Q and Q3G Treatment In Vitro Effects on Mouse Peritoneal Macrophage Cell Viabilities. To avoid excessive cytotoxicity at high concentrations or doses, Q (at the indicated final concentrations of 0.4, 4.0, 20, 50, and 100 μM) or Q3G (at the indicated final concentrations of 0.4, 0.8, 4.0, 20, 50, and 100 μM) treatments were first selected to assess their effects on primary peritoneal macrophage cell viabilities. The remaining cell viability was determined using the MTT assay showing that either Q or Q3G treatments at concentrations lower than 50 μM did not produce cytotoxic effects on the macrophages (Figure 2). Therefore, appropriate concentrations of Q or Q3G

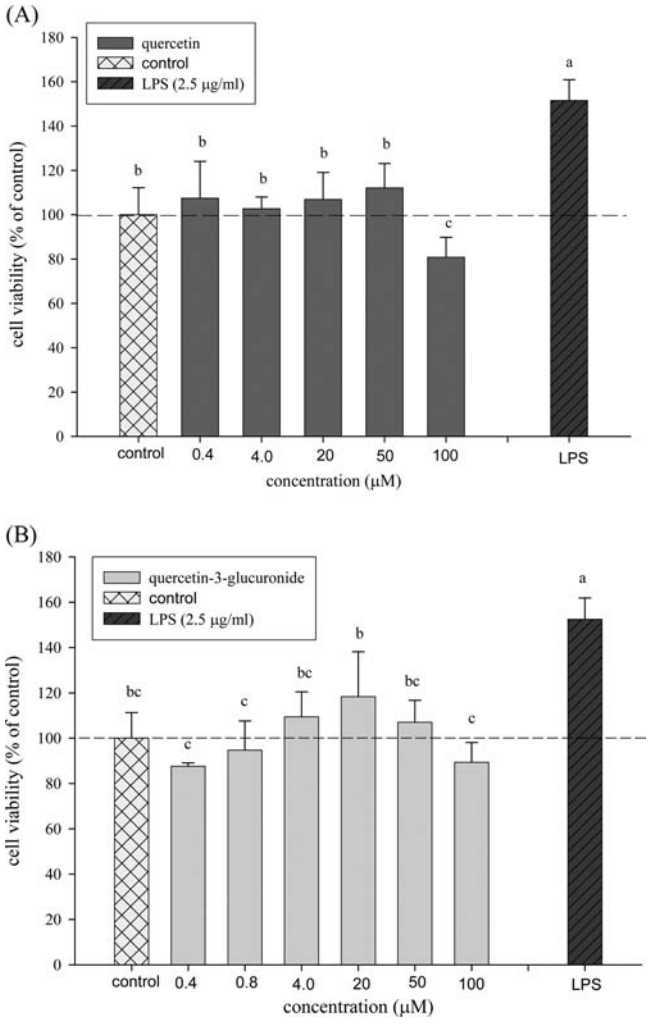

Figure 2. Effects of quercetin (A) and quercetin-3-glucuronide (B) administration in vitro on cell viabilities of primary peritoneal macrophages from female BALB/c mice. Values are means ± SD (n = 3 biological determinations), analyzed using one-way ANOVA, followed by Duncan's new multiple range test. Bars not sharing a common small letter are significantly different ($P < 0.05$) from each other. Lipopolysaccharide (LPS, 2.5 μg/mL) was selected as a positive control. Cell viability (% of control) = $[(A_{sample} - A_{sample\ blank})/(A_{control} - A_{blank})] \times 100$.

[a]Values are means ± SD (n = 4 biological determinations), analyzed using one-way ANOVA, followed by Duncan's new multiple range test. [b]Values within same row not sharing a common capital letter are significantly different (P < 0.05) from each other. [c]Asterisk (*) within same cytokine item means significantly different (P < 0.05) from TCM medium alone in the absence of quercetin treatment. [d]The original cell density was 1×10^6 cells/mL. [e]The sensitivity of the ELISA kits used in this study was <15.6 pg/mL. [f]Lipopolysaccharide (LPS, 25 μg/mL) was selected to induce inflammation in vitro. [g]Dexamethasone (Dex) was administrated i.p. to serve as a positive control.

at the indicated concentrations of 0.4, 0.8, 4.0, 20, and 50 μM were adopted to treat inflamed macrophages (1×10^6 cells/mL) in vitro. However, to avoid excessive high doses in vivo, medium noncytotoxic concentrations of Q or Q3G at 25 and 10 μM based on this in vitro study were selected to conduct the in vivo antiinflammation assessments. We presumed that there are a total of 6×10^6 peritoneal macrophages in a 20 g normal mouse according to our previous studies, reflecting the corresponding Q or Q3G doses were 0.15 and 0.06 μmol/mouse, respectively.

Q and Q3G Administration Effects on Cytokine Secretions Using LPS-Stimulated Macrophages in a Prophylactic Ex Vivo Model. To unravel the Q and Q3G administration effects on pro-/antiinflammatory cytokine secretions using LPS-stimulated macrophages in a prophylactic ex vivo model, Q or Q3G (both at 0.06 and 0.15 μmol/mouse) were administered i.p. to female BALB/c mice, respectively. The negative control animals received the same volume of PBS, and the positive control animals received the same volume of Dex (0.03 μmol/mouse). At 12 h after Q, Q3G, PBS, or Dex injection, all experimental animals were sacrificed to collect peritoneal macrophages. The peritoneal macrophages were cultured for 48 h in the absence or presence of LPS. Table 1 shows the intraperitoneal injection effects with Q in a prophylactic ex vivo model on cytokine secretions by LPS-stimulated peritoneal macrophages from female BALB/c mice.

Table 3. Effects of Quercetin in a Therapeutic Ex Vivo Model on Cytokine Secretions by Normal or Inflamed Peritoneal Macrophages from Female BALB/c Mice Intraperitoneally Injected with Phosphate-Buffered Saline or 8 mg/kg BW Lipopolysaccharide for 12 h[a,b,c]

dx.doi.org/10.1021/jf405630h | J. Agric. Food Chem. 2014, 62, 2872−2880

The results showed that LPS stimulation in vitro significantly ($P < 0.05$) increased TNF-α, IL-1β, IL-6, and IL-10 secretions by peritoneal macrophages compared with those stimulated by TCM medium alone. Quercetin administration in vivo significantly ($P < 0.05$) decreased IL-10 (an antiinflammatory cytokine) secretions, but increased TNF-α/IL-10, IL-1β/IL-10, and IL-6/IL-10 (pro-/antiinflammatory cytokines) secretion ratios by the macrophages in dose-dependent manners in the absence or presence of LPS in vitro. Our results indicated that quercetin administration in a prophylactic ex vivo model might activate macrophages but enhance inflammation in the macrophages in the absence or presence of LPS. It was found that Dex treatment i.p. could effectively inhibit LPS-induced systemic inflammation in mice.[28] However, we found that Dex treatment in this prophylactic ex vivo model did not significantly ($P > 0.05$) affect TNF-α, IL-1β, IL-6, and IL-10 secretions by peritoneal macrophages in the absence or presence of LPS. Our results further suggested that Dex treatment for antiinflammation might not have a prophylactic effect.

Table 2 shows the intraperitoneal injection effects with Q3G in a prophylactic ex vivo model on cytokine secretions by LPS-stimulated peritoneal macrophages from female BALB/c mice. The results showed that Q3G administration in vivo did not significantly ($P > 0.05$) affect TNF-α, IL-1β, IL-6, and IL-10 secretions by peritoneal macrophages in the absence or presence of LPS. However, Q3G administration in vivo at 0.06 μmol/mouse significantly ($P < 0.05$) increased TNF-α/IL-10, IL-1β/IL-10, and IL-6/IL-10 (pro-/antiinflammatory cytokines) secretion ratios by the macrophages in the presence of LPS in vitro. Our results indicated that Q3G administration in a prophylactic ex vivo model slightly enhanced inflammation in macrophages in the presence of LPS.

In comparison with Q, Q3G, and Dex administration effects on LPS-stimulated inflammation using mouse peritoneal macrophages in the prophylactic ex vivo model, we found that Dex did not have a prophylactic effect on LPS-induced inflammation (Tables 1 and 2). Dex, a glucocorticoid, is widely used to treat many inflammatory and autoimmune diseases, including rheumatoid arthritis, bronchospasm, and idiopathic thrombocytopenic purpura. Importantly, our results indicated that Dex administration did not exert a prophylactic effect on LPS-induced inflammation. However, Dex treatment may still have therapeutic (curative) effects on inflammatory diseases.[29] In contrast to Dex administration effects, our results indicated that Q and Q3G administration, particularly Q, in a prophylactic ex vivo model might activate macrophages but enhance inflammation (Tables 1 and 2). Quercetin is found to have diverse physiological effects, such as antioxidant and antiinflammatory effects in different tissues.[30,31] Our results further suggest that Q treatment in a prophylactic manner might have an immuno-stimulatory effect on macrophages. Quercetin-3-glucuronide that is a major quercetin metabolite was also found to have antioxidant functions in vitro and to regulate coronary venular barrier function through improving blood-borne inflammatory mediators and pharmacological tools in a novel microvascular wall model.[22] Q3G was found in this study to have less effective immunostimulatory functions on macrophages than quercetin in a prophylactic ex vivo model. We hypothesized that a glycoside in Q3G might enhance its water solubility in blood but might disturb its uptake by macrophages in vivo.[32] Most recently, we proved that quercetin uptake improved metabolism in mouse primary immune cells, including macrophages and splenocytes (data not shown); however, the immunostimulatory mechanisms of Q and Q3G on macrophages in a prophylactic ex vivo model remain to be further studied.

Q and Q3G Administration Effects on Cytokine Secretions Using LPS-Induced Inflamed Macrophages in a Therapeutic Ex Vivo Model. We assumed that Q and Q3G administration might have therapeutic or curative potential against normal or inflamed macrophages through regulating pro- and antiinflammatory cytokine secretion profiles. Normal or inflamed peritoneal macrophages were obtained from female BALB/c mice intraperitoneally injected with PBS or 8 mg/kg BW LPS for 12 h, respectively. To unravel the Q and Q3G administration effects on in vitro on pro-/antiinflammatory cytokine secretions, Q or Q3G at the indicated noncytotoxic concentrations (0, 0.4, 0.8, 4, 20, and 50 μM) were added to normal or inflamed peritoneal macrophage cultures for 48 h. Table 3 shows the quercetin administration effects in a therapeutic ex vivo model on cytokine secretions using normal or inflamed peritoneal macrophages from female BALB/c mice intraperitoneally injected with PBS or LPS for 12 h. The results showed that quercetin treatments at >20 μM in vitro significantly ($P < 0.05$) decreased TNF-α, IL-6 (proinflammatory cytokines) or IL-10 (antiinflammatory cytokine) secretions as well as TNF-α/IL-10 and IL-6/IL-10 (pro-/antiinflammatory cytokines) secretion ratios by normal or inflamed macrophages. Our results indicated that Q exerted antiinflammatory effects on normal or inflamed macrophages through decreasing pro-/antiinflammatory cytokine secretion ratios.

In addition, Q might have a therapeutic effect on spontaneous or LPS-induced inflammation in vivo. Dex (1 μM) was also selected as a positive control in this therapeutic ex vivo model. Importantly, Dex treatment in vitro significantly ($P < 0.05$) decreased TNF-α, IL-1β, IL-6 (proinflammatory cytokines) and IL-10 (antiinflammatory cytokine) secretions as well as TNF-α/IL-10 and IL-6/IL-10 (pro-/antiinflammatory cytokines) secretion ratios by normal or inflamed macrophages. Our results indicated that Dex exerted strong antiinflammatory or immunosuppressive effects on normal or inflamed macrophages, evidencing that Dex has a therapeutic effect on spontaneous or LPS-induced inflammation in vivo (Table 3). Our results have proven that Dex administration exerted a therapeutic but not prophylactic effect on inflammation (Tables 1 and 3). Dex was found to have antiinflammatory and immunosuppressive functions to inhibit LPS-induced inflammation in J774 macrophages at 0.1−10 μM in vitro.[27] The results from this study are identical to previous published reports.[29]

Table 4 shows Q3G administration effects in a therapeutic ex vivo model on cytokine secretions by normal or inflamed peritoneal macrophages from female BALB/c mice intraperitoneally injected with PBS or LPS for 12 h. The results showed that Q3G treatment in vitro significantly ($P < 0.05$) decreased IL-1β (proinflammatory cytokine) and IL-10 (antiinflammatory cytokine) secretions by normal or inflamed macrophages. However, Q3G treatment at 50 μM significantly ($P < 0.05$) increased the TNF-α/IL-10 (pro-/antiinflammatory cytokines) secretion ratio by normal macrophages, suggesting that Q3G had less therapeutic effects on inflammation. In contrast, the presence of high concentrations of Q3G might enhance spontaneous inflammation. Conjugated quercetin glucuronides were suggested to be bioactive metabolites and

precursors of aglycone in vivo. The cardiovascular and central nervous system seemed to be the major targets of the conjugated quercetin glucuronides circulating in the human bloodstream.[33] However, it was found that Q3G treatment could not mediate TNF-α, IL-1β, and IL-6 mRNA expression levels in LPS-stimualted RAW264.7 cells, suggesting that Q3G had less antiinflammatory potential than Q.[34] Importantly, our results evidenced that Q3G had less therapeutic effects on LPS-induced inflammation than Q using an ex vivo model.

IL-10 is produced in late stage inflammation by immune effector cells to inhibit the synthesis of other cytokines; therefore, IL-10 has been recognized as an antiinflammatory cytokine.[20] In contrast to antiinflammatory cytokines, proinflammatory cytokines, such as IL-1β, IL-6, and TNF-α, present their maximum secretion at 12−48 h, when inflammation starts.[35,36] Undoubtedly, cytokine secretion profiles can reflect the status of inflammatory cells. This study established both prophylactic and therapeutic ex vivo models to verify the antiinflammatory potential of Q and Q3G using mouse primary macrophages in the absence or presence of LPS. Our results indicated that these prophylactic and therapeutic ex vivo models were suitable for evaluating the antiinflammatory potential of Q and Q3G and suggesting appropriate concentrations or doses of Q and Q3G administered in vitro and in vivo.

Quercetin is a flavonoid and phenolic compound that has been an interesting resource from functional food products and other foods targeted for reducing age-related macular degeneration risk.[37] We found that quercetin exists in different fruit juices and might have the ability to regulate Th1/Th2 and pro-/antiinflammatory cytokine secretion profiles in splenocytes.[38] It was suggested that particularly efficient compounds found among polyphenol-rich extracts should be carefully considered for medicinal and other applications.[39] We have evidenced that quercetin might be ingested in vitro, although a small quantity metabolized by immune cells, indicating that certain flavonoid compounds may exert their effects via directly entering cells (data not shown). We further proved that quercetin, but not its metabolite Q3G, exerted antiinflammatory effects in a therapeutic manner; however, there is a limitation to this ex vivo study. We assumed that the absorption rate of Q, Q3G, and Dex by macrophages might be low in this acute experimental model. Q, Q3G, and Dex were administered i.p. for only 12 h in the present study; therefore, it is too soon to conclude that those drugs had no prophylactic effects against inflammation. Studies targeting oral administration of Q for alleviating chronic inflammation and confirming a therapeutic effect in an in vivo model should be performed in the future. Importantly, we found an antiinflammatory signal pathway effect of Q at the molecular level. Q exerted antiinflammatory effects through modulating Toll-like receptor (TLR)2 and Janus kinase 2/signal transducers and activators of transcription 3 (JAK2/STAT3) pathways and inhibiting STAT3 tyrosine 705 phosphorylation within inflamed cells (data not shown).

This study isolated primary peritoneal macrophages in the absence or presence of LPS from female BALB/c mice to evaluate Q and Q3G antiinflammatory potential using both prophylactic and therapeutic ex vivo models. The results showed that either Q or Q3G treatments lower than 50 μM did not produce in vitro cytotoxic effects on the macrophages. Noncytotoxic concentrations or doses of Q and Q3G were adopted to evaluate their antiinflammatory potential. The results showed that Q or Q3G administration in a prophylactic ex vivo model might activate macrophages but enhance inflammation status in the absence or presence of LPS. However, Q3G was found to have fewer immunostimulatory functions on macrophages. Quercetin and Dex exerted antiinflammatory effects on normal or inflamed macrophages, suggesting that Q and Dex, but not Q3G, might have a therapeutic effect on spontaneous or LPS-induced inflammation ex vivo. Overall, Q and Q3G administrations in a prophylactic manner might act as an immunostimulatory agent, but Q exhibited better ability than its metabolite Q3G. In addition, both Q and Dex might have a therapeutic, but not prophylactic, effect on spontaneous or LPS-induced inflammation ex vivo.

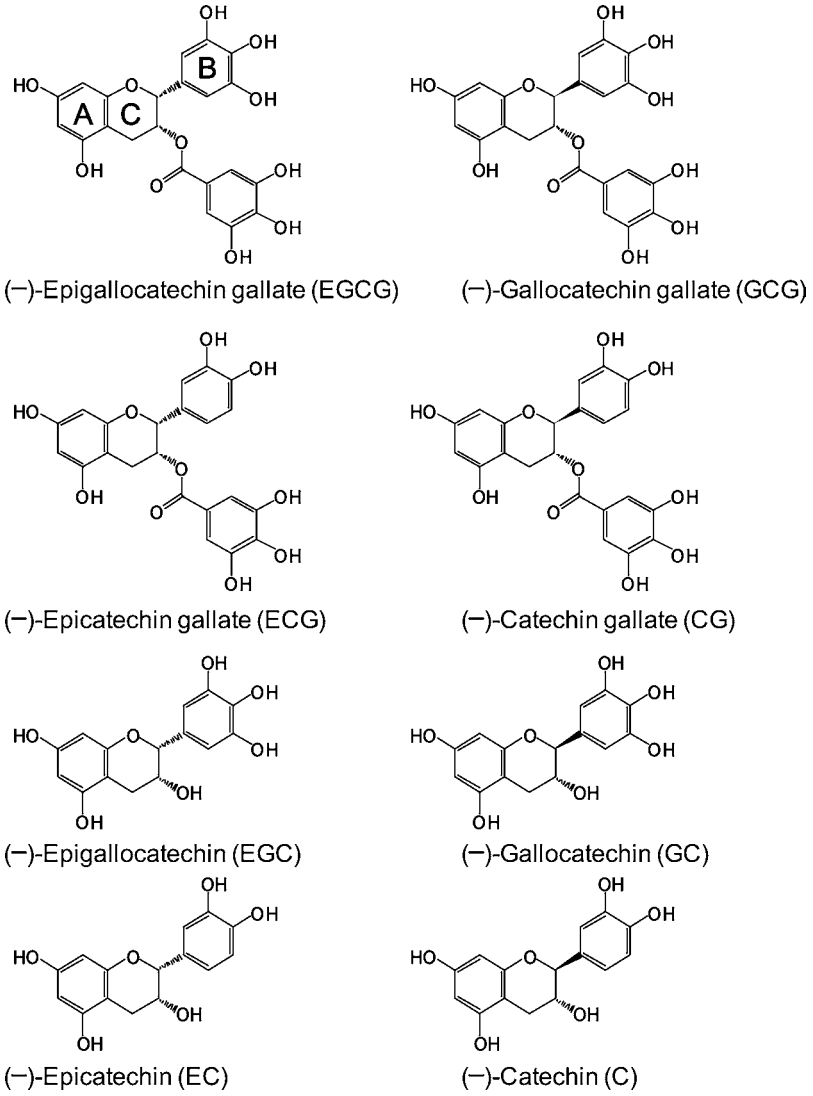

Figure 1. Chemical structures of various green tea catechins and heat-epimerized tea catechins: (left) green tea catechins; (right) heat-epimerized tea catechins.

is also a hydrophobic molecule. However, we provided direct experimental evidence that the EGCG molecule interacts with a lipid bilayer containing dimyristoylphosphatidylcholine by solid-state ^{31}P and ^{2}H nuclear magnetic resonance (NMR).[28] We also showed that ECG and EGCG interact with the surface of lipid membranes through the trimethylammonium group in phosphatidylcholine (PC) by using solution NMR techniques.[29] Therefore, it is possible that the interaction between green tea catechins with a galloyl moiety and phosphatidylcholine leads to the precipitation of micellar cholesterol and, as a result, the micellar solubility of cholesterol is decreased. In this study, the mechanisms underlying the EGCG-mediated decrease in the micellar solubility of cholesterol were examined.

MATERIALS AND METHODS

The purified catechins, EGCG, GCG, ECG, CG, EGC, GC, EC, and C, were purchased from Wako Pure Chemicals (Osaka, Japan). The purity of all catechins was confirmed to be >98% by NMR analysis. PC from egg yolk, phosphatidic acid (PA) from egg yolk, phosphatidylethanolamine (PE) from egg yolk, phosphatidylinositol (PI) from soybean, phosphatidylserine (PS) from soybean, 1-palmitoyl-2-oleoylphosphatidylcholine (POPC), and 1,2-dioleoylphosphatidic acid (DOPA) were purchased from Sigma-Aldrich Co. LLC (St. Louis, MO, USA). Sodium 2,2-silapentane-5-sulfonate (DSS), 2-(9-anthroyloxy)stearic acid (2-AS), and 12-(9-anthroyloxy)stearic acid (12-AS) were purchased from Wako. Deuterium oxide (D_2O; deuterium purity, 99.8%) was purchased from Kanto Chemicals Co. (Tokyo, Japan).

Effects of EGCG, EGC, and GCG on the Micellar Solubility of Cholesterol and PC *in Vitro*. The effects of purified catechins on the micellar solubility of cholesterol and PC were examined as described in our previous study.[17] A bile salt micellar solution containing 6.6 mmol/L sodium taurocholate, 0.6 mmol/L PC, 0.5 mmol/L cholesterol, 132 mmol/L NaCl, and 15 mmol/L sodium phosphate (pH 6.8) was prepared by sonication and stored at 37 °C for at least 24 h. Various amounts of EGCG, EGC, or GCG in deionized water (100 μL) stored at 37 °C were added to the 3 mL micellar solutions. The mixture was incubated for 1 h at 37 °C. The supernatant was passed through a 0.2 μm syringe filter (25 mm; GDD/X; Whatman Inc., Piscataway, NJ, USA), and the cholesterol and fatty acid contents originating from the phospholipids were analyzed by gas chromatography using an SPB-1 column (Supelco, Bellefonte, PA, USA) and a DB-WAX column (Agilent Technologies, Santa Clara, CA, USA), respectively.

Effect of EGCG on the Micellar Solubility of Cholesterol and Different Types of Phospholipids *in Vitro*. Five types of bile salt micellar solutions containing 0.6 mmol/L PC, PA, PE, PI, or PS were prepared as previously described. The effects of EGCG on the micellar

solubility of both cholesterol and the phospholipids were examined as previously described.

Effect of EGCG on the Vesicular Solubility of Different Phospholipids *in Vitro*. For the purpose of conveniently examining the interaction between EGCG and phospholipids, five vesicular solutions containing 0.6 mmol/L PC, PA, PE, PI, or PS in ultrapure water were prepared by sonication and stored at 37 °C. Various amounts of EGCG in ultrapure water (in a volume of 200 μL) were added to the 6 mL vesicular solutions. The mixture was incubated for 1 h at 37 °C and then centrifuged at 25000*g* for 1 h. In a preliminary study, we confirmed that centrifugation did not precipitate the phospholipids from vesicular solution. The supernatant was passed through a 0.2 μm syringe filter (25 mm; GDD/X; Whatman), and the phospholipids in the filtrate were chemically analyzed as previously described.[30]

Effects of EGCG, GCG, and EGC on the Vesicular Solubility of PC *in Vitro*. A vesicular solution containing 0.6 mmol/L PC in ultrapure water was prepared by sonication and stored at 37 °C. The effects of EGCG, GCG, and EGC on the vesicular solubility of PC were examined as previously described.

Determination of the Apparent Equilibrium Dissociation Constant (K_D) for the Binding of Eight Green Tea Catechins to POPC Using an SPR-Based Biosensor Assay. Experiments were performed using L1 sensor chips (GE Healthcare U.K. Ltd., Buckinghamshire, England) on a Biacore X100 Plus package analytical system (GE Healthcare) at the Biomedical Research Core of the Tohoku University Graduate School of Medicine. The running buffer used for all experiments was a 0.01 mmol/L phosphate buffer containing 2.7 mmol/L KCl and 137 mmol/L NaCl (pH 6.8). The washing solution was 40 mmol/L *N*-octyl-β-D-glucopyranoside. All solutions were freshly prepared, degassed, and filtered through a 0.2 μm filter. A 50 μmol amount of POPC (the ligand; phase transition temperature, −2 °C) or DOPA (the control ligand; phase transition temperature, −8 °C) in $CHCl_3$ was placed in a round-bottomed glass flask, and the solvent was removed under nitrogen. POPC was then resuspended in 0.5 mL of the running buffer, and DOPA was resuspended in 0.5 mL of the running buffer containing 500 mmol/L NaCl to suppress the electrostatic repulsion between DOPA and the alkyl surface of the L1 sensor chip for effective immobilization because DOPA is negatively charged. The resulting phospholipid suspension was mixed vigorously and then recapitulated by five freeze−thaw cycles. To obtain homogeneous liposomal solutions, the liposomal solutions were then passed through 50 nm pore polycarbonate filters 20 times using a mini-extruder (Avanti Polar Lipids Inc., Alabaster, AL, USA). The liposomal solutions were diluted 20-fold with the running buffer with or without 500 mmol/L NaCl. The final concentration of POPC or DOPA in the liposomal solution was 0.5 mmol/L.

The liposome was immobilized on the L1 sensor chip surface using the method of Subasinghe et al.[31] with some modifications. The alkyl surface of the L1 sensor chip was cleaned by a 50 μL injection of 40 mmol/L *N*-octyl-β-D- glucopyranoside at a flow rate of 10 μL/min. The POPC or DOPA liposomal solution was then immediately applied to the L1 sensor chip surface at a flow rate of 5 μL/min. The immobilization levels of POPC and DOPA were equalized as accurately as possible using an "aim for immobilized level" command. To remove any multilamellar structures from the synthetic phospholipid bilayer surface, 2 μL of 10 mmol/L sodium hydroxide was injected at a flow rate of 5 μL/min. Generally, the injection of bovine serum albumin solution is recommended for sealing the remainder of the alkyl surface of the L1 sensor chip, which is not bound to the phospholipid bilayer. However, in preliminary studies, we observed that EGCG (one of the analytes) nonspecifically and tightly bound to bovine serum albumin and the surface of the L1 sensor chip. Therefore, 5 μL of a 1 mmol/L EGCG solution prepared in the running buffer was repeatedly injected until the baseline elevation stopped to suppress nonspecific binding to the gap. Then, the running buffer was injected until a stable baseline was achieved. The aim of this injection was to dissociate the EGCG from the phospholipid bilayer. The operating temperature was 25 °C.

An SPR-based biosensor assay was performed using the single-cycle kinetics method.[32] This method involves the sequential injection of various concentrations of an analyte without any regeneration steps. Eight green tea catechin solutions were prepared at 5−80 μmol/L (green tea catechins with a galloyl moiety) and 50−800 μmol/L (green tea catechins without a galloyl moiety) in running buffer. To associate the green tea catechins with POPC or DOPA, the green tea catechin solutions were injected over the lipid surface at a flow rate of 5 μL/min for 1,080 s. To dissociate the POPC− or DOPA−green tea catechin complexes, the green tea catechin solutions were replaced with the running buffer at a flow rate of 5 μL/min for 180 s. The sensorgrams obtained from the injection of the running buffer were subtracted from the sensorgrams obtained from the injection of green tea catechin solutions. Then, the sensorgram obtained from the reference flow cell, in which DOPA was immobilized, was subtracted from the sensorgram obtained from the measurement flow cell, in which POPC was immobilized, to yield apparent binding responses. The sensorgrams did not have appropriate curvature for curve fitting to determine association and dissociation rates. Furthermore, an unexpected finding was that EGCG weakly bound to DOPA in a dose-dependent manner. Therefore, the apparent K_D for the eight green tea catechins to POPC were calculated from the equilibrium resonance signals as a function of analyte concentration according to the manufacturer's instructions (Biacore X100 evaluation software).[33]

^{1}H NMR Measurement of EGCG in the Absence and Presence of Bile Salt Micelles. A bile salt micellar solution (in D_2O) containing 6.6 mmol/L sodium taurocholate, 0.6 mmol/L PC, 0.5 mmol/L cholesterol, 132 mmol/L NaCl, and 15 mmol/L NaD_2PO_4 (pD 6.8) was prepared by sonication and stored at room temperature overnight. EGCG was then added to 1 mL of the micellar solution. The amount of EGCG added was adjusted to 0.5 mmol/L of micelles. Then, 20 μL of a 1 mg/mL DSS solution was added to the micellar solution as an internal standard, and the mixture was incubated for 1 h at room temperature. ^{1}H NMR spectra were recorded on an AVANCE III 400 (Bruker BioSpin, Billerica, MA, USA) operating at a resonance frequency of 399.7 MHz with 20 Hz spinning at 300 K. Typically, an excitation pulse length of 14.0 μs and a pulse delay time of 1.0 μs were used. Signal assignments were performed as described in our previous study.[29]

NOESY Experiments on Bile Salt Micelle/EGCG Samples. Preparation of a bile salt micellar solution (in D_2O) and addition of EGCG and DSS solution were performed as described above. NOESY spectra were acquired on an AVANCE III 400 (Bruker BioSpin) operating at a resonance frequency of 399.7 MHz with 0 Hz spinning at 300 K. The typical acquisition parameters used were as follows: a pulse delay of 2.0 s, 0.03 and 0.3 s acquisition times in the f_1 and f_2 axes, respectively, a mixing time of 800 ms, 64 scans, and 1,024 data points acquired in both the f_1 and f_2 axes. The sine-bell-squared function was adopted as a window function.

Measuring the Fluorescence of 2-AS or 12-AS in Bile Salt Micelles in the Presence of EGCG. A bile salt micellar solution containing 6.6 mmol/L sodium taurocholate, 0.6 mmol/L PC from egg yolk, 0.5 mmol/L cholesterol, 132 mmol/L NaCl, and 15 mmol/L NaH_2PO_4 (pH 6.8) containing 1 mmol/L 2-AS or 12-AS was prepared by sonication and stored at room temperature overnight. The micellar solutions (100 μL) were incubated with 100 μL of phosphate-buffered saline (PBS) containing EGCG for 20 min at 20 °C. The amount of EGCG added was adjusted to 0, 0.1, 0.3, 0.5, 0.7, 1.0, and 2.0 mmol/L of micelles. The fluorescence of 2-AS (excitation, 362 nm; emission, 446 nm) or 12-AS (excitation, 381 nm; emission, 446 nm) in the bile salt micellar solution was measured.[27] The fluorescence intensity was calculated as the percentage of the fluorescence intensity of 2-AS or 12-AS in the absence of EGCG.

Binding Analyses of EGCG to Cholesterol by an SPR-Based Biosensor Assay. Binding analyses were performed using L1 sensor chips on the Biacore X100 Plus package analytical system. Preparations of 0.5 mmol/L POPC or DOPA liposomes with or without 0.05 mmol/L or 0.15 mmol/L cholesterol and immobilizations to the phospholipid bilayer with or without cholesterol on the surface of the L1 sensor chip were performed as described above with some

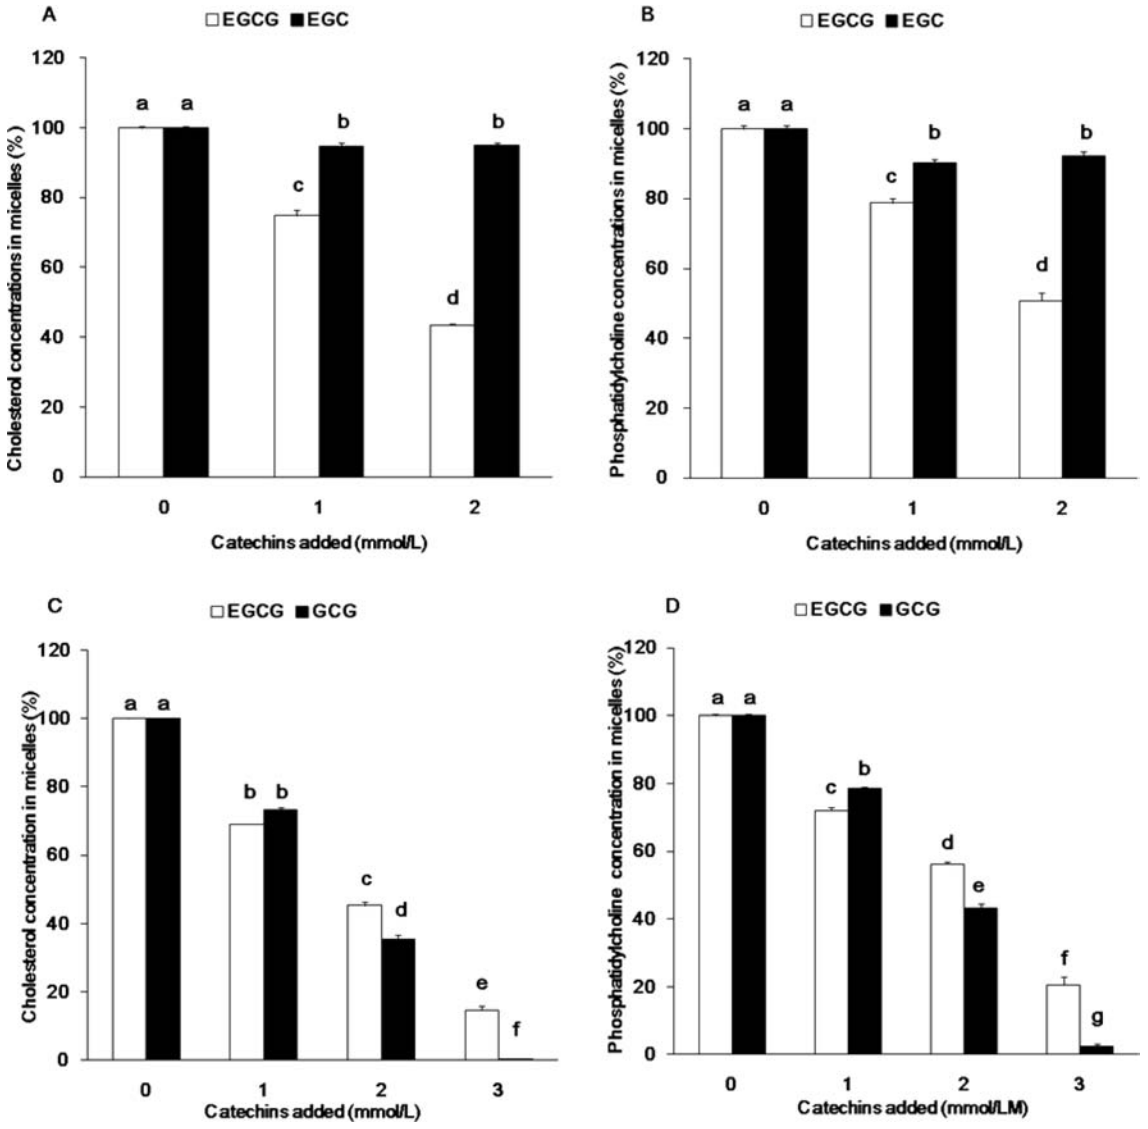

Figure 2. Effect of green tea catechins on micellar solubility of cholesterol and phosphatidylcholine *in vitro*. Comparison of effect of epigallocatechin gallate (EGCG) and epigallocatechin (EGC) on the micellar solubility of cholesterol (A) and phosphatidylcholine (B) *in vitro*. Comparison of the effect of EGCG and gallocatechin gallate (GCG) on micellar solubility of cholesterol (C) and phosphatidylcholine (D) *in vitro*. Various amounts of EGCG, EGC, or GCG in deionized water (100 μL) stored at 37 °C were added to 3 mL micellar solutions. The micellar cholesterol and phosphatidylcholine concentration at 0 mmol/L tea catechins was adjusted to 100%. Data are means ± SE of triplicate experiments. Means not sharing a common letter differ significantly ($P < 0.05$). Two-way ANOVA: (A–D) effect of catechins type, $P < 0.0001$; effect of catechin concentration, $P < 0.0001$; interaction between catechins type and catechin concentration, $P < 0.0001$.

modification. The 10 mmol/L sodium hydroxide injection was avoided because this decreased immobilization levels, particularly in the measurement flow cell, in which cholesterol was immobilized. EGCG solutions were prepared at concentrations from 0.05 to 1.6 mmol/L using the running buffer. The solutions were injected over the lipid surface at a flow rate of 5 μL/min for 60 s. The solutions were then replaced by the running buffer at a flow rate of 5 μL/min for 60 s. The operating temperature was routinely 25 °C.

Statistical Analysis. Data are expressed as the means ± standard error (SE). Statistical analysis of the data was performed by two-way ANOVA followed by a Bonferroni/Dunn test to evaluate the significance of differences between pairs of means. Differences were considered significant at $P < 0.05$.

RESULTS

Effects of EGCG, EGC, and GCG on the Micellar Solubility of Cholesterol and PC *in Vitro*. In the absence of green tea catechins, the amounts of cholesterol incorporated into the bile micelles in Figure 2A,C were 94.2% and 91.0%, respectively. These values were adjusted to 100% in Figure 2. EGCG and GCG effectively decreased the micellar solubilities of cholesterol and PC in a dose-dependent manner (Figure 2C,D). EGC slightly decreased the micellar solubilities of cholesterol and PC (Figure 2A,B). The concentrations of micellar cholesterol and PC following the addition of GCG were significantly lower than those following the addition of EGCG at concentrations of 2 and 3 mmol/L of micelles (Figure 2C,D).

Effects of EGCG on the Micellar Solubility of Cholesterol and Different Phospholipids *in Vitro*. In the absence of EGCG, the percentages of cholesterol incorporated into the bile micelles containing PC, PA, PE, PI, and PS were 85.5%, 91.0%, 95.4%, 84.0%, and 94.8%, respectively. These values were adjusted to 100% in Figure 3A. When the bile salt

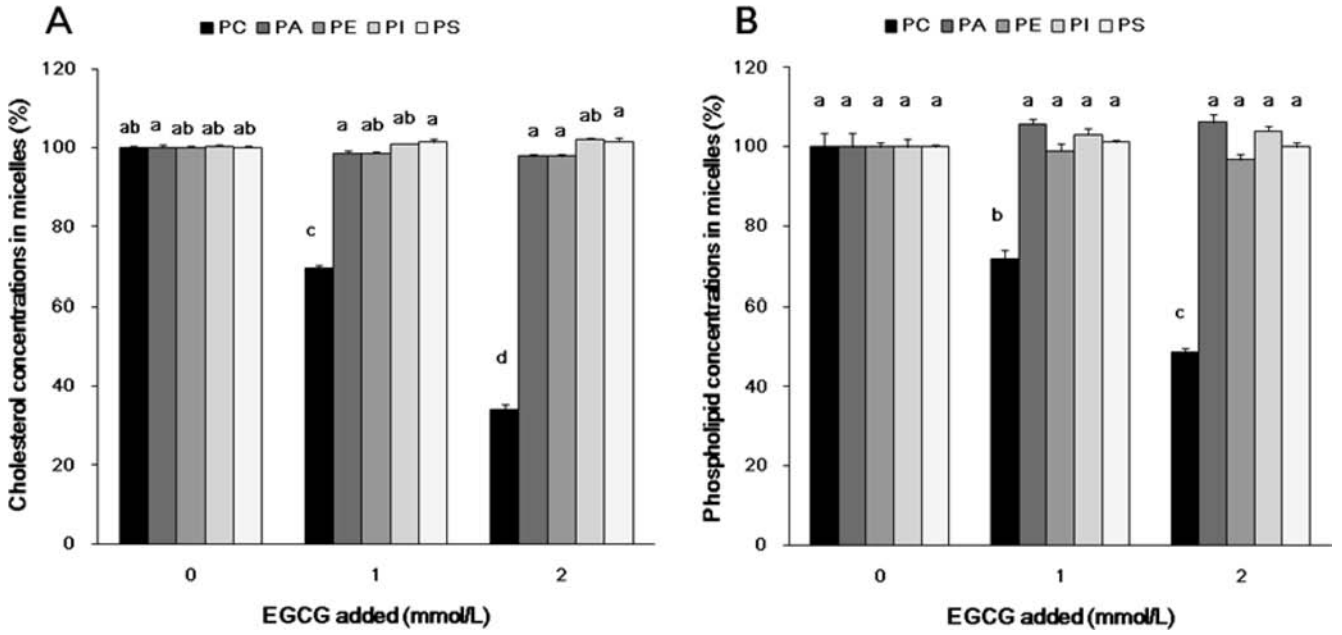

Figure 3. Effect of epigallocatechin gallate on the micellar solubility of cholesterol (A) and different phospholipids (B) *in vitro*. Various amounts of epigallocatechin gallate (EGCG) in deionized water (100 μL) stored at 37 °C were added to 3 mL micellar solution containing 0.6 mmol/L phosphatidylcholine (PC), phosphatidic acid (PA), phosphatidylethanolamine (PE), phosphatidylinositol (PI), or phosphatidylserine (PS). The micellar cholesterol and phospholipid concentrations at 0 mmol/L of EGCG were adjusted to 100%. EGCG was added at 1 and 2 mmol/L. Data are means ± SE of triplicate experiments. Means not sharing a common letter differ significantly ($P < 0.05$). Two-way ANOVA: (A, B) effect of phospholipid type, $P < 0.0001$; effect of EGCG concentration, $P < 0.0001$; interaction between phospholipid type and EGCG concentration, $P < 0.0001$.

micelles contained a phospholipid other than PC, neither cholesterol nor the phospholipid was eliminated following the addition of EGCG. (Figures 3A,B).

Effect of EGCG on the Vesicular Solubility of Different Phospholipids *in Vitro*. EGCG effectively decreased the vesicular solubility of PC and slightly decreased the vesicular solubility of PS (Figure 4). EGCG did not decrease the vesicular solubilities of PA, PE, or PI.

Effects of EGCG, GCG, and EGC on the Vesicular Solubility of PC *in Vitro*. EGCG and GCG similarly and effectively decreased the vesicular solubility of PC in a dose-dependent manner (Figure 5). EGC slightly decreased the vesicular solubility of PC (Figure 5). The concentrations of vesicular PC following the addition of EGCG or GCG were significantly lower than those following the addition of EGC at concentrations of 0.5, 1, and 2 mmol/L of vesicles (Figure 5).

Determination of the Apparent K_D for the Binding of Eight Green Tea Catechins to POPC by an SPR-Based Biosensor Assay. We immobilized DOPA in the reference flow cell as the control ligand because green tea catechins were not expected to interact with DOPA based on the result shown in Figure 4. However, the green tea catechins weakly bound to DOPA, and the resonances in the reference flow cell with immobilized DOPA were slightly elevated. Therefore, we calculated the apparent K_D values for the eight green tea catechins to POPC. The immobilization levels of POPC in the measurement flow cell and DOPA in the reference flow cell were 5,705.6 and 5,090.3 resonance units (RU), respectively. Figure 6 shows the sensorgrams of sequentially injected EGCG and EGC obtained using a single-cycle kinetics method. The sensorgrams were obtained by subtracting of the sensorgram obtained for the reference flow cell from the sensorgram obtained for the measurment flow cell. The binding of EGCG

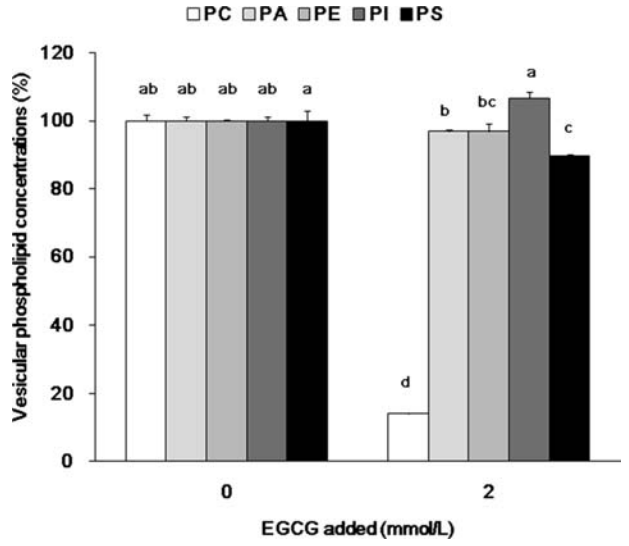

Figure 4. Effect of epigallocatechin gallate on the vesicular solubility of different phospholipids *in vitro*. Various amounts of epigallocatechin gallate (EGCG) in ultrapure water (200 μL) were added to the vesicular solutions (6 mL). The mixture was incubated for 1 h at 37 °C and then centrifuged at 25000*g* for 1 h. In a preliminary study, we confirmed that centrifugation did not precipitate the phospholipids from the vesicular solution. The vesicular phospholipid concentration at 0 mmol/L EGCG was adjusted to 100%. EGCG was added at 2 mmol/L. Data are means ± SE of triplicate experiments. Means not sharing a common letter differ significantly ($P < 0.05$). Two-way ANOVA: effect of phospholipid type, $P < 0.0001$; effect of EGCG concentration, $P < 0.0001$; interaction between phospholipid type and EGCG concentration, $P < 0.0001$.

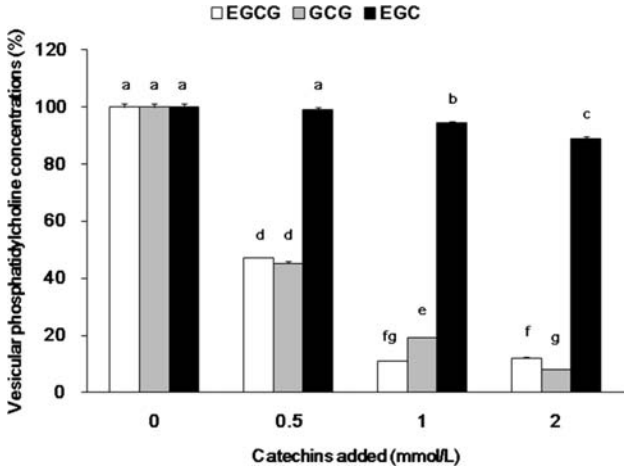

Figure 5. Effect of epigallocatechin gallate, gallocatechin gallate, and epigallocatechin on the vesicular solubility of phosphatidylcholine *in vitro*. Various amounts of epigallocatechin gallate (EGCG), gallocatechin gallate (GCG), and epigallocatechin (EGC) in ultrapure water (200 μL) were added to the PC vesicles (6 mL). The mixture was incubated for 1 h at 37 °C, and then centrifuged at 25000*g* for 1 h. The vesicular phosphatidylcholine concentration at 0 mmol/L of tea catechins was adjusted to 100%. Tea catechins were added at 0.5, 1, and 2 mmol/L. Data are means ± SE of triplicate experiments. Means not sharing a common letter differ significantly ($P < 0.05$). Two-way ANOVA: effect of phospholipid type, $P < 0.0001$; effect of EGCG concentration, $P < 0.0001$; interaction between phospholipid type and EGCG concentration, $P < 0.0001$.

and EGC to POPC was initially fast but then slowed, and concentration-dependent binding was observed (Figure 6A,B). Table 1 shows the apparent K_D for eight green tea catechins to POPC. The apparent K_D values of the green tea catechins with a galloy moiety to POPC were lower than those of the green tea catechins without a galloyl moiety. These results show that green tea catechins with a galloyl moiety have higher affinity for POPC than those without a galloyl moiety.

Table 1. Apparent Equilibrium Dissociation Constants for the Binding of Eight Green Tea Catechins to POPC Obtained from Surface Plasmon Resonance-Based Biosensor Assays[a]

	apparent K_D (mol/L)
EGCG	1.535×10^{-5}
GCG	2.485×10^{-5}
ECG	2.888×10^{-5}
CG	3.662×10^{-5}
EGC	6.685×10^{-4}
GC	9.488×10^{-4}
EC	1.036×10^{-3}
C	4.316×10^{-4}

[a]Eight green tea catechin solutions were prepared at 5−80 μmol/L (green tea catechins with a galloyl moiety) and 50−800 μmol/L (green tea catechins without a galloyl moiety) in the running buffer. To measure the association of green tea catechin with POPC or DOPA, the solutions were injected over the lipid surface at a flow rate of 5 μL/min for 1,080 s. To measure the dissociation of the POPC− or DOPA−green tea catechin complex, the green tea catechin solutions were then replaced with the running buffer at a flow rate of 5 μL/min for 180 s. The sensorgrams obtained from the injection of the running buffer were subtracted from the sensorgrams obtained from the injection of the green tea catechin solutions. Then, the sensorgram obtained from the reference flow cell, in which DOPA was immobilized, was subtracted from the sensorgram obtained from the measurement flow cell, in which POPC was immobilized, to yield the apparent binding responses. Because the sensorgrams did not have the appropriate curvature for curve fitting to determine the association and dissociation rates and because EGCG weakly bound to DOPA, the apparent equilibrium dissociation constants (K_D) for eight green tea catechins to POPC were calculated from the equilibrium resonance signals as a function of analyte concentration according to the manufacturer's instructions (Biacore X100 evaluation software).[33]

^{1}H NMR Measurement of EGCG in the Absence and Presence of Bile Salt Micelles. Interaction of EGCG with the bile salt micelles resulted in a considerable shift of the A-

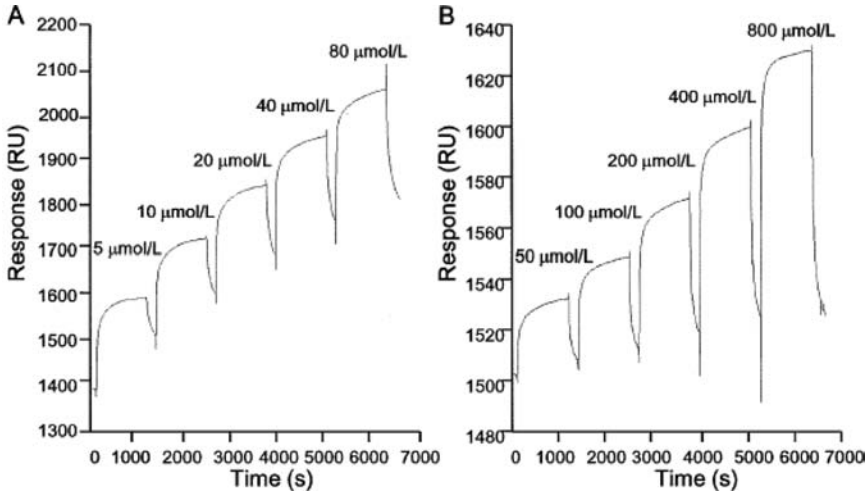

Figure 6. Sensorgrams showing the binding of various concentrations of (−)-epigallocatechin gallate (A) and (−)-epigallocatechin (B) obtained from single-cycle kinetics assays. EGCG in running buffer at 5, 10, 20, 40, and 80 μmol/L (A) and EGC in running buffer at 50, 100, 200, 400, and 800 μmol/L (B) were sequentially injected over the lipid surface at a flow rate of 5 μL/min for 1,080 s. To dissociate the POPC− or DOPA−green tea catechin complex, the green tea catechin solutions were then replaced with the running buffer at a flow rate of 5 μL/min for 180 s. The sensorgrams obtained from the injection of the running buffer were subtracted from the sensorgrams obtained from the injection of the green tea catechin solutions. Then, the sensorgram obtained from the reference flow cell, in which DOPA was immobilized, was subtracted from the sensorgram obtained from the measurement flow cell, in which POPC was immobilized, to yield the apparent binding responses.

ring (6- and 8-H), the B-ring (2′- and 6′-H), C-ring (2- and 3-H), and the galloyl moiety (2″- and 6″-H) signals in EGCG (Figure 7). These changes of chemical shift following the

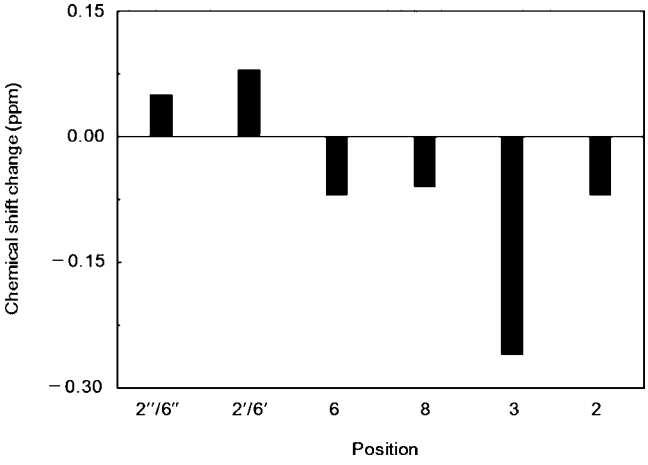

Figure 7. Change values of the chemical shift of (−)-epigallocatechin gallate following its addition to the bile salt micelles. The changes of (−)-epigallocatechin gallate (EGCG) signals in the presence of the bile salt micelles are compared to those in the absence of the bile salt micelles.

addition of EGCG to the bile salt micelles were similar to those to isotropic bicelles, which are composed of PC and frequently used as a lipid bilayer model, in our previous study.[29] These observations suggest that EGCG interacts with PC in the bile salt micells as well as in lipid bilayers. 4α- and 4β-H signals were not observed because they overlapped large signals derived from several molecules that existed in the bile salt micelles.

NOESY Experiment on Bile Salt Micelles/EGCG Samples. NOESY experiments are suitable for estimating both intermolecular and intramolecular proton distances up to 5 Å.[34] NOESY spectra were first measured with various mixing times. By increasing the mixing time, an NOE was observed. We found that a mixing time of 800 ms was optimal for observing the cross-peak in the bile salt micelle/EGCG sample. Figure 8A shows the NOESY spectra of EGCG interacting with bile salt micelles containing cholesterol and PC prepared with D_2O at 300 K. Intermolecular NOE was observed between the γ-H of the PC molecule and the 2″- and 6″-H on the galloyl moiety in EGCG (Figure 8B). An intermolecular NOE between cholesterol and EGCG was not observed. Several intramolecular cross-peaks in the EGCG molecule were observed between the protons on the B-ring and the protons on the galloyl moiety (data not shown).

Measuring the Fluorescence of 2-AS or 12-AS in Bile Salt Micelles in the Presence of EGCG. The localization of EGCG in bile salt micelles containing cholesterol and PC was investigated by fluorescence quenching of 2-AS and 12-AS with EGCG. Fluorescence was measured using a Flex Station II system (Molecular Devices, Sunnyvale, CA, USA). The anthroyl group of 2-AS should be located on the surface of the bile salt micelles, whereas that of 12-AS should be located in the hydrophobic core of the bile salt micelles. EGCG effectively quenched the fluorescence of 2-AS in a dose-dependent manner (Figure 9). EGCG (at 0.1, 0.3, 0.5, 0.7, 1, and 2 mmol/L) more strongly quenched the fluorescence of 2-AS than that of 12-AS (Figure 9).

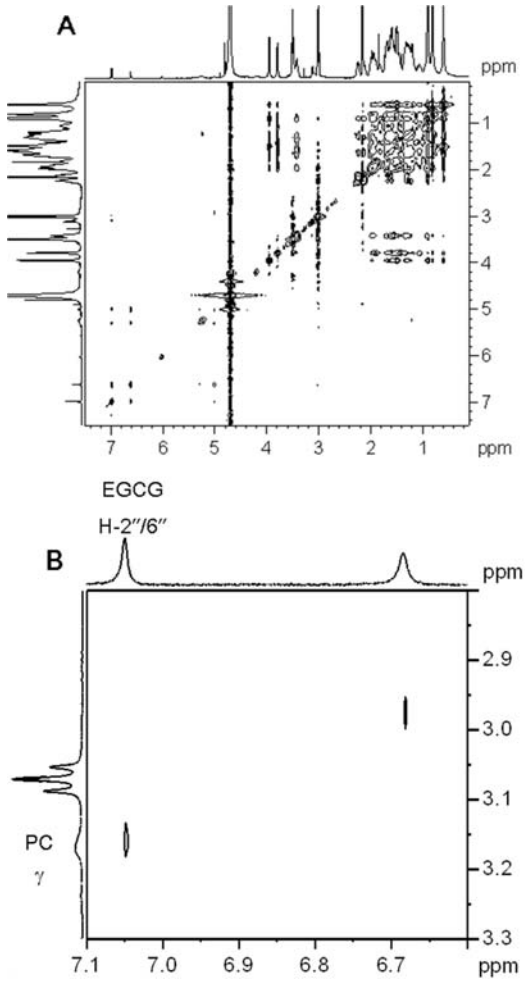

Figure 8. NOESY spectra of epigallocatechin gallate and bile salt micelles containing cholesterol and phosphatidylcholine, with a 800 ms mixing time at 300 K. (A) Overall view of the NOESY spectra. (B) Enlarged view of the NOESY spectra.

Binding Analyses of EGCG to Cholesterol by an SPR-Based Biosensor Assay. Four immobilization experiments were performed (reference flow cell/measurement flow cell: 0.5 mmol/L POPC/0.5 mmol/L POPC and 0.05 mmol/L cholesterol, 0.5 mmol/L POPC/0.5 mmol/L POPC and 0.15 mmol/L cholesterol, 0.5 mmol/L DOPA/0.5 mmol/L DOPA and 0.05 mmol/L cholesterol, and 0.5 mmol/L DOPA/0.5 mmol/L DOPA and 0.15 mmol/L cholesterol). The immobilization levels of phospholipid on the measurement flow cell and the reference flow cell were equalized as accurately as possible. The EGCG binding to cholesterol was not observed in any immobilization experiments (data not shown).

■ DISCUSSION

We previously showed that the addition of green tea catechins with a galloyl moiety to a bile salt micellar solution precipitated cholesterol and decreased the micellar solubility of cholesterol in a dose-dependent manner.[16] In contrast, green tea catechins without a galloyl moiety did not precipitated cholesterol. When purified EGCG was added to the bile salt micellar solution, the amount of EGCG precipitated from the micellar solution was highly positively correlated with the amount of cholesterol precipitated (correlation coefficient = 0.99). These results strongly suggested that EGCG eliminated the cholesterol from

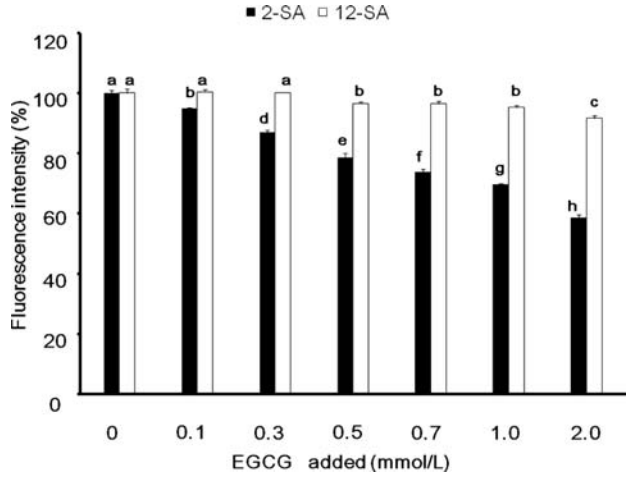

Figure 9. Effects of epigallocatechin gallate on the fluorescence intensity of 2-(9-anthroyloxy) stearic acid or 12-(9-anthroyloxy)stearic acid in bile salt micelles. A bile salt micellar solution containing 1 mmol/L 2-AS or 12-AS was prepared by sonication and stored at room temperature overnight. The micellar solutions (100 μL) were incubated with 100 μL of PBS containing epigallocatechin gallate (EGCG) for 20 min at 20 °C. The amounts of EGCG added were adjusted to 0, 0.1, 0.3, 0.5, 0.7, 1.0, and 2.0 mmol/L micelles. The fluorescence of 2-AS or 12-AS in the bile salt micellar solution were measured. The fluorescence intensity was calculated as the percentage of the fluorescence intensity of 2-AS or 12-AS in the absence of EGCG. Data are means ± SE of triplicate experiments. Means not sharing a common letter differ significantly ($P < 0.05$). Two-way ANOVA: effect of AS type, $P < 0.0001$; effect of EGCG concentration, $P < 0.0001$; interaction between AS type and EGCG concentration, $P < 0.0001$.

the bile salt micelles and co-precipitated with cholesterol. Therefore, we hypothesized that the micellar cholesterol-lowering activities of green tea catechins with a galloyl moiety could be a major cause for the inhibition of cholesterol absorption in rats.[16,17]

In the present study, we showed for the first time that green tea catechins with a galloyl moiety, but not those without a galloyl moiety, eliminated not only cholesterol but also PC from bile salt micelles (Figure 2). When bile salt micelles contained a phospholipid other than PC, neither cholesterol nor the phospholipid was eliminated by the addition of EGCG (Figure 3A,B). The same phenomenon was also observed in vesicles containing various phospholipids. EGCG effectively eliminated only the PC in the vesicles (Figure 4). We also showed that EGCG and GCG, but not EGC, effectively decreased the vesicular solubility of PC in a dose-dependent manner (Figure 5). Furthermore, we showed that green tea catechins with a galloyl moiety had higher affinity for POPC than those without a galloyl moiety in an SPR-based biosensor assay (Figure 6A,B and Table 1). The different affinity to PC between green tea catechins with a galloyl moiety and those without a galloyl moiety may be a reason why the concentrations of vesicular PC following the addition of EGCG or GCG were significantly lower than those following the addition of EGC (Figure 5). These observations suggest that green tea catechins with a galloyl moiety interact with PC and the binding of EGCG to PC decreases PC solubility. In our preliminary study, when a bile salt micellar solution containing 0.5 mmol/L cholesterol was prepared by sonication in the absence of phospholipids, the amount of cholesterol incorporated into the bile salt micelles was extremely low, and no more than 2.47% was incorporated, whereas the rest of the cholesterol was precipitated. These results suggest that because PC is eliminated from the bile salt micelles through its interaction with green tea catechins with a galloyl moiety, the micellar solubility of cholesterol is reduced; therefore, the cholesterol precipitated.

The result from Figure 7 suggested that EGCG interacted with PC in the bile salt micelles. To clearly investigate how EGCG interacts with the PC in a bile salt micellar solution and whether the interaction between EGCG and PC indirectly leads to the precipitation of cholesterol from the bile salt micelles or the formation of a complex containing EGCG, PC, and cholesterol, we performed a NOESY experiment and estimated the location of EGCG in the bile salt micelles containing cholesterol and PC. Intermolecular NOE was observed between the γ-H of PC and 2″- and 6″-H on the galloyl moiety of EGCG when EGCG was added to the bile salt micelles containing cholesterol and PC (Figure 8B). The cation−π interaction between the trimethylammonium group of PC and the galloyl moiety of EGCG was inferred from this observation. Furthermore, several intramolecular cross-peaks in the EGCG molecule were observed between the protons on the B-ring and the protons on the galloyl moiety (data not shown). Therefore, there is a strong possibility that the cation−π interaction between the trimethylammonium group of PC and the galloyl moiety of EGCG may lead not only to a considerable shift of the galloyl moiety (2″- and 6″-H) signals in EGCG but also to a considerable shift of the A-ring (6- and 8-H), the B-ring (2′- and 6′-H), and the C-ring (2- and 3-H) signals in EGCG (Figure 7). In contrast, the intermolecular NOE between cholesterol and EGCG was not observed. These observations support our expectation that EGCG specifically interacts with only PC, but not cholesterol in the bile salt micelles, and agree with the results of our previous study in which we showed that EGCG specifically interacts with isotropic bicelles, which are composed of PC and frequently used as lipid bilayer models.[29]

When the localization of EGCG in the bile salt micelles containing cholesterol and PC was investigated, EGCG effectively quenched the fluorescence of 2-AS in a dose-dependent manner (Figure 9). Because the trimethylammonium group of PC is a hydrophilic group, it should be located on the surface of the bile salt micelles. Therefore, this observation suggests that EGCG is located on the surface of the bile salt micelles via its interaction with micellar PC. The concentration of EGCG added to the micelles in this experiment was less than the amount that precipitated following the addition of EGCG to the bile salt micelles. It is thought that PC could be eliminated from the bile salt micelles by increasing the EGCG concentration added to the micelles.

The results from our previous study suggested that cholesterol directly precipitated with EGCG.[16] To investigate whether EGCG interacts with cholesterol, we performed binding analyses using an SPR-based biosensor assay. Binding of EGCG to cholesterol was not observed (data not shown). This observation strongly suggests that EGCG does not directly interact with cholesterol in a bile salt micelle. The results from the present study suggest that EGCG formed a complex with PC, and then this complex interacts with cholesterol. Hénin et al. showed that cholesterol and dimyristoylphosphatidylcholine formed a complex with a 1:1 stoichiometry in a fully hydrated cholesterol−dimyristoylphosphatidylcholine bilayer through

molecular dynamics simulations.[35] Furthermore, in preliminary studies, we observed that cholesterol and PC formed a complex with a 1:1 stoichiometry in $CDCl_3$ (data not shown). These observations suggest that cholesterol and PC form a complex in bile salt micelles and that the interaction between EGCG and PC leads to the formation of a complex containing EGCG, PC, and cholesterol. However, we could not provide direct evidence that the interaction between EGCG and PC leads to the formation of a complex containing EGCG, PC, and cholesterol in the present study. We could not assign all spectra in the bile salt micelles in the NOESY study, because too many protons derived from several molecules existed in the bile salt micelles. Furthermore, NOESY experiments are suitable for estimating specific interactions, but not nonspecific interactions. If cholesterol nonspecifically interacts with the EGCG/PC complex, it would be difficult to observe the intermolecular NOE between the protons in the cholesterol molecule and the EGCG/PC complex. Further research is required to confirm these results.

We previously suggested the possibility that the B-ring and the plane of the ring in the galloyl moiety in EGCG or ECG were stacked via the $\pi-\pi$ interaction in lipid bilayers and that the cation$-\pi$ interaction between the trimethylammonium group of PC and the galloyl moiety in EGCG or ECG was enhanced by the $\pi-\pi$ interaction between the B-ring and the plane of the ring in their galloyl moiety of EGCG or ECG.[36] Several intramolecular cross-peaks were observed between the protons on the B-ring and the protons on the galloyl moiety in the EGCG molecule in the NOESY experiment in this study (data not shown). The intramolecular NOE between the protons on the B-ring and the protons on the galloyl moiety was also observed in our previous NOESY experiment using bicelle/EGCG and ECG samples.[29] Therefore, there is a strong possibility that the intramolecular interactions in the EGCG molecule enhanced the cation$-\pi$ interaction between the trimethylammonium group of PC and the galloyl moiety of EGCG in bile salt micelles as well as in lipid bilayers.

Both exogenous and endogenous phospholipids exist in the intestinal lumen. The dietary intake of phospholipids is typically estimated to be 2−8 g/day in humans, and the biliary pathway delivers 10−20 g/day to the intestinal lumen.[37] The predominant phospholipid in the intestinal lumen is PC. Therefore, the intestinal lumen can be a suitable environment for the inhibitory effect of EGCG on cholesterol absorption because the interaction between green tea catechins with a galloyl moiety and PC is important in eliminating cholesterol from bile salt micelles.

In conclusion, our study showed that EGCG decreased the micellar solubility of cholesterol via specific interaction with PC, but not through a direct interaction with cholesterol. At any rate, the limited solubility of cholesterol by green tea catechins with a galloyl moiety can be a major cause of the inhibition of cholesterol absorption.[16,17] In this study, we could not sufficiently describe the mechanism underlying the EGCG-mediated elimination of cholesterol from bile salt micelles. Therefore, detailed studies are necessary to understand how green tea catechins with a galloyl moiety cause the precipitation of cholesterol from bile salt micelles.[16,17]

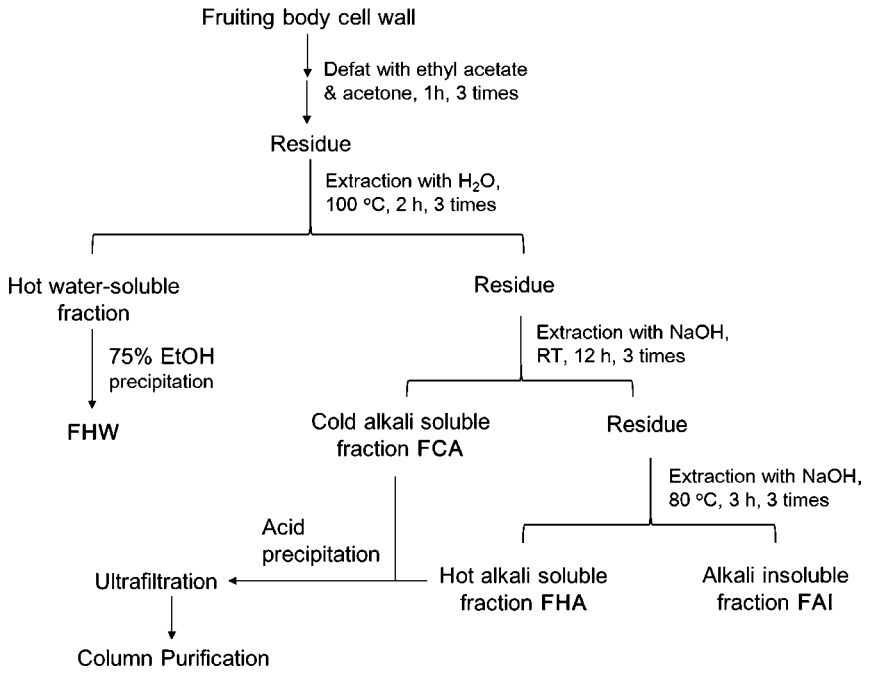

Figure 1. Fractionation scheme of mushroom cell wall of PTR fruiting body.

dietary fiber. This paper focuses on the fractionation of the major soluble MCW polysaccharides from PTR fruiting body and their structural elucidation by use of chemical, spectroscopic, and microscopic techniques.

MATERIALS AND METHODS

Cultivation of Fruiting Body and Preparation of Mushroom Cell Wall. Fruiting body was obtained from the incubation of PTR sclerotium embedded in soil kept in a greenhouse under humid and warm conditions (30−35 °C) for 2 months. The harvested fruiting body was freeze-dried and stored at −20 °C before use. Freeze-dried sample of fruiting body was pulverized into powders to pass through a screen with an aperture of 0.5 mm by using a cyclotech mill (Tecator, Höganäs, Sweden). The milled powders were suspended in distilled water and ultrasonicated at 300 W with a 30% duty cycle for 10 min (Sonics & Materials Vibracell, model VC 600) for cell breakage. The degree of cell breakage was monitored by a phase contrast microscope (PCM, Eclipse 80i, Nikon). Cleaved mushroom cells were washed sequentially with wash solution A [1 mM phenylmethanesulfonyl fluoride (PMSF)], wash solution B [5% (w/v) NaCl, 1 mM PMSF], wash solution C [2% (w/v) NaCl, 1 mM PMSF], wash solution D [1% (w/v) NaCl, 1 mM PMSF], and then wash solution A again to remove intracellular contaminants.[16] Each step was repeated three times until no carbohydrate and protein could be determined from the washed buffer using the phenol−sulfuric acid method and bicinchoninic acid (BCA) protein assay,[17,18] respectively. The isolated MCW was lyophilized prior to its fractionation.

Fractionation and Purification of MCW from PTR Fruiting Body. MCW of PTR fruiting body was fractionated according to the scheme shown in Figure 1. After the successive extraction using hot water, cold alkali, and hot alkali solution (1 M NaOH), three soluble MCW fractions including the hot water-soluble fraction (FHW), the cold alkali-soluble fraction (FCA), and the hot alkali-soluble fraction (FHA) were obtained from the supernatants after centrifugation (4000*g* for 10 min at 4 °C), leaving behind an alkali-insoluble residue (FAI). The FHW fraction was concentrated and subjected to ethanol fractional precipitation up to 75% ethanol. The supernatants of the two alkali-soluble fractions FCA and FHA were precipitated using 75% ethanol to precipitate the polysaccharides and then washed five times using 75% ethanol until the washings were neutral. FAI was washed with Milli-Q water five times to remove any residual chemicals.

FCA and FHA were subjected to further fractionation by membrane ultrafiltration (Millipore, stirred ultrafiltration 8040) with molecular weight (MW) cutoff of 10000 Da to give two fractions (FCA-I and -II; FHA-I and -II) with MW >10000 and <10000 Da, respectively. As larger MW fractions, FCA-I and FHA-I were further purified by gel filtration on a Sephacryl S-1000 Superfine column combined with a Sephacryl S-400 high-resolution column (90 × 2.6 cm i.d., Amersham Pharmacia Biotech, UK) eluted with 0.2 M NaCl at 1.5 mL/min. Being smaller MW fractions, FCA-II and FHA-II were further purified to a single fraction by a Sephacryl S-200 high-resolution column (70 × 2.6 cm i.d., Amersham Pharmacia Biotech, UK) eluted with 0.2 M NaCl at 1.5 mL/min. All of these purified fractions were desalted by gel filtration on a Sephadex G10 column (70 × 2.6 cm i.d.; Amersham Pharmacia Biotech, UK) eluted with distilled water and then freeze-dried prior to further analyses.

Chemical Composition Analysis. The carbohydrate content of the MCW was estimated by using the phenol−sulfuric acid method,[17] whereas the uronic acid was determined colorimetrically according to the *m*-hydroxydiphenyl−sulfuric acid method.[19] Protein content was analyzed using the bicinchoninic acid (BCA) protein assay as described previously.[18]

The monosaccharide composition of the purified polysaccharides from the MCW of PTR fruiting body was determined by the alditol acetate derivatives of the sugars after acid hydrolysis, reduction, and acetylation as described previously[20] using a gas chromatograph (GC) (6890N, Agilent Technology, USA) fitted with an Alltech DB-225 capillary column (15 m × 0.25 mm i.d., 0.25 μm film) and coupled with a mass spectrometer (MS) (5973N, Agilent Technology, USA)]. The oven temperature program were as follows: initial temperature, 170 °C; temperature raised at 2 °C/min to 220 °C, and final hold for 15 min. Helium was used as carrier gas at a flow rate of 1.0 mL/min. The injector temperature and interface temperature were set at 250 and 280 °C, respectively. The MS conditions were as follows: ion source temperature at 250 °C, ionization energy at 70 eV, detector voltage at 1.5 kV, and mass range from 50 to 400.[20] Individual sugars were corrected for losses during hydrolysis and derivatization as well as their different responses to the MS detector.[20]

Linkage Analysis by Methylation. The purified polysaccharides from fruiting body cell wall material (FCWM) were permethylated to partially methylated alditol acetates (PMAA) using methyl iodide and solid NaOH in dry DMSO as described in a modified protocol reported previously.[21] The PMAA samples were then analyzed by GC-

MS with an Alltech DB-225 capillary column (15 m × 0.25 mm i.d., 0.25 μm film) as mentioned above. The oven temperature was increased from 130 to 220 °C by 4 °C/min. The MS detector conditions were the same as mentioned above. Each PMAA was identified by matching its mass spectrum with the literature database.[22]

Molecular Mass and Size. The molecular parameters (including molecular mass and size) of purified polysaccharide were determined using a size exclusion chromatograph (SEC) (Agilent 1200 series LC system) coupled with a multiangle laser light scattering (MALLS) photometer (DAWN EOS, Wyatt Technology Co., USA) and refractive index detector (RI, G1362A, Agilent Technologies Inc., USA). The purified soluble MCW polysaccharide fractions were dissolved in 0.15 M NaCl to a concentration of 1.0 mg/mL and filtered through a 0.22 μm nylon syringe filter before determination. A serial column that combined TSK G-5000 (30 cm × 7.5 mm i.d., Supelco, USA) with TSK G-3000 columns was then employed to separate the samples at 30 °C. The predegassed 0.15 M NaCl aqueous solution was applied as the elution buffer at a flow rate of 0.5 mL/min. A specific refractive index increment (dn/dc) value of the polysaccharides in 0.15 M NaCl aqueous solution was determined with a differential refractometer (OPTILAB DSP) (λ = 690 nm) to be 0.140 mL/g. Astra software (Wyatt Technology Co.) was utilized for data recording and further analysis.

Infrared Spectrum Analysis. The infrared spectra of the purified MCW polysaccharides, hot water-soluble fractions, and alkali-insoluble fractions from MCW of PTR fruiting body were recorded with a Fourier transform infrared spectrometer (FT-IR, Nicolet 670) in the range of 4000−400 cm^{-1} using a KBr disk method.

Microscopic Analysis. The protocols used were according to the previous analysis of MCW polysaccharides from PTR sclerotium[16] and hyper-branched glucans.[14] To observe the microstructure of a single molecule, sodium dodecyl sulfate (SDS) (used as a small molecular surfactant to disperse the entangled molecules) was added to a 1 mg/mL FHA-I aqueous solution at a ratio of 1:1 (w/w) and heated together at 80 °C for 2 h. The solution was diluted stepwise to a final concentration of 5 μg/mL and was heated to 80 °C for 2 h with constant stirring.

The holey carbon film (200 mesh, Beijing Zhongjingkeyi Technology, China), supported by a copper grid, was used to prepare the sample for the TEM viewing. After filtration through a 0.22 μm nylon syringe filter, a droplet of the sample (5 μg/mL) was deposited on the specimen, which was finally dried in air at ambient temperature and humidity. The molecular morphology of the prepared samples was performed on a TEM (H-7650, Hitachi, Japan) at an accelerating voltage of 80 kV.

To observe the AFM image, 5 μL of filtered sample solution (5 μg/mL) was pipetted briefly onto the freshly cleaved surface of a mica disc (Ted Pella, Inc., USA). The surface was air-dried for 20 min in a covered Petri dish and then washed with a large amount of distilled water before fixing with ethanol. After the surface was dried under the same condition as the TEM sample, it was examined using an AFM (Nanoscope III, Velco Instruments Inc., USA) in the tapping mode, which was equipped with a Si probe (Tap 150-G-10, Ted Pella, Inc., USA) with a quoted spring constant of 1.5−15 N/m at a cantilever driving frequency of 300 kHz and a scanning frequency of 1−2 Hz. Nanoscope software was used to obtain and process AFM images.

RESULTS AND DISCUSSION

Cell Wall Content and Composition. The cell wall content of PTR fruiting body was determined to be 46.6 ± 0.9% dry weight (DW), which was significantly less than that from sclerotium (78.4 ± 0.7% DW) according to our previous analysis of sclerotial cell wall.[14] In general, PTR fruiting body MCW contained 74.6% carbohydrate, 4.27% uronic acids, and 3.27% protein (Table 1). In contrast, the chemical composition of the mycelial cell wall was found to contain 79.0% carbohydrates, 5.1% uronic acids, and 3.8% proteins, whereas that of sclerotial cell wall contained 71.6% carbohydrates, 1.6% uronic acids, and 7.0% proteins (unpublished data).

Table 1. Composition of Fractions from Fruiting Body Cell Wall[a]

sample	% DW	total carbohydrate (%)	uronic acid (%)	protein (%)
FHW	3.37 ± 0.13	42.7 ± 0.4	0.22 ± 0.04	49.4 ± 0.61
FCA	20.5 ± 0.16	90.1 ± 0.4	0.76 ± 0.07	8.18 ± 0.38
FHA	52.4 ± 0.77	98.5 ± 0.8		
FAI	17.6 ± 0.54	72.9 ± 0.4	5.96 ± 0.23	
MCW		74.6 ± 0.8	4.27 ± 0.18	3.27 ± 0.03

[a]Data are the mean ± SD (n = 3).

Four crude fractions (FHW, FCA, FHA, and FAI) were obtained from the MCW of PTR fruiting body, and their chemical compositions are shown in Table 1. Hot-water-soluble fraction (FHW) accounted for only 3.4% DW of the MCW of PTR fruiting body, whereas the two alkali-soluble fractions constituted 72.9% of the MCW (20.5 and 52.4% for FCA and FHA, respectively). The relative percentage of these two alkali-soluble fractions (FCA and FHA) was similar to that of mycelial cell wall (22.0 and 47.0% for mycelial cold-alkali and hot-alkali fractions, respectively) but was different from sclerotial cell wall with the main component being the cold alkali-soluble fraction (41.2 and 35.3% for sclerotial cold-alkali and hot-alkali fractions, respectively).[14] FAI constituted 17.6% of MCW, which was similar to that from mycelial and sclerotial alkali-insoluble cell residues (19.0 and 16.9%, respectively) (unpublished data). FHW had a very high level of protein (49.4% by weight), indicating the existence of proteins or glycoproteins in the outer layer of the MCW of PTR fruiting body. A relatively lower level of proteins (8.18%) found in the FCA fraction suggested the existence of proteins in the middle layer of the MCW of PTR fruiting body. Levels of uronic acids were very low among the MCW fractions except for FAI. The alkali-soluble fractions (FCA and FHA) of the PTR fruiting body were predominantly composed of carbohydrates, whereas the FAI fraction contained 72.9% carbohydrates, which was higher compared with that in mycelial and sclerotial alkali-insoluble residues (45.7 and 57.4%, respectively) (unpublished data).

On the basis of the fractionation, the arrangement of the cell wall components in PTR fruiting body from outer layer to inner layer was suggested to be in the following order: proteins or glycoproteins, polysaccharides, complex of polysaccharide and chitin.

Purification of Polysaccharides from PTR Fruiting Body MCW. Other than FHW, which had little amount, FCA and FHA were purified by using membrane filtration and column chromatography. After purification by use of membrane filtration, fractions with larger molecular weight (MW > 10000) were obtained and then further purified using column chromatography to give a single fraction (FCA-I and FHA-I). Fractions with smaller MW (<10000) (FCA-II and FHA-II) obtained from membrane separation were then subjected to column chromatography purification, but very little amount of samples could be recovered (<7% of total fraction). Therefore, the analysis of purified MCW polysaccharides was mainly focused on two high MW soluble fractions (FCA-I and FHA-I).

Monosaccharide Composition of Polysaccharides from PTR Fruiting Body MCW. The monosaccharide composition of FHW was mainly glucose with small amounts

Table 2. Chemical Composition of Cell Wall Polysaccharide Fractions from PTR Fruiting Body[a]

	monosaccharides (%)						
sample	xylose	mannose	galactose	glucose	glucosamine[b]	total carbohydrate (%)	uronic acid (%)
FHW	3.19	19.64	3.45	73.72		42.2	0.22
FCA-I		22.22	11.24	66.54		92.1	0.77
FHA-I				100.00		97.4	
FAI				72.23	27.77	72.9	5.96

[a]Data are the means of triplicates. [b]Glucosamine is derived from chitin

of mannose, galactose, and xylose as shown in Table 2. Compared with FHW, the cold alkali-soluble polysaccharide (FCA-I) contained more mannose and galactose, but without xylose. After purification, protein was not detected in FCA-I, although 8.17% protein was found in FCA. FHA-I as the main fraction of PTR fruiting body MCW was composed of almost purely glucose (Table 2). Different from the other soluble MCW fractions, FAI contained 72.2% glucose [similar to the total carbohydrate content of 72.9% (Table 1)], whereas 27.3% of this fraction was composed of glucosamine (the structural subunit of chitin). FAI was thus composed of an insoluble glucan−chitin complex that is commonly found in fungi.

Glycosidic Linkages of FHA-I. Due to the poor solubility of FCA-I and FAI in DMSO, linkage analysis was performed only on FHA-I. PMAAs in the GC-MS chromatogram of FHA-I were identified by their retention time in the total ion chromatogram (TIC) and by comparison with mass spectrum patterns from the literature database.[22] The glycosidic linkages and their corresponding percentages are listed in Table 3. The molar ratio of monosaccharide residues was calculated according to the peak areas and response factors for individual sugars in the TIC as mentioned above.

Table 3. Peak Area and Molar Ratio of Glycosidic Linkages in FHA-I by Methylation Analysis[a]

		FHA-I	
linkage pattern	retention time (min)	peak area (%)	molar ratio
T-Glc*p*[b]	13.999	26.61	5.64
1,3-Glc*p*	16.991	5.13	1.00
1,6-Glc*p*	17.972	10.93	2.13
1,4-Glc*p*	18.170	32.05	6.25
1,3,6-Glc*p*	21.097	8.19	1.48
1,4,6-Glc*p*	21.319	17.09	3.08
TU/BP[c]		1.05	
DB[d]			0.52

[a]Data are the means of triplicates. [b]Glc*p*, glucopyranose. [c]TU/BP, terminal units/branching points. [d]DB = (NT + NB)/(NT + NB + NL), the degree of branching, where NT, NB, and NL are the numbers of the terminal residues, branch residues, and linear residues, respectively.

Consistent with the results of polysaccharides from PTR sclerotium MCW,[14] FHA-I consisted of a nonreducing terminal glucose, 1,3-D-Glc*p*, 1,4-D-Glc*p*, 1,6-D-Glc*p*, 1,3,6-D-Glc*p*, and 1,4,6-D-Glc*p*. The molar ratios of these six sugar residues were similar to those polysaccharides from PTR sclerotial MCW.[14] However, the percentages of 1,4-D-Glc*p* and 1,3,6-D-Glc*p* in FHA-I had obviously increased, whereas residues of T-D-Glc*p* and 1,4,6-D-Glc*p* had decreased. The major glycosidic linkage in FHA-I was 1,4-D-Glc*p* residues (32.1%), followed by T-D-Glc*p* (26.6%) (Table 3). The major branched sugar residues in FHA-I were 1,4,6-D-Glc*p*, which accounted for 17.1% of the total sugar residues, whereas 8.19% of 1,3,6-D-Glc*p* existed in this fraction. The ratio between terminal units (T-D-Glc*p*) and branching points (1,4,6-D-Glc*p* and 1,3,6-D-Glc*p*) was 1.05 (TU/BP ratio) (Table 3). Consistent with the structure of polysaccharides from PTR sclerotial MCW,[14] the data from the above methylation analysis suggested that FHA-I was also mainly composed of →1)-D-Glc*p*-(4→ residues as the backbone with some →1)-D-Glc*p*-(6→ residues in the side chains, whereas some →1)-D-Glc*p*-(3→ residues might exist in the backbone or side chains. The major branching points of FHA-I were at *O*-4 and/or *O*-6 positions of the Glc*p* chain. The degree of branching (DB) of FHA-I was calculated by the equation [DB = $(N_T + N_B)/(N_T + N_B + N_L)$] to be 52%. With such a high DB value, FHA-I would be likely to be a hyper-branched glucan consistent with polysaccharides purified from PTR sclerotial MCW.[14]

Molecular Mass and Size of FHA-I. The SEC chromatogram of FHA-I indicated that there was only a very small shoulder peak (<9% total peak area) present in front of the major peak (Figure 2) that might be caused by the aggregation of the polysaccharide. The values of M_w, M_n, root-mean-square (RMS) radius/radius of gyration ($\langle S^2 \rangle^{1/2}$) of the samples were obtained by computing a classical Zimm plot from light-scattering data (data not shown).[23] The d_f value can be determined from the relationship between M_w and RMS radius and v according to eqs 1 and 2, known as the inverse power law functions.[24]

$$\text{RMS radius} = kM_w^{\ v} \quad (1)$$

$$d_f = 1/v \quad (2)$$

From the slope of the angular dependence (Figure 3), the M_w of the FHA-I was estimated to be 4.224×10^6 g/mol, whereas its RMS radius was calculated to be 30.4 nm (Table 4). FHA-I, which was purified from FHA, accounted for 52.4% DW of the PTR fruiting body MCW, indicating that this fraction is the major structural skeleton in the cell wall. The value of M_w/M_n is known as the polydispersity index, which reflects MW homogeneity and a value of 1 for monodispered molecules.[25] The value of M_w/M_n (1.089) for FHA-I (Table 4) indicated the relatively high purity of FHA-I.

According to previous studies, the exponent v in eq 2 reflects the molecular shape of a polymer with values of 0.33, 0.50−0.60, and 1.0 representing a sphere, random coil, and rigid rod, respectively.[26,27] The small RMS radius of FHA-I (30.4 nm) (Table 4) suggested that this macromolecule might exist as a compact conformation in aqueous solution.[28,29] The v value of FHA-I was found to be 0.33, and its corresponding d_f value was 3.06 (Table 4), indicating that the conformation of the FHA-I was spherical.[26,27,30] As described in previous studies,[31−33] this was consistent with the highly branched structure suggested by the above linkage analysis (Table 3).

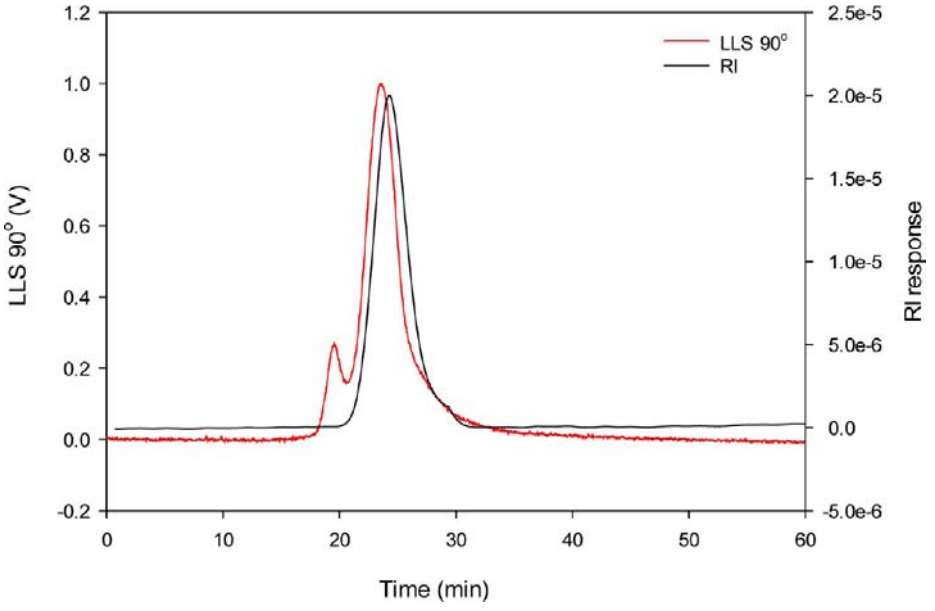

Figure 2. SEC-MALLS chromatograms of FHA-I.

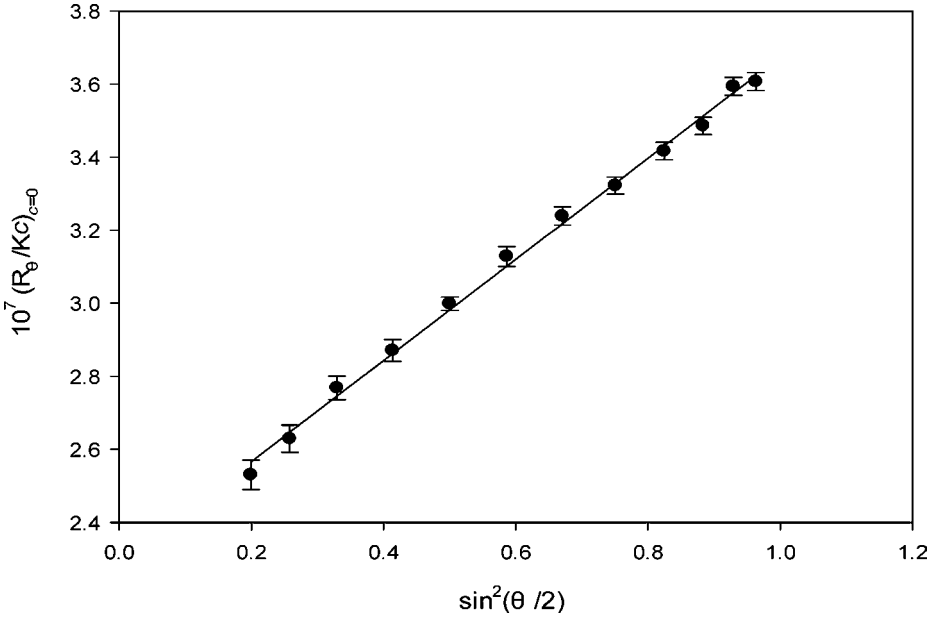

Figure 3. Angular dependence of $(R_\theta/Kc)_{c=0}$ for FHA-I, where K is the optical constant, c is the concentration, R_θ is the Rayleigh ratio, and θ is the scattering angle.

Table 4. Results of SEC-MALLS for FHA-I[a]

sample	$M_w \times 10^{-6}$ (g/mol)	RMS radius (nm)	M_w/M_n	d_f	ν
FHA-I	4.224 ± 0.77	30.4 ± 4.9	1.089	3.06	0.33 ± 0.08

[a]Data are the mean ± SD. M_w, weight-average molecular mass; M_n, number-average molecular mass; d_f, fractal dimension; ν, exponent in eq 1.

IR Spectrum of Polysaccharides from PTR Fruiting Body of MCW. All of the IR spectra of the four fractions from MCW (Figure 4) exhibited an absorption peak at ~900 cm^{-1}, which was similar to the characteristic absorption peak for the β configuration of glucan (890 cm^{-1}).[34] The absorption peak at 834 cm^{-1} of FCA-I indicated the existence of an α configuration of glucan. The unique absorption of double peaks at 1661 and 1629 cm^{-1} combined with the peak at 1565 cm^{-1} in the spectrum of FAI indicated that a secondary amide group (−CO−NH−C) existed in this fraction due to the presence of a large amount of chitin and was consistent with the monosaccharide composition data (Table 2) for a glucan−chitin complex.

Molecular Morphology of FHA-I. To further observe the microstructure of the spherical FHA-I, SDS was added to break the hydrogen bonds inside the sphere. Both branched conformations and crossed chains were observed under this condition (Figure 5). Figure 5A shows part of a particular FHA-I molecule with an extended conformation. Similar to the hyper-branched PTR sclerotium MCW cold alkali-soluble fraction (SCA-I),[15] a high degree of branching was observed from the TEM image of FHA-I (Figure 5A) with a large

dx.doi.org/10.1021/jf500112j | J. Agric. Food Chem. 2014, 62, 2891−2899

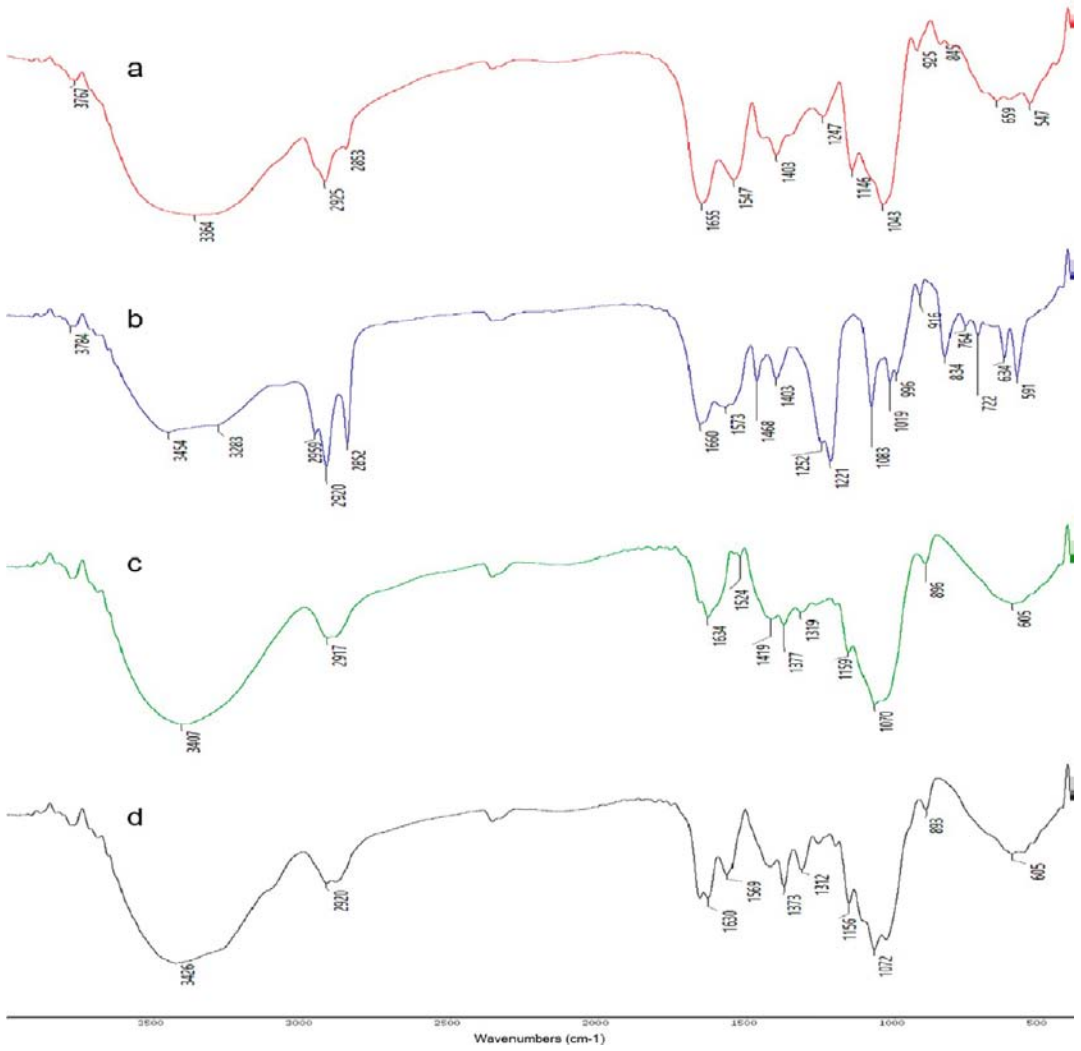

Figure 4. IR spectrum of polysaccharide fractions derived from mushroom cell wall of PTR fruiting body: (a) FHW; (b) FCA-I; (c) FHA-I; (d) FAI.

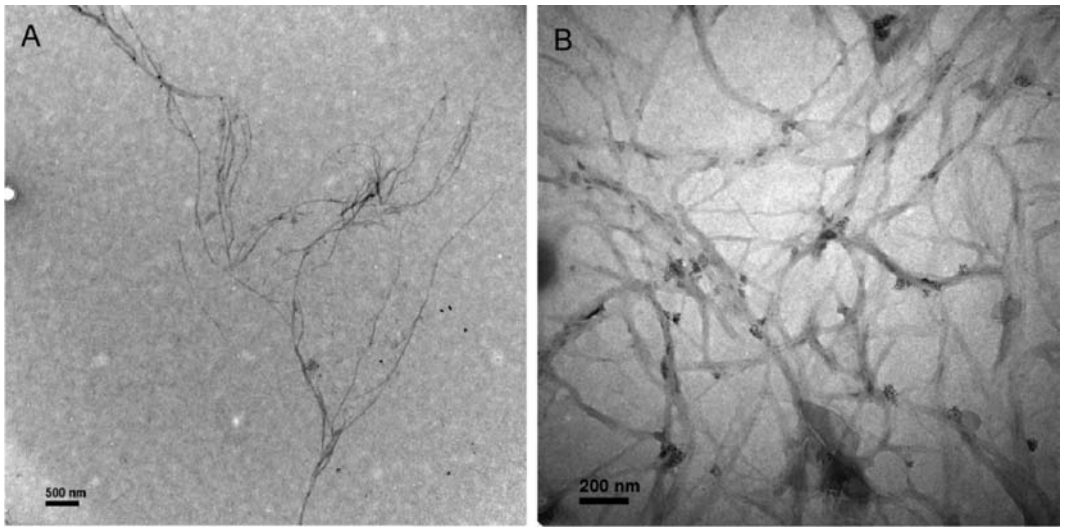

Figure 5. TEM images of FHA-I in SDS solution: (A) unfolded conformation; (B) entangled chains.

number of the polymer chains entangled together in the fully extended state shown in Figure 5B.

Branched conformation of FHA-I molecule in SDS could also be found in AFM (Figure 6A), which was similar to the result in TEM (Figure 5). Furthermore, the thickness of the molecules (indicated by the red pointers in the cross-section line in Figure 6B) varied from 4.8 to 40.4 nm, indicating that multiple chains of FHA-I molecules rather than a single-chain

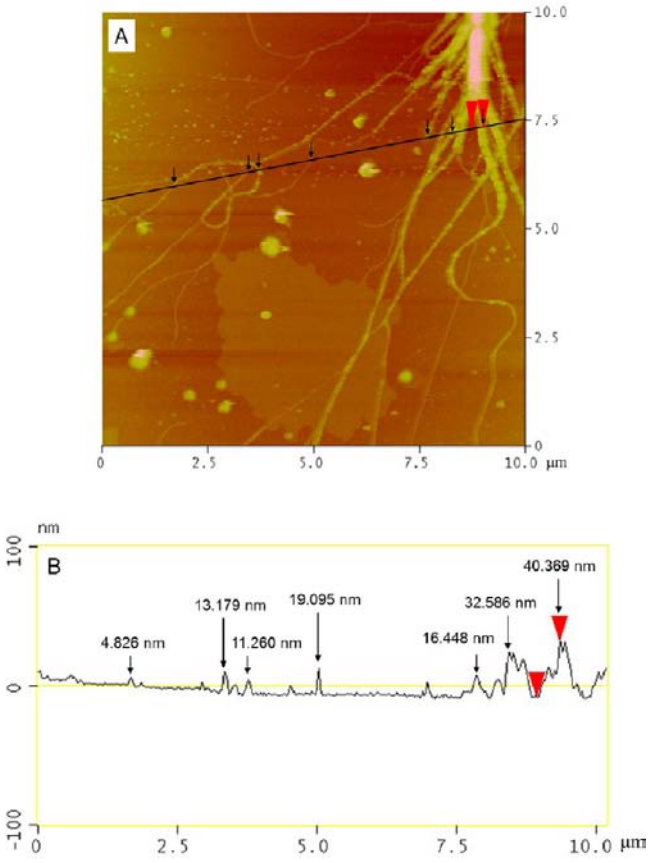

Figure 6. Tapping mode AFM images (A) and cross-sectional profile (B) of FHA-I dispersed in 80 °C SDS solution.

one existed in the SDS medium. With such thickness, it was possible that up to eight chains of macromolecules might be stacked up or bundled together to give such a dimension.

Mushroom Cell Wall Structure of PTR Fruiting Body. A sandwich model was proposed to represent the amount and chemical nature of the cell wall components sequentially extracted from the MCW of PTR fruiting body (Figure 7). Apart from proteins, a small amount of glycan−protein complexes could be found in the first fraction of MCW (Table 1), all of which could be linked with other cell wall components via noncovalent bonding because these proteins and glycan−protein complexes could be extracted using boiling water.[16] The second fraction of MCW is mainly composed of cold alkali-soluble heteropolysaccharides with glucose, mannose, and galactose (Table 2) with small amounts of proteins (Table 1), suggesting that the glycans are associated with proteins via noncovalent linkage because these proteins could be removed in the purification procedure. The third fraction of MCW could be considered as the main structural skeleton due to its abundance, and it is composed of hyper-branched glucans (Table 3 and Figure 6). The MCW polysaccharides in this fraction could be removed using alkali solution at 80 °C. The innermost fraction of MCW could be composed of glucan−chitin complexes, which contain >70% glucan and <30% chitin (Table 2). This protective barrier could not be removed by hot alkali solution. The normalized relative percentage of the above four fractions in MCW was found to be 3.6:21.9:55.7:18.8 from outer layer to inner layer on the basis of the results in Table 1.

The cell wall structure of other mushroom fruiting bodies has not been studied in detail, but some cell wall polysaccharides have been derived and characterized.[35,36] A cold alkali-soluble polysaccharide has been purified from the fruiting body of *Laetiporus sulphureus* (Bull.: Fr.) Murr and was named latiglucan I, which was characterized to be a linear β-1,3-glucan (molecular weight = 1.8×10^5 Da) constituting 42.7% by weight of the fruiting body.[36] The structure of some polysaccharides obtained from the fruiting body of *Pleurotus* species other than PTR has also been investigated. For instance, the main MCW polysaccharides of the fruiting body of *P. ostreatus* and *P. eryngii* were branched β-1,3-/1,6-glucan and linear α-1,3-glucan, respectively.[6] Furthermore, the fruiting body of *P. florida* contained two different types of glucans: a water-soluble one consisting of a main chain of α-1,3-linked D-glucan partially substituted at *O*-3 and *O*-6 by β-D-glucose[37] and a water-insoluble β-1,3-/1,6-D-glucan.[38] The structure and degree of branching (DB) of MCW polysaccharide from PTR fruiting body therefore are unique as compared with those found previously in other *Pleurotus* species.

Despite the fact that mushroom cell wall is composed of a water-soluble fraction, an alkali-soluble fraction, and an alkali-insoluble fraction that are similar to the cell wall in lower fungi,

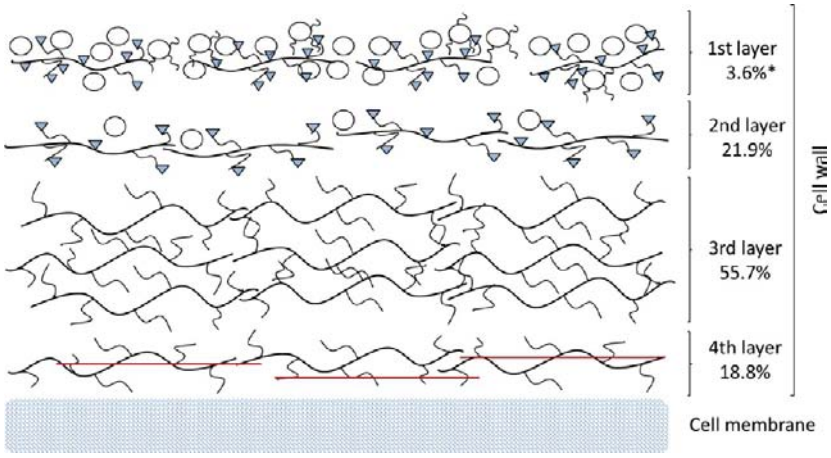

Figure 7. Proposed cell wall structure of PTR fruiting body. (*) The normalized relative percentage of individual cell wall fractions is not shown in an absolute scale. Symbol key: (open circles) protein; (open circles with "legs") glycoprotein; (lines with "legs") glucan; (red line) chitin; (blue triangles) other sugar residues (including mannose, galactose, and xylose).

dx.doi.org/10.1021/jf500112j | J. Agric. Food Chem. 2014, 62, 2891−2899

the structure of mushroom cell wall of PTR fruiting body is more complicated than and very different from the cell wall of lower fungi in terms of the chemical fine structure of the cell wall polysaccharides.[39−41] Such differences could mainly be found in the alkali-soluble fractions. This fraction has been characterized to be β-glucans in the cell wall of yeast and filamentous fungi, which is mainly composed of a long β-1,3 main chain or short β-1,6-linked side chains.[42−45] However, many more β-1,4 residues was found in the alkali-soluble fractions of MCW in PTR fruiting body. β-1,4-Glucose is commonly recognized as the sugar residue of structural polysaccharides of plant cell wall, such as cellulose.[46−48] More mannose, galactose, and xylose were found in the alkali-soluble cell wall polysaccharides from the fruiting body in PTR. Moreover, differing from the linear structure of β-glucans found in the cell wall of lower fungi, the alkali-soluble fractions from MCW of PTR fruiting body are mainly hyper-branched polymer with a relatively higher DB (52%) than that of lower fungal cell wall polysaccharides mainly composed of linear β-1,3-/1,4-glucan with 4% of β-1,6 branch points.[42] The innermost fraction of MCW is composed of glucan−chitin complexes, which account for only <20% by weight. The relative thickness of this fraction in MCW of PTR fruiting body is therefore thinner than that of lower fungi, which accounts for about 40% of their cell wall.[42]

In summary, the fruiting body of PTR has 47% MCW by dry weight, of which the main components (total 78% of MCW) are the alkali-soluble fractions (FCA and FHA), and this was in contrast with the cell wall of filamentous fungi and yeast. The major fraction of FCWM in PTR is hyper-branched β-1,4-glucans with 52% DB on the *O*-6 position as compared to the linear β-1,3-glucans with very few branches on the *O*-6 position found in the cell wall of lower fungi. These results provide some new insights in the study of the structural organization of fungal cell wall, especially for higher fungi. Mushroom fruiting body of PTR thus represents a potential source of novel dietary fiber with unique structural features that might have potential applications in the food industry. Furthermore, research on the biological functions and physiological activities of the fractionated cell wall components of FCWM from PTR is currently underway.

and baking. Additionally, changes in free amino acids were also determined during fermentation, especially to evaluate tryptophan consumption by yeasts.

MATERIALS AND METHODS

Chemicals and Consumables. Acetonitrile (HPLC grade), ethanol (HPLC grade), and melatonin (*N*-acetyl-5-methoxytryptamine) (>98%) were obtained from Sigma-Aldrich (Steinheim, Germany). Formic acid (98%) and high-purity (>98%) alanine (Ala), arginine (Arg), asparagine (Asn), aspartic acid (Asp), glutamic acid (Glu), glutamine (Gln), glycine (Gly), histidine (His), isoleucine (Ile), leucine (Leu), lysine (Lys), methionine (Met), phenylalanine (Phe), proline (Pro), serine (Ser), tryptophan (Trp), tyrosine (Tyr), valine (Val), and γ-aminobutyric acid (GABA) were purchased from Merck Co. (Darmstadt, Germany). Ultrapure water was used throughout the experiments (Milli Q-System, Millipore, Milford, MA, USA). Syringe filters (nylon, 0.45 μm) were purchased from Waters (Milford, MA). ZORBAX Rapid Resolution SB-C18 column (50 mm × 4.6 mm i.d., 3.5 μm) and SeQuant ZIC-HILIC column (150 mm × 4.6 mm i.d., 3.5 μm) were supplied by Agilent Technologies (Waldbronn, Germany) and Merck Co. (Darmstadt, Germany), respectively.

Preparation of Dough and Breads. All-purpose wheat flour (Söke Un, Turkey), sugar (Bal Küpü, Turkey), salt (Billur Tuz, Turkey), and instant baker's yeast (*Saccharomyces cerevisiae*) (Yuva, Turkey) for preparing breads were purchased from a local market. Breads were prepared using the AACC (American Association of Cereal Chemists) Method 10-10.03 (1983) with some modification.[16] 100 g of wheat flour, 38 mL of water, and 20 mL of yeast suspension composed of 5.3 g of instant yeast and 11 mL of sugar−salt solution containing 6 g of sugar and 1.5 g of salt were mixed with a mixer until dough development. After the dough was divided into equal pieces, the pieces were fermented at 30 °C for 0 (control), 30, 60, 90, 120, and 180 min. During fermentation, punching was carried out every 30 min. Before baking, a small piece of fermented dough was set apart and stored at −20 °C for melatonin and amino acid analysis. Following fermentation, the dough was baked in a temperature-controlled oven (Memmert Une 400, Germany) at 215 °C for 17 min.

Analysis of Melatonin and Melatonin Isomer. *Extraction.* Crumb and crust samples were ground with a grinder prior to analysis. Two grams of sample (dough, ground crumb, and ground crust) was extracted with ethanol in three stages (5−2.5−2.5 mL) by vortexing (3 min). After centrifugation (7500*g* for 5 min) in each stage, supernatants were collected in a test tube and evaporated to dryness under a gentle stream of nitrogen. The final residue was redissolved in 1 mL of ethanol−water (50:50, v/v). After centrifugation (13000*g*) supernatant was passed through a 0.45 μm syringe filter into an autosampler vial prior to LC−MS/MS analysis.

LC−ESI-MS/MS analysis. The analysis of melatonin and its isomer was carried out according to the method described previously.[14] Melatonin was determined by using an Agilent 1200 series HPLC system coupled to an Agilent 6460 triple quadrupole mass spectrometer (Waldbronn, Germany). The chromatographic separations were performed on a ZORBAX Rapid Resolution SB-C18 column (50 mm × 4.6 mm i.d., 3.5 μm) using a mixture of 0.1% formic acid in water and 0.1% formic acid in acetonitrile (65:35, v/v) at a flow rate of 0.5 mL/min at 40 °C. The injection volume was 5 μL. The electrospray source had the following settings: drying gas (N_2) flow of 10 L/min at 325 °C, nebulizer pressure of 30 psi, sheath gas (N_2) flow of 10 L/min at 375 °C, nozzle voltage of 1000 V, and positive capillary voltage of 4000 V. MS data were acquired in the positive mode, and melatonin was identified by multiple reaction monitoring (MRM). Fragmentor voltage of precursor ion was 80 V. The ion transitions for melatonin were determined as 233.2 → 174.2 (collision energy of 10 V) and 233.2 → 216.2 (collision energy of 4 V). A dwell time was set at 250 ms for each.

The 233.2 → 174.2 MRM transition was selected to quantitate melatonin. Concentration of melatonin was calculated by means of external calibration curves covering the range between 0.05 and 20 μg/L. Working solutions of melatonin were prepared in ethanol−water (50:50, v/v). Determination of the melatonin isomer was semi-quantitative, and its content was calculated from total ion chromatogram (sum of the area of the MRM transitions (233.2 → 174.2 and 233.2 → 216.2) of melatonin). The linearity was evaluated by plotting the peak area against the concentrations of melatonin standards. Limit of detection (LOD) and limit of quantitation (LOQ) were determined at a signal-to-noise ratio of 3 and 10, respectively.

Analysis of Free Amino Acids. *Extraction.* One gram of sample (dough, ground crumb, and ground crust) was extracted with water in three stages (10, 5, and 5 mL) by vortexing (3 min). After centrifugation (7500*g* for 5 min) in each stage, supernatants were collected in a test tube. Combined extract was diluted subsequent to centrifugation with a mixture of acetonitrile−water (50:50, v/v), and a part of the diluted extract was filtered through a 0.45 μm syringe filter into an autosampler vial prior to LC−MS/MS analysis.

LC−ESI-MS/MS Analysis. The analysis of free amino acids was carried out according to the method described previously.[17] An Agilent 1200 series HPLC system coupled to an Agilent 6460 triple quadrupole mass spectrometer (Waldbronn, Germany) was used. The chromatographic separations were performed on a SeQuant ZIC-HILIC column (150 mm × 4.6 mm i.d., 3.5 μm) using a gradient mixture of 0.1% formic acid in water (A) and 0.1% formic acid in acetonitrile (B) at flow rate of 0.75 mL/min at 40 °C. The eluent composition starting with 25% of A was linearly increased to 60% in 5 min and was held for 5 min. Then, it was linearly decreased to its initial conditions (25% of A) in 5 min. Electrospray ionization was operated in positive mode. The electrospray source had the following settings: drying gas (N_2) flow of 10 L/min at 325 °C, nebulizer pressure of 30 psi, sheath gas (N_2) flow of 10 L/min at 375 °C, nozzle voltage of 1000 V, and capillary voltage positive of 4000 V. Amino acids were identified by their specific MRM transitions, and the dwell time was 0.1 s for all. Concentration of amino acids was calculated by means of external calibration curves built for individual amino acids in a range between 0.1 and 5.0 mg/L.

Statistical Analysis. The results were reported as mean ± standard deviations. Significant differences ($p < 0.05$) were evaluated by Duncan test after the analysis of variance (ANOVA), by using SPSS 17.0 statistical package.

RESULTS AND DISCUSSION

Evaluation of Analytical Method. The chromatographic separation and ion transitions of melatonin and its isomer are given in Figure 2. Retention time, specific MRMs (233.2 → 174.2 and 233.2 → 216.2), and fragment ion ratios acquired from the standard compound were used to confirm the presence of melatonin in the samples. Figure 2A illustrates the chromatogram of 1 ng/mL melatonin standard for the MRM transitions of 233.2 → 174.2 (upper panel) and 233.2 → 216.2 (bottom panel). Since relative abundance of the fragment ion of 174.2 was higher than that of 216.2 for melatonin, the fragment ion of 174.2 was used for the quantitation of melatonin. The ratio of 174.2/216.2 for melatonin was found to be 14.2 ± 2.0.

The fragment ion 174.2 originates from the cleavage of amide substituent ($-NH_2COCH_3$) from main ion and 216.2 by OH removal. Although the melatonin isomer has the same fragment ions, their ratios were found to be quite different. The abundance of fragment ion 216.2 was much higher than that of 174.2 in the fragmentation pattern of the isomer. Diamantini et al.[18] indicated that 174.2 is the base peak for all isomers except where the substituent is bound to nitrogen of the pyrole ring. Therefore, the possible molecular structure of the melatonin isomer, **2**, was proposed as shown in Figure 1. However, the position of the methoxy group on the indole ring could not be determined by tandem mass spectrometry. The purification of the isomer is needed for the identification of exact molecular structure by using either NMR spectroscopy or X-ray

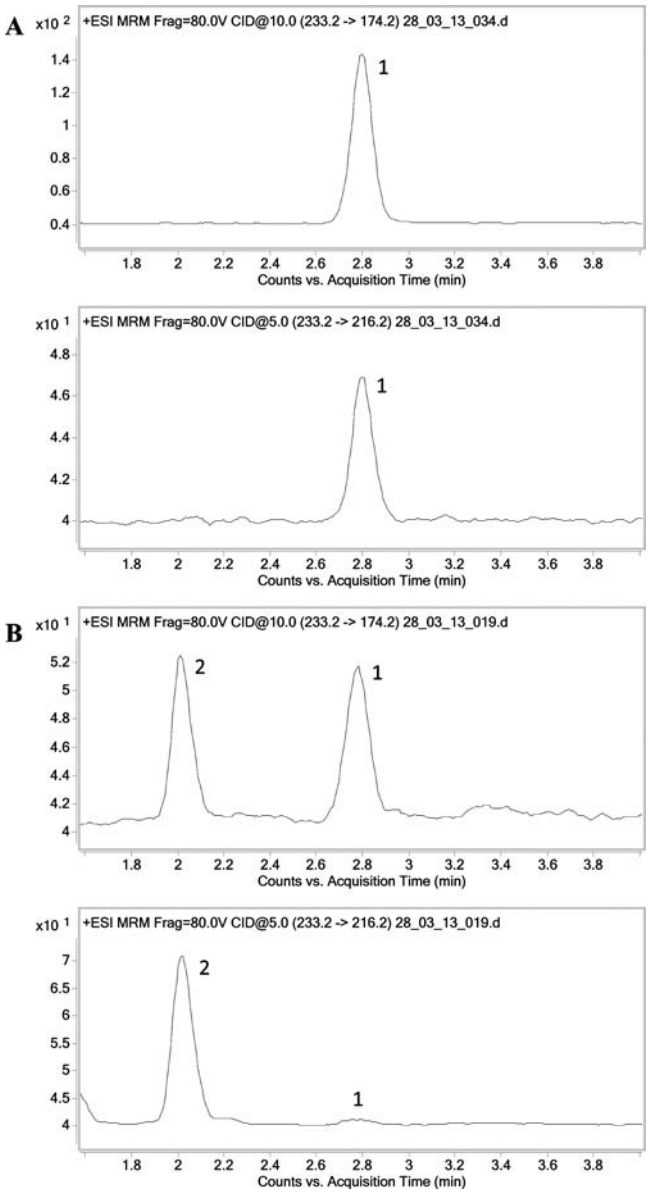

Figure 2. LC–MS/MS chromatograms for (A) 1.0 ng/mL melatonin standard, (B) bread crumb (nonfermented). Upper panel illustrates the MRM of 233.2 → 174.2, and lower panel illustrates the MRM of 233.2 → 216.2 (1, melatonin; 2, melatonin isomer).

diffraction spectroscopy. Other investigators have also observed similar fragmentation patterns.[12,19] Vitalini et al.[11] used MS/MS and Orbitrap MS with a collision cell, but they did not mention the 233.2 → 216.2 transition for the detection of melatonin and its isomer.

Figure 2B illustrates the chromatogram of bread crumb prepared from nonfermented dough for the MRM transitions of 233.2 → 174.2 (upper panel) and 233.2 → 216.2 (bottom panel). As shown in Figure 2B, bread crumb contained melatonin isomer having relatively shorter retention time (2.1 min) than melatonin (2.8 min). Differently from melatonin, relative abundance of the fragment ion of 216.2 was higher than that of 174.2 and the ratio of 216.2/174.2 for melatonin isomer was found to be 2.9 ± 0.2. Since there was no standard compound found for the melatonin isomer, it was specifically distinguished from melatonin by retention time and fragment ion ratio. For quantitation of melatonin isomer, calibration curve of melatonin was used. Although the abundant ion of 216.2 is suitable for the quantitation of the isomer, its abundance in fragmentation of melatonin itself was very low, i.e., the transition ratio of 233.2/216.2 is quite different as mentioned. Thus, sum of the ions of 174.2 and 216.2 was used for calibration and quantitation of the isomer in the samples as reported previously.[14]

An external calibration was built for 0.05–20 ng/mL with melatonin standard, and a good linearity was obtained for the fragment ion 174.2 and for the sum of both fragments. Linearity equations of $y = 595.1x + 68.3$ and $y = 629.5x + 54.1$ and good correlation coefficients (R^2 = 0.9998 and 0.9997, respectively) were obtained in both quantitations. LOD values of melatonin were 0.03, 0.05, and 0.03 ng/g and LOQ values of melatonin were 0.10, 0.18, and 0.09 ng/g for dough, bread crumb, and bread crust samples respectively.

Formation of Melatonin. Figure 3A illustrates the effect of fermentation time on melatonin in bread dough. According to

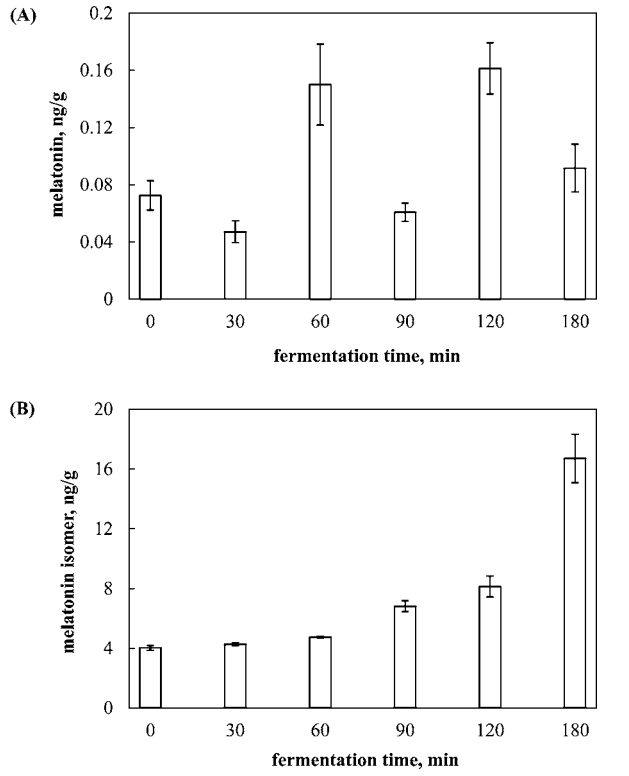

Figure 3. Change of the concentrations of (A) melatonin and (B) melatonin isomer in bread dough during fermentation (on dry matter basis).

results, nonfermented dough was found to contain 0.07 ng/g melatonin. At the end of the 30, 60, 90, 120, and 180 min of fermentation, 0.05 (<LOQ), 0.15, 0.06 (<LOQ), 0.16, and 0.09 (<LOQ) ng/g melatonin was detected, respectively. There was no trend in melatonin concentration as a result of dough fermentation. Melatonin concentrations ranged between 0.19 and 0.63 ng/g and between 0.14 and 0.82 ng/g for crumb and crust parts, respectively. Favorable conditions attained during certain stages of baking could be the reason for the occurrence of melatonin at higher concentrations in crumb than dough. The results suggested that *Saccharomyces cerevisiae* was ineffective in changing melatonin concentration during bread dough fermentation. However, some authors have previously

reported that melatonin concentration was increased by anaerobic activity of yeasts. Rodriguez-Naranjo et al.[9] reported that, although melatonin is absent in grape and musts, it is synthesized during the wine fermentation process. According to the results reported by Garcia-Moreno et al.,[10] a second fermentation step caused melatonin formation in beer. Rodriguez-Naranjo et al.[13] also reported that the synthesis of melatonin largely depends on the growth phase of the yeast. It should be mentioned that bread dough fermentation is mainly an aerobic process unlike the fermentation of beer and wine.

Formation of Melatonin Isomer. The melatonin isomer content of nonfermented dough was estimated to be 4.02 ng/g (Figure 3B). The initial concentration might come from both the yeast culture and the flour since flour has also a natural microbial load. The concentration of isomer in dough increased up to 16.71 ng/g during fermentation. At the beginning its concentration was slightly increased; however, this change was not significant in 30 and 60 min fermented dough samples ($p > 0.05$). Similar trends were also observed for almost all amino acids. This might be because of the limited activity of yeasts in the early stages of dough fermentation. Instant baker's yeast requires some time to revive and adapt to a new environment to show maximum activity. After 60 min of fermentation an apparent increase was observed in melatonin isomer concentration. Gomez et al.[12] also reported that concentration of isomer increased during a laboratory scale wine making process and in an aqueous medium containing yeast and nutrients.

Effect of Baking on Melatonin Isomer. Compared to their corresponding dough, both the crumb and crust parts of breads baked at 215 °C for 17 min contained significantly lower amounts of melatonin isomer (Figure 4). This indicated that

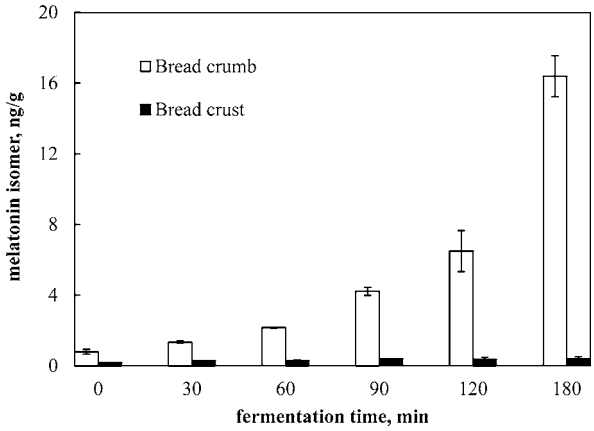

Figure 4. Effect of baking on the resulting concentration of melatonin isomer in crust and crumb for different fermentation times of bread dough (on dry matter basis).

melatonin isomer is not stable at elevated temperatures attained during baking of bread. In the crust part, approximately 95% of melatonin isomer was degraded during baking. On the other hand, a different degradation trend was observed in the crumb samples. As the fermentation time increased, the degree of degradation was found to be decreasing. This must be due to the accumulation of CO_2 and ethanol leading to a spongelike texture in oven spring, which limits the heat transfer into the loaf during baking. The degradation was 80, 69, 54, and 38% in the crumb samples fermented for 0, 30, 60, and 90 min. Also, no significant degradation was observed in the samples of 120 and 180 min fermented dough after baking ($p > 0.05$).

Consumption of Free Amino Acids. Free amino acids are important growth factors for fermentative microorganisms.[20] They utilize tryptophan as the source of nitrogen and yield metabolites such as indolacetic acid, tryptophol, or biogenic amines.[21] Changes in the concentrations of 18 proteinogenic free amino acids and γ-aminobutyric acid (GABA) are given in Table 1. At the beginning the rate of utilization was limited and a significant decrease was observed usually after 60 min of fermentation. At the end of the 180 min, fermentation resulted in a considerable reduction (approximately 50%) in the total free amino acid content of dough. It was shown that the consumption of total amino acids followed first order kinetics ($r^2 = 0.94$, $k = 0.0037$ 1/min, see Supporting Information). In the dough after 180 min of fermentation the highest rates of reduction were observed in Asn and Glu (82% and 76%, respectively). Meanwhile no statistically significant ($p > 0.05$) reduction was observed in Gly, Lys, and Pro. It was previously reported that the more preferred nitrogen sources for yeasts are Gln and Asn whereas Pro is qualified as a poor nitrogen source.[22,23] In contrast to the other amino acids, GABA concentration increased during fermentation. The increased amount of GABA is found mainly in fermented foods, and it is formed from Glu by the enzyme glutamate decarboxylase.[24] The initial concentration in dough might be due to the activities of natural microflora and the endogenous enzymes of flour.

The decrease in the concentration of tryptophan followed first order kinetics ($r^2 = 0.97$, $k = 0.0043$ 1/min, see Supporting Information). Trp concentration decreased by a ratio of 58% during 180 min of fermentation. Although Trp is the precursor of melatonin, it is unknown whether melatonin isomer is synthesized via tryptophan or not. Sprenger et al.[25] found that melatonin appears more quickly when there is a precursor (Trp, serotonin, or *N*-acetylserotonin) in the growth medium. Rodriguez-Naranjo et al.[13] reported that melatonin did not form at all when it was absent from synthetic grape must medium. Contrastingly, in a previous study, there were no significant differences in the melatonin content between red wine samples in which Trp was added and not added.[9] Gomez et al.[12] also reported that the production of melatonin and its isomer during the process of wine fermentation is independent of external Trp. Reduction of Trp content during dough fermentation could be attributed to the fact that Trp might be utilized by yeast to synthesize melatonin and melatonin isomer with its enzyme system.

Effect of Baking on Free Amino Acids. Figure 5 illustrates the effect of baking on total free amino acids and tryptophan contents of bread fermented for 120 min. In the baking process (215 °C for 17 min), loss of amino acids was most likely to occur in the crust part as a result of the Maillard reaction. With regard to dough, 71% of total amino acids and 46% of Trp were lost in the crumb part during baking. The loss increased to 89% for total amino acids and 89% for Trp in the crust part (Figure 5). It was previously reported that Trp degradation in cookie model systems was temperature and time dependent.[26] Considering a possible effect of Trp rich food intake on melatonin and its isomer synthesis, the reducing effect of baking should be taken into consideration.

The results revealed for the first time the formation of melatonin isomer in bread dough during yeast fermentation. Its quantities formed in dough were significantly higher than those of melatonin itself. The formation rate of melatonin isomer and the degradation rate of Trp were compatible with each other.

Table 1. Concentration of Free Amino Acids (μg/g) in Dough during Fermentation[a]

	fermentation time, min

[a]Values followed by different spaced letters are significantly different within each row ($p < 0.05$). Concentrations were given on dry matter basis.

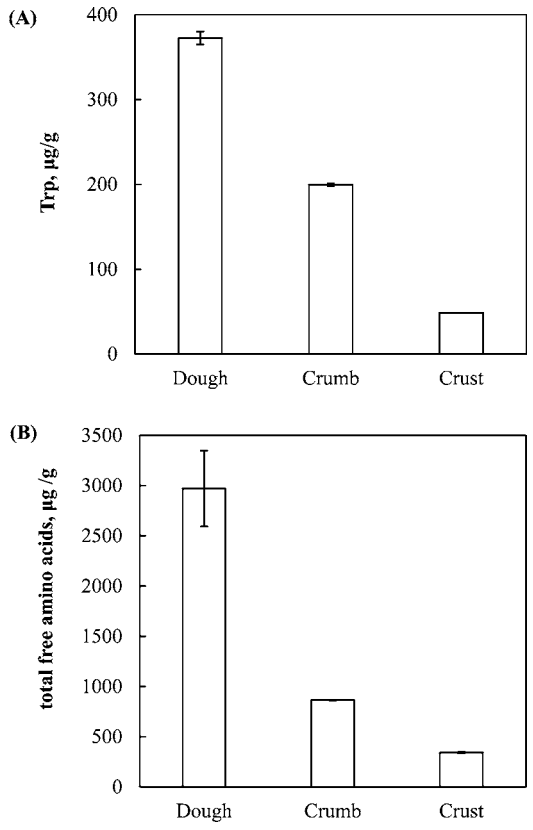

Figure 5. Baking effect on (A) tryptophan and (B) total free amino acid content of breads fermented for 120 min (on dry matter basis).

This indicated a potential role of Trp in the formation mechanism during yeast fermentation. At extreme conditions applied during baking, concentration of melatonin isomer significantly decreased in bread. Comparing to crumb, this effect was more pronounced in the crust part expectedly, in which higher temperatures were attained during the process. It is a fact that the degradation products of melatonin and its isomer are unknown, but this needs further clarification. Primarily, the precise structure of the melatonin isomer needs to be revealed. Since bread as a yeast leavened staple food appears as the major source of melatonin isomer, its biological consequences should be investigated in depth.

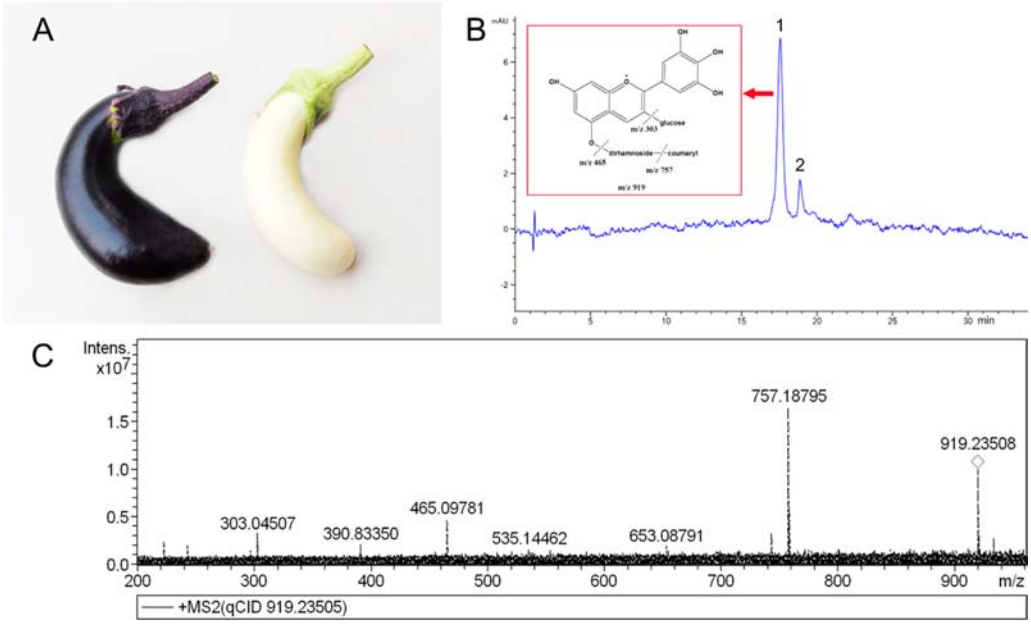

Figure 1. Anthocyanin component analysis in the fruit of eggplant. (A) Photographs of the two eggplant cultivars (Zi Chang on the left and Bai Xue on the right) used in this study. (B) HPLC profiles of anthocyanins in Zi Chang skin. Peak numbers refer to the anthocyanins listed in Table 1. Structures and major cleavage of delphinidin-3-glucoside-5-(coumaryl)dirhamnoside in reference to peak 1 is framed in the red box. (C) LC-MS/MS ion graphs of the major anthocyanin delphinidin-3-glucoside-5-(coumaryl)dirhamnoside (*m/z* 919.2, 757.2, 465.1, 303.0 ($[M + H]^+$)) from the Zi Chang cultivar.

On the basis of the extensive studies reported, it is obvious that the increased expression of some structural genes is directly associated with enhanced levels of anthocyanin accumulation.[14,15] Moreover, transcriptional activation of anthocyanin biosynthesis-related transcription factors always accounts for tissue specific upregulation of structural genes in nature conditions.[16,17] Numbers of regulatory genes including R2R3MYB transcription factors, basic helix−loop−helix (bHLH) transcription factors, MADS transcriptional factors, and WD40 proteins have been cloned from many plants, such as *Arabidopsis*, potato, petunia, and other species.[18] In addition, the two major families of anthocyanin biosynthesis-related regulatory proteins, R2R3MYB and bHLH transcription factors, are found to form regulatory complexes with WD40 proteins in regulating the expression of structural genes.[19,20] Therefore, expression analysis of anthocyanin structural genes and associated transcriptional factors should be helpful for the explanation of tissue specific pigment accumulation in eggplant fruit skin.

In this article, the purple cultivar Zi Chang and the control cultivars Bai Xue that has no pigment accumulation in the fruit were used for this study (Figure1A). Anthocyanin production in eggplant was analyzed by high-performance liquid chromatography−electrospray ionization tandem mass spectrometry (HPLC-ESI-MS/MS). To investigate the molecular mechanism of anthocyanin biosynthesis, the dynamic transcriptional levels of anthocyanin structural genes and regulatory transcriptional factors were analyzed by quantitative real-time reverse transcription polymerase chain reaction (qRT-PCR) in the fruit skin and the flesh in these two cultivars. Then, the tissue specific expression gene *SmMYB1* was transformed into wild eggplant under the drive of the 35s promoter. In the regenerating shoots with abundant anthocyanin accumulation, we examined the expression level of *SmMYB1* and some vital structural genes of the anthocyanin biosynthetic pathway. This work expanded our knowledge about anthocyanin accumulation and the underlying molecular mechanism in eggplant. It will be helpful for the breeding of high anthocyanin content eggplant cultivars in both traditional breeding and genetic engineering.

MATERIALS AND METHODS

Plant Materials. Eggplant (*S. melongena* L.) seeds of the white cultivar (Bai Xue) and the purple cultivar (Zi Chang) were obtained from Chongqing Academy of Agriculture Sciences. The seeds were sown directly into soil and grown in a greenhouse with a 16 h photoperiod at 28 °C. The fruits of eggplant were harvested at 12−15 days after anthesis. Both the skin and the flesh of Bai Xue are white. Zi Chang has purple pigment accumulated in the skin but not in the flesh (Figure 1A). The fruit skins of the two cultivars were manually peeled in the thickness of about 2 mm. The fruit flesh was cut into tiny cubes. All the samples were frozen in liquid nitrogen and stored at −80 °C for RNA extraction and other analyses.

RNA Extraction and qRT-PCR Analysis. The skin and flesh samples of the two cultivars were grounded into powder in liquid nitrogen. Total RNA was isolated from various tissues for three biological repeats using RNAiso reagent according to the manufacturer's instruction (Takara, Dalian, PRC). RNA samples (1 μg) were reverse transcripted into complementary DNA (cDNA) with an oligo(dT)20 primer and M-MLV reverse transcriptase (Promega, Madison, WI) following the manufacturer's protocol. The synthesized cDNAs were diluted five times in H_2O for qRT-PCR analysis.

qRT-PCR was carried out using the CFX96 Real-Time System (C1000 thermal cycler). All reactions were performed using the GoTaq qPCR Master Mix according to the manufacturer's instructions. Reactions were performed in triplicate using 5 μL of Master Mix, 0.25 μM each primer, 1 μL of diluted cDNA, and DNase-free water to a final volume of 10 μL. The PCR amplification was as follows: 1 cycle of 3 min at 95 °C, 40 cycles of denaturation for 15 s at 95 °C, annealing for 30 s at 60 °C, and elongation for 15 s at 72 °C. Amplification was followed by a melting curve analysis with continual fluorescence data acquisition during the 60−95 °C melt. Melt curve analysis of qPCR samples revealed that there was only one product for

dx.doi.org/10.1021/jf404574c | J. Agric. Food Chem. 2014, 62, 2906−2912

each gene primer reaction. The primers used for qPCR analysis were designed by Primer Premier 5 and are listed in Supplementary Table 1 (Supporting Information). The PCR products were sequenced to confirm the specific amplifications. The gene expression was normalized to *SmGAPDH* as a reference gene. Values reported here were calculated from three biological repeats for each sample.

Gene Cloning and Sequence Analysis. The full-length coding sequence of anthocyanin biosynthesis-related transcription factors were cloned from eggplant by RT-PCR with degenerate primers and finally named *SmMYB1*, *SmMYB2*, *SmAN11*, *SmbHLH1*, and *SmMADS1*, respectively, referring to the corresponding genes from tomato and potato. Sequence similarities were calculated with DNAMAN version 5.2.2. The phylogenetic and molecular evolutionary analysis was used with MEGA (Molecular Evolutionary Genetics Analysis) version 3.1.

Chemicals. Anthocyanin (delphinidin 3-rutinoside chloride) for external standards was purchased from Phytolab (Germany). HPLC-grade formic acid and methanol (MeOH) were bought from Sigma. All the other solvents were provided from Aldrich (St. Louis, MO).

Anthocyanin Extraction and HPLC-ESI-MS/MS Analysis. Anthocyanin extraction of eggplant was carried out as the same way as for radish.[21] The extract was filtered through a 0.2 μm PTFE syringe filter. The samples were then analyzed by an Agilent Technologies 1200 Series HPLC (Agilent Technologies, Palo Alto, CA), equipped with an Agilent 1200 HPLC variable wavelength detector. The results were analyzed by Agilent 1200 HPLC ChemStation software. The chromatographic separation was performed on a Zorbax Stablebond Analytical SB-C18 column (4.6 mm × 250 mm, 5 μm, Agilent Technologies, Rising Sun, MD). The injection sling was 10 μL. Elution was performed using mobile phase A (aqueous 5% formic acid solution) and mobile phase B (methanol). The detection was at 520 nm, and the column oven temperature was set at 40 °C. The flow rate was 1 mL/min. The gradient program is described as follows: 0−5 min, 10−20% B; 5−10 min, 20−30% B; 10−15 min, 30−40% B; 15−25 min, 40% B; 25−30 min, 40−60% B; 31−32 min, 90% B; 32−35 min, 10% B. Quantification of the different anthocyanins was based on peak areas and calculated as equivalents of the standard compounds. All contents were expressed as milligrams per grams of dry weight. Low-resolution electrospray mass spectrometry was performed with a solariX ion trap mass spectrometer (Bruker Daltoniks, Billerica, MA). The experimental conditions were as follows: ESI interface, nebulizer, 50 psi; dry gas, 15.0 psi; dry temperature, 320 °C; MS/MS, scan from m/z 200 to 2000; ion trap, scan from m/z 200 to 2000; source accumulation, 50 ms; ion accumulation time, 300 ms; flight time to acq. cell, 1 ms; smart parameter setting (SPS), compound stability, 50%; trap drive level, 60%.

Total Anthocyanin Analysis. Spectrophotometric differential pH method was used for the measurement of total anthocyanins. The protocols are described as follows. Frozen samples (100 mg) were crushed into powder in liquid nitrogen and then extracted separately with 2 mL of pH 1.0 buffer and 2 mL of pH 4.5 buffer. In addition, pH 1.0 buffer contains 50 mM KCl and 150 mM HCl, while pH 4.5 buffer contains 400 mM sodium acetate and 240 mM HCl. The mixtures were centrifuged at 14 000*g* for 10 min at 4 °C. The supernatants were gathered for measurement of absorbance at 510 nm. The amount of total anthocyanin was calculated according to the equation which follows:

$$\text{amount } (\text{mg g}^{-1}\text{ FW}) = (\text{A1} - \text{A2}) \times 484.8/24.825 \times \text{dilution factor}$$

A1 represents the absorbance of supernatants gathered from pH 1.0 buffer solution at 510 nm while A2 represents the other. The value 484.8 represents the molecular mass of cyaniding-3-glucoside chloride, while 24 825 reflects its molar absorptivity at 510 nm. The total anthocyanins of sample were analyzed in triplicate.

Vector Construction and Transformation of Eggplant. The complement DNA was synthesized with total RNA with M-MLV (Promega, Madison, WI) as the recommendation of manufacturer. The full-length coding sequence of *SmMYB1* was cloned into pBI121 for the replacement of GUS. Primers used for amplification of *SmMYB1* are SmMYB1-con-F, GCGATCTAGAAATAAAATGAATAATCCTCC, and SmMYB1-con-R, GACTGAGCTCCGAAAACAGACAATATTACTA. The binary vector pBI121-SmMYB1 containing the *SmMYB1* cDNA driven by the 35S promoter was transferred into *Agrobacterium tumefaciens* strain LBA4404 by the freeze−thaw method. Eggplant (*S. melongena*) 'Bai Xue' was used for the generation of transgenic callus by Agrobacterium-mediated transformation, using the protocol previously reported.[22]

RESULTS AND DISCUSSION

Identification and Quantitative Analyses of Anthocyanins. By analyzing the extracts from the fruit of Zi Chang and Bai Xue cultivar with LC-MS/MS, two kinds of anthocyanins were separated and identified (Table 1 and Figure1B,C). Then, the MS/MS (m/z) fragmentation pattern was applied to verify the identity of anthocyanins in purple fruit skin with the information provided by earlier reports.[12] These results show that delphinidin may be the unique aglycone present in all eggplant fruits.[10−12] However, the major component of anthocyanin in Zi Chang cultivar is delphinidin-3-glucoside-5-(coumaryl)dirhamnoside, which is apparently different from the anthocyanins identified in other cultivars. These results show that the purple eggplant cultivars reported up to now share the same pattern of anthocyanidin biosynthesis but with different modification patterns. The total anthocyanins content from Zi Chang skin was found to be 1.24 mg/g of dry weight. (Table 2). The content of major identity delphinidin-3-glucoside-5-(coumaryl)dirhamnoside is 1.10 mg/g, while the minor identity is only 0.14 mg/g. So, eggplant should be classified in the food category containing simple anthocyanins in contrast with cabbage and radish.[12,14,21] Consequently, it is the major anthocyanin delphinidin-3-glucoside-5-(coumaryl)-dirhamnoside that contributes to the purple color in fruit skin principally.

Table 1. Anthocyanins Identified in the Eggplant Zi Chang Skin

no.[a]	RT[b] (min)	$[M + M]^+$ (m/z)	MS/MS (m/z)	anthocyanin

Institute for Genomic Research, our research focused on the cloning of regulatory gene sequences with primers designed according to conserved sequences from other species. Then, the full-length coding sequences of a bHLH transcriptional factor (*SmbHLH1*), a MADS transcriptional factor (*SmMADS1*), two R2R3MYB transcriptional factors (*SmMYB1* and *SmMYB2*), and a WD40 protein (*SmAN11*) are obtained. The gene identities were further verified by sequence alignment with orthologous sequences from other plants. The results of sequence alignment show that the orthologous genes from different eggplant cultivars share the same predicted protein sequence in spite of some inconsistencies in the nucleotide sequence. Then, it is reasonable to speculate that the accumulation of anthocyanins in purple eggplant may be the result of the alternation in expression level of some transcription factors.

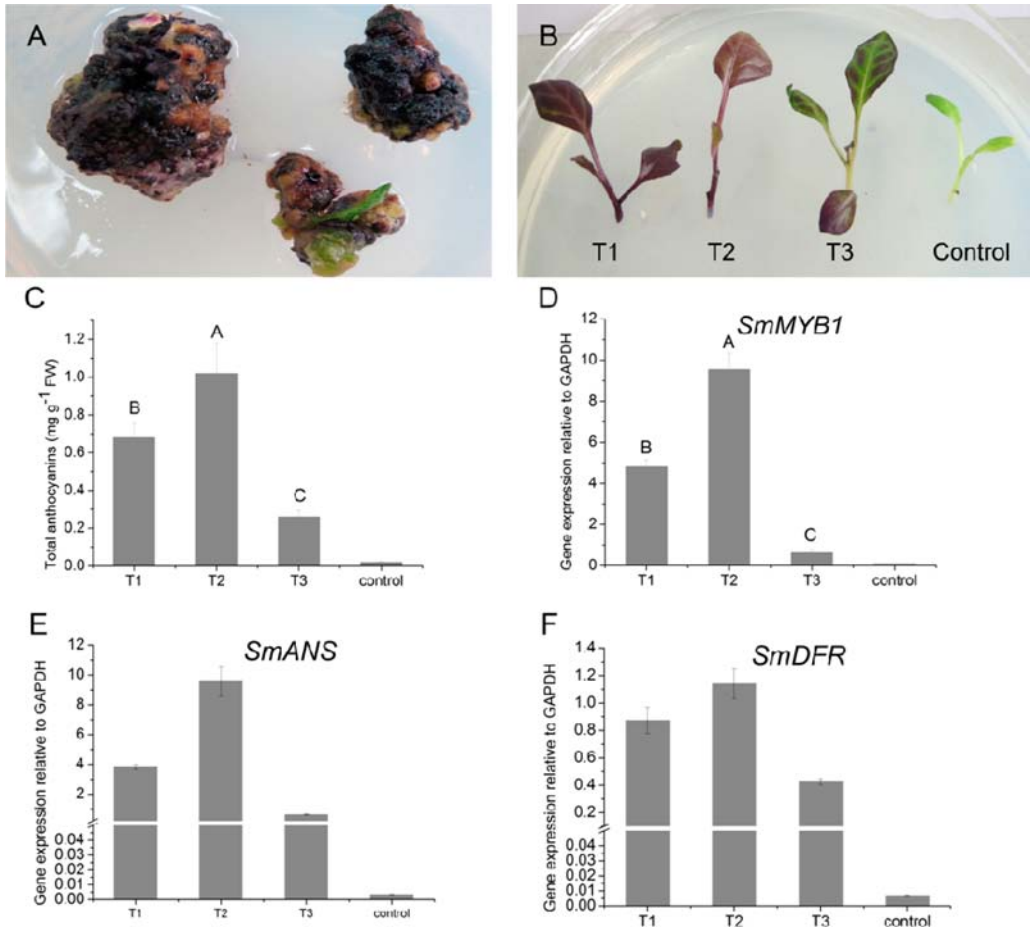

Figure 4. Overexpression of SmMYB1 in eggplant elevates the expression levels of structure genes and anthocyanin production. (A) Pigmented callus transformed with 35S-SmMYB1. (B) Three independent regenerating shoot lines transformed with 35S-SmMYB1 with one regenerating shoot transformed with empty vector. (C) Anthocyanin content in different lines of shoot. (D) transcriptional analysis of SmMYB1 in different regeneration shoots. (E, F) transcriptional analysis of anthocyanin biosynthesis genes SmANS (E) and SmDFR (F) in different regeneration shoots.

Expression Analysis of Anthocyanin Biosynthetic Genes in the Skin and Flesh of Different Eggplant Cultivars. For the purpose of investigating the molecular mechanisms underlying anthocyanin biosynthesis in eggplant, the transcriptional level of anthocyanin synthetic genes including *SmPAL*, *SmCHS*, *SmCHI*, *SmF3H*, *SmF3′5′H*, *SmDFR*, *SmANS*, and *Sm3GT* were examined in the skin and the flesh from two eggplant cultivars (Figure 2). The expression levels of all these genes except *SmPAL* are dramatically upregulated in the Zi Chang fruit skin compared with the other three tissues. Especially, the expression levels of *SmF3′5′H*, *SmDFR*, *SmANS*, and *Sm3GT* are upregulated to at least 1000 fold in the purple fruit skin. From the results reported previously,[23,24] the phenomenon that small amounts of transcripts of all the structural genes were always detected in the green cultivars with no visible anthocyanin pigmentation was apparently observed. Here, we speculate that sufficient transcripts of some structural genes are essential for a large amount of anthocyanin production in the fruit skin of the Zi Chang cultivar.

Expression Analysis of Anthocyanin Biosynthesis-Associated Regulatory Genes in the Skin and the Flesh of Different Eggplant Cultivars. According to recent research, anthocyanin structural genes are regulated by a complex composed of MYB, bHLH, and WD40 proteins from three different families of transcriptional factors.[18] MYB and bHLH transcription factors play essential roles in activating anthocyanin biosynthetic genes among various plant species, while WD40 proteins play a critical role in the process of complex formation. In addition, the transcriptional factor of MADS family is also found to be involved in anthocyanin accumulation in sweet potato.[25] Therefore, expression analysis of anthocyanin biosynthesis-associated regulatory genes provides critical information to reveal the molecular mechanisms of pigment accumulation in eggplant fruit skin. The expression level analyses of *SmMYB1*, *SmMYB2*, *SmbHLH1*, *SmAN11*, and *SmMADS1* are shown in Figure 3. The R2R3MYB gene *SlANT1* was identified from tomato as a transcriptional regulator of anthocyanin biosynthesis, modification, and transport.[26] Hence, two MYB genes were cloned and designated as *SmMYB1* and *SmMYB2* because of high similarity with *SlANT1*. Sequence analysis of SmMYB1 reveals that the predicted protein contains a R2R3 DNA binding domain that is involved in the interaction with bHLH cofactor (Supplementary Figure 1, Supporting Information). *SmMYB1* was the only transcription factor that was significantly upregulated in the fruit skin of the Zi Chang cultivar. The enhanced expression of the MYB gene in certain tissue was in accordance with the anthocyanin distribution pattern of the two cultivars. These results indicate that SmMYB1 may play a major role in the anthocyanin biosynthesis regulation. It is worth mentioning that SmMYB2 is unlikely necessary for the anthocyanin

biosynthesis in purple eggplant for the reason that the transcripts of *SmMYB2* are little to detect by qPCR. The expression analyses of *SmbHLH1* and *SmAN11* in the different cultivars show that these two genes are not accounted for the transcriptional activation of anthocyanin structural genes in purple eggplant. Furthermore, *SlTDR4*, which is the orthologous gene of *SmMADS1*, was proved to be an important switch that regulates the process of fruit ripening in an ethylene-independent manner including the accumulation of pigments.[27] However, the transcripts of *SmMADS1* in fruit skin in contrast with flesh indicate that the pathway of anthocyanin biosynthesis is probably independent of *SmMADS1*.

Overexpression of SmMYB1 in Transgenic Eggplant. Phylogenetic analysis shows that SmMYB1 lays in the same cluster with the anthocyanin synthesis activator SlANT1 and CaMYB1 (Supplementary Figure 1, Supporting Information). To further study the function of the *SmMYB1* gene, the full-length coding sequence of *SmMYB1* driven by the 35S promoter was overexpressed in the callus of eggplant. Compared with the kanamycin resistant callus transformed by the empty vector, there were large amounts of anthocyanin accumulation on the surface of kanamycin resistant callus transformed by the vector containing the *SmMYB1* gene (Figure 4A). Overexpression of the *SmMYB1* gene resulted in the high level of anthocyanin accumulation in purple regeneration shoots (Figure 4B,C). Furthermore, the expression of *SmMYB1* and two key anthocyanin biosynthesis genes in regenerating shoots was confirmed by qRT-PCR (Figure 4D−F). The enhanced expression of SmMYB1 was in accordance with a coordinated increase in transcript levels of SmANS and SmDFR. In addition, the enhanced expression of SmMYB1 was also in accordance with the total anthocyanin content in regenerative shoots. These results demonstrate that overexpression of SmMYB1 is able to activate anthocyanin biosynthesis by the way of significantly raising the expression level of anthocyanin structural genes.

In this study, delphinidin-3-glucoside-5-(coumaryl)-dirhamnoside was identified as the major anthocyanin in Chinese purple eggplant cultivar Zi Chang. In contrast to the control, SmF3′5′H that mainly catalyzes the hydroxylation at the 3′- and 5′-position of the B ring is dramatically upregulated at the transcript level.[28] Therefore, delphinidin should be the unique aglycone in the purple eggplant skin despite a lack of MS/MS (m/z) data of peak 2. Furthermore, the substantially upregulation of most of anthocyanin structural genes provides a reasonable explanation for large amounts of pigmentation accumulation in Zi Chang fruit skin. By expression analysis of flavonoid biosynthetic regulatory genes, *SmMYB1* is found to be significantly upregulated in the tissue where considerable pigments accumulate. Similarity and phylogenetic analysis of SmMYB1 with other MYBs from various species suggests that SmMYB1 might participate in the activating of anthocyanin biosynthesis in eggplant.[29,30] Moreover, the pigments displayed in the kanamycin resistant callus and regenerating shoots confirmed the hypothesis proposed above. Besides, the total anthocyanins content of other tissues in Zi Chang cultivar was measured by the spectrophotometric differential pH method (Supplementary Figure 3, Supporting Information). The distribution pattern of anthocyanin content agrees well with the expression level of *SmMYB1* in the tissues above (Supplementary Figure 4, Supporting Information). Therefore, all of these results prove that SmMYB1 plays an important role in activating anthocyanin biosynthesis in Zi Chang fruit skin by transcriptional activation of anthocyanin structural genes.

Owing to the great benefits anthocyanins bring to human health, foods rich in anthocyanins are attracting more and more attention from the public gradually. Since eggplant is an important food crop world widely cultivated, the consumption of high anthocyanin-containing fruit in the diet will raise the intake of health-promoting phytonutrients undoubtedly. Unfortunately, the existing cultivars of eggplant only have purple pigments accumulated in the skin but not in the flesh. Although we can elevate the anthocyanin content of eggplant fruit by overexpression of exogenous genes like tomato, the potential risks still exist.[6] Hence, an intragenic approach that improves the agricultural traits of the crop by modifying the genome of the plant provides us a new method to elevate the anthocyanin content of eggplant fruit.[31] However, the isolation of anthocyanin biosynthesis activator gene *SmMYB1* made an important progress toward the breeding of high anthocyanin-containing eggplant with little potential risk.[32] In summary, this work not only promotes our understanding of the molecular mechanisms underlying anthocyanin biosynthesis in eggplant but also provides a candidate gene for the development of eggplant cultivar that is rich of anthocyanins.

TatA complex is then recruited to form a pore through which substrates are translocated.[19] *E. coli* usually does not secrete Tat substrates into the growth medium because of the presence of the outer membrane.

The *Bacillus subtilis* Tat machinery lacks TatB and consists of three TatA (namely, TatAd, TatAy, and TatAc) and two TatC (TatCd and TatCy).[20] The TatA and TatC proteins form two active Tat translocation complexes, TatAdCd and TatAyCy, which display different substrate specificities.[21] Recently, a working model has been proposed for *B. subtilis*, in which the TatA protein has a dual function, because it can complement for the absence of both TatA and TatB in *E. coli*.[22] Moreover, Tat pathway specificity in *B. subtilis* is determined by twin-arginine signal peptide interactions with TatCd or TatCy.[21] In *B. subtilis*, Tat substrates can be secreted directly into culture media because of the absence of an outer membrane.

In a previous study, the twin-arginine signal peptide of TorA from *E. coli* directed secretion of MPH via the *B. subtilis* Tat pathway into the culture medium.[23] In this study, the MPH secretion directed by the *B. subtilis* YwbN signal peptide was achieved, leading to 1.8-fold improvement in extracellular MPH activity compared to the activity achieved with the TorA signal peptide. Furthermore, we demonstrated that the MPH secretion was specifically mediated by the TatAyCy system.

MATERIALS AND METHODS

Strains, Plasmids, Primers, and Culture Conditions. The strains, plasmids, and primers used in this study are listed in Table 1. *E. coli* DH5α was used for construction of recombinant plasmids. *B. subtilis* 168 was used for expressing recombinant MPH. All strains were grown at 37 °C in Luria–Bertani (LB) medium.[24] If necessary, media were supplemented with ampicillin (Ap; 100 μg/mL), tetracycline (Tc; 15 μg/mL), erythromycin (Em; 5 μg/mL), spectinomycin (Sp; 100 μg/mL), or kanamycin (Km; 10 μg/mL). When the *B. subtilis* culture reached an OD_{600} of 0.6, 0.5% xylose was added to induce protein expression for 24 h at 37 °C.

Construction of Recombinant *B. subtilis* 168. The nucleotide sequence encoding the twin-arginine signal peptide of *B. subtilis* YwbN was amplified from *B. subtilis* 168 chromosomal DNA[25] using primers P1 and P2, digested with *Eco*RI/*Pst*I and ligated into *Eco*RI/*Pst*I digested pUC18 to generate pUY18. The *mpd* gene was amplified from *Stenotrophomonas* sp. YC-1 chromosomal DNA[9] using primers P3 and P4, digested with *Pst*I/*Hin*dIII, and ligated into *Pst*I/*Hin*dIII-digested pUY18 to generate pUYM18. The *ywbN–mpd* fusion gene was amplified from pUYM18 using primers P5 and P6, digested with *Kpn*I/*Sph*I, and subcloned into *Kpn*I/*Sph*I-digested pWH1520,[26] an *E. coli–B. subtilis* shuttle vector, to create pWYM20. All plasmid constructions were verified by DNA sequence analysis. Transformation of plasmid into *B. subtilis* 168 was carried out according to the method by Sadaie and Kada.[27]

Western Blot Analysis. Cells were resuspended in lysis buffer with 5 mg/mL lysozyme, incubated at 37 °C for 30 min, and disrupted by sonication. Extracellular proteins were precipitated by adding 10% trichloroacetic acid for 12 h at 4 °C. Samples of total cell protein and extracellular protein were analyzed on 12% sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE)[24] and electrophoretically transferred onto a nitrocellulose membrane with a tank transfer system. After blocking non-specific binding sites with 3% bovine serum albumin (BSA) in TBST solution (20 mM Tris–HCl at pH 7.5, 150 mM NaCl, and 0.05% Tween-20), the membrane was incubated with rabbit anti-MPH serum at a 1:1000 dilution at 30 °C for 2 h and washed with TBST. Subsequently, the membrane was allowed to react with alkaline phosphatase-conjugated goat anti-rabbit IgG antibody (Promega) at a 1:2000 dilution at 30 °C for 1 h. The membrane was then stained with NBT/BCIP (Novagen) for visualizing antigen–antibody conjugates. The rabbit polyclonal antiserum was raised against the purified His_6-tagged MPH as described by Yang et al.[23]

MPH Assays. MPH activity was measured with MP as the substrate by monitoring an increase in absorbance at 405 nm (ε_{405} = 17 700 M^{-1} cm^{-1} for *p*-nitrophenol) at 30 °C.[28] For each assay, 100 μL of concentrated supernatant and 5 μL of 10 mg/mL MP (methanol stock solution) were added to 895 μL of 100 mM phosphate buffer (pH 7.4). One unit of activity was defined as the formation of 1 μmol of *p*-nitrophenol per minute.

Purification of His_6-Tagged MPH. For purification of the recombinant MPH from the culture supernatant of *B. subtilis* 168 carrying pWYM20, 5 mL of preculture was inoculated into 1 L of LB medium and grown to an OD_{600} of 0.6 at 37 °C. Subsequently, 0.5% xylose was added to induce protein expression at 37 °C for 24 h. The culture supernatant was concentrated 10-fold by ultrafiltration and dialyzed overnight against 20 mM *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) buffer (pH 7.5). Recombinant His_6-tagged MPH was purified using nickel–nitrilotriacetic acid (Ni–NTA) affinity chromatography, following the procedure described by Fu et al.[28] In brief, the concentrated fraction was loaded onto a Ni–NTA column (Novagen). His_6-tagged MPH tightly bound to the Ni–NTA

matrix and fusion proteins were eluted with elution buffer (20 mM Tris-HCl, 0.5 mM NaCl, and 300 mM imidazole at pH 7.9). The purity of purified MPH was examined by 12% SDS–PAGE. Protein concentrations were determined by the Bradford method.[24] The N-terminal sequence of purified MPH was determined by high-performance liquid chromatography–electrospray ionization mass spectrometry (HPLC–EIMS).

Pesticide Degradation Experiments. *B. subtilis* 168 cells harboring pWYM20 or pWTM20 were grown to an OD_{600} of 0.6 and then induced with 0.5% xylose for 24 h at 37 °C. Cells and supernatant were separated by centrifugation. Subsequently, 0.4 mM MP was added to the supernatant. Samples were incubated for 2 h at 30 °C and 150 rpm on a shaker. Then, residual pesticides were extracted twice with ethyl acetate, and the amounts of pesticides were determined by gas chromatography (GC). The detection conditions for GC were the same as those described by Yang et al.[23] Degradation of pesticide residues on cabbage was also performed as described by Yang et al.[23] using the supernatant of *B. subtilis* 168 cultures expressing YwbN–MPH.

RESULTS AND DISCUSSION

Tat-Dependent Secretion of MPH Directed by the YwbN Signal Peptide. Protein substrates of the Tat pathway are folded prior to translocation and are targeted to the Tat machinery by cleavable N-terminal signal peptides containing an almost invariant pair of arginine residues.[11,12] In a previous work, MPH was secreted by the *B. subtilis* Tat pathway into the growth medium when fused to the twin-arginine signal peptide of TorA from *E. coli*.[23] In this study, to enhance secretion of MPH to extracellular milieu, we used the twin-arginine signal peptide of YwbN from *B. subtilis*. A secretory expression vector pWYM20 coding for YwbN–MPH fusion protein was constructed and transformed into *B. subtilis* 168. A typical cleavage site (ASA-A) for signal peptidase I[29] was designed for producing mature MPH with an authentic N-terminal sequence of AAPQVR by cleaving the YwbN signal peptide.

To evaluate the efficiency of *B. subtilis* as the host strain for the Tat-dependent secretion of MPH, the distribution of MPH in cell lysate and culture supernatant was determined by western blotting with MPH antiserum. After 24 h of induction, the *B. subtilis* culture was fractionated into cells and culture supernatant and then these fractions were probed with anti-MPH serum. As shown in Figure 1, two specific bands corresponding to the unprocessed YwbN–MPH precursor (37 kDa) and the mature-sized MPH (32 kDa) were detected in the cell lysate of *B. subtilis* 168. As expected, mature-sized MPH was found predominantly in the culture supernatant of *B. subtilis* 168.

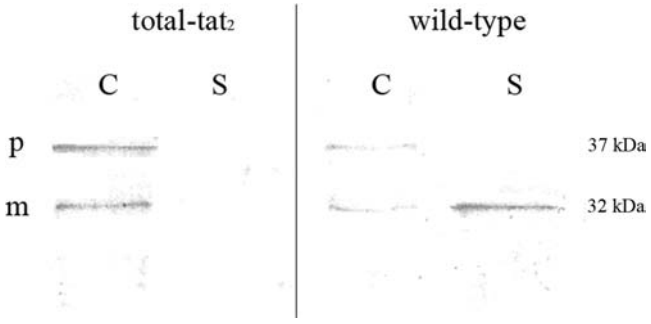

Figure 1. Secretion of MPH by the Tat pathway in *B. subtilis*. The culture of *B. subtilis* 168/pWYM20 or 168 total-tat_2/pWYM20 was fractionated into cells (C) and supernatant (S). The samples were used for SDS–PAGE and western blot using anti-MPH serum. p, YwbN–MPH precursor; m, mature-sized MPH. The protein sample loaded onto each lane in SDS–PAGE was 10 μg.

To determine whether the translocation of MPH was mediated specifically by the Tat pathway of *B. subtilis*, the secretory expression vector pWYM20 was also transformed into 168 total-tat_2 mutant strain, in which all *tat* genes encoding Tat translocases have been inactivated by insertional mutagenesis.[21] In contrast to wild-type strain, no secreted MPH was found in the culture supernatant of total-tat_2 mutant (Figure 1). Interestingly, mature-sized MPH was also found in the cellular fraction of the 168 total-tat_2 mutant, possibly resulting from proteolysis of YwbN–MPH. The degradation of TorA or YwbN chimeric proteins has previously been reported,[11,23] suggesting that the Tat signal peptides may be easily accessible to proteases. As shown in Figure 2, extracellular MPH activity

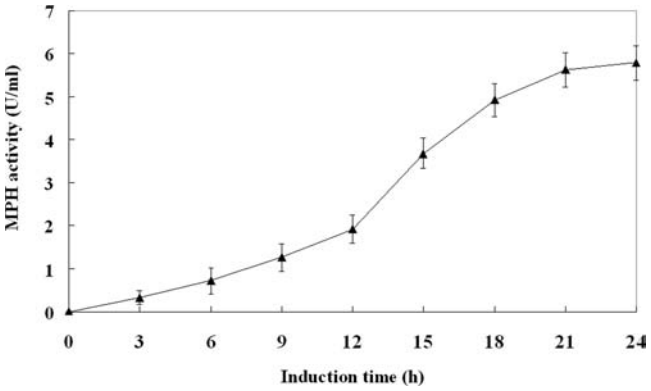

Figure 2. Extracellular MPH activity in *B. subtilis* 168 cultures capable of secreting MPH with the *B. subtilis* YwbN signal peptide. Cells were cultured in LB medium containing 15 μg/mL tetracycline at 37 °C and 250 rpm and then induced at OD_{600} = 0.6 by adding 0.5% xylose. The data are the mean ± standard deviation of three replicates.

of *B. subtilis* 168 cultures expressing YwbN–MPH increased gradually after induction and accumulated to a maximum level (5.78 units/mL) at 24 h. In contrast, no MPH activity was detected in the culture supernatant of 168 total-tat_2 mutant strain expressing YwbN–MPH fusion protein. These results clearly showed that MPH could be secreted by *B. subtilis* 168 in a strictly Tat-dependent manner.

Secretion of MPH with the YwbN Signal Peptide Is TatAyCy-Dependent. The *B. subtilis* Tat machinery comprises two active Tat translocation complexes with distinct substrate specificities: PhoD is secreted by the TatAdCd complex, whereas YwbN is secreted by the TatAyCy complex.[21] To examine whether the MPH secretion directed by the YwbN signal peptide would also be TatAyCy-dependent, we expressed the YwbN–MPH fusion protein in a *tatAyCy* or *tatAdCd* mutant strain. Secretion of MPH by these *tat* mutant strains was verified by western blot with MPH antiserum. MPH was detected in the culture medium of the *tatAdCd* mutant producing YwbN–MPH, which indicated that the *tatAdCd* mutant was still capable of secreting MPH, relying on using the other TatAyCy system. In contrast, MPH was not secreted into the culture medium of the *tatAyCy* mutant expressing YwbN–MPH (data not shown).

To further demonstrate whether the MPH secretion was specifically mediated by the TatAyCy system, extracellular MPH activity was also detected with these *tat* mutant strains. As a result, no MPH activity was detected in the culture

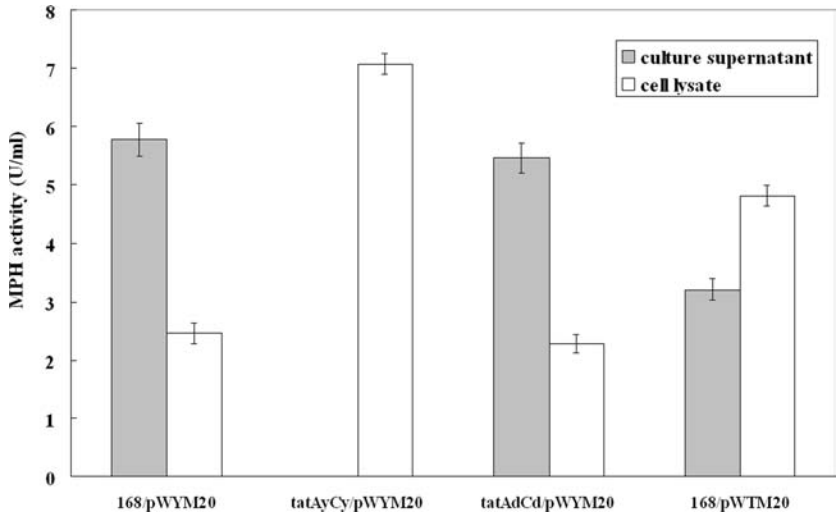

Figure 3. Specific MPH activities of the culture supernatant and total cell lysate derived from *B. subtilis* 168 and its *tat* mutant strains. 168/pWYM20, *B. subtilis* 168 expressing YwbN−MPH; *tatAyCy*/pWYM20, *tat* mutant strain of *B. subtilis* 168 lacking functional TatAyCy translocase; *tatAdCd*/pWYM20, *tat* mutant strain of *B. subtilis* 168 lacking functional TatAdCd translocase; and 168/pWTM20, *B. subtilis* 168 expressing TorA−MPH. Cells carrying pWYM20 or pWTM20 were incubated at 37 °C for 24 h after induction with 0.5% xylose. The data are the mean ± standard deviation of three replicates.

Table 2. Purification of Recombinant His_6-Tagged MPH from 1 L of Culture Supernatant by Metal Affinity Chromatography

purification step	total protein (mg)	total activity (units)	specific activity (units/mg of protein)	yield (%)	fold
culture supernatant	426	5260	12	100	1
Ni−NTA column	13	4576	352	87	29

supernatant of the *tatAyCy* mutant expressing YwbN−MPH. In contrast, MPH activity (5.46 units/mL) was found in the culture supernatant of the *tatAdCd* mutant expressing YwbN−MPH (Figure 3). These results indicated that the YwbN signal peptide directed MPH secretion in a strictly TatAyCy-dependent manner.

Efficiency of Tat-Dependent Secretion of MPH in *B. subtilis* 168. The majority of total MPH activity (70%) was found in the supernatant of *B. subtilis* 168 cultures expressing YwbN−MPH. The cell lysate contained lower activity (30% of total), and the data are consistent with the MPH immunoblots. Extracellular MPH activity of *B. subtilis* cultures expressing YwbN−MPH was 1.8-fold higher than that of *B. subtilis* cultures expressing TorA−MPH (Figure 3). Enhanced secretion of MPH activity was achieved with the YwbN signal peptide, indicating that the selection of Tat signal peptides is crucial to improve Tat-dependent protein secretion efficiency.

To determine the amount of MPH that was secreted by *B. subtilis* 168, the recombinant MPH was purified from 1 L of culture supernatant by metal affinity chromatography using a Ni−NTA column following the procedures described in the Materials and Methods. His_6-tagged MPH tightly bound to the Ni−NTA matrix, and fusion proteins were eluted with elution buffer containing 300 mM imidazole, thereby allowing for their one-step purification to electrophoretic homogeneity. The purified His_6-tagged MPH gave a single band appearing at the position of 32 kDa in SDS−PAGE (data not shown), which is in good agreement with the molecular mass estimated from the deduced amino acid sequence of the fusion protein. From 1 L of culture supernatant, we routinely obtained 13 mg of purified MPH with a purification of 29-fold, 87% final yield, and a specific activity of 352 units/mg. The data on the purification are summarized in Table 2. The N-terminal sequence of the purified MPH was determined by HPLC−EIMS as AAPQVR, demonstrating that the YwbN signal peptide had been processed correctly.

Degradation of Methyl Parathion by Recombinant *B. subtilis*. In this study, *B. subtilis* 168 cultures capable of secreting MPH (pWYM20) degraded MP 12-fold faster than *B. subtilis* 168 cultures expressing cytoplasmic MPH (pWM20). In contrast, no MP degradation was observed with *B. subtilis* 168 transformed with the empty vector pWH1520. Extracellular secretion of MPH is advantageous over intracellular production, because it allows MPH to freely bind extracellular substrates. This will greatly improve the application efficiency of the engineered strain to degrade organophosphorus pesticides in farm products and contaminated soil and water.

In this study, the supernatant can be separated from the cells by one-step centrifugation and used as the crude enzyme for the removal of pesticide residues on vegetables. The removal efficiencies for MP and chlorpyrifos on cabbage were 99 and 96%, respectively. Moreover, the supernatant containing secreted MPH was shown to effectively degrade MP (Figure 4). In contrast, the supernatant from *B. subtilis* cultures expressing YwbN−MPH (pWYM20) degraded MP 2-fold faster than the supernatant from *B. subtilis* cultures expressing TorA−MPH (pWTM20), which indicated that the efficiency of MPH secretion had been improved by use of the YwbN signal peptide.

To test whether extracellular secretion of MPH inhibits cell growth, the growth kinetics of cells carrying pWYM20 or pWH1520 were compared. No growth inhibition was observed for cells expressing YwbN−MPH. The two cultures showed the same growth profile and reached the same final cell density after 48 h of incubation. To monitor the stability of MPH activity of the concentrated supernatant, the activity was

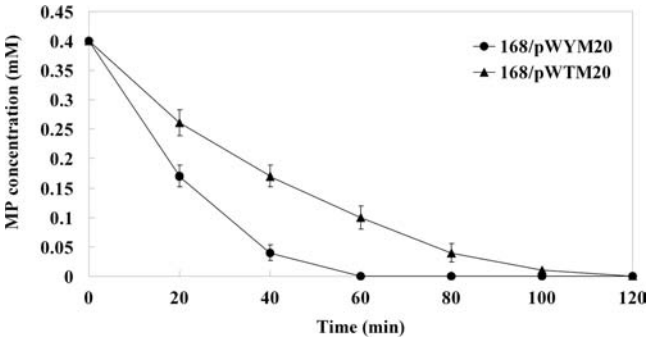

Figure 4. Degradation of MP by the culture supernatant of *B. subtilis* 168 cells capable of secreting MPH with the *B. subtilis* YwbN signal peptide (pWYM20) or *E. coli* TorA signal peptide (pWTM20). Methyl parathion was added at an initial concentration of 0.4 mM. The data are the mean ± standard deviation of three replicates.

determined each day over a 2-week period. MPH activity of the concentrated supernatant remained at essentially the original level over the duration of 2 weeks (Figure 5). The stability of

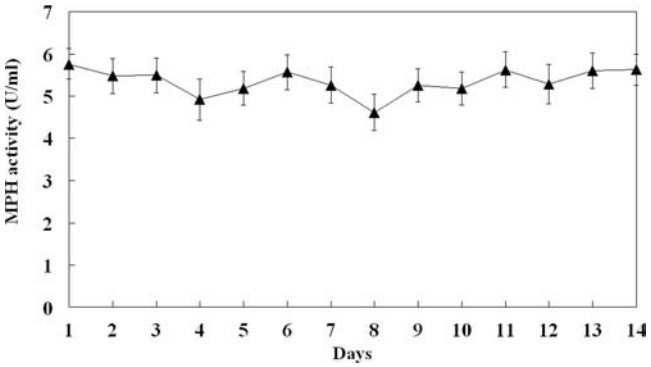

Figure 5. Stability of MPH activity of the culture supernatant of *B. subtilis* 168 cells capable of secreting MPH with the *B. subtilis* YwbN signal peptide (pWYM20) over the duration of 2 weeks. MPH activity was measured with MP as the substrate. The data are the mean ± standard deviation of three replicates.

the MPH activity observed here is in line with the results of previous studies in which MPH was secreted by *B. subtilis* 168 with the TorA signal peptide of *E. coli*.[23]

The suitability and popularity of *B. subtilis* as one of the main hosts for recombinant protein production are due to several reasons: generally recognized as safe as a result of its lack of pathogenicity and the absence of endotoxins, the absence of an outer membrane, easy for genetic manipulation and handling, and capable of large-scale fermentation.[25] These merits make recombinant *B. subtilis* a promising candidate for extracellular production of MPH for practical industrial applications, for example, enzyme-based products.

In previous studies, the YwbN signal peptide directed secretion of the *B. subtilis* subtilisin via the TatAyCy route. In contrast, the YwbN signal peptide directed secretion of the *Bacillus licheniformis* α-amylase and the *E. coli* SufI in a Tat-independent manner.[29] The *E. coli* phytase AppA was shown to export TatAdCd dependently when fused to the twin-arginine signal peptide of PhoD.[30] Tat-dependent secretion of the green fluorescent protein was reported, albeit in an inactive form.[31] Thus far, there are no reports of TatAyCy-dependent export of an active heterologous protein in *B. subtilis*. In this study, active MPH was exported to the extracellular environment via the *B. subtilis* TatAyCy system when fused to the twin-arginine signal peptide of YwbN. Here, we demonstrated for the first time TatAyCy-dependent secretion of an active heterologous protein in *B. subtilis*. In future studies, we will further explore the capability of the *B. subtilis* TatAyCy system for secretion of other heterologous proteins.

investigate the effects of silica nanoparticles prepared using the sol−gel process (nanosilica sol) on the activity and thermostability of the β-CGTase from *B. circulans* STB01 and the mechanisms by which this unique additive might activate and/or stabilize the enzyme. Silica nanoparticles had small size, high surface energy, and unsaturated chemical bonds on the surface,[17] so they showed not only flexibility like organic materials but also thermal stability, chemical stability, and high strength like inorganic materials.[18] Nanosilica sols have been available for some time,[19,20] but the ability of unmodified silica nanoparticles to stabilize proteins has not, to our knowledge, been investigated. The data presented here provide an effective approach for improving the thermostability of CGTases, or related enzymes, and give a deeper understanding of the mechanism by which PEG molecules and silica nanoparticles enhance the thermostability of proteins.

MATERIALS AND METHODS

Materials. The *cgt* gene encoding wild-type β-CGTase was from *B. circulans* STB01, and the β-CGTase was produced with *Bacillus subtilis* WB600 harboring plasmid *cgt*/pST.

Nanosilica sol (Bindzil 2034DI, particle diameter approximately 20 nm, pH 4.2, 33 wt % solid content) was purchased from Eka Chemicals Co. (Sweden).

Production and Purification of β-CGTase. A single colony of *B. subtilis* WB600 harboring plasmid *cgt*/pST was inoculated into 50 mL of LB medium containing kanamycin (5 μg/mL) and gibberellin (5 μg/mL) and grown at 37 °C overnight. The overnight culture (2 mL) was then diluted into 50 mL of terrific broth with kanamycin (5 μg/mL) and gibberellin (10 μg/mL) and incubated on a rotary shaker (200 rpm) at 37 °C for 48 h. The CGTase present in the supernatant was purified as previously described.[16] The purified enzymes were aliquoted and stored at −80 °C.

Protein Concentration Determination. The protein concentration was quantified using the Bio-Rad protein assay reagent kit, which employs the Bradford method.[21] Bovine serum albumin was used as the standard.

β-CGTase Assay. Enzyme assays was performed by incubating 0.1 mL of appropriately diluted purified enzyme with 0.9 mL of 1% (w/v) maltodextrin (DE = 5, Roquette Freres) in 10 mM phosphate buffer (pH 6.5) at 50 °C for 10 min.

The β-cyclization activity was determined by using the phenolphthalein method.[22] Corresponding samples containing inactivated enzyme were used as controls. One unit of each activity was defined as the amount of enzyme required to produce 1 μmol of β-cyclodextrin per minute under the assay conditions.

Thermostability Determination. The thermostability of the β-CGTase was determined by incubating the purified enzyme, at a concentration of approximately 3.2×10^{-8} M, in 10 mM phosphate buffer (pH 6.5) at 60 °C. Samples were taken at several time intervals, and the residual β-cyclization activity was determined.

Kinetic Parameters. To determine the kinetic parameters (K_m, V_{max}, and K_{cat}/K_m), the purified enzymes were assayed at substrate (maltodextrin, DE = 5) concentrations ranging from 0.1 to 10 mg/mL under standard assay conditions. The enzymes were prepared at a concentration of 1.1×10^{-8} M in 10 mM phosphate buffer (pH 6.5). Kinetic parameters (K_m and V_{max}) were determined by the Michaelis−Menten and Hanes−Woof plots. The specificity constants, K_{cat}/K_m, were calculated to determine the substrate specificity of each enzyme.

Surface Hydrophobicity Analysis. Surface hydrophobicity (S_o) of the enzymes were measured using 1-anilino-8-naphthalenesulfonate (ANS) as the fluorescence probe.[23,24] Protein dispersions were diluted (0.02, 0.04, 0.06, 0.08, and 0.1 mg/mL) in 10 mM phosphate buffer solution (pH 6.5), and then aliquots (10 μL) of ANS (8.0 mM in the same buffer) were added to 2 mL of each sample. Fluorescence intensity (FI) was measured using an F-7000 fluorescence spectrometer (Hitachi, Ltd., Tokyo, Japan) with an excitation wavelength of 390 nm and an emission wavelength of 470 nm. S_o was calculated by linear regression analysis using the initial slope of the FI versus protein concentration plot. Measurements were performed in triplicate.

Atomic Force Microscopy (AFM) Analysis. The β-CGTase samples (50 μL; 3.2×10^{-8} M) in the presence or absence of additives were deposited onto freshly cleaved mica coverslips (Goodfellow, Cambridge, UK). After 10 min, the samples were washed with water and air-dried. Imaging was performed at room temperature using a scanning probe microscope (Dimension ICON, Bruker, Germany), in tapping mode with a drive frequency of ∼300 kHz and a root-mean-square amplitude of 0.7 V. RTESPA probes (Digital Instruments, Santa Barbara CA, USA) were used in the analysis.

Intrinsic Fluorescence Analysis. Intrinsic fluorescence spectra of β-CGTase samples (0.1 mg/mL), in the presence or absence of additives, were measured in 10 mM phosphate buffer (pH 6.5) at room temperature with a fluorescence spectrophotometer (F-7000; Hitachi, Japan). The emission spectra from 300 to 400 nm were recorded at an excitation wavelength of 295 nm and a scanning speed of 1200 nm/min. The excitation and emission slit widths were 2.5 nm. All spectra were performed in triplicate and corrected for the corresponding protein-free sample.

Far-UV Circular Dichroism (CD) Analysis. The CD spectra (190−250 nm) were determined on a MOS-450 CD spectropolarimeter (Biologic, Claix, Charente, France) with a 1 mm path length cell at room temperature. The final spectra were the average of four scans with a bandwidth of 0.1 nm, a step resolution of 0.1 nm, and a scan rate of 1 nm/s. The CD spectra of β-CGTase (0.1 mg/mL) with or without additives were recorded in 10 mM phosphate buffer (pH 6.5); blank spectra of protein-free buffer solutions were subtracted to correct for background effects. The CD data were expressed in terms of mean residue ellipticity, $[\theta]$, in degree·cm^2·dmol^{-1}. Analysis of the protein secondary structure was performed using Dichroweb.[25]

Statistical Analysis. Experimental results are reported as the average of triplicate measurements. Statistical analyses were carried out using the statistical package from SPSS Inc., Chicago, IL, USA. Significant differences ($p < 0.05$) between means were identified by one-way analysis of variance (ANOVA) and the Student−Newman−Keuls (SNK) procedure.

RESULTS

PEG 1000 and Nanosilica Sol Activate the Cyclization Activity of β-CGTase. The effects of the addition of PEG 1000 and/or nanosilica sol on the β-cyclodextrin formation activity of the β-CGTase *B. circulans* STB01 at 50 °C are presented in Table 1. The addition of 0.05% (w/v) nanosilica sol resulted in a modest enhancement of the formation of β-cyclodextrin. Addition of 10% (w/v) PEG 1000 produced a similar enhancement. Titration of nanosilica sol in reaction mixtures also containing 10% PEG 1000 increased the enhancement of β-cyclodextrin formation, with 0.02, 0.05, or 0.10% nanosilica sol producing statistically significant increases.

Table 1. Activation of β-CGTase by PEG 1000 and Nanosilica Sol

additive	relative activity[a] (%)
10% (w/v) PEG 1000	109.8 ± 1.2ab
0.05% (w/v) nanosilica sol	106.7 ± 1.6a
10% (w/v) PEG 1000−0.01% (w/v) nanosilica sol	112.4 ± 2.2bc
10% (w/v) PEG 1000−0.02% (w/v) nanosilica sol	115.0 ± 2.8cd
10% (w/v) PEG 1000−0.05% (w/v) nanosilica sol	117.2 ± 1.4d
10% (w/v) PEG 1000−0.1% (w/v) nanosilica sol	115.0 ± 0.9cd

[a]Values are the means ± SD ($n = 3$), given as percent of activity relative to the activity of the control that had no added additives. Means with different letters within the same row are significantly different ($p < 0.05$).

[a]Values are the means ± SD (n = 3). Means with different letters within the same column are significantly different ($p < 0.05$). [b]PEG, 10% (w/v) PEG 1000; NSS, 0.05% (w/v) nanosilica sol.

The greatest increase in β-cyclodextrin formation, 17.2%, was achieved by a combination of 10% PEG 1000 with 0.05% nanosilica sol. To investigate the underlying mechanism of this enhancement, the kinetics of the cyclization reaction were investigated. The results are presented in Table 2. Addition of either PEG 1000 or nanosilica sol, alone, significantly increases the K_{cat}/K_m value, with PEG 1000 increasing the K_{cat}/K_m value significantly more than does nanosilica sol. The primary contributor to this increase in efficiency is a decrease in apparent K_m, because both additives decrease K_{cat} somewhat. The simultaneous addition of 10% PEG 1000 and 0.05% nanosilica sol produced the greatest increase in the mean value of K_{cat}/K_m, although this increase was not significantly different from that observed with 10% PEG 1000 alone. This increase in efficiency was due to a decrease in the apparent K_m, because the apparent K_{cat} actually decreased by approximately 40%.

Mixtures of PEG 1000 with Nanosilica Sol Increase β-CGTase Thermostability. The effects of the addition of 10% PEG 1000 and/or nanosilica sol on the thermostability of β-CGTase at 60 °C are shown in Figure 1. Addition of 10% PEG 1000 alone significantly enhanced the thermostability of the β-CGTase, increasing the half-life approximately 6-fold at 60 °C. Addition of 0.05% nanosilica sol alone, in contrast, had essentially no effect on the thermostability of β-CGTase. However, simultaneous addition of both 10% PEG 1000 and 0.01−0.05% nanosilica sol enhanced the thermostability of β-CGTase to a greater extent than the addition of either substance alone. The enhancement increased gradually with increasing concentration of nanosilica sol. However, addition of 0.1% nanosilica sol decreased the thermostability rapidly to the level a little lower than that with 10% PEG 1000 added individually. At the point of greatest stabilization (10% PEG 100 with 0.05% nanosilica sol) the β-cyclodextrin-forming activity remaining after incubation at 60 °C for 60 min was 61.3% of that possessed by a mixture of β-CGTase with the same additives that had not undergone heating.

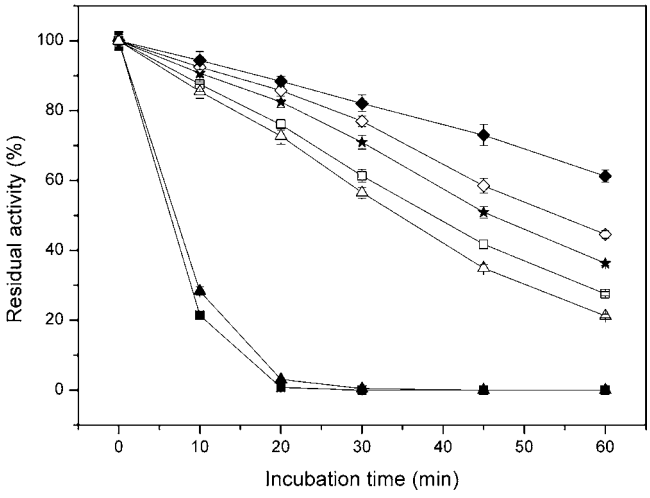

Figure 1. Effects of PEG 1000 and nanosilica sol on the thermostability of wild-type β-CGTase. β-CGTase without additives was incubated at 60 °C for up to 60 min with (■) no additives, (□) 10% (w/v) PEG 1000, (▲) 0.05% (w/v) nanosilica sol, (★) 10% (w/v) PEG 1000−0.01% (w/v) nanosilica sol, (◇) 10% (w/v) PEG 1000−0.02% (w/v) nanosilica sol, (◆) 10% (w/v) PEG 1000−0.05% (w/v) nanosilica sol, or (△) 10% (w/v) PEG 1000−0.1% (w/v) nanosilica sol. The activity before incubation was set as 100%. Each value represents the mean of three independent measurements, and the deviation from the mean is <5%.

Surface Hydrophobicity Analysis. A fluorescence method, using ANS as the probe, was used to determine the surface hydrophobicity (S_o) of β-CGTase samples after incubation at 60 °C for 20 min. The results are presented in Table 3. Incubation of β-CGTase at 60 °C for 20 min increased its S_o significantly by nearly 8.8-fold. The addition of 10% PEG 1000, either alone or together with nanosilica sol, further enhanced the S_o of the enzyme. Interestingly, the addition of 0.05% nanosilica sol alone reduced the S_o of the enzyme by nearly 40%.

Table 3. Surface Hydrophobicity (S_o) and Estimated Secondary Structural Content of β-CGTase before and after Incubation at 60 °C for 20 min

sample	S_o value[a]	α-helix (%)	β-sheet (%)	turn (%)	random coil (%)
control[b]	2.5 ± 0.1a	27.0	21.7	20.0	31.3
no additive[b,c]	24.4 ± 0.8c	20.0	7.8	9.8	62.4
PEG[b,c]	30.9 ± 0.9d	32.2	19.5	20.3	28.0
NSS[b,c]	15.4 ± 0.7b	20.8	24.4	21.2	33.6
PEG + NSS[b,c]	32.1 ± 0.7d	36.9	17.3	18.9	27.2

Aggregation State of β-CGTase Proteins under Heat Treatment Revealed by Atomic Force Microscopy. AFM was used to determine the surface morphology and aggregation state of the enzyme under heat treatment. The results are presented in Figure 2. Before heat treatment, the β-CGTase was seen as small dots or assemblies (Figure 2a,A). After being incubated at 60 °C for 20 min, the β-CGTase was seen in dramatically larger circular assemblies (Figure 2b,B). Addition of 10% PEG 1000 alone appeared to form a gel around the aggregated β-CGTase protein (Figure 2c,C), whereas addition of nanosilica sol formed a crust-like matrix that makes the protein more difficult to see (Figure 2d,D). Adding both 10% PEG and 0.05% nanosilica sol formed a surface that was much

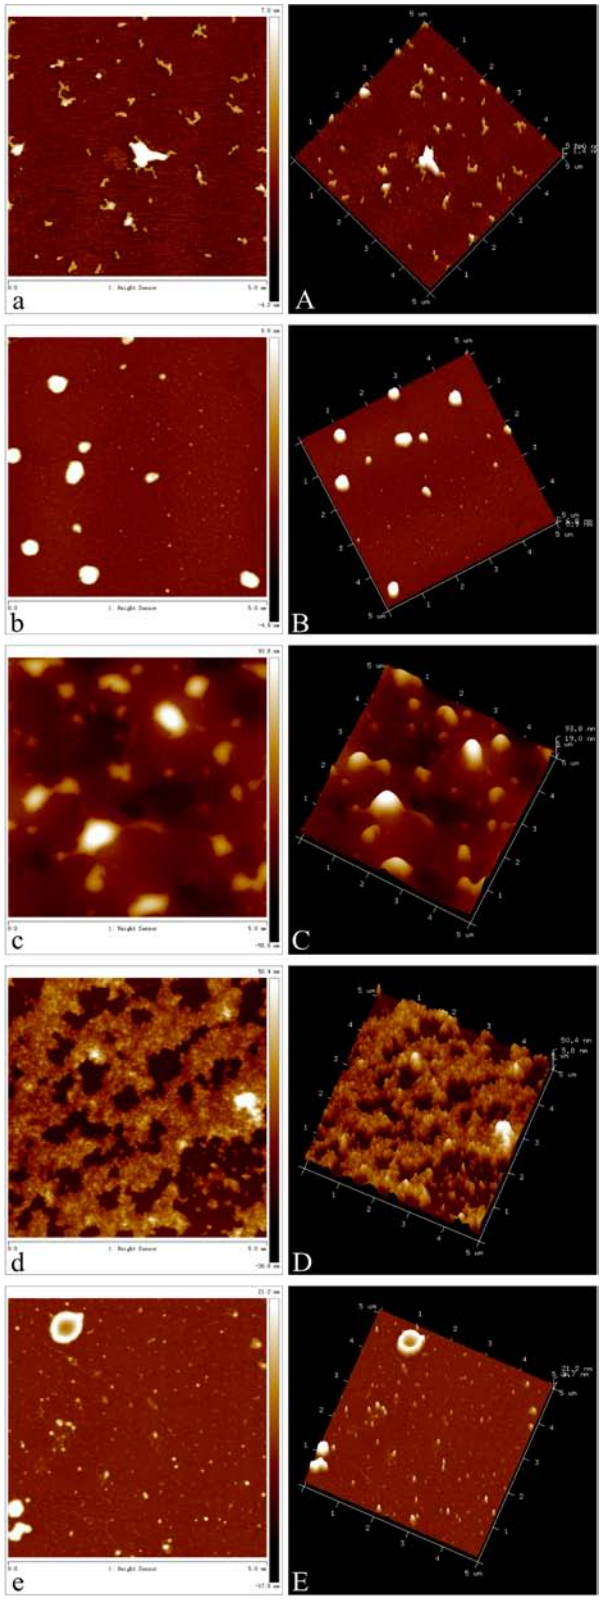

Figure 2. AFM images obtained using tapping mode: (a) β-CGTase without additives prior to heat treatment; (b) β-CGTase without additives incubated at 60 °C for 20 min; (c) as in (b), but with addition of 10% (w/v) PEG 1000; (d) as in (b), but with addition of 0.05% (w/v) nanosilica sol; (e) as in (b), but with addition of both 10% (w/v) PEG 1000 and 0.05% (w/v) nanosilica sol. All scan sizes: μm × μm. (A), (B), (C), (D), and (E) are 3D images corresponding to (a), (b), (c), (d), and (e), respectively.

more uniform than that produced by either PEG 1000 or nanosilica sol alone (Figure 2e,E), featuring fewer large aggregates than seen without the addition of additives (Figure 2b,B).

Intrinsic Protein Fluorescence Spectra. The β-CGTase from *B. circulans* contains 13 tryptophan residues per chain, 3 of which (W75, W101, and W258) are within approximately 15 Å of the active site tyrosine.[26] Variations in the β-CGTase microenvironment caused by the addition of PEG 1000 and/or nanosilica sol were investigated using the intrinsic fluorescence of the β-CGTase protein. The results are presented in Figure 3a. The fluorescence spectrum of β-CGTase without additives,

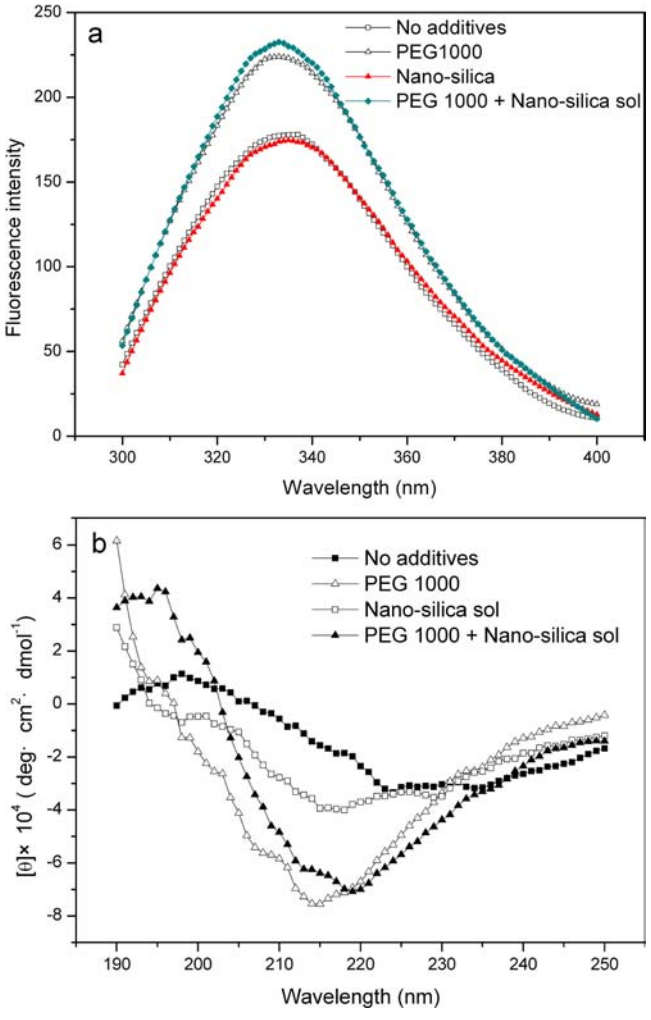

Figure 3. Intrinsic fluorescence spectra (a) and far-UV CD spectra (b) of β-CGTase samples incubated at 60 °C for 20 min in the absence of additives or in the presence of 10% (w/v) PEG 1000, 0.05% (w/v) nanosilica sol, or a combination of 10% (w/v) PEG 1000 and 0.05% (w/v) nanosilica sol.

excited at 295 nm, had a maximum fluorescence emission at 335 nm (data not shown). The fluorescence maximum exhibited a slight red shift, to 337 nm, and the fluorescence intensity decreased substantially after incubation for 20 min at 60 °C. The addition of 10% PEG 1000 to the incubation mixture increased the maximum fluorescence intensity by approximately 26%. In contrast, the addition of 0.05% nanosilica sol decreased the maximum fluorescence intensity slightly and caused a slight blue shift in the fluorescence

dx.doi.org/10.1021/jf500322b | J. Agric. Food Chem. 2014, 62, 2919−2924

maximum, to 335 nm. Addition of both 10% PEG 1000 and 0.05% nanosilica sol enhanced the maximum fluorescence intensity to a greater extent than 10% PEG 1000 alone and caused a more significant blue shift in the fluorescence maximum, to 333 nm.

Circular Dichroism Spectra. CD measurements in the far UV (190−250 nm) were performed to investigate the secondary structure of β-CGTase after incubation at 60 °C for 20 min. The results are presented in Figure 3b. These data, and the web tool Dichroweb, were used to determine the detailed secondary structural specifications of β-CGTase; the results are summarized in Table 3. Before heating, the β-CGTase without additives has relatively balanced content (20−32%) of α-helix, β-sheet, turn, and random coil, whereas additions of 10% PEG 1000 and/or 0.05% nanosilica sol show almost no effect on the secondary structure (data not shown). After heating in the absence of additives, the α-helix, β-sheet, and turn contents decreased by 7.0, 13.9, and 10.2%, respectively, whereas the random coil content increased significantly, by 31.3%. Random coil is the main secondary structural element seen in the heated β-CGTase. Addition of 10% PEG 1000 during the incubation dramatically decreases the amount of random coil and increases the content of α-helix, β-sheet, and turn by 12.2, 11.7, and 10.5%, respectively. Addition of 0.05% nanosilica sol during the incubation also dramatically decreases the content of random coil and increases the content of β-sheet (by 16.6%) and turn (by 11.4%). However, the addition of nanosilica sol has almost no effect upon the content of α-helix, increasing it by a mere 0.8%. Combining 10% PEG 1000 with 0.05% nanosilica sol gives the greatest decrease in random coil content (35.2%) and the greatest increase in the α-helix content (16.9%). The increases in β-sheet and turn content are still substantial, but they are lower than those caused by either 10% PEG 1000 or 0.05% nanosilica sol alone.

DISCUSSION

The aims of this study were to investigate the effect of silica nanoparticles and the combination of silica nanoparticles with PEG 1000 on the activity and thermostability of the β-CGTase from *B. circulans* STB01, as well as to analyze the mechanisms through which the activation or stabilization was achieved. We found that the addition of silica nanoparticles, by themselves, induced a modest increase in the production of β-cyclodextrin by β-CGTase at 60 °C, but a negligible increase in thermostability. However, when these same silica nanoparticles were combined with 10% PEG 1000, they offered a statistically significant increase in both activity and thermostability at 60 °C.

Activation and stabilization of enzymes by the addition of various forms of PEG are not unprecedented. Addition of 10% (w/v) PEG 3000 to the reaction mixture was shown to increase the activity of the β-CGTase from *Bacillus agaradhaerens* LS-3C[27] and the cyclomaltodextrin glycosyltransferase from *Bacillus macerans*.[28] PEGs of various types have been also been found to stabilize a number of enzymes, including α-amylase,[29,30] chymotrypsin,[31] and penicillin G acetylase.[32] On the other hand, the only data available about the activation of enzymes with silica nanoparticles appear to involve the covalent immobilization of enzymes to the silica surface, such as the investigations of Wang et al. with papain.[33] This paper is the first to show that nanosilica sol alone is of little use as an additive but that it augments the activating and stabilizing effects of PEG 1000.

Several different techniques were employed to ascertain the mechanism or mechanisms by which the activation and stabilization were achieved. Evaluation of the kinetic parameters revealed that addition of 10% PEG or the combination of 10% PEG and nanosilica sol decreased the substrate K_m by 58.2 and 62.3%, respectively, while decreasing K_{cat}. This suggests that PEG, or the combination of PEG with nanosilica sol, has an effect upon the interaction of the enzyme with the substrate, rather than increasing the fraction of active enzyme molecules or increasing the rate at which the enzyme molecules perform the required chemistry. The AFM images, which showed that the PEG 1000−nanosilica sol−enzyme mixture combined to form a gel network that was much more uniform than that produced in the absence of either PEG or the nanosilica sol, are consistent with this interpretation. According to the study of Wang et al.,[34] nanosilica particles may interact with the random coils of PEG to form stable PEG−SiO_2 complexes through hydrogen bonding, which may prevent the enzyme from aggregating. In fact, these data suggest that the effect may, at least in part, be a reflection of an interaction of the PEG and nanosilica sol with the substrate. However, when the concentration of nanosilica was increased to 0.1%, combinations of nanosilica sol with 10% PEG 1000 decreased the thermostability rapidly, compared with the addition of 0.05% nanosilica sol−10% PEG 1000. Perhaps excess nanosilica sol might cause more silica nanoparticles to be liberated, which might promote the formation of a crust-like matrix, like that seen in the AFM image containing only nanosilica sol and protein, which can damage the gel formed by the combination of nanosilica sol and PEG with the β-CGTase protein.

The surface hydrophobicity data, intrinsic fluorescence data, and CD spectra are all consistent with the PEG 100−nanosilica sol network having an effect upon the stability of the enzyme. Denaturation of enzymes in aqueous solution occurs through disruption of hydrophobic interactions and hydration of the polypeptide.[35] The surface hydrophobicity data demonstrate that the combination of PEG 1000 with nanosilica sol may expel the water molecules around the enzyme, which may help prevent the heat-induced exposure of hydrophobic amino acids to the solvent. Similarly, the dramatic decrease in fluorescence intensity and red shift of the fluorescence maximum that accompanied heating of β-CGTase to 60 °C, which indicate a shift of its tryptophan residues to a more hydrophilic environment, were prevented by the addition of PEG 1000 or PEG 1000−nanosilica sol. Finally, the CD data generally support the notion that the addition of PEG 1000−nanosilica sol to the mixture preserved secondary structure in the protein.

study of tissues (histological observations) and cells (cytological observations) confirms the biochemical assays: on the one hand, during grape berry development there are textural changes in the cell walls that lead to softening of the cell walls;[29] and on the other hand, green-berry tissues are rich in phenolic compounds. During berry development, phenolic compound content decreases until veraison (grape color change) and then stabilizes until maturity.[30−32] Tannins in the internal cell fractions are polymerized to a lesser degree than those in the cell wall.[32,33] All of these histological and cytological phenomena are essential to the extraction of both juice from the pulp and phenolic and aromatic compounds from the skin. The degree of extraction of these compounds has a significant influence on the duration of maceration and the quality of the resulting wine. Thus, the red wines of Bordeaux ought to be quite tannic to be well structured and to have good aging potential.[34] Throughout maceration, tannins are extracted from either skins or seeds, but during conventional winemaking it is very difficult both to extract seed tannins and to know how much tannin is extracted from seeds. Therefore, the availability of a technique which enhances the extraction of tannins is advantageous in that such a technique may produce a better tannin balance. Moreover, in the case of harvests that are not fully ripe, maceration ought to be of longer duration to improve the extraction rate. However, this may concomittantly release unwanted flavors (vegetable aromas, for example). Thus, the use of a technique that reduces maceration time may avoid such complications. According to recent studies, the development of an extraction process such as PEF technology in the wine industry seems to be one of the less time-consuming and more energy-efficient[18,20] alternatives. Indeed, this method has proved highly efficient in terms of both molecule extraction and yield.[15−20]

In previous works, we studied the effects of PEF treatment on must and wine composition.[19,20] The present work is complementary to our previous study and shows the effects of PEF treatment on the histocytological structure and the cell wall composition of berry, providing a better understanding of how polyphenol extraction can be modified by PEF. The objective was to study the effects on grape berries of two pulsed field treatments of medium strength. Light and transmission electron microscopy were both used to observe structural changes to the skin cell walls of treated grape berries. These observations completed the results obtained in biochemical analyses of skin cell walls of the grape berries examined.

MATERIALS AND METHODS

Plant Material. One hundred and twenty kilograms of grapes berries of *Vitis vinifera* L. cv. Cabernet Sauvignon were manually harvested at maturity (sugars = 225 g/L; extractability of anthocyanins = 50%; total polyphenols richness = 48) in a Bordeaux vineyard in September 2009. These berries were then destemmed by hand.

PEF Treatments. Three batches of 20 kg of lightly crushed and pressed berries were prepared, two of which were subjected to two different PEF treatments. The third batch corresponded to the control group. The PEF parameters described below were chosen in to compare the effects of a treatment of short duration (1 ms) and high strength (4 kV/cm) with the effects of a treatment of long duration (200 ms) and low strength (0.7 kV/cm). Cabernet Sauvignon grape berries were placed between two parallel stainless steel electrodes, and PEF was subsequently applied. [PEF1: E = 4 kV/cm; t_{PEF} = 1 ms, W = 3.99 Wh/kg (n = 1; t_i = 10 μs; Δt = 10 ms; Δt_t = 10 s; N = 100). PEF2: E = 0.7 kV/cm; t_{PEF} = 200 ms; W = 31 Wh/kg (n = 100; t_i = 100 μs; Δt = 10 ms; Δt_t = 10 s; N = 20).] N series of pulses were used for the treatment. Each series consisted of n pulses, pulse duration (t_i), time interval between pulses (Δt), and there was a pause (Δt_t) after each train of pulses. The effective time of the PEF treatment was regulated by the variation of the number of series N and is calculated as $t_{PEF} = nNt_i$. A sample of grape berries (0.7−4.2 kg) was placed in the PEF treatment cell between two stainless plane electrodes (230 mm × 265 mm). The distance between electrodes was 70 mm for PEF1 and 12 mm for PEF2. The value of the electric field E was evaluated as $E = U/d$, where U is the applied voltage. The initial conductivity of the samples was approximately 2.5 mS/cm. The specific energy consumption was calculated using the following formula: $W = UIt_{PEF}/m$, where m is the mass of grapes. These protocols allowed fine regulation of the treatment without any noticeable temperature elevation ($\Delta T \leq 6$ °C for PEF1 and $\Delta T \leq 14$ °C for PEF2) during the PEF treatment.

Three batches of 50 "control" berries were collected on the same day as the treated berries and stored in the same way to await the different biochemical analyses.

Microscopy Skin Characterization and Cytological Preparation for Light and Transmission Electron Microscopy (Method Described by Colin et al.[35]). A first sampling of 10 berries from each batch, treated and untreated, was carried out immediately after the various PEF treatments (day 0) to observe the immediate effects of the treatment on their cellular structure. A second sampling was carried out after the end of alcoholic fermentation (day 14) to note the indirect effect of the treatment on extraction from cells.

For each PEF treatment, 10 berries were randomly selected and immediately prepared for microscopy as described by McManus[36] for fixation and by Thiéry[37] for staining. Control (untreated) and treated berries were dissected into four sections each, always in the same manner and fixed (4 °C for 90 min in 2.5% glutaraldehyde in a phosphate buffer, pH 7.2), then washed in the same buffer, and postfixed (4 °C for 90 min in osmium tetroxide). The berry pieces were dehydrated progressively in successive baths of ethyl alcohol from 40% (v/v) to absolute (100% v/v) and were then embedded in epoxy resin (Epon).

Light Microscopy (MO). Semithin sections (2 μm thick) were stained via the periodic acid Schiff (PAS) method for the detection of polysaccharides.[37] Two hundred cross sections were observed by light microscopy for each treatment mode. Ten cross sections per treatment mode were photographed using an Olympus camera. The PAS-stained sections were used to determine the general histocytological morphology and to evaluate the polysaccharide content of the cell walls according to the different shades of pink obtained (negative PAS = light pink, positive PAS = dark and intense pink).

Transmission Electron Microscopy (TEM). Thin sections were cut using an ultramicrotome UCT (LEICA, Vienna, Austria) and picked up on 150-mesh copper grids. The sections were counterstained with uranyl acetate and lead citrate.[38] One hundred cross sections were examined for each treatment using a transmission electron microscope at 120 kV (Tecnai 12, FEI) and photographed with an ORIUS 832-11 MPixel (Gatan) camera.

Biochemical Analysis of Total Flavan-3-ols and Pectic Fractions of Skin Cell Walls. Frozen berries were peeled with a razor blade to retain only their skins. The skins were then very finely ground in a mortar under liquid nitrogen until a powder form was obtained.

Extractions of Cell Wall Fraction.[32,39] The cell wall isolation procedure followed the method described by Harris et al.[40] with slight modifications to allow us to perform the assay of tannins and polysaccharides on the same extraction sample.

One and a half grams of "skin powder" was suspended in 10 mL of 0.2 M Tris-HCl buffer, pH 7.5, containing 2.5% (w/v) EDTA (homogenization buffer) and homogenized at 4 °C to prevent the activation of the pectolytic enzymes[41] and the polyphenol oxidases.[42] This sample was then centrifuged at 15000 rpm for 20 min at 4 °C. The resulting pellet was resuspended in 10 mL of homogenization buffer and recentrifuged at 15000 rpm for 30 min at 4 °C. The pellet was further resuspended twice in 10 mL of 2.5 M saccharose and recentrifuged at 15000 rpm for 30 min at 4 °C. The pellet was

resuspended six more times in 10 mL of homogenization buffer and centrifuged anew after each resuspension, each time with different settings: 16000 rpm, 30 min, 4 °C; 14000 rpm, 30 min, 4 °C; 10000 rpm, 20 min, 4 °C; 9000 rpm, 15 min, 4 °C; 8000 rpm, 10 min, 4 °C; 5000 rpm, 10 min, 4 °C. The pellet was resuspended in 10 mL of Triton X-100 0.1% and recentrifuged at 3000 rpm for 10 min at 4 °C. The pellet was resuspended twice in 10 mL of homogenization buffer and recentrifuged at 3000 rpm for 10 min at 4 °C and at 2000 rpm for 5 min at 4 °C. The sample was subsequently filtered through a 3 μm PTFE filter and dried in an oven at 35 °C. This fraction was designated the "cell wall fraction of the skin".

Extraction of Polysaccharidic Fractions of the Cell Wall Fraction of the Skin (Adapted from Saulnier and Thibault [43]). For all samples, extraction and analysis were performed in triplicate. One-tenth of a gram of the cell wall fraction of the skin was suspended in a mixture of 20 μL of ethanol 95% and 20 mL of distilled water, stirred for 24 h at room temperature, and centrifuged at 1200 rpm for 30 min. The resulting supernatant corresponded to the PSE fraction (polysaccharides soluble in water). The pellet was resuspended in 20 mL of ammonium oxalate 2% (w/p), stirred for 2 h at room temperature, and centrifuged at 1200 rpm for 30 min. The resulting supernatant corresponded to the PSOX fraction (polysaccharides soluble in ammonium oxalate). The pellet was again suspended in 20 mL of 0.05 N HCl, stirred for 2 h at 85 °C, and centrifuged at 1200 rpm for 30 min. The resulting supernatant corresponded to the PSH fraction (polysaccharides soluble in acid). The pellet was once more suspended in 20 mL of 0.05 N NaOH, stirred for 2 h at 4 °C, and centrifuged at 1200 rpm for 30 min. The resulting supernatant corresponded to the PSOH fraction (polysaccharides soluble in sodium hydroxide). The pellet corresponded to the residual matter and was designated RP (residual pellet).

Extraction of Tannins.[44] For all samples, extraction was performed in triplicate. Either 0.1 g of the cell wall fraction of the skin and the residual pellet or 10 mL of pectic fraction was suspended in 10 mL of methanol containing 0.1% HCl. This solution was stirred for 3 h at 20 °C. The extract was filtered through 20 μm PTFE filters. For pectic fractions, this extract was designated the "phenolic extract of the skin pectic fraction". In the same manner as for the cell wall fraction of the skin and the residual pellet, the powder remaining on the filter was suspended in 10 mL of methanol containing 0.1% HCl (v/v) and stirred anew for 3 h at 20 °C. The resulting extract was filtered through 20 μm PTFE filters. This extract was designated the "phenolic extract of skin cell wall" from the cell wall fraction or the "phenolic extract of the residual pellet" from the residual pellet.

Analysis of Tannins by Reverse Phase HPLC following Phloroglucinolysis.[33,34,45] The mean degree of polymerization (mDP) and the subunit composition of procyanidins in the different fractions were analyzed. Six hundred microliters of phenolic extract, desiccated under nitrogen flow, plus 200 μL of reagent (0.2 Nmethanol-HCl + ascorbic acid + phloroglucinol) were mixed and incubated at 50 °C for 20 min. The reaction was stopped with 200 μL of sodium acetate. This extract was filtered and placed in a 2 mL HPLC sealed vial. Ten microliters was injected into the HPLC for analysis (column, 250 × 4.6 μm, 5 μm, ODS (Beckman, Roissy Charles de Gaulle, France): precolumn, 10 × 4.6 mm, 5 μm, BDS C18 (Thermo Hypersil); flow rate, 1 mL/min; solvent A, water/acetic acid (19:1 v/v); solvent B, MeOH/acetic acid (19:1 v/v); gradient, 5% B from 0 to 30 min, 20% B from 30 to 55 min, 40% B from 55 to 60 min, 90% B from 60 to75 min, 5% B from 75 to 80 min; injection volume, 10 μL; detection wavelength, 280 nm.

Spectrophotometric Analysis of Polysaccharides.[46] One hundred and fifty microliters of extract diluted at 1/10 plus 750 μL of 95% H_2SO_4 were stirred for 3 min at 0 °C and then for 6 min at 100 °C and then cooled for 10 min at 0 °C. After the addition of 15 μL of 3-hydroxydiphenyl (MHDP), the extracts were left in the dark for 20 min at room temperature before dosing at a wavelength of 520 nm.

Statistical Data Treatment. Two-way analysis of variance (ANOVA) could not be performed (non-normality of the residues and/or nonhomogeneity of the variance). We thus performed nonparametric tests. The statistical significance of differences was determined by the Freidman test ($\alpha = 0.05$) for paired samples and by the Kruskal and Wallis test ($\alpha = 0.05$) for unpaired samples. Experimental data detected as being significantly different are marked in the tables with different letters.

RESULTS

Immediate and Long-Term Effects of Different Pulsed Electric Field Treatments on Skin Histocytological Structure. Skin histocytological structures of grape berries were observed in both light microscopy (200 cross sections) and transmission electron microscopy (100 cross sections) for the two PEF treatment modes. Observations were carried out soon after treatment (day 0) to observe the immediate effects of PEF treatment and at the end of the alcoholic fermentation (day 14) to note the modifications to the cell structure of the grape berry skin.

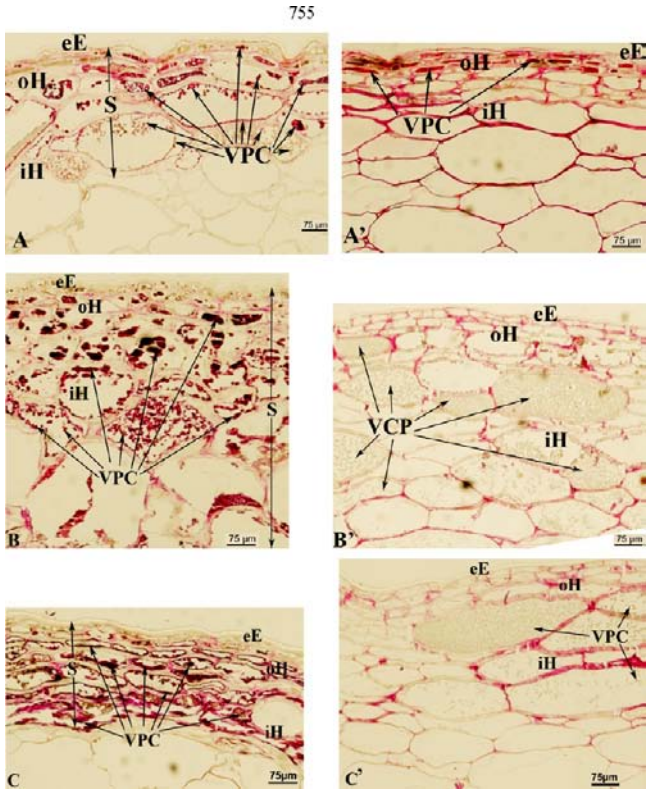

Figure 1. Evolution of the skin cross sections immediately after PEF treatments (day 0) (A, untreated (0 kV/cm); B, PEF1-treated (4 kV/cm; 1 ms; 4 Wh/kg); C, PEF2-treated (0.7 kV/cm; 200 ms; 31 Wh/kg)) and 14 days after PEF treatments (day 14) (A′, untreated (0 kV/cm); B′, PEF1-treated (4 kV/cm; 1 ms; 4 Wh/kg); C′, PEF2-treated (0.7 kV/cm; 200 ms; 31 Wh/kg)), under optical microscopy. eE, external epidermis; oH, outer hypodermis; iH, inner hypodermis; S, skin; VPC, vacuolar phenolic compounds.

Control Berries (Figures 1, 2, and 4). At day 0, all berry skins observed were characterized by one layer of epidermal cells and by five to six layers of hypodermal cells (Figure 1A), which were found to be rich in organelles (o) such as mitochondria (m) (Figure 2A). Vacuolar polyphenols (VPC) appeared as dense amorphous precipitates from the epidermis and the outer hypodermis (Figures 1A and 2A) and as gray granules originating from the inner hypodermis (Figures 1A and 2B). Despite slight staining with PAS (Figure 1A), it was

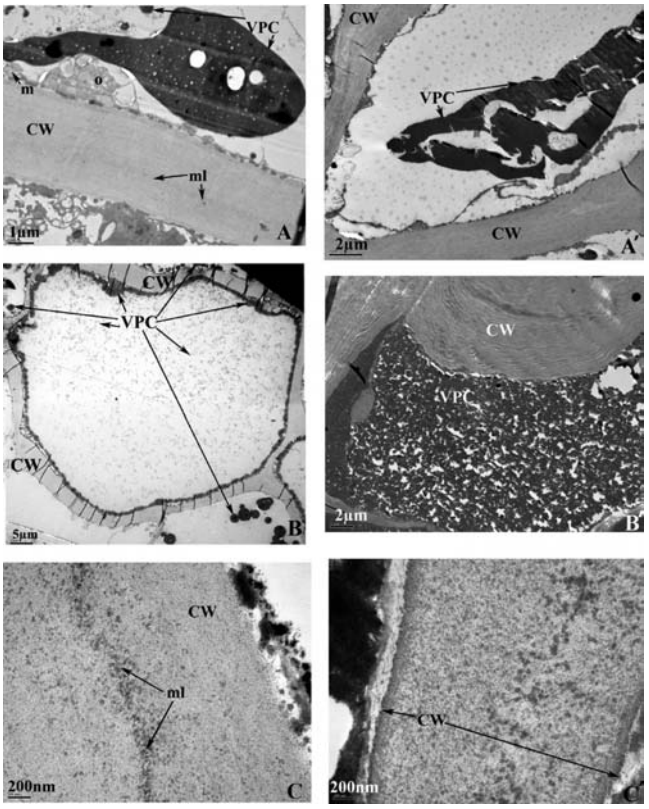

Figure 2. Skin cross sections of (A, B, C) untreated-berries (0 kV/cm) and of (A′, B′, C′) PEF1-treated berries (4 kV/cm; 1 ms, 4 Wh/kg) observed at day 0, under transmission electron microscopy: (A, A′) outer hypodermis; (B, B′) inner hypodermis; (C, C′) outer hypodermis. CW, cell wall; o, organelles; ml, middle lamella; m, mitochondria; VPC, vacuolar phenolic compounds.

possible to observe that the cell walls (CW) showed no signs of deterioration (Figure 2A–C).

At 14 days, almost all of the vacuolar polyphenols had been evacuated (Figure 1A′). Very few vacuolar polyphenols were still present in the epidermis and outer hypodermis, where they appeared as very dense, dark red or brown, amorphous precipitates. Curiously, contrary to day 0, cell walls were found to show homogeneous dark pink PAS staining (Figure 1A′), and the contrast under TEM was seen to be homogeneous and electron-dense (Figure 4A,B). Most organelles, such as plastids (p), were senescent (Figure 4B).

PEF 1 (4 kV/cm, 1 ms, 4 Wh/kg) (Figures 1, 2, and 4). At day 0, the skin of all treated berries was more distended (Figure 1B) than that of the control batch (Figure 1A). Vacuolar polyphenols of the epidermis (Figure 2A′) and hypodermis (Figure 2B′) were less dispersed and more condensed in the vacuole. Small spherical structures, which were localized only at the middle lamella level in the control batch (Figure 2C′), were observed over a large portion of the hypodermis cell wall thickness (Figure 2C′).

At day 14 (Figure 1B′), the hypodermis of all treated berry skins contained no vacuolar phenolic compounds with a dense dark red or brown aspect, as was the case in the control batch. However, it was richer in vacuolar phenolic compounds in the form of small gray granules dispersed throughout the vacuolar space. It can therefore be concluded that these phenolic compounds were probably chemically different from those present in the control berries at the same time. Furthermore, the cell walls of the outer hypodermis showed perforations (Figure 4A′, arrowed). At the inner hypodermis, fiber cell wall polysaccharides were more distended than in the control batch (Figure 4, panel B vs panel B′).

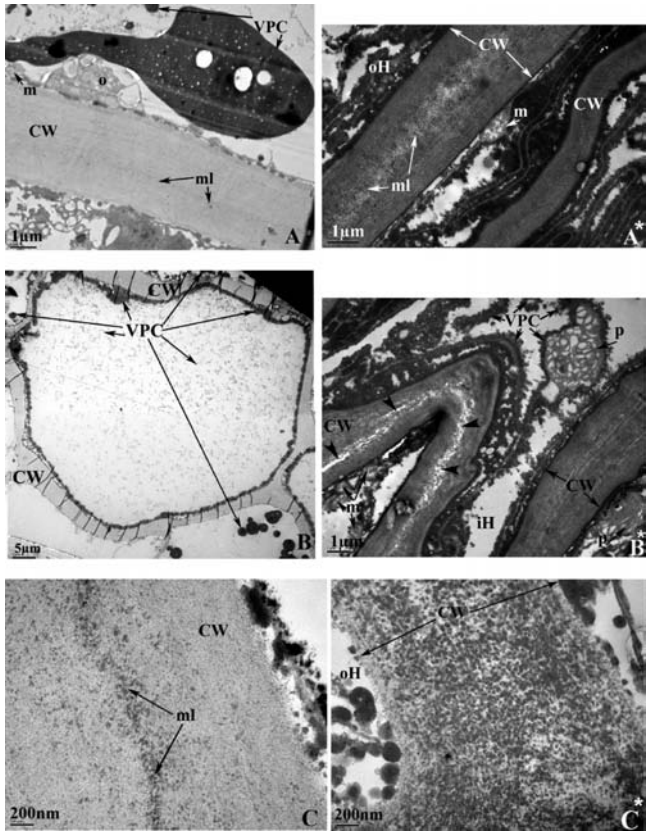

Figure 3. Skin cross sections of (A, B, C) untreated berries (0 kV/cm) and of (A*, B*, C*) PEF2-treated berries (0.7 kV/cm; 200 ms, 31 Wh/kg) observed at day 0, under transmission electron microscopy: (A, A*) outer hypodermis; (B, B*) inner hypodermis; (C, C*) outer hypodermis. CW, cell wall; iH, inner hypodermis; m, mitochondria; ml, middle lamella; o, organelles; oH, outer hypodermis; p, plastid; VPC, vacuolar phenolic compounds.

PEF 2 (0.7 kV/cm, 200 ms, 31 Wh/kg) (Figures 1, 3, and 4). At day 0, in contrast to PEF1, the skin of all treated berries was seen to be much more degraded than in the control batch, especially in the deepest layers of the inner hypodermis of the skin (Figure 1C). The vacuolar polyphenols of the outer cell layers of the skin appeared denser and more contrasted, as was the case for PEF1. The outer hypodermis cells (Figure 3A*), and even more so those of the inner hypodermis (Figure 3B*), were disorganized, showing destructuring of the middle lamella of cell walls (arrowed) and organelles, such as mitochondria (m) or plastids (p), that had been disrupted. At highest magnification, the aspect of the cell wall appeared unstructured, with the presence of small spherical structures throughout the whole thickness (Figure 3C*).

At day 14 the skin of the treated berries was, in 80% of cases, less rich in vacuolar polyphenols than that of the untreated berries. However, some areas could be observed in which phenolic compounds of a dense gray appearance persisted in the cells (Figure 1C′). In all cases, cell wall structure and the organization of the polysaccharide fibers had a very different

dx.doi.org/10.1021/jf404804d | J. Agric. Food Chem. 2014, 62, 2925–2934

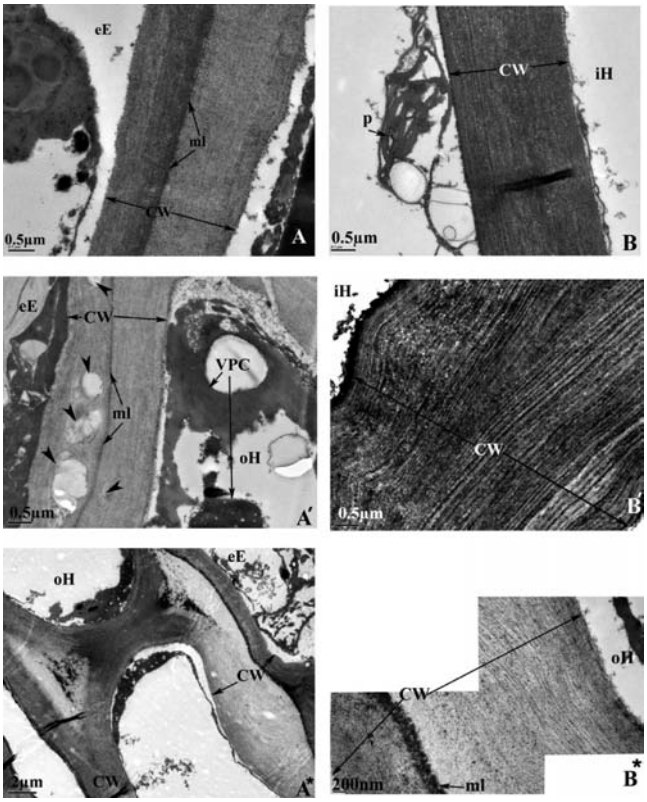

Figure 4. Skin cross sections of (A, B) untreated berries (0 kV/cm), (A′, B′) PEF1-treated berries (4 kV/cm; 1 ms, 4 Wh/kg), and (A*, B*) PEF2-treated berries (0.7 kV/cm; 200 ms, 31 Wh/kg) observed at day 14, under transmission electron microscopy: (A, A′, A*, B*) outer hypodermis; (B, B′) inner hypodermis. CW, cell wall; eE, external epidermis; iH, inner hypodermis; ml, middle lamella; oH, outer hypodermis; p, plastid; VPC, vacuolar phenolic compounds.

appearance from the control batch. In treated skins, cell angles were observed to be rather distended with high-contrast deposits and perforations that evoke meatus (Figure 4A*). Tangential walls of contiguous layers of cells were asymmetrical on either side of the middle lamella (Figure 4B*). Moreover, the middle lamella was observed under TEM as being more highly contrasted and electron dense (Figure 4B*), which could be one of the consequences of changes in the wall that contained more sites where the counterstaining metal salts of the different sections could be lodged. In conclusion, the immediate impact of PEF1 was characterized by a distension of the skin and a condensation of most of the vacuolar polyphenols. The impact on the cell walls was more limited, but remained significant, at 14 days after perforations were first observed. The immediate impact of PEF2 was much more pronounced: the skin became very dense, the polyphenols were more highly concentrated, and, more especially, the cell walls were greatly modified. They were observed at 14 days as being very eroded and degraded.

Immediate Effects of Pulsed Electric Field Treatments on Skin Cell Wall Condensed Tannins. PSE and PSOX fractions correspond to the easily extractable peripheral pectic fractions, whereas PSH and PSOH fractions correspond to the internal pectic fractions that are only extractable with greater difficulty.[42] The residual pellet (RP) corresponds to the "heart" of the cell wall.

Control Berries (Table 1). The pectic fractions richest in condensed tannins were PSH and PSOH, which were internal and strongly bonded with the cell wall fibers. The larger condensed tannins with the highest mDP were found in the PSH fraction.

PEF 1 (4 kV/cm, 1 ms, 4 Wh/kg) (Table 1). In the different peripheral cell wall fractions (PSE; PSOX), the treatment did not have a marked effect. However, levels of condensed tannins in the PSE fraction (TPSE) tended to be higher (C, 0.17, vs PEF1, 0.24) and mDP tended to decrease (C, 3.42, vs PEF1, 2.91), reflecting a probable decondensation of tannins and their accumulation in this fraction. In the PSOX fraction, tannin levels (TPSOX) tended to be lower (C, 0.29, vs PEF1, 0.2) and mDP tended to increase (C, 2.43, vs PEF1, 3.26), reflecting a probable loss of tannins further to their condensation in this fraction.[32] In the different internal cell wall fractions (PSOH,

dx.doi.org/10.1021/jf404804d | J. Agric. Food Chem. 2014, 62, 2925−2934

PSH, RP), the same phenomenon was observed because levels of condensed PSH tannins (TPSH) tended to be lower (C, 2.81, vs 1.13), and mDP levels tended to increase (C, 15.83, vs PEF1, 58.03), as was the case for the PSE fraction. The tannin level of the PSOH fraction (TPSOH) tended to be higher (C, 2.57, vs PEF1, 5.19), and mDP tended to decrease (C, 3.59, vs PEF1, 1.63), as was the case for the PSOX fraction. Moreover, in the residual pellet (TRP), mDP tended to decrease (C, 5.79, vs PEF1, 2.64), whereas levels of condensed tannins showed no variation (C, 0.75, vs PEF1, 0.66). This could reflect a breakdown of the tannins present in this fraction and a leakage of decondensed tannins into adjacent fractions.

PEF2 (0.7 kV/cm, 200 ms, 31 Wh/kg) (Table 1). The two peripheral cell walls (PSE; PSOX) were affected by the treatment as compared to the control batch. The level of condensed PSE tannins (TPSE) increased significantly (C, 0.17, vs PEF2, 0.42) and mDP also tended to increase (C, 3.42, vs PEF2, 4.26). In the PSOX fraction the level of condensed tannins (TPSOX) decreased significantly (C, 0.29, vs PEF2, 0.14) and mDP also tended to increase (C, 2.43, vs PEF2, 2.79). It is conceivable that either the TPSOX were depleted after their condensation in this fraction or a part of TPSOX was decondensed under the action of PEF2, which spontaneously migrated from this fraction to accumulate in PSE, in which bonds are of the same nature, and spontaneously condensed in this fraction where the amount of condensed tannins increased. This migration would thus explain the large increase in the level of TPSE, whereas mDP also showed an increase. The PSE fraction was enriched in condensed tannins from TPSE and TPSOX (therefore, the average value of mDP was higher in these fractions), contributing to the significant decrease in the level of TPSOX. Among the internal fractions (PSOH; PSH; RP) only PSOH was significantly affected; mDP tended to decrease (C, 3.59, vs PEF2, 1.64), reflecting a rupture due to treatment, and the level of condensed tannins (TPSOH) increased (C, 2.57, vs PEF2, 9.29), reflecting an accumulation of these tannins. Moreover, the mDP of condensed PSH tannins (TPSH) tended to be lower than in the control batch (C, 15.83, vs PEF2, 13.84), reflecting a rupture, whereas the level of TPSH tended to decrease (C, 2.81, vs PEF2, 2.17). This decrease in the level of TPSH can be explained by a leakage of TPSH to the PSOH fraction, contributing to the increased levels of TPSOH. In the RP, mDP tended to decrease as compared with the control batch (C, 5.79, vs PEF2, 4.79) and the level of condensed tannins (TRP) increased (C, 0.75, vs PEF2, 1.67), reflecting an accumulation of these decondensed tannins.

Finally, whereas PEF1 did not significantly affect the tannic skeleton of skin cell walls, the consequences of PEF2 were much more significant: the tannic skeleton of skin cell walls was highly disorganized, especially the external fractions.

Immediate Effects of Different Pulsed Electric Field Treatments on Skin Cell Wall Polysaccharidic Fractions. The peripheral pectic fractions PSE and PSOX are easily extractable because they are connected by weak bonds. The internal pectic fractions PSH and PSOH are not easily extractable because they are connected by strong bonds. Each of the fractions contains mainly galacturonic acid, arabinose, and galactose, which correspond to pectic compounds.[43] It is thus possible to refer indifferently to the polysaccharide fraction or the pectic fraction.

Control Berries (Table 2). In descending order, the most abundant polysaccharide fraction corresponded to the PSE fraction, which is the most easily extractable, followed by PSOH, PSOX, and PSH.

Table 2. Effects of PEF1 and PEF2 on the Contents of External Polysaccharide Fractions (PSE, PSOX) and Internal Polysaccharide Fractions (PSH, PSOH) in Berry Skins[a]

polysaccharide content (mg/g of skin)	C	PEF1 (4 kV/cm, 1 ms, 4 Wh/kg)	PEF2 (0.7 kV/cm, 200 ms, 31 Wh/kg)
PSE fractions	8.80 ± 2.25 a*	9.71 ± 3.12 a*	3.88 ± 2.66 b*
PSOX fractions	1.32 ± 0.36 a*	1.57 ± 0.47 a*	2.54 ± 0.73 b*

PSOH fractions	2.59 ± 0.50 a*	1.76 ± 0.74 a*	1.55 ± 0.63 b*

[a]Values are means ± standard deviations. (*) Significant difference in Kruskal and Wallis test ($\alpha = 0.1$). PEF1, treatment 1 of pulsed electric field; PEF2, treatment 2 of pulsed electric field; C, control berries; PSE, extracted polysaccharide fraction in water; PSOX, extracted polysaccharide fraction in oxalate; PSH, extracted polysaccharide fraction in acid; PSOH, extracted polysaccharide fraction in sodium hydroxide.

PEF 1 (4 kV/cm, 1 ms, 4 Wh/kg) (Table 2). This treatment mode did not cause changes in the distribution of pectic fractions in the cell walls. Furthermore, external fractions of cell wall were not significantly affected (Table 2) because the levels of PSE and PSOX remained stable, but these fractions tended to increase, which seems to imply a slightly increased density of weak bonds (noncovalent) in the cell wall. However, PEF1 significantly modified the internal fractions, showing decreased levels of PSH, which is the cause of disruption of strong bonds (covalent) and a rearrangement of molecular bonds at this level.

PEF2 (0.7 kV/cm, 200 ms, 31 Wh/kg) (Table 2). This treatment mode significantly affected all polysaccharidic fractions of the cell walls, principally in the peripheral fractions. At the periphery of the cell wall, the PSOX level was increased significantly and may have been enriched by some of the PSE, the level of which decreased (Table 2). However, the density of weak bonds (noncovalent) decreased in PSE and increased in PSOX; therefore, the molecular affinity of these fractions was totally modified. Toward the inside of the cell wall, as was the case for PEF1 but more pronounced, levels of PSH and PSOH were decreased significantly (Table 2), which is the cause of a decrease of strong bonds (covalent) and of an upheaval and rearrangement of molecular bonds at this level.

As seen above in the case of the tannic skeleton, PEF1 had only a slight impact on the pectic skeleton of skin cell walls. Conversely, the consequences of PEF2 were more far-reaching seeing as this treatment mode caused the disorganization of cell wall polysaccharides and molecular bonds, which induced a modification of polyphenol extraction phenomenon.[47−49]

DISCUSSION

The main action of PEF is the induction of a phenomenon of electroporation in the form of hydrophilic pores on small portions of cell membranes of the cells facing the electrodes. Cells exposed to the transmembrane energy of an external electric field undergo a reorganization of membrane phospholipids.[4,5] In this way, the shape and size of the affected cells directly influences the phenomenon of electroporation. Grape berries being composed of heterogeneous tissues, with cell shape and membrane potential variables,[21−27] the spread and consequences of PEF are not homogeneous in the skin.

Moreover, the presence of the cell walls is an important factor in the spread of PEF. Few studies have examined the influence of PEF on the walls. Furthermore, Janositz and Knorr[3] have demonstrated, with tobacco cells and protoplasts, the protective effect of cell walls vis-a-vis PEF treatment, having observed that protoplast cell size increased slightly after reversible permeabilization by PEF treatment with few pulses. In the present study, PEF treatment has been shown for the first time to have an effect on several cellular compartments such as cell walls in addition to the membranes: the skin of the treated berries was, overall, only slightly affected by the PEF1 treatment (4 kV/cm, 1 ms, 4 Wh/kg), but very largely degraded following the PEF 2 treatment (0.7 kV/cm, 200 ms, 31 Wh/kg).

The most striking histological effect observed immediately after the PEF1 treatment concerned the thickness of the skin that was much greater than in the control batch, the most strongly affected cells being the large cells of the inner hypodermis.[19,20] From a cytological point of view, skin-cell membranes of treated berries were found to be little affected by PEF1, which is logical in view of the PEF1 parameters (pulses of short duration (1 ms) and high strength (4 kV/cm)) that had induced electroporation on a lesser scale[4] and which remained reversible. Conversely, cell walls of treated berries were more highly affected by PEF1 than membranes and, especially, the aspect of cell walls of the inner hypodermis immediately after the treatment (Figure 2). At the end of 14 days, cell walls were more distended in the inner hypodermis, showing certain areas with perforations in the outer hypodermis (Figure 3), which confirmed our findings that the consequences of PEF are not homogeneous.[21−27] In this way, cytological observations revealed modifications of the polysaccharide skeleton interior, as did biochemical analysis of the pectic fractions (galacturonic acid, arabinose, and galactose).[43]

Pectic cell wall organization was only slightly but measurably affected further to the treatment: external fractions (PSE, PSOX) tended to increase, which probably increased the number of weak bonds,[43] and the quantity of internal fractions (PSH, PSOH) was decreased, which also decreased the number of strong bonds.[43] It can be hypothesized that the disappearance of PSH and PSOH had disturbed the microfibrillar interactions of cell walls,[29] thus freeing new space at the heart of the cell walls into which water may penetrate, thus inducing a stretching thereof. The distension of the walls that was observed immediately after the treatment would then allow the expansion of these cells, which would explain the thickening of the treated skin. The largest cells being the most strongly affected,[3,7,13] this expansion was most noticeable at the inner hypodermis, which is made up of very large cells.[23,25] Moreover, this upheaval of pectic skeleton has probably induced a change of affinity for the various parietal molecules such as polyphenols.[47−50,53] With regard to the polyphenolic organization of the treated skin, biochemical analysis of the cell walls of total tannins in the different pectic fractions did not reveal any significant effect. However, a trend was observed: levels of TPSOX (inside the external pectic fraction) and TPSH (inside the internal pectic fraction) decreased, and their mDP increased. Following PEF1 treatment, PSOX and PSH fractions were depleted of total tannins because of the condensation of these tannins (mDP increased). It was possible to confirm this observation with TEM observations, in which structures resembling small balls were observed in the middle lamella walls (Figure 2). These structures may correspond to the condensation of TPSH in the space freed by the disappearance of the PSH pectic fraction. Renard et al.[50] demonstrated that affinity and binding between cell wall procyanidins and polysaccharides in apples increased with the degree of polymerization of these phenolic compounds. Thus, in the present case, this polymerization may help strengthen cell walls[32] and slow extraction phenomena.[51,52] This would explain why, at day 14, the hypodermis of treated berries was still rich in vacuolar phenolic compounds (Figure 1). However, TPSOX, TPSH, and TRP were highly condensed by the PEF1 treatment, inducing, on the one hand, a strong bond with pectic compounds, particularly in the PSOX fraction where the number of noncovalent bonds probably increased, thus limiting their depolymerization.[53] On the other hand, the formation of new spaces in the heart of the cell walls resulted in a diminished extractability of these tannins, which are more strongly encapsulated within microfibrillar pores and therefore strongly adsorbed by cell wall components.[47] Thus, PEF1 slowed the phenomena of diffusion and extraction of most tannins from the skin of treated berries. It was also noted that the cytological aspect of vacuolar phenolic compounds was modified after the PEF1 treatment: they appeared more condensed in the cell vacuoles. This seems to demonstrate that the PEF1 treatment had had an effect mainly on vacuolar phenolic compounds.[20] Therefore, it can be seen that phenolic compounds and skin cell wall pectic fraction skeletons were little affected by the PEF1 treatment, and it can be confirmed that the polyphenols affected by high-intensity short duration PEF treatment are the vacuolar tannins rather than the cell wall tannins.[20] In this way, PEF1 can be considered as a treatment that has little immediate destructive effect on cells, this effect remaining reversible, which explains the increase in skin size, without cell destruction. However, in the longer term, the skins of treated berries release their condensed tannins less easily, as they are strongly bonded to the affected pectic cell wall fractions. Their liberation takes place with a "delayed action effect", which implies a lower rate of tannin extraction from the skins during maceration[20]

With regard to the PEF2 treatment, the skin structure of the treated berries was very largely degraded following the treatment. It was observed that the histological (Figure 1) and cytological (Figure 3) impacts on the cells were very significant. PEF2 was of lesser intensity, but was of longer duration than PEF1, which explains the more destructive effects of the PEF2 treatment.[4,5,7] As berries are composed of heterogeneous tissues,[23,25] with cells of differing shapes and sizes, PEF propagation cannot be uniform,[3,7,13] which partly explains this result. Moreover, the increase in treatment energy (W = 31 Wh/kg) applied caused a higher degree of cell lysis[19] than was the case for PEF1 (W = 4 Wh/kg). In parallel, TEM observations revealed skin cells with severely affected membranes and organelles, with distension of the cell walls and rupture of the middle lamella (Figure 2). These effects can be compared with the structural changes induced by PEF treatment on bacteria[10,54] or yeast,[6,11] in which a much greater critical electric field strength is required to obtain this result. This is mainly related to their diameter, which is much smaller, and to their cell wall thickness, which is greater than that of grape skin cells.[3,7,13] The cytological structure of the cell walls was very largely modified by the PEF2 treatment, which explains the modified aspect of the cell walls observed with TEM (Figure 2). This finding was confirmed by biochemical studies in which analysis of the polysaccharide fractions revealed that the entire pectic skeleton had been disrupted. The whole polysaccharide mesh was greatly weakened, only

one internal fraction being strengthened. Except for PSOX, which increased, the quantities of all fractions were significantly decreased, which probably caused a loss of PSE, which is the most easily extractable fraction,[42] and a reduction in the number of binding sites between polysaccharides and phenolic compounds.[47,53]

In the same way, biochemical analysis of total cell wall tannins demonstrated that the treatment profoundly modified the organization of the tannic skeleton. In the external fractions of the cell walls, TPSE were ruptured (mDP was decreased) contributing to the increase of their numbers in this fraction and probably inducing a decrease in their affinity for the polysaccharides of this fraction.[53] At the same time, TPSOX became even more condensed (mDP was increased), which increased their affinity for the PSOX polysaccharide fraction, for which the numbers of weak bonds were increased. In the internal fractions of the cell walls, TPSOH were ruptured (mDP decreased) and remained in this fraction, whereas TPSH were also ruptured (mDP decreased) but migrated to the PSOH fraction in view of TPSH values, which decreased (Figure 2). Despite this enrichment in tannins, cell walls may have been weakened by a loss of the protective effect of the phenolic compounds against pectin depolymerization.[32,53] The PEF2 treatment induced, on the one hand, an overall decrease in the number of weak bonds due to the loss of peripheral pectic fractions and loss of the strong bonds due to the loss of the internal pectic fraction and, on the other hand, a liberation of the majority of the cell wall tannins, which implies an overall decrease in the affinity of polyphenols for the cell wall fraction. In this way, the biochemical and physical structures of the cell walls were weakened by treatment, favoring the early release of cellular polyphenols, which explains why, at day 14, the skin vacuolar tannins of treated berries were depleted. The destructuring of the cell walls by the treatment facilitated the extraction and diffusion of phenolic compounds. This hypothesis seems to confirm the results of Delsart et al.[19,20] concerning musts. These phenomena may have been facilitated at all layers of the skin by modification of the skeleton of tannins and the pectic fibers[55,56] combined with ion leakage in cells and cell walls brought about by PEF treatment.[7] Thus, low-intensity, long-duration PEF treatment profoundly modified the organization of the skin cell walls, which explains how the application of a PEF treatment enhanced phenolic compound extraction.[15,18] This treatment mainly affected the cells wall tannins[20] and severely affected cell wall protection. This suggests a more rapid release of cellular tannins due to the parietal system being disrupted and thus becoming more permeable to intracellular compounds. The extraction of polyphenols during maceration is facilitated by PEF2 treatment of the grapes.

In conclusion, the comparison of the impact of two types of PEF treatment on the structure of grape berry skin allowed the very different consequences of the two treatment modes to be brought to light. In the case of PEF treatment of high intensity, short duration, and low energy, the effects on the structure of phenolic compounds and pectic cell walls of the skin were measurable but relatively limited. This study demonstrated a strengthening of the phenolic skeleton of skin cell walls, which has a protective effect, slowing polyphenol extraction phenomena. In the case of PEF treatment of higher strength, longer duration, and high energy, the consequences for the parietal structures of the skin were very significant, the pectic and phenolic skeletons being largely disorganized, which facilitated polyphenol extraction. Thus, the choice of treatment modality is of prime importance because this choice can modify the kinetics of polyphenol extraction and, thus, wine quality. Moreover, it appears that there is a correlation between the mDP of tannins, astringency, and structure of wine, which has an influence on wine quality (low mDP tannins seem less astringent than strong mDP tannins).[34] The availability of a technique that allows the extraction of more and better skin tannins during maceration or a technique that reduces maceration time, especially in the case of unripe harvests, and which, in addition, lead to a reduction of mDP (which is relatively high when the harvest is unripe), may be interesting from a qualitative point of view.[34,38] This study is a first approach to the study of the impact of PEF on cell walls, and further research is required to better understand exactly which cell wall compounds are affected by PEF treatments and to better comprehend the mechanisms involved in improving the extractability of tannins by PEF treatment.

Some of these compounds were detected for the first time in the genus *Brassica* and species *B. napus*.

MATERIALS AND METHODS

Chemicals. NaOH and HCl were purchased from Sangon Biological Engineering Technology and Service Co., Ltd. (Shanghai, China). Methanol, formic acid, acetone, and acetonitrile were of HPLC grade (Sigma, St. Louis, MO). Water was purified using a Milli-Q system (Millipore, Bedford, MA). Procyanidin B2, (−)-epicatechin, and quercetin-3-*O*-β-D-glucoside were purchased from Sigma. Isorhamnetin-3-*O*-glucoside was purchased from ChromaDex (Irvine, CA). Sephadex LH-20 was purchased from GE Healthcare BioSciences AB (Uppsala, Sweden).

Plant Materials and Sample Collection. According to previous research, some flavonoids and hydroxycinnamic acid derivatives normally combine with other seed coat components, which makes them difficult to identify. The flavonoid and hydroxycinnamic acid derivative contents of rapeseed accumulate in the early periods of seed development and reach their peak about 5 weeks after flowering (WAF).[23] In the present study, *B. napus* L. var. *napus* (cv.Yang 6) grown in a greenhouse at approximately 25 °C with a 16 h light/8 h dark cycle was used as the plant material. Two weeks after seedling development, rapeseed lines were planted into 15 cm diameter pots filled with the same soil (20% vermiculite and 80% orchid soil). The plants were vernalized for 2 months at 4 °C. Each flower on the primary raceme was tagged on the day of pollination. Developing seeds were harvested at 5 WAF for phenolic analysis. Five pods from individual plants of one rapeseed line were collected, pooled, and immediately frozen in liquid nitrogen for further analysis.

Preparation of Crude Methanol Extract. The powder (40 g) of dissected rapeseeds was extracted with 200 mL of 80% methanol in an ultrasonicator bath at 4 °C for 1 h. The supernatant was collected after centrifugation (10 000 rpm, 10 min, 4 °C) and stored at −80 °C. The pellet was again extracted overnight with 100 mL of the same extraction buffer at 4 °C under agitation (200 rpm). The supernatant from the second extraction was collected and pooled with the supernatant collected from the previous day. The extracts were subsequently concentrated using a vacuum rotary evaporator at 35 °C, and the slurry was washed with ddH_2O to a final volume of 4 mL. Finally, the obtained crude extract was diluted with 5 volumes of methanol, filtered through a 0.45 μm Teflon membrane (Interchim, Montluc-on, France), and analyzed by HPLC-PDA−ESI(−)-MS^n (IonTrap) and HPLC-DAD−ESI(−)-HRMS (Q-TOF).

Preparation of Sephadex LH-20 Column Chromatography Fractions. Column chromatography of the crude extract described above was carried out according to the method described by Yang et al.[26] with several modifications. The crude extract (2 mL) was loaded onto a 22 mm i.d. × 470 mm length glass column packed with 25 g of Sephadex LH-20 medium resin (dry particle size 18−118 μm); the resin was swelled in ddH_2O overnight and equilibrated with ddH_2O before use. Finally, the column was eluted with the solvents listed in Table 1. The elution speed was controlled to 1 mL min^{-1}, and 150 mL of each collection was produced. The column was regenerated by washing with 10 column volumes of ddH_2O. Each fraction was again concentrated using a vacuum rotary evaporator at 35 °C, and the slurry was washed with ddH_2O to a final volume of 3 mL, which was transferred into a 10 mL glass tube and evaporated using nitrogen flow. Finally, the slurry was washed with 1 mL to 2 mL 80% methanol, filtered with Teflon membrane, and analyzed with HPLC−PDA−ESI(−)/MSn (LCQ) and HPLC−DAD−ESI(−)/HRMS (Q-TOF).

Table 1. Eluotropic Series for Sephadex LH-20 Column Chromatography

fraction	H_2O concn (%)	MeOH concn (%)	acetone concn (%)
F1	100	0	0
F2	70	30	0

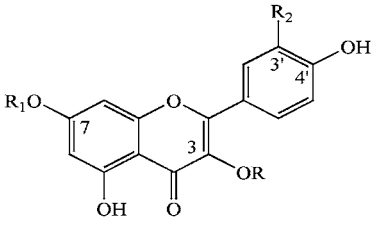
Alkaline Hydrolysis of Crude Extracts. Alkaline hydrolysis of the crude extracts was carried out according to the method described by Lin et al.[8] with minor modifications. The crude extract (0.4 mL) was evaporated by nitrogen flow, and the residue was mixed with 0.3 mL of 2 N NaOH under a N_2 atmosphere for 18 h. Then, 0.1 mL of HCl (37%) was added to the reaction mixture to adjust the pH to 1.0, and 1.6 mL of methanol was added. After filtering through a Teflon membrane, the extract was analyzed by HPLC-PDA−ESI(−)-MS^n (IonTrap) and HPLC-DAD−ESI(−)-HRMS (Q-TOF).

HPLC-PDA−ESI(−)-MS^n (IonTrap) Analysis. The crude extract, alkaline-hydrolyzed extract, and eight fractions of the crude extract were analyzed using an LCQ Deca XP MAX (ThermoFinnigan, San Jose, CA) instrument to determine the UV absorption characteristics and MS^n fragmentation patterns of the flavonoids and other compounds. The instrument was operated using Xcalibur version 1.4 software. An LCQ Deca XP MAX system with an ion-trap mass spectrometer including an LC pump, a Finnigan Surveyor autosampler, and a Thermo Finnigan Surveyor PDA detector was used. Separation was performed on an RP-C18 column (150 mm × 4.6 mm, 5 μm, Agilent Technologies, Waldbronn, Germany) at 30 °C. The flow rate was set to 0.8 mL min^{-1}, and the injection volume was set to 10 μL. The mobile phase consisted of a combination of solvent A (0.1% formic acid in water, v/v) and solvent B (0.1% formic acid in acetonitrile, v/v). The linear gradient was as follows: 4%−20% B (v/v) for 40 min, 35% B for 60 min, 100% B for 61 min, hold at 100% B for 76 min, 4% B for 77 min, and hold at 4% B to 86 min. UV−vis spectra were recorded from 200 to 600 nm. The mass analyzer was a ThermoFinnigan LCQ IonTrap instrument coupled with an ESI source. The instrument was set to negative ion mode with an m/z range of 90−2000. The following conditions were adopted: capillary temperature of 300 °C, sheath gas of 70 arbitrary units, capillary voltage of 20 V, and tube lens of 70 V. Under 50% normalized collision energy, the most intense ion was selected to obtain the MS^2, MS^3, and MS^4 data. The collision gas used was nitrogen.

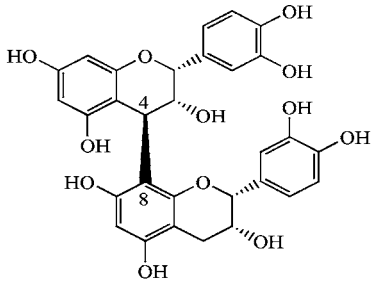
HPLC-DAD−ESI(−)-HRMS (Q-TOF) Analysis. The extracts were subjected to HPLC-DAD−ESI(−)-HRMS (Q-TOF) analysis to determine their exact molecular mass, identify the elemental composition of the compounds, and verify the result of MS^n (IonTrap) analysis. An Ultimate 3000 series instrument (Dionex Sunnyvale, CA) coupled with an Ultimate 3000 pump including an autosampler, a column compartment, and a DAD detector was used for liquid chromatography. Separation was performed using the same gradient described above; here, an Ultimate XB-C18 column (3.5 μm, 2.1 mm × 150 mm, Welch) and a Phenomenex precolumn (2 mm × 4 mm, Torrance, CA) were used at 30 °C. The flow rate was set to 0.2 mL min^{-1}, and the injection volume was 10 μL. The DAD was set to 520, 330, and 280 nm to record peaks, and UV−vis spectra were recorded from 190 to 800 nm. A Bruker Daltonik (Bremen, Germany) maXis Q-TOFHRMS instrument with an ESI source was used for mass analysis. The instrument was operated by the microTOF control (Bruker Daltonik) software package. Negative ion mode and an m/z range of 100−2000 were selected during operation. The nebulizer gas (N_2) pressure was 1.5 bar, the drying gas flow was 6 L min^{-1}, the drying gas temperature was 180 °C, and the capillary voltage was 2500 V.

RESULTS AND DISCUSSION

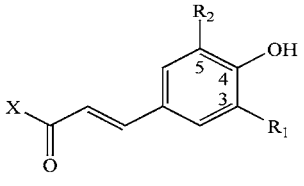
Confirmation of Flavonol Glycosides. The structures of the compounds identified in seeds of *B. napus* L. var. *napus* are shown in Figure 1. The HPLC−UV (330 nm) profiles of flavonoids and hydroxycinnamic acid derivatives obtained from the crude extracts and chromatography fractions are presented in Figure 2. Fifteen flavonol glycosides were successfully



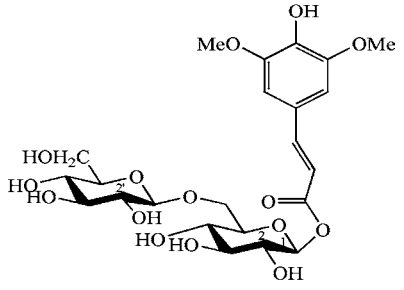
Flavonols and their glycosides:
Kaempferol: $R=R_1=R_2=H$ (MW=286 Da)
Quercetin: $R=R_1=H$, $R_2=OH$ (MW=302 Da)
Isorhamnetin: $R=R_1=H$, $R_2=OMe$ (MW=316 Da)
Glycosides: R or R and R_1=glycosyls



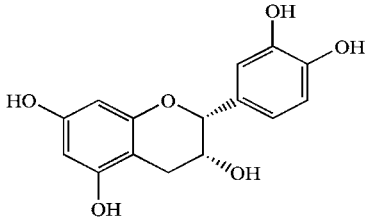
Procyanidin B2 ([DP 2], MW=578 Da)



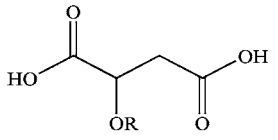
Hydroxycinnamoyls (the mass data):
p-Coumaroyl: $R_1=R_2=H$ (+146 Da)
Caffeoyl: $R_1=OH$, $R_2=H$ (+162 Da)
Feruloyl: $R_1=OMe$, $R_2=H$ (+176 Da)
Hydroxyferuloyl: $R_1=OMe$, $R_2=OH$ (+192 Da)
Sinapoyl: $R_1=R_2=OMe$ (+206 Da)



1-Sinapoylgentiobiose (MW=548 Da)



(-)-Epicatechin (MW=290 Da)



Malic acid (R=H, MW=134 Da)

Figure 1. Structures of compounds identified in seeds of *B. napus* L. var. *napus*.

identified according to their retention times, UV−vis wavelength maxima (λ_{max}), MS^2, MS^3, and MS^4 ion characteristics, alkaline hydrolysis patterns, and HRMS profiles. The corresponding chemical information of the identified phenolic compounds is listed in Table 2.

On the basis of previous conclusions,[8,14,16] the identified flavonol glycosides were analyzed according to their UV wavelength maxima (λ_{max}) and MS^n fragments. For example, the UV spectra of the 3-*O*-glycosides and 3-*O*-,7-*O*-diglycosides in both quercetin and isorhamnetin showed λ_{max} at approximately 255−270 nm (band II) and 345−355 nm (band I), respectively. The 7-*O*-glycosides in quercetin and isorhamnetin showed λ_{max} at 255−270 nm (band II) and 370 nm (band I), respectively. By contrast, the λ_{max} values of 3-*O*-glycosides, 3-*O*-,7-*O*-diglycosides, and 7-*O*-glycosides on kaempferol were detected at around 255−270 nm (band II), 345−350 nm (band II), and 365 nm (band I), respectively.

During the formation of flavonol derivatives in Cruciferae, glycosylation initially occurs at 3-OH and then at 7-OH. During MS^n analysis with negative ionization, the major MS^2 product ions resulting from the loss of 7-*O*-glycosides were first detected, followed by the main MS^3 product ions formed by the loss of 3-*O*-glycosides.[16,27] According to the size of the MS^n fragments, losses of glucosyl (162 Da) and sophorosyl (2-*β*-D-glucopyranosyl-D-glucopyranosyl)/sophorotriosyl (2-*β*-D-glucopyranosyl-20-*β*-D-glucopyranosyl-D-glucopyranosyl) (120 Da/180 Da) were also detected. Several compounds could be confirmed on the basis of the chemical formulas obtained from HRMS analysis and alkaline hydrolysis characteristics. For instance, kaempferol-3-*O*-sophoroside-7-*O*-glucoside (peak 5), which has been previously reported,[21] exhibited UV spectra with λ_{max} at 255 and 350 nm. The major MS^2 fragment at m/z 609 obtained from the loss of a glucosyl (162 Da) was first detected, followed by two major MS^3 fragments, including an ion fragment at m/z 429 from the partial loss of a sophorosyl (180 Da) and a parent ion at m/z 285 from the complete loss of a sophorosyl. The presence of peak 5 after alkaline hydrolysis indicates the presence of glucosyl rather than caffeoyl in this compound, which is in agreement with the HRMS analysis.

In summary, 15 glucosylated flavonols were successfully identified (Table 2), including 6 isomers of kaempferol diglucoside and 2 isomers of quercetin triglucoside. We found that the number of glycosides varied among the different flavonol derivatives. The 15 glucosylated flavonols consisted of 9 glycosylated kaempferol compounds, 3 glycosylated quercetin compounds, and 3 glycosylated isorhamnetin compounds. Five

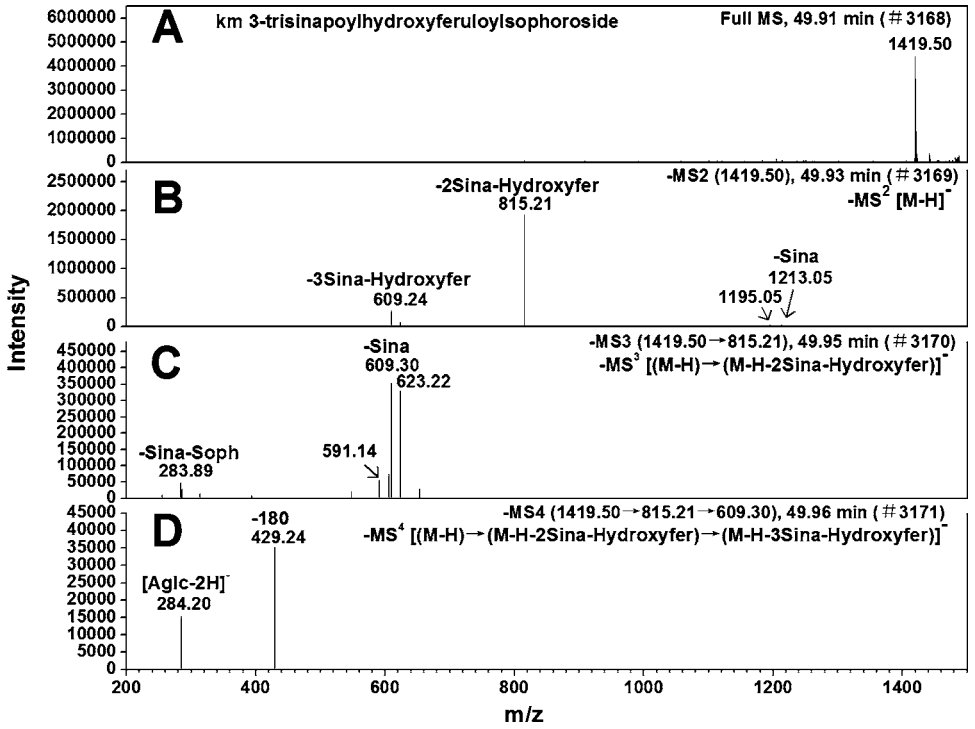

Figure 3. MS^n analysis of kaempferol-3-*O*-trisinapoylhydroxyferuloylsophoroside (peak 77), (km = kaempferol). (A) $[M - H]^-$, (B) MS^2 $[M - H]^-$, (C) MS^3 $[(M - H) \rightarrow (M - H - 2Sina - hydroxyfer)]^-$, (D) MS^4 $[(M - H) \rightarrow (M - H - 2Sina - hydroxyfer) \rightarrow (M - H - 3Sina - Hydroxyfer)]^-$.

of these compounds have previously been reported in *B. napus* and genus *Brassica*; these compounds include quercetin-3-*O*-sophoroside-7-*O*-glucoside,[11,21,28] kaempferol-*O*-diglucoside, [24] kaempferol-3-*O*-sophoroside-7-*O*-glucoside,[11,21,28] kaempferol-3-*O*-glucoside,[11,16,20,29] and isorhamnetin-3-*O*-glucoside.[11,22] Ten of the flavonols, including quercetin-3-*O*-diglucoside-7-*O*-glucoside,[13,16,17,27] kaempferol-3-*O*-triglucoside-7-*O*-glucoside,[12,13,16,17,27] kaempferol-3-*O*-glucoside-7-*O*-glucoside,[8,11,16] isorhamnetin-3-*O*-glucoside-7-*O*-glucoside,[8,11,28] kaempferol-3-*O*-sophoroside,[8,10,11,28] quercetin-3-*O*-sophoroside,[8,10] kaempferol-3-*O*-diglucoside,[13,14,16,29] isorhamnetin-3-*O*-diglucoside,[16] kaempferol-7-*O*-sophoroside,[8] and kaempferol-*O*-sophoroside,[8] have previously been reported in the genus *Brassica.* For example, km-3-*O*-sophoroside (peak 31) presented MS^2 fragments at m/z 447 and 429 from the loss of a glucosyl (162 Da) and the partial loss of a sophorosyl (180 Da). Qn-3-*O*-sophoroside (peak 32) presented MS^2 fragments at m/z 463 and 445 from the loss of a glucosyl (162 Da) and the partial loss of a sophorosyl (180 Da). The parent ions of peaks 31 and 32 were respectively observed at m/z 285 and 300 from the complete loss of a glucosyl. Thus, peaks 31 and 32 may be concluded to contain sophorose. Consistent with the alkaline hydrolysis characteristics and HRMS data, we found that peaks 31 and 32 feature λ_{max} at 265 and 345 nm, respectively, which indicate that peaks 31 and 32 are kaempferol-3-*O*-sophoroside and quercetin-3-*O*-sophoroside, respectively.

Confirmation of Acylated Flavonol Glycosides. In *Brassica*, acyl groups on flavonol glycosides were mainly observed in *p*-coumaroyl, caffeoyl, feruloyl, hydroxyferuloyl, and sinapoyl. Acylation greatly affects the UV absorption of flavonol glycosides. For example, the λ_{max} of flavonol glycosides (band I) normally shifts to 310−312 nm when they are combined with *p*-coumaroyl. However, the λ_{max} of band I may also shift to 320−340 nm when the flavonol glycosides are combined with caffeoyl, feruloyl, hydroxyferuloyl, and sinapoyl.[14,16,25,28]

Acylated flavonol glycosides, such as flavonol-3-*O*-acylglycoside-7-*O*-acylglycoside, produce a major MS^2 ion peak from the loss of 7-acyl and glucosyl as well as a parent peak of flavonol from the loss of 3-acyl and glucosyl. *p*-coumaroyl, galloyl, caffeoyl, feruloyl, hydroxyferuloyl, and sinapoyl could be identified from losses of 146, 152, 162, 176, 192, and 206 Da, respectively. As such, deduction of unknown compounds according to the glycosyl products of flavonols after alkaline hydrolysis of acylated flavonol glycosides, accompanied by their UV absorption characteristics, MS^n fragments, and HRMS analysis results, is possible. For instance, Olsson et al.[21] characterized kaempferol-3-*O*-sinapoylsophoroside-7-*O*-glucoside (peak 18) with λ_{max} at 265 and 330 nm, which are considered typical UV absorption peaks of acylated flavonol glycosides. This compound presents a major MS^2 fragment at m/z 815 from the loss of 162 Da and three MS^3 fragments at m/z 609, 591, and 285 from the loss of 206 Da (sinapoyl), 224 Da (sinapic acid), and all acyl and glycosyl groups, respectively. The MS^3 fragment at m/z 609 can be further fragmented into an ion peak at m/z 429, which indicates the presence of sophorosyl.

In this study, we identified 35 acylated flavonol glycosides, including 29 kaempferol derivatives, 3 quercetin derivatives, and 4 isorhamnetin derivatives (Table 2). These flavonols were also clarified in terms of different numbers of glucosyls. Of these 35 compounds, 31 were found for the first time in rapeseed and 21 were discovered for the first time in the genus *Brassica*.

Seven derivatives of kaempferol sinapoyltriglucosides were distributed as peaks 14, 18, 45, 49, 57, 58, and 62. Peaks 14, 45, 49, and 57 were identified as isomers of kaempferol-3-*O*-sinapoyldiglucoside-7-*O*-glucoside, and peaks 18 and 58 were

identified as isomers of kaempferol-3-*O*-sinapoylsophoroside-7-*O*-glucoside on the basis of ion peaks (loss of 180 Da) in the MS^3 spectra. Peak 62 was detected with an ion peak at m/z 609 from losses of (206 Da) and glucosyl (162 Da). We thus hypothesize that sinapoyl is ligated to 7-glucosyl. Peaks 18, 58, and 62 have been previously reported in rapeseed.[21,30] Peak 14 was reported for the first time in *B. napus*, and peaks 45, 49, and 57 were discovered for the first time in the genus *Brassica*.

Ion fragments of peaks 3, 7, and 37 obtained from low-resolution MS in negative mode were found at m/z 933. However, the λ_{max} (band 1) of peak 7 observed at 330 nm was obviously smaller than that of peak 3; this result indicates that peak 7 is an acylated flavonol glycoside. Whereas peak 3 was observed even after alkaline hydrolysis, peak 7 disappeared. HRMS analysis demonstrated that peak 7 ($C_{42}H_{45}O_{24}$) possesses three more carbon atoms than peak 3 ($C_{39}H_{49}O_{26}$). An MS^3 ion fragment from the loss 180 Da was observed after further analysis of peak 7, which indicates that the peak is kaempferol-3-*O*-caffeoylsophoroside-7-*O*-glucoside. We also confirmed that peak 37 is kaempferol-3-*O*-caffeoyldiglucoside-7-*O*-glucoside.

Peaks 66, 71, and 86 showed the same molecular mass, and peaks 66 and 71 were further ascertained as acylated flavonol glycosides according to their UV absorption characteristics. The major MS^2 fragment of peaks 66 and 71 was found at m/z 815 (from the loss of 368 Da), while the major MS^3 fragment of peak 86 was observed at m/z 609 (from the loss of 206 Da). The parent ions of these compounds were about 285 Da, arising from the complete loss of acyl and glucosyl. The m/z 609 ions of peaks 66 and 86 could be fragmented into other ions at m/z 429 from the loss of 180 Da. Thus, we can identify peaks 66, 71, and 86 as kaempferol-3-*O*-sinapoylsophoroside-7-*O*-sinapoylglucoside, kaempferol-3-*O*-sinapoyldiglucoside-7-*O*-sinapoylglucoside, and kaempferol-3-*O*-sinapoylsophoroside-7-*O*-sinapoylglucoside, respectively.

Figure 3 depicts the MS^n spectra of peak 77, which was identified as kaempferol-3-*O*-trisinapoylhydroxyferuloylsophoroside. The spectra of peak 77 show λ_{max} at 270 and 330 nm, which implies that peak 77 is an acylated flavonol glycoside. Further MS^n analysis proved the presence of sinapoyl and hydroxyferuloyl in this compound. Two isomers of kaempferol-3-*O*-trisinapoylhydroxyferuloylsophoroside at peaks 81 and 82 were successfully identified. Peaks 64 and 67 were similarly identified as isomers of kaempferol-3-*O*-disinapoylhydroxyferuloyldiglucoside. Peaks 40 and 44 were identified as kaempferol-3-*O*-disinapoylgalloyldiglucoside and 3-*O*-glucoside-7-*O*-acetylglucoside, respectively. Multiple acylated flavonol glycosides have never been reported in rapeseed, and 21 of these compounds were discovered for the first time in the genus *Brassica* (Table 2). Several compounds found in our work have been previously reported in the genus *Brassica*; these compounds include quercetin-3-*O*-sinapoylsophoroside-7-*O*-glucoside,[21] kaempferol-3-*O*-sinapoylsophoroside-7-*O*-glucoside,[21,31] isorhamnetin-3-*O*-sinapoyldiglucoside-7-*O*-glucoside,[22] kaempferol-3-*O*-sophoroside-7-*O*-sinapoylglucoside,[30] kaempferol-3-*O*-caffeoylsophoroside-7-*O*-glucoside,[8,11] kaempferol-3-*O*-sinapoyldiglucoside-7-*O*-glucoside,[11,16,17,29] kaempferol-3-*O*-sinapoylsophorotrioside-7-*O*-glucoside,[8] kaempferol-3-*O*-feruloylsophoroside-7-*O*-glucoside,[8,28] kaempferol-3-*O*-*p*-coumaroylsophoroside-7-*O*-glucoside,[8,28] kaempferol-3-*O*-sinapoylsophotrioside-7-*O*-glucoside,[8,10,12] quercetin-3-*O*-sinapoylsophoroside-7-*O*-glucoside,[11] kaempferol-3-*O*-sinapoylsophoroside,[8,11] kaempferol-3-*O*-sinapoylsophoroside-7-*O*-glucoside,[12] and kaempferol-3-*O*-sinapoylsophoroside.[8]

Confirmation of Sulfated Flavonol Glycosides. In the present study, we identified four sulfated isorhamnetin compounds. Peak 48 was previously reported by Auger et al.,[22] whereas peaks 15, 36, and 60 have never been reported in the genus *Brassica*. Peak 36 was identified as an isorhamnetin-*O*-diglucoside-sulfate, which presents an MS^2 fragment at m/z 639 from the loss of a SO_3^{2-} (80 Da) and an MS^3 parent fragment at m/z 315. Peaks 15 and 60 were confirmed as isorhamnetin-*O*-diglucoside-sulfate and isorhamnetin-3-*O*-sinapoylglucoside-sulfate-7-*O*-glucoside, respectively. Among the four isorhamnetins found, three were reported for the first time in the genus *Brassica*; only isorhamnetin-*O*-glucoside-sulfate has been previously reported.[22]

Confirmation of Flavanol and its Oligomers. Flavanols show λ_{max} at 202 and 280 nm. The molecular mass of flavanol polymers can be determined as follows: $290 + 288(n - 1)$, where n stands for the number of polymers. A previous report found that fragments of 290 or 288 Da are always lost during the fragmentation of these polymers.[32]

Using (−)-epicatechin and procyanidin B2 as standards, we identified six (−)-epicatechins and their oligomers [DP 2], [DP 3], and [DP 4] [DP = degree of polymerization of the (−)-epicatechin unit] on the basis of their UV absorption characteristics, MS^n fragments, and HRMS analysis results. Identification of these compounds was performed in accordance with previous research.[22,23] We observed that flavanols and their oligomers are generally found in F4 fractions obtained by column chromatography and that isomers of flavanol oligomers in F4 are obviously more abundant than those in crude extracts. These results indicate the possibility of polymer degradation during the experiment and that flavanol polymers are abundant in seeds of *B. napus*.

Confirmation of Hydroxycinnamic Acid Derivatives. Hydroxycinnamic acid derivatives in *Brassica* principally include *p*-coumalic acid, caffeic acid, ferulic acid, hydroxyferulic acid, and sinapic acid, which could be combined with glucose, gentiobiose, quinic acid, malic acid, and malonic acid to form hydroxycinnamic acid derivatives.[19,23,33] The λ_{max} of these derivatives ranged from 230 to 250 nm and from 320 to 330 nm.[14]

Hydroxycinnamoyl or hydroxycinnamic acid may be lost during MS^n analysis, and the presence of gentiobiose can be deduced from the loss of 306 Da. Peak 78 was defined as 1,2-disinapoylglucoside, which has been previously reported.[30] 1,2-Disinapoylglucoside shows an MS^2 ion fragment at m/z 367 from the loss of 224 Da and MS^3 fragments at m/z 352, 223, and 179 from losses of 15 Da (a methyl on sinapoyl), 144 Da (a glucosyl without H_2O), and 188 Da (a sinapoyl without H_2O), respectively.

Eighteen phenypropanoid derivatives were determined according to their retention times, UV absorption characteristics, MS^2 and MS^3 fragments, and HRMS molecular ions $[M - H]^-$. Most of these compounds were derivatives of sinapic acid in conjunction with monosaccharides or disaccharides. While all of the hydroxycinnamic acid derivatives obtained have been previously reported in the genus *Brassica*, 11 of them were discovered for the first time in *B. napus* (Table 2). Four isomers of sinapoylhexose (peaks 6, 12, 23, and 29) were further identified; of these, peaks 12, 23, and 29 were reported for the first time in *B. napus*. Three isomers of sinapoylgentiobiose (peaks 24, 28, and 34) and three isomers of disinapoylgentio-

biose (peaks 34, 69, and 74) were reported for the first time in *B. napus*. A trisinapoylgentiobiose (peak 90) and a sinapoylferuloylgentiobiose (peak 91) were also discovered in this study.

Among the hydroxycinnamic acid derivatives observed, seven have been previously reported in both *B. napus* and genus *Brassica*; these compounds include *cis*-sinapic acid,[33] sinapoylhexose,[19,24] sinapoylmalic acid,[30] *trans*-sinapic acid,[33] 1,2-disinapoylglucoside,[30] 1,2,2′-trisinapoylgentiobiose,[14,16,30] and 1,6-disinapoylglucoside.[8,12,30] Another 11 of these acid derivatives, including sinapoylhexose,[12] sinapoylgentiobiose,[8] sinapoylhexose,[8] sinapoylgentiobiose,[8,12] sinapoylgentiobiose,[8,12] sinapoylhexose,[17] disinapoylgentiobiose,[8,12,14] disinapoylgentiobiose,[8,12] disinapoylgentiobiose,[12] trisinapoylgentiobiose,[12] and sinapoylhydroxyferuloylgentioside,[8] have also been previously reported in the genus *Brassica*

Unknown Flavonoids and Hydroxycinnamic Acid Derivatives. Although multiple phenolic compounds were successfully identified in this research, many chemical compounds remain unknown. These compounds may include specific hydroxycinnamic acid derivatives and flavonoids and always present in conjunction with several unknown chemical groups. For instance, peak 19 was ascertained as a kaempferol combined with three hexoses, a sinapine, and an unknown 68 Da group. Twelve unknown hydroxycinnamic acid derivatives (peaks 8, 20, 27, 54, 55, 75, 79, 80, 84, 87, and 89) produced MS^n fragments of sinapoyl, feruloyl, and gentiobiose. Peaks 20, 75, 76, and 84 exhibited an unknown compound (196 Da) during MS^n analysis. Further confirmation of these unknown compounds must be carried out by purification of single components and subsequent application of infrared spectroscopy and/or nuclear magnetic resonance spectroscopy.

The UV absorption characteristics and MS^n fragments of the target compounds were principally investigated to identify new components by HPLC analysis. HPLC analysis of the crude extracts of flavonoids and hydroxycinnamic acid derivatives in rapeseed is limited by the fact that many of the compounds are simultaneously washed away during the determination, thereby leading to UV spectrum overlaps and identification difficulties.[23] As well, minute amounts of certain compounds may be neglected because of their weak signals in the UV spectra. Sephadex LH-20 column chromatography was performed to separate the crude methanol extract of rapeseed into different fractions that could be further analyzed by HPLC-PDA−ESI(−)-MS^n (LCQ) and HPLC-DAD−ESI(−)-HRMS (Q-TOF), thereby allowing comprehensive and detailed characterization of the crude extract. Although some of the compounds may be dehydrated during subsequent concentration, no adverse effects on their identification were noted. Alkaline hydrolysis transformed acylated flavonol glycosides into glycosylated chemicals of the parent ion, thereby promoting the identification of acylated compounds. Compounds released after alkaline hydrolysis also directly demonstrate the type of phenypropanoid available.[14,16,34]

The development of HPLC-PDA−ESI(−)-MS^n/HRMS greatly facilitates the identification of unknown compounds according to their molecular mass; this analytical technique further allows calculation and deduction of the element composition of relevant chemical compounds. Several flavonol derivatives were identified in this research, 70% of which were confirmed as kaempferol derivatives, 20% of which were isorhamnetin derivatives, and 10% of which were quercetin derivatives. In a previous study, the kaempferol content was found to be higher than those of quercetin and isorhamnetin.[23] Epicatechin, a compound related to the flavonoid biosynthetic pathway, varies obviously in content in differently colored rapeseed.[23] A comprehensive dissection of flavonoid biosynthesis patterns indicates that kaempferol formation is related to epicatechin accumulation.[35,36] In the present study, we found that sinapic acid, the main derivative of phenypropanoids in rapeseed, greatly increases after alkaline hydrolysis. This result suggests that sinapic acid is the main antinutritional factor of rapeseed.

In conclusion, we detected 91 flavonoids and hydroxycinnamic acid derivatives in *B. napus* L. var. *napus* seeds through HPLC-PDA−ESI(−)-MS^n/HRMS (IonTrap and Q-TOF) analysis. Seventy-eight of these compounds were identified tentatively; 55 of the compounds were reported for the first time in *B. napus*, and 24 were reported for the first time in the genus *Brassica*. Comprehensive interpretation of flavonoids and hydroxycinnamic acid derivatives in rapeseed is fundamental to studies on the antinutrition properties of rapeseed. The results of this study improve the scientific knowledge of the phenolic composition of rapeseed and provide a reliable guide for selecting rapeseed for breeding with better seed quality. We also successfully prove that HPLC-PDA−ESI(−)-MS^n/HRMS is a highly efficient and elaborate technique for plant phenolic analysis and chemical identification.

This study was a part of the Novinpak project. The first objective of the latter was to develop a monolayer PET bottle containing recycled PET (RPET) and suitable for wine. In addition, this bottle had to be light and suitable for incorporation in present industrial recycling and recovery processes. The second objective concerned gas management during bottling (dissolved oxygen (DO_2), headspace or gaseous oxygen ($HspO_2$), and dissolved carbon dioxide (DCO_2)) that ensured satisfactory conservation of rosé wine. Indeed, the oxygen content of headspace and wine during bottling can be the equivalent of several months of O_2 ingress through packaging.[25,26] The management of both dissolved and headspace gases during bottling and the choice of packaging are the key factors in the control of the quality and shelf life of wine. Bottling is the last step before selling wine, and O_2 trapped during bottling is consumed by wine and has consequences on wine aging.[6,25,27−29] The final objective of the project was to be able to ensure the good conservation of the organoleptic quality of wine by gas management during bottling and oxygen ingress management during storage. Several research teams and companies worked on this project in order to attain these objectives. Wine color and aroma evolution were studied, and sensory evaluation was performed. Life cycle analyses of glass and PET bottles were compared. Inertness, food contact suitability, and the barrier properties of PET were also studied. These studies are not reported in the present paper. Our study examines the limits of a standard monolayer PET bottle for wine packaging, with regard to the three main gases present in headspace and in wine (O_2, CO_2, N_2) and their exchanges with air in order to propose monolayer packaging for the wine targeted and its required shelf life. The impact on wine aging during 372 days of storage and SO_2 content are also examined. To the best of our knowledge, this is the first complete gas balance study for PET and glass bottles in time.

MATERIALS AND METHODS

A Cinsault rosé wine was bottled at Pech Rouge Experimental Unit (INRA, UEPR, Gruissan) in 75 cL colorless glass and PET bottles. Gas management in the bottling line used achieved homogeneous bottling with negligible losses of CO_2 and a low DO_2 content.[26,27] Two PET bottles were studied: a 38 g standard PET bottle (PET38) and a 38 g 100% recycled PET bottle (PET38R). Different methods were used to measure fSO_2, TSO_2, and headspace and dissolved gases (O_2, CO_2, N_2) for one year as described in Table 1. Analyses were scheduled throughout bottle storage to characterize the changes in the wines. A PreSens probe was used for frequent measurement of $HspO_2$ and DO_2 in the same three bottles for 372 days (noninvasive analyses). However, it was not possible to measure $HspCO_2$, $HspN_2$, or DCO_2 using this method. We therefore used other methods such as polarography and gas chromatography (invasive analyses) to measure all these parameters (gas balance) in three different bottles on several dates.

Experimental Bottling. The line was first purged with N_2 from preparation tank to head filler machine (to $HspO_2$ < 1% (v/v)). The preparation tank was filled by gravity with rosé wine. The wine was sparged with N_2 gas until DO_2 reached 0.3 mg/L. DCO_2 was then regulated with CO_2 gas using a porous injector bolted to the bottom of the preparation tank until DCO_2 reached 1 g/L. DCO_2 was monitored by sampling in the preparation tank using a Carbodoseur (Dujardin-Salleron laboratories, Noizay, France). Wine was forced into the circuit by N_2 to the filler tank through the filtration skid using overpressure of 150 kPa applied to the preparation tank. Bottles were blanketed before filling. Filled bottles were placed in the capping machine, where a screwcap was crimped. To achieve good bottling homogeneity, we discarded the first three and the last three bottles as DO_2 at the beginning and the end of bottling is higher than during the rest of the process.[27,30] Certain bottling parameters, kind of bottles, headspace and wine volume, and gas management are summarized in Table 2. Bottles were stored upright for 12 months in a thermostatically controlled room (20 ± 0.7 °C) with a relative humidity (RH) of 68 ± 9% (monitored but not controlled). Half of the bottles were stored in light (400 Lux) 24 h a day and 7 days a week and the other half stored in the dark (packed in cardboard boxes).

Table 1. Summary of Analyses Performed during Storage*

analyses	method	no. of bottles/ procedure	dates of analyses (days after bottling)
DO_2 (mg/L) converted in (mg/bt)	polarography	3	0 ($12 < n < 18$), 35, 91, 162, 278, 372
	luminescence	3	1, 7, 15, 21 and approx each month from 0 to 372
$HspO_2$ (% (v/v)) converted in (mg/bt)	micro gas chromatography	3	0 ($12 < n < 18$), 35, 91, 162, 278, 372
	luminescence	3	1, 7, 15, 21 and approx each month from 0 to 372
DCO_2 (mg/L)	volumetry	3	0 ($12 < n < 18$), 35, 91, 162, 278, 372
P_{aphro} (hPa)	pressure potentiometer	3	0 ($12 < n < 18$), 35, 91, 162, 278, 372
alcohol (%), TA (g/L H_2SO_4), pH	FTIR	3	0, 35, 91, 162, 278, 372
RS (mg/L)	FTIR	3	0
VA (g/L H_2SO_4)	enzymatic	3	0, 35, 91, 162, 278, 372
fSO_2 (mg/L), TSO_2 (mg/L)	colorimetric	3	0, 35, 91, 162, 278, 372

*At least 3 bottles per procedure were analyzed for each analysis. At t = 0, "n" represents the number of bottles analyzed per procedure. To monitor bottling homogeneity throughout the process, dissolved and headspace gases were measured in a larger number of bottles ($12 < n < 18$).

Determination of Headspace and Wine Volume with Unfilled Level. O_2 trapped in headspace directly determines consumption by wine after bottling.[28] To be able to compare procedures, the same screwcap was used whatever the packaging and the headspace volume/wine volume ratios ($Hsp_{vol}/wine_{vol}$) were as close as possible in each procedure. The unfilled level, directly related to headspace and wine volumes, was set before bottling. Different unfilled levels and volumes of reverse osmosis water (22 °C) were tested by Sidel Blowing Service (Le Havre, France) on several bottles of each procedure. It appeared that correlation between Hsp_{vol} measured and the unfilled level was good ($R^2 \approx 0.98$, data not shown). Experiments conducted at UEPR indicated the accuracy and reproducibility of this method for wine (data not shown). To achieve the closest $Hsp_{vol}/wine_{vol}$ in all procedures, the headspace level at 20 °C was set at 46 mm for PET bottles and 60 mm for glass bottles. As a result, the wine volume was not exactly the same for each packaging type (Table 2).

Noninvasive Analyses. On line O_2 monitoring was performed using a PreSens luminescent probe (PreSens Precision Sensing GmbH, Regensburg, Germany) and PSt3 O_2-sensitive optical spots (PreSens Precision Sensing GmbH; oxygen range, 0−22 mg/L; limit of detection, 15 μg/L; accuracy, ±1% at 100% air-saturation and ±0.15% at 1% air-saturation) integrated at four checkpoints on the bottling line and at the top and bottom of the preparation and filler tank. In bottles, DO_2 and $HspO_2$ were also measured using this method.[22] Data acquisition was performed using PST3v541 software (PreSens Precision Sensing GmbH). Analytical monitoring was performed on 19 dates of analyses after bottling (Table 1). The system measured oxygen partial pressure (PO_2) in hPa. It could also express the values in mg/L or in % (v/v) according to the phase studied, temperature, and pressure. Headspace was measured in % (v/

Table 2. Bottling Parameters at $t = 0$*

*Averages and standard deviations of bottling parameters: "n" represents the number of samples per analysis. TO_2 is the sum of DO_2 measured by Orbisphere probe and $HspO_2$ measured by PreSens spots.

v) and converted into milligrams per bottle (mg/bt) according to Hsp_{vol}, using eq 1:

$$HspO_2 = \frac{HspO_2'}{100} \times Hsp_{vol} \times \frac{M_{O_2}}{V_M \times \frac{T + 273.15}{273.15}} \quad (1)$$

$HspO_2$ is headspace oxygen (mg/bt), $HspO_2'$ is headspace oxygen (% (v/v)), Hsp_{vol} is headspace volume (mL), T is wine temperature (°C), M_{O_2} is the molar mass of oxygen (32 g/mol), and V_M is the molar volume (22.414 L/mol). DO_2 values were measured in mg/L and converted into mg/bt as the volume of wine in the bottle was known.

Invasive Analyses. DO_2 was measured using an Orbisphere 31110A polarographic probe equipped with a 25 μm 2956A membrane (Hach Ultra Analytics, Trappes, France). The membrane range of O_2 measurement was 0.25 Pa to 50 kPa (limit of detection, 1 μg/L; accuracy, 0.02 μg/L). The probe was connected to an Orbisphere Moca 3600 single channel microprocessor analyzer for oxygen measurements. Results were expressed in mg/L and converted into mg/bt according to the volume of wine. At $t = 0$, the Orbisphere probe was used to measure DO_2 in bottles because the response time of PreSens spots in liquid is greater than in gas. As a result, measurement of DO_2 should take place at least 40 min after bottling with the PreSens probe, whereas it can be measured immediately after bottling with the Orbisphere probe (Table 2).

$HspO_2$, headspace CO_2 ($HspCO_2$), headspace N_2 ($HspN_2$), and aphrometric pressure (P_{aphro}) were measured by gas chromatography (μGC, micro GC CP4900, Varian, Les Ullis, France) (accuracy = 0.25%). A specific sampling system was set up, consisting of a peek tube with a needle, a Genie 170 membrane to prevent any liquid contamination, a four-way valve to purge the needle or to load the sample into the injectors, and an electronic manometer to measure the internal pressure of the sample (P_{aphro}). After the piercing of the screwcap, the internal pressure was monitored and then the sample was pumped for 30 s through the circuit to ensure satisfactory clearance. A 400 μL sample was then injected in the columns. The results were expressed in % (v/v) and converted into mg/bt using eq 2:

$$Hsp_{gas} = \frac{Hsp_{gas}' P_{tot} Hsp_{vol} \times 10^{-6}}{\left(\frac{R}{M_{gas}} \times 10^3\right)(273.15 + T)} \quad (2)$$

Hsp_{gas} is gas headspace (mg/bt), Hsp_{gas}' is gas headspace (% (v/v)), Hsp_{vol} is headspace volume (mg/L), M_{gas} is the molar mass of gas (O_2, 32 g/mol; CO_2, 44 g/mol; or N_2, 28 g/mol), R is the universal gas constant (8.314 J/mol/K), T is headspace temperature (°C), and P_{tot} is total pressure (hPa), the sum of atmospheric and aphrometric pressure of the day 3

$$P_{tot} = P_{atm} + P_{aphro} \quad (3)$$

DCO_2 was measured by sampling in the preparation tank or bottles. Determination was performed using a Carbodoseur (repeatability 90 mg/L).[31] Results were expressed in mg/L and converted into mg/bt.

The methods used to determine alcohol content (% vol), total and volatile acidity (TA and VA: g/L H_2SO_4), pH, and free and total SO_2 (fSO_2 and TSO_2: mg/L) are reported in Table 1.

Calculation of Gas Flow Directions inside the Bottle and between Bottle and Air. In glass bottles, exchanges with air can only take place through the screwcap. As monolayer PET is gas-permeable, exchanges can also take place through the bottle wall as well. In general, as soon as a difference in the concentration of a chemical species appears in an environment, matter flows appear to reach balance. In our case, diffusion was the main driver for gas exchange between bottle and air and between headspace and wine. To determine gas exchange direction between bottle and air, we used the comparison of partial pressure of each gas in the headspace (P_{HspO_2}, P_{HspCO_2}, P_{HspN_2}) and the partial pressure of each dissolved gas (P_{DO_2}, P_{DCO_2}, P_{DN_2}) with the partial pressure of each gas in air at RH 68% (as monitored in our experiment). The partial pressure of each gas was expressed in hPa using results of the headspace composition in a bottle given by μGC in % (v/v). We consider that the air in the headspace was water vapor saturated. Oxygen partial pressure in headspace is given by eq 4:

$$P_{HspO_2} = \frac{HspO_2'}{100} \times (P_{tot} - P_{w(T)}) \quad (4)$$

P_{HspO_2} is the partial pressure of O_2 in headspace (hPa), $HspO_2'$ is headspace O_2 measured by μGC (% (v/v)), P_{tot} is total pressure (hPa) (eq 3), and $P_{w(T)}$ is the saturated water vapor pressure (hPa).

The saturated water vapor pressure at a known temperature can be expressed using Campbell's eq 5 in this form (T expressed in °C):

$$P_{w(T)} = \exp\left(52.57 - \frac{6690.9}{T + 273.15} - 4.681 \times \ln(T + 273.15)\right) \quad (5)$$

Equation 6 was deduced from eqs 4 and 5 and used to calculate oxygen partial pressure in the headspace using $HspO_2'$:

$$P_{HspO_2} = \frac{HspO_2'}{100} \times \left(P_{tot} - \exp\left(52.57 - \frac{6690.9}{T + 273.15} - 4.681 \times \ln(T + 273.15)\right)\right) \quad (6)$$

Similarly we calculated P_{HspN_2} (partial pressure of N_2 in headspace) and P_{HspCO_2} (partial pressure of CO_2 in headspace) using $HspN_2'$ (headspace N_2 in (% (v/v))) and $HspCO_2'$ (headspace CO_2 in (% (v/v))).

We calculated the partial pressure of O_2 in air at RH 68% (P_{O_2atm}) using eq 7 (pressure in hPa):

$$P_{O_2atm} = (P_{atm} - 0.68P_{w(T)}) \times 0.2095 \quad (7)$$

Likewise, we calculated the partial pressure of N_2 and CO_2 in air at RH 68% (P_{N_2atm}, P_{CO_2atm}) using eqs 8 and 9:

$$P_{N_2atm} = (P_{atm} - 0.68P_{w(T)}) \times 0.7808 \quad (8)$$

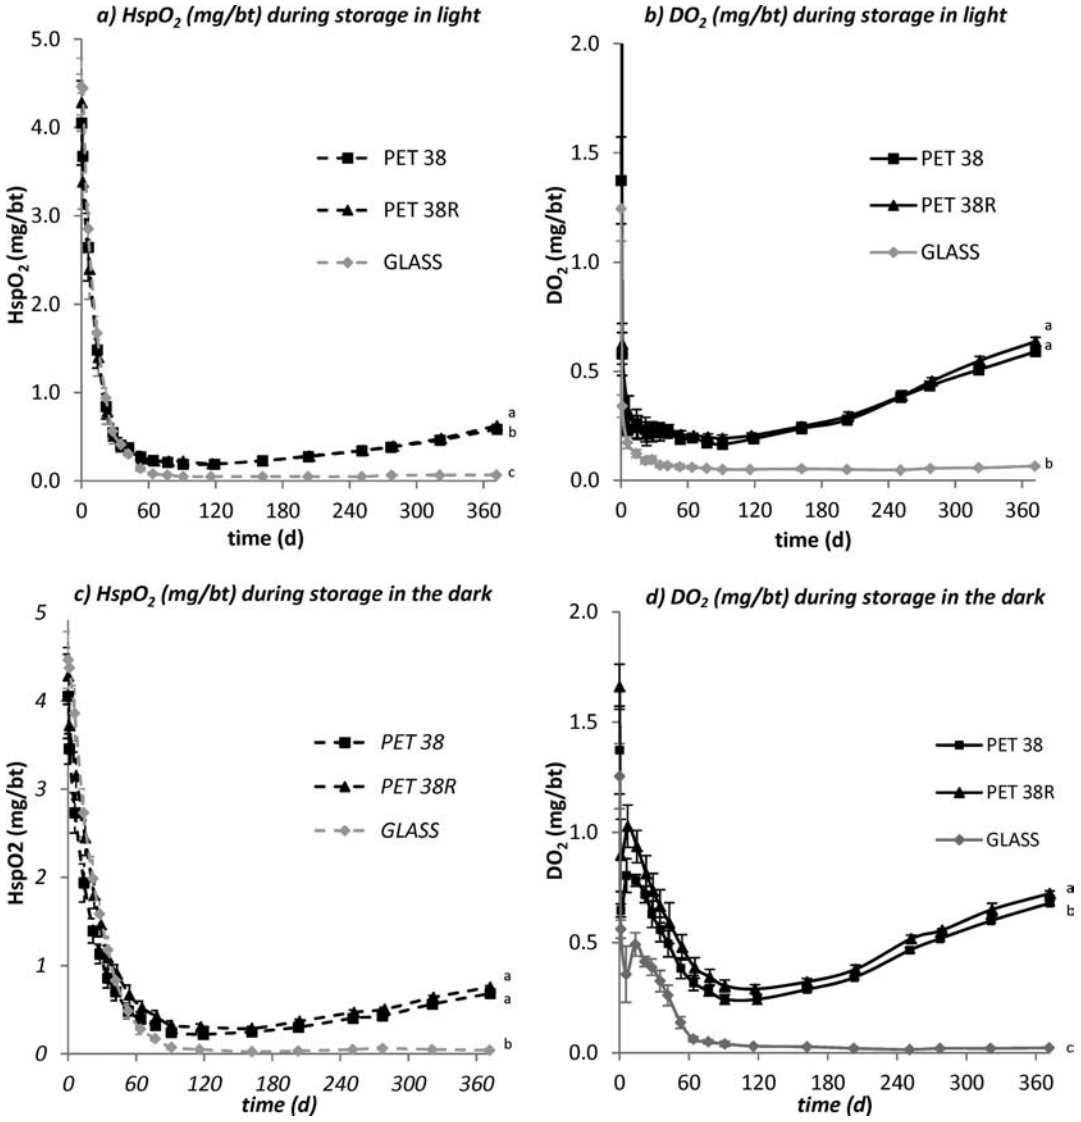

Figure 1. $HspO_2$ and DO_2 for PET and glass bottles during storage time in light (a, b) and in the dark (c, d). Averages and standard deviations are calculated from 3 bottles per procedure. Data were analyzed by analysis of variance (ANOVA) at 372 days, followed by Newman−Keuls multiple comparison tests ($\alpha = 0.05$). Similar letters denote no significant differences between the tested groups. $HspO_2$ and DO_2 values were obtained by PreSens, except for DO_2 at t = O where values were obtained by using an Orbisphere probe. Dotted lines with squares, triangles, and diamonds indicate $HspO_2$ of PET38, PET38R, and glass bottles respectively. Continuous lines with squares, triangles, and diamonds indicate DO_2 of PET38, PET38R, and glass bottles respectively.

$$P_{CO_2atm} = (P_{atm} - 0.68P_{w(T)}) \times 0.0003 \quad (9)$$

We compared $P_{Hsp_{gas}}$ with P_{gasatm} to identify gas flow directions between bottle and air 10 (pressures in hPa):

$$Hsp_{gas}{}^{\%} = \frac{P_{Hsp_{gas}}}{P_{gasatm}} \times 100 \quad (10)$$

$Hsp_{gas}{}^{\%}$ is expressed as the gas saturation percentage in air at RH 68%. As long as $Hsp_{gas}{}^{\%}$ is below 100% (respectively above 100%), gas from the air tends to diffuse through the bottle wall into the headspace to reach equilibrium (respectively headspace gas tends to diffuse from bottle to air).

Furthermore, we were interested in exchanges in the bottle between headspace and wine. O_2, N_2, and CO_2 are present in the headspace and are also dissolved in the wine. These exchanges are governed by both Fick's law and Henry's law: the solubility of a gas in a liquid is directly proportional to the partial pressure of the gas above the liquid. To calculate the pressure of dissolved gases (P_{Dgas}), we used formulas that took into account O_2 and N_2 dissolution in water, for lack of bibliographical references on wine. For dissolved gases, we were able to measure DCO_2 and DO_2 as described above, but we could not measure DN_2. It was estimated using eq 11 based on Dalton's law (3% is an estimate for water, ethanol, and the vapor pressure of noble gases):

$$P_{DN_2} = 0.97 \times P_{tot} - P_{DO_2} - P_{DCO_2} \quad (11)$$

DO_2 was given using Orbisphere probe in mg/L and was used to calculate partial pressure of O_2 dissolved in wine (hPa). The solubility of oxygen in water was used here and can be described by the Bunsen absorption coefficient $\alpha(T)$ (eq 12):[32]

$$P_{DO_2} = \frac{DO_2 \times 1013.25}{\alpha(T) \times 1000 \times \frac{32}{22.41 \times \frac{T+273.15}{273.15}}} \quad (12)$$

P_{DO_2} is the partial pressure of dissolved O_2 (hPa), DO_2 is oxygen concentration (mg/L), T is temperature (°C), and $\alpha(T)$ is the Bunsen absorption coefficient ($mL(O_2)/mL$), that determines the partition between gas and liquid phases (eq 13) (T expressed in °C):

dx.doi.org/10.1021/jf405392u | J. Agric. Food Chem. 2014, 62, 2946−2955

$$\alpha(T) \times 10^3 = 48.998 - 1.335T + 2.755 \times 10^{-2} \times T^2 - 3.220 \times 10^{-4} \times T^3 + 1.598 \times 10^{-6} \times T^4 \quad (13)$$

As this solubility was given for dissolved oxygen in water, we used it for wine as well.

DCO_2 was given by Carbodoseur methodology in mg/L, and the partial pressure of dissolved CO_2 (P_{DCO_2}) was then calculated. The formula according to the OIV Reference Method at 20 °C (OIV, 2008) was used for calculations and applications in wine. Equation 14 takes into account the temperature correction factor as proposed by Liger-Belair.[33]

$$P_{DCO_2} = \left(\frac{DCO_2}{\exp\left(2984 \times \frac{1}{293.15} - \frac{1}{T + 273.15}\right)} \times \frac{1}{0.01951(0.86 - 0.01E)(1 - 0.00144 \times RS)} \right) \times \frac{1}{100} \quad (14)$$

P_{DCO_2} is the partial pressure of dissolved CO_2 (hPa), DCO_2 is CO_2 concentration (mg/L), T is wine temperature (°C), E is the alcohol content (12.6% vol alcohol), and RS is the residual sugar in wine (0.23 g/L).

As explained for eq 10, if we compare P_{Dgas} (partial pressure of dissolved gases) with P_{gasatm} (partial pressure of gas in air at RH 68%), we can understand the direction of gas flows between wine and air (eq 15) (pressures are expressed in hPa).

$$Dgas^{\%} = \frac{P_{Dgas}}{P_{gasatm}} \times 100 \quad (15)$$

$Dgas^{\%}$ is expressed as the percentage of gas saturation in air at RH 68% (% (sat)). Equations 10 and 15 are also used to deduce the direction of gas exchanges between headspace and wine. As long as $Dgas^{\%}$ is below $Hsp_{gas}{}^{\%}$ (respectively above), gas tends to dissolve from the headspace into the wine (respectively to diffuse from wine to headspace).[25,28]

Wine. The wine was a Cinsault rosé "Vin de Pays d'Oc" (12.6% vol alcohol; RS, 0.23 g/L; TA, 3.40 g/L H_2SO_4; VA, 0.17 g/L H_2SO_4; pH, 3.28; free and total SO_2, 36 and 130 mg/L, respectively).

Bottling Raw Materials. PET bottles were 75 cL colorless Bordeaux bottles supplied by Sidel. The OTRs of PET38 and PET38R bottles were respectively 0.0637 ± 0.0008 and 0.0527 ± 0.0009 mg/bt/day. Glass bottles were 75 cL colorless Bordeaux bottles (BSN Glasspack SA, Villeurbanne, France). PET and glass bottles were capped with Novatwist 30H60 screwcaps (Novembal, Edison, NJ, USA) with Saranex seals (OTR: 0.0016 mg/cap/day). These caps were made of PE (polyethylene) and PP (polypropylene) and were 100% recyclable. The OTR values mentioned above were measured using a Mocon Ox-Tran 2/20 (Mocon, Minneapolis, MN. Tests were carried out by Sidel on an entire bottle at 23 °C (RH 60%), and the test gas was ambient air. Tests were performed on five bottles per procedure. Bottles of pure N_2 and pure CO_2 (food quality, purity ≥99.9%, Air Liquide, France) were used to manage gases during bottling as described above.

Bottling Line. The bottling line used consisted of three components: (1) a filtration skid with one preparation tank (105 L), 2 cartridge housings for 1 μm prefiltration, and 0.65 μm filtration membrane cartridges; (2) a single head filler MTB 1/1 (Perrier, Le Cheylard, France) with a 46 L tank; (3) a single head capping machine (TM3, Zalkin, Rueil-Malmaison, France).

Data Analysis. Statistical analyses were performed with analysis of variance (ANOVA) and Newman−Keuls multiple comparisons test (α = 0.05) using XLSTAT version 2007.1 program (Addinsoft, Paris, France).

RESULTS AND DISCUSSION

Bottling. Results showed inter- and intraprocedure homogeneity (Table 2). $HspO_2$ formed the major part of total oxygen content (TO_2) ($HspO_2 \approx 75\%$ TO_2) because of the low wine level (wine volume of 742.4 mL instead of 750 mL). Furthermore, average DO_2 was 1.38 mg/bt whereas average $HspO_2$ was higher (4.27 mg/bt). Another study conducted at UEPR showed that $HspO_2$ could reach 0.38 mg/bt to 3.58 mg/bt according to Hsp_{vol}, the kind of stopper, and the use of inert gas, whereas average DO_2 was 3.91 mg/bt.[28] TO_2 was between 5.40 mg/bt and 5.95 mg/bt. However these results could have been lower if the headspace had been flushed with N_2 before capping and PET bottles had a wine volume of 750 mL. Average DCO_2 was 615 mg/bt (≈800 mg/L), and $HspCO_2$ formed less than 1% of the total carbon dioxide content (TCO_2) at bottling.

Evolution of Headspace and Dissolved Oxygen. Figures 1a and 1b represent $HspO_2$ and DO_2 evolution for PET and glass bottles during storage in light. O_2 decreased in both graphs whatever the packaging because of consumption by wine.[28] This decrease was not linear and was faster during the first month.[6,25] After 3 months, it increased for PET but remained stable for glass, and at 12 months, $HspO_2$ and DO_2 were 0.59/0.59, 0.63/0.64, and 0.07/0.07 mg/bt respectively for PET38, PET38R, and glass. The Newman−Keuls multiple comparison test showed that differences between procedures were significant (α = 0.05) for $HspO_2$ and DO_2 between PET and glass (for DO_2 there was no difference between PET and RPET).

Figures 1c and 1d represent $HspO_2$ and DO_2 during storage in the dark. We found the same behavior as previously. However, O_2 consumption was slower: on day 7, $HspO_2$ and DO_2 values were higher than in light, and this was still the case after 372 days. The estimated average rate of TO_2 consumption in 7 days in light was 0.49 ± 0.02 mg/bt/d (PET and glass), whereas it was 0.25 ± 0.03 mg/bt/d in the dark (Table 3). Data were analyzed by Newman−Keuls multiple comparison tests, and there was a statistical difference (α = 0.05) between O_2 consumption rate in light and O_2 consumption rate in the dark. Furthermore, a transient increase in DO_2 was observed between 7 and 20 days. This means that, during this time, the rate of oxygen dissolution in wine was higher than consumption. This phenomenon was observed by Dimkou et al. (2011) for wine samples in glass bottles closed with a screwcap.[6] The increase was not observed for wine stored in

Table 3. Estimated Average Rates of TO_2 Consumption between 0 and 7 Days for PET and Glass Bottles Stored in Light and in the Dark*

	TO_2 consumption rate (mg/bt/d)	
	light	darkness
PET38	0.49 ± 0.02 a	0.25 ± 0.03 b
PET38R	0.44 ± 0.01 a	0.28 ± 0.02 b
glass	0.44 ± 0.02 a	0.25 ± 0.05 b

*TO_2 consumption rate is an average of oxygen consumption for the first 7 days calculated with the following formula: TO_2 consumption rate = $(TO_{2_{t=0}} - TO_{2_{t=7}})/7$. Averages and standard deviations were based on 3 bottles per procedure. Data were analyzed by ANOVA followed by Newman−Keuls multiple comparison tests (α=0.05). Similar letters denote no significant differences between the tested groups.

Table 4. fSO_2 during Storage Time for PET and Glass Bottles*

	fSO_2 (mg/L)				
	0[b]	35[b]	162[b]	278[b]	372[b]
PET38	37 ± 1 a	24 ± 2 a	11 ± 0 b	3 ± 1 b	3 ± 1 b
PET38R	36 ± 1 a	24 ± 2 a	11 ± 1 b	3 ± 0 b	3 ± 2 b
glass	38 ± 1 a	26 ± 1 a	28 ± 1 a	19 ± 4 a	19 ± 1 a

*Averages and standard deviations are based on 6 bottles per procedure (3 bottles in light + 3 bottles in the dark), except for glass bottles at 162 days (n = 4). Data were analyzed at each date by ANOVA followed by Newman−Keuls multiple comparison tests (α = 0.05). Similar letters denote no significant differences between the tested groups. [b]Time (d).

light, probably because of faster O_2 consumption than dissolution from headspace to wine. DO_2 was subsequently close to minimum on the 14th day in light but did not reach minimum in darkness before the 60th day, meaning that after the consumption of initial DO_2, O_2 consumption was limited by the diffusion from headspace into wine for bottles stored in light. At 12 months, $HspO_2$ and DO_2 were 0.68/0.68, 0.76/0.72, and 0.04/0.02 mg/bt respectively for PET38, PET38R, and glass. PET38 and PET38R exhibited similar but statistically different behavior.

Evolution of SO_2. Table 4 represents losses of fSO_2 during storage. As there were no significant differences between storage in light and in the dark (data not shown), values represent averages at each month. Similar profiles were obtained for TSO_2 (data not shown). At bottling, fSO_2 was higher than 30 mg/L, and after one month, around 30% of initial fSO_2 had been lost, whatever the packaging. In the early stages of storage, fSO_2 decrease was consistent with other studies[6,7] and was associated with the oxygen present at bottling, especially with $HspO_2$, which represented, in our case, 75% of TO_2 at t = 0. These results showed the importance of managing O_2 and SO_2 at bottling: the results would have been better if the headspace had been flushed by N_2 just before capping.[6] In wine, the reaction between oxygen and SO_2 is extremely slow.[9] Sulfites react with the products of wine oxidation and in particular with the hydrogen peroxide that is produced when polyphenols are oxidized.[10,11] Finally, after 162 days, fSO_2 in PET reached around 10 mg/L. It is widely accepted that below this limit wine is not protected anymore. Godden et al. (2001) showed that, below this concentration, the sensory perception of a Semillon wine was affected by oxidized aroma, in contrast with wines that retained higher concentrations of SO_2, and had higher scores for citrus and fruity aromas.[8] After one year, wine in glass bottles had still 19 ± 1 mg/L of fSO_2. Data were analyzed by Newman−Keuls multiple comparison tests at 372 days and the difference between PET and glass was significant (α = 0.05). These results corroborated those found in an experiment conducted on a Sauvignon Blanc wine using 75 cL glass bottles containing 6.26 mg/bt of TO_2 just after closure and stored at 17.1 °C, where fSO_2 losses were 44% after one month.[25] Another study showed that, for a white wine packed in 3 L PET containers and stored 12 months at 20 °C, fSO_2 fell from 30 to 12 mg/L in the first month, then, to less than 4 mg/L after 12 months (similar results were found for rosé and red wines), whereas fSO_2 in glass fell from 30 to 14 mg/L in the first month and then to 10 mg/L after 12 months.[4] The same behavior was observed for 18.7 cL PET bottles with 2% oxygen scavenger and stored at 20−25 °C: in a white wine, the initial fSO_2 was 36 mg/L and then decreased to 9 mg/L at 12 months, in contrast with 18 mg/L in glass bottles.[5] After 12 months of storage of different wines, those stored in PET generally contain less SO_2 than those stored in glass.

Evolution of Headspace and Dissolved Carbon Dioxide. The results shown in Table 5 were obtained using a Carbodoseur for DCO_2 and μGC for $HspCO_2$. As there were no differences between storage in light or away from light (data not shown), values are averages for each month. At 162 days, TCO_2 losses were 21% for PET38 and PET38R. Finally, after 372 days, TCO_2 decreased by more than 40% for PET, whereas it remained almost stable for glass bottles. This decrease could have consequences on the perception of the wine.[24] Lonvaud-Funel (1976) showed that, for a red wine with different low DCO_2 contents (below 600 mg/L), differences can be detected by an untrained jury.[23] Furthermore the diffusion of O_2 in wine is facilitated when the CO_2 concentration decreases.[34] In our experiment, $HspCO_2$ represented less than 4% of TCO_2 at any time during storage. It appeared that DCO_2 was very close to TCO_2 and could be compared directly with it. DCO_2 losses were observed in different wines stored in 75 cL PET bottles with no special barrier to prevent CO_2 permeation,[15,19] and also in 25 cL PET bottles where the DCO_2 content decreased in wine whose initial DCO_2 was more than 100 mg/L.[2]

Table 5. TCO_2 during Storage Time for PET and Glass Bottles*

	TCO_2 (mg/bt)			CO_2 losses (%)	
	0**	162**	372**	0−162**	0−372**
PET38	627 ± 19 a	498 ± 10 b	370 ± 0 b	21	41
PET38R	605 ± 37 a	478 ± 23 c	357 ± 30 b	21	41
glass	621 ± 25 a	590 ± 15 a	633 ± 33 a	5	−2

*The results were obtained using a Carbodoseur for DCO_2 and the μGC for $HspCO_2$ (TCO_2 = $HspCO_2$ + DCO_2). Averages and standard deviations are based on 6 bottles per procedure (3 bottles in light + 3 bottles in the dark). Data were analyzed at each date by ANOVA followed by Newman−Keuls multiple comparison tests (α = 0.05). Similar letters denote no significant differences between the tested groups. **Time (d).

Evolution of Other Parameters. There were no significant differences in alcohol content, residual sugars, TA, VA, and pH after 372 days of storage (data not shown).

Direction of Gas Flows inside the Bottle and between Bottle and Air. As results for PET38R were close to those for PET38, and as there were no fundamental differences between storage in light or in the dark, the results for glass and PET38 bottles stored in light are presented here. Figure 2a covers glass bottles and represents $HspO_2^{\%}$ and $DO_2^{\%}$.

These values were calculated using eqs 4 to 15 cited previously. As $HspO_2^{\%}$ and $DO_2^{\%}$ were below 100% saturation, O_2 tended to permeate into the bottle from air to reach

dx.doi.org/10.1021/jf405392u | J. Agric. Food Chem. 2014, 62, 2946−2955

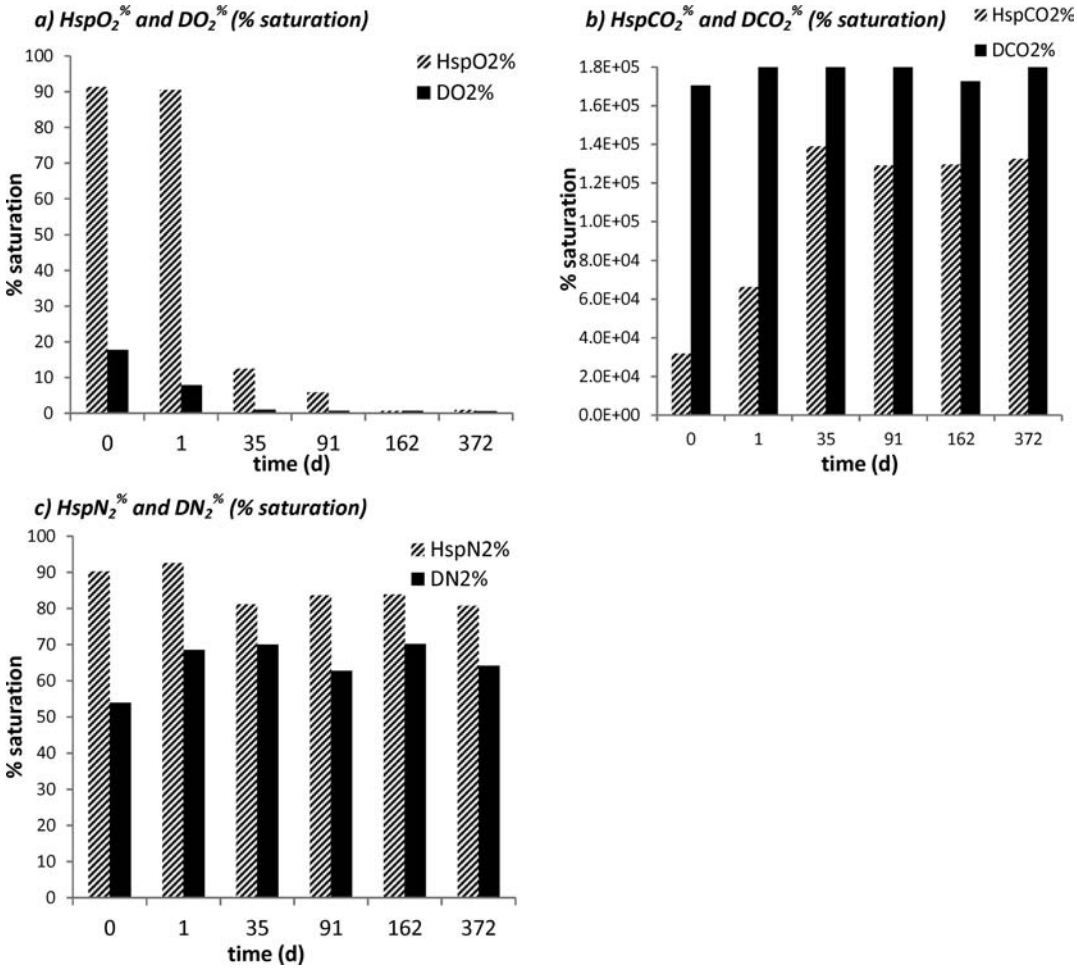

Figure 2. Comparison of $Hsp_{gas}^{\%}$ and $Dgas^{\%}$ with saturation of each gas in air at RH 68% for glass bottles stored in light. Hsp_{gas} were measured using the μGC, DO_2 was measured using the Orbisphere, DCO_2 was measured using the Carbodoseur, and DN_2 was calculated as described previously (eq 11). For panels a, b, and c respectively, solid squares indicate $DO_2^{\%}$, $DCO_2^{\%}$, and $DN_2^{\%}$ and striped squares indicate $HspO_2^{\%}$, $HspCO_2^{\%}$, and $HspN_2^{\%}$.

equilibrium. Furthermore, whatever the date of analyses, $DO_2^{\%}$ was lower than $HspO_2^{\%}$, so O_2 tended to dissolve in wine.[28] During the first month, $HspO_2^{\%}$ and $DO_2^{\%}$ decreases were due to wine oxygen consumption (as seen in Figure 1). After three months, DO_2 content was very low and remained stable at around 0.1 mg/bt (0.12 mg/L), corresponding to $P_{DO_2} \approx 1$ hPa ($P_{HspO_2} \approx 2$ hPa). These results were consistent with those found of Vidal and Moutounet (2006) in which DO_2 reached value of 0.06 mg/L in a rosé wine after 150 days of storage at 20 °C.[28] Figure 2b concerns CO_2. As $HspCO_2^{\%}$ and $DCO_2^{\%}$ were far above 100% saturation, CO_2 tended to diffuse from the bottle. In contrast with O_2, $HspCO_2^{\%}$ was lower than $DCO_2^{\%}$ and so CO_2 tended to diffuse from the wine to the headspace. After one month, $HspCO_2^{\%}$ and $DCO_2^{\%}$ remained stable for P_{HspCO_2} (≈460 hPa) and P_{DCO_2} (≈560 hPa), showing that diffusion through screwcaps is negligible in glass bottles. Finally, N_2 displayed the same behavior as O_2 (Figure 2c). N_2 was below 100% saturation, and so it tended to permeate into the bottle, and as $DN_2^{\%}$ was below $HspN_2^{\%}$, N_2 dissolved in wine in the first month and then equilibrium was nearly attained for P_{HspN_2} (≈640 hPa) and P_{DN_2} (≈520 hPa).

Figure 3 is for PET38. In the first month, O_2 consumption by wine was the dominant factor in oxygen kinetics, but after 3 months both $HspO_2^{\%}$ and $DO_2^{\%}$ increased (Figure 3a). This meant that wine O_2 consumption became slower than O_2 ingress. Between 91 and 372 days, P_{HspO_2}, (respectively P_{DO_2}) increased from 11 hpa (respectively 7 hPa) to 28 hpa (respectively 25 hPa). For CO_2 (Figure 3b), during first month, a phase of equilibrium between $HspCO_2^{\%}$ and $DCO_2^{\%}$ was observed like for glass bottles before P_{HspCO_2} and P_{DCO_2} decreased by respectively 148 hPa (0.24 mg/L) and 171 hPa (235 mg/L) between 91 and 372 days. Finally for N_2, differences with glass bottles could be seen after 1 month (Figure 3c): $HspN_2^{\%}$ and $DN_2^{\%}$ increased. Between 91 and 372 days, P_{HspN_2} (respectively P_{DN_2}) increased slightly from 607 hPa (respectively 480 hPa) to 616 hPa (respectively 561 hPa).

These results could be compared with those of P_{aphro} (Table 6). Standard deviations showed that there was substantial variability within each procedure. It was observed for PET bottles that P_{aphro} decreased from 41 ± 33 hPa to −68 ± 21 hPa during one year of storage. For glass bottles, P_{aphro} decreased but remained positive. As standard deviations were substantial, it was difficult to make a conclusion although a decrease of P_{aphro} for PET bottles could be expected: eq 11 cited previously can be used for partial pressure in bottle headspace:

$$0.97(P_{aphro} + P_{atm}) = P_{HSO_2} + P_{HSCO_2} + P_{HSN_2} \quad (16)$$

dx.doi.org/10.1021/jf405392u | J. Agric. Food Chem. 2014, 62, 2946−2955

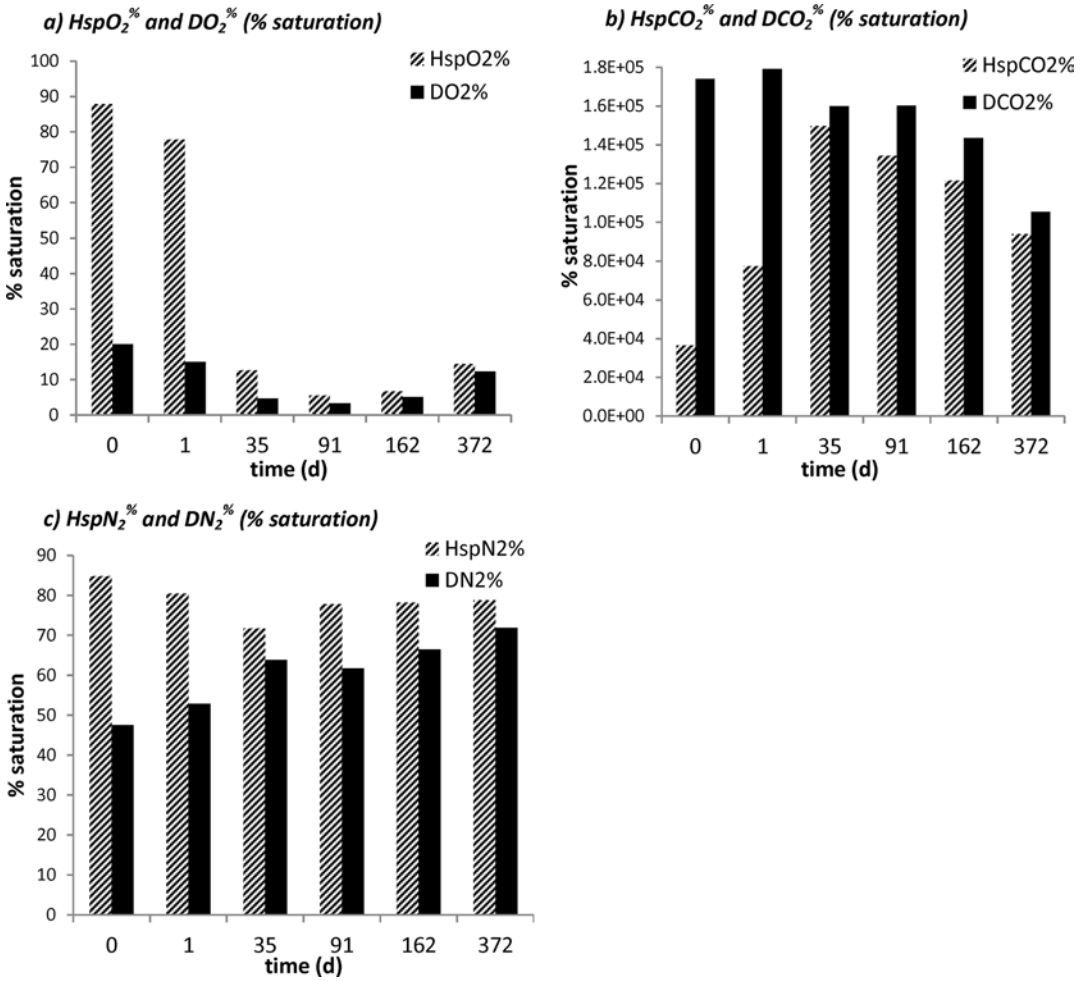

Figure 3. Comparison of $Hsp_{gas}^{\%}$ and $Dgas^{\%}$ with saturation of each gas in air at RH 68% for PET38 bottles stored in light. Hsp_{gas} were measured using the μGC, DO_2 was measured using the Orbisphere, DCO_2 was measured using the Carbodoseur, and DN_2 was calculated as described previously (eq 11). For panels a, b, and c respectively, solid squares indicate $DO_2^{\%}$, $DCO_2^{\%}$, and $DN_2^{\%}$ and striped squares indicate $HspO_2^{\%}$, $HspCO_2^{\%}$, and $HspN_2^{\%}$.

Table 6. P_{aphro} during Storage Time for PET and Glass Bottles*

	P_{aphro} (hPa)				
	1**	91**	162**	278**	372**
PET38	30 ± 38	−3 ± 19	−5 ± 17	−48 ± 32	−76 ± 19
PET38R	55 ± 22	17 ± 9	13 ± 10	−44 ± 15	−59 ± 20
PET average	41 ± 33	7 ± 18	4 ± 16	−46 ± 24	−68 ± 21
glass	167 ± 19	94 ± 19	111 ± 6	79 ± 28	84 ± 29

*P_{aphro} is measured by μGC. Averages and standard deviations are based on 6 bottles per packaging (3 bottles in light + 3 bottles in the dark), except for PET38R bottles at 1 day (n = 5). **Time (d).

P_{atm} varied slightly during one year (<1%). For PET38 bottles, between 91 and 372 days, P_{HspO_2} (respectively P_{HspN_2}) increased by 16 hPa (respectively 8 hPa) whereas P_{HspCO_2} decreased by 148 hPa. This balance between CO_2 losses and O_2 ingress can explain the observed decrease of P_{aphro} during storage.

O_2 Balance during One Year of Storage. To estimate O_2 ingress from bottling to one year of storage, we used TO_2 values at bottling and OTR of PET bottles and screwcaps given by Sidel (Table 7). After one year of storage, we could estimate O_2 ingress for each procedure, which was 4 to 5 times higher for PET bottles than for glass bottles. These values were between 25 and 30 mg/bt/year for PET bottles whereas they were estimated at 6 mg/bt/year for glass bottles. The oxygen content of wine saturated from air at atmospheric pressure is about 6 or 8 mg/L, depending on wine composition and temperature.[35] In our experiment, the rosé wine was saturated with O_2 approximately 4 times. Furthermore, these results showed the importance of O_2 management at bottling in PET bottles because TO_2 at bottling represented around 3 months of O_2 ingress through packaging.

Effect of Light and Packaging on the Evolution of Bottled Wine. After 372 days of storage, it appeared that light had an influence on O_2 consumption, which was faster in light, especially during the first week, where $HspO_2$ and DO_2

dx.doi.org/10.1021/jf405392u | J. Agric. Food Chem. 2014, 62, 2946−2955

Table 7. Evaluation of O_2 Ingress with TO_2 at Bottling and OTR of Bottles and Screwcaps*

	O_2 ingress through packaging** (mg/bt/year)	TO_2 trapped at bottling (mg/bt)	estimated TO_2 ingress (mg/bt/year)
PET38	23.8 ± 0.3	5.42 ± 0.68	29.3 ± 1.0
PET38R	19.8 ± 0.3	5.94 ± 0.42	25.7 ± 0.8
glass	0.6	5.70 ± 0.47	6.3

*Estimated TO_2 ingress is equal to O_2 ingress through packaging (OTR × 365 days) plus TO_2 trapped at bottling. **Tests carried out by Sidel at 23 °C RH = 60% under air. These OTR take into account bottle and screwcap. The OTR of glass bottle represents only the OTR of the screwcap.

decreased strongly. DO_2 then reached a minimum on day 14 in light against day 60 in darkness, meaning that O_2 consumption in light was soon limited by diffusion from the headspace into the wine. In contrast, light had no influence on parameters such as fSO_2, $HspCO_2$, and DCO_2. To the best of our knowledge, this is the first time that oxygen consumption kinetics in wine are reported to be accelerated by light although the impact on wine sensory quality was not investigated in the present study.

The impact of PET could be seen in different parameters. Wine stored in a monolayer PET bottle with no oxygen scavenger aged faster than in a glass bottle. After 162 days of storage, fSO_2 in a PET bottle reached the critical value of 10 mg/L, which meant that wine was not protected anymore, whereas wine in a glass bottle was still protected after a year. At the same time, after 3 months, $HspO_2$ and DO_2 in PET bottles increased, meaning that wine O_2 consumption became slower than O_2 ingress. Furthermore, O_2 at bottling played a key role in wine conservation because in our case it represented 3 months of O_2 ingress through PET packaging. TCO_2 losses were more than 40% after one year for PET bottles whereas it remained stable for glass bottles. These losses were linked to PET permeability and to a low bottle weight. CO_2 losses and O_2 ingress during storage seemed to be similar overall for PET38 and PET38R.

This experimental bottling enabled us to draw up the first complete gas balance for a bottle of wine including the three main gases present in headspace and in wine (O_2, CO_2, N_2) and their exchanges with air. The goal of the work reported here was to assess the limits of a monolayer PET bottle. According to this study, it appeared that a 38 g monolayer PET bottle was not sufficient to conserve wine for one year, given the losses of fSO_2 and CO_2 and the increase of O_2 content during storage. The next step in the study was to find a solution to increase the wine conservation period to 12 months using better gas management during bottling and by adding oxygen scavengers in PET packaging.

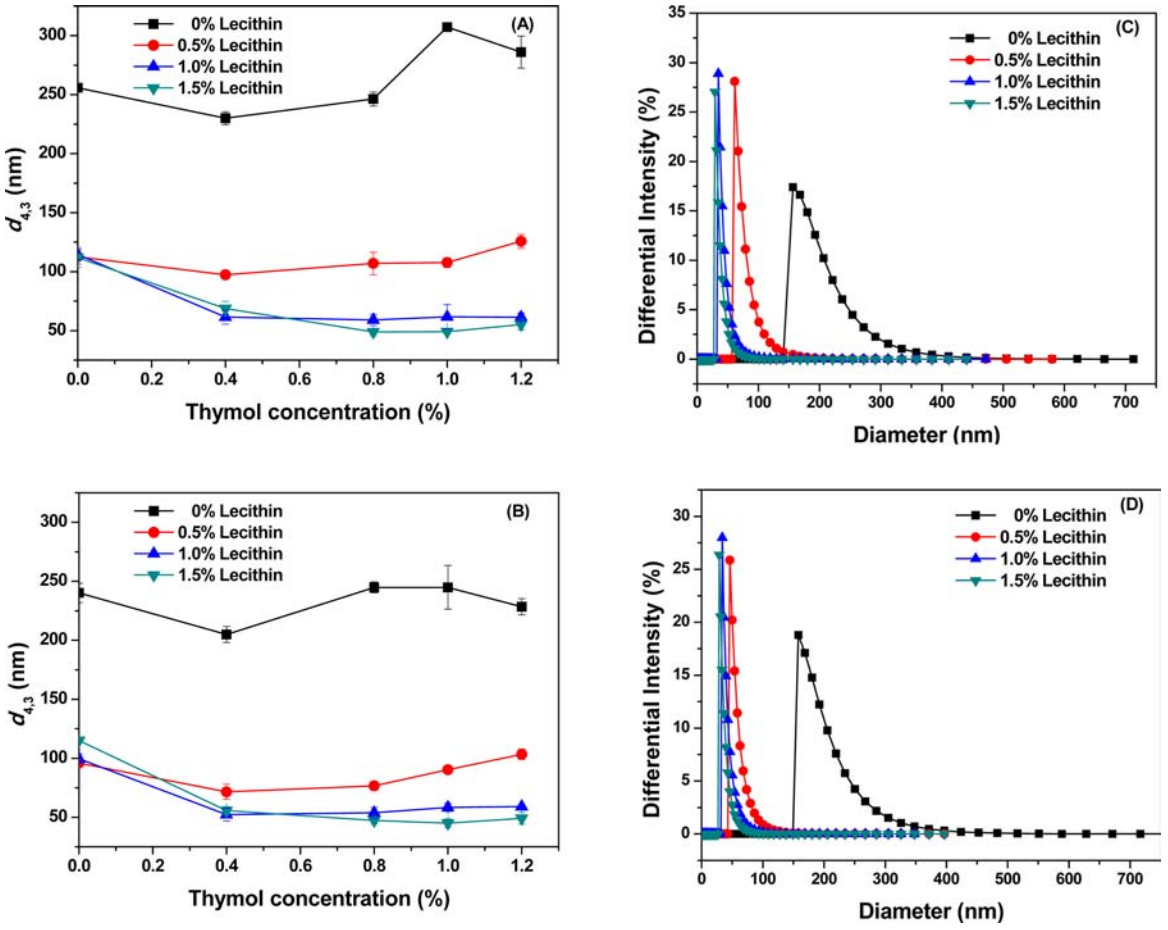

Figure 1. Volume fraction−length mean particle diameter ($d_{4,3}$) of thymol dispersions prepared with 0.2% (w/v) type A (A) and type B (B) gelatin and different amounts of lecithin. Size distributions are shown in C and D for samples containing 0.8% thymol emulsified by gelatins A and B, respectively. Error bars are standard deviations from duplicates.

MATERIALS AND METHODS

Materials. Thymol (99% purity) and type A gelatin were purchased from Acros Organics (Morris Plains, NJ, USA). Type B gelatin, soy lecithin (phosphatidylcholines), and other chemicals, such as PG and methanol, were obtained from Fisher Scientific (Pittsburgh, PA, USA).

Preparation of Nanodispersions. The 0−0.06 g of gelatin was dissolved in 9 mL of deionized water. Different amounts of lecithin (0, 0.05, 0.1, and 0.15 g) were added into the gelatin solution, followed by vortexing for 1 h at room temperature (21 °C), and the pH was 6.8. The working thymol solution was prepared separately by dissolving various amounts (0, 0.04, 0.08, 0.10, and 0.12 g) in 1 mL of PG. The gelatin/lecithin sample and thymol solution were mixed and emulsified at 15,000 rpm for 2 min using a model Cyclone I.Q.^{2} microprocessor homogenizer (The VirTis Co., Inc., Gardiner, NY, USA).

Particle Size Measurement. Particle size distributions of dispersions were measured using a Delas nano-ζ potential and sub-micrometer particle size analyzer (Beckman Coulter, Inc., Brea, CA, USA). The volume−length mean particle diameter ($d_{4,3}$) was calculated from the number of particles (n_i) with the corresponding diameter (d_i) based on the following equation:

$$d_{4,3} = \frac{\sum_{i=1} n_i d_i^4}{\sum_{i=1} n_i d_i^3} \quad (1)$$

Turbidity. The absorbance of dispersions was measured at 600 nm (Abs_{600}) as the indicator of turbidity using a UV−vis spectrophotometer (model Biomate 5, Thermo Electron Corp., Woburn, MA, USA).

Transmission Electron Microscopy. The morphology of thymol dispersions prepared with gelatin alone, lecithin alone, and gelatin−lecithin blend was characterized using a Zeiss Libra 200 transmission electron microscope (Carl Zeiss SMT Inc., Oberkochen, Germany). A 5 μL aliquot of the emulsion was placed onto a copper grid and stained with a drop of 2% (w/w) uranyl acetate solution. After 2 min, the grid was tapped with filter paper, followed by air-drying at room temperature (21 °C) before imaging.

Quantification of Protein in the Serum of Dispersions. The nanodispersions were prepared with the aqueous phase with 0.2% (w/v) gelatin B and 1.0% (w/v) lecithin at pH 7.0. After homogenizing 0.8% (w/v) thymol as discussed previously, nanodispersions were adjusted to pH 2.0−6.0 using 1.0 M HCl or pH 8.0 using 1.0 M NaOH. The gelatin B−lecithin blend without thymol was also prepared using the same procedures. All samples were centrifuged at 16,110g for 30 min at 25 °C using an Optima MAX ultracentrifuge (Beckman Coulter) to obtain the supernatant for protein assay. Because thymol interferes with protein assay, 200 μL of the supernatant was mixed with 6 mL of an acetone−hexane (1:1, v/v) mixture to extract thymol and precipitate protein. [27] After vigorous mixing and centrifugation at 6,700g for 5 min using an Eppendorf MiniSpin plus centrifuge (Hamburg, Germany), the supernatant (organic phase) was discarded, and the bottom protein precipitate was re-dissolved in 300 μL of 100 mM NaOH and was quantified using the bicinchoninic acid (BCA) method (Thermo Fisher Scientific Inc., Morris Plains, NJ, USA). Gelatin was used as a reference protein in the BCA assay.

ζ Potential. The ζ potentials of thymol dispersions were measured using a DelasTM nano-ζ potential and sub-micrometer particle size analyzer (Beckman Coulter). Samples were diluted 100 times using

dx.doi.org/10.1021/jf405828s | J. Agric. Food Chem. 2014, 62, 2956−2962

deionized water and adjusted to pH 3.0−7.0 before analysis. Three dispersion replicates were tested for three times each.

Storage Stability. Storage stability of thymol dispersions at room temperature (21 °C) was assessed over a period of 1 month. The dispersions were monitored weekly for changes in particle size.

Statistical Analysis. Analysis of variance (ANOVA) test was conducted using the SPSS 16.0 statistical analysis system (SPSS Inc., Chicago, IL, USA). The least significant difference (LSD) test was used to determine the significant difference of mean values at a P level of 0.05.

RESULTS AND DISCUSSION

Effects of Gelatin Type and Lecithin Concentration on Particle Dimension at Neutral pH. The $d_{4,3}$ and particle size distribution of dispersions prepared with two types of gelatin and different amounts of lecithin are shown in Figure 1. The $d_{4,3}$ of dispersions prepared with gelatin alone was around 250 nm. Blending lecithin with gelatin significantly decreased the $d_{4,3}$ when compared to gelatin alone without thymol ($P < 0.05$), indicating the formation of gelatin−lecithin complexes. When thymol was present, the $d_{4,3}$ of the dispersions prepared with gelatin−lecithin blends further decreased, which may have resulted from the increased particle packing due to the strengthened intraparticle attraction by hydrophobic thymol. Generally speaking, $d_{4,3}$ decreased with an increase in lecithin concentration until about 1% (w/v), above which there was no significant further decrease in $d_{4,3}$ ($P > 0.05$). The increase of lecithin content also corresponded to the narrowed particle size distributions of dispersions containing 0.8% thymol (Figure 1C,D). A greater amount of lecithin enables the stabilization of a larger interfacial area, leading to smaller particles, until the radius of droplet curvature reaching a critical value beyond which no further decrease in the particle size is enabled.[28] Furthermore, a greater $d_{4,3}$ was observed at a higher thymol concentration between 0.4 and 1.2% (w/v) when 0.5% (w/v) lecithin and 0.2% (w/v) gelatin were used. In contrast, there was no significant change in $d_{4,3}$ when 0.4−1.2% (w/v) thymol was dispersed by 0.2% (w/v) gelatin and 1 or 1.5% (w/v) lecithin ($P > 0.05$). Therefore, the combination of 1% (w/v) lecithin and 0.2% (w/v) gelatin was sufficient to disperse 1.2% (w/v) thymol.

When two gelatin types were compared, it was observed that dispersions prepared with gelatin A had significantly bigger $d_{4,3}$ than those with gelatin B when 0 and 0.5% (w/v) lecithin was used ($P < 0.05$, Figure 1A,B), which indicates that complexes formed with gelatin B are more effective in dispersing thymol. As discussed previously, gelatin A has pI ∼ 8−9 and has net positive charges at neutral pH. [17] In contrast, gelatin B has pI ∼ 4−5 and is net negatively charged at neutral pH. [17] The electrostatic attraction between gelatin A and highly negatively charged lecithin may enable the formation of more compact complexes than those of gelatin B, which may reduce the ability to disperse thymol. When more lecithin (1 and 1.5% (w/v)) was used with 0.2% (w/v) gelatin, the $d_{4,3}$ of the dispersions prepared with gelatin B was slightly smaller than those with gelatin A, which indicates that the effect of gelatin type was not significant when a sufficient amount of lecithin was used. Furthermore, it was observed that dispersions prepared with gelatin A precipitated after storage for 2 to 3 days at room temperature (21 °C), while those prepared with gelatin B were stable after several months. This likely is due to the net surface charge being smaller for samples with gelatin A, due to opposite charges between gelatin A and lecithin but the same types of net charges for the case of gelatin B and lecithin. Based on this set of experiments, gelatin B and 1% (w/v) lecithin were chosen for further studies.

Effects of Gelatin B Concentration on Dispersion Properties at Neutral pH. Appearance, Abs_{600}, and $d_{4,3}$ of thymol dispersions prepared with 1% (w/v) lecithin, 0.8% (w/v) thymol, and 0−0.6% (w/v) gelatin B are presented in Figure 2. The dispersion prepared with lecithin only was very turbid

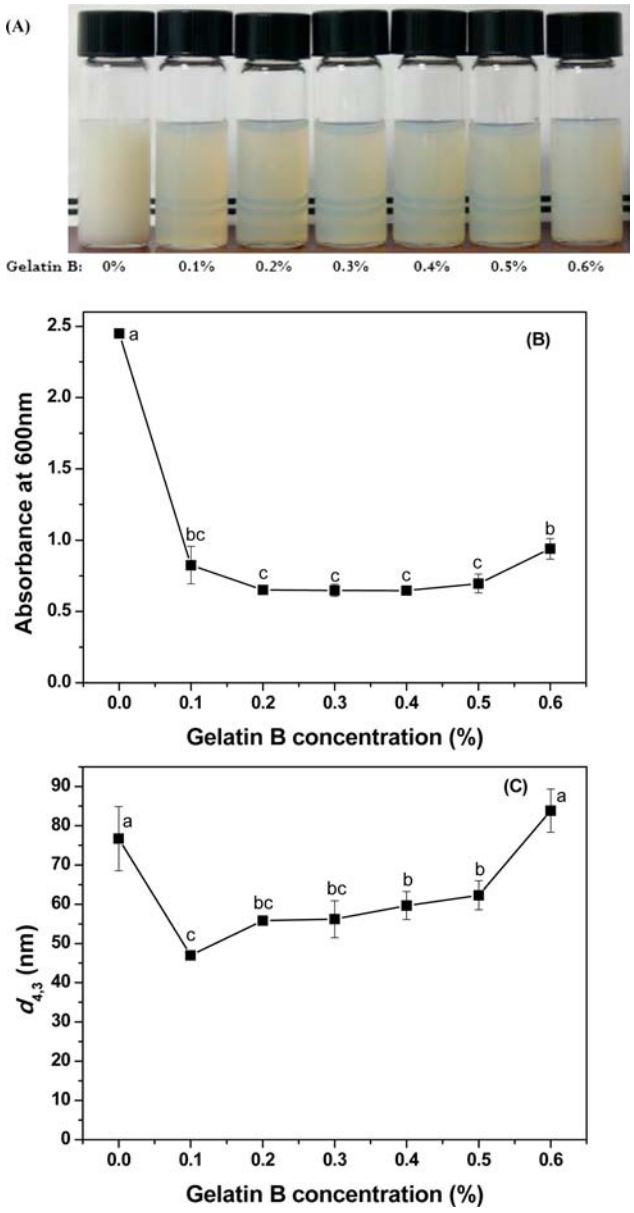

Figure 2. Appearance (A), absorbance at 600 nm (B), and volume−length mean particle diameter ($d_{4,3}$) of thymol dispersions prepared with 0−0.6% (w/v) gelatin B, 1% (w/v) lecithin, and 0.8% (w/v) thymol. Error bars are standard deviations from duplicates. Different letters next to symbols indicate significant differences in the mean ($P < 0.05$).

(Figure 2A), which became translucent after blending with gelatin B. The dispersions prepared with intermediate gelatin B concentrations (0.2−0.5% (w/v)) showed the lowest turbidity. The sample with 0.6% (w/v) gelatin B was more turbid, possibly because of the limited solubility of gelatin B. The Abs_{600} data (Figure 2B) generally agreed with the visual

dx.doi.org/10.1021/jf405828s | J. Agric. Food Chem. 2014, 62, 2956−2962

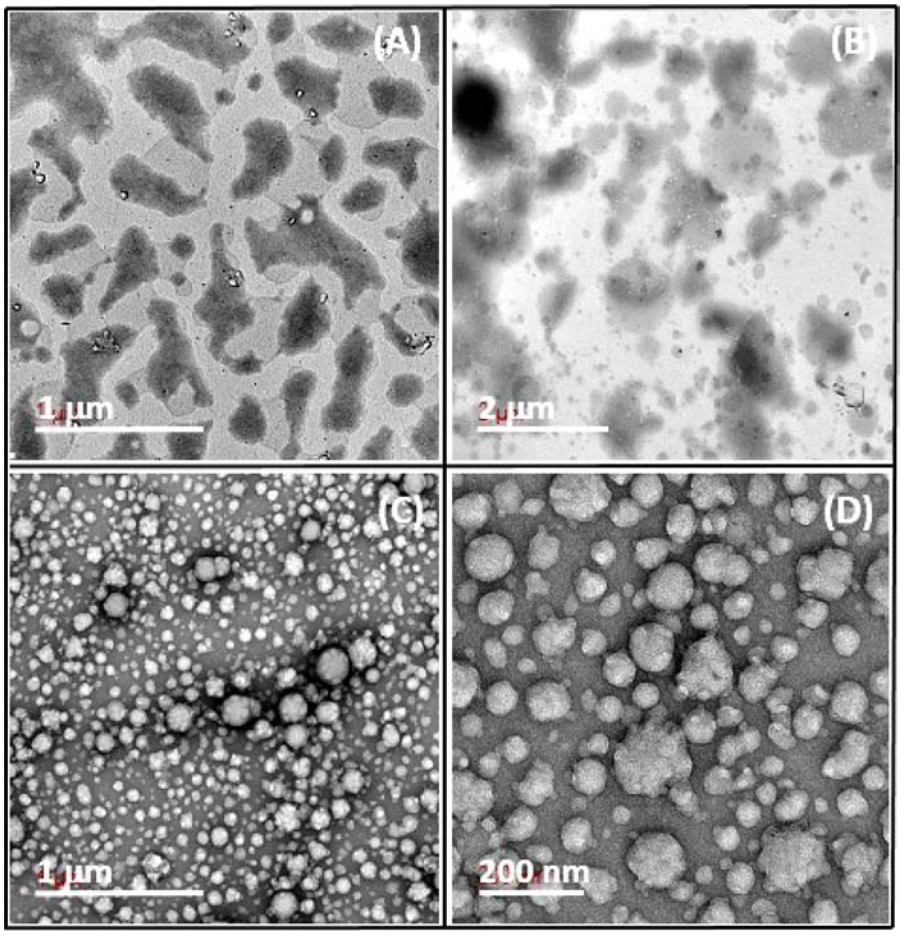

Figure 3. TEM images of dispersions prepared with 0.8% (w/v) thymol and 1.0% (w/v) lecithin only (A), 0.2% (w/v) gelatin B only (B), and their blend (C and D, in two magnifications).

appearance (Figure 2A). No obvious differences in Abs_{600} of treatments with 0.2−0.5% (w/v) gelatin B indicate the 0.8% (w/v) thymol was well dispersed at these conditions. Conversely, a sharp decrease in $d_{4,3}$ was observed when gelatin B concentration increased from 0 to 0.1% (w/v), followed by gradual increases in particle dimension as gelatin B concentration further increased. The $d_{4,3}$ was not significantly different for the treatments with 0.2−0.5% (w/v) gelatin B ($P > 0.05$), while that with 0.6% (w/v) gelatin B was significantly bigger than other treatments with gelatin B ($P < 0.05$, Figure 2C). In a study encapsulating drug Amphotericin B, the lipophilic drug was mixed with lecithin in an organic solvent mixture of dimethyl sulfoxide and methanol, followed by mixing with an aqueous gelatin solution to form sub-micrometer particles. [29] Confocal laser scanning microscopy and fluorescent resonance energy transfer analyses showed that lecithin was present in the particle interior and gelatin was present on the particle surface. This study suggests that the more hydrophobic lecithin is preferably in contact with the lipophilic drug, while the hydrophilic gelatin binds with lecithin on the particle surface. In our study, if thymol particles are preferentially emulsified by lecithin, the particles with adsorbed gelatin B would be bigger than those with lecithin only. The expectation from this sequential adsorption of lecithin and gelatin on thymol particles is opposite to the data in Figure 2C. Therefore, it is more likely that gelatin B forms complexes with lecithin, which adsorb on thymol particles simultaneously during emulsification. Since 0.2% (w/v) of gelatin B was sufficient to form a translucent dispersion, this concentration was selected for further studies.

Morphology of Thymol Particles. The morphology of thymol particles (Figure 3) was studied for dispersions prepared with 0.8% (w/v) thymol dispersed by 0.2% (w/v) gelatin B alone, 1.0% (w/v) lecithin alone, and their combination. The dispersion prepared with the blend (Figure 3C,D) had mostly spherical particles with a mean diameter of 60 nm that agrees with the $d_{4,3}$ of 49 nm (Figure 1B) and the translucent appearance (Figure 2A). In contrast, bigger and irregular particles were observed for dispersions prepared with lecithin only (Figure 3A) and gelatin B only (Figure 3B), which agrees with the turbid appearance of both dispersions (Figure 2B for the sample dispersed with lecithin only; the other sample is not shown). The heterogeneity of particle structures (Figure 3) overall agrees with the particle size distributions in Figure 1D. Lecithin used in this study (phosphatidylcholines) is soluble in hexane and its poor water solubility can contribute to turbidity (Figure 2) and irregular structures (Figure 3A). In contrast, 0.2% (w/v) gelatin B is dissolved in water as a transparent solution, but the turbid dispersion and irregular big particles after emulsifying thymol indicate the weak emulsifying property of gelatin. In addition, the particle dimension observed by transmission electron microscopy (TEM) was bigger than the $d_{4,3}$ values of dispersions made with gelatin B alone (250 nm, Figure 1B) or lecithin alone (76 nm, Figure 2C). The

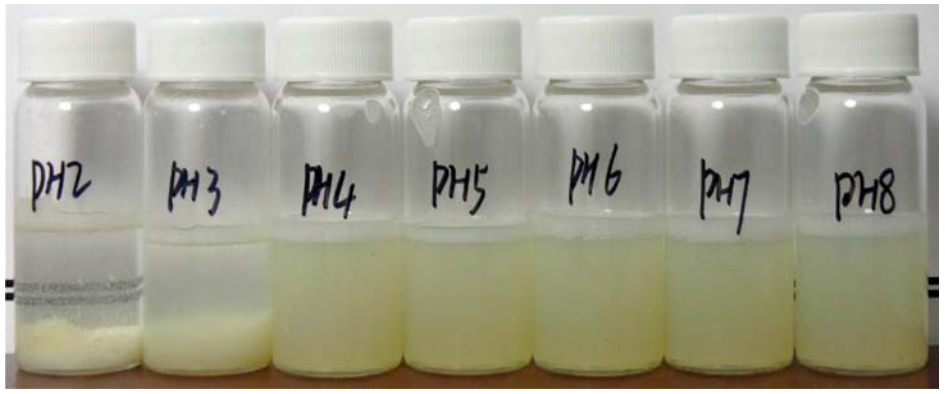

Figure 4. Appearance of aqueous mixtures with 1.0% (w/v) lecithin and 0.2% (w/v) gelatin B adjusted to different pH.

difference can be contributed by sample preparation with (in light scattering) and without (in TEM) dilution. Dilution can separate weakly flocculated particles/structures, lowering the measured particle dimension.

Effects of pH on Dispersion Stability. The stability of dispersions prepared with 0.8% (w/v) thymol, 0.2% (w/v) gelatin B, and 1% (w/v) lecithin was investigated at pH 2.0−8.0. The first set of samples was prepared for aqueous mixtures of gelatin B and lecithin without thymol to study the complex formation of the two molecules. Figure 4 shows that samples at pH 4.0−8.0 were turbid and those at pH 2 and 3 precipitated quickly. The turbidity is due to the poor water solubility of lecithin, as discussed previously. The precipitation at pH 3.0 contrasts with stable samples with gelatin or lecithin alone (not shown). After centrifugation of the mixture at pH 3.0, the serum contained 0.0169% (w/v) protein (gelatin), less than 10% of the total gelatin concentration (0.2% (w/v)), which indicates the co-precipitation of lecithin and gelatin B.

In the second set of treatments, thymol dispersions prepared at pH 7.0 were adjusted to pH 2.0−6.0. Like the mixture (Figure 4), dispersions at pH 2.0 and 3.0 also showed significant precipitation. The dispersion at pH 4.0 showed some precipitated structures, while dispersions at pH 5.0−7.0 were stable. The acidification increased the $d_{4,3}$ (Table 1), with that at pH 5.0 being significantly bigger ($P < 0.05$). In comparison, the $d_{4,3}$ of gelatin−lecithin mixture (without thymol) was not significantly different at pH 5.0−7.0 ($P > 0.05$) but was significantly bigger than comparable samples with thymol at pH 6.0 and 7.0 ($P < 0.05$). This suggests that the adsorption of gelatin B−lecithin complexes on thymol particles resulted in much ordered structures. The inclusion of thymol in nanoparticles increases the overall hydrophobicity that can cause some particle aggregation when repulsive electrostatic interactions are weakened below pH 5.0, as discussed further in subsequent text for ζ-potential data.

Table 1. Volume Fraction−Length Mean Diameter ($d_{4,3}$, nm) of Dispersions with 0.8% (w/v) Thymol Dispersed by 0.2% (w/v) Gelatin B and 1.0% (w/v) Lecithin at pH 7.0 and after Acidification to pH 5.0 and 6.0, with Comparison to the Blend (without Thymol) Prepared at Identical Conditions[a]

	$d_{4,3}$		
	pH 5	pH 6	pH 7
with thymol	159.3 ± 11.9a	58.9 ± 2.0cde	45.3 ± 2.1e
without thymol	135.2 ± 3.0ab	132.7 ± 4.9ab	109.1 ± 7.7ab

[a]Numbers are mean ± standard deviation from triplicates. Different letters represent significant differences in the mean.

To further study the surface composition of thymol particles, the protein content in the serum of dispersions with and without thymol after centrifugation was measured as the content of free gelatin (Table 2). At pH 5.0, close to the pI of gelatin B, [17] the protein content in the thymol dispersion serum was lower than that at pH 6.0 and 7.0 ($P < 0.05$), which was in agreement with the significantly bigger particles at pH 5.0 (Table 1). Conversely, similar to $d_{4,3}$ (Table 1), there was no significant difference in the serum protein content in the blend dispersions (without thymol) at pH 5.0−7.0 ($P > 0.05$). Because gelatin only solutions had the gradually decreased protein contents after acidification to 5.0 and centrifugation (Table 2), similar serum protein contents in the blend dispersions suggest the complex formation between gelatin B and lecithin that resulted in the stability at pH 5.0−7.0. The thymol dispersion at pH 5.0 did not show visible precipitation, and the lowered serum protein content after centrifugation is likely due to the sedimentation of aggregated particles (Table 1).

ζ Potential of Thymol Dispersions. To study the role of electrostatic interactions on dispersion formation and stability, ζ potentials of thymol dispersions prepared with gelatin B alone, lecithin alone, and their blend were measured (Figure 5). The ζ potentials of dispersions prepared with lecithin only were highly negative at pH 3.0−7.0, with a reduced magnitude at a lower pH. This is due to the presence of ionized phosphate group of lecithin that is protonated to a greater extent at a lower pH, as previously reported. [30] In comparison, dispersions prepared with gelatin B only showed the characteristics expected from gelatin B, with ζ potential being zero at about pH 4.8 that corresponds to the pI of gelatin B. At pH 6.0 and 7.0, the negative ζ potential of dispersions prepared with gelatin B only had much smaller magnitudes than those prepared with lecithin.

For dispersions prepared with gelatin B−lecithin blend, ζ potentials at pH 5.0, 6.0, and 7.0 were close to those prepared with lecithin alone. Besides, thymol dispersion prepared with the blend exhibited similar ζ potential at pH 5.0, 6.0, and 7.0, which contradicts with the different $d_{4,3}$ and serum protein content of thymol nanodispersions at pH 5.0, 6.0, and 7.0 (Tables 1 and 2). The ζ -potential data suggest additional colloidal forces causing particle aggregation at pH 5.0. It may be caused by the increased particle hydrophobicity due to gelatin B at the acidity close to its pI (Figure 5). The strong electrostatic

Table 2. Percentages of Total Protein in the Serum of Dispersions with 0.8% (w/v) Thymol Dispersed by 0.2% (w/v) Gelatin B and 1.0% (w/v) Lecithin at pH 7.0 and after Acidification to pH 5.0 and 6.0, with Comparison to the Blend or Gelatin B Only (without Thymol) Prepared at Identical Conditions[a]

	protein % in the serum		
	pH 5	pH 6	pH 7
thymol dispersion	49.51 ± 12.28f	73.23 ± 1.39bcde	83.73 ± 0.57ab
gelatin B–lecithin blend	67.06 ± 1.52cdef	71.75 ± 2.55bcde	56.93 ± 4.37ef
gelatin B only	75.32 ± 0.82bcd	87.18 ± 1.23ab	93.25 ± 1.73a

[a]Numbers are mean ± standard deviation from triplicates. Different letters represent significant differences in the mean.

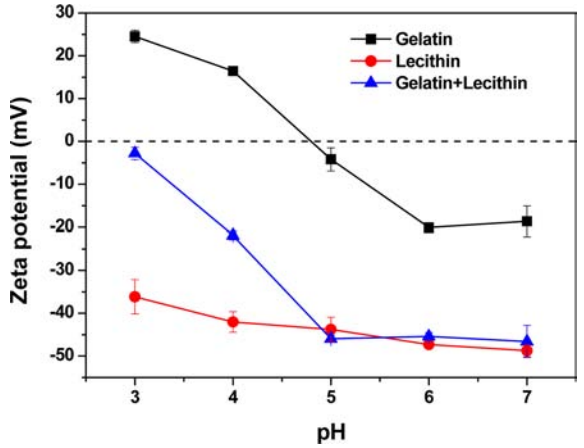

Figure 5. ζ potential of dispersions with 0.8% (w/v) thymol dispersed by 0.2% (w/v) gelatin B alone, 1.0% (w/v) lecithin alone, or their blend at pH 3.0–7.0. Error bars are standard deviations from triplicates.

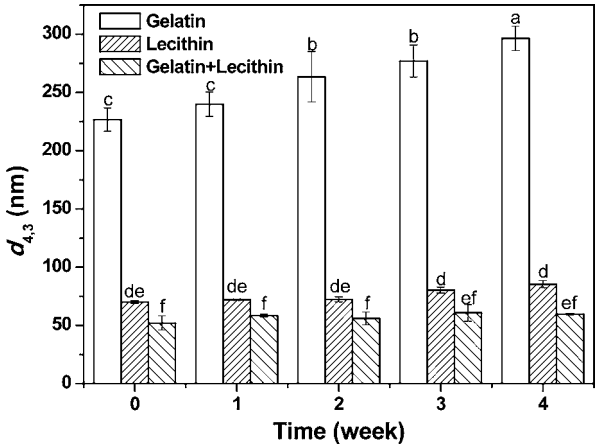

Figure 6. Changes of $d_{4,3}$ of dispersions with 0.8% (w/v) thymol dispersed by 1.0% (w/v) lecithin alone, 0.2% (w/v) gelatin B alone, or their blend at pH 7.0 during storage at room temperature (21 °C) for 4 weeks. Error bars are standard deviations from triplicates. Different letters above bars indicate significant differences in the mean of the same sample ($P < 0.05$).

repulsion at pH 5.0 was able to limit the particle aggregation (Table 1) so that the overall dispersion showed the absence of macroscopic precipitation.

At pH 4.0, ζ potential of the thymol nanodispersion prepared by the gelatin B–lecithin blend reduced to about one-half of the dispersion prepared with lecithin only (Figure 5), indicating that gelatin B also had a significant influence on the droplet surface charge. At pH 4.0, gelatin B is positively charged and neutralizes negative charges of lecithin. The reduced ζ potential at pH 4.0 may have caused some precipitation of thymol particles, as discussed previously. At pH 3.0, as gelatin B had more positive charges, the ζ potential of the dispersion prepared with the blend decreased further in magnitude to be close to zero, which caused severe precipitation. Therefore, electrostatic interactions are the major colloidal force responsible for the stability of thymol dispersions prepared with gelatin B–lecithin blend. The stable dispersions at pH 5.0 and above are significant for their applications, as many foodborne pathogens can grow in low-acid foods (>pH 4.6).

Storage Stability of Dispersions at Neutral pH. The storage stability of dispersions containing 0.8% (w/v) thymol at neutral pH was evaluated by measuring $d_{4,3}$ weekly for 1 month at room temperature (21 °C). Figure 6 shows that the dispersion prepared with lecithin–gelatin B blend had a constant $d_{4,3}$ of around 55 nm during storage. In contrast, $d_{4,3}$ of dispersions prepared with gelatin B alone increased significantly after 4 weeks ($P < 0.05$), from 220 to 280 nm. For dispersions prepared with lecithin alone, $d_{4,3}$ also increased from 68 to 85 nm. Because thymol has a solubility of about 0.048% (w/v) in water, [7] Ostwald ripening has been observed to cause the increase of particle size in thyme oil nanodispersions emulsified by Tween 80, which can be eliminated by blending with lipids with low water solubility.[31,32] The use of low water solubility lipids however reduced the loading and antimicrobial efficacy of essential oils. Therefore, stable thymol nanodispersions prepared by the gelatin B–lecithin blend are promising for use as antimicrobial delivery systems. Furthermore, in our recent studies, the minimum inhibitory concentration of thymol increased or remained unchanged after encapsulation in whey protein–maltodextrin conjugates[33,34] and sodium caseinate,[35] respectively. Whey proteins have more ordered secondary structures and are more hydrophobic than caseins.[36] Since gelatin is less hydrophobic than whey proteins and caseins and does not have secondary structures,[36] impacts of gelatin on antimicrobial activity of thymol may be insignificant. Characterizations of antimicrobial activities of these dispersions and their impact on sensory properties of food products are underway.

In conclusion, gelatin B and lecithin, both GRAS emulsifers, can be used as a blend to prepare translucent thymol nanodispersions with a mean diameter of about 50 nm at pH 5.0 and above. The synergistic surface activity of the blend is likely due to complex formation of the blend. The electrostatic repulsion, contributed mostly by lecithin, prevented particles from aggregation. The blend complexes on thymol particle surface prevented Ostwald ripening and maintained particle dimension during storage at neutral pH. Therefore, the stable nanodispersions prepared from GRAS ingredients have great potential to incorporate lipophilic food antimicrobials such as thymol in low-acid foods to enhance the microbiological safety.

helical cavity. The objectives of this study were to determine the effects of these treatments on the formation of soluble and insoluble complexes and their complexation yields and physicochemical properties.

MATERIALS AND METHODS

Materials. Potato starch was obtained from Penford Food Ingredients (Centennial, CO, USA) and used without further treatment. Isoamylase (specific activity = 59000 units/mg protein) was purchased from Hayashibara Biochemical Laboratories Inc. (Okayama, Japan). β-Amylase from *Bacillus cereus* (specific activity = 2484 units/mg protein) was purchased from Megazyme International Ireland Ltd. (Wicklow, Ireland). Stearic acid was from Sigma-Aldrich (St. Louis, MO, USA). All other chemicals were of ACS grade.

Acetylation of Starch. Acetylation was carried out following the method described by Wang and Wang.[20] Starch (160 g, dry basis (db)) was weighed into a 2 L reaction vessel, and water was added to make up a final weight of 457.2 g. The mixture was stirred and hydrated for 30 min, and then the pH was adjusted to 8−8.5 with 1 M NaOH. Acetic anhydride (6.4 g, 4% based on starch db) was used for a low acetylation, or 9.6 g (8% based on starch db) was used for a high acetylation. Acetic anhydride was added very slowly to the starch mixture while the starch slurry pH was maintained between 8 and 8.5 and stirred. After the addition of acetic anhydride, the slurry was left to stand for 60 min with stirring. The resulting mixture was adjusted with 1 M HCl to a pH of 5.5, washed with a 3-fold volume of deionized water, filtered, and dried in an oven at 40 °C for 24 h. The acetyl content of starches was determined according to the method of McComb and McCready[21] and expressed as DS.[22]

Enzymatic Modification of Starch. *Debranching.* Starch (15 g wet basis) was added to 400 mL of water (3.75% w/v) and placed in a boiling water bath for 1 h with constant stirring to achieve complete gelatinization. The solution was equilibrated in a water bath at 45 °C and adjusted to pH 3.5 with 0.5 M HCl; 0.5% (v/w starch db) isoamylase was added, and then the mixture was incubated at 45 °C with constant stirring for 48 h. The starch was recovered with a 4-fold volume of pure ethanol, centrifuged, dried at 40 °C for 48 h, and milled using a UDY cyclone mill (UDY Corp., Ft. Collins, CO, USA) fitted with a 0.5-mm screen.

β-Amylase Treatment. A portion of the debranched starch was further subjected to β-amylase hydrolysis to reduce the DP. After incubation with isoamylase for 48 h, the starch slurry was adjusted to pH 6.5 with 0.5 M NaOH, and incubated with 0.5% (v/w starch db) β-amylase at 40 °C for 4 h. The enzyme reaction was terminated by boiling for 15 min. Starch was recovered by precipitating with 4-fold volume of pure ethanol, dried at 40 °C for 48 h and milled using the UDY cyclone mill fitted with a 0.5-mm screen.

Characterization of Starch Structure. The molecular size distribution of debranched unacetylated and acetylated starch with or without β-amylase treatment prior to complexation was characterized using a high-performance size exclusion chromatography (HPSEC) system (Waters Corp., Milford, MA, USA). Starch (10 mg) was dissolved in 5 mL of 90% dimethyl sulfoxide (DMSO), boiled for 1 h, and filtered through a 5.0 μm filter prior to injection into the HPSEC system. The HPSEC system consisted of a guard column (OHpak SB-G, 6.0 × 500 (mm) i.d. × length), two Shodex columns (OHpak KB-804 and KB-802, both 8.0 × 300 (mm) i.d. × length), a 200 μL injector valve (model 7725i, Rheodyne, Cotati, CA, USA), an inline degasser, a model 515 HPLC pump, and a model 2414 refractive index detector. The mobile phase of 0.1 M ammonium acetate with 0.02% sodium azide was eluted at a flow rate of 0.4 mL/min. The temperature of the columns was maintained at 55 °C and that of the detector at 40 °C. Dextran standards with molecular weights of 5,200, 11,600, 23,800, 48,600, 273,000, and 410,000 g/mol from Waters Corp. (Milford, MA, USA) and 1,050,000 g/mol from Sigma-Aldrich (St. Louis, MO, USA) were used to establish the calibration curve. An Ultrahydrogel 250 column (Waters Corp., Milford, MA, USA) was used for analyzing the molecular size distribution of starches recovered after complexation with stearic acid.

Amylopectin chain-length distribution was characterized by high-performance anion exchange chromatography equipped with pulsed amperometric detection (HPAEC-PAD) according to the method of Wong and Jane.[23] The HPAEC-PAD system (Dionex ICS-3000, Sunnyvale, CA, USA) consisted of the components of an AS40 autosampler, a single pump, detector/chromatography module (DC), a 4 × 50 mm CarboPac PA1 guard column, and a 4 × 250 mm CarboPac PA1 analytical column. Starch (20 mg) was boiled in 3.2 mL of distilled water for 1 h, cooled, and then filtered through a 0.45 μm filter (NYL w/GMF, Whatman, Clifton, NJ, USA) prior to injection into the HPAEC-PAD system. The mobile phase consisted of two eluents, A (150 mM NaOH) and B (150 mM NaOH containing 500 mM sodium nitrate) and was eluted at a flow rate of 1 mL/min. The gradient program was as follows: 94% of eluent A at 0 min, 92% at 11 min, 87% at 31 min, 80% at 81 min, 75% at 105 min, and 94% at 106 min. Column temperature was at 25 °C, and injection volume was 25 μL. Sugar standards, including glucose (DP1), maltose (DP2), maltotriose (DP3), maltotetraose (DP4), maltopentoase (DP5), maltohexaose (DP6), and maltoheptaose (DP7), were used as calibration standards to identify the chromatographic peaks. Each successive peak after DP 7 was considered to represent one glucose unit longer than the previous peak. The chains were divided into DP ranges and classified as follows: A chains (DP 6−12), B1 chains (DP 13−24), B2 chains (DP 25−36), and B3+ chains (DP 37+).[24] The average chain length was calculated as the cumulative sum of the product of DP and percentage relative areas for all the identified peaks.

Complexation of Starch and Stearic Acid. The starch solution (3.75% w/v) after debranching and with or without the β-amylase treatment as previously described was adjusted to pH 7.0 prior to the addition of 1 g of stearic acid. The mixture was heated at 80 °C for 30 min with continuous stirring, and then the temperature was lowered and maintained at 45 °C overnight with continuous stirring. Then the starch−stearic acid mixture was centrifuged at 7000*g* for 10 min, from which the precipitate, that is, "insoluble complex", was obtained, and the "soluble complex" was recovered from the supernatant by precipitation with a 4-fold volume of pure ethanol. Uncomplexed stearic acid was removed from both the insoluble and soluble complexes by rinsing with 95% ethanol using a labquake shaker rotisserie (Barnstead/Thermolyne, Dubuque, IA, USA) at room temperature for 2 h. Complexes were recovered by centrifugation at 7000*g* for 10 min, dried at 40 °C for 48 h, milled using a mortar and pestle, sieved through a 250 mm sieve, and stored for further analysis.

Hydrolysis of Complexes and Stearic Acid Analysis. To the complex (100 mg), both soluble and insoluble, was added 10 mL of 1 M HCl, and the mixture was heated in a boiling water bath for 1 h. The complex mixture was cooled, and 5 mL of hexane was added to extract the released stearic acid by rotation on the rotary shaker for 1 h. The hexane layer was recovered, and the previous step was repeated with another 5 mL of hexane for 1 h. Boron trifluoride−methanol (BF_3) was added to the recovered hexane phase to prepare fatty acid methyl esters (FAMEs), and an internal standard of methyl heptadecanoate (~1 mg) was subsequently added. The fatty acid methyl esters extracted in the hexane layer were injected into a gas chromatography (GC) system (GC-2010, Shimadzu, Kyoto, Japan) equipped with a BP 21 capillary column (30 m × 0.25 mm i.d.; SGE Inc., Austin, TX, USA) with a flame ionization detector (FID), and responses were collected by a Shimadzu GCsolution Workstation 2.3 (Kyoto, Japan). The carrier gas was helium at a flow rate of 30 mL/min, and the temperature of the column oven was equilibrated at 130 °C for 2 min, ramped at 10 °C/min to 250 °C, and maintained at 250 °C for 3 min. The injector and detector temperatures were set at 250 and 270 °C, respectively. Stearic acid was methylated, and the concentrations of stearic acid were determined from a standard curve prepared by using stearic acid solution (0.1, 0.2, 0.4, 0.6, 0.8, and 1.0 mg/mL) containing the internal standard of methyl heptadecanoate (0.5 mg/mL).

Physicochemical Properties. The thermal stability of all complexes was measured using a differential scanning calorimeter (DSC, Pyris-Diamond, PerkinElmer, Shelton, CT, USA). Starch samples (approximately 8 mg) were weighed into aluminum pans,

16 μL of distilled water was added with the aid of a microsyringe, and the pans were hermetically sealed. The pans were equilibrated for at least 1 h at room temperature before scanning. The samples were scanned from 25 to 180 °C at a rate of 10 °C/min. The onset temperature (T_o), peak temperature (T_p), conclusion temperature (T_c), and enthalpy (ΔH) of the endotherms were calculated using the Pyris data analysis software.

The powder X-ray diffraction pattern of complexes was determined using a diffractometer (PW1830 MPD, Philips, Almelo, The Netherlands). The generator voltage was set at 45 kV and the current at 40 mA. The sample was scanned over the 2θ angular range from 5° to 35° with a step size of 0.02° and time of 1 s per step.

Statistical Analysis. All measurements were conducted in replication, and the data were analyzed using JMP software (SAS Institute Inc., Cary, NC, USA); the means were compared using Tukey's honestly significant differences (HSD) test.

RESULTS AND DISCUSSION

Degree of Substitution. The DS values of the prepared low acetylated and high acetylated starches were 0.041 and 0.078, respectively. After both acetylated starches were debranched and treated with or without β-amylase and complexed with stearic acid, the insoluble and soluble fractions were recovered and analyzed for their structures and properties. It was found that the soluble fractions had significantly higher DS of acetylation, 82−173% higher, than their insoluble counterparts for the same treatment (Table 1). The differences in DS between the soluble and insoluble fractions of acetylated starch complexes were apparently responsible for the type of complexes formed because starch solubility increases with an increase in acetyl groups. A further increase in DS was observed when acetylation was combined with β-amylase treatment for both soluble and insoluble fractions. Because starch was acetylated in its native state, most acetyl groups were present in the amorphous lamella close to the branching points. Therefore, most acetyl groups were retained after β-amylase hydrolysis, resulting in an increase in DS of acetylation for samples treated with β-amylase.

Wulff et al.[19] reported that for the formation of soluble complexes of fenchone, a minimum DS of 0.16 was required for acetylated amylose, and only insoluble complexes were formed when acetylated amylose with a DS < 0.16 was used. In the present study, soluble complexes were produced from acetylated potato starch with DS ≥ 0.063. The difference in the DS observed in the two studies might be because starch was used in the present study, whereas amylose was used in the study by Wulff et al.[19] Although a different guest molecule was used in the present study, these results imply that amylopectin chains participated in complexation, and the required DS of acetylation for soluble complex formation was proportional to the DP of amylose and amylopectin chains. Nevertheless, the present results are in agreement with Wulff et al.[19] that there is a minimum DS of acetylation for the formation of soluble complex.

Table 1. Degree of Substitution (DS) of Acetylated Starches and Stearic Acid Complexes[a]

starch	β-amylase treatment	type of complex	DS
low acetylated starch	N/A[b]	N/A	0.041 ± 0.001f
low acetylated starch complex	no	soluble	0.063 ± 0.002d
		insoluble	0.029 ± 0.000g
	yes	soluble	0.093 ± 0.002b
		insoluble	0.034 ± 0.000f
high acetylated starch	N/A	N/A	0.078 ± 0.001c
high acetylated starch complex	no	soluble	0.089 ± 0.002b
		insoluble	0.049 ± 0.001e
	yes	soluble	0.133 ± 0.002a
		insoluble	0.052 ± 0.002e

[a]At least replicate samples were prepared for each complex. Data of two measurements with standard deviation. Means in a column not sharing the same letter are significantly different based on Tukey's honestly significant difference test ($p < 0.05$). [b]N/A, not applicable.

Complex Recovery and Complexation Yield. The recovery of complex was calculated by comparing the weight of recovered fractions to the weight of initial materials. The highest recovery for the insoluble complex was 0.72 g/g from the unacetylated starches with the β-amylase treatment. The recovery of unacetylated insoluble complex is in agreement with previous studies,[5,25] in which only insoluble fractions were reported. The total recovery, including both soluble and insoluble complexes, was highest for the unacetylated starch and decreased with increasing acetylation, which was probably because the increased solubility of starches from acetylation resulted in a significant reduction complex recovery (Table 2).

Table 2. Complex Recovery and Percentage Stearic Acid Content Recovered from All Complexes[a]

starch	type of complex	β-amylase treatment	recovery (g/g)	stearic acid in complex (mg/g)
unacetylated	soluble	no	0.24 ± 0.00d	15.7 ± 1.5f
	insoluble	no	0.58 ± 0.00a	42.7 ± 5.6d
	soluble	yes	0.11 ± 0.01e	33.8 ± 5.4de
	insoluble	yes	0.72 ± 0.04a	63.1 ± 1.2c
low acetylated	soluble	no	0.26 ± 0.00cd	23.4 ± 1.3ef
	insoluble	no	0.32 ± 0.01cd	101.0 ± 5.9b
	soluble	yes	0.28 ± 0.01cd	34.6 ± 2.9de
	insoluble	yes	0.47 ± 0.01b	123.1 ± 4.2a
high acetylated	soluble	no	0.26 ± 0.02cd	36.8 ± 7.4d
	insoluble	no	0.28 ± 0.02cd	40.3 ± 3.8d
	soluble	yes	0.38 ± 0.02bc	61.2 ± 12.2c
	insoluble	yes	0.36 ± 0.02c	16.6 ± 1.9f

[a]Data of at least two measurements with standard deviation. Means in a column not sharing the same letter are significantly different based on Tukey's honestly significant difference test ($p < 0.05$).

These results support previous findings that the presence of acetyl groups increased the solubility of starch and prevented the precipitation of starch−stearic acid complexes after complexation, thereby resulting in a lower recovery for insoluble complexes but a higher recovery for soluble complexes.

The additional β-amylase treatment increased recovery for the insoluble fractions of acetylated and unacetylated starches and for the soluble fractions of high acetylated starch. When acetylated starches received the β-amylase treatment, there was presumably an increase in favorable chain lengths of starch chains for the formation of both insoluble and soluble complexes, thus resulting in an increase in complexation.

However, for β-amylase-treated unacetylated starches the recovery of the insoluble complex increased, which was probably due to the absence of acetyl groups. The absence of acetyl groups may have led to an increase in starch reassociation and a reduction in solubility of unacetylated starches, which ultimately prevented complexes from staying in solution. The recovery of soluble fractions from acetylated-only starch was similar to that from the unacetylated starch at 0.26 g/g, implying that acetylation alone might not be sufficient to increase the recovery of soluble complexes. The recovery of soluble fractions of acetylated starches increased when the β-amylase treatment was incorporated, and this increase became more noticeable with the high acetylated starch. The increase in recovery of the soluble fraction of high acetylated was ascribed to the increase in the acetyl groups that promoted the preference of stearic acid to interact with the hydrophobic cavity of starch helix. This may be ascribed to the alignment of acetyl groups toward the cavity, thereby increasing overall hydrophobicity of the cavity and encouraging more stearic acid interaction, and this increased complexation.[26]

Stearic acid was recovered from all starch complexes, and the amount of stearic acid recovered was higher in the insoluble fractions than in the soluble fractions except for the high acetylated and β-amylase treated starch (Table 2). The highest amounts of stearic acid were recovered from the insoluble fractions of low acetylated starches fractions without (101.0 mg/g) and with (123.1 mg/g) the β-amylase treatment. Lui et al.[27] reported that acetylated pea starch with DS of 0.1 had a reduced iodine affinity of ∼4.4% compared to native pea starch with a value of ∼6.4%. They concluded that acetyl groups interfered with complex formation and reduced complexation yield. Similarly, Wulff et al.[19] reported that the complexing ability of amylose with fenchone decreased when amylose was modified with hydroxypropyl, hydroxyethyl, acetyl, and carboxymethyl groups. In contrast, the present results show that although acetylation of starch decreased the recovery of the insoluble fractions, the amount of complexed stearic acid was increased by 95−135% at a low acetylation level with or without the β-amylase treatment, but then decreased at a high acetylation level.

For the soluble complexes, both acetylation and β-amylase treatment enhanced the complexation of stearic acid. The high acetylated, β-amylase-treated starch had the highest amount of complexed stearic acid (61.2 mg/g), which was about 81% higher than the amount of stearic acid recovered from the soluble fraction of unacetylated starch (33.8 mg/g). The present results demonstrate that there is an optimum DS of acetylation to increase the amount of complexed stearic acid with starch in both soluble and insoluble complexes. This supports our hypothesis that apart from acetylation, an optimum starch chain length may also be critical for increasing the complexation yield of stearic acid and formation of soluble complexes.

Molecular Size Distribution. The molecular size distributions of debranched unacetylated and acetylated starches prior to complexation with stearic acid are displayed in Figure 1. For the unacetylated starches, the chromatogram shifted to lower DP with the β-amylase treatment, and the proportion of amylose fraction between 26 and 31 min was clearly reduced. The hydrolysis by β-amylase reduced the molecular size of amyloses to the range of amylopectin long chains and also lowered the molecular size of amylopectin chains. For the acetylated starches, the proportion of the amylose fraction

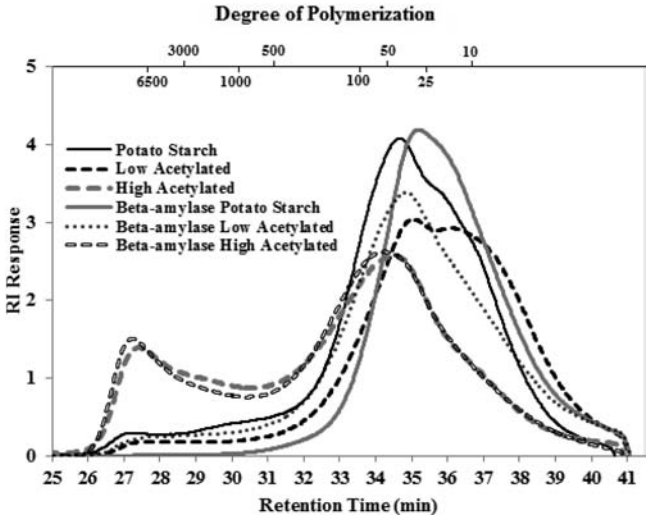

Figure 1. Normalized HPSEC profiles of debranched only or debranched and β-amylase-treated unacetylated and low and high acetylated potato starch.

increased with acetylation, and a further increase was noted with the additional β-amylase treatment. This increase was attributed to an increase in the hydrodynamic volume of the starch due to the presence of acetyl groups rather than an increase in the proportion of amylose. This supports previous DS results (Table 1) that during β-amylase hydrolysis of acetylated starch most acetyl groups were retained and responsible for the increased hydrodynamic volume of the acetylated starches.

The molecular size distributions of recovered soluble and insoluble fractions of all starches are presented in Figure 2. All starches displayed a peak at ∼14.5 min, signifying the presence of amylose fractions. The peak at 14.5 min (∼DP 3400) was more pronounced in the insoluble fractions than in the soluble fractions, became larger with acetylation, and then further increased when combined with the β-amylase treatment. These results support previous findings (Figure 1) that the increase in amylose fraction was due to the presence of acetyl groups not hydrolyzed by β-amylase. The acetylated fractions not treated with β-amylase also displayed two additional peaks at ∼19.5 min of DP 67 and ∼21 min of DP 23, which represent the long and short chains of amylopectin, respectively. However, the acetylated and β-amylase-treated starch fractions only had an additional peak around 19 min (DP 96).

It has been reported that approximately DP 18−24 glucose units are required for complexation of one fatty acid or monoacyl glycerol of 14−18 carbons,[10] DP 30−40 for two palmitic acid (C16:0),[28] DP 34 for two stearic acid,[29] and DP 40 for two docosanoic acid (C22:0).[13] Therefore, it can be deduced that the minimum chains required for complexation of one or two stearic acid would be DP 18−40, and were available in both soluble and insoluble fractions in the present study.

The chain-length distributions of recovered starch chains from the soluble and insoluble fractions without and with β-amylase treatment are presented in Figures 3 and 4, respectively. The soluble fraction displayed a more unimodal-like distribution after the β-amylase treatment (Figure 4A,C,E) with peak DP 30 and 33 for low and high acetylated starches, respectively. The insoluble fractions of all starches with or without β-amylase treatment displayed a bimodal distribution with peak DP 13−14 and 43−45. These results indicate that

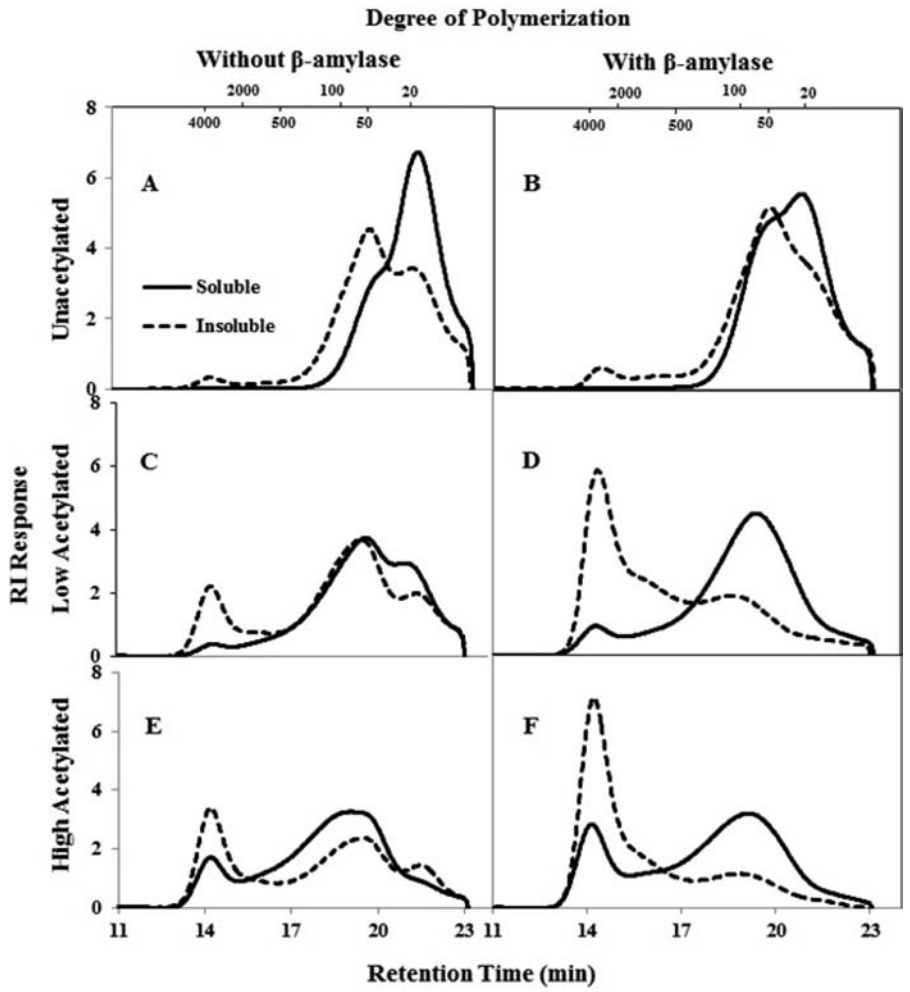

Figure 2. Normalized HPSEC profiles of recovered unacetylated and acetylated potato starches from the soluble and insoluble fractions after complexation.

upon complexation, different fractions of the starch chains form different types of complexes, that is, soluble or insoluble complex. When the amounts of complexed stearic acid (Table 2) were compared with the chain length distributions (Figures 3 and 4), it was found that the DP range 20−43 from amylopectin chains might be more favorable for soluble complex formation, and the proportion of this DP range was increased after the β-amylase treatment. The first fraction of chains consisting of ~DP 6−17 present in all unacetylated and acetylated starches was decreased after β-amylase treatment. These results are in agreement with the molecular size distribution results in Figure 2 and indicate that DP 6−17 represent chains that are too short to participate in stearic acid complexation. The present results also agree with Eliasson,[30] who found that amylopectin chains could participate in complex formation because the favorable DP for complex formation was observed in all fractions.

Characterization of Starch-Fatty Acid Complexes. *Melting Properties by Differential Scanning Calorimetry.* The melting thermogram of starch−stearic acid complex was observed in all soluble and insoluble fractions except for the soluble fractions from the low and high acetylated starch without the β-amylase treatment (Table 3). This is in contrast to the stearic acid recovery results, which showed that stearic acid was recovered from all soluble and insoluble starch fractions, which will be discussed later in this section. All unacetylated starch−stearic acid complexes displayed peak melting temperatures (T_p) of 92.4−116.1 °C, similar to those reported in previous studies,[25,31] which indicate the presence of both type I and type II starch−stearic acid complex. The type I complex has a lower T_p of around 90 °C and is formed at lower temperatures of about 60 °C; thus, it is less ordered and exhibits low heat stability.[10,32] The type II complex has a T_p of around 110 °C[31] and is formed with continuous heat treatment and rearrangement of the type I complex at higher temperatures of about 90 °C.[15] Although both type I and II starch−stearic acid complexes were present in the unacetylated starch complexes, the type II complex was more dominant as shown by its higher enthalpy value.

The low acetylated starch complexes exhibited a lower T_p than the unacetylated starch complexes for the same type of complex, and the T_p was further decreased with a higher DS of acetylation. This implies that for unacetylated starch, the nucleation rate for complexation was low, leading to sufficient propagation[10] and rearrangement of the complexes and, hence, more ordered, heat-resistant complexes were formed. In contrast, the presence of acetyl groups may hinder the rearrangement of included helices and prevented the formation of the type II complex. The T_p values of all insoluble complexes were higher than their soluble counterparts for all acetylated

starches; the high acetylated starch fractions did not always exhibit lower melting temperatures than their low acetylated counterparts. Previous studies[13,28] have proposed that T_p of amylose−fatty acid complexes increased with an increase in amylose size. Therefore, the present results suggest that longer starch chains are responsible for the formation of insoluble complexes and shorter starch chains for the soluble complexes, supporting the previous HPSEC results (Figure 2).

More energy was required to disrupt the insoluble complex because it is composed of more highly organized or longer helices compared with the soluble complexes. Whittam et al.[33] reported that although the same energy was required to disrupt the helical complex structures of both crystalline and amorphous complexes of amylose and alcohols (chain length of four to eight carbon atoms), the crystalline complexes required an additional energy to break the crystal lattice that is absent in amorphous complexes. Hence, this might explain why higher enthalpy values were observed for the insoluble complexes. Eliasson et al.[34] found that the enthalpy of an acetylated high-amylose maize starch−cetyltrimethylammonium bromide (CTAB) complex was lower than that of the native high-amylose maize starch−CTAB complex. They concluded that acetylation of starch decreased its tendency to crystallize or form the starch−CTAB complex. However, in the present study, the enthalpy was higher in acetylated starches than the unacetylated starches for the same treatment. Later, Karkalas et al.[15] concluded that enthalpy values of amylose−lipid complexes should not be regarded as good indicators for measuring complex formation because precise results could not always be obtained because some samples could have polymorphs in the intermediate polymorphic state or contain free amylose that could give false low-enthalpy readings.[12]

According to Lui et al.,[27] a different type of supramolecular structure of complexes could exist in acetylated starch complexes due to the presence of acetyl groups. The presence of acetyl groups may promote the formation of a complex that is not crystalline in nature, which was supported by the absence of the endotherm for the soluble complexes of acetylated starches without the β-amylase treatment. However, when acetylation was combined with the β-amylase treatment, the endotherm of the soluble complex appeared, indicating that the presence of the nonacetylated portion of the amylose and amylopectin chains may interfere with the arrangement of the included stearic acid when the other portion was more acetylated as evidenced by the increased DS after β-amylase treatment (Table 1). Therefore, when the less acetylated portion was hydrolyzed by β-amylase, stearic acid was capable of better arranging itself within the starch helical structure, thus resulting in increased crystalline structure.

X-ray Diffraction Pattern. Except the unacetylated and without β-amylase treatment (Figure 5A) all insoluble starch complexes showed the V-type diffraction patterns with characteristic peaks at diffraction angle 2θ = 7.4°, 12.9°, and 20° (Figure 5). Debranched unacetylated starch complexes (Figure 5A,B) had additional peaks at 2θ = 17.0°, 22°, and 24° for soluble complexes and at 2θ = 17.0° and 24° for insoluble complexes, which indicate the presence of retrogradation. These peaks were absent in all acetylated starch complexes because the acetyl groups hindered starch retrogradation except for the soluble low acetylated starch (Figure 5C). This may be due to the reassociation of longer chains with low DS of

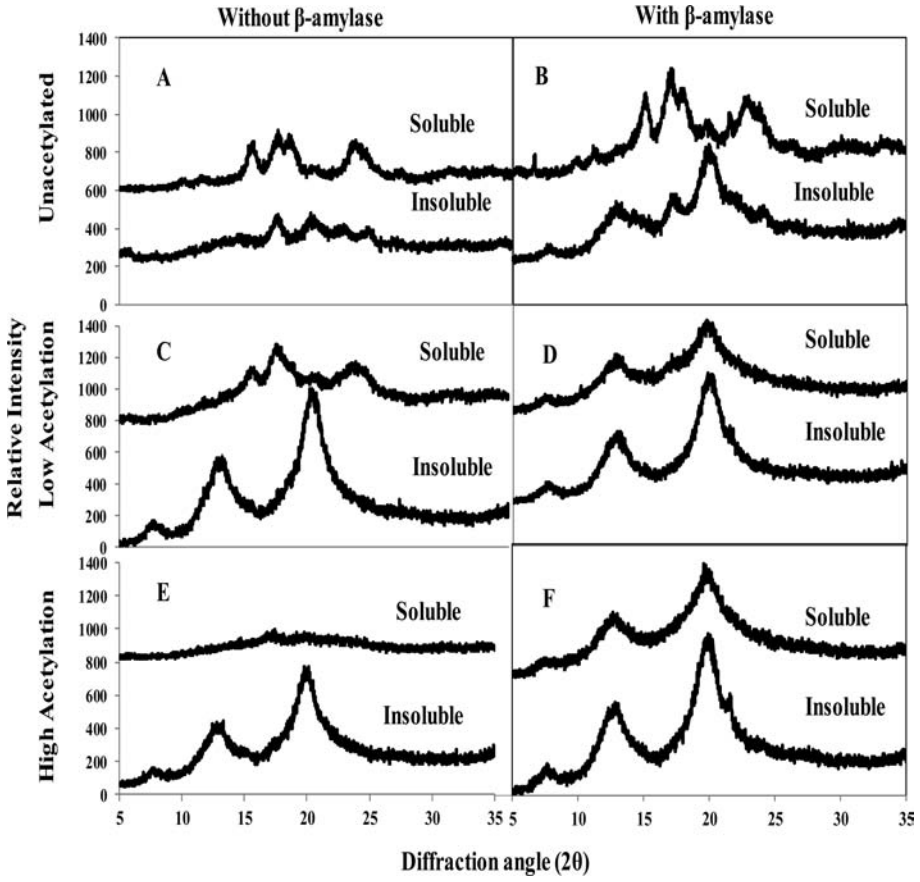

Figure 5. X-ray diffraction patterns of the soluble and insoluble fractions of debranched unacetylated and acetylated potato starches and their stearic acid complexes: (A) potato starch; (B) *β*-amylase-treated potato starch; (C) low acetylated potato starch; (D) low acetylated *β*-amylase-treated potato starch; (E) high acetylated potato starch; (F) high acetylated *β*-amylase-treated potato starch.

acetylation and not involved in stearic−acid complexation. For the unacetylated insoluble starches complexes, the additional *β*-amylase treatment increased the intensity of the V-type pattern and the peak at $2\theta = 20.0°$ increased noticeably. These results agree with previous DSC enthalpy data (Table 3) that for insoluble complexes, the additional *β*-amylase treatment resulted in starch with chain lengths that favored interaction with stearic acid instead of reassociation. The characteristic peak for the starch−stearic acid complex $2\theta = 20.0°$ was also observed in the soluble fractions of unacetylated starch complexes, indicating that native starches also formed soluble complexes, although only in small quantities. The present results again agree with previous results on the amount of complexed stearic acid (Table 2).

When low acetylation only was applied to starch, the X-ray diffraction peaks of the starch−stearic acid complex became predominant in the insoluble fraction, but the intensity of the peaks decreased at the high acetylation (Figure 5C,E). At high acetylation, the acetyl groups may interfere with proper arrangement of stearic acid in the complexes, thus resulting in complexes of low crystallites. These results support previous DSC results that for insoluble fractions, the low acetylated starch complex had higher enthalpy than the high acetylated one (Table 3). These results agree with Lui et al.,[27] who suggested that acetyl groups caused a reduction in the crystallinity of complexes and that acetylation resulted in complexes that existed mainly in the amorphous state rather than in the crystalline form. The same trend was also noted for corresponding soluble complex fractions, in which peak intensity decreased for the high acetylated-only starch complex. The characteristic peaks of starch−stearic acid complex were barely noticeable in both acetylated-only soluble starch complexes, which supports the DSC results (Table 3) and indicates that no crystalline structure was present in these soluble complexes. Nevertheless, the presence of an amorphous structure does not suggest the absence of a starch−stearic acid complex because it may still consist of unpacked helical amylose chains[28] as evidenced by the presence of complexed stearic acid (Table 2).

The V-type X-ray pattern was not evident for the soluble fractions until the *β*-amylase treatment was combined with acetylation (Figure 5D,F). This again supports previous DSC and DS findings that an optimum chain length of starch chains together with high acetyl content encouraged the formation of crystalline soluble complex. In addition, when a combination of acetylation and *β*-amylase treatment was employed, the peak intensities increased with increasing acetylation in both the soluble and insoluble complexes (Figure 5D,F). However, in the debranched-only acetylated potato starch complexes (Figure 5C,D), the reverse was noted as the peak intensities of complexes decreased with increasing acetylation, which further emphasized the importance of starch chain length in complex formation.

Some insoluble complexes showed a small peak at $2\theta = 21.5°$ (Figure 5D,F), which has been ascribed to pure stearic acid that is only physically trapped between starch helices[35] but not

dx.doi.org/10.1021/jf5004682 | J. Agric. Food Chem. 2014, 62, 2963−2972

included in the starch helix cavity. Overall, the highest crystallinity for insoluble fractions was observed for low acetylated, debranched-only starch (Figure 5C), and for the soluble fractions, the highest crystallinity was observed for high acetylated, debranched, and β-amylase-treated starch (Figure 5F), which agree with the amount of complexed stearic acid quantified (Table 2).

In conclusion, the present results show that low acetylation encouraged the formation of complexed stearic acid with debranched potato starch for insoluble complexes, whereas high acetylation increased the amount of complexed stearic acid for soluble complexes. The acetylation reduced retrogradation, increased the hydrophobicity of the cavity, and ultimately encouraged more starch−stearic acid interaction. A combination of acetylation, debranching, and β-amylase treatment was required to produce soluble, crystalline starch−stearic acid complex; soluble, amorphous starch−stearic acid complexes were formed in acetylated and debranched-only starches. Acetylation reduced melting temperature and increased the enthalpy values of all starch−stearic acid complexes compared with unacetylated ones. There was an optimum range of chain length to encourage the formation of starch−stearic acid complexes. Information on the generation and properties of soluble starch−stearic acid complex from this study may provide insight into the creation of soluble complexes between starch and other insoluble bioactive compounds and may pave the way for applications whereby soluble complexes are desired to improve bioavailability.

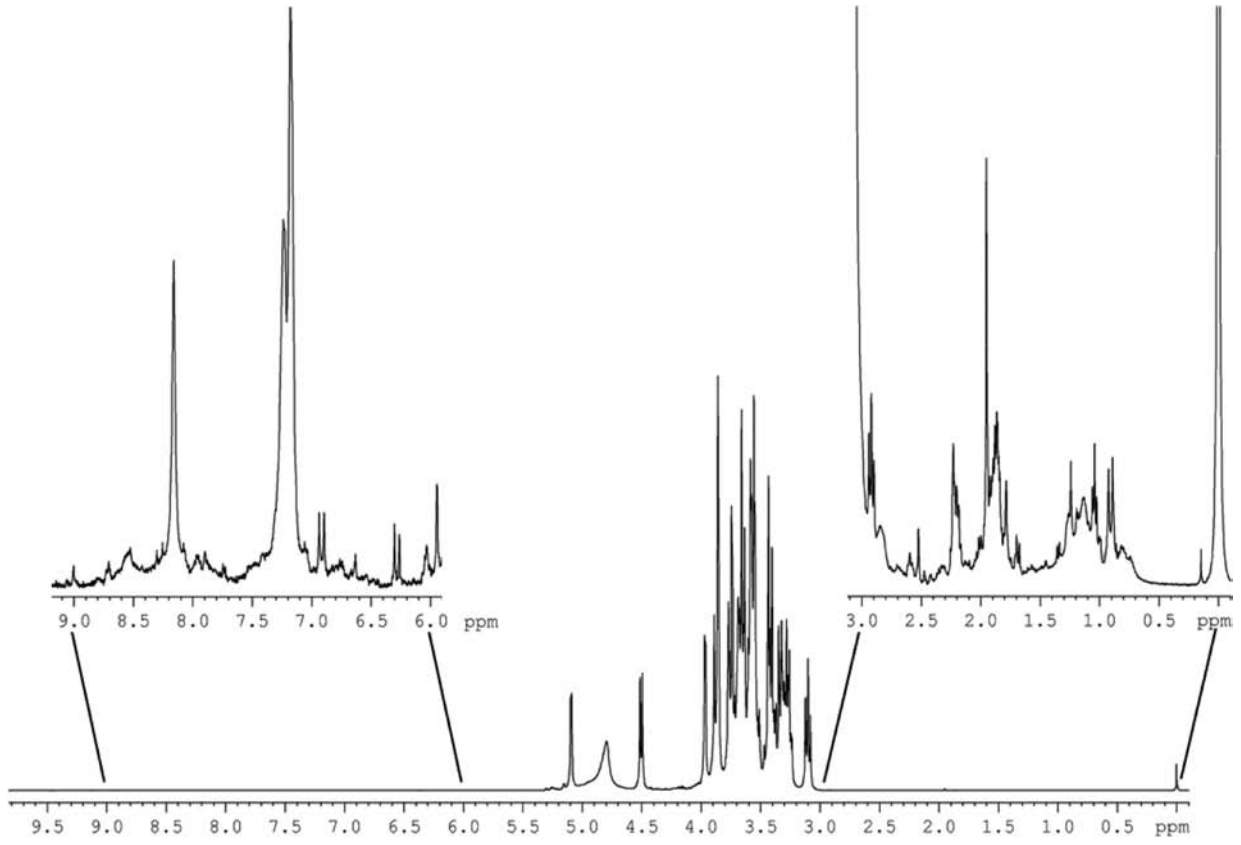

Figure 1. Spectrum of honey sample. Because the most prominent components in honey are carbohydrates, which overwhelm other compounds, the spectrum was broken into three regions: aliphatic region (0.5−3 ppm), carbohydrate region (3−6 pmm), and aromatic region (6−9 ppm).

to current environmental and living conditions. In this method not only is the presence of given individual molecules important, but their proportions are crucial. Therefore, acquiring data-rich chemical fingerprints for specific types of honeys is a next step in building chemical biomarkers profile of certain types of honeys and to identify their botanical and geographical origins. The utility of such an approach has been recently positively validated for identification of the botanical origin of some of American honeys.[12]

The aim of this study was to determine if chemical fingerprints generated using ^{1}H NMR spectroscopy and analyzed using chemometric tools might be useful to define the botanic origin of five brands of Polish unifloral honeys, namely, heather (derived from *Calluna vulgaris* L.), buckwheat (from *Fagopyrum esculentum* L.), lime (from *Tilia* L.), acacia (*Acacia* Mill.), and rape (*Brassica napus* L. var. *napus*) ones. For reference, Polish multifloral honeys were also studied.

MATERIALS AND METHODS

Honey Samples. Thirty-five honey samples of six different botanic origins (multifloral, heather, lime, rape, buckwheat, acacia) were analyzed. The origin of each honey sample was declared either by beekeepers or by the seller in the case of commercial honeys. Honey samples were stored at room temperature without daylight. Details considering geographical origin and production year of honey samples are presented in Table S1 in the Supporting Information.

Sample Preparation. Honey samples were dissolved at a concentration of 0.529 g/mL in 10% D_2O (Armar Chemicals, 100% atom % D, Switzerland). Dissolving was performed with the use of an ultrasonic bath (Cole-Parmer model 08891-26) at 298 K. After filtration, the pH was adjusted to 3.00 (± 0.01) using 2 M HCl (POCH, Poland) using a Beckman Coulter pHi 510 pH-meter. Honey solution and external standard (trimethlsilyl)tetradeuteropropionic acid sodium salt (TSP), closed in a coaxial insert tube (Wilmad Labglass), was placed in a NMR tube (5 mm o.d., 7′ Wilmad selected to 500 MHz). TSP concentration was matched in such a manner that the signal was $^{1}/_{10}$ of the maximum signal from sample (4.6 mg/mL). Each sample was analyzed in triplicate with random order.

Melissopalinological Analysis. Pollen analysis was performed in The Research Institute of Horticulture, Apicultural Division in Pulawy (Poland), an Accredited Laboratory (PCA AB 715) for performing pollen analysis, according to Polish Quality Standard number PN-88/A-77626.

Sample Solid Phase Extraction for 2D NMR Experiments. Ten grams of honey was mixed with 50 mL of acidic water (pH 2 by addition of HCl), and the mixture was subjected to an ultrasonic bath for 1 h. Undissolved particles were removed by filtration. Fluid was passed through the column (2 cm × 20 cm) with Amberlite XAD-2 (Supelco Analytical). Hydrophobic compounds remained on the Amberlite XAD-2 with a capacity of 95%;[14] other compounds such as sugars and amino acids were eluted with 100 mL of acidic water (pH 2) and 100 mL of distilled water. The hydrophobic fraction was obtained by elution with 150 mL of methanol. The methanol was evaporated on a rotary evaporator (40 °C). The acquired extract was dissolved in 600 μL of MeOD and transferred into a NMR tube.

NMR Analysis. All NMR measurements were performed with a Bruker 400 MHz Ultrashield NMR spectrometer (Bruker, GmBH, Germany) operating at a proton frequency of 400.13 MHz. Standard one-dimensional spectra with water suppression were recorded at 293 K with a relaxation delay of 3.5 s. During acquisition, 256 following scans were collected and stored in 32K data points with a spectral width of 20.55 ppm. Both phase and baseline corrections were done manually. The whole spectral set was aligned to β-glucose anomeric proton signal (doublet at 4.505 ppm). Additionally, two-dimensional HSQC experiments were acquired for spectra assignments. HSQC spectra were recorded in AntyEcho mode with a 20.55 ppm ^{1}H

window and a 238 ppm ^{13}C window, 2 s realxation time, 1K data points, 64 scans, and 256 experiments.

Data Analysis. Prior to multivariate data analysis ^{1}H NMR spectra were preprocessed. In the spectral region covering the range of 0.5−10.0 ppm data reduction was conducted by segmenting the spectra into 0.005 ppm equal width integrals, which gave 1840 new variables, after exclusion of the residual water signal region laying in the range of 4.7−5.5 ppm. The obtained data set (X matrix) was exported to Microsoft Office Excel 2003 (Microsoft Corp., Redmond, WA, USA), in which normalization to the TSP integral was performed. The data matrix was transferred into SIMCA-P+ software (v 13.0, Umetrics, Umeå, Sweden), where principal component analysis (PCA) and orthogonal partial least-squares discriminant analysis (OPLS-DA) analyses were conducted. Data were scaled using Pareto and unit variance (UV) scaling. The supervised OPLS-DA models were validated by means of cross-validation analysis of variance (CV-ANOVA) at a level of statistical significance $\alpha = 0.05$ to provide evidence that the observed separation was not due to random effects. A heatmap was generated using PermutMartix software, in which column normalization (Z score) was used.[15]

RESULTS AND DISCUSSION

NMR Fingerprint of Honey. The aim of this study was to find a fast and unequivocal method to determine the botanic origin of Polish nectar honeys, collected mainly in southern Poland. During the study the differences and similarities between chemical fingerprints of each type of Polish nectar honey were identified.

Due to the variability of signal intensities in various parts of the spectra and for the purpose of discussion, spectra were divided into three sections: aliphatic region (0.5−3 ppm), carbohydrate region (3−6 ppm), and aromatic region (6−10 ppm) (Figure 1). Variable chemical composition of nectar honeys is reflected in the quantity and intensity of signals in NMR spectra. Therefore, to specify differences and similarities, multivariate data analysis has been used.

Preliminary Chemometric Analysis and Influence of Scaling Methods. Significant differences in the intensity of the three regions of the spectrum may be an issue in multivariate data analysis. There are two major scaling methods applied in NMR-based metabolomics: unit variance (UV) and Pareto scaling. Pareto scaling partially reduces the relative importance of large signals; however, it keeps somehow the structure of the original data. Pareto scaling may be sensitive to large fold changes. On the other hand, when using UV scaling, all resonances become equally important, but noise regions or signal artifacts may have a stronger influence on the results.[16] Therefore, it was essential to determine which scaling method gives the most reliable and unbiased results. For that reason, it was decided to analyze (by means of principal component analysis (PCA)) all three regions independently and compare the obtained results with the whole chemical fingerprint analysis.

When PCA was performed for the whole ^{1}H NMR fingerprint, it revealed a huge influence of the scaling method (Figure 2a,b). Contrary to UV scaling, where the majority of groups were well separated (Figure 2a), in Pareto scaling a strong overlap was observed (Figure 2b). Subsequent analysis of each region showed that it is due to the carbohydrate resonances, which overwhelm the model when using Pareto scaling. The PCA score plot based on the whole chemical fingerprint was very similar to the PCA results based solely on the carbohydrate region (Figure 2, panel b vs panel d). Interestingly enough, the carbohydrate region exhibited the lowest discrimination potential, regardless of the scaling method used (Figure 2c,d). Previously it was shown that the carbohydrate region may be sufficient for honey discrimination;[17] however, in our study it was more efficient to utilize aliphatic and aromatic regions. Both aliphatic and aromatic regions could be used for discrimination of the honeys, regardless of the used scaling method, whereas still slightly better separation was achieved with the application of UV scaling. Results for the aliphatic region showed that in Pareto scaling samples present compact groups (Figure 2f), whereas in UV scaling they were spread more (Figure 2e); however, intragroup separation was similar in both cases. Only in the case of the aromatic region did both scaling methods give almost identical results (Figure 2g,h). Therefore, UV scaling was decided to be more suitable for the comprehensive analysis of honey chemical fingerprints.

Although PCA is an unsupervised method, it gave sufficient results for most of the analyzed types of honey (Figure 2a). The best discrimination was achieved between buckwheat, heather, and (surprisingly) multifloral honeys, whereas honeys derived from rape and acacia overlapped strongly. The group resulting from multifloral honeys was always located in the center of the PCA score plot. It is in agreement with the origin of multifloral honey, which is composed from nectars of many flowers and therefore might be seen as a composite of several unifloral honey types. Consequently, many chemical markers of variable botanic origin are present in this type of honey.

Revealing Incorrect Honey Classification. To distinguish rape from acacia, a supervised chemometric modeling OPLS-DA was performed. There was no model that passed the validation procedure and crossed the level of statistical significance (α = 0.05). Hence, analysis of three spectrum fragments (aliphatic, 0.5−3 ppm; aromatic, 6−10 ppm; and whole region from 0 to 10 ppm) showed that it was not possible to distinguish between rape and acacia honeys because of unclear reasons. It suggested, however, that despite the producer's claims these two branches might be in fact rape honey, because acacia and rape flower at the same time. Trying to explain this phenomenon and confirm sources of honey species, rape and acacia honey samples were sent to The Research Institute of Horticulture, Apicultural Division in Pulawy (Poland), for pollen analysis. Melissopalinological examination revealed incorrect declaration of origin of the whole acacia group of honeys because it was indicated that their main plant source was rape (*Brassica napus*) instead of acacia (*Acacia* Mill.). All of them contained >60% of rape pollen, which in two cases amounted to >90%. Other pollens (amount of which exceeded 5%) were derived from aesculus, raspberry, corn flower, prunus, willow, and maple. These data clearly show that honeys described by producers as acacia-derived ones did not contain acacia pollen at all. Because acacia and rape flower at the same time, it seems that honey bees are preferring rape as a major collecting source. Results of melissopalinological analysis are presented in Table S2 in the Supporting Information. Therefore, all further analyses were performed using a new group of rape honeys (made by merging the "acacia" and rape groups).

referred to the Supporting Information, where all OPLS-DA score plots and their cross-validated counterparts are given (Figures S2−S6 in the Supporting Information). The most differing of all other honeys, in all types of comparisons, were

dx.doi.org/10.1021/jf4056715 | J. Agric. Food Chem. 2014, 62, 2973−2981

buckwheat and heather ones (Figure 3b,d). Lime presented good separation from all other samples, however, not complete; in every model, the triplicate of one sample was overlapped with other honeys (Figure 3c; Figure S4 in the Supporting Information). Finally, rape and multifloral honeys exhibited similar separation qualities (Figure 3a,e). Although OPLS-DA score plots showed good separation of multifloral honeys, it became poor in cross-validated score plots (Figure S6 in the Supporting Information). This indicates that it is hard to extract one reliable marker in such a diverse group. On the other hand, it was hard to efficiently separate rape honey; however, this group was well clustered (Figure S2 in the Supporting Information). The overlap may result from the fact that many multifloral honeys contain relatively high rape components.

For each comparison loadings plots were obtained and utilized to locate specific resonances that could be marker candidates (Figure 4).

Potential Markers of Honey. Over 600 chemical compounds have been identified in honey so far. Such a rich chemical constitution makes defining the botanic origin based on individual chemicals difficult, although possible. The presence of a single chemical compound unique for the honey may indicate its botanic origin.[18−20] However, such compounds frequently occur in low or very low concentrations, which require sophisticated analytical methods or expensive and time-consuming extraction procedures.[21−23] Instead, honey origin can be defined by determining the proportion of common, for certain groups of honeys, compounds, with flavonoids being a good example here.[24−26] In both cases, the extraction process is essential and the type of extraction procedure imposes not only the applied analytical technique but also the composition of the studied samples.

In this work, sample preparation lacking an extraction process was performed. That approach to botanical origin determination of honey has not been previously used. It allows quantitative and qualitative analyses of all chemical components present in the honey sample to be performed and thus provides comprehensive information about honey. On the basis of complete chemometric analysis, the most differentiating components between species were pointed out (Figure 4). Those components, in the form of NMR resonances, were assigned to compounds by proton−carbon correlation obtained in HSQC experiments taking also into consideration data available in the literature. To confirm correct assignment, NMR experiments of honey extracts obtained by solid phase extraction were performed. Obtained in this way spectra confirmed the original assignment of signals to analyzed compounds (Figure S7 in the Supporting Information).

Dark Monofloral Honey Markers. Heather honey, falling into the category of dark honeys, contains two dominating characteristic chemical markers. The first one was identified as dehydrovomifoliol (formed from abscisic acid), which was already reported as a marker of eucalyptus honey.[13,27] The second one is phenylacetic acid produced from phenylpyruvic acid.[28] Furthermore, high contents of lactic and acetic acids were detected in heather honey, which corresponds to the high acidity of dark-type honeys. The chemical structures of the foregoing markers are presented in Figure 5B.

The second honey tested, buckwheat honey, is also classified as a dark honey. According to recent studies, the presence of 3-methylbutanal, 3-hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolon), and β-damascenone as markers had been expected.[29] However, attendance of these markers has not been seen and, thus, new chemical markers were proposed. The first of them was tyrosine, 1 of 20 natural amino acids, present in significantly high concentrations in buckwheat honey. The second one was formic acid. The presence of both was confirmed by addition of internal standards, where an increase in the intensity of their characteristic proton NMR resonances was observed (Figure S8 in the Supporting Information). Additionally, high amounts of proline and lactic acid were detected.

Light Monofloral Honey Markers. In our studies it was not possible to identify any markers for rape honey, due to the low concentration of possible ones. However, two proton and carbon NMR resonances were found to be characteristic for this type of honey. They are seen as peaks at 8.704 and 8.328 ppm in proton spectra correlated with peaks at 178.2 and 113.1 ppm in carbon spectra. We were unsuccessful in determining their chemical origin. Additionally, an unusually low amount of proline might be considered as a characteristic feature.

Lime honey is characterized by the high level of acetic acid as well as the presence of 4-(1-hydroxy-1-methylethyl)-cyclohexane-1,3-dienecarboxylic acid. This compound was reported as characteristic for lime honey from Italy.[30] The two signals that could not be identified but were specific to these honeys occur at the following chemical shifts: 1.369/29.98 and 6.16/118.56 ppm (proton/carbon NMR).

Multifloral Honey and Common Chemicals as Markers. It is assumed that multifloral honeys are produced from the nectar of many flowering plants. Therefore, small amounts of various chemical markers in the constitution of this type of honey could be observed. Furthermore, depending on the flowering plants (or main flowering plant) different chemical markers might be detected. Analyzed samples of multifloral honeys showed a chemical composition similar to light honeys. This is mostly due to the presence of chemical compounds characteristic for lime and rape honey.

Proposed markers had been used to construct a heatmap (Figure 5a), a matrix in which the relationships between intensities of peaks characteristic for all proposed markers and groups of honey are shown. The warmth of colors in a single cell represents the amount of marker in a honey sample. This resulted in a code system that might be used to identify the botanical origin of any new honey sample by examining its NMR spectrum and relating the concentration of these markers within the heatmap. In addition, compounds commonly present in honey, such as hydroxymethylfurfural (HMF) and ethyl alcohol, detected in all tested honey samples were included in this map.

In summary, studies presented in this work indicate the possibility of using chemical fingerprinting as a tool for defining the origin of Polish monofloral honeys by analysis of proton nuclear magnetic resonance spectra of crude honey preparations. Moreover, an optimum scaling method suitable for this purpose was selected. Unit variance scaling performs better in the case of honey, where significant differences in the intensity of the spectrum regions are present. Results of chemometric analysis classified all acacia honey samples as rape. Further evaluation by pollen analysis revealed the incorrect classification of acacia honeys by the producer/beekeeper and confirmed the usefulness of the chemical fingerprinting approach. Heatmaps, which might be useful for differentiation of honeys, were constructed. They are somewhat similar to the popular barcodes used in the wholesale trade. All of this confirms that NMR-based fingerprinting combined with chemometric tools

may be considered as an alternative method of honey botanical origin determination. This method of origin determination of honey might be supplementary to or a fast replacement of pollen analysis.

because the transesterification method used in the analysis of epoxy fatty acids does not esterify free fatty acids,[17,18] which is mainly used as an IS and because during solid phase extraction (SPE) separation of FAMEs, the FAMEs IS can be lost in the neutral fraction if it is added at the beginning. To improve the analytics of epoxy fatty acids in oils, a sensitive and accurate method used two internal standards, and this required two methylation steps.[13,18] In another study on food sample matrices, Fankhauser-Noti et al.[19] used a direct methylation method developed by Suter et al.[17] to analyze epoxy fatty acids without SPE column separation. This direct transesterification method in food matrices has a drawback that it sometimes involves use of pretreatment steps which differ per food matrix, and this limits its universal applicability to all food matrices.[17] Besides, epoxy fatty acids must be analyzed after the SPE separation step to reduce the amount of neutral fatty acids so as to be able to analyze them on a GC-FID.[8,12,18] Recently we developed a method that separates the coeluting hydroxy fatty acids and thus determined the epoxy fatty acids more accurately in oil.[8] On the basis of the fact that epoxy fatty acids are available in various fatty foods, there is a need for better methods of analysis that can be applied to a wide range of food sample types.

To analyze epoxy fatty acids from food samples, a method that can reliably extract oil from the food matrix is required. A good method for extraction of lipids from various food matrices should be able to overcome the interaction between the lipid and tissue matrix.[20] Although many methods are available for lipid extraction from various foods,[21,22] the most outstanding ones are the Folch method and Bligh and Dyer method.[20,23] These two methods have been a basis of lipid extraction, and because of their robustness, modifications have been presented by different researchers.[24,25]

In this study a universal method for the extraction of epoxy fatty acids from different fat-containing food matrices based on a modified Bligh and Dyer method was validated and implemented. This method uses a synthesized epoxy FAMEs IS at the beginning of the analysis, which reduces analytical variation within and between samples and has proved to be a robust and successful method. The method can be used to analyze epoxy fatty acids in various fat food matrices. Various food matrices have been analyzed, and results obtained are presented.

MATERIALS AND METHODS

Chemicals and Reagents. Methyl *tert*-butyl ether (MTBE) and 3-chloroperoxybenzoic acid (70−75%) were purchased from Acros Organics (Geel, Belgium). Dichloromethane (99% purity) was bought from Chem-Lab NV (Zedelgem, Belgium), and methanol was obtained from Fischer Scientific (Tournai, Belgium). Sodium methoxide solution (25% w/v) and silica gel 60 for column chromatography (particle size = 0.063−0.100 mm) were bought from Sigma-Aldrich (St. Louis, MO, USA). Methyl oleate (C18:1), methyl *cis*-10-heptadecenoate (C17:1), and a mixed FAMEs GLC 68D standard were obtained from Nu-Chek-Prep, Inc., USA. All other chemicals and reagents were of analytical grade and obtained from reliable local suppliers.

Standards. *Synthesis of Methyl cis-10,11-epoxyheptadecanoate (IS) and cis-9,10-epoxystearate.* Both epoxy FAMEs of the IS and the *cis*-9,10-epoxystearate (analyte) were synthesized on the basis of a stereospecific method described by Gunstone and Jacobsberg.[26] Briefly, the corresponding FAMEs of the IS and the analyte were reacted with 3-chloroperoxybenzoic acid in chloroform at room temperature for 4 h with periodic agitation. The formed epoxy esters were purified on dry activated silica gel column (25 g) by eluting the unreacted fatty acids with 200 mL of hexane/diethyl ether (98:2 v/v) as the mobile phase, and the epoxy FAMEs were collected with 300 mL of hexane/diethyl ether (90:10 v/v). Confirmation of the identity and purity of the synthesized compounds was done by use of gas chromatography−mass spectrometry (GC-MS).

Standard Preparations. The synthesized IS and analyte at a concentration of 20 mg mL^{-1} each were prepared in iso-octane. Stock solutions at a concentration of 10 mg mL^{-1} each were also prepared in iso-octane, and all were stored at −20 °C. From the individual stock standard solutions, working solutions were prepared by making dilutions in iso-octane to obtain a calibration range of 40, 80, 120, 160, 200 and 200, 400, 600, 800, and 1000 μg mL^{-1} for the lower and upper range, respectively. The upper range was diluted 10 times before injection on GC-FID. All necessary precautions were taken to avoid photodegradation of the light-sensitive standards, such as wrapping the standard solutions and the extracts with aluminum foil and storing them in the dark.

Samples. Validation was based on the following samples, namely, coconut oil, crisps, milk powder (infant formula), and pork samples, which were purchased from a supermarket in Belgium. Normally the samples would be brought to the laboratory on the day of analysis and analyzed immediately. A number of different food samples here referred to as market samples were screened for epoxy fatty acids, namely, mayonnaise, crisps, biscuits, peanuts, minced beef, cooked ham, butter, and a special biscuit known as speculoos, and were bought from supermarkets in Belgium and analyzed.

Sample Preparation. *Validation Samples.* A ground and homogenized sample (except oil) of 500 ± 0.50 mg was weighed into a 250 mL glass centrifuge tube and spiked with a mixture of epoxy IS and epoxy analyte at different concentrations (0−200 μg g^{-1} of sample). A fixed concentration (50 μg) of the IS was always added. Water was adjusted to reach a final water content of 14.5 g as determined by the initial water content of the sample. Thereafter, 26 mL of methanol and 11 mL of dichloromethane were added and homogenized using an Ultra-Turrax blender (Janke & Kunkel, IKA-Werk, Staufeb, Germany) for 1 min at 14000 rpm. Another 15 mL of dicholoromethane was added and then homogenized for 30 s, and finally 15 mL of water (pH ≤2) was added and homogenized for 30 s. The tubes were centrifuged at 3600*g* for 10 min, the pH of the aqueous layer was checked to be <2; if not, it was adjusted by using 5 M hydrochloric acid. The top aqueous layer was siphoned off, and the organic layer was dried on sodium sulfate over a 150 mm filter paper. The solvents were removed using a rotary evaporator and finally dried on nitrogen.

Market Samples. When the extraction procedure was applied to the screening market samples, a weight (depending on the amount of lipid in the sample) that does not exceed 200 mg of oil was taken. The IS amount always added was 10 μg, and the same extraction procedure above was followed.

Transmethylation and SPE Separation. *Transmethylation.* Base-catalyzed transmethylation procedures and the SPE separation steps followed have previously been described.[8] Briefly, 5 mL of MTBE was added to the extracted oil in a 25 mL glass centrifuge tube. Then, 2.5 mL of a 0.2 M sodium methoxide solution in methanol was added, vortexed for 1 min, and allowed to stand at room temperature for 2 min. Then 0.17 mL of 0.5 M sulfuric acid was added, and the mixture vortexed for a few seconds. Finally, 5 mL of water was added, vortexed for 30 s, and centrifuged at 3600*g* for 1 min. The organic layer was collected over a layer of sodium sulfate, and the extraction was repeated two times with 5 mL of MTBE. The organic layer was evaporated on a rotary evaporator and finally dried under a stream of nitrogen. The resultant FAME was dissolved into 2 mL of *n*-hexane/diethyl ether (98:2, v/v) and then loaded onto the silica column.

SPE Separation. The SPE cartridge column (6 mL, 6.5 cm × 1.3 cm) was filled with 1 g of activated silica and 5 mL of the elution solvent; *n*-hexane/diethyl ether (98:2, v/v) was added and thoroughly mixed in the column to prepare a slurry. Care was taken to ensure uniform packing and to avoid air bubbles by tapping the column slightly, and 1 cm of sand was added.

Column Chromatography Partitioning. An aliquot of FAMEs dissolved in 2 mL of *n*-hexane/diethyl ether (98:2, v/v) was loaded onto the prepared silica column, and the nonpolar fraction, which comprises the nonaltered FAMEs, was eluted with 15 mL of *n*-hexane/diethyl ether (98:2, v/v). The epoxy FAMEs were eluted with 15 mL of *n*-hexane/diethyl ether (90:10, v/v). This was dried using a stream of nitrogen and dissolved into 200 μL of iso-octane ready for GC-FID analysis.

Instrumentation. *GC-FID Conditions.* The epoxy FAMEs were analyzed by GC-FID using an Agilent 6890N series gas chromatograph (Agilent, USA). The samples were dissolved in iso-octane, and 0.1 μL was injected directly into the column using a cold on-column injector; separation was performed in a CP-Sil 88 for FAME (50 m × 0.25 mm i.d.) capillary column coated with a 0.2 μm film. A deactivated fused silica precolumn, 3 m × 0.25 mm i.d. (Agilent, Belgium), was fitted to protect the column. The oven temperature program was set as follows: 50 °C hold for 4 min, then ramp to 225 °C at 20 °C min^{-1}, and hold for 25 min. The flame ionization detector temperature was set at 300 °C. The detector flow rates for hydrogen, air, and helium (makeup) were 40, 400, and 20 mL min^{-1}, respectively. Helium was used as carrier gas at a flow rate of 1 mL min^{-1}. Identification of individual epoxy FAMEs was carried out by comparison of retention times with those of authentic standards (GLC 68D, Nu-Chek Prep, Inc., USA).

GC-MS Conditions. A GC-MS was used for the qualitative identification the epoxy FAMEs, especially in the screened samples. The epoxy FAMEs were injected in an Agilent 7890A GC equipped with a 5975C mass spectrometer (Agilent Technologies, Palo Alto, CA, USA). Chromatographic conditions and column were the same as those applied on GC-FID. The injection volume was 1 μL, and the programmed temperature vaporizing (PTV) injector was kept at 53 °C for 0.2 min and then ramped to 200 °C at a rate of 700 °C min^{-1}. The mass selective detector (MSD) conditions were as follows: capillary direct interface temperature, 250 °C; ionization energy, 70 eV; operating in scan mode between m/z 30 and 600; scan rate, 3.64 cycles s^{-1}.

Method Validation. The analytical method here presented was optimized using four different food matrices covering a wide category of common fat foods as indicated under Samples. Although foods were analyzed to obtain blank samples, it was not possible to obtain one without a signal of the analyte; however, the IS did not have any interfering signal. In-house validation procedures were followed as recommended by Commission Decision 2002/657/EC[27] and Ricard et al.[28] Performance criteria assessed included linearity, matrix effect, limit of detection (LOD), limit of quantification (LOQ), repeatability (intraday; RSDr), reproducibility (interday; RSDR), and stability. Because there are no certified reference materials available for epoxy fatty acids, trueness of the obtained results was assessed by the use of spiked samples.[28] The concentration levels used to spike the different food matrices were decided on after considering the epoxy levels obtained in fresh oil samples.[8] This study revealed that epoxy fatty acids occur in a wide range (0−1.4 mg g^{-1} of oil) in fresh oils.

Intraday Repeatability, Interday Reproducibility, and Stability. Precision of the method was assessed by repeatability and the intermediate precision called interday reproducibility. The repeatability was assessed by spiking the epoxy standard solutions to the different food matrices at five different concentration levels with three replicates at each level (n = 3) and analyzing on the same run of the day on GC-FID. Interday reproducibility was determined by repeating the experiment on two different days for all of the matrices. Stability was evaluated by storing the extracts at −20 °C and analyzing them after 4 months of storage.

Calibration Curves, LOD, LOQ, and Recoveries. Linearity and working ranges were evaluated by the correlation coefficient of standard calibration curve and by plotting the residuals for the curve. Because epoxy fatty acids are occurring at a wide concentration range, two calibration curves with uniformly spaced ranges were used in the beginning, 0−200 and 200−1000 μg g^{-1} of sample. The calibration curve was obtained by directly injecting to the GC the mixture of IS and analyte. The calibration and standard addition curves were constructed by plotting area ratios of analyte to IS (y) versus the concentration ratios of the analyte to that of the IS (x). During standard addition, the same concentrations as those in the calibration curve were used, and known amounts of the epoxy analyte were added to a fixed mass of each matrix separately. Regression of the calibration curve using the general linear regression model was performed to obtain the calibration curve equation (R^2, slope, and intercept). LOD and LOQ were determined from the standard addition curves using the linest function of the Microsoft Office Excel 2007 program. LOD was defined as the concentration equal to 3 (SEb/slope) and LOQ = 2 × LOD, where SEb is the standard error of the intercept.[28] Because certified reference materials are not available, it is acceptable that trueness of measurements is assessed through apparent recovery of additions of known amounts of the element to the unknown samples.[27] The same addition curves (spiked samples) used to calculate the LOD were further used to obtain the apparent recoveries of the method. Apparent recovery is defined as the quantity observed value/reference value, obtained using an analytical procedure that involves a calibration graph.[29] Quantification of the validation samples was based on external calibration curve, and for real samples it was based on the response factor of epoxystearate.

Matrix Effect Evaluation. The matrix effect was assessed by comparing the slopes of the calibration curve with that of the standard addition curves.[30] When there was no matrix effect, the same slope was obtained.

Statistical Analyses. Analytical determinations were conducted in triplicate, and when duplicate analysis was performed, evaluation of precision was done according to the method of Synek.[31] Comparison of the calibration and addition curve slopes was done by performing a one-way ANCOVA test carried out using the GraphPad Prism 6 2012 program.

RESULTS AND DISCUSSION

Method Development. During method development and validation both the Folch method and Bligh and Dyer method were applied, and the recovery results (not shown) for both methods were not different. Because the Bligh and Dyer method has an advantage of using less solvent,[23] it was chosen so as to reduce the use of expensive and hazardous solvents.[32]

An important factor during method development was that liquid−liquid extraction of oil had to optimize the solvent ratios to be used. The possible extraction agents are dichloromethane and chloroform. Because dichloromethane is less hazardous, it was preferred in the extraction. As a quality note, high-quality solvents should be used, and where such a quality is not achievable, the solvents should be distilled and the use of glassware is highly recommended.

Because the Bligh and Dyer method was initially developed using chloroform, it was required to optimize the use of dichloromethane. The ternary diagram of water + methanol + dichloromethane[21,33] was used to optimize both sample and solvent ratios required during extraction. The water content of dry samples had to be adjusted as indicated below because this had a bearing on the phase separation, which is the basis of this method. Addition of solvent mixtures in the following ratio and in the following order was optimal; water, 29 mL (considering water in the sample); dichloromethane, 22 mL; and methanol, 52 mL. The system should be monophasic; there should not be phase separation if the solvent ratio is correct and if sufficient homogenization is done. Addition of 30 mL of dichloromethane to the mixture, followed by addition of 30 mL of acidic water (pH ≤2 acidified with 6 M hydrochloric acid) and homogenizing again with an Ultra-Turrax blender for 30 s, allowed phase separation. Methanol is a poor solvent for triacylglycerols but is fully miscible with water in all proportions. It can thus serve to strip away the hydrating water and allow dichloromethane to dissolve the polar fatty

dx.doi.org/10.1021/jf405664c | J. Agric. Food Chem. 2014, 62, 2982−2988

acids. The water in the system causes the dichloromethane to separate cleanly, with the methanol component retaining the water and suppressing emulsion formation.[20]

Because epoxy standards are not available from commercial sources,[8] the IS and epoxy analyte used during this study were both synthesized by use of a solvent-based epoxidation procedure described by Gunstone and Jacobsberg.[26] Although it is possible to synthesize epoxides using hydrogen peroxide-based catalytic epoxidation, the "Tetrakis" phosphotungstate catalyst, and lipase-mediated reactions,[15,34] the internal standard used was prepared by using the method reported by Gunstone and Jacobsberg.[26] The method had a yield of >90%, which is a sign of purity. The synthesized compounds were confirmed by mass spectral data after GC-MS analysis. It is well-known that during the analysis of epoxy fatty acids, the method of sample preparation has to take into account the fact that the highly reactive epoxide ring can be opened by heat or chemicals.[35] Thus, the methylation procedure adopted for the formation of FAMEs during the study was room temperature methylation. However, this has a disadvantage that a free fatty acid cannot be used as an IS during the analysis of epoxy fatty acids. As observed by Suter et al.,[17] methylation and saponification reactions both compete in the presence of water, so care had to be taken that the reaction mixture was not kept unnecessarily long for the formed methyl esters to be saponified. Use of acidified water also helped to stop the possibility of saponification. The FAMEs were extracted twice in MTBE to increase the efficiency of the extraction procedure. During this study the use of a methylated IS was evaluated by calculating the area ratios of both the analyte and the methylated IS. It was found out that there was no change in the ratios; furthermore, during validation, the analyte and the IS were both epoxy FAMEs, which reduced variability during the analysis. However, it is important to note that care should be taken during the evaporation step not to lose the IS, so finally after the rotary evaporation step, extracts were always dried under a gentle stream of nitrogen. The use of an epoxy FAME IS has made this method more sensitive and accurate because analytical variations can be corrected by the IS added at the beginning of the extraction as recommended by Commission Decision 2002/657/EC.[27] In analytical methods where the IS may not be added at the start of the analysis, control of analytical variations is not possible.

Method Validation. *Linearity, LOD, LOQ, and Recovery.* Because the epoxy fatty acids occur over a wide range, in the beginning of method development, two calibration ranges were chosen, the low and the high ranges. Six concentration levels (0, 40, 80, 120, 160, and 200 $\mu g\ g^{-1}$) plus the blank were used during method development and validation. In both ranges the linearity was evaluated by plotting the residuals and linear regression (R^2) values. It must be emphasized that concentrations of the high-range calibration curve could not be injected directly onto the GC-FID, so they were diluted 10 times. In all the two ranges there was no sign of detector saturation, which would be a cause of loss of linearity, so a good linear range was observed in both calibration curves. When the two concentration ranges data were pooled and plotted into one calibration curve, still good linearity with a regression coefficient of 0.9994 and a slope of 1.23 was obtained. The calibration curves showed a measure of goodness-of-fit of linear regression (R^2) ranging from 0.9979 to 0.9999, whereas the standard addition curves showed coefficients (R^2) ranging from 0.9959 to 0.9973 in oil, 0.9885−0.9927 in crisps, 0.9990−0.9994 in milk powder, and 0.9915−0.9995 in pork. The curves with $R^2 \geq 0.995$ are considered linear,[36] and these results show how well the developed method can estimate epoxy fatty acids in the different matrices.

Mean percent recoveries based on spiked samples for the epoxy fatty acids in the different matrices were in the range from 94 to 115 (Table 1). The values are the mean of three replications of analysis performed on two different days.

Table 1. Intraday Precision (RSDr), Interday Precision (RSDR) Expressed as Relative Standard Deviation, and Apparent Recovery Obtained for Oil, Crisps, Pork, and Milk Powder at Five Concentration Levels of *cis*-9,10-Epoxystearate Analyte

matrix	concentration ($\mu g\ g^{-1}$)	RSDr (%)	RSDR (%)	apparent recovery (%)
oil	40	3	9	100
	80	4	4	100
	120	6	5	101
	160	8	5	101
	200	2	3	101
crisps	40	19	3	115
	80	1	5	99
	120	3	2	95
	160	4	6	97
	200	5	6	97
pork	40	10	7	96
	80	1	8	94
	120	2	3	96
	160	7	9	99
	200	5	6	96
milk powder	40	3	4	98
	80	2	5	98
	120	2	6	99
	180	3	3	101
	200	2	5	102

The LOD was determined according to the definition given by IUPAC and the regression of the calibration equation using the linest method was used. Accordingly, the LOD values ($\mu g\ g^{-1}$ of sample) determined for the different matrices validated were 2.75 in oil, 10.23 in crisps, 1.66 in milk powder, and 5.16 in pork. The lowest LOD was obtained in milk (Table 2).

Table 2. Limits of Detection (LOD) and Limits of Quantification (LOQ) Obtained for the Different Matrices

	oil	crisps	pork	milk powder
LOD ($\mu g\ g^{-1}$ of sample)	2.8	10.2	5.2	1.7
LOQ ($\mu g\ g^{-1}$ of sample)	5.5	20.5	10.3	3.3

The matrix effect on the recovery of the analytes was evaluated by comparing the slopes of the calibration curves with those of the addition curves. The comparison was done by using a statistical tool in GraphPad Prism to obtain a p value. The results of the statistical evaluation of the slopes of the calibration and addition curves are shown in Table 3. Only crisps samples appear to have a statistically significant matrix effect ($p = 0.0002$). The observed matrix effect in crisps could

Table 3. Matrix Effect Evaluation by Statistical Comparison of the Calibration Curve with the Standard Addition Curve

	calibration curve		addition curve		
matrix	slope	R^2	slope	R^2	p value[a]
oil	1.209	0.9999	1.222	0.9973	0.6019
crisps	1.180	0.9987	0.986	0.9885	0.0002*
pork	1.174	0.9998	1.185	0.9998	0.2615
milk powder	1.180	0.9987	1.200	0.9994	0.3498

[a]An asterisk indicates statistical difference within rows between the two slopes ($p < 0.05$).

be attributed to the high signal of epoxy fatty acids that is detected in the blank samples. Normally a good evaluation of matrix effect is obtained if a sample without the analyte of interest (blank) is obtained, but in all cases, it was not possible to get one. However, in other matrices for which the signal was low, it was possible to objectively evaluate whether it is the matrix interfering with the analysis or not.

Intraday Precision (Repeatability), Interday Precision (Reproducibility), and Stability. Results for intraday and interday precision measures are presented in Table 1. These results are presented as percent relative standard deviations in both cases as a measure of precision. The repeatability values presented are the highest that were obtained during the validation study. Although it was not possible to vary all factors that may affect precision as recommended in method validation studies,[27,28] the relative standard deviations obtained revealed that accurate estimation of precision was obtained. In the lower concentration ranges, higher variations of up to 19% were observed in crisps. The stability of the extracts was evaluated by reinjection of the same extracts after storage. Results after reinjection of the same extracts for all three matrices used did not show any degradation after 4 months of storage. This was true with the calibration standards, for which, when reinjected after 4 months, the slopes obtained did not differ significantly. This is a clear indication that epoxy fatty acid extracts can be stored at −20 °C for some time without any degradation.

Application of the Method on Market Samples. After validation and optimization of the analytical method, it was applied on commercially available samples collected from Belgian supermarkets. For each sample, the analytical determination was performed in duplicate. The results of the analysis are summarized in Table 4. The food samples analyzed were chosen to cover a wide range of samples of fat origin with differing physical and chemical composition. It was important to note that for samples which had a high dry matter content, their weight during analysis was reduced significantly as to avoid the solid matter covering the organic layer. Furthermore, depending on the fat content of the sample, the sample weight and the solvent ratio were increased so as to be able to recover enough fat. The results obtained indicate that the epoxy fatty acids are occurring in high amounts in most samples, although beef samples had less. The coefficient of variation for duplicate analysis ranged from 13.9 to 14.1%. It was generally observed that on a fat basis, biscuits had the highest total epoxy content. There is no clear relationship between the sample type and the total epoxy fatty acids determined. However, the levels of epoxy fatty acids are expected to depend on the amount of unsaturated fatty acids present, which are the precursors of epoxy fatty acids,[8] sensitivity to oxidation, and the level of oxidation.

The method presented and validated is accurate and reproducible and can be applied in the determination of epoxy fatty acids in a wide range of food samples of fat origin. The well-resolved and clean chromatograms obtained on real sample matrices indicate the reliability of the method for confirmatory purposes. The method developed is robust and can be applied to such a wide coverage. High recoveries for the epoxy fatty acids and the low LOD and LOQ levels indicate that the method is sensitive and can be used in risk assessment studies.

[a]All antisense primers used in NASBA contain the T7-cap sequence that is designed so that the T7 segment is bound to the 5′-end in addition to the given sequence. [b]All sense primers used in NASBA contain the SP6 sequence that is designed so that the SP6 is bound to the 5′-end in addition to the given sequence. [c]The T7-cap extension primer is composed of the T7-RNA polymerase promoter sequence (5′-end) and an abiotic cap sequence (3′-end, in italic) [d]The SP6-extension primer differs from the SP6 sequence used in sense primers in that it lacks the first four nucleotides (in bold) contained in the latter sequence.

diagnostics at the National Institute of Biology.[10,13] All of the primers were submitted to BLAST against different databases (only *R. solanacearum*, all *Ralstonia* without *R. solanacearum*, no *Ralstonia*, PSTVds, all viroids, plant) to obtain the selection of the most specific and selective primers. The primers for the multiplex template synthesis reaction were designed by addition of universal tail sequences to the target-specific sequences, as previously reported.[4] The primers designed for the NAIMA procedure are listed in Table 1. For *R. solanacearum*, the primers were highly similar (one additional nucleotide was inserted at the 3′ region of the antisense primer) to those previously described.[14] The universal primers for the second step of amplification are the same as previously reported.[4] The primers were synthesized and HPLC-purified by MWG Biotech AG (Eurofins MWG, Ebersberg, Germany). The experimental specificity of the primers and probes was assessed on samples of different species (Table 2, Table 4).

Design of Microarray Probes. The ArrayTube platform consists of a custom microprobe array integrated into a microreaction vial. The probes for the ArrayTubes (Alere Technologies, Jena, Germany) were designed in the region amplified by the NAIMA reactions. Briefly, windows of 30 nucleotides (±3 nucleotides) with a calculated T_m of 65 °C (±1 °C) were slid onto the NAIMA amplicon sequences with increments of 3 nucleotides. All of the candidate probe sequences were submitted to BLAST against different databases (as for the primer design). The candidates with best hits against the target (identity, similarity, lowest *E*-values) and the least number of hits were selected (and/or less significant scores; i.e., high *E*-values). The selected sequences were then checked for secondary structure (M-fold, at 55 °C), and those with no significant structure (ΔG positive or only slightly negative; i.e., $\Delta G > -1$ kcal/mol) were finally chosen. For *Ralstonia* species, the selection was made from the best ones, as specific as possible for *R. solanacearum* (for one probe), and for *Ralstonia* genus for the other two.

NAIMA Amplification Setup. *First Step: Multiplex Template Synthesis.* This first step consisted of a multiplexed template synthesis reaction, during which several pairs of tailed primers annealed to the specific DNA or RNA target and were extended to produce DNA templates bound to the universal regions (Figure 1). For this, 5 pmol of each of the SP6-specific and T7-specific tailed primers (i.e., two pairs of tailed primers for duplex NAIMA), 100 U SuperScriptII reverse transcriptase (Invitrogen, Carlsbad, CA), 10 mM dithiothreitol (Invitrogen, Carlsbad, CA), 1× First-Strand buffer (Invitrogen, Carlsbad, CA), 1 mM dNTP (Promega, Fitchburg, WI), and 5 μL of RNA, DNA, or RNA/DNA mixture were mixed in a final reaction volume of 10 μL. Template synthesis was carried out for 30 min at 42 °C in a Gene Amp PCR system 9700 (Applied Biosystems, Foster City, CA). The final product of this reaction (independently of whether the target is RNA or DNA) is the DNA template consisted of target region, tailed with universal sequence that is crucial for universal NASBA amplification step.

Second Step: Universal NASBA Amplification. The DNA templates from the first step were used directly in the NASBA amplification step (Figure 1) as follows: 2 μL template DNA from the first step was added to 5 μL of resuspended 2× NASBA Reaction Buffer Accusphere (Life Sciences Advance Technologies, St. Petersburg, FL) and mixed with 0.5 μL of the universal primers (T7 universal primer, SP6 universal primer; each at 50 μM). When the product was to be hybridized to the ArrayTube, an additional 1.1 μL of bio-UTP (Ambion; Foster City, CA) was added to the reaction mixture. This mixture was preincubated at 95 °C for 15 min and then incubated at

dx.doi.org/10.1021/jf5002149 | J. Agric. Food Chem. 2014, 62, 2989−2996

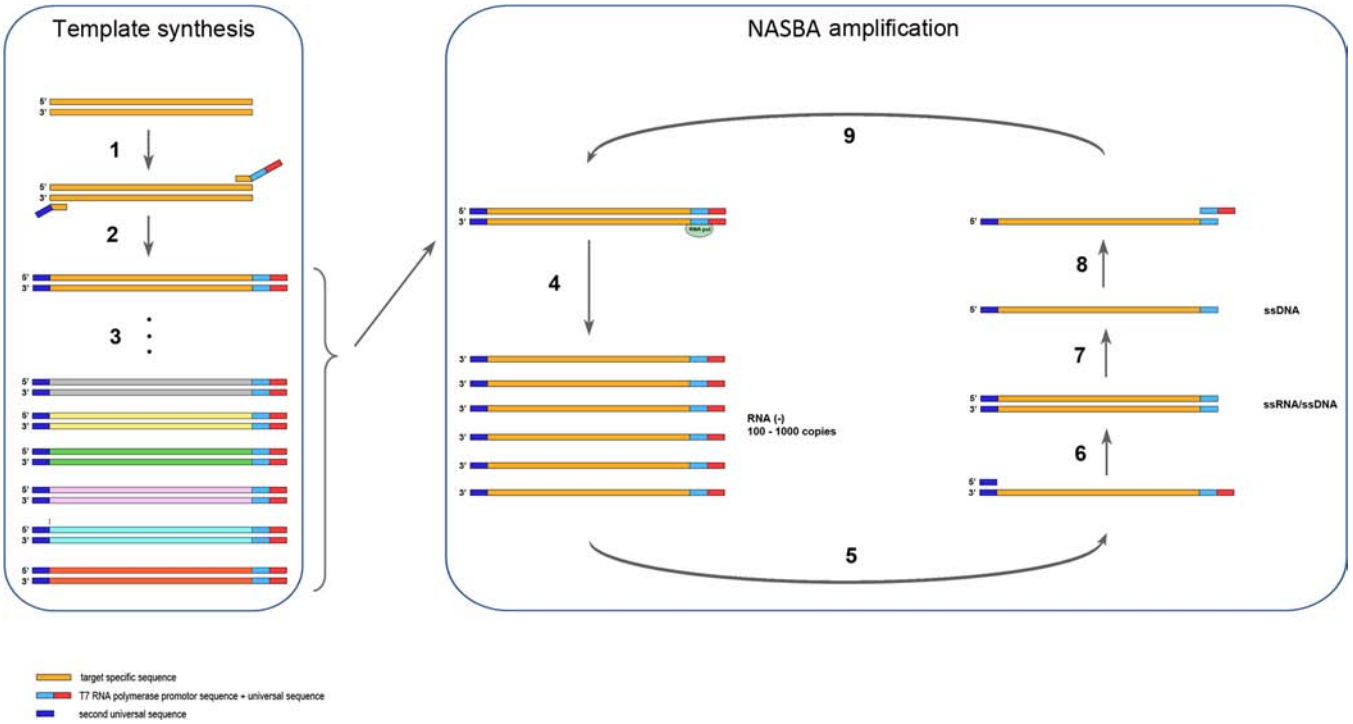

Figure 1. Schematic representation of the NAIMA amplification. The NAIMA amplification consisted of two steps: template synthesis and NASBA amplification. In the template synthesis step, the NAIMA tailed primers with sequence complementary to the target and the 5′-end sequences necessary for the multiplex amplification bind to the target (1) and are extended by the reverse transcriptase (2), producing the DNA templates for all of the targets present with identical 5′-ends (3). These templates were used in the amplification step, where T7 RNA polymerase transcribed them into several copies of antisense RNA molecules (4), and they were further reverse transcribed into single-stranded sense DNA (ssDNA) (5,6) to form an RNA−DNA duplex. The RNA−DNA duplex was later degraded by RNase H activity (7), and the ssDNA was then used as a template by the reverse transcriptase, followed by T7-cap-extension primer annealing (8) to synthesize a second DNA strand (9). These dsDNAs enter new cycles of amplification. The main product of the NAIMA amplification was antisense cRNA. Only one pair of primers was needed in this amplification step for all of the targets to be amplified.

41 °C for 2.5 min in a Gene Amp PCR system 9700 (Applied Biosystems, Foster City, CA). Afterward, 2.5 μL of resuspended NASBA Enzyme Accusphere (Life Sciences Advanced Technologies, St. Petersburg, FL) was added. NASBA Enzyme Accusphere is a cocktail of following enzymes: AMV reverse transcriptase (3.2 units/reaction), RNase H (0.04 units/reaction), and T7 RNA polymerase (16 units/reaction). The reactions were incubated at 41 °C for 40 min in a Gene Amp PCR system 9700.

Determination of NAIMA Amplification Performance and Monitoring with qPCR. The main final product of NAIMA amplification is cRNA. To estimate the amplification rate of the multiplex NAIMA amplification with qPCR, reverse transcription was performed on the NAIMA amplification products to obtain double-stranded cDNA, as previously described.[4] The primers and probes used for the qPCR detection of PSTVd and *R. solanacearum* are listed in Table 1. The qPCR reaction setup followed recommendations described by Cankar et al.,[15] and the reactions were performed as in Morisset et al.[4] using reverse-transcribed NAIMA amplification products and control samples (*R. solanacearum* DNA or reverse-transcribed PSTVd samples) (see workflow in Supporting Information Figure S1). Two dilutions of each sample were used in the qPCR, and each dilution was assayed in duplicate. The results were analyzed using the SDS 2.3 software (Applied Biosystems, Foster City, CA), after an automatic adjustment of the baseline and manual adjustment of the fluorescence threshold. The signals were considered positive if the Cq value was <40. The copy numbers of PSTVd for the sensitivity estimates were determined as described previously.[10,12] The exported data were further analyzed in a basic Excel spreadsheet. Briefly, the Cq values of the NAIMA amplification products were compared to the Cq values of the control samples. The control sample in our experiments was DNA used for NAIMA that had been diluted in the same proportion as the amplified DNA in the NAIMA reactions and reverse transcription. The differences in the Cq values between the NAIMA amplification products and the control indicated the amplification rate of the NAIMA amplification reaction. The relative efficiencies were calculated based on the assumption that the efficiency between qPCR cycles was 100% (the amount of target doubles for every cycle). The copy number estimation for PSTVd was done on the dilution series that was used in sensitivity experiments, as previously described.[12]

Array Tube Hybridization and Signal Detection. The ArrayTubes were conditioned with 500 μL of water and incubated at 55 °C in a shaking heated block for 2 min at 500 rpm. The water was then removed, and 500 μL of Nexterion hybridization buffer (Schott; Mainz, Germany) was added to the ArrayTube and incubated at 55 °C in a shaking heated block for 2 min at 500 rpm.

For the ArrayTube hybridization, 5 μL of each NAIMA amplification product was mixed with 25 μL of water and 70 μL of Nexterion hybridization buffer. This hybridization mixture was preheated to 95 °C for 4 min and cooled to 55 °C. The Nexterion hybridization buffer was removed from the ArrayTube, and 100 μL of hybridization mixture was added directly to the ArrayTube, followed by incubation at 55 °C in a shaking heated block at 500 rpm. The optimization of the hybridization time was performed on limited amounts of samples in the later stages of the experiments; however, the hybridization time of 15 min was shown to be as efficient as 60 min. Nevertheless, all of the reported tests were performed with 60 min of hybridization.

Arrays were washed by addition of 250 μL of washing buffer I that contained 2× saline-sodium citrate buffer and 0.01% Triton X-100, and the tubes were then inverted five times. The washing buffer I was removed, and 250 μL of washing buffer III containing 0.2× saline−sodium citrate buffer was added to the array, which was then inverted five times. To block the arrays, the washing buffer III was removed and 100 μL of blocking solution containing PBS, 2% milk powder, and

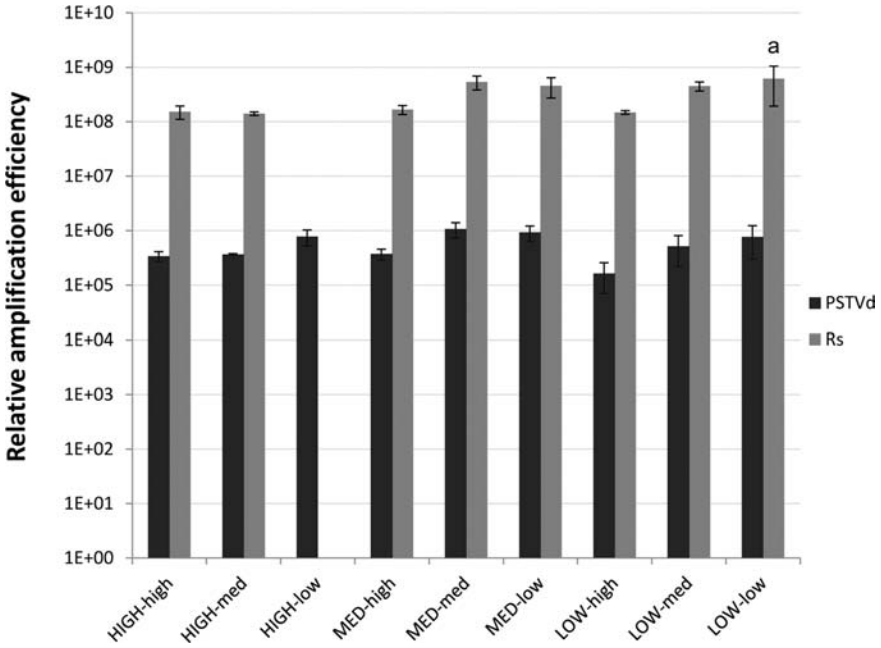

Figure 2. Efficiency of the duplex NAIMA amplification with asynchronous target concentrations. The amplification efficiency is expressed as the relative increase in copy number of the target, starting the reaction with value 1. Each bar represents the mean ± standard error of four replicates. PSTVd: HIGH, 2.5×10^4–2.5×10^6 copies; MED, 2.5×10^3–2.5×10^4 copies; LOW, 250–2500 copies. *R. solanacearum*: high, 10^8 cells/mL; med, 10^6 cells/mL; low, 10^4 cells/mL. (a) In 2 out of 4 replicates, there was no amplification.

0.005% Triton X-100 was added to the array, which was then incubated at 30 °C for 5 min without shaking. For conjugation, the blocking solution was removed and 100 μL of conjugation solution (1:100 dilution of antibiotin HRP-linked antibody (NEB, Ipswich, MA) in blocking solution) was added to the array, which was then incubated at 20 °C for 5 min without shaking. After the conjugation, the arrays were washed twice with 250 μL of PBS containing 0.1% Tween 20. For detection, the washing buffer was removed and 100 μL of SeramunGrün chip (Seramun Diagnostica, Heidesee, Germany) was added to the array. The array was scanned after 20 min incubation at room temperature, using an ATR 03 Reader (Alere Technologies, Jena, Germany). The image analysis was carried out using the IconoClust software (Alere Technologies, Jena, Germany) and the 10441_CSL_12_1.0_package analysis template. The signals were calculated within the software by the use of the proportion of the background and the mean spot intensity (241/256 × (1 − "Mean"/"Background")). The signal for each probe was considered positive if the mean of the replicates on the array diminished by a standard deviation was greater than the signal with one standard deviation of the other nonspecific probes on the array, with the confidence of the signal >0.95.

RESULTS AND DISCUSSION

In the course of the method development (Supporting Information Figure S2), the NAIMA amplification (template synthesis together with NASBA amplification, Figure 1) efficiency was always measured using qPCR as an independent assessment technique, where relative differences in the amounts of target before and after the NAIMA amplification were compared (Supporting Information Figure S1). The qPCR assay used for checking the *R. solanacearum* is routinely used in *R. solanacearum* diagnostics.[13] The sensitivity and specificity of the amplification were evaluated at different experimental stages and at two different procedure steps: after NAIMA amplification and after product hybridization on the microarray.

Primer design is of key importance, especially in multiplex reactions, due to the complexity of primer–pair combinations and issues with possible nonspecific background amplification.[16] Three different primer–pair combinations were initially designed for each pathogen target (data not shown), from which the best combination (Table 1) was chosen based on their amplification efficiencies. Likewise, different amplification protocols were initially tested for singleplex assays to obtain optimal amplification efficiency and sensitivity. Briefly, the changes included a combination of the following parameters: elimination of the denaturation step, supplying the reaction with additional reverse transcriptase enzyme, and performing both steps of the reaction in one tube. Amplification of *R. solanacearum* was not affected by changes in the protocols, whereas PSTVd amplification was shown to be more sensitive to these protocol modifications. Namely, no amplification was observed for PSTVd when the reverse transcriptase was absent from the reaction. Moreover, the absence of denaturation before NAIMA amplification decreased its efficiency. Thus, the selected protocol is the one that provides the optimal amplification efficiencies of both of these targets. The efficiencies of this duplex assay were assessed with the protocol that was optimal for both singleplex assays. For the custom-made ArrayTubes, three different probes were designed for each target (Table 1). For *R. solanacearum*, one targeted an *R. solanacearum*-specific region of the 16S rRNA gene (Rs-NAIMA-16S/3) and the two others targeted less specific sequences of the same gene, which shares a common pattern with bacteria closely related to *R. solanacearum*.

The sensitivity of the PSTVd RNA amplification in the singleplex NAIMA reactions was estimated to be from 250 to 2500 copies, four times higher than the conventional RT-PCR[12,17] and approximately 25 times lower than the reverse transcriptase (RT)-qPCR,[10] and for *R. solanacearum*, the sensitivity was 10^4 cells/mL, which is slightly lower than for the qPCR assay, where it was set between 10^2 and 10^4 cells/mL.[13] The same sensitivity for both targets was achieved when the multiplex reactions (containing both sets of primers) were

dx.doi.org/10.1021/jf5002149 | J. Agric. Food Chem. 2014, 62, 2989–2996

performed in the presence of each single target. This is the expected situation when testing actual samples, in which only one of the pathogens is usually present. Nevertheless, we also tested the sensitivities of the multiplex reactions in the presence of both targets in four parallel situations using asynchronous target concentrations, where the pathogens titers were not equal. In these cases, the multiplex amplification efficiency for *R. solanacearum* dropped significantly when the target concentration was close to or at the limit of detection of the respective NAIMA system, irrespective of the concentration of the PSTVd target in the sample (Figure 2). These results suggest that when the *R. solanacearum* target is at the limit of detection, the amplification is affected by the presence of the PSTVd target. Of note, the sensitivity of the *R. solanacearum* qPCR assay was lower than most of the other qPCR assays that are commonly used in our laboratory for routine plant health detection (data not shown). This lower qPCR sensitivity can therefore be correlated with the observed drop in the NAIMA amplification efficiency for the *R. solanacearum* system in the multiplex mode. Anyway, in the cases where the amplification was successful for *R. solanacearum* at this limit situation, it was as efficient as in the other reactions (Figure 2). However, we have shown that in the rare case where both of these targets are in the same plant sample, the NAIMA duplex would allow the detection of at least one of them and thus would trigger further analysis for quarantine-pest confirmation, with an alternative approach.

The specificities of both systems were tested on several PSTVd isolates and other related viroids (Supporting Information Table S1) as well as on several *R. solanacearum* strains and other nontarget and potentially cross-reactive strains (as listed in European Union Council Directive 2000/29/EC)[9] (Supporting Information Table S2). Moreover, we tested NAIMA on denatured bacterial suspensions without any DNA isolation and purification. The specificity of the singleplex and multiplex NAIMA assays was also compared to that of the singleplex qPCR.[13,17] The NAIMA assays showed suitable specificity for their respective targets, which matches the performance of the qPCR (Table 2).

For practical reasons, and as the microarrays were already shown to be suitable for detection of multiplex amplification products,[18−21] we have coupled the multiplex NAIMA amplification to product detection on microarrays. To do so, custom-made ArrayTubes were chosen, as this technology allows simple and relatively fast hybridization procedures. Moreover, the ArrayTubes can be scanned using a small and inexpensive benchtop machine, the ATR03 ArrayTube reader (Alere Technologies). To enable visualization of the hybridized products on the arrays, biotin was incorporated into the NAIMA amplification product. To do so, several ratios of different concentrations of biotinylated UTPs (bio-UTPs) versus nonbiotinylated UTPs were evaluated during the NAIMA reactions, with the focus on the amplification efficiency. None of the tested bio-UTP concentrations negatively affected the NAIMA amplification (data not shown), and therefore the highest tested concentration (1 mM, 20% of the total UTPs in the reaction) was used to maximize the final signal. All of the NAIMA products were checked with qPCR in parallel to the hybridization for confirmation of the array readings.

The sensitivity of the ArrayTubes detection platform was compared to that of the previously measured NAIMA amplification. For the PSTVd amplicon, similar sensitivity was

[a]qPCR results presented are for control samples that were not subjected to NAIMA amplification (see workflow in Supporting Information Figure S1). [b]Different isolates of the same species were tested and all showed the same result. [c]*R. syzigii* and blood-disease bacterium are part of the *R. solanacearum* species complex phylotype 4. [d]One out of two samples was positive. [e]+, target was successfully amplified and detected; −, target was not amplified and not detected.NAIMA targets are indicated with a clear background, nontarget organisms are indicated with the gray background. *R. solanacearum*-negative samples, samples of *Clavibacter michiganensis* DNA, used as the *R. solanacearum*-negative sample.

observed (250−2500 RNA copies), which is comparable to RT-PCR,[12,17] and about 25 times lower than for RT-qPCR[10] (Table 3). For the *R. solanacearum* amplicon, the sensitivity of the ArrayTubes detection (10^6 cells/mL) is about two log units lower than the NAIMA amplification sensitivity, which shows a loss of signal (Table 3) that probably occurs due to the lower numbers of incorporated biotinylated UTPs that is caused by the packed structure of the DNA chromosome. However, on the basis of the experience in our laboratory that shows that asymptomatic *R. solanacearum* infections of potato tubers show bacterial concentrations of 10^6 CFUs/mL (unpublished data), the displayed sensitivity is sufficient even for the testing of these samples.

The importance of the probe design is illustrated by the different probes used, which were mainly targeting specific regions of both of the amplicons. The probes present on the

arrays spanned different regions than the probes used in the (RT-)qPCR assays. Often, the detection of the NAIMA products on the ArrayTubes appeared more specific than the (RT-)qPCR assays. For example, one of the probes (Rs-NAIMA-16S/3) that was designed to be specific for *R. solanacearum* was shown to provide more specific detection toward *R. solanacearum* than qPCR, as it did not detect the related *Ralstonia mannitolilytica* (Table 4). In comparison, the other two ArrayTubes probes designed to cover the wider range of the *Ralstonia* genus led to positive signals when hybridized with the NAIMA products from the reaction performed on other *Ralstonia* species or in *R. solanacearum*-negative samples. Intriguingly, some of the NAIMA reactions performed on a PSTVd RNA sample also gave positive signals when hybridized on these two ArrayTubes *Ralstonia*-specific probes. Further bioinformatic analysis of the bacterial

sequences revealed that these signals were most probably due to the presence of the ubiquitous *Ralstonia pickettii*[22] in the samples, as they came from a natural environment. For the PSTVd target, all of the ArrayTubes probes provided detection that was at least as specific as that for the RT-qPCR assay. NAIMA appeared to be even slightly more specific, as it did not detect the nontarget TPMVd and TCDVd. However, it could be argued that this difference in specificity between qPCR and NAIMA is linked to the higher sensitivity of the former rather than the better performance of the latter. Nevertheless, the general finding is that the NAIMA primers allow the amplification of a wider, less specific range of targets than the qPCR assays (because of the high specificity of the TaqMan probe), with the overall specificity of the NAIMA assay determined by the ArrayTubes probe. In addition to the above-discussed specificity, the selectivity of the multiplex assay was satisfying, as when one of the targets or both the *R. solanacearum* and PSTVd targets were present in the samples and were amplified, a signal was detected for all of the relevant ArrayTubes probes (Figure 3, Table 4).

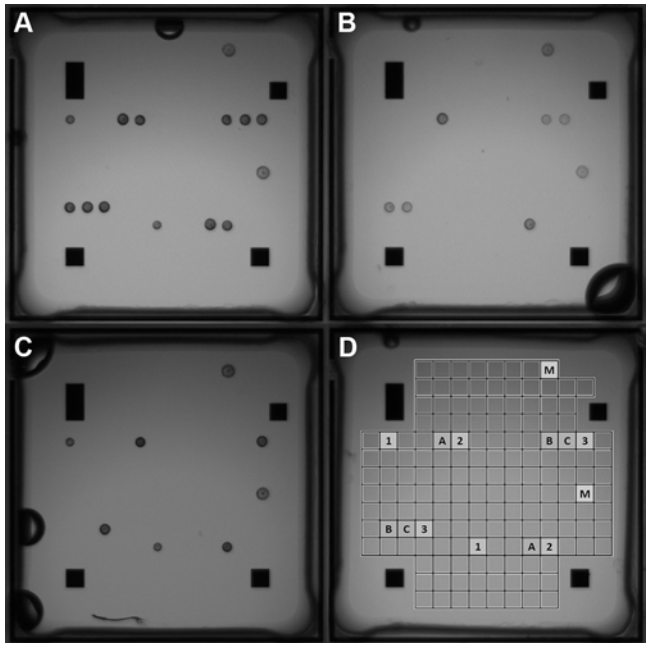

Figure 3. Samples of the scanned arrays after the hybridization of the NAIMA-amplified products. Duplex amplification was performed in the presence of both targets (A), with only the PSTVd target (B), and with only *R. solanacearum* (C). The legend for the probes is shown in (D): 1, Rs-NAIMA-16S/3; 2, Rs-NAIMA-16S/1; 3, Rs-NAIMA-16S/2; A, PSTVd-NAIMA-1; B, PSTVd-NAIMA-2; C, PSTVd-NAIMA-3.

In conclusion, the herein-proposed NAIMA method allows simultaneous, multiplex amplification and detection of RNA and DNA targets in the same reaction with satisfying performance for plant pathogen screening in terms of sensitivity and specificity. To our knowledge, this is the first report of an assay that allows both RNA and DNA target detection in a single experimental setup without PCR cycling. The time needed for the complete analysis is comparable to that of real-time PCR, although there was no particular focus on the shortening of the NAIMA procedure. As proof of concept, we tested a duplex reaction; however, the method itself has higher multiplexing capabilities, as has already been demonstrated.[4,6] As the method is isothermal, it can also be applied for on-site diagnostics after further optimization, especially as it is robust enough to detect the bacterial DNA directly from denatured bacterial suspension. Moreover, the limited size of the microarray reader and the ArrayTubes hybridization phase should allow the use of the NAIMA procedure out of the laboratory. The method as described here is a general approach for sensitive and specific multiplex RNA and DNA target identification, and it can be applied to domains of research and molecular testing where multiplex amplification and detection of DNA, RNA or both of these target types are required.

technology or are due to natural variation resulting from genetic and environmental effects, interaction of genotypes with environments, or even stochastic differences between plants. For this purpose it is necessary to evaluate the reproducibility of these analytical methods and natural variation of the results of applying these methods to crop species, such as maize. Without this understanding it would be impossible to interpret the -omics data and declare equivalence. Therefore, the International Life Sciences Institute (ILSI) recommended establishing baseline ranges for natural variations and validating these -omics technologies before they can be used for regulatory assessment of biotech crops.[15] This paper is directed toward fulfilling this function for transcriptomic and metabolomic methods.

Microarray analysis of transcriptomes is available for both model and crop plants, including *Arabidopsis*, maize, rice, potato, tomato, soy, pepper, barley, *Brassica*, and sugar cane.[21] Microarrays provide high-throughput, simultaneous detection of differences in mRNA abundance between samples for thousands of genes. Use of microarray technology for safety assessment of GM crops faces some challenges. First, nucleic acid probe hybridization is not able to detect genes expressed at very low level or genes with alternate splicing forms. Second, it is difficult to achieve high reproducibility for microarray experiments due to variations resulting from sample handling, experiment processes, environmental impact on plants, and crop variety differences.[22−24]

Technologies for simultaneous analysis of metabolites have been developed[25,26] and offer the possibility of surveying significantly more metabolites than conventional chemical analyses in a much shorter time and with much lower cost per analyte. However, comparing data from different laboratories remains challenging. This challenge is usually due to relative rather than absolute quantification and different methodologies adopted by different groups, including equipment platforms and statistical analysis methods. High sample-to-sample and experiment-to-experiment variability, even within the same laboratory, and the wide concentration range of the same metabolite between plants add to the complexity of the analysis.[10] We applied microarray and metabolomic technologies to a randomized field study as conventionally used in regulatory studies. To evaluate the reproducibility and technical variations of the microarray and metabolomic technologies, the samples were tested individually or as pools of plants and RNA and metabolites were extracted and analyzed by microarray and GC-MS. Overall, we evaluated the reproducibility of the microarray and metabolomic technologies to explore the capability of these methodologies in our experimental settings to detect the natural variation of gene expression and metabolite levels between plants and maize varieties.

MATERIALS AND METHODS

Plant Tissue. Seven inbred and four non-GM commercial hybrid maize varieties were planted in a randomized plot at DuPont Stine Haskell Research Center, Newark, DE, USA. Twenty-five seeds were sowed per row for each variety. Leaves at the V5 growth stage and immature kernels at 25 days after pollination (DAP) were collected in the morning between 8:30 a.m. and 12 p.m. for microarray and GC-MS-based metabolomics.

Three leaf punches avoiding midribs were collected at the middle of the V5 leaf area and placed on dry ice immediately after harvest, transported to the laboratory on dry ice, and stored at −80 °C before processing for metabolomic analysis. The remaining leaf was collected and frozen in liquid nitrogen immediately after harvest, transported to the laboratory on dry ice, and stored at −80 °C before processing for microarray analysis.

For 25 DAP kernels, 10 kernels in the middle row of the ear were collected for metabolomics, and the remaining kernels were used for microarray analysis. The ears at 25 DAP were removed from the plants and placed on wet ice immediately after harvest and transported to the laboratory on wet ice. Immature kernels were removed from the cobs, frozen in the liquid nitrogen, and stored at −80 °C before processing for microarray and metabolomics analyses.

Mature kernels at R6 growth stage (about 60 DAP) were also collected for metabolomics analysis. The ears at R6 stage were removed from the plants and placed on wet ice immediately after harvest and transported to the laboratory on wet ice. Ten mature kernels in the middle row of the ear were removed from the cob, frozen in the liquid nitrogen, and stored at −80 °C before processing for metabolomics analyses.

For microarray analysis, tissues were ground into fine powders. For metabolomics analysis, tissues were lyophilized before they were ground to fine powders. Additional pooled samples were obtained by combining equivalent amounts of ground material from three individual plants.

Microarray. Total RNA was isolated from ground frozen tissue using the EZNA SQ RNA Isolation Kit (Omega Bio-Tek, Norcross, GA, USA), treated with DNase-I, and used for mRNA isolation with an Illustra mRNA Purification Kit (GE Biosciences, Pittsburgh, PA, USA). The total RNA and mRNA samples were visualized and quantified on a Bioanalyzer 2100 (Agilent Technologies, Santa Clara, CA, USA). Each mRNA sample was converted into double-stranded DNA by an in vitro transcription reaction and labeled with Cy3 fluorescent dye using the Low RNA Input Fluorescent Linear Amplification Kit (Agilent Technologies). The cRNA product was purified with an Agencourt RNAClean Kit (Beckman Coulter, Indianapolis, IN, USA). Hybridizations were performed overnight with equal amounts of labeled cRNA to a custom 4x44K Maize Oligo Microarray from Agilent Technologies according to Agilent's One-Color Microarray-Based Gene Expression Analysis protocol. After hybridization, the microarray slides were washed and immediately scanned with the a G2505C DNA microarray scanner (Agilent Technologies). The images were visually inspected for artifacts, and feature intensities were extracted, filtered, and normalized with Feature Extraction software (v 10.5.1.1) (Agilent Technologies). Quality control and downstream analysis were performed using data analysis tools in Genedata Expressionist and the statistical language R. Further data analysis and bioinformatic analyses were carried out according to methods described in Hayes et al.[27]

Metabolomics. Metabolites were extracted from approximately 3 mg (dry weight) of lyophilized tissues for each sample. In a 1.1 mL polypropylene microtube containing two $^{5}/_{32}$ in. stainless steel ball bearings, each sample was added with 500 μL of chloroform/methanol/water (2:5:2, v/v/v) solution containing a 0.015 mg ribitol internal standard. Samples were homogenized in a 2000 Geno/Grinder ball mill at setting 1650 for 1 min and then rotated at 4 °C for 30 min before being centrifuged at 1454*g* for 15 min at 4 °C. Aliquots (300 μL) were transferred to 1.8 mL high recovery glass autosampler vials, evaporated to dryness in a speed vac, and redissolved in 50 μL of 20 mg mL^{-1} methoxyamine hydrochloride in pyridine. The vials were capped, agitated with a vortex mixer, and incubated in an orbital shaker at 30 °C for 90 min to form methoxyamine derivatives. Next, 80 μL of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) was added to each sample to form trimethylsilyl (TMS) derivatives by a Gerstel autosampler 30 min prior to injection to minimize sample variations due to derivatization differences. This "just in time" derivatization eliminates variation due to differences in reaction time or temperature. Furthermore, the gas chromatograph inlet liner and septum were replaced daily, mitigating the known influence of sample residue in the inlet on trimethylsilylation completeness.[28] However, trimethylsilylation can vary with the sample matrix.[28] Thus, for molecules such as amino acids that present multiple reaction sites leading to the possibility of two or more chemical derivatives, the relative abundance

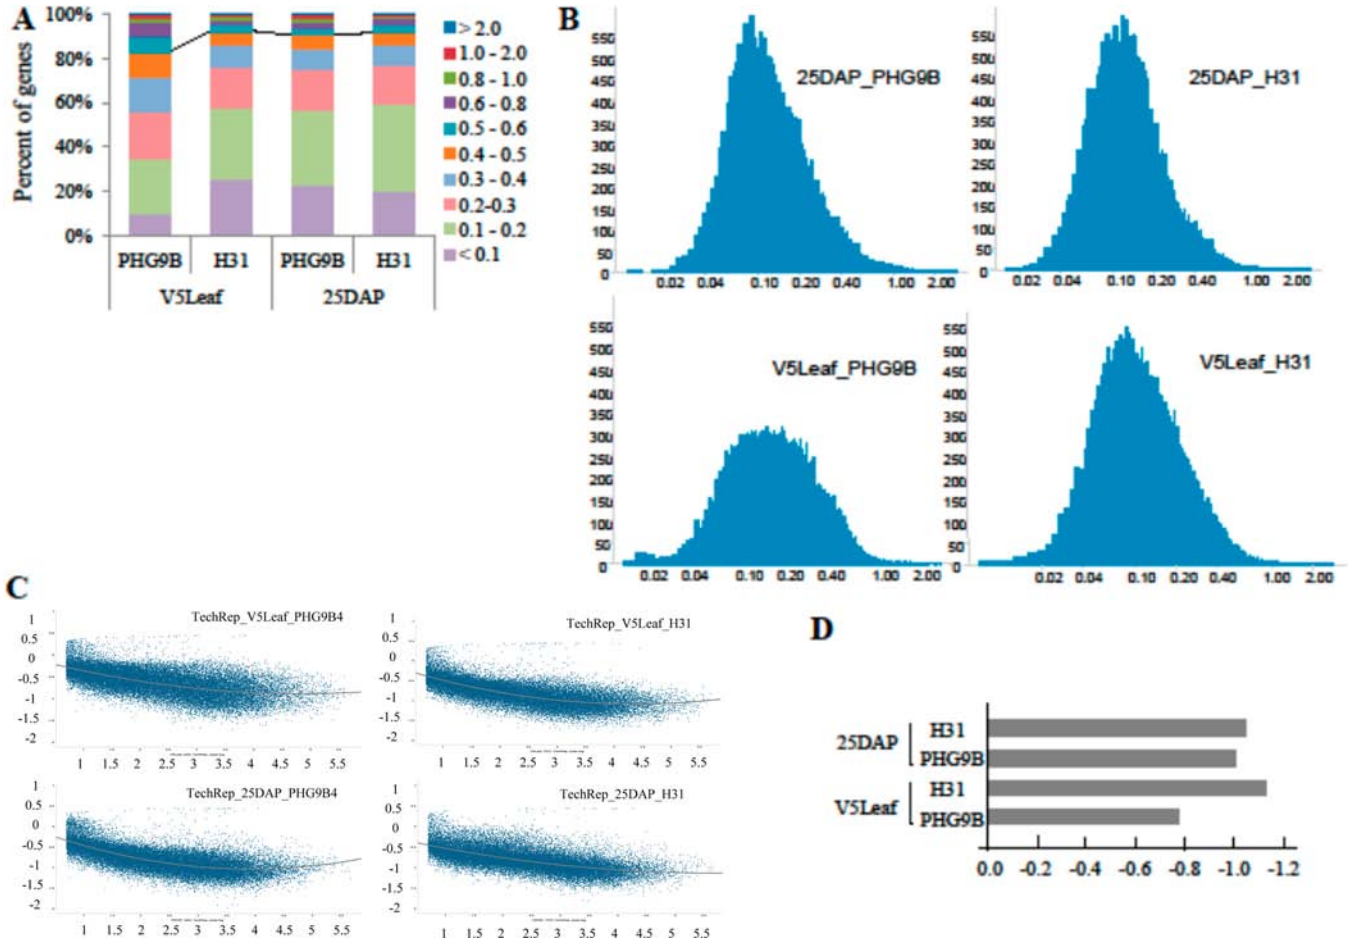

Figure 1. CVs of gene expression calculated from technical repeat microarrays: (A) percentages of genes within different CV ranges; (B) CV distributions generated by TIBCO Spotfire (*x*-axis, CV values in log scale; *y*-axis, gene counts); (C) plots of log10 (CV)s (*y*-axis) and against log10 (mean)s (*x*-axis) (curves are polynomial fittings generated by TIBCO Spotfire); (D) log10 (CV) values of inflection points calculated from curves in panel C.

of these trimethylsilylated forms can vary among the three different tissue types assayed in this study.

The derivatized samples were separated by gas chromatography on a Restek 30 m × 0.25 mm × 0.25 μm film thickness Rtx-5Sil MS column with a 10 m Integra-Guard column. One microliter injections were made with a 1:30 split ratio using a Gerstel autosampler. An Agilent 6890N gas chromatograph was programmed for an initial temperature of 80 °C for 0.5 min and increased to 350 °C at a rate of 18 °C min^{-1}, at which it was held for 2 min before being cooled rapidly to 80 °C and held there for 5 min in preparation for the next run. The injector and transfer line temperatures were 230 and 250 °C, respectively, and the source temperature was 200 °C. Helium was used as the carrier gas with a constant flow rate of 1 mL min^{-1} maintained by electronic pressure control. Data acquisition was performed on a LECO Pegasus III time-of-flight mass spectrometer with an acquisition rate of 10 spectra s^{-1} in the mass range of m/z 45−600. An electron beam of 70 eV was used to generate spectra. Detector voltage was 1750 V. An instrument autotune for mass calibration using perfluorotributylamine (PFTBA) was performed prior to each sample sequence.

Metabolomics Data Processing and Analysis. Raw Leco GC-MS .peg datafiles were converted into .netcdf (Andi) formats using Leco ChromaTof ver. 4.13 software. Data preprocessing was performed with Genedata Refiner MS ver. 5.2.1 software. For each .netcdf file, retention times were converted into retention indices using an in-house program. Preprocessing consisted of gridding chromatograms in the m/z value (80−437) and retention index dimensions, subtracting chemical noise, aligning the retention indices of each selected ion chromatogram, and detecting nominal mass peaks, using empirically optimized settings for each process. Data from each of the three tissue types were processed separately to maximize alignment and peak peaking. The resulting three matrices consisted of intensities for each m/z value−retention index combination and each sample. The aligned and denoised data matrices were passed to Genedata Analyst ver. 2.1 software, where each intensity value by sample was normalized for both the ribitol internal standard signal and sample dry weight.

Because m/z value−retention index fingerprint data are redundant, significant signatures were reduced to named known metabolites on the basis of matching both the retention index and mass spectrum to those of authentic standards. Relative quantitation of each metabolite in each sample was derived from the intensity of each metabolite's representative m/z value obtained from the Genedata Analyst output. In a few cases, peak heights obtained from ChromaTof quantification ion chromatograms were used instead when signals were below the threshold set for fingerprinting and thus not present in the Genedata Analyst output. Metabolite detection from either source was dependent on reaching a conservative limit of detection to mitigate false-positive peaks that would have an undue effect on subsequent statistical analyses. Percent CV values were calculated for each metabolite across selected samples. Data matrices were reformatted and imported into the PLS_Toolbox version 7.0.1 (Eigenvector Research, Inc.), with which principal component analysis (PCA) was performed on autoscaled (mean centered and each variable scaled to unit variance) data.

Experimental Design. For both microarray and metabolomics experiments, 11 maize varieties were used, including (1) 7 inbred lines, PHG9B (high oil), H31 (low oil), PH2WBS (high protein), PH2WBR (low protein), PH0GP (median starch), PH14T (median starch), and 658 (low starch); and (2) 4 commodity hybrid lines, 38B85, 37Y12, 34A15, and 34P88. These lines were chosen as a partial representation of the range of U.S. cultivated maize diversity and include lines differing in protein, oil, and starch contents. Three types of tissues, V5 leaf, 25 DAP immature kernel, and mature kernel, were used for metabolomic experiments. Because the mature kernels are dormant and have very limited gene expression,[29,30] only the V5 leaf and the 25 DAP immature kernels were used for microarray experiments. Due to limited tissue availability for some varieties, some microarray or metabolomic experiments were not conducted.

For microarray technical repeat controls, eight independent RNA samples were isolated from either V5 leaves or 25 DAP immature kernels of a single plant from the high-oil variety PHG9B and the low-oil line H31 and used for eight different microarray hybridizations. The signal differences among these hybridizations were considered the technical variation of the microarray methodology. Similarly, eight independent metabolite extractions were made from bulk collections of V5 leaves or 25 DAP immature kernels of PHG9B and H31 and from bulk mature kernels of PH2WBS (high-protein line) and PHG9B. They were used for independent GC-MS analyses and technical variation assessment. Multiple sample preparation and testing steps were used to evaluate the reproducibility of both technical methods. Sample variations were also evaluated by comparing data from different individual plants and different pooled plants.

qRT-PCR. Genes, primers, and probes are listed in Supplementary Table 1 in the Supporting Information. Primers and probes were designed with Primer Express 3.0.1 (Applied Biosystems, Carlsbad, CA, USA) and purchased from Integrated DNA Technologies, Inc. (Coralville, IA, USA). First-strand cDNA was synthesized from the same mRNA samples used for microarray. Fifteen pooled samples from either V5 leaf or 25 DAP kernel were chosen on the basis of sample availability. For each RT reaction, 240 ng of mRNA was used as a template in a total volume of 80 μL following the manufacturer's instruction for the SuperScript VILO cDNA synthesis kit (Invitrogen, Carlsbad, CA, USA). All qRT-PCR primers and Taqman probes were designed using the Primer Express program (Applied Biosystems) and tested for specificity by Blast search against the NCBI public sequence database. The qPCR reactions were carried out in 384-well plates in a ViiA 7 real-time-PCR machine (Applied Biosystems) using the TaqMan Gene Expression Master Mix (Applied Biosystems). The qPCR program was 50 °C for 2 min, 95 °C for 10 min, followed with 40 cycles of 95 °C for 15 s and 60 °C for 1 min. Each reaction contains 200 nM of each primer, 100 nM of probe, and 2 μL of the RT reaction solution as template in a final volume of 20 μL. Every reaction was repeated three times. The ViiA 7 software V1.2 was used to record and process the data. The Rn (normalized reporter) values of each reaction for every cycle were exported and used to calculate the single-well qPCR efficiencies using a real-time PCR Miner program.[31]

RESULTS

Microarray Reproducibility. To compare the reproducibility of expression levels of the same genes on repeated microarrays, the data were analyzed using correlation statistics. The coefficient of variation (CV) for each set of repeats was calculated and compared as an indication of reproducibility.[32] Mean CV values of gene transcripts for technical repeats were 0.25, 0.23, 0.33, and 0.23 for 25 DAP PHG9B, 25 DAP H31, V5 leaf PHG9B, and V5 leaf H31 samples, respectively, relatively low compared to the microarray literature,[33−35] indicating good technical reproducibility. Expression of most of genes on the microarrays had low CV values, with 82.4, 92.1, 90.4, and 91.6% of genes from V5 leaf PHG9B, V5 leaf H31, 25 DAP PHG9B, and 25 DAP H31 microarrays exhibiting CV values below 0.5 (Figure 1A). In addition, these CV values showed log-normal distribution centered at 0.1 (Figure 1B), indicating good reproducibility. However, the reproducibility of eight technical repeat microarrays for PHG9B V5 leaves was little higher than other technical repeat microarrays (Figure 1A). Alternatively, the CV values were log transformed and plotted against the log transformed mean values. Polynomial curve fitting showed as expected that CV values decreased as the mean intensities increased (Figure 1C). The inflection points calculated on the basis of the polynomial curves showed that technical repeat microarrays for PHG9B V5 leaves have higher background noise (Figure 1D), similar to that shown by the CV distributions (Figure 1A).

We further investigated the reproducibility of microarray results by a linear regression model correlating data between any pair of microarrays within each group. Four groups were analyzed this way for both V5 leaf and 25 DAP kernel samples, including the eight technical arrays for H31, the six individual biological repeats for H31, the eight technical arrays for PHG9B, and the nine individual biological repeats for PHG9B. The box plots represent the distributions of *R* square values of all pairwise comparisons of linear regression modeling (Figure 2). The technical replicates had consistently higher correlations

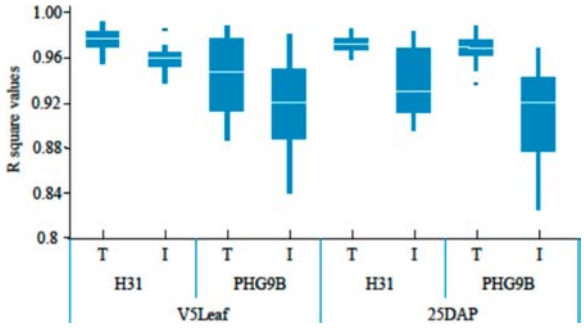

Figure 2. Technical reproducibility of microarrays. Pairwise correlation coefficients between pairs of technical replicates (T) or between pairs of biological repeats (I). Box plots were generated with TIBCO Spotfire. The white bar represents the median value. Edges of boxes represent values at 75 and 25% percentiles. Edges of bars represent the ranges of values with outside dots as outliers.

than the biological replicates (Figure 2). We conclude that gene expression variation from microarrays resulted primarily from maize variety differences rather than from plant-to-plant differences, pooled sample-to-sample differences, or technical variations, indicating that the method is sensitive enough to detect biological variation among individual or pooled plant samples.

Correlation between Gene Expression of Individual and Pooled Samples. Next, CV values for the microarrays from the six varieties analyzed both as individual samples (I) and as pooled samples (P) were calculated. For each variety, six or nine individual plants and two or three pools of samples (three plants per pool) were analyzed. The pools were created by combining equal amounts of RNA extracts from individual plants. Overall, 73.7% (34A15_I)−93.3% (38B85_P) of the genes had CV values below 0.5 from V5 leaf samples, and 73.8% (38B85_I) − 96.8% (PHG9B_P) of genes had CV values below 0.5 from 25 DAP kernel samples (Supporting Information Supplementary Table 2), representing very good experimental reproducibility. The distributions of the CV values from both 25 DAP kernel and V5 leaf samples are shown in Supplementary Figure 1 in the Supporting Information. When

[a]Values are Pearson correlation coefficients (R) comparing mean gene expression intensities between all I and all P samples for each variety−tissue combination, calculated using Excel function PEARSON. [b]Values are Pearson correlation coefficients (R) comparing gene expression intensities from V5 leaf and 25 DAP for the same plant samples, calculated using Excel function PEARSON, for individual plants (I) or pooled plants (P).

the overall CV distribution patterns of individual or pooled samples were compared, microarrays for 25 DAP kernel samples showed larger CV differences, compared to V5 leaf samples. Additionally, log10 (CV) versus log10 (mean) plots were generated for all of the microarrays to reveal the relationship between CV and mean intensities (data not shown). The inflection point values were very similar to what was shown by the CV distribution patterns (Supporting Information Supplementary Figure 1).

The Pearson's correlation coefficient was calculated by comparing mean gene expressions between individual samples and pooled samples for each variety and tissue type. The R values were between 0.9743 and 0.9959 (Table 1), indicating that the signals obtained from individual plants and pooled plants were highly correlated and similar. When samples from the same variety but different tissue types were compared, the Pearson correlation R values were between 0.234 and 0.317 (Table 1), indicating significant gene expression differences between leaves and kernels, as expected. For every variety−tissue combination, the pooled samples showed a smaller mean CV value than the one from corresponding individual samples (Supporting Information Supplementary Table 3). Therefore, the plant-to-plant variation detected from the same variety was reduced by pooling three plants into a single sample, essentially transforming plant-to-plant variation into sample-to-sample variation. In addition, the distribution patterns of CV values from I and P samples were very similar (Supporting Information Supplementary Figure 2), indicating that our pooling strategy was efficient in capturing the variations existing among maize varieties while realizing a cost savings.

Gene Expression Differences between Varieties. To evaluate gene expression variation between maize varieties, mean microarray spot intensities from six or nine individual samples (I) and two or three pooled samples, with three individuals per each pool (P), were determined and used for CV calculations comparing the six varieties that had both I and P samples.

When the CV distributions of individual samples representing variety-to-variety variations (Supporting Information Supplementary Figure 2 and Table 4) were compared to the CV distributions representing plant-to-plant variation within a certain variety (Supporting Information Supplementary Figure 3 and Table 2), we found that the former were larger. For V5 leaves, 65.4% of genes showed a CV value <0.5 when different maize varieties were compared (Supporting Information Supplementary Figure 2 and Table 4), but 73.7% (34A15)−93.1% (38B85) of genes had a CV <0.5 when individual plants within a given variety were compared (Supporting Information Supplementary Figure 1 and Table 2). For 25 DAP kernels, 68% of genes showed a CV value <0.5 when different maize varieties were compared (Supporting Information Supplementary Figure 2 and Table 4), but 73.8% (38B85)−85.1% (H31) of genes had a CV <0.5 when individual plants within a given variety were compared (Supporting Information Supplementary Figure 1 and Table 2). These results indicate that higher variations exist among different maize varieties compared to those among individual plants of the same variety, likely due to the genetic differences and/or genetic and environmental interactions affecting gene expression among varieties.

In addition, the variety-to-variety variation detected in 25 DAP kernels is similar to that among V5 leaf tissues on the basis of their CV distributions (Supporting Information Supplementary Figure 2), indicating that gene expression variations among different maize varieties are similar between these two tissue types.

Confirmation of Microarray Results by qRT-PCR. To confirm the gene expression levels measured by the microarray experiments, two groups of 18 different genes were chosen for V5 leaf and 25 DAP kernel, respectively (Supporting Information Supplementary Table 1). The expression levels of these genes are ranked across all microarrays at 80 or 50% percentiles. Expression of these genes was measured by qRT-PCR reactions using the same RNA samples used for microarrays. Due to limited sample availability and possible polymorphisms among different maize varieties at primer annealing locations, we used a real-time PCR Miner program[31] that has been validated by many other groups[36−43] to monitor the single-well qRT-PCR efficiency. The *dapA* gene was used as a control for comparison between microarray and qRT-PCR data. Gene expression levels from qRT-PCR reactions were calculated on the basis of the *dapA* expression and compared to levels detected on microarrays that were also quantified on the basis of the *dapA* expression. The ratio of expression levels for each gene detected by these two techniques was log transformed for proper comparison (Figure 3).

For V5 leaf tissue samples, two genes (pco602011 and pco603626) were not amplified from any of the 15 templates by qRT-PCR and therefore not included in the analysis. Two genes, pco627753 and pco643043 (genes 2 and 11 in Figure 3A, respectively), had expression detected only in some of the samples, and four genes, pco624384, pco521467, pco652567, and pco658406 (genes 13, 14, 15, and 16 in Figure 3A, respectively), showed higher expression (ca. 2−32-fold higher), relative to microarray, in all 15 samples. For the remaining genes tested, the expression levels were close to those measured by the microarrays, although there were some variety-specific expression differences between the two techniques (Figure 3A). For 25 DAP kernel samples, one gene (pco621453) did not

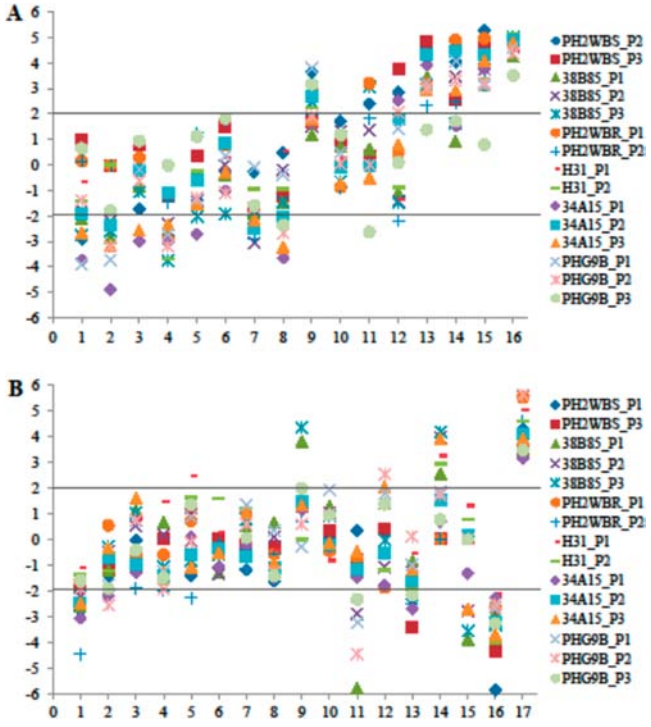

Figure 3. Gene expression analysis comparing qRT-PCR to microarray hybridization with V5 leaf (A) or 25 DAP (B) samples. Numbers are log 2 transformed ratios between expression levels detected by qRT-PCR and microarray that were defined against dapA expression levels.

show any amplification from qRT-PCR and was not included for further analysis. Two genes, pco653893 and pco598383 (genes 14 and 15 in Figure 3B, respectively), were amplified from 11 and 8 samples of 15 varieties, respectively. Two genes, pco601999 and pco632057 (genes 16 and 17 in Figure 3B, respectively), had very different expression levels from microarray across all varieties (Figure 3B). Gene 16 showed 4−60 times lower expression and gene 17 showed 8−60 times higher expression when detected by qRT-PCR compared to microarray results. The rest of the genes tested in 25 DAP kernel samples showed good consistency with microarray data (Figure 3B). A few qRT-PCR expression data points were different from the microarray data, but only for one or two maize varieties.

Metabolomic Data Analysis. The three processed data matrices contained 3891 metabolomic signatures or fingerprints (m/z value−RI combinations) for V5 leaves, 4300 for 25 DAP immature kernels, and 3891 for mature kernels. Of these, 87−103 metabolites were successfully identified in tissues examined. These numbers, reduced relative to the raw data set, take into account the elimination of the inherent redundancy in metabolomics signatures and ignore metabolites for which the identity could not be unambiguously established. The substantial reductions are due to (1) eliminating the inherent redundancy in metabolomics signatures wherein each metabolite can be represented by multiple m/z values in its electron impact mass spectrum and (2) ignoring metabolites for which the identity could not be unambiguously established.

To evaluate technical variations including the sampling, analytical, and data analysis variability, eight technical repeats were produced from V5 leaves of PHG9B and H31, 25 DAP kernels from PHG9B and H31, and mature kernels from PH2WBS and PHG9B. For each tissue−variety combination, a single bulk tissue sample was aliquoted into eight extraction tubes, producing eight metabolomic samples. Mean CV values calculated from technical repeat metabolite relative levels were

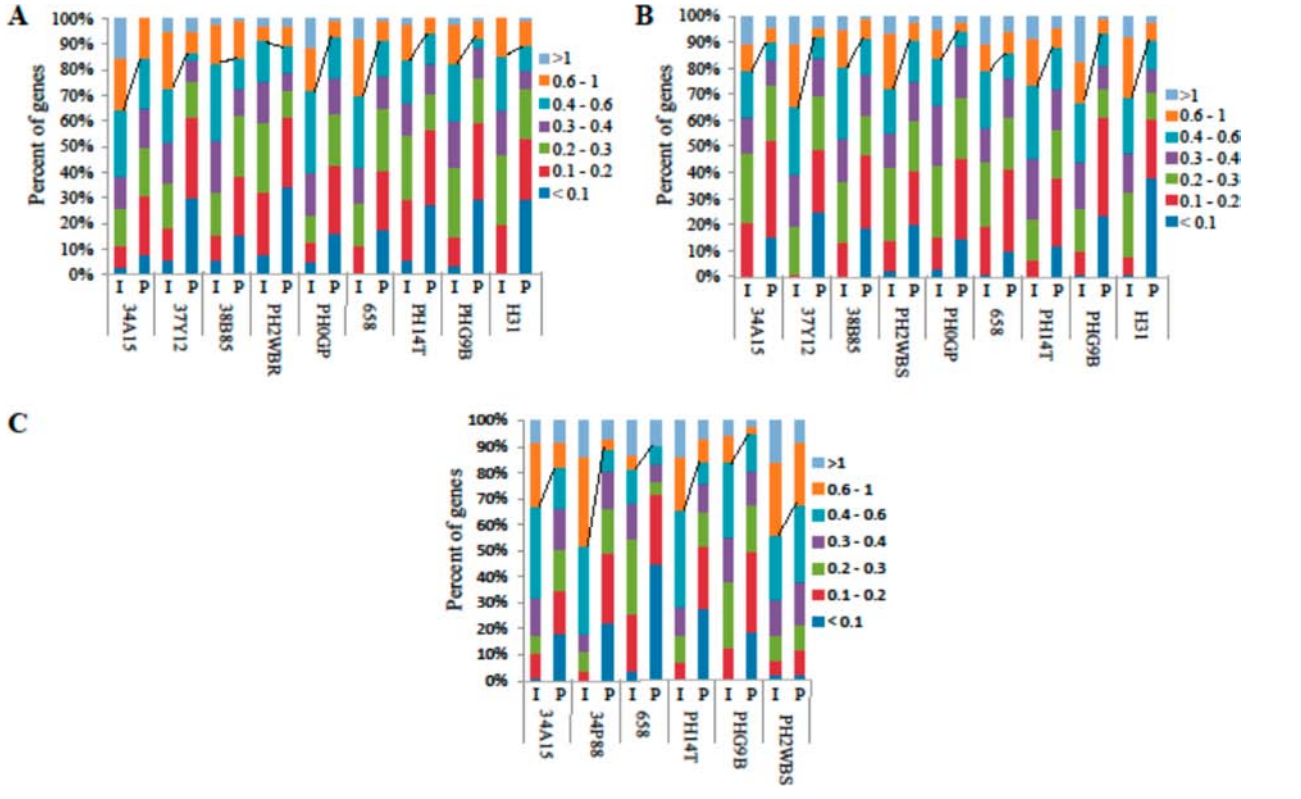

Figure 4. CV distribution of metabolite levels detected from V5 leaf (**A**), 25 DAP immature kernel (B), and mature kernels (C).

dx.doi.org/10.1021/jf405652j | J. Agric. Food Chem. 2014, 62, 2997−3009

between 0.33 and 0.54, and median values were between 0.27 and 0.46, indicating good reproducibility despite some outliers in the upper ranges (Supporting Information Supplementary Figure 3). The majority of metabolites detected showed CV values <0.6, with 76.7 and 87.4% metabolites from V5 leaves of PHG9B and H31, 76.1 and 80.2% of metabolites from 25 DAP immature kernels of PHG9B and H31, and 77.6 and 60.9% of metabolites from mature seeds of PH2WBS and PHG9B, respectively (Supporting Information Supplementary Figure 3). We also found that pooled samples had lower variances compared to the individual samples (Figure 4; Supporting Information Supplementary Table 5), similar to what was observed from the transcript data. Particularly, metabolomics for mature seed samples showed much less variation than for immature seeds (Supporting Information Supplementary Table 5), probably due to a less complex metabolome and terminal differentiation state of mature kernels.

Mean metabolite levels detected from individual and pooled samples of the same tissue–variety combination are highly correlated, with Pearson correlation *R* values all close to 1 (Table 2). For PHG9B and H31, the high correlations are observed despite the fact that the individual samples were from nine different plants, compared to the technical variation tests for which metabolites were extracted from eight aliquots of the same plant sample. These results also demonstrate consistent derivatization, GC, MS data acquisition, and data processing.

Table 2. Mean Metabolite Levels Detected from Individual Plant (I) and Pooled Plants (P) Samples for the Same Tissue Type of a Variety Are Highly Correlated[a]

[a]Pearson correlation coefficients (*R*) by Excel function PEARSON.

Tissue or Variety Separation Based on Metabolomics. When the metabolites detected from the three different tissues were compared, PCA clearly indicated tissue separation (Figure 5), reflecting tissue specificity of metabolic processes, as expected. However, PCA revealed variety specificity for only certain variety–tissue combinations. For example, for V5 leaf tissues, there was clear separation of PH2WBR, PH14T, and H31 from other varieties based on PC1 and PC3 (Figure 6A). Likewise, PH2WBS and PH2WBR in 25 DAP kernels were readily distinguished from other varieties with PC1 and PC4 (Figure 6E). For mature kernels, PH2WBS and PHG9B showed good separation from other varieties based on PC2 and PC3 (Figure 6I).

For the most part, the tissue and variety classifications observed with individual plants were also evident in pooled plant samples, although sometimes with different principal component projections (Figures 5 and 6A,J). This result suggests that pooling did not degrade the discriminating power afforded by individual samples. Interestingly, the combined percent variance included in the PCA scores plots was slightly higher for pooled samples compared to that generated for analogous individual samples, suggesting that pooling removed some uninformative signal.

Loadings associated with examples of the above variety classifications were selected graphically (Figures 6C,D; G,H; and K,L; in purple) and listed in Supplementary Table 6 in the Supporting Information. The very significant increases in the amount of amino acids in developing kernels, including glutamic acid, glutamine, histidine, leucine, lysine, pyroglutamic acid (which could be derived from glutamine during sample preparation), and tryptophan, are expected for PH2WBS, a genotype with elevated grain protein. Explanations for the genotype-specific differences (loadings) in the other tissues are less obvious. For the three examples shown, loadings from pooled plants were very similar to those from individual plants. Thus, pooling generated similar PCA scores and loadings, maintaining the ability to classify sample groups (varieties) as well as to identify the prominent metabolites underlying said classifications.

In this GC-MS metabolomic study, we also found that some metabolites were detected in only one or two tissue types. Among individual plant samples, there were 19 metabolites uniquely detected in V5 leaves, 2 only in immature kernels, and 3 only in mature kernels (Table 3). It is expected that the

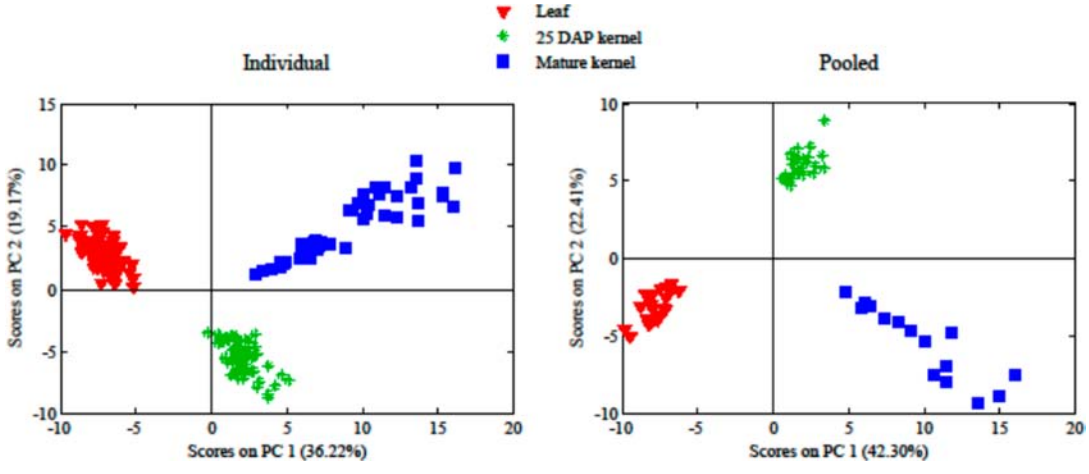

Figure 5. PCA score plots from individual or pooled plants showing tissue specificity of metabolomes.

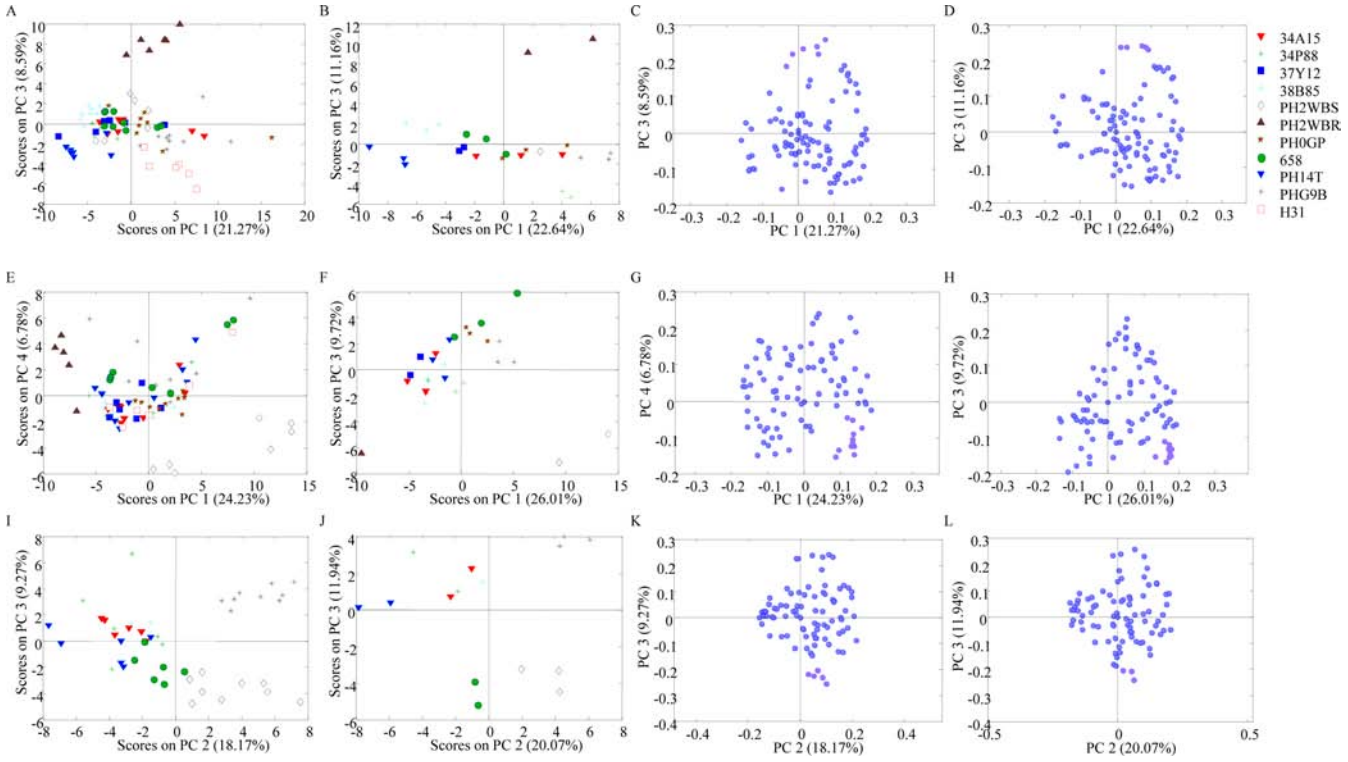

Figure 6. PCA scores and loadings plots from individual plants (A, C; E, G; I, K) or pooled plants (B, D; F, H; J, L) showing classifications of PH2WBR from the leaf metabolome (A–D), PH2WBS from the 25 DAP kernel metabolome (E–H), and PH2WBS from the mature kernel metabolome (I–L). Significant loadings are shown in purple.

Table 3. Apparent Tissue-Specific Metabolites

tissue	analyte	class
V5 leaf	tyramine	polyamine
	tryptophan	amino acid
	chlorogenic acid	phenolic acid
	citramalic acid	organic acid
	dehydroascorbic acid, secondary peak 1	vitamin
	dehydroascorbic acid, secondary peak 2	vitamin
	dehydroascorbic acid, secondary peak 3	vitamin
	heptadecanoic acid	fatty acid
	itaconic acid	organic acid
	maleic acid	organic acid
	pyruvic acid	organic acid
	salicylic acid	phenolic acid
	cis-caffeic acid	phenolic acid
	trans-caffeic acid	phenolic acid
	α-tocopherol	vitamin
	rhamnose	sugar
	trehalose	sugar
	glyceric acid-3-phosphate	phosphorylated acid
	phytol	alkane alcohol
	margaric acid	fatty acid
25 DAP	myristic acid	fatty acid
	cysteine, partial derivative	amino acid
mature kernel	adenosine-5-monophosphate	nucleic acid
	pipecolic acid	organic acid

metabolome of leaves is more divergent than that of immature or mature kernels. Some of these metabolites are present but not detected in other tissues, given our conservative limit of peak detection. Moreover, immature and mature kernels contain more polysaccharides by weight than leaves. Because approximately 3 mg dry weight samples were used for all three tissue types, it is expected that the concentration of many small molecule metabolites will be greater in leaf than in kernel samples. This could result in apparent tissue specificity, as seen in Table 3.

Range and Variations of Metabolite Abundances. We observed large ranges in relative levels for many metabolites across all varieties. The ratio between the maximum value and the minimum value detected for a metabolite in individual samples ranged from 1.8 to 1663 for V5 leaf tissues, from 3.3 to 16815 for immature kernels, and from 2.7 to 585 for mature kernels (Supporting Information Supplementary Table 7). However, when samples were pooled, the ranges narrowed to 1.4–167 for V5 leaves, 2.1–4828 for immature kernels, and 1.6–86 for mature kernels (Supporting Information Supplementary Table 7). Similarly, when the mean values within each variety for each metabolite from either individual samples or pooled samples were compared across all varieties with box plots, the pooled samples showed much narrower distribution compared to the individual samples (data not shown). This observation indicated that the biological variation among individual plants combined with variety variation was very large. However, our pooling strategy effectively decreased the biological variation between plants. The actual relative levels are specific to the current data set and should not be compared to other data sets, unless they were processed (aligned and scaled) together.

[a]CV values were calculated from metabolite levels from all individual (I) and pooled (P) samples for all varieties. Only metabolites that were detected from all I and P samples of all varieties were included for the calculation. Only metabolites with CV values of <0.30 (relatively stable) and >1.00 (highly variable) are shown. Metabolites in *italic* were found in all three tissues, and metabolites in **bold** were found in two tissues for the same category.

Multiple derivative forms for certain metabolites are characteristic of GC-MS-based metabolomics, as illustrated by asparagine in Supplementary Table 7 in the Supporting Information. Asparagine with four TMS groups (one attached to the carboxyl and three to the amines) was found in mature kernels, whereas asparagine with just three TMS moieties (one attached to the carboxyl and two to the amines) was specific to V5 leaves. This dichotomy might be explained by differential trimethylsilylation due to the different sample matrices.[28] Consequently, comparing metabolomes across tissue types or species should be undertaken with caution.

We also compared the levels of metabolites in all samples across all varieties for a given tissue type and identified metabolites that are quite stable as well as those that are highly variable among varieties. There were 21 metabolites from V5 leaves, 20 metabolites from 25 DAP immature kernels, and 11 metabolites from the mature kernels that showed a CV value of <0.4 across all varieties (Table 4), representing tissue-specific stable metabolomes. Among them, sucrose and *myo*-inositol were identified from all three tissues, and another 10 metabolites appeared in two tissue types. On the other hand, there were 17 metabolites from the V5 leaves, 13 from the 25 DAP immature kernels, and 16 from the mature kernels that showed CV values >1, indicating that these metabolites are highly variable among different maize varieties (Table 4). A partial derivative form of glutamine seemed to be highly variable in all three tissue types, and another three metabolites were highly variable for two tissue types. The high variability of the partial derivative of glutamine may be due, at least in part, to inconsistent transformation to pyroglutamic acid, which was

also highly variable in two of the tissues. The inconsistent transformation of pyroglutamic acid is a process known to be associated with trimethylsilylation.

As with gene expression levels detected from microarrays, mean metabolite abundances from individual samples or pooled samples were calculated for each variety and used to calculate CV values among varieties. For all three tissue types, metabolite variations among different varieties detected from individual or pooled samples are well-correlated. Linear regression R^2 values are 0.90, 0.92, and 0.82 for V5 leaves, 25 DAP developing kernels, and mature kernels, respectively. Furthermore, the CV distribution patterns are very similar between individual and pooled samples (Supporting Information Supplementary Figure 4). For V5 leaves, 43.7% of metabolites showed higher CV values in pooled samples compared to individual samples. In 25 DAP developing kernels and mature kernels, the numbers are 61.5 and 47.6%. This observation indicated that using pooled samples revealed variety-to-variety metabolomic variation similar to that using individual samples.

DISCUSSION

Thorough evaluation of the applicability and limitations of the -omics technologies for food safety assessment is necessary before their acceptance for this purpose. Toward this end, we evaluated high-throughput gene expression and metabolomic technologies by characterizing the transcriptomes and metabolomes of several conventional maize varieties using alternative protocols. Our observations led us to conclude that in applying these methods to regulatory issues, consideration should be given to natural variation in maize transcriptome and to the high degree of variation in metabolite concentrations between plant varieties and individuals of the same variety.

Technical Variation. To validate methods for both microarray and metabolomics, selected samples were analyzed multiple times to serve as technical repeats. The CV distribution for the technical microarrays showed small variations between different microarray runs for the same sample (Figure 1), validating the method and technical consistency. When compared to CVs detected from individual plant samples, the technical CVs are much smaller (Figure 1A; Supporting Information Supplementary Table 2), indicating that our microarray technology is consistent and sensitive enough to detect biological variations outside technical variations. The data correlation analysis among repeat arrays comparing individual samples and technical repeat samples confirmed this conclusion (Figure 2). Technical plus biological CVs detected from metabolomics, however, were much larger compared to microarrays (Supporting Information Supplemetary Figure 3). This increase is not unexpected because expression of many metabolites is dynamically affected by microenvironment. Furthermore, different metabolites have very different physical and biochemical properties as well as ranges of expression and, therefore, can be affected by the extraction and derivatization methods employed. Nevertheless, biological variability was found to be greater than analytical variability. The mean CVs observed are similar to those reported in the plant metabolomic literature.

Sample Pooling. Profiling techniques are a powerful tool for gene discovery research as long as appropriate statistical tools are used to analyze the data. Pooling of mRNA samples from different individuals of the same variety for microarray hybridizations has the following advantages: (1) controls cost, (2) generates data when the amounts of individual samples are insufficient, and (3) decreases variation between individuals. A design of multiple pools with multiple individual samples in each pool was established as a compromise.[44−47] Thus, the ability to detect the difference between biological subject-to-subject variations and the experimental technical variations is combined with the efficiency of the pooling strategy designed to reduce overall variance. The larger the individual-to-individual variability is, as compared to technical variability, the greater the reduction of variability is achieved by pooling samples.[44,45]

We designed the microarray and metabolomics experiments to include both individual samples and sample pools. Gene expression levels detected from microarray and metabolite abundances both showed very good correlation between individual and pooled samples within the same tissue type and variety (Tables 1 and 2). Using pooled samples lowered sample-to-sample variation, resulting in lower CV values (Figure 4; Supporting Information Supplementary Figure 1 and Tables 2, 3, 5, and 6). Interestingly, pooling microarray samples reduced the CV values more dramatically for 25 DAP samples compared to V5 leaf samples (Supporting Information Supplementary Figure 1C,D), presumably due to the higher transcriptome variation among 25 DAP individual samples compared to V5 leaf individual samples.

The mean CV values for each variety calculated from either individual plants or pooled samples represent variety-to-variety variations. The CV values representing variety-to-variety variations were similar when obtained from either individual plants or pooled samples for both microarrays and metabolomics (Supporting Information Supplementary Figures 2 and 4). Furthermore, the distribution patterns of variety CV values were similar for both microarrays and metabolomics. A slight increase of variation in pooled samples compared with individual samples from microarrays was detected (Supporting Information Supplementary Figure 2 and Table 3), presumably due to fewer pooled samples.

Pooling plants prior to analysis also did not adversely affect the ability to classify tissues or varieties or identify discriminating metabolites by PCA (Figures 5 and 6). In fact, pooling appeared to enhance discriminating power, presumably by eliminating some noise from the data sets. Overall, our pooling strategy of three sample pools of three is a cost-saving design that does not sacrifice analytical power.

qRT-PCR and Microarray. The use of microarray profiling for comparative assessment of biotech crops requires a gene expression sequence database for probe design, gene annotation, and expression level interpretation. For many plant species, genomes or transcriptomes have not been completely sequenced except for a few model genotypes. The maize genome has an especially high level of DNA sequence polymorphisms, approximately an order of magnitude higher than that in humans.[48−50] A high level of genotypic variation in maize introduces challenges for gene expression profiling such as microarray or PCR-based technologies, because experimental designs are based on knowledge obtained from just one or two varieties. As most of the genomic sequence and transcriptome for the varieties used in this study are not available, microarray hybridization efficiency is expected to vary between varieties. In the microarray study and in qRT-PCR, the primers and probes were designed using gene sequences of the B73 reference genome. Consequently, we observed substantial variation in single-well qRT-PCR efficiencies for the amplification of the same gene from different maize variety samples (data not

shown). This resulted in some inconsistency in expression values detected by qRT-PCR and microarrays across different varieties (Figure 3). For some genes, expression values assayed by qRT-PCR were very different from the corresponding microarray expression levels (Figure 3). This observation raises concerns about the validity of probe homology-dependent methodologies in highly diverse species. In some cases, very large variation in measured expression levels between varieties may be due to the presence or absence of variation.[51] For future studies, caution should be exercised when using microarray technology under similar circumstances. When transgenic and nontransgenic varieties are compared, pairs of lines should be used that are isogenic except for the presence of transgenes.

Metabolomics. The physiological concentration range of metabolites is very broad (Supporting Information Supplementary Table 7).[52,53] The lower technical variation for microarrays compared to metabolomics (Figure 1; Supporting Information Supplementary Figure 3) can be partially explained by quantile normalization of microarray data, which helps reduce CV. The CV ranges observed in our study are nevertheless comparable to those seen by others using different systems.[54−57]

The levels of many metabolites measured by metabolomics are extremely sensitive to not only the experimental procedures and instrument type used but also the environment from which the samples are collected. Nevertheless, large changes in the amounts of many metabolites within a plant rarely make significant overall contributions to the nutritional composition or raise safety concerns.[12,53,58−60] Genetic background strongly affects metabolite levels,[60,61] usually more than transgene insertions.[16,20,63] Per-sample cost for metabolomics is much lower compared to microarrays, allowing more sample replicates, increasing statistical power and lowering technical variation while retaining true variation in physiological metabolite levels.

GC-MS-based high-throughput metabolomics requires a uniform extraction and sample processing protocol for hundreds of metabolites differing in chemical properties and in vivo concentrations, which leads to suboptimal analytical conditions for many metabolites. Most metabolomic techniques lack sufficient analytical breadth to accurately measure hundreds of metabolites with very diverse chemical properties.[64−66] Analytical compromises must be made to achieve high-throughput and high metabolome coverage, rendering metabolomic data fundamentally different from targeted analysis of specific analytes. Even augmented with LC-MS and CE-MS, metabolomics does not cover all of the compounds presumed to be present in maize leaves or kernels. Also, metabolomics results include a large amount of unidentified metabolites that currently cannot be mapped to a biochemical pathway. Thus, a traditional metabolic pathway-centric evaluation of metabolomic data for safety assessment is not conceptually appropriate. The lack of knowledge of metabolic pathways and the limited availability of reference standards and databases also have restricted the use of metabolomic technology for tasks best served by traditional targeted analytical methods. Therefore, it might be preferable to combine nontargeted methods with multivariate tools such as PCA and hierarchical clustering to visualize sample relationships, rather than to focus on individual metabolite tolerance levels.[62]

Although our metabolomic study identified metabolites present at significantly different levels in different maize varieties, the biological significance of these differences should be interpreted with caution.[16,67] We reported relative metabolite abundances rather than absolute abundances; therefore, only metabolomic data generated using the same experimental procedures, detection methodologies, and internal controls should be compared to this data set directly. This consideration is additional to significant biological variability. As recommended by *Codex Alimentarius*,[68] "The statistical significance of any observed differences should be assessed in the context of the range of natural variations for that parameter to determine its biological significance." Our study strongly supports this recommendation.

varies significantly among the *Citrus* species and/or varieties. For example, sweet orange contains 83−97%, lemon, 54−80%, and bergamot, 25−32% limonene. [32] The nonvolatile residue, which forms about 1−15% of the oil, contains hydrocarbons, sterols, fatty acids, waxes, carotenoids, coumarins, psoralens, and flavonoids,[31] among which flavonoids are a group of components useful in differentiating between species.[17] By the end of 1970, approximately 200 different compounds had been described from orange oil, among which around 100 have been identified. In the review by Shaw,[32] the quantitative values for individual components of cold-pressed oils of different citrus species and varieties were presented, which gave us a general idea of the oil compositions of different citrus types. On the basis of previous studies,[28−30,33−36] the 75 most-reported monoterpenes and sesquiterpenes in CEOs extracted from different organs (flowers, leaves, and peels), species, and/or varieties are summarized in Table 1.

The chemical compositions of CEOs are influenced by both internal and external factors.[37,38] The genetic factors, including species, cultivars, and different parts of the fruits, are the major determinant of the composition and contents of essential oils. A comparison study of essential oils from the peels of four selected Tunisian citrus species showed that δ-cadinene, a sesquiterpene in CEOs, was found only in pummelo and α-calacorene, another sesquiterpene, was observed only in mandarin.[30] Furthermore, cultivars also influence the citrus oil profiles.[28,39] Lota et al.[28] reported that the composition and content of CEOs were different among 58 mandarin cultivars belonging to 15 different species, and the contents of the major components of these essential oils varied considerably from sample to sample. In addition, the chemical compositions of CEOs also vary significantly depending on the organs extracted. For example, terpineol-4 was one of the major compounds in the leaf oils of lemon, whereas it was not detected in peel oils.[29] Environmental factors such as soil, cultural practices, insects, ripening stage, and weather can contribute to the quantitative variations of essential oils.[38] Azizi et al.[40] compared the response of oregano (*Origanum vulgare* L.) populations to soil moisture regimens (optimal, consistent water deficiency, and water deficiency from the beginning of flowering) and nitrogen application, and they found that water deficiency after the beginning of blooming could induce an increase in essential oil content, whereas higher nitrogen levels caused a decrease. Besides soil and cultural practice factors, weather differences such as seasonal variations can also induce a difference in the composition and content of essential oils. For example, Vekiari et al.[34] measured the components of essential oil from Zambetakis (*Citrus limon* Burm.f.) at six different time intervals over a period of greater than a year. They found significant differences between the aroma profiles and quantitative variations between lemon leaves and peels and attributed those variations to the different harvest periods of citrus leaves and fruits. Their study suggested that the ripening effect influenced significantly the chemical compositions of the essential oil. Genetic and environmental factors not only influence the oil compositions and contents but also affect the bioactivity of the oils. For example, Fisher and Phillips[41] investigated the antibacterial activity of oils from lemon, sweet orange, and bergamot. They found that bergamot was the most effective among the tested oils due to its high linalool content.

CEOs and their chemical compositions possess a wide spectrum of biological activities, including antimicrobial,[34,42−49] antioxidant,[50,51] anticancer,[52−55] anti-inflammatory,[56−60] insecticidal,[61−67] embryo-fetotoxicity, [68] and metabolism disorder regulating activity.[69−76] All of the bioactivities mentioned above are summarized in Table 1. The biological activity of monocyclic monoterpene D-limonene has been evaluated by a number of studies, such as antioxidant,[77−79] anti-inflammatory, [38] anticancer,[80,81] and metabolic disorder alleviating activities.[75,82] In addition, geraniol, a terpene alcohol in CEOs, represents a new class of chemoprevention agents for cancer and other biological activities such as antimicrobial, antioxidant, anti-inflammatory, and some vascular effects.[50] Taken together, CEOs and their chemical compositions may be of great importance in many fields, from food chemistry to pharmacology and pharmaceutics.

METHODS USED IN THE ASSESSMENT OF ANTIFUNGAL ACTIVITY OF CEOS

The major methods used for the assessment of antimicrobial activity of essential oils have been summarized in several recent reviews, which include the agar diffusion test, the agar or broth dilution test, and the vapor phase test.[17,83] The particular advantages and disadvantages of these different methods are

Table 2. In Vitro Antifungal Activity of CEOs Reported in Current Literature

Aspergillus niger	lemon (*C. limon* Burm.f.)	citral, eugenol	agar diffusion method	inhibition halo =10 mm	Souza et al. (2005)
	lemon (*C. limon* Burm.f.)		agar diffusion test	inhibition zone =7 mm	Pawar and Thaker (2006)
	sour orange (*C. aurantium* L.)		agar diffusion test	inhibition zone =6 mm	Pawar and Thaker (2006)
	orange (*C. sinensis* Osb.)	limonene (84.2%)	poisoned food assay; volatile activity assay	MIC = 600 ppm (PF[a]) MIC = 500 ppm (VA[b])	Sharma and Tripathi (2008)
	lemon (*C. limon* Burm.f.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	mandarin (*C. reticulata* Blanco)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	orange (*C. sinensis* Osb.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	grapefruit (*C. paradisi* Macf.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	Citri-V[c]	limonene (603.99 mg/mL)	vapor phase test	67% reduction at 15 mg/L air	Phillips et al. (2012)
Aspergillus flavus	lemon (*C. limon* Burm.f.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	lemon (*C. limon* Burm.f.)	citral, eugenol	agar diffusion method	inhibition halo =13 mm	Souza et al. (2005)
	mandarin (*C. reticulata* Blanco)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	orange (*C. sinensis* Osb.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	orange (*C. sinensis* Osb.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	orange (*C. sinensis* Osb.)	limonene	agar dilution method	MIC = 0.5% (v/v)	Bosquez-Molina et al. (2010)
	grapefruit (*C. paradisi* Macf.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	pummelo (*C. maxima* Burm.)	limonene	agar dilution method	MIC = 0.5% (v/v)	Bosquez-Molina et al. (2010)
	pummelo (*C. maxima* Burm.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	lime (*C. hystrix* DC)	limonene, citronellol, linalool	agar diffusion method; broth microdilution	MIC = 1%, 4% (v/v)	Rammance and Hongpattarakere (2011)
	acid lime (*C. aurantifolia*)	limonene, *p*-cymene	agar diffusion method; broth microdilution	MIC = 1%, 4% (v/v)	Rammance and Hongpattarakere (2011)
	orange (*C. sinensis* Osb.) vapor	limonene (96.62%)	vapor phase test	MIC = 8000 EO/air	Velázquez-Nuñez et al. (2013)
	orange (*C. sinensis* Osb.)	limonene (96.62%)	agar dilution method	MIC = 16000 mg/L	
Aspergillus fumigatu	orange (*C. sinensis* Osb.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	pummelo (*C. maxima* Burm.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
Aspergillus terreus	orange (*C. sinensis* Osb.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	pummelo (*C. maxima* Burm.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
Aspergillus parasiticus	lime (*C. hystrix* DC)	limonene, citronellol, linalool	agar diffusion method; broth microdilution	MIC = 1%, 4% (v/v)	Rammance and Hongpattarakere (2011)
	acid lime (*C. aurantifolia*)	limonene, *p*-cymene	agar diffusion method; broth microdilution	MIC = 1%, 4% (v/v)	Rammance and Hongpattarakere (2011)
Penicillium chrysogenum	lemon (*C. limon* Burm.f.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	mandarin (*C. reticulata* Blanco)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	orange (*C. sinensis* Osb.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	orange (*C. sinensis* Osb.)	limonene (77.49%); myrcene (6.27%)	agar diffusion method; broth microdilution	inhibition zone = 18.99 mm; MIC = 9.33 μL/mL	Tao et al. (2009)
	grapefruit (*C. paradisi* Macf.)		modified agar dilution	MIC = 0.94% (v/v)	Viuda-Martos et al. (2008)
	Citri-V	limonene (603.99 mg/mL)	vapor phase test	43.8% reduction at 14 mg/L air	Phillips et al. (2012)

Cladosporium cladosporioides	orange (*C. sinensis* Osb.)	limonene (84.2%), linalool (4.4%)	poisoned food assay; volatile activity assay	MIC = 500 ppm (PF); MIC = 400 ppm (VA)	Sharma and Tripathi (2006)
Myrothecium roridum	orange (*C. sinensis* Osb.)	limonene (84.2%), linalool (4.4%)	poisoned food assay; volatile activity assay	MIC = 700 ppm (VA)	Sharma and Tripathi (2006)
Mucor hiemalis	orange (*C. sinensis* Osb.)	limonene (90.42%), myrcene (2.81%)	agar dilution method	36.5% inhibition at 2000 ppm	Van Hung et al. (2013)
	mandarin (*C. reticulata* Blanco)	limonene (91.58%), myrcene (2.79%)	agar dilution method	37.1% inhibition at 2000 ppm	Van Hung et al. (2013)
	lime (*C. aurantifolia*)	limonene (41.4%), β-pinene (18.54%)	agar dilution method	100% inhibition at 2000 ppm	Van Hung et al. (2013)
	pummelo (*C. grandis* Osb.)	limonene (70.46%), γ-terpinene (11.09%)	agar dilution method	42.1% inhibition at 2000 ppm	Van Hung et al. (2013)
Helminthosporium oryzae	orange (*C. sinensis* Osb.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	pummelo (*C. maxima* Burm.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
Trichoderma viride	orange (*C. sinensis* Osb.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
	pummelo (*C. maxima* Burm.)	limonene (31.83%), citral (31.0%)	poisoned food assay	100% inhibition at 750 ppm	Singh et al. (2010)
Saccharomyces cerevisiae	orange (*C. sinensis* Osb.)	limonene (77.49%), myrcene (6.27%)	agar diffusion method; broth microdilution	inhibition zone = 14.57 mm; MIC = 18.75 μL/mL	Tao et al. (2009)

[a]Citri-V, a 50:50 mix of orange/bergamot essential oils (AMPHORA, Bristol, UK). [b]PF, poisoned food technique. [c]VA, volatile activity assay.

dx.doi.org/10.1021/jf5006148 | J. Agric. Food Chem. 2014, 62, 3011−3033

extensively discussed in the book by Pauli et al.[84] and the reviews mentioned above. In this review, we summarize several of the most commonly used in vitro testing methods for the antifungal assessment of CEOs, especially the agar diffusion, the broth/agar dilution test, the broth microdilution method, and the poisoned food technique.

Agar Diffusion Test. This method was described and utilized as a standardized method for the screening of essential oils in the past decades and has been adapted in numerous ways based on the same principle.[85] The agar diffusion test is performed by placing an essential oil impregnated filter disk on the surface of agar containing the microbe to be tested, and the antifungal activity of tested essential oils is evaluated by measuring the inhibition zones. The agar diffusion method seems to be the most popular method for examining antimicrobial activity as it allows for the simultaneous testing of a large number of antimicrobials in a relatively easy and flexible manner.[86] As shown in Table 2, the agar diffusion test has been widely used in the assessment of antifungal activity of CEOs. However, it is noteworthy to point out that the size of inhibition zones is difficult to be interpreted due to the unknown diffusion coefficients, the different volatilities of single constituents, and other factors such as agar type, agar−agar content, pH, and volume of agar.[83] In particular, the results obtained from this method have shown misleadingly low antifungal activity when the components have low water solubility. [83]

Broth/Agar Dilution Test. The dilution test is another in vitro method widely used for assessing the antifungal activity of CEOs (Table 2). In the broth dilution test, a concentration series of the antifungal substance is established using a broth medium, which is seeded with fungal strains, whereas in the agar dilution test, a concentration gradient of the tested substance is placed onto an agar plate.[83] For both methods, a minimum inhibition concentration (MIC) is used to evaluate the antifungal activity of the tested substance(s), which presents the lowest concentration of tested substance(s) that prevents the growth of seeded fungal strains. The advantages and disadvantages of these two dilution test methods have been summarized in detail by Jiang.[86] Generally, in the agar dilution method, the agar with supplements is able to adequately support fungus growth, whereas in the broth dilution method, lack of or poor growth of many anaerobic microorganisms was observed because of insufficient supplements. The agar dilution test has been declared to be the "gold standard" as it overcomes some limitations of the agar diffusion method, primarily the capability to draw a quantitative conclusion by determining the MIC value of the tested substance(s).[86−88] This method can also be used to test the susceptibility of a number of substance(s) in one plate simultaneously, as well as to test fastidious organisms due to the agar being able to adequately support microorganism growth.[86] However, it is not used frequently due to its high-cost, labor-intensive, and time-consuming properties. [83]

Broth Microdilution Method. Broth microdilution is another quantitative reference method for the fungitoxicity test of CEOs, which allows for the simultaneous testing of multiple antimicrobials with ease, particularly when commercially prepared microtiter trays are used.[16,86,89] In the study by Jiang,[86] the agar diffusion, the broth/agar dilution test, and the broth microdilution method have been compared on several bacterial strains. Jiang suggested that the broth microdilution be used for MIC determination, compared to other methods, due to its time and labor savings, as well as its capability of quantitative determination. However, inconsistent and unreliable results can occur when some fastidious anaerobes are tested because of their poor growth due to excessive exposure to oxygen during the setup procedure.

Poisoned Food Technique. The poisoned food technique has been used widely in the antifungal assessment of CEOs (Table 2). In this method, the fungitoxicity was expressed in terms of percentage of mycelia growth inhibition and calculated as follows: percentage of mycelial growth inhibition = $(dc - dt)/dc \times 100$, where dc = average diameter of fungal colony in control and dt = average diameter of fungal colony in treatment.[90,91]

As shown in Table 2, there are other methods that have been used for the antifungal activity test of CEOs, such as mycelium dry weight determination test[20,91,92] and volatile activity assay.[20,93] As for the vapor phase test of CEOs, the related methodology has been discussed and summarized in the reviews by Cavanagh[94] and Laid and Phillips;[95] however, there is no standardized method available. In general, a seeded agar plate is placed upside down onto a reservoir, which comprises a certain amount of volatile oil. In this case the generated inhibition zone is considered to be a criterion for the antimicrobial activity.[83]

In general, each method has its own advantages and disadvantages. Antifungal tests of essential oils are difficult to perform because of their high volatility, which can result in distorted results. Another problem is the hydrophobicity of the essential oils, which sometimes demands the use of surfactants that might lead to noteworthy differences between outcomes.

■ IN VITRO ANTIFUNGAL EFFECTS OF CEOS

The antimicrobial property of CEOs was recognized a long time ago.[17] In the past decades, the antifungal activity of CEOs has attracted the attention of many researchers.[19,21,22,96−98] Table 2 summarizes the in vitro antifungal effects of CEOs reported in the current literature. In vitro experiments are valuable precursors to more costly food trials and enable the identification of effective essential oils and determination of the concentrations required for inhibition of a specific pathogen or a spectrum of pathogens.[99] The following part of this review will focus on the antifungal activity of CEOs against some food spoilage or phytopathogenic fungal species, especially *Aspergillus* and *Penicillium* species.

Aspergillus is a genus consisting of several hundred species, which are highly aerobic and found in almost all oxygen-rich environments. *Aspergillus* species are common contaminants of starchy foods such as bread and potatoes. The current literature has shown that CEOs have a broad anti-*Aspergillus* spectrum including *A. niger*, *A. flavus*, *A. fumigatus*, *A. terreus*, and *A. parasiticus* (Table 2). Among these species, *A. niger* and *A. flavus* are the most commonly used strains in the antifungal test of CEOs (Table 2).[2,10,16,19,21,22,89,93,100]

The first anti-*Aspergillus* research of CEOs can be traced back to 1985, when Karapinar[101] found that CEOs could inhibit the growth and aflatoxin formation of *A. parasiticus*. In 2006, Pawar and Thaker[100] compared the effects of 75 plant essential oils on the hyphal growth and spore formation of *A. niger*, among which the essential oils of sour orange (*Citrus aurantium* L.), bergamot (*Citrus bergamia* Risso and Poit), lemon (*Citrus limon* Burm.f.), and *Citrus bigaradia* Hook.f. exhibited inhibitory effects. In agreement with this, Viuda-Martos et al.[21] reported that lemon, mandarin, grapefruit, and sweet orange essential

oils could reduce or inhibit the growth of *A. niger* and *A. flavus* in a dose-dependent manner, with sweet orange essential oil being the most effective against *A. niger* and mandarin being the best inhibitor of *A. flavus*. Sharma and Tripathi[91] found that the sweet orange essential oil treatment resulted in the flattening and ultimate death of *A. niger* hyphae, and limonene was the major component (84.2%) of the oil. The study conducted by Singh et al.[19] found that pummelo (*Citrus maxima* Burm.) and sweet orange (*Citrus sinensis* Osb.) essential oils and their combination were all effective against *A. flavus*, with the essential oil of pummelo being the most effective. In the study by Rammanee and Hongpattarakere,[16] the essential oils prepared from citrus epicarps exhibited stronger antifungal activity to all *Aspergillus* strains than their ethyl acetate extracts. In particular, the essential oils from kaffir lime (*Citrus hystrix* DC) and acid lime (*Citrus aurantifolia* Swingle) were most inhibitory to mold growth as well as aflatoxin production among all of the tested citrus cultivars. On the basis of the studies mentioned above, it can be concluded that the CEOs are effective against *Aspergillus* species.

The genus *Penicillium* is another prevalent airborne fungus, which belongs to the same family as *Aspergillus*. There are over 300 different species described in the genus. *P. digitatum*, *P. italicum*, and *P. chrysogenum* are among the most reported *Penicillium* species that have been used for the fungitoxicity test of CEOs. In 1995, Caccioni and his colleagues[102] found that CEOs could exert an important bioregulatory action on the fungal spores of *P. digitatum* (Pers.) Sacc. and *P. italicum* Wehm, which are the two most dangerous postharvest pathogens of citrus fruit. Viuda-Martos et al.[21] found that lemon, mandarin, grapefruit, and sweet orange essential oils had the capacity to reduce or inhibit the growth of *P. chrysogenum* in a dose−response manner, and grapefruit was the best inhibitor among those four CEOs, followed by lemon essential oil. Tao et al.[89] reported that Bingtang sweet orange essential oil exhibited high antifungal activity against *P. chrysogenum* ATCC 10106, with an inhibition zone of 18.99 mm. In a study by Sharma and Tripathi,[93] sweet orange essential oil completely inhibited the radial growth and spore germination of *P. chrysogenum* and *P. expansum*, as well as other postharvest pathogens. Van Hung et al.[103] compared the antifungal activity of the essential oils from four citrus species and found that pummelo essential oil was the most effective against *P. expansum*. In addition, CEOs have been reported to have antifungal activity against *Penicillium* spp.[2] and *P. verrucosum* (Table 2).[21]

Besides these most studied *Aspergillus* and *Penicillium* species, CEOs have also been reported to have antifungal activity against *Fusarium*,[2,19,20,103] *Alternaria*[19,20,93] (Table 2), and other fungal strains.[97,98]

Furthermore, the vapor phase of CEOs has also been assessed for their antifungal activity, and they exhibited antifungal activity against several fungal strains, such as *A. flavus*[10] and *Alternaria alternata*.[22] The study performed by Velázquez-Nuñez et al.[10] showed that the vapor state was more effective than the liquid state of orange peel essential oil in antifungal activity, and lower concentrations were required to achieve the same antifungal effect. The advantages of vapor phase of essential oils over the direct application of the oils themselves have been summarized in the review by Cavanagh,[94] such as reduced toxicity and ease of application. The author also suggested that the vapor phase of essential oils had great potential for use in fungal control and/or treatment.

On the basis of the reports mentioned above, we may conclude that CEOs are effective in inhibiting the growth of mycelia and spores and in reducing the production of mycotoxins against different fungal species. The essential oils from the same citrus species have about the same antifungal activity, but it also varies from cultivar to cultivar. On the basis of GC-MS analysis data, different chemical compositions have been identified in different CEOs, among which limonene was found to be the major component (Table 2). Table 2 shows the concentrations of limonene varied from 31.83 to 96.62% in the essential oil samples used for the antifungal experiments. From this information, the fungitoxicity of CEOs can be attributed to their chemical composition and the concentration of active compounds. This conclusion is in agreement with the reports that the antifungal activity of CEOs relied on their chemical composition.[1,17] However, the exact active compounds that contribute to the fungitoxicity of CEOs still need to be further clarified in future studies.

Antifungal Activity of CEOs on Food. To explore the potential of CEOs as alternative additives or fungicides on food, their antimicrobial effectiveness, especially antibacterial activity, has been investigated by using several common foodborne pathogens. CEOs have been reported to be effective against a number of bacteria that cause food spoilage or poisoning, but their antibacterial activities on the strains tested were less effective in food systems than in vitro.[41,104] The antifungal assessments of CEOs on food, however, have not been performed until recently. For example, Bosquez-Molina et al.[3] reported that the Mexican lime essential oils had inhibitory effects against *Colletotrichum gloeosporioides* and *Rhizopus stolonifer* growth of storage rots in papaya fruit. Vitoratos et al.[98] found that lemon essential oils were very effective against the fungus *Botrytis cinerea* in tomatoes, strawberries, and cucumbers.

The fungitoxicity assessment on food is necessary and essential for the screening and confirmation of the antifungal activity of CEOs before they are applied in the food industry, as the efficacy of bioactive compounds might decay due to possible interactions of these compounds with the food matrix. For example, Phillips et al.[22] assessed the antifungal effects of CEOs both in vitro and on food, including tomatoes and grain, against three fungal strains (*A. niger*, *P. chrysogenum*. and *Alternaria alternata*). They found that citrus essential oil vapors completely inhibited the mycelial growth and spore germination of those three fungi in in vitro tests; however, similar results were not observed on tomatoes or grain. It is important to point out that higher concentrations of CEOs or their chemical components should be used in food products to obtain the same effect observed in in vitro experiments, as highly hydrophobic and volatile active substances are often bound by food surfaces.[1] Unfortunately, Dusan and his colleagues[105] demonstrated that higher dose of essential oils showed detrimental effects on intestinal cells. Therefore, animal and human toxicity studies of CEOs should be carried out before their commercial use.

Antifungal Components of CEOs and Their Mechanism of Action. CEOs are a complex mixture of volatile compounds. The antifungal activity of CEOs has been attributed to a single major compound or to the synergistic or antagonistic effect of different compounds.[106] Some authors suggested that the flavonoids likely play a contributing role in the antifungal activity of CEOs.[107] However, more and more authors tend to attribute the antifungal function to the presence

Table 3. Antifungal Effects of CEOs on Food Reported in Current Literature

test CEO	effective against	test food	effect	reference
lime (*C. aurantifolia*)	*Rhizopus stolonifer*	papaya fruits	reduction of up to 40% of decay	Bosquez-Molina et al. (2010)

of the volatile compounds of CEOs, mainly terpenoids, especially monoterpenes and sesquiterpenes.[108−113] In the following, the antifungal effective components in CEOs (Tables 3 and 4) and their suggested mechanisms of action are reviewed.

Antifungal Activity of Flavonoids in CEOs. Flavonoids are a group of polyphenolic compounds that include flavanone, flavone and polymethoxy flavone aglycones, flavanone- and flavone-*O*-glycosides, and flavone-*C*-glycosides.[114] Citrus flavonoids have been reported to have many biological activities, such as antioxidant, antimicrobial, and anti-inflammatory properties.[114−119] The antifungal activity of citrus flavonoids has been investigated by many authors in the past decades. To our knowledge, citrus flavanones including naringin, hesperidin, neohesperidin, eriodictyol, prunin, and hesperitin glucoside[116,120,121] and polymethoxylated flavones such as sinensetin, nobiletin, heptamethoxy flavone, quercetogetin, and tangeretin[107,120,122] have been reported to have antifungal activity. The research conducted by Ortuño et al.[120] found that polymethoxylated flavones were more active than the flavanones, with nobiletin being the most effective one.

The polymethoxylated flavones in CEOs have also been examined for their antifungal activity. Del Río et al.[107] reported that sinensetin, nobiletin, heptamethoxyflavone, quercetogetin, and tangeretin could confer resistance against *Phytophthora citrophthora*, *P. digitatum*, and *Geotrichum* species. Almada-Ruiz et al.[123] found that 3,5,6,7,3′,4′-hexamethoxyflavone, 3,5,6,7,8,3′,4′-heptamethoxyflavone, 5,6,7,8,4′-pentamethoxyflavone, and 5,6,7,8,3′,4′-hexamethoxyflavone were effective in inhibiting mycelial growth of *Colletotrichum gloeosporioides* (Penz) Penz & Sacc, a major plant pathogen of fruits that causes significant damage to crops in tropical, subtropical, and temperate regions. These studies suggested that the polymethoxylated flavones in CEOs could be involved in the antifungal activity; however, this postulation was not convincing as polymethoxylated flavones occurred at low levels in CEOs. Another reason that polymethoxylated flavones were not suggested as the major antifungal component is that the citrus essential oil vapors have been reported to have antifungal activity,[95] and polymethoxylated flavones were not detected in the vapor state of CEOs. The antifungal activity of the flavonoids in CEOs still needs to be clarified.

Antifungal Activity of Terpenoids in CEOs. Terpenoids are a group of secondary metabolites in higher plants and are believed to have evolved in defense against herbivores and pathogens. Terpenoids, especially sesquiterpenes and monoterpenes, have been considered to be the most possible antifungal candidates in CEOs.[92,124] Caccioni and Guizzardi[124] found citrus oxygenated monoterpenes exhibited the highest antifungal activity among examined compounds. Caccioni et al.[92] reported that there was a positive correlation between the monoterpene content of the essential oils from various citrus species and the pathogen fungus inhibition. More recently, an increasing body of research has found that the terpenoids in CEOs, including citral, geranial, eugenol, γ-terpinene, *p*-cymene, myrcene, thymol, and carvacrol, had a wide spectrum of fungitoxicity.[2,11,125−130] Among these compounds, citral and limonene have been suggested as the most significant antifungal candidates of CEOs.

Citral is an acyclic α,β-unsaturated monoterpene aldehyde with two isomers, geranial and neral. The antifungal activity of citral has been demonstrated by several authors, either in CEOs or in other plant essential oils.[131,132] In the works carried out by Caccioni and his colleagues,[92,102] citral proved to have the best antifungal activity against *P. digitatum* and *P. italicum*, among the tested components including nonanal, citral, α-pinene, myrcene, α-phellandrene, and D-limonene. Souza et al.[2] determined the antifungal activity of different phytochemicals from lemon essential oils and found that citral, eugenol, and myrcene were fungitoxic. Overall, citral showed the best fungitoxicity. Wuryatmo et al.[133] examined the inhibitory effects of vapor citral, its isomers geranial and neral, and related compounds (such as *R*-citronellal, *S*-citronellol, and citronellic acid) on *P. digitatum*, *P. italicum*, and *Geotrichum candidum*, the major fungi responsible for postharvest spoilage of citrus. They found that the inhibitory effect of citral and its isomers differed among the three fungi, and citral was the most effective one even at lower concentrations. The above studies showed that citral and its isomers likely played important roles in the antifungal activities of CEOs, with citral having the most significant role.

Recently, more and more studies have suggested that limonene played an important role in the antifungal activity of CEOs.[3,16,20,89,92,93,103] Singh et al.[19] studied both CEOs and their major component limonene for their antifungal activity and found that limonene showed a better effect against *A. flavus* compared to the whole oils, even at lower concentrations. Mahdavi et al.[134] compared the antifungal effects of limonene and orange peel extract and found that limonene (*S*)-(−) isomer had better antifungal effect than its (*R*)-(−) isomer, whereas orange peel extract did not show any antifungal activity against the tested fungi. In addition, several studies have showed that limonene also had inhibitory activity against a wide range of fungi, including *A. niger*, *P. digitatum*, *Rhizoctonia solani*, *Fusarium oxysporum*, and *Fusarium verticillioides*, compared to other monoterpenes.[135,136] On the basis of the studies mentioned above, we can conclude that limonene has a higher antifungal activity against a wide range of fungi than other terpenoids and it is most likely one of the major contributors to the fungitoxicity of the CEOs.

The fungitoxicity of CEOs may be determined by their complex chemical compositions and the concentration profiles

[a]MFC, minimum fungicidal concentration. [b]AFST-EUCAST, Antifungal Susceptibility Testing Subcommittee of the European Committee on Antibiotic Susceptibility Testing.

of their constituents. The terpenoids, especially citral and limonene, most likely play an important role in the antifungal activity of the CEOs. However, the total number of compounds in CEOs that have antifungal activity has not been defined yet. Furthermore, the antagonistic, synergistic, or additive antifungal activities of different components in CEOs on fungal species and/or strains have not yet been explored.

Mechanism of Action of Antifungal Compounds in CEOs. The antifungal activities of CEOs against a wide range of fungal species and their potential active compounds have been clearly demonstrated, as can be seen from the studies mentioned above. However, the antifungal mechanism of the compounds in CEOs remains poorly understood.

The difficulties for exploring the mechanism of action of the natural bioactive compounds have been summarized in detail in a previous review.[137] Generally speaking, the antifungal effects of the natural products can be influenced by a wide variety of factors, such as the different quantitative and qualitative ratios of the compounds in essential oils, their target microorganisms, and the minimum inhibitory concentrations. In addition, the methods used to test the antifungal activities, including the procedures adopted for the extraction, diffusion, and dilution of the substances, can also have an effect. In addition, the different components of an essential oil can have antagonistic, synergistic, or additive effects on microbial cells, which can influence their overall antifungal activity. To solve these problems, Caccioni et al.[92] proposed a holistic approach to explore the antifungal mechanism of CEOs, and found that the antifungal performances of CEOs could be the result of a certain quantitative balance of various components.

Many papers have suggested that the cell membrane is the possible target of bioactive volatile compounds because of the fact that essential oils are mixtures of molecules characterized by their poor solubility in water and high hydrophobicity.[1,17,83,95] Several studies have showed that terpenes and phenolic compounds can disrupt the membrane of both fungi and bacteria.[138,139] Terpenes have been suggested to have the ability to disrupt and penetrate the bacterial cell wall, which can lead to the denaturing of proteins and destruction of the cell membrane.[17] The antimicrobial activity of the active compounds in essential oils can be explained by the lipophilic character of the monoterpenes contained in the oils. Monoterpenes act by disrupting the microbial cytoplasmic membrane, resulting in the loss of membrane impermeability. If the disturbance of membrane integrity occurs, then its functions are compromised not only as a barrier but also as a matrix for enzymes and as an energy transducer.[137,139−142] In a more recent study by Tao et al.,[143] the antifungal activity of mandarin essential oils against *P. italicum* and *P. digitatum* was attributed to the monoterpenes in the oils, such as limonene, octanal, and citral. They also suggested that mandarin essential oils generated cytotoxicity by disrupting cell membrane integrity, causing the leakage of cell components.

Generally, the antimicrobial mechanism of action of the bioactive compounds of essential oils can be explained by the degradation of the cell wall, the disruption of cytoplasmic membrane, or membrane proteins (Figure 1).[17,144] This leads to cytoplasmic leakage, cell lysis, and eventually cell death. However, the exact mechanism of the antimicrobial action of the compounds in essential oils remains poorly characterized, and further studies on the antifungal mechanism of the active compounds in CEOs are especially needed.

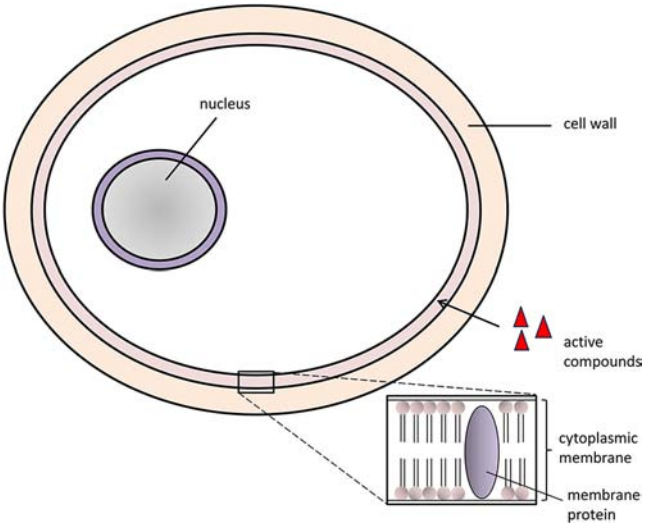

Figure 1. Possible targets or mechanisms of action of antimicrobial compounds of essential oils. The antimicrobial mechanism of the bioactive compounds of essential oils can be explained by the degradation of the cell wall or the disruption of cytoplasmic membrane or membrane proteins, which lead to cytoplasmic leakage, cell lysis, and eventually cell death.

APPLICATIONS OF CEOS IN THE FOOD INDUSTRY

Use of CEOs for Postharvest Disease Control. Alternative measures have been developed for crop protection, including biological agents, mineral salts, and plant extracts, as the use of synthetic fungicides in crops and trees can result in problems such as environmental pollution, phytotoxicity, and selection of resistant pathogen populations.[145] Of various biological approaches, the use of plant essential oils as fungicides for postharvest disease control is becoming popular throughout the world.[146,147] Several plant essential oils, such as thyme and lemongrass oils, have been demonstrated to be effective in stopping disease development caused by plant pathogens.[99,148−150] For example, Plotto et al.[149] explored the potential of several plant essential oils as natural postharvest disease control of tomato (*Lycopersicon esculentum*) and found that emulsions of oils of thyme and oregano at 5000 and 10000 ppm when used as dip treatments reduced disease development in tomatoes inoculated with *Botrytis cinerea* and *Alternaria arborescens*.

Both in vitro and on food assessments of CEOs have been performed to explore their potential as alternative fungicides to prevent or control postharvest disease.[3,22,96,97,103] Kuate and his colleagues[97] studied the effects of 22 varieties of citrus essential oils on in vitro growth and sporulation of *Phaeoramularia angolensis*, causing citrus leaf and fruit spot disease, and found that both pummelo and grapefruit oils were very effective against it. Lazar-Baker et al.[96] found lemon essential oils exhibited the strongest antifungal activity among tested oil samples in controlling brown rot caused by postharvest pathogen *Monilinia fructicola* in nectarines. In addition, in a recent study performed by Vitoratos et al.,[98] lemon essential oils were found to be very effective in controlling disease severity of infected fruits by *Botrytis cinerea* in tomatoes, strawberries, and cucumbers. Taken together, these studies suggested that CEOs have the potential to replace synthetic fungicides in the management of postharvest diseases of fruits and vegetables.

Use of CEOs in Fresh or Fresh-Cut Food Production. Food spoilage fungi can produce mycotoxins and cause food decay, which causes considerable economic losses and constitutes a health risk for consumers. Following the natural food preservation trends, research has been focused on the effect of essential oils on microbial inhibition of fresh and fresh-cut products in recent years. Plant essential oils stand out as an excellent alternative to chemical preservatives to extend the foodstuffs' shelf life, owing to their antimicrobial properties against both food pathogens and food spoilage organisms, as well as their aromas and flavors. In a previous review by Fisher and Phillips,[17] the applications of CEOs in different kinds of food including fish, meat, dairy products, fruits, and vegetables to control fungi spoilage and mycotoxin production were summarized. They concluded that CEOs could fulfill the requirements of both the food industry and the consumer for natural antimicrobials.

With fresh-cut fruit and vegetable salads becoming more and more popular among consumers, the fresh-cut industry has become one of the most successful businesses within the food-processing industry in recent years. However, fruit decay and loss of quality caused by microbial growth, including *Pseudomonas* spp., *E. herbicola*, *E. agglomerans*, lactic acid bacteria, molds, and yeasts, seriously limit the safety and shelf life of fresh-cut fruits and vegetables.[151] In addition, the sensorial appeal of fresh-cut fruits and vegetables, such as flavor and aroma, is another major indicator of shelf life and freshness from the view of consumers. The studies mentioned above showed that essential oils can serve as candidates to solve these problems owing to their antimicrobial activity and aroma nature. Ayala-Zavala and his colleagues[151] summarized the successful and unsuccessful uses of essential oils and their combinations for enhancing safety, aroma, and appearance of fresh-cut fruits and vegetables. For example, oregano and thyme essential oils exhibited excellent antimicrobial and sensorial efficacy in fresh-cut lettuce and carrots.[152] However, and according to their study, most of the present research has focused on the antibacterial effects of plant essential oils in fresh-cut fruits and vegetables, whereas the antifungal efficacy of plant essential oils, especially CEOs, have not been well investigated in the current literature.

Although plant essential oils including CEOs can be used as alternative food preservatives for improving the quality and sensorial appeal of fresh-cut fruits and vegetables, it needs to be pointed out that the antifungal compounds derived from plants may impart a strong flavor to the food they applied to, thus restricting their applicability to only those products with compatible flavor. In view of this problem, researchers have proposed different ideas, such as using the plant extract not only as a preservative but also as a flavor component or applying only some of the most active components rather than the whole extracts.[1] In a word, in this field there is still a lot of work that needs to be done.

Use of CEOs in Edible Coatings of Fruits during Storage. Recently, the use of essential oils in edible coatings has become one of the most important practices in preserving fruit quality during storage.[1,153] More and more research has shown that bioactive edible coatings enriched with essential oils exhibited excellent antimicrobial effects while maintaining fruit qualities.[154−156] The advantages and limitations of this promising technology were discussed in the review by Sánchez-González et al.[153] According to their research, the major advantage of this technology was that the edible coatings

can gradually release those antimicrobial compounds in essential oils over time, maintaining a proper concentration of antimicrobial components on the product surface during the storage period. CEOs have been applied in the edible films of oranges and papaya fruits during storage to extend their shelf life.[3,157] In addition, Sánchez-González et al.[156] applied bergamot essential oil to biodegradable coatings based on hydroxypropylmethylcellulose or chitosan for cold-stored grapes as an environmentally friendly, healthy treatment to better preserve fresh fruit quality and safety during postharvest cold storage. In their study, chitosan coatings containing bergamot oil were found to be more effective than pure hydroxypropylmethylcellulose and chitosan coatings owing to their highest antimicrobial activity and the greatest control of respiration rates.

Besides the whole essential oils mentioned above, some individual compounds in CEOs have also been applied to food to explore their antifungal potential. In a series of subsequent semicommercial and commercial trials carried out by du Plooy et al.,[158] excellent disease control was achieved with the amended essential oil coatings and terpenoid components such as D-limonene and *R*-(−)-carvone, whereas the overall fruit quality was maintained. More recently, Vu and his colleagues[159] observed that coatings with limonene reduced the decay of strawberries at most time points during the experiment, compared to chitosan alone, peppermint coatings, or uncoated strawberries. They also reported that a limonene coating did not cause any phytotoxicity during the experiment, and the appearance of strawberries was not changed compared to other groups.

The application of CEOs or their individual compounds in the edible film of coatings for foods eliminates the need for synthetic food preservatives, thereby complying with consumer preferences and organic requirements and reducing environmental pollution. However, several issues still need to be resolved such as the absorption of aromatic volatile constituents by the food product and altered sensory characteristics. In addition, the reactions of plant essential oils or their active compounds with lipids, proteins, carbohydrates, and other additives may result in an overall decrease in the activity of the antimicrobial compounds.[160] Taken together, the efficacy of amended coatings as viable alternatives or supplements to existing fruit protection strategies needs to be demonstrated in more semicommercial and commercial trials taking into consideration all factors such as costs and legal and safety issues.

In conclusion, CEOs have obvious in vitro and on food antifungal activities against a wide array of fungal species, and their fungitoxicity may be attributed to the chemical compositions, molecular structure, and concentrations of the bioactive compounds. Compared with the traditional food preservative, the application of CEOs can reduce environmental pollution, eliminate the need for synthetic fungicides, and make good use of the byproducts of the citrus-processing industry. In view of their good fungitoxic function, natural aromas and flavors, as well as their environmentally friendly property, CEOs are potentially an excellent alternative to traditional preservatives in developing highly efficient, safe, and economic fungicides for the future food industry. The fungitoxicity research of CEOs will be of great utility for the utilization of citrus byproducts and for postharvest disease control of fruits and vegetables in the agricultural industry. For a better application of the antifungal activity of CEOs, the antagonistic, synergistic, or additive effects of different components of CEOs will be likely the focus of future studies. Moreover, the antifungal mechanism of action of CEOs and their active components need further investigation. Finally, more on food studies in combination with commercial application trials would be necessary before CEOs can be applied fully as natural fungicides in the future food industry.

levels. Hence, it is not known if UV-B radiation affects ergothioneine concentrations in mushrooms.

In addition to ergothioneine, polyphenolic compounds have been shown to contribute to mushroom antioxidant activity. Polyphenolics are naturally occurring chemicals that belong to diverse classes, including isoflavones, lignans, flavones, stilbenes, flavanones, flavonols, and anthocyanidins, among others. Several studies have found polyphenolic compounds in mushrooms. For example, Liu et al. (2012)[18] measured the flavonol quercetin in wild edible mushrooms from China, while Kim et al. (2008)[19] found naringin, resveratrol, quercetin, naringenin, kaempferol, hesperetin, formononetin, and biochanin A in edible and medicinal mushrooms from Korea. Kim et al. (2008)[19] reported that the antioxidant activity, including free radical scavenging activity of edible and medicinal mushrooms, was well correlated with concentrations of polyphenolic compound measured in mushrooms. It has been reported that UV-B irradiation increased amounts of some polyphenolic compounds, specifically flavonoids naringenin, rutin, and quercetin in tomato fruits[20] and some flavonols and flavonoids in apples,[21] but no reports have been found for mushrooms.

This study intended to fill these gaps by investigating the effects of UV-B radiation at different levels on the natural bioactive compounds: ergothioneine, phytosterols, and polyphenolic compounds in mushroom powders made of brown, white (*Agaricus bisporus*), oyster (*Pleurotus ostreatus*), and shiitake (*Lentinula edodes*) mushrooms, used as dietary supplement ingredients.

MATERIALS AND METHODS

Mushroom Powder Preparation. All mushrooms were grown, harvested, and handled in the Monterey Mushroom, Inc., facility under commercial practices. Fresh mushrooms of brown, white (*Agaricus bisporus*), oyster (*Pleurotus ostreatus*), and shiitake (*Lentinula edodes*) varieties were sliced to 0.3 cm thickness with an Urschel slicer (Valparaiso, IN) and placed in twelve clear plastic bags, with each bag containing approximately 2.26 kg of the sliced material. The bags were labeled with mushroom and assigned treatment type. There were three treatment groups: treatment group one was a control group with no UV-B treatment; in group two (low treatment), the mushrooms were exposed to 80−90 mJ/cm^2 UV-B irradiation for 25 s at 49−54 °C expected to produce 100−200 IU/g (2.5−5 μg/g) vitamin D_2; and in group three (high treatment), the mushrooms were exposed to 2800−2900 mJ/cm^2 UV-B irradiation at 60−66 °C for 10 min to produce 6000−8000 IU/g (150−200 μg/g) vitamin D_2.

For high UV-B radiation treatment, 2.26 kg each of four sliced mushroom samples (white, brown, oyster, and shiitake) were distributed onto the UV line conveyor in a monolayer (1.25 cm thickness) across the width of the conveyor, with 60 cm separating different mushroom type samples. The UV line (Monterey Mushrooms, Inc., proprietary) was set up with commercial UV specifications. The final energy output was measured in mJ/cm^2 with an EIT radiometer UV Power Puck II (Watsonville, CA 95076). After 10 min UV exposure, UV-treated mushrooms were directly placed on trays for dehydration. Low UV-B radiation treatment followed the same technique, with the UV line specifications modified to produce low UV-B levels by removing bulbs and adjusting the conveyor speed to obtain low energy readings. Total exposure time was 25 s, and the treated mushrooms were placed on trays for dehydration. For control samples with no UV treatment, sliced mushroom were directly placed on trays for dehydration.

Trays were loaded into a Harvest Saver (tray dryer) dehydrator (Commercial Dehydrator Systems, Inc.) for 16 h at 93.3 °C, and an empty tray was placed in between each tray with samples to prevent cross contamination. After the dehydration cycle, each sample was placed in a laminated prelabeled bag and sealed. A coffee grinder was used for grinding samples. After each sample, the coffee grinder was washed and dried before the next sample. Mushroom powder samples were placed in laminated bags, sealed and labeled accordingly.

The samples were shipped on dry ice overnight to the USDA laboratories. The samples were stored at −20 °C away from light exposure until the analysis. Moisture content was determined gravimetrically for each mushroom powder sample after drying the mushroom powder in an oven at 110 °C overnight. Each sample of mushroom powder was analyzed in triplicate to test for analytical variability.

Reagents and Materials. Standards of ergosterol (purity >95%), cycloartenol (purity >90%), cholesterol, methimazole, and ergothioneine (purity >99% for all) were purchased from Sigma Aldrich (St. Louis, MO, USA); standards of β-sitosterol, campesterol, stigmasterol, brassicasterol, sitostanol (stigmastanol), lupeol, and campesterol-d_3 (purity >98% for all) were from Santa Cruz Biotechnology, Inc. (Dallas, TX, USA). Stock solutions were individually prepared from neat materials at concentrations of 1 mg/mL in methanol, acetone, isopropanol, or their mixtures, depending on the compound solubility, and stored at −18 °C. A standard mixture of phytosterols at 10 μg/mL in methanol/acetone was prepared and used as a spiking solution for recovery experiments.

Standards of genistein, daidzein, glycetein, daidzin, and genistin were obtained from LC Laboratories (Woburn, MA). Standards of biochanin A, *trans*-resveratrol, quercetin dehydrate, kaempferol, coumestrol, naringin, formononetin, delphinidin, naringenin, eriodictyol, enterodiol, rutin hydrate, and cyanidin were purchased from Sigma Aldrich (St. Louis, MO, USA). (±)-Equol, matairesinol, (±)-enterolactone, apigenin, hesperetin, luteolin, and piceatannol were from the Cayman Chemical Company (Ann Harbor, MI). Genistein-d_4 was from the CDN Isotopes (Pointe-Claire, Quebec, Canada). All standards were ≥95% purity. A standard mixture of polyphenols at 10 μg/mL in methanol was prepared and used as a spiking solution for recovery experiments. Concentrations were not corrected for the purity of the standards.

All solvents were HPLC grade. Methanol was purchased from Sigma Aldrich (St. Louis, MO, USA), and acetone was from EMD Chemicals (Gibbstown, NJ, USA). Isopropanol was purchased from Honeywell Burdick and Jackson (Muskegon, MI, USA). Certified ACS grade hexane was purchased from Fisher Scientific (Fair Lawn, NJ, USA). Deionized water of 18.2 Ω-cm was prepared with an E-Pure model D4641 from Barnstead/Thermolyne (Dubuque, IA, USA). Formic acid (88% purity) was obtained from Spectrum Quality Products Inc. (New Brunswick, NJ, USA). Potassium hydroxide (KOH) pellets (purity 86.8%) and anhydrous sodium sulfate (purity 99.49%) were obtained from Mallinckrodt, Inc. (Paris, KY, USA). Pyridine (purity 99.8%) was from Sigma-Aldrich. *N*,*O*-Bis-(trimethylsilyl)trifluoroacetamide (BSTFA) and trimethylchlorosilane (TCMS) were purchased from Fisher Scientific (Pittsburgh, PA, USA).

National Institute of Standards and Technology (NIST) Standard Reference Material (SRM) 3251 *Serenoa repens* extract was purchased from NIST (Gaithersburg, MD, USA).

Phytosterol Analysis. The sample preparation method was based on that of Laakso (2005)[22] with some modifications. Briefly, mushroom powder samples (100 mg) were spiked with an internal standard (ISTD) of cholesterol (2 μg), then saponified with 2.0 mL of 3 N KOH in methanol by sonication (Branson 5510 Ultrasonicator, Branson Ultrasonics (Danbury, CT, USA)) for 10 min and heating in a water bath at 60 °C for 60 min. Phytosterols were extracted by adding 2 mL of hexane to the samples, vortexing, and then centrifuging to allow separation of the layers. The top organic layer was removed into a clean centrifuge vial, and then the extraction was repeated two more times. The combined hexane extract was then evaporated to dryness at room temperature under nitrogen. Pyridine (25 μL) was added, and the extract was derivatized with 25 μL of BSTFA + 1% TCMS by placing in a water bath at 60 °C for 30 min. After hexane (950 μL) was added, the extract was transferred to an autosampler vial and subjected to gas chromatographic (GC) analysis.

Table 1. Average Retention Times (t_R), Multiple Reaction Monitoring (MRM) Transitions, Collision Energy (CE) for Each Transition, and the Lowest Calibrated Level (LCL)

TMS ether of	t_R (min)	quantifier (m/z)	CE (V)	qualifier (m/z)	CE (V)	LCL ($\mu g\ g^{-1}$)
cholesterol	6.788	368.3 → 159.2	40	368.3 → 145.1	40	ISTD
brassicasterol	6.943	470.4 → 201.3	20	470.4 → 69	20	0.025
ergosterol	7.15	363.2 → 143	40	363.2 → 128	40	0.01
campesterol	7.223	382.3 → 145.1	40	382.3 → 105	40	0.01
stigmasterol	7.328	484.4 → 169.3	40	484.4 → 145	40	0.025
campesterol-d_3	7.422	346.3 → 121.1	10	346.3 → 95.1	10	ISTD

lupeol	8.14	369.3 → 109.1	10	369.3 → 94.9	10	0.05

The detection and quantification of the trimethylsilyl (TMS) ethers of sterols was performed using an Agilent (Little Falls, DE, USA) 7000B with high sensitivity electron ionization (EI) source triple-quadrupole mass spectrometer (GC–MS/MS). The GC was an Agilent 7890A gas chromatograph operated in low pressure vacuum outlet mode.[23] The GC column was a 15 m × 0.53 mm × 1 μm film thickness SLT-5 MS (Supelco, Bellefonte, PA, USA) connected to a 5 m × 0.18 mm noncoated guard column from Restek (Bellefonte, PA, USA). Ultrahigh purity He was used as a carrier gas at 2 mL min^{-1} constant flow rate as described previously.[24] At the transfer line the GC column was connected to a ∼17 cm × 0.53 mm i.d. piece of phenyl-methyl deactivated guard column (Restek).

The GC oven temperature program was as follows: 70 °C held for 1.5 min, ramped 80 °C min^{-1} to 180 °C, then ramped 40 °C min^{-1} to 250 °C, followed by 70 °C min^{-1} to 290 °C, and held 4.5 min. The total run time was 9.7 min. The transfer line was at 250 °C, and ion source was set at 320 °C. The MS/MS collision gas was nitrogen at 1.5 mL min^{-1}, and the quench gas was He at 2.25 mL min^{-1}. The EI energy was −70 eV, quadrupole temperatures were set at 150 °C, and the solvent delay was 6 min. An Agilent Multimode Inlet (MMI) was operated as a programmable temperature vaporizer (5 μL injection volume) with solvent vent mode of He flow at 55 mL min^{-1}. The MMI temperature program was 70 °C held for 0.31 min (at which point the vent was closed), then ramped to 420 °C at 320 °C min^{-1}, and held at 420 °C for the rest of the GC run.

Each phytosterol individual standard solution at 1000 ng mL^{-1} was derivatized individually with pyridine and BSTFA + TCMS as described above and injected in full scan mode to determine the most intense ions of the corresponding TMS ether. Product ion and collision energy experiments were performed to determine the optimum two product ions, collision energies, and ratios between quantifier and qualifier ions. The method detection limit was defined as a compound's lowest calibrated level. Multiple reaction monitoring (MRM) transitions, collision energy for each transition, average retention times (t_R), and the lowest calibration levels are presented in Table 1. In the finalized MRM method, a dwell time of 2.5 ms and the "wide" MS resolution were used for all transitions. The MRM transitions were monitored in one time segment from 6 to 9 min. Cholesterol was used as a main ISTD, and campesterol-d_3 was used as a backup if needed. Calibration curves were linear from 0.01 to 0.05 to 10 μg/mL for all sterols. Due to the abundance of ergosterol relative to the other sterols in mushroom powder, its calibration curve was from 1 to 50 μg/mL. Separate extraction was performed for ergosterol analysis, the mass of extracted mushroom powder was 20–30 mg, and the extracts were diluted in hexane 10 times prior to GC–MS/MS analysis.

Ergothioneine Analysis. Mushroom powder (100 mg) was placed into a 15 mL polypropylene centrifuge tube, 10 μg of ISTD methimazole was added, and the sample was extracted with 10 mL of 4:1 (v:v) methanol/water by vigorous shaking for 20 min in a shaker, following by centrifugation at 3650 rcf (×g) for 3 min. After centrifugation, 0.1 mL of the extract was transferred to an autosampler vial containing 0.9 mL of 3:7 (v:v) methanol/water, and the extract was subjected to LC–MS/MS analysis.

An HPLC column (Luna C8(2) 3 μm, 100 Å, 100 × 4.6 mm) integrated with a 4 × 3 mm i.d. Security Guard C8 column (Phenomenex Inc., Torrance, CA, USA) was used for separation. An isocratic program of 0.1% formic acid buffer (A) at 30% and MeOH (B) at 70% with a constant flow rate of 0.4 mL min^{-1} was applied with an injection volume of 20 μL, and the column oven was at 30 °C. The total run time was 5 min. The calibration curves were linear from 0.001 to 2.5 μg/mL of ergothioneine with 0.1 μg of the ISTD. The method detection limit was 1 μg/g ergothioneine.

The mass spectrometer was an API 3000 (Applied Biosystems/MDS Sciex, Ontario, Canada) with electrospray ionization (ESI) operated in the positive mode. The ion spray potential was 4500 V, and the source temperature was set at 500 °C. MRMs of m/z 230.2 → 127.1 and m/z 230.2 → 186.1 were used for ergothioneine (t_R = 2.75 min) and MRMs of m/z 114.9 → 57.1 and m/z 114.9 → 74.1 were used for methimazole (t_R = 3.05 min) with dwell times of 250 ms.

Polyphenolic Compound Analysis. Mushroom powder (100 mg) was placed into a 15 mL polypropylene centrifuge tube, 1 μg of an ISTD genistein-d_4 was added, and the sample was extracted with 5 mL of 4:1 (v:v) methanol/water by sonication for 30 min at room temperature. A 0.5 mL aliquot of the extract was filtered through a 0.2 μm PVDF filter and transferred into an autosampler vial, 0.5 mL of DI water was added to each vial, and the extract was subjected to LC–MS/MS analysis.

A Luna C8(2) 3 μm, 100 Å, 100 × 4.6 mm column with a 4 × 3 mm i.d. Security Guard C8 column (Phenomenex Inc.) was used for separation. The binary gradient of 0.2 mM ammonium formate buffer at pH 4.7 (A) and MeOH (B) at a constant flow rate of 0.4 mL min^{-1} was applied with an injection volume of 20 μL. Column oven temperature was at 40 °C. The gradient program started at 70% A held for 1 min, then ramped to 90% B over the course of 7 min, and held for 2 min. Re-equilibration time at 70% A was 4 min. The mass spectrometer with ESI was operated in the negative mode. The detailed information on the LC–MS/MS method used for polyphenols is reported elsewhere.[25] The calibration curves were linear from 0.001 to 2.5 μg/mL. The method detection limit was 0.1 μg/g.

Vitamin D Analysis. Vitamin D analysis was performed as previously described in detail by Byrdwell (2013)[26] using a "dilute-and-shoot" method and analyzed using liquid chromatography quadruple parallel mass spectrometry (MS) with UV detection at 265 nm. Comparison of MS and UV results is a separate study, which will be presented in a future work.

Each mushroom powder sample was prepared in 5 replicate analytical samples, which were each run in triplicate. A set of three calibration standards were bracketed before, between, and after the five samples. Samples that were expected to have low values (control and low treatment) used a low set of standards, consisting of 500, 1000, and 2000 IU. Samples that were expected to have higher values (high treatment) used a higher set of standards, consisting of 1000, 2000, and 5000 IU.

Statistical Analysis. Statistical data analysis was performed with the SAS System for Windows version 9.4 (SAS Institute Inc., Cary, NC, USA). Analysis of variance (ANOVA) was conducted to investigate the effects and interactions of treatment and mushroom type on ergosterol, campesterol, ergothioneine, and vitamin D. Dunnett's and Bonferroni tests were used with $p = 0.05$ significance.

RESULTS AND DISCUSSION

Sample Preparation Method Evaluation. Phytosterol recoveries were evaluated using reagent spikes (300 mg of anhydrous Na_2SO_4) and matrix spikes (100 mg of mushroom powder) fortified with 2.5 and 5 mg/g of phytosterol standard mixture. Five replicate samples were prepared for both reagent spikes and matrix spikes at each spiking level (see Table 2).

Table 2. % Recoveries of Phytosterols (and % RSDs)[a]

	reagent spike		matrix spike	
	2.5 mg/g	5 mg/g	2.5 mg/g	5 mg/g
brassicasterol	113 (6)	104 (12)	89 (3)	103 (5)
ergosterol	95 (9)	80 (7)	n/a	n/a
campesterol	107 (5)	104 (7)	107 (20)	113 (7)
stigmasterol	98 (12)	107 (4)	120 (14)	**133** (5)
β-sitosterol	112 (2)	105 (5)	120 (2)	118 (6)
stigmastanol	108 (12)	106 (13)	**121** (9)	119 (15)
cycloartenol	105 (17)	108 (17)	**125** (8)	106 (4)
lupeol	107 (11)	110 (6)	117 (8)	112 (6)

[a] $n = 5$; bold indicates recoveries outside of 70−120%; n/a, not applicable.

Unfortified mushroom powder and reagent blank samples (1 mL of DI water) were analyzed along with the spiked samples. Due to the abundance of ergosterol in mushroom powder, it was impossible to calculate its recoveries for fortified mushroom powder samples, therefore only reagent spike recoveries were evaluated in its case.

Campesterol and ergosterol were measured in mushroom powders used for the fortification experiments. Campesterol recoveries were calculated after subtracting the amounts found in the control mushroom powder from the amounts measured in the fortified mushroom powder. However, this was impossible for ergosterol, as the mushroom powders contained a very high amount of ergosterol.

The recoveries of phytosterols from reagent spike samples were within satisfactory limits of 95−113% (5−17% RSDs) for the 2.5 mg/g spiking level and 80−110% (4−17% RSDs) for the 5 mg/g level. For fortified mushroom powders, however, the recoveries ranged from 89 to 125% (2−20% RSDs) for 2.5 mg/g and 103−133% (4−15% RSDs) for the 5 mg/g spiking level. Cycloartenol and stigmasterol (125 and 133%, respectively) recoveries were outside of satisfactory limits of 70−120%. RSDs for 5 replicate measurements in the recovery experiment were at or below 20%, indicating acceptable method performance.

To estimate the accuracy of measurements (or "trueness") of the developed method, the standard reference material SRM 3251 *Serenoa repens* extract with certified values for campesterol, β-sitosterol, and stigmasterol was analyzed in 5 replicates. Due to high amounts of these sterols in the reference material, only small portions of the material (20−28 mg) were extracted. The measured values were in good agreement with certified values for campesterol and stigmasterol (see Table 3). The average accuracy measured as a percent of measured concentration vs certified concentration was 97% for campesterol and 93% for stigmasterol. For β-sitosterol concentrations measured in SRM 3251, the average accuracy was 124%. β-Sitosterol has the highest concentration in SRM 3251, and even after extraction of small amounts of the reference material, several serial dilutions 1:10 and 1:100 were required to fit its concentration in the calibration curve range. In contrast to the SRM material, β-sitosterol concentrations in mushrooms are very low[9] and were not measured in mushroom samples in our study. RSDs for five parallel measurements of selected phytosterols in SRM 3251 were 11−16%, indicating the method's acceptable repeatability.

Table 3. Determined Phytosterol Concentrations in SRM 3251 *Serenoa repens* Extract

	certified value, mg g^{-1} ± SD	measd value, mg g^{-1} ± SD, $n = 5$	% accuracy (RSD), $n = 5$
campesterol	0.533 ± 0.031	0.519 ± 0.081	97 (16)
β-sitosterol	1.666 ± 0.064	2.065 ± 0.321	124 (16)
stigmasterol	0.247 ± 0.040	0.231 ± 0.037	93 (11)

For evaluating egrothioneine recoveries, the mushroom powder was spiked with ergothioneine standard solution at the levels 0.5, 2, and 5 mg/g ergothioneine. Five replicate samples were prepared as described above for each spiking level. Unfortified mushroom powder and reagent blank samples were analyzed along with the spiked samples, and ergothioneine concentrations for the recovery calculations were adjusted for the amount measured in unfortified mushroom powder. The ergothioneine recoveries were 109 ± 20%, 105 ± 8%, and 119 ± 10% for the spiking levels of 0.5, 2, and 5 mg/g, respectively.

The recoveries of polyphenols from fortified mushroom powder samples were evaluated at spiking levels of 5 and 10 μg/g for five replicates per level. Unfortified mushroom powder and reagent blank samples were analyzed along with the spiked samples. No polyphenols were detected in the reagent blank and unfortified mushroom powder samples used in the recovery study. The recoveries of polyphenols were satisfactory (70−120%) with the exception of naringin (63%) and matairesinol (65%) at the 5 μg/g spiking level, and enterolactone (123%) at the 10 μg/g spiking level (see Table 4).

Phytosterols. Only ergosterol and campesterol were present for determination in the mushroom powder samples. Matrix spike sample recoveries were 107−113%, and precision measurement of duplicate samples was 3−20%.

Ergosterol concentrations were 2.4−4.0 mg/g dw (shiitake), 2.9−4.5 mg/g dw (oyster), 4.6−6.2 mg/g dw (brown), and 4.6−5.2 mg/g dw (white) mushroom powder samples (Figure 1). A Bonferroni test showed significantly higher ($p < 0.05$) ergosterol levels in brown and white mushroom powder than in the oyster and shiitake (See Figure 2). This is consistent with the recent findings by Villares et al. (2014)[8] reporting ergosterol concentrations in *A. bisporus* (white and brown) mushrooms (6.42 mg/g dry wt) being significantly greater ($p < 0.05$) than in *L. edodes* (shiitake) (3.64 mg/g dw) and *P. ostreatus* (oyster) (3.31 mg/g dw).

When examining the effect of UV-B treatment among different types of mushroom powder samples, shiitake and oyster mushroom powders had significantly lower concentrations of ergosterol in high UV-B treatment samples compared to control. For brown mushroom powders, samples from high UV-B treatments had significantly lower concen-

[a] $n = 5$; bold indicates recoveries outside of 70−120% and RSDs >20%.

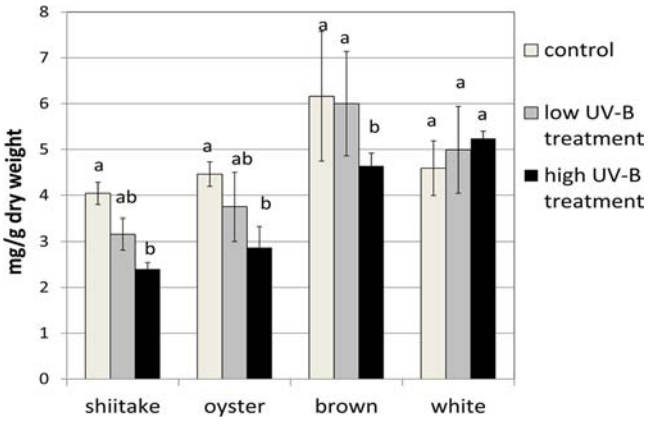

Figure 1. Ergosterol average concentrations (mg/g dry weight) in different types of mushroom powder in control and different treatment conditions; error bars represent standard deviations for $n = 3$. Any two values with no letter in common are significantly ($p < 0.05$) different according to the Bonferroni test within any specific mushroom type.

trations of ergosterol compared to low UV-B treatment and control (see Figure 1).

No statistical difference in ergosterol concentrations was observed for white mushroom powder samples exposed to different treatments. Simon et al. (2011)[27] observed the same effect when ergosterol concentrations remained stable in the same type of mushrooms (*Agaticus bisporus)* exposed to UV-B light. These observations may warrant future studies to better understand a mechanism of ergosterol conversion to vitamin D_2 in different types of mushrooms exposed to UV-B radiation.

Only a small portion of ergosterol converts to vitamin D under UV-B treatment, where ergosterol concentrations in mushrooms are in mg/g levels, and the amounts of formed vitamin D are in μg levels, therefore mushroom powder used as a dietary supplement ingredient provides high levels of ergosterol. According to Phillips et al. (2011),[9] the potential contribution of ergosterol by fresh mushrooms is 0.27−0.86 mg/g. Nuts and seeds are regarded as foods providing the highest amounts of ergosterol: 0.95−4.01 mg/g.[28] In comparison, mushroom powder made of brown mushrooms in our study provides up to 6 mg/g of ergosterol.

Besides ergosterol, campesterol was measured in mushroom powder samples in our study in concentrations of 31−41 μg/g dw (shiitake), 15−20 μg/g dw (oyster), 36−42 μg/g dw (brown), and 38−43 μg/g dw (white) mushroom powder samples (Figure 3). Campesterol concentrations were significantly lower ($p < 0.05$) in oyster mushroom powder compared to three other types (Figure 4). Shiitake mushroom powder had significantly lower concentrations of campesterol in high UV-B treated samples compared to low UV-B treated samples (Figure 3). This is an interesting finding, as we are not aware of any published studies to date reporting the effects of UV-B radiation on campesterol concentrations.

Compared to other studies, concentrations of campesterol in our study were 10 times lower compared to concentrations of campesterol found by Phillips et al. (2011)[9] in morel mushrooms (12.3−45.4 μg/g fresh weight). However, they were comparable with campesterol concentrations measured in *Tuber* fermentation mycelia (15−24 μg/g dw) by Tang et al. (2012).[29] Also, brassicasterol was measured in morel mushrooms[9] and *Tuber* fermentation mycelia,[29] but was not detected in mushroom powder in our study.

Polyphenolic Compounds. No individual polyphenolic compounds were detected in mushroom powder samples in our study (method detection limit 0.1 μg/g). In contrast, quercetin was measured in concentrations 9.64−66.74 μg/g dry weight in wild edible mushrooms from China by other researchers.[18] Another study analyzed phenolic compounds in edible and medicinal mushrooms from Korea and measured naringin (not detected (nd)−38 μg/g), resveratrol (nd−12 μg/g), quercetin (nd−52 μg/g), naringenin (nd−36 μg/g), kaempferol (nd−53 μg/g), hesperetin (nd−3 μg/g), formononetin (nd−1 μg/g), and biochanin A (nd−3 μg/g).[19] Similar to our study, rutin was not detected in mushrooms from Korea. Another study found no flavonoids or lignans in the cultivated mushrooms (white and brown *A. bisporus*, *L. edodes*, and *P. zostreatus*).[30]

Previously published studies have reported that UV-B irradiation increased concentrations of selected polyphenolic compounds, such as flavonoids and flavonols in tomatoes[20] and apples,[21] however the measured amounts were in low mg/g levels, while polyphenolic compounds reported in mushrooms are usually reported in the low μg/g range. According to Kalac (2013),[1] wild and cultivated mushrooms as well as several specific mushroom species may greatly differ in polyphenolics composition and concentrations. Polyphenolic compounds easily degrade when exposed to light, elevated temperatures, and pH changes.[31,32]As it was described by other researchers, elevated temperatures, for example, boiling mushrooms in water, resulted in decreased amounts of total polyphenols and ergothioneine.[33] A recent study indicated that up to 73% of flavonoids were lost during freeze-drying of a perennial herb *Centella asiatica*.[34] It is unclear if polyphenolic compounds were not detected in the mushroom powder samples due to

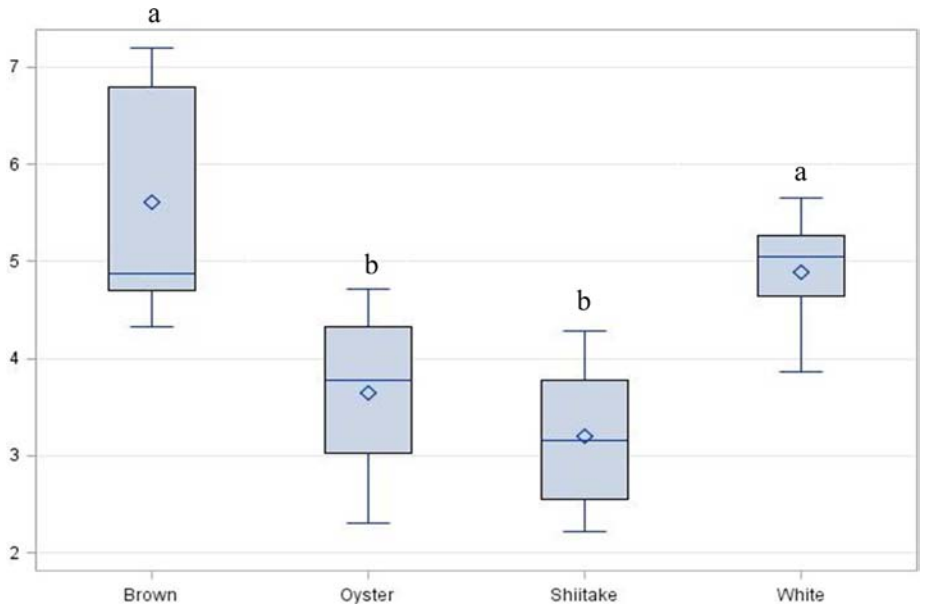

Figure 2. Distribution of ergosterol mean concentrations (mg/g dry weight) among different mushroom powder types. Any two values with no letter in common are significantly ($p < 0.05$) different according to the Bonferroni test.

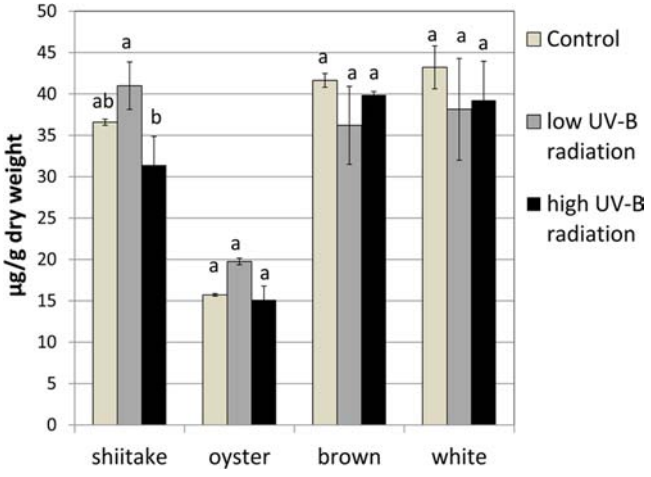

Figure 3. Campesterol average concentrations (μg/g dry weight) in different types of mushroom powder in control and different treatment conditions; error bars represent standard deviations for $n = 3$. Any two values with no letter in common are significantly ($p < 0.05$) different according to the Bonferroni test within any specific mushroom type.

compositional differences in mushroom types, or degradation during the drying process to produce mushroom powder.

Ergothioneione. Ergothioneine recoveries in matrix spike samples were 67−115%, and precision for replicate samples was 0.1−8%. Ergothioneine concentrations found in mushroom powder samples were 0.37−0.48 mg/g dw (brown), 0.81−0.92 mg/g dw (white), 7.2−7.9 mg/g dw (shiitake), and 9.7−10.4 mg/g dw (oyster) (Figure 5). Ergothioneine average concentrations were significantly greater in oyster mushroom powders compared to shiitake, and both types had significantly higher concentrations compared to brown and white (Figure 5). For comparison, Nguyen et al. (2012) found 2 mg/g dw ergothioneine in the cultivated mushroom *Flammulina velutipes*.[33] Other researchers measured 0.21 mg/g, 1.98 mg/g, and 2.59 mg/g dw of ergothioneine in white, shiitake, and oyster mushrooms, respectively.[17] While these amounts are approximately four times lower than amounts of ergothioneine measured in our work, they follow the same trend with oyster mushrooms having the highest amount of ergothioneine, followed by shiitake and white mushrooms. Ey et al. (2007)[16] measured 119 μg/g wet weight of ergothioneine in oyster mushrooms (*Pleurotus ostretus*). Assuming the moisture content of these mushroom was ≈90%, this corresponds to 12 mg/g dw of ergothioneine, which is similar to the 9.7−10.4 mg/g dw of ergothioneine measured in our study. Ergothioneine concentrations were not appreciably affected by UV-B radiation for all mushroom types, except shiitake, for which concentrations of ergothioneine decreased significantly from control to low and high UV-B treatments (Figure 5). This is an important finding, as to our knowledge this is the first study investigating ergothioneine concentration changes in UV-B exposed mushrooms.

Mushrooms can serve as an excellent source of the naturally occurring antioxidant ergothioneine. Shiitake and oyster mushroom powders in this study had the highest amounts of ergothioneine, and only 0.5−1 g of these mushroom powder supplements is needed to provide 4−5 mg of ergothioneine, compared to the need for a ≈70 g serving of fresh mushrooms to receive a similar amount of ergothioneine.

Vitamin D. Vitamin D average concentrations ($n = 5$) and standard deviations, expressed in IU/g, are given in Table 5. % precision for replicate samples ($n = 5$) ranged from 0.53 to 3.14%. No vitamin D was measured in control samples of oyster and shiitake mushroom powder. For statistical analysis, zeroes were used for these samples. In contrast, control samples of brown and white mushroom powder had 179 ± 4 (brown) and 179 ± 5 (white) IU/g of vitamin D. For low UV-B treatment, which was expected to increase vitamin D levels to 100−200 IU/g, vitamin D measured value was close to expected only for shiitake mushroom powder (217 ± 7 IU/g). Vitamin D concentrations measured in brown (1942 ± 30 IU/g) and white (2156 ± 43 IU/g) mushroom powder exposed to low UV-B radiation were statistically greater than expected. For high UV-B treatment, expected to increase vitamin D levels to 6000−8000 IU/g, the vitamin D concentration measured in

Table 5. Vitamin D Average Concentrations and Standard Deviations ($n = 5$), IU/g in Mushroom Powder Samples[a]

	shiitake	oyster	brown	white
control	nd[b] (**I**)	nd (**I**)	179 ± 4 (**H**)	179 ± 5 (**H**)
low UV-B treatment (expected 100–200 IU/g)	217 ± 7 (**H**)	1245 ± 9 (**F**)	1942 ± 30 (**E**)	2156 ± 43 (**D**)
high UV-B treatment (expected 6000–8000 IU/g)	1036 ± 13 (**G**)	4411 ± 23 (**C**)	6292 ± 109 (**A**)	4739 ± 61 (**B**)

[a]Bold letters in parentheses represent level of statistical difference. Any of the twelve values with no letter in common are significantly different ($p < 0.05$) according to the Bonferonni test. [b]Not detected.

brown mushroom powder (6292 ± 109 IU/g) was at the expected level. Concentrations of vitamin D for oyster (4441 ± 23 IU/g), white (4739 ± 61 IU/g), and shiitake (1036 ± 13 IU/g) mushrooms were statistically lower than expected.

It is interesting to note that shiitake mushroom powder had the lowest levels of ergosterol (significantly lower than in other mushroom powder samples), and the lowest levels of vitamin D were produced in these samples.

This study investigated effects of UV-B radiation on the bioactive natural compounds in different types of mushroom powders used as dietary supplement ingredients. Mushroom antioxidant, ergothioneine, concentrations were 0.37–0.48 mg/g dw (brown), 0.81–0.92 mg/g dw (white), 7.2–7.9 mg/g dw (shiitake), and 9.7–10.4 mg/g dw (oyster) mushroom powder samples, and were mostly not affected by UV-B radiation. Polyphenolic compounds were not detected. Mushrooms' most abundant phytosterol, ergosterol, concentrations were highest for brown (2.9–4.5 mg/g dw) followed by white (4.6–5.2 mg/g dw), oyster (2.9–4.5 mg/g dw), and shiitake (2.4–4.0 mg/g dw) mushroom powder samples. Ergosterol concentrations were significantly higher in brown and white mushroom powders compared to oyster and shiitake, and significantly decreased with the increased level of UV-B treatment for all mushroom powder types, except for white. Campesterol concentrations were greatest for white (38–43 μg/g dw), followed by brown (36–42 μg/g dw), shiitake (31.4–41.0 μg/g dw), and oyster (15.1–19.8 μg/g dw), and were significantly lower in oyster mushroom powder samples compared to the other three types. Campesterol concentrations significantly decreased in shiitake mushroom powder in high UV-B treated samples compared to low UV-B treated samples. These results provide some new information on UV-B radiation effects on the important natural bioactive compounds in mushrooms, and suggest that mushroom powder dietary supplements not only provide vitamin D but also may be a good source of phytosterols and ergothioneine.

tional markers of sunburning predisposition, with the aim of developing high-throughput methods useful in exploring the phenotypical variability of the grapes' susceptibility to sunburn damage.

MATERIALS AND METHODS

All of the *Vitis vinifera* L. accessions tested were grown in the same germplasm collection vineyard, located at the Regional Research Station of Riccagioia (Lombardy region, northern Italy) already described in a previous paper.[14] The experimental layout provided for the selection of 17 Lombard germplasm accessions named Bianca Botticina, Bianca Gabana, Pinot bianco, Chiavennasca bianca, Colombaia bianca, Croatina bianca, Erbamat, Favorita, Invernenga, Cortese, Marzemino bianco, Pollini A, Malvasia Istriana, Verdicchio, Uva bianca dura invernale, Verdea, and Vernassa. For each accession one shaded bunch was chosen. On August 29, 2012, at 12.30 p.m. solar time, the bunches were exposed to direct sunlight by leaf removal from the southwestern side facing the sun; the epicuticular waxes were mechanically removed through a slight rubbing of the berry surface with paper towels to facilitate the sunburning symptoms' appearance and to exclude the wax heterogeneity as an additional source of variability. After 5 h, at 5.30 p.m., all of the bunches were collected.

To describe grape temperatures during the experiment, the BerryTone model[21] was used to simulate the hourly temperature of the bunches. The model has been fed maximum and minimum daily air temperatures gathered by the weather station located in the vineyard.

All grape samples were kept at 10 °C and analyzed within 24 h from their harvesting. Forty berries were selected for each accession. Twenty of them were taken from the inner part of the shaded side of the cluster, with the purpose of describing the varietal reflectance spectra (control berries). Twenty berries on the exposed side of each bunch were also sampled (exposed berries). The most symptomatic berries (visual evidence of browning/discoloration), if present, were taken. When no symptoms were clearly visible, the most exposed berries were chosen. Before the spectrophotometric analysis, epicuticular waxes, still present in the control berries, were mechanically removed with a paper towel to avoid their interference with the optical properties.[10] Overall, 680 reflectance spectra were obtained using a Jaz System spectrometer (Ocean Optics), completed with a channel with a DPU module and an ILX511b detector, an OFLV-3 filter, an L2 lens, and a 50 μm slit as installed options. A reflection probe QR600-7-VIS125 consisting of a tight bundle of seven optical fibers (600 μm in diameter), in a stainless steel ferrule (six illumination fibers around one read fiber), was coupled to the spectrophotometer. The instrument was set up with a NIR−vis light source (Ocean Optics) 4095 power setting and an integration time automatically corrected by the instrument. Collected spectra ranged between 341 and 1025 nm and had a spectral resolution of about 0.3 nm. In this work, the visible spectral changes (450−750 nm) will be presented and discussed. Each spectrum was set up to be the average of nine spectra, which were directly calculated by the instrument. The spectra were converted in percentage of reflectance (%R) after a calibration with a blank, obtained by using a white Spectralon surface (Labsphere). The relationship between reflectance signal and chromophore content is nonlinear. Thus, the reflectance spectra were converted to approximate to the (quasi)linear relationship between pigment content and optical reflectance-based indices using reciprocal reflectance ($1/R$) spectra. The difference between exposed and shaded spectra was than calculated (Figure 3a). To make the browning contribution more apparent, a normalization to chlorophyll red maximum (678 nm) was also performed before the differential spectra were calculated, obtaining the "$1/R$ (chlorophyll normalized)" spectra (Figure 3b).

Chlorophyll content was estimated by using a reflectance index previously developed by Merzlyak and Solovchenko:[22]

$$\text{chlorophyll index} = R_{800}/R_{678}$$

This index was developed in apple fruits, but we decided to apply it to grapes because (i) the optical effect of chlorophylls in the red region is clearly identified in white grape spectra and (ii) no interferences from other white grape pigments are expected at these wavelengths.[14]

The index was computed on the basis of the average control spectrum of each cultivar. The objective was to evaluate the berry susceptibility to sunburn in relation to the initial chlorophyll content.

A browning intensity index was developed to evaluate the degree of sunburning symptoms in each accession. It was calculated as the difference of the inverse reflectance spectra, normalized to chlorophyll "$1/R$ (chlorophyll normalized)" at the maximum absorption wavelength (490 nm) of melanin-like pigments.

$$\text{browning intensity index} = \frac{100R_{e678}}{R_{e490}} - \frac{100R_{s678}}{R_{s490}}$$

where R_{e678} = exposed berries' reflectance at 678 nm, R_{e490} = exposed berries' reflectance at 490 nm, R_{s678} = shaded berries' reflectance at 678 nm, and R_{s490} = shaded berries' reflectance at 490 nm.

The statistical significance of the differences between reflectance data from exposed and control skins was estimated for each wavelength according to the classical computation of the mean confidence intervals per p = 0.95, with the lower limit = $M - (t_{0.95})(s_m)$ and the upper limit = $M + (t_{0.95})(s_m)$, where M = average value, t = Student's t per p = 0.95, and s_m = standard error (standard deviation/number of berries$^{1/2}$). This analysis, as well as correlations and ANOVA models, was performed by SPSS statistical software (version PASW Statistics 19, SPSS Inc., Chicago, IL, USA).

RESULTS

During the experiment, the global solar radiation ranged from 2.6 to 2.7 MJ m^{-2} h^{-1} and the air temperature from 24.3 to 29.2 °C. The hourly course of berry temperature for the day of the experiment was simulated with reference to a southwestern exposed part of the bunch in comparison to the shaded side (Figure 1). The exposed berries reached a maximum temperature of 34.2 °C at 2:00 p.m. At the same time the control berries were at 30.4 °C and the air at 29.2 °C. The difference between air and berry temperature was maximum at 1:00 and 2:00 p.m., when 6.1 °C was reached. At that time the difference between exposed and shaded berries was 4.3 °C.

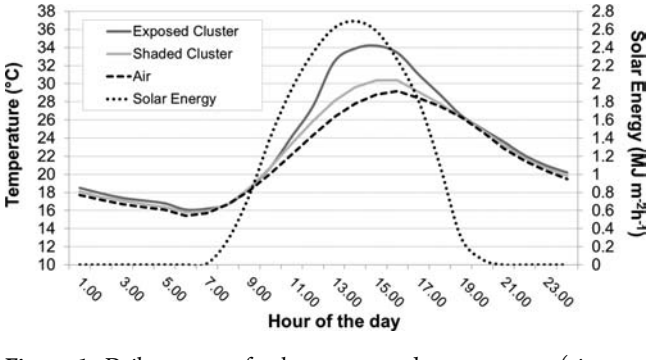

Figure 1. Daily course of solar energy and temperatures (air, sun-exposed and shaded berries). Bunches were exposed on August 29, 2012, at 12.30 p.m. solar time for 5 h.

Reflectance spectra were measured and their relative standard error was calculated for control and exposed berries to describe sunburning effects (Figure 2). Reflectance spectra minima indicate the presence of compounds absorbing in the corresponding spectral band. Figure 3 represents the variation of reciprocal reflectance ($1/R$) (Figure 3a) and $1/R$ (chlorophyll normalized) (Figure 3b) spectra in relation to sunburning. In Figure 3, when the interval of confidence overlaps zero, no significant compositional changes occurred in relation to sunlight exposure of berries. If it is above zero, new

dx.doi.org/10.1021/jf405772f | J. Agric. Food Chem. 2014, 62, 3043−3046

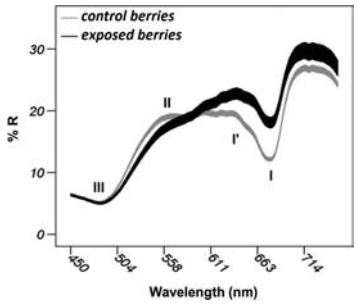

Figure 2. Control and exposed berry average spectra (±standard errors). Roman numbers indicate spectral regions of specific absorption interest.

molecules absorbing in the corresponding wavelength range have been generated (e.g., melanin-like pigments). Differences lower than zero are indicative of chromophore loss as a consequence of sunburn-induced bleaching.

It is possible to note three spectral regions (Figure 2) related to different grape skin compounds. Molecules related to region I (chlorophylls, Figure 2) evidently undergo degradation during sunburn (Figure 3a). In Figure 2, region II mainly indicates a difference between control and exposed spectra, related to the formation of brown compounds. In Figure 3 the absorption signature of melanin-like pigments clearly appears. The maximum of reciprocal reflectance ($1/R$) spectra (Figure 3a) underwent an 18 nm shift toward shorter wavelength after normalization to the chlorophyll red absorption maximum (Figure 3b). Region III (Figure 2) indicates a strong overlapping absorption by several chromophores (e.g., chlorophylls, carotenoids, melanin-like pigments).

DISCUSSION

In the red region, a broad band of combined chlorophyll *a* and *b* absorption was detected in the control and exposed berry spectra (Figure 2, region I). In Figure 2 the minimum of reflectance near 678 nm should be mostly due to chlorophyll *a* (spectral region I), whereas the little shoulder near 650 nm should be related to chlorophyll *b* absorption (spectral region I′), as suggested by Merzlyak et al.[23]

In comparison with the control spectrum, the exposed one (Figure 2) showed a decrease in reflectance in region II. This trend, emerging during browning, may be explained by the generation of melanin-like pigments,[5,24] for example, via the oxidation of polyphenols by polyphenol oxidases.[25]

In the blue and green region (Figure 2, region III), no significant difference was recorded. In this region, different molecules absorb, including chlorophylls. Chlorophylls underwent degradation (Figure 3a). Nevertheless, the expected increase in reflectance in the Soret band (see band III in Figure 2) was not detected, probably due to accumulation of other chromophores, most probably the browning pigments.[20] The normalization of reciprocal reflectance spectra to chlorophyll allows the exclusion of the overlap in region III between the absorption of chlorophylls and melanin-like pigments. Thus, the hypsochromic shift of the melanin-like pigments λ_{max} between panels a and b of Figure 3 should be related to the removal of this overlapping contribution by chlorophylls to overall.

Figure 4 shows the correlation between the varietal (shaded bunches) chlorophyll concentrations and the browning intensity index and, thus, melanin-like pigment generation. A quadratic model was able to describe the nonlinear relationship. As expected in oxidative processes, the reaction kinetics appears above a threshold. After a chlorophyll index value of about 2, the production of melanin-like compounds suddenly increased. Below the threshold, no relationships could be detected. Thus, it is possible to suggest a central role of photo-oxidation in the sunburn symptom physiology. For this reason it is possible to

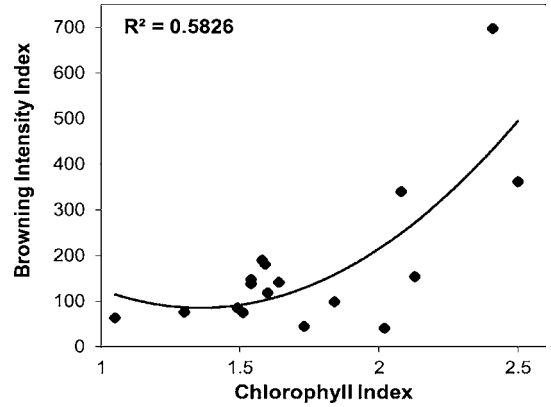

Figure 4. Nonlinear correlation between chlorophyll index and browning intensity index ($p < 0.01$).

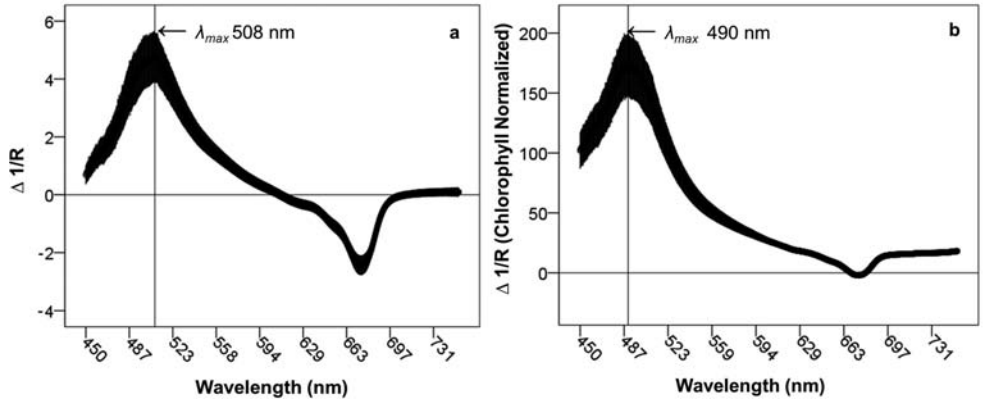

Figure 3. Differences (mean ± confidence interval 95%) in the (a) reciprocal reflectance ($1/R$) and (b) $1/R$ (chlorophyll normalized) spectra between exposed and shaded berries.

dx.doi.org/10.1021/jf405772f | J. Agric. Food Chem. 2014, 62, 3043−3046

propose the use of a chlorophyll index threshold as a marker for grapes' susceptibility to sunburning browning. Further experiments could confirm this hypothesis, studying the kinetics of browning of individual berries and relating the parameters of these kinetics to the initial chlorophyll content.

With the development of rapid, noninvasive, and low-cost methods, reflectance spectroscopy could support grapevine variety characterization with respect to sunburn susceptibility, as well as the study of the physiological processes involved in the symptoms' appearance.

Actin*	AB116565.1	CGAGGCTCAATCCAAAAGAG/ GGGGCCTCAGTTAGGAGAAC	159	97.3	0.994
Glyceraldehyde 3-phosphate dehydrogenase (GAPDH2)*	AF421145.1	TTCCGTGTACCCACTGTTGA/ TCACCAATGAAGTCGGTTGA	170	106.6	0.971
Histone H4*	AB197150.1	TCAAGCGTATCTCCGGTCTC/ AGTGTCCTTCCCTGCCTCTT	163	106.2	0.996

[a]PCR amplification efficiencies and regression coefficients for the standard curves are reported for each primer pair. *, reference genes.

3-hydroxylase (F3H), dihydroflavonol 4-reductase (DFR), flavonol synthase (FLS), anthocyanidin synthase (ANS), and flavonoid 3-*O*-glucosyltransferase (UFGT); cell-wall degradation enzymes, including *endo-β*-1,4-glucanase (endo*β*Glu), polygalacturonase (PG), polygalacturonase-inhibiting protein (PGIP); and encoding of PR proteins, including *β*-1,3-glucanase (*β*Glu), class III Chitinase (Chi3), and PR-1. In the same way, the enzyme activities related to PAL, *β*Glu, total Chitinase (Chi), and guaiacol peroxidase (GPX) were tested. The results of this study provide new information on the effect of resistance inducers on strawberry fruit.

MATERIALS AND METHODS

Fruit Material. Experiments were carried out on fruits of strawberries cv. Camarosa grown according to organic agriculture practices, from commercial orchards located in the Marche region, central-eastern Italy. The fruits were selected for the absence of defects, uniformity in size, and degree of ripening (2/3 of surface red), and they were used for the experiments on the day of their harvest.

Treatments. The physiological changes in the strawberry fruit were analyzed following treatments with commercial elicitor formulations: 1% (w/v) chitosan (Chito Plant, ChiPro GmbH, Bremen, Germany), 1% (v/v) COA (Fitocalcio, Agrisystem, Lamezia Terme, CZ, Italy), and 1% (w/v) BTH (Bion, Syngenta, Milano, MI, Italy). The commercial products were prepared by dissolving or diluting them in distilled water. Distilled water was used as the control.

Strawberry fruits (800 g) were pooled together and randomized, and then they were immersed for 30 s in 1 L of one of the three resistance inducers or water. After the treatments, the strawberries were dried in air for 30 min and then subdivided into 4 groups of 200 g each. After air drying, one group was stored at −80 °C (0.5 h post-treatment), and the other groups were arranged in small plastic boxes that were placed in bigger covered plastic boxes. These groups were stored up to a total of 6, 24, and 48 h post-treatment, at 20 °C and 95%−98% relative humidity. At each time, fruits corresponding to 20 g were randomly selected and stored in two separated tubes at −80 °C, until RNA extraction. The experiments were repeated at least twice.

Gene Expression Analysis. Gene expression analysis on the strawberry fruit after the treatments with the different resistance inducers was performed by RT-qPCR, using a SYBR-green dye system, according to Minimum Information for Publication of Quantitative Real-Time PCR Experiments (MIQE) guidelines.[17] The comparative $-\Delta\Delta C_t$ method[18] was used to evaluate the relative quantities of each of the amplified products in the samples.

RNA Extraction. High quality total RNA was obtained from the fruit according to the protocol of Landi and Romanazzi.[19] Briefly, 10 g of strawberry tissue samples including both achenes and receptacle was ground in liquid nitrogen, and 400 mg of the resulting fruit powders was randomly collected for RNA extraction. Extraction buffer was added (1 mL; 100 mM Tris-HCl, pH 8.0, 25 mM EDTA, pH 8.0, 2% [w/v] CTAB [Sigma], 2% [v/v] β-mercaptoethanol, 2.5 M NaCl, and 2% [w/v] soluble PVP-40), and the samples were incubated at 65 °C for 30 min. The supernatants were transferred to new tubes with an equal volume of chloroform/isoamyl alcohol (24:1) and centrifuged at 10,000*g* for 5 min at 4 °C. This last step was repeated two more times. The total RNA were precipitated in 0.25 vol 10 M LiCl, with the reaction left to proceed overnight at 4 °C. The samples were then centrifuged at 10,000*g* for 30 min at 4 °C, washed in 70% ethanol, dried, and resuspended in 50 μL of double-distilled diethyl pyrocarbonate water. RNA integrity was verified by agarose gels that were stained using SYBRSafe (Invitrogen, Carlsbad, CA, USA). RNA purity was assessed based on an absorbance ratio of 1.80 to 1.90 at 260/280 nm, using BioPhotometer plus (Eppendorf Inc., Westbury, NY, USA) and 1.8 to 2.0 at 230/260 nm.

Reverse Transcription. A total of 40 ng to 50 ng RNA was used for cDNA synthesis with reverse-transcription PCR, using iScript TM cDNA synthesis kits (Bio-Rad, Hercules, CA, USA), according to the manufacturer's instructions. From each RNA extraction, cDNA synthesis was performed twice, and the products were mixed before the gene expression studies.

Primers and Reference Gene Selection. Specific primer sets were designed using the Primer3 software (http://biotools.umassmededu/bioapps/primer3_www.cgi) from the specific sequence of *Fragaria* × *ananassa* deposited in NCBI GenBank (Table 1). The primer pairs were chosen and validated in silico using primer BLAST-specific analysis (http://www.ncbi.nlm.nih.gov/Blast.cgi) and then according to the melting profiles obtained from the quantitative real-time PCR conditions (qPCR), as described later.

The relative expression stabilities of the candidate reference genes of 18S-rRNA, actin, histone H4, and GAPDH2 were validated using the geNorm method, using the 3.5 version.[20]

Quantitative Real-Time PCR. qPCR reactions were performed in 96-well clear multiplate PCR plates (Bio-Rad, Hercules, CA, USA) using the iQ SYBR Green Supermix (Bio-Rad) on an iCycler iQ Real-Time PCR Detection System (Bio-Rad) under the following conditions: an initial denaturating cycle (5 min at 95 °C), followed by 40 cycles of three steps of denaturation, annealing, and polymerization (30 s at 95 °C, 20 s at 55 °C, and 30 s 72 °C). PCR amplification was carried out in a total volume of 22 μL, containing 9 μL of diluted (1:10) cDNA (duplicates), 0.25 μM of each primer, and 11 μL of iQ SYBR Green Supermix. All of the assays included no-RT and no-template controls, to determine the nonspecific amplification. To determine the specificity of the amplicons, melting curve analysis was performed over the range of 55 to 98 °C. The qPCR efficiency (E) of each primer pair was determined using standard curves generated according to the equation $E = 10^{-1/\text{slope}}$ of five triplicate cDNA pool dilutions (undiluted, 0.25, 0.0625, 0.015, and 0.003).

Enzyme Activities. Spectrophotometric assays were used to determine the βGlu EC 3.2.1.6, Chi EC 3.2.1.14, PAL EC 4.3.1.24, and GPX EC 1.11.1.7 activities of the strawberry fruits at 0.5, 6, 24, and 48 h post-treatment with chitosan, COA, and BTH. Frozen fruits (1 g fresh weight) were ground, and βGlu and Chi were extracted using 1% (w/v) polyvinylpolypyrrolidone in 50 mM sodium acetate buffer (pH 5.0) containing 1 mM dithiothreitol and 0.2% (w/v) phenylmethylsulfonyl fluoride. The PAL was obtained using 100 mM potassium phosphate buffer (pH 8.0) containing 1% (w/v) polyvinylpolypyrrolidone and 1.4 mM β-mercaptoethanol. The GPX was obtained with 100 mM potassium phosphate buffer (pH 7.3) containing 1 mM EDTA. The homogenates were centrifuged at 15000*g* for 15 min at 4 °C, and the resulting supernatants were used as the crude enzyme extracts. The protein content in the enzyme extracts was determined according to the Bradford assay[21] (Sigma-Aldrich), using bovine serum albumin as the standard. βglu activity was assayed according to Derckel et al.[22] The Chi and PAL activities were measured according to Trotel-Aziz, et al.[23] and the GPX according to Amako et al.[24] All of the enzyme activities were analyzed using a UV 1800 spectrophotometer (Shimadzu Corp., Tokyo, Japan). For all of the assays, the absorbance was measured against a blank (crude protein extract in incubation mixture). The specific activities of the enzymes are expressed as Units (U) mg^{-1} protein.

Data Analysis. The gene expression study was performed using the $-\Delta\Delta C_t$ method.[18] According to this method, the expression of target genes was given as the mean fold-changes in gene expression normalized to an endogenous reference gene and compared to the untreated controls. For each individual sample, three replications were analyzed. The gene expression calculations were performed using the Excel program Gene Expression Analysis for iCycler iQ Real Time PCR Detection System (Bio-Rad). The calculations in this spreadsheet were derived from the algorithms outlined by Vandesompele et al.[20] All of the analyses were performed twice.

For the analysis of the enzyme activities, for each individual sample three replications were analyzed. The experiments were performed twice. The data from each sampling point are shown as the mean ± SD and were statistically evaluated by ANOVA, followed by individual comparisons using Duncan's Multiple Range Test, at $p \leq 0.05$.

RESULTS

Selection of Appropriate References Genes for RT-qPCR in the Treated Strawberry Fruits. For this study, the RT-qPCR was set up for analysis of the strawberry fruits treated for 30 s with the three elicitors. The specific primer sets identified for all of the genes analyzed showed specific single-peak melting curves (data not shown), which confirmed the homogeneity and specificity of the amplicons produced in the RT-qPCR for each of the 18 target genes. No amplification was observed in any of the control assays, which confirmed that the samples were free of contamination with genomic DNA or RNA, or the cDNA template (data not shown). The amplification efficiency (E) ranged from 96.2% to 106.2%, according to the standard curve analysis in RT-qPCR of each gene-specific primer pair (Table 1).

The validation of four putative candidate reference genes, 18S-RNA, actin, glyceraldehyde 3-phosphate dehydrogenase (GAPDH2), and histone H4, according the geNorm method, showed differences within the treatments. However, these reference genes had M values <1.1, which is below the default limit of $M < 1.5$ (Figure 1). For the analysis, the two most stable genes were selected. In particular, on strawberry fruits treated with COA, among these reference genes the most stable were the 18S-RNA and GAPDH2 genes ($M = 0.49$) (Figure 1A). According to the analysis of reference genes on the strawberry fruits treated with BTH, the genes for actin and histone H4 were the most stable ($M = 0.43$) (Figure 1B). Using chitosan and the water control, the best expression stability was using the 18S-RNA and actin genes. In particular, the M value was 0.46 in samples treated with chitosan (Figure 1C), and 0.51 in the control samples (Figure 1D).

Effects of Three Resistance Inducers on the Expressions of Defense Genes. The biochemical reactions in the cell that are catalyzed by enzymes and genes that were up-regulated in strawberry fruits after the chitosan, COA, and BTH treatments are illustrated schematically in Figure 2.

The expression level of the 18 genes was compared to water control treatment, and it was defined as fold-stimulation over the control according to these analysis times, as shown in Figures 3 and 4. In general, the shortest time from the treatment of 0.5 h had no significant effects across these data (except where specified below).

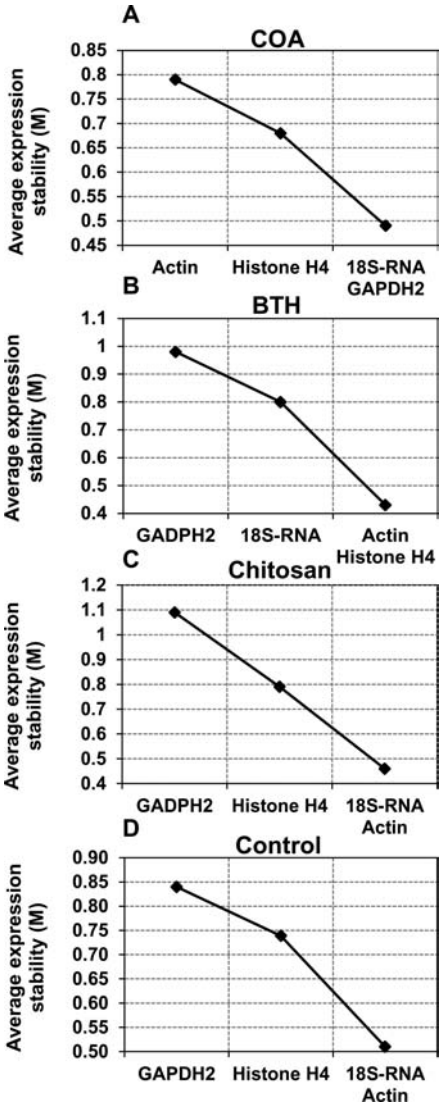

Figure 1. Stability of the reference genes in strawberry fruit. Stability value (*M*) for a set of reference genes was analyzed with the geNorm algorithm. Strawberry fruits were treated with COA (A), BTH (B), chitosan (C), and water, as the control (D). The reference genes on the *X*-axis are ranked from left to right based on their mean gene expression stability. In each panel, the genes on the right show the highest expression stability among the reference genes. See Table 1 for the names of the reference genes.

The expression levels of CDPK were increased in the strawberry fruit treated with BTH, by 2.8-fold (6 h post-treatment), 2.5-fold (24 h post-treatment), and 3.6-fold (48 h post-treatment). This gene was affected by chitosan only at 24 h post-treatment, with a 2.7-fold increase seen. There were no changes in CDPK gene expression with COA (Figure 3). For the gene encoding a K^+ channel protein, the transcript levels increased with all of the resistance inducers tested. In particular, after chitosan and COA, the K^+ channel expression increased at 6, 24, and 48 h post-treatment by 8.3-fold, 15.4-fold, and 9.7-fold, respectively, with chitosan, and 13.3-fold, 8.8-fold, and 13.4-fold, respectively, with COA. After the BTH treatment, a significant increase of the transcript was observed only after 48 h post-treatment, with an 11.4-fold increase (Figure 3).

The genes encoding for enzymes involved in the scavenging of oxygen species that were analyzed here were those of APX and GST. These showed increased gene expression with BTH at 6, 24, and 48 h post-treatment of 7.4-fold, 3.8-fold, and 1.8-fold, respectively, for APX, and of 3.2-fold, 4.9-fold, and 1.7-fold, respectively, for GST (Figure 3).

For the expression patterns of the flavonoid upstream pathway gene PAL and for the genes that are more related to biosynthesis across the different flavonoids branches, as CHS, CHI, F3H, DFR, FLS, ANS, and UFGT, different data were obtained according to the resistance inducers tested (Figure 3). The PAL gene was up-regulated at 24 and 48 h post-treatment by 4.0-fold and 4.5-fold, respectively, after chitosan treatment, and 6.1-fold and 5.0-fold, respectively, after COA treatment, with no significant changes in transcription with BTH. Conversely, CHS gene expression was enhanced only after BTH treatment, by 3.2-fold (6 h post-treatment), 2.9-fold (24 h post-treatment), and 5.6 fold (48 h post-treatment). Among the CHS downstream pathway genes, the CHI gene showed increased expression after the chitosan and BTH treatments. In particular, it increased by 7.5-fold (24 h post-treatment) and 4.9-fold (48 h post-treatment) with chitosan, and 3.5-fold (6 h post-treatment), 2.9-fold (24 h post-treatment), and 4.8-fold (48 h post-treatment) with BTH. The DFR and F3H genes were up-regulated after the BTH treatment. For DFR, the transcript levels were increased by 9.6-fold at 48 h post-treatment, while for the F3H gene, the increase was 3.2-fold at both 6 and 48 h post-treatment. For the flavonoid biosynthetic pathway, the gene showing the highest expression levels was FLS. The expression of the FLS gene increased following the treatments with each of the elicitors tested, although at different times of treatment. In particular, at 6, 24, and 48 h post-treatment, the increases were 5.2-fold, 6.7-fold, and 11.4-fold, respectively, for chitosan, and 12.8-fold, 20.4-fold, and 14.1-fold, respectively, for COA; BTH only produced a significant increase in FLS gene expression at 48 h post-treatment of 4.3-fold (Figure 3). For the ANS gene, which leads to anthocyanin and proanthocyanidin synthesis, the only significant increases in gene expression were seen for the chitosan treatment: 8.9-fold (6 h post-treatment), 7.4-fold (24 h post-treatment), and 12.6-fold (48 h post-treatment). UFGT gene expression was increased after BTH treatment, by 2.6-fold (6 h post-treatment), 3.2-fold (24 h post-treatment), and 2.0-fold (48 h post-treatment), while with COA it increased by 2.5-fold at 6 h post-treatment and 3.0-fold at 24 h post-treatment. No significant increase in UFGT transcript induction was seen after the chitosan treatment (Figure 3).

According to the cell wall degrading enzymes (Figure 4), for PG gene expression, there was a similar pattern across all of these resistance inducers, with a significant increase at 6 h post-treatment, which was lost at 24 h post-treatment but returned again at 48 h post-treatment. In particular, at 6 and 48 h post-treatment there were 3.8-fold and 5.6-fold increases, respectively, with chitosan, 7.2-fold and 7.4-fold, respectively, with COA, and 4.7-fold and 14.1-fold, respectively, with BTH; COA also showed significant up-regulation of the PG transcript at 24 h post-treatment of 2.5-fold. However, the PGIP transcripts showed an inverted pattern of expression compared to that of the PG gene, with maximum gene expression at 24 h post-treatment using all of the elicitors. Here, significant gene up-regulation was seen at 0.5, 6, 24, and 48 h post-treatment with the chitosan and COA treatments, as 2.9-fold, 3.7-fold, 3.9-fold, and 3.4-fold, and as 3.1-fold, 5.9-fold, 8.7-fold, and 3.7-fold, respectively. With BTH, PGIP gene expression was only significantly increased at 6 and 24 h post-treatment, by 4.4-fold

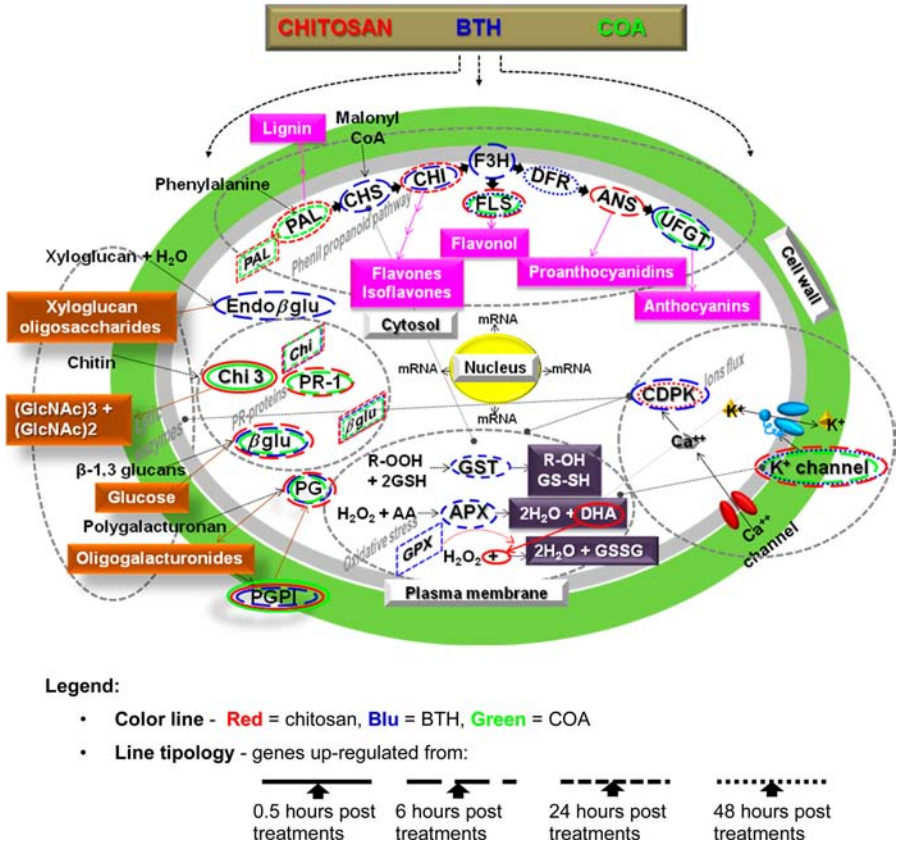

Figure 2. Gene expression and enzyme activity involved in resistance induced by chitosan, COA, and BTH (see legend). The metabolic roles of both the genes and enzymes analyzed are shown. Genes associated with ion fluxes, CDPK, the K^+ channel; genes associated with oxidative stress, GST, APX; genes associated with secondary metabolism, such as phenylpropanoid, PAL, CHS, CHI, F3H, FLS, DFR, ANS, and UFGT; genes associated with cell-wall degradation enzymes, endoβgluc, PG, and PGPI, some of which are known as PR proteins, as βglu, Chi3, and with the addition of the PR-1 protein. The up-regulation of genes by the resistance inducers and post-treatment times are shown with circular lines surrounding the abbreviated gene names, with different colors and typologies (see legend). The metabolic reactions of the analyzed enzyme activities are also shown: GPX, PAL, Chi, and βglu, surrounded by square lines (see legend).

and 3.3-fold, respectively. The βGlu gene expression was significantly increased with all of the resistance inducers tested. Starting from 6 h post-treatment, with chitosan there was a consistent increase through 24 and 48 h post-treatment, of 16.7-fold, 16.2-fold, and 21.3-fold, respectively. For BTH and COA, while remaining significantly increased, at 24 h post-treatment the effects were reduced, with increased βGlu gene expression at 6, 24, and 48 h post-treatment of 10.3-fold, 2.9-fold, and 16.6-fold, respectively, for BTH, and 14.4-fold, 4.5-fold, and 10.3-fold, respectively, for COA. The other two genes involved on plant-cell degradation, as those for endoβGlu and Chi3, showed different results again. endoβGlu gene expression was only significantly increased with BTH treatment, by 5.4-fold (6 h post-treatment), 5.8-fold (24 h post-treatment), and 12.9-fold (48 h post-treatment). Conversely, Chi3 gene expression was significantly increased only after chitosan and COA, showing increases at 0.5, 6, 24, and 48 h post-treatment of 2.7-fold, 13.6-fold, 13.6-fold, and 22.0-fold, respectively, for chitosan, and 1.4-fold, 9.4-fold, 8.6-fold, and 5.5-fold, respectively, for COA.

As for Chi3, expression of the gene coding for PR protein-1 (PR-1) was only significantly increased with chitosan and COA (Figure 4). After chitosan treatment, the PR-1 transcript levels were significantly increased at 6, 24, and 48 h post-treatment, by 7.6-fold, 13.0-fold, and 23.1-fold, respectively. The different effects with COA showed the increased PR-1 transcript level at 6, 24, and 48 h post-treatment of 17.8-fold, 9.7-fold, and 5.1-fold, respectively.

The relationships between the paired resistance inducers and these gene responses were then calculated with respect to the numbers of genes showing the same response (unvaried, up-regulated, or down-regulated) of the total set of 18 genes analyzed. The highest similitude level was seen at 0.5 h post-treatment, as at this time, a few of the genes showed some changes with the elicitors: chitosan/COA, 100%; BTH/chitosan, 88%; and BTH/COA, 88%. The similitude levels across these elicitors then differed substantially at 6, 24, and 48 h post-treatment. In particular, the paired chitosan/COA gene expression similarity was the greatest, at 88%, 72%, and 88%, respectively, with BTH/chitosan at 33%, 38%, and 28%, respectively, and BTH/COA, at 38%, 33%, and 27%, respectively (Figure 5).

Effects of Three Resistance Inducers on Enzyme Activity. For strawberry fruits, the PAL, βGlu, Chi, and GPX enzymatic activities were also assayed following the 30-s chitosan, COA, and BTH treatments, at 0.5, 6, 24, and 48 h post-treatment (Figure 6).

The control PAL activity (12.4−15.58 U mg^{-1} protein) increased after chitosan and COA treatments only. In particular, for chitosan treatment, PAL activity was significantly increased at 24 and 48 h post-treatment, by 11.8 units mg^{-1} protein (1.9-fold) and 17.9 U mg^{-1} protein (2.1-fold),

dx.doi.org/10.1021/jf404423x | J. Agric. Food Chem. 2014, 62, 3047−3056

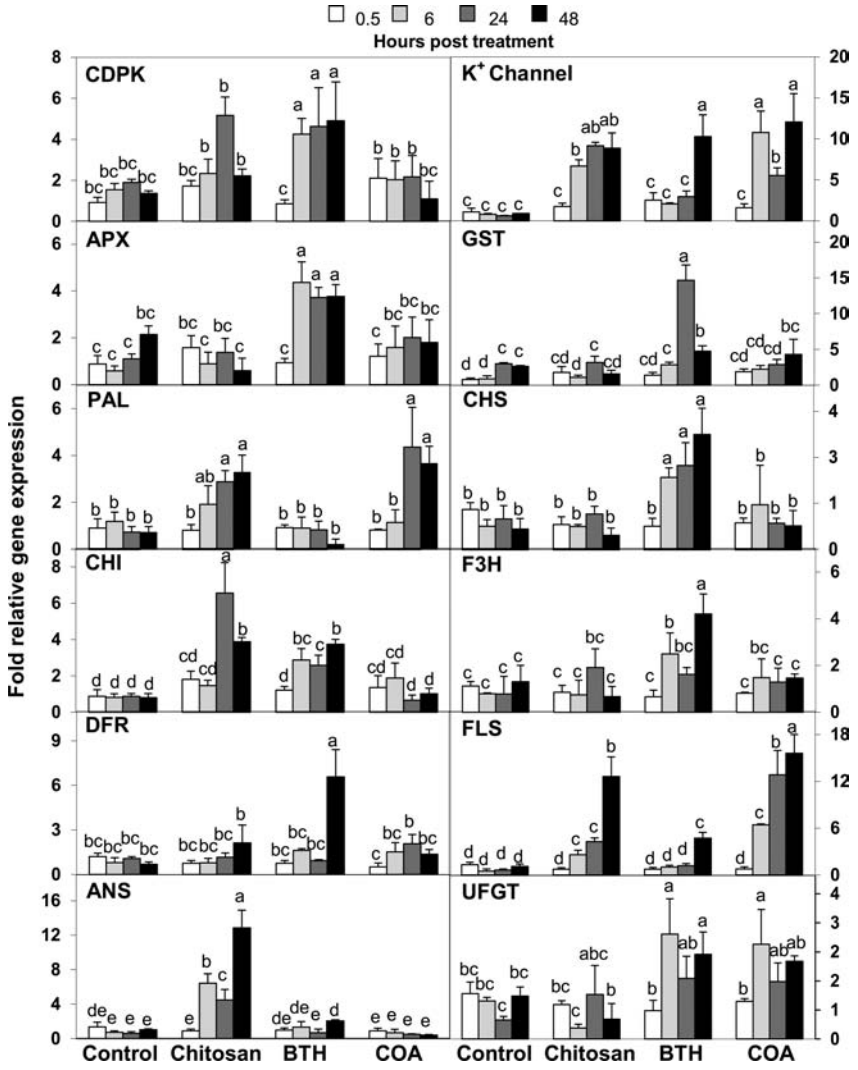

Figure 3. Relative gene expression of defense genes in strawberry fruit after treatment with resistance inducers. Strawberry fruits were treated with chitosan, BTH, and COA, and with water as the control. The relative gene expression of the defense genes (as indicated) is referred to as 0.5, 6, 24, and 48 h post-treatment. Data are the means + SD, and values with the same letter are not statistically different, according to Duncan's multiple range test, at $P \leq 0.05$. See Table 1 for the names of the genes.

respectively. Similarly, for COA treatment, the increases were 9.1 U mg^{-1} protein (1.7-fold) and 12.9 U mg^{-1} protein (1.8-fold), respectively.

The control βGlu activity (2.2−3.2 U mg^{-1} protein) increased with all of the inducers. For both chitosan and COA, this was significant at 24 and 48 h post-treatment, with 1.9 U mg^{-1} protein (1.7-fold) and 1.8 U mg^{-1} protein (1.6-fold) increases, respectively, for chitosan and 4.8 U mg^{-1} protein (2.7-fold) and 4.5 U mg^{-1} protein (2.4-fold) increases, respectively, for COA. With BTH, the βGlu activity was increased only at 48 h post-treatment by 5.6 U mg^{-1} protein (2.8-fold).

The control total Chi activity (0.9−1.4 U mg^{-1} protein) also increased with all of the elicitors tested. At 24 and 48 h post-treatment, these increases in Chi activity were of 0.8 U mg^{-1} protein (1.8-fold) and 1.8 U mg^{-1} protein (2.9-fold), after chitosan treatment, 1.4 U mg^{-1} protein (2.4-fold) and 1.6 U mg^{-1} protein (2.7-fold), with COA, and only at 48 h post-treatment of 2.7 U mg^{-1} protein (3.0-fold), with BTH.

For the control GPX activity (10.1−16.0 U mg^{-1} protein), this was significantly increased only after BTH treatment at 6 and 24 h post-treatment by 5.4 U mg^{-1} protein (1.4-fold) and 14.2 U mg^{-1} protein (2.4-fold), respectively.

DISCUSSION

The ability to quickly induce defense mechanisms is a characteristic of incompatible (resistant) plant−pathogen interactions, whereby the plant can efficiently block pathogen penetration. The application of resistance inducers promotes increases in the potential immunity of susceptible plants and allows the plants to combat possible future pathogen infections. In the present study, we investigated the gene expression of selected markers associated with defense mechanisms of strawberry fruits exposed to resistance inducers.

This study determined the relationships between the different resistance inducers of BTH, chitosan, and COA that have been shown to be effective in the control of post-harvest diseases of strawberry[4] and 18 defense-related genes that are associated with different biological processes. With this aim, we set up an analytical protocol based on RT-qPCR, and we defined the appropriate reference genes for the strawberry fruits under elicitor stress conditions. It is known that the expression

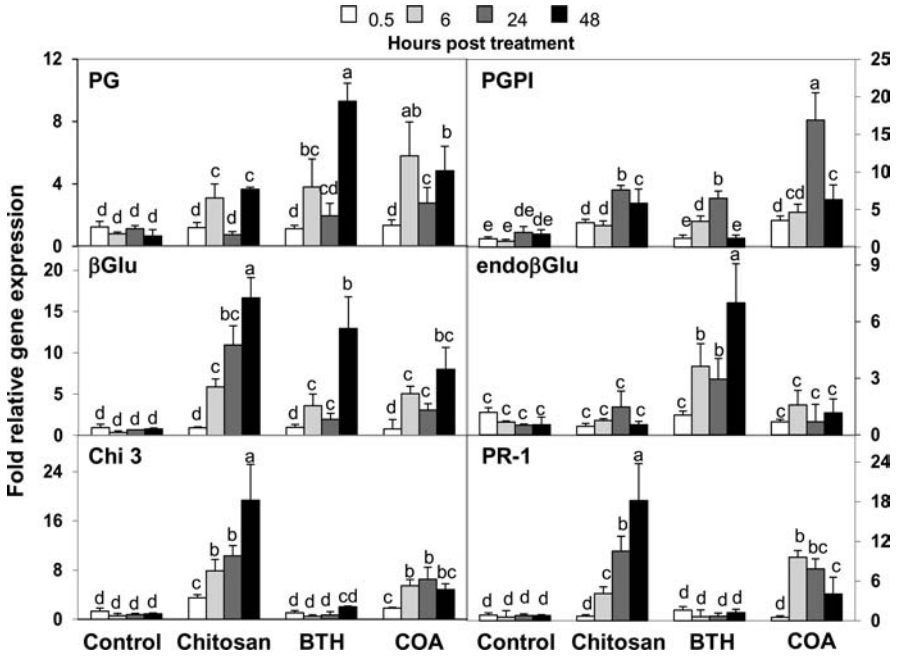

Figure 4. Relative gene expression of defense genes in strawberry fruit after treatment with resistance inducers. The strawberry fruits were treated with chitosan, BTH, and COA, and with water as the control. The relative gene expression of the defense genes (as indicated) are referred to as 0.5, 6, 24, and 48 h post-treatment. Data are the means + SD, and values with the same letter are not statistically different, according to Duncan's multiple range test, at $P \leq 0.05$. See Table 1 for the names of the genes.

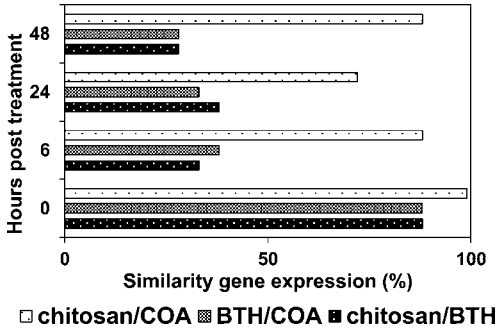

Figure 5. Relationships between the resistance inducers used and the correspondent gene responses in treated strawberry fruit. The relationships between the resistance inducers and gene responses calculated according to the numbers of genes showing the same induction response of the total genes analyzed.

stability of reference genes varies with the environment, plant growth, plant tissue, and different biotic and abiotic stress.[17] Therefore, normalization of the relative RT-qPCR data using suitable reference genes is a crucial prerequisite for obtaining reliable data. Our results showed differences between the elicitor treatments and suggested the appropriate reference gene selection for RT-qPCR analysis for new materials.

Our data show that the target genes analyzed associated with plant natural defense mechanisms are involved in different ways according to the elicitors. The earliest responses of plant cells to elicitors involve changes in membrane potential, Ca^{2+} signaling, and the production of ROS. [25] Our study shows the more constant involvement of the CDPK transcript, which is known in plants as a Ca^{2+}-binding sensor protein[26] in the strawberry fruit BTH response, with chitosan effects only seen at 24 h post-treatment in these strawberry fruits. However, although the expression of the K^+ channel was enhanced following the use of all of these elicitors, its early activation was only seen in the strawberry fruits treated with chitosan and COA; with BTH, there was only an enhancement of this gene at 48-h post-treatment. CDPKs have roles in early signal processes for multifaceted functions in the complex immune and stress signaling networks, including for oxidative burst, stomatal movements, hormonal signaling, and gene regulation.[27] In the same way, K^+ channel activation during stress is accompanied by an oxidative burst.[28] Our data suggest differences between these chitosan, COA, and BTH treatments in the activation of strawberry fruit plasma-membrane ion fluxes. This might be associated with different innate immunity signal transduction in these fruit, which might involve downstream signaling events, such as oxidative stress.[29] In this regard, the genes associated with the nonenzymatic components of the antioxidative defense system that were analyzed in this study, such as APX and GST, which can remove H_2O_2 from the cell,[30] were up-regulated in these strawberry fruits treated with BTH; likewise, the enzyme activity of GPX increased only after the BTH treatment. Our data suggest the involvement of oxidative stress in strawberry fruits treated with BTH, although we do not exclude the involvement of oxygen scavenger enzymes belonging to other biosynthetic pathways using the other elicitors, as previously hypothesized.[3,4]

Furthermore, as some of the major secondary metabolites in plants, phenolic compounds are well-known to have antioxidant properties[31] and to lead to the synthesis of phytoalexins, which are known to have antimicrobial activity.[32] In the present study, differences in the expression of the genes involved in the phenylpropanoid pathway were observed according to the elicitor used and the time from the treatment. In particular, the BTH treatment enhanced the expression of most of these genes. Some increases were apparent from 6 h post-treatment (CHS, F3H, CHI, and UFGT), while others were more delayed to 48 h post-treatment (FLS, DFR). Chitosan up-regulated

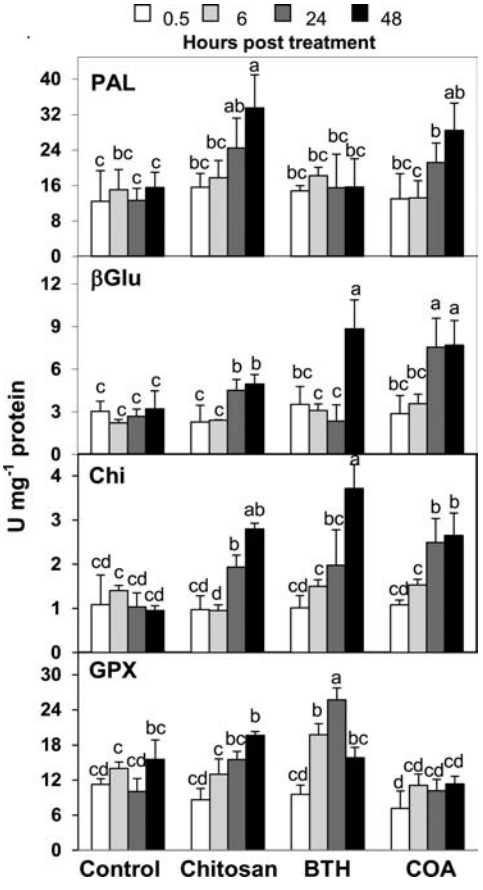

Figure 6. Enzyme activities of defense enzymes in strawberry fruits after treatment with resistance inducers. The strawberry fruits were treated with chitosan, BTH, and COA, and with water as the control. The enzyme activities (as indicated) are referred to as 0.5, 6, 24, and 48 h post-treatment. Data are the means + SD, and values with the same letter are not statistically different, according to Duncan's multiple range test, at $P \leq 0.05$.

PAL, CHI, FLS, and ANS; COA only up-regulated PAL and FLS, and usually from 6 h post-treatment. Between these genes, there was the remarkable involvement of the FLS and ANS genes, which encode the main enzymes that lead to the flux of anthocyanin and proanthocyanidin synthesis.[33] Interestingly, the PAL gene, which is pivotal for the phenylpropanoid pathway that includes, among others, the lignin branch pathway[34] was enhanced only in strawberry fruit treated with the chitosan and COA elicitors, while the downstream gene CHS, which is the key enzyme of flavonoid synthesis[35,36] was up-regulated in the strawberry fruit treated with the BTH elicitor.

Although our data suggest the prevalent involvement of flavonoid branches relative to all of the elicitors, the involvement of other pathway branches for lignin synthesis can be proposed as among the effects of the chitosan and COA treatments. The analysis of the PAL enzyme activity confirmed these PAL gene expression data.

Genes involved in cell-wall-modifying processes, such as PG, PGIP, and endoβGlu were also analyzed. Here, their expression patterns provided evidence for the synchronized expression of PG and PGIP according to all of the elicitors analyzed. In particular, the complementary gene expressions of the PG and PGPI transcripts with time could suggest a feedback mechanism, where PGPI gene expression is modulated in response to plant PG gene expression. PG is involved in pectin metabolism in the production of oligogalacturonides, which can elicit different cellular responses during plant−pathogen interactions in strawberry fruit.[37] The PGIPs that have roles in strawberry defense[38] are extracellular plant proteins that can inhibit fungal endopolygalacturonases, while endoβGlu acts on hemicellulose degradation.[39] Differences between the resistance inducers were seen for endoβGlu gene expression, which was only affected by BTH treatment. The role of this enzyme in plant defense is still unknown, although it is clear that also in this case, the elicitor typology affected the gene expression.

However, the βGlu and Chi enzymes that are involved in cell-wall degradation are those most frequently analyzed in terms of these plant−elicitor interactions.[3] βGlu, which is also a PR-2 protein,[13] showed both early gene expression and enzyme activity enhancement with all of the tested elicitors. This emphasizes the wide involvement of some structural genes in immune responses. However, related to the Chi group, our study shows Chi3 (PR-8 family) up-regulation by the chitosan and COA elicitors but not by BTH, while the total Chi enzyme activity was up-regulated with all of the elicitors tested. Our data thus indicate that there are roles for other classes of Chi following BTH treatment. The differences observed associated with Chi3 as well as in the PR-1 gene expression might be related to the elicitor-specific induction of these PR proteins in strawberry fruit and to the relationships between elicitors doses and the plant species.[13] Our study shows different levels of involvement of these genes that are associated with plant defense that depends on the resistance inducer applied. Usually, gene activation was apparent from 6 h post-treatment. Only the PGPI and Chi3 genes were up-regulated at the first time point of 0.5 h post-treatment and only when using the chitosan and COA elicitors. In this regard, starting from 6 h post-treatment, the highest similarities in the changes in gene expression were seen between the commercial formulations of chitosan and COA (>70%), compared to the similarities between BTH and both chitosan and COA (both <40%). Microarray analysis of *Arabidopsis thaliana* in response to treatment with chitin showed 43% similarity with the genes that are up-regulated by salicylic acid treatment,[40] and BTH is a light-resistant form of this SAR signaling compound. Thus, a similar level of similarity is seen in the present study in terms of the relationship between the gene expression responses of strawberry fruit treated with chitosan, which is the N-deacetylated form of chitin, and BTH, which is, as indicated, an analogue of salicylic acid. This suggests that the expression of these defense genes occurs according to the nature of the elicitor.

In investigating the possible similarities between the actions of these resistance inducers, both chitosan and COA provide a protective physical barrier to pathogen invasion, although in different ways. Chitosan forms a surface coating on the fruit, while COA uses calcium to reinforce the structural composition of the plant cell wall, through the binding of pectins with salts.[4,11] Instead, as an analogue of salicylic acid, BTH is known to primarily induce the expression of SAR without interactions with the plant cell wall.

In conclusion, in this study we set up the relevant RT-qPCR method to test for different gene expressions in strawberry fruits treated with different resistance inducers. Our data show different suitable combinations for reference genes according to the resistance inducer, also indicating the importance of the validation of the reference genes before the experiments. In this study, all of the resistance inducers analyzed had previously

been shown to reduce both gray mold and Rhizopus rot disease in postharvest strawberry fruit,[4] and here, they triggered the expression of a large number of genes that lead to the physiological events involved in plant defense. This supports the effectiveness of these compounds for the induction of resistance in strawberry fruit. However, there were differences between the elicitor resistance at both the transcriptional level of the genes analyzed and the enzyme activities of some of their products that were observed at different times from treatments. This suggests that there is a similarity between chitosan and COA in their target defense gene activation, while their gene responses differ from those due to BTH. This study thus indicates that the composition of the resistance inducers and their interaction with the host plant determine the pattern of induction of the specific defense-marker genes. Information gained with this study can be useful to choose proper resistance inducers for gray mold management.

and identify the metabolizing enzymes responsible for its hydrolysis.

MATERIALS AND METHODS

Chemicals and Reagents. Flucetosulfuron Technical (purity, 98.4%) was provided by LG Life Sciences Ltd. (Daejeon, Korea). Pooled HLMs were purchased from BD Gentest (Woburn, MA). Glucose-6-phosphate, glucose-6-phosphate dehydrogenase, and nicotinamide adenine dinucleotide ($NADP^+$) were purchased from Sigma-Aldrich (St. Louis, MO). Various esterase inhibitors, such as bisnitrophenyl phosphate (BNPP), calcium chloride, cobalt chloride, dibucaine, ethylenediaminetriacetic acid (EDTA), eserine, magnesium chloride, mercuric chloride, and quinidine, were also purchased from Sigma-Aldrich (St. Louis, MO).

Potassium phosphate monobasic/dibasic and sodium hydroxide (NaOH) were purchased from Daejung Chem (Ansan, Korea). The solvents were high-performance liquid chromatography (HPLC) grade (Burdick and Jacson, MI), and the other chemicals were of the highest quality available.

Preparation of *threo*-Flucetosulfuron. Flucetosulfuron (0.03 g) was dissolved in acetonitrile (10 mL) and injected into a Waters Delta Prep-4000 preparative chromatography system equipped with a Waters deltapak column (50 mm i.d. × 300 mm, 15 μm, 100 A). An isocratic mobile phase was used where A:B = 64:36 at a flow rate of 20.0 mL/min for 120 min (A, buffer solution with 0.02 M ammonium acetate; B, 0.1 M acetic acid). The first fraction (retention time of 80−90 min) was collected (150−170 mL) and partitioned twice with 70 mL of dichloromethane. The dichloromethane layer was washed with 100 mL of distilled water, dried over 30 g of sodium sulfate, and evaporated under reduced pressure at 30 °C to obtain 2.6−4.0 mg of *threo*-flucetosulfuron from one fractionation/purification cycle. About 0.3 g of *threo*-flucetosulfuron was obtained by repeating this process several times.

Preparation of *erythro*-Flucetosulfuron. A second HPLC fraction (retention time of 94−110 min) was collected (~250 mL) and processed as described above for *threo*-flucetosulfuron, producing 23−26 mg of *erythro*-flucetosulfuron from one cycle of the fractionation/purification process. After repeating the same processes many times, about 2.0 g of *erythro*-flucetosulfuron was obtained.

Metabolism of Flucetosulfuron in HLMs. The incubation mixtures containing 0.5 mg of pooled HLMs (H161, Gentest) were reconstituted in 50 mM phosphate buffer (pH 7.4) and preincubated for 5 min at 37 °C. The reaction was initiated by adding the *threo*- or *erythro*-flucetosulfuron isomer (100 μM) and the NADPH-generating system (0.8 mM $NADP^+$, 10.0 mM glucose-6-phosphate, 1.3 mM $MgCl_2$, and 1.0 unit/mL glucose-6-phosphate dehydrogenase) and further incubated for 30 min at 37 °C in a shaking water bath. The reaction was terminated by the addition of 250 μL of acetonitrile, and the samples were centrifuged at 15000*g* for 5 min at 4 °C. Control incubations were conducted with denatured HLMs, which had been boiled in water for 5 min at 100 °C. To confirm whether metabolite formation was NADPH-dependent, NADPH-free incubations were also performed.

Synthesis of *threo*-*N*-(4,6-Dimethoxypyrimidin-2-ylcarbomoyl)-2-(2-fluoro-1-hydroxy propyl)pyrimidine-3-sulfonamid (TM1). *threo*-Flucetosulfuron (149 mg, 1 equiv) was dissolved in 30 mL of acetonitrile in a round-bottom flask (100 mL), 7.5 mL of 0.1 M NaOH solution (30 mg, ~2.5 equiv) was added dropwise, and the reaction mixture was stirred for 1.5 h. The reaction mixture was then transferred to a separatory funnel (250 mL), and 20 mL of distilled water was added. The reaction mixture was washed twice with 25 mL of dichloromethane. The water layer was adjusted to pH 3.0 with 0.1 N HCl to obtain TM1 as a white solid, which was filtered, washed with distilled water, and dried under nitrogen purging for 10 h (90 mg, yield 70%).

Synthesis of *erythro*-*N*-(4,6-Dimethoxypyrimidin-2-ylcarbomoyl)-2-(2-fluoro-1-hydroxy propyl)pyrimidine-3-sulfonamid (EM1). *erythro*-Flucetosulfuron (487 mg, 1 equiv) was dissolved in 100 mL of acetonitrile in a round-bottom flask (250 mL), 25 mL of 0.1 M NaOH solution (100 mg, ~2.5 equiv) was added dropwise, and the reaction mixture was stirred for 1.5 h. The workup process was the same as described above for TM1. EM1 was obtained as a white solid (370 mg, yield 89%).

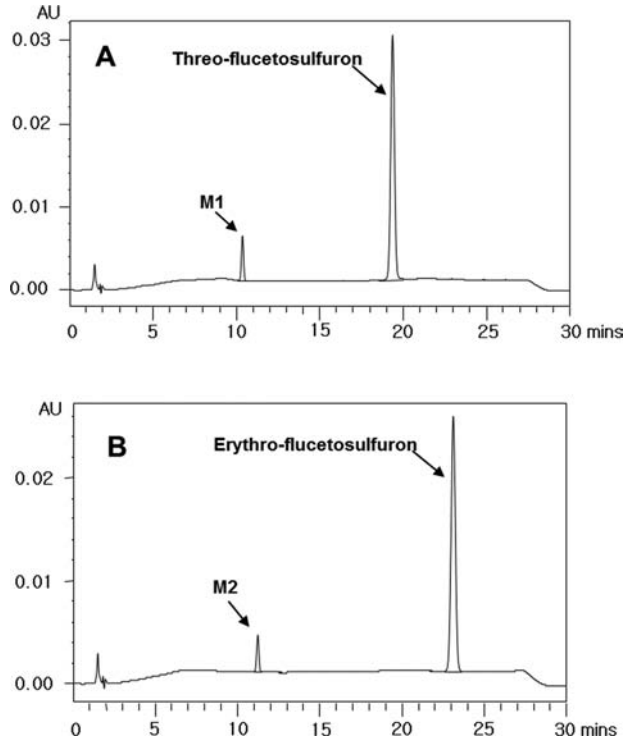

Figure 1. Formation of metabolite M1 from *threo*-flucetosulfuron (A) and M2 from *erythro*-flucetosulfuron (B) when flucetosulfurons (100 μM) were incubated with 0.125 mg human liver microsomes for 30 min at 37 °C.

Metabolite Identification. First, 2 μL of the supernatant from each metabolic reaction was analyzed using HPLC and LC-MS/MS. Again, tandem mass spectrometry (MS/MS) analysis of metabolites, TM1, EM1, and the parent flucetosulfuron isomers was conducted to compare their fragmentation patterns. Solutions of the synthesized metabolites (TM1 and EM1) were prepared in acetonitrile at 10 mg/kg level, and 20 μL of a 1:1 mixture each of TM1 and EM1 solution and the corresponding metabolic reaction supernatant was analyzed using HPLC for confirmation.

Optimization of Metabolic Conditions and Kinetic Studies. The metabolic reactions described earlier were performed with various concentrations of HLMs (0.16, 0.24, 0.32, 0.48, 0.64, 0.96, and 1.28 mg/mL) and each flucetosulfuron isomer (10, 20, 100, 200, 1000, 2000, and 10000 μM) and for 10, 20, 30, 60, 120, 180, and 240 min in a total volume of 250 μL. The incubation mixtures containing pooled HLMs were preincubated for 5 min at 37 °C. The metabolites TM1 and EM1 in the reaction mixture were determined using HPLC analysis.

Optimized conditions were used to analyze enzyme kinetics. These used an incubation time of 30 min (0.16 mg/mL HLMs) and a concentration range of each flucetosulfuron isomer (10, 20, 100, 200, 1000, 2000, and 10000 μM).

Inhibition of Metabolism by Specific Esterase Inhibitors. Incubation mixtures containing 0.16 mg/mL HLMs and one of the following esterase-selective inhibitors [BNPP (100 μM), calcium chloride (1000 μM), cobalt chloride (1000 μM), dibucaine (100 μM), EDTA (3000 μM), eserine (100 μM), magnesium chloride (1000 μM), mercuric chloride (200 μM), and quinidine (100 μM)] were preincubated for 5 min at 37 °C. The reaction was initiated by adding each flucetosulfuron isomer (100 μM) and incubating for a further 30 min at 37 °C in a shaking water bath.

The percentage inhibition was calculated using the ratio of the amount of metabolite (TM1 or EM1) formed in the presence of the

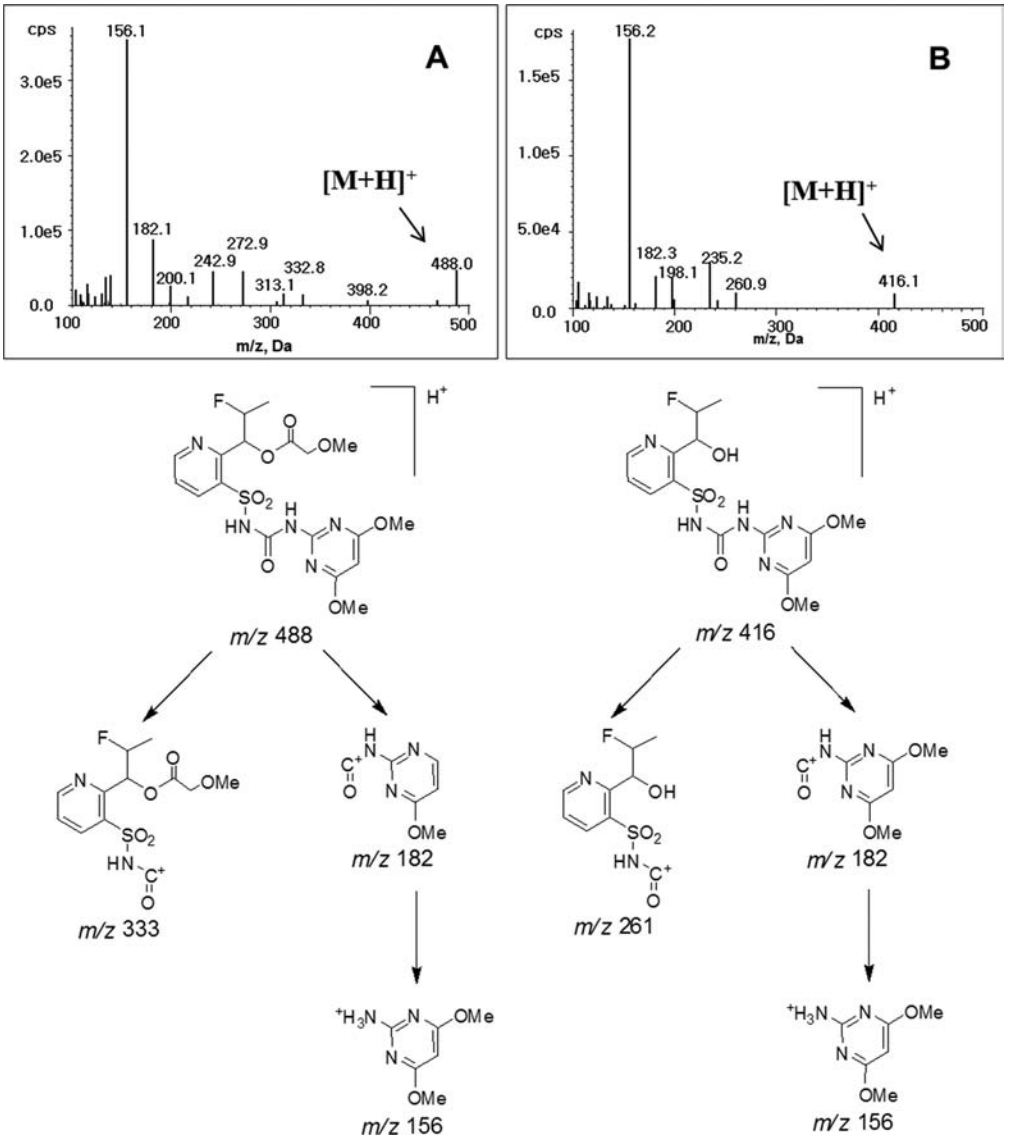

Figure 2. LC-MS/MS spectra and fragmentation of m/z 488 from flucetosulfuron ((A) $[M + H]^+$), and of m/z 416 from metabolite of *erythro* isomer ((B) $[M + H]^+$).

specific inhibitor to the amount formed under control conditions in the absence of inhibitor.

Analytical Instruments and Conditions. *HPLC.* The concentrations of flucetosulfuron isomers and metabolites (TM1 and EM1) were measured using a Waters Alliance 2690 HPLC equipped with a Capcell pak C18 UG120 column (4.6 mm i.d. × 150 mm, 3 μm; Shiseido, Tokyo, Japan) at 40 °C. The mobile phase consisted of 20 mM ammonium acetate buffer with 0.1 M acetic acid (A) and acetonitrile (B). The gradient conditions used were as follows: 20% B at 0 min, 27% B at 4 min, 30% B at 25 min, and 20% B at 28−33 min. The injection volume was 10 μL, and peaks were detected at 254 nm (UV 4890 detector; Waters, Milford, CA). Stock solutions (1 mM) were prepared by dissolving flucetosulfuron isomers, TM1, and EM1 in acetonitrile and diluting serially with acetonitrile to obtain final standard concentrations of 0.05, 0.1, 0.2, 1.0, 10, and 100 μM. The calibration curve was fitted with high linearity ($r^2 > 0.999$).

LC-MS/MS. For the identification of flucetosulfuron and its metabolites, a quadrupole MS/MS (API2000, Applied Biosystems, Foster City, CA) coupled with an Agilent 1100 series HPLC system (Agilent, Wilmington, DE) was used. The separation was performed on a Capcell pak C18 UG120 column (4.6 mm i.d. × 150 mm, 3 μm; Shiseido, Tokyo, Japan) by using a mobile phase consisting of 10 mM ammonium acetate with 0.1% formic acid (A) and acetonitrile (B) at a flow rate of 1.0 mL/min. Mass spectra were recorded by electrospray ionization in positive mode. The turbo ion spray interface was operated at 4500 V and 550 °C. The operating conditions, optimized by flow injection of analytes, were as follows: nebulizer gas flow, 50 psi; curtain gas flow, 10 psi; and collision energy, 30 eV. Quadrupole Q1 and Q3 were set on unit resolution.

Nuclear Magnetic Resonance (NMR) Analysis. ^{1}H and ^{13}C NMR spectra were recorded on a 400 MHz NMR spectrometer (Jeol JNM-LA400 with LFG, JEOL, Japan) in $CDCl_3$ (99.8%, Merck) at 297 K. TMS was used as reference ($\delta = 0$).

Data Analysis. Results are expressed as mean ± standard deviation (SD) of estimates obtained from pooled HLMs in triplicate experiments. In the microsomal incubation studies, the apparent kinetic parameters of metabolite formation (TM1 and EM1) (K_m and V_{max}) were determined by fitting a one-enzyme Michaelis−Menten equation ($V = V_{max} \times [S]/(K_m + [S])$ or a Hill equation ($V = V_{max} \times [S]^n/(K_m + [S]^n)$). The calculated parameters were the maximum rate of formation (V_{max}), the Michaelis constant (apparent K_m), intrinsic clearance (CL_{int} = V_{max}/apparent K_m), and Hill coefficient (n). Calculations were performed using Minitab 16 software (Minitab Inc., State College, PA).

RESULTS AND DISCUSSION

Preparation of Flucetosulfuron Isomers. Flucetosulfuron consists of *threo*-flucetosulfuron and *erythro*-flucetosulfuron, and these isomers could be separated using HPLC, in which *threo*-flucetosulfuron eluted before *erythro*-flucetosulfuron.[17] These two flucetosulfuron isomers were isolated using preparative HPLC and purification processes. Because one cycle of the fractionation/purification process produced only a small quantity of each isomer, the same processes were repeated many times to obtain larger amounts with high purity for use in the metabolic studies. About 0.3 g of *threo*-flucetosulfuron and 2.0 g of *erythro*-flucetosulfuron were obtained with 99.8% and 99.7% purity, respectively. LC-MS/MS analysis showed $[M + H]^+$ at m/z 488, clearly confirming the identity of both isomers.

Flucetosulfuron Metabolism by HLMs and Analysis of Metabolites. *threo*-Flucetosulfuron and *erythro*-flucetosulfuron, which were isolated using preparative HPLC, were incubated with HLMs in the presence of NADPH; one metabolite, M1, was observed in the *threo*-flucetosulfuron reaction mixture, while another metabolite, M2, was observed in the *erythro*-flucetosulfuron reaction mixture. No metabolites were formed in reactions using denatured HLMs, suggesting that these were responsible for the formation of M1 and M2 from flucetosulfuron isomers (Figure 1). However, those metabolites were not oxidation products resulting from CYP450 activity in HLMs because they were also formed in NADPH-free reactions. On LC-MS/MS analysis, M1 and M2 gave the same $[M + H]^+$ at m/z 416, indicating a cleavage reaction, rather than insertion of oxygen, when compared with the parent flucetosulfuron isomers ($[M + H]^+ = m/z$ 488). MS/MS analysis of flucetosulfuron ($[M + H]^+$ at m/z 488) in the microsomal reaction mixture showed fragment ions at m/z 156, 182, and 333 (Figure 2A), while the MS/MS spectrum of MI and M2 ($[M + H]^+ = m/z$ 416) showed fragmentation ions at m/z 156, 182, and 261 (Figure 2B). This result suggested that the metabolites were hydrolysis products, which could be formed by cleavage of the flucetosulfuron ester bond.

Identification of M1 and M2. Because LC-MS/MS analysis indicated that M1 and M2 were hydrolysis products of the parent compounds, TM1 and EM1 were prepared from each flucetosulfuron isomer by chemical hydrolysis to confirm their identity. TM1 and EM1 were synthesized with good yields, and their structures were confirmed unambiguously using LC-MS/MS ($[M + H]^+ = m/z$ 416) and ^{1}H and ^{13}C NMR as *N*-(4,6-dimethoxypyrimidin-2-ylcarbomoyl)-2-(2-fluoro-1-hydroxypropyl)pyrimidine-3-sulfonamid (Table 1 and Figure 3) Finally, by comparing LC-MS/MS and MS/MS fragmentation spectra and co-chromatography, M1 and M2 were identified as TM1 and EM1, respectively. Although various studies of pesticide metabolism by HLMs showed that NADPH-dependent oxidation by CYP450s was a major metabolic pathway,[8,10,18−21] only a hydrolysis product was formed in the present study. Hydrolytic metabolism of sulfonylureas has only been reported in soil and water to date.[7−15]

Liver microsomes are a rich source of enzymes, such as CYP450s, FMOs, carboxylesterases, reductases (azo-, carbonyl, and quinone), and aldehyde dehydrogenases for phase I

reactions,[22] and these results indicated the involvement of hydrolysis enzymes in HLM-mediated metabolism of flucetosulfuron.

Enzyme kinetics to establish the optimal metabolic transformation of flucetosulfuron by HLMs, protein (HLMs) concentration, substrate (each flucetosulfuron isomer) concentration, and incubation time were optimized, resulting in the use of 100 μM of each isoform of flucetosulfuron, 0.16 mg/mL of HLMs, and 30 min incubations. Under these optimized metabolic conditions, the formation pattern of TM1 and EM1 from each flucetosulfuron isomer by HLMs was best fitted to a Michaelis−Menten equation ($V = V_{max} \times [S]/(K_m + [S])$), while the Hill model and two-enzyme model did not significantly improve the regression (Figure 4). No significant difference was observed in V_{max} and K_m values for the formation of TM1 and EM1 from *threo*- and *erythro*-flucetosulfuron, respectively (Table 2). The CL_{int} values of TM1 and EM1 were 51.2 and 48.0 μL/min/mg protein for *threo*-flucetosulfuron and *erythro*-flucetosulfuron, respectively. In this study, there was no difference in the kinetics of TM1 and EM1 formation, while previous metabolic studies of endosulfan (α-, β-) showed stereoselectivity by CYP450s and permethrin (*cis*-, *trans*-) showed stereoselectivity of carboxylesterases.[8,16]

Identification of Esterases Involved in the Hydrolysis of Flucetosulfuron. Because the metabolites were formed through ester bond cleavage and the major xenobiotic metabolizing esterases include A-esterases (paraoxonases/arylesterases), cholinesterases, and carboxyesterases,[21] identification of the esterase responsible for hydrolysis was performed through an

inhibition study with class-specific esterase inhibitors[23] (Table 3). The concentration of each inhibitor was adopted from previous studies of their inhibitory effects on their target esterases. Addition of Hg^{2+} into the metabolic mixture significantly inhibited the production of TM1 and EM1, suggesting that arylesterases,[24] carboxylesterases,[21,25] and cholinesterases[26] were involved. However, treatment with an activator (Ca^{2+}) or inhibitor (Mg^{2+}, Co^{2+}, and EDTA) for A-esterases[27] did not produce any significant effect on metabolite formation, indicating that flucetosulfuron-metabolizing enzymes were not A-esterases.[28,29] The specific carboxylesterase inhibitor, BNPP,[21,30,31] produced almost complete suppression (>80%) of metabolite formation, and addition of eserine,[23,32] dibucaine, and quinidine, which are specific cholinesterase inhibitors, also reduced metabolite formation. These results indicated that the formation of TM1 and EM1 must be mediated by microsomal carboxylesterases and cholinesterases. Such hydrolytic reactions by carboxylesterases were reported with organophosphate pesticides,[33] pyrethroids,[14,16] and pyribenzoxim.[21] Although cholinesterase-mediated pesticide hydrolysis has not been reported, cocaine and heroin were hydrolyzed by both carboxylesterase and cholinesterase.[34,35]

In conclusion, the primary metabolic pathway for flucetosulfuron in HLMs involved hydrolysis, producing TM1 and EM1. The esterase-specific inhibition study showed that carboxylesterases and cholinesterases were responsible for the formation of these metabolites. Metabolite formation kinetics did not show any significant difference between *threo*- and *erythro*-isomers. On the basis of these findings, a metabolic pathway for both flucetosulfuron isomers was proposed (Figure 5).

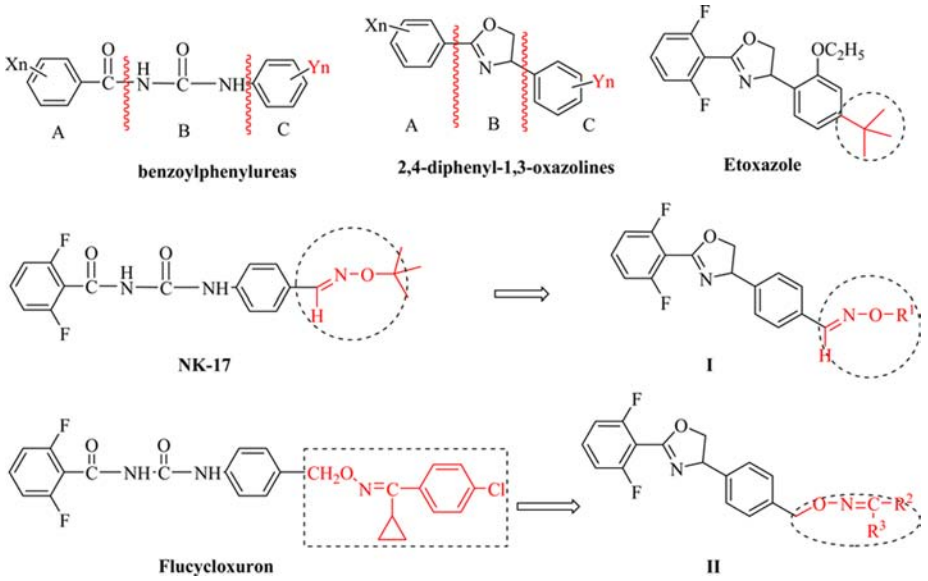

Figure 1. Design of the target compounds **I** and **II**.

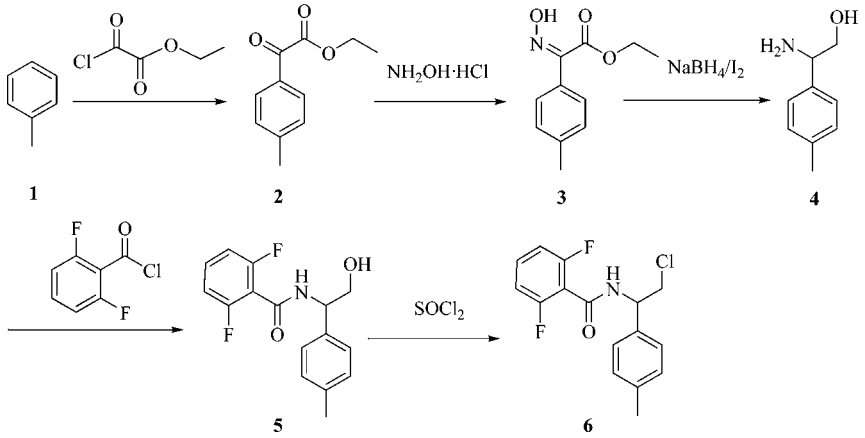
Scheme 1. Synthetic Route of 6



group at the 4-phenyl moiety of 2,4-diphenyl-1,3-oxazoline were designed by referring to benzoylphenylurea NK-17, which was discovered by our research group and showed excellent larvicidal activity.[3] Similarly, another series of compounds **II** were designed by referring to the commercial benzoylphenylurea flucycloxuron which was created by Solvay-Duphar B.V. as a CSI and also contained an oxime ether group.[14] The acaricidal activity of all the target compounds (**I-a**−**I-l** and **II-a**−**II-n**) against *T. cinnabarinus* was assayed in the laboratory. Furthermore, the effects of the **II-l** on *T. cinnabarinus* and *Panonychus citri* (*P. citri*) were evaluated in the field.

In 2004, diflubenzuron, a CSI belonging to benzoyphenylurea, was testified to act on the target site of sulfonylurea receptor (SUR) protein by means of the isotope labeling technology,[15] and later the mechanism of NK-17 was also proposed to bind to the same site of SUR by fluorescence polarization (FP) method in our previous report.[16] Since numerous experimental data had indicated that the action mechanism of etoxazole was similar to that of the benzoylphenylureas, we would like to know if etoxazole and the target compounds (**I-a**−**I-l** and **II-a**−**II-n**) that we synthesized in this paper can also bind to the same site of SUR. To raise awareness to the mode of action of the target compounds and help to discover some superior compounds, in this paper, we preliminarily determined the affinity activity of all the target compounds binding to the SUR in vitro by FP method, and the results were discussed.

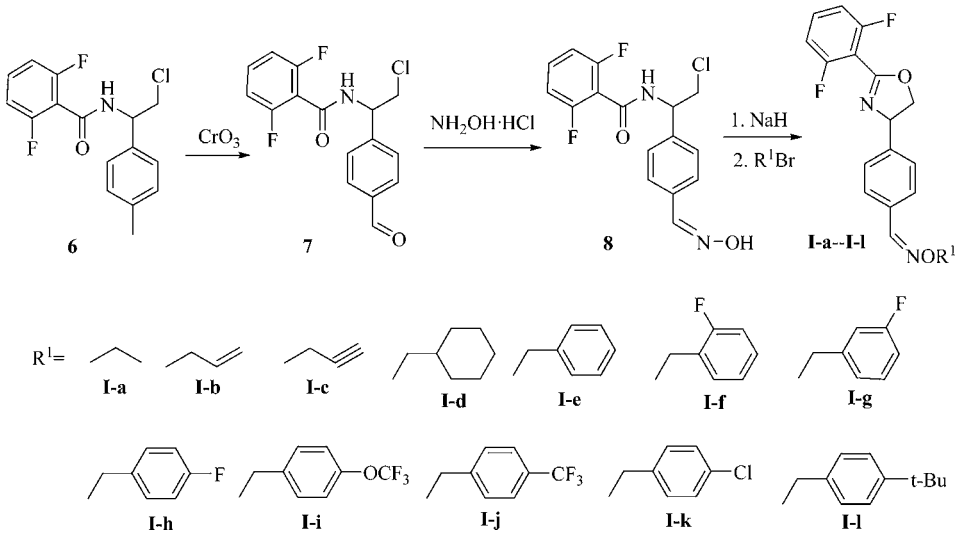
MATERIALS AND METHODS

Instruments and Chemicals. ^{1}H NMR spectra were recorded at 300 or 400 MHz by respectively using a Bruker AV300 spectrometer or a Bruker AV400 spectrometer with $CDCl_3$ or DMSO-d_6 as solvent and tetramethylsilane as the internal standard. Chemical shift values (δ) are reported in parts per million (ppm). High-resolution mass spectrometry (HRMS) was obtained by means of FTICR-MS (Ionspec 7.0T). The melting points were obtained utilizing an X-4 binocular microscope melting point apparatus (Beijing Tech Instruments Co., Beijing, China) and are uncorrected. Yields were not optimized. The values of the FP were obtained by CARY eclipse fluorescence spectrophotometer (Agilent Technologies, Santa Clara, CA, USA). All of the reaction reagents were analytically or chemically pure, which were dried and distilled according to standard methods before use when necessary. All other biochemical reagents used in the FP determination were of the highest purity grade from Sigma-Aldrich Chemical Co., Ltd.

General Synthetic Procedure for Compound 6 (Scheme 1). *Synthesis of Ethyl 2-p-Tolyl-2-oxoacetate (2).* To a solution of ethyl chloroglyoxylate (4.5 g, 33 mmol) in anhydrous dichloromethane (50 mL) was added anhydrous $AlCl_3$ (4.40 g, 33 mmol), and the mixture

dx.doi.org/10.1021/jf500461a | J. Agric. Food Chem. 2014, 62, 3064−3072

Scheme 2. General Synthetic Route of the Target Compounds I-a−I-l



was stirred at room temperature until $AlCl_3$ was dissolved. The mixture was cooled to −10 °C, toluene (2.76 g, 30 mmol) in dichloromethane (50 mL) was added dropwise over a period of 2 h, and then the reaction mixture was stirred at room temperature for another 5 h until the reaction was complete, indicated by TLC. The mixture was poured to ice−water (80 mL), and the value of the pH was adjusted to 2. After the organic phase was separated, the aqueous phase was extracted with dichloromethane. The combined organic phase was washed with saturated brine, dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo to give **2** as a yellow liquid (5.08 g, yield 88%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.91 (d, J = 8.0 Hz, 2H), 7.31 (d, J = 8.0 Hz, 2H), 4.45 (q, J = 7.2 Hz, 2H), 2.45 (s, 3H), 1.42 (t, J = 7.2 Hz, 3H).

*Synthesis of Ethyl 2-(Hydroxyimino)-2-(p-tolyl)acetate (**3**).* To a solution of **2** (86.21 g, 450 mmol) in ethanol (400 mL) was added hydroxylamine hydrochloride (52.98 g, 760 mmol), and the mixture was refluxed for 8 h and monitored by TLC. After removal of ethanol, the solid residue obtained was redissolved in ethyl acetate. The mixture was washed twice with water, dried with anhydrous sodium sulfate, filtered, and concentrated in vacuo to give a crude product, which was purified by recrystallization using carbon tetrachloride and petroleum ether to give **3** (45.80 g). The mother liquid was purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 20:1, 10:1) to give another portion of **3** (21.5 g). Overall yield: 72%. Mp: 116−117 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.65 (s, 1H), 7.42 (d, J = 8.1 Hz, 2H), 7.25 (d, J = 8.1 Hz, 2H), 4.35 (q, J = 7.2 Hz, 2H), 2.39 (s, 3H), 1.36 (t, J = 7.2 Hz, 3H).

*Synthesis of 2-Amino-2-(p-tolyl)ethanol (**4**).* To a solution of compound **3** (25.25 g, 120 mmol) in anhydrous tetrahydrofuran (200 mL) under stirring was added sodium borohydride (13.83 g, 370 mmol). Iodine (46.37 g, 180 mmol) in THF (180 mL) was added dropwise over a period of 6.5 h at 0 °C. Afterward, the reaction mixture was refluxed for 5 h. The excess reducing agent was quenched with methanol at 0 °C, and then the solvent was removed. After the residue was added to a solution of 5% sodium hydroxide in water, the mixture was refluxed for 5 h. When it was complete, indicated by TLC, the reaction mixture was cooled to room temperature and extracted by dichloromethane. Then, the organic layer was dried by sodium sulfate, filtered, and concentrated to give **4** as a yellow solid (17.45 g, yield 94%). Mp: 68−70 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.22 (d, J = 8.0 Hz, 2H), 7.16 (d, J = 8.0 Hz, 2H), 4.01 (dd, J = 8.4, 4.4 Hz, 1H), 3.72 (dd, J = 10.8, 4.4 Hz, 1H), 3.53 (dd, J = 10.8, 8.4 Hz, 1H), 2.34 (s, 3H).

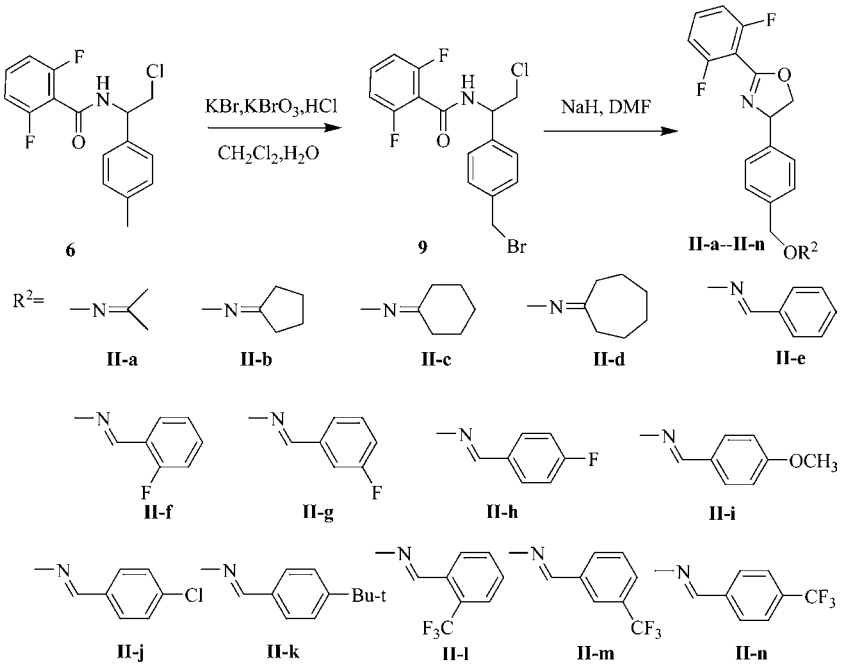
*Synthesis of 2,6-Difluoro-N-(2-hydroxy-1-(p-tolyl)ethyl)-benzamide (**5**).* To a mixture of **4** (5.0 g, 33 mmol) and triethylamine (5.51 g, 40 mmol) in anhydrous tetrahydrofuran (70 mL) at 0 °C was added dropwise a solution of 2,6-difluorobenzoyl chloride (6.14 g, 35 mmol) in tetrahydrofuran (60 mL) over a period of 2.5 h, and then the reaction mixture was warmed to room temperature for 5 h until the reaction was complete. The mixture was filtered, concentrated, and purified by recrystallization using ethyl acetate and petroleum ether to give **5** as a solid (4.57 g). The mother liquid was concentrated and purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 2:1) to give another portion of **5** (2.89 g). Overall yield: 77%. Mp: 125−127 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.43−7.35 (m, 1H), 7.28 (d, J = 8.0 Hz, 2H), 7.20 (d, J = 8.0 Hz, 2H), 6.97 (t, J = 8.0 Hz, 2H), 6.55 (d, J = 6.8 Hz, 1H), 5.55 (dd, J = 12.8, 5.2 Hz, 1H), 4.02−3.91 (m, 2H), 2.35 (s, 3H).

*Synthesis of N-(2-Chloro-1-(p-tolyl)ethyl)-2,6-difluorobenzamide (**6**).* To a solution of **5** (41.7 g, 140 mmol) in chloroform (120 mL) was added dropwise thionyl chloride (19.59 g, 165 mmol) in chloroform (60 mL) over a period of 70 min. The reaction mixture was refluxed for 100 min until the reaction was complete. After the value of the pH of the mixture was adjusted to 8 with saturated sodium bicarbonate solution, the organic phase was separated, washed with saturated brine, dried with magnesium sulfate, filtered and concentrated to give **6** as a white solid (41.7 g, yield 94%). Mp: 62−63 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ 7.44−7.37 (m, 1H), 7.29 (d, J = 8.1 Hz, 2H), 7.21 (d, J = 8.1 Hz, 2H), 6.97 (t, J = 8.1 Hz, 2H), 6.53 (d, J = 6.0 Hz, 1H), 5.56 (dd, J = 12.9, 5.1 Hz, 1H), 4.03−3.91 (m, 2H), 2.36 (s, 3H).

General Synthetic Procedure for the Target Compounds I-a−I-l (Scheme 2). *Synthesis of N-(2-Chloro-1-(4-formylphenyl)-ethyl)-2,6-difluorobenzamide (**7**).* To a solution of **6** (10.0 g, 32 mmol) in glacial acetic acid (60 mL) was added dropwise concentrated sulfuric acid (7 mL) over a period of 1 h at the temperature range of −10 °C to −5 °C. Then powdered CrO_3 was added, after which the reaction mixture was stirred for 6 h. The reaction mixture was poured to ice−water (300 mL) and extracted by ethyl acetate (100 mL × 5). The combined organic phase was successively washed with water, saturated sodium bicarbonate, and saturated brine and dried with anhydrous magnesium sulfate. After filtration, the solvent was removed under reduced pressure to give a crude black residue. The residue was added to a mixture of methanol (30 mL) and concentrated hydrochloric acid (10 mL), and then the reaction was stirred under tepidity for 5 h. The reaction mixture was cooled to room temperature, concentrated under reduced pressure, and then extracted by ethyl acetate (50 mL × 3). The organic layer was washed with saturated sodium bicarbonate solution and saturated brine successively, dried with anhydrous magnesium sulfate, filtered and concentrated under reduced pressure. The residue was purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 3:1) to give **7** as a yellow oil (4.1 g, yield 41%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 10.03 (s, 1H), 7.93 (d, J = 8.4 Hz, 2H), 7.59 (d, J = 8.4 Hz, 2H), 7.47−

dx.doi.org/10.1021/jf500461a | J. Agric. Food Chem. 2014, 62, 3064−3072

Scheme 3. General Synthetic Route of the Target Compounds II-a−II-n



7.40 (m, 1H), 7.00 (t, J = 8.4 Hz, 2H), 6.73 (d, J = 7.6 Hz, 1H), 5.71−5.67 (m, 1H), 4.05 (dd, J = 11.6, 4.4 Hz, 1H), 3.97 (dd, J = 11.6, 4.4 Hz, 1H).

*Synthesis of N-(2-Chloro-1-(4-((hydroxyimino)methyl)phenyl)-ethyl)-2,6-difluorobenzamide (**8**).* To a mixture of **7** (2.43 g, 8 mmol), triethylamine (1.90 g, 19 mmol), and hydroxylamine hydrochloride (1.30 g, 19 mmol) in anhydrous tetrahydrofuran (50 mL) were added molecular sieves (4 Å), and then the mixture was refluxed for 4 h and monitored with TLC. After the reaction was complete, the mixture was filtered to remove molecular sieves, concentrated in vacuo, and purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 3:1) to give **8** as a white solid (1.93 g, yield 76%). ^{1}H NMR (400 MHz, DMSO-d_6): δ 11.26 (s, 1H), 9.47 (d, J = 8.4 Hz, 1H), 8.14 (s, 1H), 7.61 (d, J = 8.4 Hz, 2H), 7.61−7.57 (m, 1H), 7.49 (d, J = 8.4 Hz, 2H), 7.22−7.13 (m, 2H), 5.34−5.29 (m, 1H), 3.95 (dd, J = 11.2, 4.8 Hz, 1H), 3.80 (dd, J = 11.2, 9.6 Hz, 1H).

*Synthesis of 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-Ethyl Oxime (**I-a**).* To a mixture of **8** (0.82 g, 2.4 mmol) in *N*,*N*-dimethylformamide (DMF) (30 mL) stirred for 10 min at 0 °C was added sodium hydride (0.23 g, 10 mmol), and the reaction mixture was stirred for 1 h. After ethyl iodide (0.57 g, 4 mmol) was added, the reaction mixture was stirred for another 2 h. When the reaction was complete, as indicated by TLC, ethyl acetate (150 mL) was added. The mixture was washed with a large amount of water three times and saturated brine once, dried with anhydrous magnesium sulfate, filtered, and concentrated under reduced pressure. The residue was purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 12:1) to give the target compound **I-a** as an oil (0.51 g, yield 64%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.07 (s, 1H), 7.60 (d, J = 8.4 Hz, 2H), 7.48−7.40 (m, 1H), 7.35 (d, J = 8.4 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 10.4, 8.4 Hz, 1H), 4.83 (dd, J = 10.4, 8.4 Hz, 1H), 4.28 (t, J = 8.4 Hz, 1H), 4.23 (q, J = 7.2 Hz, 2H), 1.33 (t, J = 7.2 Hz, 3H). HRMS (ESI): calcd for $C_{18}H_{16}F_2N_2O_2Na$ $[M + Na]^+$ 353.1072, found 353.1073.

Compounds **I-b**−**I-l** were synthesized according to a method similar to that for **I-a** using the corresponding alkyl bromide instead of ethyl iodide.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-Allyl Oxime (**I-b**).* Oil; yield 58%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.12 (s, 1H), 7.60 (d, J = 8.0 Hz, 2H), 7.48−7.41 (m, 1H), 7.35 (d, J = 8.0 Hz, 2H), 7.01 (t, J = 8.0 Hz, 2H), 6.10−6.00 (m, 1H), 5.48 (dd, J = 10.4, 8.4 Hz, 1H), 5.36 (dd, J = 17.2, 1.6 Hz, 1H), 5.26 (dd, J = 10.4, 1.2 Hz, 1H), 4.83 (dd, J = 10.4, 8.4 Hz, 1H), 4.68 (d, J = 5.6 Hz, 2H), 4.28 (t, J = 8.0 Hz, 1H). HRMS (ESI): calcd for $C_{19}H_{16}F_2N_2O_2Na$ $[M + Na]^+$ 365.1072, found 365.1075.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-Prop-2-yn-1-yl Oxime (**I-c**).* Oil; yield 47%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.13 (s, 1H), 7.62 (d, J = 8.1 Hz, 2H), 7.49−7.39 (m, 1H), 7.36 (d, J = 8.1 Hz, 2H), 7.01 (t, J = 8.1 Hz, 2H), 5.49 (dd, J = 10.2, 8.2 Hz, 1H), 4.83 (dd, J = 10.2, 8.2 Hz, 1H), 4.78 (d, J = 2.1 Hz, 2H), 4.27 (t, J = 8.1 Hz, 1H), 2.51 (t, J = 2.4 Hz, 1H). HRMS (ESI): calcd for $C_{19}H_{14}F_2N_2O_2Na$ $[M + Na]^+$ 363.0916, found 363.0912.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-Cyclohexylmethyl Oxime (**I-d**).* Oil; yield 44%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.07 (s, 1H), 7.59 (d, J = 8.0 Hz, 2H), 7.47−7.42 (m, 1H), 7.34 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 10.0, 8.8 Hz, 1H), 4.82 (dd, J = 10.0, 8.8 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H), 3.98 (d, J = 6.4 Hz, 2H), 1.82−1.72 (m, 5H), 1.31−1.21 (m, 6H). HRMS (ESI): calcd for $C_{23}H_{24}F_2N_2O_2Na$ $[M + Na]^+$ 421.1698, found 421.1693.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-Benzyl Oxime (**I-e**).* Yellow oil; yield 50%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.14 (s, 1H), 7.60 (d, J = 8.0 Hz, 2H), 7.47−7.31 (m, 8H), 7.01 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 12.0, 8.0 Hz, 1H), 5.21 (s, 2H), 4.83 (dd, J = 12.0, 8.0 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H). HRMS (ESI): calcd for $C_{23}H_{19}F_2N_2O_2$ $[M + H]^+$ 393.1409, found 393.1402.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(2-Fluorobenzyl) Oxime (**I-f**).* Oil; yield 63%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.13 (s, 1H), 7.60 (d, J = 8.0 Hz, 2H), 7.49−7.41 (m, 2H), 7.34 (d, J = 8.0 Hz, 2H), 7.32−7.28 (m, 1H), 7.16−7.12 (m, 1H), 7.10−7.05 (m, 1H), 7.01 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 10.4, 8.0 Hz, 1H), 5.28 (s, 2H), 4.83 (dd, J = 10.4, 8.0 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H). HRMS (ESI): calcd for $C_{23}H_{17}F_3N_2O_2Na$ $[M + Na]^+$ 433.1134, found 433.1129.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(3-Fluorobenzyl) Oxime (**I-g**).* Oil; yield 53%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.15 (s, 1H), 7.60 (d, J = 8.0 Hz, 2H), 7.48−7.40 (m, 1H), 7.35 (d, J = 8.0 Hz, 2H), 7.32−7.30 (m, 1H), 7.19−7.11 (m, 1H), 7.03−6.98 (m, 3H), 5.48 (dd, J = 10.4, 8.4 Hz, 1H), 5.19 (s, 2H), 4.83 (dd, J = 10.4, 8.4 Hz, 1H), 4.27 (t, J = 8.4 Hz,

dx.doi.org/10.1021/jf500461a | J. Agric. Food Chem. 2014, 62, 3064−3072

1H). HRMS (ESI): calcd for $C_{23}H_{17}F_3N_2O_2Na$ $[M + Na]^+$ 433.1134, found 433.1130.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(4-Fluorobenzyl) Oxime (**I-h**).* White solid; mp 97−100 °C; yield 69%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.12 (s, 1H), 7.59 (d, J = 8.0 Hz, 2H), 7.48−7.38 (m, 3H), 7.34 (d, J = 8.0 Hz, 2H), 7.07−6.99 (m, 4H), 5.48 (dd, J = 10.4, 8.0 Hz, 1H), 5.16 (s, 2H), 4.83 (dd, J = 10.4, 8.0 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 163.8, 162.5, 162.5, 161.4, 160.0, 159.9, 157.8, 148.7, 143.6, 133.3, 133.3, 132.6, 132.5, 132.4, 131.6, 130.3, 130.3, 127.6, 127.0, 115.4, 115.2, 112.1, 112.1, 112.1, 111.9, 111.9, 75.7, 74.7, 70.0. HRMS (ESI): calcd for $C_{23}H_{17}F_3N_2O_2Na$ $[M + Na]^+$ 433.1134, found 433.1130.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(4-(Trifluoromethoxy)benzyl) Oxime (**I-i**).* White solid; mp 102−103 °C; yield 65%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.13 (s, 1H), 7.59 (d, J = 8.4 Hz, 2H), 7.47−7.42 (m, 3H), 7.35 (d, J = 8.0 Hz, 2H), 7.21 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 10.4, 8.0 Hz, 1H), 5.20 (s, 2H), 4.82 (dd, J = 10.4, 8.0 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H). HRMS (ESI): calcd for $C_{24}H_{17}F_5N_2O_3Na$ $[M + Na]^+$ 499.1052, found 499.1050.

*Data for 4-(2-(2,6-difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(4-(Trifluoromethyl)benzyl) Oxime (**I-j**).* White solid; mp 91−93 °C; yield 56%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.15 (s, 1H), 7.62 (d, J = 8.0 Hz, 2H), 7.59 (d, J = 8.0 Hz, 2H), 7.52 (d, J = 8.0 Hz, 2H), 7.47−7.40 (m, 1H), 7.35 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.48 (dd, J = 10.4, 8.0 Hz, 1H), 5.25 (s, 2H), 4.82 (dd, J = 10.4, 8.0 Hz, 1H), 4.27 (t, J = 8.0 Hz, 1H). HRMS (ESI): calcd for $C_{24}H_{17}F_5N_2O_2Na$ $[M + Na]^+$ 483.1102; 483.1104.

*Data for 4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(4-Chlorobenzyl) Oxime (**I-k**).* Yellow solid; mp 77−80 °C; yield 83%. ^{1}H NMR (400 MHz, DMSO-d_6): δ 8.33 (s, 1H), 7.72−7.62 (m, 3H), 7.44 (s, 4H), 7.37 (d, J = 8.0 Hz, 2H), 7.30 (t, J = 8.0 Hz, 2H), 5.52 (t, J = 9.2 Hz, 1H), 5.17 (s, 2H), 4.86 (t, J = 9.2 Hz, 1H), 4.20 (t, J = 8.4 Hz, 1H), HRMS (ESI): calcd for $C_{23}H_{18}ClF_2N_2O_2$ $[M + H]^+$ 427.1019, found 427.1020.

*Data for 4-(2-(2,6-difluorophenyl)-4,5-dihydrooxazol-4-yl)-benzaldehyde O-(4-tert-Butylbenzyl) Oxime (**I-l**).* Yellow solid; mp 70−73 °C; yield 75%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.13 (s, 1H), 7.60 (d, J = 8.1 Hz, 2H), 7.49−7.33 (m, 7H), 7.01 (t, J = 8.1 Hz, 2H), 5.48 (dd, J = 10.2, 8.4 Hz, 1H), 5.18 (s, 2H), 4.83 (dd, J = 10.2, 8.7 Hz, 1H), 4.27 (t, J = 8.4 Hz, 1H), 1.32 (s, 9H). HRMS (ESI): calcd for $C_{27}H_{26}F_2N_2O_2Na$ $[M + Na]^+$ 471.1855, found 471.1858.

General Synthetic Procedure for the Target Compounds II-a−II-n (Scheme 3). *Synthesis of N-(1-(4-(Bromomethyl)phenyl)-2-chloroethyl)-2,6-difluorobenzamide (**9**).*[17,18] To a solution of **6** (5.0 g, 16.1 mmol) in dichloromethane (40 mL) were successively added water (40 mL), potassium bromide (1.9 g, 16.1 mmol), and potassium bromate (1.33 g, 8.05 mmol), and then a solution of concentrated hydrochloric acid (6.1 mL) in water (14 mL) was added dropwise at 0 °C. The reaction mixture was stirred for 25 h until reaction was complete. The organic phase was separated and washed with saturated sodium carbonate. The water phase was extracted with dichloromethane. Then the combined organic phase was washed with brine, dried over anhydrous magnesium sulfate, and concentrated to give a white solid, which was purified by recrystallization using toluene and petroleum ether to give **9** as crystals (3.5 g, yield 56%). Mp: 127−128 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.45−7.36 (m, 5H), 6.97 (t, J = 8.0 Hz, 2H), 6.62 (d, J = 7.6 Hz, 1H), 5.61−5.57 (m, 1H), 4.49 (s, 2H), 4.04−3.91 (m, 2H).

*Synthesis of Cyclopentanone O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-b**).* To a mixture of cyclopentanone oxime (0.51 g, 5.15 mmol) in DMF (50 mL) was added sodium hydride (0.49 g, 20.59 mmol). The mixture was stirred for 40 min, and then **9** (1.00 g, 2.57 mmol) was added. The reaction mixture was stirred at 0 °C until TLC showed that the reaction was finished. The reaction mixture was extracted with ethyl acetate, and the organic layer was dried over anhydrous magnesium sulfate, filtered, and concentrated to give a reddish brown oil. The crude was purified by flash chromatography on silica gel with petroleum ether and ethyl acetate (v/v = 10:1) to give the target **II-b** as a yellow oil (0.65 g, yield 69%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.49−7.31 (m, 1H), 7.38 (d, J = 8.0 Hz, 2H), 7.32 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.47 (dd, J = 10.0, 8.4 Hz, 1H), 5.07 (s, 2H), 4.81 (dd, J = 10.0, 8.4 Hz, 1H), 4.30 (t, J = 8.4 Hz, 1H), 2.44 (t, J = 6.8 Hz, 2H), 2.36 (t, J = 6.8 Hz, 2H), 1.77−1.71 (m, 4H). HRMS (ESI): calcd for $C_{21}H_{21}F_2N_2O_2$ $[M + H]^+$ 371.1566, found 371.1570.

Compounds **II-a** and **II-c−II-n** were synthesized according to a method similar to that for **II-b**.

*Data for Propan-2-one O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-a**).* Yellow oil; yield 52%. ^{1}H NMR (400 MHz, $CDCl_3$): 7.41−7.46 (m, 1H), 7.37 (d, J = 7.6 Hz, 2H), 7.32 (d, J = 7.6 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.49−5.44 (m, 1H), 5.06 (s, 2H), 4.83−4.79 (m, 1H), 4.32−4.28 (m, 1H), 1.88 (s, 3H), 1.87 (s, 3H). HRMS (ESI): calcd for $C_{19}H_{19}F_2N_2O_2$ $[M + H]^+$ 367.1229, found 367.1224.

*Data for Cyclohexanone O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-c**).* Yellow oil; yield 40%. ^{1}H NMR (400 MHz, $CDCl_3$): 7.46−7.41(m, 1H), 7.36 (d, J = 8.0 Hz, 2H), 7.32 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.4 Hz, 2H), 5.52−5.42 (m, 1H), 5.05 (s, 2H), 4.85−4.78 (m, 1H), 4.32−4.28 (m, 1H), 2.50 (t, J = 6.2 Hz, 2H), 2.24−2.15 (m, 2H), 1.64−1.66 (m, 4H), 1.59−1.61(m, 2H). HRMS (ESI): calcd for $C_{22}H_{23}F_2N_2O_2$ $[M + H]^+$ 385.1722, found 385.1722.

*Data for Cycloheptanone O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-d**).* Yellow oil; yield 46%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.46−7.41 (m, 1H), 7.37 (d, J = 8.0 Hz, 2H), 7.32 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 5.47 (dd, J = 10.4, 8.0 Hz, 1H), 5.06 (s, 2H), 4.81 (dd, J = 10.4, 8.4 Hz, 1H), 4.30 (t, J = 8.4 Hz, 1H), 2.59−2.54 (m, 2H), 2.38−2.34 (m, 2H), 1.73−1.56 (m, 8H). HRMS (ESI): calcd for $C_{23}H_{25}F_2N_2O_2$ $[M + H]^+$ 399.1879, found 399.1875.

*Data for Benzaldehyde O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-e**).* Yellow oil; yield 68%. ^{1}H NMR (400 MHz, $CDCl_3$): 8.13 (s, 1H), 7.64−7.54 (m, 2H), 7.45−7.41(m, 3H), 7.41−7.30 (m, 5H), 7.00 (t, J = 8.4 Hz, 2H), 5.53−5.42 (m, 1H), 5.21 (s, 2H), 4.88−4.76 (m, 1H), 4.27−4.31(m, 1H). HRMS (ESI): calcd for $C_{23}H_{19}F_2N_2O_2$ $[M + H]^+$ 393.1409, found 393.1408.

*Data for 2-Fluorobenzaldehyde O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-f**).* Yellow oil; yield 61%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.38 (s, 1H), 7.81 (t, J = 6.6 Hz, 1H), 7.45−7.32 (m, 6H), 7.15−6.96 (m, 4H), 5.48 (dd, J = 10.2, 8.1 Hz, 1H), 5.22 (s, 2H), 4.82 (dd, J = 10.2, 8.4 Hz, 1H), 4.31 (t, J = 8.1 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 164.1, 162.6, 162.5, 161.7, 160.0, 157.6, 147.93, 147.90, 141.6, 136.8, 134.5, 134.4, 132.5, 132.4, 132.33, 130.28, 130.2, 129.0, 126.8, 123.2, 123.2, 116.9, 116.7, 113.4, 113.2, 112.1, 112.1, 111.8, 76.3, 74.8, 70.1. HRMS (ESI): calcd for $C_{23}H_{18}F_3N_2O_2$ $[M + H]^+$ 411.1315, found 411.1307.

*Data for 3-Fluorobenzaldehyde O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-g**).* Yellow oil; yield 32%. ^{1}H NMR (300 MHz, $CDCl_3$): δ 8.08 (s, 1H), 7.47−7.26 (m, 8H), 7.09−6.93 (m, 3H), 5.47 (dd, J = 10.2, 8.1 Hz, 1H), 5.20 (s, 2H), 4.80 (dd, J = 10.2, 8.4 Hz, 1H), 4.28 (t, J = 8.1 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 164.1, 162.6, 162.5, 161.7, 160.0, 157.6, 147.93, 147.90, 141.6, 136.8, 134.5, 134.4, 132.5, 132.4, 132.3, 130.3, 130.2, 129.0, 126.8, 123.25, 123.22, 116.9, 116.7, 113.4, 113.2, 112.1, 112.1, 111.8, 76.3, 74.8, 70.1. HRMS (ESI): calcd for $C_{23}H_{18}F_3N_2O_2$ $[M + H]^+$ 411.1315, found 411.1315.

*Data for 4-Fluorobenzaldehyde O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-h**).* Yellow solid; mp 85−87 °C; yield 33%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.10 (s, 1H), 7.60−7.52 (m, 2H), 7.47−7.39 (m, 3H), 7.35 (d, J = 8.0 Hz, 2H), 7.07−6.98 (m, 4H), 5.48 (dd, J = 10.4, 8.0 Hz, 1H), 5.19 (s, 2H), 4.82 (dd, J = 10.4, 8.4 Hz, 1H), 4.29 (t, J = 8.0 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$): δ 147.9, 141.6, 137.0, 132.5, 132.4, 132.3, 128.9, 126.8, 115.9, 115.7, 112.1, 111.8, 76.1, 74.8, 70.1. HRMS (ESI): calcd for $C_{23}H_{18}F_3N_2O_2$ $[M + H]^+$ 411.1315, found 411.1313.

*Data for 4-Methoxybenzaldehyde O-(4-(2-(2,6-Difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) Oxime (**II-i**).* Yellow oil; yield 46%. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.08 (s, 1H), 7.51 (d, J = 8.8 Hz, 2H), 7.46−7.39 (m, 3H), 7.34 (d, J = 8.0 Hz, 2H), 7.00 (t, J = 8.0 Hz, 2H), 6.88 (d, J = 8.8 Hz, 2H), 5.50− 5.46 (m, 1H), 5.18 (s, 2H), 4.84−4.79

Biological Assay. All biological assays were performed on representative test organisms prepared in the laboratory. Each bioassay was replicated three times at 25 ± 1 °C for the statistical requirements. Percentage mortalities were evaluated according to a percentage scale of 0−100, in which 0 indicates no activity and 100 indicates total kill. When the percentage mortality of the blank control was less than 5%, the results of the treats were directly used. However, if the percentage mortality of the blank control was less than 20% and more than 5%, the results were corrected by means of $V = ((X - Y)/X) \times 100$ (V = value of corrected mortality, X = livability of the blank control, Y = livability of the treat). Etoxazole was evaluated using the entirely same procedure as contrast.[19]

Acaricidal Activity against Eggs and Larvae of Spider Mite (*Tetranychus cinnabarinus*). The acaricidal activities of all the target compounds and the contrast etoxazole against eggs and larvae of spider mite (*T. cinnabarinus*) were measured on the basis of previously reported procedure.[20,21]

[a]Treatments: the unit of concentration is mg kg^{-1}. [b]The number of days between spraying insecticides and investigating the effects. [c]The amount sprayed is about 1000 g ha^{-1}. [d]The amount sprayed is about 2000 g ha^{-1}. [e]The amount sprayed is about 900 g ha^{-1}. [f]10 days. [g]15 days. [h]The amount sprayed is about 750 g ha^{-1}.

Affinity of the Target Compounds and Etoxazole Binding to SUR. *Preparation of SUR.* According to our previous reported method, the buffer of SUR was prepared from German cockroach (*Blattella germanica*, *B. germanica*) through the process of chopping, homogenization, centrifugation, etc.[15]

Assay of Binding to SUR. The affinity of the target compounds and etoxazole to SUR was tested using a method similar to our previously published method. After the superior concentration of *N*-phenyl-1-naphthylamine (1-NPN) that acted as fluorescence probe was determinated, ligands such as etoxazole and the target compounds in different concentrations were respectively added to a mixture solution containing SUR, buffer, and 1-NPN. After the mixture was incubated for 1 h at room temperature, the binding affinity was tested by FP.[16]

Evaluation of Acaricidal Activity in the Field. The field trials were carried out between April and June in 2013. The trial against *T. cinnabarinus* in tomato field was performed in the trial area of Institute of Plant Protection, Tianjin Academy of Agricultural Science, Tianjin City, China. Moreover, the trials against *Panonychus citri* (*P. citri*) in orange orchard were performed in the trial area of Institute of Plant Protection, Hunan Academy of Agricultural Science, Changsha City; Citrus Institute of Guangxi, Guilin City; and College of Agricuture, Yangtze University, Jingzhou City. The treated plots of tomatoes or oranges were designed in a random block array with four replicates. The untreated plots served as a blank control. The formulation of compound **II-l** and etoxazole (2.5% emulsifiable concentrates (EC)) was prepared in our research group. They were diluted to 10, 15, or 22 mg kg^{-1} before use. The amount sprayed on the field area varied from 750 to 2000 g ha^{-1} at different sites. The control effects expressed as percentages were arcsine transformed to homogenize variances before analysis, which of different spraying treatments were examined using analysis of variance (ANOVA).[22]

RESULTS AND DISCUSSION

Synthesis. *N*-(2-Chloro-1-(*p*-tolyl)ethyl)-2,6-difluorobenzamide (**6**), as a critical intermediate for all the target compounds, was synthesized from toluene (**1**) as shown in Scheme 1. Ethyl 2-oxo-2-(*p*-tolyl)acetate (**2**) was obtained by Friedel–Crafts acylation of toluene with ethyl 2-chloro-2-oxoacetate. **2** was reacted with hydroxylamine hydrochloride to afford hydroxyimino compound **3**, which was further reduced by sodium borohydride and iodine to give α-amino alcohol **4**. After **4** was reacted with 2,6-difluorobenzoyl chloride to give the corresponding benzamide **5**, the hydroxyl in **5** was converted to chloro group in **6** by thionyl chloride using chloroform as solvent.

The target compounds **I-a**–**I-l** were synthesized from **6** as shown in Scheme 2. The methyl group in **6** was oxidized with CrO_3 in the presence of concentrated sulfuric acid and glacial acetic acid to give aldehyde **7**, which was further reacted with hydroxylamine hydrochloride to afford **8** containing an oxime moiety. **8** was treated with sodium hydride and reacted with a series of alkyl or substituted-benzyl bromide to give 2,4-diphenyl-1,3-oxazolines **I-a**–**I-l** containing oxime ether moiety after nucleophilic cyclization and substitution.

The target compounds **II-a**–**II-n** were also synthesized from compound **6** as shown in Scheme 3. The key intermediate **9** was obtained through bromination of **6** according to the reported method using water as solvent, in which the reaction temperature was strictly maintained between 0 °C and 5 °C to minimize the formation of byproduct. A series of oximes were successfully reacted with **9** in the presence of sodium hydride to give the target compounds **II-a**–**II-n** via cyclization and substitution.

Acaricidal Activity against Eggs and Larvae of *T. cinnabarinus* in the Laboratory. Table 1 shows acaricidal activities of the target compounds **I-a**–**I-l** and **II-a**–**II-n** against eggs and larvae of *T. cinnabarinus*, with etoxazole, the only 2,4-diphenyl-1,3-oxazoline acaricide widely used in China, as a contrast. The result showed that all of the target compounds had much higher activities than etoxazole, as the ovicidal and larvicidal activities of the target compounds **I-a**–**I-l** and **II-a**–**II-n** against *T. cinnabarinus* were all over 90% at 0.001 mg L^{-1}, but etoxazole gave only 30% and 40% respectively at the same concentration. Therefore, the modification at the para site of the 4-phenyl moiety of 2,4-diphenyl-1,3-oxazolines was favorable to the acaricidal activity, which was in accordance with our design ideas. Especially, **I-i** and **I-j**, respectively bearing trifluoromethoxyl and trifluoromethyl group at the para position of the benzyl moiety, showed the highest ovicidal and larvicidal activities at 0.0001 mg L^{-1}. Compounds **II-l** and **II-m**, that bear a trifluoromethyl at the ortho and meta positions of the benzene ring, respectively, had obviously higher ovicidal and larvicidal activities than the others.

Evaluation of Acaricidal Activity of II-l in the Field. Based on the comprehensive analysis of bioactivity, physical properties, synthetic procedure, and so on, compound **II-l**, which had exhibited excellent acaricidal activity in the laboratory, was chosen to evaluate the acaricidal activity in the field. 2.5% EC of **II-l** and etoxazole were separately prepared and evaluated for the control of *P. citri* in Jingzhou City (Hubei Province, South China), Changsha City (Hunan Province, South China), and Guilin City (Guangxi Zhuang Autonomous Region, South China) and *T. cinnabarinus* in Tianjin City (North China). Part of the result of the field trials is shown in Table 2. It was shown that **II-l** at the concentration of 22 mg kg^{-1} had a better control effect than etoxazole at the same concentration. The data of the field trial in Jingzhou showed that, 3 days after the spray, the control efficiency of **II-l** against *P. citri* at 22 mg L^{-1} was 75%, whereas that of etoxazole was 55% at the same condition; this phenomenon suggested that the speed of action of **II-l** was faster than that of etoxazole. Fourteen days after the spray, the control efficiency of **II-l** and etoxazole was respectively 91% and 87%. The control efficiency of **II-l** and etoxazole against *P. citri* in Changsha and Guilin was similar, if not identical, to that in Jingzhou. In Tianjin, the control efficiency of both **II-l** and etoxazole against *T. cinnabarinus* at 22 mg L^{-1} was 92% when tested 14 days after the spray. Therefore, it was suggested that **II-l** could be considered as an alternative to the excessively employed acaricide for further development on the basis of the field trials.

Affinity of the Target Compounds Binding to SUR. The binding affinity of each series of the target compounds to the isolated SUR were tested by FP method with etoxazole as a contrast.[23] Since the accurate determination of concentration and stability of the SUR have not been realized up to now, in order to make the data comparable and minimize the errors, the binding affinity was assayed within the same set of experiments and containing 5 replicates. In the paper, that is to say, the target compounds **I-a**–**I-l** and etoxazole were tested with the same vesicle prepared, and so were compounds **II-a**–**II-n**.

In the buffer solution having the most proper concentration of 1-NPN-SUR, each of the target compounds **I-a**–**I-l** and etoxazole in different concentrations was separately added, and the FP data were recorded (Figure 2). From the figure we could find all the FP data were related to the concentration of the added compounds, which meant all these compounds could replace 1-NPN and then bind with SUR by themselves. The affinity with SUR is relevant to the value of the FP: the more decreased polarization was tested, the stronger affinity was exhibited. Thus from the figure, the order of affinity of these compounds was approximately deduced as **I-i** > **I-j** > **I-d** > **I-f** > **I-b** > **I-c** > **I-l** > **I-a** > **I-e** > **I-g** > **I-h** > **I-k** > etoxazole. The result indicated that the binding affinity to SUR of the target compounds **I-a**–**I-l** in vitro was almost consistent with their acaricidal activity against *T. cinnabarinus* in vivo, since **I-i** and **I-j** showed the strongest acaricidal activity against eggs and larvae of *T. cinnabarinus* in vivo, and **I-k** exhibited the lowest activity among the target compounds **I-a**–**I-l**.

Likewise, the FP data against the concentration of **II-a**–**II-n** and etoxazole are shown in Figure 3, from which the affinity order was deduced as **II-m** > **II-l** > **II-f** > **II-g** > **II-k** > **II-n** > **II-h** > **II-j** > **II-e** > **II-i** > **II-a** > **II-c** > **II-d** > **II-b** > etoxazole. The result was also almost consistent with the acaricidal activity against *T. cinnabarinus* in vivo, supported by the fact that **II-m** and **II-l** had the highest acaricidal activity, and **II-a**–**IId** had relatively lower activity in vivo. Therefore, it was verified that

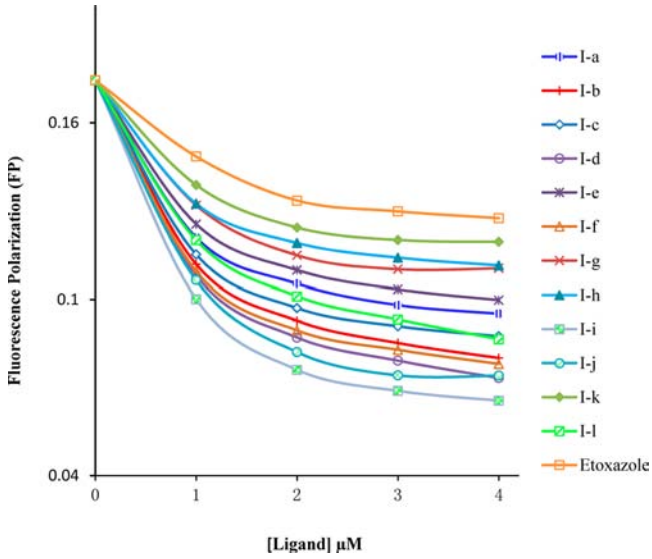

Figure 2. Binding curves of compounds **I-a**–**I-l** and etoxazole to sulfonylurea receptor.

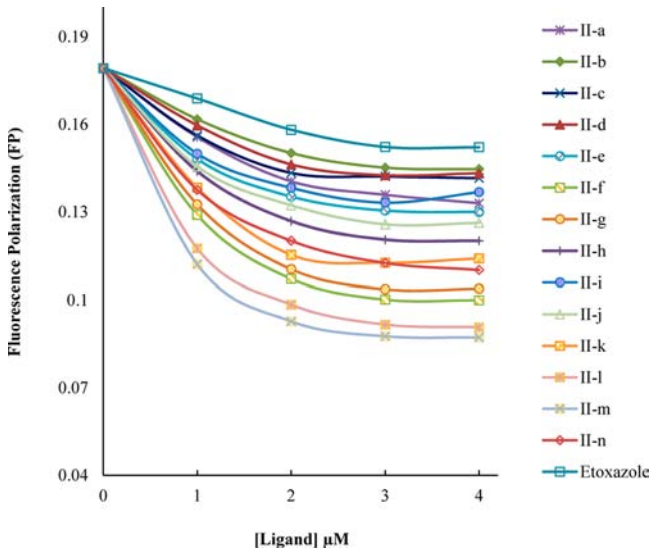

Figure 3. Binding curves of the compounds **II-a**–**II-n** and etoxazole to sulfonylurea receptor.

the target compounds and etoxazole could act on the site of SUR to suppress the chitin synthesis in mite body.

In summary, two series of novel 2,4-diphenyl-1,3-oxazoline compounds both containing an oxime ether group were designed and synthesized on the basis of etoxazole, flucycloxuron, and NK-17. The bioassay results indicated that all of the target compounds exhibited considerable acaricidal activities against *T. cinnabarinus* in the laboratory. Especially, compound **II-l**, 2-(trifluoromethyl)benzaldehyde *O*-(4-(2-(2,6-difluorophenyl)-4,5-dihydrooxazol-4-yl)benzyl) oxime, showed 100% ovicidal activities and 100% larvicidal activities at 0.0001 mg L^{-1}, much higher than etoxazole, thus it was selected to proceed to field trial. The field trial results from four sites in different parts of China clearly showed that **II-l** had nearly equivalent activity with etoxazole against *T. cinnabarinus* and *P. citri* at the same doses. Furthermore, when the fluorescence polarization method was employed to study the action mechanism, the target compounds and etoxazole were all

dx.doi.org/10.1021/jf500461a | J. Agric. Food Chem. 2014, 62, 3064–3072

speculated to act on the SUR then resulting in the suppression of chitin biosynthesis. Because of the easy preparation, good acaricidal activity, and unique mechanism, the new 2,4-diphenyl-1,3-oxazoline compound was expected to be developed as a promising candidate. Further research on acute toxicity, field residues, and their inhibitory activities against resistant mite species is ongoing and will be reported in the future.

attention has been paid to new methods such as those based on multidimensional systems comprising liquid chromatography (LC) to separate peptides or proteins and MS to analyze them.[15] Chromatography and MS-based techniques have become much more widely used for analyses of proteins and peptides.[16−35]

IDMS is a primary method in the metrological field. It allows highly accurate and precise measurements of various substances and has been used widely since its development in the 1980s.[17−19] It has been used to detect and quantify drugs, hormones, pesticides and veterinary drug residues in serum, and other organic small molecules with high accuracy. With the development of the life science and biotechnology industries, IDMS methods have been further developed to quantify proteins,[21−35] nucleic acids,[36] and other biological macromolecules.[37−40] Especially, IDMS has been successfully applied into analyses with milk powders and shows several advantages. Zhang et al. developed an IDMS method to quantify12 mycotoxins in milk-based infant formula and foods. The average recoveries in fortified milk, milk-based infant formula, milk powder, and baby yogurt ranged from 89% to 126% with CVs of <20%. The validated method provides sufficient selectivity, sensitivity, accuracy, and reproducibility to screen for aflatoxin M1 at nanogram per kilogram concentrations and other mycotoxins, without using standard addition or matrix-matched calibration to compensate for matrix effects.[20] In 2008, Burkitt et al. first reported the accurate quantification of a protein in solution by an IDMS method.[21] In that study, the absolute concentration of a protein was determined using an SI-traceable peptide quantification method in which a standard peptide was quantified by amino acid analysis with IDMS, and amino acid standards of known purity were used. This allowed fully SI-traceable measurements of protein concentration. However, this method was not used to determine the protein content in mixtures or complex matrices. In another study, researchers enzymatically digested a protein into polypeptides; then, using an isotope-labeled peptide as an internal standard, they measured the specific peptide content by an IDMS method and further calculated the total protein content. This allowed them to accurately determine the protein content in mixtures and matrices.[22]

εIn recent years, LC−MS/MS and IDMS have been used to detect protein allergens in food. Weber et al. developed a LC−MS/MS method of the tryptic digest of a cleaned-up food matrix extract for the detection of milk allergens.[23] Careri et al. developed MS-based technology for the detection and quantification of contaminant or allergen traces.[24]Cryar developed IDMS method for the analysis of lysozyme in wine and the production of CRMs.[25] To date, there have been no reports on quantitation of β-LG in milk powders by HPLC−IDMS. Development of an SI-traceable quantification method for β-LG in milk powders can improve the accuracy and reliability of β-LG detection. Such a method would benefit the development of a β-LG CRM and improve the comparability of β-LG quantification results among different laboratories.

MATERIALS AND METHODS

Chemicals and Reagents. DL-Dithiothreitol (DTT), iodoacetamide (IAM), ammonium bicarbonate, D_3-leucine, perfluoroheptanoic acid, β-LG, and trypsin were purchased from Promega Co.. The specific activity of the trypsin is 18704 U/mg (BAEE as substrate). The trypsin is diluted in 50 mM acetic acid with a protein concentration of 0.5 mg/mL. RapiGest SF was obtained from Waters Co. Ltd. (Milford, MA, USA).The peptides of TPEVDDEALEK (TK-11) and isotope-labeled TPEVDDEAL*EK (L-TK-11, where L* is D_3-Leu) were synthesized by GL Biochem. Co. Ltd. (Shanghai, China). The CRMs of proline, valine, leucine, and phenylalanine were obtained from the National Institute of Metrology (NIM, Beijing, China). Milk powder samples were obtained from domestic manufacturers.

Reagent Preparation. To prepare 50 mmol/L ammonium bicarbonate (pH = 8.0), 0.179 g of ammonium bicarbonate was dissolved in 45 mL of water, and then the pH was adjusted to 8.0 with aqueous ammonia. To prepare 1 mg/mL RapiGest SF, approximately 1 mg of solid RapiGest SF was dissolved in 1 mL of 50 mmol/L ammonium bicarbonate buffer. To prepare 0.1 mol/L DTT: 0.154 g of DTT was dissolved in 0.01 mol/L NaOAc (pH = 5.2) and then filtered through a 0.22 μm filter. To prepare 0.1 mol/L IAM: 0.185 g of IAM was dissolved in 10 mL of pure water. The peptides and β-LG solutions were prepared as follows: each peptide/protein (TK-11, L-TK-11, and β- LG) was dissolved in pure water containing 0.1% formic acid to a final concentration of 1 mg/mL. The peptide solutions were distributed into 1.5 mL centrifuge tubes and stored at −80 °C until analysis.

Peptide or Protein Hydrolysis. 1 mg of TK-11 or β-LG was weighed with a balance capable of 1 μg imprecision, and it was dissolved in about 1 g of 0.1 mol/L HCl. The mass of the HCl was weighed with a balance capable of 0.01 mg imprecision. 100 μL of TK-11(1 mg/mL) or β-LG (1 mg/mL) was added to a 2 mL ampule and lyophilized. Then 500 μL of 6 mol/L HCl was added. The solution was flushed with nitrogen for 2 min before sealing. Then the ampules were put into an oven and hydrolysis was carried out at 110.0 ± 0.5 °C for 48 h for TK-11 and for 24 h for β-LG. Isotope-labeled amino acids were added to the mixture after hydrolysis, and then the mixture was flushed with nitrogen and dried. Finally, it was reconstituted with 0.1% formic acid and filtered for instrumental analysis.

Enzymatic Digestion. Approximately 2.7 mg of β-LG was dissolved in 600 μL of RapiGest SF buffer. Then, 30 μL of 0.1 mmol/L DTT was added and the mixture was incubated in a water bath at 60 °C for 30 min before addition of 60 μL of 0.1 mol/L IAM. The mixture was cooled to room temperature and then kept in the dark for 40 min. Then, 30 μL of trypsin was added and the mixture was kept at 37 °C for 48 h for digestion. An additional 5 μL of trypsin was added to the digestion mixture every 24 h. The proteolysis reaction was terminated by adding 200 μL of 0.1 mmol/L HCl. The mixture was kept at −80 °C until instrumental analysis.

Protein Identification. The digested samples were analyzed by a Synapt G1 mass spectrometer (UBA171, Waters) with a capture column (5 μm Symmetry C_{18}, 180 μm × 20 mm) and an analytical column (1.7 μm BEH130 C_{18}, 100 μm × 100 mm). The column temperature was 35 °C and the sample temperature was 8 °C during analysis. The injection volume was 2 μL, and the flow rate was 0.5 μL/min. The mobile phase A was pure water from a Milli Q system with 0.1% formic acid, and the mobile phase B was MeCN. The sample loading time was 3 min, and the trapping flow rate was 5 μL/min. The separation was performed as per the gradient shown in Table S1 in the Supporting Information.The total runtime was 60 min.

The operating parameters of the nano-ESI source were set as follows: positive ionization mode; capillary voltage, 3.0 kV; source temperature, 100 °C; desolvation nitrogen gas flow rate, 500 L/h; nano gas pressure, 2.0 bar; sampling cone voltage, 30 V. The mass to charge ratios of the target fragment ions were captured from m/z 100 to m/z 2000. The data were processed with MassLynx 4.1, and the data acquisition time was from 8 to 37 min.

Protein identification was carried out with Proteinlynx, with the following parameters: databank was Swiss-Prot; fixed modification was carbamidomethyl C; variable modifications were deamidation N, deamidation Q, and oxidation M; minimum fragment ion matches per peptide was 3; minimum fragment ion matches per protein was 7; minimum peptide matches per protein was 1.

Determination of the Mass Fraction of Pure TK-11 or β-LG in Solid Powder by Acid Hydrolysis. The mass fraction of pure peptide or pure protein in the solid powder was determined by HPLC−IDMS after acid hydrolysis. The exact mass fraction of proline,

valine, leucine, or phenylalanine in the hydrolyzed mixture was quantitatively determined by HPLC−IDMS with amino acid CRMs as standards and relative isotope-labeled amino acids as internal standards. An Agilent ZORBAX SB-Aq column (3.5 μm, 2.1 × 150 mm) was used for separation. The column temperature was 40 °C during analysis. The injection volume was 20 μL, and the flow rate was 0.2 mL/min. The mobile phase A was 0.8 mmol/L perfluoroheptanoic acid with 0.05% TFA, and the mobile phase B was MeCN. The gradient is shown in Table S2 in the Supporting Information.

A Thermo-Finnigan TSQ quantum triple quadrupole mass spectrometer (San Jose, CA, USA) equipped with an ESI ion source was used for detection. The ESI ionization was operated in positive mode, and the multiple reaction monitor (MRM) mode was used for detection of Pro (116 → 70), L-Pro (121 → 74), Val (118 → 72), L-Val (123 → 76), Leu (132 → 86), L-Leu (142 → 96), Phe (166 → 120), and L-Phe (175 → 128). The flow rate of sheath gas and auxiliary gas was 30 and 10 arbitrary units (au), respectively. The capillary temperature was set at 270 °C, and the spray voltage was set at 3000 V.

The mass fraction of each amino acid was calculated according to formula 1:[22,27,41]

$$c = \frac{Pm_s[R_s(I_1 - I_2) - (I_1R_2 - I_2R_1)}{M(R_1 - R_2)} \quad (1)$$

where c is the mass fraction of each amino acid (g/g); m_s is the absolute mass of isotope-labeled amino acid in the sample solution (g); R_s is the ratio of the peak area of an amino acid to its isotope-labeled one of the sample; I_1 is the mass ratio of an amino acid to its isotope-labeled one of the high-level standard; I_2 is the mass ratio of an amino acid to its isotope-labeled one of the low-level standard; R_1 is the peak area ratio of an amino acid to its isotope-labeled one of the high-level standard; R_2 is the peak area ratio of an amino acid and its isotope-labeled one of the low-level standard; M is the absolute mass of the sample (g); and P is the purity of the amino acid CRM.

The mass fraction of pure TK-11 or pure β-LG in the solid was calculated according to formula 2, as follows:

$$c = \frac{c_1 \cdot MW_P}{c_0 \cdot MW_{AA} \cdot N} \quad (2)$$

where c is the mass fraction of the pure peptide or protein in the solid matrix; c_1 is the mass fraction of each amino acid (g/g); MW_P is the molecular mass of the peptide or protein; MW_{AA} is the molecular mass of the amino acid; N is the number of specific amino acids in one peptide or protein molecule; and c_0 is the gravimetric prepared solid concentration (g/g).

Determination of the Mass Fraction of β-LG in Milk Powders by Proteolysis. 0.1 g of milk powder was dissolved in 0.8 mL of commercial extraction buffer (R-Biopharm, R4902). The solution was incubated in a water bath at 60 °C for 15 min and was shaken every 2 min. Then 15.2 mL of 50 mmol/L ammonium bicarbonate was added into the sample and was centrifuged at 8437*g* for 20 min. 3 mL of the supernatant was taken out and diluted three times with 50 mmol/L of ammonium bicarbonate. 2.7 g of the diluted sample solution was added into the ultrafiltration tube with the cutoff molecular mass of 3 kDa, and was centrifuged at 6500*g* for 15 min to remove the extraction buffer. Then the sample was rinsed 5 times by adding 1 mL of 50 mmol/L ammonium bicarbonate and centrifuging. Finally, 100 μL of L-TK-11 solution was added into the ultrafiltration tube and mixed well with the sample. 100 μL of the solution was taken out for proteolysis according to the protocol described in Enzymatic Digestion except the proteolysis time was 16 h.

A ZORBAX SB-Aq column (3.5 μm particle size, 2.1 × 150 mm; Agilent, Palo Alto, CA, USA) was used to separate the digested mixture. The column temperature was 40 °C during the analysis. The injection volume was 10 μL, and the flow rate was 0.2 mL/min. The mobile phase A was water containing 0.1% formic acid, and the mobile phase B was acetonitrile containing 0.1% formic acid. The gradient is shown in Table S3 in the Supporting Information.

The Thermo-Finnigan TSQ equipped with an ESI ion source was used for IDMS analysis. The ESI ionization was operated in positive mode, and selected ion mode (SIM) was used to monitor TK-11 (m/z = 623) and L-TK-11 (m/z = 625). The flow rate of sheath gas and auxiliary gas was 30 and 10 arbitrary units (au), respectively. The capillary temperature was set at 270 °C, and the spray voltage was set at 3000 V.

The mass fraction of TK-11 in the proteolysis mixture was calculated according to formula 1, where c is the mass fraction of TK-11 in the proteolysis mixture (g/g); m_s is the mass of L-TK-11 added to the sample (g); R_s is the peak area ratio of TK-11 to L-TK-11 of the sample; I_1 is the mass ratio of TK-11 to L-TK-11 of the high-level standard; I_2 is the mass ratio of TK-11 to L-TK-11 of the low-level standard; R_1 is the peak area ratio of TK-11 to L-TK-11 of the high-level standard; R_2 is the peak area ratio of TK-11 to L-TK-11 of the low-level standard; M is the mass of the proteolysis sample (g); and P is the mass fraction of pure TK-11 determined by the HPLC−IDMS method.

The mass fraction of β-LG in the solid matrix was calculated according to formula 3:

$$c = \frac{c_1 \cdot MW_P}{c_0 \cdot MW_{pep}} \quad (3)$$

where c is the mass fraction of β-LG in the solid matrix (g/g); c_1 is the mass fraction of TK-11 (g/g); MW_{pep} is the molecular mass of TK-11; MW_P is the molecular mass of β-LG; and c_0 is the gravimetric prepared milk concentration (g/g).

RESULTS AND DISCUSSION

Selection of a Specific Peptide for β-LG Quantification. As different protein molecules may produce the same peptides after proteolysis, a specific peptide is generally filtered and selected for quantification to avoid interference from other peptides. To select a peptide specific to β-LG, pure β-LG was digested with trypsin and the peptides were analyzed. The total ion chromatogram and identified TK-11 are shown in Figure S1 in the Supporting Information. The identified peptides covered 59% for the amino acid sequence of the target protein. Among all the identified peptides, TK-11 (TPEVDDEALEK) had the strongest signal intensity and the peptide sequence was only found in the Swiss-Prot entries of LACB_BOVIN (P02754) and LACB_BUBBU (P02755), which show a difference of two amino acid residues. Therefore, TK-11 was chosen for peptide-based quantification of β-LG.

Optimization of Hydrolysis Times for TK-11 and β-LG. The mass fraction of TK-11 or β-LG was determined by amino acid analysis coupled with the IDMS method. However, the hydrolysis time should be optimized to ensure the complete hydrolysis of the target peptide or protein. TK-11 and β-LG were hydrolyzed according to the above protocol. The ratio of each amino acid to its isotope-labeled one vs hydrolysis time was plotted to determine the optimum hydrolysis time (Figure S2a,b in the Supporting Information).

The ratio rapidly increased at the early stage of the hydrolysis reaction (Figure S2 in the Supporting Information). For TK-11, the ratio reached a plateau after 48 (Figure S2 in the Supporting Information), and 48 h was therefore selected as the optimum time for TK-11 hydrolysis. Similarly, 24 h was selected as the best time for β-LG hydrolysis.

Determination of the Mass Fraction of Pure TK-11 or β-LG in a Solid Matrix. We used nine vials of TK-11 or β-LG for mass fraction determination by the IDMS procedure. The average mass fraction of TK-11 was 79.1% with a relative standard deviation of 5.6%, and the average mass fraction of β-LG was 82.9% with a relative standard deviation of 3.7%.

Optimization of Proteolysis Conditions for β-LG. The proteolysis reaction reaches a chemical equilibrium. To ensure that the reaction proceeded efficiently, we optimized the following conditions: digestion time, amount of denaturing agent and reductive alkylation reagent, and time and temperature of reductive alkylation.

To optimize the digestion time, β-LG was digested according to the above protocol for various times. The ratio of TK-11 to L-TK-11 vs proteolysis time was plotted to determine the optimum time for proteolysis (Figure 1). As shown in Figure 1,

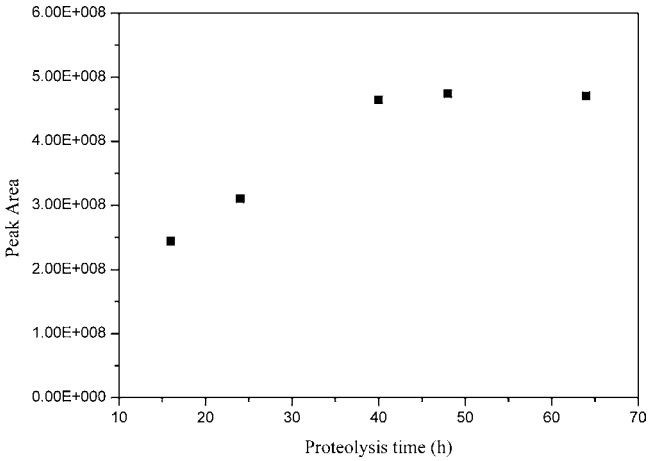

Figure 1. Optimization of proteolysis time for β-LG.

the proteolysis reaction occurred rapidly in the early stages, but reached a plateau after 48 h. Therefore, the proteolysis time of 48 h was used for proteolysis of β-LG.

Next, we optimized the amounts of denaturing agent and reductive alkylation reagent. We conducted four parallel experiments with different amounts of denaturing agent and reductive alkylation reagent (Table 1). As shown in Figure S3

Table 1. Optimization of Amounts of Denaturing Agent and Reductive Alkylation Reagent for Hydrolysis Reaction

	amount of reagent (μL)			
reagent	expt 1	expt 2	expt 3	expt 4
0.1% RapiGest SF	100	100	×[a]	×
DTT	5	×	5	×
IAM	10	×	10	×
trypsin	5	5	5	5

[a]×: Reagent omitted.

in the Supporting Information, the maximum peak area was observed in Experiment No. 3, indicating that those experimental conditions gave the best proteolysis efficiency for β-LG. Experiment No. 3 contained reducing reagents but lacked denaturants.

Then, we optimized the amount of reductive reagent by digesting β-LG according to the above protocol with various amounts of DTT. The peak area of TK-11 vs quantity of the reducing reagent was plotted to determine the optimum amount of DTT (Figure S4 in the Supporting Information).

As shown in Figure S4 in the Supporting Information, the peak area of TK-11 increased with increasing amounts of DTT. The maximum peak area was observed in the reaction containing 35 μL of DTT solutions; therefore, this amount of DTT was used for the proteolysis reactions.

Finally, we optimized the temperature by conducting the reductive alkylation reaction at different temperatures for various times (Figure S5 in the Supporting Information). As shown in Figure S5 in the Supporting Information, the optimum temperature and duration of the reductive alkylation reaction were 60 °C and 15 min, respectively.

Determination of Proteolytic Efficiency. As the proteolysis reaction reaches a chemical equilibrium, or the inhibitors may exist in the extraction buffer, the proteolysis efficiency of β-LG cannot reach 100% even in the optimized digestion conditions.

To determine the proteolytic efficiency of pure β-LG, the mass fraction of β-LG in solid was simultaneously determined by amino acid based IDMS and peptide-based IDMS. As amino acid analysis is a traditional method for protein quantitation, the proteolytic efficiency can be calculated by comparing the ratio of the mass fraction obtained by peptide-based IDMS with that obtained by amino acid based IDMS, assuming complete hydrolysis. The proteolytic efficiency was determined to be 75.7% with a relative standard deviation of 3.0% for seven repeats.

However, the inhibitors in the extraction buffer will depress the proteolytic efficiency greatly. Therefore, ultrafiltration was performed to remove the extraction buffer with 50 mmol/L ammonium bicarbonate to avoid the inhibitory effect of the extraction buffer, which was described in Determination of the Mass Fraction of β-LG in Milk Powders by Proteolysis. In order to determine the proteolytic efficiency of β-LG in milk powders when extraction buffer was applied, some amount of pure β-LG was taken out and treated as the sample according to the protocol described in the section Determination of the Mass Fraction of β-LG in Milk Powders by Proteolysis. Then the proteolytic efficiency can be calculated by comparing the ratio of the mass fraction obtained by peptide-based IDMS to the gravimetric prepared value. However, due to the different β-LG concentrations and different operations, the proteolytic efficiency varied for each run. Nine runs for 3 β-LG levels (0.01 g/g, 0.05 g/g, 0.10 g/g) were carried out for proteolytic efficiency investigation. The proteolytic efficiency was from 6.1% to 15.1% with an average of 11.0% (Table 2). Compared with the proteolytic efficiency of 38% of pure β-LG with digestion time of 16 h, the depression of the inhibitors was also significant even after buffer exchange.

Method Performance of the Peptide-Based β-LG Quantitation by HPLC–IDMS. The performance of the

	0.1	96.2–110.1	5.5	8.8

peptide-based HPLC−IDMS was evaluated for quantitation of both pure β-LG and β-LG in milk powder.

For the quantitation of pure β-LG in solution, a pure β-LG CRM developed by NIM was used to evaluate the accuracy and repeatability of the method. The bias, which can reflect the accuracy of the method, was calculated according to the formula 4

$$A = \frac{|c - c_0|}{c_0} \times 100\% \quad (4)$$

where c is the measured mass fraction of β-LG by TK-11 coupled with the IDMS method (g/g); c_0 is the certified value of β-LG (g/g); and A is the relative bias. The relative bias was determined to be 1.9%, and the relative standard deviation was 3.0% for seven repeats. The limits of detection (LOD) and quantification (LOQ) were calculated based on the S/N ratio of 3 and 10 by single point calibration shown in formula 5, which were 4.8×10^{-8}g/g and 1.6×10^{-7}g/g pure β-LG in solution, respectively. The relative expanded uncertainty was evaluated[42] and it was 4.2% with a coverage factor of 2, which corresponded to a 95% confidence level.

$$m_{\text{sample}} = \frac{R_{\text{h-sample}}}{R_{\text{h-STD}}} \cdot R_{\text{m-STD}} \cdot M_{\text{sample}} \quad (5)$$

where $R_{\text{m-STD}}$ is the mass ratio of TK-11 to L-TK-11 in the standard solution; $R_{\text{h-STD}}$ is the peak height ratio of TK-11 to L-TK-11 of the standard solution; M_{sample} is the mass of L-TK-11 in the sample solution (g); m_{sample} is the mass of TK-11 in the sample solution (g); and $R_{\text{h-sample}}$ is the ratio of signal-to-noise.

For quantitation of β-LG in milk powder, the pure β-LG was added into the native milk powders. And it was treated following the protocol of Determination of the Mass Fraction of β-LG in Milk Powders by Proteolysis. The recovery was calculated as the ratio of the measured concentration difference of the spiked and native milk samples to the concentration of the addition. Therefore, the recovery can be obtained although there is β-LG in native milk powder. As the proteolytic efficiency varied from sample to sample, the proteolytic efficiency for each sample was measured for correction with pure β-LG in extraction buffer as described in Determination of Proteolytic Efficiency. Then the recovery can be obtained by formulas 6 and 7.

$$c_0 = \frac{m_0}{m_s} \cdot P \quad (6)$$

$$R = \frac{c_1 - c_2}{E \cdot c_0} \times 100\% \quad (7)$$

where m_0 is the mass of the pure β-LG added into the spiked sample (g); P is the mass fraction of pure β-LG; m_s is the mass of the sample (g); c_0 is the β-LG concentration added into the sample (g/g); c_1 and c_2 are the measured concentrations of the β-LG in spiked and native samples, respectively (g/g); E is the proteolytic efficiency; and R is the recovery.

Three different brands of milk powders with 3 different spiked levels of each brand were analyzed in the recovery study. The recoveries ranged from 86.0% to 118.3% with maximum CV of 9% (Table 2). The LOD and LOQ were calculated based on the S/N ratio of 3 and 10 by single point calibration, which were 4.8×10^{-5} g/g and 1.6×10^{-4} g/g β-LG in milk powder, respectively. The relative expanded uncertainty was evaluated,[42] and it was 5.9% with a coverage factor of 2, which corresponded to 95% confidence level.

Compared with previously reported methods, the LOD of the proposed method is comparable to that by instrumental methods, such as CE-MS (10^{-6} g/g), LC−MS (10^{-6} g/g), CE (10^{-5}g/g), and HPLC (10^{-6} g/g).[9,11,16] However, the LOD of the proposed method is considerably higher than LOD values reported for ELISA methods (10^{-8} to 10^{-12} g/g).[4,7] However, the proposed HPLC−IDMS method is a potential primary method, which has advantages for a better recovery of 86.0−118.3% and a lower average standard deviation compared with other methods reported.[4,16]

Determination of the Mass Fraction of β-LG in Milk Powders by HPLC−IDMS. Ten samples from the domestic market were analyzed, covering defatted, full cream, infant formula, and partially hydrolyzed formula milk powders. All samples were analyzed according to the protocol described in Determination of the Mass Fraction of β-LG in Milk Powders by Proteolysis. Two subsamples were taken out for each sample, and 3 repeat analyses were performed for each subsample. The results are shown in Table 3, and the typical total ion and extracted ion chromatograms are shown in Figure 2. All of the ten samples were successfully analyzed by the proposed IDMS method with CVs of <5.6%. The contents of β-LG ranged from 0.02 g/g to 0.04 g/g for most samples except one brand had a higher β-LG content of 0.13 g/g.

Table 3. The Mass Fractions of β-LG in 9 Milk Powder Matrices by HPLC−IDMS

sample no.	β-LG content (g/g)	CV (%)
1	0.03	1.9
2	0.02	1.4
3	0.04	1.4
4	0.02	1.4
5	0.03	1.6
6	0.03	5.6
7	0.04	2.8
8	0.13	3.7
9	0.04	5.1

As no β-LG free milk was available, the extraction buffer was used as the blank and negative control. No TK-11 peak was detected of the negative control. To reduce the chance of the false positive, all the samples were treated identically without digestion and analyzed by HPLC−IDMS. No TK-11 peak was detected for all the samples except partially hydrolyzed formula milk powder, demonstrating that no free TK-11 or similar m/z interferences with the same retention time of TK-11 appeared in the samples except partially hydrolyzed formula milk powder. As the proposed method cannot differentiate the intact β-LG from β-LG segments, the proposed method is not suitable for partially hydrolyzed formula milk samples. Though the β-LG content can be calculated for the partially hydrolyzed formula milk sample, it did not reflect the real content; therefore, the result of the partially hydrolyzed formula milk sample was not included in Table 3. In addition, the single charged TK-11(m/z = 1245) and L-TK-11(m/z = 1248), instead of double charged TK-11(m/z = 623) and L-TK-11(m/z = 625), were also captured by HPLC−IDMS to confirm the results of the ten samples, and no clear difference was observed, which demonstrates the reliability of the proposed method.

dx.doi.org/10.1021/jf4054337 | J. Agric. Food Chem. 2014, 62, 3073−3080

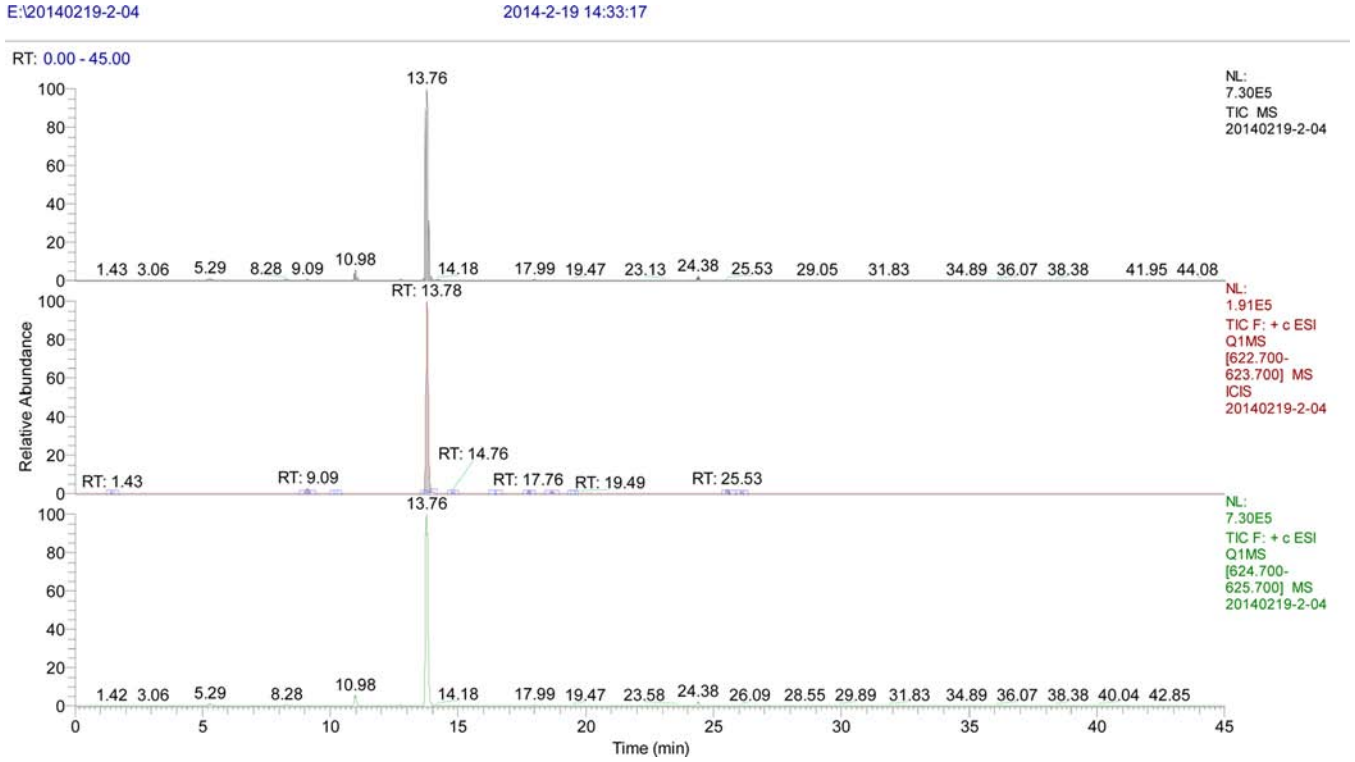

Figure 2. The typical total ion and extracted ion chromatograms of a real sample by HPLC−IDMS.

The quantification results are SI-traceable via the amino acid CRM and IDMS methods (Figure 3). This method is accurate and sufficiently sensitive to detect β-LG in milk powders. It will be useful to develop both pure β-LG CRM and CRM of β-LG in milk powders. The method is also expected to improve the comparability of β-LG quantification results among different laboratories.

[a]Values estimated by EPI Suite v4.11 programs HenryWin v3.2 and KOWWIN v1.68.

Standard and Sample Preparation. Two stock solutions were made; the first (stock 1) was used for extraction phase evaluation and method optimization and contained 500 μL L^{-1} of each analyte, except of the aldehydes and limonene, which were added to the compound set later. The second stock solution (stock 2) was prepared to adjust for the differences in sensitivity between analytes and was composed to cover the whole linear range of all analytes for a more efficient calibration procedure. The composition of the second stock solution is given in Table 1. The highest concentrated calibration solution was prepared with 200 μL of stock 2 filled to 200 mL with water; the lower concentration levels were prepared by a serial dilution with a dilution factor of 2, resulting in a 14-point calibration spanning a concentration factor of 8192.

Forty-six beers from 6 German varieties, Altbier (A, n = 4), Helles (H, n = 6), Kölsch (K, n = 6), Pilsener Bier (P, n = 25), Schwarzbier (S, n = 1), and Weizenbier (wheat beer) (W, n = 4), were analyzed. Three varieties are produced with top-fermenting yeast; they were Kölsch, which is a light lager; Weizenbier, in which a major proportion of barley is replaced by malted wheat; and Altbier, a dark lager that gets its color from roasted malt. The other three varieties are produced with bottom-fermenting yeast and are Helles, a light lager; Schwarzbier, a dark lager; and Pilsener Bier, which is a pale lager with a hoppy aroma. Two Pilsener beers and one Weizen beer were alcohol-free beers (designated \alc). Top- or warm-fermenting yeast ferments at temperatures of 15−25 °C, whereas bottom- or cold-fermenting yeast ferments at temperatures of 6−14 °C and can also use melibiose, which top-fermenting yeast cannot.[15] The fermentation at higher temperatures is faster and results in higher concentrations of higher alcohols and esters.[16] Traditionally, top-fermenting yeast is also known as ale yeast and bottom-fermenting yeast as lager yeast, although the brewing procedure of some top-fermented beers are also subjected to cold storage for conditioning.

The beer samples have been cooled on ice to minimize the loss of volatile compounds to the gas phase before they were diluted by a factor of 10. Because precise measurement of the liquid volume of beer is difficult due to foam formation, 10 g of beer has been weighed in a 100 mL volumetric flask, which was then filled with water. The gas content of the diluted solution was then low enough to be handled by a volumetric pipet.

Ten milliliters of each standard or sample solution was transferred into a 20 mL amber headspace vial (BGB Analytik AG, Boeckten, Switzerland), with an 8 × 3 mm PTFE laminated magnetic stir bar (VWR International GmbH, Darmstadt, Germany). The vials were

Table 2. Properties of Sorbent Materials Used (Manufacturer's Data, If Not Stated Otherwise)

sorbent	sorbent type	specific surface area (m^2 g^{-1})	temperature limit (°C)	water affinity	typical applications
Carbopack C	graphitized carbon black	10	500	relatively low	low to medium boilers (C12−C20)
Carboxen 1000	carbon molecular sieve	1200	225	moderate	permanent gases, volatiles (C2−C5)
Carbosieve S III	carbon molecular sieve	975	400	moderate	volatile organics (C2−C5)
Tenax GR	70% porous organic polymer/30% graphitized carbon	24	350	low	volatiles, flavors
Tenax TA	porous organic polymer	35	350	low	volatiles and semivolatiles (C7−C26)
HayeSep D	porous organic polymer	795	290	low	volatiles (C1−C6)
MWCNT	multiwall carbon nanotubes	211[a]	na[b]	na	na
PDMS and PDMS blue	silicone rubber	absorbent	250	low	unpolar volatiles, semivolatiles
Carbowax 20M	polyethylene glycol	absorbent	225	high	polar semivolatiles

[a]BET measurement. [b]na, not available.

closed by magnetic screw caps with rubber/PTFE septa (BGB Analytik AG).

Sorbent Materials. Nine sorbent materials were tested for their extraction efficiency for the target analytes; they were Carbopack C (CC), Carboxen 1000 (C1000), Carbosieve S III (CSIII), Tenax TA (TTA) (poly(2,6-diphenyl)-*p*-phenyloxide), Tenax GR (TGR) (Tenax TA with graphitized carbon), HayeSep D (HSD) (divinylbenzene (DVB)), multiwalled carbon nanotubes (MWCNTs) (Baytubes C 150 HP, Bayer Material Science, Leverkusen, Germany), polydimethylsiloxane (PDMS), and Carbowax 20 M (polyethylene glycol (PEG) with a molecular weight of 20000) (more information can be found in Table 2). PDMS and PDMS blue (PDMSb) particles were prepared from white silicone and IceBlue septa (Restek Corp., Bellefonte, PA, USA), which have been frozen with liquid nitrogen and were ground and sieved subsequently. Carbowax 20 M could be applied only as a fraction of 10% in a mixed-bed trap with PDMS because it melts at desorption temperature and might drip out of the trap or block it, after cooling again. A two-sorbent bed, prepared of two-thirds Tenax GR and one-third Carbosieve S III, was used on the basis of previous experiences,[18] resulting in a total of 11 different ITEX traps tested.

Sample Extraction and Injection. Sample extraction and injection were executed by a CTC Combi PAL autosampler (Axel Semrau, Sprockhövel, Germany), holding a thermostatic TrayCooler2 for 20 mL headspace vials, a heatable Single Magnet Mixer (SMM) (Chromtech, Idstein, Germany), and the ITEX II option kit (CTC Analytics AG, Zwingen, Switzerland), consisting of a heated syringe holder for a 1.3 mL gastight Hamilton syringe with side port (Hamilton, Bonaduz, Switzerland) and the ITEX trap heater. The extraction was performed by custom-made macros. Only the optimized ITEX procedure, used for sample analysis, is presented here; more details regarding method development are given under Results and Discussion.

The samples were incubated and stirred at 70 °C for 20 min in the SMM to equilibrate the sample headspace prior to extraction. During the incubation time, the ITEX trap was heated to 250 °C while being flushed with 5 mL min^{-1} of nitrogen for 10 min, for preconditioning. After the trap was cooled to 30 °C and the incubation time was over, 65 extraction strokes of 1 mL were performed with a flow of 100 μL s^{-1}. Then 1 mL of helium was aspirated and dispensed at an unconnected ATAS GL Optic 3 injection port (Axel Semrau) to remove residual carbon dioxide of the sample from the void volume of the trap. Following the transfer of the trap to the split/splitless injector (SSL), 500 μL of helium was aspirated as desorption gas and, after the trap was heated to 250 °C, injected with a desorption flow of 50 μL s^{-1}. The whole procedure for each sample (including incubation/equilibration, extraction, injection, and needle flushing) takes about 42 min and can be performed in parallel to the GC analysis, thus making the GC temperature program the total analysis time-determining step.

GC-MS Measurements. All measurements were made using a Thermo Trace GC Ultra, coupled to a Thermo DSQ II single-quadrupole mass spectrometer (S+H Analytik, Mönchengladbach, Germany). The GC was equipped with an Optic 3 programmable temperature vaporizer with a nitrogen-cooled cold trap for on-column focusing and a SSL injector, where the column was connected. Injection was performed into the SSL set to 200 °C in splitless mode; the column flow was set to 1.5 mL min^{-1} constant flow for 31 min and was then raised to 2 mL min^{-1} until the end of the temperature program, to accelerate the elution of low volatile compounds. After injection, the analytes were transferred to an uncoated 0.53 mm inner diameter (i.d.) fused silica capillary (BGB Analytik AG) and cryofocused in the cold trap at −150 °C. After a hold time of 2 min, the trap was heated at 50 °C s^{-1} to 250 °C and the analytes were transferred to the chromatographic column. Separation of compounds was performed on a Stabilwax-DA fused-silica capillary column (cross-bonded Carbowax (PEG)) with 60 m length, 0.32 mm i.d., and 1 μm film thickness (Restek GmbH, Bad Homburg, Germany). The GC oven temperature program started at 35 °C for 5 min and then rose at 5 °C min^{-1} to 110 °C, was held for 2 min, and heated further at 10 °C min^{-1} to 200 °C with a hold time of 10 min. The MS transfer line was set to 220 °C, and the ion source temperature was 200 °C. Electron ionization (EI), with an ionization energy of 70 eV, was used in scan mode (m/z 29−200), with a scan rate of 500 amu s^{-1}. Instrument automation, data acquisition, and data processing were performed using the Xcalibur 1.4 data system (S+H Analytik).

RESULTS AND DISCUSSION

Method Optimization. The ITEX procedure comprises three main steps: sample extraction, sample injection, and trap conditioning for the next analysis; several parameters can be optimized in each of these steps. The extraction parameters, next to the choice of the most suitable extraction material, are the temperatures of the trap and the sample solution and the number, volume, and flow of the extraction strokes. The parameters for injection are the desorption gas volume and flow and the desorption temperature; trap conditioning includes conditioning temperature and time.

Two of the extraction parameters will not be discussed here. The first is the choice of the extraction material, which will be covered in the next section, because it was performed after the optimization of the parameters, and the second is the trap temperature, which should normally be set to the lowest possible value, due to the exothermic nature of the sorption process. Sample temperatures were tested from 40 to 80 °C in intervals of 10 °C. The majority of analytes show increasing extraction efficiency in the whole tested range, but about a third of the analytes begin to lose sensitivity when the temperature is raised from 70 to 80 °C. Here it is an advantage of ITEX that the sorption material is located outside the heated sample vial, because a similar loss of sensitivity has been observed for the

analysis of terpenes using HS-SPME already at temperatures above 40 °C.[24] The extraction flow and the number of extraction strokes have to be optimized together, because their combination defines the efficiency and duration of the extraction procedure. An extraction flow of 10 μL s^{-1} gives the highest peak areas for all compounds, which drop to 33−94% of the area at 50 μL s^{-1} and 28−88% at 100 μL s^{-1}, with averages of 63 and 52%, respectively. On the other hand, when 10 extraction strokes is defined as 100%, the extracted amount increases to 119−1337% for 100 extraction strokes, with an average of 626%. The average peak areas for 25, 50, and 75 extraction strokes were 228, 299, and 399%, respectively. No analyte reached equilibrium within the tested 100 extraction strokes. As an increase in the number of extraction strokes by a factor of 10 results in about 6 times larger peak areas, whereas the same increase of the extraction flow only halves the peak areas, a high number of extraction strokes with a high flow gives a better extraction efficiency in the same extraction time. Consequently, 65 extraction strokes with an extraction flow of 100 μL s^{-1} was chosen, which was the maximum to be performed in parallel to the GC oven run time.

Desorption volumes of 100, 500, and 1000 μL were tested. An increase of the resulting peak areas for most compounds can be observed from 100 to 500 μL, whereas a further increase is visible only for low-volatile compounds, such as geraniol, ethyl decanoate, or diethyl succinate, when the desorption volume is raised from 500 to 1000 μL. Because the gain in sensitivity was not significant and limited to a few compounds, a desorption volume of 500 μL was chosen. The desorption flow showed a similar behavior, with a decline of peak areas from a flow of 10 to 50 μL s^{-1}, whereas only the peak areas of the low-volatile compounds further decrease at a flow of 100 μL s^{-1}. As the reproducibility got better with higher desorption flows, 50 μL s^{-1} was used. The optimization results also agree with the ones found for environmental contaminants in an earlier work.[18]

Choice of Extraction Phase Material. The comparison of the extraction materials was performed with a 5 μg L^{-1} standard solution and the optimized method parameters given before, but with adapted desorption temperatures for each trap. On the basis of previous experiences, which indicated that the best desorption efficiency is reached at high desorption temperatures,[18] the desorption temperature was set at or near the maximum temperature for each sorbent (see Table 2). The desorption temperatures were set to 300 °C for Carbopack C, Carbosieve S III, Tenax GR, Tenax TA, and the MWCNTs, to 250 °C for HayeSep D and PDMS, and to 200 °C for the trap containing Carbowax 20 M and C1000.

A summary of the total extracted amounts with each trap is given in Figure 1. The best overall extraction yield was achieved with HayeSep D, Tenax GR, Tenax TA, and Carbopack C; the PDMS -based absorbent traps were in a medium range, and the traps using molecular sieves and carbon nanotubes had the lowest yield. Information on the extracted amount per compound can be found in Table 3. HSD was most effective for the trapping of long-chain esters and terpenes, but less suitable for the more polar alcohols, for which TTA was the best sorbent. TGR had a lower efficiency for alcohols than TTA and was best suited for short-chain esters. CC as an apolar material also had the highest yields for esters and long-chain alcohols, but, complementary to HSD, very low efficiency for long-chain esters and terpenes, which may be caused by irreversible adsorption or the degradation of analytes; similar reasons might be responsible for the low extraction yields of the

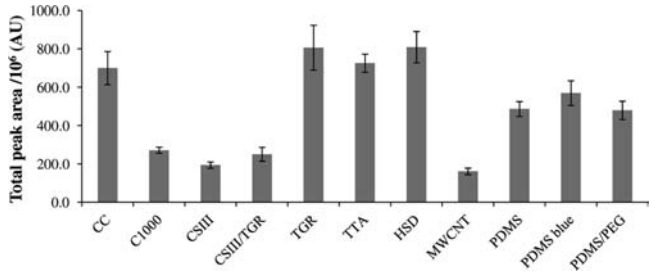

Figure 1. Summarized peak areas with average repeatability of all analytes (CC (Carbopack C), C1000 (Carboxen 1000), CSIII (Carbosieve S III), TGR (Tenax GR), TTA (Tenax TA), HSD (HayeSep D), MW CNT (multiwalled carbon nanotubes), PDMS (polydimethylsiloxane), PEG (polyethylene glycol)).

traps containing carbon molecular sieves. It has been found that the surface of carbon-based adsorbents can be activated during the conditioning, even with a stream of inert gas, and then cause analyte loss by transformation reactions, especially for alcohols and carbonyl compounds.[25] This may also apply for the MWCNTs, for which more research is currently being carried out. Because the sensitivity for esters was generally better than for alcohols and the differences in the total extracted amount were quite small, the carbon-based adsorbents were excluded and TTA was initially chosen as sorbent material.

However, when the linear range was determined during method evaluation, it proved to be quite limited for TTA (see Table 4), which led to an inferior repeatability for beer samples relative to standard solutions because of competition and displacement effects of ethanol. Moreover, the compound set was extended with aldehydes, including benzaldehyde, which can be formed as a degradation product of Tenax TA during thermal desorption.[26] When the carbon- and Tenax-based sorbents were ruled out because of their reactivity with alcohols and carbonyl compounds or interfering degradation product formation, only HSD- and the PDMS-based traps remained. However, HSD as adsorbent material would suffer from the same competition effects as TTA while the equilibrium conditions of absorbent materials do not vary until loadings of several percent are present.[27] This rendered a re-evaluation of sorbent materials for the enhanced compound set unnecessary and, consequently, the trap containing PDMS blue was used, which had the best performance of the remaining sorbents and promised to possess a wider linear range, being an absorbent material.

Method Performance Parameters. Method performance parameters were evaluated for the initially used TTA trap and the finally used PDMSb trap. The method detection limit (MDL), precision, and linear range were determined for both traps, the recovery and extracted analyte fraction only for the latter one. The results are summarized in Table 4.

The MDL of each analyte was determined by using a procedure of the U.S. Environmental Protection Agency, as the minimum concentration of an analyte that can be reported greater than zero with a confidence of 99%. It is based on the standard deviation of a seven-fold analysis with an analyte concentration resulting in a signal-to-noise ratio of about 3−5.[28] The linear range was determined as result in a constant slope between the calibration points. The precision was calculated as the average of all calibration points within the linear range, and a range factor (RF) was defined by dividing

the upper limit of the linear range by the lower limit, for an easier comparison of linear ranges between sorbent materials. The MDLs achieved with the TTA trap ranged from 0.01 to 17.5 μg L^{-1} with a median of 0.2 μg L^{-1}, except for benzaldehyde, for which no quantitation was possible because of artifact formation by TTA during desorption. The average MDL for the alcohols is 1 μg L^{-1}, whereas it is 0.17 μg L^{-1} for the esters without diethyl succinate (2.1 μg L^{-1} when included), which is mainly influenced by the much higher air−water partitioning coefficient (K_{aw}, see Table 1) of most of the esters rather than by the selectivity of TTA toward the analytes. K_{aw} of diethyl succinate is 3 orders of magnitude lower than of the other esters and the lowest of all analytes. Precision with TTA was consistent in a narrow band between 6.2 and 10.0%, but the linear range was quite limited, and RF spanned from 25 to 540, with an average of 136 and a median of 88, giving <2 orders of magnitude for most analytes. The precision achieved for beer samples was worse than for standard solutions (>20% RSD), due to the low RF, the wide range of analyte concentrations in the samples, and competition effects, even when the beer has been diluted by a factor of 50. Zapata et al. experienced similar problems with mass saturation of TTA and solved it by using a stronger sorbent (Bond Elut ENV) and very small sample amounts (10 μL, diluted by a factor of 5) to achieve quantitative analyte extraction.[13] A different approach has been chosen here, where an absorbent material was used, which does not suffer from competition and saturation effects.[29]

The MDLs for the PDMSb trap were mostly higher than for TTA, ranging from 0.3 to 13 μg L^{-1}, with a median of 1.6 μg L^{-1}. They were lower for diethyl succinate, which had by far the highest MDL with TTA, 2-phenethyl acetate, and geraniol; furthermore, the quantitation of benzaldehyde was possible with PDMSb, because no artifacts were formed by the sorbent. The largest difference was observed with 3-methylbutyl acetate, for which the MDL was 410 times higher with PDMSb, but apart from this, the difference was about a factor of 10 and the sensitivity was still good enough to dilute the samples by a factor of 10 before the analysis. The same trend for the sensitivities of alcohols and esters that has been observed with TTA also applied for the extraction with PDMSb. The precision was less consistent, ranging from 1.2% for 3-pentanol to 19.9% for *trans*-2-nonenal, but overall it was better, with <5% for the majority of analytes. The linear range improved, as expected, using a sorbent based on analyte partitioning rather than adsorption. RF was between 32 and 4485, with an average of 666 and a median of 391, being about 5 times larger. The

[a]Method detection limit (MDL), precision (as relative standard deviation (RSD)), linear range (absolute and range factor (RF) from lowest to highest concentration, + indicates upper limit not reached within applied concentration range), recovery from spiked samples and extracted analyte fraction (F_e).

limit of the linear range was not reached within the applied concentration range for 1-propanol, 2-propanol, 2-methylpropanol, 2-butanol, 2-methylbutanol, 3-methylbutanol, and 3-pentanol, which could make the difference even bigger.

When the MDLs are compared to those of a solid phase dynamic extraction (SPDE) method for a similar compound set, which was previously used to analyze wine samples,[30] the ITEX method is more or less sensitive, depending on the applied sorbent material. Compared to the results with TTA, the MDLs of the SPDE method are lower for diethyl succinate and 2-phenethyl acetate, equal for ethyl hexanoate and 3-pentanol, and between 1.3 and 570 times higher for the other compounds, with a median of 3.6. With the PDMSb phase, the MDLs of the ITEX method are lower by a factor of 4 for 7 of 22 analytes, equal for 2-phenethyl acetate, and higher by an average factor of 5 for the other 14 compounds, analyzed in both methods. The lower MDL using the TTA phase should be caused by stronger sorption of the analytes and the larger sorbent volume of ITEX, compared to the 4.5 μL PEG phase that was used in SPDE. On the other hand, PEG is more polar than PDMS, making the SPDE method more sensitive for 9 of 13 of the analyzed alcohols. As no data on the linear range of the SPDE method are available, it is difficult to estimate if the smaller sorbent volume has negative effects on the extraction capacity. Liu et al. presented a method for similar analytes from beer samples, using sol−gel-derived SPME fibers. The limits of detection are comparable to those of the ITEX method with TTA sorbent and lower than ITEX with PDMSb, but the linear range of the SPME method is smaller.[31] The detection limits of the earlier mentioned ITEX method for quantitative extraction by Zapata et al. are between 3 and 117 times larger than for the method presented here; however, they were still low enough for the analysis in natural abundance in beer and wine. A comparison of linear ranges is not feasible because it has been determined only in the expected analyte range.[13]

The recovery was calculated by the analysis of pure and spiked beer samples, which were measured undiluted, diluted by a factor of 10, and diluted by a factor of 100; the spike was

made using 1, 5, and 10 μL of the standard solution stock 2 in 100 mL of sample, respectively. In this way, the recovery for all analytes could be calculated from at least one analysis within the linear range; when two or all measurements were within the linear range, an average was calculated. The recoveries were between 91.8% for diethyl succinate and 131.7% for 3-pentanol, with an average of 111%. Considering the difficult handling of the undiluted samples, due to foam formation, that had to be transferred to the sample vials after spiking, it seems acceptable that most analytes show recoveries of 100 ± 15%. The recovery for 2-propanol could not be determined because the peak coeluted with ethanol, and in this period, the detector was turned off to avoid detector saturation when beer samples were analyzed.

The extracted fraction (F_e) of analyte, which is removed from the sample vial in each analysis, was calculated following the depletion method proposed by Zimmermann et al., by consecutive analyses from the same sample vial.[32] To that end three samples have been extracted five times each, and the logarithmic peak areas of the analytes were plotted over the number of extractions to obtain a linear graph, from which F_e could easily be calculated by the slope. F_e ranged from 2.3% for linalool to 77.9% for limonene. Here it was apparent that the octanol–water partitioning coefficient (K_{ow}, Table 1), which can be used to estimate the sorption of analytes to PDMS,[29,33]

has lower influence on the extraction efficiency than K_{aw}. Limonene has the highest F_e and the highest values for K_{aw} and K_{ow}, but ethyl hexanoate and linalool have similar log K_{ow} values of 2.83 and 2.97 with extracted fractions of 34.7 and 2.3%, respectively, so that the difference must originate in K_{aw}. Also, 1-pentanol and geraniol have similar log K_{aw} values of −3.27 and −3.33, respectively, but whereas log K_{ow} of geraniol is larger by a factor of 2, F_e of 1-pentanol is 2 times larger (7.2%) than for geraniol (3.56%). When F_e is plotted over log K_{aw} (Supporting Information Figure S1a)) and log K_{ow} (Figure S1b)), a roughly linear trend can be observed for K_{aw}, whereas no trend is visible for K_{ow}. However, this should be considered merely as a rule of thumb for ITEX users to estimate the probable extraction efficiency, because the system is not in equilibrium and the air−water and octanol−water partitioning coefficients that can be found in the literature can show quite large variations for some compounds.

Quantitative Analysis. An overview on the detected concentration ranges of all analytes and the number of samples, in which they were detected is given in Table 5; the results for all samples can be found in the Tables S1−S5 in the Supporting Information. 2-Propanol could not be detected in the actual beer samples because it coeluted with the ethanol peak, for which the detector was turned off to avoid saturation. If the peak would have been detected, quantitation could have been performed by the mass selective detector, but, as previous work showed, only with a high RSD of about 20%.[30] Three analytes were not detected in any beer sample; 3-pentanol, 3-methylpentanol, and benzaldehyde were always below the method detection limits. *trans*-2-Nonenal was detected in only two samples (H06 and P04) at a concentration of about 6 μg L^{-1}, making acetaldehyde the only one of the investigated aldehydes that was found in considerable amounts, with concentrations between 2.6 and 13.2 mg L^{-1}.

The sample concentration exceeded the determined linear range for four analytes, acetaldehyde, ethyl acetate, 2-methylpropanol, and 3-methylbutanol. Eleven samples contained acetaldehyde above the linear range of the method, but only four exceeded it by >20%. In the case of ethyl acetate, 5 of 46 samples had higher concentrations, 4 were about 20% higher, and 1 was 78% higher. Twenty-one samples contained 2-methylpropanol above the upper limit of the determined linear range, which was also the upper limit of the used calibration solutions, with the highest value being almost 3 times higher than the linear range. Thirty-three of 46 samples had concentrations of 3-methylbutanol above the highest concentrated calibration solution, similar to 2-methylpropanol. Finally, the problems with 2-methylpropanol and 3-methylbutanol have not been evident during the method development, because the concentration in the beer, which was used for test measurements, was within the linear ranges of each analyte. For future applications it needs to be checked if the problem can be solved by an increased calibration range, a stronger dilution of the samples, or a combination of both.

Eight analytes were detected in all 46 beer samples; they were 1-propanol, 2-methylpropanol, 2-methylbutanol, 3-methylbutanol, ethyl acetate, ethyl hexanoate, ethyl octanoate, and acetaldehyde. Ethyl butanoate, 3-methylbutyl acetate, and 2-phenethyl acetate were detected in 45 samples, and all three were missing in sample P25\alc, an alcohol-free Pilsener beer. Ethyl decanoate was not found in two alcohol-free beers, P25\alc and W01\alc, and diethyl succinate was absent in four samples (P05, P24\alc, P25\alc, and W01\alc), three of which were again alcohol-free variants.

Alcohol-free Beer. A regular wheat beer and the corresponding alcohol-free variant of the same brand were analyzed. The overlaid total ion chromatograms of the two beers are presented in Figure S2 (Supporting Information), where it can clearly be seen that the peaks of most compounds are much smaller in the alcohol-free version. A detailed view of the analytes found in these two samples, together with the fraction that was lost in the making of the alcohol-free beer, is given in Table 6. The average loss was 21% for acetaldehyde, 79% for the alcohols, and up to 88% for the esters. The levels dropped below the method detection limit for ethyl decanoate, diethyl succinate, and *tert*-butanol, for which, with the corresponding MDLs set as maximum possible remaining concentrations, the losses were at least 87, 66, and 49%, respectively. Exceptions were 1-butanol, 2-butanol, and linalool, for which the levels in the alcohol-free beer were higher than in the regular beer. However, the value for the regular beer of 1-butanol is below the lower limit of the linear range, which starts at 127 μg L^{-1}, due to sample dilution. Linalool is just above the MDL; in this way the differences might, as well as for 1-hexanol, originate in measurement uncertainty.

Variety Discrimination by Linear Discriminant Analysis (LDA). A LDA was performed with the free software environment R 3.0.1 (The R Foundation for Statistical Computing, www.r-project.org) using the "lda" function from the "MASS" package,[34] on semiquantitative data. To that end, the peak areas of quantified analytes present in almost all samples were combined with the peak areas of several

additional compounds, which were detected in many samples, resulting in 31 components as explanatory variables for the LDA, which are given in Table S6 in the Supporting Information. The number of useful discriminant functions is limited to the minimum of either the number of the groups minus one or the number of variables. Because the beer samples originated from eight different varieties, seven discriminant functions could be found. Their proportions of trace are shown in Figure 2. This shows that the first two linear discriminants explain about 95% of the between-group variance and should provide good separation. Most of the additional compounds were identified only by a mass spectral database; however, isoamyl propionate was the only one with a significant influence on the loadings on LD1 and LD2, which are given in Table S6, also. The main loadings on LD1 were given to isoamyl propionate in the positive direction and to 1-hexanol in the negative direction; the main loadings on LD2 were ethyl 3-methylbutanoate in the positive and diethyl succinate in the negative direction.

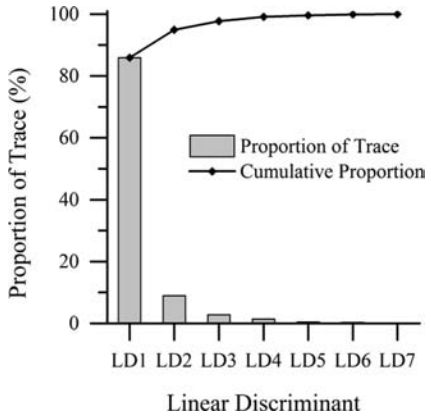

Figure 2. Proportion of trace and cumulative proportions of the seven found liniear discriminants.

Table 7 shows the prediction results using these two first discriminants. The proportion of correct predictions was almost 90%, and four of the five false predictions are between Pilsener beer and Helles, which have very similar brewing processes, their main difference being the lower hop content of Helles. Moreover, one of the falsely predicted Pilsener beers is marketed to be especially mild and another one had an increased alcohol content, which might separate them from the other beers of their variety.

A graphical representation of this situation is given in Figure S3 (Supporting Information), which shows a scatter plot based on the first two discriminant functions with boundaries for each beer variety. The distance of the two kinds of alcohol-free beers between themselves and to the rest of the beer varieties was so large that they were not included in the plot. As already discussed using Table 7 a good discrimination is achieved, and only the quite similar varieties of Pilsener beer and Helles are partially overlapping. The production conditions of these two varieties can also be quite different, as the samples originated from breweries throughout Germany, but there were also beers from Poland and Turkey and specialty beers that were brewed with higher alcohol content. On the other hand, the variations within the small groups of the top-fermenting beers Alt, Kölsch, and wheat beer were relatively small, as they are regional beers. A separation between the two general classes of top-fermenting (K, W, A) and bottom-fermenting (H, S, P) is also visible, as the top-fermenting beers are by trend more located in the lower left area of the plot, whereas the bottom-fermenting beers tend to be in the upper right-hand area.

The developed method was appropriate to perform a sensitive and robust analysis of beer samples. The performance was mostly comparable to results obtained with other microextraction techniques such as SPDE or SPME (utilizing also a special prepared coating) and in some cases also much better. The data, obtained during method evaluation, highlight that it is not always significant to have the most sensitive method, but a robust method, which also complies with factors such as precision and linear range, where it is important to choose the appropriate sorbent material for the analytical task at hand. Still, the presented ITEX method was sensitive enough to allow the dilution of the samples to minimize the influence of the matrix. A satisfying chemometric discrimination of all analyzed beer varieties was possible, and the alcohol-free beers could clearly be separated from the regular beers, also. Therefore, it would be possible to use it for quality control screening of beers to check if the well-known brand character is consistent over time to satisfy the expectations of customers.[10]

This way, information about the difference in folate distribution within or between individual potatoes of the same variety, age, and size can be used to gain further insight into the divergence of reported results.

Here, we report on the development, the validation, and the application of an ultrahigh-performance liquid chromatography−tandem mass spectrometry (UHPLC-MS/MS) method, capable of providing a folate profile (encompassing six folate monoglutamates), starting from only 200 mg (FW) of potato flesh. To expand the use of our method, we opted for a single calibration curve, covering a wide dynamic range. This way, potatoes with higher folate content (obtained, for example, through biofortification via breeding[2] or genetic engineering[23−25]) can also be analyzed. The method was used to investigate the differences in folate distribution in tubers of the potato variety Désirée at different stages of maturation. Moreover, this method was used to compose, for the first time, a two-dimensional folate profile throughout potato tubers in order to visualize the biological variability both within and between potato tubers of the potato variety Désirée.

MATERIALS AND METHODS

All manipulations involving folates were done under subdued light. The air in the headspace was not displaced by use of an inert gas, but the solutions used for preparation of the stock solutions, the working solutions, and the extraction buffer were flushed with nitrogen.

Tetrahydrofolate (THF), 5-methyltetrahydrofolate (5-MTHF), 5,10-methenyltetrahydrofolate (5,10-CH+THF), 10-formyl folic acid (10-CHOFA), 5-formyl tetrahydrofolate (5-CHOTHF), and folic acid (FA) were purchased from Schirck's Laboratories (Jona, Switzerland). [$^{13}C_5$]-THF, [$^{13}C_5$]-5-MTHF, [$^{13}C_5$]-5,10-CH+THF, and [$^{13}C_5$]-FA were obtained from Merck Eprova (Schaffhausen, Switzerland) and were used as internal standards (ISs, labeling yield for all >98%) for their respective analogues. [$^{13}C_5$]-FA was also used as an IS for 5-CHOTHF and 10-CHOFA, based on its chromatographic retention characteristics.

Ultrapure water was obtained from a Synergy ultrapure water purification system (Millipore, Brussels, Belgium). Formic acid, sodium phosphate, ascorbic acid, dithiotreitol (DTT), and activated charcoal were purchased from Sigma (Diegem, Belgium). Methanol and acetonitrile of LC-MS grade were purchased from Biosolve (Valkenswaard, The Netherlands). BCR-121 wholemeal flour was obtained from the European Commission, Institute for Reference Materials and Measurement (Brussels, Belgium).

α-Amylase (type I-A, from porcine pancreas, 23.5 units/μL, EC no. 232-565-6) and protease (type XIV, from *Streptomyces griseus*, ≥3.5 units/mg, EC no. 232-909-5) were purchased from Sigma. Male rat serum was acquired from Harlan (Horst, The Netherlands). Protease was dissolved in distilled water (4 mg/mL). To remove most of the endogenous folates, protease and rat serum were mixed with a $^1/_{10}$th volume of activated charcoal and stirred for 1 h on ice, centrifuged, filtered, and divided into 500 μL aliquots. Both enzymes were stored at −80 °C. α-Amylase was used without pretreatment and stored at 4 °C.

Homogenization was either performed by manually grinding single samples in liquid nitrogen with mortar and pestle or with an IKA-18 basic Ultra-Turrax (Labo service, Kontich, Belgium). Larger volumes were mixed and subsequently divided into representative aliquots of actual samples. For ultrafiltration, 3 mL (Amicon, Millipore) 3 kDa molecular weight cutoff membrane filters were used. Ultrafiltration was done in an Eppendorf centrifuge 5804 R at 4 °C (Hamburg, Germany).

The potato variety Nicola was bought in a local supermarket (for optimization of sample preparation) or provided by a local distributor (for profiling). The potato variety Désirée, which we used for genetic engineering purposes,[25] was provided by the Laboratory of Functional Plant Biology (for determination at different stages of maturation) or bought in a local supermarket (for validation experiments).

Preparation of Stock and Working Solutions. All folate stock solutions were prepared in a 50 mM phosphate buffer, pH 7.5 or 3 (for 5,10-CH+THF, as this compound is more stable at acidic pH) containing 1% ascorbic acid and 0.5% DTT/methanol (50/50, v/v). Both standard and IS stock solutions were stored at −80 °C. Working solutions were prepared daily by appropriate dilution with the extraction buffer, which was a 50 mM phosphate buffer at pH 7.5, containing 1% ascorbic acid, 0.5% DTT, and the IS (with a concentration of 20 ng/mL for [$^{13}C_5$]-THF and 40 ng/mL for the other ISs).

Lyophilization. Dry matter content determination and freeze-drying of frozen homogeneous samples were performed by an Amsco FINN-AQUA GT4 freeze-dryer (GEA, Köln, Germany). The cycle comprised primary drying at −20 °C overnight, followed by a secondary drying step at 0 °C for three hours. The pressure for both cycles was held at 100 μbar.

Chromatography. Chromatography was performed on a Waters Acquity UHPLC system including a binary pump, controlled by analyst 1.5.2 software (AB Sciex, Toronto, Canada). The column oven temperature was maintained at 60 °C, and the autosampler was at 4 °C. An Acquity HSS T3 column (C18, 150 mm × 2.1 mm; 1.8 μm particle size, from Waters) with a VanGuard precolumn (C18, 5 mm × 2.1 mm; 1.8 μm particle size, from Waters) was used. The injection volume was 10 μL. For gradient elution, the mobile phase consisted of eluent A (0.1% formic acid in water) and eluent B (0.1% formic acid in acetonitrile) and was pumped at a flow rate of 0.6 mL/min. Initially, the same gradient was applied as described by De Brouwer et al.[26] However, we adapted this gradient to eliminate an interference coeluting with FA. The starting condition (100% A) was kept for 1 min. Subsequently, there was a nonlinear, convex increase to 95% B in 3 min, which was kept for 1 min. The mobile phase was then immediately adjusted to its initial composition and held for 3 min for re-equilibration, resulting in a total time of 8 min.

MS Instrumentation and Settings. The detection was performed by positive electrospray ionization (ESI) utilizing heated auxiliary gas (Turbospray), in the scheduled MRM mode on an Applied Biosystems API 4000 tandem mass spectrometer (Ontario, Canada). On the basis of the largest peak width at the base (5-MTHF), an MRM detection window of 30 s was chosen, together with a 0.5 s target scan time, generating at least 27 data points for 5-MTHF. The source conditions were optimized and were set as follows: source temperature, 500 °C; ion spray voltage, 3.5 kV; Q1 and Q3, unit mass resolution. The interface heater was on (100 °C); nitrogen was used for the nebulizer (gas 1), heater (gas 2), curtain, and collisionally activated dissociation (CAD) gas. Gasses 1 and 2 and the curtain gas had respective pressure settings at 70, 90, and 25 psi. The vacuum setting for CAD was set at 8, a configuration-dependent arbitrary value of the instrument. Compound parameters, together with retention times are given in Table 1.

Sample Preparation. The general sample preparation protocol included boiling, homogenization, extraction with trienzyme treatment (α-amylase, protease, and conjugase), and additional heat treatments to stop enzyme activities. The resulting solutions were ultrafiltrated at 12 851*g* for 15 min prior to UHPLC-MS/MS analysis. Before all manipulations, 1.5 mL of the extraction buffer was added to ±200 mg of fresh potato flesh, taken with a kitchen knife from the center of a single tuber. When samples were prepared in bulk (for optimization and validation purposes), a corresponding volume of extraction buffer was added to central sections of potato tubers (8−10 g, collected from 2−3 mature tubers). This quantity was afterward divided into aliquots corresponding to 200 mg of fresh potato flesh. Several variables in distinct steps of this general protocol were evaluated to obtain the best folate recovery. These included a comparison of homogenization by mixing or grinding with liquid nitrogen, boiling or not, freeze-drying or not, and varying the volumes of the three enzymes: 0, 20, 30, or 40 μL of α-amylase (0, 470, 705, or 940 units, respectively); 0 or 150 μL of the charcoal-treated protease solution (0 or 2.1 units, respectively); 100 or 150 μL of the charcoal-treated rat serum conjugase solution. Since starch is a main component of potato flesh, we opted to test three increasing volumes of α-amylase. The evaluation of boiling and

lyophilization prior to storage was done in a joint experiment: skinless fresh potato was boiled or kept on ice and immediately homogenized by mixing. Subsequently, representative aliquots were weighed individually before and after lyophilization. These samples were kept at −80 °C until analysis.

VALIDATION

Selectivity. Selectivity for the folate monoglutamates was investigated by injecting aliquots of neat buffer solutions, spiked with the six monoglutamates and the four ISs (individually and together).

Sensitivity. The limit of detection (LOD) and lower limit of quantitation (LLOQ) are defined as the concentrations with a signal-to-noise ratio equal to or larger than 3 and 10, respectively. In this case, the LLOQ was arbitrarily set as the lowest point of the calibration curve because of the lack of a blank matrix. For determination of the LOD, potato matrix was diluted 1:20 in ultrapure water and boiled in the presence of light to destroy most endogenous folates. As this still yielded a measurable signal for 5-MTHF, the matrix was further diluted 1:20 and ultrafiltrated to approach a blank matrix. The matrix was prepared this way because the LOD is a qualitative descriptor of sensitivity, in contrast to the LLOQ, where possible matrix effects can affect calibration. It was then used to serially dilute the six folate standards. The average short-term noise of five independent injections of these serially diluted standards was used to correlate the peak heights with the corresponding concentrations.

Linearity and Calibration. Prior to testing the linearity of a calibration model, homoscedasticity of the calibrators was investigated. Therefore, residual plots were generated and Fisher's tests ($p < 0.01$) were performed. To obtain a linear model, the most common weighting factors ($1/\sqrt{x}$, $1/x$, $1/x^2$, $1/\sqrt{y}$, $1/y$, and $1/y^2$) and transformations (logarithmic or square rooted) were tested by comparing the sums of percent relative error (%RE, calculated as the difference between the obtained and the nominal concentration, divided by the nominal concentration and multiplied by 100), in accordance with the protocol described by Almeida et al.[27] Linearity of the most appropriate model for each folate was then tested by performing analysis of variance (ANOVA) lack of fit (LOF) tests.

Calibration curves with seven calibrators were constructed by spiking a mix of the six standards to a 1:20 dilution of potato matrix in extraction buffer. Four quality controls (QCs), including the lower and upper limits of quantitation (ULOQ), were prepared similarly but in a 1:2 diluted potato matrix, except the LLOQ QC, which was prepared in a 10-fold diluted matrix, so the endogenous folate content would not exceed the spiked concentration. The concentrations (in μg/100 g of FW) spiked to the calibrators and QCs are depicted in Table S2 (Supporting Information). After completing the sample preparation protocol, extracts of these samples were injected onto the UHPLC-MS/MS, not randomly but in increasing order of calibrator concentration. To make sure this did not contribute to heteroscedasticity, the carry-over effect was investigated by injecting a blank water sample after injection of the calibrator with the highest concentration. Lack of a significant carry-over requires that the signal obtained at the retention times of the respective folates should at all times be less than 20% or less than 5% of the LLOQ of the folate standards and ISs, respectively.

Accuracy, Precision and Measurement Uncertainty. Experiments for accuracy and precision were performed at four QC levels on three nonconsecutive days, in duplicate ($n = 3 \times 2$). Every day, fresh calibrators and QCs were prepared and analyzed as described above. Zero samples (i.e., samples with only IS spiked) were also included to subtract the endogenous folate content of the matrix. Intra- and interday precision (% relative standard deviation or %RSD), together with accuracy (%bias) were calculated as reported by Wille et al.[28] and should be less than 15%, except at the LLOQ, where they should be less than 20%. The measurement uncertainty is represented by a 95% confidence interval (CI). The interval was constructed by the combination of %bias and the %RSD (interday) of the measured value. This way, the interval becomes [measured value ± (|%bias| + 2 × %RSD)].

Matrix Effect and Recovery. To evaluate the matrix effect (ME, where percentage values <100% represent ion suppression and >100% represent ion enhancement) and recovery (REC), three separate batches of samples ($n = 3$) were prepared as suggested by Matuszewski et al.[29] Batch A contained the "neat" standards and consisted of extraction buffer, spiked at three QC levels (LOW, MED, and HIGH). Batches B and C contained 1:2 diluted potato matrix spiked after and before sample preparation, respectively. For the latter two batches, zero samples were again included. The ME and REC were then calculated as B/A*100 and C/B*100, respectively, where the zero sample signals were subtracted from B and C.

Short-Term Stability (STS) and Freeze−Thaw Stability (FTS). Aliquots of sample extracts ($n = 3$), spiked at the four QC levels, were immediately injected onto the UHPLC-MS/MS (and stayed in the autosampler at 4 °C for reanalysis after 24 h) or were frozen at −20 °C (FTS). Three freeze−thaw cycles were also performed in one day and after each cycle analysis was performed.

Analysis of Reference Material BCR-121 (Wholemeal Flour). Samples of 200 mg ($n = 5$) were treated the same way

Figure 1. as fresh potato flesh, apart from the homogenization step, and underwent the full trienzyme treatment.

Application to the Potato Variety Désirée. The developed procedure was applied to the potato variety Désirée at three stages of maturation. Potato samples (200 mg, taken from the center of the tubers) were treated or not with conjugase to gain information about the polyglutamylation status. Immature tubers were grown at the Laboratory of Functional Plant Biology, harvested 17 weeks after plantation, and kept frozen at −20 °C until analysis. Store-bought mature tubers were kept at room temperature and analyzed that same day or after two months (when tubers were sprouting).

Folate Profiling of Potato Variety Nicola. Three potatoes with the same level of maturation and of uniform size were chosen. From each of these, a central slice was cut with a kitchen knife and divided into segments, to form a two-dimensional representation of the tuber. From the basal to the horizontal opposite apical end, 13 segments were taken, including 1 central and 2 marginal segments containing peel. From the upper surface to below, seven segments were taken, again including one central and two marginal segments. Each of these segments was further subdivided into two subsections. The first subsection was used for determination of dry matter content, the second subsection was further divided into two 200 mg sections to create genuine replicates.

RESULTS AND DISCUSSION

Eliminating Coeluting Interferences in Potato Matrix. The experiments involving sample preparation were conducted on the variety Nicola with a HPLC-MS/MS procedure as described by De Brouwer et al.[30] The initially determined total and free monoglutamate contents of this variety were respectively 21.78 ± 1.42 and 13.62 ± 0.35 μg/100 g, indicating a polyglutamylation status of 37.5%. Because of a coeluting interference, FA had to be quantified using its second MRM transition (442.1 → 176.2). To eliminate this problem, we switched the linear increase of the gradient to a convex type, which resulted in a more swift increase of mobile phase B. This modification caused a change in retention of the matrix-specific interference, now allowing a selective detection of FA with its first transition (442.1 → 295.3). Application of this gradient also improved the peak shape of 5-CHOTHF, which now eluted in a shorter time interval. Representative chromatograms, obtained with the optimized gradient, are depicted in Figure 1. Figure 1a shows a chromatogram of diluted potato extracts, spiked at the lowest calibrator level, that is, at LLOQ, while Figure 1b depicts the folate profile of potato variety Désirée. In the former, the respective scan windows of the scheduled MRM algorithm are indicated for each folate and IS at the bottom of the chromatogram. It should be noted that the fact that 10-CHOFA and 5-CHOTHF are not baseline separated does not pose a problem, since MS can distinguish these compounds. We deliberately chose not to detect or distinguish between 5,10-methylenetetrahydrofolate (5,10-CH_2THF) and 10-formyl tetrahydrofolate (10-CHOTHF), since these are highly susceptible to interconversion and oxidation at neutral (extraction protocol) and acidic (chromatographic run) pH, even with the use of antioxidants.[31,32]

Sample Preparation. Experiments involving the trienzyme treatment were performed twice. The influence of the treatment was initially investigated using a previously validated HPLC-MS/MS method.[30] α-Amylase and protease were added in increasing amounts to evaluate folate recovery, and conjugase was added in two volumes to evaluate the deconjugation efficiency (Figure S2a, Supporting Information). A one-way ANOVA and complementary t tests showed no significant impact ($p < 0.05$) on folate recovery when using α-amylase or protease, supporting the findings by Konings et al.[14] There was also no significant difference ($p < 0.05$) between the addition of 100 and 150 μL of conjugase. These results were confirmed using the newly optimized UHPLC-MS/MS

method. Yet, although trienzyme treatment did not significantly affect folate recovery from the center of the potato matrix, we still opted to include this treatment: the resulting extracts were less gummy and easier to manipulate after consecutive heating and cooling steps. In addition, implementation of trienzyme treatment may overcome potential variability, introduced by the somewhat different composition of different sections of a tuber; for example, the dry matter content is typically lowest in the center.[33] Evaluation of the homogenization step revealed that there was no significant difference ($p < 0.05$) in folate recovery between mixing and grinding with liquid nitrogen. We therefore used mixing, which is less laborious, for further experiments and validation of the method. Since boiling prior to homogenization may aid in degrading the matrix and reducing the enzymatic and oxidative degradation of folates,[1,34−36] the impact of this manipulation on recovery was also investigated (Figure S2b, Supporting Information). In the same experiment, samples were also lyophilized or not after homogenization. The purpose of this manipulation was to find out if freeze-drying compensates for the increased variability caused by differences in moisture content, rather than preparing them for storage. Samples that were only boiled had a significantly higher folate content (13.32 ± 0.85 μg/100 g of FW, $p < 0.05$) than samples that were left untreated or that were lyophilized (with or without prior boiling). The advantage that lyophilization may offer, that is, compensating for the variable moisture content of potatoes,[2] was clearly lost, so we decided not to include a lyophilization step but to immediately freeze the samples after boiling and homogenization. Freeze-drying did provide information about the water content of the center of boiled and raw potatoes: 84.34% and 79.41%, respectively, in accordance with literature findings.[15] Therefore, freeze-drying can still be used to determine the dry matter content of frozen potato segments that do not undergo folate analysis. In conclusion, sample treatment comprised an initial boiling step followed by mixing. Subsequently, the samples were subjected to a trienzyme treatment: α-amylase (30 μL, 20 min at 37 °C) followed by an incubation with protease (150 μL, 1 h at 37 °C) and with deconjugase (100 μL rat serum, 2 h at 37 °C). The protease and conjugase incubations were each followed by a boiling step (10 min at 100 °C) to stop the respective enzyme activities. After each boiling step, samples were cooled down on ice. Samples intended for direct analysis of free monoglutamate content were spiked with water (instead of conjugase) and kept on ice (Figure S3, Supporting Information).

Validation. No signals from other folates or the IS were seen at the respective retention times of the injected standards, demonstrating the selectivity of the method. The calculated LODs of the six folates can be found in Table 2, together with the linear ranges, slopes, intercepts, and R^2 values of the final calibration curves. Visual evaluation of residual plots and performing Fisher's tests showed that the calibrator distribution was heteroscedastic. There was no carry-over: signals at the respective retention times of each folate or its IS, obtained after injection of a water sample, were all less than 5% of the LLOQ. Evaluation of several weighting factors and transformations demonstrated that applying a weighting factor of $1/x^2$ yielded the lowest sum of %RE. Subsequent performing of ANOVA LOF tests on this model showed a linear relationship for the chosen calibration ranges of all six folates. Intra- and interday precision (%RSD) and accuracy (%bias) were determined on three nonconsecutive days, in duplicate, by analyzing QCs that covered the whole calibration range (including the LLOQ and ULOQ). The data on precision and accuracy are summarized in Table 3, together with the 95% confidence limits of measurement uncertainty. Requirements for both intra- and interday precision were met for the six folates: all QCs had a % RSD lower than 15%, even at the LLOQ level. The accuracy also met acceptance criteria, except for 5-CHOTHF at its LLOQ, where accuracy was 22.69%.

The IS-corrected matrix effect exceeded the 85−115% range (Table 4, together with the recovery), though not excessive. While normalization using the IS did not compensate for matrix effects, it did compensate for the losses during sample preparation. Recoveries of more than 60% were observed for all folates at the three tested concentration levels. The (relatively) lower recovery of THF can be explained by its labile nature, while finding the actual cause for the recovery obtained for 5,10-CH+THF is more difficult: interconversion into 5-CHOTHF and the very unstable 10-CHOTHF at neutral pH, in the presence of antioxidants, has been described.[32] Subsequent oxidation of 10-CHOTHF to 10-CHOFA and other, nonfolate degradation products could result in a low recovery of 5,10-CH+THF. Alternatively, 10-CHOTHF and 5-CHOTHF might interconvert to 5,10-CH +THF at high temperature in acidic environment (as is the case during the chromatographic run). Since the recovery of 5,10-CH+THF was reproducible (%RSDs of 6.42, 13.67, and 13.58 for LOW, MED, and HIGH, respectively) and since other validation parameters yielded acceptable results, we consider quantitative determination of 5,10-CH+THF sufficiently reliable.

In general, our newly developed UHPLC-MS/MS shows improved sensitivity and precision at LLOQ, in comparison with a previously described method in rice.[26] In addition, changing to a scheduled MRM mode lowered the LODs. Although the matrix effects exceeded 15% at some instance, IS-corrected ME did not exceed the 75−125% range and given the acceptable results obtained for accuracy and precision can be regarded as "under control".

Stability. Two postextraction stability experiments were set up to find out whether or not the processed samples could be preserved over a short period of time for subsequent reanalysis. The resulting extracts could easily be kept in the autosampler

Table 3. Accuracy, Intra- and Interday Precision, and Measurement Uncertainty ($n = 3 \times 2$)

[a]Five QCs were used because one outlier confirmed with the Grubbs test ($p < 0.01$) was excluded. [b]Values in μg/100 g (calculated as [measured value ± (|%biasl + 2 × %RSD)]).

for 24 h after injection (STS, 24 h at 4 °C): the decrease was below 10% for all of the folates at the four concentration levels (Figure S4a, Supporting Information). This is sufficient to allow the samples to be reanalyzed the next morning, in case of a technical failure. The same was observed for vials with extracts that were submitted to three freeze−thaw cycles (FTS, three cycles at −20 °C) on the day of analysis. Again, the decrease did not exceed 10% (Figure S4b, Supporting Information). After performing these experiments, we concluded that reanalysis of treated samples can be performed after storage for up to 24 h at 4 °C or after freezing samples at −20 °C, followed by thawing up to three times.

Analysis of Reference Material BCR-121. Analysis of the BCR-121 wholemeal flour reference material confirmed the validity of our method: the total folate content (53.26 ± 4.93 μg/100 g of DW) as measured by UHPLC-MS/MS agreed well with the certified value (50 ± 7 μg/100 g), determined with a microbiological assay. Furthermore, the folate species concentration and distribution (1.01 ± 0.12, 5.34 ± 0.24, 5.34 ± 0.80, 10.31 ± 1.59, 29.04 ± 4.99, and 2.26 ± 0.17 μg/100 g for THF, 5-MTHF, 5,10-CH+THF, 10-CHOFA, 5-CHOTHF, and FA, respectively) were also in accordance with the literature.[18,37]

Application to Potato Tubers at Different Stages of Maturation (Variety Désirée). The folate content and distribution of individual folates (Figure 2a, b) in immature and mature Désirée tubers was comparable to those in Nicola tubers (determined with a previous method). The total folate content at these growth stages was 23.58 ± 1.51 and 24.01 ± 0.23 μg/100 g of FW, respectively, with polyglutamylation rates of only 5.4% and 5%. Hence, a comparable folate content and distribution was observed in lab-grown immature and store-bought mature potatoes. The polyglutamate content of sprouting potatoes was remarkably higher (60.49%), although their folate content had decreased (10.35 ± 0.95 μg/100 g of FW). This significantly lower folate content ($p < 0.05$) contrasts with Goyer and Navarre,[8,9] who reported a higher folate content in stored potatoes near sprouting. This discrepancy may be explained by the fact that our determination was performed on central potato flesh. Several authors[4,8,16] reported on the fact that the folate concentration is higher in potato peels, and Goyer and Navarre hypothesized that folate levels may increase when a tuber is sprouting (occurring at the peel).[8] The higher polyglutamylation level in sprouting potatoes approached the one reported by Konings et al. (90%),[14] but the distribution was different: 5-MTHF was still the predominant species, but it only accounted for 41% instead of 95% (Konings et al.)[14] of the total folate content.

Composing a Two-Dimensional Folate Profile of Mature Potato Tubers (Variety Nicola). To further investigate the biological variability, we first tried to exclude as many confounding (maturation stage, growth, harvest, and storage facilities) factors as possible: a batch of Nicola tubers at the same stage of maturation were obtained from a local distributor. From that batch, three tubers with the same dimensions were chosen for profiling of their cross sections. Comparison of genuine replicates within a tuber and corresponding segments of different potatoes were used for evaluating the variability within a certain potato variety.

Analysis of all segments resulted in a horizontal and vertical (x and y) profile, as shown in Figure 3a. In these tubers, the folate concentration was consistently higher in segments containing peel, than in central segments. The average total folate concentration of all the different segments was 17.95 ±

Table 4. Matrix Effects and Recovery (n = 3) for LOW, MED, and HIGH QCs

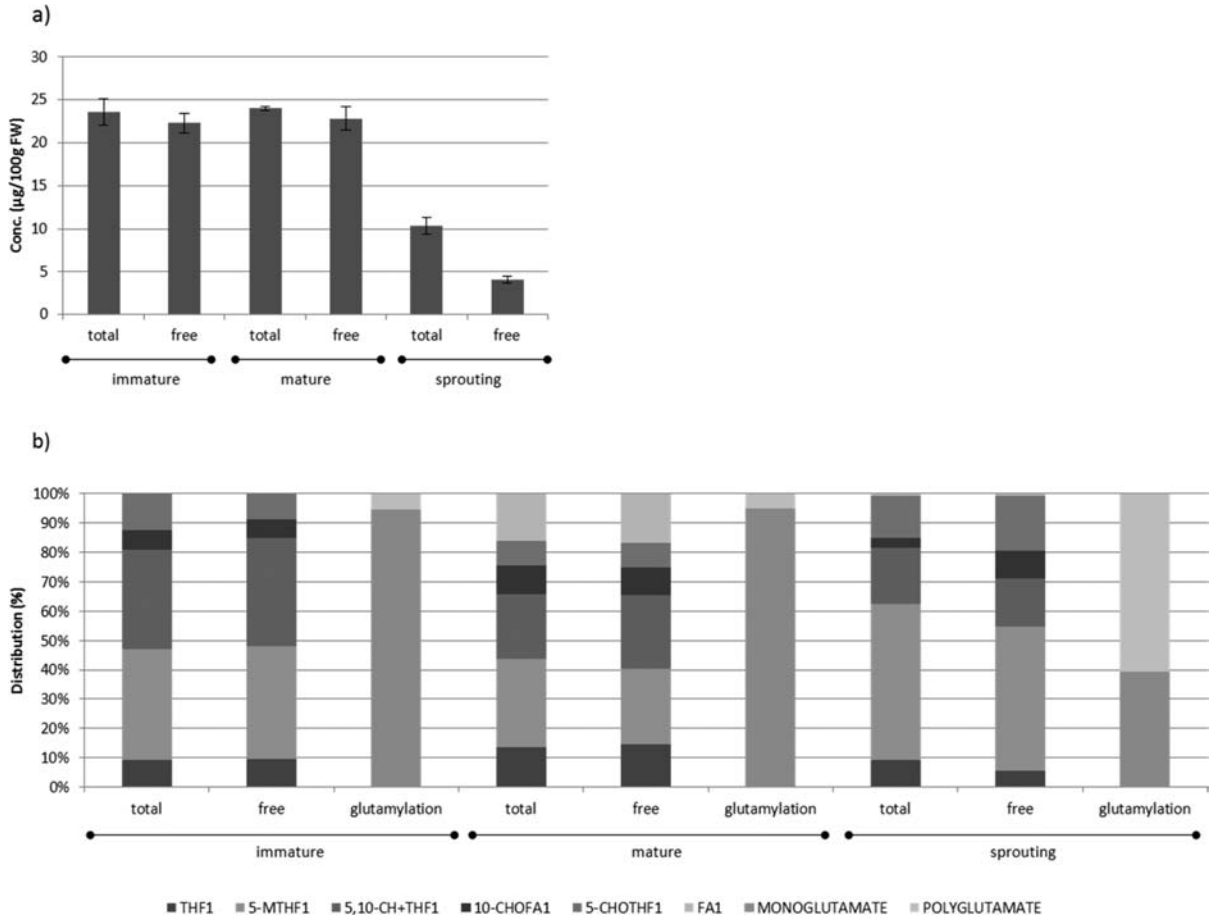

Figure 2. (a) Total and free folate monoglutamate content (error bars indicate the standard deviation) and (b) relative monoglutamate and polyglutamate distribution of immature, mature, and sprouting Désirée tubers.

3.17 μg/100 g of FW, but the average profiles of the horizontal and vertical sections (Figure 3b, c) show that this was not representative for a homogeneous distribution in the tuber: the average folate concentration in central segments was 14.08 ± 2.16 μg/100 g, increasing up to 86% toward segments containing peel (26.26 ± 11.24, 21.54 ± 5.61, 23.52 ± 3.92, and 20.31 ± 4.83 μg/100 g of FW for the peels at the basal, apical, upper, and lower ends, respectively). Interestingly, despite the increase of total folate concentration toward the peel, folate species distribution and polyglutamylation rates remained the same throughout the entire sections: 5-MTHF was still the predominant folate, representing an average 69% of the total folate. From this total folate, an average 78% was polyglutamylated. The comparable profiles of the three individual tubers also confirmed that 5-MTHF was the predominant folate in mature potato tubers variety Nicola.

The median variability (%RSD, Figure 3d) of genuine replicates within a single potato was 12%, increasing to 30% when considering corresponding segments of different potatoes. To make sure these results were not biased by the differences in dry matter content, the folate concentrations were also converted to their DW equivalents. This resulted in a moderate decrease in median variability (to 11% and 26% within and between the individual potatoes, respectively), demonstrating that folate concentrations in potato tubers may be expressed as FW as well as their DW equivalent.

The distribution of total folate, folate species, and glutamylation was similar throughout the cross sections of the three individual tubers. In addition, the "inter-tuber" variability of corresponding segments exceeded that of genuine replicates (<15%). Therefore, it is sufficient to analyze the segments from one single tuber in order to obtain a general image about a certain potato variety's folate profile and

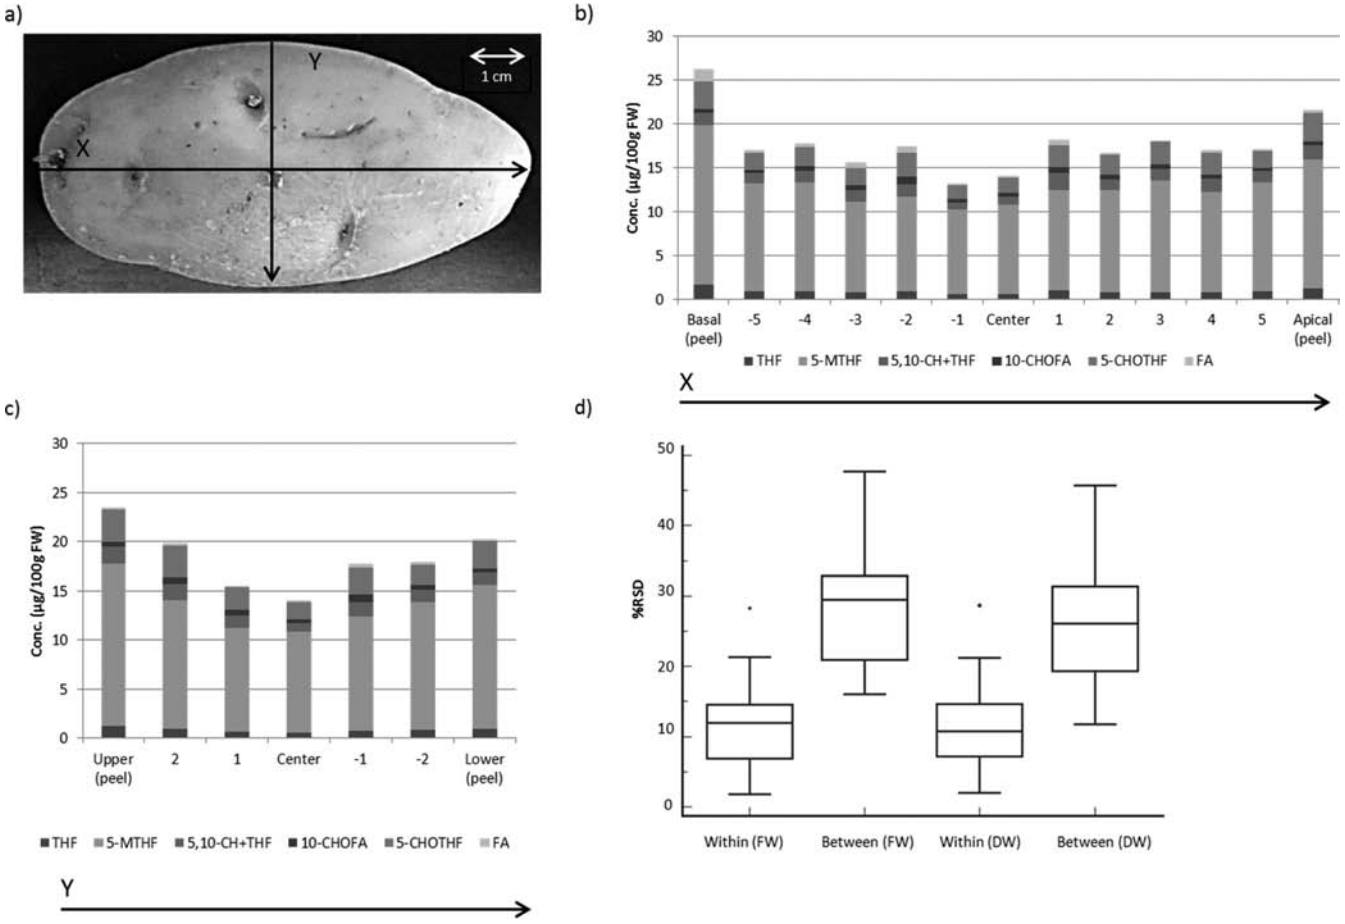

Figure 3. (a) Division of a tuber in a horizontal (x) and vertical (y) cross section. (b) Average folate profile (encompassing THF, 5-MTHF, 5,10-CH+THF, 10-CHOFA, 5-CHOTHF, and FA) of the horizontal (x) and (c) vertical (y) cross section of three potato tubers variety Nicola. (d) Boxplots demonstrating the difference in median variability within and between individual potato tubers variety Nicola, expressed as %RSD for fresh and dry weight (FW and DW, respectively).

glutamylation status at a certain stage of maturation. When knowledge about the average nutritive value (regarding absolute folate content) of a certain variety is the objective, pooling of the potato flesh will compensate for the large intravariety variability.

In conclusion, we successfully validated a UHPLC-MS/MS method for the quantitation of six folate vitamers in potato tubers. The extremely unstable folate species 5,10-CH_2THF and 10-CHOTHF prone to interconversion and oxidation were not included in the folate profile. The work is original in its application of the MS/MS technique and in the profiling of six different folate species throughout cross sections, providing a two-dimensional folate profile of a potato tuber. The use of a single, weighted calibration curve with a wide dynamic range allows determination with high sensitivity in very small amounts of potato flesh, allowing potatoes with a higher folate content (through biofortification) to be analyzed.

Table 1. Key Methods Being Used for Total Phosphate or Total Phospholipid Determination

method	contributor and reference	comments
molybdenum blue	AOCS Ca 12-55[3]	standard method, tedious ashing, and calorimetric procedures
nephelometric	AOCS Ca 19-86[4]	poor accuracy, low detection limit
vanadomolybdate	Szydlowska-Czerniak and Szlyk (2003)[5]	complex sample preparation
malachite green	Szydlowska-Czerniak and Szlyk (2003)[5]	complex sample preparation
TLC	Fuchs et al. (2011)[6]	requires appropriate standards
TLC	Dynska-Kukulska (2012)[7]	requires appropriate standards
HPLC	Amalia (1997)[8]	low detection limit, low sample throughput
SPE-HPLC	Brouwers (2011)[9]	low throughput, complicated preparation
NMR	Nouri-Sorkhabi (1996)[10]	not suitable for routine analysis
NMR	Yao and Jung (2010)[11]	not suitable for routine analysis
FTIR	Nzai and Proctor (1998)[12]	workable, but limited accuracy and precision
FTIR	Nzai and Proctor (1999)[13]	workable, but limited accuracy and precision
ATR-FTIR	Kuligowski et al. (2008)[14]	workable, but limited sensitivity
FTIR/PLS	Szydlowska (2007)[15]	chemometric, limited applicability, and generality
FTIR/PLS	Meng et al. (2014)[16]	chemometric, limited applicability, and generality
FT-NIR/PLS	Rathjen et al. (1998)[17]	chemometric, limited applicability, and generality
FT-NIR/PLS	Li et al. (2009)[18]	chemometric, limited applicability, and generality

Proctor[12,13] demonstrated that the phospholipid content of soybean oil could be determined quantitatively and used FTIR as a replacement for the Bartlett and TLC methods. Although workable, these FTIR methods have relatively high coefficients of variance (CV) in terms of both accuracy and precision, ranging from 3 to 9%. Another approach, developed for phospholipid dietary supplement analysis,[14] has been to combine gel permeation chromatography (GPC) with attenuated total reflectance FTIR (ATR-FTIR) spectrometry to remove spectrally interfering triacylglycerols. Again, this is workable methodology, but complicated, and its analytical sensitivity is limited, in this case largely due to the low sensitivity of ATR. Chemometric-based FTIR methods have been developed, for both mid-FTIR[15,16] and near-FTIR[17,18] usually based on the use of partial least-squares (PLS). These methods relate the phospholipid content obtained by a standard reference method to IR spectral changes in the oil matrix. Although such methods can be viable, it can be quite difficult to devise robust and representative calibration and validate its performance; such methods tending to be heavily oil-type dependent and thus usually not applicable to a wide variety of oils and are of limited applicability. Thus, at this point in time, there is still no simple, effective, reliable, and generalized means of determining TPL in oils by FTIR spectroscopy. In this paper, a mid-FTIR method is devised that combines a single-step in-vial extraction of oil using a phospholipid-specific extraction solvent mixture that is predominantly oil-immiscible. By analyzing the solvent extract after centrifugation and using differential FTIR spectroscopy to measure a single phospholipid-specific absorption band, the TPL content can be predicted from a calibration based on a single representative PL added to the extraction solvent mixture.

MATERIALS AND METHODS

Materials. Refined soybean and canola oils were obtained locally and further degummed by silica gel column chromatography to remove any residual PL. Oil (50−100 g) was put through a 3 mm i.d. × 400 mm glass column packed with ∼200 g of 200−300 mesh activated (2 h at 105 °C) silica gel (Qingdao Haiyang Chemical Co. Ltd., China); the oil pulled through the column using a vacuum with the degummed oils was collected and used as zero-TPL reference standards. Crude rapeseed and soybean oils as well as lecithin tablets were obtained from Yihai Kerry Ltd. Co., China. Various solvents, ethanol, methanol, acetonitrile, dimethyl sulfoxide (DMSO), and dimethylformamide (DMF) were obtained from Sigma-Aldrich Co. Ltd., USA. A phosphatidylcholine (PC) phospholipid standard was purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA), which served as the sole PL standard for addition to 1:1 MeOH/CAN or degummed oils.

Phosphorus Analysis. The AOCS Ca 12-55 molybdenum blue method[3] was used to determine the phosphorus content of samples (oils or solvent extracts) by ashing them in the presence of zinc oxide followed by the visible spectrophotometric measurement of phosphorus as a blue phosphomolybdic acid complex. The phosphorus content of the sample was determined using NaH_2PO_4 as the phosphorus standard for which a standard curve was prepared, and the phosphorus content obtained was converted to TPL by multiplying the phosphate content determined by a factor of 25.

FTIR Spectroscopy and Calibration Standards. *Spectroscopy.* FT-IR spectra were collected using a Tensor 27 (Bruker Co., USA) equipped with a deuterated triglycine sulfate (DTGS) detector and purged with dry air using a Balston dryer (Balston, Lexington, MA, USA). A 25 μm CaF_2 transmission flow cell (International Crystal Laboratories, Garfield, NJ, USA) equipped with Luer-Lok fittings was employed for sample handling. The cell inlet was connected to a 10 cm, 18-gauge stainless steel aspiration needle via flexible silicone tubing to the cell Leur inlet. The cell outlet Leur fitting had a line connected to vacuum via a trap fitted with a valve to facilitate facile loading and emptying of the cell at will by aspiration. All spectra were collected using 32 scans at a resolution of 4 cm^{-1} over the spectral range of 4000−400 cm^{-1}. Each sample was analyzed in triplicate, and the spectra collected were processed and analyzed using Omnic version 7.0 (Thermo Electron Corp., USA).

Calibration Standards. PL calibrations were developed by adding the PC standard to MeOH/ACN (1:1 v/v) covering a TPL concentration range of 20−50000 ug/g. The spectra of these standards were taken and ratioed 1:1 against the spectrum of the same solvent mixture used to prepare the PC standards to produce their corresponding differential spectra. A 5-5 gap segment second-derivative of these differential spectra was also taken and multiplied by −10000 to produce positive "absorbance" values of a magnitude more readily worked with. The peak intensities (heights) of specific bands, for example, 970 cm^{-1} (asymmetric C—N stretching of $(CH)_3N^+$), 1090 cm^{-1} (C—O stretch in C—O—PO_2^-), 1172 cm^{-1} (asymmetric C—O stretch in C═O—O—C), 1243 cm^{-1} (asymmetric PO_2^- stretch), and 1740 cm^{-1} (C═O stretch), of the PL differential spectra and second-derivative differential spectra were related to the PC concentrations added. The regression equations obtained for each of these absorption bands were compared in terms of their regression statistics, and the best-performing calibration was used to calculate the PL content (μg/g) of PC-spiked canola oil as well as for crude and refined oils and lecithin tablets in subsequent validation experiments.

Sample Preparation and Analysis. Oil samples were prepared for FTIR analysis in a standardized manner using a constant oil to solvent ratio (1:2 v/v) by adding 10 mL of oil to 20 mL of 1:1 MeOH/ACN in a tarred 30 mL clinical centrifuge tube. The tube was capped, shaken

on a reciprocal shaker for 60 s, and centrifuged for 10 min at 4000 rpm to separate the oil from the PL-enriched solvent. A portion of the upper solvent layer was aspirated into the IR cell for FTIR analysis and its spectrum taken (spectrum S_1), followed by loading the solvent used to prepare the sample and collecting its spectrum (spectrum S_0). The differential spectrum of the sample was generated by subtracting S_0 from S_1; the subtraction factor used was based on the overlapping acetonitrile and methanol overtone bands, which absorb over the range of 2020−2060 cm^{-1}. Using this technique the spectral contribution of solvent is removed as well as correcting for any bias associated with solvent dilution/displacement by the sample. The absorption maximum at 1243 cm^{-1} in the differential and second-derivative spectra was measured and processed using the solvent PL-spiked calibration standard curves derived for various spectral regions to calculate the TPL content of the samples analyzed.

Method Validation. Two sets of samples were used to validate the effectiveness of the method developed: (a) ideal samples, prepared from fully degummed oil and spiked with known amounts of PC, and (b) real samples that were undefined in phospholipid composition and content. For the ideal samples, refined canola oil was used, which underwent a further laboratory degumming step and was verified to be devoid of measurable PL. This oil was serially spiked with the PC standard and extracted, and the FTIR predictions obtained using the solvent-spiked PC calibration curve were compared to the known amount of PC standard added to determine both reproducibility and accuracy. The second sample set comprised real samples for which the PL levels and composition were unknown and included four crude oils and two refined oils, as well as a commercial lecithin tablet. These were all analyzed by FTIR as well as AOCS Ca 12-55, and the relative accuracy of the FTIR method to the reference AOCS method was expressed as percent relative error for accuracy (%RA):

$$\%RA = [(TPL_{FTIR} - TPL_{AOCS})/TPL_{AOCS}] \times 100 \quad (1)$$

Reproducibility of both methods was expressed as its percent relative standard deviation (%RSD):

$$\%RSD = (SD/mean) \times 100 \quad (2)$$

RESULTS AND DISCUSSION

PL Extraction Optimization. Preliminary spectral work was carried out in relation to developing an in-vial extraction procedure of PL from a PC-spiked, degummed soybean sample using various solvents, including ethanol, methanol, acetonitrile, DMSO, and DMF using an initial solvent/oil ratio of 2:1. High and low PC-spiked soybean samples (10000 and 1000 $\mu g/g$) were extracted using each solvent and, after centrifugation, a portion of the upper solvent layer was taken for phosphate analysis by AOCS Ca 12-55 and the balance used for FTIR spectral analysis. The extract was aspirated into the IR cell, and its spectrum was taken and ratioed against the solvent used for extraction to produce a differential spectrum of the extract, the bulk of the solvent spectral contribution thus having been removed. The main spectral feature monitored in this part of the work was the ester linkage of the triglycerides, which is indicative of the relative amount of triglyceride extracted, which is known to interfere with FTIR quantitation of PL.[16] The results of the extraction procedure and the relative PL recovery obtained by coanalysis using Ca 12-55 are summarized in Table 2.

Although MeOH extracted the PL the most efficiently, spectrally it also coextracted a very substantial amount of the triglyceride. Whereas ACN does not perform as well in terms of PL extraction, spectrally it extracted almost no triglyceride. All of the other solvents performed between these two extremes in regard to PL and triglyceride extraction. As a result, MeOH was mixed with ACN in various proportions to determine if an optimal balance could be struck between maximizing the PL extraction and minimizing the extraction of triglycerides. Ratios of methanol to acetonitrile of 1:9 through 9:1 were assessed, with the recoveries presented in Table 3.

Table 2. Extraction Efficiency of Added Phospholipid Using Various Organic Solvents

solvent	phospholipid ($\mu g/mL$)	AOCS Ca 12-55 ($\mu g/mL$)	recovery (%)
DMSO	10000	5230	52
DMSO	1000	615	62
DMF	10000	7896	79
DMF	1000	724	72
MeOH	10000	9388	94
MeOH	1000	924	93
EtOH	10000	9122	91
EtOH	1000	879	88
ACN	10000	6278	63
ACN	1000	709	71

Table 3. Influence of MeOH/ACN Ratios on Phospholipid Extraction

MeOH/ACN (v/v)	PL added ($\mu g/mL$)	AOCS ($\mu g/mL$)	recovery (%)
1:9	10000	6982	70
2:8	10000	8271	83
4:6	10000	9523	95
5:5	10000	9490	95
8:2	10000	904	90
1:9	1000	803	80
2:8	1000	826	83
4:6	1000	961	96
5:5	1000	975	98
8:2	1000	954	95

It was found that for recoveries obtained from 5:5 MeOH/ACN onward, with more MeOH, the triglyceride component also increased; thus, 1:1 MeOH/ACN was considered optimal. Subsequently, the ratio of solvent/oil was assessed at 1:1 and 5:1, the former providing inadequate extraction, whereas 5:1 worked well from the standpoint of phosphate recovery but resulted in the PL extracted being too dilute for accurate quantitative analysis. As a result of these preliminary experiments, for the balance of this work, in-vial extraction was carried out using 1:1 MeOH/ACN using a 2:1 solvent to oil ratio.

FTIR Spectroscopy and Calibration Development. FTIR spectra for serially diluted PC standards prepared in 1:1 MeOH/CAN over the spectral range from 2500 to 500 cm^{-1} are presented in Figure 1 along with an inset of the variance spectrum of these spectra over the range of 4000−500 cm^{-1}. The latter represent a facsimile of an ideal PL oil extract, one in which no triglyceride is coextracted and only the phospholipid component is present in the solvent extract.

The inset variance spectrum in Figure 1 provides an overall indication of the spectral changes expected to occur when only the sample phospholipid concentration changes. Here the broad 3300 cm^{-1} band is due to the O−H stretching band of MeOH, next to which are several C−H stretching bands, which are predominantly solvent contributions that are not shown in the spectral region covered by the main spectra of Figure 1. In

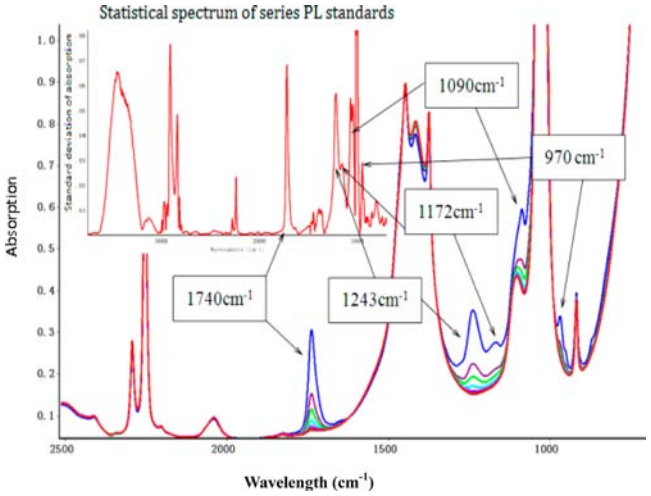

Figure 1. FTIR transmission spectra of a serial dilution of PC in 1:1 MeOH/ACN recorded in a 25 μm CaF_2 cell and their variance spectrum (inset).

the latter, the most obvious absorbance is at 1739 cm^{-1}, which is the C═O stretching mode of the ester carbonyl linkage of the lipidic component of the phospholipid. Only selected phospholipid bands are identified in Figure 1; however, all of the common phospholipid-related band assignments[22] are summarized in Table 4, reflecting the information outlined by Nzai[12] and Kuligowski,[14] although minor differences may be ascribed to the solvents the samples were measured in.

Table 4. Mid-infrared Phospholipid Band Assignments

assignment	absorption (cm^{-1})
δ CH_2 bending vibration	1451
symmetric CH_3 bending vibration	1376
asymmetric phosphate diester stretch PO_2^-	1243
symmetric phosphate diester stretch PO_2^-	1090
asymmetric ester C—O stretch in C═O—O—C	1173
symmetric ester C—O stretch in C═O—O—C	1037
asymmetric ester C–O–P stretch in C–O–PO_2^-	1068
symmetric ester C–O–P stretch	1025
asymmetric C–N stretching of $(CH_3)_3$–N^+	970

The variance spectrum of the PC serial dilution points to potential bands that may be useful for quantitation. The absorptions at 1037 and 1025 cm^{-1} bands are obviously significant; however, they are off-scale, even in such a short path length cell. Aside from these, the bands at 1740, 1243, 1172, 1090, and 973 cm^{-1} were considered as potential wavelengths for developing a PC calibration in 1:1 MeOH/ACN. Figure 2 presents the spectra of the individual solvents separately (a, b), their 1:1 mixture (c), the spectrum of an oil sample containing 5000 μg/g PC added to phospholipid-free oil and extracted into a 1:1 solvent mixture (d), and its differential spectrum (e) as well as its second-derivative spectrum (f).

The spectra of MeOH illustrate their C–O overtone band at 2040 cm^{-1}, whereas in the spectra of acetonitrile the 2070 cm^{-1} absorption could be assigned to C–N overtone band or combinations of different vibration bands related with C–N. Their combination is a good measure of the amount of solvent present. This combined spectral region (2020–2060 cm^{-1}) was used to correct for the displacement of the solvent by constituents extracted from the sample, predominantly oil

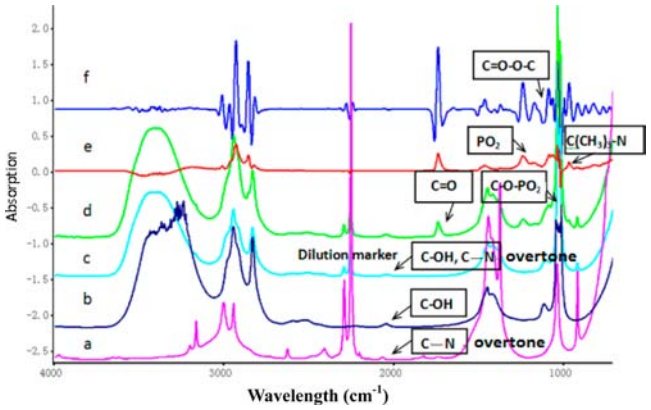

Figure 2. FT-IR spectra of (a) acetonitrile, (b) methanol, (c) mixture solution of methanol and acetonitrile with volume ratio of 1:1, (d) 5000 μg/mL PC in mixture solution, and their processed spectra (e) spectrum d − spectrum c and (f) second-derivative spectra of spectrum e.

(triglyceride). Figure 2d is a spectrum of a MeOH/ACN extract of a PC oil standard, which when ratioed against the extraction solvent spectrum is corrected for displacement by measuring the overtone band, which is thus devoid of the solvent overtone marker band (Figure 2e), indicating that spectral contribution from solvent has been removed. Figure 2f is the second-derivative spectrum of the same sample, the transform leading to sharper bands, in particular those at 1243 and 1173 cm^{-1}, which could potentially assist in quantitation. Selected phosphate bands were examined to determine whether the added PC could be tracked quantitatively, with Table 5 presenting the regression equations obtained when PC-spiked MeOH/ACN standards were analyzed in triplicate by FTIR in both their differential spectra format and their second-derivative transform.

It is clear from the regression data presented in Table 5 that the second-derivative differential spectra perform somewhat better than the simple differential spectra on the basis of their overall lower RSD. All of the phosphate-related bands used work reasonably well, with the carbonyl (γ C═O) band at 1740 cm^{-1} having the best linearity and the lowest RSD of 1.2%. However, it is well-known that the 1740 cm^{-1} phosphate ester band is problematic[12] for TPL determination because it is susceptible to interference by coextracted triglyceride absorptions that overlap. Although triglycerides have been minimized using the solvent mixture, a small and variable amount of lipid is still extracted; thus, for more reliability the PO_2^- band at 1243 cm^{-1} was chosen as the primary band for quantitative TPL analysis. The PO_2^- absorption is common to most if not all PL components found in oils and should respond to a calibration based on a single phospholipid, such as phosphatidylcholine (PC), while still responding to other PL components, such as phosphatidylethanolamines, phosphatidylinositols, and phosphatidylserines. For comparative purposes, Figure 3 presents the FTIR spectra over the spectral range of 1850–500 cm^{-1} of the 1:1 MeOH/ACN solvent and its in-vial extracts of phospholipid-free (laboratory degummed and refined) soybean oil and regular soybean oil.

In these spectra there are clear differences in the 1740 cm^{-1} band; however, as noted earlier, an undefined portion of that signal is due to coextracted triacylglycerol, which can confound quantitation. The 1243 cm^{-1} (PO_2^-) band also responds with crude soybean oil producing a higher absorbance than the

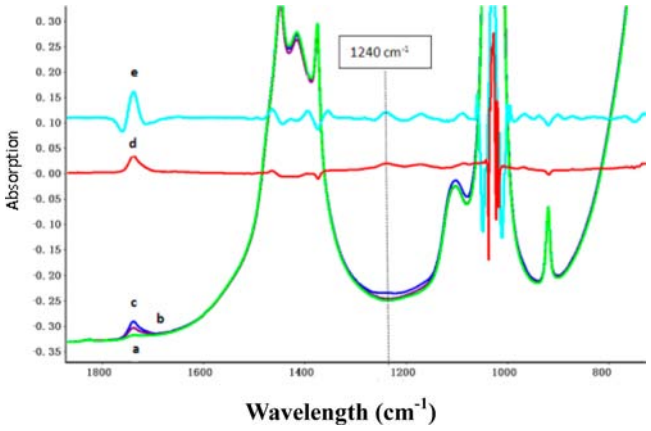

Figure 3. FT-IR spectra of (a) 1:1 methanol/acetonitrile extraction solvent, (b) 1:1 methanol/acetonitrile extract of a degummed soybean oil, (c) methanol/acetonitrile extract of soybean oil, (d) differential spectrum of soybean oil and degummed soybean oil (spectrum c − spectrum b), and (e) the second-derivative spectra of the differential spectrum of (d).

degummed sample and the solvent. Their differences are made more apparent in the differential spectrum when the degummed sample is subtracted from the regular soybean sample, with the gap segment second-derivative differential spectrum further enhancing this band as underlying absorptions associated with coextracted lipid tend to be minimized. These differential spectra have spectral attributes similar to the model PC-spiked MeOH/ACN standards once the bulk of the oil has been eliminated by the in-vial extraction and the PC component concentrated into the extraction solvent.

To evaluate the basic performance of the selected 1243 cm^{-1} band, ideal samples, canola oils spiked with known amounts of PC, were extracted in-vial and centrifuged, and their FTIR spectra were taken and processed using the 1243 cm^{-1} second-derivative calibration equations listed in Table 5 to determine how well the added PC could be determined when expressed as TPL. Table 6 presents the accuracy and precision of triplicate analyses for TPL obtained for these PC-spiked canola oils.

From the FTIR predictions obtained by analyzing the in-vial extracts of samples containing 528−30005 μg/mL of added PC, it is clear that measurements made using the 1243 cm^{-1} band of oil extracts obtained using 1:1 MeOH/ACN in a 2:1 solvent/oil ratio allow the accurate determination of the PC added to oils when extracted under these standardized conditions. The

[a]Sample analyzed in triplicate.

regression relationship obtained between the FTIR predicted values versus actual spiked PL values is

$$PL_{predicted} = 1.0544 \times PL_{added} - 123.66 \quad (3)$$

$$R^2 = 0.9999 \qquad D = 134$$

Using a zero regression to remove the intercept produced the following relationship (eq 4), with only minor changes in the regression statistics, indicating that the intercept is basically not significant as it is within the SD of the original relationship.

$$PL_{predicted} = 1.0484 \times PL_{added} \quad (4)$$

$$R^2 = 0.9999 \qquad D = 162$$

Both of these relationships indicate that the in-vial extraction−FTIR phospholipid method is capable of responding linearly to PC-spiked oil within an SD of <200 μg/g. These results indicate that the basic recovery of PC added to oil is adequate as is its ability to be measured by FTIR, the key question being whether this holds for real oil samples that contain phospholipids other than simply PC.

To assess the general applicability of the in-vial solvent extraction procedure and the predictive power of the model MeOH/ACN-PC calibration, crude and refined soybean and rapeseed oils, as well as a lecithin tablet, were extracted and analyzed in triplicate by FTIR and coanalyzed as well as by AOCS Ca 12-55, with the results obtained presented in Table 7.

Because the FTIR method is a secondary method, validation of its performance requires direct comparison to an established primary method for TPL analysis such as AOCS Ca 12-55. It is

mean	NA	4.9		3.2	2.2

[a]TPL content (μg/g, n = 3). Sample analyzed in triplicate.

apparent from the data presented in Table 7 that the two methods track each other well for these samples, with the AOCS method being somewhat more variable than the FTIR procedure in terms of reproducibility (RSD 4.9 vs 3.2%). This implies that the accuracy statistic obtained for FTIR is limited to some extent by the lower reproducibility of the reference method. Even so, it is clear that the FTIR procedure as developed is tracking the reference method responses well. Comparatively, Nzai et al.[12,13] used the 970−1200 cm^{-1} band area (assigned to PO_2 + P−O−C) to determine TPL of soy lecithin samples, which were compared the results obtained using Bartlett's method, a procedure similar to AOCS Ca 12-55. The CV reported for 10 duplicates having TPL contents covering 1−20% ranged from 3.6 to 9.5% for their FTIR method versus 8.9−48.7% for the reference chemical procedure. On the basis of these results, the authors implied that the FTIR method could still be used to determine the PL concentrations found in refined oil samples. The FTIR method developed here, as applied to real samples, tracked the AOCS Ca 12-55 results much better; the linear regression of the FTIR predictions versus the AOCS results presented in Table 7 produced the relationship

$$\mathrm{FTIR_{PL}} = 0.9889 \times \mathrm{AOC_{PL}} - 8.24 \quad (5)$$

$$R^2 = 0.9999 \qquad D = 95.83$$

which has a slope close to the ideal of 1.0, a negligible intercept, and an overall SD of <100 μg/g.

The key to developing this TPL methodology is the simple and efficient extraction and concentration of phospholipids using a solvent mixture which simultaneously minimizes the extraction of lipids that can spectrally interfere with quantitation. The spectrum of the extract is further simplified by accurately removing the solvent spectral contribution using the solvent overtone bands,[23] basically leaving the spectra of the phospholipids, which can be further enhanced in terms of quantitation using a second-derivative transform. With this simplified analytical system to work with, a calibration based simply on a single representative PL standard (in this case PC) to the extraction solvent becomes a possibility, focusing on phosphate bands for quantitation. Once a responsive band is found, one can assess the effect of the presence of oil on the extraction and predictions by spiking degummed oil with PC to assess both the extraction procedure and predictive capability of the solvent-spiked FTIR calibration. Validation of the extraction procedure in combination with the simplified calibration to track the TPL content of real oils is then carried out and compared by coanalysis by a reference method. The results obtained indicate that this simplified approach works adequately and that the triglycerides which usually interfere spectrally with FTIR PL quantitation have been minimized adequately. Of the phosphate bands, 1745 cm^{-1} is not in contention as it is overlapped by triglyceride ester absorptions, and 1243 cm^{-1} was found to be the most responsive in terms of quantitation of all the other bands. It appears that PC is an adequately representative calibration standard for most phospholipids and that the PO_2^- band at 1243 cm^{-1} is generally workable for TPL determination even if some residual lipid is present. The FTIR method as structured is more reproducible than AOCS Ca 12-55 and is ultimately limited in its accuracy by the reference method it is being compared to. As presented, the FTIR method developed provides a simple means for TPL determination, requiring only an in-vial extraction of the oil with solvent and centrifugation to separate the solvent from the oil, followed by FTIR analysis of the solvent. Calibration is straightforward, and the spectral manipulations required to remove the solvent contribution, obtain the second-derivative differential spectrum of the sample, and measure the absorbance at 1243 cm^{-1} can readily be programmed as a macro to directly deliver the TPL of the sample in micrograms per gram. With an FTIR configured in this manner and equipped with an autosampler, vials containing pre-extracted, centrifuged samples can be loaded into an autosampler tray and analyzed automatically in a manner similar to that of other quantitative automated FTIR methods that have been developed[24] for both oil and lubricant analysis. At a more practical level, even the manual version of this method provides a simpler, less tedious, and accurate alternative to standard chemical methods currently in use.

competitive ELISA (dcELISA) was also described for evaluation and comparison of the IATC.

MATERIALS AND METHODS

Reagents and Apparatus. Apramycin (APR), dihydrostrepmycin, gentamicin, neomycin, and spectinomycin were purchased from Dr. Ehrenstorfer (Augsburg, Germany). Strepmycin, kanamycin, and tobramycin were obtained from China Institutes for Food and Drug Control (Beijing, PRC). Mouse anti-HRP antibody was purchased from LifeSpan Biosciences, Inc. (Seattle, WA, USA). Bovine serum albumin (BSA), ovalbumin (OVA), and 1-(3-dimethylaminopropyl)-3-ethyl carbodiimide (EDC) were obtained from Sigma Chemical Co. (St. Louis, MO, USA). CNBr-activated Sepharose 4B was purchased from GE Healthcare (Piscataway, NJ, USA). All other chemicals and solvents were of analytical grade or better and were obtained from Beijing Chemical Reagent Co. (Beijing, PRC).

Polystyrene microplate was purchased from Corning Inc. (Costar 2592, Corning, NY, USA). Empty SPE cartridges (Bond Elut reservoir, 1 mL) and polyethylene frits ($^1/_4$ in. diameter) were provided by Agilent Technologies (Santa Clara, CA, USA). The ELISA plate reader was obtained from TECAN Inc. (Durham, NC, USA).

Buffers and Solutions. The following buffers were used: (1) coating buffer was 0.05 M carbonate buffer, pH 9.6; (2) blocking buffer consisted of 0.01 M phosphate-buffered saline (PBS), pH 7.4, 0.5% BSA, and 0.05% Tween 20; (3) washing buffer was PBS with 0.05% Tween 20; (4) antibody dilution buffer was PBS, pH 7.4, containing 0.2% albumin; (5) enzyme-labeled secondary antibody dilution buffer was antibody dilution buffer containing 5% albumin; (6) substrate was 0.1% TMB and H_2O_2 in 0.05 M citrate buffer, pH 4.5; and (7) 2 M H_2SO_4 was the stopping reagent. Standard stock solutions (1 mg/mL) of analyte were prepared by dissolving an appropriate amount of standard drug in dimethylformamide (DMF). The individual stock solutions of analyte were stored at −20 °C in amber glass bottles. Working standards of APR and related antibiotics were prepared by diluting the stock solution in PBS (0.01 M, pH 7.4).

Synthesis of Complete Antigens. *APR-GA−BSA_1 (120:1).* APR (51 mg) and BSA (44.6 mg) were dissolved in 0.1 M carbonate buffer (10 mL, pH 9.5). Glutaraldehyde (0.5 mL, 0.1%) was added dropwise to the mixture, which was gently stirred for 5 h at room temperature. Then, sodium borohydride (0.05 mL, 10% solution) was dropped into the reaction system for another 1 h. The reaction mixtures were dialyzed against 0.01 M PBS for 3 days.

APR-GA−OVA_1 (80:1). APR-GA−OVA_1 was prepared according to the same method as used for APR-GA−BSA_1 by using 51 mg of APR and 45 mg of OVA.

APR-GA−OVA_2 (120:1). APR-GA−OVA_2 was prepared according to the same method as used for APR-GA−BSA_1 by using 51 mg of APR and 30 mg of OVA.

APR-EDC−BSA_2 (80:1). APR (51 mg) was dissolved in 0.1 M carbonate buffer (5 mL, pH 9.5), and the pH of the buffer was adjusted to pH 7.0 with 0.1 M PBS. EDC (40 mg) was added to the APR solution and stirred at room temperature overnight. BSA (67 mg) was dissolved in 5 mL of 0.01 M carbonate buffer (pH 8.0) and added dropwise to the active solution with continuous stirring and further stirred at room temperature for 4 h. The APR−BSA conjugates were dialyzed against 0.01 M PBS (pH 7.0) at 4 °C for 72 h.

APR-EDC−OVA_3 (120:1). APR-EDC−OVA_3 was prepared according to the same method as used for APR-EDC−BSA_2 by using 51 mg of APR and 30 mg of OVA.

Synthesis of HRP−APR Conjugate. HRP (10 mg) was dissolved in 1 mL of distilled water. One milliliter of 0.06 M sodium periodate and 1 mL of 0.16 M ethanediol solution were added into the HRP solution independently, which was stirred for 1 h at 4 °C. Then APR (28.7 mg) was added in the mixture and the reaction continued for 3 h at room temperature. Sodium borohydride (1 mL, 0.5% solution) was dropped into the reaction system for another 2 h at 4 °C. The reaction mixtures were dialyzed against 0.01 M PBS for 3 days.

Production of Antibodies. Female BALB/c mice were immunized for mAb production. The first injection consisted of immunogen emulsified with Freund's complete adjuvant at a dosage of 100 μg/mouse. Subsequent booster immunizations were administered biweekly with the same dosage of immunogen emulsified with Freund's incomplete adjuvant. After the fifth immunization, the mouse exhibiting the highest antibody titer was sacrificed, and the splenocytes were fused with SP2/0 myeloma cells. The growing hybridoma cells were screened for antibody production by a noncompetitive indirect ELISA and an indirect competitive ELISA using APR-EDC−BSA_2 as coating antigen with the amount of 100 μL/well.[23] The positive hybridomas were subcloned twice by limiting dilution, and the positive clones were used for ascites production. The antibody was purified from ascites using saturated ammonium sulfate, and the purified mAb was stored at −20 °C in 500 μL aliquots.

Preparation of Immunogels and Test Column. *Goat Anti-mouse IgG Antibody Immobilized Gels (Coupled Gels).* Briefly, freeze-dried CNBr-activated Sepharose 4B gel powder (1.0 g) was washed on a sintered glass filter (G3) using 100 mL of 1 mM HCl. Four hundred microliters of goat anti-mouse IgG (2.0 mg/mL) and 1 mL of coupling buffer (0.1 M $NaHCO_3$, 0.5 M NaCl, pH 8.3) were mixed with the gel on a shaker for 2 h at room temperature.The gel was washed with 20 mL of coupling buffer to remove the excess of antibody. After this, the unlinked active groups were blocked with 12 mL of blocking buffer (0.2 M glycine, 0.1 M $NaHCO_3$, 0.5 M NaCl, pH 8.0) for 2 h at room temperature. Afterward, three cycles of washing were conducted to wash away the excess glycine. Each cycle consisted of a wash with 0.1 M acetate buffer, pH 4.0, containing 0.5 M NaCl (10 mL) followed by a wash with coupling buffer (10 mL). The prepared gel was suspended in PBS containing 0.03% Proclin 300 and stored at 4 °C.

Glycine Immobilized Gels (Blocked Gels). Freeze-dried CNBr-activated Sepharose 4B gel powder (2.0 g) was washed on a sintered glass filter (G3) using 200 mL of 1 mM HCl. The gel was washed with 100 mL of coupling buffer to adjust the pH. Then, blocking buffer (50 mL) was added for blocking with 2 h at room temperature. Afterward, three cycles of washing were conducted to wash away the excess glycine. Each cycle consisted of a wash with 0.1 M acetate buffer, pH 4.0, containing 0.5 M NaCl (50 mL) followed by a wash with coupling buffer (50 mL). The prepared gel was suspended in PBS containing 0.03% Proclin 300 and stored at 4 °C.

Anti-APR Antibody Immobilized Gels (Anti-APR Gels). Coupled gels and blocked gels (1:4, v/v) were mixed well in a 10 mL polyethylene centrifuge tube, and then anti-APR antibodies (dilution 1/50000) were added into the mixture quickly in equal proportion volume of coupled gel. The mixture was shaken for 5 min at 400 rpm.

Anti-HRP Antibody Immobilized Gels (Anti-HRP Gels). Anti-HRP gels were prepared according to the same method as used for anti-APR gels by using mouse anti-HRP antibodies with 2000-fold dilution.

Development of IATC Assay. *Preparation of Test Column.* The test column consisted of three layers, which is a test layer, a control layer, and an air layer. Assembled steps were as follow: anti-HRP gels (200 μL) were added into the 1 mL empty cartridge with a frit at the bottom, and the excess liquid was pushed away from the outlet of the syringe. The second frit was used to cover the control layer, and the third frit was inserted to form the air layer, which is designed to prevent diffusion of the color reagents. Then, by a a similar step, an aliquot of 200 μL of anti-APR gels was added to prepare the test layer and the last frit was covered on the top of the test layer.

Assay Procedure. Drug standard solution (or sample) was added into the test column, which is passed through the cartridge with a constant speed. One milliliter of PBST (containing 0.1% Tween 20) was used for the washing step. Then 150 μL of APR−HRP conjugate prepared in PBS was added and incubated for 5 min. Another 7 mL of PBST was added to wash away the excess enzyme tracer. Then, 300 μL of the chromogenic substrate was added and squeezed out after 10 s of incubation. The color shown in the layers could be observed to detect the presence of APR.

Development of dcELISA. dcELISA was performed as follows: Polystyrene microtiter plate wells were coated with 100 μL of goat anti-mouse IgG for 2 h of incubation at 37 °C. After coating, plates were blocked for 1 h at 37 °C with 150 μL/well of blocking solution.

One hundrec microliters of anti-APR antibody was added in each well for 0.5 h at 37 °C. The solution was then discarded, and plates were washed three times with washing solution. Then, 50 μL of drug standard solution (or sample) and 50 μL/well of HRP-labeled APR prepared in PBS were added and incubated for 45 min at 37 °C. The final washing procedure was followed by a color development, which was initiated by adding 100 μL of the substrate/chromogen solution. The solution was incubated for 15 min at 37 °C before the enzymatic reaction was stopped by adding 2 M H_2SO_4 (50 μL/well). The optical density (OD) of each well was measured at 450 nm.

The B/B_0 ratio was selected to express the competitive inhibition curve, where B_0 and B are the absorbances obtained from binding at zero and certain concentrations of APR standard. A four-parameter logistic equation was used to fit the immunoassay data. Calculations were performed using OrginPro 8.0 software (OriginLab Corp., Northampton, MA, USA). The IC_{50} value, assay dynamic range, and limit of detection (LOD) served as criteria to evaluate the dcELISA. These different characteristics represent the analyte concentrations obtained at 50%, between 20 and 80%, and at 90%, respectively.

RESULTS AND DISCUSSION

Synthesis of Immunogen and mAb Production. The hapten design and the synthesis of the required immunogens are critical to the success of rapid immunoassays. Because it is a small molecule, APR lacks immunogenicity. To generate a specific antibody, APR should be conjugated with macromolecules to elicit an immune response via an active group, such as a carboxyl or an amino group. As shown in Figure S1 in the Supporting Information, there are six hydroxyl groups and four amino groups in the APR molecule, which allowed us to involve them in linkage with the protein. In this study, the glutaraldehyde method and EDC method was used to conjugate APR to carrier proteins (BSA and OVA). Theoretically, any of the four amino groups could be linked with the carrier, and both methods are nondirectional reaction.

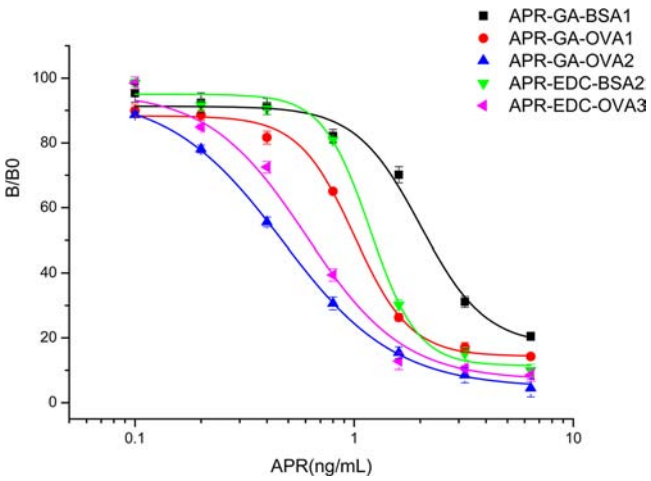

Figure 1. Standard curves of apramycin icELISA using homologous and heterologous coating antigens based on monoclonal antibody. For the concentrations of coating antigen and corresponding antibody, refer to Table S2 in the Supporting Information.

Two immunogens (APR-GA−BSA and APR-EDC−BSA) were used to immunize mice for mAb production. Mouse serum had been collected and detected after the third immunization. The results found that the titer of mouse 3, which was immunized by APR-GA−BSA, was the best with a titer of 2000, so mouse 3 was selected for the next cell fusion. During hybridoma screening, four wells of the culture supernatants were screened to contain APR-specific antibody by using indirect competitive ELISA (icELISA) after three cycles of subcloning. The results are summarized in Table S1 in the Supporting Information. Then mAb secreted by APR-2A2 was the most sensitive with an IC_{50} of 1.2 ng/mL, and its isotype was IgG_{2b}, whereas the type of light chain was κ. Therefore, APR-2A2 was chosen for further study.

Both homologous and heterologous coating antigens were utilized to further evaluate the performance of mAb. Inhibition curves of the APR using five different coating antigens are shown in Figure 1. There was a remarkable difference in the sensitivity of the antibodies, and the three heterologous coating antigens, with carrier protein OVA, expressed much higher sensitivity and affinity. The lowest IC_{50} value (0.46 ng/mL) and highest dilution of mAb (0.3 μg/mL) and antigen (0.16 μg/mL) were observed in APR-GA−OVA_2 (Supporting Information Table S2). That is, assay sensitivity may be improved using a heterologous coating antigen strategy, whereas a combination of antibody and coating antigen is proper.[23]

IATC Method. The principle of the IATC assay was similar to that of the dcELISA, and the main difference between them is the difference in type and carrier for immobilizing antibody. In IATC, there are three layers, including test, air, and control layers. For the test layer, CNBr-activated Sepharose 4B beads were utilized as the medium to immobilize capture antibody by cyanogen bromide method. APR in sample and HRP−APR conjugate compete with each other for the limited antibody on the column. After the addition of enzyme substrate and color development, the test result can be determined by the naked eye; a negative sample will produce a blue line on the column, whereas a positive sample will not produce any visible line at the respective position. While in the control layer, anti-HRP antibodies were immobilized on the gel beads and could recognize HRP enzyme to lead the color appearance after substrate existence. Compared with dcELISA, this method does not need multiple wash steps, and the washing buffer could easily drive the unbound components through the frit with 20 μm pore size, whereas the 40 μm beads bound with capture antibody and binding antigens were retained in the column.

There are four amino and six hydroxyl groups in APR, which make the drug very hydrophilic. Therefore, nonspecific sorption effect should be paid more attention for APR detection. In this study, the concentration of HRP−APR conjugate was optimized first. Six columns were divided into three groups, and one group consisted of test layers without anti-APR antibodies to control unspecific interaction (designed as control). A series of enzyme tracers (diluted with PBS at 5000, 10000, and 20000) were added to test columns in each group. The results showed that in the control group, a weak blue color appeared on the test layer in 5000-fold dilution, which means a little enzyme tracer existed with unspecific absorption on the bead, but the others did not appear. Meanwhile, the test layer showed better color intensity in 10000-fold dilutions in the test group. Thus, the concentration of 10000-fold dilution was chose for the next study (Supporting Information Figure S3).

Washing buffer is also important for eliminating nonspecific absorption. Different concentrations of Tween 20 (0.1, 0.5, and 1.0%) in washing buffer and different volumes (3, 5, 7, and 9 mL) were investigated. The results revealed that the optimal ratio of Tween 20 was 1.0% (v/v), and the amount of washing buffer was 7 mL.

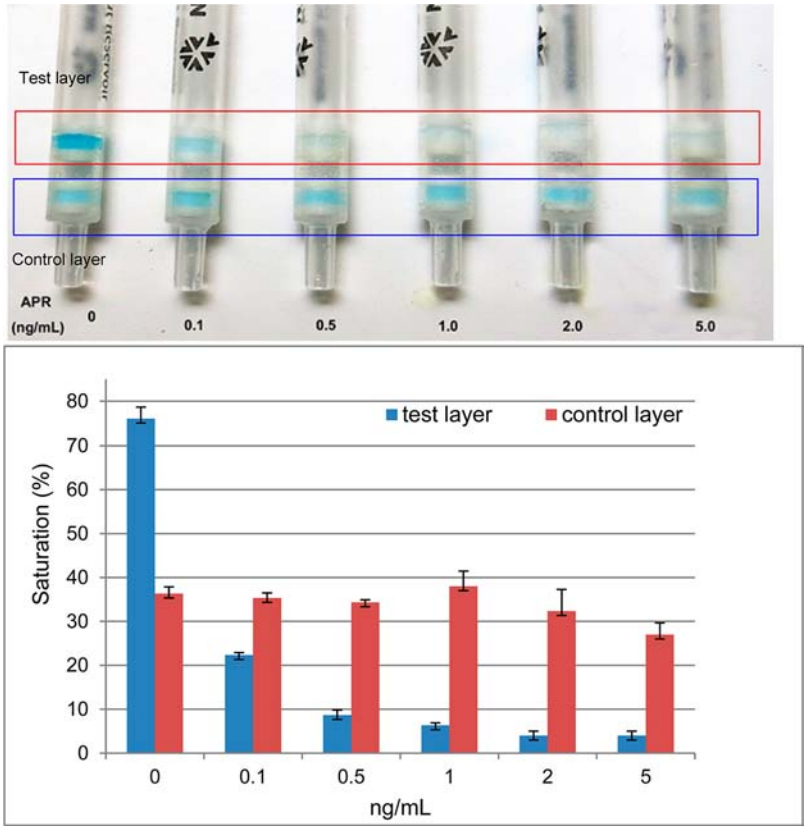

Figure 2. (a, top) Set of results for IATC assay in standard solution. From left to right, the concentrations of APR were 0, 0.1, 0.5, 1.0, 2.0, and 5.0 ng/mL, respectively. The LOD of the method could be set as 0.5 ng/mL. (b, bottom) Color intensity of the test layers and control layers.

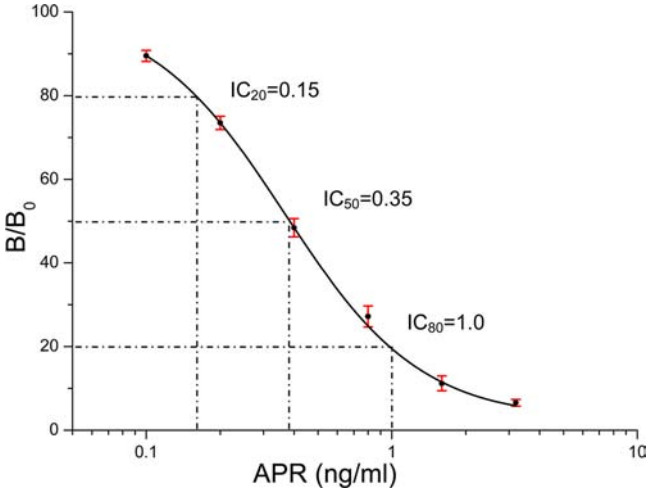

Figure 3. Standard curve of APR in buffer solution by dcELISA.

Figure 2a illustrates a set of results for IATC assay in standard solution with the concentrations of APR from 0 to 5.0 ng/mL. With the increase of drug concentration, the color fades in the test layer. When the concentration was higher than the cutoff level (defined as LOD), it could occupy enough binding sites of antibodies and lead to color disappearance. The LOD of this method was 0.5 ng/mL.

More intuitive results could be seen by quantifying the color intensity in Figure 2b. According to the method published in a previous study,[24] the IACT results were taken by a digital camera (Canon Powershot G15) and the images were saved in JPG format. The software "Adobe Photoshop 7.0.1" was used to evaluate the colors inside the test columns as saturation (parameter *S*, HSB mode). The value of parameter *S* was obtained three times, and the average value and standard deviation were calculated. Compared with observation by the naked eye, it has higher resolution to decide the cutoff value clearly. Furthermore, color quantization plays an important role for further semiquantitative analysis.

The specificity of the IATC was evaluated by determining the cross-reactivity using other common aminoglycoside drugs with high concentrations. As shown in Figure S2 (Supporting Information), 0.5 ng/mL of APR and 500 ng/mL of strepmycin (STR), gentamicin (GEN), kanamycin (KANA), and neomycin (NEO) diluted in the standard solution were respectively applied to the IATC assay. The results showed that there was no elimination of the color intensity in the test layers for the other four aminoglycoside drugs, which indicated that the assay is highly specific for the detection of APR.

dcELISA Method. To compare with the IATC, a dcELISA assay was developed and optimized on the basis of the anti-APR antibody secreted by APR-2A2. By using checkerboard titration and contrast test, many factors, such as the concentrations of the reactants (goat anti-mouse IgG antibody with 4000, anti-APR antibody with 50000, enzyme tracer with 10000), the best pH (7.4), the optimum ionic strength (0.1 M), and reaction time (see Materials and Methods), were optimized and selected in this study (detailed data not shown). Figure 3 shows the competitive inhibition standard curves for APR after fitting with Origin Pro 8.0 software. The dynamic range IC_{20}–IC_{80} was calculated as 0.15–1.0 ng/mL, and the IC_{50} and LOD of the dcELISA were 0.35 and 0.1 ng/mL, respectively, after optimization.

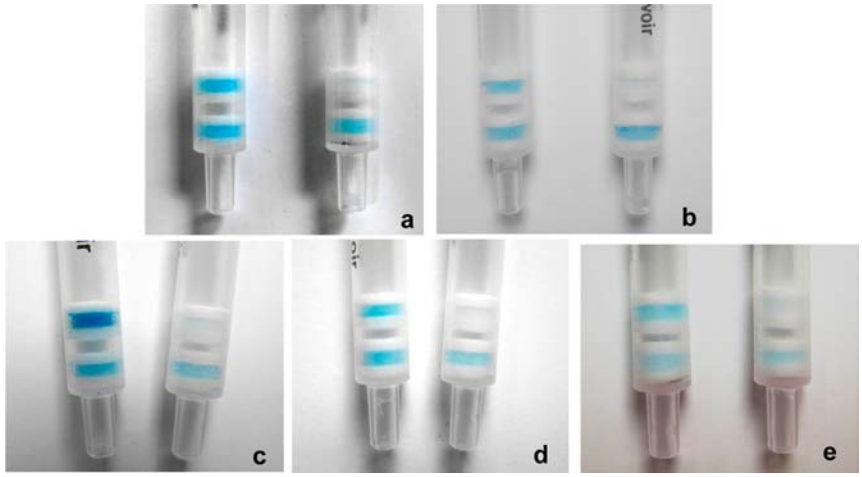

Figure 4. Results of IATC assay for different food matrices: (a) pork; (b) chicken; (c) raw milk; (d) pig liver; (e) chicken liver. Blank samples appear on the left in each panel; and spiked samples at LOD levels appear on the right.

Table 1. Recoveries of APR in Spiked Samples by dcELISA (n = 3)

sample	spiked (μg/kg)	mean recovery (%)	CV (%)
raw milk	3	103.0	5.6
	6	97.0	3.8
	12	95.6	10.1
pork	2	87.5	4.4
	4	77.0	7.5
	8	101.5	4.9
chicken	2	85.5	6.7
	4	105.5	8.6
	8	93.4	10.3
pig liver	3	80.5	5.0
	6	97.0	6.6
	12	87.2	6.8
chicken liver	20	103.5	8.9
	40	87.5	11.2
	80	93.1	5.8

The specificity of the ELISA was evaluated by determining the cross-reactivity using other common aminoglycoside drugs. Negligible cross-reactivity (<1%) was found for strepmycin, gentamicin, dihydrostrepmycin, kanamycin, tobramycin, spectinomycin, and neomycin.

Sample Analysis for dcELISA and IATC. The IATC and dcELISA assays were applied to analyze raw milk, chicken, pork, chicken liver, and pig liver. The blank samples used in the study were certified by LC-MS/MS for free APR. To eliminate interference of sample matrix, muscle and liver samples were deproteinized by trichloroacetic acid, adjusted to neutral by 1 M NaOH, and then diluted by PBS in different folds, and milk samples were diluted directly by PBS (see Table 2).

Loading volume plays a key role in improving the sensitivity of assay. For the IATC method, the loading volume of sample was not restricted, which was generally from 0 to 5 times bed volumes. Therefore, at the beginning of the study, samples were only prepared with 2−4-fold dilution. It was found that the samples containing free APR did not bind anti-APR antibody effectively, and the color appeared after addition of the enzyme tracer, especially in livers. In contrast, the color disappeared after protein precipitation was developed. This means that the protein in the sample matrix interferes the inhibition effect and affects the sensitivity of the method. Thus, for tissue samples, deproteinization steps were employed in the sample preparation. The cutoff value for raw milk was 3 ng/mL, those for pork and chicken muscles were 3 μg/kg, and those for chicken liver and pig liver were 10 μg/kg, which are summarized in Table 2 and shown in Figure 4.

For the ELISA method, in general, the loading volume of sample was 50 μL, so sample extracts needed to be diluted

Table 2. Comparison between dcELISA and IATC

	dcELISA	IATC
carrier	polystyrene well	gel bead
type	semiquantitative	qualitative
instrument	yes	no
sample treatment	depro[a] + centri[b] + dilution	depro[a] + centri[b] + dilution
dilution factor	raw milk (1:10), pork and pig liver (1:7.5), chicken (1:6), chicken liver (1:27)	1:2
method LOD (ng/mL)	0.1	0.5
sample LODs/cutoff (μg/kg)	raw milk (3), pork (2), chicken (2), pig liver (3), chicken liver (20)	raw milk (3), pork (3), chicken (3), pig liver (10), chicken liver (10)
detection time[c] (min)	90−120	15−20

[a]Deproteinization. [b]Centrifugation. [c]Include sample treatment.

dx.doi.org/10.1021/jf405379r | J. Agric. Food Chem. 2014, 62, 3108−3113

more to eliminate interference of sample matrix. When the blank samples were spiked at three concentration levels, the mean recovery ranged from 80.5 to 105.5%, with intra-assay CVs ranging from 3.8 to 11.2%; the detection limit for raw milk was 2 ng/mL, those for pork, chicken, and pig liver were 3 μg/kg, and that for chicken liver was 20 μg/kg (Tables 1 and 2).

Comparison of Two Assays. Compared with dcELISA, IATC was a new type of detection mode. Table 2 lists the difference between IATC and dcELISA. In the term of methodology itself, it is not more sensitive than dcELISA, but for the test samples, it has unique advantages. First, the loading volume is very broad, from 0 to 5 times the column bed, which could improve the sensitivity of detection effectively, whereas the volume of the ELISA microplate is only 300 μL and the loading volume is usually from 50 to 100 μL. Second, the operation is very simple and rapid and without instruments; the naked eye can be used for judgment, and repeated plate washings are avoided.

From the results of the experiments, similar sensitivities for the samples were found in two kinds of methods, which indicated that the IATC method could also act as an effective screening method for APR residues in food.

suppression in positive ionization mode. Esterified xanthophylls tend to elute together with the bulk of triglycerides during RP-LC (e.g., on a C18 column), and this can hamper correct quantification or even identification. Triglycerides do not ionize in negative APCI mode and one could therefore suggest using negative APCI mode instead. However, some carotenoids do not ionize in negative ionization mode.[17] For proper identification and quantification of esterified carotenoids in samples with high lipid content, it is therefore essential that these lipids are removed before detection.

Saponification is most often used to hydrolyze glycerolipid interferences during carotenoid analysis. Ester bonds of other plant metabolites such as carotenoids are however also hydrolyzed during saponification, thus altering the natural carotenoid composition.[18] Preparative column chromatography has been used to separate lipids from carotenoids.[18] This procedure is, however, tedious if performed manually and expensive if performed automatically. Beyond that, this separation procedure has to be optimized for every different matrix as the composition of glycerolipids and carotenoids is matrix dependent.

Triacylglycerol hydrolases or lipases are an important group of biotechnologically relevant enzymes that find immense applications in food, dairy, detergent, and pharmaceutical industries. Lipases act under aqueous conditions on the carboxyl ester bonds present in triacylglycerols to liberate fatty acids and glycerol. The reaction is catalyzed at the lipid−water interface.[19] Lipase enzymes have, however, not only been tested for the cleavage of triacylglycerides. Several publications have been written on the use of lipase enzymes for the hydrolysis of carotenoid esters to their free form.[10,20] Conversion rates from esterified to free carotenoids ranged from 0 to 89% and are largely dependent on the type of enzyme. As free carotenoids have been reported to have a better bioavailability, the aim of these studies was to create more elegant alternatives for chemical saponification of marigold flower extracts and red paprika extracts on an industrial scale.

Breithaupt et al. were the first to report the use of lipase enzymes for the selective removal of triacylglycerides for the identification of carotenoid esters in potatoes.[21] During the first cleanup step, open bed column chromatography was used to obtain a fraction containing the carotenoid esters. This fraction was then further purified by the selective enzymatic cleavage of residual triacylglycerides with two commercial lipase enzymes. To our knowledge this is the only peer-reviewed publication written on the selective removal of triacylglycerides with the emphasis on the preservation of the natural carotenoid ester composition. As this procedure involves a fractionation step, the full natural carotenoid profile is, however, lost. Furthermore, open bed column chromatography is often laborious and tedious. Therefore, the aim of this study was to optimize this method to an efficient one-step enzymatic cleanup method without prefractionation to simplify the method and to preserve the natural carotenoid profile of the samples.

MATERIALS AND METHODS

Chemicals. LC-MS grade methanol, acetonitrile, and ethyl acetate were purchased from Biosolve (Valkenswaard, The Netherlands). Ultrapure water with a resistivity of 18.2 MΩ·cm at 25 °C was generated with a Millipore system. Dichloromethane (DCM) for gas chromatography, *n*-hexane for gas chromatography, acetone for gas chromatography, sodium hydrogen carbonate, potassium phosphate, and sodium chloride for analysis were purchased from Merck (Darmstadt, Germany). Ammonium acetate, (D-Ala^2)-leucin enkephalin, bile salts, and butylated hydroxytoluene (BHT) were purchased from Sigma-Aldrich (Bornem, Belgium). Commercially available mixtures to calibrate the mass spectrometer, namely, MSCAL5-1EA (caffeine, tetrapeptide "Met-Arg-Phe-Ala", Ultramark) for positive ion mode and MSCAL6-1EA (sodium dodecyl sulfate, taurocholic acid sodium salt, Ultramark) for negative ion mode, were purchased from Supelco (Bellefonte, PA, USA).

Capsanthin, astaxanthin dipalmitate, and astaxanthin were purchased from Carotenature (Ostermundigen, Switzerland). β-Carotene and β-sitosterol were purchased from Sigma-Aldrich (Bornem, Belgium). Paprika oleoresin 65000 CU (900 g) was obtained from Natural Spices (Mijdrecht, The Netherlands), and Asta Krill 8 (60 softgels of approximately 1 g) was obtained from Swanson vitamins (Fargo, ND, USA). The content of the Asta Krill 8 soft gels consists of *Euphausia superba* Antarctic krill oil combined with an astaxanthin-rich extract from the microalga *Haematococcus* (as stated by the supplier). The food grade enzyme formulations Lipozyme TL 100 L (100 KLU/g) and Lipozyme CALB L (5 KLU/g) were kindly provided by Novozymes (Bagsvaerd, Denmark). Sodium lauryl sulfate, glycerol dioleate, and glycerol trioleate were obtained from Chem Service (West Chester, PA, USA). Extra virgin olive oil was obtained from a local store.

Preparation of Standard Solutions. Standard stock solutions and working solutions were prepared for each analyte separately at a concentration of approximately 200 μg/mL. Stock solutions for glycerolipids were prepared in methanol. The stock solution of β-sitosterol was prepared in methanol + 0.1% BHT. Stock solutions for carotenoids were prepared in DCM + 0.1% BHT. Standard stock and working solutions were stored at −25 °C in the dark under an inert atmosphere (nitrogen). Dilutions of the stock solutions were prepared in DCM + 0.1% BHT for analysis.

Instrumental Analysis. All analyses were performed with an ultrahigh-performance liquid chromatography−photodiode array−accurate mass mass spectrometry (UHPLC-PDA-am-MS) configuration. The LC system consisted of an Accela quaternary solvent manager, a "Hot Pocket" column oven (Thermo Fisher Scientific, Bremen, Germany), and a CTC PAL autosampler (CTC Analytics, Zwingen, Switzerland). The LC system was hyphenated to an Accela PDA detector and an Orbitrap mass spectrometer (Exactive, Thermo Fisher Scientific, Bremen, Germany).

The method of analysis was previously described by Bijttebier et al.[17] Briefly, 1.25 μL was injected on a thermostatically heated (35 °C) Acquity UPLC HSS C18 SB column (2.1 mm × 100 mm, 1.8 μm; Waters, Milford, MA) and chromatographically separated by gradient elution. The mobile phase solvents consisted of 50:22.5:22.5:5 (v/v/v/v) water + 5 mM ammonium acetate/methanol/acetonitrile/ethyl acetate (A) and 50:50 (v/v) acetonitrile/ethyl acetate (B), and the gradient was set as follows (min/%A): 0.0/90, 0.1/90, 0.8/70, 20.0/9, 20.1/0, 20.4/0, 20.5/90, 23.0/90. APCI was used as MS ionization technique, and polarity switching was applied. The scanning range was set to m/z 90−1400 and a mass resolution of 50,000 fwhm was applied. The corona discharge current was set at 5 μA, the vaporizer and capillary temperatures were set at 450 °C, and a capillary voltage of ±25 V was used for both positive and negative APCI. Lock mass correction with (D-Ala)^2-leucin enkephalin was applied, and mass deviations of no more than 2 ppm were observed. The PDA detector was set to scan from 190 to 800 nm. Xcalibur software (Thermo Fisher Scientific) was used to process the data.

Sample Preparation. Red paprika fruits (*Capsicum annuum*) were bought in a local store. After removing the stems and kernels, they were cut into pieces, frozen with liquid nitrogen and immediately freeze-dried. After drying they were milled and homogenized with a Grindomix GM 200 from Retsch (Haan, Germany) at 10,000 rpm and stored in the dark under nitrogen at −25 °C. Before sample preparation, the sample was allowed to equilibrate to room temperature. To 20 g of freeze-dried paprika were added 20 g of sodium hydrogen carbonate and 330 mL of 70:30 acetone/methanol +

Table 1. Summary of the Accurate Masses Obtained for the MS Protonated and Deprotonated Molecules and Product Ions in Positive and Negative APCI Mode and the Maximum Absorbances, Used for the Identification of the Compounds Described Throughout the Paper

					positive APCI mode		negatve APCI mode

0.1% (v/v) BHT. The bottle was flushed with N_2 gas and closed. After shaking for 30 min and subsequent centrifugation for 5 min at 5000 rpm, the solvent was transferred into a round-bottom flask. This extraction procedure was repeated two more times. The three supernatants were pooled, evaporated, and dissolved in 20 mL of DCM + 0.1% BHT. The extract was stored in the dark under nitrogen at −25 °C. For the lipase treatment, an aliquot of the extract was evaporated and dissolved in the solvent of the treatment.

A commercially available paprika oleoresin was bought and stored at 4 °C. Before hydrolysis with lipase enzymes, the bottle was shaken vigorously by hand for 30 s and an aliquot was taken for enzymatic hydrolysis. The Asta Krill 8 soft gels were bought and stored at 4 °C. The oil present in the Asta Krill 8 soft gels was obtained by cutting the soft gels open. This oil was subsequently used for lipase assays.

Lipase Efficiency and Selectivity Determination. A UV wavelength of 440 nm was chosen to compare carotenoid profiles in the samples before and after lipase treatment without interferences from glycerolipids because di- and triacylglycerides do not absorb light in this region. To compare the lipid profile before and after enzymatic hydrolysis, the total ion current (TIC) signal obtained by the Orbitrap MS detector in positive APCI mode was used. Due to the high lipid content of the samples used during this study, lipids dominated the TIC chromatograms before the enzyme assay. Identification of glycerolipids was achieved with the protonated molecules and in-source product ions generated during am-MS detection. The order of the fatty acids bound to glycerol (i.e. *sn*-1, *sn*-2, or *sn*-3 position of the glycerol backbone) could not be deduced from the spectra during the experiments, and the lipids were therefore noted as "TG(C18:2, C18:2, C16:0)" instead of "TG(C18:2/C18:2/C16:0)". The decline of the level of individual lipids by lipase treatment was monitored with the extracted ion chromatograms (EIC) of selected ions. Loss in ionization efficiency during the elution of high lipid concentrations can lead to an underestimation of the percentage of lipids hydrolyzed.[22] Lipid hydrolysis rates are therefore most probably higher in practice than described in this paper.

The spectral and chromatographic data used for compound identification are listed in Table 1. Mass accuracies of <2 ppm were obtained during analysis. The identities of the compounds are tentative but reliable as the mass/charge (m/z) values and molecular formulas of the (de-)protonated molecules and product ions in am-MS are in agreement with the proposed structures. Furthermore, the fragmentation pathways of the identified carotenoids and lipids correspond to the fragmentation patterns of analytical standards of structural homologues analyzed with the same method. Confirmation of the proposed carotenoid backbones was obtained by the PDA spectra. Representative structures for the different compound groups are given in Figure 1.

RESULTS AND DISCUSSION

Lipase Treatment. *Application of the Lipase Enzymes As Described by Breithaupt et al. .*[21] The lipase procedure described by Breithaupt et al. was used as a starting point for method optimization.[21] The fractionation by column chromatography described in this procedure was not applied to preserve the natural carotenoid profile of the samples.[21] The procedure by Breithaupt et al. described the use of the enzyme formulations Novozym 868 L (6 kilo lipase units (KLU)/g) and Lipolase (100 KLU/g) (Novozymes, Bagsvaerd, Denmark) which are no longer commercially available.[21] Therefore, new enzyme formulations Lipozyme TL 100 L and Lipozyme CALB L were selected. Lipozyme TL 100 L (100 KLU/g) is the new food grade formulation of Lipolase and contains the identical enzyme. The enzyme formulation Novozym 868 L contained an enzyme from *Candida antarctica* (A), and a replacement was not readily found. Novozym 435 was tested by Zorn et al. for its

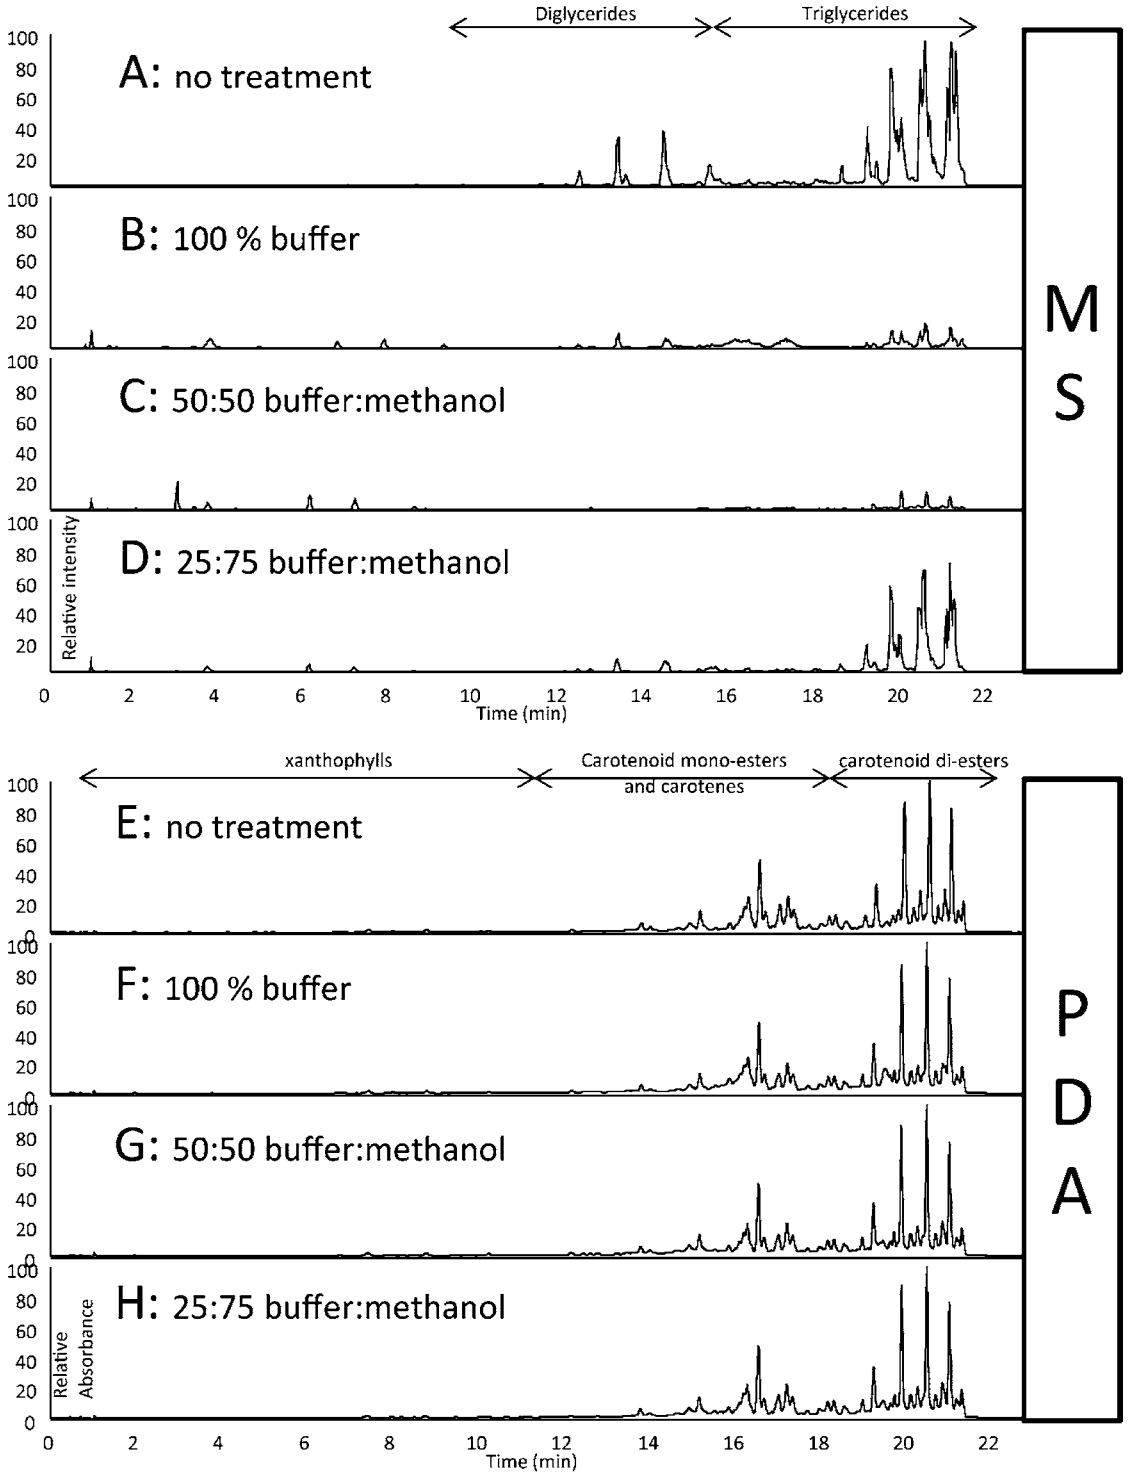

Figure 2. Chromatograms (fixed scale) of paprika oleoresin before and after lipase treatment with different solvent compositions (100 μL of oleoresin in 20 mL of solvent, 2 h at 40 °C, 25 μL of sodium *n*-octyl sulfate, 30 mg of bile salts, and 250 μL of sodium chloride solution (5 mM), 1 mL of 5 KLU of Lipozyme CALB L and 1 mL of 100 KLU of Lipozyme TL 100 L): full scan MS signal (A) before lipase treatment, (B) after lipase treatment with 100% aqueous phosphate buffer (0.1 M, pH 7.4, 10 mL), (C) after lipase treatment with 50:50 (v/v) aqueous phosphate buffer/methanol, and (D) after lipase treatment with 25:75 (v/v) aqueous phosphate buffer/methanol; UV signal at 440 nm (E) before lipase treatment, (F) after lipase treatment with 100% aqueous phosphate buffer, (G) after lipase treatment with 50:50 (v/v) aqueous phosphate buffer/methanol, and (H) after lipase treatment with 25:75 (v/v) aqueous phosphate buffer/methanol. The arrows indicate the elution order of the compound groups.

ability to hydrolyze carotenoids esterified with fatty acids and showed no significant activity toward these compounds.[10] Lipozyme CALB L (5 KLU/g) was therefore chosen because it contains the same lipase enzyme from *Candida antarctica* (B) as Novozym 435.

The altered Breithaupt et al. procedure was tested on an in-house produced paprika extract.[21] An aliquot of the paprika DCM extract (1 mL) was transferred into an Erlenmeyer flask covered in aluminum foil and subsequently dried under a gentle stream of N_2 gas. A potassium phosphate buffer solution (0.1

[a]Tested solvent compositions for (A) and (B): 100:0 (v/v), 50:50 (v/v), and 25:75 (v/v) aqueous phosphate buffer (0.1 M, pH 7.4, 10 mL)/MeOH. Tested incubation times for (C): 1, 2, and 3 h. Method conditions: 100 μL of oleoresin or extract spiked with 300 μL of olive oil, 20 mL of solvent, incubation at 40 °C, 25 μL of sodium *n*-octyl sulfate, 30 mg of bile salts, and 250 μL of 5 mM NaCl. Enzyme formulations: 1 mL of 5 KLU of Lipozyme CALB L and 1 mL of 100 KLU of Lipozyme TL 100 L for (A), 1 mL of 100 KLU of Lipozyme TL 100 L for (B).

M, pH 7.4, 10 mL), 30 mg of bile salts, and 250 μL of sodium chloride solution (5 mM) were added. As the paprika extract is an apolar extract, it does not dissolve in the aqueous buffer solution. Therefore, the solution was continuously stirred magnetically during preincubation and incubation to increase the surface area at the lipid−water interface. After a preincubation time of 30 min at 40 °C, the enzymes were added. In the procedure of Breithaupt et al., the enzyme formulations Novozym 868 L and Lipolase were diluted and subsequently added to the Erlenmeyer flask at levels of 0.024 and 0.4 KLU, respectively.[21] The same level of lipase units was added to the incubation mixture for the two selected lipase enzymes (0.024 KLU of Lipozyme CALB L and 0.4 KLU of Lipozyme TL 100 L). After addition of the diluted enzyme formulations, the mixture was incubated for 2 h at 40 °C. After incubation, the carotenoids were extracted immediately using a mixture of 1:1:1 methanol/ethyl acetate/hexane (v/v/v) using a separation funnel. The upper apolar layer, containing the carotenoids and remaining glycerolipids, was collected. This extraction procedure was repeated three times, and the extracts were combined. After extraction, the polar phase containing glycerol and fatty acids was discarded. The combined extracts (upper layers) were washed twice with 100 mL of water to remove all alkali and acids. The organic layer was dried over anhydrous sodium sulfate and subsequently evaporated to dryness at 35 °C under a gentle stream of N_2. The dried extract was dissolved in 1 mL of DCM + 0.1% BHT. Analysis with LC-PDA-am-MS showed that there was no clear signal drop of glycerolipids before and after hydrolysis. This low hydrolysis rate could be due to several factors. No lipid concentrations or conversion factors were mentioned in the study of Breithaupt et al., therefore making comparison impossible.[21] The enzyme/lipid concentration ratios could be too low to hydrolyze a significant level of glycerolipids. Furthermore, the used enzyme formulations were not identical to those applied by Breithaupt et al.[21] On the other hand, as mentioned before, the apolar paprika extract did not dissolve in the aqueous buffer solution. Therefore, only a low contact surface area was available for the enzymes to catalyze the hydrolysis of glycerolipids. Several method parameters were therefore adjusted to optimize the enzymatic hydrolysis of glycerolipids.

Optimization of the Lipase Treatment. Zorn et al. reported the use of purified soy lecithin to improve emulsification during enzymatic hydrolysis of carotenoid esters in paprika oleoresins.[10] It was therefore decided to add 25 μL of sodium *n*-octyl sulfate as emulsifying agent before preincubation to all of the experiments described below. This detergent was chosen as it was more readily available than lecithin and thought to be less prone to being a source of natural plant metabolites. To improve the rate of hydrolysis of the glycerolipids, 1 mL of each of the enzyme formulations, corresponding to approximately 5 KLU of Lipozyme CALB L and 100 KLU of Lipozyme TL 100 L, was added to the incubation mixtures. According to the manufacturer, the enzyme formulations that were used during the current study have sales values of approximately 40 and 80 euro/kg. The cost of the enzymes was thus approximately 0.12 euro per analysis, which is a relatively small cost in sample preparation.

Solvent Composition. A commercial paprika oleoresin was chosen for the optimization of the lipase treatment as it contains high concentrations of both carotenoids and lipids. Because of the high viscosity of the oleoresin, an aliquot of only 100 μL was used per test, and 20 mL of solvent was added. This solution contained much higher concentrations of lipids compared to the in-house prepared paprika extract used under Application of the Lipase Enzymes As Described by Breithaupt et al. As solvent, different ratios of phosphate buffer and methanol were tested. The addition of methanol could

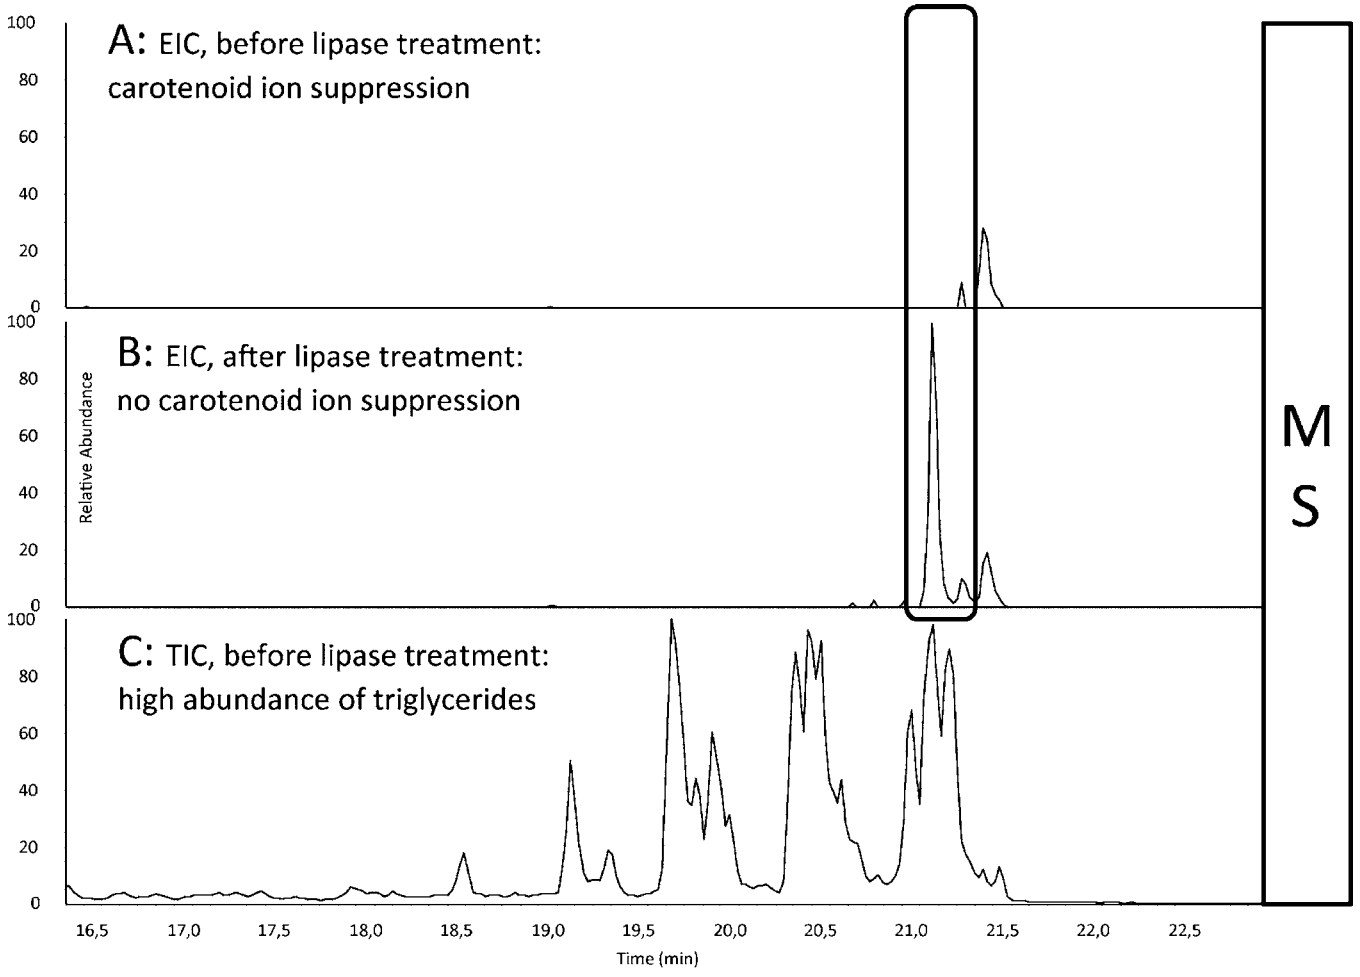

Figure 3. Extracted ion chromatograms (EIC) of the isomers of a capsanthin diester (C14:0, C16:0) in the paprika oleoresin before (A) and after (B) lipase treatment (50:50 (v/v) phosphate buffer/methanol) and the total ion chromatogram (TIC) chromatogram of the paprika oleoresin before lipase treatment (C).

improve the solubility of the oleoresin. Although organic solvents are also known to denature enzymes and thus inhibit their mode of action, lipases are known to have high stability in organic solvents.[19] Three different solvent combinations were tested: 20 mL of phosphate buffer, 20 mL of 50:50 (v/v) phosphate buffer/methanol, and 20 mL of 25:75 (v/v) phosphate buffer/methanol. The samples were all prepared in duplicate and compared to the untreated paprika oleoresin. Unfortunately, one of the samples prepared with 100% phosphate buffer was biased by a human error, and only one sample of that experiment could therefore be used for comparison. To study the removal of glycerolipids by enzymatic hydrolysis, five triglycerides (TGs) and five diglycerides (DGs) that were highly abundant in the TIC MS signal before hydrolysis were selected. The results of these tests are shown in Figure 2 and Table 2A.

On average, approximately 89, 98, and 41% of the selected TGs were hydrolyzed by the lipases with 100% phosphate buffer, 50:50 (v/v) phosphate buffer/methanol and 25:75 (v/v) phosphate buffer/methanol, respectively (calculated against the untreated sample). On average, approximately 81, 96, and 80% of the selected DGs were hydrolyzed by the lipases with 100% phosphate buffer, 50:50 (v/v) phosphate buffer/methanol and 25:75 (v/v) phosphate buffer/methanol, respectively (calculated against the untreated sample). These results show that using 75% methanol as solvent inhibits the enzyme activity compared to the other solvent compositions. This could be due to enzyme denaturation or immiscibility of the phosphate buffer and/or bile salts in 75% methanol. During both the enzymatic assay with aqueous phosphate buffer and 50:50 (v/v) phosphate buffer/methanol as solvents, high percentages of DGs and TGs were hydrolyzed. The results in Table 2A indicate that the addition of methanol as solvent improves the hydrolysis rate, probably due to a better miscibility, and thus increased contact between the lipids and the enzymes. In the MS full scan chromatograms B and C in Figure 2, the levels of DGs and TGs have clearly diminished compared to the levels in chromatogram A. In chromatogram C the natural carotenoid profile of carotenoid diesters becomes visible, indicating higher intensities for carotenoids than lipids. Figure 3 shows the extracted ion chromatograms of the isomers of a capsanthin diester (C14:0, C16:0) in the paprika oleoresin before (A) and after (B) hydrolysis with 50:50 (v/v) phosphate buffer/methanol as solvents. The signal of the most intense isomer of the capsanthin diester (C14:0, C16:0) at 21.1 min is completely suppressed in the sample without enzymatic hydrolysis by coelution with a very high concentration of TGs. The less intense isomer at 21.5 min does not suffer from suppression effects, as it elutes in a region that is less populated by TGs.

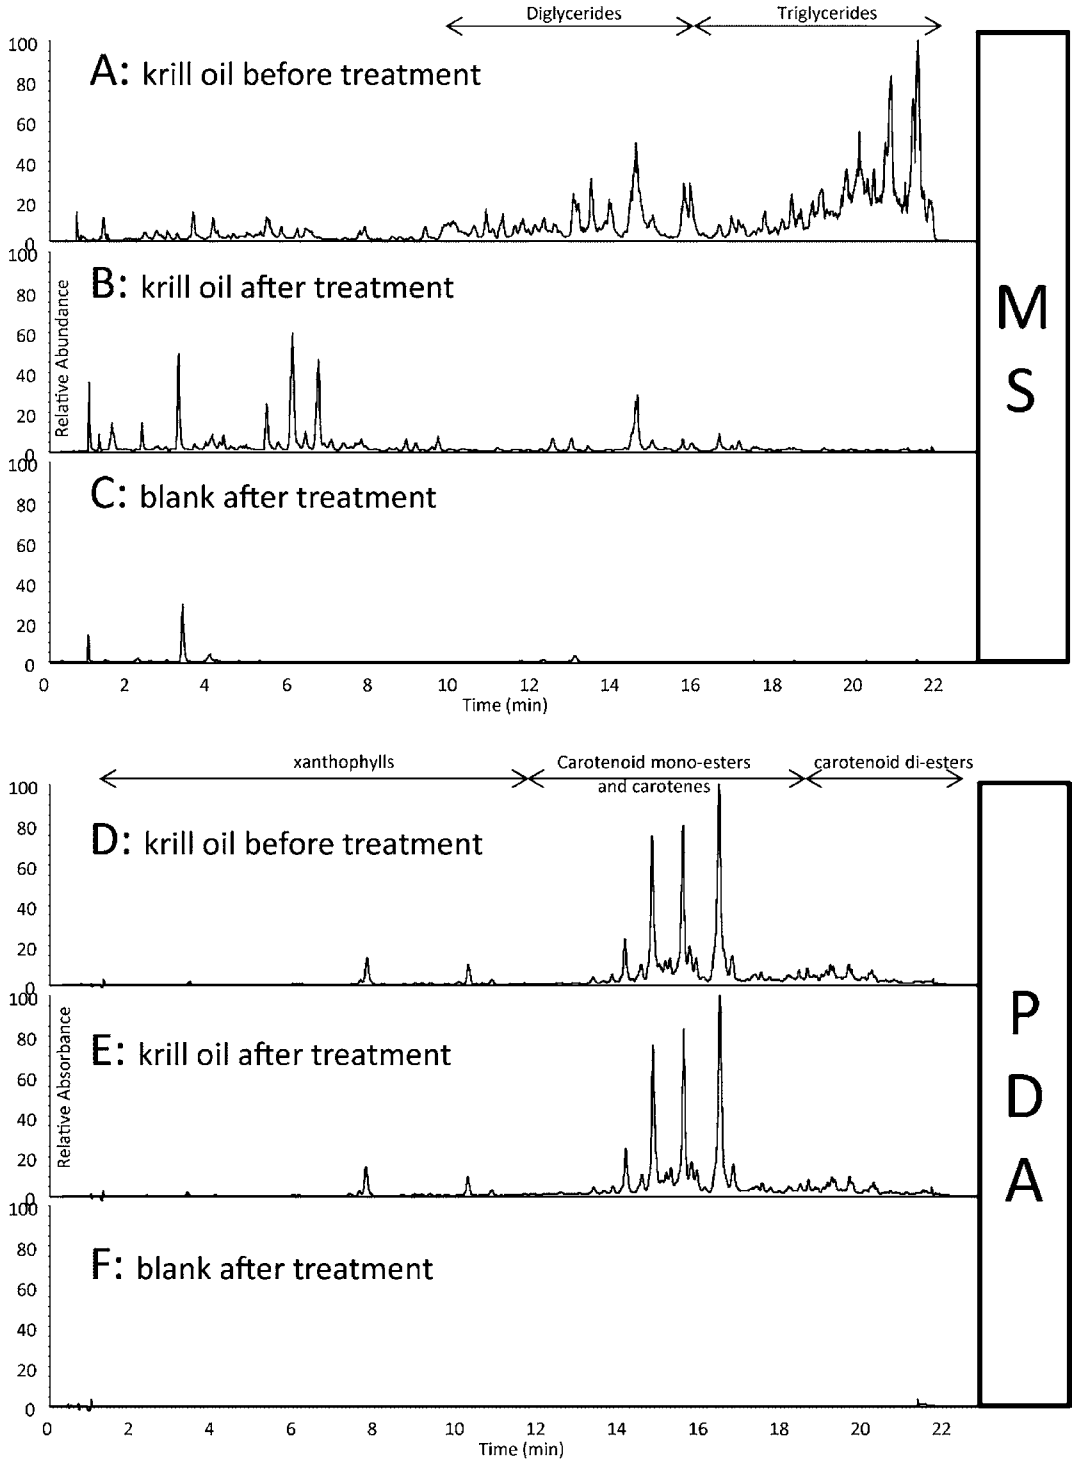

Figure 4. Total ion current MS chromatograms (fixed scale) of Asta Krill 8 oil before (A) and after lipase treatment in 50:50 phosphate buffer/methanol under optimized conditions (B) and for lipase treatment without a sample (blank) (C); chromatograms of the UV signal at 440 nm (fixed scale) for Asta Krill 8 oil before (D) and after lipase treatment under optimized conditions (E) and for lipase treatment without a sample (blank) (F). The arrows indicate the elution order of the compound groups.

Next to the rate of hydrolysis of the DGs and TGs, the PDA chromatograms were studied to compare the composition of carotenoids in the extract before and after the enzymatic assay (E, F, G and H in Figure 2). The elution profiles of the carotenoids in all chromatograms overlap completely before and after lipase treatment, indicating that the natural carotenoid profile is preserved during enzymatic hydrolysis. In both chromatograms of the untreated and treated sample, the carotenoid profile predominantly consists of esterified carotenoids: only very few, low abundant free carotenoid peaks are present.

To confirm that DGs and TGs are better hydrolyzed when 50:50 (v/v) phosphate buffer/methanol is used, both solvents (100% phosphate buffer and 50:50 (v/v) phosphate buffer/methanol) were compared in another enzymatic assay, using only 1 mL of Lipozyme TL 100 L. Previous tests had shown

dx.doi.org/10.1021/jf405477s | J. Agric. Food Chem. 2014, 62, 3114−3124

that Lipozyme TL 100 L is the most active of the two enzymes in lipid hydrolysis (data not shown). As sample matrix, an in-house produced paprika extract (1 mL of DCM extract, evaporated to dryness) was spiked with 300 μL of extra virgin olive oil to obtain a sample with a very high lipid content. The concentration of TGs was much higher in comparison to when only 100 μL of paprika oleoresin was used as test sample. This was observed from the flat and broad TG peaks that were obtained during analysis with MS because of saturated column stationary phase material and saturated detector signals (chromatograms not shown). Results showed that after 2 h of enzymatic incubation, TGs were up to almost 9 times more efficiently hydrolyzed in the 50:50 (v/v) phosphate buffer/methanol solution compared to in the 100% phosphate buffer solution (77 and 8.8% conversion for TG (C18:1, C18:1, C18:2), respectively) (Table 2B). The greater difference in lipid conversion during this test compared to the previous one can be explained by the very high amount of lipids (addition of 300 μL of olive oil). For some DGs, higher concentrations were found in the sample extract after lipase treatment (Table 2B), owing to the very high level of TGs and consequently the high conversion of TGs into DGs. This higher abundance of lipids because of olive oil spiking emphasizes the higher reaction rate when 50:50 (v/v) aqueous phosphate buffer/methanol is used as solvent. On the basis of the results of the above-mentioned experiments, 50:50 (v/v) buffer/methanol in the presence of sodium *n*-octyl sulfate was chosen as incubation solvent for future hydrolysis experiments.

Incubation Time. Three different incubation times were tested with 50:50 (v/v) phosphate buffer/methanol as incubation solvent. The commercial paprika oleoresin was used as sample matrix. The samples were all prepared in duplicate as described above. The results of these tests are shown in Table 2C. On average, approximately 96, 97, and 99% of the selected TGs and 92, 94, and 98% of the selected DGs were hydrolyzed by the lipases with an incubation time of 1, 2, and 3 h, respectively (calculated against the untreated sample). The small decline in DG and TG concentration after 1 h of incubation indicates that the enzymatic hydrolysis reaction rate decreases significantly within 1 h. This observation could be the result of first- or more likely second-order reaction kinetics. Although incubation times of <1 h are possible, 2 h was chosen for later experiments within the scope of the present work as the method was considered as sufficiently optimized for analytical purposes. The optimized enzymatic hydrolysis consists of the following steps:

- weigh 100 μL of oleoresin and add internal standard;
- add 20 mL of 50:50 (v/v) phosphate buffer (0.1 M, pH 7.4)/methanol;
- add 25 μL of sodium *n*-octyl sulfate, 30 mg of bile salts, and 250 μL of NaCl solution (5 mM);
- preheat for 30 min at 40 °C while stirring;
- add 1 mL of 5 KLU of Lipozyme CALB L and 1 mL of 100 KLU of Lipozyme TL 100 L;
- incubate for 2 h at 40 °C while stirring;
- add 20 mL of 1:1 ethyl acetate/hexane, shake vigorously and transfer the apolar fraction;
- wash the polar fraction twice with 30 mL of 1:1:1 (v/v/v) methanol/ethyl acetate/hexane;
- back-extract combined apolar fraction twice with 100 mL of water;
- dry extract with Na_2SO_4 and evaporate;
- dissolve in 1 mL of DCM + 0.1% BHT.

Repeatability. Enzymatic hydrolysis of the paprika oleoresin was carried out in 5-fold to test the repeatability of the optimized method. The average hydrolysis rates of the selected individual TGs ranged between 97.5 and 98.4%. The relative standard deviations (RSDs) ranged between 1.1 and 1.7%, indicating that lipid hydrolysis is repeatable. The average hydrolysis rates of the selected individual DGs ranged between 91 and 98% (calculated against the untreated sample). The RSDs ranged between 1.0 and 5.4%. The larger variations during DG hydrolysis can be explained by the conversion of TGs into specific DGs. For example, DG (C18:2, C18:2) can be formed from TG (C18:2, C18:2, C18:2) or TG (C18:1, C18:2, C18:2) or TG (C18:2, C18:2, C16:0). Depending on which fatty acid side chain is hydrolyzed first, the monitored amount of DG (C18:2, C18:2) will differ. DGs that are less likely to be formed because of a lower concentration in the TG profile, for example, DG (C18:3, C18:3) or DG (C18:3, C16:0), will show a smaller variability.

To investigate the recovery of the carotenoids after enzymatic hydrolysis, five highly abundant carotenoids were selected. Their chromatographic peaks were integrated in the PDA chromatogram at 440 nm and compared to the respective areas in the analysis of the untreated sample. The average recoveries of the four capsanthin diesters and β-carotene ranged between 96 and 105%, which shows that esterified carotenoids were not hydrolyzed during the enzymatic assay (calculated against the untreated sample).

To test the applicability of the method to other matrices, the optimized lipase procedure was applied in 4-fold on oil that was obtained from commercial krill oil soft gels. The samples were treated with the optimized conditions (2 h, 50:50 (v/v) phosphate buffer/methanol). The oil contains high amounts of both TGs and DGs that dominate the TIC signal in the MS chromatogram (chromatogram A, Figure 4). Chromatogram B in Figure 4 shows the TIC MS chromatogram after lipase treatment: the majority of the lipids were removed by the enzymatic hydrolysis. To study the removal of glycerolipids by the lipase assay in more detail, three TGs and three DGs that were highly abundant in the TIC MS signal before the enzymatic assay were selected. On average, approximately 99.9 and 99.6% of the selected TGs and DGs were hydrolyzed by the enzymes, respectively (calculated against the untreated sample). A higher percentage of lipids was hydrolyzed compared with the paprika oleoresin, most probably because of high levels of phospholipids present in the sample (368 mg of phospholipids/g of lipids according to the manufacturer). Phospholipids are known as great emulsifiers, which augments the contact area between glycerolipids and enzymes.[10]

The carotenoid profile of PDA chromatograms D and E in Figure 4 completely match, indicating that esterified carotenoids were not hydrolyzed during the enzymatic assay. To investigate the recovery of the carotenoids after enzymatic hydrolysis in more detail, five astaxanthin esters with a high PDA signal and free astaxanthin were selected (free astaxanthin and its esters were the main carotenoids present in the sample). Their chromatographic peaks were integrated in the PDA chromatogram at 440 nm, and the ratios of esterified astaxanthin versus free astaxanthin were calculated for each ester. These ratios were subsequently compared to the respective ratios in the untreated sample. Decrease in the ratio during the hydrolysis by lipase enzymes would indicate

hydrolysis of esterified carotenoids. The recoveries (average of four samples) of the five individual astaxanthin ratios ranged between 98 and 101%. This shows that esterified astaxanthin compounds were not hydrolyzed into free astaxanthin during the lipase assay.

The lipase treatment was performed on paprika oleoresin in duplicate over three different days using the optimized incubation conditions (50:50 (v/v) phosphate buffer/methanol, 2 h incubation) to investigate the consistency in hydrolysis rates for between- and within-day experiments. The average hydrolysis rates for the individual TGs ranged between 97.0 and 98.0% with RSDs ranging between 1.2 and 1.9%. The average hydrolysis rates for the individual DGs ranged between 89.6 and 97.5% with RSDs ranging between 1.5 and 6.9%. These average hydrolysis rates are in line with the hydrolysis rates obtained during the repeatability experiments. The RSDs are slightly higher than the RSDs obtained during the repeatability experiments. These data indicate the consistency in hydrolysis rates for between- and within-day experiments.

Applicability of the Lipase Treatment to Other Natural Compounds. Comparison of chromatograms A and B in Figure 4 shows that after sample treatment with lipase enzymes new peaks appear in the first half of the MS TIC chromatogram. To study if these signals were caused by conversion of sample compounds or by sample preparation, a method blank was prepared. Chromatogram F in Figure 4 shows the PDA chromatogram of the method blank: no peaks are visible at a wavelength of 440 nm. Chromatogram C in Figure 4 shows the MS TIC chromatogram of the method blank: only a few of the additional peaks that appear after hydrolysis by lipases can be related to sample preparation. This means that compounds originating from the sample extract, other than carotenoids, were converted into new compounds, probably by the cleavage of ester bonds. These peaks could not be related to products of DG and TG hydrolysis (FAs and MGs): accurate mass confirmed that these compounds were removed by liquid−liquid extraction after the lipase assay. These new peaks, however, could be products of phospholipid hydrolysis, as Asta Krill 8 oil contains high levels of phospholipids.

Other interesting groups of secondary metabolites such as phytosterols can also occur esterified with fatty acids. Phytosterols occur in four common forms: as the free alcohol, as fatty acid esters, as steryl glycosides, and as acylated steryl glycosides (Figure 1).[23,24] The different derivatives of β-sitosterol were identified by a common product ion at m/z 397.383 in positive APCI mode, corresponding to the breakage of the C−O-bond at the β-sitosterol moiety (Table 1). The β-sitosteryl glucoside and β-sitosterol peaks in paprika oleoresin before (B) and after (A) enzymatic hydrolysis did not change significantly. On the other hand, the acylated steryl glycosides (C18:3, C18:2, C18:1, and C16:0, respectively) almost completely disappeared by the lipase treatment. The acylated steryl glycosides were not hydrolyzed during lipase treatment to form β-sitosteryl glucoside as no elevated peak area was observed for this compound. However, a low abundant peak appeared in the chromatogram after the enzymatic assay, which corresponded to $C_{39}H_{66}O_9$ (m/z 677.464 in negative APCI mode), presumably due to conversion of acylated β-sitosteryl glucosides into β-sitosteryl glucoside ethyl ester by transesterification. Care should thus be taken when the lipase hydrolysis is used for the analysis of compounds other than carotenoids.

To conclude, carotenoid esters were not hydrolyzed by the cleanup protocol, thereby preserving the natural carotenoid composition of the sample. Even for samples with very high lipid loadings, the greater part of the lipids was selectively removed by this cleanup procedure, thereby enabling the exclusion of the fractionation step and significantly simplifying the procedure. The method was optimized on an analytical scale to enable the identification and quantification of carotenoids in lipid-rich matrices by LC-MS analysis. Next to vegetable and algal oils, the method could prove its use in the analysis of carotenoids in lipid-rich biological samples (e.g., to study the bioavailability of carotenoids and their metabolization in the human body).

type of solvent used in the extraction with the yield and efficiency achieved in the flavonoid extraction. Most of the papers are aimed at finding the solvents with the best extraction power,[16,19] but very few authors have considered the effect that solvents can have on the analysis of the compounds.[20]

Therefore, the aim of this work was to propose a quality control method of the floral bioresidues from *C. sativus* L. by the analysis of phenolic compounds after extraction with different solvents.

MATERIALS AND METHODS

Chemicals. All reagents and solvents employed were of HPLC purity or analytical grade. Standards of kaempferol 3-*O*-glucoside (purity > 99%), kaempferol aglycone (purity > 99%), and delphinidin 3,5-di-*O*-glucoside were purchased from Extrasynthese (Genay, France). Kaempferol 3-*O*-sophoroside was isolated as described Sánchez et al.[21] Ultrahigh-purity water was produced using a Milli-Q System from Millipore (Bedford, MA, USA). Acetonitrile (ACN), ethanol, acetone, *tert*-butyl methyl ether (TBME), *n*-butanol, dichloromethane, methanol, hydrochloridric acid (HCl), trifluoroacetic acid (TFA), anisaldehyde, sulfuric acid, glacial acetic acid, and formic acid were supplied from Scharlau (Barcelona, Spain).

Plant Material. The floral bioresidues from the production of saffron spice were obtained from the company Agrícola Técnica de Manipulación y Comercialización S.L. (Minaya, Spain) after separation of the stigma from the flower of saffron during the 2010−2011 harvest. Stigma separation was performed using traditional procedures for the Protected Designation of Origin "Azafrán de La Mancha" according to DOCM.[22] Floral bioresidues were formed by all parts of the flowers except the stigmas.

Fresh floral bioresidues from *C. sativus* L. were freeze-dried in a LyoAlfa 6-50 freeze-dryer (Telstar, Terrassa, Spain) for 48 h to constant weight.[14] The conditions used for freeze-drying the samples were as follows: mass load, 100 g; initial temperature, −50 ± 2 °C; and pressure, 10^{-3} mbar. They were crushed, sieved through a 500 μm mesh size, and then stored at −20 °C until their further analysis.

Isolation of Anthocyanins. *Sample Preparation for High-Speed Counter-Current Chromatography (HSCCC).* Floral bioresidues (835 g) were extracted with 25 L of water/HCl (100:1, v/v) at 40 ± 5 °C by stirring for 1 h and then decanted and filtered through a fabric filter. The supernatant was filtered through a Buchner funnel (sintered disk of porosity grade 2) and concentrated with a rotary evaporator under vacuum and freeze-dried. This crude extract was redissolved in water, centrifuged at 3000 rpm for 5 min, and filtered with a paper filter prior to the application onto an Amberlite XAD-7 column (Fluka, 100 × 7 cm), conditioned with 2 L of methanol and then with 2 L of water. The column was rinsed with 3 L of water, and anthocyanins were eluted with 2 L of a mixture of water/ACN/TFA (49.5:50:0.5, v/v/v). The eluate was concentrated, dissolved in water, and freeze-dried. An amount of 3.9 g of purified XAD-7 extract was obtained from 74.1 g of crude extract.

High-Speed Counter-Current Chromatography. The XAD-7 extract was fractioned with a CCC-1000 high-speed countercurrent chromatograph manufactured by Pharma-Tech Research Corp. (Baltimore, MD, USA) equipped with three preparative coils and connected in series (tubing diameter of 2.6 mm and total volume of 850 mL).

TBME/*n*-butanol/water/ACN (1:3:5:1, v/v/v/v) acidified with 0.5% TFA was used as solvent system. The elution mode was head to tail with the lighter (organic) phase acting as the stationary phase and the aqueous phase acting as the mobile phase. The flow rate was set at 3 mL min^{-1} and delivered by a BT 3020 HPLC pump (Jasco, Gross-Umstadt, Germany). The separation was run at a speed of 1000 rpm. One gram of XAD-7 extract was dissolved in 25 mL of a mixture of the upper (organic) and lower (aqueous) phases (50:50, v/v) and injected into the system by a loop injection. Volumes of 12 mL were collected with a fraction collector. Elution was monitored with a K-2501 UV−vis absorbance detector (Knauer, Berlin, Germany) at 280 nm to detect anthocyanins and also flavonols.

Thin-Layer Chromatography (TLC). The screening of the composition of the volumes collected by HSCCC was performed by TLC using water/methanol/dichloromethane (3:27:75, v/v/v) in silica gel 60 F254 aluminum plates and water/ACN/TFA (90:9.5:0.5, v/v/v) in C18 plates. Anthocyanins were visualized under a UV lamp at 254 and 366 nm, and then TLC plates were sprayed with anisaldehyde/sulfuric acid/glacial acetic acid spray reagent and heated at 100 °C. Tubes with a similar anthocyanin composition were reunited. After the evaporation of organic solvents, the fractions were frozen and freeze-dried. The HSCCC fractions with their corresponding retention times (t_R) are shown in Table 1.

Table 1. Isolated Amounts and Retention Times (t_R) of the Fractions Obtained by HSCCC

fraction	t_R (min)	isolated amount (mg)
F1	204−212	301.93
F2	212−220	77.54
F3	220−232	46.24
F4	232−252	35.20
F5	252−308	39.43
F6	308−324	<2.00
F7	324−336	<2.00
F8	336−364	<2.00
F9	364−380	1.89
F10	coil residue	18.38
F11	cleaning in methanol	36.42

Preparative HPLC-UV. Fractions 3 and 4 obtained from HSCCC were purified by preparative HPLC from Knauer (Berlin, Germany). Preparative HPLC consisted of an HPLC pump WellChrom K-1001, solvent organizer K-1500 and degasser, and a UV detector K-2600. The separation was carried out on a 250 × 10 mm, 5 μm, RP-18 Luna (18/2) column from Phenomenex (Aschaffenburg, Germany). The eluents were water/ACN/formic acid, 92:3:5, v/v/v, as solvent A and water/ACN/formic acid, 45:50:5, v/v/v, as solvent B, operating in the following gradient: 0 min, 2% B; 20 min, 14% B; 25 min, 14% B; 40 min, 18% B; 45 min, 18% B; 50 min, 90% B; 55 min, 2% B, followed by a 5 min equilibration period. The flow rate was 4 mL min^{-1}, and the detector was set at 280 and 520 nm. Two fractions were collected and freeze-dried due to their highest absorbance at 520 nm, which were the two isolated anthocyanins (t_R = 32.0−36.0 min for the first isolated anthocyanin and t_R = 44.0−47.3 min for the second isolated anthocyanin) from floral bioresidues.

Extraction of Floral Bioresidues. Floral bioresidues (0.5 g) were extracted with 25 mL of water/ACN/TFA (47:50:3, v/v/v) according to the method of Nørbæk et al.[13] Other solvents, such as water/HCl (100:1, v/v), water/ACN/HCl (50:50:1, v/v/v), water/ethanol/HCl (50:50:1, v/v/v), and water/acetone/HCl (50:50:1, v/v/v), were also used to extract floral bioresidues at the same ratio (0.5 g in 25 mL). Extracts were shaken for 1 h at 500 rpm followed by centrifugation at 3500 rpm for 5 min to remove the material plant. The supernatants of these extracts were separated, and their pH values were measured.

Addition of Acetonitrile to the Supernatant of Water/HCl (100:1, v/v) Extracts. Acetonitrile was added to the supernatant of the extract prepared with water/HCl (100:1, v/v) in a 50% ratio.

TFA (in a 3% ratio) or HCl (in a 1% ratio) was added to the supernatant of the extract prepared with water/HCl (100:1, v/v).

Acetonitrile in various ratios (from 10 to 50%, v/v) with TFA in a 50:3 ratio (ACN/TFA, v/v) or acetonitrile from 10 to 50% (v/v) with HCl in a 50:1 ratio (ACN/HCl, v/v) was added to the supernatant of the extracts prepared with water/HCl (100:1, v/v). These solutions were shaken for 1 h at 500 rpm, and their pH values were measured.

Addition of Acetonitrile to a Solution of Delphinidin 3,5-Di-*O*-glucoside. A commercial standard (5 mg) of delphinidin 3,5-di-*O*-glucoside was dissolved in 25 mL of water/HCl (100:1, v/v) by shaking for 1 h at 500 rpm.

[a]sh, shoulder. [b]%, relative height of ion in mass spectrum.

Acetonitrile in a 50% ratio (v/v) and TFA in a 3% ratio (v/v) were added to the solution of delphinidin 3,5-di-*O*-glucoside prepared above.

The solvents of this mixture composed of 47% of the solution of delphinidin 3,5-di-*O*-glucoside, 3% of TFA, and 50% of acetonitrile were removed by rotary evaporation under vacuum. The concentrate obtained was redissolved in water/HCl (100:1, v/v) by shaking for 1 h at 500 rpm.

HPLC-DAD-ESI-MS^n Analysis. All extracts of floral bioresidues were analyzed by HPLC with diode array detector coupled to electrospray ionization tandem mass spectrometry techniques (HPLC-ESI-DAD-MS^n). XAD-7 extracts as well as HSCCC fractions, preparative HPLC fractions, and commercial standards were redissolved in water/HCl (100:1, v/v/v) and also analyzed by HPLC-ESI-DAD-MS^n. All of the samples were filtered through PTFE filters with 0.45 μm pore size and 11 mm diameter (Millipore).

Separation was carried out on a Luna RP-18 column (150 × 2.0 mm, 3 μm, Phenomenex) at a flow rate of 0.2 mL min^{-1}, using an injection volume of 5 μL. Water/ACN/formic acid, 95:3:2 (v/v/v) (A), and water/ACN/formic acid, 48:50:2 (v/v/v) (B), were used as mobile phases with the following gradient: 0 min, 2% B; 20 min, 14% B; 25 min, 14% B; 40 min, 18% B; 45 min, 18% B; and 70 min, 90% B, followed by a 10 min equilibration period. ESI-MS^n measurements were performed on a Bruker Esquire-LC multiple ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany). Mass spectral analyses were recorded under the following operating conditions for negative and positive ion modes: capillary, −3500 V; capillary exit offset, 70 V; end plate offset, −500 V; skimmer, 40 V; dry gas (N_2), 11 L min^{-1}; dry temperature, 330 °C; nebulizer, 60 psi; scan range, m/z 50−3000. Esquire NT 4.0 software (Bruker Daltonics) was used for analysis and data collection.

HPLC-DAD Analysis. To quantify, all extracts of floral bioresidues were analyzed by HPLC-DAD. XAD-7 extracts as well as HSCCC fractions, preparative HPLC fractions, and commercial standards were redissolved in water/HCl (100:1, v/v/v) and also analyzed by HPLC-DAD.

Aliquots of 30 μL of the samples were filtered through a PTFE filter (0.45 μm) and analyzed by reverse-phase HPLC technique, using an Agilent 1200 chromatograph (Palo Alto, CA, USA) operating with a 250 × 4.6 mm, 5 μm, Develosil ODS-HG-5 chromatographic column (Phenomenex, Le Pecq Cedex, France) at 40 °C. Eluents were water/TFA (99.5:0.5, v/v) (A) and ACN (B) with the following elution gradient: 0 min, 0% B; 30 min, 30% B; 40−45 min, 80% B; 50 min, 20% B, followed by a 5 min equilibration period. The flow rate was 1.0

dx.doi.org/10.1021/jf4057023 | J. Agric. Food Chem. 2014, 62, 3125−3133

mL min^{-1} and the DAD (Hewlett-Packard, Waldbronn, Germany) was set at 266 nm for flavonols and at 520 nm for anthocyanins.

Internal Validation of the HPLC-DAD Method. The linearity of the detector response for the prepared standards was assessed by means of linear regression regarding the amounts of each standard, measured in milligrams, and the area of the corresponding peak on the chromatogram. Six-point calibration curves of kaempferol 3-*O*-sophoroside and kaempferol aglycone were used (Table 2). The rest of the flavonols were quantified using a six-point calibration curve of kaempferol 3-*O*-glucoside. Most anthocyanins were quantified using a six-point calibration curve of delphinidin 3,5-di-*O*-glucoside (isolated as under Isolation of Anthocyanins). Petunidin 3,5-di-*O*-glucoside was quantified using a six-point calibration curve of petunidin 3,5-di-*O*-glucoside (isolated as under Isolation of Anthocyanins). Signal-to-noise ratios of 3:1 and 10:1 were used for estimating the limits of detection (LOD) and quantification (LOQ) of the method, respectively.

The repeatability of the injection integration was determined for standard phenolics and the samples. A standard solution containing kaempferol 3-*O*-sophoroside, kaempferol 3-*O*-glucoside, kaempferol aglycone, delphinidin 3,5-di-*O*-glucoside, and petunidin 3,5-di-*O*-glucoside was injected 10 times, and the RSD were calculated for both the retention time and integration area. Floral bioresidues were also extracted 10 times to evaluate the repeatability of the extraction process. The mean amount and RSD values of each compound were calculated.

The accuracy of the method was determined by analyzing the recovery percentage of the main constituents in the extracts. The samples were spiked with three different amounts of standard compounds before extraction. The spiked samples were extracted in triplicate and analyzed under the previously established optimal conditions. The obtained average contents of the target compounds were used as the "real values" to calculate the spike recoveries.

Statistical Analysis. One-way analysis of variance (ANOVA) was performed on each determination. Mean values were compared by Tukey's test at $p < 0.05$ using SPSS 19.0 for Windows (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Phenolic Identification by HPLC-DAD-ESI-MS^n. As can be observed in Table 3, 15 phenolic compounds were tentatively identified in the 5 different extracts, which included 10 flavonols and 5 anthocyanins. The flavonol fraction was mainly composed by kaempferol, isorhamnetin, and quercetin glycosides. Seven glycosides of kaempferol, namely, kaempferol 3-*O*-sophoroside-7-*O*-glucoside (compound **1**, $[M - H]^-$ at m/z 771), kaempferol 3,7-di-*O*-glucoside (compound **2**, $[M - H]^-$ at m/z 609), kaempferol 3,7,4′-tri-*O*-glucoside (compound **3**, $[M - H]^-$ at m/z 771), kaempferol 3-*O*-sophoroside (compound **6**, $[M - H]^-$ at m/z 609), kaempferol 3-*O*-rutinoside (compound **7**, $[M - H]^-$ at m/z 593), kaempferol 3-*O*-glucoside (compound **8**, $[M - H]^-$ at m/z 447), kaempferol 7-*O*-glucoside (compound **9**, $[M - H]^-$ at m/z 447), and kaempferol aglycone (compound **10**, $[M - H]^-$ at m/z 285) were identified on the basis of MS^2 and MS^3 fragmentation patterns and their maximum wavelengths in the UV–vis absorption spectrum, by comparison with previously published data.[13] Identification of compound **6** as kaempferol 3-*O*-sophoroside was also confirmed after comparison of their $[M - H]^-$ ions, MS^2 product ions, and retention times with those of their corresponding standard isolated from floral bioresidues (see Chemicals). Compounds **8** and **10** were also identified as kaempferol 3-*O*-glucoside and kaempferol aglycone, respectively, by comparison of their $[M - H]^-$ ions, MS^2 product ions, and retention times with those of their corresponding commercial standards (see Chemicals). Compounds **4** and **5** with $[M - H]^-$ ions at m/z 625 and 639 were identified as quercetin 3-*O*-sophoroside and isorhamnetin 3,4′-di-*O*-glucoside, respectively, by comparison of their MS^2 profiles and their maximum wavelengths in the UV–vis absorption spectrum with published data.[13]

With respect to the anthocyanins, isolation of the major anthocyanins by HSCCC was carried out, as can be seen in Figure 1. HSCCC is a liquid–liquid chromatographic technique

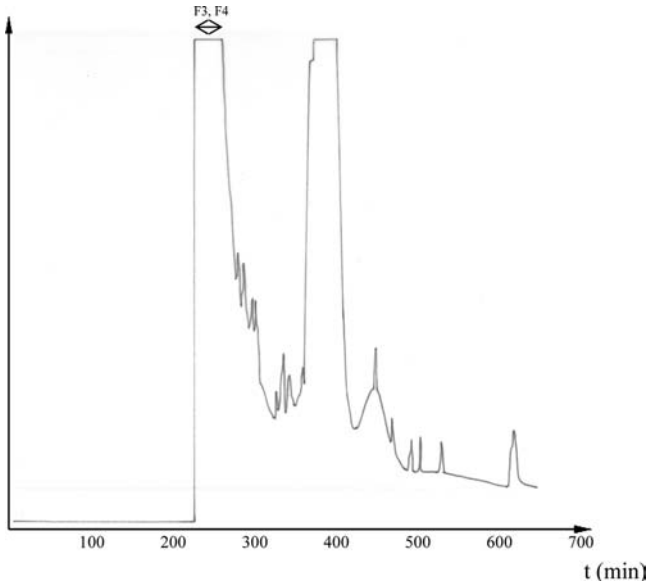

Figure 1. HSCCC chromatogram at 280 nm of the XAD-7 extract of floral bioresidues obtained from the production of saffron spice.

based on partitioning of compounds between two immiscible liquid phases.[23] The two main advantages of HSCCC compared to classical liquid chromatography are its solute loading capacity and the absence of an adsorptive matrix, which prevents irreversible adsorption of the solutes.[24] The separation was finished after 6 h. Nine major fractions were observed in the CCC separations of the XAD-7 extract of floral bioresidues. All fractions were analyzed by HPLC-DAD-ESI-MS^n. HSCCC fractions 3 and 4 were selected to be subjected to preparative HPLC separation because they showed two anthocyanins with the highest DAD signals and the lowest interferences with other phenolic compounds (Figure 1). The identification of individual anthocyanins was based on the data from HPLC-ESI-MS^n analysis, their maximum wavelengths in the UV–vis absorption spectrum, and comparison with literature data of anthocyanins.[13] The first preparative HPLC fraction (29.01 mg) contained delphinidin 3,5-di-*O*-glucoside in a purity of 90%. Upon HPLC-ESI-MS^n analysis, a molecular ion $[M - H]^+$ at m/z 627 was obtained along with fragments at m/z 465 and 303, respectively. The second preparative HPLC fraction (4.07 mg) contained petunidin 3,5-di-*O*-glucoside in a purity of 86%. Its structure was confirmed by HPLC-ESI-MS^n measurements. The molecular ion at m/z 641 yielded fragments of m/z 479 and 317, respectively.

On the basis of the MS^2 fragmentation pattern obtained, their maximum wavelengths in the UV–vis absorption spectrum, and published data,[13] five anthocyanins were identified in the extracts of floral bioresidues (Table 3): delphinidin 3,5-di-*O*-glucoside (compound **11**, $[M - H]^+$ at m/z 627), petunidin 3,5-di-*O*-glucoside (compound **12**, $[M - H]^+$

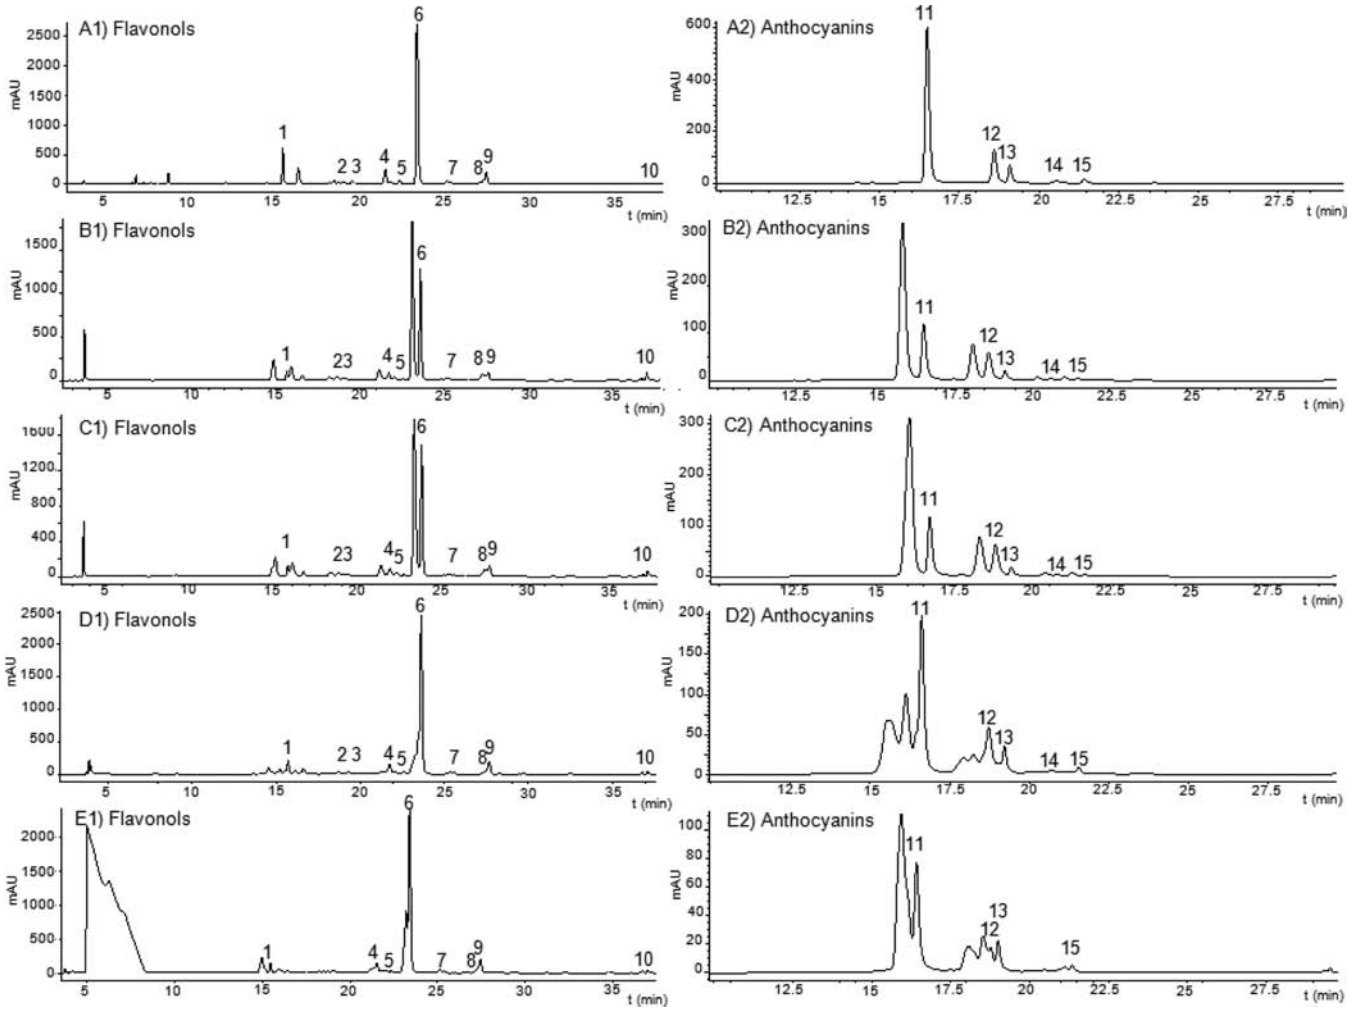

Figure 2. HPLC-DAD chromatograms of flavonols at 266 nm (1) and anthocyanins at 520 nm (2) of extracts of floral bioresidues prepared with water/HCl (100:1, v/v) (A), ACN/water/TFA (50:47:3, v/v/v) (B), ACN/water/HCl (50:50:1, v/v/v) (C), ethanol/water/HCl (50:50:1, v/v/v) (D), and acetone/water/HCl (50:50:1, v/v/v) (E). Phenolic compounds corresponding to each number can be seen in Table 3.

at m/z 641), delphinidin 3-*O*-glucoside (compound **13**, $[M - H]^+$ at m/z 465), malvidin 3,5-di-*O*-glucoside (compound **14**, $[M - H]^+$ at m/z 655), and petunidin 3-*O*-glucoside (compound **15**, $[M - H]^+$ at m/z 479). Identification of delphinidin 3,5-di-*O*-glucoside and petunidin 3,5-di-*O*-glucoside was also confirmed by comparison with the retention time and fragmentation profile of the standards isolated from floral bioresidues under Isolation of Anthocyanins. In the case of delphinidin 3,5-di-*O*-glucoside, these data were also compared with the commercial standard (see Chemicals).

Phenolic Profile by HPLC-DAD. HPLC-DAD chromatograms of flavonols (266 nm) and anthocyanins (520 nm) obtained from the five different extracts of floral bioresidues are shown in Figure 2. The extracts showed very different chromatographic profiles of flavonols and anthocyanins. The water/HCl extract showed a very good chromatographic separation of the compounds (Figure 2A1,A2). Moreover, the chromatographic peaks obtained showed high symmetry, with symmetry factors between 0.8 and 1.2. This extract showed the least number of phenolic compounds, but their peak areas were much higher than those of the rest of the extracts. Extracts prepared with water/ACN/TFA or water/ACN/HCl (water/ACN/TFA(HCl)) (Figure 2B1,B2,C1,C2) also showed a very good chromatographic separation with symmetrical peaks, but new chromatographic peaks were present that had not been detected in the water/HCl extracts (Figure 2A1,A2). Extracts prepared with water/ethanol/HCl (Figure 2D1,D2) or water/acetone/HCl (Figure 2E1,E2) showed poor peak shapes and a very low chromatographic separation efficiency in comparison with extracts prepared with water/HCl or water/ACN/TFA(HCl). Moreover, acetone interferes in the chromatogram obtained at 266 nm, the wavelength used for the flavonol identification. Therefore, the mixtures of water/ethanol/HCl or water/acetone/HCl were excluded as extractants for the determination of phenolic compounds in floral bioresidues.

Internal Validation of the HPLC-DAD Method. The HPLC-DAD method was validated by defining the linearity, LOD, LOQ, precision, specificity, and robustness. A high repeatability in the retention times was obtained with RSD values of <2% for both standards and extracts. Linearity, LOD, LOQ, accuracy, and precision were evaluated for quantitative purposes (Table 2). Linear behavior was observed in the ranges studied for all of the phenolic compounds considered, presenting good correlation coefficients (between 0.9992 and 0.9997). LOD and LOQ values ranged from 0.01 to 7.04 mg L^{-1} and from 0.22 to 27.91 mg L^{-1}, respectively, which suggested full capacity for the quantification of each phenolic compound investigated. The precision of the injection integration exhibited RSD values

[a]Data expressed as mean ± SD (n = 5). Different letters within a row indicate significant differences ($p < 0.05$). <LOD, not detected. <LOQ, not quantified.

lower than 1 and 10% for both standards and extracts, respectively. Accuracy was evaluated from recovery studies. The high recovery values (close to 100%) and a high repeatability indicated a satisfactory accuracy in the proposed method. Furthermore, the accuracy was independent of the compound concentration and their chemical structure.

The HPLC-DAD method in extracts of floral bioresidues prepared with water/HCl (100:1, v/v),water/ACN/TFA (47:50:3, v/v/v), or water/ACN/HCl (50:50:1, v/v/v) can be considered selective, precise, and accurate.

Quantitative Analysis. Table 4 shows the composition in flavonols and anthocyanins of the five different extracts of floral bioresidues, although the HPLC-DAD method for the water/acetone/HCl and water/ethanol/HCl extracts was not validated. Extracts prepared with water/HCl and water/ACN/TFA(HCl) showed all identified flavonols and anthocyanins (Figure 2; Table 4). However, extracts prepared with water/ethanol/HCl and water/acetone/HCl did not show kaempferol 3,7-di-*O*-glucoside and kaempferol 3,7,4′-tri-*O*-glucoside. Malvidin 3,5-di-*O*-glucoside was not detected in water/acetone/HCl extract.

Nørbæk et al. extracted saffron tepals with water/ACN/TFA (47:50:3, v/v/v) for flavonol and anthocyanin determination.[13] In this work, an extract (Figure 2B1,B2) was prepared according to themethod of Nørbæk et al.,[13] and another extract was prepared with water/ACN/HCl (50:50:1, v/v/v) (Figure 2C1,C2) to determine if the use of different acids in different proportion could affect the phenolic composition. The use of TFA or HCl in the extractants composed by water/ACN did not significantly modify the phenolic composition or extraction, because both extracts showed the same number of phenolic compounds and very similar contents (Figure 2B1,B2,C1,C2; Table 4).

Kaempferol 3-*O*-sophoroside constituted between 96 and 99% of total flavonols identified in all extracts (Table 4). This compound has also been identified in saffron spice samples.[25] The rest of the flavonols identified were present in only trace amounts. These results showed that the quantification of this single compound could be sufficient for the rapid quality control of flavonols in this plant material by the food industry. The water/HCl extract showed the highest concentration of kaempferol 3-*O*-sophoroside, followed by water/ethanol/HCl and water/acetone/HCl extracts. The lowest concentrations were observed in water/ACN/TFA(HCl) extracts. With regard to the chromatograms of the detected flavonols at 266 nm, kaempferol 3-*O*-sophoroside (compound **6**, t_R = 23.57 min) was the main flavonol in extracts prepared with water/HCl, water/ethanol/HCl, and water/acetone/HCl (Figure 2A1,D1,E1). Extracts prepared with water/ACN/TFA(HCl) showed a compound with a t_R = 23.09 min prior to kaempferol 3-*O*-sophoroside having a peak area higher than that of kaempferol 3-*O*-sophoroside (Figure 2B1,C1). The fragmentation pattern of this compound was exactly equal to that of kaempferol 3-*O*-sophoroside (Table 3) isolated from floral bioresidues (see Chemicals).

Delphinidin 3,5-di-*O*-glucoside, followed by petunidin 3,5-di-*O*-glucoside and delphinidin 3-*O*-glucoside, was the main anthocyanin in all of the extracts studied (Table 4). Malvidin 3,5-di-*O*-glucoside and petunidin 3-*O*-glucoside were present in lower concentrations. The water/HCl extract showed much higher concentrations of the five anthocyanins identified than those of the rest of the extracts. The anthocyanin concentration was higher in water/ethanol/HCl extract than in water/ACN/TFA(HCl) extracts. The lowest concentration of the five anthocyanins identified was observed in the water/acetone/HCl extract. With regard to the chromatograms of the anthocyanins detected at 520 nm, delphinidin 3,5-di-*O*-

dx.doi.org/10.1021/jf4057023 | J. Agric. Food Chem. 2014, 62, 3125−3133

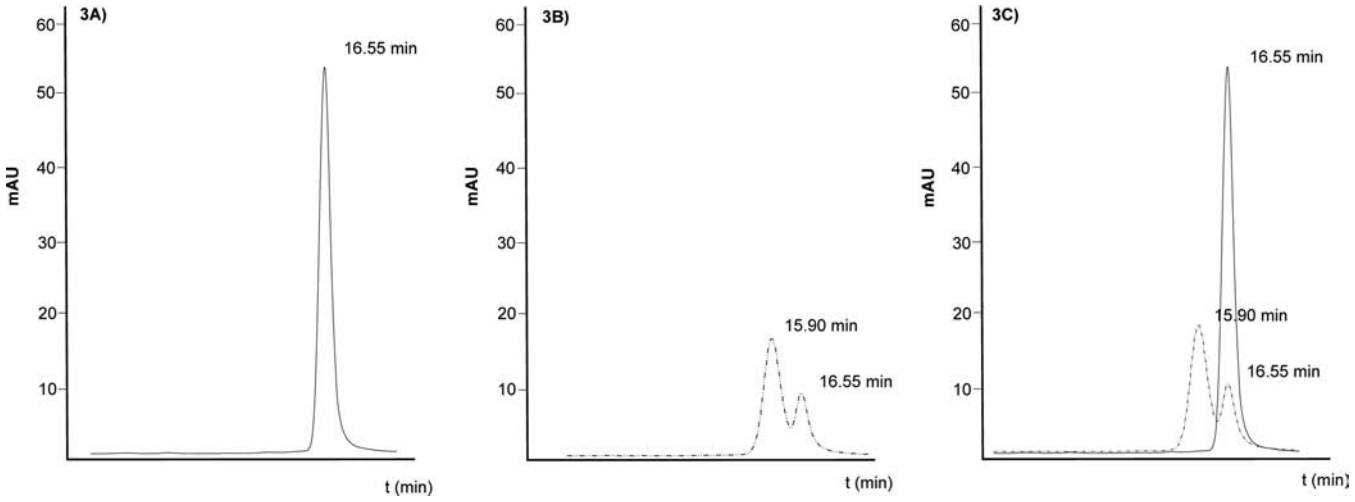

Figure 3. Commercial standard of delphinidin 3,5-di-*O*-glucoside by HPLC-DAD at 520 nm of (A) delphinidin 3,5-di-*O*-glucoside dissolved in water/HCl (100:1, v/v) and (B) solution composed of 47% of the solution analyzed in Figure 2A with the addition of 3% of TFA and 50% of acetonitrile. (C) Overlay of panels A and B.

glucoside (compound **11**, t_R = 16.55 min) was the major anthocyanin in the water/HCl extract (Figure 2A2). The rest of the extracts (Figure 2B2,C2,D2,E2) showed other anthocyanins with lower retention times (t_R = 15.62 and 15.90 min) having peak areas much higher than that of delphinidin 3,5-di-*O*-glucoside. When ESI-MS^n analysis was performed (Table 3), their fragmentation profiles were equal to that of the commercial standard of delphinidin 3,5-di-*O*-glucoside (Table 3) and to that of anthocyanins isolated from floral bioresidues (section Isolation of Anthocyanins).

Effect of Solvent on the Analysis of Phenolic Compounds. *Extracts of Floral Bioresidues.* As mentioned before, extracts prepared with water/HCl showed only one major flavonol, kaempferol 3-*O*-sophoroside (Figure 2A1), and one major anthocyanin, delphinidin 3,5-di-*O*-glucoside (Figure 2A2). However, extracts prepared with water/ACN/TFA(HCl) showed two major flavonols (Figure 2B1,C1) and two major anthocyanins (Figure 2B2,C2). In both cases, a compound with a t_R prior to kaempferol 3-*O*-sophoroside (at 266 nm) and another compound with a t_R prior to delphinidin 3,5-di-*O*-glucoside (at 520 nm) were observed. These compounds showed fragmentation patterns exactly equal to those of kaempferol 3-*O*-sophoroside and delphinidin 3,5-di-*O*-glucoside, respectively (Table 3). In the case of water/ethanol/HCl and water/acetone/HCl extracts, the same effect was observed. Due to less efficient separation of the phenolic compounds in these two extracts, this study was focused on the comparison between water/HCl with water/ACN/TFA(HCl) extracts.

First, it was hypothesized that water/ACN/TFA(HCl) extracts were capable of extracting more phenolic compounds than the water/HCl extracts. On the other hand, it could be also the case that ACN or the acids were responsible for this effect. To rule out any of these hypotheses, an extract of floral bioresidues in water/HCl (100:1, v/v) was prepared, the plant material was discarded after centrifugation, and only the supernatant of the water/HCl extracts was used. Then, ACN without acids (TFA and HCl) and/ on the other hand, TFA or HCl without ACN were added to the supernatant of the water/HCl extracts to determine whether ACN or the acids may be responsible for producing two main flavonol and two main anthocyanin peaks in the water/ACN/TFA(HCl) extracts instead of a single compound. ACN, TFA, and HCl were added in similar ratios to the initial extracts where this effect was observed, that is, ACN at 50%, TFA at 3%, and HCl at 1%. The flavonol and anthocyanin composition by HPLC-DAD was unchanged when TFA or HCl was added to the supernatant of the water/HCl extract. However, the same two flavonol and two anthocyanin peaks found in the extracts prepared with water/ACN/TFA(HCl) were observed (Figure 2B2,C2) when ACN without acids was added to the supernatant of the water/HCl extract in a 50% ratio. These results showed that water/ACN/TFA(HCl) did not extract more phenolic compounds from floral bioresidues than water/HCl. ACN caused a splitting of the chromatographic peaks of kaempferol 3-*O*-sophoroside and delphinidin 3,5-di-*O*-glucoside detected in the water/HCl extract.

Commercial Standard of Delphinidin 3,5-Di-O-glucoside. To confirm the results obtained under Extracts of Floral Bioresidues, the commercial standard of delphinidin 3,5-di-*O*-glucoside was dissolved in water/HCl (100:1, v/v) as the extract of floral bioresidues had been prepared previously. The chromatogram at 520 nm of the delphinidin 3,5-di-*O*-glucoside is shown in Figure 3A. ACN was added in a 50% ratio and, then, the same splitting of the chromatographic peak of the delphinidin 3,5-di-*O*-glucoside into two peaks was also observed for the commercial standard (Figure 3B), as had been produced in the water/ACN/TFA(HCl) extracts of floral bioresidues. The t_R of the first anthocyanin generated by the addition of ACN was 15.9 min; however, the second anthocyanin detected showed the same t_R as delphinidin 3,5-di-*O*-glucoside (Figure 3C). The percentage of peak area of the first anthocyanin with respect to the sum of areas of the first and second anthocyanins was 65 ± 2%. The first anthocyanin generated by addition of ACN had a fragmentation pattern similar to that of delphinidin 3,5-di-*O*-glucoside (Table 3).

When the solvents were removed under vacuum and the delphinidin 3,5-di-*O*-glucoside was redissolved in water/HCl (100:1, v/v), the chromatogram at 520 nm was exactly equal to the initial chromatogram of the delphinidin 3,5-di-*O*-glucoside dissolved in water/HCl (100:1, v/v) without the addition of ACN (Figure 3A). The first anthocyanin generated by the addition of ACN was not found in the chromatogram, and the

dx.doi.org/10.1021/jf4057023 | J. Agric. Food Chem. 2014, 62, 3125−3133

peak area of the delphinidin 3,5-di-*O*-glucoside increased again. Some authors stated that the chromatographic splitting of peaks can occur if the sample solvent is of higher strength than the HPLC mobile phase,[26] but really the mechanism or why this happens is still unknown.

Study of the Lowest Solvent Volume Capable of Splitting the Chromatographic Peaks of Phenolic Compounds. Different ratios (from 10 to 50) of ACN were added to the supernatant of water/HCl extracts to find the lowest ratio of ACN capable of producing the chromatographic splitting of the peak of delphinidin 3,5-di-*O*-glucoside. The pH values of the extracts prepared with water/HCl and all of the solutions containing this extract, ACN, and TFA(HCl) in different ratios ranged from 0.90 to 1.16. The effect of the chromatographic splitting of the peak of delphinidin 3,5-di-*O*-glucoside into two peaks was progressive when ACN in different ratios was added. Changes in the chromatograms at 520 nm were not observed when ACN was added in ratios from 10 to 30%. With ACN ratios from 30 to 40%, the separation between the two peaks was greater when the ratios of ACN were also higher. The chromatographic splitting resulting into two well-separated peaks was observed when ACN was added in a 40% ratio to the supernatant of the water,HCl extract. The sum of areas at 520 nm of the two peaks generated by ACN addition was approximately equal to the original peak area of the delphinidin 3,5-di-*O*-glucoside in the water/HCl extract.

The appearance of new chromatographic peaks due to the addition of solvents could produce an erroneous quantification of flavonols and anthocyanins, because the original chromatographic peak and the chromatographic peak generated by the solvent effect correspond to the same compound. Hence, both chromatographic peak areas should be added to be considered as a single compound. The best choice is the complete evaporation of the organic solvent used for extraction prior to analysis. Then the concentrated samples could be redissolved in appropriate solvents for HPLC analysis, as water acidified with HCl.

The FDA[27] proposed HCl to be GRAS (generally recognized as safe) as a direct ingredient of food, so this could be of great relevance for the food industry because floral bioresidues are rich natural sources of antioxidants according to the proposal established by Serrano-Díaz et al.[1] In conclusion, the analytical HPLC-DAD method proposed allows the quantification of phenolic compounds in floral bioresidues with good selectivity, sensitivity, and accuracy. The extract prepared with water/HCl (100:1, v/v) would be best suited for the quality of these products.

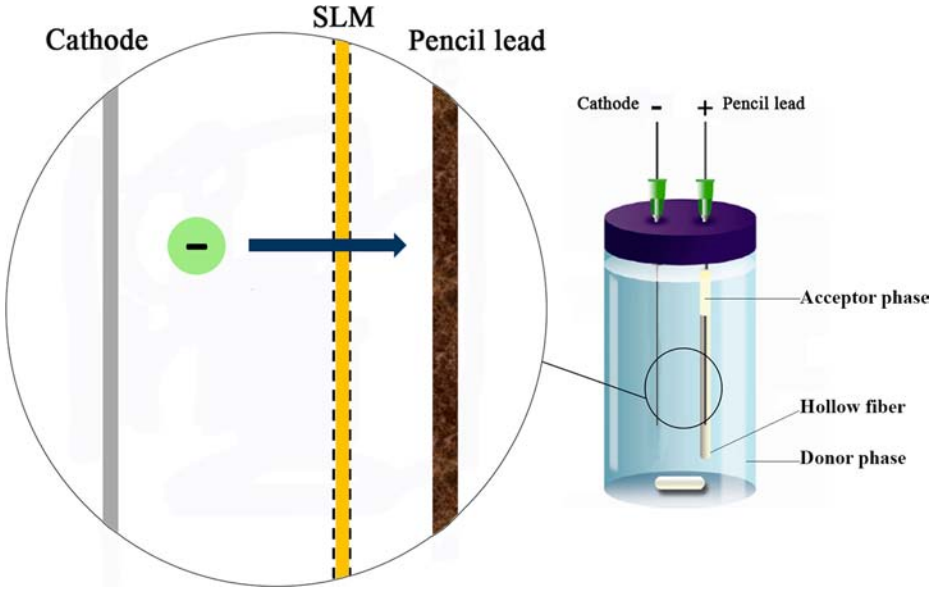

Figure 1. Equipment used for the EM-SPME method, and mechanism of transportation across liquid−liquid—liquid−solid boundaries.

electrical resistance of the system, which reduces the extraction efficiency as a result of diminishing the strength of the electrical field and lengthening the extraction time.[21] EME conjugated with dispersive liquid−liquid microextraction (EME-DLLME) is another route to transferring the analytes into an organic solvent.[22,23] However, EME-DLLME is an off-line coupling of two extraction techniques and requires sufficient time for conducting both procedures.

Rezazadeh et al. have introduced electromembrane surrounded solid phase microextraction (EM-SPME) as a simple and effective method to benefit from high extraction efficiency, sample cleanup, and fast kinetics related to EME technique as well as solid phase microextraction (SPME) compatibility with GC.[24] EM-SPME setup was the same as that of EME, unless one of the electrodes, located in the lumen of the hollow fiber, was substituted with a conductive sorbent. EM-SPME was implemented for extraction of basic drugs utilizing a platinum electrode and a piece of pencil lead as anode and cathode, respectively.[24] Thus, the basic analytes migrated in an electrical field from aqueous sample solution through a liquid membrane and into an aqueous acceptor phase, and then they were adsorbed on the solid sorbent, which acted as cathode. It was shown that EM-SPME has a great potential as a microextraction technique and could be established as a simple and inexpensive method for analysis of nonvolatile or ionizable compounds in complex matrices.[24]

The present study was focused on EM-SPME of acidic herbicides, to explore the capacity of the technique for extraction of this class of analytes by means of a sorbent as anode. Hence, the suggested method followed by GC combined with flame ionization detection (GC-FID) was exploited, for the first time, for extraction of CPA herbicides from plant tissue. In this work, an electrical field was applied to cause the CPAs, which existed in aqueous sample solution as anions, to migrate through the supported liquid membrane (SLM) into an aqueous phase inside the lumen of the hollow fiber. Using organic liquid membrane (SLM), not only the selectivity can be increased but also the sample cleanup highly improves and makes it possible to apply high voltages that increase extraction recoveries. Afterward, the target analytes were adsorbed on the solid adsorbent, which was also the anode. After derivatization to enhance the volatility of the CPAs, the carbonaceous sorbent was directly introduced into the GC-FID injection port. The goal of this work is to examine the possibility of employing EM-SPME as an effective and relatively fast extraction technique for analysis of both acidic and basic compounds in complicated matrices.

EXPERIMENTAL SECTION

EM-SPME Equipment. The equipment used for the extraction procedure is illustrated in Figure 1. A 24 mL vial with an internal diameter of 2.5 cm and a height of 5.5 cm was exploited. The platinum electrode employed in this work, with a diameter of 0.25 mm, was acquired from Pars Pelatine (Tehran, Iran). The electrodes were connected to a power supply model 8760T3 with a programmable voltage in the range of 0−600 V and a current output within the range of 0−500 mA from Paya Pajoohesh Pars (Tehran, Iran). During the extraction, the EM-SPME unit was stirred with a speed in the range of 100−1250 rpm via a heater−magnetic stirrer, model 3001 from Heidolph (Kelheim, Germany), using a 1.5 cm × 0.3 cm magnetic bar. A 40 kHz and 0.138 kW ultrasonic water bath with temperature control (Tecno-GazSpA, Parma, Italy) and a Sepand Teb Azma centrifuge (Tehran, Iran) were employed to carry out pretreatment steps for real samples.

Chemicals and Materials. 2-Methyl-4-chlorophenoxyacetic acid (MCPA) and 2,4-dichlorophenoxyacetic acid (2,4-D), were purchased from Aldrich (Milwaukee, WI, USA). 1-Octanol, 1-hexanol, 1-undecanol, 1-dodecanol, and tetrabutylammonium iodide (TBA), were supplied by Merck (Darmstadt, Germany). All of the chemicals used were of analytical reagent grade. The porous hollow fiber, utilized for supporting the liquid membrane, was a PPQ3/2 polypropylene hollow fiber from Membrana (Wuppertal, Germany), with inner diameter of 0.6 mm, wall thickness of 200 μm, and pore size of 0.2 μm. Ultrapure water was prepared by a Young Lin 370 series aquaMAX purification instrument (Kyounggi-do, Korea).

The HB pencil lead fibers with the diameter of 0.3 mm (Owner, Seoul, Korea) were purchased from a local market. The fibers were conditioned via heating under N_2 atmosphere from room temperature to 350 °C with a ramp of 3 °C min^{-1}, held for 120 min at 350 °C, and then were allowed to cool to ambient temperature.

Standard Solutions and Real Samples. A stock solution, containing 1 mg mL^{-1} of each analyte, was prepared in methanol and stored at −4 °C, protected from light. Working standard solutions were prepared by dilution of the stock solution with methanol.

dx.doi.org/10.1021/jf500017r | J. Agric. Food Chem. 2014, 62, 3134−3142

The whole wheat plant was analyzed as the real sample. For analysis of the target herbicides in the plant tissue, wheat was harvested after 1 h, 2 days, and 6 days following field spraying. The whole wheat plants were first washed and completely blended. A 20 mL aliquot of a 100 mM NaOH solution was subsequently added to 100 g of the blended sample, and the sample was immersed in the ultrasonic water bath. After 2 min of sonication (at 25 ± 3 °C), the sample was centrifuged at 2500 rpm for 10 min to separate the phases. The final liquid phase was diluted (1:9) with pure water and, following pH adjustment (pH 9.0), was transferred into the EM-SPME vial for analysis.

Gas Chromatography Conditions. Separation and detection of MCPA and 2,4-D were executed through an Agilent 7890A gas chromatograph (Palo Alto, CA, USA), equipped with a split−splitless injector, and a flame ionization detector. A 30 m HP-5 Agilent fused-silica capillary column (0.32 mm, i.d.; 0.25 μm, film thickness) was exploited for separation of the target compounds. Helium (purity, 99.999%) was utilized as carrier gas at the constant flow rate of 2.0 mL min^{-1}. The temperatures of injector and detector were set at 290 and 300 °C, respectively. The injection port was operated at the splitless mode. The oven temperature program was 100 °C for 2 min, increasing to 220 °C with a ramp of 9 °C min^{-1}, then increasing to 280 °C at 100 °C min^{-1}, and eventually holding at 280 °C for 3 min.

EM-SPME Procedure. A 24 mL aliquot of the sample solution, containing the analytes in aqueous medium, was transferred into the sample vial. To impregnate the organic liquid membrane in the pores of the hollow fiber wall, a 2.8 cm piece of the hollow fiber was cut out and dipped into 1-octanol for 5 s, and subsequently the excess of the organic solvent was gently wiped away by blowing air with a Hamilton syringe. Pure water, as the acceptor phase, was introduced into the lumen of the hollow fiber by means of a microsyringe, and the lower end of the hollow fiber was mechanically sealed afterward. The pencil lead fiber (the anode) was placed in the lumen of the hollow fiber. After that, the hollow fiber, containing the anode, together with the SLM and the acceptor solution was directed into the sample solution. The platinum cathode was led directly into the sample solution. The electrodes were subsequently connected to the power supply, and the extraction unit was placed on a stirrer with stirring rate of 700 rpm. When the extraction was accomplished, the pencil lead was retracted into the SPME syringe needle. The tractable nature of the pencil lead facilitated its insertion into the SPME syringe. The carbonaceous fiber was well fitted into the syringe by some wearing on top of it, where it was in contact with the needle. Then, the pencil lead was immersed in a concentrated TBA solution, as derivatization reagent, and withdrawn very fast and immediately inserted into the GC injection port for thermal desorption of the analytes at 290 °C for 2 min. The contact time of the fiber and TBA solution should be long enough to form a stagnant thin layer of derivatization reagent around the fiber but it must be too short to prevent dissolving of analytes in TBA solution.

Data Analysis and Statistical Methods. Response surface methodology (RSM) is effective for responses that are influenced by many factors as well as by their interactions and was originally described by Box and Wilson.[25] Optimization of the parameters affecting the extraction efficiency of the analytes by PEME was performed by a face-centered central composite design. In all cases, design generation and statistical analyses were performed by the software package Design-Expert version 8.0.5 trial for Windows (State-Ease, MN, USA).

RESULTS AND DISCUSSION

In order to figure out how the impressive parameters affected the final signals of the analytes, a number of experiments were designed. Two different influential parameters in the final chromatographic signals included EM-SPME related variables and those linked to GC analysis (i.e., derivatization process and desorption conditions). GC instrument associated parameters were optimized in terms of derivatization procedure, TBA concentration, injection port temperature, carrier gas flow rate, and desorption time. EM-SPME affected parameters consisted of SLM composition, compositions of donor and acceptor phases, extraction time, applied voltage, and stirring rate. It is obvious that stirring of the sample solution possesses a positive impact upon the kinetics and efficiency of extraction via enhancing the mass transfer of the analytes and decreasing the thickness of the double layer around the SLM. The influence of the stirring rate on extractability was investigated up to 1250 rpm. A stirring rate of 700 rpm was selected, because of creation of an intense vortex in the sample solution and bubble formation around the hollow fiber at higher rates. The SLM composition was optimized separately, and other EM-SPME variables, comprising extraction time, applied voltage, and pHs of sample solution and acceptor phase, were evaluated by means of experimental design methodology.

Derivatization Procedure and GC Analysis. Direct injection port derivatization with ion-pair reagents, known as tetraalkylammonium salt pyrolysis derivatization method, is a rapid and simple alternative to conventional derivatization techniques for aliphatic and aromatic acids.[26,27] The product of the reaction of an acidic analyte with tetraalkylammonium salt is a carboxylate ion pair, which is derivatized to its corresponding volatile alkyl ester in a high-temperature GC injection port.

$$RCOOH + N(Bu)_4{}^+X^- \leftrightarrow RCOO^-N(Bu)_4{}^+ + HX \quad (1)$$

$$RCOO^-N(Bu)_4 \leftrightarrow RCOO\,Bu + N(Bu)_3 \quad (2)$$

Two different methods were tested to form the carboxylate ion pair. In the first technique, TBA was added to the acceptor phase of EM-SPME and once the extraction was completed, the pencil lead was directly introduced into the GC injection port. The second method of carboxylate ion pair production was through the immersion of pencil lead in a TBA solution following accomplishment of EM-SPME. Comparison of the attained results demonstrated that good derivatization performance was gained by immersion of the SPME fiber in TBA solution. The main point of the injection port derivatization technique is that both analyte and derivatization reagent should simultaneously exist in the injection port during the process. When TBA was added into the acceptor solution, its adsorption on the surface of the pencil lead was difficult since both of them have positive charges. The charge of TBA is positive in the neutral acceptor phase while the positive charges of pencil lead is attributed to the connection of the fiber to the positive pole of the power supply during the extraction procedure. Therefore, the derivatization efficiency decreases due to reduction of the TBA concentration in the injection port. However, immersion of the fiber into a concentrated TBA solution occurred after completion of the extraction and disconnection of the electrical field. In this way, a thin stagnant layer of TBA solution was formed on the surface of the fiber by means of the porous nature of the pencil lead. When the fiber together with the TBA solution layer is introduced into the GC injection port, the TBA solvent (methanol) is evaporated and thus a considerable amount of TBA is available. Hence, desorption of both TBA and analytes lead to formation of derivatized analytes.

The TBA concentration was assessed thereafter, to find the best derivatization conditions. The concentration of the derivatization reagent in methanol was varied in the range of 30−400 mM. After EM-SPME of the analytes, the carbonaceous fiber was immersed in 30 μL of TBA solution and instantly inserted into the GC injection port. It was noticed that

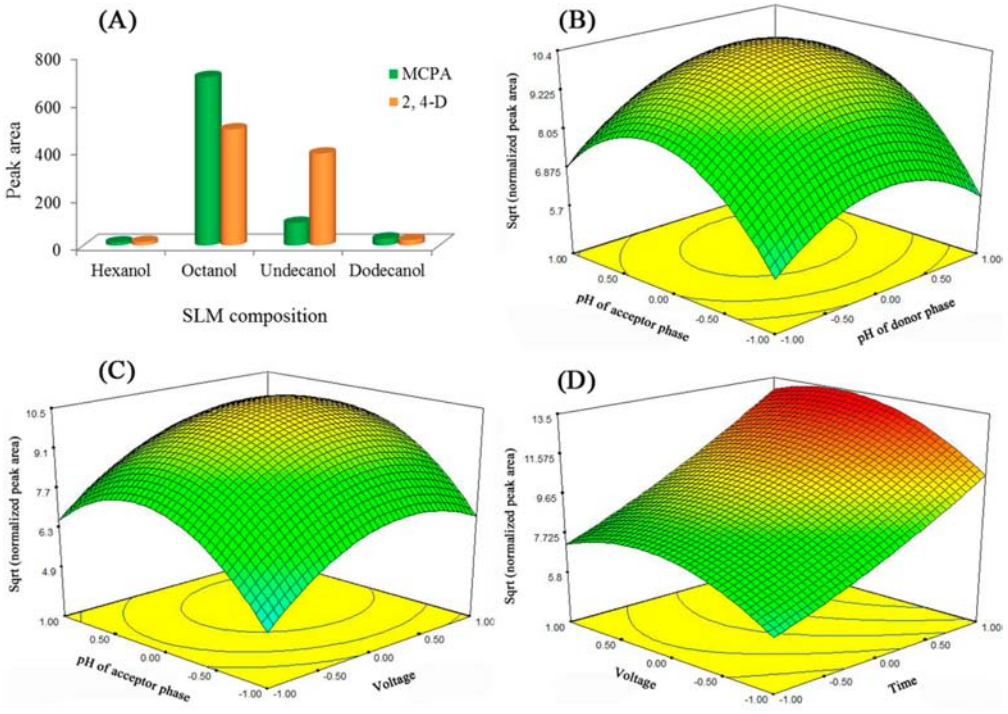

Figure 2. (A) Optimization of membrane composition, (B) response surface of the square root of the normalized peak area vs pH of donor phase and pH of acceptor phase, (C) response surface of the square root of the normalized peak area vs pH of the acceptor phase and applied voltage, and (D) response surface of the square root of the normalized peak area vs extraction time and applied voltage.

the peak areas of both CPA herbicides initially increased via enhancing the concentration of the derivatization reagent up to 200 mM and then reached a plateau with a further rise in TBA concentration. Therefore, 200 mM TBA in methanol was selected as the derivatization solution.

Another effective parameter on the efficiency of the analyte desorption as well as the injection port derivatization process is the injection port temperature that was considered in the range of 250−300 °C. The peak areas of the derivatized analytes were enhanced by raising the temperature to 290 °C. Since no changes in the derivatization yields were observed at higher temperatures, 290 °C was chosen to reach the maximum desorption and derivatization efficiencies and also prevent the entrance of the pencil lead from interfering with compounds going into the GC injection port.

The carrier gas flow rate can influence the derivatization efficiency through altering the delay time of the analytes in the injection port of the GC apparatus. The flow rate of the carrier gas was scrutinized in the range of 1−4 mL min^{-1}. The maximum peak areas for butyl esters of the herbicides were achieved at a flow rate of 2 mL min^{-1}.

Furthermore, desorption time was explored in the range of 0.5−5.0 min while the desorption temperature was 290 °C. The efficiency of thermal desorption improved as the desorption time was increased from 0.5 to 2.0 min. The chromatographic signals slightly increased after 2.0 min, but desorption of some interferences from the pencil lead fiber resulted in crowded chromatograms. Consequently, the desorption time of 2.0 min was selected.

EM-SPME Affecting Parameters. *Composition of Organic Liquid Membrane.* One of the most significant parameters, which could influence the extractability of analytes in EM-SPME technique, is the SLM composition. Extraction selectivity, range of applied voltage, extraction efficiency, and extraction time are directly affected by the composition of organic liquid membrane. Analytes should have a proper affinity for SLM so that adequate selectivity and favorable extraction efficiency could be acquired. In fact, SLM provides the major electrical resistance for the system and the range of applied voltage could be extended via raising the electrical resistance of SLM. Accordingly, system stability and extractability may improve utilizing organic solvents with high electrical resistance such as SLM. Nevertheless, the organic phase should possess satisfactory conductivity to enable ion transportation across the phases. Regarding all of these factors, 1-hexanol, 1-octanol, 1-undecanol, and 1-dodecanol were tested as the organic liquid membrane. It was proved that long-chain alcohols are the most desirable organic solvents for extraction of acidic compounds.[6,28] Among the examined alcohols, 1-hexanol has the least electrical resistance, and a system operated with 1-hexanol, such as the SLM, underwent instability problems owing to increasing the electric current (Figure 2A). Therefore, 1-hexanol offered nonrepeatable results, and the chromatographic signals substantially declined, which was probably caused by the enhancement of electrochemical reactions due to increasing the electric current of the system. On the other hand, 1-dodecanol could not provide a continuous electric field in the entire system, since it possesses a low electrical conductivity; for this reason, the extractability diminished using 1-dodecanol as the SLM. 1-Undecanol was capable of effectively extracting the 2,4-D, although it was not a suitable solvent for MCPA. Ultimately, 1-octanol was chosen as the SLM due its ability to give the best results for both of the analytes.

Optimization of Extraction Time, Applied Voltage, and pHs of the Sample Solution and Acceptor Phase Using Central Composite Design. The experiments for optimization of the rest of the EM-SPME affected parameters were modeled through face-centered central composite design

(FCCCD) methodology. CCD is one of the most frequently used response surface designs; it is a second-order model, correlating the response functions with the independent factors. In this way, the amount of response can be predicted at any point within the factor domain, even though that point is not incorporated in the design. CCD consists of factorial points, center points, and star (axial) points. One type of CCD is FCCCD that is considered unity in α (star point). In this step, 1-octanol was exploited as the SLM for all of the experiments, and the sample solution was stirred at a speed of 700 rpm. To find the optimal conditions, four variables, including extraction time (t), applied voltage (V), and pHs of donor (pH_d) and acceptor (pH_a) phases, had to be assessed. It should be noted that to investigate the composition of donor and acceptor phases, experiments were designed by changing the concentration of HCl and NaOH solutions in the range of 0−100 mM. However for graphical presentation and to obtain a total view of the effect of the concentration of H^+ or OH^- on extractability, the results should be changed to pH. Therefore, 28 experiments were executed, in order to figure out the optimum conditions with four factors and four center points. The normalized peak area for each run was selected as the response objective for the study.[6,12,13] To normalize the peak areas, all of the experiments were first conducted and then the peak area of each analyte was divided by its smallest peak area that was attained from the entire experiments. The normalized peak areas for the analytes were subsequently added for each run and utilized in the calculation of the total normalized peak area. Analysis of variance (ANOVA) in Table 1 depicts that the model is well fitted to the significant variables by means of multiple regression analysis. Meanwhile, an acceptable coefficient of determination ($R^2 = 0.9685$) was gained, indicating that the obtained equation had good adequacy to be correlated with the experimental results. The model is described as follows:

$$\begin{aligned}\sqrt{(\text{normalized peak area})} &= 10.28 + 2.61t + 0.9V + 0.35pH_d + 0.82pH_a \\ &\quad + 0.24tV + 0.27t\,pH_d - 0.26t\,pH_a + 0.057V\,pH_d \\ &\quad + 0.00084V\,pH_a + 0.25pH_d pH_a + 0.34t^2 - 1.47V^2 \\ &\quad - 1.43pH_d{}^2 - 2.15pH_a{}^2\end{aligned}$$

Three-dimensional representation of response surfaces, seen in Figure 2B−D, displays the interaction among the independent variables and assists in establishing the optimum operating conditions for the desirable responses. Parts B−D of Figure 2 illustrate that the response for the analytes is enhanced via increasing the extraction time. Nonetheless, an average amount of applied voltage was appropriate for effective extraction; as low voltages could not provide the needed driving force, and high voltages led to system instabilities and increasing the likelihood of electrochemical reactions as a result of increasing the electric current. Results in Table 1 confirm that the pH of sample solution is not an essential factor. This could be justified by the fact that both of the analytes were ionized within the preferred range for this parameter (Table 1) and that OH^- had little competition with the analytes, owing to its low affinity for the SLM. Consequently, favorable extraction recoveries could be achieved throughout the selected range of

[a]CE = capillary electrophoresis; SPE = solid phase extraction.

pH_d. On the other hand, the extraction efficiency was small at large pH values of the acceptor phase, due to the OH^- predomination in the electrostatic migration toward the pencil lead electrode. At moderately low pH values of the acceptor phase, the extraction yield severely declined; because the analytes occurred primarily as their neutral forms (this phenomenon verified that the extraction mechanism was through the electrokinetic migration of anionic species). Desirability function was considered to find the optimal conditions. To this end, a desirability of 1.0 was assigned to the maximum, 0.0 to the minimum, and 0.5 to the middle responses. Hence, according to the analysis, the plots in Figure 2 and the desirability score of 1, the values of 50 V and 20 min were chosen as the optimum voltage and extraction time, respectively. Additionally, the pH amounts of sample solution and acceptor phase were adjusted to 9.0 and 7.0, respectively, for the remaining experiments.

Evaluation of Method Performance. The applicability of the proposed EM-SPME technique was evaluated for extraction of the acidic herbicides, according to the recommendations of the Food and Drug Administration (FDA). With this aim, linearity was investigated in pure water via the analysis of extracts acquired from the aliquots of each sample in triplicate. The extraction recovery (ER%) was defined as the percentage of the number of moles of the analyte adsorbed on the sorbent (n_f) to those originally present in the sample solution (n_i).

$$\mathrm{ER\%} = \frac{n_f}{n_i} \times 100 \tag{3}$$

The coefficient of variation (CV%) was determined by intra- and interassays and by five- and three-replicate measurements, at three concentrations of 20, 100, and 400 ng mL^{-1}, respectively. Accuracy was determined through the triplicate analysis of samples containing known amounts of the analytes at three concentrations within the expected range. The relative recovery (RR%) and accuracy (error%) were calculated by the equations below:

$$\mathrm{RR\%} = \frac{C_{found} - C_{real}}{C_{added}} \times 100 \tag{4}$$

$$\mathrm{error\%} = 100 - \mathrm{RR\%} \tag{5}$$

where C_{found}, C_{real}, and C_{added} are the concentrations (ng mL^{-1}) of analyte after addition of a given amount of standard into the real sample, the concentration of analyte in the real sample, and the concentration of a known amount of standard spiked into the real sample, respectively.

The investigation of the figures of merit confirmed that EM-SPME could also be effectively implemented for the extraction of acidic analytes using pencil lead as sorbent. The method was linear in the ranges of 1.0−2000.0 and 10.0−2000.0 ng mL^{-1} for the analyses of MCPA and 2,4-D, respectively, with coefficients of determination (R^2) larger than 0.9958. Limits of detection (LODs) were 0.5 ng mL^{-1} for MCPA and 5.0 ng mL^{-1} for 2,4-D, and ERs% were 4.8% and 0.6% for MCPA and 2,4-D, respectively. The precision of the technique was evaluated via the intra- and interassay CVs% varied in the ranges of 5.2−8.5% and 8.8−12.0%, respectively (Table 2). Moreover, the calculated error% for the analytes in the range of −5.5% to +9.5% depicted that the EM-SPME method offered acceptable accuracy for analysis of these acidic herbicides.

Comparison of the EM-SPME with other analytical techniques for determination of MCPA and 2,4-D is shown in Table 3. However, EM-SPME requires simple and low-cost equipment; it offers excellent LODs in fairly short times compared to the other reported methods. Since the organic liquid membrane amplifies the electrical resistance of the system, it is practically feasible to apply high voltages that strengthen the electric field and improve the extraction recovery. Furthermore, uncrowded chromatograms are attained, even by extraction from very dirty matrices. Thus, the use of expensive extraction and analysis methods, such as in-tube SPME and mass spectrometry detection, is avoidable. The present work was the first attempt to extract acidic herbicides by means of EM-SPME method. It was proved that EM-SPME even possesses a great potential for the extraction of acidic

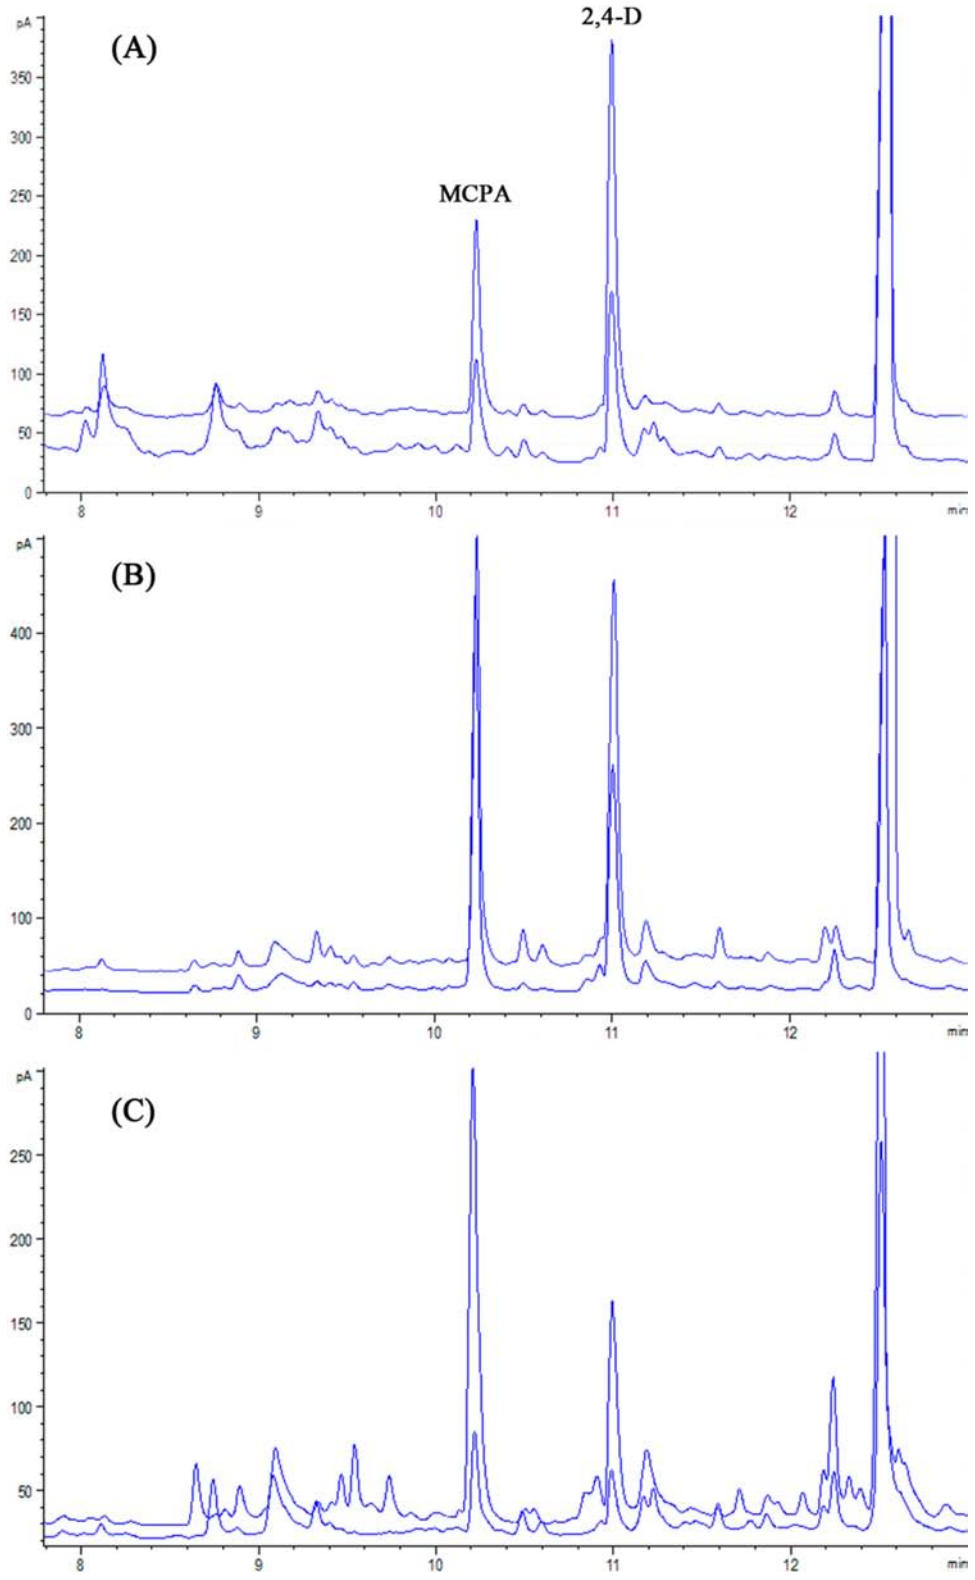

Figure 3. Chromatograms obtained by extraction of herbicides from wheat plant tissues collected after (A) 1 h, (B) 2 days, and (C) 6 days from field spraying.

compounds utilizing a sorbent as anode. Since the use of a thin hydrophobic SLM (which also acts as the principal electric resistance) significantly decreases the electric current of the system, the pencil lead could be successfully employed as both the sorbent and the anode electrode. The conducting nature, good thermal stability, low cost, and high adsorption capacity of the pencil lead made it an exceptional choice for EM-SPME–GC-FID technique. EM-SPME is a newborn extraction method, and more studies are required to figure out the best conditions for it and to develop qualified sorbents for analysis of various compounds. Indeed, the ability of this technique to efficiently

dx.doi.org/10.1021/jf500017r | J. Agric. Food Chem. 2014, 62, 3134–3142

extract the acidic and basic targets from complicated matrices is undeniable.

Analysis of Real Samples. EM-SPME was performed for analysis of the model herbicides in wheat plant tissue, to scrutinize its practical applicability. The entire wheat plant was blended and prepared, as explained in Standard Solutions and Real Samples. The pH of the final 10-fold diluted liquid extract was adjusted to 9.0 through the addition of proper amounts of hydrochloric acid solution, and quantitative analysis was conducted under optimal conditions. The chromatograms which were gained from EM-SPME of three samples, collected after 1 h, 2 days, and 6 days from field spraying, are displayed in Figure 3. The obtained results could be justified by taking into account that the reported concentration values are related to the analytes which were absorbed into the plant tissue. For preparing the real samples, whole wheat plants were first washed to remove the nonabsorbed herbicides and then were used for quantitative analysis. Whereof 1 h is not sufficient time for absorption, the obtained value for 1 h is lower than 48 h.

Since real samples (wheat plant tissue) were transformed into dirty complex solutions, some experiments were required to determine the accuracy of analysis as well as the matrix effects. Based on the FDA's definition, a matrix effect is the direct or indirect alteration or interference in response, owing to the existence of unintended analytes or other interfering substances in the sample. The error% was determined via the addition of 500 ng mL^{-1} of each analyte into the real samples, and EM-SPME was implemented afterward. Results in Table 4

Table 4. Determination of MCPA and 2,4-D in Plant Tissues Collected after 1 h, 2 days, and 6 days from Field Spraying

sample	analyte	C_{real} ($\mu g\ mL^{-1}$)	C_{added} ($\mu g\ mL^{-1}$)	C_{found} ($\mu g\ mL^{-1}$)	RR%	RSD%
1 h	MCPA	0.23	0.50	0.74	102	6.4
	2,4-D	0.76	0.50	1.23	94	9.8
48 h	MCPA	1.41	0.50	1.87	91	6.7
	2,4-D	1.19	0.50	1.67	97	8.5
6 days	MCPA	0.20	0.50	0.72	105	3.8
	2,4-D	0.16	0.50	0.61	91	8.6

demonstrate that there is no significant matrix effect in the examined real samples and that the obtained precision values are admissible. Accordingly, the calibration curves could be exploited directly in the analysis of real samples.

suspension cultures of *Glycine max* to maximize isoflavone production using RSM. In the present study, RSM was employed to optimize a proper medium for biomass and isoflavone content in *G. max* cell suspension culture.

MATERIALS AND METHODS

Chemicals. All of the isoflavone standards (daidzein, genistein, and glycitein), PGRs [2,4-dichlorophenoxyacetic acid (2,4-D), 1-naphthalene acetic acid (α-NAA), and kinetin (Kn)], and fluorescein diacetate (FDA) used in the present study were purchased from Sigma-Aldrich, St. Louis, MO. High-performance liquid chromatography (HPLC)-grade solvents were obtained from Sisco Research Laboratories (SRL, Mumbai, India). Sucrose and agar were obtained from Himedia Lab (Mumbai, India). All other analytical-grade chemicals were obtained from Merck (Darmstadt, Germany).

Plant Material and Surface Sterilization. Seeds of cv. JS 335 of *G. max* were collected from AICRP, Soybean, GKVK campus, Bangalore, India. Uniform size soybean seeds were handpicked, surface-sterilized, germinated, and maintained using a standardized protocol.[24] Seeds were surface-sterilized using 70% (v/v) ethanol for 30 s, followed by 0.2% (w/v) carbendazium for 5 min and 0.1% (w/v) mercuric chloride for 1 min. The surface-sterilized seeds were rinsed 3 times in sterile distilled water and then cultured in Petri dishes containing Murashige and Skoog (MS) basal medium[25] for the germination. The medium pH was set up to 5.8 and then autoclaved at 121 °C for 20 min. The cultures were maintained at a light intensity of 57 μmol m^{-2} s^{-1} (illumination supplied by cool-white fluorescent tubes) with a 16 h photoperiod at 25 ± 2 °C.

Callus and Cell Suspension Culture and Initiation. The 3-week-old *in vitro* germinated seedlings were used as a source of explants for initiation of callus cultures. Cotyledonary nodal leaves were incised into small pieces (9−10 mm) and aseptically transferred to callus induction medium containing full-strength MS solid medium supplemented with 3% sucrose, 0.8% (w/v) agar, and different concentrations of three variables (2,4-D, α-NAA, and Kn), as mentioned in Table 1. The media pH was adjusted to 5.7 before autoclaving (121 °C and 1.2 kg/cm^2 pressure for 20 min). Cultures were routinely subcultured every 3 weeks, and further, the suspension cultures were initiated from friable callus. For this, the callus cultures were propagated in 150 mL Erlenmeyer flasks containing 40 mL of MS liquid medium supplemented with three different variables and 3% sucrose. Cultures were incubated on a rotary shaker at 100 rpm with a 16 h light/8 h dark photoperiod at 26 ± 1 °C. Cell suspension cultures were established uniformly after 8−10 passages, and then regular subcultures were performed by transferring a packed cell volume (PCV) of cells to fresh medium with 2 week intervals. All experiments had at least three replicates, and each growth regulator combination treatment was repeated 3 times.

Growth Parameters. To analyze biomass, the cell growth was measured as dry weight (dw) basis. Cells were harvested by filtration after 18 days of inoculation (three flasks per treatment) and then recovered from the filter paper (Whatmann No. 1) after washing 3 times with distilled water. The dry weight was measured after drying the fresh cell mass in an oven at 45 ± 2 °C until it reached a constant weight, and thus, fresh weight (fw) and dw of cells were estimated. Growth of cells was determined using the growth index (GI) using the following formula on a dw basis:

$$\mathrm{GI} = \frac{\text{final weight of biomass} - \text{initial weight of biomass}}{\text{initial weight of biomass}}$$

Microscopic Observations. To determine the viability of cells, 10 mL of suspension culture was incubated for 15 min with 30 μM FDA at 1 mg/mL stock in dimethyl sulfoxide (DMSO). The extracellular fluorescence in the cells was discolored by 10 volumes of fresh medium followed by resuspension by fresh culture medium. Dye loaded with live cells was monitored in fluorescence microscopy using an Olympus BX 51 (Japan) microscope equipped with camera ProResC5 and an ultraviolet (UV) light source.

Isoflavone Extraction. The soybean-powdered sample (400 mg) from each treatment was finely ground and extracted with 2 mL of concentrated HCl and 10 mL of ethanol for 2 h in a boiling water bath using a standard method,[26] which relies on acid hydrolysis of 12 endogenous isoflavone isomers to their respective aglycone forms. The resulting suspensions were cooled and centrifuged at 111800*g* for 10 min, and further, the supernatant was filtered through a syringe filter (Whatman 0.5 μm, 13 mm diameter).

Chromatographic Conditions. The HPLC analysis of isoflavones in extracts was performed using a Shimadzu chromatograph (LC 10-AS HPLC), equipped with dual pump, UV detector (SPD 10A), and a C-18 silica column (Sunfire; 5 μm, with dimensions of 250 × 4.6 mm). The isoflavone separation and its elution were employed by a binary gradient mode,[12] and the chromatographic conditions were followed as mentioned in the earlier publication.[12]

Isoflavone Standards. All three isoflavone standards were identified by their retention times and co-chromatography with standard compounds. The relative individual isoflavone concentration in the sample was calculated manually on the basis of each peak area. Individual isoflavone concentrations were expressed as micrograms per gram on a dw basis. A mixture of the standards was analyzed, and the total isoflavone (TI) concentration was the sum of aglycones (daidzein, glycitein, and genistein).[27]

Optimization of Isoflavones and Biomass Using RSM. *Central Composite Design (CCD) and RSM.* RSM is a combination of mathematical and statistical techniques useful for empirical model building and search optimum conditions of factors for desirable responses. The natural response surface in the optimum region was illustrated by performing a Box−Behnken and CCD.[19,28] CCD was employed to study the interaction of process variables, and the optimum process condition for biomass and TI content was obtained by applying RSM.[21,29] Statistical analysis was implemented using a linear regression model in the SPSS software.

The experimental design was constructed using a five-level, three-factor variable, and second-order CCD with five replications on the center points (0, 0, and 0) in coded levels of variables (−1.682, −1, 0, 1, and 1.682).[28,29] The total number of experiments was 20 with two replications to evaluate error. The three independent variables for biomass (Y_1) and TI (Y_2) content responses were concentrations of 2,4-D (X_1), α-NAA (X_2), and Kn (X_3). The experimental design in the actual (X) and coded (x) levels of variables was represented in Table 1. A second-degree polynomial with linear, quadratic, and interaction effects (in the coded level of variables) by the method of least-squares represents the response functions (y_{ijk}) of biomass and TI content in the cell suspension culture denoted in the following equation:

$$y_{ijk} = b_0 + \sum_{i=1}^{n} b_i x_i + \sum_{i=1,i\le j}^{n} \sum_{j=1,i\le j}^{n} b_{ij} x_i x_j + \varepsilon_{ijk}$$

The numbers for variables represented by n and i, j, and k are integers. The coefficients of the polynomials are denoted by b_0, b_i, and b_{ij}, and ε_{ijk} is the random error. When $i < j$, b_{ij} represents the interaction effects of the variables x_i and x_j. The response surface graphs are obtained from the regression equations in the actual level of variables, keeping the response function on the z axis, with x and y axes representing the two independent variables while keeping the other variable (third) constant at its center (corresponding to the 0 level in coded level) points. To assess the empirical model in a statistical manner, analysis of variance (ANOVA) was carried out using software SPSS version 17.0 (SPSS Inc., Chicago, IL) at the level of $p < 0.05$. The efficiency of the polynomial model equation was calculated by means of the coefficient of correlation (R), and its statistical significance was evaluated by the F test. When detailed ANOVA was performed in the coded level of variables, the effects of individual variables were identified. Stepwise deletion of individual non-significant ($p < 0.10$) terms was performed, followed by recalculation of the coefficients of the TI regression equation, to attain the final regression equation in the coded level, which was further converted to the actual level of variables.

Optimization Conditions. Canonical analysis[28] was employed to analyze the optimal conditions, in which the levels of control variables (x_1, x_2, and x_3) (within the experimental range) were determined to obtain the maximum yield of biomass and TI production individually. Stationary points in the response surface were defined by the translation and rotation of the response function (y_k),[19] the axes of which correspond toward the principal axes of the contour system. Moreover, the roots (λ_1, λ_2, and λ_3) of the auxiliary equation ($\lambda^2 - \lambda + 1 = 0$) were calculated initially to know the optimum nature. If all of the roots have negative values, the response function is maximal and vice versa. The stationary point was defined as a saddle point, if the roots have positive and negative values,[19] and when the contours are superimposed, the optimum levels of the variables are further attained.

RESULTS AND DISCUSSION

Despite the fact that phytoalexins (daidzein and genistein) were released only under stress conditions, enhancing their level in *in vitro* cultures could be achieved by the elicitation approach. In the preliminary screening experiments, various concentrations of PGRs [2,4-D, α-NAA, indole-3-acetic acid (IAA), and indole-3-butyric acid (IBA)] with a single concentration of Kn were treated in *G. max* cell suspension cultures. Interestingly, we found that the α-NAA and Kn combination improved the isoflavone content but biomass was better with 2,4-D and Kn (data not shown). However, optimization of selective media with enriched cell growth and bioactive content is laborious and time-consuming, as suggested by various researchers.[21,22] As a result, the PGRs, such as 2,4-D, α-NAA, and Kn, were selected for statistical optimization studies by employing RSM for the first time. In the present study, optimization of the medium constituents for increased production of the isoflavone content with profound biomass in *G. max* suspension cultures was achieved. In the same way, this RSM technique has been applied successfully nowadays in many biotechnological and biochemical studies, such as *in vitro* growth characteristics of *Centella asiatica*,[30] β-carotene in *D. carota*,[22] lycopene from suspension cultures of *L. esculantum*,[23] micropropagation of *Dianthus caryophyllus*,[31] and isoflavone extraction from *G. max*,[29,32] respectively.

The results on the TI content in the present investigation demonstrated daidzein as a major component (63%), followed by genistein (30%) and glycitein (7%), and TI was not detected in the spent media. The outcome of three independent variables (concentrations of 2,4-D, α-NAA, and Kn) on the response functions Y_1 and Y_2 was summarized in Table 1. The results on the ANOVA (in the coded level of variables) are shown in Table 2 for all three response functions. The roots (λ_1, λ_2, and λ_3) of the auxiliary equation of isoflavone and biomass are calculated and depicted in Table 3. The three-dimensional and contour plots represented in Figures 1 and 2 aid in envisaging the consequence

optimized level of the response function		70.6	38.59

of three independent variables on response functions generated by the regression equation.

Biomass. The biomass (Y_1) content in suspension cultures for the 20 experiments is shown in Table 1. An extensive variation in the content ranged from 47.15 to 63.56 g/L on a dw basis upon the variable conditions. Plots were designed for each pair of variables, while the third variable was considered as a constant at the middle level. The consequence of 2,4-D and α-NAA on biomass with Kn as the constant value in soybean cell suspension cultures was illustrated in Figure 1a. Similarly, Figure 1b represented the influence of 2,4-D and Kn with α-NAA as a constant value on biomass in cell cultures. Besides, the effect of α-NAA and Kn with 2,4-D as a constant value on the biomass was depicted in Figure 1c.

Fitness of the second-order polynomial to predict biomass in independent variable terms was put in view by the high correlation coefficient (R = 0.915; $p \leq 0.01$) value (Table 2). Amid the variables, the total quadratic effect (significant at $p \leq 0.01$) predominates over the total interactive effect ($p \leq 0.05$) and linear effect ($p \leq 0.1$). The effect of 2,4-D on the yield of biomass has a significant effect ($p \leq 0.05$) on the individual variables, while α-NAA and Kn have no significant results (Table 2). The individual quadratic effects of "2,4-D" and "Kn" variables are significant ($p \leq 0.01$), and α-NAA has no significant results. Nevertheless, interactive effects of α-NAA and Kn concentrations have a predominant effect on the yield of biomass ($p \leq$

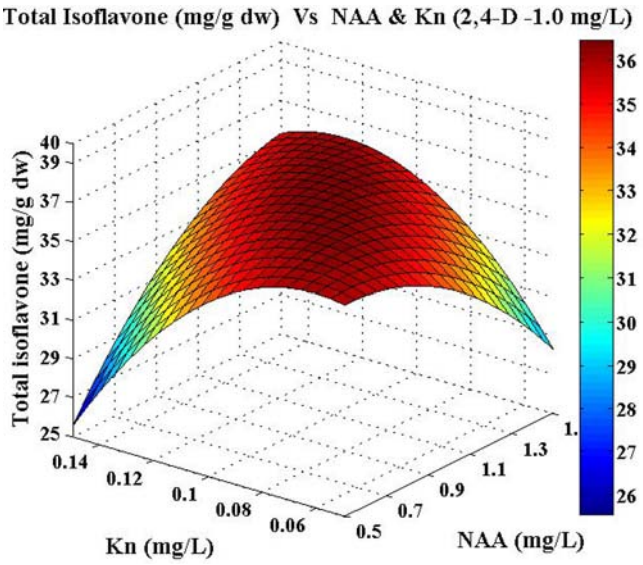

Figure 4. Response surface for the effects of variables on the TI (Y_2) in the cell suspension cultures of *G. max* with 2,4-D as a constant value of 1.0 mg/L.

0.01), while there is no significant effect of the interaction among 2,4-D−α-NAA and 2,4-D−Kn.

TI Content. The TI content (Y_2) ranged from 23.30 to 39 mg/g of dw with respect to the experimental conditions illustrated in Table 1. In Figure 2, the results of 2,4-D and α-NAA on TI with Kn as the constant value in soybean cell suspension cultures were depicted as response surface. Correspondingly, the influence of 2,4-D and Kn with α-NAA as a constant value on the TI content in cell cultures was shown in Figure 3. The effect of α-NAA and Kn with 2,4-D as a constant value on the TI was portrayed in Figure 4.

TI content in the proposed model depicted a high multiple correlation coefficient (R = 0.963;$p \leq 0.01$), pointing out the aptness of the second-order polynomial to calculate the Y_2 values of three independent variables (Table 2). With these variables,

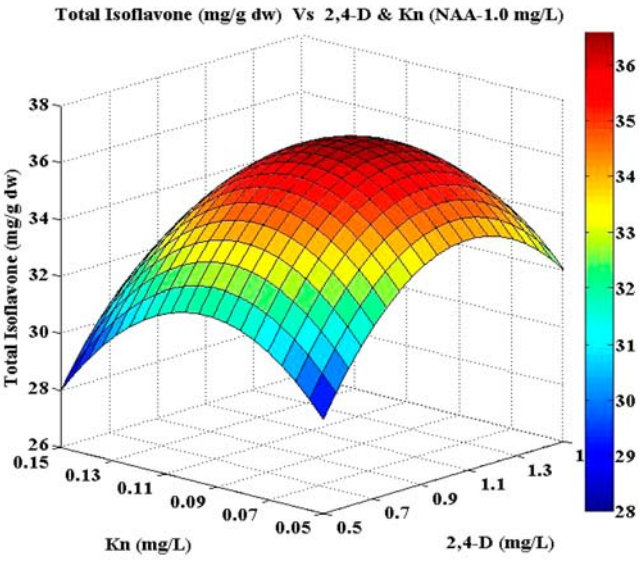

Figure 3. Response surface for the effects of variables on the TI (Y_2) in the cell suspension cultures of *G. max* with α-NAA as a constant value of 1.0 mg/L.

total quadratic and interactive effects ($p \leq 0.01$) dominate over the linear effects ($p \leq 0.05$) and the interaction among α-NAA and Kn is significant in comparison to 2,4-D and α-NAA. There are significant individual quadratic effects for 2,4-D and Kn ($p \leq 0.01$), followed by α-NAA ($p \leq 0.05$).

Optimization. The optimization process for maximizing biomass (Y_1) and TI content (Y_2) was conducted separately. The roots (λ_1, λ_2, and λ_3) of the auxiliary equation were shown in Table 3. However, the roots of the auxiliary equation for biomass and TI content indicate (negative values) maximization of the response function. For this reason, the canonical test was applied and the optimum conditions in coded and actual levels of variables were obtained (Table 3). Consequently, the maximum value for the yield of biomass is 70.62 g/L dw, and the maximum TI content is 38.59 mg/g of dw. The predicted optimized levels for all three variables are represented in Table 3 for production of biomass and TI content confirmed experimentally. By optimization, we achieved 38.59 mg/g of dw of isoflavones in JS 335, which was approximately 37 times greater than that of the field-grown greenhouse soybean plants, along with 7% of biomass as dry matter.

It is noteworthy to find a region with a "sweet spot" for multiple responses, which could be accomplished by superimposing the contours. The superimposed contour plot for optimization of Y_1 and Y_2 was given in Figure 5. The effect of x_1, x_2, and x_3 terms on Y_1 and Y_2 is positive. The optimum value of x_1 is between 1.33 and 2.10 mg/L, specifically at an average of 1.72 mg/L for x_1. The optimum value for x_2 is between 1.76 and 5.52 mg/L, which is at an average of 3.64 mg/L for x_2. The optimum value for x_3 is between 0.35 and 0.15, which is at an average of 0.25 mg/L for x_3. The contour plots against x_1 (α-NAA) and x_3 (Kn) constructed independently and later on superimposed (Figure 5) were used to identify the levels of the two variables. Moreover, the optimum conditions for the responses were found from the superimposed graph. At this point, we preferred a value of biomass to be more than 65 g/L dw and TI production to be more than 30 g/L dw (Figure 5). The optimum region was depicted obviously as the hatched zone in Figure 5. The results obtained by superimposition were validated (TI, 37.34 mg/g of

dx.doi.org/10.1021/jf500207x | J. Agric. Food Chem. 2014, 62, 3143−3149

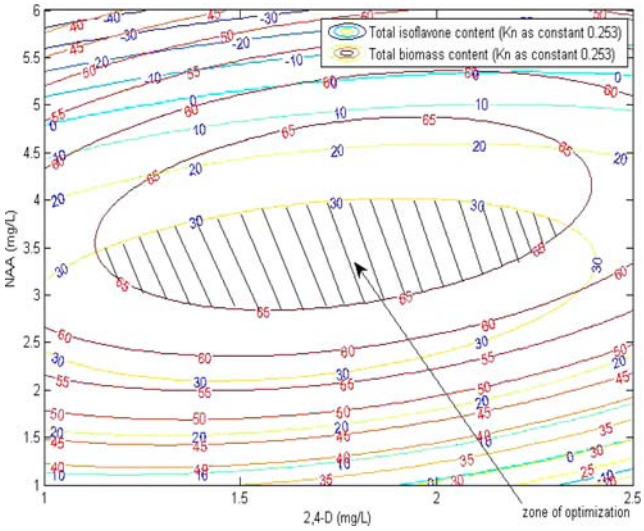

Figure 5. Superimposed contour plots with the optimized region of the responses.

dw; biomass, 67.83 g/L dw), in which callus formed in the optimized medium was found to be friable, soft, and pale greenish brown, and the same was used for the cell suspension culture initiation (Figure 6) and analysis of the responses.

Figure 6. *G. max in vitro* cultures on the MS medium with optimized concentrations of 1.72 mg/L 2,4-D, 3.64 mg/L α-NAA, and 0.25 mg/L Kn: (a) cell suspension cultures in shake flasks, (b) cell suspension cultures in round-bottom- and cylindrical-shaped flasks, and (c) FDA staining of cell suspension cultures for confirmation of viability (bar = 124 μm).

Microscopic Observation. Also, the viability of cells was confirmed by staining with FDA, followed by visualization under fluorescence microscopy. Microscopic observations of cell suspension cultures showed fluorescence yellow for viable cells (Figure 6).

In the present study, the daidzein content was more in cell suspension cultures compared to genistein and glycitein. However, in seeds of soybean, genistein levels are reported to be high.[7] Still, the results were consistent with the earlier reports of *in vitro* cultures of soybean,[3,16] which show the predominant production of daidzein than that of genistein. Similarly, the interactive effects of α-NAA and Kn concentrations positively influenced the biomass yield; however, no such effect was found for 2,4-D−α-NAA and 2,4-D−Kn. Significant individual quadratic effects were found for 2,4-D and Kn ($p \leq 0.01$). This in correspondence with earlier reports[31] in *D. caryophyllus* L., in which optimization of PGRs and $AgNO_3$ using RSM exhibited better callus growth with a high concentration of α-NAA. However, the results, in contrast with earlier reports of soybean cell cultures,[3] show that 2,4-D influences the biomass as well as isoflavone content. In *C. asiatica* cell suspension cultures, RSM applied for the optimization of sucrose, IAA, and 6-benzylaminopurine (BAP) and results revealed sucrose as a prime factor for cell growth.[30] Several studies found the significance of applying RSM.[22] RSM was used for the optimization of basal media components (sucrose, nitrogen, and phosphorus) for maximum production of β-carotene from *D. carota* cells. In addition, a 3.7-fold increase in lycopene production was observed by optimizing several lycopene extraction parameters in *L. esculentum* cell cultures.[23] To maximize the isoflavone content using RSM, acid hydrolysis conditions in soybean hypocotyls[32] and ethanol extraction and purification in soybean sprouts[29] were optimized. Biomass (7% dw) achieved in the study is considered as high for secondary metabolite production in plants. This result is in agreement with the earlier study[3] that high producing soybean cultivar strains contained a significant level of isoflavones. As a part of optimization, we obtained 37.34 mg/g of dw of isoflavones.

Because large-scale production of isoflavones for therapeutic and commercial purposes could not be achieved by natural sources, the development of cell culture technology has had a great scope in recent years.[5] Besides, various factors influenced the stimulation of isoflavone synthesis, such as manipulation of the basal nutrient medium components, physical factors, and PGRs.[33] Although there are several reports that dealt with media components, there is none on the optimization of PGRs and the same is essential before performing elicitation, precursor feeding, and biotransformation and bioreactor studies. It was hypothesized that, in most of the Fabaceae plants, 2,4-D and Kn combination was selected best for both cell growth and isoflavone content,[3,15] while its mechanism in the biosynthetic pathway is still not understood.[33] Nevertheless, a rather interesting feature in the present study was α-NAA having a more predominant role than 2,4-D.

Furthermore, as suggested by earlier reports, the isoflavone content varies with the genotype of the species.[3,16,18] Nonetheless, it could be hypothesized that variability in isoflavone composition observed within the cell suspension compared to seeds[7] might be due to the effect of PGRs on metabolic pathways (differentiation), somaclonal variation,[3] or differential gene expression. However, it was obvious that *in vitro* plant tissues represent a high level of variability in the gene expression pattern.[34] Moreover, the isoflavone pathway is one of the most complex metabolic pathways involved in plants,[11] elicited by several stress agents.[16] Overall, the optimization studies using RSM augmented the isoflavone content as well as biomass.

It is evident from the study that RSM is a reliable experimental tool, not only achieving optimized media with pronounced biomass and isoflavone content but also simplifing the time course of experiments. Results also suggested that soybean cell suspension cultures could be used as a fascinating model system for augmenting isoflavones. In future, research efforts pertaining to elicitation, scale up in bioreactors, selection of high producing cell lines, and mechanism of isoflavone biosynthesis in cell suspension cultures could be attempted to assess the possibility of an enhancement strategy with a prospective value in the nutraceutical viewpoint.

the pith cells of the stalk ranging from 10% to 25%, with glucose and fructose as the main reducing sugars.[11] As a result, they have a smaller grain yield and thicker, taller stalks when compared to grain sorghums.[11] There is a growing interest worldwide in using sweet sorghum as a replacement crop for sugar cane in the production of biofuels. Advantages of sweet sorghum over cane sugar include reduced water requirements, shorter growing periods, and reduced cultivation cost.[10] Sweet sorghum can grow in marginal lands and therefore does not have to compete with food production.[10,12] This is an attractive element to sweet sorghum, as biofuel production from sweet sorghum can add to the food supply instead of competing with it.

Biofuel production of sweet sorghum results in the generation of a large amount of biomass[13] comprised of stalks, leaves, and leaf sheaths, which is commonly treated as waste or utilized as a fodder. In addition, these products, particularly the leaves and leaf sheaths, have been used by traditional healers in Africa and India for anemia, epilepsy, stomach ache, and, interestingly, cancer.[14] Having been reported to be high in phenolic acids and other compounds,[15] it has been shown that sorghums contain high levels of small-molecule bioactive compounds in the stalk, leaf, leaf sheath, glumes, and seed[16−19] with reported bioactive properties.[20−22] Apigeninidin and luteolinidin belong to the 3-deoxyanthocyanidin subclass of flavonoids (Figure 1) and are reported to be expressed in the

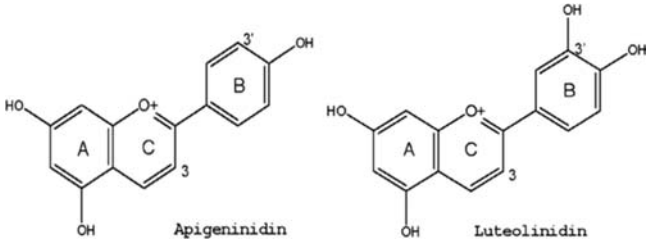

Figure 1. Structures of 3-deoxyanthocyanidins reported in this study.[30]

glume, grain, leaf, and leaf sheath[16−18] in *S. bicolor*. Furthermore, these compounds have been shown to be potent inhibitors of the HT-29 colon cancer cell line.[23]

This combination of biomass and bioactive compounds makes an attractive combination for generating large quantities of bioactive compounds for human health. In a process developed by Great Valley Energy LLC, processing of sweet sorghum strips the inner sugary cells of the pith from the outer dermal layer, resulting in two fractions, the pith and dermal layer. Currently, it is unknown if these fractions contain 3-deoxyanthocyanidins or the contribution of these compounds to its bioactivity. The pith is then further processed into biofuel, while the dermal layer can be processed to make other byproducts in a "biorefinery" approach to making biofuels. In this approach, the entire above ground sweet sorghum plant is utilized in creating products, which adds value to the process, reducing the costs of generating biofuels.[24] The aims of this study are to (1) determine the content and composition of the pith and dermal layer from the Dale and M81E varieties, (2) characterize the antiproliferative and proapoptotic activities of these extracts in human colon cancer HCT116 cells and colon cancer stem cells, (3) assess the bioactivity of apigeninidin and luteolinidin, and (4) determine if p53, a critical tumor suppressor protein, is necessary for in vitro anticancer activity.

MATERIALS AND METHODS

Chemicals and Reagents. For quantification of total phenolic and antioxidant activity, sodium bicarbonate, monobasic sodium phosphate, dibasic sodium phosphate, and sodium chloride were purchased from Fisher Scientific (Pittsburgh, PA), potassium persulfate was purchased from Mallinckrodt Chemicals (Hazelwood, MO), and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) reagent, Folin−Ciocalteu reagent, Trolox, and gallic acid were purchased from Sigma (St. Louis, MO).

For cell culture and experiments, 5-fluorouracil (5-FU) was purchased from Sigma, apigeninidin and luteolinidin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA) and Indofine Chemical Co. (Hillsborough, NJ), respectively, McCoy's medium and colon cancer stem cell medium were obtained from Sigma and Celprogen (San Pedro, CA), respectively, and fetal bovine serum and streptomycin/penicillin mixture were procured from Fisher Scientific.

Sweet Sorghum Materials and Extraction Preparation. Sweet sorghum materials from the Dale and M81E varieties used in this study were grown in Bakersfield, CA, and generously provided by Great Valley Energy LLC (Bakersfield, CA). Two extraction solvents were utilized for the study. Acetone (80%) was identified in the literature and empirically as a superior extraction solvent for sweet sorghum dermal and pith layers. Ethanol (80%) was used as a GRAS alternative. Fresh sweet sorghum sample (2 g) was extracted with 20 mL of extraction solvent chilled to −20 °C. This was to prevent excessive heating during the homogenization of the sample. This mixture was then homogenized for 2 min using an IKA T25 digital ultra TURRAX at 10 000 rpm. The tubes were then vortexed, and the resulting mixture was then centrifuged at 4000 rpm for 5 min. The supernatant was filtered using a 0.45 μm PTFE syringe filter (Tisch Scientific, North Bend, OH). The resulting pellet was then resuspended in 20 mL of extraction solvent by vortexing for 1 min and centrifuged, and the supernatant was collected and filtered. This was repeated for a third round of extraction, after which the filtrates were combined and the final volume was brought to 100 mL. The phenolic extracts were then stored at −20 °C until analysis for total phenolics and antioxidant activity and by LC−MS.

Phenolic-enriched extracts were prepared by extracting 2 g of sample in 20 mL of extraction solvent chilled to −20 °C. This mixture was homogenized for 2 min with an IKA T25 Digital Ultra TURRAX set to 10 000 rpm. The homogenate was then placed on a reciprocal shaker overnight in the dark at 4 °C to allow for diffusion of phenolics to create an enriched extract. The mixture was then centrifuged, and the supernatant was filtered with 0.45 μm PTFE filters (Tisch Scientific). Extracts prepared with 80% acetone were dried in a Buchi rotavapor (Flawil, Switzerland) to remove the acetone. The aqueous portion was then lyophilized, which yielded a brown powder. This was redissolved in 80% ethanol, aliquoted, and stored at −80 °C. Extracts prepared with 80% ethanol were concentrated under a nitrogen flow in a 35 °C water bath for 10 h. The extracts were then aliquoted and stored at −80 °C.

Quantification of Dry Matter, Total Phenolics, and Antioxidant Activity. Dry matter quantification was determined by freeze-drying 2 g samples in triplicate and measuring changes in mass due to water loss. The results are expressed as percent dry matter.

For quantification of total phenolics, the Folin−Ciocalteu assay was used as described in Singleton's work[25] with minor modifications. In triplicate, 35 μL of extract, standard, or solvent was added to individual wells of a 96-well plate followed by the addition of 150 μL of 1 N Folin−Ciocalteu reagent. The contents were mixed and allowed to react for 5 min under dark conditions. After 5 min, 115 μL of 7.5% sodium bicarbonate was added, and the contents were mixed and incubated in the dark at 45 °C for 30 min. The plate was then cooled for 1 h in the dark at room temperature. Finally, the absorbance was measured at 765 nm with a Biotek Synergy 2 plate reader (Winooski, VT). Gallic acid was used as a standard, and equivalency was calculated from a linear regression of standard concentrations. Data are reported as mean milligrams of gallic acid equivalents per gram of sweet sorghum sample (mg of GAE/g) ± standard error.

Antioxidant activity was measured by the ABTS assay as previously described[26,27] with minor modifications. In brief, 3 mM ABTS radical and 8 mM potassium persulfate were mixed in equal parts and reacted for at least 12 h at room temperature in the dark. Then this solution was mixed 1:30 with pH 7.4 phosphate buffer to create a working ABTS solution. In triplicate, 290 μL of the working solution was added to 10 μL of sample, standard, or solvent in a 96-well plate. This was allowed to react for 30 min at room temperature under dark conditions, after which the absorbance was measured at 734 nm using the aforementioned plate reader. The antioxidant activity is expressed as mean (n = 3) milligrams of Trolox equivalents per gram of sweet sorghum sample (mg of TE/g) ± standard error.

LC−MS Analysis. For LC−MS analysis, ethanolic extracts prepared from the pith and dermal layer of the Dale variety were concentrated 10-fold in triplicate before 1 μL of sample was injected into a Waters Acquity UPLC system fitted with a Waters Acquity UPLCT3 column (1.8 μM, 1.0 × 100 mm). The sample was injected into 100% solvent A (water, 0.1% formic acid), and this was held for 1 min. This was followed by a 12 min linear gradient to 95% solvent B (acetonitrile, 0.1% formic acid). The flow rate was held constant at 200 μL/min for the complete run. The column temperature was 50 °C, and the samples were held at 5 °C.

Eluent from the UPLC system was infused into a Waters Xevo G2 Q-Tof MS instrument fitted with an electrospray source. Data were collected in the positive ion mode, scanning from 50 to 1200 at a rate of 0.2 s per scan, alternating between MS and MS^E mode. The collision energy was set to 6 V for MS mode and 15−30 V for MS^E mode. The capillary voltage was set to 2200 V, the source temperature was 150 °C, the desolvation temperature was 350 °C, and the desolvation gas flow rate was 800 L/h of nitrogen. Waters raw data files were converted to .cdf format using Databridge software (Waters), and feature detection was performed using XCMS. Raw peaks were normalized to total ion signal in R. The UPLC−MS system was quality checked by making five injections of a standard solution containing a 2 μg/mL concentration each of caffeine, reserpine, sulfadimethoxine, and terfenadine in 50% methanol. The performance was evaluated using the final three injections, and acceptable performance is indicated by a retention time error of ±0.05 min, peak area RSD of <25%, and mass accuracy of <3 ppm error for all four compounds. Calibration was performed prior to analysis via sodium formate, with mass accuracy within 1 ppm. Compounds were identified by comparing MS spectra obtained from LC−MS analysis to the NIST, METLIN, and MassBank databases using 10 ppm as the upper limit for accuracy. In cases where spectra were not obtainable, accurate mass was used to identify the compounds.

Cell Lines and Culturing Procedures. HCT116 and HCT116 $p53^{-/-}$ cells were generously provided by Dr. Bert Vogelstein (School of Medicine, Johns Hopkins University, Baltimore, MD). Colon cancer stem cells (CCSCs) positive for CD34, CD44, and CD133 were purchased from Celprogen. All cells were maintained at a temperature of 37 °C and 5% CO_2. HCT116 cells were maintained in McCoy's medium with 5% FBS. For experiments, HCT116 cells were treated in 10% charcoal stripped serum McCoy's medium. CCSCs were maintained in colon cancer stem cell medium. For experiments, CCSCs were treated in serum-free colon cancer stem cell medium (Celprogen). Concentrated extracts were dosed in medium normalized to total phenolic content as assessed by Folin−Ciocalteu assay. We used 80% ethanol and 5-FU as negative and positive controls, respectively.

Lentiviral shRNA Mediated Knockdown of p53 in CCSCs. CCSCs were infected with lentiviral particles encoding shRNA targeting p53 (Santa Cruz Biotechnology) according to the supplier's protocol. Briefly, CCSCs were infected at a multiplicity of infection of 10 in CCSC growth medium containing 5 μg/mL Polybrene at 37 °C and 5% CO_2. After 24 h, the medium was replaced, and the cells were cultured for 2 d. Infected cells were then selected in the presence of puromycin (7.5 μg/mL) for an additional 5 d.

Proliferation and Apoptosis. Cell proliferation was assessed via 5-bromo-2′- deoxyuridine (BrdU) assay (Cell Signaling Technologies, Beverly, MA) and cell counting using an automated cell counter (Nexcelom Bioscience, Lawrence, MA). Briefly, HCT116 cells and CCSCs were grown in 96-well plates at 2×10^4 cells per well. After 24 h, the medium was aspirated, and the cells were treated with controls and sweet sorghum extracts. The treatments were added in triplicate at a volume of 150 μL per well and then allowed to incubate for 20 h at 37 °C. At this point, BrdU was added at a concentration of 10 μM per well, and the treatments were incubated at 37 °C for an additional 4 h to allow incorporation of BrdU into cellular DNA (24 h total). The medium was removed, and the BrdU assay was performed according to the manufacturer's protocol. For cell counting, cells were seeded at 1×10^5 cells per well in 12-well plates. After 24 h, control compounds and sweet sorghum extracts were added at a volume of 1 mL per well. After 24 h, the cells were removed from the plates and counted according to the manufacturer's protocol.

Apoptosis was analyzed by measuring active caspase activity with a Caspase-Glo 3/7 assay kit (Promega Corp., Madison, WI) and confirmed with the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) method. For measuring caspase activity, cells were seeded and treated with control compounds and test extracts the same as in the cell counting experiments. After 24 h of incubation, 100 μL of HCT116 cells and CCSCs were transferred into a white 96-well plate, and the Caspase-Glo 3/7 assay was performed according to the company's protocol. The data were normalized to cell count and are expressed as percentages of the solvent control. For TUNEL, cells were seeded into four-well chambered glass slides at a density of 1×10^5 cells per chamber. After the treatments, the slides were prepared and analyzed for TUNEL staining according to the manufacturer's protocols (Roche Diagnostics, Indianapolis, IN). For analysis, 10 images from each well were taken, containing at least 50 cells per image. The cells were counted, and the data are expressed as the percentage of TUNEL positive cells to total cells (percent apoptosis).

Colony Formation Assay. The colony formation assay was performed as described[28] with slight modifications. Colon cancer stem cells were seeded at 1.5×10^5 cells per well in a six-well tissue culture plate (TPP, St. Louis, MO). After adhesion (24 h), the cells were treated with controls and test compounds for 24 h. The cells were then replated at a density of 100 cells per well in another six-well tissue culture plate, and colony formation was measured as described.[29]

Statistical Analysis. Data are presented as means ± standard error. Statistical significance was determined by one-way ANOVA, followed by the posthoc Fisher least significant difference test for multiple means comparisons using IBM's SPSS version 21. Means not sharing the same letter are statistically significant (P < 0.05).

RESULTS AND DISCUSSION

Sweet sorghum processing generates significant amounts of biomass containing bioactive phytochemicals and represents a promising source of human health-promoting bioactive compounds. In this study, the dermal layer and pith of two varieties of sweet sorghum were grown, processed, and

Table 1. Determination of TP, ABTS, and Dry Matter of the Pith and Dermal Layer from the Dale and M81E Sweet Sorghum Varieties[a]

	Dale		M81E	
	dermal layer	pith	dermal layer	pith
TP[b]	172 ± 6 a	127 ± 5 b	225 ± 11 c	88 ± 3 d
ABTS[c]	570 ± 54 a	248 ± 12 b	365 ± 12 c	128 ± 12 d

[f]Significant differences ($P < 0.05$) observed among dermal and pith extracts.

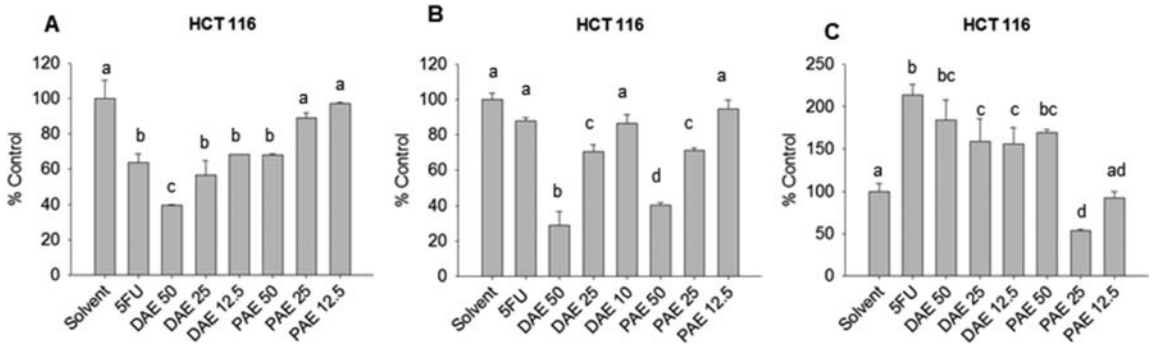

Figure 2. Antiproliferative proapoptotic activities of Dale dermal and pith phenolics measured by (A) cell count, (B) BrdU assay, and (C) Caspase 3/7 Glo assay. HCT116 cells were treated for 24 h with acetone extracts (DAE and PAE) at 10, 12.5, 25, and 50 μg of GAE/mL before estimation of proliferation and apoptosis. Values are presented as percentages of the solvent control. For cell count and Caspase 3/7 Glo, means ($n = 2$) ± standard deviation are presented. For BrdU, means ($n = 3$) ± standard error are presented. Different letters indicate significant differences ($P < 0.05$) among treatments. Solvent = solvent control, and 5-FU = 5-fluorouracil (18 μg/mL).

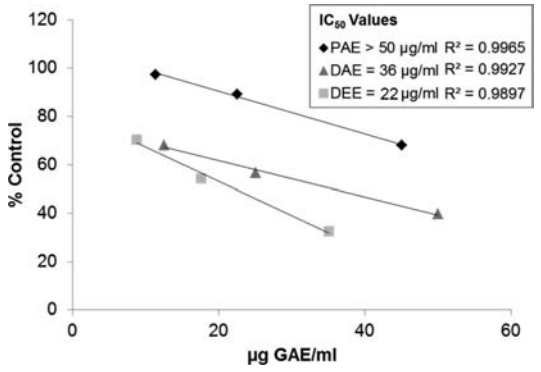

Figure 3. Dose−response curves for HCT116 cells. Cells were treated for 24 h with pith and dermal phenolic-rich extracts prepared by extraction with either acetone (AE) or ethanol (EE). The response is based on cell proliferation as estimated by cell counting. Simple linear regression was used to estimate IC_{50} values. Values are presented as percentages of the solvent control (*y* axis) at a specific dose of the respective phenolic-rich extract in micrograms of GAE per milliliter (*x* axis).

analyzed for total phenolics and antioxidant activity. The effects of sweet sorghum pith and dermal layer extracts on colon cancer stem cell proliferation, apoptosis, and stemness were also studied. For cell-based experiments, cells were dosed with sweet sorghum phenolic-rich extracts based on micrograms of gallic acid equivalents per milliliter of medium (μg of GAE/mL), which was determined by the Folin-Ciocalteu assay.

Dry Matter, Total Phenolics, Antioxidant Activity, and LC−MS Analysis. For dry matter content, we observed similar levels of dry matter in pith and dermal samples across both the Dale and M81E varieties. The dry matter content is summarized in Table 1. The dry matter of the pith from Dale and M81E was 22%. The dry matter content of the dermal layer was 39% and 42% for Dale and M81E, respectively (Table 1). These findings are in agreement with previously published data reporting dry matter content for the pith of sweet sorghum stalks of 30%,[15] reflecting the high moisture content necessary to store and concentrate sugars. To the best of our knowledge, this is the first study reporting the difference between the moisture content in pith cells and dermal cells of sweet sorghum.

We next sought to characterize the total phenolics and antioxidant activities of sweet sorghum stalk components. Acetone (80%) extracts were used to determine total phenolics and antioxidant activities of sorghum samples by Folin−Ciocalteu and ABTS, respectively (Table 1). The total phenolic content of the dermal layer was higher than that of the pith in both varieties by 35% and 155% in Dale and M81E, respectively. A similar relationship was also observed for the antioxidant activity. Among the two varieties, Dale dermal extracts yielded more Trolox equivalents, yet fewer gallic acid equivalents as assessed by ABTS and Folin−Ciocaltue assays,

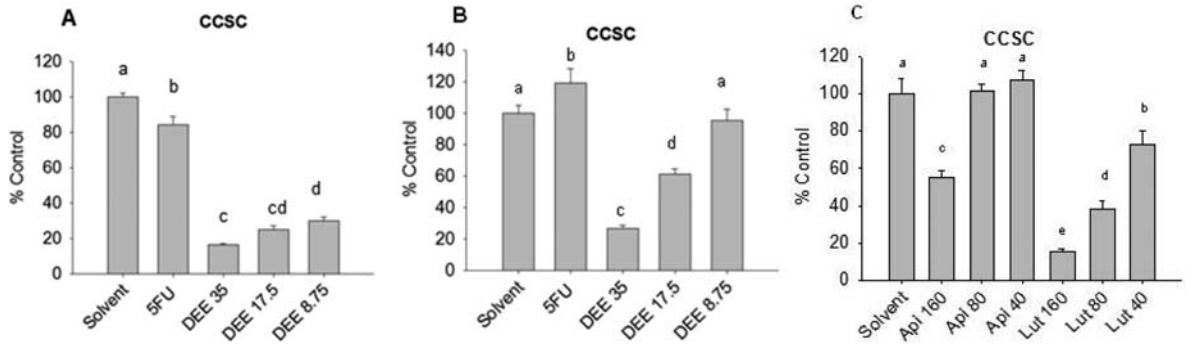

Figure 4. Antiproliferative activities of Dale dermal phenolics measured by (A) cell count and (B) BrdU assay. (C) Antiproliferative activities of apigeninidin and luteolinidin measured by BrdU. Colon cancer stem cells (CCSCs) were treated for 24 h with dermal phenolic-rich ethanol extracts of the Dale variety (DEE) at 8.75, 17.5, and 35 μg of GAE/mL before estimation of proliferation. Values are presented as percentages of the solvent control. For cell count, means (n = 2) ± standard deviation are presented. For BrdU, means (n = 3) ± standard error are presented. Different letters indicate significant differences (P < 0.05) among treatments. Solvent = solvent control, and 5-FU = 5-fluorouracil (18 μg/mL).

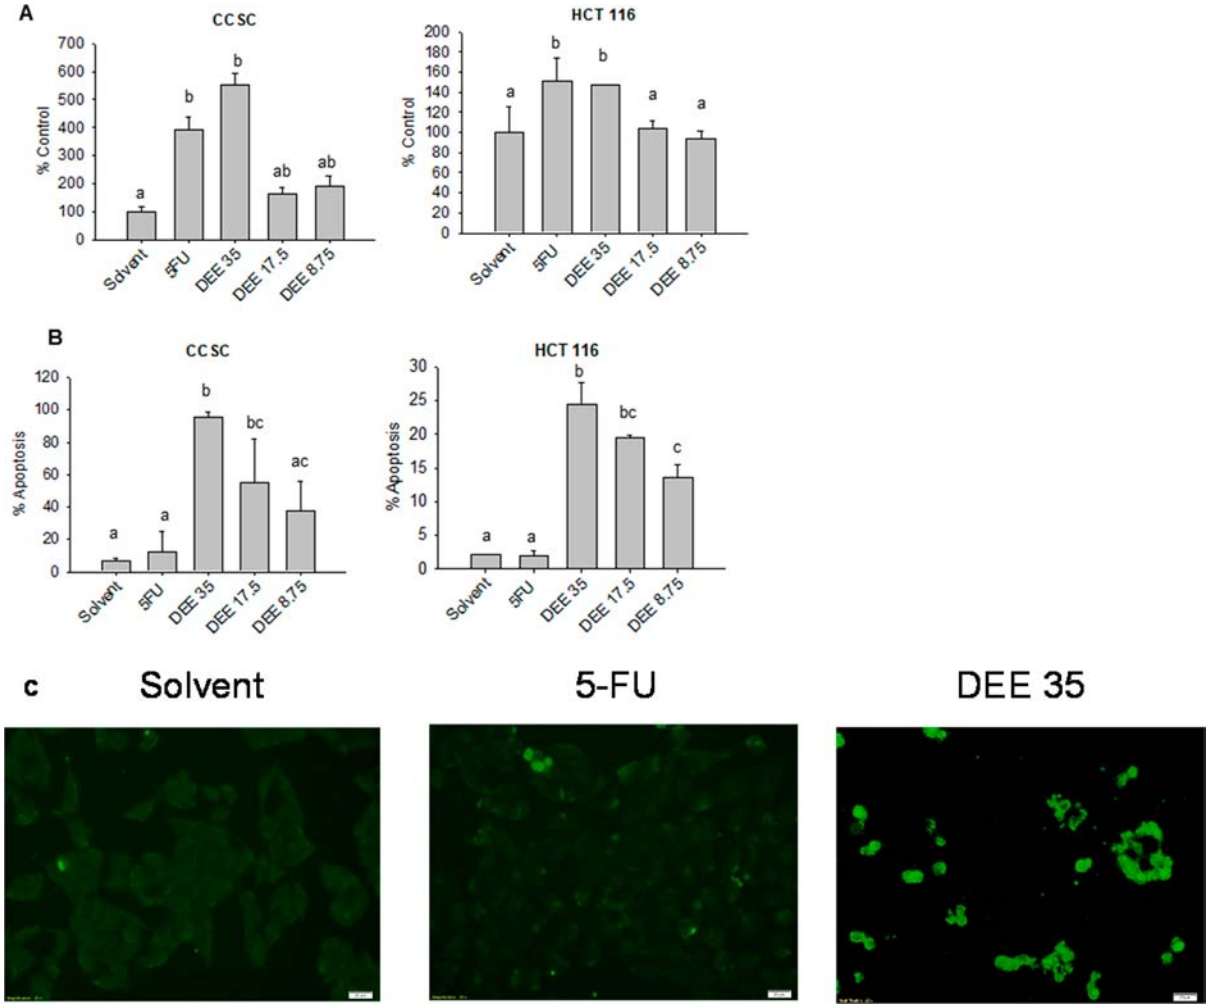

Figure 5. Proapoptotic activities of Dale dermal phenolics measured by (A) Caspase 3/7 Glo assay and (B) TUNEL assay. Colon cancer stem cells (CCSCs) and HCT116 cells were treated for 24 h with dermal phenolic-rich ethanol extracts of the Dale variety (DEE) at 8.75, 17.5, and 35 μg of GAE/mL before being tested. Values are presented as mean (n = 2) percentages of the solvent control ± standard deviation. (C) Representative images of CCSCs from TUNEL assay. Different letters indicate significant differences (P < 0.05) among treatments. Solvent = solvent control, and 5-FU = 5-fluorouracil (18 μg/mL).

respectively (P < 0.05). When the pith and dermal layer are combined, there is no difference between the gallic acid equivalents of Dale and M81E, but there are significantly more Trolox equivalents. This could be a result of a difference in the compositions of the phenolics, antioxidant, and other reducing substances contained in the two varieties. Reducing sugars such as sucrose, fructose, and glucose are concentrated in the pith of sweet sorghum and contribute to total phenolic readings.

dx.doi.org/10.1021/jf405415u | J. Agric. Food Chem. 2014, 62, 3150−3159

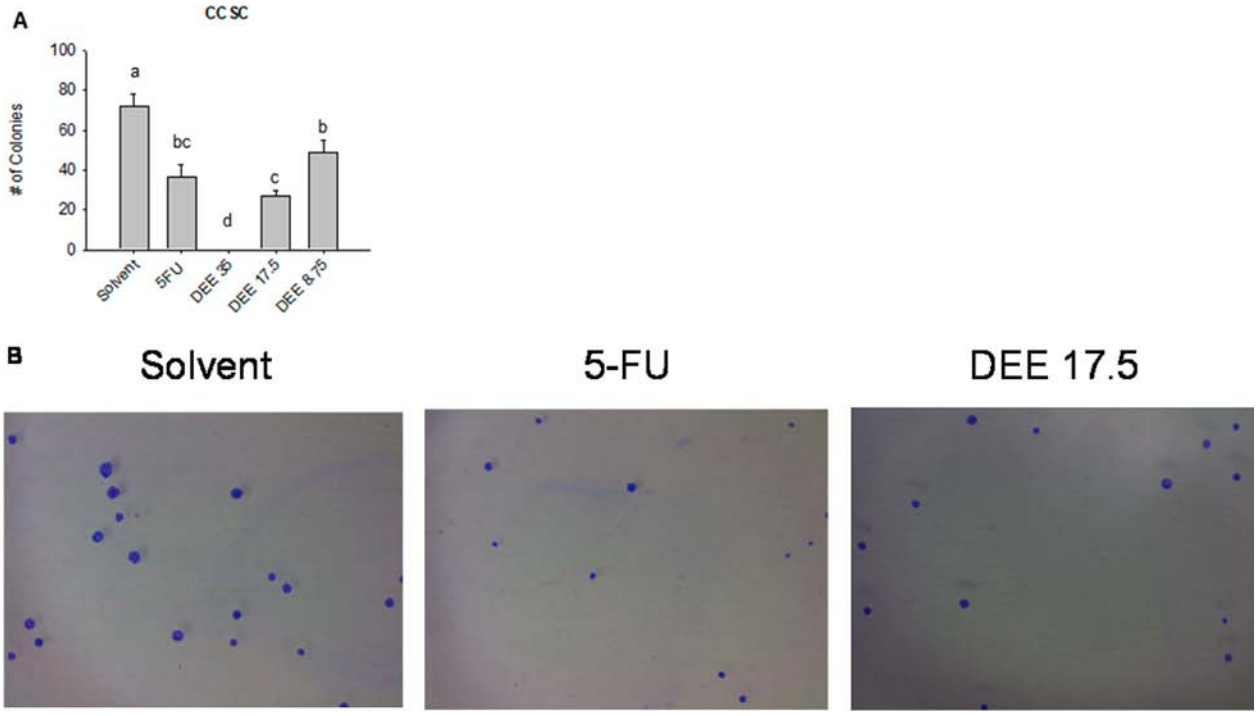

Figure 6. Effects of Dale dermal phenolics on colony formation. (A) Colon cancer stem cells (CCSCs) were treated for 24 h with dermal phenolic-rich ethanol extracts of the Dale variety (DEE) at 8.75, 17.5, and 35 μg of GAE/mL before estimation of colony formation by colony forming assay. (B) Representative images taken from the colony forming assay. Values are presented as the mean (n = 3) number of colonies formed containing at least 50 cells ± standard error. Different letters indicate significant differences ($P < 0.05$) among treatments. Solvent = solvent control, and 5-FU = 5-fluorouracil (18 μg/mL).

Reducing sugars are known to be approximately twice as concentrated in the pith as in other components of the stalk,[15] and differences in reducing sugars could explain this discrepancy.

We next sought to analyze bioactive compounds from the pith and dermal components of sweet sorghum stalk by LC–MS analysis. We were able to identify phenolic acids, flavonoids, and stilbenoids from the phenolic extracts of the sweet sorghum pith and dermal layer, which are summarized in Table 2. These compounds have been identified previously in sorghum and have also been reported to have potent in vitro and in vivo anticancer activities. For example, we were able to identify luteolinidin and apigenidin, which have been previously reported in the leaf sheaths and leaves of sorghum.[17,18] These compounds have been reported to have anticancer activities toward a number of cancer cell lines, including liver, leukemia, and colon.[22,23,30] Previous studies have identified primarily two major classes of bioactive phenolic compounds, phenolic acids and flavonoids, in sorghums and sweet sorghums. These investigations primarily focused on the grains or seed heads from grain sorghum for its relevance as a staple in human diets. Other investigations have focused on the leaf, leaf sheath, infected sorghum seedlings, and glume,[17−19,31] and these parts of the plants are pertinent to traditional medicine. These studies have identified multiple phenolic compounds with potent in vitro and in vivo activities. These include phenolic acids, anthocyanidins, and flavones. Few studies have investigated sweet sorghum with respect to its bioactive content, especially the stalk components, pith and dermal layer. On the basis of these observations, we hypothesized that extracts from the sweet sorghum stalk components pith and dermal layer containing multiple bioactives would suppress proliferation and induce apoptosis in colon cancer cells.

Anticancer Activities of Sweet Sorghum Pith and Dermal Extracts. Early in the pathogenesis of colorectal cancer, hyperproliferation of colonocytes resulting from a deregulation of cellular proliferation and a suppression of apoptosis results in the formation of aberrant crypt foci and, subsequently, adenomas. Colon stem cells, residing in the base of the crypt, are responsible for renewing the colonic epithelium during one's lifetime.[32,33] Furthermore, they are long-lived, self-renewing cells and have a high capacity for proliferation, a combination that makes them a likely candidate to acquire the mutations necessary to give rise to colon cancers.[34] Today's therapies are ineffective at targeting cancer stem cells, only targeting the bulk of the rapidly dividing tumor cells.[6] Therefore, effective treatment strategies for colon cancer should suppress proliferation and induce apoptosis in the rapidly dividing tumor mass as well as the cancer stem cells. This would rid the tumor mass of the tumor-promoting stem cells as well as remove the bulk of the tumor. We assessed the pith's and dermal layer's bioactivity by measuring (1) antiproliferative effects in colon cancer HCT116 cells and CCSCs as evaluated by cell count and BrdU assay, (2) proapoptotic effects in HCT116 cells and CCSCs as evaluated by activated caspase 3/7 activity and subsequently confirmed by TUNEL assay, and (3) self-renewal capability in CCSCs as analyzed by colony forming assay.

Differential Activities of Pith and Dermal Extracts. To investigate the differences in the anticancer effects between pith and dermal extracts, colon cancer HCT116 cells were treated with phenolic-rich extracts prepared from Dale pith 80% acetone extract (PAE) and Dale dermal 80% acetone extract

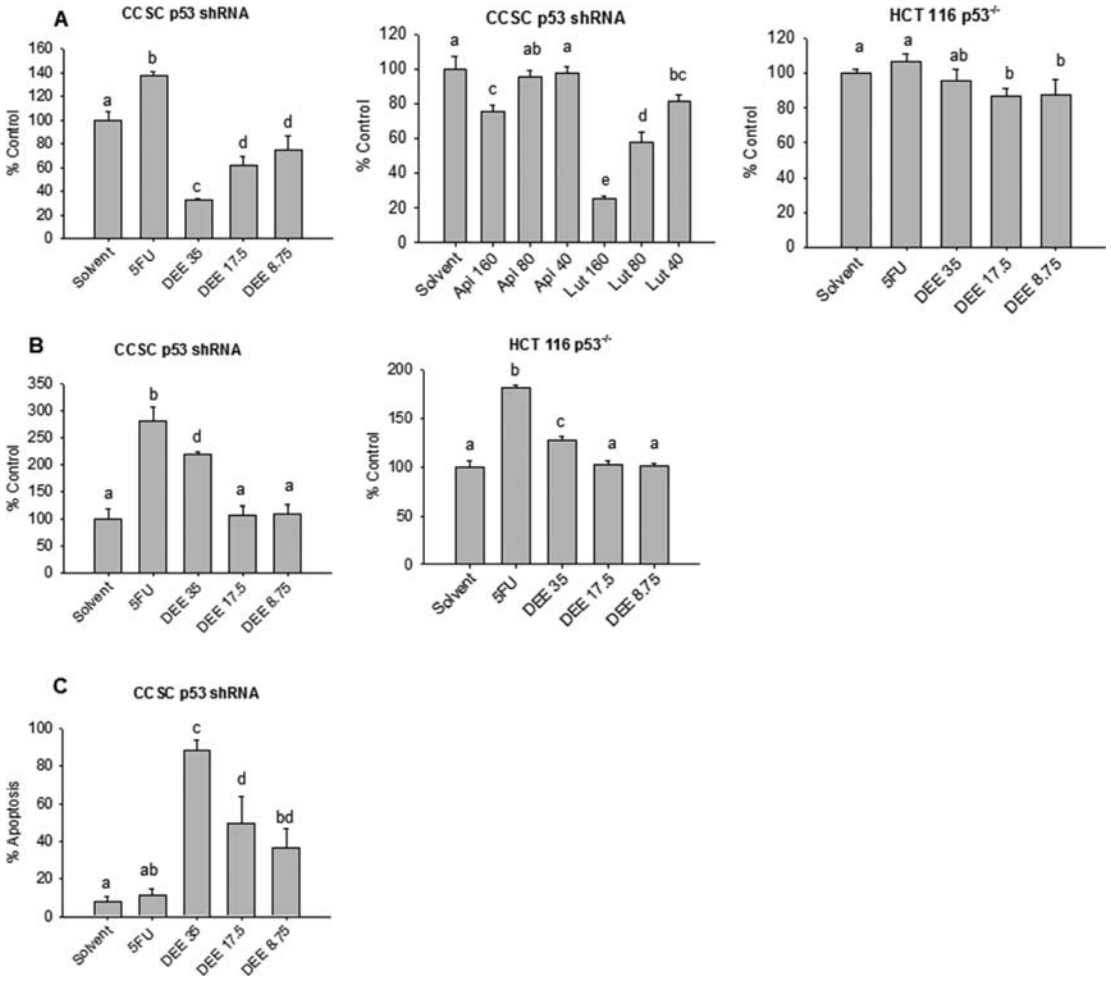

Figure 7. Antiproliferative and proapoptotic activities of Dale dermal phenolics in a p53-independent manner as measured by (A) BrdU assay, (B) Caspase 3/7 Glo assay, and (C) TUNEL assay. The antiproliferative effects of apigeninidin and luteolinidin were also measured by BrdU assay. Colon cancer stem cells (CCSCs) with p53 shRNA and HCT116 $p53^{-/-}$ cells were treated for 24 h with dermal phenolic-rich ethanol extracts of the Dale variety (DEE) at 8.75, 17.5, and 35 μg of GAE/mL before being tested. For BrdU assay, values are presented as mean (n = 3) percentages of the solvent control ± standard error. For Caspase 3/7 Glo and TUNEL assays, values are presented as mean (n = 2) percentages of the solvent control ± standard deviation. Different letters indicate significant differences ($P < 0.05$) among treatments. Solvent = solvent control, and 5-FU = 5-fluorouracil (18 μg/mL).

(DAE) for 24 h as shown in Figure 2. Extract from DAE suppressed cell proliferation more than PAE, as shown by cell count and BrdU assays. This may be due to higher levels of reducing sugars in the pith. At 25 μg of GAE/mL, DAE suppressed the cell count 43% compared to only an 11% reduction for PAE. IC_{50} values were calculated for PAE and DAE. The IC_{50} for PAE was calculated to be above 50 μg of GAE/mL, while DAE was calculated to be 36 μg of GAE/mL. DAE was also able to induce apoptosis at lower concentrations than the pith as measured by caspase activity. At concentrations of 12.5, 25, and 50 μg of GAE/mL, DAE was able to increase active caspase levels to 155%, 159%, and 184% of that of a solvent control, respectively. Only 50 μg of GAE/mL of PAE was able to increase active caspases 3 and 7 in HCT116 cancer cells (169%, $P < 0.05$). These data implicated DAE as a more effective antiproliferative and proapoptotic extract than PAE, and therefore, further experiments focused solely on extracts from the dermal layer of the Dale variety. These differences in bioactivities between the pith and dermal layer of the Dale variety stalk may be explained by the differences in their composition and content of bioactive compounds. These results are analogous to differences observed in the bioactivities of different parts of edible fruits. For example, only the ethanolic extracts from the peel of mango, but not the flesh, induced apoptosis in cervical cancer HeLa cells.[35] Interestingly, our LC−MS analysis showed marked and significant differences between extracts from the dermal layer and pith (Table 2). For example, the ethanolic pith extract contained only 8% of the apigeninidin and 5% of the luteolinidin as compared to the levels of these compounds in the ethanolic dermal extract on the basis of relative peak intensities. This may explain the increased potency observed in dermal extracts.

Solvent-Dependent Activities of Dermal Extracts. Previous quantitative and in vitro experiments demonstrated that aqueous acetone makes a good extraction solvent for dermal phenolic compounds with antioxidant and anticancer activity. However, acetone is not an environmentally safe solvent for extraction of bioactive compounds, especially for extracts intended for human consumption. Turkmen and colleagues[36] tested the ability of different organic solvents with varying percentages of water to extract phenolics from mate and black tea. They found that while 100% ethanol was

ineffective at extracting tea polyphenols, addition of 20% water increased polyphenol extraction by approximately 27-fold when compared to 100% ethanol. Furthermore, 80% ethanol yielded approximately 60% of the phenolics as compared to 80% acetone. On this basis, we hypothesized that ethanol, a GRAS organic solvent, with water could be used to extract phenolics from the sweet sorghum dermal layer with effectiveness similar to that of aqueous acetone. Similar to Turkmen's findings, 80% ethanol yielded approximately 84% of the phenolics compared to 80% acetone (data not shown). We next tested the bioactivity of the phenolic-rich dermal extract prepared from 80% ethanol (DEE) in HCT116 and compared it to that of DAE. As demonstrated by Figure 3, DEE had a superior IC_{50} value of 22 μg of GAE/mL compared to the IC_{50} of 36 μg of GAE/mL for DAE. Given the GRAS status of ethanol and the greater in vitro bioactivity against HCT116 cells, further experiments utilized DEE. We further tested DEE for proapoptotic activities by the Caspase 3/7 Glo assay and TUNEL assay. When compared to the solvent control, DEE at all concentrations significantly increased apoptosis. Furthermore, this increase in apoptosis was more than that for the positive control, 5-FU. Our findings highlight the important aspect of solvent selection when extracting and analyzing in vitro bioactivities of plant-based extracts.

DEE Effectively Eliminates Colon Cancer Stem Cells. There is growing evidence that cancers arise from a small population of adult cancer stem cells. They are also resistant to many standard of care therapies (e.g., chemotherapy and radiotherapy), and the inability to rid the body of these persistent cells is thought to be a primary cause of colon cancer recurrence.[7] There is a need for standardized bioactive compounds and extracts that can effectively eliminate these cells, as current anticancer drugs often fail.[7] We tested DEE against colon cancer stem cells and compared it to 5-FU, a common chemotherapeutic for the treatment of colon cancer. We treated colon cancer stem cells with DEE at 8.75, 17.5, and 35 μg of GAE/mL and 5-FU (18 μg/mL, 100 μM) for 24 h and measured proliferation and apoptosis (Figures 4 and 5). DEE potently suppressed proliferation to 73% of the control, as measured by BrdU, and increased the percentage of TUNEL positive cells (Figure 5B) from 7% to 95% of total cells ($P < 0.05$). Imaging of TUNEL stained cells (Figure 5C) shows increases in DNA fragmentation (increased fluorescence) and changes in cell morphology consistent with apoptosis. We further tested the antiproliferative activity of apigeninidin and luteolinidin against CCSCs with BrdU assay, and IC_{50} values were calculated as demonstrated in Figure 4C. Luteolinidin suppressed CCSC proliferation more than apigeninidin, as demonstrated by a lower IC_{50} value of 76 μg/mL as compared to >160 μg/mL.

To further assess DEE's ability to target CCSC properties other than proliferation and apoptosis, the self-renewal capability of CCSCs' self-renewal was measured by colony forming assay (Figure 6). We treated CCSCs with DEE and found a dose-dependent suppression in colony formation. Figure 6B shows representative images collected from the colony forming assay and demonstrates the decreased colony number and size associated with treatment in comparison to the control. At the highest concentration, DEE completely suppressed CCSC colony formation, and this activity was greater than that of 5-FU treatment. This demonstrates that, in addition to the antiproliferative and proapoptotic activities, DEE alters the stemlike properties by inhibiting colon cancer stem cell self-renewal.

There has been little research done on the in vitro anticancer activities of sorghum stalk, especially sweet sorghum, on cancer cells and advanced cancer stem cells. Research from Yang et al.[23] demonstrated that grain extracts from pigmented grain sorghums contained high levels of 3-deoxyanthocyanins and had strong antiproliferative activities in vitro against colon cancer HT-29 cells. Furthermore, they tested the antiproliferative effects of individual 3-deoxyanthocyanidins. They reported IC_{50} values ranging from 180 to 557 μg/mL for crude extracts and from approximately 13 to 20 μg/mL for 3-deoxyanthocyanidins. In agreement with Yang's findings, we too have demonstrated that phenolic-rich extract from the dermal layer of sweet sorghum stalks contains 3-deoxyanthocyanidins and has potent antiproliferative and proapoptotic activities. The fact that dermal phenolic-rich extract has activities in colon cancer cells and colon cancer stem cells highlights a need for further research of sweet sorghum's anticancer activity in vivo for its potential as a chemotherapeutic agent against colon cancer.

Effects of p53 on the Anticancer Activity of DEE. The p53 tumor suppressor gene is an integral regulator of cell cycle control, DNA repair, and apoptosis.[3] It is estimated that half of all tumors carry some form of mutated p53 and the synergy of phytochemicals may provide p53-dependent and -independent mechanisms to compensate.[37,38] Effective preventive and therapeutic colon cancer strategies should successfully target p53-dependent and -independent pathways. To test the p53 dependency of DEE's anticancer activity, we treated HCT116 $p53^{-/-}$ cells carrying p53 deletions in both alleles of the p53 gene with DEE for 24 h and measured changes in proliferation and caspase activity (Figure 7). We observed no significant changes between HCT116 $p53^{-/-}$ cells treated with DEE and solvent controls in cellular proliferation as measured by the BrdU assay, indicating that DEE's ability to suppress cellular proliferation is p53-dependent. However, we did observe a significant increase in active caspase activity at the highest dose of DEE. This indicates that DEE may act through p53-independent pathways of apoptosis only at concentrations at and above 35 μg of GAE/mL, and this may also be true of DEE's antiproliferative effects.

We further tested p53 dependency in CCSCs by knocking down p53 expression with lentiviral infection containing p53 shRNA (CCSC p53 shRNA). The shRNA is constitutively expressed due to the presence of a strong promoter binding to p53 mRNA, preventing its translation. In this model of p53 knockdown, DEE suppressed proliferation up to 33% of the control and elevated apoptosis of CCSC p53 shRNA cells in a dose-dependent fashion as measured by BrdU and TUNEL assays (Figure 7). We further tested the antiproliferative effects of apigeninidin and luteolinidin in CCSC p53 shRNA cells with BrdU (Figure 7). We show that both of the 3-deoxyanthocyanidins suppress proliferation in p53 knockdown cells with IC_{50} values of >160 and 103 μg/mL for apigeninidin and luteolinidin, respectively. In agreement with previous results, the antiproliferative effect of luteolinidin surpassed that of apigeninidin. Our findings may be due to the slight variation in structure, as luteolinidin contains one extra hydroxyl group on the 3′ carbon of the B-ring of the flavonoid structure, and it has been shown to have a 3-fold increase in antioxidant activity when compared to apigeninidin.[39] Our findings agree with

those of Marko et al.,[40] who reported increased activity of anthocyanidins with a higher degree of B-ring hydroxylation.

In this study, we demonstrated differential activity observed between CCSCs and the early-stage HCT116 cell lines. This differential activity is thought to be a result of the selective toxicity of complex bioactive extracts against cancer cells as compared to normal epithelial cells. Earlier staged and more differentiated cancer cell lines more resemble the normal differentiated epithelial cells than do more advanced cancer cell lines. This was demonstrated in work by Seeram et al.[41] with total cranberry extract in four colon cancer cell types (SW480, SW620, HCT116, and HT29). SW480 and SW620 represent two cell lines from the same patient, the former representing the earlier staged primary tumor and the latter derived from a metastasis. Total cranberry extract showed 35% more antiproliferative activity against the advanced metastatic SW620 cell line compared to SW480 cells. HCT116 and HT29 cells are colon cancer cell lines representing early- and late-stage disease, respectively. Total cranberry extract showed greater proliferation inhibition activity in the advanced HT29 cell line compared to HCT116 cells. These reports corroborate our findings that sweet sorghum extract was more efficacious against CCSCs as compared to HCT116 cells. While our results point to p53-independent activity, more work is needed to conclude the dermal extract's mechanisms of action.

In the present study, we have shown for the first time that the dermal layer of sweet sorghum is rich in total phenolics and antioxidants, including 3-deoxyanthocyanidins, with potent in vitro anticancer activity against colon cancer HCT116 cells and CCSCs. This activity was greater than that of the pith, and we believe this to be due to the different compositions of phenolics as illustrated in Table 2. Furthermore, we demonstrated that the ethanolic extract was more potent in suppressing the proliferation of colon cancer cells, highlighting the importance of solvent selection in developing natural-based phenolic-rich extracts. In addition to being a source of renewable biofuel, sweet sorghum may also serve as a source of health-promoting compounds for the prevention and treatment of inflammatory diseases such as colon cancer. For this to be a reality, further research is needed to determine potential toxicities and the bioactivities of sweet sorghum dermal extracts in vivo.

Author Contributions

A.R.M. conducted research, writing of the manuscript, and contributed to the study's design. L.R. provided intellectual contributions, study design, and assisted in research. J.V. provided intellectual contributions, study design, and review of the manuscript.

Funding

This research was funded by Great Valley Energy LLC, Bakersfield, CA.

Notes

The authors declare the following competing financial interest(s): patent pending. Brian M. Pellens and D. Edward Settle, the Managing Principals of Great Valley Energy LLC, approached the authors with the idea of studying the bioactive and antioxidant properties of sweet sorghum fractions. They have applied for a patent for sorghum extract and its therapeutic uses. In recognition of the authors' contribution, they have invited the authors to be named as co-inventors.

ACKNOWLEDGMENTS

We thank the Proteomics and Metabolomics Facility at Colorado State University for performing the LC-MS analysis of the pith and dermal samples and Sridhar Radhakrishnan and Venkata Rohit for laboratory assistance and manuscript review.

glucans,[19,20,22,26,27] and for a specific MW, gelation rate can be increased by increasing concentration.[19] Low molecular weight β-glucans (≤100,000) produced gels with greater G′ values than higher MW β-glucans,[20,22,27] although large deformation measurements obtained opposite results, whereby gels from high molecular weight β-glucans formed harder gels, more resistant to mechanical stress.[19,20,27] β-Glucan source was the other significant parameter in determining gelation rate and gel elasticity. β-Glucans where β-(1→3) linked cellotriosyl units form a greater proportion of the molecular structure gel faster and produce more elastic gels. Therefore, when comparing 10% oat, barley, and lichenan β-glucan gels with similar M_w values, melting temperature and rate of gelation decreased in the order lichenan, barley, and oat.[19] Essentially, lichenan solutions gelled very quickly and, once gelled, required more heat to melt. Conversely, oat β-glucan required the most time to gel and the least amount of heat to melt. Structurally, lichenan has the highest proportion of β-(1→3) linked cellotriosyl units, followed by barley and then oats. Similarly, Tosh et al.[22] found that storage modulus G′ declined in the order lichenan, wheat, rye, barley, and oat for 6% β-glucan gels aged 7 days at 5 °C. There was a significant positive relationship between the proportion of β-(1→3) linked cellotriosyl units in the polymer and G′.

Given the health benefits of β-glucans and the relative unpalatability of highly viscous, high MW β-glucan drinks with a slimy mouth feel, the prospect of delivering the fiber in gel form is attractive. This would be a method for delivery not only of β-glucan but, potentially, for other bioactive food components, such as anthocyanins and carotenoids, as well. In light of the variability of β-glucan gel properties based on MW and fine structure, the aim of our research was to examine whether β-glucan gels could be prepared from a mix of low and high MW polymers, thus exploiting the properties of each with respect to gelation (high molecular weight β-glucans produce stronger gels, but take a long time to gel, whereas low molecular weight β-glucan gels faster and produces more elastic gels). To this end, high and low MW β-glucans were mixed in different proportions and the resultant systems subjected to small deformation oscillatory (G′, G″) and large deformation measurements. These gels were also examined using microscopy and differential scanning calorimetry (DSC) to assess gel structure and thermal properties. Model food gels containing glucose with differing high molecular weight:low molecular weight (HMW:LMW) ratios were produced and analyzed to examine viscoelastic and mechanical properties.

2. MATERIALS AND METHODS

2.1. Sample Preparation. Unhydrolyzed oat β-glucan was prepared as previously described,[28] with modifications as reported in Tosh et al.[22] A low molecular weight fraction was prepared for use in the mixed molecular weight gels by hydrolyzing the unhydrolyzed oat β-glucan with acid as described by Tosh et al.[21] For the model food gel, LMW and HMW oat β-glucan were a gift from Megazyme International (Bray, County Wicklow, Ireland).

Mixed molecular weight gels for small (small amplitude oscillatory testing) and large deformation mechanical testing were prepared by solubilizing either HMW or LMW oat β-glucan or a mixture of the two in 20 mM phosphate/1 mM NaN_3 buffer (pH7.0) with a 3, 4, and 5% total β-glucan concentration. Solubilization took place at 90 °C with constant stirring for 3 h. The mixtures had HMW:LMW ratios of 0:100, 25:75, 50:50, 75:25, and 100:0 (the 25:75 ratio was not prepared for all analyses). Gels were set in 2.5 cm diameter molds 1 mm deep for 3, 5, or 7 day rheological tests at 25 °C. For large deformation tests, the gels prepared from HMW and LMW oat β-glucans and the mixtures thereof were set in 2 cm diameter molds 6 mm deep for 7 days at 25 °C. The freshly prepared, nongelled samples were used for apparent viscosity measurements.

Model food gels with a HMW:LMW ratio of 0:100, 50:50, and 75:25 were prepared at 4% (w/w of gum and water) by vigorously mixing the gum in boiling 0.05% potassium sorbate in distilled water with an immersion blender. Food coloring and orange oil were added, and citric acid was used to maintain a pH of 4−5. The control gels were prepared as described while the sample gels were augmented by the addition of 50 g of glucose. The β-glucan solutions were set in 2.5 cm diameter 1 mm deep molds for rheology and 2 cm diameter 9 mm deep molds for large deformation tests. Gels were aged 7 days at 21−24 °C.

2.2. Characterization. The β-glucan content of samples was determined according to AOAC Method 995.16 using an enzymatic analysis kit from Megazyme (Bray, County Wicklow, Ireland).

Molecular weight (M_w) and polydsipersity (Pd) determinations for oat samples were made using a HPSEC system equipped with multiple detectors. The chromatographic system consisted of a Shimadzu (Shimadzu Scientific Instruments Inc., Kyoto, Japan) SCL-10Avp system controller, a SIL-10ADvp autosampler, and a LC-10ATvp pump. Detection was achieved using a Viscotek (Malvern Instruments Ltd., Worcestershire, U.K.) model 305 triple detector array, which housed two analytical columns maintained at 40 °C, an Ultrahydrogel linear (Waters, Milford, CT) column, and a Shodex (Showa Denko, K.K., Tokyo, Japan) OHpak Kb-806M column and three detectors: an RI, differential pressure (DP), and laser light scattering detector. The light scattering detector was equipped with both right angle and low angle detection. Samples were separated in 0.1 M $NaNO_3$ with 5 mM NaN_3 at a flow rate of 0.6 mL/min. Data integration and analysis was done using Viscotek OmniSEC software. A refractive index increment (dn/dc) of 0.146 mL/g was used for calculations, and pullulan standards were used to calculate instrument constants.

Structural determinations were made by subjecting β-glucans to hydrolysis with lichenase and evaluating the proportion of the resulting two main structural components, β-(1→3) linked cellotriosyl and β-(1→3) linked cellotetraosyl. Enzyme incubation conditions and separation and analysis of released oligosaccharides are as described by Tosh et al.,[21] with the exception that data analysis was performed with Dionex Chromeleon software, version 6.5 (Dionex Corp., Sunnyvale, CA).

2.3. Rheology. Apparent viscosity measurements were taken using a controlled strain rheometer (ARES, TA Instruments, New Castle, DE) fitted with a cone and plate geometry (cone angle of 0.04 radians, 50 mm diameter). Apparent viscosity was measured in a shear rate range of 100−0.1 s^{-1}, and viscoelastic parameters G′, G″, and tan δ were obtained in the linear viscoelastic range (2% strain) using a parallel plate (25 mm plate, 1 mm gap) configuration from 0.01 to 10 Hz. For mixed molecular weight gels, viscosity and viscoelastic measurements were taken at 25 °C, while viscoelastic measurements for the model food gel were done at 37 °C. All measurements were performed in triplicate at minimum.

2.4. Large Deformation Mechanical Testing. Compression tests were performed using a TA.HD plus texture analyzer (Stable Micro Systems, Ltd., Godalming, Surrey, U.K.) equipped with a 38 mm diameter cylinder probe. Gels were compressed using a crosshead speed of 0.3 mm/s. Gels on a Teflon sheet were placed on the stationary bottom plate of the instrument, and mineral oil was applied to the top of the gel to prevent friction during compression and to allow for biaxial expansion of the gel. Force−displacement curves were used to determine hardness at 40% compression and Young's modulus (E). Measurements are the mean of at least 10 replicates for the mixed molecular weight gels and 6 replicates for the model food gels.

2.5. Differential Scanning Calorimetry (DSC). Gels for DSC analysis were prepared as outlined in section 2.1 and ,after setting 7 days, were weighed (80−90 mg) into high volume DSC pans. Using a model 2920 DSC from TA Instruments (TA Instruments, New Castle, DE), a temperature ramp of 5−120 °C was applied to the samples and reference pan containing 10 mM sodium phosphate buffer/1 mM

NaN_3. The peak temperature, calculated as the temperature at which point the heat flow was at a minimum, was obtained using Universal Analysis software (TA Instruments, New Castle, DE).

2.6. Microscopy. Micrographs were taken for 3, 4, and 5% LMW oat gels and HMW oat viscous solutions and mixed oat gels at HMW:LMW ratios of 50:50 and 75:25. Microscopic slides were prepared by creating an enclosed space for the β-glucan solutions to gel using 3 coverslips as described by Tosh et al.[21] Microscopic observation was conducted using a Zeiss Axioskop2 light microscope (Carl Zeiss MicroImaging Inc., Thornwood, NY) equipped with a 63× phase contrast oil immersion lens. A Spot CCD camera and Advanced Spot software (Diagnostic Instruments, Inc., Burlingame, CA) was used to capture images.

2.7. Statistical Analysis. Significant differences between measurements were determined using the data analysis package in Microsoft Excel or SigmaPlot 12.0. Two tailed *t* tests were used to determine significance in peak melting temperatures (T_p), and one way analysis of variance was used for hardness and firmness values. A confidence interval of 95% was required for determining significance ($P < 0.05$).

3. RESULTS AND DISCUSSION

3.1. Mixed Molecular Weight Oat β-Glucan Gels. Characteristics of each β-glucan used are given in Table 1.

Table 1. Characteristics of Oat β-Glucan (BG) High Molecular Weight (HMW) and Low Molecular Weight (LMW) Samples

	purity % (dwb)[a]	M_w[b]	Pd[c]	MR[d]
	Mixed MW Gels			
oat BG-HMW	92.0 ± 1.3	1,190,500	1.20	2.36
oat BG-LMW	92.0 ± 1.3	31,200	1.27	2.55
	Model Food Gels			
oat BG-HMW	95.8 ± 2.0	580,000	1.5	nd[e]
oat BG-LMW	93.5 ± 0.3	145,000	1.7	nd

[a]Dry weight basis. [b]Weight average molecular weight. [c]Polydispersity (weight average/number average molecular weight). [d]Molar ratio, peak area of DP3/DP4 × 1.321. [e]Not determined.

The original oat gum, with a weight average molecular weight (M_w) of 1,190,000, was used to prepare a LMW fraction, with a M_w of 31,200. The purity of the HMW glucan used in the mixed molecular weight gels was 92.0% and did not change during the preparation of the LMW fraction, although the molar ratio (MR) increased from 2.36 to 2.55 and the polydispersity (Pd) increased from 1.20 to 1.27.

Hydrolysis with lichenase yields 3-*O*-β-cellobiosyl-D-glucose (DP3) and 3-*O*-β-cellotriosyl-D-glucose (DP4) in proportion to the number of β-(1→3) cellotriosyl and β-(1→3) cellotetrosyl units, respectively. These two oligosaccharides represent the majority of the structure of cereal and lichenan β-glucans, but it is the relative proportion of the two that differentiates the samples. The MR of β-glucan, calculated as (DP3/DP4) × 1.321, has been used to characterize the relative proportion of these two oligosaccharides and typical values for oat, barley and lichenan are 1.9−2, 3−3.8 and 30, respectively (Cui et al.,[5] 2000; Tosh et al.,[21] 2004).

Figure 1 shows the shear rate dependence of apparent viscosity for freshly prepared 3% β-glucan solutions with HMW:LMW ratios of 0:100, 50:50, 75:25, and 100:0. These are initial measurements taken before the solutions were allowed to gel. Only the 3% is shown for simplicity, however its profile is representative of the 4 and 5% as well. As expected, for all concentration levels, the apparent viscosity declines with declining HMW β-glucan proportion in the sample. All

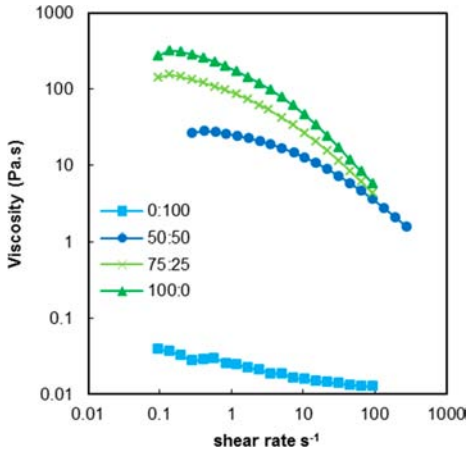

Figure 1. Shear rate dependence of viscosity for 3% β-glucan solutions with high molecular weight:low molecular weight (HMW:LMW) ratios of 0:100, 50:50, 75:25, and 100:0.

solutions were shear thinning, although the samples which included HMW β-glucan were markedly so when compared to the solution of only LMW oat β-glucan. This behavior is typical of polysaccharides because longer polymers tend to participate in more entanglements which are responsible for the shear thinning phenomenon.

Upon aging, the β-glucan solutions become more viscoelastic and, hence, more suitable for comparison by the moduli G' and G''. These were measured for the 3, 4, and 5% gels for all HMW:LMW proportions on days 3, 5, and 7 of aging. The elastic modulus G' on days 3 and 7 of aging for 3% gels at all four HMW:LMW proportions are shown in Figure 2A. The G' in the 100% and 50% LMW gels was the least frequency dependent, suggesting that the lower molecular weight β-glucan contributes to a more elastic gel structure. Low molecular weight β-glucan solutions are lower in apparent viscosity at the same concentration because they have fewer entanglements. The increased mobility of LMW β-glucans permits them to move more easily into conformations which allow the development of junction zones through hydrogen bonds. The 50% LMW gels had higher G' values than the 100% LMW gels, and the values were consistent at all frequencies, showing that they had the most stable network structure. The LMW β-glucan molecules appear to act as linker molecules between the HMW molecules so that the mixed molecular weight gels derive stiffness from both network formation and entanglements.

From a rheological perspective, a true elastic gel network has been established when G' is at least 1 order of magnitude greater than G'' and either modulus is not or is only slightly dependent on frequency.[29] The solutions prepared from 50 and 100% LMW β-glucan gelled by 3 days at all concentrations, while the 100% HMW solution did not gel, as indicated by the absence of a significant difference in magnitude between G' and G'' and the continued frequency dependence of G'. At 3% concentration, gels with 75% HMW β-glucan had G' and G'' traces that progressed from typical concentrated solution behavior (G'' predominating over G' at low frequencies while G' predominates at higher frequencies) on days 3 and 5 of aging to G' and G'' running in a parallel but frequency dependent manner by day 7. At 4%, the gels gave slightly frequency dependent but parallel G' and G'' traces by day 3 and by day 7 the moduli were frequency independent. At 5%

dx.doi.org/10.1021/jf405131d | J. Agric. Food Chem. 2014, 62, 3160−3167

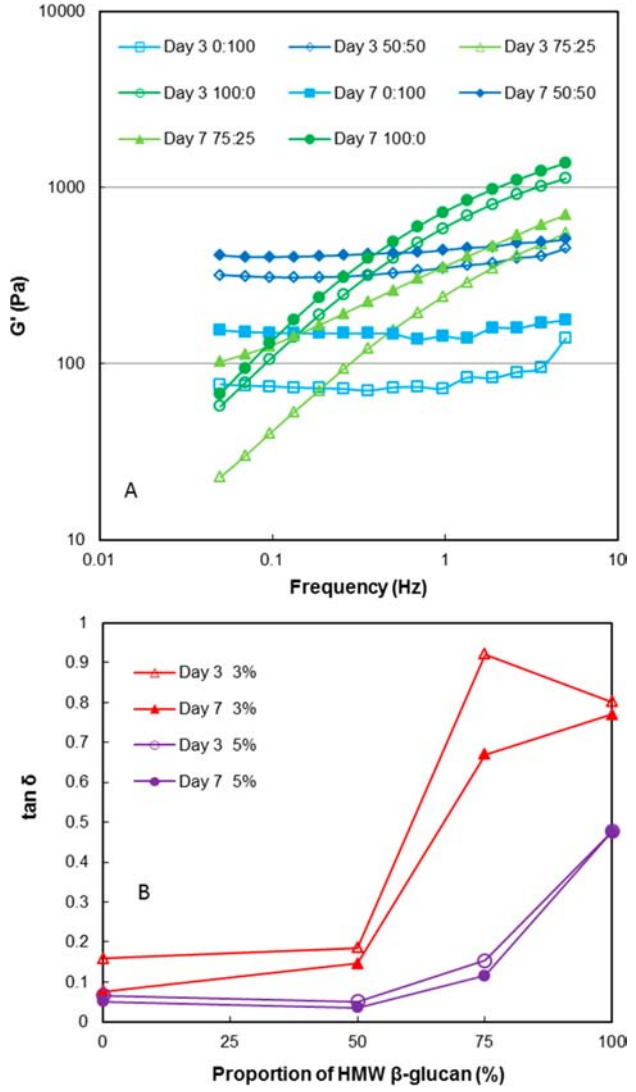

Figure 2. Frequency dependence of G' for 3% gels with high molecular weight:low molecular weight (HMW:LMW) ratios of 0:100, 50:50, 75:25, and 0:100 (A) and tan δ values at 1 Hz for 3% gels with increasing proportion of HMW β-glucan on days 3 and 7 (B).

concentration, the moduli were frequency independent by day 3.

The tan δ, which relates the energy lost to the energy stored (G''/G') in a system when subjected to a specific frequency, gives an indication of whether the system is dominated by viscous properties (tan δ >1) or solid properties (tan δ <1), and the values generally fall below 0.1 for gels, above 1 for concentrated solutions, and much higher for dilute solutions. Figure 2B shows tan δ values at 1 Hz for 3 and 5% gels on days 3 and 7. The 5% gels had lower tan δ values than the 3% gels at all HMW:LMW ratios. The tan δ values decreased from day 3 to day 7 at all points except the 100% HMW viscous solution at 5%. The effect of time was more pronounced in the 3% gels versus the 5% gels. The 4% gels had tan δ values between values for the 3 and 5% gels, however the data followed the same pattern (data not shown). More elastic gels, as indicated by lower tan δ values, were obtained when there was more LMW material in the gels. All solutions produced elastic gels or viscoelastic gels after 7 days with tan δ values below 1, however, the only samples with tan δ at or below 0.1 were the 3% gel with HMW:LMW ratio 0:100, the 4% gel with HMW:LMW 0:100 and 50:50, and the 5% gel with HMW:LMW 0:100, 50:50, and 75:25. Essentially, as the total β-glucan concentration of the gels increased, more HMW β-glucan could be incorporated while still achieving a true elastic gel. The dynamic rheological behavior of the gels can be explained by considering the mobility of the polymer molecules. The large number of entanglements encountered by the HMW β-glucan constrained their movement into suitable conformations for gelation and rearrangement into larger aggregated structures that make up the gel network. Therefore, as previously shown,[20,22,24] the low molecular weight β-glucan produced true gels because of their greater mobility. Addition of HMW β-glucan impeded the formation of intermolecular interactions and rearrangement of strands into aggregated networks.[23]

Calorimetric measurements were conducted to assess the effect of β-glucan concentration (3, 4, or 5%) and HMW:LMW ratio on the peak melting temperature (T_P) of the gels. Consistent with previous research,[20−22] the DSC endotherms were very broad, indicative of a system experiencing the effects of multiple interactions (Figure 3A). The peak temperature of the melting endotherm, which varied from 66 to 86 °C, was plotted versus the percent of HMW β-glucan in the gel for gels

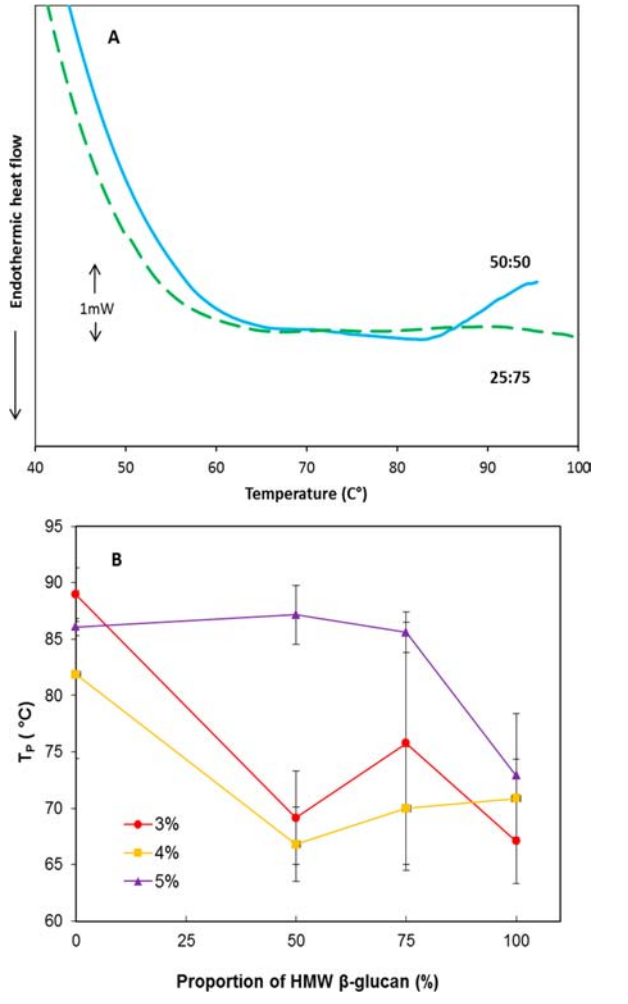

Figure 3. Typical DSC endotherms for 4% gels made using 50 and 75% high molecular weight (HMW) β-glucan (A) and peak melting temperature (T_P) of 3, 4, and 5% β-glucan gels as a function of proportion of HMW β-glucan.

dx.doi.org/10.1021/jf405131d | J. Agric. Food Chem. 2014, 62, 3160−3167

at 3, 4, and 5% (Figure 3B). The overall trend was toward higher T_P values at 0% HMW and lower T_P values at 100% HMW; however there was variability within this trend. For the 3% gels, significant differences were found between HMW:LMW ratio 0:100 and 50:50 (P = 0.00005) and 0:100 and 100:0 (P = 0.0001). For 4% gels, the T_P decreased from 100% LMW to 50%, then increased for the 75 and 100% HMW gels. A broad peak with a similar T_P was found for a 4% LMW barley β-glucan previously.[30] Significant differences were found between HMW:LMW ratios 0:100 and 100:0 (P = 0.031), 0:100 and 50:50 (P = 0.0013), and 0:100 and 75:25 (P = 0.0106). The 5% sample had a decrease in T_P from 0 to 25% HMW, then an increase until 50%, and then a decrease to 100%. At the 5% level, significant differences were observed between HMW:LMW ratios 0:100 and 100:0 (P = 0.0025).

An increase in T_P with a higher proportion of LMW β-glucan is consistent with a diffusion limited mechanism of gelation whereby β-glucan molecules in a system with a lower viscosity are able to move around and set up junction zones more quickly and easily. When the solution for gelation is composed entirely of HMW material, the entanglement that develops precludes swift movement of molecules into positions appropriate for junction zone formation and hence gelation. Rearrangement of the initial gel microstructure into aggregated structures was also constrained by HMW polymers.[23] With the exception of the 100% LMW gels, the highest T_P values were associated with the 5% gels with 0, 50, and 75% HMW. It was expected that gels of greater concentration would result in higher T_P values, given that T_P is a function of the number and stability of molecular interactions. The 3 and 4% gels generally had lower T_P values than the 5% gels, however at HMW:LMW ratio 0:100, the 3% gel had the highest T_P, although only significantly so versus the 4% gel (P = 0.035). At a HMW:LMW ratio of 0:100, the 3% concentration may have allowed more stable junction zone formation than the 4 or 5% because the molecules were more mobile. At HMW:LMW ratio 50:50, the T_P of the 5% gel was significantly higher than the 3 (P = 0.0005) or 4% (P = 0.0029) gel, at 75:25 the 5% was significantly higher than the 4% (P = 0.00096) only, and there was no significant difference in T_P among the concentrations of gels at 100:0.

The hardness (N) at 40% compression and firmness (Young's modulus) of mixed molecular weight gels varied with concentration and proportion of HMW β-glucan (Figure 4). The force required to compress the gels by 40% increased with increasing concentration and increasing proportion of HMW material, but only up to 25 or 50%. Hardness values declined between 50% and 75% HMW β-glucan across all concentrations (P > 0.05 for 3, 4, and 5% gels), and there was no significant difference between hardness values for gels with a 25:75 and 50:50 HMW:LMW ratio at the 3 and 5% concentration. However, at the 4% level, the hardness of 50:50 gels was significantly lower than that of 25:75 gels (P = 0.031). Essentially, when more than 50% of the β-glucan in the gel was HMW, the gel hardness declined. Similarly, Young's modulus increased with increasing gel concentration and the highest values were obtained for gels with either 25 or 50% HMW β-glucan. Essentially, gels with no HMW β-glucan or more than 50% HMW β-glucan deformed more with less force than did gels with an equal amount of HMW and LMW β-glucan. There was a significant difference (P < 0.05) in Young's modulus between the first two levels of HMW proportion (0 and 25%) for the 5% gels, however there was no significant

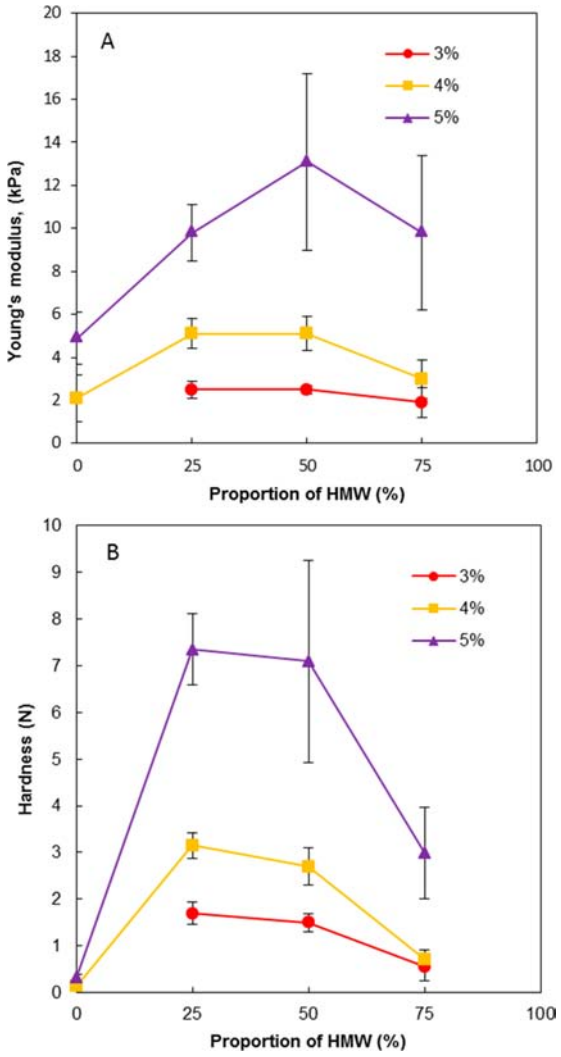

Figure 4. Firmness (A, Young's modulus) and hardness (B) for 3, 4, and 5% β-glucan gels with high molecular weight:low molecular weight (HMW:LMW) ratios of 0:100, 25:75, 50:50, and 75:25.

difference between the 50:50, 25:75, and 75:25 HMW:LMW ratios. The maximum firmness for the 4% gels occurred at 25% (5.13 kPa) and 50% (5.1 kPa) HMW β-glucan, with significantly lower values obtained at 0 and 75% HMW. As shown by small deformation measurements, the 100% LMW gels were the most elastic, indicating a structure that stored and released energy, but the gel network was weak and did not require a lot of force to compress. The addition of up to 50% HMW β-glucan increased the firmness and hardness of the gels, but this effect diminished as more HMW β-glucan was added. After 25 or 50% HMW β-glucan, the high viscosity of the mixtures hinders the movement of molecules into conformations conducive to hydrogen bonding and, therefore, junction zone formation. The LMW molecules appear to stabilize the gel structure at short distances whereas the HMW polymers contribute entanglements and longer range resistance to deformation. Hence, the gels are more viscoelastic and offer less resistance to flow. In 2003, Lazaridou et al.[20] found an increase in Young's modulus with increasing concentration for oat β-glucan gels (M_w 110,000, 6−12%), however, at constant concentration, the values initially increased with molecular weight, then decreased from M_w 65,000 to 250,000. Similarly, we found that firmness and hardness increased with the

dx.doi.org/10.1021/jf405131d | J. Agric. Food Chem. 2014, 62, 3160−3167

addition of HMW β-glucan to the gels, but after 50% addition, they decreased. By contrast, Vaikousi et al.[27] found that Young's modulus for 8% barley β-glucan gels decreased as molecular weight increased from 40,000 to 180,000, after which it stabilized.

There is substantial variation in published β-glucan gel firmness values, and the results obtained here are between the extremes of values reported thus far. Irakli et al.[26] reported Young's modulus values under 1 for 6% barley gels ranging from M_w 450,000 to 1.3 million, Lazaridou et al.[20] obtained values of 9.37−30.45 kPa for 8% β-glucan gels with molecular weights from 35,000 to 250,000, and values of 39.71 and 36.62 kPa for 8% oat beta-glucan gels where the M_w was 105,000 and 203,000, respectively, have been published.[20] Disparate results are expected given the dependency of gel properties on solubilization temperature,[31] concentration, molecular weight,[20,22,32] distribution,[19] and molecular structure .[22,32,33]

Microscopic examination of the gels reveals that the range in gel hardness and firmness results from differences in the gel network structure. The micrographs in Figure 5 show the

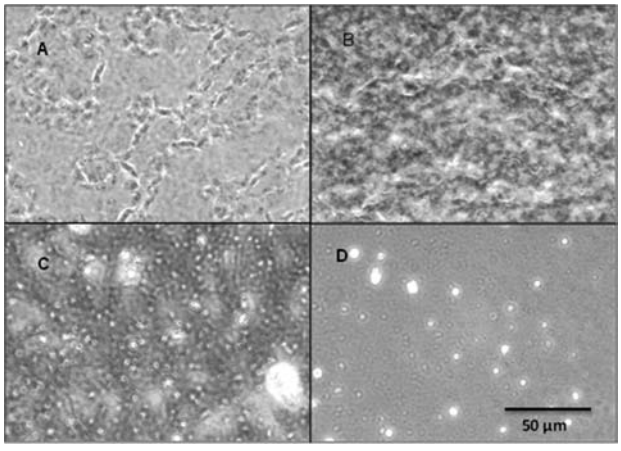

Figure 5. Micrographs obtained using phase contrast light microscopy of 4% β-glucan gels with HMW:LMW ratios of A, 0:100, B, 50:50, C, 75:25, and D, 100:0.

structure of gels with a total β-glucan concentration of 4% using phase contrast light microscopy. The aggregated β-glucan structures are clearly visible in image A, which contains only LMW β-glucan. In this sample, the β-glucan exists as hydrated fibers in a liquid solution. Low molecular weight β-glucan does not form a stable gel network that can bind sufficient water, and the network collapses easily, as indicated by the low firmness and hardness values from the large deformation tests. Gels with 50 or 75% LMW material gave the hardest, most elastic gels, as indicated respectively by the compressive force and Young's modulus data. Figure 5B shows a 50:50 gel which has a structure that is well-defined and regular in nature. In gels with a HMW:LMW ratio of 75:25 (Figure 5C) the gel structure is not as well-defined. The gelation process is diffusion limited, and the highly viscous, entangled HMW polymers retard gelation. However, the LMW polymers are able to diffuse through the solution and set up bridges between reactive sites on the longer polymers. Micrographs of gels composed entirely of HMW material (Figure 5D) do not show a regular structure, but bright spots may indicate aggregates.

During gelation, the number of hydrogen bonds between polymer molecules increases as they diffuse into conformations where runs of consecutive cellotriosyl units are aligned and form junction points. In the LMW solution, the polymers have more freedom to diffuse and the junction points form more frequently. In the solutions containing HMW β-glucan the entanglements retard the diffusion of the polymers, which hinders the formation network junction points. Each junction point that does form further impedes the mobility of the molecules, further slowing network formation. The entanglements and slow diffusion rates prevents gelling of the HMW solution. The greater mobility of the LMW polymers in solution allows them to act as linker molecules which create hydrogen bonded bridges between the slower, entangled HMW polymers. Previous investigations using atomic force microscopy have shown that HMW β-glucan tends to form larger clusters than LMW β-glucan.[24] After the initial clusters of polymers have formed, they rearrange in aggregated structures which make up the network visible in the light microscope. The dissimilarity in the aggregated network structures visible in the light microscope indicated that the differences in the initial gelation changed aggregation patterns and the final microstructure observed. Thus, mixed HMW−LMW gels exhibit high gel stiffness by maximizing both the entanglements and the number of junction points in the material.

3.2. Model Food Gel. A model food gel prepared from oat β-glucan solutions in HMW:LMW ratios of 0:100, 50:50, and 75:25 was used to assess the influence of added glucose on the gel properties. Measurements of molecular weight and purity for the β-glucans used to make model gel systems are available in Table 1. Although the terms HMW and LMW are used, it should be noted that oat β-glucans used for the model food gels were different from β-glucans used for the mixed molecular weight studies and, hence, had different molecular weights (M_w), polydispersities (Pd), and molar ratios (MR). The HMW oat β-glucan had a weight average molecular weight (M_w) of 580,000 versus 1,190,000 for the mixed molecular weight gels. Similarly, the MW of the LMW β-glucan used in the model food gel was higher (M_w 145,000 versus 31,200) than the β-glucan used for the mixed molecular weight gels. The LMW β-glucan was slightly more polydisperse than the HMW gum.

Gelled samples and controls (without added glucose) were subjected to small deformation oscillatory measurements to determine the relative contribution of viscous and elastic factors to the overall behavior of the gels. Figure 6 shows the frequency dependence of G' for samples and controls with differing HMW:LMW ratios. Overall, G' increased with increasing proportion of HMW β-glucan, however the 100% LMW gels were the least frequency dependent, regardless of the presence or absence of glucose. The 0 and 75% HMW gels without glucose had higher G' values than gels with the same ratio but no glucose. The behavior was different for the 50% HMW samples, which gave higher G' values for the sample with glucose at frequencies below 10 Hz, but lower G' values for the sample with glucose at higher frequencies. An examination of G' values shows that those without glucose were more frequency dependent at each HMW:LMW ratio.

The tan δ values at 1 Hz (Figure 7) increased with increasing proportion of HMW such that the values for 0% HMW, 50% HMW, and 75% HMW gels were 0.09, 0.3, and 0.5 respectively for gels with glucose and 0.1, 0.6, and 0.8 respectively for gels without glucose. The gels composed entirely of LMW β-glucan display more typical gel behavior, with tan δ values near 0.1, indicating behavior dominated by elastic properties. Overall, tan

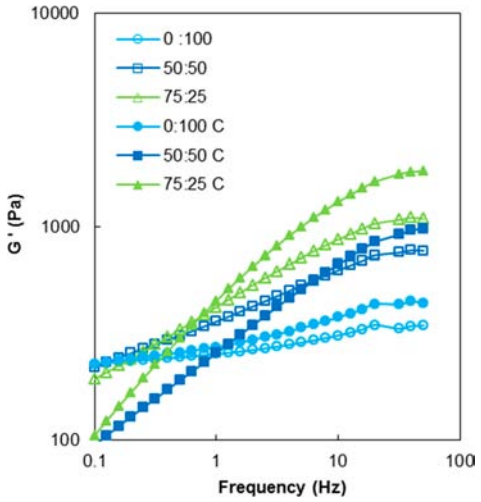

Figure 6. Frequency dependence of G' for model food gels with high molecular weight:low molecular weight (HMW:LMW) ratios of 0:100, 75:25, and 50:50.

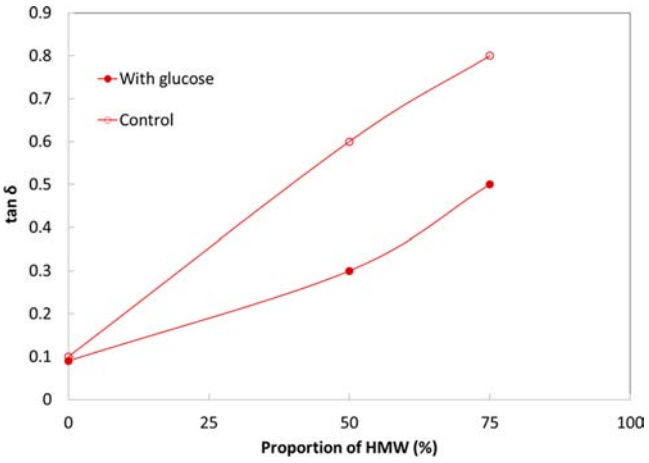

Figure 7. Tan delta at 1 Hz for model gels with high molecular weight:low molecular weight (HMW:LMW) ratios of 0:100, 50:50, and 75:25 with glucose and control gels without glucose.

δ values were slightly higher for gels without glucose, suggesting a contribution to elastic behavior by the glucose.

The hardness (N) at 40% compression and Young's modulus (E) were determined from the force displacement curves for the three model food gels and controls without glucose (Table 2). When no glucose was present, the firmness increased with increasing proportion of HMW β-glucan, and the hardness values were highest for the gel with 75% HMW. However, these trends were not observed when glucose was added to the gels, where no significant difference between hardness and firmness values was found, although the gel with 75% HMW gave the lowest hardness values. Added glucose competes for water, thereby slowing diffusion rates. Glucose may mitigate the effect of varying molecular weight by effectively increasing the concentration of β-glucan in solution and inhibiting the formation of junction zones. Additionally, these gels were less firm and required less force to compress than the similar gels prepared for the mixed molecular weight trial, perhaps reflecting the addition of a small amount of citric acid. For example, the firmness and hardness values for the 50:50 HMW:LMW gel at 4% were 5.1 and 2.7 N respectively,

Table 2. Young's Modulus and Hardness Measurements for Model Food Gels with and without Glucose

	Young's modulus[a]	hardness[a,b]
HMW:LMW[c] Ratio: Gels with Glucose		
0:100	0.86 ± 0.14 d	0.53 ± 0.10 d
50:50	0.79 ± 0.13 d	0.55 ± 0.12 d
75:25	0.88 ± 0.12 d	0.47 ± 0.10 ed
HMW:LMW Ratio Gels without Glucose (Control)		
0:100	0.51 ± 0.08 e	0.38 ± 0.04 e
50:50	0.54 ± 0.11 e	0.37 ± 0.10 e
75:25	0.82 ± 0.26 d	0.44 ± 0.12 ed

[a]Values are means ± SD. Values with different letters are significantly different ($p < 0.05$). [b]Hardness in Newtons at 40% compression (N). [c]High molecular weight:low molecular weight.

whereas for a gel prepared with the same composition but with the addition of citric acid and a small amount of flavoring, firmness and hardness values of 0.54 and 0.37 N were obtained. While the gels with citric acid gave much lower large deformation results than those without, the effects of the acid may have been mitigated by the addition of glucose as, overall, hardness and Young's modulus values were lower for the model food gels without glucose compared to gels with glucose.

3.3. Conclusions. Gel properties, as measured by small and large deformation measurements, varied with proportion of HMW or LMW β-glucan. The mix of 50% HMW and 50% LMW produced the hardest, but also the most elastic, gels. By mixing high and low molecular weight β-glucans together, the relative contribution by each type of molecule to gel structure and texture is exploited. The differences observed in gel texture based on proportion of HMW and LMW β-glucan are diminished by the incorporation of other components in the gel such as citric acid and glucose. Hence, by controll of β-glucan molecular weight and product formulations, gel properties can be controlled in order to achieve desired textural properties.

in the molecular weight, M/G ratio, MG sequence, and the entire molecular conformation of alginates seem to be responsible for their diversity of physicochemical properties and bioactivities.[16] It has been reported that unsaturated AOS promote the growth of bifidobacteria and induce the cytotoxic cytokines in human mononuclear cells and murine macrophage RAW264.7 cells, whereas the original alginate polymers or saturated AOS have no such effects.[18,19] Further study showed that unsaturated AOS improved the growth rate of *Chlamydomonas reinhardtii* and increased the levels of the fatty acids C16:0, C18:2 cis, and C18:3 n-3 but not saturated AOS.[12] Similar structure−activity relationship profiles were also found in the inducing effects of AOS on IL-1α, IL-1β, and IL-6 secretion from RAW264.7 cells, and the most potent activities in G8 and M7 oligomers were observed.[18] Moreover, the M/G ratio also seems to influence these activities, besides the molecular sizes.[20]

In the present study, we investigated the mechanisms of the immunomodulatory effects of alginate oligosaccharides on murine macrophage RAW264.7 cells and their structure−activity relationships from the following aspects: (1) the effect of several AOS, such as guluronate oligosaccharides and mannuronate oligosaccharides prepared by enzymatic degradation, acid hydrolysis and oxidative degradation, respectively, and also the effect of G2−G9 from GOS-ED on NO production in RAW264.7 cells; in addition, we investigated (2) the potent stimulatory effect of GOS-ED on RAW264.7 macrophages activation to induce the production of NO, ROS, and TNF-α and the activation of NF-κB and MAP kinase signaling pathways.

MATERIALS AND METHODS

Reagent. Sodium alginate (1000-cps grade) was purchased from Nuotai (Shanghai, China) and used without further purification. Bacterial alginate lyase from *Pseudoalteromonas* sp. strain no. 272 was prepared as described previously.[21] Trizol reagent was purchased from Invitrogen Co. (Carlsbad, CA). 2′, 7′-Dichlorofluorescein diacetate (DCF-DA) was from Beyotime Inst Biotech (Jiangsu, China). Pyrrolidine dithiocarbamate (PDTC) and NG-nitro-L-arginine methyl ester (L-NAME) were purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals were commercially available products with the highest grade.

Preparation of Alginate Oligosaccharides (AOS). Polyguluronate (PG) and polymannuronate PM (DP = 20−24) were prepared from sodium alginate as described previously.[22] The homogeneity of the prepared polyuronates was confirmed by the analysis of circular dichroic (CD) spectrum using a Jasco spectropolarimeter J-815 based on the method of Morris et al.[23] The chemical structures of PG and PM were analyzed by the infrared (IR) spectra with Bruker Vertex 70 according to the method of Linker et al.[24]

PG and PM were digested with bacterial alginate lyase[21] to produce GOS-ED and MOS-ED, which have an unsaturated terminal structure with a double bond. GOS-AH and MOS-AH, which lack the unsaturated terminal structure with a double bond, were prepared from PG and PM by the acid hydrolysis method.[12] To prepare GOS-OD and MOS-OD, which have a carboxyl group at the 1-position of the reducing end, PG and PM were incubated with 5% H_2O_2 solutions at a final concentration of 8% at 90 °C for 2 h. Before use, all alginate samples were filtered through an endotoxin-removing filter (0.22 μm) (Millipore Co., Billerica, MA). The schematic representations of chemical structures of AOS using three different preparation ways were shown in Figure 1.

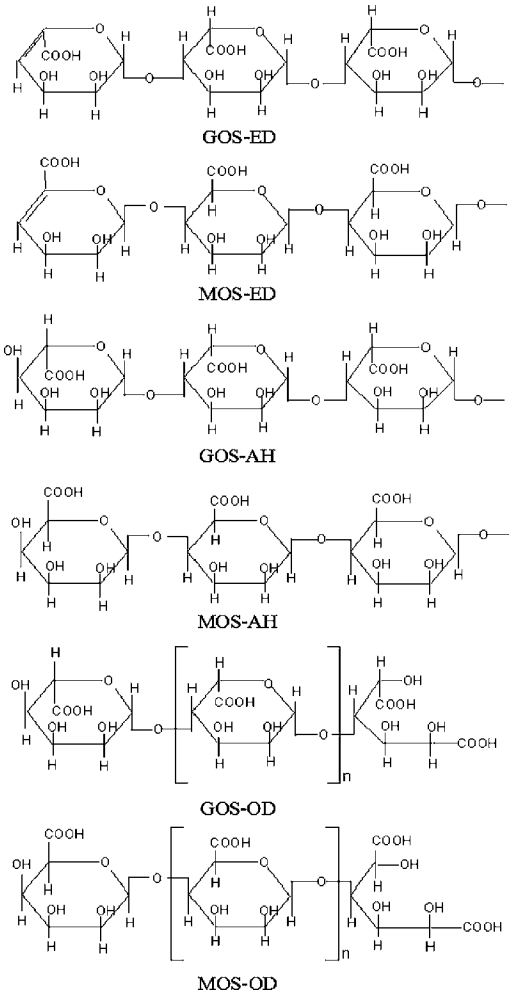

Figure 1. Schematic representation of chemical structures of guluronate and mannuronate oligosaccharides (enzymatic degradation—acid hydrolysis and oxidative degradation) used in this study.

TLC Analysis. Thin-layer chromatography (TLC) analysis was used to analyze the size and the DP of each AOS. The reaction product mixtures were loaded onto a precoated Silica Gel 60 TLC aluminum plate (2.5 cm × 7.0 cm, Merck, Germany) and developed with a solvent system consisting of *n*-butanol/formic acid/water (2:2:1 or 6:6:1, v/v/v). The developed plate was stained by dipping in a diphenylamine−aniline−phosphoric acid reagent (1 mL of 37.5% HCl, 2 mL of aniline, 10 mL of 85% H_3PO_4, 100 mL of ethyl acetate, and 2 g of diphenylamine) at RT for 3 s and then heated at 100 °C for 10 s.

Isolation and Purification of GOS-ED. The isolation and purification of each oligosaccharide derived from GOS-ED were conducted by a P-6 Bio Gel chromatography (Bio-Rad Labs, Richmond, CA) (2.6 × 100 cm) as described previously.[21] The phosphate in each fraction was removed by gel-filtration chromatography equipped with a P-2 Bio Gel (Bio-Rad Labs, Richmond, CA) (1.6 × 60 cm).

Cell Culture. Murine macrophage RAW264.7 cells, purchased from Shanghai Inst of Biochem and Cell Biol (Shanghai, China), were cultured at 37 °C in RPMI-1640 medium supplemented with 10% FBS, 100 IU/ml penicillin, and 100 μg/mL streptomycin in humidified atmosphere with 5% CO_2.

dx.doi.org/10.1021/jf405633n | J. Agric. Food Chem. 2014, 62, 3168−3176

Cytotoxicity. The cytotoxic effects of saccharide samples were assessed by measuring cell viability using a tetrazolium salt (WST-8)-based colorimetric assay in the Cell Counting Kit-8 (Dojindo, Kumamoto, Japan).[25]

NO Assay. To estimate NO level in RAW264.7 cells, nitrite, a stable reaction product of NO with molecular oxygen, was measured by Griess assay as described previously.[10] Briefly, adherent RAW264.7 cells in 96-well plates (2×10^5 cells/well) were treated with saccharide samples at the concentration of 1 mg/mL in the growth medium at 37 °C. After 24 h of treatment, 50 μL of each cultured supernatant was collected and mixed with 100 μL of Griess reagent.[10] After 10 min of incubation at RT, the optical density was measured at 540 nm using a Spectra Max microplate reader (Molecular Devices, LLC, Sunnyvale, CA). A calibration curve was made with a known concentration of $NaNO_2$ standard solution. For the time-course analysis of NO production, RAW264.7 cells were treated with tested samples at the concentration of 1 mg/mL in the growth medium at 37 °C, and nitrite levels in each cultured supernatant were measured at 3, 6, 12 and 24 h, respectively. For the concentration-dependent analysis of NO production, RAW264.7 cells were treated with varying concentrations of tested samples (0−1 mg/mL) for 24 h in the growth medium at 37 °C, and then the nitrite levels in each well were measured. LPS (1 μg/mL), which can significantly induce NO production in RAW264.7 cells, was used as positive control.

RNA Isolation, cDNA Synthesis, and RT-PCR for iNOS mRNA. Total cellular RNA was extracted from treated cells with Trizol reagent ($RNA_{fast200}$, Fastagen, China). Total RNA (1 μg) was reverse transcribed with an oligo dT primer in a 10 μL using PrimeScript first strand cDNA Synthesis Kit (TaKaRa Biotechnology Co., Ltd., Dalian, China) according to the manufacturer's instruction. PCR was performed with 1 cycle of 3 min at 95 °C, 25 cycles of 55 s at 93 °C, 45 s at 60 °C, 40 s at 72 °C and 1 cycle of 100 s at 72 °C, in a 50 μL reaction mixture containing 25 μL of Premix Taq (TaKaRa Biotechnology Co., Ltd., Dalian, China), 1 μL of forward and reverse inducible nitric oxide synthase (iNOS) primers (20 μM each) or β-actin primers (20 μM each), 5 μL of first strand cDNA, and 18 μL of nuclease-free water. The primer sequences used were 5′-CAACCAGTATTATGGCTCCT-3′ (forward) and 5′-GTGACAGCCCGGTCTTTCCA-3′ (reverse) for mouse iNOS and 5′-GGAGAAGATCTGGCACCACACC-3′ (forward) and 5′-CCTGCTTGCTGATCCACATCTGCTGG-3′ (reverse) for mouse β-actin.[10] The β-actin primer was used as an internal control. Each PCR reaction (6 μL) product was run on 1% agarose gels containing 0.1 μg/mL ethidium bromide, and the amplified products (845 bp for iNOS, 850 bp for β-actin) were observed by an G: BOX Syngene imaging system (Gene Company Ltd., Hong Kong).

Western Blot Analysis. After different treatments, cells (3×10^6 cells) were lysed in radio immunoprecipitation assay lysis buffer (Biocolors, Shanghai, China) at 4 °C for 30 min. Cell lysates (30 μg of protein for each sample) were separated by 8% SDS-polyacrylamide gel electrophoresis (SDS-PAGE), transferred onto a polyvinylidene difluoride (PVDF) membrane (Amersham Pharmacia Biotech., England, U.K.), blocked with 5% skim milk, and hybridized with antimouse iNOS antibody (dilution, 1:1,000) (Cell Signaling Technology, Inc., Beverly, MA). After incubation with a horseradish-peroxidase-conjugated secondary antibody at RT, immune-reactive proteins were detected by using a chemiluminescent ECL assay kit (Amersham Pharmacia Biosciences, England, U.K.) according to the manufacturer's instructions. Western blot bands were visualized using a LAS3000 Luminescent image analyzer (Fujifilm Life Science, Tokyo, Japan).

The analyses of IκB-α and phospho-IκB-α in cytosolic extracts and NF-κB p65 in nuclear extracts were performed. Adherent RAW264.7 cells (4×10^6 cells) were incubated with 1 mg/mL of saccharides at 37 °C for 1 h. Thereafter, the cells were washed three times with ice-cold PBS and incubated with 100 μL ice-cold cytosol extraction buffer (10 mM HEPES, pH 7.9, 1.5 mM $MgCl_2$, 10 mM KCl, 0.2% Igepal CA-630, 1 mM dithiothreitol, 20 mM β-glycerophosphate, 1 mM sodium orthoranadate, 0.5 mM phenylmethysulfonyl fluoride, 1 μg/mL leupeptin, and 1 μg/mL aprotinin) for 25 min on ice. The cytosolic extracts were collected after centrifugation at 7000*g* for 5 min at 4 °C. The nuclear pellets were resuspended in 30 μL of ice-cold nuclear extraction buffer (20 mM HEPES, pH 7.9, 1.5 mM $MgCl_2$, 0.45 M NaCl, 25% glycerol, 0.2 mM EDTA, 1 mM dithiothreitol, 0.5 mM phenylmethysulfonyl fluoride, 1 μg/mL leupeptin, and 1 μg/mL aprotinin) and incubated on ice for 25 min. The nuclear extracts were then obtained after centrifugation at 15 000*g* for 10 min at 4 °C. After protein quantitation, the nuclear and cytosolic extracts were separated by 12.5% SDS-PAGE. The Western blot analysis was conducted similar to the method described above with anti-NF-κB p65, anti-IκB-α, and antiphospho-IκB-α antibodies (Cell Signaling Technology, Inc., Beverly, MA).

For the analysis of MAP kinases, adherent RAW264.7 cells (3×10^6 cells) were treated with 1 mg/mL of each saccharide in the serum-free medium at 37 °C for 10 min. The whole-cell lysates were prepared from the treated cells. Samples containing 30 μg of proteins were subjected to SDS-PAGE in 12.5% polyacrylamide gel, and Western blot analysis using appropriate antibodies against phosphorylated and nonphosphorylated p38, JNK, and ERK MAP kinases (Cell Signaling Technology, Beverley, MA) were carried out as described above.

Intracellular ROS Measurement. The fluorescent probe DCF-DA was used to measure intracellular accumulation of ROS as described previously.[26] For this purpose, DCFH-DA solution (10 μM) was added to the suspension of each saccharide-treated cells (5×10^5 cells/ml), and the mixture was incubated at 37 °C for 20 min. Cells were then washed three times with PBS by centrifugation (1500*g*), and finally the fluorescence intensity of cell suspension was measured by the fluorescence activated cell sorting (FACS) system (Becton Deckinson, San Jose, CA) with excitation and emission wavelengths of 488 and 525 nm, respectively.

Cytokine Measurement. Adherent RAW264.7 cells in 96-well plates (2×10^5 cells/well) were treated with saccharides at the concentration of 1 mg/mL for 24 h in the growth medium at 37 °C. The levels of TNF-α in the culture medium were measured using a mouse TNF-α quantikine ELISA kit (R&D Systems, Inc., Minneapolis, MN), following the manufacturer's instructions.

Statistical Analysis. All of the experiments were repeated at least three times. The data are expressed as the means ± standard deviation (SD) and analyzed using a *t*-test or one-way ANOVA to determine any significant differences. A value of $p < 0.05$ was considered statistically significant.

RESULTS

Preparation and Structure Analysis of AOS. The CD analysis showed a high homogeneity of polyguluronate (PG) and polymannuronate (PM) (data not shown). The IR spectra

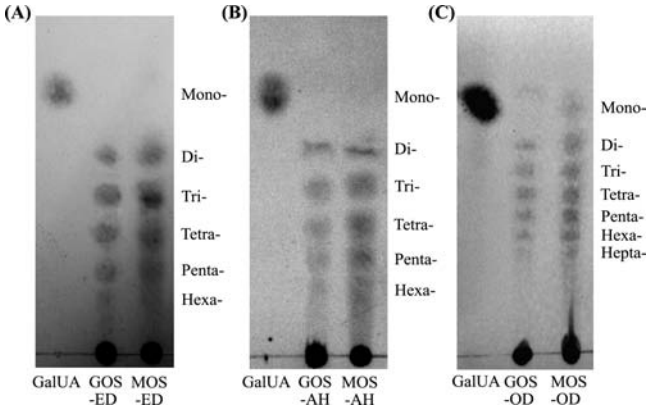

Figure 2. TLC of AOS prepared by different ways. The oligosaccharide solutions (25 mg/mL, 0.5 μL of each) were loaded onto a precoated Silica Gel 60 TLC aluminum plate and developed with a solvent system consisting of *n*-butanol/formic acid/water (2:2:1 or 6:6:1, v/v/v). The developed plate was stained by dipping in diphenylamine−aniline−phosphoric acid reagent (1 mL of 37.5% HCl, 2 mL of aniline, 10 mL of 85% H_3PO_4, 100 mL of ethyl acetate, and 2 g of diphenylamine) for 3 s and heated at 100 °C for 10 s. The average DP of GOS-ED and MOS-ED (A), GOS-AH and MOS-AH (B), and GOS-OD and MOS-OD (C) was measured using TLC analysis.

of PG and PM are very similar, but they show differences in the absorption peaks at 789 cm^{-1} and 821 cm^{-1}, indicating the unique distinction of PG and PM (data not shown).

The average DP of all kinds of AOS was measured by TLC analysis. As shown in Figure 2A−C, in all lanes, the spots corresponding to the oligosaccharides having 2−7 saccharide units were detected, whereas the spots at the origin corresponding to polysaccharides and oligosaccharides with >16 saccharide units were the most intense, indicating that AOS with average DP of 5 were obtained by three preparation ways used in this study.

GOS-ED Induces NO Production in RAW264.7 Cells. None of alginate polysaccharides (PG and PM) or AOS (-ED, -AH, and -OD) showed cytotoxic effects on RAW264.7 cells even up to a concentration of 1 mg/mL in WST-8 assay (data not shown). Hence, it is considered that any observed changes on NO production in RAW264.7 cells or related events in the following studies are not due to the cytotoxicity of alginate-derived saccharides.

Next, we investigated NO production induced by PG, PM, and AOS (GOS-ED, -AH, -OD and MOS-ED, -AH, -OD) in RAW264.7 cells. As shown in Figure 3A, only GOS-ED significantly enhanced NO production within all tested alginate polysaccharides and oligosaccharides, whereas all other saccharides showed no significant activity. Furthermore, GOS-ED-induced NO production in a time- and concentration-dependent manner, and the nitrite level reached the maximum in RAW264.7 cells treated with 1 mg/mL of GOS-ED for 24 h (Figure 3B,C).

To further analyze the structure−activity relationship of GOS-ED, the enzymatically digested PG was applied to a column Bio Gel P-6. The elution profile shown in Figure 4A

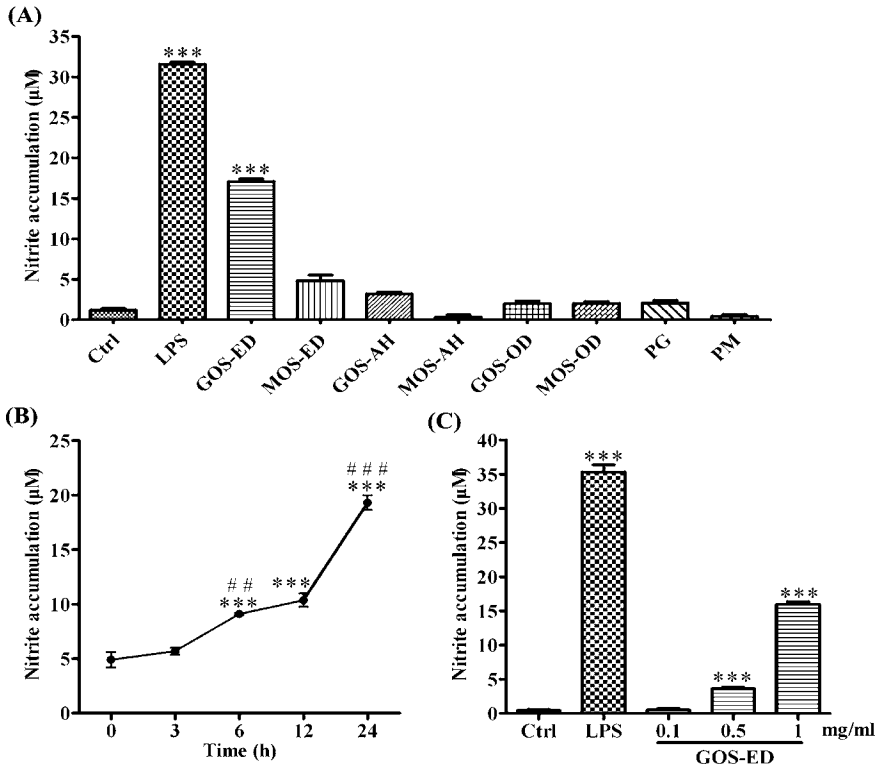

Figure 3. Effects of GOS (-ED, -AH, -OD), MOS (-ED, -AH, -OD), PG, and PM on NO production in RAW264.7 cells. Adherent RAW264.7 cells (2×10^5 cells/well) were cultured in 96-well plates. (A) RAW264.7 cells were incubated with 1 mg/mL of GOS (-ED, -AH, -OD), MOS (-ED, -AH, -OD), PG, and PM at 37 °C in the growth medium, respectively. After 24 h, the nitrite levels in the culture medium were measured by Griess assay, as described in Methods. (B) RAW264.7 cells were incubated with 1 mg/mL of GOS-ED for 3, 6, 12, and 24 h. After that, the nitrite levels in the culture medium were measured. (C) RAW264.7 cells were incubated with GOS-ED in different concentrations (0.1, 0.5, and 1 mg/mL). After 24 h, the nitrite levels in the culture medium were measured. LPS (1 μg/mL) was used as a positive control. Each value represents mean ± SD of triplicate measurements. * indicates significant differences between various time groups and 0 time group, * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$, respectively. # indicates significant differences between time groups and previous time group, ## $p < 0.01$ and ### $p < 0.001$, respectively.

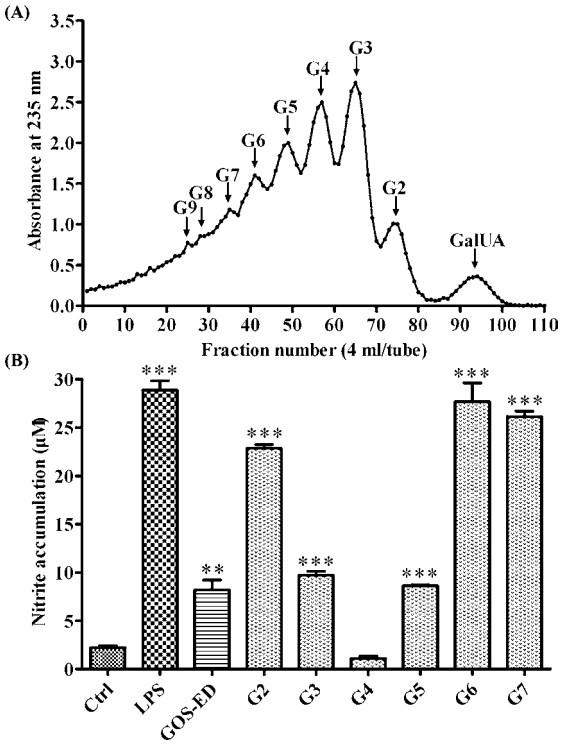

Figure 4. Effects of guluronate dimer to heptamer (G2−G7) on NO production in RAW264.7 cells. (A) GOS-ED solution (3 mL, 50 mg/mL in distilled water) was put on a column of Bio Gel P-6 equilibrated with 50 mM phosphate buffer, pH 6.5. Eluates were examined for absorbance at 235 nm. Gal UA: monomer; G2−G9: guluronate dimer-nonamer. (B) RAW264.7 cells were incubated with 0.5 mg/mL of GOS-ED and G2−G7, respectively. After 24 h, the nitrite levels in culture medium were measured. LPS (1 μg/mL) was used as a positive control. Each value represents mean ± SD of triplicate measurements.

indicated that GOS-ED was a mixture of oligomers from dimer to nonamer (G2−G9), and the fractions from G2 to G9 were obtained as relatively purified fractions. As shown in Figure 4B, purified G2, G6, and G7 fractions showed even higher activity than GOS-ED, and the highest activity was observed in G6 fraction. Meanwhile, G3 and G5 fractions showed nearly equal activity to GOS-ED, although the G4 fraction had almost no activity. The other notable founding was that G8 and G9 fractions were detected as precipitation with Griess reagent, so they were not suitable for this analysis.

GOS-ED Induces iNOS Expression in RAW264.7 Cells. As we have known, NO is produced by the activation of iNOS from L-arginine in macrophages.[27] As shown in Figure 5A−C, GOS-ED significantly induced iNOS mRNA expression in RAW264.7 cells in a time- and concentration-dependent manner. Consistent with mRNA expression, iNOS protein expression was also detected in GOS-ED-treated RAW264.7 cells (Figure 5D). In addition to GOS-ED, MOS-ED also induced iNOS mRNA and protein expression, although the expression was very low and even trace levels (Figure 5A,D). Furthermore, NO production by GOS-ED-treated RAW264.7 cells was significantly suppressed by L-NAME, a NOS inhibitor (Figure 5E).

GOS-ED Induces ROS Production in RAW264.7 Cells. As shown in Figure 6A, the intensity of the DCF fluorescence was significantly increased in GOS-ED-stimulated RAW264.7 cells compared to control cells, indicating that GOS-ED enhanced intracellular ROS production. In contrast, other saccharides including GOS (-AH, -OD), MOS (-ED, -AH, -OD), and original polymers (PG/PM) showed no statistical effect on ROS production. As shown in Figure 6B, a similar tendency was observed with the effects of G2−G9 on NO production. The purified G2, G3, and G6−G9 fractions showed higher ROS-inducing activity than GOS-ED, and the highest activity was observed in the G9 fraction. Meanwhile, the G5 fraction showed

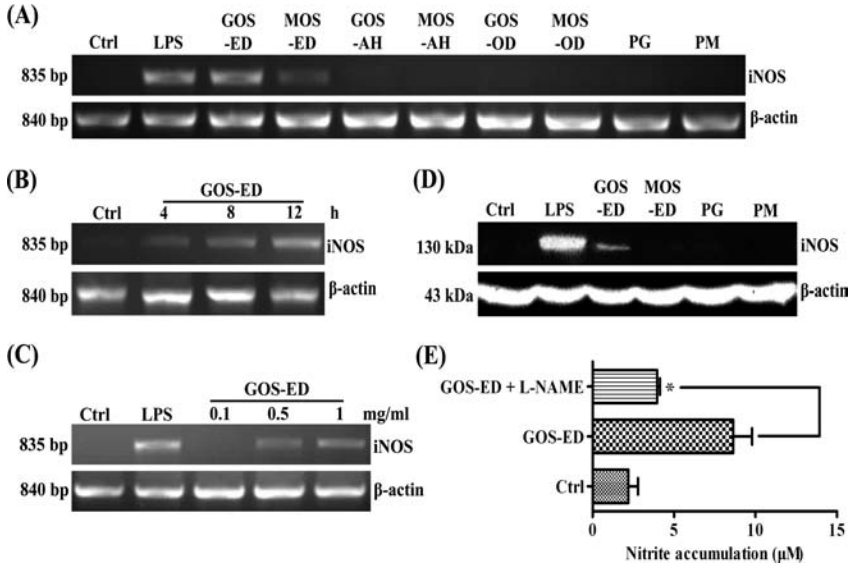

Figure 5. Effects of GOS (-ED, -AH, -OD), MOS (-ED, -AH, -OD), PG, and PM on iNOS expression in RAW264.7 cells. (A) Adherent RAW264.7 cells (2×10^6 cells/well in 6-well plates) were incubated with 1 mg/mL of GOS (-ED, -AH, -OD), MOS (-ED, -AH, -OD), PG, and PM at 37 °C in the culture medium, respectively. After 12 h of incubation, iNOS gene levels in RAW264.7 cells were analyzed by RT-PCR. (B) iNOS gene expression after 4, 8, and 12 h of stimulation with 1 mg/mL of GOS-ED was measured. (C) iNOS gene expression after 12 h stimulation with various doses (0.1, 0.5, and 1 mg/mL) of GOS-ED was measured. (D) Adherent RAW264.7 cells (2×10^6 cells/well in 6-well plates) were incubated with 1 mg/mL of GOS-ED, MOS-ED, PG, and PM at 37 °C, respectively. After 24 h of incubation, the whole-cell lysates were prepared from the treated cells and analyzed by Western blot analysis. (E) Adherent RAW264.7 cells were incubated with 1 mg/mL of GOS-ED for 24 h by the addition of the NOS inhibitor L-NAME (100 μM). The nitrite levels in the culture medium from the treated cells were measured by Griess assay. Each value represents mean ± SD of triplicate measurements. The * is representative of $p < 0.05$, when compared to control group.

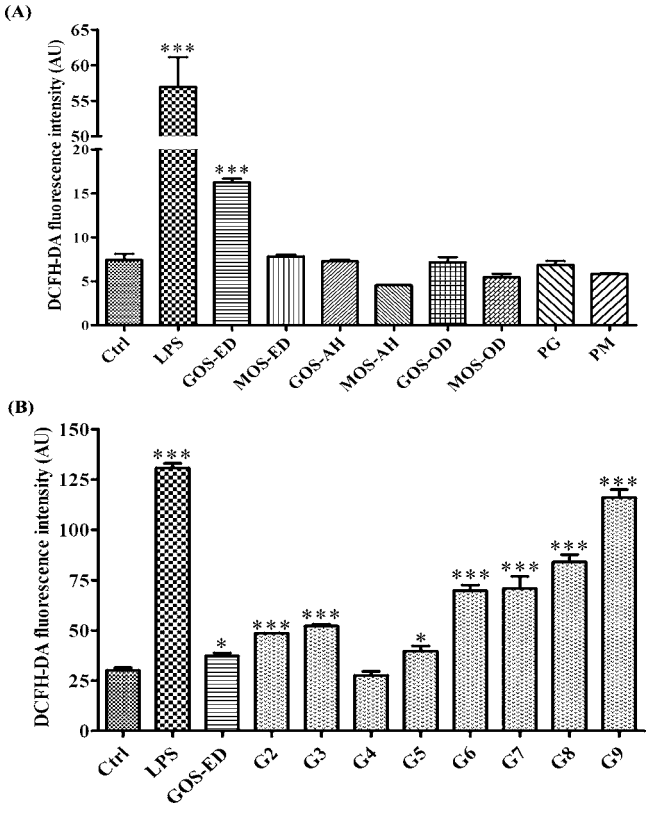

Figure 6. Effects of alginate oligosaccharides and polysaccharides on ROS production in RAW264.7 cells. (A) Adherent RAW264.7 cells (5×10^5 cells/well in 24-well plates) were incubated with 1 mg/mL of GOS (-ED, -AH, -OD), MOS (-ED, -AH, -OD), PG, and PM at 37 °C, respectively. After 24 h, intracellular ROS were measured by flow cytometry utilizing an oxidation-sensitive fluorescent probe, DCFH-DA. LPS (1 μg/mL) was used as a positive control. (B) Adherent RAW264.7 cells were incubated with 0.5 mg/mL of GOS-ED and G2−G9, respectively. After 24 h, intracellular ROS were measured. LPS (1 μg/mL) was used as a positive control. Each value represents mean ± SD of triplicate measurements. The * is representative of $p < 0.05$ and *** is representative of $p < 0.001$, when compared to the control group.

this activity nearly equal to that of the GOS-ED, whereas the G4 fraction had almost no activity.

GOS-ED Induces TNF-α Secretion in RAW264.7 Cells. As displayed in Figure 7, the levels of TNF-α secretion in the culture medium from GOS-ED- and MOS-ED-treated RAW264.7 cells were elevated in a concentration-dependent manner. A significant level of TNF-α secretion was capable to be detected at 0.1 mg/mL of GOS-ED and MOS-ED, and further increased levels were detected at 0.5 and 1 mg/mL of GOS-ED and MOS-ED. Meanwhile, the slightly stronger TNF-α-inducing activity of GOS-ED than MOS-ED was observed. On the contrary, PG or PM before depolymerization had much lower effect than oligomers on TNF-α secretion.

GOS-ED Activates the NF-κB signaling Pathway in RAW264.7 Cells. As shown in Figure 8A, the nuclear level of NF-κB p65 protein increased in GOS-ED- and MOS-ED-treated RAW264.7 cells with a greater extent than those induced by PG and PM. In addition, GOS-ED and MOS-ED, but not PG or PM, also induced both the phosphorylation and degradation of IκB-α. As the results indicated, GOS-ED and MOS-ED could induce the NF-κB activation in RAW264.7 cells. To test the potential involvement of the NF-κB activation

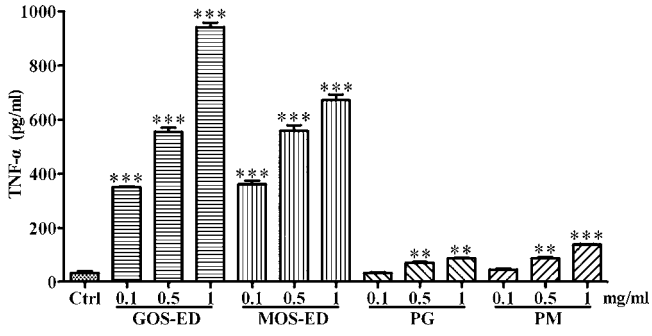

Figure 7. Effects of GOS-ED, MOS-ED, PG, and PM on TNF-α secretion in RAW264.7 cells. Adherent RAW264.7 cells (2×10^5 cells/well in 96-well plates) were incubated with various concentrations (0.1, 0.5, and 1 mg/mL) of GOS-ED, MOS-ED, PG, and PM at 37 °C, respectively. After 24 h of incubation, the TNF-α levels in the culture medium were measured by ELISA. Each value represents mean ± SD of triplicate measurements.

in GOS-ED-induced production of NO, ROS, and TNF-α, we used a NF-κB inhibitor PDTC to block the NF-κB signaling pathway. Our results demonstrated that PDTC significantly inhibited the productions of NO (Figure 8B), ROS (Figure 8C), and TNF-α (Figure 8D) in GOS-ED-treated cells, suggesting that GOS-ED-induced NO, ROS, and TNF-α production in RAW264.7 cells were partly mediated through the NF-κB signaling pathway.

GOS-ED Activates the MAP Kinase Signaling Pathway in RAW264.7 Cells. To further investigate the involvement of MAP kinase signaling pathway in immunomodulatory effects of enzymatically degraded alginate oligosaccharides and polysaccharides, RAW264.7 cells were treated with each saccharide and the levels of phosphorylated and nonphosphorylated ERK, p38, and JNK MAP kinases were analyzed by Western blot. As shown in Figure 9, a significant increase in the phosphorylation levels of ERK, p38, and JNK MAP kinases were observed in GOS-ED-treated RAW264.7 cells, whereas the phosphorylation levels of these three MAP kinases induced by MOS-ED were evidently lower than that induced by GOS-ED.

DISCUSSION

Many polysaccharides isolated from seaweeds have been recently reported to induce immune activation as molecules target to immune cells in a host immune system, such as macrophages, lymphocytes, and natural killer cells, and stimulate cytokines release and other immune responses.[28] Alginate, currently used widely in commercial enterprises, has been known to induce cytokine production *via* NF-κB signaling pathway from murine macrophage RAW264.7 cells[29] and exert antitumor activities against Sarcoma-180 solid tumor transplanted in mice without toxicity *via* the activation of the host immune system.[30] Although the properties of alginate have been widely investigated, the actual application of alginate polymers into *in vivo* system is limited due to the higher molecular weight. It is likely that the depolymerization of polymers is one possible way to overcome this drawback of alginate.[18] Our previous studies have reported that AOS-ED could stimulate RAW264.7 macrophages to produce cytokines[14] and induce multiple immunocompetent cytokines in mice *via* intraperitoneal injection,[31] suggesting that AOS-ED were potentially capable of stimulating macrophages and the host immune system activation, but the detailed mechanisms and the structure−activity relationships are unclear so

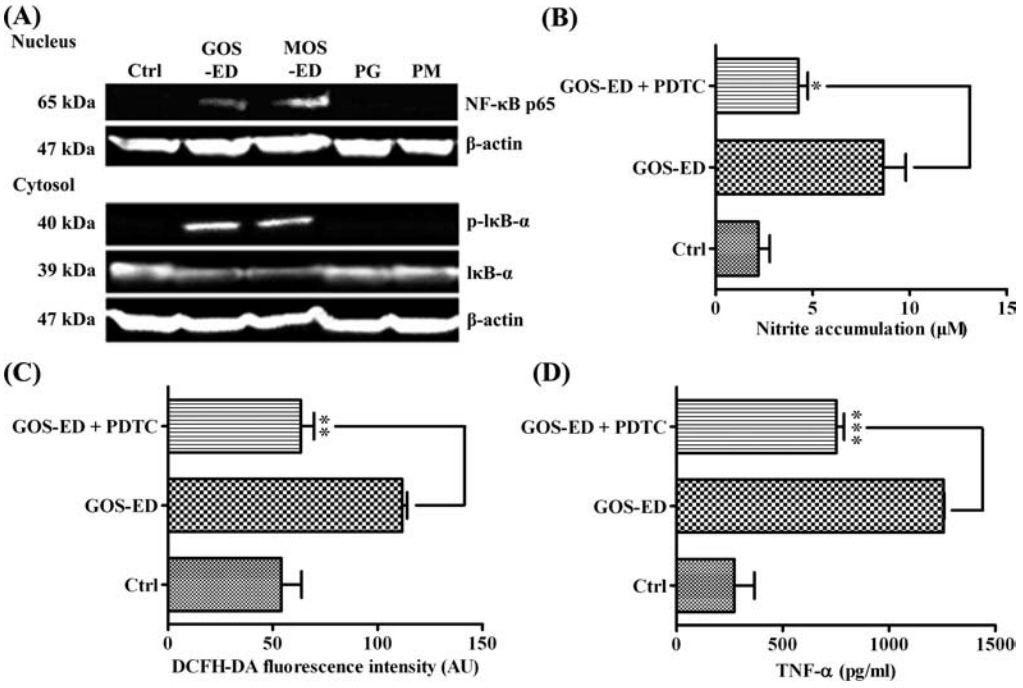

Figure 8. Effects of GOS-ED, MOS-ED, PG, and PM on the activation of NF-κB signaling pathway in RAW264.7 cells and the involvement of NF-κB in GOS-ED-induced NO, ROS, and TNF-α production. (A) RAW264.7 cells were treated with 1 mg/mL of GOS-ED, MOS-ED, PG, and PM, respectively. Afterward, Western blot analysis was conducted to detect the expression of NF-κB p65 in the nuclear extracts and the expression of IκB-α and phosphorylated IκB-α in the cytosolic extracts. (B) Adherent RAW264.7 cells were incubated with 1 mg/mL of GOS-ED for 24 h by the addition of the NF-κB signaling pathway inhibitor PDTC (50 μM). The nitrite levels in the culture medium from the treated cells were measured by Griess assay. (C) Adherent RAW264.7 cells were incubated with 1 mg/mL of GOS-ED for 24 h by the addition of the NF-κB signaling pathway inhibitor PDTC (50 μM). Intracellular ROS were measured by a FACS analysis. (D) Adherent RAW264.7 cells were incubated with 1 mg/mL of GOS-ED for 24 h by the addition of the NF-κB signaling pathway inhibitor PDTC (50 μM). The TNF-α levels in the culture medium of the treated cells were measured by ELISA. Each value represents mean ± SD of triplicate measurements. The *, **, and *** are representative of $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively, when compared to control group.

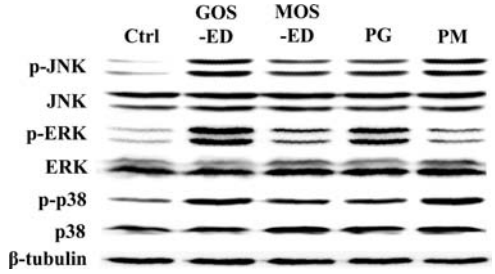

Figure 9. Effects of GOS-ED, MOS-ED, PG, and PM on the activation of MAP kinases in RAW264.7 cells. Adherent RAW264.7 cells (3×10^6 cells/3.5 cm dishes) were incubated in serum-free medium with 1 mg/mL of GOS-ED, MOS-ED, PG, and PM, respectively. The whole-cell lysates were prepared from the treated cells, and the levels of both phosphorylated and nonphosphorylated MAP kinases were analyzed by Western blot.

far. Here, we prepared GOS-ED, -AH, -OD and MOS-ED, -AH, -OD using three different depolymerized ways to compare their macrophage-activating activities and provided key insights into potential mechanisms.

Macrophages play important roles in host defense systems, and activated macrophages can kill tumor cells and pathogens either by direct contact or by releasing diffusible cytotoxic molecules, such as NO, ROS, and TNF-α.[32] As we have known, NO plays a critical role in host defense during pathogen infection and tissue damage during autoimmune responses.[33] The expression of iNOS is responsible for NO production in activated macrophages.[34] In the present study, our results revealed that GOS-ED showed significant NO-inducing activity in RAW264.7 cells in a time- and concentration-dependent manner, and this activity of GOS-ED was much higher than other oligosaccharides (GOS-AH, -OD and MOS-ED, -AH, -OD) and original polysaccharides (PG and PM). Consistent with this finding, significantly increased iNOS gene and protein expression levels were observed in GOS-ED-treated RAW264.7 cells in a time- and concentration-dependent manner, whereas MOS-ED only slightly induced iNOS gene expression. Other oligosaccharides (GOS-AH, -OD and MOS-AH, -OD) and polysaccharides (PG and PM) showed no such effects on the expression of iNOS gene and protein (Figure 5A–D). Because L-NAME, a NOS inhibitor, significantly inhibited GOS-ED-induced NO production in RAW264.7 cells (Figure 5E), GOS-ED is considered to be a potent macrophage activator capable of inducing NO production through the induction of iNOS expression. Next, the ROS and TNF-α production induced by these saccharides on RAW264.7 cells was evaluated. Our results indicated that GOS-ED significantly stimulated ROS production in RAW264.7 cells, but no significant effect was observed in other tested saccharides (Figure 6). Interestingly, contrary to the NO- and ROS-inducing activities, both kinds of AOS-ED (GOS-ED and MOS-ED), but not polysaccharides (PG and PM), significantly induced TNF-α secretion in RAW264.7 cells in a concentration-dependent manner, even though MOS-ED evidently showed lower activity than GOS-ED (Figure 7). These findings further support the notion that GOS-ED is a potent macrophage activator.

dx.doi.org/10.1021/jf405633n | J. Agric. Food Chem. 2014, 62, 3168–3176

NF-κB regulates many important biological and pathological processes in cells, and it is also a key to modulate various gene expressions involved in immune and inflammatory responses, including the production of NO, ROS, and TNF-α in macrophages.[35] In our present studies, it was found that GOS-ED showed much higher RAW264.7 macrophage-stimulating activity than other saccharides derived from alginate. Meanwhile, MOS-ED exhibited less activity on macrophage activation than GOS-ED, but the activity was higher than other saccharides, especially the induction of TNF-α production. Although alginate has been reported to stimulate RAW264.7 cells activation to release immune cytokines *via* the NF-κB signaling pathway, there has been no available information on the precise action mechanisms of AOS-ED on macrophage-stimulating activity so far. Our results showed that the NF-κB signaling pathway was potently activated in GOS-ED- and MOS-ED-treated RAW264.7 cells, whereas the activation levels in PG- or PM-treated cells were hardly distinguishable from the unstimulated control level (Figure 8A). Interestingly, the activation level of NF-κB in MOS-ED-treated RAW264.7 cells seems to be higher than that of GOS-ED-treated cells (Figure 8A). As we have known, the MAP kinase signaling pathway plays an important role in NO, ROS, and TNF-α production in activated macrophages. Our previous report showed that AOS-ED were capable of activating JNK and p38 MAP kinases involved signaling pathway leading to TNF-α secretion from RAW264.7 cells.[20] Considering the differences between GOS-ED and MOS-ED in macrophage-stimulating activities and the NF-κB-activated effects, it is speculated that the MAP kinase signaling pathway involved in GOS-ED- and MOS-ED-induced macrophage activation might be different. Our results showed that ERK, p38, and JNK MAP kinase signaling pathways were potently activated in GOS-ED-treated RAW264.7 cells, whereas the activation levels of these MAP kinases in MOS-ED-treated cells were quite low compared to the levels of unstimulated control (Figure 9), considering NO, ROS, and TNF-α production and NF-κB signaling pathway activation, suggesting that the underlying mechanisms of macrophage activation activity were different between GOS-ED and MOS-ED. To determine the possible involvement of NF-κB signaling pathway in the induction of NO, ROS, and TNF-α production by GOS-ED, NF-κB inhibitor PDTC was used to block the NF-κB activation. Our results showed that significantly inhibitory effects of PDTC on GOS-ED-inducing NO, ROS, and TNF-α production were observed (Figure 8B−D), further demonstrating that the NF-κB signaling pathway is responsible for the production of NO, ROS, and TNF-α in GOS-ED-treated RAW264.7 cells. The results obtained in this study may provide valuable basic information to the mechanisms of AOS-induced macrophage activation, especially in terms of NO, ROS, and TNF-α production in RAW264.7 cells.

It has been reported that enzymatically depolymerized alginate oligomers were capable to enhance the growth of bifidobacteria,[36] plant roots,[21] and green alga.[12,37] Our previous reports revealed that unsaturated AOS-ED were highly active inducers for cytokine production in RAW264.7 cells, whereas saturated AOS-AH showed smaller effects.[18] It seems that unsaturated terminal structure with double bonds of alginate oligomers play important roles in their biological activities, including inducing cytokines production. In fact, we presented an idea that the biological activities of AOS are strongly influenced by their molecular size, M/G composition, and the entire molecular conformation.[16] This study revealed that GOS-ED and MOS-ED showed much higher activities on the induction of NO, ROS, and TNF-α production in RAW264.7 cells than other AOS (GOS-AH, -OD, and MOS-AH, -OD) and polysaccharides (PG and PM), and these effects induced by GOS-ED were evidently greater than those of MOS-ED (Figures 3A, 6, and 7). These findings provided valuable evidence to the idea that unsaturated end structure and the composition (M/G ratio) were important structural elements for their biological activities. Previous structural studies have proposed that mannuronate and guluronate adopt different chair conformations; mannuronate block predominately forms an extended ribbon structure, whereas guluronate block forms a buckled chain.[18] Moreover, the highest NO-inducing activity among unsaturated G2−G7 fractions was found in G6 and G7 fractions (Figure 4B), which suggested that G6 and G7 oligomers were the most effective structure or molecular size in the specific activities. Interestingly, the smaller oligomer G2 also showed relatively high cytokine-inducing activities. The reason for this is uncertain now, but the finding may provide a clue to understand the recognition site or mechanism on RAW264.7 cells by alginate oligomers.

In conclusion, these results first revealed that AOS-ED but not AOS-AH, AOS-OD, or polysaccharides activated the NF-κB and MAPK signaling pathways, resulting in significant induction of NO, ROS, and TNF-α production. Our findings suggested that the structural characteristics of AOS, especially the unsaturated terminal structure, molecular size, and M/G ratio, are important in RAW264.7 macrophage activation. On the basis of these findings, it is worthwhile to develop GOS-ED as a promising agent used to regulate immune responses and vascular relaxation in functional foods and pharmacological fields.

peptides interact with tight junctions or epithelial cells.[20−23] Unfortunately, the interaction between food-derived substance and epithelium is still obscure.

Gln-Ile-Gly-Leu-Phe (QIGLF) was an ACE-inhibitory peptide, with an IC_{50} value of 75 μM, identified from egg white ovalbumin. The result of simulated gastrointestinal digestion by pepsin and trypsin showed that QIGLF had a strong resistance to gastrointestinal proteases, providing a possibility for oral administration.[8] However, the bioavailability and permeability through intestinal epithelium have not been studied. Therefore, the objective of the present study was to investigate the transport of QIGLF in human intestinal Caco-2 cell monolayers. Furthermore, the effect of QIGLF on the viability of Caco-2 cells in oxidative stress induced by H_2O_2 was evaluated.

MATERIALS AND METHODS

Materials. Caco-2 cell lines were purchased from American Type Culture Collection. The ACE-inhibitory peptide QIGLF with a purity of 95% was synthesized by GL Biochem Ltd. (Shanghai, China) by the solid-phase procedure peptide using Fmoc protected amino acids synthesis methods. Dulbeco's Modified Eagle's Medium (DMEM), fetal bovine serum, penicillin-streptomycin, Hank's balanced salt solution (HBSS), and 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) were purchased from Gibco BRL Life Technology. Nonessential amino acid, trypsin, L-glutamine, dimethyl sulfoxide (DMSO), ethylene diamine tetraacetic acid (EDTA), cytochalasin D, wortmannin, sodium azide, glycyl-proline (Gly-Pro), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetra-zolium bromide (MTT), acetonitrile, trifluoroacetic acid (TFA), and methanol were all purchased from Sigma-Adrich. 3-(4,5-Dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS) was purchased from Promega Biotechnology Co. Ltd. All other reagents were analytical grade.

Cell Culture. The Caco-2 cells were grown in Dulbecco's modified Eagle's medium containing 10% fetal bovine serum, 1% nonessential amino acid solution, 100 units/mL penicillin, 100 μg/mL streptomycin, and 4 mM L-glutamine at 37 °C in an atmosphere of 5% CO_2 and 90% relative humidity. Stock cultures were grown in 75 cm^2 tissue culture flasks and were split at 80−90% confluency using 0.25% trypsin and 0.02% EDTA solution. The cells from passage numbers of 10−20 were used and seeded on the permeable polycarbonate inserts (0.4 μm pore size, 12 mm diameter, 1.12 cm^2 grown surface, Costar, Corning, NY) in 12 transwell plates at a density of 1×10^5 cells/insert. The culture medium (0.5 mL in the apical side and 1.5 mL in the basolateral side) was replaced every 2 days for the first week and then daily until they were used for experiments 21 days after the seeding. The integrity of the cell monolayer was evaluated by measuring transepithelial electrical resistance (TEER) values with an EVOM epithelial volt/ohmmeter (Millicell-ERS, Millipore, U.S.). Only the cell monolayers with TEER values higher than 250 Ω cm^2 were used for the transport studies.

Cytotoxicity Assay. MTT was used to determine the cytotoxicity of QIGLF in Caco-2 cells as described previously.[24] Caco-2 cells were grown in 96-well culture plates and incubated with 1−10 mM QIGLF, which dissolved in DMEM, at 37 °C in 5% CO_2 for 24 h followed by addition of 0.05 mg of MTT and incubation for another 4 h. The culture medium then was replaced with 150 μL of DMSO to dissolve the MTT crystals, and the absorbance at 595 nm was measured using a multimode microplate reader (BioTek Instruments, U.S.).

Stability Assay. The stability of QIGLF in the apical surface of Caco-2 cells was studied. The Caco-2 cell monolayers were rinsed with HBSS twice and then incubated with HBSS for 30 min at 37 °C in 5% CO_2. The medium in the surface apical was replaced with 1 mM QIGLF (dissolved in HBSS, pH 7.4) and incubated at 37 °C in 5% CO_2. At the indicated time points, an aliquot of 50 μL from the apical surface was collected and analyzed by HPLC.

Transport Experiments. The transepithelial transport of ACE inhibitory peptide QIGLF was investigated as previously described by Hubatsch with minor modifications.[25] The Caco-2 cell monolayers were rinsed with HBSS twice and then incubated with HBSS for 30 min at 37 °C in 5% CO_2 before the transport experiment. We then aspirated the HBSS from both apical side and basolateral side of all wells. The peptide of 1−10 mM QIGLF in HBSS buffer (pH 7.4) was added in apical side, and fresh HBSS (pH 7.4) was added in basolateral side. All of the plates were incubated at 37 °C in 5% CO_2 for 2 h. At the appointed time points of 0, 30, 60, 90, and 120 min, an aliquot of 50 μL of sample was collected from the basolateral side. After each sampling, an equivalent volume of HBSS buffer with 25 mM HEPES was added in basolateral side to maintain a constant volume. The QIGLF concentration in each sample was determined by HPLC.

To identify which transport routes were involved in the transepithelial absorption of QIGLF, the Caco-2 cell monolayers were preincubated with transport inhibitor cytochalasin D (a tight junction disruptor, 0.5 μg/mL), wortmannin (a transcytosis inhibitor, 500 nM), sodium azide (an ATP synthesis inhibitor, 10 mM), or Gly-Pro (a peptide transport PepT 1 substrate, 10 mM) for 30 min followed by addition of 1 mM QIGLF to apical side. The cytochalasin D, wortmannin, and sodium azide were dissolved in DMSO (final concentration in HBSS 0.044%), and Gly-Pro was dissolved in HBSS. As a control, DMSO was used. All of the experiments were conducted in triplicate.

Induction of Oxidative Stress. The induction of in vitro oxidative stress was conducted as previously described by Katayama with modifications.[26,27] Caco-2 cells were seeded in 24-well culture plates (Costar, Corning, NY) at a density of 2×10^5 cells/mL and incubated at 37 °C in 5% CO_2. The oxidative stress was induced until the confluent Caco-2 cell monolayers formed by addition of H_2O_2. The Caco-2 cell monolayers were rinsed with HBSS twice, and then incubated with 1 and 5 mM QIGLF (dissolved in HBSS, pH 7.4) for 2 h followed by addition of various concentrations of H_2O_2 (250, 500, and 1000 μM) for 6 h. MTS was added in the plates (20 μL of MTS per 100 μL of culture medium was used) and incubated at 37 °C in 5% CO_2 for another 2 h followed by detection of the absorbance at 595 nm using a microplate reader (BioTek Instruments, U.S.).[28]

RP-HPLC. The peptide was quantified using a LC-2010HT HPLC system (SHIMADZU, JP) equipped with an autosampler, a quaternary pump, an online degasser, a UV detector, and a LC-2010HT workstation. The analytical column was a C18 reverse-phase column (ZORBAX SB-C18 column, 250 × 4.6 mm, particle size 5 μm, Agilent, U.S.). The mobile phases were solvent A (0.1% TFA in water) and solvent B (0.1% TFA in ACN). Samples were eluted with a gradient of solvent B from 25% to 50% in 25 min, from 50% to 100% in 10 min, and 100% for 5 min at a flow rate of 1.0 mL/min. The injection volume was 10 μL, and the absorbance detector wavelength was set at 220 nm. The peptide QIGLF concentration was calculated by a linear regression analysis of the peak area as described previously.[29]

Statistical Analysis. All data were expressed as the mean ± SD (n = 3). The difference was carried out by one-way analysis of variance (ANOVA) with the significance level at $P < 0.05$ by SPSS 19.0 software.

The apparent permeability coefficient (P_{app}, cm/s) was calculated as follows:

$$P_{app} = \frac{dQ}{dt} \times \frac{1}{A} \times \frac{1}{C_0} \quad (1)$$

where dQ/dt was the permeability rate (mmol/s); A was the area of membrane (cm^2); and C_0 was the initial concentration of QIGLF in the donor chamber (mM). After each sampling, the QIGLF concentration on the receiving side was diluted, so a correction equation was used as follows:

$$Q = C_n V + \sum_{i=0}^{n-1} C_i V_i \quad (2)$$

where Q was the accumulation of QIGLF on the receiving side (mmol); C_n and C_i were the concentrations of QIGLF in sample n and

dx.doi.org/10.1021/jf405639w | J. Agric. Food Chem. 2014, 62, 3177−3182

sample i, respectively; and V and V_i were the volumes of receiving chamber and sample i, respectively. To evaluate the kinetics in the transepithelial transport of QIGLF, K_m and V_{max} were calculated using the Michaelis−Menten equation, and the transport rate (V, μM/min cm^2) was calculated as follows:

$$V = \frac{dC}{dt} \times \frac{1}{A} \quad (3)$$

where dC/dt was the change of QIGLF concentration in basolateral side (μM/min).

RESULTS AND DISCUSSION

Validation of QIGLF. The primary structure and basic properties of QIGLF (the 204−208 residues of egg white ovalbumin, molecular weight 576.69 g/mol) were evaluated as described.[30] It was a neutral pentapeptide at pH 7.4 with a log D value of −2.287. The isoelectric point was 6.00, and the pK_a value was 3.76. Moreover, QIGLF had two intramolecular hydrogen bonds. The volume was 383.47 Å^3, and the total surface area was 603.88 Å^2 with polar surface area of 222.80 Å^2. In the present study, the retention time for QIGLF (dissolved in HBSS, pH 7.4) was 17.59 min, and the total run time was 30 min in the chromatogram of RP-HPLC analysis.

Cytotoxicity of QIGLF in Caco-2 Cells. As shown in Table 1, the result of MTT assay demonstrated that QIGLF did not have any cytotoxic effect in Caco-2 cells at the concentrations of 1−10 mM (dissolved in HBSS, pH 7.4), which were used in the transport experiments. Moreover, the transport experiments were performed within 2 h, which was much shorter than the time used for MTT assay. Therefore, the QIGLF (1−10 mM) showed no cytotoxicity in Caco-2 cell monolayers in our studies.

Table 1. Cytotoxicity of QIGLF in Caco-2 Cells As Evaluated by MTT Assay

QIGLF concentrations (mM)	absorbance at 595 nm[a,b]
0 (HBSS, control)	0.4993 ± 0.03
1	0.4932 ± 0.04
2	0.4875 ± 0.04
4	0.4814 ± 0.02
8	0.4806 ± 0.02
10	0.4796 ± 0.02

[a]No significant difference as compared to control group existed. [b]All values were the means ± SD (n = 3).

Stability of QIGLF on Caco-2 Cell Monolayers. The peptide of QIGLF at 1 mM (dissolved in HBSS, pH 7.4) was added to the apical surface Caco-2 cell monolayers and incubated 2 h. The recovery of QIGLF within 2 h was as shown in Figure 1. QIGLF was hardly degraded within 1 h, and had a good stability to Caco-2 cell monolayers with a recovery of 96.33% after 2 h incubation time. This result was associated with the strong resistance of QIGLF to gastrointestinal proteases described previously,[8] and comparable to the stability of VLPVP[31] and VYIHPF[30] to Caco-2 cell monolayers. In general, food-derived protein and peptide are degraded by proteases and peptidases in the gastrointestinal tract prior to being absorbed into the systemic blood circulation and target sites. The extensive enzyme system in gastrointestinal lumen, epithelial cells, and mucosal membrane constituted an important enzymatic barrier, and the brush border membrane enzymes might mainly cleave the peptide entered into Caco-2 cells to free amino acids or dipeptides.[32] However, QIGLF had a strong resistance to these enzymes. Iwan et al. reported that treating Caco-2 cell monolayers with diprotin A, a dipeptidyl peptidase IV inhibitor, resulted in lower degradation of β-casomorphin-5 and -7 in the donor chamber and higher transport rate.[33] Cakir-Kiefer et al. also found that the presence of bile salts appeared to modulate the peptidase activities of the Caco-2 cells leading to higher degradation of α-casozepine but lower degradation of α_{s1}-casein-(f91−97).[34]

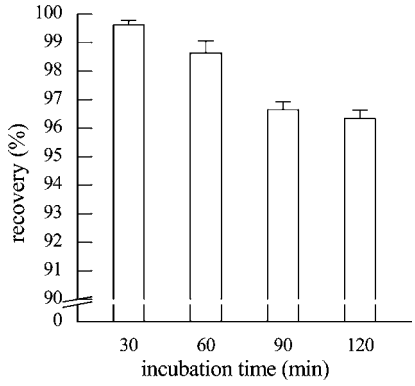

Figure 1. Stability of QIGLF (1 mM in HBSS, pH 7.4) in the AP side of Caco-2 cell monolayers within 2 h. One mM QIGLF (dissolved in HBSS, pH 7.4) was added to AP side, and samples were collected from AP side for HPLC analysis at 30, 60, 90, and 120 min. The recovery analysis revealed that the degradation of QIGLF was not significant within 2 h (P > 0.05). All values were the means ± SD (n = 3).

Transport of QIGLF across Caco-2 Cell Monolayers. The time-dependent uptake of QIGLF across Caco-2 cell monolayers was as shown in Figure 2. The accumulated amount of QIGLF in the basolateral side increased linearly up to 2 h, and the corresponding P_{app} values increased from 2.43 × 10^{-7} cm/s at 30 min to 9.11 × 10^{-7} cm/s at 120 min. Figure 3 showed the effect of QIGLF concentration in apical side on the transport. The transport kinetic parameters were also examined (K_m, 32.37 ± 12.59 mM; V_{max}, 1.23 ± 0.49 μM/min cm^2). The P_{app} value of QIGLF at 1 mM from the apical to basolateral side for 2 h was (9.11 ± 0.19) × 10^{-7} cm/s, suggesting that less than 2% QIGLF was transepithelial transported intact across Caco-2 cell monolayers. This was higher than that of KVLPVP,[35] HLPLP,[36] Gly-Ala-Hyp-Gly-Leu-Hyp-Gly-Pro,[37] VYIHPF,[30]

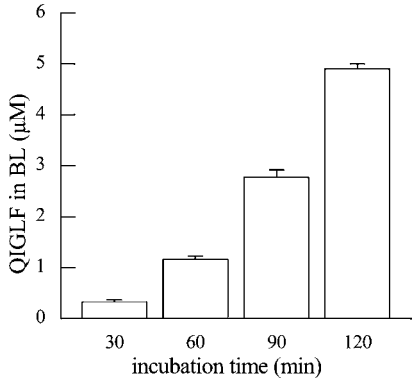

Figure 2. Effects of incubation time on the transport of QIGLF across Caco-2 cell monolayers. One mM QIGLF (dissolved in HBSS, pH 7.4) was added to AP side, and samples were collected from BL side for HPLC analysis at 30, 60, 90, and 120 min. All values were the means ± SD (n = 3).

dx.doi.org/10.1021/jf405639w | J. Agric. Food Chem. 2014, 62, 3177−3182

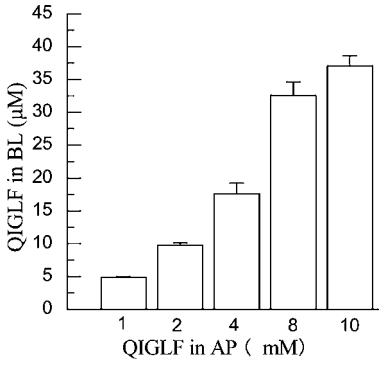

Figure 3. Effects of concentration of QIGLF on the transport across Caco-2 cell monolayers. Different concentrations of QIGLF (1, 2, 4, 8, and 10 mM; dissolved in HBSS, pH 7.4) were added to AP side, and samples were collected from BL side for HPLC analysis at 120 min. All values were the means ± SD (n = 3).

YPFPG, and SRYPSY,[38] but lower than that of VLPVP,[31] all of which had been identified with significant ACE inhibitory activities. The high absorptivity of QIGLF might be due to its hydrophobic uncharged residues such as Ile, Leu, and Phe.

Effects of Various Compounds on QIGLF Transport. To determine which transport pathways were involved in the transepithelial absorption of QIGLF, some inhibitors were added to Caco-2 cell monolayers to preincubate for 30 min before the transport experiment. As shown in Figure 4, Gly-Pro,

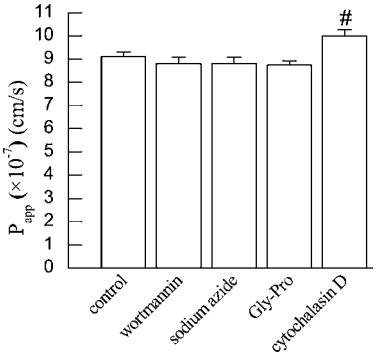

Figure 4. Effects of various compounds on the transport of QIGLF across Caco-2 cell monolayers. One mM QIGLF (dissolved in HBSS, pH 7.4) was added to AP side following the preincubation with transport inhibitors (wortmannin, sodium azide, and Gly-Pro and cytochalasin D) for 30 min, and samples were collected from BL side for HPLC analysis at 120 min. #P < 0.05 as compared to the control group. All values were the means ± SD (n = 3).

a good substrate for peptide transport PepT 1, had little effect on the transport (P > 0.05), suggesting that transport of QIGLF across the Caco-2 cell monolayers was not mediated by PepT1. The finding was unchanged when adjusted for the use of sodium azide, an ATP synthesis inhibitor, suggesting that QIGLF transport was energy-independent. It is known that PepT1 was mainly responsible for the transepithlelial transport of many di- and tripeptides, such as IRW and YPI,[29,39] bur not for the QIGLF in our present study.

Furthermore, the effect of transcytosis initiated by endocytosis at the apical cell membrane on QIGLF transepithelial transport was examined by a 30 min preincubation for Caco-2 cell monolayers with wortmannin, a transcytosis inhibitor. However, the presence of wortmannin did not significantly alter the P_{app} value of QIGLF (P > 0.05, Figure 4), suggesting that transcytosis was not the main mechanism for the transport of QIGLF.

In general, beside the transporter-mediated transport for basic molecules and the transcytosis for macromolecules, there are two other pathways for the intestinal transport of nutrients, transcellular passive diffusion for hydrophobic substances, and paracellular transport for water-soluble low-molecular substances. The transcellular passive diffusion depends on the liposolubility of substance to the lipid bilayers. However, the paracellular permeability is regulated by tight junctions, which could be evaluated by measuring the TEER. In the present study, the effect of paracellular pathway on QIGLF transport was also examined. Cytochalasin D, a tight junction disruptor, was added to Caco-2 cell monolayers and preincubated for 30 min to reduce the tight junction. The result exhibited that the TEER value decreased 10% (data not show), and the P_{app} value of QIGLF increased significantly (P < 0.05, Figure 4), suggesting that the QIGLF was transepithelial transported through Caco-2 monolayers possible mainly via paracellular pathway. This result resembled the transport route of oligopeptides VLPVL,[31] KVLPVP,[35] HLPLP,[36] Gly-Ala-Hyp-Gly-Leu-Hyp-Gly-Pro,[37] GGYR,[40] and tripeptide VPP,[41] which were all described previously. Besides cytochalasin D, bile salts[34] and sodium deoxycholate[35] were also often used to increase peptides paracellular permeability across Caco-2 cell monolayers by regulating the tight junction of Caco-2 cells and influencing the hydrolysis of peptides on the microvilli. What should be noted was that Caco-2 cell monolayers had a higher tight junction than human intestinal epithelial cells, indicating that the paracellular permeability of QIGLF across Caco-2 cell monolayers was lower than in vivo human intestine.[42]

Cytoprotective Effects of QIGLF on Caco-2 Cells Exposed to H_2O_2. To determine the effects of QIGLF on the viability of Caco-2 cells exposed to H_2O_2, Caco-2 cells were cultured with varying concentrations of QIGLF (1 and 5 mM) for 2 h followed by exposure to varying concentrations of H_2O_2 (250, 500, and 1000 μM) for another 6 h, and the cell viability was evaluated by MTS assay. As shown in Figure 5 A, the viability of Caco-2 cells decreased significantly when exposed to H_2O_2 with a dose−response effect (P < 0.05). When the concentration of H_2O_2 was up to 500 μM, 90.52% viability was maintained through the test period (P < 0.05); however, 1000 μM H_2O_2 led to only 86.90% viability remained (P < 0.01), which would bring excessive damage to Caco-2 cells. Therefore, 500 μM H_2O_2 was selected in the present study. Interestingly, treating with QIGLF could significantly improve the Caco-2 cells viability by protecting from oxidative damage induced by H_2O_2 (P < 0.05, Figure 5B). The QIGLF at high concentration of 5 mM offered a strong protection by enhancing H_2O_2-decreased cell viability up to 99.48%, with a slightly greater effect than that shown by 1 mM (95.53%), and those concentrations were all lower than the toxic concentration.

Human intestinal epithelium composes a nature barrier that selectively regulates the absorption of nutrients. However, the oxidative damage of intestinal epithelium might result in the loss of barrier function and chronic diseases.[43] It is well-known that H_2O_2 is not only an important member of the reactive oxygen species (ROS) family, but also can penetrate the cell membrane and react with intracellular metal ions to form hydroxyl radicals, both of which can cause severe damage to cultured cells. In addition, H_2O_2 and ROS are involved in the modulation of nuclear factor erythroid 2-related factor (Nrf2),

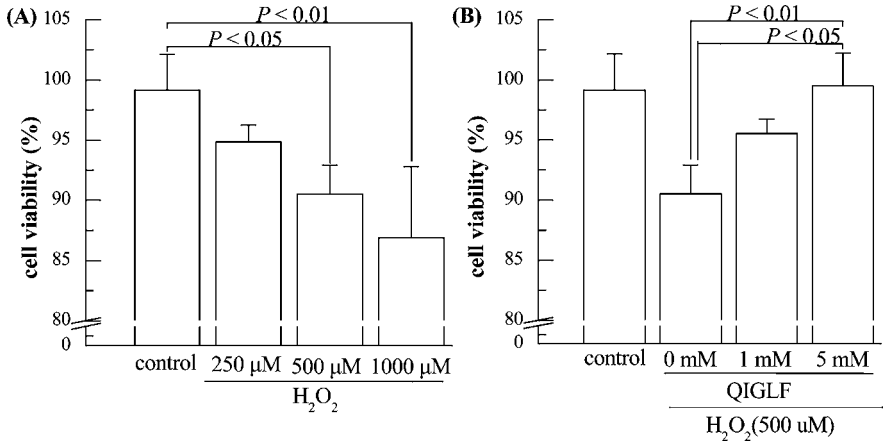

Figure 5. Cytoprotective effects of QIGLF on Caco-2 cells. (A) The cytotoxicity of H_2O_2 on viability in normal Caco-2 cells. Caco-2 cells were exposed to H_2O_2 at indicated concentrations of 250, 500, and 1000 μM for 6 h at 37 °C in 5% CO_2. (B) The cytoprotective effect of QIGLF on oxidative damage induced by H_2O_2 in Caco-2 cells. Caco-2 cells were incubated with couple concentrations of QIGLF (1 and 5 mM, dissolved in HBSS, pH 7.4) for 2 h at 37 °C in 5% CO_2 followed by the addition of 500 μM H_2O_2 for another 6 h incubation. The cell viability was evaluated by MTS assay. All values were the means ± SD (n = 3).

an emerging regulator of cellular resistance to oxidative stress.[44] In the present study, we observed that the treatment with 5 mM QIGLF could improve Caco-2 cells viability by protecting from oxidative damage induced by H_2O_2. However, QIGLF showed very low DPPH radical-scavenging activity in vitro in our previous work.[6] Thus, in synthesis, the cytoprotective effect might be involved in the Keap1/Nrf2/ARE signaling pathway, thereby upregulating the gene expression of antioxidant enzyme.

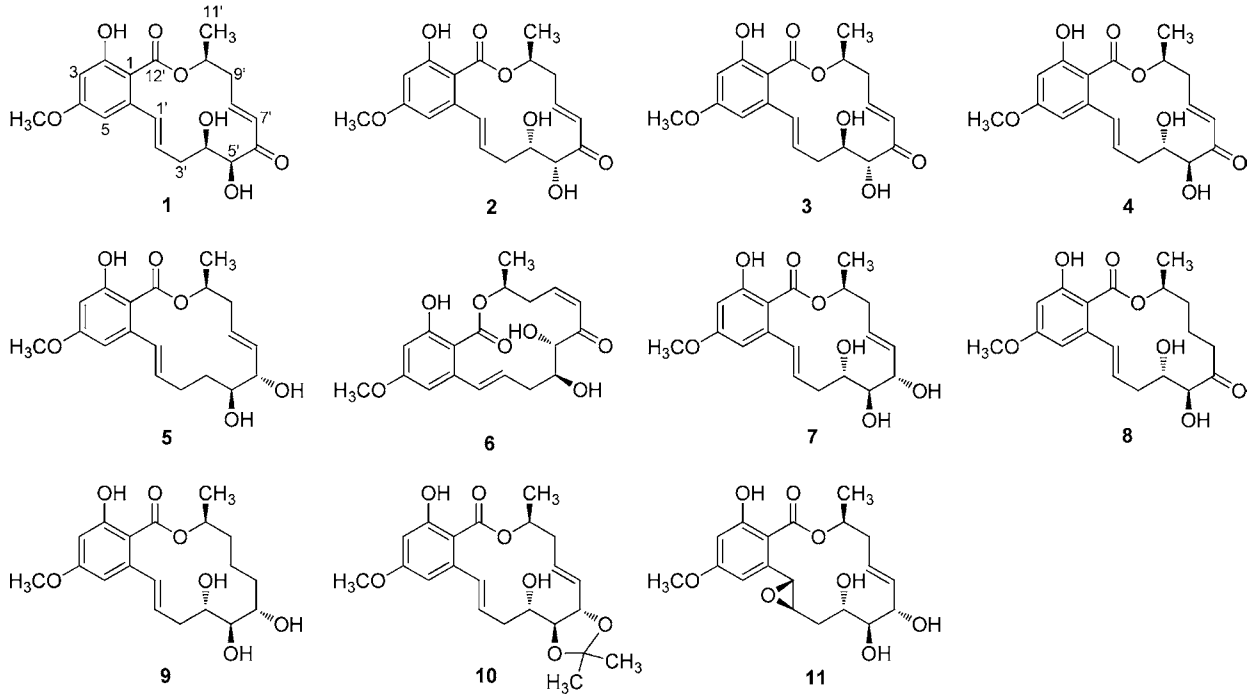

Figure 1. Structures of resorcylic acid lactones **1**−**11** isolated from *C. lunatus* (TA26-46).

Co., Ltd., Yantai, China) were used for thin layer chromatography (TLC).

Fungal Strain. The fungal strain *Cochliobolus lunatus* (TA26-46) was isolated from a piece of fresh tissue from the inner part of the sea anemone *Palythoa haddoni*, collected from the Weizhou coral reef (21° 02′ N, 109° 06′ E) in the South China Sea in April 2010. The fungus was identified as *C. lunatus* according to its morphological traits and a molecular protocol by amplification and sequencing of the DNA sequences of the ITS region of the rRNA gene. The 545 base pair ITS sequence had 100% sequence identity to that of *C. lunatus* (JN943462). The strain was deposited in the Key Laboratory of Marine Drugs, Ministry of Education of China, School of Medicine and Pharmacy, Ocean University of China, Qingdao, P.R. China, with the GenBank (NCBI) access number JF819163.

Fermentation, Extraction, and Isolation. The fungal strain *C. lunatus* (TA26-46) was fermented on solid media in 100 1-L Erlenmeyer flasks (each containing 80 g of rice, 120 mL of water, and 3.6 g of sea salt) at 28 °C for 4 weeks. The fermented solid medium was extracted three times with 300 mL of EtOAc for each Erlenmeyer flask. The combined EtOAc solution was evaporated to dryness under a vacuum to give an EtOAc extract. The EtOAc extract (80.0 g) was subjected to vacuum liquid chromatography (60.0 cm × 8.0 cm i.d.) on silica gel (100−200 mesh) using step-gradient elution with 5 L of petroleum ether/EtOAc (20:1 to 0:1, v/v) to afford five fractions (fractions 1−5). Fraction 4 was purified repeatedly by column chromatography (60.0 cm × 3.0 cm i.d.) on silica gel (200−300 mesh) eluted with 3 L of EtOAc/MeOH (v/v, 10:1) to yield **7** (2.0 g). Fraction 3 was isolated by column chromatography (60.0 cm × 3.0 cm i.d.) on silica gel (200−300 mesh) eluted with 3 L of petroleum ether/EtOAc (10:1 to 7:3, v/v), then subjected to Sephadex LH-20 column chromatography (120.0 cm × 3.0 cm i.d.) with 1 L petroleum ether/CH_2Cl_2/MeOH (2:1:1, v/v/v), and further purified by using semipreparative HPLC on an octadecylsilyl (ODS) column (150 mm × 7.8 mm i.d., 7 μm, Kromasil C18). The dried eluate was dissolved in 5 mL of MeOH and microfiltered. A 100-μL injection volume was used at a flow rate of 2 mL/min and elution of MeOH/water (11:9, v/v) to give **1** (15.0 mg), **2** (1.3 mg), **3** (2.3 mg), **4** (55.5 mg), **5** (145.5 mg), **6** (250.0 mg), **7** (5.0 mg), **8** (20.3 mg), **9** (1.5 mg), **10** (25.0 mg), and **11** (1.2 mg). The structures of the isolated compounds are depicted in Figure 1.

Cochliomycin D (1). White amorphous powder; $[\alpha]^{25}_{D}$ −125 (*c* 0.16, MeOH); UV (MeOH) λ_{max} (log ε) 198 (3.27), 232 (4.30), 271 (3.88), 312 (3.62) nm; CD (1.38 mM, MeOH) λ_{max} ($\Delta\varepsilon$) 219 (+8.07), 246 (+10.95), 273 (−14.44), 310 (−3.85), 351 (+0.31) nm; IR (KBr) ν_{max} 3747, 3648, 1700, 1650, 1540, 1510 cm^{-1}; ^1H and ^{13}C NMR data, see Tables 1 and 2; ESIMS *m*/*z* 385.1 $[M + Na]^+$, 747.2 $[2M + Na]^+$; HRESIMS *m*/*z* 385.1266 $[M + Na]^+$ (calcd for $C_{19}H_{22}O_7Na$, 385.1258).

Preparation of the Acetonide Derivatives, 1a, 3a, and 4a. A mixture of **1** (3.0 mg), 2,2-dimethoxypropane (1.5 mL), and *p*-TsOH (0.2 mg) was stirred at room temperature for 1 h. Saturated aqueous $NaHCO_3$ (5 mL) was then added, and the reaction mixture was extracted with EtOAc (5 mL × 3). The organic solvents were removed under a vacuum, and the crude mixture was subjected to semipreparative HPLC to obtain **1a** (2.8 mg). By the same procedures, the acetonides **3a** (1.0 mg) and **4a** (2.5 mg) were prepared from **3** (1.2 mg) and **4** (3.0 mg), respectively.

*Compound **1a**.* White amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6) δ 11.37 (1H, s, 2-OH), 7.21 (1H, dt, *J* = 16.7, 7.1 Hz), 7.17 (1H, dd, *J* = 15.3, 2.0 Hz), 6.51 (1H, d, *J* = 2.5 Hz, H-5), 6.44 (1H, d, *J* = 2.5 Hz, H-3), 6.15 (1H, d, *J* = 16.7 Hz), 6.07 (1H, ddd, *J* = 15.3, 10.1, 3.7 Hz), 5.40 (1H, m, H-10′), 5.04 (1H, d, *J* = 8.8 Hz, H-5′), 4.05 (1H, ddd, *J* = 8.8, 4.1, 2.9 Hz, H-4′), 3.86 (3H, s, 4-OCH_3), 2.82−2.91 (2H, m), 2.66 (1H, ddd, *J* = 15.5, 7.7, 1.2 Hz), 2.54 (1H, ddd, *J* = 16.0, 10.1, 2.7 Hz), 1.47 (3H, d, *J* = 6.3 Hz, H-11′), 1.41 (3H, s, H-14′), 1.37 (3H, s, H-15′); ^{13}C NMR (acetone-d_6, 125 MHz) δ 196.4 (C), 171.1 (C), 165.3 (C), 165.0 (C), 146.7 (C), 143.6 (CH), 135.8 (CH), 133.8 (CH), 127.0 (CH), 110.0 (C), 108.7 (CH), 105.7 (C), 101.0 (CH), 79.4 (CH), 77.6 (CH), 71.9 (CH), 56.0 (OCH_3), 38.0 (CH_2), 34.2 (CH_2), 27.3 (CH_3), 26.4 (CH_3), 20.2 (CH_3); ESIMS *m*/*z* 403.3 $[M + H]^+$, 425.3 $[M + Na]^+$, 827.5 $[2M + Na]^+$.

*Compound **3a**.* White amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6) δ 11.60 (1H, s, 2-OH), 7.06 (1H, dt, *J* = 16.1, 6.2 Hz), 6.83 (1H, d, *J* = 15.6 Hz), 6.60 (1H, d, *J* = 16.1 Hz), 6.50 (1H, d, *J* = 2.2 Hz, H-5), 6.42 (1H, d, *J* = 2.2 Hz, H-3), 6.07 (1H, ddd, *J* = 15.6, 8.5, 5.9 Hz), 5.53 (1H, m, H-10′), 4.99 (1H, d, *J* = 6.7 Hz, H-5′), 4.64 (1H, ddd, *J* = 9.6, 6.7, 2.0 Hz, H-4′), 3.85 (3H, s, 4-OCH_3), 2.86 (1H, m), 2.70−2.60 (2H, m), 2.44 (1H, m), 1.56 (3H, s, H-15′), 1.47 (3H, d, *J* = 6.5 Hz, H-11′), 1.36 (3H, s, H-14′); ^{13}C NMR (acetone-d_6, 125 MHz) δ 196.6 (C), 171.3 (C), 165.2 (C), 164.8 (C), 143.2 (C), 142.3 (CH), 134.0 (CH), 130.8 (CH), 128.6 (CH), 109.8 (C), 108.5 (C), 105.9 (CH), 100.9 (CH), 81.9 (CH), 77.9 (CH), 71.7 (CH), 55.9 (OCH_3), 37.3 (CH_2), 34.4 (CH_2), 27.0 (CH_3), 25.9 (CH_3), 18.7 (CH_3); ESIMS *m*/*z* 425.0 $[M + Na]^+$.

*Compound **4a**.* White amorphous powder; ^{1}H NMR (500 MHz, acetone-d_6) δ 11.39 (1H, s, 2-OH), 7.06 (1H, dt, *J* = 15.5, 7.9 Hz), 6.96 (1H, dd, *J* = 15.5, 2.2 Hz), 6.55 (1H, d, *J* = 2.6 Hz, H-5), 6.48 (1H, d, *J* = 15.5 Hz), 6.42 (1H, d, *J* = 2.6 Hz, H-3), 6.03 (1H, ddd, *J* = 15.5, 10.0, 3.9 Hz), 5.58 (1H, m, H-10′), 4.85 (1H, d, *J* = 6.6 Hz, H-5′), 4.65 (1H, ddd, *J* = 10.9, 6.6, 2.6 Hz, H-4′), 3.85 (3H, s, 4-OCH_3), 2.69 (1H, ddd, *J* = 15.7, 6.4, 2.7 Hz), 2.65−2.60 (2H, m), 2.34 (1H, dt, *J* = 16.2, 10.5 Hz), 1.59 (3H, s, H-14′), 1.47 (3H, d, *J* = 6.5 Hz, H-11′), 1.35 (3H, s, H-15′); ^{13}C NMR (acetone-d_6, 125 MHz) δ 196.7 (C), 171.1 (C), 165.2 (C), 164.8 (C), 143.2 (C), 142.2 (CH), 133.7 (CH), 132.1 (CH), 128.8 (CH), 109.9 (C), 109.9 (C), 108.2 (CH), 101.7 (CH), 82.3 (CH), 78.5 (CH), 72.2 (CH), 55.9 (OCH_3), 37.7 (CH_2), 35.3 (CH_2), 27.0 (CH_3), 26.0 (CH_3), 19.0 (CH_3); ESIMS *m*/*z* 425.0 $[M + Na]^+$.

Preparation of Tri-*p*-bromobenzoyl Derivatives, 1b, 3b, and 4b. Cochliomycin D, **1** (2.0 mg), was treated with *p*-bromobenzoyl chloride (15 mg) and 4-*N*,*N*-dimethylaminopyridine (DMAP, 2.5 mg) in 1.5 mL of pyridine/CH_2Cl_2 (1:2) at 40 °C for 2 h. The mixture was diluted with EtOAc and washed with H_2O and 1 M $NaHCO_3$, and the organic layer was concentrated under a vacuum to obtain a colorless solid. It was then purified by Sephadex LH-20 column chromatography and semipreparative HPLC to obtain **1b** (2.9 mg). Tri-*p*-bromobenzoyl derivatives **3b** (0.5 mg) and **4b** (1.8 mg) were prepared similarly from cochliomycin F, **3** (0.3 mg), and (7′*E*)-6′-oxozeaenol, **4** (1.2 mg), respectively.

*Compound **1b**.* White amorphous powder; CD (0.87 mM, CH_2Cl_2) λ_{max} ($\Delta\varepsilon$) 262 (−11.64), 242 (+11.18) nm; ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.05 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.90 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.75 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.66 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.57 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.49 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.11 (1H, ddd, *J* = 15.5, 8.7, 5.4 Hz), 6.93 (1H, d, *J* = 15.5 Hz), 6.88 (1H, d, *J* = 2.2 Hz, H-5), 6.73 (1H, d, *J* = 2.2 Hz, H-3), 6.34 (1H, d, *J* = 16.1 Hz), 6.12 (1H, m), 5.78 (1H, d, *J* = 3.4 Hz), 5.77 (1H, m), 5.33 (1H, m), 3.85 (3H, s, 4-OCH_3), 2.84 (1H, dt, *J* = 14.7, 7.4 Hz), 2.64 (2H, m), 2.42 (1H, m), 1.20 (3H, d, *J* = 6.3 Hz, H-11′); ESIMS *m*/*z* 933.0 $[M + Na]^+$.

*Compound **3b**.* White amorphous powder; CD (0.32 mM, CH_2Cl_2) λ_{max} ($\Delta\varepsilon$) 276 (−0.63), 249 (+5.40) nm; ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.04 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.95 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.85 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.66 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.61 (2H, d, *J* = 8.5 Hz, *p*-bromobenzoyl), 7.57 (2H, d, *J* = 8.5 Hz, *p*-

bromobenzoyl), 7.05 (1H, m), 6.92 (1H, d, J = 15.2 Hz), 6.88 (1H, d, J = 2.2 Hz, H-5), 6.72 (1H, d, J = 2.2 Hz, H-3), 6.52 (1H, d, J = 16.0 Hz), 6.13 (1H, m), 6.03 (1H, dd, J = 2.8, 0.5 Hz), 5.83 (1H, m), 5.32 (1H, m), 3.85 (3H, s, 4-OCH_3), 1.99−2.82 (4H, m), 1.11 (3H, d, J = 6.3 Hz, H-11′); ESIMS m/z 933.2 $[M + Na]^+$.

Compound ***4b***. White amorphous powder; CD (0.87 mM, CH_2Cl_2) λ_{max} ($\Delta\varepsilon$) 266 (+21.28), 243 (−8.26) nm; ^{1}H NMR (500 MHz, $CDCl_3$) δ 8.05 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.77 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.66 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.63 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.54 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.41 (2H, d, J = 8.5 Hz, p-bromobenzoyl), 7.04 (1H, ddd, J = 15.5, 10.3, 5.2 Hz), 6.96 (1H, d, J = 2.3 Hz, H-5), 6.78 (1H, d, J = 2.3 Hz, H-3), 6.67 (1H, d, J = 15.5 Hz), 6.41 (1H, d, J = 15.5 Hz), 6.29 (1H, m), 6.12 (1H, d, J = 3.9 Hz), 5.95 (1H, m), 5.30 (1H, m), 3.87 (3H, s, 4-OCH_3), 2.76 (2H, m), 2.49 (1H, dd, J = 13.8 Hz, 5.1), 2.32 (1H, m), 1.02 (3H, d, J = 6.3 Hz, H-11′); ESIMS m/z 933.2 $[M + Na]^+$.

Double-Bond Isomerization of LL-Z1640-2 (6) to Yield 4. Compound **6** (3.0 mg) was dissolved in 2.0 mL of pyridine, and the solution was stirred vigorously at 50 °C for 2 h. H_2O (5 mL) was then added, and the reaction mixture was extracted with EtOAc (5 mL × 3). The organic solvents were removed under a vacuum, and the crude mixture was subjected to semipreparative HPLC to give the reaction product, the spectroscopic data of which were consistent with **4** (2.2 mg).

Biological Assays. *Antifouling Bioassay*. The antifouling activities against the larval settlement of the barnacle were determined using cyprids of *Balanus amphitrite* Darwin according to literature procedures.[11] Larval settlement assays were performed using 24-well polystyrene plates (Becton Dickinson, Franklin Lakes, NJ, USA). The tested compounds were first dissolved in a small amount of dimethyl sulfoxide (DMSO) and then diluted with filtered seawater to achieve final concentrations of 50, 20, 10, 5, 2.5, 1.25, and 0.625 μg/mL. About 15−20 competent larvae were gently transferred into each well with 1 mL of testing solution in three replicates, and wells containing larvae in filtered seawater with DMSO only served as a control. SeaNine 211 (Rohm & Haas, Philadelphia, PA, USA), a new type nontoxic antifouling agent developed by Rohm & Haas, was used as a positive control. The plates were incubated for 24−48 h at 23 °C. The effects of the test samples against biofouling were determined by examining the plates under a dissecting microscope to check for (1) settled larvae and (2) nonsettled larvae, as well as (3) any possible toxic effects of the treatments, such as death or paralysis of larvae, which were also recorded. The EC_{50} (50% inhibition of settlement of cyprids in comparison with the control) and LC_{50} (50% lethality of cyprids in comparison with the control) were calculated using the Probit software program with the means of three repeated experiments using different batches of larvae.

Antifungal Assays. Antifungal bioassays were conducted following the National Center for Clinical Laboratory Standards (NCCLS) recommendations.[12] Three phytopathogenic fungal strains, *Thielaviopsis paradoxa*, *Pestalotia calabae*, and *Glorosprium musarum*, were grown on potato dextrose agar. Targeted microbes (three to four colonies) were prepared from broth culture (28 °C for 48 h), and the final spore suspensions of fungi were 10^4 mycelial fragments/mL. Test samples (100 μM as stock solution in DMSO and serial dilutions) were transferred to a 96-well clear plate in triplicate, and the suspension of the test organisms was added to each well achieving a final volume of 200 μL. Ketoconazole was used as a positive control. After incubation, the absorbance at 492 nm was measured with a microplate reader. The minimum inhibitory concentration (MIC) was defined as the lowest test concentration that completely inhibited the growth of the test organisms.

Fungicide Screening.[13] Fungicidal activities were tested by pathogens on leaf-piece assays at a rate of 100 ppm for *Septoria tritici* on wheat and *Uromyces viciae-fabae* on bean and at rates of 200 and 60 ppm for *Phytophthora infestans* on tomato. Fungicidal activities were also evaluated in mycelial growth tests on artificial media against *Pythium dissimile*, *Alternaria solani*, *Botryotinia fuckeliana*, and *Gibberella zeae*, at rates of 20 and 2 ppm. Rates of tested compounds were adjusted to accommodate intrinsic differences in sensitivities of pathogens in the different test systems. All testing was undertaken on 96-well microtiter plates using azoxystrobin and prochloraz as positive controls. Chemicals were applied to leaf pieces prior to inoculation with spores of the pathogen or in the case of the artificial media assays. The plates were stored in controlled-environment cabinets from 4 to 14 days, depending on the assay, and disease inhibition or mycelial growth was then assessed. Each well was scored using a three-banded system, with complete inhibition of mycelial growth or disease symptoms as 99, partial inhibition as 55, and no inhibition as 0.

Fungicide Whole-Plant Assay. Fungicide whole-plant assessment was conducted against *P. infestans* and *Plasmopara viticola* on glasshouse-based whole-plant assays. All preventative, curative, and persistence tests against *P. infestans* on potato and *P. viticola* on grapevine were applied at rates of 200, 60, 20, 6, and 2 ppm as foliar sprays, whereas the preventative soil drench test against *P. infestans* on tomato was applied at rates of 20, 6, and 2 ppm/kg of soil. Mefenoxam and mandipropamid were used as positive controls. Chemical applications were made 2 days prior to inoculation for preventative foliar tests, 3 days prior to inoculation for drench tests, 6 days prior to

inoculation for persistence tests, and 1 day after inoculation for curative tests. For the inoculation, sporangial suspensions were made up to the required rate (approximately 70000 sporangia/mL for *P. viticola* and 50000 sporangia/mL for *P. infestans*) and applied to the treated plants using a hand-held spray gun. After inoculation, the plants were kept under controlled conditions either in the glass house for trials with *P. viticola* (14 h of light/day at 100% relative humidity and 20 °C) or in a climate chamber for trials with *P. infestans* (14 h of light/day at 100% relative humidity and 18 °C). Assessments of disease development were made visually between 5 and 11 days after treatment, depending on the assay. The preventative and persistence tests against *P. infestans* also included a second evaluation of disease development 2 days after the initial assessment.

RESULTS AND DISCUSSION

An EtOAc extract from the solid fermentation of the fungus *Cochliobolus lunatus* (TA26-46) was separated by vacuum liquid chromatography on silica gel using step-gradient elution to yield five fractions (fractions 1−5). Fraction 3 showed a series of peaks in the HPLC profile (Figure 2) with similar UV absorptions at 223, 271, and 312 nm, indicative of the presence of resorcylic acid lactones.[2] Fraction 4 showed only a main peak in the HPLC profile with the same UV absorptions as the of peaks in fraction 3. Eleven resorcylic acid lactones, **1**−**11**, were isolated from fractions 3 and 4 by column chromatography and semipreparative HPLC guided by the characteristic UV absorption spectra of resorcylates.

Cochliomycin D, **1**, was isolated as a white powder, and its molecular formula was established to be $C_{19}H_{22}O_7$ (nine degrees of unsaturation) by HRESIMS. The ^{1}H NMR spectrum (Table 1) exhibited an exchangeable proton singlet at δ_H 10.46 assignable to the chelated phenolic hydrogen. The downfield ^{1}H NMR spectrum revealed two meta-coupled aromatic proton signals (δ_H 6.48, d, J = 2.4 Hz; 6.35, d, J = 2.4 Hz), and two trans double bonds (δ_H 6.42, d, J = 15.9 Hz and 6.18, ddd, J = 15.9, 7.8, 6.7 Hz; 6.21, d, J = 15.9 Hz and 6.82, ddd, J = 15.9, 9.8, 5.2 Hz). Additional resonances attributable to three oxymethines (δ_H 3.79, m; 4.25, t, J = 5.9 Hz; and 5.33, m), one oxymethyl (δ_H 3.75, s), and one methyl (δ_H 1.32, d, J = 6.3 Hz) were observed. The ^{13}C NMR spectrum (Table 2) revealed the presence of one keto carbonyl (δ_C 200.2), one ester carbonyl (δ_C 167.9), and one tetra-substituted benzene ring. These spectroscopic features suggest that **1** belongs to the family of resorcylic acid lactones and is very similar to (7′*E*)-6′-oxozeaenol, **4**.[6,9] The conspicuous differences between the ^{13}C NMR spectrum of **1** and that of **4** are the chemical shifts of C-4′ (δ_C 72.7 in **1** vs 71.9 in **4**) and C-5′ (δ_C 75.8 in **1** vs 78.2 in **4**). The planar structure of **1** was further confirmed on the basis

dx.doi.org/10.1021/jf500248z | J. Agric. Food Chem. 2014, 62, 3183−3191

of the 2D NMR [^{1}H−^{1}H correlation spectroscopy (COSY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond correlation (HMBC)] spectroscopic data. The connection from C-1′ to C-5′ and the local structure from C-7′ to C-11′ were addressed on the basis of the ^{1}H−^{1}H COSY correlations. A trans-olefin (C-1′/C-2′) was attached to the benzene ring at C-6 position, as indicated by the HMBCs from the olefinic proton H-1′ to C-1, C-5, and C-6 and from H-2′ to C-6. The carbonyl (δ_C 200.2) was placed at the C-6′ position, because the HMBC spectrum exhibited correlations from H-5′, H-7′, and H-8′ to this carbon. Thus, the planar structure of cochliomycin D, **1**, was established as the same as that of **4**.

Cochliomycins E and F, **2** and **3**, were also isolated as white powders, with the same molecular formula, $C_{19}H_{22}O_7$, as **1** based on HRESIMS. The ^{1}H and ^{13}C NMR spectra of **2** and **3** (Tables 1 and 2) were strikingly similar to those of **1**. Detailed analysis of the 1D and 2D NMR spectra established the same planar structures for **2** and **3** as for **1**.

Subsequently, detailed analysis of the ^{1}H and ^{13}C NMR spectra of **1**−**4** (Tables 1 and 2) revealed that these four compounds showed high similarity in NMR spectroscopic data. The significant differences among them were the carbon signals of the oxymethines at C-4′ and C-5′. These NMR features implied that **1**−**4** are diastereomers differing from each other by the absolute configurations of the 4′,5′-diol chiral centers.

The relative configurations of 4′,5′-diol in **1**, **3**, and **4** were determined by nuclear Overhauser effect (NOE) experiments of their acetonide derivatives. Compounds **1**, **3**, and **4** were treated with *p*-TsOH·H_2O in 2,2-dimethoxypropane, which gave the respective acetonide derivatives **1a**, **3a**, and **4a**. In the selective NOE experiments of **1a**, irradiation of H-4′ (δ_H 4.05) resulted in the enhancement of the signal for H_3-14′ (δ_H 1.41, s), and irradiation of H-5′ (δ_H 5.04) resulted in the enhancement of the signal for H_3-15′ (δ_H 1.37, s) (Figure 3). Therefore, H-4′ and H-5′ should be placed on opposite sides of the acetonide ring, suggesting a trans-fused acetonide in **1a**. Similarly, the selective NOE experiments indicated that both **3a** and **4a** were *cis*-acetonide derivatives (Figure 3). The acetonide formation of **2** was not conducted because of its limited quantity. It should be noted that the cis-fused acetonide derivative of **4** was reported previously,[9] but its absolute configuration has not been determined.

The absolute configurations of the 4′,5′-diol in **1**, **3**, and **4** were established by applying CD exciton chirality method.[14] To obtain derivatives suitable for CD exciton chirality analysis, additional chromophores had to be introduced into the original structures. The *p*-bromobenzoyl chromophore was selected to avoid the interference of the enone chromophore, which has an $n-\pi^*$ transition occurring around 335 nm. Acylation of **1**, **3**, and **4** with excess *p*-bromobenzoyl chloride in CH_2Cl_2 and pyridine gave their respective triacyl derivatives, **1b**, **3b**, and **4b** (Figure 4). The CD spectrum of **1b** (Figure 4) showed a negative first Cotton effect at 262 nm ($\Delta\varepsilon$ = −11.76) and a positive second Cotton effect at 242 nm ($\Delta\varepsilon$ = +11.29), suggesting negative chirality for **1b**. Furthermore, according to the Karplus formula, the $^3J_{H4'-H5'}$ value of 3.4 Hz of **1b** suggests the Newman projections of four possible conformations for the 4′*R*,5′*S* isomer, A1, A2, A3, and A4 (Figure 4). Examinations of the macrocycle conformations with a molecular model strongly suggested that conformations corresponding to the projections A3 and A4 were disfavored due to steric hindrance of the two *p*-bromobenzoyl groups. The anticlockwise manner in space of two *p*-bromobenzoyl chromophores in the projections A1 and A2 were consistent with the negative chirality of **1b**. Thus, on the basis of the exciton chirality rule, the absolute configuration of **1b** was defined as 4′*R*,5′*S*. Similarly, **3b** exhibited negative chirality in the first Cotton effect at 276 nm ($\Delta\varepsilon$ = −0.63) in its CD spectrum, consistent with the anticlockwise manner in the projection B1, suggesting the 4′*R*,5′*R* configuration, whereas **4b** showed positive chirality in the first Cotton effect at 266 nm ($\Delta\varepsilon$ = +21.28), matching the clockwise manner in the projection C1, which revealed the 4′*S*,5′*S* configuration (Figure 4). Therefore, the absolute configurations of the 4′,5′-diol in **1**, **3**, and **4** were designated as 4′*R*,5′*S*, 4′*R*,5′*R*, and 4′*S*,5′*S*, respectively.

The absolute configurations at C-10′ in **1**−**4** were determined by their CD spectra (Figure 5). The negative

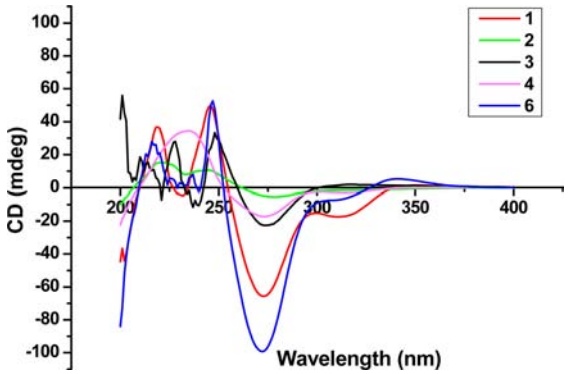

Figure 5. CD spectra of **1**−**4** and **6**.

Cotton effects around 275 nm suggested the *S* configuration at C-10′ for **1**−**4**, by comparison with that of the coisolated known compound **6** and other similar resorcylic acid lactones described in the literature.[15,16] Furthermore, **4** could be obtained by a double-bond isomerization reaction from **6**, whose absolute configuration was described as 4′*S*,5′*S*,10′*S* in the literature.[7] This isomerization experiment further confirmed the absolute configuration of **4**.

Because **1**, **3**, and **4** were determined above as having the 4′*R*,5′*S*,10′*S*, 4′*R*,5′*R*,10′*S*, and 4′*S*,5′*S*,10′*S* configurations, respectively, the absolute configuration of **2** was tentatively assigned as 4′*S*,5′*R*,10′*S*. To verify the absolute configuration of **2**, time-dependent density functional theory (TDDFT) electronic circular dichroism (ECD) calculations were applied to **2**, together with its stereoisomer **1** with the enantiomeric 4′,5′-diol. First, conformational analysis was carried out by Monte Carlo searching using molecular mechanism with the MMFF94 force field in the Spartan program.[17] The results showed four lowest-energy conformers for **1** and five for **2** whose relative energies were within 2 kcal/mol. Subsequently, the conformers were reoptimized using DFT at the B3LYP/6-31+G(d) level in a vacuum with the Gaussian 09 program.[18] The B3LYP/6-31+G(d) harmonic vibrational frequencies were further calculated to confirm their stability. The energies, oscillator strengths, and rotational strengths of the first 30 electronic excitations were calculated using the TDDFT methodology at the B3LYP/6-311++G(2d, 2p) level in a vacuum. The ECD spectra were simulated by the overlapping Gaussian function,[19] in which the first 15 velocity rotatory strengths for **1** and the first 11 for **2** were employed. To obtain the final ECD spectrum, the simulated spectra of the lowest-

dx.doi.org/10.1021/jf500248z | J. Agric. Food Chem. 2014, 62, 3183−3191

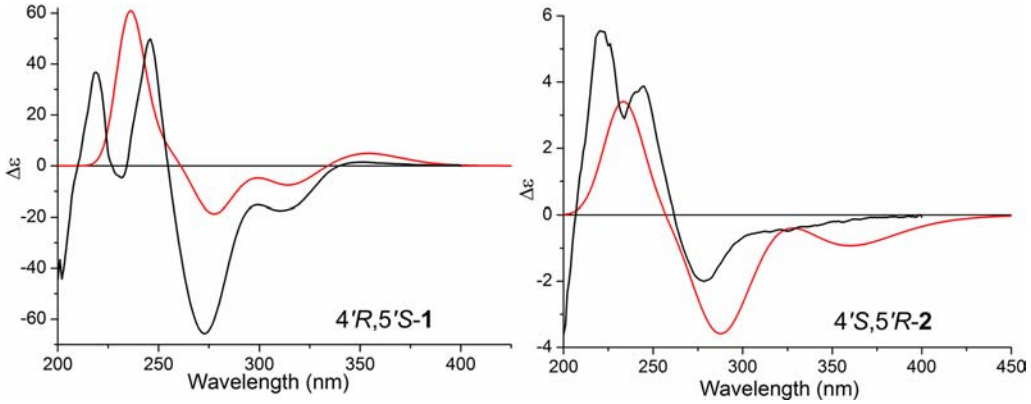

Figure 6. B3LYP/6-311++G(2d,2p)//B3LYP/6-31+G(d)-calculated ECD spectra (red) of 4′*R*,5′*S*-**1** and 4′*S*,5′*R*-**2** and experimental ECD spectra (black) of **1** (σ = 0.2) and **2** (σ = 0.4).

energy conformations were averaged according to the Boltzmann distribution theory and their relative Gibbs free energies (ΔG). In the 200−400-nm region, the experimental ECD spectrum of **1** showed a small positive first Cotton effect around 350 nm, whereas **2** showed a negative effect around this band. The calculated spectra for the two compounds matched the corresponding experimental spectra (Figure 6). Therefore, qualitative analysis of the above information confirmed the absolute configuration of **2** as 4′*S*,5′*R*,10′*S*.

The structures of the other known compounds, *deoxy*-aigialomycin C (**5**),[8] LL-Z1640-2 (**6**),[7] zeaenol (**7**),[9] LL-Z1640-1 (**8**),[7] paecilomycin F (**9**),[10] cochliomycin A (**10**),[5] and aigialomycin B (**11**),[2] were determined by comparison of their spectroscopic, MS, and specific rotation data with those in the literature. It is worth pointing out that this is the first report of **5** as a natural product. Its relative and absolute configurations were confirmed using NOE experiments of its acetonide derivative and the CD exciton chirality method with its *p*-dimethylaminobenzoyl derivative.

From the chemistry point of view, these resorcylic acid lactones might be unstable because of the existence of enone moieties and many hydroxy groups, especially phenol hydroxy groups, causing chemical conversions under acidic conditions, such as intramolecular hetero Michael addition[20] and carbon migration of hemiacetal.[3] During acquisition of their NMR spectra, all compounds were found to be quite stable, and no trace of conversions was observed in deuterated solvents (DMSO-d_6, acetone-d_6, and $CDCl_3$), even with prolonged time of more than 3 months. The stability of these lactones under various conditions is worth further investigation.

In our previous study, the resorcylic acid lactones showed potent antifouling activity against the larval settlement of the barnacle *Balanus amphitrite*.[5] In our current research, the isolated resorcylic acid lactones and the acetonide derivatives **1a** and **3a**−**6a** were also evaluated for their antifouling activities. Compounds **1**, **3**−**6**, and **6a** exhibited potent antifouling activity at nontoxic concentrations with the EC_{50} values of 17.3, 6.67, 18.1, 22.5, 1.82, and 3.85 μg/mL, respectively (Table 3), which were lower than the standard requirement of an EC_{50} value of 25 μg/mL established by the U.S. Navy program.[21] The *cis*-enone moiety in **6** (1.82 μg/mL) improved the EC_{50} value approximately 9-fold over that of **4** (18.1 μg/mL) with *trans*-enone, indicating that the *cis*-enone functionality might contribute to the antifouling activity. Moreover, the antifouling activity of **6a** (EC_{50} of 3.85 μg/mL), more than 6 times that of **4a** (EC_{50} > 25 μg/mL), also confirmed this possibility. Our previous study indicated that the acetonide functionality might have a positive effect on antifouling activity.[5] For the enone resorcylic acid lactones, however, the acetonide functionality (**1a**, **3a**, **4a**, and **6a**) was found to decrease the antifouling activity significantly (**1a**, **3a**, **4a**: EC_{50} > 25 μg/mL). Comparison of the activities of **1**−**4** indicated that the configurations of 4′,5′-diol might affect the antifouling activity, with the 4′*R*,5′*R* configuration in **3** exhibiting the highest activity. The above findings suggest that small changes in the structures, especially the enone and acetonide functionalities and hydroxy configurations, among these resorcylic acid lactones can result in obvious changes of antifouling activity. The therapeutic ratio (LC_{50}/EC_{50}) is a way of expressing the effectiveness of the compound in relation to its toxicity. A compound with LC_{50}/EC_{50} > 15 is often considered to be a nontoxic antifouling compound, and a much higher LC_{50}/EC_{50} ratio is highly recommended when selecting candidate compounds.[22] All of the active compounds, **1**, **3**−**6**, and **6a**, had high therapeutic ratios (LC_{50}/EC_{50} > 50), suggesting that they might be useful as environmentally benign antifouling agents.

Table 3. Antifouling Activity

compd	EC_{50} (μg/mL)	LC_{50}/EC_{50}

[a]Positive control.

Simultaneously, the antifungal activities of all isolated compounds against phytopathogenic fungi *Thielaviopsis paradoxa*, *Pestalotia calabae*, and *Glorosprium musarum* were evaluated. Noticeably, among the tested compounds, only **6** exhibited promising inhibitory activity against *P. calabae*, with an MIC value of 0.39 μM, which was approximately 25-fold more potent than that of the positive control, ketoconazole (MIC = 10 μM).

As a result of its antifungal activity, **6** was provided to Syngenta for agricultural fungicide screening. In primary- and secondary-tier fungicide assays, **6** showed moderate activity against a limited range of pathogens in laboratory-based tests. It totally inhibited the disease development of *P. infestans*

[a]Scores are given as percentages of disease control relative to untreated plants (100 indicates complete control of disease symptoms, 0 indicates no control); –, not tested at that rate; le, late evaluation. Mefenoxam and mandipropamid as positive controls. [b]*P. infestans* (tomato). [c]*P. infestans* (potato). [d]*P. viticola* (grapevine).

(tomato) at concentrations of 200 and 60 ppm and of *U. viciae-fabae* (bean) at 100 ppm, as well as the hyphal growth of *P. dissimile* at 2 ppm.

To further characterize its fungicidal potency, **6** was assessed against *P. infestans* and *Plasmopara viticola* on glass-house-based whole-plant assays. Mefenoxam and mandipropamid were used as positive controls. The selection of the standard was based on the properties of candidate active ingredients and the nature of the assays. Mefenoxam is highly systemic; therefore, it was used as the standard in the drench and curative assays. Mandipropamid has an excellent rain-fastness and long-lasting activity because it sticks and distributes quite well in the wax layer of the cuticle, so it was used in persistence test. For the preventive test, both standards can be used, one to ensure that the method is working sufficiently. In this case, the standards serve as quality control for the respective test methods. The results indicated that **6** displayed good activity on both tests, stronger than originally observed on the primary- and secondary-tier assays (Table 4). On the preventative foliar applications against *P. infestans* (potato), **6** showed potent rate-for-rate activity, with disease control rates (DCRs) of 98%, 98%, and 92% at 200, 60, and 20 ppm, respectively, comparable to the values for the positive control mefenoxam (98%, 98%, and 98%) in the initial assessment (Table 4). Compound **6** also showed promising activity on the *P. infestans* drench test (DCR of 86% at 6 ppm). More remarkably, the DCR of **6** was 91% at 6 ppm on the preventative foliar applications against *P. viticola* (grapevine) compared to the positive control mefenoxam (6 ppm, DCR = 0), highlighting the promising activity of **6** against *P. viticola* (Table 4). In the persistence application test against *P. infestans*, **6** showed weaker activity than in the preventative application test, and it also produced no significant activity on the curative tests against either *P. infestans* or *P. viticola*.

In addition, the cytotoxicity of **6** was also determined against tumor cell lines of Hela, A549, HCT-116, HL-60, and K562. It was found that **6** showed cytotoxicity against only HCT-116 with an IC_{50} value of 3.24 μM. The antibacterial, antiviral, insecticidal, and herbicidal activities of the isolated and synthetic resorcylic acid lactones were also determined, but no significant activity was observed.

In summary, 11 resorcylic acid lactones, **1**–**11**, including three new compounds, **1**–**3**, were isolated from the sea anemone-derived fungus *C. lunatus* (TA26-46). The absolute configurations of **1**–**4** were established by the CD exciton chirality method and TDDFT ECD calculations. Compounds **1**, **3**–**6**, and **6a** exhibited potent antifouling activities against the larval settlement of the barnacle *B. amphitrite*, of which **6** showed the highest activity with low toxicity. More remarkably, **6** showed excellent agricultural fungicidal activity against *P. viticola* and *P. infestans* on the whole-plant assay, which would be helpful for the research and development of new natural potential fungicide leads.

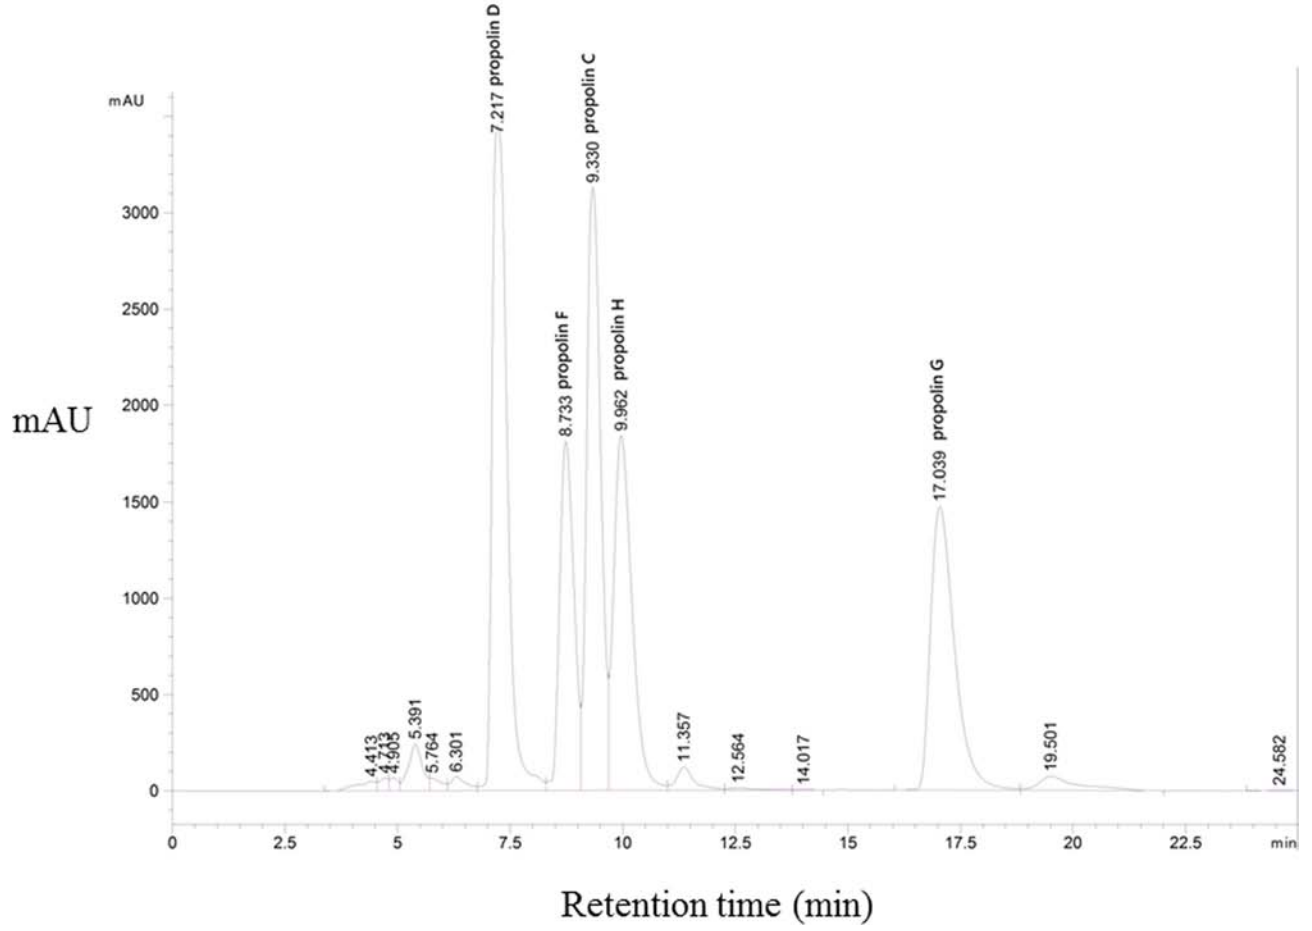

Figure 1. Separation of standard authentic compounds, using HPLC-UV. Peaks: 1, propolin D; 2, propolin F; 3, propolin C; 4, propolin H; 5, propolin G. The conditions of separation were as follows: column, Luna Phenomenex (C18, 250 mm × 4.6 mm); mobile phase, methanol/water 88.75/11.25; flow rate, 1.0 mL/min; detection, UV 280 nm; injection volume, 5 μL.

Six propolins, A–G, can be isolated from Taiwanese green propolis (TGP) and exert a broad spectrum of biological activities.[11] TGP is widely used in Taiwanese traditional medicine and reportedly exhibits anticancer,[12−18] antioxidant,[12,14,18] and antimicrobial[19] properties. Chen et al. used NMR and fast atom bombardment mass spectrometry to identify the chemical structure of propolin G and showed it to be identical to that of the compound nymphaeol C.[15] In our previous study, we found several active ingredients with TGP, including propolin G. It was revealed that propolin G can efficiently induce apoptosis in brain cancer cell lines (glioma and glioblastoma) through mitochondrial- and caspase-dependent pathways. Using the 1,2-diphenyl-2-picrylhydrazyl (DPPH) assay, we also showed that propolin G displays free radical scavenging activity and that propolin G, TGP, and Brazilian propolis (BP) extracts exert neuroprotective activity against oxidative stress in rat primary cortical neurons.[16] Because the apoptosis is an important response in physiological condition, especially in liver steatosis, we would like to investigate whether TGP and propolin G can modulate the process of liver fibrosis in hepatocytes. Propolis was collected from Chang-Hwa, a county in the middle of Taiwan. In the past, we collected propolis from northern, central, and southern Taiwan for analysis. We found that propolin G was most abundant from central Taiwan. Therefore, we utilized propolis from Chang-Hwa for this study. Therefore, we modified the previous purification method and used a prepared column and improved analysis method for mass propolin G collection (Figure 1). This study aimed to identify the underlying antifibrotic molecular mechanisms of TGP and propolin G to potentially facilitate the development of a novel treatment for liver fibrosis targeting Smad3 signaling components. According to our research, this study is the first to show that TGP and propolin G selectively down-regulate the expression of Smad2/3, but not Smads 4 and 7, mRNA, and protein in cultured rat HSCs. This process, in turn, significantly attenuates the TGF-β-induced deposition of Col Iα1 in the HSCs. Our results suggest that TGP and propolin G exert their antifibrogenic effects by directly or indirectly down-regulating Smad2/3 protein expression and phosphorylation through TGF-β signaling.

Alcoholic liver injury is a complex process involving several injury mechanisms and multiple cellular targets.[20] Ethanol oxidation and ethanol-induced injury occur in hepatocytes; thus, determining the mechanism by which ethanol primes and sensitizes hepatocytes is very important.[21] It was revealed that ethanol exposure inhibits hepatocyte regeneration in in vitro and in vivo systems.[22,23] Free radicals can bind to cellular molecules (i.e., nucleic acids, proteins, lipids, and carbohydrates),[24] induce lipid peroxidation, damage the membranes of liver cells and organelles, cause the swelling and necrosis of hepatocytes and result in the release of cytosolic enzymes such as aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP) into the circulating blood.[25,26] It is well-known that superoxide dismutase

(SOD), catalase (CAT), and glutathione peroxidase (GPx) act by scavenging the superoxide anion and H_2O_2 to prevent reactive oxygen species (ROS)-induced damage.[27] The present research therefore has the objective to explore the antioxidant properties and hepatoprotective effects of Taiwanese green propolis against ethanol-induced liver injury in mice. In this study, it was revealed that administration of TGP inhibited plasma or hepatic malondialdehyde (MDA) and ALT activation, whereas TGP has no influence on plasma or hepatic SOD and GPx levels in ethanol-treated mice. Further study is necessary to evaluate the effect of TGP on liver fibrosis prevention and to determine the molecular mechanisms.

MATERIALS AND METHODS

Propolis Origins. Taiwanese green propolis was collected from Taiwan. All samples were collected from May to July 2011, using propolis collectors. Propolis from the collectors at each location was gathered every month and kept at −20 °C until processed.

Extraction and Isolation of Propolin G. The TGP (50 g) was extracted with 95% ethyl alcohol (250 mL × 3), sonicated for 3 h, and left to stand for 21 h at 25 °C. The filtered ethanol extract was evaporated to dryness under reduced pressure to yield a brown gum (34.5 g), which was kept at −20 °C until used. The brown gum was dissolved in methanol and applied to an open silica column for the purification of propolin G. An *n*-hexane/EtOAc solvent system was used as the eluting solvent. Fraction 4 (*n*-hexane/EtOAc, 40:60) contained higher levels of propolin G than the other fractions. Fraction 4 was evaporated to dryness under reduced pressure to yield a yellow gum. The yellow gum was dissolved in methanol and carried out on a reversed-phase (RP) preparative high-performance liquid chromatograph (HPLC)-UV. Fractions of retention times at 17.0 min for propolin G were collected. Conditions were as follows: column, Macherey-Nagel (VP 250/10 NUCLEODUR C18 HTEC, 5 μm); solvent system, methanol/water (88:12); flow rate, 3.5 mL/min; and detection, UV 280 nm. We identified the compound as propolin G (Figure 1). The purity of the propolin G was estimated to be no less than 95% by HPLC-UV on the basis of the peak area.

Analysis Conditions. The propolin profile in the TGP extracts was analyzed with a RP HPLC-UV. The conditions were as follows: column, ZORBAX SB-C18 (4.6 × 250 mm; Agilent, Santa Clara, CA, USA); solvent system, methanol/water (88.8:11.2); flow rate, 1.0 mL/min; and detection, UV 280 nm.

Chemicals and Reagents. TGP and propolis G were stored as a stock solution in DMSO, which was used after dilution with medium for each assay. Trizol reagent and RevertAidi MMLV reverse transcriptase were obtained from Fermentas Life Science (Lithuania); Taq polymerase, dNTPs, and DNA marker were from TaKaRa Biotechnology Co. (Dalian, China). Primers for rat PAI-1, Smad3, Smad2, Smad7, Smad4, type I, type II, Col Iα1, FN, and β-actin (as internal control) were designed by our group in accordance with the gene sequence in GenBank. Cytokine recombinant human TGF-β was purchased from R&D System (Minneapolis, MN, USA). Precision protein standards and protein molecular weight markers were obtained from Bio-Rad (Hercules, CA, USA). All antibodies, including primary and secondary antibodies, were provided by Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA); Phospho-Smad3 antibody (Ser433/435) was purchased from Cell Signaling Technology Inc. (Beverly, MA, USA). All other reagents were analytically pure.

Cell Culture. HSC-T6 cells, derived from immortalized and activated rat HSCs transfected by SV40, were kindly donated by Professor Friedman from Mount Sinai Medical Center and were maintained at 37 °C in Dulbecco's modified Eagle medium (DMEM) containing 10% fetal calf serum (FCS), 100 units/mL penicillin, and 100 μg/mL streptomycin under a 5% CO_2 atm.

Cell Viability Assays. HSC-T6 cells were seeded overnight at 10000 cells/well in 96-well plates in DMEM, and the subconfluent cells in culture (75%) were washed twice with phosphate-buffered saline and serum-starved for 24 h with serum-free medium. To determine the optimal concentration of TGP or propolin G for use in these experiments, dose-dependent cytotoxicity was initially performed with different concentrations of TGP or propolin G added to culture for 48 h. Cell viability was determined by incubating each well with 10 μL of WST-1 for 4 h at 37 °C. Metabolically active cells cleave WST-1 to water-soluble formazan, which is directly quantitated with an enzyme-linked immunosorbent assay plate reader (Bio-Rad 3550). Each experiment was performed at least twice, and treatment for the cell line was done in triplicate.

Preparation of RNA and Protein Extracts. HSC-T6 cells were plated at a confluence of approximately 75% in the wells of a 6-well dish and allowed to attach overnight. Cells were treated with 10 ng/mL TGF-β for 12 h before being treated with a variety of concentrations of propolis, propolin G, or SB-431542 for 12 h to determine RNA levels and for 24 h to analyze TGF-β-regulated protein expression. Treated cells were harvested, washed, and lysed in ice-cold buffer [250 mM Tris-HCl, pH 7.4, containing a mixture of protease inhibitors (100 2 g/mL phenylmethanesulfonyl fluoride, 1 μg/mL E-64, 0.5 μg/mL leupeptin, and 1.7 μg/mL peptatin A)]. The debris was removed by centrifugation at 13000*g* for 20 min at 4 °C. Total protein amount in the extracts was measured using the Bio-Rad Bradford reagent. Total RNA was isolated from HSC-T6 cells as described by Chomczynski and Sacchi.[28]

Reverse Transcription Polymerase Chain Reaction Assay. After treatment, RNA was harvested with Trizol (Invitrogen, Carlsbad, CA, USA). For each reaction, 1 μg of total RNA was reverse-transcribed to cDNA using an RT kit (MBI) for reverse transcription polymerase chain reaction (RTPCR) (Ambion) as recommended by the manufacturer. The resulting cDNA was subsequently subjected to 40 cycles of PCR. PCR products were quantitated to confirm that they were in the linear range of amplification. PCR products were quantitated by Quantum RNA18S internal standards (Ambio). The following primers were used in this study: rat α-SMA (Genbank L26110), forward 5′-TTC GTT ACT GCT GAG CGT GAG-3′, reverse 5′-CGG GGA ATT AGG TCG ATT TC-3′ (product size 202 bp); and rat G3PDH (Genbank BC063166), forward 5′-CCC TTC ATT GAC CTC AAC TAC ATG G-3′, reverse 5′-CAT GGT GAA GAC GCC AG-3′ (product size 452 bp). The conditions for RT-PCR were as follows: cDNA synthesis and predenaturation were at 42 °C for 60 min, followed by 94 °C for 10 min. PCR amplification sequence was performed for 40 cycles at 94 °C for 45 s and at 57 °C for 45 s. After amplification, each sample was applied to 1.2% agarose/ethidium bromide gel. The resolved PCR products were photographed under UV illumination.

Western Blot. For Western blot, treated cells were harvested by the addition of ice-cold lysis buffer as described above. Centrifuged lysates (30 μg) from each sample were analyzed by SDS−polyacrylamide gel electrophoresis and transferred to a PVDF membrane by semidry transfer. The membranes were blocked for 1 h at room temperature in Tris-buffered saline containing 0.1% Tween 20 and 3% BSA. Blots were probed overnight at 4 °C with the following primary antibodies: anti-α-SMA, anti-Smad2/3, antiphospho-Smad2/3, anti-Col Iα1, and anti-β-actin antibodies. This was followed by incubation with the appropriate horseradish peroxidase-conjugated secondary antibody at a dilution of 1:1000 for 1 h. Detection was achieved by enhanced chemiluminescence (Amersham Pharmacia Biotech) followed by luminescent image analyzer (ImageQuant LAS4000). Digital data were further were quantitated by scanning densitometry using ImageQuant TL with a 1-D Analyst software package for Macintosh. The relative expression fold was all normalized with internal control (GAPDH or tubulin).

Animal Study. The animal study was approved by the Review Boards of National Ilan University with approval no. 102-8. Briefly, mice were housed in the animal center of National Ilan University according to general guidelines at 25 ± 1 °C with a 12 h dark/light cycle. For hepatic injury experiments, male 7-week-old C57BL/6J mice (approximately 21 g) were obtained from the National Laboratory Animal Center, Taipei, Taiwan. The study protocol was in accordance with the animal experimental guidelines of the Council of Agriculture, Executive Yuan. Each experimental group consisted of six mice, and

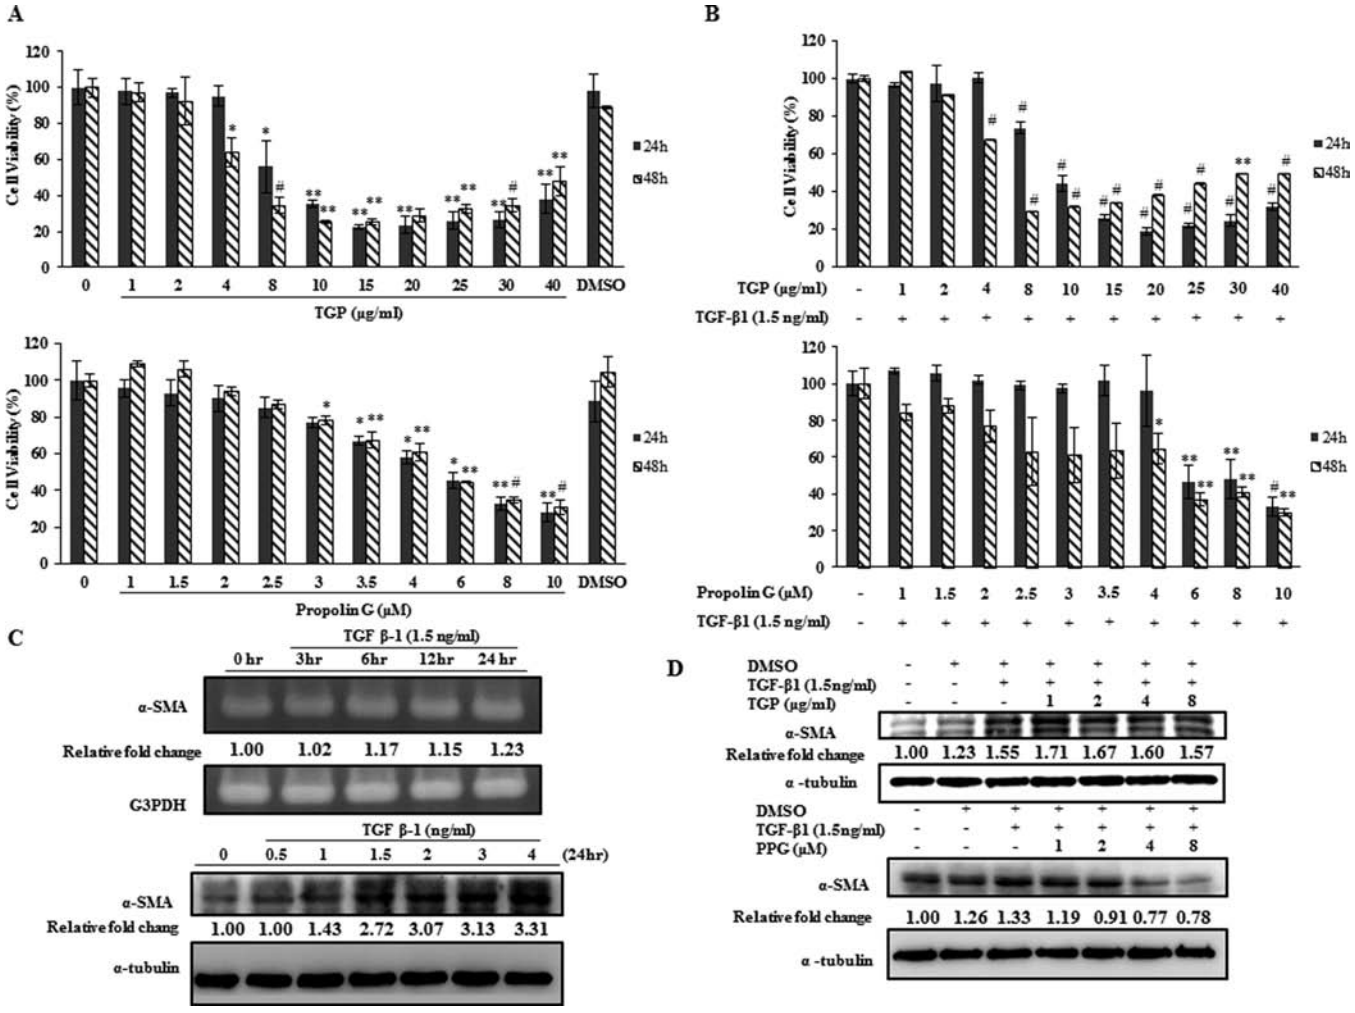

Figure 2. Inhibitory effects of TGP and propolin G on HSC-T6 cell viability. (A) HSC-T6 cells were treated with various TGP and propolin G concentrations for 24−48 h, and then cell viability was evaluated using the MTT assay. Each concentration was replicated three times. Data are expressed as mean ± standard deviation (SD). (*) $P < 0.05$, (**) $P < 0.01$, and (#) $P < 0.001$ indicate significant differences from the control group. (B) Inhibitory effects of TGP and propolin G on HSC-T6 cells in the presence of TGF-β1. Cells were treated with various TGP and propolin G concentrations in the presence of TGF-β1 (1.5 ng/mL) for 24−48 h, before the evaluation of cell viability using the MTT assay. Each concentration was replicated three times. Data are expressed as mean ± SD. (*) $P < 0.05$, (**) $P < 0.01$, and (#) $P < 0.001$ indicate significant differences from the control group. (C) Effects of TGF-β1 on α-SMA expression in HSC-T6 cells. HSC-T6 cells were treated with 1.5 ng/mL TGF-β1 for various time periods (3, 6, 12, and 24 h). α-SMA mRNA expression was then evaluated using RT-PCR. HSC-T6 cells were treated with 0−4 ng/mL TGF-β1 for 24 h. The expression of α-SMA protein was then evaluated using Western blotting (D). HSC-T6 cells were treated with 1.5 ng/mL TGF-β1 and TGP or propolin G for 24 h. The expression of α-SMA protein was then evaluated using Western blotting.

each of them was administered TGP (200 and 400 mg/kg/day) for 28 days. For injury, mice were administered alcohol (5 g/kg) followed by sacrifice after 24 h. Blood was drawn from the heart for serum analysis, and livers were quickly excised to analyze the levels of SOD, catalase, GPx, and lipid peroxide. Serum was separated by centrifugation at 3000*g* for 5 min for assays of ALT and ALS, activity, and protein levels. These samples were preserved at −80 °C until biochemical assay.

Statistical Analysis. All values are given as means ± SE. Data analysis involved one-way ANOVA with subsequent Scheffé test. * and ** indicate significant differences at the levels of $P < 0.05$ and $P < 0.01$, respectively, compared to PBS alone.

RESULTS AND DISCUSSION

Effects of TGP or Propolin G on TGF-β1-Induced α-SMA mRNA and Protein Expression in HSC-T6 Cells. To evaluate the cytotoxic effects of TGP and propolin G on HSC-T6 cells, we used the MTT assay to analyze HSC-T6 cell viability after treatment with TGP or propolin G. Our results showed that HSC-T6 cells can be treated with TGP (up to 2 ug/mL) or propolin G (up to 2 μM) for up to 48 h without any effects on cell viability (Figure 2A). The IC50 of TGP on HSC-T6 cell was 9.22 μg/mL at 24h and 7.61 μg/mL at 48 h while the IC50 of propolin G was 6.61 μM at 24h and 6.22 μM at 48h. We also evaluated the potential inhibitory effects of TGP and propolin G on TGF-β-mediated biological effects in HSC-T6 cells. To do this, we pretreated the cells with 1.5 ng/mL TGF-β before exposing them to TGP or propolin G. Around IC50 concentration, the cell viability was elevated 24h after treatment, however, with prolong treatment for 48h, the cell viability was reduced when compared with those of 24h after treatment. Thus, TGP and propolin G treatments can attenuate TGF-β-stimulated HSC cell viability in a dose-dependent manner (Figure 2B). We then analyzed the cells' responsiveness to TGF-β by evaluating α-SMA mRNA and protein expression. We observed significant up-regulation of α-SMA mRNA and protein expression following the treatment of HSC-T6 cells with 1.5 ng/mL TGF-β for 24 h (Figure 2C).

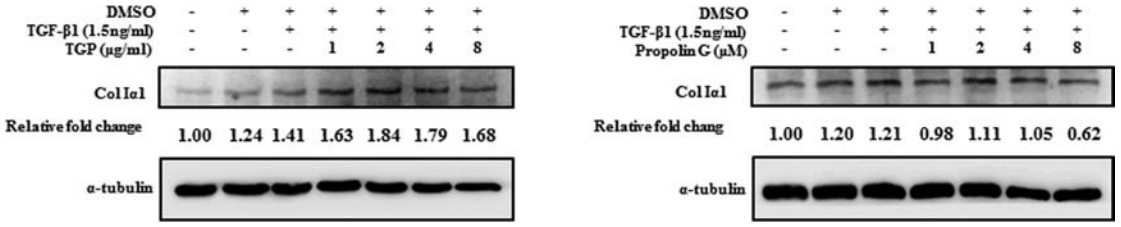

Figure 3. Effects of TGP and propolin G on Col Iα1 expression. Cells were treated with 1.5 ng/mL TGF-β1 and various TGP or propolin G concentrations for 24 h. Western blot analyses were then performed to evaluate Col Iα1 expression.

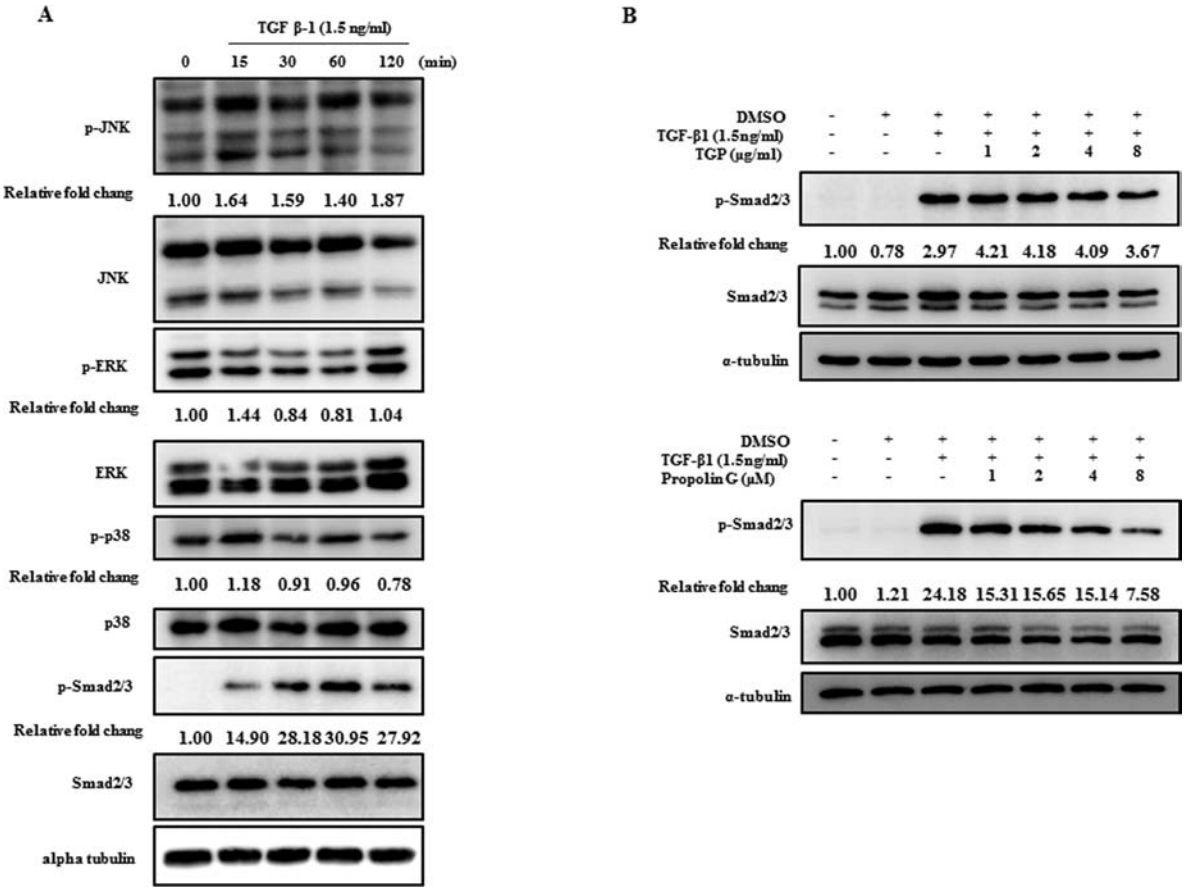

Figure 4. Effects of TGP and propolin G on Smad3 expression and phosphorylation. (A) Time-course of the effects of TGF-β1 on the phosphorylation of MAPK and Smad2/3 in HSC-T6 cells. The cells were treated with TGF-β1 (1.5 ng/mL) for various time periods (15, 30, 60, and 120 min), before Western blot analysis of JNK, extracellular signal-regulated kinase (ERK) 1/2, p38, and Smad2/3 expression. (B) TGP and propolin G down-regulated phosphor-Smad2/3 expression in HSC-T6 cells. HSC-T6 cells were pretreated with TGP or propolin G for 1 h and then treated with TGF-β1 for 1 h. Whole hepatic cell extracts were immunoblotted with the antibodies against phosphor-Smad2/3.

Furthermore, we observed the reduction of TGF-β-induced α-SMA protein expression especially after 4 μM propolin G treatment in the HSC-T6 cells (Figure 2D). However, although the inhibitory effect was more significant after 8 μM treatment, we cannot exclude the cytotoxicity effect. These results indicated that TGP and propolin G attenuated the TGF-β-dependent up-regulation of α-SMA mRNA and protein expression in HSCs. This is the first study to show that TGP and propolin G can reduce the TGF-β-induced accumulation of ECM in cultured HSC-T6 cells. One potential underlying mechanism of these effects might be the disruption of TGF-β signaling by selectively targeting Smad2/3. To evaluate this mechanism, we first investigated the cytotoxicity of TGP and propolin G to HSC-T6 cells using the MTT assay. Our results showed that TGP and propolin G have low cytotoxicity to HSCs, with an IC_{50} value of 100 μM (data not shown). The study by Well et al. described the antiproliferative activity of TGF-β in HSCs and rats, showing that the disruption of TGF-β signaling leads to increased HSC proliferation.[6] In this study, nontoxic concentrations of TGP and propolin G minimally promoted HSC-T6 cell propagation (Figure 2), indicating that these compounds might antagonize TGF-β signaling.

TGP and Propolin G Down-regulate the TGF-β-Induced Expression of Profibrotic Gene and Inhibit TGF-β-Induced Smad2/3 and Smad2/3 Phosphorylation. We used Western blotting to quantify the Col Iα1 protein level, in comparison with α-tubulin control. After pretreatment with TGF-β and treatment with TGP and propolin G in HSC-T6 cells, the expression level of Col Iα1 had no significant change after TGP or propolin G treatment except a slight reduction at

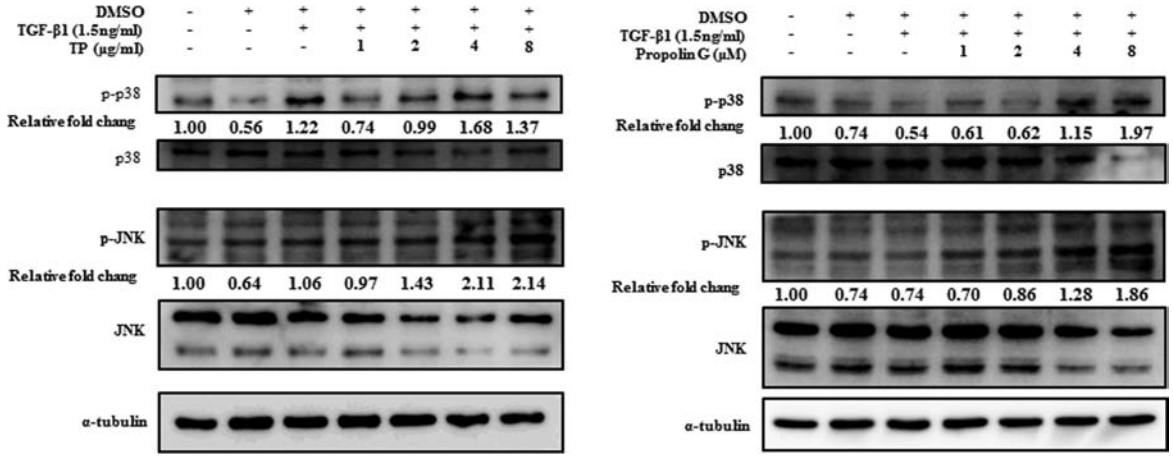

Figure 5. TGP and propolin G up-regulate phospho-JNK MAPK expression in TGF-β-stimulated HSC-T6 cells. TGP and propolin G up-regulated the expression of phospho-JNK and phospho-p38 MAPK in HSC-T6 cells. HSC-T6 cells were pretreated with TGP or propolin G for 1 h before treatment with TGF-β1 for 15 min. Whole hepatic cell extracts were immunoblotted with the antibodies against phospho-JNK and phospho-p38.

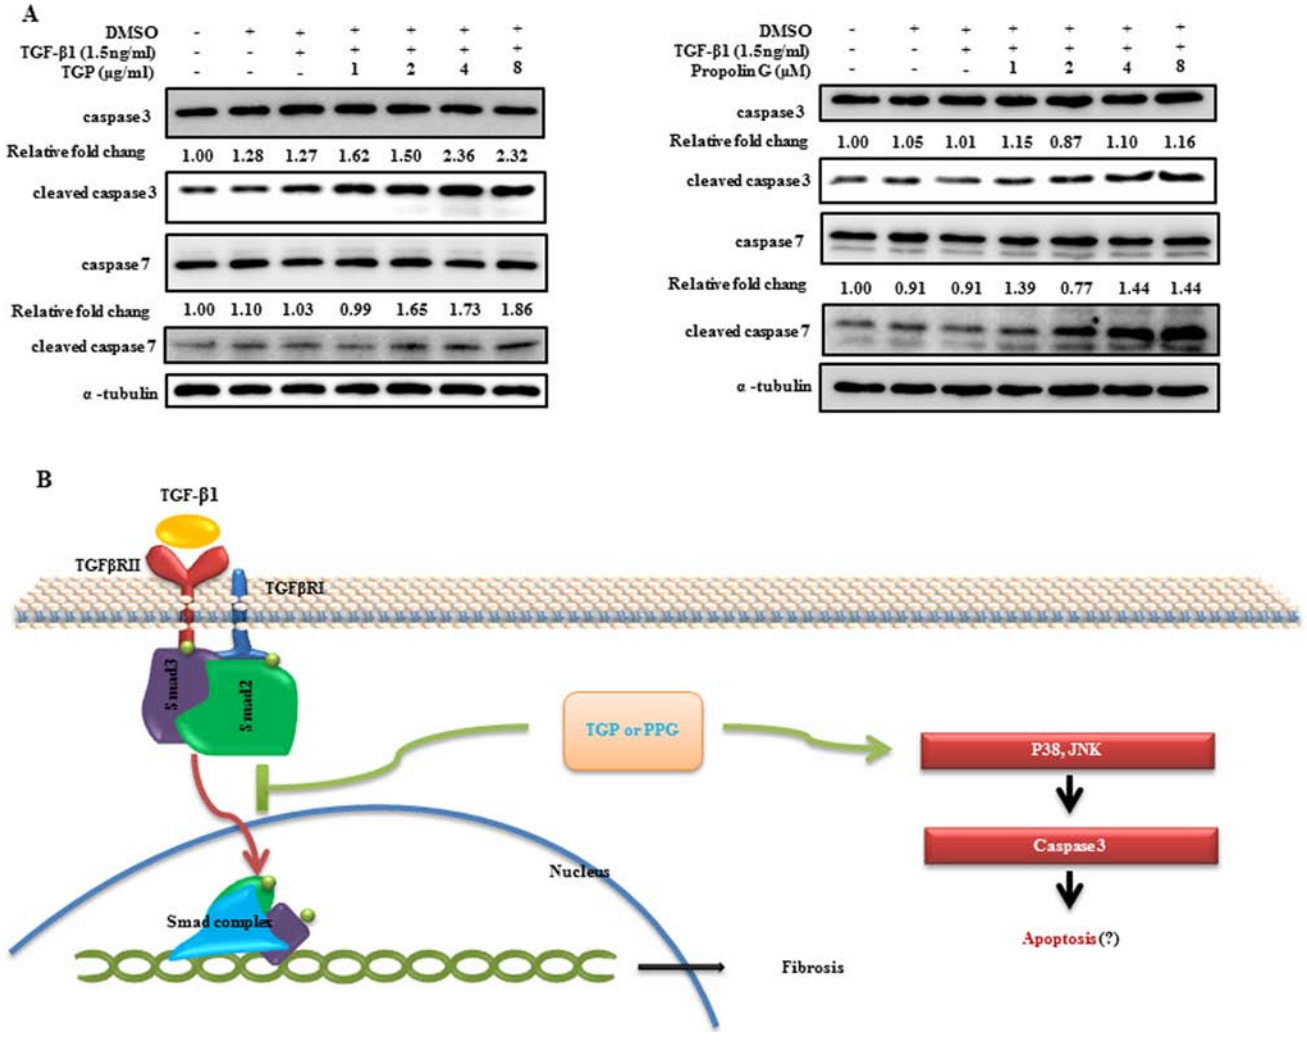

Figure 6. Effects of TGP and propolin G on the expression of apoptosis-related proteins in HSC-T6. (A) Cells were treated with 1.5 ng/mL TGF-β1 and various TGP or propolin G concentrations for 24 h. Western blotting was used to evaluate the expression of caspase-3 and caspase-7. (B) Illustration of signaling for hepatic fibrosis inhibition by TGP and propolin G.

8 μM propolin G treatment, which might be due to cytotoxicity (Figure 3). Smad3 is considered the essential mediator of TGF-β signaling, because it directly activates genes encoding transcriptional regulators and signal transducers through the Smad2/3 DNA-binding motif characteristics of the immediate early target genes of TGF-β. In this study, we used RT-PCR

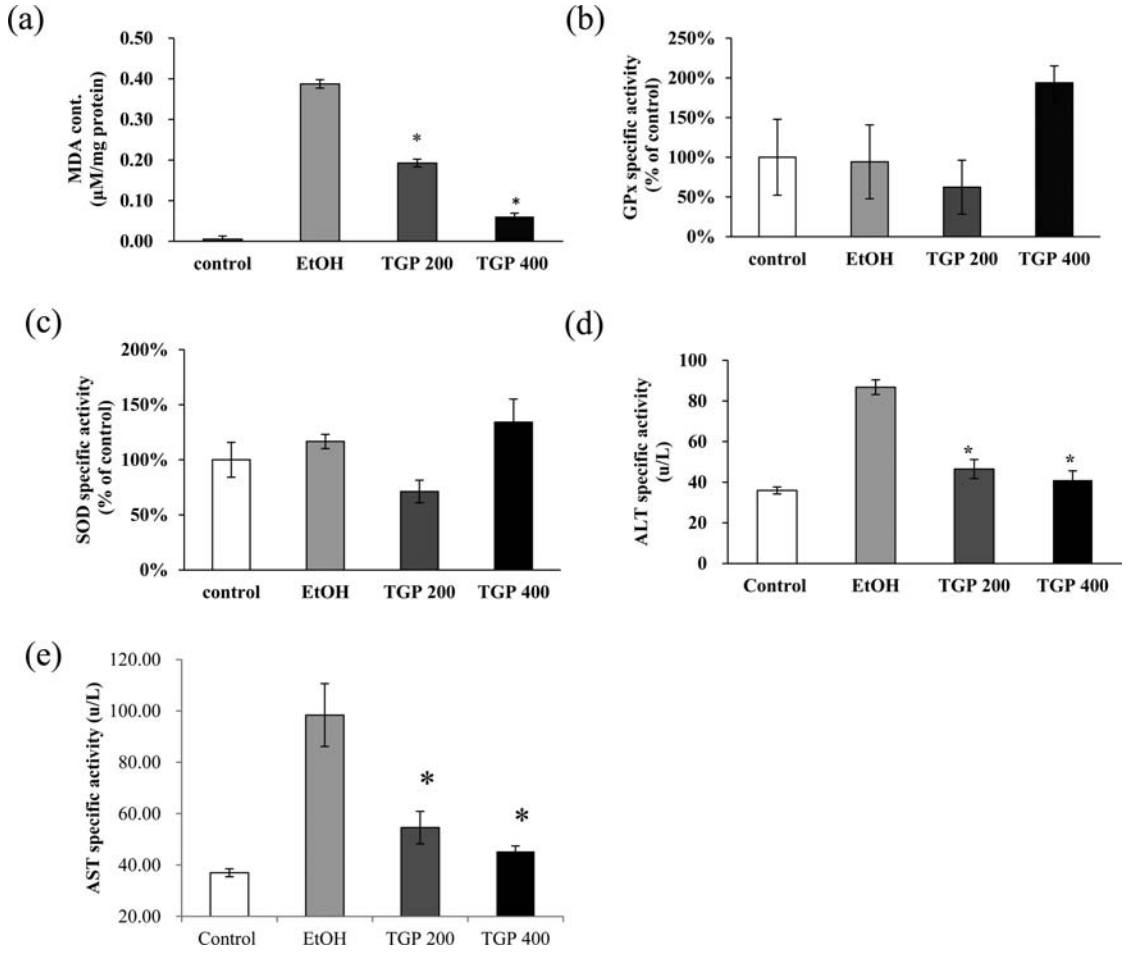

Figure 7. Effect of TGP on plasma MDA ALT levels and SOD and GPx activities in ethanol (Et)H)-treated mice. The control group received oral administration of olive oil. The EtOH group received EtOH (5 g/kg, oral). TGP (200, 400 mg/kg) + EtOH (5 g/kg) groups received TGP (200, 400 mg/kg, oral) for 4 weeks and were gavaged with EtOH (5 g/kg). TGP (200, 400 mg/kg) treatment attenuated the EtOH-induced damage of increased MDA (a) level but did not affect SOD and GPx activities. Also, TGP can reduce ALT (d) and AST (e) levels and exert liver protection function. Data are presented as mean ± standard deviation (SD) (n = 6 mice). $P < 0.05$ versus the EtOH group.

and Western blotting to evaluate the potential inhibitory effects of propolin G on TGF-β-mediated Smad2/3 and Smad2/3 phosphorylation in HSC-T6 cells. As shown in Figure 4A, TGF-β can significantly induce Smad2/3 phosphorylation in HSC-T6 cells in a time-dependent manner (from 15 to 120 min), suggesting that the phosphorylation of Smad3 by TβRII is the initial step in signal transduction. We also evaluated the potential inhibitory effects of propolin G on TGF-β-induced Smad2/3 phosphorylation in HSC-T6 cells. We observed that propolin G reduced TGF-β-induced Smad3 phosphorylation in a dose-dependent manner in the HSC-T6 cells (Figure 4B). The HSCs are considered the primary sites of hepatic fibrogenesis, and studies have shown activated HSCs to be the key sources of excess ECM proteins in liver fibrosis.[29,30] With regard to liver fibrosis, there are several pieces of evidence indicating that apoptosis played an important role in this process. For example, in CCl_4-induced acute liver fibrosis damage animal model, Fas and FasL were overexpressed in liver followed by caspase cascade activation.[30,31] In fact, in chronic hepatitis and liver damage, the progression of liver fibrosis was due to the reduced apoptosis because of other undamaged cells and growth factors contributing to tissue regeneration.[32] During liver fibrogenesis, increased extracellular TGF-β initiates TGF-β-Smad3 signaling before activated Smad3/Smad4 complexes translocate into the nucleus and immediately bind and activate target genes, including Col Iα1, TIMP-1, PAI-1, FN, and other ECM genes.[33−36] PAI-1 is a specific target gene of Smad3 and is typically used as a marker of activated TGF-β-Smad2/3 signaling.[37,38] In our study, TGP and propolin G significantly down-regulated TGF-β1-induced α-SMA mRNA and protein expression in HSCs (Figure 2), indicating that these compounds might directly or indirectly inhibit TGF-β1-Smad2/3 signaling. These results were similar to those of Tang et al. that blockage of TGF-β-Smad2/3 signaling can efficiently protect liver from fibrosis.[39] Furthermore, according to a study by Bissell et al., the down-regulation of PAI-1 protein expression could indirectly increase matrix degradation through increased plasmin activity.[40] SB-431542 is a small molecular inhibitor of the type I TGF-β receptor through a specific and competitive A TGP-binding site kinase and inhibits the phosphorylation of Smad2/3 by binding TβRI.[38] This process, in turn, inhibits the exogenous TGF-β1-induced synthesis of FN, PAI-1, and Col Iα1. In our study, TGP and propolin G down-regulated Smad2/3 mRNA and protein expression and reduced TGF-β1-induced Smad2/3 phosphorylation in HSC-T6 cells (Figure 4).

Propolin G Increases Phosphor-JNK MAPK Expression and Induces Apoptosis in TGF-β-Stimulated HSCs in

TGF-β-Stimulated HSCs. To investigate the apoptotic signaling pathways underlying the effects of propolin G on HSC-T6 cells, we evaluated the expression of two signaling proteins associated with oxidative stress: phospho-JNK MAPK and phospho-Akt. The result indicated that p-P38 and p-JNK were significantly elevated 30 min and 2 h after TGF-β treatment; this was consistent with the previous study.[41] However, we did not observe the elevation of p-ERK. We treated the HSCs with various concentrations of TGP (1−8 μg/mL) or propolin G (1−8 μM) prior to treatment with TGF-β for 15 min. Our Western blotting results showed that TGP and propolin G significantly up-regulated phospho-JNK and phospho-P38 MAPK expression in TGF-β1-stimulated cells (Figure 5). To investigate the effects of TGP and propolin G on apoptosis, we treated the HSCs with various concentrations of TGP (1−8 μg/mL) or propolin G (1−8 μM) for 24 h, before evaluating apoptosis. As shown in Figure 6A, TGP and propolin G activated caspase-7 and caspase-3 in a dose-dependent manner (Figure 6A). TGP and propolin G also activated caspase-9 and induced the cleavage of caspase-3 and PARP, in a time-dependent manner. Taken together, these results indicated that TGP and propolin G can not only attenuate TGF-β signaling via Smad2/3 inhibition but also enhance apoptosis through inducing p38 and JNK mediated caspase activity (Figure 6B). Because we cannot exclude the reduction of Smad2/3 phosphorylation by TGP or propolin G may due to cell apoptosis at this time, the results indicate TGP or propolin G can affect the process of fibrosis possibly through both TGF-β signaling inhibition and cell apoptosis below IC_{50} concentration. However, the issue of cell cytotoxicity at high dose in our findings should be carefully addressed when considering applications in the furture when compared with other low toxicity compounds.[39] On the other hand, these findings suggested that naringenin might reduce ECM components through a molecular mechanism different from SB-431542. Naringenin increases PI3K and MAPK ERK1/2 (p 38) activity in HepG2 cells in a manner similar to that of insulin. In previous studies, TGP and propolin G did not induce insulin receptor substrate phosphorylation.[42,43] Although other studies have shown that insulin- and insulin-like growth factor-I-mediated signaling pathways modulate TGF-β signaling,[44,45] the molecular details of the effects of these pathways on TGF-β signaling have yet to be fully elucidated. One mechanism by which anti-apoptotic signaling, mediated by PI3K-PKB, inhibits TGF-β signaling is the induction of interaction between PKB and Smad3, thus reducing the pool of Smad3 available for TGF-β signaling. The process is based on the down-regulating effects of insulin and insulin-like growth factors on TGF-β-regulated gene expression and can be reversed by using highly specific inhibitors of PI3K, LY294002, or wortmannin. Insulin significantly inhibits the phosphorylation of TGF-β1-induced Smad3, but not Smad2, whereas Smad2/3 protein expression remains unaffected by insulin treatment.

Ethanol Extract of Taiwanese Green Propolis against the Ethanol-Induced Hepatic Injury in Mice. We measured the activities of SOD and GPx and the MDA level in the plasma of mice. The MDA and ALT levels in EtOH-treated mice were significantly increased, as compared to that in the control group (Figure 7). Administering TGP (200 and 400 mg/kg/day) significantly inhibited the increase of MDA (Figure 7a) and GPx (Figure 7b) as well as SOD (Figure 7c). The SOD and GPx expression in the liver tissue was similar to plasma (data not shown). Furthermore, to examine whether the liver function can be rescued by TGP, we tested the ALT (Figure 7d) and AST (Figure 7e) to add support to the in vivo animal result. The data indicated that TGP can significantly reduce ALT and AST levels induced by ethanol, suggesting that TGP had a liver protection function. The production of ROS can also be evaluated indirectly by analyzing the level of MDA, a product of free radical-induced lipid peroxidation. To protect cells against oxidative damage induced by ROS, the antioxidant system in the body is activated, and endogenous antioxidant enzymes, such as SOD and GPx, scavenge ROS or prevent their formation. It has been reported that naturally fermented noni juice (NJ) contains polyphenols, polysaccharides, and some trace minerals. NJ promotes hepatoprotection against alcohol-induced injury due to regulations of lipid homeostasis, antioxidant status, alcohol metabolism (Chang et al., 2013).[46] TGP is widely used in Taiwanese traditional medicine and reportedly exhibits anticancer,[12−18] antioxidant,[12,14,18] and antimicrobial [19] properties. Interestingly, TGP has no influence on plasma or hepatic SOD and GPx levels but significantly decreased the MDA value. It is possible that TGP acts by several mechanisms, mediating a potential role in liver fibrosis retrieval in mice. Further study is necessary to evaluate the effect of TGP on liver fibrosis prevention and to determine the molecular mechanisms.

In conclusion, our results indicate that TGP and propolin G exert antifibrotic effects through the disruption of TGF-β-Smad2/3 signaling by directly or indirectly reducing Smad2/3 formation. These findings verify that Smad3 is a crucial mediator of TGF-β-modulated fibrogenic function and indicate that the inhibition of Smad2/3 protein function could potentially provide an effective strategy for the treatment of liver fibrosis. Although more detailed mechanistic studies are necessary to clarify the mechanisms of antifibrosis using TGP or propolin G, these results should encourage further studies to explore the potential antifibrosis effects of TGP or propolin G in chronic liver diseases.

point at which diabetic nephropathy occurs. All of the above evidence clearly indicate that MGO is a key factor in *in vivo* AGE production. Thus, scavenging reactive dicarbonyl species has been used as an effective strategy to prevent protein modification and AGE formation.[12−14] Driven by this strategy, several pharmacological reagents, such as aminoguanidine,[15,16] tenilsetam,[17,18] carnosine,[19] metformin,[20,21] and pyridoxamine,[22,23] have been developed for inhibiting the formation of AGEs and preventing the development of diabetic complications. However, all of these pharmaceutical agents have serious side effects. For example, the nucleophilic hydrazine compound aminoguanidine failed in phase III clinical trials because of the high toxicity in diabetic patients.[24] Therefore, it is critical to develop effective and safe agents to protect diabetics from complications.

Flavonoids are polyphenolic compounds that are ubiquitous in nature, many of which occur in fruits, vegetables, and beverages (tea, coffee, beer, wine, and fruit drinks). Recently, flavonoids have aroused considerable interest because of their potential beneficial effects on human health. They have been reported to reduce the risk of chronic diseases, such as cancer, cardiovascular disease, asthma, and diabetes. Certain flavonoids have shown more effective inhibition of AGE formation than aminoguanidine, a well-known AGE inhibitor.[25] For example, luteolin, rutin, (−)-epigallocatechin-3-gallate (EGCG), and quercetin demonstrated significant inhibitory effects on MGO-mediated AGE formation by 82.2, 77.7, 69.1, and 65.5%, respectively.[25] Researchers have documented the effects of added natural phenolic compounds on the generation of reactive carbonyl intermediates.[26] Previous studies in our lab have shown that EGCG from green tea, phloretin and phloridzin from apple, and genistein from soybean were able to effectively trap MGO to form mono- and di-MGO adducts.[27−29] Besides, in a study by Ma et al., phloretin or phloridzin exhibited great inhibitory effects on arginine residue modification by MGO,[30,31] which indicated that a direct capture of the reactive α-dicarbonyl species, such as MGO, would effectively inhibit the formation of AGEs and eventually benefit the prevention of diabetic complications.

In studying the mechanism that flavonoids can scavenge reactive dicarbonyl species, we revealed that the A ring of EGCG played significant role in trapping of reactive dicarbonyl species.[27−29] We also found that the A ring is the active site of phloretin or phloridzin on both MGO and glyoxal (GO) trapping. However, the structure−activity relationship (SAR) of flavonoids in scavenging reactive α-dicarbonyl species was not thoroughly investigated. In addition, the daily intake of individual flavonoids may not be high enough to significantly decrease the levels of reactive dicarbonyls in humans; however, the total intake of flavonoids from a variety of foods can reach the effective doses to trap a significant amount of exogenous and endogenous reactive dicarbonyls. Therefore, it is important to study the potential additive effects of different flavonoids. In the present study, we investigated the reaction of some naturally occurring flavonoids together with their subcomponents with MGO, in an attempt to establish the SAR of flavonoids in scavenging dicarbonyl species. The additive effects of trapping MGO at different concentrations by phloretin and quercetin were also carried out under an *in vitro* system.

MATERIALS AND METHODS

Materials. Quercetin, luteolin, epicatechin, genistein, daidzein, apigenin, phloretin, gallic acid, phloroglucinol, methylglyoxal (40% in water), 2-methylquinoxaline, and 1,2-diaminobenzene (DB) were purchased from Sigma (St. Louis, MO). Pyrogallol (Pg), pyrocatechol, resorcinol, and liquid chromatrography/mass spectrometry (LC/MS)-grade MeOH and water were purchased from Thermo Fisher Scientific (Pittsburgh, PA). High-performance liquid chromatography (HPLC)-grade solvents and other reagents were obtained from VWR Scientific (South Plainfield, NJ). HPLC-grade water was prepared using a Millipore Milli-Q purification system (Bedford, MA).

Kinetic Study of Trapping MGO by Dietary Flavonoids and Simple Phenols. MGO (0.33 mM) was mixed with 1 mM quercetin, luteolin, epicatechin, genistein, daidzein, apigenin, gallic acid, phloroglucinol, Pg, pyrocatechol, or resorcinol in pH 7.4 phosphate-buffered saline (PBS, 100 mM). The mixed solutions were incubated at 37 °C and shaken at 40 revolutions per minute (rpm) for 0, 10, 30, 60, 120, 240, 480, and 1440 min. Afterward, 200 μL of reacted mixtures were collected at each time point, 1 μL of acetic acid was added to stop the reaction, and 100 mM DB was allowed to react with the remaining MGO for 30 min. The level of methylquinoxaline was determined using the HPLC method described below.[28]

Trapping of MGO by Phloretin, Quercetin, and the Combination of Phloretin and Quercetin. MGO (300 or 60 μM) was incubated with phloretin (50 or 10 μM), quercetin (50 or 10 μM), or a combination of phloretin and quercetin (50 or 10 μM each) in pH 7.4 PBS (100 mM) at 37 °C and shaken at 40 rpm for 24 h. Then, 400 μL of each reacted mixture was collected, and 2 μL of acetic acid was added to stop the reaction. Half of this solution was used for LC/MS analysis, and the other half was used for the derivatization of the remaining MGO by adding 100 mM DB according to our previous method.[28]

Trapping of MGO by Pg. Pg (12.6 mg, 0.1 mmol) was dissolved in 10 mL of PBS (100 mM, pH 7.4) and treated with a diluted solution of MGO (0.033 or 0.1 mmol) in PBS (100 mM, pH 7.4). The mixture was incubated at 37 °C for 3 h and then quenched by adding 200 μL of acetic acid. After dilution, 100 times by MeOH, the reaction mixture was then analyzed by LC/MS.

HPLC Analysis. The level of methylquinoxaline was determined using our previous HPLC method, with slight modification.[28] Briefly, the HPLC system was equipped with a Waters 717 refrigerated autosampler, a HITACHI L-6200 Inteligent pump, and a Waters 490E programmable multi-wavelength ultraviolet−visible (UV−vis) detector. A Supelcosil C18 reversed-phase column (150 × 4.6 mm inner diameter, Supelco Co., Bellefonte, PA) was used with a flow rate of 1 mL/min. Both the column and sample temperatures were set at ambient conditions. The binary mobile phase system consisted of 5% aqueous acetonitrile with 0.2% acetic acid as A and 95% aqueous acetonitrile with 0.2% acetic acid as B. The column eluted with a binary gradient system: 100−65% A from 0 to 5 min, 65−60% A from 5 to 15 min, 60−0% A from 15 to 20 min, and then 100% A from 21 to 30 min. The injection volume was 50 μL. The wavelength of the UV detector was set at 280 nm with 100 ng/mL as the limit of detection (LOD) and 1 μg/mL as the limit of quantification (LOQ).

LC/MS Analysis. LC/MS analysis was carried out with a Thermo-Finnigan spectra system, which consisted of an Accela high-speed MS pump, an Accela refrigerated autosampler, and a LCQ Fleet ion trap mass detector (Thermo Electron, San Jose, CA) incorporated with electrospray ionization (ESI) interfaces. For the analysis of Pg or its main MGO adducts, a 150 × 3.0 mm inner diameter, 5 μm Gemini C18 column (Phenomenex, Torrance, CA) was employed with a flow rate of 0.3 mL/min in the current study. The column was eluted with 100% solvent A (100% water with 0.2% acetic acid) for 5 min, followed by linear increases in B (100% methanol with 0.2% acetic acid) to 30% from 5 to 20 min, 80% from 20 to 40 min, 100% from 40 to 50 min, and then 100% from 50 to 55 min. The column was then re-equilibrated with 100% A for 5 min. As far as phloretin, quercetin, or their major MGO adducts were concerned, a 50 × 2.0 mm inner diameter, 3 μm Gemini C18 column (Phenomenex, Torrance, CA) was used for separation at a flow rate of 0.2 mL/min. The column was

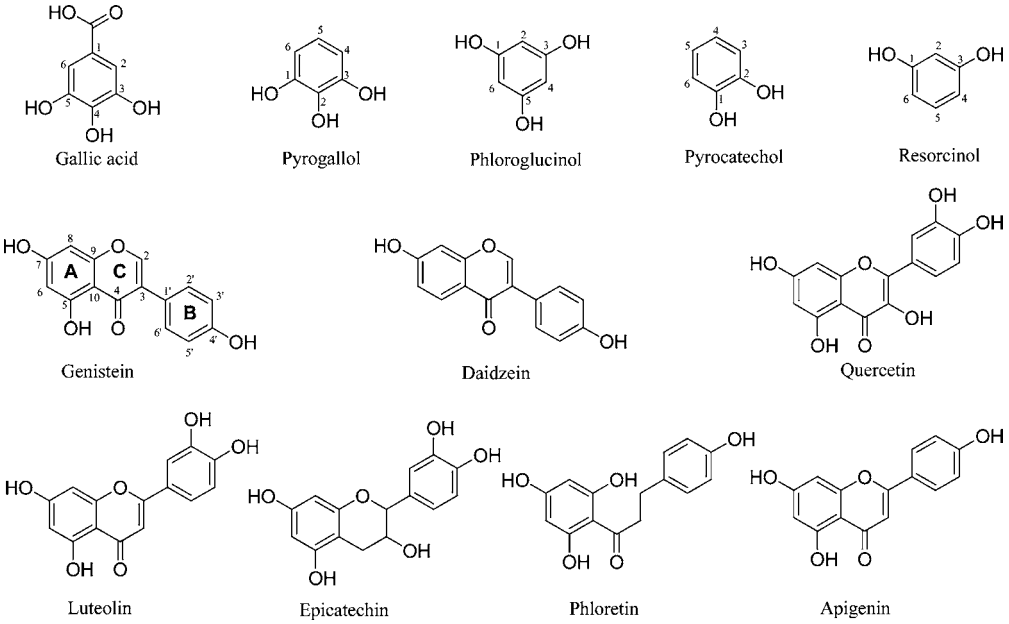

Figure 1. Chemical structures of gallic acid, pytogallol (Pg), phloroglucinol, pyrocatechol, resorcinol, genistein, daidzein, quercetin, luteolin, epicatechin, phloretin, and apigenin.

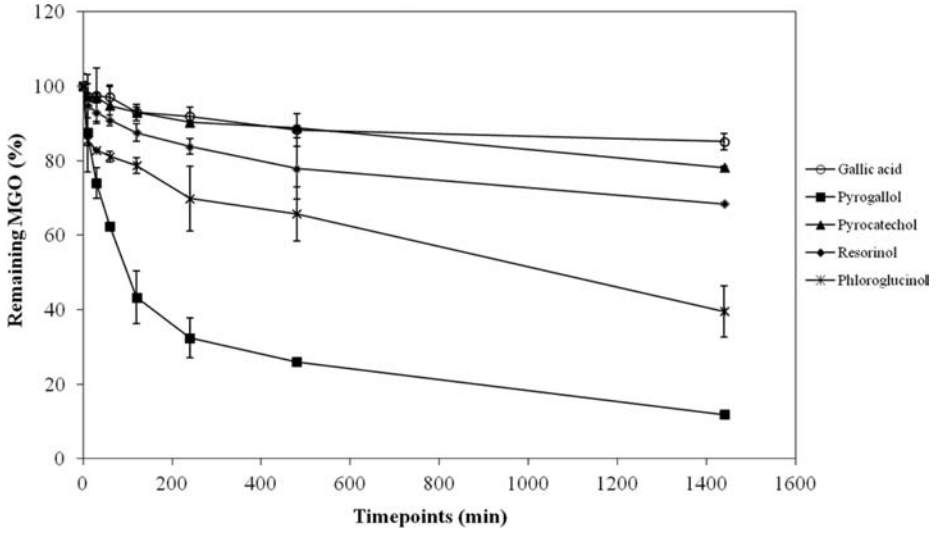

Figure 2. Trapping of MGO by gallic acid, pytogallol (Pg), phloroglucinol, pyrocatechol, and resorcinol.

eluted with 100% solvent A (100% water with 0.2% acetic acid) for 5 min, followed by linear increases in B (95% aqueous methanol with 0.2% acetic acid) to 20% from 5 to 10 min, 50% from 10 to 20 min, 100% from 20 to 28 min, and then 100% from 28 to 33 min. The column was then re-equilibrated with 100% A for 7 min. The LC eluent was introduced into the ESI interface. The negative-ion polarity mode was set for the ESI ion source with the voltage on the ESI interface maintained at approximately 5 kV. Nitrogen gas was used as the sheath gas at a flow rate of 30 arbitrary units and the auxiliary gas at 5 arbitrary units. The structural information of phloretin, quercetin, Pg, and the major MGO adducts was obtained by tandem mass spectrometry (MS/MS) through collision-induced dissociation (CID) with a relative collision energy setting of 35%. Data acquisition was performed with Xcalibur, version 2.0 (Thermo Electron, San Jose, CA).

RESULTS

Trapping of MGO by Simple Phenols. In general, flavonoids are composed of three different small units, rings A, B, and C (chalcones are ring C cleavage products). To obtain the essential SAR in trapping dicarbonyl species by dietary flavonoids, we selected some typical sub-components of flavonoids to simplify the influential factors. Five simple phenols, gallic acid, Pg, pyrocatechol, resorcinol, and phloroglucinol (Figure 1), were chosen for our current study. Among these compounds, Pg showed the highest scavenging activity by trapping almost 90% MGO within 24 h of incubation, followed by phloroglucinol, which could trap 60.5% MGO (Figure 2). Resorcinol and pyrocatechol showed relatively lower scavenging activity by trapping 31.6 and 21.8% MGO, respectively (Figure 2). In contrast, gallic acid was found to be the least active agent by trapping only 14.9% MGO within 24 h of incubation, even if it has the same *vic*-trihydroxyl groups as Pg (Figure 2).

MGO Adducts of Pg. To further investigate the MGO-trapping mechanism of Pg, the reaction of Pg and MGO was

tried at two different ratios (3:1 or 1:1 Pg/MGO). After 3 h of incubation (3:1 Pg/MGO), one major new peak [retention time (RT) of 13.04 min] appeared in the LC chromatogram (Figure 3A). This new peak had a molecular ion at m/z 197 [M − H]$^-$, which is 72 mass units (molecular weight of MGO of 72) higher than that of Pg, indicating that it is a mono-MGO

dx.doi.org/10.1021/jf500204s | J. Agric. Food Chem. 2014, 62, 3202−3210

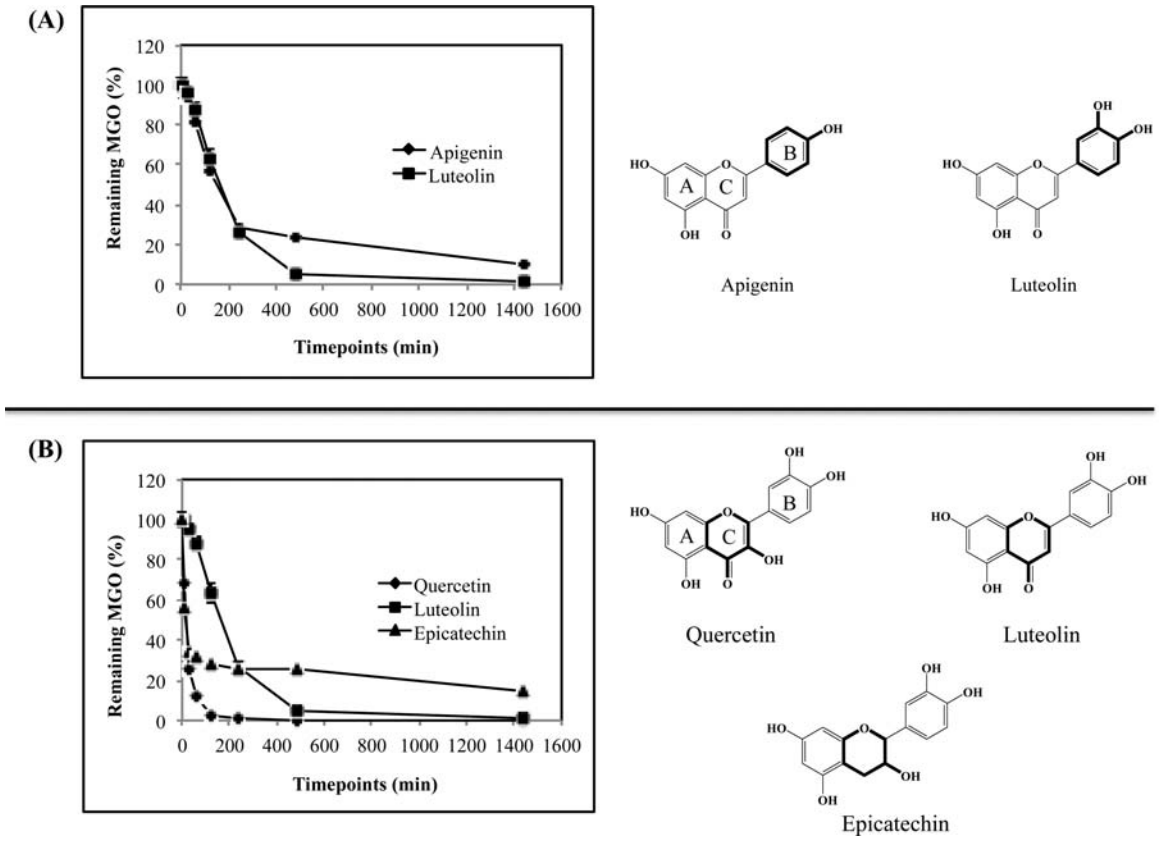

Figure 5. Trapping of MGO by (A) apigenin and luteolin and (B) quercetin, luteolin, and epicatechin.

conjugated pyrogallol (MM−Pg). Its MS^2 spectrum displayed a predominant dehydration ion at m/z 179 $[M - H_2O - H]^-$ (Figure 3B), while one more peak (RT of 13.90 min) was observed besides the peak of MM−Pg (RT of 12.83 min) with Pg and MGO at a 1:1 ratio (Figure 3C). This peak had a molecular ion at 269 $[M - H]^-$, which is 72 mass units higher than that of MM−Pg, suggesting that this product is the di-MGO conjugated pyrogallol (DM−Pg). Similarly, its MS^2 spectrum also displayed a predominant dehydration ion at m/z 251 $[M - H_2O - H]^-$ (Figure 3D). Because of the instability of these adducts, we failed to purify either MM−Pg or DM−Pg from the reaction mixture. However, the proton nuclear magnetic resonance (^{1}H NMR) spectrum (600 MHz in CD_3OD) of the crude mixture with MM−Pg as the major component showed only singlet signals for the aromatic ring protons (data not shown), suggesting that MGO was located at C-5 of Pg in MM−Pg (Figures 1 and 3B). The formation of mono- and di-MGO conjugated products of Pg was tentatively proposed in Figure 3E. The identification of position 5 as the active site of Pg further explained why gallic acid has almost no trapping effect of MGO and the B or D ring of EGCG is not the active site to trap MGO.

Effects of the A Ring on MGO-Trapping Efficacy. We used phloroglucinol and resorcinol to represent the A-ring structures of flavonoids. Our result that phloroglucinol is a better MGO scavenger than resorcinol indicates that the hydroxyl group on C-5 of the A ring will enhance the trapping efficacy of flavonoids. To test this hypothesis, we compared the MGO-trapping effects of genistein and daidzein, which have A-ring structures almost identical to phloroglucinol and resorcinol, respectively. In addition, they have the same B- and C-ring structures. Similar to our finding on phloroglucinol and resorcinol, genistein was more effective than daidzein (Figure 4). At 4 h, genistein could trap almost 90% MGO, whereas daidzein could only trap 54.5% MGO. Our results clearly support our hypothesis that the hydroxyl group on C-5 of the A ring is crucial for the trapping of MGO by flavonoids. This is also supported by our previous observation that glycosylation of the hydroxyl group at C-5 of the A ring of phloretin tended to decrease its activity.[27] In addition, glycosylation of the 5-hydroxyl group may increase the steric hindrance of position C-6 and, therefore, decrease its activity.

Effects of B and C Rings on MGO-Trapping Efficacy. By comparing the trapping of MGO by apigenin and luteolin (Figure 5A), which possess the same A and C rings but a different number of hydroxyl groups on the B ring, we found that the number of hydroxyl groups on the B ring does not play a significant role on the trapping efficacy of flavonoids, albeit that luteolin with two hydroxyl groups at C-2′ and C-3′ positions shows a slightly stronger trapping capacity than apigenin that has only one hydroxyl group on the B ring (Figure 5A). To understand how the C ring of the flavonoids affects the MGO-trapping capacity, we studied the MGO-trapping effects of quercetin, luteolin, and epicatechin, which have identical A and B rings with a different structure of the C ring. Quercetin and luteolin belong to the flavone with a double bond between C-2 and C-3 and one ketone group at C-4 (Figure 5B). Epicatechin belongs to flavan-3-ol with a hydroxy group on C-3 but with no double bond and a ketone group on the C ring. Quercetin showed the best MGO trapping efficacy, followed by luteolin and epicatechin. More than 90% MGO was trapped within 8 h by both quercetin and luteolin. Epicatechin also had strong trapping efficiency by quenching more than 85% MGO within 24 h. Both quercetin and epicatechin could

dx.doi.org/10.1021/jf500204s | J. Agric. Food Chem. 2014, 62, 3202−3210

rapidly trap MGO; almost 50% MGO was scavenged within 11.25 min.

Additive MGO-Trapping Effects by Phloretin and Quercetin. To test whether different flavonoids have additive effects in terms of trapping reactive dicarbonyl species, we investigated the MGO-trapping capability of phloretin, quercetin, or the combination of phloretin and quercetin at two different concentrations (50 and 10 μM) under a ratio of each flavonoid/MGO at 1:6 at pH 7.4 and 37 °C. Our results indicated that phloretin and quercetin trapped about 16 and 23% MGO, respectively, at a concentration of 50 μM within 24 h. About 37% MGO was trapped by the combination of phloretin and quercetin (50 μM each) (Figure 6). At a lower concentration (10 μM) with the same ratio, both phloretin and quercetin showed similar trapping capability of scavenging nearly 19 and 23% MGO within 24 h, respectively. Almost 35% MGO was trapped by the combination of phloretin and quercetin (10 μM each) (Figure 6). Our results clearly indicate that different flavonoids can additively trap MGO.

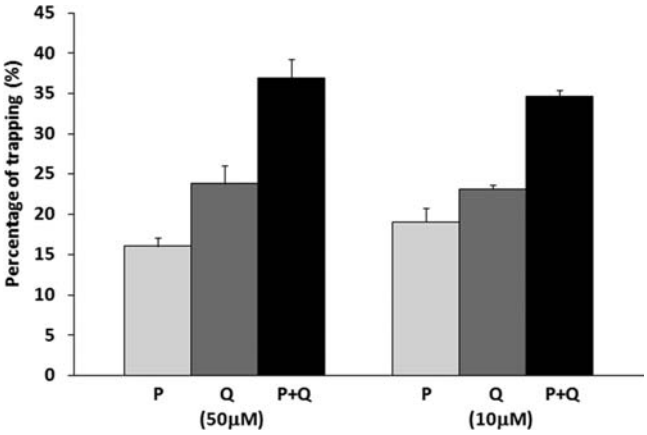

Figure 6. Tapping of MGO (300 or 60 μM) by phloretin (P), quercetin (Q), and the combination of phloretin and quercetin (P + Q, equal molar combination) at different concentrations (50 or 10 μM) in phosphate buffer (pH 7.4 and 37 °C) at 24 h. Bars on left and right sides represent the concentrations of MGO with 300 or 60 μM, respectively. Data are presented as the means ± standard deviation (SD) of three replications.

Studying the Formation of MGO Adducts of Quercetin and Phloretin by LC/MS. To understand the underlying mechanism that different flavonoids can additively trap MGO, we analyzed the formation of MGO adducts under each flavonoid along or the combination of phloretin and quercetin using LC/MS. Figure 7 shows the LC chromatograms of the reaction mixtures of quercetin with MGO (A), phloretin with MGO (B), and the combination of phloretin and quercetin (C). Both mono- and di-MGO adducts of quercetin were the major products under the ratio of quercetin/MGO at 1:6 (Figure 7A). Similar to our previous observation, mono- and di-MGO adducts of phloretin were identified as the major products for phloretin (Figure 7B). Under the combination of phloretin and quercetin, the same MGO adducts of each flavonoid were formed, which further confirmed the additive effect of phloretin and quercetin (Figure 7C).

We have confirmed the structures of the mono- and di-MGO adducts of phloretin in our previous study.[27] The structural information of the MGO adducts of quercetin was obtained using LC/MS/MS analysis under selective ion monitoring (SIM) mode (Figures 8). Three major new peaks appeared in the LC chromatogram of the reaction mixture of quercetin with MGO at a ratio of 1:6 after 24 h of incubation (Figures 7A). Two of the three peaks had the same molecular ion (m/z 373 $[M - H]^-$) and MS/MS fragments but different RTs (18.34 and 18.86 min). Both of the two compounds had the fragment ion 301 ($[M - 72 - H]^-$), showing that they both lost one MGO (m/z 72) molecule (Figure 8A), thus indicating that they are mono-MGO adducts of quercetin. Furthermore, the tandem mass spectrum of product ion 301 (MS^3, m/z 301/373) of the two compounds (Figure 8A) was almost identical to the MS^2 spectrum of authentic quercetin (MS^2, m/z 301), suggesting that the two compounds were the mono-MGO adducts of quercetin. The third peak (16.77 min) showed the molecular ion at m/z 445 $[M - H]^-$, which was 72 mass units higher than that of mono-MGO quercetin, indicating that it was the di-MGO quercetin. The tandem mass spectrum of its product ion 373 (MS^3, m/z 373/445) was almost identical to the MS^2 spectrum of mono-MGO quercetin (MS^2, m/z 373), suggesting that this peak was the di-MGO adduct of quercetin.

DISCUSSION

Flavonoids are biologically active, polyphenolic constituents of plant foods and are present in many fruits, vegetables, and beverages (tea, coffee, beer, wine, and fruit drinks), as well as dietary supplements and herbal remedies. The flavonoids are further divided into six major subclasses known as flavanols, flavanones, flavonols, flavones, isoflavones, and anthocyanidins on the basis of the connection of the B ring to the C ring, as well as the oxidation state and functional groups of the C ring.[32] All of the major classes of flavonoids are comprised of three six-membered rings: an aromatic A ring fused to a heterocyclic C ring that is attached through a single carbon−carbon bond to an aromatic B ring. Chalcone, an important precursor in the synthesis of anthocyanin pigments and other flavonoids in plants, is another type of important dietary flavonoid. In contrast to other flavonoids, the middle three carbon atoms in chalcones do not form a closed ring. Several *in vivo* and *in vitro* studies have indicated that dietary flavonoids could inhibit the formation of AGEs and prevent diabetes-related complications.[25,33,34] Previously, we found three different types of flavonoids, flavanol (EGCG), chalcone (phloretin and phloredzin), and isoflavone (genistein), could rapidly trap MGO at pH 7.4 and 37 °C and, therefore, inhibit the formation of AGEs.[27−29] We also demonstrated that the two unsubstituted carbons at the A ring of these flavonoids were the active sites for trapping reactive dicarbonyl species and forming mono- and di-MGO adducts. Most of the flavonoids have the same A-ring structure as EGCG, phloretin, phloridzin, or genistein. It is unclear whether they can also efficiently trap reactive dicarbonyl species to form mono- and di-MGO adducts. More importantly, it is largely unknown whether the number of hydroxyl groups on the A ring and the structures of B or C rings will play an important role in the trapping of reactive dicarbonyl species. To tackle these questions, we conducted the SAR studies of flavonoids as the scavengers of reactive dicarbonyl species.

We first compared the trapping efficacy of the sub-components of flavonoids, gallic acid (gallate ring of EGCG), Pg (B ring of flavonoids), pyrocatechol (B ring of flavonoids), resorcinol (A ring of flavonoids), and phloroglucinol (A ring of flavonoids). Our results showed that the MGO scavenging potency of these sub-components is in the order of Pg >

dx.doi.org/10.1021/jf500204s | J. Agric. Food Chem. 2014, 62, 3202−3210

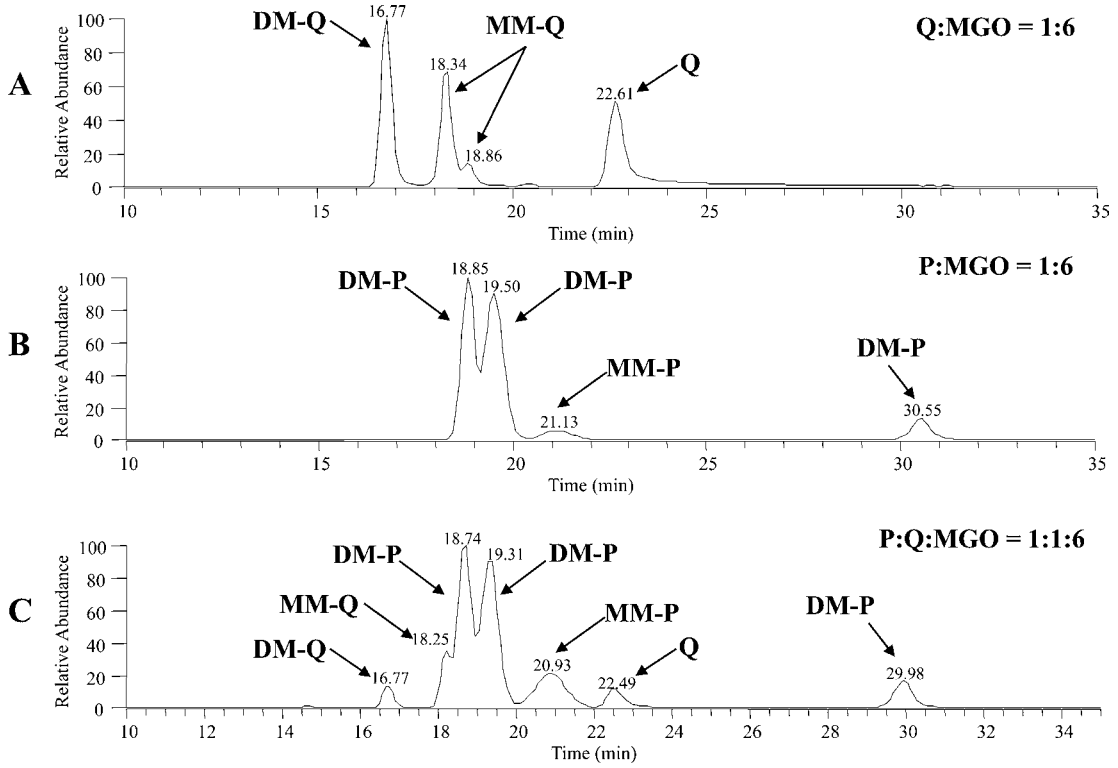

Figure 7. LC chromatogram of reaction mixtures of (A) quercetin (50 μM) with MGO (300 μM) under a ratio of 1:6 in PBS (100 mM, pH 7.4) at 37 °C for 24 h, (B) phloretin (50 μM) with MGO (300 μM) under a ratio of 1:6 in PBS (100 mM, pH 7.4) at 37 °C for 24 h, and (C) quercetin/phloretin with MGO under a ratio of 1:1:6.

phloroglucinol > resorinol > pyrocatechol > gallic acid, indicating the pivotal influence of the number and position of the hydroxyl group on the trapping activity. The trihydroxylbenzene (Pg and phloroglucinol) had a higher reactivity than the dihydroxylbenzene (pyrocatechol and resorcinol). In general, the hydroxyl group has electron-donating property. The more hydroxyl groups on the phenyl ring, the stronger the scavenging activity, because the reaction between phenol and MGO is a nucleophilic reaction. Our results also shown that the addition of a carboxyl group to position 5 of Pg almost completely diminished its trapping activity, indicating that position 5 is the active site of Pg. A further study on the trapping mechanism of Pg confirmed that MGO is conjugated at position 5 of Pg as the mono-MGO adduct of Pg, which provides the answer why gallic acid is the least active compound, albeit it has the same *vic*-trihydroxyl group as that of Pg. This also resolves the puzzle of our previous observation that the major active site of EGCG is at positions 6 and 8 of the A ring, instead of the B ring and the gallate ring, which have the *vic*-trihydroxyl group and are generally considered as the active sites for its antioxidant activities.[28] In addition, the position of the hydroxyl group also plays a significant role in contributing to the trapping capability of these small phenolic compounds. Pg with three *ortho*-hydroxyl groups demonstrated a much stronger trapping effect on MGO than phloroglucinol, which contains three *meta*-hydroxyl groups.

To extend our observation on the sub-components of flavonoids to the influence of A, B, or C ring of flavonoids on their MGO-trapping effects, we chose flavonoids containing these specific sub-components for our study. To demonstrate how the number of hydroxyl groups on the A ring of flavonoids affects the MGO-trapping efficiency, genistein and daidzein were chosen as our model compounds, because they possess identical B and C rings but with a different number of hydroxyl groups on the A ring. Genistein contains one more hydroxyl group at position C-5 than daidzein. Our finding that genistein showed stronger capability and efficacy in trapping of MGO than that of daidzein is in line with the conclusion drawn from phloroglucinol and resorcinol, which represent the A-ring structure of genistein and daidzein, respectively. In the same way, the effect of the number of hydroxyl groups on the B ring in the trapping dicarbonyl species by flavonoids was revealed by comparing the MGO-trapping capacity between apigenin and luteolin. A simple comparison among quercetin, luteolin, and epicatechin was carried out to demonstrate how the C ring of flavonoids affects the MGO-trapping ability. Even these simplified comparisons cannot provide the full picture of the essential SAR between dicarbonyl species and flavonoids; our results can still shed light on the following conclusions: (1) 1,2,3-trihydroxybenzene (Pg) has higher MGO scavenging reactivity than 1,2- and 1,3-dihydroxybenzene, and substitution at position 5 of Pg diminished the scavenging activity, indicating that position 5 is the active site of Pg; (2) the A ring is the active site of flavonoids in contributing the MGO-trapping efficacy, and the hydroxyl group at C-5 on the A ring enhances the trapping efficacy; (3) the double bond between C-2 and C-3 on the C ring could facilitate the trapping efficacy; and (4) the number of hydroxyl groups on the B ring does not significantly influence the trapping efficacy.

This is the first study to show that quercetin, luteolin, and apigenin can trap MGO at pH 7.4 and 37 °C, indicating flavonol and flavone types of flavonoids can also serve as scavengers of reactive dicarbonyl species. Further studies on the trapping mechanism of quercetin identified mono- and di-

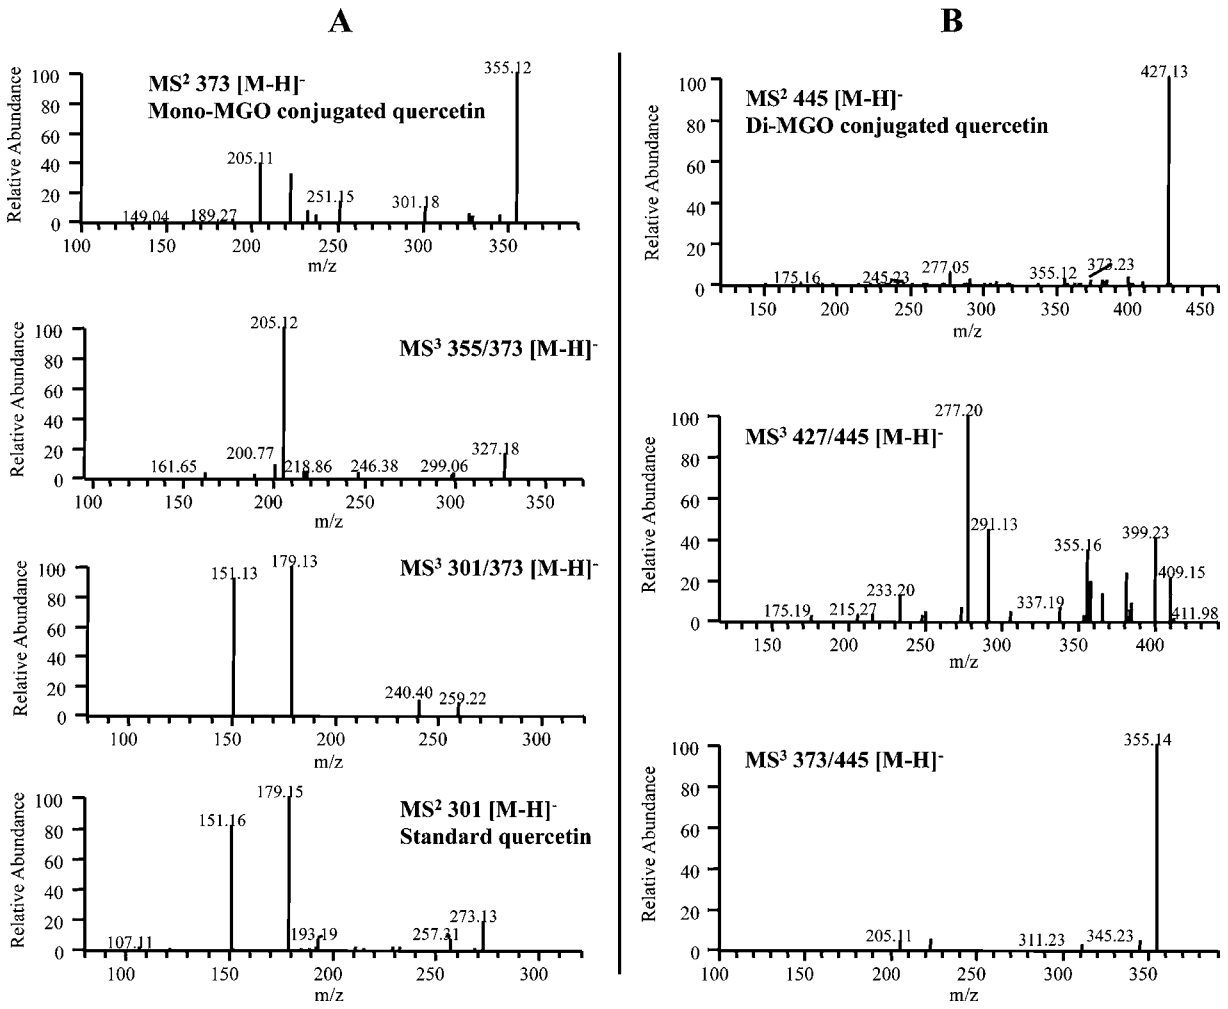

Figure 8. MS/MS spectra of (A) mono-MGO conjugated quercetin and authentic quercetin and (B) di-MGO conjugated quercetin.

MGO adducts as the major products of the reaction between quercetin and MGO. On the basis of our previous studies of EGCG, phloretin, and genistein, we suspect that the MGO conjugation should occur at positions C-6 and C-8 of the A ring. However, this needs to be further confirmed by NMR analysis of the pure mono- and di-MGO quercetin adducts. Our finding that many dietary flavonoids can trap reactive dicarbonyls through the same mechanism indicates that they may have an additive effect if not a synergistic effect. It has been reported that the total intake of flavonoids in the United States is 189.7 mg/day, which is difficult to be achieved for individual flavonoids.[35] Therefore, results on the effectiveness of the combination of individual flavonoids can be applied directly to translational studies in humans. To verify this hypothesis, phloretin and quercetin were chosen as the model compounds. Phloretin is a flavonoid found exclusively in apples and in apple-derived products. We previously reported that phloretin can effectively trap MGO.[27] Quercetin was selected because of its wide distribution in dietary plants.[36] Our results clearly indicated an additive MGO-trapping effect of these two flavonoids in two different concentrations (Figure 6). Thus, flavonoid-enriched foods and beverages as effective dietary strategies hold great promise to prevent the development of diabetic complications and, therefore, reduce the morbidity and mortality in individuals with diabetes. This topic needs to be further studied, especially under *in vivo* conditions.

limited extent, chiefly focusing on comparisons with other vegetable oils. Moreover, to our knowledge no data have been published on the factors influencing the CoQ10 content of olive oil.

The objective of this study was to investigate some factors that could influence the quantity of CoQ10 and CoQ9 in olive oils. We particularly focused on the influence of genetic factors (the cultivar) and the degree of ripeness. We also compared the composition of commercial oil blends and fresh extra virgin olive oil samples.

MATERIALS AND METHODS

Olive Oil Samples. The commercial olive oil and olive-pomace oil samples were purchased in stores in Slovenia, Spain, the United States, and Japan (seven samples of extra virgin olive oil blends, two samples of refined olive oil, two samples of olive-pomace oil) (Table 2).

Table 2. Coenzyme Q9 and Q10 Content in Olive Oils Purchased in Different Markets

description	no. of samples	content (mg/L) CoQ9	CoQ10	CoQ
olive oil (market)				
extra virgin	7	23 ± 12	56 ± 4	79 ± 12
refined	2	14 ± 9	54 ± 10	68 ± 2
olive-pomace oil	2	61 ± 19	83 ± 12	144 ± 31
Fresh olive oil (extra virgin, monocultivar)	79	21 ± 8	52 ± 17	73 ± 20

The monocultivar oil samples were provided by local producers or from local laboratories in Slovenia, Spain, Italy, Greece, France, Italy, Morocco, South Africa, Chile, and New Zealand (Tables 3 and 4). Monocultivar samples (n = 79) were stored in amber-colored glass at 4 °C in a nitrogen atmosphere until analyses. Thirteen of those samples were frozen when fresh for one season (−70 °C) and considered as fresh in the further analyses. Olive oils of the following cultivars (number of samples) were also analyzed: Picual (7 samples), Istrska belica (7), Leccino (7), Arbequina (4), Hojiblanca (4), Coratina (4), Frantoio (4), Maurino (4), Blanqueta (3), Koroneiki (3), Aglandau (2), Alfafara (2), Buga (2), Farga (2), Manzanilla (2), Olivière (2), Picholine (2), Tanche (2), Villalonga (2), and one sample per cultivar for Arbusana, Ascolano, Athinolia, Barnea, Barouni, Cacereña, Carolea, Itrana, Kalamata, Kolovi, Ladolia, Manaki, Mission, and Nocellara.

Table 4. Coenzyme Q9 and Q10 Content in Other Fresh Monocultivar Olive Oils

cultivar	no. of samples (country origin[a])	content (mg/L) CoQ9	CoQ10	CoQ
Aglandau	2 (GR)	15 ± 7	50 ± 9	65 ± 2
Alfafara	2 (ES)	11 ± 3	47 ± 23	58 ± 27
Blanqueta	3 (ES)	12 ± 2	56 ± 4	68 ± 5
Buga	2 (SI)	20 ± 4	49 ± 7	69 ± 11
Farga	2 (ES)	14 ± 4	24 ± 4	39 ± 8
Koroneiki	3 (GR)	10 ± 1	62 ± 4	71 ± 5
Manzanilla	2 (ES, SA)	17 ± 5	27 ± 3	44 ± 8
Olivière	2 (FR)	11 ± 1	52 ± 17	63 ± 15
Picholine	2 (FR)	40 ± 20	64 ± 10	104 ± 30
Tanche	2 (FR)	11 ± 2	58 ± 1	68 ± 3
Villalonga	2 (ES)	21 ± 4	81 ± 18	103 ± 14
other cultivars	14[b]	23 ± 7	49 ± 19	71 ± 23

[a]Country of origin: ES = Spain; CL = Chile; SI = Slovenia; IT = Italy; US = United States/California; SA = South Africa; GR = Greece; FR = France. [b]Other cultivars: Arbusana (CL), Ascolano (US), Athinolia (GR), Barnea (CL), Barouni (US), Cacereña (ES), Carolea (IL), Itrana (SI), Kalamata (SA), Kolovi (GR), Ladolia (GR), Manaki (GR), Mission (US), Nocellara (CL).

The monocultivar fresh samples of extra virgin olive oils for studying the CoQ10 and CoQ9 content as a function of the harvest time within a season were provided by the Experimental Centre for Olive Growing (COG) at Agricultural and Forestry Institute in Nova Gorica, Slovenia. Seventeen samples of the cultivars Istrska Belica and Leccino (9 and 8 samples, respectively) were included for the analyses. Samples were collected from an experimental groove at Beneša (Slovenia) as part of a national program to monitor the maturity of olives. Trees with a similar fruit load were selected for the monitoring program. The earliest harvest date was set for mid-October 2010, and subsequent harvest dates were approximately one week apart. COG also provided an olive maturity index (MI) for these samples that was determined[28] on a sample of 100 randomly sampled fruits.

Quantification of CoQ10 and CoQ9 Levels in the Olive Oil Samples. CoQ10 and CoQ9 levels were determined based on ESA App Note[29] (ESA, Dionex Corp.) modified as follows: Olive oil samples were diluted 1:100 shortly before the analyses

Table 3. Coenzyme Q9 and Q10 Content in Fresh Extra Virgin Olive Oils of the Cultivars Picual, Istrska Belica, Leccino, Arbequina, Hojiblanca, Coratina, Frantoio, and Maurino[a]

cultivar	no. of samples (country origin)	content (mg/L) CoQ9	CoQ10	CoQ
Arbequina	4 (2 ES, CL, US)	21 ± 10	58 ± 22	79 ± 28
Coratina	4 (ES, IT, CL, US)	30 ± 5 d,e	48 ± 5 b,c,d,g	79 ± 9 b,d
Frantoio	4 (2 CL, SA, IT)	25 ± 6	36 ± 7 a,c,f,g	61 ± 6 a,c,d,f,g
Hojiblanca	4 (ES)	24 ± 16	98 ± 22 a,b,d,e	122 ± 38 b,d,e
Istrska belica	7 (SI)	19 ± 3 a,f	30 ± 4 a,c,e,f,g	48 ± 7 a,b,c,e,f,g
Leccino	7 (4 SI, IT, ES, SA)	22 ± 7 a	41 ± 11 c,d,f,g	63 ± 18 c,d,f,g
Maurino	4 (SI)	26 ± 4 d	63 ± 11 b,d,e	89 ± 14 b,d,e
Picual	7 (6 ES, CL)	22 ± 7	63 ± 6 a,b,d,e	85 ± 13 b,d,e

[a]Country of origin: ES = Spain; CL = Chile; SI = Slovenia; IT = Italy; US = United States/California; SA = South Africa. Statistical difference (P < 0.05) in comparison with other cultivars: a, Coratina; b, Frantoio; c, Hojiblanca; d, Istrska belica; e, Leccino; f, Maurino; g, Picual.

using 2-propanol. After 30 s of vortexing at 1500 rpm at room temperature in polypropylene tubes, the solution was centrifuged for 5 min at room temperature prior to HPLC injection. Determinations of CoQ9 and CoQ10 were performed using HPLC equipment with a diode array UV−vis detector (HPLC System Gold, Beckman Coulter Ltd.) and electrochemical coulometric detector (ESA Coulochem III, Dionex Corporation). Separation was carried out at a 40 °C flow rate of 0.8 mL/min using an Ultrabase C18 column (5 μm, 4.6 × 150 mm) (Análisis Vínicos, Spain). The mobile phase was composed of solvent A (methanol/propanol/0.33 M ammonium acetate pH 4.4, 84:10:6) and solvent B (propanol/0.33 M ammonium acetate pH 4.4, 98:2). Initial conditions were 95% solvent A 5% solvent B, at min 12 the mobile phase turned to 65% solvent A 45% solvent B in 4 min. At min 33 the mobile phase composition returned to the initial conditions in 3 min. The typical sample injection volume was 50 μL. Electrochemical detection was used for the CoQ determination. The ESA Coulochem III electrochemical detector was programmed with the following settings: conditioning guard cell +400 mV, reducing cell at −500 mV followed by the analytical cell at +500 mV, full scale was 100 nA. HPLC-grade solvents were purchased from Scharlab (Spain). The CoQ9 and CoQ10 standards were purchased from Sigma-Aldrich. All other chemicals were of analytical grade and available from commercial suppliers. CoQ9 and CoQ10 concentrations were calculated using calibration curves. Stock solutions of CoQ10 and CoQ9 standards were prepared by reading their absorbance at 275 nm in ethanol. They were then used to prepare five calibration standards for each compound studied by dilution with an extraction solvent (25 pmol, 50 pmol, 75 pmol, 100 pmol, 125 pmol). Values of the slope (b), intercept (a), correlation coefficient (R), and standard deviation of the slope $V(b)$ were calculated using the 32Karat software (Beckman Coulter Ltd.).

Statistics. The results are the average of at least two replicates analyses; the standard deviation of the de novo analyses was determined to be below 10%. Average ± SD was calculated for various groups of samples (commercial samples: extra virgin olive oils, refined olive oils, and olive-pomace oils; monocultivar oil samples: a group of all monocultivar samples, a group of samples of the same cultivar). Group comparisons were performed using an unpaired t test and differences of $P < 0.05$ were considered significant. Between group comparisons for olive oils from various cultivars are presented in Table 3.

RESULTS AND DISCUSSION

CoQ10 and CoQ9 Levels in the Commercial Olive Oil Blends. We analyzed extra virgin olive oils, refined olive oils, and olive-pomace oils purchased in different markets (Table 2). Although the average levels of CoQ10 and CoQ9 in the extra virgin olive oils (56 ± 4 and 23 ± 12 mg/L, respectively) were a little higher than those in the refined olive oils (54 ± 10 and 14 ± 9 mg/L, respectively), the differences were not significant. However, higher levels of both CoQ10 and CoQ9 were observed in the olive-pomace oil (83 ± 12 and 61 ± 19 mg/L, respectively) although we note that only two samples of olive-pomace oils were investigated. Olive-pomace oil is obtained by treating olive pomace with solvents or other physical treatments[30] and this might explain the better extraction of CoQ from the fruit. Due to its undesirable organoleptic properties olive-pomace oil is considered a low-quality oil and is very rarely found in markets; it was therefore not studied further. Nevertheless, if an opportunity were to emerge for the sustainable extraction of valuable biological compounds from vegetable oils, olive pomace oil might be a valuable raw material in such processes. Such an extraction procedure was studied by Laplante et al. using mackerel and herring oils as starting material.[31]

CoQ10 and CoQ9 Levels in the Fresh Monocultivar Extra Virgin Olive Oil Samples. Commercial olive oil samples are commonly blends produced from the fruits of various cultivars. To gain an insight into preharvest factors that could affect the composition of olive oils, monocultivar samples are more appropriate. A series of 79 monocultivar olive oil samples was therefore selected; samples were provided by local producers or local laboratories from different geographical regions (Chile, Spain, Italy, Slovenia, South Africa, the United States, Greece, and France). To limit the influence of postharvest processing, only extra virgin olive oil samples were included. Although CoQ10 is relatively stable in food matrixes,[32] the included samples were either fresh or fresh-frozen.

In case of the cultivars Arbequina, Coratina, Frantoio, Hojiblanca, Istrska belica, Leccino, Maurino, and Picual, four to seven samples of olive oil per cultivar were available. Results of the determination of CoQ in those samples are presented in Table 3 together with between group statistical comparisons. For the cultivars Aglandau, Alfafara, Buga, Farga, Koroneiki, Manzanilla, Olivière, Picholine, Blanqueta, Tanche, and Villalonga, where less than four samples were available, we did not perform between group statistical comparisons (Table 4). Results for cultivars where only one sample per cultivar was available (Arbusana, Ascolano, Athinolia, Barnea, Barouni, Cacereña, Carolea, Itrana, Kalamata, Kolovi, Ladolia, Manaki, Mission, and Nocellara) are presented in aggregate form in Table 4 (other cultivars).

The average content of CoQ10 of all the monocultivar olive oil samples was 52 ± 17 mg/L and is comparable with results for the commercial extra virgin olive oil samples. However, the averages for different cultivars of which at least four samples of olive oil were available (Arbequina, Coratina, Frantoio, Hojiblanca, Istrska belica, Leccino, Maurino, and Picual) ranged from 24 ± 4 to 98 ± 20 mg/L and several statistically important differences in CoQ10 levels (Table 3) among them were observed. The highest content of CoQ10 was observed in the cultivar Hojiblanca (98 ± 22 mg/L; a statistically significant difference when compared to the Istrska belica (30 ± 4 mg/L; $P = 0.01$), Leccino (41 ± 11 mg/L; $P = 0.02$), Frantoio (36 ± 7 mg/L; $P = 0.02$), Coratina (48 ± 5 mg/L; $P = 0.03$) sets), followed by Picual (63 ± 6 mg/L; a statistically significant difference when compared to Istrska belica ($P < 0.01$), Leccino ($P < 0.01$), Frantoio ($P < 0.01$), Coratina ($P = 0.01$)), and Maurino (63 ± 11 mg/L; a statistically significant difference when compared to Istrska belica ($P = 0.01$), Leccino ($P = 0.02$), and Frantoio ($P = 0.01$)). This confirms our hypothesis that the expression of CoQ10 is also driven by genetic factors. For the Picual cultivar, our data on CoQ10 levels (63 ± 6 mg/L) are comparable with the report by Venegas et al. (77 ± 12 mg/L),[21] whereas the other cultivars were not investigated in previous studies.

The average content of CoQ9 of all the monocultivar olive oil samples was 21 ± 8 mg/L (23 ± 12 mg/L in the commercial extra virgin olive oil samples). A comparison of the CoQ9 contents between the cultivars shows less significant differences than with CoQ10. The CoQ9 levels in the studied

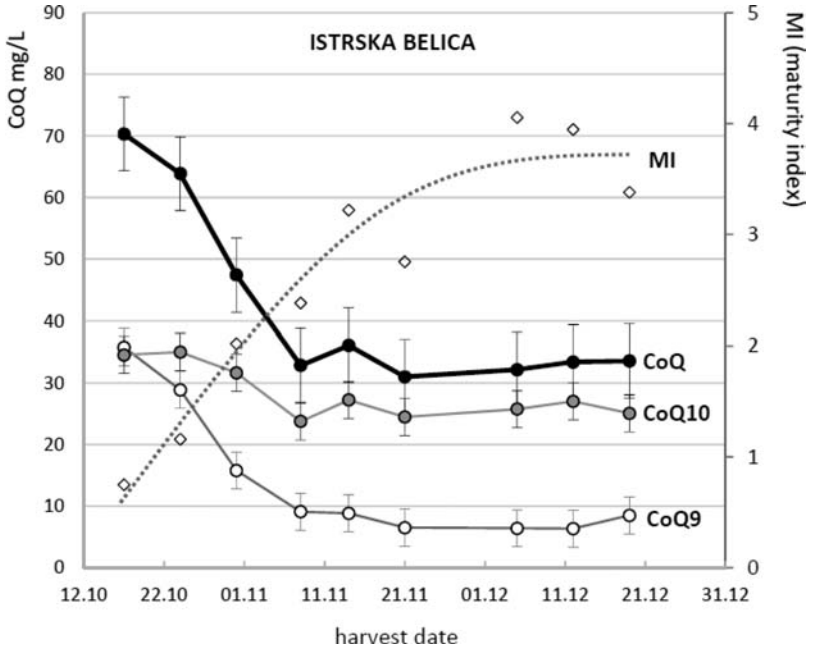

Figure 1. Coenzyme Q9 and Q10 content in olive oil as a function of harvest time for the cultivar Istrska belica (Experimental Grove, Beneša, Slovenia).

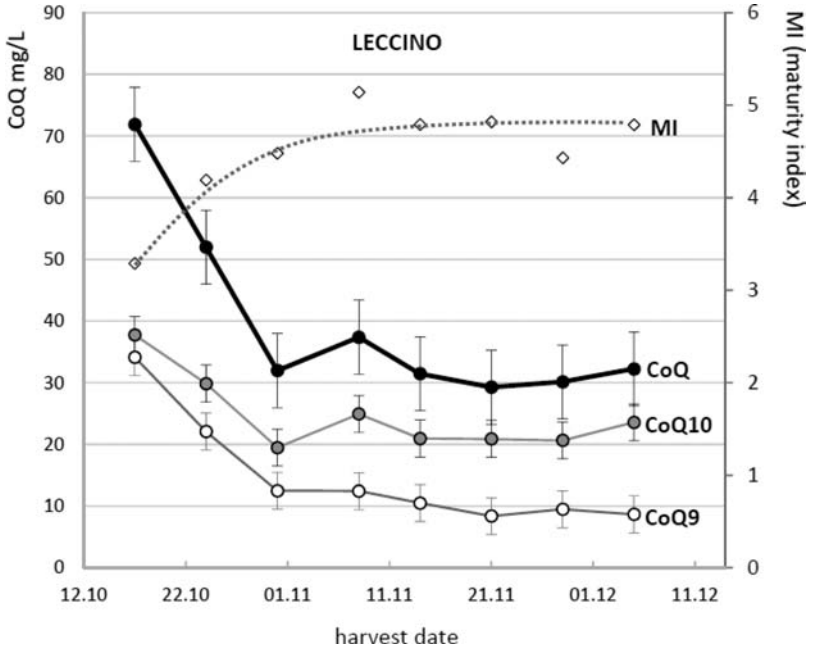

Figure 2. Coenzyme Q9 and Q10 content in olive oil as a function of harvest time for the cultivar Leccino (Experimental Grove, Beneša, Slovenia).

cultivars ranged from 10 ± 1 to 30 ± 5 mg/L. A statistical comparison of the CoQ9 content between sets of olive oils of different cultivars for which at least four samples were available showed the highest CoQ9 content in the Coratina series (30 ± 5 mg/L) with statistically significantly lower levels in Leccino (22 ± 7 mg/L; $P = 0.05$) and Istrska belica (19 ± 3 mg/L; $P = 0.01$). The observed CoQ9 levels are a little higher than reports in the literature where levels of up to 18 ± 2 mg/L were observed.[20] However, we also observed lower CoQ9 levels in some cultivars (i.e., 10 ± 1 mg/L in Koroneiki).

Foods containing over 50 mg CoQ10/kg are considered to be *very rich sources* of CoQ10.[10] We established that extra virgin olive oils generally meet this criterion and can be considered among the best natural sources of dietary CoQ10. In contrast, our results confirm that olive oils are not a very important source of CoQ9, especially when compared to other vegetable oils (i.e., corn oil with 93−373 mg CoQ9/L).[17,20]

Levels of CoQ10 and CoQ9 Content in Fresh Olive Oil with Different Harvest Times. During the maturation process, the color, oil content, and composition change dramatically in olive fruit. The magnitude of these changes depends on the cultivar and parameters such as geoclimatic and growing conditions, with processing also having an important effect.[27,33] Due to variability in cultivar response between growing seasons and the influence of varying crop loads on

dx.doi.org/10.1021/jf5002167 | J. Agric. Food Chem. 2014, 62, 3211−3216

maturation rates, the determination of the optimal harvest time of olives is difficult.

In our study we also observed relatively high average standard deviations in CoQ10 and CoQ9 contents within oil samples of the same cultivar (on average 20% and 28%, respectively). To gain further insights into the impact of preharvest conditions on the composition of olive oil, we investigated whether CoQ levels in olive oil are also affected by the degree of ripeness of olive fruit at the time of pressing.

To evaluate the possible influence of harvesting time on CoQ content in olive oil, two cultivars prevalent in Slovenia were selected. The cultivar Istrska belica (Istrian white olive) is a domestic variety grown in Slovenian Istra and the neighboring countries, while the cultivar Leccino originates in Tuscany (Italy).[34] CoQ levels were monitored in oil samples taken from an experimental groove at Beneša (Slovenia) during the approximately three-month harvesting season. We determined that the CoQ10 and CoQ9 levels in both cultivars were strongly influenced by the harvest time (Figures 1 and 2). We observed a lowering of total CoQ levels with maturation; an almost linear lowering was observed for the first 2−3 weeks of the investigation (R^2 0.98 and 0.99 for Istrska belica and Leccino, respectively) and after that the CoQ levels continued to be stable. In the case of Istrska belica, the total CoQ dropped by 53% in the first three weeks of the investigation, while in Leccino a 56% reduction was observed. The changes in the CoQ9 levels (75% and 65% for Istrska belica and Leccino, respectively) were higher than in the CoQ10 levels (29% and 47%). Although these measurements were performed on samples collected within a single season and focused only on investigation of the maturation phase, the results reveal that olive oils that are harvested early might be richer in CoQ. Further studies are needed to examine this phenomenon in greater detail and should include sampling of the same cultivars in different locations and in different growing seasons. We should note that these results cannot be simply generalized to other cultivars as it has already been established that the influence of harvest and maturity index on olive oil yield and quality can fundamentally differ between various cultivars.[33]

In conclusion, this study shows for the first time the important influence of some pre- and postharvest factors on the content of CoQ10 and CoQ9 in olive oil. By investigating the effects of the degree of ripeness on the Istrska belica and Leccino cultivars we established that the maturity of fruits significantly affects the content of CoQ in olive oil; the highest levels of both CoQ10 and CoQ9 can be found in the early maturation stages. Our investigation of CoQ10 and CoQ9 levels in numerous monocultivar samples allowed us to determine that genetic parameters (cultivars) also have an important influence on the composition of olive oils, particularly the content of CoQ10. However, we observed relatively high variations in CoQ levels also within cultivars. In addition to the maturity effects, there could be several other reasons for this, including agricultural and geo-climatic effects. Therefore, in further studies, comparisons within cultivars should be made also using samples with comparable maturity and growing conditions. While such studies would enable a comparison between only a small number of cultivars, they would provide an insight into several other possible factors influencing the composition of olive oils. Interestingly, the results of our study indicate the limited influence of postharvest processing, except when the processing technique is changed drastically, i.e. by introducing organic solvents which not only improve the extraction of oil from olive fruits but also the extraction of CoQ. However, to explore this in detail more studies are needed, covering a higher number of processed oils, preferably involving the use of the same sample of olive fruit as the starting material. These results are an important contribution to knowledge on the composition and quality of olive oils and will provide a basis for additional studies to further explore the factors influencing the contents of Coenzyme Q in olive oils.

Funding

The present study was financially supported by the Nutrition Institute Research Fund (ID-M10) and by Pablo de Olavide University, Seville, Spain.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We acknowledge the help of Viljanka Vesel (Experimental Centre for Olive Growing, Agricultural and Forestry Institute Nova Gorica, Slovenia) for providing olive oil samples from the national program monitoring olive growing. We further acknowledge the assistance of Milena Miklavčič (LABS LLC, Institute for Ecology, Olive Oil and Control, Izola, Slovenia), Vanja Dujc (Slovenia), Boris Jenko (Slovenia), Luisa Ruiz (Jefe Sección, Jefe Pnal de cata de la Comunidad Valenciana, Spain), Juan Ramón Izquierdo (Laboratorio Arbitral Agroalimentario, Madrid, Spain), Luciana Di Giacinto (C.R.A. − Centro di Ricerca per l'Olivicoltura e l'Industria Olearia, Italy), Maria Lazaraki (Chemical Laboratories of the Ministry of Economy, Competitiveness & Shipping, Greece), Christian Pinatel (Centre Technique de l'Olivier, Maison des Agriculteurs, France), Sandy Jeffery (Helluva, South Africa), Albert Viljoen (Waverley Hills Organic Farm, South Africa), Pablo Cáceres F. (Olivares de Quepu, Chile), María Luz Hurtado P. (Olave, Chile), and Steve McCulley (Appollo Olive Oil, Oregon House, CA) for support in providing the monocultivar oil samples. We also acknowledge Murray Bales for providing help with the language of this text.

MATERIALS AND METHODS

Chemicals. Benzyl-DL-arginine-*p*-nitroanilide hydrochloride (BAPNA), trypsin from porcine pancreas (1000−2000 benzyl arginine ethyl ester (BAEE) units/mg solid), and PHA-P (8754) were purchased from Sigma (St. Louis, MO, USA). All other reagents were purchased from Shanghai BOAO Biochemical Co. (China).

Sample Preparation. *C. Kkorshinskii* Kom. was collected from Liang Cheng County of Inner Mongolia (China). Leaves and tissues were air-dried, milled, and passed through a 60 mesh screen. The milled *C. korshinskii* Kom. was stored at −20 °C until further use.

Preparation of *C. korshinskii* Kom. Protein Isolates (CPI). Alkali extraction and acetone precipitation methods were used to prepare CPIs from the milled powder of *C. korshinskii* Kom.[1]

For an alkaline extraction method, the milled *C. korshinskii* Kom. was dispersed in 0.12 M NaOH with the solid to liquid ratio of 1:20 (w/v) and then incubated at 37 °C for 1 h. The slurry was centrifuged at 4000*g* for 20 min to obtain a supernatant. The pH of the supernatant was adjusted to 4.5 with 0.1 N HCl, and then the supernatant was heated in a water bath at 75 °C for 10 min. After centrifugation at 4000*g* for 20 min, the protein precipitate was freeze-dried to obtain Al-CPI.

For an acetone precipitation method, the milled *C. korshinskii* Kom. was dispersed in an extraction buffer in the ratio of 1:20 (w/v). The slurry was incubated at 4 °C for 7 h and centrifuged at 4000*g* for 20 min to obtain a supernatant. Precooled acetone was added to the supernatant, which was then incubated at −20 °C overnight. The mixture was centrifuged at 4000*g* for 20 min, and the resulting precipitate was then rinsed with precooled acetone three times. The A-CPI was obtained when the precipitate was dried under nitrogen gas.

Analysis of Nutritional Ingredients. *Approximate Composition Analysis.* The contents of moisture, crude protein, crude lipid, and ash were determined according to the standard methods described by the Association of Official Analytical Chemists (AOAC).[5] Crude fiber was determined by GB/T 5009.10-2003 (Recommended National Standard of China).[6] Samples were successively dispersed in boiling solutions of 1.25% H_2SO_4 and 1.25% NaOH. The oven-dried residual was then weighed to calculate the content of crude fiber. The carbohydrate content was determined according to the data of moisture, crude protein, crude lipid, crude fiber, and ash contents. The gross energy was calculated according to the following formula:

$$\begin{aligned}&\text{gross energy (kJ 100/g dry substance)}\\&\quad=(\text{protein}\times 16.7)+(\text{lipid}\times 37.7)\\&\qquad+(\text{carbohydrates}\times 16.7)\end{aligned}\tag{1}$$

Total Starch Analysis. Total starch was measured as described by Goni[7] with some modifications. Samples (100 mg) were dispersed in 12 mL of 2 M KOH and vigorously shaken at room temperature for 30 min. The mixture was adjusted to pH 7.0 with 0.4 M sodium acetate buffer, followed by an addition of 0.5 mL of amyloglucosidase (Aladdin, 100000 U/mL), and then incubated at 60 °C for 45 min in a shaking water bath. Glucose oxidase/peroxidase reagent (Shang Hai Rong Sheng Biotech Co., Ltd.) was utilized to measure glucose content. The conversion factor from glucose to starch was 0.9.

Soluble Sugar Analysis. Soluble sugar was extracted with 70% (v/v) ethanol, and sugar content was determined by using a phenol−sulfuric acid method.[8]

Mineral Composition. *C. korshinskii* Kom. powder was digested with the mixed acids (concentrated nitric acid, sulfuric acid, and perchloric acid in the ratio 10:0.5:2, v/v). The contents of minerals (sodium, potassium, calcium, magnesium, iron, copper, zinc, and manganese) were determined by atomic absorption spectrophotometer (Shimadzu, AA-6800) accoring to the AOAC procedure.[5] Total phosphorus was determined according to GB/T 5009.87-2003.[9] Samples (0.5 g) were digested with mixed acids to obtain a digestive solution, and then digestive solution (1 mL), $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ reagent (2 mL), 0.5% hydroquinone solution (1 mL), 20% sodium sulfite reagent (1 mL), and water (15 mL) were added. After 0.5 h, the absorbance of the solution was observed at 660 nm with KH_2PO_4 as standard.

Amino Acid Analysis. The derivatization method described by Hainida[10] was followed by assay amino acids. The hydrolysate (1 mL) of amino acids was evaporated to dryness under vacuum and then redissolved with 1 mL of deionized water. Hydrolysate (50 uL), acetonitrile/triethylamine solution (25 μL, 43:7, v/v), and phenyl isothiocyanate (PITC)/triethylamine solution (25 μL, 1:80, v/v) were mixed and incubated for1 h at room temperature. The mixed mobile phase of acetonitrile, sodium acetate solution, and water was used. The essential amino acid (EAA) score was calculated as

$$\text{EAA score}=\frac{\text{g of EAA in 100 g crude proteins}}{\text{g of EAA in 100 g FAO/WHO (2007) reference pattern}}\tag{2}$$

Analysis of Various Antinutritional Factors (ANFs). *Trypsin Inhibitor.* Trypsin inhibitor activity (TIA) was measured according to the method of Siddhuraju.[11] Defatted ground samples (0.5 g) were incubated in 25 mL of 0.01 M NaOH at pH 9.4−9.5 for 3 h. The mixture was centrifuged at 4000*g* for 15 min, and the supernatant was collected to estimate the TIA content of material.

Lectin. The lectin content was analyzed by using the hemagglutination assay.[12] Samples (0.5 g) were incubated at room temperature in 10 mL of the phosphate buffer for 10 h with agitation using a magnetic bar. The slurry was centrifuged at 4000*g* for 20 min. The collected supernatant was then added in microtiter plates with 2% (v/v) rabbit blood erythrocyte suspension in phosphate buffer (pH 7.0). When >50% of the erythrocytes was aggregated, it was considered as agglutination. PHA-P was used as a positive control. The hemagglutination activity was defined as

$$C=(S_0\times H\times V)/(H_0\times M)\tag{3}$$

where C is the content of lectin that produced agglutination (mg/g), S_0 is the concentration of PHA-P solution (mg/mL), H is agglutinin titers (the minimum amount of samples producing hemeagglutination, 2^n), V is the volume (mL), H_0 is agglutinin titers (the minimum amount of standard producing hemeagglutination, 2^n), and M is sample quantity (g).

Phenolic Substances. The Folin−Ciocalteu method[13] was adopted to determine the total phenol and tannin levels with some slight modifications. Samples (0.2 g) were incubated with 10 mL of 70% acetone in an ultrasonic bath (frequency, 35 kHz; acoustic power, 85 W) for 20 min at room temperature. The mixture was centrifuged at 4000 rpm for 10 min. Extraction processes were performed once again. The obtained supernatants were mixed together. A certain amount of the supernatant was used to determine the content of total phenols. The tannin content was reflected by the decrease of total phenol content in the supernatant after polyvinylpyrrolidone treatment. Gallic acid was used as equivalents for total phenols and tannins.

Phytic Acid. The $FeCl_3{\cdot}6H_2O$−sulfosalicylic acid colorimetric procedure[11] was utilized to determine the content of phytic acid. Samples (0.5 g) were stirred with 10 mL of 3.5% HCl for 1 h at room temperature. The mixture was centrifuged at 4000 rpm for 10 min to obtain the supernatant. Phytic acid (98%, Guizhou Di-Da Biotech Co. Ltd.) was used as standard in the assay.

Saponins. The extraction method of total saponins was reported by Chen[14] with some slight modifications. Defatted samples (0.5 g) were incubated with 10 mL of 80% aqueous methanol in an ultrasonic bath (frequency, 35 kHz; acoustic power, 85 W) for 30 min at room temperature. The mixture was centrifuged at 3000 rpm for 10 min. Extraction processes were conducted once again. The obtained supernatants were mixed together. A certain amount of the supernatant was used to determine the content of total saponins.

Statistical Analysis. All experiments are conducted in three replicates. One-way analysis of variance (ANOVA) was carried out to compare the mean values, followed by Duncan's multiple-range tests. Significant differences in the mean values were determined at $p < 0.05$ (SPSS 19).

Table 1. Proximate Analysis of *C. korshinskii* Kom., Al-CPI, and A-CPI[a]

	C. korshinskii Kom.	Al-CPI	A-CPI
moisture (%)	6.25 ± 0.25c	8.6 ± 0.37b	10.02 ± 0.49a
ash (%)	3.63 ± 0.10c	8.95 ± 0.42a	7.28 ± 0.27b
crude protein (%)	9.09 ± 0.31c	50.06 ± 1.40a	42.59 ± 1.17b
crude fiber (%)	56.86 ± 0.97a	0.79 ± 0.03b	0.81 ± 0.02b
crude lipid (%)	1.77 ± 0.04a	0.91 ± 0.04b	ND[b]
total available carbohydrate (%)	22.40 ± 1.40c	30.70 ± 1.72b	39.30 ± 1.59a
gross energy (kJ/100 dry substance)	592.65 ± 17.70b	1382.79 ± 12.65a	1367.57 ± 8.75a

[a]Values are expressed as mean ± SD of three measurements. Values with different letters are significantly different at $p < 0.05$ within the same row. [b]ND, not detected.

RESULTS AND DISCUSSION

Analysis of Nutritional Ingredients. The proximate chemical compositions of *C. korshinskii* Kom., Al-CPI, and A-CPI are summarized in Table 1. For *C. korshinskii* Kom., crude fiber constituted about 56.9%, followed by total carbohydrate (22.4%) and crude protein (9.1%). Protein content in the plants may be varied using different growth environments and harvest times. A recent study[15] has shown that the protein level of phloem from *C. korshinskii* Kom. was about 11%. In our study, the feedstock of *C. korshinskii* Kom. was a mixture of leaves and tissues. The contents of crude protein in Al-CPI and A-CPI were 50.1 and 42.6%, respectively, which was lower than that of most protein isolate from beans, such as fava bean (81.9%), pea (88.8%), and soy (87.6%),[16] but higher than that of barley flour (35.5%).[17]

As shown in Table 2, the contents of starch in *C. korshinskii* Kom., Al-CPI, and A-CPI were not significantly different (24.1−25.4 g/100 g dry substance). In addition, the soluble sugar in A-CPI (6.5%) was about 2.5-fold that in Al-CPI (2.6%).

Table 2. Total Starch and Soluble Sugar in *C. korshinskii* Kom., Al-CPI, and A-CPI (Grams per 100 g Dry Substance)[a]

	C. korshinskii Kom. powder	Al-CPI	A-CPI
total starch	24.12 ± 0.98a	24.8 ± 0.40a	25.44 ± 0.29a
soluble sugar	5.50 ± 0.11b	2.60 ± 0.01c	6.47 ± 0.19a

[a]Values are expressed as mean ± SD of three measurements. Values with different letters are significantly different at $p < 0.05$ within the same row.

Table 3 shows that phosphorus and calcium existed in *C. korshinskii* Kom., which exceeds the demand for adults.[18] Phosphorus and calcium are the essential ingredients in human and animal skeleton series and teeth. In addition, phosphorus is a necessary component for nucleic acid, protein, and lecithin. It also participates in the metabolism process of saccharides and lipids and forms high-energy phosphate bonds to store energy. Compared with *C. korshinskii* Kom., the content of sodium in Al-CPI shows a dramatic increase, which may have resulted from the extraction solution (NaOH). However, the contents of calcium and iron in Al-CPI decreased sharply. This result may be attributed to the possibility that calcium and iron were more likely to chelate with phytic acid when Al-CPI was precipitated at pH 4.5.[19] Moreover, the contents of trace elements, such as Fe, Mn, Zn, and Cu, were higher in A-CPI than in *C. korshinskii* Kom. and Al-CPI.

Table 3. Mineral Composition of *C. korshinskii* Kom., Al-CPI, and A-CPI (Milligrams per 100 g Dry Substance)[a]

	C. korshinskii Kom. powder	Al-CPI	A-CPI
sodium	1.17 ± 0.11c	1878 ± 77a	145 ± 12b
potassium	140 ± 12a	154 ± 11a	58.82 ± 5.21b
calcium	1163 ± 44b	183 ± 17c	1712 ± 168a
phosphorus	3562 ± 88a	551 ± 17b	503 ± 16b
magnesium	24.82 ± 0.10b	15.76 ± 0.84b	284 ± 27a
iron	8.11 ± 0.23c	13.71 ± 1.01b	21.44 ± 0.40a
copper	0.22 ± 0.02c	2.64 ± 0.22b	12.91 ± 0.72a
zinc	0.40 ± 0.04c	1.49 ± 0.11b	3.32 ± 0.32a
manganese	0.61 ± 0.06b	0.49 ± 0.05b	10.48 ± 0.79a

[a]Values are expressed as mean ± SD of three measurements. Values with different letters are significantly different at $p < 0.05$ within the same row.

The compositions of essential amino acids in *C. korshinskii* Kom., Al-CPI, and A-CPI are shown in Table 4, together with those of soybean, wheat grains, rice, and FAO/WHO reference pattern. The important plant species used for humans or animals are mainly cereal grains and food legumes. Compared with animal-based proteins, many plant-based proteins do not provide essential amino acids in a balanced proportion, which restricts their potential application. The typical amino acids are lysine (Lys), threonine (Thr), and sulfur-containing acid amino acids (methionine and cysteine). The Lys content is normally deficient in cereal grains,[3] such as wheat grains, rice, and maize, but it was relatively plentiful in *C. korshinskii* Kom. (4.1 mg/100 mg crude protein), Al-CPI (3.1 mg/100 mg crude protein), and A-CPI (3.8 mg/100 mg crude protein) relative to that in cereals, but lower than that in buckwheat seeds.[29] In fish, poultry, or pig fodder, Lys was found to be the first limiting amino acid.[21] Thr is the second limiting amino acid in grain sorghum, barley, and wheat, as well as the third limiting amino acid in maize. It also becomes the first limiting amino acid when animal fodder is supplemented with lysine.[23] The content of Thr in *C. korshinskii* Kom. (4.7 mg/100 mg crude protein) or A-CPI (4.7 mg/100 mg crude protein) was even higher than that in soybean, rice, wheat grains, and FAO/WHO reference pattern for preschool children and adults.[22] However, the Thr content in Al-CPI (2.8 mg/100 mg crude protein) exceeded only rice and FAO/WHO reference pattern for adults. According to EAA scores, sulfur-containing amino acids are the first limiting amino acids for *C. korshinskii* Kom. and CPIs. Some legumes had relatively lower levels of methionine (Met) and cysteine (Cys) than animal-based proteins.[20] Met was the first limiting amino acid for soybean, the amino acid composition of which was mostly closed to animal-based protein. It has to be noted that the Met content in A-CPI (1.4 mg/100 mg crude protein) was slightly higher than that in soybean. The total amounts of aromatic amino acids (phenyl-

[a]ND, not detectable. [b]Data from Bau et al. (1994). [c]Data from Abdel-Aal and Hucl (2002). [d]Data from Sosulski and Imafidon (1990). [e]FAO/WHO (2007) essential amino acids pattern for adults. [f]Methionine + cystine. [g]Phenylalanine + tyrosine. [h]FAO/WHO (2007) essential amino acids pattern for preschool children, individuals aged 2−5 years.

alanine and tyrosine) in *C. korshinskii* Kom. and A-CPI were 7.5 and 8.6 mg/100 mg crude protein, respectively. They are even higher than those in soybean, rice, wheat, and FAO/WHO pattern for children. Phenylalanine has been widely used as human food and animal feed additives, as well as resources to synthesize some active materials.[24] For *C. korshinskii* Kom., Al-CPI, and A-CPI, the contents of essential amino acids generally exceeded the FAO/WHO reference pattern for adults except tryptophan and sulfur-containing amino acids. The ample qualities of Lys, Thr, and aromatic amino acid make it a good alternative additive in the feed or food industry.

The compositions of nonessential amino acids in *C. korshinskii* Kom., Al-CPI, and A-CPI are shown in Figure 1. In *C. korshinskii* Kom., compared with others, proline (10.1 mg/100 mg crude protein) and glycine (3.5 mg/100 mg crude protein) ranked first and last in nonessential amino acids. Proline was adequate in the plants with high abilities of cold hardiness and drought resistance. However, in Al-CPI or A-CPI, the highest level of nonessential amino acid was aspartic acid, whereas the lowest was tyrosine.

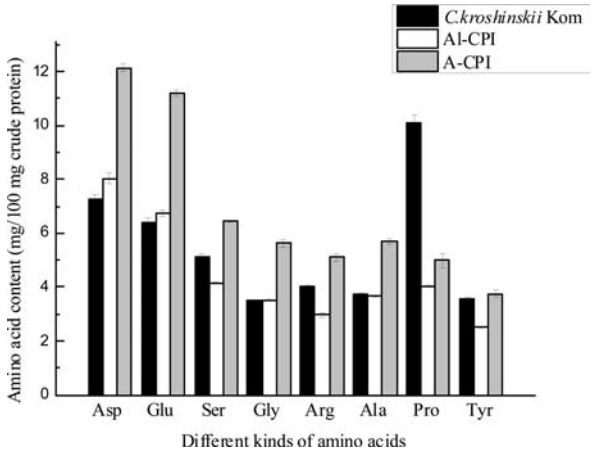

Figure 1. Nonessential amino acid composition of *C. korshinskii* Kom., Al-CPI, and A-CPI (mg/100 mg crude protein). Values are expressed as mean ± SD of triplicate measurements. All samples were significantly different ($p > 0.05$) except for aspartic acid and proline. Asp, aspartic acid; Glu, glutamic acid; Ser, serine; Gly, glycine; Arg, arginine; Ala, alanine; Pro, proline; Tyr, tyrosine.

In general, the total amount of amino acids in A-CPI was higher than that in Al-CPI. Different pH values utilized in the protein extraction processes may account for this variance. A pH of 6.8 was utilized in the extraction process of A-CPI, and most amino acids were stable at this pH.[40]

The contents of essential and nonessential amino acids in *C. korshinskii* Kom. were higher than those in Al-CPI, but lower than those in A-CPI with the exception of histidine. Different extraction methods could lead to different amino acid contents and compositions in protein isolates. Therefore, a suitable extraction method for proteins should be chosen to satisfy the demand of food and feed additives.

Analysis of Antinutritional Factors. Some ANFs exert their effects on the digestion and assimilation of some nutriments, as well as the immune system of animals. In our study, the ANF values of *C. korshinskii* Kom., Al-CPI, and A-CPI are investigated in Table 5.

Table 5. Antinutritional Factor Contents in *C. korshinskii* Kom., Al-CPI, and A-CPI (Milligrams per Gram Dry Substance)[a]

	C. korshinskii Kom.	Al-CPI	A-CPI
trypsin inhibitor[b]	2.07 ± 0.10a	ND[c]b	2.46 ± 0.10a
lectin	3.74 ± 0.0b	NDc	4.73 ± 0.0a
total phenol	10.67 ± 0.24b	19.02 ± 0.57a	NDc
tannins	7.70 ± 0.19a	5.66 ± 0.23b	NDc
phytic acid	1.70 ± 0.09a	NDc	0.96 ± 0.04b
saponin	ND	ND	ND

[a]Values are expressed as mean ± SD of three measurements. Values with different letters are significantly different at $p < 0.05$ within the same row. [b]Trypsin inhibitor, mg pure trypsin inhibited per g of dry sample. [c]ND, not detected.

The TIA contents of *C. korshinskii* Kom. and A-CPI were 2.07 and 2.46 mg pure trypsin inhibited/g dry substance, respectively. However, TIA was not detected in Al-CPI. Using the alkaline extraction, the TIA contents in protein isolates from *Vicia faba* were less than one-third of those in their raw materials.[25] The TIA value of *C. korshinskii* Kom. in this study

was lower than those of some kinds of mucuna beans (13.8−19.2 mg/g).[26,39] Combined with protease, trypsin inhibitor could lead to a decrease of protease activity and a low digestibility of proteins.

The lectin contents in *C. korshinskii* Kom. and A-CPI were 3.74 and 4.73 mg/g dry substance, respectively. However, lectin was undetectable in Al-CPI. A previous study indicated that alkaline extraction led to decreased contents of lectin in pea protein isolates (14 mg/g) compared with their raw materials (35 mg/g).[27] As a kind of glycoprotein, lectin was not digested by proteases, and it disturbed other protein digestion in humans and animals. Additionally, lectin can affect the human immune system and reduce the content of hormones secreted by the gut.[28]

The total phenols content of *C. korshinskii* Kom. (10.54 mg/g dry substance) was higher than that in *Vigna radiata* (4.5 mg/g) and lower than that in *Sesbania* (20.4−30.0 mg/g).[11] The content of total phenols in Al-CPI (19.02 mg/g) was higher than that in *C. korshinskii* Kom. Our results compared well with a previous alkaline extraction process,[29] in which the total phenols in protein isolates of buckwheat seeds (29.3 mg/g) were higher than those in their materials (6 mg/g).

The content of tannins in *C. korshinskii* Kom. was 7.61 mg/g dry substance. It was lower than that in pea (27.80−30.93 mg/g) and cowpea (22.63−26.14 mg/g).[30] Tannin content in Al-CPI was 5.66 mg/g, which was higher than that in protein isolate of mung bean (1.52 mg/g).[31] Total phenols and tannins could be united with diet proteins and digestive enzymes to form indigestible compounds, which could result in a low digestibility of food. However, in recent years, some ANFs, such as tannins and phytic acids, were also found to have some beneficial biological functions, such as oxidation resistance, antitumor promotion, and antiviral activity.

The contents of phytic acid were 1.70 and 0.96 mg/g dry substance in *C. korshinskii* Kom. and A-CPI, but it was undetectable in Al-CPI. Mwasaru[32] had reported that phytic acid contents were not detected in pigeonpea and cowpea protein isolates extracted by alkaline extraction. The phytic acid content in *C. korshinskii* Kom. was less than that in many kinds of legume beans, such as mung bean seeds (5.8 mg/g), chickpea (12.1 mg/g), cowpea (14 mg/g), and horse gram (10.2 mg/g).[33] Phytic acid could combine with minerals to form infusible precipitates, which could lead to interference with the absorption of mineral substances, especially calcium, zinc, and iron.[19]

Saponins was not detected in *C. korshinskii* Kom., A-CPI, and Al-CPI. Saponins could cause hemolysis and decrease the adsorption of nutrition in humans and animals.[34] Hydroxy steroids or bile acids can form insoluble complexes with saponins.

In an alkaline extraction process, protein extraction was followed by isoelectric precipitation. Hagerman[35] reported that phenolic substances could effectively combine with proteins during the protein isoelectric precipitation. In our study, some ANFs, such as the total phenols and tannins, in Al-CPI were higher than those in *C. korshinskii* Kom. On the other hand, the phytic acid in Al-CPI was lower than that in *C. korshinskii* Kom. Proteins and phytic acid did not combine when the pH was >11, and most of the phytic acid was removed with insoluble materials.[36] In addition, trypsin inhibitor and lectin in Al-CPI were not detected. The pH values used in the extraction process may lead to reduced bioactivity of proteins.[41]

In an acetone precipitation method, some ions derived from *C. korshinskii* Kom. may be entrapped in the extraction buffer, which might lead to an increase in the ionic strength of acetone and the precipitation efficiency of proteins.[37] This may explain the higher contents of TIA and lectin in A-CPI than those in *C. korshinskii* Kom. Additionally, phenolic substances could be solubilized in acetone during the protein precipitation,[38] which may lead to undetectable total phenols or tannins in A-CPI.

In summary, the protein contents of *C. korshinskii* Kom., Al-CPI, and A-CPI were 9.1, 50.1, and 42.6%, respectively. The contents of essential amino acids in the three materials were higher than those in FAO/WHO reference pattern for adult (2007) except sulfur-containing amino acids and tryptophan. As the limiting amino acids in cereal grains, the contents of Lys and Thr in *C. korshinskii* Kom., Al-CPI, and A-CPI exceeded those in the cereal grains, such as rice and wheat grains. The methionine in A-CPI (1.39 mg/100 mg crude protein) was even higher than that in soybean. The ANFs in *C. korshinskii* Kom. and Al-CPI were generally lower than those in other legumes except total phenols and tannins. Total phenols and tannins in Al-CPI were 19.02 and 5.66 mg/g dry substance, respectively, but they were undetectable in A-CPI. Our study provides a detailed analysis of the nutritional compositions and antinutritional factors in *C. korshinskii* Kom. and its protein isolates, indicating that they have great potential as food and feed additives.

[a]2.85 represents the sample of corn stover pretreated by steam explosion at the strength of 2.85. So do 3.37, 3.59, 3.89, 3.97, and 4.19.

(international unit) of endo-β-1,4-glucanase activity, 4.3 IU mL^{-1} of exo-β-1,4-glucanase, and 63.7 IU mL^{-1} of β-glucosidase activity. Small phenolic compound model substances, analytical grade, were purchased from Aladdin Industrial Corporation. All the other chemicals were analytical grade and purchased from Beijing Chemicals & Reagent Corp., China.

Pretreatment. The severity of steam explosion influenced the release of small phenolic compounds;[5,14] therefore, corn stover was steam exploded at various severity levels to get the exact information about the small phenolic compounds released during steam explosion. The severity of steam explosion (l g R_0) was decided by the severity factor, which was calculated as follows:[20]

$$R_0 = t \exp^{(T-100)/14.75} \quad (1)$$

where R_0 is severity factor, t is the time (min) for keeping constant pressure, and T is the temperature (°C) while keeping constant pressure.

According to eq 1, steam explosion severity (l g R_0) was designed as follows: 2.85 (1.0 MPa for 5 min), 3.37 (1.5 MPa for 3 min), 3.59 (1.5 MPa for 5 min), 3.89 (1.5 MPa for 10 min), 3.97 (1.5 MPa for 20 min), 4.19 (1.95 MPa for 5 min). The kneaded corn stover (about 200 g) was put into a batch steam explosion tank (2 L). The tank was then filled with saturated steam to the required pressure and maintained for a certain time. Finally, the pressure was discharged immediately to get the steam exploded corn stover (SECS). Corn stover was also milled with a microgrinder for plants into the size of smaller than 0.9 mm to examine the content of small phenolic compounds in raw stover.

The contents of cellulose, hemicelluloses (both of which were determined according to the literature[21]), and moisture of pretreated corn stover (Supporting Information, Figure S1) were 25.75−34.91%, 2.61−12.18%, 4.00−10.20%, respectively, and the pH was 4.0−6.0.

Washing of Pretreated Stover. The SECS and the milled corn stover (MCS) were washed separately with water by mixing in a flask with the weight ratio of solid to liquid 1:10, and then the flask was shaken at 50 °C, 150 rpm for 2 h. Finally, each mixture was separated by vacuum filtration to obtain the washing liquid of SECS, the washing liquid of MCS, the solid of steam exploded corn stover (S-SECS), and the solid of milled corn stover (S-MCS). All experiments were carried out in duplicate.

Determination of Small Phenolic Compounds in Pretreated Stover. Small phenolic compounds in washing liquid of both SECS and MCS were identified by a high-performance liquid chromatography (HPLC, Agilent 1200, Agilent Technologies, USA) with a YMC-Triart C18 column (250 × 4.6 mm L.D., YMC Co. Ltd.) and an ultraviolet detector. For each phenolic compound, the peak heights at different wavelengths were compared, and the final wavelengths to detect different small phenolic compounds were chosen as follows: 250 nm for *p*-hydroxybenzoic acid and syringaldehyde, 280 nm for syringic acid, vanillin, vanillic acid, *p*-hydroxybenzaldehyde, 320 nm for ferulic acid and coumaric acid. The elution time of each small phenolic acid were provided in Supporting Information (Table S1). The mobile phase was 60% acetic acid solution (1%) with 40% methanol at a flow rate of 0.6 mL/min. The temperature of column and detector was 30 and 35 °C, respectively. The small phenolic compound yield was calculated according to the following equation:

$$\text{PC yield (\%)} = \frac{\text{phenol weight (g)}}{\text{total material weight (g)}} \times 100\% \quad (2)$$

Cellulase Activity Analysis. Cellulase activity was tested[22,23] with 50 ± 1 mg Whatman No. 1 filter paper as substrate and 2 mL of acetic acid-sodium acetate (pH 4.8, 0.2 M) as the buffer. Cellulases were diluted 1000 times. The enzymatic hydrolysis process was carried out at 50 °C for 60 min.

The effect of small phenolic compounds, washing liquid and 5-hydroxymethylfurfural (5-HMF) on cellulase activity was examined as follows.

According to the small phenolic compounds identification results, the small phenolic compound model substances were used to examine their individual effect on cellulose activity (FPU) including vanillin, vanillic acid, coumaric acid, *p*-hydroxybenzoic acid, *p*-hydroxybenzaldehyde, syringic acid, syringaldehyde, and ferulic acid. Individual small phenolic compound was combined with enzyme and substrate immediately at the beginning of the assay. On the basis of the identified results above, the concentration of each small phenolic compound model substance was 0.05−8.00 g/L. The experiments were carried out in duplicate.

To examine the interactive effect of small phenolic compounds on cellulase activity (FPU), the small phenolic compounds mixture was prepared according to their total weight ratios of different steam exploded samples (Table 1). The small phenolic compounds mixture was added immediately while testing cellulase activity (FPU) with a total concentration 0.05−8.00 g/L. The experiments were carried out in duplicate.

When detecting the effect of washing liquid on cellulase activity (FPU), the amount of washing liquid added was calculated based on the constant ratio of cellulases to substrate in the process of enzymatic hydrolysis (0.15 mL/g). In the process of analyzing cellulase activity, 0.002 mL of cellulases was added. The equivalent volume of washing liquid should equal that from 0.002/0.15 g substrate. Buffer was added to reach 2 mL together with the washing liquid. The sample of cellulases and substrate without the washing liquid was taken as the control group.

To explore which component in the washing liquid of both SECS and MCS influences cellulase activity, the effect of 5-HMF on cellulase activity (FPU) was also carried out because 5-HMF was found in the washing liquid. The method was the same as that above. The amount of 5-HMF added was 0.2−2.0 g/L. The sample, including only cellulases and substrate without 5-HMF, was taken as the control group. The experiments were carried out in duplicate.

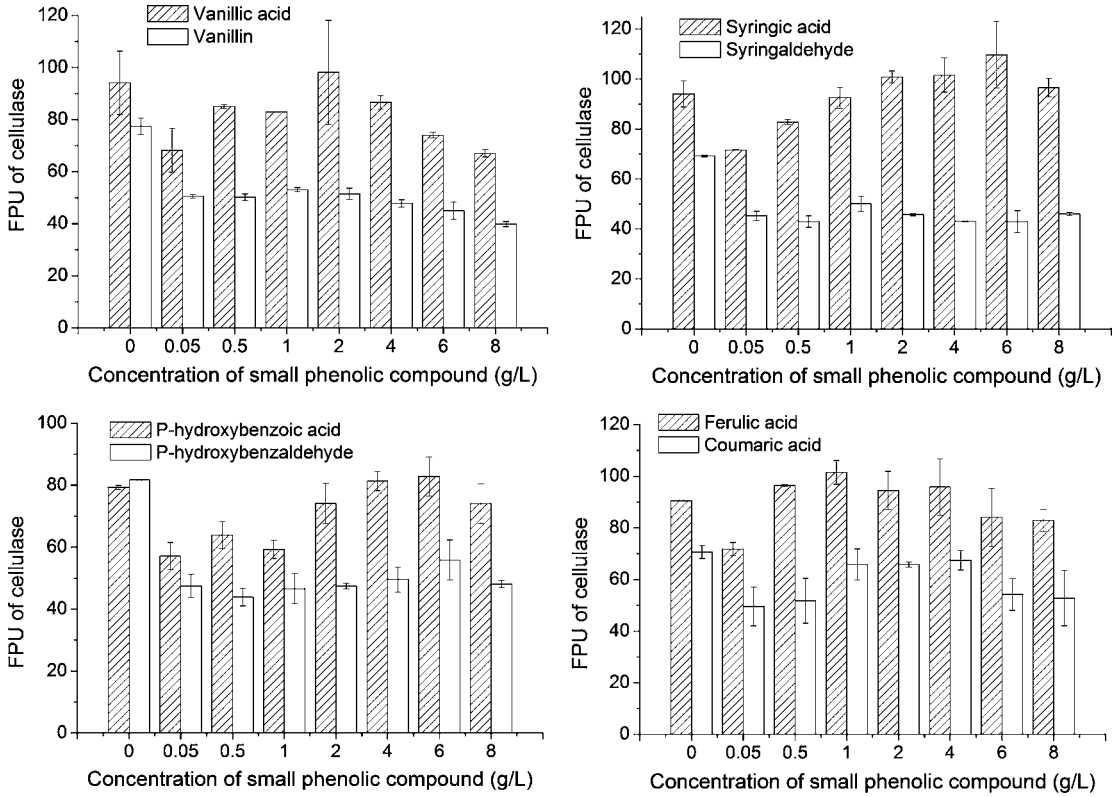

Figure 1. Effect of small phenolic compound model substance on cellulase activity. Each small phenolic compound model substance was added separately at the beginning of testing cellulase activity. Reducing sugar was tested with the DNS method.

Enzymatic Hydrolysis Process. Two assays were designed to examine the effect of small phenolic compounds on enzymatic hydrolysis.

For the first assay, the washing liquid of MCS and the washing liquid of SECS were separately put into the enzymatic hydrolysis mixture of the MCS (particle was smaller than 0.9 mm). The reaction was carried out in a 250 mL flask which was filled with 2 g (dry weight) of MCS, equivalent washing liquid (volume equal to that from 2 g of corn stover pretreated), buffer (acetic acid−sodium acetate pH 4.8, 0.2 M, the total volume of buffer and washing liquid was equal to 120 mL), and 0.6 mL of cellulases. The flask was shaken at 50 °C, 150 rpm for 48 h.

For the second assay, the enzymatic hydrolysis of pretreated corn stover before and after washing was directly compared. The reaction was carried out in a 100 mL flask which was filled with 2 g (absolute dry) of pretreated corn stover, 60 mL of buffer (acetic acid−sodium acetate pH 4.8, 0.2 M), and 0.3 mL of cellulases. The flask was covered and shaken at 50 °C, 150 rpm for 48 h.

After enzymatic hydrolysis for the required time, the flask was put into the water at 100 °C for 5 min to deactivate cellulases, and then the mixture in flask was cooled and separated by standing naturally for reducing sugar analysis.

All of the experiments were carried out in duplicate.

Reducing Sugar Analysis. While the effect of small phenolic compound model substances and small phenolic compounds mixture on cellulase activity was tested, reducing sugars were tested with the 3,5-dinitrosalicylic acid (DNS) method.[23] To exclude the color interference from the reaction between reducing phenolic aldehyde and DNS, a sample of cellulases and small phenolic compound model substances or their mixture at the same concentration without substrate was also prepared, and the optical densities of these samples (Supporting Information, Tables S2−S4) were subtracted from that of the related sample. Filter paper unit (FPU) was calculated according to the literature.[19,22]

There was 5-HMF in washing liquid, and 5-HMF might interfere with DNS by supplying active reducing groups as well as a characteristic interfering color.[24] Therefore, while the influence of washing liquid was detected, reducing sugars were all analyzed by HPLC (Agilent 1200, Agilent Technologies, USA) with an Aminex HPX-87H column (300 mm × 7.8 mm, Bio-Rad Laboratories Inc.) and a refractive index detector. The mobile phase was 0.5 mM H_2SO_4 at a flow rate of 0.6 mL/min. The temperature of column and detector was 65 and 35 °C, respectively. The content of 5-HMF in pretreated stover was also examined with this HPLC method.

While the enzymatic hydrolysis rate and yield of SECS and MCS were calculated, the content of reducing sugars in washing liquid was excluded from the sugar produced from the SECS and the MCS. The enzymatic hydrolysis yield of cellulose was calculated with the following equation,[19,22] in which the constant for cellobiose was 0.947 (324/342 = 0.947).

$$\text{enzymatic hydrolysis yield (\%)} = \frac{\text{glucose weight (g)} \times 0.9 + \text{cellobiose weight (g)} \times 0.947}{\text{cellulose weight (g)}} \times 100\% \quad (3)$$

Statistical Analysis. Experiments conducted in duplicate were analyzed at least in triplicate and expressed as mean ± standard deviation. The one-way analysis of variance test[25] was carried out using the Statistical Product and Service Solution (SPSS) 16.0 package for the effect of individual small phenolic compounds, small phenolic compounds interaction, and 5-HMF on cellulase activity. Moreover, univariate analysis of variance was also carried out with the SPSS package for the comparison of enzymatic hydrolysis of SECS before and after washing, in which two factors were analyzed: enzymatic hydrolysis time and pretreatment method (steam explosion strength, washing). Least square deviation analysis was performed to determine the significant differences of mean value ($p < 0.05$).

RESULTS AND DISCUSSION

Analysis of Small Phenolic Compounds in Pretreated Corn Stover. To examine the effect of small phenolic compounds on cellulase activity, the compositions of water-soluble small phenolic compounds of pretreated corn stover were analyzed first. Table 1 shows that there is only *p*-hydroxybenzoic acid in washing liquid of MCS, suggesting that only *p*-hydroxybenzoic in corn stover is in the free state. However, there are other small phenolic compounds in the washing liquid of SECS including syringic acid, vanillic acid, ferulic acid, coumaric acid, syringaldehyde, *p*-hydroxybenzaldehyde, and vanillin. The amounts of different small phenolic compounds were different, and the total small phenolic compounds yield increased with the enhancement of steam explosion strength, reaching 2.17% when the strength was 4.19.

Results revealed that steam explosion caused small phenolic compounds to be released, especially for *p*-hydroxybenzoic acid and coumaric acid which were released from stover pretreated atdifferent steam explosion strengths. In corn stover, the ferulic acid mainly connects hemicelluloses and lignin with a covalent bond. Other small phenolic compounds are mainly from lignin hydrolysis.[2] For many biomass feedstocks, steam explosion pretreatment being applied to or developed for biomass conversion can transform insoluble, polymeric lignin into soluble small phenolic compounds.[26,27]

According to the small phenolic compounds identified above, eight small phenolic compound model substances were used to examine their individual effect on cellulase activity (FPU), and the influence of concentration was mainly examined.

Effect of Small Phenolic Compound Model Substances on Cellulase Activity. Results revealed that syringic acid, etc. might have a concentration-dependent stimulation effect on cellulase activity (Figure 1). At a suitable concentration (at 2−4 g/L), syringic acid, etc. might slightly stimulate cellulase activity. However, at the lower (0.05 g/L) concentration, syringic acid, etc. exhibited a significant inhibition effect on cellulase activity. At other concentrations, the slight stimulation or inhibition effect depended on different small phenolic compounds. The stimulation effect of syringic acid reached 16.65%, followed by ferulic acid, *p*-hydroxybenzoic acid, and vanillic acid (in decreasing order) at their suitable concentration. The reason for the inhibition effect of coumaric acid might be that it was insoluble in acetic acid−sodium acetate buffer at 50 °C when the concentration was higher than 2 g/L. Therefore, cellulases could hardly touch the substrate. At 0.05 g/L, the inhibitory effect of phenolic acid on cellulase activity was arranged as follows: *p*-hydroxybenzoic acid (27.96%) ≈ vanillic acid (27.55%) > syringic acid (23.84%) > ferulic acid (20.70%).

As shown in Figure 1, *p*-hydroxybenzaldehyde, etc. significantly inhibit cellulase at all concentrations. At 0.05 g/L, the inhibitory effects of different phenolic aldehydes on cellulases were arranged as *p*-hydroxybenzaldehyde (41.83%) > syringaldehyde (34.60%) > vanillin (34.71%). While at the concentration of 8 g/L, the inhibitory effects were arranged as follows: vanillin (33.51%) > *p*-hydroxybenzaldehyde (41.14%) > syringaldehyde (33.51%). These results demonstrated that the inhibitory effect of *p*-hydroxybenzaldehyde, etc. on cellulases was stronger than that of phenolic acid at the same concentration.

The above results help explain why there were contrasting reports about the effect of small phenolic compounds on cellulases.[9,28] For the enzymatic hydrolysis of steam exploded wheat straw, the concentration of small phenolic compounds in the hydrolysis mixture was 0.281−0.356 g/L.[9] Though the concrete small phenolic compounds were not identified and reported, their total concentration fell in the slight stimulation range of phenolic acid in our text.[9] Therefore, the detoxification with laccase before enzymatic hydrolysis reduced the enzymatic hydrolysis yield. The concentration of small phenolic compounds in the hydrolysis mixture of corn stover pretreated with hot water was 5 g/L, which fell in the inhibition range of small phenolic compounds, especially phenolic aldehyde in our study, so it decreased enzymatic hydrolysis yield.[28] Other reports[29] about the effect of small phenolic compounds on cellulases or enzymatic hydrolysis could also be explained by the concentration-dependent effect.

Though the inhibition or inactivation effect of small phenolic compounds on cellulases has been reported,[10,11] the mechanism of the combination between cellulases and small phenolic compoundis is not yet clear. According to the previous work, tannic acid connects with cellulases by an affinity binding.[30] For lignocellulosic substrates, the nonproductive binding and inactivation of enzymes by lignin appear to be important factors limiting catalytic efficiency.[31−33] According to the interaction mechanism between protein and small phenolic compounds in the food industry, small phenolic compounds could form a hydrophobic monolayer on the surface of protein when their concentrations were low, enhancing the hydrophobic property of protein. Cellulases are known to connect with substrates through van der Waals forces and aromatic ring polarization interaction between three exposed aromatic amino acids located in the binding site and crystal face of the pyranose ring.[34−36]

Therefore, small phenolic compounds at low concentrations might increase the hydrophobic property of the cellulase surface, which would be helpful for cellulase to connect with substrates. However, if the concentration of small phenolic compound is too low to form a hydrophobic layer on the surface of cellulase, the small phenolic compound−cellulase complex might connect substrate nonfunctionally, resulting in an inhibitory effect on cellulases. If the concentration of small phenolic compounds is too high, the hydrophobic property on the cellulase surface might increase, causing the interaction among protein molecules to result in precipitation, resulting in an inhibitory effect.[28]

The inhibitory effect of *p*-hydroxybenzaldehyde, etc. on cellulases might be similar to that of coumarin on plant growth.[37] In that there is also no active group in the molecule, making it hard to form a hydrophobic layer on the surface of cellulase. However, *p*-hydroxybenzaldehyde, etc. might connect with the aromatic ring in cellulose-binding domains through a hydrophobic interaction to hamper the binding between cellulases and substrate.

This paper mainly concerns the small phenolic compounds identified in SECS; the effects of other phenolic acid and phenolic aldehyde on cellulase activity need further research. Moreover, a more generalized conclusion about the effect of small phenolic compounds on cellulase activity and cellulose enzymatic hydrolysis could be made, which might be helpful to improve different pretreatment technologies for various plant biomass.

According to identification results of washing liquid of both SECS and MCS, there were both phenolic acid and phenolic aldehyde. The total concentration of small phenolic com-

pounds changed with different pretreatment conditions. Therefore, further research was carried out to explore how the small phenolic compounds presented in and released from pretreatment of corn stover influenced the cellulase activity and enzymatic hydrolysis of cellulose.

Effect of Small Phenolic Compounds in Pretreated Stover on Cellulase Activity. Figure 2 shows cellulase activity is stimulated by washing liquid of SECS pretreated at the strengths of 2.85−3.89, and the highest enhancement of FPU reaches 34.48%, while cellulase activity decreases only 1.72% by washing liquid of SECS pretreated at the strengths of 3.97 and 4.19.

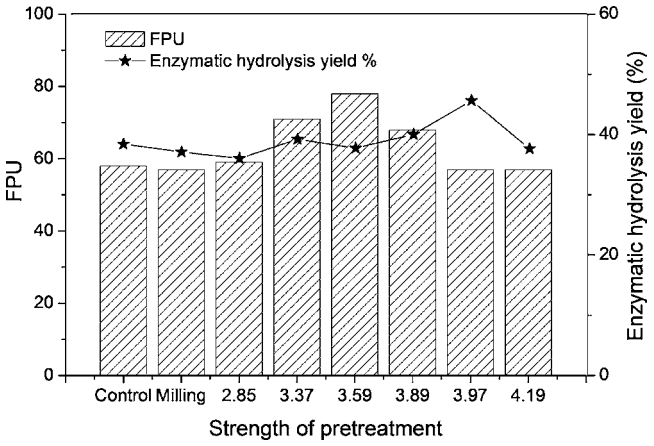

Figure 2. Effect of washing liquid on celluase activity and enzymatic hydrolysis of MCS. Reducing sugar was all analyzed with HPLC. Control represents the sample of cellulases and substrate at the same concentration without washing liquid. M indicates that the washing liquid added was from the sample of MCS. The datum 2.85 indicates that the washing liquid added was from the sample of corn stover pretreated by steam explosion at the strength of 2.85. So do 3.37, 3.59, 3.89, 3.97, and 4.19.

By composition analysis of the washing liquid of both SECS and MCS, it revealed that there were mainly sugars, 5-HMF, levulinic acid, and acetic acid.[5] While the effect of small phenolic compound on cellulase activity was tested, acetic acid−sodium acetate was taken as buffer. Therefore, the influence of small molecule acids such as levulinic acid and acetic acid could be excluded. For 5-HMF, its concentration was in the range of 0.28−0.81g/L while examining the effect of washing liquid of SECS on cellulase activity. Therefore, the effect of 5-HMF at a definite concentration on cellulase activity was also examined and shown in Figure 3. Results revealed that 5-HMF might inhibit cellulase activity at the concentration of 0.28−0.81 g/L. Therefore, it might be the small phenolic compounds in the washing liquid of SECS that stimulated cellulase activity, especially when the inhibition effect of 5-HMF was excluded.

Effect of Small Phenolic Compounds in Pretreated Stover on Enzymatic Hydrolysis. Enzymatic hydrolysis of MCS might be slightly improved by washing liquid of SECS pretreated at the strengths of 2.85−3.89, and the inhibition effect on enzymatic hydrolysis was only 2.63% for the washing liquid of SECS pretreated at the strength of 3.97 and 4.19 (Figure 2). It is different for the effect of the washing liquid on cellulase activity and enzymatic hydrolysis. This reveals that the stimulation or inhibition effect is also related to the substrate, which requires further research.

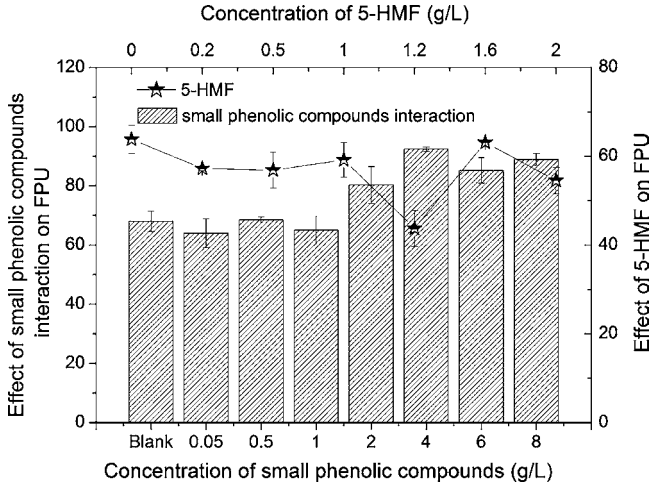

Figure 3. Left Y and bottom X is the interaction effect of individual small phenolic compound on cellulase activity. Reducing sugar was analyzed with the DNS method. Right Y and top X is the effect of 5-HMF on cellulase activity. Reducing sugar was tested with HPLC.

The average and initial enzymatic hydrolysis rates of SECS and MCS are all significantly higher than that of solid after washing steam exploded corn stover and solid after washing steam exploded corn stover, respectively (Figure 4). If the inhibition effect of 5-HMF on cellulases were excluded, the stimulation effect of phenolic acid (in pretreated stover) on enzymatic hydrolysis would be more significant. At the initial 8 h of hydrolysis, the average enzymatic hydrolysis rate of SECS increased 36.89% compared with that of the solid after washing steam exploded corn stover when the pretreatment strength was 3.97. For the last 8 h (40−48 h), the average enzymatic hydrolysis rate was 5.01 times higher than that of solid after washing steam exploded corn stover when the pretreatment strength was 3.89. These results demonstrate that water washing liquid of both SECS and MCS could stimulate enzymatic hydrolysis. Therefore, the highest enzymatic

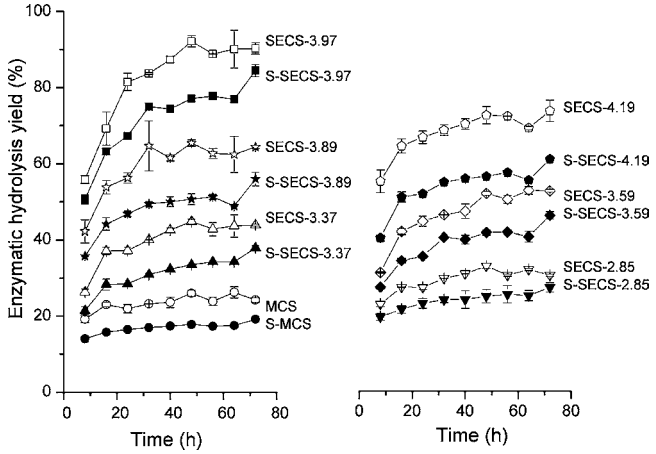

Figure 4. Effect of small phenolic compounds in pretreated stover on enzymatic hydrolysis. Reducing sugars produced at different times were analyzed with HPLC. SECS-2.85 represents the sample of corn stover pretreated by steam explosion at the strength of 2.85. So do SECS-3.37, SECS-3.59, SECS-3.89, SECS-3.97, and SECS-4.19. S-SECS-2.85 represents the solid after washing and separating corn stover pretreated by steam explosion at a strength of 2.85. So do SECS-3.37, SECS-3.59, SECS-3.89, SECS-3.97, and SECS-4.19.

dx.doi.org/10.1021/jf405046m | J. Agric. Food Chem. 2014, 62, 3223−3229

hydrolysis yield was obtained after reaction for 48 h for most SECS but 72 h for solid after washing SECS.

Results revealed that water washing liquid of both SECS and MCS could also enhance the highest enzymatic hydrolysis yield (Figure 4). Water washing liquid of MCS made the highest enzymatic hydrolysis yield increase by 37.13%, even though only *p*-hydroxybenzoic acid was identified in it. In the enzymatic hydrolysis solution of MCS, the concentration of *p*-hydroxybenzoic acid was 0.061 g/L, which would inhibit cellulases according to the analysis above. This revealed that the effect of small phenolic compounds on enzymatic hydrolysis might be related to substrates besides cellulases. As discussed above, further work is necessary to explore this finding.

The highest enhancement of enzymatic hydrolysis yield reached 20.79% when enzymatic hydrolysis was stimulated by water washing liquid of SECS pretreated at a strength of 3.97, and that pretreatment at a strength of 3.37 had the lowest stimulation effect on enzymatic hydrolysis. In the enzymatic hydrolysis solution of sample pretreated at a strength of 3.97, the concentrations of phenolic acid and phenolic aldehyde were 0.456 g/L and 0.555 g/L, respectively, while for the sample pretreated at the strength of 3.37, the concentrations of phenolic acid and phenolic aldehyde were 1.273 g/L and 0.103 g/L, respectively. When the concentration of individual small phenolic compounds was lower than 1 g/L, most of them inhibit cellulases according to Figure 1. Therefore, there might be interaction among the different small phenolic compounds. According to the content of small phenolic compounds in pretreated stover, the interaction among the different small phenolic compounds was analyzed.

Results (Figure 3) show that the mixed small phenolic compounds exhibit a slight stimulation effect on cellulase activity even at a concentration of 0.5 g/L. Moreover, compared with the effect of individual small phenolic compounds on cellulase activity, the inhibition effect of mixed small phenolic compounds at low concentration was much slighter. The highest stimulation effect reached 35.93%, which was higher than that of the individual phenolic acid (syringic acid reached the highest 16.65%). This explains why the enzymatic hydrolysis of samples pretreated at the strengths of 3.37 and 3.97 was stimulated significantly by the small phenolic compounds with a total concentration of 1.011 g/L and 1.376 g/L, respectively.

The higher enzymatic hydrolysis rate and yield of pretreated stover before washing further proved that washing liquid could stimulate enzymatic hydrolysis of cellulose. It was proven that the stimulation effect was mainly from small phenolic compounds especially phenolic acid or their interaction. Therefore, small phenolic compounds released during steam explosion should remain in the process of enzymatic hydrolysis to utilize their stimulation effect and be removed before fermentation to avoid their inhibition effect.[16] This paper also provides reference for analyzing the effect of small phenolic compounds released from other pretreatment technologies on the enzymatic hydrolysis of cellulose.

To remedy the issue of environmental hazards, waste should be recycled, and new technology should be promoted. The oil and isoflavones extraction from SSR using the proposed technology was investigated. The physicochemical properties and fatty acid composition of crude oil, as well as the yield of extracted isoflavones and their components, were analyzed. Results showed that the crude oil is refined through molecular distillation and may be used as feedstuff oil. The isoflavones remaining in SSR mainly exists in the form of daidzein and genistein. This study may be referential to the comprehensive utilization of SSR.

MATERIALS AND METHODS

Materials. SSRs were donated by the PRB Biotech Co., Ltd. (Zhongshan, Guangdong, China), and the main components are shown in Table 1. Samples were stored at 4 °C inside a polythene drum until extraction. *n*-Butane (99.99%) was purchased from Shenzheng Shenyan Gas Co., Ltd. (Shenzhen, Guangdong, China). All other reagents were purchased from Sigma Chemical Co. (St. Louis, MO, USA) and of analytical grade.

Table 1. Main Components of Fresh and Defatted SSR (Dry Basic, %)

	content (%)	
main component	fresh SSR	defatted SSR
crude fat	29.2 ± 0.68	0.62 ± 0.18
crude protein	21.8 ± 0.57	29.3 ± 0.84
crude fiber	18.1 ± 0.82	24.8 ± 0.32
ash	29.5 ± 1.02	43.3 ± 0.69

Experimental Design. On the basis of previous single-factor experiments, a central composite design (CCD) was applied to evaluate the effects of extraction temperature, time, and raw material granularity (RMG) on oil yield. The coded and uncoded independent variables used in the response surface methodology (RSM) design, as well as their respective levels, are listed in Table 2.[12]

Table 2. Experimental Design and Data for the Yield of SSR Oil from the CCD[a]

[a] X_1 = temperature (°C), X_2 = time (min), X_3 = RMG (mesh), Y_1 = oil yield (%).

All experiments were performed randomly to minimize the effect of extraneous factors. A quadratic polynomial regression was assumed in the prediction of oil yield (Y_1) as a function of the independent variables, as shown in eq 1:

$$Y_1 = K_0 + K_1X_1 + K_2X_2 + K_3X_3 + K_{11}X_1^2 + K_{22}X_2^2 + K_{33}X_3^2 + K_{12}X_1X_2 + K_{13}X_1X_3 + K_{23}X_2X_3 \quad (1)$$

where K_0 is a constant. K_i, K_{ii}, and K_{ij} are linear, quadratic, and interactive regression coefficients, respectively. The statistical significance of the model and the goodness of fit were evaluated using analysis of variance (ANOVA). The RSM was used to investigate the effect of the process variables on the response and to determine the optimal conditions for maximum oil yield. The experimental data were statistically analyzed using Design-Expert version 8.0.0 software (StatEase Inc., Minneapolis, MN, USA).

Oil Extraction. Prior to extraction, the SSRs were dried at 60 °C to ensure that moisture content was less than 5%, and the samples were grounded into powder. Extractions were conducted by continuous *n*-butane in a 3 L extraction pot. The solvent and extracted oil were separated through low-temperature vacuum evaporation. The oil yield was calculated using the following equation:

$$\text{oil yield (\%)} = \frac{\text{the weight of extracted oil (g)}}{\text{the weight of raw materials (g)}} \times 100 \quad (2)$$

Physicochemical Analyses of Crude Oil. Assays were performed for the determination of acid value (AV), peroxide value (POV), iodine value, saponification value, and refractive index, in accordance with GB 1535-2003 (an officially recognized Chinese criterion for physicochemical property detection and quality standard of soybean oil).[13]

Fatty Acid Analysis. Fatty acid composition was determined by conversion of the oil to fatty acid methyl esters (FAMEs) and analyzed by gas chromatography−mass spectrometry (GC-MS) (Agilent Co., Santa Clara, CA, USA) equipped with a flame ionization detector (FID). FAMEs were prepared by adding 50 mg of extracted oil, which was dissolved with 4 mL of isooctane; afterward, 200 μL of sodium methoxide was mixed with the solution.[14] The mixtures were allowed to settle for 5 min, and the supernatant (0.2 μL) was injected into the gas chromatograph−mass spectrometer. The components were identified by comparing their retention time with those of the standards in the mass spectra library. In addition, their relative content was calculated from the GC peak area.

The GC-MS conditions were as follows: a polar capillary column HP-INNOWAX (30 m × 0.25 mm, 0.25 μm film thickness) was used at a column head pressure of 0.04 MPa. The oven temperature was from 120 to 220 °C at heating rate of 8 °C/min, which was held for 1 min, continuously increased to 250 °C at 4 °C/min, and held for 5 min. The detector and injector temperatures were 220 and 230 °C, respectively.[15] Helium was used as the carrier gas at approximately 40 mL/min.

Deacidification by Molecular Distillation. Crude oil deacidification was performed using a laboratory-scale molecular distillation unit (model DCH70, Meichengaoxin Separation Technology Co., Ltd., Guangzhou, Guangdong, China). The distillation unit consisted of an evaporator with an internal condenser. For feeding, a jacketed vessel equipped with a flow regulation valve and level indication was used. The vacuum was achieved using a mechanical pump and a diffusion pump. The samples were first fully melted by circulating hot water (45 °C). Then, the melted samples were placed into the circulating hot oil-heated evaporator (220 °C), with a feed flow rate from 1.5 to 2.5 mL/min under 0.05 mbar pressure.[16] Thin-film samples were achieved using a roller wiper system (475 rpm), and the condensation temperature was 25 °C. Free fatty acids were collected as the distillate, with the refined oil as the residue.

Isoflavone Extraction. The SSRs were defatted prior to isoflavone extraction. Extractions were conducted by continuous 95% (v/v) ethanol in a 3 L extraction pot under 1.0 MPa at 60 °C for 90 min. The solvent and extracted isoflavones were separated through low-

dx.doi.org/10.1021/jf405459v | J. Agric. Food Chem. 2014, 62, 3230−3235

temperature vacuum evaporation. The isoflavone yield was calculated using the following equation:

$$\text{isoflavone yield}\ (\%) = \frac{\text{the weight of extracted isoflavone (g)}}{\text{the weight of defatted SSR (g)}} \times 100 \quad (3)$$

Isoflavone High-Performance Liquid Chromatography (HPLC) Analysis. HPLC analysis was performed on a LC-10A system (Shimadzu, Kyoto, Japan) equipped with an UV detector (200−600 nm) and a Diamonsil C_{18} column (5 μm, 250 mm × 4.6 mm) at room temperature. Extracted isoflavones and standard substances were dissolved in ethanol. The injection volume was 20 μL, and the absorption was measured at 260 nm. The mobile phase was deionized water (A) and acetonitrile (B). Gradient elution was operated at a flow rate of 1.0 mL/min according to the following gradient procedure: 0.0−10.0 min, 10.0−45.0% B; 10.0−25.0 min, 45.0% B; 25.0−45.0 min, 85.0% B; 45.0−60.0 min, 10.0% B.[17] The components were identified by comparing their retention times with those of the standards, and their contents were calculated from the peak area.

Statistical Analysis. All assays were performed in triplicate, and the results were expressed as mean values ± standard deviations. ANOVA was performed, and the differences were considered statistically significant at $P < 0.05$.

RESULTS AND DISCUSSION

Model Fitting. SSR oil yield obtained for each experiment is listed in Table 2.

The response and variables were fitted to each other by multiple regressions. A good fit was obtained, and the second-order polynomial equation is shown below by eq 4:

$$Y_1 = 27.5 + 0.46{*}X_1 + 0.44{*}X_2 - 2.53{*}X_3 - 0.20{*}X_1{*}X_2 + 0.99{*}X_1{*}X_3 + 0.31{*}X_2{*}X_3 - 4.17{*}X_1^2 - 0.82{*}X_2^2 - 1.55{*}X_3^2 \quad (4)$$

Results from ANOVA showed that the polynomial model had a satisfactory P value ($P < 0.0001$), which indicated significant results at 1% (Table 3). The P value of lack-of-fit was 0.172 ($P > 0.05$), which means that each lack-of-fit was not significantly related to pure error. The large value of the multiple determination coefficient ($R^2 = 0.9886$) revealed that the model adequately represented the experimental results.

Table 3. ANOVA for Response Surface Model Fitting[a]

Analysis of Response Surfaces. The relationship between independent variables and responses in a three-dimensional response surface curve generated by the models is shown in Figure 1.

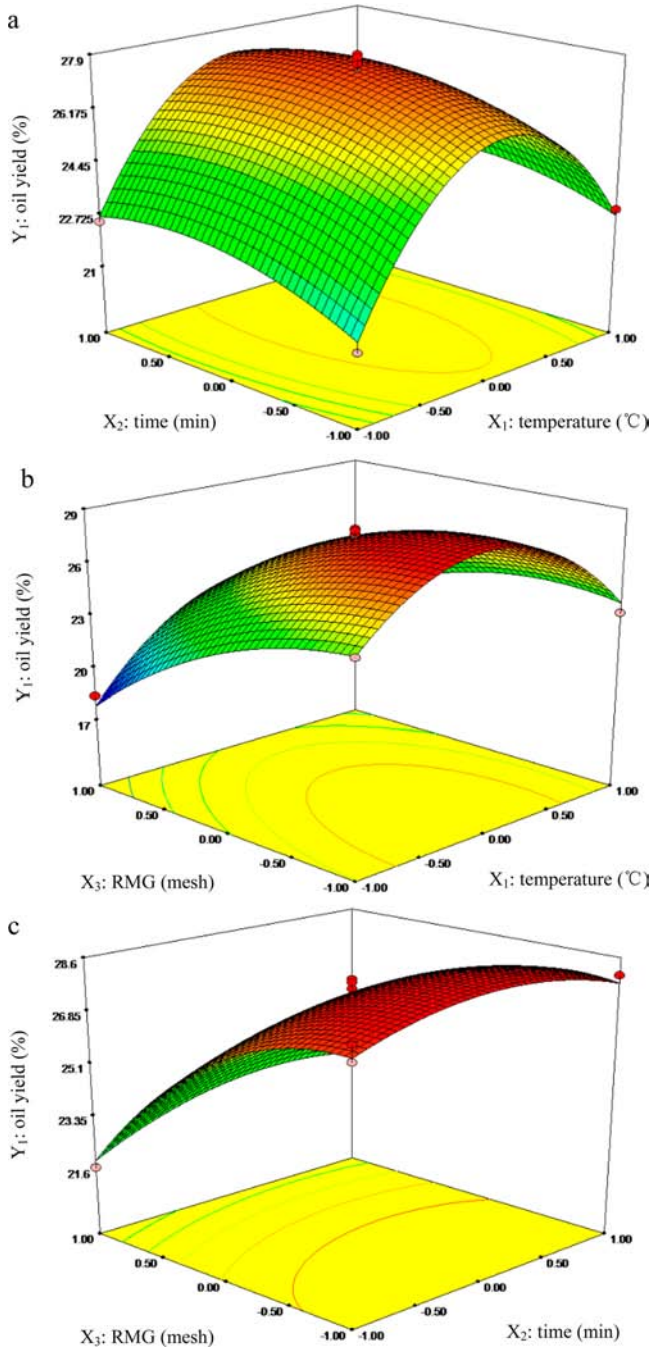

Figure 1. Three-dimensional response surface graphs for the effects on oil yield under the following parameters: (a) temperature and time; (b) RMG and temperature; and (c) time and RGM.

Time showed a positive effect on the response, which increased with a longer extraction period. This effect was more pronounced at the beginning of the extraction. When the process subsequently reached equilibrium, the freely available oil was exhausted, resulting in complete extraction with a slight increase of oil yield.[18] When the temperature increased, the response displayed an early increase and a subsequent

decreased state. Initially, high temperature reduced the viscosity of the solvent and enhanced solute vapor pressure, thereby increasing the diffusion coefficient of the oil.[19] However, when temperature was increased to a certain extent, the solvent was easily converted into gas, which decreased the mass transfer driving force and subsequently decreased the response. For RMG, the response declined dramatically when the mesh was increased from 40 to 80. Very small particles resulted in easy caking of SSR and the increase in mass transfer resistance, thereby loss of efficiency and yield decrease was caused.[20] Thus, the 40 mesh materials were enough for extraction. Results from ANOVA showed that the RMG had the maximum effect on the response, followed by the temperature. Both parameters were significant. The above analysis of response surfaces was preferential for SSR oil extraction by continuous *n*-butane.

Model Verification. With the aid of Design-Expert software, according to the solution of eq 4, the optimum conditions for maximum oil yield were 44.77 °C temperature, 61.8 min extraction time, and 43.6 mesh RMG. The predicted yield was 28.60%. The model was verified by three confirmatory tests. However, given the actual feasibility and convenience, the above condition was slightly modified as follows: 45 °C temperature, 62 min extraction time, and 45 mesh RMG. Under this condition, the actual yield was 28.43% ± 0.17%, which was relatively close to the predicted yield.

Traditional techniques, such as mechanical press extraction, can hardly extract the oil from SSR. This reason is related to the excessive degeneration of protein, which could reduce material plasticity and exploding pressure. Moreover, the phospholipids and proteins are good surfactants, which results in the decrease in interfacial tension between oil and water.[21] With petroleum ether as solvent, SSR oil can be extracted for 2 h per instance thrice.[22] After prepress, the oil yield increased by 7% through organic solvent extraction. However, the oil was further oxidized in the high-temperature process during prepress and can almost reach 18 mmol/kg. It still needs 40 min per time, twice, using subcritical fluid extraction.[23] Oil extraction from soybean using SFE is easier than that from SSR, which still requires a high pressure of 30 MPa and 4 h extraction time.[24] By using the novel extraction, the method only required 0.5 MPa and approximately 1 h extraction time. Apparently, the latter condition was more safe and efficient. Compared with these methods, continuous solvent could ensure complete oil extraction. Protection of heat-sensitive components and prevention of hazardous substances are also guaranteed in the whole low-temperature process.

The parameters were validated through comparative analysis, which showed reliable results. The developed model is advantageous for industrial production.

Physicochemical Properties. The quality and stability of the SSR oil extracted by continuous *n*-butane were determined by analyzing the physicochemical properties (Table 4).

Table 4. Physicochemical Properties of SSR Oil Extracted by Continuous Phase Transition Extraction

physicochemical index	property
refractive index (25 °C)	1.465 ± 0.08
acid value (mg KOH/g)	63.9 ± 0.10
peroxide value (mmol/kg)	9.05 ± 0.30
iodine value (g I/100 g)	138.93 ± 0.15
saponification value (mg KOH/g)	242.1 ± 0.21

Compared with the standard soybean oil in GB 1535-2003, the main drawback of the crude oil was the excess of AV (63.9 ± 0.1 mg KOH/g) and POV (9.05 ± 0.3 mmol/kg).[13] The oil is easily hydrolyzed and oxidized under acidic conditions during soy sauce fermentation.[25] The other determined indices were mostly in range. Thus, the crude oil is not appropriate for edible cooking oil but may be used for the feedstuff oil. From the main components of the defatted SSR listed in Table 1, the oil was almost extracted completely. The crude protein and fiber of defatted SSR accounted for more than half of the products. The rest of the ash was only washed away. A high amount of defatted SSR was still obtained.

Crude Oil Refining. The crude oil was refined through molecular distillation, and the results are shown in Figure 2.

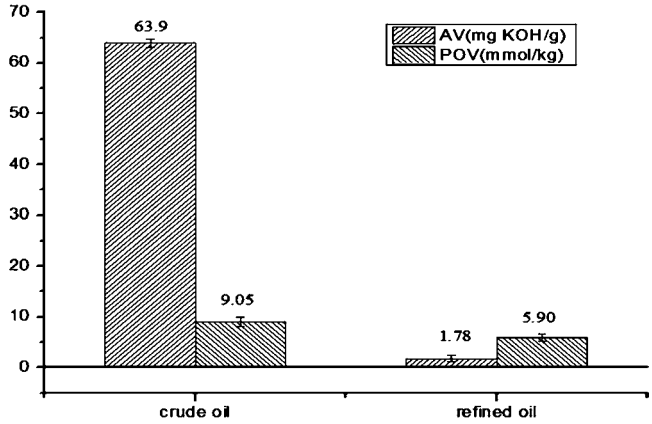

Figure 2. AV and POV of crude oil and refined oil.

Through molecular distillation, AV and POV sharply drop to 1.78 ± 0.12 mg KOH/g and 5.9 ± 0.08 mmol/kg, respectively. Compared with the conventional deacidification through alkali neutralization or esterification by adding methanol, molecular distillation avoids effluents and prevents corrosion of machines.[26] The refinement is simplified, and refined oil is easy to manufacture.

Fatty Acid Compositions and Contents. The fatty acid compositions and their relative refined oil contents were determined by GC-MS, and the results are shown in Table 5.

Table 5. Fatty Acid Compositions and Contents of Refined Oil

fatty acid composition	retention time (min)	relative content (%)
palmitic acid	11.34	13.07 ± 0.26
stearic acid	13.58	5.71 ± 0.33
oleic acid	13.84	21.44 ± 0.11
linoleic acid	14.43	50.23 ± 0.05
linolenic acid	15.22	9.54 ± 0.19

The refined oil mainly contained five fatty acids, with linoleic acid (50.23% ± 0.05%) as the principal content (>50%), followed by oleic acid (21.44% ± 0.11%). The fatty acids comprised 82% unsaturated and 18% saturated fatty acids. Compared with the first class soybean oil (GB1535-2003, China), most of the fatty acid compositions and relative content were still in range.[13]

Isoflavone Extraction and HPLC Analysis. From Figure 3, the dedicated retention times of daidzein and genistein were 15.8 and 19.6 min, respectively. No UV absorption peak was

dx.doi.org/10.1021/jf405459v | J. Agric. Food Chem. 2014, 62, 3230−3235

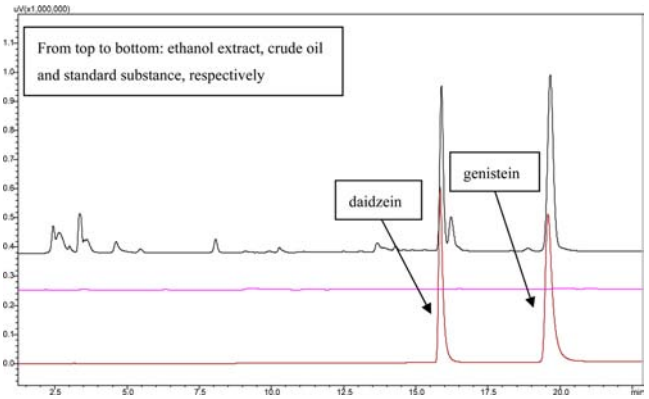

Figure 3. HPLC chromatograms of different substances.

found in the crude oil chromatogram. By contrast, two main peaks corresponding to the standard substances were observed. The results showed that isoflavones could not be extracted with oil extraction and still remained in the defatted SSR. The isoflavones mainly comprised daidzein and genistein, two kinds of aglycones.

Isoflavones reduce the risk of cardiovascular diseases and prevent certain cancers.[27] Instead of glycosidic form, aglyconic isoflavones play a major role in the biological effects. However, most isoflavones in natural food materials exist in glycosylated form and are not readily absorbed in the intestines.[28] During fermentation, glycosidic forms of isoflavones are converted to isoflavone aglycones with β-glucosidase enzymolysis. Thus, isoflavones extracted in SSR are of great value. Daidzein and genistein were calculated to be about 0.08% and 0.10%, respectively. The total isoflavones yield was 0.18% ± 0.012%. The amount of isoflavones varied according to genetics and growth location of the soybeans. The total isoflavone content ranged from 0.05% to 0.78%, with a mean of 0.1−0.2%, which indicates that, with 95% (v/v) ethanol solvent under 1.0 MPa at 60 °C temperature for 90 min, isoflavone could be extracted efficiently from defatted SSR using the proposed method.

With soybean as the main brewing material, abundant oil was remained in the SSR. The best oil extraction conditions by the novel, continuous phase transition extraction were investigated using RSM. The established optimal conditions for the maximum oil yield were *n*-butane solvent, 0.5 MPa extraction pressure, 45 °C temperature, 62 min extraction time, and 45 RGM. Under this condition, the actual yield was 28.43% ± 0.17%, relatively close to the predicted yield. Meanwhile, isoflavone was extracted from defatted SSR using the proposed method under the following parameters: solvent, 95% (v/v) ethanol; extraction pressure, 1.0 MPa; temperature, 60 °C; and extraction time, 90 min. The extracted isoflavones, with 0.18% ± 0.012% yield, mainly comprised daidzein and genistein, two kinds of aglycones. The main drawback of the crude oil was the excess of AV (63.9 ± 0.1 mg KOH/g) and POV (9.05 ± 0.3 mmol/kg). However, through molecular distillation, AV and POV could drop to 1.78 ± 0.12 mg KOH/g and 5.9 ± 0.08 mmol/kg, respectively. The refined oil may be used as feedstuff oil. The novel continuous phase transition extraction under low temperature could provide favorable conditions from the extraction of nonpolar to strongly polar substances. The proposed method is very suitable for industrial application. Results from this study may be used as reference for further development and utilization of SSR.

human MFGs.[16,18,19] These studies discussed the possibility that the nonfluorescent dark domains are lipid rafts (liquid-ordered phase, L_o) enriched in SM and cholesterol[15,16] as Rd-DOPE is preferably portioned into liquid-disordered phase (L_d).[20] This proposal remains controversial as it has been demonstrated that the coexistence of phase regions [for instance, gel (L_β) + liquid crystalline (L_α) and L_d + L_o)] may not always distinguish between L_o and gel regions, thus giving misleading information about lipid surfaces when using fluorescent imaging techniques.[21] MFGM contains relatively high L_β–L_α phase transition temperature (T_m) phospholipids [for instance, 16:0-PC (DPPC) makes up ∼11.1% (w/w) and SM makes up ∼29.6% (w/w) of total polar lipids in bovine milk][2] which remain in a gel-phase state at ambient temperature, and the L_β may contribute to the dark regions on MFG surfaces by CLSM. Although the L_β phase may be transformed to the L_o phase by the inclusion of cholesterol,[21] the molar amount of cholesterol is less than the molar amounts of the high T_m phospholipids in the MFGM,[1] consequently, the existence of an L_β phase in the MFGM at ambient temperature is expected.

A supported monolayer model system was prepared from milk-derived phospholipids to examine lipid–lipid interactions and phase coexistence.[22] However, nonsupported phospholipid bilayer systems are rarely used to model the MFGM. Giant unilamellar vesicles as an artificial bilayer membrane system constructed from phospholipids with/without cholesterol have been used to mimic the morphology of native biomembranes and to investigate interactions between proteins and lipids and specific functions of lipid domains.[9,23] Techniques such as fluorescent imaging[24,25] have provided fundamental knowledge of GUV formation. In the current study, we have constructed GUVs from milk-derived phospholipids and use this as a model to examine the lipid morphology of the MFGM.

MATERIALS AND METHODS

Materials. Indium tin oxide (ITO)-coated glass slides (surface resistivity 30–60 Ω/cm^2) were purchased from Sigma-Aldrich (Saint Louis, MO). The fluorescent fatty acid-labeled phospholipid analogue 1-palmitoyl-2-{6-[(7-nitro-2-1,3-benzoxadiazol-4-yl)amino]hexanoyl}-*sn*-glycero-3-phosphocholine (16:0–12:0, NBD-PC, 1 mg/mL in chloroform) and the fluorescent headgroup-labeled phospholipid analogue 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-N-(lissamine rhodamine B sulfonyl) ammonium salt (18:1, Rd-DOPE, 1 mg/mL in chloroform) were chosen as fluorescent probes; 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (16:0-PC, DPPC in powder form, L_β/L_α phase transition temperature 42 to 52 °C),[26] 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine (18:1-PE, DOPE in powder form, L_β/L_α phase transition temperature −9.9 to −2.9 °C),[27] and sphingomyelin (SM, fractionated from bovine milk and 16:0, L_β/L_α phase transition temperature 35 to 82 °C)[28] were all provided by Avanti Polar Lipids, Inc. (Alabaster, AL). Sucrose and glucose (both anhydrous) and chloroform, acetone, methanol, and water (HPLC grade) were all sourced from Fisher Scientific (Fair Lawn, NJ). A function generator (model 72-7710) was purchased from TENMA test equipment (Springboro, OH), and a digital phosphor oscilloscope (model TDS 3012, 100 MHz, 1.25 GS/s, 10K point) was provided from Tektronix (Beaverton, OR).

Electroformation of Giant Unilamellar Vesicles (GUVs). GUVs were generated from combinations of phospholipids under an alternating current (AC) electrical field[24,29−33] with modifications. The detailed sample plan and operation are explained as follows.

Sample Plan and Preparation. GUVs were formed from unitary, binary (SM is considered as unitary), and quaternary systems including DPPC, DOPE, SM, and/or cholesterol. Two sets of sample groups were prepared for studying the effects of DPPC and SM on regulating the lipid domain formation. Set 1: DPPC, DPPC + DOPE (7/3, 1/1, 3/7, mol/mol), and DOPE; set 2: SM, SM + DOPE (7/3, 1/1, 3/7, mol/mol), and DOPE. In simulating the MFGM composition, an extra sample containing DPPC, SM, DOPE, and cholesterol (8/8/8/4, mol/mol or 28.6 mol % for polar lipids and 14.3 mol % for cholesterol) was prepared to mimic the morphology of the native MFGM. It has been reported that the weight ratio between phospholipid and cholesterol in the MFGM is 25:2, w/w (∼25:4, mol/mol, calculated based on the mean molecular weight) in which phosphatidylethanolamine (PE), phosphatidylcholine (PC), and sphingomyelin (SM) are the major phospholipid constituents (>90% w/w of total phospholipid);[1] moreover, DOPE (47.0% PE, w/w) and DPPC (32.2% PC, w/w) are the major subspecies.[34] DPPC, DOPE, and SM were chosen in this study as they are the major phospholipid species in bovine milk,[2] and they have a broad range of L_β/L_α phase transition temperatures.[26,27,35,36] Phospholipids were dissolved in chloroform to yield 10 mg/mL sample solutions which contained Rd-DOPE or NBD-PC (0.25 mol %) as a fluorescent dye during the electroformation of GUVs.

Electroformation of GUVs. Briefly, 2.5 μL lipid formula sample solutions were placed on the surface of ITO slides. After completely evaporating any residual moisture in a desiccator (room temperature, 1 h), the samples were rehydrated in 100 mM sucrose solution. GUVs were formed under AC field conditions (3 V, 10 Hz, ∼55 °C) in a custom designed chamber for 45 min.[24,32] The prepared GUVs were taken from the electroformation chamber and placed into 100 mM glucose solutions (1/4, v/v) using a wide-mouth pipet (>1 mm diameter), at which point the newly formed GUVs were ready for CLSM observation. It was reported (supported by our own observations) that aging or insufficient cleaning of ITO slides may affect the GUV electroformation process resulting in a low yield of GUVs; therefore, the ITO slides were handled by a standard cleaning procedure following a mild annealing process.[31] The fluorescent intensities at the boundary of vesicles (liquid crystalline phases) were measured to ensure that these exhibited a bilayer structure.[29] Electroformation was carried out in duplicate for each lipid combination.

CLSM Observation of GUVs. GUV preparations were pipetted onto observation slides containing a small well (∼3 mm depth) for holding GUVs without extrinsic pressure from the coverslip. An Olympus FV1000 inverted confocal laser scanning microscope (Olympus America Inc., Center Valley, PA) with oil-immersion objective lenses (40× and 60 ×) was used to observe the structural properties and morphology of GUVs. Fluorescent signal collection (for rhodamine B and NBD) and the CLSM configuration were adopted from our previous work,[16] with modification. Rd-DOPE and NBD-DLPC were excited by a diode laser (559 nm) and Ar$^+$ laser (488 nm), respectively, and the emitted spectrum was measured between 570 and 670 nm and 500–600 nm, respectively. 3D images of GUVs were constructed from a group of individual 2D images taken across a defined *z*-axis section. Differential interfacial contrast illumination was used in the transmitted light channel for determination of the positioning of GUVs. All of the image processing was carried out at 22 ± 1 °C. The operating parameters of the CLSM were not necessarily kept constant for each image as the parameters were optimized to obtain the clearest images of GUVs. This was deemed to be acceptable as relative quantification of phospholipids was not the focus of the study.

RESULTS AND DISCUSSION

1. Fluorescent Staining and Electroformation of GUVs. To test the staining ability of the headgroup dye (Rd-DOPE) and fatty acid-group dye (NBD-DLPC) for fluorescent labeling of different phospholipids and sphingolipids in the model membrane system, the two dyes were applied to two unitary GUV systems (DPPC and SM), respectively. The zwitterionic glycerophospholipid PC and the zwitterionic phosphosphingolipid SM are more enriched in the outer leaflet

monolayer in the membranes of human and animal cells; moreover, in the case of MFGM, it has also been reported that PC and SM are located on the outside layer of the MFGM.[14,37] Therefore PC and SM unitary systems were used in the preliminary experiments. The headgroup-labeled DOPE phospholipid analogue appeared to stain the surfaces of DPPC- and SM-induced GUVs systems well; the fatty acid group-labeled DLPC phospholipid analogue stained the DPPC GUV system well, whereas GUVs could not be successfully constructed from the NBD-DLPC-labeled SM system under the same GUV generation conditions. The reason for this unsuccessful construction is uncertain; it may be due to the current electroformation conditions not being capable of generating GUVs from this specific lipid combination (NBD-DLPC + SM). Consequently, headgroup-labeled Rd-DOPE, a widely used fluorescent probe in MFG studies[15,38] was used as the primary dye for probing the surface morphology of constructed GUV systems derived from milk phospholipids. No noticeable differences were apparent between headgroup-labeling and fatty acid-labeling when comparing DPPC bilayer systems (images not shown).

In previous work, Rd-DOPE was first used for labeling the surface layer of native MFGs: the dark regions, which were not stained by Rd-DOPE, were interpreted as L_o (lipid rafts) domains thought to be enriched in SM and cholesterol.[15] A possible hypothesis is that the PE-coupled headgroup fluorescent dye (Rd-DOPE) may not stain the outer monolayer components properly, which mainly consists of PC and SM. This would create unstained or heterogeneously stained regions on the surface of MFGs where dark regions occur through the absence of Rd-DOPE, and these regions may not necessarily be liquid disordered (L_o) regions. Consequently, a GUV system in which the membrane composition can be controlled is an ideal tool for testing the staining capability of fluorescent labels in different bilayer systems (such as Rd-DOPE). Electroformation of GUVs was carried out successfully where the Rd-DOPE probe was located at the periphery of the GUV, and the yield of GUVs was sufficient for further analysis.

2. GUVs Constructed From DPPC and/or DOPE. The combinations of DPPC (T_m: 42 to 52 °C) and DOPE (T_m: −9.9 to −2.9 °C) in the formulation of GUVs was based on the range of L_β/L_α phase transition temperatures. No dark regions (nonfluorescent regions) could be found in the DPPC unitary and two DPPC-DOPE binary (7/3, 1/1, mol/mol) GUVs systems (Figure 1). There were no characteristic differences in surface morphology of these samples. The 3D images (Figure 1A), that were built from 2D cross-sectional images, show that the Rd-DOPE fluorescent probe was homogenously spread on the surfaces of GUVs. Nonfluorescent regions were found on the surfaces of GUVs made from a DPPC-DOPE (3/7, mol/mol) binary system (Figure 2).

C: 3D image showing apparent morphology of GUV in mimicking the morphology of native MFG. Scale bar: 5 μm.

Lissamine rhodamine B is a well-characterized fluorescent probe used for studying phase coexistence on GUV surfaces.[29,39] Bagatolli and Gratton[29] reported that Rd-DPPE molecules are segregated from the gel domains and locate in the liquid (crystalline) disordered domains in a DPPE-DPPC GUV system, which supports the current results where the liquid disordered domains are characterized as the location of Lissamine rhodamine B-labeled PE. Rd-DOPE, as a primary fluorescent dye, has been also used to probe the lateral segregation and morphology of the native MFGM.[4,15,16] Lopez and co-workers (2010) applied Rd-DOPE as a probe to determine the location of milk phospholipids in the MFGM and found that Rd-DOPE did not partition into the triacylglycerols interior of MFGs but was distributed heterogeneously on the surfaces of MFGs.[15] Consequently, the black interior regions of GUVs with no fluorescent emission are not considered in the current research.

In previous work,[15] the sizes of liquid-ordered or gel domains ranged from 0.6 to 2.7 μm depending on the size of the MFGs, and this is comparable with our current results as shown in Figure 2A and B from an artificial phospholipid membrane system containing only DPPC-DOPE (3/7, mol/mol). Also, the apparent morphology of the nonfluorescent emission domains, which correspond to the circular shapes on the GUV surface (Figure 2A), is in close agreement with that reported for MFGM by Lopez and co-workers.[15]

Evers et al. (2008)[40] observed heterogeneity on the MFGM using different fluorescent probes and concluded that the lack of MFGM fluorescent emission was due to the absence of an outer bilayer. Lopez et al. (2010)[15] challenged this hypothesis and suggested that the triacylglycerol inner core of the MFGs is unlikely to be directly in contact with the aqueous phase without surface coverage. Nevertheless, considering the current and widely accepted trilayer topology of the MFGM,[4,5,15,41,42] it is reasonable to expect that the primary monolayer containing glycerolphospholipids and membrane proteins located underneath the outer bilayer may still maintain the stability of MFGs.

An exposed protein inner monolayer on the surface of MFGs has been observed after centrifugal mechanical treatments;[43] therefore, the explanation of the bare surfaces on MFGs, as reported by Evers et al. (2008),[40] can be rationalized. However, this theory cannot explain the appearance of dark domains in the current GUV system containing only phospholipids, as a trilayer system is not present. Several CLSM studies[4,15,16,18,19] suggest that the dark domains on Rd-DOPE fluorescently labeled MFGM are lipid rafts[44−46] (analogous to L_o), comprising of saturated phospho/sphingo-lipids (mainly SM) and cholesterol. Dark domains, however, were generated in our artificial nonsupported model membrane system (Figures 2), containing only DPPC and DOPE (3/7, mol/mol). This phenomenon, to some extent, supports our hypothesis that the presence of nonfluorescent dark domains on the MFGM depends upon the proportion of the liquid phase: nonfluorescent regions found for DPPC/DOPE 3/7 mol/mol but not for DPPC/DOPE 7/3 nor 1/1 mol/mol. Consequently, the L_o phases (lipid rafts), which are mainly formed from SM and cholesterol,[47] and the gel phases formed by the high T_m phospholipids (DPPC ∼11.1%, w/w in total bovine milk polar lipids,[2] in this case) may both contribute to the formation of dark regions.

In previous research[4,15,16] and in our current work, CLSM characterization was carried out at ambient temperature (19−22 °C), which is lower than the T_m of DPPC required to induce gel structure formation. Bagatolli et al. (2000)[29] characterized the phase state of the lipid domain by using an excitation generalized polarization (GP) function at different temperatures. The CSLM GP images clearly show gel−liquid crystalline phase separation (DPPE/DPPC, 7/3, mol/mol) at the solid and fluid phase coexistence temperature region, 58−42 °C.[29] This is in close agreement with our results where ambient temperature is within the range of the phase coexistence temperatures (Figure 2).

The 3D image (DPPC/DOPE, 3/7, mol/mol, Figure 2C) shows more details about the gel-phase (DPPC) segregation from the liquid-phase (DOPE) in the GUV model, where irregular dendritic, flower shapes, and regular circular shapes were found. Whether the irregular shapes were formed spontaneously and individually or were formed due to the aggregation of regular circular gel-phases induced by the fluidity of liquid-phases is not known. The dark regions on GUVs (Figure 2C) are similar to the dark regions that were found on the surface of native MFGs.[15,16,18,19] It was difficult to observe gel−liquid crystalline phase separation in the GUVs systems as presented in Figure 1. This may be related to the preferred molecular arrangement of different phospholipids (DPPC and DOPE) in the nonsupported model membrane systems, as shown in Figure 3. According to the critical packing parameter

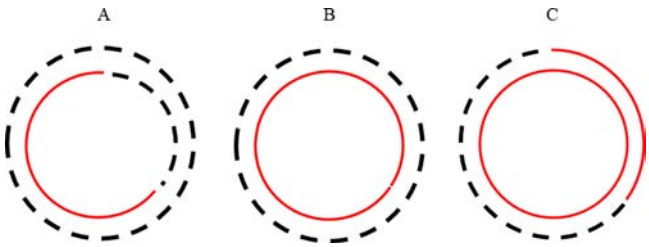

Figure 3. Highly schematic illustration of proposed molecular arrangement of GUV (bilayer) systems formed from different species of phospholipids. A: DPPC/DOPE (7/3, mol/mol); B: DPPC/DOPE (1/1, mol/mol); C: DPPC/DOPE (3/7, mol/mol). Black (dashed): DPPC; Red (solid): DOPE.

and critical packing shape of phospholipid molecules[48] it is proposed that PE is more favorably packed in the inner leaflet, with the bilayer system containing PC and/or SM, as the fatty acid tails of PE form cylindrical or inverted truncated cone shapes which favor planar bilayers or inverted micelles structures. Moreover, in this current work, the GUVs could not be constructed from the Rd-DOPE + DOPE sample under the same electroformation conditions which were used for the other samples. This negative result indirectly suggests that unlike PC and SM, PE molecules are difficult to form a flexible spherical bilayer structure, implying localization in the inner leaflet of the MFGM bilayer or GUV systems when PC and SM are present. Consequently, the outer leaflets of GUV bilayers made from DPPC and specific DPPC+DOPE mixtures (7/3 and 1/1, mol/mol) may be constructed from only DPPC (Figure 3).

It is necessary to point out that CLSM is an appropriate technique for characterizing the homogeneity of the surface of fluorescently labeled phospholipid bilayers. The characterization depends upon the instrumental configuration; by setting up a correct configuration on the CLSM, Rd-DOPE-labeled DPPC concentrated GUVs (Figure 1) may be visible. Therefore, in the current work, CLSM was applied for characterizing the "immiscible phases" on the surfaces of GUVs rather than characterizing the individual absolute ordered or disordered phases.

3. GUVs Constructed From SM and/or DOPE. In GUV systems containing only bovine milk-derived SM, the nonfluorescent regions were observed with long elongated shapes (Figure 4A and B) where the images were taken at the top and bottom section of selected GUVs. The 2D GUV image taken from the middle section (Figure 4C) is similar to the MFGM images from previous reports;[4,15,16] the tiny dark dots on the fluorescent GUV surface may contribute to the linear shaped microdomains in constructed 3D images.

Unlike DPPC, SM derived from bovine milk is a mixture of lipid molecules with different lengths of fatty acids and headgroups which gave three major peaks for the purchased sample (Avanti Polar Lipids) in HPLC-ELSD analysis. The presence of other minor SM species are also expected. This is

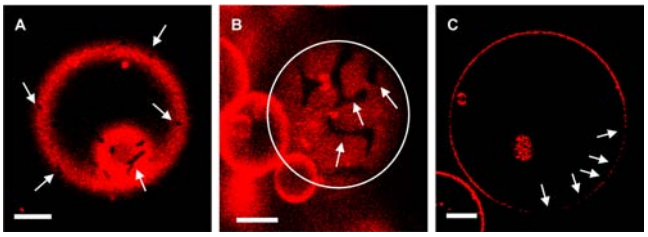

Figure 4. Dark regions (DRs, shown by white arrows) presented on GUVs formed from SM. A: 2D image, top/bottom and middle section of two GUVs, DRs were observed as elongated and dot shapes; B: 2D image, top/bottom section (in white circle), DRs were observed as irregular shapes; C: 2D image, middle section. Scale bar: 5 μm.

the same three-peak profile as our extracted bovine milk phospholipid mixture (results not shown); therefore, the proposed surface arrangement shown in Figure 3, which only represents two types of pure lipid molecules, does not apply in this case, and dark domains can occur in all SM containing samples (Figures 4, 5, and 6). These dark domains were

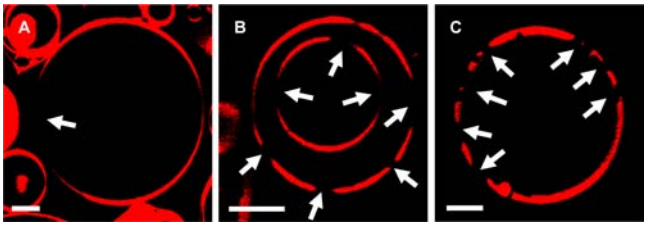

Figure 5. DRs (shown by white arrows) were found in GUVs formed from binary systems containing SM and DOPE. A: SM/DOPE, 7/3 (mol/mol); B: SM/DOPE, 1/1 (mol/mol); C: SM/DOPE, 3/7 (mol/mol). Scale bar: 5 μm.

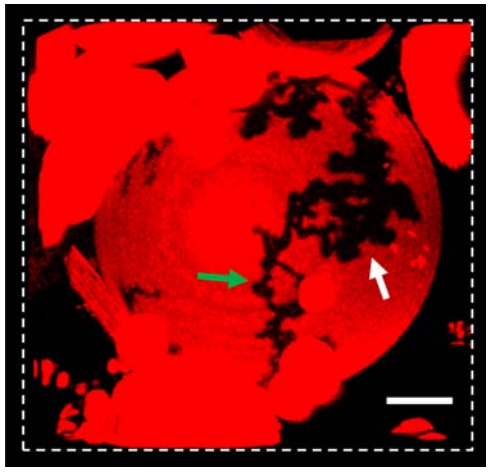

Figure 6. Apparent morphology of a GUV (SM/DOPE, 1/1, mol/mol) in a 3D image modeling part of the morphology of a native MFG. White arrow: irregular dendritic shape; green arrow: linear shape. Scale bar: 10 μm.

probably induced by heterogeneous distribution of Rd-DOPE on the surfaces of GUVs which contained different types of milk SM. The composition of milk SM in terms of fatty acid and sphingoloid population varies considerably,[2] and it was proposed that physical behavior (melting) of SM depends on both the sphingosine chain and the fatty acid distribution;[49] therefore, different physical behaviors and molecular packing of milk SM molecules in GUVs may be expected. The hosting capacity of fluorescent probes in phospholipid membranes depends on the phospholipid molecular packing,[16] consequently, the observation of phase separation, which could be induced by heterogeneous distribution of fluorescent probes in the GUV system containing different types of SM, is rationalized.

Shipley et al. (1974)[49] characterized a single lamellar bilayer structure in a SM (bovine brain) bilayer system and found phase separation for a higher degree of hydration in a SM bilayer system (>42% water, v/v) occurred at a lower phase transition temperature (25 °C). This is in close agreement with the current study where bovine milk SM is highly hydrated and characterized at ambient temperature; pulsed-field gradient NMR has shown that the lateral diffusional behavior is the same in a bilayer comprised of SM of either brain and milk origin.[50] The dark regions only account for a small proportion of GUV (SM unitary system) surfaces as discrete linear/dot shapes and larger regular shapes are not seen (Figure 4, containing only milk SM). This unique structure and morphology is probably due to the specific individual molecular profile of SMs derived from bovine milk and their packing structure in the bilayer. Filippov et al. (2006)[50] found that SM derived from brain and egg may induce larger phase coexistence areas in phospholipid bilayers than milk SM, probably due to the heterogeneous hydrocarbon chain in SM which gives a less tightly packed molecular structure. Therefore, the small dark regions could be formed by a small amount of tightly packed homogeneous hydrocarbon chains of specific SM molecules.

Bagatolli et al. (2000)[29] found similar elongated microdomains in GUV systems (DLPC/DPPC, 1/1, mol/mol) which were stained by different probes (including Rd-DPPE). Based on a previously proposed model,[51] the elongated domains were formed due to a particular topology (unlike a pure gel phase) of specific phospholipid molecules (DPPC in this case), presented as filaments of gel in a particular liquid crystalline phase. Moreover, in a good agreement with our current results shown in Figure 6 (SM/DOPE, 1/1, mol/mol), elongated and polygonal domains have also been found in other GUV systems containing only pure phospholipids, where it has been pointed out the GUV radius of curvature and fluid line defects formed by liquid crystalline domains are important for forming and shaping lipid domains.[29,52] Therefore, we can conclude that both intrinsic factors (composition, chemical and physicochemical nature of phospholipids, including hydrocarbon chain, T_m, and molecular packing shape) and extrinsic factors (size of the bilayer, environmental temperature, and physical property of liquid-domains) are important for forming lipid domains with specific morphology.

4. GUVs Mimicking the Morphology of Native MFGs. Lateral mobility of lipid domains (dark regions) with regular circular shapes was observed (Figure 7, DPPC/DOPE, 3/7, mol/mol), in good agreement with previous work where mobility of the MFGM constituents was found.[15] The composition of the mobile nonfluorescent regions is difficult to ascertain due to the complexity of the composition and structure of the MFGM; however, in artificial membrane systems with controlled composition (Figure 7), it can be concluded that the mobile microdomain was formed from a gel phase and flowed into the liquid phase. The shape and the size of nonfluorescent microdomains did not change as a function of time, as reported before in the bovine MFGM.[15] The specific shapes of nonfluorescent microdomains on the surface of

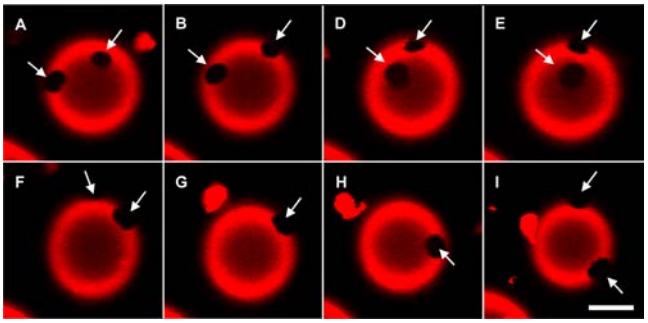

Figure 7. Monitoring mobility of DRs (pointed by arrows) on the surface of specific GUVs (DPPC/DOPE, 3/7, mol/mol). 2D images were taken at the top/bottom section of GUVs. A–I were obtained individually along a fixed time interval (20 s). Scale bar: 5 μm.

GUVs, as shown in Figures 2 and 6 (without SM, and without a combination of SM and cholesterol), shows good agreement with the previously published surface morphology of native MFG.[16] Based on the current results, we may conclude that the nonfluorescent microdomains on the surface of MFGs are not necessarily represented by the L_o phase, enriched in SM and cholesterol, but may also be formed from the gel phase containing the major MFGM phospholipid species DPPC and SM.

A lipid formulation of DOPE/DPPC/SM/cholesterol (8/8/8/4, mol/mol) was used for mimicking the composition of the native MFGM. A large integrated dark region is shown in the 3D micrograph (Figure 8). The surface morphology is in good

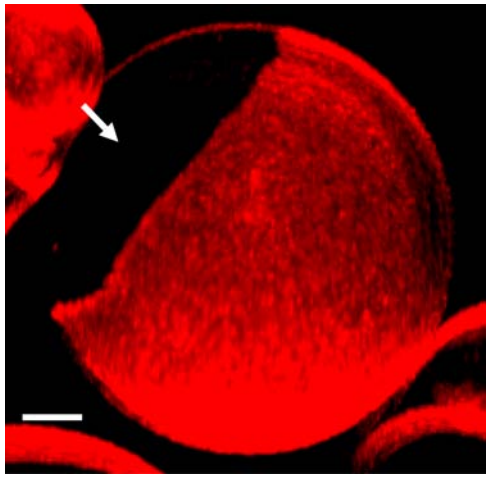

Figure 8. 3D image of a GUV formed from a lipid formula (DOPE/DPPC/SM/cholesterol, 8/8/8/4, mol/mol) mimicking the lipid composition of the native MFGM. DR is shown by the arrow. Scale bar: 5 μm.

agreement with previous GUV systems containing cholesterol where the existence of microdomains and domain patterns was regulated by the amount of cholesterol.[53] Morales-Penningston et al. (2010)[24] showed a similar pattern of microdomains on the surface of GUVs (composed from 18:0-SM/DOPC/cholesterol in the molar ratio of 0.56/0.24/0.20), where the larger and regular circular microdomains were formed by the merging of smaller separated microdomains, as induced by osmotic swelling. This osmotic swelling mechanism may explain the apparent morphology on our GUV containing cholesterol (Figure 8) as an osmotic pressure gradient is formed between the external (100 mM glucose) and internal solutions (100 mM sucrose). Cholesterol has a role in inducing domain formation[54,55] and is dependent on the amount present.[53] Scherfeld et al. (2003) reported that phase separation may be reduced by adding 10 mol % cholesterol into the phospholipid binary system (DOPC/DPPC. 0.5/0.5, mol/mol) and can increase by adding 20 mol %.[53] Cholesterol accounts for ~14 mol % in our current formulation for mimicking the lipid molar composition of MFGM, and phase separation can readily be observed with CLSM (Figure 8).

Based on CLSM experimental evidence, a model of lateral topology of MFGM lipid organization can be deduced in which PC and SM are located in the outer leaflet of the bilayer and specific phospholipids having high gel–liquid crystalline phase transition temperatures contribute to lateral segregation in the MFGM. This suggests that association of SM and cholesterol is not the only contributing factor to ordered domain formation.

hydrophilicity. Hepatic metabolites can then return to the intestinal lumen via the enterohepatic circulation and undergo further transformations. Then, luminal phenolic metabolites and phenolic compounds that have not been absorbed by the intestine reach the colon where they are subjected to microbial degradation.[11] Microbial metabolites are absorbed from the colon and are also subjected to the conjugation processes in the liver, resulting in their glucuronidated and sulfated derivatives. Finally, the phenolic microbial metabolites are excreted from the body via urine as hepatic conjugates.[4] The absorption, as well as the extent of hepatic conjugation and microbial deconjugation, is strongly affected by the structure of phenolic compounds.[12] Although hepatic metabolism leads to the generation of numerous combinations of methylated, glucuronidated, and/or sulfated phenolic metabolites, colonic microbial metabolism follows a general pattern leading to a relatively small number of metabolites, mainly phenolic acids and derivatives of phenylpropionic and phenylacetic acids.[5]

Direct evidence of the bioavailability of phenolic compounds can be obtained by characterizing the profile of metabolites in the plasma. This requires the use of a sensitive analytical methodology such as UHPLC with tandem MS, associated with microelution SPE (μSPE) technology, which allows the characterization of numerous metabolites in biological fluids at low concentrations, in a small volume of sample and in a short time.[13]

Among foods rich in phenolic compounds, strawberry, cranberry, and onion have previously demonstrated some beneficial effects on blood glucose regulation in rodents,[14−16] constituting a promising natural therapeutic approach in the prevention of obesity and type-2 diabetes. The purpose of the present work was thus to study the bioavailability of strawberry and cranberry phenolic compounds in a representative context of a diet-induced obesity model (rats fed a high-fat, high-sucrose diet) and compare it to a concomitant supplementation with an onion extract. Male Wistar rats were either administered a vehicle, a single intake of GlucoPhenol extract, or the same extract supplemented with an onion extract. Blood samples were collected pre- and postingestion, and plasma phenolic metabolites were characterized using an optimized UHPLC-MS/MS method, after their extraction with μSPE, and compared with the native phenolic composition of the studied extracts.

MATERIALS AND METHODS

Plant Material. Strawberry-cranberry (*Fragaria* × *ananassa*, Duch. cv. *authentique*, and *Vaccinium macrocarpon* L.) extracts blend GlucoPhenol (GP) and onion (*Allium cepa* L.) extract were provided by Nutra Canada company (total phenolic content of 18% and 45% dry weight respectively, as determined by Folin−Ciocalteu method).

Chemicals. The following phenolic standards were purchased from Sigma-Aldrich (St. Louis, MO): ellagic acid, 5-caffeoylquinic acid, protocatechuic acid, *p*-hydroxybenzoic acid, *p*-coumaric acid, vanillic acid, gallic acid, quercetin, quercetin 3-glucoside, kaempferol, myricetin, isorhamnetin, catechin, epicatechin, and rosmarinic acid. Ascorbic acid, citric acid, and hydrochloric acid were also purchased from Sigma-Aldrich (St. Louis, MO). Pelargonidin 3-glucoside was obtained from Extrasynthèse (France). Liquid chromatography grade solvents acetone, methanol, and acetonitrile were purchased from EMD Millipore Chemicals (Billerica, MA), and formic acid, glacial acetic acid, and phosphoric acid were obtained from Anachemia (Canada). Ultrapure water was obtained from a Millipore Milli-Q water purification system (Billerica, MA).

Determination of Strawberry−Cranberry and Onion Extracts Phenolic Composition. *Characterization of Anthocyanins.* The anthocyanin composition of GP extract was analyzed as previously described[17] by reverse-phase analytical HPLC using an Agilent 1100 series system (Santa Clara, CA). The separation was performed with a flow rate of 1 mL/min using a Develosil C18 reverse phase column (250 mm × 4 mm, 5 μm particle size), protected with an Ultrasep C18 guard column (Phenomenex, CA). A binary gradient of 5% formic acid in ultrapure water (solvent A) and methanol (solvent B) was as follows for the anthocyanins separation: 0−2 min, 5% B; 2−10 min, 5−20% B; 10−15 min, 20% B; 15−30 min, 20−25% B; 30−35 min, 25% B; 35−50 min, 25−33% B; 50−55 min, 33% B; 55−65 min, 33−36% B; 65−70 min, 36−45% B; 70−75 min, 45−53% B; 75−80 min, 53−55% B; 80−84 min, 55−70% B; 84−88 min, 70−5% B; 88−90 min, 5% B. Chromatographic data were acquired at 520 nm, and the quantification was performed using pelargonidin 3-glucoside as standard.

Characterization of Procyanidins. The procyanidin composition of GP extract was analyzed as previously described[18] by normal-phase analytical HPLC using an Agilent 1260/1290 infinity system (Santa Clara, CA) equipped with a fluorescence detector. The separation was performed at 35 °C with a flow rate of 0.8 mL/min using a Develosil Diol column (250 mm × 4.6 mm, 5 μm particle size), protected with a Cyano SecurityGuard column (Phenomenex, CA). The elution was performed using a solvent system comprising solvents A (acetonitrile/acetic acid 98/2 v/v) and B (methanol/ultrapure water/acetic acid 95/3/2 v/v/v) mixed using a linear gradient from 0% to 40% B for 35 min, 40% to 100% B for 5 min, 100% isocratic B over 5 min, and 100% to 0% B for 5 min. The fluorescence was monitored at excitation and emission wavelengths of 230 and 321 nm. Procyanidins with degrees of polymerization (DP) from 1 to >10 were quantified using an external calibration curve of epicatechin, taking into account their relative response factors in fluorescence.[19]

Determination of Total Ellagitannins. Total ellagitannins were estimated by reverse-phase analytical HPLC quantification of released ellagic acid following acid hydrolysis. Briefly, GP extract was dissolved in 25 mL of 50% methanol in ultrapure water containing ascorbic acid and hydrochloric acid (final concentrations of 10 mM and 1.2 M respectively). The mixture was heated to 85 °C in the dark for 2 h and then cooled in ice for 5 min. Ellagic acid separation was performed on an Agilent 1100 series HPLC system (Santa Clara, CA) using a Develosil C18 reverse phase column (250 mm × 4 mm, 5 μm particle size), protected with an Ultrasep C18 guard column (Phenomenex, CA, USA). The elution was performed at a flow rate of 1 mL/min using a solvent system comprising solvents A (methanol/ultrapure water/acetic acid 10/88/2 v/v/v) and B (methanol/ultrapure water/acetic acid 90/8/2 v/v/v) mixed using a gradient as follows: 0−15 min, 0−15% B; 15−25 min, 15−50% B; 25−34 min, 50−70% B; 34−35 min, 70−0% B. Chromatographic data were acquired at 250 nm, and the quantification was performed using ellagic acid standard.

Characterization of Phenolic Acids and Flavonoids. Phenolic acids and flavonoids were characterized using a Waters Acquity UPLC-MS/MS equipped with an H-Class quaternary pump system, a flow through needle (FTN) sample manager system, and a column manager. The MS detector was a TQD mass spectrometer equipped with a Z-spray electrospray

Table 1. Description of Phenolic Supplementation Treatments: Dose of Extract, Equivalent Phenolic Content, and Total Phenolic Intake (mg/kg of Weight Body)[a]

	dose of extract (mg/kg)		dose of phenolic compounds (mg/kg)		
group identification	GlucoPhenol	onion	GlucoPhenol	onion	total phenolic intake (mg/kg)
(1) control					0
(2) 2.7 mg/kg GP	15		2.7		2.7
(3) 5.4 mg/kg GP	30		5.4		5.4
(4) 27 mg/kg GP	150		27		27
(5) 36 mg/kg GP	200		36		36
(6) 36 mg/kg GP + O	30	68	5.4	30.6	36

[a]The experimental groups are numbered from (1) to (6).

interface. The analysis was achieved using an Agilent Plus C18 column (2.1 mm × 100 mm, 1.8 μm) (Santa Clara, CA). The separation was performed at 40 °C at a flow rate of 0.4 mL/min with a mobile phase consisting of 0.1% formic acid in ultrapure water and acetonitrile (solvent A and B, respectively) using a gradient elution as follows: 0−4.5 min, 5−20% B; 4.5−6.45 min, 20% B; 6.45−13.5 min, 20−45% B; 13.5−16.5 min, 45−100% B; 16.5−19.5 min, 100% B; 19.5−19.52 min, 100−5% B; 19.52−22.5 min, 5% B. The MS/MS analyses were carried out in negative mode using electrospray source parameters as follows: electrospray capillary voltage was 2.5 kV, source temperature was 140 °C, desolvation temperature was 350 °C, cone and desolvation gas flows were 80 l/h and 900 l/h, respectively. Data were acquired through multiple reaction monitoring (MRM) using Waters Masslynx V4.1 software. Phenolic standards were analyzed using the same parameters and used for the quantification, when available. Otherwise, the phenolic compounds were quantified using their aglycone or the most similar phenolic structure.

Animals and Plasma Preparation. Sixty male Wistar rats (Charles River, St. Constant, QC) were placed in temperature- and humidity-controlled rooms (21 ± 2 °C, 35−40%), with a daily 12h−12h light−dark cycle. Animal facilities met the guidelines of the Canadian Council on Animal Care, and the protocols were approved by the Animal Care Committee of Laval University (reference CPAUL-2011-111). Animals were acclimated to their environment for a minimum of 5 days and consumed a nonpurified rodent diet ad libitum (rodent chow no. 2918, Harlan Teklad, Madison, WI). All animals had continuous access to tap water. After the acclimation period, rats were fed a high-fat, high-sucrose (HFHS) diet containing 27% sucrose and 40% fat for 7−8 days. The day before the test, rats were fasted for 12 h. The animals were randomly allocated to 6 groups (9 to 12 per group, Table 1). A first control group (group 1) consisted of animals which only received the vehicle (0.1% citric acid in water). The animals of four groups (groups 2−5) were administered a single dose of GP extract corresponding to a phenol intake of 2.7, 5.4, 27, and 36 mg/kg, respectively. The animals of an additional experimental group (group 6) were administered a single dose of GP extract supplemented with onion extract, corresponding to a total phenol intake of 36 mg/kg (5.4 mg/kg from GP extract and 30.6 mg/kg from onion extract). Blood samples were collected from the saphenous vein with EDTA-containing syringes preingestion and at 30, 60, 120, 180, and 360 min postingestion. Plasma samples were obtained by centrifugation (3500 rpm, 10 min at 4 °C) and stored at −80 °C until analysis.

Extraction of Plasma Phenolic Compounds. Phenolic compounds extraction was realized according to a previously described methodology.[13] Waters OASIS HLB μelution plates (Milford, MA) were preconditioned using 250 μL of methanol and 250 μL of 0.2% acetic acid. Plasma samples (20 to 200 μL) were mixed with 4% phosphoric acid in ultrapure water (v/v) to disrupt phenol−protein binding prior loading into the plates. The loaded plates were washed with 200 μL of ultrapure water and 200 μL 0.2% acetic acid, and the retained phenolic compounds were then eluted with 2 × 50 μL of acetone/ultrapure water/acetic acid solution (AWA) 70/29.5/0.5 v/v/v. Rosmarinic acid (1 μg/mL final concentration) was added in AWA elution solution and used as internal standard to check the homogeneity of the SPE extraction procedure. The eluted solutions, in the collecting plates, were directly injected in UHPLC-MS/MS for phenolic acids and nonanthocyanins flavonoids analysis (negative mode). The extracts were then lyophilized and dissolved in 30 μL of 20% methanol 0.1% acetic acid for anthocyanins analysis (positive mode).

Characterization of Metabolites by UHPLC-MS. The analysis of plasma extracted phenolic metabolites was achieved with UHPLC-MS/MS using a previously developed methodology for the detection of anthocyanins and procyanidins,[13] slightly modified to also allow the detection of phenolic acids and flavonols.

The separation of phenolic acids and nonanthocyanins flavonoids was performed at 30 °C using an Agilent Plus C18 column (2.1 mm × 100 mm, 1.8 μm) (Santa Clara, CA). A flow rate of 0.4 mL/min was used with a mobile phase consisting of 0.2% acetic acid in ultrapure water and acetonitrile (solvent A and B, respectively) following this gradient elution: 0−8 min, 5−50% B; 8−9.10 min, 50−90% B; 9.10−10 min, 90% B; 10−10.10 min, 90−5% B; 10.10−13 min, 5% B. The MS/MS analyses were carried out in negative mode using electrospray source parameters as follows: electrospray capillary voltage was 3.01 kV, source temperature was 150 °C, desolvation temperature was 400 °C, and cone and desolvation gas flows were 80 l/h and 800 l/h, respectively.

The separation of anthocyanins was performed at 30 °C with a flow rate of 0.45 mL/min with a mobile phase consisting of 10% acetic acid in ultrapure water and acetonitrile (solvent A and B, respectively) using a gradient elution as follows: 0−3.50 min, 2−50% B; 3.50−4 min, 50−90% B; 4−4.50 min, 90% B; 4.50−4.55 min, 90−2% B; 4.55−6 min, 2% B. The MS/MS analyses were carried out in positive mode using electrospray source parameters as follows: electrospray capillary voltage was 1.3 kV, source temperature was 130 °C, desolvation temperature was 350 °C, and cone and desolvation gas flows were 80 l/h and 900 l/h, respectively.

Cone voltage and collision energy parameters were optimized for each compound. The identification of metabolites was performed by comparing their retention times with those of available phenolic standards and/or analyzing their fragmenta-

Table 2. Phenolic Standards, MRM Transitions, and Optimized MS Parameters Used for the Analysis of Native Phenolic Compounds and Their Metabolites by UHPLC-MS

compound	standard for quantification	ionization mode	MRM	cone voltage (V)	collision energy (eV)

tion. Data were acquired through the multiple reaction monitoring (MRM) mode, tracking the transition of parent product ion specific for each compound. The detected metabolites were quantified using standards when available. Otherwise, a relative quantitation was achieved using the calibration curve of their aglycone or most similar phenolic structure. The phenolic standards, the MRM transitions, and the optimized MS parameters used for the characterization of phenolic metabolites in plasma are listed in Table 2.

Data Analysis. All phenolic characterizations were carried out in triplicate, and results were expressed as percentage of extract weight ± standard deviation (SD). Time 0 values being very close to 0, phenolic concentrations in rat plasma were expressed as variation of concentration from baseline (Δ mg/L for total phenolic content and Δ nM or Δ μM for individual phenolic compounds). Metabolites quantification was expressed as area under the plasma concentration (μM) time (min) curve (AUC), with AUC calculated according to the linear trapezoidal rule. Results were expressed as means ± standard error (SEM) of the mean. The main effect of phenol intake on AUC values was estimated by one-way analysis of variance (ANOVA) using the MIXED procedure in SAS 9.3 (Cary, NC). When necessary, log transformation was applied on raw data to meet the criteria for normality. A priori contrasts between selected groups were analyzed using the LSD method. The REG procedure of SAS was used to analyze if plasma metabolites concentrations (determined as AUC) followed a linear regression model with GP phenol intake and to obtain the determination coefficients (R^2). Differences were considered to be significant at $p < 0.05$.

RESULTS

Phenolic Composition of Strawberry−Cranberry and Onion Extracts. The phenolic composition of the two extracts is presented in Table 3. GP extract contained 0.8% of anthocyanins, with the main presence of pelargonidin 3-glucoside. This extract also contained about 3% of total procyanidins with a large spectrum of degree of polymerization, the monomers catechin and epicatechin representing around 0.1%. The extract presented a total ellagitannins content of 1.8%, including 0.8% of free ellagic acid. About 1.3% of phenolic acids were also identified in this extract, mainly chlorogenic acid and *p*-coumaric acid, and 1.3% of flavonols with the main presence of quercetin 3-glucoside. Conversely, onion extract did not contain any anthocyanins, procyanidins, or ellagitannins and contained almost exclusively aglycone quercetin and protocatechuic acid (about 14% and 8%, respectively). Chromatographic profiles of anthocyanidins and procyanidins of GP extract are available as Supplemental Figures S1 and S2, respectively.

Rat Plasma Phenolic Content. The evolution of the total phenolic concentration in rat plasma after ingestion of the extracts is presented in Figure 1A. The presence of phenolic compounds was detected in all treated groups, with a maximum phenolic concentration ranging from 0.5 to 8 mg/L in GP groups (groups 2−5; phenolic intake from 2.7 to 36 mg/kg) and 10 mg/L for the onion supplemented GP group (group 6; phenolic intake of 36 mg/kg). The kinetic profile of plasma total phenolic metabolites strongly differed depending on the phenolic source. GP-fed animals presented a high phenolic content 30 min after ingestion of the extract, followed by a rapid elimination of the metabolites by the organism (>85% over 360 min). GP/onion fed animals also presented a high phenolic content 30 min after ingestion of the mix, but the metabolites concentration remained high over time. Interestingly, the groups 5 and 6, which have ingested both the same dose of phenolic compounds (36 mg/kg) but from different sources, had the same phenolic concentration 30 min postingestion (about 8 mg/L; $p = 0.7829$) but a 10-fold

difference in the phenolic concentration 360 min postingestion (about 1 mg/L for the group 5 and about 10 mg/L for the group 6; $p < 0.0001$). On the basis of mean rat body weight and blood volume (400 g and 26 mL respectively), absorption rates were estimated up to 1.4% of the total phenolic intake for GP fed rats and up to 1.8% for GP/onion fed rats.

Plasma Phenolic Metabolites: Identification, Quantification, and Kinetic Profile. The designed UHPLC-MS methods enabled the characterization of 21 phenolic compounds in rat plasma after the consumption of the extracts. These metabolites are listed in Tables 4 and 5 and their kinetic profiles are represented in Figures 1A–C.

Among anthocyanins, strictly present in GP extract, pelargonidin 3-glucoside and peonidin 3-galactoside were detected in their native form but at an extremely low level (0.01 and 0.001 nM max, respectively). A well-known metabolite

of pelargonidin 3-glucoside, *p*-hydroxybenzoic acid, was detected in significant amounts (12 μM max) and was also detected in its glucuronidated form, in a 10 times lower quantity. Among flavan-3-ols, also strictly present in GP extract, catechin and epicatechin were not detected in significant amounts in their native form but under conjugated forms. As the conjugated forms of catechin and epicatechin were not distinguishable by MS, these isomers were quantified together and referenced as "catechins". Catechins metabolites were detected under glucuronidated and both methylated and glucuronidated forms (until 20 μM max). A

[a]Results are expressed as mean of replicate (9 to 12) ± SEM. GP: GlucoPhenol; GP + O: GlucoPhenol + onion. The experimental groups are numbered from (1) to (6). *$p < 0.05$ in comparison with control group.

low amount of both methylated and sulfated forms of catechins were also detected (0.1 μM max). Among phenolic acids, *p*-coumaric acid and a well-known degradation product of the ellagitannins, dimethyl ellagic acid glucuronide, were detected in significant amounts (until 10 μM). Native anthocyanidins, metabolites of flavan-3-ols and *p*-coumaric acid, presented a kinetic profile with a high concentration 30−60 min postingestion followed by a progressive decrease, whereas dimethyl ellagic acid glucuronide showed an increase of its concentration until 180 min postingestion followed by a plateau until 360 min postingestion.

Protocatechuic acid, a phenolic acid present in a very high amount in onion extract and in a low amount in GP extract, was detected in high quantities (15 μM max) and presented a kinetic profile similar to that of *p*-coumaric acid with a concentration peak at 30 min postingestion. Flavonols were the major phenolic constituents of onion extract, but they were also present in GP extract in smaller quantities. Quercetin, detected in its native aglycone form in a very low amount (0.2 μM max), was mostly detected in circulation in its conjugated forms: glucuronidated, diglucuronidated, and sulfated quercetin (30, 45, and 1.5 μM max, respectively); it was also detected as conjugates of its methylated form isorhamnetin: glucuronidated, diglucuronidated, and sulfated isorhamnetin (about 15−20 μM max). A very high concentration of both a glucuronidated and a sulfated form of isorhamnetin was also detected (about 120 μM max). Some metabolites of myricetin, present in very low quantities in GP extract, were also detected under glucuronidated and diglucuronidated forms (15 and 6 μM max, respectively). The kinetic profiles of the glucuronidated forms of quercetin were characterized by an increase of its concentration until 60 min postingestion followed by a plateau until 360 min postingestion, whereas the sulfated form of quercetin showed a continuous increase until 360 min postingestion. All the isorhamnetin metabolites also displayed a kinetic profile with a strong increase of their concentration until 360 min postingestion. Glucuronidated myricetin reached a high concentration peak 30 min postingestion followed by a rapid decline, whereas diglucuronidated myricetin reached its highest concentration 120 min postingestion and remained constant until 360 min postingestion.

Statistical Analysis: Linear Regression and A Priori Comparison between Groups. The individual metabolites, together with their AUC values and their statistical parameters, are listed in Tables 4 and 5. A linear regression analysis was performed on individual metabolite concentrations (expressed as AUC values) quantified in control and GP groups (groups 1 to 5) and GP ingested dose (phenolic intake from 0 mg/kg to 36 mg/kg). Almost all the detected phenolic metabolites fitted with the linear regression model (p max = 0.0021, R^2 ranging from 0.267 to 0.775), with the exception of native catechins and quercetin (p = 0.5161 and 0.7592, respectively). These results indicate that, in the range of tested doses, there is a relatively strong proportionality between the amount of phenolic compounds

[a]Results are expressed as mean of replicate (9 to 12) ± SEM. GP: GlucoPhenol; GP + O: GlucoPhenol + onion. The experimental groups are numbered from (1) to (6). *$p < 0.05$ in comparison with control group.

ingested by animals and the concentration of phenolic metabolites in plasma.

A comparison was made between the groups 5 and 6 for the total circulating phenolic concentration, expressed in AUC values (Table 4). Whereas the rats of these two groups have ingested the same phenolic dose (36 mg/kg), the total AUC value in group 6 was more than 3-fold the AUC value in group 5 ($p < 0.0001$). The groups 3 and 6 were also compared for their individual circulating metabolites concentrations, expressed in AUC values (Tables 4 and 5). These two groups have ingested the same GP dose (5.4 mg/kg), but the animals of group 6 have also received an onion supplementation, resulting in a different total phenolic intake (5.4 mg/kg and 36 mg/kg for groups 3 and 6, respectively). Protocatechuic acid and flavonol metabolites, mainly coming from onion extract, obviously presented strongly different AUC values between these two groups (from 5- to 329-fold more in group 6; $p \leq 0.0005$) as only the animals of group 6 have received the onion extract (Table 5). Among phenolic metabolites coming from GP extract (Table 4), peonidin 3-galactoside, pelargonidin 3-glucoside, *p*-hydroxybenzoic acid, *p*-coumaric acid, and methyl catechins sulfate presented as expected close AUC values in groups 3 and 6 (p value ranging from 0.1502 to 0.9467) as all the animals have received the same GP dose. However, glucuronidated metabolites showed higher AUC values in group 6 than in group 3, meaning that for the same intake of GP extract, the onion-supplemented animals have produced more glucuronide metabolites of strawberry–cranberry phenolic compounds. Indeed, *p*-hydroxybenzoic glucuronide, catechins glucuronide, and methyl catechins glucuronide AUC values were found higher in group 6 in comparison with group 3: +252% ($p < 0.0001$), +279% ($p = 0.0018$), and +118% ($p = 0.0131$), respectively. The glucuronidated dimethyl ellagic acid was an exception, because it showed similar AUC values in the two groups ($p = 0.8352$). UHPLC-MS/MS MRM profiles of *p*-hydroxybenzoic glucuronide, catechins glucuronide, and methyl catechins glucuronide are available as Supplemental Figure S3.

DISCUSSION

The present study aimed at investigating the bioavailability of strawberry and cranberry phenolic compounds after oral administration to rats, with or without onion supplementation. The human daily intake of plant phenols is estimated to be between 150 and 1000 mg.[20] In this study, the rats received a phenol intake from 2.7 to 36 mg/kg, which corresponds to a human intake from 25 to 333 mg (mean body weight of 60 kg) according to the Food and Drug Administration's (FDA) body surface area (BSA) normalization.[21] The selected doses were lower than the recommended doses in order to be relevant in a nutritional supplementation context and to be further compared with human clinical trials.

The evidence of the absorption of phenolic compounds was earlier based on the increase of the antioxidant status of the plasma after the consumption of phenolic-rich foods. This

approach has been largely criticized,[22] and direct measurements of phenolics in plasma using HPLC with DAD or MS detection have been preferred but provided limited information due to a low sensitivity. Numerous bioavailability studies were conducted using enzymatic hydrolysis but provided limited information regarding the actual metabolites present in biological fluids. To obtain an overview of the absorption and metabolism of phenolic compounds, it is essential to be able to characterize most of the circulating metabolites, generally present at low concentrations. This requires the use of an appropriate extraction method to isolate phenolic metabolites from plasma-like microelution SPE (μSPE) and a sensitive analytical methodology such as UHPLC with tandem MS for their detection and quantification. The μSPE plates are packed with a high-capacity sorbent both lipophilic and hydrophilic to give maximum retention ability for different polarity compounds from a biological matrix. In comparison with conventional SPE cartridges, μSPE plates present a better extraction recovery and a better preservation of the molecular integrity. Indeed, the eluate can directly be analyzed in the collecting plates in UHPLC-MS, and thus an evaporation step previous to the chromatographic analysis can be avoided.[13] The optimized methods developed allowed the characterization of 21 phenolic metabolites in a volume as small as 20 μL of rat plasma after their consumption of GP extract supplemented or not with onion extract.

As expected when using nutritional doses of phenolic compounds, the phenolic compound transporters and metabolic pathways were probably not saturated, which could explain the general linear increase in the concentration of plasma phenolic metabolites in response to the increase in the dose ingested of GP extract. After ingestion of the extracts, the native phenolic compounds were extensively metabolized and were thus present in the circulation almost exclusively as conjugate metabolites and microbial degradation products.

Quercetin (both aglycone and glycosides forms) was intensively conjugated in glucuronidated and diglucuronidated forms, and to a lesser extent in sulfated form. Quercetin was especially methylated at a high level into isorhamnetin, leading to the formation of isorhamnetin metabolites being present in high quantities, whereas the extracts contained only low levels of isorhamentin. Isorhamnetin glucuronide sulfate was the metabolite identified in the highest quantity in rat plasma following the extracts ingestion, showing the intensive metabolization of quercetin, with both methyl, glucuronide, and sulfate conjugations. Moreover, the presence of myricetin metabolites in onion-fed rats' plasma, even though the onion extract did not contained any myricetin, suggests a probable hydroxylation of quercetin during its metabolization. A wide variety of metabolites resulting from quercetin conjugation has been previously reported in rats and humans.[23,24] Similarly, catechins monomers have undergone extensive conjugation processes with high contents of glucuronidated forms of catechins and methylated catechins, as well as low content of sulfated forms of methylated catechins detected in strawberry−cranberry-fed animals. Such catechins conjugates were earlier reported in rat plasma.[25]

Anthocyanins constitute an exception to the classical deconjugation−reconjugation sequence involved in the metabolization of phenolic compounds as they can be absorbed in their native glycoside structure.[26] These compounds are known to be poorly available due to their microbial and spontaneous degradation and also to their high sensitivity to pH.[26−28] Pelargonidin 3-glucoside and peonidin 3-galactoside were thus detected in circulation but in extremely low concentrations. However, high amounts of a known degradation product of pelargonidin 3-glucoside, *p*-hydroxybenzoic acid,[29] and its glucuronidated conjugate were identified in rat plasma following GP extract consumption.

As expected, no polymeric phenolic compounds were detected in rat plasma. These compounds, such as procyanidins and ellagitannins, are known to be poorly absorbed.[30,31] Ellagitannins are depolymerized in stomach followed by the absorption of ellagic acid directly in the stomach or in the intestine.[31] Ellagic acid metabolization then leads to the formation of ellagic acid derivatives, like the dimethyl ellagic acid glucuronide detected here, and urolithins.[30] Procyanidins reach the colon where they are subjected to microbial degradation leading to the generation of phenolic acids, which are further absorbed and metabolized.[32] Some phenolic acids were detected here, either coming from the release from food matrix or resulting from more complex phenolic structure degradation.[4] *p*-Coumaric acid, which was present in GP extract in the same amount as chlorogenic acid, was detected in high quantities in rat plasma following their ingestion of this extract, whereas chlorogenic acid was not detected at all. Chlorogenic acid is poorly metabolized because of a lack of esterases in the intestine tissues.[10] Consequently, the only significant site for chlorogenic acid metabolism is the colonic microflora, which generates a wide variety of metabolites, including *p*-coumaric acid.[33,34] Protocatechuic acid, which constituted a major phenolic compound of onion extract, was detected in rat plasma either in its native form and/or mostly probably as a degradation product of native flavonoids such as cyanidin,[35] catechins,[36] and quercetin.[11]

Identified phenolic metabolites presented some specific kinetic profiles, reflecting the biological site of conjugation. Indeed, a low T_{max} may be indicative of conjugation taking place in the intestine before the prior passage of metabolites in the circulation, whereas a higher T_{max} may reflect a postabsorption conjugation.[28] Therefore, glucuronidated catechins conjugates, which presented a high concentration 30−60 min postingestion followed by a progressive decrease, appeared to be early conjugated in the intestine. The delay in the elimination time of methyl catechins glucuronide metabolite suggested a postabsorption methylation of glucuronidated catechins in the liver.

Similarly, glucuronidated quercetin seemed to be conjugated early in the intestine and accumulate over time, which has previously been demonstrated in humans[37] and has been attributed to the high affinity of this compound with serum albumin.[38] The increasing plasma concentration of sulfated quercetin over time probably reflects its hepatic formation. Regarding the kinetic profiles of isorhamnetin metabolites, it appears that they were likely resulting from a postabsorption methylation of already conjugated quercetin metabolites, in the liver.

Anthocyanins are highly soluble and among the few compounds that can be directly absorbed from the stomach,[39] leading to their probable rapid intestinal metabolization, as reflected by their kinetic profiles and those of their metabolites.

The kinetic profile of dimethyl ellagic acid glucuronide, a biomarker of the ellagitannins intake,[11] suggests an extensive hepatic metabolization and active enterohepatic circulation of this compound. However, the solubility of phenolic compounds should be a factor to consider as it can greatly influence the kinetics of metabolites. Indeed, because quercetin and ellagic acid

are poorly soluble, their metabolites might precipitate in blood and thus be delayed in their circulation and metabolization.

The absorption and metabolization of phenolic compounds was shown to be strongly modulated by the structure of the phenolic compounds. Indeed, although a similar phenolic metabolites absorption rate was observed 30 min postingestion in groups 5 and 6 (Figure 1A—total metabolites), which have ingested both the same phenolic amount but from different sources (GP extract or GP supplemented with onion extract), a significantly different absorption rate was observed 360 min postingestion, with the elimination of strawberry−cranberry phenolic metabolites and the accumulation of onion metabolites in rat plasma. These results support the idea that the phenolic structure prevails over the phenolic dose for absorption and metabolization. In all cases, and in accordance with previous reported data, the estimated phenolic absorption was low, as it did not exceed 2% of the ingested phenolic dose. Despite the low circulating concentrations of phenolic metabolites and their rapid elimination (for most of them), those compounds exert various regulating biological activities in vivo, which go beyond direct antioxidant activity.[40]

Phenolic compound absorption and metabolization can be modulated by phenolics themselves. Indeed, some phenolic compounds are known to specifically modify some metabolic processes that govern bioavailability, such as the modulation of gut microbiota or xenobiotics transporters activity, as well as the modulation of conjugation enzymes.[41]

Here, we observed the presence of four glucuronidated metabolites resulting from strawberry−cranberry extract phenolic compounds. Among them, three compounds, *p*-hydroxybenzoic acid glucuronide, catechins glucuronide, and methyl catechins glucuronide, which were suggested to be produced in the intestine regarding their kinetic profile, were found in 2 to almost 4 times higher concentrations in the plasma of animals that have ingested onion extract together with GP extract, for the same GP intake. On the contrary, dimethyl ellagic acid glucuronide, a highly metabolized compound whose kinetic profile indicated a hepatic conjugation, were present in the same quantities in the animals of the two groups. Glucuronidation processes of some strawberry−cranberry phenolic metabolites thus appear to be enhanced in the presence of onion phenolic compounds but specifically in the intestine. This modulation could be attributed to quercetin, which has already been demonstrated to be involved in the induction of glucuronidation enzyme UDP-glucuronosyl-transferase in intestinal cell lines in vitro and in rats in vivo.[42−44] These data therefore indicate an opportunity to increase the circulating metabolites concentration using synergistic interactions between phenolic compounds and thus to increase the bioactivity of some plant extracts by improving their oral bioavailability.

In conclusion, this study reported the use of an optimized technique combining μSPE and UHPLC-MS/MS methods for the simultaneous identification and quantification, for the first time, of about 20 phenolic metabolites in rat plasma following the ingestion of GP, a strawberry−cranberry extracts blend alone or with an onion extract. In most cases, native compounds were not detected in rat plasma and were extensively metabolized into conjugates and degradation products. Quercetin metabolites were found in greater amounts in plasma, the rats being supplemented with the onion extract or not, illustrating the differences existing between phenolic compounds in terms of absorption and metabolization. This study also highlighted a possible synergistic activity of phenolic compounds for improving bioavailability, with a possible induction of intestinal UDP-glucuronosyl-transferase by onion quercetin. This work allowed the identification and quantification of actual metabolites generated in vivo following phenolic consumption, as well as the analysis of their pharmacokinetic, data which are fundamental to unravel their mechanisms of action.

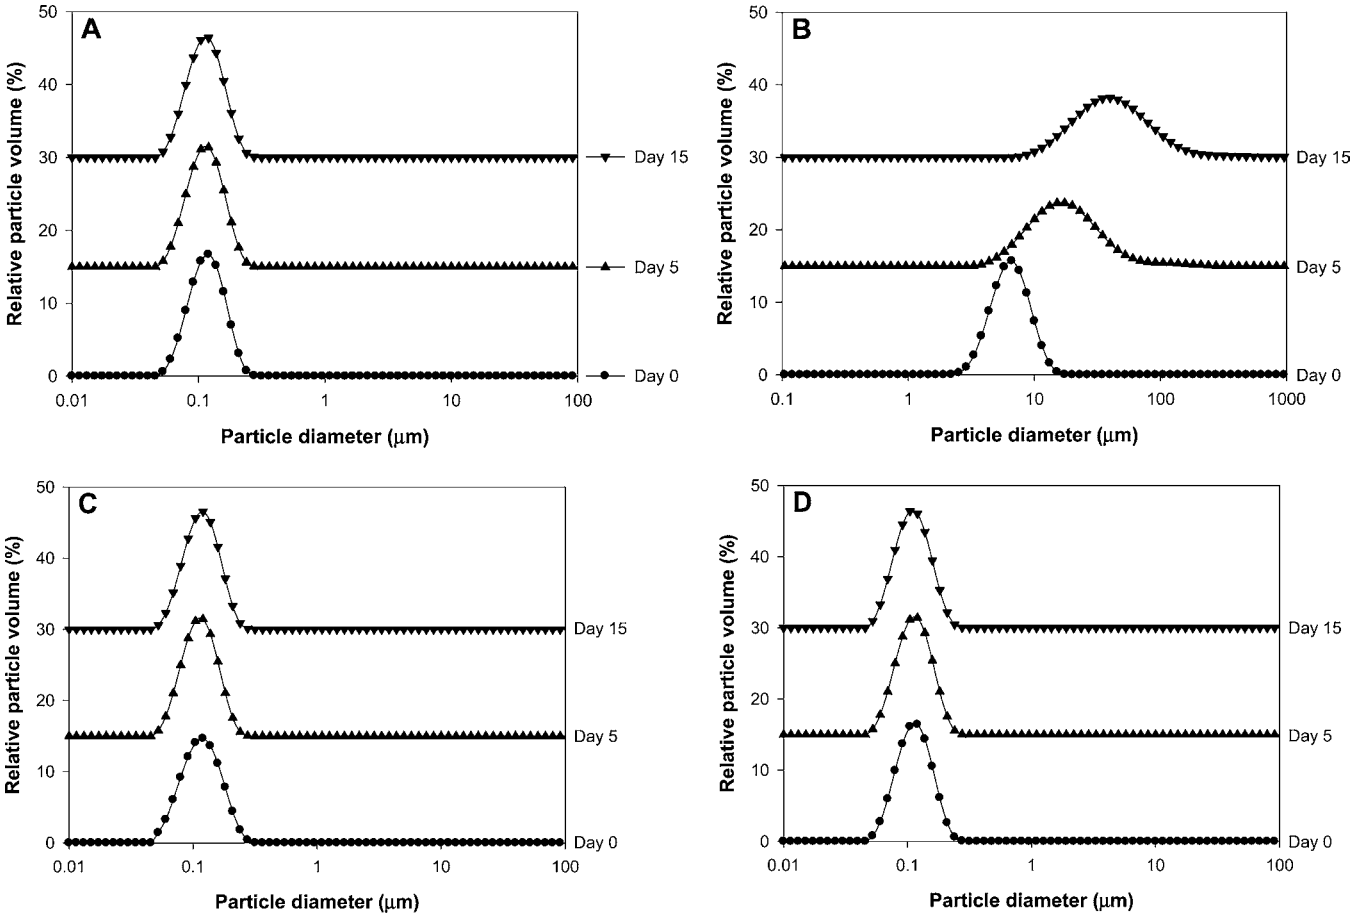

Figure 1. Evolution of the particle size distribution of SMP- or SMP/lysolecithin-stabilized orange oil-in-water emulsions (1% SMP and 5% orange oil) stored at 20 °C: (A) SMP-stabilized emulsion stored at pH 7; (B) SMP-stabilized emulsion stored at pH 3; (C) SMP/0.1% lysolecithin-stabilized emulsion at pH 3; (D) SMP/0.5% lysolecithin-stabilized emulsion at pH 3.

at 10000 rpm at room temperature. For reduction of droplet size, the premixed emulsions were homogenized by five passes through a microfluidizer (M-100L, Microfluidics, Newton, MA, USA) at 48.3 MPa. Then, the emulsion was adjusted to pH 3.0 using 1.0 and 0.1 N hydrochloric acid solutions. The final concentrations of lysolecithin in the whole emulsions varied from 0 to 0.5% (w/w), and the final concentration of SMP in the whole emulsions was 1% (w/w). To avoid the effect of light, all samples were stored in the dark before analysis.

Stability to Environmental Stresses. To determine the stability of SMP/lysolecithin-stabilized emulsions against heat treatment, emulsions were placed in glass test tubes and then incubated in a water bath for 15 min at different temperatures (30−90 °C). The emulsions were then allowed to cool to room temperature and held overnight prior to subsequent analysis. To evaluate the stability of SMP/lysolecithin-stabilized emulsions against the change in the electrostatic interaction, a series of 2.5 wt % emulsions with different NaCl concentrations was prepared by diluting the concentrated emulsions with 10 mM phosphate buffer (pH 3.0) containing different concentrations of sodium chloride. Then, the emulsions were kept at room temperature overnight prior to subsequent analysis.

Droplet Size Measurements. Mean droplet diameters of emulsions were measured using static light scattering (laser diffraction). To avoid multiple scattering effects, all emulsion samples were diluted to a droplet concentration of approximately ≈0.005% (w/w) using buffer solution at the pH of the sample and stirred continuously throughout the measurements to ensure they were homogeneous. The droplet size distribution of the emulsions was then measured using a commercial static light scattering instrument (Mastersizer 2000, Malvern Instruments, Worcestershire, UK). Droplet size data are reported as either the volume-surface mean diameter, $d_{32} = (\sum n_i d_i^3 / \sum n_i d_i^2)$, or the volume-weighted mean diameter, $d_{43} = (\sum n_i d_i^4 / \sum n_i d_i^3)$, where n_i is the number of droplets with diameter d_i. If an emulsion sample to be analyzed had phase-separated due to droplet creaming, then it was gently mixed to evenly disperse the droplets prior to collection of an aliquot for making the particle size measurements.

Electrical Charges of Oil-in-Water Emulsions. The ζ-potential of the emulsion droplets was measured using a microelectrophoresis instrument (ZetaSizer Nano, Malvern Instruments). The ζ-potential was calculated from measurement of the electrophoretic mobility of droplets in an applied oscillating electric field using laser Doppler velocimetry. Samples were prepared by diluting emulsions 1:500 with buffer solution at the pH of the sample and placing the diluted emulsions into disposable capillary cells (DTS1060, Malvern Instruments). If an emulsion sample to be analyzed had phase-separated due to creaming, then it was evenly dispersed by gentle stirring before collection of an aliquot for analysis.

Statistical Analysis. Experiments were repeated two or three times using freshly prepared samples, and the mean and standard deviations were calculated from these measurements.

RESULTS AND DISCUSSION

Influence of Lysolecithin. Previously, we examined the influence of pH on the stability of SMP-stabilized orange oil emulsions.[12] Stable orange oil emulsions with small mean droplet diameters (d_{43} < 0.15 μm) could be formed at neutral pH. However, when the emulsion was stored under acidic conditions (pH 3−5), a large increase in mean droplet diameter

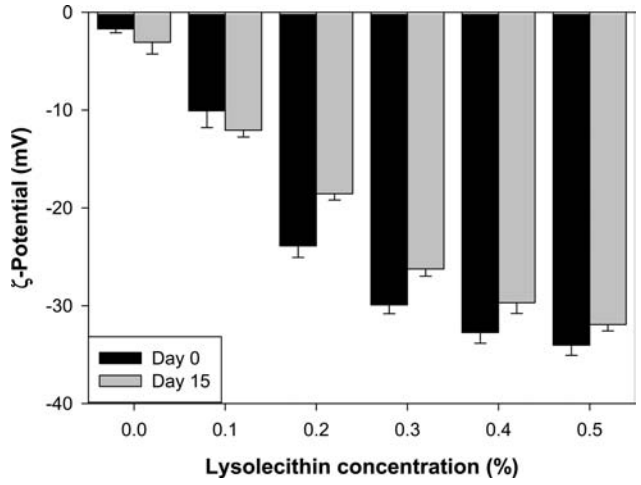

Figure 2. Influence of lysolecithin concentration on the ζ-potential of SMP-stabilized orange oil-in-water emulsions (1% SMP and 5% orange oil) at pH 3, stored at 20 °C.

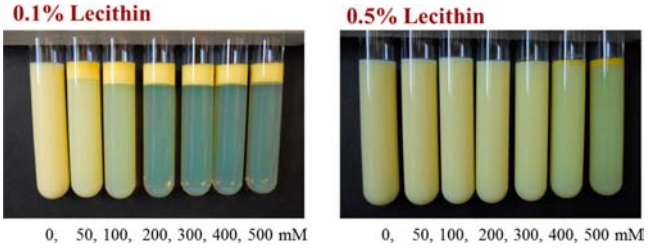

Figure 3. Photographs of SMP-stabilized orange oil-in-water emulsions (0.5% SMP, 2.5% orange oil, and 20 °C) with different NaCl concentrations.

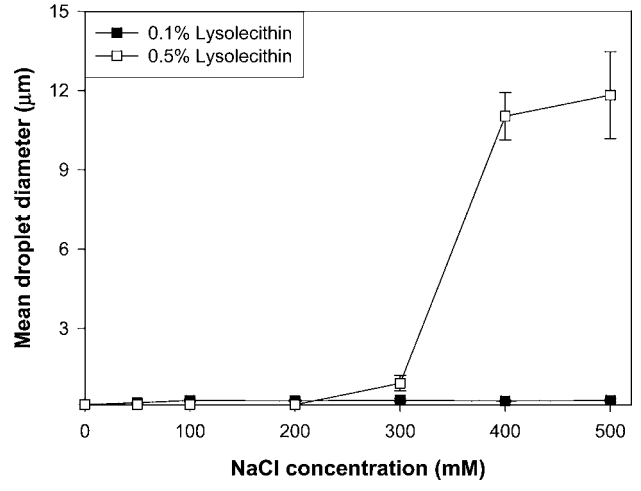

Figure 4. Influence of NaCl concentration on the mean droplet diameter of SMP-stabilized orange oil-in-water emulsions (1% SMP and 5% orange oil) at pH 3, stored at 20 °C.

was observed during storage. The reason for this phenomenon was attributed to the presence of small amounts of impurities (such as palmitic acid) in the SMP ingredient used to prepare the emulsions.[12] Because most of the palmitic acid molecules are ionized at pH values above the pK_a (≈4.9),[13] they are negatively charged. However, the predominant form of palmitic acid is neutral at pH values below the pK_a, indicating a low or almost zero net charge on the oil droplets. Therefore, the oil

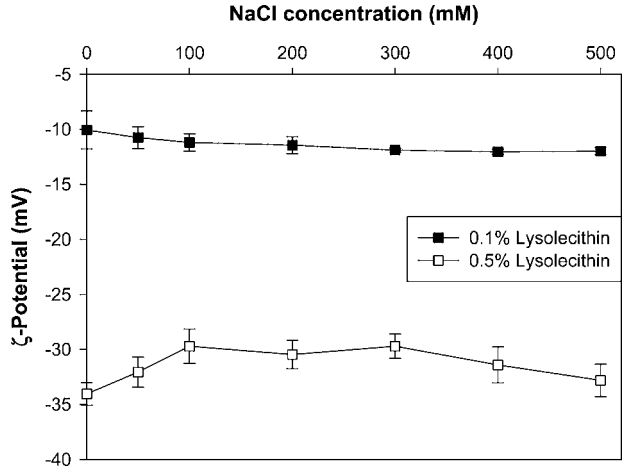

Figure 5. Influence of NaCl concentration on the electrical charge of SMP-stabilized orange oil-in-water emulsions (1% SMP and 5% orange oil) at pH 3, stored at 20 °C.

droplets have a high negative charge at high pH values, which stabilizes them from aggregation due to electrostatic repulsion. On the other hand, they have a low net charge at low pH and are therefore susceptible to aggregation due to the dominance of attractive colloidal interactions (such as van der Waals or hydrophobic attractions).

We therefore examined the impact of adding an anionic cosurfactant (lysolecithin) on the aggregation stability of orange oil-in-water emulsions under acid conditions (Figure 1). We hypothesized that this cosurfactant would improve the physical stability of the emulsions by increasing the electrostatic repulsion between the droplets. Emulsions were initially prepared under neutral pH conditions to ensure that they were stable. The initial mean droplet diameter at pH 7 was around 0.125 μm for all of the emulsions prepared (Figure 1A), independent of the lysolecithin concentration present, which suggested that the initial particle size was primarily governed by the homogenization conditions or the SMP. All of the emulsions were then adjusted to pH 3 and stored for 15 days.

In the absence of lysolecithin, the emulsions were highly unstable to droplet growth at pH 3, which was attributed to droplet coalescence during storage (Figure 1B). Conversely, in the presence of lysolecithin (0.1−0.5%), all of the emulsions were stable to droplet growth throughout 15 days of storage (Figures 1C,D). These results indicated that lysolecithin was an effective cosurfactant for improving the stability of SMP-coated droplets to growth, which can be attributed to the increased electrostatic repulsion between the droplets in the presence of this anionic surface active substance.

Figure 2 shows the ζ-potential of the SMP-stabilized orange oil emulsions with various lysolecithin concentrations. The ζ-potential of the oil droplets was close to zero (−1.7 mV) in the absence of lysolecithin, but it became increasingly negative as the amount of lecithin incorporated into the system increased. The ζ-potential reached a value of around −35 mV at 0.5% lysolecithin, which should be large enough to provide good stability through electrostatic repulsion. Theoretically, sucrose esters containing SMP are nonionic surfactants,[8] but they may have a negative charge at high pH because of the presence of ionized impurities, such as palmitic acid.[12] As described above, palmitic acid should have little charge at acid pH, which would account for the low net charge on the emulsions in the absence

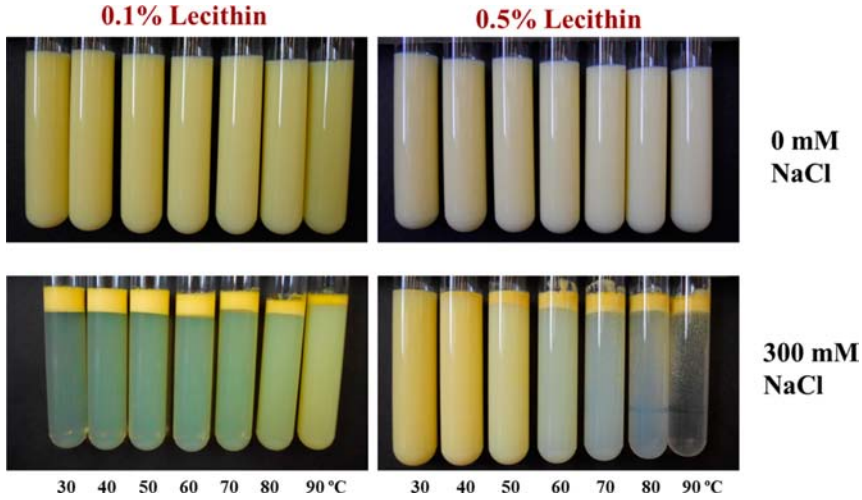

Figure 6. Photographs of 2.5 wt % orange oil-in-water emulsions stabilized by SMP and different amounts of lysolecithin after heat treatment in the presence of 0 or 300 mM NaCl.

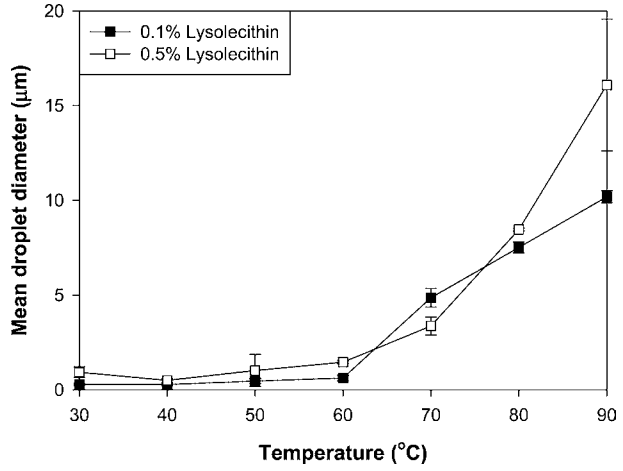

Figure 7. Influence of heat treatment on the mean droplet diameter of SMP-stabilized orange oil-in-water emulsions (0.5% SMMP, 2.5% orange oil, and 300 mM NaCl) containing lysolecithin at pH 3.

of lysolecithin. Lysolecithin has been reported to have a negative charge over a wide range of pH values.[14] Because the pK_a value of the phosphate groups on lysolecithin is typically around pH 1.5,[15] lysolecithin should still be negatively charged at pH 3.0. The presence of lysolecithin at the oil droplet surfaces would therefore account for the good stability of the orange oil emulsions to droplet growth at acidic conditions.

Influence of Ionic Strength. Commercial food and beverage products often contain different types and amounts of mineral ions, and therefore it is important to understand how ionic strength influences their stability. We therefore examined the influence of salt addition on the stability of orange oil-in-water emulsions stabilized by a combination of SMP and lysolecithin. Visual observations of orange oil emulsions containing different salt levels were made after they were stored at room temperature for 8 h. In the absence of added salts, the emulsions were visibly stable to phase separation, but in the presence of salt many of them separated into two distinct layers: a cream layer at the top and a serum layer at the bottom (Figure 3). Emulsions containing 0.1% lysolecithin were unstable to phase separation from 50 to 500 mM, whereas emulsions containing 0.5% lysolecithin were only unstable to visible phase separation at the highest salt concentrations (400 and 500 mM).

Interestingly, the particle size measurements suggested that the emulsions containing 0.1% lysolecithin remained relatively small across the entire salt range (Figure 4). We hypothesize that droplet flocculation occurred in these emulsions because they exhibited rapid creaming (indicative of an increase in particle size), but still had relatively small particle sizes when measured by static light scattering. This effect can be attributed to dissociation of flocs due to dilution and stirring within the measurement chamber of the light-scattering instrument. For the emulsions containing 0.5% lysolecithin, the mean particle diameter remained relatively small for low salt concentrations (0−300 mM NaCl), but increased steeply at higher salt levels. This result suggests that phase separation occurred due to an increase in droplet diameter (coalescence), followed by droplet creaming. Droplet aggregation can be attributed to screening of the electrostatic repulsion between negatively charged emulsion droplets at increasing ionic strength, leading to droplet flocculation and/or coalescence.[16] Emulsions containing 0.1% lysolecithin had a lower net charge than those containing 0.5% lysolecithin at all salt concentrations (Figure 5), which would account for the fact that they were less stable to salt addition. A low droplet charge leads to a lower energy barrier that has to be overcome before droplets can come into close proximity; therefore, less salt is needed to promote aggregation. However, the screening of the electrostatic repulsion between negatively charged emulsion droplets could not explain the difference in the origin of destabilization of emulsions stabilized with 0.1% (mainly flocculation) and 0.5% (mainly coalescence) lysolecithin. This effect may have been due to differences in interfacial composition: emulsions containing higher levels of lysolecithin are presumably more sensitive to electrolyte addition because of their charge characteristics. Electrolytes could change the hydrophilic−lipophilic balance and hydration conditions of the surfactants by depletion of the hydration shell around the polar head groups of surfactant molecules.[17] Because of the greater amount of lysolecithin, which is charged negatively over a broader range of pH values, the interfacial layer of emulsions containing 0.5% lysolecithin could be much more sensitive to these alterations in the physical properties of the surfactant molecules. Even if oil droplets are able to come into close

proximity due to attractive interactions, the presence of more nonpolar surfactants (SMP) within the interfacial layer of emulsions containing 0.1% lysolecithin may give better resistance against coalescence.

Influence of Temperature. Commercial food and beverage emulsions are commonly subjected to thermal processing, and so it is important to understand how heating influences their physical stability. In the absence of salt, all of the emulsions appeared to be visibly stable to phase separation after they were heated (Figure 6). In the presence of salt (300 mM NaCl), emulsions containing 0.1% lysolecithin were highly unstable to phase separation at all holding temperatures (from 30 to 90 °C). On the other hand, emulsions containing 0.5% lysolecithin were stable to phase separation at relatively low temperatures (30 and 40 °C), but unstable at higher temperatures. Previous studies have reported that SMP-stabilized emulsions were also unstable to droplet growth when they were stored at 40 °C for prolonged periods.[18] A possible reason for the destabilization of SMP-coated droplets at elevated temperatures is dehydration of the hydrophilic surfactant head groups. Dehydration leads to an alteration in the optimum curvature of the surfactant monolayer and to reduced steric repulsion between droplets.[15] The fact that the emulsions were stable to droplet aggregation in the absence of salt suggests that electrostatic repulsion was strong enough to overcome any attractive interactions in these systems. In the presence of 0.5% lecithin and 300 mM NaCl, the emulsions may have become unstable to aggregation at elevated temperatures due to the combined influence of a reduction in electrostatic repulsion and in steric repulsion.

Particle size analysis of emulsions exposed to different holding temperatures was also carried out (Figure 7). The mean droplet diameter remained relatively small (<1 μm) at low holding temperatures (30−60 and 30−50 °C for 0.1 and 0.5% lysolecithin, respectively), but increased appreciably at higher temperatures. The fact that we did not observe a large increase in mean diameter but did observe rapid phase separation at temperatures of <50−60 °C suggests that flocculation rather than coalescence occurred in this temperature range. On the other hand, the fact that we observed rapid creaming and an increase in droplet diameter at higher temperatures suggests that coalescence occurred. Droplet coalescence may have been promoted at elevated temperatures due to dehydration of the polar head groups of the surfactant molecules. At lower temperatures the surfactant molecules form a rigid monolayer that is more resistant to coalescence, but at higher temperatures they form a flexible monolayer that is more susceptible to coalescence.

biochemical parameters of fatty livers to identify the potential parameters involved in cooking loss variability.

MATERIAL AND METHODS

Chemicals. Acrylamide, Bisacrylamide, Coomassie Brilliant Blue, and materials for minigels were purchased from Bio-Rad (Marnes la Coquette, France). Fastprep-24 was purchased from MP BioMedicals (Illkirch, France). All other chemicals were supplied by Sigma-Aldrich (Saint-Quentin Fallavier, France).

Animals. Fatty livers used in this experiment were issued from commercial flocks of male Mule ducks (*C. moschata* × *A. platyrhynchos*) reared until the age of 14 weeks according to standard practices. The birds were then force-fed by the distribution of a soak-corn mixture (25% grain, 35% flour, and 40% water, 3330 kcal/kg, 8.28% crude proteins and 3.38% lipids) twice daily for 12 days. The experiments described here fully comply with legislation on research involving animal subjects according to the European Communities Council Directive of Nov 24, 1986 (86/609/EC). Investigators were certificated by the French governmental authority for carrying out these experiments (accreditation no. 31-11 43 501).

Slaughter, Fatty Liver Selection, and Sampling. At the end of the force-feeding period, the slaughtering procedure was conventionally conducted in a commercial plant. Twenty minutes after bleeding, the livers were removed from the carcasses, weighed to select those with a mass ranging from 500 to 550 g (n = 100), and placed at 4 °C for 6 h. Selected livers were further sorted according to their cooking loss rate on the basis of the melting microtest method (MMTM) results. Briefly, 10 g of liver was placed in metallic spoonlike cups before being heated in an oven at 80 °C for 15 min. Immediately after, a trained operator sorted low- and high-melting samples by visually estimating the quantity of fat released during heating. On the basis of the result, the MMTM allowed two extreme groups, i.e., L+ (high melting rate or high CL) and L− (low melting rate or low CL), of 20 livers each to be distinguished.

Following this subjective classification, samples of 100 g were taken from the middle part of the big lobe of the 40 selected livers to be further controlled with a quantitative cooking yield test. Samples of 10 g were also taken from the upper part of the big lobe, to be assigned for biochemical and proteomic analysis, and immediately frozen in liquid nitrogen before storage at −80 °C until analysis.

Fatty Liver Cooking Loss Measurement. A 100 g sample of liver was placed in a perforated plastic pot to drain the exudates. The mass of each pot containing the samples was recorded to know the exact amount of raw liver placed in each perforated pot (W_{raw}). This set (liver + perforated pot) was then placed in a second pot and kept in a water bath (85 °C) for 1 h (water bath cooking). Finally, the sample was removed from the two pots, drained, gently wiped, and reweighed to determine the mass of the sample after cooking (W_{cooked}). CL (%) was then calculated according to the following formula: $CL = 100 - (W_{cooked}/W_{raw}) \times 100$.

Fatty Liver Biochemical Analysis. All biochemical analyses were performed with ground samples of liver and in duplicate to minimize technical variations.

Dry Matter. The dry matter content of the fatty livers was determined by drying a mass of ground liver (Wdm_{raw}) in an oven at 105 °C for 24 h.[8] Sand was added to previously weighed cups (Wdm_{cup}) to increase the surface of exchange. Just after being dried in the oven, the samples were placed in desiccators to be cooled to room temperature before weighing (Wdm_{dry}). The percentage of dry matter (DM) was then determined by the formula $DM\ content = ((Wdm_{dry} - Wdm_{cup})/Wdm_{raw}) \times 100$.

Lipid Content. The total lipid content of the raw samples was determined according to Folch's method.[14] After the extraction of lipids by a chloroform/methanol solution, quantification of the total lipid content of each sample was performed gravimetrically after evaporation of the chloroformic phase. The total lipid content is expressed as a percentage of dry matter for each sample.

Protein Extraction. The livers were primarily crushed into powder in liquid nitrogen. Liver lysis was then achieved using Fastprep-24 for 20 s. Briefly,[15] 1.5 mL of gelatin-degrading protease extraction buffer (50 mM Tris base, pH 7.5, 150 mM NaCl, 1 mM $CaCl_2$, 0.05% Brij 35, 10 μg/mL leupeptin, 1 mM PMSF) and 1.2 mL of casein-degrading protease extraction buffer (50 mM Tris base, pH 8.3, 20 mM EDTA, 10 mM EGTA, 0.1% β-mercaptoethanol) were added respectively to 75 and 300 mg of liver tissue to extract gelatin- and casein-degrading proteases, respectively. The samples were then centrifuged at 12000g at 4 °C for 15 min, and the fat cake (extracted lipids) was removed. This operation was repeated twice to guarantee good separation of soluble proteins from lipids and other cell components. Finally, the supernatants were collected and stored at −80 °C. The total protein concentration in the extracts (supernatants) was determined using Bradford's method with bovine serum albumin (BSA) as the protein standard. For each extraction buffer, the extractabilities (xtgelt and xtcalp for gelatin- and casein-degrading protease extraction buffers, respectively) were calculated by assuming a total protein content of 7% DM as reported in a previous study.[5]

MMP-2 Gelatin Zymography. Matrix metalloproteinase 2 (MMP-2) gelatinolytic activity was detected according to Kizaki.[15] Briefly, samples containing 40 μg of proteins were mixed (1/4, v/v) with the sample buffer (150 mM Tris base, pH 6.8, 30% glycerol, 4% SDS, 40 μM $ZnCl_2$, and 0.1% Bromophenol Blue) and loaded onto a 12% polyacrylamide gel containing 0.2% gelatin A (1 mm spacers, 5 mL per minigel). The gels were then run under denaturing but nonreducing conditions (4 °C, 125 V, 2 h). Proteolytic activity was finally achieved through washing gels for 30 min in TBS-T buffer (20 mM Tris base, 150 mM NaCl, 0.05% Tween) and 1 h in the incubation buffer (50 mM Tris−HCl, pH 7.5, 6 μM $ZnCl_2$, 5 mM $CaCl_2$, 0.05% Brij, 0.02% NaN_3) with 2.5% Triton X-100. Following that, the gels were incubated overnight (18 h) at 37 °C in the same buffer but without Triton X-100. Finally, zymograms were stained with a solution containing 0.1% Naphthol Blue Black for 2 h and then washed with a destaining solution (45% ethanol and 10% acetic acid). Digestion of the gelatin due to MMP-2 activity appeared as white bands on a dark blue background.

Cathepsin Gelatin Zymography. Cathepsin activities were detected according to Afonso.[16] Briefly, samples containing 15 μg of extracted proteins were loaded onto 0.2% gelatin gels containing SDS (12%) and run as previously described. The resulting gels were then washed twice for 30 min in a 0.1 M sodium acetate buffer solution (pH 5.2) containing 2.5% Triton X-100. Then the gels were incubated overnight with the incubation buffer (0.1 M sodium acetate + 2 mM DTT) at 37 °C. The gels were then stained in a 0.5% Coomassie Brilliant Blue R-250 solution for 2 h before being washed in a destaining solution (45% ethanol and 10% acetic acid). Digestion of the gelatin due to cathepsin activities appeared as white bands on a blue background.

Calpain Casein Zymography. Using the method of Raser,[17] calpain activities were detected on 10% polyacrylamide gels containing 0.2% casein and previously loaded with samples containing 40 μg of proteins diluted (1/4, v/v) in the calpain sample buffer (150 mM Tris base, 20% glycerol, 0.05% Bromophenol Blue, 0.75% β-mercaptoethanol). The gels were run in a calpain running buffer (192 mM glycine, 1 mM EDTA, 1 mM EGTA, 1 mM DTT, 25 mM Tris base, pH 8.3) for 2 h (4 °C, 100 V). Then the gels were washed twice in a calpain activation solution (20 mM Tris base, pH 7.4, 10 mM $CaCl_2$) for 30 min and incubated (overnight, 37 °C) in the same buffer containing 10 mM DTT. Finally, the gels were stained and destained as previously described for cathepsins. Digestion of the casein due to calpain activity appeared as white bands on a blue background.

Image Analysis. According to the procedure described by Bax,[9] the gels were scanned with an Image Scanner III using Image Master Platinum software (GE Healthcare, Uppsala, Sweden). Each liver sample was processed individually, and the value of the main bands was calculated by using an Image Master Platinum application. Each gel also included a pool of all the samples run and was used as an internal standard. Protease activity was considered as the combination of computerized measurements of both the intensity and volume of the main bands for each sample. Then the relative protease activity was estimated as protease activity/pool activity within each gel.

Statistical Analysis. For statistical analysis, the general linear model procedure of SAS software was used with a one-way ANOVA to compare L− and L+ samples. Correlations between variables were computed according to Pearson's method.[18]

In addition, a principal component analysis (PCA) was performed with all samples and the biochemical and proteomic measured variables. This statistical method calculates new variables, called principal components, which are linear combinations of the original variables to account for the variability in the data on the basis of the study of the covariances and the correlations between the original variables.[19] The results are presented in a 2D projection graph where proximate variables at the periphery of the circle are positively correlated, while those separated by 180° are negatively correlated. The closer the variables are to the periphery of the circle, the higher the coefficient of correlation between variables. Individuals are also presented in the same 2D projection. When liver samples are located in the same part of the projection with a given variable, the values of these samples for the considered variable are high. The PCA was performed with the Princomp procedure of SAS software.[18]

RESULTS AND DISCUSSION

As reported in Table 1, the mean liver masses were very similar (520 g) in both L+ and L− ducks. This value is very similar to that reported by Fernandez[20] for this typical program of force-feeding. From previous studies,[2,21] it is well-known that the greater the liver mass, the higher the cooking loss. On the contrary, in the present study, thanks to the original sorting, the mass of fatty livers cannot explain cooking loss differences as illustrated by the very low coefficient of correlation between liver mass and cooking loss ($r = 0.16$, $p > 0.05$). The percentage of cooking loss was 1.72-fold higher ($p < 0.001$) in L+ than in L− samples. This indicates that the subjective MMTM is relevant in distinguishing low- from high-melting livers. Livers from the L+ group presented higher dry matter and total lipid contents than those from the L− group ($p < 0.001$). As reported in previous studies,[3,11,21] the higher the lipid content, the higher the cooking loss ($r = 0.76$, $p < 0.001$). The buffer used for gelatin-degrading protease extraction allowed collection of similar amounts of proteins in both groups. On the contrary, the buffer used for casein-degrading protease extraction allowed collection of more proteins ($p < 0.05$) from L− than from L+ samples.

Table 1. Cooking Losses (CL) and Biochemical Characteristics of Fatty Livers from the Two Studied Groups L− (Low Cooking Loss) and L+ (High Cooking Loss)[a]

	L−	L+	p^b
CL (%)	20.9 ± 4.33	36.0 ± 9.97	***
mass (g)	519 ± 13.0	520 ± 10.2	ns
DM content (%)	63.8 ± 2.21	69.0 ± 2.23	***
lipid content (%)	53.7 ± 3.22	61.0 ± 3.04	***
xtcalp (%)	12.7 ± 3.27	9.98 ± 4.17	*
xtgelt (%)	12.1 ± 1.44	11.5 ± 2.03	ns

[a]Values are expressed as the mean ± standard deviation ($n = 20$ per group). [b]Key: ***, $p < 0.001$; **, $p < 0.01$; *, $p < 0.05$; ns, not significant ($p > 0.05$).

The MMP gelatin protease assay permitted the detection of a 72 kDa proteolytic band corresponding to MMP-2 (Figure 1b). The protocol described by Kizaki[15] allows detection of MMP-2 and MMP-9 (respectively gelatinases A and B), but in the present experiment only one isoform corresponding to MMP-2 was detected, probably because it is the most abundant MMP in the cellular extract. This gelatinolytic activity was inhibited in the presence of EDTA and DTT and in the absence of Ca^{2+} ions (data not shown). As reported in a previous study[22] on cathepsin activity in Pekin and Muscovy ducks' livers, three proteolytic bands were detected for the cathepsin proteolytic assay. The upper band being considerably smaller in Mule ducks, we chose to focus on the other two presenting molecular masses of ∼30 and ∼25 kDa, respectively (Figure 1c). Unlike MMP-2, the activities of cathepsin isoforms were not affected by the addition of DTT or EDTA, but were inhibited in the presence of PMSF (data not shown). Unfortunately, no specific antibodies directed against cathepsin isoforms from ducks are commercially available for a better identification of the detected isoforms in the present study. Moreover, an identification test of those cathepsins using mass spectrometry analysis failed to reveal reliable results. As a consequence, we chose to let the precise identification of the two detected cathepsin isoforms in the present study remain unknown and reported a total activity of cathepsins (CtsT, Figure 2) calculated as the sum of the individually detected activities. Calpain proteolytic assays revealed two bands which were active in the presence of 4 mM Ca^{2+} for the upper one and 10 mM of Ca^{2+} for the lower one (Figure 1d). These results indicate that the two bands correspond to the μ- and m-calpain isoforms, respectively. The m-calpain is also electrophoretically distinguishable from the μ-calpain because of its higher mobility in the gel.[23] To further confirm the identification of these two caseinolytic proteases, the effects of calpain inhibitors (leupeptin and E-64 both purchased from Sigma-Aldrich, Saint-Quentin Fallavier, France) were assessed before electrophoresis. As expected, the presence of these calpain inhibitors completely blocked the activity of both neutral cysteine proteases (data not shown).

Results concerning extracted protease relative activities are reported in Figure 2. In both L+ and L− samples, the zymogram profiles were similar but clearly exhibited higher values in L+ than in L− samples except for the relative activity of Ct-1. The values of protease relative activities reported in the present experiment for L− samples were close to those reported for Pekin and Muscovy force-fed ducks by Awde et al.[22] Finally, the total extracted protease activities appeared to be 1.37-fold ($p < 0.001$) higher in L+ than in L− fatty livers. Due to the fact that proteases remain active during postmortem storage, we think that these higher proteolytic activities have led to a higher degradation of cellular structure. Therefore, at the time of cooking, the overall fragility of the L+ hepatocyte structure might have been higher, and consequently, more internal fluids were released from liver cells and finally led to higher cooking loss values. This hypothesis was previously reported by Theron.[5,11]Nevertheless, it has been reported that the postmortem cooling rate largely influences the extent of cooking losses in fatty livers.[4] For example, fatty liver evisceration immediately after slaughter, associated with a rapid cooling, decreases cooking losses. On the contrary, when the livers are kept inside the carcass during postmortem cooling, the final cooking losses are increased. Besides, protease activities are known, as for other enzymes, to decrease at low temperatures.[24] As a consequence, we can hypothesize that the rate of cooling of the livers postmortem could influence the cooking losses by modulating the total activities of the proteases: the more active the proteases are (under the influence of temperature, for example) during the postmortem period, the more the structure of the hepatocytes might be altered and the more their lipid content will be exuded during cooking. In the present study, the cooling rate was the same for

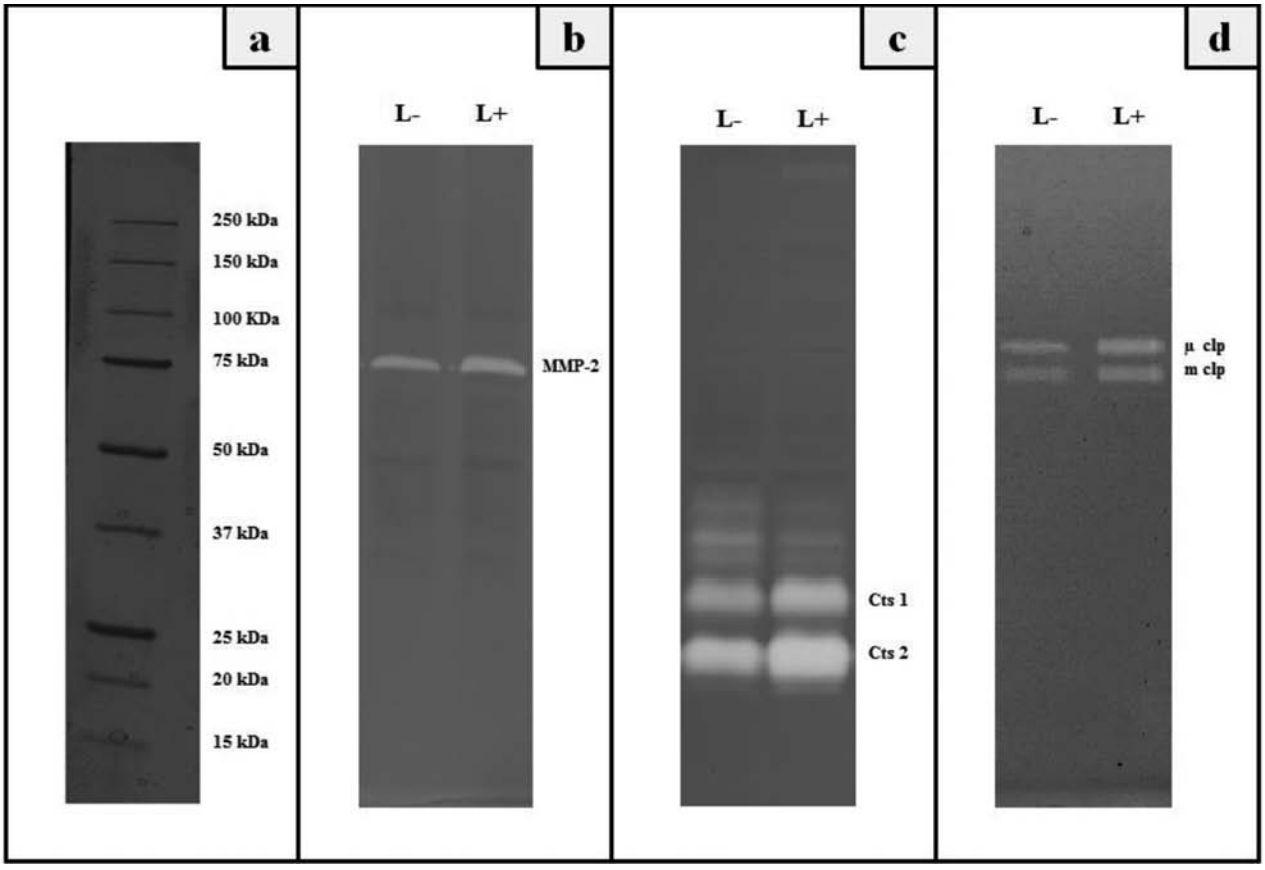

Figure 1. Molecular mass standards (a) and zymograms of the 72 kDa MMP-2 band (b), the 2 cathepsin bands (c) Cts-1 (30 kDa) and Cts-2 (25 kDa), and the μ- and m-calpain (μ-calp and m-calp) 80 kDa bands (d) analyzed by zymography in L− and L+ fatty liver samples.

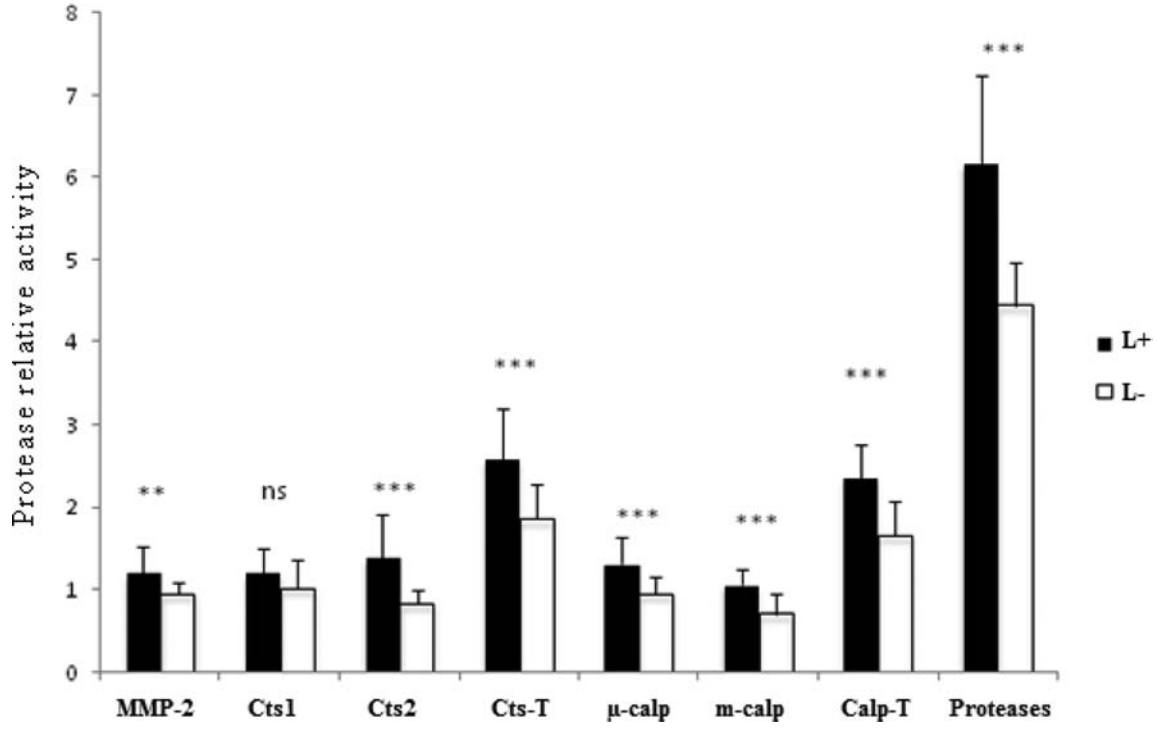

Figure 2. Protease relative activities in L+ and L− fatty liver samples. Values are the mean ± standard deviation. Key: ***, $p < 0.001$; **, $p < 0.01$; ns, not significant ($p > 0.05$). MMP-2 = matrix metalloproteinase 2, Ct-1 = cathepsin isoform 1, Ct-2 = cathepsin isoform 2, Ct-T = Ct-1 + Ct-2, μ-calp = μ-calpain, m-calp = m-calpain, Calp-T = μ-calp + m-calp, and proteases = MMP-2 + Ct-T + Calp-T.

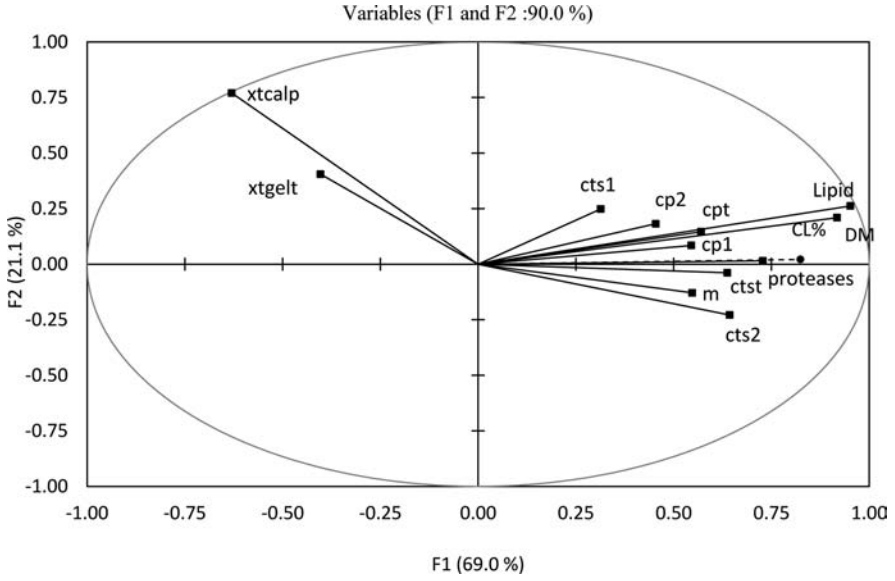

Figure 3. First two principal component score vectors showing relationships between cooking losses and liver biochemical characteristics. m = matrix metalloproteinase 2, cts1 = cathepsin isoform 1, cts2 = cathepsin isoform 2, ctst = cts1+ cts2, cp1 = μ-calpain, cp2 = m-calpain, cpt = cp1 + cp2, proteases = m + cpt + ctst, lipid = lipid content (%), DM = dry matter content (%), xtgelt = extractrability for gelatin-degrading protease buffer, and xtcalp = extractability for casein-degrading buffer. Key: ●, added variable (CL, %); ■, active variables.

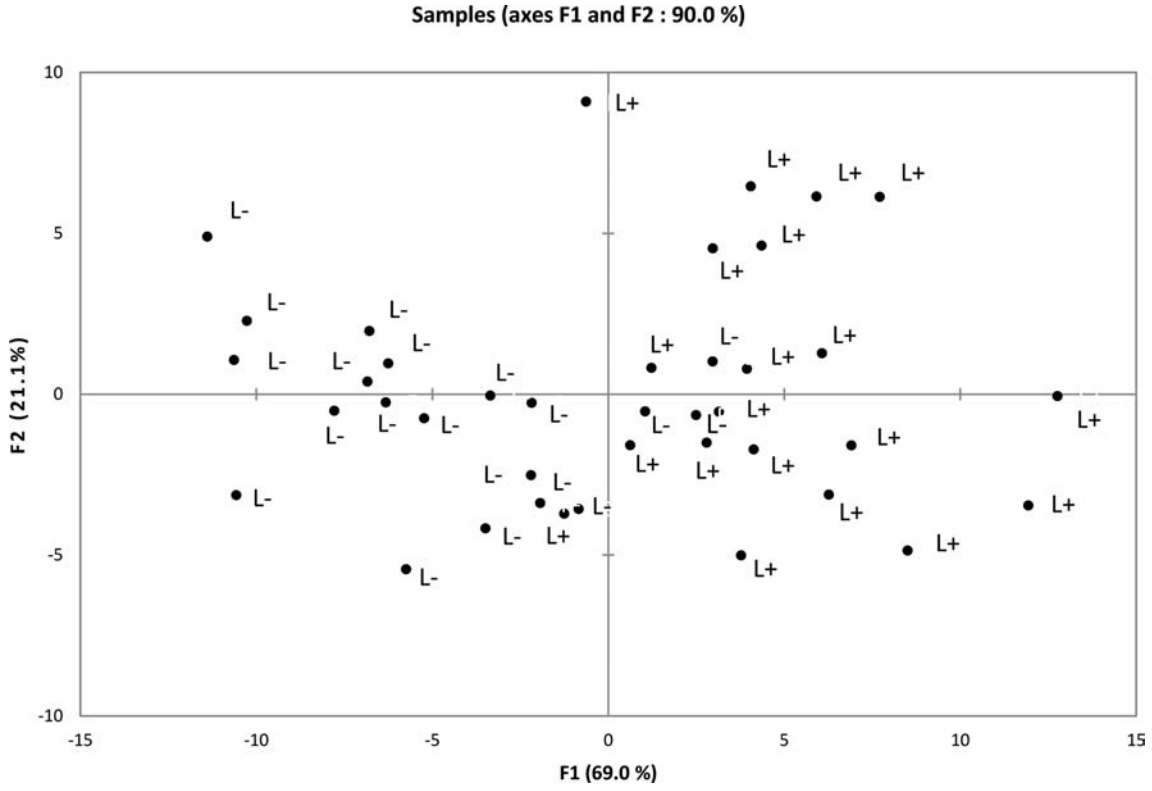

Figure 4. First two principal component score vectors showing variability according to liver groups (L+ = high cooking loss; L− = low cooking loss).

both L+ and L− livers (same process, same liver masses), but the protease activities were originally higher in L+ than in L− samples (Figure 2). Consequently, more cellular degradations occurred in L+ livers and might lead to more important cellular content releases during cooking. Nevertheless, this assumption needs to be further verified by performing SDS−PAGE with proteins extracted from fatty livers at different times postmortem. Finally, it seems that, for a given mass, the livers could differ according to the level of their metabolisms at the time of slaughtering, and this will influence the final quality of the product after cooking. When hepatic metabolisms are very active (high level of lipid accumulation, high proteolytic activities), the livers tend to be more weakened, leading to higher cooking loss values.[3,21] Differences in the levels of activity of hepatic proteases can have different origins, such as the structure of the enzyme by itself (different isoforms) or different concentrations of cellular activators (calcium content) or inhibitors (calpastatine, cystatine, or tissue inhibitors of

dx.doi.org/10.1021/jf4051057 | J. Agric. Food Chem. 2014, 62, 3262−3268

metalloproteinases). These hypotheses will have to be further investigated by comparing hepatocyte contents between L− and L+ samples.

The relationships between biochemical content, protease activities, and cooking losses are well illustrated by the principal component analysis (Figure 3) that clearly associates lipid and dry matter contents with protease activities and cooking losses along the first principal component. It also illustrates the strong correlation between DM and lipid contents (r = 0.88, p < 0.001) and their strong opposition with extractabilities (xtcalp and xtgelt) of soluble proteins. The new linear combination of original variables given by the PCA allows a good distinction of L+ and L− samples (Figure 4). Indeed, without using the CL (%) variable, 85% of the examined samples were correctly grouped according to their CL determination. By combining the results of Figures 3 and 4, it appears that L+ samples are mainly positively associated with lipid and DM contents as well as with protease activities, while the opposite is true for L− samples. On the contrary, L− samples are better associated with extractability values. Finally, we can report that the lipid and DM contents associated with the main proteolytic activities are positively associated with L+ samples, while L− samples are rather negatively associated with those variables but positively with extractability values.

In conclusion, this study demonstrates that both the lipid and DM contents as well as the main hepatic protease activities have a strong influence on cooking losses in fatty livers issued from force-fed Mule ducks. Samples issued from animals with the highest hepatic metabolisms (both lipidic and proteic) at the time of slaughter will exhibit the highest cooking loss values. It would be interesting to investigate why some ducks have a better adapted hepatic metabolism than others in their response to force-feeding and how to identify them as soon as possible to reduce final variability in cooking loss values recorded in processing plants. Associated with higher protease activities, we hypothesized that more cellular degradations occurred during the postmortem period and led to a more important weakening of cellular structures associated with higher cooking losses. New investigations are currently under way to confirm that point.

Solid-state glycation of β-Lg conserves its native-like structure[29,30,32] and its association tendency[29] and yields a heterogeneous mixture of glycoforms that differ in the degree and sites of glycation.[33] In contrast, aqueous glycation induces significant changes in the native β-Lg structure[29,34] and leads to sugar-induced protein cross-linking.[27,29,35] The effects of β-Lg glycation include improved heat stability,[10,36−38] lowered isoelectric point,[39,40] decreased surface hydrophobicity due to polar sugar groups,[10,37] and inhibition of aggregation due to the steric effect of sugar residues.[37,38]

Modification of the amine groups of amyloidogenic proteins α-synuclein[41] and insulin[42] by dicarbonyl compounds slowed their self-assembly into fibrils in vitro. On the other hand, glycation promoted the self-assembly of bovine serum albumin.[43] Glycation is likely to affect β-Lg self-assembly since almost all of the potential glycation sites are located on the regions involved in fibril formation.[18,20,23]

Liu and Zhong[44] recently prepared nanofibrils from whey protein isolate after solid-state incubation with lactose. However, the incubation produced changes in secondary structure, and Maillard reactions progressed well beyond the addition of integer numbers of sugars, due to the extreme incubation conditions (80 °C for 2 h at 70% relative humidity). Lactose-reacted β-Lg fibrils had modified functional properties, but little mechanistic information could be obtained due to the heterogeneity of the starting material.

In this study, we focused on how glycation affects the structural and chemical events involved in fibril formation and examined both the extent of glycation and the sugar type (monosaccharide or disaccharide). We glycated β-Lg under mild conditions to prevent advanced Maillard reactions and produce a well-defined starting material without marked changes to the secondary or tertiary structure of the protein. This systematic approach has produced new insights into the mechanism of amyloid-like fibril self-assembly.

MATERIALS AND METHODS

Unless otherwise mentioned, all chemicals were of analytical grade and were purchased from Sigma-Aldrich (St. Louis, MO). Unless otherwise stated, Milli-Q water was used for preparing the reagents.

Isolation of β-Lactoglobulin. β-Lg was isolated in-house from whey protein isolate 8855 (Fonterra Cooperative Ltd., Auckland, New Zealand) using the method described previously.[18] The β-Lg powder had a protein content of 97% and was a mixture of variants A and B, which did not have any glycation (Figure S1, Supporting Information).

Preparation of Glycated β-Lg. *Preliminary Experiments for Selection of Glycation Times.* A stock solution of β-Lg (pH 7) was allowed to hydrate at 4 °C overnight. The solution was then centrifuged at 44000*g* for 30 min at 20 °C, and the supernatant was filtered using a syringe filter (pore size 0.2 μm, Minisart CE, Sartorius Stedim Biotech GmbH, Goettingen, Germany). Glucose and lactose powders were mixed with the filtered β-Lg solution (molar ratio β-Lg:sugar =1:100), and the pH values of the solutions were readjusted to 7.00 ± 0.02 using 1 N NaOH. The samples were then frozen at −18 °C overnight and freeze-dried. For glycation, the freeze-dried powders were placed in a glass Petri dish and transferred to separate desiccators with a saturated potassium bromide (KBr) solution. The desiccators were sealed, and a vacuum of 125 mbar was applied to them. Then the desiccators were transferred to an oven maintained at 40.0 ± 0.5 °C. The saturated KBr solution gave a relative humidity of 80% inside the desiccators. For glucosylation, the samples were removed from the desiccators after 8, 16, or 36 h, while for lactosylation the durations were 3, 5, and 7 days. Longer heating times were not investigated since samples heated for longer than the above-mentioned times showed extensive brown discoloration indicating the presence of advanced Maillard reaction products in the samples. After completion of the glycation reaction, the samples were dissolved in Milli-Q water (pH 7) and dialyzed (molecular mass cutoff of 6−8 kDa, Spectra/Por, Spectrum Laboratories Inc., Rancho Dominguez, CA) for 48 h at 4 °C to remove the excess unreacted sugar. The dialyzed protein solution was then freeze-dried to obtain the glycated β-Lg.

Determination of the Degree of Glycation. Glycated β-Lg was dissolved in water (pH 2) and filtered using a 0.2 μm syringe filter before being subjected to RP-HPLC (C_{18}, Jupiter, Torrance, CA) at a flow rate of 1 mL/min. The compositions of the buffers were 10% (v/v) acetonitrile (MeCN) in water containing 0.1% trifluoroacetic acid (TFA) for buffer A and 90% MeCN with 0.08% TFA for buffer B. Upon loading, the sample was eluted using the following program: 2 min wash with buffer A followed by a linear gradient of buffer B from 0% to 65% in 13 min and then to 100% B in 1 min. This was followed by isocratic elution of buffer B for 5 min and then a gradient to 0% B in 1 min, after which a wash with buffer A for 2 min followed. A single large peak was eluted when the MeCN concentration was 38%, and this peak was collected and concentrated to approximately 100 μL (Savant SpeedVac SC100, Holbrook, NY) under vacuum (Varian DS 102, Varian Vacuum Technologies, Torino, Italy). The samples were stored at −86 °C until further analysis. The degree of glycation in modified β-Lg was analyzed by liquid chromatography−mass spectrometry.

RP-HPLC-purified samples (2 μL) were autoinjected into an Agilent 1200 LC system (Agilent Technologies, Santa Clara, CA) on bypass mode. The isocratic mobile phase was composed of 0.1% (v/v) formic acid/50% MeCN/water at a flow rate of 100 μL/min. The LC eluant was directed to the electrospray ionization (ESI) source at a capillary voltage of 3.4 kV of the mass spectrometer (Agilent 6520 Q-TOF, Agilent Technologies, Hanover, Germany). Sample analysis was performed in positive ion mode, and the data were stored in profile mode. MS scans (100−1700 m/z) were obtained with fragmentor and skimmer voltages at 175 and 65 V, respectively. Other source parameters were a drying gas temperature of 325 °C, gas flow rate of 6 L/min, and nebulizer gas pressure of 30 psig. The total ion chromatograms (TICs) obtained were examined and spectra deconvoluted using Agilent MassHunter Workstation Qualitative Analysis software (version B.03.01) with a BioConfirm plugin (Agilent Technologies, Santa Clara, CA). The intensity of the peaks was normalized by assigning the most intense peak in the spectrum to 100%.

Preparation of Samples for Self-Assembly Studies. The unmodified β-Lg showed only two peaks corresponding to variants A and B (Figure S1, Supporting Information). The degrees of glycation for β-Lg with glucose and lactose after different glycation times are shown in deconvoluted MS spectra in Figures S2 and S3 (Supporting Information), respectively. The degrees of glycation after 8 h of glucosylation and 3 days of lactosylation were similar, and these glycation times were selected for further investigation. From this point onward, samples made using these heating times will be referred to as low-glucose (LowGlu) and low-lactose (LowLac) β-Lg, respectively. Similarly, for the high degree of glycation, the durations selected were 36 h for glucosylation and 7 days for lactosylation. The samples made using these heating time points will be referred to as high-glucose (HighGlu) and high-lactose (HighLac) β-Lg, respectively. Fresh glycated samples were made using the selected glycation time points and analyzed by MS using the above methodology. For each of the glycation mixtures, a β-Lg sample without sugar was used as a control. The freeze-dried glycated proteins prepared as described above were stored at −18 °C until further analysis.

Self-Assembly from β-Lg. β-Lg samples intended for self-assembly were made according to a method described previously.[24] Protein concentrations in the samples were determined by spectrophotometry (Ultraspec 2000, Pharmacia Biotech, Cambridge, U.K.) using an extinction coefficient of 0.94 cm^2/mg.[45] β-Lg (with or without glycation; 1%, w/v) samples, at pH 2.00 ± 0.02 were heated in a temperature-controlled water bath (Jeio Tech, Seoul, South Korea) maintained at 80.0 ± 0.2 °C. The control sample used in the study was untreated and unglycated β-Lg. Since we were interested in investigating the effects of glycation on nucleation, heating was done

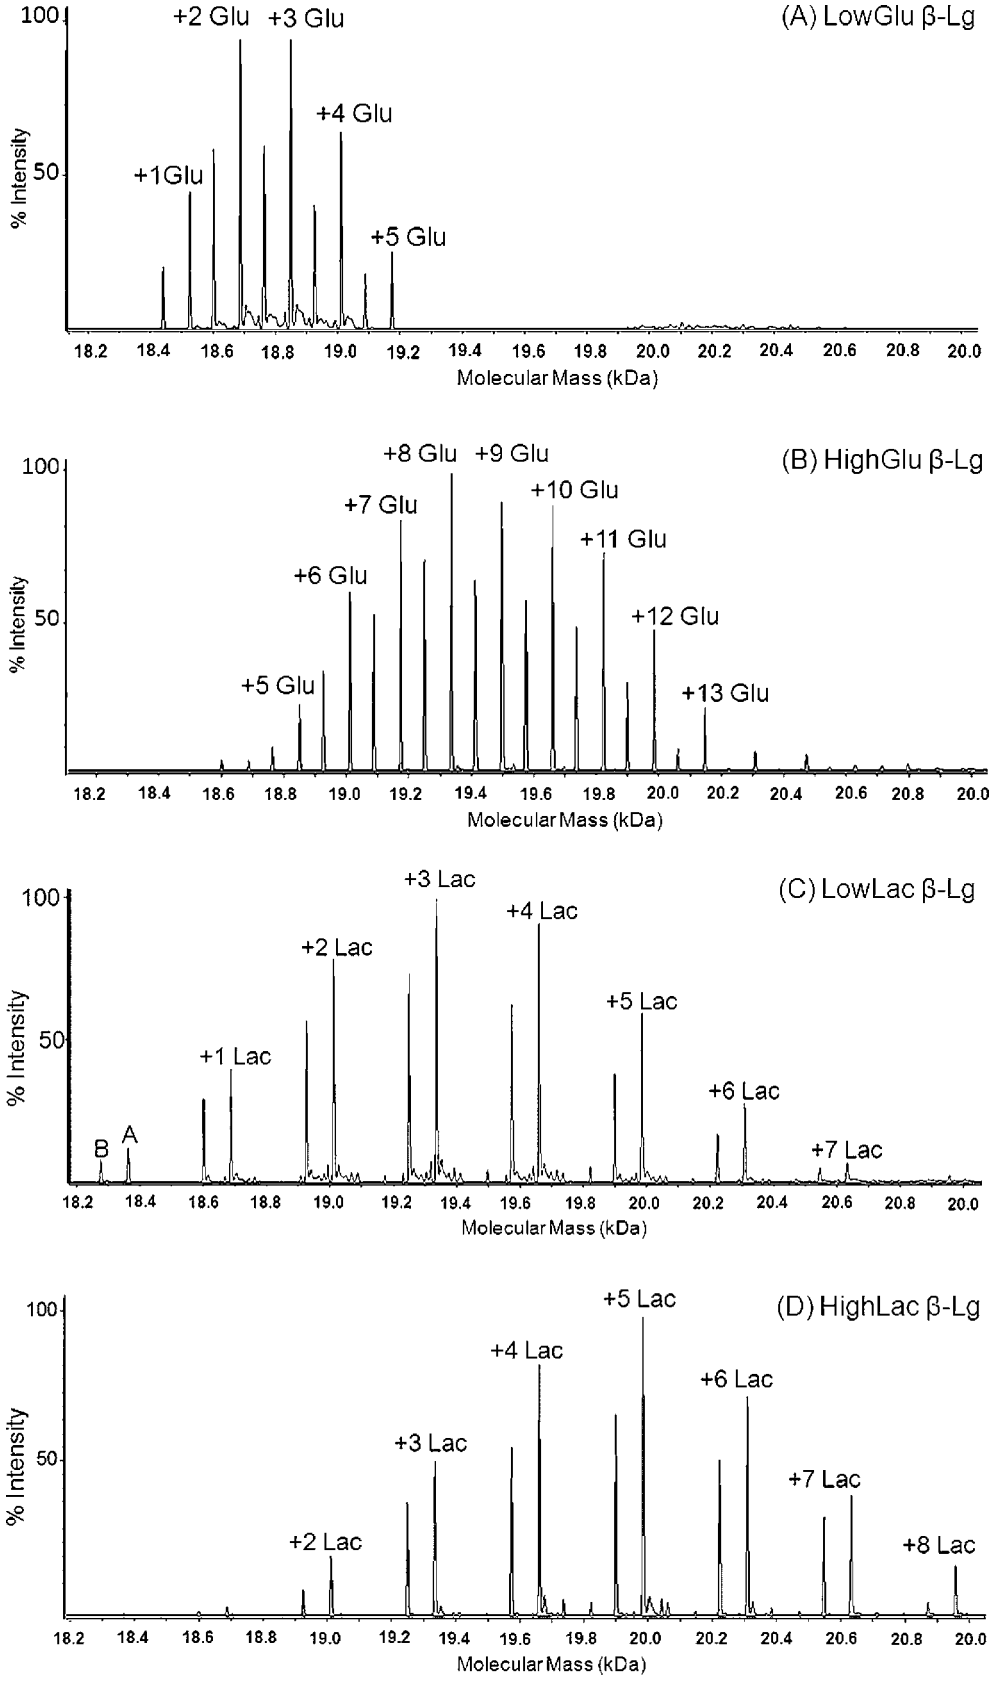

Figure 1. Deconvoluted MS spectra of glucosylated (A) LowGlu β-Lg and (B) HighGlu β-Lg and lactosylated (C) LowLac β-Lg and (D) HighLac β-Lg. Peak labels show the number of attached glucose or lactose residues.

without agitation to minimize secondary nucleation, which would otherwise obscure other phenomena. After being heated for different holding times (2−24 h), the samples were cooled rapidly using an ice bath. The cooled samples were analyzed by the thioflavin T assay and

dx.doi.org/10.1021/jf405441g | J. Agric. Food Chem. 2014, 62, 3269−3278

SDS−PAGE. The lactose used in the study was found to be stable under conditions of glycation and fibril formation (data not shown).

Thioflavin T (ThT) Fluorescence Assay. Fibril formation from β-Lg was studied by the ThT assay as previously described.[24] The fluorescence intensities in the samples were corrected against that of the unheated sample and ThT solution without any protein sample. The corrected intensities were then fitted using the mathematical model given in the following equation:

$$f_t = \alpha - \frac{\frac{\beta}{\gamma} + \alpha}{1 + \frac{\beta}{\alpha\gamma}\exp[t(\beta + \alpha\gamma)]} \quad (1)$$

where α, β, and γ are empirical constants and f_t denotes fluorescence at a given time t (h). The kinetic parameters for β-Lg self-assembly for each of the samples were calculated using the following equations:[24]

$$t_{lag} = \frac{1}{\beta + \alpha\gamma}\left(\ln\left(\frac{\alpha\gamma}{\beta}\right) - 4\frac{\alpha\gamma}{\beta + \alpha\gamma} + 2\right) \quad (2)$$

$$t_{1/2max} = \frac{\ln\left(2 + \frac{\alpha\gamma}{\beta}\right)}{\beta + \alpha\gamma} \quad (3)$$

$$\left(\frac{df}{dt}\right)_{max} = \frac{\left(\frac{\beta}{\gamma} + \alpha\right)(\beta + \alpha\gamma)}{4} \quad (4)$$

where t_{lag} represents the duration of the lag phase, $t_{1/2max}$ is the time required for attaining half of the maximum fluorescence value, and $(df/dt)_{max}$ represents the maximum rate of fluorescence increase. The value of the empirical constant α represents the fitted maximum fluorescence in the stationary phase, and is relabeled f_{max}. Equation 1 was fitted to data using SigmaPlot 12.1, and the standard deviations of t_{lag}, $t_{1/2max}$, and $(df/dt)_{max}$ were calculated using partial derivatives and the covariance matrix, as detailed in the Supporting Information.

Separation of Fibrils. Fibrils in the samples were separated using ultracentrifugation and washed using the method described previously.[18] Briefly, 9 mL volumes of heated and cooled samples were subjected to ultracentrifugation at $(2.4 \times 10^5)g$ for 1 h. The pellets obtained were dispersed in 9 mL of water and vortexed, followed by ultracentrifugation. These washing and ultracentrifugation steps were repeated twice. The washed pellet was used for analysis.

SDS−PAGE. Heated samples were analyzed by tricine SDS−PAGE methodology described elsewhere.[18] Heated samples were diluted 1:10 in reducing PAGE sample buffer (4% SDS and 100 mM dithiothreitol (DTT)). For centrifuged samples, the supernatants were diluted 1:10 while the pellets were suspended directly in the PAGE sample buffer. The PAGE gels were scanned and analyzed using Image Lab software (Bio-Rad Laboratories, Hercules, CA). The quantification of the hydrolysis of β-Lg was done as per the method described in the reference. For each of the samples, the hydrolysis rate constants (k_h) were calculated from the following equation:

$$I = I_0 e^{-k_h t} \quad (5)$$

Circular Dichroism (CD) Spectroscopy. The β-Lg solutions for CD spectroscopy were prepared in HPLC-grade water at pH 2.00 ± 0.02 according to the method described in a previous report.[18] The β-Lg concentrations for near-UV (NUV) scans (260−320 nm) and far-UV (FUV) scans (180−250 nm) were 1 and 0.01 mg/mL. Scans were recorded using a CD spectrometer (Chirascan, Applied Photophysics Ltd., Surrey, U.K.) and a cuvette of path length 10 mm either at 20 °C or continuously for 1 h at 80 °C. The time required for raising the temperature from 20 to 80 °C was excluded, and the time at which the temperature reached 80 °C was designated as 0 min. Scans were averaged sequentially to obtain data at 2 min intervals and corrected by subtracting baseline scans from each of the sample scans. Molar ellipticity was calculated using the following equation[46] with data from the β-Lg scans after baseline subtraction:

$$[\theta]^{\lambda}_{M} = \frac{100\theta_{\lambda}}{LC} \quad (6)$$

where θ_λ is the measured ellipticity (deg) at a given wavelength λ, L represents the path length of the cuvette used (cm), and C is the protein concentration (dmol/L). The data were smoothed in SigmaPlot 12.1, and the relative changes in ellipticities at 293 and 208 nm were calculated from the following equations:[18]

$$\left(\frac{\Delta[\theta]_t}{\Delta[\theta]_0}\right)_{293} = \frac{[\theta]_t - [\theta]_{60}}{[\theta]_0 - [\theta]_{60}} \quad (7)$$

$$\left(\frac{\Delta[\theta]_t}{\Delta[\theta]_{60}}\right)_{208} = \frac{[\theta]_t - [\theta]_0}{[\theta]_{60} - [\theta]_0} \quad (8)$$

θ_0 represents the ellipticity in the unheated sample, θ_t that at time t (min) during heating, and θ_{60} that at the end of the heating period after 60 min.

Transmission Electron Microscopy (TEM). Fibrils in heated solutions were separated using the methodology previously described.[24] A 200 μL volume of the heated solution was diluted 10-fold using water (pH 2) and centrifuged at 3000*g* for 15 min in a centrifuge filter (Amicon Ultra-4, Millipore) with a nominal cutoff of 100 kDa, rinsed previously with water (pH 2). The sample was washed with pH 2 water three times and recentrifuged to get fibrils in the retentate. The fibrils in the retentate were then suspended in 1 mL of the pH 2 water. For TEM, 200 μL of the suspension was mixed with 200 μL of water (pH 2) and 20 μL of BSA (0.5%, w/v) in a polypropylene tube before being stained by a negative staining protocol that is described in the reference.

RESULTS

Characterization of Glycated β-Lg. The deconvoluted MS spectra of glycated β-Lg are shown in Figure 1. All samples showed a series of peak pairs with mass increments of either 162 Da (Figure 1A,B, glucosylation) or 324 Da (Figure 1C,D, lactosylation), indicating that both variants B (18277 Da) and A (18364 Da) participated in glycation. Peaks corresponding to unglycated β-Lg appeared only in the scans of LowLac β-Lg, and at low levels in that case. Variants A and B showed a similar propensity for glycation, and the glucosylation of both variants was faster than lactosylation. The presence of multiple peaks in the spectrum suggests heterogeneity of glycoforms of β-Lg in samples with respect to the number of sugar residues attached to the β-Lg. These results are in agreement with previous studies which show similar reactivities of β-Lg A and B,[47] a heterogeneous mixture of glycoforms in samples upon glycation with respect to the number of attached sugar residues,[27,30,33,36,39] and faster rates of glucosylation than those of lactosylation of β-Lg.[10]

Unfolding Behavior of Glycated β-Lg. The effect of glycation on the β-Lg native structure and thermal unfolding was investigated using CD spectroscopy with in situ heating at 80 °C, as described previously.[18] In the NUV region, all unheated samples showed characteristic troughs at 293 and 286 nm (Figure S4A, Supporting Information) arising due to the tryptophan residue at position 19,[48] indicating that the environment around Trp19 was unaffected by glycation. In addition, the scans showed a small trough at 265 nm contributed by the phenylalanine residues in the native β-Lg structure. These troughs in the NUV region have been shown to rapidly decrease in intensity upon heating β-Lg under fibril-forming conditions.[18] Heating of glycated samples resulted in rapid loss of the characteristic troughs at 293, 286, and 265 nm. Figure 2A shows an example of scans recorded for LowGlu β-

Lg during heating, and Figure 3A shows the comparison of relative loss of ellipticities at 293 nm upon heating.

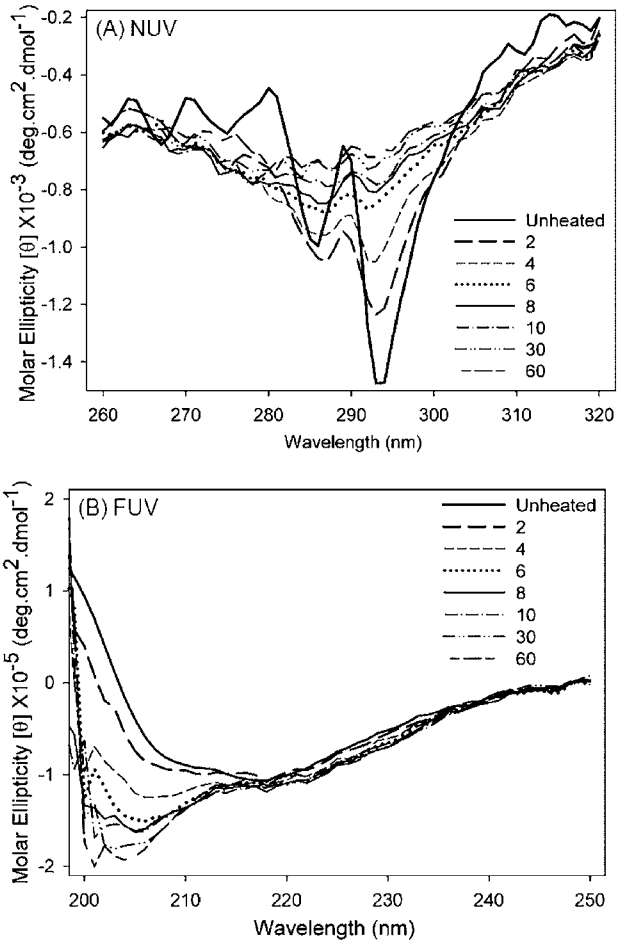

Figure 2. CD spectra of LowGlu β-Lg in the (A) NUV region (10 mg/mL β-Lg) and (B) FUV region (0.01 mg/mL β-Lg). The numbers in the legends indicate the heating time in minutes.

In the FUV region, glycated samples showed a broad trough with a minimum at 217 nm (Figure S4B, Supporting Information), indicating that in all the samples β-sheets were the dominant secondary structural conformation.[48] It has been shown that heating β-Lg at 80 °C and pH 2 resulted in a shift of the trough toward lower wavelengths,[18] representing unfolding of the secondary structure. All glycated samples showed a rapid shift in the trough during heating. Figure 2B illustrates the shift of the trough in the FUV region for LowGlu β-Lg during heating. The plot of $([\Delta\theta_t]/[\Delta\theta_{60}])_{208}$ against time comparing the change in the ellipticity at 208 nm upon heating is shown in Figure 3B.

Heat-Induced Hydrolysis. To investigate the effect of glycation on the acid hydrolysis of β-Lg, the composition of samples heated for different times was analyzed by tricine SDS−PAGE under reducing conditions. All samples showed hydrolysis of the β-Lg monomer with heating. A comparison of PAGE profiles of samples after heating for 12 h at 80 °C is shown in Figure 4. The peptide bands in glycated samples appeared less distinct than in control β-Lg. This may be attributed to the presence of a heterogeneous mixture of peptides with different degrees of glycation in the samples. In addition, the modification of amine groups on peptides may

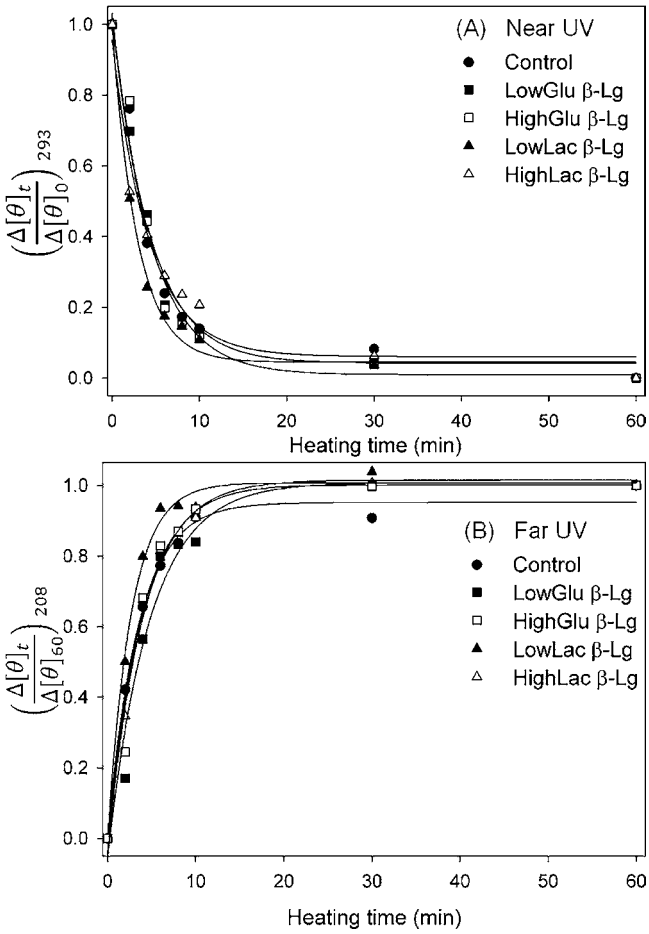

Figure 3. Relative change in ellipticity at (A) 293 nm in the NUV region and (B) 208 nm in the FUV region. Solid lines are for visual reference. For details of the *y*-axis parameters, see the Materials and Methods.

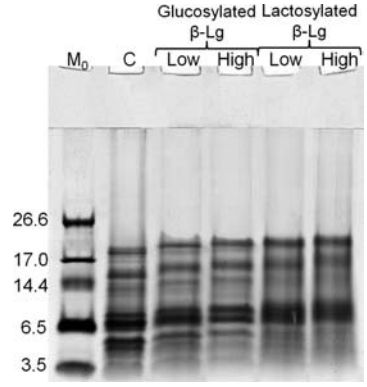

Figure 4. Tricine SDS−PAGE profiles of control and glycated samples after heating for 12 h at 80 °C. Key: M_0, molecular mass markers (kDa); C, heated control.

have altered the affinity of these peptides to bind to the staining dye.[49] Among the glycated samples, the peptide bands in lactosylated samples were the least well-defined.

The intensity of the band corresponding to the unhydrolyzed β-Lg in the SDS−PAGE gels at different times was quantified and plotted against the heating times. Hydrolysis of the monomer in all samples followed first-order exponential decay kinetics (Figure S5, Supporting Information), and the rate

dx.doi.org/10.1021/jf405441g | J. Agric. Food Chem. 2014, 62, 3269−3278

constants (k_h) were calculated using eq 5; these are listed in Table 1. Glycation reduced k_h by ~15%, and this effect was

Table 1. Rate Constants of Acid Hydrolysis of β-Lg Calculated from Eq 5

sample details	k_h ($min^{-1} \times 10^{-3}$)	adj R^2	$S_{y/x}$[c] $\times 10^{-3}$
control	2.8 (0.10)[b]	0.9921	0.50
LowGlu β-Lg[a]	2.4 (0.08)	0.9925	0.41
HighGlu-β-Lg	2.3 (0.07)	0.9752	0.40
LowLac β-Lg[a]	2.3 (0.10)	0.9609	0.55
HighLac β-Lg	2.5 (0.11)	0.9746	0.60

[a]The degrees of glycation in LowGlu and LowLac β-Lg were similar. [b]Numbers in parentheses indicate standard deviations. [c]Standard error of regression.

independent of the type of sugar or the degree of glycation. However, the glycation effect was not significant (p = 0.29) in the likelihood ratio test. The SDS–PAGE analysis of β-Lg glycation controls showed that hydrolysis rates were unaffected (p = 0.25, likelihood ratio test) by sample treatments in the absence of sugars (Figure S6 and Table S1, Supporting Information).

Self-Assembly from Glycated β-Lg. Self-assembly from glycated samples followed a three-phase sigmoidal growth pattern (Figure 5A), which is typical of β-Lg self-assembly under unstirred conditions. The ThT data were fitted well by eq 1, and results from a likelihood ratio test confirmed that the effect of glycation treatments on the parameters was statistically significant (p < 0.0001). The kinetic parameters of self-assembly calculated from eqs 2–4 are listed in Table 2. A comparison of kinetic parameters of self-assembly is shown in Figure 5B. LowGlu β-Lg and LowLac β-Lg showed only a small increase in t_{lag} (6 and 7 h, respectively, against 5.6 h for the control), whereas in HighGlu β-Lg and HighLac β-Lg the t_{lag} values were nearly twice that of the control (11.3 and 11 h, respectively).

In the growth phase, glycation greatly decreased $(df/dt)_{max}$. For glucosylated samples, this effect was more pronounced at high degrees of glycation. In contrast, lactosylation had a strong effect irrespective of the degree of glycation. The effect of glycation on the stationary phase fluorescence (f_{max}) followed a similar trend. Control β-Lg samples were freeze-dried, incubated, and dialyzed as with glycated samples but without sugars, and these controls self-assembled normally (Figure S7, Supporting Information). Thus, glucosylation and lactosylation had different effects on the different stages of self-assembly, and the effect of lactosylation was stronger than that of glucosylation.

Composition of Fibrils. Fibrils in samples heated for 24 h were separated using ultracentrifugation and analyzed using SDS–PAGE under reducing conditions. The residual ThT intensities in the supernatant samples remained low, indicating complete separation of fibrils upon ultracentrifugation (Figure S8, Supporting Information). HighGlu and HighLac β-Lg showed long t_{lag} and lower $(df/dt)_{max}$, so a heating time of 24 h was selected for studying the composition of the fibrils. Figure 6 shows the peptide bands in centrifugally-separated fibrils from glycated β-Lg. Figure 4 shows the results of analyzing noncentrifuged solutions, which contain both fibril and nonfibril material, whereas only the fibril fraction (the pellet) was analyzed in Figure 6. All pellet samples contained only peptides, indicating that the building blocks of fibrils were

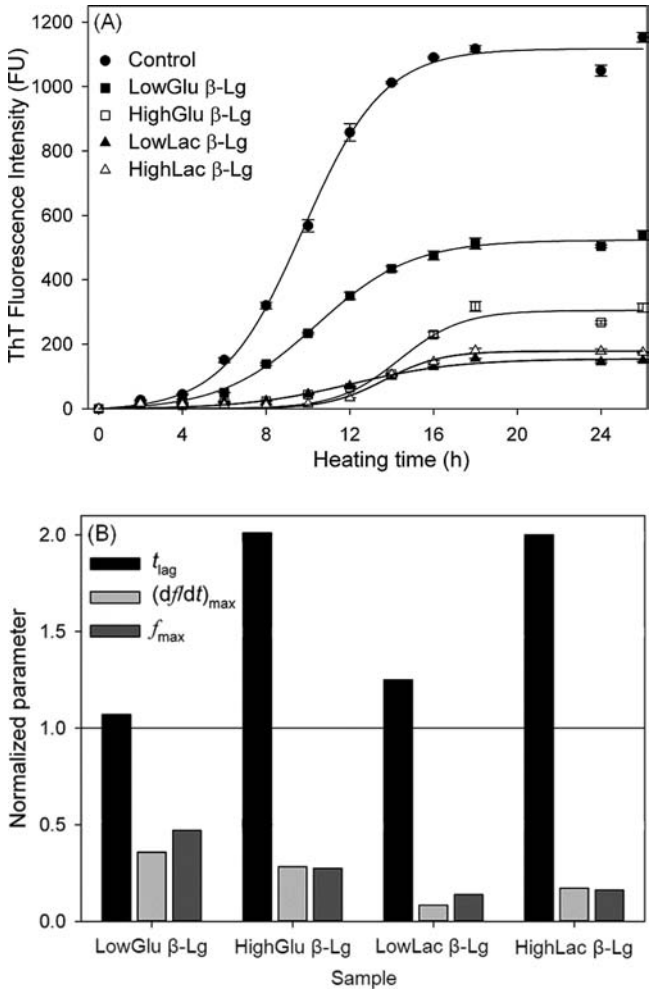

Figure 5. Self-assembly from glycated β-Lg. (A) Thioflavin T fluorescence intensity of control and glycated β-lg (1%, w/v) during heating at pH 2 and 80 °C. Each data point is an average of triplicates from two independent experiments, and error bars are standard errors. Solid lines indicate the fit to eq 1. (B) Normalized parameters of self-assembly calculated from eqs 2–4. The kinetic parameters of individual samples were normalized by those of the control sample.

predominantly peptides under the conditions used here (1% (w/v) protein, pH 2, heating at 80 °C). The unmodified control β-Lg showed seven peptide bands. The same bands appeared in all glycated samples, but they were less distinct in glycated samples and showed slightly reduced mobility, indicating that these peptides may be glycated. The lighter overall intensity in LowLac β-Lg and HighLac β-Lg lanes may result from lower fibril yields (Figure 5).

Morphology of Fibrils. The morphology of fibrils from glycated β-Lg was examined by TEM (Figure 7). The morphology of the fibrils was unaffected by glycation. The fibrils appeared long, straight, and unbranched, similar to those in unmodified β-Lg (Figure S9, Supporting Information), irrespective of glucosylation or lactosylation. Furthermore, all samples showed both long and short fibrils.

DISCUSSION

The CD studies showed that glucosylation and lactosylation had only very minor effects on the native structure of β-Lg. The structural changes in β-Lg upon heating were very fast, and CD results did not show differences between control and/or

Table 2. Kinetic Parameters Describing β-Lg Self-Assembly Calculated Using Eqs 1−4

sample details	t_{lag} (h)	$(df/dt)_{max}$ (FU·h^{-1})	$t_{1/2max}$ (h)	f_{max} (FU)
control	5.6 (0.2)[b]	158.0 (8.4)	9.1 (0.1)	1117 (16.0)
LowGlu β-Lg[a]	6.0 (0.2)	56.0 (2.9)	10.7 (0.2)	523 (6.7)
HighGlu-β-Lg	11.3 (0.7)	51.0 (10.7)	14.3 (0.4)	305 (17.0)
LowLac β-Lg[a]	7.0 (0.8)	15.5 (2.0)	12.0 (0.5)	155 (7.0)
HighLac β-Lg	11.0 (0.4)	32.7 (4.8)	13.8 (0.3)	178 (6.0)

[a]The degrees of glycation in LowGlu and LowLac β-Lg were similar. [b]Numbers in parentheses indicate standard deviations.

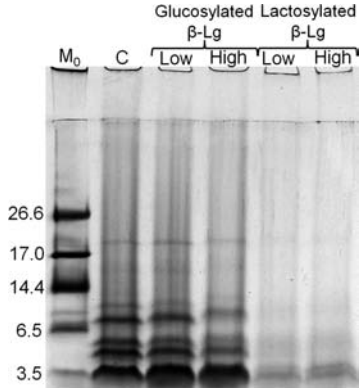

Figure 6. Tricine SDS−PAGE profiles of centrifugally precipitated fibrils made by heating glycated β-lg at 80 °C for 24 h. Key: M_0, molecular mass markers (kDa); C, nonglycated control fibrils made with the same heat treatment.

glycated samples. However, the CD method used in this study took 40−60 s to collect a spectrum, which meant that the temporal resolution was not high enough to detect subtle changes in the kinetics of unfolding. More targeted scanning of only selected wavelengths would be faster and could potentially quantify the rate of unfolding with higher precision. An innate limitation of this method is that structural changes take place during the heating of the sample to 80 °C, thus making it impossible to define an accurate $t = 0$.

Glycation produced a consistent ∼15% decrease in k_h, which we are unable to explain. However, the proportion of unhydrolyzed β-Lg monomer at any one time ("I/I_0" in Figure S5, Supporting Information) never spanned more than 10 percentage points across all treatments. Thus, glycation had a minor impact on the amount of hydrolyzed material present, and the effects of glycation on fibril formation were primarily at the self-assembly stage.

Glycation of the lysine residues on β-Lg would reduce the net charge at pH 2 by +1 per lysine, and a charge reduction alone would be expected to increase the rate of self-assembly by reducing the electrostatic repulsion between peptides. However, glycation always reduced the rate of peptide self-assembly, indicating that the charge reduction effect was counterbalanced by a more dominant assembly-inhibiting factor.

Using succinylated ovalbumin, Weijers et al.[50] have shown that the net charge on the protein influences the morphology of its aggregates. However, glycation of β-lg did not appear to modify the fibril morphology (Figure 7), even though MS spectra and SDS−PAGE patterns indicated that the fibrils must be composed of glycated peptides.

The kinetic parameters shown in Table 1 and Figure 5 reveal some important details about the effects of glycation on self-assembly. The rate of nucleation (related to t_{lag}) was largely unaffected in LowGlu and LowLac β-Lg, which had a similar number of lysine residues modified (Figure 1). The longer t_{lag} values for HighGlu β-Lg and HighLac β-Lg suggest that the amount of glycation had to reach a threshold before nucleation was adversely affected, and the size of the adduct had no effect. In contrast, fibril growth (related to $(df/dt)_{max}$) was affected by even low levels of glucosylation or lactosylation, and this effect was stronger for lactosylation than for glucosylation. In the stationary phase, increasing glucosylation progressively decreased the fibril yield (i.e., f_{max}), whereas even a small amount of lactosylation dramatically reduced the yield. Lactose is approximately twice the size of glucose, and the stronger impact of lactose on the growth kinetics and yield indicates that the effects of glycation on self-assembly are related to the size of the sugar residue.

Steric hindrance from bound sugar residues is thought to inhibit whey protein aggregation at pH 7,[37,38] and it is likely that glycation inhibited self-assembly of peptides at pH 2 by a similar mechanism. The spacing between adjacent β-strands in an amyloid fibril is on the order of 4.87 Å.[51] The hydrodynamic diameters of glucose and lactose molecules in solution are 7 and 9 Å, respectively,[52] so these adducts would certainly disrupt β-strand packing and thereby inhibit fibril assembly. In addition, the hydrophilic −OH side groups of sugar residues may interfere with hydrophobic interactions between fibril-forming peptides, which contain many hydrophobic residues.[18,20]

Glycation appears to reduce or abolish the ability of peptides to self-assemble, and glycated peptides may instead undergo further hydrolysis and/or may assemble into nonfibril aggregates,[53] reducing the potential yield of fibrils. A schematic illustrating our hypothesis is shown in Figure 8.

It may be questioned why fibril growth was sensitive to low levels of glycation, whereas nucleation was affected only by high levels of glycation. The answer lies in considering that the susceptibility of lysine residues to glycation varies from site to site. At shorter glycation times, lysines 47, 91, and 100 are preferentially glycated.[26,27,29] With an average of three bound sugar residues in LowGlu β-Lg and LowLac β-Lg (Figure1A,C), it is likely that these lysine residues were glycated. More extensive glycation in HighGlu and HighLac would also affect amine groups in the N-terminal region (Lys8 and Lys14 and the N-terminal amine). We suggest the N-terminal region containing these late-glycating lysines may be the main region involved in nucleation, whereas regions containing lysines that are preferentially glycated first are involved mainly in fibril growth.

This work has shown that even heavily glucosylated or lactosylated β-Lg retains the secondary and tertiary structures of native unglycated β-Lg. However, the steric constraints introduced by glycation substantially inhibit the self-assembly of glycated β-Lg fragments into fibrils, the effect being greater for the larger lactose moiety, even though the extent of lactosylation was smaller than that of glucosylation. We

propose that the inhibitory effect of glycation is influenced by the location of glycated residues, which is related to the varying glycation susceptibility of different lysine residues in the natively folded protein.

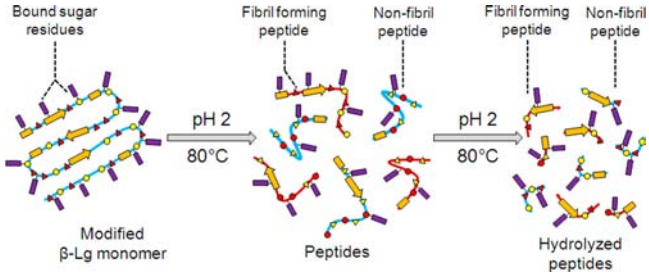

Figure 8. Proposed mechanism of inhibition of self-assembly of glycated β-Lg by the steric effect of the sugar adduct.

flavor. Therefore, low-alcohol or alcohol-free beers produced by the technologies applied up to now will at best reach only approximately the high sensory quality of a "normal" beer. Nevertheless, these beers make up distinctive, high-quality products, which have earned significance in the market.[21]

The sensory quality of beer depends on the complex balance of flavor-active components. In many cases, the dealcoholization could negatively affect the organoleptic quality of beer, leading in some cases to the unacceptability of the product. The low-alcohol and alcohol-free beers are required to meet certain quality conditions regarding their stability and sensory features, which should be comparable to those of normal beers. It is likely that the sensory qualities of the beer will change over the course of the dealcoholization, where a loss of aroma, body, and flavor can be seen.[22] A reduced foaming property (especially foam head retention) is another drawback. This issue is also related to the lack of ethanol, which improves foamability and foam stability in the range of 1−3.5% v/v.[23] In any case, the addition of glycerol or other sugar alcohols can reinforce the foaming properties of beer.[24,25]

Principle of Osmotic Distillation. Osmotic distillation (OD) or evaporative pertraction (EP) is a membrane process used for removing ethanol from beverages, especially for wine partial dealcoholization. This membrane technology has been presented as a novel and promising technology to reduce the ethanol content in alcoholic beverages without unacceptably altering the organoleptic properties of the product.[26,27] OD uses hydrophobic porous membrane contactors to provide the ethanol transfer from beer to stripping solution (usually water). In this process water and beer flow countercurrently. The mechanism is similar to membrane distillation,[28] but in this case, the process is carried out at ambient temperature,[26] in which the partial pressure gradient due to the high relative volatility compared to water is the driving force for ethanol transport. Due to this mechanism the OD has also been defined "isothermal membrane distillation"[29] and in some specific cases, such as dealcoholization, the term evaporative pertraction is more precise.[30] OD is a form of dialysis, in which a liquid mixture containing a volatile component is contacted with a microporous, non-liquid-wettable membrane whose opposite surface is exposed to a second liquid phase capable of absorbing that component. The most important difference compared to more common liquid−liquid contacting processes (such as reverse osmosis) is the membrane's composition, which is porous and hydrophobic and typically made of PTFE or polypropylene.[31] The most important advantages of the membrane contactors are well-defined and constant interfacial area, high interfacial area in small volumes, small size and weight, no dispersion between phases, no need of phase separation downstream, no need to work with fluids of different densities, no flooding, loading, or foaming, wide range of operating flow-rates, flow-rates can be varied independently, and lower operating temperatures compared to distillation processes. The most important drawbacks are membrane fouling, pressure drop caused by the membrane unit, membrane lifetime, and a high stripping solution volume requirement.[32−35] The transport mechanism of ethanol by OD process can be divided into three steps: (i) evaporation of ethanol at the membrane pores on the feed side, (ii) diffusion of ethanol vapor through the membrane pores, and (iii) condensation of ethanol vapor in the stripping solution at the membrane pore exit.[36] The aim of this work was to investigate both theoretically and experimentally the effects of the different process parameters. The operating parameters which affect the

ethanol content, such as flow rate, system temperature, and types of stripping solutions, were investigated. Furthermore, the quality parameters (present gravity, pH, color, turbidity, total soluble nitrogen, CO_2) and the losses of volatile compounds of the beer were also monitored.

MATERIALS AND METHODS

Alcoholic beers of five different commercial brands were obtained. The alcoholic beers contained between 3.5% and 5% v/v. The dealcoholization tests were carried out by a small pilot plant equipped with a polypropylene hollow fiber membrane contactor (Liqui-Cel, MiniModule 1.7 × 5.5, Membrana GmbH, Wuppertal, Germany) (Figure 1). The typical membrane surface area was 0.54 m^2, with an approximate priming volume of 78 and 53 mL, for shellside and tubeside, respectively. For the first trials the membrane operating parameters were as follows: beer inlet pressure 0.3 bar gauge, beer outlet zero pressure (atmospheric), water inlet pressure 0.3 bar gauge, water outlet zero pressure, beer flow 500 mL min^{-1}, and water flow 500 mL min^{-1}. These parameters were subsequently adjusted in an experimental matrix to ascertain optimum process (below). The ethanol content of the beers and all quality parameters were determined in accordance with Analytica EBC.[37]

The aromatic profile of the beer and corresponding dealcoholized beer was analyzed by gas chromatography (Perkin-Elmer, Auto System XL, Waltham, MA). The chemical standards (acetaldehyde, *n*-propanol, 2-methyl-1-butanol, 3-methyl-1-butanol, ethyl acetate, isoamyl acetate, ethyl hexanoate, diacetyl) used for the identification and quantification of the volatile compounds of interest were purchased from Sigma-Aldrich (Milwaukee, WI). The internal standard for the determination of aldehydes and vicinal diketones, 2-chlorobenzaldehyde (Sigma-Aldrich, Milwaukee, WI), was prepared weekly in a solution of 5% ethanol with a concentration of 10 mg L^{-1}. The internal standard for determination of ethanol, higher alcohols, and esters was 1-butanol (Sigma-Aldrich, Milwaukee, WI), which was prepared weekly in water with a concentration of 60 mg L^{-1}. The gas chromatograph was equipped with an electron capture detector (ECD) for the analysis of vicinal diketones (diacetyl and 2,3-pentanedione) and with a flame ionization detector (FID) for the analysis of the other volatile compounds.The separation column was a CP-WAX 57CB wall coated open tubular (WCOT) fused silica column (polyethylene glycol stationary phase, 60 m × 0.25 mm i.d. with 0.4 μm film thickness; Chrompack, Netherlands). Ten mL of the beer samples was added to 500 μL of internal standard 2-chlorobenzaldehyde (10 mg L^{-1}) and 1 mL of the internal standard 1-butanol (60 mg L^{-1}) in a 20-mL glass vial, which was heated for 30 min at 60 °C and stirred at 250 rpm for 30 s of every minute in order to allow the volatilization and derivatization of the compounds of interest. The injection was performed by means of a 2.5-mL headspace syringe at 70 °C. The syringe was placed in the sample headspace to draw the volatile compounds and to inject them in the gas chromatograph. The injection volume was 1 mL. The front inlet temperature was 150 °C. The injection was in the splitless mode with the purge valve set at 20 mL min^{-1}. Helium was the carrier gas at a flow rate of 1.1 mL min^{-1}. The oven temperature program used was 34 °C for 2 min, followed by an increase of 45 °C min^{-1} up to 55 °C, the held for 8 min, then raised to 98 °C at 5 °C min^{-1}, and finally increased to 150 °C at 45 °C min^{-1}. The detector temperature was 200 °C.

Experimental Section. A series of experiments was performed to ascertain optimum operation of the process. The feed and stripping solutions were fed into the module by peristaltic pumps. The process temperature was controlled by a water bath fitted with temperature controllers. Six pressure gauges for inlet and outlet were installed for monitoring the pressure of the feed and stripping solutions. During processes, the beer continuously circulated from a sealed container to the dealcoholization apparatus while water flowed counter-currently on the other side of the membrane (Figure 1). Beer ethanol content was monitored throughout the process until the target level was achieved.

Experimental Conditions. The beer feed was maintained at 10, 15, or 20 °C in separate trials, in order to investigate the effect of temperature changing on separation efficiency. During these trials, the stripping water temperature was kept at 10 °C. Similarly, different amounts of stripping solution, 3, 4, 5, or 6 L were employed in separate trials, while the beer volume was 1 L for each trial. Furthermore, the effects of types of stripping solution, i.e. normal pure water and carbonated water, were investigated. Moreover, different flow rates of stripping solution were tested, namely 500 mL min^{-1} and 1 L min^{-1}. Finally, different beer brands were employed to ascertain the effect of variations in e.g. membrane fouling, different volatile concentrations, etc.

Membrane Cleaning. After dealcoholization, the membrane was cleaned by flowing filtered and deionized water in tubeside and in shellside without recycling for 15 min. Subsequently, a 0.5% (w/w) and 30 °C NaOH solution was circulated for 30 min. Finally, the system was rinsed with RO water without recycling for 10 min and then it was dried in both tube and shell side by using nitrogen gas for 20 min according to manufacturer cleaning guidelines.

RESULTS AND DISCUSSION

Different Stripping Solution Volumes. The effect of the different ratios of stripping solution (deaerated water) to beer

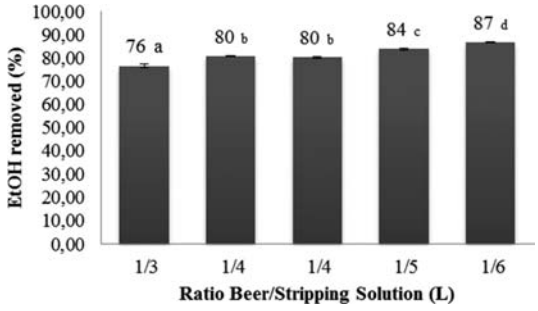

Figure 2. Percent of ethanol removed using different ratios of beer/stripping solution (% of original amount) after 4 h processing. Values with different superscript letters are statistically different ($P < 0.05$).

feed in terms of ethanol flow transfer rate (mL min^{-1}) and in terms of percentage of ethanol removed (%) was measured. The different stripping solution volumes (3, 4, 5, and 6 L) noticeably influenced the percentage ethanol removed as shown in Figures 2 and 3. The matrix of experiments also included varying the feed beer temperature. The beer temperature (10 and 20 °C) did not significantly change the ethanol transfer rate and ethanol removed (Figure 3). Furthermore, Figure 3 shows that the process was essentially finished after 2 h; hence, it was

not necessary to run it for 4 h. As well as the ethanol, the increase of the stripping solution quantity caused a diminution of volatile compounds concentration at the end of treatment (Table 1). The quality parameters monitored did not change significantly (Table 2), except for carbon dioxide, which was decreased considerably, and turbidity, which was increased slightly after dealcoholization.

Different Stripping Solution. The effect of different kinds of stripping solution was studied in this part of the work. Carbonated water (CW) was compared with normal deaerated water (DW) in order to reduce the loss of carbon dioxide by the end of the process. If possible, the stripping solution was pure water, which had been previously deoxygenated by boiling and/or flushing with a gas, usually nitrogen. In other words, if the stripping solution is similar to beer from a compositional point of view (especially in the case of carbon dioxide and low oxygen content), the pressure gradient between carbon dioxide in the beer and in the stripping solution would be minimal, preventing its diffusion across the membrane.[28] The amount of alcohol removed was the same with both strip solutions (Figure 4). On the contrary, the carbonation initially appeared to restrict ethanol transfer as shown in Figure 5 (mechanism

unknown), but at the end of the process no difference was found. This would be explained by the equilibrium being reached between the beer and stripping solution. In other words, the ethanol concentration became the same in both beer and stripping solution. As expected, low-alcohol beer obtained using CW showed about 2 g L^{-1} of carbon dioxide, whereas the process with normal deaerated water resulted in about 0.4 g L^{-1} in each trial. The results showed that the use of carbonated water is a viable option to reduce the carbon dioxide loss, allowing a low-alcohol beer with an acceptable carbon dioxide concentration. In these experiments the final carbon dioxide level, even when carbonated water was employed as stripping solution, was low compared to a typical specification for beer, and it would have been necessary to add more before packaging in a commercial process. On the other hand, the employment of stripping solutions with higher concentrations of carbon dioxide may have resolved the problem. Concerning the most important volatile compounds, no significant difference was found when using CW or DW (i.e., similar losses) (Tables 3 and 4).

Effect of Stripping Solution Flow Rate. The effects of the stripping solution flow rate on the ethanol decrease are shown in Figure 6. In this case two different flow rates were employed: first 500 mL min^{-1} for feed and stripping solution, second 500 mL min^{-1} of feed solution and 1000 mL min^{-1} of stripping solution. A similar study was performed by Liguori et al. [38] That work showed that when increasing the stripping flow rate from 1.2 to 2.4 mL min^{-1}, a more rapid decrease in ethanol content was observed. In this case no significant effect was observed as shown in Figures 6 and 7. Figure 7 was in agreement with Diban,[30] confirming that flow rate has little influence on mass transfer resistance because the transmembrane resistance was the limiting stage in this transport mechanism. The volatile compounds and quality parameters did not change significantly when different stripping solution flow rates were employed (Tables 5 and 6).

Feed Solution and Stripping Solution Inversion. In the trials above, the stripping solution flowed in the shellside so that the beer flowed tubeside. In the following trials these operating conditions were inverted so that the beer flowed shellside and stripping solution flowed tubeside. In this dealcoholization trial 83% of ethanol was removed instead of 79% when it was used with beer tubeside (Figures 8 and 9). Thus, the beer shellside and water tubeside could be a better option. More significantly, the ethanol results after 30, 60 and

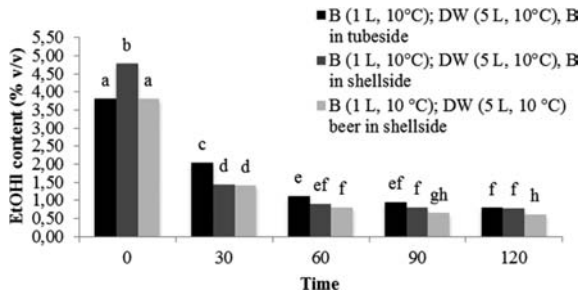

Figure 9. Decreasing ethanol during dealcoholization using different flowsides (B: beer; DW: deaerated water, CW: carbonated water). Values with different superscript letters are statistically different ($P < 0.05$).

90 min suggested that the ethanol was being removed more quickly with the beer shellside. Equilibrium may be achieved more quickly, making the process more efficient and cost-effective. With regard to the volatile compounds a larger amount of isoamyl and ethyl acetate was lost with beer in tubeside, while other compounds exhibited no significant differences (Table 7). These findings appeared to be similar to the performance of reverse osmosis when applied to dealcoholization in terms of ethanol, *n*-propanol, and esters removal (Table 8). Osmotic distillation appeared to compare favorably with vacuum distillation, which is a commonly employed dealcoholization technique and also the process with the highest ethanol and volatile compounds removal.

However, as shown in Table 8, for all dealcoholization techniques surveyed substantial losses of volatile compounds occurred, which would have had a significant effect on the flavor. However, OD compared favorably with alternative techniques such as dialysis, vacuum distillation, falling film evaporation, and reverse osmosis (Table 8).

Operating Cost Examination. A cost examination was performed in order to appraise OD as an economically viable technique. It was assumed an annual production of 100 000 hL of a low-alcohol beer with the initial ethanol content of 4.5 and a final one of 0.5% v/v. The finished plant cost (pumps, pipes, valves) emerged directly from a request for a quotation by a manufacturer, which is approximately 340 000 €, Thus, considering the plant amortization over 10 years, the annual plant cost is 34 000 €, with a cost of 0.0034 € L^{-1} of produced beer. The membrane replacement cost, assuming a membrane life of 2 years, is approximately 25 000 € per year. Membrane cost information was obtained from a private company specializing in membrane production. Finally, assuming United Kingdom industrial energy unit cost of 0.09895 € kW h^{-1}, the estimated energy cost was about 0.00021 € L^{-1} (www.energy.eu). Regarding water cost, supposing a unit water cost in United Kingdom of 1.9 € m^{-3}, the value produced is approximately 0.0114 € L^{-1}, including water required for processing and cleaning. Regarding manpower, this is always an estimate because of a wide variability across the European Member States, where the average labor cost is 23.50 € h^{-1} (Eurostat, 2013). Although membrane plants have a low requirement for supervision compared to many processes, it is important to take into account membrane maintenance, cleaning, and controlling. It could be right to consider one person per day, in this case the manpower cost would be about 50 000 € $year^{-1}$. Operating costs, investment, and membrane replacement costs could be problems that inhibit the commercialization. Improved profitability could be reached with a few process improvements such as employing sparkling and flavored water as stripping solution, thereby generating another valuable product stream.

The process settings and control was relatively simple, as well as membrane and plant cleaning. A membrane unit setup with the beer on the shellside resulted in the most efficient ethanol removal (Tables 7 and 8, Figures 8 and 9), whereas employing different temperatures and different stripping solution flow

rates did not result in improved performance. A significant decrease in the concentration of beer volatile compounds was measured after dealcoholization in all experiments, demonstrating that the volatile compounds loss is directly related to the ethanol percentage removal. This is in accordance with other studies on alcoholic beverages dealcoholization.[29,38,43−45] Furthermore, it is crucial to focus on stripping solution, which is slightly alcoholic (in this case in the range of 0.5−1% v/v) and flavored after the dealcoholization of the original beer stream. Therefore, it could be reusable in the brewing process, for instance for high gravity dilution, as brewing liquor into the mashing, sparging, or whirlpool phase, or even as a new innovative product, for example, as flavored water with a small amount of alcohol.

In this experimental work some important characteristics of the beer were not analyzed, such as the foam stability and the evaluation of flavor by trained panel, two crucial attributes and often considered weak points of low-alcohol beers. Anyway, this study was primarily proof of feasibility of the OD to produce low-alcohol beer, where the behavior of the membrane about removal of ethanol in response to the variation of process parameters was investigated. However, this data collection will be taken into account in the next step, in order to give more and more information on this method of dealcoholization.

10	2.0	1.5	15	0.1	98	0:100 0:0:43:57

[a] D-Glucose (300 mg), TCT (1.5 or 2.0 equiv), DMSO (1.5, 8.5, 17, 25.5, or 34 equiv), MeOH (2, 3, 4, 5, or 15 mL), 0.5 h (entries 9 and 10) or 6 h (entries 1−8), 25 °C. [b] Isolated yield. [c] Determined by ^{13}C NMR analysis.

quantitative yield, and the α and β isomers were about equally formed (Table 1, entries 1−4). Reducing the concentrations of DMSO to 4.3 or 1.7 equiv/mL resulted in an increase in the amounts of furanoside **3** to 22, 16, 43, or 42% (Table 1, entries 5−8). Further decreasing the concentration of DMSO to 0.1 equiv/mL led to the formation of furanoside in nearly quantitative yields (Table 1, entries 9 and 10). When the amount of TCT was changed from 1.5 to 2.0 equiv, the α/β ratio changed from 62:38 to 43:57. The reaction time for the pyranoside was 6 h, and that for furanoside was 0.5 h.

After the above optimization, the yields for both methyl D-glucopyranoside **2** and D-glucofuranoside **3** were nearly quantitative. The reaction yield of acetone and sugar for 1,2:5,6-di-isopropylidene-α-D-glucofuranose is >90%. For the other currently used preparation methods, the highest reported yields for D-glucofuranoside are all <80%,[7,11,20] and these products have to be separated from their isomer glucopyranoside (produced in >20% yield). The reason that **2** and **3** can be separately synthesized as the sole product with this method is probably because methanol is more polar than DMSO, and presumably when the concentration of DMSO in methanol is lower, the reaction medium is more polar and the D-glucose exists in the furanose form. In contrast, when the concentration of DMSO is higher, D-glucose exists in the pyranose form.

To validate this assumption, ^{13}C NMR analysis of the D-glucose in 3, 17, and 170 equiv of DMSO-d_6 in CD_3OD was performed. With 170 equiv of DMSO-d_6, the ^{13}C NMR spectrum revealed two hemiacetal isomers in a 13:87 ratio (Table 2, entry 2). After the addition of 0.1 equiv of TCT, only α-D-glucopyranose existed. No detectable amounts of methyl glucoside were formed within 15 min (Table 2, entry 3). With 3 equiv of DMSO-d_6, the ^{13}C NMR spectrum showed two hemiacetal isomers in a 10:90 ratio (Table 2, entry 4). Five minutes after the addition of 0.1 equiv of TCT, there were two isomers and methyl α-D-glucofuranoside in a 7:59:34 ratio (methyl α-D-glucofuranoside, β-D-glucopyranose, α-D-glucopyranose; Table 2, entry 5). This agrees with the fact that the formation rate of furanoside is higher than that of pyranoside.[1,21] With 17 equiv of DMSO-d_6, the ^{13}C NMR spectrum indicated the existence of four hemiacetal isomers in a 3:8:31:58 ratio

Table 2. ^{13}C NMR Analysis of D-Glucose Isomers at Difference Concentration of DMSO-d_6 in CD_3OD at 25 °C

entry	concn[a]	no. of major isomers	C_1 (ppm) (ratio)
1	340	2	92.15, 92.05 (38:62)
2	170	1	92.12, 92.02 (13:87)
3	170 + TCT[b]	1	92.04
4	3	1	95.51, 91.25 (10:90)
5	3 + TCT[b]	2	99.49, 91.27, 91.23 (7:59:34)[c]
6	1.5	1	94.00
7	17	2	95.56, 95.48, 91.31, 91.32 (3:8:31:58)[d]
8	17 + TCT[b]	2	95.48, 91.24 (53:47)

[a]Concn, concentration of DMSO-d_6 in CD_3OD (equiv/mL). [b]TCT = 0.1 equiv. [c]Methyl α-D-glucofuranoside:β-D-glucopyranose:α-D-glucopyranose. [d]β-D-Glucofuranose:α-D-glucofuranose:β-D-glucopyranose:α-D-glucopyranose.

(β-D-glucofuranose, α-D-glucofuranose, β-D-glucopyranose, α-D-glucopyranose; Table 2, entry 7). These are probably the four possible isomers of D-glucose. Five minutes after the addition of 0.1 equiv of TCT, there are two major isomers in a 53:47 ratio (Table 2, entry 8). This is in agreement with the fact that methyl pyranoside and furanoside were formed in roughly the same amounts (Table 1, entries 7 and 8). The isomer numbers indicated by the ^{13}C NMR analysis with 170, 17, and 3 equiv of DMSO-d_6 correlate well with the major product numbers from Table 1, entries 1, 2, and 7−10. Further increasing the concentration of DMSO-d_6 in CD_3OD to 340 equiv exhibited ^{13}C NMR signals of two isomers and decreasing that to 1.5 equiv exhibited ^{13}C NMR signals of one isomer. This again indicates that the equilibrium between pyranose and furanose is related to the solvent ratio (Table 2, entries 1 and 6). A literature survey indicates that the NMR analysis of D-glucopyranose could be performed in D_2O,[22−26] dioxane-d_8,[27] and DMSO-d_6[28] and that for D-glucofuranose in D_2O.[29,30] It is known that D-glucopyranose is dominant in aqueous solution.[31,32]

To further verify the assumption that the ratio of pyranose to furanose is controlled by the polarities of the solvents, other alcohols were used in place of methanol as the solvent. For the ethylation of glucose, 8.5, 17, and 25.5 equiv of DMSO in EtOH were used as 0.1equiv of DMSO in EtOH resulted in a poor yield. As expected, the D-glucopyranosides of the other alcohols were readily obtained as the sole product (Table 3, entries 1−12). However, the D-glucofuranosides could not be synthesized as the sole product. The proportions of the D-glucofuranosides decreased from 10 to 0% as the acceptor alcohols increased in carbon number from ethanol to *n*-pentanol with 1.7 equiv of DMSO (Table 3, entries 3, 6, 9, and 12). These results indicate that the solvent polarity is critical to the ratio of furanoside and pyranoside because all of these higher alcohols are less polar than methanol. Alkyl furanosides have been synthesized as the major products in solvents less polar than methanol, which has been attributed to metal complexions with the sugars because these glycosylation are often catalyzed by metal salts.[20]
