (Milwaukee, WI, USA). Deionized water was produced by a Milli-Q system (Billerica, MA, USA).

Standards. Standard reference materials were purchased from the National Institute of Standards and Technology (NIST, Gaithersburg, MD, USA): 1847, ethanol−water solution set. The *NIST2* sample contained 1.55 ± 0.02 mass % ethanol, *NIST6* contained 6.04 ± 0.04 mass % ethanol, and *NIST25* contained 25.2 ± 0.2 mass % ethanol. Ethanol reference standards also were purchased from Sigma-Aldrich: E2385, ethanol standards 10% (v/v); this sample was identified in this work as *Sigma10*. Sigma-Aldrich reported *Sigma10* to contain 7.7 mass % ethanol.

Samples. The commercial products used, such as beer, wine, liquor, mouthwash, and flavor extracts, were Bud Light (Anheuser-Busch Inc., St. Louis, MO, USA), chardonnay (Gallo Family Vineyards, Modesto, CA, USA), Crown Royal (The Crown Royal Co., Norwalk, CT, USA), Scope Mint (Procter & Gamble Co., Cincinnati, OH, USA), and pure almond extract (Penzeys Spices, Arlington, TX, USA).

Gas Chromatography-TCD. Gas chromatography was performed with an Agilent 6890N gas chromatograph equipped with a thermal conductivity detector and a 7683B series autosampler (Agilent Technologies, Inc., Santa Clara, CA, USA).

Gas Chromatography-BID. Gas chromatography was performed using a Shimadzu Tracera GC system consisting of a Shimadzu barrier discharge ionization detector coupled with a Shimadzu GC-2010 Plus capillary gas chromatograph and a Shimadzu AOC-5000 liquid GC injection system (Shimadzu Scientific Instruments, Inc., Columbia, MD).

Gas Chromatography Column. The column selected for all analyses was bis(3-hydroxyalkylimidazolium)-polyethylene glycol triflate: SLB-IL107, 30 m × 0.25 mm i.d. × 0.20 μm (Supelco, Bellefonte, PA, USA).

Software. The chromatographic software analysis was performed on an Agilent ChemStation rev. B.01.03 (Agilent Technologies, Inc.) and Shimadzu GCsolution version 2.41 (Shimadzu Corp.). The nonlinear regression was completed using Microsoft Excel 2013 (Microsoft Corp., Redmond, WA, USA). The calculations for solving the polynomials was performed using Wolfram Mathematica 9 (Wolfram Research, Champaign, IL, USA).

Methods. *Gas Chromatography-TCD.* Instrumental conditions were isothermal at 110 °C, constant flow at 1 mL/min, 0.1 μL injection, split 100:1 or 200:1, and TCD and inlet at 250 °C.

Gas Chromatography-BID. Instrumental conditions were isothermal at 110 °C, flow at 1 mL/min, 0.1 μL injection, split 100:1 or 200:1, and BID and inlet at 250 °C.

Standards. Ethanol and water standards for calibration were made gravimetrically using anhydrous ethanol and water with the concentration in mass percent (m/m). Conversion of concentration to volume percent (v/v) was performed by density values at measured temperatures.

Samples. All commercial samples and standards were injected neat.

Calculations. The retention factor (k) was calculated using $k = (t_r - t_o)/t_r$, where t_r is the retention time and t_o is the dead time, which is determined by the air peak in TCD and BID. Selectivity (α) was calculated by $\alpha = k_2/k_1$, where k_1 and k_2 are the retention factors of the first and second species, respectively. The resolution (R_s) was determined using $R_s = 2(t_{r2} - t_{r1})/(w_1 + w_2)$, where w_1 and w_2 are the base peak width of the first and second species, respectively. Efficiency or plate count, N, was determined by $N = 16\,(t_r/w_b)^2$ where w_b is the width at the base of the peak and t_r is the retention time of the analyte. Peak symmetry factor, A_s, was determined by $A_s = b/a$, where b is the distance from the point at peak midpoint to the trailing edge of the peak measured at 10% of peak height and a is the distance from the leading edge of the peak to the midpoint of the peak measured at 10% of peak height.

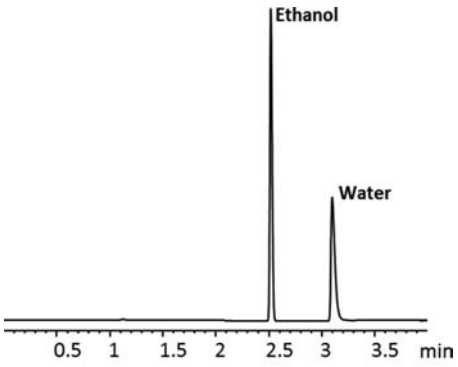
RESULTS AND DISCUSSION

The separation of ethanol and water standards was obtained in under 3.5 min (Figure 1) using a capillary ionic liquid column



Parameter	Ethanol	Water
Retention Factor (*k*)	0.7	1.1
Plate Count (*N*)	64000	33000
Peak Symmetry Factor (A_s)	0.95	1.30
*Selectivity (α)	1.6	
*Resolution (R_s)	6.4	

Figure 1. Chromatographic separation and data of ethanol and water using a thermal conductivity detector. Standard sample analyzed is 60% ethanol and 40% water (m/m). See Materials and Methods for method details and equations of retention factor (k), plate count (N), peak asymmetry factor (A_s), selectivity (α), and resolution (R_s). *Selectivity and resolution are calculated using the ethanol and the water peak.

at isothermal conditions of 110 °C. Chromatographic data are shown in Figure 1. Peak symmetry factors (A_s) for ethanol and water were 0.95 and 1.3, respectively. Selectivity (α) between ethanol and water is 1.6, and resolution (R_s) between ethanol and water is 6.4. The chromatographic data show excellent selectivity between ethanol and water and excellent method resolution. Injector considerations are important when water is a large component of the injected sample. Water can cause inlet backflash given its large expansion volume.[50] The direct injection of water requires small injection volumes and appropriate inlet liner selection. The inlet liner used is a cup style liner with glass wool that allows turbulent flow for adequate sample vaporization and mixing. Injection volume was chosen to be 0.1 μL to avoid backflash and error in quantitation. The split ratio was adjusted between 100:1 and 200:1. The calibration and quantitation used a split ratio of 200:1. To investigate column stability a standard consisting of 10% by mass ethanol and 90% by mass water was injected 800 times on the SLB-IL107 ionic liquid capillary column. The chromatogram at injection 1 is overlaid with the chromatogram at injection 800 (Figure 2). No changes in column performance can be seen.

Method Range. The method range can be seen in Figure 3. The concentrations of water and ethanol are usually high in commercial products such as beer, wine, liquor, mouthwash, and flavor extracts. Consequently, an examination of the method response to water and ethanol over a broad range of concentrations was performed.

Analysis using TCD, shown in Figure 3A, produced a nonlinear plot of the peak area of water versus concentration of water (m/m) at a split ratio of 200:1, whereas ethanol shows

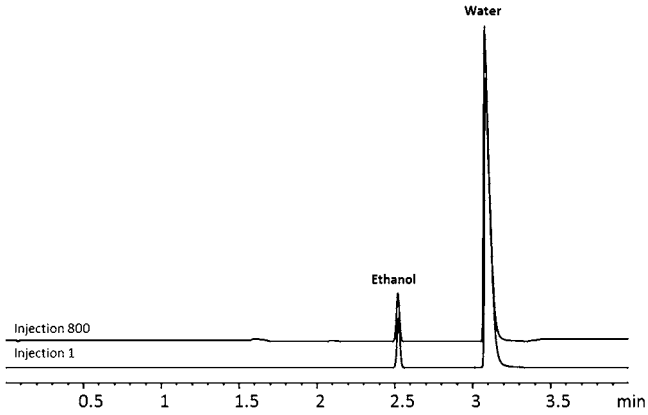


Figure 2. Column stability after 800 injections of a sample containing 10% by mass ethanol and 90% by mass water. Chromatographic separation was performed using a thermal conductivity detector. See Materials and Methods for method details.

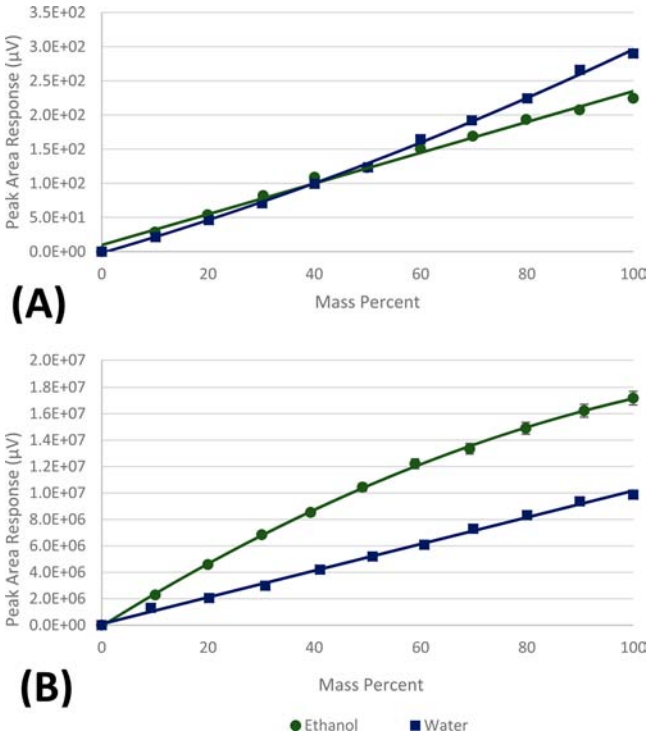

Figure 3. (A) Thermal conductivity detector (TCD) experimental linear range of peak area response versus mass percent of ethanol and water. TCD was set at 250 °C. Water showed a nonlinear response that yielded a polynomial best fit equation $y = 0.0072x^2 + 2.2633x - 2.0212$ with a square correlation coefficient of 0.9984. Ethanol showed a linear response that yielded a best fit equation $y = 2.2523x + 9.4708$ with a square correlation coefficient of 0.993. (B) Barrier discharge ionization detector (BID) experimental linear range of peak area response versus mass percent of ethanol and water. BID was set at 250 °C. Water showed a linear response that yielded a best fit equation $y = 100786x + 88459$ with a square correlation coefficient of 0.997. Ethanol showed a nonlinear response that yielded a polynomial best fit equation $y = -797.35x^2 + 251945x - 76451459$ with a square correlation coefficient of 0.9996. For both panels A and B, the standards consisted of a binary solution of water and ethanol that ranged in concentration from 0 to 100 mass %. See Materials and Methods for method details.

dx.doi.org/10.1021/jf4050167 | J. Agric. Food Chem. 2014, 62, 1832−1838

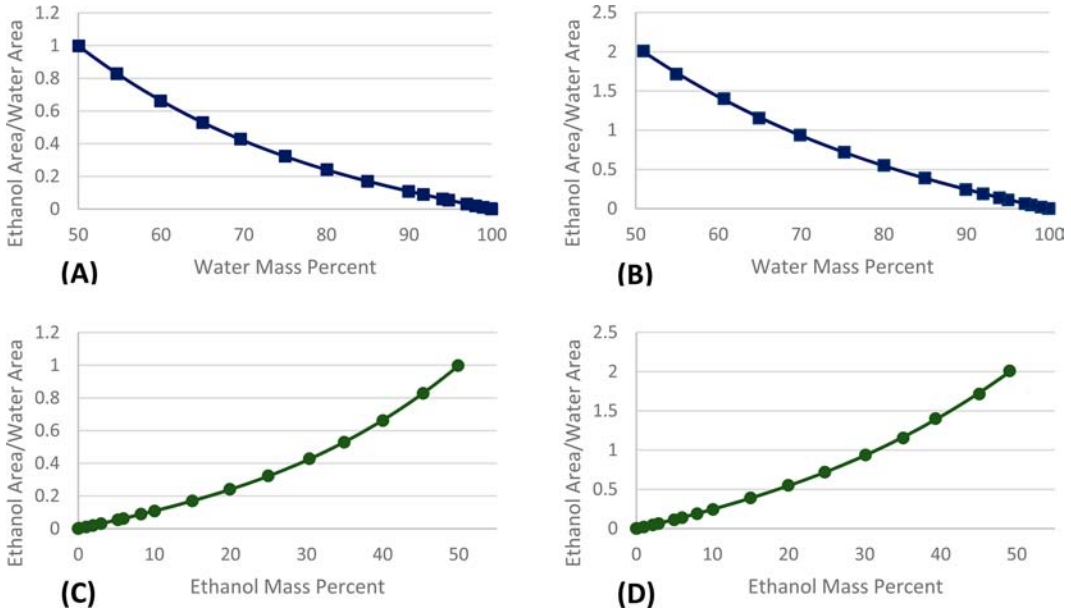

Figure 4. (A) Thermal conductivity detector (TCD) calibration plot of ethanol peak area divided by water peak area versus mass percent of water. The standards consisted of a binary solution of water and ethanol that ranged in concentration from 50 to 100 mass % water. (B) Barrier discharge ionization detector (BID) calibration plot of ethanol peak area divided by water peak area versus mass percent of water. The standards consisted of a binary solution of water and ethanol that ranged in concentration from 50 to 100 mass % water. (C) TCD calibration plot of ethanol peak area divided by water peak area versus mass percent of ethanol. The standards consisted of a binary solution of water and ethanol that ranged in concentration from 0 to 50 mass % ethanol. (D) BID calibration plot of ethanol peak area divided by water peak area versus mass percent of ethanol. BID was set at 250 °C. The standards consisted of a binary solution of water and ethanol that ranged in concentration from 0 to 50 mass % ethanol. See Materials and Methods for method details.

linearity through all concentrations. The TCD nonlinear response of water is due to the high concentration of water saturating the TCD flow cell, and this causes a positive deviation from linearity. In addition, the response of water is linear at concentrations lower than approximately 50% by mass.

Performing the same analysis using a BID (see Materials and Methods and Figure 3B) shows a nonlinear plot for the peak area of ethanol versus concentration at a split ratio of 200:1, whereas water shows a linear range through all concentrations. The BID nonlinear response of ethanol is due to the ionizability of water as compared to ethanol. The ionization energies of water and ethanol are 12.6 and 10.6 eV, respectively. The ionization energy of water is higher compared to that of ethanol, and thus the BID is more sensitive to ethanol than to water. The nonlinear response of ethanol using the BID is due to the saturation of the detector causing a negative deviation from linearity due to the ease of ionizability of ethanol. The linearity in the BID detectors also is dependent on the gas phase concentration of ethanol or water in the detector cell. In addition, the BID response to ethanol is linear at concentrations lower than approximately 30% by mass.

A study was performed to observe changes in the linear range in the TCD and BID by adjusting the split ratio from 200:1 to 100:1 (see Figures S1 and S2 in the Supporting Information and Figure 3). The decrease in the split ratio to 100:1 reduced the linear range of both the TCD response to water and the BID response to ethanol by almost 10 mass %.

Calibration and Quantitation. Calibration can be accomplished by the response of ethanol divided by the response of water (or vice versa) plotted against the concentration range of a series of ethanol and water standards, and no internal standard is needed. This is possible by taking advantage of two things. One is the volatile components of beer, wine, liquor, mouthwash, and flavor extracts of commercial products consisting mainly of a binary solvent mixture of a total concentration greater than approximately 99.5% (m/m) (determined gas chromatographically by total trace volatile component presence)[63] and eliminates the need for an internal standard. The other is that the use of nonlinear calibration corrects for the nonlinear response of the detectors.

All calibrations are shown in Figure 4. The calibration process can be described via an approach that is analogous to external calibration with the addition of the response of water and ethanol normalizing injection reproducibility. This shortens the analysis time. In addition, this process shows a nonlinear plot. This is due to detector response of ethanol and water at high concentrations as previously described. Nonlinear calibration is possible as long as the reproducibility of the calibration is assured.[64,65] Quantitation is simplified by solving a polynomial equation of a nonlinear calibration curve using mathematical software.

The standards for calibration consisted of binary solutions of water and ethanol that ranged in concentration from 0 to 50 mass % ethanol and from 50 to 100 mass % water. All of the calibration curves (Figure 4) could be described with third-order polynomials created in Microsoft Excel using the response data to obtain the best fit model. The GC split ratio of 200:1 was chosen for the calibration and quantitation. Figure 4A shows the TCD calibration plot of water (ethanol peak area divided by water peak area vs mass percent of water), and the calibration plot (Figure 4A) yielded a polynomial best fit equation $y = -4 \times 10^{-6}x^3 + 0.0011x^2 - 0.1234x + 4.821$ with a square correlation coefficient of 0.9999. Figure 4B shows the BID calibration plot of water (ethanol peak area divided by water peak area vs mass percent of water), and the calibration plot (Figure 4B) yielded a polynomial best fit equation $y = -5$

Table 1. Reported and Calculated Values of Ethanol and Water Concentration by Mass Percent[a]

	reported value[b]		TCD		BID	
sample	ethanol, mass %	water, mass %	ethanol, mass %	water, mass %	ethanol, mass %	water, mass %
NIST2	1.55 ± 0.02	98.4	1.5 ± 0.1	99 ± 2	1.5 ± 0.1	98 ± 4
NIST6	6.04 ± 0.04	94.0	5.8 ± 0.2	94 ± 2	6.0 ± 0.3	94 ± 6
NIST25	25.2 ± 0.2	74.8	24.7 ± 0.3	75 ± 1	25.0 ± 0.2	75 ± 1
Sigma 10	7.7	92.3	7.6 ± 0.1	92 ± 1	7.7 ± 0.3	92 ± 3
almond extract	25.3	74.7	24.4 ± 0.4	76 ± 1	24.9 ± 0.8	75 ± 3
Bud Light	3.3	96.7	3.2 ± 0.2	97 ± 7	3.3 ± 0.1	97 ± 2
Scope Mint	15.0	85.0	15.5 ± 0.2	84 ± 1	15.5 ± 0.1	85 ± 1
chardonnay	10.6	87.1[c]	11.0 ± 0.3[c]	88 ± 3[c]	11.1 ± 0.2[c]	88 ± 2[c]
Crown Royal	34.5	65.5	32.8 ± 0.5	67 ± 2	33.4 ± 0.6	67 ± 2

[a]Calculated values were extrapolated from the calibration curves. Chromatographic conditions were isothermal at 110 °C, flow = 1 mL/min, 0.1 μL injection, split 200:1, thermal conductivity detector (TCD), barrier discharge ionization detector (BID), and inlet at 250 °C, column SLB-IL107 (30 m × 0.25 mm i.d. × 0.20 μm). See Materials and Methods for descriptions of samples. [b]Deviation of the reported values is listed only for NIST samples. Other manufacturers did not provide a deviation for the values shown. The reported value for water was determined from the difference of the concentration of ethanol from 100%. [c]Adjusted for nonvolatile component. Nonvolatile component mass percent is determined by weight of residue after drying from an initial weight of consumer product.

$\times 10^{-6}x^3 + 0.0016x^2 - 0.1977x + 8.496$ with a square correlation coefficient of 0.9999. Figure 4C shows the TCD calibration plot of ethanol (ethanol peak area divided by water peak area vs mass percent of ethanol), and the calibration plot (Figure 4C) yielded a polynomial best fit equation $y = 4 \times 10^{-6}x^3 + 2 \times 10^{-6}x^2 + 0.0105x - 0.0006$ with a square correlation coefficient of 0.9999. Figure 4D shows the BID calibration plot of ethanol (ethanol peak area divided by water peak area vs mass percent of ethanol), and the calibration plot (Figure 4D) yielded a polynomial best fit equation $y = 5 \times 10^{-6}x^3 + 0.0001x^2 + 0.0233x - 0.0041$ with a square correlation coefficient of 0.9999. For a faster calibration, a two to three point linear calibration within a short concentration range of the consumer product being analyzed can be performed. The BID and TCD showed good intraday reproducibility of the method. The BID showed good interday reproducibility. However, interday reproducibility is limited for the TCD due to the dependence to the response of the TCD to humidity.

Standard reference materials were purchased for validation of method accuracy (see Materials and Methods; Table 1). The samples chosen for quantitation of water and ethanol commercial products consisted of beer, wine, liquor, mouthwash, and flavor extract. These samples are used to illustrate the range of applicability of this method to different commercial products. Table 1 lists the reported values from the manufacturer and the calculated concentrations with GC-TCD and GC-BID analysis of ethanol and water. The value of water in the reported values column in Table 1 was calculated by the difference of the concentration of ethanol reported from the manufacture from 100. The calculated values were determined by solving for x with the calibration polynomial in Wolfram Mathematica 9 by the input of the response of ethanol divided by the response of water as the variable, y (see Materials and Methods). Both TCD and the BID yielded results in agreement with the standard reference materials (Table 1).

Figure 5 shows a chromatogram of the commercial almond extract sample analyzed using the BID. This chromatogram shows the method's effectiveness in the analysis of the commercial products with ample efficiency and selectivity for water and ethanol and no trace components observed. The overall water and ethanol content determined for the commercial products was similar to the values stated by the

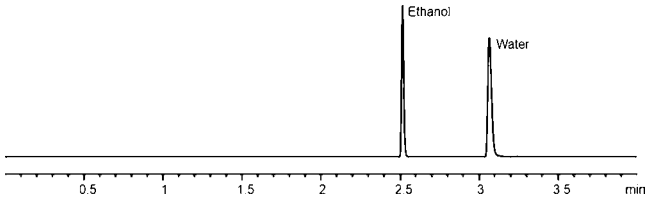

Figure 5. Chromatogram of commercial almond extract sample analyzed with barrier discharge ionization detection. The method for the analysis can be seen under Materials and Methods.

manufacturers. However, initial analysis of the wine sample, chardonnay, resulted in a low value for ethanol (8.3% mass) compared to the manufacturer's reported value (10.6% mass). It was found that this deviation was due to the presence of nonvolatiles, such as sugar, in the wine sample. Adjustment for nonvolatile components can be made by weight analysis of the residue by drying. The nonvolatile component mass percent was determined by the measurement of the weight of residue after drying from an initial weight of the wine product. The wine was found to consist of 2.3% mass of nonvolatiles. The final value of the ethanol and water mass percent was adjusted using the residue value, and the adjusted results agreed with the manufacturer's reported values. The uncertainties in the measurements of the water analysis compared to ethanol analysis were slightly larger. This was due to the high concentration of water in the samples and the dependency on humidity. To reduce the error, all samples and standards were parafilm sealed and stored at 4 °C. In addition, all samples and standards were minimally exposed to the atmosphere when opened.

A method for the quantitation of both ethanol and water that is simple, rapid, cost-effective, precise, and accurate has been developed. Simplicity, reduction of cost, and decreased analysis time have been accomplished by the removal of the internal standard method. This was accomplished by using the response of ethanol divided by the response of water (or vice versa) plotted against the concentration range of a series of ethanol and water standards. Using capillary ionic liquid gas chromatography, a fast analysis with high selectivity and resolution of the water and ethanol was obtained. This method shows both ethanol and water can be determined at all concentrations in commercial products. This method is

transferable to other binary solvent systems other than ethanol and water. The BID is linear at all concentrations of water with the described method. This makes it advantageous for development of external calibration methods for water analysis that cannot be performed with a TCD.

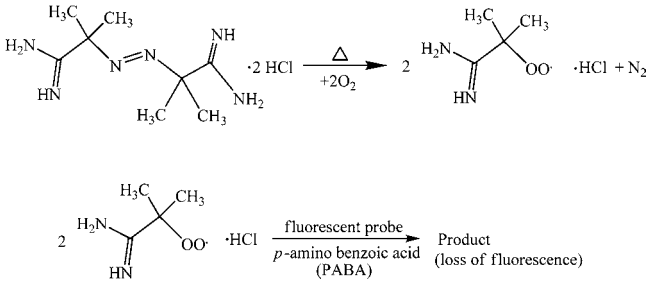

Figure 1. Scheme of competitive reactions showing the decomposition of AAPH, generation of peroxyl radicals, and conversion of the PABA probe to non-fluorescent products.

would be observed. As the reaction proceeds, the antioxidants are consumed by the constant flux of ROO• and the oxidation of the probe would progress at a slower rate when compared to the control (i.e., absence of antioxidant compounds). When the antioxidants are depleted, the rate of oxidation of the probe is similar to that of the control.[2]

The oxygen radical absorbance capacity (ORAC) assay is one of the most common methods for assessing ROO• scavenging activity based on the fluorescence intensity decrease of the ORAC probe with time under a reproducible and constant flux of ROO•, generated from the thermal decomposition of AAPH in aqueous buffer. The area under the fluorescence decay curve (AUC) is the parameter used to analyze the results in conventional ORAC tests. In the presence of chain-breaking antioxidants, the decay of fluorescence is inhibited.[11] The protein isolated from *Porphyridium cruentum*, β-PE, was initially used as the fluorescent probe, which reacts with ROO• to form a non-fluorescent product.[12] However, some shortcomings were observed with this probe, such as large lot-to-lot variability of production, photobleaching of β-PE after exposure to excitation light, and interaction with polyphenols by non-specific protein binding.[13] To overcome these limitations, the synthetic non-protein fluorescent probe, FL, has replaced the original β-PE,[14] but FL has also been criticized to undergo fluorescence quenching, side reactions, and undesired interactions.[15] The conventional ORAC method is limited to the measurement of hydrophilic chain-breaking antioxidants but ignores lipophilic ones. The application to both lipophilic and hydrophilic chain-breaking antioxidants was carried out using a mixture of acetone/water containing 7% randomly methylated β-cyclodextrin (M-β-CD) oligosaccharide as a water solubility enhancer,[16] but such high concentrations of oligosaccharides may not release the tested antioxidants to undergo oxidation because of the formation of relatively stable inclusion complexes.

The total radical-trapping antioxidant parameter (TRAP) assay was based on the measurement of the time period in which oxygen uptake was inhibited by plasma during a controlled ROO• peroxidation reaction.[17] TRAP measures oxygen consumption during controlled lipid oxidation induced by thermal decomposition of AAPH as the radical generator and R-phycoerythrin (PE) as the fluorescent probe and reports results in micromoles of peroxyl radical deactivated per liter of solution.[17] In the crocin bleaching assay, which has found limited applications in food and biochemistry, the ability of antioxidant compounds to protect the carotenoid derivative crocin from oxidation by ROO• is measured.[18]

The selectivity of a probe for ROO• detection mainly depends upon its standard redox potential. Although ROO• has a wide range of reduction potentials ($E°$) ranging between 0.77 and 1.44 V, the $E°$ of alkyl peroxyl radicals derived from polyunsatured fatty acids (PUFA) is 1.00 V at pH 7.0.[19] On the other hand, in strongly to weakly acidic solutions, the oxidation peak potentials of the *p*-aminobenzoic acid (PABA) probe (on a carbon paste electrode) vary in the range of 0.84−0.98 V.[20] With other modified electrodes (e.g., with crown ethers), the PABA oxidation potential may rise up to 1.055 V. Thus, it may be envisaged that ROO• can oxidize PABA, whereas $O_2^{\bullet -}$ ($E°$ = 0.940 V), $^1O_2$ ($E°$ = 0.650 V), PUFA alkyl radicals ($E°$ = 0.600 V), and H_2O_2 ($E°$ = 0.320 V)[21] may not easily do so. The oxidation potential of the ORAC probe, FL, was reported as 0.78 and 1.21 V versus saturated calomel electrode (SCE) in protonated and deprotonated forms, respectively, corresponding to 1.024 and 1.45 V calculated potentials versus standard hydrogen electrode (SHE),[22] and consequently, FL was characterized as "prone to be oxidized by several reactive species into a non-fluorescent product".[23] Thus, the PABA probe is expected to be a right choice for ROO• detection.

We report herein the development of a novel fluorescence probe for ROO•, PABA, which can specifically detect ROO• and measure its scavenging activity in terms of an increase of fluorescence in the presence of a scavenger compound. ROO• scavenging activity of several pure compounds (thiol-type antioxidants, glutathione (GSH), cysteine, *N*-acetyl-cysteine (NAC), homocysteine, 1,4-dithioerythritol (DTE), and cysteamine; amino acids, methionine, serine, and proline; plasma antioxidants, albumin, bilirubin, uric acid, and ascorbic acid) and tissue homogenates (kidney, liver, and heart) was determined by the proposed method in comparison to the classical ORAC method.

MATERIALS AND METHODS

Reagents and Apparatus. Bilirubin, serine, cysteamine, homocysteine, uric acid, GSH, AAPH, N-acetyl-L-cysteine, and dithioerythritol were purchased from Sigma-Aldrich (St. Louis, MO). Ascorbic acid, albumin from bovine serum, and proline were donated from Merck (Darmstadt, Germany), and PABA, cysteine, methionine, and FL were obtained from Fluka (Buchs, Switzerland). All other reagents used were of analytical grade.

The fluorescence spectra were measured in quartz cuvettes using a Varian Cary Eclipse model spectrofluorometer (Mulgrave, Victoria, Australia). A Waters Breeze 2 model high-performance liquid chromatography (HPLC) system (Milford, MA) equipped with a 2998 photodiode array detector (Chelmsford, MA) was used for chromatographic measurements.

Preparation of Solutions. For the PABA method, the following solutions were prepared: PABA solution (20 μM) and AAPH (20 mM) were prepared in pure distilled water (Millipore Simpak 1 Synergy 185, Billerica, MA). For the classical ORAC method, FL (78 nM) and AAPH (221 mM) were prepared in phosphate buffer (pH 7.4). This buffer (7.5×10^{-2} M NaH_2PO_4−Na_2HPO_4 equimolar mixture) was prepared in distilled water. All scavengers were freshly prepared in distilled water from 1.0×10^{-5} to 5.0×10^{-5} M concentrations, except uric acid and bilirubin, which were initially prepared in 0.5 M NaOH solution and then diluted with distilled water for the PABA method. The original uric acid and bilirubin solutions in 0.5 M aqueous NaOH were diluted with phosphate buffer (pH 7.4) for the classical ORAC assay.

Preparation of Tissue Homogenates. Male, 8−10-week-old, Wistar rats (weight range of 290−310 g) were supplied by the animal facility from the Faculty of Veterinary Medicine of Istanbul University. The rats were housed in polycarbonate cages (450 cm^2 area per animal), acclimatized for 2 weeks under laboratory conditions (21 ± 2 °C, humidity of 60 ± 5%, and 12 h light/dark cycle), and fed with water and standard rat chow *ad libitum*. Liver, heart, and kidney tissues

were isolated after sacrifice by decapitation of the rat. The tissue samples were washed with 0.9% (w/v) NaCl solution, weighed (10%, w/v), and homogenized by adding cold 1.15% (w/v) KCl solution in a glass homogenizer. Homogenates were immediately frozen in liquid nitrogen and kept at −80 °C until analysis.[24] Homogenates were centrifugated at 12 000 rpm for 15 min at 4 °C and filtered through a 0.45 μm membrane filter before analysis.

PABA Assay (Proposed Method). To a test tube were added 0.5 mL of 20 μM PABA (probe), 0.5 mL of scavenger solution (at different concentrations), 2.0 mL of distilled water, and 2.0 mL of 2.0×10^{-2} M AAPH in this order. The reaction started by adding AAPH solution. The mixture in a total volume of 5.0 mL was incubated for 30 min in a water bath kept at 37 °C. At the end of this period, the fluorescence intensity (λ_{ex} = 267 nm, and λ_{em} = 334 nm) of the reaction mixture was recorded. The half-maximal inhibitory concentration (IC_{50}) values of the scavengers (i.e., defined as the concentration of the scavenger antioxidant that results in 50% inhibition of the fluorescence-decay reaction caused by peroxyl radicals) were determined with the use of PABA by means of a linear plot of inhibition percentage as a function of $C_{scavenger}$, where I_0 is the initial fluorescence intensity of the original PABA solution and I_1 and I_2 are the fluorescence intensities of PABA subjected to peroxyl radical action in the absence and presence of a scavenger compound (having a molar concentration, C), respectively. The IC_{50} values were then compared to those found with the classical ORAC method. The fluorescence intensity of PABA was higher in the presence of ROO• scavengers; therefore, a higher intensity of the reaction mixture was an indication of enhanced ROO• scavenging activity.

ROO• scavenging activity was calculated using the following equation:

$$\text{inhibition ratio } (\%) = 100[(I_2 - I_1)/(I_0 - I_1)] \quad (1)$$

The inhibition percentage (y) can be linearly correlated to the concentration of the scavenger antioxidant (x)

$$y \approx mx + n \quad (2)$$

where m and n are the slope and intercept of this line, respectively.

IC_{50} can then be calculated for 50% inhibition by substituting an ordinate (y) value of 50.

$$y = 50 = m(IC_{50}) + n \quad \text{or} \quad IC_{50} = (50 - n)/m \quad (3)$$

Classical ORAC Assay. The ORAC method, using FL as the fluorescent probe, was carried out as described by Ou et al.[14] Briefly, to a test tube were added 2.0 mL of 78 nM FL, 2.0 mL of scavenger solution (at different concentrations), and 1.0 mL of 221 μM AAPH rapidly in this order. The reaction was started by adding AAPH solution. The reaction was performed at 37 °C through the thermal decomposition of AAPH because of the sensitivity of FL to pH.[13] The mixture in a total volume of 5.0 mL was incubated for 10 min in a water bath kept at 37 °C. At the end of this period, the fluorescence intensity (λ_{ex} = 493 nm, and λ_{em} = 515 nm) of the reaction mixture was recorded. ROO• scavenging activity was calculated using eqs 1−3.

HPLC Assay. The chromatographic analysis was carried out on a Waters Breeze 2 model HPLC system (Milford, MA), equipped with a 2998 model photodiode array detector (Chelmsford, MA). A total of 20 μL of incubation solution was injected into a reverse-phase ACE C18 column (4.6 × 250 mm, 5 μm particle size) (Milford, MA), and the separation was performed by gradient elution. The mobile phase consisting of a mixture of (A) 5% methanol/94% water (v/v) and 1% acetic acid and (B) 55% methanol, 44% water, and 1% acetic acid was delivered to the column at a flow rate of 1.0 mL min^{-1}. The gradient elution program for the analysis of the incubation mixture was 0−3 min, mobile phase A (slope 1.0); 3−8 min, gradient to 100% mobile phase B (slope 1.0); 8−23 min, mobile phase B (slope 1.0); 23−23 min, and linear gradient to 100% mobile phase A (slope 1.0).[25] The detection wavelength was set at 286 nm with a total run time of 23 min. Data acquisition and handling were performed by Empower PRO (Waters Associates, Milford, MA).

ROO• scavenging activity was calculated using a modified version of eq 1

$$\text{inhibition ratio } (\%) = 100[(A_2 - A_1)/(A_0 - A_1)] \quad (4)$$

where A_1 and A_2 are the peak areas of the PABA probe in the absence and presence of the ROO• scavenger, respectively, and A_0 is the peak area of the PABA probe at the initial concentration in the reaction mixture.

Statistical Analysis. The two-way analysis of variance (ANOVA) was used for data evaluation, and the significance of the difference between means was determined (p = 0.05) using SPSS software for Windows (version 13).[26] Results were reported as the mean ± standard deviation (SD) by carrying out measurements for at least three replicates of each scavenger compound or biological sample.

RESULTS AND DISCUSSION

Optimization of the PABA Assay Parameters. In this study, we developed a rapid and sensitive ROO• scavenging activity assay for pure antioxidant compounds (i.e., amino acids, thiol-type antioxidants, and plasma antioxidants) and biological fluids. PABA has first been used as a specific probe for the determination of ROO• scavenging activity. The PABA assay measures ROO• scavenging potential based on the ability of a compound to protect the oxidative probe PABA from oxidation by ROO•. In the competitive reaction, ROO• generated by thermal dissociation of AAPH attacks both the PABA probe and scavengers to form non-fluorescent products. The attenuation in the fluorescence intensity loss of the PABA probe is dependent upon the ROO• scavenging activity of the tested compound or sample. With the aid of PABA fluorescence values recorded in the presence and absence of scavengers, the ROO• scavenging activity of scavenger compounds can be calculated.

Although the non-fluorescent oxidation products were not identified under the same conditions of this assay, photochemical oxidation products were detected by Shaw et al., which may give some idea about the nature of such products.[27] Rapid discoloration of the photolyzed sample was observed when PABA was irradiated in aerated solution. Although a number of products were detected under these conditions, the three most abundant stable compounds have been isolated and identified [by nuclear magnetic resonance (NMR) spectroscopy] as 4-amino-3-hydroxybenzoic acid, 4-aminophenol, and 4-(4′-hydroxyphenyl)aminobenzoic acid. Likewise, a rapid reaction of singlet oxygen with PABA was reported by Allen et al.,[28] but oxidation products were not identified.

Under the optimized conditions, the molar fluorescence coefficient for PABA in the proposed method was $\varepsilon = 1.0 \times 10^8$ M^{-1} cm^{-1} and the linear range of relative fluorescence intensity versus the concentration of PABA was in the interval of 0.5−5.0 μM, with a correlation coefficient (r) of 0.992 (N = 3), within which the relative standard deviation (RSD) was 3.1%. The limit of detection (LOD) and limit of quantification (LOQ) of the proposed method were calculated using the equations: $LOD = 3s_{bl}/m$ and $LOQ = 10s_{bl}/m$, respectively, where s_{bl} is the standard deviation of a blank and m is the slope of the calibration line. LOD and LOQ were found to be 0.09 and 0.30 μM, respectively. Assay precision and accuracy were assessed by analyzing two spiked homogenates (i.e., liver and kidney) at clinical relevant concentrations of 1, 2, and 5 μM analyzed (Table 1). The precision data of the proposed assay (expressed as the percent RSD values) was approximately 4.14%. Recovery values from 97.5 to 105.0% were obtained. Reproducibility studies were carried out in five replicates for PABA at 2.0 μM.

Table 1. Precision and Recovery of the Proposed Method

PABA additions to tissue homogenates	added concentration (μM)	mean (μM)	SD[a]	RSD (%)[b]	REC (%)[c]
liver	1.0	1.02	0.04	4.14	101.5
	2.0	2.08	0.05	2.16	104.3
	5.0	5.01	0.03	0.52	100.2
kidney	1.0	1.05	0.03	3.05	105.0
	2.0	1.95	0.03	1.32	97.5
	5.0	4.98	0.07	1.36	99.5

[a]SD = standard deviation. [b]RSD = relative standard deviation. [c]REC = recovery (N = 3).

The intraday and interday precisions of the developed method, expressed as the RSD for the analyte, were 0.98 and 2.27% (N = 5), respectively.

For comparison, time-dependent fluorescence intensity changes were recorded using final mixture solutions (PABA, PABA + AAPH, and PABA + AAPH + cysteine) incubated under identical conditions (Figure 2). There was no noteworthy change in intensity of the PABA standard solution within the 0−35 min time interval (Figure 2). It was observed that the fluorescence intensity response in the presence of cysteine decreased with the increase in incubation time from 0 to 30 min and reached a plateau after 30 min. Therefore, 30 min was chosen as the optimal measurement time. Thus, because of the high conversion yield of PABA, IC_{50} values of the studied scavengers could be relatively rapidly and precisely determined by recording the relative intensities within 30 min. On the other hand, for a typical human serum sample using the ORAC assay system originally used by Cao et al.,[12] oxidation of β-PE was reported to reach completion within about 90 min.

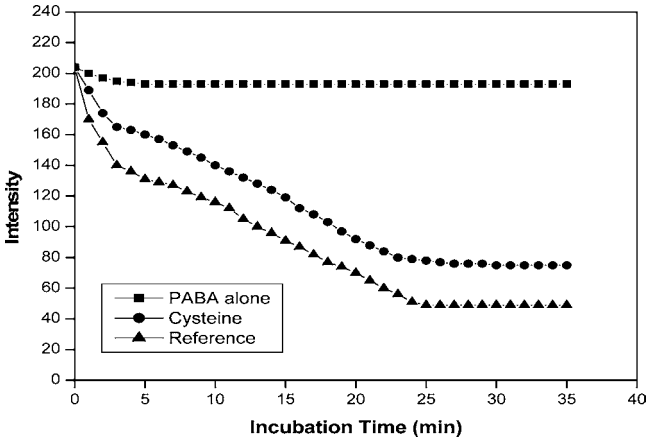

Figure 2. Fluorescence intensity versus incubation time curves of PABA alone and PABA subjected to peroxyl radical in the absence (reference) and presence (5.0×10^{-5} M cysteine) of a scavenger.

The fluorescence spectra of PABA, recorded in aqueous solutions at pH 7.0 with varying cysteine concentrations, are shown in Figure 3, where the maximal decrease in fluorescence intensity of PABA was due to ROO• oxidation of the probe without competition and its relative increase from the baseline level was proportional to the scavenging ability of the competitive scavenger. Upon mixing PABA (2.0 μM) with ROO• in the presence of cysteine at various concentrations (1.0−5.0 μM), the fluorescence intensities of PABA (remaining intact after ROO• attack) at 334 nm were greater than that of the reference (containing no cysteine) because of the competitive scavenging effect of cysteine. The results indicate that PABA is converted into non-fluorescent products with ROO• and also there is a proportional increase of 334 nm peak heights (Figure 3) with an increasing concentration of scavenger (cysteine). With the aid of PABA fluorescence intensity values recorded in the presence and absence of scavengers at varying concentrations, the IC_{50} values of scavengers and tissue homogenates can be calculated.

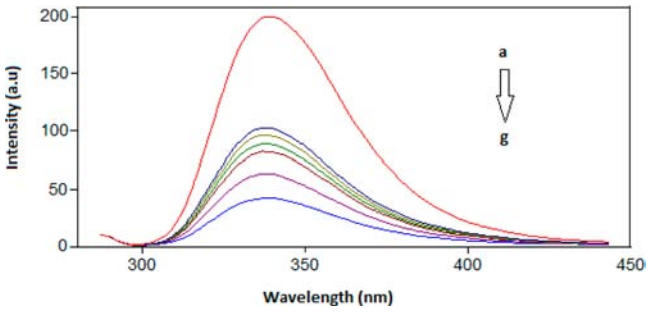

Figure 3. Fluorescence spectra of the remaining PABA in the absence and presence of cysteine: (a) 2 μM PABA, (b) 5 μM cysteine, (c) 4 μM cysteine, (d) 3 μM cysteine, (e) 2 μM cysteine, (f) 1 μM cysteine, and (g) 0 μM cysteine (reference).

HPLC Results of the Tested Scavengers. The developed method for measurement of ROO• scavenging activity was validated by quantifying the probe (PABA) and its oxidation product(s) by the HPLC method, followed by statistically comparing the results. Conversion of the PABA probe to products and inhibition of this reaction with a scavenger (i.e., NAC) were followed by the proposed and HPLC methods. As shown in Figure 4, the peak area of the PABA probe (retention time of PABA of 8.8 min) was higher in the presence of a ROO• scavenger, such as NAC, compared to its absence under identical conditions of radical attack (AAPH). The concentrations of PABA (in μg mL^{-1}) remaining after ROO• attack to PABA in the presence of NAC (3.0×10^{-4} M) measured by the proposed method and HPLC method were 6.76 ± 0.03 (N = 3) and 6.62 ± 0.07 (N = 3), respectively, where the initial concentration of PABA was 13.71 ± 0.09 (N = 3). The results obtained using these two methods were quite close, and the proposed method was verified (Figure 4b). As a result of the incubation reaction, the conversion ratio of the original probe to products in the absence of scavenger (reference) were found to be 78.9 and 81.1% with respect to the HPLC and proposed methods, respectively.

Evaluation of Results for Synthetic Scavengers. The PABA assay results for ROO• activity measurement were compared to those of the ORAC assay. Albumin had the lowest IC_{50} value among the studied antioxidants [i.e., highest peroxyl radical scavenging (PRS) activity] with respect to both the developed fluorometric (PABA) and ORAC methods. IC_{50} values of albumin were found to be 0.6 and 2.8 μM, respectively (Table 2). Zulueta et al. reported that,[29] in terms of PRS activity, albumin, a very powerful chain-breaking and transition-metal-binding extracellular antioxidant,[30] was the most effective antioxidant among plasma antioxidants, in accordance with the findings of the proposed method. Inspection of IC_{50} values of amino acids reveals that the highest scavenging activity was found for methionine (i.e., an amino acid not containing a free thiol group) and the lowest scavenging activity was found for serine with respect to classical ORAC and PABA methods

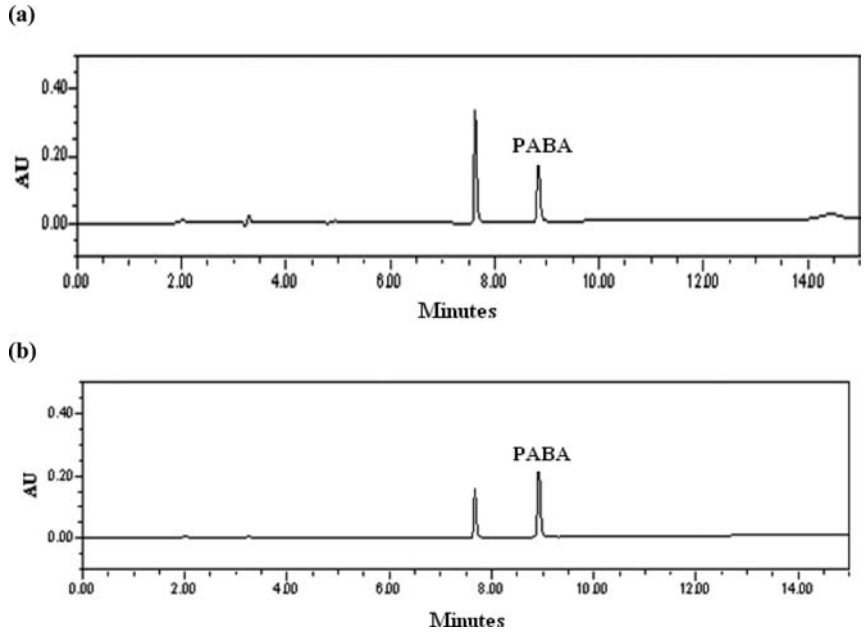

Figure 4. HPLC chromatograms for remaining PABA after AAPH reaction in the absence (reference) and presence of NAC (λ = 280 nm): (a) reference (0.5 mL of 1.0 × 10^{-3} M PABA + 2.5 mL of water + 2.0 mL of 0.4 M AAPH) and (b) 0.5 mL of 1.0 × 10^{-3} M PABA + 0.5 mL of 3.0 × 10^{-4} M NAC + 2.0 mL of water + 2.0 mL of 0.4 M AAPH.

Table 2. ROO• Scavenging Activity of Various Scavengers Measured by the PABA Method in Comparison to the ORAC Method (IC_{50} Values Were Calculated with Respect to Equations 1 and 4; N = 4 or 5 Data Points)[a]

peroxyl scavengers	IC_{50} value with respect to the PABA method (μM)	IC_{50} value with respect to the ORAC method (μM)
	Thiol-Type Antioxidants	
GSH	6.5 ± 0.3	16.2 ± 1.0
NAC	8.7 ± 0.4	9.3 ± 0.4
cysteine	6.7 ± 0.3	24.9 ± 1.1
homocysteine	5.7 ± 0.2	14.2 ± 0.4
DTE	12.1 ± 1.4	13.0 ± 1.2
cysteamine	121 ± 12	197 ± 19
	Amino Acids	
methionine	97.9 ± 8.2	21.9 ± 2.5
serine[b]	136 ± 15	338 ± 39
proline[b]	129 ± 9	326 ± 30
	Plasma Antioxidants	
albumin	0.6 ± 0.1	2.8 ± 0.1
uric acid	11.6 ± 1.1	9.6 ± 0.3
ascorbic acid	5.6 ± 0.4	10.7 ± 1.3
bilirubin	6.2 ± 0.3	10.8 ± 1.1

[a]Data presented as the mean ± SD (N = 3). All tested samples: $1.98IC_{50(PABA)} - 6.91 = IC_{50(ORAC)}$ (r = 0.882). Excluding amino acids: $1.61IC_{50(PABA)} + 1.09 = IC_{50(ORAC)}$ (r = 0.993). [b]IC_{50} values were calculated in millimolar.

(Table 2). The IC_{50} values for NAC (8.7 ± 0.4) and DTE (12.1 ± 1.4) obtained by the proposed method were similar to those of the classical ORAC assay (9.3 ± 0.4 and 13.0 ± 1.2, respectively). It is also noteworthy from Table 2 that cysteamine exhibited a much greater IC_{50} value (therefore lower peroxyl scavenging activity) than cysteine, having a similar structure. Cysteamine has less electron donation ability through the −SH group than cysteine because the electronegative N atom of the amine group in cysteamine counterbalances the effect of thiol. Although cysteine and cysteamine have quite close rate constants for radical disulfide anion formation in pulse radiolysis[31] and exhibited very close trolox equivalent antioxidant capacities (TEAC) in the ABTS/persulfate assay,[32] these two thiol compounds may behave differently against lipid peroxidation. Aruoma et al. have shown that, although cysteamine is an excellent scavenger of hydroxyl radicals and hypochlorous acid, it reacts slowly with hydrogen peroxide and does not react at an appreciable rate with superoxide anion radicals.[33] As a general drawback for the measurement thiols, the original ORAC method suffers a limitation from protein −SH, because the antioxidant action of plasma proteins was included in the total radical-trapping antioxidant parameter (TRAP) calculation independent of their thiol groups[34] and the ORAC values found for GSH with the two probes (β-PE and FL) of the assay greatly differ by a ratio of 1:2.[14] Some researchers even found zero ORAC value for cysteine in water or acetone−water solvents using the classical ORAC assay with the FL probe.[35]

Lussignoli et al. reported that both ascorbic and uric acids exhibited high PRS activities,[5] again compatible with the results of the PABA method, because the IC_{50} values obtained by the developed method for ascorbic acid and uric acid were 5.6 and 11.6 μM, respectively (in a microplate-based crocin bleaching assay of ROO• scavenging, the IC_{50} values of ascorbic and uric acids were reported as 3.97 and 8.15 μM, respectively).[5] Using the classical ORAC method, the IC_{50} values for ascorbic and uric acids were found to be 10.7 and 9.6 μM, respectively (Table 2). The differences between the types of assays and their conditions (pH, temperature, etc.) may compensate for the different activities reported. Both thiol-type antioxidants and plasma antioxidants with lower IC_{50} values had higher ROO• scavenging activity than non-thiol amino acids with respect to the PABA method, and this finding is in accordance with the results of other antioxidant activity assays, regardless of the mode of action, i.e., HAT- or electron transfer (ET)-based reactions.[33,36,37]

dx.doi.org/10.1021/jf405464v | J. Agric. Food Chem. 2014, 62, 1839−1845

The findings for the 13 ROO• scavengers (IC_{50} values) were statistically compared to those of classical ORAC using the two-way ANOVA test. It is concluded that there was no significant difference between the precisions of these two methods at the 95% confidence level ($p = 0.05$; $F_{exp} = 2.416$; $F_{crit} = 4.747$; and $F_{exp} < F_{crit}$). For IC_{50} values of all of the tested samples, PABA correlated linearly with ORAC ($r = 0.882$); by exclusion of the values for amino acids, this correlation was higher ($r = 0.993$). Thus, the proposed methodology was validated against the classical ORAC method of wide use.

Application of the Proposed Method to Some Tissue Homogenates. The PRS activity of heart homogenate as inhibition percentage versus dilution ratio is shown in Figure 5, where the inhibition percentage was curvilinearly correlated to the homogenate dilution ratio within the interval of 1:50–1:600 dilution.

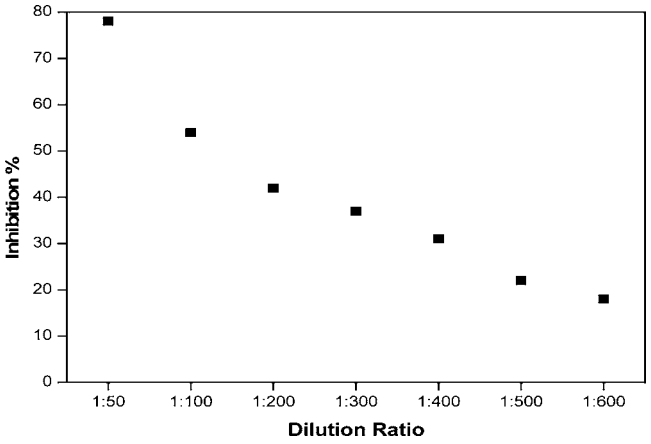

Figure 5. Inhibition percentage of tissue homogenates (heart) as a function of the homogenate dilution ratio using the PABA method.

The proposed method was successfully applied to tissue homogenate samples. The ROO• scavenging activity values measured with the proposed PABA and classical ORAC methods are comparatively depicted in a bar diagram (Figure 6), and the percentage inhibitions of identical tissue homogenates found with PABA were very close in relative intensity to those measured with the reference method. The ROO• scavenging activity of liver tissue homogenate was found to be higher than that of kidney and heart homogenate with respect to both methods. Since the liver was described as the most important organ involved in the regulation of the redox metabolism because of the synthesis of key enzymes responsible for ROS clearance and the production of GSH,[38] this result is acceptible. Linear regression analysis of PRS activity data presented in Figure 6 found with the PABA assay showed that this assay correlated well with the classical ORAC assay. The correlation equation between PABA and classical ORAC methods was calculated ($y = 0.940x + 12.98$; $r = 0.991$; and $N = 3$), with the closeness of the slope to unity showing one-to-one correspondence between results. Thus, the proposed methodology was validated for real samples.

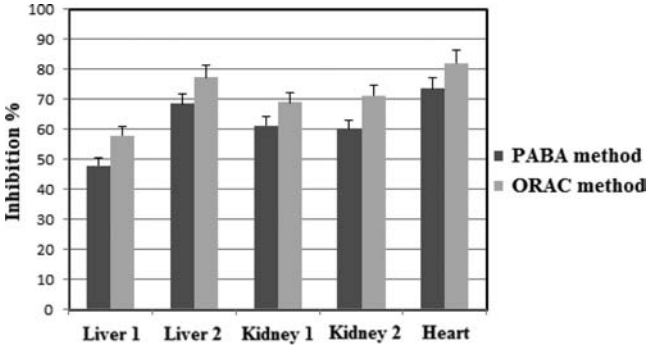

Figure 6. Inhibition percentage of some tissue homogenates calculated with the PABA method in comparison to the classical ORAC method (1:50 diluted homogenate). Data are presented as the mean ± SD (error bars) ($N = 3$) ($p = 0.05$; $F_{exp} = 0.584$; $F_{crit(table)} = 7.709$; and $F_{exp} < F_{crit(table)}$).

Because the existing ROO• scavenging assays require much labor and strictly optimized conditions, new assay development using the PABA probe may be useful for more comparable applications in food and biochemical research. ORAC as the most widely used PRS measurement assay has used two probes since it was first launched. The initial probe, β-PE, showed variable performance from one production cycle to another, undesired photobleaching, and non-specific protein binding to polyphenols. Thus, it was replaced with FL, but this latter probe showed rather high ORAC values, some photobleaching and undesired side reactions, and inconsistent findings with thiols. As alternative peroxyl scavenging measurement methods, TRAP uses a lag phase detection of antioxidants, but not all antioxidants possess a lag phase, giving rise to difficulties in comparison of end-point detection. The less frequently used crocin bleaching assay suffers from the initial color of crocin in the presence of other carotenoids and colored compounds, and there are no standard formats for expressing results.[39] In regard to redox potential data, the new PABA probe is expected to be more specific for ROO•, because the R-PE and β-PE protein probes of TRAP and ORAC assays, respectively, have been claimed to respond to more than one ROS. Moreover, PABA responds relatively quickly (i.e., within 30 min) to ROO• scavengers, such as cysteine, in reaching a plateau of fluorescence intensity, whereas the classical ORAC assay generally requires longer times for completion of the oxidation reaction for most antioxidants. It is envisaged that future research in HAT-based antioxidant assays (preferentially showing comparable results to those of one or more ET-based assays) should be directed to the design of "turn-on" fluorescence/absorbance probes for selectively detecting a given reactive species [ROS/reactive nitrogen species (RNS)] at a time. It is also preferable to develop probes not affected from side reactions with compounds not having genuine antioxidant status.

substrate, also considering the clinical and experimental data reported above.

MATERIALS AND METHODS

Chemicals. The commercial sources of proteases were as follows: pepsin (from porcine gastric mucosa; EC 3.4.23.1; commercial code P6887), trypsin (from bovine pancreas; EC 3.4.21.4; commercial code T1426), chymotrypsin (from bovine pancreas; EC 3.4.21.1; commercial code C4129), and flavourzyme (from *Aspergillus oryzae*; EC 232.752.2; commercial code P6110) from Sigma-Aldrich (St. Louis, MO, USA), corolase PP (from porcine pancreas; EC 3.4.21.4; commercial code 89082) from AB Enzymes (Darmstadt, Germany), and umamizyme (from *Aspergillus oryzae*; EC not specified; declared activity of 74.3 U/g) from Amano Enzyme Inc. (Nagoya, Japan). Amicon Ultra-0.5 filters (centrifuge tubes) were bought from Millipore (Billerica, MA, USA). HPLC-grade water was prepared with a Milli-Q purification system (Millipore). Bio-Safe Coomassie and Precision Plus Protein Standards Dual Color marker for SDS-PAGE were from Biorad (Biorad Laboratories Inc., Hercules, CA). All other chemicals (reagents and solvents) were from Sigma-Aldrich.

Sampling. Lupin seeds of the species *L. albus* (cultivar Ares) were provided by Terrena (Matrignè-Ferchaud, France), *L. angustifolius* (cultivar Boregine) by Fraunhofer institute IVV (Freising, Germany), and *L. luteus* (cultivar Mister) by Prof. Biagina Chiofalo (University of Messina, Messina, Italy).

TPE Preparation. The total protein extracts (TPEs) of the lupin seeds were obtained as previously reported[17] and stored at −20 °C. Briefly, proteins were extracted from defatted flour with 100 mM Tris-HCl/0.5 M NaCl buffer, pH 8.2, for 2 h at 4 °C. The solid residue was eliminated by centrifugation at 6500*g* for 20 min at 4 °C, and the supernatant was dialyzed against 100 mM Tris-HCl buffer, pH 8.2, for 24 h at 4 °C. The protein content was assessed according to Bradford, using bovine serum albumin (BSA) as standard.[18]

Enzymatic Hydrolysis. TPEs were dissolved in Tris-HCl buffer 100 mM, pH 8. The pH value were adjusted to the optimal hydrolysis conditions for each enzyme with the addition of 1 M NaOH or 1 M HCl, if necessary. The enzymes were dissolved in appropriate solutions: 30 mM NaCl for pepsin, and 1 mM HCl for trypsin, chymotrypsin, and corolase PP. Umamizyme was added as a powder to the TPEs, whereas flavourzyme was a ready-to-use solution.

Both enzyme solutions and the umamizyme powder were directly added to the TPE solutions. Reaction mixtures were incubated at a fixed temperature for different reaction times. For the two-stage digestion with pepsin + trypsin, TPEs were initially incubated with pepsin at pH 2 for 4 h, the pH was adjusted to 8 with 1 M NaOH, and trypsin was added to the reaction mixture.

Finally, pepsin was inactivated by adjusting the pH to 7 with 1 M NaOH, whereas all other enzymes were inactivated by heating the solutions at 100 °C for 10 min. Then the solutions were cooled and stored at −20 °C.

SDS-PAGE. Drawings were taken at various intervals and analyzed by SDS-PAGE. They were separated on 15% SDS-polyacrylamide gel using Mini Protean 3 Cell (Biorad Laboratories Inc., Hercules, CA). Electrophoresis was performed at a constant voltage of 80 V for stacking and 120 V for separation. Gels were stained with Bio-Safe Coomassie (Biorad), scanned with Versa Doc 3000 (Biorad), and analyzed with Quantity One 4.6.8 Software (Biorad).

Ultrafiltration. After the hydrolysis, all low-molecular-weight peptides were separated from intact enzymes, proteins, and high-molecular-weight polypeptides by ultrafiltration through 3000 Da cutoff centrifuge filters (Amicon Ultra-0.5, Millipore, Billerica, MA, USA) at 12000*g* for 30 min at 4 °C. The permeates were then stored at −20 °C.

Determination of Peptide Concentration. The peptide concentration in the hydrolyzed samples was measured according to literature methods[19,20] based on chelating the peptide bonds by Cu(II) in alkaline media and monitoring the change of absorbance at 330 nm. In brief, a solution of X μL peptide mixture, (500 − X) μL of water, 500 μL of 6% (w/w) NaOH in water, and 50 μL of active reagent (containing 0.6 M sodium citrate, 0.9 M sodium carbonate, and 0.07 M copper sulfate, 2.4 M NaOH, pH 10.6) was prepared. The reaction mixture was carefully mixed, incubated for 15 min at 20 °C, and then the absorbance was measured at 330 nm. A sterile solution of peptone from casein at 10 mg/mL in water was used as standard for the calibration curve; the assay is linear in the range 100−1000 μg of peptides in cuvette.

ACE-Inhibitory Activity Assay. After hydrolysis and filtration, all samples were tested for determining their ACE-inhibitory activity, as recently reported.[16] Briefly, 100 μL of 2.5 mM hippuryl-histidyl-leucine (HHL) in buffer 1 (100 mM Tris-HCOOH, 300 mM NaCl pH 8.3) was mixed with 30 μL of sample in buffer 1 at different concentrations. Usually, six concentrations were used for each sample, and each solution was tested twice. Samples were preincubated at 37 °C for 15 min, then 15 μL of ACE solution, corresponding to 3 mU of enzyme in buffer 2 (100 mM Tris-HCOOH, 300 nM NaCl, 10 μM $ZnCl_2$, pH 8.3), were added; samples were incubated for 60 min at 37 °C. The reaction was stopped with 125 μL of 0.1 M HCl. The aqueous solution was extracted twice with 600 μL of ethyl acetate; the solvent was evaporated at 95 °C and the residue was dissolved in 500 μL of buffer 1 and then analyzed by HPLC.

HPLC analyses were performed with a HPLC 1200 series equipped with an autosampler (Agilent Technologies, Santa Clara, US) with a Lichrospher 100, C18 column (4.6 mm × 250 mm, 5 μm; Grace, Italy) using water and acetonitrile as solvent and following the gradient: 0 min 5% acetonitrile, 10 min 60% acetonitrile, 12 min 60% acetonitrile, 15 min 5% acetonitrile. Injection volume was 10 μL, wavelength 228 nm, flow 0.5 mL/min. The evaluation of ACE inhibition was based on the comparison between the concentrations of HA (hippuric acid) in the presence or absence of an estimated inhibitor. The phenomenon of autolysis of HHL to give HA was evaluated by a reaction blank, i.e., a sample with the higher evaluated inhibitor concentration and without the enzyme. The percentage of ACE inhibition was computed considering the area of HA peak with the following formula:

$$\%\ \text{ACE inhibition} = \left[\frac{(A_{IB} - A_N)}{(A_{IB} - A_{RB})}\right] \times 100$$

where A_{IB} is the area of HA in inhibitor blank (IB) sample (i.e., sample with enzyme but without any estimated inhibitor), A_N is the area of HA in the *n* samples containing different amounts of the estimated inhibitor (in our case the hydrolyzate), and A_{RB} is the area of HA in the reaction blank (RB) sample (i.e., sample without enzyme and with the estimated inhibitor at the highest concentration).

The percentages of ACE inhibition were plotted vs the peptide concentrations. When the maximum ACE-inhibition concentration was over 50%, the percentages of ACE-inhibition were plotted vs the $\log_{10}$ peptide concentrations obtaining a sigmoid curve. This curve permitted to calculate the inhibitory concentration 50% (IC_{50}), i.e., the concentration needed to observe a 50% inhibition of ACE activity. The IC_{50} values were obtained testing independently each sample three times and are expressed as mean value ± standard deviation. The most active peptides have the lowest IC_{50} values.

Statistical Analysis. Statistical analyses were performed with Statgraphics Plus (version 2.1 for Windows). The data were evaluated using one-way analysis of variance followed by Fisher's least significant difference (LSD) procedure; values with different letters are significantly different for $p < 0.05$.

RESULTS AND DISCUSSION

In a preliminary part of the present investigation, we tested the total protein extract from the seeds of *L. albus* before hydrolysis. As expected, it resulted to be inactive as ACE-inhibitor, according to literature.[13,21] In fact, owing to the dimension of the active site of the enzyme, the interaction may take place only when bioactive peptides are released from the parent protein by enzymatic or hydrolytic reactions, such as digestion, or industrial processing, such as fermentation.

Preparation of Enzymatic Hydrolyzates. The first part of the experimental work was devoted to establish the best reaction conditions for each proteolytic enzyme. Drawings were taken at various intervals and analyzed by SDS-PAGE in order to evaluate the hydrolysis efficiency, changing the following parameters: enzyme/substrate (E/S) ratio, pH, temperature, and reaction time. In the case of pepsin, the best pH was 2, the temperature 37 °C, the E/S ratio 1/100, and 18 hours were necessary to complete the reaction. Figure 1a shows the SDS-PAGEs of the drawings of the hydrolysis of *L. albus* (A) and *L. luteus* (L) proteins collected immediately after the enzyme addition (A_0 and L_0), after 1 h (A_{1h} and L_{1h}), and after 18 h (A_{18h} and L_{18h}).

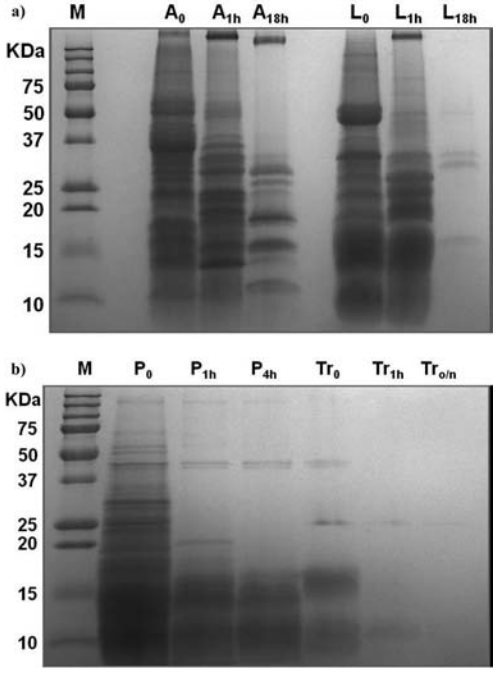

Figure 1. SDS-PAGE obtained after digestion of: a) *Lupinus albus* (A) and *Lupinus luteus* (L) proteins with pepsin, at 37 °C with enzyme/substrate (E/S) ratio 1/100; drawings collected immediately after enzyme addition (A_0 and L_0), after 1 h (A_{1h} and L_{1h}), and after 18 h (A_{18h} and L_{18h}). b) *Lupinus angustifolius* proteins digested with pepsin + trypsin drawings collected immediately after pepsin addition (P_0), after 1 h (P_{1h}), after 4 h (P_{4h}), immediately after trypsin addition (Tr_o), after 1 h (Tr_{1h}), after 24 h (overnight, $Tr_{o/n}$). M is the marker.

In general, the optimal conditions for using trypsin are 37 °C and pH 7−8; in our experience, the best pH value for hydrolyzing lupin proteins is 8. With an E/S ratio of 1/100, the digestion was complete after 18 h. The same conditions were used also for chymotrypsin. The double digestion with the sequence pepsin + trypsin was performed treating with pepsin at pH 2 for 4 h and then, after changing the pH value to 8, adding trypsin and incubating for 24 h. Figure 2b shows the SDS-PAGE of the two-step digestion.

For corolase PP digestion, better results were obtained by changing the E/S ratio to 1/50. For flavourzyme and umamizyme, several changes were performed; the reaction time was extended to 24 h and the E/S ratio was changed to 1/20 because both 1/50 and 1/100 ratios were ineffective. In addition, the incubation temperatures were increased to 45 and 60 °C, respectively. Table 1 reports the final conditions used for producing the samples used in the following experimentations.

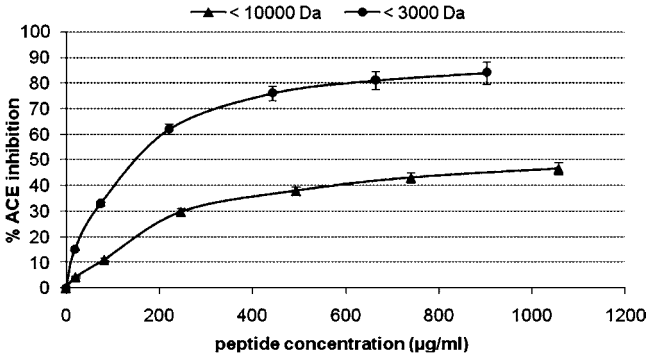

Figure 2. Total protein extract of *Lupinus albus* seed digested with pepsin: comparison between the ACE inhibition curves obtained filtering with 10000 and 3000 Da cutoff membranes.

Table 1. Optimized Parameters for the Hydrolysis of the Lupin Total Protein Extract: Enzyme, pH, Temperature (°C), Enzyme/Substrate Ratio (E/S ratio), and Time (h)

enzyme	pH	temperature (°C)	E/S ratio (w/w)	time (h)
pepsin	2	37	1/100	18
trypsin	8	37	1/100	18
chymotrypsin	8	37	1/100	18
corolase PP	8	37	1/50	18
umamizyme	7	45	1/20	24
flavourzyme	7	60	1/20	24

After the digestion, the samples were ultrafiltered in order to separate low-molecular-weight peptides from high-molecular ones and intact enzymes.

To select the best filtration conditions for maximizing the ACE-inhibitory activity, the digested mixture obtained by hydrolyzing *L. albus* protein with pepsin was ultrafiltered either with 10000 or 3000 Da cutoff membranes. Figure 2 shows two ACE inhibition curves obtained by plotting the peptide concentration vs the percentage ACE-inhibition for the samples with molecular weight (MW) lower than 3000 or 10000 Da, respectively. Whereas the latter sample did not reach the 50% ACE-inhibition even at the highest tested concentration (1110 μg/mL), the former, having molecular weight less than 3000 Da, was much more active, showing a 87% ACE-inhibition at the concentration of 893 μg/mL. A possible explanation is that the sample having MW lower than 10000 Da contains numerous inactive peptides (with MW in the range 3000 and 10000 Da), which decrease the concentration of the active peptides. Low MW peptides, usually under 3000 Da, are known as ACE-inhibitors in vivo because they can be absorbed at gut level.[21] After these results, all subsequent experimentation was performed on hydrolyzed mixtures filtered through a 3000 Da cutoff membrane.

Evaluation of ACE-Inhibitory Activity. The ACE-inhibitory activity assays were performed after having equalized the peptide concentrations of all samples. The peptide concentration was determined by using a literature colorimetric assay optimized for peptides.[19,20] In our opinion, the evaluation of the peptide concentrations and their equalization before performing the ACE-inhibitory test are of outmost importance in order to get a reliable comparison of their activities.

The results of the ACE inhibition assays (maximum percentage of ACE inhibition and IC_{50} value) of the peptide mixtures from *L. albus*, *L. angustifolius*, and *L. luteus* are reported in Tables 2, 3, and 4, respectively.

Table 2. Results of ACE Inhibition Assay for *Lupinus albus* Proteins: Digestion Enzyme, Highest Inhibitor Concentration (μg/mL), Maximum ACE Inhibition (%), and IC_{50} Value (μg/mL)[a]

enzyme	highest inhibitor concentration (μg/mL)	max ACE inhibition (%)	IC_{50} (μg/mL)
pepsin	856	76 ± 6.3	197 ± 1.6a
trypsin	939	67 ± 4.3	427 ± 16.8c
pepsin + trypsin	908	84 ± 2.5	205 ± 4.5a
chymotrypsin	989	73 ± 3.0	301 ± 4.8b
corolase PP	1039	60 ± 4.7	488 ± 42.8c
umamizyme	1066	58 ± 2.6	1053 ± 77.8e
flavourzyme	1037	51 ± 0.6	930 ± 3.71d

[a]IC_{50} values are reported as mean value ± standard deviation of three independent experiments; values with different letters are significantly different ($p < 0.05$).

Table 3. Results of ACE Inhibition Assay for *Lupinus angustifolius* Proteins: Digestion Enzyme, Highest Inhibitor Concentration (μg/mL), Maximum ACE Inhibition (%), and IC_{50} Value (μg/mL)[a]

enzyme	highest inhibitor concentration (μg/mL)	max ACE inhibition (%)	IC_{50} (μg/mL)
pepsin	723	80 ± 3.9	185 ± 13.3a
trypsin	614	58 ± 3.2	446 ± 17.5b
pepsin + trypsin	1047	82 ± 3.2	210 ± 1.9a
chymotrypsin	894	79 ± 4.6	203 ± 5.9a
corolase PP	953	67 ± 2.3	470 ± 27.5b
umamizyme	990	53 ± 1.5	933 ± 0.7d
flavourzyme	1151	55 ± 2.8	827 ± 41.9c

[a]IC_{50} values are reported as mean value ± standard deviation of three independent experiments; values with different letters are significantly different ($p < 0.05$).

Table 4. Results of ACE Inhibition Assay for *Lupinus luteus* Proteins: Digestion Enzyme, Highest Inhibitor Concentration (μg/mL), Maximum ACE Inhibition (%), and IC_{50} Value (μg/mL)[a]

enzyme	highest inhibitor concentration (μg/mL)	max ACE inhibition (%)	IC_{50} (μg/mL)
pepsin	1014	84 ± 3.7	176 ± 2.3a
trypsin	999	72 ± 3.5	343 ± 28.1b
pepsin + trypsin	999	83 ± 4.0	181 ± 2.4a
chymotrypsin	1014	87 ± 4.3	136 ± 4.5a
corolase PP	896	66 ± 2.6	533 ± 5.7c
umamizyme	1232	67 ± 3.9	608 ± 64.1d
flavourzyme	1081	54 ± 3.8	1009 ± 33.0e

[a]IC_{50} values are reported as mean value ± standard deviation of three independent experiments; values with different letters are significantly different ($p < 0.05$).

IC_{50} values range from 136 μg/mL in the case of the *L. luteus* sample treated with chymotrypsin to 1053 μg/mL in the case of the *L. albus* sample treated with umamizyme.

Comparing the three species, generally, the effects of the enzymes on the three lupin species are comparable: pepsin, followed by pepsin + trypsin, and chymotrypsin samples give the lowest IC_{50} values, i.e., the highest ACE-inhibitory activities, whereas corolase PP gives intermediate IC_{50} values and umamizyme and flavourzyme give the least active samples (Tables 2, 3, 4).

Pepsin gives always peptide mixtures with the highest ACE-inhibitory activity, with a mean IC50 value among the three species of 186 ± 10 μg/mL. When a trypsin treatment follows the pepsin one, for mimicking the physiological digestion, the ACE inhibition does not improve, but instead slightly decreases (mean value 198 ±16 μg/mL), even if no significant differences are revealed towards pepsin digestion (same letter in the statistical analysis for each species in Tables 2, 3, 4). Also chymotrypsin gives samples with good ACE-inhibitory activities with a mean value of 213 ± 83 μg/mL. Lower activities were observed treating the proteins with trypsin and corolase PP, with mean IC50 values of 405 ± 54 μg/mL and 497 ± 32 μg/mL, respectively. The other two enzymes gave even less satisfactory results: umamizyme gave a mean IC50 value of 865 ± 230 μg/mL and flavourzyme of 922 ± 91 μg/mL.

Figure 3 enables a direct comparison of the three species. The statistical analysis indicates that the treatment of the proteins of the three lupin species with pepsin and corolase PP produces peptide mixtures whose activities do not depend on the species, whereas by treating with trypsin, pepsin + trypsin as well as with chymotrypsin, significant differences are observed, the peptides from *L. luteus* being the most active. Also with umamyzime, the peptides from *L. luteus* were significantly the most active, whereas the peptides from *L. angustifolius* were the best after proteolysis with flavourzyme.

The comparison of data from different papers is a complex task because the differences in the ACE-inhibitory activity may be related to several different causes such as the protein extraction procedure, the enzyme selected for the proteolysis, the parameters of the digestion process (substrate/enzyme ratio, pH, time, temperature), or the different analytical method used for the determination of the ACE-inhibitory activity.[22]

As already indicated in the introduction, very few data are available on ACE-inhibitory activity of lupin proteins. In a previous paper by our group, *L. albus* and *L. angustifolius* proteins were digested with pepsin showing an ACE-inhibitory activity similar to soybean and higher than other legumes (pea, common bean, lentils, chickpea).[16]

Bioactive peptides are usually formed by sequences of 3−20 amino acids encrypted within the primary sequence of proteins. During food processing, fermentation, and/or gastrointestinal digestion, they are released through proteolysis of the parent protein. Although the complexity of the tested hydrolyzates impairs their direct comparison, it is clear that the observed activities reflect the different specificities of the tested enzymes. Pepsin and chymotrypsin are specific endopeptidases, which mainly break the peptidic bonds involving hydrophobic and aromatic amino acids; for this reason they produce peptides having a hydrophobic and/or aromatic amino acid as terminal group, preferably, proline, tryptophan, phenylalanine, or tyrosine. These features are particularly suitable for interacting with the ACE catalytic site, thus permitting the inhibition.[21] Trypsin, instead, is a specific endopeptidase that cleaves mainly peptidic bonds involving basic amino acids.[23] Combining pepsin + trypsin in a two-stage process resulted in a small overall reduction of ACE-inhibitory activity. Possibly, the active peptides formed during the pepsin digestion are in part degraded by trypsin. The same explanation was proposed for other sequential enzymatic treatments impairing the ACE-inhibitory activity: in particular, the two-step digestion with

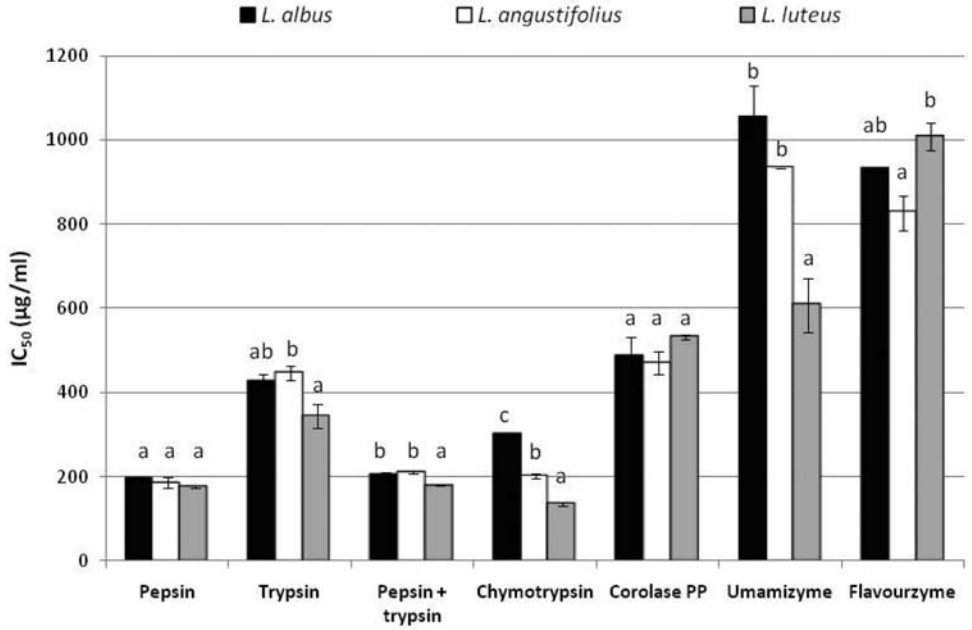

Figure 3. Comparison of mean values of ACE-inhibition IC_{50} values (expressed in μg/mL) of peptides mixtures obtained from *Lupinus albus*, *Lupinus angustifolius*, and *Lupinus luteus* proteins digested with pepsin, trypsin, pepsin + trypsin, chymotrypsin, corolase PP, umamizyme, and flavourzyme. Values with different letters are significantly different ($p < 0.05$).

alcalase and flavourzyme performed on common bean protein and chicken protein isolates.[24,25]

Corolase PP, a patented enzymatic complex used to simulate the in vitro protein digestion in the intestinal tract, consists of a mixture of proteolytic enzymes from pig pancreas, containing trypsin and chymotrypsin, together with other aminopeptidases and carboxypeptidases. Its moderate ACE-inhibitory activity may be related to the absence of pepsin that seems to be the best enzyme to produce lupin peptides with good ACE-inhibitory activity. Obviously, this enzyme may give good results with other proteins; for example, satisfactory results were obtained on sea cucumber proteins digested with pepsin and subsequently with corolase PP.[26]

Flavourzyme and umamizyme are "generally recognized as safe" (GRAS) enzymes used in the food industry. They are food-grade fungal protease/peptidase complexes produced by submerged fermentation of a strain of *Aspergillus oryzae*, exhibiting both endoprotease and exopeptidase activities. They were tested with the final aim of a large-scale production of hydrolyzates to be used as food supplements production but did not provided useful results. In the literature, flavourzyme digestion was applied to cowpea proteins, giving peptides with IC_{50} values in the large range 0.04−170.6 μg/mL and to rapeseed protein producing peptides with an ACE-inhibitory activity of about 50%.[27,28] Moreover a double digestion with alcalase/flavourzyme on two different chickpea varieties gave peptide mixtures with IC_{50} values of 316 and 228 μg/mL, while on yellow pea proteins gave an IC_{50} value of 412 μg/mL.[22] Umamizyme was used to digest canola meal proteins, giving peptide mixtures with low ACE-inhibitory activity.[29] Unfortunately, with lupin proteins, they give lower ACE-inhibitory activity than the other tested enzymes.

In conclusion, this investigation confirms that lupin seed may be a valuable source of ACE-inhibitory peptides, possibly explaining the activity observed in experimental and clinical studies.[5−8] This may foresee their future applications into either functional foods or dietary supplements.

Of course, this is only a first step in the study of ACE-inhibitory activity of lupin peptides because other studies are necessary to determine their stability and bioavailability. In fact, an open question is their capability to survive to the gastrointestinal digestion and to be absorbed in order to reach the bloodstream in their active form. Indeed, the literature shows that peptides from other food sources (for example milk) are systemically distributed.[21,30] The problem could be overcome also by using new emerging technologies, such as micro- or nanoencapsulation, that may offer feasible solutions for improving the stability of peptides in various food products and during digestion.[21,30] The bioavailability of ACE-inhibitory peptides may also be increased by cross-linking the target peptide to protein transduction domains or by means of specific peptide carriers able to deliver biologically active peptides into cells. Moreover, peptide permeation may be achieved by chemical enhancers and surfactant-like agents.[31] Finally, further studies are needed to determine the composition of active peptide mixtures, to isolate the peptide(s) responsibles for ACE-inhibitory activity, and to confirm their activity through in vitro and in vivo studies.

MATERIALS AND METHODS

Materials. Quercetin dihydrate (90%) was purchased from VWR Scientific (Seattle, WA, USA). Polyoxyethylene (20) sorbitan monooleate (Tween 80), ethanol, ferric chloride ($FeCl_3 \cdot 6H_2O$), hydrochloric acid, AAPH (2,2′-azobis(2-amidinopropane) dihydrochloride), Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid), and methanol were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Maltodextrin (MaltrinM100) was provided from Grain Processing Corp. (Muscatine, IA, USA). DPPH (1,1-diphenyl-2-picrylhydrazyl), TPTZ (2,4,6-tripyridyl-s-triazine), and sodium fluorescein were purchased from Fluka (Buchs, Switzerland). Milli-Q water (18.3 MΩ) was used in all experiments.

High-Pressure Homogenization Processing. Quercetin (0.5%, w/w) was dispersed in either water or water−Tween 80 mixtures and held on an oil bath for 20 min at 70 °C. The suspensions were subjected to premilling treatments to reduce quercetin particle sizes to the micrometer range by high-speed homogenization (HSH) (high-speed homogenizer, Ultra-Turrax T-25 basic, IKA Works Inc., Wilmington, NC, USA) at 24000 rpm for 5 min. After filtration (cellulose filters, 6 μm mesh, grade 3, Whatman), the mixture was kept on a magnetic stirrer overnight at room temperature. The next day, the water that was either evaporated or lost during filtration was reconstituted, and the samples were homogenized at 24000 rpm for an additional 5 min (the samples referred to as cycle 0). The quercetin suspensions were further homogenized by high-pressure homogenizer (HPH) (EmulsiFlex-C3, 90 Avestin Inc., Ottowa, Canada) at pressure levels ranging from 50 to 200 MPa and for up to 40 HPH cycles. The process temperature of HPH was kept constant at 25 °C.

Lyophilization. The quercetin nanosuspension was frozen at −20 °C overnight and lyophilized using a Freezone 4.5 freeze-dry system (Labconco, Kansas City, MO, USA).

Spray-Drying. Maltodextrin with a final concentration of 30% (w/w) was utilized as the carrier for quercetin, and powder was retrieved by a spray-drying technique applied with Yamato Pulvis Mini-Spray GA32 (Yamato Scientific Co., Ltd., Tokyo, Japan). Quercetin suspensions were passed at a spray rate of 4 mL/min, with inlet temperature and outlet temperature fixed at 200 and 120 °C, respectively. Dry air flow was set at 800 L/h, and the atomization pressure was set at 1.5 bar.

CHARACTERIZATION

Particle Size Measurements. Particle sizes of quercetin dispersions were measured by photon correlation spectroscopy (PCS) based BIC 90 plus particle size analyzer equipped with a Brookhaven BI-9000AT digital correlator (Brookhaven Instrument Corp., New York, NY, USA). The light source of the particle size analyzer is a solid state laser operating at 658 nm with 30 mW power, and the signals were detected by a high-sensitivity avalanche photodiode detector. All measurements were made at a fixed scattering angle of 90° and temperature of 25.0 ± 0.1 °C. The mean diameter, or z-diameter, was determined by cumulant analysis of the intensity−intensity autocorrelation function, $G(q,t)$.[19−23]

Solubility Test. Saturation solubility was measured through ultraviolet−visible (UV−vis) absorbance determination at 373 nm using a Cary Eclipse UV−vis spectrophotometer with a 1 cm optical path length. The suspensions prepared in water and Tween 80 solutions as described above were subjected to HPH process, and the samples were collected at predetermined pressures and cycles. Afterward, they were centrifuged for 10 min at 10000 rpm prior to analysis, and the upper phase was extracted with ethanol. All measurements were completed on the same day for each cycle at predetermined pressure. Quercetin concentration was determined by the calibration curve ($R^2 = 0.999$; $y = 0.069x - 0.041$) which was linear within the range of 2−15 ppm. It should be mentioned that the presence of residual fine solid particles, if not sedimented by the centrifugation method applied, may affect the UV−vis measurement. Nevertheless, particle size measurements after centrifugation showed that the mean sizes of residual solid particles dispersed in the liquid were always <300 nm for all tested samples.

Dissolution Rate Measurements. Dissolution rate shows how fast dried particles redisperse into submicrometer suspensions upon rehydration. Dried powder of maltodextrin-entrapped quercetin was prepared for dissolution experiments with a typical formulation of 0.5 g of powder in 5 mL of distilled water. The samples held in independent flasks were agitated at 140 rpm on an ital shaker for different time periods. At definite times, a flask was collected from the shaker, the content was filtered through Whatman no. 4 and centrifuged at 10000 rpm for 10 min, and supernatant was assayed through UV−vis absorbance determination at 373 nm.

Atomic Force Microscopy (AFM). The image of quercetin nanoparticles was collected by using a commercial Nanoscope IIIa Multi-Mode AFM (Veeco Instruments, Camaillo, CA, USA) equipped with a J scanner, which was operated in tapping mode using a silicon cantilever. The quercetin nanosuspension sample for AFM imaging was prepared by treating the mixture of 0.5% (w/w) quercetin in water with 20 cycles of high pressure homogenization at 150 MPa. A drop of quercetin submicrometer suspension was deposited on a precleaned silicon wafer surface and evaporated naturally.

Differential Scanning Calorimetry (DSC) Measurements. The thermal properties of HPH-treated quercetin powder were investigated in comparison to the thermal properties of pure quercetin, with DSC (model Q10, TA Instruments, New Castle, DE, USA). Powder samples were placed in aluminum sealed pans at an amount of 5−10 mg. The thermal analyses were performed, with a temperature scanning range from 25 to 400 °C and a heating rate of 10 °C/min. Nitrogen was used as blanket gas.

Antioxidant Activity Assays. All samples (0.5 g of HPH-treated and nontreated spray-dried powders) were dissolved in water (5 mL) and then centrifuged at 10000 rpm for 10 min, and supernatant was used for further antioxidant assays. Maltodextrin was used as blank.

2,2-Diphenyl-1-picrylhydrazyl Hydrate Free Radical Scavenging Activity Assay. The DPPH assay was done according to the method of Brand-Williams et al.,[24] with little modifications. DPPH solution (6×10^{-5} M) was prepared in methanol; 2.9 mL of DPPH solution was mixed with 100 μL of sample, and the reaction mixture was incubated in the dark at room temperature for 30 min. Absorbance was taken at 517 nm against blank solution. The radical scavenging activity was calculated using the following equation:

$$\text{scavenging activity (\%)} = \left(\frac{A_{\text{blank at 517 nm}} - A_{\text{sample at 517 nm}}}{A_{\text{blank at 517 nm}}} \right) \times 100 \quad (1)$$

Ferric Reducing/Antioxidant Power (FRAP) Assay. The FRAP assay was done according to the method of Benzie et al.,[25] with little modifications. The working solution was prepared by mixing 25 mL of acetate buffer (pH 3.6), 2.5 mL of 10 mM TPTZ solution in 40 mM HCl, and 2.5 mL of 20 mM ferric chloride solution. Three milliliters of working solution was mixed with 40 μL of sample. The increase in absorbance at

593 nm was measured after 4 min, and higher absorbance values indicate higher reduction ability of samples.

Oxygen Radical Antioxidant Capacity (ORAC) Assay. The ORAC procedure used an automated plate reader (Synergy HT Multi-Mode Microplate Reader; BioTek Instruments, Inc., Winooski, VT, USA) with 96-well plates.[26] Analyses were conducted in 75 mM phosphate buffer (pH 7.4) at 37 °C. Peroxyl radical was generated using AAPH, which was prepared fresh for each run. Fluorescein was used as the substrate. Fluorescence conditions were as follows: excitation was performed at 485 nm with a 20 nm bandpass, and emission was measured at 520 nm with a 25 nm bandpass. The plate reader was controlled by Gen5 Data Analysis software (BioTek Instruments, Inc.). The standard curve was linear between 0 and 100 mM Trolox. Results are expressed as micromoles of Trolox equivalents (TE) per gram of powder (μmol TE/g).

Briefly, AAPH (0.2069 g) was dissolved in 5 mL of 75 mM phosphate buffer (pH 7.4), and a fluorescein stock solution (4 μM) was made in 75 mM phosphate buffer (pH 7.4) and stored in foil at 4 °C. Immediately prior to use, the stock solution was diluted 1:50 with phosphate buffer. In all experimental wells, 150 μL of sodium fluorescein working solution was added. In addition, blank wells received 25 μL of 75 mM phosphate buffer (pH 7.4), whereas standards received 25 μL of Trolox dilution and samples received 25 μL of sample. The plate was then allowed to equilibrate by incubation for a minimum of 30 min at 37 °C. Reactions were initiated after pipetting each well with 25 μL of AAPH solution for a final reaction volume of 200 μL. The fluorescence was then monitored kinetically with data taken every minute for a duration of 120 min.[26]

Scanning Electron Microscopy (SEM). The morphology of pure nontreated quercetin crystals and lyophilized HPH-treated quercetin was observed using a scanning electron microscope (JSM-5410- SEM, Jeol Co., Japan). Prior to analysis, the samples were diluted with water to obtain a suitable concentration. Then, the samples were mounted onto separate, adhesive-coated aluminum pin stubs, dried naturally, and sputtered with gold. The SEM was operated at high vacuum with an accelerating voltage of 10 kV. Images were taken at 3500 magnification.

Statistical Analysis. All measurements were repeated at least three times using duplicate samples. Means and standard deviations were calculated from these measurements using Excel (Microsoft, Redmond, WA, USA).

RESULTS AND DISCUSSION

Effect of High-Pressure Conditions on Particle Size. The suspension of quercetin, surfactant, and water is forced through a valve having a narrow orifice under pressure. According to Bernoulli's equation, the flow volume of liquid in a closed system per cross section is constant. That means that when the liquid is in the homogenizer gap, the reduction in the diameter leads to a tremendous increase in the dynamic pressure and simultaneous decrease in static pressure to maintain constant energy. A liquid boils when its vapor pressure is equal to the air/static pressure of the environment. In the gap, the static pressure falls below the vapor pressure of water, causing the boiling of water at room temperature. This is followed by the formation of gas bubbles, which implode vigorously, and the cleavage along the drug crystal is caused by cavitation, fluid shear, and particle collision against each other. As the suspension leaves the gap, the pressure suddenly rises to normal air pressure again.[11,13,20,27]

Altough the implosion forces in this instantaneous progress are sufficiently high to break down the drug microparticles into nanoparticles, the energy generated in such a short time (generally within miliseconds) is not sufficient to break down all particles into uniform nanocrystals even at the higher applied pressures. The increased homogenization cycles provided more energy to break down the crystalline structure. Therefore, homogenization often is performed in 5, 10, or more cycles that depend on the hardness of the drug and the desired particle size.[11,18]

Figure 1 shows the effect of the number of cycles on the mean particle sizes and polydispersity of quercetin suspensions

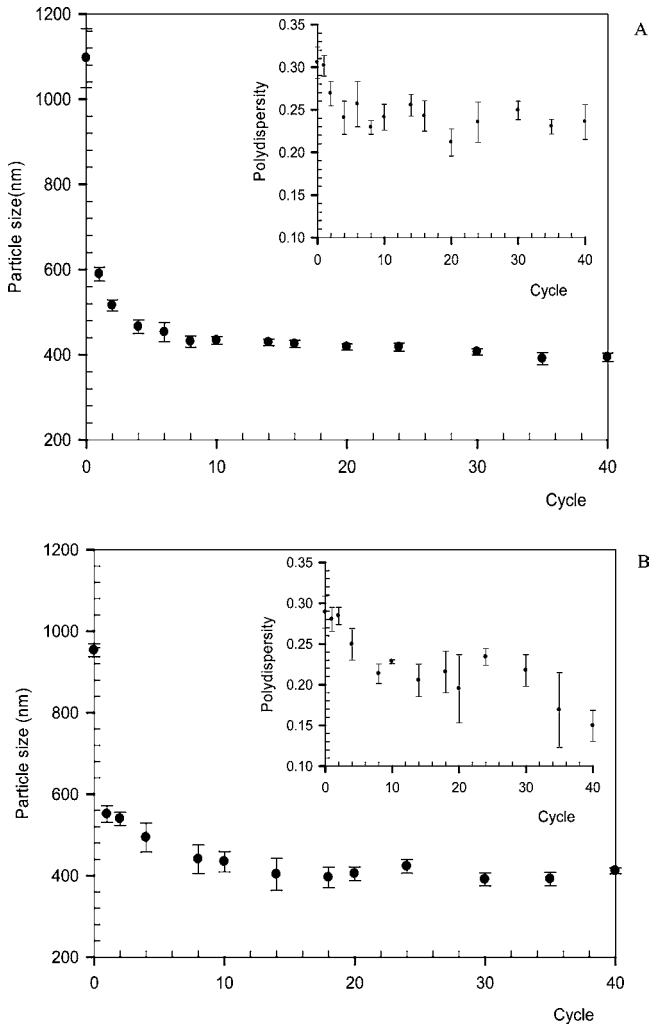

Figure 1. Change in particle size and polydispersity of quercetin in water (A) and in 1% Tween 80 (w/w) solution (B) as a function of HPH cycle. HPH pressure and processing temperature were fixed at 150 MPa and 25 °C, respectively. Duplicate samples were prepared, and the results are reported as the mean and standard deviation of three measurements made per sample.

at a fixed operating pressure of 150 MPa and 25 °C inlet temperature. The mean particle sizes of quercetin crystals in water and 1% Tween 80 (T80) solution (w/w) exhibited around 50% reduction after only two cycles. Reduction rate decreased with the following cycles and got a steady value (~430 nm) after 10 cycles. After that point, increasing the

dx.doi.org/10.1021/jf404065p | J. Agric. Food Chem. 2014, 62, 1852−1859

number of cycles did not change the particle size, which was in agreement with previous studies.[19,20] The polydispersity of samples reached a value of 0.2 for samples after around 10 cycles, but between cycles it showed fluctations, which could indicate a slightly reversible formation of aggregates that were disaggregated in the subsequent cycles (Figure 1).

Generally, the energy delivered into the system is proportional to the homogenization pressure, because higher pressure causes higher velocity of the fluid in the gap; as a result, static pressure will drop to a larger extent, leading to generation of more bubbles eventually to comminute the particles. Thus, it is anticipated that the higher the homogenization pressure, the smaller the particle size obtained as is observed in Figure 2.

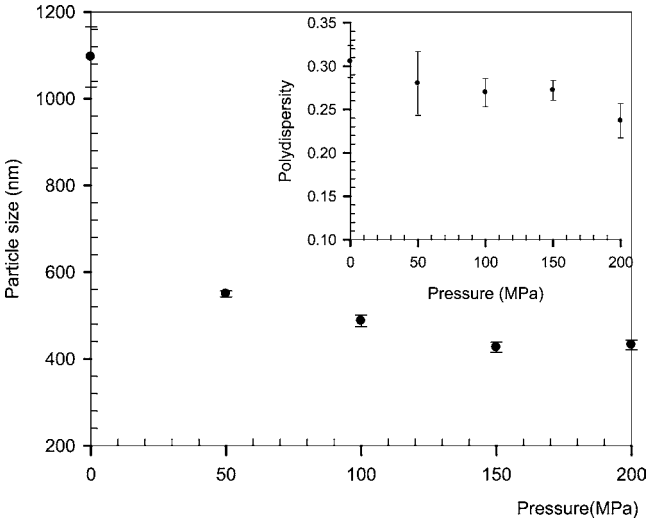

Figure 2. Change in particle size and polydispersity of quercetin in water as a function of homogenization pressure. HPH cycle and processing temperatures were fixed at 20 and 25 °C, respectively. Duplicate samples were prepared, and the results are reported as the mean and standard deviation of three measurements made per sample.

However, it should be noted that there is no linear relationship between increase in pressure and decrease in size. Because the HPH process breaks the particles/crystals preferentially at weaker points, that is, imperfections, and by decreasing the size, the number of imperfections becomes less and the remaining crystals become more perfect. If the force in the homogenizer is equal to the interaction forces in the crystal, the particles will not diminish further, even if additional cycles are applied. The force required to break down the crystals seems to increase rather exponentially with decreasing particle size.[27]

The smallest particle size achieved at the end of 30 cycles does not depend on the concentration of stabilizer (Table 1), but the polydispersity index of the system using Tween 80 has lower values, which indicates that having surfactant in the system provides fineness of particle (Figure 1). The role of surfactant in emulsion and suspension systems is theorotically different. In the case of emulsions, the stabilizer/surfactant reduces the interfacial tension between the oil and the water phase. Consequently, the required energy to produce nanoemulsion decreases because the energy is equal to surface area × interfacial tension. On the other hand, in a suspension, the main energy is utilized to break the crystal itself, which means overcoming the binding forces in the crystal lattice.

The presence of nanosized quercetin particles was confirmed by an AFM height image suggesting that most particles were

mainly irregularly shaped (Figure 3A). Panels B and C of Figure 3 show the SEM images of pure nontreated quercetin and lyophilized HPH-treated quercetin nanosuspension, respectively. Pure quercetin showed lack of particle size uniformity and relatively larger size. On the other hand, HPH-treated particles exhibited particle size uniformity and lack of larger needle-type crystalline structures.

Effect of High-Pressure Conditions on Water Dispersity. In general, the water solubility of a particle increases with a decrease of particle size because it causes a linear increase of the specific surface area, which is in an inverse relationship with the particle diameter. The relationship between particle size and water dispersity can be axplained by Ostwald−Freundlich theory[11,13]

$$\log \frac{C_s}{C_\infty} = \frac{2\sigma V}{2.303RT\rho r} \quad (2)$$

where C_s is the solubility, C_∞ is the solubility of the solid consisting of large particles, σ is the interfacial tension substance, V is the molar volume of the particle material, R is the gas constant, T is the absolute temperature, ρ is the density of the solid, and r is the radius. It is obvious that the solubility (C_s) of the drug increases with a decrease of particle size (r). However, this effect is pronounced for materials that have mean particle size of <1 μm.[11]

Another possible explanation for the enhancement in the solubility is the creation of high-energy surfaces when the drug microcrystals are disrupted to nanoparticles. Hence, by raising the interfacial area through particle size reduction, the transition among different polymorphic forms occurs.[19] The increase in water solubility of quercetin by increase in number of cycles and the level of pressure (Figures 4 and 5) can be explained by the application of higher energy during HPH processing to the quercetin system causing more transitions from crystal to amorphous phase; however, the DSC thermogram in Figure 6 shows the preservation of a part of crystal structure of original quercetin.

To further visualize the improved solubility of quercetin nanosuspension after HPH, photographs of quercetin suspensions prepared in water and in 1% Tween 80 (w/w) solution treated by 40 cycles of HPH at 150 MPa as well as nontreated quercetin (undissolved parts were removed by filtration) were taken and are presented in Figure 4. The nontreated quercetin suspension in water was nearly colorless; however, HPH

treatment provided a yellowish color. When Tween 80 was added to the system, the color difference became more pronounced. The presence of Tween 80 in the solution increased the quercetin solubility in both HPH-processed and

dx.doi.org/10.1021/jf404065p | J. Agric. Food Chem. 2014, 62, 1852−1859

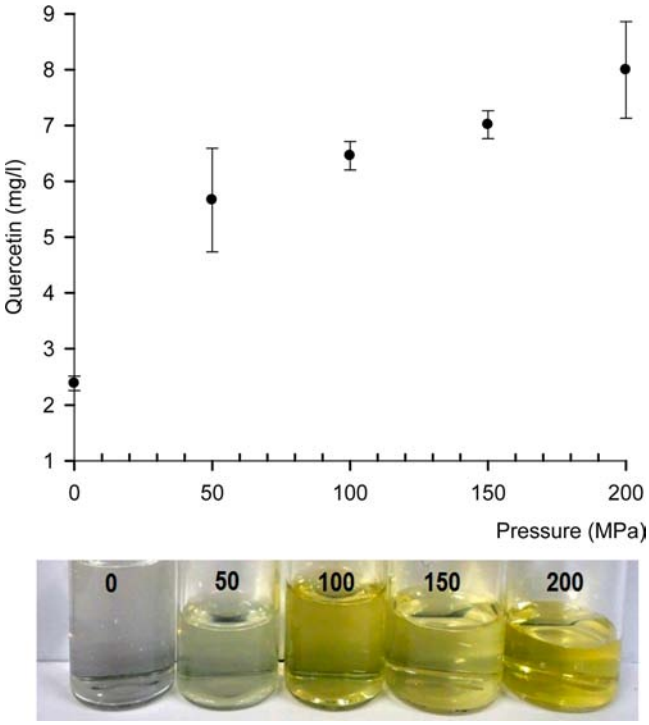

Figure 5. Water solubility of HPH-treated quercetin nanosuspensions in water at different pressures for cycle 20 at 25 °C. The insoluble part of quercetin was removed by ultracentrifugation.

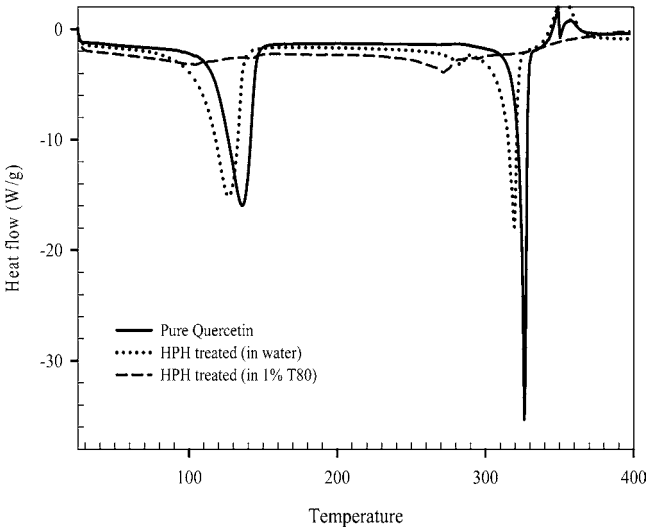

Figure 6. DSC thermograms of pure quercetin crystals and lyophilized HPH-treated quercetin nanosuspensions prepared in water and in 1% T80(w/w) solution. HPH was carried at 150 MPa for 20 cycles at 25 °C.

nonprocessed suspensions depending on its concentration (Table 1). The utility of the surfactant systems in solubilization is well-known. Due to its amphilphilic nature, the presence of Tween 80 improved quercetin solubility by forming micelles and providing regions for hydrophobic interactions in solution.[28] As a surfactant, Tween 80 provides particle wetting and it would adsorb onto the surface and decrease the interfacial tension between water and quercetin particles, and thus water can penetrate into the pores of quercetin particles, which would facilitate the dispersion of particles.

Although according to Ostwald ripening theory, increased solubility of dispersed solid particles would facilitate particle size growth during storage, in our study an increase in the amount of the micellar solubilized drug did not have a significant effect on the particle size on the day of preparation. A similar result was also pointed out in another study in which the role of stabilizers on Ostwald ripening in nanosuspensions was investigated and no effect of the amount of solubilized drug on Ostwald ripening was observed.[15]

Thermal Properties of Quercetin before and after HPH Treatment. Thermograms of pure nontreated quercetin and lyophilized HPH-treated quercetin samples with scanning temperatures ranging from 25 to 400 °C are presented in Figure 6. The curve of quercetin showed two endothermic peaks: a broad endotherm peak centered at around 120 °C corresponds to the loss of bound water; the other was a sharp endothermic peak at 325 °C indicating the melting point of quercetin. This result was consistent with other reports.[20,21] The melting peak of HPH-treated quercetin suspensions shifted to lower temperature values, which was the indication of reduced particle size and having surfactant in the system. Enthalpies of fusion, proportional to the amount of crystallinity, of pure quercetin and HPH-treated samples were different. They might be considered as the loss of crystalline structure; however, the appearance of recrystallization peaks indicates the maintenance of the initial crystalline state. It was also reported that HPH application had slightly reduced the crystallinity of querctin nanocrystals,[20] and when the HPH method was compared with the evaporative precipitation into aqueous solution method, the crystalline structure of quercetin had been partly retained through HPH cycles.[21]

Dissolution Rate. HPH-treated (at 150 MPa for 20 cycles at 25 °C) quercetin suspensions in the presence of carrier matrix of maltodextrin (30%, w/w) were obtained by the spray-drying technique. The obtained powder is convenient for handling and storage and is ready for redispersion in water. Figure 7 shows the plot of the water solubility of HPH-treated quercetin powders as a function of agitation time. The dissolution times (time to reach the concentration plateau) for spray-dried samples were nearly the same within a 10 min period. The effect of spray-drying on water solubility can be evaluated by comparing the final values of water solubility after complete powder dissolution to the solubility of the original quercetin suspension. For the HPH-treated sample prepared in water, spray-drying caused a certain increase of water solubility, from 9 to ~15 mg/L. The effect of spray-drying on the increasing water solubility of quercetin can be attributed to the reduced crystallinity of the quercetin powder through the incorporation of maltodextrins.[29,30]

Antioxidant Assays. The 2,2-diphenyl-1-picrylhydrazyl hydrate (DPPH) radical scavenging assay is routinely practiced for the assessment of the antioxidant activity of single compounds and their mixtures. The DPPH radical is stable at room temperature and produces a deep purple solution in organic solvents. The method is based on the discoloration due to the reaction that occurs between radical and antioxidant, which can be determined spectrophotometrically.[31]

The FRAP assay is based on the ability of phenolics to reduce yellow ferric tripyridyltriazine complex (Fe(III)−TPTZ) to blue ferrous complex (Fe(II)−TPTZ) by the action of electron-donating antioxidants. The resulting blue color measured spectrophotometrically at 593 nm is taken as linearly

dx.doi.org/10.1021/jf404065p | J. Agric. Food Chem. 2014, 62, 1852−1859

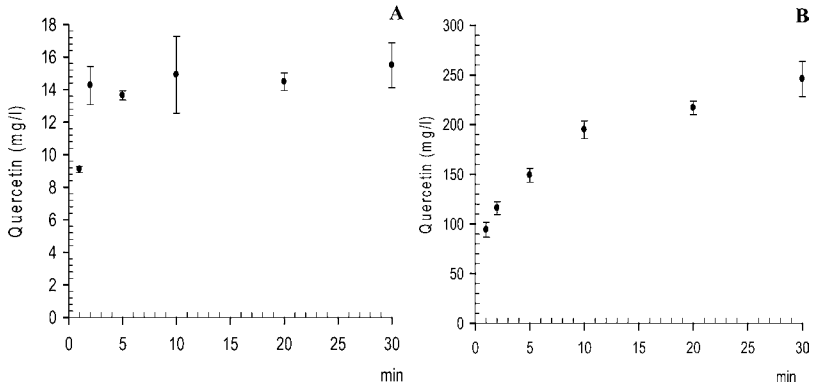

Figure 7. Dissolution of HPH-treated quercetin powder spray-dried with MD in water as a function of the agitation time: predried suspension prepared in water (A) and in 1% T80 (w/w) solution (B). HPH was carried at 150 MPa for 20 cycles at 25 °C.

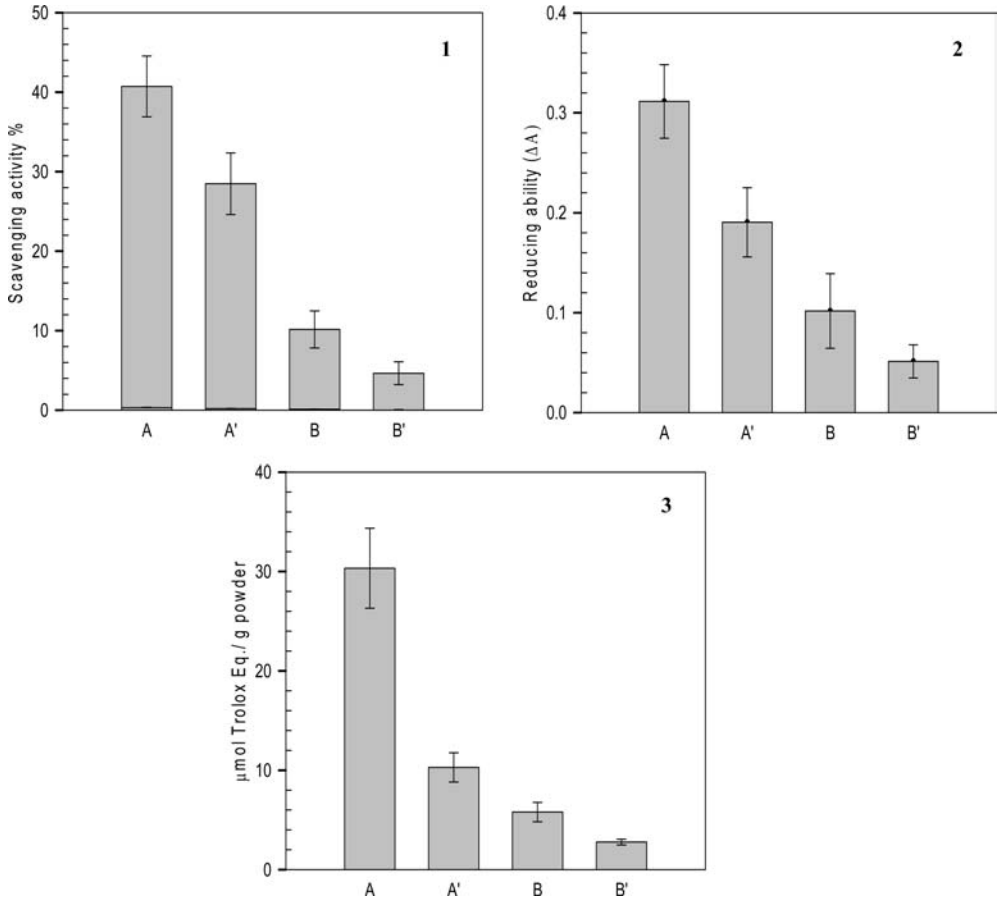

Figure 8. Scavenging activities (1), reducing abilities (2), and oxygen radical absorbing capacities (3) of spray-dried quercetin suspension powders prepared in 1% T80 (w/w) solution [(A) HPH treated and (A′) nontreated] and prepared in water [(B) HPH treated and (B′) nontreated samples].

related to the total reducing capacity of electron-donating antioxidants.[31]

In our study, spray-dried samples were first dissolved in water followed by the removal of undissolved portion by ultracentrifugation; after that, the supernatant was extracted with methanol. The radical scavenging activities and reducing abilities of spray-dried HPH-treated and nontreated quercetin powders are exhibited in Figure 8. Consistent with increased water solubility of quercetin by the application of high pressure, the HPH-treated powders scavenged more DPPH radical in the reaction medium and showed higher reducing power.

The ORAC assay as originally designed is limited to measurement of hydrophilic chain-breaking antioxidant capacity. To solve this disadvantage, the method is modified by using a solubility enhancer, that is, methylated β-cyclodextrin.[31] In our study, the ORAC assay was done as originally designed, although quercetin is a hydropohobic antioxidant and has very poor water solubility. Because one of the goals in our study was the enhancement of the water solubility of quercetin, we expected an increase in ORAC values depending on HPH treatment, which is also presented in Figure 8.

In summary, high-pressure homogenization was used to increase the water solubility of quercetin crystals, and very fine suspensions in the nanometric range were produced. The effects of the pressure, number of cycles, and concentration of stabilizer (Tween 80) on particle size, water solubility, and structure were examined. Particle size reduction rate was decreased by increasing the number of cycles and reached a steady value (~430 nm) after 10 cycles. The force required to break down the crystals seemed to increase rather exponentially with decreasing particle size. The smallest particle size achieved did not depend on the concentration of stabilizer, but the polydispersity index of the systems using Tween 80 had lower values, which indicated that having surfactant in the system provides fineness of particle by preventing agglomeration during HPH cycles. Furthermore, the formation of nanosized particles was confirmed by AFM and SEM images showing uniformity in size and lack of large needle-type crsytals. DSC thermograms also showed the loss of crystallinity through shifting to lower melting temperature and enthalpy of fusion values of HPH-treated samples. Easily water redispersible powders were fabricated by using a spray-drying process when maltodextrin was used as a carrier agent. HPH-treated spray-dried powders showed higher antioxidant activity than nontreated powders through increased water solubility in terms of radical scavenging activity, reducing ability, and oxygen radical absorbance capacity determinations. HPH has been proven to be an appropriate method to produce readily dispersible quercetin powders with high water dispersity, which is of vital importance for enhancement of the oral bioavailability.

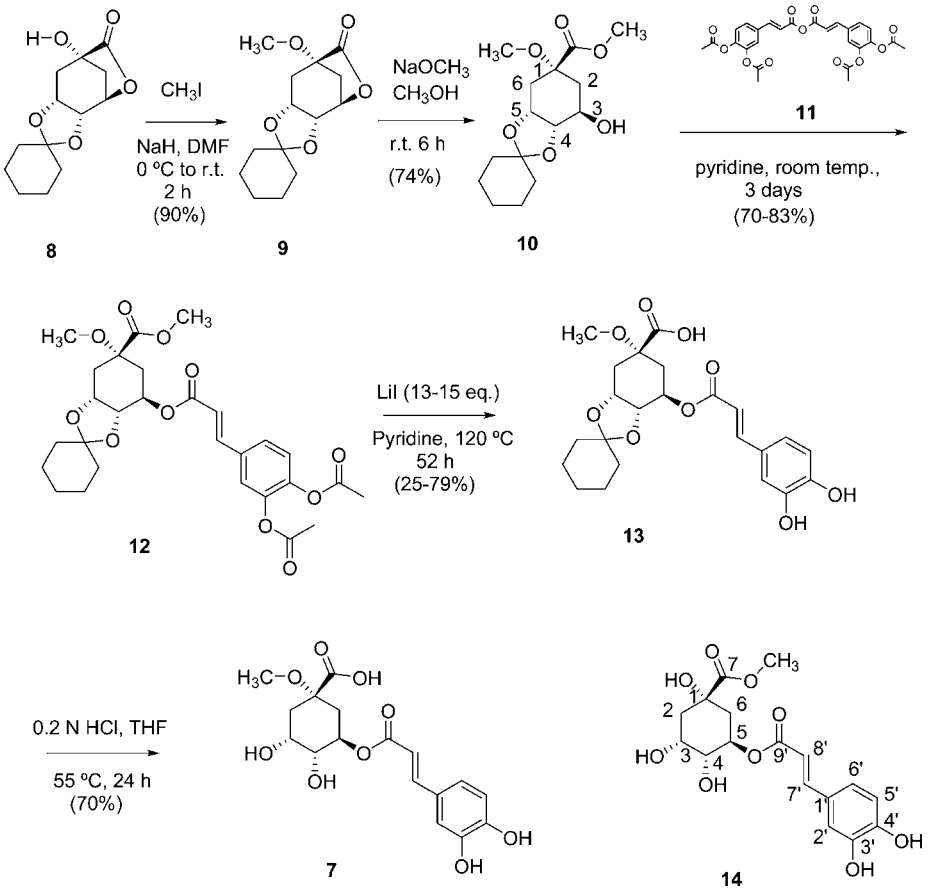

Figure 2. Synthesis of 1-*O*-methylchlorogenic acid, **7**.

and C-4 hydroxyl groups of chlorogenic acid, **7** and **6**, respectively. Evaluation of these compounds revealed strong antioxidant properties in standard tests with compound **7** showing activity superior to that of chlorogenic acid and compound **6** in both the DPPH scavenging assay and the iron-induced rat microsomal lipid peroxidation system.[32] Compound **7** was reported to possess unique antioxidant properties, including induction of heme oxygenase-1 mRNA and protein and providing protection of bovine aortic pulmonary endothelial cells against ROS-mediated necrosis when challenged with the oxidant *tert*-butyl hydroperoxide.[33] Further studies have shown that this compound also induces additional selected phase II genes including ferretin, γ-glutamylcysteine lygase, glutathione reductase, and glutathione transferase at the micromolar level.[34] Lastly, the compound assigned structure **7** was shown to enhance ultraviolet A-mediated apoptosis via activation of p21 in HaCaT keratinocytes, potentially leading to prevention of sunlight-induced photocarcinogenesis.[35]

Our interest in this class of compounds is coupled to recent reports showing that the presence of compounds containing the *o*-diphenol functionality during ensilage of dairy cow forages, containing either naturally occurring or plants transfected with polyphenoloxidase (PPO),[36] results in enhanced protein preservation of the stored forage. Thus, our interest lies in securing sufficient quantities of naturally occurring *o*-diphenols to evaluate them as PPO substrates and allow investigation of the mechanism by which these compounds alter forage protein composition toward rumen digestion. We have initiated a program to produce naturally occurring caffeoyl-containing *o*-diphenols[37] and examine their ability to serve as substrates for PPO and protein preservations.[38] The extraordinary activities reported for **7**, abbreviated as MCGA3 in reports of subsequent studies, prompted us to develop a laboratory synthesis of this compound.

MATERIALS AND METHODS

General Experimental. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker Avance 360 instrument operating at 360 MHz (^{1}H) and 90 MHz (^{13}C), respectively. Spectra (presented in Supporting Information) obtained were referenced to the residual signals: for acetone-d_6 at 2.04 and 29.8 ppm; for methanol-d_4 at 3.30 and 49.0 ppm; for ^{1}H and ^{13}C, respectively. Mass spectra were obtained on a Waters LCT instrument. Melting points were obtained on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were obtained on a Shimadzu IRPrestige-21 spectrometer operating in the ATR mode. Elemental analyses were performed by Midwest Microlabs, LLC, Indianapolis, IN. Optical rotations were determined on a Rudolph Research (Flanders, NJ) Autopol III Automatic Polarimeter. Thin-layer chromatography was performed on precoated DC-Fertigplatten SIL G-25 UV254 plates (Alltech, Deerfield, IL). Flash chromatography was conducted on silica gel, Merck, grade 9385, 230−400 mesh, 60 Å. Pyridine was dried over activated 4 Å sieves. For clarity in interpretation of NMR assignments, all assignments are made according to numbered structure **14** in Figure 2. Mention of trade names or commercial products in this article is solely for the purpose of providing specific information and does not imply recommendation or endorsement by the U.S. Department of Agriculture.

Synthesis of 1-*O*-Methyl-3,4-cyclohexylidenequinic Acid Lactone, 9. To a 50 mL, two-necked, round-bottomed flask equipped with a magnetic stir bar, an equalizing addition funnel, and a septum were added sodium hydride (193 mg, 8.02 mmol, 60% in mineral oil) and anhydrous DMF (10 mL), and the flask was placed under an argon atmosphere using a gas inlet adapter. The stirring suspension

dx.doi.org/10.1021/jf4042112 | J. Agric. Food Chem. 2014, 62, 1860−1865

was cooled in an ice bath, and a mixture of (−)-4,5-cyclohexylidenequinic acid lactone, **8** (1.36 g, 5.35 mmol), and iodomethane (1.14 g, 8.02 mmol) in anhydrous DMF (15 mL) was added dropwise via the addition funnel over a 30 min period. The mixture was allowed to slowly warm to room temperature over 2 h. The mixture was cautiously quenched by adding it to a stirred solution of half-saturated aqueous ammonium chloride and ethyl acetate (50 mL each). The layers were separated, the aqueous layer was extracted with ethyl acetate (2 × 50 mL), and the combined organic extracts were washed with water (3 × 50 mL) and brine (20 mL), dried (Na_2SO_4), filtered, and concentrated to give an off-white solid. This material was recrystallized from hexanes (10 mL/g of residue) to give 1.30 g (90%) of an off-white solid. R_f = 0.45 (7:3 hexanes/EtOAc), $[\alpha]_D^{25}$ = +1.4 (*c* = 1.02, $CHCl_3$), mp 95.5−97 °C (hexanes), ^{1}H NMR (360 MHz, acetone-d_6) δ 4.68 (dd, 1, *J* = 6.3, 2.5 Hz, H5), 4.56 (m, 1, H3), 4.30 (ddd, 1, *J* = 6.4, 2.4, 1.2 Hz, H4), 3.30 (s, 3, OCH_3), 2.57 (dddd, 1, *J* = 11.7, 6.2, 2.3, 1.3 Hz, H6a), 2.33 (d, 1, *J* = 11.7, H6b), 2.30 (ddd, 1, *J* = 14.6, 7.7, 2.4 Hz, H2a), 2.04 (dd, 1, *J* = 14.6, 3.0 Hz, H2b), 1.66−1.72 (m, 2), 1.56−1.66 (m, 4), 1.48−1.56 (m, 2), 1.35−1.42 (m, 2). ^{13}C NMR (90 MHz, acetone-d_6) δ 175.8 (C═O), 110.6 (acetal C), 77.6 (C1), 75.6 (C5), 72.9 (C4), 71.8 (C3), 52.0 (OCH_3), 37.6, 36.8 (C2), 34.3, 29.9 (C6), 25.7, 24.7, 24.2 ppm. IR (ATR) ν_{max} 2926, 2842, 1777, 1653, 1452, 1163, 1085, 983, 913 cm^{-1}. Anal. Calcd for $C_{14}H_{20}O_5$: C: 62.67; H: 7.51. Found: C; 62.99, H; 7.58.

Synthesis of Methyl 1-*O*-Methyl-3,4-cyclohexylidenequinate, 10. To a 100 mL, pear-shaped, one-necked flask equipped with a magnetic stir bar and a ground glass stopper were added compound **9** (1.26 g, 4.69 mmol) and anhydrous methanol (28 mL). To this stirring solution was added freshly prepared 1.0 M sodium methoxide in methanol (14.0 mL, 14.0 mmol, 2.98 equiv) dropwise over ∼2 min at room temperature. After 21 h of being stirred at room temperature, the reaction was quenched through the addition of glacial acetic acid (1.70 mL, 29.6 mmol), diluted with EtOAc (150 mL), and washed with water (50 mL). The layers were separated, the aqueous layer extracted with EtOAc (50 mL), and the combined EtOAc extracts were washed with water (50 mL), saturated $NaHCO_3$ (50 mL), and brine (25 mL) and dried (Na_2SO_4). The mixture was filtered, concentrated, and dried to give a white solid residue. The residue was purified via flash chromatography on silica gel (80 g) using 9:1 $CHCl_3$/ acetone as eluent to give 1.08 g (76%) of a white solid. R_f = 0.23 (9:1 $CHCl_3$/acetone); $[\alpha]_D^{25}$ = −16.7 (*c* = 0.86, $CHCl_3$), ^{1}H NMR (360 MHz, acetone-d_6) δ 4.37 (dd, 1, *J* = 10.6, 5.2 Hz, H3), 4.08 (d, 1, *J* = 4.5 Hz, C3-O*H*), 3.99 (m, 1, H5), 3.88 (t, 1, *J* = 6.2 Hz, H4), 3.69 (s, 3, CO_2CH_3), 3.19 (s, 3, OCH_3), 2.22 (dd, 1, *J* = 15.1, 5.2 Hz, H6a), 2.14 (ddd, 1, *J* = 15.1, 4.7, 1.6 Hz, H6b), 1.99 (ddd, 1, *J* = 13.5, 4.0, 1.6 Hz, H2a), 1.70 (dd, 1, *J* = 13.5, 10.5 Hz, H2b), 1.53−1.66 (m, 4), 1.49−1.53 (m, 4), 1.30−1.40 (m, 2H). ^{13}C NMR (90 MHz, acetone-d_6) δ 174.1 (C7, C═O), 109.5 (acetal C), 80.8 (C4), 79.9 (C1), 73.5 (C5), 68.4 (C3), 52.3 (OCH_3), 52.2 (CO_2CH_3), 39.1 (C2), 39.0, 35.9, 31.2 (C6), 25.8, 24.8, 24.5. Synthesis of Methyl 1-*O*-Methyl-3,4-cyclohexylidene-5-*O*-bis(3′,4′-*O*-acetylcaffeoyl)quinate, 12. To a pear-shaped, one-necked flask equipped with a magnetic stir bar and a septum were added ester alcohol **10** (855 mg, 2.85 mmol) and pyridine (12 mL). To this stirred solution was added caffeic acid anhydride tetraacetate (**11**, 2.17 g, 4.27 mmol, 1.5 equiv) in one portion, and the resulting mixture was capped with a septum and stirred at room temperature for 72 h. The mixture was diluted with EtOAc (350 mL) and transferred to a 500 mL separatory funnel. The mixture was washed with 2 N aqueous HCl (2 × 75 mL, second washing acidic w/litmus), saturated aqueous $NaHCO_3$ (4 × 60 mL), brine (50 mL) and dried ($MgSO_4$). The solution was filtered, concentrated, and dried to give an off-white foam (2.0 g). The residue was purified via chromatography on flash silica gel (200 g) using 96:4 $CHCl_3$/acetone (1.5 L) followed by 9:1 $CHCl_3$/acetone (500 mL) as eluent to afford 1.10 g (71%) of an off-white foam. $[\alpha]_D^{25}$ = −28.3 (*c* = 1.05, $CHCl_3$), ^{1}H NMR (360 MHz, acetone-d_6) δ 7.67 (d, 1, *J* = 16.0 Hz, H7′), 7.64−7.60 (m, 2, H2′, H6′), 7.31 (d, 1, *J* = 7.9 Hz, H5′), 6.54 (d, 1, *J* = 16.0 Hz, H8′), 5.34 (ddd, 1, *J* = 11.5, 7.5, 4.2 Hz, H5), 4.48 (ddd, 1, *J* = 5.3, 5.3, 2.9 Hz, H3), 4.17 (dd, 1, *J* = 7.3, 5.8 Hz, H4), 3.70 (s, 3, CO_2CH_3), 3.27 (s, 3, OCH_3), 2.43 (br d, 1, *J* = 15.8 Hz, H2a), 2.27−2.17 (m, 8, H2b, H6a, O_2CCH_3, O_2CCH_3), 1.82 (dd, 1, *J* = 13.2, 11.3 Hz, H6b), 1.71−1.65 (m, 2), 1.60−1.50 (m, 6), 1.40−1.25 (m, 2) ppm. ^{13}C NMR (90 MHz, acetone-d_6) δ 173.6 (COOH), 168.6 (O_2CCH_3), 168.5 (O_2CCH_3), 166.2 (C9′), 145.0 (C3′ or C4′), 143.9 (C3′ or C4′), 134.0 (C1′), 127.3 (C6′), 125.0 (C5′), 123.9 (C2′), 120.0 (C8′), 110.1 (acetal C), 80.0 (C1), 77.2 (C4), 73.7 (C3), 72.2 (C5), 52.6 (OCH_3), 52.5 (CO_2CH_3), 38.8, 36.0, 35.4 (C2), 31.1 (C6), 25.7, 24.7, 24.5, 20.5 (O_2CCH_3), 20.4 (O_2CCH_3) ppm. Synthesis of 1-*O*-Methyl-3,4-cyclohexylidene-5-*O*-caffeoylquinic Acid, 13. To an 8 mL vial equipped with a magnetic stir bar and a screw cap were added compound **12** (200 mg, 0.366 mmol) and anhydrous pyridine (5.0 mL). To this solution was added LiI (740 mg 5.53 mmol) in one portion, and the mixture was degassed by bubbling Ar gas through the solution for 2 min by which time the LiI had completely dissolved. The vial was sealed and heated in an oil bath at 120 °C for 52 h. The cooled reaction mixture was diluted with EtOAc (70 mL) and washed with 1 N aqueous HCl (30 mL). The aqueous layer was extracted with EtOAc (30 mL), and the combined EtOAc extracts were washed with 0.5 M aqueous sodium thiosulfate (2 × 30 mL), water (30 mL), brine (30 mL) and dried ($MgSO_4$). The solution was filtered, concentrated, and dried to give a light tan foam. This residue was purified via column chromatography on flash silica gel (30 g) using 92:8:1 CH_2Cl_2/CH_3OH/AcOH as eluent to give 131 mg (79%) of an off-white foam. R_f = 0.25 (92:8:1 CH_2Cl_2/CH_3OH/AcOH); $[\alpha]_D^{25}$ = −37.2 (*c* = 1.04, MeOH), mp 118−120 °C. ^{1}H NMR (360 MHz, acetone-d_6) δ 7.55 (d, 1, *J* = 15.9 Hz, H7′), 7.16 (d, 1, *J* = 2.0 Hz, H2′), 7.04 (dd, 1, *J* = 8.2, 2.0 Hz, H6′), 6.86 (d, 1, *J* = 8.2 Hz, H5′), 6.27 (d, 1, *J* = 15.9 Hz, H8′), 5.34 (ddd, 1, *J* = 11.5, 7.5, 4.2 Hz, H5), 4.49 (m, 1, H3), 4.17 (dd, 1, *J* = 7.4, 5.7 Hz, H4), 3.32 (s, 3, OCH_3), 2.41 (m, 1, H2a), 2.29−2.22 (m, 2, H2b, H6a), 1.83 (dd, 1, *J* = 13.2, 11.3 Hz, H6b), 1.70−1.60 (m, 2), 1.60−1.50 (m, 6), 1.45−1.30 (m, 2). ^{13}C NMR (90 MHz, acetone-d_6) δ 174.2 (CO_2H), 166.8 (C9′), 148.7 (C4′), 146.3 (C3′), 145.9 (C7′), 127.6 (C1′), 122.6 (C6′), 116.3 (C5′), 115.7 (C8′), 115.2 (C2′), 110.0 (acetal C), 79.9 (C1), 77.3 (C4), 73.8 (C3), 71.7 (C5), 52.6 (OCH_3), 38.8, 36.0, 35.5 (C6), 31.2 (C2), 25.7, 24.7, 24.5. Synthesis of 1-*O*-Methyl-5-*O*-caffeoylquinic Acid (1-*O*-Methylchlorogenic Acid), 7. To an 8 mL vial containing acetal **13** (20.8 mg, 0.0463 mmol) was added tetrahydrofuran (5 mL) followed by 0.2 M aqueous HCl (600 μL). The resulting solution was degassed by bubbling Ar gas through the solution for 1 min, and the vial was sealed with a screw cap and placed in a 55 °C oil bath for 24 h. The resulting mixture was cooled to room temperature, diluted with ethyl acetate (40 mL), washed with water (5 mL) and 80% brine (2 × 5 mL), and dried ($MgSO_4$). The solution was filtered and concentrated to give a light brown residue. The residue was diluted with water (1 mL) to provide a suspension which was frozen in liquid nitrogen and freeze-dried on a vacuum line to give 12.0 mg (70%) of a fluffy white solid. Attempted melting point determination of this hygroscopic material resulted in formation of a glass below 140 °C. $[\alpha]_D^{25}$ = −16.1 (*c* = 0.55, MeOH), ^{1}H NMR (360 MHz, CD_3OD) δ 7.52 (d, 1, *J* = 15.9 Hz, H7′), 7.04 (d, 1, *J* = 1.9 Hz, H2′), 6.94 (dd, 1, *J* = 8.2, 1.9 Hz, H6′), 6.76 (d, 1, *J* = 8.0 Hz, H5′), 6.21 (d, 1, *J* = 15.9 Hz, H8′), 5.13, (m, 1, H5), 4.11 (m, 1, H3), 3.75 (m, 1, H4), 3.31 (s, 3, OCH_3), 2.32−2.24 (m, 2, H2a, H6a), 2.11 (m, 1, H6b), 2.01 (m, H2b) ppm. ^{13}C NMR (90 MHz, CD_3OD) δ 175.0 (COOH), 168.4 (C9′), 149.6 (C4′), 147.2 (C7′), 146.8 (C3′), 127.8 (C1′), 123.0 (C6′), 116.4 (C5′), 115.2 (C2′), 115.1 (C8′), 81.2 (C1), 72.2 (C4), 72.0 (C5), 69.7 (C3), 52.2 (OCH_3), 35.9 (C2), 34.2 (C6) ppm. RESULTS AND DISCUSSION

The approach taken for the production of MCGA3 was similar in design to a previous report outlining a synthesis of a closely related derivative.[39] However, detailed synthetic procedures were not presented in this communication. Previous reports have indicated that alkylation of the C-1 hydroxyl of the 4,5-ketal-protected quinic acid lactone can be accomplished with iodomethane.[39] Reaction of lactone **8** with methyl iodide and sodium hydride in DMF afforded methyl ether **9** in 90% yield after recrystallization from hexanes (Figure 2). Hydroxide opening of lactone **9** afforded the corresponding hydroxyl carboxylate. In our hands, acylation of this carboxylate with acetate-protected caffeoyl chloride and imidazole derivatives[39] resulted in poor isolated yields from complex mixtures. We opted to examine the feasibility of unmasking the lactone functionality to the hydroxyl methyl ester **10**. Reaction of lactone **9** with freshly prepared sodium methoxide (Na, CH_3OH)[40] afforded hydroxy ester **10** in 74% yield after chromatographic purification. The caffeoyl moiety was introduced through acylation of the secondary alcohol using caffeic acid anhydride tetraacetate, **11**,[37] a reagent developed specifically for construction of caffeoyl-containing compounds, and afforded the fully protected target compound **12**. The methyl ester functionality was cleaved with lithium iodide in pyridine (120 °C, 52 h)[41] which also resulted in concomitant loss of the caffeoyl acetate protecting groups to give the intermediate acetal **13** in 79% yield after chromatographic purification. Completion of the first synthesis of 1-*O*-methyl chlorogenic acid, **7**, was accomplished after treatment of acetal **13** with aqueous HCl in THF (70%).

Extensive NMR examination of **7** (^{1}H, ^{13}C, HSQC, and HMBC) confirmed the structure as assigned. Conclusive evidence for the assigned structure comes from diagnostic absorption in the HMBC spectrum of compound **7** where, as predicted, the methyl ether protons show only a single cross-peak interaction with the assigned C-1 carbon atom. The C-5 hydrogen atom shows three-bond correlations with C-1, C-3, and the carbonyl carbon of the caffeoyl group, as the expected arrangement for the C-5 attachment of the caffeoyl group to the quinic acid unit.

However, these spectroscopic absorptions differ significantly from those reported for MCGA3.[32] Unfortunately, an authentic sample or spectroscopic data of MCGA3 is not available for comparison purposes. No response was received through attempted contact (e-mail) with the corresponding author of the original isolation/activity paper.[32] The corresponding author of another laboratory which utilized MCGA3 in additional studies[34,35] indicated that they are not in possession of any authentic sample of the isolated MCGA3 and have no spectroscopic data for the compound. After closer examination of the reported spectroscopic data, we surmised that the CH_3 signal at 3.7 ppm in the reported ^{1}H NMR data for MCGA3 was most likely arising from a methyl ester and not an aliphatic methyl ether (typically absorbing at 3.2−3.3 ppm) and that the ^{1}H NMR data as a whole was strikingly similar to that reported for methyl chlorogenate. Literature NMR spectroscopic data appearing both before[42] and after[43] the initial structure assignment disclosure[32] supports these observations. To verify this conjecture, we converted commercially available chlorogenic acid to methyl chlorogenate, **14**, in methanolic HCl[11] at room temperature. Comparison of reported ^{1}H and ^{13}C NMR absorption data for MCGA3 with the data obtained for **14** and **7** in CD_3OD are given in Tables 1 and 2. Both the ^{1}H and ^{13}C NMR data of methyl chlorogenate from the published literature

values and the authentic sample correlate well with the data reported from the isolation paper[32] for MCGA3, leading to the conclusion that the compound isolated from bamboo (*Phyllostachys edulis*) leaves is instead methyl chlorogenate, **14**. In addition, subsequent reports[33−35] detailing the biological activities of MCGA3 need to be amended to indicate the correct structural formula.

Shanghai, China. We prepared the CTMSs used in this work in our laboratory via a previously reported procedure.[8,15] The microparticles were approximately 600−1000 nm in size. All other reagents and solvents were of analytical grade.

CCMS Preparation. CCMSs were prepared as follows. Briefly, CAP was dissolved in distilled water containing Tween-80, and CTS was dissolved in 1% ethylic acid solution. The CAP and CTS solutions were mixed using a magnetic stirrer, and the desired microspheres were spontaneously obtained upon addition of an aqueous basic solution of sodium tripolyphosphate (TPP) to the CAP-CTS solution. After 30 min, a CCMS suspension was obtained. Factors affecting drug entrapment efficiency, including CTS concentration, TPP concentration, CAP concentration, pH, and CTS/TPP composition ratio were investigated. The suspension was dried by spray drying to yield CCMSs as a powder. The effects of input temperature, flow rate, and hot air flow rate on particle size and microsphere yield were investigated.

CAP Determination in CCMS. The CAP in the CCMS was extracted by methanol from the CCMS powder and determined by HPLC. A Diamonsil C_{18} (250 mm × 4.6 mm, 5 μm) column was used for this procedure. The mobile phase was 32% H_2O in methanol (V/V), and the detection wavelength was 281 nm.

CCMS Characterization. The particle size and ζ potential of the CCMSs were determined with a laser diffraction size analyzer. The surface morphology of the CCMSs was investigated by SEM (S3700N). HPLC was used to analyze the drug entrapment efficiency and drug loading capacity of the microspheres. The CCMSs were mixed with 25 mL of methanol for ultrasound extraction. CAP in the supernatant was analyzed by HPLC after high-speed centrifugation, and the results obtained were used to calculate the drug entrapment efficiency and drug loading capacity of the products.

Antiobesity Activity of CCMS in Male SD Rats. The SD obese rat model was used in animal studies. A total of 90 male SD rats aged 4 weeks were purchased from Guangdong Medical Laboratory Animal Center (Guangzhou, China). All of the animal protocols were approved by the Institutional Animal Care and Use Committee of the Guangdong Pharmaceutical University (Guangzhou, China) (Protocol no. SPF2013100). All of the rats were housed under standard conditions at 23 ± 2 °C, a 12 h light and dark cycle, and relative humidity of 55%. Food and water were provided ad libitum throughout the experiment.

Experimental Design. Ten rats were randomly separated as (1) the normal diet (standard rodent chow) group (NF); this group was fed with a standard diet. The remaining 80 rats were fed with a high-fat diet to obtain the obesity model. This high-fat diet comprised 60% basic feed, 10% lard, 10% egg yolk powder, 2.5% cholesterol, 0.5% bile salts, 5% sucrose, 5% peanut, 5% milk powder, and 2% salt. After a 4 week high-fat diet, the obesity model was considered complete when the average weight of the rats fed a high-fat diet was greater than 20% that of the rats fed a normal diet. The 80 rats were then randomly divided into eight groups by weight: (2) high-fat feeding group (FF), (3) CTS group (CTS), (4) Orlistat group (Orlistat), (5) CTMS group (CTMS), (6) CAP group (CAP), (7) CCMS high-dose group (H-CCMS), (8) CCMS middle-dose group (M-CCMS), and (9) CCMS low-dose group (L-CCMS). The corresponding "drugs" were administered orally by gavage at a dose of 1 mL/100 g per day at the same time for 5 weeks. The "drugs" were suspended in water. The doses of "drugs" for each group were as follows: CTS, 440 mg/kg/d; CTMS, 440 mg/kg/d; Orlistat, 75 mg/kg/d; CAP, 30 mg/kg/d; H-CCMS, 3382 mg/kg/d (containing 30 mg CAP); M-CCMS, 1128 mg/kg/d (10 mg CAP); L-CCMS, 367 mg/kg/d (3 mg CAP). All rats were weighed every week, and food intake levels for each group were recorded every day. During the experimental period, no rat died and no untoward effects were observed. At the end of the experiment, the rats were fasted overnight, and blood samples were withdrawn from the orbital vein using a capillary after ether anesthesia. The rats were then subjected to ether anesthesia, sacrificed, and necropsied. The liver, heart, white subcutaneous adipose tissues, and mesenteric adipose tissues were quickly removed and weighed on ice. Tissues were stored at −80 °C until biopsy.

Serum Lipid Determination. The serum was prepared, and lipid levels in the blood samples were detected. The levels of TC, TG, HDL-C, and LDL-C were measured with commercial assay kits using an automated biochemistry analyzer BC200 instrument (Beijing Precil Instrument Co. Ltd., Beijing, China).

Quantitative RT-PCR. Total RNA was extracted from the rat livers using TRIzol reagent (Invitrogen). First-strand cDNA was generated using a commercial Bestbio RT kit (Bestbio, Shanghai, China). The cDNA product was amplified by real-time RT-PCR using a Takara SYBR Premix EX Taq kit (TaKaRa, Otsu, Shiga, Japan) and Bio-Rad IQ5 real-time PCR instrument and analysis software (Applied Biosystems, Foster City, CA). The primer sequences (Table 1) used in the PCR were designed by Sangon Biotech (Shanghai) Co., Ltd.

The relative quantification of gene expression was analyzed by the $2^{-\Delta\Delta Ct}$ method. If the average gene expression of the experimental groups was considered lower than that of the FF group. If $2^{-\Delta\Delta Ct} > 1$, the average gene expression of the experimental groups was considered higher than that of the FF group. PCR was performed as follows: 94 °C for 30 s, 61 °C for 30 s, and 72 °C for 15 s after a 5 min warm-up. The system was then cooled to 72 °C for 5 min and finally heated from 65 to 95 °C (1 °C/s and 36 cycles).

ELISA. The concentrations of obesity factors in the serum were measured using an ELISA kit (R&D Systems China Co. Ltd., Shanghai, China), and the ELISAs were read with a multifunctional microplate reader (Berthold Mithras LB 940; Berthold Technologies GmbH & Co. KG, Germany).

Statistical Analysis. All of the data are expressed as means ± SE. Differences between groups were determined by one-way ANOVA using SPSS for Windows, version 16.0 (SPSS Inc., Chicago, IL, USA). Student−Newman−Keuls Multiple-Range Test comparisons at $P < 0.05$ were carried out to determine significant differences among means.

RESULTS

CCMS Preparation. On the basis of the results of single-factor experiments (the effects of the concentration of CTS, sodium TPP, and CAP, the pH of the reaction system, and the mass ratio of CTS/TPP are not presented here), we selected the factors that had the greatest influence on the encapsulation efficiency for orthogonal experiments (Table 2A). The key factors were encapsulation efficiency and drug loading. Parts B and C of Table 2 clearly indicate that the order of influence is pH > concentration of CTS > ratio of CTS/TPP. The optimum conditions for preparation are as follows: CTS concentration, 1 mg/mL; pH 4.5; CTS/TPP ratio, 4:1.

CCMS Optimization. Spray drying is a key technique in preparing samples for the present study. Parts D−F of Table 2 show the effects of inlet temperature, flow rate, and hot air flow on the particle size and microsphere yield. On the basis of the results, we selected 160 °C as the inlet temperature, 600 mL/h as the flow rate, and 32 m^3/h as the hot air flow rate for CCMS preparation.

Characterization. Parts A and B of Figure 1 show the particle distribution and ζ distribution of the resultant products, respectively; the mean particle size and ζ potential of the CCMSs were 4.5 μm and +3.48 mV, respectively. SEM images of the CCMSs (Figure 1C) showed a spherical morphology with uniform diameters. The mean entrapment efficiency of the CCMSs was 85.17%, and the mean drug loading was 8.87% [entrapment efficiency = (total amount of CAP − free amount of CAP)/total amount of CAP, drug loading = (total amount of CAP − free amount of CAP)/microsphere weight].

Pharmacodynamics Study. *Body Weight, Lee's Index, Food Intake, Organ Index, and Proportion of Body Fat.* Body weight was recorded each week. Figure 2 shows the changes in body weight, food intake, Lee's index (body $mass^{1/3}$ × 1000/body length), liver index (liver mass × 100/body mass), and proportion of body fat.

Among the treatments studied, high doses of CCMSs best controlled weight gain (Figure 2B), ΔLee's index (Figure 2C), liver index (Figure 2D), and proportion of body fat (Figure 2F) without affecting food intake (Figure 2A). The ability of the CCMSs to control body weight and ΔLee's index was better than that of Orlistat. While high doses of CCMSs controlled obesity indices favorably, no differences were observed in terms of ΔLee's index, organ index, and proportion of body fat between the H-CCMS and M-CCMS groups. Therefore, 3382 mg/kg/d is an efficient CCMS dosage for controlling obesity in rats. The CCMSs exhibited better obesity control than either the CTMSs or CAP alone; this finding indicates that cooperation may occur between the CTMS and the CAP.

Serum Lipid Determination. Lipid levels in serum were detected using an automatic biochemical analyzer, and the results are shown in Figure 3. TC, TG, and LDL levels in the CCMS group were similar to those in the normal group, but HDL levels were higher in the former than in the latter. Orlistat, CTS, CTMS, CAP, and CCMS showed good control of TC levels. TG levels were lower and HDL levels were higher in the FF group than in any of the other groups. Compared with the TG and HDL levels of the normal group, the Orlistat, CTS, CTMS, and CCMS groups shows varying degrees of reduction in TG levels and increases in HDL levels. The CCMS groups showed higher HDL levels than the CTMS or CAP groups. These results indicate that CCMSs exhibit potential as an antihyperlipidemic for decreasing TC.

Antiobesity Mechanism Study. *Quantitative RT-PCR.* To identify the mechanism by which CCMSs exert their antiobesity effects, adiponectin, leptin, PPARα, PPARγ, FTO,

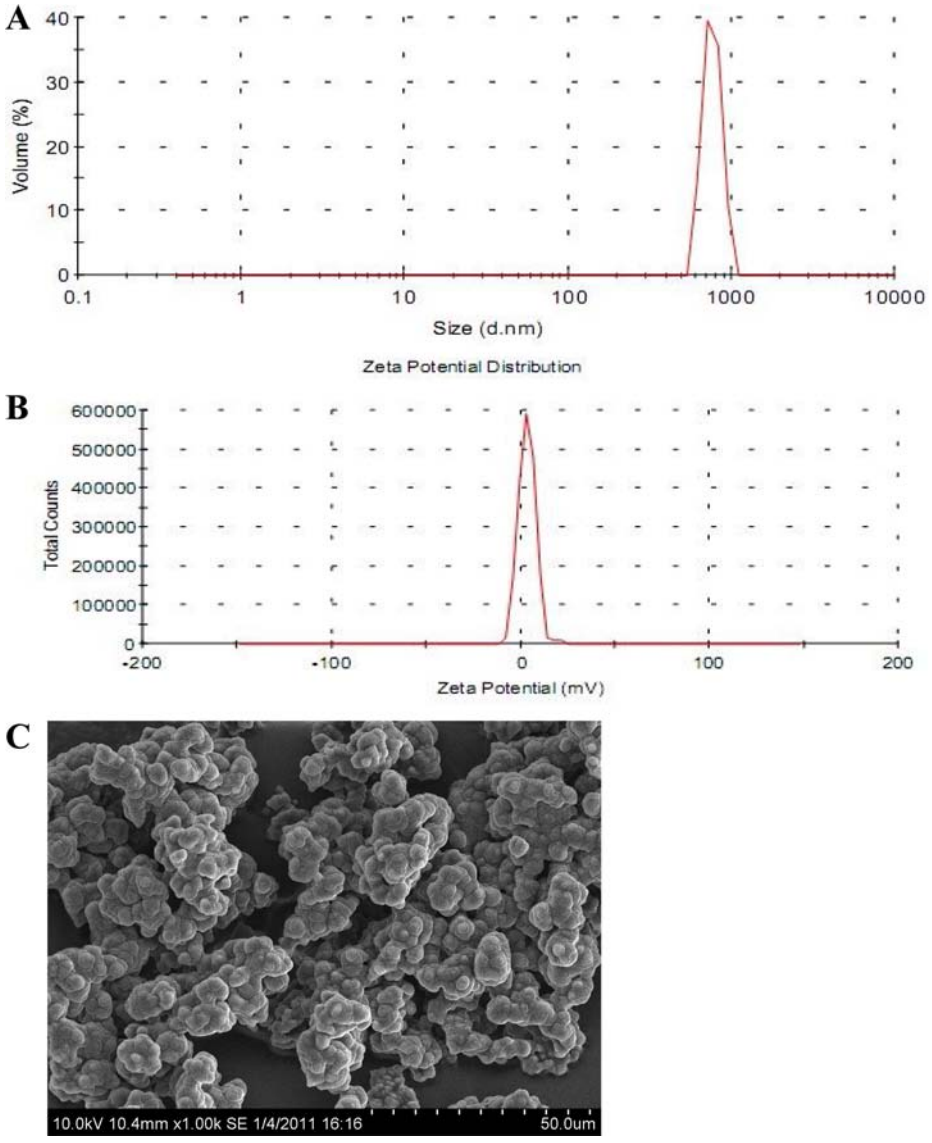

Figure 1. Characterization of CCMS. Particle distribution (A), ζ potential (B), and SEM (C) of CCMS. The particle distribution and ζ potential of the CCMS were determined with a laser diffraction size analyzer, and the surface morphology of the CCMS was studied by SEM (S3700N).

GPR120, and UCP2 were selected for RT-PCR detection (Figure 4A). The mRNA expression of adiponectin, PPARα, PPARγ, FTO, GPR120, and UCP2 increased among the groups to varying degrees, and the mRNA expression of LE decreased. The CCMS and CTMS groups showed significantly increased expression of AD, PPARα, and UCP2 and decreased expression of LE. In the CAP group, the expression of AD, PPARα, and UCP2 was upregulated while the expression of LE was slightly downregulated. The H-CCMS and M-CCMS groups showed better regulation of AD, PPARα, leptin, and UCP2 mRNA expression than the CTMS, CAP, and Orlistat groups. This finding may be attributed to the improved obesity control afforded by CCMSs in rats.

ELISA. RT-PCR analysis results indicated that the key obesity factors are AD, LE, PPARα, and UCP2 mRNA. Therefore, we detected the protein expression of these obesity factors in the serum by ELISA; the results are shown in Figure 4B−F. The AD, UCP2, and HL contents in serum from CCMS groups were much higher than those in the HF group. No significant difference in the expression of PPARα was found between the CCMS and HF groups. HL results showed that the HL may possibly be one of the reasons of CCMS for controlling obesity. RT-PCR and ELISA study results indicate that CTMSs and CCMSs affect the protein expression of AD, UCP2, and LE by exerting effects on obesity-associated genes.

Slices of Different Tissues. Tissue sections were stained with hematoxylin and eosin (H&E), and H&E images of different tissues are shown in Figure 5. The heart slices (Figure 5A) showed no myocardial hypertrophy in the NF, M-CCMS, and L-CCMS groups. The myofibers were in order, the stripes and muscle space were clear, and the nucleus was not enlarged. Figure 5B clearly shows that the liver cells of the fat group underwent vacuolation. The cells contained a pale, watery cytoplasm. Several differently shaped lipids and a large number of both small and large cytoplasmic lipid droplets were present. Large fat droplets were fairly noticeable. Spotty and focal necrosis occurred in the liver cells of the fat group, and an inflammatory cell infiltrate was observed in the normal group. Compared with the CTS, CAP, CTMS, and CCMS groups, the fatty liver-like Fat group was much better than the Fat group. In Figure 5C, the adipocytes of the Fat group were larger than those of other groups, except for the M-CCMS and L-CCMS

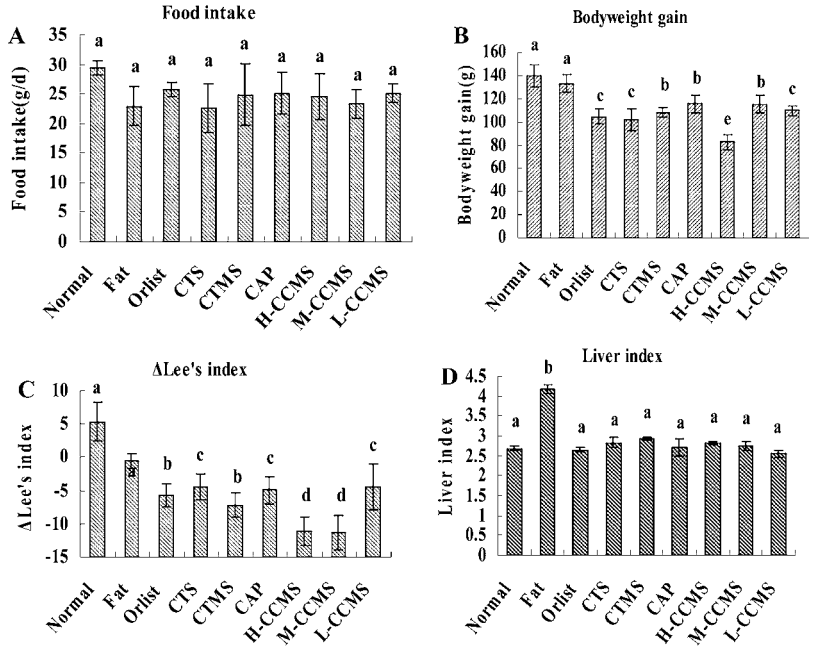

Figure 2. The main antiobese index of CCMS ($P < 0.05$). Changes in the body weight (A), food intake (B), Lee's index (C), liver index (D), body fat (E), and ratio of the body fat and weight (F) after 5 weeks treatment. Lee's index (body mass$^{1/3}$ × 1000/body length), Liver index (liver mass × 100/body mass), a low value of Lee's index, or liver index means that it is better at controlling obesity. The data are the means ± SE ($n = 10$). $P < 0.05$.

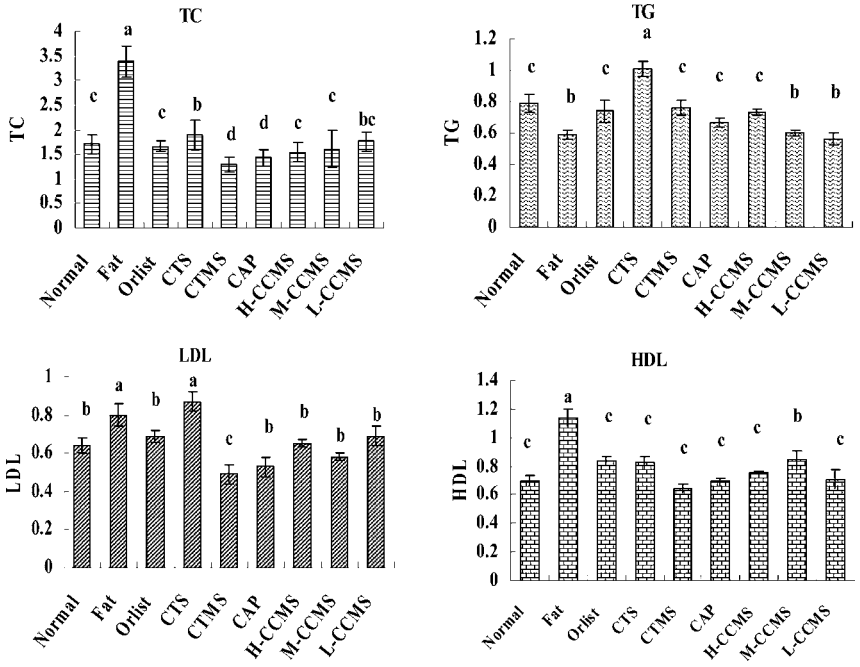

Figure 3. The serum lipid levels in rats ($P < 0.05$). The levels of TC, TG, LDL, and HDL in each group after 5 weeks treatment. The data are the means ± SE ($n = 10$). $P < 0.05$.

groups. Treatment with Orlistat, CTS, and high doses of CCMS clearly inhibited the proliferation of adipocytes. The same phenomena were observed in the mesentery fatty tissue slices (Figure 5D). In summary, the CCMSs are beneficial to the fatty liver and cardiac hypertrophy, which are caused by obesity.

DISCUSSION

Obesity is associated with a number of diseases and metabolic disturbances, including type 2 diabetes, hypertension, dyslipidemia, gallbladder disease, and some cancers.[17−19] Developing new types of antiobesity drugs is thus rapidly becoming an urgent necessity. Natural products, such as *Cassia* mimosoides, CTS, and CAP, and some types of food show promising antiobesity activities.[20−22]

dx.doi.org/10.1021/jf4040628 | J. Agric. Food Chem. 2014, 62, 1866−1874

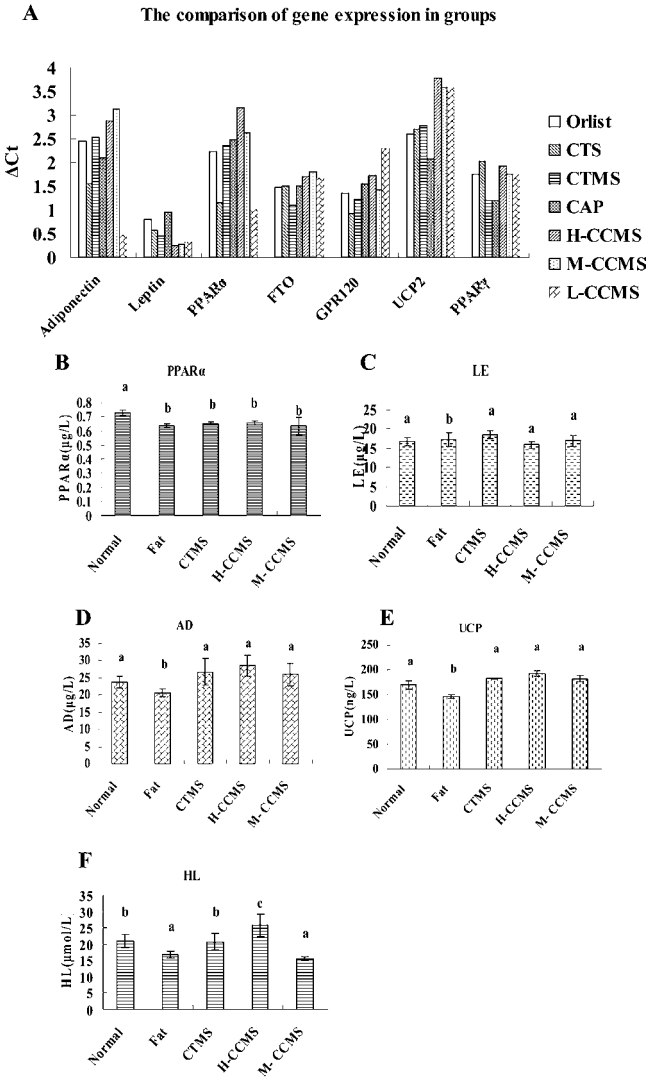

Figure 4. Gene expression and protein expression comparisons in the different treatment groups. The expression of adiponectin, leptin, PPARα, FTO, GPR120, UCP2, and PPARγ mRNA (A) in different treatment groups after 5 weeks of treatment. The level of mRNA was detected by Q-PCR. The changes of protein expression of adiponectin (B), leptin (C), PPARα (D), UCP2 (E), and hepatic lipase (F) in different treatment groups were detected by ELISA. Δ^{Ct} is the average value of 10 samples in the formulation (average gene expression of experiment groups/average gene expression of FF groups) = $2^{-\Delta\Delta Ct} = 2^{(-\Delta Ct_{control} - \Delta Ct_{FF})}$. If $2^{-\Delta\Delta Ct} < 1$, the average gene expression of the experiment groups is lower than that in the FF group. If this value is higher than 1, the average gene expression of the experiment groups is higher than that in the FF group.

CAP is a natural active substance extracted from red pepper.[23] The substance has been shown to be effective for weight loss and exhibited antihyperlipidemic activity in both animal and human studies.[15,24−27] However, CAP has limited use because of its pungency. This current study provides a solution that may partially eliminate this problem. During CCMS administration, the rats showed better tolerance toward the CCMSs than toward CAP (the compliance of the CCMS groups was better than that of the CAP group). The antiobesity activity of the CCMSs was also better than that of the CAP and CTMS groups, which may be attributed to the fact that CAP absorption is promoted by the CTMSs and additive effects exist between CAP and the CTMSs.

CTS is a polysaccharide material extracted from shell; it is generally considered a good excipient because of its biocompatibility.[28−30] CTS-based nanoparticles have been widely studied as drug carrier systems for many years,[31−33] and relevant studies show that these nanoparticles could improve the intestinal absorption of a drug in vivo.[34−36] Our research showed that CTMSs were significantly lowered blood lipid levels.[12] Combining microspheres with CAP may thus present a good solution to compensate for limitations associated with CAP use.

In this study, we prepared CCMSs by cross-linking and spray drying. CTS and TPP were combined by chemical bonding, and CAP was encapsulated inside the sphere. Many experiments have demonstrated that CTS has active functions in weight control and may be used as an antiobesity agent.[6,37,38] Therefore, CCMSs may be more functionally active than either CTS or CAP alone. The CCMSs may be applied as a future drug for weight loss.

The oral LD_{50} values of CAP were 118.84 and 97.40 mg/kg for male and female rats, respectively.[39] Prior to this research, we carried out a brief experiment to determine the highest dosage. No deaths occurred with 10-fold dosage of CCMS (CAP) in mice, which indicates that CCMSs may reduce CAP toxicity.

Compared with the CTMS, CAP, and Orlistat groups, the CCMSs grouped showed better inhibition of increases in rat body weight, body mass index, organ index, body fat, and proportion of fat to body weight (Figure 2). CCMSs maintained these parameters at normal or lower levels in rats and exhibited no effect on the appetite of rats. Rats treated with CCMSs showed more controlled body weight gains than rats treated with CAP or CTMS. Additive effects were also observed. Treatment with CCMSs significantly reduced the TC, TG, and LDL of rats to normal levels, and these decreases were lower than those shown by either CTMSs or CAP alone (Figure 3). The CCMSs could potentially lower blood lipids, but they are not as effective as the CTMSs, CTS, or CAP. While many studies have shown that CTS or chitin has potential use as an antiobesity agent and lowering lipid levels, concerns regarding CTS/chitin use remain. Low-molecular-weight CTS is easily absorbed,[40] and its small size exhibits great effects on body weight.[9] CCMSs, which are composed of small particles, may be easily absorbed and exhibit good antiobesity activity.

The mechanism of obesity is complex, and various genes have different effects on obesity.[41] In this study, we selected seven significant genes associated with obesity or hyperlipidemia for analysis. In the study of the antiobesity mechanism of CCMS, the expression of PPARα, PPARγ, leptin, adiponectin, UCP2, GPR120, and FTO genes was assayed by real-time RT-PCR at the mRNA level (Figure 4A). Genome-wide association studies have shown a strong correlation between a single nucleotide polymorphism in the first intron of the FTO gene with increased body mass index and obesity risk.[42] Adiponectin is an adipokine that antagonizes excess lipid storage in the liver and protects against inflammation and fibrosis.[43] GPR120 dysfunction has been demonstrated to cause obesity in mice and humans.[44] UCP2 is a key regulator of energy balance and mediates proton leaks across the inner membrane via the uncoupling of substrate oxidation from ATP synthesis.[45] Obese individuals have high circulating levels of leptin, which is a hormone secreted by adipose tissue and is involved in energy homeostasis.[46] PPARs

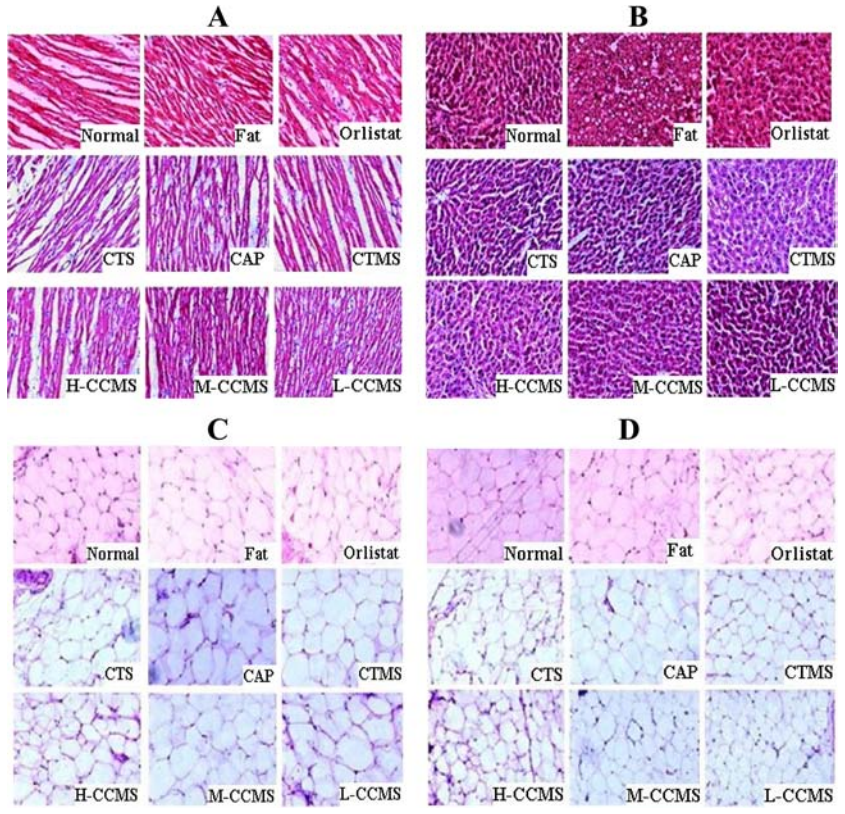

Figure 5. The tissue slices from different organs (200×). Heart slices (A), liver slices (B), subcutaneous fatty tissue slices (C), and mesentery fatty tissue slices (D). Tissue sections were stained with hematoxylin and eosin (H&E).

are important in the control of lipid metabolism.[47] The CCMSs were found to upregulate the expression of PPARα, UCP2, and adiponectin genes and downregulate the expression of the leptin gene. These results were confirmed by the serum protein contents determined using ELISA. The results of genes and protein (Figure 4 B−F) showed that PPARα, UCP2, leptin, and HL and were the key reasons of CCMS for controlling obesity.

Tissue slices showed that the rats fed with CCMSs had thinner myocardial and liver cells than the model group (Figure 5). Moreover, fewer inflammatory cell infiltrates and fatty degeneration of hepatocytes were observed in the heart and liver cells, respectively, of the CCMS-treated rats. The CCMS-treated groups also showed smaller subcutaneous and mesentery fat cells. Hsu demonstrated that CAP efficiently induces apoptosis and inhibits adipogenesis in 3T3-L1 preadipocytes and adipocytes.[48] Overall, the CCMSs possessed good efficacy in reducing weight and have potential therapeutic effects on fatty liver and myocardial hypertrophy caused by obesity. The CCMSs also inhibited the growth of fat cells to a certain extent.

On the basis of the results of the present study, CCMSs could be used as "natural products" with good ability to control obesity and hyperlipidemia. CCMSs may achieve weight loss effects by increasing the mRNA and protein expression of PPARα, UCP2, and adiponectin genes and downregulating the expression of leptin. The antiobesity activity of CCMSs was better than those of either CTMS or CAP. This result indicates that an additive effect exists between CTMSs and CAP.

Garlic and sprouted garlic were minced, ground, and extracted with 10 volumes of 100% ethanol as a solvent. The extract was prepared by removing the solvent with rotary evaporation. The sample solution was prepared by redissolving the extract in ethanol at 40 mg/mL and diluting, if necessary, before use. The garlic extract was further fractionated with *n*-hexane, ethyl acetate, butanol, and water consecutively for use in the 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging assay.

Determination of the Total Phenolic Content. The total phenolic content was measured using the Folin−Ciocalteu reagent.[23] Briefly, 100 μL of extract was mixed with 50 μL of sodium bicarbonate (10%, w/v) solution; 15 μL of the Folin−Ciocalteu reagent, which was diluted by 5-fold with distilled water, was then added. After 5 min at room temperature, the sample mixture was transferred to a 96-well microplate, followed by measuring the absorbance at 593 nm using a microplate reader (Sunrise, Tecan Retisoft, Inc., Mississauga, Ontario, Canada). The total phenolics were expressed as gallic acid equivalents (GAE).

DPPH Radical Scavenging Activity Assay. The DPPH radical scavenging activity assay was performed following a published method, with some modifications.[24] Briefly, 50 μL of each sample was mixed with 200 μL of 200 μM DPPH methanolic solution in a 96-well plate, followed by gentle shaking. After incubation at 37 °C for 30 min, the absorbance was measured at 515 nm. The sample-dissolving solvent and Trolox were used as negative and positive controls, respectively.

Oxygen Radical Absorbance Capacity (ORAC) Assay. The peroxyl radical scavenging capacity of the sample extracts was evaluated by an ORAC assay system.[25] All data were expressed as micromoles of Trolox equivalents (TE), and 1 ORAC unit was equivalent to the net protection by 1 μM Trolox.

Neuroprotective Effect of SGE. HT22 mouse hippocampal neuronal cells were routinely maintained in Dulbecco's modified Eagle's medium (DMEM) with 10% FBS and 100 units/mL penicillin and streptomycin in a humidified CO_2 incubator (MCO-19-AIC, Sanyo, Osaka, Japan) at 37 °C and 5/95% CO_2/air.

The cells were seeded in a 96-well culture dish in DMEM supplemented with 10% FBS at a density of 2×10^3 cells per well. The next day, various doses of SGE and 5 mM glutamate were added to the cells.[26] After cells were cultured for 20 h, the cell survival rate was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) cell proliferation assay. The cell viability was presented as the percentage of the untreated control.

Assessment of Intracellular Reactive Oxygen Species (ROS). The intracellular ROS level was determined by a previously reported method.[27] HT22 cells (2×10^3 cells/well) were seeded in a 96-well black culture plate and cultured for 24 h. After cells were attached on the culture plate, the cells were incubated in the presence of 5 mM glutamate and garlic samples for 6 h. The cells were then washed with phosphate-buffered saline (PBS), incubated for 30 min with DCFDA dissolved in DMEM (final concentration of 30 μM), and then washed with PBS. The fluorescence generated by the interaction of the ROS with dichlorofluorescein (DCF) was observed and photographed under a fluorescence microscope (Eclipse 80i, Nikon, Tokyo, Japan).

Ultraperformance Liquid Chromatography Quadruple Time-of-Flight Mass Spectrometry (UPLC-Q-TOF-MS) Analysis of SGEs. To analyze the metabolites of garlic and sprouted garlic, ethanolic extracts from garlic and sprouted garlic were redissolved in ethanol. The metabolites were analyzed using an Acquity UPLC system (Waters, Milford, MA) equipped with a Waters Micromass Q-TOF Premier mass spectrometer and an Acquity UPLC BEH C18 column (100 × 2.1 mm, 1.7 μm, Waters, Milford, MA). Two solvents, 0.1% formic acid (v/v) and acetonitrile containing 0.1% (v/v) formic acid, were used as the mobile phase. The elution was initiated with the mobile phase containing 5% acetonitrile that was maintained for 1 min, gradually increased to 100% acetonitrile over 10 min, remained at 100% acetonitrile for 1 min, and decreased to 5% acetonitrile for 1 min. The sample (5 μL) was injected, while the flow rate was maintained at 0.3 mL/min. Electron spray ionization was conducted in the negative and positive modes within a m/z range of 100−1000. The ion source and desolvation temperatures were 200 and 250 °C, respectively. The capillary and cone voltages were 3.0 kV and 30 V, respectively. The cone gas flow was 50 L/h. Leucine enkephalin was used as the lock mass (m/z 554.2615) at a concentration of 0.5 ng/μL and a flow rate of 3.0 μL/min.

Data Processing, Multivariate Analysis, and Tentative Identification of Discriminative Variables. The DataBridge program in the MassLynx software package (version 4.1, Waters) was used to export raw data sets to the net CDF file format, in which the net CDF files were automatically aligned using the XCMS package in R 3.0.1 (www.bioconductor.org). The result .txt file, which included the sample name, peak area, and retention time as a variable, was processed using SIMCA-P software 12.0 (Umetrics, Umea, Sweden) for multivariate statistical analysis. The data sets were autoscaled (unit variance scaling) and log-transformed before principal component analysis (PCA) modeling. To identify the different metabolites, we used partial least-squares discriminant analysis (PLS-DA, data not shown) models and created box-and-whisker plots with the mean data using STATISTICA (version 7.0, StatSoft, Inc., Tulsa, OK). We selected metabolites based on the variable important to projection (VIP) values (VIP > 1.0) and p values ($p < 0.05$) and tentatively identified them by comparing their molecular weights to those in the 2008 *Dictionary of Natural Products* (CRC Press, Taylor and Francis Group, Boca Raton, FL) and related references. In addition, the accurate mass from TOF-MS was matched with the elemental composition and the theoretical isotope distribution (i-FIT).

Statistical Analysis. Data were assessed by analysis of variance, followed by Duncan's multiple range test, using SPSS software (SPSS, Inc., Chicago, IL). The significance level was set at $p < 0.05$.

RESULTS

Total Phenolic Contents. Plant polyphenols are multifunctional; they can act as reducing agents, hydrogen-donating antioxidants, and singlet oxygen quenchers. As shown in Figure 1, the total phenolic content in garlic increased slightly during sprouting but there was no significant difference when garlic was sprouted for different periods.

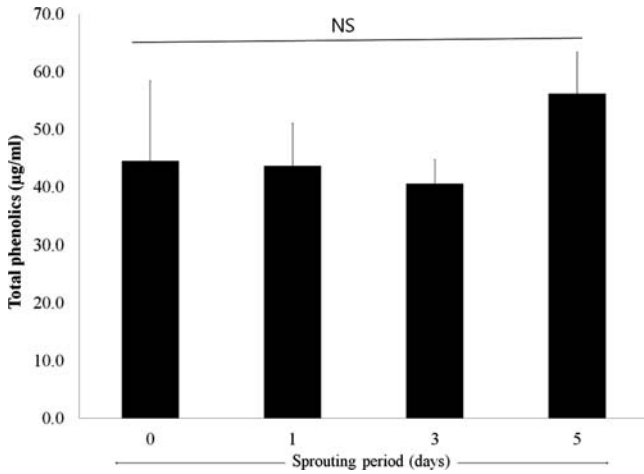

Figure 1. Total phenolic content of SGE. Data are expressed as the mean ± standard deviation (SD) of four independent experiments. NS = no significant difference between the groups.

DPPH Radical Scavenging Activity of Sprouted Garlic. The antioxidant activities of garlic and sprouted garlic are shown in Figure 2 as the percentage of DPPH radical scavenging activity in the control. The DPPH radical scavenging activity of sprouted garlic was higher than that of unsprouted garlic. Of the extracts from samples sprouted 0, 1, 3, or 5 days, the ethanol extract from garlic sprouted for 5 days showed the highest DPPH radical scavenging activity; the

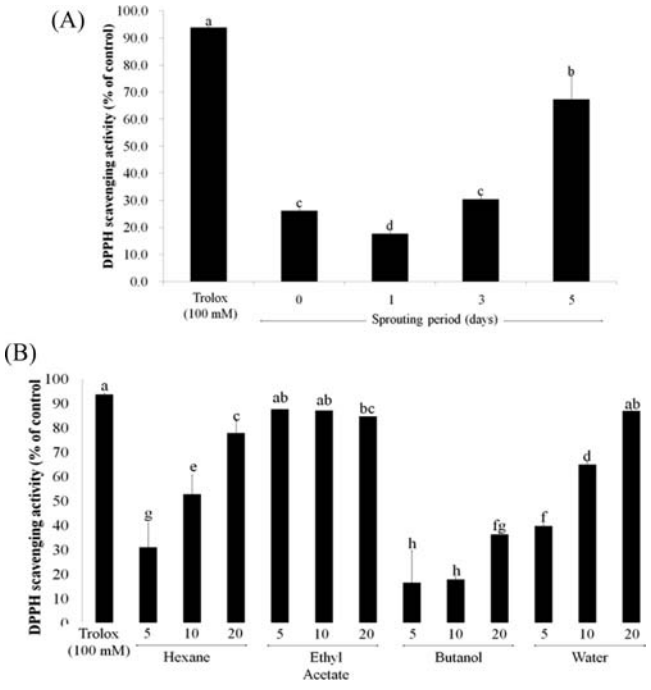

Figure 2. DPPH radical scavenging activity of (A) SGE and (B) solvent fractions. Data are expressed as the mean ± SD of four independent experiments. Values not sharing a common letter differ significantly from each other ($p < 0.05$).

scavenging activity of the 10 mg/mL extract was 80−100% of the control (Figure 2).

ORAC of Sprouted Garlic. The ORAC assay measures the loss of fluorescence caused by the oxidative degradation of fluorescein, a fluorescent molecule, when mixed with 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) (final concentration of 11.4 mM), a peroxyl radical generator (Figure 3). The presence of an antioxidant suppresses or slows the loss of fluorescence, resulting in a high ORAC value. Extracts from garlic sprouted for 5 days suppressed the generation of the peroxy radical more than extracts from raw garlic and garlic sprouted for shorter times, consistent with the results of the other antioxidant assays.

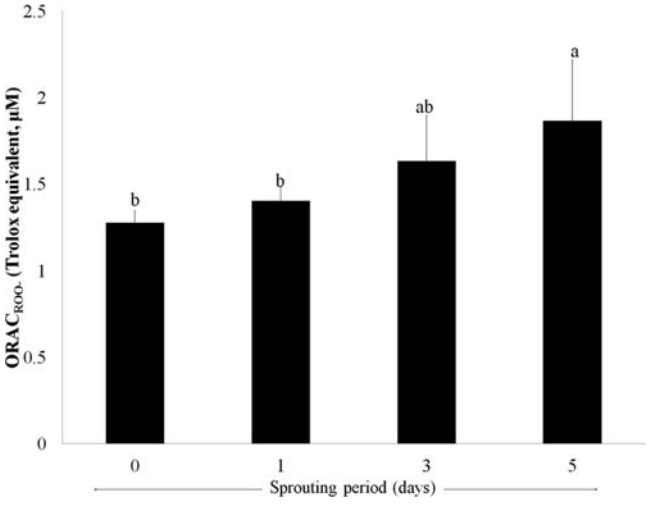

Figure 3. Oxygen radical absorbance activity of SGE. All data are expressed as micromoles of TE. One ORAC unit is equivalent to the net protection area provided by 1 μM Trolox. Values not sharing a common letter differ significantly from each other ($p < 0.05$).

Suppression of Intracellular ROS Generation by SGE in Mouse Hippocampus Cells. We investigated the inhibitory effect of SGE on ROS generation using the oxidant-reactive fluorescent dye DCFDA. SGE prevented glutamate-induced cytotoxicity in the HT22 mouse hippocampal neuronal cell line (Figure 4), whereas raw garlic extract had a limited protective effect. Furthermore, ROS generation mediated by glutamate treatment in HT22 cells was significantly suppressed by the ethanolic extract from garlic sprouted for 4−5 days. These results confirm that sprouted garlic has higher antioxidant potential than non-sprouted garlic (Figure 5).

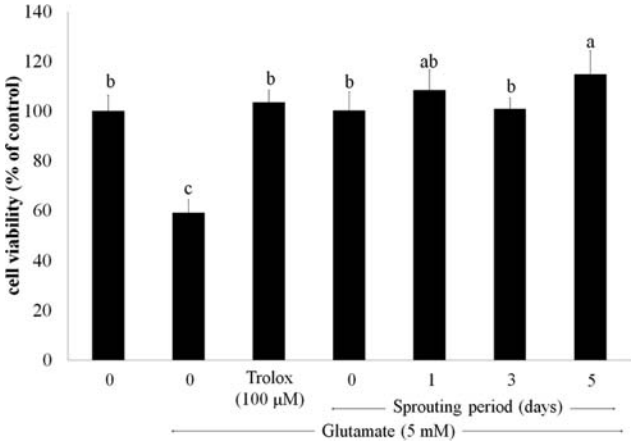

Figure 4. Inhibition of glutamate-induced cell death by SGE in HT22 cells. Cells were treated with 5 mM glutamate in the absence and presence of sprouted garlic samples for 24 h. Cell viability was measured with the MTT assay. The cell survival rate is presented as the percentage of the untreated control. Values not sharing a common letter differ significantly from each other ($p < 0.05$).

Multivariate Analysis of Raw and Sprouted Garlic Metabolites. After aligning the UPLC-Q-TOF-MS spectral data, we obtained 1098 and 1904 variables with the negative and positive detection modes, respectively. The aligned data were presented as two-dimensional PCA (Figure 6) score plots: vector t[1] explained 37.99 and 40.62% of the variation, and vector t[2] explained 16.55 and 22.77% of the variation in the positive and negative modes, respectively. The PCA score plots demonstrated that the metabolite profiles of garlic differed depending upon the sprouting period. In particular, in PC1 of the positive and negative analyses, the metabolite profile of garlic that sprouted for 5 and 6 days (group 1) differed from the metabolite profile of garlic that sprouted for <5 days (group 2). The metabolites that discriminated between the two groups were identified on the basis of the criteria of $p < 0.05$ and VIP > 1.0 (Table 1). Among these metabolites, we identified isoguanosine (or 1-aminoinosine) (**2**), γ-glutamyl-*S*-*trans*-1-propenyl cysteine, glucoside (**3**), 8,11,12-trihydroxy-9-octadecenoic acid (**5**), and spirostane-3,6-diol, 6-*O*-D-glucopyranoside (**7**). These metabolites increased during the sprouting period (Figure 7).

DISCUSSION

Garlic (*Allium sativum*) has long been used for medicinal purposes, owing to its immune-enhancing functions and

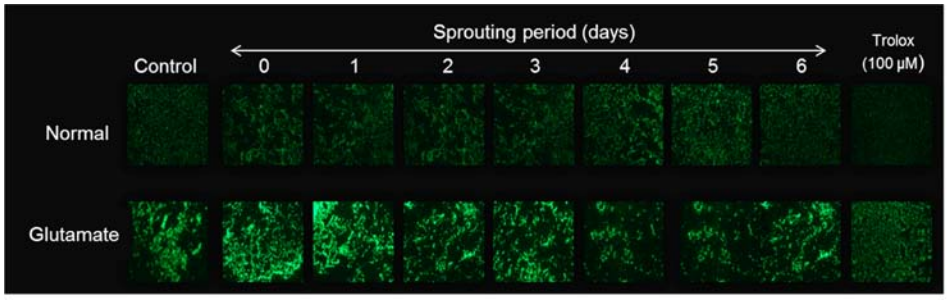

Figure 5. Inhibition of glutamate-induced ROS production by SGE in HT22 cells. The cells (2×10^3 cells/well) were seeded in a 96-well black-bottom plate and cultured for 24 h. After cell attachment, the cells were incubated in the presence of 5 mM glutamate and garlic samples for 6 h. The treated cells were washed with PBS, incubated for 30 min with DCFDA dissolved in DMEM (final concentration of 30 μM), and then washed with PBS. The fluorescence generated by the interaction of ROS with DCF was visualized under a fluorescence microscope.

antibacterial, antifungal, antiviral, and anticancer activities. Garlic prevents platelet aggregation, and it has hypotensive and cholesterol- and triglyceride-lowering effects.[28]

We found that sprouting enhanced the DPPH radical scavenging activity and ORAC of garlic. Sprouting also increased the capacity of garlic to suppress intracellular ROS induced by hydrogen peroxide in HT22 cells. The HT22 mouse hippocampal cell line, a subclone of the original HT4 clone, is sensitive to amyloid-β (Aβ) and particularly vulnerable to glutamate; thus, HT22 cells provide a good model system with which to study neuronal cell degeneration and screen for potential agents, such as antioxidants, that prevent Aβ- or glutamate-induced cell death.[19,26,29,30] Glutamate reduced the viability of HT22 cells, but viability was restored by treatment with an extract from garlic sprouted for 5 days. Furthermore, the same effect was observed with extracts prepared from garlic at an early stage of sprouting, suggesting that certain

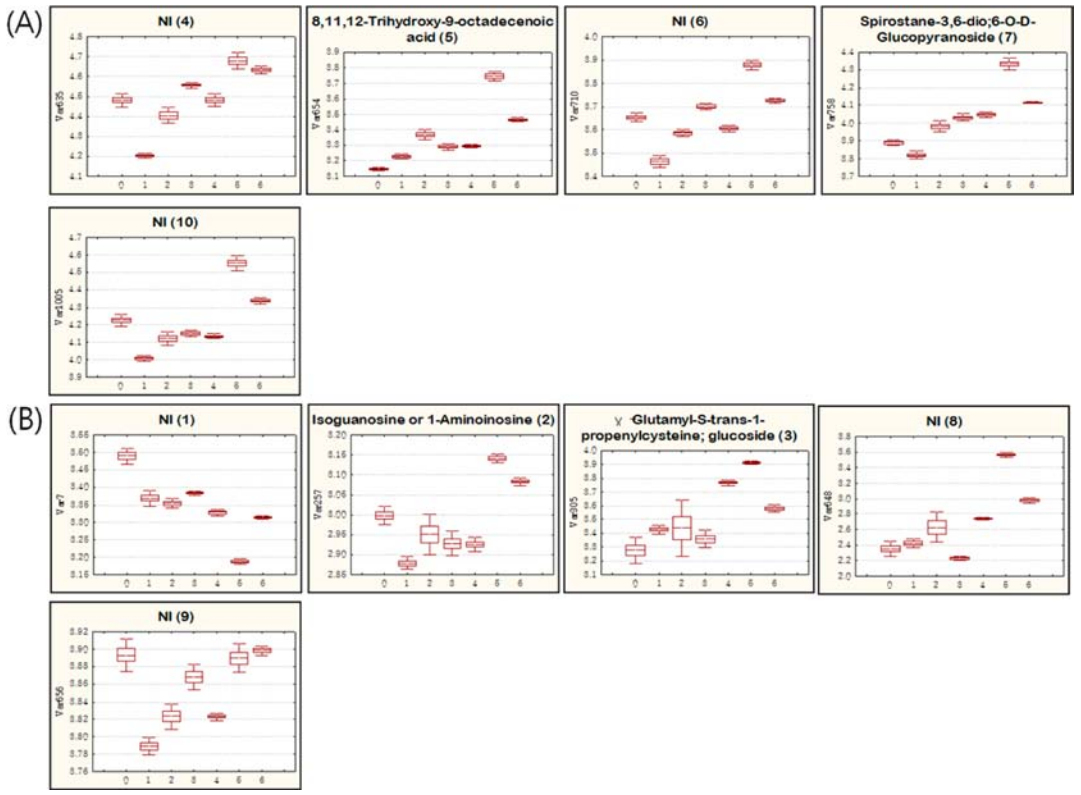

Figure 7. Box-and-whisker plots of changes in metabolite levels with sprouting time when mass spectrometry was run in (A) positive and (B) negative modes.

antioxidants or neuroprotective compounds like flavonoids are produced during the early stage of sprouting.

Although the increased neuroprotective effect could be ascribed to the enhanced antioxidant capacity of sprouted garlic, it is not clear which components in sprouted garlic are primarily responsible for the increased antioxidant capacity. Furthermore, sprouting did not increase the total phenolic content of garlic, suggesting that phenolics are not associated with the increased antioxidant activity and neuroprotective effect of SGE.

The health benefits of garlic are attributed to organosulfur compounds that mainly derive from alliin. Alliin is quickly converted into allicin through extremely reactive intermediates, sulfenic acids (R-SOH), by the enzyme alliinase (alliin lyase EC.4.4.1.4) when garlic is physically damaged. Alliin, allyl disulfide, and allyl cysteine scavenge hydroxyl radicals, whereas allicin does not.[18] In our multivariate analysis, the metabolite patterns differed depending upon the sprouting period and correlated closely with the antioxidant activities. Moreover, the PCA score plots were different before and after 4 sprouting days. Among the 10 metabolites that influenced the multivariate analysis, γ-glutamyl-*S*-*trans*-1-propenyl cysteine; glucoside (**3**) and spirostane-3,6-diol, 6-*O*-D-glucopyranoside (**7**) were previously detected in their derivative forms, γ-glutamyl-*S*-*trans*-1-propenyl cysteine (GSPC)[31] and steroidal oligoglycoside,[32] respectively, in *Allium* species. GSPC is a major metabolite[33] in garlic and a precursor of isoalliin, which has antioxidant activity. Spirostane-3,6-diol, 6-*O*-D-glucopyranoside is a steroidal oligoglycoside and an antineoplastic agent. Although there is no information on the antioxidant activities of these two compounds in their glycosidic forms, the glucosidic forms of flavonoids have a similar level of antioxidant activity as the aglycone forms.[34] Furthermore, it has been reported that certain glycosidic forms could be hydrolyzed into aglycones by intracellular glucosidases in neuronal tissues.[35] However, further studies are required to define the antioxidative potential of the compounds that increased in sprouted garlic and to characterize the components responsible for the antioxidative and neuroprotective activities.

In conclusion, sprouting could be a useful way to increase the antioxidative potential of garlic and thereby expand its use.

scavenging functions, germination, development, photosynthesis, carbon and nitrogen metabolism, flowering, stress responses, and senescence.[13] Finally, previous experiments demonstrated that also application of the amino acid methionine, as a biosynthetic precursor, led to enhanced GLSs contents in radish as well as in broccoli heads.[14,15]

The aim of this study was to investigate the effect of the most active elicitors found in the literature, the JA,[16] methyl jasmonate,[17,18] salicylic acid,[18] glucose,[19] sucrose,[20,21] and DL-methionine,[18] using 5 days of treatment from 3- to 8-day of sprouting under controlled growth conditions of *B. oleraceae* (broccoli), *B. napus* (rutabaga), *B. rapa* (turnip), and *R. sativus* (China rose and red radishes), rich in aliphatic and indolic GLSs because their young physiological state, in order to provide fresh, safe, and ready-to-eat sprouts, maximizing their health-promoting compounds.

MATERIAL AND METHODS

Chemicals. Jasmonic acid, sucrose, and glucose were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA); methyl jasmonate was purchased from SAFC (St. Louis, MO, USA); salycilic acid and ethanol absolute were obtained from Panreac S.A. (Barcelona, Spain). DL-Methionine was from Alfa Aesar GmbH & Co. (Karlsruhe, Germany). Formic acid (98−100%) for analysis was obtained from EMSURE, ACS, Reag. Ph Eur, Merck, KGaA (Darmstadt, Germany). Trifluoroacetic acid for optima LC/MS was purchased from Fisher Scientific Co. (New Jersey, USA). Methanol and acetonitrile were LC-MS grade from HiPerSolv Chromanorm, BDH Prolabo (Leuven, Belgium). Sinigrin monohydrate was obtained from Phytoplan (Germany).

Plant Material and Germination Conditions. Seeds provided by Intersemillas S.A. (Valencia, Spain) were of commercial quality for ready-for-sprouting lines. Five varieties from the *Brassicaceae* family were used: broccoli (*B. oleracea* L. var. *italica*), rutabaga (*B. napus* L. var. *napobrassica*), turnip (*B. rapa* L. subsp. *rapa*), China rose radish (*R. sativus* L. cv. China rose), and red radish (*R. sativus* L. cv. Rambo). Seeds were rinsed in distilled water and immersed in 5 $g{\cdot}L^{-1}$ sodium hypochlorite under aeration for 24 h. After pouring off the soaking water, the seeds were weighed (day 0) and spread evenly on trays (5 g per tray) lined with cellulose growth pad (CN Seeds, U.K.) and irrigated everyday with Milli-Q water with 5 $g{\cdot}L^{-1}$ sodium hypochlorite. Aliquots of 5 g of seeds were frozen in liquid nitrogen and stored at −80 °C pending phytochemical analysis.

The three replicates (trays) per sample were germinated for 2 days in a controlled dark chamber at 28 °C, for increasing the stem elongation of sprouts. Then, trays were transferred to a controlled environment chamber with a 16 h light/8 h dark cycle and air temperatures of 25 and 20 °C, respectively. The relative humidity (RH) was 60% (day) and 80% (night). Photosynthetically active radiation (PAR) of 400 $\mu mol\ m^{-2}\ s^{-1}$ was provided by a combination of fluorescent tubes (Philips TLD 36 W/83, Hamburg, Germany; Sylvania F36W/GRO, Danvers, MA, USA) and metal halide lamps (Osram HQI.T 400 W, Munich, Germany). Three replicates per treatment of *Brassicaceae* sprouts samples were rapidly and gently collected at day 8 after germination, in the middle of the light period, for analysis. All samples were weighed (fresh mass), collected separately, flash frozen in liquid nitrogen, and stored at −80 °C prior to analyses.

Treatments with Elicitors. The phytohormones jasmonic acid (JA) (150 μM), methyl jasmonate (MeJA) (25 μM), and salicylic acid (SA) (100 μM), the oligosaccharides glucose (277 mM) and sucrose (146 mM), and the amino acid DL-methionine (5 mM) were selected as elicitors according to a literature review. JA, MeJA, and SA were dissolved in 0.2% ethanol in Milli-Q water. Sucrose and glucose were also dissolved in Milli-Q water. DL-Methionine was dissolved in 0.04% ethanol in Milli-Q water. Elicitors were applied as exogenous spraying on the cotyledons (not as soaking or irrigation solution) with 30 mL of test solution per sample (10 mL per tray) from day 3 to day 7 of sprouting (5 days of treatment) using Milli-Q water as control.

Extraction and Determination of Glucosinolates. *Sample Extraction.* Freeze-dried samples (100 mg) were extracted with 1.5 mL of methanol 70% V/V in a US bath for 10 min, then heated at 70 °C for 30 min in a heating bath, with shaking every 5 min using a vortex stirrer, and centrifuged (17 500 × *g*, 15 min, 4 °C). Supernatants were collected, and methanol was completely removed using a rotary evaporator. The dry material obtained was redissolved in 1 mL of ultrapure water and filtered through a 0.45 μm Millex-HV13 filter (Millipore, Billerica, MA, USA).

HPLC-DAD-ESI-MS^n Qualitative and Quantitative Analysis of Glucosinolates. First, the separate intact GLSs were identified from the extracted samples following their MS^2 $[M-H]^-$ fragmentations in HPLC-DAD-ESI-MS^n, carried out on a Luna C18 100A column (150 × 1.0 mm, 3 μm particle size; Phenomenex, Macclesfield, U.K.). Water:formic acid (99:1, v/v) and acetonitrile were used as mobile phases A and B, respectively, with a flow rate of 20 μL/min. The linear gradient started with 1% of solvent B, reaching 17% solvent B at 15 min up to 17 min, 25% at 22 min, 35% at 30 min, 50% at 35 min, which was maintained up to 45 min. The injection volume was 3 μL. Chromatograms were recorded at 227 nm. HPLC-DAD-ESI/MS^n analyses were carried out in an Agilent HPLC 1200 (Agilent Technologies, Waldbronn, Germany) and coupled to a mass detector in series. The HPLC system consisted of a binary capillary pump (model G1376A), an autosampler (model G1377A), a degasser (model G1379B), a sample cooler (model G1330B), and a photodiode array detector (model G1315D) and controlled by ChemStation software (v.B.0103-SR2). The mass detector was a Bruker, model UltraHCT (Bremen, Germany), ion trap spectrometer equipped with an electrospray ionization interface (ESI) and controlled by Bruker Daltonic Esquire software (v.6.1). Ionization conditions were adjusted at 350 °C and 4 kV for capillary temperature and voltage, respectively. The nebulizer pressure and flow rate of nitrogen were 65.0 psi and 11 L/min, respectively. The full-scan mass covered the range from m/z 50 to 600. Collision-induced fragmentation experiments were performed in the ion trap using helium as the collision gas with voltage ramping cycles from 0.3 up to 2 V. Mass spectrometry data were acquired in the negative ionization mode for glucosinolates. MS^n was carried out in the automatic mode on the more abundant fragment ion in MS$^{(n-1)}$. Then, the extracted samples (20 μL) were analyzed and quantified in a Water HPLC-DAD system (Waters Cromatografia S.A., Barcelona, Spain) as previously described by Pérez-Balibrea et al.[22] Intact GLSs were identified following their UV spectra and the order of elution previously described for the acquisition conditions. Glucosinolates were quantified using sinigrin as external standard, because of the similar structure to the glucosinolates in the sample.[22,23]

Statistical Methods. All assays were conducted by triplicate. Data were processed using the SPSS 15.0 software package (LEAD Technologies, Inc., Chicago, IL, USA). We carried out a multifactorial analysis of variance (ANOVA) and the Ducan's Multiple Range Test to determine significant differences at P values < 0.05.

RESULTS AND DISCUSSION

Biomass. The weight of seeds and sprouts was collected on day 0 (embebed seeds) and day 8. The ratio of fresh weight between sprouts and seeds as an indication of biomass production (Table 1) showed the expected increase in weight over sprouting and served as a quality index to select species with higher biomass production. Growing plants are exposed to a range of genetic, environmental, biotic, and abiotic factors which affect their growth and yield.[24] The biomass of the *Brassicaceae* sprouts treated with sucrose increased significantly over other treatments, ranging from about 15% in turnip and China rose radish to 80% in Red radish (Table 1), in agreement with results of Guo et al.[25] using a 146 mM sucrose treatment. Stewart et al.[26] explained that sucrose (88 mM) alters the growth rate and causes a dramatic increase in hypocotyl length.

Table 1. Biomass of Sprouts:Seeds Ratio in Cruciferous Edible Sprouts on a Fresh Weight Basis

species	broccoli	rutabaga	turnip	china rose radish	red radish

[b]Least significant difference (LSD) for separating means in the respective column. The LSD was computed only after analysis of variance indicating a significant ($p < 0.05$) entry effect. Levels of significance for each sampling day between species. Nonsignificant at $P > 0.05$ (n.s.); significant at $P < 0.05$ (*); significant at $P < 0.01$ (**); significant at $p < 0.001$ (***).

Sucrose could supply a balanced carbon source for cell growth by hydrolysis of invertase and sucrose synthase, with the resulting hexose directly participating in the glycolytic and pentose phosphate pathway (required for cells to synthesize nucleic acids and quickly replicate).[27] Stressful conditions such as starvation or hypoxia result in low energy status in the cell; Smeekens et al.[28] showed that sugars repressed the bZIP growth regulatory system activity in a concentration-dependent manner; therefore, our employed dose (5g/100 mL) was appropriate for biomass increase in sucrose treatment sprouts but not in the case of glucose, also in accord with Mirnezhad.[29]

DL-Methionine also showed a positive effect, increasing the fresh weight of sprouts in almost all varieties, 30% in broccoli, 4% in turnip, 57% in China rose radish, and 75% in red radish, except for rutabaga, agreeing with previous reports.[30,31] Gigolashvili et al.[32] reported a relationship between the overexpression of the HAG1/MYB28 gene, specific for methionine-derived GLSs (aliphatics), and strongest growth phenotype in *Arabidopsis thaliana*. On the other hand, glucose and the phytohormones (JA, MeJA, and SA) did not increase the fresh weight of sprouts and even reduced the size as for the control, as happened in broccoli, turnip, and China rose radish, founding a decrease around 60% in JA- and SA-treated sprouts, as also found by Kastell et al.[33] MeJA and SA regulate the overexpression of the OBP2 transcription factor involved in GLS biosynthesis, which altered the phenotype of *A. thaliana*, with smaller leaves,[34] supporting our result. In red radish sprouts, nonsignificant differences were found between the glucose- and phytohormones-treated sprouts and the controls. Higher values of biomass ratio not only means better growth (data not shown) but also higher fresh weight, making the sprouts more palatable. Concentration of elicitor and interval between treatment and harvest induce different responses characteristic of plant species, making it necessary to find the required effective dose and time empirically.[35]

Glucosinolate Profiles of *Brassicaceae* Sprouts. Identification and quantification of individual GLSs in seeds and 8-day-old sprouts of the five *Brassicaceae* cultivars are presented in Tables 2–5. The molecular ion $[M - H]^-$ (m/z) of GLSs, their fragment ion pattern, and retention times allowed identification of 16 different compounds.[3] The MS^2 fragmentation of aglycone side chain produces the most consistent ion at m/z 259, and the MS^3 fragmentation of this ion gives rise to fragments at m/z 97 (corresponding to the sulfate group) by disassociation of GLSs in the ion trap mass spectrometer, constituting a very useful preliminary screening method for determining the presence of GLSs in sprouts.[36] Sixteen GLSs, belonging to the aliphatic, indolic, and aromatic classes based on their different side chain structure, were detected. Results showed significant differences of the characteristic GLSs profile among cruciferous seeds and sprouts (Tables 2–5). The aliphatic GLSs were the major group in *B. oleraceae*, *B. napus*, and *R. sativus* sprouts, corresponding to 60% in *Brassica* and 90% in *Raphanus* varieties. In contrast, *B. rapa* sprouts showed higher amount of indolic GLSs, corresponding to 65% of the total (Table 4). Seeds exhibited the largest amount of GLSs being the nutrient reservoir organ, containing ranging concentrations from 563.79 to 1731.32 mg·100 g^{-1} F.W. in turnip and broccoli, respectively (Table 2), of interest for the composition of the sprouts during germination. According to Pérez-Balibrea et al.,[18,22] the major source of glucoraphanin are broccoli seeds and sprouts (987.02 and 182.46 mg·100 g^{-1} F.W., respectively) (Tables 2 and 3), which has been intensively studied because of its derived product sulforaphane, a potential chemopreventive beneficial compound against cancer, cardiovascular, and neurological diseases.[4] Turnip and rutabaga seeds and sprouts showed the antinutrient progoitrin as the major GLS, and glucoraphanin and gluconasturtiin were absent in the sprouts, probably degraded or diluted during germination.[22] In radish cultivars, specific GLSs in seeds were found as well (traces of the aromatic glucoberteroin). The major characteristic GLS in this species is glucoraphenin, containing 1051.88 and 32.78 mg·100 g^{-1} F.W. in China rose radish and 887.20 and 166.93 mg·100 g^{-1} F.W. in red radish in seeds and sprouts, respectively (Table 5). The bioactive sulforaphene, like sulphoraphane, is a potential anticancer agent.[8] In *Brassica* species, in addition to the parent indole GLS glucobrassicin, 4-hydroxyglucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin were also detected in the samples (Tables 2–5). Only the indole 4-hydroxiglucobrassicin GLS was present in all species, being also one of the major compounds in seeds (from 152.49 to 358.34 mg·100 g^{-1} F.W. in China rose radish and broccoli, respectively). On the contrary, in *Raphanus* sprouts only 4-hydroxiglucobrassicin and 4-methoxyglucobrassicin were detected.[6]

Phytohormones as Elicitors. The jasmonates are signal compounds in the elicitation process leading to de novo transcription, translation, and, ultimately, biosynthesis of secondary metabolites in plant cell cultures. Methyl jasmonate (MeJA) is believed to be, at least, partially hydrolyzed by endogenous esterases to free jasmonic acid (JA) within the plant tissue.[12] MeJA elicitor (25 μM) was found highly effective for almost all the 8-day-old *Brassicaceae* sprouts, increasing by 84%, 50%, 123%, 25%, and 23% the total GLSs amount in broccoli, turnip, rutabaga, China rose radish, and red radish, respectively, increasing the indoles more than the aliphatic GLSs (Tables 3–5). After MeJA treatments, the broccoli sprouts showed significantly much more glucoraphanin, glucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin by 60%, 241%, 48%, and 247%, respectively, associated with

potential health benefits due to the biological activity of their products.[4] The enhancement of the aliphatic GLS glucoraphenin in China rose and red radish sprouts after MeJA treatment was 278% and 35%, respectively. Indole GLSs in turnip, rutabaga, red radish, and China rose radish sprouts were also higher than the controls and increased by 109%, 223%, 54%, and 200%, respectively. The JA (150 μM) also produced an increase of total GLSs, especially in broccoli (by 50%), rutabaga (by 95%), and turnip (by 24%), having a higher effect on the indoles than on the aliphatic GLSs (Tables 3 and 4). In contrast, scarce differences were found in total GLSs in the treated radish sprouts compared to control samples (Table 5). Salicylic acid (SA) caused an increase of 20% in total GLSs in broccoli and radish sprouts, with aliphatic GLSs being the most affected (Tables 3 and 5), and no effects were found in turnip or rutabaga sprouts (Table 4). This phytohormone produced an increase in glucoraphanin in broccoli (by 58%) as well as in glucoraphenin (by 50% and 14%) and dehydroerucin (by 18% and 29%) in China rose and red radish sprouts, respectively (Tables 3 and 5).

Biosynthesis of glucosinolates can be drastically induced by wounding, hormone application, and pathogen or herbivore attack. Berger[34] demonstrated the induction of several pathway genes after phytohormones spraying application in *A. thaliana*, where IQD1 protein, OBP2 transcription factor, and ATR1/MYB34 and HIG1/MYB51 genes were overexpressed and regarded as a regulator with respect to increased concentrations of major indole GLSs. Nevertheless, the genes respond differently to biotic stress conditions in time and the site of metabolites accumulation in the plant.[34] These treatments increased the concentration of individual health-promoting glucosinolates (such as glucoraphanin, glucoraphenin, dehydroerucin, and indole GLSs) and also of great interest had not effect or even decreased the concentrations of the antinutrient progoitrin by JA and MeJA, present in rutabaga and turnip sprouts (Tables 3–5). Similar induction of GLSs by exogenous application of phytohormones as elicitors has been previously found by different authors, particularly, increased indole-GLSs.[16−18,33,34] Consistent with Brader et al.,[37] MeJA is able to trigger accumulation of the indole GLSs by inducting the tryptophan biosynthesis as demonstrated in *A. thaliana*, in contrast to SA, which seems to play a minor role in this response. The above-mentioned treatments, particularly, JA and its ester MeJA, were highly effective elicitors in *Brassica* sprouts. On the other hand, SA was more effective in radish sprouts than JA, with the MeJA solution being an interesting common elicitor to enrich in GLSs all species studied.

Sugars as Elicitors. Nonstructural carbohydrates, both sucrose and glucose, used as elicitors, enhanced the total GLSs amount in all sprouts under study, in accordance with some studies on broccoli, cabbage, and radish sprouts.[19,20] Sucrose (146 mM) showed higher effects in *Brassica* species, increasing by 42%, 31%, and 159% the total GLSs in broccoli, turnip, and rutabaga, respectively (Tables 3 and 4). By contrast, total GLSs in radish sprouts were increased higher after glucose treatment (277 mM) by 22% and 26% in China rose and red radish, respectively (Table 5). It must be emphasized the elicitation effect observed in broccoli sprouts, where glucoraphanin was increased by 40% and 60% under sucrose and glucose treatments, respectively (Table 3). Glucoraphanin was enhanced as well, by 50% and 30%, under both sucrose and glucose spray in China rose and red radish, respectively (Table 5). The other major aliphatic GLS from radish, dehydroerucin, was increased by the glucose treatment by 22% and 33% in China rose and red radish, respectively. In contrast to what was found by Wei et al.,[19] who showed a decrease in this compound. These results were consistent with those previously reported by Guo et al.,[25] indicating that the *Bo-Elong* gene involved in the aliphatic GLSs pathway was up-regulated by sucrose. Gigolashvili et al.[32] described glucose as an important signaling molecule that may induce transcriptional regulatory mechanisms, integrating carbohydrate availability and hormone action, regulating this class of GLSs by the HAG1/MYB28 gene, in response to carbohydrate availability, in *A. thaliana*.

As for the indole-GLSs, no effects were found on radish sprouts, while both sucrose and glucose highly and significantly enhanced 4-hydroxiglucobrassicin, 4-methoxyglucobrassicin, and neoglucobrassicin in *Brassica* species, with the glucobrassicin being mainly increased by sucrose (Tables 3 and 4). Sivanandhan et al.[38] showed that the type and concentration of carbon source induces profound effects on growth and quality of the metabolites produced. Sugars serve as the carbon and energy source and also affect the osmotic pressure of the medium, which stimulates mitochondrial activity and, hence, energy production for metabolites synthesis.[39] The secondary product formation after sugar application could be attributed to a certain level of osmotic stress, which initiated the signal perception through a receptor in the cell membrane to activate the signal transduction network. This activates the transcription factors, which regulates gene expression involved in biosynthesis of the target metabolites.[38,40]

DL-Methionine as Elicitor. Aliphatic GLSs, such as glucoraphanin and glucoiberin, are secondary metabolites derived from amino acids, mainly methionine.[31] The effect of the exogenous spray application of this amino acid (5 mM) has been studied in order to increase the amount of GLSs in sprouts, mainly aliphatic ones.[17,18] In the biosynthesis of glucosinolates, first, methionine is transaminated to the corresponding α-keto-acids, and subsequently, the side-chain elongation of the amino acid is produced, followed by formation of the GLS core structure mediated by cytochrome P450 mono-oxygenase.[32] Only in broccoli and rutabaga sprouts a significant effect after application of this amino acid was found, where the total GLSs were increased by 19% and 85%, respectively (Tables 3 and 4). China rose radish sprouts remained without changes in GLSs contents, while turnip and red radish sprouts showed a small decrease in total GLSs after the DL-methionine applications (Tables 4 and 5). Opposite to our first hypothesis, aliphatic GLSs were not affected to a higher degree than indole GLSs upon DL-methionine treatment, probably resulting from expression of HAG1/MYB28 in young sprouts, reported by Gigolashvili et al.[32] Broccoli-treated sprouts showed a weak increase of 7% and 28% in aliphatic (glucoiberin and glucoraphanin) and indole GLSs (4-hydroxiglucobrassicin, glucobrassicin, 4-methoxyglucobrassicin), respectively. Rutabaga sprouts registered a significant increase (by 85%) in both aliphatic (progoitrin and gluconapin) and indole GLSs (glucobrassicin and 4-methoxyglucobrassicin). Some authors reported that application of methionine to growing broccoli plants increased not only their aliphatic GLSs content but also the indolic GLSs.[41] Few reports on the effect of methionine elicitor have been found, and based on our results we may conclude that low concentrations of methionine, such as 5 and 10 mM applied by Pérez-Balibrea et al.,[18] allowed a certain increase of total GLSs (23% and 21% respectively) than higher concentrations, such as 200 mM applied by Scheuner et al.,[41] where a similar increase by 28% was found in broccoli at the time of head formation, while no significant impact on total GLSs was found in broccoli heads or radish hypocotyls.

All elicitors promoted the accumulation of GLSs in *Brassicaceae* sprouts. Detected differences in the quantified total and individual GLSs between controls and treated sprouts were not only due to cultivar differences but also due to the specific elicitor nature used. Indole GLSs in all species were found to either increase or remain stable after elicitor treatments. The total GLSs performed in similar way. Major desirable aliphatic GLSs, such as glucoraphanin, glucoraphenin, and dehydroerucin, were increased by elicitors, except with DL-methionine. Only undesirable aliphatic progoitrin and the glucoiberin decreased after the treatments, and minor GLSs, such as glucoerucin or gluconapin, were not affected. Elicitation practices, particularly using MeJA, could be established as an effective treatment to enrich in health-promoting GLSs cruciferous sprouts, for natural functional foods, a source of bioactive ingredients. The increase in the production of desirable healthy GLSs (glucoraphanin, glucoraphenin, dehydroerucin, and indole-GLSs) is important in order to enhance the intake of beneficial phytochemicals on a daily basis. Understanding the changes in the metabolism of sprouts is crucial to design strategies that would enhance the biosynthesis of secondary metabolites as novel cost-effective tools for nutrition and health applications that guarantee further research.

Cell Culture. Pheochromocytoma PC12 cells, a cell line derived from rat adrenal medulla, were obtained from American Type Culture Collection (ATCC, Manassas, VA, USA). The cells were maintained in Dulbecco's modified Eagles medium (DMEM) supplemented with 6% fetal bovine serum (FBS), 6% horse serum (HS), 100 U/mL penicillin, and 100 μg/mL streptomycin at 37 °C in a water-saturated 7.5% CO_2 incubator. Fresh medium was supplied every other day. Reagents for cell cultures were purchased from Invitrogen Technologies (Carlsbad, CA, USA).

Neurite Outgrowth Assay. The determination of neurite outgrowth in cell cultures was performed according to a previous paper.[17] Briefly, PC12 cells (5×10^4 cells/well) were seeded into a 6-well plate. After 24 h, the cells were changed with DMEM containing 1% FBS, 1% HS, 100 U/mL penicillin, and 100 μg/mL streptomycin for 3 h. Cultured PC12 cells were treated with the jujube extract (2.0 mg/mL) in the absence or presence of H89 for 72 h and changed with medium containing jujube extract every 24 h. NGF (Alomone Laboratories, Jerusalem, Israel) at a concentration of 50 ng/mL was used as positive control routinely. After treatment, cells were fixed with ice-cold 4% paraformaldehyde. A light microscope (Diagnostic Instruments, Sterling Heights, MI, USA) equipped with a phase-contrast condenser, 10× objective lens, digital camera, and SPOT imaging software was used to capture and analyze the neurite presence and neurite length, and approximately 100 cells were counted from at least 10 randomly chosen visual fields for each culture. The cells were scored as differentiated if one or more neurites were longer than the diameter of the cell body and also classified according to their neurite length in <15, 15−30, and >30 μm.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophrosesis (SDS-PAGE). For the study on the expression of neurofilament, PC12 cells (8×10^4 cells/mL) were seeded into 12-well plates in normal serum medium for 24 h and then transferred to low serum (1% FBS, 1% HS, 100 U/mL penicillin, and 100 μg/mL streptomycin) as indicated for 3 h prior to exposure of the jujube extract in the absence or presence of H89. After 72 h of treatment, the cultures were collected in high salt lysis buffer (1 M NaCl, 10 mM HEPES, pH 7.5, 1 mM EDTA, 1 mM EGTA, 0.5% Triton X-100), followed by centrifugation at 16100 *g* for 10 min at 4 °C. Total protein content was measured by using Bradford's method with a kit from Bio-Rad Laboratories (Hercules, CA, USA). Samples of equal amounts of total protein were treated with 2× direct lysis buffer (0.125 M HCl, pH 6.8, 4% SDS, 20% glycerol, 2% 2-mercaptoethanol, and 0.02% bromophenol blue) and boiled for 10 min before an 8% gel electrophrosesis was performed.

Protein Phosphorylation on PC12 Cells. PC12 cells were seeded onto a 12-well plate. After the degree of confluence reached to >90%, the culture medium was changed to DMEM without serum over 5 h. The cells were treated with jujube extract or forskolin at different time points in the absence or presence of H89 (0, 5, 10, and 20 min). Then, the cells were harvested, digested with 200 μL of 2× direct lysis buffer, and boiled for 10 min before an 8% gel electrophrosesis was performed.

Western Blot Analysis. Following the electrophoresis, proteins that were separated on an 8% SDS-PAGE were transferred to the nitrocellulose membrane, using a Mini Trans-Blot cell at 40 V and 0.1 A for 16 h in 1× transfer buffer containing 24 mM Tris, 192 mM glycine, 15% ethanol, and 0.1% SDS. Transfer and equal loading of the samples were confirmed by staining with Ponceau-S. The nitrocellulose was blocked with 5% fat-free milk in Tris-buffer saline/0.1% Tween 20 (TBS-T) and then incubated in the primary antibody diluted in 2.5% fat-free milk in TBS-T overnight in a cold room (4 °C). The primary antibodies used were antineurofilament 200 (NF200; Sigma, St. Louis, MO, USA), anti-NF160 (Sigma), anti-NF68 (Sigma), antiphospho-CREB (Cell Signaling Technology, Beverly, MA, USA), antitotal CREB (Cell Signaling Technology), and antiglyceraldehyde 3-phosphate dehydrogenase (GAPDH; Abcam Ltd., Cambridge, UK). Following that, the nitrocellulose was rinsed with TBS-T and incubated for 2 h at room temperature in horseradish peroxidase (HRP)-conjugated anti-mouse secondary antibody (Invitrogen) diluted in the 2.5% fat-free milk in TBS-T. After intensive washing with TBS-T, the immune complexes were visualized using the enhanced chemiluminescence (ECL) method (GE Healthcare, Piscateway, NJ, USA). The intensities of the bands in the control and different samples running on the same gel and under strictly standardized ECL conditions were compared on an image analyzer, using a calibration plot constructed from a parallel gel with serial dilutions of one of the samples.

Statistical Analysis. Individual data were expressed as the mean ± standard error of the mean (SEM). Statistical tests were performed with *t* test (version 13.0, SPSS, IBM Corp., Armonk, NY, USA). Statistically significant changes were classified as significant (∗) when $p < 0.05$, more significant (∗∗) when $p < 0.01$, and highly significant (∗∗∗) when $p < 0.001$.

RESULTS

Jujube Induces the Neurite Outgrowth of PC12 Cells. Before the application of jujube extract onto cell cultures, the water extract was chemically standardized.[15] The amounts of nucleobases, including uracil, xanthine, hypoxanthine, guanine, and/or adenine in water extract, should be no less than 80 μg/g of dried extract. The amounts of nucleosides, including cytidine, uridine, and/or guanosine in jujube extract should be no less than 150 μg/g. The amounts of cyclic nucleotides, including cGMP and cAMP, in the extract should be no less than 100 μg/g. The amounts of flavonoids, including quercetin 3-*O*-rutinoside, quercetin 3-*O*-galactoside, quercetin 3-*O*-β-D-glucoside, and kaempferol 3-*O*-rutinoside, in jujube extract should be no less than 35 μg/g. In addition, the extraction efficiency of the extract was 77.3 ± 0.1% (w/w, mean ± SEM, $n = 4$).

PC12 cells are a widely employed model for the study of neuronal differentiation.[18] To investigate the efficacies of jujube on PC12 differentiation, water extract of jujube was applied onto cultured PC12 cells for 72 h before examination under microscope. As shown in Figure 1A, the water extract of jujube induced neurite outgrowth of PC12 cells. To quantify the change of morphology, 10 areas in the cultures were randomly selected, and then the number of differentiated cells and neurite length were calculated. The results indicated that after the treatment with water extract on PC12 cells for 3 days, the differentiated cells were counted to about 25% of the total cells in cultures (Figure 1B, upper panel). The length of neurite was also measured. The number of cells possessing neurite length at 15−30 μm was more significantly increased in water extract-treated cells (Figure 1B, lower panel).

In addition to the morphological exploration, the differentiation could also be evaluated by a biochemical analysis in determining the expression of neurofilament that is the neuronal cell-specific cytoskeleton proteins, including NF68 (at ∼68 kDa), NF160 (at ∼160 kDa), and NF200 (at ∼200 kDa). NGF served as positive control, which could induce the expression of neurofilament in a dose-dependent manner (Supporting Information Figure S1). As for jujube water extract, the treatment of 72 h at various concentrations (0.75, 1.5, and 3.0 mg/mL) induced the expressions of NF68, NF160, and NF200, with the highest induction by ∼150, 150, and 100%, respectively (Figure 2).

PKA Signaling Mediates Jujube-Induced Neuronal Differentiation on PC12 Cells. An activation of the cAMP pathway is essential for neuronal differentiation on PC12 cells.[19] Thus, the potency of jujube extract in stimulating neurite outgrowth and neurofilament expression via the cAMP pathway was investigated. Forskolin, a CREB phosphorylation inducer, was reported to induce neurite outgrowth and protein

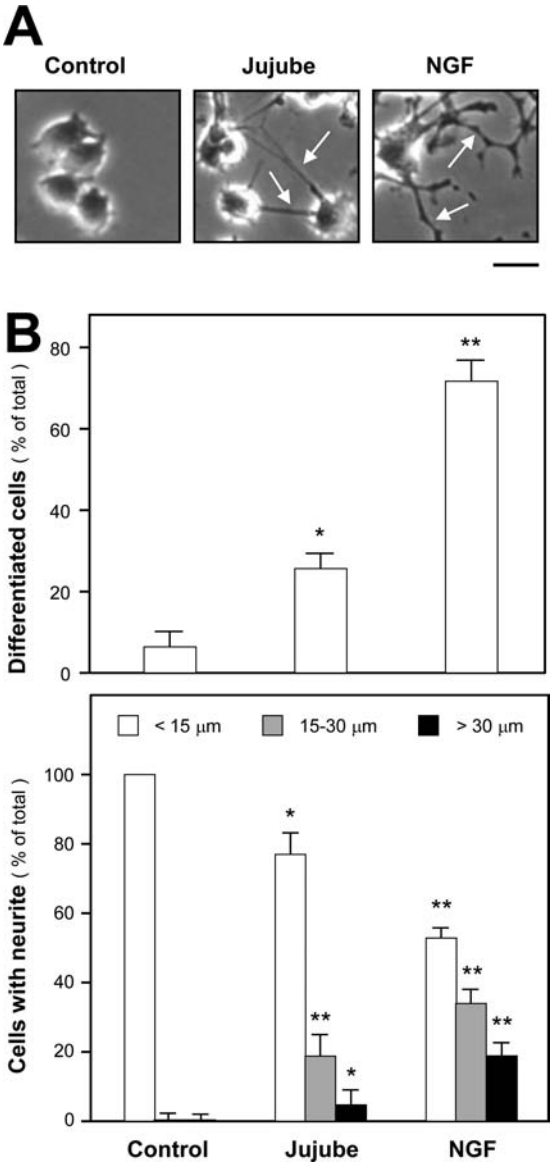

Figure 1. Jujube induces neurite outgrowth in cultured PC12 cells. (A) Jujube water extract (2.0 mg/mL) was applied into cultured PC12 cells for 72 h, with fresh medium or jujube extract every 24 h. NGF (50 ng/mL) served as the positive control. Cells were fixed with ice-cold 4% paraformaldehyde, and then the neurite outgrowth was examined under microscope. Representative images are shown, $n = 5$. Bar = 20 μm. Arrowheads indicate cell neurite. (B) To quantify the differentiation effect, the percentage of differentiated cell numbers (upper panel) and length of neurite (lower panel) were counted as described under Materials and Methods. Data are expressed as the percentage of cells in 100 counted cells, mean ± SEM, $n = 5$. Statistical comparison was made with the control; (∗) $p < 0.05$; (∗∗) $p < 0.01$.

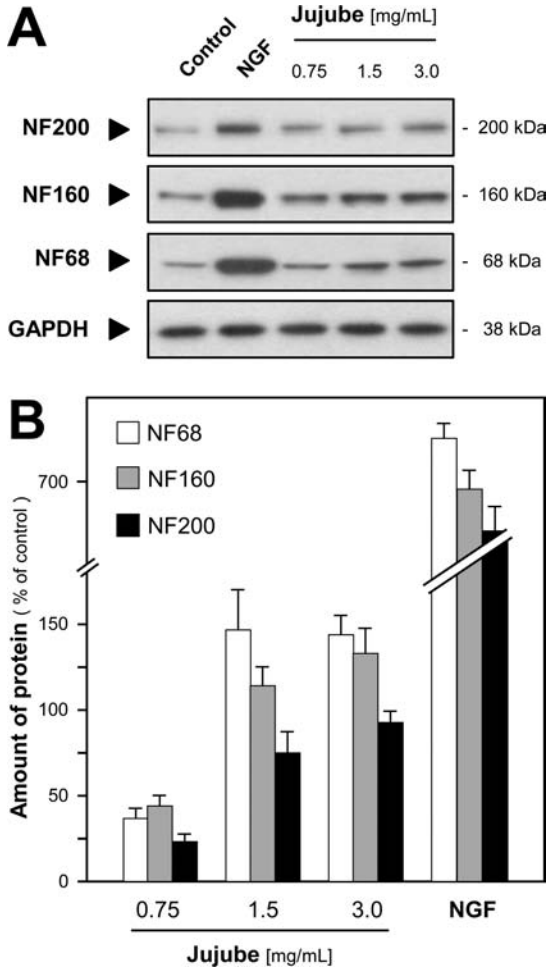

Figure 2. Jujube induces the expression of neurofilament on cultured PC12 cells. (A) Cultured PC12 cells were treated with jujube water extracts (0.75−3.0 mg/mL) for 72 h. The cell lysates were collected to determine the expressions of NF68, NF160, and NF200. NGF (50 ng/mL) served as the positive control. GAPDH served as loading control. (B) Quantification plot is shown in histograms. Values are expressed as the percentage of increase to basal reading (untreated culture), mean ± SEM, $n = 5$.

phosphorylation on PC12 cells. The effect of forskolin could be inhibited by H89, a cyclic AMP-dependent[20] and a marketed selective PKA inhibitor. To explore the possible mechanism of jujube-induced neuronal differentiation, PC12 cells were pretreated with H89 for 3 h. Then, the culture was treated with jujube extract for 72 h. Their effects on neurite outgrowth and neurofilament expression were evaluated. The forskolin-induced neurite outgrowth and neurofilament expression were inhibited by H89 (Figures 3 and 4). Similarly, the jujube-induced neurite outgrowth could be blocked by H89 (Figure 3). In addition, neurofilament expressions, induced by jujube, were also attenuated by H89 (Figure 4). The blockage did not apply to the induction by NGF. Besides, the application of H89 did not fully abolish the jujube effect in both cases of neurite outgrowth and neurofilament expression.

The nuclear transcription factor CREB has been well-documented to play a crucial role in neuronal differentiation on PC12 cells.[21] The phosphorylated CREB recruiting the coactivator CREB-binding protein allows its binding at the promoter and further stimulates target gene transcription that leads to neuronal differentiation. Therefore, the role of jujube in inducing the phosphorylation of CREB was investigated. As indicated in Figure 5A, the jujube extract could induce the phosphorylation of CREB at ∼43 kDa, and its inductive role could be fully abolished by H89 (Figure 5B).

On the basis of the aforementioned studies, the jujube extract has been demonstrated to induce neuronal differentiation in terms of neurite outgrowth and neurofilament expression. Still it is less known which active component accounts for the neuronal differentiation. On the one hand, cAMP was found in jujube.[22] Interestingly, its content was determined to be much higher in comparison with all other horticultural fruits, that is,

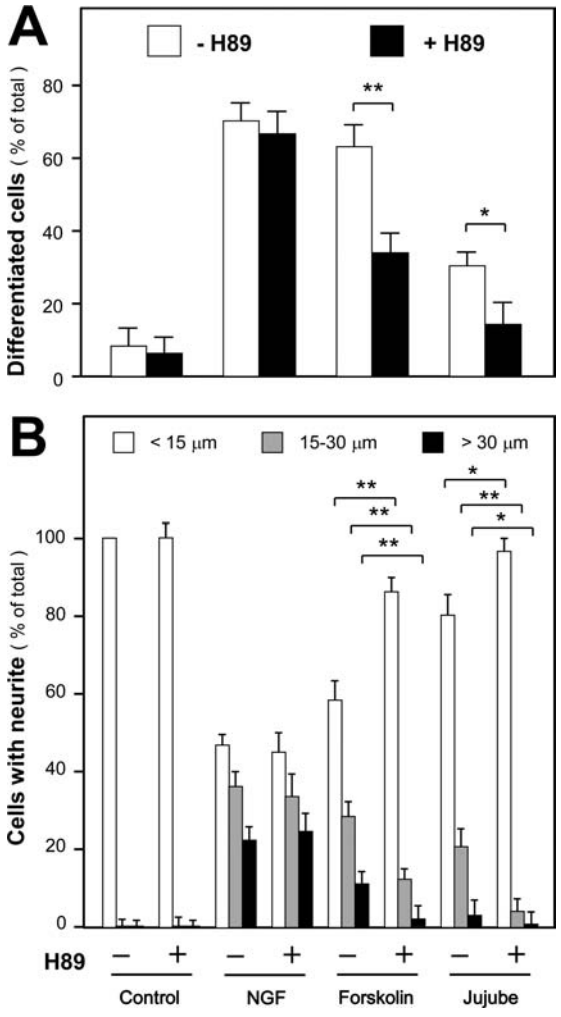

Figure 3. Inhibition of PKA signaling attenuates jujube-induced neurite outgrowth on cultured PC12 cells. Cultured PC12 cells were pretreated with or without H89 (5 μM; a PKA inhibitor) for 3 h and then treated with forskolin (10 μM), NGF (50 ng/mL), and jujube extract (2.0 mg/mL) for 72 h, with fresh medium or extract every 24 h. Cells were fixed with ice-cold 4% paraformaldehyde, and then the neurite outgrowth was examined under a microscope. To quantify the differentiation effect, the percentage of differentiated cell numbers (A) and length of neurite (B) were counted as described in Figure 1. Data are expressed as the percentage of cells in 100 counted cells, mean ± SEM, n = 5. Statistical comparison was made with the H89-treated group; (∗) $p < 0.05$; (∗∗) $p < 0.01$.

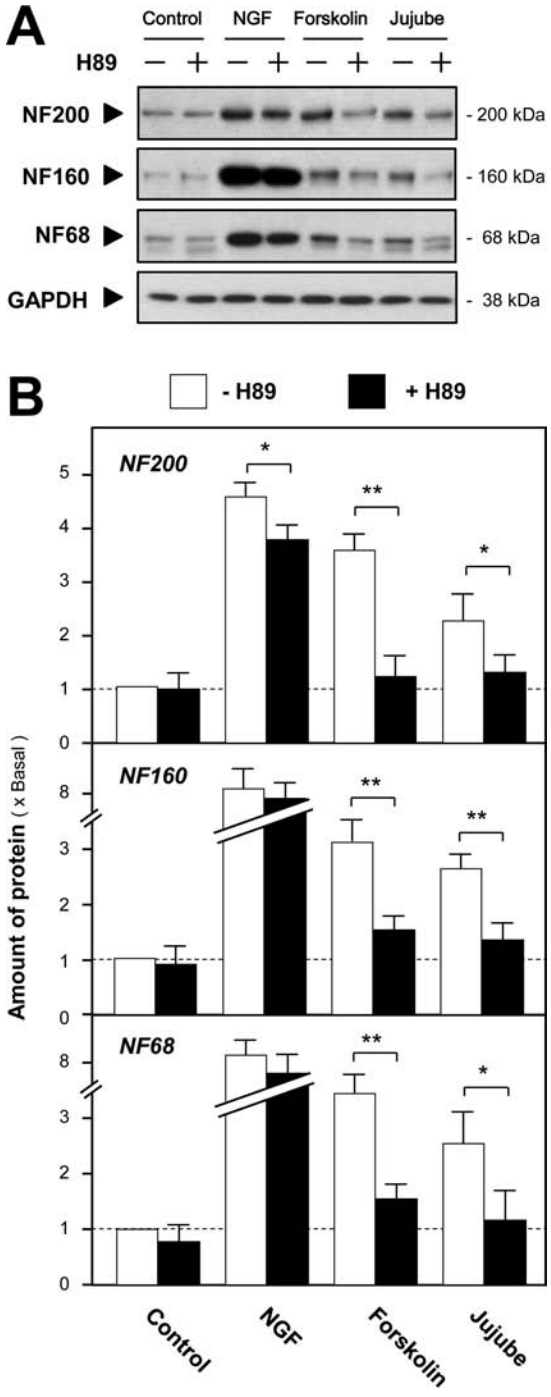

Figure 4. Inhibition of PKA signaling suppresses jujube-induced neurofilament expression on cultured PC12 cells. (A) Cultured PC12 cells were pretreated with or without H89 (5 μM; a PKA inhibitor) for 3 h and then treated with forskolin (10 μM), NGF (50 ng/mL), and jujube extract (2.0 mg/mL) for 72 h. The cell lysates were collected to determine the expressions of NF68, NF160, and NF200. GAPDH served as loading control. (B) Quantification plot (NF68, NF160, and NF200) is shown in histograms. Data are expressed as the fold of change (× Basal) against the control (no treatment; set as 1), mean ± SEM, n = 5. Statistical comparison was made with the H89-treated group; (∗) $p < 0.05$; (∗∗) $p < 0.01$.

apple and pear.[15,23,24] On the other hand, it is well-known that the increase in cAMP level could activate PKA and subsequently phosphorylate CREB. Thus, we speculated that the cAMP in the jujube extract might contribute to its effect on neuronal differentiation. Here, cAMP at 2 μM (approximately the amount in 2 mg/mL extract) was applied to PC12 cells. As shown in Figures 6 and 7, it could also induce both neurite outgrowth and neurofilament expression on cultured PC12 cells. In comparison with cAMP, the effect of jujube extract was better than that of cAMP in inducing neurite outgrowth, especially in neurite length between 15 and 30 μm (Figure 6). In addition, other possible ingredients including cGMP and a flavonoid mixture containing (−)-catechin, procyanidin B2, (−)-epicatechin, quercetin 3-*O*-galactoside, quercetin 3-*O*-rutinoside, quercetin 3-*O*-β-D-glucoside, and kaempferol 3-*O*-rutinoside (approximately the amount in 2 mg/mL extract) were also investigated, yet no significant effect was observed (Figure 6). The jujube extract performed better effect on the expression of NF200 than that of cAMP, whereas cAMP possessed better activity in the expression of NF160 than jujube

dx.doi.org/10.1021/jf405093f | J. Agric. Food Chem. 2014, 62, 1890−1897

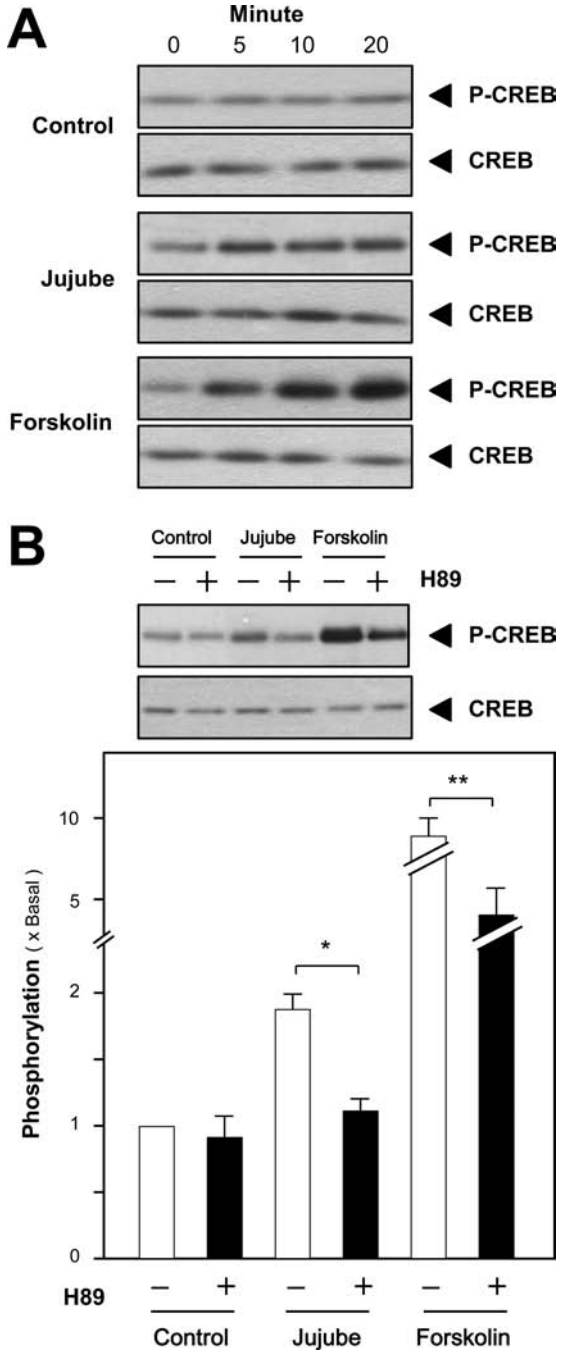

Figure 5. Jujube extract promotes CREB phosphorylation on PC12 cells. (A) Cultured PC12 cells were serum starved over 5 h before treatment with jujube (2 mg/mL) or forskolin (10 μM) for different times. Total CREB and phosphorylated CREB (both at ~43 kDa) were revealed by using specific antibodies. (B) Cultured PC12 cells, serum starved for over 5 h, were pretreated with or without H89 (5 μM; a PKA inhibitor) for 3 h prior to treatment with forskolin (10 μM) and jujube (2.0 mg/mL) for 10 min. Total CREB and phosphorylated CREB were revealed by using specific antibodies (upper panel). Quantification plot is shown in histograms (lower panel). Data are expressed as the fold of change (× Basal) against the control (no treatment; set as 1), mean ± SEM, n = 5. Statistical comparison was made with the H89-treated group; (∗) $p < 0.05$; (∗∗) $p < 0.01$.

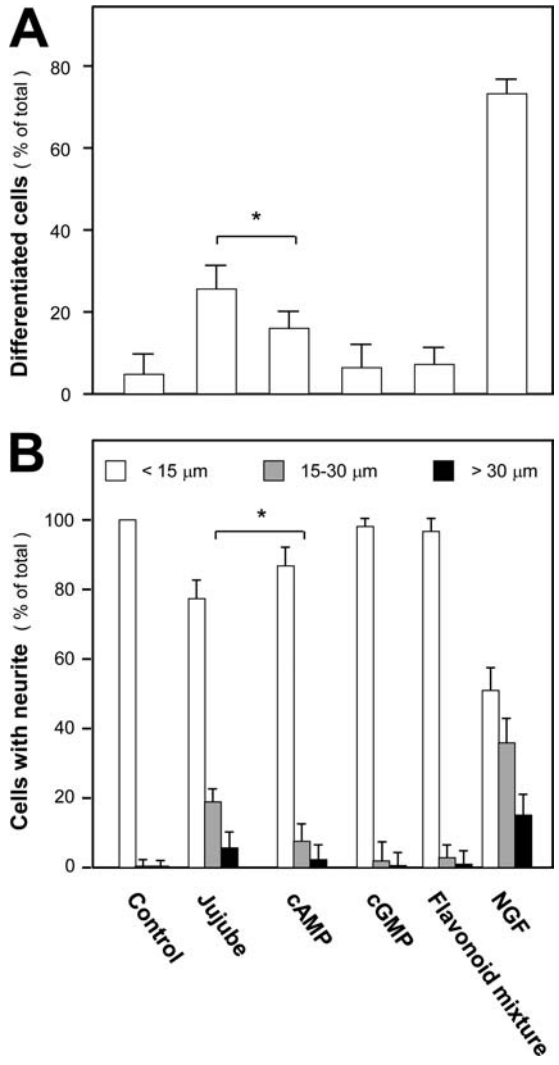

Figure 6. cAMP found in jujube induces neurite outgrowth in cultured PC12 cells. Jujube extract (2 mg/mL), cAMP at 2 μM, cGMP at 1.2 μM, or flavonoid mixture including (−)-catechin (52 nM), procyanidin B2 (49 nM), (−)-epicatechin (40 nM), quercetin 3-*O*-galactoside (2 nM), quercetin 3-*O*-rutinoside (157 nM), quercetin 3-*O*-β-D-glucoside (6 nM) and kaempferol 3-*O*-rutinoside (4 nM) was applied into cultured PC12 cells for 72 h, with fresh medium or drugs every 24 h. The concentrations of cAMP, cGMP, and flavonoids were the same as in 2 mg/mL of jujube extract. NGF (50 ng/mL) served as the positive control. Cells were fixed with ice-cold 4% paraformaldehyde, and then the neurite outgrowth was examined under a microscope. To quantify the differentiation effect, the percentage of differentiated cell numbers (A) and length of neurite (B) were counted as described under Materials and Methods. Data are expressed as the percentage of cells in 100 counted cells, mean ± SEM, n = 5. Statistical comparison was made between extract and cAMP; (∗) $p < 0.05$.

extract. No significant difference was found on NF68 between the extract and cAMP (Figure 7).

■ DISCUSSION

In the developing neuron, neuronal differentiation is a vital and first stage of development, in which the axon and neurite are promoted to prepare for synapse formation. Recently, morphological observation and biochemical detection were considered as the main approaches to evaluate neuronal differentiation. Here, we found that treatment with jujube extract in cultured PC12 cells could robustly stimulate the expression levels of NF68 and NF160. Both NF68 and NF160 are protein markers for the early stage of the differentiation. In

dx.doi.org/10.1021/jf405093f | J. Agric. Food Chem. 2014, 62, 1890−1897

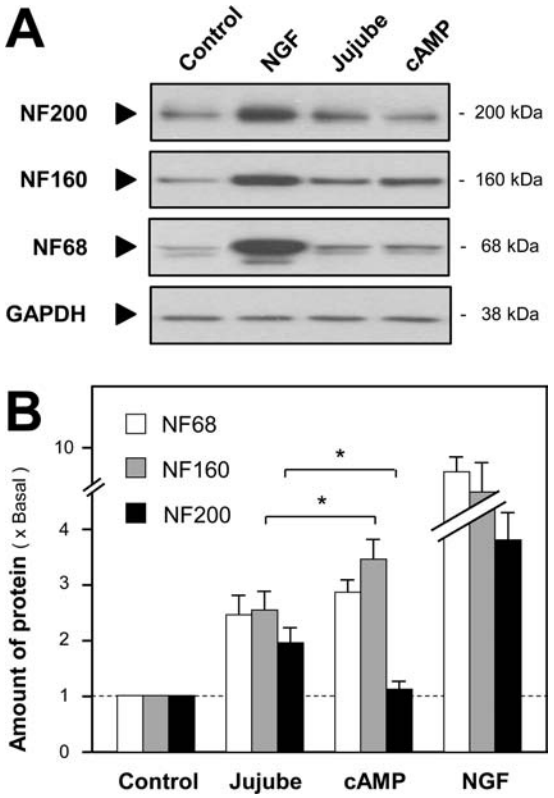

Figure 7. cAMP found in jujube induces the expression of neurofilament on cultured PC12 cells. (A) Cultured PC12 cells were treated with jujube extract (2 mg/mL) and cAMP (2 μM) for 72 h. The cell lysates were collected to determine the expressions of NF68, NF160, and NF200. NGF (50 ng/mL) served as the positive control. GAPDH served as loading control. (B) Quantification plot is shown in histograms. Data are expressed as the fold of change (× Basal) against the control (no treatment; set as 1), mean ± SEM, $n = 5$. Statistical comparison was made between extract and cAMP; (*) $p < 0.05$.

contrast, the expression of NF200, a marker for the late stage of neuron differentiation,[24] was also altered but to a lesser extent. Thus, the involvement of jujube in neuronal differentiation could be mainly at the early stage, but might not fully support the entire differentiation process at late stage.[17] In addition to neurofilament expression, the jujube-induced neurite outgrowth on PC12 cells was also observed morphologically, which was in line with the role of neurofilaments being the structural components of differentiated neurons.[25] In the cases of other neurite-inducing agents, however, the robust inductive effect on neurofilament expression was not consistent with neurite outgrowth, suggesting that the neurofilament expression and the neurite outgrowth could be two independent events.[17]

An increase of cAMP level activates PKA, followed by subsequent CREB phosphorylation, and the transcription factor binding on the promoter finally triggers target gene expression and leads to neurite outgrowth.[26] Here, we found that the inhibition of PKA signaling by H89 suppressed the jujube-induced neuronal differentiation, but not that of NGF-treated cultures. Our study was in good agreement with a previous report that NGF-induced neurite outgrowth could not be blocked by H89.[20] This implied that the differentiation mechanisms could be different between the inductions triggered by jujube and NGF.[27] Further study also revealed that jujube could also promote the phosphorylation of CREB. The aforementioned studies therefore elucidated the involvement of PKA−CREB signaling in jujube-induced neuronal differentiation on PC12 cells.

As reported previously, the water extract contained a higher amount of cyclic nucleotides, as well as their derivatives,[15] which could be one of the crucial ingredients in contributing to the jujube-induced beneficial effect. In addition, cyclic nucleotides and their derivatives also have been reported to participate in the regulation and modulation of numerous physiological processes in the human body.[28−32] In parallel, 20 of these chemicals have been identified from jujube.[33] Among many of these chemicals, cAMP showed a relatively high amount in jujube, and interestingly its content was much higher than in other horticultural fruits, that is, apple and pear.[15,22−24] In line with this notion, the amount of cAMP at approximately the amount contained in 2 mg/mL of jujube extract possessed neuronal differentiation, that is, neurite outgrowth and neurofilament expression. This strongly suggested that jujube cAMP played a role in neuronal differentiation, at least in cultured PC12 cells. In support of this hypothesis, a study revealed that the jujube extract could increase the level of cAMP in the plasma and hippocampus of jujube-treated animals.[34] However, the amount of cAMP within jujube did not fully account for its functions, as the jujube extract showed better neuronal differentiation function when compared to the same amount of cAMP. Thus, other active ingredients of jujube should not be eliminated.

Flavonoids have been reported to possess biological activities in promoting neuronal differentiation.[17] The flavonoids within jujube, including (−)-catechin, (−)-epicatechin, kaempferol 3-*O*-rutinoside, and quercetin 3-*O*-rutinoside, were also included in this screening study, yet no effect was found among them, which suggested that flavonoids were not the active ingredients for jujube-induced neuronal differentiation. Furthermore, the water extract of jujube was found to contain a higher amount of cGMP; however, it did not induce differentiation. Thus, the effect of other possible ingredients in jujube should not be eliminated. We speculated that other chemicals such as saponins might also contribute to the effect of jujube, which will be investigated in the future.

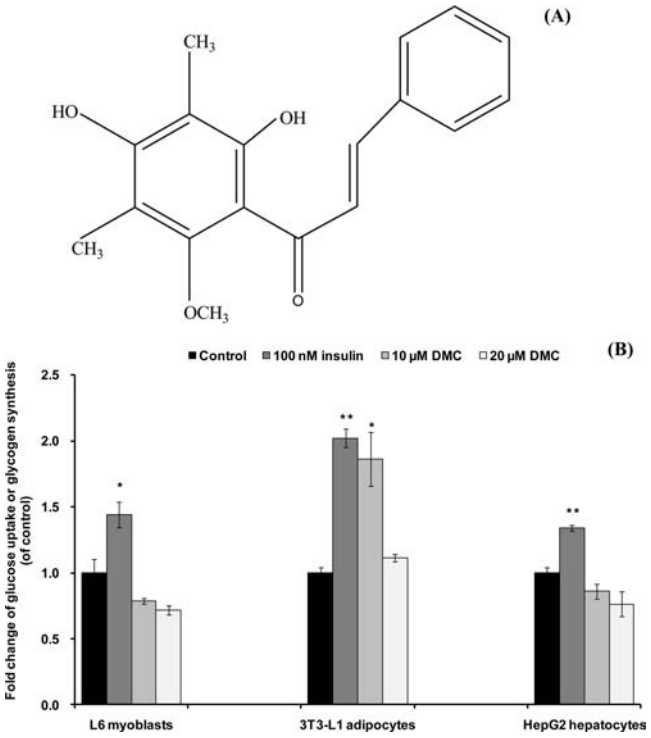

Figure 1. (A) Chemical structure of DMC. (B) Effect of DMC on glucose uptake in L6 myoblasts and 3T3-L1 adipocytes and on glycogen synthesis in HepG2 hepatocytes. Values are presented as the mean ± SEM (n = 3). Significant differences between groups and the control are indicated by ∗ for $P < 0.05$, and by ∗∗ for $P < 0.01$.

The hypoglycemic effects of *C. operculatus* flower bud aqueous extract and DMC have been demonstrated by several studies. However, the focuses were more on pancreatic islets, and studies of DMC in insulin-sensitive organs are rare. In the present study, the effects of DMC on glucose uptake in insulin-sensitive 3T3-L1 adipocytes and L6 skeleton muscle cells, as well as glycogen synthesis in HepG2 hepatocytes, were investigated, with its effects and mechanism on lipid accumulation in 3T3-L1 adipocytes unveiled.

MATERIALS AND METHODS

Reagents. DMC (purity is 98%) was isolated from the dried flower buds of *C. operculatus* as previously described.[16] Bicinchoninic acid (BCA) Protein Assay Kit was purchased from Pierce (Rockford, IL, USA), and dimethyl sulfoxide (DMSO) was purchased from Merck (Gibbstown, NJ, USA). All of the primers used in this study were synthesized by Life Technologies (Carlsbad, CA, USA). Cell culture reagents were acquired from Life Technologies as well. All other chemicals were of analytical reagent grade and acquired from Sigma-Aldrich (St. Louis, MO, USA).

Cell Culture and Differentiation for Glucose Uptake Assessments. L6 myoblasts were derived from rat skeletal muscle. L6 myoblast cell line was obtained from the Cell Bank of Type Culture Collection of the Chinese Academy of Sciences (Shanghai, China) and maintained in DMEM, supplemented with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin under a condition of saturated humidity atmosphere containing 5% CO_2 at 37 °C. When the cells reached 90% confluence, the medium was switched to DMEM containing 2% FBS and 1% penicillin/streptomycin. Cells were allowed to differentiate into myotubes for 7 days with medium changed every other day. 3T3-L1 preadipocytes were purchased from American Type Culture Collection (ATCC, Manassas, VA, USA) and were grown to confluence in DMEM containing 25 mM glucose, 10% FBS, and 1% penicillin/streptomycin at 5% CO_2 at 37 °C. Two days after confluence, cells were placed in DMEM containing 25 mM glucose, 0.5 mM isobutylmethylxanthine (IBMX), 1 μM dexamethasone, 10 μg/mL insulin, 10% FBS, and 1% penicillin/streptomycin (day 0) for 2 days of induction and then in DMEM that contained 25 mM glucose, 10 μg/mL insulin, 10% FBS, and 1% penicillin/streptomycin for 2 days for continuous differentiation. Thereafter, cells were maintained and refed every 2 days with DMEM containing 25 mM glucose, 10% FBS, and 1% penicillin/streptomycin until subjected to glucose uptake experiments (7 days from induction). The HepG2 cell line (ATCC) derived from human hepatocellular carcinoma was maintained in DMEM supplemented with 10% FBS and 1% penicillin/streptomycin under a condition of saturated humidity atmosphere containing 5% CO_2 at 37 °C.

Glucose Uptake Assays. Glucose uptake assay was performed on fully differentiated L6 myoblasts or 3T3-L1 adipocytes in 96-well plates. In detail, after differentiation, cells were serum-starved in DMEM with 0.2% bovine serum albumin (BSA; Sigma-Aldrich) overnight and treated with or without DMC (10 and 20 μM) in the same medium for 24 h. After that, 100 μL of Krebs−Ringer phosphate (KRP)/HEPES buffer (pH 7.4) containing 128 mM NaCl, 4.7 mM KCl, 1.65 mM $CaCl_2$, 2.5 mM $MgSO_4$, and 5 mM Na_2HPO_4, with or without 100 nM insulin, was placed in each well after three washings with KRP/HEPES and incubated for 30 min at 37 °C. Subsequently, 50 μL of KRP/HEPES containing 2 μCi/mL 2-deoxy-D-[^{3}H] glucose (China Isotope Co., Beijing, China) was added to the wells, and the plate was incubated for 20 min at 37 °C. Then, cells were solubilized in lysis buffer (0.5 M NaOH and 0.1% SDS) after three washings with ice-cold PBS. After 100 μL of optiphase supermix (PerkinElmer Life and Analytical Sciences, Boston, MA, USA) was added and thoroughly mixed, the relative radioactivity in the cells was measured in a Microbeta liquid scintillation counter (PerkinElmer).

Glycogen Synthesis Assay. HepG2 cells were seeded in 24-well plates at a density of 4×10^5 cells/well in DMEM supplemented with 10% FBS. After 24 h, the cells were serum-starved for 24 h. Then, insulin (100 nM) or DMC (10 and 20 μM) together with 0.5 μCi/mL of D-[^{3}H] glucose (China Isotope Co.) was added directly, and the incubation was continued for 2 h. After that, cell medium was replaced with 200 μL of 0.2 N KOH containing 1 mg of glycogen (5 mg/mL final concentration), and cells were incubated for 40 min at 60 °C. Then, cells were solubilized in lysis buffer, and the cell lysates were transferred to tubes, followed by 1 h of incubation at 60 °C. Subsequently, the tubes were placed on ice, and 1 mL of cold ethanol was added. Glycogen was separated by centrifugation at 5000 g for 5 min, and the pellets were washed twice with cold ethanol containing 0.1% LiBr and 0.2 N KOH. The final precipitable radioactivity was counted with MicroBeta.

Lipid Accumulation in 3T3-L1 Adipocytes. 3T3-L1 preadipocytes were seeded in a 24-well plate at a density of 5×10^4 cells/well. 3T3-L1 cells were differentiated as described above, with or without the addition of various concentrations of DMC or pioglitazone (1 μM) in the culture medium during the differentiation process for 7 days. After differentiation, the supernatant was collected for measurement of secreted adiponectin by a quantitative adiponectin mouse ELISA kit (Abcam, Cambridge, UK) according to the manufacturer's instructions. The cells were stained with Oil Red O for neutral lipid (mainly triglycerides and cholesteryl oleate) using a method adopted from the literature and modified.[41] In detail, cells were washed once by PBS and fixed by 10% formalin (3.7% formaldehyde) for 10 min. After removal of the fixation liquid and a washing with 60% isopropyl alcohol, 200 μL of Oil Red O solution (0.05% in 70% ethanol) was added to each well for 30 min of incubation. Then, cells were washed with dH_2O four times and extracted by 100% isopropyl alcohol. The extraction was transferred to a 96-well plate, and optical density (OD) was determined by a Safire 2 microplate reader (Tecan, Mannedorf, Switzerland) at a wavelength of 500 nm.

RNA Isolation and Quantitative RT-PCR. 3T3-L1 preadipocytes were seeded in 12-well plates at a density of 1×10^5 cells/well and differentiated as well as treated as above. Total RNA from each well was extracted and purified using the RNeasy mini kit (Qiagen NV, Venlo, The Netherlands). Complementary DNAs (cDNAs) were

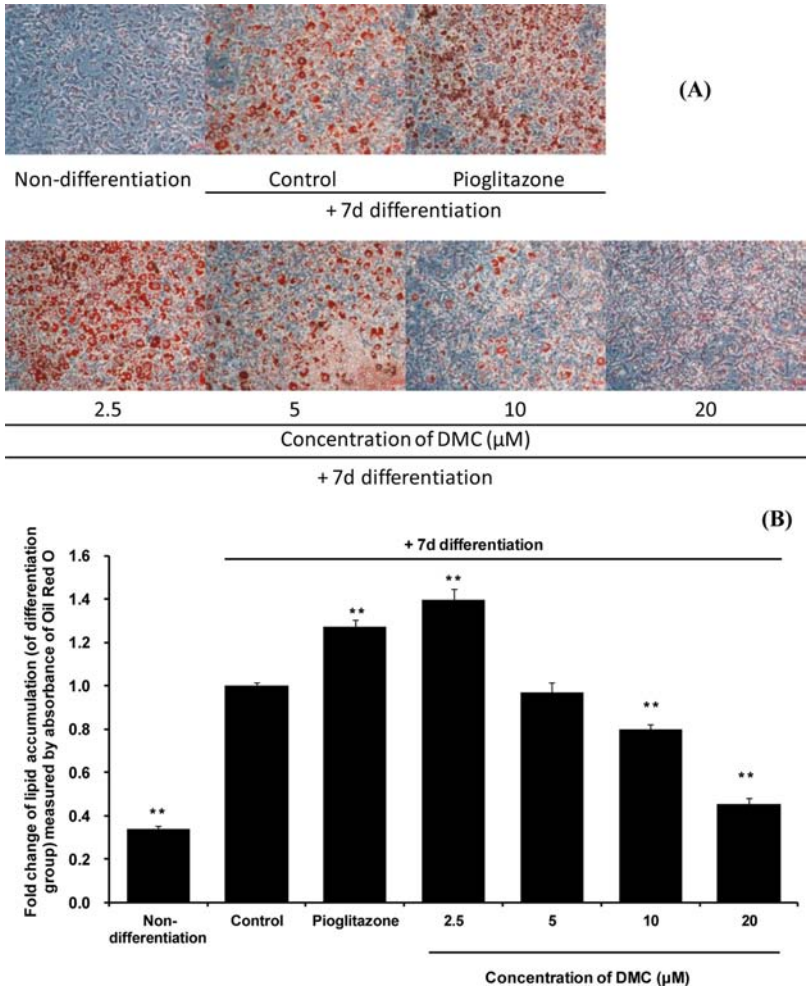

Figure 2. Paradoxical effect of DMC on 3T3-L1 adipocyte differentiation: (A) photographed representative lipid droplet stained with Oil Red O; (B) corresponding absorbance values of Oil Red O staining. Values are shown as the mean ± SEM (n = 3). The data values in (B) are compared versus 7 day differentiation control, with significant differences indicated by ∗ for $P < 0.05$ and by ∗∗ for $P < 0.01$.

synthesized using a primescript first-strand DNA synthesis kit (Takara Biotech, Shiga, Japan) according to the manufacturer's instruction. Quantitative reverse transcription PCR (qRT-PCR) was carried out using the kit of SYBR Premix ExTaq (Takara) and an ABI Prism 7500 sequence detection system (Applied Biosystems, Foster City, CA, USA) to determine the gene expression level. Each PCR was performed in a total of 20 μL of solution containing 0.8 μL (10 μM) of each pair of forward and reverse primers, 10 μL of Premix Ex Taq DNA polymerase, 0.4 μL of ROX reference dye, 6 μL of dH_2O, and 2 μL of reverse transcription reaction products. The primer sequences used in the experiment were as follows: PPAR-γ (forward) 5′-GGCCGAGAAGGAGAAGCTGTTG-3′ and (reverse) 5′-TGGCCACCTCTTTGCTCTGCTC-3′; C/EBP-α (forward) 5′-CCGGGAGAACTCTAACTC-3′ and (reverse) 5′-GATGTAGGCGCTGATGT-3′. All experiments were done in triplicate. Relative expression was determined by the $2^{(-\Delta ct)}$ method using GAPDH as the internal control, and fold change was calculated in comparison to the control group.

Determination of PPAR-γ Protein Expression by Western Blotting. PPAR-γ protein expression level in 3T3-L1 adipocytes was examined using Western blotting. Following the same culture, differentiation, and treatment regimen as described above, cells were washed twice with ice-cold PBS before lysis in 200 μL of CelLytic-M cell lysis reagents (Sigma-Aldrich). The lysate was centrifuged at 14000 g for 15 min at 4 °C, with supernatant collected and total protein determined using a BCA assay. For Western blotting, equal amounts of total cellular protein (10 μg) were resolved by SDS-PAGE and transferred onto polyvinylidene difluoride (PVDF) membranes (Bio-Rad, Hercules, CA, USA) with a Bio-Rad Transblot apparatus and probed with primary antibodies against PPAR-γ and GAPDH overnight at 4 °C, followed by 1 h of incubation with a horseradish peroxidase (HRP)-conjugated secondary antibody (all antibodies were from Cell Signaling Technologies, Beverly, MA, USA). The immune complexes of bound antibody were visualized with an enhanced chemiluminescence (ECL) system according to the manufacturer's instructions (GE Healthcare, Piscataway, NJ, USA). Equal loading was confirmed by analysis of the internal control of GAPDH, and bands were quantified using densitometry by Image J software (NIH, Bethesda, MD, USA).

Statistics. Results were expressed as the mean ± SEM. The data were analyzed by one-way analysis of variance (ANOVA) followed by Dunnett's post hoc comparisons to determine the significant differences between treatment groups and the control group. Differences with $P < 0.05$ were considered statistically significant.

RESULTS

DMC-Promoted Glucose Uptake in 3T3-L1 Adipocytes. To determine the effect of DMC on glucose uptake in skeletal muscle and fat, ^{3}H-labeled 2-deoxyglucose was measured in a differentiated L6 rat skeleton muscle cell and 3T3-L1 mouse adipocytes, respectively. As shown in Figure 1B, 100 nM insulin significantly increased glucose uptake in L6 and 3T3-L1 cells by 44 and 102%, respectively ($P < 0.05$ vs control group), as expected. Interestingly, 10 μM DMC treatment also

remarkably promoted glucose uptake in 3T3-L1 adipocytes by 78% ($P < 0.05$ vs control group), but 20 μM DMC did not show statistical significance. DMC (10 and 20 μM) was not effective for glucose uptake in L6 myoblasts. Glycogen synthesis by detecting ^{3}H-labeled D-glucose was measured in HepG2 hepatocytes. Insulin (100 nM) significantly increased glycogen synthesis by 34% ($P < 0.05$ vs control group), but DMC (10 and 20 μM) did not show significant difference compared to control group.

Paradoxical Effect of DMC on Lipid Accumulation in 3T3-L1 Adipocytes. First, we examined the effects of DMC on the differentiation of 3T3-L1 adipocytes through the microscopic examination of Oil Red O-stained lipid droplets (Figure 2A), and the results were further verified by the spectrophotometric quantification of the Oil Red O extracted from the cells (Figure 2B). Differentiation was initiated in induction medium and continued in differentiation medium by treating the cells with or without pioglitazone (1 μM) or in the presence of various doses of DMC (0, 2.5, 5, 10, or 20 μM). On day 8, it was found that 3T3-L1 cells were significantly differentiated compared to the nondifferentiation group with a 3-fold increase ($P < 0.01$) in Oil Red O staining for intracellular neutral lipids (Figure 2B). Pioglitazone was used as positive control, and 3T3-L1 cells markedly promoted lipid production by 27% ($P < 0.01$ vs differentiation control group). DMC promoted lipid accumulation of 3T3-L1 cells in a dose-dependent manner, and its effect was paradoxical compared with control. A low concentration DMC (2.5 μM) enhanced lipid content in 3T3-L1 cells by 39% ($P < 0.01$ vs differentiation control group), whereas 5 μM DMC did not lead to a significant difference (Figure 2B). However, high concentrations DMC (10 and 20 μM) markedly diminished lipid accumulation by 55 and 20%, respectively ($P < 0.01$ vs differentiation control group). On the other hand, DMC had no effect on cell proliferation or viability, and DMC alone did not affect lipid accumulation in nondifferentiation 3T3-L1 cells (data not shown).

Paradoxical Effect of DMC on Adiponectin Production in 3T3-L1 Adipocytes. As shown in Figure 3, the adiponectin level in 3T3-L1 cells treated with a well-established standard adipocyte differentiation protocol was increased about 50-fold compared with the nondifferentiation group. Pioglitazone (1 μM), as a positive control, enhanced the adiponectin level by 59% ($P < 0.01$ vs differentiation control group). DMC (2.5−20 μM) increased adiponectin production during cell differentiation dose-dependently, but their effects were paradoxical compared with the differentiation control group. DMC, at dosages of 2.5 and 5 μM, enhanced the production of adiponectin in 3T3-L1 cells by 56 and 30%, respectively ($P < 0.01$ vs differentiation control group); at concentrations of 10 and 20 μM, DMC markedly suppressed adiponectin level by 53 and 85%, respectively ($P < 0.01$ vs differentiation control group), whereas under nondifferentiated conditions, DMC did not show a significant effect compared with control (data not shown).

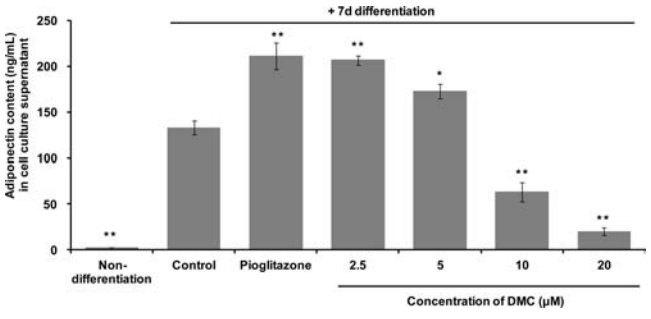

Figure 3. Paradoxical effect of DMC on adiponectin production in 3T3-L1 adipocytes. Values are shown as the mean ± SEM ($n = 3$). All values were compared versus 7 day differentiation control, and significant differences are indicated by * for $P < 0.05$ and by ** for $P < 0.01$.

Quantification of C/EBP-α and PPAR-γ at Gene Expression Level. To study the effect and the corresponding mechanism of DMC in 3T3-L1 adipocyte differentiation, the gene expression levels of C/EBP-α and PPAR-γ were determined as adipocyte differentiation markers. Semiquantitative RT-PCR analysis data showed that differentiated 3T3-L1 expressed C/EBP-α and PPAR-γ, whereas neither was detectable in the nondifferentiation group (Figure 4A). Pioglitazone (1 μM) significantly increased the mRNA expression of C/EBP-α and PPAR-γ by 1.8- and 1.5-fold compared with the differentiation control group ($P < 0.05$). DMC at a concentration of 2.5 μM markedly enhanced both gene expressions compared with the differentiation control (4.4-fold for C/EBP-α; 3.9-fold for PPAR-γ, $P < 0.01$), which was even higher than pioglitazone. On the contrary, treatments with high concentrations of DMC (20 and 10 μM) down-regulated these two gene expressions compared with differentiation control group (0.3/0.5-fold for C/EBP-α; 0.2/0.3-fold for PPAR-γ, $P < 0.05$), and 5 μM DMC treatment did not show significant effects in the gene expressions (Figure 4A).

Determination of PPAR-γ at Protein Level. PPAR-γ is involved in adipocyte differentiation by stimulating adipogenesis and glucose metabolism. To investigate the effect of DMC on the expression of PPAR-γ, Western blot analysis was employed in 3T3-L1 adipocytes. The protein expression of PPAR-γ in the differentiation group was significantly enhanced compared with the nondifferentiation condition ($P < 0.01$). DMC (2.5−20 μM) treatment decreased the protein expression level of PPAR-γ in a dose-dependent fashion, and its effect was paradoxical compared with the differentiation control group. DMC at a dosage of 2.5 μM significantly enhanced the protein expression of PPAR-γ by 40%, which was comparable to pioglitazone by 30% ($P < 0.01$ vs differentiation control group). However, 5 μM DMC treatment did not show a significant effect compared with the differentiation control group. Surprisingly, application of 20 and 10 μM DMC effectively decreased 3T3-L1 adipocyte differentiation by suppression of PPAR-γ after an extensive period of treatment, accompanied with around 8- and 3-fold decreases in PPAR-γ protein expression, respectively ($P < 0.01$ vs differentiation control group) (Figure 4B,C).

DISCUSSION

For diabetes, two major mechanisms contribute to hyperglycemia. One is a shortage of insulin release in the pancreas; the other is insulin resistance in key glucose-metabolizing organs such as the liver, fat, and cardiac and skeletal muscles. The effects of an aqueous extract of *C. operculatus* flower buds[2] and DMC[32,33] on the protection of pancreatic islets and MIN6 cells and insulin release have been demonstrated, but the effects on insulin target tissues are rare. Physiologically, insulin secreted from the pancreas reduces glucose output from the liver and enhances glucose uptake by skeletal muscle and fat

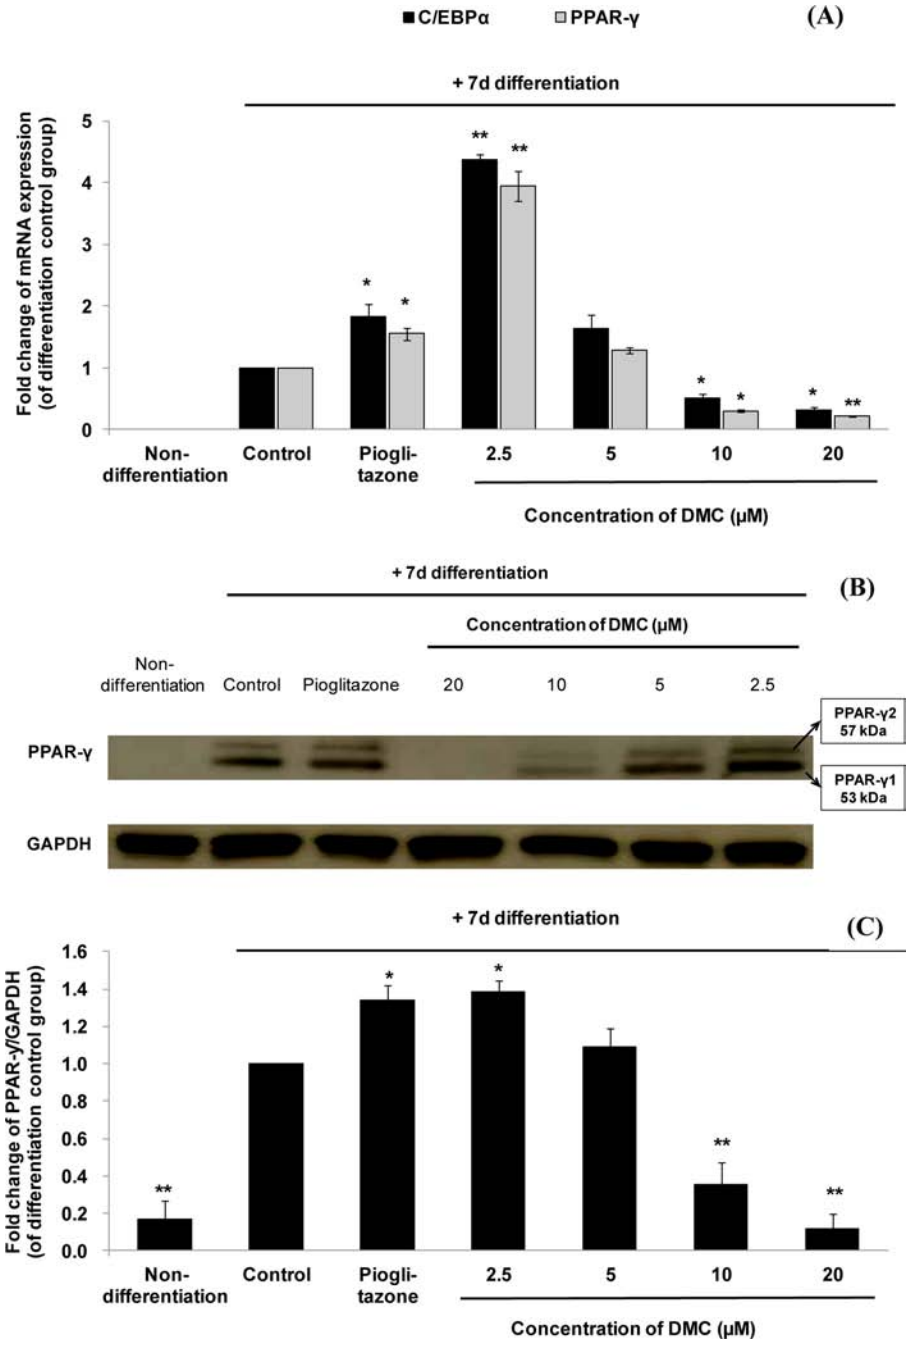

Figure 4. (A) Relative mRNA expression of C/EBP-α and PPAR-γ under different treatments in 3T3-L1 adipocytes. (B) Effect of DMC on PPAR-γ protein expression in 3T3-L1 adipocytes: representative image of protein expression of PPAR-γ and GAPDH measured by Western blot. (C) Quantification of PPAR-γ protein expression. The level of PPAR-γ expression was normalized against GAPDH, and the results were expressed as relative fold change compared to 7 day differentiation control. Values in (A) and (C) are shown as the mean ± SEM (n = 3). Significant differences between treatment groups and the differentiation control are indicated by ∗ for $P < 0.05$ and by ∗∗ for $P < 0.01$.

tissue.[42] In diabetes, insulin-sensitive tissues are functionally impaired, as manifested by a reduction in glucose uptake, lipid accumulation, and glycogen synthesis.[42] In the present study, we evaluated the effect of DMC on glucose uptake in differentiated L6 skeleton muscle cells and 3T3-L1 adipocytes, as well as glycogen synthesis in HepG2 hepatocytes. Our studies showed that DMC, at a dose of 10 μM, but not 20 μM, had the effect in 3T3-L1 adipocytes of remarkably enhanced glucose uptake, and it was aligned with the report that DMC improved glucose uptake in adipocytes.[34] At the same time, DMC showed no direct insulin mimicking effect on glucose uptake in L6 skeleton muscle cells or on glycogen synthesis in HepG2 hepatocytes.

3T3-L1 is a well-studied cell line that could provide an in vitro model for adipogenic differentiation from preadipose to adipose.[43] In this study, DMC was demonstrated to have paradoxical effects on cell differentiation and lipid accumulation in this cell line. High concentrations of DMC (10 and 20 μM) markedly diminished lipid accumulation, whereas a low dose (2.5 μM) enhanced lipid content in 3T3-L1 cells ($P < 0.05$ vs differentiation control group). To further understand the mechanism, we explored relevant terminal differentiation

dx.doi.org/10.1021/jf405368q | J. Agric. Food Chem. 2014, 62, 1898−1904

markers PPAR-γ and C/EBP-α.[44] PPAR-γ is the core of the adipogenesis and forms a feedback loop with C/EBP-α.[35] Similar paradoxical effects of DMC were observed in adipocyte differentiation by examining the gene expressions of PPAR-γ and C/EBP-α. Also, the protein level of PPAR-γ by Western blotting was consistent with our previous findings of lipid accumulation in differentiation 3T3-L1 cells. Therefore, we postulated that DMC may play a role as a key modulator affecting 3T3-L1 adipocyte differentiation (lipid accumulation) via regulating PPAR-γ. It was reported that DMC was a ligand of PPAR-γ,[34] yet it cannot explain why high concentrations of DMC decreased the expression of PPAR-γ. We hypothesize that high doses of DMC stimulated and low doses suppressed the expression of PPAR-γ, leading to a paradoxical effect on cell differentiation and fat accumulation in 3T3-L1 adipocytes. DMC was capable of inhibiting adipocyte differentiation and diminishing lipid accumulation with concomitant down-regulation of PPAR-γ at high dose.

Adiponectin, also known as the adipocyte complement-related protein, is mainly expressed in adipose tissue. DMC showed similar paradoxical effects on the production of adiponectin as on lipid accumulation and PPAR-γ expression in 3T3-L1 adipocytes. Because PPAR-γ activation leads to increased adiponectin gene expression and protein production and PPAR-γ and adiponectin have overlapping effects on downstream metabolic pathways,[45] we postulated that the adiponectin increasing and decreasing effect of different doses of DMC resulted from parallel regulation on PPAR-γ.

In conclusion, the present study provided evidence that DMC improved glucose uptake in differentiated 3T3-L1 adipocytes at 10 μM, but not at 20 μM, and that it had paradoxical effects on lipid accumulation during the process of adipocyte differentiation by controlling the expression of PPAR-γ. At a low dose, DMC promoted lipid production, whereas it suppressed the differentiation from preadipocytes to adipocytes at high concentrations. The study suggested the potential application of certain levels of DMC in the management of hyperglycemia. At the same time, the molecular mechanisms underlying the apparently paradoxical dose–response remain to be unveiled.

(C_4mim·Cl) was an efficient system for hydrolyzing lignocellulosic biomass. These authors attributed the excellent behavior of the system to the dispersion of most of the cellulose and hemicellulose molecules within the ionic liquid. Amarasekara et al.[18] successfully immobilized the sulfonic acid functionalized ionic liquid, C_4mim·Cl, on a silica surface to synthesize a silica-supported acid catalyst, showing that an effective heterogeneous acid catalyst can be produced by tethering an imidazolium moiety functionalized by attachment of a sulfonic acid group to a solid support. To better understand the mechanism of cellulose solvation by the above-mentioned ionic liquid, Remsing et al.[19] conducted a study and found that there was a 1:1 stoichiometry for the hydrogen-bonded interaction between the hydroxyl protons of carbohydrate and the chloride ions of ionic liquid. The chloride concentration in this system was as high as 20%. To expand on this bifunctional strategy, we have produced a unique artificial catalyst that mimics the structure of not only the catalytic active sites found in homogeneous acid catalysis but also the active sites of enzymes in the biocatalytic transformation of lignocellulose. In this present study, sucralose was chosen as a satisfactory carbonaceous material for the introduction of chlorine groups in carbon-based solid acid catalysts that can be prepared expediently by carbonization and sulfonation of various sugar in a manner that gives a relatively stable solid acid catalyst for hydrolyzing cellulose to glucose (**2**).[14] The incorporation ability of hydrophilic molecules will make it more easy for a cellulose chain in solution to be in contact with the $-SO_3H$ groups in the carbon material, thus giving rise to higher catalytic performance.[20] We propose that this study will enable the future rational design of new catalytic strategies by bonding chloride as a functional group to promote binding of cellulose to catalysts to overcome the intrinsic bottleneck of biomass hydrolysis, the severe mass-transfer limitation hampering progress, and thus enable the development of methods for processing widely available water-insoluble polymeric biomass under heterogeneous conditions.

EXPERIMENTAL SECTION

Materials. Sucralose (**4**) (biological reagent grade) was purchased from Shiyuanye Co., Ltd. (Shanghai, China). Sucrose was purchased from Jinhuada Chemical Reagent Co., Ltd. (Guangzhou, China). Microcrystalline cellulose (Avicel PH101) was obtained from FMC (Philadelphia, PA), and its degree of polymerization (DP) was 220. Starch (29.0% amylose content), was supplied by Huanglong Food Industry Co., Ltd. (Jilin, China). Rice straw and hardwood obtained locally was mechanically powdered to a particle size of 50−400 μm. C_4mim·OAc was from Lanzhou Institute of Chemical Physics (Lanzhou, China). Cellulase from *Trichoderma reesei* (6 U/mg) was bought from Sigma (St. Louis, MO, USA). All other chemicals were obtained from commercial sources and were of the highest grade available.

Catalyst Preparation and Characterization. The SUCRA-SO_3H catalyst and SUCRO-SO_3H catalysts were prepared from sucralose (**4**) and sucrose (**5**), respectively, according to a method similar to that reported previously by Hara et al.[14] Characterization of the carbon-based solid acid catalysts was carried out by a combination of Fourier transform infrared spectroscopy (FT-IR), X-ray photoelectron spectroscopy (XPS), Branauer−Emmett−Teller analysis (BET), scanning electron microscopy (SEM), temperature-programmed desorption of ammonia anaysis (NH_3-TPD), and acid−base titration.

Hydrolysis of Cellobiose and Cellulose. The standard reaction conditions for the hydrolysis reactions were as follows: cellobiose (**1**) (0.1 g) or cellulose (0.05 g), catalyst (0.1 g) or 1 mL of 4% dilute sulfuric acid and water (4 mL) were loaded into a 10 mL flask with a suitable rubber plug sealed with an aluminum cap to prevent loss of water by evaporation. After stirring (500 rpm) for 1 min the mixture was heated for 0−48 h to the temperature specified for each reaction. The flask was then placed into a mixture of ice and water for 10 min to stop reaction, and the mixtures (1−1.5 mL) were transferred into a 2 mL microcentrifuge tube and separated by centrifugation (1150*g*, 10 min) . Aliquots (100 μL) were withdrawn from the supernatant prior to HPLC analysis. The residual solids in the pipet, microcentrifuge tube, and flask were all collected together by filtration. Reasonable leaching water volume was heated to 80 °C to elute the remaining sugars adsorbed on the surface of the catalyst. The resultant liquor volume was concentrated down to 2 mL for subsequent HPLC analysis. In the reactions containing sulfuric acid, the solution was neutralized with $CaCO_3$ powder after the reaction, the $CaSO_4$ precipitate was removed by centrifugation, and the supernatant solution was analyzed. All reactions were performed in duplicate, and yields of glucose (**2**) had margins of error of up to ±3.4%.

Saccharide Adsorption Capacity of the Prepared Catalysts. Glucose (**2**) (600 mg) or cellobiose (**1**) (600 mg) was added into 12 mL of water and vortexed. The mixture was divided into 12 equal portions in microtubes. Then 100 mg of the catalyst was loaded into each microtube, and the contents were mixed well. All microtubes were kept at room temperature and vortexed for 2 min every 5 min. One microtube was taken and centrifuged at each of the following reaction times: 10, 20, 30, 60, 90, and 120 min. **2** and **1** in the supernatant were determined via high performance ion chromatograph to calculate the adsorption capacity of the catalyst. Other catalysts were treated in the same manner with a reaction time of for 2 h to investigate their adsorptive properties. Error bars represent standard deviations from three experiments.

Hydrolysate Analysis. Glucose (**2**) and cellobiose (**1**) were determined using an HPLC system consisting of a Waters 515 HPLC pump, a Bio-Rad organic acid column, and a Waters 2410 refractive index detector. The column used was a 300 mm × 7.8 mm i.d., Aminex HPX-87H (BIO-RAD Laboratories, Hercules, CA, USA). The mobile phase consisted of 5 mmol/L sulfuric acid aqueous solution with a flow rate of 0.5 mL/min. The column temperature was 65 °C. The cellulose and xylan contents were calculated from glucose (**2**) and xylose (**3**) contents multiplied by conversion factors of 0 0.90 and 0.88, respectively. The concentration of each compound in the liquid phase was determined using calibration curves obtained by analyzing standard solutions with known concentrations. TOC (total organic carbon), which is mostly composed of water-soluble polysaccharide and products from the dehydration of saccharides, was analyzed using a model 5000A TOC Analyzer (Shimadu, Tokyo, Japan). Y_{WSOC}, which represents the yield of total amount of water-soluble organic compounds in the reaction liquid, was calculated based on the data from TOC analysis. Concentration curves ranging from 1 to 150 ppm were prepared from a TOC standard solution (100 ppm) purchased from Sigma with a resulting R^2 value of 0.998.

Glucose yields were calculated as follows:

$$\text{glucose yield (\%)} = \{[\text{mol of glucose (produced)}] / (\text{theoretical yield of glucose in mol})\} \times 100$$

Glucose selectivity was calculated on the basis of TOC results as follows:

$$\text{glucose selectivity (\%)} = (\text{mol of carbon present in the form of glucose}) / (\text{mol of total water} - \text{soluble organic carbon})$$

Estimation of the Activation Energy of Glycosidic Bond Cleavage. The activation energy of cellobiose (**1**) hydrolysis using the sucralose- and sucrose-derived carbon-based solid acid catalysts was studied by comparing the reaction rate at four temperatures (373 K, 383 K, 393 K, and 403 K). Results were plotted as Arrhenius plots in the form of rate constants at each temperature, and activation

energies were calculated by multiplying the slope by the gas constant *R*.

Reuse Experiment. The catalyst reuse experiments were performed at 393 K. Reaction conditions were as follows: 0.1 g of cellobiose, 0.1 g of catalyst, 4 mL of deionized water, and reaction time 3 h, reaction temperature 393 K. The solid catalysts were washed by filtration with distilled water until sulfate ions could no longer be detected in the washings, after which the catalyst was reused in the next cycle of the reaction.

RESULTS AND DISCUSSION

Fourier transform infrared (FT-IR) spectra of the catalysts displayed peaks at approximately 1180 cm^{-1} and 1030 cm^{-1}, which are typically attributable to the stretching modes of SO_3H groups. X-ray photoelectron spectroscopy (XPS) revealed only one peak at 168 eV, assigned to the SO_3H groups, implying that all sulfur in the carbon catalyst is contained in the SO_3H groups. The elemental compositions of the catalysts were measured using the XPS data in order to determine the content of sulfonic acid group. The amount of sulfur per gram of catalyst was 0.28 mmol for the sucralose-derived catalyst (SUCRA-SO_3H), 0.47 mmol for the sucrose-derived catalyst (SUCRO-SO_3H), and 0.67 mmol for the sulfonated sucralose. As expected, the carbonized sucralose contained no detectable sulfur. The specific surface area of SUCRA-SO_3H catalyst was 0.317 m^2/g, which was similar to the 0.282 m^2/g measured for the SUCRO-SO_3H catalyst. Sulfonated sucralose showed a clear advantage in the amount of sulfonyl group attachment compared to other catalysts, indicating that both the carbonization and sulfonation processes cause a decrease in chloride group content, negatively affecting adsorption ability and reaction results. Here, we evaluated the best catalyst among different materials that were capable of hydrolyzing polysaccharide. Both SUCRO-SO_3H and SUCRA-SO_3H catalysts are composed of irregular shaped amorphous carbon particles with layer structures, and the size of catalyst particles was between 0.4 and 1.0 mm. However, there were no obvious mesoporous or microporous particles observed in the SEM micrographs. The acidic properties of SUCRO-SO_3H, SUCRA-SO_3H, and carbonated sucralose were investigated by temperature-programmed desorption of ammonia analysis. Both samples of SUCRO-SO_3H and SUCRA-SO_3H show a distinct broad peak at around 473 K due to the presence of abundant hydroxyl groups. The curve of incompletely carbonated sucralose shows a little higher intensity and desorption in the temperature range of 723–923 K than the other two samples, due to the more severe decomposition of the solid sample. Both SUCRO-SO_3H and SUCRA-SO_3H catalysts showed the presence of medium acid sites, as their respective desorption temperatures are around 623 K, which corresponded to the carboxyl groups.

Initially, we tested the capacity of the catalysts to hydrolyze β-1,4-glycosidic bonds by using cellobiose (**1**) as the substrate, which is commonly used as model compound for cellulose. Figure 1 shows time courses for D-glucose (**2**) formation from cellobiose (**1**) by the SUCRA-SO_3H catalyst. As a comparison, the results for the SUCRO-SO_3H catalyst are also included. Conversion of cellobiose (**2**) reached 100% after 3 h with both catalysts. Taking the sulfur content of the catalysts into account, which based on the XPS results equates to the content of sulfonic acid groups in the catalysts, the SUCRA-SO_3H catalyst (containing 0.28 mmol/g of sulfur) performs much better than the higher sulfur content SUCRO-SO_3H catalyst (containing 0.47 mmol/g of sulfur).

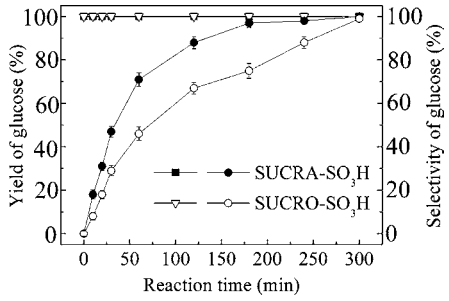

Figure 1. Time courses for D-glucose formation from cellobiose.Yield of glucose (**2**) (circular symbols) and selectivity of glucose (**2**) (square symbols and triangles) during hydrolysis of cellobiose (**1**) over SUCRA-SO_3H (closed symbols) and SUCRO-SO_3H (open symbols).

To investigate the performance of the new catalysts in comparison to other catalytic systems, their performance was compared with that of sulfonated sucralose, sulfonated sucrose, Amberlyst-15, and niobic acid (Figure 2). Only trace amounts

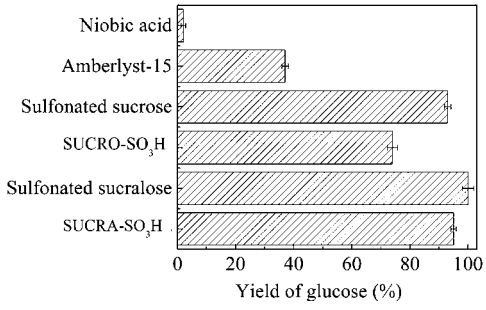

Figure 2. Hydrolysis of cellobiose (**1**) catalyzed by various catalysts.

of cellobiose (**1**) were converted over niobic acid, presumably due to the lack of efficient acid catalytic sites,[21] while the catalysts bearing Brønsted acid sites (Amberlyst-15 and the sulfonated carbon materials) generally exhibited good catalytic performance. Furthermore, the addition of halogen as cellulose binding sites in SUCRA-SO_3H significantly enhanced the reaction activity compared to the SUCRO-SO_3H catalyst, which does not contain halogen.

This encouraging progress could be attributed to increases in adsorption capacity. Catalysts with cellulose binding sites are thought to be superior at adsorbing cellobiose (**1**) (the shortest β-1,4-linked polysaccharide, which is often used to model the cellulose hydrolysis reaction) and **2** (the expected product), since the chloride group is a strong hydrogen bond acceptor that may enter into hydrogen bonding with the hydroxyl groups on cellulose, cellobiose (**1**), and glucose (**2**). To confirm this conjecture, 0.1 g portions of the solid catalyst were added to separate 2 mL aliquots of aqueous cellobiose (**1**) and glucose (**2**) solutions (50 g/L), and the mixture was oscillated at room temperature (298 K). As shown in Figure 3, 21.5% of the added cellobiose (**1**) was absorbed by the SUCRA-SO_3H catalyst within 2 h, which was higher than the value of 18% absorbed by the SUCRO-SO_3H catalyst, and the Cl-bearing catalyst SUCRA-SO_3H required a shorter time before adsorption equilibrium was reached compared to the Cl-free SUCRO-SO_3H catalyst. Similarly, the SUCRA-SO_3H catalyst absorbed 8.5% of the added glucose (**2**), which was more than the 5% absorbed by the SUCRO-SO_3H catalyst and agrees with the

dx.doi.org/10.1021/jf405712b | J. Agric. Food Chem. 2014, 62, 1905–1911

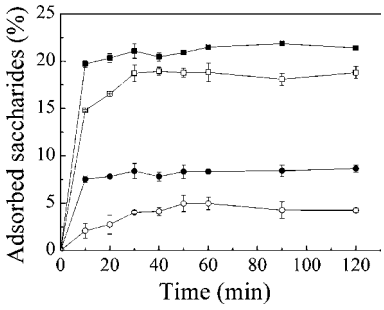

Figure 3. Adsorption curve of glucose (**2**) (circular symbols) and cellobiose (**1**) (square symbols) onto SUCRA-SO_3H catalyst (closed symbols) and SUCRO-SO_3H catalyst (open symbols) in aqueous solution. 100% adsorption would correspond to binding of 50 mg of carbohydrate to 100 mg of catalyst in a volume of 1 mL.

results of Suganuma et al.[21] and Shuai et al.[16] The ability of the catalysts to take up large amounts of saccharides is likely caused by the simultaneous incorporation of water and adsorption of saccharides. It is possible that the formation of hydrogen bonds occurs between the hydroxyl groups of cellulose and not only the chloride groups but also the hydroxyl groups on catalyst as minor electronegative groups. Furthermore, the stronger electrophilicity of surface chloride groups than hydroxyl groups on the carbon affords better adsorption capacity.

Further, the adsorption capacity of the SUCRA-SO_3H catalyst was compared with those achieved with other heterogeneous catalysts (Figure 4). Among the range of

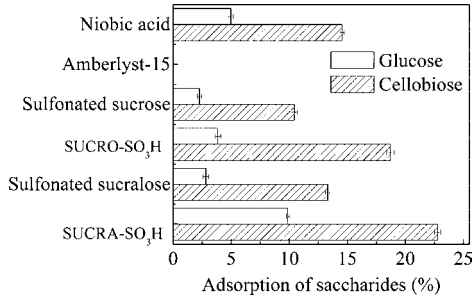

Figure 4. The adsorption capacity of the tested catalysts. 100% adsorption would correspond to binding of 50 mg of carbohydrate to 100 mg of catalyst in a volume of 1 mL.

catalysts tested, the sulfonated sucralose shows the best adsorption ability, which correlates with its highest chloride group loading. Although niobic acid showed the third greatest saccharide-binding capacity, possibly caused by swelling of the solid acid catalyst, it exhibited poor catalysis presumably owing to its low acidity (70% that of sulfuric acid). However, Amberlyst-15, with its strong acid groups, performed conversely, indicating that only when a certain amount of acid groups and requisite electron pair acceptor are present on the catalyst will a highly effective catalyst result.[22]

Catalytic activity was further investigated by examining the effectiveness of the catalysts for cellulose and starch hydrolysis. Compared to starches, cellulose is more difficult to hydrolyze due to its crystalline form and the abundant hydrogen bonding present in the cellulose molecule, and the β-glycosidic linkage of cellobiose (**1**) among the various types of simple disaccharides is one of the most recalcitrant bonds to acid hydrolysis compared to maltose, sucrose, lactose, and xylobiose.[23] As shown in Table 1, in the case of starch, the carbon-based catalyst SUCRA-SO_3H showed a glucose (**2**) yield of approximately 90%, with an equivalent amount of fructose observed after a 6 h reaction. For hydrolysis of unpretreated cellulose, however, only 4% glucose (**2**) yield was achieved after 24 h of reaction. Nonetheless, the glucose (**2**) yield from this reaction could be increased to 53% by converting the water-soluble polysaccharide in the resulting reaction liquid through a 48 h enzyme hydrolysis, and 48% saccharide was detected in the final product according to the TOC result based on mass.

To improve the accessibility of the catalytic sites of the catalyst to the β-1,4-glycosidic bond in cellulose, we pretreated cellulose with the ionic liquid C_4mim·OAc and then regenerated it with water. It is generally accepted that the primary mechanism for dissolution of cellulose by ionic liquids proceeds through disruption of the interstrand hydrogen-bonding network between adjacent polymer chains, and C_4mim·OAc has been found to be an efficient ionic liquid for reducing the crystallinity of cellulose.[24] XRD analysis indicated that the amorphous region increased greatly in the regenerated cellulose, and thereby it is possible that the glycosidic bonds in the substrates become more exposed to the catalysts. Three diffraction peaks, at around 2θ of 16°, 22°, and 34°, respectively, for untreated microcrystalline cellulose, but only one weak peak remained at around 22° after treatment with C_4mim·OAc. The most important result of pretreatment is that it enables maximum sugar yield and minimizes the loss of sugars and the subsequent formation of inhibitory products. The yield of glucose (**2**) increased up to 55% with a 98%

Table 1. Hydrolytic Degradation of Polysaccharides to Glucose Using Various Catalysts

[a]The optimum reaction time for the hydrolysis. [b]Y_{Glu} was the yield of glucose. [c]Y_{WSOC} was the yield of water-soluble organic compounds determined via a TOC analyzer. [d]S_{Glu} was the selectivity of glucose on tested catalysts. – represents "not detected".

dx.doi.org/10.1021/jf405712b | J. Agric. Food Chem. 2014, 62, 1905−1911

selectivity for regenerated cellulose using SUCRA-SO_3H catalyst at an optimum reaction time of 24 h and 393 K, which was superior to that with SUCRO-SO_3H catalyst (49%) at an optimum reaction time of 24 h and 393 K and that with dilute sulfuric acid (25%) at an optimum reaction time of 30 h and 393 K (Table 1). Additionally, in comparison with other liquid acid catalysts reported previously such as maleic acid[25] and phosphoric acid,[26] our prepared SUCRA-SO_3H catalyst gave a higher yield of glucose (**2**) in hydrolysis of cellulose. Figure 5A–C illustrates the effects of reaction time on

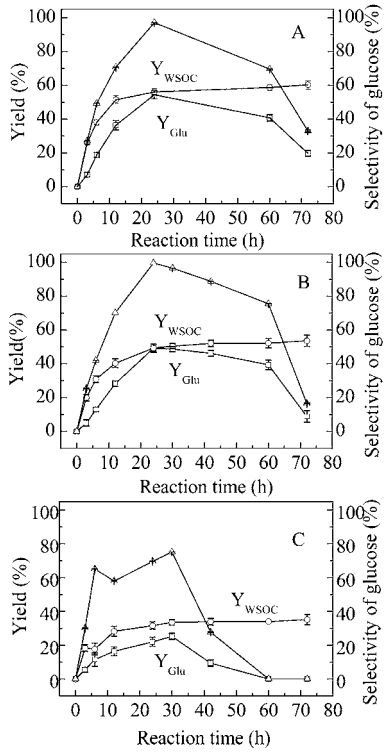

Figure 5. Hydrolysis of cellulose pretreated with C_4mim·OAc over various catalysts: (A) SUCRA-SO_3H, (B) SUCRO-SO_3H, and (C) dilute sulfuric acid.

hydrolysis of cellulose pretreated by ionic liquid with SUCRA-SO_3H, SUCRO-SO_3H, and dilute sulfuric acid as the catalyst, respectively. It was found that the reaction time had significant influence on yield of glucose (**2**), selectivity of glucose (**2**), and yield of water-soluble organic compounds (Y_{WSOC}) in hydrolysis of cellulose using various catalysts. The yield and selectivity of glucose (**2**) and the Y_{WSOC} with SUCRA-SO_3H increased clearly with increasing reaction time up to 24 h, but a further increase in reaction time resulted in a significant drop in the yield and selectivity of glucose (**2**) (Figure 5A). The Y_{WSOC} with SUCRA-SO_3H showed only slight increase when reaction time was more than 24 h, suggesting that there is a recalcitrant portion of insoluble cellulose present in the cellulose that is not accessible to hydrolysis. This similar trend was seen with increasing reaction time in hydrolysis of cellulose catalyzed by SUCRO-SO_3H (Figure 5B). Obviously, the optimum reaction time for hydrolysis of cellulose using SUCRA-SO_3H or SUCRO-SO_3H was 24 h. In the case of dilute sulfuric acid, the yield and selectivity of glucose (**2**) reached maximum values at reaction time of 30 h, being the optimum reaction time for the reaction. Similarly, no significant variation in the Y_{WSOC} was observed when reaction time was further prolonged. Although both carbon-based catalysts and dilute acid suffered from an undesirable side reaction, namely, the conversion of glucose (**2**) into hydroxymethyl furfural (HMF), the yield of glucose (**2**) showed a sharper decline with prolonged reaction time in the case of the dilute acid catalyst, in comparison with SUCRA-SO_3H and SUCRO-SO_3H. The result suggests that the formed glucose (**2**) from cellulosic biomass may be less converted into byproducts by the carbon-based catalysts. When reaction temperature was elevated, the formed glucose (**2**) was further converted into HMF with high concentrations, thus lowering the selectivity of glucose (**2**) (Table 1). We also performed the reaction using rice straw and hardwood (Table 2) as commercially significant lignocellulosic substrate to check the practicability of tested catalysts. When rice straw pretreated with C_4mim·OAc was hydrolyzed by the SUCRA-SO_3H catalyst, the obtained yield of glucose (**2**) was much less than that of hydrolysis of pure cellulose similarly pretreated under the same conditions. As evident from the data summarized in Table 2, rice straw was more easily degraded by the SUCRA-SO_3H and SUCRO-SO_3H catalysts than hardwood. SUCRA-SO_3H slightly surpassed SUCRO-SO_3H for hydrolysis of both rice straw and hardwood. Hemicellulose as an important component of ligincellulose can be hydrolyzed by our prepared solid acid catalysts as well as by liquid acid catalysts.[27] Interestingly, both the cabon-based catalysts preferentially hydrolyzed hemicellulose.

It has been reported that cellulose hydrolysis can be modeled based on a pseudo-first-order reaction followed by degradation of the generated glucose (**2**).[28] The reaction rate constant obeys modified Arrhenius equations, including effects of temperature and acid concentration. The advantage of adsorbing the substrate onto the catalyst surface is that it will increase the opportunity for the substrate to come into contact with the local acid moieties dispersed on the surface of the amorphous carbon sheet, thereby increasing the rate of the reaction associated by reducing activation energy (Figure 6). Kinetic studies showed that the apparent activation of cellobiose (**1**) hydrolysis was 94 kJ/mol at 373–403 K for

Table 2. Hydrolytic Degradation of Lignocellulose to Glucose Using SUCRA-SO_3H

	composition of regenerated lignincellulose (%)				yield (%)					
					SUCRA-SO_3H			SUCRO-SO_3H		
raw material	cellulose	hemic-ellulose	lignin	ash	Y_{Glu} [a]	Y_{Xyl} [b]	Y_{WSOC} [c]	Y_{Glu} [a]	Y_{Xyl} [b]	Y_{WSOC} [c]
rice straw	47.7	15.6	14.5	16.4	19.5	57.3	36.0	16.5	56.0	34.5
hardwood	54.3	16.5	14.4	1.3	12.7	44.4	32.0	11.2	39.8	29.8

[a] Y_{Glu} was the maximum yield of glucose based on the weight of cellulose in regenerated lignincellulose. [b] Y_{Xyl} was the maximum yield of xylose (**3**) based on the weight of hemicellulose in regenerated lignincellulose. [c] Y_{WSOC} was the yield of water-soluble organic compounds determined via a TOC analyzer.

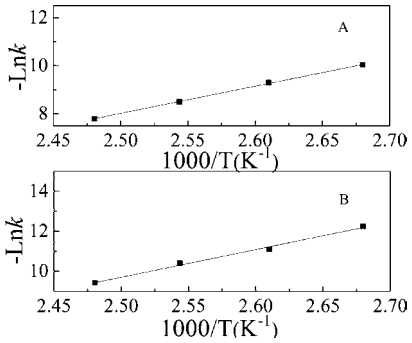

Figure 6. Arrhenius plot of cellobiose (**1**) hydrolysis over (A) SUCRA-SO_3H and (B) SUCRO-SO_3H. Rate constant k was calculated on the basis of the average rate during the initial reaction period (<50% conversion).

SUCRA-SO_3H catalyst (Figure 6A), which is significantly lower than values for microcrystalline cellulose-derived carbon catalyst (110 kJ/mol),[21] SUCRO-SO_3H catalyst (114 kJ/mol) (Figure 6B), and sulfuric acid (133 kJ/mol).[16]

Figure 7 shows the operational stability of the resulting solid catalysts by conducting sequential hydrolytic reactions with the same sample of catalyst using cellobiose (**1**) as substrate at 393 K for 3 h reaction time per cycle. The SUCRA-SO_3H catalyst showed no significant loss in activity after successive reuse of six batches, but an obvious loss in activity was observed after seven batches, and the SUCRA-SO_3H catalyst remained around 56% of the original activity after being repeatedly used for 10 batches, which was attributable to the partial leach of SO_3H groups from the catalyst with the increase of reuse batch. We subsequently detected the pH of the reaction system after the removal of the SUCRA-SO_3H catalyst by filtration during the course of each run, including those at the beginning and the end. The pH of the reaction system showed only a slight fall after successive reuse of six batches, but manifested a relatively obvious decrease after seven batches, particular at the end of the tenth batch, implying the partial leach of SO_3H groups into the reaction system to form free acids through possible self-hydrolysis of the sulfonated catalysts, which was also confirmed by analyzing the S content of the catalyst (data not shown). This could well explain the observation that the SUCRA-SO_3H catalyst indicated relative instability after seven batches of reuse. Moreover, as can be seen in Figure 7, the stability of the SUCRA-SO_3H catalyst prepared by carbonization and sulfonation was clearly superior to that of the sulfonated sucralose, possibly due to the increase of the COOH groups and the rigidity of the carbon skeleton structure in SUCRA-SO_3H by carbonization, which was similar to the observation reported by Siril et al.[29] In fact, it is known that aromatic carbon−SO_3H bonds in sulfoaromatic compounds bearing electron-withdrawing functional groups such as halogens, COOH, and phenol OH are more stable against loss of the sulfonyl group as a result of the increased electron density between the carbon and sulfur atoms. Moreover, the prepared SUCRA-SO_3H catalyst was incubated for 24 h at a relatively higher temperature of 413 K to evaluate its thermal stability, and still maintained more than 80% of its initial activity, showing good stability which was comparable to that of the catalyst Amberlyst 35.[23] A possible mechanism for the hydrolysis process over the solid acid catalysts prepared is that the stronger affinity for β-1,4-glucan of the novel carbon-based catalyst than the traditional solid acid catalysts may provide better access by reactants to the −SO_3H groups in the carbon material to cleave the β-1,4-glucosidic bonds. Catalysis over the tentative carbon catalyst with −SO_3H, −COOH, −Cl, and phenolic −OH groups thus resulted in high catalyst activity.

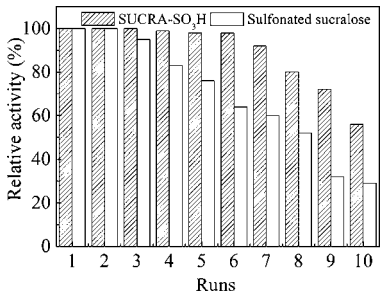

Figure 7. Reusability of SUCRA-SO_3H and sulfonated sucralose in hydrolysis of cellobiose. The relative activity for both catalysts tested prior to use is defined as 100%, and activity is shown after each cycle.

Table 1. Elemental Content of Poultry Manure (PM) and PM Chars Obtained at 350, 450, and 600 °C for Heating Times of 30, 60, 90, and 120 min[a]

sample	heating time (min)	C (%)	H (%)	N (%)	C/H
poultry manure (PM)		30 ± 2	4 ± 1	2.6 ± 0.3	7 ± 2
PM char at 350 °C	30	32 ± 2	2.6 ± 0.3	2.1 ± 0.1	12 ± 2
	60	34 ± 1	2.63 ± 0.03	2.4 ± 0.3	13.0 ± 0.3
	90	30 ± 2	2.4 ± 0.2	2.1 ± 0.2	12 ± 2
	120	31 ± 2	1.9 ± 0.2	2.3 ± 0.3	16 ± 3
PM char at 450 °C	30	27 ± 2	1.3 ± 0.2	1.62 ± 0.08	21 ± 4
	60	30 ± 1	1.4 ± 0.1	1.75 ± 0.06	21 ± 2
	90	29 ± 1	1.5 ± 0.1	1.88 ± 0.02	19 ± 2
	120	24 ± 1	0.9 ± 0.2	1.5 ± 0.2	27 ± 7
PM char at 600 °C	30	26 ± 7	0.6 ± 0.2	1.2 ± 0.4	42 ± 25
	60	24 ± 2	0.50 ± 0.01	1.08 ± 0.04	48 ± 5
	90	24 ± 1	0.64 ± 0.09	1.23 ± 0.02	37 ± 7
	120	25 ± 3	0.62 ± 0.06	1.24 ± 0.09	40 ± 8

[a]All values are uncorrected for ash and moisture contents.

and microbial recalcitrance, which is also the cause of their long mean residence time in soils.[33]

The physical characteristics of the charred materials also depend on the nature of the biomasses subjected to the thermal stress.[34,35] Indeed, plant species with many large-diameter cells in the stem tissues can lead to biochars containing larger amounts of macropores.[31] Macropores in biochar applied to soils may enhance soil-draining properties and the capacity to retain larger molecules such as phenolic compounds.[36]

On this basis, we can infer that understanding the char chemical and physical properties is crucial to address its agronomical and environmental uses and allow meaningful preapplication quality assessments.

The aim of the present paper is to report on the changes occurring in the structure of poultry manure biochar when it is obtained at different temperatures and heating times. For this reason we applied cross-polarization magic angle spinning (CPMAS) ^{13}C NMR spectroscopy and thermogravimetric analysis (TGA). Results will show that production temperature is more important than heating time in the chemical−physical characteristics of PM biochar. Our findings appear to confirm recent data obtained on other different animal and vegetal biomasses.[35,37]

MATERIALS AND METHODS

Sample Preparation. Poultry manure (PM) was collected from a Sicilian chicken farm, Conca d'Uovo, Misilmeri, Palermo, Italy (38°3′4″ N, 13°25′32″ E). After sampling, the material was air-dried to a maximum moisture content of 20%. The manure was then charred in 300 mL Pyrex flasks at atmospheric pressure by applying three temperatures: 350, 450, and 600 °C. At the beginning, residual air was still present in the system. Once the reaction started, oxygen was consumed and pyrolysis proceeded under anoxic conditions. The effectiveness of the pyrolysis was confirmed by the NMR analyses described below. For each temperature, heating times of 30, 60, 90, and 120 min were employed. PM chars were allowed to cool to room temperature after pyrolysis. They were then finely ground in a ceramic mortar and dried again at 105 °C overnight. The dried materials were stored in a desiccator until analyses.

Chemical Analyses of PM Chars. Elemental contents (C, H, N) for all samples were achieved by using a Vario MicroCUBE Elemental Analyzer (Elementar, Hanau, Germany). All of the results are reported in Table 1. C, H, and N values were not corrected for the ash and moisture contents.

CPMAS ^{13}C NMR Spectroscopy. A 7.05 T Varian UNITY INOVA (Varian Inc., Palo Alto, CA, USA), equipped with an Apex HX wide-bore probe operating at a ^{13}C frequency of 75.4 MHz, was used to acquire the ^{13}C NMR spectra. The samples were packed in 6 mm zirconium rotors with Teflon bottom and top spacers and Vespel drive tips. The temperature was kept constant at 25.0 ± 0.1 °C. Magic angle spinning was carried out at 8000 ± 1 Hz. A ^{1}H RF field strength of 50.3 kHZ and a ramp of 16 kHz to account for inhomogeneity of the Hartmann−Hahn condition were applied.[38] VNMRJ software (version 1.1 revision D, Varian Inc.) was used to acquire all of the free induction decays (FID). Spectra were processed by Mestre-C software (version 4.9.9.9, Mestrelab Research, Santiago de Compostela, Spain). All of the FIDs were transformed by applying first a 2K zero filling and then an exponential filter function with a line broadening (LB) of 50 Hz. Fully automatic baseline correction using a Bernstein algorithm was applied for baseline corrections.

Thermogravimetric Analyses. TGA was carried out using a Netzsch Simultaneous Thermal Analyzer STA 449 F3 Jupiter (Netzsch-Gerätebau GmbH, Selb, Germany). Alumina crucibles were used as sample holder. Prior to analyses, ground PM chars were equilibrated in a chamber with controlled humidity (relative humidity of 40%). For the thermoanalytical experiments, the following conditions were applied: heating rate of 10 °C min^{-1} from 30 to 1000 °C, under dynamic air atmosphere, flow rate of 50 mL min^{-1}, and sample mass about 10 mg (weighted with an accuracy of ±0.001 mg). The measurements were repeated three times for each sample. Data were analyzed using the Netzsch Star software (NETZSCH Proteus software). The TG curves were derivated (DTG) to improve their resolution with respect to the number of degradation steps and their onsets. The first derivative of the TG trace represents the mass loss rate (expressed as % min^{-1}) as a function of temperature. DTG curves are represented as a series of peaks, instead of an "integrate" stepwise curve (TG), in which the areas under the peaks are proportional to the total mass change of the sample.[39] In this way, even subtle mass changes, not evident in the TG curves, can be highlighted by a DTG peak.[39]

RESULTS AND DISCUSSION

CPMAS ^{13}C NMR Investigations. Figure 1 shows the CPMAS ^{13}C NMR spectra of the PM and Figure 2 its char derivatives produced at 350, 450, and 600 °C for charring times of 30, 60, 90, and 120 min.

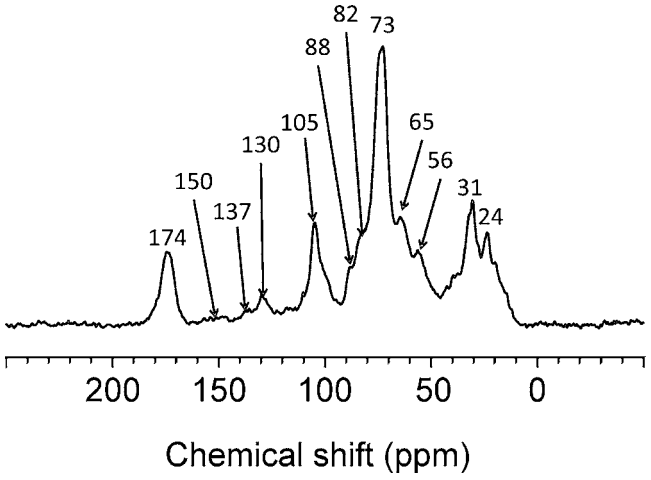

Figure 1. CPMAS ^{13}C NMR spectrum of the poultry manure.

The PM spectrum (Figure 1) reveals a signal pattern that is due to the typical plant material provided to chickens as food. In fact, signals in the region 0−50 ppm are traditionally attributed to alkyl systems. Here, a predominance of methylene ($-CH_2-$) chains (peaks at 24 and 31 ppm) due to lipids, cutin-like structures, and other aliphatic biomolecules can be observed.[40,41]

The region in the interval of 50−60 ppm is assigned to both nitrogenated and oxygenated alkyl systems. However, only a signal at 56 ppm is visible. The latter is usually attributed to methoxyl groups in lignin-like structures.[40,41]

The NMR signal pattern between 60 and 110 ppm is assigned to carbohydrates. Here, cellulose carbons resonate at 65 ppm (C-6), 73 ppm (C-2, C-3, C-5), 82 ppm (C-4 in amorphous cellulose, hemicellulose, and cellulose oligomers), and 88 ppm (C-4 of cellulose on fibril surfaces).[41] Finally, the anomeric carbon in cellulose appears at 105 ppm.[40,41]

The aromatic carbon spectral region is represented by the interval 110−160 ppm. The PM spectrum in Figure 1 reveals aromatic signals at 130, 137, and 150 ppm. Due to the aforementioned signal at 56 ppm, aromatic signals are most likely assigned to lignin-like systems.[41,42] In particular, the signal at 130 ppm is generated by *p*-hydroxyphenol derivatives, whereas those at 137 and 150 are by syringyl-like systems.[41]

The last signal at 174 ppm is assigned to carboxyl groups.

After pyrolysis at 350 °C, the chemical composition of PM drastically changed (Figure 2A). In fact, regardless of the muffle residence time, only two sets of broad bands are observed in the alkyl (0−45 ppm) and aromatic (110−160 ppm) regions. In particular, three main signals can be recognized in the alkyl interval of the spectra, whereas the aromatic carbons produce only one broad signal centered at 130 ppm (Figure 2A). The three main alkyl signals are placed at 14, 24, and 31 ppm. Whereas the latter two can be attributed to methylene chains as reported above, the former signal (14 ppm) is generated by methyl groups terminating alkyl chains. The presence of large amounts of alkyl carbons in the 350 °C charred PM (Figure 2A) shows that the temperature of 350 °C is not sufficient to completely pyrolyze the poultry manure. In particular, aliphatic chains and carbohydrates are converted partly to polycyclic aromatic systems and partly to shorter alkyl moieties. These can either be immobilized to bridge aromatic moieties or be methyl-containing linear substituents on aromatic rings.[17,31] At the longest residence time of 120 min, the signal at 31 ppm, which stems from $-CH_2-$ groups inside aliphatic chains, is noticeably reduced compared to the signals at 24 and 14 ppm. This indicates not only that the aliphatic content decreases with longer residence times but also that the chain length is reduced.

As reported in the literature,[31] the amount of alkyl carbons decreases while that of the aromatic moieties increases, as

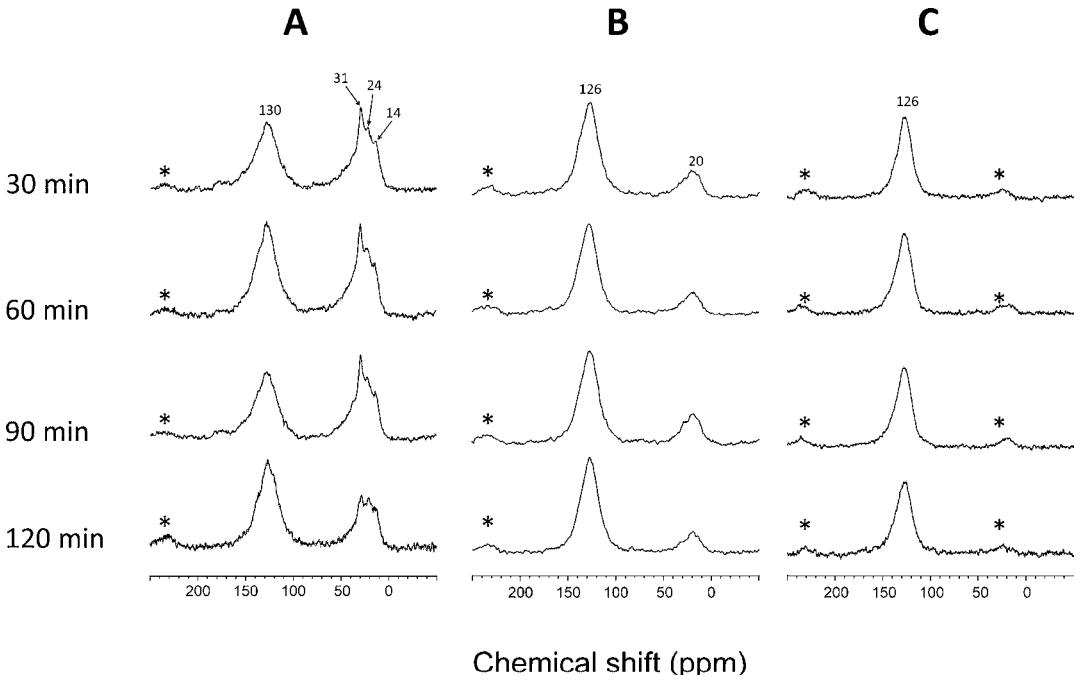

Figure 2. CPMAS ^{13}C NMR spectra of the poultry manure chars produced at 350 °C (A), 450 °C (B), and 600 °C (C) for heating times of 30, 60, 90, and 120 min. The positions of spinning side bands (SSBs) are marked with asterisks (*). Note that the high-field SSB is overlapped by the alkyl resonances in the chemical shift interval 0−50 ppm.

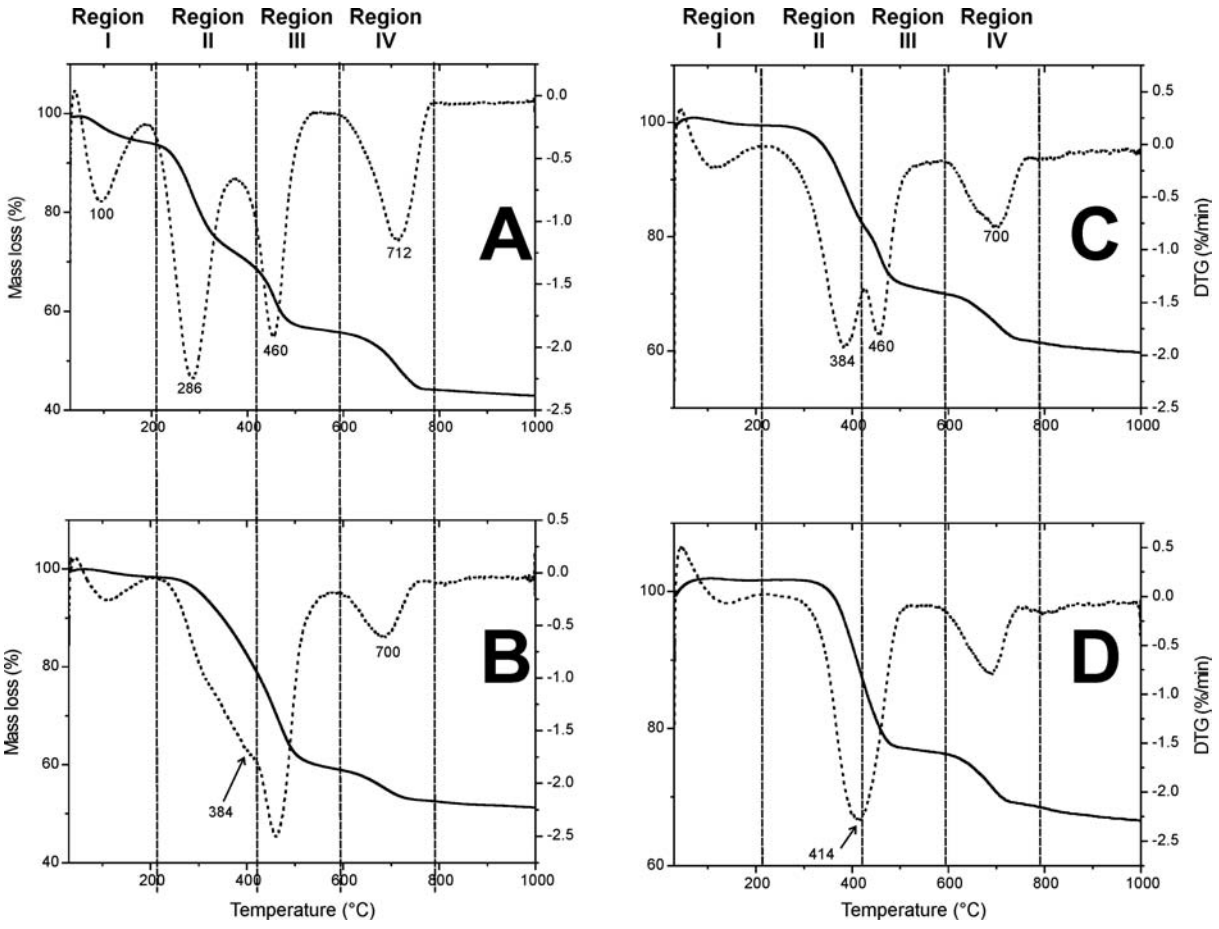

Figure 3. Thermograms (TG, solid lines) and first derivatives of the thermograms (DTG, dotted curves) for the poultry manure (A) and the chars obtained at 350 °C (B), 450 °C (C), and 600 °C (D) and heating time of 120 min. Four different regions can be identified. Region I refers to water removal, region II describes the mass loss due to thermal transformation of carbohydrates and alkyl labile systems, region III is associated with the thermal transformation of aromatic moieties; and region IV is due to transformation of the inorganic components of poultry manure chars.

charring temperature is raised. This is confirmed by the spectra of the poultry manure charred at 450 and 600 °C (Figure 2, panels B and C, respectively). The pyrolysis at 450 °C at all muffle residence times produces charred materials containing mainly aromatic carbons (broad band at 126 ppm in the spectra of Figure 2B). A strong reduction of the alkyl signal intensity is observed as compared to the spectra in Figure 2A. The comparison between the spectra in panels A and B of Figure 2 shows also a loss of resolution of the alkyl band in the spectrum of the biochar retrieved at 450 °C. This finding can be explained by the reduction of the number of methyl-rich linear substituents and the formation of methyl-free alkyl bridges between aromatic rings.

The alkyl signal completely disappears after pyrolysis at 600 °C (Figure 2C), thereby supporting previous results showing that aromatic carbons are the main components in char systems when they are produced with temperatures above 500 °C.[17,35]

It is worth noting that the NMR spectra of the chars obtained at each temperature were similar to each other regardless of the applied charring time (i.e., comparison of the spectra in Figure 2 from top to bottom along columns A, B, and C). However, a shift of 4 ppm of the aromatic carbon chemical shift value can be observed when the spectra in Figure 2 are compared at the same charring time for the different temperatures. In fact, the aromatic carbons resonate at 130 ppm in the spectrum of the PM charred at 350 °C, whereas they appear at 126 ppm in the spectra of the PM chars obtained at 450 and 600 °C. According to McBeath and Smernik,[43] the higher the heating temperature applied for PM charring, the lower is the chemical shift value for the resonance of the aromatic carbons. This is due to the enhancement of the aromatic polycondensation degree as the charring temperature is raised. The elemental content reported in Table 1 further confirms the results from CPMAS ^{13}C NMR experiments. In fact, on the one hand, no changes are observed in the elemental compositions of the chars retrieved at the different heating times when pyrolysis is done at the three temperatures of 350, 450, and 600 °C. This indicates that heating temperature is more important than heating time in affecting the chemical nature of PM chars, thereby confirming recent results by Wolf et al.[37] and Zhao et al.[35] on different char materials. On the other hand, the C/H ratio increases with increasing charring temperature (Table 1). The larger the C/H ratio, the higher the polycondensation degree of organic systems. This supports the conclusion that higher charring temperatures favor formation of polycondensed aromatic rings.[43]

TGA. Figure 3 reports the thermogravimetic (TG) records (solid lines) of the poultry manure and its char products together with the first-derivative curve (DTG, dotted lines). The latter curve reflects the rate of the thermo-oxidative degradation.[44] The chemical similarity among chars as evidenced by CPMAS ^{13}C NMR spectroscopy (see above) is

dx.doi.org/10.1021/jf405549z | J. Agric. Food Chem. 2014, 62, 1912−1918

also reflected in the TG/DTG curves reported in Figure 3. For this reason, only the TG/DTG profiles of the chars obtained at the heating time of 120 min are reported in Figure 3.

TG investigations revealed that mass loss (ML) was in the order $ML_{600\ °C} < ML_{450\ °C} < ML_{350\ °C} \approx ML_{PM}$ (Figure 3). This is expected because charring processes progressively reduce sample carbon, hydrogen, and nitrogen contents as heating temperature is increased.[45,46] Table 1 supports the latter findings. In fact, the carbon amount varied from a mean value of ≈30% in the PM and PM chars obtained at 350 °C to an average of ≈28% in the 450 °C PM chars and to an average of ≈25% in the chars retrieved at 600 °C. Reduction of H and N contents followed the same trend. In fact, they were in the orders $H_{PM} \approx H_{(PM\ chars\ at\ 350)} > H_{(PM\ chars\ at\ 450)} > H_{(PM\ chars\ at\ 600)}$ and $N_{PM} \approx N_{(PM\ chars\ at\ 350)} > N_{(PM\ chars\ at\ 450)} > N_{(PM\ chars\ at\ 600)}$, respectively.

Each TG/DTG curve has been operationally subdivided into four different mass loss steps at four specific temperature intervals (Figure 3).[44,47] The first interval, in the temperature range 40−210 °C (region I in Figure 3) with a progressive mass loss with the maximum rate around 100 °C, is common for all samples. It refers to the loss of moisture adsorbed on PM and chars during the equilibration stage (RH 40%) prior to analysis[44] (see Materials and Methods).

Region II spans a temperature interval from 210 to 420 °C, whereas region III includes the interval 420−570 °C (Figure 3). Poultry manure evidenced the maximum rate of the progressive mass loss at around 286 °C in region II. Conversely, the chars retrieved at 350 and 450 °C showed a maximum mass loss rate at around 384 °C in the same region. Moreover, both PM and PM chars produced at 350 and 450 °C revealed a maximum ML rate at around 460 °C in region III. Finally, the char sample retrieved at 600 °C showed only one DTG peak at around 414 °C placed between regions II and III (Figure 3). The last thermal region, IV, between 600 and 800 °C (Figure 3), with a DTG peak at around 700 °C in all of the samples, is attributed to the degradation of mineral and biogenic salts such as calcium and potassium carbonates usually present in poultry manure.[47,48]

Poultry manure has already been described as a complex mixture of alkyl moieties, sugars, aromatic systems, and acidic functions (see discussion above on CPMAS ^{13}C NMR spectroscopy). The TG/DTG curves reported in Figure 3A confirm those findings. In fact, region II in biomass thermograms is usually due to the thermo-oxidative degradation of labile alkyl systems, carbohydrates, and fatty acids.[47,49] Conversely, region III is mainly assigned to mass loss of more recalcitrant aromatic moieties.[47,49] The latter come from original structures and, partially, from structures that developed in previous stages during the degradation and recombination of aliphatic molecules.[50] In particular, the highly oxygenated degree of the organic PM systems favors mass loss at the temperature of 286 °C in region II (Figure 3A). Conversely, the larger chemical stability of aromatic systems is responsible for the thermal degradation at the temperature of 460 °C as evidenced in region III (Figure 3A).

Following pyrolysis at 350 and 450 °C, PM transforms into a char mainly made by alkyl and aromatic domains. All of the oxygenated functions are lost (see the CPMAS ^{13}C NMR spectroscopy discussion above). Alkyl systems are thermally more stable than the oxygen-rich moieties. For this reason, region II in Figure 3B,C reveals a mass loss at a temperature of 384 °C, which is around 100 °C higher than that observed in Figure 3A.

According to literature data,[44,49,51] linkages of recalcitrant aromatic moieties disrupt between 430 and 600 °C. This arises in region III at 460 °C in poultry manure (Figure 3A), and the chars retrieved at 350 °C (Figure 3B) and 450 °C (Figure 3C). Conversely, the aromatic systems of the chars obtained at 600 °C degraded at 414 °C (Figure 3D), which is a temperature 46 °C lower than that observed in Figure 3A−C and placed on the border of regions II and III.

To explain the thermo-oxidative instability of the aromatic domains of the 600 °C PM chars as compared to the thermo-oxidative stability of the same domains in PM and PM chars at 350 and 450 °C, differences in the conformational arrangements of the different molecular domains have been considered.[52] In fact, it is conceivable that the nonaromatic domains in poultry manure and its 350 and 450 °C chars are mainly displaced on the surface of highly condensed or strongly associated polyaromatic systems.[52] Due to this, the surficial nonaromatic components are degraded first during the TG investigation. The stable products obtained by this first degradation step[50,53] protect the inner aromatic constituents toward the thermo-oxidative degradation, thereby decelerating the effective heat flow and preventing the char particles from penetration of reactive atmosphere.[54] Conversely, the polyaromatic domain in the 600 °C PM chars is degraded at a lower temperature (≈400 °C in Figure 3C) than the other chars due to the absence of the protective effect of the nonaromatic components.

In conclusion, spectroscopic and thermal characterization of poultry manure and its char derivatives obtained at different temperatures and charring times revealed that char chemical nature is affected more by the former than by the latter. Although such a conclusion confirms findings from other authors,[35] our study showed in addition an unexpected stability of the aromatic systems in the low-temperature-retrieved materials than in those obtained at the highest temperature. This result was explained by hypothesizing that the alkyl domains in chars produced at 350 and 450 °C were mainly displaced on the surface of a rigid aromatic core. For this reason, the thermal destruction of the original aromatic core was retrieved only after the complete degradation of the products developed from the original alkyl systems.

Alkyl removal by charring poultry manure at 600 °C left the aromatic domain unprotected, thereby allowing thermal degradation of the aromatic systems at a temperature lower than that measured for the PM chars produced at the two lowest temperatures (350 and 450 °C).

Due to the knowledge that conformation has on the sorption properties of chars (e.g., kinetics and thermodynamics of char sorption or residence time of adsorbed species), the understanding of the role of alkyl and aromatic domains in these interactions is of great importance.

environmentally controlled room (20−22 °C, 60% relative humidity, 12 h alternating light/dark cycle). Hamsters were acclimatized and given water and a rodent diet (LabDiet 5001, PMI International, Redwood, CA, USA; protein, 239 g/kg; fat, 50 g/kg; non-nitrogenous substances, 487 g/kg; crude fiber, 51 g/kg; ash, 70 g/kg; energy, 17 MJ/kg; and sufficient amounts of minerals and vitamins for healthy maintenance) ad libitum for 1 week prior to the initiation of the experimental diets. Hamsters were weighed and randomized into four groups of 10 hamsters each and fed HF diets ad libitum containing 10% (w/w) grape seed flours (Chardonnay (ChrSd), Cabernet Sauvignon (CabSd), Syrah (SyrSd) from Sonomaceuticals, LLC/WholeVine products, Santa Rosa, CA, USA) and a control diet containing 5% microcrystalline cellulose (MCC; Dyets Inc., Bethlehem, PA, USA) for 3 weeks (Table 1). MCC is an insoluble fiber that has little effect on sterol metabolism.[12] Grape pomace was sourced from coastal vineyards in Sonoma County, California. Seeds from the 2010 vintage were separated from skins and stems by screening and dried using hot air (55−70 °C). Oil was pressed from the seed, and the residual press cake was subsequently milled to pass through an 85 mesh sieve. Body weights were recorded weekly, and food intake was monitored twice per week. The study was approved by the Animal Care and Use Committee, Western Regional Research Center, USDA, Albany, CA, USA.

Table 1. Diet Composition (Grams)

ingredient	control	ChrSd	CabSd	SyrSd
butter	80.0	80.0	80.0	80.0

calories/kg	4582.0	4461.4	4464.8	4463.3

Plasma and Tissue Collection. Hamsters were feed-deprived for 12 h and anesthetized with isoflurane (Phoenix Pharmaceutical, St. Joseph, MO, USA). Blood was collected by cardiac puncture with syringes previously rinsed with potassium EDTA solution (15 wt %/v). The plasma was separated after centrifugation at 2000*g* for 30 min at 4 °C. Livers, intestines, and adipose tissues (epididymal and perirenal adipose tissues) were collected, weighed, and immediately frozen in liquid nitrogen for analysis.

Extractable Flavonoid Content. A 0.2 g sample was extracted with 20 mL of MeOH for 30 min with shaking, followed by 10 min of sonication and then centrifuging. Supernatant was taken for HPLC and total phenolic analysis. Total phenols and flavonoid compounds were analyzed using the Folin−Ciocalteu and standard HPLC methods, respectively, as previously described.[13,14]

Plasma Lipids, Hepatic Lipids, and Glucose Analysis. Cholesterol in plasma lipoproteins was determined by size exclusion chromatography as previously described.[15] Briefly, an Agilent 1100 HPLC chromatograph with a Superose 6HR HPLC column (Pharmacia LKB Biotechnology, Piscataway, NJ, USA), a postcolumn derivatization reactor, consisting of a mixing coil (1615-50 Bodman, Aston, PA, USA) in a temperature-controlled water jacket (Aura Industrials, Staten, NY, USA), was employed. A Hewlett-Packard (Agilent, Palo Alto, CA, USA) HPLC pump 79851-A was used to deliver cholesterol reagent (Roche Diagnostics, Indianapolis, IN, USA) at a flow rate of 0.2 mL/min. Bovine cholesterol lipoprotein standards (Sigma-Aldrich, St. Louis, MO, USA) were used to calibrate the signal on the basis of peak areas. Lipoproteins were separated by injecting 15 μL of plasma onto the Superose column. The lipoproteins were eluted with a solution containing 0.15 M NaCl and 0.02% sodium azide at a flow rate of 0.5 mL/min. Liver lipids were prepared by grinding freeze-dried livers into a powder, weighing out about 0.2 g, and mixing with 2 mL of $CHCl_3$/MeOH (2:1), sonicated for 5 min, and then extracted overnight. The samples were centrifuged for 10 min × 1000 rpm, and the supernatant was removed with a glass pipet. Another 2 mL of $CHCl_3$/MeOH was added, sonicated, and allowed to stand overnight to extract. The solvent of the combined extracts was removed under nitrogen. After solvent extraction, hepatic total lipid contents were determined gravimetrically. Blood glucose concentration in feed-deprived hamsters was measured in tail vein samples using a OneTouch Ultrameter (LifeScan Inc., Milpitas, CA, USA).

Real-Time RT-PCR. Total RNA from livers, intestines, and adipose tissues was extracted using a TRIzol plus RNA purification kit (Invitrogen, Life Technologies, Carlsbad, CA, USA), and cDNA was synthesized using a GeneAmpRNA PCR kit (Applied Biosystems, Foster City, CA, USA) per the manufacturer's protocol. One microliter of diluted cDNA (1:10) was used in each real-time RT-PCR using SYBR Green Supermix (Bio-Rad, Hercules, CA, USA) with an Mx3000P instrument (Stratagene, Cedar Creek, TX, USA). The cycle conditions were as follows: 5 min at 95 °C followed by 40 cycles of incubation at 94 °C for 15 s, then 58−60 °C for 1 min, and 72 °C for 30 s. The sequences of the primers used for this study are shown in Table 2 and previous studies.[16−18] The primers were validated by size and sequencing of PCR products. No accumulation of nonspecific products and primer dimers was observed in a gel electrophoresis test of the PCR products. The results were analyzed using the software provided with the Stratagene Mx3000P QPCR system. Differences in mRNA expression for liver, intestines, and adipose tissue were calculated after normalization to β-actin or 36B4 mRNA expression.

Fecal Total Lipid Analysis. Feces were collected during the last 3 consecutive days of the feeding period and were lyophilized, milled, and stored at −20 °C. Fecal total lipid contents were determined gravimetrically after solvent extraction.

Statistical Analysis. All data are expressed as means ± SE. One-way analysis of variance (ANOVA) was performed to examine the effect of treatment on plasma biomarkers, lipid levels, and body and tissue weights using the JMP7 statistical program (SAS Institute, Cary, NC, USA). Tukey−Kramer HSD (honestly significant difference) tests were used to determine the significant differences in group means. Pearson correlation coefficients were calculated for investigating relationships between expression of hepatic gene and plasma cholesterol concentrations. Significance was defined at $P < 0.05$.

RESULTS

Procyanidin Content in Grape Seed Flour. The total methanol-extractable flavonoid content of the Chardonnay grape seed (ChrSd) flour was 1.4- and 1.9-fold greater, respectively, than those in Cabernet Sauvignon (CabSd) and Syrah (SyrSd). The total methanol-extractable catechin content of the ChrSd flour was also greater by 6.4- and 8.4-fold, respectively, compared to CabSd and SyrSd. Total catechins made up 13, 3, and 3% of the total flavan-3-ol content of ChrSd, CabSd, and SyrSd flours, respectively. Catechin content of the ChrSd flour was 5- and 8.7-fold greater, and the epicatechin content was 7.2- and 7.6-fold greater, respectively, than that of CabSd and SyrSd (Table 3). With the exception of ChrSd epigallocatechin, the content of the epicatechin gallate contents was <10 mg/100 g.

Metabolic Effects of Grape Seed Flour Supplementation. ChrSd supplementation into HF diet for 3 weeks lowered plasma very low density lipoprotein (VLDL)-, low-density lipoprotein (LDL)-, and total-cholesterol concentrations by 73, 56, and 38%, respectively, compared with the control diet ($P <$

moisture	7.84	6.32	3.77
total dietary fiber	31.3	46.9	50.5
total sugars	8.6	2.9	3.2

[a]The contents of epigallocatechin gallate, gallocatechin gallate, catechin gallate, and gallocatechin were all <10 mg/100 g. [b]ChrSd, Chardonnay seed; CabSd, Cabernet Sauvignon seed; SyrSd, Syrah seed.

0.05) (Figure 1). However, plasma lipoprotein cholesterol concentrations of the hamsters fed the CabSd and SyrSd diets were not different from the control diet (Figure 1) with the exception of lower HDL cholesterol by the CabSd diet. Although HDL was lowered by CabSd and tended to be lower by ChrSd and SyrSd, the LDL/HDL ratio was significantly improved only with the ChrSd diet (0.5) compared to 0.8 for the control diet and 1.2 and 1.0 for the CabSd and SyrSd diets, respectively. Hepatic total lipid concentration of the hamsters on the ChrSd diet was 24% lower than the control diet ($P < 0.05$) (Figure 1B). Fecal total lipid percent was not changed by the ChrSd diet (Figure 1C).

Hamsters on the HF diets supplemented with ChrSd gained 31% less weight than those on the HF control diet, although total energy intake was not significantly different (Table 4). Total energy intake by hamsters on the SyrSd diet was 12% greater than those on the control diet ($P < 0.05$) (Table 4). The liver weight of hamsters on the ChrSd diet was 38% lower compared to the control diet ($P < 0.05$) (Table 4). The ChrSd diet also significantly lowered the sum of the epididymal and perirenal adipose tissue weights by 23% when compared with control diet by *t* test (Table 4). Blood glucose concentration of the grape seed diets did not significantly differ from the control diet (Table 4).

Expression of Hepatic Genes Related to Cholesterol, Bile Acid, and Fatty Acid Metabolism. Hepatic expression of genes regulating the biosynthesis of cholesterol and bile acids was determined to understand the molecular basis for the observed cholesterol lowering by ChrSd supplementation. The mRNA levels of hepatic genes involved in cholesterol synthesis, SREBP-2 (sterol response element binding protein-2), HMG-CoAR (3-hydroxy-3-methylglutaryl CoA reductase), and

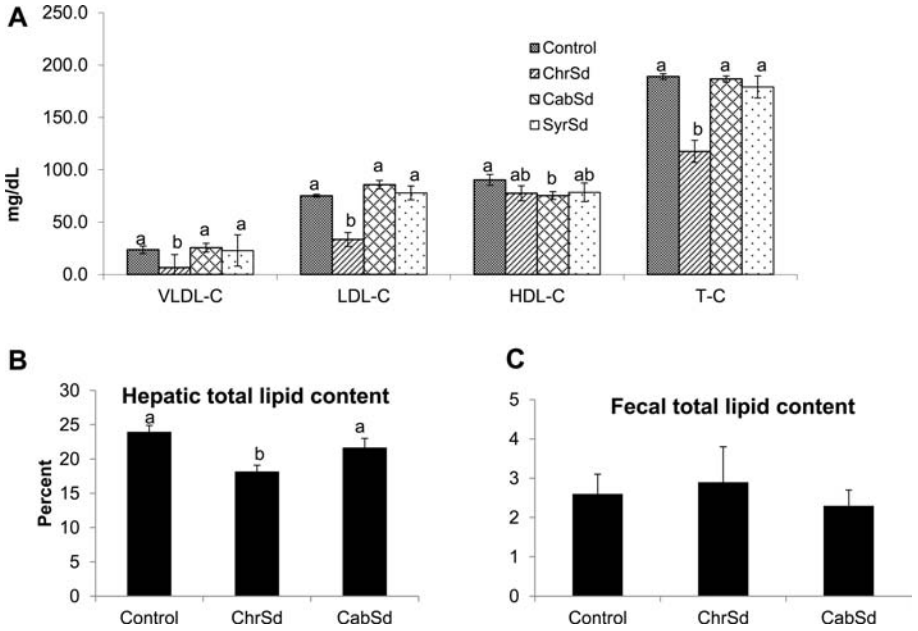

Figure 1. Effect of grape seed flour diets on concentration of plasma lipids (A), hepatic lipids (B), and fecal lipid contents (C). Male Golden Syrian hamsters were fed high-fat diets containing 10% (w/w) Chardonnay (ChrSd), Cabernet Sauvignon (CabSd), and Syrah (SyrSd) grape seed flours and 5% microcrystalline cellulose (MCC, control) for 3 weeks, and blood was collected in a food-deprived state. Data are expressed as means ± SE; n = 8−10/group. Different letters indicate significant difference at $P < 0.05$.

Table 4. Anthropometrics in Hamsters Fed MCC, ChrSd, CabSd, and SyrSd Diets for 3 Weeks[a]

	control	ChrSd	CabSd	SyrSd
body weight gain (g)	34.7 ± 1.9a	23.9 ± 1.9b	38.8 ± 1.9a	40.5 ± 2.2a
total energy intake (kcal)	750 ± 14.6a	809 ± 40.7ab	824 ± 16.6ab	849 ± 24.0b

adipose tissue weight[b] (g)	3.0 ± 0.1ab	2.3 ± 0.1b	3.7 ± 0.2a	3.6 ± 0.3a
blood glucose (mg/dL)	96.0 ± 7.5a	87.0 ± 6.1a	92.7 ± 4.9a	111.8 ± 11.2a

[a]Values are means ± SE, n = 10. Different letters indicate significant difference at $P < 0.05$. [b]Sum of epididymal and perirenal adipose tissue weight.

CYP51 (lanosterol 14α-demethylase), were 1.6-, 1.6-, and 5.6-fold greater, respectively in the hamsters on the ChrSd diet than on the control diet (Figure 2). The mRNA level of ABCG5 (ATP binding cassette subfamily G member 5) was 4-fold lower in ChrSd diet than in the control diet (Figure 2). The mRNA levels of RAPTOR (regulatory associated protein of MTOR) and LDLR (LDL receptor) were greater by 1.4- and 1.5-fold, respectively, compared with the control diet (Figure 2).

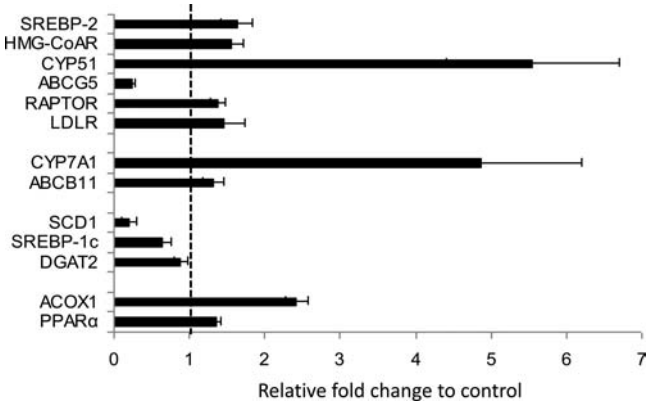

Figure 2. Relative hepatic expression of SREBP-2, HMG-CoAR, CYP51, ABCG5, RAPTOR, LDLR, CYP7A1, ABCB11, SCD-1, SREBP-1c, DGAT2, ACOX1, and PPARα genes. Male Golden Syrian hamsters were fed high-fat diets containing 10% (w/w) Chardonnay (ChrSd) and 5% microcrystalline cellulose (MCC, control) for 3 weeks. Data are expressed as means ± SE n = 6/group.

The expression of the gene controlling the rate-limiting step of bile acid synthesis from cholesterol, CYP7A1 (cytochrome P450 7A1), was 4.9-fold greater relative to the expression in livers of hamsters fed control diet (Figure 2). In addition, the mRNA level of ABCB11 (ATP-binding cassette, subfamily B member 11) was 1.3-fold greater in the ChrSd diet compared with the control diet (Figure 2).

Expression levels of SREBP-1c, a transcription factor for fatty acid synthesis and its target gene, SCD-1 (stearoyl-CoA desaturase-1), were 1.6- and 2-fold lower, respectively in the ChrSd diet compared with the control diet (Figure 2). In contrast, expression levels of PPARα, a transcription factor regulating fatty acid β-oxidation and its target gene, ACOX (acyl-CoA oxidase) 1, were 1.4- and 2.4-fold greater, respectively, in the ChrSd diet than in the control group. The expression of DGAT2 (diacylglycerol O-acyltransferase 2), the gene coding for the enzyme to catalyze the final step of triglyceride synthesis by forming an ester bond between a long-chain fatty acid and diacylglycerol, was not different from control. Expression of a gene regulating bile acid absorption in

the intestine, ileal apical sodium bile acid transporter (ASBT), was not affected by ChrSd diet (data not shown).

Expression of Adipose Tissue Genes Related to Lipid Metabolism and Inflammation. The relative expression of peroxisome proliferator-activated receptor (PPARγ2), a transcription factor for adipocyte differentiation, was lower by 1.8-fold in epididymal adipose tissue of hamsters fed the ChrSd diet compared with the control diet (Figure 3). The mRNA level of adipose ADPN (adiponectin) from ChrSd fed hamsters was not significantly different from in the control diet, but the expression level of leptin was 1.6-fold lower in the ChrSd diet (Figure 3). The expression levels of the inflammatory marker genes TNF-α and MCP-1 were 1.3- and 1.1-fold lower in the ChrSd diet than in the control diet (Figure 3). The expression level of LBP (lipopolysaccharide binding protein), a gene related to innate immune and inflammatory response, was lower by 1.3-fold in the ChrSd diet compared with the control diet (Figure 3).

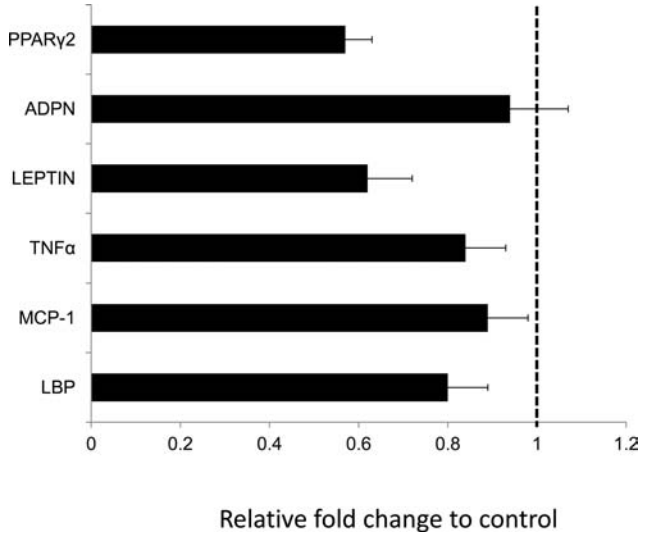

Figure 3. Relative expression of PPARγ2, adiponectin (ADPN), leptin, TNFα, MCP-1, and LBP genes in epididymal adipose tissue of hamsters fed HF diet supplemented with 10% (w/w) Chardonnay (ChrSd) and 5% microcrystalline cellulose (MCC, control) for 3 weeks. Data are expressed as means ± SE n = 5/group.

Correlation between Plasma Lipid and Hepatic Gene Expression. There were significant negative correlations between plasma concentrations of total-, VLDL-, LDL-, and HDL-cholesterol and hepatic expression of CYP51, CYP7A1, ABCB11, and LDLR genes (Table 5). There was a significant positive correlation between plasma VLDL-cholesterol concentration and mRNA levels of the cholesterol transporter ABCG5 (Table 5).

Table 5. Correlations between Plasma Cholesterol Concentrations and Expression of Hepatic Genes[a]

gene	total-C	VLDL-C	LDL-C	HDL-C
CYP51	−0.76***	−0.74***	−0.69**	−0.61*
CYP7A1	−0.44	−0.58*	−0.41	−0.12
ABCG5	0.48	0.52*	0.40	0.42
ABCB11	−0.26	−0.30	−0.24	−0.13
LDLR	−0.52*	−0.39	−0.50*	−0.41

[a]Values are Pearson correlation, n = 12. *, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.005$.

DISCUSSION

Studies of cholesterol-lowering effects by grape seed flavonoids have been typically conducted with aqueous and/or alcoholic extracts. In a meta-analysis of nine human studies on the relationship between grape seed extract, blood pressure, and lipid concentration, it was concluded that the daily intake of 0.15−2.0 g flavonoids/day reduced systolic pressure but did not influence plasma cholesterol concentration.[19] The intake of a red grape pomace byproduct called GADF (grape antioxidant dietary fiber) lowered total plasma cholesterol but not LDL-cholesterol in hypercholesterolemic subjects.[20]

The present study showed for the first time, to our knowledge, that hamsters fed a HF and hypercholesterolemic diet supplemented with Chardonnay grape seed flour (ChrSd diet) significantly lowered plasma LDL-, VLDL-, and total-cholesterol concentrations, abdominal adipose tissue weight, and body weight gain in comparison to control diet. Although red wine is associated with lower plasma cholesterol in Mediterranean countries, cholesterol-lowering and antiobesity properties were not observed in CabSd and SyrSd diets containing red wine grape seed flours, possibly due to low content of flavonoids from the winemaking process. Lower plasma cholesterol levels were associated with higher total content of catechins in the grape seed diets, supporting the role of flavonoids as the bioactive component behind cholesterol-lowering and antiobesity effects of Chardonnay grape seed flour. The flavonoid contents of white and red wine grape seeds vary considerably due to varietal differences, viticultural regions, viticultural practices, and processing methods. In the production of red wines, the whole fruit, including the seed, is fermented; in typical white wine production, only the juice is fermented. The higher levels of flavonoids in red wines and lower levels in seeds are partly due to the ethanol extraction of flavonoids during fermentation.

Cholesterol-lowering and antiobesity effects of Chardonnay wine grape seed flours could be ascribed to the content of monomers, oligomers, and polymers. Chardonnay grape seed extract containing mainly monomers and oligomers induced cholesterol-lowering effects without changes in body weight. This effect was mediated via increased hepatic expression of CYP7A1 and enhanced fecal bile acid excretion in hamsters.[21] Chardonnay grape seed extract containing mostly polymeric flavonoids did display antiobesity effects in hamsters.[9] Grape seed polymeric tannins induced greater cholesterol-lowering properties and fecal bile acid excretion than those in grape seed monomeric tannins in rats.[22] Grape seed extract high in oligomers and polymers showed greater lipase inhibitor activity as well as increased fecal lipid excretion.[6,23] In contrast, monomeric catechin-rich grape seed extract supplementation did not change fecal lipid content compared with high-fat diet controls in C57BL/6J mice despite the presence of antiobesity effects.[24] In the present study, ChrSd diet did not affect fecal lipid content but did induce cholesterol-lowering and antiobesity effects, suggesting that ChrSd diet's beneficial effects possibly represent the effects of multiple constituents in Chardonnay grape seed flour. Calculated intakes of flavonoids from ChrSd, CabSd, and SyrSd diets are, respectively, about 1000, 700, and 600 mg/kg body wt/day and total epicatechin intakes of about 138, 21, and 18 mg/kg body wt/day.

The ChrSd diet may increase hepatic cholesterol and bile acid synthesis as well as hepatic LDL-cholesterol uptake by up-regulating expression of hepatic CYP7A1, CYP51, and LDLR genes. A result similar to ours was reported for catechins from green tea up-regulating CYP7A1 expression in HepG2 hepatocytes.[25] Epigallocatechin gallate (EGCG) was reported to up-regulate LDLR expression in HepG2 hepatocytes via enhanced LDLR mRNA stability.[26,27] These findings suggest that catechins in the ChrSd diet play a direct role in the regulation of hepatic genes (CYP7A1 and LDLR) by accelerating hepatic cholesterol uptake from the circulation and directing the use of hepatic cholesterol to synthesize bile acids. Additionally, the down-regulation of hepatic ABCG5 was observed, which retains hepatic cholesterol by limiting cholesterol efflux to the bile duct to compensate bile acid synthesis demand for cholesterol. Moreover, expression of ileal ASBT was not changed by ChrSd diet, indicating intestinal bile acid absorption was not affected. The ChrSd diet significantly down-regulated expression of ileal SRB1 and ABCG5, suggesting that reduced cholesterol reabsorption by the intestine plays a role in the overall cholesterol-lowering effect of ChrSd diet.

Catechin-rich grape seed extract supplementation up-regulated expression of genes related to fatty acid oxidation including ACOX1 and CPT-1 in livers of mice.[24,28] In accordance with this previous study, we also show that the catechin-rich ChrSd diet down-regulated genes related to fatty acid synthesis (SCD-1 and SREBP-1) while it up-regulated genes related to fatty acid β-oxidation (ACOX1 and PPARα) compared to control diet. As a result, ChrSd diet lowered hepatic lipid content, thus contributing to the potential beneficial effect on hepatic steatosis. We should note that this study did not determine enzymatic activities of fatty acid oxidation and synthesis. Changes in mRNA expression levels are not always a measure of pathway flux; however, previous studies have shown a linear relationship between fatty acid oxidation/synthesis activity and gene expression related to these fatty acid metabolic pathways. For example, dietary supplementation with tea catechins up-regulates both ACOX1 mRNA and fatty acid activity in the liver.[29]

Consumption of the ChrSd diet lowered the sum of epididymal and perirenal adipose tissue weights compared to the HF control diet. Relative expression of PPARγ2 and leptin was down-regulated by ChrSd diet, indicating inhibition of adipogenesis and HF-induced leptin resistance. In 3T3-L1 cell culture, catechin and epicatechin suppressed expression of PPARγ2, adipogenesis, and lipid accumulation.[30,31] These results indicate that monomeric catechins in Chardonnay grape seed flour are likely involved in its antiobesity effect. The low bioactivity of grape seed flavonoids in targeted tissues may be due to their poor bioavailability. However, a recent study has shown that by using ^{14}C-labeling, grape polyphenols or their metabolites were detected in the brain, suggesting possible biological activity in the brain.[32] Further studies are required to determine distribution of flavonoids in target tissues after consumption of grape seed flour.

In summary, flavonoid-rich Chardonnay grape seed flour (a potential byproduct of winemaking) attenuates HF-induced body weight gain, abdominal fat content, hepatic steatosis, hepatic cholesterol, and lipid metabolism. We have demonstrated that the improvements in plasma lipid profiles with the Chardonnay grape seed flours are linked to the regulation of bile acid, cholesterol, and fatty acid metabolism in the liver, which appears to be mediated through regulation of hepatic genes. Expression of genes associated with cholesterol and bile acid transport in and out of hepatocytes was also modified. An antiobesity effect appears to be associated with expression of genes related to adipogenesis and inflammatory markers of adipose tissue. This study supports the potential dietary use of Chardonnay grape seed flour as a flavonoid-rich whole food ingredient for the prevention or management of obesity-related metabolic diseases such as cardiovascular disease and fatty liver in populations consuming a Western diet.

group is a long nonpolar alkyl group, and all the derivatives that lose it form a polar, colored chlorophyll derivative family and a suffix (-ide) is added to their names. Some processes call for a high-temperature blanching pretreatment (dipped in boiling water for a few seconds), which deactivates the chlorophyllase enzyme;[10] thus, chlorophyllides can no longer be formed from chlorophylls. The loss of the carboxymethoxy group at $C13^2$ is due to a decarboxymethylation reaction that happens during severe heat treatment such as canning.[11] This reaction eliminates the asymmetry at $C13^2$, and thus, no a′ and b′ derivative epimers can be formed. All the derivatives losing their carboxymethoxy group get a prefix (pyro-) added to their names. Another color-related transformation is the removal of chelated magnesium from the center of the porphyrin ring leading to derivatives with an olive-brown pigmentation. When plants are harvested leaf cell membranes break allowing sap acidic compounds to interact with chlorophylls. Acid conditions promote the loss of Mg^{2+} from the porphyrin ring, converting chlorophylls into olive-brown pheophytins. This conversion is the most frequent chlorophyll degradation, giving the product a brownish-greying surface color. Pheophytins can be formed through both dry-heating and moist-heating processes.[7] All the derivatives losing their chelating Mg^{2+} get a prefix (pheo-) added to their names. Finally, the formation of hydroxylchlorophylls and hydroxypheophytins caused by oxidation at $C13^2$ has been described in analytical studies on traditional Chinese herbs as well as other colored chlorophylls allomers like lactone derivatives.[12−14]

Chlorophylls and their derivatives have been extensively studied for both their implication in the color preservation in plants and for their reported biological activities.[15] Surface color is an important quality attribute of herbal products; that is why numerous studies have been conducted to investigate color changes or chlorophyll degradation during various processes such as blanching, drying, or heat-treatment. The bright green color of chlorophylls is more pleasing to the consumer than the olive-brown color brought on by certain derivatives. Browning and greying of culinary herbs during drying processes is the most obvious visible symptom. A challenge to culinary herb processors is to preserve the natural color associated with quality attributes in a particular herb.

Many publications in food process engineering and related fields deal with processes such as blanching, heat-treatment, or cooking that keep the plant wet at the end. However, culinary aromatic herbs such as oregano, basil, or dill are generally sold in a dried form to inhibit the growth of microorganism at ambient temperature. Freeze-drying, oven-drying, and sun-drying are the processes commonly used in the aromatic herb industry, but they must be used carefully so as to preserve as much of both the aroma and the color of the (fresh) raw material as possible. International standards for the quality specifications, including moisture content, of most culinary aromatic herbs are available, but none mention color specifications. Therefore, the drying treatment step is crucial to preserve the color quality of culinary herbs.

In this Article we focused our attention on chlorophylls and their colored derivatives (both polar and nonpolar) present in dried culinary herbs. The first objectives were to detect and quantitate the largest range of chlorophyll colored derivatives possible. From this work we developed a knowledge and understanding of the various degradation pathways responsible for color changes in the dried herbs. With these findings our next goal was to find a novel way of determining the global level of dried culinary herb quality in terms of color. We thus designed an interesting color degradation ladder enabling us to classify drying processes according to their impact on culinary herb surface color.

MATERIALS AND METHODS

Materials. Fresh spinach was obtained from a local store in Avignon. No commercial frozen spinach was used, because it is generally subjected to a blanching step leading to important epimerization of chlorophylls.[7] Culinary aromatic herbs were cultivated and dried in Turkey and Egypt. Fresh culinary herbs were obtained from fields in east-southern France and kept between 2 and 8 °C prior to analysis.

Chemicals. Analytical grade (acetone) and HPLC grade solvents (methanol, acetone, water) as well as all analytical grade chemicals (ammonium acetate, sodium citrate, hydrochloric acid, sodium hydroxide) were obtained from Sigma-Aldrich (St. Louis, MO). Nylon filters were obtained from Macherey-Nagel (Hoerdt, France).

Instrumentation. The HPLC system consisted of an Alltech Elite degassing system (Nicholasville, KY), a Thermo SpectraSystem P1000 pump (San Jose, CA), a Thermo Spectra Series AS100 autosampler equipped with a 20-μL loop, and a Kinetex stainless-steel column (100 × 4.6 mm i.d.) packed with XB-C18 (2.6-μm) from Phenomenex (Torrance, CA). A Thermo SpectraSystem UV6000LP diode array detector (DAD) was used to both monitor the separation and determine the absorption spectra of chlorophylls and their derivatives. Spectral data from the DAD system were recorded between 350 and 700 nm. For mass spectra, the HPLC described above was equipped with an AB-Sciex 4000 Q-trap mass spectrometer (MS) (Foster City, CA) with an electrospray ionization source.

A UV-1800 spectrophotometer from Shimadzu (Kyoto, Japan) was used.

An IKA T25 Ultra-Turrax homogenizer (Staufen, Germany) equipped with a stainless steel disperser (18 mm in diameter) and a Waring Lab blender (Winsted, CT) equipped with 1-L stainless-steel container were used to grind plant samples in solvents. A Retsch MM400 benchtop mixer mill (Haan, Germany) was used to grind dry plants.

A Minolta CR310 colorimeter (Osaka, Japan) was used to measure in the LCh° colorimetric space. Data reported are the average of 3 determinations.

Xlstat version 2012.4.03 from Addinsoft (Paris, France) was used for processing principal components analyses (PCA) and principal component regression (PCR).

Dehydration Processes. Several dehydration processes were used: sun-drying as the commonly used approach, freeze-drying as the reference in term of preserving green color, and last oven-drying. The latter two methods were used as control treatments. Two other proprietary types of dehydration processes were used and were named DP1 and DP2. DP1 is an innovation brought to the traditional sun-drying process. DP2 is a recently developed process designed to preserve the green appearance of aromatic herbs.

Preparation of Standard Solutions. Chlorophyll a and b standard solutions were extracted and prepared from fresh spinach leaves. The chlorophyll derivatives comprising the pheophorbides and pyropheophorbides, although available commercially,[16] were synthesized as deemed necessary.

Approximately 54 g of fresh spinach leaves were weighed into a 1-L container to which 200 mL of acetone was added. The mixture was homogenized for 1 min. Part of the extract was passed through a 0.45-μm nylon filter. The ratio of 54 g of spinach−200 mL acetone was prepared to obtain a final chlorophyll solution composed of 80:20 acetone−water. This solution was subjected to a 10-fold dilution with acetone−water 80:20 and used as the standard chlorophyll solution for realizing regression curves for external calibration. A pheophytin standard solution was prepared by acidification of the chlorophyll standard solution according to Schwartz et al.[17] Hydrochloric acid (1 N) was added dropwise to 100 mL of the chlorophyll standard solution, and the solution was shaken after each addition. The complete conversion was reached once the color of the solution turned

from green to olive brown. The absence of remaining chlorophylls could be confirmed by HPLC.

Chlorophyllides were prepared in situ by the action of chlorophyllase enzyme on chlorophylls as substrate.[10] Fresh spinach leaves were gently dehydrated for 48 h in an oven at 40 °C and finely ground with a mixer mill. This resulting powder contained both enzyme and substrate (the substrate was the chlorophyll already present in the spinach leaves). A 500 mg portion of the dried spinach leaf powder and 10 mL of a 50:50 acetone−aqueous citrate solution (0.04 M) were added. The mixture stood for 2 h at ambient temperature and was then passed through a 0.45-μm nylon filter.

Pheophorbides were obtained by using a chlorophyllase enzyme solution described below on the pheophytins substrate. Around 5 g of dry spinach leaf powder, dried according to the procedure above for chlorophyllides, was weighed on a glass Buchner filtration system with a round paper filter. All the glassware as well as the sample and 500 mL of acetone were kept in a freezer at −20 °C. Immediately after taking all the materials out of the freezer, the cold acetone was passed through the spinach leaf powder in the cold Büchner filtration system in order to remove the chlorophylls. Once the acetonic eluent became transparent, the sample was put in an oven at 37 °C for solvent evaporation. To 500 mg of the resulting powder was added 5 mL of neutralized standard pheophytin solution along with 5 mL of deionized water previously equilibrated to pH 8 with aqueous sodium hydroxide solution (0.1 N).

Pyrochlorophylls were obtained from the chlorophyll standard solution. Briefly, 10 mL of the chlorophyll standard solution was extracted with diethyl ether and the ether extract evaporated to dryness. The residue was dissolved in 20 mL of pyridine and heated under reflux in an oil bath at 100 °C for 2 h.[18] Pyridine was removed in a rotary evaporator, and 10 mL of an acetone−water 80:20 mixture was added. Pyropheophytins were prepared from the standard pheophytin solution using the same procedure with additional steps consisting of neutralization of the pheophytin solution with 0.1 M NaOH solution prior to evaporation. Pyropheophorbides were prepared from the pheophorbide solution using the protocol described above and time allotted to turn the chlorophylls into pyrochlorophylls. Finally, pyrochlorphillides were prepared from the chlorophillide solution using the same procedure described, but in this chemical preparation, no heat was necessary for the reaction to occur.

To summarize, a solution with chlorophylls and all the synthesized derivatives was prepared. The more acidic solutions (i.e., pheophytins and pheophorbides) were neutralized by a 0.1 N NaOH solution so that the chlorophylls and other derivatives with chelated magnesium remained stable. All solutions prepared were kept at −20 °C.

Extraction of Chlorophylls and Their Derivatives from Culinary Herb Samples. Approximately 1 g of fresh or dry herb was weighed into a 150 mL beaker to which 100 mL of an 80:20 acetone−sodium citrate solution (0.1M) was added. The mixture was homogenized for 8 min at medium speed. The homogenate was filtered on a nylon filter prior to chromatographic analysis. The mixture volume lost upon extraction was accurately measured for adjustment in the final calculations. A 10-fold dilution can be necessary for samples of fresh herbs or herbs subjected to efficient color-protective dehydration processes.

Preparation of the Stock and Working Solutions for External Calibration. Chlorophyll and pheophytin concentrations in the stock solutions were determined according to Vernon.[19] The pheophytin stock solution was neutralized with 0.1 M NaOH. Five working solutions containing chlorophylls and pheophytins (between 1 and 20 mg/L for chlorophyll a and pheophytin a) were prepared by mixing the stock solutions and dilution with acetone−water (80:20). The calibration curves were generated by plotting the five concentrations of each compound against peak area measured at 654 nm. A working solution was injected every five sample injections to check for drift effect on the calibration. Final results of pigment levels in herbs were expressed in mol/g on dry wt basis; therefore, the moisture content was measured for every sample.

Analysis of Chlorophylls and Their Derivatives by HPLC-DAD-MS. A solvent system of acetone−methanol−0.5 M NH_4OAc was used to separate chlorophylls and their breakdown compounds (see Table 1). The injection volume was 20 μL.

Table 1. Solvent Composition Evolution of the Elution Phase During the HPLC-DAD Analysis

time	MeOH	ammonium acetate 0.5 M	acetone	flow (mL/min)
0	80	20	0	0.5
2	80	20	0	0.5
15	65	5	30	1
18	65	5	30	1.2
24	30	5	65	1.2
26	30	5	65	1.2
28	0	0	100	1.2
30	0	0	100	1.2

Chlorophylls and their various derivatives were identified by retention time and by comparison of the absorption spectra between 350 and 700 nm of unknown peak with those in the literature, as well as with reference standards obtained by synthesis.

In addition, the pigments were confirmed for their molecular weight ($[M + H]^+$) by a quadrupole MS in positive mode with a 500−1000 Da scanning range. The source temperature was at 500 °C, ion spray voltage at 5500 V, curtain gas at 30 psi, declustering potential at 125 V, and the entrance potential at 10 V.

Moisture Content Determination. For culinary aromatic herbs the recommended method to measure the moisture content is by distillation with toluene according to ISO 939:1980.

Chlorophylls and Derivatives Breakdown: PCA and PCR Analyses. Using the experimental protocol described in this paper, chlorophylls and their derivatives were detected and quantified in 50 samples of diverse culinary herbs prepared fresh and after five different drying treatments described below. Herb samples included tarragon, coriander, parsley, dill, chive, oregano, mint, basil, and marjoram. All the samples were independent of each other. Drying treatments were the following: no process (fresh), sun-drying, freeze-drying, oven-drying, DP1 and DP2. The data (average of duplicate analyses) was evaluated using principal component analysis (PCA) and principal component regression (PCR) techniques.

RESULTS AND DISCUSSION

Extraction of Chlorophylls and Their Derivatives from Culinary Aromatic Herb Samples. An experimental design was carried out to optimize the parameters ruling the pigment extraction yields from fresh and dried herbs by means of an Ultra-Turrax homogenizer. The extraction mixture contained a 0.1 M sodium citrate solution to maintain a neutral pH while protecting the pigments against oxidation. The extraction time and the homogenizer rate of revolution were two key parameters. Other important factors were the extraction solution temperature and total molar contents of chlorophylls and their derivatives. The experimental design showed a strong interaction between the key parameters. For example, regardless the type of culinary herb or whether it was fresh or dry, the final optimized parameters were found to be an extraction time of 8 min at medium rotation speed.

Preparation of the Stock and Working Solutions for External Calibration. Internal standards like Fast green FCF or zinc-phtalocyanine were used in some publications with varying levels of success.[12,20] Chlorophyll and derivate quantitation was also realized using external calibration.[7]

The UV−vis absorption properties of chlorophylls and their derivatives can be attributed to three parameters: the primary porphyrin ring structure, the presence of chelated magnesium at its center, and the type of functional group or constituent at C7. With that in mind we could approximate to first order that both epimerization and decarboxymethylation at C13[2], and also

phytol loss at C17, do not affect the global UV−vis spectra of chlorophyll derivatives because $C13^2$ and C17 are not part of the porphyrin ring. Consequently, there are 4 types of UV−vis spectra: two groups for the green pigments (chlorophyll, chlorophyllide, pyrochlorophyllide, and pyrochlorophyll) according to the substituent at C7 (a or b) and likewise two groups for the olive-brown pigments (pheophytin, pheophorbide, pyropheophytin, and pyropheophorbide, a or b). This first approximation also takes into consideration the slight effect on the absorption spectra of the elution phase composition change throughout the chromatographic analysis. This effect is very low for the visible part of the spectrum, that is, why 654 nm was chosen as the quantitation wavelength for all green and olive-brown pigments. Furthermore, at this wavelength the carotenoid interferences are also eliminated. An external calibration method was used to quantitate each pigment. The two groups of green pigments were quantified using the calibration curve of chlorophyll a and b. Likewise, the 2 groups of olive-brown pigments were quantified using the calibration curves of pheophytin a and b.

With working solutions containing known concentrations of chlorophylls a and b and pheophytins a and b, 5 injections were sufficient to cover the quantitation of all 24 chlorophylls and derivatives. The calibration curves showed a high linearity, with a correlation coefficient ≥0.9993, as long as the concentration was below 25 mg/L (see Table 2).

Table 2. Analytical Parameters of Calibration Regression Curves

	chlorophyll a	chlorophyll b	pheophytin a	pheophytin b
conc range (mg/L)	1−19	05−10	1−22	0.5−13
slope ± SD (n = 6) (1×10^3 AU)[a]	315 ± 10	139 ± 6	140 ± 7	69 ± 4
r^2 (av, n = 6)	0.9993	0.9995	0.9997	0.9998

[a]AU = area units.

The final results of pigment contents in fresh or dried culinary herbs were expressed in mol/g on dry weight basis. In order to assess the global level of green pigment breakdown and to further estimate the visual color appearance of the herb product, the molar percentage of the green pigments was calculated (see equation below), with the remainder of the components representing the percentage of the olive-brown pigments.

$$\%\text{green pigments} = 100 \times \frac{\sum_{i=a,a'}^{b,b'} (\text{chlorophyll}_i + \text{pyrochlorophyll}_i + \text{chlorophyllide}_i + \text{pyrochlorophillide}_i)}{\sum_{i=a,a'}^{b,b'} (\text{chlorophyll}_i \text{ and derivates}_i)}$$

Analysis of Chlorophylls and Their Derivatives by HPLC-DAD-MS. In order to separate chlorophylls and their polar and nonpolar colored derivatives, a combination of two gradient mobile phases reported in previous studies was utilized.[9,12] Polar derivatives were separated using a solvent system of methanol/aqueous ammonium acetate (0.5 M).[9] These polar pigments are acidic pigments with pK_a ranging from 2 to 4.[21] Ammonium acetate was used in HPLC analysis because it provides excellent results in the separation of highly polar acidic chlorophyll derivatives. In addition, it buffers the elution phase at a pH around 7 and thus reduces the likelihood of porphyrin rings losing their chelating magnesium during analysis. Nonpolar derivatives were separated using a solvent system of methanol/acetone.[12]

Figure 2 shows the HPLC chromatogram of chlorophylls and their derivatives from a standard solution by employing a ternary solvent system of acetone/methanol/ammonium acetate (0.5 M). Following the described gradient program, good resolution of the chlorophyll derivative peaks was achieved.

All the peaks showing chlorophyll-like or pheophytin-like spectra were checked for their molecular weight by LC-MS. With a single injection and a 28 min run, a total of 24 pigments could be detected. The retention time increased in the order presented in Figure 2 in agreement with results reported previously for chlorophillide/pheophorbide/chlorophyll/pheophytin.[22] We noticed different clusters of peaks on the pigment chromatogram. Each cluster contains the peak of the main pigment (chlorophyll or chlorophillide or pheophytin or pheophorbide, either a or b), the peak of its epimer form, and the peak of the -pyro form. The -pyro form elutes last in each cluster likely due to the elimination of the carbomethoxy group. This slightly reduces the polarity of the pigments resulting in greater interactions with the C18 stationary phase, as well as a lower solubility in the eluent.[23] Therefore, the entire chromatogram in Figure 2 shows eight clusters of 3 peaks that make the final identification easier.

Chlorophylls and Derivatives Breakdown: PCA Analyses. In our study we decided to quantitate chlorophylls and their colored derivatives in fresh and dried culinary aromatic herbs subjected to different dehydration processes. There were 50 different herb samples. Of the 24 chlorophylls and their derivatives detected and identified by our method, only 14 of them were found in the different herb samples, namely the following: chlorophyll a and a′, chlorophyll b and b′, chlorophyllide a, pheophytin a and a′, pheophytin b and b′, pheophorbide a, pyrochlorophyll a and b, pyropheophytine a and b. No compounds were identified by MS as hydroxychlorophyll or hydroxypheophytin with a hydroxyl group at $C13^2$.

The raw data are presented in Table 3, and they were used to build Table 4. Chlorophyllide a and pheophorbide a were rarely found in the 50 samples (only in samples 3 and 1, respectively). Chlorophillide a appeared after a low-temperature blanching step on fresh herbs prior to dehydration which allowed the chlorophyllase to be activated. Chlorophyll epimers were present in highest concentrations in the samples with oven- and sun-drying processes. Table 4 shows that chlorophyll a′/chlorophyll a ratio is generally lower than chlorophyll b′/chlorophyll b ratio. Similar results were reported previously in cooked wet spinach.[20] In our study, these epimer ratios varied noticeably according to the type of treatment. Surprisingly, the pheophytin a′/pheophytin a ratio values were less dependent on the type of process used for drying the herbs. Pheophytin b′/pheophytin b ratio values (when detected) were high, showing that pheophytin b is subjected to a strong epimerization in every type of process.

In the plants with less degraded chlorophylls (freeze-drying, DP1, and DP2 treatments), chlorophyll a was in higher amounts than chlorophyll b, which was also mentioned elsewhere.[13]

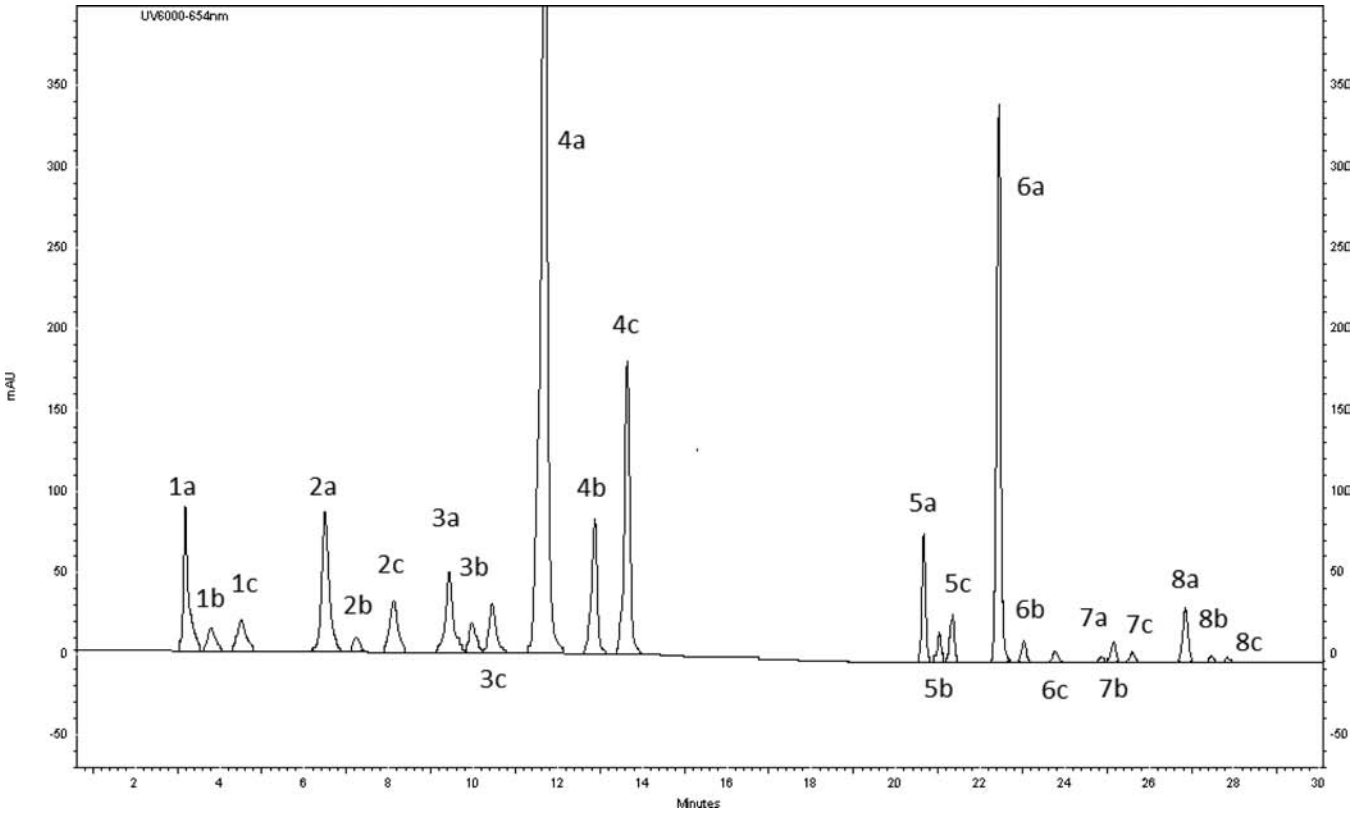

Figure 2. HPLC chromatogram of a mixture of chlorophylls and their colored derivatives. Chromatographic conditions described in the text. Peaks: 1a,b = chlorophyllide b,b′; 1c = pyrochlorophyllide b; 2a,b = chlorophyllide a,a′; 2c = pyrochlorophyllide a; 3a,b = pheophorbide b,b′; 3c = pyropheophorbide b; 4a,b = pheophorbide a,a′; 4c = pyropheophorbide a; 5a,b = chlorophyll b,b′; 5c = pyrochlorophyll b; 6a,b = chlorophyll a,a′; 6c = pyrochlorophyll a; 7a,b = pheophytin b,b′; 7c = pyropheophytin b; 8a,b = pheophytin a,a′; 8c = pyropheophytin a.

Pyrochlorophyll b was found in most of the samples, even in fresh herb samples, and the only degradation pathway available is from chlorophyll b. Fresh plants were kept several days in a refrigerator prior to analysis, and the degradation process may have already started, which could explain the presence of pyrochlorophyll b. This phenomenon has not been described elsewhere. As for pyrochlorophyll a, it has not been detected in fresh herb samples, nor after the DP2 process, the quickest process.

The presence of pheophytin b was not observed in fresh herbs or in DP2 processed samples. In the other processes, this pigment was not present all the time, except for samples subjected to sun-drying. Unlike pheophytin b, pheophytin a was detected in all 50 samples. It is well-known from numerous reports[11] that chlorophyll a is more susceptible to forming pheophytin than chlorophyll b. This slower conversion of chlorophyll b to pheophytin presents two aspects: on one hand, after the long sun-drying process that produces the highest level of chlorophyll breakdown, the concentration of chlorophyll a became lower than that of chlorophyll b. On the other hand, it allows an easier conversion of chlorophyll b into pyrochlorophyll b through decarboxymethylation, which is thus the dominant breakdown reaction for chlorophyll b. This degradation pathway is confirmed by looking at the pyrochlorophyll b/chlorophyll b + b′ ratio (Table 4) which is much higher than the pyrochlorophyll a/chlorophyll a + a′ ratio, except in the sun-drying process. Pyrochlorophyll b content was generally found to be higher than that of pyrochlorophyll a, except in the sun-dried herb samples. This unique sun-drying exception can be explained: it is a long process leading to further pigment degradation toward the appearance of pyropheophytins, with pyrochlorophylls and pheophytins as potential precursors. In that case, pyrochlorophyll b turns into pyropheophytin b more rapidly whereas pyrochlorophyll a tends to accumulate. This means that pheophytin b tends to accumulate as well, allowing an important conversion into pheophytin b′ that is well-observed for herbs subjected to sun-drying processes (Table 3). However, the presence of pyropheophytin a in measurable amounts, especially in sun-dried herb samples, suggests that it might have been formed from pheophytin a. These findings demonstrate that pyropheophytins cannot only be formed under relative severe heat treatment as previously described,[11] but also during long mild drying processes such as sun-drying. In conclusion, the total of pyroderivatives in the b series (pyrochlorophyll b + pyropheophytin b) is always higher than the total of pyroderivatives in the a series and contrary to what happens to chlorophylls a and b. This kinetic tendency in the pyroderivative formation has not been described elsewhere to date. Figure 3 attempts to describe the degradation pathways and the novel kinetic qualitative tendencies described above. Normally, the loss of Mg^{2+} ion is supposed to be the primary and direct way of chlorophyll breakdown, but in the case of dried aromatic herbs both Mg^{2+} removal and decarboxymethylation can be dominant reactions, depending on whether one considers the a or b chlorophyll form. The primary focus of literature references on chlorophyll degradation pathways includes wet plants (leaf senescence, cooking processes, fruit ripening) or vegetable oils.[2−11,16,17,19,20] For dried culinary herbs, the dehydration process is done rapidly after harvesting, and thus,

[a]% green pigments = percentage of total green pigments.

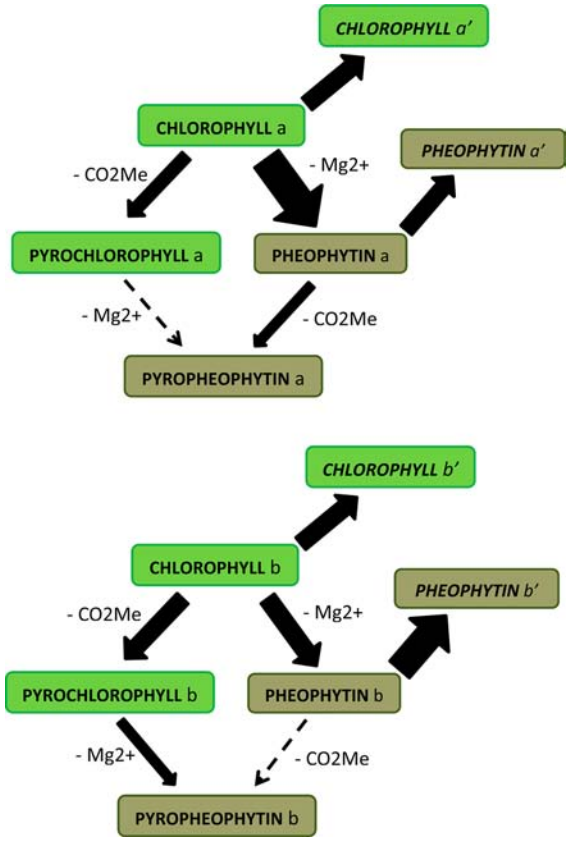

Figure 3. Chlorophyll a and b degradation pathways in culinary aromatic herbs during drying processes. Arrow width is proportional to the qualitative importance of the degradation pathway kinetic.

the final water activity ranges from 0.3 to 0.55. This low range significantly reduces the effect of enzymatic reactions involved in Mg-dechelatase, chlorophyllase, or enzymatic reduction of chlorophyll b.[24] Consequently, no chlorophyllide was detected in this study except in one product subjected to a blanching step prior to dehydration. Moreover, neither pyrochlorophyllides nor pyropheophorbides were detected, because both need the chlorophyllase action to occur somewhere in the chlorophyll degradation process. The chlorophyll catabolic pathway is stopped;[24] a simpler chemical degradation occurs instead. The raw data in Tables 3 and 4 and illustrated pathways in Figure 3 show how different dry culinary herb species chosen independently of each other can show similar behavior with respect to noncatabolic chlorophyll degradation. In those conditions, the type of process became an important factor for differentiation.

The raw data were evaluated by PCA, which is mainly a statistical treatment of the data. The objective was to present a maximum of information by converting a set of observations (herb samples) of possibly correlated variables (pigments) into a set of values of orthogonal variables called principal components. As explained above, the use of these variables did not aim to differentiate the types of dried herbs, but rather the types of processes they were subjected to. The first two components represent the plane of best fit through the data. As PCA is sensitive to the relative scaling of the original variables, observation values expressed in mol/g on dry wt basis were reduced and centered prior to calculations. In our case, there were 14 variables composed of the 14 detected chlorophylls and derivatives leading to a 14D space composed of the final orthogonal principal components. The 2D (F1, F2) principal plane with the orthogonal projections of the 14 initial variables as well as the scatterplot diagram with scores of the observations are displayed in Figure 4 showing an interesting cumulative variability: F1 and F2 axes account for 57% of the total variability, and the following principal components show Eigenvalues below 1.15.

On principal plane with the variable projections (Figure 4A), most of the variables are away from the plane center meaning that they were not that distorted by the projection. Chlorophyllide a and pheophorbide a have a low contribution to F1 and F2, but they were rarely found in the 50 samples. Apart from pyrochlorophyll a, all the relevant variable projections related to green pigments are on the left half of the plane. All the relevant variable projections related to olive-brown pigments are on the right half. This suggests that globally green and olive-brown pigments are negatively correlated along the F1 axis. In practical terms, it reflects the fact that a drop in the green pigment concentrations leads to an increase of the brown-olive ones. As pyrochlorophyll a tends to accumulate, its behavior is like that of the olive-brown pigments. That is why its projection is atypically in the right half of the (F1, F2) plane. Chlorophyll epimer variables (a′ and b′) point upward on the principal plane suggesting that samples subjected to mild processes will be placed rather at the top of this plane.

On the scatterplot (Figure 4B), observations coming from the same drying treatments were plotted so that they form clusters. As mentioned for the variable projection directions, fresh and freeze-dried plants, as well as the group of plants subjected to treatment DP2 (which is supposed to protect the green color effectively), are in the left half of the (F1, F2) plane considered as the region where green pigments are well-preserved. Treatment DP1 and oven-drying are more central, and sun-drying on the right part is driven by the olive-brown pigment variables. The freeze-drying cluster extends toward the upper-left portion of the (F1, F2) plane in the direction of the pyrochlorophyll b projection. Consequently, this process produces the highest levels of pyrochlorophyll b.

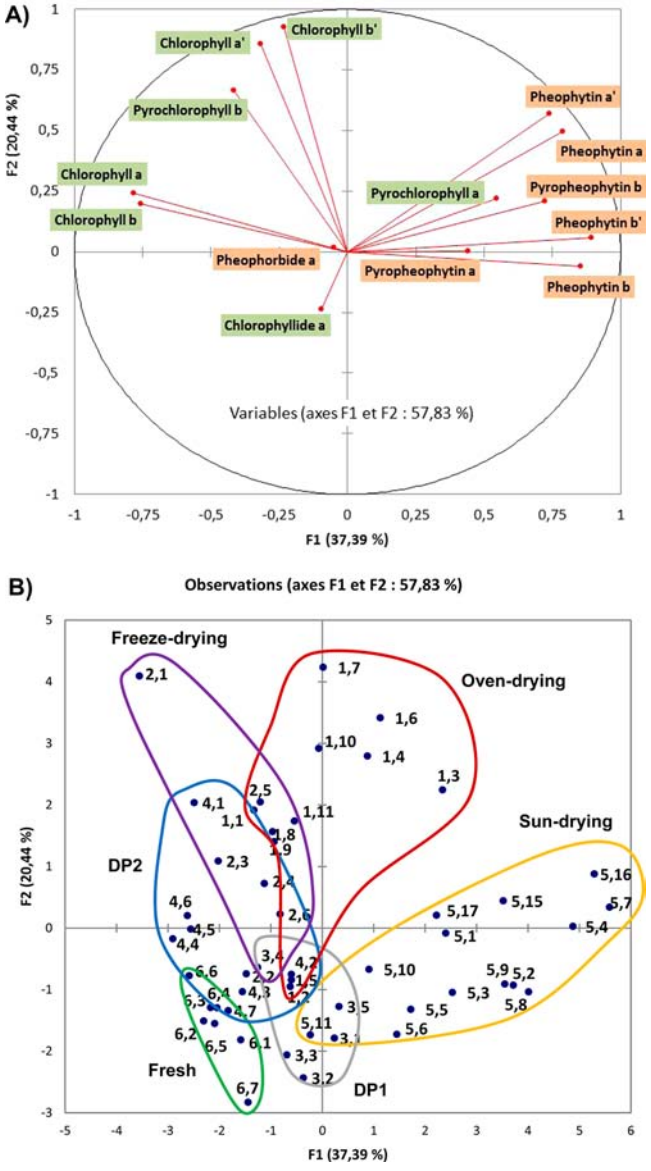

Figure 4. Projection of the pigment variables on (A) the principal (F1, F2) plane, and (B) scatterplot of the culinary herb samples on the first 2 principal component plane.

Oven-drying and sun-drying clusters are the most scattered groups of observations but elongate in different directions. For oven drying, higher energy is brought to the product in a medium period of time. High energy and medium time preserve relatively well the green color; that is why the cluster of oven-drying observations tends to extend toward the upper part of the (F1, F2) plane, the direction between the chlorophyll epimer and pheophytin projections. Thus, herbs subjected to this process showed that chlorophylls had been partly turned to both other green pigments and olive-brown pigments. The oven-drying cluster is scattered, presumably due to the impact of the oven temperature parameter on the color result.

As for sun-drying, a process with low energy and long delay time impacting chlorophyll breakdown, samples are situated on the right part of the plane. That is the consequence of a massive chlorophyll conversion into olive-brown derivatives such as pheophytin a, pheophytin b and b′ and moderately pheophytin a′, pyropheophytin a and pyrochlorophylls. The efficiency of this process on color preservation depends on numerous factors: cloudy or sunny conditions during drying, windy or calm, exposure to the sun light for long or short periods of time, high, low or moderate temperature fluctuations and, finally, whether or not a a pretedding step is included. The variability of these parameters can vary greatly and make the sun-drying cluster large.

On the F1 axis representing the greenness scale, the DP2 process (high energy, short time) cluster is the closest to the fresh herb cluster and elongates toward the pyrochlorophyll b and chlorophyll epimer in direction. Very few olive-brown pigments are thus produced.

Chlorophylls and Derivatives Breakdown: PCR Analyses. After the PCA treatment of the data we chose to extract quantitative information from the results. It was interesting to test if quantitative information could be forecasted for unknowns from the available measures. In that case, PCR (principal component regression) can help, since it calculates a single principal component regression model using the given number of principal components to predict unknown quantitative information (response) from available measurements (observations). The calculated orthogonal principal components from the PCA data were used to run the PCR model. Herb surface color was chosen as an interesting response for variables and especially the LCh° colorometric space according to three axes: lightness (L), chroma or saturation (C), and hue ($h°$). This colorometric space describes how well the human eye can perceive the different colors.

Unfortunately, no significant correlation was found between the variables and the 3 colorimetric responses. A slight linearity was observed for the hue $h°$ response. Additionally, the relationship between hue and the total green pigment content (on dry wt basis, mol/g) was plotted. Hue values ranged from 85° to 128°, which correspond to the yellow-green part of colorimetric space. The curve $h°$ as a function of total green pigment content reached rapidly an asymptote at $h° = 128°$ for contents above 4×10^{-7} mol/g. This interesting result shows that no surface color improvement can be realized by having greater concentrations of green pigments. It also tells us that below 4×10^{-7} mol/g the surface green color rapidly worsens.

Color Degradation Ladder. In order to understand the tendency for chlorophyll to degrade toward olive-brown derivatives, a degradation ladder was designed. The idea was to find a sole and easy-to-use indicator using the complex set of chlorophyll and derivative results in order to assess the plant material color after processing. This ladder was thus based on the percentage of total green pigments present (presented earlier in this paper), while understanding that green chlorophyll derivatives do not bring about any change in color insofar as the light absorption properties remain globally the same. This ladder was divided into four categories. Category limits were fixed according to the visual color estimation of each sample. Figure 5 shows the ladder visually and allows one to check whether the processing and treatment of a herb has an impact on the visual quality of the final product when dried. The various herb process treatments from Table 4 were evaluated with the ladder definitions. Fresh herbs, freeze-dried herbs, and DP2 treatment (high energy short time) of herbs belong to the category "no significant impact" with percentage of total green pigments above 90% on average with a well-preserved green appearance of the dried herb samples. Oven-drying (high energy medium time) and DP1 treatment (low energy long time) belong to the "low impact" category, with a percentage ranging from 65% to 90%. Sun-drying (low energy long time) falls into the fourth

dx.doi.org/10.1021/jf4054947 | J. Agric. Food Chem. 2014, 62, 1926−1935

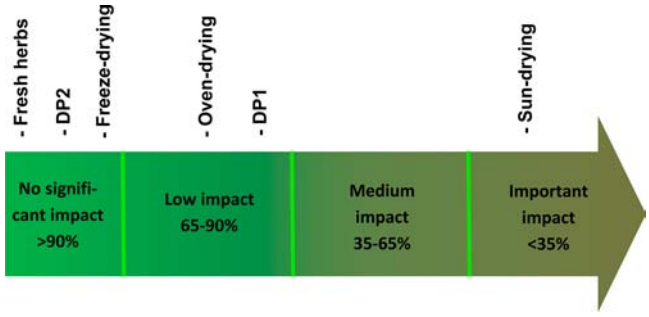

Figure 5. Color degradation ladder of culinary aromatic herbs. The percentages are the level of total green pigments (figure colors are arbitrary).

category, named "important impact", and characterized by an average percentage below 35%. Sun-drying is a commonly used process to dry herbs; however, the technique greatly impacts the global herb color.

promising method for natural compounds extraction, there are still some limitations (security, appropriate reactors, and craft determination, et al.) for its industrial applications. Therefore, further fundamental study on natural compounds extraction by MAE method is needed for large scale production.

In the present work, water-soluble pigments were quickly obtained from *C. mollissima* shells by water/ethanol (1:1, v/v) with microwave-assisted extraction, and purified by a two-step precipitation for the first time. The chemical composition and physical properties of the new pigments were subsequently determined by a combination method of spectroscopic techniques (UV, FT-IR, ^{13}C NMR), elemental analysis, and chromatographic techniques (HPAEC, GPC). Furthermore, the physical properties, DPPH radical scavenging capacity, antimicrobial activity, and the acute oral toxicity test were also investigated. The comprehensive and systematic knowledge of the new pigments from *C. mollissima* shells will help to maximize the exploitation of these agricultural residues for possible use in food additives production.

MATERIALS AND METHODS

Materials. Ten kg of *C. mollissima* fruit was collected from Qianxi, Hebei province, China. After peeling, about 1.47 kg of *C. mollissima* shells was obtained. The shells were washed extensively with distilled water. After drying at 55 °C for 16 h in an oven, the shells were smashed in an FZ120 plant shredder (Truelab, Shanghai, China), then sieved to 20−40 mesh. The resulting powder was stored in sealed bags (under N_2 atmosphere) at room temperature. All chemicals used were of analytical grade and purchased from Sigma Chemical Co. (Beijing, China).

Extraction and Purification of Pigments. The extraction and purification procedures of pigments are shown in Figure 1. MAE experiments were performed on an Ethos T microwave extractor (Milestone, Sorisole, Italy) with a maximum delivered power of 600 W at 70 °C for 30 min. Briefly, *C. mollissima* shell powder was submitted to aqueous ethanol/water (1:1, v/v) in a 2-L round-bottom flask with a solid to liquid ratio of 1:20 (g/mL) under magnetic stirring at 50% of nominal power. After centrifugation, 1500 mL of crude pigments supernatant was obtained and evaporated at 60 °C under reduced pressure (−0.09 MPa) until the final volume was 50 mL. The concentrated solution was then purified by a two-step precipitation method. First, the concentrated solution was poured into 3 volumes of 95% ethanol to remove hemicelluloses by precipitation. Second, the above solution was concentrated again and then the solubilized lignin could be removed by precipitating the solution into 10 volumes of deionized water.[15,16] After the two-step precipitation, the pigments were redissolved in the solution of ethanol/water (1:1, v/v), and successively extracted by 3 volumes of organic solvents (ethyl acetates, petroleum ether) for three times to remove lipids.[17] Finally, the water layer was freeze-dried overnight.

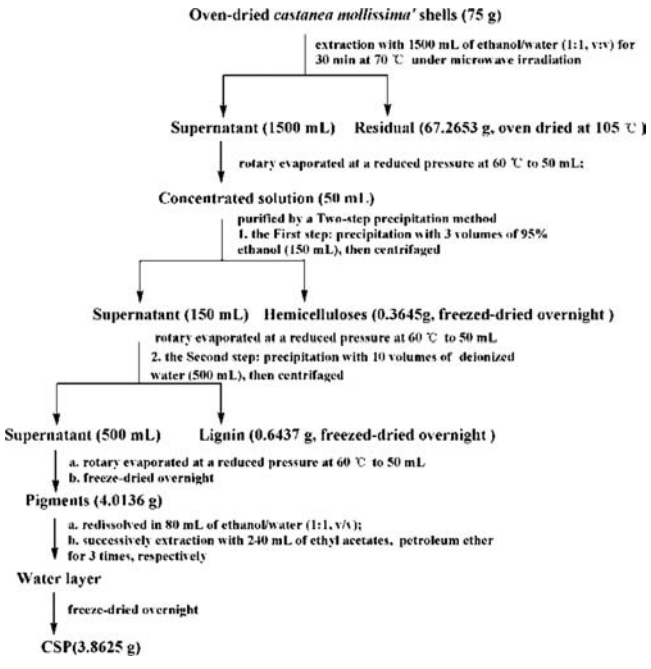

Figure 1. Extraction and purification procedures of CSP.

Chemical Composition and Structural Analysis. To analyze the associated sugars in pigments, sugar analyses were conducted by acid hydrolysis according to the procedures described in a previous paper.[18] Then the hydrolysate analyses were performed on a high-performance anion chromatography system (ICS3000, Dionex, Sunnyvale, CA) with pulsed amperometric detector and an ion exchange Carbopac PA-1 column (40 × 250 mm). The neutral sugars were separated in 18 mM NaOH (carbonate free and purged with nitrogen) with post column addition of 0.3 M NaOH at a rate of 0.5 mL/min. Run time was 45 min, followed by a 10-min elution with 0.2 M NaOH to wash the column and then a 15-min elution with 18 mM NaOH to reequilibrate the column. Calibration was performed with a standard solution of L-rhamnose, L-arabinose, L-glucose, L-galactose, D-mannose, and D-xylose. Measurements were conducted with two parallels, and reproducibility of the values was found within the range of 5%. The elemental composition of the pigments before and after acid hydrolysis was recorded on a Vario EL analyzer (Elementar Analysensysteme GmbH, Hanau, Germany). Infrared spectra of pigments were collected on a Thermo Scientific Nicolet iN 10 FT-IR Microscopy instrument (Thermo Nicolet Corp., Madison, WI) equipped with a liquid nitrogen-cooled MCT detector. The weight-average (M_w) and number-average (M_n) molecular weights of the pigments were determined by Agilent1200 gel permeation chromatography (Agilent, Santa Clara, CSA) on a 300 mm × 7.7 mm i.d., 10 μm, PL aquagel−OH column of the same material (Agilent, England), calibrated with PL pullulan polysaccharide standards (peak average molecular weights of 783, 12 200, 100 000, 1 600 000 g/mol, Polymer Laboratories Ltd.). ^{13}C NMR spectra of the pigments were recorded on a Bruker AVIII 400 MHz spectrometer (Germany) instrument at 25 °C and chemical shifts were referenced to solvent signal. The preparation of 100 mg of CSP was carried out using 0.5 mL of DMSO-d_6 (δ_C 39.5). ^{13}C NMR spectra were obtained in the pulse FT mode (100.6 MHz). A 30° pulse angle, a 9.2-μs pulse width, 1.89-s delay time, and 1.36-s acquired time between scans were used. All chemical shifts were expressed in ppm (δ_C) from TMS.

Physical Properties Determination. The solubility and stability studies of the pigments were based on the previous literature with minor alterations.[19] The solubility in water and other common solvents (benzene, chloroform, diethyl ether, acetone, ethyl acetate, petroleum ether, hexane, methanol, ethanol, acetic acid, DMSO, and alkaline solutions) was investigated by adding 0.05 g of the pigments in 5 mL of solvents with stirring at 25 °C for 1 h, and standing for 1 h. As for the stability, 0.005 g/100 mL water/ethanol (1:1, v/v) solution was used for studying the pigment stability of temperature (25, 50, 75, and 100 °C), light (natural light, ultraviolet light, and dark), and different kinds of metal ions (Ca^{2+}, Cu^{2+}, Na^{+}, Zn^{2+}, Al^{3+}, Mg^{2+}, Fe^{3+}, and K^{+}). All absorption coefficients of samples were determined at λ_{max} by a UV 2300 spectrophotometer (Techcomp, Shanghai, China). All the determinations were carried out in triplicate. The results are expressed as mean values and standard deviation (SD). Analysis of variance (ANOVA) was performed by using the data analysis tools in Microsoft Excel 2007, and a least significant difference (LSD) test was used to determine the differences of means. P values less than 0.05 were considered to be statistically significant.

Antioxidant Activity of the Pigments. The pigments were reacted with a stable free radical, 2,2′-diphenyl-1-picrylhydrazyl radical (DPPH), to evaluate antioxidant activity.[20] The DPPH radical scavenging capacity was estimated using the reported method.[21] The antioxidant activity was expressed as a percentage of reduction of the

DPPH radical: radical scavenging rate (SC%) = [1 − (absorbance of sample)/(absorbance of control)] × 100%. For comparison, the DPPH radical scavenging capacity of synthetic antioxidant butylated hydroxytoluene (BHT, 0.5 mg/mL) and butylated hydroxyanisole (BHA, 0.5 mg/mL) was also tested. The DPPH solution with no CSP added was used as control. The EC_{50} value (mg extract/mL), an effective concentration at which 50% radical was scavenging, was also calculated. All tests were performed in triplicate.

Antimicrobial Activity of the Pigments. To evaluate the antimicrobial activity of CSP, disc-diffusion assay was carried out using 6-mm filter disc.[22] Gram-negative bacteria strain *Escherichia coli* (CMCC (B) 44103) and gram-positive bacteria strains *Streptomyces somaliensis* (NBRC 12916 (T)), *Staphylococcus aureus* (ATCC 25923), *Bacillus subtilis* (CGMCC 3376), and fungus *Penicillium oxalicum* (CGMCC 13428), and *Aspergillus japonicus* (ATCC 204480) used were kindly given by the Institute of Microbiology, Beijing Forestry University, Beijing, China. After culturing, the microorganisms were adjusted with sterile saline to a concentration of 1.0×10^7 to 10^9 cfu/mL. The suspension was added to the top of the agar plates and dissolved in Petri dishes (20 μL/agar plate) with solid agar. The filter paper discs with pigment solution (concentrations of 0.05, 0.10, and 0.15 g/mL, 20 μL/disc) were placed on agar plates. After 24 h of incubation for bacteria and 3−4 days of incubation for fungus at 28 °C, the diameters of the growth inhibition zones were measured. Additionally, the 5% aqueous phenol as a positive control and 50% aqueous ethanol and water as negative controls were used. All tests were done in triplicate.

Acute Oral Toxicity Test of the Pigments. The acute toxicity of the pigments was determined according to the U.S. Food and Drug Administration (FDA) guidelines for toxicity tests IV C 2.[23] Briefly, the animals were divided into four groups (two groups of male and two groups of female), and same-sex animals were housed together in groups of three at room temperature (20 ± 2 °C), 30−60% relative humidity, and 12 h light−dark cycle. Prior to testing, the animals were starved for 4 h. After fasting, 200 mg/mL of pigments suspension (single dose of 5 g/kg body weight) was administered orally to the experimental groups, while the vehicle control groups were given distilled water (10 mL/kg). Food and water were provided 2 h later. Symptoms of toxicity and mortality were observed for 14 days after the administration. On day 14, all mice were sacrificed and subjected to necropsies. Kunming mice (17.5−20.0 g) used in the tests were purchased from the Laboratory Animal Center of the Academy of Military Medical Sciences (Beijing, China) and allowed to acclimate for 1 week prior to beginning experiment. All procedures used in this experiment were compliant with the local ethics committee.

RESULTS AND DISCUSSION

Yield and Sugar Analysis. Conventionally, pigments can be obtained by extracting for several hours or overnight using hot water, bases, acids, or some organic solvents. Compared with traditional extractive methods, MAE has been considered as an efficient and rapid process to extract pigments or antioxidants from plants with higher yield.[24] In this study, the polar ethanol/water (1:1, v/v) and the temperature of 70 °C accelerated the mass transfer of water-soluble pigments from chestnut shells. A two-step (by 95% ethanol, and water subsequently) precipitation method was first applied to remove hemicelluloses (0.3645 g/75 g dry weight) and lignin (0.6437 g/75 g) from the pigments. After purification, the total yield of pigments was 3.8625 g/75 g, which was a little higher than traditional extraction for 36 h by aqueous alkaline (Fr. 3, a yield of 2.7 g/100 g from chestnut shells), but much lower than that from tea leaves under the same condition (about 29%).[5,25] This phenomenon might be the result of severe purification and the high level of lignification of chestnut shells.

Table 1. Average Neutral Sugar Contents (%) (± 3%)[a] of CSP

	CSP-1 (%)	CSP-2 (%)	average (%)
ara	4.35	4.23	4.29
gal	1.69	1.75	1.72
glu	16.23	15.58	15.9
xyl	0.99	0.38	0.68
total	23.26	21.94	22.6

[a]Pooled standard error.

The sugar analysis of CSP was applied to estimate the associated neutral sugars. It is well-known that pigments are readily bound to proteins, polysaccharides, and lipids. To figure out the associated polysaccharides, CSP was hydrolyzed by acid and analyzed through HPAEC. The results of sugar analysis are listed in Table 1. Results showed that the total amount of the neutral sugars in CSP was 22.6%. The sugars in the isolated pigments demonstrated a predominance of glucose (70.35%), followed by arabinose, galactose, and xylose. This suggested that the main associated monosaccharide in CSP was glucose and it might attach to pigments to some extent.

Table 2. Elemental Composition and Molar Ratio of CSP

	elemental composition (wt%)				molar ratio		
	C	H	O	N	N/C	H/C	O/C
P1[a]	46.00	5.43	47.62	0.95	0.018	1.42	0.78
P2[b]	56.15	4.17	39.68	0	0	0.89	0.53

[a]The original CSP. [b]CSP after acid hydrolysis.

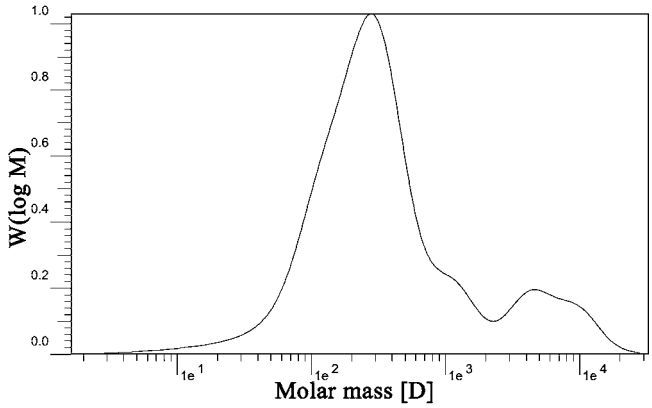

Figure 2. Actual gel permeation chromatograms of CSP.

Elemental Composition. The average elemental compositions for the pigments before (P1) and after (P2) acid hydrolysis are presented in Table 2. As noted, the original elemental composition of P1 was C = 46.00%, N = 0.95%, H = 5.43%, O = 47.62%, and the C element content increased while N element was in too trace a concentration to be detected after acid hydrolysis (P2). The H/C ratio (1.42) in P1 was high, which reflected a relatively high content of aliphatic chains. The low content of N element and N/C ratio in P1 suggested that the content of bounding protein was low and was comparable with the deproteinated samples extracted by alkaline.[5] In addition, a high ratio of O/C showed a high degree of oxygen substitution in the pigments, especially the bounding glycosides. This was in line with the sugar analysis aforementioned. After acid hydrolysis, both H/C and O/C ratios were decreased, suggesting that the linked sugars were almost removed during the hydrolysis. As the ether bonds in

Figure 3. FT-IR spectrum of CSP.

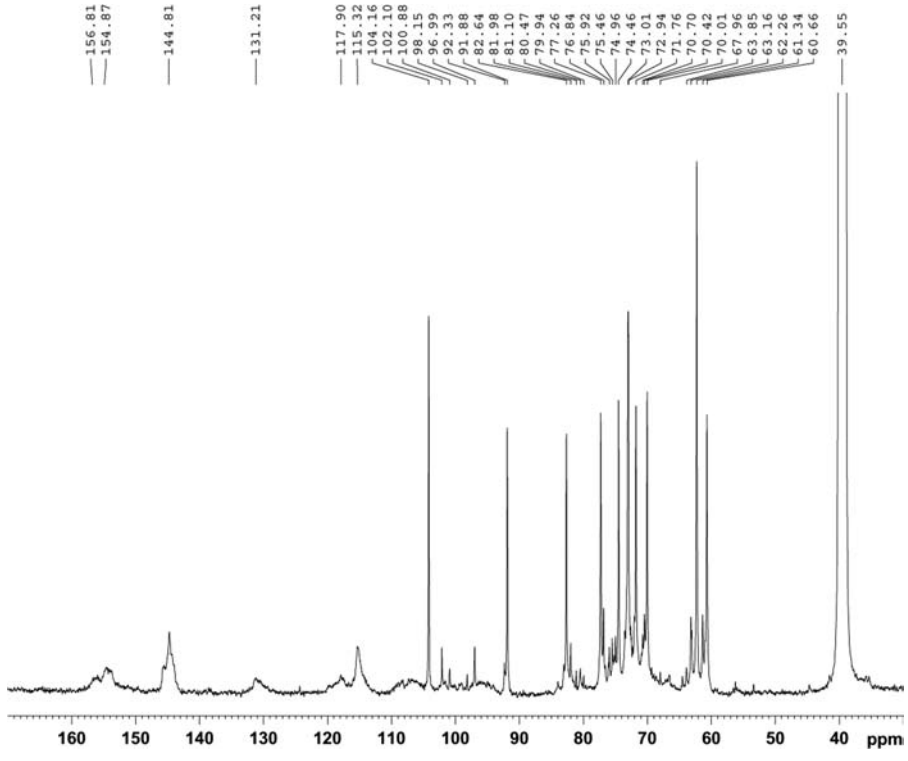

Figure 4. ^{13}C NMR spectrum (in DMSO-d_6) of CSP.

compounds are apt to cleave by acid, this probably inferred that the associated carbohydrates were attached to pigments via ether bonds. Furthermore, the disappearance of N element in P2 suggested the extracted pigment was lacking chlorophyll *a*, betacyanin, phycocyanobilin, or rubropunctamine, which are relatively rich in N element.[12]

Molecular Weight Distributions. The values of the weight-average (M_w) and number-average (M_n) molecular weights, estimated from GPC curves, and polydispersity indexes (M_w/M_n, PI) of the pigments extracted from chestnut's shells are shown in Figure 2. The M_w of pigments from chestnut shells was 1240 g/mol with a PI of 8.25, indicating an inhomogeneous molecular weight distribution of CSP.

FT-IR Analysis. FT-IR spectroscopy provides information on the main functional groups in the pigment structure. The FT-IR spectrum of the pigments is illustrated in Figure 3. As shown, a broad band at 3450 cm^{-1}, which is attributed to stretching vibrations of phenolic OH group, was evidently distinguished. The peak at 1442 cm^{-1} was indicative of a strong aliphatic character.[26] The 1607 cm^{-1} band was assigned to aromatic C═C stretching. The 1047 cm^{-1} band attributing to C−O stretching of polysaccharides suggested a certain amount of glycosidic bonds in the pigments. Moreover, the absorption peak at 1280 cm^{-1} represents bending vibration of hydroxyl.[27] The results of FT-IR spectrum demonstrated a certain amount of aliphatic chains in the pigments structure, accompanying OH

[a]Signals were assigned by comparison with the literature.[20,23,36−40]

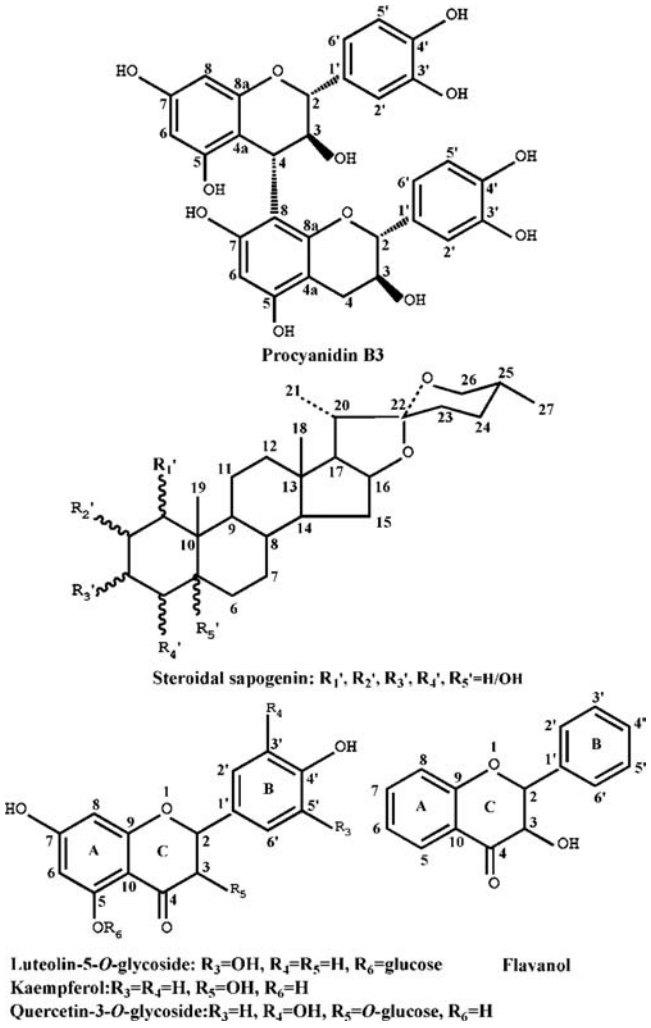

Figure 5. Main components of CSP, involving procyanidin B3, flavanol, kaempferol, quercetin, luteolin, and steroidal sapogenins identified by ^{13}C NMR.

and C−O groups. This was supported by the data of the elemental analysis.

^{13}C NMR Analysis. Application of ^{13}C NMR technique allows quick qualitative determination of different components in pigments. To further investigate the structural features and the main components in pigments, the pigments were analyzed by solution-state ^{13}C NMR. The ^{13}C NMR spectrum of the pigments is shown in Figure 4. The spectrum can be divided into aliphatic (δ_C 20−90) and aromatic (δ_C 90−160) regions.[28] The main signals in the ^{13}C NMR spectrum were assigned by comparison with the published literatures, and are listed in Table 3; the main components are depicted in Figure 5.[28−35]

The upfield signals ranging from δ_C 20 to 90 were due to the aliphatic carbons in pigments, which mainly resulted from the associated sugars and some micromolecule substances. As can be seen, Figure 4 apparently showed the spectral characteristic of sugars in this region. Based on the previous publications, the signals at δ_C 75.5, 76.8, 70.7, 77.3, 61.3 were assigned to carbon atoms 2, 3, 4, 5, and 6 in β-glucose, respectively.[30] The signals for atoms 5 and atoms 4 of xylose were discovered at δ_C 62.3 and 70.0. Signals resulted from α-galactose could be detected at δ_C 70.4.[31] Among these, signals from the β-glucose could be seen at higher contour levels, which indicates a higher amount of β-glucose in CSP. Weak signals at 102.1, 74.5, 75.9, and 63.8 ppm, which are assigned respectively to C-1, C-3, C-4, and C-5 positions of the arabinoxylan, suggested that the associated arabinose in CSP appeared in the form of arabinoxylan. Above all, β-glucose was the most predominant in CSP, followed by similar amounts of arabinose, xylose, and galactose, which was in agreement with the results obtained by sugar analysis. In addition, some interglycosidic linkages such as phenolic glycosides were also recognized in the sugar region of the spectrum. It has been reported that two signals at δ_C 79.9 and 74.5 are assigned to phenolic glycosides.[32] The most important glycosides found in the CSP might be flavonoids-*O*-glycosides, such as quercetin-3-*O*-glycoside, which had strong signals at δ_C 77.3, 76.8, 74.5, 70.7, 70.4, 68, and 61.3 in the sugar region.[33] Furthermore, some micromolecule substances were also distinguished. Interestingly, flavanoid procyanidin B3 (condensed tannin) was also revealed by the signals at 82.6, 82.0, 73.0, 72.9, and 68.0 ppm in this region.[28] It could be concluded that the condensed tannins in *C. mollissima* shells could be extracted by aqueous ethanol. Except for the flavonoids, signals at 81.1 and 63.2 ppm could be probably assigned to 5β-steroidal sapogenin.[29]

The aromatic region of the spectrum gave more useful information about different groups of flavonoids and some micromolecular substances present in the pigments. Most of the downfield signals at δ_C 156.8, 154.9, 144.8, 131.2, and 102.1, are caused by C-5, C-7, C-3′, C-1′, and C-4a positions of

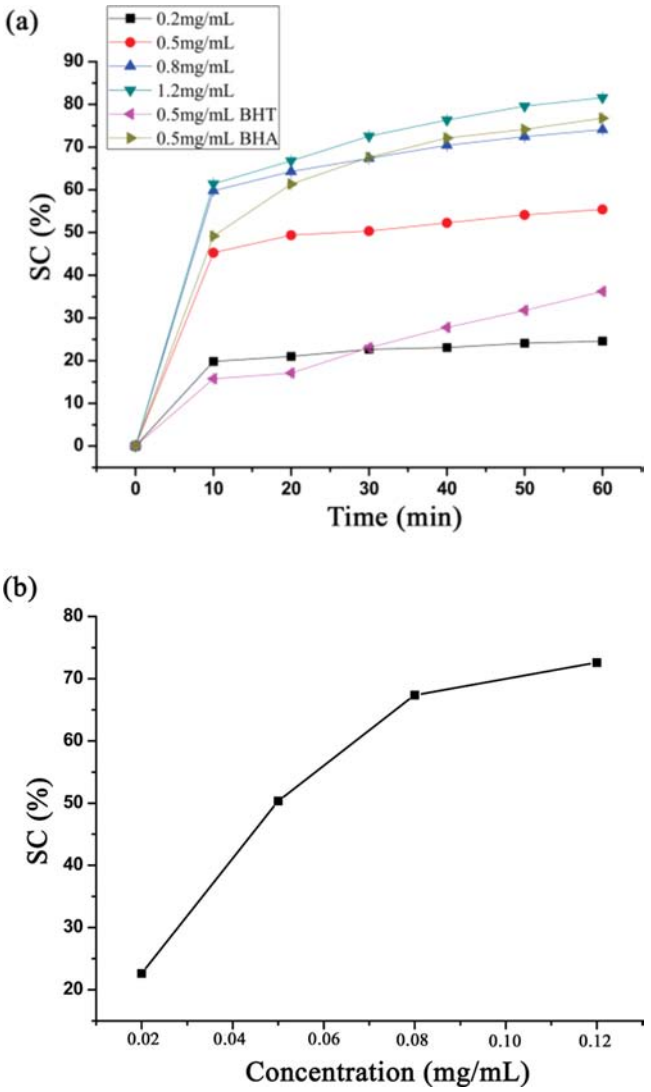

Figure 6. (a) Scavenging abilities of different concentrations of CSP, BHT (0.5 mg/mL), and BHA (0.5 mg/mL) on DPPH radical with increasing time. (b) DPPH radical scavenging rate of CSP with increasing concentration when the mixture was treated for 30 min. Error bars represent standard deviation of the means (n = 3); $P \leq 0.05$.

the procyanidin B3, respectively.[28] As for quercetin-3-*O*-glycoside, signals in this region were detected at δ_C 156.8, 144.8, 115.3, 104.2, 100.8, and 98.1. In addition, the luteolin-5-*O*-glycoside showed a prominent signal for glucose carbon atom 1 at δ_C 104.2. A weak signal at 98.1 ppm may originate from C-8 of luteolin-5-*O*-glycoside, C-6 of kaempfero,l and quercetin. Moreover, the signal at δ_C 117.9 was attributed to C-8 of flavonol.[34] In short, the ^{13}C NMR spectrum indicated that the main components in CSP were flavonoids, steroidal sapogenins, and the ether linked sugars which may be flavonoid glycosides, such as quercetin-3-*O*-glycoside and luteolin-5-*O*-glycoside. Flavanol and procyanidin were observed as the major flavonoids in CSP, whereas signals of kaempferol, free quercetin, and luteolin appeared in a trace amount.

Physical Properties Analysis. As the UV spectrum indicated, the absorption spectrum of the pigments exhibited strong optical absorbance in a spectral range from 270 to 290 nm, and relatively weak absorbance range from 290 to 650 nm. The wavelength of maximum absorption was 278.5 nm, which is a typical peak of flavonoids. Therefore, as the main components in pigments, the absorbance of flavonoids at 278.5 nm was selected as reference in the following experiments.

Solubility of CSP. The solubility results indicated that the pigments were scarcely soluble in benzene, chloroform, diethyl ether, acetone, ethyl acetate, petroleum ether, and hexane. However, the pigments could be dissolved in methanol, ethanol, and acetic acid. Furthermore, they displayed a good solubility in water, DMSO, and alkaline solutions (such as Na_2CO_3, NaOH, and NH_4OH). The solubility in water and DMSO may be due to the flavonids and water-soluble glycosides in CSP.

Stability of CSP. The effect of temperature on the CSP stability was evaluated to investigate the potential use as an antioxidant. The absorbance of the pigment solution at λ_{max} changed slightly from 25 to 50 °C after incubating in a thermostatically controlled bath for 3 h. On the contrary, the absorbance of CSP solution at 75 °C increased during the early incubation period, and decreased gradually to meet the initial value. This phenomenon was probably related to the thermal auto-oxidation and degradation of the flavonoids in CSP.[36,37] Unfortunately, the CSP was extremely unstable at the temperature of 100 °C, which might be correlated with the polarity of the CSP.[37] These results suggested that the pigments were stable when the temperature was below 75 °C.

To study the effect of light on CSP, the pigment solutions were performed under ultraviolet light, indoor natural light, and stored in a dark place for 1−10 d. Only 0.03 and 0.01 of absorbance were increased under natural light and dark after 10 days' treatment, respectively. However, the absorbance increased first and then decreased with the increasing irradiation time when the solution was irradiated under ultraviolet-light. After being treated for 3 days, about 0.07 of the absorbance was increased. These results indicated that the pigments were stable to the indoor natural light and under dark condition, while the ultraviolet light had a relatively strong effect on the light stability. This phenomenon might be explained by the degree of glucosylation in CSP, which has an important contribution to pigment stability for light.[7]

Table 4. Antibacterial Activity of CSP by Diameter of Inhibition Zones (mm)

Figure 7. Results of antibacterial activity against Gram-positive bacteria strain *Streptomyces somaliensis* and *Bacillus subtilis* of CSP in disc-diffusion method. (1) a: 1 mg/disc CSP; b: 1 mg/disc phenol; c: 50% aqueous ethanol; d: sterile water. (2) a: 2 mg/disc CSP; b: 1 mg/disc phenol; c: 50% aqueous ethanol; d: sterile water. (3) a: 3 mg/disc CSP; b: 1 mg/disc phenol; c: 50% aqueous ethanol; d: sterile water.

With regard to metal ions stability, it was apparent that the absorbance of the pigment solution diminished sharply when mixed with Zn^{2+} solution for 48 h, whereas the pigment solutions mixed with the other metal ions (Ca^{2+}, Cu^{2+}, Na^{+}, Zn^{2+}, Al^{3+}, Mg^{2+}, Fe^{3+}, and K^{+}) had no obvious change. Therefore, most of the metal ions aforementioned affected the pigments slightly.

DPPH Radical Scavenging Capacity of CSP. DPPH is a stable free radical, gives rise to the deep violet solution in ethanol, and has a strong absorption at 515 nm. When the solution is added with an antioxidant, the free radical of DPPH can be paired and reduce the amount of the free radical, resulting in a decrease in the absorbance of DPPH at 515 nm.[38] The scavenging ability of CSP, BHT, and BHA on DPPH radical is shown in Figure 6. As illustrated, the scavenging capacity of the pigments was increased with the increasing reaction time (Figure 6a) and concentration (Figure 6b). Compared with the synthetic antioxidant BHT, the CSP had a strong DPPH radical scavenging capacity, and was closed to BHA. At 0.2−1.2 mg/mL, CSP showed scavenging abilities of 22.6−72.6% on DPPH radicals in 60 min (Figure 6a), which was better than that of pigments from the seeds of *Osmanthus fragrant*.[21] Moreover, the EC_{50} value was 0.057 mg/mL (Figure 6b), which was significantly lower than that of polysaccharides isolated from *Ganoderma tsugae* and comparable to that of the flavonoid glycosides from *Daphniphyllum calycinum*, indicating a higher antioxidant activity of CSP.[39,40] The significant DPPH radical scavenging capacity of CSP may reflect a certain amount of substances with an available OH group,[41] such as tannins and procyanidin, which was verified by FT-IR and ^{13}C NMR spectra. These results implied that the 50% ethanol extracted and a two-step precipitation purified pigments from *C. mollissima* shells processed excellent DPPH scavenge capacity.

Antimicrobial Activity of CSP. With respect to the antimicrobial activity of CSP, the disc-diffusion method was used to test the diameter of inhibition zones effect on bacteria and fungus and the results are listed in Table 4. As shown, the pigments (1, 2, and 3 mg/disc) indicated an increased antibacterial activity with the increasing pigments content per disc. However, the pigments were not sensitive to the fungus (*P. oxalicum* and *A. japonicus*), which exhibited considerable antibacterial activity, especially the Gram-positive bacteria. This was in agreement with the antimicrobial activities of extracts from some other plants.[22] The highest inhibition zones could be obtained for *S. somaliensis*, which may refer to pathogens,[42] ranging from 10.60 to 13.68 mm. The pigment solution was active against *B. subtilis* as well, with inhibition zones of 9.96−13.46 mm (Figure 7). Moreover, the lowest inhibition zones (6.12−7.50 mm) were recorded for *E. coli*, while *S. aureus* possessed almost the same activity, with inhibition zones 6.57−7.59 mm.

The antimicrobial potential of pigments tested in the disc-diffusion method can be presented as *S. somaliensis* > *B. subtilis* > *S. aureus* > *E. coli* > fungus. Compared with the commercial antibiotic phenol, it was remarkable that the pigments showed stronger antibacterial potential toward *S. somaliensis*, while almost the same with regard to *B. subtilis*. The excellent antibacterial activity of CSP might be a good proof of the presence of the natural antioxidants procyanidin and quercetin-3-*O*-glycoside. The interesting results display the eminent antibacterial activity of CSP, which will broaden the potential applications of CSP as food additives.

Acute Toxicity Effect of CSP. Acute toxicity of CSP was assessed at a maximum dose of 5.0 g/kg of body weight. No treatment-related mortality, body weights, or clinical signs of toxicity including hair loss, scabbing, soft or mucoid feces,

decreased defecation or feces smaller than normal, wet yellow material in urogenital area, or vocalization upon handling, were observed for 14 days following the oral administration of CSP. All animals gained weight and appeared active and normal. After sacrifice on the 14th day, macroscopic and gross pathology observations conducted at the necropsy examination revealed no visible lesions in any animals. Relative weight of organs in mice of control and experimental groups did not show significant difference. These phenomena indicated that the mice could tolerate maximum dose at 5.0 g/kg of body weight of CSP, and the LD_{50} should be greater than 5.0 g/kg in both male and female mice according to the guidance for the safety assessment of botanicals and botanical preparations for use in food and food supplements.[43] Based on the toxicity classification proposed by Loomis and Hayes, substances with LD_{50} between 5000 and 15 000 mg/kg body weight are regarded as being practically nontoxic.[44] The present results suggested that CSP could be regarded as being practically nontoxic, which might be related to the quercetin-3-*O*-glycoside in CSP.[45]

In summary, the water-soluble pigments from *C. mollissima* shells extracted by 50% ethanol with microwave assisted were purified by a two-step precipitation method for the first time. The comprehensive and systematic evaluation of the pigments provided valuable results in relation to the chemical composition and characteristics of these natural pigments. It demonstrated a predominance of flavonoids (procyanidin B3) and ether-linked sugars (quercetin-3-*O*-glycoside), followed by a small amount of steroidal sapogenins. As a consequence, CSP was water-soluble, practically nontoxic, and exhibited wonderful DPPH radical scavenging ability and antibacterial activity. With respect to physical properties, CSP revealed good stability with temperature, natural light, and metal ions. However, CSP was not resistant to UV light. The detailed study of pigments from *C. mollissima* shells will shed light on the utilization of these agricultural residues.

for 15 min using an ultrasonic bath (Tru-Sweep 275D, Crest Ultrasonic, Malaysia). The solution was delivered from an amber glass bottle, which was connected via a helium gas balloon to prevent oxygen contamination, through a tubular reactor comprising stainless steel tubing (0.75 mm i.d., 1.58 mm o.d.) immersed in a temperature-controlled silicone fluid bath using a high-performance liquid chromatography (HPLC) pump (LC-20AD, Shimadzu, Kyoto, Japan). The length of the reactor coil and the flow rate were adjusted to obtain the desired treatment times (40−1080, 20−340, 20−240, 10−80, and 5−30 s for 160, 180, 200, 220, and 240 °C, respectively). A thermocouple (type K) was connected via a tee connector near the initial part of the reactor (~10 cm under the fluid surface) to monitor the temperature of the solution inside the tube. After treatment, the solution flowed through a cooling coil immersed in an ice−water bath to rapidly stop the reaction. A miniature back-pressure regulator (P-880, Upchurch Scientific, WA, USA) was connected to the end of the tube to maintain a constant pressure of 5 MPa. This pressure was high enough to ensure that the solution remained in the liquid state throughout the temperature range.

HPLC-DAD Analysis of Caffeic Acid and Its Degradation Products. Caffeic acid and its degradation products in the treated solution were quantitatively analyzed using an HPLC system (Shimadzu, Kyoto, Japan) comprised of a solvent delivery unit (LC-20AD), a diode array detector (DAD; SPD-M20A), and a system controller (CBM-20A). The sample was chromatographically separated using an Inertsil ODS-3 column (4.6 mm × 150 mm, GL Sciences, Tokyo, Japan). The mobile phase consisted of 0.5% v/v aqueous acetic acid (A) and methanol (B), and the following gradient was used at a flow rate of 1.5 mL/min: 0−5 min, 5% B; 5−9 min, linear increase to 50% B; and 9−12 min, 50% B. The treated sample was filtered through a 0.45 μm nylon syringe filter, and 20 μL of sample was injected into the HPLC instrument. Caffeic acid and its degradation products were monitored at 280 nm with authentic caffeic acid as a calibration standard. However, since one of the major degradation products (4-vinylcatechol) is not commercially available, the concentrations of degradation products were estimated, after identification by liquid chromatography-diode array detection/mass spectrometry (LC-DAD/MS), using a calibration curve of caffeic acid corrected by the ratio of the molar absorptivities of caffeic acid (ε = 18 200 M^{-1} cm^{-1}) and the products, that is, 2951 M^{-1} cm^{-1} for hydroxytyrosol,[9] 10 233 M^{-1} cm^{-1} for protocatechuic aldehyde,[10] and 2692 M^{-1} cm^{-1} for 4-vinylcatechol.[11]

Identification of Degradation Products Using LC-DAD/MS. Agilent 1100 LC/MSD Trap SL (Agilent Technologies, CA, USA) equipped with a solvent delivery unit (G113A), a diode array detector (G1315D), and an ion-trap mass spectrometer (G2445D) with an electrospray ionization ion source was used to identify the degradation products. Chromatographic separation was accomplished using the same column described above. The mobile phase consisted of 0.5% v/v aqueous acetic acid and methanol (85:15 v/v) and flowed at a rate of 0.4 mL/min. The treated sample was filtered through a 0.45 μm nylon syringe filter, and 30 μL of sample was injected. Both positive and negative modes were performed over the m/z range 50−400.

Online HPLC-DPPH Assay. Evaluation of the DPPH radical scavenging activity of caffeic acid and each degradation product in the treated samples was conducted using an online HPLC-DPPH assay.[12] This method is based on the chromatographic separation of components in the sample and a postcolumn reaction with DPPH solution. In this study, only one DAD detector was used to monitor caffeic acid, the degradation products at 280 nm, and the negative peaks due to DPPH bleaching at 517 nm. A first pump was used to deliver the mobile phase that consisted of 0.5% v/v aqueous acetic acid and methanol (85:15 v/v) at a flow rate of 1 mL/min for separating the compound on the column described above, while another pump delivered 6 × 10^{-5} M DPPH in methanol or pure methanol at a flow rate of 0.8 mL/min through tubing that was connected via a tee connector to the column outlet. A reaction coil made with PEEK tubing (28.8 m) was connected to enable the compounds eluted from the column to react with DPPH for 47 s. Ascorbic acid (AA) was used for calibration of the DPPH radical scavenging assay via the negative peak area.

RESULTS AND DISCUSSION

Degradation Products of Caffeic Acid in Subcritical Water. A typical HPLC chromatogram of the solution treated under subcritical water conditions is shown in Figure S1 (Supporting Information). There were many compounds in the treated solution, but only the following three main compounds, which could be accurately identified by the LC-DAD/MS, are proposed to be degradation products of caffeic acid: hydroxytyrosol (3,4-dihydroxyphenylethanol), protocatechuic aldehyde (3,4-dihydroxybenzaldehyde), and 4-vinylcatechol (2-hydroxy-4-vinylphenol) (Figure 2). The mass/charge ratio (m/z) and maximum absorbance (λ_{max}) values were used to identify these compounds, as shown in Table 1. Only the standard

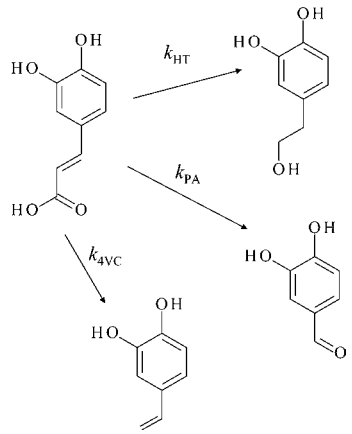

Figure 2. Proposed pathway of caffeic acid degradation in subcritical water.

Table 1. Characteristics of Caffeic Acid and Its Degradation Products Obtained by LC-DAD/MS

peak no.	compd	λ_{max} (nm)	$[M - H]^-$ m/z	negative ions m/z
1	hydroxytyrosol	220, 279	153	153 $[M - H]^-$
2	protocatechuic aldehyde	228, 278, 311	137	137 $[M - H]^-$; 108 $[M - CHO]^-$
3	caffeic acid	324	179	179 $[M - H]^-$; 135 $[M - COOH]^-$
4	4-vinylcatechol	259	135	135 $[M - H]^-$

caffeic acid was injected to confirm the accuracy of the mass spectrometer. Decarboxylated products are the main products of the degradation of phenolic acids under subcritical water conditions. For example, degradation of vanillic acid gave 2-methoxy-phenol,[5] whereas degradation of syringic acid gave syringol (1,3-dimethoxy-2-hydroxybenzene).[6] In this study, 4-vinylcatechol was detected as a decarboxylated product and was a main product in the treated solution (~38−57 mol %). It is known that 4-vinylcatechol can be formed through thermal degradation[13] and photodegradation[14] and can also be prepared by heating caffeic acid at 110 °C using a sodium acetate catalyst.[15] However, 4-ethylcatechol, which was also formed during pyrolysis, was not detected in this study. Hydroxytyrosol was found at moderate amounts in the treated solution (~14−43 mol %); this compound is an effective antioxidant that is naturally found in olive oil.[16] However, the pathway for the

dx.doi.org/10.1021/jf404850a | J. Agric. Food Chem. 2014, 62, 1945−1949

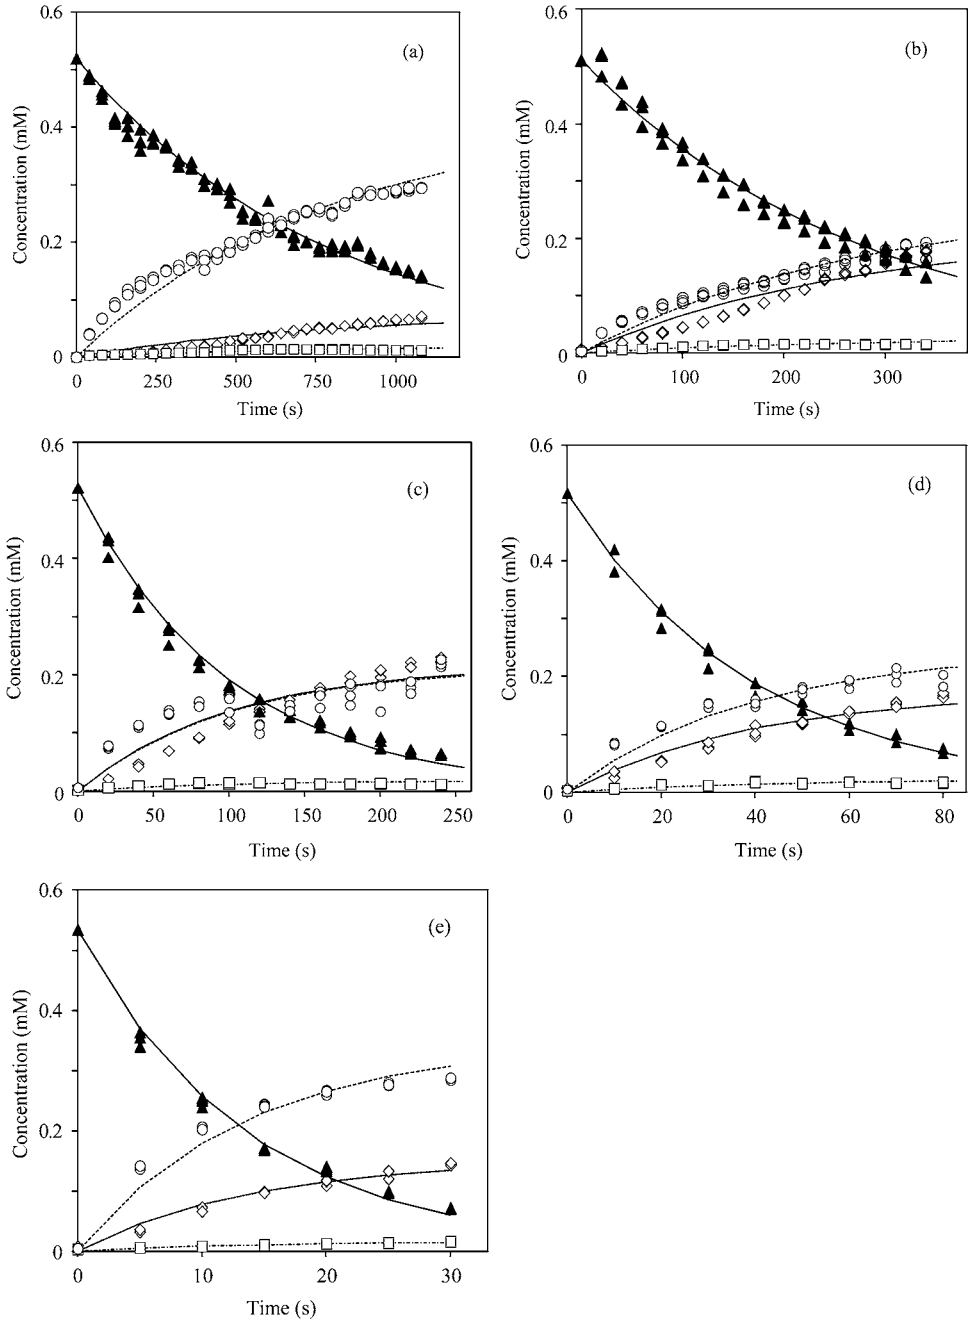

Figure 3. Caffeic acid degradation products at (a) 160, (b) 180, (c) 200, (d) 220, and (e) 240 °C. Caffeic acid (▲), hydroxytyrosol (◇), protocatechuic aldehyde (□), and 4-vinylcatechol (○).

formation of hydroxytyrosol from caffeic acid remains unclear. A small amount of protocatechuic aldehyde was also found in the treated solution. It has been reported that thermal degradation of chlorogenic acid, which is an ester of caffeic acid and quinic acid, can form a small amount of protocatechuic aldehyde.[17] In addition, protocatechuic aldehyde has been reported to be a main oxidation product of caffeic acid in the Fenton oxidation system.[18]

Kinetics analysis was performed along the pathways shown in Figure 2. The reactions can be described using the following first-order rate equations:

$$\frac{dC_{CA}}{dt} = -k_{HT}C_{CA} - k_{PA}C_{CA} - k_{4VC}C_{CA} \quad (1)$$

$$\frac{dC_{HT}}{dt} = k_{HT}C_{CA} \quad (2)$$

$$\frac{dC_{PA}}{dt} = k_{PA}C_{CA} \quad (3)$$

$$\frac{dC_{4VC}}{dt} = k_{4VC}C_{CA} \quad (4)$$

where C_{CA}, C_{HT}, C_{PA}, and C_{4VC} are the concentrations of caffeic acid, hydroxytyrosol, protocatechuic aldehyde, and 4-vinylcatechol, respectively, and the k terms are the rate constants for each reaction step. Equations 1−4 were solved by integration and substitution to generate the following equations:

dx.doi.org/10.1021/jf404850a | J. Agric. Food Chem. 2014, 62, 1945−1949

$$C_{CA} = C_{CA0}e^{-k_{total}t} \quad (5)$$

$$C_{HT} = \frac{k_{HT}}{k_{total}}C_{CA0}(1 - e^{-k_{total}t}) \quad (6)$$

$$C_{PA} = \frac{k_{PA}}{k_{total}}C_{CA0}(1 - e^{-k_{total}t}) \quad (7)$$

$$C_{4VC} = \frac{k_{4VC}}{k_{total}}C_{CA0}(1 - e^{-k_{total}t}) \quad (8)$$

where k_{total} is the overall degradation rate constant of caffeic acid and therefore equal to $k_{HT} + k_{PA} + k_{4VC}$, and C_{CA0} is the initial concentration of caffeic acid.

First, the overall degradation rate constant (k_{total}) was determined by nonlinear regression fitting of eq 5 to the changes in the caffeic acid concentration with time; then, eqs 6−8 were fitted to obtain the rate constants. All the reaction rate constants and their standard errors were estimated using the *nls* function in R statistical language;[19] the results are shown in Figure 3. The standard errors of the estimated rate constants were less than 5% in all cases. It is evident that the experimental results were in good agreement with the proposed reaction pathway. The overall degradation rate constants (k_{total}) increased with temperature and followed the Arrhenius relationship (Figure S2 in the Supporting Information) with an activation energy (E_a) of 93 kJ/mol and a pre-exponential factor (A) of 1.78×10^8 s^{-1}. This value is significantly higher than that for vanillic acid degradation (57 kJ/mol) in the temperature range 280−375 °C.[5] The formation rate constant for each product also obeyed the Arrhenius equation with E_a values of 103, 85, and 87 kJ/mol and A values of 8.24×10^8, 1.06×10^6, and 2.46×10^7 s^{-1} for hydroxytyrosol, protocatechuic aldehyde, and 4-vinylcatechol, respectively.

Online HPLC-DPPH Assay. The antioxidant activity of caffeic acid and its degradation products during subcritical water treatment at 240 °C were estimated using an online HPLC-DPPH assay. A typical chromatogram is shown in Figure 4. The seven peaks that were detected at 280 nm appeared as negative peaks at 517 nm, which indicates their ability to quench the DPPH radicals. Changes in the DPPH radical scavenging activity of each identified product are shown in Figure 5. The total radical scavenging activity of the treated solution, which was calculated from the areas of all seven negative peaks, was not affected by the treatment time (t test, $p \geq 0.05$) even though the caffeic acid content gradually decreased. We found that the radical scavenging activity changed linearly with the concentration of each compound; from these relationships, the DPPH radical scavenging activity of each compound was estimated to be ~88, 212, 230, and 292 g AA/mol for hydroxytyrosol, protocatechuic aldehyde, caffeic acid, and 4-vinylcatechol, respectively. However, because the concentrations of the degradation products were estimated, we can only conclude that protocatechuic aldehyde, caffeic acid, and 4-vinylcatechol showed higher DPPH radical scavenging activities than hydroxytyrosol. Obied et al. reported that caffeic acid was more active for DPPH radical scavenging than hydroxytyrosol.[20] It should be noted that the DPPH radical scavenging activities of these four compounds accounted for more than 90% of the overall activity.

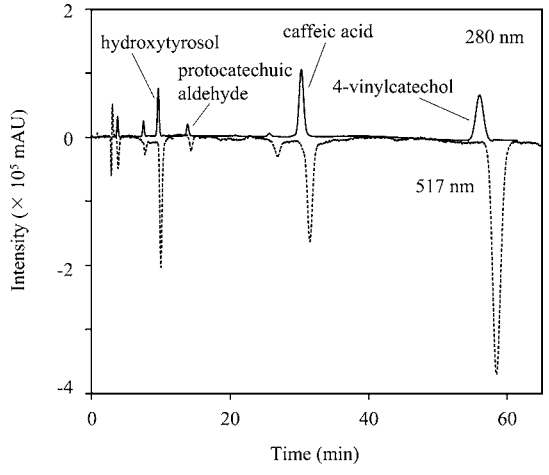

Figure 4. HPLC chromatogram of caffeic acid after subcritical water treatment detected at 280 and 517 nm. The negative peaks indicate DPPH radical scavenging activity.

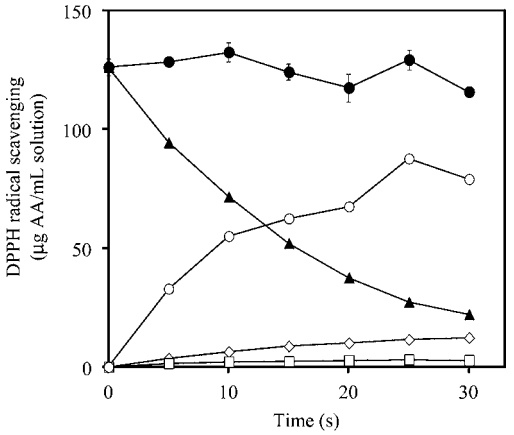

Figure 5. DPPH radical scavenging activity of caffeic acid (▲), hydroxytyrosol (◇), protocatechuic aldehyde (□), and 4-vinylcatechol (○) in the solution treated by subcritical water at 240 °C. The overall activity (●) was calculated from the summation of the areas of the negative peaks in Figure 5.

From these results, it can be expected that, during an extraction of plant materials containing phenolic compounds using the subcritical water technique, which is usually performed in a batch type extractor for longer periods, similar circumstances might occur for caffeic acid and other compounds as well. More complex reactions might also be possible because there are several compounds existing in sample matrices. This can be an advantage if degradation products possess some required bioactive activities or a disadvantage if undesirable or even toxic products are formed.

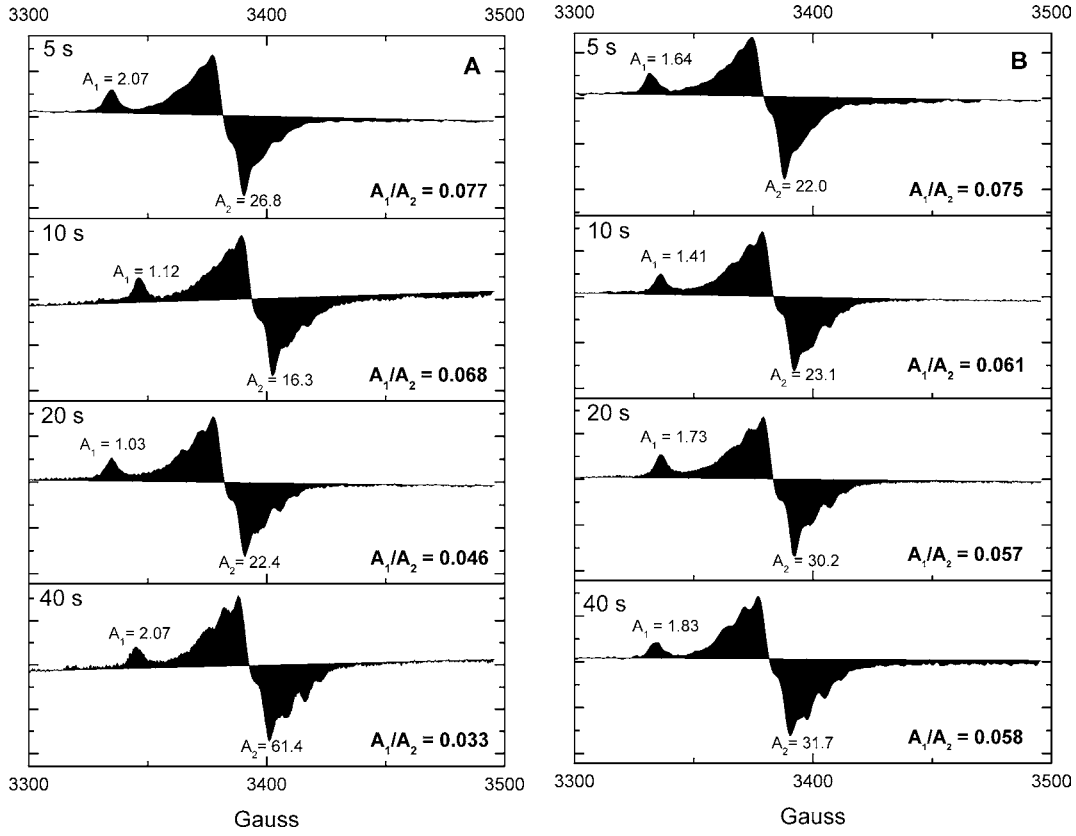

Figure 1. EPR spectra at 77 K of perferrylmyoglobin ($^{\bullet}$MbFe(IV)=O) during reduction to ferrylmyoglobin (MbFe(IV)=O) in aqueous solution of pH 7.4 at 25 °C saturated with CO (A) or in the absence of CO (B) at different aging times, as indicated using a stopped-flow freeze-quench technique. Each spectrum is from an independent experiment, and the decay of the tryptophan peroxyl radical (g_x = 2.036) is normalized relative to the tyrosine carbon-centered radical (g = 2.005). The ratio of the integrated signals A_1/A_2 is probing the tryptophan peroxyl radical decay.

After irradiation, the Rose Bengal was removed by filtering the solution through a Teflon membrane filter of 0.2 μM (Chromafil, Macharey-Nagel GmbH & Co., Dueren, Germany). The TrpOOH, tryptophan hydroperoxide derivatives, were further isolated from the reaction mixture by semipreparative liquid chromatography (HPLC20A Prominence system equipped with a DAD detector SPDM20A, Shimadzu Co., Kyoto, Japan) employing a Luna C18 reverse-phase column (250 mm × 7 mm × 10 μm; Phenomenex Inc., North Hill, CA, USA) with aqueous formic acid 0.05% containing 4% acetonitrile as isocratic mobile phase at a flow rate of 1 mL/min. The product peaks were collected in an ice bath protected from light and immediately lyophilized using a ModulyoD freeze-dryer (Thermo Electron Corp., São Paulo, Brazil). The hydroperoxide concentration was evaluated by the ferric-xylenol orange method (FOX) using H_2O_2 as a standard.[21] Typically, a yield of 10% for the high-purity TrpOOH derivative was obtained after the purification step.

NMR Spectroscopy. NMR analyses (^{1}H, COSY, and HSQC) were recorded at 25.0 °C on a Bruker AVANCE III, 14.1 T instrument (600 MHz for hydrogen frequency) equipped with an automatic sample changer, a cryo-probe TCI (^{1}H/^{13}C/^{15}N) of 5 mm with ATMA (automatic tuning matching) and z-field gradient (Bruker BioSpin, Rheinstetten, Germany). Aliquots of each isolated product were dissolved in D_2O containing 0.050% w/w TMSP-d_4 for NMR analysis. The ^{1}H NMR experiment was based on the 1D version of the NOESY sequence, using water suppression during the relaxation delay (2.40 s). The spectrum was acquired using 64K data points in a 12019.23 Hz spectral width, giving an acquisition time of 2.73 s. Processing was performed using exponential multiplication, applying a line broadening factor of 0.3 Hz. ^{1}H−^{1}H COSY experiments were performed using a spectral width of 12019.23 Hz, an acquisition time of 0.17 s, a relaxation delay of 1 s, and 16 scans for each increment (256 increments). The ^{1}H−^{13}C HSQC experiment employed spectral widths of 12019.23 Hz for the F2 (^{1}H) dimension and 36057.69 Hz for the F1 (^{13}C) dimension. The acquisition time was 0.17 s, the relaxation delay was 1 s, and 64 scans were performed for each increment (256 increments). TopSpin 3.0 software (Bruker BioSpin) was used for data acquisition and processing.

FT-IR Spectroscopy. Experiment type A: 2 mL of a solution of 2 × 10^{-4} mol L^{-1} of MbFe(III), or lactoperoxidase, or Fe(III)TPPS in aqueous phosphate buffer, pH 7.4 (0.16 M), was saturated with CO for 20 min in a half-filled cylindrical quartz cuvette (5 cm optical path), and the reaction was initiated by the addition of an equimolar quantity of H_2O_2. A blank solution without heme iron or iron compound was also investigated. The equilibrated gas-phase spectra were recorded after 1 h using a FT-IR IRAffinity-1 instrument (Shimadzu Co., Kyoto, Japan). Experiment type B: 2 mL of a solution of 2 × 10^{-4} mol L^{-1} of Fe(III)TPPS or Fe(II) or Fe(III) ions in aqueous formate buffer, pH 4.7 (0.16 M), was saturated with CO for 20 min in the half-filled cylindrical quartz cuvette (5 cm optical path), and the reaction was initiated by the addition of an equimolar quantity of TrpOOH. A blank solution without Fe(III)TPPS or iron salt was also investigated. The equilibrated gas-phase spectra were recorded after 1 h using a FT-IR IRAffinity-1 instrument. Experiment type C: 2 mL of a solution of 2 × 10^{-4} mol L^{-1} of preformed MbFe(IV)=O (H_2O_2 plus MbFe(III) after 10 min of reaction) in aqueous phosphate buffer pH 7.4 (0.16 M) was saturated with CO for 20 min in the half-filled cylindrical quartz cuvette (5 cm optical path), and the reaction was initiated by the addition of an equimolar quantity of TrpOOH. A blank solution without TrpOOH was also investigated. The equilibrated gas-phase spectra were recorded after 1 h using a FT-IR IRAffinity-1 instrument.

Freeze-Quench EPR Spectroscopy. An SFM-20 freeze-quench apparatus (Biologic Scientific Instruments, Claix, France) with a minimal aging time of 9 ms and an EMXplus X-band EPR instrument (Bruker Biospin GmbH, Karlsruhe, Germany) using a TM101 cylindrical cavity were used for freeze-quench kinetics. For this experiment, a solution containing 1.7 × 10^{-4} mol L^{-1} MbFe(III)

dx.doi.org/10.1021/jf4053176 | J. Agric. Food Chem. 2014, 62, 1950−1955

saturated or not with CO was loaded in syringe A and a solution of 7.7 × 10^{-4} mol L^{-1} of H_2O_2 was loaded in the opposite syringe B. The solutions of syringes A and B were mechanically pushed to the reaction chamber at a ratio of 1:1 at 25 °C and aged inside the calibrated aging loop for different reaction times from 5 to 40 s before being sprayed by the ejection nozzle into a cryogenic bath at 77 K. EPR spectrometer parameters: center field, 3395.58 G; sweep width, 200 G; MW power, 2.00 mW; MW frequency, ~9.52 GHz; modulation frequency, 100.00 kHz; modulation amplitude, 3.00 G; time constant, 81.92 ms; conversion time, 81.92 ms; temperature, 77 K. Each spectrum is an average of eight scans.

RESULTS AND DISCUSSION

Purified metmyoglobin (MbFe(III)) when reacting with hydrogen peroxide (H_2O_2), in neutral aqueous solution, forms perferrylmyoglobin (dot-MbFe(IV)═O), a protein radical of the iron(IV) heme pigment.[22] Perferrylmyoglobin decays to ferrylmyoglobin (MbFe(IV)═O), the iron(IV) pigment for ambient conditions with a half-life of 30 s at 25 °C and neutral pH.[23] The EPR spectrum of perferrylmyoglobin shows under aerobic conditions two features (see Figure 1), one assigned to a tryptophan peroxyl radical (g_x = 2.036, g_y = 2.008, g_z = 2.0028) and another septet EPR signal with g = 2.005 assigned to a carbon-centered tyrosyl radical.[23,24]

The tryptophan peroxyl radical of perferrylmyoglobin decays by reaction with external reductants or by slower intramolecular electron transfer.[15,16,21] The ratio between the two integrated signals, as shown in Figure 1, was used to follow the decay of the tryptophan peroxyl radical in aqueous solution at 25 °C in the absence of CO (Figure 1B) or for aqueous solution saturated with CO (Figure 1A), using a freeze-quench stopped-flow technique. The decay of the tryptophan peroxyl radical was found both in the absence and in the presence of CO to follow first-order kinetics (see Figure 2), but clearly the presence of CO accelerated the decay, as is seen for the values of the rate constant in the absence of CO, k = (5.3 ± 0.1) × 10^{-2} s^{-1}, and for water saturated with CO, k = (2.8 ± 0.1) × 10^{-1} s^{-1}. Formation of CO_2 was detected by FT-IR spectroscopy of the gas phase in equilibrium with aqueous solution (see Figure 3). The absorption maximum for CO_2 at 2335 and 2361 cm^{-1} increased for the reaction mixture as the one illustrated in Figure 3, for which the FT-IR spectrum is presented for a reaction time of 60 min.[25,26]

Tryptophan hydroperoxide, as a mixture of *cis* and *trans* isomers, was synthesized photochemically using Rose Bengal as a sensitizer for singlet-excited oxygen generation and isolated by HPLC employing a semipreparative C18 reverse-phase column (see Figure 4) and included as reactant with CO for comparison with activated myoglobin. The photolysis of an oxygen-saturated solution of 30 mM tryptophan in D_2O containing 8 μM Rose Bengal using 532 nm light from a green LED diode (5 mW) for 2 h at 0 °C resulted in the formation of mainly the tryptophan-derived hydroperoxides as *cis* and *trans* isomers, as may be seen in Figure 4. The identity of the compounds seen as peaks P_1 and P_2 was confirmed by 1D and 2D NMR analysis (^{1}H/COSY/HSQC) after isolation as the HSQC spectrum collected for peak P_2, the *cis*-TrpOOH isomer (Figure S1 in the Supporting Information). The *cis*- and *trans*-TrpOOH, after the purification step, were quantified using the ferric-xylenol orange method (FOX) and fully characterized by ^{1}H, COSY, and HSQC NMR experiments (Table 1); the obtained data were consistent with literature values for the proposed structures.[20,21] The most remarkable difference in the ^{1}H NMR spectrum for the *cis*- and *trans*-TrpOOH derivatives is

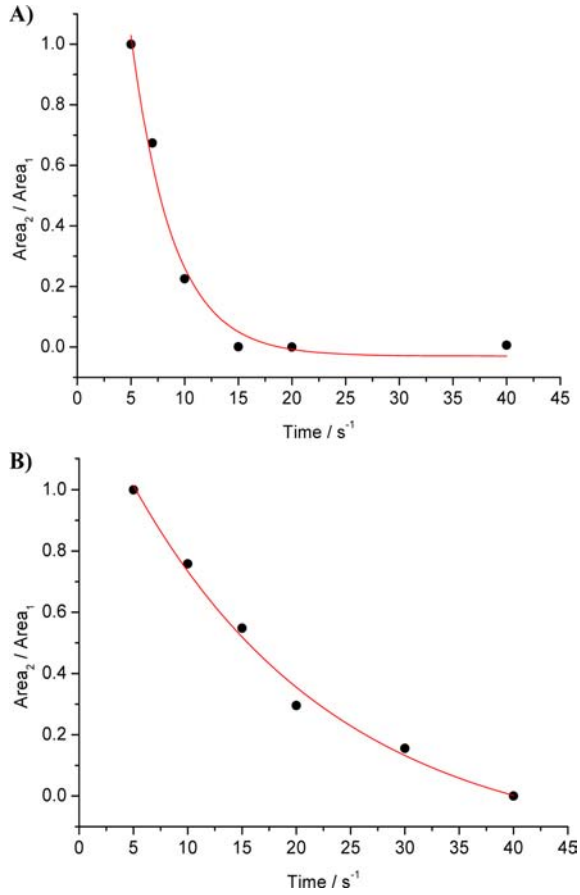

Figure 2. Decay of tryptophan peroxyl radical of perferrylmyoglobin (•MbFe(IV)═O) in aqueous solution of pH 7.4 at 25 °C saturated with CO (A) or in the absence of CO (B) as probed by the A_1/A_2 ratio from EPR spectra obtained by a stopped-flow freeze-quench technique (see Figure 1). Curves are exponential fits corresponding to first-order decay kinetics with observed rate constants of k_1 = 0.28 ± 0.04 s^{-1} (A) and k_1 = 0.05 ± 0.01 s^{-1} (B) to yield k_1 = 0.23 ± 0.04 s^{-1} for CO reduction of •MbFe(IV)═O.

associated with the C_3 methylene hydrogens. As may be seen from Table 1, for the *cis*-TrpOOH derivative, the C_3 methylene hydrogens are magnetically equivalent and appear as one doublet at 2.66 ppm. On the other hand, the C_3 methylene hydrogens for the *trans*-TrpOOH derivative show a double−doublet coupling pattern for nonequivalent hydrogens in an ABX system, the nonequivalent hydrogens being the AB part and the H_2 hydrogen the X part.

Tryptophan hydroperoxide did not react with CO to form CO_2 unless catalyzed by tetra(4-sulfonatophenyl)-porphyrinate iron(III) (Fe(III)TPPS) or by $FeSO_4$ or $FeCl_3$ as simple iron salts. The efficiency by which these and other reactant mixtures were oxidizing CO to CO_2 for comparable reaction conditions and reaction time is depicted in Figure 5 as the integrated FT-IR signal to provide a relative concentration of CO_2.

From the results presented in Figure 5, it is evident that H_2O_2 and CO do not produce CO_2 in buffered aqueous solution of pH 7.4 at 25 °C in the absence of iron salts or in the presence of Fe(III)TPPS. Solutions of tryptophan incubated with CO in the presence of hydrogen peroxide and in the absence of heme iron or iron salts do not produce CO_2. Tryptophan hydroperoxide plus CO likewise does not produce CO_2 in the absence of iron salts, but CO_2 is clearly produced when iron(II) or iron(III) is present and especially when

dx.doi.org/10.1021/jf4053176 | J. Agric. Food Chem. 2014, 62, 1950−1955

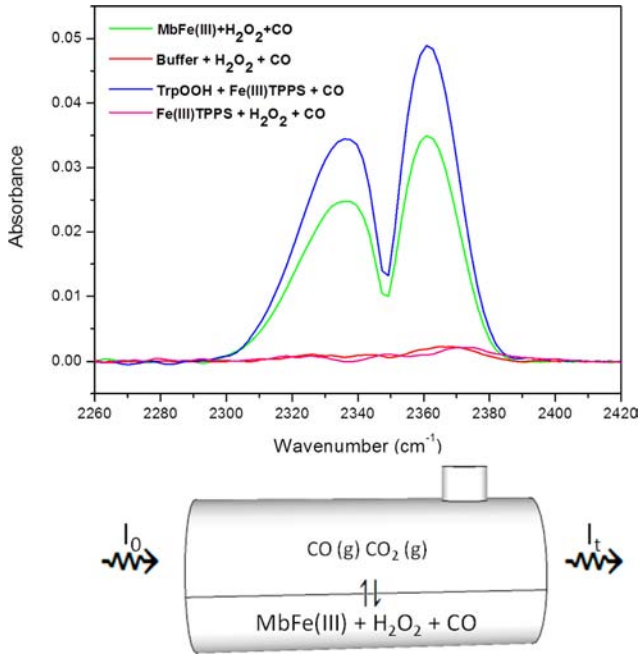

Figure 3. FT-IR spectra of equilibrated gas phase of aqueous solution of pH 7.4 with reactants shown in sketch of quartz cylindrical cuvette at 25 °C for metmyoglobin following 60 min of reaction and equilibration. [MbFe(III)] = 1×10^{-4} mol L^{-1}; [H_2O_2] = 1×10^{-4} mol L^{-1}; [CO] = 7×10^{-4} mol L^{-1}; [TrpOOH] = 1×10^{-4} mol L^{-1}; [Fe(III)TPPS] = 1×10^{-4} mol L^{-1}.

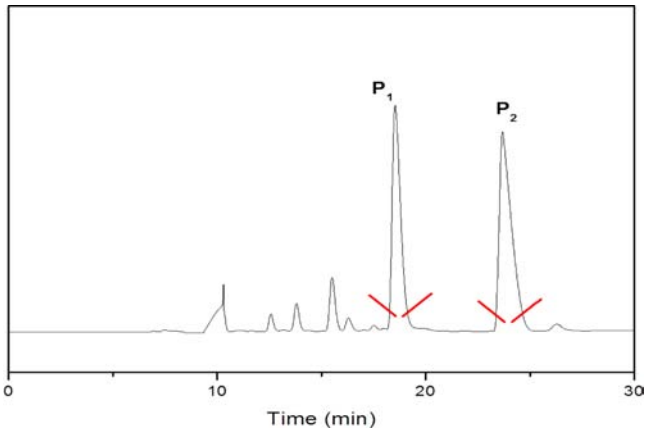

Figure 4. Separation and characterization of tryptophan hydroperoxide *trans*/*cis* isomers as formed by singlet oxygen addition to tryptophan in oxygen-saturated D_2O with Rose Bengal added as photosensitizer and exposed to green light (see Materials and Methods). HPLC separation of *trans* isomer (P_1) and *cis* isomer (P_2) is marked to indicate collection range.

Fe(III)TPPS is present. This identifies a tryptophan radical rather than tryptophan peroxide as the reactant for oxidation of CO to CO_2, as iron(III) and iron(II) may cleave hydroperoxides by oxidation or by reduction, respectively:

$$TrpOOH + Fe^{3+} \rightarrow TrpOO^{\bullet} + H^{+} + Fe^{2+} \quad (1)$$

$$TrpOOH + Fe^{2+} \rightarrow TrpO^{\bullet} + OH^{-} + Fe^{3+} \quad (2)$$

The tryptophan radicals will react with CO by oxygen atom transfer[27] according to

$$TrpOO^{\bullet} + CO \rightarrow TrpO^{\bullet} + CO_2 \quad (3)$$

$$TrpO^{\bullet} + CO \rightarrow Trp^{\bullet} + CO_2 \quad (4)$$

of which the reaction of $ROO^{\bullet}$ with CO has been reported to be faster than the reaction of $TrpO^{\bullet}$ with CO by a factor of 10^2.[27]

For perferrylmyoglobin, a similar reactivity is recognized, as activation of MbFe(III) by hydrogen peroxide prior to addition of CO yields no reaction compared to activation of MbFe(III) by hydrogen peroxide in the presence of CO, indicating that when $^{\bullet}$MbFe(IV)=O has decayed to MbFe(IV)=O, the reactivity toward CO will disappear. The presence of tryptophan hydroperoxide in experiments with preformed ferrylmyoglobin enhances the reaction moderately, showing that the heme iron may cleave the peroxide oxidatively corresponding to the reaction of eq 1 to yield reactive peroxyl radicals or that the tryptophan hydroperoxide may have reactivated ferrylmyoglobin to perferrylmyoglobin. Lactoperoxidase, as heme enzyme also with solvent-exposed tryptophan, included for comparison in the resting iron(III) form, showed less activity than MbFe(III) when both heme compounds were activated by H_2O_2 in the presence of CO.[28]

The reactivity of the two tryptophan radicals, $TrpOO^{\bullet}$ and $TrpO^{\bullet}$, in oxygen transfer reaction to CO finds a parallel in the activated MbFe(III). The solvent-exposed tryptophan of MbFe(III) becomes oxidized to $TrpOO^{\bullet}$ during the oxidation of MbFe(III) by H_2O_2 in aerated aqueous solution:

$$\begin{aligned} &MbFe(III) + H_2O_2 \\ &\quad \rightarrow {}^{\bullet+}MbFe(IV)=O + H_2O \\ &\quad \rightarrow {}^{\bullet}MbFe(IV)=O + H^{+} + H_2O \end{aligned} \quad (5)$$

$^{\bullet}$MbFe(IV)=O is a tryptophan peroxyl radical, as shown in eq 5 and will react with CO in a reaction similar to the reaction of eq 3 to yield CO_2, and the tryptophan alkoxyl radical still capable of transferring an oxygen atom to CO will react as in the reaction of eq 4. The carbon-centered tryptophan radical thus formed will decay by intramolecular reaction to form a carbon-centered tyrosine radical of higher stability, which may undergo an intermolecular reaction to form heme dimers. This reaction sequence as depicted in eq 5 accounts for the experimental observations related to CO_2 formation from the different reaction mixtures described in Figure 5 and also the EPR spectra of Figure 1. Notably, only $^{\bullet}$MbFe(IV)=O and not MbFe(IV)=O is capable of oxidizing CO to CO_2.

From the observed rate of disappearance of $^{\bullet}$MbFe(IV)=O in the presence of CO (saturated water corresponding to 0.7 mM CO in the reaction chamber), it becomes possible to estimate the rate constant for the bimolecular reaction between $^{\bullet}$MbFe(IV)=O and CO to have the value of 330 ± 60 L mol^{-1} s^{-1}. This seems to be the first value available for the rate constant for deactivation of perferrylmyoglobin by an external reductant. For the reaction of perferrylmyoglobin with the water-soluble carotenoid crocin, a lower limit for the rate constant was estimated to be 4×10^5 L mol^{-1} s^{-1},[17] and for the reaction with 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid (ABTS) to form the $ABTS^{\bullet+}$ radical the lower limit was 6×10^5 L mol^{-1} s^{-1}.[18] The reaction with crocin is an electron-transfer reaction

$$\begin{aligned} {}^{\bullet}MbFe(IV) &= O + crocin \\ &\rightarrow {}^{-}MbFe(IV) \\ &= O + crocin^{\bullet+} \end{aligned} \quad (6)$$

as in the reduction with ABTS, explaining the higher rate compared to the oxygen atom transfer for the reaction of eqs 3 and 4.

Activated myoglobin, which will be formed during digestion of red meat through reaction of MbFe(III) with peroxides, has been shown to be deactivated by reaction with CO. The reaction of CO involves oxygen atom transfer to form CO_2 in principle in two-reaction steps, eventually forming a heme dimer through a dityrosine linkage. The scavenging of activated myoglobin by CO may protect sensitive structures against oxidative damage involving proteins and unsaturated lipids. CO may in this respect function as an inherent antioxidant. Future experiments are required to investigate whether CO may act synergistically with dietary antioxidants such as polyphenols and carotenoids through binding to ferrous myoglobin or through a subsequent reduction of MbFe(IV)=O following the initial reduction of perferrylmyoglobin by CO.

oil	ND	2.73 ± 0.13	ND	0.05 ± 0.00	0.10 ± 0.00	17.06 ± 2.16	19.94 ± 2.16	28.53 ± 0.65

[a]Values are means ± standard deviation, n = 3. ND = not detected. TPCC = total phenolic compounds content as estimated by UPLC. TPC = total phenolic content as estimated by Folin-Ciocalteu method. SA = sinapic acid.

have provided free sinapic acid by hydrolysis during roasting.[22−24]

Microwave pretreatment of seeds is a simple and desirable method for production of high-quality vegetable oils. Using microwave radiation, a higher oil extraction yield by press can be obtained due to rupturing of the cell membrane and generation of permanent pores. In addition, microwave pretreatment of oilseeds can increase phytosterols, tocopherols, and phenolic compounds in the oil extracted by press and improve the oxidative stability of oil.[25−30] However, there is a lack of information in the literature on the effect of pretreatment with microwaves on phenolic compounds (sinapic, caffeic, ferulic, cinnamic acid, and canolol) and esterified sinapic acid derivatives (sinapine) content in rapeseed. Moreover, transfer of the phenolic to oil has not been determined when pressing the oil from rapeseed treated with microwave. It is not known whether there is similar transfer ratio for difference phenolic compounds. Thus, the objectives of this research were (1) to evaluate the effect of microwave treatment on phenolic compounds, including sinapine, sinapic, caffeic, ferulic, cinnamic acid, and canolol content in the rapeseed and (2) to investigate the differences in transfer of the difference phenolic compounds to the oil extracted from microwave-treated rapeseed by press.

MATERIALS AND METHODS

Materials. Double low rapeseed containing no erucic acid and low amounts of glucosinolates (11.67 μmol/g) was collected from the local market in China. All reagents were of analytical or HPLC grade. 4-Acetoxy-3,5-dimethoxystyrene (purity ≥ 99.0%) was purchased from Apin Chemicals Limited (Abingdon, Oxon, U.K.). Sinapic acid (purity ≥ 99.0%), sinapine (purity ≥ 98.0%), ferulic acid (purity ≥ 98.0%), cinnamic acid (purity ≥ 98.0%), and caffeic acid (purity ≥ 99.0%) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). Chromatographic-grade methanol and acetic acid were purchased from Merck (Darmstadt, Germany). Other chemicals and reagents were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shang-hai, China).

Methods. *Microwave Pretreatment of Rapeseed and Oil Extraction.* For each sample, 400 g of whole rapeseed were placed in eight Pyrex Petri dishes (9 cm diameter) inside a microwave (Model Mars, 800 W, CEM, USA). Samples were microwave treated at a frequency of 2450 MHz for a roasting period between 1 and 8 min (interval 1 min). Each microwave treatment was done with three replicates, and samples were collected and allowed to cool to ambient temperature prior to oil extraction by pressing. A rapeseed sample without microwave radiation (0 min radiation time) was used as a control sample.

Rapeseed was pressed at room temperature with a cold-pressing machine (CA59G, German Monforts Group, Moenchengladbach, North Rhine-Westphalia, Germany), and the oil was centrifuged at 8983 × g for 15 min. The oil was separated and stored in stoppered glass containers.

Synthesis of 2, 6-Dimethoxy-4-vinylphenol (Canolol). Canolol was synthesized according to the method described by Harbaum-Piayda et al.[31] Potassium hydroxide (250 mg) was dissolved in 1.25 mL of methanol and added to a solution of 250 mg of 4-acetoxy-3,5-dimethoxystyrene in 1.5 mL of methanol. The suspension was stored at ambient temperature overnight (15 h). Afterward, the suspension was acidified by acetic acid (250 μL) and extracted three times with ethylacetate (3 × 5 mL). The organic phase was washed with water (2.5 mL) and 5% sodium hydrogen carbonate solution (2.5 mL).

Identification of Canolol. Identification of canolol was carried out on the basis of nuclear magnetic resonance (NMR) and mass spectrometry (MS).

NMR Spectroscopy. The organic solvent of synthetic product was removed under vacuum, and the fraction was dissolved in deuterated chloroform. Proton (^{1}H) and carbon (^{13}C) NMR spectra were taken using an Oxford NMR (600 MHz) spectrophotometer (USA).

Liquid Chromatography-Mass Spectrometry (LC-MS) Spectroscopy. The MS used for analysis was a hybrid, triple-quadrupole/linear ion trap mass spectrometer, API 4000 Q-Trap, with an APCI interface (AB SCIEX, Foster City, CA, USA).

ESIMS/MS analysis was performed in the positive ionization mode. DP, CE, and CXP were optimized for production of precursor-to-production transitions. Other instrument parameters were also optimized for generating the highest signal intensities. The nebulizer gas pressure, drying gas pressure, curtain gas pressure, source voltage, and source temperature were set at 60 psi, 50 psi, 30 psi, 5.5 kV, and 500 °C, respectively.

UPLC-Diode Array Detector (DAD) Analysis for Quantification of Phenolic Compounds. Extraction Procedure. (1) For rapeseed sample: 0.1 g (accuracy 0.001 g) of grounded rapeseed sample and 4 mL of methanol−water (1:1 v/v) were transferred into a 10 mL centrifuge tube and shaken at room temperature for 20 min. Each sample was extracted in triplicate, and the residual rapeseed flour was separated by centrifugation (1383 × g, 10 min). Extracts were filtered through a 0.22 μm nylon filter and analyzed directly by UPLC. (2) For oil sample: 1.25 g (accuracy 0.001g) of oil sample was dissolved in 1.5 mL of hexane; the polar compounds were extracted into aqueous 80% methanol (3 × 1.5 mL) and centrifuged (2823 × g, 10 min). Pooled extracts were through a 0.22 μm nylon filter and analyzed directly by UPLC.

UPLC Analysis. Analysis was carried out using Acquity UPLC (Waters, Milford, USA), equipped with a degasser, two solvent delivery modules, an autosampler, a column oven, and a DAD. Separation was carried out using a 2.1 × 100 mm, 1.7 μm, Waters Acquity BEH RP18 column (Waters, Milford, USA) maintained at 30 °C. The injection volume was 3 μL, and compounds were eluted with 2% acetic acid in water (v/v) (mobile phase A) and 100% methanol (mobile phase B) at a flow rate of 0.21 mL/min. The gradient program was as follows: 0−25% B (7.40 min), 25−29% B (2.67 min), 29−36% B (6.66 min), 36−45% B (6.67 min), 45−5% B (2 min), 5% B−100% A (2 min), and 100% A (2.67 min).

Eluates were detected at 325 (sinapine, sinapic, caffeic, and ferulic acid), 295 (cinnamic acid), and 280 nm (canolol). Peak identities were confirmed from retention data and by spiking of extracts with six standards. Calibration curves: y = 16 700x −1460, y = 28 400x − 9140, y = 28 200x − 2370, y = 34 000x + 942, y = 29 100x − 829, and y = 19 030x − 25 134 with determination coefficients of R^2 = 0.9994, 0.9998, 0.9995, 0.9998, 0.9999, and 0.9999 in the concentration range 0.5−20.0 mg/L of standard solutions of sinapine and cinnamic acid, 0.5−100.0 mg/L of standard solutions of sinapic acid, 0.25−10.0 mg/L of standard solutions of caffeic acid, 0.5−20.0 mg/L of standard solutions of ferulic acid, and 5−500.0 mg/L of standard solutions of canolol

were obtained for quantification of individual phenolic compounds. Calculated values of the slope relative standard deviations (RSD = 0.4−2.9%, n = 5) and the average recovery rate (100.6−106.7%) indicate reasonable repeatability and accuracy of the UPLC method. Moreover, limits of detection and quantification ranged as follows: 0.065−0.114 and 0.224−0.381 mg/L, respectively, for UPLC analysis of all studied phenolic compounds.

Statistical Analysis. Analysis was performed in triplicate. Results were expressed as means with standard deviation (SD). An ANOVA test (using SPSS 18 statistical software; SPSS Inc., Chicago, IL) was used to compare the mean values of each treatment. Mean differences were considered significant at the $P < 0.05$ level. The Pearson correlation test was used to determine the correlations.

RESULTS AND DISCUSSION

Individual Phenolic Compounds in Seed and Cold-Pressed Oil from Rapeseed. Results of phenolic compounds in untreated rapeseeds and cold-pressed oils from them analyzed by the UPLC-DAD method are listed in Table 1. Five phenolic compounds (sinapine, sinapic acid, caffeic acid, ferulic acid, and canolol) were identified comparing the UV spectral data and retention time of standard. The main phenolic compound in rapeseed was sinapine (459.22 mg/100 g), while the content of ferulic acid was the lowest (2.17 mg/100 g). On the basis of various reports, the major phenolics in rapeseed are sinapine, sinapic acid, and sinapoylglucose.[4,11] Among them, sinapine is the most abundant species accounting for about 1−2% (w/w) in rapeseed.[32] A higher content of sinapine was found in the defatted rapeseed and canola cotyledons, on average, accounting for 2.67% and 2.85%, respectively.[33] Liu et al. found that sinapine contents ranged from 93 to 176 mg/100 g and from 1565 to 2188 mg/100 g in defatted rapeseed hulls and dehulled flours from 10 rapeseed varieties (*Brassica napus*) in China, respectively.[34] The differences in sinapine levels might arise from factors such as the cultivars, climate, growth conditions, degree of maturity, and method of analysis.

The main free phenolic acid found in rapeseed was sinapic acid, with its content being 76.80 mg/100 g (Table 1). This result was in agreement with the results obtained by Krygier et al. (73.2−80.1 mg/100 g),[7] whereas it is higher than the results obtained by Kozlowska et al. (41.3−51.6 mg/100 g),[8] Cai and Arntfield (34.0−49.0 mg/100 g),[11] Siger et al. (19.8−67.3 mg/100 g),[16] and Szydłowska-Czerniak et al. (17.4−36.4 mg/100 g).[35] Moreover, 10.26 mg/100 g of caffeic acid, 2.17 mg/100 g of ferulic acid, and 14.07 mg/100 g of canolol in our rapeseed sample were detected (Table 1). Our results were higher than those of Szydłowska-Czerniak et al.[35] Szydłowska-Czerniak et al. reported the six individual phenolic acid in seven rapeseed varieties: sinapic acid was the dominant phenolic acid, with concentrations from 17.4 to 36.4 mg/100 g, followed by gallic acid (0.97−1.97 mg/100 g), ferulic acid (0.10−1.96 mg/100 g), *p*-coumaric acid (0.57−0.92 mg/100 g), and caffeic acid (0.01−0.07 mg/100 g). Gallic acid and *p*-coumaric acid were not detected in our rapeseed sample. The high variability in the amounts of the individual phenolic compounds in rapeseed varieties has been widely reported and depends on several factors, such as genetic, agronomic, environmental, and extraction procedures.[6,11,13,16,35] The canolol content in our rapeseed sample was higher than those reported by Shrestha et al. (2.47 mg canolol/100 g)[23] and Spielmeyer et al. (0.58 mg canolol/100 g).[24] The total phenolic content determined by the Folin-Ciocalteu method was 1017.12 mg SA/100 g of rapeseed (Table 1). The obtained results of total phenolic content are similar to those reported by other authors.[11,13,35]

When pressing the oil from rapeseed, most of the phenolic compounds remain in the cold-pressed rapeseed cake, and only a small proportion is transferred to the crude oil (Table 1). However, approximately 56% of the canolol is transferred to the crude oil. There were differences in the phenolic compounds and contents between the rapeseeds and the cold-pressed oil from them. Only four phenolic compounds (sinapic acid, ferulic acid, cinnamic acid, and canolol) were detected, and canolol was the main phenolic compound in the oil from untreated rapeseed by press. The canolol content was 17.06 mg canolol/100 g of rapeseed oil. This result was higher than those reported by Spielmeyer et al.,[24] whereas it was lower than those of Koski et al.[5] Spielmeyer et al. reported that the canolol content ranged from 0.67 to 8.14 mg canolol per 100 g in 4 rapeseed kernel oils and 5 cold-pressed oils, and canolol was not detectable in 2 refined rapeseed oils. Koski et al. detected higher amounts of canolol: 62.9 and 29.7 mg caffeic acid/100 g in post-expelled crude turnip rapeseed and post-expelled crude oil, respectively, but only 4.8 mg of caffeic acid/100 g of canolol was detected in superdegummed oil.[5]

In rapeseed, phenolic acids consist mostly of sinapic acid;[4,6,11,14] therefore, sinapic acid is also the main phenolic acid in rapeseed oil. UPLC analyses revealed the presence of sinapic acid (2.73 mg/100 g), cinnamic acid (0.10 mg/100 g), and ferulic acid (0.05 mg/100 g) in the oil from untreated rapeseed by press (Table 1). In the rapeseed oil, sinapic acid accounts for about 95% of free phenolic acids, but that only accounts for about 9% of four phenolic compounds (three phenolic acids and canolol); thus, canolol is the main phenolic in the cold-pressed oil. The level of sinapic acid in our sample was higher when compared to the results obtained by Siger et al.[16] (0.24 mg/100 g for cold-pressed rapeseed oil), Vuorela et al.[36] (0−2.8 mg/100 g for commercial rapeseed oil, post-expelled crude rapeseed oil, pre-expelled crude rapeseed oil, and superdegummed rapeseed oil), and Harbaum-Piayda et al.[31] (0.09−1.94 mg/100 g for cold-pressed rapeseed oil). Moreover, the concentration of ferulic acid (0.0056 mg/100 g) reported by another author was also lower than that of our cold-pressed oil from rapeseed.[36] In minor amounts, sinapine (0.4−1.9 mg/100 g), *p*-hydroxybenzoic (0.0016 mg/100 g), syringic acid (0.68 mg/100g), *o*-coumaric, and *p*-coumaric acids (0.013 mg/100g) were identified in the cold-pressed rapeseed oil as well.[16−18,33]

The total phenolic compounds content calculated from UPLC data was 19.94 mg/100 g, whereas total phenolic content determined by the Folin-Ciocalteu method was 28.53 mg SA/100 g in cold-pressed rapeseed oil (Table 1). Our obtained result of total phenolic content was higher than that reported by Zacchi et al.,[37] Siger et al.,[16] and Koski et al.[17] Zacchi et al. found that the mixed oil (the pressed oil and the solvent-extracted oil coming from the same batch of seeds) contained 17.8 mg of sinapic acid/100 g of polyphenol compounds. Siger et al. determined the content of total phenolic compounds at a level of 1.31 mg/100 g caffeic acid equivalents in cold-pressed rapeseed oil.[16] Koski et al. reported that cold-pressed rapeseed oil contained only minor amounts (0.3−0.4 mg caffeic acid/100 g) of polar phenolics.[17] However, Koski et al. detected higher total amounts of phenolic compounds: 106.6, 73.0, 19.3, 4.4, and 1.6 mg caffeic acid/100 g in post-expelled crude turnip rapeseed, post-expelled crude oil, superdegummed oil, oil refined, bleached, and deodorized under modified, milder conditions, and refined, bleached, and deodorized oil, respectively.[5] The phenolic acid

content in rapeseed oil is the result of complex interactions among several factors, including the method of analysis, processing technology, rapeseed cultivar and ripening degree, and climate.

Influence of Microwave on Phenolic Compounds in Rapeseed. Tocopherols, photosterols, and phenolic compounds are minor components of rapeseed oils. Our previously published results revealed that total tocopherols content in the oil extracted by press first increased and then decreased depending on the period of microwave radiation, whereas phytosterols and total phenolics contents increased with increasing microwave time.[30] It has been reported that microwave pretreatment of rapeseed could increase the canolol content, and higher temperatures (>160 °C) can cause a reduction in the canolol content.[24] Canolol can be formed by thermal decarboxylation of the sinapic acid during the roasting process. Previous studies have indicated that the loss of free sinapic acid was far below the amount of sinapic acid converted into canolol, and esterified sinapic acid derivatives must have provided free sinapic acid by hydrolysis during roasting.[22−24] Thus, study on the changes of sinapine (the main esterified sinapic acid derivatives) in rapeseed during the microwave roasting process is necessary.

The amount of sinapine in the rapeseed sample first increased and then decreased ($p < 0.01$) depending on the microwave pretreatment time (Table 2). A 3 min microwave exposure period could increase the sinapine content of the rapeseed to the maximum (502.81 mg/100 g), and it was 43.59 mg/100 g higher than that of the untreated rapeseed. When the microwave time increased to 8 min, the sinapine content was the minimum; it was 409.20 mg/100 g, and 50.02 mg/100 g lower than the initial content. The decrease in sinapine content after roasting by microwave could be observed in Figure 1. Our results suggest that the microwave pretreatment may result in the reduced sinapine content with increased microwave time. This result must be due to a partial hydrolysis of sinapine by the elevated temperature from the relatively long period of microwave exposure.

Sinapic acid is the main phenolic acid in rapeseed. The unroasted samples possessed 76.80 mg per 100 g of rapeseed. As shown in Table 2, the trend seen was clear: similarly to sinapine, the content of sinapic acid first increased and then decreased depending on the period of microwave radiation ($p < 0.05$) too. When the rapeseed was treated for 2 min with microwaves, the sinapic acid content was the maximum (86.14 mg/100 g); it was 9.34 mg/100 g higher than that of the untreated sample. Microwave treatment of rapeseed sample for a period of 8 min could make the sinapic acid content decreased to the minimum (31.20 mg/100g) that it was 45.60 mg/100 g lower than that of the untreated sample, representing about 40% of its initial value (Figure 1). This fact can be explained by the fact that damage to the rapeseed cell membrane by microwave radiation favors the increase of extraction efficiency of sinapic acid in an earlier stage of the pretreatment. However, along with the extension of microwave treatment time, the temperature of the sample increased, the thermal decarboxylation of the sinapic acid naturally occurred, and canolol was formed in rapeseed.

The unroasted sample possessed 14.07 mg of canolol per 100 g of rapeseed (Table 2). The roasting treatment by microwave significantly increased the amount of canolol in rapeseed ($p < 0.001$). After exposure to a microwave treatment of 7 min duration, the canolol content increased from 14.07 mg/100 g to

dx.doi.org/10.1021/jf4054287 | J. Agric. Food Chem. 2014, 62, 1956−1963

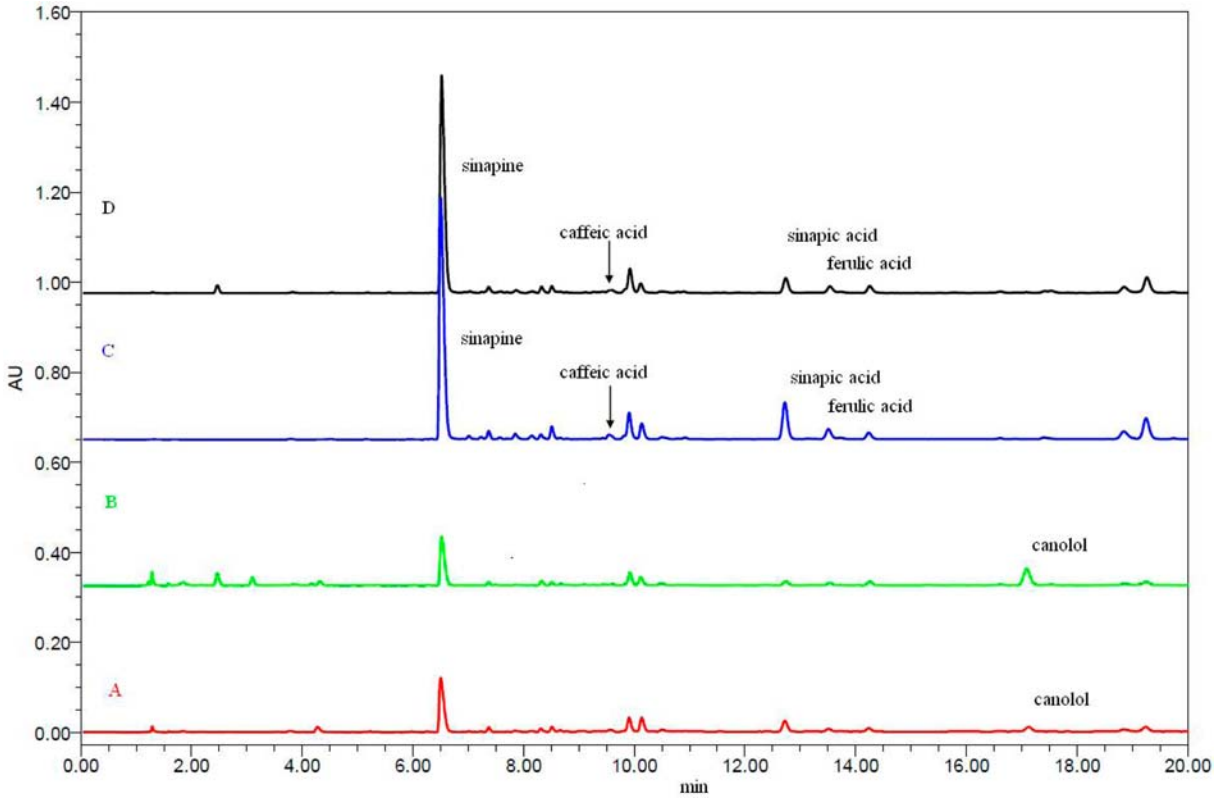

Figure 1. Reverse-phase UPLC chromatogram of the phenolic compounds: (A) unroasted seed measured at 280 nm, (B) 8 min roasted seed measured at 280 nm, (C) unroasted seed measured at 325 nm, and (D) 8 min roasted seed measured at 325 nm. Time axis is in minutes.

89.89 mg/100 g. The canolol content of 7 min microwave pretreatment rapeseed was approximately six times greater than that of the unroasted rapeseed. Spielmeyer et al. reported that the optimal roasting conditions (exposure to a microwave roasting of 7.5 min duration with a temperature of 160 °C) produced increased canolol content 120 times that found in the unroasted sample.[24] The increase in the amount of canolol content in our sample was lower than that reported by Spielmeyer et al., but the canolol content in 7 min microwave rapeseed was in accordance with the result presented by Spielmeyer et al.[24] Canolol was shown to be thermally unstable, and fast degradation during longer roasting was previously reported.[24] In our study, when the microwave time was extended to 8 min, the rapeseed sample possessed 83.48 mg of canolol per 100 g of rapeseed. This result concurs with previously published results.[24]

As shown in Table 2, when the microwave treatment time was 7 min, the decrease in sinapic acid content was 48.05 mg/100 g, compared with the content in 2 min microwave rapeseed, and the increase in canolol content was 67.77 mg/100 g in rapeseed. Thus, it was very clear: loss of sinapic acid was far below the amount of sinapic acid converted into canolol. This fact can be explained by the decrease in sinapine content: when the rapeseed was exposed to microwave radiation for 7 min, the sinapine content decreased from the maximum 502.81 mg/100 g to 463.21 mg/100 g and there was a 39.40 mg/100 g of decrease in sinapine content. Thus, hydrolysis of sinapine favors canolol formation during roasting. The amount of canolol formed was highly correlated with the content of sinapic acid and sinapine and also the loss of sinapic acid and sinapine during rapeseed roasting. The coefficients of correlation were −0.950 between the content of canolol and sinapic acid in the rapeseed treated by microwave for 0−8 min and 0.997 between the increase of canolol and loss of sinapic acid in the rapeseed treated by microwave for 2−8 min ($p < 0.001$). The coefficients of correlation were −0.828 between the content of canolol and sinapine in the rapeseed treated by microwave for 0−8 min and 0.952 between the increase of canolol and loss of sinapine in the rapeseed treated by microwave for 3−8 min ($p < 0.05$). The content of sinapic acid and sinapine in rapeseed was the maximum when microwave time was 2 and 3 min, respectively, as shown in Table 2. Previous studies have shown that the decrease in free sinapic acid (FSA) content and total sinapic acid content after basic hydrolysis (TSAH) content in rapeseed was 17.04 mg/100 g and 287 mg/100 g after roasting for 10 min at 160 °C, respectively. Furthermore, canolol formation was highly correlated with the initial FSA content, the residual FSA content after roasting, and also the loss of TSAH during seed roasting.[23]

Similarly to sinapine and sinapic acid, the content of caffeic and ferulic acid in the sample first increased and then decreased with increasing microwave time ($p < 0.01$) (Table 2). Caffeic, ferulic, and sinapic acids belong to hydroxycinnamic acids and have a similar molecular structure. It has been reported that 4-vinylguaiacol and 4-vinylphenol are formed from ferulic and *p*-coumaric acid during thermal treatment and by enzyme activity.[38,39] Moreover, the decarboxylation products of *p*-coumaric, caffeic, ferulic, and sinapic acids have been obtained by decarboxylation of 4-hydroxycinnamic acids.[40,41]Therefore, the decrease of caffeic and ferulic acid content can be explained by the thermal decarboxylation of them during rapeseed roasting by microwave.

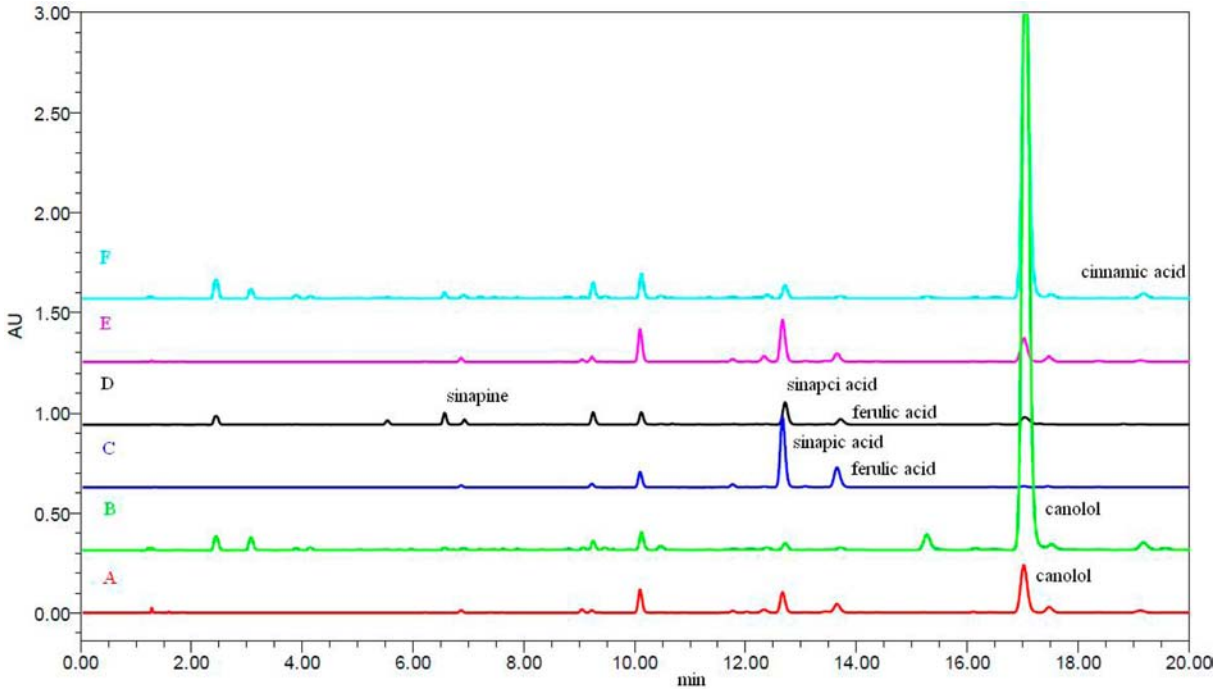

Figure 2. Reverse-phase UPLC chromatogram of the phenolic compounds: (A) oil from unroasted seed measured at 280 nm, (B) oil from 8 min roasted seed measured at 280 nm, (C) oil from unroasted seed measured at 325 nm, (D) oil from 8 min roasted seed measured at 325 nm, (E) oil from unroasted seed measured at 295 nm, (F) oil from 8 min roasted seed measured at 295 nm. Time axis is in minutes.

Transfer of Phenolic Compounds from Rapeseed to Oil by Press. Rapeseeds are much richer in phenolic compounds (Table 2). Most of these phenolics remain in the meal after pressing, and only a small proportion are transferred to the crude oil. However, owing to the difference in molecular structure, polarity, and fat solubility, there were differences in the quantities and transfer ratios of these phenolic compounds transferred to the crude oil.

The phenolic compounds of the studied rapeseeds and oil extracted from them by press by UPLC-DAD are presented in Table 2. Formation of canolol after roasting by microwave could be observed in Figure 2. As shown in Table 2, although the sinapine content in rapeseed up to about 500 mg/100 g it was not detected in the pressed oils from rapeseed by microwave pretreatment for 1−3 min, and sinapine content in the oils from rapeseed by microwave pretreatment for 4−8 min ranged from 0.05 mg/100 g to 0.66 mg/100 g and did not exceed 1 mg/100g. This result can be explained by the fact that sinapine is present in rapeseed in thiocyanate forms and is a water-soluble substance. Moreover, we observed that the content of sinapine in the oil sample increased with microwave time after roasting for 3 min ($p < 0.05$). This fact can be explained by the fact that the oil extraction yield by pressing increased with increasing microwave pretreatment time of rapeseed.[27−30]

We can see from Table 2 that the quantities of sinapic acid transferred to the pressed crude oil were few, and the transfer ratios increased with microwave pretreatment time: they were1.6%, 1.6%, 1.4%, 1.5%, 1.6%, 2.0%, 2.3%, 2.4%, and 2.7% when rapeseed was exposed for 0, 1, 2, 3, 4, 5, 6, 7, and 8 min, respectively. Table 2 shows that the content of sinapic acid in the oil first increased and then decreased depending on the period of microwave radiation ($p < 0.001$), similarly to the change of sinapic acid in the rapeseed. Small amounts of caffeic and ferulic acid were detected in the rapeseed samples (Table 2). Caffeic acid in the oil was not detected, and all of the caffeic acid remained in the meal after pressing, whereas a small amount of ferulic and cinnamic acid were detected in all oil samples. It was noteworthy that cinnamic acid was not detected in the rapeseed sample. The cinnamic acid content in the oil significantly increased with microwave time ($p < 0.001$), and the ferulic acid content in oil was not significantly different ($p > 0.05$). This result may be explained by the fact that there was a difference in the polarity of caffeic, ferulic, and cinnamic acids in the following order caffeic acid > ferulic acid > cinnamic acid.

However, the phenomenon of transferring in canolol was completely different from sinapic, caffeic, ferulic, and cinnamic acids: most of the canolol was transferred to the crude oil when pressing the oil from rapeseed, and the content and transfer ratio of canolol significantly increased depending on the period of microwave radiation ($p < 0.001$). This result may be due to the strong fat solubility of canolol. As shown in Table 2, the canolol content of oil pressed from 4 min microwave pretreatment rapeseed increased from 17.06 mg/100g to 47.40 mg/100g and was approximately three times greater than that of the oil pressed from untreated rapeseed. When the microwave time of rapeseed reached 7 min, the canolol content in the oil increased to 162.71 mg/100g and was approximately nine times greater than that of the oil from unroasted rapeseed. The transfer ratio of canolol transferred to the crude oil was 56%, 60%, 64%, 68%, 71%, 73%, 74%, 79%, and 83% when rapeseed was exposed for 0, 1, 2, 3, 4, 5, 6, 7, and 8 min, respectively. Shrestha et al. found that 49−56% of the canolol formed during seed roasting was transferred to the oil.[23] The transfer rates of canolol in our study were higher than the results obtained by Shrestha et al. The difference in transfer rate levels might arise from factors, such as the oil sample preparation and oil content of seed.

We observed that there was an inflection point of rapid increase in the canolol content of oil from rapeseed by roasting

dx.doi.org/10.1021/jf4054287 | J. Agric. Food Chem. 2014, 62, 1956−1963

for 5 min: the canolol content increased to 79.79 mg/100 g. Moreover, there was faster growth in the canolol content in the oil from rapeseed by roasting for 5−8 min than that for 1−4 min (Table 2). This result might arise from the following factor: the temperature of rapeseed increased with microwave pretreatment time and lead to an increase in the amount of sinapic acid and esterified sinapic acid derivatives, such as sinapine, converted into canolol. Moreover, more canolol transferred to the pressed crude oil as a result of an increase in the oil extraction yield with increasing microwave pretreatment time.

The induction period (IP, 110 °C) was 9.59, 9.72, 9.52, 10.00, 11.77, 14.27, 16.99, 28.77, and 30.15 h of the oil from rapeseed treated with microwaves for 0, 1, 2, 3, 4, 5, 6, 7, and 8 min, respectively. Thus, microwave pretreatment of rapeseed is a beneficial step for improving the oxidative stability of oil. Canolol has very good antioxidative activity. The IP was positively correlated with the canolol content in oil, and the correlation coefficient was 0.895, p = 0.001. The significant correlations between the amount of canolol formation and the loss of sinapic acid and sinapine during roasting were found. Engels et al. identified eight kinds of sinapic acid derivatives from mustard seed meal using UHPLC-DAD-ESI-MS^n.[42] The roles of these sinapic acid derivatives in canolol formation need further study.

produces the CP4 EPSPS protein,[4] which allows for full vegetative and reproductive tissue glyphosate tolerance in the hybrid seed.

The research reported here compares the composition of grain and forage from MON 87427 and MON 87427 × MON 89034 × NK603 to the composition of near-isogenic conventional hybrid comparators. Compositional analysis is a key component of the comparative assessment process of new crops containing traits derived from modern agricultural biotechnology. It involves comparisons of levels of key nutrients, antinutrients, and secondary metabolites in the new biotech or genetically modified (GM) crop to levels in a near-isogenic conventional counterpart. Assessments of differences between the two comparators typically use statistical significance testing. Harrigan et al.[5] recently reviewed the results of GM crop composition studies conducted over multiple geographies and growing seasons and concluded that significant differences ($\alpha = 0.05$) in mean values between a GM crop and its near-isogenic comparator were typically of very small magnitudes and that these differences were considerably less than the differences resulting from germplasm and environmental factors. This has led to increased emphasis that statistical significance does not necessarily imply biological relevance[6] and that the well-documented sources of compositional variability and its influence on overall crop composition must be considered in comparative assessments. In this investigation, we highlight types of further evaluations to consider in the assessment of compositional outcomes in the context of natural variability.

MATERIALS AND METHODS

Maize Samples for Compositional Analyses. The control for MON 87427 was EXP262, a conventional maize hybrid, with a genetic background similar to that of MON 87427. The control for MON 87427 × MON 89034 × NK603 was MPA636B, a conventional maize hybrid, with a genetic background similar to that of MON 87427 × MON 89034 × NK603. Commercially available conventional reference hybrids were planted concurrently with the experimental (MON 87427 or MON 87427 × MON 89034 × NK603) and control hybrids to provide in-study data on the variability of each compositional component assessed.

Materials for composition analyses were generated in 2010 at eight locations within the primary maize-growing regions. For the MON 87427 study, hybrids were grown in Jackson county, Arkansas; Greene and Jefferson counties, Iowa; Clinton and Stark counties, Illinois; Boone county, Indiana; Pawnee county, Kansas; and York county, Nebraska. For the MON 87427 × MON 89034 × NK603 study, hybrids were grown in Jackson county, Arkansas; Clinton and Stark counties, Illinois; Jefferson county, Iowa; Pawnee county, Kansas; Shelby county, Missouri; York county, Nebraska; and Miami county, Ohio.

At each location, hybrids were planted in a randomized complete block design with four blocks. Within each block, plots (six rows × 6.1 m) were assigned randomly to experimental hybrid (MON 87427 or MON 87427 × MON 89034 × NK603), control (EXP262 or MPA636B), or one of the four of the conventional reference hybrids. For the MON 87427 study, a total of 24 unique reference hybrids were planted across the eight-site multilocation study. For the MON 87427 × MON 89034 × NK603 study, a total of 22 unique reference hybrids were planted across the eight-site multilocation study. These conventional reference hybrids were representative of maize hybrids typically grown at each specific location.

Standard agronomic practices for each region were followed. A single application of Roundup WeatherMAX (Roundup and Roundup WeatherMAX are registered trademarks of Monsanto Technology LLC) was applied, according to the label, at a rate of 1.0 lb ae/acre to the MON 87427 × MON 89034 × NK603 plots at approximately the V2−V4 growth stages for weed control. The genetic purity of MON 87427, MON 87427 × MON 89034 × NK603, control, and commercial reference maize was maintained by bagging the tassels and ear shoots at anthesis and hand-pollinating each plant.

Forage and grain harvest, sampling, shipping, storage and sample preparation protocols for compositional analysis were followed as previously described.[7] Event-specific polymerase chain reaction analysis[8] was conducted to confirm the genetic identity of the harvested grain. From the MON 87427 field production, one experimental sample from one location and a total of 11 samples of nine reference substances from six locations were excluded from compositional analyses due to the adventitious presence of unintended traits. From the MON 87427 × MON 89034 × NK603 field production, 15 samples of nine reference substances from seven locations were also excluded from analysis due to the adventitious presence of unintended traits.

Compositional Analysis Methods. Forage samples were analyzed for proximates (ash, fat, moisture, and protein), acid detergent fiber (ADF), neutral detergent fiber (NDF), and minerals (calcium and phosphorus).[9] Grain samples were analyzed for proximates, ADF, NDF, total dietary fiber (TDF), amino acids, fatty acids (FA), minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, sodium, and zinc), secondary metabolites [ferulic acid, 2-furaldehyde (furfural), and *p*-coumaric acid], antinutrients (phytic acid and raffinose), and vitamins [folic acid, vitamin A (β-carotene), niacin, vitamin B_1, vitamin B_2, vitamin B_6, and vitamin E]. Carbohydrate levels in forage and grain were determined by calculation, and moisture levels were measured for the re-expression of fresh weight values on a dry weight basis. The compositional analyses were conducted using industry standard analytical methods (AOAC, AOCS, or other published methods) that are used in routine compositional characterization of foods and feeds[3,10] at Covance Laboratories Inc. (Madison, WI, USA) and EPL Bio-Analytical Services (Niantic, IL, USA). Samples from each study were analyzed in a randomized order to reduce assay bias.

Statistical Analysis of Compositional Data. Statistical analysis of the data involved a comparison of MON 87427 to EXP262 and MON 87427 × MON 89034 × NK603 to MPA636B for every analyte across all sites to determine significant differences ($\alpha = 0.05$) using analysis of variance (ANOVA). To complete a statistical analysis for a component in each separate study, at least 50% of the values for an analyte had to be greater than the assay limit of quantitation (LOQ).[11] The following 13 analytes, which had >50% of observations less than the LOQs, were excluded from statistical analysis from both MON 87427 and MON 87427 × MON 89034 × NK603: capric acid, caprylic acid, lauric acid, myristic acid, myristoleic acid, pentadecanoic acid, pentadecenoic acid, heptadecenoic acid, γ-linolenic acid, eicosadienoic acid, eicosatrienoic acid, arachidonic acid, erucic, and furfural. In addition, heptadecanoic acid and sodium in MON 87427 were below the assay LOQ. The fatty acids reported above are present in only low amounts in maize grain, if present at all.[5] This investigation confirmed that this observation extended to MON 87427 and MON 87427 × MON 89034 × NK603.

For analytes with individual measurements less than the LOQ and with >50% of all of the values greater than the LOQ, a value equal to half of the LOQ was assigned prior to statistical analyses.[3] Assigned values for grain in the MON 87427 study included 127 values of palmitoleic acid, four values of behenic acid, and one value of calcium. For the MON 87427 × MON 89034 × NK603 study, assigned grain values included five values of palmitoleic acid, 102 values of heptadecanoic acid, two values of ecosenoic acid, 85 values of behenic acid, three values of copper, 95 values of sodium, 14 values of vitamin A, and 33 values of vitamin B_1.

A studentized PRESS residual test was applied to the adjusted data set to identify outliers. Data points that were outside the ±6 studentized PRESS residual range were considered for exclusion, as outliers, from the final statistical analysis on the basis of a biological assessment of the data point. For the MON 87427 study, one ash value was identified as an outlier and was removed from the statistical

Table 1. Summary of Maize Grain Fat and Fatty Acids (FA) for MON 87427, MON 87427 × MON 89034 × NK603 and the Respective Conventional Controls

analysis. Statistical analysis of the data from samples collected from each separate study was conducted at Certus International, Inc. (Chesterfield, MO, USA). Statistical analyses were conducted on forage and grain using a mixed model analysis of variance from the combination of all sites using the following model:

$$Y_{ijk} = U + T_i + L_j + B(L)_{jk} + LT_{ij} + e_{ijk}$$

Y_{ijk} is the unique individual observation, U is the overall mean, T_i is the substance effect, L_j is the random location effect, $B(L)_{jk}$ is the random block within location effect, LT_{ij} is the random location by substance interaction effect, and e_{ijk} is the residual error. Within grain and forage, data for each compositional component from the experimental hybrids (MON 87427 or MON 87427 × MON 89034 × NK603) were compared to data from their respective control (EXP262 or MPA636B). Statistically significant differences between the experimental hybrid values and the control values were declared at $\alpha = 0.05$. For both studies, the field designs included other experimental hybrids not related to this study but included in the overall ANOVA. The conventional reference hybrids were used to estimate natural compositional variation that can generally be attributed to differences in the germplasm and environment.

Variance components analysis (VCA) was also conducted for both studies (MON 87427 and MON 87427 × MON 89034 × NK603) separately to estimate the proportion of random effects contributing to the total variance. In this application, the effects of substance, location, location × substance interaction, and replication (block) in the ANOVA model were set as random effects. The SAS procedure PROC MIXED was employed to run the analysis. The output table of covariance parameter estimates from SAS PROC MIXED procedure gives estimates of the variance component parameters for each of model components.[12] The variance component parameters of each model component were divided by the total variance to get the variance proportions for each of the components (see Suppl. Tables 3 and 4 in the Supporting Information). For both studies, the field designs included other experimental substances not related to this work but included in the overall ANOVA and VCA.

RESULTS AND DISCUSSION

Comparisons of MON 87427 and MON 87427 × MON 89034 × NK603 to their respective near-isogenic conventional control were on data combined across all field sites from each separate study (Tables 1−5; Suppl. Table 1 in the Supporting Information) using ANOVA. The analysis from both studies showed few statistically significant differences ($\alpha = 0.05$). For MON 87427, differences were observed for histidine, methionine, proline, palmitic acid, oleic acid, and vitamin B_6 in grain (Tables 1, 2, and 5). No differences were observed for forage (Suppl. Table 1). For MON 87427 × MON 89034 × NK603 differences were observed for calcium, manganese, phosphorus, zinc, niacin, and *p*-coumaric acid in grain (Tables 2−4). No differences were observed for forage (Suppl. Table 1).

These results are consistent with numerous prior studies that have illustrated the lack of impact of transgenesis on composition and highlighted that compositional variability is dominated by germplasm and environmental factors. The purpose of the following section is (i) to further describe the compositional equivalence of the MON 87427 products to their near-isogenic comparators, (ii) to illustrate how well-documented influential sources of compositional variability can be considered in comparative assessments,[5] and (iii) to further explain how statistical significance does not imply biological relevance from a composition or food/feed perspective.[5,6] Evaluation of the differences observed in the combined-site analysis therefore focused on the following logic:

(1) Consideration of the magnitude of the mean difference between experimental hybrid (MON 87427 or MON 87427 × MON 89034 × NK603) and the respective control in the context of the variation observed

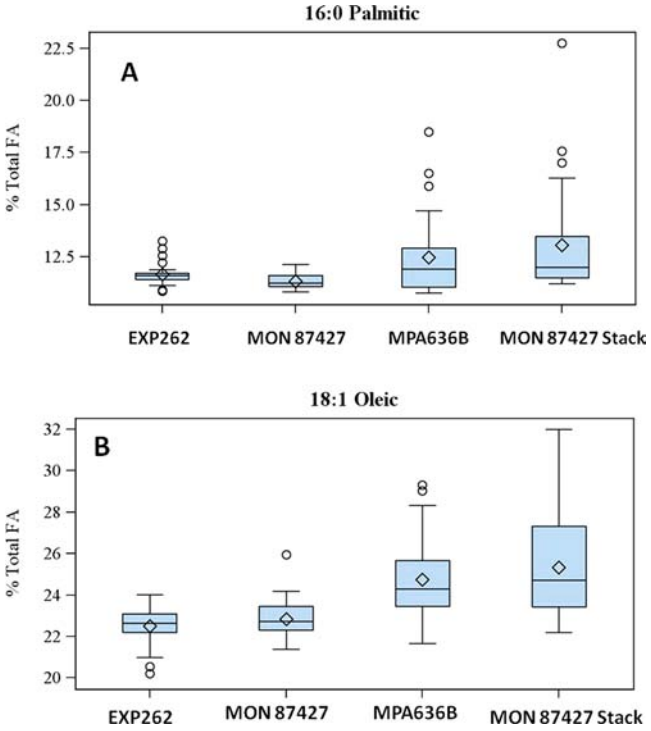

Figure 1. Box plot representing observed variability for palmitic acid and oleic acid values in MON 87427 and MON 87427 × MON 89034 × NK603 (MON 87427 Stack) and their respective conventional control. Each box extends from the lower (25th) to the upper (75th) quartile, and the line in each box represents the median. The whiskers extend to minimum and maximum data points. See Table 1 for details.

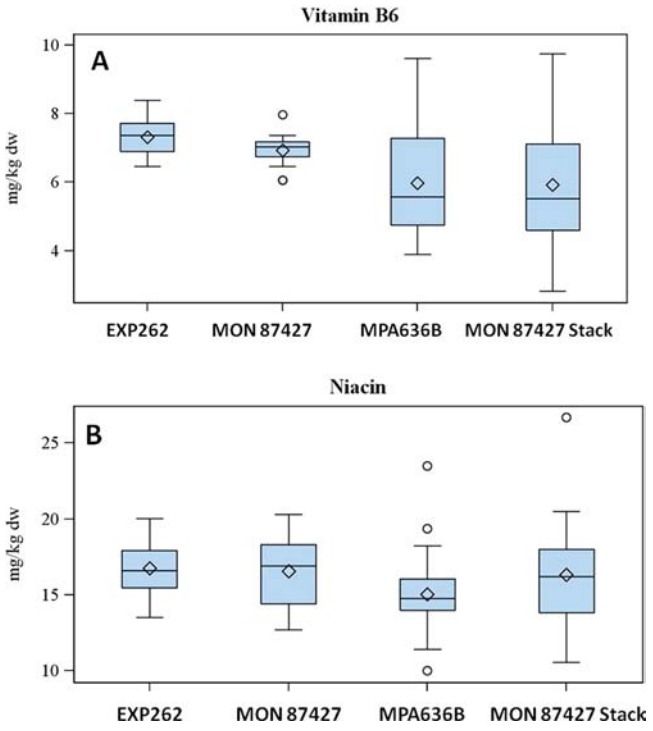

Figure 2. Box plot representing observed variability for niacin and vitamin B_6 values in MON 87427 and MON 87427 × MON 89034 × NK603 (MON 87427 Stack) and their respective conventional control. Legends are the same as described in Figure 1. See Table 2 for details.

(maximum value minus the minimum value) for the control. This allows a meaningful evaluation of the impact of transgene insertion relative to the environmental variability observed in a single genotype (with and without transgene). The individual replicate values of the experimental hybrid and control were also compared to each other to further demonstrate similarity. A significant difference in mean values between an experimental hybrid and the respective control values does not imply a meaningful difference from a compositional perspective, especially if the difference is much less than variation attributable to other sources (e.g., environmental influences).

(2) Comparison of the magnitude of the mean difference between the experimental hybrid (MON 87427 or MON 87427 × MON 89034 × NK603) and the respective control to variation in conventional maize as estimated

Table 2. Summary of Maize Grain Vitamins for MON 87427, MON 87427 × MON 89034 × NK603 and the Respective Conventional Controls

[a]dwt = dry weight. [b]Mean (SE) = least-squares mean (standard error). [c]Statistically significant at 5% level (α = 0.05).

by in-study reference hybrid values, the scientific literature, and the ILSI Crop Composition Database (ILSI-CCDB). This provides further information that a difference in mean values between the experimental hybrids and respective controls does not imply a meaningful difference from a food and feed safety perspective, especially if the difference is much less than natural variation due to other sources (i.e., environmental and varietal influences).

(3) Evaluations of graphical representations of the compositional data. Proponents of graphical approaches consider that the "location, range, and distribution of numerical values[6a] within a data set should be understood" to provide context to results from significance testing. Box plots (Figures 1−4) are presented to compare the variation observed in the selected experimental hybrid and control components. Results from VCA are also presented to understand and convey sources of variation in the data (Figure 5; Suppl. Tables 3 and 4).

Total Fat and Fatty Acids. No significant differences (α = 0.05) between total fat mean values were observed between the MON 87427 products and their respective near-isogenic controls (Table 1) using ANOVA. Differences were observed for only two of 10 fatty acids assessed (palmitic and oleic acids, Table 1) in MON 87427, and no differences in fatty acids were observed for MON 87427 × MON 89034 × NK603. By evaluating the observed differences for palmitic and oleic acid in MON 87427 using the logic described above, these differences are shown to be irrelevant from a compositional and food/feed perspective. The mean palmitic acid value was 11.34% total FA for MON 87427 and 11.67% total FA for the control, a difference of −0.32% total FA. This difference was less than the range of the control values, 2.39% total FA (Table 1; Figure 1A) calculated from the minimum (10.87% total FA) and maximum (13.26% total FA) palmitic acid values. The mean oleic acid values were 22.86% total FA for MON 87427 and 22.50% total FA for the control, a difference of 0.36% total FA. This was less than the range of the control values, 3.79% total FA (Table 2; Figure 1B), calculated similarly to above from minimum and maximum oleic acid values. The mean differences in palmitic and oleic acid values between MON 87427 and the control were less than the ranges of the control values, indicating that MON 87427 does not affect levels more than natural variation within the control grown at multiple locations. The mean differences in palmitic acid and oleic acid were also less than the variation seen in the reference values (palmitic acid range = 9.27−14.17% total FA and oleic acid range = 21.23−34.93% total FA; Suppl. Table 2), and the MON 87427 mean values were within values observed in the literature and the ILSI-CCDB values[13] (Suppl. Table 5). Maize is known to exhibit extensive variability in total fat and fatty acid levels,[14] and these results are consistent with the literature. Figure 1 illustrates how the concepts of variability discussed

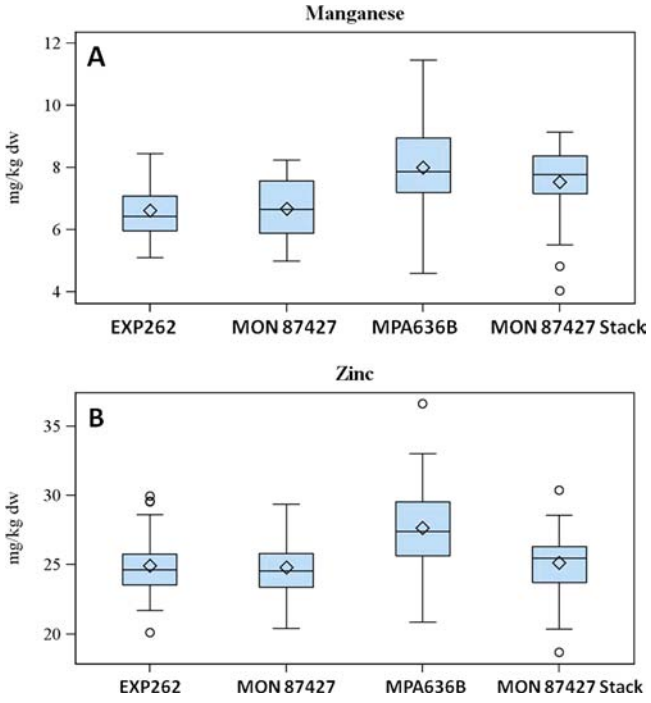

Figure 3. Box plot representing observed variability for manganese and zinc values in MON 87427 and MON 87427 × MON 89034 × NK603 (MON 87427 Stack) and their respective conventional control. Legends are the same as described in Figure 1. See Table 3 for details.

above can be presented graphically by comparing the observed variability in the experimental and control substances for palmitic and oleic acid. Figure 1 also demonstrates the similarities observed in values between the experimental and control hybrids. VCA results for all fatty acids are shown in the Supporting Information (Suppl. Tables 3 and 4). Overall, the greatest contributors to variation in both studies were location and residual error. Block and location × substance contributed least to variation in fat and fatty acid levels.

Vitamins. Significant differences (α = 0.05) between vitamin mean values were observed only for vitamin B_6 in MON 87427 compared to the near-isogenic control and for niacin in MON 87427 × MON 89034 × NK603 compared to the near-isogenic control (Table 2).

For vitamin B_6, the mean values were 6.92 mg/kg dwt for MON 87427 and 7.31 mg/kg dwt for the control, a difference of −0.39 mg/kg dwt. This difference was less than the range of the control values, 1.93 mg/kg dwt, indicating that MON 87427 does not affect levels of vitamin B_6 more than natural variation within the control grown at multiple locations. The corresponding range of values for MON 87427 was 1.92 mg/kg dwt (Table 2; Figure 2A).

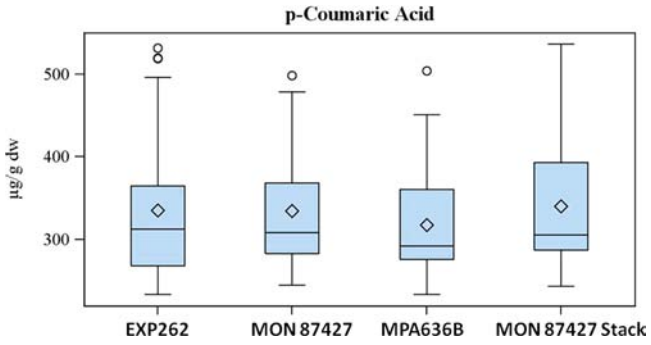

Figure 4. Box plot representing observed variability for *p*-coumaric acid values in MON 87427 and MON 87427 × MON 89034 × NK603 (MON 87427 Stack) and respective conventional control. Legends are the same as described in Figure 1. See Table 4 for details.

For niacin, the mean values were 16.33 mg/kg dwt for MON 87427 × MON 89034 × NK603 and 15.06 mg/kg dwt for the control, a difference of 1.27 mg/kg dwt. This difference was less than the range of the control values, 13.48 mg/kg dwt, indicating that MON 87427 × MON 89034 × NK603 does not affect levels of niacin more than natural variation within the control grown at multiple locations. The corresponding range of values for MON 87427 × MON 89034 × NK603 was 16.14 mg/kg dwt (Table 2; Figure 2B). The mean difference in vitamin B_6 and niacin was also less than the variation seen in the respective reference values (vitamin B_6 range in MON 87427 = 5.51−8.22 mg/kg dwt, niacin range in MON 87427 × MON 89034 × NK603 = 9.53−25.00 mg/kg dwt, respectively, Suppl. Table 2) and values observed in the literature and the ILSI-CCDB (Suppl. Table 5). Figure 2 compares the variation observed in experimental and control hybrids in individual values across sites for vitamin B_6 and niacin and emphasizes the observed similarities in values between experimental and control hybrids. VCA results for all vitamins are shown in Suppl. Tables 3 and 4 in the Supporting Information. Overall, the greatest contributions to variation in both studies were location and residual error. Block and location × substance overall contributed least to variation in vitamin levels.

Table 4. Summary of Maize Grain Antinutrients and Secondary Metabolites for MON 87427, MON 87427 × MON 89034 × NK603 and the Respective Conventional Controls

component (% dwt)[a]	MON 87427 (treated) mean (SE)[b] range	control EXP62 mean (SE) range	MON 87427 × MON 89034 × NK603 mean (SE) range	control MPA636B mean (SE) range

	2120.18−3179.78	1943.50−3636.36	2709.97−3710.76	2560.99−3492.06
p-coumaric acid (µg/g dwt)	331.99 (28.49)	335.25 (28.48)	340.37 (27.71)[c]	317.80 (27.71)
	244.09−498.88	232.77−532.51	242.97−537.25	232.58−504.50

[a]dwt = dry weight. [b]Mean (SE) = least-squares mean (standard error). [c]Statistically significant at 5% level (α = 0.05).

dx.doi.org/10.1021/jf4041589 | J. Agric. Food Chem. 2014, 62, 1964−1973

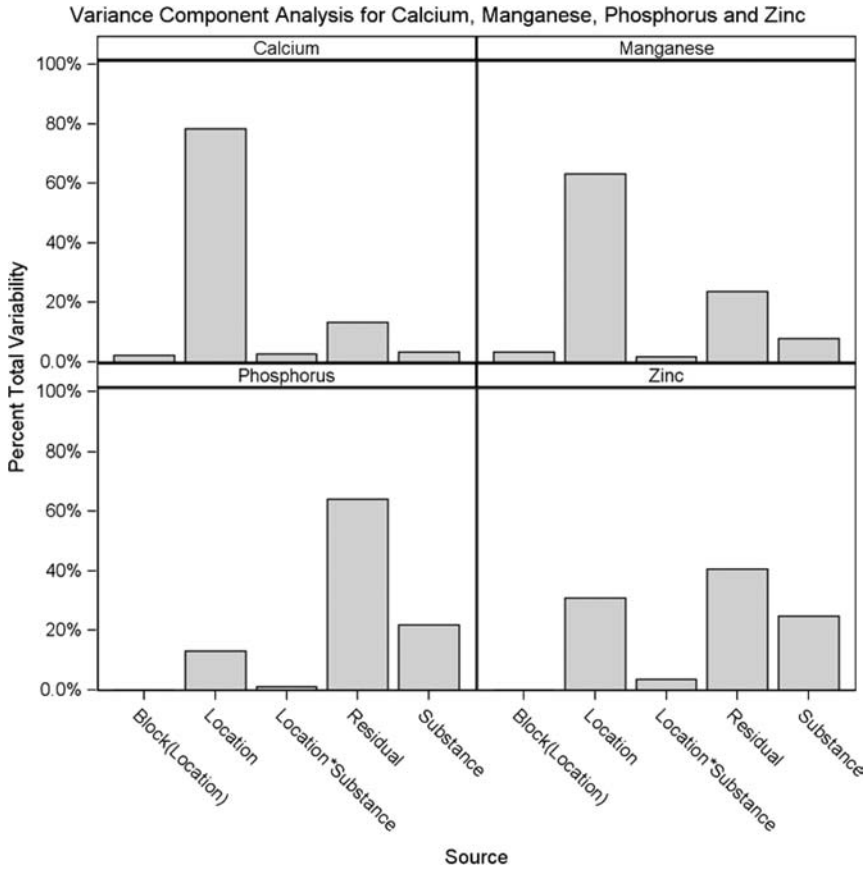

Figure 5. Sources of variation estimates from variance component analysis for calcium, manganese, phosphorus, and zinc values in MON 87427 × MON 89034 × NK603 (MON 87427 Stack).

Ash and Minerals. For MON 87427, no significant difference (α = 0.05) was observed for ash (Table 3) or minerals. For MON 87427 × MON 89034 × NK603, differences were observed for calcium, manganese, phosphorus, and zinc. Similar to the results observed for the fatty acids and vitamins discussed above, the logic applied above illustrated that observed significant mean differences (α = 0.05) for calcium, manganese, phosphorus, and zinc for MON 87427 × MON 89034 × NK603 were small relative to ranges of values observed for the control and reference hybrids as well as in the scientific literature. In other words, these data confirm that MON 87427 by itself or as part of a combined-stack product does not affect levels of minerals more than natural variation within the control grown at multiple locations. Mineral content in maize is known to vary by environment and germplasm.[15] Figure 3 compares the variation observed in experimental and control hybrids for manganese and zinc and highlights observed compositional similarity. VCA results for all minerals are shown in Suppl. Tables 3 and 4. Even though there were clear differences in the contribution of "location", "residual", and "substance" effects for different minerals, the greatest contributor to variation in both studies for most minerals was location. "Block" and "location × substance" overall contributed least to variation in mineral levels. Figure 5 shows results for calcium, manganese, phosphorus, and zinc from the MON 87427 × MON 89034 × NK603 study.

Antinutrient and Secondary Metabolites. Significant differences (α = 0.05) between antinutrient and secondary metabolite mean values were observed only for *p*-coumaric acid between MON 87427 × MON 89034 × NK603 and the near-isogenic control (Table 5). The mean *p*-coumaric acid values for MON 87427 × MON 89034 × NK603 were 340.37 and 317.80 μg/g dwt for the control, a difference of 22.57 μg/g dwt. This difference was much less than the range of the control values, 271.92 μg/g dwt, indicating that MON 87427 × MON 89034 × NK603 does not affect levels of *p*-coumaric acid more than natural variation observed within the control grown at multiple locations. The corresponding range of values from MON 87427 × MON 89034 × NK603 was 294.28 (Table 4; Figure 4). The mean difference was also less than the variation seen in the reference hybrid values (range = 104.18−608.45 μg/g dwt, Table 4) as well as the values observed in the literature and the ILSI-CCDB (Suppl. Table 5). Figure 4 shows the extensive variation associated with *p*-coumaric acid, and this variation can be attributed to location. The estimates of source of variation from variance component analysis are provided in Suppl. Tables 3 and 4 in the Supporting Information and highlight a major contribution (>75%) in both studies due to location.

Protein and Amino Acids. No significant differences (α = 0.05) in protein mean values were observed between the MON 87427 products and their respective near-isogenic controls (Table 5). The actual observed differences were small relative to the control; 2.33% for MON 87427 and −1.01% for MON 87427 × MON 89034 × NK603. To allow an assessment of the difference in amino acids in relation to a difference in protein, relative magnitudes of difference were expressed as a percent of control. Consistent with the changes observed with the protein values, the magnitudes of differences for amino acids were also small with statistical significance observed only for histidine,

Table 5. Summary of Maize Grain Protein and Amino Acids for MON 87427, MON 87427 × MON 89034 × NK603, and the Respective Conventional Controls

component (% dwt)[a]	MON 87427 mean (SE)[b] range	control EXP62 mean (SE) range	MON 87427 × MON 89034 × NK603 mean (SE)[b] range	control MPA636B mean (SE) range

[a]dwt = dry weight. [b]Mean (SE) = least-squares mean (standard error). [c]Statistically significant at 5% level (α = 0.05).

methionine, and proline in the assessment of MON 87427 and no difference for MON 87427 × MON 89034 × NK603 (Table 5). The rationale applied above for other components reinforced how small these differences were by highlighting that MON 87427 did not affect levels of any amino acids acid more than natural variation within the control grown at multiple locations (Table 5). The mean histidine value was 0.27% dwt for MON 87427 and 0.26% dwt for the control, a difference of 0.0091% dwt. This difference was much less than range of the control values, 0.112% dwt (Table 1). Mean differences in methionine (0.011% dwt) and proline (0.032%) were also much less than the respective control ranges (0.081 and 0.383% dwt, respectively). The mean differences in histidine, methionine, and proline values were also less than the variation seen in the reference values (histidine range = 0.22−0.34% dwt, methionine range = 0.13−0.30% dwt, and proline range = 0.65−1.17% dwt; Suppl. Table 2), and the MON 87427 mean values were within values observed in the literature and the ILSI-CCDB (Suppl. Table 3). Together, these data confirm that the differences in mean values observed for the amino acids histidine, methionine, and proline in MON 87427 were not meaningful from a food/feed safety perspective. It is known that the levels of protein and amino acids in maize can vary widely depending on environmental conditions and agronomic practices.[4,16] The estimates of the source of variation for protein and amino acids from the VCA are provided in Suppl. Tables 3 and 4. The greatest sources of variation were "location" and "residual error".

Fibers and Carbohydrates by Calculation. No significant differences (α = 0.05) between carbohydrates and fiber mean values were observed between the MON 87427 and MON 87427 × MON 89034 × NK603 and their respective near-isogenic controls, respectively (Table 3).

Concluding Remarks. In summary, comprehensive compositional analysis shows that levels of key nutrients, antinutrients, and secondary metabolites in forage and grain of MON 87427, an inducible male sterile and tissue selective glyphosate-tolerant maize product, are comparable to the near-isogenic conventional control. Multiple sources (germplasm and location) of variation in the study were accounted for to aid in the interpretation of compositional outcomes. This methodology highlighted that differences between MON 87427 and the control were of small magnitude and inconsequential from a food/feed safety perspective. This study also highlights the fact that transgene insertion was a much smaller source of variation in the composition when compared to environmental effects. Results from analysis of MON 87427 × MON 89034 × NK603 confirm that this observation extends to the combined-trait product. With increasing global demand for food production, developments of new strategies for seed production are important to sustainable agriculture. MON 87427 offers a novel biotechnology-derived trait to produce hybrid seeds with decreased costs and labor while maintaining seed purity. The investigation reported here demonstrated that biotechnological approaches can be applied in enhancing hybrid maize seed production without affecting compositional quality.

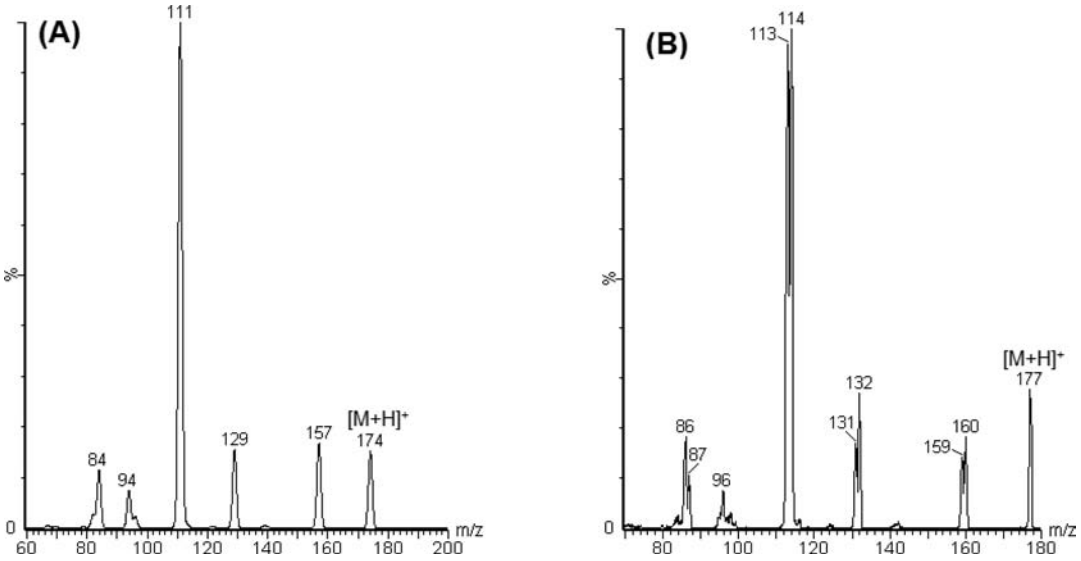

Figure 2. Tandem mass spectrometry fragmentation spectra of (A) indospicine and (B) D_3-L-indospicine.

times", and *I. linnaei* and *I. basedowii*, which are"preferred food plants".[18] Short-lived mass developments of forbs were reported to be seasonally utilized by camels, including *Indigofera* species in summer. Despite the reported dog poisoning incident,[16] the extent of indospicine (**2**) contamination of camel meat in Australia remains largely unknown. Consequently, this study was undertaken to develop and validate a high-throughput ultra-performance liquid chromatography–tandem mass spectrometry (UPLC–MS/MS) method to quantitate indospicine (**2**) in camel meat tissue. The validated method was then used to determine the concentrations of indospicine (**2**) in a number of collected camel meat samples obtained from a high camel density area of Australia, the Simpson Desert in the Northern Territory of Australia.

Indospicine (**2**) has previously been measured in plant material by amino acid analysis,[1,19,20] HPLC,[4,9] and, more recently, LC–MS/MS with phenylisothiocyanate derivitization.[21] Analysis of indospicine (**2**) in meat is more challenging due to the lower levels of toxin and the complex matrix. Indospicine (**2**) in animal tissues have previously been analyzed by lengthy (nearly 2 h) amino acid analysis[1,22] and by phenylisothiocyanate derivatization and UV detection, with resolution from other amino acids being problematic.[9] The incorporation of D_3-L-indospicine (**3**) (Figure 1) in this present study overcomes matrix effects noted in our previous LC–MS/MS analysis of camel tissues.[16]

MATERIALS AND METHODS

Indospicine Standards. Synthesized indospicine (**2**) and D_3-L-indospicine (**3**) were provided by Dr. James De Voss and Dr. Robert Lang, The University of Queensland.

Meat Materials. A total of 99 camels were sampled as part of a cull exercise under the Australian Feral Camel Management Project[23] in the Simpson Desert in central Australia. Rump muscle samples were excised from culled camels, placed in specimen containers, frozen, and transported to Health and Food Science Precinct, Brisbane, Australia. All of the samples were stored frozen (−30 °C) prior to extraction and analysis. Camel muscle samples free from indospicine (**2**) contamination (used for negative control and spike samples) were obtained from a pet food supplier, and these samples had been sourced from 200 km northwest of Rawlinna in Nullabor Plain, West Australia (an area relatively free from *Indigofera* species),[24] and stored frozen.

Indospicine Extraction. Prior to analysis, Amicon Ultra 0.5 mL, 3K centrifugal filter units (Merck Millipore, Kilsyth, Australia) were prerinsed and centrifuged (10 000 rpm, 20 min) with reverse osmosis water (2 × 300 μL) to remove glycerine and then inverted and spun for 1 min at 1000 rpm. Camel muscle samples were thawed, finely chopped, weighed (0.5 g), and mixed with 0.1% heptafluorobutyric acid (HFBA, 25 mL), follow by homogenization with a Polytron T25 Basic homogenizer (Labtek, Brendale, Australia) for 15 s. The homogenized samples were chilled (4 °C) for 20 min and then centrifuged at 4500 rpm for 20 min at 18 °C. Aliquots of supernatants (1.0 mL) spiked with the internal standard D_3-L-indospicine (**3**) (1 mg/L in 0.1% HFBA, 100 μL) were vortexed for 10 s. A portion (450 μL) was transferred into prerinsed Amicon Ultra 0.5 mL, 3K centrifugal filters, which were centrifuged (10 000 rpm, 20 min), with the filtrates transferred to a limited volume insert for UPLC–MS/MS analysis.

UPLC–MS/MS Equipment and Conditions. Sample data were collected by MassLynx 4.1 and processed by TargetLynx application managers. Separation of indospicine was done by a Waters ACQUITY UPLC system liquid chromatography (Waters, Rydalmere, Australia). LC separations were performed using a 100 mm × 2.1 mm i.d., 1.7 μm, BEH C18 column (Waters, Rydalmere, Australia) at 30 °C with flow rate of 0.2 mL/min. The mobile phase was a mixture of (A) H_2O with 0.1% HFBA (v/v) (pH 2.15) and (B) acetonitrile with 0.1% HFBA, which were prepared freshly for each analysis. The following gradient was used: 0 min, 99% A; 4 min, 70% A; 7 min, 70% A; 8 min, 99% A; 10 min, 99% A.

MS/MS detection was made using a Waters Micromass Quattro Premier triple quadrupole mass spectrometer with an electrospray ionization (ESI) source (Waters, Rydalmere, Australia), operated in the positive mode. Eluted indospicine (**2**) was quantitated by utilizing selected reaction monitoring (SRM) transitions of m/z 174.2 → 111.0 (verified by transition of m/z 174.2 → 157.1) for indospicine (**2**) and m/z 177.1 → 114.0 (verified by transition of m/z 177.1 → 113.0) for D_3-L-indospicine (**3**) as internal standard. The capillary voltage was 2.79 kV, cone gas flow was 50 L/h, and desolvation gas flow was 600 L/h. The source and desolvation temperatures were set at 150 and 350 °C, respectively. The argon gas collision energies for indospicine (**2**) (15 and 12 eV) and D_3-L-indospicine (**3**) (15 and 15 eV) were set with cone voltage at 25 V.

Synthesized indospicine (**2**) (external standard) and D_3-L-indospicine (**3**) (deuterium-labeled internal standard, >99% pure) were used in UPLC–MS/MS analysis. Internal (1 mg/L) and external standard (0.002–2 mg/L) solutions for indospicine (**2**) were prepared in H_2O with 0.1% HFBA. Solutions were frozen for no longer than 1 month.

Accurate Mass Analysis. Accurate mass analysis of both parent and daughter ions was performed on an AB SCIEX TripleTOF 5600+ system (AB SCIEX, Mt. Waverley, Australia) via direct injection and fragmentation of standard solutions of both indospicine and D_3-L-indospicine.

RESULTS AND DISCUSSION

UPLC−MS/MS Fragmentation of Indospicine and D_3-L-indospicine. Fragmentation of the protonated molecular ion of indospicine (**2**) ($[M + H]^+$ m/z 174) in positive-ion ESI mode produces a number of daughter ions, notably m/z 157 (loss of NH_3), m/z 129 (loss of NH_3 and CO), m/z 111 (loss of NH_3 and HCO_2H), and m/z 84 (loss of NH_3, CO_2H, and HCN), as seen in Figure 2. Accurate mass MS and MS/MS data confirmed the composition of each of the daughter ions, particularly the perhaps unexpected composition of m/z 129 as $C_6H_{13}N_2O$ (observed 129.1029, calculated 129.1028). We postulate then that the required loss of NH_3 and CO occurs via loss of NH_3 from the amidine group followed by formation of a cyclic lactone intermediate, from which it is possible to lose CO while retaining the second oxygen atom.

In the labeled standard D_3-L-indospicine (**3**), deuterium atoms are incorporated at C-5 (two deuterium) and C-6 (one deuterium), and this is evident in the fragmentation of the protonated molecular ion $[M + H]^+$ m/z 177, which produces corresponding daughter ions of m/z 160/159 (loss of NH_3/NH_2D), m/z 132/131 (loss of NH_3/NH_2D and CO), m/z 114/113 (loss of NH_3/NH_2D and H_2CO_2H), and m/z 86/87 (loss of NH_3/NH_2D, H_2CO_2H, and HCN), as seen in Figure 2. The fragmentation to almost equal proportion of each of these ion pairs is consistent with the proposed initial loss of NH_2 from the terminal amidine group with concomitant loss of either H or D from the monodeuterated C-6 position. Accurate mass MS and MS/MS data again confirmed that the composition of each of the daughter ions is consistent with the listed mass losses.

The most dominant daughter ion observed at m/z 111 was chosen as the transition (m/z 174 → 111) for quantitation of indospicine (**2**) using the selected reaction monitoring (SRM) program on the UPLC−MS/MS, with the m/z 157 daughter ion selected as the transition (m/z 174 → 157) for verification. The efficiency of the ionization and the detection of the precursor and fragments ions were optimized by adjusting collision energy (15 and 12 eV) and cone voltage (25 V). Similarly, the transition m/z 177 → 114 was selected for SRM quantitation of D_3-L-indospicine (**3**), with the transition m/z 177 → 113 for verification with optimized collision energy and cone voltage (15 eV and 25 V, respectively).

Development and Validation of a UPLC−MS/MS Method for Indospicine in Camel Meat Samples. The UPLC−MS/MS method reported here is a high-throughput yet sensitive analysis method for indospicine (**2**) in camel meat tissue, and this is the first reported indospicine analysis in unprocessed camel meat tissue based on the developed and validated UPLC−MS/MS method. The method involves a simple tissue extraction into aqueous solution followed by physical deproteinisation using centrifugal ultrafiltration before UPLC−MS/MS detection. The described UPLC separation on BEH C18 column eluting with water and acetonitrile (0.1% HFBA) gradients provides good peak shape and column retention. Heptafluorobutyric acid (HFBA) is an effective ion-pairing agent that is widely used in reverse-phase peptide/amino acid separations.[25] Concentrations of indospicine (**2**) in camel meat extracts (spiked samples and Simpson Desert samples) were determined by interpolating the relative intensity with a calibration curve. Calibration curves were constructed for each batch and involved plotting the ratio of the intensity of the positive-ion ESI SRM transition m/z 174 → 111 relative to the internal standard (D_3-L-indospicine, **3**) SRM transition m/z 177 → 114, versus the indospicine (**2**) concentrations for standard solutions of 0.002−2.00 mg/L. Seven-point calibration curves with the overlaid chromatograms of internal and external standards are shown in Figure 3.

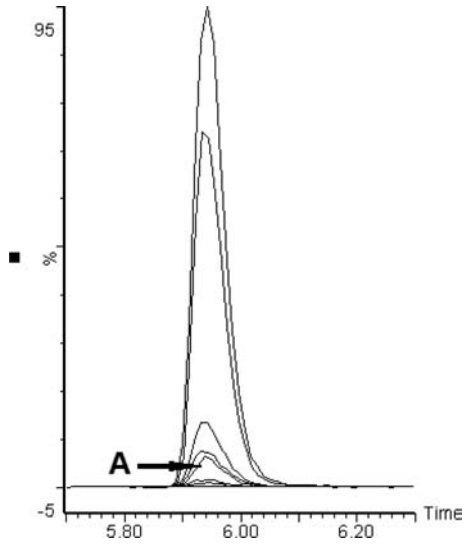

Figure 3. Overlaid SRM chromatograms of indospicine standards (0.002−2.00 mg/L) and internal standard (A) monitored by UPLC−MS/MS with ESI.

The limit of quantitation (LOQ) determined for this work was at least 9:1 for the peak-to-peak signal-to noise ratio for the quantitation transition (m/z 174 → 111). Both quantitation and qualification ions were monitored for each analysis. The average ratio of the quantitation peak to that of the qualification peak for spiked samples (n = 21) was 4.49. Confirmation of indospicine (**2**) was also carried out by examining the quantitation/qualification ion ratio, with the requirement that the ratio be within ±20%. Hence, only samples that have the ratio of 3.59 to 5.39 are considered to contain actual indospicine (**2**).

The calibration curves (n = 8) demonstrated good linearity with R^2 values of 0.9960 ± 0.004 throughout the analysis. Recovery efficiency and reproducibility of this analytical method were demonstrated by replicate analyses (n = 7) of the matrix spiked at three concentration levels: 2.5, 5.0, and 50.0 mg/kg indospicine-free camel meat. The spiked matrices were then extracted by the method described in indospicine (**2**) extraction. These spiking studies had recoveries of 106, 109, and 102%, respectively. The mean concentrations (standard deviation (SD), relative standard deviation (RSD)) of seven analyses for each spiked sample were 2.65 mg/kg (SD 0.24, RSD 9.06%), 5.43 mg/kg (SD 0.42, RSD 7.82%), and 51.01 mg/kg (SD 5.02, RSD 9.85%), respectively. The relative standard deviation was in all cases below 10% for three spiked samples, and this indicated that the method is reproducible with good precision. A significant clinical challenge with UPLC−MS/MS is the potential for matrix effects that cause interferences or impact ionization efficiency. The matrices of

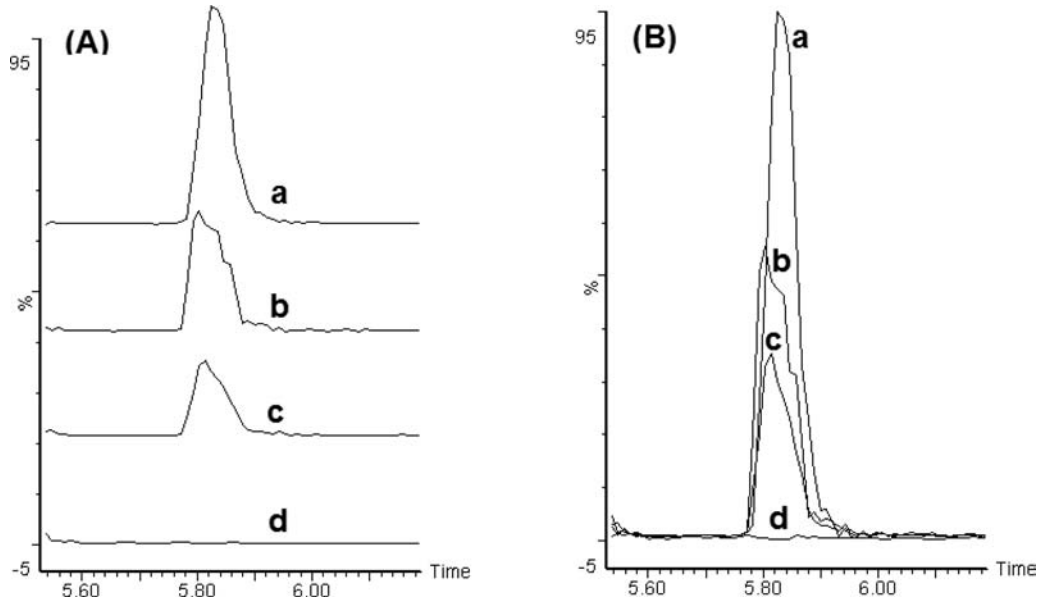

Figure 4. UPLC−MS/MS analysis of (A) individual and (B) overlaid SRM chromatograms for indospicine: (a) 0.05 mg/L standard, (b) 2.5 mg/L spiked sample, (c) Simpson Desert camel meat sample (SD_79) (1.41 mg/L), and (d) blank sample.

the extract can significantly ($p \leq 0.05$) suppress the indospicine and isotope-labeled internal standard responses. However, the use of stable isotope-labeled internal standards in this study to compensate for matrix effects and to increase accuracy resulted in the quantitation of matrix and matrix-free extracts having no substantial differences. Reagent spike recovery efficiency was not done due to this internal standard compensation principle. A blank matrix sample, spiked matrix samples, and spiked check samples were analyzed for each batch of analyses as part of the quality control for the validity of the analyses. The validity of indospicine (**2**) present in camel meat samples was ensured by spiked check samples being reported within 70% ≤ spike ≤130%. The study showed that the developed and validated method is reproducible with good recovery. Figure 4 shows UPLC−MS/MS analysis of individual and overlaid SRM chromatograms corresponding to indospicine (**2**), standard, spiked, real, and blank samples.

Trace amounts of glycerine present on the Amicon Ultra 0.5 mL, 3K centrifugal filter unit used in the extraction could interfere with the analysis by enhancing UPLC−MS/MS indospicine (**2**) responses. Hence, Amicon Ultra 0.5 mL, 3K centrifugal filter units are prerinsed twice to remove the interference. The response of indospicine (**2**) was then not significantly affected by the ultrafiltration step. To further minimize the effect of the Amicon Ultra 0.5 mL, 3K centrifugal filter, the internal standard was added prior to filtration in the sample preparation steps. While the use of an internal standard can correct for the effects of matrix on measured signals, as discussed earlier, an internal standard can also compensate for centrifugal filtration effects that occur when it cofilters with indospicine. In the method development process, recovery efficiency referrals to centrifugal filtered and noncentrifugal filtered external standards were carried out, and there was no significant difference between them. Therefore, the preparation of external standards for each batch of quantitation did not involve the ultrafiltration step. The indospicine (**2**) concentrations of the matrix spike samples were analyzed after 2 months of frozen storage and were still within standard deviation ranges. Thus, indospicine (**2**) is stable under cold storage conditions with low storage losses. This is in line with an indospicine stability study reported by Simpson and Hegarty.[22]

The current developed method is less time-consuming than the amino acid analyzer method,[2,19,20] more accurate and specific than the HPLC method,[9] and less tedious through the absence of derivatization in the sample preparation.[21] The indospicine (**2**) method reported here and the method developed by Gardner and Riet-Correa[21] are generally alike in their ease at achieving indospicine resolution from other components.

Indospicine in Camel Meat. To demonstrate the applicability of the developed and validated method, an analysis of a large number of meat samples from feral camel sampled as part of a cull exercise in the Simpson Desert was carried out. UPLC−MS/MS analysis of the feral camel meat samples revealed the presence of indospicine (**2**) at concentrations of 0−3.73 mg/kg. Figure 5 shows the number of contaminated camel meat samples by range of indospicine (**2**) concentrations.

The indospicine (**2**) concentrations have a skewed distribution toward a zero value. These results show that indospicine (**2**) does contaminate camel meat in central Australia and are consistent with the previous detection of indospicine (**2**) in minced camel meat.[16] However, more than 50% of the samples analyzed in this study have concentrations that are below the LOQ (0.1 mg/kg), while less than 5% of the samples have concentrations ≥1 mg/kg. Even so, several samples contained concentrations as high as 3.73 mg/kg. These results suggest caution, since a clinical investigation found that dietary exposure to an indospicine-contaminated pet food diet, of sweet potato/camel meat (2:1) containing indospicine at 2.1 mg/kg, could cause severe hepatic disease in dogs when consumed over extended time periods.[16] The camel meat used to make this diet would have contained 3 times this level (or 6.3 mg/kg), almost twice the maximal levels seen in the present study. The low prevalence of indospicine (**2**) residues in camels in this study may, however, have been affected by the below average and very much below average rainfall in central Australia for the past 12 months (April 2012−May 2013)[26]

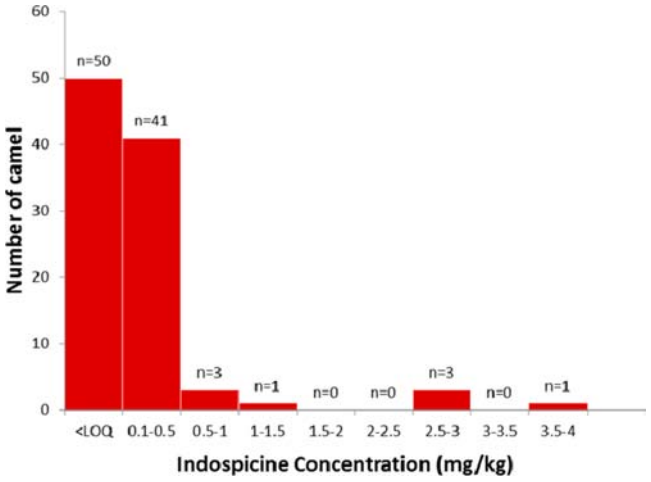

Figure 5. Number of camel meat samples contaminated by a range of indospicine concentrations (mg/kg).

before camel meat samples were being collected from Simpson Desert. *Indigofera* plants are known to be seasonally abundant, with the greatest density occurring after rain, which may lead to sporadic instances of higher *Indigofera* consumption by camels and potentially much higher indospicine (**2**) residues than found in the present study.

In conclusion, this is the first nonderivatized UPLC−MS/MS method developed and validated for the quantitation of indospicine (**2**) in camel meat samples, with a limit of detection down to 0.1 mg/kg. It was used for the definitive identification of indospicine (**2**) in feral camel meat samples collected from central Australia and has confirmed the presence of indospicine in them, but at levels far lower than has been previously associated with canine fatalities.[1,16]

nitrosative stress during digestion of meat. For this purpose, uncured and nitrite-cured cooked chicken, pork, and beef as low, medium, and high sources of heme-Fe, respectively, were subjected to a multicompartment in vitro digestion model. In the digests, the major toxic lipid oxidation products MDA and 4-HNE and the less toxic simple aldehydes pentanal, hexanal, heptanal, and nonanal were determined. During the oxidation of proteins, carbonylation is one of the most prominent protein modifications[19] and, hence, measurement of protein carbonyl compounds (PCC) was used to estimate protein oxidation during digestion. The NOC-specific DNA adduct O^6-carboxymethyl-guanine (O^6-C-MeG) was determined in digesta to estimate DNA damage induced by nitrosative stress. O^6-C-MeG is a far more specific end point than the commonly used "apparent total nitroso-compounds" (ATNC) because (i) it demonstrates DNA damage caused by alkylating NOCs and (ii) ATNC also include noncarcinogenic nitrosyl-Fe and nitrosothiols along with the carcinogenic NOCs.

MATERIALS AND METHODS

Experimental Setup. Uncured and nitrite-cured cooked chicken, pork, and beef were compared before and after mimicked duodenal and colonic digestion. Each incubation run included all treatments in quadruplicate, from which two duplicates underwent digestion until the duodenum and two until the colon step. Each incubation run was performed three times with fecal inoculum originating from three different human volunteers.

Manufacturing of Meat Samples. Lean meat samples from the *m. Pectoralis profundus* (chicken), *m. Longissimus dorsi* (pork), and *m. Biceps femoris* (beef) were purchased in a local supermarket. The meat was manually chopped into cubes of approximately 1−2 cm^3. To exclude a possible confounding effect of differences in fatty acid composition, 4% subcutaneous pork fat was added to the different lean meat sources. Meat samples with added fat were first minced in a grinder (Omega T-12) equipped with a 10 mm plate, followed by grinding through a 3.5 mm plate. Thereafter, nitrite curing was applied by adding 20 g of 0.6% nitrite salt/kg meat, corresponding to an added concentration of 120 mg nitrite/kg meat. All meat samples were heated in a warm water bath for 15 min after the core temperature had reached 65 °C. After manufacturing, all meat samples were homogenized in three 5 s bursts using a food processor (Moulinex DP700), vacuum packed, and stored at −20 °C until the start of the incubation.

Incubations. The in vitro digestions consisted of an enzymatic digestion simulating the mouth, stomach, and duodenum gastrointestinal tract compartments, followed by a simulation of colonic fermentation. For the enzymatic digestion, the protocol described by Versantfoort et al.[18] was adapted by adding oxidants and antioxidants that are normally present in digestive juices (Table 1). Hence, peroxidase[21] and $NaNO_2$[22] were added to the saliva juice, and ascorbic acid,[23] H_2O_2,[24] and ferrous iron[24] were added to the gastric juice. Meat samples (4.5 g) were sequentially incubated for 5 min with 6 mL of saliva, for 2 h with 12 mL of gastric juice, and for 2 h with 2 mL of bicarbonate buffer (1 M, pH 8.0), 12 mL of duodenal juice, and 6 mL of bile juice. These enzymatic incubations were performed in quadruplicate. After completion, two replicates were diluted with 44 mL of H_2O to obtain the same solid/liquid ratio as in the colonic digestion (see below) and homogenized with an Ultraturrax (9500 rpm). While stirring on a magnetic field in the dark, samples were subdivided in 1.3 mL aliquots and stored at −20 and −80 °C pending analysis. The two remaining replicates underwent the additional colonic fermentation stage according to the method of Van de Wiele et al.[25] Simulation of the human intestinal microbial ecosystem (SHIME) medium (22 mL)[26] and a human fecal inoculum (22 mL) (for preparation, see Preparation of Human Fecal Inoculum) were added to the digesta. The vessels were flushed with N_2 for 30 min to obtain an anaerobic environment. Anaerobic conditions in flasks with digesta in the colon phase were confirmed, using resazurin-saturated test strips. Subsequently, the vessels were incubated for 72 h with stirring at 37 °C. To evaluate the rate of bacterial fermentation, total anaerobic bacteria were counted after 72 h of fermentation. One milliliter of digesta was serially diluted (10-fold) using a sterile peptone solution (1 g/L peptone, 0.4 g/L agar, 8.5 g/L NaCl, and 0.5 g/L cystein), after which 0.1 mL was added on an reinforced clostridial medium (RCM) plate. After 48 h of incubation at 37 °C, colony-forming units (CFU) were counted and expressed as $\log_{10}$ CFU/mL digesta. As for the duodenal samples, colonic digestion samples were homogenized by Ultraturrax at 9500 rpm. While stirring on a magnetic field in the dark, samples were subdivided in 1.3 mL aliquots and stored at −20 and −80 °C until analyses. Undigested control samples were obtained in duplicate by homogenizing 4.5 g of meat in 82 mL of H_2O, mimicking the liquid/solid ratio in the digested samples.

Preparation of Human Fecal Inoculum. Fresh fecal material was collected from three volunteers without known gastrointestinal diseases and without intake of antibiotics for at least 6 months. All volunteers were male, nonvegetarians on a Western diet, and aged 49, 26, and 38 years, respectively. Fresh fecal material was diluted in preheated PBS solution (1:4; w/v), to which sodium thioglycolate (1 g/L) was added as a reducing agent. The fecal slurry was filtered by a 1 mm metal sieve to remove particulate matter. Afterward, the inocula were stored at −80 °C on a glycerol stock (20%) in different aliquots. Before use in the colonic fermentation phase, the bacterial inoculum was cultured during 24 h at 37 °C to obtain the necessary microbiotic culture. For this purpose, fecal inoculum was diluted with brain heart infusion (BHI) broth (37 g/L BHI and 0.5 g/L cysteine) at a 1:9 ratio. Subsequently, anaerobic conditions in the flask were reached by flushing the headspace with N_2 during 1 h.

Chemical Composition of the Meat Samples. Meat samples were analyzed for dry matter, crude protein, and crude fat content according to ISO 1442-1973, ISO 937-1978, and ISO 1444-1973 methods, respectively. Lipids were extracted using chloroform/methanol (2:1; v/v)[27] and subsequently, fatty acids (FA) were analyzed as described by Raes et al.[28] Briefly, FA were methylated and analyzed by gas chromatography (HP6890, Brussels, Belgium) using a CP-Sil88 column for fatty acid methyl esters (FAME; 100 m × 0.25 mm × 0.25 μm; Chrompack, Middelburg, The Netherlands). Peaks were identified, on the basis of their retention times corresponding with standards (NuChek Prep. Inc., Sigma, Bornem, Belgium). Nonadecanoic acid (C19:0) was used as an internal standard to quantify the individual and total FA. The fatty acid profiles were expressed in grams per 100 g of FAME. Residual nitrite concentrations were measured colorimetrically at 538 nm after diazotization with sulfanilamide and *N*-(1-naphthyl)ethylenediamine dihydrochloride (ISO 2918-1975). Nitrite concentrations were calculated on the basis of a standard curve obtained with sodium nitrite and expressed as milligrams of nitrite per kilogram of meat. Hematin was determined colorimetrically according to the method of Hornsey et al.[29] and converted to heme-Fe using the formula heme-Fe = hematin × atomic weight Fe/molecular weight hematin. Total Fe was determined by ICP-AES (Iris Intrepid II XSP, Thermo Electron Corp.) following destruction by Bunsen burner and dry incineration at 550 °C for 4 h, followed by dissolving in 3 mL of concentrated HNO_3, diluting to 10 mL of HNO_3, and filtration. Total Fe was calculated on the basis of a standard curve and expressed as milligrams per 100 g of meat.

Oxidation Products. MDA concentrations in digesta (−20 °C) were measured according to a modified method in accordance with Grotto et al.[30] TBARS were formed from the reaction of MDA with 2-thiobarbituric acid in an acid environment. After extraction in 1-butanol, the absorbance of the colored complex was measured colorimetrically at 532 nm. A standard curve with 1,1,3,3-tetramethoxypropane was used, and the concentration was expressed as nanomoles of MDA per milliliter of solution.

Levels of 4-HNE, pentanal, hexanal, heptanal, octanal, and nonanal were analyzed in digesta (−80 °C) through HPLC (Agilent 1200 series, provided with a degasser, autosampler, quaternary pump, column oven, fluorescence detector) using an adapted method of Holley et al.[31] All solutions were purified with activated carbon and

filtered. For preparation of the cyclohexanedione (CHD) reagent, 10 g of ammonium sulfate and 0.29 mL of acetic acid were dissolved in 100 mL, adjusted to pH 5, and purified with activated carbon. After filtration, 0.25 g of CHD, dissolved in 2 mL of activated carbon purified MeOH, was added to the mixture. All glassware was cleaned with ethanol and H_2O and dried in a 100 °C oven to remove contaminating aldehydes. One milliliter of digest was mixed with 4 mL of $CHCl_3$/MeOH (2:1, v/v) and 0.4 mL of NaCl (9%). After a 30 s vortex, the mixture was centrifuged (5 min, 1100*g*) and the $CHCl_3$ phase was collected. The remaining aqueous solution was mixed again with 2 mL of $CHCl_3$/MeOH, and the $CHCl_3$ phase was collected as described before. The combined $CHCl_3$ phases were dried under a gentle N_2 stream. The dried residue was resolved in 0.1 mL of MeOH, 0.4 mL of H_2O, and 1 mL of CHD reagent. After 1 h of heating at 60 °C in a warm water bath, samples were filter sterilized (0.2 μm cellulose membrane filter) in dark HPLC vials. The injection volume was 80 μL and the flow rate, 1 mL/min. Separation was done on a Supelcosil LC-18 column (25 cm × 4.6 mm, 5 μm, catalog no. 58295, Supelco), using stepwise elution (50% tetrahydrofuran from 0 to 40 min). The derivatized aldehydes were detected by a fluorescence detector at an excitation wavelength of 380 nm and an emission wavelength of 446 nm. Aldehydes were quantified using a standard curve and expressed as picomoles of aldehyde per milliliter of solution.

The measurement of PCC following their covalent reaction with 2,4-dinitrophenylhydrazine (DNPH) was done according to the method of Ganhão et al.[32] This reaction leads to the formation of a stable 2,4-dinitrophenyl hydrazone product. Total carbonyl content was quantified colorimetrically at 370 nm, using a molar absorption coefficient of 21.0/(mM·cm) and expressed as nanomoles of DNPH per milligram of protein. Protein concentrations were measured at 280 nm after reaction with 2 M HCl instead of DNPH, quantified using a standard curve with BSA, and expressed as milligrams per milliliter of solution. Both PCC and protein concentrations were reported separately.

O^6-Carboxy-methylguanine (O^6-C-MeG). The internal standard O^6-methyl-d_3-guanine (O^6-d3-MeG) was obtained from Toronto Research Chemicals Inc. (Toronto, Canada). O^6-Carboxymethyl-deoxyguanosine (O^6-C-MedG) was a gift from S.A. Moore (Liverpool John Moores University, UK). The NOC-specific DNA adduct O^6-C-MeG was quantified using U-HPLC-MS/MS.[33] In brief, 182 μL of filter-sterilized sample was incubated for 18 h at 37 °C with 100 μg of calf thymus (CT)-DNA. After addition of the internal standard (50 μL, 20 ng/mL O^6-d3-MeG), the mixture was dissolved in 2 mL of 0.1 M formic acid and hydrolyzed by heating (80 °C for 30 min). The hydrolysate was cooled on ice and then applied to an Oasis HLB cartridge (SPE) (30 mg, 1 mL), which was conditioned with 2 mL of 100% MeOH and equilibrated with 2 mL of deionized water. After loading the hydrolysate, a vacuum suction was applied on the SPE cartridge, followed by the elution step with 2 mL of 100% MeOH. The collected fraction was evaporated to dryness (90 min, 20 °C) using a SpeedVac Plus (Savant, Holbrook, NY, USA). Finally, the dried residue was dissolved in a total volume of 100 μL of mobile phase consisting of 95:5 0.05% aqueous acetic acid/H_2O. Chromatographic separation of the DNA adducts was achieved by reversed phase chromatography and gradient elution. Separation of the DNA adducts was carried out on a Nucleodur C18 ISIS column (5 μm, 250 × 4 mm, Machery Nagel, Düren, Germany), kept at 30 °C. Analysis was performed on a triple-quadrupole mass analyzer (TSQ Vantage, Thermo Electron, San Jose, CA, USA), fitted with a heated electrospray ionization (HESI-II) source operating in the positive ion mode. A standard curve of O^6-C-MeG was made by derivatization of O^6-C-MedG with 0.1 M formic acid at 70 °C for 1 h.[34] O^6-C-MeG was quantified using the standard curve and the area ratio of internal standard O^6-D3-MeG and expressed as nanograms of O^6-C-MeG per milliliter of digesta.

Statistical Analysis. For the meat characteristics, a linear model ANOVA procedure (SAS enterprise guide 5) was used with the fixed effects of heme-Fe, nitrite, and heme-Fe × nitrite. Data on MDA, 4-HNE, simple aldehydes, PCC, and protein content were analyzed for the undigested meat, duodenum step, and colon step, separately. For the undigested meat, the same linear model as for the meat characteristics was used, whereas for the duodenum and colon phases a mixed model ANOVA procedure was used with the fixed effects heme-Fe, nitrite, and heme-Fe × nitrite and the random effect incubation run. Data on O^6-C-MeG were analyzed for each run (fecal inoculum) separately due to very high variation between the different applied inocula, using a linear model with the fixed effects heme-Fe, nitrite, and heme-Fe × nitrite. Tukey-adjusted post hoc tests were performed for all pairwise comparisons. $P < 0.05$ was considered significant.

RESULTS

Meat Characteristics. Characteristics of the used meats are shown in Table 2. Pork contained a marginally higher fat content compared to the other meats. The fatty acid profile showed no significant differences in SFA between the different meats, whereas minor differences were observed for total MUFA and PUFA. The beef sample contained significantly

more ALA, LC n-3 PUFA, and LC n-6 PUFA and less LA compared to the other meats, whereas the chicken sample contained significantly more ALA and LC n-3 PUFA compared to pork. A clearly lower amount of residual nitrite in cured meat samples was found, compared to the added amount (120 mg/kg meat). The lowest amount of residual nitrite was found in beef, followed by pork and chicken. Beef had significantly higher heme-Fe and total Fe compared to chicken and pork.

Lipid Oxidation. Table 3 shows the concentrations of lipid aldehydes before the digestion and after duodenal and colonic digestion of the meats. Uncured beef showed significantly higher amounts of all lipid oxidation products before digestion, except for nonanal, compared to pork, followed by chicken. Concentrations of lipid oxidation products were significantly lower when meats were nitrite-cured to even undetected for 4-HNE and heptanal. Compared to uncured chicken, nitrite-cured chicken had significantly lower MDA and hexanal concentrations, whereas 4-HNE and heptanal concentrations were hardly detectable. An increase in all oxidation products was observed in the duodenum step; however, this was less distinctive for 4-HNE. Also, after duodenal digestion, uncured beef resulted in significantly higher concentrations of lipid aldehydes compared to pork, followed by chicken. Hexanal concentrations in duodenal digested uncured beef increased 2-fold during digestion while the hexanal concentrations in the uncured chicken and pork remained similar. Nonanal increased 3-fold during digestion of uncured beef, but only 2-fold in uncured chicken and pork. After duodenal digestion of nitrite-cured meats, 4-HNE and heptanal were detected, but in accordance with the other lipid oxidation products in much lower concentrations compared to their uncured equivalents. Except for MDA, the concentration of lipid oxidation products was clearly lower after 72 h of colonic digestion compared to the duodenum step or before digestion. Similar significant

effects of nitrite curing and heme-Fe content on most aldehyde concentrations were observed in the colon digestive samples. In contrast to other aldehydes in the colonic digestive fluids, heptanal was significantly lower in beef compared to chicken and pork and significantly higher in nitrite-cured meats compared to the uncured equivalents. Nitrite curing had no significant effect on nonanal in the colonic digestion samples. Octanal was not detected or close to no detection and hence was not included in the statistical analysis.

Protein Oxidation. Undigested nitrite-cured meats had significantly lower PCC concentrations than their uncured equivalents (Table 4). Higher PCC concentrations were observed after duodenal and colonic digestion with significantly higher PCC levels in uncured beef digests compared to chicken and pork after duodenum digestion and compared to chicken after colon digestion. Nitrite curing of the meat also resulted in lower protein oxidation in simulated duodenum and in marginally lower values in the colonic step.

A clear decrease in protein levels was observed starting from the nondigested meat to the duodenal and colonic digestive fluids (Table 4). No significant differences were observed between different meat samples before digestion. Cured meats had significantly lower protein levels in duodenum and colon compared to uncured equivalents. A marginal effect of heme-Fe was also observed in the colonic phase.

***O^6*-Carboxy-methylguanine.** No O^6-C-MeG was detected in meats before digestion or at the end of the duodenal phase (Table 5). In contrast to the other parameters, detection of O^6-C-MeG after 72 h of colonic digestion was highly dependent on the individual bacterial inoculum. Inoculum originating from the first test subject did not allow detection of O^6-C-MeG in any sample. When fermented using inoculum originating from the second and third test persons, O^6-C-MeG levels were low or very high, respectively. After 72 h of fermentation, a significant effect of heme-Fe concentration was observed. When fermented by inoculum 2, uncured beef had significantly more O^6-C-MeG than chicken, whereas no difference was seen in nitrite-cured meats. Fermentation by the third inoculum resulted in higher O^6-C-MeG formation in both uncured and nitrite-cured beef compared to chicken and pork. No significant effect of nitrite curing was found.

DISCUSSION

The objective of the present study was to test the involvement of heme-Fe and nitrite curing on the formation of toxic compounds during the digestion of meat. In uncured meats, the promoting effects of heme-Fe on oxidation and NOC-induced DNA damage during digestion were distinct. Our data confirm the importance of heme-Fe as catalyst of endogenous oxidation and nitrosation reactions, and hence it is likely to be involved in the association between red meat consumption and CRC. Curing with nitrite drastically inhibited the formation of the major toxic oxidation products MDA, 4-HNE, the minor toxic simple aldehydes, and PCC with no stimulating effect on the formation of NOC-specific DNA adducts. Consequently, nitrite curing of meat was not perceived as a risk factor in the presented study.

In accordance with our results, Hur et al.[11] already demonstrated a rise in TBARS during in vitro digestion of beef patties until duodenal digestion. Increased oxidation during digestion of meat under simulated duodenal conditions was confirmed in our study using more specific markers. Changes in 4-HNE concentrations before and after duodenal digestion were less distinct compared to other lipid oxidation products. However, measurable levels of 4-HNE were noted in nitrite-cured meat samples under simulated duodenal and colonic conditions, whereas it was not detected before digestion, indicating the formation of 4-HNE during digestion. Gorelik et al.[35] demonstrated absorption and accumulation of MDA in human plasma and urine after consumption of turkey cutlets. Increased plasma 4-hydroxy-2-hexenal (4-HHE) in mice after consumption of oxidized n-3 fatty acids was associated with oxidative stress and inflammation in the upper intestine.[36] Through systemic circulation, lipid oxidation products can reach sensitive tissues where MDA and 4-HNE can form adducts with DNA, increasing cancer risk.[37] In this way, higher plasma and tissue MDA in rats fed beef compared to chicken were associated with higher colonic DNA strand breaks.[38] In our experiment, the clearly lower concentrations of lipid oxidation products after colonic digestion, with an exception for MDA, could be attributed to degradation into volatile compounds and adduct formation with proteins or bacterial DNA. Oxidation of aldehydes by previously demonstrated aldehyde dehydrogenase activity of colonic bacteria[39] could also explain the observed decrease throughout colonic digestion. It should be noted that the fecal inocula likely also contained aldehydes. The net disappearance of the aldehydes during colonic digestion was thus probably underestimated.

The antioxidative effect of nitrite was clearly demonstrated in meats before and after digestion. Whereas high concentrations of the major cytotoxic 4-HNE were found in uncured beef, undetected to very low traces were observed for nitrite-cured beef. Nitrite curing of meat samples was performed by mixing with 0.6% nitrite salt. In contrast, adding salt without nitrite to meat increased TBARS and peroxides in meat.[40] Adding nitrite (1 g/L) in drinking water significantly reduced lipid oxidation in the colon of rats on a heme diet.[41] These results should be

interpreted with care because a dual role of •NO on oxidative stress has been described. Because a 1:1 ratio of •NO to ROS enhances lipid peroxidation whereas an excess of •NO inhibits oxidation,[17] consumption of oxidized nitrite-cured meat could result in a reversed effect. In contrast to other aldehydes in the colonic digests, heptanal was surprisingly lower in beef compared to chicken and pork and higher in nitrite-cured meats compared to their uncured equivalents. This unexpected result should be clarified in future experiments.

Because lipid oxidation products arise from PUFA, we aimed to exclude a possible confounding effect of different fatty acid profiles by adding 4% subcutaneous pork fat to the lean chicken, pork, and beef meats (approximately 1% intramuscular fat) of the present study. Despite this, there were some minor differences in the PUFA subgroups. Total PUFA was very similar across the different samples. 4-HNE and hexanal arise specifically from n-6 PUFA.[42] The small differences in n-6 PUFA content among the different meat samples in the present study are not expected to explain the large differences in 4-HNE and hexanal formation. LA, which belongs to the n-6 PUFA subgroup, was even higher in the chicken meat, but was associated with the lowest 4-HNE and hexanal formation.

Measurement of PCC as a marker for protein oxidation compared well with our observations on lipid oxidation. Higher heme-Fe concentrations in meats induced more protein oxidation, whereas nitrite curing prevented oxidation before and during in vitro digestion. It was previously demonstrated that CRC patients had higher plasma PCC levels than healthy controls.[43] The formation of PCC affects the nature and function of the protein, but the importance of dietary PCC to human health is still not completely clear. As protein oxidation is believed to be a free radical chain reaction,[44] it could be hypothesized that oxidized dietary proteins catalyze the oxidation of cellular proteins and hence induce cell damage.

The significantly lower PCC and protein levels in nitrite-cured meats compared to uncured meats during simulation of duodenum and colon digestion agree with Santé-Lhoutellier et al.,[45] who found a highly significant negative correlation between PCC concentrations and proteolytic susceptibility to pepsin. MDA and 4-HNE can also react with proteins, leading to the formation of Schiff bases, which are known to play a role in protein aggregation. Previously, it was shown that a higher amount of protein reaching the colon fermentation resulted in a higher formation of potentially toxic protein fermentation products such as ammonia, phenol, *p*-cresol, and indole. However, higher formation of these products was not associated with enhanced colon cancer promotion in rats.[46]

The increased O^6-C-MeG concentrations in colon samples when meats contained higher heme-Fe contents were in accordance with Bingham et al.,[8] who showed a dose-responsive increase in ATNC with consumption of red meat, whereas consumption of large amounts of white meat did not influence fecal ATNC. Cross et al.[9] showed that heme-Fe was responsible for endogenous intestinal N-nitrosation arising from red meat. Elevated O^6-C-MeG was also observed in colonic exfoliated cells of humans on a high red meat diet.[10] These observations are in agreement with extensive epidemiologic studies that showed a moderate but significantly increased CRC risk with high red meat consumption.[2,3] IJssennagger et al.[47] provided evidence for selective susceptibility of Gram-positive bacteria to heme cytotoxic fecal water, which was not observed for Gram-negative bacteria. Furthermore, heme-Fe increased colonic *Enterobacteria* and *Bacteroidetes* spp. and decreased *Lactobacilli* and *Firmicutes* spp.[47,48] Possibly, a bacterial shift induced by heme-Fe toxicity or heme-induced oxidative stress could alter the bacterial metabolic capacity and contribute to higher O^6-C-MeG formation in beef digesta. The pronounced differences in the detection of the NOC-specific DNA adduct O^6-C-MeG among the individual fecal inocula are most likely the result of variation in the gut bacterial composition of the fecal donor or varying concentrations of compounds in the fecal inoculum that are involved in formation of the DNA adduct O^6-C-MeG. More research is needed to clarify how and which bacterial species or compounds are responsible for the formation of O^6-C-MeG.

A higher formation of O^6-C-MeG when meats were nitrite-cured was not observed and, hence, our results do not support an earlier suggestion about the importance of nitrite curing on NOC formation.[5] Rats on a high heme-Fe diet displayed 3-fold higher fecal ATNC when drinking water contained sodium nitrate and nitrite (0.17 g/L $NaNO_2$ and 0.23 g/L $NaNO_3$).[41] However, because the increase in ATNC was mainly attributed to an increase of the nongenotoxic iron-nitrosyl, the authors concluded this was probably not associated with an increased colon cancer risk. Nitrite-cured meats also contain far less residual nitrite than many vegetables, which are not associated with increased risk in epidemiologic studies. Furthermore, nitrite is formed endogenously and recycled with the saliva. Santarelli et al.[49] showed clearly higher fecal ATNC in 1,2-dimethylhydrazin injected rats on a diet of dark, nitrite-cured, cooked, and oxidized meat. In contrast, no increase was observed in rats on a diet of dark, nitrite-cured, cooked, and anaerobically stored meat. Meats used in our experiment were stored anaerobically at −20 °C to prevent oxidation during storage. Our results did not show an increased O^6-C-MeG formation when nitrite-cured meats were stored properly.

In conclusion, our study presents a valuable in vitro tool to study oxidation and nitrosation processes during digestion of meat. Our results confirm an earlier-described catalyzing effect of heme-Fe in meat on oxidative stress and demonstrate NOC-induced DNA damage during digestion. Nitrite curing of meat resulted in a lower formation of toxic oxidation products, whereas no effect was observed on the formation of the NOC-specific DNA adduct O^6-C-MeG.

develop analytical model systems that delineate plant constituent−therapeutic response relationships.

To meet this challenge, we developed a model system that compares the ^{1}H NMR spectra of relatively crude BR extracts with the cellular proliferation of HT-29 human colon cancer cells.

Our approach to modeling linked variable bioassay results to variation in plant sample extract secondary metabolite complements and employed multivariate statistical analyses to identify specific regions of the extract NMR spectra that were associated with the array of biological responses. Once spectral regions responsible for these relationships were identified by the model, compound structures were verified using 2D NMR methods, such as heteronuclear single-quantum coherence (HSQC)[16] and heteronuclear multiple-bond correlation (HMBC)[17] experiments.

To validate this approach, we first ensured that BR extract profile variability could be achieved by capitalizing upon the genetic and environmental influences on fruit composition.[18,19] In addition, we verified that specific signals within complex NMR profiles responsible for known chemical relationships could be identified through multivariate statistical analyses. Specifically, we regressed BR extract NMR profiles against standard biochemical analyses [total monomeric anthocyanin content (TMA) and antioxidant capacity assays, ferric-reducing antioxidant power (FRAP) and 2,2-diphenyl-1-picrylhydrazl (DPPH)].[20] This verification model successfully recognized the specific protons within the NMR spectra associated with anthocyanins that played significant roles in the activity of extracts in these assays. Furthermore, the model found structure−activity relationships to be statistically identifiable.

Here we have applied our system to model the biological relationship between bioactive compound variability among 73 BR extracts and their ability to inhibit HT-29 colon cancer cell proliferation. We previously reported the effects of these extracts on cancer cell cultures in this study.[21] The variable BR juice extracts inhibited HT-29 colon cancer cell growth broadly from 33 to 118% when included in the culture media at low and high doses of 0.6 or 1.2 mg extract/mL, respectively (Table S1 in the Supporting Information). Cell responses were dose-dependent, and the response arrays between doses were highly correlated. Although anthocyanins are known to contribute substantially to BR's chemoprotective properties,[2,5−8] extract anthocyanin concentrations as measured by TMA were not correlated to levels of growth inhibition, suggesting that nonanthocyanin components also contribute to BR extract bioactivity in the HT-29 colon cancer cell assay. Recently, we identified a cadre of nonanthocyanins present in our extracts, some of which had yet to be reported as BR constituents.[22]

In this paper, we present the description of anthocyanin as well as nonanthocyanin compounds identified by our modeling system that are responsible for the antiproliferative properties of BR extracts within the HT-29 colon cancer cell bioassay. Our model also indicates that compounds of various classes present in extracts over a broad concentration range may act together to affect cancer cell growth.

MATERIALS AND METHODS

Sample Acquisition and Extract Preparation. Marketable BR fruit samples of three cultivars ('Bristol', 'Jewel', or 'MacBlack') varying in ripeness (slightly under-ripe, ripe, or slightly over-ripe)[21] from seven Ohio commercial farms were obtained for this study. Fruit were hand-harvested in fiber-board containers and transported on ice to the Ohio Agricultural Research and Development Center. Sample extracts from 75 samples for both NMR and cell assay procedures were prepared as described by Johnson and coauthors.[21] This process included the following steps: sample handling, over-ripening fruit, sample storage, preparation of BR juices, isolation of secondary product constituent-rich methanolic extracts via solid phase extraction (SPE), evaporation of solvents under an N_2 stream, and freeze-drying of solvent-free SPE column eluates.

NMR Data Collection. All NMR studies of BR extract samples were performed with a Varian INOVA 750 MHz NMR spectrometer (Varian Inc., Palo Alto, CA, USA) using a Varian triple-resonance ^{1}H{^{13}C/^{15}N} pulsed field gradient cryoprobe. Solid materials derived from the column eluate were diluted with appropriate amounts of methanol-d_4/trifluoroacetic acid-d (95:5 v/v) and 5 mM 2,2-dimethyl-2-silapentane-5-sulfonate sodium salt (DSS) in methanol-d_4 to give 800 μL aliquots that contained 20 mg of dried berry extract and 0.5 mM DSS. The samples were filtered through glass wool and placed in 5 mm NMR tubes. All samples were stored at 4 °C prior to analysis. Two of the 75 samples were prepared incorrectly for NMR analysis and were excluded from further examination.

The spectra were collected at 25 °C over a spectral width of 9023 Hz using a 6.2 μs (90°) pulse. The acquisition time was 2.7 s, and 128 transients were accumulated with presaturation of the HDO resonance in the 4.91−5.07 ppm region. Data were processed with 0.5 Hz exponential line broadening and zero filled to 131,072 points before Fourier transformation.

NMR Data Binning. ^{1}H NMR free induction decays (FIDs) were processed as a batch, using KnowItAll Metabolomics software 8.1 (Bio-Rad Laboratories, Informatics Division, Philadelphia, PA, USA) with a Lorentzian apodization of 0.3 Hz, baseline correction with automatic base point detection, and spline fitting. The DSS reference peak was manually set to 0 ppm for each spectrum. After the region containing solvent (CD_3OD) resonances (3.257 −3.373 ppm) had been flat-lined, each spectrum was normalized against the DSS peak. Alignment macros were applied as a batch process to numerous specific locations along the spectrum to compensate for peak shifting due to variation in pH and in the constituent concentrations among samples. Prior to statistical analysis, binning/bucketing was conducted from 0.550 to 9.200 ppm using the Bio-Rad IntelliBucket method, where the bin width was automatically adjusted on the basis of the overlap density heatmap (ODH) consensus spectrum and a bin width setting of 0.004 ± 0.002 ppm. Regions that were excluded from binning were as follows: (1) 4.910−5.070 ppm (presaturation region for HDO); (2) 3.257−3.373 ppm (flat-lined for solvent); (3) highly overlapping peaks (3.220−4.000 ppm) of the saccharide region; and (4) regions throughout the spectrum of low signal/noise. However, all regions containing resonances for anomeric protons were included in the binning process. This resulted in a data set of 1003 bins from each of 73 BR extract samples that was further reduced to 464 bins by selecting bins with intensities above the analytically justified limit of quantitation[23] (LOQ, i.e., ≥10 times the standard deviation of intensity of bins from data representative of spectral noise).

PLS Modeling. The PLS regression-based predictive model building using Pirouette 4.0 (Infometrix, Bothell, WA, USA) started with the 464 bin data sets. Peak intensities of bins for each of the 73 BR samples were regressed against the bioassay responses[21] as shown in Table S1 in the Supporting Information. A maximum number of 15 factors and a probability threshold of 0.95 were set. Two-component orthogonal signal correction[24] (OSC) was used to remove components in our large X block that were orthogonal to the Y block, thus segregating the portion of the X block that was correlated. To aid the interpretation of chemical information from the regression models, one subset of relevant variables (NMR bins) was selected from the entire block of X-variables. The criteria for variable selection were software-dependent measures of fit [prediction residual error sum of squares (PRESS) and r]. The regression vector values from this subset of bins were then ranked from highest to lowest for the low- and high-dose bioassays, respectively.

RESULTS AND DISCUSSION

Classical biochemical studies of chemoprevention and cancer cell antiproliferation, in response to berry fruits and BR in particular, are challenging because several berry fractions and many specific secondary products have been shown to have some effect on the cancer cell performance, but no single fraction or compound can account for the efficacy of whole fruit or crude fruit extracts.[2,7] Our approach uses "omics" and bioinformatic procedures to identify active components by NMR spectroscopy and to link them to their impact on cell proliferation in HT-29 colon cancer cells in a manner similar to that described by Leiss et al.[25] and Gavaghan et al.[26] to determine important effectors of host-plant resistance and maize salt stress, respectively. Because many BR secondary compounds have been shown to have roles in BR regulation of cancer cell development, there exists a large body of data for the potential verification of the compounds identified by the model.

Modeling of secondary product chemistry, in conjunction with medical efficacy, provides an opportunity to examine complex mixtures of secondary products that are present in plant materials and determine how they affect cell health, chemoprevention, and/or cancer cell proliferation. NMR is a powerful method used to elucidate chemical structures of molecules; here we have used it to identify components of complex mixtures of small molecule metabolites simultaneously, at a high resolution. Moreover, samples were readily prepared in a reproducible manner without the need for additional separation techniques. Processing the data with KnowItAll statistical software permitted the BR components that play significant roles in the control of HT-29 cell proliferation to be identified.

Our model generated large blocks of data concerning the chemical nature of the extracts, which were evaluated against a complex series of chemical reactions that we monitored as cell proliferation. The impact of these secondary compounds on cell proliferation represents the sum of all of the reactions controlling cell growth, metabolism, and apoptosis that have been demonstrated by a host of research.[2,5,7,8,15]

^{1}H 1D-NMR Analyses. Model development was initiated by obtaining the ^{1}H NMR spectra of the 73 BR extracts. The spectra of three representative BR extract samples are shown in Figure 1 [a, slightly under-ripe sample (BR-2); b, ripe sample (BR-47); and c, slightly over-ripe sample (BR-28)]. In all ^{1}H spectra of BR extract samples, the HDO resonance from water that had been observed in the 4.91−5.07 ppm region was suppressed using a presaturation pulse sequence. The singlet peak at 0.0 ppm is from DSS, which was added as an internal standard for chemical shift measurement as well as a calibration standard for quantitation. The strong peaks centered at 3.31 ppm (quintet), 3.35 ppm (singlet), and 3.97 ppm (singlet) are attributed to the resonances of residual $C\underline{H}D_2OD$ from methanol-d_4, a solvent-like impurity, and an artifact compound, respectively. The resonances in the complex region, 4.00−3.22 ppm, are attributed to nonanomeric resonances from the saccharides that are attached to the phenolic structures. The suppression of these signals and the regions of low signal-to-noise ratios (see Materials and Methods) in the initial data sets were made to ensure a robust analysis.

The spectra of BR extract samples are dominated by the resonances from cyanidin 3-glycosides (**1**, Figure 2) as well as defining peaks for cyanidin 3-rutinoside (Cy 3-rut, **2**), cyanidin 3-xylosylrutinoside (Cy 3-xylrut, **3**), cyanidin 3-glucoside

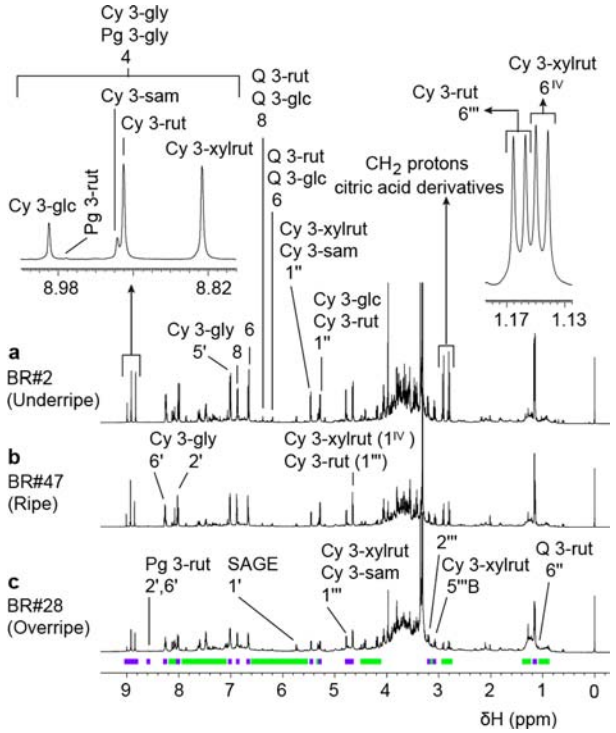

Figure 1. 750 MHz ^{1}H NMR spectra of three representative methanolic BR juice extract samples: (a) sample BR-2 from slightly under-ripe berries; (b) sample BR-47 from ripe berries; (c) sample BR-28 from slightly over-ripe berries. Resonances from anthocyanins are indicated in purple and those from nonanthocyanins are indicated in green bars above the chemical shift scale.

(Cy 3-glc, **4**), and cyanidin 3-sambubioside (Cy 3-sam, **5**), the major phenolic antioxidants of BR fruits.[19] The unique resonances from the minor anthocyanin, pelargonidin 3-rutinoside, are also detected. In Figure 1, the resonances from these anthocyanin phenolics are indicated in purple bars above the chemical shift scale.

Several resonances from nonanthocyanin metabolites and the aliphatic moieties associated with citric acid derivatives (**6**) were also observed (Figure 1, indicated in green bars above the chemical shift scale). The structures of nonanthocyanin phenolics, which were readily detected in the ^{1}H NMR spectra of BR extracts, are shown in Figure 3. Compounds based on the quercetin moiety (**7**, Q, where R_n = H) included quercetin 3-glucoside (Q 3-glc, **8**) and quercetin 3-rutinoside (Q 3-rut, **9**). Compound **11**, salicylic acid glucosyl ester (SAGE), where the glucose moiety is attached to a salicylic acid (SA, **10**), was also evident. Additional nonanthocyanin compounds that have been detected in the ^{1}H NMR spectra of BR extract samples are epicatechin (**12**), benzoic acid β-D-glucopyranosyl ester (BAGE, **13**), a salicylic acid derivative (SAD, **14**), *p*-coumaric acid (**15**), and methyl ellagic acid acetylpentose (MEAAP, **16**).

Although these minor metabolites are present at concentrations approximately 10^{-2}−10^{-3} times the concentrations of the cyanidin 3-glycosides,[5] some of their proton resonances are clearly visible in the ^{1}H NMR spectra of the BR extracts (Figure 1). For example, the H-8 and H-6 resonances from the quercetin glycosides, namely, Q 3-rut and Q 3-glc, are seen at 6.39 and 6.20 ppm, respectively. Likewise, for SAGE, one of the readily detected resonances is H-1′ (5.73 ppm), the anomeric proton resonance from the glucose attached to the phenolic structure via an ester linkage.

dx.doi.org/10.1021/jf404998k | J. Agric. Food Chem. 2014, 62, 1989−1998

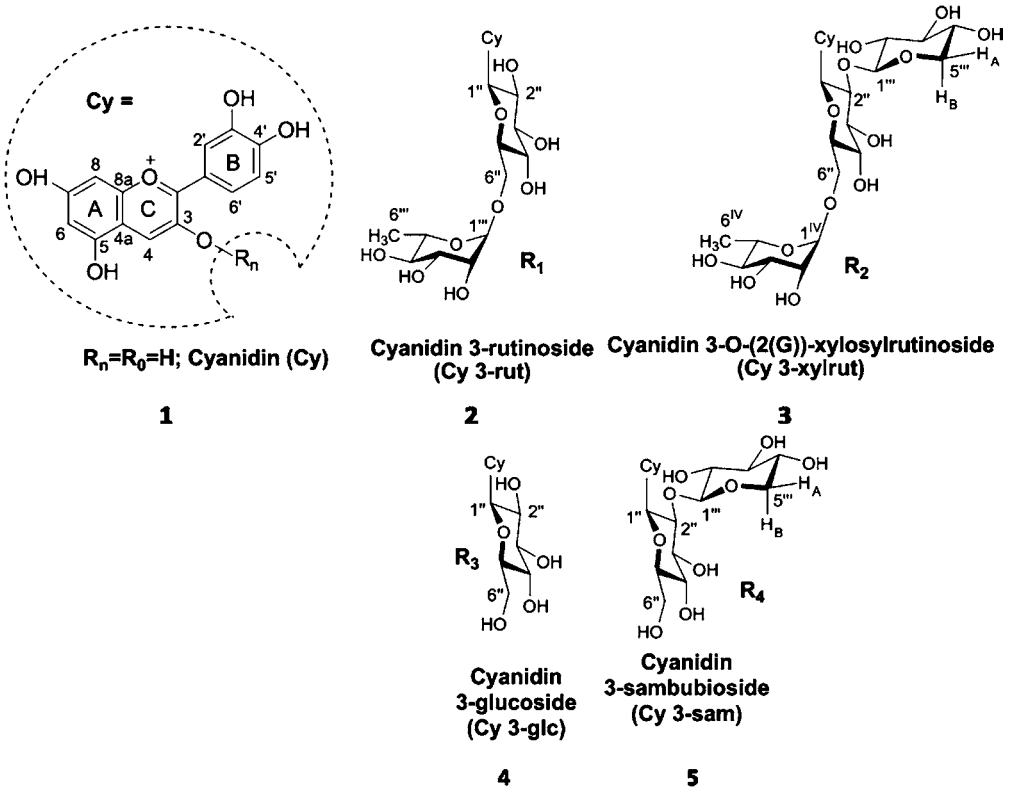

Figure 2. Structures of the cyanidin aglycone and four major anthocyanin phenolic compounds of black raspberry. **1**, cyanidin aglycone (Cy); **2**, cyanidin 3-rutinoside (Cy 3-rut); **3**, cyanidin 3-xylosylrutinoside (Cy 3-xylrut); **4**, cyanidin 3-glucoside (Cy 3-glc); and **5**, cyanidin 3-sambubioside (Cy 3-sam).

Our model simultaneously analyzed a number of regions of the 1D ^{1}H NMR spectra to ensure that participating components of the BR could be identified. This approach was demanding, because several proton resonances can be associated with one compound and intensities may differ depending on the number of protons in the compound structural unit. In addition, similarities in structures (e.g., phenolics) can result in overlapping peaks yielding complex spectral patterns. To verify structures, especially for compounds present at low concentrations, additional NMR experiments such as 1D selective total correlation spectroscopy, TOCSY, and 2D-NMR (gDQCOSY, gHSQCAD, and gHMBC) were conducted (Figures S1−S11 in the Supporting Information). Furthermore, during the statistical analysis, the NMR data were subjected to Pareto scaling,[27] where the square root of the standard deviation was used as a scaling factor. This minimized the effect of larger intensities in the presence of much smaller intensities.

To make regression modeling possible, we needed large amounts of variation in the extracts with a corresponding amount of variability in the cancer cell responses. This methodology differs from traditional medicinal chemistry approaches in which consistency in treatments is essential to understanding experimental outcomes. To verify the variability among our samples, the concentrations (μM) of cyanidin structures were obtained for all 73 spectra on the basis of the manual integration of the H-4 resonances using Bio-Rad's ProcessIt NMR application. Normalized peak areas were obtained relative to the integration of the CH_3 peak of DSS calibration standard at 0.0 ppm set to 100. These data revealed that the concentrations of the anthocyanin components in the 73 BR extract samples exhibited the desired high level of variability needed for our modeling efforts (Table S2 in the Supporting Information). In this study, Cy 3-xylrut was the most abundant phenolic component of the berry extracts (mean = 58 μM; CV = 34%), and the second most abundant component was Cy 3-rut (mean = 51 μM; CV = 31%). In general, the amounts of Cy 3-xylrut and Cy 3-rut were higher in ripe samples than in the under-ripe samples, whereas the amounts of Cy 3-glc and Cy 3-sam (mean = 24 μM, CV = 52%; and mean = 13 μM, CV = 40%, respectively) both decrease with increasing ripeness.

Bioactivity Model Development. Initially, a model of the low-dose assay was generated with a data set of 464 bins determined using Pareto scaling and leave-one-out cross-validation. NMR bins were ranked according to their regression vector values. Subsets of the highest ranked bins were then created and modeled against the low-dose bioassay to determine the best fit of the NMR spectra to the extract impact on cell proliferation. Figure 4a shows a plot of PRESS as well as r values against model sets with various numbers of X-variables. Figure 4b shows the corresponding line plot between model factors and number of bins. The arrows A_4 and A_5 represent the regions of minimum PRESS and maximum r, respectively. Because the maximum number of bins does not exceed 2 times the number of samples, the minimum value of PRESS, maximum value of r, and minimum number of model factors are the quality indices of a good model. A compromise among these quality indices indicated that the optimum number of bins for the low-dose bioassay was 125 (Figure 4, indicated by arrow A_5). The indicators of the fit for this five-factor model are shown in Table 1. This model has r and slope values approaching 1 and values of the standard error of cross-validation (SECV) and PRESS that approached their minima.

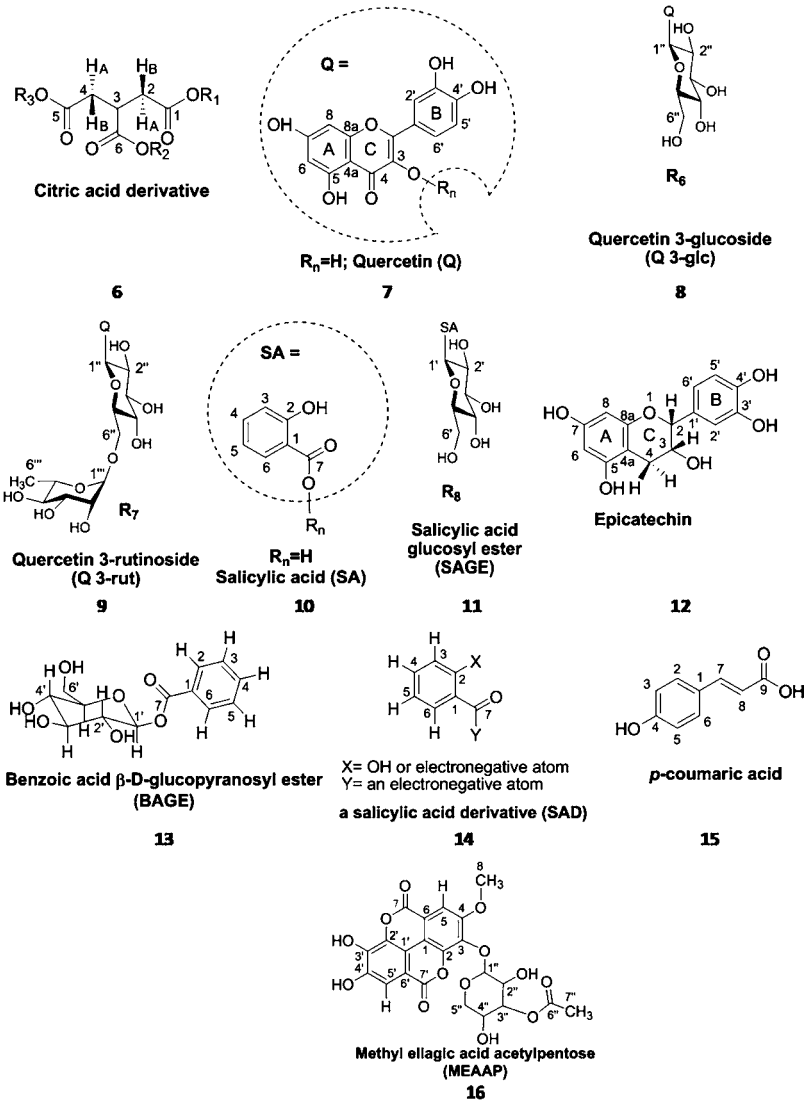

Figure 3. Structures of a citric acid derivative and nonanthocyanin phenolics detected in BR juice extract samples and their aglycones. **6**, citric acid derivatives; **7**, quercetin aglycone (Q); **8**, quercetin 3-glucoside (Q 3-glc); **9**, quercetin 3-rutinoside (Q 3-rut); **10**, salicylic acid aglycone; **11**, glucose ester of salicylic acid (SAGE); **12**, epicatechin; **13**, glucose ester of benzoic acid (BAGE); **14**, salicylic acid derivative (SAD); **15**, *p*-coumaric acid; and **16**, methyl ellagic acid acetylpentose (MEAAP).

In addition, Figure 5a shows the goodness of the *Y*-fit between predicted and measured values. The random distribution of the residuals (Figure 5b) also indicates that the assumption of linearity between the *X*- and *Y*-variables is warranted.

When the top 125 bins of this model were ranked according to their regression vector values, the contribution of specific compounds became evident. Because regression vectors are the weighted sum of loadings included in the model, they reveal the importance of each independent variable. These predictor variables are the basis for interpreting the effect of NMR bins (our independent variables), which carry the information about the chemical components, on the dependent variable, percent inhibition of cell proliferation. For the low-dose bioassay, Table 2 shows some of these compounds by their defining atom assignments and their rank/bin number, with corresponding atomic assignments being illustrated in Figures 2 and 3. The complete table of all 125 bin assignments can be found in Table S3 in the Supporting Information. In Table 2, specific bins corresponding to each of the four major anthocyanins in BR are shown to be important with Cy 3-xylrut and Cy 3-rut as the top-ranked. Cy 3-sam and Cy 3-glc also have an impact on bioassay results. A large number of bins were attributed to resonances of these cyanidin glycosides.

Bins corresponding to nonanthocyanin compounds were also shown to augment inhibition of cell proliferation in the HT29 low-dose bioassay (Table 2). BR anthocyanins and nonanthocyanin phenolic compounds share some similarities in structure (Figures 2 and 3); therefore, their ^{1}H NMR spectra (Figure 1) would be expected to contain some overlapping resonances. Although this overlap confounded compound identification, defining bins were found to be important for MEAAP, epicatechin, Q 3-rut, Q 3-glc, *p*-coumaric acid, SAGE, a salicylic acid derivative (SAD), BAGE, and citric acid derivatives.

When a model was calculated for the high-dose bioassay, similar but not identical results were obtained. This model was optimized at 100 bins (Figure S12 in the Supporting Information), and indicators of fit are shown in Table 1 and Figure 5c,d. When the 100 bins were ranked according to their regression vector values, a trend similar to the low-dose results was evident (Table 3 and Table S4 in the Supporting Information). The highest ranked

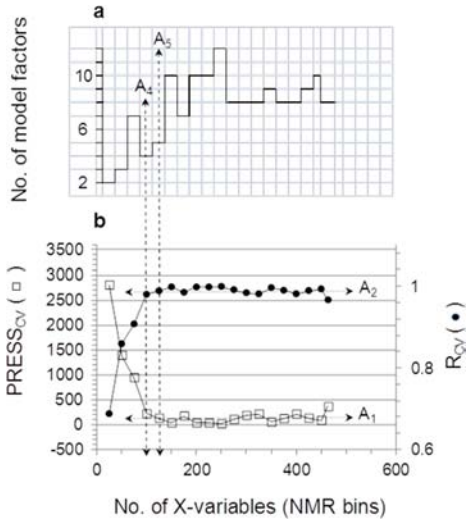

Figure 4. Partial least-squares (PLS) plots for the selection of *X*-variables (NMR bins): (a) number of factors; (b) indicators of fit. Arrow A_1 represents the regions of minimum prediction residual error sum of squares (PRESS) values, and arrow A_2 represents the regions of maximum *r* values. The vertical arrow indicated by A_5 represents the subset of optimum of *X*-variables and its PLS-derived low-dose model factors.

Table 1. Pirouette PLS-Derived Summary of Fit Measurements for the Low- and High-Dose Bioassay Activity of BRs

statistical parameter	low-dose bioassay[a]	high-dose bioassay[b]
no. of BR samples	73	73
no. of independent variables (NMR bins)	125	100
SECV[c]	1.3353	0.9338
PRESS[d]	130.1561	63.6579
r[e]	0.9878	0.9953
factors	5	5
slope	0.9897	0.9949
intercept	0.6496	0.4723

[a]Data are taken from the best PLS model with 125 highest ranked *X*-variables (NMR bins) from the first test model. [b]Data are taken from the best PLS model with 100 highest ranked *X*-variables (NMR bins) from the first test model. [c]SECV, standard error of cross-validation. [d]PRESS, prediction residual error sums of squares. [e]*r*, correlation coefficient.

bin corresponded to Cy 3-xylrut and a defining bin for Cy 3-rut was ranked 11th. Bins consistent with Cy 3-sam and Cy 3-glc were also evident as well as a large number of bins that corresponded to resonances of cyanidin glycosides. The same nonanthocyanin compounds that affected the low-dose model were also evident. However, the rankings of these compounds, especially a citric acid derivative, differed from those in the low-dose model (Table 3). In general, many of the nonanthocyanin constituents appeared to gain in predictive value in the high-dose model.

Overall, the importance of the nonanthocyanins was evident. As shown in Tables 2 and 3, of our original 1003 bins for each of 73 samples, the rankings of the NMR bins based on their regression vector values ranged from 30 to 121 for the low-dose bioassay and from 6 to 81 for the high-dose bioassay. Furthermore, error analyses of PLS models that were calculated using only anthocyanin-related bins proved to be less than optimal when compared to our PLS models containing both anthocyanin- and nonanthocyanin-related bins.

Model-Identified Cell Antiproliferative Compounds. As with other "omics" approaches, the cell assay (our *Y*-variable), provided a simple phenotypic-like response to the treatments, here, control of the HT-29 colon cancer cell proliferation. However, just as a simple phenotypic response is controlled by changes in many overlapping and/or independent biochemical pathways, cell proliferation reflects the combined impacts of the extract components on the stimulation of apoptosis, regulation of cell cycle gene expression, and the impact of BR extract components on overlapping and independent biochemical pathways. Therefore, the model must integrate all of these interactions to determine the impact of the extracts on cancer cell growth. This integration then provides data to identify compounds that affect any of a myriad of chemical reactions.

Cy 3-xylrut and Cy 3-rut were identified by the model as the most important contributors to the inhibition of proliferation of HT-29 colon cancer cells. Anthocyanins constitute a major group of phenolic antioxidants produced in most small fruits.[28] According to Stoner,[5] anthocyanins are present in BR at concentrations that exceed those of ellagic acid by approximately 15-fold and of all other phenolic materials by factors of 10^2 or 10^3. BR anthocyanins are known to effectively intercede against various forms of aerodigestive cancers[2,5−8] at several stages by initiating and maintaining the enzymatic defenses against oxidative stress, reducing inflammation, and inhibiting mutagenesis, as well as decreasing cell proliferation and stimulating apoptosis.[8] BR anthocyanins or anthocyanin-rich fractions affect these chemopreventive processes at cellular and subcellular levels by direct interaction or interaction with controlling elements of kinase-based signaling cascades that influence gene expression, mRNA translation, or enzymatic activity of key cancer-related factors.[2,4−8]

However, the model data also support our previous conclusion that the antiproliferative effectiveness of these BR extracts is not directly correlated with their TMA contents.[21] When we compared the NMR-determined concentrations of individual anthocyanins herein with the low- and high-dose bioassay data using a simple Pearson correlation analysis, only the Cy 3-rut correlation values ($r = -0.32$ and $r = -0.31$, respectively) were significant ($p < 0.01$). However, this relationship was weak, suggesting that the effects of BR extracts on HT-29 colon cancer cell proliferation arise from the activity of multiple compounds in concert. Moreover, bins associated with protons of nonanthocyanin constituents appeared to gain in importance in the anthocyanin-rich extract/high-dose assay PLS model over their position in the model constructed with low-dose assay data developed with extracts containing lower levels of anthocyanins. Together, these findings suggest that anthocyanins may reach a maximum effect on cells and that further increases in their total content or alterations in anthocyanin profiles may not increase the activity of the specific extract.

Supporting this contention, Seguin and co-workers[29] recently reported four temperate berries (BR, blueberry, red raspberry, strawberry) and a cyanidin-containing tropical fruit acai (*Euterpe oleraceae*), presumably with differing anthocyanin profiles, to be similar in their antiproliferative activities. In a study by Wang and co-workers,[7] dietary treatments with freeze-dried BR powder, an aqueous ethanol extract, and an anthocyanin-enriched subfraction of the extract were found to affect rat esophageal papilloma formation and mass, proteins associated with proliferation, and markers of apoptosis similarly.

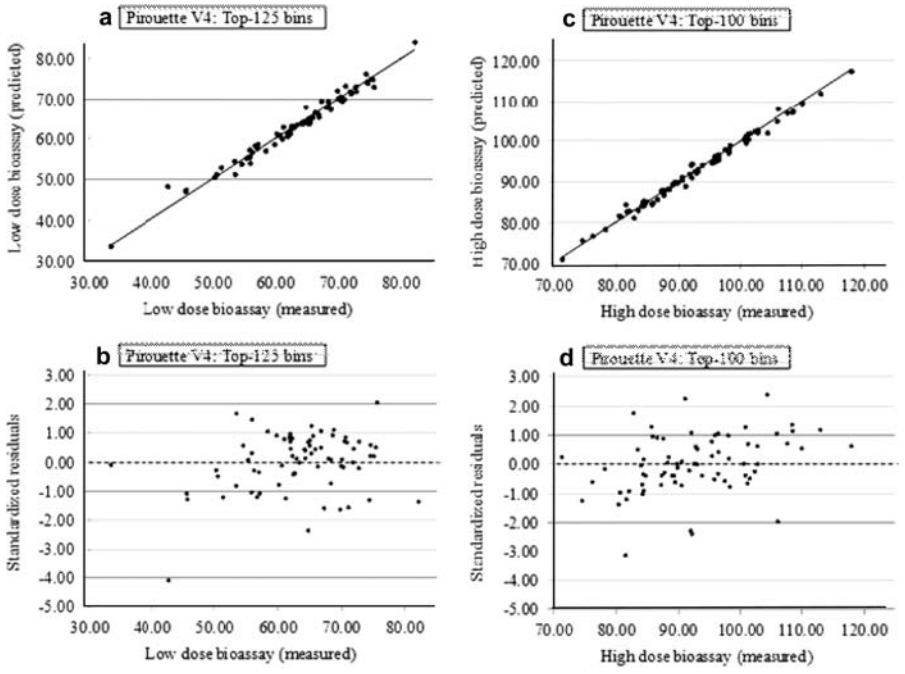

Figure 5. *Y*-fits and residual plots for the models produced with low-dose (a, b) and high-dose (c, d) bioassays.

Wang and co-workers[7] also noted similar antiproliferative properties associated with a diet formulated with the insoluble residue of the extraction with anthocyanin concentrations reduced by approximately 200-fold. These authors noted that among the potential nonanthocyanin constituents of the extract insoluble residue, ellagitannins (polymers of ellagic acid) were likely responsible for the chemoprotective effects of the residue diet. Due to their low solubility in methanol, ellagitannins were likely to be present at minimal concentrations in our extracts. However, our model clearly identified MEAAP as one of the important antiproliferative components of BR extracts. The metabolism and chemoprotective properties of ellagic acid and its polymers, derivatives, and colonic microflora-generated metabolites (urolithins, a series of bioactive dibenzopyran-6-one biomarkers of ellagic acid consumption) were recently reviewed by Landete.[30] Similar to other polyphenols, these compounds act chemoprotectively by reducing the activity of signaling cascades, limiting inflammatory responses, controlling cell cycling and proliferation, reducing angiogenesis, and stimulating apoptosis.[8,30]

Our model also identified epicatechin, Q 3-glc, Q 3-rut, SAGE, SAD, BAGE, and *p*-coumaric acids as important BR extract components in the control of HT-29 cell proliferation. Flavan-3-ols (e.g., epicatechin), flavonol glycosides (e.g., Q 3-glc, Q 3-rut), and salicylates (e.g., SAGE, SAD) are powerful phenolic antioxidants that have been shown to have chemopreventive properties against colon cancer[31−34] and other types of cancers.[3,6,31,32,34,35] In vitro cell assays and animal studies have shown these compounds inhibit proliferation or tumor growth by controlling cell cycle genes and enzymes and by promoting genes and enzymes associated with apoptosis. In a study of bioactive constituents isolated from freeze-dried strawberry, Zhang and co-workers[34] demonstrated that a *p*-coumaric acid glucose ester strongly inhibited proliferation in two colon cancer cell line assays. There is also evidence that hydroxycinnamic acids may play an active role in cancer cell regulation when acylated to anthocyanins.[36] The chemopreventive activity of hydroxybenzoic acids and their derivatives (e.g., protocatechuic acid) has also been extensively studied.[37] However, to our knowledge, this is the first report of a benzoic acid glucose ester (BAGE) showing antiproliferative potential against cancer cells.

Altered metabolism favoring cytoplasm-centered "aerobic glycolysis" is an "emerging hallmark" of cancer,[38] leading to the production of metabolites necessary for continued proliferation and sufficient energy for tumor growth.[39,40] However, aerobic glycolysis and its effects can be curtailed by high levels of cytosolic citrate.[39−41] Elevated citrate levels in cancer cells may lead to cell cycle arrest, metabolic changes favoring pro-apoptotic over anti-apoptotic proteins, and increased cytosolic- or mitochondrial-induced caspase activity leading to cell death[39−42] in a threshold-dependent manner. The increased importance of citric acid derivatives in the high-dose model (Table 3 and Table S4 in the Supporting Information) perhaps reflects this concentration threshold dependency.

The ^{1}H NMR-based model that was developed here has made a significant contribution to our understanding of the impact of the crude BR extracts in controlling HT-29 cell proliferation and provides insights as to the chemopreventive nature of BR fruits. The nonanthocyanin components of the fruit that affect cell proliferation represent a very small percentage of the total phenolic and organic acid derivatives found in the BR extracts, but both the low- and high-dose models indicated their importance in curtailing cancer cell growth. Among the model-identified nonanthocyanin components, Q 3-glc, Q 3-rut, *p*-coumaric acid, and various ellagic acid derivatives have been previously considered as bioactive

constituents of BR.[4−8,30,43,44] However, the bioactivity of MEAAP specifically, BR-derived salicylates, flavan-3-ols (e.g., epicatechin), citric acid derivatives, and/or esters of benzoic acid in controlling colon cancer cell proliferation have not been cited to our knowledge in previous work. Recognition, by the model, of the contributions of these low-concentration constituents on the impact of the extracts on cell growth clearly provides paths for new lines of research into the mechanisms of BR constituents. The data will lead to studies on the interactive effects of the extracts on the chemoprotective nature of berry fruits in general and have demonstrated the utility of using this type of approach to the study of the bioactivity of natural products.

Further advanced NMR analysis with unassigned bins (Tables S3 and S4 in the Supporting Information) may lead to the identification of additional important compounds. As this study was focused on model development and viewed as a proof of concept, recognition by the model of all of the important BR bioactive compounds was limited by the use of acidic methanol extracts and the in vitro HT-29 cell proliferation assay. However, our overall approach is readily adaptable to modeling the effects of a series of extracts including those containing compounds that differ substantially in solubility from that of phenols (e.g., carotenoids, steroids)[5] and can be adapted to accommodate other continuous *Y*-variables such as control of tumor development, enzymatic activity, or biomarker levels, which would lead to a richer understanding of the complex mechanisms by which BR compounds may affect carcinogenesis. Likewise, our approach can also be applied to assess the activity of other natural products with complex NMR spectra, not only against cancer but also for any complex interaction that can be evaluated using a biological assay.

units/mL, including ≥7500 units/mL sulfatase), S9 mix, NADP, UDP-glucuronic acid (UDPGA), Tris-dithiothreitol, $MgCl_2$, and bovine serum albumin from Sigma-Aldrich, Inc. (St. Louis, MO, USA). Isorhapontigenin was purchased from TCI (Tokyo, Japan). The compound *cis*-resveratrol (≥98%) was obtained from Cayman Chemical Co., Inc. (Ann Arbor, MI, USA). Dihydroresveratrol (≥98%) was purchased from LKT Laboratories, Inc. (St. Paul, MN, USA). The compounds *t*RV 4′-*O*-glucuronide, *t*RV 3-*O*-glucuronide, and *t*RV 3-sulfate sodium salt were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). *β*-Glucosidase from almonds (≥2000 units/g) was obtained from Shin Nihon Chemical Industries, Inc. (Aichi, Japan).

*t*RV powder, 720 mg (3.2 mmol) *t*RV/g, was obtained by extracting *t*RV from capsules of dietary supplements of resveratrol (Douglas Laboratories, Pittsburgh, PA, USA) with a 10-fold amount of ethanol three times (25 mL × 3). The MSE powder (YMP-M-100109) containing 91% MSE and 9% dextrin was obtained from Yamada Bee Co., Inc. (Kagamino, Japan).

The preparation of solutions and all experiments using resveratrol derivatives were performed in dim LED light to avoid the photochemical isomerization of the *trans* form to the *cis* form.

Contents of Resveratrol Derivatives in *t*RV and MSE Powder. Analysis of resveratrol derivatives in *t*RV and MSE powder with and without hydrolysis was performed by the Prominence high-performance liquid chromatography (HPLC) system (Shimadzu) with a Cosmosil 5C18-ARII column (Nacalai Tesque, 4.6 × 250 mm), following the analysis conditions reported by Mark et al.[16] with minor modifications. A gradient solvent system of MeOH (20%, 5 min hold; 20−70%, 45 min linear gradient; 100%, 10 min hold; and 20%, 10 min hold) in 0.1% trifluoroacetic acid was used at a flow rate of 1.0 mL/min, and detection was at 320 nm.

Enzymatic Hydrolysis of Glucosides in MSE Powder. Hydrolysis of glucosides of resveratrol derivatives in MSE powder was performed following the method reported by La Torre et al.[17] with minor modifications. Briefly, a total of 100 mg of *β*-glucosidase in 1 mL of 100 mM acetic acid was added to MSE powder (10 mg) in 1 mL of 100 mM acetic acid and incubated at 55 °C for 2 h. A volume of 3 mL of acetonitrile was added to the reaction mixture, and after stirring, was centrifuged at 13000*g* for 15 min at 4 °C. The residue was washed twice with 1 mL of acetonitrile and centrifuged at 13000*g* for 15 min at 4 °C. The supernatant was collected and evaporated with nitrogen gas and dissolved in 10 mL of 30% aqueous acetonitrile containing 1% acetic acid for HPLC analysis.

Extraction and Isolation. The extraction of melinjo was performed as previously described by Kato et al.[1] with slight modifications. In brief, the dried endosperms (250 g) were powdered and soaked in 55% ethanol (750 mL) at room temperature for 3 days. The filtrate was evaporated in vacuo to obtain the MSE (23 g). The extract was then purified as previously described[1] to obtain gnetin C (≥99%), gnemonoside A (≥99%), gnemonoside C (≥99%), gnemonoside D (≥99%), and gnetin L (≥99%).

Gnetin C monoglucuronide was obtained by following the method reported by Otake et al.[18] with minor modifications. First, gnetin C (24 mg) was incubated with incubation mixtures containing 250 μL of S9 mix (5 μg of protein), 72 mg of UDPGA, 95 mg of NADP, 570 mg of $MgCl_2$, 185 mg of dithiothreitol, and 480 mg of bovine serum albumin in 480 mL of 50 mM Tris buffer (pH 7.4). After incubation at 37 °C for 24 h, the reactions were terminated by the addition of 480 mL of acetonitrile. The samples were centrifuged at 13000*g* for 15 min at 4 °C, and supernatants were evaporated. After 6.7 g of residue was dissolved in 36 mL of water, 3 mL of the solution was loaded onto the column (Strata C18-E 55 μm, 70A, 100 mg/3 mL, Shimadzu GLC Ltd., Tokyo, Japan), which was preconditioned with 3 mL of methanol and 3 mL of water. After a washing with 9 mL of methanol, all of the eluates were collected and evaporated. The crude glucuronides (71 mg) were dissolved in 470 mL of methanol and loaded onto a preparative C18 column (Cosmosil 5C-18-AR-II, 20 × 250 mm). The semipreparative HPLC Waters 600E multisolvent delivery system was used with a 200 μL loop (Waters, Milford, MA, USA). The mobile phase consisting of water/trifluoroacetic acid (0.1%) and methanol in the ratio of (45:55, v/v) was delivered at 7.5 mL/min. The injection volume was 40 μL. The eluent was monitored at 320 nm and the fraction at 23 min was collected. The methanol was evaporated, and the aqueous layer was lyophilized to obtain the glucuronide as a white solid (2.9 mg ≥96%). The structure was confirmed by liquid chromatography−tandem mass spectrometry (LC-MS/MS).

Subjects and Study Design. The study design was approved by the Yamada Bee Co. Ethics Committee. All of the subjects gave their written informed consent.

Single-Dose Study. Ten healthy volunteers (23−34 years; six men and four women) were divided into two groups: a *t*RV dose group and an MSE dose group. Two days before the study and during the study, the volunteers were given a diet that was low in polyphenols. Grape and peanut products were excluded. Subjects in the *t*RV dose group were provided a capsule containing 1.36 mg of *t*RV powder, 149 mg of dextrin, 29 mg of cellulose, 9 mg of sucrose esters of fatty acids, and 64 mg of gelatin. Subjects in the *t*RV dose group consumed five capsules after breakfast. Subjects in the MSE dose group were provided a capsule containing 250 mg of MSE powder, 29 mg of cellulose, 9 mg of sucrose esters of fatty acids, and 64 mg of gelatin. Subjects in the MSE dose group consumed four capsules after breakfast. Blood samples were collected at 1, 2, 4, 6, 8, 12, 24, 48, 72, and 96 h after intake of the capsules. The collected blood samples were centrifuged at 1200*g* for 10 min at ambient temperature. The obtained plasma samples were stored at −80 °C until UPLC-MS/MS analysis.

Repeated-Dose Study. In a placebo-controlled study, 44 healthy volunteers (32−49 years; 22 men and 22 women) were divided into four groups: placebo and 1000, 2000, or 5000 mg of MSE powder. In the placebo capsule, 250 mg of dextrin was used instead of 250 mg of MSE powder. All subjects consumed 20 capsules every morning for 28 days in the proportion of placebo and melinjo capsule, 20:0 (placebo group), 16:4 (1000 mg MSE dose group), 12:8 (2000 mg MSE dose group), and 0:20 (5000 mg MSE dose group). During the study, the volunteers were given a diet low in polyphenols. Grape and peanut products were excluded. The portion of plasma samples obtained at 14 and 28 days after the intake of 1000 mg of MSE powder was used for measuring blood levels of resveratrol derivatives. In addition, before and 28 days after the intake of placebo, 1000, 2000, or 5000 mg of MSE powder, clinical laboratory tests, including blood pressure, pulse, body mass index, and blood and urine biochemical parameters, were performed for the volunteers.

Sample Preparation for Plasma. For UPLC-MS/MS analysis, 250 μL of human plasma was mixed with 750 μL of cold acetonitrile and centrifuged at 13000*g* for 15 min at 4 °C. The supernatant was evaporated with nitrogen gas and dissolved in 750 μL of 0.5% citric acid/acetonitrile (1:3) solution. The solution was loaded onto an SPE column (Superco HybridSPE PPT/30 mg, Sigma-Aldrich, St. Louis, MO, USA), preconditioned with 400 μL of 0.5% citric acid/acetonitrile (1:3) solution. After washing with 0.5% citric acid/acetonitrile solution, the eluate was combined and concentrated by evaporation with nitrogen gas. The pellet was resuspended in 250 μL of 30% aqueous acetonitrile before filtering with a 0.2 μm filter (DISMIC-13HP, Advantec, Tokyo, Japan), and 4 μL of the filtrate was injected onto UPLC-MS/MS.

Enzymatic Hydrolysis of Glucuronate and Sulfate Conjugates. The enzymatic cleavage of glucuronate and sulfate conjugate of plasma metabolites was performed as follows. A volume of 250 μL of human plasma was mixed with 750 μL of cold acetonitrile and centrifuged at 13000*g* for 15 min at 4 °C. The supernatant was evaporated with nitrogen gas and dissolved in 250 μL of water. The solution was mixed with 100 μL of sulfatase type H-1 from *H. pomatia* (≥10000 units/g, including ≥30000 units/g *β*-glucuronidase) solution in 0.1 M sodium acetate buffer (pH 4.7). The mixture was incubated at 37 °C in a heating block for 2 h. The reaction was terminated by adding 750 μL of 0.5% citric acid/acetonitrile (1:3) solution. The reaction mixture was centrifuged at 2000*g* for 5 min at ambient temperature. The supernatant was treated in the same way as that for samples with no hydrolysis, and UPLC-MS/MS analysis was performed.

UPLC-MS/MS Analysis. UPLC analysis was performed using an Acquity UPLC (Waters) system. Separation of metabolites was performed at 40 °C using a reversed-phase column (Acquity UPLC

BEH C18, 2.1 × 100 mm, 1.7 μm). Injections were carried out with an autosampler maintained at 20 °C. The mobile phase consisted of water and acetonitrile and was pumped at a flow rate of 0.3 mL/min. The gradient system was as follows: 5% acetonitrile (0−2 min), 5−15% acetonitrile (2−7 min), 15−50% acetonitrile (7−27 min), 50−100% acetonitrile (27−31 min), and linear gradient, 100% acetonitrile (31−35 min). There was a 5 min reequilibration period with the initial solvent mixture between analyses. MS/MS was performed on a Q-Premier XE triple-quadrupole mass spectrometer (Waters) equipped with a turbo electrospray ion source (ESI) in the positive and negative modes and a heated curtain gas interface to the high-vacuum region of the mass analyzer. Mass detection and quantification of analytes were accomplished in the multiple reaction monitoring (MRM) mode, and spectra were analyzed by MassLynx Software (Waters). The ESI source was operated in the positive/negative ionization mode at 120 °C, with a desolvation temperature of 400 °C, an 800 L/h desolvation gas flow rate, and a capillary voltage set at 3.34 kV. The extractor and radiofrequency voltage were fixed to 3.0 and 0.1 V, respectively. The cone voltage varied from 20 to 50 V depending on the compound investigated. Argon was used as the collision gas at a flow rate of 0.25 mL/min, with collision energies of 16−46 eV. Quantification of *t*RV, *cis*-resveratrol, dihydroresveratrol, piceid, isorhapontigenin, gnetin C, gnetin C monoglucuronide, gnetin L, and gnemonosides A, C, and D was performed using the plasma matrix standard curve. The limits of detection (LOD) and limits of quantitation (LOQ) were determined as the analyte concentration that gave a signal-to-noise ratio of 3 and 10, respectively. Optimal conditions, LOD, and LOQ for each compound are shown in Table 1. The retention time of *cis*-gnetin C was confirmed using gnetin C solutions irradiated with artificial UV light for 0.5 h.

Pharmacokinetic Analysis. Maximum plasma concentration (C_{max}) and the time to reach C_{max} (t_{max}) were taken directly from observed plasma concentration−time profiles. The area under the plasma concentration time curve (AUC_{0-96}, nM·h) and the area under the first moment curve ($AUMC_{0-96}$, nM·h^2) were calculated by the trapezoidal rule to the last time point, 96 h.[19] The mean residence time (MRT, h) was calculated from the following formula:[19]

$$MRT = AUMC/AUC$$

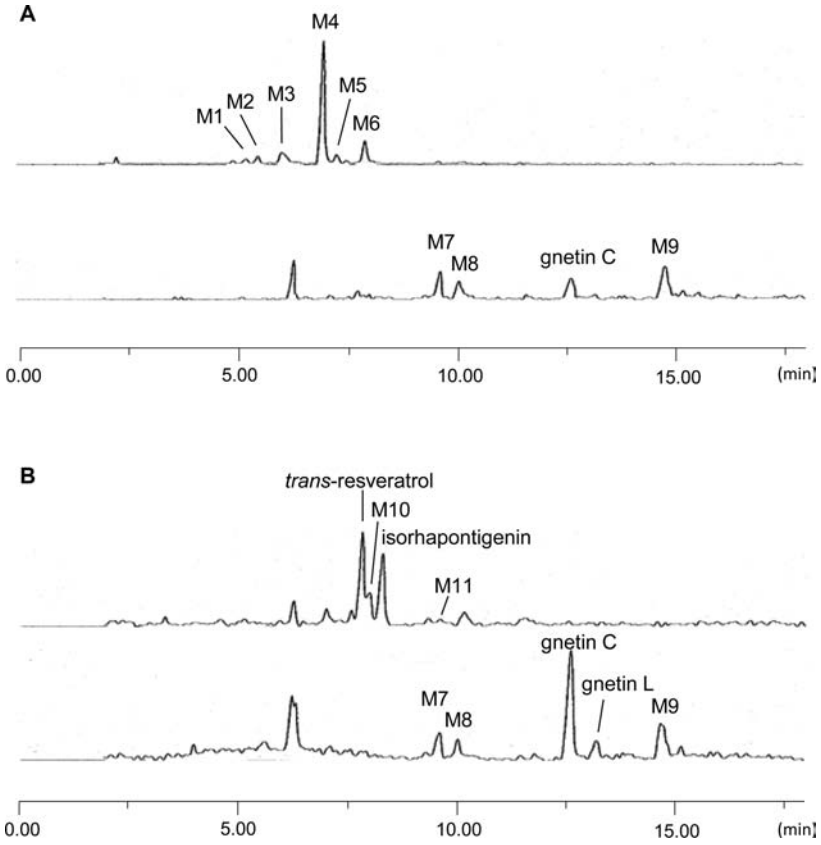

Figure 1. Liquid chromatography−mass spectrometry chromatogram of resveratrol derivatives and their major metabolites in plasma: *t*RV 4′-*O*-glucuronide (M1), isorhapontigenin monoglucuronide (M2), *t*RV 3-*O*-glucuronide (M3), *t*RV 3-sulfate (M4), isorhapontigenin monosulfate (M5), resveratrol monosulfate (M6), gnetin C monoglucuronides (M7, M8), *cis*-gnetin C (M9), dihydroresveratrol (M10), and *cis*-resveratrol (M11) without hydrolysis (A) and with hydrolysis (B) in a subject 8 h after a single oral administration of MSE powder (1000 mg).

Plasma concentration (C_p) time profiles of *t*RV and gnetin C with hydrolysis after a single dose of MSE were analyzed by a one-compartment model with first-order absorption. A curve-fitting study was performed with the least-squares regression program MULTI[20] by using the equation[19]

$$C_p = \frac{k_a FD}{V_d(k_a - k_{el})}(e^{-k_{el}t} - e^{-k_a t})$$

where k_a, k_{el}, F, D, and V_d are the absorption rate constant, elimination rate constant, bioavailability, dose, and distribution volume, respectively. Plasma concentrations after multiple doses of MSE were simulated by using the parameters obtained with the fitting study for the single dose of MSE.

Statistical Analysis. Statistical analyses were carried out using JMP for Windows 5 (SAS Institute Japan, Tokyo, Japan). In all of the tests, the criterion for statistical significance was $p < 0.05$.

RESULTS AND DISCUSSION

Identification of Metabolites for Resveratrol Monomer and Dimer Derivatives from MSE Powder. The contents of resveratrol monomer and dimer derivatives in MSE powder were as follows: resveratrol monomers, 1.2 mg/g (5.26 μmol/g) *t*RV, 5 mg/g (12.8 μmol/g) *trans*-piceid, 2.0 mg/g (7.75 μmol/g) isorhapontigenin; and dimers, 28 mg/g (61.7 μmol/g) gnetin C, 102 mg/g (131 μmol/g) gnemonoside A, 18 mg/g (29.2 μmol/g) gnemonoside C, 47 mg/g (76.3 μmol/g) gnemonoside D, 2.4 mg/L (4.95 μmol/g) gnetin L. After enzymatic hydrolysis of glucosides, the content of *t*RV was 5.4 mg/g (23.7 μmol/g) and those of isorhapontigenin, gnetin C, and gnetin L were 5.6, 150, and 12 mg/g (21.7, 350, and 24.8 μmol/g), respectively.

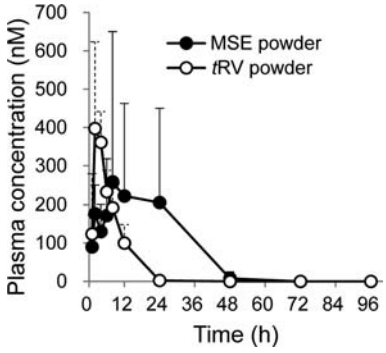

Figure 2. Plasma concentration−time curves of *t*RV with enzymatic hydrolysis in healthy human subjects who received a single dose of MSE powder (1000 mg) or *t*RV powder ($n = 5$). Results are expressed as the mean, and the bars indicate the SD.

Blood collected up to 96 h from volunteers who received 1000 mg of MSE powder was used for identification of metabolites of resveratrol monomer and dimer derivatives. Samples were prepared from plasma with and without enzymatic hydrolysis of glucuronide and sulfate. Samples were analyzed by UPLC-MS/MS.

Figure 1A shows the representative metabolites in plasma after intake of MSE powder. Five conjugates of resveratrol were found as two monoglucuronides (403/227) and two monosulfates (307/227) by MRM. The conjugate pattern of *t*RV was the same as that after intake of *t*RV powder intake (data not shown), which was also in good agreement with previous studies.[21,22] Two

Table 2. C_{max}, t_{max}, AUC, and MRT of Resveratrol Derivatives after Hydrolysis in Plasma Volunteers after a Single Oral Dose of MSE Powder[a]

sample	conjugated metabolite	C_{max} (nM)	t_{max} (h)	AUC_{1-96h} (nM h^{-1})	MRT (h)
*t*RV	*t*RV	473 ± 117	2.4 ± 0.9	3326 ± 470	6.6 ± 1.4
MSE	*t*RV	462 ± 314	11.6 ± 7.3*	7401 ± 5774	13.7 ± 7.7
	dihydroresveratrol	124 ± 228	18.0 ± 10.4	1371 ± 1770	6.7 ± 1.2
	isorhapontigenin	262 ± 155	6.7 ± 1.2	2962 ± 2010	11.3 ± 7.0
	gnetin C	143 ± 84	16.6 ± 7.5	6977 ± 4097	36.3 ± 8.1
	gnetin C monoglucuronide	77.9 ± 44.4	10.4 ± 8.3	2511 ± 990	36.5 ± 5.8
	gnetin L	13.1 ± 8.7	6.8 ± 5.0	372 ± 412	6.6 ± 1.4

[a]Results are expressed as the mean ± SD of experiments (n = 5). *, P < 0.05, Welch's test.

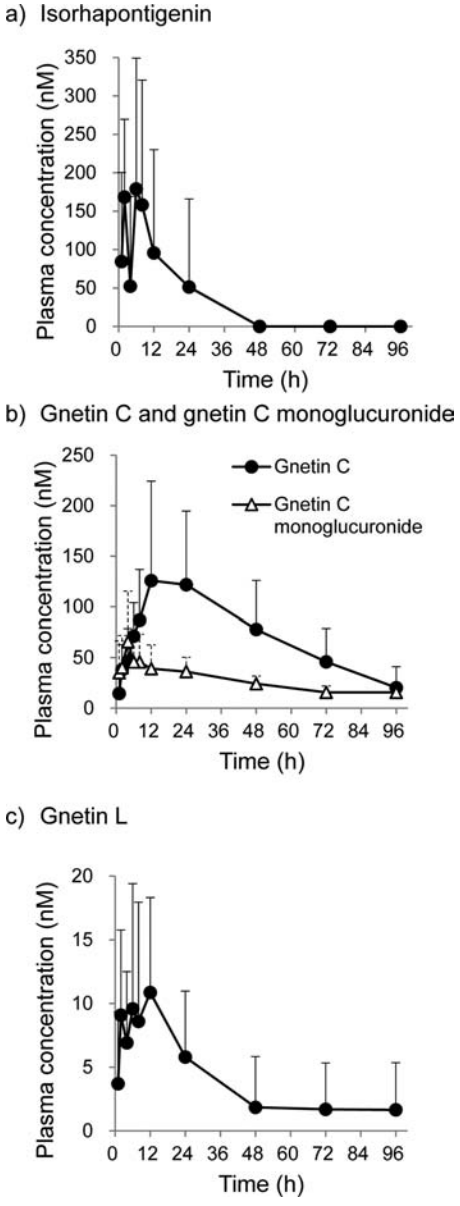

Figure 3. Plasma concentration−time curves of isorhapontigenin (a), gnetin C and gnetin C monoglucuronide (b), and gnetin L (c) with enzymatic hydrolysis in healthy human subjects (n = 5) who received a single dose of MSE powder (1000 mg). Results are expressed as the mean, and the bars indicate the SD.

conjugates of isorhapontigenin were also found as one monoglucronide and one monosulfate of isorhapontigenin by the following MRM transitions: 433.0 → 257.0 (loss of a glucuronide from isorhapontigenin) and 337.0 → 257.0 (loss of a sulfate from isorhapontigenin). Moreover, two monoglucuronides of gnetin C were found by the following MRM transitions: 631.0 → 455.1 (loss of glucuronic acid from gnetin C). In this research, the glucosides of gnetin C, such as gnemonosides A, C, and D, were not detected in plasma, suggesting that resveratrol dimers are absorbed after deglucosylation, as is the case in the intake of piceid.[15]

After enzymatic hydrolysis, most of these conjugates disappeared and *t*RV, *cis*-resveratrol, dihydroresveratrol, isorhapontigenin, and gnetin C were released (Figure 1B). However, two peaks of gnetin C glucuronides were not hydrolyzed, but the peak area of gnetin C was increased (Figure 1B). This finding indicated that several metabolites of gnetin C, other than monoglucuronide, remain to be identified.

Among the detected conjugates, two monoglucuronides and one sulfate of resveratrol were identified as *t*RV 4′-*O*-glucuronide, *t*RV 3-*O*-glucuronide, and *t*RV 3-sulfate by comparing them with their authentic samples. The conjugates of isorhapontigenin and gnetin C were characteristic metabolites of MSE, and their structures need to be elucidated in the future. On the other hand, the dihydro derivatives of gnetin C were not observed after enzymatic hydrolysis, suggesting that gnetin C is not susceptible to hydrogenation by colonic bacteria.

Pharmacokinetics of *t*RV and Its Derivative after Oral Dosing of MSE Powder. Without enzymatic hydrolysis, *t*RV, piceid, isorhapontigenin, and gnemonosides A, C, and D were not detectable in any of the plasma samples. Among *t*RV dimer derivatives, gnetin C was only detected (<25 nM) in some plasma samples after intake of MSE, but in most samples, the concentration was below the limit of quantification (data not shown).

Figure 2 and Table 2 show the plasma concentration−time profiles of *t*RV and dihydroresveratrol with hydrolysis and pharmacokinetic parameters after a single intake of MSE powder or *t*RV powder containing 4.9 mg of *t*RV only.

After intake of MSE powder, the plasma concentration of *t*RV reached 462 ± 314 nM (mean ± SD) at 12 h (Figure 2). Plasma *t*RV concentrations then declined within 48 h (Figure 2). The t_{max} of *t*RV after intake of MSE powder was significantly delayed by 9 h compared with that after *t*RV powder intake (p = 0.01) by Welch's test for parametric data, and the MRT also showed an increasing tendency compared with that after the intake of *t*RV powder (Table 2). After the intake of *t*RV powder, the plasma concentration of *t*RV with hydrolysis treatment reached C_{max}, 473 ± 117 nM, at 2 h and declined within 24 h (Figure 2), indicating that *t*RV was rapidly absorbed and mainly circulated as conjugates in plasma and then rapidly eliminated from plasma,

dx.doi.org/10.1021/jf4048435 | J. Agric. Food Chem. 2014, 62, 1999−2007

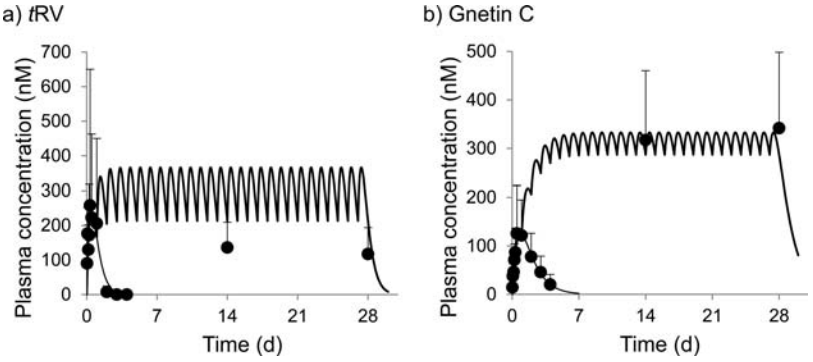

Figure 4. Effect of multiple dosing of MSE on plasma concentrations of *t*RV and gnetin C after hydrolysis. Plasma concentrations after a single dose of MSE (1000 mg, at 1−24 h) are shown together with those after multiple doses (1000 mg, 14 and 28 days) for *t*RV (a) and gnetin C (b) with hydrolysis. Thick solid lines show the fitting lines of plasma concentrations of *t*RV (a) and gnetin C (b) with hydrolysis after a single dose of MSE powder. Thin solid lines show the simulated concentrations of *t*RV (a) and gnetin C (b) with hydrolysis after multiple doses of MSE. Pharmacokinetic analysis was performed on the basis of the one-compartment model with first-order absorption as described under Materials and Methods. The parameters obtained by a fitting study, which were used for the simulation, were as follows: (a) *t*RV with hydrolysis, D = 23700 nmol as *t*RV after hydrolysis, V_d/F = 37.3 L, k_a = 0.093 h^{-1}, k_{el} = 0.086 h^{-1}; (b) gnetin C with hydrolysis, D 350000 nmol as gnetin C after hydrolysis, V_d/F = 1387.0 L, k_a = 0.064 h^{-1}, and k_{el} = 0.033 h^{-1}.

which are similar to many results.[23] With a single oral administration of MSE powder, *t*RV and its conjugates were efficiently absorbed and persisted in plasma as conjugates with a t_{max} of 12 h and a MRT of 14 h and then eliminated from plasma within 48 h (Figure 2). This delay in absorption could be because glucosides are absorbed as aglycone, which is released from glucosides by bacterial microflora in the large intestine. Indeed, after a single dose of 85.5 mg of piceid (*t*RV 3-*O*-D-glucoside) in humans, t_{max} of resveratrol conjugates in plasma was reported to be 6−8 h.[15] Furthermore, it has been reported that *t*RV is absorbed by simple diffusion and conjugated inside enterocytes to glucuronides and sulfates, which are then secreted in part to the intestinal lumen via MRP2 and BCRP.[24] The conjugates of *t*RV that avoid excretion toward the intestinal lumen are transported to the bloodstream through MRP3.[25] Therefore, several conjugates of *t*RV and its metabolites could inhibit each other in terms of elimination via transporters, leading to a long residence of *t*RV conjugates in plasma.

On the other hand, in these experiments, *cis*-resveratrol and dihydroresveratrol were also detected in some plasma samples, but in most samples, their concentrations were below the limit of quantification (data not shown).

Figure 3a shows that the concentration of isorhapontigenin reached 262 ± 155 nM at 7 h and then declined 48 h after the intake of MSE powder. In the case of tRV dimer derivatives, isorhapontigenin and gnetin L were detectable (Figure 3a,c), but gnetin C and its monoglucuronides were found to be much higher than gnetin L in plasma concentration. Because gnetin C monoglucuronides were not hydrolyzed by enzyme treatment, we isolated a monoglucuronide of gnetin C (Figure 1, M8) and quantified it separately from cleaved gnetin C. Monoglucuronides of gnetin C (Figure 1, M7) and *cis*-gnetin C could not be quantified because the authentic samples were not available. Gnetin C and gnetin C monoglucuronide had peaks of 143 ± 84.0 nM at 17 h and 77.9 ± 44.4 nM at 10 h, respectively (Figure 3b). Plasma concentrations of gnetin C and gnetin C monoglucuronide gradually declined over 96 h. Gnetin L also had a small peak of 13.1 ± 8.7 nM at 7 h, and its concentration declined over 48 h (Figure 3c). The persistence of gnetin C conjugates in plasma for >96 h might be due to slow absorption of their glucosides, because they would be absorbed as aglycone after release from glucosides by bacterial microflora as is the case of *t*RV. Furthermore, their elimination from plasma might also be mediated via several transporters as described above, and a possible inhibition by metabolites and conjugates of gnetin C and its glucoside might be responsible for their long residence in plasma. However, further studies are required to clarify the reason for this finding.

Plasma Persistence of Metabolites and Safety Assessment. In the repeated-dose administration experiment, 1000 mg of MSE powder was administered to subjects once daily after breakfast for 28 days. On days 14 and 28, blood samples were collected at 24 h after taking the dose. In this study, we focused on *t*RV and gnetin C, because gnetin C was found to be the most abundant dimer in plasma after enzymatic hydrolysis (Figure 3b,c).

Plasma concentrations of *t*RV and gnetin C that were determined after enzymatic hydrolysis are shown with those after a single administration in Figure 4a,b. Following the repeated dosing of MSE powder, a cumulative increase in plasma concentrations of *t*RV with hydrolysis was not observed (Figure 4a). Although the ratios of plasma *t*RV concentrations on days 14 and 28 to those at 24 h after the first dose were under unity, the *t*RV value at 24 h had a large variability, and observed concentrations on days 14 and 28 were not contradictory to the simulation curve calculated on the basis of a one-compartment model with first-order absorption (Figure 4a). The theoretical accumulation ratio calculated with k_a and k_{el} values was 1.28, suggesting that during multiple doses of MSE powder, *t*RV with hydrolysis follows pharmacokinetics similar to those after a single oral administration. We observed that plasma gnetin C concentrations after hydrolysis were increased by multiple dosing of MSE powder, which were in good agreement with the theoretically calculated simulation curve (Figure 4b). However, the accumulation ratio was moderate (2.8), which is also consistent with the theoretical value of 2.33 calculated by k_a and k_{el} values. This suggests that plasma gnetin C with hydrolysis during multiple doses follows similar pharmacokinetics to that after a single dose of MSE powder.

After intake of MSE powder, the variability in plasma concentrations of *t*RV and its derivatives with hydrolysis was considerably high in subjects (Figures 2 and 3; Table 2). This finding could be due to the interindividual differences of metabolism and pharmacokinetics of resveratrol derivatives.

Table 3. Blood Biochemistry Parameters in Healthy Subjects (n = 11) before and after Repeated Oral Administration of Melinjo for 28 Days[a]

		dose of MSE powder			
	days	placebo	1000 mg	2000 mg	5000 mg

[a]Results are expressed as the mean ± SD. ALT, alanine aminotransferase; γ-GTP, γ-glutamyl transpeptidase; AG ratio, albumin/globulin ratio; LDH, lactate dehydrogenase; HS-CRP, high-sensitivity C-reactive protein.

For the safety assessment of MSE powder, in addition to the 1000 mg dosing study, repeated-dose administration experiments were also performed at 0 (placebo), 2000, and 5000 mg for 28 days. Before and after 28 day multiple dosings, subjects were monitored by a physician and evaluated for body weight, heart rate, and blood pressure. Throughout the single and repeated administration experiments, no clinically noteworthy abnormalities were observed. Additionally, blood biochemistry parameters were not significantly different ($p > 0.05$) by Dunnet's test for parametric parameters, between before and after each oral administration of 1000, 2000, and 5000 mg of MSE powder (Table 3). This finding suggests that MSE is safe, at least in the short term, such as 1 month, and in an amount consumed in a usual manner.

Most studies have focused on *t*RV in the in vitro experiments, but it has been reported that *cis*-resveratrol, dihydroresveratrol, resveratrol conjugates, and other metabolites, such as piceatannol, a hydroxylated metabolite of resveratrol, have some biological activity.[26−31] Furthermore, pterostilbene, a methoxy derivative of resveratrol, is better absorbed and more bioactive once it is absorbed than *t*RV in the rat.[32] Recently, we reported that gnetin C reduces cell viability of tube-forming human umbilical vein epithelial cells more potently than *t*RV.[3] We also found that a monoglucuronide of gnetin C did not lose xanthine oxidase inhibitory activity.[6]

In animal experiments, it has been reported that resveratrol metabolites and conjugated resveratrol metabolites were distributed into several tissues and that these metabolites might provide a pool for local or systemic regulation of resveratrol metabolites.[33,34] Therefore, the metabolism and distribution of resveratrol derivatives from MSE in several tissues need to be clarified. Further studies are now in progress to elucidate the details of metabolism of resveratrol derivatives from MSE.

dx.doi.org/10.1021/jf4048435 | J. Agric. Food Chem. 2014, 62, 1999−2007

In conclusion, the repeated oral administration of a daily dose of MSE powder was well-tolerated up to 5000 mg/day. Clinical usefulness of MSE powder is likely because of the persistence of resveratrol monomer and dimer conjugates in plasma. However, the relationships between plasma concentrations of these conjugates and biological activity remain unclear.

NOTE ADDED AFTER ASAP PUBLICATION

There was an error in the fifth paragraph of the Pharmacokinetics of *t*RV and Its Derivative after Oral Dosing of MSE Powder section in the version of this paper published February 12, 2014. The correct version published February 13, 2014.

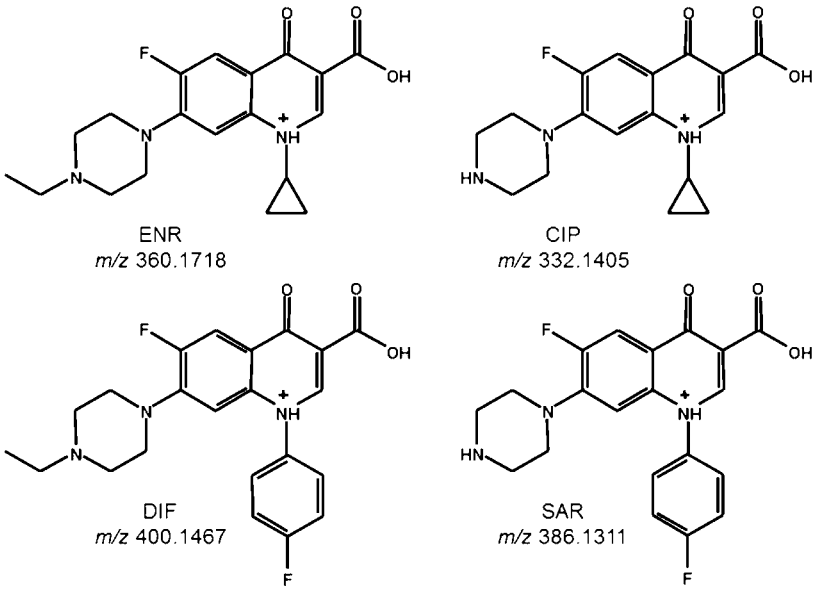

Figure 1. Structures of the four quinolones studied (ENR, CIP, DIF, and SAR).

chromatography (LC) coupled to high-resolution mass spectrometry (ToF and LTQ-Orbitrap).

EXPERIMENTAL PROCEDURES

Chemicals and Apparatus. The standards were purchased from several pharmaceutical firms: ENR from Cenavisa (Reus, Spain), CIP from Ipsen Pharma (Barcelona, Spain), DIF from Abbott (Madrid, Spain), and SAR from AK Scientific Inc. (CA,USA).

All reagents were of analytical grade unless indicated. Formic acid (HOCHO), acetic acid (HOAc), acetonitrile (MeCN), methanol (MeOH), sodium dihydrogenphosphate, and sodium hydroxide (NaOH) were supplied by Merck (Darmstadt, Germany). Water was ultrapurified by a Milli-Q system (Millipore, Bedford, MA, USA).

The quinolone individual stock solutions (ENR, CIP, DIF, and SAR) were prepared at a concentration of 500 μg mL^{-1} in 50 mM HOAc aqueous solution. The individual working solutions that were used to spike the milk samples were prepared by dilution of the individual stock solution at a concentration of 20 μg mL^{-1} in water.

Sodium dihydrogenphosphate solution 0.1 M adjusted with NaOH 5 M to pH 10 was added to milk samples prior to the cleanup step.

The SPE cartridges used in this study were Oasis HLB (3 cm^3/60 mg), obtained from Waters (Milford, MA, USA).

To simulate the thermal treatment of milk, a laboratory oven (Memmert) was used to warm the samples. A Rotanta 460RS (Hettich Zentrifuguen, Germany) centrifuge was used to separate precipitated proteins and fat of supernatant after the extraction. The SPE step was carried out in a Supelco vacuum manifold with disposable liners for 24 cartridges (Bellefonte, PA, USA), connected to a Supelco vacuum tank. Evaporation to dryness was performed in a TurboVap LV (Caliper Life Science, Hopkinton, MA, USA). A Crison 2002 potentiometer (±0.1 mV) (Crison, Barcelona, Spain) with a Crison 5203 combined pH electrode from Orion Research (Boston, MA, USA) was used to measure the pH of the phosphate solution and the mobile phase.

Milk Samples. Milk samples used in the work have been supplied by the Laboratori Interprofessional Lleter de Catalunya (ALLIC), control laboratory of milk in Catalonia. The samples were analyzed previously by ALLIC using a screening method to determine if the milk contained residues of antibiotics. The milk samples that were negative in antibiotics were used as blank samples in this work. Four positive samples in ENR were used to study the metabolites.

LC-MS Instrumentation and Working Conditions. *LC Conditions.* Quinolones, their metabolites, and degradation products were separated in a Zorbax Eclipse XDB-C8 column (5 μm, 4.6 × 150 mm) from Agilent Technologies (Santa Clara, CA, USA), using a Kromasil C8 (5 μm, 4.6 × 15 mm) precolumn supplied by Akady (Barcelona, Spain) when samples were analyzed by LC-ToF. A Pursuit UPS C18 column (2.4 μm, 2 × 50 mm) from Varian (Harbor City, CA, USA) was used when samples were injected into the LC-LTQ-Orbitrap.

For both columns, the mobile phase was composed of an aqueous solution of 0.1% HOCHO (solvent A) and MeCN with 0.1% HOCHO (solvent B) at a constant flow rate of 1 or 0.3 mL min^{-1}, respectively. The injection volume was 20 μL in LC-ToF and 10 μL in LC-LTQ-Orbitrap. Separations were carried out in a Zorbax Eclipse XDB-C8 column for 11 min under the following gradients: from 0 to 1 min, 15% B; 4 min, 45% B; 7 min, 56% B; 8.5 min, 15% B; and 11 min, 15% B. Separations were carried out in a Pursuit UPS C18 column under the following conditions: from 0 to 3.5 min, 1% B; 4.5 min, 25% B; 5 min, 50% B; 6.5 min, 50% B; 7.5 min, 25% B; 8.5 min, 10% B; and 11 min, 1% B.

LC-MS (ToF). A HP Agilent Technologies 1100 LC system was equipped with an autosampler and coupled to a 6220 oa-ToF LC/MS mass spectrometer with an electrospray ionization source (ESI) (Agilent Technologies, Santa Clara, CA, USA). The system was controlled by Mass Hunter workstation software (Agilent Technologies) for the acquisition and processing of data from the ToF mass spectrometer.

The optimum parameters of ToF in positive mode were as follows: capillary voltage, 4000 V; drying gas (N_2) temperature, 300 °C; drying gas (N_2) flow rate, 9 L min^{-1}; nebulizer gas (N_2), 40 psi; fragmentor voltage, 150 V; skimmer voltage, 60 V; and OCT 1 RF voltage, 250 V. The ToF-MS mass resolving power was approximately 10000 full width at half-maximum (fwhm) at m/z 922. Spectra were acquired over the m/z 50−1100 range. Data storage was in profile and centroid modes.

LC-MS (LTQ-Orbitrap). An Accela LC system (Thermo Scientific, Hemel Hempstead, UK) was equipped with a thermostatic autosampler and coupled to an LTQ Orbitrap Velos mass spectrometer (Thermo Scientific), with an ESI source. XCalibur software was used for the data analyses.

The operation parameters used were as follows: source voltage, 3.5 kV; sheath gas (N_2), 40 (arbitrary units); auxiliary gas (N_2), 10 (arbitrary units); sweep gas (N_2), 10 (arbitrary units); and capillary temperature, 275 °C. Default values were used for most other acquisition parameters (Fourier transform (FT) automatic gain control (AGC) target 1 × 10^6 for MS mode and 5 × 10^4 for MS^n mode). Milk samples were first analyzed in full MS mode with the Orbitrap mass resolving power set at 30000 fwhm at m/z 400. The

[a]The errors (ppm) are calculated from the theoretical and proposed structures. [b]na, nonassigned. [c]Two chromatographic peaks with the same m/z (at different retention times). [d]Three chromatographic peaks with the same m/z (at different retention times).

following analyses were carried out in MS^n mode with the Orbitrap mass resolving power set at 15000 fwhm at m/z 400. The maximum injection time was set to 100 ms with one micro scan for MS mode and to 500 ms with one micro scan for MS^n mode. TPs were fragmented in the HCD collision cell because some metabolites were not fragmented in the trap. The selected HCD voltage was 45 V, although in some cases it was raised to 50 and 60 V. The mass range was from m/z 100 to 1000.

Procedures. *Thermal Study.* In this study, individual standards of quinolones (ENR, CIP, DIF, and SAR) at 1 $\mu g\ mL^{-1}$ in water were warmed to degrade the antibiotics. All quinolones were heat-treated under conditions of temperature and time corresponding to three thermal processes of milk: pasteurization at 60 °C for 30 min (T1) or 72 °C for 15 s (T2) and sterilization at 120 °C for 20 min (T3). Subsequently, individual milk samples spiked with ENR, CIP, DIF, and SAR were warmed at 120 °C for 20 and 60 min (T3.20 and T3.60). The samples heated at different temperatures were compared with spiked nonheated samples (T0) and with blank milk samples at same thermal condition; for example, samples at T3.20 were compared with blank at T3.20. Milk samples from animals medicated with ENR were also thermally treated at T3.20 and T3.60 and compared with the same sample but nonheated. All experiments were made in triplicate.

Sample Treatment and Cleanup (SPE). The method for analyzing the milk sample was used previously to determine the antibiotics in the milk.[9−12] The extraction method consisted of the addition of 0.5 mL of 0.1 M phosphate solution at pH 10 and 2 mL of water to 2 g of milk, centrifugation of samples, and an SPE process. The SPE cartridges used were Oasis HLB, and these were preconditioned with 1 mL of MeOH, 1 mL of water, and 1 mL of 0.1 M phosphate solution at pH 10. After sample loading, the cartridge was washed with 3 mL of water and the analytes were eluted with 2 mL of MeOH.

The methanolic fraction eluted from the SPE was evaporated to dryness under a nitrogen stream by TurboVap LV and a water temperature of 35 °C. The extract was then reconstituted with 200 μL of water and filtered through membrane filters (Ultra free Durapore PVDF 0.22 μm from Millipore) before injection into the LC-LTQ-Orbitrap.

Data Treatment. The LC-ToF data were treated using two procedures to find metabolites and TPs in milk samples from medicated cows with ENR. The first corresponds to the manual comparison of mass spectra of blanks and samples. This procedure was used initially to detect the TPs in standards and spiked cow's milk. The other option consists of the use of MZmine2[42,43] free software, which provides a list of all m/z on mass spectra. The list can be shortened by removing all of the ions that appear only in the blank spectra and those that have a similar or higher intensity in the blanks than in the samples. Only the ions that appeared between 1 and 9 min and from 150 to 800 Da were considered. Also, a mass defect filter (MDF) of 120 mDa was applied.

RESULTS AND DISCUSSION

Determination of Thermal TPs by LC-ToF-MS. Blank and spiked water samples were subjected to the thermal conditions explained under LC Conditions and analyzed by LC-ToF-MS. The total ion current chromatograms (TIC) of spiked water samples were compared with the TIC of blank water samples to examine possible TPs. The two chromatograms were nearly identical except for the spiked antibiotic peak.

The mass spectra of blank and spiked water samples were compared by overlapping. The only difference between the spiked sample and the blanks was the peak of the parent compound. However, a decrease in the area of the protonated molecule of quinolones was noted when the temperature rose.

[a]The DBE calculated with the deprotonated molecular formula and the calculated error (ppm) of the assignation of structure. [b]Retention time when LC-ToF is used. [c]HX, hydroxylation; N-O, *N*-oxide; K, ketone formation; DE, deethylation; H, hydrogenation; CC, cysteine conjugation; DC, decarboxylation; DF, reductive defluorination; DM, demethylation; A, acetylation; F, formamidation; DY, dehydration; DCP, decyclopropylation; LC, lactose conjugation. [d]Concentration too low to be fragmented. [e]These masses were also observed with a molecule of water (+18.0105) but at low concentration.

The highest decrease was seen when the samples were heated at 120 °C for 20 min (T3.20), in some cases up to 20%. A new condition of 120 °C for 60 min (T3.60) was also applied to ensure that TPs were obtained in sufficiently high concentrations to be detected.

Raw cow's milk samples free of quinolones were spiked and heated under the selected conditions. To assess whether any TPs had formed, the same procedure as that used for the water standards was followed. In this case, some ions were identified in the mass spectra of the spiked milk samples that were not observed in the blank milk samples. Some ions were identified as doubly charged protonated molecules, with characteristic losses of water and carbon dioxide. These ions were also detected in the water samples. The doubly protonated identity was confirmed by the isotopic pattern. The difference between $[M + 2H]^{2+}$ and $[M + 1 + 2H]^{2+}$ was m/z 0.5. In addition, the same retention time (t_R) of the compounds in the extracted ion chromatogram (EIC) was observed.[44] The losses of H_2O (18.0105) and CO_2 (43.9898) are not considered as TPs because these were also observed in the source by CID-in-

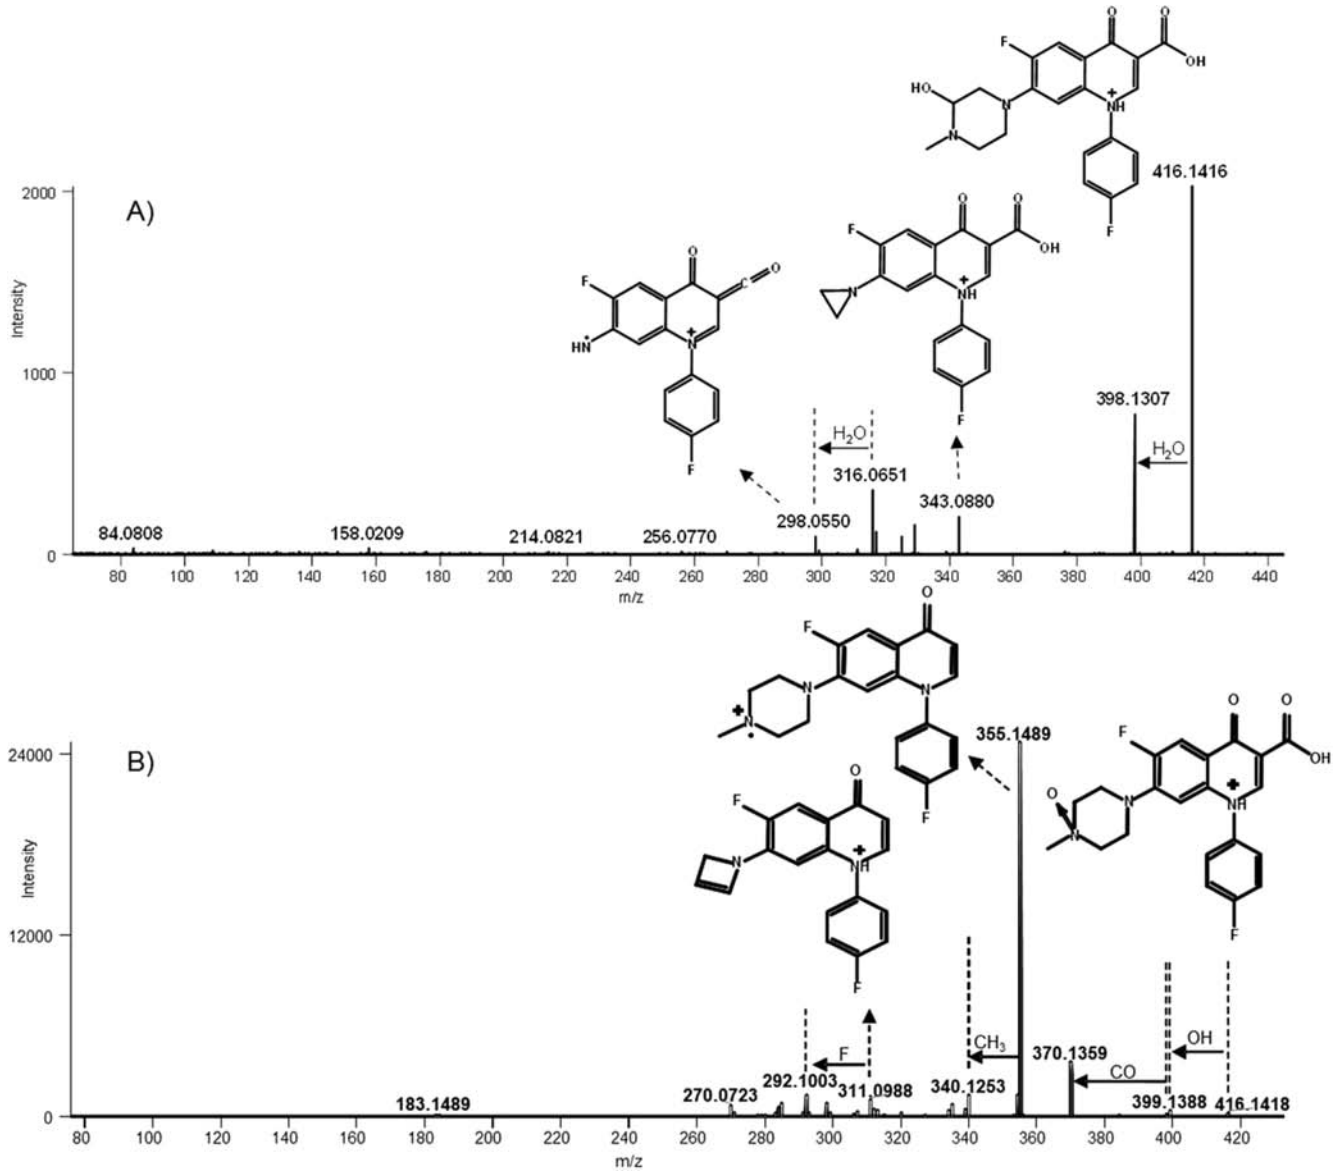

Figure 2. (A) MS^2 spectrum for the hydroxylated TP of DIF; (B) MS^2 spectrum for the *N*-oxide TP of DIF.

source fragmentation.[40,45−48] The ions m/z 332.1405 and 386.1311 were detected in samples that were spiked with ENR and DIF, respectively. These m/z values are consistent with the m/z of CIP and SAR. The EIC were obtained for blank and spiked samples to check the presence of TPs. Table 1 shows all of the ions found in milk and their identification, sorted by the original antibiotic. As can be observed, the errors between experimental mass and assigned structure were <3.0 ppm.

To assign a structure to the remaining ions that were observed, an in-house database was created using a list of 106 metabolic reactions[49] that can take place in milk and another list of milk components (including carbohydrates, amino acids, vitamins, and lipids; a total of 188 components).[50] The exact mass of the starting antibiotic or a known fragment is introduced into the database, and a series of combinations of reactions and/or possible additions are obtained that give rise to a molecule with an exact mass similar to that observed in the mass spectra of ToF.

Identification of Thermal TPs by LC-LTQ-Orbitrap-MS. As a ToF spectrometer cannot fragment molecules, we used an LTQ-Orbitrap to elucidate the TPs, as it has a higher mass resolving power than ToF and can fragment the compound to obtain structural information.

For each quinolone, Table 2 shows the retention time (t_R), m/z values, gains and losses of mass compared to the parent quinolone, m/z of the TPs observed, and fragments observed in mass spectra. Table 2 also shows the proposed reactions, with the assigned molecular formula, the double-bond equivalents (DBE) of neutral molecules, the theoretical mass, and the error (in ppm) calculated for the formula. The information is provided as common reactions that occurred in all of the studied quinolones and other reactions that were observed in only some quinolones.

Common Reactions of the Four Quinolones. Several gains and losses of mass were common among the four quinolones studied. Our database shows that the gain of m/z 15.9949 (Table 2) could correspond to two different reactions: hydroxylation and *N*-oxide formation. An evaluation of MS/MS spectra could be used to differentiate between both structures. As an example, Figure 2A shows the MS/MS

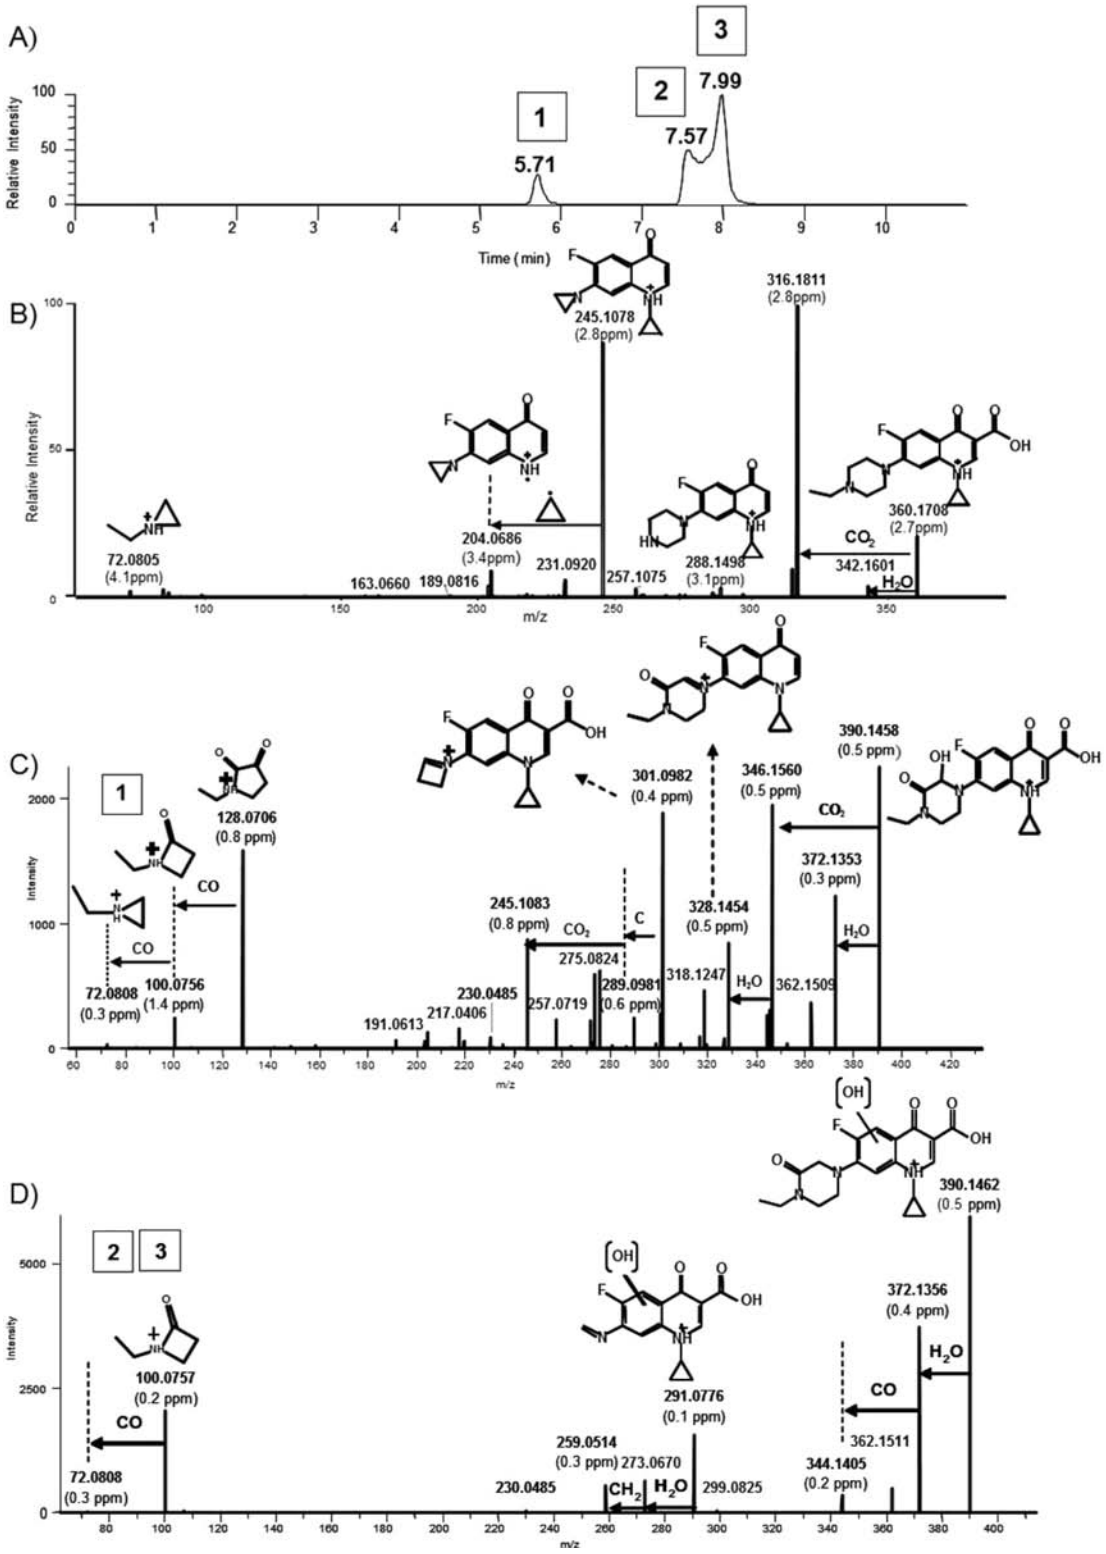

Figure 3. (A) EIC of ion m/z 390.1460 in the milk sample spiked with ENR; (B) MS^2 spectrum for ENR; (C) MS^2 spectrum for the first peak (t_R 5.71 min); (D) MS^2 spectrum for the remaining peaks (t_R 7.57 and 7.99 min).

spectrum of ions m/z 416.1416 in samples of DIF and discussion about elucidation is given in the Supporting Information. The position of OH could not be assigned with certainty, but our proposal is hydroxylation in position 3 of the piperazine ring, as in oxo-ciprofloxacin, the metabolite described in the bibliography.[36,37,40] For the four quinolones, the hydroxylated TPs were observed, but the concentrations of TPs from ENR and DIF were higher than from CIP and SAR. *N*-Oxide formation occurred only in ENR and DIF in N^4-alkylpiperazinyl. This metabolite has been described previously.[38,51] For this structure, a loss of OH is characteristic in fragmentation and was experimentally observed in Figure 2B of

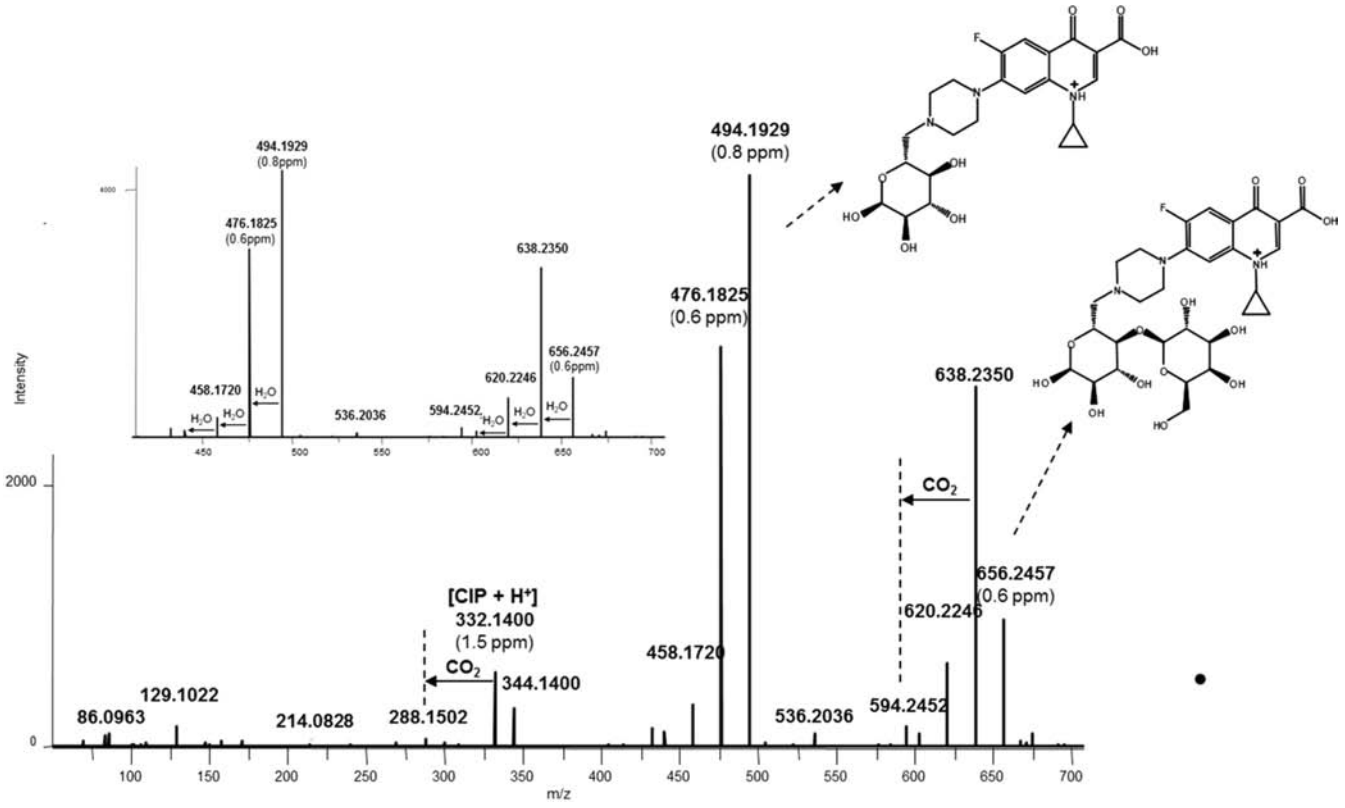

Figure 4. Product ion scan (MS^2) of CIP lactose conjugate (precursor ion m/z 656.2457): (top left) extended mass spectrum showing losses of water molecules.

the MS/MS spectrum of ions m/z 416.1416 for DIF. In this case, the DBEs of TPs undergo no alteration of values in comparison with the DBE of parent quinolones. Different fragmentation patterns were observed for the hydroxylated and *N*-oxide compounds that were found, as can be observed in Figure 2. In Figure 2B, corresponding to the *N*-oxide TP, the peak of the precursor ion disappeared almost completely when the same voltage was applied (HCD: 45). This finding suggests that hydroxylated compounds are more stable than *N*-oxide TP. The structures assigned to the rest of the ions are shown in Figure 2. Table 2 shows the fragmentation ions, the molecular formula, the DBE, and the calculated error in the assignation of the different structures.

A gain of m/z 29.9740 was also observed for the four quinolones, as shown in Table 2. Three peaks were found for ENR and DIF, whereas only one peak was observed for their main metabolites (CIP and SAR), at a concentration too low to be isolated and fragmented. The mass spectra of all peaks of ENR and DIF were studied. Figure 3 shows the mass spectra of ions with m/z 390.1460 of ENR. In Figure 3A, the separation by LC-LTQ-Orbitrap is shown with peaks at 5.71, 7.57, and 7.99 min. Although the retention time of ENR matches peak 1, the mass spectra are different, as can be observed in Figure 3B,C. A comparison of both mass spectra revealed only two ions (m/z 245.1077 and 72.0805) in common. The m/z 245.1077 indicates that the differences between the TP of peak 1 and ENR are in the loss fragment (part of the piperazinyl ring). The accurate mass of the fragment m/z 128.0706 corresponds to the molecular formula $C_6H_{10}NO_2$ with a DBE value of 3 and is the key to the elucidation as is shown in Figure 3C and in the Supporting Information.[52]

Unlike the first molecule, the other two ions of m/z 390.1460 (peaks 2 and 3) had low fragmentation as can be observed in Figure 3. Nevertheless, their structures were elucidated. The retention time of these peaks are different, but their mass spectra are identical, which indicates that they are isomers (Figure 3D). The m/z 245.1085 observed in the mass spectrum of ENR (Figure 3B) could not be found in the spectra of peaks 2 and 3. The molecules were broken up from the piperazinyl ring, resulting in the ions 100.0756 and 291.0774. The fragment 100.0756 is the same as that observed in Figure 3C, which indicates that there was only a ketone in the ring. The fragmentation of 291.0774 leads us to conclude that OH is on the aromatic ring. Two different vacant positions in the aromatic ring led to the two different isomers. For DIF, the fragmentations were similar to those shown in ENR, as can be observed in Table 2.

TPs corresponding to a net loss of 26.0146 were observed for all compounds (ENR, CIP, DIF, and SAR). For the TPs of ENR and DIF losses of N^4-alkylamine from the piperazinyl ring were observed. However, as CIP and SAR do not have an alkyl group in N^4, losses of ammonia (17.0275) were seen. Moreover, the TPs had DBE 1 unit lower than the parent compound, due to the break in the piperazinyl ring. Therefore, the peaks at m/z 334.1560, 306.1246, 374.1307, and 360.1156 have been assigned to desethylenequinolone TPs.[34−37] As Table 2 shows, when Orbitrap was used to elucidate the structures, the calculation errors (ppm) were <2 ppm. Slightly higher error values were obtained when ToF was used.

Other Reactions. The major metabolites, CIP and SAR, underwent other transformations, as can be observed in Table 2. Due to the absence of the alkyl chain in the N^4-piperazinyl ring, two reactions, acetylation (acetyl-CIP (m/z 374.1509) and

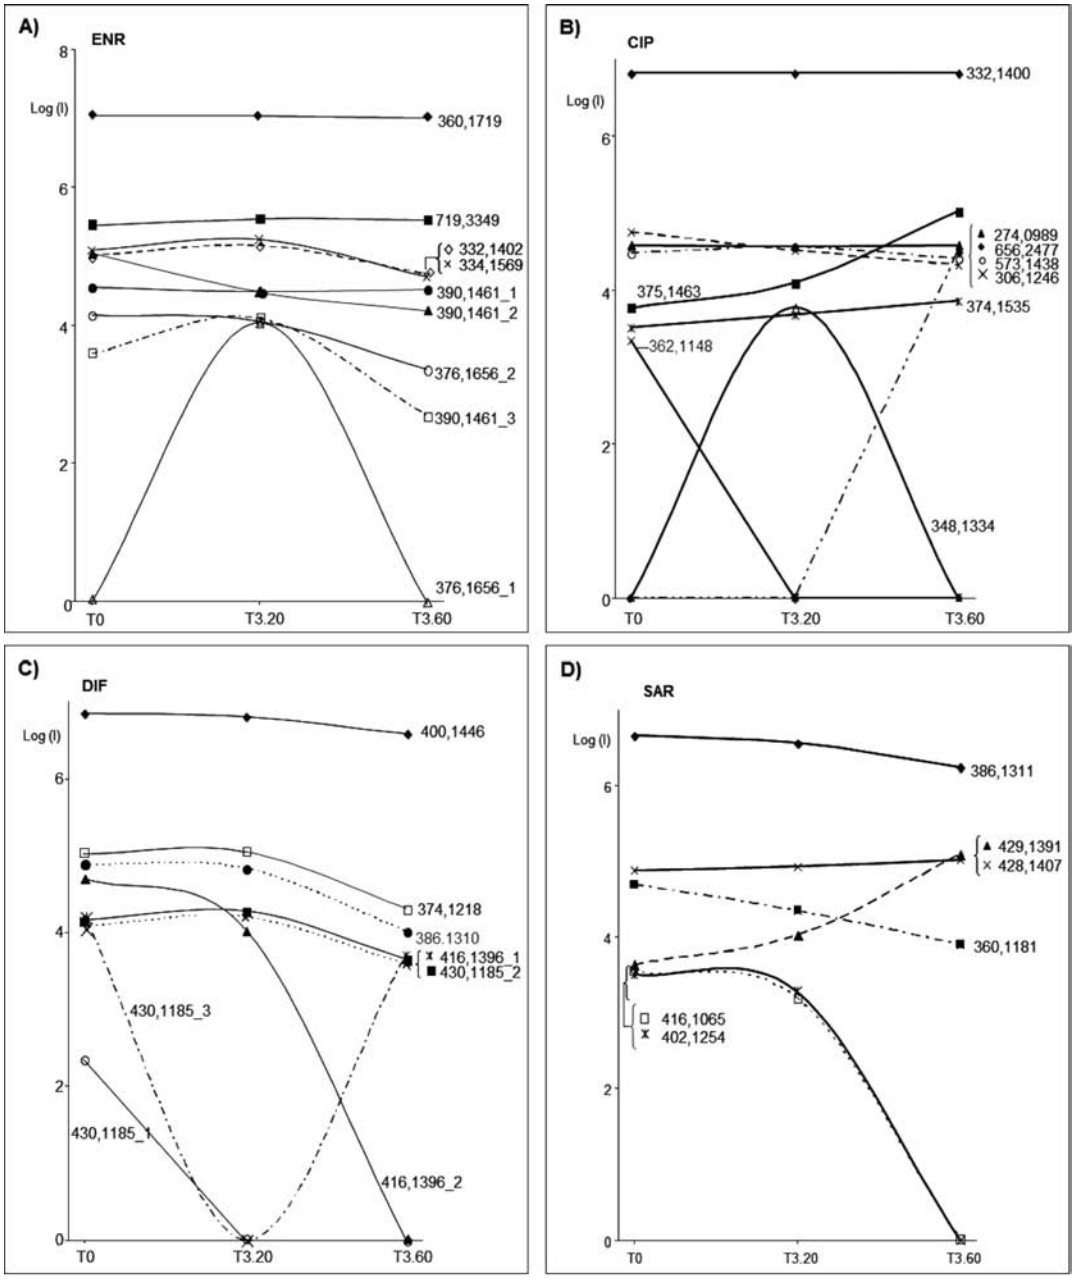

Figure 5. Influence of the different warming conditions in areas of different TPs of ENR, CIP, DIF, and SAR.

acetyl-SAR (m/z 428.1416)) and formamidation (formamide-CIP (m/z 375.1463) and formamide-SAR (m/z 429.1416)), took place. The corresponding explanation of elucidation is in the Supporting Information.

In addition to the above-mentioned reactions, CIP gave three more TPs (m/z 274.0986, 573.1429, and 656.2457). The ion 573.1429 was observed at a very low concentration and could not be fragmented. For the mass 274.0986, the ion 292.1091 could also be observed, at less intensity, corresponding to the gain of a water molecule. The main ion obtained by MS^2 of the ion 274.0986 was 231.0564, and this was isolated and fragmented again. In the MS^3 spectrum, the ion m/z 249.0668 was also observed with m/z 231.0564, which corresponds to the gain of a water molecule. This gain of water was observed only in the ions that kept the carbonyl group of acid, which is capable of hydrating the initial carboxylic acid again. The rest of the ions were mainly due to fragmentation of the piperazine ring. The structure assigned to m/z 292.1091 was CIP, with loss of the cyclopropyl group.

The last TP (656.2457) was obtained by heating the spiked milk sample with CIP at T3.60. When a HCD voltage of 45 V was used, only fragments with low m/z were found. To obtain structural information, the voltage was reduced to 35 V. The CIP ion (m/z 332.1400) could be identified among all of the fragments as can be seen in Figure 4. As can be followed in the Supporting Information, the molecule CIP (332.1405) is combined with the lactose (galactose + glucose) present in milk at high concentration. This new product was favored when samples were heated at a high temperature for a long time (60 min).

Effect of Temperature on the Stability of TPs. For each TP ion, the areas obtained from milk samples were plotted versus the heating conditions (T0, T3.20, and T3.60) (Figure 5). For ENR and CIP (Figure 5A,B), all of the TPs were

[a]Accurate masses analyzed by ToF and Orbitrap and their theorical mass assigned to molecular formula are given with calculated error (ppm) for the assignation of suggested structure for the two analysers. [a]Retention time when LC-ToF is used. [b]These molecular formulas are hypothetical in cases of metabolites without assigned structure. na, nonassigned.

observed at T0 except for hydroxylated quinolones (*m/z* 376.1656_1 and 348.1334, respectively). The concentration of these ions was raised by heating at T3.20 and disappeared at T3.60. In the case of ENR (Figure 5A), the concentration of some TPs, including CIP (332.1402), desethylene-ENR (334.1569), and two isomers of hydroxylation and ketone formation (390.1461_1 and 390.1461_3), increased slightly by warming at T3.20 and decreased at T3.60. For CIP, T3.60 was required for conjugation with lactose (656.2477) to occur (Figure 5B). The acetylated (374.1535) and formamidated (375.1463) compounds were present at T0 and their concentrations increased by heating. The 362.1148 ion

dx.doi.org/10.1021/jf405554z | J. Agric. Food Chem. 2014, 62, 2008−2021

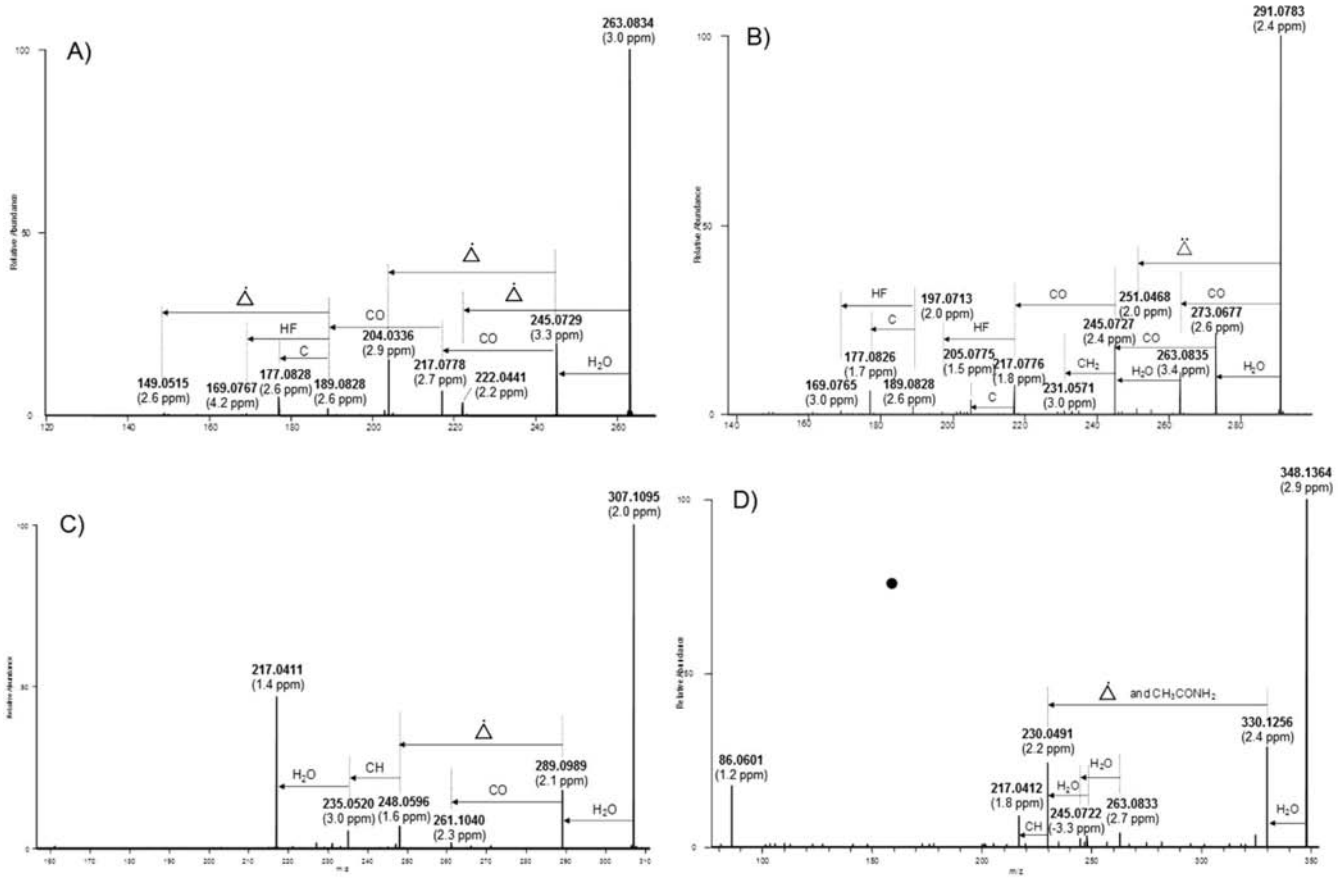

Figure 6. MS^2 spectra for the metabolites of ENR: (A) m/z 263.0828 (ENR-1); (B) m/z 291.0776 (ENR-2); (C) m/z 307.1089 (ENR-4); (D) m/z 348.1354 (ENR-9).

(corresponding to gain $[M + H + 29.974]^+$) was initially present (T0), but was destroyed by heating.

In contrast, the concentration of most of the ions in DIF samples increased slightly when the temperature was increased (Figure 5C). A general downward trend of DIF ions was seen at T3.60. Completely different behavior was observed for the 430.1185_3 ion, which underwent a sharp decrease at T3.20 and a sharp rise in formation when the warming time was increased, possibly due to the ion coming from different sources, and for the 430.1185_1 ion, which disappeared completely at T3.20. The acetylated (428.1407) and formamidated (429.1391) TPs of SAR (Figure 5D) behaved in the same way as those of CIP; that is, their concentration increased with temperature.

Determination of Metabolites and TPs in Medicated Cow's Milk. Four raw milk samples from cows medicated with ENR were submitted to the same thermal treatments as the spiked milk samples. The extracts were analyzed by LC-ToF, and the metabolites and TPs were fragmented by LC-LTQ-Orbitrap.

In this case, metabolites and TPs were found using the two data treatments (LC-MS (LTQ-Orbitrap)). When exact mass, retention time, and MS/MS spectra were compared, some of the compounds in milk spiked with ENR and CIP were also present in medicated cow's milk.

Table 3 shows the retention time (t_R) of metabolites in samples analyzed by LC-ToF, the accurate m/z of metabolites determined by ToF and LTQ-Orbitrap, the assigned molecular formula, the theoretical mass, the error (in ppm) calculated for the assigned formula, the proposed structures, and the double-bond equivalents (DBE) of the neutral molecule.

CIP (m/z 332.1405), the main metabolite of ENR, was one of the common compounds. In addition, desethylene metabolites of ENR (m/z 334.1561) (ENR-6) and CIP (m/z 306.1248) (ENR-3) were observed. The TPs of ENR corresponded to hydroxylation (ENR-16) and *N*-oxide formation (ENR-17) (m/z 376.1667), and two isomers of compound m/z 390.1460 (ENR-18 and ENR-19) (hydroxylation and ketone formation, Figure 3D) were also found. Four TPs of CIP were observed in medicated cow's milk. At 3.6 min was found the hydroxy-CIP (m/z 348.1354) (ENR-8) and at 6.1 min the m/z 362.1147 (ENR-11), although this time the MS^2 spectrum could not be obtained due to its low concentration. The other metabolites were from acetylation (m/z 374.1511) (ENR-14) and formamidation (m/z 375.1463) (ENR-15) of CIP.

Other compounds were found in milk from medicated cows, but not in spiked milk. These compounds were produced by metabolism of the antibiotic in the cow, and some of them were identified for the first time.

The metabolite with the highest intensity after CIP (332.1405) and desethylene-ENR (334.1561)(ENR-6) had m/z 263.0834 (ENR-1). The m/z of the metabolite was lower than the m/z of ENR. Therefore, the MS/MS spectrum was analyzed to find which part of the parent compound had been modified. Figure 6A shows the MS/MS spectrum of ENR-1. It was concluded that the metabolite structure corresponded to

dx.doi.org/10.1021/jf405554z | J. Agric. Food Chem. 2014, 62, 2008−2021

CIP without a piperazine ring (Supporting Information). Only the amino group was maintained, as shown in Table 3.

In the MS/MS spectrum of metabolite ENR-2 with m/z 291.0783 (Figure 6B), the ion m/z 263.0834 (ENR-1), discussed in the Supporting Information and in Figure 6A, was observed. The difference between both ions corresponded to a carbonyl group (27.9949). The assigned structure for this metabolite is given in Table 3.

Another metabolite elucidated was m/z 307.1095 (ENR-4). Some explanations of the fragments are shown in Figure 6C and the Supporting Information. Its structure can be observed in Table 3.

The ion m/z 334.1189 (ENR-5) was identified as formyldesethylene-CIP.[25] Its structure was checked by its mass spectrum. The molecule was broken up from the piperazinyl ring, resulting in the ions m/z 72.0445 and 263.0834 cited before. Other important fragments were m/z 245.0730 [263.0834 − H_2O], 230.0489 [334.1189 − H_2O − cyclopropyl − formamide], and 217.0411 [230.0489 − CH].

A compound (ENR-9) with the same m/z as hydroxy-CIP (m/z 348.1354) (ENR-8) was also studied, because the retention time differed by about 4 min from the peak observed in spiked samples. The MS/MS spectrum (Figure 6D) was very similar to the spectrum of formyldesethylene-CIP (m/z 334.1189) (ENR-5). The most striking difference between both spectra was that instead of fragment m/z 72.0444 was observed a fragment of m/z 86.0601. This fragment corresponds to the addition of a methyl group to fragment m/z 72.0444. In conclusion, a structure of acetyldesethylene-CIP (ENR-9) is suggested, which could be formed from the oxidation of the side chain of desethylene-ENR (m/z 334.1561) (ENR-6).

The EIC of ion m/z 362.1137 (ENR-12 and ENR-13) from a full-scan of ToF was very similar to that obtained for the m/z 390.1460 (ENR-18 and ENR-19) in spiked samples with ENR (Figure 3). Three peaks were observed in the EIC. The first one was at 6.1 min, which coincides with the peak observed in samples fortified with CIP. Also were seen two peaks at 6.8 and 7.1 min, with the same shape as the two peaks at 7.6 and 7.99 in Figure 3. Unfortunately, when the sample was analyzed by LC-LTQ-Orbitrap, it was degraded and only one peak was observed and fragmented. In the MS/MS spectrum, the ions m/z 291.0776 and 259.0820 were present, as elucidated previously in Figure 3D. Another fragment that helped to determine the structure corresponded to m/z 72.0444, which is like fragment 100.0757 of metabolite 390.1460 without the alkyl chain of ENR. Due to the resemblances between the EICs and mass spectra of ions m/z 362.1137 (ENR-12 and ENR-13) and 390.1460 (ENR-18 and ENR-19), it can be assumed that these compounds are the same, but one is from CIP and the other from ENR, respectively.

The last two elucidated metabolites corresponded to oxo-CIP (m/z 346.1198) (ENR-7) and formyl-CIP (360.1354) (ENR-10), which have been described previously in the literature.[36,40] Their structures were confirmed by their MS/MS spectra.

The rest of the metabolites found in medicated cow's milk could not be elucidated. In any case, Table 3 shows their m/z, retention time (t_R), hypothetical molecular formula, DBE, and errors.

Correction to Induction of Phenolsulfotransferase Expression by Phenolic Acids in Human Hepatoma $HepG_2$ Cells

Chi-Tai Yeh, Shang-Ming Huang, and Gow-Chin Yen*

J. Agric. Food Chem. **2005**, *53* (12), 4766−4773. DOI: 10.1021/jf050388n

Due to an inadvertent error noted in Figure 5B, the GAPDH data have been corrected and updated, which does not affect the findings reported in our paper.

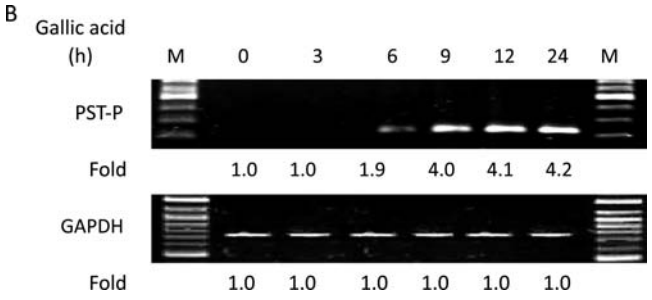

Figure 5. Induction of PST-P mRNA expression in $HepG_2$ cells by gallic acid. $HepG_2$ cells were exposed to the indicated concentrations of gallic acid for 24 h in a dose−response experiment (A) or to 50 μM gallic acid for 3−24 h in a time course experiment (B). Cellular RNA was extracted with an Invitrogen RNA isolation kit, and RT-PCR was performed as described under Materials and Methods. The RT-PCR products were separated on 1.8% agarose gel and digitally imaged after staining with ethidium bromide. GAPDH, the housekeeping gene, was used as an internal control. The results are presented as the ratios of PST-P mRNA in treated cells to those of control.

Experiments were conducted using a wetted-wall column to examine the partitioning of the nearly pure endosulfan isomers from water into air. When starting with β-endosulfan, α-endosulfan was virtually the only isomer observed in air phase.[14,15] In regional and long-range transport studies of endosulfan isomers in air, β-endosulfan was infrequently observed relative to α-endosulfan, so much so that it was disregarded in the data analyses.[16,17] The isomerization of β-endosulfan to α-endosulfan has been suggested as a possible reason for the observed overabundance of α-endosulfan in the atmosphere.[6,18] Finally, this isomerization has also been observed directly on surfaces.[19]

A mechanism for β-endosulfan conversion to α-endosulfan and its irreversibility have been proposed and has been supported with data from differential scanning calorimetry (DSC) and NMR experiments and from computational chemistry calculations.[18] DCS scans of pure α-endosulfan, pure β-endosulfan, and mixtures were acquired; temperatures ranged from 25 to 280 °C. Scans of mixtures showed a large phase transition not observed in either of the pure isomer scans, suggesting a new transition which we assigned to the isomerization process. Furthermore, analysis of the remaining material after the scans revealed a eutectic mixture of an approximately 60:40 mixture of the α:β isomers, again demonstrating conversion. No degradation other than isomeric conversion was observed. Using computational chemistry, a mechanism was proposed whereby movement of the S═O moiety followed pseudorotation of the seven-membered ring of β-endosulfan resulted in formation of α-endosulfan. Furthermore, we concluded that the increase in entropy caused by the asymmetry in α-endosulfan precluded the reverse process of α-endosulfan conversion to β-endosulfan.

The three mixtures of endosulfan (nearly pure α-endosulfan, nearly pure β-endosulfan, and mixtures) have identical chemical compositions, i.e., they differ only in spatial arrangement of the atoms, yet the phase transitions observed using DSC were markedly different in all three mixtures.[18,20] This indicates that the thermal energy is absorbed by different sets of atoms. In addition, DSC does not identify which part of the molecule or bond(s) absorb the thermal energy. Raman spectroscopy provides spectral evidence (frequency signals) identifying the sets of atoms or bonds which are affected by energy absorption. Using the technique of temperature-dependent Raman (TDR) spectroscopy recently developed in our laboratory, molecular sites which respond most strongly to the thermal temperature gradient can be identified. Frequencies which covary with intensity and/or wavenumber shift starting at a specific temperature can indicate the individual molecular site or molecular movement that triggers a reversible or irreversible transition event. From these data, the sequence of molecular movements absorbing a threshold amount of thermal energy can be organized to explain the mechanism of a transition event. The purpose of this article is to provide such evidence that, in concert with previous work, demonstrates the molecular level pathway through which phase transition events occur, particularly, the irreversible process of β-endosulfan converting to α-endosulfan.

MATERIALS AND METHODS

Materials. Certified analytical grade Thiodan (α:β-endosulfan 60:40), β-endosulfan (nearly 100%), and α-endosulfan (99.8% α; 0.2% β) were each obtained commercially from ChemServices (West Chester, PA) and used as is.

Temperature Dependent Raman Measurement System. A Raman spectroscopy system was assembled to collect temperature dependent Raman (TDR) spectra from the samples. A 16-bit CCD camera with 1024 × 256 pixels (Newton DU920N-BR-DD, Andor Technology, South Windsor, CT) was used to acquire Raman scattering signals. A Raman spectrometer (Raman Explorer 785, Headwall Photonics, Fitchburg, MA) was mounted to the camera. The spectrometer accepts light through an input slit (5 mm long × 100 μm wide) and detects a Raman shift range of 102.2−2538.1 cm^{-1} with a spectral resolution of 3.7 cm^{-1}. A 785 nm laser module (I0785MM0350MF-NL, Innovative Photonic Solutions, Monmouth Junction, NJ) served as the excitation source. A fiber optic Raman probe (RPB, InPhotonics, Norwood, MA) was used to focus the laser and acquire the Raman signals. A bifurcated fiber bundle was used to deliver the laser light to the probe and transfer the collected Raman signals to the spectrometer.

A hot plate with a ceramic top surface (Isotemp, Fisher Scientific, Hampton, NH) was used to heat the samples. The powder samples were put in a copper sample holder. Two thermocouple probes (type K) were attached to two sides of the sample area, and they were connected to a dual-input thermometer (EasyView EA15, Extech Instruments, Nashua, NH) to measure the temperature of the samples. Average values of the two probes were used as the sample temperature, and the data were transferred to a computer via a RS-232 port. A copper heat sink was placed between the ceramic heat surface and the sample holder to slow down the speed of the temperature increase. A relatively high temperature resolution was consequently achieved for the temperature-dependent Raman data. The Raman probe, the hot plate, and the sample materials were placed in a closed black box to avoid the influence of ambient light. System software was developed using LabVIEW (National Instruments, Austin, TX) to fulfill functions such as camera control, data acquisition, temperature measurement, and synchronization.[21] Each experiment was conducted in triplicate. Over 200 spectra of 1600 data points were collected for each experiment, resulting in a data set of approximately 10^6 data points.

RESULTS AND DISCUSSION

Raman Spectra Mode Assignments for Each Isomer. Endosulfan consists of two structural parts, a hexachlorinated norboryl moiety and a seven-membered, dioxathiepine-3-oxide ring system. The norbene portion is rigid, which is reflected in the absence of C−Cl Raman vibrational modes except for one signal at 374 cm^{-1}.[22] Vibrational frequencies characteristic of seven-membered ring structures, including cycloheptane and 1,3-dioxepane, have been identified.[21] The seven atoms of these simpler ring systems gave rise to eight ring-bending frequencies, four symmetrical and four asymmetrical. The seven-membered ring in the endosulfan isomers is a structural analogue of 1,3-dioxepane and, correspondingly, the same eight frequencies apply. For brevity, the same numbering of ring atoms in 1,3-dioxepane are used here: the ring oxygen atoms are atoms 1 and 3, sulfur is atom 2, the methylene carbons are C4 and C7, and the methine carbons are C5 and C6 (Figure 1).

The difference in the relative orientation of the axial hydrogens on the methylene carbons, C4 and C7, is responsible for the three discrete forms of endosulfan. In β-endosulfan, one hydrogen atom on each of the methylene carbons is axial above the seven-membered ring system, affording a symmetrical molecule in which $CHCH_2O$ on the right half of the ring is in the same conformation as the left half. This contrasts with the two α-endosulfans, where only one hydrogen atom is axial above the ring, not both, i.e., the axial hydrogen on the other methylene carbon is axial below the ring system. The right half of the ring system is not identical to the left half, giving rise to two asymmetrical enantiomers. As molecules which are direct

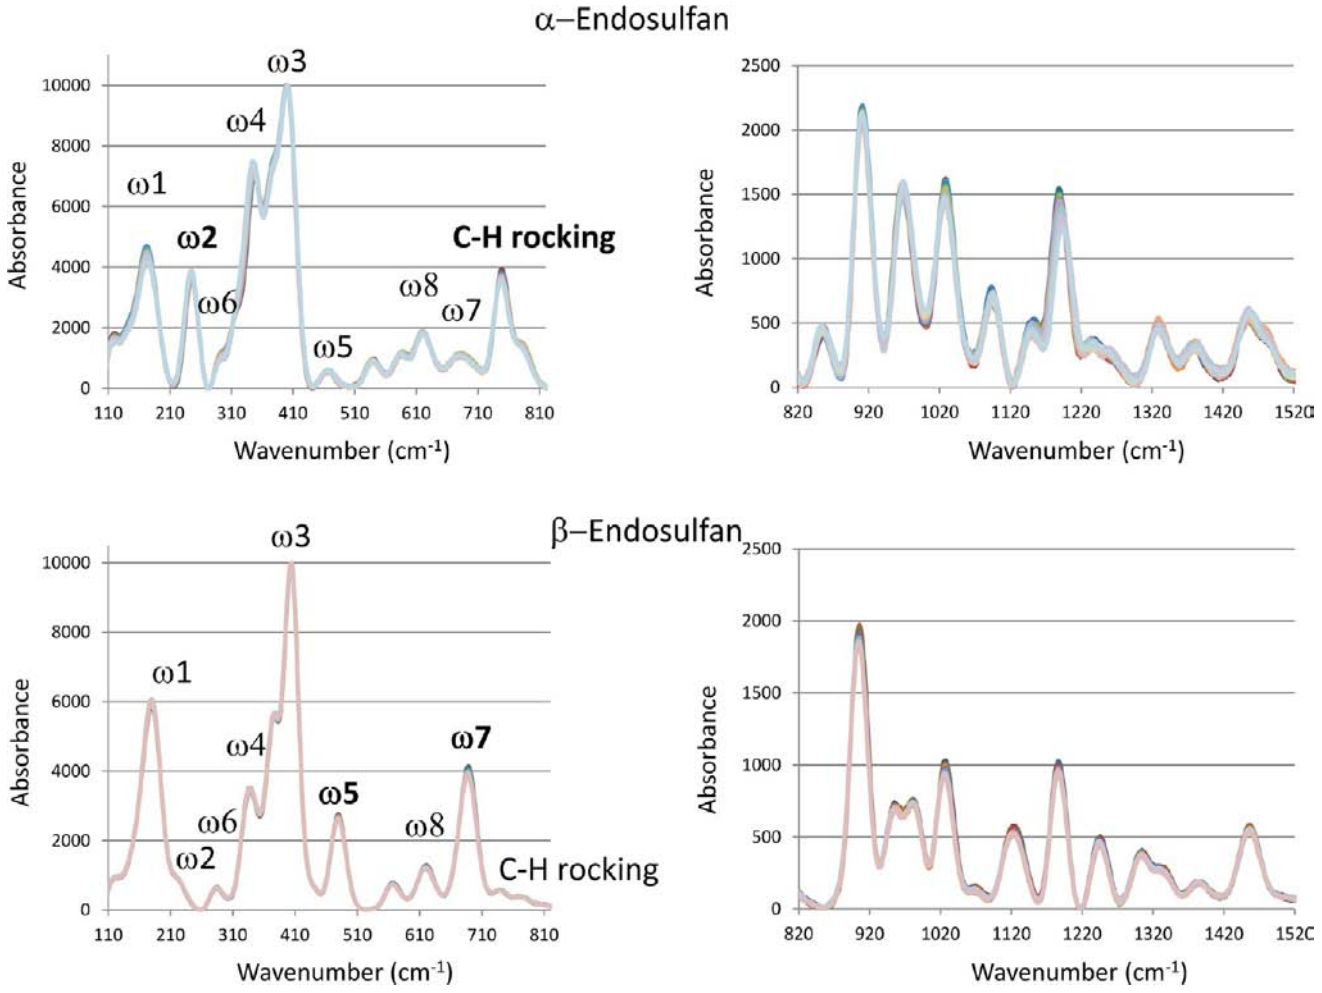

Figure 2. Raman spectra from 110 to 820 cm^{-1} and 820 to 1520 cm^{-1} acquired at 1 °C intervals from 50 to 102 °C for nearly pure α-endosulfan and for essentially pure β-endosulfan. Vibrational modes, ω1 through ω8 (Table 1), and C−H rocking, in the 110−820 cm^{-1} range are indentified. Relative intensities of each vibrational mode in the individual isomers were essentially temperature independent.

mirror images of each other, the two α-endosulfans will have identical Raman spectra.

Raman spectra were acquired at 1 °C intervals from 50 to 102 °C for nearly pure α-endosulfan and for essentially pure β-endosulfan; four major differences in the 110−810 cm^{-1} region were observed (Figure 2). Two major peaks were found in the α-endosulfan spectra at 229 cm^{-1} (ω2) and 748 cm^{-1} but were very weak in the spectra of β-endosulfan, whereas peaks seen in the β-endosulfan spectra at 460 cm^{-1} (ω5) and 686 cm^{-1} (ω7) were weak in the α-endosulfan spectra. Differences were also observed in the Raman fingerprint region, 820−1520 cm^{-1}. None of the peaks in the spectra of each nearly pure isomer showed a major change in intensity as a function of temperature.

From the work of Bocian and Strauss,[23] eight modes in the ring frequency region, 110−700 cm^{-1}, were assigned corresponding to the four symmetrical vibrational modes (ω1, ω3, ω5, and ω7) and to four asymmetrical vibrational modes (ω2, ω4, ω6, and ω8) (Table 1). Ring frequencies involve only the atoms in the ring, not the hydrogens bound to the carbons in the ring or the oxygen not part of the ring. Four of these vibrational modes represent changes in dipolar moment within the ring, that is, ω1, ω2, ω3, and ω4 correspond to changes in electron density among the ring atoms. Modes ω1 and ω3 represent symmetrical dipolar changes with respect to O−S−O, whereas modes ω2 and ω4 are asymmetrical. The asymmetrical dipolar moment ω2 is extremely weak in β-endosulfan. The other four vibrational modes correspond to ring-bending, ω5, ω6, ω7, and ω8. Modes ω5 and ω7 are symmetrical movements of the ring, and because α-endosulfan is asymmetrical, these modes are extremely weak. Asymmetrical ring-bending is depicted modes ω6 and ω8 and are weak peaks in the symmetrical β-endosulfan.

The modes observed in the fingerprint region of 720−1520 cm^{-1} correspond to the molecular vibrations of C−H. These movements include asymmetrical and symmetrical stretching, rocking, twisting, scissoring, and wagging. A peak at 748 cm^{-1} was observed in only α-endosulfan and corresponds to an asymmetrical C−H rocking movement. The remaining modes observed in the spectra of the pure isomers were difficult to assign unambiguously to specific atom vibrations.

Raman Spectra Mode Assignments for a 60:40 Mixture of α-Endosulfan:β-Endosulfan. Under similar gradient conditions for the individual isomers, Raman spectra were acquired at 1 °C intervals from 50 to 102 °C for a 60:40 mixture of α-endosulfan:β-endosulfan. The same eight ring vibrational modes, ω1−ω8, were observed in the 110−710 cm^{-1} range (Table 1; Figure 3). The peak which was only seen in the α-endosulfan spectra, 748 cm^{-1}, was also present in the

dx.doi.org/10.1021/jf404404w | J. Agric. Food Chem. 2014, 62, 2023−2030

Table 1. Assigned Vibrational Modes Observed in α-Endosulfan, β-Endosulfan, and a 60:40 Mixture α:β[a]

Vibrational Modes	Symmetry [1]	α-Endosulfan [2] (cm^{-1})	β-Endosulfan [2] (cm^{-1})	Mixture [2,3] (cm^{-1})
Dipolar Moment				
ω1	S	169 s	177 s	174 - 180 s
ω3	S	396 vs	401 vs	401 s
ω2	A	240 s	223 vw	234 - 249 s
ω4	A	339 vs	337 s	342 - 345 s
Ring Movement				
 ω5	S	460 w	476 s	476 s
 ω7	S	678 vw	686 s	683-689 s
 ω6	A	289 w	281 w	289 w
 ω8	A	616 w	619 w	619 s

[a]Assignments were made using the vibrational modes observed in the structural analogue, 1,3-dioxepane.[23]. [1]A = asymmetrical, S = symmetrical. [2]vs = very strong, s = strong, w = weak, vw = very weak. [3]60:40 mixture of α-endosulfan:β-endosulfan.

mixture, as well as the peak corresponding to C−Cl vibration at 378 cm^{-1}. The intensity of these modes remained essentially unchanged as a function of temperature until 88 °C, after which some temperature dependence in some peaks was observed. Peaks corresponding to ω2 and ω8 increased by approximately 10%, while the peak intensity of ω1 decreased by 26%. Two additional small peaks which displayed some temperature dependence were observed at 542 and 590 cm^{-1} but were not assigned.

In the more flexible fingerprint of 720−1520 cm^{-1}, temperature dependency was much more dramatic (Figure 3). Below 97 °C, temperature had little effect on peak intensity, however, above 97 °C, intensity of several modes increased substantially, indicating that these sites in the molecules of one or both isomers were more flexible and therefore absorbed the increased thermal energy. Using the assignments of Bocian and Strauss,[23] Anconi et al.,[24] and Artur et al.,[25] the vibrational modes were identified, however, these peaks cannot be assigned definitively to one or both isomers. The intensity of the peaks at 907 cm^{-1} (C−H rocking) increased by 12%, at 968 cm^{-1} (ring expansion and C−H rocking) increased by 70%, and at 1028 cm^{-1} (ring expansion and bending) increased by 35%. Larger peak intensity increases of 140% and 200% were observed at 1092 cm^{-1} (ring expansion and mixed C−H motions) and 1350 cm^{-1} (C−H wagging and twisting), respectively.

These observations indicate that the nonuniform molecular surroundings of the mixture allow for temperature dependent changes in the intensity of vibrational movements which are not observed in the pure isomers. Furthermore, the nonuniform molecular surroundings allow for the intensity of asymmetrical ring frequencies to increase and, correspondingly, the symmetrical ring frequencies to decrease in intensity. At temperatures at 150 °C and above, pure β-endosulfan begins to exhibit isomerization as a result of formation of a nonuniform molecular environment caused by the changes in the lattice structure (phase change) of the pure compound.[18]

Contour Plots of TDR Spectra. Contour plots of temperature as a function of frequency (wavenumber) and spectral density were developed for the Raman spectral data of the 60:40 mixture and are shown over the temperature range of 88−102 °C and for the wavenumbers of 110−1500 cm^{-1} (Figure 4). These plots provide a more facile visualization of the data and enable identification of concurrent changes in frequency and intensity within the temperature gradient. If the frequency of a specific peak changes with increasing temperature, the slope of the line band will change, and if no changes occur in the frequency, the band will appear vertical in the plot. Spectral density (peak intensity) is represented by color change moving from cool colors (blue to green) to warmer colors (yellow to orange to red) as intensity increases. Over this temperature range, several vibrational modes were essentially temperature independent, ω3, ω4, ω7, and C−H rocking at 748 cm^{-1}.

For all the remaining modes, discrete temperature dependent changes occurred above 97 °C. Slight intensity increases, peak broadening, and peak shifting were observed for ω2, ω8, and C−H rocking at 907 cm^{-1}, while the peak at ω1 narrowed and decreased in intensity somewhat. The most dramatic changes occurred at 970, 1027, 1092, and 1350 cm^{-1}, where spectral density increased, peaks shifted, and peaks broaden substantially as the temperature increased. The response of these four vibrational modes indicate that these molecular sites are the most sensitive to the temperature (i.e., absorption of thermal energy) and are, therefore, the most flexible.

Correlating TDR Observations with Phase Transition Data. DSC is used to measure thermal absorption based upon aggregates of molecules, or macroscopic properties, such as melting, boiling, and sublimation, changes in crystal lattice structure, or isomerization. In contrast, Raman spectroscopic data provide information about molecular changes that take place at specific molecular sites and may or may not be involved in molecular aggregation/macroscopic changes. While TDR and DSC do not necessarily measure the same physical phenomenon, when the temperature dependence over a specific temperature gradient between the two does correlate, the macroscopic and molecular properties presumably overlap.

DSC data were collected over a temperature range of 50.0−110 °C and have been presented elsewhere.[20] A phase transition for α-endosulfan was observed at 90−96 °C with a maximum at 93 °C, whereas, for β-endosulfan, a phase transition was seen at 97−102 °C. A much broader range in the phase transition temperature occurred in a 60:40 mixture of α-endosulfan:β-endosulfan beginning at 80 °C and ending at 104 °C, with a maximum at 94 °C. The DSC results identify the discretely different temperature ranges over which thermal absorption of the individual endosulfan isomers occurs. The phase transition seen at 97−102 °C for β-endosulfan corresponds to the largest spectral differences in the TDR spectra. Therefore, the observed temperature-dependent

dx.doi.org/10.1021/jf404404w | J. Agric. Food Chem. 2014, 62, 2023−2030

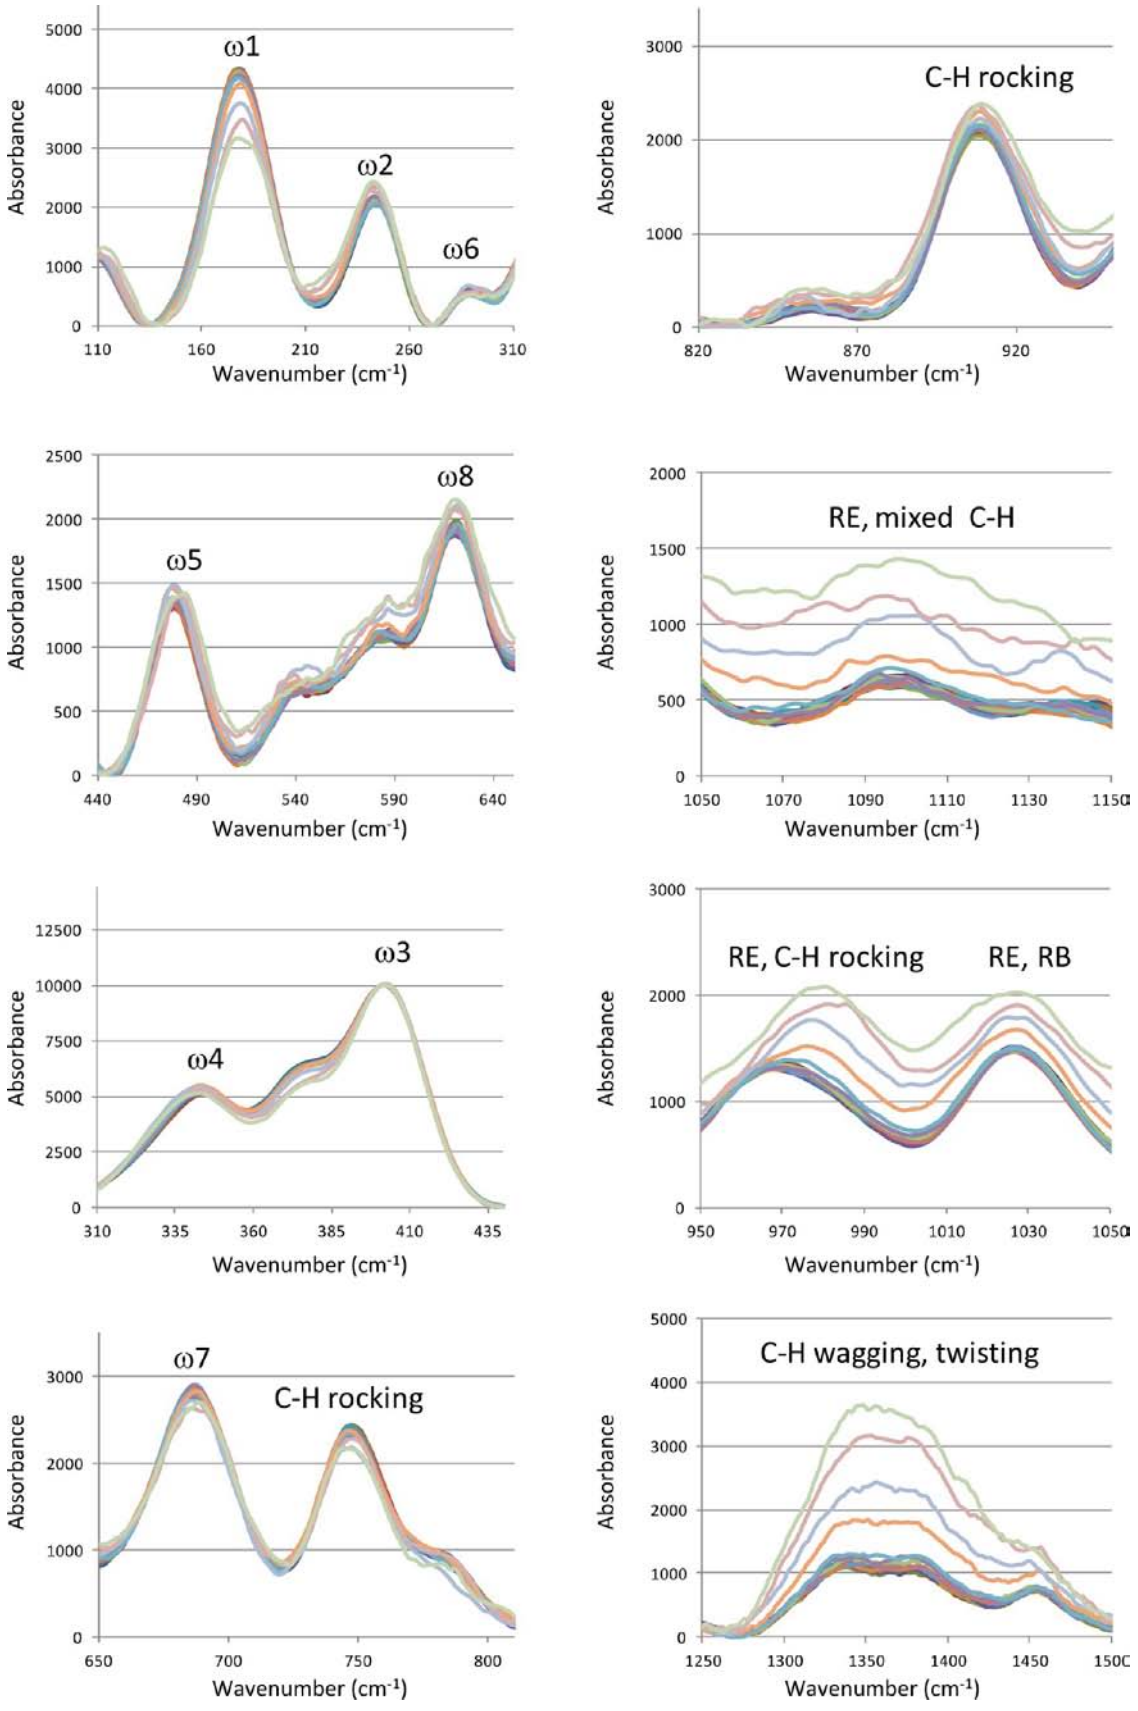

Figure 3. Raman spectra from 110 to 1520 cm^{-1} acquired at 1 °C intervals from 50 to 102 °C for a mixture of 60:40 α-endosulfan:β-endosulfan; each line represents a spectrum at an individual temperature. Vibrational modes are identified: ω1 through ω8 (Table 1), C−H rocking, wagging, and twisting, ring expansion (RE), and ring bending (RB). Relative intensities of each vibrational mode were essentially temperature independent until 97 °C. Noticeable temperature dependence was observed for vibrational modes at 177, 970, 1027, 1092, and 1350 cm^{-1}.

dx.doi.org/10.1021/jf404404w | J. Agric. Food Chem. 2014, 62, 2023−2030

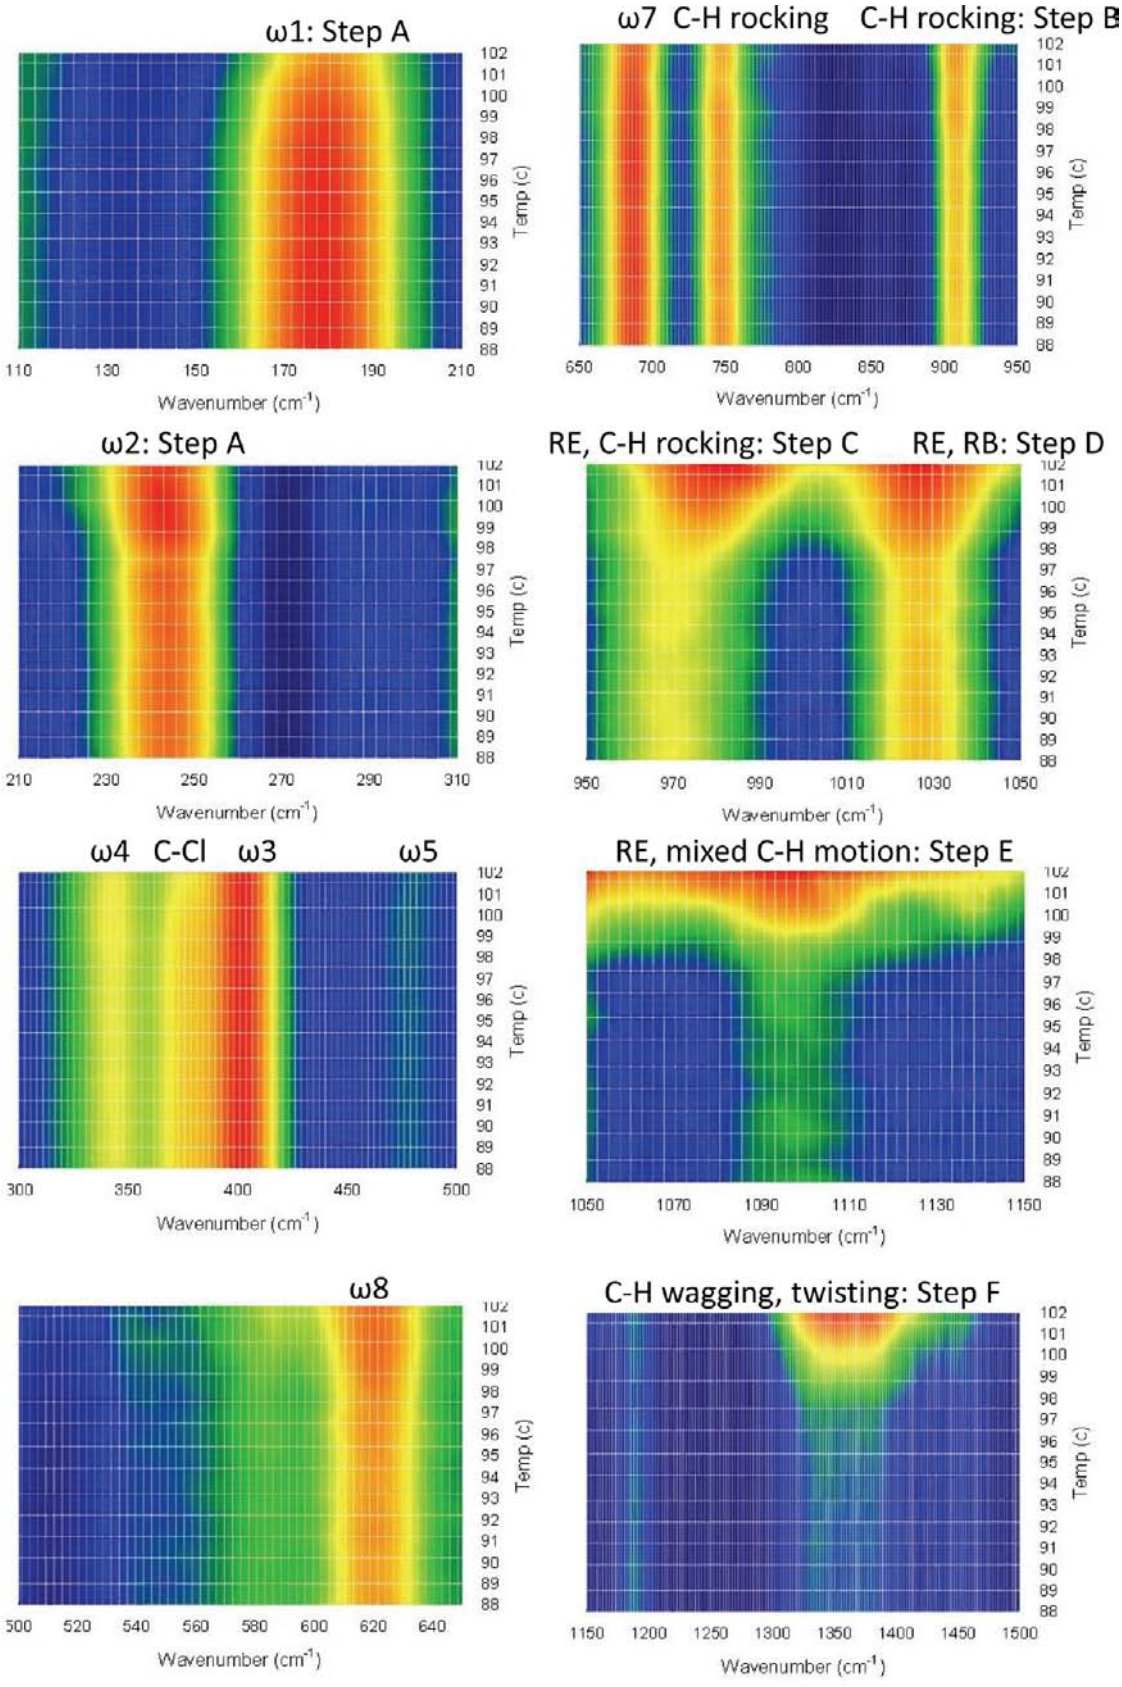

Figure 4. Contour plot of temperature as a function of frequency (wavenumber) and spectral density for the Raman spectral data of a 60:40 mixture of α-endosulfan:β-endosulfan over the temperature range of 88−102 °C and for the wavenumbers of 110−1500 cm^{-1}. Spectral density (peak intensity) is represented by color change moving from cool colors (blue to green) to warmer colors (yellow to orange to red) as intensity increases. Vibrational modes are identified as well as the mechanistic steps A−F of β-endosulfan isomerization to α-endosulfan.

dx.doi.org/10.1021/jf404404w | J. Agric. Food Chem. 2014, 62, 2023−2030

Raman spectral changes are due to changes in β-endosulfan not α-endosulfan.

Mechanism for Isomerization of β-Endosulfan to α-Endosulfan. Using the identified vibrational modes and the temperature dependence data, the mechanism for β-endosulfan isomerization to α-endosulfan becomes readily apparent (Figure 5). At 97 °C, the asymmetrical electron density

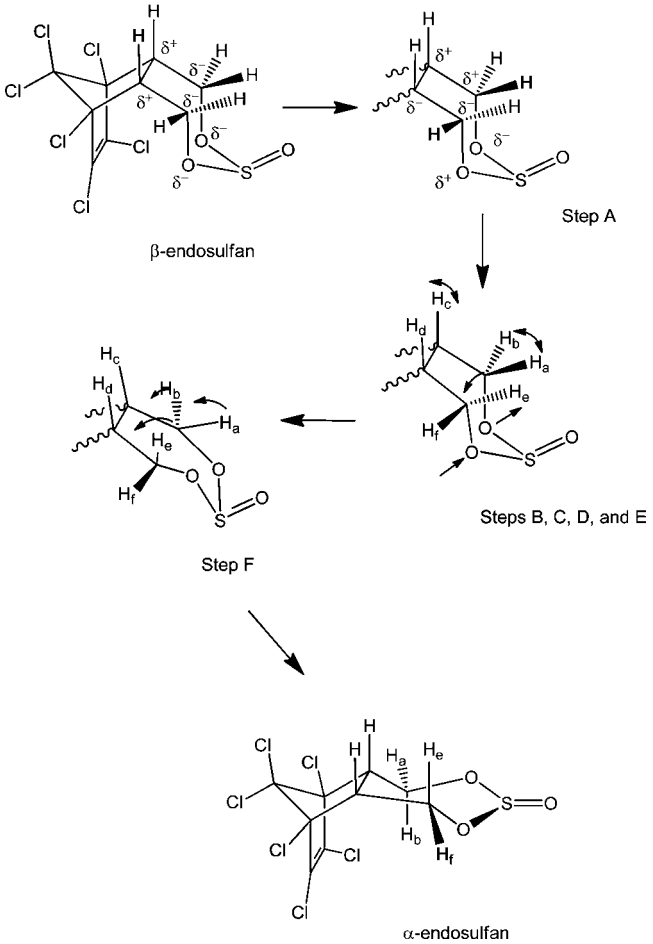

Figure 5. Mechanism steps A–F of β-endosulfan isomerization to α-endosulfan.

distribution in the seven-membered ring, ω2, begins to increase, and a corresponding decrease in the symmetrical electron density distribution, ω1, is observed (step A). Concurrently, the C–H rocking of the methylene carbons at 908 cm^{-1} increases (step B), followed by additional increases vibrational modes in C–H rocking and ring expansion at 970 cm^{-1} (step C) and ring expansion and ring bending at 1028 cm^{-1} (step D). At 99 °C, ring expansion and mixed C–H motions vibrational modes at 1092 cm^{-1} broaden substantially (step E). The final C–H wagging and twisting at 1350 cm^{-1} causes the methylene carbon to "flip", affording α-endosulfan (step F). From these data, we conclude that the reverse process of α-endosulfan isomerization to β-endosulfan is precluded.

This mechanism provides a rationale for the lack of changes in the TDR of nearly pure β-endosulfan. In the symmetrical crystal lattice of solid β-endosulfan, the symmetrical vibrational modes ω1 and ω3 are most dominant, while the asymmetrical vibrational mode ω2 is very weak (Table 1). An asymmetrical molecular surrounding appears to be critical to isomerization of β-endosulfan, as is the case in the mixture of α-endosulfan and β-endosulfan.

Relevance to the Environmental Fate of Endosulfan. In the environment, α- and β-endosulfan do not exist as pure compounds and β-endosulfan is not bound by the crystal lattice structure which inhibits isomerization. Therefore, with sufficient energy applied, isomerization of β- to α-endosulfan can occur in environmental matrices. Results presented here including the combination of DSC and TDR indicate that isomerization from α- to β-endosulfan does not occur and this process should not be observed in the environment. However, two publications have provided evidence of isomerization from α- to β-endosulfan under environmentally relevant conditions.[26,27]

The first publication describes application of individual isomers to field plots of a chickpead crop (three plots per isomer).[26] Leaf samples were collected just after application and periodically over a 15 day period. The specific purity of the solution was not reported, only that "pure" β-endosulfan was used. In the α-endosulfan-applied plots, after 7 days, 83% dissipation of α-endosulfan was observed and 2% β-endosulfan and 17% endosulfan sulfate was detected. In the β-endosulfan-applied plots, after 7 days 52% dissipation of β-endosulfan was observed and 8% α-endosulfan and 42% endosulfan sulfate was detected. The small contribution from β-endosulfan in the α-endosulfan applied plots was likely due to impurities in the original solution. Commercially available standards of endosulfan isomers are rarely 100% pure and typically contain traces of the other isomer. Because the specific purities of the starting solutions were not reported and a complete mass balance was not obtained, conclusions regarding isomerization cannot be confirmed.

The second publication[27] examined the fate of endosulfan and the formation of degradation products in estuarine mesocosms. Mesocosms were spiked separately with α-endosulfan, β-endosulfan, or the technical mixture of 70:30 α- to β-endosulfan. The purity of the single isomer standards is listed as 99.99% as determined by gas chromatography electron capture detection. Water samples were collected over a 100 h period and analyzed for both isomers and degradation products. For the β-endosulfan applied mesocosm, loss was listed as 96.9 ± 0.3%, with approximately 84% mass recovered. The authors list 2.1 ± 0.1% α-endosulfan detected. In the α-endosulfan applied mesocosm, the loss of α-endosulfan was listed as 93.6 ± 0.4%, with approximately 60% mass recovered. The percentage of β-endosulfan detected was 0.7 ± 0.1%. The percentage of β-endosulfan detected in the α-endosulfan-applied mesocosm was less than 1% and could be attributed to contamination in the original spiking material when taking into account the typical level of variability in gas chromatography–mass spectrometry analysis.

The only other published paper that has reported isomerization of α- to β-endosulfan is Guerrini et al.[28] The authors utilized surface-enhanced Raman scattering (SERS) to analyze the two isomers in their pure form as solids and then α-endosulfan as complexed with charged Ag nanoparticles coated with an organic compound (bis-acridinium lucigenin). Isomerization of α- to β-endosulfan was reported based on comparison of SERS spectral data. The SERS spectral data for the complexed α-endosulfan is reported to indicate weakening of bands associated with α-endosulfan and intensification of bands associated with β-endosulfan. However, background interferences from the bis-acridinium lucigenin coating were subtracted

from the spectra of the nanoparticle complexes, leading to a negative peak in a critical region of the spectra. No other confirmatory data concerning presence of β-endosulfan were discussed. Therefore, α- to β-endosulfan isomerization cannot be conclusively identified.
