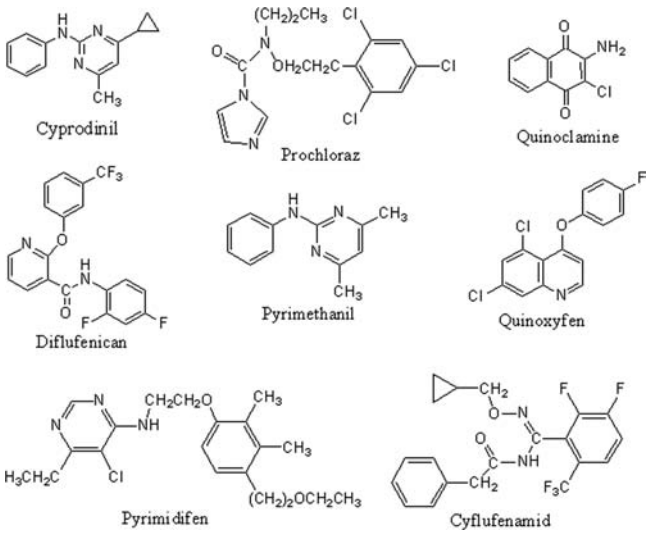

Figure 4. Chemical structures of eight compounds with low recoveries.

The validation parameters of the method in terms of analytical range, precision, recovery, and trueness showed that the proposed method meets the requirements for pesticide analysis. These findings are important for pesticide analysis at trace levels for sample cleanup. This method is expected to be widely applied for monitoring of pesticides at trace levels in the future for various agricultural commodities. The results confirm the feasibility of the proposed method, which can be easily implemented for routine testing and monitoring of pesticide residues in tomato products

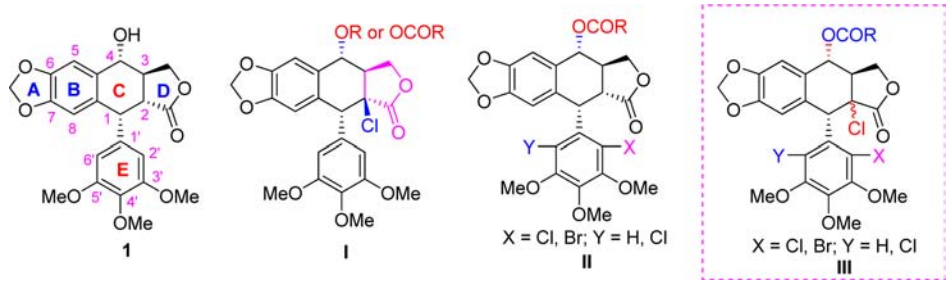

Figure 1. Chemical structures of podophyllotoxin (**1**) and its derivatives (**I**–**III**).

MATERIALS AND METHODS

General. All chemical reagents were commercially available, and solvents were purified with standard methods[31] before use. Analytical thin-layer chromatography (TLC) and preparative thin-layer chromatography (PTLC) were performed with silica gel plates using silica gel 60 GF_{254} (Qingdao Haiyang Chemical Co., Ltd. Qingdao, China), and the solvent system was a mixture of ethyl acetate and petroleum ether. Melting points were carried out on an XT-4 digital melting-point apparatus (Beijing Tech Instrument Co., Ltd., Beijing, China) and were uncorrected. Proton nuclear magnetic resonance spectra (^{1}H NMR) and carbon nuclear magnetic resonance spectra (^{13}C NMR) were recorded in $CDCl_3$ on a Bruker Avance 400 or 500 MHz instrument using tetramethylsilane (TMS) as the internal standard. High-resolution mass spectra (HR-MS) were carried out with an IonSpec 4.7 T FTMS instrument. 2′-Chloropodophyllotoxin (**2a**, 85% yield), 2′,6′-dichloropodophyllotoxin (**2b**, 90% yield), and 2′-bromopodophyllotoxin (**2c**, 85% yield) were prepared in the same way as in our previous paper.[30]

Stereoselective Synthesis of 2α-Chloro-2′(2′,6′)-(di)-halogenopicropodophyllotoxin Derivatives (5a–c). Two drops of phosphorus oxychloride were added to a solution of **2a**, **2b**, or **2c** (1.8 mmol) in dihydropyran (10 mL). Then the mixture was stirred at room temperature. After 2 h, the mixture was poured into ice-cold petroleum ether (100 mL) and vigorously stirred. The resulting solids were collected and dissolved in CH_2Cl_2 (50 mL). The corresponding solution was washed by water (25 mL × 2), dried over anhydrous Na_2SO_4, concentrated in vacuo, and purified by silica gel column chromatography to give products **3a** (89% yield), **3b** (78% yield), or **3c** (85% yield). To a solution of lithium diisopropylamide (LDA, 0.6 mmol) in dry tetrahydrofuran (THF, 5 mL) at −78 °C under N_2 was then added dropwise a solution of **3a**, **3b**, or **3c** (0.5 mmol) in dry THF (5 mL) for 10 min. After the addition, the reaction mixture was stirred for 15 min, and a solution of hexachloroethane (C_2Cl_6, 0.7 mmol) in dry THF (5 mL) was added dropwise for 10 min. Subsequently, the solution was allowed to warm slowly from −78 °C to the ambient temperature. When the reaction was complete according to TLC analysis, the solvent was removed and the residue was diluted by CH_2Cl_2 (50 mL). The corresponding solution was washed by water (25 mL), 0.5 N aqueous HCl (25 mL), and water (25 mL), dried over anhydrous Na_2SO_4, and concentrated under reduced pressure to give the residue, which was used directly for the next step without further purification. A solution of the above residue in concentrated HCl/THF (1:9, v/v, 10 mL) was stirred for 2 h and then adjusted a pH value of 5 by using 5% aqueous Na_2CO_3. After removal of THF, the mixture was extracted with CH_2Cl_2 (40 mL × 3), and the combined organic phase was washed by 5% aqueous Na_2CO_3 (20 mL) and brine (20 mL), dried over anhydrous Na_2SO_4, concentrated in vacuo, and purified by silica gel column chromatography to give **5a** (68% yield), **5b** (62% yield), or **5c** (71% yield).

*Data for **5a**:* white solid; mp = 183–184 °C; $[\alpha]^{20}_D$ = −83 (*c* 3.1 mg/mL, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.07 (s, 1H, H-5), 6.74 (s, 1H, H-8), 6.62 (s, 1H, H-6′), 5.92 (dd, *J* = 5.2, 1.2 Hz, 2H, OCH_2O), 5.48 (s, 1H, H-1), 4.90 (d, *J* = 2.8 Hz, 1H, H-4), 4.81 (dd, *J* = 9.2, 4.8 Hz, 1H, H-11), 4.47 (d, *J* = 9.2 Hz, 1H, H-11), 3.93 (s, 3H, 3′-$OCHH_3$), 3.88 (s, 3H, 5′-$OCHH_3$), 3.73 (s, 3H, 4′-$OCHH_3$), 3.14–3.16 (m, 1H, H-3), 2.47 (s, 1H, OH); ^{13}C NMR (100 MHz, $CDCl_3$) δ 172.3, 152.1, 149.7, 148.7, 148.2, 142.5, 132.3, 129.7, 128.5, 121.5, 109.1, 107.4, 101.5, 73.5, 73.0, 67.0, 61.1, 61.0, 56.3, 50.7, 45.2; HRMS *m*/*z* calcd for $C_{22}H_{20}O_8Cl_2Na$ ([M + Na]$^+$) 505.0427, found 505.0428.

*Data for **5b**:* white solid; mp = 92–93 °C; $[\alpha]^{20}_D$ = −104 (*c* 3.9 mg/mL, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.04 (s, 1H, H-5), 6.13 (s, 1H, H-8), 5.99 (s, 1H, H-1), 5.90 (dd, *J* = 7.2, 1.2 Hz, 2H, OCH_2O), 4.82 (dd, *J* = 8.8, 3.6 Hz, 1H, H-11), 4.62 (d, *J* = 9.2 Hz, 1H, H-11), 4.43 (d, *J* = 9.2 Hz, 1H, H-4), 3.98 (s, 3H, 3′-$OCHH_3$), 3.96 (s, 3H, 5′-$OCHH_3$), 3.82 (s, 3H, 4′-$OCHH_3$), 3.16 (dd, *J* = 9.6, 3.6 Hz, 1H, H-3), 1.58 (s, 1H, OH); ^{13}C NMR (100 MHz, $CDCl_3$) δ 173.3, 149.4, 148.9, 147.7, 147.5, 147.3, 134.2, 129.6, 127.4, 127.2, 125.9, 107.6, 104.7, 101.3, 70.8, 69.0, 65.6, 61.3, 61.2, 61.1, 50.8, 44.1; HRMS *m*/*z* calcd for $C_{22}H_{19}O_8Cl_3Na$ ([M + Na]$^+$) 539.0037, found 538.0051.

*Data for **5c**:* white solid; mp = 170–172 °C; $[\alpha]^{20}_D$ = −94 (*c* 3.4 mg/mL, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 7.10 (s, 1H, H-5), 6.74 (s, 1H, H-8), 6.64 (s, 1H, H-6′), 5.91 (dd, *J* = 5.2, 1.2 Hz, 2H, OCH_2O), 5.56 (s, 1H, H-1), 4.89 (d, *J* = 2.8 Hz, 1H, H-4), 4.81 (dd, *J* = 9.2, 4.8 Hz, 1H, H-11), 4.47 (d, *J* = 9.2 Hz, 1H, H-11), 3.92 (s, 3H, 3′-$OCHH_3$), 3.88 (s, 3H, 5′-$OCHH_3$), 3.72 (s, 3H, 4′-$OCHH_3$), 3.14 (t, *J* = 4.0 Hz, 1H, H-3), 2.53 (s, 1H, OH); ^{13}C NMR (100 MHz, $CDCl_3$) δ 172.3, 152.8, 150.7, 148.6, 148.2, 142.4, 134.1, 129.8, 128.4, 113.1, 109.4, 108.9, 107.5, 101.5, 73.4, 73.1, 67.1, 61.0, 61.0, 56.4, 50.7, 47.8; HRMS *m*/*z* calcd for $C_{22}H_{20}O_8ClBrNa$ ([M + Na]$^+$) 548.9922, found 548.9906.

General Procedure for the Synthesis of 2α-Chloro-2′(2′,6′)-(di)halogenopicropodophyllotoxin Esters (6a–k, 7a–i, and 8a–h). A solution of compound **5a**, **5b**, or **5c** (0.15 mmol), the corresponding carboxylic acids RCO_2H (0.18 mmol), *N*,*N*′-dicyclohexylcarbodiimide (DCC, 0.18 mmol), and 4-*N*,*N*-dimethylaminopyridine (DMAP, 0.03 mmol) in dry CH_2Cl_2 (10 mL) was stirred at room temperature. When the reaction was complete as checked by TLC analysis, the solution of the mixture was diluted with CH_2Cl_2 (40 mL). Subsequently, the solution was washed by water (15 mL), 0.1 N aqueous HCl (25 mL), 5% aqueous Na_2CO_3 (25 mL), and brine (25 mL), dried over anhydrous Na_2SO_4, concentrated in vacuo, and purified by PTLC to give the target products **6a–k**, **7a–i**, and **8a–h**. The example data of **6a–c**, **7a–c**, and **8a–c** are shown as follows, whereas data of **6d–k**, **7d–i**, and **8d–h** can be found in the Supporting Information.

*Data for **6a**:* yield 82%; white solid; mp = 150–151 °C; $[\alpha]^{20}_D$ = −78 (*c* 3.5 mg/mL, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 6.68 (s, 1H, H-5), 6.64 (s, 1H, H-8), 6.58 (s, 1H, H-6′), 5.93–5.95 (m, 3H, H-4, OCH_2O), 5.52 (s, 1H, H-1), 4.80–4.81 (m, 2H, H-11), 3.94 (s, 3H, 3′−$OCHH_3$), 3.88 (s, 3H, 5′-$OCHH_3$), 3.76 (s, 3H, 4′-$OCHH_3$), 2.97–2.98 (m, 1H, H-3), 2.16 (s, 3H, $COCH_3$); ^{13}C NMR (125 MHz, $CDCl_3$) δ 171.9, 170.6, 152.0, 149.9, 149.2, 148.2, 142.6, 132.1, 130.8, 123.9, 122.0, 108.8, 108.6, 108.3, 101.7, 75.1, 73.2, 66.8, 61.1, 61.1, 56.1, 49.3, 44.7, 21.1; HRMS *m*/*z* calcd for $C_{24}H_{22}O_9Cl_2Na$ ([M + Na]$^+$) 547.0533, found 547.0529.

*Data for **6b**:* yield 78%; white solid; mp = 179–180 °C; $[\alpha]^{20}_D$ = −80 (*c* 2.9 mg/mL, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 6.67 (s, 1H, H-5), 6.62 (s, 1H, H-8), 6.57 (s, 1H, H-6′), 5.93–5.94 (m, 3H, OCH_2O, H-4), 5.51 (s, 1H, H-1), 4.80–4.81 (m, 2H, H-11), 3.93 (s, 3H, 3′-$OCHH_3$), 3.88 (s, 3H, 5′-$OCHH_3$), 3.75 (s, 3H, 4′-$OCHH_3$),

[a]Determined by ^{1}H NMR spectra.

group) were used. Acetone solutions of compounds **6a−k**, **7a−i**, and **8a−h** were prepared at the concentration of 1 mg/mL. Toosendanin was used as the positive control at 1 mg/mL. Fresh wheat leaves were dipped into the corresponding solution for 3 s, then taken out, and dried in a room. Leaves treated with acetone alone were used as a blank control group. Several treated leaves were kept in each dish (10 larvae were raised in each dish, and three dishes were used per treatment), which was then placed in a conditioned room (25 ± 2 °C, 65−80% relative humidity (RH), 12 h/12 h (light/dark) photoperiod). If the treated leaves were consumed, additional treated leaves were added to the dish. Forty-eight hours later, untreated fresh leaves were added to all dishes until adult emergence. The corrected mortality rate was assessed by the formula

$$\text{corrected mortality rate (\%)} = (T - C) \times 100/(100\% - C)$$

where T is the mortality rate in the tested compounds group and C is the mortality rate in the blank control group (T and C were expressed as percentages).

RESULTS AND DISCUSSION

Synthesis. As shown in Scheme 1, first, three halogenation products of **1** such as 2′-chloropodophyllotoxin (**2a**), 2′,6′-dichloropodophyllotoxin (**2b**), and 2′-bromopodophyllotoxin (**2c**) were smoothly prepared by the reaction of **1** with *N*-chlorosuccinimide (NCS) or *N*-bromosuccinimide (NBS).[30] Second, the 4-hydroxy group of **2a−c** was protected by a tetrahydropyranyl (THP) group in the presence of phosphorus oxychloride ($POCl_3$) and dihydropyran (DHP) to produce **3a−c**. Subsequently, as described in Table 1, compounds **3a−c** reacted with lithium diisopropylamide (LDA) at −78 °C via the intermediates **4a−c** (lithium enolates), followed by reaction with four different chlorination reagents, such as hexachloroethane (C_2Cl_6, **La**), NCS (**Lb**), 1,3-dichloro-5,5-dimethylhydantoin (**Lc**), and 1,3,5-trichloroisocyanuric acid (**Ld**), were investigated. The chlorination of **3a−c** with **La** stereoselectively afforded 2α-chloropicropodophyllotoxins (**5a−c**) in 62−71% yields (entries 1, 5, and 9), and the chlorination of **3a** with **La−c** stereoselectively gave **5a** in 56−68% yields (entries 1−3). Although chlorination of **3a** with **Lb** or **Lc** stereoselectively produced **5a**, chlorination of **3b** and **3c** with **Lb** or **Lc** gave mixtures of two isomers, **5b**/**5b′** (2β-chloro-2′,6′-dichloropodophyllotoxin) and **5c**/**5c′** (2β-chloro-2′-bromopodophyllotoxin) (entries 6, 7, 10, and 11), respectively. The ratio of **5b**/**5b′** or **5c**/**5c′** was determined by the corresponding ^{1}H NMR spectra (see the Supporting Information). However, chlorination of **3a−c** with **Ld** did not afford any products except the starting materials, even if the reaction time was prolonged to 24 h (entries 4, 8, and 12). Obviously, chlorination reagent **La** could be used to stereoselectively prepare **5a−c**. In our previous paper, we found when **1** reacted with **La** in the presence of LDA, 2β-chloropodophyllotoxin was stereoselectively obtained.[28,29] According to the above results, this suggested that besides their 2′-halogen-substituted E ring, stereoselective α-chlorination at the C-2 position of **3a−c** was also related to the chlorination reagents. The structures of **5a−c** were well characterized by ^{1}H NMR, ^{13}C NMR, HRMS, optical rotation, and mp. Moreover, the precise three-dimensional steric structures of **5b** and **5c** were further ascertained by single-crystal X-ray diffraction (Figures 2 and 3). This obviously demonstrated that the C-2 chlorine atoms of **5b** and **5c** were clearly present in α configuration. The configuration of **5a** was

dx.doi.org/10.1021/jf405316w | J. Agric. Food Chem. 2014, 62, 3726−3733

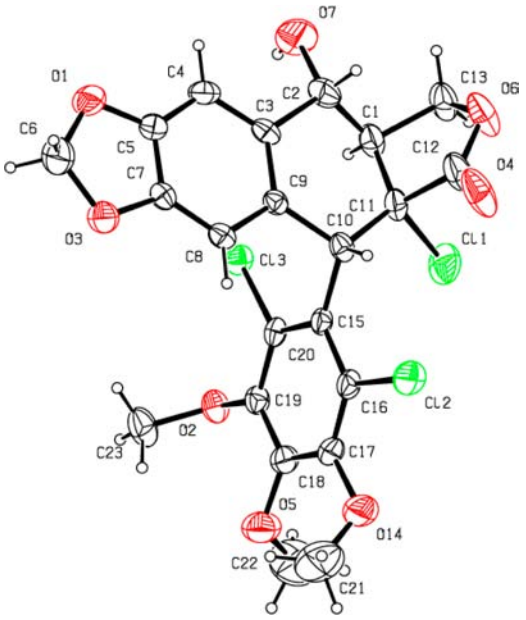

Figure 2. X-ray crystal structure of **5b**.

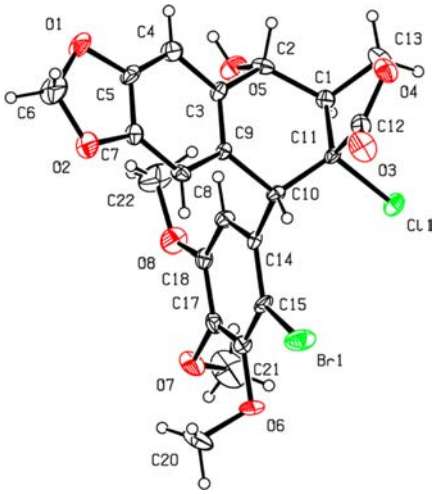

Figure 3. X-ray crystal structure of **5c**.

confirmed on the basis of the X-ray crystallography structure of its ester **6a** (see Figure 4), and the C-2 chlorine atom of **6a** adopted an α configuration. Therefore, the C-2 chlorine atom of **5a** should also adopt an α configuration. Finally, 2α-chloro-2′(2′,6′)-(di)halogenopicropodophyllotoxin esters (**6a**−**k**, **7a**−**i**, and **8a**−**h**) were afforded by reaction of **5a**, **5b**, or **5c** with the corresponding carboxylic acids (**9**) in the presence of *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 4-*N*,*N*-dimethylaminopyridine (DMAP) (Scheme 2). The structures of the title compounds were identified by ^{1}H NMR, ^{13}C NMR, HRMS, optical rotation, and mp. Crystallographic data (excluding structure factors) for the structures of three compounds, **5b**, **5c**, and **6a**, have been deposited at the Cambridge Crystallographic Data Centre with Data CCDC 918889, 918888, and 918696, respectively. These data can be obtained free of charge from the CCDC [fax +44 (0)1223 336033 or e-mail deposit@ccdc.cam.ac.uk].

Insecticidal Activity. The insecticidal activity of novel 2α-chloro-2′(2′,6′)-(di)halogenopicropodophyllotoxin esters (**6a**−**k**, **7a**−**i**, and **8a**−**h**) against the pre-third-instar larvae of *M. separata* was tested by the leaf-dipping method at 1 mg/mL. Toosendanin was used as the positive control at the concentration of 1 mg/mL. In general, we found that the mortality rates of *M. separata* caused by these derivatives after 35 days were higher than those after 10 and 20 days in the same way as in our previous studies,[28−30,32] As described in Table 2, foe **6e**, for instance, the corrected mortality rates against *M. separata* after 10 and 20 days were 10 and 43.3%, respectively, but after 35 days, the mortality rate was increased to 66.7%, which was >6 times that after 10 days. Meanwhile, the

[a]Toosendanin was used as a positive control at 1 mg/mL.

symptoms of *M. separata* in the treated groups were characterized; for example, at the larval stage some larvae with slim and wrinkled bodies were dying due to feeding too much on treated leaves during the first 48 h (Figure 5), some larvae were molting to malformed pupae or dying during the pupation period (Figure 6), and malformed moths were appearing with imperfect wings (Figure 7).[28−30,32] According to the above symptoms, the tested compounds probably exhibited the antimolting hormone effect. As shown in Table 2, nine compounds, **2a**, **2b**, **5c**, **6e**, **6f**, **7c**, **7g**, **8f**, and **8h**, displayed insecticidal activity equal to or higher than that of toosendanin. Among all of the derivatives, especially compounds **6e** and **8f** exhibited the most potent insecticidal activity with final mortality rates >60%. As in our previous studies,[29,30] introduction of a chlorine or bromine atom at the C-2′ or C-2′ and C-6′ position on the E ring or at the C-2 position of podophyllotoxin could lead to the more potent compounds **2a−c**, **5a**, and **5c** than their precursor podophyllotoxin, except

Figure 5. Representative abnormal larvae pictures of **6f**, **7c**, **7g**, **8f**, and **8h** during the larval period (CK, blank control group).

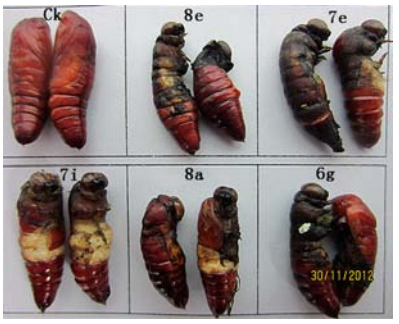

Figure 6. Representative malformed pupae pictures of **6g**, **7e**, **7i**, **8a**, and **8e** during the pupation period (CK, blank control group).

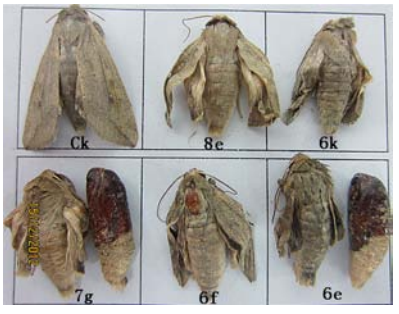

Figure 7. Representative malformed moth pictures of **6e**,**6f**,**6k**, **7g**, and **8e** during the emergence period (CK, blank control group).

5b. For 4α-(alkylacyl)oxy derivatives of **5a−c**, the effect of the length of their side chain at the C-4 position of the podophyllotoxin skeleton on the insecticidal activity was not very obvious (e.g., 37% for **6a**, 40.7% for **6b**, and 40.7% for **6k**; 33.3% for **7a** and 37% for **7b**; 44.4% for **8a** and 44.4% for **8b**). However, for 4α-(arylacyl)oxy derivatives of **5a**, introduction of the electron-withdrawing groups on their phenyl ring at the C-4 position of podophyllotoxin skeleton could lead to the potent compounds. For example, the final mortality rates of **6e** (R = Ph), **6f** (R = 2-ClPh), and **6g** (R = 3-ClPh) were 66.7, 55.6, and 48.1%, respectively, whereas the final mortality rate of **6h** (R = 3-MePh) was only 37%. For 4α-(arylacyl)oxy derivatives of **5c**, introduction of the electron-withdrawing or electron-denoting substituents on their phenyl ring at the C-4 position of podophyllotoxin skeleton could lead to the more potent compounds. For example, the final mortality rates of **8f** (R = 2-ClPh), **8g** (R = 3-ClPh), and **8h** (R = 3-MePh) were 63, 48.1, and 51.9%, respectively, whereas the final mortality rate of **8e** (R = Ph) was 44.4%. However, introduction of the (heterocyclylacyl)oxy group at the C-4 position of **5a** or **5b**

dx.doi.org/10.1021/jf405316w | J. Agric. Food Chem. 2014, 62, 3726−3733

could not afford the more potent compounds (e.g., 44.4% for **6i** and 48.1% for **6j**; 40.7% for **7i**). In our previous paper, we found that introduction of a (1-naphthylacetyl)oxy group at the C-4 position of the corresponding podophyllotoxin derivatives led to the more potent compounds,[29,30] but herein introduction of a (1-naphthylacetyl)oxy group at the C-4 position of **5a**−**c** did not result in the potent compounds. For example, the final mortality rates of **6d**, **7d**, and **8d** were only 44.4, 37, and 40.7%, respectively, so the insecticidal activity of **6d**, **7d**, and **8d** was also related to the chemical structures of their precursors.

In summary, a series of novel esters of 2α-chloro-2′(2′,6′)-(di)halogenopicropodophyllotoxin with modified C, D, and E rings of podophyllotoxin were prepared. In the meantime, an efficient method for the stereoselective α-chlorination at the C-2 position of 2′(2′,6′)-(di)halogenopodophyllotoxin derivatives in the presence of hexachloroethane (C_2Cl_6) was developed. Three steric structures of compounds **5b**, **5c**, and **6a** were determined by single-crystal X-ray diffraction. Their insecticidal activity was evaluated against pre-third-instar larvae of the oriental armyworm, *M. separata* (Walker), in vivo at a concentration of 1 mg/mL. This demonstrated that besides their 2′-halogen-substituted E ring, the stereoselective α-chlorination at the C-2 position of 2′(2′,6′)-(di)-halogenopodophyllotoxins was also related to the chlorination reagents. Among all of the derivatives, 2α-chloro-4α-(benzoyl)-oxy-2′-chloropicropodophyllotoxin (**6e**) and 2α-chloro-4α-(2-chlorophenylacyl)oxy-2′-bromopicropodophyllotoxin (**8f**) showed the most potent insecticidal activities with final mortality rates of >60%. For 4α-(alkylacyl)oxy derivatives of 2α-chloro-2′(2′,6′)-(di)halogenopicropodophyllotoxin, the effect of the length of their side chain at the C-4 position of podophyllotoxin skeleton on the insecticidal activity was not very obvious. For 4α-(arylacyl)oxy derivatives of 2α-chloro-2′-chloro/bromopicropodophyllotoxin, the electronic effect of the substituents on their phenyl ring at the C-4 position of podophyllotoxin skeleton on the insecticidal activity was observed.

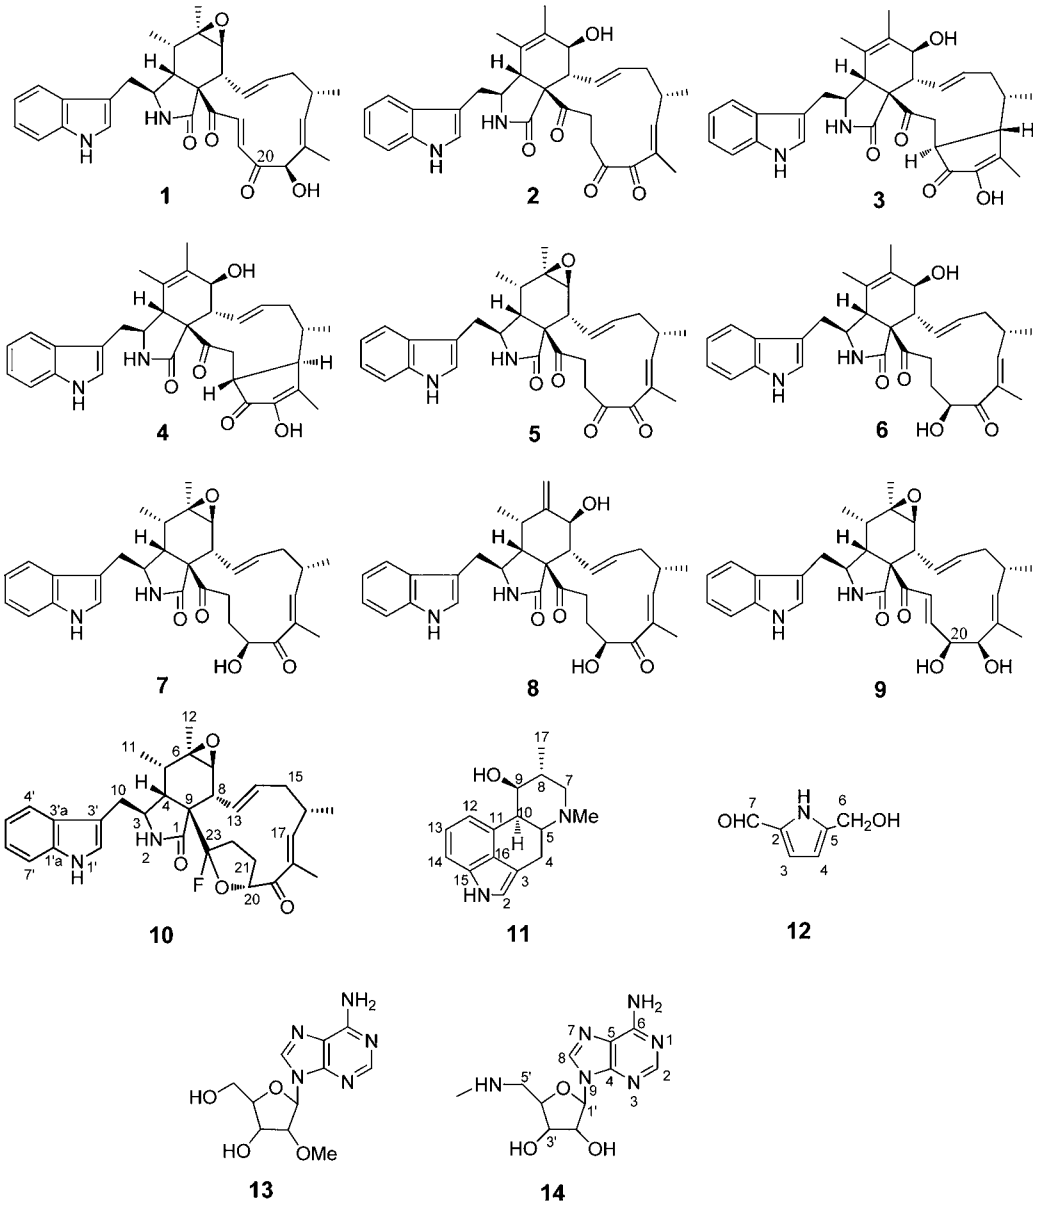

Figure 1. Structures of compounds **1**−**14**: chaetoglobosins A (**1**), G (**2**), V (**3**), V_b, (**4**), C (**5**), E (**6**), F (**7**), and F_{ex} (**8**); 20-dihydrochaetoglobosin A (**9**); and chaetoglobosin F_a (**10**), as well as fumigaclavine B (**11**), 5-(hydroxymethyl)-1*H*-pyrrole-2-carbaldehyde (**12**), 2′-*O*-methyladenosine (**13**), and 5′-deoxy-5′-methylamino-adenosine (**14**).

tetramethylsilane (TMS) or CF_3COOH as internal and external standards, respectively. Electrospray ionization mass spectrometry (ESI-MS) was obtained on a Bruker Esquire 6000 instrument, and high-resolution ESI-MS was recorded on a Thermo Fisher Scientific Q-TOF mass spectrometer.

Thin-layer chromatography (TLC) was performed on silica gel 60 F_{254} (Qingdao Marine Chemical Ltd.). Column chromatography (CC) was performed on MCI gel (75−150 mm, Mitsubishi Chemical Corp., Tokyo, Japan), 200−300 mesh silica gel (Qingdao Marine Chemical Factory, China), Sephadex LH-20 (Pharmacia), and RP-18 (Merck). Fractions were monitored by TLC, and spots were visualized by spraying with 5% H_2SO_4 in ethanol, followed by heating. All other chemicals used in this study were of analytical grade.

Five cytochalasans, chaetoglobosins A, G, V, V_b, and C (**1**−**5**), were isolated and identified previously from the cultures of *C. globosum*, an endophyte residing in the leaves of *G. biloba*, in three different media.[15−17]

Fungal Material. The fungal strain *C. globosum* was isolated from the sterilized leaves of *G. biloba*, a medicinal plant growing in Linyi, Shandong province, China, authenticated on the basis of morphological studies,[15] and has been deposited at the College of Science, Northwest A&F University.

Preparative Scale Culture. This fungus was grown on a sterilized moistened rice medium in Roux flasks (100 g/flask × 200) at 25 °C for 21 days to give green moldy rice.

Extraction and Isolation. The fungal cultures were ultrasonically extracted four times with MeOH. The solvent was removed under reduced pressure to give a crude extract. The extract was dissolved in 90% MeOH/H_2O (2 L) and treated four times with petroleum ether to give 0.5 g of residue. The remaining layer was adjusted to 50% aqueous methanol and partitioned with $CHCl_3$. The chloroform-soluble portion (20 g) was subjected to column chromatography on silica gel with $CHCl_3$/MeOH (100:1, 50:1, 20:1, 10:1) to give four fractions A−D.

Fraction A (4.5 g) was subjected to MCI column chromatography (CC) and Sephadex LH-20 ($CHCl_3$/MeOH 1:1), followed by purification with PTLC to yield compounds **5** (12 mg) and **7** (50 mg).

[a]Assignments were aided by a combination of $^{1}H-^{1}H$ COSY, HSQC, and HMBC experiments. [b]Measured in C_5D_5N. [c]Measured in DMSO-d_6.

Fraction B (1.8 g) was applied to MCI CC using MeOH/H_2O (10:90−100:0) to provide fractions B1, B2, B3, and B4. Fraction B3 was subjected to Sephadex LH-20 ($CHCl_3$/ MeOH 1:1), then followed by silica gel with $CHCl_3$/acetone (8:2) and $CHCl_3$/MeOH (35:1) to give compounds **6** (18 mg) and **8** (10 mg).

Fraction C (6.1 g) was applied to MCI CC using MeOH/H_2O (10:90−100:0) to provide fractions C1, C2, C3, C4, and C5. Fraction C2 was purified by repeated CC on Sephadex LH-20 ($CHCl_3$/MeOH 1:1) and silica gel ($CHCl_3$/MeOH, 95:5; $CHCl_3$/acetone 1:1) to give compound **14** (4.7 mg). Fraction C4 was chromatographed over Sephadex LH-20 with MeOH and repeatedly purified by CC with $CHCl_3$/acetone (8:2) and CH_2Cl_2/MeOH (98:2) to give compound **9** (5 mg).

Fraction D (2.9 g) was purified by CC on MCI, Sephadex LH-20 (MeOH), and silica gel (petroleum ether/acetone, 1:1; $CHCl_3$/ acetone, 2:1; $CHCl_3$/MeOH, 10:1), to give compounds **11** (1.8 mg), **12** (10 mg), and **13** (4 mg).

*Chaetoglobosin F (**7**):* white amorphous powder; $[\alpha]_D^{15}$ = −67.5 (*c* 0.10 in $CHCl_3$) (lit.[12] $[\alpha]_D$ = −69.0 ($CHCl_3$)); ^{1}H and ^{13}C NMR data, see Table 1; ESI-MS (negative) *m*/*z* 529.17 $[M - H]^-$. These data were identical to those recorded in the literature.[4,19,20]

*Chaetoglobosin F_{ex} (**8**):* white amorphous powder; $[\alpha]_D^{15}$ = +62.5 (*c* 0.10 in $CHCl_3$) (lit.[5] $[\alpha]_D$ = +63.8 (MeOH)); ESI-MS (negative) *m*/*z* 529.17 $[M - H]^-$; ^{1}H and ^{13}C NMR (DMSO-d_6) data were identical to those recorded in the literature.[5]

*20-Dihydrochaetoglobosin A (**9**):* white amorphous powder; $[\alpha]_D^{15}$ = −56.2 (*c* 0.10 in $CHCl_3$) (lit.[5] $[\alpha]_D$ = −52.0 (MeOH)); ^{1}H NMR (500 MHz, DMSO-d_6) δ 10.84 (1H, s, H-2), 8.15 (1H, s, H-1′), 7.38 (1H, d, *J* = 7.9 Hz, H-4′), 7.31 (1H, d, *J* = 8.1 Hz, H-7′), 7.04 (1H, m, H-5′), 7.01 (1H, s, H-2′), 6.94 (1H, m, H-6′), 6.74 (1H, dd, *J* = 15.2, 3.3 Hz, H-21), 6.42 (1H, d, *J* = 15.1 Hz, H-22), 6.06 (1H, m, H-13), 5.10 (1H, m, H-14), 4.98 (1H, d, *J* = 4.5 Hz, 20-OH), 4.87 (1H, d, *J* = 5 Hz, 19-OH), 4.60 (1H, d, *J* = 9.9 Hz, H-17), 4.44 (1H, br s, H-20), 4.01(1H, br s, H-19), 3.62 (1H, m, H-3), 2.76 (1H, dd, *J* = 14.0, 5.2 Hz, H-10a), 2.66 (1H, d, *J* = 5.4 Hz, H-7), 2.32−2.42 (3H, m, H-4, 8, 10b), 2.52 (1H, m, overlap, H-16), 2.22 (1H, m, H-15a), 1.70 (2H, m, H-5, 15b), 1.63 (3H, s, 18-Me), 1.06 (3H, s, H-12), 0.88 (3H, d, *J* = 6.5 Hz, 16-Me), 0.52 (3H, d, *J* = 7.2 Hz, H-11); ^{13}C NMR (125 MHz, DMSO-d_6) δ 198.03 (C-23), 173.35 (C-1), 147.81 (C-21), 136.08 (C-1a′), 134.74 (C-14), 133.93 (C-18), 131.40 (C-17), 127.30 (C-3a′), 126.07 (C-13), 123.51 (C-5′), 123.10 (C-22), 120.92 (C-2′), 118.43 (C-6′), 117.95 (C-4′), 111.39 (C-7′), 109.78 (C-3′), 78.14 (C-19), 76.04 (C-20), 63.21 (C-9), 61.07 (C-7), 56.82 (C-6), 52.13 (C-3), 46.74 (C-8), 45.63 (C-4), 38.82 (C-15), 35.78 (C-5), 32.96 (C-10), 31.73 (C-16), 21.26 (16-Me), 19.01 (C-12), 13.58 (18-Me),

dx.doi.org/10.1021/jf500390h | J. Agric. Food Chem. 2014, 62, 3734−3741

12.02 (C-11); ESI-MS (negative) m/z 529.17 $[M - H]^-$. These data were identical to those recorded in the literature.[5,21]

Semisynthesis of Chaetoglobosin F_a (10).[22] To a solution of compound **7** (37 mg, 0.070 mmoL) in CH_2Cl_2 (2 mL) was added DAST (28 μL, 0.21 mmoL), and the mixture was stirred at room temperature for 1.5 h. Water (2 mL) was added to the solution, and the mixture was diluted with CH_2Cl_2 (30 mL). The solution was washed sequentially with water (2 × 15 mL) and brine (15 mL), dried over Na_2SO_4, and filtered, and the solvent was removed in vacuo. The residue was chromatographed over silica gel (petroleum ether/acetone 7:3) to give compound **10** (20 mg, 53.9%).

Chaetoglobosin F_a (10): white amorphous powder; $[\alpha]_D^{29} = -98.5$ (c 0.20 in $CHCl_3$); UV ($CHCl_3$) λ_{max} (log ε) = 227(3.55), 242 (3.74), 282 (3.40), 290 (3.30); ^{1}H and ^{13}C NMR data, see Table 1; IR (KBr) υ 3390, 2955, 2923, 1686, 1638, 1073 cm^{-1}; HR ESI-MS (negative) m/z 531.2656 $[M - H]^-$ (calcd for $C_{32}H_{36}N_2O_4F$, 531.2665).

Fumigaclavine B (11): white amorphous powder; ^{1}H NMR (500 MHz, CD_3OD) δ 7.13 (1H, d, J = 8.1 Hz, H-12), 7.09 (1H, m, H-13), 6.93 (1H, d, J = 6.9 Hz, H-14), 6.90 (1H, s, H-2), 4.54 (1H, m, H-9), 3.44 (1H, dd, J = 14, 4.3 Hz, H-4a), 3.21(1H, d, J = 10.2 Hz, H-7a), 2.95 (1H, dd, J = 11.4, 2.6 Hz, H-7b), 2.68 (1H, m, H-5), 2.64 (1H, m, H-4b), 2.63 (1H, H-10), 2.47 (3H, s, NMe), 2.16 (1H, m, H-8), 1.28 (3H, d, J = 7.4 Hz, H-17); ^{13}C NMR (125 MHz, CD_3OD) δ 135.39 (C-15), 130.53 (C-11), 123.52 (C-13), 123.52 (C-16), 119.25 (C-2), 113.92 (C-12), 109.51 (C-14), 109.51 (C-3), 69.62 (C-9), 62.39 (C-5), 58.36 (C-7), 43.89 (N-Me), 41.83 (C-10), 36.88 (C-8), 26.99 (C-4), 17.12 (C-17); ESI-MS (positive) m/z 257.0 $[M + H]^+$. These data were identical to those reported in the literature.[23]

5-(Hydroxymethyl)-1H-pyrrole-2-carbaldehyde (12): white amorphous powder; ^{1}H NMR (500 MHz, CD_3OD) δ 9.36 (1H, s, H-7), 6.98 (1H, d, J = 3.6 Hz, H-3), 6.26 (1H, d, J = 3.5 Hz, H-4), 4.60 (2H, s, H-6); ^{13}C NMR (125 MHz, CD_3OD) δ 180.59 (C-7), 143.38 (C-5), 133.95 (C-2), 123.42 (C-3), 110.41 (C-4), 57.84 (C-6); ESI-MS (negative) m/z 124.08 $[M - H]^-$. These data were identical to those described in the literature.[24]

2′-O-Methyladenosine (13): white amorphous powder; ^{1}H NMR (500 MHz, DMSO-d_6) δ 8.39 (1H, s, H-2), 8.14 (1H, s, H-8), 7.37 (2H, s, NH_2), 6.00 (1H, d, J = 5.97 Hz, H-1′), 4.34 (1H, m, H-3′), 4.33 (1H, m, H-2′), 3.98 (1H, m, H-4′), 3.67 (1H, m, H-5′), 3.30 (3H, s, OMe); ^{13}C NMR (125 MHz, DMSO-d_6) δ 156.20 (C-6), 152.56 (C-8), 149.01 (C-4), 139.72 (C-2), 119.28 (C-5), 86.47 (C-4′), 85.82 (C-2′), 82.45 (C-1′), 68.81 (C-3′), 61.51 (C-5′), 57.48 (C-OMe); ESI-MS (positive) m/z 282.04 $[M + H]^+$. These data were identical to those described in the literature.[25]

5′-Deoxy-5′-methylamino-adenosine (14): white amorphous powder; ^{1}H NMR (500 MHz, CD_3OD) δ 8.48 (1H, s, H-2), 8.40 (1H, s, H-8), 6.05 (1H, m, H-1′), 4.77 (1H, m, H-2′), 4.47 (1H, m, H-4′), 4.37 (1H, m, H-3′), 3.45 (1H, m, H-5′a), 3.20 (1H, m, H-5′b), 2.67 (3H, s, N−CH_3); ^{13}C NMR (125 MHz, CD_3OD) δ 153.37 (C-6), 150.87 (C-4), 146.42 (C-2), 144.83 (C-8), 121.76 (C-5), 91.23 (C-1′), 79.58 (C-4′), 75.79 (C-2′), 75.39 (C-3′), 57.91 (C-5′), 40.19 (N−CH_3); ESI-MS (positive) m/z 281.07 $[M + H]^+$. These data were identical to those described in the literature.[26]

Phytotoxicity Bioassay. Phytotoxicity was assayed by the method reported previously.[27,28] Briefly, radish seedlings were washed by running water for 120 min and then soaked in 0.3% $KMnO_4$ for 15 min and flushed to colorless. An acetone solution containing a sample at a defined concentration (200 or 50 ppm) was poured on two sheets of filter paper in a 12-well microplate. After removal of the solvent in vacuo, 200 μL of aseptic water was added on it. Radish seedlings of uniform shape and size were placed on the filter paper. In this experiment the seedlings were grown for 4 days at 25 °C under completely dark conditions. The inhibitory effects were observed after 96 h. Glyphosate was used as the positive control. Acetone served as a blank control. Each experiment was conducted three times and presented as the mean ± standard deviation of three replicates.

Cytotoxicity Bioassay. Cytotoxicity in vitro was assessed by the SRB colorimetric assay, which estimates cell number indirectly by measuring total basic amino acids of cultured cells.[29] Briefly, 100 μL aliquots of the exponentially growing HCT116 cells containing 2.5 × 10^4 cells/mL were added to each well of a 96-well flat-microtiter plate and cells allowed to attach for 24 h. Then the medium was replaced by fresh medium, and cells were incubated with various amounts of the test compound for an additional 72 h. Four replicate wells were used in each point in the experiments. After incubation at 37 °C, culture medium was moved, cells were fixed in situ with 100 μL aliquots of cold 10% trichloroacetic acid (TCA), and plates were incubated for 1 h at 4 °C. Thereafter, supernatant was discarded and plates were washed five times with distilled water and air-dried. Sulforhodamine B solution at 0.4% (w/v) in 1% acetic acid was added to each well, and plates were incubated for 20−30 min at room temperature. The unbound dye was removed by washing five times with 1% acetic acid, and plates were air-dried. Bound sulforhodamine B was subsequently solubilized with 10 mM Tris base, and the absorbance was read at 560 nm using an Epoch (Bio-Tek) microplate reader. The percentage of cell viability was calculated relative to control wells designated as 100% viable cells. All of the results were expressed as the mean ± standard deviation of triplicate determinations. The data analysis was performed using Origin 8.0 software.

RESULTS AND DISCUSSION

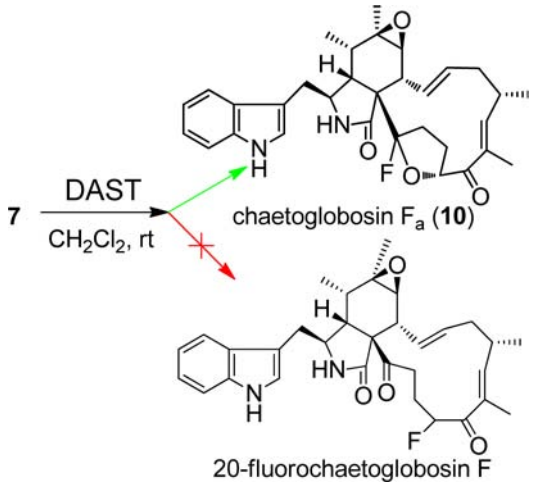
Cultivation, Isolation, and Structure Elucidation. The fungal strain was cultured in rice medium at 28 °C for 21 days. The extract of the culture was partitioned between chloroform and 50% MeOH/H_2O. The chloroform extract was repeatedly purified by RP-18 gel, silica gel, and Sephadex LH-20 CC to afford nine compounds. The structures of the known compounds were characterized by means of spectroscopic comparisons with literature data as chaetoglobosins C (**5**), E (**6**), F (**7**),[4,19,20] and F_{ex} (**8**),[5] 20-dihydrochaetoglobosin A (**9**),[5,21] fumigaclavine B (**11**),[23] 5-(hydroxymethyl)-1*H*-pyrrole-2-carbaldehyde (**12**),[24] 2′-*O*-methyladenosine (**13**),[25] and 5′-deoxy-5′-methylamino-adenosine (**14**) (Figure 1).[26]

Some of the isolated chaetoglobosins (A, C, E, and F) are well-known metabolites isolated from different fungal strains of *C. globosum*,[2] whereas 20-dihydrochaetoglobosin A (**9**), which was reported for the first time from the plant endophytic *C. globosum*, had been isolated before from *C. subaffine*.[5] A search of known *C. globosum* secondary metabolites from the CrossFire Beilstein database revealed that these four compounds, **11**−**14**, had not been previously described in *C. globosum*.

Semisynthesis of Chaetoglobosin F_a (10). Selective introduction of fluorine atom(s) to bioactive natural and unnatural products is of extreme interest in pharmaceutical research[30] because fluorine atom(s) are well-known as pharmacophore(s). (Diethylamino)sulfur trifluoride (DAST) is often used for the preparation of fluorinated compounds. This reagent can convert alcohols into fluorides or ketones into *gem*-difluoro compounds under quite mild conditions.[22,31] As a consequence, we made attempts to obtain 20-fluorochaetoglobosin F through treatment of chaetoglobosin F (**7**) with DAST (3 equiv) in dichloromethane at room temperature for 1.5 h; unexpectedly, however, this process failed to directly give 20-fluorinated product but provided 23-fluorinated product chaetoglobosin F_a (**10**) in 53.9% yield, which possesses an oxolane ring between C-20 and C-23, as shown in Scheme 1.

HR-ESIMS of compound **10** gave a pseudomolecular ion at m/z 531.2656 $[M - H]^-$ (calcd for $C_{32}H_{36}N_2O_4F$, 531.2665). These data, coupled with ^{13}C NMR spectroscopic data, established the molecular formula of **10** as $C_{32}H_{37}N_2O_4F$ (15 degrees of unsaturation), suggesting 2 amu more than the mass of chaetoglobosin F (**7**). The ^{1}H-decoupled ^{19}F NMR spectroscopic data also confirmed the existence of the fluorine atom (δ_F −100) in **10** (see Figure S3 in the Supporting

Scheme 1. Chemical Transformation of 7 into 10



Information). The IR spectrum of **10** exhibited absorption bands at 3390 (NH and/or OH), 1686 (C═O), and 1638 (C═O) cm^{-1}. The ^{13}C NMR and DEPT spectra of **10** (Table 1) displayed 32 carbon signals, including 4 methyls, 4 sp^3 methylenes, 7 sp^3 and 8 sp^2 methines, 3 sp^3 and 4 sp^2 quaternary carbons, and 1 ketone carbon (δ_C 202.62), as well as an amide carbonyl (δ_C 174.21). The ^1H NMR spectrum of **10** showed the presence of an indole moiety, including 1,2-disubstituted benzene [δ_H 7.94 (t, J = 7.5 Hz, H-4′), 7.36 (m, H-5′), 7.34 (m, H-6′), and 7.67 (t, J = 7.5 Hz, H-7′)], an olefinic proton at δ_H 7.57 (H-2′), and a broad NH singlet at δ_H 12.08 (H-1′), along with the ^{13}C NMR spectrum, which gave six aromatic carbons at δ_C 137.89 (s, C-1′a), 128.30 (s, C-3′a), 119.62 (d, C-6′), 122.08 (d, C-5′), 118.80 (d, C-4′), and 112.36 (d, C-7′) and two olefinic carbons at δ_C 124.75 (d, C-2′) and 111.74 (s, C-3′). In addition, the ^1H NMR spectrum showed the presence of two tertiary methyls (δ_H 1.30, 1.85), two secondary methyls (δ_H 0.92, 1.16), three olefinic protons (δ_H 5.35, m; 6.73, d; 7.02, dd), and an amide proton (δ_H 9.13, s). Comparison of its ^{13}C NMR data with those of **7** revealed that an additional sp^3 quaternary carbon C-23 (δ_C 123.66) with a huge coupling constant ($J_{C,F}$ = 224.7 Hz) in **10** appeared and that a corresponding ketone carbon at δ_C 204.06 in **7** disappeared. Meanwhile, two carbons adjacent to C-23, an sp^3 methylene carbon C-22 signal (δ_C 36.23, $J_{C,F}$ = 30.4 Hz) and a quaternary carbon C-9 (δ_C 56.86, $J_{C,F}$ = 28.8 Hz), were also observed. These typical splitting patterns indicated that this fluorine atom was attached to C-23, as evidenced by HMBC correlations from H-21 and H-22 to C-23. The downfield chemical shift of sp^3 hybridized C-23 (δ_C 123.66) revealed the connection with the additional oxygen atom. Considering degrees of unsaturation, this molecule should contain an oxolane ring between C-20 and C-23. This deduction was supported by HMBC correlations of H-20 (δ_H 5.40) with C-23 and H-21 with C-20 as well as $^1H-^1H$ COSY correlations of H-20/H-21/H-22 (Figure 2). This gave rise to significant differences in the chemical shifts measured in C_5D_5N of C-17 to C-23 between **7** and **10** (Table 1). Finally, comprehensive $^1H-^1H$ COSY and HMBC analysis (Figure 2) allowed the complete assignment of the proton and carbon signals for **10** (see the Supporting Information).

Rearrangement reactions are sometimes observed in DAST fluorination.[32−34] For example, preparation of γ-fluorobutyrolactones from the reaction of γ-ketoacids with DAST was

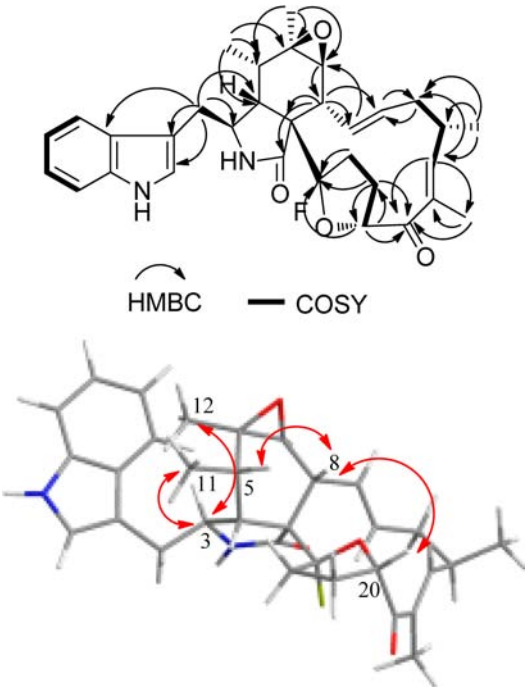


Figure 2. Key HMBC, $^1H-^1H$ COSY, and ROESY correlations in **10**.

reported by Chen et al.[34] In the current work, similarly, the mechanism of oxolane ring formation between C-20 and C-23 in **10** is postulated to occur via the pathway (Figure 3). The

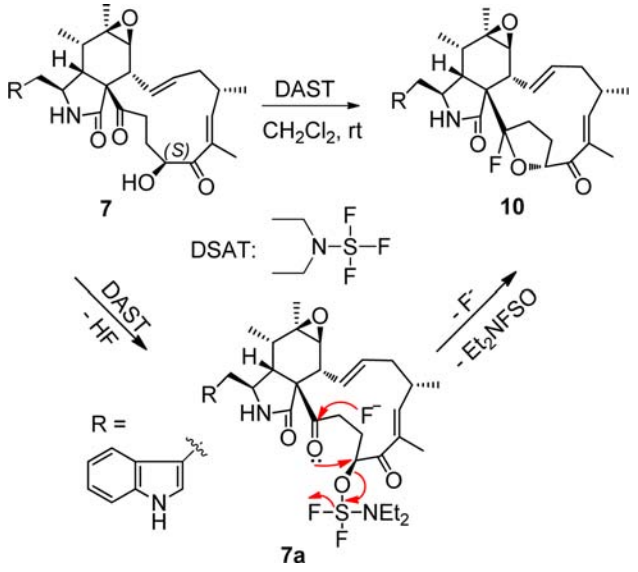

Figure 3. Potential mechanism of chemical transformation of compound **7** into **10**.

first step is the nucleophilic displacement of fluorine on sulfur by oxygen of the 20-OH accompanied by elimination of hydrogen fluoride to give the intermediate **7a**. Then, the addition of fluorine to C-23 of **7a** was accompanied by O-23 attached to C-20 from the backside and elimination of Et_2NFSO and F^-.[35,36] Consequently, an inversion of the configuration of C-20 in the resulting **10** took place, which was further confirmed by the cross-peak between H-8 and H-20 in the ROESY spectrum of **10** (Figure 2).

dx.doi.org/10.1021/jf500390h | J. Agric. Food Chem. 2014, 62, 3734−3741

The configuration of the core skeleton, 10-(indol-3-yl)-[13]cytochalasan, in these chaetoglobosins could be assigned on the basis of the biosynthesis with those of chaetoglobosin A (**1**)[21] as well as on a ROESY experiment. The absolute configuration of 20-dihydrochaetoglobosin A (**9**) was established previously by X-ray single-crystal analysis as 3*S*, 4*R*, 5*S*, 6*R*, 7*S*, 8*R*, 9*R*, 16*S*, 19*R*, and 20*S*,[21] so the absolute configuration of **7** was assigned as 3*S**, 4*R**, 5*S**, 6*R**, 7*S**, 8*R**, 9*R**, 16*S**, and 20*S**. The members of the chaetoglobosin family possess structures that are chirally dense at six (C-3, C-4, C-5, C-8, C-9, C-16) or eight vicinal positions (C-3, C-4, C-5, C-6, C-7, C-8, C-9, C-16) and one remote site (C-19/C-20). Interestingly, the sign of the rotation is not sensitive to the minor structural changes. For example, chaetoglobosin A (**1**), 20-dihydrochaetoglobosin A (**9**), and chaetoglobosin F_a (**10**) reported here and prochaetoglobosin I[21] all showed negative specific rotations, despite a large variance in structure at C-6, C-7, C-19, and C-20 and configuration at C-5 and C-8. In addition, the co-occurrence of these isolated metabolites **1**−**9** in the title fungus suggests that they shared the same biogenetic pathway, and biogenetic insights previously published[3,21] have suggested that the configuration at C-4, C-5, C-8, and C-9 is set via a stereospecific enzyme-mediated Diels−Alder reaction.[11,21] After several attempts, unfortunately, no good crystals suitable for X-ray analysis of chaetoglobosin F_a (**10**) were obtained because this compound is easily changeable in proton solvents. Consequently, the absolute stereochemistry of the new semisynthetic derivative **10** was proposed as 3*S**, 4*R**, 5*S**, 6*R**, 7*S**, 8*R**, 9*R**, 16*S**, and 20*R**. Thus, the total structure of **10** was elucidated as shown in Figure 1. It should be mentioned that the absolute configuration at the new chrial center C-23 of **10** remains undetermined.

Phytotoxic Activity of Selected Compounds. The phytotoxic effects of eight selected compounds **1**, **3**−**8** and **10**, except for **2** and **11**−**14** (due to insufficient samples) on radish seedlings were examined, and the results are listed in Table 2. Chaetoglobosin A (**1**) darkened the roots at two concentrations of 200 and 50 ppm, these results being consistent with those obtained with alfalfa seedlings,[27] and other compounds also showed similar inhibitory effects. At a low concentration of 50 ppm, compounds **1**, **3**−**8**, and **10** exhibited weak to strong phytotoxic activities against the roots with inhibition rates in the range of 26.4−67.5% and against hypocotyl elongation with inhibition rates ranging from 33.3 to 71.6% (except **10**). Among the tested compounds, at 50 ppm, inhibition rates of chaetoglobosins A (**1**), V (**3**), E, F, and F_{ex} (**6**−**8**) were >60% toward the roots, as active as positive control, glyphosate (63.5%); chaetoglobosins A (**1**), C, E, F, and F_{ex} (**5**−**8**) displayed phytotoxic activities to hypocotyls with inhibition rates of almost ≥60%, which were about 2-fold of the control. In comparison to **7**, its semisynthetic fluorinated derivative, chaetoglobosin F_a (**10**) weakly inhibited the root growth of the seedlings with 26.4 and 59.4% of inhibition at 50 and 200 ppm, respectively, but had no phytotoxicity to hypocotyls at either concentration. In addition, at low concentrations, >60% inhibition of chaetoglobosin V (**3**) on radish seedlings was >33−46% that of V_b (**4**). It seemed that the configurations of C-17 and C-21 in both molecules could influence phytotoxicity potency.

At 200 ppm, chaetoglobosins A (**1**) and C−F (**5**−**7**) exhibited phytotoxicity to roots with inhibition rates from 71.7 to 76%, which were slightly weaker than the control (81.5%). Meanwhile, chaetoglobosins A (**1**) and C−F (**5**−**7**) presented phytotoxic effects on hypocotyls with inhibition rates from 60.7 to 71.2%, almost as active as glyphosate (67.1%). These findings demonstrated that radish seedlings were highly sensitive to these tested chaetoglobosins at low concentrations but only slightly sensitive at high concentrations. It was interesting that the dose−response relationship of these tested compounds was not apparent in our bioassay.

Table 2. Inhibitory Effects of Compounds 1, 3−8, and 10 on the Growth of Radish Seedlings

		inhibition ratio[a] (%)	
compd	concn (ppm)	radish root	radish hypocotyl
1	200	74.0 ± 3.1	64.4 ± 3.0

[a]Mean ± SD.

It has been proved that some chaetoglobosins have been found to be phytotoxic to different plants. Chaetoglobosin A (**1**) and its 19-*O*-acetylchaetoglobosin A, isolated from the culture of *Calonectria morganii*, inhibited the root and shoot growth of cresson seedlings;[37] chaetoglobosins A (**1**), C (**5**), and O, phytotoxic metabolites from *Cylindrocladium floridanum*, a causal fungus of alfalfa black rot disease, caused potent growth inhibition on alfalfa seedlings.[27] Furthermore, chaetoglobosin K showed growth-inhibiting effects on wheat coleoptiles, isolated from cultures of *Diplodia macrospora*, a corn pathogen causing ear and stalk rot.[38] This is the first report of phytotoxicity of these test chaetoglobosins to radish seedlings.

In Vitro Cytotoxic Evaluation of Compounds 1−10. All 10 chaetoglobosins (**1**−**10**) were evaluated for their cytotoxic activities against the HTC116 cell line except for chaetoglobosin C (**5**), which has low solubility in DMSO, and the results are presented in Table 3. Four of them, chaetoglobosins A (**1**) and F_{ex} (**8**), 20-dihydrochaetoglobosin A (**9**), and chaetoglobosin F_a (**10**), displayed high cytotoxic activity with IC_{50} values of 3.15, 4.43, 8.44, and 5.85 μM, respectively, as compared to the antitumoral drug etoposide (IC_{50} = 2.13 μM), whereas chaetoglobosins G (**2**), V (**3**), V_b (**4**), E (**6**), and F (**7**) were found to be weak (IC_{50} > 17 μM). Among them,

chaetoglobosin A (**1**) was about 2.5 times more active than 20-dihydrochaetoglobosin A (**9**) on HCT116 cells, suggesting that reduction of the carbonyl group at C-20 lowered cytotoxicity. This deduction was consistent with that of chaetoglobosin G (**2**) (IC_{50} = 65.6 μM), showing higher toxicity than chaetoglobosin E (**6**) (IC_{50} > 100 μM), despite their lower toxicity. Chaetoglobosin F (**7**) exhibited much higher cytotoxic abilities than chaetoglobosin E (**6**), with IC_{50} values of 17.8 and >100 μM, respectively. These results suggested that the introduction of an epoxide ring at C6/C7 greatly improved cytotoxicity. Chaetoglobosin F_{ex} (**8**) (IC_{50} = 4.43 μM) showed much stronger cytotoxic effects than chaetoglobosin E (**6**), implying that the presence of a double bond at C6(12) was favorable for imparting cytotoxicity. Especially, chaetoglobosin F_a (**10**) (IC_{50} = 5.85 μM) was about 3 times more active than the parent **7** (IC_{50} = 17.8 μM) toward HCT116 cells. This indicated that the introduction of F and the formation of the furan ring in **10** could enhance activity. Chaetoglobosins V (**3**) and V_b (**4**), incorporating a five-membered ring between C-17 and C-21, were found to be weak, with IC_{50} values of 29.5 and 18.4 μM, respectively, but stronger than the parental compound **2** (IC_{50} = 65.6 μM), indicating the C-17/C-21 junction in both molecules appeared to improve toxicity. These findings suggested that an epoxide ring at C-6−C-7 or a double bond at C-6(12) is an important feature responsible for activity.

Reportedly, among chaetoglobosins is chaetoglobosin A (**1**), which has a unique inhibitory activity against actin polymerization in mammalian cells.[3] Chaetoglobosins displayed cytotoxicity on a panel of human cancer cell lines.[2,3,39,40] Chaetoglobosins A (**1**), C (**5**), E (**6**), and G (**2**) exhibited acute toxic effects against HeLa cells (IC_{50} = 3.2−20 μM).[20,41] Compound **1** possessed significant cytotoxicity against P388 murine leukemia cell line.[6] Compounds **5** and **2** showed cytotoxicities against human breast cancer (BC1) cell lines (IC_{50} = 6.27−20.0 μM).[10] Recently, chaetoglobosins C (**5**) and F (**7**) exhibited moderate cytotoxic activity against SKOV-3 cells (IC_{50} = 2−8 μM).[42] Chaetoglobosins A (**1**), G (**2**), V (**3**), C (**5**), E (**6**), F (**7**), and F_{ex} (**8**) exhibited moderate cytotoxic activities against four human cancer cell lines (KB, K562, MCF-7, and HepG2).[43] Compounds **1** and **5** presented significant growth inhibitory activity against the brine shrimp[15] and also had toxic effects to mouse and rat cells and chick embryos.[44,45] To our knowledge, this is the first report on the cytotoxicity of these chaetoglobosins to the HCT116 cell line.

In summary, in this study, nine known metabolites including chaetoglobosins C, E, F, and F_{ex}, and 20-dihydrochaetoglobosin A (**5**−**9**) and four known compounds (**11**−**14**) were identified from the solid culture of the endophytic *C. globosum*, and a new fluorinated chaetoglobosin, chaetoglobosin F_a (**10**), was semisynthesized from chaetoglobosin F. The phytotoxic compounds (**1**, **3**, and **6**−**8**) displayed marked phytotoxic activity against radish seedlings at 50 ppm, which were comparable to the positive control. Compounds **1** and **8**−**10** exhibited pronounced cytotoxicity against the HCT116 colon cancer cell, in contrast to the positive drug. The epoxide ring between C-6 and C-7 or the double bond at C-6(12) appeared to be important for cytotoxicity, and chaetoglobosin F_a (**10**) presented a markedly increased cytotoxicity but decreased phytotoxicity. On the basis of results in both bioassays, there was no relationship between cytotoxicity and phytotoxicity. The mechanisms of action of some bioactive compounds we have identified will need to be studied.

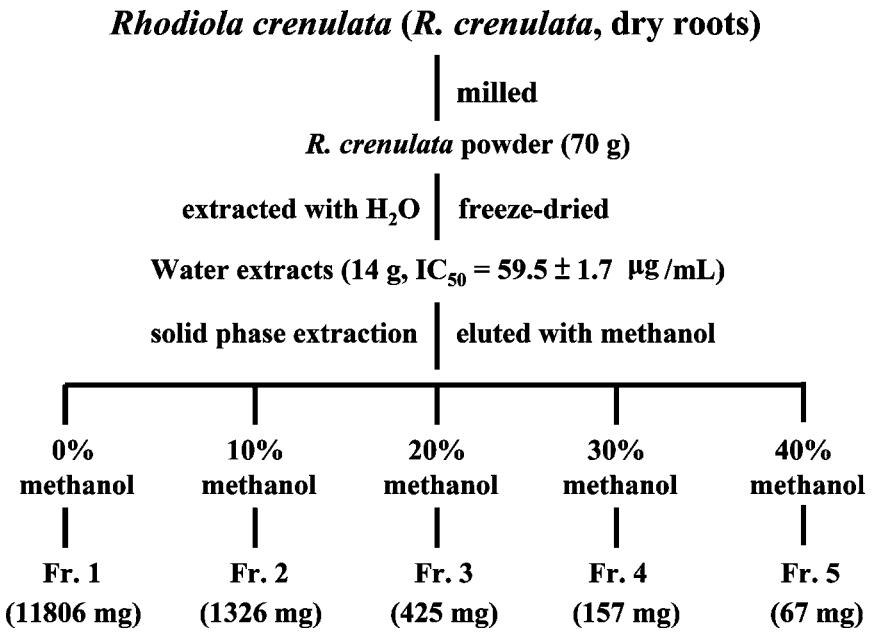

Figure 1. Scheme employed for the extraction of WE and its fractions from *R. crenulata*.

Taiwan) using DNA technology and the internal transcribed spacer sequence database. A total of 70 g of *R. crenulata* roots were milled using a laboratory-scale milling machine and extracted 3 times with distilled water (700 mL) at 30 °C. After 15 min of centrifugation at 12000g, the supernatant of collected samples were freeze-dried to yield the WE. The specimen was stored in the refrigerator (−20 °C) for further solid-phase extraction (SPE).

SPE Procedure. WE were redissolved in distilled water and underwent column chromatography on a vacuum manifold (Phenomenex, Torrance, CA) using SPE cartridges (6 mL/1000 mg, BAKERBOND octadecyl C18, J.T.Baker, Deventer, Netherlands). Each sample (50 mg) was chromatographed on a SPE cartridge. The sample was eluted with a stepwise method of 0, 10, 20, 30, and 40% methanol in distilled water. A total of five fractions, one for each methanol elution (20 mL), were collected. Samples were concentrated at 35 °C using a rotary evaporator and then freeze-dried. These five fractions (fractions 1−5) were then analyzed in the XO assay to assess the inhibitory activity.

HPLC Analysis of the WE of *R. crenulata* and Its Fractions. WE of *R. crenulata* and its fractions were dissolved in distilled water and subjected to column chromatography on the high-performance liquid chromatography (HPLC) system composed of a pump (PU-980, JASCO), a detector (UV-970, JASCO), and a C18 packed column (4.6 × 250 mm, 5 μm spherical, Dikma Technologies, Inc.). The mobile phase was solvent A (100% acetonitrile) and solvent B (ultrapure water). Elution conditions were as follows: 2−50% of A to B for 0−55 min (linear gradient) at a flow rate of 1 mL/min. The effluent was monitored through an optical absorption study carried out at 280 nm.

Isolation of Active Compounds from the WE of *R. crenulata*. WE and the fourth fraction (fraction 4) were redissolved in distilled water and subjected to column chromatography on the HPLC system composed of a pump (PU-980, JASCO), a detector (UV-970, JASCO) and a C18 packed column (4.6 × 250 mm, 5 μm spherical, Dikma Technologies, Inc.). The mobile phase was solvent A (100% acetonitrile) and solvent B (ultrapure water). Elution conditions for WE were as follows: 2−2% of A to B for 0−7 min and 2−30% A to B for 7−35 min (linear gradient). Elution conditions for fraction 4 were 14−14% A to B for 0−20 min and 14−18% A to B for 20−35 min (linear gradient). The elution began with solvent at a flow rate of 1 mL/min. The effluent was monitored through an optical absorption study carried out at 280 nm. The active compounds were then collected.

Identification of Purified Active Compounds. The chemical structures of the purified active compounds were identified by ultraviolet spectroscopy (UV, Hitachi, U-1900), Fourier transform infrared spectroscopy (FTIR, Bruker, Tensor27), polarity meter (PerkinElmer, 341), high-resolution electrospray ionization−TOF mass spectrometry (ESI−MS, BioTOF III; Bruker Daltonics, Inc., Billerica, MA), and nuclear magnetic resonance spectroscopy (NMR). NMR spectra, including ^{1}H, ^{13}C, distortionless enhancement by polarization transfer (DEPT), $^{1}H-^{1}H$ correlation spectroscopy (COSY), nuclear Overhauser effect spectrometry (NOESY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC), were recorded with a Bruker LC-SPE-NMR AVII 500 MHz spectrometer.[14]

Screening of Purified Active Compounds for XO Inhibitors. The XO inhibitory activity was assayed spectrophotometrically at 295 nm under aerobic conditions.[14] Absorbance (A) at 295 nm was measured using a UV spectrophotometer (U-1900, Hitachi High-Technologies Corporation, Minato-ku, Japan). The reaction mixture contained 200 mM sodium pyrophosphate buffer (pH 7.5), 100 μM xanthine, and 0.01 unit/mL of XO. The absorption rate at 295 nm indicates the formation of uric acid at 30 °C. The samples included WE and its five fractions (fractions 1−5), 4-HAP, B2−3′-*O*-gallate, salidroside, *p*-tyrosol, and allopurinol. Samples were dissolved directly in the buffer and incorporated into an enzyme assay to evaluate their inhibitory activities. Each sample was tested 3 times. The purified active compounds and allopurinol were tested for XO inhibitory activity at different concentrations (0−30 μM). The sample was dissolved directly in the buffer and incorporated into the enzyme assay to assess the inhibitory activity, and each sample was performed in triplicate. The inhibitory activity was determined by IC_{50}, which was obtained from percent inhibition calculated by

$$\text{percent inhibition (\%)} = [(A_{\text{without sample}} - A_{\text{with sample}})] \times 100\%/A_{\text{without sample}}$$

Lineweaver−Burk and Dixon Plots. To determine the mode of inhibition by 4-HAP and B2−3′-*O*-gallate, Lineweaver−Burk plot analysis was performed. This kinetics study was conducted in the absence and presence of inhibitors with varying concentrations of xanthine as the substrate. The initial velocity was expressed as the absorbance rate at 295 nm per 10 s in the assay. To determine the competitive inhibition constant (K_i) and uncompetitive inhibition constant (K_i'), Dixon plot analysis was performed. K_i is the

dx.doi.org/10.1021/jf5004094 | J. Agric. Food Chem. 2014, 62, 3742−3749

equilibrium constant for an inhibitor binding to XO, and K_i' is the equilibrium constant for an inhibitor binding to the XO−xanthine complex. The K_i and K_i' values of purified XO inhibitors were determined from the Dixon plot according to the method reported by Cornish-Bowden.[15] This kinetics study was carried out with varying concentrations of inhibitors and xanthine. The initial velocity was expressed as the absorbance rate at 295 nm per 10 s in the assay.

Statistical Analysis. Data were expressed as the mean ± standard deviation. The data were analyzed using the Statistical Package for the Social Sciences software (SPSS for Windows, version 10.0.7C, SPSS, Inc., Chicago, IL). Statistical significance among the treatments was determined by a one-way analysis of variation (ANOVA), followed by a Duncan's multiple range test. Three determinations for each treatment were made, and the significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

XO Inhibitory Activity of Fractionated Extracts of *R. crenulata*. The procedure for fractionation of the extracts of *R. crenulata* is shown in Figure 1. *R. crenulata* (70 g) was extracted with distilled water and freeze-dried to yield 14 g of WE, which displayed XO inhibitory activity (IC_{50} = 59.5 ± 1.7 μg/mL). The WE were then chromatographed on the SPE cartridges and eluted with varying concentrations of methanol. Finally, five fractions (fractions 1−5) were collected using a stepwise method of 0, 10, 20, 30, and 40% methanol in distilled water; the total yield of these fractions was 98.2%, and the yield of each fraction was 84.3, 9.4, 3.0, 1.1, and 0.4%, respectively. The IC_{50} values of WE and the associated fractions (fractions 1−5) were 59.5 ± 1.7, 862.2 ± 31.3, 524.2 ± 28.6, 94.7 ± 3.2, 16.1 ± 1.5, and 19.2 ± 1.8 μg/mL, respectively. Thus, we tested the inhibition of XO using WE and fractions at a final concentration of 0−60 μg/mL. Our results indicated that XO inhibition activity was 25.7% for WE and 2.8, 5.5, 17.2, 72.0, and 64.7% for fractions 1−5, respectively, at a concentration of 30 μg/mL (Figure 2). Among those fractions, the fourth

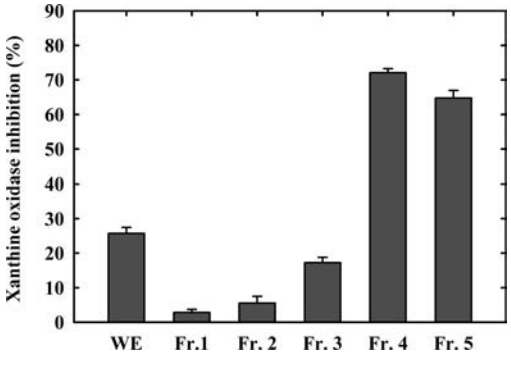

Figure 2. Inhibition of XO by the WE and its fractions at a final concentration of 30 μg/mL. Each value is represented as the mean ± standard deviation from triplicate measurements. WE, water extracts; Fr, fraction.

fraction (fraction 4) had the highest XO inhibitory activity (IC_{50} = 16.1 ± 1.5 μg/mL). Chen et al.[16] reported that the crude extracts of *Koelreuteria henryi*, *Prunus campanulata*, and *Rhodiola rosea* possessed strong XO inhibitory activity, with IC_{50} values of 91.8 ± 1.7, 64.6 ± 5.8, and 56.0 ± 1.0 μg/mL, respectively. These values indicate that the WE and fraction 4 would be plentiful sources of XO inhibitors.

HPLC Analysis of the WE and Its Fractions. To establish the fingerprint chromatogram of the WE and its five fractions, samples were analyzed by HPLC. The elution began with solvent at a flow rate of 1 mL/min, and a gradient elution from H_2O/acetonitrile (98:2) to H_2O/acetonitrile (50:50) over 55 min was performed to analyze these samples. The HPLC profile showed significant differences in the phytochemical patterns for each fraction. As shown in Figure 3, five major peaks were found in the WE at the elution times of 2−3, 5−7, 14−15, 21−22, and 23−24 min. Three peaks were found in fraction 1 at the elution times of 2−3, 5−7, and 14−15 min, while two peaks were found in fractions 2 and 3 at the elution times of 21−22 and 23−24 min. Furthermore, other minor peaks were found in fractions 3−5 at the elution time of 24−38 min. As previously mentioned, fractions 3−5 were used to inhibit XO at the concentration of 30 μg/mL, and the XO inhibitory activities were 17.2, 72.0, and 64.7%, respectively. Our results suggest that the peaks found in fraction 4 at the elution time of 24−38 min exhibit XO inhibitory properties.

Isolation and Identification of XO Inhibitors from *R. crenulata*. The WE and fraction 4 were analyzed and purified by HPLC (Figure 4). As shown in Figure 4A, a total 100 mg of WE was subjected to HPLC. Two major pure compounds (arrows, compounds **1** and **2**) were isolated, which were collected at the elution times of 21−22 and 23−24 min, respectively. The total yields of compounds **1** and **2** were 6.4 and 9.8 mg, respectively. Furthermore, a total of 157 mg of fraction 4 was then analyzed and purified by HPLC (Figure 4B). The individual peak was collected and used to inhibit XO. Consequently, two pure compounds (arrows, compounds **3** and **4**) were isolated and had XO inhibitory properties. These two compounds were collected at the elution times of 16−17 and 19−20 min, and the total yields of compounds **3** and **4** were 3.7 and 6.4 mg, respectively. Four purified compounds were analyzed using ESI−MS and NMR and were identified as salidroside, *p*-tyrosol, B2−3′-*O*-gallate, and 4-HAP. The following sections will focus on the spectral data of these compounds obtained from FTIR, UV, ESI−MS, and NMR.

Salidroside (Compound 1). Compound **1** was a white amorphous powder (Figure 4A), $[\alpha]_D^{20}$ −28.30° (*c* 0.00883, MeOH). UV (MeOH) λ_{max}, nm: 230, 273. IR ν_{max}: 3363, 2925, 2886, 1614, 1597, 1516, 1449, 1369, 1237, 1160, 1076, 1024. ESI−MS *m*/*z*: 323.1106 $[M + Na]^+$ (calculated for $C_{14}H_{20}O_7$). ^{1}H NMR (CD_3OD, 500 MHz) δ: 7.06 (2H, d, *J* = 8.4 Hz, H-2, 6), 6.69 (2H, d, *J* = 8.4 Hz, H-3, 5), 2.83 (1H, m, H-7), 4.03 (1H, m, H-8), 3.70 (1H, m, H-8), 4.29 (1H, d, *J* = 7.8 Hz, H-Glu.-1), 3.17 (1H, m, H-Glu.-2), 3.27 (1H, m, H-Glu.-3), 3.24 (1H, m, H-Glu.-4), 3.35 (1H, m, H-Glu.-5), 3.86 (1H, dd, *J* = 11.9, 2.0 Hz, H-Glu.-6), 3.66 (1H, dd, *J* = 11.9, 5.2 Hz, H-Glu.-6). ^{13}C NMR (CD_3OD, 125 MHz) δ: 130.9 (C-1), 131.1 (C-2, 6), 116.3 (C-3, 5), 157.0 (C-4), 36.6 (C-7), 72.3 (C-8), 104.6 (C-Glu.-1), 75.3 (C-Glu.-2), 78.1 (C-Glu.-3), 71.8 (C-Glu.-4), 78.3 (C-Glu.-5), 63.0 (C-Glu.-6). Compound **1** was identified as salidroside by direct comparison to commercial salidroside (Sigma Chemical Co., St. Louis, MO). On the basis of the data described above and the verified reference,[17] the structure of compound **1** was elucidated as salidroside. Yuan et al.[18] reported that salidroside exhibits antioxidant activity and a protective effect against furan-induced hepatocyte damage in mice.

***p*-Tyrosol (Compound 2).** Compound **2** was a white amorphous powder (Figure 4A). UV (MeOH) λ_{max}, nm: 223, 263. IR ν_{max}: 3386, 3141, 3024, 1598, 1510, 1452, 1363, 1230, 1105, 1051, 1015. ESI−MS *m*/*z*: 138 [M] (calculated for $C_8H_{10}O_2$). ^{1}H NMR (CD_3OD, 500 MHz) δ: 7.04 (2H, d, *J* = 8.6 Hz, H-2, 6), 6.71 (2H, d, *J* = 8.6 Hz, H-3, 5), 2.73 (2H, t,

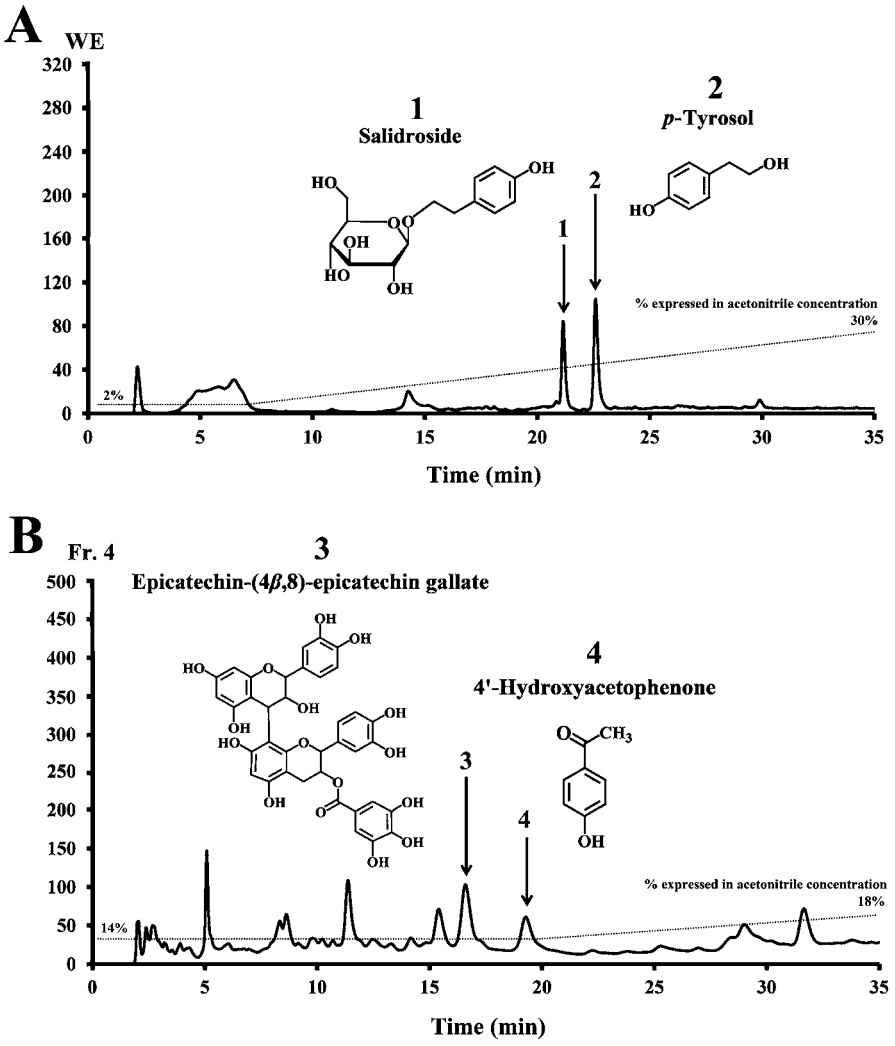

Figure 4. Isolation of active compounds from the (A) WE and (B) fraction 4. Arrow, active compounds; flow rate, 1.0 mL/min; UV detection, 280 nm.

J = 7.2 and 14.5 Hz, H-7), 3.70 (2H, t, J = 7.2 and 14.5 Hz, H-8). ^{13}C NMR (CD_3OD, 125 MHz) δ: 131.1 (C-1), 131.2 (C-2, 6), 116.3 (C-3, 5), 154.9 (C-4), 39.6 (C-7), 64.8 (C-8). Compound **2** was identified as *p*-tyrosol by direct comparison to commercial *p*-tyrosol (Sigma Chemical Co., St. Louis, MO). On the basis of the data described above and the verified reference,[19] the structure of compound **2** was elucidated as *p*-tyrosol. Dewapriya et al.[20] suggested that *p*-tyrosol has antioxidant activity and a protective effect against dopaminergic neuronal cell death in an *in vitro* model of Parkinson's disease.

B2−3′-*O*-Gallate (Compound 3). Compound **3** was a brown amorphous powder (Figure 4B), $[\alpha]_D^{20}$ −57.00° (*c* 0.00667, MeOH). UV (MeOH) λ_{max}, nm: 213, 228, 274. IR ν_{max}: 3321, 1690, 1609, 1520, 1448, 1370, 1284, 1235, 1156, 1099, 1039. ESI−MS m/z: 731.1615 $[M + H]^+$ (calculated for $C_{37}H_{30}O_{16}$). ^{1}H NMR (CD_3COCD_3, 500 MHz) δ: 5.26 (2H, s, H-2_U, 2_L), 4.06 (1H, s, H-3_U), 4.89 (1H, s, H-4_U), 6.03 (3H, m, H-6_U, 8_U, 6_L), 6.77 (3H, m, H-$2'_U$, $6'_U$, $5'_L$), 6.98 (1H, s, H-$5'_U$), 5.62 (1H, s, H-3_L), 2.98 (1H, d, J = 17.5 Hz, H-4_L), 3.13 (1H, dd, J = 17.1 and 4.4 Hz, H-4_L), 7.13 (3H, m, H-$2'_L$, $2''_L$, $6''_L$), 7.05 (1H, s, H-$6'_L$). ^{13}C NMR (CD_3COCD_3, 125 MHz) δ: 78.0 (C-2_U), 72.9 (C-3_U), 36.7 (C-4_U), 157.7 (C-5_U), 97.2 (C-6_U, 8_L), 158.2 (C-7_U), 96.3 (C-8_U), 158.2 (C-9_U), 107.9 (C-10_U), 132.5 (C-$1'_U$), 115.6 (C-$2'_U$), 145.3 (C-$3'_U$, $4'_U$, $3'_L$), 119.4 (C-$5'_U$), 119.1 (C-$6'_U$), 77.2 (C-2_L), 69.1 (C-3_L), 26.6 (C-4_L), 155.5 (C-5_L, 7_L), 95.8 (C-6_L), 156.0 (C-9_L), 99.6 (C-10_L), 131.2 (C-$1'_L$), 115.5 (C-$2'_L$), 145.2 (C-$4'_L$), 115.3 (C-$5'_L$), 114.7 (C-$6'_L$), 122.0 (C-$1''_L$), 110.2 (C-$2''_L$, $6''_L$), 145.7 (C-$3''_L$, $5''_L$), 138.7 (C-$4''_L$), 166.2 (C-$7''_L$). On the basis of the data described above and the verified reference,[21] the structure of compound **3** was elucidated as B2−3′-*O*-gallate. Lourenço et al.[22] reported that this compound has antioxidant activity and reduces the formation of UV-induced α-tocopheroxyl radicals.

4-HAP (Compound 4). Compound **4** was a white amorphous powder (Figure 4B). UV (MeOH) λ_{max}, nm: 222. IR ν_{max}: 3305, 1661, 1602, 1576, 1512, 1430, 1357, 1279, 1220, 1166, 1130, 1107, 1075, 1021. ESI−MS m/z: 136 [M] (calculated for $C_8H_8O_2$). ^{1}H NMR (CD_3OD, 400 MHz) δ: 7.88 (2H, d, J = 8.9 Hz, H-2, 6), 6.84 (2H, d, 2, J = 8.8 Hz, H-3, 5), 2.52 (3H, s, H-8). ^{13}C NMR (CD_3OD, 100 MHz) δ: 130.4 (C-1), 132.3 (C-2, 6), 116.4 (C-3, 5), 164.2 (C-4), 199.7 (C-7), 26.5 (C-8). Compound **4** was identified as 4-HAP by direct comparison to commercial 4-HAP (Sigma Chemical Co., St. Louis, MO). On the basis of the data described above and the verified reference,[23] the structure of compound **4** was elucidated as 4-HAP. Chen et al.[24] reported that 4-HAP exhibits antiallergic activities, and against β-hexosaminidase, it could release a marker of degranulation in rat basophilic leukemia (RBL)-2H3 cells.

XO Inhibitory Activity of 4-HAP, B2−3′-*O*-Gallate, Salidroside, *p*-Tyrosol, and Allopurinol. In the previous XO inhibitor studies, quercetin-3-*O*-rhamnopyranoside and luteolin isolated from *Acacia confusa* showed a strong inhibitory effect on XO, with IC_{50} values of 37.7 and 11.6 μM, respectively.[25] The inhibitory effects of 4-HAP, B2−3′-*O*-gallate, salidroside, *p*-tyrosol, and allopurinol on XO were tested at different concentrations. XO inhibition increased significantly with the addition of allopurinol ($p < 0.05$; Figure 5). When

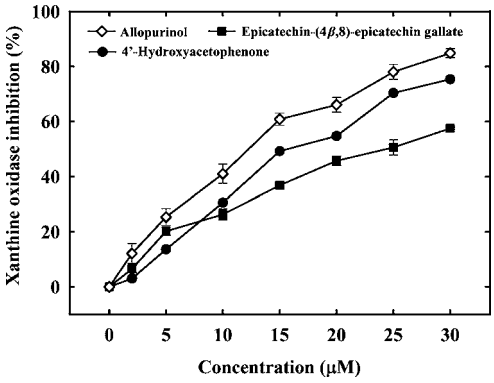

Figure 5. Inhibitory effects of allopurinol, B2−3′-*O*-gallate, and 4-HAP on XO. Each value is represented as the mean ± standard deviation from triplicate measurements.

15 μM of the inhibitor was added, the XO inhibition by allopurinol was 60.8%. Similar trends were also observed in the results for 4-HAP and B2−3′-*O*-gallate; they showed inhibitory effects on XO. When examining the inhibition of XO by 4-HAP at 25 μM and B2−3′-*O*-gallate at 30 μM, the XO inhibitory activities were 70.3 and 57.5%, respectively. 4-HAP and B2−3′-*O*-gallate showed remarkable inhibitory effects on XO ($p < 0.05$). However, we failed to observe any significant inhibitory effects on XO by salidroside or *p*-tyrosol at 30 μM (data not shown). As previously mentioned, five major peaks and one minor peak were found in the HPLC profile of WE (Figure 3). Salidroside and *p*-tyrosol indicated two major peaks in WE following elution times of 21−22 and 23−24 min, respectively. We observed that WE displayed XO inhibitory activity; however, the five major peaks in WE did not present significant inhibitory effects on XO, suggesting that the minor peak in WE at an elution time of 24−38 min exhibits XO. Nguyen et al.[26] reported that allopurinol is a substrate and a specific potent inhibitor of XO, but oxypurinol (1*H*-pyrazolo-[3,4-*d*]-pyrimidine-4,6-diol) is the basic functioning ingredient found in allopurinol. XO can catalyze the conversion of allopurinol into oxypurinol, and inhibition occurs mainly through direct substrate competition in the breakdown of purines. The XO inhibitory activities of purified salidroside, *p*-tyrosol, B2−3′-*O*-gallate, and 4-HAP from *R. crenulata* were evaluated and compared to that of allopurinol. The structure, molecular weight, molecular formula, and IC_{50} values of allopurinol, 4-HAP, B2−3′-*O*-gallate, *p*-tyrosol, and salidroside are shown in Table 1. Allopurinol, 4-HAP, and B2−3′-*O*-gallate showed strong inhibitory effects on XO, and the IC_{50} values of these compounds were 12.21 ± 0.27, 15.62 ± 1.19, and 24.24 ± 1.80 μM, respectively. This result indicated that 4-HAP and B2−3′-*O*-gallate have the potential to be XO inhibitors. However, the IC_{50} values of both salidroside and *p*-tyrosol were higher than 200 μM.

Modes of Inhibition of XO by B2−3′-*O*-gallate and 4-HAP. The 4-HAP and B2−3′-*O*-gallate were analyzed by Michaelis−Menten kinetic studies to determine their modes of inhibition of XO. In this study, the Michaelis constant (K_m) of XO was 5.33 ± 0.21 mM, which was similar to that reported by Tung et al.[27] They reported that the K_m value of XO was 21 μM. As shown in Figure 6, Lineweaver−Burk plots of B2−

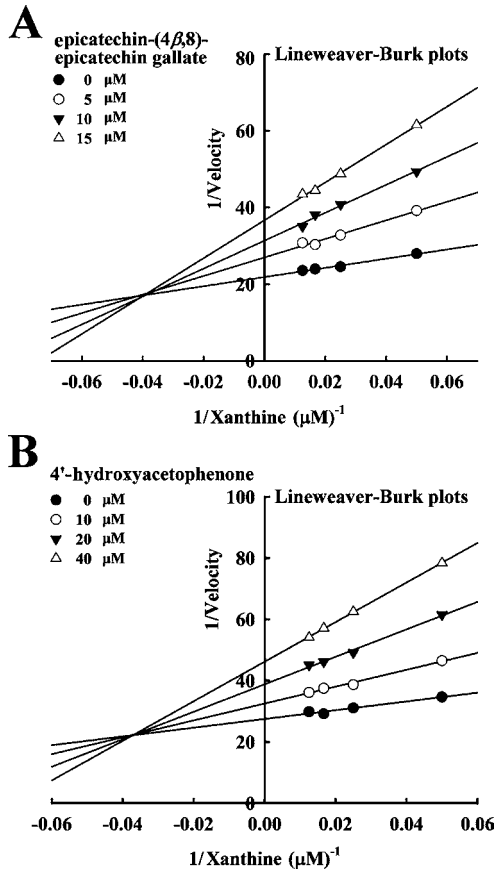

Figure 6. Lineweaver−Burk plots for the inhibition of XO by XO inhibitors with xanthine as the substrate: (A) B2−3′-*O*-gallate and (B) 4-HAP.

3′-*O*-gallate and 4-HAP were constructed. The Lineweaver−Burk plots of B2−3′-*O*-gallate (Figure 6A) and 4-HAP (Figure 6B) had no intersection on the *y* or *x* axis, indicating that the type of inhibition was a mixed-type mode. Therefore, the Lineweaver−Burk plots revealed that B2−3′-*O*-gallate and 4-HAP behaved as mixed-type inhibitors. Several mixed-type XO inhibitors have been reported. For example, a Lineweaver−Burk plot indicated that 3,4-dihydroxybenzoic acid isolated from the flowers of *Chrysanthemum sinense* appears to be a mixed-type inhibitor of XO.[26] Furthermore, Day et al.[28] reported that quercetin-3′-glucuronide showed mixed competitive inhibition of XO.

Dixon plots of B2−3′-*O*-gallate and 4-HAP on XO were also evaluated (Figure 7). The Dixon plots indicated that B2−3′-*O*-gallate (Figure 7A) and 4-HAP (Figure 7B) were mixed-type inhibitors of XO, and the values of K_i were 7.26 ± 0.38 and 8.45 ± 0.34 μM, respectively. Jiao et al.[29] reported that apigenin-4′-*O*-(2″-*O*-*p*-coumaroyl)-β-D-glucopyranoside purified from *Palhinhaea cernua* inhibits XO with mixed-type inhibition, with K_i and K_i' values of 14.35 and 93.68 μM, respectively. The K_i

dx.doi.org/10.1021/jf5004094 | J. Agric. Food Chem. 2014, 62, 3742−3749

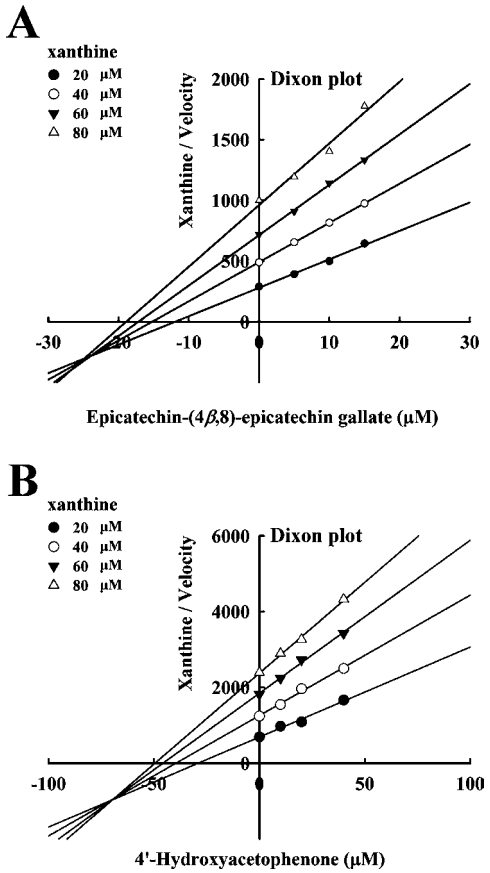

Figure 7. Dixon plots for the inhibition of XO by XO inhibitors with xanthine as the substrate: (A) B2−3′-*O*-gallate and (B) 4-HAP.

value of 4-HAP was higher than that of B2−3′-*O*-gallate. This indicated that B2−3′-*O*-gallate showed a higher binding affinity than 4-HAP to XO. Furthermore, the K_i' of B2−3′-*O*-gallate and 4-HAP were 24.43 ± 0.65 and 69.58 ± 1.13 μM, respectively. In addition, we noted that the values of K_i for B2−3′-*O*-gallate and 4-HAP were smaller than values of K_i'. As mentioned previously, K_i is the equilibrium constant for an inhibitor binding to XO, while K_i' is the equilibrium constant for inhibitor binding to the XO−xanthine complex. Cortés et al.[30] reported that, in the reversible mixed competitive inhibition, the values of K_i were smaller than the values of K_i'. This indicated that the binding affinity for the inhibitor−XO complex was higher than that for the inhibitor−XO−xanthine complex. Therefore, the inhibition kinetics study indicates that B2−3′-*O*-gallate and 4-HAP are mixed competitive inhibitors of XO. Although the binding sites and mechanisms of inhibition remain to be determined, the finding of mixed competitive inhibition of XO suggests that B2−3′-*O*-gallate and 4-HAP may bind to either XO or the XO−xanthine complex.

In summary, the WE of *R. crenulata* displayed XO inhibitory activity, and four active compounds, salidroside, *p*-tyrosol, B2−3′-*O*-gallate, and 4-HAP, were isolated from *R. crenulata*. Among these compounds, B2−3′-*O*-gallate and 4-HAP showed excellent XO inhibitory activity with a mixed competitive mode. Thus, B2−3′-*O*-gallate and 4-HAP have great potential to prevent hyperuricemia caused by XO. Therefore, our results suggest that B2−3′-*O*-gallate and 4-HAP could be adopted as candidates to treat gout, and further evaluation should be conducted with *in vivo* studies.

MATERIALS AND METHODS

Reagents and Materials. Reagents were obtained as follows: fetal bovine serum (FBS; Hyclone, South Logan, UT, USA), penicillin (Invitrogen, Carlsbad, CA, U.S.A.), Dulbecco's modified Eagle's medium (DMEM; Hyclone, South Logan, UT, U.S.A), antidinitrophenyl (DNP)-specific immunoglobulin E (IgE) (Sigma-Aldrich, St. Louis, MO, U.S.A.), DNP-bovine serum albumin (DNP-BSA, Sigma-Aldrich, St. Louis, MO, U.S.A.), PIPES (Sigma-Aldrich, St. Louis, MO, U.S.A.), PP2 (Sigma-Aldrich, St. Louis, MO, U.S.A.), and cyclooxygenase 2 (COX-2) antibody, 5-lipoxygenase (5-LO) antibody, phospho-Lyn (Tyr507) antibody, phospho-Syk (Tyr525/526) antibody, phospho-phospholipase C (PLC)γ (Tyr783) antibody, phospho-PKD/PKCμ (Ser916) antibody, phosphor-SAPK/JNK (Thr183/Tyr185) antibody, SAPK/JNK (Thr183/Tyr185) antibody, phospho-p44/42 MAPK antibody (Erk1/2), p44/42 MAPK (Erk1/2) antibody, phospho-p38 antibody, p38 antibody, and β-actin antibody (all from Cell Signaling Technology Inc., Danvers, MA, U.S.A.).

Plant Material. *A. rossii* was collected in Pyeongchang, Gangwon Province, Korea, in August 2010. A voucher specimen (DGR-012) was deposited at the Korea Institute of Science and Technology (KIST), Gangneung Institute. Extraction was performed by sonication using an RK158S ultrasonic bath (Bandelin, Germany).

Extraction and Isolation of Flavones and Flavone Glycosides from *A. rossii*. One kilogram of the dried aerial parts of *A. rossii* was extracted with 5 L of 95% ethanol at room temperature for 4 h and filtered through Whatman No. 1 filter paper (GE Healthcare Life Sciences, PA, U.S.A.). The filtrate was concentrated under reduced pessure by rotary evaporation at 40 °C, and 120 g of EtOH extract (ARE) was obtain. ARE (100 g) was sequentially partitioned into hexane (17.3 g), methylene chloride (7.3 g), ethyl acetate (12.3 g), butanol (29.1 g), and water portions (31.9 g) for β-hexosaminidase assay. Among ARE partitioned into other solvents, the ethyl acetate fraction (ARF) showed the highest inhibitory activity of mast cell degranulation (Figure S1 in Supporting Information [SI]); thus, a bioactivity-guided fractionation procedure was performed to obtain seven isolates. Ten grams of ARF was chromatographed on a silica gel column (Merck 230−400 mesh, 500 g, 5 cm diameter × 70 cm, Merck, Darmstadt, Germany) and successively eluted with a stepwise gradient of hexane/ethyl acetate [90:10 (3 L), 80:20 (2 L), 75:25 (2 L), 65:35 (2 L), 50:50 (2 L), 30:70 (2 L), 0:100 (1 L) by volume] to provide five fractions [ARF1 (168 mg), ARF2 (127 mg), ARF3 (150 mg), ARF4 (693 mg), ARF5 (790 mg)]. The subfractions were monitored by HPLC (Figure S2 in SI) and the ARF1−5 fractions showed similar inhibitory activity of β-hexosaminidase release (Figure S3 in SI). Isolation of flavone and flavone glycosides (Figure 1) from *A.rossii* was done as previously described.[14]

Cell Culture. RBL-2H3 cells obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA) via the Korean Cell Line Bank (KCLB no. 22256, Seoul, Korea) were cultured in DMEM supplemented with 10% FBS and 100 U/mL penicillin. Cells were grown in 75 cm^2 culture flasks at 37 °C with 5% CO_2 in a humidified atmosphere.

Cell Viability Assay. Cell viability was checked using a 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay (Sigma-Aldrich, St Louis, MO, U.S.A.). RBL-2H3 cells were grown in 24-well plates (2×10^5 cells/mL) for 24 h. After treating the cells with various concentrations of ARE for 6 h, the cells were washed and then treated with 200 μL MTT (0.5 mg/mL), and cells were incubated for an additional 4 h. Cells were then washed, and the insoluble formazan products were dissolved in 200 μL DMSO. Absorbance was measured by spectrophotometry at 550 nm using a microplate reader (Bio-Tek Instruments, Winooski, VT).

Measurement of Histamine and β-Hexosaminidase Release. RBL-2H3 cells were sensitized with 0.2 μg/mL monoclonal DNP-IgE. Cells were washed with modified PIPES buffer (25 mM PIPES, pH 7.2, 119 mM NaCl, 5 mM KCl, 0.4 mM $MgCl_2 \cdot 6H_2O$, 1 mM $CaCl_2$, 5.6 mM glucose, 40 mM NaOH and 0.1% BSA). Cells were treated with ARE or compounds **1**−**7** at the indicated concentrations for 1 h at 37 °C. After incubation, cells were challenged with 0.2 μg/mL DNP-BSA for 1 h at 37 °C. Histamine was then detected using an enzyme immunoassay kit (Oxford Biomedical Research, Rochester Hills, MI). Histamine release was expressed as a percentage of the total histamine produced by unstimulated cells. To determine β-hexosaminidase release, aliquots of supernatants and lysed pellets were transferred into 96-well plates. Samples were mixed with substrate solution (1 mM *p*-nitrophenyl *N*-acetyl-β-D-glucosamine in 0.05 M citrate buffer, pH 4.5) and incubated for 1 h at 37 °C. Reactions were terminated by the addition of 0.05 M sodium carbonate buffer, pH 10. Absorbance was measured by spectrophotometry at 405 nm.

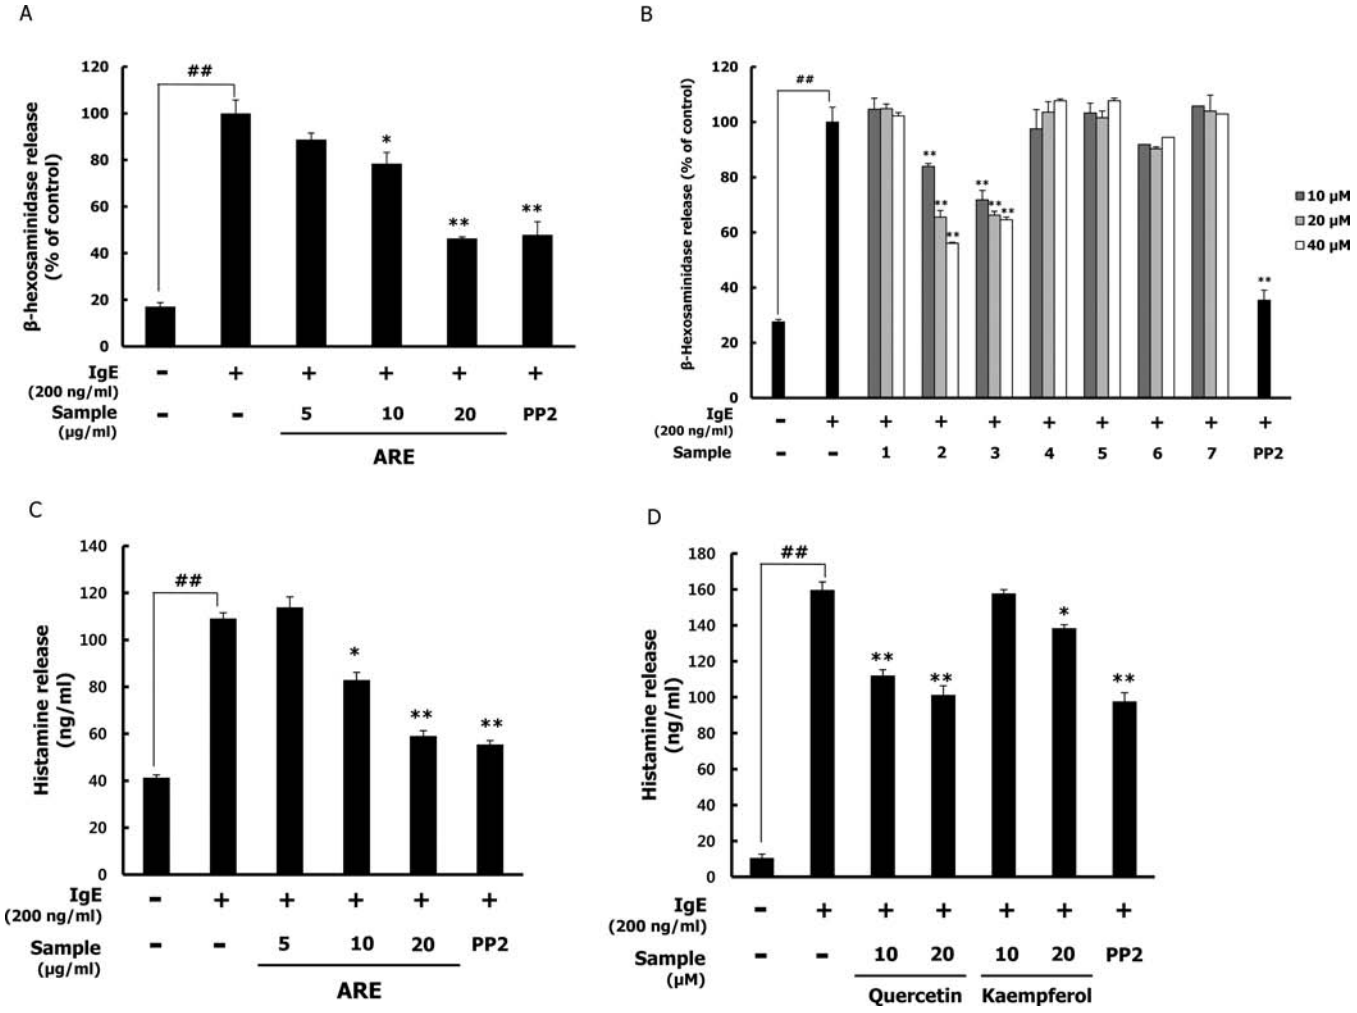

Figure 2. Effects of ARE, quercetin, and kaempferol on β-hexosaminidase and histamine release. (A) The degranulation was determined by measuring β-hexosaminidase release in DNP-IgE-sensitized RBL-2H3 cells. The RBL-2H3 cells were treated in the presence or absence of ARE (5, 10, or 20 μg/mL) for 1 h and then stimulated for 1 h with DNP-BSA. (B) The RBL-2H3 cells were treated in the presence or absence of gallic acid ethyl ester (1), quercetin (2), kaempferol (3), quercetin 3-*O*-(6″-galloyl)-β-D-glucopyranoside (4), quercetin 3-*O*-β-D-glucopyranoside (5), kaempferol 3-*O*-(6″-galloyl)-β-D-glucopyranoside (6), or kaempferol 3-*O*-β-D-glucopyranoside (7) (20 μM) for 1 h and then stimulated for 1 h with antigen. (C,D) Histamine release was determined with enzyme-linked immunosorbent assay kit. The RBL-2H3 cells were treated in the presence or absence of ARE (5, 10, or 20 μg/mL), quercetin (10 or 20 μM), or kaempferol (10 or 20 μM) for 1 h and then stimulated for 1 h with antigen. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments. ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

Measurement of Prostaglandin E_2 and Leukotriene B_4. Cell culture medium was collected, and the secretions of prostaglandin E_2 (PGE_2) and leukotriene B_4 (LTB_4) were determined using competitive radioimmunoassay kits (R&D Systems, MN, U.S.A., and Cayman Chemical, MI, U.S.A., respectively) according to the manufacturers' protocol.

Measurement of Cytokine Release. IgE-sensitized RBL-2H3 cells were incubated with ARE, quercetin, and kaempferol (various concentrations) for 1 h and stimulated with DNP-BSA for 4 h. Interleukin (IL)-4 and tumor necrosis factor (TNF)-α concentrations in cell culture supernatants were measured using enzyme-linked immunosorbent assay kits (Abcam, UK).

Reverse Transcription-Polymerase Chain Reaction. (RT-PCR). RNA was extracted with Trizol reagent (Invitrogen) according to the manufacturer's protocol and quantified by spectrophotometry at 260 nm. The cDNA was synthesized in a 20 μL reaction containing 1 μg total RNA, oligo (dT), and reverse transcriptase premix (Elpis-Biotech., Inc., Taejeon, Korea). Reverse transcription (RT) was initiated at 70 °C for 5 min, followed by incubation at 42 °C for 60 min, and was terminated at 94 °C for 5 min. Amplification of the cDNA products (5 μL) by PCR was performed with a PCR premix (Elpis-Biotech) and the following primer pairs: TNF-α forward, 5′-CAA GGA GCA GAA GTT CCC AA-3′, and TNF-α reverse, 5′-CGG ACT CCG TGA TGT CTA AG-3′ (500 bp); IL-4 forward, 5′-ACC TTG CTG TCA CCC TGT TC-3′, and IL-4 reverse, 5′-TTG TGA GCG TGG ACT CAT TC-3′ (351 bp); COX-2 forward, 5′- TGA CTG TAC CCG GAC TGG AT-3′, and COX-2 reverse, 5′-CAT GGG AGT TGG GCA GTC AT-3′ (322 bp); 5-LO forward, 5′-TAC TCA TCA AGC GCT GCA CA-3′, and 5-LO reverse, 5′-TGG CCA AAA GCC AGT CGT AT-3′ (324 bp); β-actin forward, 5′-AGC CAT GTA CGT AGC CAT CC-3′, and β-actin reverse, 5′-TCT CAG CTG TGG TGG TGA AG-3′ (227 bp). Before PCR amplification, primers for cytokines and β-actin were denatured at 94 °C for 5 min. Amplification consisted of 28 cycles of denaturation at 94 °C for 30 s, annealing for 1 min (52 °C for IL-4; 55 °C for TNF-α and β-actin), and extension at 72 °C for 1 min, followed by a final 5 min extension at 72 °C. PCR was performed using a GeneAmp PCR System 9700 (Applied Biosystems, Foster City, CA, U.S.A.). PCR products were separated by 1.5% agarose gel electrophoresis and visualized by ethidium bromide staining and UV illumination. Densitometry was performed using DIG chemiluminescent film (volume of all markers/volume of β-actin).

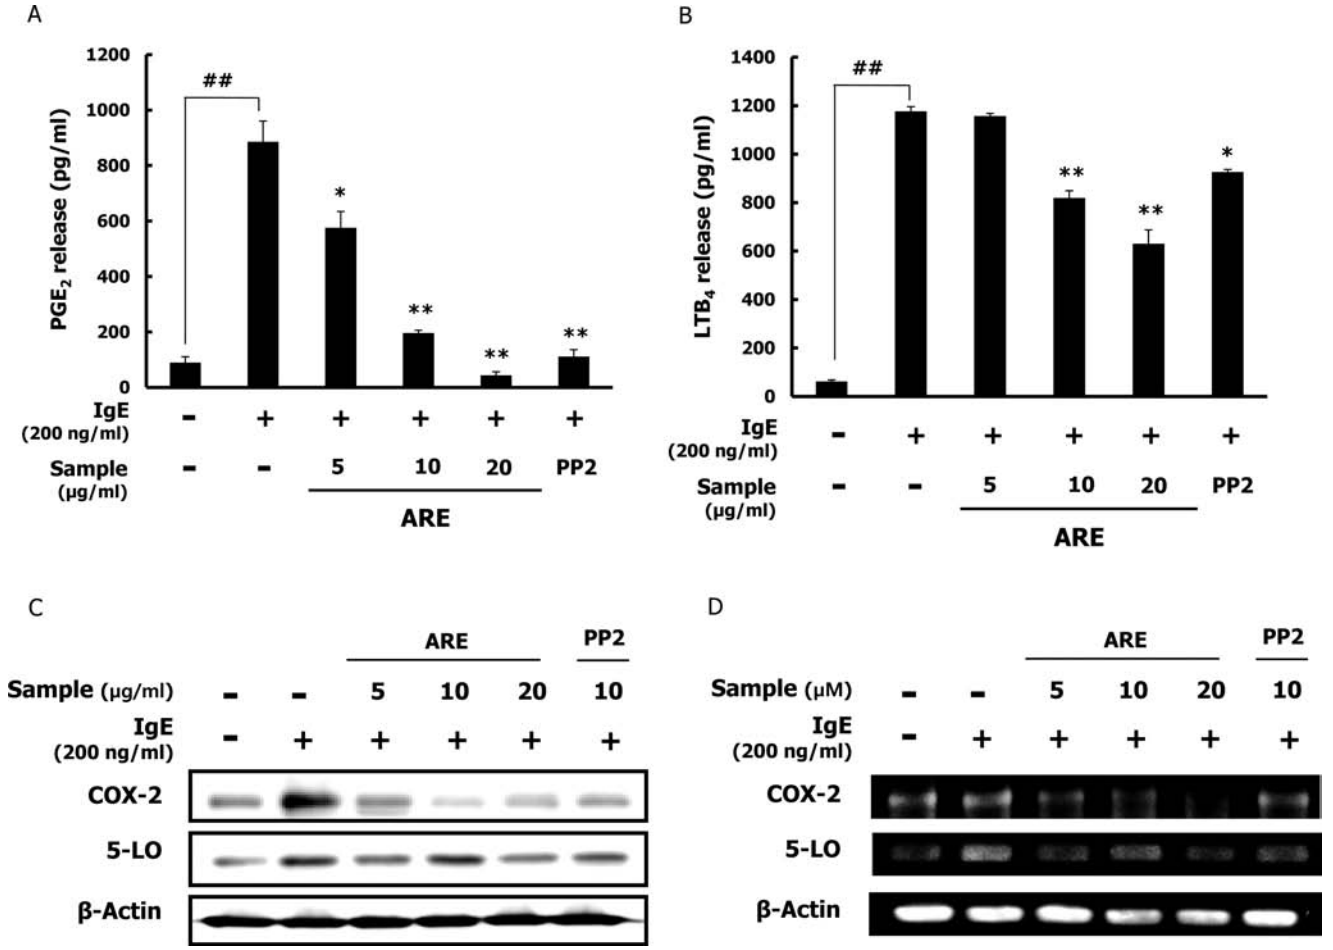

Figure 3. Effects of ARE on PGE_2 and LTB_4 secretion. RBL-2H3 cells were treated with ARE (5, 10, or 20 μg/mL) for 1 h and then stimulated for 4 h with antigen. (A,B) PGE_2 and LTB_4 secretion was determined by enzyme-linked immunosorbent assay kit. (C,D) COX-2 and 5-LO protein and mRNA level were determined with Western blot assay and RT-PCR, respectively. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments. ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

Generation of Passive Cutaneous Anaphylaxis (PCA) in Mice. A 0.5 mg of DNP-IgE was injected subcutaneously into the left ears of 4-week-old male BALB/c mice, 24 h before antigen challenge. After IgE-sensitization, the mice were orally administered with ARE (100, 300 mg/kg) or cetirizine (20 mg/kg). After 60 min, the mice were intravenously injected with 250 μg of DNP-BSA in 250 μL of 1 × phosphate-buffered saline (PBS) containing Evans Blue (5 mg/mL). After 1 h, mice were euthanized and ear tissue was collected. The ear tissue absorbed dye was extracted overnight in 700 μL of formamide at 63 °C. The absorbance was measured at 620 nm to calculate dye concentration. Procedures used in this study were approved by the Animal Care and Use Committee of KIST.

Western Blot Analysis. RBL-2H3 cells were lysed in RIPA buffer containing protease inhibitors and then placed on ice for 10 min. Lysate protein concentrations were determined by Bradford protein assay (Bio-Rad Laboratories, Hercules, CA, U.S.A.). Equal amounts of protein (30 μg) were loaded in each sample, separated by 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred to nitrocellulose membranes (Whatman GmbH, Dassel, Germany). Blotted membranes were blocked with 5% skimmed milk in Tris-buffered saline containing 0.1% Tween 20 for 1 h, and then incubated with primary antibodies for 16 h at 4 °C. After three washes in Tris-buffered saline containing 0.1% Tween 20, the membranes were incubated with horseradish peroxidase-linked secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, U.S.A.) for 2 h. Proteins were detected with enhanced chemoluminescence (Amersham Biosciences, Little Chalfont, UK) and visualized using an ECL Advanced system (GE Healthcare, Hatfield, UK).

Statistical Analysis. Each experiment was performed at least three times. Results are expressed as the mean ± standard deviation (SD). Vehicle (DMSO) and treated groups were compared by one-way analysis of variance followed by Scheffe's test (SPSS 17.0, Chicago, IL, USA). $^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$ were considered statistically significant. $^{\#\#}p < 0.01$ was compared with the control group (DNP-IgE treatment alone); $^{*}p < 0.05$, and $^{**}p < 0.01$ was compared with the DNP-IgE and DNP-BSA stimulated group.

RESULTS

Identification Flavone and Flavone Glycosides from *Aceriphyllum rossii*. Seven flavones and flavone glycosides were identified in *A. rossii* using LC−NMR/MS, including gallic acid ethyl ester, quercetin, kaempferol, quercetin 3-*O*-(6″-galloyl)-*β*-D-glucopyranoside (QGG), quercetin 3-*O*-*β*-D-glucopyranoside (QG), kaempferol 3-*O*-(6″-galloyl)-*β*-D-glucopyranoside (KGG), and kaempferol 3-*O*-*β*-D-glucopyranoside (KG) (Figure 1).

Cytotoxicity of Test Substances. The effect of ARE on RBL-2H3 cell viability was evaluated by colorimetric MTT assay. Treatment with ARE (5−20 μg/mL) had no effect on RBL-2H3 cell viability, and no cytotoxicity was observed (data not shown).

Inhibitory Effects of ARE and Flavones and Flavone Glycosides from *A. rossii* on *β*-hexosaminidase and Histamine Release in IgE-Stimulated RBL-2H3 Cells. To

dx.doi.org/10.1021/jf405486c | J. Agric. Food Chem. 2014, 62, 3750−3758

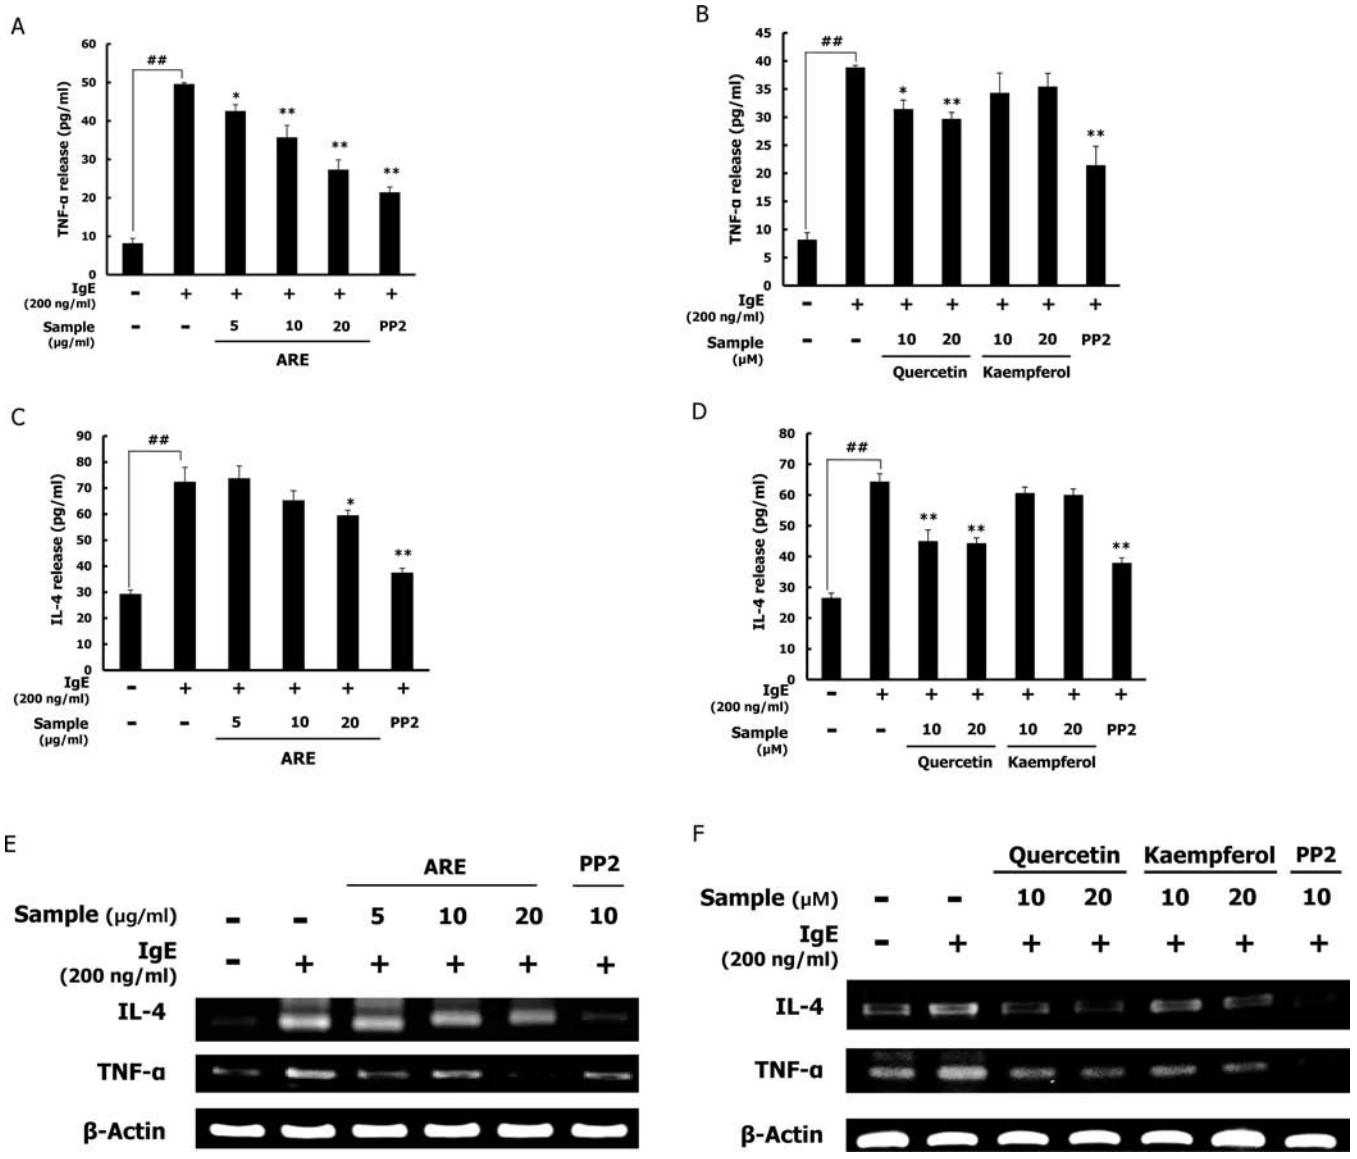

Figure 4. Effects of ARE, quercetin, and kaempferol on TNF-α and IL-4 production and expression. RBL-2H3 cells were treated with ARE, quercetin, and kaempferol for 1 h and then stimulated with DNP-BSA for 4 h. (A–D) TNF-α and IL-4 production was determined by enzyme-linked immunosorbent assay kit. (E,F) TNF-α and IL-4 mRNA levels were determined with RT-PCR. PP2 (10 μM) is a general Src-family kinase inhibitor. Results are expressed as the mean ± SD of three independent experiments. ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

determine the effect of ARE and its constituents on mast cell degranulation, its ability to inhibit the release of β-hexosaminidase was examined. ARE inhibited β-hexosaminidase release in RBL-2H3 cells treated with IgE at concentrations of 5, 10, and 20 μg/mL in a dose-dependent manner. At a concentration of 20 μM ARE, β-hexosaminidase release was inhibited by 46% (Figure 2A). In addition, quercetin and kaempferol inhibited the degranulation of DNP-BSA-stimulated RBL-2H3 cells to a greater degree than gallic acid ethyl ester, QGG, QG, KGG, or KG (Figure 2B). Therefore, further studies were performed using quercetin and kaempferol. The effect of ARE, quercetin, and kaempferol on histamine release was also evaluated to determine potential antiallergic activities. ARE, quercetin, and kaempferol inhibited histamine release in RBL-2H3 cells treated with IgE in a dose-dependent manner (C and D of Figure 2).

Inhibitory Effects of ARE on PGE_2 and LTB_4 Production and COX-2 and 5-LO Expression in IgE Stimulated RBL-2H3 Cells. The FcεRI receptor activates the arachidonate cascade in antigen-activated mast cells.[15] Thus, the effect of ARE on the production of proinflammatory lipid mediators (such as PGE_2 and LTB_4) was investigated. ARE significantly inhibited PGE_2 and LTB_4 secretion in IgE-stimulated RBL-2H3 cells in a dose-dependent manner. ARE (20 μM) inhibited PGE_2 and LTB_4 secretion by 5% and 53%, respectively (A and B of Figure 3). The effect of ARE on the expression of cyclooxygenase 2 (COX-2) and 5-lipoxygenase (5-LO), enzymes that produce PGs and LTs from arachidonic acid, was also evaluated by Western blot assay and RT-PCR. IgE treatment induced COX-2 and 5-LO protein and mRNA expression in RBL-2H3 cells. However, treatment with 5, 10, or 20 μg/mL of ARE attenuated the IgE-induced upregulation of COX-2 and 5-LO (C and D of Figure 3).

Inhibitory Effect of ARE, Quercetin, and Kaempferol on Proinflammatory Cytokine Production and Gene Expression in IgE Stimulated RBL-2H3 Cells. The

dx.doi.org/10.1021/jf405486c | J. Agric. Food Chem. 2014, 62, 3750–3758

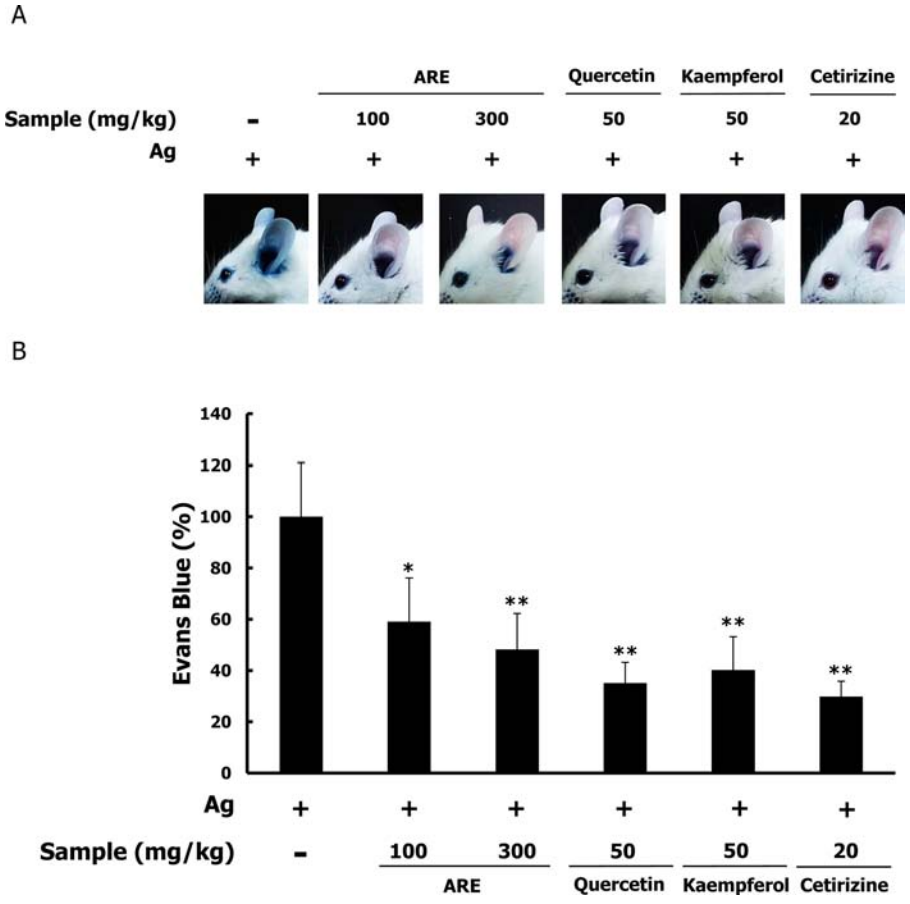

Figure 5. Effect of ARE, quercetin, and kaempferol on IgE-mediated passive cutaneous anaphylaxis (PCA). (A) ARE (100 or 300 mg/kg), quercetin (50 mg/kg), kaempferol (50 mg/kg), or cetrizine (20 mg/kg) was orally administered to mice for 1 h before IgE sensitization. Evans blue stained ears were photographed. (B) The ear absorbed dye was extracted with formamide. The quantification data is presented as % of IgE-stimulated control. Cetrizine (20 mg/kg) is an antihistamine reference drug. Results are expressed as the mean ± SD of three independent experiments. ($^{\#\#}p < 0.01$, $^{*}p < 0.05$, and $^{**}p < 0.01$).

proinflammatory cytokines, TNF-α and IL-4, are critical for allergic responses.[16] We therefore examined whether ARE, quercetin, and kaempferol regulate the production and mRNA expression of TNF-α and IL-4 in IgE-sensitized RBL-2H3 cells. As shown, ARE and quercetin inhibited both TNF-α and IL-4 production (A–D of Figure 4) and gene expression, while kaempferol did not affect production and expression of TNF-α and IL-4 (E and F of Figure 4).

Effect of ARE, Quercetin, and Kaempferol on Mast Cell-mediated PCA in Mice. PCA is widely used to determine local allergic reactions *in vivo*.[17] To investigate whether ARE, quercetin, and kaempferol inhibited allergic responses, we used a mast cell-dependent PCA model. IgE was injected subcutaneously into mouse ear tissue, followed by injection of DNP-BSA containing 5% Evans Blue. Oral administration of ARE, quercetin, and kaempferol inhibited the antigen-induced PCA response in a dose-dependent (Figures 5A and 5B). The inhibitory effect of ARE, quercetin, and kaempferol was similar to that of 20 mg/kg cetrazine,[18] a typical antihistamine drug, which was used as a positive control.

Effect of ARE, Quercetin, and Kaempferol on FcεRI Signaling in IgE Sensitized RBL-2H3 Cells. FcεRI signals through activation of Syk, Lyn, PKC, and PLCγ.[19] PP2, a general Src-family kinase inhibitor, markedly suppressed phosphorylation of Syk.[19] To investigate the mechanisms involved in ARE-, quercetin-, and kaempferol-mediated inhibition of degranulation, a number of intracellular signals were examined. DNP-BSA treatment of IgE-sensitized cells induced phosphorylation of Syk, PKD/PKCμ, and PLCγ at early time points, and this phosphorylation was reduced by treatment with ARE, quercetin, or kaempferol (A and B of Figure 6). During IgE-mediated activation of mast cells, three major subfamilies of MAPKs (extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38) can be activated, resulting in cytokine production.[20] To further identify the relevant downstream effectors that directly modulate cytokine production following ARE, quercetin, and kaempferol treatment, phosphorylation of ERK, JNK, and p38 was examined. IgE-induced phosphorylation of ERK, JNK, and p38 was inhibited by treatment with ARE, quercetin, or kaempferol (C and D of Figure 6).

■ DISCUSSION

Immediate-type hypersensitivity is initiated and amplified by inflammatory mediators (histamines, LTs, and PGs) and cytokines (TNF-α and IL-4) released from immune cells such as mast cells, eosinophils, and basophils. In particular, mast cells are crucial players in the regulation of allergic inflammatory responses due to their ability to produce proinflammatory mediators including histamines, PGE_2, and LTB_4.[21] A recent study in mast cell-deficient mice demonstrated that mast cell-derived mediators (histamines, cytokines,

dx.doi.org/10.1021/jf405486c | J. Agric. Food Chem. 2014, 62, 3750–3758

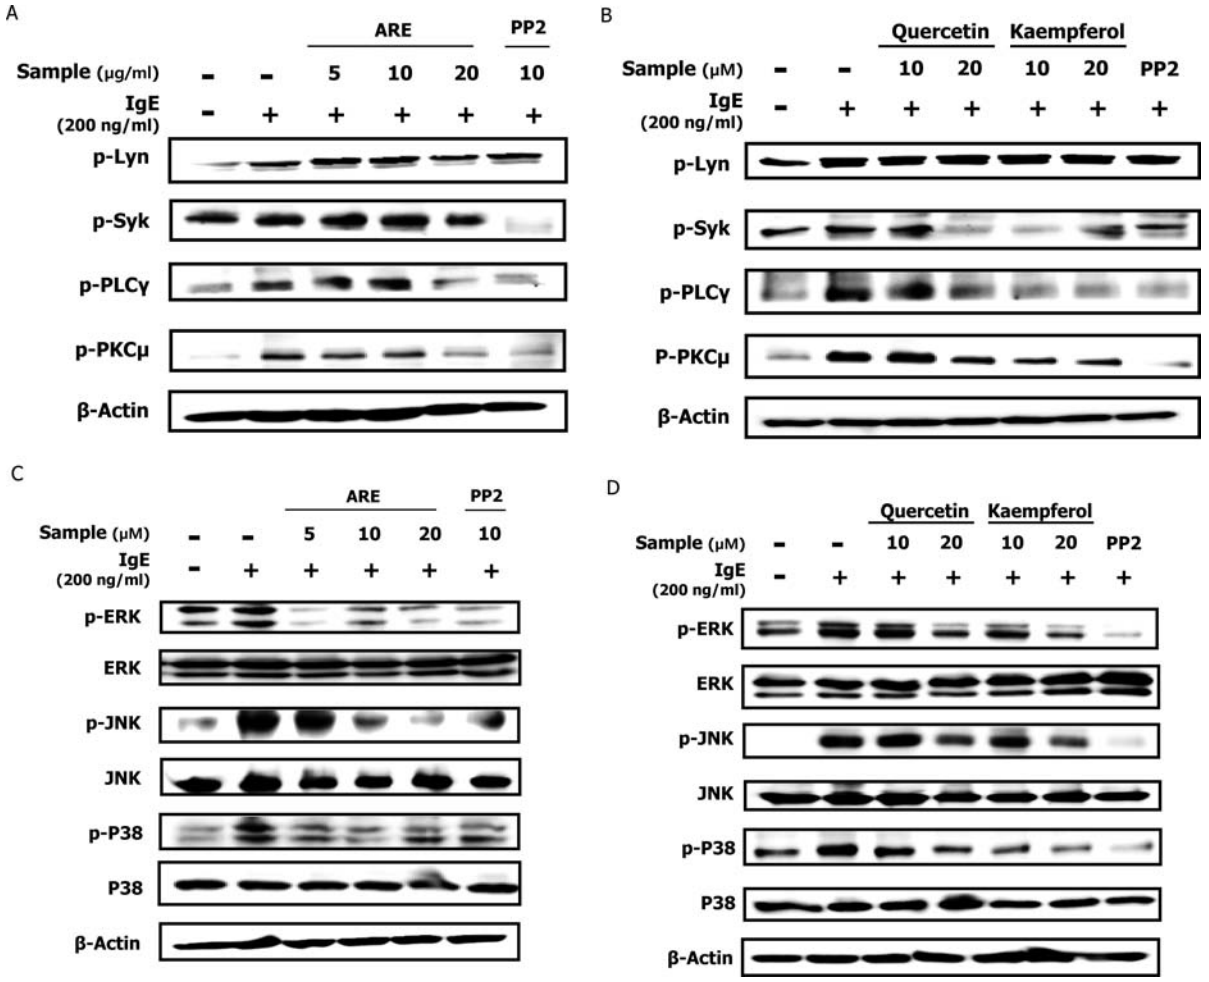

Figure 6. Effect of ARE, quercetin, and kaempferol on FcεRI Signaling. (A,B) RBL-2H3 cells were treated with ARE, quercetin, and kaempferol for 1 h and then stimulated with DNP-BSA for 10 min. Phosphorylation of Lyn, Syk, PLCγ, and PKD/PKCμ was determined with Western blot analysis. (C,D) RBL-2H3 cells were treated with ARE, quercetin, and kaempferol for 1 h and then stimulated with DNP-BSA for 30 min. Phosphorylation of JNK, ERK, and p38 was determined with Western blot analysis. PP2 (10 μM) is a general Src-family kinase inhibitor.

and proteases) play an important role during allergic inflammation.[22] Therefore, a number of studies have identified specific mediators of mast cell activation and have reported novel compounds targeting these inflammatory mediators.[3,23,24]

Quercetin and kaempferol are naturally occurring plant flavonoids found in many vegetables and fruits, and may possess anticancer, antioxidant, and anti-inflammatory properties.[25−27] Moreover, quercetin and kaempferol are also known to suppress various mediators of allergic responses. For example, quercetin, kaempferol, and several other flavonoids suppress degranulation by inhibiting β-hexosaminidase release and production of TNF-α and IL-4.[28] In addition, quercetin and kaempferol suppress IgE-mediated allergic inflammation in RBL-2H3 and Caco-2 cells.[29] However, the molecular mechanisms by which quercetin and kaempferol act on allergic disease are not fully understood. In the present study, we evaluated the inhibitory effects of ARE and its active compounds, quercetin and kaempferol, on allergic mediators in RBL-2H3 cells and in a murine PCA model.

Activation of FcεRI receptors present on mast cells through high affinity binding and aggregation of IgE initiates a signaling cascade that results in degranulation and secretion of inflammatory mediators, including histamine, lipid-derived mediators, and inflammatory cytokines.[30] We observed that ARE, quercetin, and kaempferol inhibited the release of both β-hexosaminidase (B and D of Figure 2) and histamine (C and E of Figure 2) in a dose-dependent manner. These results indicate that the antiallergic effects of ARE, quercetin, and kaempferol are due to the suppression of histamine release, known to cause vascular permeability, smooth-muscle contraction, and inflammation.

The FcεRI receptor signals through Lyn, Syk, and PLCγ to regulate degranulation.[16] The FcεRI receptor is a tetrameric complex, which binds IgE and initiates intracellular signaling to induce allergic responses. Activated FcεRI induces phosphorylation of Syk, which binds immunoreceptor tyrosine-based activation motifs (ITAMs) present on the FcεRI β and γ chains. In turn, Syk induces phosphorylation of PLCγ and PKC.[31] Notably, ARE, quercetin, and kaempferol also decreased the phosphorylation of Syk, PLCγ, and PKD/PKCμ (A and B of Figure 6). These results suggest that ARE, quercetin, and kaempferol may have antiallergic effects in antigen-induced mast cells, most likely by suppressing the activation of Syk, PLCγ, and PKC, and the consequent inhibition of mast cell degranulation.

ARE also reduced the secretion of the inflammatory mediators PGE_2 and LTB_4, which are arachidonic acid metabolites, via inhibition of the COX and LO pathways (A

dx.doi.org/10.1021/jf405486c | J. Agric. Food Chem. 2014, 62, 3750−3758

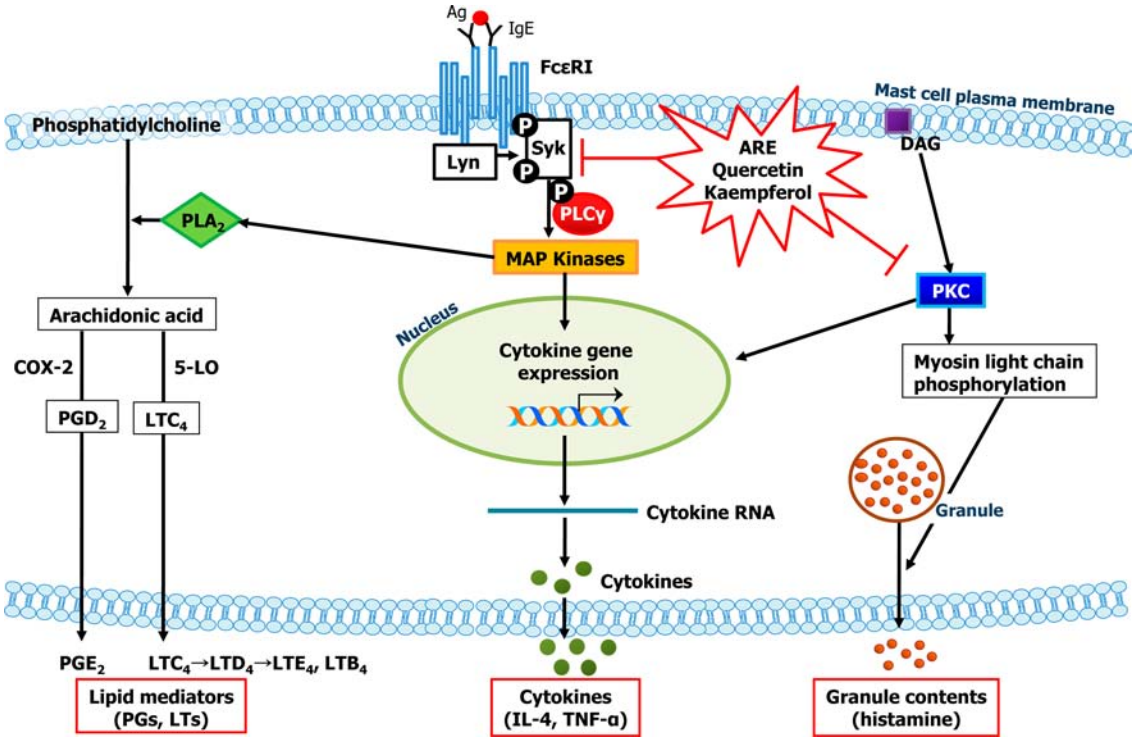

Figure 7. ARE, quercetin, and kaempferol inhibited FcεRI signaling pathways. The level of phosphorylated Syk proteins were reduced by ARE, quercetin, and kaempferol. ARE, quercetin, and kaempferol inhibited other downstream signaling molecules, including PKD/PKCμ and PLCγ. The activation of MAPKs were also suppressed by ARE, quercetin, and kaempferol.

and B of Figure 3).[32] Furthermore, ARE inhibited COX-2 and 5-LO expression, key enzymes in these pathways (C and D of Figure 3). These results indicate that ARE inhibits synthesis of inflammatory mediators by suppressing the COX and LO pathways.

We also found that ARE and quercetin significantly reduced both the production and mRNA expression of the proinflammatory cytokines TNF-α and IL-4 (Figure 4). TNF-α and IL-4 play a crucial role in triggering and sustaining allergic reactions in mast cells. IL-4 induces T-cell development and switches B-cells to the IgE isotype. TNF-α also activates physiological immune responses by promoting leukocyte infiltration and tissue fibrosis, and initiates cytokine-mediated inflammatory states via stimulation of cytokine production.[33] Although inflammation is a physiological defense mechanism against pathogens, overexpression of cytokines can also cause serious inflammatory diseases such as atopic dermatitis and asthma. The results suggest that these compounds may be useful for the treatment of allergic conditions.

MAPK pathways are a major therapeutic target in allergic disease.[34] Therefore, to investigate the mechanism by which ARE, quercetin, and kaempferol inhibit the activation of RBL-2H3 cells, MAPK (ERK, p38, and JNK) phosphorylation was evaluated. In this study, ARE, quercetin, and kaempferol inhibited IgE-induced phosphorylation of ERK, p38, and JNK, suggesting that these compounds attenuate mast cell activation by regulating MAPK signaling (C and D of Figure 6).

In conclusion, ARE and its active compounds, quercetin and kaempferol, inhibited degranulation and the release of histamine, lipid mediators, and proinflammatory cytokines in IgE-stimulated RBL-2H3 cells and had anti-inflammatory effects in a murine PCA model. ARE, quercetin, and kaempferol also inhibited downstream signaling from the FcεRI receptor by suppressing the phosphorylation of Syk, PLCγ, PKC, and MAPK, all of which mediate allergic responses in IgE-sensitized RBL-2H3 cells (Figure 7). These findings indicate that ARE, quercetin, and kaempferol may together be a useful therapeutic agent for preventing or treating IgE-mediated allergic diseases.

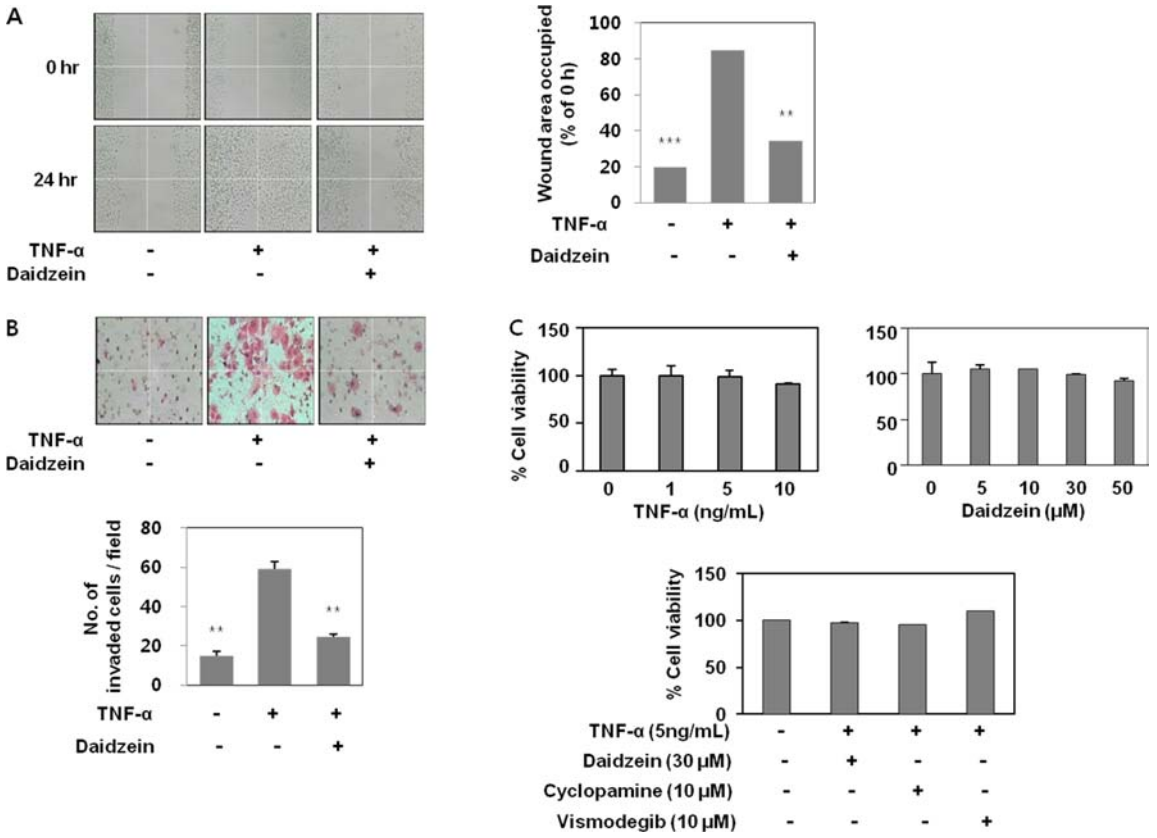

Figure 1. Effect of daidzein on TNF-α induced migration and invasion in MCF10DCIS.com human breast cancer cells. (A) Cells (5×10^5 cells/well in a 6-well plate) were treated with TNF-α (5 ng/mL) alone or together with daidzein (30 μM) for 24 h. Cell migration was assessed by light microscopy at 100× magnification and the number of cells at the injured area at 0 and 24 h was compared. (B) Cells (5×10^4 cells/well in a 24-well invasion chamber) were treated with TNF-α alone or together with daidzein for 24 h. Invasiveness was quantified by counting the number of cells that migrated to the lower side of the filter within randomly selected microscope fields. (C) Cells (5×10^3cells/well in a 96-well plate) were treated with TNF-α or daidzein alone at the indicated concentrations or cotreated TNF-α (5 ng/mL) with daidzein (30 μM), cyclopamine (10 μM), or vismodegib (10 μM) for 24 h. Cell viability was assessed with MTT assay. Values represent means ± SD $^{**}p < 0.01$, $^{***}p < 0.001$ compared to TNF-α treated cells.

MATERIALS AND METHODS

Reagents and Cell Culture. Daidzein and equol were purchased from Sigma (St. Louis, MO, USA), TNF-α from R&D Systems (Minneapolis, MN, USA), 6,7,4′-trihydroxyisoflavone from Indofine Chemical Company, Inc. (Hillsborough, NJ, USA), and vismodegib and cyclopamine from LC Laboratories (Woburn, MA, USA). MCF10DCIS.com human breast cancer cells were purchased from Asterand (Detroit, MI, USA) and cultured in DMEM/F12 (Life Technologies, Grand Island, NY, USA) supplemented with 5% horse serum, 1% HEPES, and 1% penicillin/streptomycin (Life Technologies) at 37 °C, 5% CO_2. Patched1 mutant (Ptch1(−/−)) embryonic fibroblasts (MEFs) were kindly provided by K. Anderson at Sloan Kettering Institute (New York, USA) and cultured in DMEM (Life Technologies, Grand Island, NY, USA) with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin (Life Technologies).

Cell Viability Assay. Cells were incubated with compounds at different concentrations for 24 h, and 200 μL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma) was added 4 h before harvest. Dark-blue formazan crystals were dissolved with DMSO, and absorbance was measured with an ELISA plate reader (Molecular Devices, Sunnyvale, CA, USA) at 570 nm. Cell growth was defined as the percentage of viable cells in comparison with the control.

RNA Extraction and Quantitative Real-Time PCR. Total cellular RNA was extracted using Trizol reagent (Life Technologies) and was reverse-transcribed to obtain cDNA using RevertAid First Strand cDNA Synthesis Kit (Thermo Scientific, Lafayette, CO, USA) in an Atlas Thermal Cycler (Astec, Fukuoka, Japan). The cDNA was amplified using 5× HOT FIREPol EvaGreen qPCR Mix Plus (Solis Biodyne, Tartu, Estonia) and the following primer sequences for Gli1, 5′-CCTTCTTCGCGAACGGTTT-3′ (forward) and 5′-GGGTGAAGGCTGCTCACGTA-3′ (reverse), and for GAPDH, 5′-CAATGCCAAGTATGACAT-3′ (forward) and 5′-CCTGTTAT-TATGGGGGTCTG-3′ (reverse). To detect MMP-2 and -9 mRNA expression levels, labeled TaqMan primers and TaqMan Fast Advanced Master Mix from Applied Biosystems (Foster City, CA, USA) were used, along with the ABI PRISM 7900 sequence detection system (Applied Biosystems). Results were normalized to GAPDH expression level, and relative quantitation was performed using the comparative $2^{-\Delta\Delta CT}$ method.

Protein Extraction. After treatment with a compound, cells were collected and washed with PBS. Total protein was extracted with radioimmunoprecipitation assay (RIPA) buffer (10 mM Tris-HCl, 5 mM EDTA, 150 mM NaCl, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, 0.1 mM Na_3VO_4, 1% phenylmethylsulfonyl fluoride, 1% protease inhibitor). Cytosolic and nuclear fractions were extracted using NE-PERTM Nuclear and cytoplasmic extraction reagents kit (Thermo Scientific) according to the manufacturer's instructions.

Western Blot Analysis. An equivalent amount of protein from cell lysates were resolved by 10% SDS-PAGE and transferred to polyvinylidene fluoride (PVDF, Millipore, Billerica, MA, USA) membranes which were probed with primary and secondary antibodies followed by chemiluminescence detection using EZ capture MG (ATTO, Tokyo, Japan). Primary antibodies used in this study were against Gli1, p-NFκB p65 (Ser536) (Cell Signaling Technology,

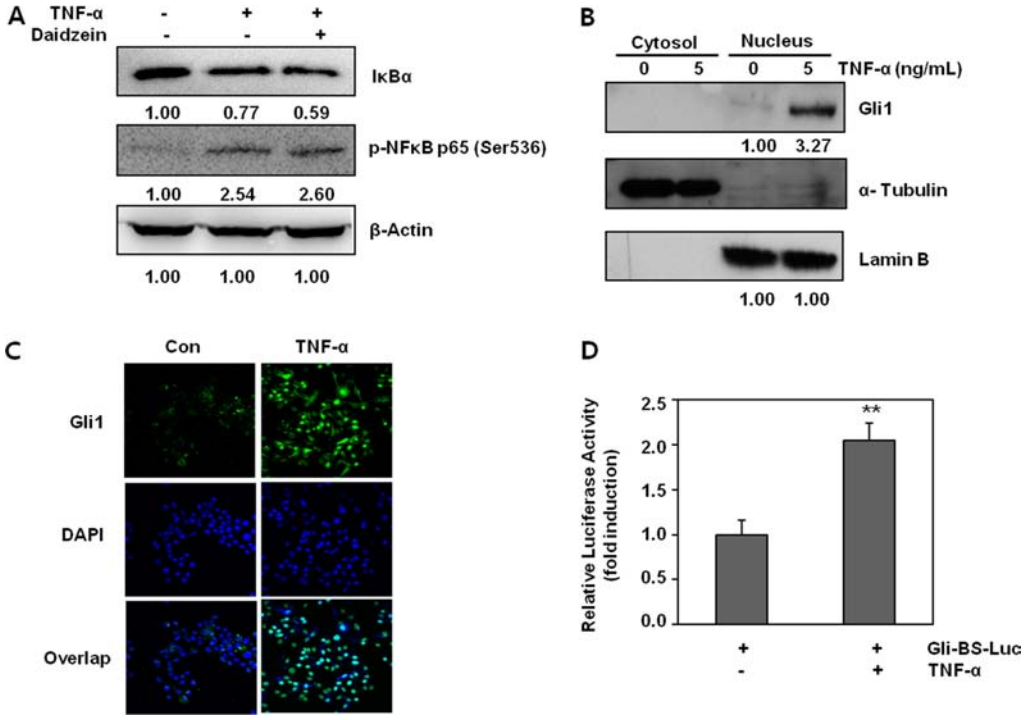

Figure 2. Effect of TNF-α on Hh signaling in MCF10DCIS.com human breast cancer cells. (A) Cells (7×10^5 cells in a 60 mm dish) were treated with TNF-α (5 ng/mL) alone or together with daidzein (30 μM) for 24 h. IκBα expression and NFκB p65 phosphorylation level at Ser 536 were determined by Western blotting. (B) Cytosolic and nuclear fractions of TNF-α treated cells were separated, and Gli1 nuclear translocation was determined by Western blotting. (C) Cells (2×10^5 cells/well in a glass bottom dish) treated with TNF-α were probed with anti-Gli1 antibody, with nuclei stained with DAPI, and cells were visualized by confocal microscopy. (D) Cells were transfected with 8X-Gli-BS-Luc and pCMV-β-gal vectors and treated with TNF-α. Relative luciferase activity from the Gli1 promoter was determined using a luminometer and normalized to β-galactosidase activity. $^{**}p < 0.001$ compared to the control.

Boston, MA, USA), IκBα, α-tubulin, lamin B, (Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA), β-actin (Sigma, St. Louis, MO, USA). Horseradish peroxidase-conjugated secondary antibodies were purchased from Santa Cruz Biotechnology Inc. The blots were quantified using EZ West Lumi Plus (ATTO)

Confocal Microscopy. Cells were cultured in a glass bottom dish (MatTex, Ashland, MA, USA) and fixed with 4% paraformaldehyde in PBS 24 h after treatment with a compound. Cells were then treated with Gli1 antibody (1:100, Santa Cruz) and Alexa Fluor 488-conjugated secondary antibody (1:200, Life Technologies), and DAPI (Vector, Burlingame, CA, USA) was used to stain nuclei. Cells were visualized using a Nikon A1 confocal microscope (Nikon, Tokyo, Japan).

Transfection. Cells were transfected with 200 ng of Gli1 vector (pCMV-FLAG-mGli1 from Dr. Chi Chung Hui, University of Toronto) or Gli1 siRNA (200 nM, Bioneer, Daejeon, Korea) using FuGENE HD transfection reagent (Promega, Madison, WI, USA) in serum free medium. After 6 h, the treatment compound was added to the culture medium for 24 h. The expression of Gli1 protein was confirmed by Western blotting. Gli1 vector-transfected cells were seeded for the invasion assay.

Luciferase Assay. 8XGli-BS-Luc and pCMV-β-gal vectors were provided by Dr. Hiroshi Sasaki (RIKEN, Wako, Japan) and Dr. David Mangelsdorf (University of Texas Southwestern Medical School, Dallas, Texas), respectively. Cells were transfected with 200 ng of 8XGli1-BS-Luc and 50 ng of pCMV-β-gal using FuGENE HD transfection reagent in serum free medium. After 24 h, the culture medium was replaced and cells were treated with TNF-α (5 ng/mL) for 24 h. Cells were dissolved in 100 μL of reporter lysis buffer (Promega), and luciferase activity was determined using GLOMAX luminometer (Promega). Transcriptional activity was normalized to β-galactosidase activity.

Wound-Healing Cell Migration Assay. Cells were grown to confluence in six-well plates and then scratched with a pipet tip to create a gap. Wells were washed with PBS before adding fresh medium containing TNF-α (5 ng/mL) alone or with daidzein (30 μM). Cells were visualized under a light microscope (100× magnification) at 0 and 24 h. after treatment, and the relative wound area at these time points was calculated using Image Pro-plus 6.0 software (MediaCybernetics, Rockville, MD, USA).

Invasion Assay. The invasion assay was performed using Matrigel-coated invasion chambers (BD Biosciences, Bedford, MA, USA). The lower section was filled with 750 μL of culture medium containing 0.1% bovine serum albumin. Cells were placed in the upper section of the transwell plate in 500 μL of the same medium. After treatment with the compounds, cells in the lower and upper chambers were incubated for 24 h, fixed with methanol, and stained with hematoxylin and eosin for 10 and 5 min, respectively. After cells on the upper surface of the transwell plate were removed with a cotton swab, invading cells were observed under a light microscope, and cells in five randomly selected fields were counted.

Zymography Assay. The enzymatic activity of MMP-2 and -9 was determined by gelatin zymography. Conditioned medium was collected 24 h after treatment with a compound and was resolved by electrophoresis using a polyacrylamide gel containing 0.1% (w/v) gelatin. The gel was washed with 2.5% Triton X-100 to remove the SDS, rinsed with 50 mM Tris-HCl buffer (pH 7.6) containing 5 mM $CaCl_2$, 200 mM NaCl, and 0.02% Brij-35 (Merck, Darmstadt, Germany), and then incubated overnight at 37 °C. The following day, the gel was stained with 0.5% Coomassie Brilliant Blue R-250 (AMRESCO, Solon, OH, USA) solution containing 10% acetic acid and 20% methanol for 30 min, then destained with 7.5% acetic acid solution containing 10% methanol. The gelatinase activity was determined using EZ West Lumi Plus (ATTO).

Statistical Analysis. Data are presented as mean ± standard deviation (SD). Mean differences were assessed using the Student's *t*-test, and a *p*-value <0.05 was considered statistically significant.

RESULTS

Daidzein Inhibits TNF-α Induced Cell Migration and Invasion in Estrogen Receptor (ER) Negative Basal-like MCF10DCIS.com Human Breast Cancer Cells. Because TNF-α is known to be involved in inducing cellular migration and invasion,[13,14] we first investigated whether daidzein can regulate them in MCF10DCIS.com cells. In a wound healing assay, the fraction of migrating cells increased from 19.5 to 84.9% upon treatment with TNF-α (5 ng/mL), which decreased to 34.6% in the presence of daidzein (30 μM, Figure 1A). The number of invading cells penetrating the artificial matrigel increased approximately 4-fold from 15 to 59 cells/field with TNF-α treatment, and daidzein (30 μM) significantly suppressed to near basal level, 25 cells/field (Figure 1B). To test whether TNF-α or daidzein may regulate the cell proliferation, the MTT assay was performed. The application of TNF-α and daidzein up to the concentrations of 10 ng/mL and 50 μM, as well as the cotreatment of TNF-α (5 ng/mL) with daidzein (30 μM), cyclopamine (10 μM), or vismodegib (10 μM), had no effects on cell viability. They also did not affect the cell viability.

TNF-α Activates the Hh Signaling Pathway in MCF10DCIS.com Human Breast Cancer Cells. The underlying mechanism of TNF-α on inducing invasion is reported to be through the NFκB signaling pathway.[13,14] Here, TNF-α treatment also induced the degradation of inhibitory κB-α (IκBα) and phosphorylation of NFκB p65 at Ser536. However, treatment with daidzein had no effect on IκBα expression and NFκB p65 phosphorylation (Figure 2A), indicating that daidzein inhibits cell migration and invasion via regulation of alternative pathways. Because it is reported that TNF-α activates the Hh signaling pathway in esophageal adenocarcinoma cells,[15] we examined whether TNF-α can modulate Hh signaling in MCF10DCIS.com breast cancer cells. As shown in Figure 2B, the treatment of TNF-α (5 ng/mL) induced the nuclear translocation of a Hh signaling mediator Gli1, which is confirmed by immunofluorescence staining (Figure 2C). Next, we performed the luciferase assay after transfecting 8X-Gli-BS-Luc to determine whether Gli1 transcriptional activity was correspondingly enhanced by TNF-α treatment. A 2-fold increase in Gli1-mediated transcription was observed in TNF-α treated cells compared to untreated control cells (Figure 2D). These results indicate that TNF-α activate the Hh/Gli1

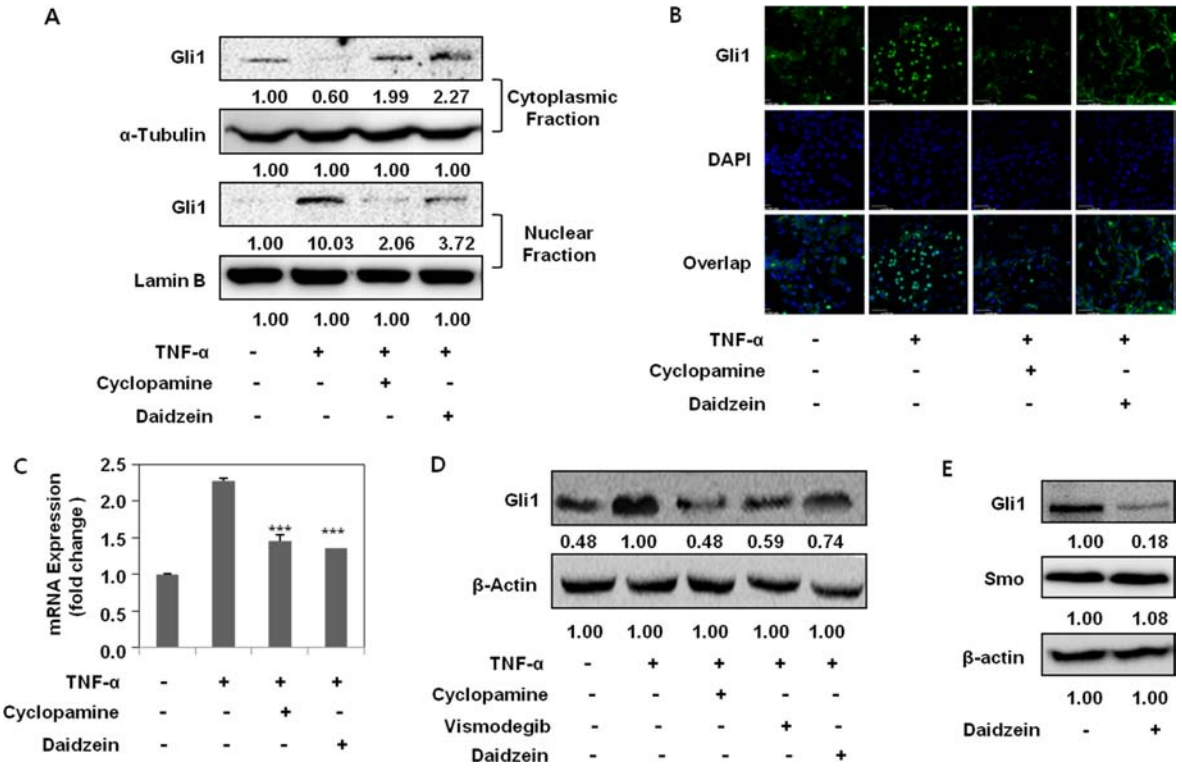

Figure 4. Effect of daidzein and Hh inhibitors on TNF-α induced Gli1 expression and translocation in MCF10DCIS.com human breast cancer cells and Ptch1(−/−) MEF cells fibroblast cells. (A) Cytosolic and nuclear fractions of cells treated with TNF-α (5 ng/mL) alone or together with daidzein (30 μM) or cyclopamine (10 μM) were separated, and Gli1 nuclear translocation was determined by Western blotting. (B) Cells (2×10^5 cells/well in a glass bottom dish) treated with TNF-α alone or together with daidzein or cyclopamine were probed with an antibody against Gli1, with nuclei stained with DAPI. Cells were visualized by confocal microscopy. (C) Cells (7×10^5 cells in a 60 mm dish) were treated with TNF-α alone or together with daidzein or cyclopamine for 12 h. Gli1 mRNA levels were analyzed by quantitative RT-PCR with GAPDH used as an internal control. Values represent means ± SD ***$p < 0.001$ compared to TNF-α treated cells. (D) Cells (7×10^5 cells in a 60 mm dish) were treated with TNF-α alone or together with daidzein (30 μM), cyclopamine, or vismodegib (10 μM) for 24 h. Gli1 protein expression was measured by Western blotting. (E) Cells (7×10^5 cells in a 60 mm dish) were treated with daidzein (30 μM) for 24 h in Ptch1(−/−) MEF cells, and the expression of Gli1 and Smo were determined.

signaling pathway in MCF10DCIS.com breast cancer cells through shifting subcellular localization of Gli1 into nucleus.

Gli1 Overexpression Induces the Cellular Invasion and Migration in MCF10DCIS.com Human Breast Cancer Cells. To examine the physiological role of Gli1 expression on the cellular invasiveness, the cells were transfected with a vector expressing full-length Gli1, and cell migration and invasion were assessed. The overexpression of Gli1 protein was confirmed by Western blotting (Figure 3A). Gli1 over-expresssion in MCF10DCIS.com cells exerted enhanced invasiveness compared to the control by increasing the invading cells from 4 cells/field to 33 cells/field (Figure 3A). In addition, the migration of the cells was enhanced from 15.2% to 73.5% (Figure 3B). Hh signaling inhibitors, cyclopamine and vismodegib, were tested to confirm the role of Hh signaling on the cellular invasion and migration. As shown in Figure 3C, both cyclopamine and vismodegib suppressed TNF-α induced cell migration from 98.9% to 36.7% and 33.3%, respectively, while invasiveness was reduced from 48 cells/field to 18 cells/field and 13 cells/field, respectively. Taken together, these findings strongly suggest that stimulation of migration and invasion in MCF10DCIS.com human breast cancer cells by TNF-α is at least in part through activation of Hh signaling.

Daidzein Blocks TNF-α Induced Gli1 Activation and Expression in MCF10DCIS.com Human Breast Cancer Cells. The studies showing that genistein can regulate Hh/Gli1 signaling in prostate cancer have been reported,[25,26] and we observed that Gli1 activation is highly linked to promoting the invasiveness of MCF10DCIS.com cells. Therefore, we determined the molecular regulatory mechanism of daidzein on Gli1 activity using the cytosolic/nuclear fractionation and confocal microscopy. As shown in Figure 4A,B, daidzein treatment at 30 μM suppressed the TNF-α induced translocation of Gli1 from the cytoplasm into the nucleus. The Hh signaling inhibitor, cyclopamine (10 μM), showed the similar inhibitory action in Gli1 nuclear translocation (Figure 4A,B). Because Gli1 is known as one of the Hh target genes,[27] we performed quantitative RT-PCR and Western blotting to check the expression level of Gli1. Daidzein, cyclopamine, and/or vismodegib significantly suppressed the mRNA and protein expression of Gli1 stimulated by TNF-α treatment (Figure 4C,D). In addition, daidzein significantly suppressed Gli1, but not Smoothened (Smo) protein expression in Ptch(−/−) cells, where Smo and Gli1 were overexpressed, suggesting that Gli1 in Hh signaling may be one of the molecular targets of daidzein in MCF10DCIS.com cells.

Daidzein Suppresses TNF-α Induced MMP-9 mRNA Expression and Its Enzymatic Activity in MCF10DCIS.-com Human Breast Cancer Cells. Tumor cell invasion is mainly derived from the enhanced activity of matrix metalloproteinases (MMPs), of which MMP-2 and -9 have been implicated in breast cancer progression.[28] Therefore, the effect

dx.doi.org/10.1021/jf500231t | J. Agric. Food Chem. 2014, 62, 3759−3767

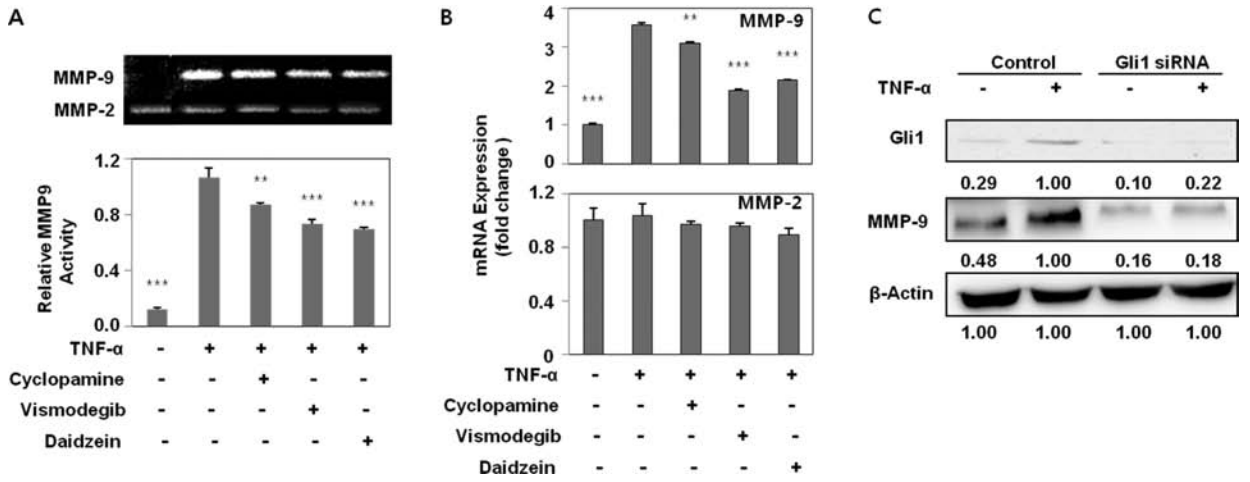

Figure 5. Effect of daidzein on TNF-α induced MMP-2 and -9 expression and activity in MCF10DCIS.com human breast cancer cells. (A,B) Cells (7×10^5 cells in a 60 mm dish) were treated with TNF-α (5 ng/mL) alone or together with daidzein (30 μM), cyclopamine (10 μM), or vismodegib (10 μM). (A) After 24 h, MMP enzymatic activity was determined by zymography. (B) After 12 h, MMP-2 and -9 mRNA expressions were determined by quantitative RT-PCR. Values are means ± SD $^{**}p < 0.01$, $^{***}p < 0.001$ compared to TNF-α treated cells. (C) Cells (7×10^5 cells in a 60 mm dish) were transfected with control siRNA and Gli1 siRNA as mentioned in Materials and Methods. After transfection, TNF-α (5 ng/mL) was treated and the protein expression of Gli1 and MMP-9 were determined.

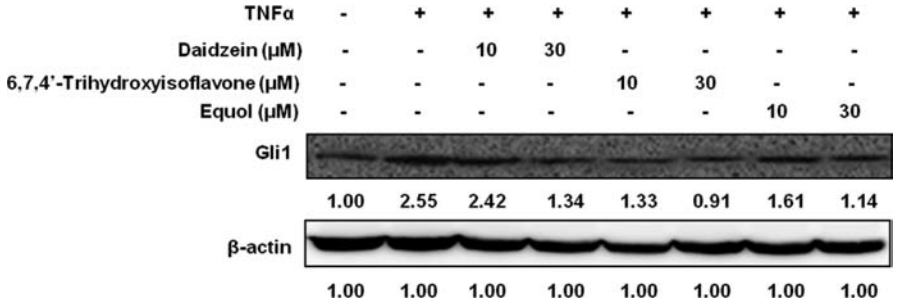

Figure 6. Effect of daidzein and its metabolites, 6,7,4′-trihydroxyisoflavone and equol, on TNF-α induced Gli1 expression in MCF10DCIS.com human breast cancer cells. Cells (7×10^5 cells in a 60 mm dish) were treated with TNF-α (5 ng/mL), alone or together with daidzein (10, 30 μM), 6,7,4′-trihydroxyisoflavone (10, 30 μM), or equol (10, 30 μM), and the protein expression of Gli1 was determined.

of TNF-α on the activity and expression of MMP-2 and -9 was assessed by zymography and quantitative RT-PCR, respectively. While TNF-α had little effect on MMP-2 activity and mRNA expression, MMP-9 activity was significantly suppressed by daidzein (30 μM), cyclopamine (10 μM), and vismodegib (10 μM) treatment (Figure 5A). In addition, TNF-α induced an upregulation of MMP-9 mRNA expression, and this effect was abrogated by daidzein and Hh signaling inhibitors (Figure 5B). To demonstrate the direct relationship between Gli1 and MMP-9 expression, we transfected Gli1 siRNA and checked the expression of MMP-9. As shown in Figure 5C, the enhanced expression of MMP-9 by TNF-α treatment was clearly abolished by inhibiting the expression of Gli1. These results indicate that TNF-α enhanced expression and enzymatic activity of MMP-9 through Hh/Gli1 signaling where the effects are significantly blocked by daidzein.

Daidzein Metabolites, 6,7,4′-Trihydroxyisoflavone and Equol, Reduce TNF-α Induced Gli1 Expression in MCF10DCIS.com Human Breast Cancer Cells. Daidzein is reported to be metabolized into equol by intestinal microflora and trihydroxyisoflavones by hepatic CYP enzymes.[29,30] To investigate in vivo physiological efficacy, we compared the effects of daidzein and its metabolites, 6,7,4′-trihydroxyisoflavone and equol, on inhibiting Gli1 expression. As shown in Figure 6, 6,7,4′-trihydroxyisoflavone and equol at 10 μM showed 48% and 37% suppression of TNF-α induced Gli1 expression, respectively, although daidzein did not exert the significant activity at the same concentration. This result indicates that in vivo metabolism of daidzein may enhance the physiological activities in regulating Hh signaling, which results in inhibiting the invasion and migration of mammary tumors.

■ DISCUSSION

Recent studies have demonstrated the regulatory effects of small botanical compounds on Hh signaling in different cancers.[25,26,31] Phytochemicals including genistein, curcumin, resveratrol, and others inhibited the proliferation of prostate cancer cells as well as tumor growth in transgenic adenocarcinoma of the mouse prostate (TRAMP) mice via modulation of Gli1 expression;[25] genistein was also shown to inhibit Hh signaling in prostate cancer cells, thereby suppressing their stem cell properties.[26] In breast cancer, cantharidin analogue, norcantharidin, suppressed Shh signaling, allowing cells to overcome multidrug resistance.[25,26,31] In the present study, application of nontoxic concentration of daidzein (30 μM, Figure 1C) significantly regulated Hh signaling by suppressing TNF-α induced Gli1 nuclear localization (Figure 4A,B) and genetic expressions into mRNA and protein (Figure 4C,D), resulting in the inhibition of TNF-α induced migration

and invasion (Figure 1A,B) in MCF10DCIS.com human breast cancer cells.

It was previously suggested that TNF-α enhances invasiveness in tumor cells by activating NF-κB signaling.[9,32] In breast cancer, an antimetastatic gene KiSS1 and costunolide identified from *Saussurea lappa* Clarke were both shown to inhibit MDA-MB-231 cell invasion stimulated by TNF-α through suppressing the NF-κB activation.[13,14] The present results confirmed that TNF-α enhanced migration and invasion in MCF10DCIS.com human breast cancer cells (Figure 1A,B), and promoted IκBα degradation, a key event for the activation of NF-κB signaling pathway (Figure 2A). Daidzein significantly suppressed TNF-α induced migration and invasion without affecting IκBα degradation and NFκB p65 phosphorylation (Figure 2A), suggesting that these effects were mediated through the regulating of an alternative pathway.

Hh signaling is known to play a crucial role in cell proliferation, differentiation, and organ patterning during embryogenesis and also in tumor initiation, progression, invasion, and metastasis during tumorigenesis.[18,27,33] In espophageal adenocarcinoma cells, TNF-α was shown to selectively activate Gli1.[15] The Hh signaling pathway is regulated by the secreted ligands such as Indian (Ihh), Desert (Dhh), and Sonic Hh (Shh) which can bind to its receptor, Patched1 (Ptch1). When Ptch1 is relieved by Hh ligand binding, Smo activates downstream intracellular signaling through zinc-finger transcriptional factors, Gli1, Gli2, and Gli3, and modulate the expression of target genes driving the development and maintenance of human cancers.[34] Dysregulation of the Hh signaling pathway, for instance by Gli overexpression, has been demonstrated to be critically involved in carcinogenesis. Ectopic expression of Gli1 or mutations resulting in overexpression of Gli1 was sufficient to induce the basal cell carcinoma,[35,36] while the loss of Gli1 function in Ptc1± mice showed significant reduction of medulloblastoma formation.[37] In addition, the involvement of Hh signaling via Gli family is reported in other malignancies such as colon and prostate cancers.[38,39] In this study, TNF-α enhanced the translocation of Gli1 into the nucleus (Figure 2B,C) and increased the transcriptional activity (Figure 2D), elucidating that TNF-α can activate the Hh signaling pathway in MCF10DCIS.com human breast cancer cells.

Several lines of evidence have demonstrated an association of aberrant Hh signaling with breast tumorigenesis.[40] Specifically, Gli1 was shown to be involved in regulating migration and invasion in estrogen independent breast cancer cells,[21,22] and the percentage of Gli1 nuclear translocation was correlated with the extent of the invasive phenotype.[20] In accordance with the previous studies, we found that the overexpression of Gli1 protein in ER negative MCF10DCIS.com cells significantly enhanced migration and invasion (Figure 3A,B). The Hh signaling inhibitors cyclopamine and vismodegib blocked the TNF-α induced migration and invasion (Figure 3C,D) and abolished the transcriptional activity through regulating the nuclear translocation of Gli1 and the expression of Hh signaling target genes (Figure 4). In addition, as one of the molecular targets of Hh signaling in tumor invasiveness and metastasis, MMP-9 was reported in gastric cancers.[41] We also found that knock-down of Gli1 using siRNA suppressed the expression of MMP-9 and abolished its expression induced by TNF-α (Figure 5C). These results strongly suggest that TNF-α enhance the invasiveness of MCF10DCIS.com human breast cancer cells through activating the Hh signaling pathway and enhancing the expression of MMP-9.

Isoflavones, which are naturally produced phytoestrogens, are reported to play a significant role in regulating the invasion in different cancers. For example, genistein and biochanin A decreased the invasive activity in U87MG human globlastoma cells,[42] and an isoflavan identified from licorice root, glabridin, suppressed migration, invasion, and angiogenesis by reducing integrin levels and inhibiting FAK/Src/AKT/Rho signaling in MDA-MB-231 cells.[43] In addition, genistein, daidzein, and a daidzein metabolite equol were reported to exert anti-invasive activity in DU145 prostate cancer cells[44] and in highly invasive MDA-MB-231 breast cancer cells by inhibiting the MMPs activity.[6,45] In line with the previous studies, we also found that treatment of daidzein and Hh signaling inhibitors significantly suppressed MMP-9 mRNA expression and its enzymatic activity without affecting MMP-2 (Figure 5A,B). These results suggest that MMP-9 regulated by daidzein could provide the mechanistic link between Hh signaling and breast cancer cell invasion.

It is also important to consider the in vivo metabolism of isoflavones. Intestinal microflora and liver CYP enzymes are known to metabolize the daidzein into equol and trihydroxyisoflavones, respectively,[29,30] indicating that daidzein, equol, and trihydroxyisoflavones can be present together in the blood system. Here, we found that daidzein metabolites, equol and 6,7,4′-trihydroxyisoflavone, exerted more significant activity in inhibiting TNF-α-induced Gli1 expression than daidzein (Figure 6), implying that we can expect the similar physiological effect of daidzein and its metabolites on regulation of in vivo invasion and migration in breast tumors.

To our best knowledge, the present study is the first report that TNF-α activated Hh signaling resulting in the stimulation of migration and invasion in ER-negative MCF10DCIS.com human mammary tumor cells which was effectively reversed by daidzein treatment. Although further studies are needed in order to understand the precise mechanisms in Hh signaling activation by TNF-α and identify the molecular targets of daidzien, the results we found may shed a new insight on the role of daidzein as possibly prevents from the mammary carcinogenesis, especially invasion and metastasis.

but neither physical methods nor competitive binding studies were able to define a specific binding site.[16,19,20]

Further study of the interactions between a series of flavan-3-ols with HSA or BSA demonstrated a role for the galloyl ester D ring of the flavonoid (Figure 1a) in the formation of stable

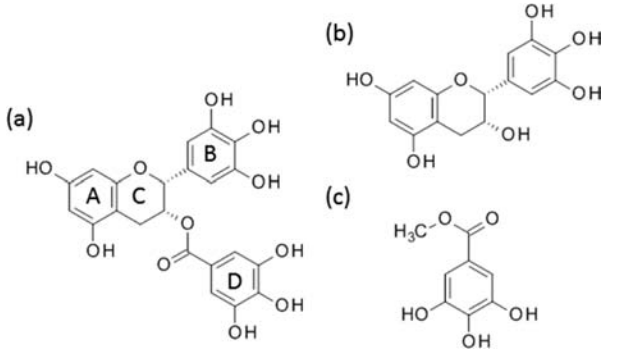

Figure 1. Structures of (a) epigallocatechin gallate (EGCg), (b) epigallocatechin (EGC), and (c) methyl gallate (MG). The A, B, C, and D rings of the flavan-3-ols are labeled in (a).

complexes.[18,20] These complexes could be covalently stabilized by reaction with cysteine or lysine residues.[12,17,21] Covalent modification of a specific cysteine residue by EGCg has been demonstrated for glyceraldehyde-3-phosphate dehydrogenase[22] but not for SA.

Only a few molecular docking studies have been performed for EGCg and SA. A docking study based on the crystal structure of HSA supports the experimental evidence for binding at both hydrophobic sites.[19] Docking studies with BSA have been hampered because the structure of the protein has not been available, but one study that used an amino acid sequence-based simulation for the BSA structure suggested preferred binding near Trp_{213}.[20] However, there is no strong experimental evidence for site-specific binding of BSA by EGCg.

In this study, we tested the model proposed by Skrt et al.[20] that describes a single binding site on BSA for EGCg. We used fluorescence, CD, and competitive binding studies to characterize the interaction and improved the molecular docking studies by using the recently established crystal structure for BSA.[15] Our data demonstrate that binding of EGCg induces a conformational change in BSA and requires the synergistic efforts of both the flavan-3-ol and galloyl moiety subunits. The former subunit binds to the entrance of the hydrophobic pocket, perhaps via covalent bonds, whereas the latter binds to the bottom mainly via hydrogen bonds. Our data provide insights into EGCg−SA interactions that are relevant to the human as well as the bovine protein.

MATERIALS AND METHODS

Materials. Bovine serum albumin (BSA) (fatty acid free, ≥96%), methyl gallate (MG), phenylbutazone (PB), and tolbutamide (TB) were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). EGCg (>95%) was provided by Lipton Tea Co. (Newark, NJ, USA). (−)-Epigallocatechin (EGC) (>95%) was purified from commercial tea (SilvaTeam, San Michele, Italy) by Sephadex LH20 column after tannase treatment and was characterized by HPLC and LC-MS (unpublished data). The chemical structures of the three phenolic compounds (EGCg, MG, EGC) are depicted in Figure 1.

All stock solutions were prepared by initially dissolving the compounds in water so there were no carrier solvent effects on ligand−protein interactions. BSA and EGCg concentrations were determined spectrophotometrically by their extinction coefficients (ε_{280} (BSA) = 43000 M^{-1} cm^{-1} and ε_{280}(EGCg) = 9700 M^{-1} cm^{-1}). Samples were diluted into 0.2 M sodium phosphate buffers (pH 3.0, 5.0, and 7.4) containing 0.1 M sodium chloride.

Fluorescence Spectroscopy and Quenching Constant Calculation. BSA was mixed with the desired amount of phenolic solution (EGC, EGCg, or MG), diluted to 5.0 mL and a final concentration of 3 μM protein with the appropriate phosphate buffer, vortexed for 10 s, immediately sparged with nitrogen for 20 min, and incubated for 1 h at 22 °C. The concentration of phenolic compound was varied from 0 to 25 μM in 5 μM increments. The stability of each phenolic compound under these conditions was checked by HPLC as described below.

The method of Soares et al.[23] was modified to evaluate the BSA fluorescence spectra between 290 and 500 nm with an LS55 luminescence spectrometer (PerkinElmer Inc., USA) with the excitation wavelength set at 280 nm. Slit widths for excitation and emission were 7.5 and 4.5 nm, respectively. Fluorescence intensity was corrected by eq 1 to compensate for the inner filter effect[24−26] due to sample absorbance at 280 and 350 nm.

$$F_{cor} = F_{obs} \times 10^{(Abs280+Abs350)/2} \quad (1)$$

F_{cor} and F_{obs} are, respectively, the corrected and observed fluorescence intensity. Abs280 and Abs350 represent the absorbances of samples in a 1 cm path length cell at the excitation and emission wavelengths. In this study, all fluorescence intensities were corrected prior to data analysis.

Fluorescence quenching is usually described by the Stern−Volmer equation (eq 2).[27] This classic model assumes that all fluorophores are equally accessible to the quencher.

$$F_0/F = 1 + K_{SV} \times [Q] = 1 + k_q \times \tau_0 \times [Q] \quad (2)$$

F_0 and F are the fluorescence intensities before and after the addition of the quencher, respectively. K_{SV} is the Stern−Volmer quenching constant, [Q] is the concentration of the quencher, k_q is the bimolecular quenching constant, and τ_0 is the native lifetime of the fluorophore. K_{SV} can thus be determined by linear regression of a plot of F_0/F against [Q].

Negative deviations from the Stern−Volmer equation are frequently found in the systems that have multiple fluorophores, such as BSA. The values of F_0/F, instead of increasing linearly with [Q] in the classic model, trend downward toward the x axis at high [Q], signifying differences in the accessibilities of fluorophores to the quencher.[27] The modified Stern−Volmer equation (eq 3) includes a factor for fractional accessibility f_a, allowing calculation for the modified SV constant K_a for systems with more than one fluorophore.

$$F_0/\Delta F = (1/(f_a \times K_a)) \times (1/[Q]) + 1/f_a \quad (3)$$

Time Domain Fluorescence Lifetime. Time-resolved fluorescence lifetime was measured with a TemPro 01 system (Horiba Jobin Yvon, USA), using a FluoroHub-B single-photon counting module with TBX detector. The excitation light (250 nm) was provided by a NanoLED light source, and the number of counts gathered in the channel of maximum intensity was 10000. The data were analyzed with CAS6 V6.6 decay analysis software. As BSA has two fluorophores with different lifetimes, eq 4 was used to describe the time-dependent decay of the biexponential fluorescence system.

$$F(t) = A + F_1 \times \exp(-t/\tau_1) + F_2 \times \exp(-t/\tau_2) \quad (4)$$

τ_1 and τ_2 are native fluorescence lifetimes for Trp_{134} and Trp_{213}, respectively, whereas F_1 and F_2 represent their relative amplitudes. Samples for the lifetime measurement were prepared in the same way as for the intensity measurements.

EGCg Stabilization and Competitive Binding. EGCg−SA interactions can be indirectly assessed by determining the BSA-mediated stabilization of EGCg.[12] We used that method to carry out competitive binding experiments between the drug PB or TB and EGCg. BSA (30 μM) was incubated at pH 7.4 with EGCg (25 μM)

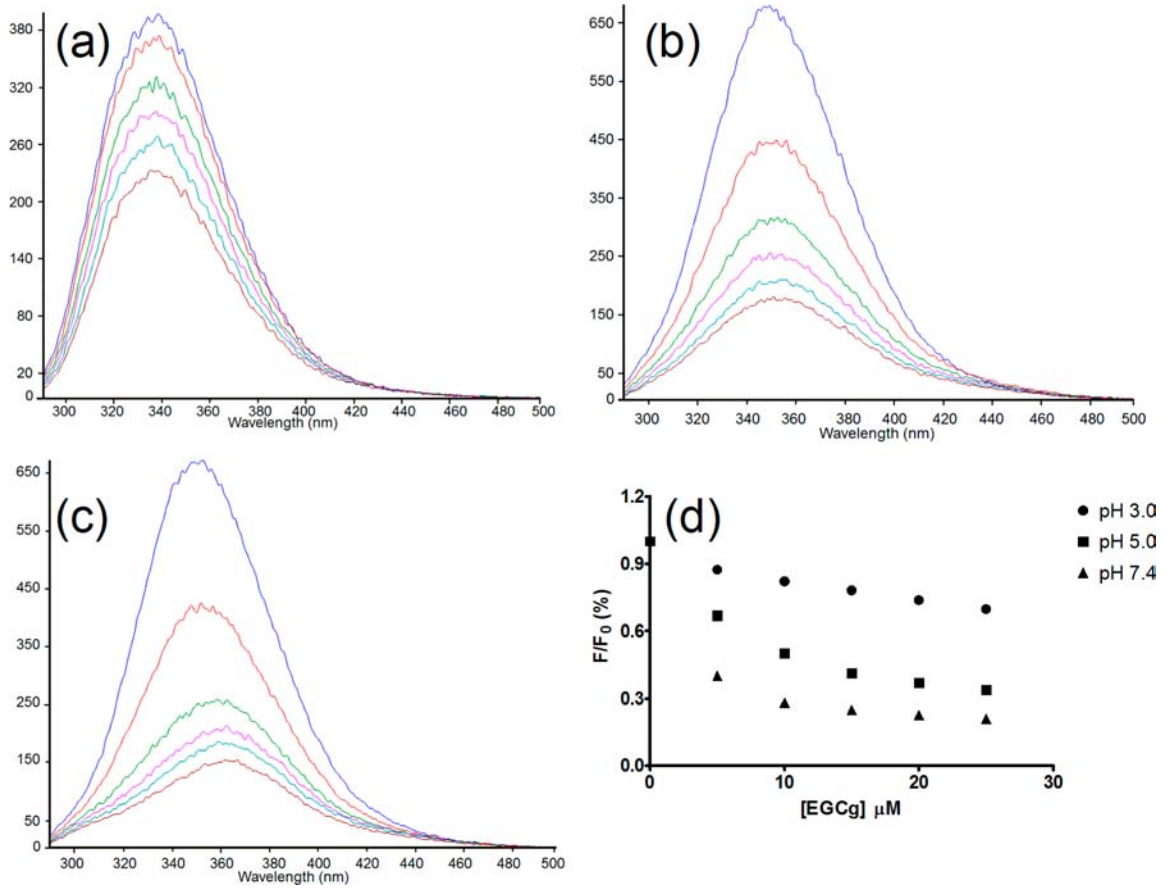

Figure 2. Quenching of 3 μM BSA by EGCg. Changes in the emission spectra of BSA were measured at (a) pH 3.0, (b) pH 5.0, and (c) pH 7.4. (d) The efficiencies of quenching were compared at pH 3.0 (●), 5.0 (■), and 7.4 (▲) by plotting the relative fluorescence intensity ($F/F_0 \times 100$) against EGCg concentration. All fluorescence intensities were corrected by eq 1 with a λ_{ex} = 280 nm and a λ_{em} = 350 nm, and the concentrations of EGCg were 0, 5, 10, 15, 20, and 25 μM.

and either PB or TB (0–900 μM) for 40 min at 37 °C before the amount of EGCg remaining was determined by high-performance liquid chromatography (HPLC) as described below. The amount of EGCg that remained in the samples at the end of the incubation was proportional to the amount of EGCg bound to the serum albumin.

HPLC Analysis. EGC, EGCg, and methyl gallate were quantitated with an Agilent 1100 series HPLC system equipped with a diode array detector (Agilent Technologies, USA). Separation was performed on a Zorbax Eclipse XD8 C8 column (5 μm, 4.6 × 150 mm i.d.) at a flow rate of 0.5 mL/min. Samples were eluted with a gradient of 0.1% trifluoroacetic acid in water (solvent A) and 0.13% trifluoroacetic acid in acetonitrile (solvent B) as follows: 0–10 min, 5% B; 10–20 min, 20% B; 20–30 min, 35% B; 30–34 min, 95% B. The elution profiles were recorded at 280 nm. Samples (10 μL) were injected into HPLC after filtration through 0.22 μm cellulose acetate spin filters. BSA solutions without EGCg were used as the background, and Agilent Chemstation A.09.03 software was used for peak integration.

Circular Dichroism Spectroscopy. The method of Nozaki et al.[28] was used in this study. A J-810 spectropolarimeter (Jasco Inc., Japan) was employed to collect CD spectra between 355 and 245 nm with a 1 mm path length cell. The system was purged with dry nitrogen gas during measurement at 298–301 K. CD spectra were built on accumulation of 12 cycles of scans with 0.5 nm data pitch, 1.0 nm bandwidth, 100 nm/min speed, and standard sensitivity.

All samples were prepared in 0.2 M sodium phosphate buffer at pH 7.4. The BSA concentration was 30 μM, whereas the concentrations of EGC, EGCg, and MG ranged from 0 to 200 μM. The spectrum of the buffer was subtracted from all samples to eliminate background noise. Induced CD spectra for BSA–EGCg samples (or EGC or MG) were obtained with eq 5.

$$\text{induced CD}_{\text{BSA-EGCg}} = \text{CD}_{\text{BSA-EGCg}} - (\text{CD}_{\text{BSA}} + \text{CD}_{\text{EGCg}}) \quad (5)$$

$\text{CD}_{\text{BSA-EGCg}}$ is the spectra of the BSA–EGCg sample, and CD_{BSA} and CD_{EGCg} represent the spectra of samples containing only BSA and EGCg.

Molecular Modeling. The crystal structure of BSA (code: 3 V03)[15] was downloaded from the Protein Data Bank. The 3D structure of EGCg (ChEBI:4806) was initially obtained from Chemical Entities of Biological Interest as a MOL file and converted afterward to a PDB file by OpenBabelGUI version 2.3.1. AutoDock Tool 4.2 v. 1.5.6rc3[29] was used to optimize both BSA and EGCg structures for docking experiments. For BSA, chain B and all water molecules were removed to produce a monomer structure. For EGCg, the structure was prepared by defaults setting with the gasteiger charges computed. Both BSA and EGCg structures had hydrogen atoms added.

The mechanism of the BSA–EGCg interaction was predicted on the molecular level with AutoDock Tool 4.2. The grid box was set up with 126 points in the *X*, *Y*, and *Z* dimensions, respectively. Each grid point had a spacing of 0.65 Å. Docking experiments were performed with default genetic algorithm parameters to generate 10 possible conformations with the lowest Gibbs free energy of binding.

RESULTS

Quenching of BSA Fluorescence Spectra by EGCg. Changes in pH affected the fluorescence spectrum of native BSA. At pH 3.0, the emission spectrum of BSA ranged from 290 to 480 nm with a maximum emission (λ_{em}) at 340 nm (Figure 2a). When the pH was increased to 5.0 or 7.4, the

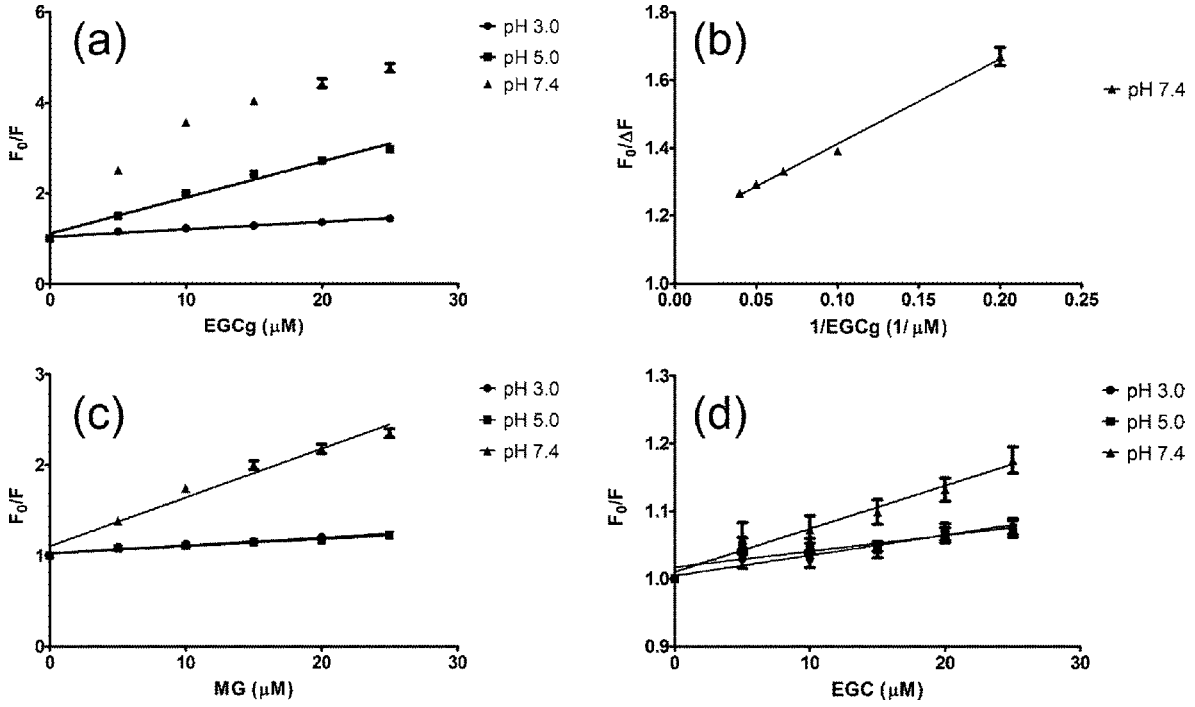

Figure 3. SV plots for the quenching of 3 μM BSA at pH 3.0 (●), pH 5.0 (■), and pH 7.4 (▲): (a) SV plots for EGCg-mediated quenching of BSA fluorescence; (b) modified SV plot for EGCg-mediated quenching of BSA fluorescence at pH 7.4; (c) SV plots for MG-mediated quenching of BSA fluorescence; (d) SV plots for EGC-mediated quenching of BSA fluorescence. All fluorescence intensities were corrected by eq 1 with a λ_{ex} = 280 nm and a λ_{em} = 350 nm, and the concentrations of EGCg were 0, 5, 10, 15, 20, and 25 μM.

spectrum was red-shifted to 280−500 nm with a λ_{em} at 350 nm (Figure 2b,c).

At all pH values tested, BSA fluorescence was affected by EGCg in a dose-dependent manner (Figure 2a−c). In acidic solutions (pH 3.0 and 5.0), addition of EGCg did not change the λ_{em} of BSA. However, λ_{em} was red-shifted from 350 to 365 nm at pH 7.4 when the EGCg concentration was increased from 0 to 25 μM. The efficacy of EGCg-induced quenching depended largely on the pH (Figure 2d). At pH 3.0, 25 μM EGCg quenched the BSA fluorescence to 68.4% of control value. At pH 5.0, the same concentration of EGCg brought the emission intensity down to 33.4% of control value. When the pH was increased to 7.4, only 20.7% of the control fluorescence remained in the presence of 25 μM EGCg.

The Stern−Volmer plots of EGCg-induced quenching of BSA fluorescence at pH 3.0 and 5.0 were linear, whereas at pH 7.4 the data were nonlinear, consistent with two fluorophores with different accessibilities[27] (Figure 3a). The data at pH 7.4 yielded a linear modified Stern−Volmer plot (Figure 3b). The Stern−Volmer constants (Table 1) were consistent with pH-dependent binding that is stronger at higher pH values.

Table 1. Stern−Volmer Constants Describing BSA Fluorescence Quenching by EGC, EGCg, or MG at pH 3.0, 5.0, and 7.4

[a]Estimated as K_a from modified SV plot.

Quenching of BSA Fluorescence Spectra by EGC or MG. MG did not quench as effectively as EGCg, but the pH dependence of quenching was similar to that of EGCg (Supporting Information Figure S1). The linear Stern−Volmer plots (Figure 3c) yielded K_{SV} values consistent with weaker interactions between BSA and MG compared to EGCg, but with a similar pH dependence (Table 1).

EGC was a very weak quencher under experimental conditions. After incubation with EGC, the spectra of BSA fluorescence were only slightly changed and the reduction of fluorescence intensity was small at λ_{em} (Supporting Information Figure S2). The linear SV plots (Figure 3d) yielded binding constants consistent with very weak, pH-independent interactions (Table 1).

BSA Fluorescence Lifetime. We used fluorescence lifetime to distinguish the effects of EGCg on Trp_{134}, a long-lifetime species, versus Trp_{213}, a short-lifetime species.[30,31] EGCg substantially diminished the fluorescence lifetime of Trp_{213} in a pH-dependent fashion, reducing the lifetime by about 50% at pH 5.0 or 7.4 (Table 2). At the same pH values, EGCg diminished the fluorescence lifetime of Trp_{134} about 15−25%

Table 2. Fluorescence Lifetime of Two Trp Residues in Bovine Serum Albumin in the Absence or Presence of 25 μM EGC, EGCg, or MG at pH 3.0, 5.0, and 7.4

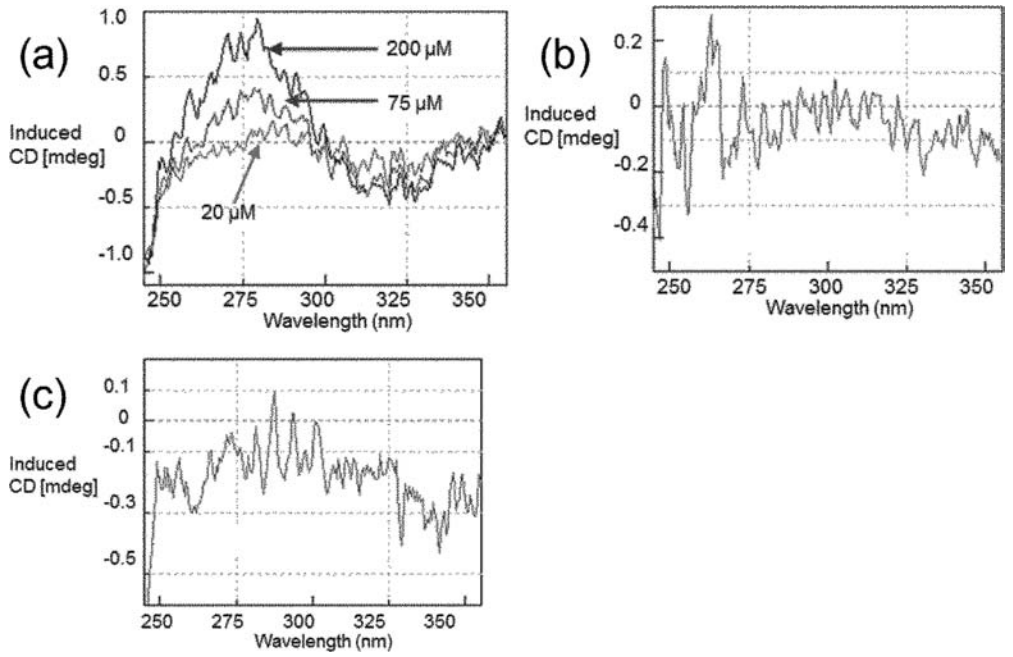

Figure 4. Induced CD spectra of 30 μM BSA in the presence of (a) EGCg, (b) EGC, and (c) MG. All induced CD spectra were obtained via eq 5. The concentrations of EGCg were 20, 75, and 200 μM, and the concentrations of EGC and MG were 200 μM.

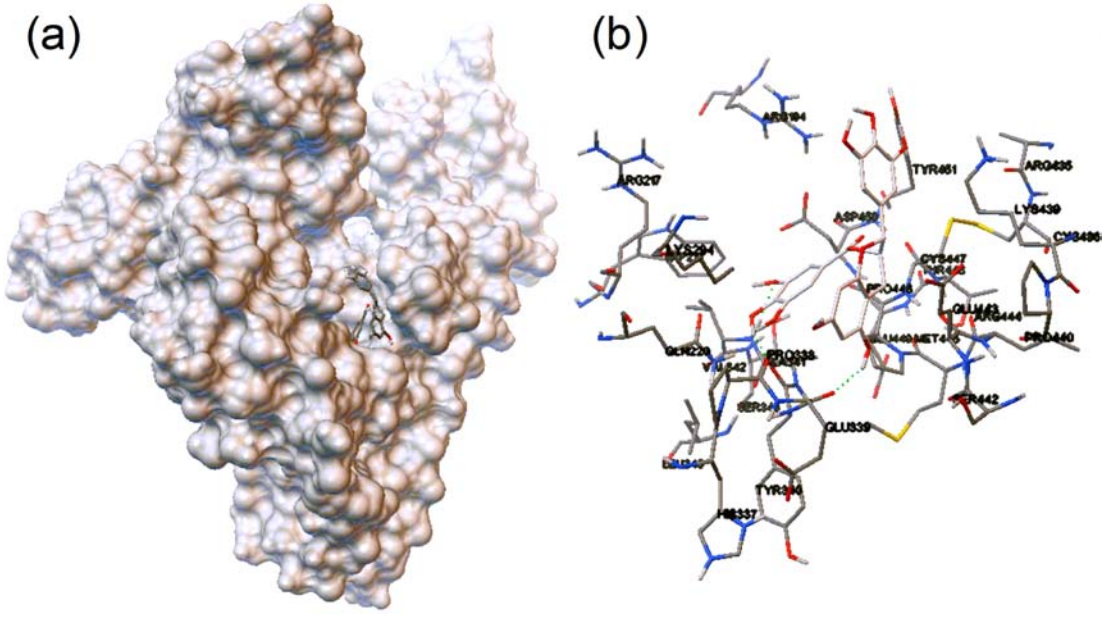

Figure 5. Docking simulation of EGCg for the hydrophobic pocket between subdomains IIA and IIIA of BSA: (a) complexation between BSA and EGCg; (b) amino residues involved in binding EGCg. The stick model indicates the involved amino acid residues and EGCg.

(Table 2). Methyl gallate diminished the lifetime of Trp_{213} only at pH 7.4 (30%), whereas EGC did not change the lifetime of either Trp at any pH (Table 2).

The bimolecular quenching constant k_q was estimated from the K_{SV} and the fluorescence lifetime data (eq 2) to distinguish static from dynamic binding. The upper limit of fluorescence lifetime is about 6 ns, so for the compounds we tested at pH 7.4, k_q ranges from about 10^{11} M^{-1} s^{-1} for EGC to about 10^{14} M^{-1} s^{-1} for EGCg.

Impact of Phenolics on the Conformation of BSA. In the presence of EGCg, the CD spectra of BSA were changed in a dose-dependent manner with positive amplitudes centering on 280 nm and negative amplitudes centering on 320 nm (Figure 4a). EGCg at 200 μM induced the largest change in the CD spectrum, giving ~0.8 mdeg at 280 nm and ~ −0.4 mdeg at 320 nm. MG or EGC did not significantly alter the conformation of BSA, as the amplitudes of the spectra fluctuated by only ~0.2 mdeg in the presence of 200 μM of either compound (Figure 4b,c).

EGCg Stabilization and Competitive Binding. In the absence of BSA, 29.2% of the EGCg remained after 40 min at pH 7.4, whereas with the addition of BSA 65.8% remained. We used the BSA-induced stabilization of EGCg as a surrogate for measuring binding of EGCg to BSA and did competitive

dx.doi.org/10.1021/jf500246m | J. Agric. Food Chem. 2014, 62, 3768−3775

binding assays with the drugs PB and TB. In competitive binding assays with 25 μM EGCg, the IC_{50} for PB was 450 μM, whereas that for TB was >900 μM (Supporting Information Figure S3).

Molecular Simulation of the Interaction between BSA and EGCg. The two docking models with the lowest free energies (−20.8 and −20.3 kJ mol^{-1}) put the Trp residues out of the effective quenching distance of EGCg. The molecular simulation with the next most favorable free energy (−17.9 kJ mol^{-1}) indicated that EGCg binds to the pocket between subdomains IIA and IIIA in the vicinity of Sudlow's site I. The galloyl moiety is projected toward the bottom, and the flavan-3-ol subunit is positioned in the entrance to the pocket (Figure 5a). The electrostatic interactions were weak between the protein−ligand pair, adding −0.46 kJ mol^{-1} to the binding energy, whereas van der Waals interactions, hydrogen bonds, and desolvation effects contributed −32.4 kJ mol^{-1}.

In this simulation model, the binding between EGCg and BSA consists of three hydrogen bonds and various hydrophobic interactions (Figure 5b). The hydrogen atom of the 3-hydroxyl group and the oxygen atom of the 4-hydroxyl group in the galloyl moiety (ring D, Figure 1a) and the hydrogen atom of the 5-hydroxyl group in ring A of the flavan-3-ol subunit of EGCg form hydrogen bonds with the atoms in the peptide backbone of Glu_{339}, Tyr_{340}, and Val_{342}. The simulation results suggest bond lengths of 2.2, 1.8, and 2.0 Å, respectively. EGCg interactions with other nearby amino acid residues, such as Trp_{134} and Pro_{446}, are dominated by van der Waals interactions and the hydrophobic effect. Electrostatic effects also contribute to EGCg binding, for example, by interactions between the electron-dense hydroxyl groups of the B and D rings with positively charged Arg_{194}, Lys_{294}, and Lys_{439}. The nitrogen atom of the Lys_{439} side chain is especially close to the oxygen atom of a B ring hydroxyl group (3.9 Å). In addition, the distance from the Trp_{213} residue to the galloyl moiety (6−10 Å) is shorter than the distance to the flavan-3-ol subunit (12−14 Å).

DISCUSSION

Our fluorescence studies demonstrated that EGCg interacts with BSA, with an apparent binding constant of about 4.6×10^{-5} M^{-1} at pH 7.4, similar to that obtained in other studies of EGCG−BSA interactions[20] and about 10-fold higher than that reported for EGCg−HSA.[18,19] However, the Stern−Volmer plot at pH 7.4 exhibited downward curvature, concave toward the x axis, at high EGCg concentrations. This phenomenon is often observed in systems with fluorophores that are unequally quenched due to their accessibility in the protein. Trp_{134}, which is responsible for 85% of the intrinsic fluorescence of BSA, is on the surface of the protein and is generally more accessible than Trp_{213}, which is buried in the hydrophobic pocket.[15,32] It has been proposed that EGCg binds near the buried Trp213 residue rather than at the surface-exposed Trp_{134},[20] and our data confirm that idea.

We used measurements of fluorescent lifetimes to more closely examine the binding site of EGCg. The two Trp residues can be distinguished by their fluorescent lifetimes, with lifetime of the surface Trp_{134} (around 5−6 ns) much longer than that of the buried Trp_{213} (around 2−3 ns) (Table 2). Fluorescence lifetime decay studies revealed large changes in the fluorescent lifetime of Trp_{213} induced by EGCg at pH 5 and 7 and demonstrate that EGCg does bind near this residue, deep in the hydrophobic pocket between domains IIA and IIIA. Our data support the binding site on BSA proposed by Skrt et al.[20] and demonstrate strong homology to binding with human serum albumin, which clearly involves the single, buried Trp_{214} on this protein.[18,19]

The pH dependence of the interaction between EGCg and BSA revealed by the magnitude of the fluorescence quenching is in accord with the importance of the hydrophobic pocket in the BSA−EGCg interaction. At pH 3.0, native BSA exhibits an expanded conformation by unfolding domains I and III,[14,33] disassembling the hydrophobic pocket and exposing Trp_{213} to a surface environment similar to that of Trp_{134}. EGCg-induced quenching effect was weak under this condition with small changes in the fluorescence lifetimes for both Trp residues, suggesting weak nonspecific binding. In addition, λ_{em} of the BSA fluorescence spectrum was neither red-shifted nor blue-shifted in the presence of EGCg, indicating a stable molecular environment around two Trp residues. When the pH is increased to 5.0 or 7.4, native BSA achieves its physiological conformation (or heart-shaped structure) with formation of the hydrophobic pocket,[14,33] and the affinity for EGCg increases, along with increased specific interaction at Trp_{213}. The λ_{em} of the BSA fluorescence spectrum was also gradually red-shifted with increasing EGCg concentration at pH 7.4 (Figure 2c), indicating possible changes in BSA conformation. We propose that EGCg specifically binds to BSA in the hydrophobic pocket between domains IIA and IIIA at physiological pH.

Our data demonstrate that both the flavan-3-ol and the galloyl group of EGCg are essential for site-specific, high-affinity binding. The apparent affinity of the flavan-3-ol EGC for BSA is only about 10^3 M^{-1}, slightly smaller than the value reported for several other flavan-3-ols in an earlier study.[23] The pH independence of EGC binding is consistent with non-specific interactions. MG has a somewhat higher affinity for BSA, and the pH dependence of the binding and the fluorescence lifetimes suggest that MG binds in the hydrophobic pocket near Trp_{213}. However, it binds an order of magnitude more weakly than EGCg. The CD spectra provide further evidence that EGCg binding requires both the flavan-3-ol and galloyl group. EGCg alters BSA conformation in a dose-dependent fashion, but neither MG nor EGC has this effect.

The molecular simulation model is consistent with our experimental work, demonstrating the favorable interaction of EGCg with the hydrophobic pocket of BSA. At pH 7.4, a positively charged microenvironment comprising Arg_{194}, Arg_{435}, Lys_{187}, Lys_{294}, and His_{438} is found at the entrance to the hydrophobic pocket, similar to that in human serum albumin.[19] These residues may be involved in the initial step of BSA−EGCg complexation by binding to the electron-dense B ring of the flavan-3-ol subunit.[22,34] In addition, the nitrogen atom of the Lys_{439} side chain is 3.9 Å from the oxygen atom in the B-ring hydroxyl group. Considering that the van der Waals radii of both nitrogen and oxygen atoms are about 1.6 Å,[35] it is plausible to assume that the distance between the surface of two atoms is <1 Å. Covalent binding to lysine has been invoked to explain the BSA-induced stabilization of EGCg,[12] and our data now suggest that the reaction might occur specifically between the B ring and Lys_{439} (Figure 5b). Covalent bonding in the hydrophobic pocket is supported by the values for the bimolecular quenching constant for the BSA−EGCg interaction, which were estimated to be 10^{14} $M^{-1}s^{-1}$ at pH 7.4, indicating static quenching typical of highly stable interaction such as covalent bonding. The B ring of EGCg is more reactive than the D ring,[17] providing additional indirect support for

covalent reaction as one component that stabilizes EGCg binding to BSA.

Although our model predicts that EGC binds in the neck of the pocket in a location similar to EGCg binding, our data showed that EGC binding was very weak and nonspecific. We speculate that in EGCg the galloyl ester is essential to position the flavan-3-ol for tight binding by its interaction at the base of the pocket. The model suggests that the critical role played by the galloyl moiety involves hydrogen bonds with the peptide backbone of two amino acids (Figure 5b), similar to the hydrogen bonds proposed by others.[18,20] Furthermore, the galloyl group appeared to rest between Arg_{217} and Asp_{450} in the bottom of the hydrophobic pocket, where it might disrupt a salt bridge and thus change the potential along the indole ring of Trp_{213}, leading to the red shift observed in the fluorescence spectra.[36]

Consistent with previous research,[11,12] our study showed that EGCg was stabilized by BSA at pH 7.4. We used that stabilization to monitor BSA−EGCg binding in competitive binding experiments with two drugs, PB and TB. The former binds Sudlow site I with an association constant of 6.2×10^5 M^{-1}, whereas the latter interacts more weakly and less specifically with BSA, binding to both Sudlow site I (8.7×10^4 M^{-1}) and Sudlow site II (0.81×10^4 M^{-1}).[37,38] PB effectively inhibited EGCg binding to BSA, consistent with our model in which EGCg binds to the hydrophobic pocket on BSA that overlaps with Sudlow site I. TB did not inhibit EGCg binding even at a 50-fold excess, supporting our model in which EGCg binds specifically and tightly in the hydrophobic pocket, not at other binding sites on BSA such as Sudlow II.

Our study indicated that EGCg binds selectively to the hydrophobic pocket on subdomains IIA and IIIA of BSA, overlapping with the Sudlow I binding site but also involving residues near Trp_{213} deep in the interior of the protein. The protein undergoes a slight conformational change upon polyphenol binding. The pH dependence of the binding is a consequence of the unfolding of BSA at low pH, destroying the hydrophobic pocket that is the EGCg binding site. The interaction requires both the flavan-3-ol and the galloyl moieties of the bioactive polyphenol and may involve site-specific covalent interaction at Lys_{439}. Lys_{195} occupies a position in the hydrophobic pocket of human SA that is similar to the position of Lys_{439} in BSA, leading us to suggest that it plays a similar role in stabilizing the HSA−EGCg interactions. Previous studies suggested a role for electrostatic binding at Lys_{195} in the interaction between human SA and EGCg,[19] but our model suggests covalent bond formation at this site. Formation of carbonyl groups on HSA during reaction with EGCg suggests that the reaction may involve Schiff base formation,[12] but direct evidence for that modification is not available. Further studies are needed to establish whether EGCg does covalently bind to a specific lysine residue in serum albumin and to further explore how SA−EGCg complexation controls both EGCg stability and redox reactivity in the bloodstream.

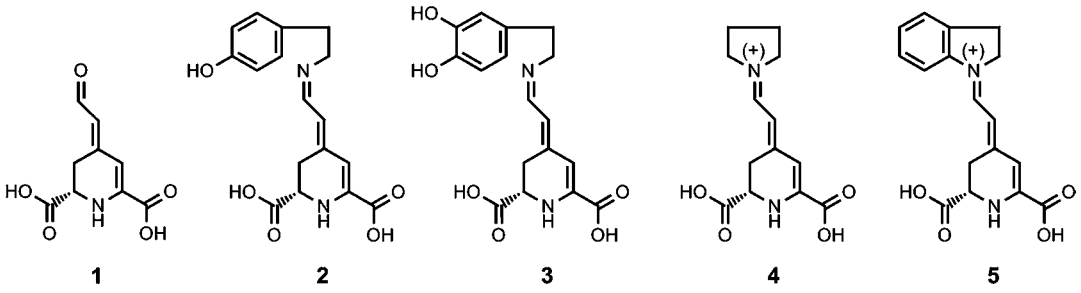

Figure 1. Structures for betalamic acid (**1**), the structural unit of betalains, and the derived pigments tyramine–betaxanthin (**2**), dopamine–betaxanthin (**3**), pyrrolidine–betaxanthin (**4**), and indoline–betacyanin (**5**).

betalamic acid and the amine groups present in the matrix surface, which can be displaced at mild conditions by the addition of amines. The novel material allows a one-step procedure for the formation of betaxanthins and betacyanins, thus significantly simplifying the process of obtaining semisynthetic betalains.

MATERIALS AND METHODS

Chemicals and Reagents. Red beet juice concentrate (B-50-WS) was purchased from CHR Hansen (Madrid, Spain). It is a liquid formulation obtained by squeezing out, concentrating, and pasteurizing the juice of beetroots, *B. vulgaris*. The starting matrix was Lewatit VP OC 1065 (surface area = 50 m^2/g), obtained from Sigma (Madrid, Spain). Solvents were from Merck (Madrid, Spain). HPLC grade acetonitrile was purchased from Labscan Ltd. (Dublin, Ireland). Other chemicals and reagents were obtained from Sigma (Madrid, Spain). Distilled water was purified using a Milli-Q system (Millipore, Bedford, MA, USA).

Development of the Betalamic Acid Support. Red beet juice concentrate was filtered by a 10 kDa ultrafiltration step (QuixStand System, GE Healthcare, Milwaukee, WI, USA). Betanin from this filtered solution was used as starting material. Basic hydrolysis (pH 11.4) of betanin in the presence of the starting matrix released betalamic acid (30 min, at room temperature) (**1**), which was then condensed with the primary amine present in the inorganic matrix after reaching pH 5.0. This bound betalamic acid to the surface of the support, which was then washed three times with 20 mM sodium acetate buffer, pH 5.0. The binding process was carried out in nitrogen atmosphere.

Semisynthesis of Betalains. For standard assays, the betalamic acid derivatized support (0.16 g) was incubated in a final volume of 0.5 mL with different amines, at the specified concentration, in 20 mM sodium acetate buffer, pH 5.0, or in 20 mM sodium phosphate buffer, pH 8.0, for tyramine. The reaction mixture for pyrrolidine–betaxanthin (**4**) and indoline–betacyanin (**5**) syntheses also contained 1.36 M sodium chloride to facilitate the release of the pigments from the support surface into the reaction medium. The formation of the corresponding betaxanthin or betacyanin was revealed by a characteristic deep yellow or violet color, respectively, in the reaction medium. After the indicated reaction time, an aliquot of 100 μL was removed for HPLC analysis. To analyze the formation of betalains with time, the reaction was scaled up to a final volume of 8 mL. The evolution of the reaction was monitored by HPLC analysis of the aliquots extracted at different times. For pH studies the reaction was carried out in 20 mM sodium acetate buffer (pH 3.5–5.5) or in 20 mM sodium phosphate buffer (pH 6.0–7.0). The buffer used for pH values >7.5 was 20 mM sodium borate.

Stability of the Betalamic Acid Support. The stability of the novel support was investigated by studying its capacity to synthesize betaxanthins as a function of storage time. Freshly made betalamic acid support (0.16 g) was incubated with 1.35 mM dopamine in 20 mM sodium acetate buffer, pH 5.0. An aliquot was taken after 40 min of reaction to analyze dopamine–betaxanthin (**3**) formation by HPLC. The betaxanthin concentration value obtained was considered as the starting capacity of synthesis. Then, the dopamine betaxanthin synthesis was performed with the support at different times throughout 6 months. Measurements were performed in triplicate, and mean and standard deviations were plotted. Relative synthetic activity was determined as the percentage of activity remaining after storage with respect to controls. Errors associated with the results provided were calculated on the basis of the residual standard deviations. The stability of the support was also studied by color assessment analysis. Color determinations of the immobilized betalamic acid support were made at 25 °C using a V-650 spectrophotometer equipped with an ISV-722 integrating sphere (Jasco Corp., Tokyo, Japan). The color parameters corresponded to the uniform CIELAB space (L^*, a^*, b^*, C^*, and $h°$) and were directly obtained from the apparatus software Spectra Manager version 2.07.[22]

Spectroscopy. A V-630 spectrophotometer (Jasco Corp., Tokyo, Japan), attached to a Tectron thermostatic bath (JP Selecta, Barcelona, Spain), was used for absorbance spectroscopy. For the quantitation of betalains, pigment concentration was evaluated by taking a molar extinction coefficient of ε = 48000/M/cm at 480 nm for betaxanthins and ε = 71000/M/cm at 524 nm for indoline–betacyanin.[7,23] Measurements were made in water at 25 °C.

HPLC Analysis. A Shimadzu LC-20AD apparatus (Kyoto, Japan) equipped with an SPD-M20A photodiode array detector (PDA) was used for analytical HPLC separations. Reversed phase chromatography was performed with a 250 × 4.6 mm Luna C-18(2) column packed with 5 μm particles (Phenomenex, Torrance, CA, USA). Gradients were formed with two solvents, A and B. Solvent A was H_2O with 0.05% trifluoroacetic acid (TFA); solvent B was acetonitrile with 0.05% TFA. A linear gradient was performed from 5 to 35% B for 35 min. The flow rate was 1 mL/min, operated at 25 °C. Injection volume was 20 μL.[24] All assays were performed in triplicate, and mean and standard deviations were plotted. Errors associated with the results provided were calculated on the basis of the residual standard deviations.

Scanning Electron Microscopy (SEM). Particle morphology was evaluated by SEM. Powders were attached to pieces of double-sided adhesive tape mounted on SEM stubs, coated with gold under vacuum using a SEM coating system by Bio-Rad Polaron Division and examined with a JSM-6100 (JEOL, Tokyo, Japan) scanning electron microscope operated at 15 kV. Images were analyzed using the open source image analysis software ImageJ (National Institutes of Health, NIH, Bethesda, MD, USA). Briefly, images were calibrated and, after that, an interactive measurement of the spheres was carried out. Micrographs were obtained with an Inca Oxford Image capture system (Oxford Instruments, Abingdon, UK).

RESULTS AND DISCUSSION

Development of a Betalamic Acid Derivatized Support. Betalamic acid (**1**) is the structural and bioactive unit of plant pigments betalains and the starting point for their formation both in vivo and in vitro. The production of individual compounds implies a purification of the acid, which leads to multistep procedures with low yields.[17,20,21] The aim of this work is the development of a novel support derivatized

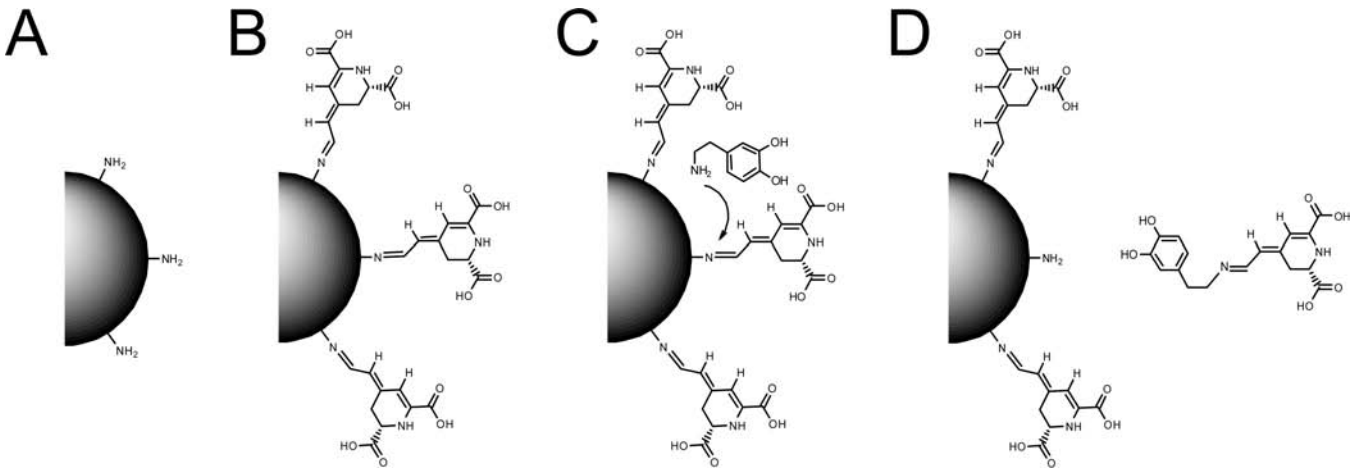

Figure 2. Schematic overview for the betalamic acid derivatized support and the surface reaction leading to pigment synthesis, exemplified for dopamine-derived betaxanthin (**3**): (A) starting material containing primary amine groups; (B) betalamic acid derivatized support; (C) amine attack to betalamic acid; (D) synthesis and concomitant release of the pigment.

with betalamic acid suitable for the synthesis of betalains. The basis of the proposed process is summarized in Figure 2.

First, betalamic acid is obtained in the presence of a resin that contains free primary amine groups. Given the reactivity of the aldehyde group of the acid, it was proposed that an imine would be formed with the amine of the support, thus causing the immobilization of betalamic acid to the resin. Betalamic acid was obtained by basic hydrolysis of purified betanin, the main pigment present in red beet root (*B. vulgaris*) extracts by the addition of ammonia.[21] Hydrolysis was carried out in the presence of the easily available cross-linked polystyrene resin VP OC 1065 (Lewatit), which contains primary amine groups, at room temperature and under nitrogen atmosphere. Under these experimental conditions betalamic acid was released from betanin. Neutralization with acetic acid was carried out after hydrolysis to promote the reaction of betalamic acid with the amines through a Schiff condensation reaction. This involved a change of color of the resin spheres from pale yellow to deep yellow, indicating the derivatization with betalamic acid. The resin was washed with 20 mM sodium acetate buffer, pH 5.0, until the washing solution was colorless. It was then allowed to dry at room temperature.

The binding reaction of betalamic acid to the matrix was confirmed by UV−vis spectrophotometry using an integrating sphere. This allowed the analysis of the color changes in the solid matrix. Figure 3A shows the spectrum obtained for the resin after betalamic acid reaction. The maximum wavelength was determined as λ_{max} 486 nm. Both the shape and maximum wavelength corresponded to the typical results of a betaxanthin, the yellow betalains formed by condensation of betalamic acid with simple amines.[7,23] Thus, the reaction between betalamic acid and the amine groups of the resin generated a solid support with the spectroscopic properties of a pseudobetaxanthin. The novel support was further characterized by SEM to analyze the effect of the treatment on the particle surface. Figure 3B shows a SEM microphotograph of the resin after betalamic acid immobilization. Particle analysis and sphericity were analogous to the results obtained for the resin without betalamic acid, indicating that the morphology of the resin was not altered by the immobilization process. Analysis of the particle morphology shows that the resin spheres possess a mean particle diameter of 0.59 ± 0.08 mm. SEM analysis also

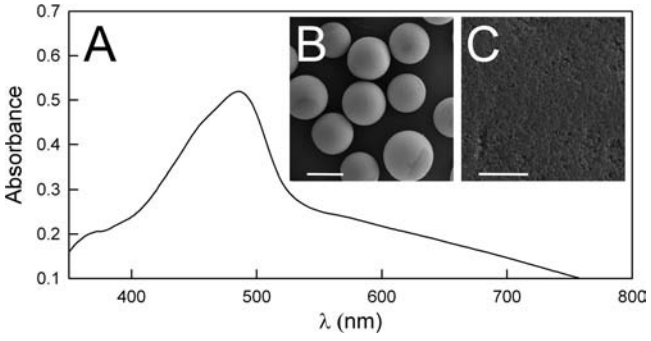

Figure 3. Spectroscopic and microscopic characterization of the betalamic acid derivatized support: (A) UV−vis spectrum for the solid matrix showing the characteristic spectrum for betaxanthins (spectrum was obtained with an integrating sphere after the subtraction of the spectrum for the basal absorbance of the starting matrix); (B) SEM image obtained for the spheres that constitute the novel matrix (scale bar = 500 μm); (C) closer SEM view showing the surface of the spheres (scale bar = 5 μm).

shows that the surface porosity of the spheres was not affected by the process (Figure 3C).

Thus, a matrix derivatized with betalamic acid was obtained for the first time. It is proposed that this support could be used for betalains synthesis simply by adding the selected amine. The reaction of betalamic with the amine would lead to the release of the pigment, as shown graphically in Figure 2.

Semisynthesis of Betalains. To test the concept of easy synthesis of betalains through the novel betalamic acid derivatized support, the resin was used for the production of different pigments. Four amines were selected as models to demonstrate this application: tyramine, dopamine, pyrrolidine, and indoline. The choice of tyramine and dopamine was based on the bioactive potential of their corresponding betaxanthins. Tyramine−betaxanthin (**2**) and dopamine−betaxanthin (**3**) possess high antioxidant and free radical scavenging activities due to the presence of phenolic hydroxyl groups (Figure 1).[25] They are natural pigments, also known by the trivial names miraxanthin III, and miraxanthin V, respectively, which were originally described in flowers of *Mirabilis jalapa* but are also present in the species *Celosia argentea* and *B. vulgaris* among others.[26−28] Structurally, these betaxanthins are derived from

primary amines and possess open structures. In contrast, pyrrolidine is a secondary amine, and the pigment derived (**4**) possesses a ring attached to the betalamic acid moiety while maintaining properties of a betaxanthin (Figure 1). Indoline is also a secondary amine and possesses the same ring of pyrrolidine plus an additional aromatic ring (Figure 1). This additional electron resonance system promotes a bathochromic shift in the absorbance spectrum, which makes the derived betalain violet. The indoline-derived pigment (**5**) is the simplest molecule with betacyanin properties and, thus, the betacyanin defining structure.[7]

When colorless solutions containing the individual model amines were added to the novel support, the solutions turned yellow in the case of tyramine, dopamine, and pyrrolidine and purple in the case of indoline. In contact with the support, the amines yielded the corresponding pigments through a Schiff condensation reaction with the aldehyde group of betalamic acid, thus releasing the synthesized betalain as postulated in Figure 2C. All pigments were characterized by HPLC-DAD, confirming the expected identity and the absence of additional coloring molecules. Retention times for tyramine-derived (**2**) and dopamine-derived (**3**) betaxanthins were 18.3 and 16.5 min, respectively, whereas for pyrrolidine-derived (**4**) and indoline-derived (**5**) betalains retention times were 15.2 and 23.6 min, respectively. The optimal experimental conditions for the novel synthesis on support were investigated by measuring the pigment generation by HPLC-DAD analysis of the solutions. Figure 4 shows the evolution of the synthesis reaction with time for each amine assayed at 25 °C. The temperature of 4 °C was also assayed in this study under the same conditions (data not shown). At this temperature the concentration of product obtained was lower than at 25 °C in all cases. Analysis of the time courses obtained at 25 °C determined the optimal times of reaction at this temperature, which varied depending on the amine used. The highest pyrrolidine-derived pigment (**4**) concentration was reached after only 4 min of reaction. For the rest of the compounds the estimated optimum reaction times were 20, 40, and 60 min for indoline-derived (**5**), dopamine-derived (**3**), and tyramine-derived (**2**) betalains, respectively. This variation may result from the different affinities of betalamic acid toward the amine groups of the support and the amines added in solution. This apparent affinity was greater for pyrrolidine. The existence of a maximum in all of the time courses presented indicates the existence of two processes taking place at the surface of the spheres. One is the synthesis and concomitant release of the pigments as discussed, causing the appearance of betalains in the medium immediately after the addition of the amines. The other is responsible for withdrawing the pigments obtained from the medium after their formation, so causing the decrease of concentration after synthesis in the solution. Pigment stability in the medium was confirmed by repetitive analysis of the pigment concentration after separation from the matrix, with no appreciable loss of the betalains (results not shown). Pigment concentration decreased only after the maximum times described above in the presence of the matrix, thus indicating an adsorption phenomenon. The nature of the adsorption process might be unspecific, but an electrostatic contribution was investigated. The addition of sodium chloride to the reaction mixture in the case of the pyrrolidine-derived betaxanthin (**4**) and the indoline-derived betacyanin (**5**) mitigated the electrostatic contribution of the positive charge of the pigments and facilitated the release of the resulting

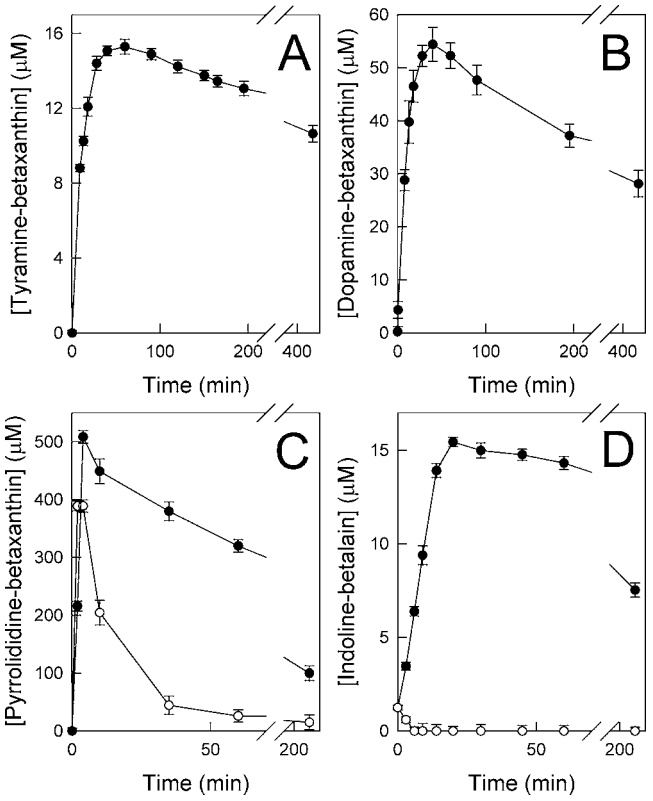

Figure 4. Time course for the evolution of pigment formation in reaction media containing the betalamic acid derivatized support at 25 °C and different amines; (A) tyramine, 0.85 M; (B) dopamine, 1.35 M; (C) pyrrolidine, 0.6 M; (D) indoline, at saturating concentration. In panels C and D, results are shown in the presence (●) and in the absence (○) of 1.36 M NaCl. Experimental conditions are detailed under Materials and Methods.

betalains from the resin surface into the solution (Figure 4C,D). This increased the amount of pigment obtained from the reaction on the novel material. An optimal concentration of 1.36 M NaCl was determined, with values below this causing a lower pigment release.

The effect of pH was also investigated in the pigment synthesis from the derivatized support. Figure 5 shows the results obtained when the pH of the amine-containing solution was varied from 3.5 to 9.0. Only in the case of dopamine was the range limited to 6.5 to avoid the catecholic substructure oxidation at higher pH values. Tyramine−betaxanthin (**2**) synthesis reached a maximum at pH 8.0 (Figure 5A), which was then selected for standard assays with this amine. However, as can be seen for the rest of amines, the pH variation did not significantly affect the synthesis. A pH of 5.0 was preferred to more alkaline values because of the higher stability of the compounds.[29,30]

Betalain synthesis was also dependent on the amine concentration. As shown in Figure 6, an increase in the concentrations of the amines resulted in a general increase in the formation and release of the derived betalains to the solution. However, the substrate concentration effect depended on the nature of each amine. Increasing concentrations of tyramine (Figure 6A) and dopamine (Figure 6B) led to a higher level of the derived betaxanthins in the solution. However, their concentrations could not be raised further because of the relatively low solubility of these compounds. In the case of pyrrolidine (Figure 6C), betaxanthin production

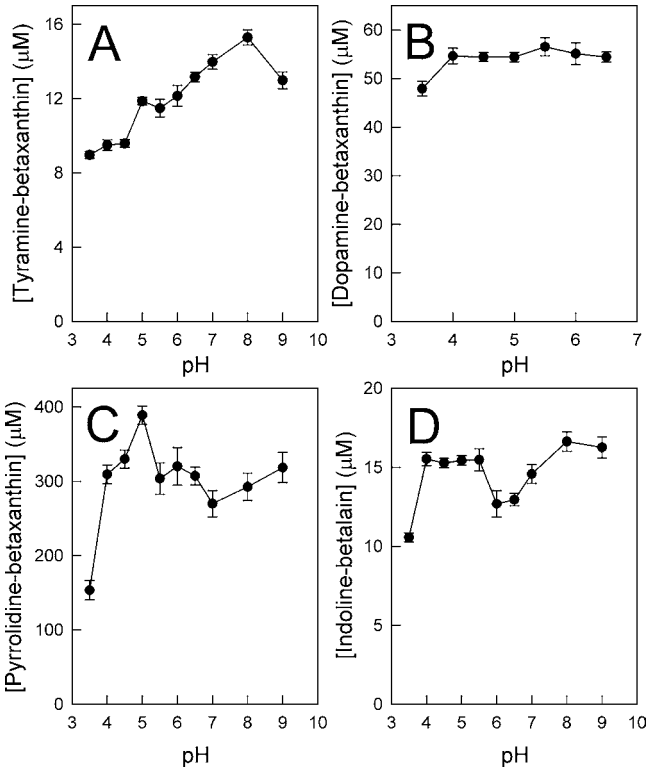

Figure 5. pH effect on the synthesis of betalains using the betalamic acid derivatized support and different amines: (A) tyramine, 0.85 M; (B) dopamine, 1.35 M; (C) pyrrolidine, 0.6 M; (D) indoline, at saturating concentration. The reaction was carried out in 20 mM sodium acetate buffer (pH 3.5−5.5), 20 mM sodium phosphate buffer (pH 6.0−7.0), or 20 mM sodium borate buffer (pH 8.0−9.0).

grew with increasing concentrations of the starting amine up to a maximum at 0.6 M. The scarce solubility of indoline in aqueous media prevented the study of the concentration effect, and this amine was always added to the reaction mixture at saturating concentration under the assay conditions.

From the above results it can be concluded that the optimization of the parameters which affect the novel one-step method for the easy synthesis of betalains should be made for each individual compound. Once optimized, the method allows a routine process to obtain individual compounds that significantly simplifies the previous methodology.[20,21] Betalamic acid obtained from red beet roots was previously used to obtain small amounts of betalain standards for pigment identification by its addition to amines after a process of hydrolysis and immediate partitioning steps with ethyl acetate followed by concentration and re-extraction prior to the synthesis reaction.[20] The combination of the hydrolysis and imine formation reactions in one merged procedure allowed higher amounts of betalains to be obtained but still required immediate purification steps with anionic exchange chromatography to avoid reversal of the reaction.[21] The methodology described here avoids the immediate purification steps and yields stable betalains in minutes, thus simplifying the process to obtain individual pigments. Figure 7 shows the use of the novel betalamic acid derivatized support as a matrix in chromatographic cartridges to speed the recovery of the pigments. The result is shown after the addition of the selected amines at the corresponding optimum concentration, pH, and reaction times determined above.

Stability of the Betalamic Acid Derivatized Support. The stability of betalamic acid after the resin derivatization was investigated by studying its capacity to synthesize betaxanthins as a function of storage time. As a control, a freshly prepared derivatized support was used to obtain dopamine−betaxanthin (**3**) as described above. The amount of betaxanthin obtained was considered to be the starting capacity of synthesis of the support. The synthesis reaction was repeated with the support at different times over 6 months. The support was stored at 4 °C in the absence of light. The results obtained for dopamine−betaxanthin (Figure 8) indicate that the resin retained approximately 50% of its potential after 6 months of storage. The loss of synthetic activity was pronounced during the first month, and from then on it remained practically stable in the production of the betaxanthin.

In addition, the stability of the derivatized support was evaluated by color assessment analysis of the resin. The changes in the appearance of the resin were quantitated by the results of the color CIELAB parameters, determined by spectrophotometry using an integrating sphere. Data were collected immediately after derivatization with betalamic acid. These results obtained for the freshly made support were compared to those found after 6 months of storage (Table 1). As can be seen, the a^* and b^* values decreased, indicating a loss in the red

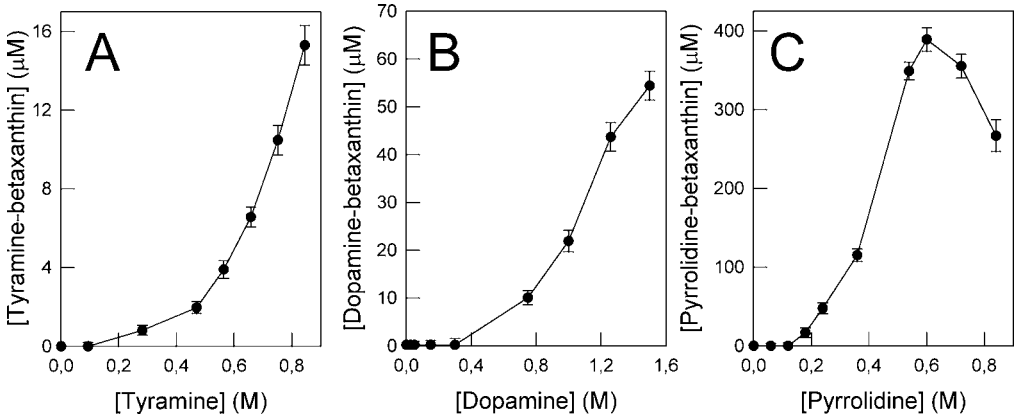

Figure 6. Effect of amine concentration on the formation of the betaxanthins derived from (A) tyramine, (B) dopamine, and (C) pyrrolidine. The reaction medium contained the derivatized support and the amine, at the specified concentration, in 20 mM sodium phosphate buffer, pH 8.0 (tyramine), or in 20 mM sodium acetate buffer, pH 5.0 (dopamine and pyrrolidine).

dx.doi.org/10.1021/jf500506y | J. Agric. Food Chem. 2014, 62, 3776−3782

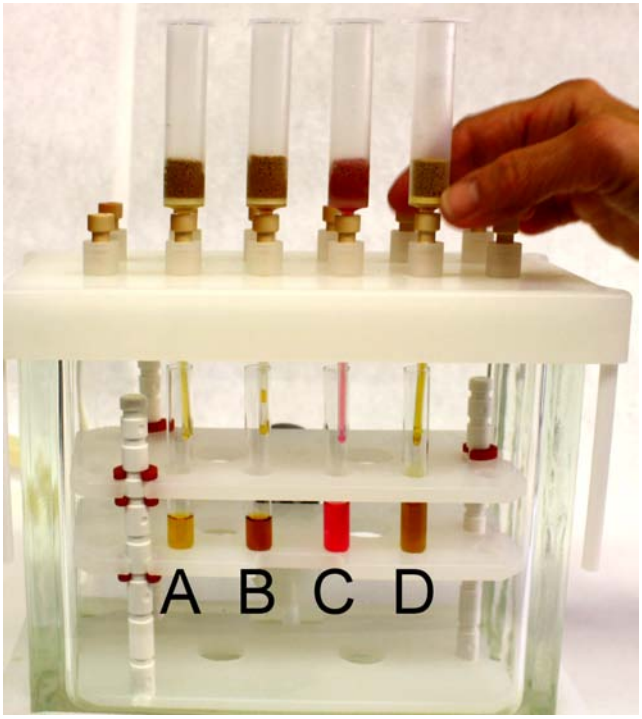

Figure 7. Application of the betalamic acid derivatized support to the synthesis of betalains in chromatographic cartridges. Solutions containing the individual pigments are obtained after the synthesis of (A) tyramine−betaxanthin (**2**), (B) dopamine−betaxanthin (**3**), (C) indoline-derived betacyanin (**5**), and (D) pyrrolidine−betaxanthin (**4**) under the optimized conditions.

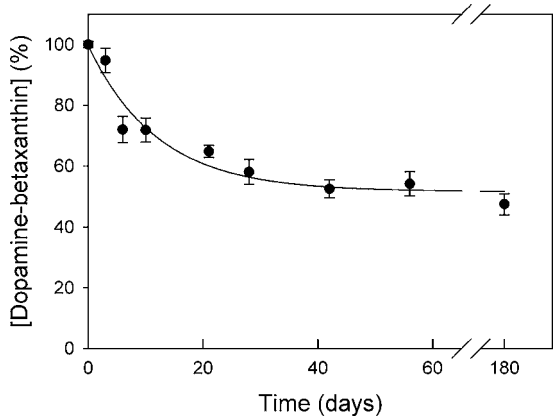

Figure 8. Effect of storage time on the capacity of the betalamic acid derivatized support to yield dopamine−betaxanthin (**3**). The optimized conditions were used for multiple assays during the indicated time.

Table 1. Color Analysis (CIELAB Parameters) for the Betalamic Acid Derivatized Support before and after a Period of 6 Months of Storage

	initial	6 months
a^*	7.18 ± 0.36	5.32 ± 0.11
b^*	32.52 ± 1.47	30.12 ± 1.01
L^*	63.25 ± 1.20	64.91 ± 1.05
$h°$	77.55 ± 0.08	79.98 ± 0.47
C^*	33.31 ± 1.51	30.59 ± 0.98
ΔE^*		3.46 ± 0.23

and yellow colors, respectively. This is probably due to a limited degradation of the pseudobetaxanthin formed, which possesses a maximum wavelength of λ_{max} 486 nm. This contributed to the change in hue angle ($h°$) and chroma (C^*). The L^* parameter was moderately increased, indicating that the color of the resin became lighter after the storage time. In conclusion, the color (a^*, b^*, $h°$), its intensity (C^*), and the lightness (L^*) of the derivatized support changed slightly after 6 months of storage, as confirmed by the value of ΔE^*. This parameter accounts for the color variation calculated with the differences between L^*, a^*, and b^* of the sample stored and the initial conditions. As can be seen, it was only slightly varied, indicating the stability of the betalamic acid resin.

The present work develops for the first time a support derivatized with the structural unit of betalains, betalamic acid. The novel material containing this natural molecule presents color properties of a pseudobetaxanthin and allows a procedure for the easy synthesis of individual betalains. The methodology is based on the addition of amines, which provokes the production of the corresponding derived pigments with the concomitant release from the matrix. The procedure is described in detail and provides a one-step method for the synthesis of betalains, thus considerably simplifying the previous methodologies. This tool opens up new perspectives in the research on betalains and may benefit current and future applications of the pigments.

samples were ground and treated with ethanol to remove oligosaccharides. DEAE was purchased from Whatman International Ltd. (Kent, UK). Sephacryl S-400 was purchased from GE Healthcare (Uppsala, Sweden). Dextrans with different molecular weights and standard monosaccharides (arabinose, glucose, mannose, galactose, rhamnose, fucose, and xylose) were purchased from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Dihydrochloride (AAPH), 2,2′-azobis(2-amidinopropane), and *myo*-inositol were purchased from J&K Scientific (Beijing, China). Iron(III) chloride, 2,2-diphenyl-1-picrylhydrazyl radical (DPPH•), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), fluorescein (FL), and dimethyl sulfoxide (DMSO) were obtained from Sigma-Aldrich (St. Louis, MO, USA). RAW 264.7 mouse macrophage was purchased from the Chinese Academy of Sciences (Shanghai, China). TRIzol reagent was bought from Invitrogen (Life Technologies, Carlsbad, CA, USA), whereas an IScript Advanced cDNA Synthesis kit was purchased from Bio-Rad (Bio-Rad Laboratories, Hercules, CA, USA). Lipopolysaccharide (LPS) from *Escherichia coli* 0111: B4 was obtained from Millipore (Millipore, MA, USA). All other reagents and chemicals were of the highest commercial grade and used without further purification.

Extraction, Isolation, and Purification of GPP-S. Ground *G. pentaphyllum* was extracted by distilled water and then decocted with 2% NaOH at 80 °C three times for 2 h for each time. The extracts were neutralized and combined after filtering and concentrated in a hot water bath. Hydrogen peroxide was added to remove the pigment at 60 °C for 6 h. The supernatant was then collected after centrifugation at 4500 rpm for 10 min and precipitated by adding 4 times volumes of ethanol. The crude polysaccharide of *G. pentaphyllum* was collected by centrifugation, followed by washing with ethanol and acetone, and finally dried with nitrogen.

The crude polysaccharide (500 mg) was dissolved in 6 mL of distilled water. After centrifugation, the supernatants were applied to a DEAE column (2.5 cm × 30 cm) and eluted with 0.6 M NaCl at a flow rate of 0.6 mL/min. Fractions were collected using an automatic fraction collector and examined with the phenol−sulfuric acid method. Each eluting peak was collected, concentrated, and loaded onto a column of Sephacryl S-400. The elutes were lyophilized to obtain the pure polysaccharide, named GPP-S.

Purity and Molecular Weight Determination. The purity and molecular weight of GPP-S were determined using an HPLC-ELSD (Shimadzu Technologies, Japan) with a gel filtration column (Shodex SUGAR KS-805, 8 mm i.d. × 300 mm, Showa Denko, Japan). The mobile phase was deionized water eluting at a flow rate of 1.0 mL/min for 30 min. The calibration curve was prepared with standard dextrans with different molecular weights (1800, 2500, 4600, 7100 and 2,000,000 Da). The mass of GPP-S was calculated by comparing the retention time of the standards.

Monosaccharide Composition Analysis. According to the method described previously,[15] GPP-S (5 mg) was incubated at 100 °C for 8 h after being dissolved in 1 mL of 2 M trifluoroacetic acid (TFA). The excess acid was removed by codistillation with 0.1% HCl−methanol. The residue was dissolved in 1 mL of distilled water ready for the following experiments.

Monosaccharide composition was analyzed according to a previously described procedure with minor modifications.[16] Each of the seven monosaccharide standards and the hydrolyzed polysaccharide were reacted with $NaBH_4$ at 65 °C for 1 h. The mixture was acetylated with pyridine and acetic anhydride at 100 °C for 2 h. Chloroform was used to extract the residues. The analysis was performed using an Agilent 7890A GC with a G4513 FID injector (Agilent Technologies, Palo Alto, CA, USA) equipped with an HP-5 capillary column (30 m × 0.32 mm, 0.25 μm). Injection volume was 1 μL. Oven temperature was first from 110 to 220 °C at 5 °C/min, held for 2 min, increased by 2 °C/min to 240 °C, held for 2 min, and then increased to a final temperature of 280 °C by 10 °C/min.

PMP derivatization of monosaccharides was performed according to a protocol described previously.[17] Briefly, 50 μL of seven standard monosaccharide mixtures or the hydrolyzed polysaccharide was mixed with 50 μL of NaOH (0.6 M), and then 50 μL of PMP methanol solution (0.5 M) was added to each sample. The mixture was allowed to react for 30 min at 70 °C, then cooled to room temperature, and neutralized with 100 μL of 0.3 M HCl. One milliliter of water was added to the solution, which was then extracted by chloroform (1.0 mL) three times. The aqueous layer was combined and centrifuged at 10000 rpm for 5 min. HPLC system equipment with a Zorbax Eclipse XDB-C18 column (250 mm × 4.6 mm, 5 μm, Agilent Technologies) was used to detect the PMP-labeled monosaccharide monitored by UV detector at 250 nm. The mobile phase was prepared by ammonium acetate solution (pH 5.5) and acetonitrile with a ratio of 78:22.

Infrared Spectral Analysis. The FT-IR spectrum was determined using a Fourier transform infrared spectrophotometer (Nicolet iN10 MX, Thermo Nicolet, USA) in the range of 4000−400 cm^{-1}. The sample was ground with spectroscopic grade potassium bromide (KBr) powder and pressed into 1 mm pellets for FT-IR measurements.

Methylation Analysis. Methylation analysis was performed according to the method of Needs and Selvendran with some modification.[18] Ten milligrams of GPP-S and NaOH (100 mg) were dissolved in 5 mL of DMSO. The mixture was methylated with 2 mL of methanol iodide with stirring. The completion of the methylation of GPP-S was confirmed by the disappearance of the OH band (3200−3700 cm^{-1}) in the IR spectrum. The methylated product was depolymerized in 3 mL of formic acid and further hydrolyzed by 2 M TFA (3 mL) at 100 °C for 3 h. After being reduced with sodium borohydride at 60 °C for 1 h, the methylated and hydrolyzed products of the GPP-S were acetylated with acetic anhydride and pyridine (1:1 molar ratio) for 1 h at 100 °C. The resulting product was washed with distilled water and dissolved in chloroform to be subjected to GC-MS analysis and identification according to the relative retention times and fragmentation patterns. The molar ratios of each residue were calibrated from peak areas and the response factor in GC.

NMR Spectroscopy. Polysaccharide was dissolved in D_2O. 1D and 2D spectra were recorded on a Bruker AV-500 MHz NMR spectrometer.

Oxygen Radical Absorbing Capacity (ORAC). The ORAC value was detected with fluorescein (FL) as the fluorescent probe using a Synergy 2 Multi-Mode Microplate Reader (BioTek, Winooski, VT, USA) according to a previously reported laboratory protocol.[19] Trolox was used as the standard. The initial reaction mixture contained 225 μL of 8.16×10^{-8} M FL and 30 μL of sample solution. After preheating at 37 °C for 20 min, 25 μL of 0.36 M AAPH was added into each reaction mixture. The reaction was measured every minute for 2 h. Excitation and emission wavelengths were 485 and 535 nm, respectively. Results were expressed as micromoles of trolox equivalents (TE) per gram of GPP-S.

DPPH• Radical Scavenging Capacity (RDSC). A laboratory protocol was used to determine the DPPH• radical scavenging capacity of the polysaccharide using a Synergy 2 Multi-Mode Microplate Reader (BioTek).[20] Briefly, each reaction mixture contained 100 μL of GPP-S, blank, or trolox standard and 100 μL of DPPH• solution. The absorbance of the reaction mixture was measured at 515 nm every minute for 1.5 h of reaction, and each sample was tested in triplicate. The RDSC was calculated using the area under the curve and reported as micromoles of TE per gram of GPP-S.

Hydroxyl Radical Scavenging Capacity (HOSC). The HOSC assay was conducted using FL as the fluorescent probe on a Synergy 2 Multi-Mode Microplate Reader (BioTek) according to a laboratory protocol reported previously.[21] FL solution was prepared in 75 mM sodium phosphate buffer (pH 7.4). The reaction mixture contained 170 μL of 9.28×10^{-8} M fluorescein, 30 μL of GPP-S or blank or standard, 40 μL of 0.199 M H_2O_2, and 60 μL of 3.43 M $FeCl_3$. The reaction was measured every minute for 6 h at ambient temperature, with the excitation wavelength at 485 nm and the emission wavelength at 528 nm. The results were expressed as micromoles of TE per gram of GPP-S.

Inhibition of IL-1β, IL-6, and COX-2 Gene Expressions in RAW 264.7 Mouse Macrophage Cells. GPP-S was dissolved in a known amount of DMSO and used for cell treatments. RAW 264.7 mouse macrophages were cultured in six-well plates overnight and reached 80% confluence. The cells were first treated with cell media

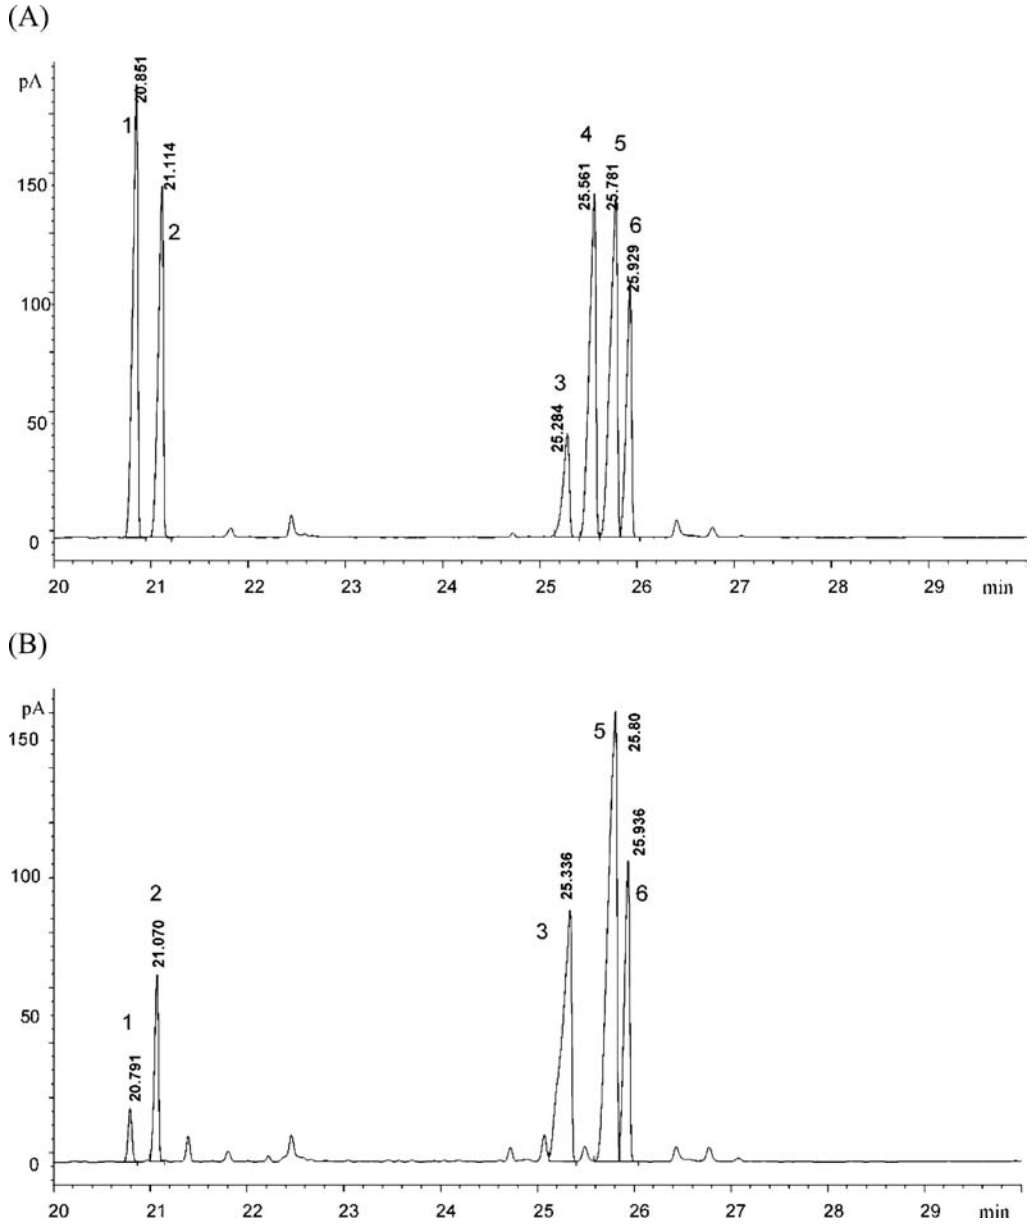

Figure 1. GC chromatograms of standard monosaccharides (A) and monosaccharide composition of GPP-S (B). Peaks: 1, rhamnose; 2, arabinose; 3, inositol; 4, mannose; 5, glucose; 6, galactose.

containing GPP-S for 24 h at 100 and 10 μg/mL concentrations. An initial concentration of 10 ng/mL of LPS was added into each well followed by incubation at 37 °C with 5% CO_2 for another 4 h. Then cells were collected for RNA isolation and real-time PCR analysis according to the previously published protocol.[22,23] After incubation, the TRIzol reagent was added for total RNA isolation, and the StrataScript First Strand complementary DNA Synthesis kit was used to reverse transcribe complementary DNA. Real-time PCR was performed using an ABI 7900HT Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, USA) with an AB Power SYBR Green PCR Master Mix. The following amplification parameters were used for PCR: 50 °C for 2 min, 95 °C for 10 min, and 46 cycles of amplification at 95 °C for 15 s and at 60 °C for 1 min.

Statistical Analysis. Data were recorded as the mean ± SD for triplicate determinations. Tukey's test and one-way ANOVA were used to identify differences in means. Correlation was presented by a two-tailed Pearson's correlation test. Statistics were analyzed using SPSS for Windows (version rel. 10.0.5, 1999, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Extraction and Purification of GPP-S. The crude polysaccharide was isolated from the alkaline extraction of tetraploid *G. pentaphyllum* with a yield of 5.07 g/100 g. After purification using DEAE and Sephacryl S-400 columns, GPP-S was obtained from the crude polysaccharides eluted by NaCl solution and distilled water, respectively. GPP-S showed a single sharp peak on the high-performance gel permeation chromatograph with a purity of 99.9% (Supporting Information Figure S1). No absorbance was detected at 260 or 280 nm in the UV spectrum, indicating that GPP-S was free of protein and nucleic acid.

Molecular Mass and Monosaccharide Composition of GPP-S. The average molecular mass of GPP-S was calculated as 1.2×10^6 Da on the basis of the standard curve of a series of standard dextran. According to the retention time showed in Figure 1 of alditol acetate derivatives of GPP-S hydrolysate in

dx.doi.org/10.1021/jf500438s | J. Agric. Food Chem. 2014, 62, 3783−3790

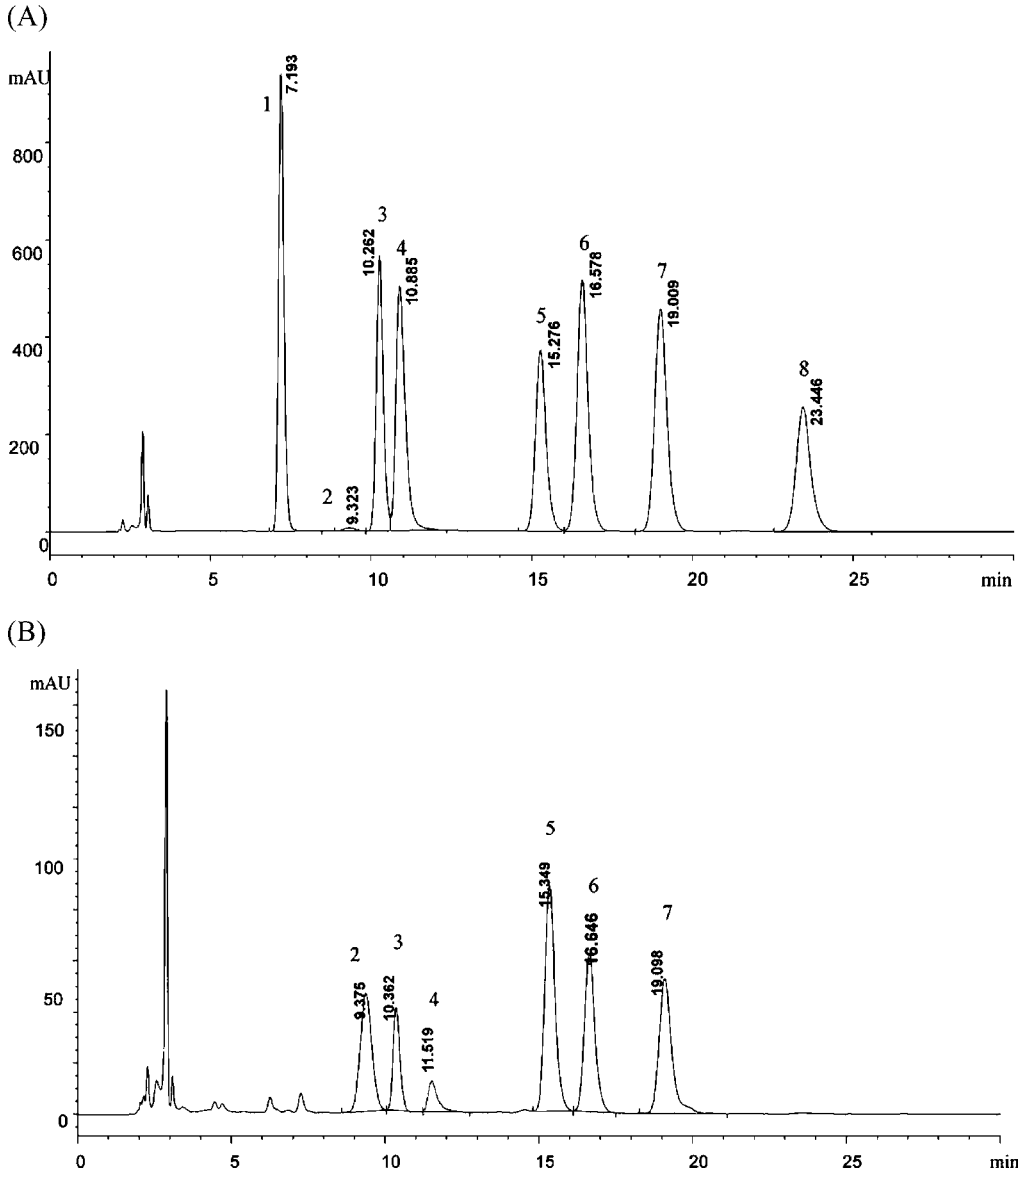

Figure 2. HPLC chromatograms of PMP derivatives of (A) seven standard monosaccharides and (B) GPP-S. Peaks: 1, mannose; 2, PMP; 3, rhamnose; 4, glucuronic acid; 5, glucose; 6, galactose; 7, arabinose; 8, fucose.

GC, GPP-S consisted of rhamnose, arabinose, glucose, and galactose with a molar ratio of 1.00:3.72:19.49:7.82. To further validate the GC analysis results, a PMP-HPLC analysis was carried out to determine the possible presence of uronic acid in GPP-S. As shown in Figure 2, GPP-S contained rhamnose, arabinose, glucose, galactose, and a small amount of glucuronic acid, which could prove the result of GC analysis. It needs to be pointed out that PMP derivatives were not stable, which made it difficult to accurately quantify the ratio of monosaccharides.

Structure Characterization of GPP-S. As shown in Figure 3, the IR spectrum of GPP-S displayed a broad stretching peak at 3346 cm^{-1}, which indicated the presence of hydroxyl groups. The weak peak at 2933 cm^{-1} was due to C−H stretching vibrations. Strong IR bands in the range of 1200−1030 cm^{-1} suggested the existence of C−O stretching vibrations of the pyranose rings.

Methylation analysis is widely used to determine the type of glucosidic bonds of polysaccharides.[24] After four methylations, the methylated polysaccharide was hydrolyzed and analyzed by GC-MS. As shown in Table 1, the four major peaks were identified as 2,3,6-tri-*O*-methylglucitol, 2,3-di-*O*-methylglucitol, 2,3,4-tri-*O*-methylgalactitol, and 2,3,4-tri-*O*-arabinitol with a molar ratio of 17.10:2.78:1.51:1.00. The results of methylation analysis indicated that the relative amount of (1→4,6)-linked glucose was 12.4%, suggesting that the backbone of GPP-S consisted of a (1→6)-linked branch every six residues.

The ^{1}H and ^{13}C NMR spectra of GPP-S are shown in Figure 4A,B. Four main signals from δ 95 to 105 were detected in the anomeric region. The anomeric proton signals (δ 5.41, 5.12, 5.14, and 5.28) and the anomeric carbon signals (δ 99.3, 101.1, 107.2, and 108.9) corresponded with H-1 and C-1 of four anomeric residues, including residue A as (1→4)-α-glucopyranose, residue B as (1→4,6)-α-glucopyranose, residue C as (1→6)-α-galactopyranose, and residue D as (1→)-α-arabinopyranose. All other carbon and proton signals are presented in Table 2 on the basis of the 1D and 2D NMR spectroscopy.[25−27] The signals of rhamnose residue were not detected in methylation and NMR analysis due to its low content. The HMBC spectra of GPP-S (Figure 4C) also showed the cross peak of H-1 and C-4 of residue A,

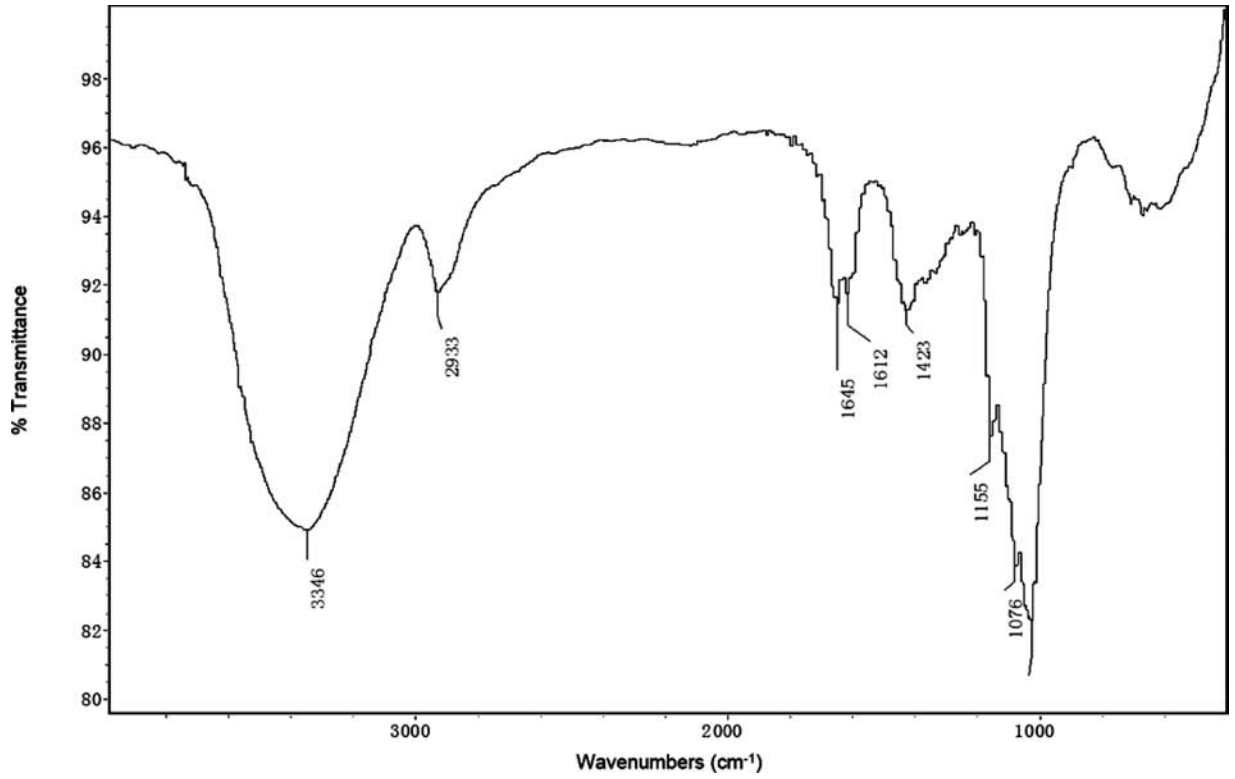

Figure 3. FT-IR spectrum of GPP-S.

Table 1. GC-MS Results of GPP-S

methylated sugar	retention time (min)	molar ratio	mass fragments (m/z)	linkage type
2,3,6-Me_3-Glc	13.64	17.1	43, 71, 87, 99, 101, 117, 129, 161, 173, 233	1,4-linked Glc
2,3-Me_2-Glc	15.23	2.78	43, 85, 101, 117, 142, 159, 201, 261	1,4,6-linked Glc
2,3,4-Me_3-Gal	12.3	1.51	45, 87, 101, 129, 161, 189, 233	1,6-linked Gal
2,3,4-Me_3-Ara	26.31	1.00	59, 87, 101, 117, 161	1-linked Ara

which suggested the linkage of two 1,4-α-Glcp residues. Both analyses of monosaccharide composition and methylation indicated that (1→4)-linked glucose was the residue at the largest amount, which formed the main structure of GPP-S. Cross peak A H1/B C4 and cross peak B H1/A C4 indicated that residue A was linked to residue B. Cross peak A H1/C C6 was observed in Figure 4C, which was possibly due to the linkage of residues A and C. No corresponding signal between residues B and C implied the branch residue linked only with 1,4-α-Glcp residues.

In summary, the structural analysis suggested that the backbone of GPP-S is (1→4)-linked glucose and (1→6)-linked galactose with a (1→4,6)-linked glucose branch every six residues. The predicted structure of GPP-S is shown in Figure 5.

Antioxidant Activity of GPP-S. The antioxidant ability of polysaccharides should be evaluated by different types of in vitro assays to avoid the influence of testing method on the antioxidant property estimation. Radical deactivation in the oxidation process has two major mechanisms, single electron transfer (SET) and hydrogen atom transfer (HAT). RDSC is a SET assay and measures the $DPPH^{\bullet}$ scavenging capacity of GPP-S. ORAC measures the oxygen radical absorbance capacity. HOSC evaluates the scavenging capacity against OH radical generated by the Fenton reaction of Fe(III) and peroxide. These two assays are based on the HAT mechanism. As shown in Figure 6, GPP-S showed the stronger scavenging capacity against $O_2^{\bullet -}$ radical and $HO^{\bullet}$ radical with ORAC and HOSC values of 28 and 19 μmol TE/g, respectively, whereas the $DPPH^{\bullet}$ radical scavenging capacity was 2 μmol TE/g. The results suggested that GPP-S may scavenge the radicals by both hydrogen atom or proton transfer mechanisms.

Effects of GPP-S on IL-1β, IL-6, and COX-2 mRNA expressions. Chronic inflammation is implicated in the pathogenesis of several chronic diseases including atherosclerosis, obesity, metabolic syndrome, diabetes, neurodegenerative diseases, and cancers.[28] The inhibitory effect of the pro-inflammatory

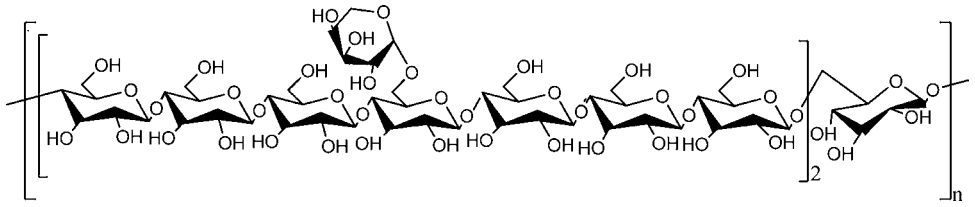

Figure 5. Possible repeating unit of GPP-S.

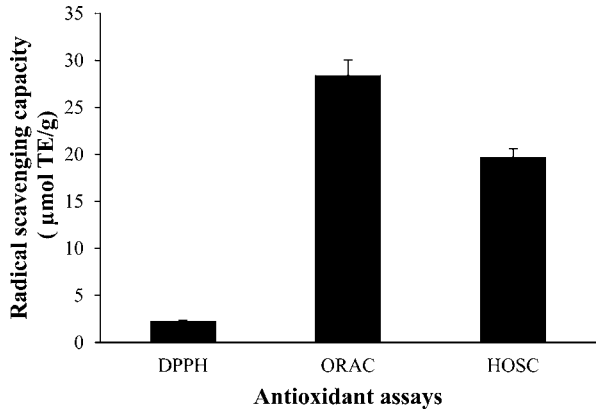

Figure 6. Antioxidant activities of GPP-S. Data are expressed as Trolox equivalents (TE) in μmol TE/g GPP-S. Antioxidant capacity was calculated using the area under the curve (AUC) against the Trolox standard. Vertical bars represent standard deviation (SD) for triplicate measurements.

The mRNA expression of IL-1β, IL-6, and COX-2 in the cells treated by 100 μg/mL GPP-S had 20.54, 82.15, and 41.75% reductions, respectively (Figure 7). The GPP-S of low concentration (10 μg/mL) showed significant suppression on IL-6 mRNA expression by 79.86% (Figure 7B), not suggesting a possible dose dependence. In conclusion, GPP-S exhibited significant inhibitory activity against mRNA expressions of the pro-inflammatory cytokine genes. Chronic inflammation involves the lining of blood vessels and many internal systems, which might contribute to the development of cancer, cardiovascular disease, diabetes, immune system decline, and other aging-associated health problems. The inflammatory process was often associated with oxidative stress and free radical damage. The antioxidant and potential anti-inflammatory activities of GPP-S implied that *G. pentaphyllum* could be used for a potential functional food ingredient to reduce the risk of chronic inflammatory diseases, warranting additional animal and human studies to further investigate and confirm the anti-inflammatory effects of GPP-S.

In summary, a novel alkaline-soluble polysaccharide (GPP-S), with a molecular mass of 1.2×10^6 Da, was isolated from tetraploid *G. pentaphyllum* Makino. It had a monosaccharide composition of rhamnose, arabinose, glucose, and galactose at a ratio of 1.00:3.72:19.49:7.82. The backbone of GPP-S is (1→4)-linked glucose and (1→6)-linked galactose with an occasional (1→4,6)-linked glucose, which terminated with 1-)-α-arabinose, glucuronic acid, and other monosaccharides.

In our previous research, two different kinds of polysaccharides, named GPP and GPP-TL, have been extracted by hot water from diploid and tetraploid *G. pentaphyllum* Makino, respectively.[15,29] Their molecular weights, monosaccharide compositions, and chemical structures were different from those of GPP-S, which led to the different antioxidant activities.

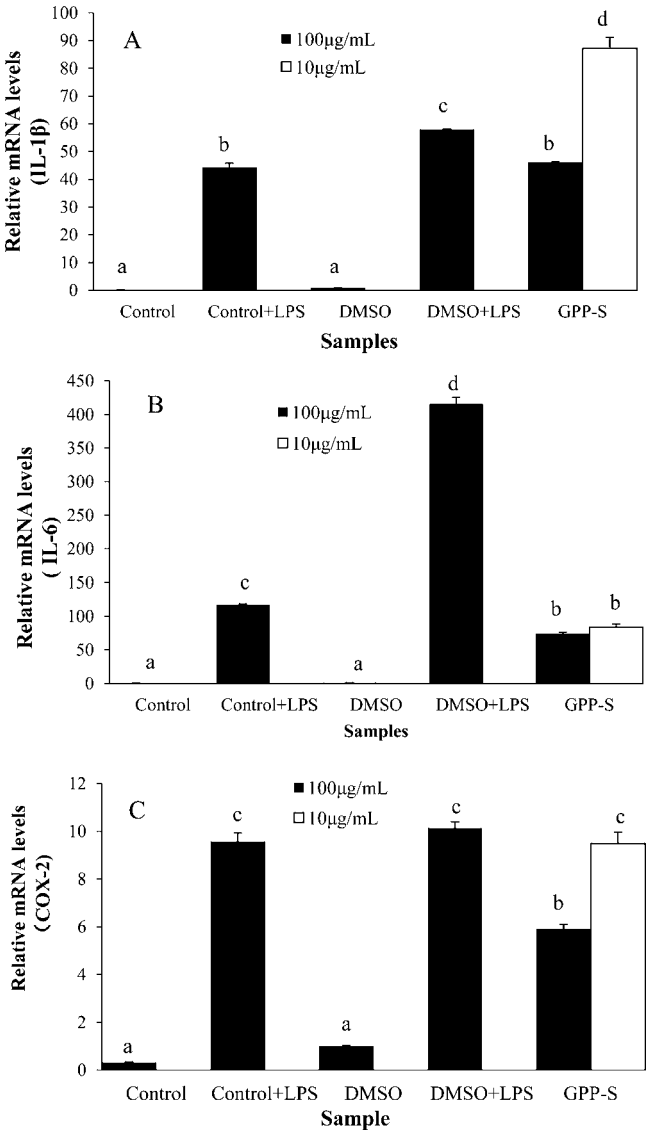

Figure 7. Effects of GPP-S on (A) IL-1β, (B) IL-6, and (C) COX-2 mRNA expressions in lipopolysaccharide (LPS)-stimulated RAW 264.7 mouse macrophage cells. DMSO was the vehicle. The solid and open bars represent initial GPP-S concentrations of 100 and 10 μg/mL, respectively. The vertical bars represent the standard deviation (n = 3) of each data point. Different letters represent significant differences ($P < 0.05$).

GPP-S showed higher scavenging ability against peroxide radicals than GPP and GPP-TL, whereas it had lower absorbance capacities for DPPH$^\bullet$ and HO$^\bullet$ than GPP and GPP-TL. In addition, GPP-S had significant inhibition of IL-1β, IL-6, and COX-2 gene expressions in RAW 264.7 mouse macrophage cells, suggesting its potential application in functional food and dietary supplement products.

through the liming effect.[9,13] In general, both pH and CEC of biochar influence the availability of nutrients to soil microbes and plants,[2] and soils amended with biochar or black carbon generally display higher CEC and SA than equivalent biochar-free soils.[3,14,15] Intensive studies showed biochar amendments increase soil pH and have significant consequent effects on plant growth.[9] On the other hand, some studies reported no or only slight changes in soil pH, CEC, and SA with biochar amendment, which is attributed to specific soil or biochar properties.[2,16] Detailed characterization of biochar is essential for forecasting and maximizing impacts of biochar amendment on soil properties.

Biochar properties have not yet been fully linked to production parameters, making the design of agronomic biochars a challenge.[3] Reasons for why this link does not yet exist may include the complexity of pyrolysis processes, which can be influenced by many factors. In addition, process parameters are difficult to control in large reactors, enhancing the complexity of biochar production processes and the heterogeneity of products.[2] Biochar properties can be assessed via a combination of rather simpler proxy-type analyses and advanced analytical techniques. Proxy-type analyses are therefore more practical also from a user standpoint as users may wish to mix various biochars for a homogeneous product. The International Biochar Initiative and a panel of experts have identified a proxy for the assessment of biochar stability,[17] and the characterization of other biochar properties will likely also rely on proxy-type analyses.

Robust assessment of biochar properties requires the existence of simple relationships, preferably linear, between production conditions or proxy measurements and complex properties. Several studies suggest that such simple relationships exist for critical chemical composition and surface property indicators. Increasing pyrolysis temperature has been reported to result in continuous increases in pH, CEC,[18] and SA.[19] However, not all studies agree with these findings. Surface area has been reported to reach a peak value and then decrease at higher HTT for both wood and wheat biochars.[20,21] Similarly, CEC has also been reported to display a localized maximum at midrange HTT.[22] Many studies use few biochar samples along a temperature continuum, and considerable uncertainty remains as to our ability to predict surface properties on the basis of biochar production methods. Here, our objective was to obtain detailed responses of selected biochar properties to HTT for three pyrolysis methods. For this, we used a ca. 15-point temperature series in slow pyrolysis of two feedstocks each as well as HTC hydrochars and flash carbonization biochars produced from the same feedstocks. This allowed us to obtain an extensive sample set for testing the hypothesis that surface properties follow simple relationships with HTT production conditions and can be predicted from chemical composition indicators.

MATERIALS AND METHODS

Carbonization. Three production methods were tested: slow pyrolysis, flash carbonization, and HTC treatment. Identical feedstocks were used for slow pyrolysis and HTC treatment: chaffed biomass of grass (*Miscanthus giganteus*) and corncob from maize (*Zea mays*) grown in Serbia (ZP Maize Hybrid 505). In addition to slow pyrolysis and HTC, flash carbonization was conducted on a batch of corncobs from Waimanalo Farm in Hawaii. In total, 34 biochars were produced (Table 1). In the present study, we used feedstock derived from plants using the C4 photosynthetic pathway, that is, miscanthus and maize. The C4 feedstock has a distinctive ^{13}C signature from that of soil organic matter, which we used in a parallel study on estimating the stability of biochar C structures in soil. Within the limited range of C4 feedstocks, miscanthus and corncob are good candidates for biochar production. Miscanthus is a high-yielding bioenergy crop requiring minimal soil preparation, and biochar prepared from it has potential for being a silicon fertilizer.[23] Corncob, in comparison, is a crop residue, which needs to be valorized and does not compete for land with food production.

Slow pyrolysis was performed in a muffle furnace at target temperatures ranging from 235 to 800 °C with a heating rate of 2.5 °C min^{-1}. Pyrolysis HTTs were selected to produce biochars containing a wide range of VM content. To aid the selection process, a set of preliminary analyses were conducted on the feedstocks using a thermogravimetric analyzer (SDT Q600, TA Instruments, New Castle, DE, USA). Fourteen miscanthus and 17 corncob biochars were generated through slow pyrolysis of chaffed miscanthus and corncobs cut into ca. 5 mm slices. A detailed procedure for the pyrolysis is provided by Wang et al.[24] Feedstock was dried at 105 °C for 24 h and

weighed prior to loading into a 1 L stainless steel retort. The retort, equipped with thermocouples placed at the center, bottom, side, and front, was then covered with a lid and placed into a furnace. The retort was purged for 1 h to create an inert atmosphere, and a constant flow of N_2 was maintained at 2 L min^{-1} during pyrolysis. After the desired final temperature was achieved, heat supply from the furnace was stopped and the sample cooled slowly to room temperature. To present a more representative sample history, we consistently reported measured HTTs from the average of the four thermocouples in the retort instead of set temperatures for the furnace. Exothermic reactions occurred during slow pyrolysis in the approximate temperature range of 250−400 °C, and actual HTTs measured by the thermocouples were higher than the set temperatures (Figure 1). As a result, few

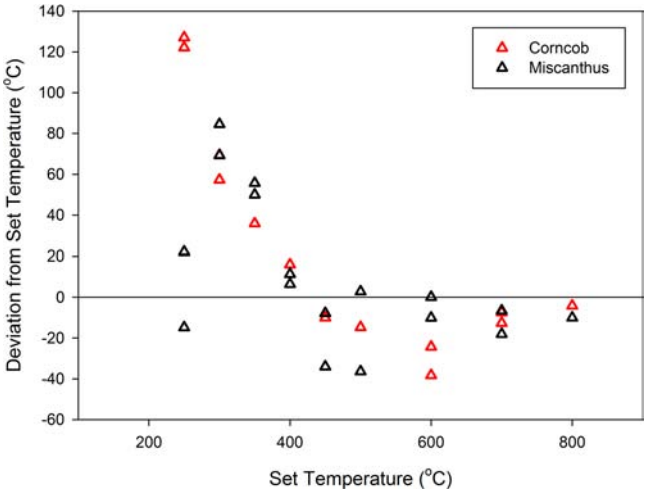

Figure 1. Deviation of measured highest treatment temperature (HTT) from oven set temperatures during slow pyrolysis.

samples are recorded at pyrolysis temperatures around 350 °C, at which the pyrolysis process is difficult to halt. At pyrolysis temperatures of ≥450 °C, measured HTTs in the retort did not exceed target values.

HTC treatment of corncob and miscanthus was performed in a 1 L steel autoclave (Anton Paar), immersed in water, and then heated at 230 °C for 6 h under autogenous pressure. After cooling, the autoclaves were opened, and the resultant hydrochar was removed from the aqueous dispersion by vacuum filtration. The resulting fine powder was dried at 40 °C. Because the hydrochar yield was not directly measured at the time of production, it was estimated from the literature[25] for the purpose of comparison.

Flash carbonization was performed on corncob to produce biochar according to the method of Antal et al.[26] The reaction lasted 20 min in a vessel pressurized to 0.8−3.4 MPa with air. Electric heating coils at the bottom of the pressure vessel ignited the lower portion of the biomass. After 360 s, compressed air was delivered to the top of the pressure vessel and flowed through the packed bed of feedstock to sustain the carbonization process. Pressure within the reactor was maintained at the specified range. After sufficient air was delivered to carbonize the corncob, air flow was halted and the reactor cooled overnight. The charcoal was removed from the reactor and allowed to equilibrate under a fume hood for 2 days.

All samples were crushed through a 2 mm sieve, and subsamples were subsequently ground for greater homogeneity with a ball mill for 3 min at 20 s^{-1} shaking frequency (MM 200, Retsch GmbH, Haan, Germany). The samples were stored in airtight bags until analyzed.

Physical and Chemical Analyses. Proximate analysis of the biomass feedstock was performed according to American Society for Testing and Materials (ASTM) methods E 871 and 872 with modifications as described by Wang et al.[24] In brief, ash content was determined according to ASTM method D 1102. The fixed carbon contents of the samples were calculated by difference between 100% and the sum of measured VM and ash contents. The VM content of the charcoal products was determined according to ASTM method D 1762-84 with the modification that samples were directly placed at the rear of a furnace for 6 min at 950 °C without preheating.[24]

Elemental composition (C, H, N) of the samples was determined on 50−100 mg samples by dry combustion using a Leco CHN1000 analyzer and coal reference material (Leco Corp., St. Joseph, MI, USA). Oxygen was determined on 2 mg samples dried at 90 °C with a TruSpec Makro analyzer and O add-on module (Leco Corp.). Results are reported on a dry weight basis. pH was determined in a biochar/water volume ratio of 1:10 using a combination Orion pH electrode (SA 720, Allometrics, Inc., Baton Rouge, LA, USA).

Potential CEC was determined by using a modified ammonium acetate compulsory displacement method. Soluble ions, which can constitute an artifact, were removed through five successive leachings of 0.5 g samples with 20 mL of deionized water. Preliminary analyses were conducted on the initial water leachates to determine the most important cations present following the method of Gaskin et al.[27] Analysis of the water leachates suggested that between 97 and 100% of the extractable/exchangeable cations were covered by five cations. After the removal of soluble ions with water, remaining cations were displaced using 50 mL of 1 M ammonium acetate buffered to pH 7. CEC was calculated by the sum of the cations Ca, Mg, K, and Na in the ammonium acetate percolate. H^+, determined by titration, was included when the pH was <7. Additional preliminary analyses involved CEC determination on a subset of samples exposed to pretreatment with acid. Acid washing is expected to remove carbonates, which may also interfere with the accurate determination of CEC. In this pretreatment, biochar−water mixtures were neutralized to pH 6.5 ± 0.02 by incremental additions of 0.5 M HCl and overnight shaking. The desired pH was obtained after 1 week, after which biochars were repeatedly washed until free of Cl^- as detected by $AgNO_3$ and dried at 50 °C for 5 days. Acid washing compared to only water leaching had little impact on the corncob biochar CEC, but it did reduce the miscanthus CEC by an average of 28%. Because the CEC of low-pH hydrochar was also reduced by 20% through acid washing, raising questions regarding the nature of the response, we chose a method that is less disruptive, namely, one without HCl washing.

Internal SA was measured using the Brunauer, Emmett, and Teller (BET) theory with N_2 as the adsorbate. Samples were dried at 106 °C for 90 min, milled, and then degassed in vacuum for 2 h at 120 or 150 °C: degassing temperature was chosen on the basis of sample HTT history. Measurements were performed on ca. 1 g samples on a NOVA 2000 (Quantachrome Instruments, Boynton Beach, FL, USA). The multipoint BET method was applied in the range of partial pressures of 0.05−0.30 P/P_0.

Statistics and Data Analysis. Multiple stepwise linear regressions and Spearman rank order correlations were performed with Sigmaplot version 11.0 (Systat Software Inc., San Jose, CA, USA).

RESULTS AND DISCUSSION

Yield and Proximate Analysis. Charcoal yield, VM content, and fixed carbon content changed nonlinearly in response to slow pyrolysis HTT (Figure 2). This type of nonlinear decrease in charcoal yield and VM and a corresponding increase in fixed carbon content are common biomass responses to increasing HTT.[5] Biochar yield and VM content responses to HTT were similar for the two feedstocks (Figure 2a,b). Eighty percent of VM loss occurred at 209−543 °C for corncob and at 241−509 °C for miscanthus. The VM contents of corncob and miscanthus feedstocks were similar, 81.1 and 78.0%, respectively. Despite the use of fairly similar C4 plants as feedstock, those being grass species of tropical origin, similar VM loss functions under pyrolysis were not necessarily obvious, as the two feedstocks differed somewhat in structural chemical composition. Our corncob and miscanthus feedstocks contained 13.8 and 21.3% lignin, respectively, as

dx.doi.org/10.1021/jf501139f | J. Agric. Food Chem. 2014, 62, 3791−3799

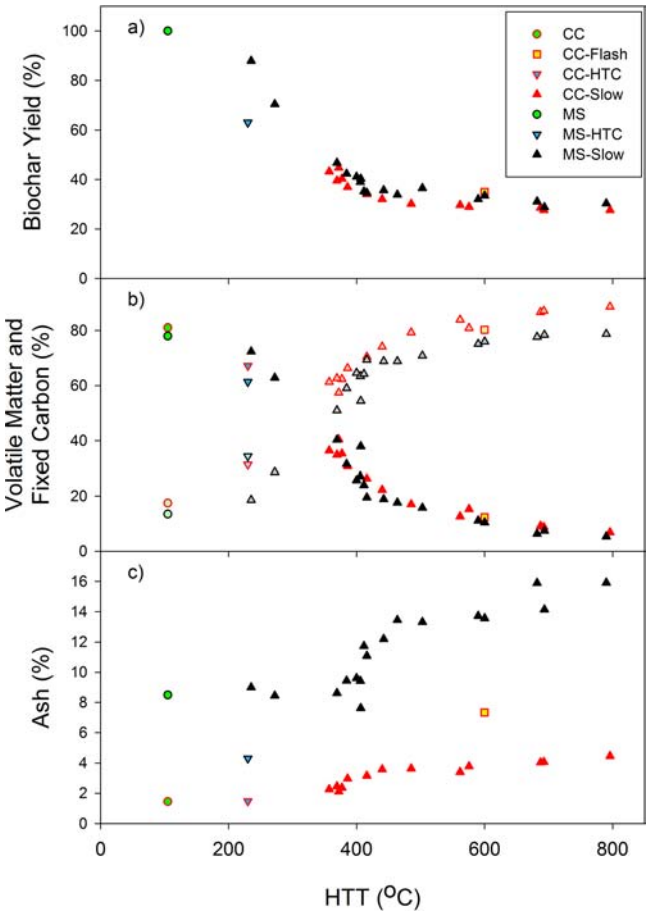

Figure 2. (a) Yield, (b) VM and fixed carbon (lighter fill) content, and (c) ash content as a function of highest treatment temperature (HTT) for corncob (CC), miscanthus (MS), and respective biochars produced through slow pyrolysis (Slow), flash carbonization (Flash), and hydrothermal carbonization (HTC). Reported biochar yield, VM, fixed carbon, and ash content are averages from three analytical replicates.

determined by advanced NMR investigations,[28] and these values are comparable to other reports of lignin in corncob and miscanthus: 14.7 and 23%, respectively.[19,29] Lignin content has been reported to affect biochar yield[30] due to the high C content of its constitutive polyphenol structure.[31] Additionally, mass loss during the pyrolysis process has been mainly attributed to degradation of cellulose at temperatures between 300 and 400 °C.[32] Our previous NMR investigations suggest that miscanthus had lower cellulose and hemicellulose contents than corncob but a higher degree of cellulose crystallinity.[28] Our results therefore suggest that the consistent biochar yield and VM contents obtained for grass-derived biochars hold across substantial variation in cellulose, hemicellulose, and lignin contents of feedstocks. The apparent absence of effect from variation in ash content and particle size would need to be confirmed with multiple grass feedstocks.

Hydrochars from HTC production displayed lower yield and VM content than slow pyrolysis biochars produced at similar HTT (Figure 2a,b). Although the hydrochars were produced at 230 °C, their VM and fixed C content were closer to those of 300 °C than of 250 °C slow pyrolysis biochars. On the basis of the amount of C recovered, Fuertes et al.[33] reported that 250 °C hydrochars are similar to slow pyrolysis biochars produced at nearly 400 °C. Our results confirm that HTC leads to a higher degree of carbonization than slow pyrolysis at comparable HTT. This is probably due to the reaction enhancement effects of pressure and the presence of water under HTC conditions. Flash carbonization HTT was not directly measured due to inhomogeneity within the reactor. The general relationship between VM and HTT for corncob (Figure 2b) suggests a production HTT for flash carbonization char between 520 and 640 °C. This temperature estimate is in the range of afterburner gas temperatures of the flash carbonizer.[34]

Ash in slow pyrolysis biochar became increasingly concentrated with increasing HTT (Figure 2c). Miscanthus hydrochar contained less ash than its feedstock, which is likely explained by mineral loss through the liquid phase during the HTC process. However, we did not observe a similar decrease in ash content for the corncob hydrochar, suggesting a feedstock-specific response. Contrasting trends in hydrochar ash content with different feedstocks were also found by Cao et al.[35] The ash content of feedstock used in flash carbonization was 6.3%, indicating that flash carbonization, like slow pyrolysis, leads to a concentration of ash. Only HTC produced a low-ash carbonization product.

Elemental Composition. Carbon and nitrogen were lost at a slower rate than oxygen and hydrogen during pyrolysis, resulting in their progressive concentration in the biochars with increasing pyrolysis HTT (Table 1). This effect has been well documented.[6] A Van Krevelen diagram relating H/C to O/C shows that the distribution of atomic ratios obtained from chars in this study was independent of feedstock and pyrolysis process (Figure 3). In our study, we directly measured O

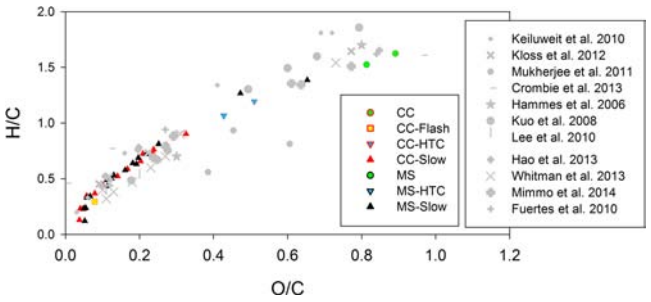

Figure 3. Van Krevelen diagram of samples analyzed in this study (in color) and literature values (gray) of grass feedstocks and biochars from 11 studies. Atomic ratios are averages from at least three analytical replicates.

contents, whereas most published studies report O values as calculated by subtracting the sum of C, H, N, and ash contents. Our measured values were more consistent than those we calculated by difference (data not shown), as the latter method combines the cumulative errors of all measurements. However, our O measurements for feedstocks were high, with O/C ratios between that of pure cellulose and sucrose. Despite the discrepancy at high O/C ratio, our atomic ratios obtained with measured O are remarkably consistent with literature values for grass-derived biochars obtained in 11 studies (Figure 3). It has been shown for biochars from a wide range of feedstocks that HTT plays a decisive role in causing the decrease in H/C and O/C ratios of produced biochar samples.[36] On the basis of the Van Krevelen plot, hydrochars and flash carbonization biochar appear equivalent to slow pyrolysis biochars produced at approximately 300 and 600 °C, respectively. This finding is

dx.doi.org/10.1021/jf501139f | J. Agric. Food Chem. 2014, 62, 3791−3799

consistent with the estimate of equivalent HTTs for chars from HTC and flash carbonization based on the relationship with VM. The independence of biochar elemental composition from feedstock and pyrolysis process is further confirmed by the consistent relationship between VM and molar ratios (Figure 4). Spokas[37] suggests that molar ratios encapsulate all

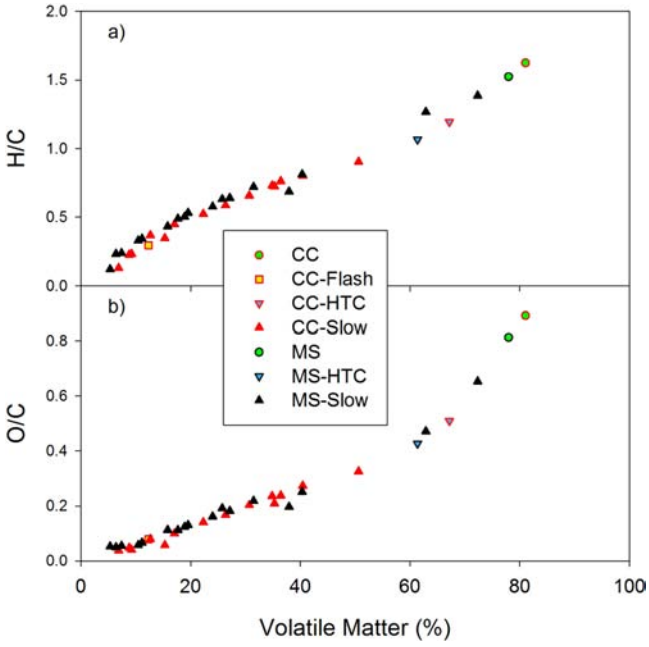

Figure 4. Atomic ratios (a) H/C and (b) O/C as a function of highest treatment temperature (HTT) for corncob (CC), miscanthus (MS), and respective biochars produced through slow pyrolysis (Slow), flash carbonization (Flash), and hydrothermal carbonization (HTC). Averages were obtained from at least three analytical replicates.

production parameters influencing carbonization. Other studies indicate that high-ash biochars such as those from food waste would require a combination of VM and atomic ratios for their characterization.[38] It has also been reported that H/C atomic ratios are not able to differentiate between the reactions occurring during HTC.[35] Our results suggest that both VM and atomic ratios can be used for characterizing the general charring history of grass-derived biochars. We further support the use of atomic ratios over volatile matter due to the stability of elemental composition measurements across studies as compared to proximate analysis.

Surface Property: pH. The pH of slow pyrolysis biochars increased with production HTT, reaching a plateau at approximately 450 °C (Figure 5a). Slow pyrolysis biochars produced above 450 °C had average pH that was 4.1 and 3.9 units higher than that of the corncob and miscanthus feedstocks, respectively. Flash carbonization biochar also had a pH that was 4.2 units above that of the feedstock. Our study shows that HTTs of 400−450 °C are sufficient for raising the biochar pH and producing C-rich biochar. Up to 7.6 pH unit increases have been shown in some biochars, with smaller increases in wood- and straw-derived biochars.[10] By contrast, HTC treatment significantly reduced the pH of the biomass by 1.3 and 2.4 units in corncob and miscanthus, respectively. Similar results were reported by Fuertes et al.,[33] who hypothesized that acidity in hydrochars may be due to a high content of carboxylic functional groups. The O/C atomic ratio, however, did not reflect the acidity of the hydrochars.

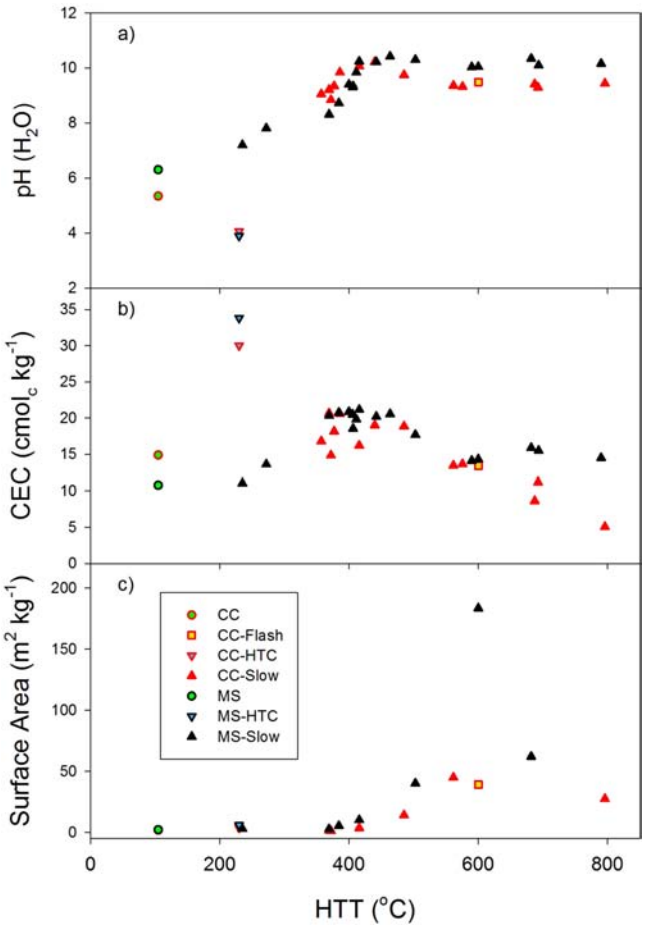

Figure 5. Surface properties (a) pH, (b) cation exchange capacity (CEC), and (c) surface area (SA), as a function of highest treatment temperature (HTT) for corncob (CC) and miscanthus (MS) and respective biochars produced through slow pyrolysis (Slow), flash carbonization (Flash), and hydrothermal carbonization (HTC). Analytical replicates, n, are (a) $n = 1$, (b) $n = 3$ for all with the exception of two points where $n = 1$ and 2, and (c) n = between 2 and 8.

A significant correlation was observed between pH and O/C ratio for the biochars in this study when hydrochars were excluded (Figure 6a, $R^2 = 0.854$). In addition, the pH was significantly correlated to VM across slow pyrolysis and flash carbonization biochars:

$$\text{pH} = 10.63 - (0.049 \times \text{VM}) \quad R^2 = 0.78 \qquad (1)$$

Alkalinity is caused by negatively charged organic groups, such as $-COO^-$ (carboxylate) and O^- (hydroxyl), and carbonates on the surface of biochar.[39] With increasing pyrolysis intensity, the number of acid functional groups (as carboxylic) decreases and the decrease is linearly correlated with the loss of volatile matter.[40] A decrease in surface acidic groups and a concomitant increase in surface basic groups with increasing HTT have been correlated to an increase in buffering capacity with HTT.[41] In addition to the decrease in acid functional groups, carbonates have been reported as a source of alkalinity for higher HTT biochars.[39] Here we obtained only a weak correlation between ash and pH (Table 2). Although we cannot exclude carbonate, the high correlation of pH with VM and corresponding weak correlation with ash content suggest that organic functional groups were the main determinant of the pH response with

dx.doi.org/10.1021/jf501139f | J. Agric. Food Chem. 2014, 62, 3791−3799

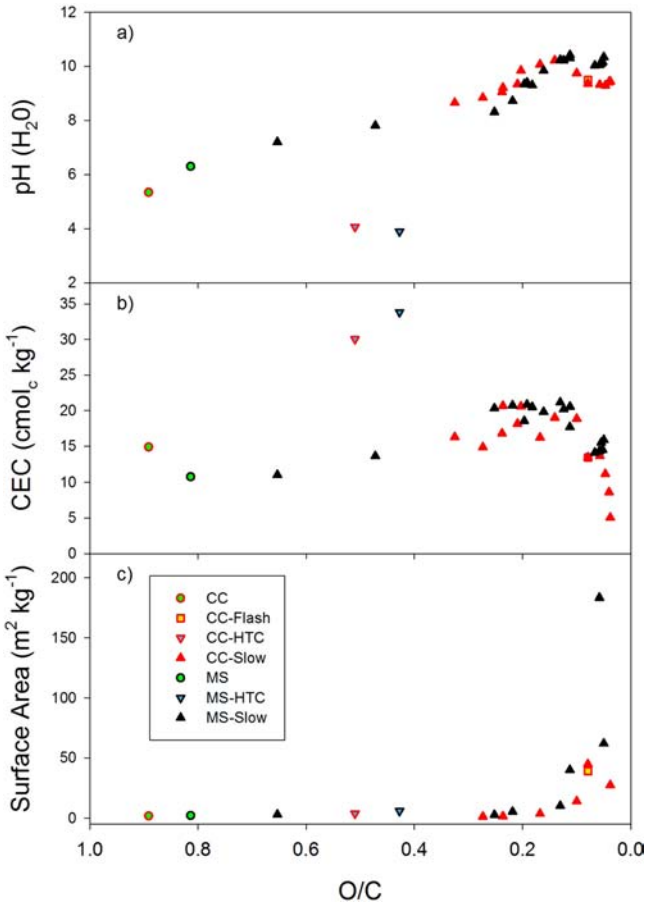

Figure 6. Surface properties (a) pH, (b) cation exchange capacity (CEC), and (c) surface area (SA) as a function of atomic ratio (O/C) for corncob (CC) and miscanthus (MS) and respective biochars produced through slow pyrolysis (Slow), flash carbonization (Flash), and hydrothermal carbonization (HTC). Analytical replicates, *n*, are (a) $n = 1$, (b) $n = 3$ for all with the exception of two points where $n = 1$ and 2, and (c) n = between 2 and 8.

HTT in slow pyrolysis biochars. Changes in pH as a function of the O/C ratio of slow pyrolysis biochars displayed a simple linear function, which did not fit the values of the hydrochars.

Surface Property: CEC. The CEC of both corncob and miscanthus slow pyrolysis biochars reached highest values at 350−475 °C (Figure 5b). The CEC of >450 °C biochars remained higher than that of feedstock for miscanthus while dropping substantially below for corncob. The lowest CEC was observed for the corncob sample pyrolyzed at 800 °C, suggesting that biochar CEC decreases with increasing HTT. Hydrochars displayed the highest CEC with an approximate doubling and tripling of CEC through HTC treatment of corncob and miscanthus, respectively. Flash carbonization, at an estimated 600 °C HTT, decreased the CEC of the feedstock only slightly, from 14.9 to 13.4 $cmol_c$ kg^{-1}.

Values of H/C and O/C atomic ratios in biochars are reported to be positively correlated to concentration in hydroxyl, carboxyl, and carbonyl groups and thereby to CEC.[25,42] Our HTC chars, however, had similar H/C and O/C values but higher CEC than low-HTT slow pyrolysis biochars. The higher CEC of our HTC chars was therefore not clearly reflected in these atomic ratios. The relationship we found between the atomic ratio O/C and CEC of both HTC and slow pyrolysis chars is presented in Figure 6b. Only at O/C ratios below 0.1 did we observe a marked reduction in CEC for corncob biochars. Simple correlations between CEC and other individual parameters were weak (Table 2), and the correlation between CEC and O/C excluding HTC was even weaker (R^2 = 0.012). We found that it is not possible to infer CEC on the basis of production parameters or chemical composition tested in this study and, therefore, could not confirm our initial hypothesis.

Changes in CEC have previously been explained by the presence of acid functional groups (AFGs).[43] Using various feedstocks, Wang et al.[44] found consistently lower CEC of biochars produced at 700 °C as compared to 500 °C and a correlating decrease in acid functional groups at the higher HTT. More specifically, Harvey and colleagues[22] observed an increase in −OH functional groups at or above 300 °C HTT and a loss of carboxylic groups at HTT above 500 °C. Although Mukherjee, Zimmerman, and Harris[40] found a correlation between VM and AFGs for 250, 400, and 650 °C chars, they also observed a lack of correlation between CEC and VM seen in our data set. They explained that not all AFGs can function as cation exchange sites and that HTT affects CEC more than it does AFGs. Especially because of the drastically different behavior of the hydrochars, our study suggests that the CEC response is difficult to predict over a wide range of temperatures because it is influenced by multiple factors with none clearly dominating.

Surface Property: SA. The surface area of biochar did not increase significantly until the raw feedstock was treated at HTT above 400 °C as shown in Figure 5c. The highest SA value of 183 m^2 g^{-1} was obtained through pyrolysis of miscanthus at 600 °C, this value being nearly 2 orders of magnitude higher than that of the feedstock. Biochar SA decreased at pyrolysis HTTs above 600 °C, corresponding to

CEC	−0.40*	−0.01	0.31	0.34*	0.34*	1		
SA	0.79***	0.58*	−0.83***	−0.81***	−0.82***	−0.12	1	
pH	0.71***	0.52***	−0.75***	−0.73***	−0.72***	0.04	0.61**	1

[a] *n* is the lowest number of samples of the two analyses: $n = 35$ for temp, $n = 18$ for SA, and $n = 36$ for all other analyses. ***, **, and * indicate respective significance levels of 0.001, 0.01, and 0.05.

O/C ratios below 0.2 (Figure 6c). HTC treatment did not increase SA, and this response is consistent with that of low-HTT slow pyrolysis biochars, both of which display high O/C ratios. The flash carbonization char exhibited a SA higher than most corncob chars in this study, and its SA appears to be similar to that of slow pyrolysis chars that underwent similar pyrolysis intensity.

Biochar SAs observed in this study are lower than values previously reported for corncob[45] and miscanthus[19] biochars of 300 and 400 $m^2 g^{-1}$. HTTs of 950 and 700 °C used to produce these respective biochars were also higher than those of the present study. Peak SA has been observed at HTTs between 650 and 850 °C for biochars from various feedstocks,[20] and HTTs >500 °C are needed to obtain significant increases in SA.[46] The increase in SA has been attributed mostly to the volatilization of organic compounds that otherwise clog pores,[42] similarly expressed in terms of loss of polar functional groups.[47] It has also been suggested that turbostratic structures harboring micropores develop through the growth of discontinuous graphene layers and that pore structures are destroyed at even higher temperatures when the turbostratic structures collapse into more organized graphite-like char.[48] Whereas HTT has been said to be the most important factor affecting SA,[49] the movement of volatiles away from char residues and the formation of cracks during pyrolysis are also influenced by carrier gas flow rate and other pyrolysis parameters involved with heat and mass transfer rates.[5,20] It is therefore not surprising that SA peaks and SA values at specific temperatures differ between studies, and although not all studies report a decrease in SA at higher HTT,[34,48] this effect might always be present if sufficiently high HTTs are applied. In our study, SA was poorly correlated to either VM content or O/C (Table 2), suggesting that the removal of VM from pores is not the only mechanism responsible for increased SA with increased HTT.

High SA, high CEC, and high pH are desirable properties of biochars for soil improvement. Here, as compared to feedstock, we increased SA by up to 2 orders of magnitude and pH by up to 4 units. In contrast, increases in CEC for slow pyrolysis remained modest irrespective of HTT. This finding suggests that designing a high-CEC biochar remains elusive, at least with the methods presently tested. This does not mean, however, that biochar transformations in soil cannot lead to improvement of soil CEC, as reported by Cheng et al.[43] Studies with wood-derived biochar suggested that concomitant increases in SA, CEC, and pH are obtained within a fairly narrow HTT range at around 400–450 °C.[18] Here, high SA was obtained only around 600 °C. This finding agrees with other grass-derived biochar studies which indicate that higher HTT is needed for obtaining high SA.[21] Proximate analysis and atomic ratios were poor predictors of SA and CEC, and our hypothesis that surface properties could be predicted from composition indicators was not confirmed. Specific production parameters appeared to have a significant impact on surface properties, indicating that specific analyses are necessary to identify and characterize high-SA biochars.

just like the high solids effect, higher concentrations of dissolved solids lead to a decrease in the product yield. We used a pure microcrystalline cellulose substrate, Avicel, for the hydrolysis experiments to rule out other potential substrate-related inhibiting factors (lignin, hemicellulose) and focus on the liquid phase. The hydrolysis was furthermore run at 5% water insoluble solids to observe the impact of soluble compounds and not of a high solids content. The findings generated from this study remind us that enzymatic hydrolysis remains a biological process; enzyme performance is very sensitive to small changes in the external environment, which have to be accounted for during process design. This study is particularly relevant in industrial settings where hydrolysis is to be performed at high dry matter contents as soluble product accumulation is high in the liquid phase during hydrolysis[11] under these circumstances.

MATERIALS AND METHODS

Enzymatic Hydrolysis of Avicel with Novozymes Cellic CTec2. Fifty milligrams of Avicel was weighed in 2 mL screw-cap tubes and filled with diluted enzyme solution for a total water-insoluble solids loading of 5% w/w. The commercial cellulolytic enzyme mixture Cellic CTec2 from Novozymes A/S, Bagsværd, Denmark, was used in all studies. The mixture had a protein content of 161 mg/g, a filter paper activity of 120 FPU/g, and a β-glucosidase activity of 2731 U/g. The protein content was measured using the ninhydrin assay with BSA as the protein standard,[19] the filter paper activity was determined according to the method of Ghose,[20] and the β-glucosidase activity was measured using 5 mM *p*-nitrophenyl-β-D-glucopyranoside (Sigma-Aldrich) as substrate.[21] The enzymatic loading for all studies was 13 mg enzyme protein/g dry matter (approximately 10 FPU/g Avicel).

The hydrolysis of Avicel was performed in pure water as well as 50 mM citrate buffer at pH 4.8. Additionally, five soluble monosaccharides (glucose, galactose, mannose, fructose, and xylose) at 50, 270, 540, and 810 mM were used (in separate experiments) to spike the samples prior to hydrolysis. For the first four monosaccharides, the molar concentrations are equivalent to approximately 10, 50, 100, and 150 g/L mass concentration, respectively, that is, in or above the range of soluble glucose found during lignocellulose hydrolysis at high dry matter for an industrial setup.[11] The samples were spiked with glucose to study its effect as a hydrolysis end product; that is, product inhibition was expected. Galactose and mannose were chosen as they are stereoisomers of glucose but are not end products of hydrolysis. Xylose was used as it is one of the major monosaccharides found in biomass, and fructose, even though not a major component in biomass, is a structural isomer of glucose and is the most water-soluble of all monosaccharides. Samples were prepared in triplicates, and the hydrolysis was carried out using an incubator at 50 °C with an orbital shaker set at 150 rpm. Hydrolysis was run for 96 h.

Control samples (without enzyme) were prepared and analyzed for their sugar content at 15 min and at the end of hydrolysis to verify whether the sugars had degraded over time. The hydrolyses were terminated by centrifuging each sample at 13200*g* and 5 °C for 10 min and filtering through a 0.45 μm syringe filter (Millipore, Bedford, MA, USA). Filtrates were stored at −20 °C for further HPLC quantification.

Enzymatic Hydrolysis of Cellobiose with Novozymes Cellic CTec2. Fifty milligrams of D-cellobiose (Sigma-Aldrich, USA) was weighed in 2 mL screw-cap tubes and filled with diluted enzyme solution in 50 mM acetate buffer at pH 4.8 for a total dry matter content of 5% w/w. The enzymatic loading was 13 mg/g of cellobiose. Furthermore, 50, 270, 540, or 810 mM glucose or galactose was added. Samples were prepared in triplicates and incubated at 50 °C with an orbital shaker set at 150 rpm for 1 h. The hydrolysis was terminated by centrifugation and filtration as described above, followed by HPLC quantification.

Enzymatic Hydrolysis of Avicel and Cellobiose with Novozymes Cellic CTec2. Avicel hydrolysis samples were prepared as described above (5% water insoluble solids, 13 mg/g enzyme loading) in 50 mM acetate buffer at pH 4.8 and additional 50, 270, 540, and 810 mM glucose or galactose. At the end of 96 h, 200 μL of hydrolysate was removed from the sample and 200 μL of cellobiose (125 g/L in 50 mM acetate buffer) was introduced. The hydrolysate aliquots were centrifuged, filtered, and frozen as described above, whereas the original samples with freshly added cellobiose were incubated for 1 h further before termination of the hydrolysis and processed as described above, followed by HPLC quantification.

HPLC Sugar Quantification. D-Cellobiose, D-glucose, D-mannose, D-fructose, D-galactose, and D-xylose (standards obtained from Sigma-Aldrich, USA) were quantified with UltiMate 3000 HPLC (Dionex, Germany) equipped with a refractive index detector (Shodex, Japan). The separation was performed in a Phenomenex Resex ROA column at 80 °C with 5 mM H_2SO_4 as eluent at a flow rate of 0.6 mL/min. As mannose and xylose, plus fructose and galactose, have the same retention time of 11 min, with this column, their concentrations were separately quantified using their respective calibration standard curves. The results were analyzed using Chromeleon software from Dionex.

LF-NMR T_2 Relaxation. NMR measurements were performed on a Bruker mq20 minispec with a 0.47 T permanent magnet (equivalent to 20 MHz proton resonance frequency). The internal magnet temperature was 40 °C. T_2 values of hydrolysis solutions (before Avicel and cellulase addition) were measured using the CPMG pulse sequence. Each sample was run with 32 scans and a 5 s recycle delay containing 8000 points and a pulse separation of 1.2 ms between each scan. The obtained relaxation curves were analyzed using the inverse Laplace transformation method CONTIN,[22] where all solutions gave a single T_2 relaxation peak. The T_2 reported are thus the peak maxima positions of this peak.

Protein Adsorption Measurements. Fifty milligrams of Avicel was weighed in 2 mL screw-cap tubes and filled with diluted Novozymes Cellic CTec2 (10 FPU) for a total water-insoluble solids content of 5% w/w. The liquid fraction contained 50, 270, 540, or 810 mM glucose, galactose, mannose, or xylose. The samples were prepared in triplicates and incubated at 50 °C for 30 min to allow the protein to bind to the substrate. Avicel blanks without enzyme were run in parallel. To determine the free protein content in solution, diluted enzyme solutions without Avicel were also run in parallel. After incubation, the samples were centrifuged at 850*g* and 5 °C for 2 min, from which 400 μL of the supernatant was sampled. Two microliters of this supernatant was then analyzed for protein content on a Thermo Scientific NanoDrop 2000 spectrophotometer (Wilmington, DE, USA) at 280 nm UV wavelength absorption.

RESULTS AND DISCUSSION

Hydrolysis of Avicel at High Monosaccharide Concentrations. Solutions containing high concentrations of monosaccharides can decrease the mobility of free water and inhibit hydrolysis. Previous studies have indicated that high concentrations of glucose have an inhibitory effect on cellulase activity.[12,23,24] End products of hydrolysis, glucose and cellobiose, inhibit cellulases based on the classical definition of end-product inhibition.[25] However, as Xiao et al.[12] and Roberts et al.[14] have shown, the presence of other monosaccharides that are not end products of hydrolysis also decrease glucose yields. Figure 1 shows the glucose yield after 96 h for samples that were spiked with different monosaccharides. As expected, the yield decreased for all sugars studied as the initial monosaccharide concentration increased. Sugars at low concentration (50 mM) slightly boosted glucose production (especially galactose), but at higher concentrations (>270 mM) the yield decreased considerably compared to pure water.

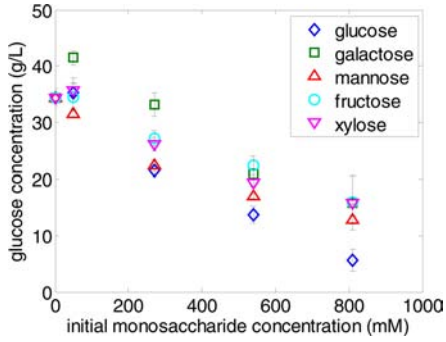

Figure 1. Hydrolysis of Avicel at 5% dry matter after 96 h spiked with glucose, xylose, galactose, fructose, or mannose from low to high concentrations of monosaccharides. Monosaccharides present at low concentrations seem to be beneficial to hydrolysis as there is a small boost in the product yield in some cases. At higher concentrations of sugars, however, they are detrimental to the cellulases as the yield keeps decreasing.

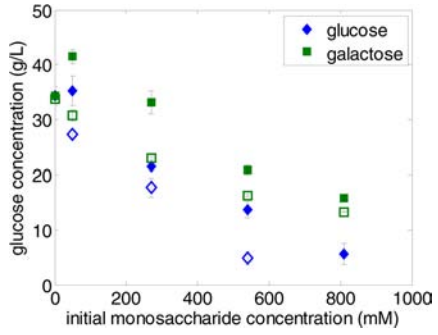

Figure 2. Glucose production after 96 h of Avicel hydrolysis in water (solid symbols) versus 50 mM acetate buffer (open symbols) with initial glucose or galactose spikes to determine additive effects between acetate and monosaccharide. Despite a more stable pH with a small added concentration of buffer, the additional presence of soluble salts at higher concentrations has a detrimental effect on the glucose yield.

Some of the sugar concentrations tested in Figure 1 are unrealistically high when compared to realistic biorefinery scenarios. For example, for hydrolysis of pretreated wheat straw at 30% dry matter content using Cellic CTec2, 95 g/L (approximately 527 mM) was the highest glucose concentration reported for a separate hydrolysis and fermentation process.[11] In a simultaneous hydrolysis and fermentation process, however, the glucose concentration will remain at <5 g/L (approximately 27 mM) as the yeast continuously ferments the glucose.[11]The study nevertheless illustrates the monosaccharide inhibition mechanisms at play.

The reasons for the increase in levels of hydrolysis at 50 mM monosaccharides are not fully understood, but it could be due to an improvement in protein stability.[16,26] At low concentrations of monosaccharide, these compounds are excluded from the protein hydration shell, but can play a role dictating the dynamic flexibility and biological activity of proteins,[27] protecting enzymes against inactivation, inhibition, and denaturation. With incremental additions of soluble compounds, these slowly will start interfering with the protein hydration shell in solution and eventually decrease enzyme performance.[27,28]

Whereas the pH fluctuations were around 4.80 ± 0.20 in all experiments shown in Figure 1, the cause of decreased glucose production had mainly to do with the presence of high sugar concentrations. As seen in Figure 2, performing the hydrolysis in 50 mM acetate buffer to stabilize the pH yields similar glucose concentrations as hydrolysis in pure water. With high concentrations of glucose or galactose in the liquid phase, however, the yield decreased compared to the hydrolysis performed in water.

Regardless of the monosaccharide structure, the general trend with increasing monosaccharides in the hydrolysate is that it is detrimental to the glucose yield of hydrolysis, which was shown by Roberts and co-workers[14] to be a mass transfer effect, the idea being that with the addition of glucose or mannose to the system, the water became more viscous, making it more difficult for the cellulases to diffuse into reaction sites. Although the mass transfer argument still holds, the experiments in this study show that the addition of the same amount of monosaccharides by weight (in the case of the C6 sugars) and by molar mass (all sugars including xylose) lower the cellulose conversion yield to different extents. At 810 mM sugars, for example, galactose and fructose give higher glucose hydrolysis yields than when having additional mannose in the hydrolysates. Thus, the saccharification rates must be limited by other factors aside from mass transfer and end-product (glucose) inhibition, which we suggest may have to do with the way each monosaccharide interacts with water. In this section, we look at three possibilities related to monosaccharide solutions: solubility, partial molar volume, and T_2 relaxation time.

Selig et al.[15] suggested that an increase in the amount of water-soluble species in the system can significantly inhibit cellulases. One can speculate that when soluble species form strong interactions with water to maintain their solubility, water has lower mobility and hydrolysis slows. In this case, it would mean that sugars which interact more with water in the solution should inhibit hydrolysis to a greater extent than those with weaker interactions. Therefore, we tested if the decrease in glucose yield could be linked to the water solubility of the monosaccharides, as more soluble monosaccharides would be expected to interact with fewer water molecules and hence produce higher glucose yields than the less soluble monosaccharides. Table 1 shows reported literature values[29,30] for the saturation point of sugars used in this study. Fructose is the most soluble sugar followed by xylose, glucose, mannose, and galactose. Whereas more soluble sugars interact with fewer water molecules in the system, our results show that despite galactose being the least soluble monosaccharide, it gave higher yields compared to the rest of the sugars. Therefore, the solubility of the monosaccharides cannot fully explain the recorded differences between hydrolysis yields.

Table 1. Sugar Saturation Points As Reported in the Literature

monosaccharide	solubility (g/L)
glucose	909
galactose	683
mannose	713
xylose	1250
fructose	3750

Another method of quantifying how much water monosaccharides take up in solution is the partial molar volume.[31] Experimental data from Shahidi et al.[32] showed larger partial molar volume for glucose followed by galactose, mannose,

dx.doi.org/10.1021/jf5012962 | J. Agric. Food Chem. 2014, 62, 3800−3805

fructose, and xylose at 25 °C. All of the C6 sugars studied contained the same number of hydroxyl groups capable of hydrogen bonding to the solvent, water. As xylose has one fewer hydroxyl group than the other sugars, it would be expected that its partial molar volume would be smaller. In this case, the strength of the solute−solvent interaction would be highly specific and dependent on the conformation of the monosaccharide in solution. Tait et al.[33] showed that monosaccharides with more equatorial groups tend to have higher partial molar volume, thus explaining why glucose (four equatorial OH groups in its open chain form) has a stronger interaction with water than mannose and galactose (both three equatorial OH groups) as it takes up more volume per mole in solution. Although this method sheds more light on the extent of inhibition caused by glucose despite its high solubility, it still does not fully explain why samples spiked with galactose consistently produced higher glucose yields despite the low solubility and high partial molar volume of galactose.

Lastly, we tested whether LF-NMR T_2 proton relaxation data could reveal differences in hydration behavior. Relaxation times depicted in Figure 3 show that galactose solutions have the highest free water mobilities (longest relaxation times) of all the monosaccharides, which correlate with the higher yields compared to the other sugars. The lower the relaxation time, the less overall free water in the system. At low concentrations of soluble molecules, the T_2 is very close to that of pure water (2696 ms). In fact, for samples with sugars that had higher T_2 than water, their cellulose conversions were actually higher than the hydrolysis performed in pure water. The trend with T_2, as discussed by Mora-Gutierrez and Baianu,[18] is that they decrease linearly as the concentration of dissolved solids increases because the average molecular distance between the solute becomes shorter.

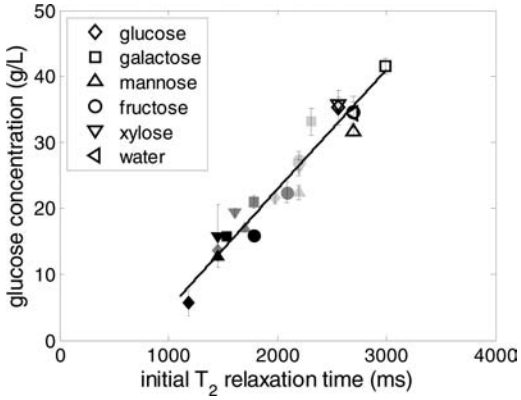

Figure 3. Initial T_2 of the liquid phase versus glucose production after 96 h of Avicel hydrolysis. Initial monosaccharide concentrations of 50 mM (open symbols), 270 mM (light gray symbols), 540 mM (dark gray symbols), or 810 mM (black symbols) show a linear correlation between the LF-NMR T_2 value and the concentration of glucose produced.

Correlations between the glucose hydrolysis yield and the T_2 of the hydrolysis liquid phase before saccharification are shown in Figure 3. At 50 mM dissolved solids, glucose yields are high regardless of which soluble molecules are present, and relaxation times have little significance over product yields. As the monosaccharide concentration increases, the relaxation time and glucose yield relationship becomes more linear, where solutions with lower free water availability produce lower glucose yields. Mora-Gutierrez and Baianu[18] give several explanations for the solution behavior under LF-NMR. Despite all C6 sugars possessing the same number of hydroxyl groups (potential solute hydration sites), their conformation in solution is different. As an example, glucose (aldo-sugar) mainly exists as two forms (α- and β-pyranose), whereas fructose (keto-sugar) has three (β-pyranose and α- and β-furanose). Therefore, the probability of forming H-bonds for fructose is lower as it is able to change to more conformations (i.e., water binding to glucose is stronger than to fructose). Our results indicate that the limitation of hydrolysis at higher monosaccharides content can be predicted by a LF-NMR T_2 measurement with a correlation coefficient of 0.94.

The way water is ordered around soluble compounds, based on solubility, partial molar volume, and water relaxation time data, has an effect on enzyme−substrate behavior and can be used to determine whether hydrolysis yields are affected. The degree of hydrolysis inhibition varied between different concentrations as well as chemical properties of the monosaccharides; for example, glucose and mannose are more inhibitory at high concentrations than galactose. Not only does the compound's solubility in water play a role but also does the overall water availability for hydrolysis.

Hydrolysis of Cellobiose at High Sugar Concentration. The saccharification results presented to this point have solely focused on glucose production. Cellobiose production has so far been neglected because, as shown in Table 2, in most cases it has been consumed by the β-glucosidases in the CTec2 mix. Its presence has been consistently below the detection limit for the HPLC (<0.5 g/L) except in the cases of glucose, galactose, and mannose at >270 mM. Despite the lack of a boiling step during the hydrolysis termination step, centrifuging at high speed followed by filtration and freezing yielded the same concentration of cellobiose and glucose when a boiling step was implemented (data not shown). Therefore, these results indicate that the cellulase components most inhibited by the high monosaccharide concentration are those acting on the insoluble substrate, that is, cellobiohydrolases and endoglucanases, and not the β-glucosidases. To investigate whether the cellobiose accumulation was an effect of low water availability or of end-product inhibition, two different experiments were performed: (1) hydrolysis of cellobiose for 1 h at 10 FPU with CTec2 (Figure 4a) and (2) hydrolysis of Avicel with additional cellobiose after 96 h (Figure 4b) to determine whether the cellobiose was still being hydrolyzed regardless of Avicel saccharification being at a standstill.

Table 2. Cellobiose Concentration (Grams per Liter) after 96 h of Hydrolysis of 50 g/L Avicel

	spike			
sugar	50 mM	270 mM	540 mM	810 mM
glucose	<0.5	0.91 ± 0.17	1.65 ± 0.18	3.63 ± 0.11
galactose	<0.5	0.95 ± 0.04	1.69 ± 0.03	2.23 ± 0.05
mannose	<0.5	1.18 ± 0.04	1.98 ± 0.05	2.60 ± 0.03
fructose	<0.5	<0.5	<0.5	<0.5
xylose	<0.5	<0.5	<0.5	<0.5

The data from Figure 4a show that the hydrolysis of cellobiose with CTec2 occurs regardless of the concentration of galactose but is inhibited in the presence of high concentrations of glucose. In other words, β-glucosidase is still active even at high concentrations of sugars, but undergoes end-product

dx.doi.org/10.1021/jf5012962 | J. Agric. Food Chem. 2014, 62, 3800−3805

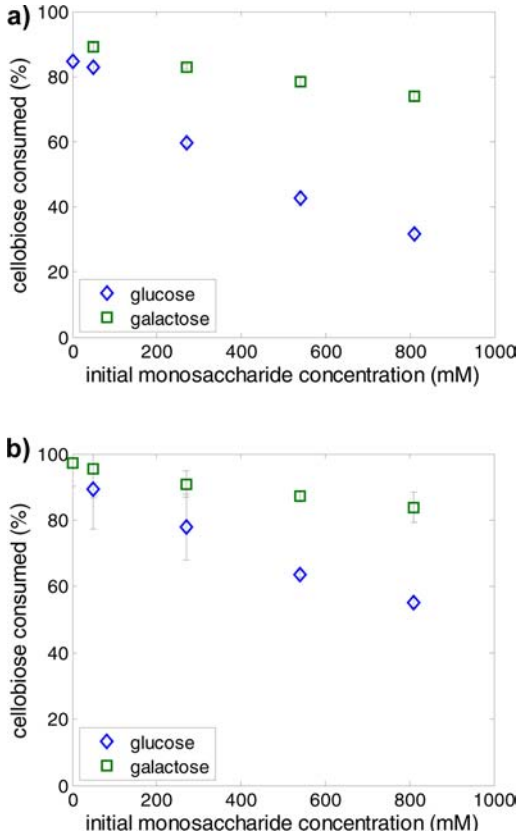

Figure 4. (a) Hydrolysis yield of 50 g/L cellobiose after incubation for 1 h with Cellic CTec2 in the presence of glucose or galactose. (b) Percentage of cellobiose consumed after the addition of 25 g/L cellobiose following Avicel hydrolysis after 96 h in the presence of glucose or galactose.

inhibition when the hydrolysates are spiked with glucose. In the case when cellobiose is added during conventional hydrolysis (Figure 4b), cellobiose is still being hydrolyzed by the β-glucosidases despite the cellobiohydrolases being inhibited in the presence of high concentrations of sugars, except glucose. Therefore, it is possible to predict hydrolysis yields based on LF-NMR T_2 measurements. However, end-product inhibition, observed only for the β-glucosidases, could not be correlated to relaxation data as it is an intrinsic property of the enzyme independent of the concentration of dissolved solids in solution.

Cellulase Adsorption at High Monosaccharide Concentration. One aspect of this study that has not been certain is whether a high concentration of sugars is preventing the cellulases from adsorbing to the substrate surface or depriving the cellulases from their biological activity. Previous work by Kumar and Wyman[34] showed that high concentrations of glucose prevented cellulase adsorption to the substrate; but it was not clear whether it was an inactivation of the catalytic domain and/or the binding domain or a combination of both. Furthermore, Kristensen et al.[9] showed that the increasing concentrations of glucose and cellobiose at high solids settings resulted in reduced enzyme adsorption, thereby potentially inhibiting the endoglucanase and cellobiohydrolase action. Binding kinetic studies are beyond the scope of this paper, but preliminary data (Figure 5) show that cellulase binding increases with increasing monosaccharide content (with the exception of glucose, for which binding to the substrate

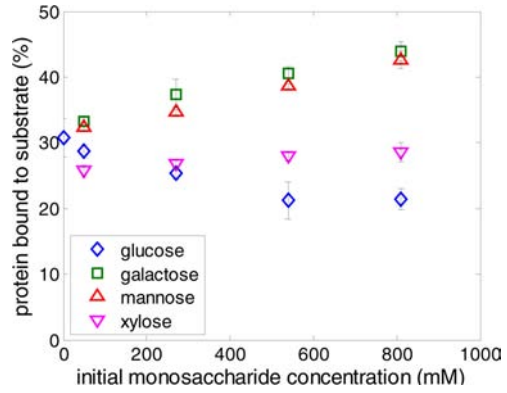

Figure 5. Percentage of protein bound to Avicel based on the protein adsorption at 280 nm of the hydrolysate liquid phase.

decreases). When high concentrations of glucose are present in the hydrolysates, both binding and activity of the cellulases are inhibited, whereas the other monosaccharides do not show a decrease in binding. These results imply that while binding is conducive to glucose production, a high binding affinity is no indication of high catalytic activity of the cellulases. There are two kinds of inhibition at play: the cellulase catalytic domain inhibition from the decrease in the free water availability for hydrolysis (all monosaccharides) and binding domain inhibition as well as end-product inhibition of the β-glucosidases (from glucose only). Monosaccharides in the hydrolysates could be seen as having a noncompetitive inhibition effect on the cellulases, where their presence disturbs the protein hydration shell and thereby affects cellulase performance.

The results obtained from this study are significant for hydrolysis carried out at high dry matter content, as there is limited free water availability and a high concentration of soluble end products. Similar to the case of the "high solids effect", where yields decrease as dry matter content increases, this study shows that yields also decrease as the dissolved solids content increases. In an industrial bioconversion setting, the additive effect of different sugars and soluble inhibitors can further decrease hydrolysis yields.

compare it with different extraction methods for extraction yield and efficiency, and to analyze the differences of chemical composition of extracts from raw and exploded samples.

MATERIALS AND METHODS

Pine (*Larix olgensis* Henry) Needles and Reagents. Pine (*Larix olgensis* Henry) needles collected from Jilin Province, China, were washed under tap water, drained and then, dried at 50 °C in a ventilated drying oven for 12 h to 5% moisture content. After drying, the sample was packed in paper bags and stored at room temperature (25 °C) in the dark. Standard of rutin (HPLC grade, ≥98%) was obtained from Sigma Chemical Company. Standards of quercetin, kaempferol, apigenin, and isorhamnetin (HPLC grade, ≥98%) were obtained from Shanghai Yuanye Biological Technology Co., Ltd.

HDSF Treatment. HDSF treatment was carried out in a batch apparatus (QBS-200B test-bed, Hebi right way bioenergy company, China) equipped with a 5 L reaction vessel. The diagram of the HDSF process is shown in Figure 1. The whole structure (Figure 1A) in catapult explosion mode is composed of a cylinder and a piston. In the steam pressurization phase, the two parts are coupled (Figure 1B). During the explosion, the piston, driven by three pneumatic linear actuators, bursts out of the cylinder, a process that is equivalent to a vessel suddenly fracturing into two halves (Figure 1C).[18] About 300 g of pine needles, soaked by water for 0.5−3.0 h, were put into the reactor, followed by HDSF treatment at a steam pressure of 0.5−2.0 MPa for 20−120 s, and finally termination by explosive decompression. The treated pine needles were collected and dried in a ventilated drying oven for 12 h at 50 °C. The dried sample contained 2.5% moisture content.

Flavonoids Extraction. The treated pine needles were extracted with 60% (v/v) ethanol solution at a solvent-to-solid ratio of 50 (mL/g) at 70 °C for 1.0 h. The solution was filtered through a 0.22 μm membrane filter. In the presence of sodium nitrite, flavonoids react with aluminum and form a chelating substance. The reaction product exhibits red-orange color by addition of sodium hydroxide solution. Therefore, the amount of total flavonoids was determined using a spectrophotometer.

Determination of Total Flavonoids. The determination of total flavonoids content was conducted using the method of Jia et al. with modification.[21] Extract solutions (1 mL) were added to a test tube containing 2 mL of 60% (v/v) ethanol solution. Sodium nitrite solution (5%, 0.5 mL) was added to the mixture and stood for 6 min, after which 0.5 mL of 10% aluminum chloride was added. After another 6 min, 1 mL of 60% ethanol solution was added and mixed, followed by 4 mL of 10% sodium hydroxide. The absorbance of the mixture at 510 nm was measured after 15 min in comparison to a standard curve that was prepared using rutin. The flavonoids contents were expressed as rutin equivalents mg/g dry weight.

Morphological Characterization. Scanning electron microscopy (SEM) analysis was performed with a Quanta 200 microscope (PHILI PS, Netherlands).

Kinetics of Flavonoids Extraction. A 1 g amount of sample and 50 mL of 60% (v/v) ethanol solution were used in all extraction experiments. For raw and steam-exploded pine needles, the samples were placed into a flask and heated at 70 °C in a water bath for 280 and 50 min, respectively. Ultrasound-assisted extraction was carried out using an ultrasonic bath of 40 kHz, a big and commonly used frequency in extraction. The sample was subjected to ultrasound treatment at 70 °C for 250 min. Microwave-assisted extraction was performed using a household microwave oven at 500 W. A 100 mL flask was exposed to microwave irradiation (irradiation cycle: 30 s of power-on, followed by 60 s of power-off) for 50 min. The extracts obtained from the aforementioned methods were filtered through a

dx.doi.org/10.1021/jf405412r | J. Agric. Food Chem. 2014, 62, 3806−3812

0.22 μm membrane filter, after which the amount of total flavonoids was determined using a spectrophotometer.

Sample Preparation for HPLC-DAD-ESI-MS Analysis. Raw and exploded pine needle samples (4.0 g) were extracted for 60 min with 160 mL of 60% (v/v) ethanol solution at 70 °C. The extracts were then filtered and centrifuged at 10 000 rpm for 20 min. The supernatant was concentrated to remove ethanol under reduced pressure and suspended in 25 mL of water. The resulting solution was extracted by 25 mL of petroleum ether and 25 mL of ethyl acetate consecutively and repeated three times. The ethyl acetate extract was dried and dissolved in 15 mL of 60% (v/v) ethanol solution. The solution was filtered through a 0.22 mm micropore membrane (Nylon-66; JinTeng, Tianjin of China) prior to LC/MS analysis. A 10 μL aliquot was introduced into the LC/MS instrument for analysis.

Instrumentation and Chromatographic Condition. The HPLC analyses were performed on a Hitachi series L-2000 HPLC instrument (Hitachi, Japan) equipped with a quaternary solvent delivery system, a diode-array detector, and a column compartment. Samples were separated on an Agilent Zorbax Sb-C18 column (5 μm, 4.6 mm × 250 mm). The mobile phase consisted of acetonitrile (A) and water containing 0.1% (v/v) formic acid (B). A gradient elution program was used as follows: 0−5 min, 15−20% A; 5−10 min, 20% A; 10−15 min, 20−15% A; 15−30 min, 15−25% A; 30−35 min, 25−30% A; 35−50 min, 30−35% A; 50−60 min, 35−40% A; 60−70 min, 40−100% A. The mobile phase flow rate was 1.0 mL/min. Spectral data were recorded using a diode-array detector over the wavelength range 200−600 nm, and the chromatogram was extracted at 370 nm. The column temperature was set at 30 °C.

The mass spectra were acquired using a Waters ZMD 4000 series SL ion trap mass spectrometer equipped with electrospray ionization (ESI) interface. Nitrogen (N_2) was used as the sheath and auxiliary gas, and helium (He) was used as the collision gas. The ESI-MS spectra were acquired in the positive ion mode recorded over a mass range of m/z 100−1500. Capillary voltage was 3.5 kV. The desolvent gas temperature was set at 350 °C with a gas flow rate of 500 L/h, and the nebulizing pressure was 35 psi.

Statistical Analysis. The data were presented as mean ± standard deviation (SD). Differences between the means of the individual groups were analyzed using the analysis of variance (ANOVA) procedure of Statistical Analysis System, SAS 16.0 (SAS Institute, Cary, NC, USA) with Duncan's multiple range tests. The significance of differences was defined at the $p < 0.05$ level.

RESULTS AND DISCUSSION

Effect of Steam Explosion on Extraction of Total Flavonoids. The effect of steam pressure on the yield of flavonoids extracted from pine needles is shown in Figure 2. The results show that the yield of extractable flavonoids from pine needles by HDSF pretreatment increased significantly. At a residence time of 60 s and an immersing time of 2.0 h, the yield of flavonoids increased with the increase of steam pressure from 0.5 to 1.5 MPa. However, there was no significant change at a steam pressure range 1.5−2.0 MPa. It is worth noting that the yield of flavonoids extracted from pine needles increased from 20.0 rutin equivalents mg/g before HDSF treatment to 50.8 rutin equivalents mg/g after 1.5 MPa HDSF treatment. This result is very important and promising for the employment of HDSF as an effective method for extraction of flavonoids from plant materials. Another noteworthy phenomenon is that, at higher pressures, which means at higher temperatures, the yield of flavonoids did not decrease significantly. This indicates that the flavonoids in pine needles could maintain stability at high temperatures of steam explosion for 60 s. This result is consistent with previous studies,[22] which reported that the flavonoids in sumac fruits could endure the high temperature of steam explosion for certain duration.

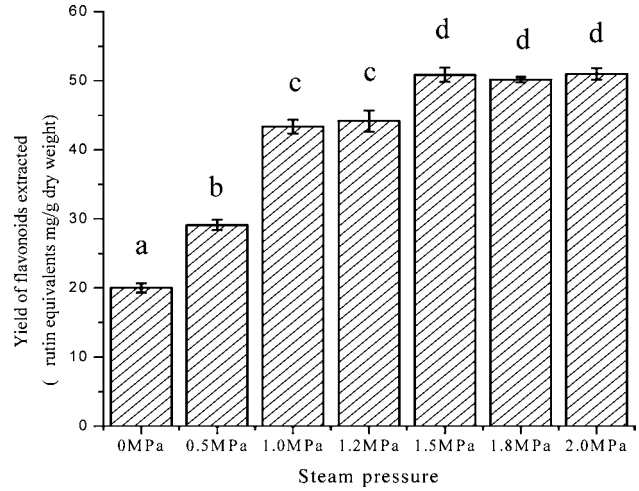

Figure 2. Effect of steam pressure on the yield of flavonoids extracted from pine needles at constant residence time (60 s) and soaking time (2.0 h). Extraction conditions: 60% ethanol, 50 mL/g, 70 °C, 1 h. Means with the different letters (a−d) are significantly different ($p < 0.05$) by Duncan's multiple range test.

As illustrated in Figure 3, residence time does not have a significant effect on the yield of flavonoids extracted from pine needles. This indicates that the most prominent factor in the action of HDSF is the kinetic energy produced by steam explosion rather than thermochemical reaction, which was also confirmed by Yu et al.[19] At residence times of 20, 60, and 80 s, the yield of flavonoids extracted increased overall with an increase in steaming time. The yield of flavonoids extracted reached its highest value of 48.8 rutin equivalents mg/g (dry pine needles) at a residence time of 80 s and a soaking time of 2.0 h. However, beyond 80 s, the yield decreased. HDSF is based on pressurization and forcing steam into fibrous tissues and cells of biomass, followed by rapidly releasing the pressure in an explosive decompression event.[18] The release of pressurized steam in an extremely short time could provide enough force to disrupt and unfold the compact structure of

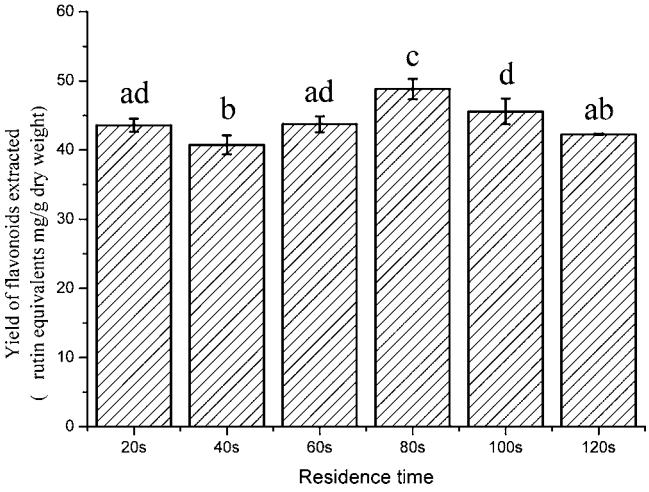

Figure 3. Effect of residence time on yield of flavonoids extracted from pine needles at constant steam pressure (1.2 MPa) and soaking time (2.0 h). Extraction conditions: 60% ethanol, 50 mL/g, 70 °C, 1 h. Means with the different letters (a−d) are significantly different ($p < 0.05$) by Duncan's multiple range test.

pine needles. Residence time (steaming time) affects the hydrolysis reaction. At a short residence time, the hydrolysis reaction did not progress enough, while at a long residence time, degraded compounds such as flavonoids were repolymerized into insoluble materials.

The effect of soaking times of 0, 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 h on the yield of extracted flavonoids was also studied. It can be seen in Figure 4 that the water content of the sample increased

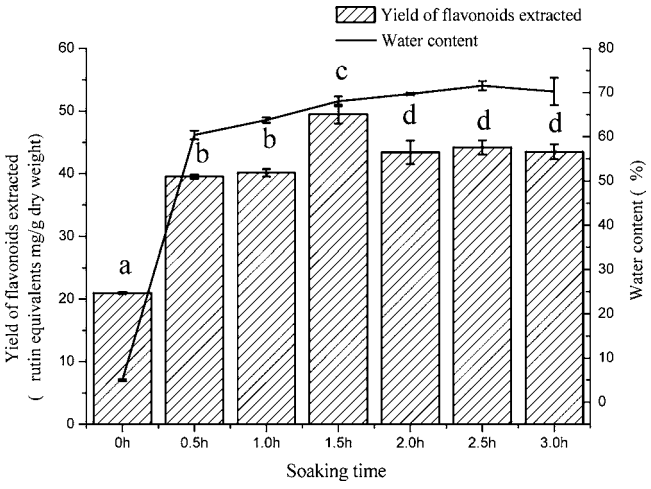

Figure 4. Effect of soaking time on yield of flavonoids extracted from pine needles at constant steam pressure (1.2 MPa) and residence time (60 s). Extraction conditions: 60% ethanol, 50 mL/g, 70 °C, 1 h. Means with the different letters (a–d) are significantly different ($p < 0.05$) by Duncan's multiple range test.

with the increase of soaking time in the first 1.5 h and then kept unchanged after 2.0 h. The yield of flavonoids reaches the maximum (49.5 rutin equivalents mg/g) at a water content of 64%. Soaking treatment followed by HDSF could greatly increase the yield of extracted flavonoids. Increased water content after soaking treatment made the hydrolysis reaction easier. In addition, Grous et al.[23] reported that steam explosion pretreatment significantly increased pore volume of the sample while oven-drying showed a reduction in available pore volume. Many stomata exist on the surface of pine needles, which results in limited pore volume in the dry state. Soaking treatment could increase the pore volume.

Researchers suggest that steam-explosion treatment efficiency is a result of several factors, including steam pressure, residence time, particle size, and moisture content.[24] High-pressure steams with a powerful seepage force will penetrate an organic tissue structure entirely. When a rapid enough decompression HDSF is triggered, most of the steam in the biomass will quickly expand and break free of the structure. This leads to disruption of the biomass internal structure by a mechanical shearing force. Residence time affects penetration and consequently softening degree of raw materials, thus affecting the disruption of internal structure of the biomass. Soaking treatment could increase the water content of pine needles. Overall, on the basis of the data in Figures 2–4, it shows that, in a certain range of steam pressure, residence time, and soaking time, the extraction yield of flavonoids from pine needles increases significantly by HDSF pretreatment.

Morphological Changes of Pine Needles Treated by HDSF. The effect of HDSF treatment on the morphology of pine needles is illustrated in Figure 5. SEM images of untreated (Figure 5A) and treated pine needles (Figure 5B, C) showed obvious morphological changes induced by HDSF treatment. Untreated pine needles still have structural integrity and a densely structured surface. This structure is not conducive for solvent extraction. It is interesting to note from Figure 5B that there are many pores on the surface of the pine needles, indicating the action of HDSF. When treated at 1.0 MPa, the pine needle structure was destroyed, and it changed into an amorphous state. HDSF treatment caused breakage and destruction of cell walls, leading to the formation of large cavities and intercellular spaces. When steam pressure was increased to 1.5 MPa, the pine needle structure was completely destroyed and changed from needlelike to particles. Micropores and smaller particles due to HDSF treatment were conducive for flavonoid extraction by increasing the specific surface area of the material. During the HDSF process, steam with a powerful seepage force penetrates the interior cells of pine needles. Upon an explosive decompression (within 0.0875 s), most of the steam in the pine needles will quickly expand and disrupt the internal structure, finally forming pores on the surface when the steam rushes out.

Comparisons of Different Extraction Methods for Extraction Yield and Extraction Efficiency of Flavonoids. The effect of extraction time on the yield of flavonoids extracted by four methods, namely, HDSF pretreatment, microwave-assisted, ultrasound-assisted, and solvent extraction is shown in Figure 6. For solvent extraction, the yield of flavonoids extracted reached a maximum of 22.7 rutin equivalents mg/g dry pine needles after 190 min. When the solvent extraction time was further increased, the yield did not increase. The yield of flavonoids extracted by ultrasound-assisted method was insignificantly higher (by 5.0 rutin equivalents mg/g) than that of solvent extraction, for the same extraction time. Ultrasound- assisted extraction took 220 min to reach a maximum yield of flavonoids (28.7 rutin equivalents mg/g). However, when the treatment time was extended, the yield decreased slightly. For microwave-assisted extraction, the yield of flavonoids increased rapidly with an increase in treatment time. It took 35 min to reach a maximum yield of 29.8 rutin equivalents mg/g flavonoids. Extraction by HDSF pretreatment resulted in huge benefits over the other three extraction methods. The yield of flavonoids extracted after explosion was greatly increased in comparison with the other three methods, for the same extraction time. In addition, extraction efficiency after explosion was higher than that of the other three methods. It took only 30 min to reach a maximum yield of 47.0 rutin equivalents mg/g. Some morphological changes, including production of smaller particles and expansion of micropores on pine needles, took place during HDSF treatment at 1.5 MPa. In addition, thick and dense wax layers were effectively removed by high-temperature steam in the HDSF pretreatment. Mass-transfer through the solid matrix is usually the rate-controlling step in food extractions.[22] Therefore, the extraction yield of flavonoids and the efficiency were greatly improved due to smaller particles and micropores caused by HDSF treatment as well as the removal of wax layers. The change in structure increased the specific surface area of pine needles, thereby increasing solvent accessibility.

Analysis by HPLC-DAD-ESI-MS. In order to investigate the effect of HDSF pretreatment on flavonoids from pine needles, the profile of raw extract and exploded pine needles was analyzed by high-performance liquid chromatography combined with photodiode-array detection and electrospray

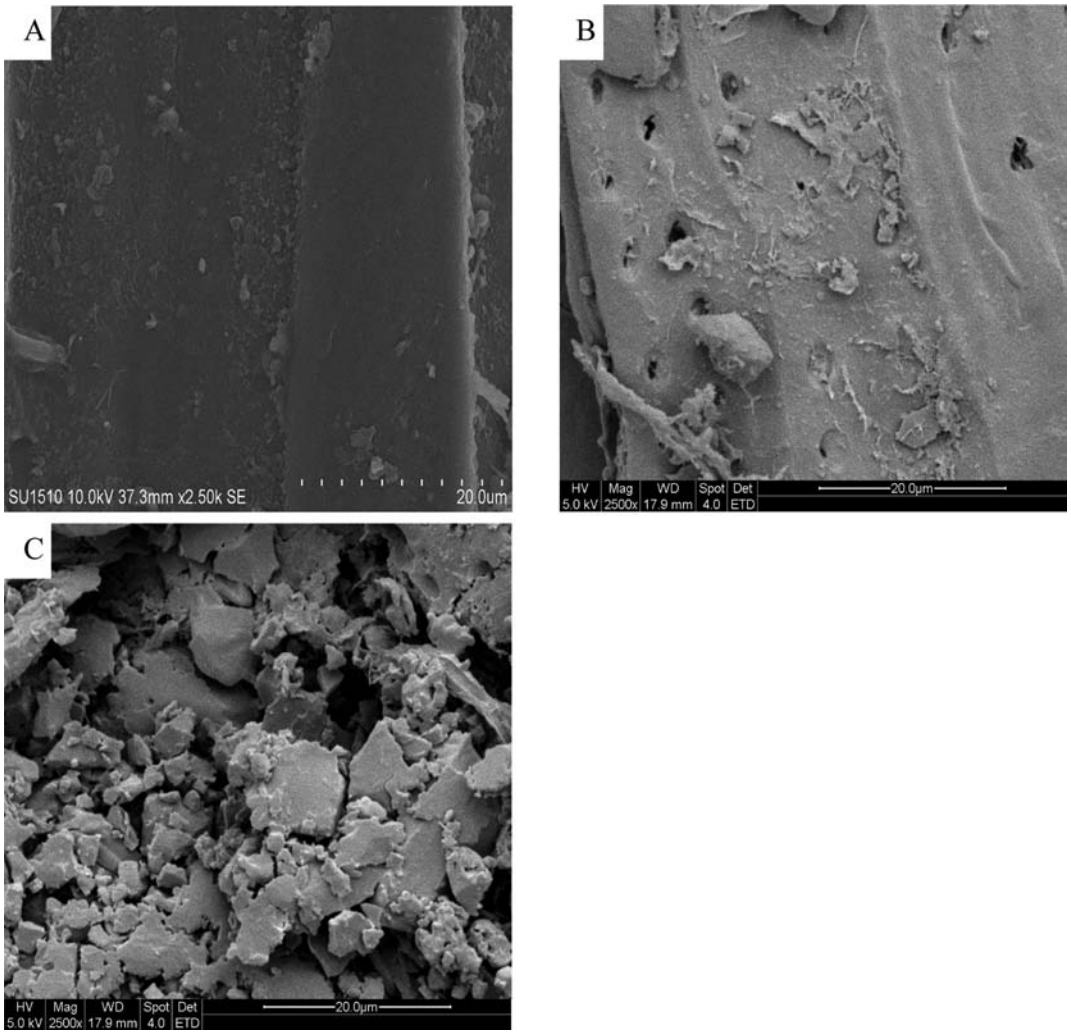

Figure 5. Scanning electron microcopy images of pine needles: (A) untreated pine needles (×2500), (B) treated pine needles (×2500) by HDSF at 1.0 MPa, and (C) treated pine needles (×2500) by HDSF at 1.5 MPa.

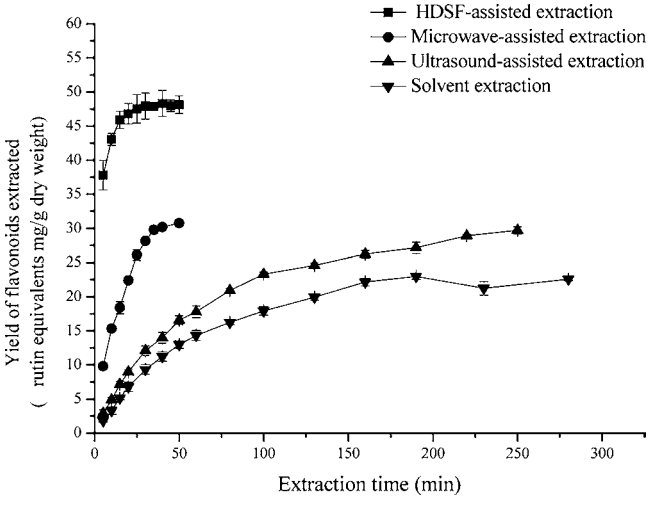

Figure 6. Effect of extraction time on yield of flavonoids extracted from pine needles.

ionization mass spectrometry (HPLC-DAD-ESI-MS). Figure 7 showed several peaks, and they were identified (Table 1). Among 11 major flavonoids, only 4 could be confirmed with authentic standards (peaks 8−11). Six were tentatively identified based on UV and MS spectral characteristics (peaks 1−3 and 5−7). Although the identity of peak 4 remained inconclusive, it was still identified as a kaempferol derivative. As shown in Figure 7, no significant differences between extracts from untreated and treated pine needles were observed at the qualitative level. However, the treated sample presented a much higher quantitative aglycone profile and lower glycosides profile in comparison with the untreated sample. The aglycones (peaks 8−11) extracted from treated pine needles were 3.17 times higher than that of untreated pine needles, while glycosides (peaks 1−7) were lower by 57% (in HPLC-DAD individuals' sum). This result indicates that the extract of treated pine needles by HDSF contain a higher proportion of flavonoid aglycone.

Flavonoids are polyphenolic compounds that can be divided into free, soluble esters or conjugates and insoluble bound forms.[25] Steam explosion could result in an increase in carboxyl and phenolic hydroxyl groups and a significant decrease in β-O-4 structures.[24] In addition, Gong et al.[25] reported that extraction yields of free phenolic acids and soluble conjugates increased sharply after steam explosion due to the hydrolysis of glycosidic linkages in hemicelluloses or celluloses and the β-O-4 ether bonds in lignin, as well as the ester and/or ether bonds between phenolic compounds, lignin, and carbohydrate. Thus,

HDSF pretreatment can successfully release insoluble bound flavonoids from pine needles. Also, it is well known that organic acids are formed under the combined effects of steam and high temperature during the steam explosion process. Steam explosion is an autohydrolytic process.[26] Therefore, soluble conjugates (flavonoid glycosides) could be hydrolyzed and converted into free aglycone under the effect of organic acids.

The absorption of flavonoids is the prerequisite for exerting diverse biological effects in the body. Although some flavonoid glycosides can be absorbed in the small intestines, it appears that, as a general rule, flavonoid glycosides are cleaved, either in the lumen or in the cells of the gut, before absorption.[27−29] Flavonoid aglycones are easier to be absorbed than glycoside due to improved solubility and smaller molecular weight. After HDSF treatment, the pine needle extract has a higher proportion of flavonoid aglycone. Moreover, the health food industry is now providing increasing numbers flavonoid aglycones as food supplements.[30] Therefore, HDSF is a practical pretreatment for extraction of flavonoids and conversion in healthy food and pharmaceutical industries.

In conclusion, the present study proposed an innovative pretreatment to assist the extraction of flavonoid compounds from pine (*Larix olgensis* Henry) needles by HDSF. The yield of total flavonoids extracted was 2.54-fold as that of the untreated sample after HDSF pretreated for 60 s at 1.5 MPa. This method led to higher extraction yield and extraction efficiency of flavonoids compared with microwave-assisted and ultrasound-assisted extraction. HDSF pretreatment caused the formation of large micropores on the pine needles and production of particles, as well as the hydrolysis of glycosides. The extract presented a much higher quantitative aglycone profile after HDSF pretreatment. HDSF was found to be effective for the extraction and conversion of flavonoids from pine (*Larix olgensis* Henry) needles.

utilized by several researchers to optimize various food processing methods such as fermentation,[26] milling,[27] extraction from vegetable matrices[28] and virgin olive oil mechanical extraction;[19] RSM has thus become one of the most popular optimization techniques in the field of food science.[29,30]

The objectives of this study were to systematically investigate the influence of temperature and oxygen concentration on the olive pastes belonging to four of the most important Italian olive cultivars during malaxation and to explore the best operative conditions for obtaining high quality EVOOs.

MATERIALS AND METHODS

Olives. In this research, olive drupes of Coratina, Peranzana, Itrana, and Ogliarola cultivars (cvs) were tested. Coratina and Ogliarola olive trees on a side and Peranzana by the other were planted in the Apulia Region, in the Province of Bari, and in the Province of Foggia, respectively. Instead, the growing area of Itrana olive trees was the Province of Latina (Lazio). All the cvs were harvested on the period October–November 2011 and the ripening stage of these olives, evaluated on the basis of the pigmentation index according to Pannelli et al.,[31] was 0.95. The olives have been processed within 48 h after harvesting.

Reference Compounds. The (*p*-hydroxyphenyl)ethanol (*p*-HPEA) was purchased from Fluka (Milan, Italy), while the 3,4-(dihydroxyphenyl)ethanol (3,4-DHPEA), produced by the Cayman Chemical Co. (Ann Arbor, MI, USA), was obtained from Cabru s.a.s. (Arcore, Milan, Italy). The dialdehydic forms of elenolic acid linked to 3,4-DHPEA and *p*-HPEA (3,4-DHPEA-EDA and *p*-HPEA-EDA, respectively), the isomer of oleuropein aglycon (3,4-DHPEA-EA), (+)-1-acetoxypinoresinol, and (+)-pinoresinol were extracted from virgin olive oil according to the method developed by Montedoro et al.[32] In this method the phenolic compounds were extracted from the extra virgin olive oil using a mixture of methanol/water (80:20 (v/v)); then, after solvent evaporation and a partial purification of the crude extract obtained from EVOO, the phenols were separated by semipreparative high performance liquid chromatography (HPLC) analysis. The HPLC separation was conducted using a Whatman Partisil 10 ODS-2 column (500 mm × 9.4 mm i.d.). The mobile phase was 0.2% acetic acid (pH 3.1) in water (A) and methanol (B), and the elution was performed at a flow rate of 6.5 mL/min. The total running time was 150 min, and the gradient changed as follows: the starting composition was 95% A/5% B, then the percentage of B was increased to 74% A/26% B in 2.5 min, 64% A/36% B in 4.5 min, and this percentage was maintained for 33 min, 61% A/39% B in 35 min, 0% A/100% B in 35 min, and this percentage was maintained for 20 min, returning at the end to the initial conditions (95% A/5% B) in 20 min. The phenols were detected using a diode array detector (DAD) at a wavelength of 278 nm.

The purity of these substances was tested by analytical HPLC,[33] and their chemical structures were verified by NMR using the same operating conditions reported in previous papers by recording ^{1}H and ^{13}C spectra.[32,34] Pure analytical standards of volatile compounds Fluka and Aldrich were purchased from Sigma-Aldrich (Milan, Italy).

Experimental Procedure. *Virgin Olive Oil Mechanical Extraction Process.* The experiments were conducted with an industrial plant using a TEM 200 system (Toscana Enologica Mori, Tavarnelle Val di Pesa, Florence, Italy) composed of a hammer mill, a malaxer with a gas controller system, and a working capacity of 200 kg of olives and a two-phase decanter; for the separation of olive oil, a UVPX 305 AGT 14 centrifuge (Alfa Laval S.p.A., Tavarnelle Val di Pesa, Florence, Italy) was used. The extraction was performed on a sample of 150 kg of olives, and malaxation was carried out for 40 min, a period commonly used in industrial plants, using a top-covered malaxing machine equipped with an O_2 valve and a Mettler-Toledo O_2 4100 sensor (Mettler-Toledo, Novate Milanese, Milan, Italy) for oxygen measurement.[35] The trials were performed at malaxing temperatures (ranging from 20 to 40 °C) and initial oxygen partial pressures in the headspace of the malaxer chamber (ranging from 21.3 to 101.3 kPa) according to a central composite circumscribed design (CCC; see Table 1 for the trial temperatures and oxygen partial pressures). The EVOO samples were filtered and stored in the dark at 13 °C until analyzed.

Table 1. Temperature and Oxygen Content According to a Central Composite Circumscribed Design Used in the Optimization Study of the Malaxation Process

trial	temp (°C)	oxygen content (kPa)

10	36	85.4
11	40	61.3

Analytical Methods. *Extraction and HPLC Analysis of the Phenolic Compounds of Virgin Olive Oils.* The extraction of EVOO phenolic compounds was performed in accordance with Montedoro et al.[36] The HPLC analyses of the phenolic extracts were conducted according to Selvaggini et al.[33] with a reversed-phase column using an Agilent Technologies system Model 1100 (Agilent Technologies, Santa Clara, CA, USA) which was composed of a vacuum degasser, a quaternary pump, an autosampler, a thermostated column compartment, a DAD, and a fluorescence detector (FLD). The C_{18} column used in this study was a Spherisorb ODS-1 250 mm × 4.6 mm with a particle size of 5 μm (Waters, Milford, MA, USA); the injected sample volume was 20 μL. The mobile phase was composed of 0.2% acetic acid (pH 3.1) in water (solvent A)/methanol (solvent B) at a flow rate of 1 mL/min and the gradient changed as follows: 95% A/5% B for 2 min, 75% A/25% B in 8 min, 60% A/40% B in 10 min, 50% A/50% B in 16 min, and 0% A/100% B in 14 min; this composition was maintained for 10 min and then returned to the initial conditions and equilibration in 13 min; the total running time was 73 min. Lignans were detected by using the FLD operated at an excitation wavelength of 280 nm and an emission of 339 nm; for the detection of all the other phenolic compounds a DAD was employed with the wavelength set at 278 nm.

Volatile Compounds Analysis. The evaluation and quantification of volatile compounds in EVOOs were done by headspace–solid phase microextraction (HS-SPME) followed by gas chromatography–mass spectrometry analysis (HS-SPME-GC/MS) according to Servili et al.[37] with few modifications.

For sampling the headspace volatile compounds, SPME was applied as follows: 3 g of EVOO were placed in a 10 mL vial and thermostated at 35 °C, then the SPME fiber (a 50/30 μm divinylbenzene/Carboxen/poly(dimethylsiloxane) (DVB/CAR/PDMS) with a length of 1 cm; StableFlex, Supelco, Inc., Bellefonte, PA, USA) was exposed to the vapor phase for 30 min to sample the volatile compounds. Afterward, the fiber was inserted into the GC injector set in splitless mode, using a splitless inlet liner of 0.75 mm i.d. for thermal desorption, where it was held for 10 min. All of the SPME operations were automated by using a Varian CP 8410 AutoInjector (Varian, Walnut Creek, CA, USA).

GC/MS Analysis. The analysis of the volatile compound sampled with SPME was conducted as reported in Servili et al.[37] with few modifications. A Varian 4000 GC/MS equipped with a 1079 universal capillary injector (Varian) was used. An Agilent J&W fused-silica capillary column was employed (DB-WAXetr, 50 m, 0.32 mm i.d., 1 μm film thickness; Agilent). The column was operated with helium at a constant flow rate of 1.7 mL/min maintained with an electronic flow controller (EFC). The GC oven heating program started at 35 °C. This temperature was maintained for 8 min, then increased to 45 °C at

a rate of 1.5 °C/min, increased to 150 °C at a rate of 3 °C/min, increased to 180 °C at a rate of 4 °C/min, and finally increased to 210 °C at a rate of 3.6 °C/min; this temperature was then held for 14.5 min. The total time of analysis was 80 min. The injector temperature was maintained at 250 °C; the temperature of the transfer line was fixed at 170 °C. The mass spectrometer was operated in the electron ionization (EI) mode at an ionization energy of 70 eV, with scanning in the mass range of m/z 25−350 amu at a scan rate of 0.79 s/scan and a trap set point temperature of 150 °C. The GC-MS was operated with the Varian MS Workstation Software, Version 6.6 (Varian). The volatile compounds were identified by comparison of their mass spectra and retention times with those of authentic reference compounds. Integration of all the chromatographic peaks was performed by choosing the three masses with the highest intensities among those specific for each compound, to selectively discriminate them from their nearest neighbors. The volatile compound results were calculated on the basis of the calibration curves for each compound and expressed in micrograms per kilogram of oil.[37]

Statistical Analysis. *Descriptive Statistics.* To show the variability of data were employed box and whisker plots, in which the lower and the upper edges of the box indicate the 25th and the 75th percentile, respectively; the line within the box shows the median while the whiskers designate the 10th and 90th percentiles. In addition, on the graphs, are reported two points representing the fifth and 95th percentiles. These plots were elaborated using the statistical software SigmaPlot version 12.3 (Systat Software, Inc., San Jose, CA, USA).

Principal Components Analysis. Principal component analysis (PCA) models were built to analyze the influence of processing parameters on the analytical data of EVOO. The SIMCA 13.0 chemometric package was used (Umetrics AB, Umeå, Sweden).

To perform multivariate statistical analysis, the analytical data were put in a matrix with the samples (n objects) in rows and the analytical parameters (k variables) in columns. The raw data were normalized, with the subtraction of the mean, and autoscaled, dividing these results by the standard deviation. The number of significant components was found by applying cross-validation. The results of PCA modeling are presented in graphical form.[38,39] First a PCA model with all data was built; then four SIMCA models, one for each cultivar studied in this work, were made for selecting a small number of variables (volatile and phenolic compounds), from among those with the highest absolute values of loadings, successively employed in the optimization study. When the distributions of these data were not normal (or Gaussian), the data were log-transformed.

Optimization by Response Surface Modeling. Response surface model (RSM) was obtained with the chemometric package MODDE. 9.1 (Umetrics AB).

To optimize the malaxation parameters in the mechanical extraction process, the original data (Y), phenols and volatile compounds chosen by previous PCA, were transformed into desirability functions (d_i), successfully used in RSM-based optimization when several response variables (several Y variables) are considered, so reducing the problem to the optimization of only one Y variable. d_i are dimensionless values, calculated using a linear transformation according to Derringer and Suich[40] with a small modification, so as to obtain desirabilities ranging between 0.1 and 1 using the following equation:

for phenolic and volatile compounds of EVOO that must be maximized:

$$d_i = \frac{0.9Y + 0.1Y_{max} - Y_{min}}{Y_{max} - Y_{min}}$$

for phenolic compounds of EVOO that must be minimized:

$$d_i = \frac{-0.9Y + Y_{max} - 0.1Y_{min}}{Y_{max} - Y_{min}}$$

Y_{min} and Y_{max} correspond to the minimum and the maximum variable values, respectively.

The overall desirability (D) was calculated as the geometric mean of the individual d_i values:

$$D = \sqrt[n]{d_1 d_2 \times \ldots \times d_n}$$

The partial least-squares analysis (PLS) was used to estimate the coefficients of the terms in the models.[41]

RESULTS AND DISCUSSION

The phenolic and volatile compounds of the EVOOs obtained in this study were determined according to the list given in Table 2.

Table 2. List of the Variables Evaluated in Extra Virgin Olive Oils

phenolic compounds	**alcohols**
hydroxytyrosol (3,4-DHPEA)	2-methyl-1-butanol
tyrosol (*p*-HPEA)	1-pentanol
3,4-DHPEA-EDA	1-hexanol
p-HPEA-EDA	1-heptanol
(+)-1-acetoxypinoresinol	1-octanol
(+)-pinoresinol	1-penten-3-ol
3,4-DHPEA-EA	(*E*)-2-penten-1-ol
total phenols	(*Z*)-2-penten-1-ol
	(*E*)-3-hexen-1-ol
volatile compounds	(*Z*)-3-hexen-1-ol
ketones	(*E*)-2-hexen-1-ol
3-pentanone	
1-penten-3-one	**esters**
	ethyl acetate
aldehydes	hexyl acetate
pentanal	(*Z*)-3-hexenyl acetate
hexanal	
octanal	**aromatic alcohols**
nonanal	benzyl alcohol
(*E*)-2-pentenal	phenylethyl alcohol
(*E,E*)-2,4-hexadienal	
2,4-hexadienal (i)	**sum of classes of volatile compounds**
(*Z*)-3-hexenal	sum of ketones
(*E*)-2-hexenal	sum of saturated aldehydes
(*E*)-2-heptenal	sum of C_6 unsaturated aldehydes
(*E*)-2-octenal	sum of saturated alcohols
	sum of C_5 unsaturated alcohols
phenols	sum of C_6 unsaturated alcohols
phenol	sum of esters

The results from the combinations of temperature and O_2 concentration applied during malaxation are shown, with respect to the phenolic compounds, as distributions in the box and whisker plots in Figure 1, while for volatile compounds the range and the average values contents are given in Table 3.

From Figure 1 can be evidenced a strong variation of the phenolic concentration among the cultivars and, in addition, the distribution of the values obtained with different malaxation conditions is cultivar-dependent (cvs Peranzana and Coratina by a side and cvs Ogliarola and Itrana by the other show similar trends). The main phenolic compounds in all the cultivars were the oleuropein and the ligstroside derivatives, while the lignans showed the lowest concentrations and the lowest variability with the operating extraction conditions. It is important to note

that the main contribution to the total phenols content was due to the oleuropein derivatives.

By the data analysis, the highest average value of total phenols was found in cv. Coratina (992 mg/kg) and the lowest in cv. Peranzana (337 mg/kg); the EVOOs obtained from cv.

dx.doi.org/10.1021/jf405753c | J. Agric. Food Chem. 2014, 62, 3813–3822

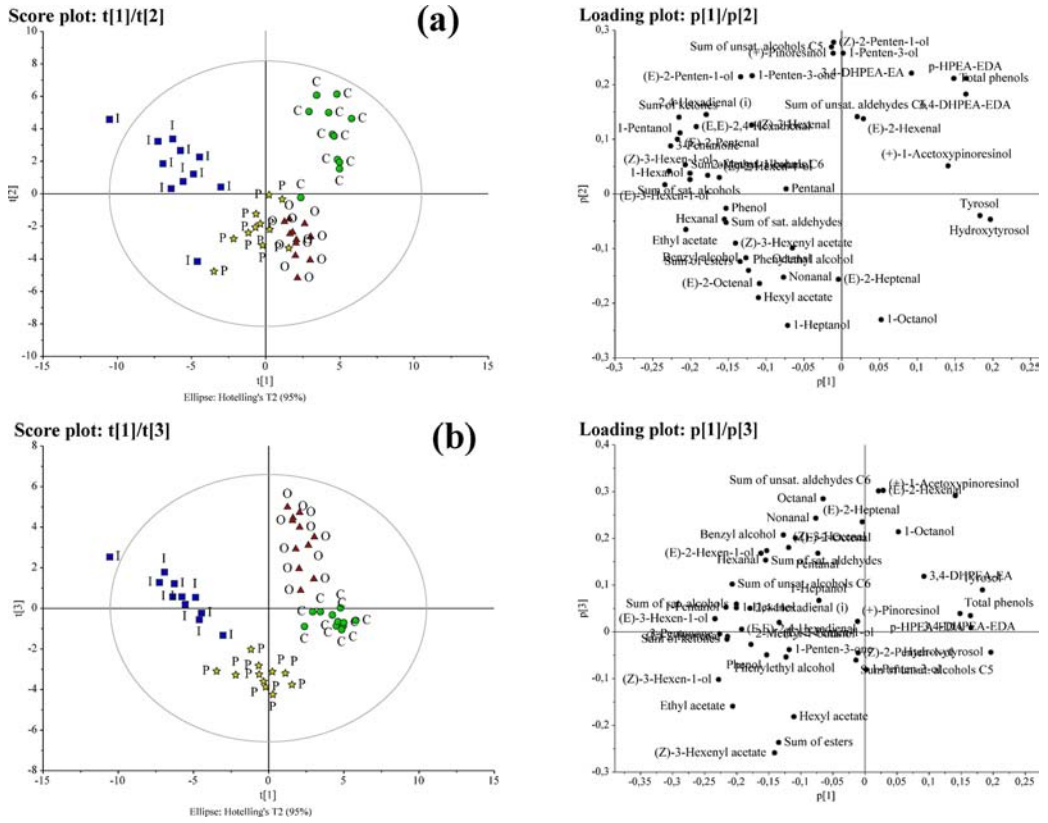

Figure 2. Score plot and loading plot of the first two principal components (a) and of the first and third components (b) of the PCA of EVOOs obtained from four Italian olive cultivars in different malaxation conditions. Abbreviations used: P = Peranzana; O = Ogliarola; C = Coratina; I = Itrana.

Itrana contained an average total phenols amount of 364 mg/kg, while that of cv. Ogliarola was 480 mg/kg. The phenolic variation among the cultivars, in agreement with the literature, indicates that genetic biodiversity is one of the most important parameters that affects the phenolic concentration in EVOOs.[1,2,42] So far, however, the impact on the bioactive phenols of the operative conditions of malaxation, such as O_2 concentration in the olive pastes and the processing temperature, was very strong in all the cultivars studied. This is demonstrated by the ranges of variability between the extreme values of the total phenols, corresponding to 1,241 mg/kg in cv. Coratina, 488 mg/kg in cv. Ogliarola, 387 mg/kg in cv. Itrana, and 351 mg/kg in cv. Peranzana.

High variability was observed also for the volatile compounds according to the cultivar and the operative conditions of malaxation, with the main variations found in the compounds, related to the lipoxygenase pathway, that include hexanal, (*E*)-2-hexenal, 1-hexanol, (*E*)-3-hexen-1-ol, (*Z*)-3-hexen-1-ol, and (*E*)-2-hexen-1-ol, together with esters such as hexyl acetate and (*Z*)-3-hexenyl acetate.

The significant differences in terms of cultivar impact in the C_6 unsaturated aldehydes show the lowest average value in cv. Peranzana (31,760 μg/kg) and the highest concentration in cv. Ogliarola (49,015 μg/kg); with regard to the C_6 unsaturated alcohols, these range between 2,202 and 5,581 μg/kg for the Coratina and the Itrana cvs, respectively. The most important variation in the volatile composition related to cultivar origin is, however, shown by the ester mean concentrations having the lowest value in cv. Coratina (65 μg/kg) and the highest in cv. Peranzana (3,889 μg/kg). All the classes of volatile compounds related to the EVOO flavor evaluated in this work are highly affected by the operative conditions. The maximum range of variability for the C_6 unsaturated aldehydes corresponding to 24,866 μg/kg was found in cv. Itrana; on the contrary, cv. Peranzana shows the minimum value with 12,432 μg/kg. The mean amounts of the C_6 unsaturated alcohols have the highest content in cv. Itrana (5,581 μg/kg), about twice the average amount of the other three cultivars; with respect to the range of variability for this class of compounds, cv. Itrana has the maximum value, 3,784 μg/kg, and cv. Coratina shows the minimum, with 1,196 μg/kg. Regarding the esters concentration, cv. Peranzana has the highest average value (3,889 μg/kg), about seven times the nearest value found in cv. Itrana, and even in this case the operative conditions of malaxation greatly affect their content: the maximum range of variability was found in cv. Peranzana, with 2,487 μg/kg, while the minimum value was found in cv. Coratina, with 72 μg/kg.

Multivariate statistical methods were used to better interpret all the data collected from the EVOO samples obtained by varying the combination of two malaxing parameters, the O_2 concentration in the olive pastes and the processing temperature, and to optimize these two variables. A PCA model was first built with the whole data set, which included the EVOOs evaluated for all four Italian cultivars studied using the list of compounds given in Table 2. The model, built with some variables log-transformed so as to obtain a distribution closer to a Gaussian, explains 93% of the total variance with seven significant principal components (37%, 22%, 15%, 9%, 5%, 3%, and 2%, respectively) and the results for the first two components are shown in Figure 2. A clear discrimination of

dx.doi.org/10.1021/jf405753c | J. Agric. Food Chem. 2014, 62, 3813−3822

the EVOOs in four clusters, corresponding to the olive cvs, is observed in the first three principal components, and in particular in the first component the oils most differentiated are Itrana (on the left side) and Coratina (on the right side), while in the second component there are the Coratina and Itrana EVOOs (on the upper side) opposite to the Peranzana and Ogliarola oils (Figure 2a). The loading plot in Figure 2a shows that the Itrana oils are characterized by higher concentration of ketones, C_6 saturated and unsaturated alcohols, (*E*)-2-pentenal, hexanal, and (*Z*)-3-hexenal; on the contrary, the Coratina EVOOs have a higher secoiridoids content, while Peranzana and Ogliarola EVOOs have lower contents of C_5 unsaturated alcohols and secoiridoids (in comparison with cv. Coratina) and higher concentrations of some saturated alcohols. In the score plot of the third component vs the first, there is a very good separation of Ogliarola (on the upper side) compared to Peranzana EVOOs and the former has higher levels of C_6 unsaturated aldehydes; on the other hand, Peranzana is very rich in esters (Figure 2b).

For the data set for each cultivar without the two lignans, due to very little differences in the samples, preliminary PCA models were built to establish the variables (with regard to the volatile compounds, those substances originated by the lipoxygenase pathway were chosen, significant in defining the flavor of EVOOs) that play an important role in the quality of this food product and that undergo the most variations under the different mechanical oil extraction conditions, temperature and oxygen concentration during malaxation, fixed with the CCC design (for a detailed description of these PCA models see the Supporting Information). For the RSM optimization, only a few analytical variables must be selected in order to define the overall desirability starting with the partial desirability functions (for the list of the variables chosen for each olive cultivar see Table 4).

The RSM models explain with two PLS components for all the cultivars analyzed 98%, 97%, 94%, and 85% of the total variance for Peranzana, Ogliarola, Coratina, and Itrana, respectively.

The results for Peranzana, given in Figure 3, show a response surface with a maximum located at about 33.5 °C and 54 kPa of oxygen. The most important effect is due to temperature, although oxygen also plays a significant role. For cv. Ogliarola, the surface shows a saddle shape and the best operative conditions can be found at the temperature of 32 °C and the lowest oxygen concentration (Figure 3); in this case, both temperature and oxygen are important in the optimization model. In the case of cv. Coratina, when transformed into desirability functions, due to very high concentration of the phenolic substances (for total phenols up to 1,690 mg/kg), a maximum total phenols value of 1,000 mg/kg was chosen for these compounds, and for secoiridoids proportional values to their original concentrations were calculated, above which the equation for the minimization of the desirability was used, because EVOOs with higher phenolic contents are unpleasant due to their bitter and pungent sensory notes.[43,44] The RSM model gave the best results with a temperature of 25 °C and an oxygen concentration of 21.3 kPa, even if in this case a high desirability function value can be obtained at a temperature of 36 °C and an oxygen concentration of 101.3 kPa with the two factors both influencing the model (Figure 4). The best malaxing conditions for cv. Itrana are a temperature of 33 °C and the lowest oxygen concentration, and as for cv. Coratina, very high response values were obtained at a temperature of 37 °C with the highest oxygen content; between the two factors now the temperature plays an important role in the modeling process (Figure 4).

[a]Compounds maximized and minimized in the cv. Coratina (for details see the text).

The results of the optimization models show that the optimal malaxing conditions are strongly affected by genetic biodiversity. These results confirm, as found in previous works,[1,2,7,8,42] that cultivars have a significant impact on the chemical and biochemical characteristics of olive fruits and the EVOOs obtained from them. The total amount of phenols in the fruit and the activities of several endogenous enzymes that are involved in phenolic oxidation and aroma generation, such as polyphenoloxidases, peroxidases, and lipoxygenases, are influenced by the genetic origins of the cultivars. As a consequence, to obtain high quality EVOOs, the operative conditions of malaxation, such as the O_2 concentration in the pastes and the processing temperature, which both affect the activities of endogenous enzymes, must be optimized according to the cultivar. In this context it is very important to stress that the EVOOs obtained from Itrana and Peranzana among the cultivars studied, rich mainly in esters among the aromatic compounds, formed in the lipoxygenase pathway, but relatively poor in phenolic substances, show the highest malaxation temperatures for obtaining the maximum response values in the optimization models. The high temperatures (near 40 °C) reduce the activity of hydroperoxide lyase responsible for the formation of C_6 aldehydes and, consequently, of the other classes of compounds originated by these, but, at the same time, improving the cell wall degradation, due to the endogenous depolymerizing enzymes, and enhancing the solubility of these substances in the oils, they increase the release of phenols in the EVOOs and in the vegetation waters.[45,46] On the basis of these results, to improve the health and the sensory properties of EVOOs for cultivars poor in phenols and characterized by high

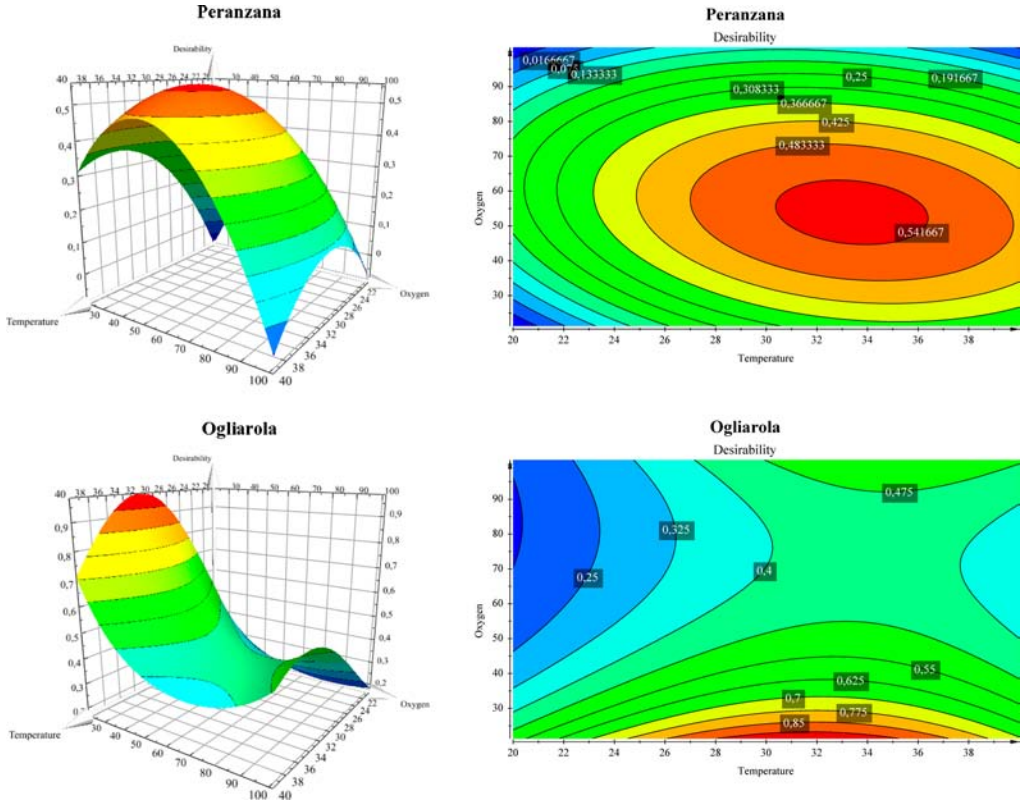

Figure 3. RSM and contour plots obtained in the PLS model built to optimize the temperature and oxygen concentration during malaxation in the Peranzana and Ogliarola cultivars.

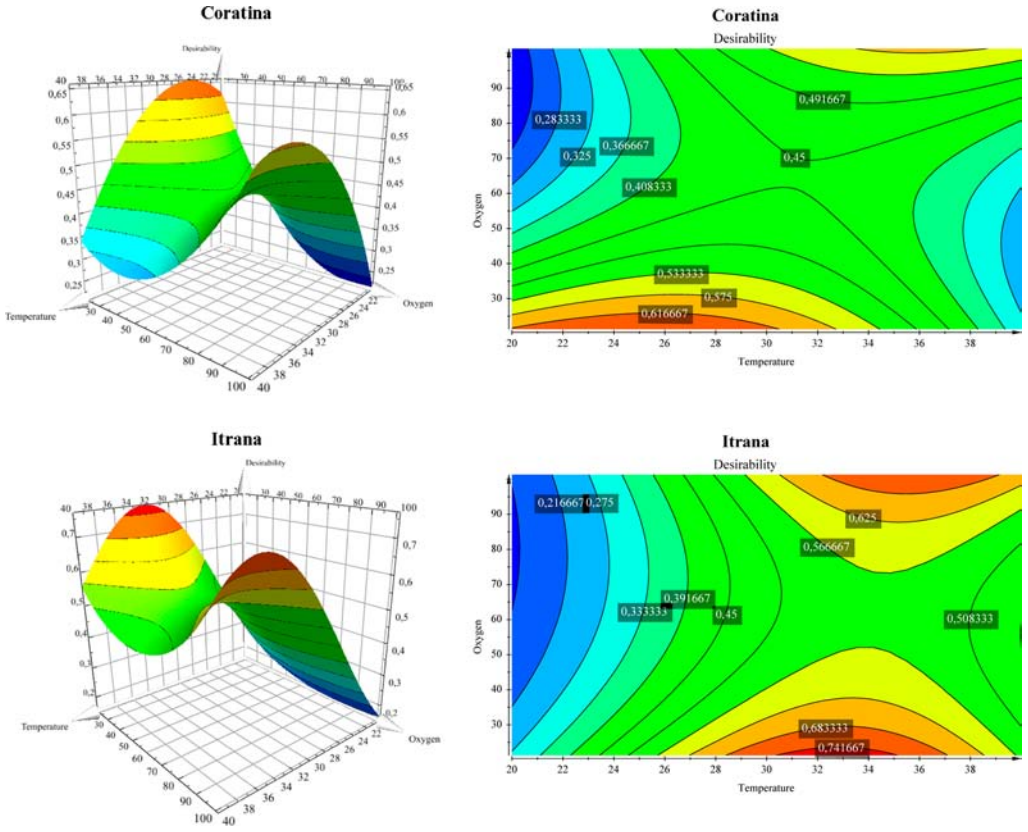

Figure 4. RSM and contour plots obtained using the PLS model built to optimize the temperature and oxygen concentration during malaxation in the Coratina and Itrana cultivars.

dx.doi.org/10.1021/jf405753c | J. Agric. Food Chem. 2014, 62, 3813−3822

LPO activity, the optimal malaxing conditions are obtained at temperatures ranging between 30 and 36 °C and low to mid O_2 concentrations. In this context the esters production seems to be increased by medium O_2 levels in the pastes, which is particularly apparent in cv. Peranzana, probably due to intense alcohol acetyltransferase activity, the last step in the lipoxygenase pathway formation of the volatile compounds. Cv. Coratina, on the contrary, which was characterized by the highest amount of phenols in the EVOOs,[33,47,48] shows that the operative conditions for obtaining the highest response value is located to quite low malaxation temperature of (25 °C) among the cultivars studied. Moreover, the results showed that the low O_2 amount in cv. Coratina seems to be in contrast with the reduction of the phenolic compounds content, which should be promoted in all cultivars extremely rich in these substances to improve the oil consumer acceptability by reducing the bitterness and the pungent sensory notes.[43,49] It is important to note, however, that this result has been obtained with the limit set at 1,000 mg/kg of total phenols content for obtaining pleasant EVOOs. Moreover, cv. Coratina is not only characterized by a high amount of phenols but, at the same time, shows a low polyphenoloxidase and peroxidase activity.[13] The low activity of these enzymes can explain why an increase of O_2 in the pastes produces a small reduction of the phenolic content in the oils, lower than that connected with the malaxing temperature; as a consequence, in cv. Coratina optimization model, low processing temperatures seem to be more important than high O_2 concentrations in the reduction of the phenolic compounds in the oils. This phenomenon could be explained by reduced activity of the depolymerizing enzymes in the pastes that decrease the release of phenols from the cell wall into the olive oil.

The optimization of the malaxing parameters of the four Italian cultivars conducted in this study pointed out the different results of the operative conditions, thus requiring specific investigations of the optimal setting for the oil mechanical extraction process for each individual cultivar due to the different influence of the temperature and oxygen concentration during malaxation. However, it is important to note that the malaxing parameters here investigated heavily modify the concentrations of both the phenolic and volatile compounds independently by olive cultivar.[10,14,15,19,50]

Especially for the acid soil, which is deficient in N and P, fertilizing with N and P could enhance the yields and growth of tea leaves.[23]

Therefore, the aim of this study was to investigate whether different four fertilizing strategies (with exogenous Se, Zn, N, and P: Se + Zn, Se + Zn + N, Se + Zn + P, Se + Zn + N + P) could improve the element contents (Al, Mn, Se, and Zn) and functional component contents (total polyphenol, total free amino acid, tea polysaccharides, catechins, and caffeine) as well as the antioxidant activity in new and old tea leaves grown in a hilly red soil region.

MATERIALS AND METHODS

Chemicals and Reagents. A ferric reducing ability of plasma (FRAP) kit was purchased from Biyuntian Reagent Co. (Jiangsu). The standards (Se, Zn, Al, Mn) were purchased from National Institutes for Food and Drug Control (NIFDC), Beijing, China. 2,2-Diphenyl-1-picrylhydrazyl (DPPH) and the standards of epigallocatechin (EGC), catechin (CA), epigallocatechin gallate (EGCG), epicatechin (EC), caffeine (CAF), and theanine were purchased from Sigma (Steinheim, Germany). Methanol and acetonitrile were of high-performance liquid chromatography (HPLC) grade; HNO_3, $HClO_4$, and other chemicals were of guaranteed grade.

Plant Culture and Treatments. This study was conducted outdoors at Huangma country, Nanchang, China (28°20′ N, 116°01′ E). The pH of the planting soil was 5.4, and the organic matter, cation exchange capacity (CEC), total nitrogen, available phosphorus, available K, and total Al contents were 27.6 mg/kg, 11.24 cmol/kg, 0.87 g/kg, 1.32 mg/kg, 28.62 mg/kg, and 131 g/kg, respectively. Typical 30 years Fuding White tea (*C. sinensis* cv. Fuding-dabaicha) was chosen as the research object. One sample plot was divided into five parts, which had uniform size (3 m × 4 m) and spacing (3 m). A total of 30 tea plants were planted in two lines in each uniform size. Four kinds of fertilizing strategies (A, Se + Zn; B, Se + Zn + N; C, Se + Zn + P; D, Se + Zn + N + P) were compared, and the control group (CK) was regular fertilizer (H_2O).[24] Chemical reagents were resolved in water and then used to fertilize the soil. A total of 12 L of solution was used to irrigate 12 m^2 of soil at a time. Fertilization was done once a month for a year. Fertilizing strategy A (Se + Zn) was made up with 21.9 mg of Na_2SeO_3 and 2.53 g of $ZnSO_4{\cdot}7H_2O$ in 12 L of water and then used to irrigate 12 m^2 of soil. Fertilizing strategy B (Se + Zn + N) was made up with 21.9 mg of Na_2SeO_3, 2.53 g of $ZnSO_4{\cdot}7H_2O$, and 14.29 g of NH_4NO_3, respectively. Strategy C (Se + Zn + P) was made up with 21.9 mg of Na_2SeO_3, 2.53 g of $ZnSO_4{\cdot}7H_2O$, and 9.68 g of NaH_2PO_4, respectively. Strategy D (Se + Zn + N + P) was made up with 21.9 mg of Na_2SeO_3, 2.53 g of $ZnSO_4{\cdot}7H_2O$, 14.29 g of NH_4NO_3, and 9.68 g of NaH_2PO_4, respectively. Depending on the different fertilizing strategies, the total quantities of Se, Zn, N, and P were 8.33×10^{-1} mg/m^2, 3.33×10^{-2} g/m^2, 4.17×10^{-1} g/m^2, and 2.08×10^{-1} g/m^2, respectively. The solutions were fertilized to the soil under tea plant (in an area 30 cm away from each stem). Moreover, continuous sunny days (5 days or more) were chosen for fertilizing to avoid the loss of fertilizers. After being fertilized for a year (conducted in March 2011 and then fertilized once a month 12 times), new leaves (two leaves and a bud) and old leaves were collected in March 2012. The harvested tea leaves were washed with distilled water and dried, ground, and then stored at −80 °C before analysis.

Assay of Elements. The Zn, Al, and Mn contents were assessed by OPTIMA 5300DV ICP-AES (PerkinElmer, Santa Clara, CA, USA). The Se content was assessed by an AFS-230E AFS (Haiguang Co., Beijing, China). Briefly, 0.5 g of sample was assimilated with 10 mL of mixed acids (nitric acid/perchloric acid, 4:1, v/v) at 250 °C until the solution turned to colorless. Then the solution was filtered and diluted to 25 mL with ultrapure water.[25,26]

Total Free Amino Acids. In brief, 0.25 g of dried tea leaf powder and 50 mL of deionized hot water (80 °C) were mixed in a screw-capped test tube and kept in a water bath at the same temperature for 25 min. Then the tube was cooled to room temperature and centrifuged at 5000*g*/s for 5 min. The supernatant was filtered and diluted to 50 mL with ultrapure water.

One milliliter of tea diluted solution, 0.5 mL of phosphate buffer (PBS), and 0.5 mL of ninhydrin solution were mixed in a 25 mL volumetric flask and heated in a boiling water bath for 15 min. Then, the flask was cooled to room temperature, and the solution was diluted to 25 mL with distilled water. The absorbance of the diluted solution was measured at 570 nm by using an SP-1910UVPC UV spectrophotometer (Spectrum Instrument Co., Shanghai, China). Theanine (99%) was used as a standard, and the results were expressed as percent.[27]

Tea Polysaccharides. In brief, 0.25 g of dried tea leaf powder and 10 mL of 80% (v/v) ethanol were mixed and incubated in the water bath at 95 °C for 1 h. The ethanol was volatilized completely, and 25 mL of deionized water was added and heated in a boiling water bath for 1 h. After centrifugation (3200*g*/s, 10 min), the supernatant was diluted to 25 mL and used for analysis. One milliliter of the solution was mixed with 1.0 mL of phenol and homogenized. After 10 min, 5.0 mL of sulfuric acid was added and then set for 20 min. The absorbance was measured at 490 nm with an SP-1910UVPC UV spectrophotometer (Spectrum Instrument Co.). D-Glucose was used as standard, and the results were expressed as percent.[28,29]

Catechins and Caffeine. In brief, 0.25 g of sample and 2.5 mL of 70% (v/v) chromatographic grade methyl alcohol were mixed together and incubated in the water bath at 70 °C for 30 min. The mixture was centrifuged at 2450*g*/s for 10 min. The extraction was repeated twice, and the supernatants were combined and made up to 5.0 mL. The freshly prepared tea infusions from samples were filtered through 0.45 μm filters.[30]

To determine the catechins and caffeine contents, reverse phase high-performance liquid chromatography (RP-HPLC) was applied in the Agilent 1100 series (Agilent, Santa Clara, CA, USA). An Inertsil octadecylsilane (ODS) C_{18} column (4.6 mm i.d. × 250 mm, 5 μm, Shima, Kyoto, Japan) was used. The flow rate was set at 0.8 mL/min, and the column temperature was kept at 30 °C. The solvent compositions used were water with 0.1% formic acid (solvent A) and methanol (solvent B). The separation was checked by the spectra recorded using the diode array detector (DAD) and the ultraviolet (UV) detector set at 280 nm.[31] A dilution series of each standard (0.01−0.1 mg/mL) had been previously prepared for quantification.

Tea Polyphenols. The total phenolic content (TPC) was determined using the Folin−Ciocalteu procedure as described in International Standards Organisation (ISO) 14502-1:2005.[30] The sample was extracted by 50% (v/v) aqueous ethanol. The extraction was also used to measure the antioxidant activity. One milliliter of tea sample extraction was followed by 5 mL of 10% (v/v) Folin−Ciocalteu reagent and mixed. After 3 min, 4 mL of 20% Na_2CO_3 was added and reached a final volume of 10 mL with water. The mixture was left for 60 min at room temperature, and the absorbance was measured at 760 nm using an SP-1910UVPC UV spectrophotometer (Spectrum Instrument Co.). The result was expressed as percent.[32]

DPPH Radical-Scavenging Capacity. The DPPH assay is one of the most widely used methods to determine the antioxidant activity. The ethanolic DPPH solution (0.2 mmol/L, 2.0 mL) was used as control. The ethanolic DPPH solution was added to 2 mL of extract solution and then shaken vigorously. The samples were measured at 517 nm using an SP-1910UVPC UV spectrophotometer (Spectrum Instrument Co.) after being kept in a dark room for 30 min.[33]

Ferric Reducing Ability of Plasma (FRAP) Assay. The FRAP assay was carried out on the basis of the reduction of Fe^{3+}-TPTZ to Fe^{2+}-TPTZ. The working FRAP reagent was prepared by mixing 2,4,6-tripyridyl-*S*-triazine (TPTZ) dilution, TPTZ solution, and detective buffer in the ratio of 10:1:1 (v/v). About 5.0 μL of extracted solution (or 5.0 μL of deionized water as the blank) was added to 180 μL of fresh working FRAP reagent. After the solution had warmed to 37 °C for 3 min, the absorbance was read at 593 nm using a Varioskan Flash micro plant reader (Thermo, Waltham, MA, USA).[34,35] The results were expressed as $FeSO_4$ equivalent millimoles per gram. Different concentrations (0.15−1.5 mmo/L) of $FeSO_4$ solution were used as abscissa in the standard curve. $FeSO_4$ values were used as ordinate in

Table 1. Contents of Se, Zn, Al, and Mn in New and Old Leaves[a]

		element			
strategy		Se (μg/kg)	Zn (mg/kg)	Al (mg/kg)	Mn (mg/kg)

the standard curves. Higher $FeSO_4$ values indicated higher ferric reducing power.

Reducing Power. One milliliter of extract solution was mixed with 2.5 mL of phosphate buffer (0.2 mol/L, pH 6.6) and 2.5 mL of potassium ferricyanide (1%, w/v). After incubation at 50 °C for 20 min, 1.0 mL of trichloroacetic acid (10%, w/v) was added to the mixture. The mixture was then shaken vigorously and centrifuged at 2450g/s for 10 min. After that, 2.5 mL of supernatant was mixed with 2.5 mL of distilled water and 0.5 mL of 0.1% ferric chloride. The absorbance was read at 700 nm using an SP-1910UVPC UV spectrophotometer (Spectrum Instrument Co.).[36] The results were expressed as the absorbance.

Statistical Analysis. Results were expressed as the mean ± SD of three independent extractions. Statistical comparisons were performed using the statistical software (SPSS 19.0) with analysis of variance (ANOVA). One-way ANOVA was used to compare the means. A level of probability at $p < 0.05$ was set as statistically significant.

RESULTS

Assay of Elements. The element contents (Se, Zn, Al, Mn) of tea leaves in the four treated groups (A–D) showed significant differences (Table 1). Compared with the control (group CK), the contents of Se and Zn in groups A–D were increased significantly ($p < 0.05$). On the other hand, the contents of Al and Mn were decreased significantly ($p < 0.05$).

Compared with the control group, the Se contents of both new and old leaves in the four treated groups were increased significantly with the order C > D > B > A > CK ($p < 0.05$). The highest Se contents were found in group C (new leaves, 0.241 μg/kg; old leaves, 0.444 μg/kg), which were much higher than those in group CK (new leaves, 0.108 μg/kg; old leaves, 0.127 μg/kg). The Zn content of new leaves in the four treated groups was higher than that in group CK, with the order B > A > D > C > CK, which was the same as the old leaves ($p < 0.05$). New leaves in group B (Se, Zn, and N treated) had the highest Zn content (34.235 mg/kg), which was 61.49% higher than group CK (21.200 mg/kg). However, the Zn contents of new leaves were higher than those in old leaves. For example, the Zn content of new leaves in group A was 32.285 mg/kg, whereas only 24.084 mg/kg Zn was found in old leaves.

The Al contents of both new and old leaves in the four treated groups were decreased significantly when compared with group CK, and the order was C < D < B < A < CK. Although the Al contents in groups A–D were significantly higher than that in group CK, no significant differences were observed in groups A–D (new leaves) and groups B–D (old leaves) ($p < 0.05$). The old leaves had consistently higher Al content than new leaves. For instance, the Al content of new leaves in group D was 243.549 mg/kg, which was only one-sixth that in old leaves (1626.053 mg/kg). By our management, the highest Se content as well as the lowest Al content (222.005 mg/kg) was found in group C (new leaves). Similarly, the Mn contents decreased significantly by new fertilizing strategies,

dx.doi.org/10.1021/jf5004286 | J. Agric. Food Chem. 2014, 62, 3823–3830

and the order was B < A < D < C < CK (Table 2). No significant differences were observed in groups A, B, and D (new leaves). However, group B had significant differences with groups C and D in old leaves ($p < 0.05$). The lowest Mn contents were found in group B (new leaves, 747.658 mg/kg; old leaves, 1907.135 mg/kg), followed by groups A (799.050 mg/kg), D (833.388 mg/kg), and C (949.784 mg/kg). Moreover, the highest Zn content as well as the lowest Mn content was found in group B (new leaves).

Total Free Amino Acid Content. The total free amino acid contents in both new and old leaves in four different treated groups were increased significantly, and the order was B > D > C > A > CK (Figure 1). In both new and old leaves, the total free amino acid contents in groups A–D were significantly higher than that in group CK ($p < 0.05$). The content of total free amino acids in new leaves was much higher than that in old leaves ($p < 0.05$). The highest total free amino acid content was found in group B (new leaves, 5.60%; old leaves, 2.90%), followed by groups D (5.48 and 2.51%, respectively), C (5.24 and 2.43%, respectively), A (5.01 and 2.27%, respectively), and CK (2.37 and 2.11%, respectively).

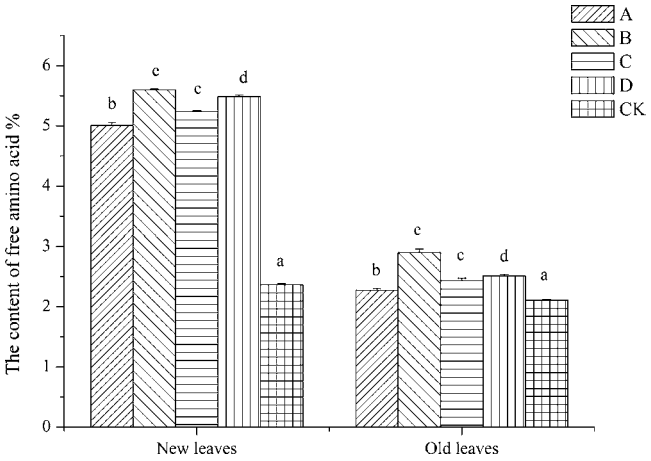

Figure 1. Contents of total free amino acids in new and old tea leaves. A, B, C, and D represent four kinds of fertilization strategies, and CK was the control group. Values represent the mean ± SD. Bars with the same letter above do not differ significantly. Different letters above the bars indicate statistical difference ($p < 0.05$).

Tea Polysaccharide Content. Using four different fertilizing strategies, the tea polysaccharide contents in both new and old leaves were significantly increased (Figure 2). The order was B > D > C > A > CK. There were significant differences among groups A, B, and C in new leaves and among groups A, B, and D in old leaves ($p < 0.05$). Furthermore, the polysaccharide contents in old leaves were much higher than that in new leaves (new leaves, 4.47%; old leaves, 5.80%). It was shown that group B had the highest tea polysaccharide content both in new leaves (4.47%) and in old leaves (5.80%), followed by groups D (4.11 and 5.37%, respectively) and C (3.87 and 5.09%, respectively). Group CK showed the lowest tea polysaccharide contents in new and old leaves (2.51 and 3.91%, respectively), which were 78.05 and 48.34% lower than those in group B.

Catechins and Caffeine Contents. Four catechins (EGC, CA, EGCG, and EC) were separated and analyzed in tea leaves (Figure 3). The total contents of catechins in new leaves were higher than those in old leaves (Table 2). The order was C > D > B > A > CK. For the total contents of catechins and EGCG, there were significant differences among groups A–D and CK in both new and old leaves ($p < 0.05$). However, there was no significant difference among groups B–D in new leaves or among groups A–D in old leaves ($p < 0.05$). For EGC, there were significant differences among groups A–D and CK in new leaves ($p < 0.05$). Groups C and D had significantly higher EC content than group CK in both new and old leaves ($p < 0.05$), which was the same as the catechin of CA. Group C showed the highest contents of EGC, CA, EGCG, and EC both in new leaves (6.630, 1.623, 108.630, and 14.970 mg/g, respectively) and in old leaves (6.912, 1.328, 86.607, and 12.504 mg/g, respectively). However, group CK showed the lowest contents of EGC, CA, EGCG, and EC in both new (5.420, 0.964, 81.278, and 11.165 mg/g, respectively) and old leaves (5.767, 0.926, 62.336, and 9.026 mg/g, respectively),

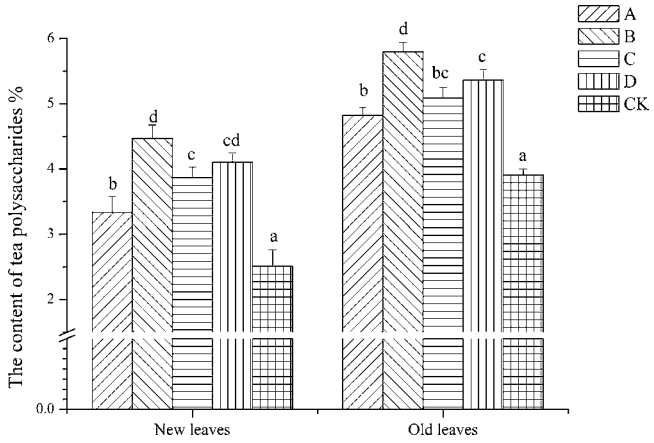

Figure 2. Contents of tea polysaccharides in new and old tea leaves. A, B, C, and D represent four kinds of fertilization strategies, and CK was the control group. Values represent the mean ± SD. Bars with the same letter do not differ significantly. Different letters indicate the statistical difference ($p < 0.05$).

The caffeine contents of both new and old leaves in four fertilizer-treated groups were higher than those in group CK, with the order B > D > C > A > CK. However, only groups B and D had significant difference with CK in new leaves, and only group B showed significant difference with CK in old leaves ($p < 0.05$). Group B showed the highest caffeine contents (56.684 mg/g in new leaves and 28.988 mg/g in old leaves), which were 16.85 and 37.99% higher, respectively, than those in group CK.

Tea Polyphenol Content. The total polyphenol contents of new leaves using four different fertilization strategies were higher than those in old leaves (Figure 4). Although all groups showed significant difference with CK in old leaves, only groups B–D had significant difference with CK in new leaves ($p < 0.05$). Group C showed the highest total polyphenol contents in new leaves and old leaves (28.29 and 27.74%, respectively), followed by groups D, B, A, and CK. The polyphenol contents in group CK were 26.62 and 25.35% in new leaves and old leaves, which were 6.27 and 9.43% lower than those in group C, respectively.

DPPH Radical-Scavenging Capacity. The orders of DPPH radical-scavenging capacities in both new leaves and old leaves were C > D > B > A > CK (Figure 5I). Although groups A–C showed significant difference with CK in new leaves, only group C had significant difference with groups A and D in old leaves ($p < 0.05$). New leaves showed higher

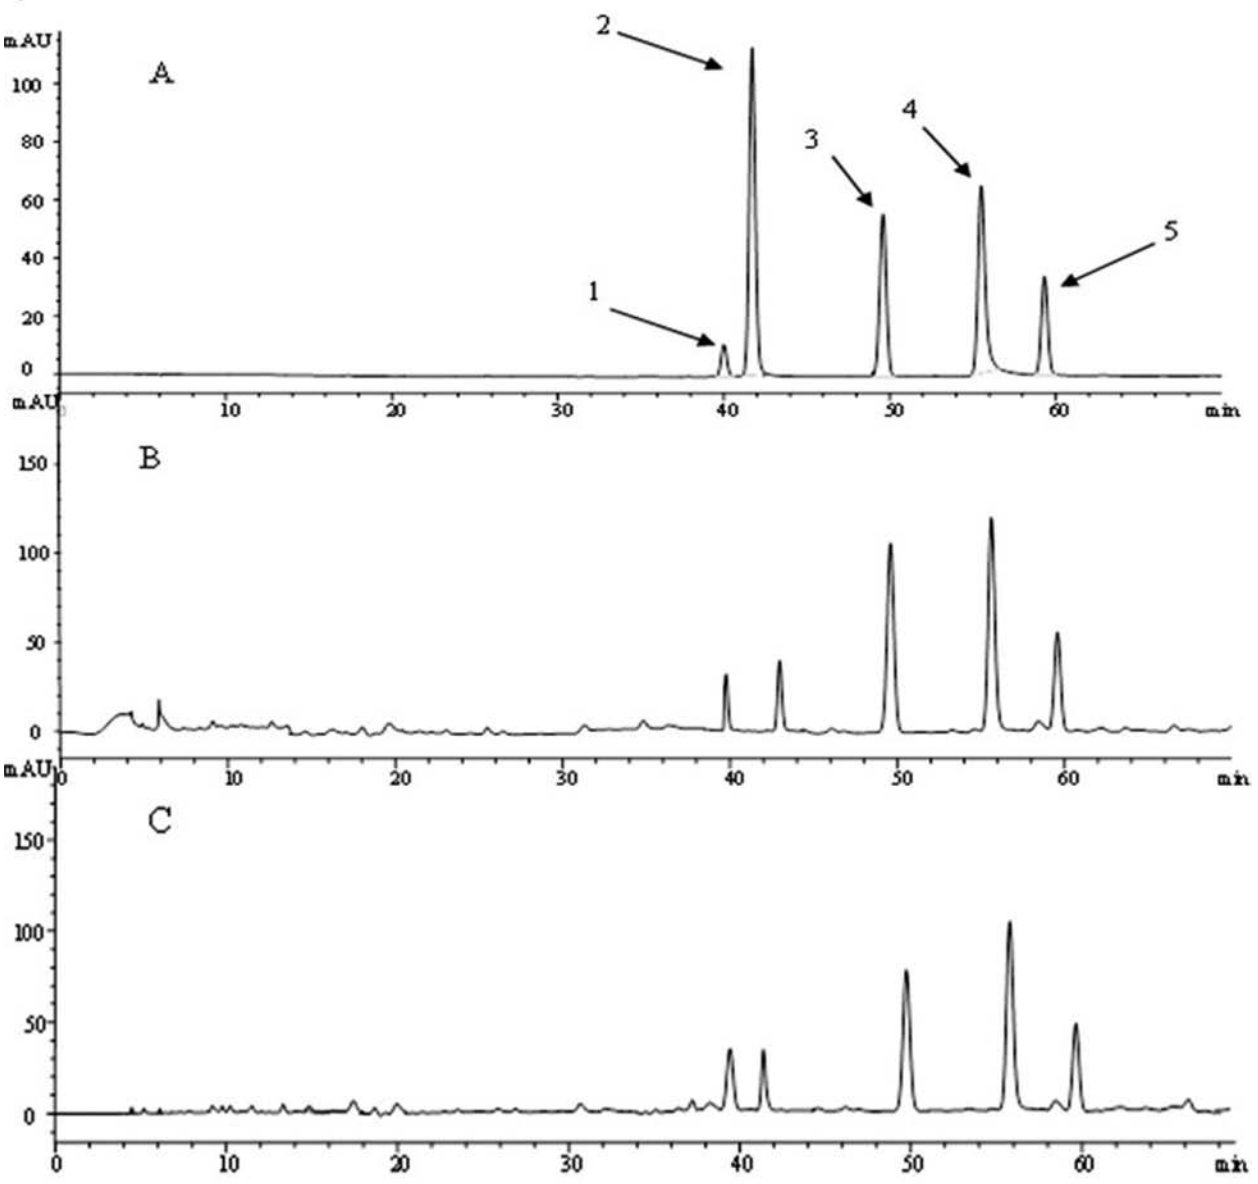

Figure 3. Mixed standards (A) and typical HPLC chromatogram of catechins and caffeine in new leaves (B) and old leaves (C). Numbers represent the different substances (1, catechins, EGC; 2, catechins, CA; 3, caffeine, CAF; 4, catechins, EGCG; 5, catechins, EC).

DPPH antioxidant activity than old leaves in all groups. The strongest DPPH antioxidant activity was found in group C (new leaves, 95.06%; old leaves, 89.65%), followed by groups D (93.22 and 85.48%, respectively) and B (91.59 and 84.43%, respectively). Nevertheless, the DPPH values in group CK were 15.70 and 11.60% (new and old leaves), which were much lower than those in other groups ($p < 0.05$).

FRAP Assay. Similarly, the order of FRAP values was C > B > D > A > CK in both new leaves and old leaves (Figure 5II). However, only groups B–D had significant difference with CK in both new or old leaves ($p < 0.05$). The FRAP values in new leaves were higher than those in old leaves (2.14% higher than old leaves). Among them, group C had the strongest FRAP values in both new and old leaves (3.81 and 3.73 mmol of $FeSO_4$/g, respectively), followed by groups B (3.76 and 3.71 mmol of $FeSO_4$/g, respectively) and D (3.71 and 3.68 mmol of $FeSO_4$/g, respectively). The weakest FRAP antioxidant activity was found in group CK, with values of 3.62 and 3.57 mmol of $FeSO_4$/g in new and old leaves, respectively.

Reducing Power. The reducing power in both new and old leaves from the strongest to weakest was C > D > B > A > CK (Figure 5III), which was similar to the DPPH and FRAP values. However, only group C showed significant difference with CK in new leaves, and groups C and D had significant difference with CK in old leaves ($p < 0.05$). Group C showed the strongest reducing power both in new leaves and old leaves (absorbance, 1.26 and 1.21, respectively), followed by groups D (1.23 and 1.20, respectively), B (1.22 and 1.18, respectively), and A (1.19 and 1.15, respectively). Group CK showed the lowest reducing power in both new (1.17) and old leaves (1.14). The reducing powers in new leaves (1.17–1.23) were higher than those in old leaves (1.14–1.20).

DISCUSSION

It was shown that the fertilizer P in red soil played a role in improving the content of Se in tea leaves. It was proven that P and Se had similar absorption sites in soil, which were

dx.doi.org/10.1021/jf5004286 | J. Agric. Food Chem. 2014, 62, 3823–3830

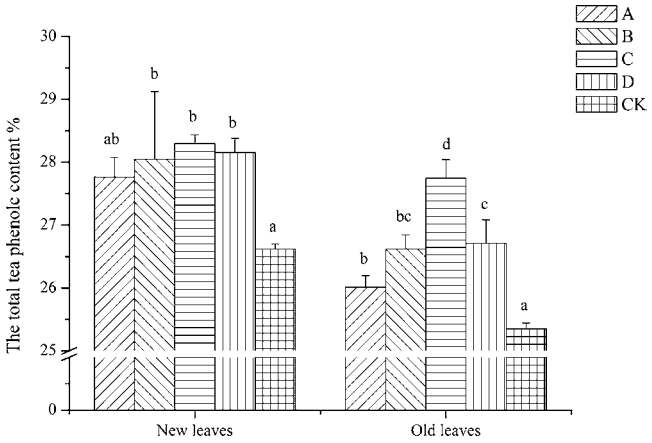

Figure 4. Contents of tea polyphenols in new and old tea leaves. A, B, C, and D represent four kinds of fertilization strategies, and CK was the control group. Values represent the mean ± SD. Bars with the same letter above do not differ significantly. Different letters indicate the statistical difference ($p < 0.05$).

competitively absorbed by soil.[35] Se showed preferential bonding with soil particle and therefore was hard to be absorbed by tea roots. Fertilizer P could exchange Se from the soil and made Se more easily absorbed by the tea plant.[37] Kopsell and Ekiza showed that the Se and Zn enriched soil could release more Se and Zn ions, which may be transferred to the tea leaves.[38,39] From our result, the content of Se in tea leaves was found to be negatively correlated with Al (Pearson's correlation coefficient, $r = -0.916$) (Table 1). It might be caused by the antagonistic effect of Se (obtain from fertilizer Se) and Al in the soil, which was less studied before. On the other hand, the content of Zn in tea leaves was negatively correlated with Mn ($r = -0.927$) in different fertilizer-treated groups, which might be caused by the competitive absorption of Zn (obtain from fertilizer Zn) and Mn in the soil.[40] Generally speaking, the four fertilizing strategies (with exogenetic N, P, Se, and Zn in soil) in our study were effective in enriching tea leaves with Se and Zn with low Al and Mn contents in an acid soil region.

It is interesting to note that fertilizer N in soil might help to increase the total amino acids in tea leaves (group B, 5.60%; blank group, 2.37%). N is necessary for the biosynthesis of amino acids, which could well explain that fertilization with N in soil contributed to the higher total amino acid contents in tea leaves. Moreover, the total amino acid content in new tea leaves was 92.97% higher than that in old leaves. The enzymes including glutamic-pyruvic transaminase (GTP), glutamate dehydrogenase (GLD), and amine oxidase were useful to the synthesis of amino acid. It was reported that the contents of these enzymes were much higher in new leaves than in old ones, which could help to increase the contents of amino acids in new tea leaves and therefore help the growth of the tea plant.[41]

Tea was mostly glycoconjugates, and the polysaccharide contents were increased significantly in the tea leaves fertilized with N. Fertilizer N in soil was found to be effective in the synthesis of chlorophyll, which could contribute to the carbon metabolism and help to enhance the tea polysaccharide contents.[42,43] The metabolism of old leaves was much slower, which might consume less carbohydrate and accumulate more polysaccharide. Therefore, the tea polysaccharide content in old leaves was higher than that in new leaves.

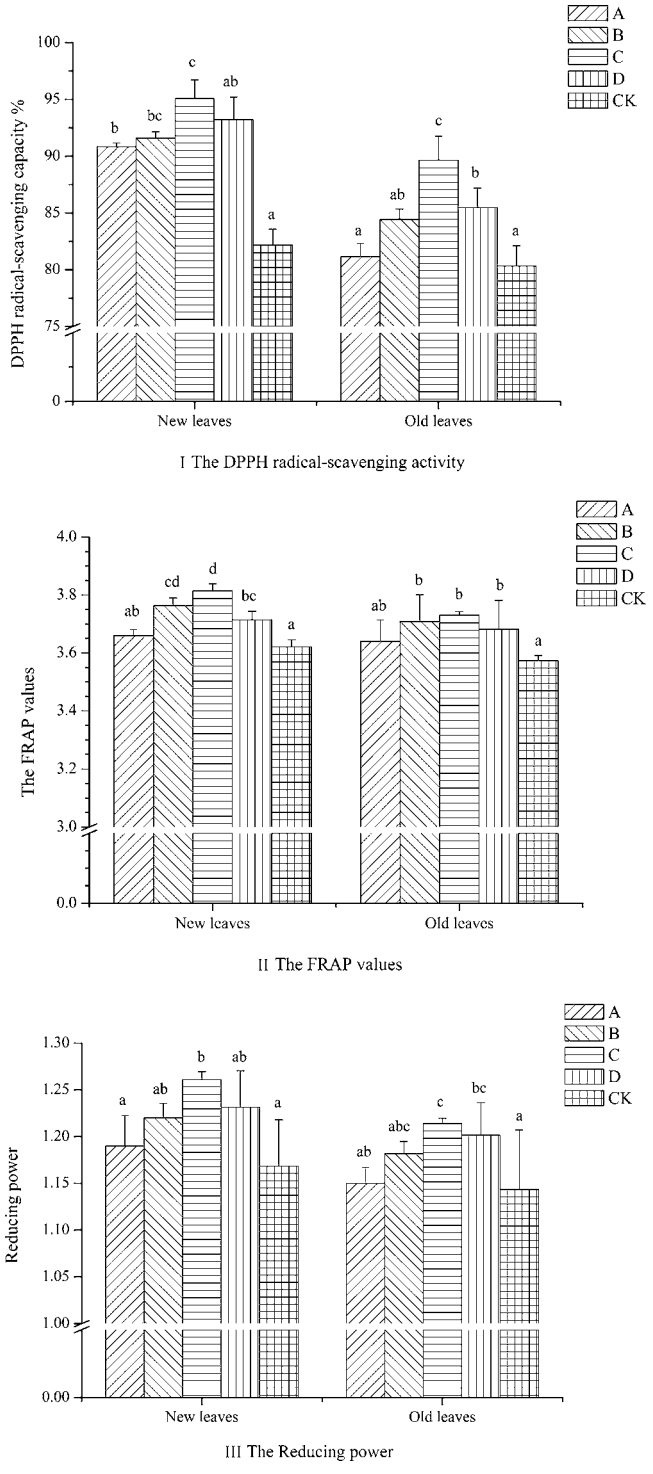

Figure 5. DPPH (I), FRAP (II), and reducing power (III) antioxidant activities in new and old tea leaves. A, B, C, and D represent four kinds of fertilization strategies, and CK was the control group. Values represent the mean ± SD. Bars with the same letter above do not differ significantly. Different letters indicate the statistical difference ($p < 0.05$).

Tea polyphenol is the major antioxidant substance in tea leaves.[44] The antioxidant activities showed good correlation with the tea total polyphenol content ($r = 0.910$). The tea leaves with higher polyphenol content also showed stronger antioxidant activities. It has been proven that P could synthesize to phenylalanine ammonia-lyase (PAL); it was very important

dx.doi.org/10.1021/jf5004286 | J. Agric. Food Chem. 2014, 62, 3823−3830

in generating the polyphenol in tea leaves.[22] Fertilizer P was therefore beneficial to increase the polyphenol content and antioxidant activity of tea leaves. It showed that the contents of EGCG in old tea leaves were lower than those in new leaves, which might be caused by the weaker activities of UDP-glucose:galloyl-1-*O*-*β*-D-glucosyl-transferase (UGGT) and epicatechin:1-*O*-galloyl-*β*-D-glucose *O*-galloyltransferase (ECGT) and the stronger galloylated catechin hydrolase (GCH) in old leaves.[45] Under the comprehensive works of these enzymes, EGCG was preferred to be hydrolyzed to EGC in old leaves. Moreover, the antioxidant and anticancer activities of EGCG was the strongest among different catechins.[46] It might also contribute to the greater antioxidant activities of new leaves with high EGCG contents. The tea leaves with higher content of Se also had stronger antioxidant activity. For example, the highest contents of Se (0.241 *μ*g/kg) and tea polyphenols (28.29%) as well as the greatest antioxidant activities (DPPH, 95.06%; FRAP, 3.81 mmol of $FeSO_4$/g; reducing power 1.26) were found in new leaves of group C. It was known that Se played an important part in the formation of GSH-Px, which was an important antioxidant enzyme in the body and helpful to improve the antioxidant activity. Elements N and P were also the most important substances to constitute the enzymes such as nitrate reductase (NR), adenosine triphosphate (ATP), and nicotinamide adenine dinucleotide phosphate (NADP), which could therefore improve the antioxidant activities in tea leaves.[23]

The Al and Mn contents in tea leaves were significantly decreased by our new fertilizing strategies (with exogenetic Se, Zn, N and P), the functional component (polyphenol, catechins, free amino acid, polysaccharide and caffeine) contents of the tea leaves planted in acid soil were increased and their antioxidant activity was also improved. The function improvement of the tea leaves could reduce the potential harm and enhance the healthcare effect in humans.

[a]Error in the calculation of molecular formulas with label incorporation.

from QTOF. Accurate mass analysis was performed with the aid of ChemCalc.[9] Structural identification was performed using AMDIS (v. 2.65) and NIST Standard Reference Databases (data v. NIST05 and software v. 2.0d) in addition to isotope-labeling data. Isotope-labeling studies were performed through replacing glycine with its labeled analogue [^{13}C-1]glycine or [^{13}C-2]glycine (99%) or [^{15}N]glycine (98%) in the model systems mentioned above. Furthermore, the MS/MS data were compared with previously reported[10] mass spectra of (+)-catechin. The correspondence of the peaks to those generated through labeling experiments was verified through matching their retention times on the Hypersil Gold PFP liquid chromatography column.

RESULTS AND DISCUSSION

Although the interaction of ring A of catechin with Maillard reaction intermediates such as 1,2-dicarbonyl compounds is well established,[1,2] the interaction of catechins with amino acids has not been observed or reported yet mainly due to the fact that

dx.doi.org/10.1021/jf5005989 | J. Agric. Food Chem. 2014, 62, 3831−3836

such studies have been conducted in the absence of air or under nitrogen and, in theory, an oxidation step is necessary to generate reactive *o*-quinonoidal moieties[8] for their interaction with amino acids. In this study, (+)-catechin hydrate was heated alone or in the presence of glycine under oxidative conditions (open flask), and the reaction mixtures were analyzed by high-resolution ESI TOF/MS. Comparison of the reaction profiles of the two systems has indicated the formation of new chromatographic peaks in the (+)-catechin hydrate/glycine model system having masses higher than that of (+)-catechin. Furthermore, isotope-labeling studies with [^{13}C-1]glycine, [^{13}C-2]glycine, and [^{15}N]-glycine indicated the incorporation of one or two glycine moieties in five of the adducts identified as shown in Figure 1 and Table 1 (structures **1**−**5**). Two of these adducts (**1** and **5**) underwent dehydration of ring C of (+)-catechin, and in the remaining three adducts (**2**, **3**, and **4**) ring C remained intact.

Interaction Pathways of Glycine with Oxidized B-Ring of Catechin. The ability of glycine to undergo either single- or double-addition reactions with 1,2-dicarbonyl compounds in general[11] and with *o*-quinonoidal moieties in particular has been observed previously.[8,12] Detailed analyses of the adducts listed in Table 1 and shown in Figure 1 have indicated that structure **1** (shown as one possible isomer) observed at m/z 328 corresponds to a single-addition product of glycine to an oxidized (+)-catechin with subsequent dehydration of ring C. Alternatively, the initial Schiff base adduct (see Figure 1) can either undergo reduction to generate structure **2** at m/z 348 or react with a second molecule of glycine and then undergo reduction, this time generating structure **4** at m/z 405. In turn, structure **2** can undergo decarboxylation to generate structure **3** at m/z 304. Finally, structure **1** can undergo Strecker decarboxylation followed by isomerization of ring B and addition of a second molecule of glycine to generate structure **5** at m/z 341. The high-resolution mass spectral data obtained (see Table 2) for structures **1**−**5** confirmed their elemental composition

Table 2. Calculated Elemental Composition of (+)-Catechin−Glycine Adducts

structure	m/z	M	elemental composition	error[a] (ppm)
(+)-catechin	291	291.0812	$C_{15}H_{14}O_6$	7.5
1	328	328.0755	$C_{17}H_{13}NO_6$	3.7
2	348	348.1015	$C_{17}H_{17}NO_7$	2.9
3	304	304.1123	$C_{16}H_{17}NO_5$	5.4
4	405	405.1216	$C_{19}H_{20}N_2O_8$	0.91
5	341	341.1072	$C_{18}H_{16}N_2O_5$	3.7

[a]Error in the calculation of elemental composition.

consistent with the proposed structures. In addition, the label incorporation data using [^{13}C-1]glycine, [^{13}C-2]glycine, and [^{15}N]glycine further supported the proposed structures (see Table 1).

MS/MS Analysis of (+)-Catechin−Glycine Adducts. To provide additional detailed evidence for the proposed structures, the characteristic ion fragmentation patterns previously reported for catechin[13] and for flavones and flavonols[14] were compared with those observed for structures **1**−**5**. In general, catechins undergo MS/MS fragmentations when exposed to collision energies >10 V through bond cleavages of the central ring C and generating fragments that retain either ring A or ring B moieties (see Figure 2). According to the accepted nomenclature rules, a fragment generated under positive ion mode and retaining the ring B moiety through cleavage of bonds 0 and 2 of the ring C

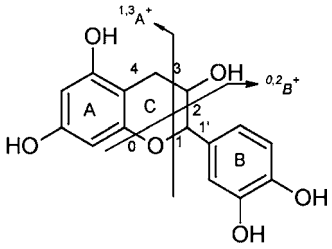

Figure 2. Nomenclature and C-ring bond cleavages in catechin.

could be designated fragment $^{0,2}B^+$ (see Figure 2). Such B^+ fragments could be used as diagnostic ions for the formation of amino acid adducts at ring B (in this case it was termed B_i^+, where i = 1, 2, 3, etc.) and A^+ fragments could be used to confirm the nature of adducts as originating from the catechin moiety. Among the five structures reported in Table 1 the adducts with nondehydrated C-rings (structures **2**−**4**) showed the characteristic A^+ and B^+ fragments of catechin and, on the other hand, the structures that underwent dehydration at the C-ring (**1** and **5**) showed only fragmentations originating from the amino acid moiety such as decarboxylation and Strecker type fragmentations (see Table 3). These observations are consistent with the fact

Table 3. Characteristic MS/MS Fragmentations Observed in Structures 1−5

proposed structures). It is interesting to note that none of the structures exhibited the known retro-Diels–Alder reaction route of flavonoid fragmentation[14] to generate $^{1,3}A^+$ or $^{1,3}B^+$ fragments. In addition, as expected, the structures with a dehydrated C-ring,

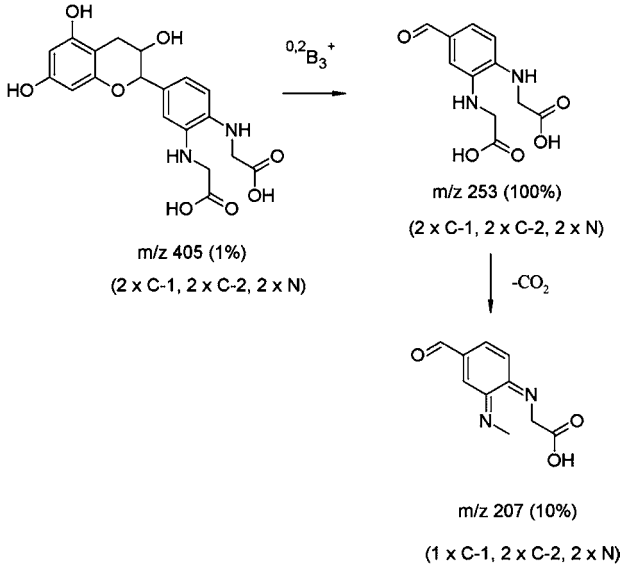

Figure 6. Proposed mass spectral fragments for structure **4**. Values in parentheses indicate the labeled atoms incorporated from glycine.

1 and **5**, did not show any of the characteristic fragmentations of catechins but exhibited fragmentations characteristic of amino acid derivatives (see Tables 4 and 8, as well as Figures 3 and 7).

Characteristic MS/MS Fragmentations of Structures 2, 3, and 4. Due to the presence of intact ring C in structures **2**, **3**, and **4**, it was not surprising to observe the characteristic fragmentations of catechin in these structures (see Figures 4−6 and Tables 5− 7). The fragmentations initiated through the cleavage of C-ring bonds can generate fragment ions retaining A- and B-ring moieties. In structures **2**, **3**, and **4** the $^{0,2}B^{+}$ series fragmentations generated base peaks at *m/z* 196, 152, and 253, respectively, and in general B series ions were found to predominate, allowing direct confirmation of the incorporation of glycine into ring B through isotope-labeling studies. Structures **2** and **3** also exhibited the A series fragmentations, further confirming the flavonoid origin of these structures. It is worth mentioning that the absence of the previously observed retro-Diels−Alder fragmentation pathway[14] could be due to the modifications in ring B structure induced by glycine.

Characteristic MS/MS Fragmentations of Structures 1 and 5. The dehydration of ring C in structures **1** and **5** precludes them from undergoing fragmentations initiated through the

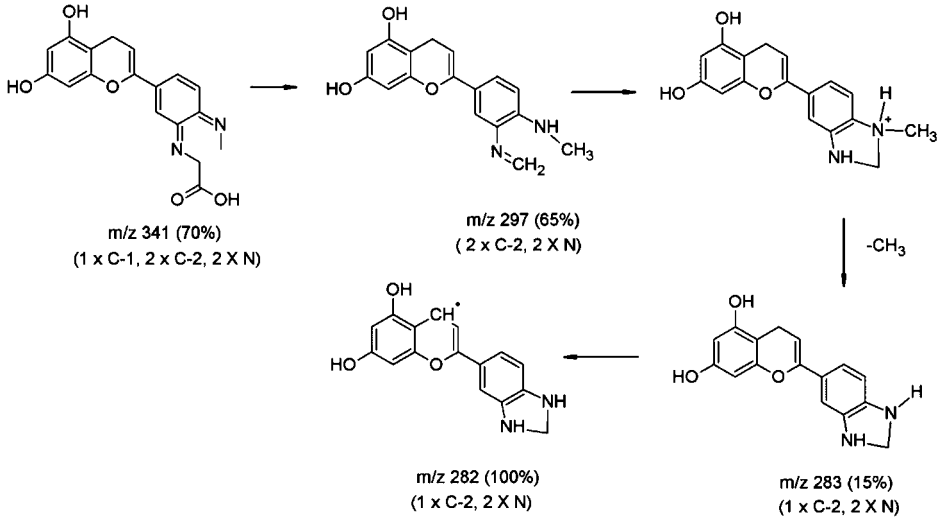

Figure 7. Proposed mass spectral fragments for structure **5**. Values in parentheses indicate the labeled atoms incorporated from glycine.

dx.doi.org/10.1021/jf5005989 | J. Agric. Food Chem. 2014, 62, 3831−3836

cleavage of C-ring bonds, and as a result they exhibit fragmentations initiated by the amino acid moiety such as decarboxylation and loss of alkyl groups of amino acids, preserving in these ions the integrity of rings A, B, and C (see Figures 3 and 7, as well as Tables 4 and 8). Interestingly, both structures **1** and **5** generated very stable 4*H*-chromen-4-yl radicals at *m*/*z* 269 and 282, respectively, as major radical ions in their MS/MS spectra. These radicals are stabilized through conjugation across both rings A and B. Formation of such radical cations under electrospray ionization conditions have been reported in the literature.[15]

It appears from the structural analysis of the products observed that the reaction of glycine and the oxidized form of catechin follows a pattern similar to that of other 1,2-dicarbonyls and leads to the formation of single- and double-addition products such as structures **2** and **4**. It seems the initial double Schiff base adduct on ring B is prone to reduction through disproportionation reaction coupled to catechin oxidation. Structures **2**, **3**, and **4** are such examples in which the oxidized moiety of catechin is reduced to its original oxidation state, and structures **1** and **5** represent examples of reaction products in which the reduced moiety is retained, most probably due to the additional stability gained through dehydration of the hydroxyl group in ring C. Formation of such nonvolatile (+)-catechin/amino acid adducts provides insight into how amino acids can have the potential of modifying the antioxidant properties of (+)-catechin through restoration of the oxidation state of ring B and how catechin-type structures interfere with the Maillard reaction in food through scavenging of amino acids.

Correction to Investigation of Ethyl Radical Quenching by Phenolics and Thiols in Model Wine

Gal Y. Kreitman, V. Felipe Laurie, and Ryan J. Elias*

J. Agric. Food Chem. **2013**, *61* (3), 685−692. DOI: 10.1021/jf303880g

We reported that we collected the data in negative-ion mode, but all of the *m*/*z* values reported are based on positive mode. The error appears in Materials and Methods, under the subheading HPLC-MS Analysis of PBN/1-HER Spin Adducts, which should read as follows:

HPLC-MS Analysis of PBN/1-HER Spin Adducts. Samples were diluted 1:20 in Millipore water and filtered over polytetrafluoroethylene (PTFE) syringe tip filters (0.45 μm, 13 mm; Acrodisc, Ann Arbor, MI, USA). The HPLC system consisted of a binary pumping system (Shimadzu LC-10ADvp) with high-pressure mixing and sample introduction by means of a Shimadzu SIL 10ADvp autosampler. PBN/1-HER spin adducts were separated on a ZORBAX Eclipse Plus C18 column (4.6 × 150 mm, 5 μm; Agilent Technologies, Santa Clara, CA, USA). The mobile phase consisted of 0.1% v/v formic acid (A) and 0.1% v/v formic acid in methanol (B). PBN/1-HER adducts were eluted by gradient according to the following program: 0 min, 0% B; 0−5 min, 80% B; 5−18 min, 90% B; 18−22 min, 90% B; 22−23 min, 0% B; 23−26 min, 0% B.

Detection and quantification of spin adducts were achieved using a Waters Quattro micro-triple-quadrupole mass spectrometer (Waters Laboratory Informatics, Milford, MA, USA) coupled to the HPLC. Mass spectra were collected in positive-ion mode using electrospray ionization (ESI). ESI capillary spray was held at 0.50 kV. Cone source voltage was set to 60 V, and source temperature was set to 120 °C. Desolvation gas flow was 250 L/h. Selected ion monitoring mode was set to monitor ions with *m*/*z* of 178, 222, 223, 224, and 268, which correspond to unreacted PBN, oxidized PBN/1-HER adduct, radical PBN/1-HER adduct, reduced PBN/1-HER adduct, and PBN-HER biadduct, respectively (Figure 1). Due to the complexity of having pure standards for all of these adducts, their quantification was performed on the basis of raw areas.

by *Alan Crozier* from the University of Glasgow, United Kingdom, showed data obtained from a combination of animal and human studies on the bioavailability and biological effects of berry phenolics. Similarly, *Wilhelmina Kalt*, from Agriculture and Agri-Foods Canada, presented data on the bioavailability and absorption of anthocyanins, particularly in animal tissues, after long-term blueberry intake. Finally, *Maurizio Battino* from the Università Politecnica delle Marche, Italy, presented recent data on the effects of a one-month strawberry supplementation study on markers of cardiovascular risk and oxidative stress in human subjects.

Session 2, Berries and Cancer. The cancer chemopreventive effects of bioactive food components, including phenolic compounds found in berry fruits, continues to attract significant research and public attention.[4,5] In this session, *Laura Kresty* from the Medical College of Wisconsin, Milwaukee, WI, presented data on the ability of a standardized proanthocyanidin-rich cranberry extract to prevent esophageal adenocarcinoma, and the underlying mechanisms of activity, in a clinically relevant rodent model. *Christine Sardo* from the University of Arizona presented data from two human clinical studies. The first evaluated the effects of a freeze-dried black raspberry powder on postprandial measures of inflammation in overweight and obese male adults. The second evaluated pooled analyses of data obtained from two large phase II, double-blind, placebo-controlled clinical trials, to elucidate the role of plant-based foodstuffs on the recurrence of colorectal adenomas. *Ramesh Gupta* from the University of Louisville focused his talk on "berry colored compounds", namely, anthocyanins, from blueberries for the prevention and treatment of different forms of cancers including lung, breast, and cervical cancers.

Session 3, Berries and Aging. With a growing aging population in the United States and other developed countries, and a concomitant increase in age-related and neurodegenerative diseases, this research area on food bioactives, especially berries, is of significant scientific and public interest. *Barbara Shukitt-Hale* from the USDA-ARS Jean Mayer Center for Aging at Tufts University, Boston, MA, presented data from an ongoing three month intervention study to evaluate the effects of a freeze-dried blueberry powder, compared to a placebo, on cognition and motor function in healthy older adults (60−75 years of age). This human study is building on previous published data showing that blueberry supplementation improves motor and cognitive function in rodent models of aging. *Elizabeth Devore* from Brigham and Children's Hospital Harvard Medical School, Boston, MA, presented data from the Nurses' Health study whose participants were administered food frequency questionnaires every four years (starting in 1980), and cognitive function in 16010 participants, aged ca. 70 years and older, were measured at two-year intervals (starting in 1995−2001). Impressively, this study showed that long-term berry and flavonoid intake led to slower rates of cognitive decline in older adults. *Robert Krikorian* from the University of Cincinnati Academic Health Center, Cincinnati, OH, discussed initial findings from a human clinical study with berry fruit supplementation in the context of age-related memory decline. These data suggested that moderate-term berry fruit supplementation can improve cognitive performance and enhance cerebral function in humans.

Session 4, Berries and Metabolism. *Ronald Prior* from the Department of Food Science, University of Arkansas, Fayetteville, AR, presented data showing that, irrespective of the berry source, in this case, cranberry, blueberry, and black raspberry, common phenolic acids and their conjugates are excreted in the urine of rats. *Dragan Milenkovic* from the National Institute for Agricultural Research, France, presented data showing the inhibition of plaque development by anthocyanins (from bilberries) in an apolipoprotein-E deficient atherosclerosis mouse model. Finally, *Rosalia Simmen* from the University of Arkansas, Fayetteville, AR, discussed data suggesting that early nutritional exposure of a freeze-dried blueberry powder to pregnant and lactating dams results in favorable breast cancer outcomes in their female offsprings in a transgenic mouse model of human breast cancer.

Session 5, Berries and Heart Health. *Britt Burton-Freeman* from the Institute for Food Safety and Health, Illinois Institute of Technology, Bedford Park, IL, presented data discussing the positive effects of strawberry consumption on risk factors for diabetes and cardiovascular disease in human subjects. In addition, this discussion called for further investigation of the effects of berry consumption on different physiological states, in particular the postprandial state, to minimize imbalances in stress, which ultimately lead to various diseases. *Ana Rodriguez-Mateos* from the University of Reading, United Kingdom, presented data from three separate randomized, controlled, double-blind, crossover human intervention trials showing that blueberry polyphenol intake improves endothelial function in healthy men. Finally, *Howard Sesso* from Harvard University, Cambridge, MA, presented a review of epidemiological data obtained from large cohort studies including the Women's Health Study, the Nurse's Health Study, and the Health Professionals Follow-up Study indicating the positive effects of berry consumption on cardiovascular disease outcomes. This discussion raised the need for consideration of complementary data obtained from basic science, clinical, and epidemiologic studies to maximize statistical power and identify mechanistically relevant scientific aims to increase our insights on the role of berries on cardiovascular disease prevention.

Session 6, Berries and Gut Health/Gut Microbiota. This area of research continues to evolve at a rapid pace as it is now well-known that polyphenol gut microbiota metabolites exert biological effects that extend beyond the native compounds alone (see ref 5 and relevant papers cited therein for detailed discussion on this topic). *Jess Reed* from the Department of Animal Sciences, University of Wisconsin—Madison, Madison, WI, presented an overview of gut metabolism and the role that berry polyphenols play in gut health. *Dhanansayan Shanmuganayagam*, also from the University of Wisconsin—Madison, WI, presented data on the ability of cranberry proanthocyanidins to stimulate the mucosal immune system in a mouse model of elemental enteral nutrition-induced mucosal immune dysfunction. Finally, *Li Shu Wang* from the Department of Medicine, Medical College of Wisconsin, Milwaukee, WI, presented data from a human clinical study in colorectal cancer patients consuming black raspberry powder for 9 weeks. The data showed that black raspberry consumption resulted in modulation of enzymes associated with fatty acid metabolism, leading to decreased proliferation and inflammation in the colorectal cancer patients.

In conclusion, it is apparent that berry fruits have a positive impact on human health and disease risk reduction as was heard yet again at another very successful symposium. Given this research trajectory, I look forward with great anticipation to the new findings that will be presented in two years at the 2015

BHBS. Finally, I thank the *Journal of Agricultural and Food Chemistry*, all of the donors and participants of the 2013 BHBS symposium, and the authors who have contributed to the cluster of papers presented here.

Figure 1. Structures of the major berry anthocyanidins.

Oligomeric and polymeric proanthocyanidins have an additional chiral center at C-4 in the "upper" and "lower" units. Type B proanthocyanidins are formed from (+)-catechin and (−)-epicatechin by oxidative coupling between the C-4 of the "upper" monomer and the C-6 or C-8 of the adjacent "lower" or "extension" unit to create oligomers or polymers, and they are present in blueberries, for example. Type A proanthocyanidins have an additional ether bond between C-2 in the B-ring of one monomer and C-7 in the A-ring of the other monomer (Figure 2), and they are found in cranberries. Proanthocyanidins can occur as polymers of up to 50 units. Proanthocyanidins that consist exclusively of (epi)catechin units are called procyanidins and are the most abundant type of proanthocyanidins in plants.[9]

The nonflavonoids present in berries include hydroxycinnamates, such as the chlorogenic acids, of which 5-*O*-caffeoylquinic acid is the most widely distributed and which has been found in substantial amounts in blueberries.[11] Other hydroxycinnamates include ferulic acid and *p*-coumaric acid.[10] Berries can also contain phenolic acids, including gallic acid, whereas ellagic acid-based ellagitannins, such as sanguiin H-6 (Figure 2), have a much more widespread occurrence, being found in a diversity of berries including raspberries, strawberries, and blackberries. Stilbenes, such a resveratrol-3-*O*-glucoside (Figure 2), occur in some berries but typically in relatively small amounts.

EVIDENCE FROM EPIDEMIOLOGICAL STUDIES

Epidemiological studies suggest that the daily intake of berry flavonoids, in particular, anthocyanins, may have cardioprotective effects in humans.[4−7,12] The Iowa Women's Health prospective study followed nearly 35,000 postmenopausal women for 16 years and estimated the intake of seven flavonoid subclasses using the USDA database. The intake of anthocyanins was associated with a reduced risk of coronary heart disease (CHD) and CVD-related mortality.[7] This study also highlighted bran, apple, pear, chocolate, red wine, and strawberries as being the foods most likely to contribute significantly to reductions in disease risk. A more recent prospective study has found an inverse correlation between flavonoid intake and risk of death from CVD in a population of nearly 100,000 men and women of around 70 years of age.[6] In this study, a higher intake of flavonoids (512 vs 94 mg/day) was associated with an 18% lower risk of CVD death. In addition, anthocyanins, flavan-3-ols, flavonols, proanthocyanidins, and flavones were also associated with a 14−17% lower risk of CVD death.

Some data have been obtained with even younger populations, in particular, women, whose CVD risk increases significantly after menopause. A 2013 study found an association between higher anthocyanin intake and a 32% decrease in the risk of myocardial infarction (MI) in nearly 100,000 women 25−45 years of age, after a follow up period of 18 years.[4] For every 15 mg increase of anthocyanins in their diet, a 17% decrease in the risk of MI was observed. Strawberry

and blueberry intake also tended to be associated with a decrease in risk.

Cardiovascular health is determined by not only the absence of CVD but also the function of the cardiovascular system. A cross-sectional study investigated nearly 2000 women between 18 and 75 years old for 11 years and found an inverse correlation between a higher anthocyanin intake and lower arterial stiffness and central blood pressure.[12] An increase in the diet of 44 mg of anthocyanins/day was associated with a decrease in systolic BP of 3 mmHg and a decrease in pulse wave velocity (PWV) of 0.4 m/s. Interestingly, berries and red wine were also associated with a decrease in PWV. Furthermore, a large prospective study in men and women under 60 years of age that were followed up for 14 years also showed an association between a higher anthocyanin intake in their diets, mainly from strawberries and blueberries, and an 8% reduced risk of incident hypertension.[5]

Despite these encouraging data sets, there are several epidemiological studies that have found no relationship between berry flavonoid intake and cardiovascular risk.[13−17] Discrepancies between studies of this nature may be due to inadequacies in the ability of commonly used dietary intake questionnaires and food composition tables to accurately assess flavonoid intake in human populations or may even result from issues surrounding the nature of the human population studied with, for example, populations with a high baseline flavonoid intake showing no effect. To avoid such discrepancies, future observational studies must attempt to assess flavonoid intake via the analysis of reliable biomarkers of their intake in plasma, urine, or stool samples.

EVIDENCE FROM RANDOMIZED CONTROLLED TRIALS

Although epidemiological investigations are showing promising results regarding the potential role of berry (poly)phenols in cardiovascular health, as described in the previous section, to confirm if such observations are genuine and to build potential cause-and-effect relationships between berry (poly)phenols and clinically relevant end points of CVD risk, RCTs are necessary, as they are the most reliable method to investigate cause-and-effect relationships. In recent years, several such trials have been conducted, although many exhibit profound limitations. The most important limitations include lack of blinding, absence of proper controls, and lack of detailed compositional analysis of the foods that were tested. For example, to make inferences related to potential causal relationships between (poly)phenol intake and the clinical outcomes being assessed, a suitable control intervention is essential. Ideally, controls should be indistinguishable in taste and appearance from the intervention tested and accurately matched for micro- and macronutrient composition, including other potential bioactive compounds. So far, the basic understanding of berry (poly)phenol pharmacokinetics is incomplete, and to date the absorption and metabolism of many berry (poly)phenols have not been investigated. It is an important prerequisite to assess whether (poly)phenols, or more likely their metabolites, are indeed entering the circulatory system and may only then qualify for mediating the observed effects.

To date, no RCTs have investigated the effects of berry (poly)phenols on hard CVD end points, such as MI, or CVD mortality. However, there have been a number of short-term, small-scale, human intervention studies designed to test the effect of (poly)phenol-rich berries on prognostically validated surrogate markers of CVD risk, including hypertension, endothelial dysfunction, arterial stiffness, lipid metabolism, and platelet activation. In this section, we will discuss the most relevant human RCTs, in which at least one of these markers has been assessed.

Effects on Blood Pressure. Hypertension is a major risk factor for CVD and has been associated with the development of atherosclerosis and the progression of the disease.[18] Several studies have investigated changes in blood pressure after intake of blueberries,[19−24] chokeberries,[25] cranberries,[26−29] strawberries,[30,31] elderberries,[32] black currants,[33] mixed berries,[34] or purified anthocyanins[35−37] (Table 1). The length of these studies ranged from 1 to 90 days, and the study populations consisted mainly of people at risk or with CVD, but in a few studies healthy individuals were also tested.[21,24,32,33,38] From these investigations, only two double-blind RCTs, conducted with MI survivors and hypercholesterolemics, have shown improvements in blood pressure after berry consumption.[25,37] A 6 week supplementation with a chokeberry extract containing 64 mg of anthocyanins, 128 mg of procyanidins, and 23 mg of phenolic acids showed decreases in both systolic (SBP) and diastolic (DBP) blood pressure by 11 and 7.2 mmHg, respectively, in 44 MI survivors receiving statin therapy.[25] In another double-blind RCT, a decrease in SBP of 6.7 mmHg was observed in hypercholesteromic individuals after 12 weeks of daily consumption of 320 mg of berry anthocyanins in comparison to baseline values. However, when compared with the placebo group, the change in SBP was not significant.[37]

In addition, two single-blinded RCTs have reported changes in blood pressure.[20,34] Decreases in SBP of 6% and in DBP of 4% were observed after a 56 day supplementation with freeze-dried blueberries containing 1624 mg of total (poly)phenols and 742 mg of anthocyanins (equivalent to 350 g of fresh berries) by individuals with metabolic syndrome (MS).[20] Although smaller, significant reductions in blood pressure were also observed in the control group (decreases of 1.5 and 1.2% in SBP and DBP, respectively). The control intervention consisted of 950 mL of water per day, which was the same amount of water taken with the blueberry drink by the volunteers on the blueberry intervention arm. Another single-blinded study has shown a modest decrease in systolic blood pressure (1.2%) after an 8 week consumption of a mixture of bilberries, lingonberries, black currants, strawberry puree, and chokeberry and raspberry juice (837 mg of total (poly)phenols, 515 mg of anthocyanins) by a middle-aged population at risk of CVD.[34] The control used in this study was a mix of porridge, sugar water, and marmalade sweets. The results of those two studies should be interpreted with caution as these studies were not double-blinded, and controls were not macro- and micronutrient-matched to the berry intervention.

In most of the investigations mentioned above, blood pressure was not the primary outcome of the study. Furthermore, with one exception, none of the studies used 24 h ambulatory blood pressure, which is the gold standard technique for the measurement of blood pressure. In a double-blind crossover RCT, Hassellund and colleagues[35] investigated the effects of a 4 week supplementation of purified berry anthocyanins (2 × 320 mg) on sitting, supine, and 24 h ambulatory blood pressure in 27 healthy men with blood pressure >140/90 mmHg. No changes in sitting systolic blood pressure (primary end point), supine, or ambulatory blood

pressure after anthocyanin supplementation were observed in this study.

In summary, there is not enough evidence to support the involvement of berry (poly)phenols in lowering blood pressure. More controlled intervention studies in relevant populations over adequate time scales are required.

Effects on Endothelial Function. In the context of prognosis, endothelial dysfunction is an important process underlying the development and progression of atherosclerosis.[39] It is characterized by decreased bioactivity of nitric oxide and impaired flow-mediated vasodilation (FMD). Measurement of FMD of the brachial artery using high-resolution ultrasound is the most widely used validated method to assess endothelial function in humans.[40] Several studies have tested the effect of (poly)phenol-rich foods on FMD. The strongest evidence is the positive effects of flavan-3-ol-rich foods, such as cocoa or tea, on endothelial function after acute or short-term supplementation.[8,41] However, limited data exist regarding the effects of berry consumption on endothelial function (Table 1),[21,23,24,27,33,37] with only four RCT studies having investigated the effects of berry (poly)phenols on FMD.[24,27,37]

A recent double-blind crossover RCT conducted with healthy young men has shown significant improvements in FMD at 1, 2, and 6 h postconsumption of a wild blueberry drink containing 766−1791 mg of total (poly)phenols (310−724 mg of anthocyanins, 137−320 mg of procyanidins, and 273−637 mg of 5-*O*-caffeoylquinic acid).[24] The effects observed at 1−2 h were correlated with increases in plasma metabolites possibly derived from the metabolism and/or breakdown of anthocyanins and 5-*O*-caffeoylquinic acid, whereas the effects observed at 6 h were linked to gut microbial metabolites. A second crossover RCT, with a very similar population, investigated the intake dependency of blueberry (poly)phenols on FMD. This revealed that FMD increased with increasing intake from 319 to 766 mg of total (poly)phenols (129−310 mg of anthocyanins, 57−137 mg of procyanidins, 114−273 mg of 5-*O*-caffeoylquinic acid, equivalent to 100−240 g of fresh blueberries), after which FMD plateaued.[24] The effects on FMD observed are likely to be at least in part related to the anthocyanin content of blueberries, as in a crossover study with 12 hypercholesterolemic individuals, 1 and 2 h after acute consumption of a purified bilberry and black currant anthocyanin extract (320 mg of anthocyanins), FMD improved, by 2.7 and 1.8%, respectively, in parallel with the increases in plasma anthocyanin levels.[37] The magnitude of the changes in FMD were very similar to those obtained after consumption of blueberries (2.4 and 1.5% at 1 and 2 h, respectively). The short-term effects of anthocyanin consumption were also investigated in a parallel study with 150 hypercholesterolemic individuals, with a 2.8% increase in FMD observed after a 12 week supplementation.[37] Another study with cranberry juice failed to show an improvement on FMD after a 4 week supplementation by 44 CHD patients. However, an uncontrolled pilot study with 15 of these patients showed a 1% improvement in FMD 4 h after cranberry juice consumption.[27]

Some studies have used alternative techniques, such as peripheral artery tonometry (PAT) of the fingertips, to measure endothelial function. No changes were observed in acute endoPAT vascular function in healthy volunteers after consumption of 300 g of blueberries containing 348 mg of anthocyanins (1 h postconsumption).[21] Similarly, no changes in endoPAT were observed after a 6 week supplementation with a blueberry drink (375 mg of anthocyanins, 127 mg of 5-*O*-caffeoylquinic acid) by men at risk of CVD.[23] In another study, laser-Doppler iontophoresis was used to measure cutaneous perfusion microvascular function, with no improvements observed 2 h postconsumption of black currant juice by healthy volunteers.[33] More studies are needed to confirm that (poly)phenol-rich berries can improve endothelial function, in particular, over longer periods of time with healthy populations.

Effects on Arterial Stiffness. Arterial stiffness has been associated with the risk of CVD, and increased arterial stiffness is a recognized cardiovascular risk factor.[42−44] PWV, in particular, carotid−femoral PWV, is considered the most robust and reproducible method for measuring arterial stiffness.[43] A crossover RCT involving volunteers with coronary artery disease (CAD) showed a decrease in carotid−femoral PWV of 0.5 m/s after consumption of cranberry juice (835 mg of total (poly)phenols, 94 mg of anthocyanins) for 4 weeks.[27] In contrast, acute supplementation of a blueberry drink (766−1791 mg of total (poly)phenols, 310−724 mg of anthocyanins, 137−20 mg of procyanidins, 273−637 mg of 5-*O*-caffeoylquinic acid) had no effect on carotid−femoral PWV in healthy men.[24] Arguably, this suggests that chronic berry supplementation may be necessary to induce improvements in arterial stiffness in healthy young men.

Augmentation index (AI), another marker of arterial stiffness, has also been correlated with cardiovascular risk.[43,44] RCTs have found no changes in AI after a 4 week supplementation with cranberry juice (400 mg of total (poly)phenols, 21 mg of anthocyanins) by obese volunteers[23] and a 6 week supplementation with a blueberry drink (375 mg of anthocyanins, 127 mg of 5-*O*-caffeoylquinic acid) by subjects at risk of CVD.[29] To date, insufficient evidence exists to correlate berry (poly)phenol intake and improvements in arterial stiffness, although data from a well-conducted double-blind RCT with cranberry juice described above[12] and a cross-sectional study described in the epidemiology section,[27] in which a decrease in PWV was reported to be associated with a higher intake of anthocyanins in the diet and with berry intake, are promising.

Effects on Blood Lipids. Hypercholesterolemia is one of the major risk factors for the development of CVD. In particular, low-density lipoprotein-cholesterol, high-density lipoprotein-cholesterol, and total serum cholesterol levels (LDL-C, HDL-C, TC, respectively) have been related to cardiovascular risk.[45,46] The strongest evidence regarding the effect of berry (poly)phenols on blood lipids comes from studies conducted in dyslipidemic populations using purified bilberry and black currant anthocyanin extracts (Table 1). A 12 week study with bilberry and black currant anthocyanins (160 mg/day) involving 120 dyslipidemic subjects reported an increase of 14% in HDL-C and a decrease in LDL-C of 14%, with no changes in TC or triglycerides (TAG).[36] In a parallel study with a similar population of hypercholesterolemics, daily consumption of 320 mg of bilberry and black currant anthocyanins resulted in a 12% increase in HDL-C, a 10% decrease in LDL-C, and no changes in TC or TAG.[37] The same investigators also reported a 14% increase in HDL-C and a 10% decrease in LDL-C when the daily 320 mg anthocyanin intake by the same or similar populations was extended to 24 weeks.[47] This suggests that long-term berry consumption leads to sustained and clinically relevant improvement in blood lipids.

In addition to these studies with pure anthocyanins, several studies have shown that similar effects on blood lipids can be observed following berry supplementation (Table 1). A 3 week RCT with freeze-dried strawberries (equivalent to 320 g fresh weight) produced a decrease in TC of about 4% in obese individuals, with no changes in HDL-C, LDL-C, or TAG.[31] Unfortunately, the (poly)phenol content of the freeze-dried strawberries was not determined. The authors speculated that the 8 g of fiber in the intervention may have been partly responsible for the observed effects, as the control was matched for sugars, flavor, and color but not for fiber. A strength of this study is that the background diet was strictly controlled over the intervention, with all subjects following a controlled diet starting 1 week before initiation of the intervention and maintained during the 7 week supplementation period. However, no washout period between the intervention and the control arm was included, which may have confounding effects on the outcomes of the study due to potential carry-over effects. Another 4 week study with freeze-dried strawberry powder (equivalent to 500 g of fresh weight, 200 mg of total (poly)phenols, 154 mg of anthocyanins) in MS subjects produced 10 and 11% decreases in TC and LDL-C, respectively.[30] This RCT was single blinded as the control arm consisted of four cups of water, which was the amount of liquid ingested with the strawberry intervention. Thus, the control was not matched to the strawberry intervention for macro- and micronutrients.

With cranberry, decreases in LDL-C and TC were observed in 32 type 2 diabetics after daily consumption of 3 × 500 mg of an encapsulated cranberry extract over 12 weeks.[28] HDL-C and TAG did not differ between the intervention and control arms. Unfortunately, the (poly)phenol content of the intervention was not reported, so it is difficult to draw conclusions on the cause and effect relationship between the effects observed and the (poly)phenol amount ingested. In contrast to these findings, no changes were observed in three RCTs with cranberry interventions involving MS, type 2 diabetes, and healthy individuals,[26,48,49] or after black currant, blueberry, chokeberry, and elderberry supplementation in healthy individuals, subjects with CVD risk factors, and MI survivors (Table 1).[19,25,32,33,38] In a single-blinded study, a 5% increase in HDL-C was reported after 8 weeks' consumption of mixed berries (837 mg of total (poly)phenols, 515 mg of anthocyanins) by a middle-aged population at risk of CVD,[34] with no changes in TAG, TC, and LDL-C being observed.

Taken together, there is consistent evidence on the favorable effects of 12−24 week daily intake of 160−320 mg of anthocyanins on blood lipids in dyslipidemic individuals, and some evidence exists regarding improvements in obese/MS subjects after strawberry supplementation for 3−4 weeks. The potential beneficial effects of other berry (poly)phenols on blood lipids is at present unclear.

Effects on Platelet Aggregation. Another significant effect that has been attributed to (poly)phenols is the ability to inhibit platelet activation and, thus, the formation of blood clots, a key mechanism implicated in the pathophysiology of atherosclerosis. Platelets play an important role in the early stages of atherosclerosis and coronary thrombosis, and several studies have reported an inhibition of platelet activation after consumption of cocoa flavan-3-ols.[50,51] Only two RCTs have investigated the effect of berry (poly)phenol consumption on platelet activation and aggregation (Table 1). In a 12 week double-blind RCT, no changes were reported in platelet reactivity in response to stimulation to ADP and collagen after daily consumption of 500 mg of elderberry anthocyanins by healthy postmenopausal women.[32] In contrast, a single-blinded study has shown a decrease in platelet aggregation after consumption of mixed berries (837 mg of total (poly)phenols, 515 mg of anthocyanins) for 8 weeks by a middle-aged population at risk of CVD.[34] Berry consumption inhibited platelet function by 11% as measured with a platelet function analyzer using collagen and ADP as platelet activators. Double-blind RCTs are needed to confirm these interesting observations.

Effect on Blood Glucose Levels and Insulin Resistance. Most of the RCTs conducted with berries have reported no changes in serum glucose levels after cranberry, blueberry, strawberry, elderberry, chokeberry, or pure anthocyanin interventions (Table 1),[19,23,25,28,31,32,36,37,48] except for one study with 31 prehypertensive men who received a daily supplement of 640 mg of purified bilberry and black currant anthocyanins for a period of 1 month.[52]

One RCT produced an improvement in insulin sensitivity after consumption of a blueberry smoothie for 6 weeks (1462 mg of total (poly)phenols, 668 mg of anthocyanins) by obese, nondiabetic insulin-resistant individuals.[19] This study used the gold standard technique for the measurement of insulin sensitivity, the hyperinsulinemic−euglycemic clamp, and observed a 22% improvement in the blueberry group as compared with 5% in the control group. Two studies investigating insulin resistance in type 2 diabetics and dyslipidemics in a cranberry and purified anthocyanin intervention detected no changes in the homeostatic model of assessment of insulin resistance (HOMA-IR).[28,37] This is a less invasive, cheaper, and less labor intensive model for assessing insulin sensitivity, but it has certain limitations. More work is needed to investigate whether berry (poly)phenols can lower blood sugar and improve insulin resistance, with the potential of being therapeutic agents for the treatment of diabetes.

MECHANISMS OF ACTION

As well as providing evidence on the efficacy of berry (poly)phenols to improve cardiovascular risk surrogates, several RCTs have attempted to supply evidence for potential mechanisms of action. For example, Zhu et al.[37] reported an increase in serum cGMP in hypercholesterolemics after a 12 week supplementation with 320 mg of purified anthocyanins, and this was paralleled by increases in FMD ($r = 0.428$, $p < 0.05$). Importantly, when an intravenous infusion of L-*N*-monomethylarginine (L-NMMA), a competitive nitric oxide synthase (NOS) inhibitor, was given to six participants, the beneficial effects of the anthocyanins on FMD were abolished, and significant changes in hyperemic blood flow and blood pressure were observed between the anthocyanin and L-NMMA/anthocyanin interventions. This suggests that the mechanism of action of anthocyanins in the vasculature involves the nitric oxide/cGMP signaling pathway. It has recently been shown with healthy volunteers, 1, 2, and 6 h postconsumption, that blueberry-related increases in FMD were correlated with plasma levels of blueberry (poly)phenol metabolites and decreases in neutrophil NADPH oxidase activity.[24] The phenolic metabolites have a structure similar to the NADPH oxidase inhibitor apocynin (acetovanillone), and it has been proposed that in an in vitro model of endothelial cells they act as potent NAPDH oxidase inhibitors.[53] A decrease in

NADPH oxidase activity has previously been linked to alterations in nitric oxide levels via inhibition of superoxide production,[53,54] and the inhibition of NADPH oxidase activity has been proposed as the main mechanism mediating the short-term improvements in FMD observed after consumption of (−)-epicatechin.[55] These findings suggest that blueberry (poly)phenol metabolites may mediate improvements in endothelial function by increasing the bioavailability of nitric oxide via their potential to inhibit NAPDH-oxidase. However, further work is needed to confirm whether this is indeed the case.

In another study with purified berry anthocyanins in dyslipidemics, anthocyanins were shown to decrease the mass and activity of plasma cholesteryl ester transfer protein (CETP), a plasma protein that mediates the removal of cholesteryl ester HDL in exchange for a triglyceride molecule derived primarily from LDL, VLDL, or chylomicrons. The decreased levels of this protein have been suggested as a possible mechanism for the increase in HDL-C and decrease in LDL-C.[36] It was also found that changes in HDL-C correlated with the changes in CETP activity and that changes in LDL-C correlated with changes in CETP mass, whereas changes in cellular cholesterol efflux to serum positively correlated with changes in HDL-C. Thus, it is feasible to hypothesize that anthocyanins may act as CETP inhibitors.[36]

Numerous in vitro and animal studies have been conducted to investigate the mechanisms of action of berry (poly)phenols. Of note, many of these investigations using cell lines have made extensive use of berry extracts, (poly)phenolic aglycones, or sugar conjugates, at concentrations in the low micromolar to millimolar range. However, following ingestion, most berry (poly)phenolics appear in plasma not as the parent compound but as phase II metabolites, and their presence in the circulation after dietary intake rarely exceeds nanomolar concentrations. With in vivo studies, the same issues apply. When animal studies, such as human RCTs, are conducted, experimental design is of importance and should take into account factors such as a suitable control, characterized intervention, and blinding. Much of the in vivo mechanistic evidence comes from studies conducted with apoE deficient mice, a widely used animal model of accelerated atherosclerosis. Using this model, after a 20 week supplementation with a diet containing 1% freeze-dried blueberries, fewer atherosclerotic lesions were observed, with a decrease of 39% in the lesion area of the aortic sinus and a 58% decrease in the descending aorta.[56] These effects were independent of the blood lipid profile and the total plasma antioxidant capacity. Furthermore, four major antioxidant enzymes were up-regulated in blueberry-fed mice (superoxide dismutase (SOD) 1 and 2, glutathione reductase (GSR), and thioredoxin reductase 1), with the activities of SOD and GSR being higher in the liver and serum. An increase in hepatic SOD and GSR has also been reported together with an increase in plasma paraoxonase activity after intake of raspberry juice for 12 weeks by Syrian golden hamsters fed an atherogenic diet.[57] These studies suggest a potential mechanism of action for berries against atherosclerosis by inhibition of lipid peroxidation and enhancement of antioxidant defenses. Similarly, supplementation of apoE deficient mice with a 0.02% bilberry extract for 16 weeks inhibited plaque development.[58] Microarray analysis of the liver and the aorta of the animals after a 2 week supplementation with the bilberry extract indicated modulated gene expression, with respective changes in 2289 and 1261 genes involved in various cellular and molecular pathways such as cholesterol metabolism, inflammatory process and cell adhesion, oxidative stress, inflammation, angiogenesis, and transendothelial migration.[59,60] Another study with apoE deficient mice fed a 1% freeze-dried blueberry diet for 20 weeks reported that the supplement attenuated foam cell formation, which is an early stage of the development of atherosclerosis, by down-regulating the scavenger receptors SR-A and CD36, which are the major receptors responsible for the binding and uptake of modified LDL in macrophages.[61] (Poly)phenol colonic catabolites found in the serum of mice after blueberry consumption were also shown to inhibit mRNA expression and protein levels of pro-inflammatory cytokines TNF-α and IL-6, by reducing phosphorylation levels of MAPK JNK, p38, and Erk 1/2 in a murine macrophage cell line.[62] In a study using diabetic apoE deficient mice, supplementation with 0.2% cyanidin-3-*O*-glucoside for 6 weeks lowered the aortic lesion area by 45%, improved endothelium-dependent vasorelaxation, and increased the capacity of in vitro adhesion to fibronectin, migration, and tube formation of endothelial progenitor cells (EPCs).[63] The mechanism for these improvements involved higher phosphorylation levels of AMP-activated protein kinase Thr 172 and endothelial nitric oxide synthase Ser1177 in EPCs derived from the cyanidin-3-*O*-glucoside-treated diabetic mice compared with those in nondiabetic mice.

Physiologically relevant berry supplementations in different animal models, such as rats, Syrian golden hamsters, or pigs, have shown an array of beneficial effects such as reduced mortality after induced MI, inhibition of aortic lipid deposition, lowering of blood pressure, improvements in endothelium-dependent vasorelaxation, and decreases in plasma TC and LDL-C.[57,64−70] More efforts are needed to confirm the mechanisms that have been proposed to mediate the observed effects, using relevant in vivo models or in vitro models with circulating metabolites and microbial catabolites at biological concentrations.

SUMMARY

Although evidence for the cardiovascular benefits of berry (poly)phenols in humans is accumulating, their role in the prevention of CVD is, at present, unclear. Recent epidemiological studies have shown associations between higher berry flavonoid intake and lower risk of CVD, and a number of small-scale, human intervention studies have shed some light on the beneficial effects of various berry (poly)phenol-rich foods on surrogate markers of CVD risk. Whereas there is some evidence to suggest that acute and/or short-term consumption of berry (poly)phenols can have a positive effect on blood lipids or vascular function, the long-term effects of berry interventions are currently unknown, and RCTs with hard clinical end points are lacking. As a consequence, uncertainty remains regarding which specific (poly)phenols are directly responsible for beneficial actions in vivo, as berries contain not only anthocyanins but a diversity of (poly)phenolic compounds.[9] Investigations using pure anthocyanins are encouraging, suggesting that anthocyanins may be at least mediating part of the observed beneficial effects. Few studies have assessed the absorption and metabolism of berry (poly)phenols, which is a critical factor in establishing potential cause-and-effect relationships. More short- and long-term double-blind randomized studies, using well-characterized interventions and adequate controls and clinically relevant end points, are needed before conclusions can be drawn regarding their efficacy. The outcomes of such studies may help to elucidate the role of

berry (poly)phenols in the prevention of CVD risk and may be used to make specific dietary recommendations regarding berry consumption to the general population.

by differences attributable to environmental conditions, ripeness at harvesting, and storage conditions. Additionally, the wide variety of structures and conjugates of (poly)phenols makes estimation in food substances extremely difficult, and therefore data on dietary intake are scarce. However, the recently developed and updated Phenol-Explorer database provides much useful information.[15] In a recent study by Pérez-Jiménez and co-workers,[16] daily consumption of total (poly)-phenols in a French population was estimated as 820 ± 335 mg/day (aglycone equivalents), which was similar to that previously observed in a Finnish cohort (863 ± 415 mg/day).[17] In both studies phenolic acids were the main (poly)phenols consumed, with intake in the Finnish cohort being twice that of the French cohort. The anthocyanin intake was reported to be marginally higher in the Finnish cohort than in the French at 47 ± 79 and 35 ± 29 mg/day (aglycone equivalents), respectively. The large variations evident in consumption likely reflect individual preferences, but it was not surprising that berries were a more prominent source of (poly)phenols in the Finnish diet than in the French.

Ileostomy feeding studies have demonstrated that substantial amounts of (poly)phenolic compounds in berries are not absorbed into circulation from the small intestine but rather pass into the large intestine where,[18,19] it is reasonable to infer, they come into direct contact with the colonic epithelium.[20,21] Moreover, the microbiota within the colon plays a key role in the fate of phytochemicals that are not absorbed in the small intestine. Once in the colon, berry (poly)phenolics are subject to the fermentative action of the microbiota, with catabolism giving rise to a diversity of phenolic acids.[19,22] Moreover, fermentable carbohydrates (fiber) present in whole foods such as berries might act in synergy with the mixture of (poly)phenols present in berries and contribute to their overall antigenotoxic activities, as these fermentable dietary fibers can beneficially modulate both the composition and metabolic output of the human gut microbiota.[23]

Several theories on the anticancer activity of (poly)phenols are supported by an expanse of data demonstrating the potential mechanisms involved. The most studied effects are those that modify proliferation and apoptosis, and these have been extensively reviewed elsewhere.[24] Other mechanisms responsible for the putative anticancer activity are still not fully understood but may include scavenging free radicals, induction of enzymes involved in metabolism of xenobiotics,[25] regulation of gene expression, and modulation of cellular signaling pathways including those involved in DNA damage detection and repair.

This review aims to assess the in vitro and in vivo evidence for anticancer activities for whole berries and berry extracts focusing particularly on the genoprotective element of these compounds.

DNA DAMAGE AND CANCER

DNA damage has a key role in cancer development. The initiating step in CRC development involves exposure to, or uptake of, carcinogens, resulting in permanent DNA damage. Considering the potentially toxic nature of the colon contents, it is not unsurprising that frequent mutations occur in colonic cells. Therefore, efficient DNA damage detection and repair mechanisms are present to prevent damage becoming a permanent sequence change. However, errors in detection and repair mechanisms may occasionally occur. Thus, reducing the frequency of DNA damage or enhancing the repair mechanisms may be a feasible explanation for the protective effects of berry (poly)phenols against initiation of CRC.

Unrepaired DNA damage can become incorporated into the genome as a permanent sequence change if the cell divides before the damage is repaired. For example, CRC is characterized by a multistep pathway involving sequential mutations and deletions of key oncogenes and tumor suppressor genes such as *APC*, K-*ras*, and *p53* in epithelial cells.[26] These genetic changes result in evasion of cell signaling pathways and cell cycle control points, leading to hyperproliferation, avoidance of apoptosis, and eventual invasion and metastasis. Under normal cellular conditions, reactive oxygen species (ROS) such as superoxide anions ($^{\bullet}O_2^-$) and hydroxyl radicals ($^{\bullet}OH^-$) are produced by endogenous metabolism and used by the cell to modulate biological processes; for example, the generation of ROS can lead to activation of receptors including G protein-coupled receptors, tyrosine, and serine/threonine kinases.[27] Downstream signaling components are stimulated as a response, and these include MAPK and protein kinase C, which are tightly regulated and are involved in proliferation, differentiation, cell survival, and apoptosis.[28] However, ROS production has also been implicated in sequential tumor development by a number of routes.[27] Reaction of ROS with DNA results in the formation of oxidized DNA bases, apurinic/apyrimidinic sites (AP sites), or DNA strand breaks. In particular, 8-oxo-7,8-dihydro-2′-deoxyguanosine (8-OHdG) is one of the most easily formed oxidative DNA lesions. Moreover, 8-OHdG can react with compounds such as peroxynitrate to produce further mutagenic lesions.[29]

ROS also react with phospholipids in the cell membrane and form lipid peroxidation products such as 4-hydroxynonenal, which in turn can react with DNA and to form cyclic-DNA adducts.[30] Other abundant lesions of oxidative DNA damage, which are also highly mutagenic, result from GC to TA transversions.[31]

ROS assault on cells in areas prone to DNA damage increases the probability that changes will go unrepaired and lead to conformational changes of the structure of DNA, rendering replication more difficult and error prone.[32,33] Furthermore, ROS may contribute toward carcinogenesis through differential regulation of cell signaling pathways. For example, modulation of MAPK, Jak/STAT, heat shock response, and PI3K/Akt pathways will affect gene expression, and, if activated, can in certain circumstances stimulate growth.[34,35] Given that STATs are generally associated with transcriptional activation, STAT-dependent transcriptional repression has also been reported.[36] Also, whereas activation of JNK signaling in response to a range of stress signals is generally thought to promote cell death or tumor suppression, there is evidence to suggest that JNK signaling may also be involved in the promotion of growth and the formation of tumors under certain circumstances.[37]

DNA damage from exogenous chemicals or radiation can have genotoxic activity and result in DNA modifications such as covalent bridging between bases as well as inducing single- and double-strand breaks. Therefore, cellular systems monitor the genome and repair DNA using different repair enzymes by removing damaged or incorrect sections of DNA and replacing them with the correct sequence. There are multiple different methods of DNA damage repair within the cell, including excision repair (for single-strand breaks), nonhomologous end joining and homologous recombination (for double-strand

Table 1. Effects of Berry Extracts or Berry Constituents on Models of DNA Damage and Scavenging Activity[a]

berry or berry constituent	colonocyte cell line	dose	end point	observation	protective/adverse effect	comment	ref
anthocyanin-rich fraction from *Vaccinium corymbosum* and *Vaccinium myrtilus*	Caco-2	0.5−50 μg/L	intracellular ROS levels, CAA assay	↓ in intracellular ROS by ∼40% after 0.5 μg/L and 1 h	+[b]	reduction of intracellular ROS at low concentrations of anthocyanin treatment	55
in vitro digested and in vitro fermented raspberry (*Rubus idaeus*), strawberry (*Fragaria* × *ananassa*) and black currant (*Ribes nigrum*) extracts	HT29	IVD = 3.125−50 μg/mL GAE	antigenotoxic activity, comet assay	↓ in strand breaks by ∼40% in all IVD berry extracts from 6.25 to 50 μg/mL after 24 h	+[b]	fermented, phenolic acid rich extracts cause a significant decrease in DNA damage and mutation frequency	64
		fermented = raspberry, 15.5 μg/mL; strawberry, 13.9 μg/mL; black currant, 12.4 μg/mL	mutation frequency assay	↓ in strand breaks by ∼30% in all fermented extracts after 24 h	+[b]		
				↓in RMF >50% in all IVD berry extracts after 24 h	+[b]		
				↓in RMF ∼40% in all fermented extracts after 24 h	+[b]		
anthocyanin-rich fraction from bilberry (*Vaccinium myrtilus*)	Caco-2	10−500 μg/mL	antigenotoxic activity, comet assay	↓ in strand breaks by ∼50% after in Caco-2 after 50 μg/mL and 24 h	+[b]	dose-dependent decrease in DNA damage and scavenging activity after anthocyanin treatment	54
	HT29		intracellular ROS levels, CAA assay	↓ in intracellular ROS by ∼30−40% in Caco-2 and HT29 after 250 μg/mL and 24 h	+[b]		
ursolic acid (UA)	Caco-2	5 μM or 10 μM	comet assay, endogenous and H_2O_2-induced DNA damage	both concentrations yielded ∼40% ↓ in strand breaks following 2 h of pre-incubation	+[b]	greater reduction in DNA damage after a short incubation period with UA; increase in BER activity	63
			base excision repair assay (BER) using enzyme 8-oxoguanine DNA glycosylase 1 (OGG1)	17% ↓ in strand breaks after 5 μM for 24 h			
				23.5% ↑ in BER activity, for Caco-2 cells pretreated (24 h) with UA			
quercetin	Caco-2	1 μM or 100 μM	comet assay, endogenous and H_2O_2-induced DNA damage	↓ in strand breaks by 42% at 1 μM and 57% at 100 μM	+[b]	quercetin shows antigenotoxic activity at low concentrations; enhanced DNA repair by modulation of DNA repair enzyme expression	62
				↑ mRNA expression of human 8-oxoguanine DNA glycosylase (hOGG1) at 0 and 4 h after H_2O_2 treatment			
ellagic acid		0−300 μM	modulation of $4E_2/CuCl_2$-induced oxidative DNA adducts	>60% ↓ of both unidentified oxidative adducts and 8-OHdG	+[b]	dose-dependent decrease in induced oxidative adducts after ellagic acid treatment	61
anthocyanin fraction from blackberry (*Rubus fruticosus*)	Caco-2	3.15−50 μg/mL	intracellular oxidation	dose-dependent ↓ in intracellular oxidation	+[b]	suggests anthocyanins protect by scavenging AAPH-induced peroxyl radicals generated within cells	53
				no ↓ in cell viability			
		0.8−25 μg/mL	oxidative cytotoxicity (CellTiter-Glo assay)	↓ cytotoxicity from 1.6 to 25 μg/mL	+[b]		
phenolics isolated from strawberries (*Fragaaria* × *ananassa*)		10 mg/mL	antioxidative ability, TEAC assay	three of the phenolics showed significant antioxidant capacity: cyanidin-3-glucoside (7156 μM Trolox/mg)	+[b]	isolation of the specific phenolics within strawberry extract has given a greater understanding on which compounds possess antioxidative capacity	52

breaks), and mismatch repair (for mismatched bases from DNA replication). However, if DNA damage goes undetected and unrepaired, this will become a mutation when the cell replicates.[38]

MEASUREMENT OF DNA DAMAGE

DNA damage can be determined in tissues and organs either by taking biopsies or by isolating exfoliated epithelial cells such as buccal, bladder, or intestinal cells. Systemic DNA damage is usually measured in peripheral blood mononuclear cells (PBMC) as they can be easily isolated from blood samples. In addition, they are believed to reflect DNA damage in other body tissues. Studies of DNA damage can be performed in vivo and ex vivo as well as in vitro. A recent study reported no genotoxic impact in human lymphocytes following exposure to radiofrequency electromagnetic field emission using four genotoxicity end points,[39] including the alkaline single-cell gel electrophoresis (comet) assay,[40] which is the most frequently applied assay to detect strand breaks and related events. The comet assay is applicable for a wide range of cell types and for in vivo and in vitro studies. It involves embedding a suspension of the target cells in agarose on a microscope slide, lysing the cells to liberate the DNA, and then treating under alkaline conditions, causing the DNA to unwind from sites of strand breakage. The slides are then subjected to electrophoresis, and DNA fragments induced by genotoxic agents migrate to the anode to form a comet "tail". The DNA is stained with a fluorescent dye and the proportion of damaged DNA in the tail assessed by image analysis. A modification to the procedure, in which enzymes that convert oxidized bases to strand breaks are added, allows oxidative DNA damage to be quantified. For example, the enzyme endonuclease III (EndoIII), which specifically nicks DNA at sites of oxidized pyrimidines, or alternatively formamidopyrimidine DNA glycosylase (FPG), which recognizes 8-oxoGua and other oxidized purines, can be added after lysis.[41]

Conversely, the combined use of fluorescence in situ hybridization (FISH)/comet assay allows for the detection of DNA damage/repair to specific genes. By combining these two well-established methods, the hybrid assay allows fragmented DNA to be separated from nonfragmented DNA, whereas the FISH element allows detection of specifically labeled DNA sequences of interest such as APC, Tp53, or KRAS.[42,43] The comet assay is widely regarded as a valuable tool for genotoxicity testing and biomonitoring of oxidative stress in humans,[44] and its applicability to cancer risk studies has been well discussed;[45,46] however, interlaboratory reproducibility remains an area for improvement.[47]

Systemic oxidative DNA damage can also be assessed by measurement of the formation of DNA adducts such as 8-hydroxy-2′-deoxyguanosine (8-OHdG, one of the predominant forms of free radical-induced oxidative lesions[48]) or by detection of lipid peroxidation products. 8-OHdG is commonly detected by HPLC with electrochemical detection or tandem MS or by GC-MS. Lipid peroxidation products in plasma or urine include hydroxyeicosatetraenoic acids (HETE), which are generally measured using HPLC with MS, chemiluminescence, or fluorescence detection.[49,50] It is interesting to note that there is evidence to suggestthat the enzymatic comet assay variant appears to be more accurate in the estimation of low background levels of oxidative damage than are the chromatographic methods.[44]

IN VITRO STUDIES

Multiple in vitro studies have assessed the anticancer activities of berry components, using cell models in attempts to represent the initiation stage of CRC. These studies have mainly assessed the efficacy of whole berry extracts, fractionated berry extracts, or purified/commercial berry components in a range of human colon cell lines. These studies are summarized in Table 1.

Berry (poly)phenols may exert potential anticancer effects by chelating redox active metals (such as iron) or by directly scavenging ROS [including hydrogen peroxide (H_2O_2), hydroxyl radicals ($^{\bullet}OH^{-}$), superoxide radicals ($^{\bullet}O_2^{-}$), and singlet oxygen ($^1O_2$)] by being effective electron donors to the ROS. ROS scavenging activity[51,52] and antioxidant capacity[53−55] in vitro vary with type of berry extract or isolated components of berries (Table 1). The scavenging activity of berry (poly)phenols in simple, cell-free antioxidant systems through the scavenging of free radicals is remarkably high compared to those of other standard antioxidants such as ascorbic acid and α-tocopherol.[51] However, although useful in assessing antioxidant potential, these chemical assays provide little in terms of mechanisms relating to biological activity. Modifications have included the use of simulated gastrointestinal digestion of fruits prior to testing: for example, cranberries mostly retained their antioxidant activity following digestion using cell-free (DPPH) and Caco-2-based assays, whereas blueberries lost 43% of their free radical scavenging activity.[56] The measurement of intracellular ROS levels is a simple method to assess efficacy in a cellular model, which has greater biological relevance with uptake, retention, and metabolism of antioxidant (poly)phenols under physiologically relevant conditions. Several authors have utilized this technique to demonstrate a reduction in intracellular chemically induced ROS upon addition of the peroxyl radical (AAPH) to induce oxidative damage and associated cytotoxicity in various colon cancer cells.[53−55] Although direct intracellular scavenging has been suggested as the mechanism for this decrease,[53,54] this may be an oversimplification of the mechanisms involved. It may be that berry (poly)phenols interact with cell receptors or enzymes resulting in altered cell redox status, which triggers redox-dependent reactions.[57] For example, Bornsek and colleagues[55] hypothesized that the level of antioxidant activity invoked was not consistent with the low concentration of berry (poly)phenols (0.5 μg/mL) and that a signaling cascade may be triggered, possibly through their binding to an extracellular receptor or acting as an intercellular secondary messenger, resulting in activation of endogenous antioxidant systems. This mechanism would result in the amplification of the signal, so that low levels of (poly)phenols would have greater efficacy.

Several in vitro studies have investigated the effects of berry (poly)phenols on H_2O_2-induced DNA strand breaks as a measure of genotoxicity and, overall, have shown a reduction in genotoxicity in response to berry extracts and isolated flavonoids[58−64] (Table 1). The suggested mechanisms responsible for this antigenotoxic activity have been described as increased antioxidant activity, enhanced DNA damage repair, or a combination of both. For example, this has been demonstrated with the flavonoid quercetin[62] and the pentacyclic triterpenoid acid ursolic acid,[63] which is found in some berry types. Both of these compounds, at physiologically relevant (colonic) concentrations (100 and 10 μM, respectively), have demonstrated potent antioxidant effects in Caco-2 cells through reducing levels of H_2O_2-induced DNA damage

and specific oxidized adducts (8-oxoG) as detected using the enzyme 8-oxoguanine DNA glycosylase 1 (OGG1) to specifically cleave DNA at these sites. Further analysis has revealed that pretreatment with ursolic acid prior to, but not following, exposure to oxidative insult enhanced the rate of repair of DNA strand breaks via base excision repair (BER),[63] possibly through up-regulation of the repair enzyme OGG1 as evidenced by Min and colleagues with quercetin.[62] However, earlier work did not detect changes in oxidative base damage with quercetin (50 μM), and Duthie et al.[58] concluded that quercetin may in fact act by stabilizing the DNA directly. Although the exact mechanism responsible is still unknown, it may be affected via augmentation of p53 in response to antioxidant molecules, leading to up-regulation of the DNA excision repair pathway.[65]

Although studies have shown the genoprotective effects of isolated components from berries,[54,58,59,62] few investigations have considered the effect of intestinal digestion and bacterial fermentation on (poly)phenols from whole berries, as would occur following human consumption. Post ingestion, the phytochemicals contained within berries undergo alterations in their structure, and possibly their function, because of the impact of the human digestive tract. We know, for instance, that substantial amounts of (poly)phenolic compounds in raspberries are not absorbed into circulation in the small intestine but pass into the large intestine[66,67] where, it is reasonable to infer, they come into direct contact with the colonic epithelium and exert beneficial effects. For example, Coates et al.[60] demonstrated a genoprotective effect in HT 29 cells for a raspberry extract that had undergone in vitro digestion. However, it is also clear that berry (poly)phenols are extensively metabolized to simpler phenolics by the colonic microbiota during passage through the large intestine,[67−69] and thus it seems reasonable to assume that the levels of intact berry (poly)phenols will decrease as they pass further through the colon, with a corresponding increase in microbiota-derived catabolites. Therefore, different parts of the proximal to distal colon will be exposed to different proportions of the original (poly)phenol components and their catabolites. Only a few studies have established that colonic catabolites of (poly)-phenols have bioactivities (at least in vitro) relevant to colon cancer.[64,70,71] We have previously demonstrated that in vitro digested and fermented raspberry, strawberry, and black currant extracts at physiological concentrations (<50 μg/mL gallic acid equiv) retained the ability to protect DNA from oxidative insult during the digestive and bacterial fermentation processes.[64] Additionally, individual phenolic compounds representative of bacterial catabolites, namely, tyrosol and 4′-hydroxyphenyl-acetic acid (5 and 10 μg/mL), offered protection against oxidative insult and reduced DNA damage to levels similar to that achieved by ursolic acid in a different study.[63] However, the level of reduction in strand breakage by individual phenolic acids was less pronounced than for the mixture of phenolics, as found in fermented berry extracts, suggesting that an additive or synergistic effect may enhance the protective effect against ROS. Similarly, Gimenez-Bastida et al.[72] reported that a mixture of ellagitannin metabolites, including urolithins A and B, improved the inflammatory response of colon fibroblasts CCD-18Co, significantly decreasing PGE(2), PAI-1, and IL8.

In conclusion, although these in vitro studies differ in choice of berry, (poly)phenolic compounds, and assays utilized, they demonstrate a consensus with respect to a protective effect for berries against ROS-induced DNA damage.

IN VIVO ANIMAL STUDIES

Following in vitro models, animal models enable the investigation of berry (poly)phenols in a living system, looking at the effects of berry extracts on different stages in colorectal carcinogenesis. In keeping with the theme of this review, studies investigating initiation (formation of aberrant crypt foci (ACF)) and markers of DNA damage including urinary 8-OHdG levels are included. For example, the Fischer 344 (F344) rat model is used to represent CRC development due to a histopathological resemblance to human CRC after azoxymethane (AOM) treatment, first forming ACF and then developing into adenomas, adenocarcinomas, and finally carcinomas.[73] ACF are early identifiable precancerous lesions present during the multistep pathway involved in CRC development in both humans and rodents.[73] Additional similarities include *APC* and *ras* gene mutations and induction of COX-2 gene expression, which occur after AOM treatment in F344 rats.[74] The $Apc^{Min/+}$ (multiple intestinal neoplasia) mouse model harbors a mutation in the *Apc* gene resulting in the spontaneous development of colorectal polyps and is utilized as a model of human familial adenomatous polyposis (FAP).[75] The effects of berry extracts and berry components on a range of end points in these animal models are summarized in Table 2.

Consumption of black currant juice effectively reduced levels of single-strand DNA breaks induced by oxidative insult in leucocytes from the circulating plasma of pigs, suggesting bioavailability of either parent (poly)phenols or perhaps, more plausibly, colonic catabolites, mediating genoprotective effects in vivo.[76] Although the mechanism still requires further elucidation, the lack of decrease in malondialdehyde (a marker of oxidative stress, produced by ROS in vivo) suggests that oxidative stress was not affected. Therefore, it is unlikely that berry (poly)phenolic compounds were acting as direct scavengers in this instance, but were instead mediating levels of DNA damage repair or detoxification enzymes. Indeed, the activation of detoxification enzymes was suggested as a possible mechanism by which grape juice protected against DNA adduct formation in the organs of mice treated with benzo(a)pyrene and dimethylbenzo(a)anthracene (heterocyclic amines produced by cooking food). A reduction in the activation of these carcinogens via decreased expression of phase I enzymes or by up-regulating the expression of phase II detoxification enzymes including glutathione-S-transferases (GSTs), which are involved in degrading and eliminating activated carcinogens, could be involved.[77]

One mechanism for protection against carcinogens is induction of enzymes involved in their metabolism, particularly the phase II enzymes (including GST), which protect against damage by activated electrophilic metabolites from phase I metabolism. GSTs, a large family of detoxification enzymes, deactivate carcinogens by conjugating them with endogenous glutathione, which also enhances their water solubility and thus their elimination.[78] A blueberry extract and cranberry juice have been shown to significantly induce hepatic GST levels in F344 rats treated with AOM, whereas a blackberry extract did not. However, the blackberry extract significantly inhibited ACF formation but failed to significantly induce GST.[79] Therefore, it is likely that different, as yet to be identified, mechanisms, working in parallel, are responsible for the total anticarcinogenic effects observed.

Table 2. Effects of Berry Extracts/Components in Animal Models of Colorectal Cancer[a]

berry or berry constituent	animal	dose and exposure	end point	observation	protective/adverse effect	comment	ref
black currant (*Ribes nigrum*) juice	pigs	A, black currant + linseed oil B, starch control C, linseed oil D, linseed + vitamin E	comet assay, DNA damage in leucocytes	↓ DNA in leucocytes by BC treatment	+[b]	black currant juice decreased DNA damage but was less effective than vitamin E treatment	76
			urinary excretion of malonaldehyde (MDA)	no effect on MDA excretion for BC	−		
blueberry (*Vaccinium corymbosum*) strawberry (*Fragaria* × *ananassa*) raspberry (*Rubus idaeus*) ellagic acid	CD-1 (F) mice	5% w/w of dehydrated berries or 400 ppm ellagic acid in diet 3 weeks	analysis of endogenous polar oxidative DNA adducts	↓ in oxidative adduct by ∼50% in mice supplemented by raspberry or ellagic acid	+[b]	reduction in oxidative adducts dependent on ellagic concentration low and moderate strawberry and blueberry showed no significant reduction	61
blueberry (*Vaccinium corymbosum*) blackberry (*Rubus fruticosus*) cranberry (*Vaccinium oxycoccus*) juice	F344 rats (M) with SC injections of AOM	5% fruit or 20% juice (final concn) 13 weeks	ACF	blueberry, blackberry, and cranberry juice ↓ ACF by 93, 85, and 77%, respectively	+[b]	treatment with whole berries and whole berry juice significantly ↓ the formation of ACF; increased GST activity may be a chemoprotective action of berries	79
			hepatic GST activity	↑ GST activity after blueberry and cranberry juice treatment but not blackberry	+[b]		
pterostilbene (PTER)	F334 rats (M) with SC injections of AOM	diet supplemented with PTER at 40 ppm 8 weeks	ACF	↓ ACF by 57%	+[b]	pterostilbene treatment ↓ ACF formation and inflammatory pathways in F344 rats	84
			PCNA	↓ in PCNA staining by ∼10%	+		
			iNOS	↓ expression of iNOS proteins	+		
			MUC2	↑ expression of MUC2	+		
bilberry (*Vaccinium myrtillus*) ARE chokeberry(*Aronis meloncarpa*) ARE grape (*Vitis vinifera*) ARE	F344 rats (M) with SC injection of AOM	3.85 g of monomeric anthocyanin/kg 14 weeks	ACF	↓ total number of ACF by 29, 26, and 27% for bilberry, chokeberry, and grape AREs	+	ARE treatment ↓ ACF incidence and ↓ number of large ACF for bilberry and chokeberry treatments as well as ↓ cell proliferation and ↓ expression of pro-inflammatory COX-2 gene expression	82
			PCNA	↓ colonic cell proliferation with bilberry and chokeberry	+		
			urinary 8-OHdG	no change in 8-OHdG levels	−		
			COX expression	↓ gene expression of COX-2 with bilberry and grape AREs	+		
Mirtoselect (extract from bilberry (*Vaccinium myrtilus*) and blueberry (*Vaccinium corymbosum*) containing 15 anthocyanins) cyanidin-3-glucoside (C3G)	*Apc* $^{Min/+}$ mice (M and F)	0.03, 0.1, and 0.3% w/w in diet 12 weeks	colon and SI tumor number	no change in colonic tumors; 30 and 45% ↓ in SI tumor number at 0.3% treatment for Mirtoselect and C3G; all doses ↓ SI tumor number	− +	↓ in tumor number in dose-dependent manner; purified C3G may be more effective but anthocyanin levels in Mirtoselect were lower than in purified C3G	83
			M_1dG levels	highly variable levels, no significant difference	−		
black raspberry (*Rubus occidentalis*) (BRB, freeze-dried)	F344 rats (M) with IP injections of AOM	0, 2.5, 5, and 10% w/w in diet 33 weeks	ACF	↓ in ACF with all treatments	+	significant ↓ in tumor number and a trend toward overall ↓ tumor burden after BRB treatment may be concentration dependent	81

Table 2. continued

[a] ↓, decrease; ↑, increase; 8-OHdG, 8-hydroxy-2′-deoxyguanosine; ACF, aberrant crypt foci; AOM, azoxymethane; ARE, anthocyanin-rich extract; F, female; GAE, gallic acid equivalents; GST, glutathione-S-transferase; IA, invasive adenocarcinoma; IP, intraperitoneal; NIA, noninvasive adenocarcinoma; M, male; M_1dG, malondialdehyde deoxyguanosine; NS, not significant; PCNA, proliferating cell nuclear antigen; SC, subcutaneous; SI, small intestine. [b]Significant result. +, protective effect; − adverse effect.

Urinary levels of 8-OHdG have been used as a biomarker for cancer risk as 8-OHdG is the base most readily formed by oxidative damage and, therefore being abundant, is the most suitable for measurements of changes in levels.[48] These base changes are promutagenic, and increased 8-OHdG levels can be assumed to reflect an increased risk of cancer.[80] Treatment with (poly)phenol-rich berry extracts demonstrated slightly contrasting results with respect to 8-OHdG levels in separate studies (Table 2). Urinary levels of 8-OHdG were diminished significantly in AOM-treated F344 rats fed black raspberries, reaching levels comparable with those of untreated control rats, suggesting an almost complete reduction in AOM-induced genotoxicity, which corresponded to a decrease in ACF and tumor number.[81] In contrast, no changes in urinary 8-OHdG levels were reported in F344 rats fed anthocyanin-rich extracts (AREs) from bilberry, chokeberry, and grape after AOM treatment; however, these extracts also reduced ACF.[82] Therefore, it is possible that (poly)phenol composition is an important factor in regulating DNA damage, as whole berry extracts were effective inhibitors of genotoxicity, whereas anthocyanin-rich extracts were not. Therefore, the reduction of ACF after berry treatment was not directly dependent on a decrease in genotoxicity, but the chemoprotection observed may be offered via several different mechanisms.

In the main, these studies have investigated whole extracts or juices[61,76−79,81−83] rather than individual components, such as pterostilbene,[84] as previous studies have demonstrated the potential synergistic or additive effect of several (poly)phenols; in addition, they are much more representative of the composition of ingested fruits. Following the consensus from the in vitro studies presented in this review, Boateng et al.[79] summarized data indicating that consumption of (poly)phenols as a food source may be of greater importance in protecting against initiation of colorectal cancer in vivo than consumption of higher levels of individual (poly)phenolic compounds.

Because inflammation undoubtedly plays a role in carcinogenesis, dysregulated activation of inducible enzymes, such as NADPH oxidase (NOX), inducible nitric oxide synthase (iNOS), and cyclooxygenase (COX)-2, may represent an important chemoprotective pathway for dietary phytochemicals as a number of dietary (poly)phenols have been reported to inhibit their activation.[85] Indeed, a recent paper by Serra and co-workers reported that anti-inflammatory activity of cyanidin-3-glucoside was in part mediated by inhibition of iNOS and Cox2 expression.[86] Furthermore, some animal studies have reported that a diet low in methoxylated pectin can increase MUC2 expression, leading to an increase in mucin production, which is considered to be protective.[87] In addition, black raspberry powder significantly reduced chronic inflammation and suppressed intestinal tumor formation in MUC 2−/− rats.[88] Unfortunately, extensive coverage of these areas is beyond the scope of this review, but the complementary role of other plant components is clearly an area of interest.

The use of animal models has confirmed the in vitro studies in that berry components have protective effects against chemically induced CRC in a living system. Although no two studies have looked at the same biomarkers to evaluate the mechanisms behind this anticancer activity, the results overall indicate that berry extracts or components are able to influence carcinogen metabolism and reduce levels of DNA adduct formation in animal models of CRC. The potential mechanisms responsible for this effect include reduction in levels of DNA damage and adduct formation through inhibition of phase I

enzymes and up-regulation of detoxification phase II enzymes, which may ultimately result in decreased levels of oxidative assault and fewer precancerous lesions, such as ACF.

HUMAN STUDIES

The task of assessing the anticancer effects of food constituents in humans is challenging[89−91] given that, for the most part, intervention studies rely on intermediate biomarkers, such as DNA damage, that are plausibly linked to cancer[92] in the absence of clinical trials using definitive end points such as cancer incidence or mortality. From a chemoprotective perspective, the antiproliferative effects of berries have previously been reviewed by Brown et al.,[24] and evidence suggests consistent effects across in vitro and animal models. Evidence is emerging from studies with CRC patients indicating that consumption of black raspberries decreases proliferation markers, improves inflammatory markers in colon tissue, results in demethylation of tumor suppressor genes, and causes modulation of other biomarkers of tumor development in the human colon and rectum.[93,94] The latter effects may be mediated in part through inhibition of DNA methyltransferase 1 (DNMT1).[95] In a pilot study in 25 CRC patients, a commercial bilberry extract (Mytocyan) significantly reduced the proliferation index (assessed by Ki67 staining) in biopsies of colorectal adenocarcinomas, although other cancer-related markers were unaffected.[96] Unlike for antiproliferative activity, no studies have yet assessed the antigenotoxic effects of berry consumption in CRC patients, although a recent study with CRC patients by Alotaibi et al.,[97] using lymphocyte samples treated in vitro with dietary (poly)phenols, reported a significant reduction in lymphocyte damage induced by oxaliplatin/satraplatin.

Although the experimental evidence discussed previously supports a role for berry consumption and decreased DNA damage, most of the human intervention studies below exclusively utilize biomarkers from surrogate tissue such as lymphocytes, measuring changes that are biologically relevant to cancer including modulation of phase II enzymes, adduct formation, and DNA damage in response to dietary intake of berry fruits.

Collectively, the consumption of berry fruits has been shown to exert protective effects against DNA damage in healthy populations (Table 3). For instance, a recent study by Del Bo et al.[98] reported that a single 300 g portion of blueberries significantly reduced (18%) exogenously induced oxidative damage (H_2O_2) in blood mononuclear cells 1 h post consumption. However, the effect was not maintained at 2 or 24 h post dose or for FPG sensitive sites. Similarly, the consumption of a wild blueberry drink for 6 weeks resulted in significant reductions in endogenously oxidized DNA damage (from 12.5 ± 5.6 to 9.6 ± 3.5%, $P < 0.01$) as well as exogenously induced oxidative damage (from 45.8 ± 7.9 to 37.2 ± 9.1%, $P < 0.01$) in blood mononuclear cells.[99] A larger study by Wilms et al.[100] reported similar findings for consumption of a mixed blueberry/apple drink daily for 4 weeks, with a 20% decrease ($p < 0.01$) in exogenously induced oxidative damage in lymphocytes. Antigenotoxicity activity in lymphocytes was also reported for consumption of a mixed berry juice (red grape, blackberry, sour cherry, black currant, and chokeberry) in a healthy population[101] and in a patient group under enhanced oxidative stress, over a 4 week period.[102] In both studies, the observed protective effect may have resulted from direct antioxidant effects as well as from enhancing the cellular antioxidant system as an increase in glutathione status was noted during the interventions. In a small parallel study, dried wolfberries (*Fructus barbarum* L.) were consumed (15 g/day) for 28 days, resulting in a slight but significant decrease DNA damage in buccal cells, in comparison to the control group.[103] Other studies that showed protection against oxidative DNA damage in lymphocytes with fruit juices include that of Riso et al.,[104] using blood orange juice, Park et al.,[105,106] using grape juice, and Bub et al.,[107] using a juice mixture containing boysenberries and blueberries providing 236 mg/day (poly)-phenols. In the Bub et al.[107] study, fruit juice intake for 2 weeks had no significant effect on DNA damage, but following a subsequent washout and a further 2 weeks of juice consumption, oxidative DNA damage was significantly decreased. This result suggests that (poly)phenols, and/or their metabolites/catabolites, may be acting not only via the mechanism of ROS scavenging but also by exerting an influence on the antioxidant defense system by modulating the activity of phase I and phase II enzymes that play a role in preventing DNA damage.

In humans, increased risk of CRC or incidence of tumors in the colonic mucosa has been associated with low GST activity, compared to higher GST activity in healthy individuals.[108] Human studies have shown that supplementation with berry (poly)phenol-rich drinks have had differing effects on GST activity (Table 3).[109,110] Over a short supplementation period (2 weeks) no change in GST activity was reported,[110] but over a longer period GST activity was increased.[109] This observed difference may be due to a time delay or a requirement for an accumulation of berry (poly)phenols to produce an effect, as evidenced by a decrease in levels of human GST protein (hGSTP1) at the beginning of supplementation followed by a significant increase in hGSTP1 levels toward the end of the supplementation.[109] Furthermore, Wilms and colleagues[100] reported that compared with wild types, polymorphisms in a range of phase I and II enzymes including Cyp1b1*5, COMT, and GSTT1 could affect how effectively an individual could protect against DNA damage in response to any intervention.

Some berry fruit interventions showed no protective effects on lymphocyte DNA damage, which could serve to highlight the importance of stratification with respect to susceptibility when the impact of dietary interventions is assessed. Such studies include the work of Carmen Ramirez-Tortosa et al.,[111] who gave a grape, cherry, blackberry, black currant, and raspberry juice mixture containing 224 mg/kg anthocyanins to elderly subjects for 2 weeks, and that of Moller et al.,[112] who used a black currant juice with 600 mg/L anthocyanins for 3 weeks. Moller et al.[112] ascribed the lack of effect to the very low DNA damage levels in the subjects at baseline. Whereas the studies by Bub et al.[107] and Wilms et al.[113] indicated an overall positive effect of berry interventions, the lack of a concurrent control group within the study design limits the conclusions that can be drawn. That the majority of, but not all, berry-based studies demonstrate significant antigenotoxic activity, is likely due as much to the well-documented diversity and variability in phytochemical content and composition of berries as to differences in study design or biological characteristics of the participants. An understanding of the comparative effectiveness of different berry polyphenols is relevant only if we improve our understanding of which components survive and are present in situ and which metabolites are formed.[114] In view of the impact that an individual's gut microbiota may have with respect to bioavailability and ultimately bioactivity of dietary phenols, the

importance of establishing an individual's (poly)phenol metabolizing phenotype or gut metabotype will become of increasing relevance in studies of colon cancer.[115,116]

To conclude, there is clearly extensive evidence from in vitro studies and animal models that berry extracts modulate biomarkers of DNA damage and that these effects may be potentially chemoprotective due to the role that oxidative damage likely plays in mutation rate and cancer risk. However, because the studies use berry extracts, it is difficult to determine which phytochemicals are responsible and whether for the most part the dose would be nutritionally achievable. Although the dietary intervention trials with berries are generally consistent and indicate a capacity to significantly decrease oxidative damage to DNA, they in themselves represent only weak evidence for anticarcinogenicity as they rely on surrogate putative markers for cancer risk. To understand the protective effects of berry consumption on colorectal cancer risk, future studies will need to be well controlled, using suitable and clinically relevant end points to support the tentative emerging evidence for a protective effect.

Table 2. Concentrations of the Main Phenolic Compounds in Strawberries (Data Obtained from Aaby et al.[15])

group	compound	concentration (mg/100 g FW)
anthocyanins	cyanidin-3-glucoside	1.10
	pelargonidin-3-glucoside	25.30
	pelargonidin-3-rutinoside	1.10
	cyanidin-3-malonylglucoside	0.40
	pelargonidin-3-malonylglucoside	6.00
flavonols	quercetin glycosides	1.81
	kaempferol glycosides	0.84
flavan-3-ols	(+)-catechin	4.50
	proanthocyanidins	
	procyanidin dimers	9.10
	procyanidin trimers	7.90
ellagitannins	agrimoniin	8.80
	ellagic acid	0.52
ellagic acid glycosides	ellagic acid penthoside, ellagic acid deoxyhexoside, methylellagic acid deoxyhexoside	0.58
cinnamic acid conjugates	coumaroyl hexoses	5.40
	cinnamoyl glucose	5.00

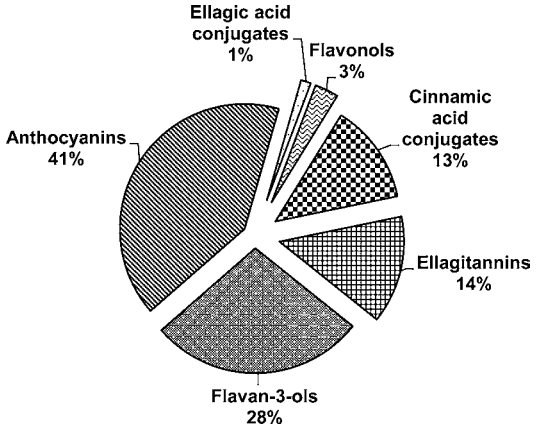

Figure 2. The most common phenolic compounds identified in strawberries. Data obtained from Aaby et al.[15]

important phenolic compounds present in strawberries and that the pelargonidin and cyanidin derivates are the most representative ones.[2,9,10,16] They have different properties (e.g., photoprotective, antioxidant, anti-inflammatory, anticarcinogenic, antimutagenic) and can also modulate enzymatic pathways; this is the way some of them may act in the prevention of oxidative stress-related diseases. Moreover, the daily intake of anthocyanins is very consistent and considered the most consumed group of phenolic compounds in the human diet: it has been estimated that the daily intake may reach 12.5 mg/day in the United States.[17]

Nowadays, it is known that fruit nutritional composition varies very considerably as a consequence of different pre- and postharvest factors, with the genetic background playing a major role in determining strawberry nutritional traits. For these reasons, breeding and biotechnological programs have focused their attention on ameliorating the productivity, aspect, shape, and firmness of the fruit, as well as its taste and aroma in different berry species. Only recently, strawberry nutritional value has been seriously studied and also requested as an added value by consumers, stimulating researchers to implement new breeding and biotechnological programs: for example, the increase of antioxidant compounds in commercial strawberries using wild germplasm as genetic material is a valid alternative to provide greater intake of healthy compounds even with a lower fruit consumption.[18,19] In this regard, only a few groups have demonstrated the correlation between the antioxidant and phenolic contents related to different genotypes, as well as the contribution of wild species to the bioactive compound contents in new genotypes.[20−22] These studies stressed the great importance of genetic background on antioxidant and chemical profiles of the strawberry. In fact, total antioxidant capacity and all classes of compounds tested, such as total phenols, flavonoids, anthocyanins, vitamin C, and folates, were significantly different according to their different genotypes. An online postcolumn antioxidant detection system adopted to evaluate the individual tribute of strawberry compounds to the total antioxidant capacity of the fruits also highlighted that vitamin C usually contributed >30% to the total antioxidant capacity in any cultivars and selections, whereas pelargonidin-3-glucoside contributed to the antioxidant capacity approximately 25% to nearly 40% of the eluting compounds depending on the cultivars tested.[20] Moreover, one of the advanced selections of the Marche Polytechnic University strawberry breeding program, obtained from a cross between a wild and cultivated species, was demonstrated as the most important genotype because of the highest total antioxidant capacity and total phenolic content, confirming once again the important role of the genetic background.

BIOAVAILABILITY AND METABOLISM OF PHENOLIC COMPOUNDS

In recent years it has become extremely important to comprehend the absorption, metabolism, and excretion of phenols after dietary intake, as proof of the possible disease-preventing and health-promoting effects of strawberry phenolic phytochemicals continues to pile up.

In general, most dietary phenols are assimilated in the intestine: indeed, after ingestion, flavonoids, in the form of glycoside conjugates, reach the brush border of the small intestine epithelial cells where they are hydrolyzed by lactase phloridizin hydrolase, leading to the release of aglycone, which is then enabled to pass into the same cells by passive diffusion as a result of its increased lipophilicity.[9,10,23,24] Another way by which glucoside conjugates are hydrolyzed is represented by a cytosolic β-glucosidase within the epithelial cells, after transportation of polar glucoside into the epithelial cells: it has been suggested that this can occur probably thanks to the active Na-dependent GLUT-1.[9,10,23,24] Aglycones resulting from this type of hydrolysis can suffer two different fates: (i) they can return into the lumen of the small intestine, possibly with the involvement of members of the ATP-binding family of transporters, or (ii) they can be processed in glucuronide, methylated metabolites, and/or sulfate, through the corresponding action of UDP-glucuronosyltransferases, catechol-*O*-methyltransferases, and sulfotransferases, and pass into the bloodstream.[9,10,23,24] They then quickly approach the liver: here, they can undergo phase II metabolism and pass to the systemic circulation; they can also move back to the small intestine thanks to bile excretion.

dx.doi.org/10.1021/jf405455n | J. Agric. Food Chem. 2014, 62, 3867−3876

All flavonoids that are not taken up in the small intestine pass into the colon and are processed by colonic microflora, which halve conjugating fractions; the resultant aglycones are transformed into phenolic acids and hydroxycinnamates that sometimes are assimilated, reaching the hepatic tissue; in the liver they can undergo phase II metabolism before being excreted in urine.[9,10,23,24]

Anthocyanins. Results from the few presently known investigations concerning anthocyanin bioavailability in humans demonstrate that these compounds are very exiguously absorbed: usually about 0.1% of the eaten amounts, or even less, has been found in urine within 24 h of consumption; lower concentrations have been detected in plasma.[9,10,23,24] The characteristics of both the anthocyanidin structure and the sugar moiety influence the limited absorption and excretion of anthocyanins. Indeed, anthocyanins do not seem to suffer wide metabolism to glucuronide derivates, unlike what happens to other flavonoids. In the stomach, the acid pH maintains anthocyanins in the stable flavylium cation form, so that a limited quantity can be quickly assimilated from the stomach after intake, through a mechanism which could implicate bilitranslocase.[9,10,23,24] The other part of anthocyanins reaches the small intestine, where they are converted into some neutral pH forms of anthocyanins: hemiketals, chalcones, and quinonoids. Such compounds appear to be just partially assimilated in the jejunum and undergo wide conjugation reactions, mostly in the liver but also in the kidney and in the intestine. Indeed, consistent quantities of ingested anthocyanins avoid absorption in the upper small intestine and pass into the colon, where they are exposed to a microbiota able to largely modify their molecular entity, breaking glycosidic linkages and heterocycle; colonic bacteria further convert the aglycones resulting from this process into smaller phenolic acids, such as protocatechuic acid for cyanidin-based anthocyanins or 4-hydroxybenzoic acid for pelargonidin-based anthocyanins.[9,10,23,24]

Ellagitannins. In the past decade, only a few studies have focused on the pharmacokinetics of dietary ellagitannins, especially after a single dose intake of red and black raspberries, walnuts, and pomegranate juice.[9,10,23,24] A complex picture emerged showing that ellagitannins are absorbed in the jejunum, where they are hydrolyzed to ellagic acid thanks to the neutral pH environment. Ellagic acid appears to be moved across the enterocyte apical membrane and rapidly transformed into methyl or dimethyl conjugated by catechol *o*-methyl transferase and presumably glucuronidated by UDP-glucuronosyltransferases. Afterward, ellagic acid metabolites undergo hepatic phase II biotransformations, producing a puzzling group of conjugated forms characterized by fast kinetics of plasma appearance and urinary excretion once they have entered the systemic circulation.[9,10,23,24]

In any case, within the intestinal lumen, most ellagitannins are subjected to microbiota transformation, resulting in the production of derivatives commonly known as urolithins (urolithins A−D). These metabolites are preferentially absorbed as their lipophilicity increases and, in the enterocyte and hepatocyte, further undergo phase II biotransformations, giving a combination of urolithin metabolites. For example, urolithin A 3-*O*-glucuronide and urolithin B 3-*O*-glucuronide are the major components found in plasma, whereas urolithin A and C glucuronides are present in urine.[9,10,23,24] Finally, it should be taken into account that the different colonic microbiota of different subjects are responsible for the consistent interindividual variability in the in vivo production of these metabolites, which makes the ellagitannin metabolism even more complex to explain.[23,24]

Proanthocyanidins. Results obtained in the few presently known investigations on the bioavailability of proanthocyanidins in the polymeric forms demonstrate that they are not absorbed to any degree.[23,24] Indeed, when they reach the large intestine unaltered, they are usually processed by colonic microbiota, leading to the production of an extensive range of phenolic acids such as 3-(3-hydroxyphenyl)propionic acid and 4-*O*-methylgallic acid; these metabolites pass into the circulatory system and are eliminated through the urine.[23,24] Only two investigations have found low levels of proanthocyanidin dimers in human plasma,[23,24] suggesting that polymerization greatly impairs intestinal absorption. According to this evidence, it is thought that the biological effects of proanthocyanidins are usually ascribed not to their direct action but to the activity of their metabolites, even though there is still little detailed information regarding this issue.

STRAWBERRY EFFECTS ON HUMAN HEALTH

Overcoming the Gap between in Vitro and in Vivo Studies. As known, polyphenols are among the most important and best known bioactive compounds present in fruits, especially berries. In the past few years, several investigations have been carried out to delineate the biological activity that these compounds exert in the maintenance of well-being and in the prevention of a huge variety of chronic pathologies (Table 3). Although berries are one of the most antioxidant-rich foods, and although the potential efficacy of polyphenols is currently receiving ample attention, most of the literature data are still obtained from in vitro studies. In this regard, one of the most interesting research areas focuses on the in vitro effects of polyphenols in skin well-being. Skin is always open to a diversity of chemical, genotoxic, and environmental agents that contribute to aging, disease, and carcinogenesis. A wide array of polyphenols from different dietary sources possess substantial skin protective effects, which has raised increasing interest in their systemic and topical applications for skin protection. Much of this interest concerns the antioxidant properties of polyphenols. A recent paper analyzed the in vitro protective capacity of an anthocyanin-rich strawberry extract on human dermal fibroblasts exposed to UV-A radiation.[2] UV-A radiation penetrates the dermis, causing oxidative damage by generating reactive oxygen species (ROS). In this study, incubation for 24 h with 0.5 mg/mL strawberry extracts led to photoprotective activity in human dermal fibroblasts subjected to UV-A radiation, with an increase in cellular viability and a decrease in DNA damage in a dose-responsive manner when compared to control cells. Yin et al.[3] obtained similar results: they found that 1 mg of quercitrin, a glycosylated form of quercitin, in mouse epidermal cells decreased ROS generation induced by UV-B irradiation and restored catalase expression and glutathione/glutathione disulfide ratio, leading to a reduction of oxidative DNA damage and apoptosis and to protection of the skin from inflammation. Likewise, another recent study[4] assessed the inhibitory effects of two powerful plant-based phenolic antioxidants (i.e., ferulic and caffeic acids) at different concentrations of 3.75, 7.5, 15, and 30 μM, on UV-A-induced cytotoxicity in human keratinocyte cells, evaluating the recovery of the antioxidant defense system. Results showed that ferulic and caffeic acids up-regulated activities and mRNA expression of catalase and

glutathione peroxidase as well as γ-glutamate cysteine ligase mRNA and glutathione concentrations in irradiated cells. However, many other recent studies[5−7] have shown new insights in the molecular mechanisms responsible for the healthful effects of polyphenols in skin application, beyond the antioxidant capacity. According to these findings, the potency of polyphenols to protect skin against harmful agents could be due to their capacity of altering signal transduction and epigenetic regulation of gene expression. For instance, green tea polyphenols,[5] quercetin,[6] and resveratrol[7] have shown an anti-inflamatory effect associated with the control of signal transduction, with the reduced expression of pro-inflammatory proteins (i.e., COX-2), inducible tumor necrosis factor-α (TNF-α), and nitric oxide synthase. These findings indicate that polyphenols may have protective effects on dermal cells in vitro, suggesting that these compounds could be helpful in protecting human dermal cells against several of the toxic agents to which the skin is frequently exposed.

Nevertheless, in vitro studies are often carried out in experimental conditions not comparable with the in vivo situation. Thus, it should be mandatory to endorse the potential health-promoting results of strawberry in vivo studies, especially in human studies. With these critical points taken into account, in recent years several studies have been carried out in vivo, in both physiological and pathological conditions, selecting strawberry varieties particularly rich in phytochemical compounds, mainly anthocyanins. For instance, in the feeding trial on rats we are currently carrying out in our laboratory, we are evaluating the possible role of strawberries in ameliorating the aging process.[25] In general, after 2 months of 15% strawberry consumption, a reduction of physiological oxidative damage has been observed at tissue, cellular, and subcellular levels as well as an enhancement in antioxidant biomarkers and an amelioration of lipid profile. A strawberry-enriched diet has also determined the reduction of oxidative stress in liver mitochondria, improving the animals' functionality and respiratory performance. These results agree with a recent feeding trial on old rats,[26] which demonstrated that the intake of polyphenols (75 mg/kg body weight) resulted in a decrease of ROS production, an enhancement of antioxidant defense, and the prevention of age-related mitochondrial respiratory impairment. Similarly, Laurent et al.[27] found that moderate oral supplementation of a red grape polyphenol extract improved the general antioxidant status of aged rats, increasing the biogenesis of mitochondria and decreasing age-dependent autophagy in gastrocnemius of the old animals. Interestingly, we obtained the same results when oxidative stress was induced by doxorubicin administration, a very toxic drug that alters DNA and produces free radicals at a very high rate. In particular, in the rat, strawberry supplementation seems to be able to give protection against oxidative injury induced by doxorubicin in plasma, lymphocytes, or liver at tissue, cellular, and subcellular levels. Our findings agree with the data obtained by Choi et al.,[28] who demonstrated that dietary supplementation with anthocyanin-rich bilberry extract (500 mg/kg body weight) was effective in reducing doxorubicin-induced oxidative damage and in improving antioxidant defense as well as in restoring hemoglobin levels and bone marrow cell and red blood cell counts, in both rats and mice. Again, another recent study[29] on rats showed that diet supplementation with grain rich in phenolic acids led to a decrease of oxidative status and of doxorubicin-induced liver inflammation and to a concomitant enhancement in antioxidant enzyme activities. These results confirm the possible health benefit of bioactive compounds in vivo against oxidative stress, also in physiological conditions characterized by a higher level of oxidative stress produced by aging or in pathological situations caused by the administration of oxidant agents.

Other in vivo studies[16,30] have recently shown that polyphenols may have a preventive function counteracting the progress of gastric ulcerations, erosions, and cancer. That is why an in vivo trial[16] on rats was carried out to examine the

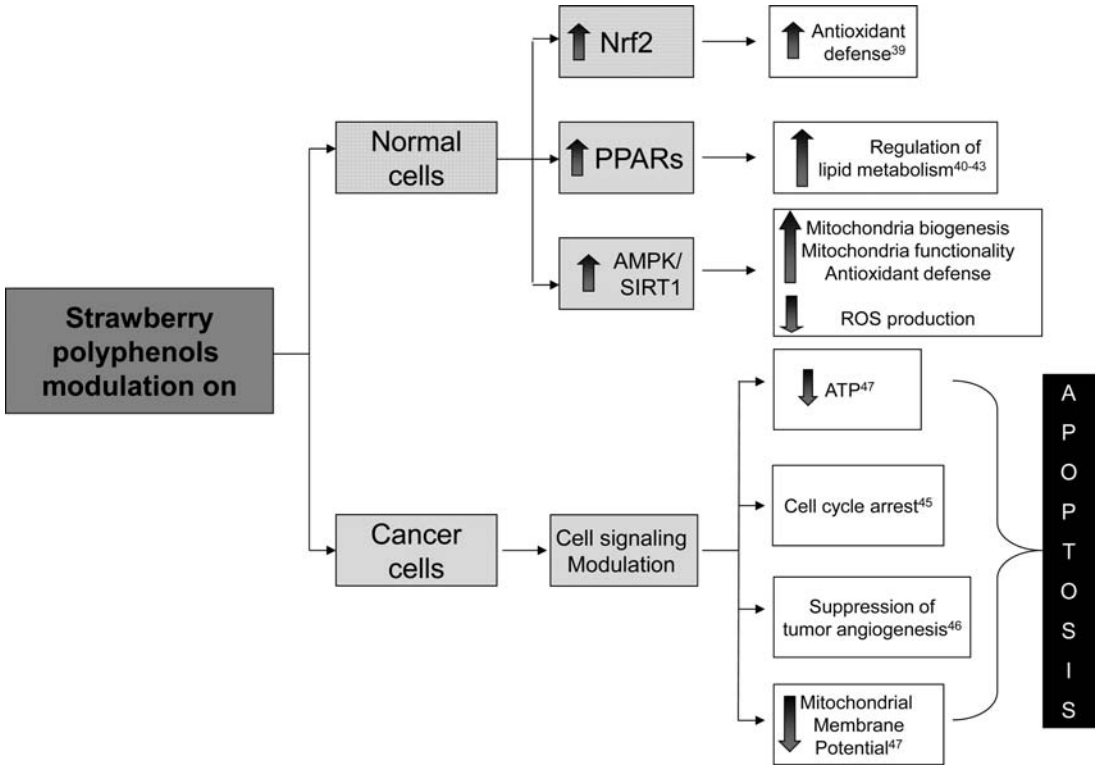

Figure 3. Mechanisms proposed for strawberry polyphenol modulation on normal and cancer cells. Abbreviations: Nrf2, nuclear factor-erythroid 2-related factor 2; PPARs, peroxisome proliferator-activated receptors; AMPK, 5′-adenosine monophosphate-activated protein kinase; Sirt1, sirtuin 1; ROS, reactive oxygen species; ATP, adenosine triphosphate.

strawberry protective and antioxidant effects toward ethanol-induced gastric mucosa damage. Strawberry consumption (40 mg/day/kg body weight) was able to protect against the deleterious role of ethanol, to significantly increase antioxidant enzyme activities, and to diminish, at the same time, gastric lipid peroxidation. Also, the percent of inhibition of ulcer index significantly correlated with total anthocyanin content. These results agree with those obtained in a recent study in rats,[30] where the administration of different concentrations of anthocyanins (5, 25, or 50 mg/kg body weight) from black rice bran was shown to significantly protect against gastric ulcer induced by a nonsteroidal anti-inflammatory drug, decreasing ROS levels and inhibiting lipid peroxidation, enhancing the antioxidant enzymes activities and attenuating the suppression of matrix metalloproteinase-2 (MMP-2) activity. Similarly, in another study[31] supplementation of different anthocyanin amounts (12.5, 25, 50, 100, or 200 μg/mL) exerted an anti-inflammatory effect in gastric epithelial cells infected by *Helicobacter pylori*, decreasing ROS concentration and inhibiting the phosphorylation of mitogen-activated protein kinases as well as the translocation of nuclear factor-κB. On the basis of this evidence, the potential of polyphenols could be taken into account for preventing/treating chronic subacute gastric lesions. The intake of a diet rich in bioactive compounds could prevent and/or ameliorate pathological states of the stomach as well as attenuate gastric mucosal damage, thereafter curing or diminishing ulcer formation, side effects of subacute chronic alcohol intake, nonsteroid anti-inflammatory-related gastritis, or *H. pylori* treatment.

The most significant outcomes of polyphenol supplementation in human studies[32−37] have addressed the possible variations in both cellular and plasma markers of antioxidant status in young and middle-aged subjects. In young healthy volunteers, total antioxidant capacity and vitamin C concentration in serum were significantly enhanced after the consumption of 300 g of strawberries (fresh fruit).[32] A concomitant decrease in oxidative biomarkers both in urine and in plasma was found after the consumption of 500 g of strawberries for 1 month.[33,34] Either oxidant-untreated or treated erythrocytes displayed improved protection to hemolysis as well as a highly reduced percentage of mortality and an increased proportion of metabolic activity in ex vivo mononuclear cells treated with H_2O_2 after consumption of 500 g of strawberries for 2 weeks.[35] Among the mechanisms of action implicated in the antioxidant effects of strawberry consumption, a reduction in DNA oxidative damage and an improvement of DNA repair capacity could be involved.

Nowadays, it is generally accepted that obesity and oxidative stress may be present at younger ages and persistent exposure to systemic inflammation could result in the onset and development of cardiovascular disease (CVD). Evidence suggests that the addition of polyphenol-rich foods in the diet may improve CVD risk factors, inhibiting inflammation and platelet aggregation and ameliorating endothelial function, plasma lipid profile, and free radical scavenging, thus increasing LDL resistance to oxidation. In overweight and obese children,[36] a short-term blueberry consumption, consisting of the weekly intake of 375 g of fresh blueberries during 8 weeks, resulted in enhanced antioxidant capacity of plasma and in a concomitant reduction of inflammation and oxidative stress markers, whereas in dyslipidemic subjects anthocyanin consumption[37] (about 160 mg twice daily for 12 weeks) was found to increase HDL-cholesterol concentrations and to decrease LDL-cholesterol concentrations and cholesteryl ester

transfer protein activity in plasma. Similarly, Cassidy et al.[38]demonstrated that, in young or middle-aged women, a reduced risk for myocardial infarction was associated with elevated anthocyanin intake. Another study[33] showed that the daily consumption of 500 g of strawberries for 1 month in young healthy volunteers was associated with a general improvement of the serum lipid profile of the subjects, through a reduction of total cholesterol, LDL-C, and triglyceride levels, indicating that some of the constituents of the fruit, such as vitamin C and anthocyanins, may favorably affect the plasma lipid profile. In this study, the intent was also to determine platelet basal activation in healthy subjects after strawberry consumption, as a preventive factor against CVD through a diet rich in antioxidants. Although the majority of platelets remained in the resting state after treatment, as expected, a significant decrease was found in the number of activated platelets during the strawberry supplementation period compared to baseline values, indicating a favorable effect of strawberry treatment on platelet function. Therefore, according to the data obtained in these studies, polyphenols seem to exert in vivo effects in the prevention of CVD risk, explaining in part the protective role of a diet abundant in vegetables and fruits in preventing CVD and other chronic diseases mediated by oxidative stress.

Effects beyond Antioxidant Capacity: 1. Possible Role in Chronic Metabolic Disorders. All of the beneficial effects that polyphenols exert in vivo on human health may not depend only on direct antioxidant properties. In fact, polyphenols are processed by the body as xenobiotics, stimulating the stress-related cell signaling pathways, which results in an increased expression of cytoprotective genes (Figure 3). Recently, it was found that polyphenols might increase gene transcription of nuclear factor-erythroid 2-related factor 2 (Nrf2), a transcription factor that binds to the antioxidant response element (ARE) and regulates enzymes involved in antioxidant functions or detoxification.[39] In this way, polyphenols may give antioxidant protection in an indirect way with the activation endogenous defense systems, mainly with the modulation of the expression of some antioxidant enzymes, and this fact may partly explain the increase in antioxidant enzymes found in in vivo studies.

Another important mechanism that should be taken into account besides the antioxidant capacity is the effect that polyphenols indirectly exert on peroxisome proliferator-activated receptors (PPARs), through Nrf2 activation.[40] PPARs are transcriptional factors that manage insulin sensitivity, glucose homeostasis, fatty acid oxidation, and lipid metabolism in general, so that their agonists are employed for treating metabolic syndrome, cardiovascular diseases, and hyperlipidemia. In this regard, a polyphenol-rich fraction from amla fruit (*Emblica officinalis* Gaertn.) in concentrations of 40 or 10 mg/kg body weight per day for 100 days was reported to improve age-related hypertriglyceridemia in young and old rats by stimulating liver PPARα expression,[41] whereas 1% of phenols and anthocyanins from cherries was found to decrease, in rat, hyperinsulinemia fasting blood glucose, hyperlipidemia, and fatty liver by enhancing hepatic PPARα mRNA and hepatic PPAR-α target acyl-CoA oxidase mRNA activity.[42] Similarly, the daily consumption of chokeberries (100 and 200 mg/kg body weight) led to a decrease in glycemia, cholesterol, LDL-cholesterol, triglycerides, and epididymal fat as well as to a reduction in plasma TNF-α and interleukin-6 levels and an up-regulation of the gene expression of PPARγ mRNA levels.[43] We also confirmed that a protracted consumption of strawberries is associated with a general improvement of the serum lipid profile in young subjects, through a reduction of total cholesterol, LDL-C, and triglyceride levels.[33] To summarize, polyphenols have different biological effects on metabolically active tissues, affecting insulin sensitivity, inflammation, lipid metabolism, and obesity, which could be switched on by PPAR activation, through Nrf2, reducing different phenotypic risk factors connected with the risk for type 2 diabetes and metabolic syndrome.

Finally, another possible mechanism to explain all of these polyphenol effects on health is the activation of the AMPk/SIRT1 (5′-adenosine monophosphate-activated protein kinase/sirtuin 1) signaling cascade that can lead to an increase in cellular metabolism, mitochondrial biogenesis and functionality, and antioxidant defense and to a concomitant decrease of ROS levels and inflammation. However, this is a new area of study that has begun to be investigated for elucidating the mechanisms and strawberry compounds implicated in these responses.

Effects beyond Antioxidant Capacity: 2. Possible Role in Cancer Prevention and Treatment. The fact that polyphenols extend their properties beyond antioxidation up to cell signaling modulation gives an interesting insight into their potential anticancer properties. In the past few years, polyphenol antioxidant capacity has been taken into account as one of the outstanding mechanisms of action in inhibiting mutagenesis and cancer initiation, by means of their capacity to scavenge ROS, activate antioxidant enzymes, prevent carcinogen-induced DNA adduct formation, enhance DNA repair, and reduce overall oxidative DNA injury[44] (Figure 3). Whereas antioxidation certainly has a pivotal function in polyphenols' anticancer effectiveness, several recent investigations have also supported their function as modulators of cellular processes connected with cancer growth: in vitro and in vivo evidence indicates in fact that phenolics may modulate cell signaling in the cancer cell by inhibiting proliferation of these cells through the demethylation of tumor suppressor genes,[45] inducing cell cycle arrest and apoptosis[45] and suppressing tumor angiogenesis.[46] A recent study[47] on PC-3 prostate cancer cells revealed that polyphenol-rich tea extracts at different concentrations (0.4, 0.8, 1.2, 1.6, or 2.0 mg/mL) inhibited cell proliferation, induced apoptosis, and provoked reduction of the mitochondrial membrane potential and ATP level decrease, whereas resveratrol metabolites (at 10, 20, and 30 μM) were reported to inhibit colon cancer cell growth and cause an accrual of cells in the S phase, inducing DNA damage and the apoptotic process.[48] Similarly, Link et al.[49] found that curcumin (7.5−10 μM) exerted chemopreventive effects, inducing DNA methylation at selected loci, rather than fully methylated sites in colorectal cancer cells, and that DNA methylation changes were obtained through analogous modifications in gene expression at either up- or down-regulated genes. Unfortunately, investigations devoted to the mechanisms underlying the anticancer efficacy of berry polyphenols are still limited. Recently, Wang et al.[45] reported that different concentrations of anthocyanins present in black raspberries canceled activity as well as protein expression of DNA methyltransferase enzymes, demethylated promoters of CDKN2A, and SFRP2, SFRP5, and WIF1 by inhibiting cell proliferation and inducing apoptosis in colorectal cancers. We are presently assaying the in vitro effects of strawberry polyphenols on a murine mammary cancer cell line N201/1A that expresses high levels of human epidermal growth

factor receptor 2 (HER-2) oncoprotein. HER2 expression in breast cancer has usually been considered an interesting therapeutic goal because it is frequently linked to an aggressive phenotype and poor prognosis. We have found that after strawberry treatment (corresponding to 2.5 μg of anthocyanins/mL), tumor cells that express the oncogene show higher levels of apoptosis at lower extract concentrations compared to tumor cells without the oncogene. This may mean that the N202/1A cells are more sensitive at lower extract concentrations, as demonstrated by the high apoptosis rate. Furthermore, strawberry treatment results in an increase in intracellular ROS and in an impairment of glycolysis and mitochondrial functionality in cells that express the oncogene compared to cells without the oncogene. Probably, there is a mechanism linked to the apoptotic pathway and cellular metabolism through the strawberry extract that can affect tumor cell viability, especially of the N202/1A cell line, which overexpresses the HER-2/*neu*oncogene. We obtained similar results also in an in vivo trial, on transgenic mice expressing the HER-2/*neu* oncogene (line FVB/N 233 neu-NT), supplemented for 4 months with 15% strawberries. A reduction of the number and size of metastases, as well as their propagation in the lung, was observed in animals fed strawberries compared to the control group. These findings lead to the conclusion that polyphenols, when investigated for their antitumoral effects, target distinct signaling mechanisms, therefore emphasizing the urgency of additional research to highlight the pathways involved in the anticancer effects of strawberries and to characterize the bioactive compounds that may play a fundamental role against cancer.

In conclusion, strawberry fruits possess a remarkable nutritional composition due to their high content of micronutrients such as folates, minerals, and vitamins, and are also a rich source of phenolic constituents. Currently, evidence on the biological activity of polyphenolic compounds is growing. Many mechanisms have been proposed to explain how polyphenols exert their biological protective effects, which, for several years, have been often ascribed mainly to their antioxidant capacity. However, this view is now challenged by recent findings, and more complex actions are being investigated. Recent findings have demonstrated that, besides antioxidant and anti-inflammatory capacities, phenolics may engage with cellular signaling flow, controlling the action of transcription factors and subsequently affecting the expression of those genes involved in cellular metabolism and cellular survival. Further in vivo investigations are required to translate the evidence obtained in vitro into actual outcomes in vivo and to understand the factors and mechanisms regulating the bioefficacy of strawberry phytochemicals.

major area of research emphasis in recent years. Fruits and vegetables contain a varied composition of bioactive compounds, many of which fall into the large family of compounds known as polyphenols. Early papers suggested that polyphenols were antinutritional components.[7] However, recent research supports the supposition that polyphenolic compounds have a strong potential to alter disease risk profiles in humans through their ability to modulate various biological pathways.[8−10]

In the past, polyphenols have been suggested to act as antioxidants in the body due to their ability to act as free radical quenchers or reducing agents. However, recent data derived from in vitro[11] and in vivo animal studies[12] suggest that they more likely alter disease risk profiles in humans through their ability to alter biological pathways via modulation of redox status, pathway signaling, and gene transcription in cells. Dietary polyphenols have been studied in a variety of clinical settings to determine whether these compounds impart health benefits.[13] The current evidence of protective effects of dietary polyphenols against chronic disease development has generated great interest from the beverage and nutritional supplements industry for the promotion and development of polyphenol-rich products.

Comprehensive reviews on the effect of high-pressure processing (HPP) on microbiological safety, quality, essential nutrients, and bioactive components are already presented by Barba et al., Barrett and Lloyd, Oms-Oliu et al., Gamlath and Wakeling, and Rastogi et al.[14−18] This review aims to complement those reviews by including the latest developments not included in or since publication of those papers (Table 1). Table 1 has summarized selective publications on the effects of HPP on the nutritional, microbiological, and physicochemical properties of fruit products.

TRADITIONAL PROCESSING OF FOODS AND BEVERAGES

Traditionally, the food industry has used thermal technologies to pasteurize and sterilize foods. Thermal processes are the established industry standard and involve subjecting foods/beverages to elevated temperatures for short periods of time with the goal of preventing growth of pathogenic microorganisms and spoilage-causing yeasts and molds to ensure safety over an extended shelf life. With the successful application of thermal processing, more people have access to a greater variety of safe foods and beverages. Although thermal processing is effective in inactivating detrimental microbiological intruders in foods and beverages, it can also destroy the functionality and flavors of many foods/beverages. For instance, reduced antiradical power values (as measured using 2,2-diphenyl-1-picrylhydrazyl radical (DPPH$^{\bullet}$) assay) were observed in strawberry purée samples treated with thermal processing when compared to unprocessed purée (reduced from 1.55 to 1.16 g/L^{-1}).[5] Increased processing temperatures can also significantly destroy heat-labile nutrients such as vitamins and bioactive phytochemicals. For example, Aaby et al. reported that exposure to relatively higher temperatures (75−80 °C) reduces the anthocyanin and total ascorbic acid content when strawberry is processed into purée.[19] In addition, thermal processing can also induce unintended formation of new compounds that may have unfavorable health effects or render the original compounds inactive.[20] Quality aspects related to flavor and color can also be compromised in thermally processed fruit juice concentrates such as strawberry concentrate stored at room temperature.[21]

CONSIDERATIONS FOR NEW PROCESSING TECHNIQUES

Currently, consumers have a greater appreciation for health-promoting properties of foods and demand foods and beverages that are fresher, nutrient dense, natural, additive-free, and minimally processed. Nonthermal food processing technologies have emerged as alternatives to thermal processing techniques to meet these consumer demands. HPP, light technologies (UV/pulsed UV), pulsed electric fields (PEF) treatment, and cold plasma are examples of nonthermal technologies. They are usually applied at (or below) room temperature and have minimal impact on the quality and freshness of food products,[22,23] including preserving nutrients and other health-promoting components. Klopotek et al. suggested that the reduction in total anthocyanins and hydrophilic antioxidant activity in strawberry beverages (nectar and juice) can be minimized if milder processing techniques are used instead of traditional thermal processing.[24]

The temperatures to which food products are exposed using advanced minimal processing techniques are relatively low and may be below pasteurization temperatures using conventional thermal processing.[25,26] For this reason, there is a tremendous potential for the production of superior quality products, especially with regard to higher nutrient content. Higher nutritive value is of no value, however, if the food is not safe. Hence, novel processing technologies that use temperatures below those used during thermal processing to enhance nutritional and other quality endpoints must also demonstrate the capability of inactivating microorganisms.[8,27,28] Research to optimize and validate novel processing conditions for different products will be of paramount importance for the industry in meeting consumer demands.

Research on processing technologies that retain freshlike appearance and high nutrient values in fruits has made tremendous progress in the past decade and will continue to develop in the future. In addition to enhancing nutrition and food safety, these novel technologies may reduce material, energy, and time costs.[29] Taste retention, shelf life extension, and fewer or no added chemical additives are also among the benefits touted, especially with HPP, making this a technology of great potential.

OVERVIEW OF THE HPP TECHNOLOGY

Among the nonthermal technologies, HPP is considered to be a promising technology for the food industry as it can result in the development of new shelf stable foods and/or extension of the shelf life of foods while preserving nutritional value and excellent organoleptic characteristics.[27,30] Therefore, food products treated with HPP have increasingly been introduced to the consumer market.[31] Formation of research consortiums across the globe and technological support from HPP manufacturing companies (Avure Technologies Inc., Elmhurst Research Inc., NC Hyperbaric, and many other established firms) have significantly contributed to the acceptance and implementation of HPP as a viable commercial alternative to thermal processing.

HPP can be used as an alternative processing method for fruit-based products while preserving the quality and nutritional properties of the products. Depending on the process temperature, HPP can be used for either pasteurization or sterilization of foods. In HPP, foods are subjected to high pressures by a hydraulic system in a pressure-sustainable

Table 1. Selected Examples of the Effects of HPP on Nutritional (Especially Bioactive Compounds), Microbiological, and Other Properties of Fruit Products

product	process conditions	effects on nutritional compounds including bioactives	effects on microorganisms	other effects (quality, physical properties, etc.)	ref
plum purée (cv. Crimson Globe, with red flesh and peel)	400, 500, and 600 MPa/1, 150, and 300 s	• slight reduction in anthocyanins and antioxidant activity after HPP, but no significant effect on total phenols	• inactivation of indigenous microorganisms (total aerobic mesophilic and psychrotrophic counts, and molds and yeasts) to undetected levels after HPP	• no significant changes in pH and soluble solid content after HPP • no sufficient inhibition of polyphenol oxidase (PPO) by HPP • significant enhancement of color: redness perception of treated purées	González-Cebrino et al.[47]
apricot nectars	300−500 MPa/5−20 min	• increased total and individual phenolics as a result of HPP, but no effect on total carotenoids and individual carotenes except for the treatment at 500 MPa/20 min, which increased total carotenoids and β-carotene		• significant activation of PPO and peroxidase (POD), but no change in the activity of pectinmethylesterase (PME) by HPP	Huang et al.[40]
fruit juice mixture (papaya, mango, orange)	300−500 MPa/5−15 min	• antioxidant compounds greatest with HPP at 300 MPa for 14 min			Carbonell-Capella et al.[71]
blueberry juice	200, 400, and 600 MPa/5, 9, and 15 min	• >92% vitamin C retention at all treatment intensities • increase in the total phenolic content mainly after HPP at 200 MPa for all treatment times • total and monomeric anthocyanin similar or higher than the value estimated for the fresh juice, being maximum at 400 MPa/15 min (16% increase) • no statistically different antioxidant capacity values for treatments at 200 MPa for 5−15 min in comparison with fresh juice • lowest values for total antioxidant capacity resulted from 400 MPa/15 min and 600 MPa for all times (8−16% reduction)		• no significant changes in pH and °Brix after HPP • no visually noticeable color changes after HPP	Barba et al.[23]
strawberry-based beverages formulated using milk vs water	200−800 MPa/1−15 min	• significant reduction of antioxidant capacity and flavonoid content by HTST pasteurization compared to HPP regardless of the matrix • potential protective effect of HPP (200−600 MPa) on antioxidant capacity that was not observed with HTST			Tadapaneni et al.[3]
avocado paste (*Persea americana* cv. Hass)	600 MPa/3 min	• significant increase (approximately 56%) in concentrations of total extractable carotenoids as a result of HPP • highest increases for individual carotenoids observed for neoxanthin-b (513%), followed by α-cryptoxanthin (312%), α-carotene (284%), β-cryptoxanthin (220%), β-carotene (107%), and lutein (40%); decrease in carotenoid levels during subsequent storage (40 days, 4 °C), but original carotenoid content was retained during product's shelf life (20 days) • decrease in ORAC values immediately after HPP followed by an increase during storage, indicating a minor contribution of the carotenoids to the total antioxidant capacity of the fruit			Jacobo-Velázquez and Hernández-Brenes[72]
blueberry juice	600 MPa/42 °C/5 min	• decrease <5% in ascorbic acid content compared with the untreated juice just after treatment • higher retention of ascorbic acid content during subsequent storage (56 days, 4 °C) in the HPP-treated juice in comparison with the untreated juice • better preservation of the antioxidant activity in the HPP-treated juice (21% loss) than in the untreated juice after 56 days at 4 °C		• slightly noticeable color changes (a^*, b^*, L, chroma, $h°$, and ΔE) after refrigerated storage in all juices	Barba et al.[22]

Table 1. continued

product	process conditions	effects on nutritional compounds including bioactives	effects on microorganisms	other effects (quality, physical properties, etc.)	ref
nectarine (*Prunus persica* L.) purées	450 and 600 MPa/ 5 and 10 min	• highest carotenoid extractability by the lowest HPP treatment intensity and holding time (450 MPa/5 min), but no differences in individual or total carotenoid levels between the purées at the end of the storage (day 60) • highest polyphenol content after treatment and during storage achieved by HPP treatment at 600 MPa for 10 min • significantly higher total antioxidant activity in the purée treated at 450 MPa for 10 min than in untreated purée at day 0, but highest antioxidant activity at the end of the purée treated at 600 MPa for 10 min	• microorganisms' inactivation by HPP and microbial stability of the purées during subsequent refrigerated storage (up to 60 days) similar to those by conventional thermal pasteurization (85 °C/5 min)		García-Parra et al.[73]
orange juice–milk beverage	100–400 MPa/ 20–42 °C/2–9 min	• ascorbic acid retention >91% after HPP • significant increase in phenolic compounds at 100 MPa/7 min, and a nonsignificant decrease at 400 MPa/9 min • significantly higher total carotenoid content in the beverages treated at all pressures for 7 and 9 min than in the untreated beverage	• 5-log reduction of *Lactobacillus plantarum* CECT 220 after HPP treatment at 200 MPa for 5 min		Barba et al.[51]
cashew apple juice	250 and 400 MPa/25 °C/ 3, 5, and 7 min	• no change in ascorbic acid or hydrolyzable polyphenol content by HPP • higher soluble polyphenol contents in the juice pressurized for 3 and 5 min • no change in the antioxidant capacity by HPP measured by the ferric-reducing antioxidant power method, but an increased value in the juice treated at 250 MPa for 3 min when 2,2-diphenyl-1-picrylhydrazyl used		• no change in pH, acidity, and total soluble solids content by HPP	Queiroz et al.[74]
pomegranate juice	350–550 MPa/ 30, 90, and 150 s	• slight reduction in the antioxidant capacity during refrigerated storage • significant increase (between 3.38 and 11.99%) in the phenolic content at day 0 in the juice treated at 350 or 550 MPa	• reduction of the microbial load by around 4.0 logs and inhibition of the microbial populations below the detection limit during storage (4 °C/35 days) by HPP at 350 MPa for 150 s		Varela-Santos et al.[52]
peach (*Prunus persica*) juice	400–600 MPa/ 25 °C/5–25 min	• better preservation of L-ascorbic acid by HPP than by thermal processing		• activation of PPO and PME by 7.3 and 2.6% at 400 MPa, but significant inactivation of PPO and PME at 500 and 600 MPa • better preservation of color and sensory quality by HPP than by thermal processing	Rao et al.[75]
mango nectars	600 MPa/1 min (steam blanching used prior to HPP to inactive endogenous enzymes)	• no significant changes in the antioxidant capacity (FRAP assay), L-ascorbic acid, sodium erythorbate, total phenols, and total carotenoids after HPP (similar to the effects observed for HTST treatment at 110 °C for 8.6 s) • no significant changes in the antioxidant activity and antioxidant compounds of the nectars after 16 weeks storage of the treated product at 4 and 25 °C • more pronounced decreases in L-ascorbic acid and sodium erythorbate in the HPP-treated product than in the HTST-treated product during storage		• no significant changes in redness (a^*), yellowness (b^*), and browning degree (BD) after HPP (similar to the effects observed for HTST treatment at 110 °C for 8.6 s) • no significant change in the lightness (L^*) after HPP (unlike a significant decrease observed after HTST treatment) • significant changes in color and BD of the nectars after 16 weeks of storage of the treated product at 4 and 25 °C, with no significant differences between HPP- and HTST-treated products	Liu et al.[76]

cylinder, generally in the range of 400−800 MPa with a lower holding time at a lower temperature than thermal treatments[32] (Figure 1). At these elevated pressures, detrimental microorganisms are destroyed without degradation of flavor and nutrients.[33] Due to the reduced thermal stress, HPP retains the nutrients and quality of fresh fruits and vegetables better than traditional thermal treatments.[2,34,35]

In addition, HPP can either activate or inactivate enzymes depending upon the treatment pressure and temperature. HPP treatment at higher pressures and temperatures led to substantial inactivation of enzymes. For example, HPP (alone or in combination with moderate heat treatment) partially or substantially inactivated quality-degrading enzymes such as pectinmethylesterase (PME), polyphenol oxidase (PPO), polygalacturonase (PG), and peroxidase (POD) in fruits and fruit products and thus minimized quality losses during storage.[3,36−39] However, HPP treatment at lower pressures and temperatures can activate enzymes or have minimal effects on their activity. For instance, Huang et al. reported significant activation of PPO and POD and no change in the activity of PME in apricot nectars as a result of HPP treatment at 300−500 MPa for 5−20 min (started at ambient temperature). In contrast, a high-temperature−short-time (HTST) treatment at 110 °C for 8.6 s induced a complete inactivation of these enzymes.[40]

Minimal effects of HPP on the color of fruit products have been reported by a number of researchers. Huang et al. reported that the color of apricot nectars was closer to that of untreated apricot nectar after HPP treatment (300−500 MPa/5−20 min) than after HTST treatment (110 °C/8.6 s).[40] Patras et al. demonstrated that processing strawberry purée with HPP resulted in minor color (red) reductions in the fruit product compared to thermally processed purées.[5]

SAFETY ENHANCEMENT AND SPOILAGE CONTROL IN FRUIT PRODUCTS BY HPP

HPP can be used for cold pasteurization (in the operating range of 5−25 °C) of fruit products. For instance, fruit jams and juices are normally processed at pressures around 400 MPa or higher for 5−10 min at ≤20 °C. The treatment significantly reduces the number of spoilage microorganisms (such as yeasts and molds) and pathogens (such as *Escherichia coli* O157:H7 and *Salmonella* spp.).[36,41−44] The refrigerated shelf life of such products can be up to 30 days or longer, and they have superior sensory quality compared with those prepared in a conventional manner.[45] García-Parra et al. reported that the inactivation of microorganisms by HPP in nectarine (*Prunus persica* L.) purées and the microbial stability of the treated product during subsequent refrigerated storage (up to 60 days) were similar to those achieved by conventional thermal pasteurization (85 °C/5 min). These treatment conditions (600 MPa for 10 min) also resulted in higher polyphenol content.[46] Donsi et al. found no fungal growth in high-pressure-treated lemon juice (450 MPa for 2, 5, or 10 min), whereas control samples were spoiled by yeasts and filamentous fungi after 10 days.[36] They also reported that HPP had minimal effect on the constituents of the lemon juice and physicochemical properties.[36] In an another study, González-Cebrino et al. reported that indigenous microorganisms (total aerobic mesophilic and psychrotrophic counts, molds, and yeasts) in plum purée (cv. Crimson Globe, with red flesh and peel) were inactivated to undetected levels after HPP treatment at 400, 500, and 600 MPa for up to 300 s.[47]

Ascospores of yeasts and molds may show higher resistance to pressure as compared to the vegetative cells. For instance, Raso et al. reported a 5-log reduction of the vegetative cells of *Zygosaccharomyces bailii* (spoilage yeasts) in apple, orange, pineapple, cranberry, and grape juices by high-pressure

dx.doi.org/10.1021/jf404400q | J. Agric. Food Chem. 2014, 62, 3877−3885

treatment at 300 MPa for 5 min, whereas the same treatment resulted in only 0.5−1.0-log reduction of the yeast ascospore.[48] The resistance of the ascospores also depends upon the food matrix and water activity. Butz et al. achieved a 4.0-log and <1.0-log reductions of *Byssochlamys nivea* mold ascospores in grape juice and bilberry jam, respectively, after a 700 MPa treatment at 70 °C for 30 min.[49] The reduced inactivation of ascospores in jam is mainly due to the reduced water activity. Application of HPP at elevated process temperatures has also been effective in the inactivation of acidophilic, spore-forming spoilage bacteria, which is of major concern in the fruit juice industry. Ardia et al. reported a 6.0-log reduction of *Alicyclobacillus acidoterrestris* DMS 2498 spores in orange juice at 700 MPa (80 °C initial temperature) for 20 min.[50] Barba et al. reported a 5-log reduction of *Lactobacillus plantarum* CECT 220 in an orange juice−milk beverage after HPP treatment at 200 MPa for 5 min.[51] Varela-Santos et al. demonstrated that HPP treatment at 350 MPa for 150 s was sufficient to reduce the microbial load in pomegranate juice by around 4.0 logs and keep the microbial populations in the product below the detection limit during storage (4 °C/35 days).[52]

In a study conducted by our group, the efficacy of HPP (400 and 600 MPa) as a cold pasteurization technique for the inactivation of pathogenic bacteria in a formulated strawberry−blueberry-based beverage (20 g of freeze-dried powder from each and 25 g of sugar in 8 oz, pH 3.70) was demonstrated. *E. coli* O175:H7 (ENT C9490),[53] *Salmonella* Typhimurium (ATCC 14028), and *Listeria monocytogenes* (FRR W2542)[54] were subjected to high-pressure processing (initial temperature = 4 °C and final temperature = 22−25 °C). The data indicated an increase in the level of inactivation with increasing pressure or pressure holding time (Figure 2). *E. coli* O157:H7 appeared to be the most pressure-resistant pathogen among the three bacteria tested. At 400 MPa, a maximum 4-log reduction of this pathogen was achieved in the beverage after a 10 min pressure holding time. In contrast, the other two pathogens, *S.* Typhimurium and *L. monocytogenes*, were inactivated by 5.5−6.0 logs after a 400 MPa pressure treatment for 5 min (Figure 2A). A 5 min holding time was sufficient to inactivate the pressure-resistant *E. coli* O157:H7 in the beverage by 5.7 logs at 600 MPa (Figure 2B). A >5-log reduction was achieved for the other two pathogens at 600 MPa after a pressure holding time as short as 1 min (Figure 2B). This study demonstrated that a 600 MPa treatment for 5 min would be sufficient to achieve a 5-log reduction of the most resistant pathogens of public health concern in the product as mandated by the U.S. Food and Drug Administration[55] and produce a beverage as safe as the thermally pasteurized product (71.1 °C for 6 s).

IMPACT OF HPP ON BIOACTIVE COMPOUNDS IN FRUIT PRODUCTS

Several researchers have investigated the effects of HPP on the nutritional quality of foods, especially fruits and vegetables, and suggested that HPP could be an effective processing method for retaining health-promoting compounds such as polyphenolic compounds.[14,15,18,56] In contrast to losses of bioactive compounds in fruit juices due to thermal processing,[57] HPP offers the benefit of retaining nutritive value of juices without compromising food safety. Recent findings on the effect of high-pressure processing on bioactive components are summarized in Table 1. Matser et al. reported that sterilizing herbs and essential oils by HPP treatment preserved the heat-sensitive bioactive phytochemicals in comparison to

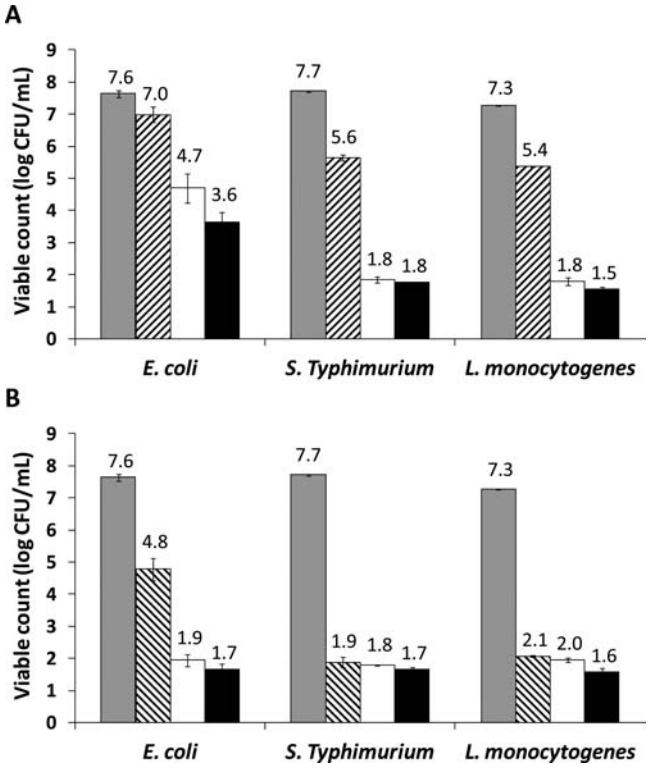

Figure 2. Viable counts of selected pathogenic bacteria (*Escherichia coli* O175:H7 (ENT C9490), *Salmonella* Typhimurium (ATCC 14028), and *Listeria monocytogenes* (FRR W2542)) inoculated in a formulated strawberry−blueberry-based beverage (pH 3.70) before treatment (gray bars) and after high-pressure treatment at 400 MPa (A) and 600 MPa (B) for 1 min (slashed bars), 5 min (white bars), and 10 min (black bars) (initial temperature = 4 °C). Bar graphs represent the mean viable counts of bacteria in the beverage obtained from two trials. Error bars indicate standard deviations, $n = 3$. Detection limit = 10 CFU/mL.

conventional retort process.[58] In a study investigating the total antioxidant capacity of reconstituted orange juice treated with different processing technologies, HPP-treated juice yielded higher total antioxidant retention under various storage conditions compared to conventional thermal pasteurization processing.[59] Other studies have indicated that the bioactive composition of strawberries is stable under pressures of 400−600 MPa, although there was a slight reduction in the anthocyanin content possibly due to interactions among flavonoid compounds under higher pressures.[60]

At the pressure of 600 MPa, total phenolics concentration in strawberry purée was increased by 9.8% and in a pressure range of 400−600 MPa the anthocyanin content was unaffected compared to thermal processing.[5] Researchers have shown that the extractability and potential bioaccessibility of compounds such as flavonols, carotenoids, and lycopene are improved with HPP.[61−63] However, the biological significance of high-pressure-processed fruit products, specifically as it relates to the bioavailability of nutrients and polyphenolic compounds, has not been studied.

The effect of food matrix may also affect the efficacy of HPP. Thermal versus HPP of strawberry-based beverages formulated using milk versus water showed that (1) the milk matrix alone (unprocessed) significantly the reduced antioxidant capacity and flavonoid content (i.e., anthocyanins and quercetin) of the beverages[3] and (2) processing with high temperatures

(pasteurization) significantly reduced the antioxidant capacity and flavonoid content compared to HPP regardless of the matrix. However, differential responses to HPP were evident depending on the matrix. Strawberry beverages without milk showed no significant difference in antioxidant capacity (as measured by oxygen radical absorbance capacity, ORAC) after HPP with pressures up to 600 MPa compared to unprocessed beverages, whereas applying higher pressures (700−800 MPa) resulted in significantly lower ORAC compared to unprocessed beverages. In contrast, beverages formulated with milk exhibited significantly higher ORAC values when treated with HPP up to 600 MPa compared to unprocessed beverages.[3] Measurements of antioxidant capacity by ferric reducing ability power (FRAP) showed that the strawberry beverage without milk had significantly lower FRAP values after HPP at all pressures tested (200−800 MPa). However, formulating the strawberry beverage with milk resulted in no change in FRAP after HPP compared to the unprocessed beverage.[3] Collectively, the data reveal an interaction of matrix and processing, suggesting a potential protective effect on antioxidant capacity with milk and HPP treatment that was not observed with HTST or water. Flavonoid composition decreased after the application of HPP (compared to the unprocessed beverages); however, reductions were modest compared to HTST processing and relatively stable until pressures of 700 and 800 MPa were applied. At higher pressures, reduced flavonoid concentrations were not different from those resulting from HTST.[3] Interestingly, the sensitivity of flavonoids to different pressures appeared to depend on the chemistry of the compound; for example, pelargonidin and quercetin linked to glucoside or malonylglucoside sugars were more stable at lower pressures than pelargonidin and quercetin compounds linked to rutinoside or coumaroylglucoside.[3]

Anthocyanins in fruit juices and purées (such as strawberry juice and purée, black currant juice, raspberry juice, and blackberry purée) have been reported to be stable to high-pressure treatment (up to 600 MPa) at ambient temperature.[5,19,64−66] Suthanthangjai et al. evaluated the effect of high-pressure treatment (200−800 MPa/18−22 °C/15 min) on anthocyanin in raspberry purée and observed the highest stability of the anthocyanin when the purée was pressurized at 200 or 800 MPa and stored at 4 °C.[67] Combined pressure and temperature treatment of blueberry juice resulted in a slightly faster degradation of total anthocyanins during storage as compared to heat treatments at ambient pressure.[67]

Ascorbic acid (vitamin C) is a heat-labile essential nutrient in fruits and vegetables. Canned fruit and vegetable products have lower ascorbic acid than fresh products.[4] Patras et al. reported that HPP treatment of strawberry purées resulted in a >90% retention of ascorbic acid, whereas significant losses of ascorbic acid were evident after thermal processing.[5] Polydera et al. reported greater retention of ascorbic acid in pressurized orange juice (500 MPa/35 °C/5 min) as compared to conventionally pasteurized juice (80 °C/30 s).[58,68,69] However, ascorbic acid content in orange juice was lower than that in untreated juice when pressurized (800 MPa/25 °C/1 min) and stored for >2 months at 4 or 37 °C.[58] These losses may be due in part to the length of storage. Fernandez Garcia et al. demonstrated that high-pressure treatment of orange juice and an orange−carrot−lemon juice product (500 or 800 MPa for 5 min) had no significant effect on the vitamin C content, antioxidant capacity, and sugar and carotene contents during storage for up to 21 days at 4 °C.[69] Retention of ascorbic acid was also found in strawberry nectar after high-pressure treatment at 500 MPa for 3 min at room temperature.[70]

Barba et al. studied the effects of HPP (600 MPa/42 °C/5 min) and PEF processing (36 kV/cm, 100 μs) on the quality and nutritional characteristics of blueberry juice. They observed a higher retention of ascorbic acid content (31% loss) and a better preservation of the antioxidant activity (21% loss) in the HPP-treated juice compared to the unprocessed and PEF-treated samples.[22] In another study, they found no statistical difference in the antioxidant capacity of blueberry juice treated at 200 MPa for 5−15 min compared to fresh juice.[23] However, the values were lowest after treatment at 400 MPa/15 min and 600 MPa/5−15 min.

HPP is among the emerging, novel, nonthermal technologies that present niche processing opportunities to commercial processors. Application of HPP to process fruit-based products has been shown to produce safe food and retain health-promoting bioactive compounds and other quality attributes compared to thermal processing. However, the biological importance of the retention of nutrients and bioactive phytochemical compounds imparted by HPP remains to be shown.

Overall, there is a critical need to deliver more opportunities to consumers to eat fruits and vegetables. HPP is poised to deliver on these opportunities by providing convenient, nutritionally improved products. In some cases, HPP may enhance the bioaccessibility of plant components, and therefore greater benefit may be afforded by the processed product. Due to the importance of diet (particularly fruits and vegetables) to health, there is no doubt that the field will continue to evolve.

effect in mixed fruit/mixed dietary polyphenol formulation were included in this review. Four studies were not included due to mixed fruit preparations[45−47] or mixed polyphenol sources (i.e., berry plus tea).[48]

INFLAMMATION – GENERAL OVERVIEW

Inflammation is the normal, protective, and (usually) temporary response of the innate immune system to pathogens and injury. However, with recurrent stimuli or inefficient regulation, chronic inflammation ensues. Quantifiable inflammatory responses are characterized by the production of pro-inflammatory molecules and anti-inflammatory cytokines acting as signals between immune cells to coordinate the inflammatory response. Cytokines are immune-modulatory molecules that control the inflammatory response. Nuclear factor kappa B (NF-κB), a redox-sensitive transcription factor, is a central orchestrator of the inflammatory response. Once NF-κB is activated, it stimulates the expression of a number of genes including those responsible for the production of cytokines (i.e., tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-1β), chemokines (i.e., monocyte chemoattractant protein (MCP)-1), adipokines (i.e., leptin, adiponectin), cell adhesion molecules (i.e., E-selectin, P-selectin, soluble vascular cell adhesion molecule-1 (sVCAM-1), and soluble intercellular adhesion molecule-1 (sICAM-1)), and acute phase proteins (i.e., (hs) C-reactive protein (CRP), fibrinogen).[49] Other important mediators of inflammation include pattern recognition receptors (PRR) such as Toll-like receptors (TLRs) and kinases such as mitogen-activated protein kinase (MAPK) and c-Jun N-terminal kinases (JNK). The inflammatory response can be triggered by stimuli such as endotoxin (lipopolysaccharide from bacteria), viruses, and changes in levels of reactive oxygen species (ROS), cellular redox status, fatty acids, cytokines, growth factors, and carcinogens among others.

LIFESTYLE CONTRIBUTORS TO INFLAMMATION

In addition to classic inflammatory stimuli (i.e., bacteria), inflammatory stress can also result from excess body fat and poor diet. Obesity is well recognized as a chronic, low-grade inflammatory state. Hotamisligil et al. first reported a positive relationship between adipose mass and expression of the pro-inflammatory gene TNF-α.[50] Nowadays, it is well recognized that adipose tissue is much more than a static depot of fat but rather a dynamic secretory tissue that produces a large number of hormones and cytokines.[51] In obesity, morphological changes in adipocytes result in altered secretory responses favoring an inflammatory state. Expanding adipose tissue mass recruits macrophages that produce pro-inflammatory proteins such as TNF-α, IL-6, and MCP-1 contributing further to the pro-inflammatory state. Elevated circulating inflammatory proteins are observed in obesity and explain the critical link between obesity and the development of insulin resistance, type 2 diabetes, and CVD.[52]

In addition to excess body adiposity, excess energy intake and poor dietary composition typical of Western eating patterns promote acute (postprandial) as well as cumulative sustained inflammatory responses in both obese and normal weight individuals.[53−56] The postprandial period is a time of active oxidative metabolism and formation of ROS. Excess energy intake stimulates overproduction of ROS, resulting in metabolic oxidative stress and cellular redox imbalance. This change in a cell's redox status activates redox-sensitive signaling molecules, such as NF-κB, JNK, and other stress-signaling molecules, ultimately resulting in increased expression of genes, many of which are inflammation mediators.[6] Hence, elevations in inflammatory molecules in the postprandial state are often accompanied, and perhaps preceded by, increases in oxidative stress markers.

MEASURING INFLAMMATORY STATUS

Several biomarkers have been identified as appropriate indicators of inflammatory status in humans. Circulating concentrations of inflammatory molecules, such as acute phase proteins, cytokines, adipokines, and adhesion molecules, are the main measures used in research as well as in some clinical practices. Gene expression of transcription factors, receptors, and protein kinases in immune cells such as monocytes and macrophages help to identify mechanisms and pathways that are either stimulated or inhibited under varying conditions resulting in a particular inflammatory outcome. The various (pro-)inflammation markers that are measured in humans include the acute phase proteins (CRP, fibrinogen, serum amyloid A); cytokines and chemokines (TNF-α, IL-6, IL-1β, MCP-1); and adhesion molecules (E-selectin, P-selectin, sVCAM-1, sICAM-1). Anti-inflammatory markers that are measured and may be suppressed in inflammation include adiponectin and IL-10. Commonly measured molecular targets for assessing inflammation include suppressor of cytokine signaling (SOCS) and NF-κB.[57] In general, modulation of these responses, negatively or positively, acutely or sustained under the various circumstances is measurable. Healthy individuals define fluctuations within a "normal" range and demonstrate a relative homeostatic flexibility. Assessing the effects of nutrition/nutritional components on inflammation/inflammatory status has been suggested to include examining patterns of change in inflammatory markers against a reference range for "normal" or prevention of modulation induced by other factors (such as poor diet) and modulation from a less favorable range to a more favorable range.[58] Other effects may include modulation from outside the reference range back into the reference range or modulation from within the range to outside the range. Even with this background, the study of nutrition and inflammation in chronic diseases (NCD) development/prevention/management is relatively new. Continued attention to the field and reviews such as this will help advance knowledge and constructive design of future research.

BERRIES, ANTHOCYANINS, AND BIOLOGICAL EFFECTS

The botanical definition of a berry is different from the average consumer's definition of "berries" in the marketplace. Botanically, berries are defined simply as fleshy fruit produced from a single ovary.[59] In common English terms, "berries" are usually described as small edible fruits that are brightly colored in shades of red-blue-purple and do not have a pit, although they may contain seeds. Consumers typically identify strawberries, blueberries, blackberries, and raspberries as "berries", but only blueberries are true berries according to the scientific definition of a berry. Despite the incongruent definitions, one unifying trait among "berries" (with few exceptions) is that they contain anthocyanins, which are pigment polyphenol compounds that give them their distinctive color.

Anthocyanins constitute a significant percentage of berry polyphenols. Anthocyanins are a type of flavonoid; they are glycosylated polyhydroxy and polymethoxy derivatives of flavilium salts and possess a characteristic C6−C3−C6 carbon

structure (Figure 1).[60] The most commonly identified anthocyanins in berries are cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin. In addition to anthocyanins, berries contain several other (poly)phenolic compounds that may contribute to their anti-inflammatory potential, such as flavonols, phenolic acids, proanthocyanidins, and ellagitannins. Anthocyanins are uniquely characterized by the presence of an oxonium ion on the C ring and are highly colored (Figure 1).[61] Selected details of the anthocyanin content of berries are presented in Table 1.

Estimates of anthocyanin intake vary widely within and between populations as does the composition of anthocyanin intake, which is based on food and beverage selection. In France, anthocyanin intake is estimated to be ~57 mg/day,[62] and in Finland, an average intake of 47 mg/day of anthocyanins has been estimated.[63] Wu et al. estimated that the daily consumption of anthocyanins in the United States in 2001−2002 from fruits, vegetables, and beverages was 12.5 mg/day.[64] Of the total anthocyanins consumed/day, almost 70% was accounted for by fruit intake (24 g of fruit contributing ~8.7 g of anthocyanins). Apples ('Red Delicious') dominated the percent of fruit intake (~50% of anthocyanin-containing fruit), yet apples contributed only 8% of anthocyanin intake. In contrast, berries were only ~13.5% of the fruit intake, but contributed ~56% of the fruit-derived anthocyanins. Americans currently eat about half the dietary recommendation for fruit (1 cup equivalent/day), and on the basis of these data, fruit variety, particularly of the red-blue-purple fruits, appears to be limited.[65,66]

Berry research has traditionally focused on their antioxidant properties. Berries (or their extracts) rank highly on in vitro antioxidant measures, such as oxygen radical absorbance capacity (ORAC) and ferric reducing antioxidant capacity (FRAP) analyses,[67−69] and have been shown in various in vitro assay systems to mitigate oxidative stress.[70−72] Polyphenols, including anthocyanins, have antioxidant capability; however, biologically, several studies suggest that their effects in vivo are not through antioxidant scavenging properties. Current dogma suggests polyphenols work via activation/inhibition of various cell signaling processes such as modulating kinase activity resulting in transcription factor activation (e.g., Nrf-2, NF-κB), altering receptor activation (PRR dimerization) as well as possible direct ligand activity (e.g., PPAR-γ).[73,74] Berry extracts and anthocyanin preparations have been shown in various in vitro and in vivo animal models to affect specific steps in cell

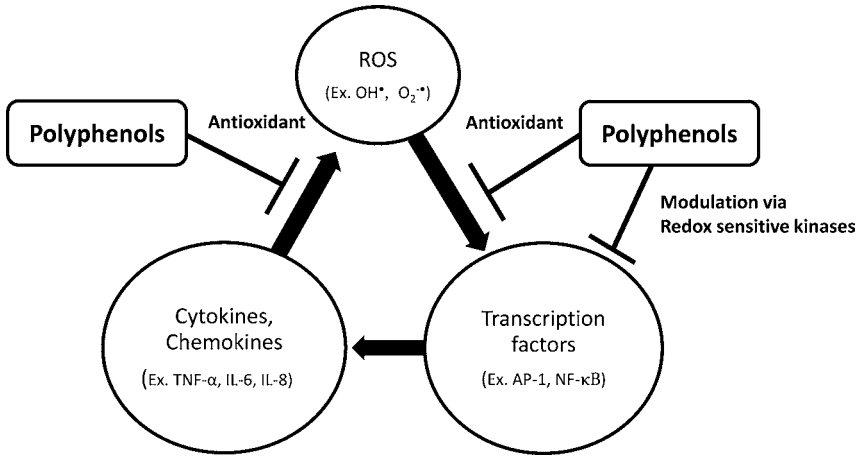

Figure 2. Schematic representation of link between antioxidative and anti-inflammatory potential of dietary polyphenols. signaling pathways that are known to be involved in chronic disease initiation and development[75−82] including anti-inflammatory-specific effects.[83−88] Recent in vitro work with red wine and grapes has also shown anti-inflammatory effects that authors attribute to their specific anthocyanin content.[89,90]

During inflammation, cells involved in the inflammatory process, which are recruited to the damage site, take up oxygen and release ROS. In addition, inflammatory cells secrete cytokine and chemokine cell mediators, which help to further recruit inflammatory cells, generating yet more ROS. As a result, transcription factors such as NF-κB and activator protein-1 (AP-1) that encode pro-inflammatory genes are activated, leading to an increased secretion of cytokines. The presence of this vicious cycle supports a sustained environment of oxidative and inflammatory stress, which contributes to several chronic diseases. Dietary polyphenols are known to act as both antioxidants and anti-inflammatory molecules, thereby conferring considerable potential protective effects against development of inflammation-related chronic diseases (Figure 2).

Overall, the preclinical literature suggests a role for berries in modifying inflammatory status, an effect that may be due to their polyphenol content in general or anthocyanins in particular. A major question that remains is whether these effects translate to humans.

EFFECTS OF "COMMON" BERRIES AND BERRY PRODUCTS ON INFLAMMATORY MARKERS IN HUMANS

Berries that are readily available and widely consumed by the general population are those that are cultivated for wide commercial distribution. Strawberries, blueberries, cranberries, and black currant are among the most common. Eighteen human clinical trial investigations have been identified examining the effects of common berries on markers of inflammation, generally or specific to CVD risk. Two studies[97,111] involved both an acute and a chronic intervention, which were counted as four separate investigations. Of the 18 studies/investigations, 5 were acute interventions (postprandial paradigm: 2.5−6 h study duration) and 13 were chronic feeding interventions (ranging between 3 and 12 weeks in duration). Blueberry, including wild blueberries, cranberries, and strawberries were investigated in 5/6, 4, and 7 of the clinical trials, respectively, and black currant was investigated in 1 of the 18 investigations (Table 2).

Black Currant. Black currants are native to parts of Europe and Asia and are an excellent source of vitamin C in addition to anthocyanin polyphenols. The major anthocyanins found in black currants include cyanidin-3-*O*-glucoside, cyanidin-3-*O*-rutinoside, delphinidin-3-*O*-glucoside, and delphinidin-3-*O*-rutinoside.[91] The rutinosides are reported to be absorbed intact and, following ingestion, reach peak concentrations in circulation 1−2 h after intake.[92] Black currant has been studied previously as part of mixed-fruit formulations; however, one study was identified that assessed markers of vascular inflammation after consumption of black currant fruit exclusively.[93] Twenty healthy men and women drank a black currant (20% juice) or placebo juice devoid of polyphenols and vitamin C. No significant effects were observed on markers of (vascular) inflammation, sVCAM-1 or sICAM-1, 3 h after beverage intake.[93] No additional inflammation associated data were available; hence, the anti-inflammatory effects of black currant in humans are inconclusive.

Blueberry. Blueberries are well-known for their antioxidant effects in vitro and in vivo.[94] In the past few years, data on blueberry consumption and inflammatory status have emerged, although results have been inconsistent. Four long-term (6−8 weeks) interventions showed no effect of blueberry supplementation on selected inflammatory markers,[95−98] whereas one acute study reported significant improvements in inflammatory status attributable to blueberry intake in an exercise model.[97]

Basu and colleagues[95] administered freeze-dried blueberry powder to 48 individuals with metabolic syndrome (MetS) for 8 weeks. The daily dose of 50 g of blueberry powder (equivalent to 350 g of the fresh fruit) was provided as a water-based drink divided into two beverages per day. At the end of the intervention, blueberry intake did not elicit significant changes in fasting plasma hs-CRP, IL-6, adiponectin, or adhesion molecules (sICAM-1 and sVCAM-1) compared to the plain water control. Stull et al. conducted a similar chronic dosing of blueberries (45 g of freeze-dried blueberry powder per day for 6 weeks) in 32 obese men and women with insulin resistance.[96] Blueberry powder (daily amount equivalent to 2 cups of fresh fruit) was blended into a yogurt plus milk beverage. At the end of the double-blinded, parallel arm intervention, there were no differences in changes in circulating hs-CRP, TNF-α, or MCP-1 in the blueberry group compared to the control. In a separate study of males presenting with at

[f]Postprandial test meal did not include strawberry beverage.

dx.doi.org/10.1021/jf4044056 | J. Agric. Food Chem. 2014, 62, 3886−3903

least one CVD risk factor, no change in inflammatory markers (IL-6, TNF-α, hs-CRP) or adhesion molecule (sVCAM-1) after 6 weeks of supplementation with a wild blueberry drink (25 g of freeze-dried powder and 375 mg of anthocyanins) compared to a polyphenol-free control beverage was observed.[98] These results are consistent with McAnulty et al., who also found no changes in fasting blood markers of inflammation (IL-1 receptor antagonist (ra), IL-6, IL-8, and IL-10) after study participants (trained athletes) ingested 250 g/day of whole blueberries for 6 weeks.[97] However, blueberry consumption increased counts of natural killer (NK) cells in the study subjects. NK cells promote natural cellular toxicity, for example, in counteracting proliferation of cancerous cells,[99] which suggests that blueberries may beneficially modulate the immunological profile separate from inhibiting pro-inflammatory molecules. The same researchers also investigated the acute effects of blueberries in an exercise-induced inflammation paradigm at the end of the 6 week experimental period. Subjects ingested either 375 g of blueberries (n = 13) or no blueberries (n = 12) 1 h prior to 2.5 h of treadmill running. Pro-inflammatory markers, including circulating total leukocyte count, IL-8, IL-6, and IL-1ra, and skeletal muscle NF-κB activity, were measured 1 h after completion of the exercise: no differences between the two groups on these measures were observed. However, blueberry supplementation increased the anti-inflammatory regulatory cytokine IL-10 following exercise, which coincided with reduced oxidative stress as measured by F2-isoprostanes. In a shorter duration exercise study (60 h), oxidative stress and inflammation were assessed after intense strenuous eccentric contractions of the quadriceps with blueberry (in a smoothie) or a placebo smoothie devoid of blueberry.[100] Whereas a faster rate of recovery was observed in the blueberry group, improvements in oxidative stress were not observed until 36 h and inflammatory indicators of damaged muscle (creatine kinase and IL-6) were still elevated in both groups ($P > 0.05$, treatment effect).

Collectively, the data supporting a beneficial association between blueberries and inflammatory status are unremarkable at present; however, the positive effects on selected beneficial immune/inflammation biomarkers[97] warrant further investigations to understand dose/amount−response of blueberries, delivery, and metabolic status of subject population on outcomes, which may help to explain the differences between clinical and preclinical studies on anti-inflammatory effects elicited by blueberries.

Cranberry. Cranberries, a popular fruit consumed as juice and jelly and in dried form are best known for their urinary tract infection-preventing benefits.[101] Cranberries are rich in cyanidin- and peonidin-glycosides,[102] pro-anthocyanidins (particularly the A-type), flavonols, and phenolic acids.[103] Clinical investigation of the anti-inflammatory effect of cranberries is supported by in vitro studies; [104] however, the clinical results are mixed. Specifically, in two of four clinical trials with cranberry juice, Ruel and colleagues[105,106] reported favorable anti-inflammatory effects of cranberry in a dose-escalation paradigm over 12 weeks in abdominally obese men (n = 30; waist circumference $\geq$ 90 cm), whereas in two other investigations no significant effect of cranberry juice supplementation was observed compared to placebo[107,108] (Table 2). Distinct differences in study design, doses, supplement duration, and populations may account for at least part of the discrepancy in outcomes.

Ruel et al. used a dose escalation schema wherein subjects increased their daily intake of cranberry juice every 4 weeks starting with 125 mL, then moving to 250 mL, and finally ending their last 4 weeks of the 12 week study with 500 mL/day (total phenols, 100 mg/125 mL juice).[105,106] No control group was used for comparison. At the end of 4 weeks, subjects had significantly lower plasma concentrations of sVCAM-1 and sICAM-1[105] and MMP-9[106] compared to baseline. Plasma soluble E-selectin remained unchanged. Two subsequent studies from different researchers recruited individuals with MetS[107] and patients with coronary heart disease (CHD)[108] and supplemented cranberry juice for 8 and 4 weeks, respectively. Amounts of cranberry juice did not differ remarkably between the two Ruel et al. studies and the Basu et al. and Dohadwala et al. studies (500 vs 480 mL); however, the dose of total phenols was nearly double (835 mg) in the Dohadwala et al. trial.[108] Basu et al. reported no significant improvements in plasma hs-CRP or IL-6,[107] and, similarly, Dohadwala and colleagues reported no significant change in circulating hs-CRP and sICAM-1 concentrations after 4 weeks of the double-strength juice.[108] Whether a longer duration of consumption or an acclimation to higher doses over time is needed to observe effects is not clear. Likewise, much like the research with other berries, it is not clear what amounts of fruit may be necessary to impart anti-inflammatory benefits in the different populations being studied.

Strawberry. Strawberries, widely consumed fruit in North America, contain a number of essential nutrients, such as vitamin C and potassium as well as polyphenolic components, including anthocyanins, ellagitannins, and various flavonols. Pelargonindin-3-*O*-glucoside is the main anthocyanin of strawberries, with lesser amounts of cyanidin glycosides.[109,110] Published human studies assessing strawberry intake and inflammation outcomes have been from acute[7,111] as well as long-term-feeding studies.[111−114] The two acute postprandial studies tested a freeze-dried strawberry powder incorporated into a challenge meal paradigm to test the ability of strawberries to attenuate meal-induced inflammation. Edirisinghe et al. studied the acute postprandial effects of strawberries in a milk-based beverage (10 g of freeze-dried strawberry powder; 94.7 mg of total polyphenols) on selected inflammatory markers in 24 overweight individuals.[7] A beverage matched for sensory attributes, total calories, and macronutrients was used as the placebo. Blood sampling was conducted at baseline (0 h) and up to 6 h post-challenge meal (with strawberry or placebo beverage). Inclusion of the strawberry drink with a high-calorie breakfast resulted in lower cumulative plasma concentrations of IL-6 and hs-CRP over the 6 h period following the meal. Concentrations of TNF-α, IL-1β, and plasminogen activator inhibitor-1 (PAI-1), a thrombolytic factor, did not differ between strawberry and placebo conditions. This group of men and women was then subjected to the same postprandial protocol (high-calorie challenge meal with placebo beverage only) after 6 weeks of daily supplementation with either the strawberry beverage or the placebo beverage.[111] Contrary to the results of the acute study, there were no differences between treatments on post-challenge meal/postprandial IL-6 or hs-CRP after 6 weeks of strawberry intake or placebo intake. However, significant decreases in postprandial IL-1β and PAI-1 were observed in those individuals who consumed the strawberry beverage for 6 weeks. Whereas the effect of strawberry on endpoints of inflammation differed between study paradigms, an anti-inflammatory effect

was consistently found with strawberry consumption. Follow-up investigations to understand the different mechanisms involved with the observed responses under different feeding conditions are ongoing. Possible explanations for the different responses may be related to the milieu of strawberry metabolites circulating in an acute setting versus on the background of a dietary pattern including daily consumption of strawberries.

Chronic feeding studies with strawberries were conducted in four different subject populations: overweight,[111] individuals with MetS,[112,113] obese,[114] and patients at risk for cancer.[115] Outcome measures were fasting concentrations of inflammatory markers following strawberry interventions ranging from 3 to 6 weeks. In overweight individuals (n = 24) who consumed 10 g of freeze-dried strawberry powder in a beverage daily for 6 weeks (compared to energy-matched control beverage), no significant treatment effects were reported on fasting concentrations of inflammatory markers (i.e., hs-CRP, IL-6, IL-1β).[111] Consistent with these findings, no significant differences in fasting hs-CRP, complement C3, serum amyloid A, fibrinogen, IL-1β, IL-6, IL-8, TNF-α, leptin, sICAM-1, or sVCAM-1 were reported in obese men and women (n = 20) after 3 weeks of supplementation with freeze-dried strawberry powder (equivalent to ∼320 g of frozen fruit) incorporated into yogurt, cream cheese, and smoothie compared to the same foods without strawberry powder.[114] In MetS subjects,[112,113] 50 g/day of freeze-dried strawberry powder (equivalent to ∼500 g of fresh fruit) prepared in water and drunk daily for 8 weeks significantly reduced sVCAM-1, but not sICAM-1.[113] Individuals with MetS have higher blood levels of adhesion molecules,[116] which are associated with endothelial inflammation and higher CVD risk. In a smaller (n = 16) and shorter duration (4 weeks) pilot study with MetS women ingesting 50 g of freeze-dried strawberry daily (no comparator group), no significant changes in plasma hs-CRP or adiponectin were observed.[112] Chen et al. studied strawberry supplementation in patients with esophageal dysplastic lesions who are at risk for developing esophageal cancer.[115] Using a parallel design study, subjects consumed either 60 or 30 g (n = 36 per group) of freeze-dried strawberry powder in the form of a water-based drink for a period of 6 months. At the end of the supplementation period, patients who had consumed the 60 g dose had significantly lower protein expression of iNOS (79.50% reduction), COX-2 (62.9% reduction), pNF-κB-p65 (62.6% reduction), and pS6 (73.2% reduction) in esophageal mucosa. Reductions in the same parameters were also observed in the group receiving 30 g of strawberry powder/day, but the changes were not statistically significant from baseline measurements.

Overall, the available data on strawberry consumption support future research to better understand dose−response dynamics in different populations, acute versus chronic intake (eating) regimens, matrix effects, and the relationship between polyphenol metabolite profiles and (anti-)inflammation outcomes.

Among the four types of berries reviewed in this section, cranberries and strawberries showed "inhibitory" effects on selected pro-inflammatory markers,[7,105,106,111,113] whereas blueberry intake resulted in beneficial effects on immune function by increasing anti-inflammatory/regulatory molecules.[97] In four studies in which a relative oxidative and inflammatory stress was imposed, after exercise,[97,100] or after eating meals typical of Western meal composition,[7,111] or in MetS[113] or abdominal obesity,[105,106] consuming cranberries, blueberries, and strawberries resulted in beneficial anti-inflammatory responses.

EFFECTS OF "LESSER-KNOWN" (LIMITED DISTRIBUTION) BERRIES AND BERRY PRODUCTS ON INFLAMMATORY MARKERS IN HUMANS

Several berry fruits remain underutilized due mainly to harvest in the wild and local consumption.[117] They are indigenous to different parts of the world, with limited cultivation for commercial distribution. However, many, if not all, of these berries are rich sources of anthocyanins[118,119] and other polyphenolic compounds, which have been shown to mitigate the negative effects of oxidative and inflammatory stress in animal and in vitro experiments.[37,120−122] This section of the review discusses human intervention studies of the less commonly known berries on selected clinically relevant inflammatory markers associated with chronic diseases. Details of the investigations are presented in Table 3. A total of 12 studies are presented in this section and include clinical trials on bilberry,[123−125] black raspberry,[126,127] chokeberry,[128] sea buckthorn berry,[124,129−131] wolfberry,[132] and a berry mixture of lingonberry, bilberry, black currant, and sea buckthorn berry.[133] All interventions were chronic feeding studies except for one postprandial experiment with sea buckthorn berries.[131]

Bilberry. Bilberries are rich sources of polyphenols. Anthocyanins comprise nearly half to three-fourths of the total polyphenol content of bilberries.[134] Three clinical trials were identified that included markers of inflammation as study endpoints. All three investigations reported anti-inflammatory effects associated with bilberry consumption for 4−8 weeks. Karlsen et al. studied the effects of 330 mL of bilberry juice/day for 4 weeks in men and women (n = 62) who were at risk for CVD development based on the presence of at least one predisposing risk factor such as cigarette smoking, hypertension, or elevated LDL-cholesterol concentrations.[123] At the end of the 4 weeks, bilberry supplementation compared to water control resulted in lower levels of circulating IL-6, hs-CRP, and monokine induced by interferon-γ (MIG). However, the authors also reported an increase in plasma TNF-α, which was incongruent with the IL-6 and hs-CRP findings: these cytokines are known to be positively related. In contrast, Lehtonen et al. reported a decrease in plasma TNF-α concentration with frozen whole bilberries (equivalent to 100 g fresh fruit) at the end of a 33−35 day intervention in overweight and obese women (n = 110).[124] In addition, while there was no impact on levels of hs-CRP, IL-6, or sICAM-1 concentrations, bilberries resulted in a decrease in plasma sVCAM-I and adiponectin. Epidemiological studies show that circulating adiponectin levels are inversely proportional to body fat and inflammation and positively associated with insulin sensitivity, and thereby adiponectin is inversely associated with CVD risk. According to the authors,[124] the decreased adiponectin concentrations in response to bilberry consumption may be reflective of a lack of sufficient adaptation time required to observe changes in adiponectin concentrations in circulation[135] and not necessarily a detrimental effect of bilberries.

Kolehmainen et al. reported outcomes from an intervention in which men and women with MetS supplemented their habitual diet with bilberries.[125] The parallel arm study included a 4 week run-in phase, an 8 week intervention, and a 4 week follow-up period. Individuals in the bilberry group consumed daily 200 g of berry puree (524 mg anthocyanins/100 g) plus 40 g of dried berries (832 mg anthocyanins/100 g; equivalent to 200 g of fresh berries) to provide a total dose equivalent to

Table 3. Effects of Lesser-Known (Limited Distribution) Berries on Inflammatory Markers in Humans[a]

[g]Lingonberry, bilberry, black currant, sea buckthorn. [h]Juice, bread, berry powder, berry oil, dried berries.

dx.doi.org/10.1021/jf4044056 | J. Agric. Food Chem. 2014, 62, 3886−3903

400 g/day of fresh bilberries. Control subjects consumed only their habitual diet but were allowed to occasionally include a maximum of 80 g of fresh berries/day. Compared to the control group, subjects in the bilberry group showed significant improvements in serum hs-CRP and IL-12 ($p < 0.05$), whereas IL-6 and LPS tended to be lower ($p = 0.074$ and $p = 0.094$, respectively). Bilberry supplementation did not affect leptin and adiponectin levels.

Black Raspberry. Black raspberries are native to North America and are darkly pigmented, reflective of their high anthocyanin content (about 214−589 mg/100 g).[136] Black raspberries exhibit potent antioxidative capacity in vitro, and a considerable amount of research on black raspberries pertains to their preventative effects on different cancers both in vitro and in animals.[137,138]

Two human interventions with black raspberries have been recently published. Patients with colorectal cancer were supplemented with 60 g/day freeze-dried powder for approximately 3 weeks (10−63 days).[126] A daily dose of 60 g/day (20 g in a water slurry 3 times a day) provided 1669 mg of anthocyanins. Plasma levels of cytokines (IL-1β, IL-2, IL-6, IL-8, IL-10, IL-12p70, granulocyte macrophage colony stimulating factor (GM-CSF), IFN-γ, and TNF-α) were measured before and after treatment with black raspberries. The berry intervention increased plasma GM-CSF concentrations. Patients receiving berries for more than 10 days also had decreased plasma concentrations of IL-8. An increase in IL-8 has been observed in colorectal carcinoma.[139]

Sardo et al. tested postprandial effects of 45 g of freeze-dried black raspberry powder consumed with an inflammatory high-fat high-carbohydrate (HFHC) meal in overweight men ($n = 10$). The postprandial investigation (up to 12 h) was preceded by 4 consecutive days of black raspberry intake (45 g/day). Under the control condition, no berry powder was consumed either preceding or during the postprandial testing day.[127] The HFHC meal provided 1090 calories, 56 g of total fat, and 156 g of carbohydrates. The areas under the curve (AUC) for IL-6, TNF-α, and CRP during the postprandial period were compared between the black raspberry−HFHC meal regimen and the control condition. Black raspberry powder consumption with the HFHC meal resulted in a significant decrease in IL-6 AUC compared to no berry intake (HFHC meal alone). No effects were observed with black raspberry powder on TNF-α and CRP.

Sea Buckthorn Berry. Sea buckthorn berries are native to India, China, and Eastern Europe and have traditionally been used in Eastern medicine.[130] The polyphenols in sea buckthorn berries are composed mainly of flavonol glycosides (isorhamnetin-3-rutinoside, -galactoside, and -glucoside) but also contain smaller amounts of the anthocyanins delphinidin, cyanidin, and peonidin.[118] In vitro studies indicate that sea buckthorn berries may have potent inhibitory effect on CVD risk markers including exerting anti-inflammatory activity.[141] A single postprandial study[131] and three chronic supplementation studies with sea buckthorn berries have been reported.[124,129,130] In a relatively small group of men ($n = 10$), intake of dried and crushed whole sea buckthorn berries (equivalent to 200 g of fresh whole berries and providing 22.8 mg of flavonol glycosides/portion) did not significantly affect levels of TNF-α in circulation during a postprandial investigation.[131] The study used a crossover design in which sea buckthorn berries were incorporated into a yogurt-based meal containing 50 g of glucose. The same meal without berries represented the control. Although blood samples were collected for up to 360 min during the postprandial phase, TNF-α was measured only at baseline (0 min) and 60 min after meal consumption. The trajectory of the TNF-α response suggested that the meal was inducing an increase in TNF-α and that concomitant intake of sea buckthorn berries with the meal was attenuating the increase; however, this was not significant ($p = 0.175$). An insufficient sample size and high between-subject variability along with measuring a single inflammatory biomarker (TNF-α) at only two time points (0 and 60 min) are insufficient to understand the potential benefits of sea buckthorn berries on postprandial inflammation in humans, particularly when others have shown the response may not be evident until 3−6 h.[7,54,142] In 2002, Eccleston et al. conducted a parallel arm intervention in men ($n = 10$/group) to study the effect of ingesting 300 mL of a sea buckthorn berry juice (containing 1182 mg/L of flavonoids) for 8 weeks.[129] No effect of supplementation was found on plasma sICAM-1 concentrations, which was the only marker measured. Two recent human studies[124,130] reported favorable effects of sea buckthorn berries on inflammatory markers. Two hundred and thirty-three subjects were supplemented for 90 days with either a frozen sea buckthorn puree or a placebo puree that had similar sensory attributes. The daily dose of 28 g of berry puree provided about 8.4 mg of flavonols. At the end of the intervention, consumption of sea buckthorn berries resulted in lower hs-CRP concentrations in serum compared to placebo.[130] A similar anti-inflammatory effect was observed in the second published intervention in which overweight and obese women ($n = 110$) consumed air-dried whole sea buckthorn berries (representing approximately 100 g of fresh berries).[124] Plasma TNF-α, hs-CRP, IL-6, sVCAM-I, adiponectin, and sICAM-1 concentrations were measured before and at the end of the 33−35 day intervention. Supplementation with the sea buckthorn berries resulted in lower circulating TNF-α concentrations, but no change was observed in hs-CRP.

Lehtonen et al. studied the long-term effects of 20 weeks of supplementation of four different berries (bilberry, black currant, lingonberry, and sea buckthorn berry) in the form of traditional berry products, as well as berry oils.[133] Sixty-one disease-free women were randomized to either the treatment group or a control group (lifestyle intervention but no additional berries). The active group consumed 3 servings of berry products daily plus 0.5 g of berry oil/day (equivalent to 163 and 245 g of fresh berries, respectively). The control group consumed lower amounts of berries per day (27 g). The 18 berry products, comprising breads, juices, berry powder, dried berries, and berry oils, were consumed according to a specified consumption cycle. At the end of the 20 week intervention with the mixture of berries, there was a significant increase in levels of adiponectin from baseline, but also an unfavorable increase in soluble adhesion molecules (sVCAM-1 and sICAM-1) in the active group; however, there were no significant treatment differences observed between active and control groups. No effect of berry supplementation was observed on hs-CRP and TNF-α levels in either group.

Wolfberry. The results of a single intervention on wolfberry (also known as goji berry) in a sample population of 60 healthy men and women utilizing a parallel design have been reported by Amagase et al.[132] Goji berries have been traditionally used in Chinese medicine and are rich sources of carotenoids, particularly zeaxanthin, but also flavonoids and betaine.[143,144] To the best of our knowledge, goji berries are an example of

berries that do not contain anthocyanins or, if they do, quantities are too low to detect. The intervention included supplementation of the berries as a fruit juice. A beverage with comparable taste, color, and flavor was used as the placebo control. Subjects consumed a total of 120 mL of juice/day in two equal doses after the morning and evening meals for a period of 30 days. At baseline and the end of the treatment period, the following immunological markers were measured: counts of CD4, CD8, lymphocytes, and NK cells, in addition to circulating concentrations of IL-2, IL-4, immunoglobulin (Ig) G, and IgA. At the end of the 30 days, significant increases were found in the levels of serum IL-2, IgG, and NK cells with consumption of the goji berry juice compared to placebo. Similar beneficial immunological changes were observed when baseline to phase end differences between the two groups were compared.

Chokeberry. Chokeberries, which are native to parts of North America and Eastern Europe, are rich in the anthocyanins cyanidin-3-arabinoside, cyanidin-3-galactoside, cyanidin-3-glucoside, and cyanidin-3-xyloside, with total anthocyanin concentrations varying from 357 to 1790 mg/100 g fresh weight.[140] One investigation was identified reporting inflammation biomarkers after consumption of chokeberries.[128] Fifty-eight nonmedicated hypercholesterolemic men drank 250 mL/day of 100% chokeberry juice (total polyphenol content = 40−70 mg/g dry weight) for 6 weeks followed by 6 weeks of discontinuation of juice intake (washout) and followed by another 6 weeks of juice intake. Fasting blood concentrations of hs-CRP and fibrinogen were measured at the beginning of the study and three more times at the end of each 6 week period (two juice periods and one washout period). Chokeberry juice intake did not significantly change hs-CRP concentrations in these subjects compared to baseline. However, circulating fibrinogen levels were lower at the completion of all phases compared to baseline, and significantly so at the end of the second chokeberry intervention phase ($p < 0.01$). Fibrinogen is a known coagulation factor, but also has a pro-inflammatory role in a number of chronic diseases: several studies suggest fibrinogen is a key regulator of inflammation.[145]

In summary, 10 of the 12 studies reviewed in this section showed a beneficial effect of lesser known berries on selected pro-inflammatory and adhesion molecules in circulation. The single study on wolfberry showed that intake increases beneficial immune cells and molecules in humans.[132] The two studies that showed no effect of sea buckthorn intake may have been mainly due to the small sample of subjects ($n = 10$) or to study/sampling design. Compared to the commonly consumed berries such as strawberries and blueberries, the lesser known berries appear to exert an overall consistent anti-inflammatory effect in humans. These promising data support the value of including these berries in the diet and support research to advance cultivation and distribution for widespread sale and consumption.

EFFECTS OF BERRY EXTRACTS AND ANTHOCYANINS ON INFLAMMATORY MARKERS IN HUMANS

The use of whole fruit and whole fruit products, comprising several beneficial components, has been demonstrated to mitigate inflammatory burden in some human intervention studies. Although little is known about dose−response, the lack of effect reported in some studies may be due to failure in achieving the required levels of relevant compounds in circulation when berries and berry products are consumed normally in the diet, that is, as "food". Purifying active principles in berries and delivery in the form of berry extracts/berry fractions is one way to increase "dose" and possibly circulating concentrations, assuming higher concentrations are needed to achieve benefit.

A relatively large body of data from in vitro and in vivo animal experiments provides evidence for a protective role of purified polyphenolic compounds and berry fractions against increased inflammatory stress. A small number of clinical trials have been conducted to study the effects of berry extracts and purified anthocyanins from berries on inflammatory markers associated with chronic diseases (Table 4). Of the nine studies presented in this section, all involved chronic administration of either (1) purified anthocyanins[146−148] or (2) extracts of black currant,[149] chokeberry,[150] cranberry,[151,152] or sea buckthorn berry.[124]

Anthocyanins. Zhu et al. tested a commercially available purified anthocyanin supplement: 41% total anthocyanins/capsule composed of 58% delphinidins and 33% cyanidins extracted from bilberries and black currants; the remaining 59% composed of nonpolyphenolic constituents.[148] One hundred and fifty ($n = 150$) hypercholesterolemic men and women took the supplement (320 mg of anthocyanins/day) 30 min after breakfast and dinner meals. Supplementation with anthocyanins led to a significant decrease in serum sVCAM-1 concentrations compared to placebo (delta placebo vs delta anthocyanins, $p = 0.023$). In two other studies, anthocyanin extracts from bilberries and black currants (primary anthocyanins were cyanidin-3-*O*-β-glucosides and delphinidin-3-*O*-β-glucosides) were tested against a control maltodextrin supplement.[146,147] The first intervention was conducted by Karlsen et al., in which 118 men and women were randomized to either the placebo or active treatment providing 300 mg anthocyanins/day (two capsules each in the morning and evening; 75 mg of anthocyanins/capsule) for a period of 3 weeks.[146] Of the several inflammatory markers that were measured (hs-CRP, IL-1β, IL-1ra, IL-2, IL-4, IL-6, IL-8, IL-10, IL-12, IL-13, IL-17, TNF-α, IFN-α, IFN-γ, GM-CSF, macrophage inflammatory protein (MIP)-1α, MIP-1β, immunoprotein (IP)-10, MCP-1, eotaxin, and regulated upon activation, normal T cell expressed and secreted (RANTES)), the anthocyanin-supplemented group showed a decrease in plasma levels of IL-8, RANTES, IFN-α, IL-4, and IL-13 compared to placebo. A subsequent study by the same group of researchers tested the anthocyanin supplement in 27 men with elevated blood pressure (137/85 ± 12/7 mmHg).[147] Subjects ingested four capsules (80 mg of anthocyanin each) in the morning and four capsules in the evening separate from mealtimes to provide a total daily dose of 640 mg of anthocyanins (approximately equal to 100 g of a mixture of blueberries and black currants). The intervention lasted for 4 weeks. Endpoints measured were hs-CRP, TNF-α, IL-6, IL-4, MCP-1, CD40L, sICAM-1, and sVCAM-1, P-selectin, von Willebrand factor, and total nitric oxide. Anthocyanin supplementation had no effect on levels of cytokines, markers of endothelial function, or oxidative stress. Anthocyanin supplementation resulted in a significant increase in von Willebrand factor, a marker of endothelial function associated with CVD. The authors noted that although this may be an unfavorable effect, the clinical significance of increased von Willebrand factor relative to endothelial inflammation in this population is unknown.

Table 4. Effects of Berry Extracts/Fractions, Including Anthocyanins, on Inflammatory Markers in Humans[a]

berry	duration (weeks)[b]	design	subjects	n[c]	format	dose/day	circulating biomarkers[d]	ref

Black Currant. An encapsulated concentrated black currant powder was supplemented to exercisers to study effects on exercise-induced oxidative and inflammatory stress.[149] The dose was approximately equivalent to 48 g of fresh blackcurrants (providing 240 mg of anthocyanins and <1 mg of vitamin C): 89% of the total phenolics comprised anthocyanins. Men and women ingested two capsules before and two capsules following the 30 min exercise regimen. Blood was sampled prior to the first two capsules and exercise and at 1, 2, and 24 h after exercise and the second set of capsules. Sugar capsules were used as placebo. Black currant anthocyanin supplement decreased exercise-induced inflammatory stress (plasma creatine kinase activity) significantly at 24 h compared to placebo.

Chokeberry. To date, one study has been published on chokeberry extracts in which inflammation was assessed.[150] This study included 44 patients who survived a myocardial infarction and were on statin treatment for a minimum of 6 months. Study participants ingested a chokeberry flavonoid extract for 6 weeks in a double-blinded, placebo (maltodextrin)-controlled parallel arm clinical trial. The supplements were administered as three daily doses that delivered 0 or 255 mg/day of flavonoid extract (anthocyanins (~25%), monomeric and oligomeric procyanidins (~50%), and phenolic acids (~9%)). Compared to the control group (statin plus placebo supplement), the combination of chokeberry extract and statin therapy resulted in a significant decrease in all inflammatory biomarkers tested, namely, hs-CRP, IL-6, sICAM-1, sVCAM-1, and MCP-1, at the end of 6 weeks. In addition, there was a favorable increase in the concentration of serum adiponectin in these patients. These data are interesting because they suggest that some berries/their components in a concentrated form may be useful adjuncts to some medicines.

Cranberry. In a study with type 2 diabetic patients, a cranberry extract (or placebo capsule) was supplemented for 12 weeks.[151] The placebo or cranberry extract capsules were ingested after each main meal to provide a daily dose of 0 or 1500 mg of extract (500 mg/capsule): composition was not provided by authors. At the end of the intervention period there was no significant difference in circulating CRP between treatment groups. Similar results were reported by Vidlar et al., who supplemented 42 men with lower urinary tract symptoms with 1500 mg of cranberry fruit powder (3 × 500 mg capsules, each containing 52 mg of polyphenols, 1.65 mg of anthocyanins) or placebo capsules for 6 months and found no significant change in fasting plasma hs-CRP concentrations.[152] However, in both studies subjects had within normal range levels of circulating CRP at baseline.

Sea Buckthorn Berry. Extracts of sea buckthorn berries were supplemented to 110 overweight and obese women for approximately 35 days.[124] The two forms that were tested were sea buckthorn berry oil, which was extracted from both the flesh and seeds of the berries, and an ethanol extract of the whole berry.[124] The supplemented berry oil elicited a significant decrease in sVCAM-1 and adiponectin and increased hs-CRP levels. The spray-dried ethanol extract of sea buckthorn berries lowered both sICAM-1 and TNF-α in circulation.

Of the nine studies on berry products, berry extracts, and purified anthocyanins from berries, six studies reported anti-inflammatory activity. A range of doses of purified anthocyanins were tested (150−640 mg), and beneficial effects were reported for lowering selected inflammatory markers.[146−148] In contrast, cranberry extracts did not appear to affect inflammatory markers under the conditions that were tested, even when supplemented for longer durations (12−24 weeks). Sea buckthorn berry fractions showed mixed results, with the ethanol extract showing more favorable results than an oil extract of sea buckthorn.[124] Overall, the efficacy of certain berry extracts as anti-inflammatory agents in humans appears to be comparable to the effects elicited with consumption of whole berries and berry products.

■ CONCLUSIONS

The purpose of this review was to critically assess the existing clinical data on berries and inflammation. Data reviewed included whole fruit products as well as extracts of whole berries.

Berries were shown to reduce inflammatory stress in humans when supplemented in various forms, including extracts and anthocyanin components, suggesting that anthocyanins are an important part of the biological activity delivered by berries. Anti-inflammatory effects were observed both in healthy persons and in people with different inflammation-associated chronic conditions supplemented daily for weeks to months, although variations in results requires follow-up. Study designs modeling acute bouts of inflammation revealed that consuming berries can have short-term homeostatic maintaining (protective) effects, such as modulating inflammatory responses induced by exercise and meals representing modern eating patterns. The data suggest that berries may offer their greatest benefit in times of or in conditions of metabolic stress. The lack of benefit on measures in the fasting state or during unchallenged conditions requires further investigation. Understanding these short-term responses has important implications in understanding long-term responses and may explain, at least in part, discrepancies in chronic feeding results.

In addition to the commonly known and consumed berries, we also reviewed the emerging literature of lesser known berries. These berries are not widely promoted and consumed, but in their own right showed consistent anti-inflammatory effects compared to common berries. Whereas the incongruent results between common and lesser known berries may be due to study design differences (one important design difference was sample size/power to detect effects; with the common berry studies using overall smaller sample size compared to the lesser known berries), it is also possible that the specific polyphenol profile of the lesser known berries may render them more effective in humans. Cultivation practices for commercial interests could certainly affect the content and composition of fruit.[153] Additionally, although the current review represents a complete collection of available berry (product) studies reporting on inflammation, inflammation was not necessarily the primary endpoint. Therefore, in several instances only a single marker of inflammation may have been reported. This review has highlighted the need for intervention studies to include a more comprehensive analysis of inflammatory status to better understand the role of berries and their components on modulating inflammation and immune function.

Emerging interest is also focused on the potential of polyphenols to alter the composition and function of the gut microbiota, gut permeability, and gut-derived pro-inflammatory stimuli.[154−156] Alternatively, colon microbiota are known to metabolize polyphenols in the large intestine, generating metabolites, which may remain undetected in circulation but may possibly contribute to overall biological effects of the parent compound.[157,158]

Finally, from a practical and public health standpoint, consuming fruits and vegetables is a key dietary recommendation

for health promotion globally.[159] In the United States, Americans currently eat about half the dietary recommendation for fruit (recommendation is 2 cup equivalent/day).[65,66] In addition to fiber and micronutrient content, fruits, including berries, deliver a variety of other phytochemicals, including polyphenols. Berries are unique because they are rich sources of anthocyanin polyphenols. Cell culture, animal and human epidemiological, and clinical studies have revealed biological activity consistent with health when berries or anthocyanins were tested. The data from the present review focused on inflammation, a critical process underlying multiple predisease and disease conditions, and showed that consuming berries affects inflammatory/immune processes favorably. Hence, the body of evidence suggests that eating berries is an important part of a healthy eating pattern to reduce disease risk. Promotional efforts aimed at increasing fruit consumption to meet dietary guidance should include communications focused on berry intake to increase fruit variety and composition of nutrients and phytochemicals delivering health benefits. Perhaps the challenges of getting people to eat "more" fruit to meet recommendations for health can be offset by improving the diversity of fruit selection to include a rainbow of deep and brightly colored fruits delivering polyphenol content and variety.

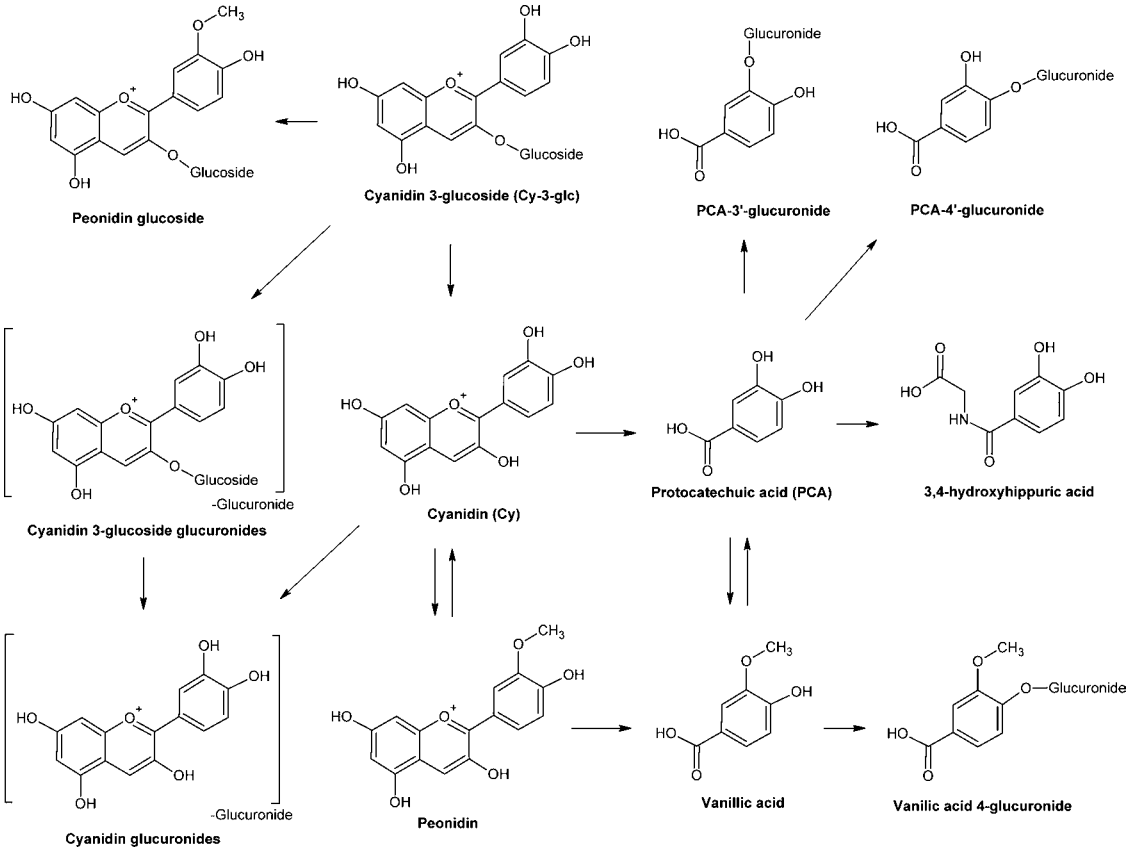

Figure 1. Major metabolic pathways of cyanidin 3-glucoside.[29,34,46,62,78,84,91]

PCA are formed during first-pass metabolism in the intestinal wall or liver (Figure 2).

Anthocyanins Could Efficiently Permeate into the Intestinal Wall. Native anthocyanins found in the small intestine tissue amounted to 7.5% of the ingested dose 2 h following administration of black raspberries in rats.[36] In another study, rats were administered a blackberry anthocyanin-enriched diet for 15 days. The jejunum contained 605 nmol/g tissue of Cy-3-glc and its methylated and glucurono-conjugated metabolites.[37] The exceptionally high anthocyanin concentrations in gastrointestinal tissues were in great contrast to their concentrations in blood. In addition, cell culture studies also demonstrated that anthocyanins can permeate Caco-2 cell monolayers.[38−40] This suggests that anthocyanins undergo extensive first-pass metabolism and enter the systemic circulation as metabolites. The concentrations in gastrointestinal tissues are similar to those used in some in vitro studies on the health effects of anthocyanins.[1−5] Anthocyanins could achieve pharmacologically relevant local concentrations and exert their protective effects in the gastrointestinal wall.[41−43]

Cy-3-glc Is Not a Substrate of β-Glucosidase or Lactase-Phlorizin Hydrolase. Unlike a number of other flavonoids, Cy-3-glc was found not to be a substrate of cytosolic β-glucosidase[44] or lactase-phlorizin hydrolase.[31] Because lactase-phlorizin hydrolase was localized to the apical membrane of small intestinal epithelial cells, it was suggested that some flavonoids are deglycosylated on the luminal surface before being absorbed.[31] Whereas this could be true for the substrates of the luminally exposed lactase-phlorizin hydrolase such as quercetin-3-glucoside,[31] it is unlikely to be the case for Cy-3-glc. This is consistent with the fact that intact Cy-3-glc can accumulate in the intestine tissue in rats following oral administration.[36,37] This is also consistent with the observation that only the glycosides, not their metabolites, were recovered in the intestinal lumen following perfusion of anthocyanins.[45] Thus, Cy-3-glc can probably be absorbed intact into the gastrointestinal wall, undergo extensive first-pass metabolism, and enter the systemic circulation as metabolites.

The mechanism of cleavage of the sugar moiety of Cy-3-glc remains to be established. With regard to the further breakdown of the anthocyanin aglycones, it was found that human liver microsomes can metabolize Cy to PCA, which is further metabolized to form three glucuronide conjugates.[46] Similarly, pelargonidin is metabolized to 4-hydroxybenzoic acid, which is further metabolized to form two additional glucuronide conjugates by human liver microsomes.

Chemical Decomposition in the Gastrointestinal Tract Is Unlikely To Account for Most Plasma Phenolic Acid Metabolites for the Relatively Stable Anthocyanins. Because phenolic acids such as PCA can be absorbed from the gastrointestinal tract,[33,47,48] it was suggested that the phenolic acids could be produced by chemical decomposition within the intestinal lumen before being absorbed. However, the literature outlined below indicates that chemical degradation is unlikely to be the main source of plasma 4-hydroxybenzolic acid and PCA following oral administration of Pg-3-glc and Cy-3-glc, respectively.

Many anthocyanins are rather stable in the upper gastrointestinal tract. Anthocyanins are known to be stable in the acidic environment of the stomach.[49−51] As absorption of anthocyanins was shown to take place in the stomach,[49,52−54]

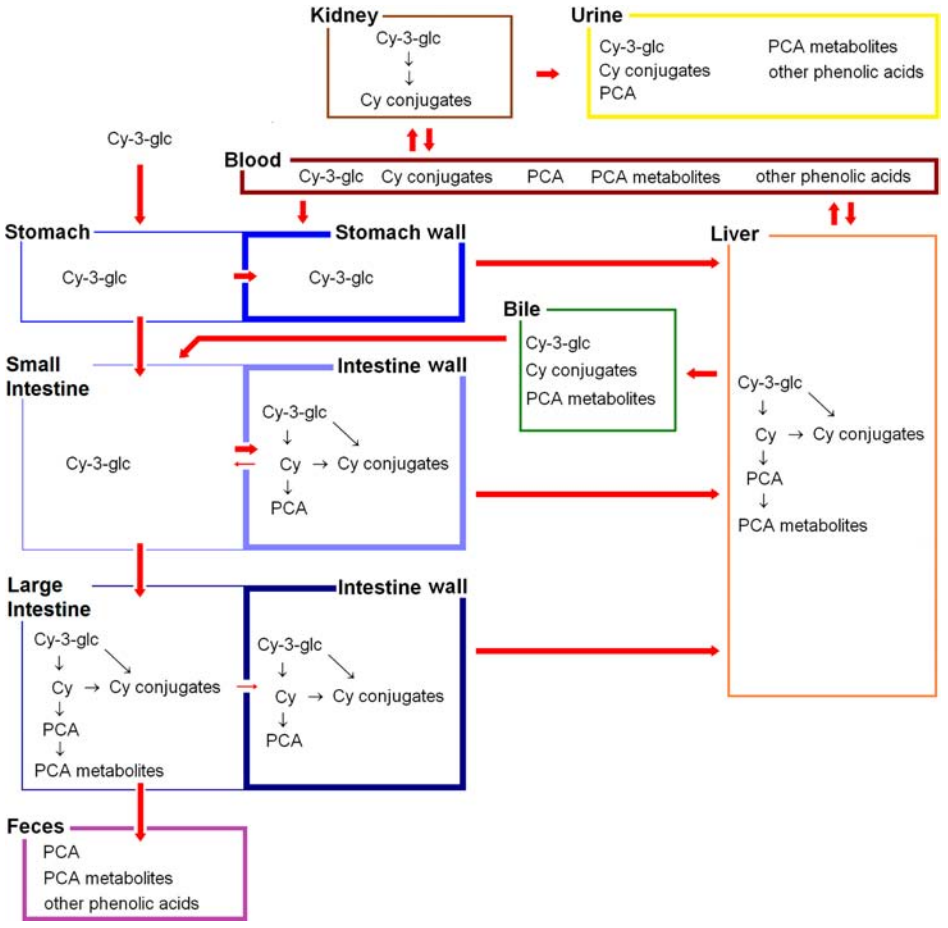

Figure 2. Schematic diagram of the absorption, first-pass metabolism, and further disposition of Cy-3-glc following its ingestion.[37,92−94] Abbreviations: Cy, cyanidin; Cy-3-glc, cyanidin 3-glucoside; PCA, protocatechuic acid.

significant amounts of anthocyanins could be absorbed in the stomach in their native forms.

In the small intestine, many anthocyanins such as Pg-3-glc are stable in this relatively neutral environment.[46] In an in vitro study, strawberry anthocyanin (mostly Pg-3-glc) decomposition was minimal when incubated at 37 °C in a simulated intestinal fluid (pH7) for 48 h.[55] Thus, it is unlikely that chemical decomposition of Pg-3-glc was primarily responsible for the high blood concentrations of 4-hydroxybenzoic acid in the absence of microbiota.

For those anthocyanins that do decompose, there seems to be a delay between the loss of anthocyanin aglycones and the formation of the phenolic acids probably due to the relatively stable transition products.[46,56,57] This delay could further reduce the concentrations of phenolic acids in the upper gastrointestinal tract. More detailed kinetic studies are needed to clarify the relationship between the disappearance of anthocyanins and the formation of their phenolic acid decomposition products.

In studies using ileostomists, the percentages of some anthocyanins remaining in ileal fluids did not seem to correlate with their stabilities.[58] For example, Cy-3-glc is far more stable than delphinidin 3-glucoside in simulated intestinal buffer,[50,59] but less of it remains in the ileal fluid following oral ingestion of wild blueberries.[58] These differences could be explained by the possibility that Cy-3-glc is more efficiently absorbed in the upper gastrointestinal system. A similar conclusion can also be derived from another study on Concord grape juice in ileostomists.[50] Cyanidin glycosides were found to be far more stable than delphinidin glycosides following in vitro incubation with simulated gastric and pancreatic juices, yet the percentages recovered in ileal fluid were comparable for the two anthocyanins following ingestion of 350 mL of the grape juice.

For the few anthocyanins that are unstable in the upper gastrointestinal tract, such as delphinidin 3-glucoside,[59] chemical degradation may play a role in the formation of their phenolic acid metabolites. A total of 40.7% of delphinidin 3-glucoside was found to remain in ileal fluid in ileostomists administered blueberries.[58] Therefore, 59.3% delphinidin 3-glucoside was either absorbed or decomposed before reaching the large intestine. On the other hand, delphinidin 3-glucoside was found to be absorbed into the bloodstream in its native form.[50,60,61] It is therefore perceivable that first-pass metabolism also contributes to the formation of the phenolic acid metabolites of delphinidin 3-glucoside.

Gut Microbiota Decomposition Products May Not Be Extensively Absorbed. In the large intestine, the microbiota can facilitate the formation of phenolic acid metabolites from anthocyanins.[50,55,62−70] However, they would not affect the plasma concentration versus time curve until a later time when anthocyanins reach the large intestine. The maximum rate of excretion of food components in ileal fluid took place at around 2 h when 1 L of apple juice or 300 g of blueberries was consumed by a group of ileostomists.[58] Most polyphenols passed the small intestine 4−8 h after the consumption of fruits or fruit juices.[50,58,71,72] The intestinal transition time would be

longer if solid food were ingested together with the fruits or fruit juices. Following administration of blood orange juice, plasma PCA concentrations increased rapidly and reached maximum concentrations at 2 h.[32] This is partly because anthocyanins can be absorbed from the stomach.[52,53] Thus, high plasma PCA concentrations were achieved before Cy-3-glc reached the large intestine and underwent microbiota decomposition.

Furthermore, only 5.9−28.3% of administered Cy-3-glc was excreted in ileal fluid from ileostomists administered blueberries, grapes, or raspberries.[50,58,71] Animal studies also indicated that Cy-3-glc is mostly absorbed in the stomach and upper part of the small intestine.[36,41,73,74] It is worth noting that fecal recoveries were 32.1 and 44.5% of administered [^{13}C]- or [^{14}C]-Cy-3-glc in humans[75] and mice,[76] respectively. This indicates that most Cy-3-glc entering the large intestine is excreted in feces. Thus, degradation products of Cy-3-glc may not be extensively absorbed from the large intestine.

Gut microbiota can produce large amounts of phenolic acids from those anthocyanins that reach the large intestine in large quantities.[50,58,71,72] In one study, the percentages remaining in ileal fluid relative to food content are in the following order: malvidin 3-arabinoside (85.1%) > petunidin 3-arabinoside (73%) > petunidin 3-galactoside (59.1%) > malvidin 3-galactoside (54.4%) > petunidin 3-glucoside (47.5%) > delphinidin 3-galacotoside (45.3%) > cyanidin 3-arabinoside (44.6%) > malvidin 3-glucoside (42.8%) > delphinidin 3-glucoside (40.7%) > delphinidin 3-arabinoside (37.8%) > cyanidin 3-galactoside (36.8%) > peonidin 3-glucoside (29.9%) > Cy-3-glc (28.3%).[58] It is perceivable that anthocyanins such as malvidin 3-arabinoside and petunidin 3-arabinoside would mostly be degraded by gut microbiota[65,66,77] and produce large quantities of metabolites.[68,69] However, the microbiota decomposition products may not be absorbed extensively into the bloodstream as is the case for Cy-3-glc. Further studies are needed to confirm the poor absorption of phenolic acids in the large intestine by introducing anthocyanins or their phenolic acid metabolites directly into the large intestine.

To summarize the above discussion, first-pass metabolism probably plays an important role in the formation of 4-hydroxybenzoic acid and PCA from Pg-3-glc and Cy-3-glc, respectively, after they are absorbed from the upper gastrointestinal lumen.

In addition to the phenolic acid metabolites, the bioavailabilities of some anthocyanins were found to be higher when phase II metabolites were also accounted for. The major metabolites of anthocyanins recovered in urine were glucuronidated and/or methylated conjugates.[78−83] Enzymes responsible for these biotransformations may include UDP-glucuronosyl transferase, UDP-glc dehydrogenase, or catechol-*O*-methyltransferase (COMT) located in the small intestine, liver, or kidney. For example, the bioavailability of delphinidin 3-rutinoside was found to be 2.67% when its 4′-methylation product was also accounted for in both the urine and bile of rats.[28] In other studies, total urinary excretion of anthocyanins and their metabolites was found to be 0.26−1.8% of the anthocyanins ingested.[29,30]

STUDIES USING ^{13}C- OR ^{14}C-LABELED ANTHOCYANINS

In a recent human study using [^{13}C]-Cy-3-glc, 12.4% of the ^{13}C-label was recovered from urine and breath following oral ingestion.[75] The actual percentage of [^{13}C]-Cy-3-glc absorbed across the gastrointestinal wall should be higher because of involvement of bile secretion in the disposition of anthocyanins (Figure 2). In mice administered [^{14}C]-Cy-3-glc, a high concentration of radioactivity was found in bile, indicating an important role of bile secretion in the disposition of Cy-3-glc.[76] Extensive bile secretion of [^{14}C]-PCA was also found following intraperitoneal injection in rats,[84] probably as its conjugates.[46] Extensive bile secretion of delphinidin 3-rutinoside and its 4′-methylated metabolite was also observed in rats.[28]

In human studies, an indication of extensive involvement of enterohepatic recycling is a second peak observed on the plasma concentration versus time curve. The second peak is due to the secretion of anthocyanins accumulated in bile into the duodenum and their subsequent reabsorption. This phenomenon was observed for delphinidin-3-glucoside and petunidin-3-glucoside in healthy volunteers administered Concord grape juice.[50] A second peak was also visible for malvidin-3-glucoside and mean plasma total anthocyanin concentration following consumption of red wine[85] and purple carrot juice,[86] respectively, in human volunteers. A similar pattern of the plasma concentration versus time curve has been observed for phase II metabolites of PCA.[75] In another study, a second peak of PCA was visible following administration of strawberries (containing Cy-3-glc as a minor component) in human volunteers.[34] This could also be due to enterohepatic recycling where conjugates of PCA were secreted into the duodenum and underwent cleavage to release the free PCA either within the intestinal lumen or during first-pass metabolism. Thus, due to the extensive involvement of enterohepatic recycling, the percentage of [^{13}C]-Cy-3-glc absorbed across the gastrointestinal wall would be higher than the 12.4% found in urine and breath in humans.[75]

Animal studies were also conducted on the absorption of [^{14}C]-Cy-3-glc. In a study in mice, the pharmacokinetics of anthocyanins were investigated using Cy-3-glc labeled with ^{14}C on its B-ring.[76] At 3 h after oral administration of [^{14}C]-Cy-3-glc, 3.3% of the radioactivity was detected in urine, mostly as metabolites. Plasma PCA concentrations were not measured in this particular study. However, on the basis of the HPLC chromatograms in the paper, it is evident that the concentrations of metabolites in plasma are many times higher than that of Cy-3-glc.[76] In a human study, there was a 42-fold higher abundance of ^{13}C-labeled metabolites relative to [^{13}C]-Cy-3-glc.[75]

In the above-mentioned study in mice, it is projected that the total percentage of radioactivity excreted in urine would be about 4.4% of the administered [^{14}C]-Cy-3-glc under the assumption that urine excretion of Cy-3-glc and its metabolites is proportional to plasma concentrations.[76] This total urinary recovery of Cy-3-glc is similar to that found in humans administered [^{13}C]-Cy-3-glc (5.4%).[75] This percentage represents the lower limit of Cy-3-glc absorbed into the systemic circulation including the metabolites produced during its presystemic metabolism. In addition to urine excretion, the absorbed [^{14}C]-Cy-3-glc and its metabolic products can also be eliminated from the body by secretion through bile. Bile contained a high concentration of radioactivity (7.81 Bq/mg tissue in bile as compared to 0.35 Bq/mg tissue in liver),[76] indicating a prominent role for bile in the disposition of [^{14}C]-Cy-3-glc. Indeed, 13% of PCA was found to be excreted in bile (as its conjugates) following intraperitoneal injection in rats.[84] In addition to bile, expiration of volatile metabolites or

autoxidation products into the air was found to be another elimination pathway for [^{13}C]-Cy-3-glc in humans, accounting for 6.9% of the administered dose.[75] Taken together, it is probable that the actual percentage of [^{14}C]-Cy-3-glc absorbed across the gastrointestinal wall is much higher than the observed total urine recovery (4.4%).

In another study using ^{14}C-labeled flavonoids, between 16 and 43% of radioactivity was found to be excreted in urine 24 h after oral administration of the anthocyanin glycoside fractions biosynthesized by grape cell suspension cultures.[87] These results are also consistent with the high percentage absorbed suggested by the above-mentioned studies.[32−34,49,59,75]

IN SITU GASTRIC AND INTESTINAL ABSORPTION OF ANTHOCYANINS

Efficient absorption of anthocyanins was also observed following in situ gastric and intestinal perfusion in rats. High plasma anthocyanin concentrations were found in both portal vein and systemic circulation following gastric perfusion.[52,53] In another study, the observed decreases of bilberry anthocyanins in the gastric fluid were 19−37% following 30 min in situ gastric absorption.[49] With regard to Cy-3-glc, the percentage absorbed was found to be 23% within the stomach under the experimental conditions. In a cell culture study, anthocyanins were found to be able to cross MKN-28 cell monolayers (differentiated adenocarcinoma stomach cells), probably via a saturable transporter mechanism.[54] Anthocyanins are stable under acidic conditions and do not degrade in simulated gastric juice.[49−51] In humans, anthocyanins were found in the bloodstream within minutes of consumption.[88] Five-fold higher urine concentrations of anthocyanins were observed in two patients following administration of a bilberry extract (Mirtoselect) via nasal intubation into the stomach rather than the jejunum.[89] It is therefore likely that anthocyanins can be absorbed from the stomach in their native forms.

An in situ perfusion model was used to evaluate the absorption of anthocyanins in the jejunum and ileum of rats. Between 10.7 and 22.4% of the anthocyanins were absorbed following perfusion at a flow rate of 0.75 mL/min.[59] The percentage of Cy-3-glc absorbed was found to be 22.4%. Degradations of anthocyanins in simulated intestinal buffer (pH 6.6, incubated at 37 °C for 45 min) are in the following order: Cy-3-glc (percentage decomposed = 2.32%), malvidin 3-glucoside (3.63%), cyanidin 3-galactoside (4.13%), and cyanidin 3-rutinoside (5.15%).[59] Cy-3-glc was found to be more stable when present in blackberry extract with only 0.69% decomposed. Delphinidin glycosides were the least stable, with a percentage of degradation of 9.31%. Their decline in the perfusion solution was not reported as a result of absorption. Therefore, it is reasonable to assume that the decreases of most anthocyanins in the perfusion solutions were mainly due to absorption rather than chemical degradation.

FUTURE PERSPECTIVES AND CONCLUSION

In addition to the research needed to confirm or clarify some issues outlined above, it is now clear that many studies conducted on anthocyanins need to be repeated in light of the formation of their phenolic acid metabolites, the plasma concentrations of which are 1−2 magnitudes higher than their respective parent compounds.[32−34] These studies include bioavailability studies of individual anthocyanins; studies using ileatomist volunteers; studies on the effects of food matrices on the absorption of anthocyanins; animal studies on the tissue concentrations of anthocyanins; and ex vivo absorption studies using human or animal tissues and cell culture models. It is also apparent that different anthocyanins are vastly different in their stability, absorption, metabolism, and elimination.[24] These differences are important in determining the sites of their health effects and the contribution of microbiota and chemical degradation to their disposition. Thus, different anthocyanins should be studied individually to ease the interpretation of experimental results. Cy-3-glc and Pg-3-glc are two anthocyanins extensively studied because they are predominant components in fruits such as blackberries[90] and strawberries.[15] Other purified or synthesized anthocyanins could also be used for studies using animal models and human volunteers.[75]

In conclusion, the extensive literature indicates that absorption and first-pass metabolism play important roles in the disposition of some anthocyanins, such as Cy-3-glc and Pg-3-glc, in the upper gastrointestinal tract. Metabolites such as PCA and 4-hydroxybenzoic acid could be responsible for the systemic health effects of anthocyanins. High permeations of native anthocyanins into the gastrointestinal wall also suggest that anthocyanins could achieve pharmacologically relevant local concentrations and exert their protective effects in the gastrointestinal system.

bioavailability of anthocyanins/anthocyanidins and their metabolites in lung tissues.

MATERIALS AND METHODS

Chemicals. HPLC grade water, acetonitrile, methanol, and other HPLC solvents, hydrochloric acid (HCl), formic acid, acetic acid, and trifluoroacetic acid were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Authentic anthocyanin standards were obtained from Chromadex (Irvine, CA, USA). All other chemicals used in the study were of analytical grade. Freeze-dried highbush blueberry powder (50:50 blend of Tifblue and Rubel) was received from the U.S. Highbush Blueberry Council (Folsom, CA, USA). The native mixture of anthocyanidins (~95% pure) was isolated in our laboratory from 36% anthocyanin-enriched bilberry extract (Indena, Seattle, WA, USA), which contains five major anthocyanidins, delphinidin, cyanidin, malvidin, peonidin, and petunidin in the ratio of 33:28:16:16:7, as described in our previous study.[3]

Extraction and Isolation of Purified Anthocyanins/Anthocyanidins from Bilberry. Extraction, enrichment, and hydrolysis of the bilberry were carried out using essentially the same method as described previously.[15] Briefly, the enriched bilberry extract powder was extracted with 75% aqueous ethanol containing 0.1% HCl and enriched by loading the concentrated extracts on an XAD-761/Diaion HP-20 (1:1) column. The polyphenols, including anthocyanins, were eluted with methanol. Pooled elutes were concentrated and hydrolyzed with 2 N HCl (~5 volumes). Hydrolysates were purified using C18 Sep-Pak cartridges (Waters, Milford, MA, USA). Anthocyanidins and other polyphenols were eluted with acidified (0.01% HCl) methanol. The enriched extracts were dried under reduced pressure using a Savant Speed-Vac (Thermo Scientific, USA) and stored at −20 °C until use. The enriched extracts were dissolved in acidified water, and anthocyanidins were selectively extracted in isoamyl alcohol and dried under vacuum.[16] The extracted anthocyanidins were further purified by loading on the C18 cartridges per the manufacturer's guidelines.

Diet. AIN-93 M diet supplemented with blueberry powder at 5% (w/w) was prepared in pellet form by Harlan-Teklad (Madison, WI, USA) and stored at 4 °C in the dark in vacuum-sealed bags until use.

Animal Study. Animal experiments were performed in agreement with an approved protocol from the Institutional Animal Care and Use Committee of the University of Louisville. Female athymic nude mice (5−6 weeks old) were purchased from Harlan Sprague−Dawley, Inc. (Indianapolis, IN, USA). Two animal studies were conducted to test different routes of administration. In study 1, after a week of acclimatization, animals were randomized into two groups ($n = 4$) and provided either AIN-93 M diet or diet supplemented with 5% blueberry powder (w/w). Animals received diet and water ad libitum. The diet was changed every other day, and the food intake was monitored. No difference was found in food consumption in control and experimental groups. The animals had free access to food and water until euthanasia. After 10 days of treatment, animals were euthanized by CO_2 asphyxiation, and lung was collected, snap frozen, and stored at −80 °C until use. Blood was collected by cardiac puncture; plasma was separated and stored at −80 °C.

In study 2, animals were treated with a bolus dose of the native mixture of anthocyanidins isolated from bilberry (10 mg/mouse) by gavage in 10% dimethyl sulfoxide. Two hours after the treatment, animals were euthanized; lung tissue was collected, snap frozen, and stored at −80 °C until use. Blood was collected by cardiac puncture; plasma was separated and stored at −80 °C.

Effect of Acids/Solvents on Anthocyanidin Stability. To test the stability of anthocyanidins in various solvents, cyanidin chloride (100 μg/mL) was dissolved in (i) acetonitrile, (ii) methanol, and (iii) methanol acidified with 0.1% HCl. The solutions were immediately analyzed by ultraperformance liquid chromatography (UPLC). Samples maintained at room temperature were analyzed at 1 h intervals for 5 h. The concentration was plotted against percent of cyanidin chloride at initial time point. Because methanol provided complete stability as described under Results, all of the analyses from tissue were done by using methanol containing 0.1% HCl.

Recovery of Anthocyanins from Biological Matrix. Anthocyanins in biological samples (see below) were analyzed at anthocyanidin level. Conversion of anthocyanins to anthocyanidins in the presence of biological matrix was optimized as follows: To 500 μL of plasma was added 100 μL of bilberry extract (1 mg/mL), the mixture was acidified with 0.1% formic acid, acetic acid, trifluoroacetic acid, phosphoric acid, or hydrochloric acid. Samples were incubated for 15 min at 37 °C and then extracted with 5 volumes of acetonitrile. The sample was centrifuged at 10000*g*, and the supernatant was collected and evaporated to dryness under vacuum (Savant Speed-Vac). The dried extracts were dissolved in acidified (0.1% HCl) methanol and analyzed by UPLC.

Extraction of Anthocyanidins from Tissues. Parameters such as the stability of anthocyanidins in different buffers and acid environment, extraction efficiency, and selectivity in different solvents, etc., were established before tissue extractions. First, we analyzed the recovery of anthocyanidins by spiking lung tissues collected from untreated rats from another study. Methods described previously[14] were used to detect berry anthocyanins/anthocyanidins,[14] except for the following modifications: extraction of anthocyanins in acidified (0.1% HCl) acetonitrile, evaporation of solvent, and reconstitution in 50% methanol containing 2 N HCl followed by acid hydrolysis and selective extraction of anthocyanidins in isoamyl alcohol without any use of solid−liquid chromatography. Furthermore, UPLC separation method was developed by identifying solvents to separate reference anthocyanidins and protocatechuic acid (PCA), a bioactive metabolite of Cy,[17] and spiking the tissue homogenate with Dp, Cy, and PCA.[14] Briefly, after the optimization, lung tissue from two mice was pooled (two pools per group) in both animal studies and homogenized in 400 μL of 1.15% KCl; anthocyanins were extracted in acetonitrile containing 0.1% HCl as described above. The supernatant was evaporated and reconstituted in 50% methanol containing 2 N HCl. The extract was then hydrolyzed (100 °C/1 h) to convert anthocyanins to anthocyanidins, and the latter were selectively extracted in isoamyl alcohol.[16] Finally, the samples were dried under reduced pressure (Savant Speed-Vac) and reconstituted in 40 μL of acidified (0.1% HCl) methanol just before injection, and 10 μL was analyzed by UPLC. The limits of detection for the various anthocyanidins (Cy, Dp, Pt, Pe, and Mv) (0.3−0.75 ng) and PCA (0.2 ng) were established.

UPLC Analysis. Anthocyanins and anthocyanidins were analyzed on a Shimadzu UPLC system composed of two LC-20AD-XR pumps, an SIL-20A-XR autosampler, and an SPD-M20A photodiode array detector (PDA) controlled by Class VP software (ver 7.4, SP3) attached to a Shim-pack XR-ODS-II column (3.0 × 150 mm; 2.2 μm). A linear gradient of 3.5% phosphoric acid (solvent A) and acetonitrile (solvent B) with a flow rate of 0.75 mL/min was used. In the gradient, solvent B was initially 15% for 2 min and increased to 20% by 3 min. Solvent B was further increased to 60% from 3 to 10 min, held for 1 min, and returned to 15% by 12 min.

LC-MS Analysis. Reversed-phase chromatography of anthocyanidins was performed on a Thermo Scientific (San Jose, CA, USA) Accela LC system. The mobile phases consisted of buffer A, water/formic acid (100:0.1, v/v), and buffer B, acetonitrile/formic acid (100:0.1, v/v). Five microliters of sample was injected onto a Hypersil GOLD C_{18} column (50 × 2.1 mm, 1.9 μm, 175 Å) from Thermo Scientific. A step gradient at a flow rate of 100 μL/min was used to elute the compounds. The gradient started at 5% buffer B and increased to 40% buffer B in 10 min, then increased to 90% buffer B in 3 min, and was maintained at 90% buffer B for 7 min. Elute from the LC was directed to an LTQ-Orbitrap XL mass spectrometer (Thermo Scientific). The compounds were ionized by electrospray ionization and detected by Orbitrap at 30000 mass resolution (full scan, m/z 220−1000) or by multiple reaction monitoring (MRM). The spray voltage was 4.0 kV, and the capillary temperature was 250 °C. The sheath, auxiliary, and sweep gas flows were set to 15, 5, and 0, respectively. In MRM, molecular ions of anthocyanidins were selected with 3.0 m/z isolation window and fragmented by collision-induced

Malvidin	$-OCH_3$	$-OCH_3$

Figure 1. Blueberry fruits and chemical structure of anthocyanins and anthocyanidins found in blueberry/bilberry. Shaded portion shows the difference in anthocyanidins and anthocyanins.

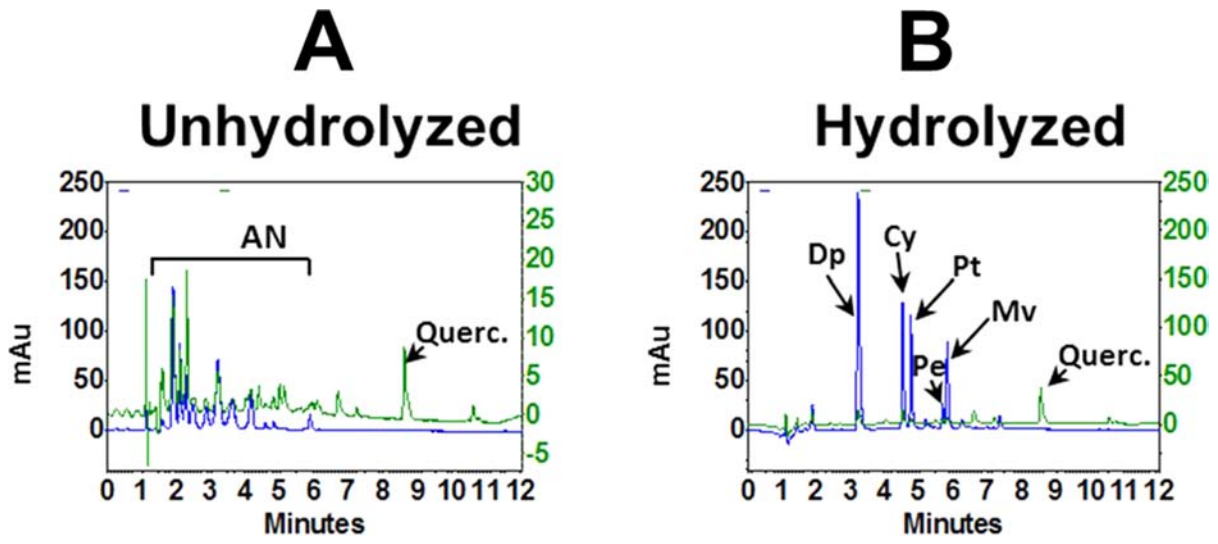

Figure 2. UPLC profiles of unhydrolyzed and hydrolyzed extract of blueberry in anthocyanins (A) and anthocyanidins (B). AN, anthocyanins; Dp, delphinidin; Cy, cyanidin; Pt, petunidin; Pe, peonidin; Mv, malvidin; Querc., quercetin.

dissociation (CID). For CID, collision energy, activation Q, and activation time (mS) were 35, 0.25, and 30, respectively. Full scan MS/MS spectra of the compounds (m/z 100−400) were acquired by Orbitrap at 7500 mass resolution. The transitions used for anthocyanidin detection are shown in panel C of Figure 4. The limits of detection by LC-MS for Dp and Cy were >0.5 and 0.25 ng, respectively, whereas those for Pt, Pe, and Mv were 2.5 pg.

RESULTS

Isolation of Blueberry Phytochemicals and Their Characterization. Blueberry extract was applied onto the XAD-761/HP-20 column (1:1) for the enrichment of anthocyanins and other polyphenols, and the enriched extract was hydrolyzed to convert the glycones to aglycones (i.e., anthocyanins to anthocyanidins; Figure 1). The enriched anthocyanidins were extracted in isoamyl alcohol and further purified by C18 column chromatography. The final extract contained highly pure (>94%) anthocyanidins (Figure 2). When analyzed by UPLC, the purified extract showed five anthocyanidins in the following descending order: Dp (33%), Cy (28%), Pt (16%), Ma (16%), and Pe (7%); a small amount of quercetin was also found in the sample (Figure 2).

Effect of Solvent on Stability of Anthocyanins. The cyanidin was highly unstable in acetonitrile. The rate of degradation was slow initially, but nearly 60% was degraded in 5 h (Supporting Information Figure S1). The stability was better in methanol, where there was only a slight decline and 80% of the compound was found intact. Interestingly, acidified methanol provided complete stability to cyanidin, and no degradation or loss was observed even after 5 h at room temperature. Hence, all of the analyses from tissues were done by using methanol containing 0.1% HCl.

Recovery of Anthocyanins and Anthocyanidins from Biomatrix. The recovery of anthocyanins and anthocyanidins was variable depending on the type of acid used. Formic acid and acetic acid did not provide any recovery of anthocyanins/anthocyanidins from PBS, whereas trifluoroacetic acid, phosphoric acid, and hydrochloric acid gave good recoveries. When these three acids were tested for recovery of anthocyanins/anthocyanidins from plasma, the recovery was in the following order: hydrochloric acid > phosphoric acid > trifluoroacetic acid (Table 1). However, hydrochloric acid extraction also resulted in conversion of some anthocyanins to anthocyanidins. Nearly 55−95% of anthocyanins and 63−100% of anthocyanidins were recovered from plasma (Table 1). Quantification of Pe and Mv was skewed due to the lack of separation of these two peaks in the UPLC conditions used. For measurement from biological matrices from animal experiments, the hydrochloric acid treatment was extended in a boiling water bath for 60 min to convert all anthocyanins to anthocyanidins and then quantified by UPLC-PDA.

Extractions and Detection of Anthocyanidins in Vivo. Blueberry has been reported to contain a variety of

[a]TFA, trifluoroacetic acid. When plasma was acidified with acetic acid or formic acid, below 2% amounts were recovered. When acidified with HCl, some of the anthocyanins were converted to anthocyanidins. Due to interfering peak with Pe-glucoside and Mv, their recoveries were skewed.

anthocyanins. In this study, we demonstrated the presence of anthocyanins in the blueberry-fed rodent tissues following conversion to anthocyanidins. Sensitivity of detection of the individual reference anthocyanidins was determined by LC-MS and UPLC-PDA and ranged from 0.25 ng to 2.5 pg and from 0.3 to 0.75 ng, respectively. The detection limit for PCA, a metabolite of Cy, was 0.2 ng. Cy was readily detected by UPLC (Figure 3) in the samples extracted from mouse lung with a limit of detection of 0.3 ng, whereas the other anthocyanidins were undetectable due to higher detection limits. A small peak was detected at the retention time for Dp; however, it was not confirmed by MS. However, with LC-MS analysis by specific ion monitoring, Pe, Pt, and Mv were readily detectable below

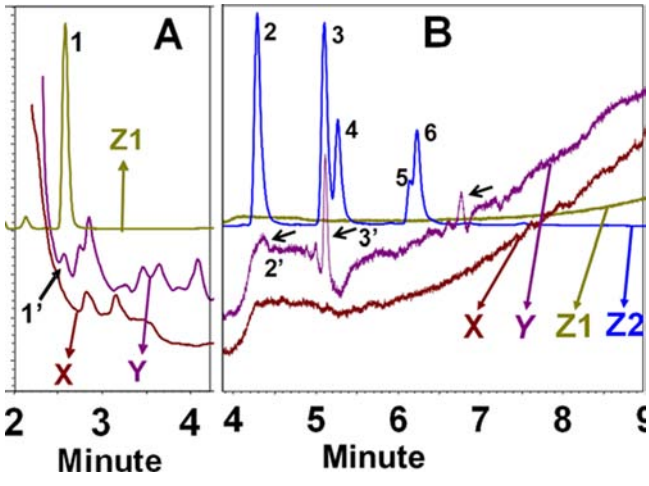

Figure 3. Detection of anthocyanidins at 520 nm (B) and 260 nm for protocatechuic acid (PCA) (A), a bioactive metabolite of cyanidin in lung tissue of rats given dietary blueberry (5% w/w) for 10 days by UPLC-PDA. Chromatograms shown are composites: X, lung tissue from rats on control diet; Y, lung tissue from rats on blueberry diet. Reference compounds: Z1, peak 1 (PCA); Z2, reference anthocyanidins. Peaks: 2, Dp; 3, Cy; 4, Pt; 5, Pe; 6, Mv. Solvent, gradient of 3.5% phosphoric acid in acetonitrile. Chromatograms are cropped for presentation purposes.

≤0.25 ng; Pe could be detected in the picogram range. No peak corresponding to anthocyanidins was detected in the lung of control animals by UPLC or LC-MS.

Several anthocyanidin peaks were found in the samples extracted from the lungs of mice fed blueberry diet by LTQ-MRM (low mass resolution). To confirm the presence of anthocyanidins in lung samples, an MRM with Orbitrap (high mass resolution) method was set up and used to reanalyze the extracted samples. Ion chromatograms of standards from Orbitrap MRM are shown in Figure 4, with a m/z window width of 0.06 that provides better selectivity. Dp and Cy were not detected in lung samples by Orbitrap MRM, but other anthocyanidins (Pe, Pt, and Mv) were detected by MRM (Figure 5) and further confirmed by MS/MS.

DISCUSSION

Several studies in recent years have focused attention on anthocyanin bioavailability both in humans and in experimental animals. Most of these studies reported that anthocyanins were poorly absorbed and were excreted unmetabolized.[18−20] Few studies have also reported that anthocyanins are bioavailable when delivered at very high doses; however, most of the bioavailability studies are focused on individual anthocyanidins, particularly Cy.[14,21−24]

The plausible reasons for lack of anthocyanins' detection include (i) instability of anthocyanins, (ii) metabolism by gut microflora, (iii) high rate of excretion, and (iv) unavailability of suitable analytical techniques. The aim of this work was to develop a method to assess the stability of anthocyanins/anthocyanidins, their selective extraction, and the impact on tissue bioavailability of anthocyanins.

There are several reports on the solubility and stability of anthocyanins in acidic environment.[25,26] Acidified methanol enhances the stability of anthocyanidins compared to acetonitrile. In methanol, the degradation of anthocyanins was very slow, with >80% of anthocyanins remaining intact after 5 h, whereas after acidification no degradation occurred. These results are consistent with published data demonstrating higher stability of anthocyanins in acidic pH.[25,26]

Several methods of anthocyanin extraction are available describing varying recovery of anthocyanins from a biological matrix.[27−30] These methods involve solid phase extraction using Water's Oasis HLB and Sep-Pak C18 cartridges. We standardized the extraction of anthocyanins from tissues of rats administered dietary blueberry by converting them to anthocyanidins, which reduces the number of compounds to five, and allowed us their detection due to their higher amounts. In complex matrices, where interference in peak separation was observed, use of isoamyl alcohol significantly improved the selectivity of anthocyanidins, albeit with a slight loss of recovery (6−7%, data not shown).

In this study, first, we determined stability and extractability of anthocyanidins isolated from bilberry and then determined their tissue bioavailability. Bilberry contains 15 anthocyanins containing galactose, glucose, and arabinose derivatives of Dp, Cy, Pt, Pe, and Mv. These anthocyanins were converted to five anthocyanidins upon acid hydrolysis. Glycones of the same anthocyanidins are also reported in blueberry.[13]

In the present work, we initially failed to detect anthocyanins in lung tissue from rats fed for 10 days with a 5% blueberry diet. The dietary route provides a slow ingestion of the berry phytochemicals. Under these conditions, the lung anthocyanin levels were presumably too low to be detected. Anthocyanins

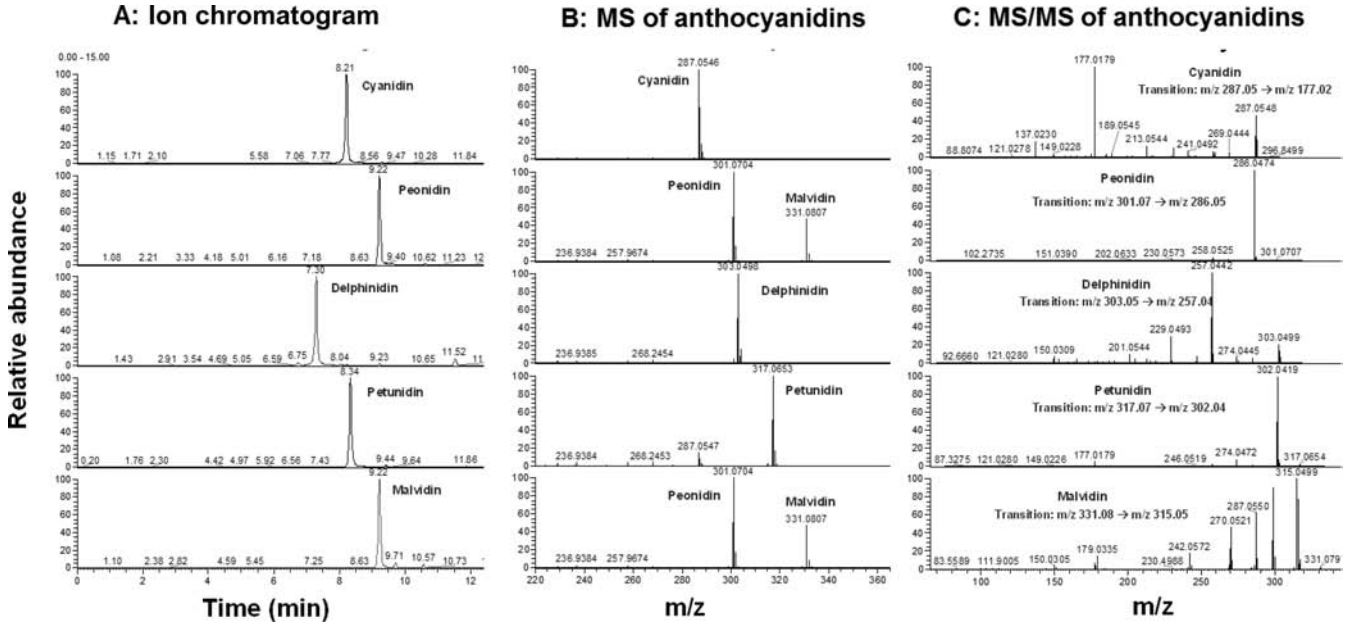

Figure 4. Multiple reaction monitoring (A) and the respective MS (B) and MS/MS (C) of indicated reference anthocyanidins. Peonidin and malvidin were eluted at the same retention time, and therefore they appear in the same spectrum. Anthocyanidins were separated with a Hypersil GOLD C18 column (50 mm × 2.1 mm) in a binary gradient of 1% formic acid and acetonitrile containing 1% formic acid as described under Materials and Methods.

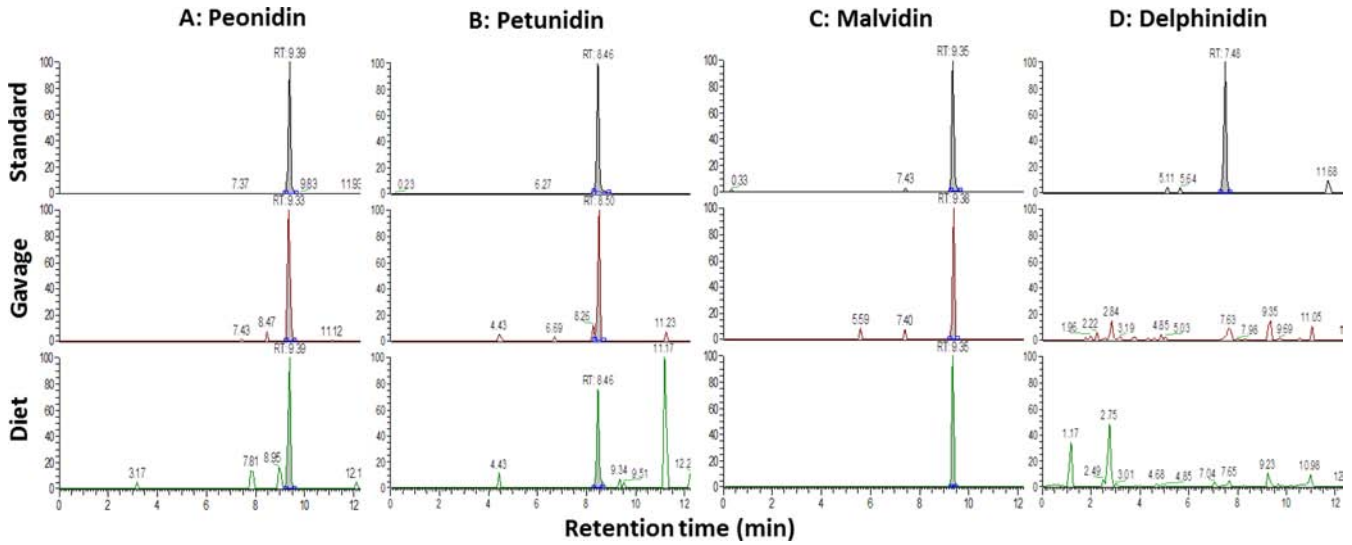

Figure 5. MRM detection of peonidin (A), petunidin (B), and malvidin (C) from the lung tissue of rats provided a native mixture of anthocyanidins isolated from bilberry by gavage (a bolus dose of 10 mg/mouse) or by diet supplemented with blueberry (5% w/w) for 10 days. Delphinidin (D) and cyanidin (not shown) could not be detected by LC-MS analysis. Chromatographic conditions are described under Materials and Methods.

were also not detected in the lung tissue following a bolus dose (10 mg/mouse) by gavage. On the other hand, when the tissue anthocyanins were converted to their respective aglycons by acid hydrolysis and selectively extracted in isoamyl alcohol, Dp and Cy were detected in the lung tissue, indicating that anthocyanins can reach and exert their effects beyond the GI tract. The possibility of bioavailable proanthocyanins being converted to anthocyanidins during acid hydrolysis cannot be ruled out. This presence of anthocyanins in lung tissue could be explained by their ability to permeate the gastrointestinal barrier.[31] These data demonstrate that the conversion of anthocyanins to anthocyanidins prior to analysis is an effective method for detecting anthocyanins in tissues. However, conversion of proanthocyanidins to anthocyanidins in vivo could also enhance the levels on anthocyanidins in animal tissue. PCA, which is produced by degradation of Cy,[32] was also detected in lung tissue, suggesting that lung PCA and anthocyanins along with some unknown metabolites are presumably bioactives responsible for the known anticarcinogenic potential of blueberry in the lung.[33]

A series of papers have shown the bioavailability of anthocyanins in brain tissue,[21,22] and a few other studies report the presence of anthocyanins in other organs including the lung following treatment of rodents with individual anthocyanin at high doses.[14,23,24] Our study is the first demonstration indicating the presence of anthocyanidins in lung tissue

following low-dose dietary blueberry. The blueberry dose used in this study is the same or just 2-fold higher as used in our previous study in which it was found to inhibit estrogen-mediated mammary tumorigenesis.[8,13] The results from our other study also showed the efficacy of the native mixture of anthocyanidins from bilberry against lung cancer xenografts.[3]

In summary, we show for the first time that anthocyanins are bioavailable in the lung following a low dose of dietary blueberry powder. The detection has been possible by conversion of anthocyanins to their native anthocyanidins, followed by extraction in isoamyl alcohol. This technique can be utilized to demonstrate bioavailability of anthocyanins in different tissues and correlate their levels with disease inhibition.

Aldrich, (St. Louis, MO, USA). Sephadex LH-20 was purchased from GE Healthcare (Uppsala, Sweden). Tryptose and dextrose were obtained from BD (Sparks, MD, USA). Fetal bovine serum (FBS) was purchased from Atlanta Biologicals (Lawrenceville, GA, USA). HyClone Dulbecco's PBS without calcium and magnesium, Hyclone Roswell Park Memorial Institute medium (RPMI-1640), and Hyclone trypsin 0.25% in 0.1% ETDA were obtained from Thermo Scientific (South Logan, UT, USA). Caco-2 cells ATCC HTB-37 were obtained from ATCC (Manassas, VA, USA).

Samples. Cranberry fruits (*Vaccinium macrocarpon* Ait. cv. 'Stevens') were obtained from the United Cranberry Growers Cooperative (Wausau, WI, USA) and apple fruits (*Malus pumila* cv. 'Golden Delicious') were obtained from a privately owned fruit tree in October 2011. The fresh fruits were homogenized to a fine powder by blending with liquid nitrogen. The fruit powders were stored at −80 °C until extraction.

Isolation of Proanthocyanidins. *Extraction Procedure.* The proanthocyanidin extraction procedure was adapted from our previous work.[14,15] Cranberry powder (100 g) was extracted with 70% aqueous acetone (v/v; 400 mL) in an ultrasonic bath for 15 min. The extract was centrifuged at 400*g* at 15 °C for 10 min, and the supernatant was collected. The extraction was repeated two additional times, and the supernatants were combined. After filtration with cellulose paper, acetone was removed by rotary evaporation under vacuum at 35 °C, and the remaining suspension was solubilized in ethanol. The extract was then centrifuged at 13416*g* at 0 °C for 10 min to eliminate insoluble material. The apple extract was produced in the same manner, adding the 70% aqueous acetone (v/v) to the frozen apple powder immediately to prevent long thawing processes, which favor polyphenol oxidase activity.[16] The supernatants were used to isolate proanthocyanidin fractions by chromatography on Sephadex LH-20 as described below.

Proanthocyanidin Isolation. The ethanolic proanthocyanidin extracts were loaded on glass columns (2.5 cm i.d. × 60 cm length, Kontes, Chromaflex) packed with Sephadex LH-20 that was previously swollen and washed in water and equilibrated with ethanol for 45 min at a flow rate of 4 mL/min. Preliminary work had shown that a combination of three solvents was sufficient to achieve a proanthocyanidin fraction that was devoid of other classes of polyphenols. The resin bed was consecutively eluted with ethanol, ethanol/methanol (1:1), and 80% aqueous acetone (v/v). The 80% aqueous acetone (v/v) fraction that contained PAC was evaporated as described above and solubilized in methanol.

Proanthocyanidin Characterization. The proanthocyanidin content of the cranberry and apple fractions was quantified by using the Folin−Ciocalteu method,[17] and proanthocyanidin concentrations are expressed as gallic acid equivalents (GAE). Previously developed matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) methods were applied to characterize the cranberry and apple PAC.[18] An aliquot of each sample was evaporated to dryness and suspended in 20 μL of ethanol to a final concentration of 20 μg GAE/mL. An aliquot (0.5 μL) of each sample was then mixed with 1 μL of DHB (50.0 mg/mL in ethanol) in three different wells on the stainless steel MALDI target. Mass spectra were collected on a Bruker ULTRAFLEX-III MALDI-TOF/TOF mass spectrometer (Billerica, MA, USA). All analyses were performed in positive reflectron mode. Spectra were the sum of different locations in each well, accumulating a total of 500 shots to minimize intrawell variability, and deflection was set at 800 Da. After analysis, the deconvolution method based on the relative intensity of proanthocyanidin isotope patterns was used to calculate the ratios of "A-type" to "B-type" bonds in cranberry and apple PAC.[18]

Bacterial Culture. P fimbriae expression is an important virulence factor for ExPEC colonization of the gut[19] and is critical for attachment of *E. coli* to epithelial cells in the urinary tract, colon, and ileum.[20,21] The strain of ExPEC (strain 5011) used in this study was isolated from a woman with recurrent UTI at the University of Wisconsin Hospital and Clinics. The selected strain was found in both the gastrointestinal and urinary tracts and expresses fimH and papA, the adhesins of type 1 and P fimbriae, respectively.

Strain 5011 was cultured from frozen stock under static culture conditions in tryptose broth (10 g of tryptose, 2.5 g of sodium chloride, 0.5 g of dextrose, and 0.0025 g of thyamin hydrochloride in 500 mL of deionized water) at 37 °C and washed twice with 1× PBS + Ca^{2+}/Mg^{2+} by centrifugation at 1840*g* for 10 min. The optical density of the inoculum suspension at 450 nm was used to calculate and adjust the bacterial cell density using a previously established bacterial density−absorbance curve.

Bacterial Agglutination Assay. The agglutination assay was conducted in 3.0 mL microcuvettes using 1.0 mL total reaction volume. First, ExPEC stock solutions (50 μL) were added to the cuvettes, resulting in a final ExPEC concentration of 5.0×10^8 colony forming units (CFU)/mL. Next, proanthocyanidin solutions of either apple (13.6 mg GAE/mL) or cranberry (121.2 mg GAE/mL) were diluted 1/10 and 1/100, respectively, and added to each bacterial inoculum to reach final concentrations of 0, 5, 10, 25, 50, and 100 μg GAE/mL in a total volume of 1 mL with 1× PBS + Ca^{2+}/Mg^{2+}. The cuvettes were sealed and shaken vigorously for 20 s. Absorbances were read at 450 nm every 5 min for 300 min on a Beckman DU 640 spectrophotometer equipped with a six-position cuvette holder (Schaumburg, IL, USA), and the absolute values were converted to transmittance (%). The area under the transmittance curve (AUC) for each concentration level was calculated as a function of the ability of PAC to agglutinate ExPEC from 0 to 300 min.

Gut Epithelial Cell (Enterocyte) Culture. Caco-2 (HTB-37) cells were cultured in DMEM supplemented with 10% FBS (v/v), 1% nonessential amino acids (v/v), 1% L-alanyl-L-glutamine (v/v), and 1% penicillin/streptomycin (v/v) at 37 °C with 5% CO_2. For use in experiments, cells at approximately 80% confluence, based on surface area coverage, were split 1:1.6 into 24-well cell culture treated plates. Once the cells reached confluence (approximately 8.0×10^5 cells/well), they were allowed to differentiate for 8−10 days to become phenotypic polarized enterocytes with medium changes every other day. For maintenance purposes, stock cells were passaged biweekly using 0.25% trypsin.

Invasion Assay. Bacteria were cultured as described previously in this section and were added to 5 mL tubes to reach a multiplicity of infection of 100 (8.0×10^7 CFU/well) relative to the number of Caco-2 cells (8.0×10^5 cells/well). 1× PBS + Ca^{2+}/Mg^{2+} and proanthocyanidin treatments (0, 5, 10, 25, 50, and 100 μg GAE/mL) were added to a total volume of 75 μL, gently mixed, and then incubated for 10 min. RPMI medium, supplemented with 5% FBS (v/v), was added to bring the final volume to 2.5 mL and incubated for 5 min. Caco-2 cell plates were washed twice with 1× PBS + Ca^{2+}/Mg^{2+}, and 0.5 mL of each treatment was added to the plate in quadruplicate. After 1 h at 37 °C to allow for bacterial invasion, Caco-2 cells were washed twice with 1× PBS + Ca^{2+}/Mg^{2+}, and extracellular bacteria were killed by incubating 1 mL of RMPI medium supplemented with 5% FBS (v/v) and gentamicin at a final concentration of 100 μg/mL for 1 h. Caco-2 cells were washed twice with PBS (without Ca^{2+} and Mg^{2+}) and lysed with 1 mL/well Triton 1X for 30 min on a shaker. After intracellular bacteria were released from Caco-2 cells, each well content was homogenized via pipetting, vortexed, and diluted 1:10 in PBS without Ca^{2+} and Mg^{2+}, and 100 μL was plated in duplicate on LB plates (25 g LB Miller, 15 g of agar in 1 L of deionized water). All plates were incubated for 18 h at 37 °C, and the number of CFU/plate was counted. The results were expressed in percentage of enterocyte invasion using the following formula: (CFU sample/CFU control) × 100.

Data and Statistical Analysis. All data were reported as the mean ± standard deviation of at least three replicates. mMass version 3.9.0[22] was used for mass spectra analysis, and SAS was used for AUC calculation using the trapezoidal method (version 9.3; SAS Institute Inc., Cary, NC, USA). Statistical analysis was done using JMP Pro (version 10.0.0; SAS Institute Inc.), setting $\alpha = 0.05$. Results were analyzed with two-way ANOVA models with interaction between the independent variables "sample" and "concentration" to assess significant differences. The dependent variables were AUC and $\arcsin[\sqrt{(\%\ \text{invasion}/100)}]$ for the agglutination and invasion assays, respectively.

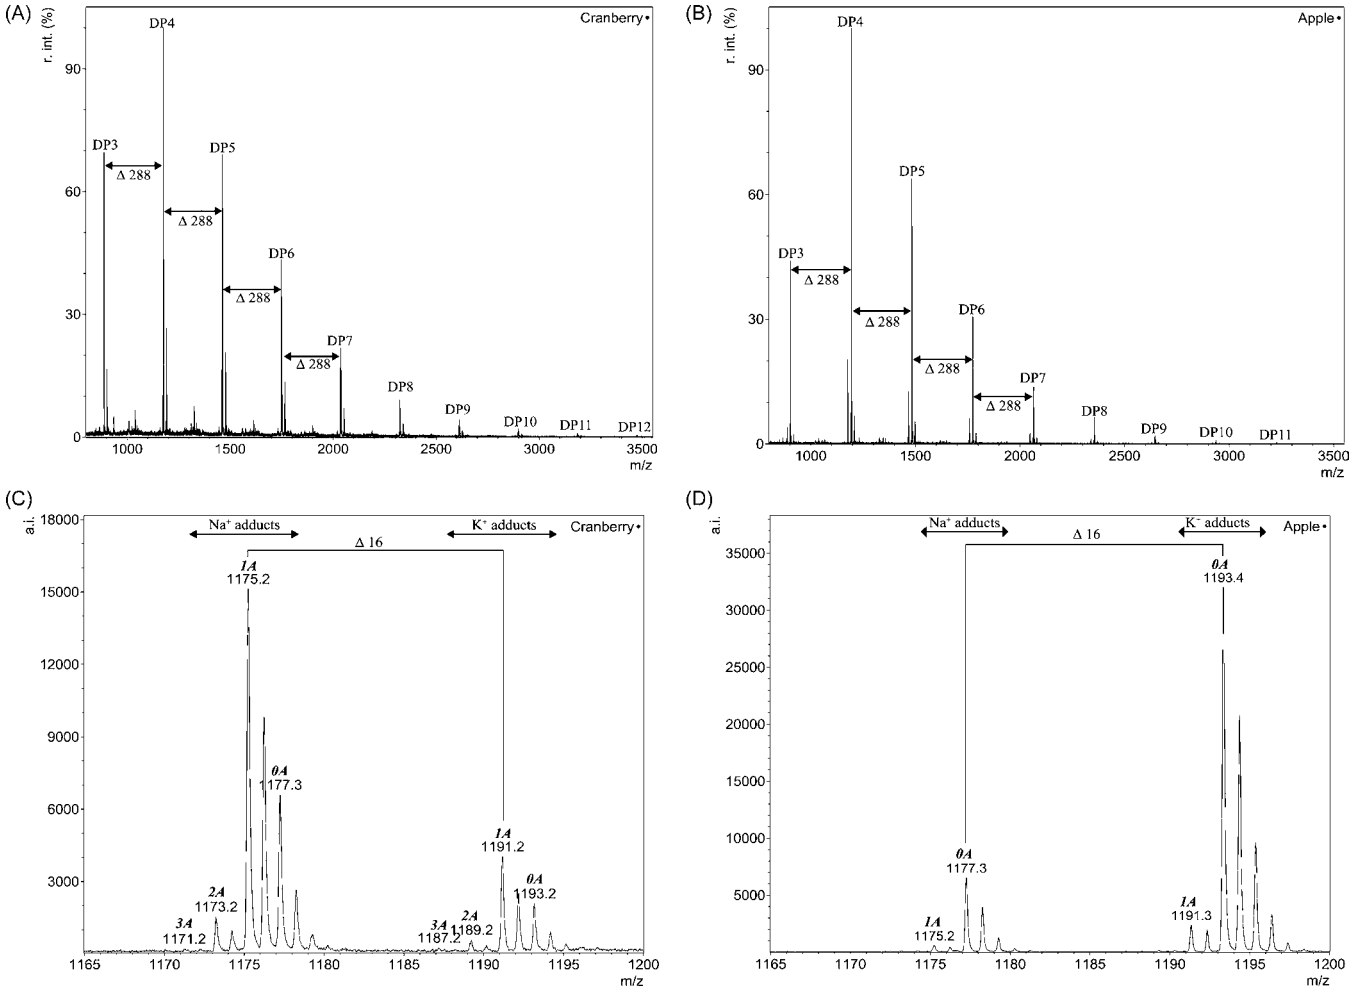

Figure 1. (A, B) Mass spectra obtained with MALDI-TOF MS in positive reflectron mode for cranberry (A) and apple (B) proanthocyanidins (PAC). PAC with different degrees of polymerization (DP) have a 288 mass difference. "r.i." corresponds to relative intensity. (C, D) Mass spectra obtained with MALDI-TOF MS in positive reflectron mode for cranberry (C) and apple (D) proanthocyanidins (PAC) tetramers displaying sodium and potassium adducts showing a 16 units mass difference. The number of "A-type" bonds is assigned to each peak. "a.i." corresponds to absolute intensity.

RESULTS

MALDI-TOF MS Characterization of PAC. Chromatography on Sephadex LH-20 produces fractions from cranberries and apples that contain only PAC.[15] Analysis by MALDI-TOF MS showed that the predominant mass at each DP (Δ288 amu) for cranberry (Figure 1A) and apple (Figure 1B) samples are representative of proanthocyanidin structures that consist of multiple linked catechin/epicatechin units with predominantly either "A-type" or "B-type" bonds for cranberries and apples, respectively. These observed masses and mass distribution are consistent with previously described proanthocyanidin composition of cranberry[23] and apple.[27] Mass spectral analysis indicated that cranberries contain an oligomeric distribution of PAC with a DP from 3 (trimer) to 12 (dodecamer) (Figure 1A) and that apples contain a distribution of PAC with DP from 3 (trimer) to 11 (undecamer) (Figure 1B).

PAC associate with sodium $[M + Na]^+$ and potassium $[M + K]^+$ forming alkali metal adducts,[24] thereby splitting the signal unevenly, leading to Δ16 amu between $[M + Na]^+$ and $[M + K]^+$ in both cranberry (Figure 1C) and apple PAC (Figure 1D). Cranberry PAC predominantly ionized as sodium adducts (Figure 1C), whereas apple PAC predominantly ionized as potassium adducts (Figure 1D). In cranberry PAC, the MALDI-TOF MS spectrum shows that the most predominant linkage type corresponds to 1 "A-type" but peaks corresponding to 2 and 3 "A-type" bonds have enough intensity to resolve above baseline noise (Figure 1C). For each additional "A-type" bond there is a 2 amu decrease due to the loss of two hydrogen atoms that are involved in forming the ether bond typical of this type of interflavan linkage (Figure 2). For example, in tetramers the sodium adduct series shows four distinct peaks: m/z 1177.3 (0 "A-type" and 3 "B-type" bonds), m/z 1175.2 (1 "A-type" and 2 "B-type" bonds), m/z 1173.2 (2 "A-type" and 2 "B-type" bonds), and m/z 1171.2 (3 "A-type" and 0 "B-type" bonds) (Figure 1C). The intermediary peaks that are present between each DP in cranberry PAC correspond to anthocyanins that are covalently bonded to PAC and have been previously described.[15]

In spectra from apple PAC, the peaks with the highest absolute intensity correspond to 0 "A-type" bonds. For example, in tetramers the sodium adduct series shows only two distinct peaks: a predominant peak at m/z 1177.3 (0 "A-type" and 3 "B-type" bonds) and a peak at m/z 1175.2 (1 "A-type" and 2 "B-type" bonds) with only 6% of the intensity of the all "B-type" tetramer (Figure 1D).

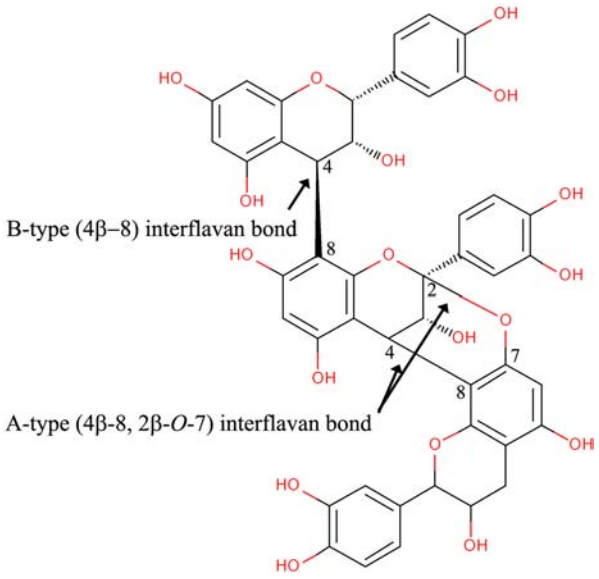

Figure 2. Representative structure of a cranberry proanthocyanidin trimer (epicatechin-(4β-8)-epicatechin-(4β-8, 2β-*O*-7)-epicatechin).[39] Variation in degree of polymerization, position, and number of "A-type" versus "B-type" interflavan bonds leads to large structural heterogeneity among cranberry PAC.[23,29]

When our deconvolution method[18] was applied to the MALDI-TOF MS spectra, median values showed that 94.5% of cranberry PAC were "A-type" and 88.3% of apple PAC were "B-type" (Table 1). Our results indicate that apple PAC contain

Table 1. Percentage of Proanthocyanidins (PAC) with at Least One or Two "A-type" Bonds per Degree of Polymerization (DP) in Cranberry and Apple[a]

	PAC with at least one "A-type" bond		PAC with at least two "A-type" bonds	
DP	apple	cranberry	apple	cranberry
3	3.1 ± 5.4	93.5 ± 2.4	0.0 ± 0.0	1.7 ± 0.7
4	10.1 ± 1.9	88.0 ± 3.2	0.0 ± 0.0	5.4 ± 0.7
5	12.3 ± 1.4	90.1 ± 1.8	1.7 ± 1.3	13.1 ± 3.3
6	12.1 ± 1.9	95.4 ± 1.8	0.7 ± 0.7	39.0 ± 3.5
7	11.3 ± 2.9	99.6 ± 0.7	0.0 ± 0.0	51.7 ± 1.9
8	12.4 ± 3.4	97.4 ± 4.4	0.0 ± 0.0	60.1 ± 0.6
median	11.7	94.5	0.0	26.1

[a]The results are expressed as the average of three independent replicates ± standard deviation.

a median value of 11.7% "A-type" PAC as determined by predictive equations.[25] Furthermore, median values showed that 26.1% of cranberry PAC had 2 or more "A-type" interflavan bonds, whereas none of the apple PAC had 2 or more "A-type" bonds (Table 1). However, mass spectrometry alone does not provide sufficient information for the structural elucidation of "A-type" PAC. To our knowledge, the confirmation of "A-type" interflavan bonds in apple PAC has not yet been described. Thus, whereas our interpretation of the data is that the detected masses represent "A-type" PAC in apples, reactions resulting from polyphenol oxidase activity may also alter PAC oligomer structure, resulting in modifications that involve the loss of two hydrogen molecules. This observation has also been reported for MALDI-TOF MS analysis of apple juices.[26]

The absence of PAC "A-type" to "B-type" interflavan linkage ratios for proanthocyanidin oligomers greater than an octamer (DP >8) is a result of the MALDI-TOF MS instrument parameters. The nature of the MALDI-TOF MS analysis requires the sample to be mixed with a matrix (DHB) to afford ionization and subsequent detection of charged compounds. This process produces numerous low molecular weight (<800 Da) matrix adducts resulting in background noise (unwanted signals). To improve the quality of the PAC spectra and allow for quantification of relative "A-type" to "B-type" interflavan bonds, the MALDI-TOF MS instrument parameters are set to gate (deflect) masses below a 800 Da threshold. As a result of this gating process, dimers (m/z 599 and 601) are also deflected and not detected. In the case of proanthocyanidin oligomers with DP >8, spectra are excluded from analysis when one or more of the peaks included in the deconvolution of isotope patterns have signal-to-noise ratios of <3.0.[18] On the basis of these predefined criteria, the MALDI-TOF MS instrument parameters are adjusted to provide high-resolution spectra for PAC trimers through octamers (DP 3–8). These parameters allow the relative proportions of "A-type" to "B-type" interflavan bonds for 23 individual proanthocyanidin masses to be compared across samples.

Bacterial Agglutination Assay. In our study design, we compared "A-type" to "B-type" PAC for their ability to increase ExPEC agglutination. We monitored the increase in transmittance of light (450 nm) that results when PAC interact with ExPEC, causing agglutination and precipitation from suspension. To correct for baseline transmittance, all values were normalized to zero at the beginning of the experiment. The AUC for each concentration level was calculated as a function of the ability of PAC to agglutinate ExPEC. Results showed that both "A-type" and "B-type" PAC significantly increased agglutination in a dose-dependent manner when compared to control. Figure 3 shows an example of an agglutination experiment using the "B-type" PAC from apples. Bacterial agglutination was 77, 58, 28, 27, and 32% higher for 5, 10, 25, 50, and 100 μg GAE/mL, respectively, when "A-type" were compared to "B-type" PAC. "A-type" PAC were significantly more effective (p values < 0.05) at increasing agglutination

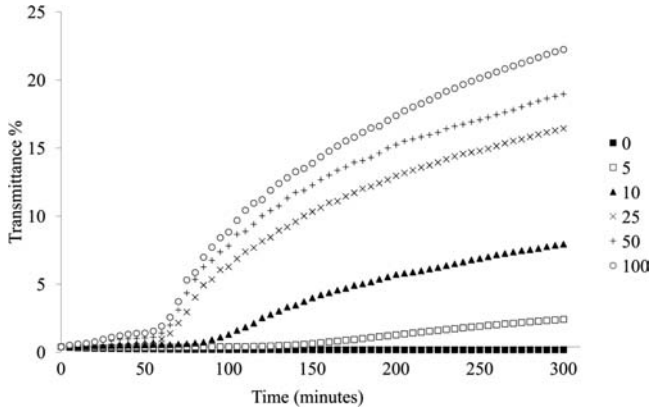

Figure 3. Relationship between transmittance (%) at 450 nm and time over 300 min of the agglutination assay with ExPEC in PBS and six levels of apple proanthocyanidins concentration (0, 5, 10, 25, 50, and 100 μg GAE/mL). The results represent the average of three independent replicates.

when compared to "B-type" PAC at all concentrations, except for the lowest concentration (Figure 4A).

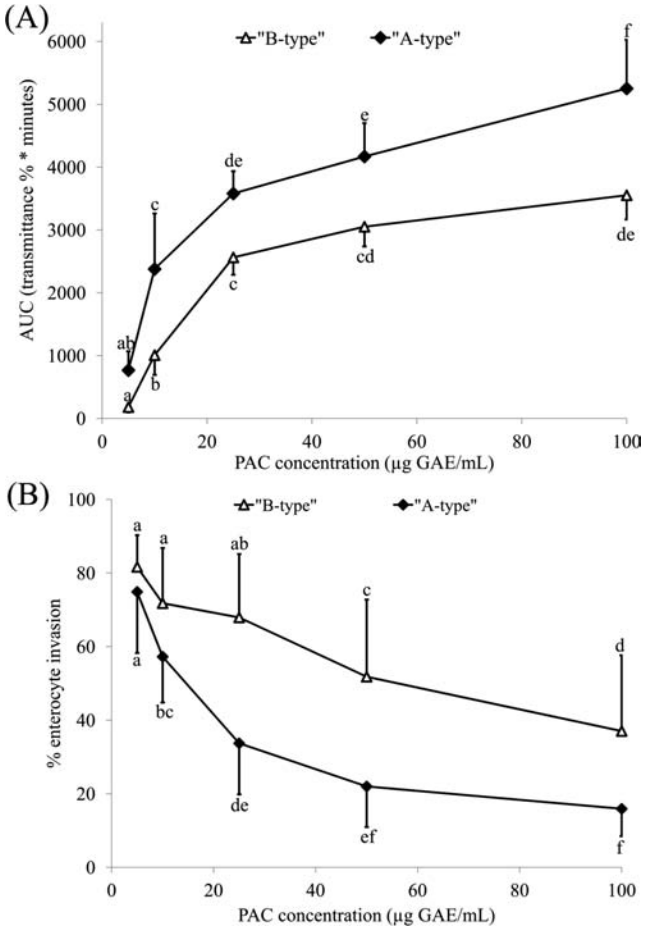

Figure 4. (A) Area under the curve obtained for the agglutination assay of *E. coli* 5011 for increasing concentrations of apple and cranberry PAC, expressed in μg GAE/mL. The results are expressed as the average of three independent assays ± standard deviation. Different letters correspond to significant differences at $p < 0.05$. (B) Dose−response curves on the effect of PAC extracted from apples and cranberries on the ability of *E. coli* to invade Caco-2 cells, expressed in μg GAE/mL, as quantified by the Folin−Ciocalteu method. Different letters correspond to significant differences at $p < 0.05$.

Invasion Assay. In the current study, we compared the ability of "A-type" and "B-type" PAC to inhibit invasion of gut epithelial cells by ExPEC. The results showed that both "A-type" and "B-type" PAC were able to significantly inhibit ExPEC invasion of Caco-2 cells in a dose-dependent manner (Figure 4B). However, "A-type" PAC produced significantly greater inhibition in comparison to "B-type" PAC. ExPEC invasion was reduced by 7, 15, 34, 30, and 21% for 5, 10, 25, 50, and 100 μg GAE/mL, respectively, when "A-type" were compared to "B-type" PAC.

The shape of the dose−response curve indicated that for "A-type" PAC, a plateau is attained at concentrations of 50 μg GAE/mL (Figure 4B). The curve for "B-type" PAC did not plateau, suggesting that this class of PAC required a higher concentration to reach a level of inhibition similar to that of "A-type" PAC.

The results of the two-way ANOVA model showed that the greater inhibitory effect of "A-type" PAC was statistically significant except for the lowest concentration (Figure 4B). Because every assay was run on a different day, we tested the effect of day within PAC treatment, and no significant differences of the dose−response curves were found.

DISCUSSION

MALDI-TOF MS Characterization of PAC. The goal of this work was to compare the effect of "A-type" with "B-type" PAC on ExPEC agglutination and invasion of gut epithelial cells. To determine the difference between "A-type" and "B-type" PAC we chose apples because this fruit contains only "B-type" PAC,[27] with catechin/epicatechin monomers, which yielded a MALDI-TOF MS spectrum with excellent baseline resolution.

PAC are oligomers of flavan-3-ols that have variable chain lengths.[23] There are two common series of procyanidin dimers. The "B-type" series are dimers linked in either the C4−C6 or C4−C8 position,[28] whereas the "A-type" series are dimers linked in the C4−C8 position with an additional C2−*O*−C7 ether linkage (Figure 2). PAC oligomers with a DP >2 may contain both "A-type" and "B-type" interflavan bonds. Therefore, for the purpose of discussing differences between PAC oligomers from cranberries and apples, cranberry PAC that contain one or more "A-type" interflavan bonds in their structure are referred to as "A-type" PAC, whereas apple PAC that contain only "B-type" interflavan bonds are referred to as "B-type" PAC.[28]

Analytical methods such as MALDI-TOF MS are routinely used to characterize unique structural features of PAC.[23−26,28−32] An understanding of the natural abundance of C, H, and O isotopes within proanthocyanidin oligomers allowed us to develop a novel MALDI-TOF-MS isotope deconvolution method.[18] We were able to quantify ratios of "A-type" to "B-type" interflavan bonds on the basis of theoretical isotope distributions by applying matrix algebra to the experimental spectra. In the context of this publication, MALDI-TOF MS methods were applied to provide both quantitative and qualitative assessment of proanthocyanidin structures.

Cranberry fruit (*Vaccinium macrocarpon* Ait.) has previously been shown to contain PAC that predominately include one or more "A-type" interflavan bonds.[23,33] Apple fruit (*Malus pumila* cv. 'Fuji') conversely has been shown to contain PAC that predominately contain all "B-type" interflavan bonds.[27]

Agglutination and Inhibition of Enterocyte Invasion. Bacterial agglutination, a bacterium-to-bacterium interaction, corresponds to an increase in concentration of bacteria in a limited area of the human body. This phenomenon can inhibit bacterial growth, cause structural damage to bacteria,[34] and increase bacterial clearance by macrophages and other phagocytic cells, potentially leading to a decrease in enteroctye invasion by ExPEC. We developed an agglutination assay to compare cranberry "A-type" PAC to apple "B-type" PAC. This assay is fundamentally different from the antiadherence assay that evaluates the ability of bacteria to adhere to uroepithelial cells based on the similarity of receptors on the uroepithelium with P blood group antigens.[26] Cranberry PAC inhibit this specific adhesion at low concentrations. Our new method allowed us to measure the effect of PAC with different structural characteristics on ExPEC agglutination over time and at low concentrations and demonstrated that cranberry "A-

type" PAC have greater agglutination activity than apple "B-type" PAC.

The results suggest that the direct effect of PAC on ExPEC agglutination is related to the specific inhibition in the red blood cell antiadherence assay because "A-type" PAC appear to have greater activity than "B-type" PAC. The ExPEC strain used in our agglutination study expresses both type 1 and P fimbriae. The red blood cell antiadhesion assay is based on the specific interaction of P-fimbriated *E. coli* with the Gal-Gal receptor on red blood cells that express the P blood group antigens.[26] Cranberry "A-type" PAC inhibit the adhesion of P-fimbriated *E. coli* to these red blood cells and thus prevent agglutination. The "B-type" PAC do not have activity in this assay. In contrast, both types of PAC have bioactivity in our agglutination assay, although cranberry "A-type" PAC showed greater activity than apple "B-type" PAC. Because strain 5011 expresses both type 1 and P fimbriae along with several other virulence factors, our results suggest that interactions of PAC with ExPEC surface virulence factors that lead to agglutination may result from specific binding of "A-type" PAC to P fimbriae and nonspecific binding to other proteins on the bacterial surface that can be mediated by both "A-type" and "B-type" PAC.

In vivo, bacterial invasion of gut epithelial cells provides a mechanism by which pathogens are protected from complements, antibodies, and other immune defense molecules, which in turn allows the pathogens to colonize and persist in the gut.[35,36] We developed an in vitro cell culture assay of bacterial invasion to assess the ability of compounds and immune factors to interfere with this mechanism of gut colonization. Proanthocyanidin concentrations used in this work are physiologically relevant because these concentrations in the gut are obtainable after the ingestion of a single serving of cranberry juice, which contains approximately 36 mg of PAC. If there was instantaneous mixing in the gut, then PAC concentration would be 7.2 μg/mL, assuming that gut volume is approximately 5000 mL (36 mg/5000 mL = 7.2 μg/mL). However, instantaneous mixing is impossible and PAC are poorly or not absorbed. Therefore, the concentration of PAC in the chyme would be much higher following ingestion and passage.

In summary, the results indicate that exposure of ExPEC to PAC consisting of either "A-type" or "B-type" interflavan linkages significantly produces bacterial agglutination and inhibits invasion of gut epithelial cells in a physiologically relevant dose-dependent manner. "A-type" PAC were observed to be significantly more effective in causing agglutination and reducing invasion when compared to "B-type" PAC at equivalent concentrations. Furthermore, it is known that the exposure of "A-type" PAC from cranberries to *E. coli* CFT073, a highly virulent uropathogenic strain, down-regulates *fliC* gene expression, which is responsible for flagellin expression, the major protein in bacterial flagellum, reducing bacterial motility[37] and compromising adherence to enterocytes. Our results suggest that "A-type" PAC act in a manner similar to opsonization of pathogens by secretory immunoglobulin A, which may also agglutinate bacteria, inhibit invasion of enterocytes, increase intestinal clearance, and promote killing by immune cells.[38]

This work provides a new insight on the specificity of the interaction PAC interflavan bond type with bacterial virulence factors highlighting the importance of this area of research in the context of understanding the mechanism by which "A-type" PAC prevent UTI by inhibiting gut colonization by ExPEC. This new understanding of proanthocyanidin structure/bioactivity relationships can be applied to develop a clinically relevant hypothesis of how proanthocyanidin-containing fruits, juices, botanicals, and dietary supplements can be used to develop therapeutic strategies against ExPEC.

NOTE ADDED AFTER ASAP PUBLICATION

There were errors in Figures 3 and 4, and the first paragraph of the Bacterial Agglutination Assay section of the version of this paper published November 18, 2013. The correct version published February 21, 2014.

despite their complex Acn profile, blueberries do not contain pelargonidin (Pel) and contain only about 6% peonidin (Peo).[17−19] Considering the complex in vivo metabolism reported for C3g alone,[7,8,15] the diverse array of blueberry Acn significantly complicates the study of their bioavailability.

A significant limitation in the study of Acn metabolism is that pure standards of Acn metabolites are not commercially available. Our current knowledge of Acn in vivo metabolism is based almost entirely on the MS/MS detection of parent and daughter fragments for predicted Acn metabolite(s) (AcnM). The AcnM concentration is then estimated on the basis of the MS signal of the 3-glucoside of the corresponding anthocyanin, whereas the actual MS response of Acn phase II metabolites is unknown. Recent Acn bioavailability studies may benefit from improvements in more modern LC-MS technology that allow the concurrent scanning of large numbers of predicted mass transitions using multiple reaction monitoring (MRM). Earlier technology allowed for the scanning of perhaps 10 or fewer mass transitions, due to limitations in scan rate.

This clinical study examines qualitatively and quantitatively urinary Acn before and then for 24 h following the ingestion of blueberry juice (BJ). Although the urinary disposition of Acn reflects only one aspect of the fate of Acn in vivo, their measurement was an effective means to examine the metabolism and excretion of the complex array of Acn that are found in blueberries. LC-MS scanning for a large number of Acn phase II metabolites revealed new aspects of the in vivo metabolism of Acn, which are relevant in clinical research.

MATERIALS AND METHODS

Study Design. Seventeen normal, healthy volunteers (ages 24−60 years, 13 women, 4 men) entered the study with informed consent (clinicaltrials.gov identifier NCT01789359). Prior to the study, participants completed an Acn intake questionnaire to estimate their typical consumption of various Acn-containing foods (Table 1) over the previous 8 weeks. Intake was measured in total servings per week, with 1 serving size equal to half a cup of fruit or a 6 oz glass of pure juice, 100% juice blend, or red wine.

Table 1. Foods Containing Anthocyanins (Acn) That Were Included in a Prestudy Acn Intake Questionnaire and for Diet Restrictions during the Study[a]

food category	sample foods
berries	acai berry; blackberry; blueberry; chokeberry; cranberry; elderberry; lingonberry; raspberry; red or black cherries; red or black currants; red or black grapes; strawberry
other fruits	blood orange/red orange; pomegranate; red or black plums; red-fleshed peach; red-skinned apple
vegetables	blue or purple tomatoes; eggplant; purple carrot; purple corn; purple sweet potato; red-leaf lettuce; red onion; red potato; red radish; red, purple, or black olives
grains and pulses	red or black rice
beverages	blueberry juice; cranberry juice/cocktail; fruit punches (blends with grape ± strawberry ± blueberry, etc.); grape juice; herbal teas (with red/blue/purple fruits); red wine
other	products that contain red/blue/purple fruits including yogurt, bakery products, jams and jellies, trail mix

[a]Participants reported their intake in servings where one serving was 1/2 cup (113 mL) of food or 6 oz (177 mL) of beverage. Intake scores included more than once daily; once daily; four or five times weekly; two or three times weekly, less than once weekly.

During the trial participants abstained from all Acn-containing foods except for wild BJ as specified. Compliance was monitored by self-reporting questionnaires, and participants were encouraged to document when any other Acn-containing foods had been consumed. For the first 5 days, participants consumed no Acn-containing foods (Table 1). The next day, volunteers consumed 250 mL of single-strength BJ containing 216 mg of C3g equivalents. The nonacylated Acn profile of wild blueberry is discussed in this study on the basis of three studies.[17−19]

Chemicals. Acetonitrile, methanol, and formic acid were LC-MS Optima grade and purchased from Fisher Scientific (Mississauga, ON, Canada). Trifluoroacetic acid (TFA) was purchased from Sigma-Aldrich Canada Co. (Oakville, ON, Canada). Petunidin 3-*O*-glucoside was purchased from WUXIAPPTEC Co. Ltd. (Tainjin, People's Republic of China). All other Acn glycosides were purchased from Indofine Chemical Co. (Hillsborough, NJ, USA) and were >95% pure.

Urine Collection. After the 5 day Acn-free run-in, participants provided a sample of their urine before, and then for the next 24 h after, drinking BJ. For each void, the entire urine volume was collected by the participant by using a graduated basin that fit over the toilet seat. The total urine volume was recorded, and then approximately 3.5 mL of urine was transferred using a disposable pipet into a labeled cryo-vial. Cryo-vials contained TFA to stabilize Acn so that the final TFA concentration in the ±3.5 mL of urine was about 0.29−0.43 M. Samples were immediately refrigerated and stored there for ≤8 h before transfer to −80 °C.

Sample Preparation for LC-MS. In preparation for solid phase extraction (SPE) samples were thawed in a 35 °C water bath, vortexed briefly, and then centrifuged at 14000 rpm (4 °C) for 10 min to remove any particulates. An aliquot of 500 μL of urine was diluted with 500 μL of 0.1% TFA. For SPE a positive pressure manifold (Waters Ltd., Mississauga, ON, Canada) was used in conjunction with microelution plates (Oasis HLB μelution plates (30 μm) 2 mg cartridges (Waters Ltd.)). The microelution wells were preconditioned with 200 μL of methanol and 200 μL of 0.1% TFA. The 1 mL diluted urine sample was loaded into the microelution well in two 500 μL aliquots and then washed with 200 μL of 5% methanol in 0.1% TFA. The remaining bound materials, including Acn, were desorbed from SPE into collection plates using 25 μL of 0.1% TFA in methanol followed by 100 μL of 1.2% acetonitrile−2% formic acid in water. Recovery (%) of urine samples spiked with Acn 3-glycoside standards ranged from an average of 70% for peonidin 3-glucoside to 87% for petunidin 3-glucoside (data not shown).

Calibration standards were the 3-glucoside of the six common anthocyanidins and were run before and after every 18 samples, which was every 24 h. The six Acn 3-glucoside levels included 0 and 1×, 2×, and 8× concentrations. The concentration of the stock solution for each Acn 3-glucoside varied depending on its MS response and its relative abundance in urine in representative samples. The 8× stock concentration ranged from 86 ng/mL for Del to 1720 ng/mL for Pet. A calibration level at 12× was run but not used in quantitation because it fell outside the linear portion of the signal response to concentration.

HPLC-ESI-MS/MS Analysis. A 25 μL volume of the diluted methanolic SPE eluent was injected onto a PFP Kinetix 2.6 μm column (2.1 × 50 mm) (Phenomonex, Torrance, CA, USA), and analytes were separated using an Ultimate 3000 HPLC (Dionex, Mississauga, ON, Canada). Column temperature was 55 °C, and flow rate was 600 μL/min. Solvent A was 2% HFo, and solvent B was 2% HFo−90% acetonitrile. The gradient program was as follows: 0−1 min, 1.2% B; 1−31 min, 1.2−21.2% B; 31−37 min, 21−100% B; 37−42 min, 100% B; 42−44 min, 100−1.2% B; 44−52 min, 1.2% B. The LC was coupled to an ABSciex QTrap 4000 (Toronto, ON, Canada) linear ion trap and using a Turbospray (ABSciex) electrospray ionization (ESI) source, which offers unit mass resolution (i.e., ±0.5 amu). The ESI/MS, which was carried out in positive ion mode, parameters were as follows: gas 1 and 2, 60 psi; temperature, 700 °C; curtain gas, 25 psi; declustering potential, 65 V; entrance potential, 10 V; collision energy, 26 V; and collision cell exit potential, 17 V. Tandem mass spectrometry (MS/MS) was carried out for 60 MRM corresponding to parent Acn (PAcn) that were found in BJ and predicted AcnM. Also, an MRM for phospholipid (184/184) was monitored (Table 2). Peaks were named on the basis of their signal arising for a given MRM and at a given retention time (RT).

LC-MS/MS Signal Quantitation and Statistical Analysis. Raw LC-MS data were filtered to remove all peaks with signal-to-noise ratio (S/N) of <10. Peaks with S/N of ≥10 were integrated and statistically analyzed using Genstat.[20] In the statistical analysis Acn were denoted either as PAcn or as an AcnM. Peaks denoted PAcn were 18 Acn glycosides that were monitored using pure standards (Table 2) so that LC-MS signals with a matching RT and mass transition (MRM) were denoted PAcn. All other MRM signals were denoted AcnM. For each anthocyanidin, only the 3-glucoside was used for quantification of all signals.

RESULTS

LC-MS Analysis. Results of four kinds of urine samples are reported. Three of these urine samples were based on a single void: (1) urine before intake (Pre-BJ); (2) the first void after BJ intake; and (3) the last void before 24 h. The fourth sample, 24hB, was urine that was blended proportionally from each void (1 μL/mL) during the 24 h after BJ. Results are reported as Acn concentration (ng/mL) in urine to best illustrate the continuous excretion of Acn before and after BJ. For convenience, the Acn are named for their equivalent common anthocyanidin; however, these Acn may also include their positional isomers and/or chalcones that give rise to the same parent and daughter fragment mass.

A sample chromatogram (Figure 1) illustrates typical signal strength of selected Acn MRM as well as the phospholipid signal (184/184) that led to MS signal dampening. Phospholipids were detected as distinct peaks and as a high baseline throughout the entire chromatographic profile. The Acn 3-glucosides used for calibration were run in a urine matrix to attempt to control for this signal-dampening effect.

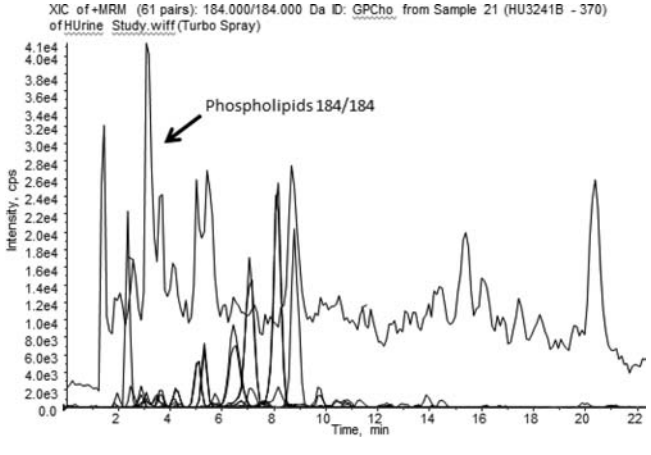

Figure 1. Representative LC-MS chromatogram showing phospholipids (184/184) in urine samples after solid phase extraction.

Total Urinary PAcn and AcnM before and after BJ Ingestion. Before BJ was ingested, and after participants had abstained from all Acn-containing foods for 5 days, the PAcn (i.e., 18 Acn glycosides) were present in urine at a low total concentration of 20.26 ± 6.536 ng/mL (Table 3). In the first urine void after BJ ingestion, which occurred on average 2.48 h after BJ intake, the concentration of PAcn was 20-fold greater (416.7 ± 92.38 ng/mL). Then over the following 24 h, the total urinary PAcn remained on average 17 times greater than Pre-BJ (Table 3). Given the BJ Acn dose of 216 mg of C3g equivalents and that the mean 24 h urine volume for the 17 participants was 620 mL, 0.0752% of the PAcn in the BJ could be accounted for after 24 h. In the final void of the 24 h period, the PAcn concentration (20.97 ± 4.089 ng/mL) was essentially the same as it was Pre-BJ (Table 3). Compared to PAcn, the AcnM concentration was substantially greater in all urine samples (Table 3). Even before BJ intake, the urinary AcnM concentration was 6.6 mg/mL, which increased to 7.6 mg/mL in the 24hB urine. In the 24hB urine 95.7% of the total Acn concentration was AcnM, whereas the PAcn made up only 4.3%.

There was no correlation between the Pre-BJ urinary total Acn (PAcn plus AcnM) concentration of the 17 participants and their questionnaire response regarding typical food Acn intake or their compliance during the 5 day Acn-free run-in (Figure 2). Also, the urinary Acn concentration of two participants who reported drinking their BJ one day too soon was not different from that of the other 15 participants who were compliant (Figure 2).

Individual Urinary PAcn and AcnM before and after BJ Ingestion. Compared to the urine Pre-BJ, the first void after BJ had a PAcn concentration greater by Cyn, 45-fold; delphinidin (Del), 4.7-fold; malvidin (Mal), 30-fold; Peo, 22-fold; and petunidin (Pet) 37-fold. The PAcn concentration in the first void after BJ ranged between 2-fold greater (Del) and 1.05-fold greater (Mal) (Table 3) than in the 24hB. No Pel glycosides were detected in any urine sample.

In all urine samples there was a far greater concentration of AcnM for each of the six anthocyanidins compared to their

[a]Values are the mean for the n = 17 participants ± standard error of the mean. Results are shown for four urine samples: (1) before blueberry juice (BJ); (2) first urine void after ingestion of 216 mg of cyanidin 3-glucoside equivalents in BJ; (3) urine blended from all voids for 24 h after BJ; and (4) last urine void in 24 h.

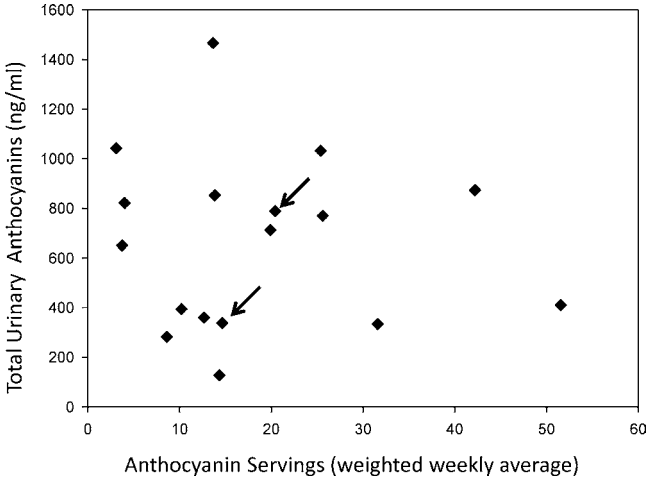

Figure 2. Relationship between typical anthocyanin (Acn) intake based on questionnaire results for 17 participants and their total urinary Acn concentration after 5 days with no dietary Acn. Arrows indicate participants (2) who drank their blueberry juice 24 h too early, after only a 4-day Acn-free run-in.

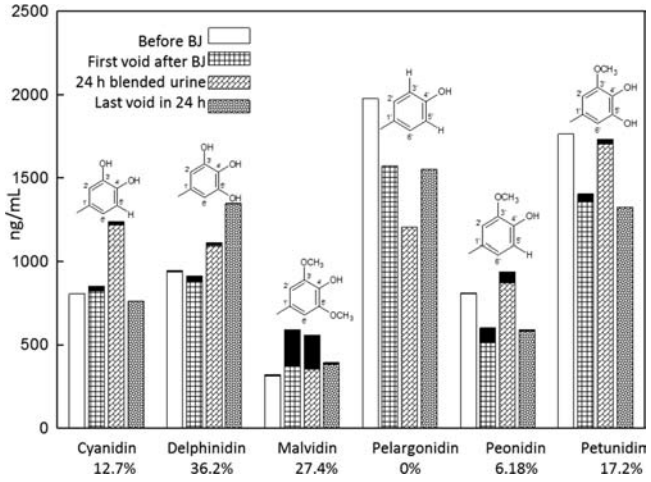

Figure 3. Total anthocyanin (Acn) concentration (ng/mL) in urine samples obtained after 5 days free of dietary Acn and before ingestion of blueberry juice (BJ); in the first void after BJ; in the 24 h blended urine, and in the final urine void after 24 h. Parent Acn are shown in solid black. Values and standard errors are in Table 4. The contribution of each anthocyanidin (%) to the total found in wild blueberry juice is also shown.

PAcn. In the 24hB the AcnM concentration exceeded that of PAcn by around 60-fold for Cyn, Del, and Pet and by about 13-fold for Peo. However, in 24hB the concentration of Mal AcnM was only 1.7-fold greater than that of Mal PAcn (Table 3; Figure 3). The intake of BJ had a relatively small effect on the AcnM concentration for each anthocyanidin. Compared to Pre-BJ, the AcnM concentration in the 24hB urine was 50% greater for Cyn, but 37% lower for Pel. In 24hB compared to Pre-BJ, the increase in AcnM concentration was 16% or less for Del, Mal, Pet, and Peo.

Changes in the total concentration of each anthocyanidin after BJ ingestion were due almost entirely to changes in their AcnM concentration (Table 3; Figure 3). The total Acn concentration in the first void after BJ was actually lower than before BJ for Pel (−20%), Peo (−26%), and Pet (−20%). In fact, the Pel concentration (which was all Pel AcnM) was greatest in the Pre-BJ compared to urine after BJ ingestion. Cyn and Del were similar in that their total Acn in the Pre-BJ and in the first void after BJ urine were roughly the same (Table 3; Figure 3). The total Cyn concentration (PAcn and AcnM) was greatest in the 24hB, whereas the Del concentration was 20% greater in the last void than in the 24hB. Similarly, the Pel concentration was 29% greater in the last void as compared to the 24hB (Figure 3). Among the four urine samples and the six anthocyanidins, Mal had the lowest total Acn concentration and the greatest proportion of Acn as PAcn (Table 3; Figure 3).

The relative proportion of the anthocyanidins was different in urine compared to BJ (Figure 3). Most striking was Pel, which is not found in BJ, but was a particularly abundant AcnM. Similarly, Mal made up 27% of the total Acn in BJ, but its total concentration among the urine samples was the lowest for all anthocyanidins (Figure 3).

Types of AcnM Observed in Urine over 24 h after BJ. In the 24hB urine from 17 individuals a total of 226 combinations of RT and mass transitions with S/N > 10 were observed for the six anthocyanidins (Table 4). Of these

[a]RT corresponds to the number of retention times at which a given mass transition (MRM) was observed. Concentration (ng/mL) is based on the Acn 3-glucoside, and the sum is the concentration for each combination of MRM and retention time.

226, 18 signals corresponded to the PAcn that were also monitored using pure standards.

The aglycone forms of AcnM were almost 19-fold more abundant (ng/mL) than the glycoside-based AcnM (Table 4). Among the aglycones, glucuronide conjugates were in greatest abundance for all Acn except Pet. The aglycone methylated glucuronides were the second most abundant for Cyn, Del, Peo, and Pel (Table 4). The numbers of RT for the methylated aglycone and nonmethylated aglycone glucuronides were similar, differing by no more than two (Table 4). Together the Acn aglycones, their glucuronides, and their methyl glucuronides made up 91% of the total AcnM concentration. AcnM glycosides made up the remaining 9% of the total urinary AcnM observed in the 24hB. Of these AcnM glycosides, 72% were methylated conjugates (Table 4).

Interindividual Variation in AcnM Profiles. Interindividual variation in the profile of AcnM among the 17 participants was assessed specifically for Acn aglycone glucuronides, which were the most diverse (number of RT) and abundant (ng/mL) AcnM group (Table 4). There was no correlation between the mean concentration of any particular urinary Acn aglycone glucuronide and the number of participants in whom it was observed (Figure 4). Two Pel aglycone glucuronides were notable because of their comparatively high mean concentration. One of these Pel aglycone glucuronides was detected in eight participants; however, one participant contributed about 72% of the total amount measured for the eight. The same participant was responsible for 77% of the total amount of the other abundant Pel aglycone glucuronide that was found in 6 of the 17 participants. On the basis of the self-reporting, this participant complied with the dietary restrictions.

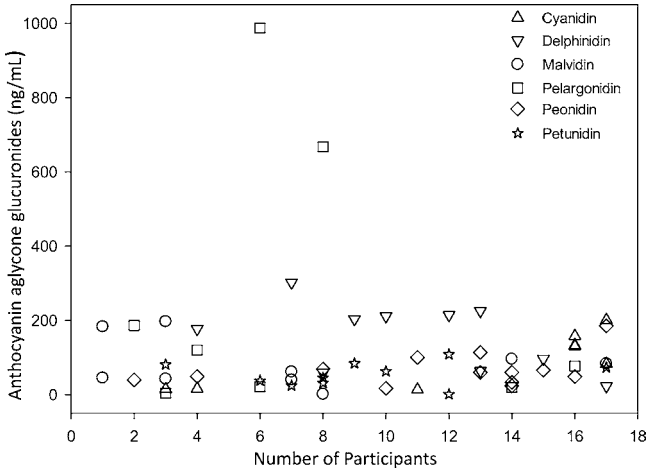

Figure 4. Concentration of anthocyanidin aglycone glucuronides and the number of the total 17 study participants in whom it was observed.

DISCUSSION

Figure 3 and Table 3 provide evidence of a large number of Acn xenobiotic metabolites that likely include early-stage Acn breakdown products and were present in urine both before and after BJ intake. The total concentration of these intermediates was many-fold greater than the concentration of Acn glycosides (i.e., PAcn) (Table 3) that have been the focus of most of the Acn bioavailability studies to date. The large array of AcnM-related MRM signals reported here likely constitutes the intermediates involved in the conversion of Acn to phenolic acids during digestive absorption.

In discussing the significance of these results it is important to consider the kind of evidence provided by LC-MS/MS using MRM. MRM cannot conclusively identify a given compound

unless a pure standard is available. And although the lack of Acn xenobiotic metabolite standards has been a significant obstacle, studies have nevertheless offered parent and daughter mass fragment data, often using MRM, as evidence of the occurrence of a given AcnM. Because berry anthocyanidins are differentiated by the number and arrangement of their B-ring hydroxyl and methoxy groups and because phase I and II metabolism can include hydroxylation and methylation of flavonoids,[21] LC-MS/MS investigation of in vivo anthocyanidin profiles and their xenobiotic metabolites is significantly complex (Figure 5). Also, at physiological pH in vivo formation of

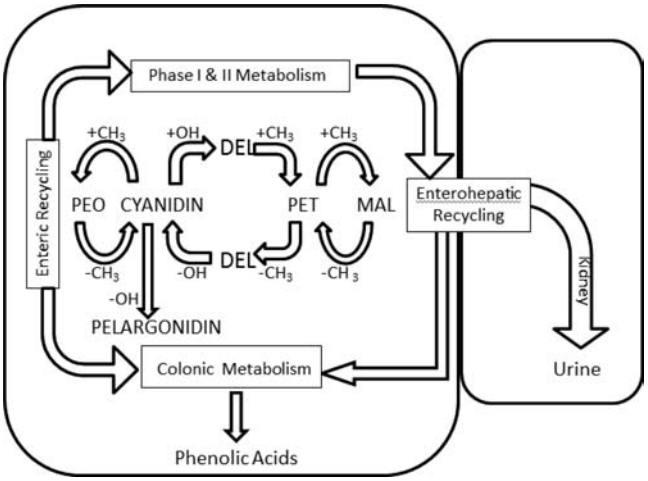

Figure 5. Schematic outline of anthocyanin interconversion in vivo due to xenobiotic and gut bacterial metabolism involving addition and removal of methyl and hydroxyl groups. Enteric and enterohepatic recycling will lead to isomeric modification before partitioning of anthocyanin metabolites into urine.

chalcones will occur due to the conversion of Acn to their quinoidal form, followed by A-ring opening and the addition of a hydroxyl group at carbon-9.[22] Even greater complexity in the suite of Acn-related in vivo metabolites occurs because phase II reactions can add conjugating groups at more than one site on the anthocyanidin, giving rise to positional isomers. Enterohepatic recycling of Acn conjugates, involving deconjugation and reconjugation with glucuronides, methyl, and possibly sulfate groups can add yet another level of chemical heterogeneity to the complex mixture of AcnM. For convenience, results of the current study are discussed in terms of the plant forms of Acn; however, the heterogeneous suite of AcnM MRM signals points to a complex array of isomeric forms of Acn and chalcone metabolites that arise from pH effects, phase I and II metabolism, and enterohepatic recycling. Aspects of these results are discussed in more detail below.

Abundance and Persistence of AcnM in Urine. The rise and fall in the concentration of PAcn over 24 h were similar to previously published results[1,4,23] as was the very low total recovery of PAcn in urine (0.0752%). In the present study total urinary PAcn concentration in 24hB increased by about 2.92 μmol/L (based on C3g equivalents) after BJ (Table 3), which was comparable to the study by Czank et al.,[8] who examined the fate of ^{13}C-labeled C3g in eight men. However, the present study also documented a very high relative concentration of AcnM in urine even before BJ intake. After BJ intake, the AcnM concentration was only 15% greater for the following 24 h than before BJ. In 24hB urine, the AcnM concentration exceeded that of PAcn by 22-fold.

The high basal level of urinary AcnM in the Pre-BJ urine even after 5 days of an Acn-free diet (Table 3; Figure 3) reflects the persistence of AcnM in the gastrointestinal tract. Flavonoid persistence in vivo has been previously reported and is suggestive of enterohepatic recycling (for review, see Wu et al.[21]). Young et al.[24] reported that after 1 week during which clinical participants (n = 5) avoided flavonoid-containing foods, quercetin was detected in the urine of all subjects, after urine samples were subjected to enzymatic deconjugation. In a recent study[25] quercetin aglycone was detected in baseline plasma samples of all participants (after treatment of plasma with deconjugating enzymes) after 3 days of a flavonoid-free diet. Even more striking was that after 6 weeks of a diet free of berries and low in flavonoids (average 2.6 mg of quercetin per day), quercetin (after deconjugation) was still detectable in human plasma.[26] In the present study the lack of a correlation between the typical Acn ingestion of study participants and their Pre-BJ urinary AcnM concentration (Figure 2) supported the notion that AcnM were persistent in vivo. Persistence of AcnM was also apparent when the total Pre-BJ Acn concentration of two participants who drank their BJ one day too early was indistinguishable from the other 15 participants Pre-BJ (Figure 2).

Aglycone and Glycoside AcnM. AcnM aglycones were 91% of the total AcnM in 24hB (Table 4), indicating that deglycosylation was a predominant event in the in vivo metabolism of Acn. Because the concentration of PAcn (18 Acn monoglycosides) was not substantially different between the first void after BJ and in the 24hB, it appears that Acn deglycosylation was rapid (Figure 3). However, the decline in glycosides after BJ ingestion will be investigated in the analysis of the individual voids that make up the 24hB (in progress). The similar concentration of PAcn in the Pre-BJ void and in the last void 24 h after BJ also suggests that Acn deglycosylation during the 24 h was complete.

Acn aglycones are reported to be chemically unstable at physiological pH,[1,11,27] but their predominance among the AcnM based on MRM signals suggests that they were relatively stable in vivo. However, Acn aglycone reactivity at physiological pH can lead to chalcone formation, and although chalcone bioavailability is not well-studied,[16] they have been suggested[14] to be more stable than their corresponding anthocyanidins in vivo. It has been suggested that the stability of Acn may be improved by their adsorption to other molecules (e.g., food matrix, bile acids).[28] In the present study this possibility is supported by the presence of phospholipids that were detected throughout the chromatographic profile (Figure 1) even after urine cleanup using SPE.

Glucuronides of Acn. Of the 91% of the total AcnM that were aglycones, 79% of these were conjugated to glucuronide groups (Table 4), supporting earlier reports[15,21,29−31] that glucuronidation of flavonoid aglycones constitutes a major route of flavonoid metabolism in vivo. The almost complete absence of urinary Acn glycoside glucuronides (Table 4) may be due to the fact that the phase II enzyme responsible for glucuronidation, uridine diphosphate glucuronosyl transferase (UGT), cannot easily accommodate flavonoid glycosides due to their size and polarity.[21]

The large number of Acn aglycone glucuronides observed (55 for the 6 anthocyanidins) may relate to the collectively broad substrate specificities of numerous UGT isoforms.[21]

Human UGT isoforms are localized in membranes of the small intestine, colon, and liver and may be coupled to efflux transporters to release glucuronides into the intestinal lumen, blood circulation, or bile.[21,32] UGT isoforms each have particular substrate affinities, so that the pool of glucuronides can include conjugates at various positions on the AcnM molecule. Our findings of positional isomers of AcnM support earlier studies.[7,9,15,33] Ichiyanagi et al.[15] detected 17 Cyn-based AcnM 4 h after feeding pure C3g to rats. Of these Cyn AcnM, 12 were Cyn glycoside conjugates and 8 were methylated conjugates and included 6 positional isomers of methylated C3g glucuronide.

The chromatographic elution of the multiple AcnM, including the predominant aglycone monoglucuronides, occurred over a wide range of RT (data not shown), which was also observed by Marczylo et al.[7] Whereas the RT of individual peaks would have been determined by chemical and structural features, their MS/MS signal at that RT indicated only an aglycone monoglucuronide. Therefore, multiple RT possessing the same MS/MS signal suggest a chemical and structural diversity that may be due to positional isomers of AcnM and chalcone conjugates. Adding to the apparent significant diversity of AcnM, chalcones can also occur as both cis and trans forms.[22] It is also possible that more complex Acn glucuronides may have been present, whereas the MRM detected only a remaining parent/daughter fragment. Related to this, Wu et al.[21] suggested that multiple glucuronidation events by UGT may be possible owing to multiple reactive hydroxyl groups on the flavonoid and ample space in the UGT binding pocket. Felgines et al.[9] report the occurrence of Cyn diglucuronide, and we have also detected diglucuronides of Acn aglycones in a subsequent reanalysis of the 24hB samples (data not shown). The association of AcnM with other matrix components[28] (e.g., phospholipid) may affect the RT of the MRM detected. The association of quercetin with mixed lipid micelles has recently been suggested to improve quercetin absorption when taken as part of a high-fat diet.[25]

Methylation of Acn. The number of methyl conjugates of Acn aglycones may reflect the substrate affinity of methylation enzymes, for example, catechol-*O*-methyl transferase. Related to this, quercetin 4-glucuronide was not subject to methylation in HepG2 cells, whereas quercetin 7-glucuronide and quercetin 3-glucuronide were.[34] The facts that methylated aglycone glucuronide conjugates made up about 36% of the total aglycone glucuronide pool and aglycone glucuronides made up about 72% of the total AcnM 24hB (Table 4) re-emphasize that glucuronidation of Acn aglycones was a major in vivo pathway for Acn conjugation. In their review, Wu et al.[21] indicate that small differences in the arrangement of OH and OCH_3 groups on flavonoids can affect the ease of glucuronidation by UGT.

Enterohepatic Recycling of AcnM. The presence and persistence of a large number of AcnM conjugate isomers (i.e., multiple RT for the same MRM) (Table 4) are due, at least in part, to their enteric and enterohepatic recycling. This recycling involves phase I and II conjugation of ingested compounds with hydroxyl, methyl, and glucuronide moieties, which occurs in the small intestine and liver. This is followed by the release of xenobiotic conjugates into the lumen of the small intestine or into hepatic and renal circulation and bile. Migration of these conjugates into the lower part of the small intestine and colon leads to their deconjugation by colonic bacteria. Hydrolyzed phase II conjugates can be reabsorbed through the colon and return to the small intestine or via the portal vein to the liver, where they can be reconjugated via phase I and II reactions.[21] Reconjugation at different reactive hydroxyls of AcnM gives rise to positional isomeric forms of AcnM. These recycling processes extend the half-life and overall bioavailability of parent compounds and their metabolites.[21,35] It is conceivable that novel anthocyanidin structures which were not predicted or monitored by MRM were also formed in vivo as part of enterohepatic recycling.

Effects of in Vivo Metabolism on the Anthocyanidin Profile. Anthocyanidins are distinguished by the number and position of their B-ring methoxyl and hydroxyl groups; therefore, apparent interconversions of anthocyanidins can occur due to methylation and hydroxylation during xenobiotic and bacterial metabolism (Figure 5) and based on MS/MS evidence. In phase I processes, cytochrome P450 isoforms can substitute hydroxyl groups and remove methyl groups from flavonoids,[21,31] whereas in phase II metabolism, methyl groups can be substituted at phenolic hydroxyls.[21,31] Therefore, the methylation of Cyn produces an Acn with the mass of Peo,[2] methylation of Del produces an Acn with the mass of Pet, and Pet methylation produces an Acn with the mass of Mal (Figure 5). Phase I hydroxylation of Cyn gives rise to an Acn with the mass of Del. In the colon dehydroxylation and demethylation can give rise to moieties with the parent mass of common anthocyanidins (Figure 5). Therefore, reactions catalyzed by both human and bacterial enzymes lead to Acn interconversion based on their detection by LC-MS/MS.

Chalcones have hardly been studied in relation to Acn bioavailability,[16] but are expected to be formed from Acn at physiological pH. Recyclization of cis forms of chalcones can occur to a limited degree at high temperatures and over time; however, trans forms are not subject to recyclization.[22] Of importance to this work is that chalcones are distinguished from their corresponding Acn by the addition of a hydroxyl at C-9.[22] Therefore, the chalcone formed from Cyn will have the mass of Del, the Pel chalcone will have the mass of Cyn, and the Peo chalcone will have the mass of Pet. Chalcones are also subject to xenobiotic metabolism[16] and in the present study probably contribute significantly to the large number of putative AcnM identified on the basis of MRM. Chalcones are intermediates in the formation of phenolic acids that become abundant after Acn intake.[14]

Acn interconversions help to explain the presence and predominance of Pel-based AcnM (Figure 3) when BJ does not even contain Pel. Pel may be considered an advanced catabolic Acn product, because its B ring possesses the least number of methyl and hydroxyl groups among the six common anthocyanidins. Therefore, progressive demethylation and dehydroxylation of the other five anthocyanidins favor the formation of an anthocyanidin with the mass of Pel (Figure 5). Pel has been noted in other studies as having a much greater apparent bioavailability than other Acn.[23,29,30,36] For example, Wu et al.[36] fed weanling pigs marionberry, in which Pel is <0.5% of the total Acn, and reported that Pel glucuronide had the highest percentage recovery in urine, exceeding the other marionberry AcnM by between 7 and 540 times. When strawberry doses were fed to humans, approximately 2% of the Pel in each strawberry dose was recovered in urine, well above the amount typically reported for other Acn, which is <0.1%.[1−3,29]

Xenobiotic and bacterial enzyme specificities may help to explain the relative amounts of Mal. Mal, which is 36% of the BJ Acn and the most methylated of the Acn (Figure 3), was

present in the lowest total concentration among the six anthocyanidins in all urine samples. The proportion of Mal PAcn to AcnM was much greater than for the other five anthocyanidins (Figure 3), suggesting that Mal conjugation was relatively impaired due to steric hindrance on the B-ring and that Mal demethylation to Pet was active. The concentration of Pet-based AcnM exceeded that of Mal-based AcnM by at least 3.4-fold, although in BJ, Mal exceeded Pet content by almost 2-fold (Figure 3).

The high concentration of AcnM in human urine supports the notion that Acn is more bioavailable than originally reported[1,8] and does not support the notion that in vivo Acn bioavailability is poor.[4,11] However, it must be qualified whether "in vivo bioavailability" pertains to PAcn only or PAcn plus AcnM. This distinction becomes important if AcnM are found to be bioactive. Phase II and other metabolites of polyphenolics can be bioactive;[31,37−39] therefore, the bioactivity of urinary AcnM reported here and the extent of their in vivo circulation are of key importance. Glucuronides of quercetin are antiangiogenic[37] and can affect human lung cancer cell growth in vitro.[39] The 5-*O*-glucuronide of epicatechin is a potent antioxidant in vitro like the native epicatechin.[31] Equol, a bacterial catabolite of soy isoflavones, has significantly greater estrogenic activity than the parent isoflavone in vitro and in animal models.[38]

This study helps to illustrate the nature of the in vivo intermediates arising from the intake of food Acn and before their conversion to phenolic acids. The continuous urinary excretion of a high concentration of AcnM even after 5 days of abstaining from dietary Acn should be considered in the design of Acn-related clinical trials. The persistence of AcnM in urine (Table 3; Figure 3) complicates interventions with Acn and the availability of compliance and noncompliance biomarkers of Acn intake.[5] However, retention of a high urinary concentration of AcnM suggests that systemic exposure to intact Acn moieties is significantly greater than previously thought.

found in berry fruit play a fundamental role in the antioxidant, chemopreventive, and anti-inflammatory activities,[5] but in addition to anthocyanins, other phenolic compounds, such as ellagitannins and flavonols, seem to exert a protective role in carcinogenesis by reducing the bioavailability of carcinogens.[9] Many studies have also confirmed the influence of genotype on the phytochemical composition of strawberry fruit antioxidant capacity, so that it is possible to find new genotypes and cultivars producing fruit with higher contents of bioactive compounds, explore new genetic resources, or develop tailored breeding programs.[10−12]

The aim of this study was to analyze the potential antioxidant effects of freeze-dried strawberry powder, added to a semisynthetic and isoenergetic diet, on doxorubicin-induced oxidative stress in rats. The effect of freeze-dried strawberry powder was tested by comparing two strawberry cultivars originated by the strawberry breeding program of the university: Sveva and Adria. These two genotypes were selected after previous studies[10−12] that allowed the differentiation of their fruits according to the total antioxidant capacity (TAC) and the vitamin C and polyphenolics they contained: Sveva presents higher total antioxidant capacity, associated with a higher value of total polyphenol and vitamin C, whereas Adria shows higher values of anthocyanin contents but lower TAC.

MATERIALS AND METHODS

Chemicals. Doxorubicin was obtained as doxorubicin hydrochloride (2 mg/mL) from Sigma-Aldrich (St. Louis, MO, USA), as well as 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid (ABTS) diammonium salt, potassium persulfate, Trolox ≥98.0%, ascorbic acid, dipotassium hydrogen phosphate, potassium dihydrogen phosphate, Folin−Ciocalteu reagent, sodium carbonate, gallic acid, potassium chloride (KCl), sodium acetate (NaAc), and hydrochloric acid (HCl). Ethanol of HPLC grade, phosphate buffer solution 10×, 2-thiobarbituric acid 0.8%, acetic acid 99.9%, 2′,7′-dichlorofluorescein (DCF) ≥90%, sucrose, Tris 10 mM, EDTA-Na, bovine serum albumin (BSA), succinic acid disodium salt hezahydrate, 5,5-dithiobis(2-nitrobenzoic acid) (DTNB), dinitrophenylhydrazine (DNPH), 1-chloro-2,4-dinitrobenzene (CDNB), heparin, carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP), tetramethylphenylenediamine (TMPD), cyanidin-3-glucoside, pelargonidin-3-glucoside, quercetin-3-*O*-glucoside, and ellagic acid were also purchased from Sigma-Aldrich. Methanol and ethanol of ACS grade were purchased from Carlo Erba Reagenti, Milano, Italy, whereas $DCFH_2DA$, cell-permeant indicator for reactive oxygen species, was acquired from Molecular Probes, Invitrogen (Carlsbad, CA, USA). High-purity water (Milli-Q Water System, Millipore Corp., Bedford, MA, USA) was employed throughout.

Fruits and Fruit Analysis. Ripe fruits of Adria and Sveva cultivars were harvested from plants grown in an experimental open field in the Aso valley area (Italy), frozen at −20 °C, lyophilized by Labconco Freezone 12L model 78670 (Kansas City, MO, USA), and then kept under vacuum condition until milled with a Mixer B-400 (Büchi Labortechnik, Flawil, Switzerland). Samples of strawberry fruit powder were analyzed to determine their nutritional composition; each freeze-dried strawberry sample was assayed in triplicate for each parameter analyzed. The strawberry powder was kept under vacuum, in darkness, at a temperature of 4 °C until meal preparation.

Fruit analysis was carried out as illustrated in detail in our previous publications.[11,13] Briefly, TAC and total phenol (TPH) content of the strawberry fruits were measured spectrophotometrically, whereas vitamin C was quantified by reversed-phase HPLC.[12,13] Anthocyanin extraction and HPLC-MS/MS analysis were performed as previously described.[14] The HPLC-DAD/ESI-MS-driven analysis for the identification and quantification of phenolic compounds was performed through a Hewlett-Packard 1200 series liquid chromatography. The separation was achieved using a 150 mm × 4.6 mm i.d., 5 μm, Aqua C18 column (Phenomenex). The chromatographic conditions were similar to those previously described for anthocyanin determination.[14] Double online detection was carried out by the combined use of a DAD and an API 3200 Qtrap MS equipped with an ESI source and a triple-quadrupole ion trap mass analyzer (Applied Biosystems, Darmstadt, Germany) controlled by Analyst 5.1 software and connected to the HPLC system via the DAD cell outlet. Mass spectrometry data were acquired in the negative mode for all phenolic compounds except anthocyanins, which were acquired in positive mode. Anthocyanins were quantified using the external standards of cyanidin-3-glucoside (Cy-3-glucoside) and pelargonidin-3-glucoside (Pg-3-glucoside) (at 520 nm), flavonols as quercetin-3-*O*-glucoside (at 360 nm), ellagic acid and ellagic acid glycosides as ellagic acid (at 360 nm), and ellagitannins as gallic acid (at 280 nm). Each freeze-dried strawberry sample was assayed in triplicate for each parameter analyzed.

Experimental Design. Twenty-four male Wistar rats (*Rattus norvegicus*), initially weighing 110−130 g, were allocated in groups of three animals per box and maintained on a 12 h light/12 h darkness cycle, with free access to drinking water. Animals were match-fed for 16 weeks at 25 g/day on semisynthetic and isoenergetic diets according to the AIN93 criteria or an AIN93-modified diet supplemented with 10 g/100 g of strawberry lyophilized extract, as shown in Table 1, according to the method of Prior et al.[15] For the formulation of the diet supplemented with strawberry extract, the nutritional composition of the extract was considered according to the USDA database. The remaining energetic nutrients were recalculated to make both diets isocaloric. The rats were randomly assigned to four experimental groups of six animals as follows: two groups fed AIN93 diet, a group fed AIN93 diet supplemented with Adria strawberry powder, and a group fed AIN93 diet supplemented with Sveva strawberry powder. Food intake was indirectly monitored through the weekly body weight control and daily spillage monitoring.

Table 1. Composition of Control Diet and Contribution of Strawberry Daily Dose

	AIN-93M (groups C and C-DOX) (g/kg diet)	AIN-93M + strawberry (groups A-DOX and S-DOX)[a] (g/kg diet)
cornstarch	465.7	465.6
casein	140.0	133.0
dextrinized cornstarch	155.0	155.0
sucrose	100.0	30.0
soybean oil	40.0	34.0
fiber	50.0	33.1
mineral mix	35.0	35.0
vitamin mix	10.0	10.0
L-cystine	1.8	1.8
choline bitartrate	2.5	2.5
strawberry powder[b]	0.0	100.0

[a]Strawberry extract was made from the Adria variety for the A-DOX group and from the Sveva variety for the S-DOX group. [b]100 g of strawberry powder contains 7 g of protein, 6 g of fat, 70 g of carbohydrates, and 27.1 g of fiber. This was considered when in the formulation of the AIN-93M + strawberry diet to make both diets isocaloric.

At the end of the 16 weeks, rats were subjected to two intraperitoneal injections of 10 mg/kg/day DOX or saline solution with a 24 h gap between each injection, according to the method of Quiles et al.[16] Thus, experimental groups were organized as follows: C-group, animals fed AIN93 diet for 16 weeks and subjected to two intraperitoneal injections of saline solution 48 h before death; C-DOX group, animals fed AIN93 diet for 16 weeks and subjected to two intraperitoneal injections of DOX 48 h before death; A-DOX group, animals fed AIN93 freeze-dried Adria strawberry powder diet for 16 weeks and subjected to two intraperitoneal injections of DOX 48 h

Table 2. Fruit Nutritional Contents for Processed Fruit of Adria and Sveva Cultivars[a]

cultivar	TAC (mmol Trolox equiv/kg FW)	TPH (mg GAE/kg FW)	vitamin C (g ascorbic acid/kg FW)
Adria	18.08 ± 0.33b	1749.47 ± 48.31b	0.45 ± 0.02b
Sveva	19.67 ± 0.30a	2594.67 ± 54.59a	0.90 ± 0.08a

[a]Mean values followed by different letters are significantly different. Test SNK, $p \leq 0.05$.

before death; S-DOX group, animals fed AIN93 freeze-dried Sveva strawberry powder diet for 16 weeks and subjected to two intraperitoneal injections of DOX 48 h before death. At the end of the experimental period (24 h after the second intraperitoneal injection), animals were killed by cervical dislocation followed by decapitation at the same time of day to avoid any circadian fluctuation.

After decapitation, blood was collected by decantation onto glass tubes coated with lithium-heparin; isolated plasma and the "buffy coat", enriched in white cells, were removed, diluted 1:1 with RPMI-1640 medium, and layered onto an equivalent volume of Histopaque to obtain peripheral blood lymphocytes. Weights of the heart, liver, and right kidney were taken to evaluate the relative weight of organs (%) calculated as grams per 100 g of body weight. A part of the livers was homogenized on ice at 4 °C in 5 mM Tris-HCl buffer (pH 7.4) containing 1 mM EDTA, in a ratio (10%) of 1 g of wet tissue to 10 mL of buffer, using an IKA-Werk (Janke Kunkel, UE) homogenizer. After centrifugation at 9143 rpm for 20 min at 4 °C, the supernatant was kept; proteins were measured according to the Lowry procedure[17] using BSA as standard and then stored at −80 °C until analysis.

Animals were handled according to the guidelines of the Spanish Society for Laboratory Animals, and the investigation was approved by the Ethical Committees of the Ministry of Science and Technology and the University of Granada.

Evaluation of Rat Plasma Lipophilic Antioxidant Contents. Plasma levels of retinol and α-tocopherol were determined by reversed-phase HPLC as previously described[16] using a Spherisorb S5 ODS1 (Merck, Darmnstadt, Germany) column and ethanol/purified water 97:3 (v/v) as mobile phase. The HPLC system was a Beckman in-line diode array detector, model 168 (Fullerton, CA, USA), connected to a Waters (Milford, MA, USA) 717 plus autosampler. Determinations were performed at 325 nm for retinol and at 292 nm for α-tocopherol. Antioxidant molecules were identified by predetermining the retention times of individual standards and quantified through two calibration curves, daily prepared with known concentrations of retinol (0.1−1.7 μg/mL) and α-tocopherol (1.7−30.2 μg/mL) standards. Each measurement was repeated in duplicate, with two readings for each replicate.

DNA Double-Strand Break (Comet) Analysis. The comet assay was used to measure DNA double-strand breaks in peripheral blood lymphocytes as previously described.[18] Analysis was performed using a CCD camera and Komet 3.0 image analysis program (Kinetic Imaging Ltd., Liverpool, UK). The percent of DNA in the tail (mean of 100 comets per gel) is taken as a measure of DNA break frequency. The comet-like DNA formations were placed into five arbitrary classes (0−4) according to the extent of DNA damage represented by a comet-like "tail". Each comet was assigned a value according to its class, and the overall score for 100 comets ranged from 0 (100% of comets being class 0) to 400 (100% of comets in class 4). Each lymphocyte sample was assayed in duplicate, and 50 comets (i.e.,100 comets/sample) on two different slides were evaluated for every sample in each experiment.

Evaluation of Liver Biomarkers of Oxidative Stress. Protein carbonyl content was determined in liver homogenates by the DNPH method as described by Levine,[19] whereas the GSH content was determined through the DTNB assay as carried out by Ellman.[20] Liver lipid peroxidation was measured by the assay of thiobarbituric acid-reactive substances (TBARS) according to a standardized method,[21] whereas the oxide−xylenol orange (FOX2) method was used to determine hydroperoxides according to a method reported by Jiang.[22] Each measurement was repeated in duplicate, with two readings for each replicate.

Determination of Liver Antioxidant Enzyme Activity. Catalase activity (Cat) was measured following the method described by Aebi,[23] by monitoring H_2O_2 decomposition at 240 nm as a consequence of the catalytic activity of catalase. Superoxide dismutase (SOD) was determined according to the method of Kakkar,[24] on the basis of the inhibition of the formation of NADH−phenazine methosulfate−nitroblue tetrazolium formazan by SOD, measured by spectrophotometry at 540 nm. For glutathione peroxidase (GPx) measurement the method used[25] was based on the ability of GPx to remove H_2O_2 by coupling its reduction to H_2O with oxidation of reduced glutathione. Glutathione reductase (GRx) activity was assayed by using the modified method of Carlberg and Mannervik,[26] based on the capacity of GRx to reduce oxidized glutathione (GSSG) back to reduced glutathione (GSH). Glutathione transferase activity (GST) was determined according to the modified method described by Habig,[27] which measures the conjugation of CDNB with GSH, producing a dinitrophenyl thioether detected at 340 nm spectrophotometrically. Each measurement was repeated in duplicate, with two readings for each replicate.

Evaluation of Reactive Oxygen Species (ROS) in Liver Mitochondria. Liver mitochondria were isolated by differential centrifugation as previously described.[16] Mitochondria protein was measured according to the Lowry procedure[17] using BSA as standard.

ROS production by mitochondrial preparations was measured in fluorescence plate readers.[28,29] The results obtained are expressed as arbitrary fluorescence units (AFU) and are converted into nanomoles of ROS by linear regression method, using the DCF dilutions. Each measurement was repeated in duplicate, with two readings for each replicate.

Liver Mithocondrial Respiratory Efficiency. The oxygen consumption rate (OCR) in liver mitochondria was measured with an XF24 Extracellular Flux Analyzer (Seahorse Bioscience, Billerica MA, USA), as previously described.[27] The mitochondrial assay solution (MAS) consists of 70 mM sucrose, 220 mM mannitol, 10 mM KH_2PO_4, 5 mM $MgCl_2$, 2 mM HEPES, 1 mM EDTA, and 0.2% (w/v) fatty acid-free BSA, pH 7.2 at 37 °C. To minimize variability between wells, mitochondrial suspension were first diluted 10 times in cold MAS buffer to which was added 10 mM pyruvate, 2 mM malate, and 4 μM FCCP to achieve the final concentration of 10 μg of mitochondria in 50 μL of MAS solution. Then, 50 μL of the mitochondria diluted solution was delivered to each well (except for background correction wells) while the plate was on ice. The plate was then transferred to a centrifuge equipped with a swinging bucket microplate adaptor, and spun at 4089 rpm for 20 min at 4 °C. After centrifugation, 450 μL of MAS plus substrate was added to each well. The mitochondria were then placed at 37 °C for 10 min in the XF Prep Station incubator (Seahorse Bioscience). The plate was transferred to the XF24 instrument and the experiment initiated. Changes to the concentrations of dissolved oxygen in the media were measured for each 2 s interval by solid state sensor probes. After determination of the basal mitochondrial respiration, rotenone (2 μM), succinate (10 mM), antimycin A (4 μM), and ascorbate plus 1 mM TMPD (10 mM and 100 μM, respectively) were sequentially added to each well. Data are presented as the average of three replicates per well ± standard error. Results are expressed as OCR in picomoles of consumed oxygen per minute and were adjusted for protein concentration (pmol O_2/min/mg protein).

Statistical Analysis. Results are presented as the mean ± standard error (SE). One-way variance analysis was used to test the differences between genotypes, groups, and treatments. Statistically significant differences ($p \leq 0.05$) were determined with the SNK test. Pearson correlation was evaluated for fruit nutritional parameters and biological

assays. Statistical processing was carried out using STATISTICA software (Statsoft, Tulsa, OK, USA).

RESULTS

Strawberry Fruit Nutritional Composition. Fruit nutritional composition was analyzed on freeze-dried fruit (Table 2). Sveva freeze-dried powder presented a higher TAC value than Adria (19.67 vs 18.08 mmol Trolox equiv/kg FW, respectively) as well as higher phenols and vitamin C levels (Table 2), whereas Adria freeze-dried powder showed higher total anthocyanin contents (Table 3). The use of optimized HPLC conditions coupled to diode array and mass detection allowed detection of seven different anthocyanin pigments in freeze-dried strawberry fruits (Table 3). For both varieties, up to five pigments could be assigned to Pg derivates, and the major peak in the HPLC chromatograms corresponded to Pg-3-glucoside; one pigment could be identified as (epi)afzelechin-(4→8)-Pg 3-glucoside and the last one as a Cy derivative. Individual concentrations of the anthocyanin identified in the freeze-dried cultivars are shown in Table 3 with total concentrations of anthocyanin in samples of approximately 1331.52 ± 3.6 and 893.04 ± 2.3 mg/kg for Adria and Sveva, respectively.

Table 3. Identification and Quantification of Anthocyanin Pigments in Adria and Sveva Freeze-Dried Fruits

peak	identification	Adria cultivar (mg/kg)	Sveva cultivar (mg/kg)
1	(epi)afzelechin-(4→8)Pg-3-glucoside	3.798 ± 0.4	1.754 ± 0.1
2	Cy-3-glucoside	32.232 ± 2.1	25.974 ± 2.2
3	Pg 3,5-diglucoside	0.588 ± 0.0	0 ± 0.0
4	Pg 3-glucoside	1157.376 ± 12.0	790.234 ± 7.0
5	Pg 3-rutinoside	97.848 ± 4.0	26.176 ± 2.0
6	Pg 3-malonylglucoside	32.562 ± 3.0	45.62 ± 2.2
7	Pg 3-acetylglucoside	7.114 ± 4.0	3.284 ± 1.0
	total anthocyanin content	1331.518 ± 4.6	893.042 ± 2.3

With regard to flavonols, two compounds were identified and quantified as quercetin derivates and three as kaempferol derivates in both cultivars (Table 4), with total concentrations of flavonols in sample of about 2.10 ± 0.03 and 7.49 ± 2.0 mg/kg for Adria and Sveva, respectively. Quercetin-3-glucuronide was, in accordance with previous studies,[30] the most abundant flavonol in the two varieties, approximately 1 ± 0.0 and 3.5 ± 0.7 mg/kg in Adria and Sveva, respectively.

Table 4. Identification and Quantification of Total Flavonols, Total Ellagic Acid Conjugates, and Ellagitanins in Adria and Sveva Freeze-Dried Fruits

identification	Adria cultivar (mg/kg)	Sveva cultivar (mg/kg)
flavonols		
quercetin-3-hexose	0.48 ± 0.0	1.2 ± 0.3
quercetin-3-glucuronide	1.005 ± 0.0	3.5 ± 0.7
kaempferol-3-glucoside	0.21 ± 0.0	1.2 ± 0.3
kaempferol-3-glucuronide	0.413 ± 0.0	0.89 ± 0.3
kaempferol-3-malonylglucoside		0.74 ± 0.2
total	2.10 ± 0.03	7.49 ± 2.0
ellagic acid conjugates		
ellagic acid pentoside	0.55 ± 0.02	0.96 ± 0.1
ellagic acid deoxyhexoside	1.8 ± 0.3	6.9 ± 0.03
ellagic acid + ellagic acetyl rhamnoside	4.1 ± 0.5	10.9 ± 1.8
total	6.5 ± 0.1	18.7 ± 0.9
ellagitannins		
agrimoniin	21.4 ± 3.3	39.0 ± 3.0

An ellagic acid pentoside, an ellagic acid deoxyhexoside, and ellagic acid/ellagic acetyl rhamnoside were also detected and quantified in both strawberries (Table 4) with a total of ellagic acid conjugates of about 6.5 ± 0.1 and 18.7 ± 0.9 mg/kg in Adria and Sveva varieties, respectively. Finally, as previously reported,[31] a major ellagitannin pigment was identified as agrimoniin, with concentrations of 21.4 ± 3.3 mg/kg in Adria and 39.0 ± 3.0 mg/kg in Sveva (Table 4). Although proanthocyanidins have been previously identified and quantified in strawberries,[30] in our samples several minor peaks corresponding to these polyphenols were detected but not quantified because of their low concentration.

Hematological and Clinical Analysis. Data on body weight and organ ratios showed slight differences among rat groups but no significant variations were found, thus indicating that the strawberry diet did not interfere with animal development (Table 5) while sacrifice after doxorubicin injection occurred before any possible modification could be identified.

Evaluation of Rat Plasma Retinol and α-Tocopherol Content. Concerning plasma levels of retinol (Figure 1), the highest value were found in C group while the lowest in C-DOX group; freeze-dried strawberry supplementation buffered the decrease of retinol in A-DOX group and in S-DOX group ($p < 0.05$) compared to C-DOX group. Plasma α-tocopherol did not show differences among all groups, although higher values were obtained in rats fed with freeze-dried strawberries, both Adria and Sveva (Figure 1).

DNA Double-Strand Break Assays. The comet assay for the evaluation of DNA damage was performed on peripheral blood lymphocytes collected before and after DOX injection to evaluate DNA damage due to endogenous oxidative DOX-mediated stress and the efficacy of long-term freeze-dried strawberry diet in preventing such oxidative-induced damage.

Before the DOX injection, all groups showed similar base values of DNA damage, whereas after the DOX injection an increase of DNA damage was observed in all groups, but with different rates: indeed, as shown in Figure 2, comparing the variation of DNA damage values detected before and after the DOX injection, the lower increase of DNA damage was found in the C group, as expected for rats not submitted to DOX injection, whereas greater variation was observed in C-DOX and S-DOX groups. Freeze-dried Adria supplementation buffered the increase in DNA damage, as demonstrated by the lower increase ($p < 0.05$) in the A-DOX group compared to the C-DOX group.

Evaluation of Liver Biomarkers of Oxidative Stress. Table 6 shows the changes in liver biomarkers of oxidative stress. Treatment with DOX resulted in a significant increase in protein carbonyl levels (3.2-fold, $p < 0.05$) as well as a dramatic decrease in GSH levels (1.7-fold, $p < 0.05$) in the C-DOX group compared to the C group, whereas the supplementation with freeze-dried strawberry restored the condition of the C group in A-DOX and S-DOX groups, especially for protein carbonyl levels. Similar trends were observed in markers of lipid oxidation. A significant increase in TBARS concentration was in fact observed in the liver (2.0-fold, $p < 0.05$) of C-DOX rats, whereas in A-DOX and S-DOX groups, treatment with freeze-dried strawberry powders resulted in values similar to those of

Table 5. Body Weight and Organ Body Ratio of the Rat Groups Fed the Four Diets[a]

group[b]	body wt (g)	heart ratio (% of body wt)	liver ratio (% of body wt)	Rx kidney ratio
C	401.4 ± 19.9ns	0.29 ± 0.02ns	2.51 ± 0.15ns	0.31 ± 0.02ns
C-DOX	397.6 ± 15.8ns	0.26 ± 0.01ns	2.76 ± 0.05ns	0.31 ± 0.02ns
A-DOX	421.4 ± 7.1ns	0.26 ± 0.01ns	2.58 ± 0.07ns	0.27 ± 0.01ns
S-DOX	424.4 ± 15.1ns	0.27 ± 0.02ns	2.58 ± 0.05ns	0.27 ± 0.01ns

[a]Values are expressed as group mean values and SE; mean values followed by different letters are significantly different. Test SNK $p \leq 0.05$. ns, nonsignificant. [b]C group, AIN93 diet; C-DOX group, AIN93 diet + DOX; A-DOX group, AIN93 diet + 10% Adria strawberry fruit + DOX; S-DOX group, AIN93 diet + 10% Sveva strawberry fruit + DOX.

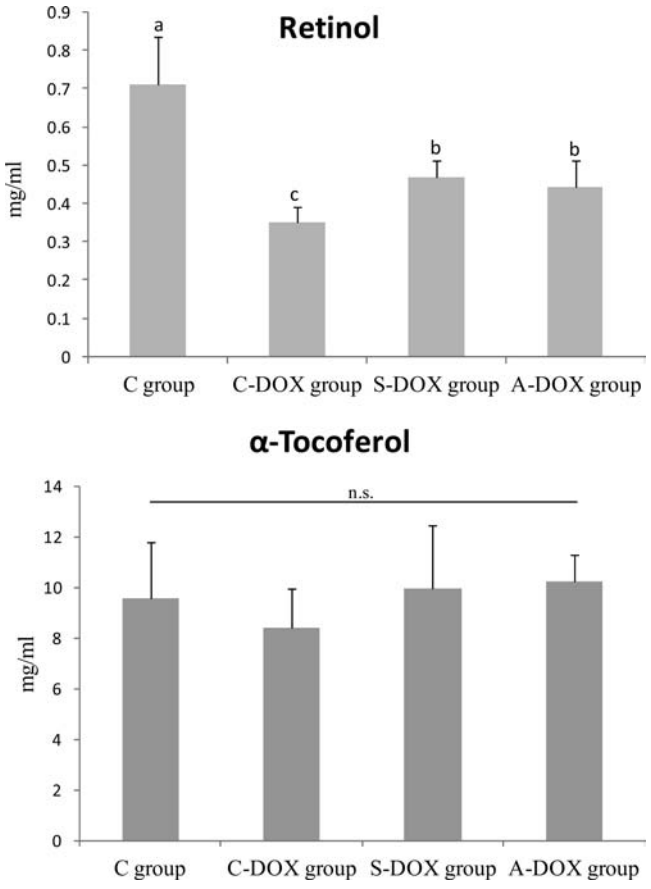

Figure 1. Effect of strawberry and DOX treatment on the plasma content of retinol and α-tocopherol. Results are expressed as the mean ± SE. Columns labeled with different letters are significantly different ($p < 0.05$). C group, AIN93 diet; C-DOX group, AIN93 diet + DOX; A-DOX group, AIN93 diet + 10% Adria strawberry fruit + DOX; S-DOX group, AIN93 diet + 10% Sveva strawberry fruit + DOX.

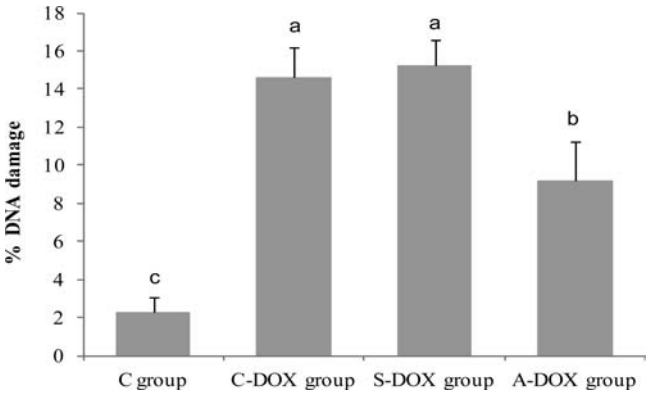

Figure 2. Percentage of DNA damage detected before and after DOX injection. Columns labeled with different letters are significantly different ($p < 0.05$). C group, AIN93 diet; C-DOX group, AIN93 diet + DOX; A-DOX group, AIN93 diet + 10% Adria strawberry fruit + DOX; S-DOX group, AIN93 diet + 10% Sveva strawberry fruit + DOX.

the C group. In the C-DOX group a significant increase (1.8-fold, $p < 0.05$) was outlined also for hydroperoxide levels, whereas supplementation with freeze-dried strawberry restored the condition of the C group only in the A-DOX group but not in the S-DOX group.

With regard to the activity of the antioxidant enzymes, a positive effect of freeze-dried strawberry-enriched diet on liver antioxidant enzymes was found (Table 7). GPx, GR, and GST activities were significantly decreased ($p < 0.05$) in the C-DOX group compared to the C group, whereas after xx months, freeze-dried strawberry supplementation significantly increased ($p < 0.05$) GPx, GR, and GST levels in the A-DOX and S-DOX groups compared to those of the C-DOX group, leading to values similar to those of control group. The same trends were found also for catalase and SOD activities (Table 7): they were significantly reduced ($p < 0.05$) in the C-DOX group when compared with control groups. Freeze-dried strawberry supplementation significantly ($p < 0.05$) increased the enzyme activities with respect to the C-DOX group, with values close to those of the C group, especially for the A-DOX group.

Liver Mitochondria Respiration Efficiency and ROS Contents. To examine the protection of strawberries on mitochondrial function against DOX-induced stress, we measured the OCR of isolated rat liver mitochondria. This experiment began assessing mitochondrial basal respiration in an uncoupled state (pyruvate, malate, and FCCP). After the measurement of basal OCR, the following compounds were sequentially added at four different fixed times: rotenone, succinate, antimycin A, and ascorbate plus TMPD. Injection of rotenone inhibited complex I and, as expected, respiration fell to a minimum in all groups (Figure 3a). Injection of succinate allowed the mitochondria to respire via complex II, bypassing complex I, so that OCR values increased. Indeed, A-DOX and S-DOX groups reached the maximal respiration rate (78.53 ± 0.9 and 81.50 ± 1.0 pmol O_2/min/protein, respectively) with a significant increase ($p < 0.05$) compared to the C group, whereas for the C-DOX group a significant decrease was found (40.39 ± 1.1 pmol O_2/min/protein). Electron flow was then inhibited at complex III level by the addition of antimycin A and, in fact, respiration stopped again as expected in all groups. Finally, addition of ascorbate and TMPD, which act as electron donors to complex IV, elicited a moderate increase in the OCR, especially in the A-DOX and S-DOX groups, although without any significant difference from the C-group except for C-DOX.

To assess if improved mitochondrial functionality observed in A-DOX and S-DOX groups could be due to lower mitochondrial ROS levels, we analyzed the ROS concentration

Table 6. Liver Changes in Protein and Lipid Markers of Oxidative Stress[a]

(b) Average changes in mitochondrial OCR after succinate injection. Data are presented as means ± SEM (pmol/min). Columns labeled with different letters are significantly different ($p < 0.05$). C group, AIN93 diet; C-DOX group, AIN93 diet + DOX; A-DOX group, AIN93 diet + 10% Adria strawberry fruit + DOX; S-DOX group, AIN93 diet + 10% Sveva strawberry fruit + DOX.

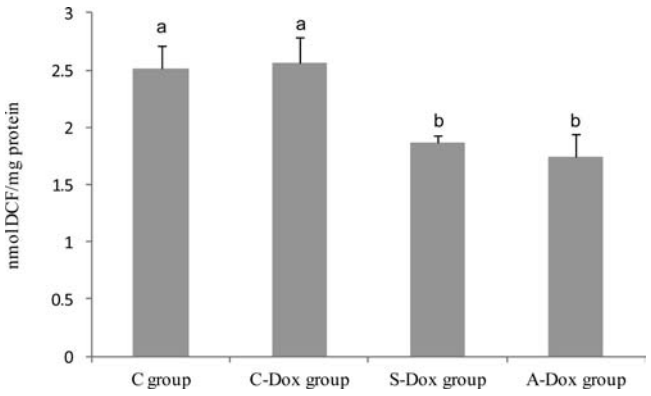

Figure 4. Effect of strawberry and DOX treatment on mitochondrial ROS concentration. Results are expressed as the mean ± SE. Columns labeled with different letters are significantly different ($p < 0.05$). C group, AIN93 diet; C-DOX group, AIN93 diet + DOX; A-DOX group, AIN93 diet + 10% Adria strawberry fruit + DOX; S-DOX group, AIN93 diet + 10% Sveva strawberry fruit + DOX.

in liver mitochondria (Figure 4). We found the highest values of ROS in mitochondria of the C-DOX group, although not significantly different from the C group (2.56 ± 0.2 and 2.50 ± 0.2 nmol DCF/mg protein, respectively), whereas the lowest values were found for groups fed Adria and Sveva fruits (1.74 ± 0.2 and 1.86 ± 0.1 nmol DCF/mg protein, respectively), highlighting that the lower the ROS mitochondrial levels are, the higher is the mitochondrial respiration.

DISCUSSION

This study evaluates the effect of a long-term diet supplemented with freeze-dried strawberry powder against DOX-induced oxidative stress in rats. AIN93 diet was supplemented with diverse freeze-dried strawberry powders of two cultivars with marked differences regarding fruit phenol and anthocyanin contents. In fact, fruits of Sveva cultivar possessed higher contents of phenols, vitamin C, and TAC than the fruits of Adria cultivar (Table 2), which instead possessed higher anthocyanin contents but lower vitamin C and TAC (Tables 2 and 3). The strawberry fruit quantity was related to a human diet, which considers a calorie intake of 2000 kcal/day: this means that it was equivalent to a substitution of 200 calories with strawberry fruit, calculated to correspond approximately to a quantity of 60 g of strawberry freeze-dried powder or, if expressed in anthocyanidins present in the

powder, 80 mg per day for the Adria-fed group and 54 mg per day for the Sveva-fed one (calculated on the results for nutritional compounds of freeze-dried strawberry of cv. Adria and Sveva in Table 3).

First, initial and final body weights of the rats were measured. There were no differences in final body weight (p = 0.38) between the treatment groups. It is known that increased liver weight is one symptom of toxicity; however, there were no statistically significant differences in mean liver weight per 100 g of body weight between treatment groups (p = 0.38), suggesting that strawberry supplementation did not affect the liver, as previously reported.[32] For plasma analysis, we observed a higher concentration of retinol in A-DOX and S-DOX groups than in the C-DOX group, suggesting that strawberry supplementation could increase the levels of this vitamin and could contribute to strengthen the antioxidant status of rat plasma. However, we did not observe any difference in α-tocopherol concentration among groups, but this result is consistent with the very low concentration of this vitamin in strawberries with respect to retinol.[5] Retinol and α-tocopherol have a high antioxidant capacity and play a key biological role, especially in protecting cells and tissues from oxidative damage, as well as membrane lipids and lipoproteins from peroxidation.[33] Some studies found that retinol significantly reduces lipid oxidation, providing good results in the heart, brain membranes, liver microsomes, and kidney,[32] and that it also possesses a protective dose-dependent effect against the chromosomal aberrations induced by doxorubicin in rat bone marrow cells.[34] Similarly, other studies showed that intraperitoneal vitamin E (100 mg/kg/day) for 8 days inhibits the general toxic and hepatotoxic effects of DOX and hepatotoxicity in rats, by decreasing malondialdehyde, glutathione peroxidase, and catalase activities.[35]

The freeze-dried strawberry supplementation seems to protect DNA from DOX-induced stress. Indeed, the evaluation of delta values of percentage damage before and after DOX injection showed that rats fed freeze-dried Adria cultivar, characterized by high anthocyanin contents, presented lower values of DNA damage among all other rat groups subjected to DOX injection, suggesting that a diet rich in anthocyanin is able to protect DNA against in vivo induced oxidative stress. In recent years many in vitro and in vivo studies have focused on the capacity of anthocyanins in protecting against DNA damage. For example, blueberry anthocyanin extracts were found to decrease ROS and DNA damage by tail moment of comet assay as well as to reduce gene and protein expression of p53, phospho-p53, and p21 in UV-irradiated HepG2 cells.[36] Similarly, an anthocyanin-rich strawberry extract was able to increase cell viability and decrease DNA damage in fibroblasts exposed to UV-A irradiation,[37] whereas cyanidin-3-glucoside (C3G) was found to prevent DNA fragmentation and procaspase-3 cleavage in UV-induced skin damage, very likely by blocking cellular oxidative stress-related events, in particular inflammation and apoptosis.[38] However, several in vivo studies have documented the presence of conflicting evidence. In studies with cranberry juice or black currant juice, no increase in protection from oxidative DNA damage was found,[39,40] nor was any damage found in a study involving women consuming a polyphenol-rich blueberry.[41] On the contrary, in another intervention study, consumption of a high-polyphenol juice determined a decrease in oxidative DNA damage,[42] whereas the intake of a mixture of blueberry and apple juices reduced the levels of H_2O_2-induced DNA damage after 4 weeks of supplementation in healthy female volunteers.[43] Some authors attribute this protection against DNA damage to different mechanisms that could involve pathways such as DNA repair and alkylation or formation of anthocyanin−DNA complexes and antioxidant enzymes.[44] Moreover, it can be considered that an anthocyanin-rich diet[45] indirectly acts on DNA protection through up-regulation expression of different genes involved in detoxification molecules,[46] even if this aspect seems to depend on the time of exposure to dietary components as mentioned previously.[47]

In the present work, the antioxidant capacity provided by the strawberry diet resulted also in enhanced protection of liver components such as proteins and lipids against oxidative stress. Liver protein carbonyls and TBARS/hydroperoxide levels were significantly increased (p < 0.05) by DOX injection in the C-DOX group, due to the ROS-induced production, demonstrating that the natural antioxidant defense mechanism to scavenge excessive free radicals has been compromised. The freeze-dried strawberry diet prevented this increase in A-DOX and S-DOX rats, because they showed values similar to those of the C group. The ability of strawberries to modulate the activity of hepatic antioxidant enzymes has been demonstrated in our study, too. We found that DOX administration resulted in a significant decrease in GSH concentration and in the activities of antioxidant enzymes GR, GPx, GST, SOD, and catalase in the C-DOX group compared to the C-group. The effects of DOX were partially reduced by freeze-dried strawberry diet, suggesting that the increase of GSH and endogenous antioxidant enzymes might be one of the important mechanisms of the strawberry against oxidative stress damage, as previously reported.[48]

Mitochondria are key targets in DOX toxicity, especially their inner membrane.[1] DOX can be metabolized into a lipophilic aglycone able to diffuse throughout the mitochondrial membrane, accumulating within it; this aglycone is the starting point for several reactions that release electrons, producing ROS and disturbing the functional integrity of membranes and of the respiratory chain.[1] In the present study, the treatment of rats with two doses of 10 mg/kg doxorubicin showed negative effects in liver mitochondria: in fact, the drug increased the total mitochondrial ROS concentration in C-DOX rats, whereas in A-DOX and S-DOX rats, supplementation with strawberry resulted in a decrease of ROS levels induced by DOX injection. To assess if the decrease of ROS, due to freeze-dried strawberry supplementation, could affect mitochondrial functionality, we performed the electron flow experiment to follow and interrogate each complex of the electron transport chain. As expected, respiration stopped with all of the inhibitor (rotenone and antimycin A) injection in all groups, whereas it rose with the injection of the electron donors, especially with succinate (Figure 3b) in S-DOX and A-DOX, demonstrating an improved functionality of the electron transport chain in rats fed strawberry. Interestingly, the extent of the increase was more relevant in the same groups that also presented lower ROS levels.

These results could be explained by the possible protection mechanisms of the strawberry: first of all, the well-known antioxidant capacity of the fruits to counteract, both in vitro and in vivo, oxidative stress[33,48] and then the interaction between polyphenols and membranes.[5] Indeed, from the results obtained in studies conducted to assess the potential of polyphenols to access the inner mitochondrial membrane,[49] it seems that mitochondria are able to absorb significant

concentrations of polyphenols. Once compartmentalized into the cell membranes, these substances seem to enhance membrane integrity and to protect the functional integrity of the mitochondrial respiratory chain.[50] Another possible mechanism of strawberries is the activation of the endogenous defense systems, mainly by the modulation of the expression of some antioxidant enzymes. Even if literature data report controversial results that can differ among the several types of cells or pathological conditions studied, it is reasonable to hypothesize that coordination of the endogenous and exogenous antioxidant response is achieved, at least in part, through antioxidant responsive elements (AREs), which are found in the promoters of many of the genes that are inducible by oxidative and chemical stress. For instance, an increasing number of studies indicate that the dietary polyphenols are able to stimulate the transcription of gene coding for antioxidant and phase II detoxifying enzymes, through selective activation of AREs sequences localized in specific gene promoters.[45]

In conclusion, our in vivo feeding trial on rats submitted to long-term diet supplemented with freeze-dried strawberry powders confirms the potential health benefits of strawberry fruit against oxidative stress; in fact, a reduction of physiological oxidative damage in rats was observed, and this protective effect was strictly linked to the bioactive composition of strawberry fruit. More studies have evidenced that the genotype plays a fundamental role in the phytochemical composition of strawberry fruit, and this variability among fruit genotype is also reflected in the bioactive action developed against oxidative stress.[11−13] For this reason it is important to characterize the bioactive composition of strawberries to better understand which compounds are able to improve human health benefits.

Additional studies are necessary to characterize the bioactive compounds that play a fundamental role against oxidative stress; these efforts could possibly elucidate by which mechanisms strawberry fruit and their phytochemicals (anthocyanins and polyphenols) can improve antioxidant defenses and would add to the understanding of their potential role in protecting against DNA damage, both in vitro and in vivo.

Table 1. Families, Corresponding Parents, and Number of Offspring Evaluated for Fruit Sensorial and Nutritional Quality

family	progenitors			no. of selections	type of crossing	
	mother		father			
AN07,003	AN94,414,52	×	Romina	11	F2 backcross	BC2
AN07,216	AN00,239,55	×	Romina	9	F3 backcross	BC3

Total antioxidant capacity (TAC) is a very common parameter for the evaluation of antioxidant activity strictly related to the amount of bioactive compounds in strawberry. TAC provides a measure of the radical scavenger activity of the fruit and is therefore a quality parameter related to the healthfulness of the fruit. The antioxidant capacity of strawberries has been shown to be due to the activity of high amounts of antioxidant compounds such as polyphenols and vitamin C[5]. As demonstrated for fruit sensorial traits, the composition of antioxidant compounds can vary considerably among strawberry cultivars,[25−29] so breeding and/or biotechnology have potential for obtaining better tasting and more nutritious fruits.[30−32] The breeding process can be successful if the variability and heritability of bioactive compounds is assured for the progenies derived from parental fruits. The biotechnological approach is a methodology that is able to provide a genetic improvement through modification of specific biosynthetic pathways.[33] The application of such technology is still mostly limited to functional studies on specific pathways,[34] whereas the commercial exploitation of new products is highly limited by public concerns and biosafety rules now standing for the commercial release of new genetically modified products. In any case, a deep knowledge of both the cultivated and wild genetic resources, which may be utilized for genetic and genomic studies, is an essential prerequisite for obtaining new cultivars of high interest for both the fresh market and the processing industry.[35] Recently, the possibility to improve the fruit content of such phytochemicals by traditional breeding programs has been demonstrated[36] and, to this end, the detailed characterization of the genetic resources to be used in the cross combination was an important component. The inclusion in breeding programs of wild species with a genetic background able to produce progeny that have increased health-related phytochemicals is also important.[37] Furthermore, if the nutritional quality of strawberry is enhanced in association with favorable sensorial parameters (such as titratable acidity, sugar content, fruit firmness, and aroma), the consumption of fruit by consumers will be encouraged, leading to strawberries having a positive effect on health. Consequently, the biochemical characterization and the biomedical health validation of new products resulting from new genetic material, characterized by increased content of health-related phytochemicals, is an important issue. With this aim, high competencies in compositional analyses are needed to give a complete profile of the health-related phytochemicals present in the new type of fruit. Such an approach will complement a description of the potential health benefits of the fruit.

The aim of this work was to evaluate the fruit sensorial and nutritional quality of 20 selections derived from a strawberry interspecific backcross breeding program. All selections were evaluated for their fruit sensorial (color, firmness, total soluble sugars, and acidity) and nutritional parameters (phenol and anthocyanin contents and total antioxidant capacity) by quantitative spectrometry analysis. Data on nutritional parameters allowed the identification of selections that produce fruit with higher contents of phytochemicals combined with interesting sensorial characteristics, together with agronomic performances as required at a commercial level. The phytochemical composition of the genotypes with the most potential, and of their parents used in the intraspecific (cv. 'Romina') and interspecific backcrossing (BC) (AN94,414,52 and AN00,239,55), together with the important commercial variety 'Elsanta', were further characterized by HPLC-PDA-MS analyses. The prevalent type of phytochemicals relevant to the improvement of fruit nutritional value was determined.

MATERIALS AND METHODS

Plant Material. New selections originated from an interspecific backcross program having as common parents the cv. 'Romina', the F1 selection AN94,414,52 from the interspecific cross of *Fragaria* × *ananassa* (Don) × *Fragaria virginiana glauca* (FVG), and AN00,239,55, a BC2 selection produced by backcrossing the F1 selection AN94,414,52 with 91,143,5 (*F.* × *ananassa* advanced selection) (Table 1) were planted in 2011 in nonfumigated soil at the P. Rosati University experimental farm, Agugliano (Ancona, Italy), and grown in open-field conditions using the plastic hill culture production system. Selections were planted as frigo plants in single plots of six plants each, cultivated with the standard Integrated Pest Management system, then harvested and evaluated in May 2012. In the same field, under the same conditions, the corresponding parents of each cross combination were also grown. Fruit samples of fully red berries were harvested at the second, third, and fourth main pickings. In the evaluation, plant productivity (fruit weight and commercial plant production), fruit sensorial (fruit firmness, solid soluble content, titratable acidity, and color), and nutritional parameters (fruit TAC, phenol content, and anthocyanin content) were taken into account. Fruit sensorial and nutritional quality was determined on fresh (color and firmness) and on frozen (total soluble sugars and acidity) samples. HPLC-PDA-MS was performed on freeze-dried fruit and included the commercial variety 'Elsanta', shipped by express mail to James Hutton Institute in the United Kingdom.

Chemicals. Methanol 99% ACS-ISO for analysis and bromothimol blue were purchased from Carlo Erba Reagenti (Milano, Italy). Acetonitrile, formic acid, double-distilled water, Folin−Ciocalteu reagent, sodium carbonate anhydrous, potassium chloride, sodium acetate, chloridric acid, glacial acetic acid, dihydrogen potassium phosphate, dipotassium hydrogen phosphate, 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS$^{\bullet+}$), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), potassium persulfate, 3,4,5-trihydroxybenzoic acid (gallic acid), and sodium hydroxide were purchased from Sigma-Aldrich (Sigma-Aldrich s.r.l., Milano, Italy). Pelargonidin-3-*O*-glucoside chloride and kaempferol-3-glucoside were purchased from Extrasynthese (Genay, France).

Strawberry Production Parameters. In 2012, strawberry plant production was evaluated in the single plot of all selections by measuring commercial production, total weight (g) of ripe fruit with commercial diameter ($\varnothing \leq 0.22$ mm) and undamaged, and fruit weight, average weight (g), of 20 commercial fruits from each harvest.

Strawberry Sensorial Parameters. Fruit sensorial quality of selections and parents was analyzed on the harvesting day, at each of the second, third, and fourth harvests, on 10 commercial fruits by measuring the following parameters: (a) soluble solids (SS), determined using a hand-held refractometer (ATAGO), results expressed as °Brix; (b) titratable acidity (TA), determined from 10 mL of juice diluted with distilled water (1:2 v/v) and titrated with 0.1 N NaOH solution, to pH 8.2, and expressed as milliequivalents

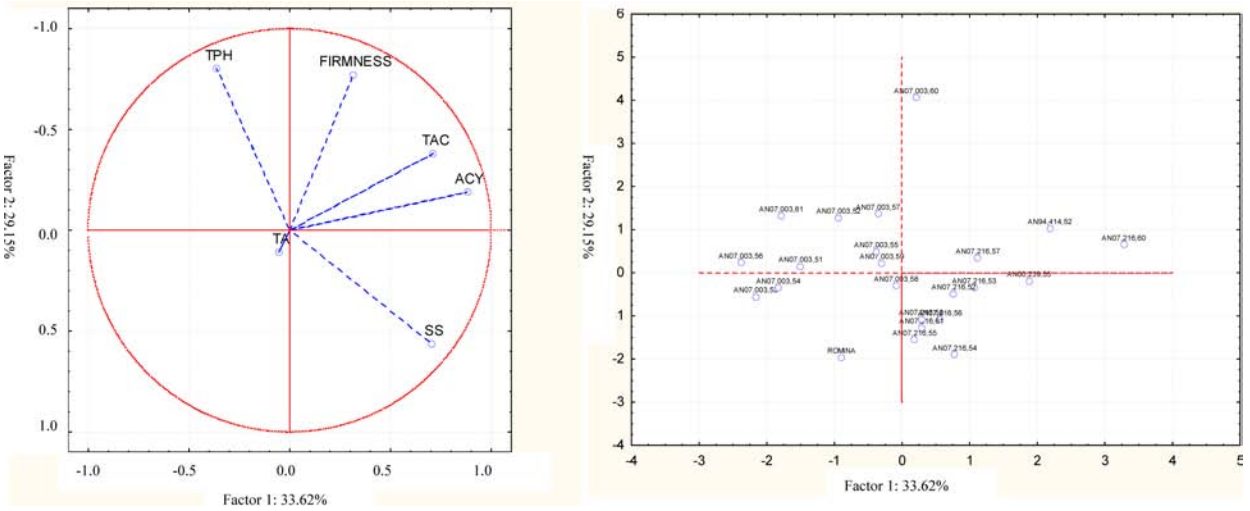

Figure 1. Principal component analysis: (A, left) variable vector distributions; (B, right) case distributions. Biplot of qualitative (SS, TA, and firmness) and nutritional parameters (TAC, TPH, and ACY) of the selections and the corresponding parents of the interspecies cross populations. Factors 1 and 2 explain 62.77% of the data variation.

(mEQ) of NaOH per 100 g of fresh weight (FW); (c) fruit firmness, measured by a penetrometer 327 (Effegì, Ravenna, Italy), results expressed as grams; (d) fruit color, determined by a Minolta Chromameter CR 400, for two faces of 10 ripe, undamaged, and uniform fruits of each harvest. The instruments measured three parameters L^* (luminescence), a^* (red tone), and b^* (yellow tone). Data were elaborated and expressed as chroma index and hue angle. A high chroma index indicated pale fruit and a low chroma index represented dark fruit, whereas a high hue angle indicated yellow fruit and a low hue angle denoted red fruit.

Strawberry Nutritional Parameters. *Fruit Extraction Method.* As described by Diamanti,[37] briefly, from a pool of fruit for each genotype, harvested in 2012 and stored at −20 °C, 10 ripe-commercial fruits were sampled and from each fruit two opposite slices were cut and milled into small pieces. Ten grams of this blend was weighed and placed in a tube for extraction with methanol (1:4, fruit/methanol, w/w), including two subsequent steps. The first step consisted of homogenization, with an Ultraturrax T25 homogenizer, of fruit blend in 20 mL of methanol (Janke and Kunkel, IKA Labortechnik, Staufen, Denmark). The homogenized suspension was continuously agitated for 30 min in the dark. The suspension was centrifuged at 4500*g* for 10 min (Centrifuge Rotofix32, Hettich Zentrifugen, Tuttlingen, Denmark), and 3 × 1 mL of the supernatant was collected and stored in three amber vials at −20 °C. For a more exhaustive extraction, the pellet of the fruit was extracted a second time by adding another 20 mL of methanol and repeating the previously described procedure. The supernatant was collected and added to the previous ones, and 3 × 1 mL per sample was stored in amber vials at −20 °C.

Total Antioxidant Capacity (TAC). Fruit extract of each genotype was used to analyze TAC by using the ABTS assay, according to a previously validated procedure.[38,39] ABTS, a chromogen and colorless substance, is changed into its colored monocationic radical form ($ABTS^{\bullet+}$) by an oxidative agent. Addition of antioxidants reduces $ABTS^{\bullet+}$ into its colorless form. The extent of decolorization as a percentage of inhibition of $ABTS^{\bullet+}$ is determined as a function of concentration and calculated relative to the reactivity of Trolox, a water-soluble vitamin E analogue. The experiment was performed in triplicate, and antioxidant activity was expressed as millimoles of Trolox equivalent (TE) per kilogram of fresh pulp weight ± standard error (SE). The calibration was calculated as the linear regression from the dose response Trolox standard.

Total Phenol Content (TPH). Fruit TPH was evaluated on fruit extracts by the Folin−Ciocalteu reagent method[40] using gallic acid as standard for the calibration curve. Briefly, a test tube (glass) was filled with 7.0 mL of water, then 1 mL of the diluted sample (1:20) was added, followed by the addition of 500 μL of Folin−Ciocalteu reagent, and the mixture was vortexed. After 3 min, 1.5 mL of sodium carbonate (0.53 mol/L) was added, and the tube was mixed again and then stored in the dark for 60 min. The absorbance of the sample was measured at 760 nm after exactly 60 min. Results were calculated and expressed as milligrams of gallic acid per kilogram of fresh fruit ± SE on three replications, by using a standard curve with a range of values of standards of 10−50 mg of gallic acid (GA)/L.

Anthocyanin Content (ACY). Fruit total ACY was measured on fruit extracts by using the pH differential shift method.[41] The assay is based on the anthocyanins' property to change intensity of hue depending on pH shifting. The samples were diluted to a 1:10 ratio with potassium chloride (pH 1.00) and with sodium acetate (pH 4.50), and then the corresponding maximum absorbance for both solutions was measured, respectively, at λ = 500 nm and λ = 700 nm. Analyses were performed in triplicate, and results were expressed as milligrams of pelargonidin-3-glucoside (the most representative anthocyanin compound in strawberry) per kilogram of fresh weight (mg of Pel-3-Glu/kg FW) ± SE.

Analysis of Polyphenolics by HPLC-PDA-MS. *Sample Preparation.* Strawberry samples were frozen at harvest and then freeze-dried by using a Freezone (Labconco) freeze-drying system. Samples were stored in a −20 °C freezer until analysis. Prior to use, double-distilled water (2 mL) and 0.5% formic acid in acetonitrile (2 mL) were added to the sample, (500 mg) in a 15 mL polypropylene centrifuge tube. Samples were shaken on an orbital shaker for 30 min and centrifuged at 4000 rpm for 5 min, and the supernatant was transferred to another 15 mL centrifuge tube. The extraction was repeated with water (1 mL) and 0.5% formic acid in acetonitrile (1 mL) and the supernatant was added to the first one. After centrifugation at 13200 rpm for 5 min, 0.5 mL aliquots were transferred to microfuge tubes and stored in a −20 °C freezer. The solvent was removed from the sample at 45 °C using a Speed Vac, completely dried, using a freeze-drier, and stored in a −20 °C freezer until analysis. Prior to analysis, the sample was dissolved in 475 μL of 0.5% formic acid in water/acetonitrile (70:30, v/v), 25 μL of morin internal standard (1 mg mL^{-1} in methanol) was added, and, following vortexing and centrifugation at 13200 rpm for 3 min, 0.4 mL was transferred to a 0.45 μm filter vial. The sample was injected via an autosampler at 6 °C onto a HPLC column Synergi 4 μ Hydro-RP 80A (150 mm × 2.0 mm; 4 μm reversed-phase HPLC column, Phenomenex) at 30 °C, linked to a PDA system (Thermo Accela) and then an electrospray ionization ion trap mass/Fourier transform spectrometer (Thermo LTQ Orbitrap XL). The mobile phase was a gradient with (A) 0.1% (v/v) aqueous formic acid and (B) 0.1% (v/v) formic acid in acetonitrile/water (50:50, v/v), the flow rate was 300 μL min^{-1}, and the gradient was as follows: 0−4 min, 95% A; 4−28 min,

50% A; 28−32 min, 0% A; 32−34 min, 0% A; 34−36 min, 95% A; 36−45 min, 95% A. The PDA detector range was 200−600 nm, and channels were (A) 280 nm (general polyphenols), (B) 365 nm (flavonols), and (C) 520 nm (anthocyanins). Mass spectrometer mass range was m/z 120−2000 with alternative full scan MS and MS/MS (data-dependent scan). The sample was run twice, in positive ion and negative ion modes. Identification of polyphenols was based on PDA characteristics and mass spectra including accurate MS and MS/MS data, and comparison to the PDA, MS, and elution times of authentic standards when available. Quantification of flavonols and anthocyanins was based on the area of $[M - 1]^-$ and $[M + 1]^+$ ions, respectively, using calibration curves generated for standards of kaempferol-3-*O*-glucoside and pelargonidin-3-*O*-glucoside, respectively. Relative levels of ellagitannins and flavan-3-ols were based on areas of $[M - 1]^-$ ions, assuming that different compounds within each class had similar response factors.

Experimental Trial and Statistical Analysis. Fruit sensorial (SS, TA, fruit firmness, fruit color) and nutritional (TAC, TPH, ACY) parameters were analyzed in triplicate for each selection and for their corresponding parents. All of these data were subjected to the two-way nested analysis, the MANOVA test. The analysis of variance was performed for genotype as random effects. The differences were calculated according to the SNK test and were considered significant at $p \leq 0.05$.

To evaluate also the association among the fruit qualitative and nutritional parameters of the samples and their respective parents, PCA was used. As described by Diamanti et al.,[37] factor loading values ≥0.7 were used to identify the most important variables and observations in each dimension (PC). Variables and observations (Figure 1) that are closest to each other in the same geometric plane of the biplot are considered as interrelated, and therefore they are distant from those to which they are negatively related or not related. The greater the distance of a vector from the origin of the axis, the higher the correlation of the variable with the PC represented in that dimension.

All analyses were performed using STATISTICA software (Statsoft Inc., Tulsa, OK, USA).

RESULTS AND DISCUSSION

Commercial Production and Fruit Weight. All 20 selections had a low commercial production and fruit weight due to their backcross origin (BC2 and BC3). Selections of both backcrosses (AN07,003 and AN07,216 families) showed intermediate commercial production values with respect to their parents; values were higher than those of their wild parents AN94,414,52-F1 and AN00,239,55-BC1 (selections of AN07,003 family produced 422 g/plants against 92 g/plants for their AN94,414,52 parent; selections of AN07,216 family produced 484 g/plants against 188 g/plant for their AN00,239,55 parent), but lower than those of 'Romina', the only commercial variety. Furthermore, fruit weight values were lower for all of the selections and the wild parents (15.2 g for BC3 selections AN07,216, 11.2 g for their wild parent AN00,239,55, 11.2 g for BC2 selections of AN07,003 family, and 11.5 g for their wild parent AN94,414,52), compared with 'Romina' (21 g).

Strawberry Sensorial Parameters. Fruit of selections AN07,003,60 and AN07,003,59 had very high soluble solids values (Table 2); in particular, they were significantly higher than the parent 'Romina'. The lowest values of soluble solids were detected in AN07,216,53, AN07,216,56 and 'Romina', and in general fruit of all selections of the AN07,216 family presented lower values than AN07,003 selections. The parent AN00,239,55 had the highest value of titratable acidity, and that of the parent AN94,414,52 was also high, both having higher values than 'Romina', which possessed a medium value (Table 2). The BC3 selections AN07,216,60 and AN07,216,55 also had high values, intermediate between the two parental lines 'Romina' and AN00,239,55. Two other selections, AN07,003,59 and AN07,216,57, had lower values with respect to their respective "mothers" (AN94,414,52 and AN00,239,55 respectively), but similar values with respect to their "father" 'Romina'. It is interesting to note that all of the selections showed lower values of titratable acidity compared with their female parents. The lowest values were registered for selections AN07,003,55, AN07,003,53, AN07,003,58, and AN07,003,60.

'Romina' fruit had the highest value of firmness; none of the new selections were able to reach it, AN07,003,52 having the lowest value (Table 2). The selection that reached the closest value to that of 'Romina' was AN07,216,53 followed by AN07,216,60, from the BC3 family.

With regard to color, L^*, chroma index, and hue angle were evaluated for all of the selections and parents (Table 2). Interestingly, the AN07,003 family (BC2) generally showed the highest values for L^*, chroma index, and hue angle. In particular, fruit of selection AN07,003,53 possessed the highest values for chroma index, whereas AN07,003,56 and AN07,003,54 had the highest hue angle and L^* value, respectively. In contrast, fruits of BC3 (AN07,216 family) generally had the lowest values for L^* (AN07,216,52), chroma index (AN07,216,60), and hue angle (AN07,216,54). AN00,239,55 had the highest L^* value among parents, whereas AN94,414,52 had the lowest. 'Romina' had average values for all of the color parameters analyzed. Interestingly, the AN07,003 family (BC2) showed a higher average value of all color parameters compared to both parents. In contrast, the AN07,216 family (BC3) had lower values of all color parameters compared to its parents.

Fruit Nutritional Quantitative Analysis. The quantitative analysis performed to evaluate the nutritional quality of backcross genotypes involved in the study have highlighted main differences among them, specifically between parents and progenies, thus allowing the selection of those genotypes that had shown the highest improvements for each parameter. Phenol content of strawberry genotypes revealed an improvement in all of the progenies of second-generation backcrossing in comparison with their parent 'Romina', whereas some genotypes revealed also an improvement with respect to the other parent AN94,414,52. On the contrary, there was a decline in phenol content in most genotypes of third backcross generation in comparison to the BC3 parent AN00,239,55, but most had higher values than the parent 'Romina' (Table 2). The most elevated values were shown by the AN07,003 family and in particular by selections AN07,003,60 and AN07,003,55.

The results of ACY content revealed that only one genotype (AN07,216,60) showed an improvement in ACY content compared to its wild parent (AN00,239,55), whereas there was a decrease in ACY in most of the progenies, but at least the majority of the genotypes showed higher values than the parent 'Romina', as shown in Table 2. Selections that revealed the highest ACY content were AN07,216,60, AN07,216,55, and AN07,216,57 from BC2 and AN07,003,57 and AN07,003,60 from BC3.

TAC analysis revealed modest increased values of almost all progenies of both backcrosses in comparison with the parent 'Romina' (Table 2), whereas compared to the F1 parent AN94,414,52 there was a decrease in the BC2 progeny and compared to the BC3 parent AN00,239,55 there was no significant improvement in BC3 progenies. The selections

[a]Sum of four bis-HHDP-hexoside peaks. [b]Sum of two galloyl-bis-HHDP-hexoside peaks. [c]Ellagitannin with a mass spectrum similar to that of sanguiin H6. [d]Ellagitannin with a mass spectrum similar to that of lambertianin C. [e]Sum of five dimer peaks. [f]Sum of five trimer peaks.

AN07,003,60, AN07,216,53, AN07,216,58, and AN07,216,60 had the highest TAC values. Fruits of selection AN07,003,60 also had the highest TPH value, whereas AN07,216,60 had the highest TPH value of all the BC3 selections and the highest ACY value of all genotypes.

PCA. In the PCA biplot for fruit nutritional parameters of TAC, TPH, and ACY, combined with qualitative parameters of SS, TA, and firmness (Figure 1A), the selections and their parents are distributed in the four quadrants of the plot (Figure 1B). The female parent AN00,239,55 is located on the right-hand side of the plot, near the ACY vector. The other female parent, AN94,414,52 was located slightly higher in the right-hand side of the plot, near the ACY and TAC vectors. Finally, the common male parent 'Romina' is located on the lower left part of the plot, far from all of the vectors.

The AN07,003 selections were mainly positioned in the central left-hand area of the plot, not far from the TPH vector location. The only exception was AN07,003,60, which is located in the upper slightly right-hand side of the graph, where the firmness vector is located (Figure 1B).

The selections of the AN07,216 family are mainly located in the lower right-hand quadrant (Figure 1B), where the SS vector is placed (Figure 1A). However, fruits of AN07,216,57 and AN07,216,60 were located in the upper right quadrant, slightly higher than the other AN07,216 selections, where the TAC and ACY vectors are also located.

On the basis of the PCA, the three best selections were chosen for further characterization by HPLC-PDA-MS: AN07,003,59 BC2, which was characterized by medium TAC, TPH, and ACY values; AN07,216,57 BC3, which presented medium TAC value, medium/low TPH value, and high ACY; and AN07,216,60 BC3, which had the highest ACY and also one of the highest TAC and TPH values among the BC3 progenies.

dx.doi.org/10.1021/jf500708x | J. Agric. Food Chem. 2014, 62, 3944−3953

Polyphenolic Composition by HPLC-PDA-MS. The phenolic compositional analyses of flavonols, anthocyanins, ellagic acid conjugates, ellagitannins, and flavan-3-ols (catechin and proanthocyanidins) were performed on the selected selections. Fruits of the two parents, AN00,239,55 and cv. 'Romina', and of 'Elsanta', a widely available commercial variety, were also profiled.

The results (Table 3) showed that the BC2 parent AN00,239,55 and the BC2 selection AN07,003,59 contained the highest content of total flavonols, 2-fold higher than that of the commercial cultivar 'Elsanta'. The levels in both BC3 selections were not enhanced compared to the parents. The flavonol profile was similar for all genotypes with the exception of 'Elsanta'. Quercetin glucuronide was the main compound present in all genotypes except for 'Elsanta', in which the levels were up to about 20-fold less. Kaempferol glucuronide, the second main flavonol compound in strawberry, was higher in the selections and the parent AN00,239,55 than in the parent 'Romina' and much higher than in 'Elsanta'. The highest content of kaempferol coumaroyl hexoside 1 was found in fruit of 'Elsanta' and then BC2 AN07,003,59. Another kaempferol coumaroyl hexoside was at lower levels and showed a distribution similar to that of the major component. Kaempferol glucoside content was highest in fruit of BC3 parent AN00,239,55 and 'Elsanta', but was not enhanced in the progeny and was particularly low in 'Romina'. Quercetin hexoside and methylquercetin glucoronide were of low abundance, and there were only minor variations among genotypes, although they were at even lower levels in 'Elsanta'. Kaempferol acetylglucoside was highest in 'Elsanta', but was lowest in fruit of AN00,239,55 and of BC2 AN07,003,59. Kaempferol rutinoside was most abundant in fruit of AN00,239,55, whereas it was not detected in AN07,216,57 and 'Elsanta'.

ACY profiling revealed marked differences in anthocyanin content, in both anthocyanins quantity and quality. The total ACY (Table 3) followed the same trend as the values obtained from the spectrophotometric assay (Table 2). The levels in the selections were higher than in 'Romina' but not the parent AN00,239,55 or 'Elsanta'. Pelargonidin glucoside, the major anthocyanin, was about twice as abundant in the interspecific BC genotypes compared to 'Romina' and 'Elsanta'. Interestingly, pelargonidin malonylglucoside was observed in high amounts in fruit of 'Elsanta' and both BC3 selections AN07,216,57 and AN07,216,60, followed by 'Romina', whereas very low levels were detected in AN00,239,55 (BC3 parent) and BC2 AN07,003,59; it was enhanced in both BC selections compared to both parents. Cyanidin glucoside was detected in highest amounts in BC2 and then in BC3 selections, whereas the lowest value was detected in fruit of 'Elsanta'. Pelargonidin rutinoside was present in AN00,239,55, BC2 AN07,003,59, and BC3 AN07,216,60, and a small amount was found also in 'Romina', whereas it was not detected in the other BC3 selection or in 'Elsanta'. Pelargonidin acetyl-glucoside was a minor anthocyanin in fruits of AN00,239,55, AN07,216,57, and 'Romina', followed by AN07,003,59, whereas only a very low concentration was detected in AN07,216,60 and 'Elsanta'. Finally, cyanidin rutinoside was detected, at very low levels, only in fruits of AN07,003,59, AN07,216,60, and 'Romina'. The pattern of ellagic acid conjugates was similar for all genotypes, with the exception of BC2 selection AN07,003,59, which was the only genotype to contain a methylellagic deoxyhexoside (Table 3). Ellagic deoxyhexoside 1 was the most prevalent compound in the majority of genotypes, but there were no marked differences in the levels among genotypes. Ellagic acid was also a major component, and the highest values were evident for 'Romina' and BC2 AN07,003,59. Another ellagic deoxyhexoside and an ellagic hexoside were detected at lower levels in all genotypes.

Ellagitannins were highest in AN00,239,55, AN07,003,59, and AN07,216,57 and lowest in 'Elsanta'. The levels were enhanced in the BC2 selection (AN07,003,59) and one BC3 selection (AN07,216,57) compared to the parent 'Romina' but not the BC3 parent AN00,239,55. Galloyl-bis-HHDP-hexoside and unidentified ellagitannin A (with a mass spectrum similar to that of sanguiin H6) were the major components, followed by bis-HHDP-hexoside, in all genotypes except 'Elsanta', where ellagitannin A predominated.

Among the flavan-3-ols, catechin and proanthocyanin dimers and trimers were identified, and the dimers predominated. Larger proanthocyanidin compounds were detected but they were not characterized in this study. The levels were highest in 'Romina' and 'Elsanta' and were at similar levels in the BC2 and BC3 selections compared to the BC3 parent.

Most studies on strawberry genetic improvement have focused their attention on the evaluation and amelioration of agronomical and productive parameters. Only recently has attention shifted increasingly to the development of more healthful fruits, with emphasis on sensorial and nutritional characteristics. With this aim, a detailed study on the content of fruit bioactive compounds is a crucial aspect in evaluating new genetic material, because the profiling of at least the most important phytochemicals present in the fruit can provide a better estimation of the health-promoting potential of new future commercial material. The utilization of wild strawberries as a source of genetic variability for the improvement of nutritional value is being demonstrated as an important breeding strategy.[37] A problem with such wild germplasm is the lack of other important commercial attributes with respect to fruit yield, size, and firmness. In fact, several studies have recently demonstrated that breeding programs based on the use of wild and cultivated strawberries led to the achievement of selections with better nutritional qualities compared to the existing cultivated strawberry,[42] but then a long-term backcross program is needed to associate the improved nutritional traits with the commercially important agronomic and sensorial traits. Contemporary strawberry breeding programs, with the specific focus on improving strawberry nutritional quality, are using TPH, ACY, and TAC as preliminary screening methods. Then, more detailed compositional analyses are used to better characterize the phytochemicals that are responsible for the potential health benefits of the more interesting new genotypes. In the present study such an approach was taken to evaluate progenies from two backcross generations (BC2 and BC3) of an interspecific strawberry breeding program.

The commercial production and the average fruit weight of all selections and their respective parents were the first parameters to be analyzed. It is interesting that for commercial production, the *F.* × *ananassa* parent 'Romina' showed a very high value compared to the other wild-derived parents and to all BC2 and BC3 selections. However, the breeding program has generated selections that, even if they possess lower values than 'Romina', have an average commercial production much higher than their wild parents. Also, for average fruit weight (see the Supporting Information), 'Romina' had the highest value, whereas all other genotypes had lower values. Indeed, the

two backcross generations showed a breeding progress comparable with their corresponding parents. In fact, BC2 selections (AN07,003) had higher average production values than their parent AN94,414,52, and the BC3 selections (AN07,216) possessed average higher value compared to their parent AN00,239,55. Such results indicate an improvement in production parameters from the second to the third backcross generation, but to achieve the common commercial standards at least a further backcross generation is needed.

On the contrary, fruit from the BC2 and BC3 generations had, in general, higher values for sensorial quality parameters compared with the commercial parent. In fact, for soluble solids, 'Romina' had the lowest value (7.5 °Brix) compared to the wild parents and the majority of selections. Interestingly, the backcross selection BC2 AN07,003, derived from 'Romina' and AN94,414,52, showed a higher value (10.4 °Brix) compared to both 'Romina' and AN94,414,52 (10.1 °Brix, statistically different only from 'Romina'). Conversely, the BC3 AN07,216 selections had a much lower value (8.6 °Brix) than their parent AN00,239,55 (11.1 °Brix), but at least slightly higher than that of 'Romina'. These data indicate that the backcrossing program can be associated with a loss of fruit sugar contents that had previously been improved in the parents.

With regard to the titratable acidity, the wild parents had very high values compared to the majority of selections and 'Romina'. Fruit from most BC2 and BC3 selections did not show significant differences compared to 'Romina', but in some cases, such as for fruit of AN07,216,54, AN07,216,55, and AN07,216,60, titratable acidity is significantly higher than that of 'Romina', indicating that the interspecific cross of this cultivar with the wild selections improved the titratable acidity of the BC3 selection families (AN07,216).

Fruit firmness was improved in both BC2 and BC3 selections compared to 'Romina'. Although 'Romina' had a very high value (520 g), the interspecific cross with wild genotypes produced BC2 (377 g for AN07,003) and BC3 (376 g for AN07,216) selections with relatively low values that were generally very similar and not statistically different from their respective wild parents (363 g for AN00,239,55 and 366 g for AN94,414,52); the exception was AN07,216,53, which had a statistically higher value than the wild parent.

With regard to color, the BC2 AN07,003 family had the highest values for all the parameters evaluated; in particular, AN07,003,53 for chroma index (52.5), AN07,003,54 for L^* (40.3), and AN07,003,56 for hue angle (35.6). In this case, the backcrossing of wild and cultivated germplasm generated progeny that showed much higher values of all the color parameters compared to both parents, closer to the red brilliant type of color requested by the market for fresh strawberries. The situation is completely different for the BC3 family AN07,216; in fact, AN07,216,60 showed the lowest values of chroma index (37.9), AN07,216,52 the lowest value of L^* (31.4), and AN07,216,54 the lowest value of hue angle (23.6). For this family it is clear that the breeding program did not improve the color of the progeny; indeed, the average values of AN07,216 family were lower than in both parents ('Romina' and AN00,239,55) for all color parameters.

The nutritional quantitative analysis performed on parents and selections demonstrated well the effect of genetic improvement, through the utilization of wild germplasm. In fact, for TAC, TPH, and ACY, the lowest values were always detected in fruit of 'Romina'. On the contrary, the highest values for TAC and ACY were shown by the wild-derived parents AN94,414,52 and AN00,239,55. As a consequence, average TAC and ACY values of selections AN07,003 and AN07,216 were statistically lower than those of their respective wild parents, but significantly higher compared to their "father" 'Romina'. Furthermore, the TPH values of AN07,003 (BC2) selections and AN07,216 (BC3) selections were significantly higher than those of 'Romina', and that of AN07,003 was even higher than that of its "mother" AN94,414,52.

The PCA biplot analysis for nutritional and qualitative parameters clearly showed the distributions of the BC2 and BC3 selections and of their respective parents. Selections of the AN07,003 family were mainly located in the left upper quadrant (Figure 1B), where the TPH vector is located (Figure 1A). In fact, all of the higher values of TPH were registered for selections belonging to the AN07,003 family (Table 2). On the contrary, selections of the AN07,216 family are mainly located in the right side of the blot (Figure 1B), where ACY and TAC vectors are located (Figure 1A). This is in accordance with the values in Table 2, where selections of the AN07,216 family possessed higher values for both of these parameters.

On the basis of the results of the nutritional quantitative analysis, one BC2 and two BC3 selections, together with 'Romina', AN00,239,55, and the commercial cultivar 'Elsanta', were further analyzed by HPLC-PDA-MS for polyphenolic characterization and quantification. For flavonols content, all selected genotypes showed a modest increase in total flavonols compared to the "father" 'Romina' and much higher compared to 'Elsanta'. This finding represented a crucial result in this study, because it demonstrated that the interspecific crossing of cultivated strawberry with a wild-derived selection such as AN00,239,55, which has a high concentration of flavonols, generated BC2 (AN07,003,59) and BC3 (AN07,216,60) progeny with flavonol levels higher than the cultivated parent 'Romina' while retaining the overall pattern of individual flavonols, which was also similar to that of the wild parent (but different from that of Elsanta). The enhancement of flavonols in AN07,003,59 was mainly due to increases in quercetin glucuronide, kaempferol glucuronide, and a kaempferol coumaroyl hexoside, whereas in AN07,216,60 kaempferol glucuronide alone was mainly responsible. For the anthocyanins, the effect of breeding is even more evident than what was observed for flavonols. The total anthocyanin content of selections was up to 2-fold higher (highest was in AN07,216,60) than in 'Romina'. In BC2 selections (AN07,216,57 and AN07,216,60) the increase was mainly due to the two major anthocyanins, pelargonidin malonylglucoside and pelargonidin glucoside, whereas in the BC3 selection (AN07,003,59) only pelargonidin glucoside was the major contributor. Cyanidin glucoside was increased in all selections by up to 2-fold, and likewise pelargonidin rutinoside was enhanced in all selections, except AN07,216,57 where it was absent, compared to 'Romina', and to an even greater extent compared to 'Elsanta'. It is interesting that the anthocyanin profile of 'Romina' was retained in the BC3 selections with discrepancies only in minor anthocyanins (pelargonidin rutinoside and pelargonidin acetylglucoside were either absent or at trace levels in AN07,216,57 and AN07,216,60, respectively), but the BC2 selection was notable in the low level of pelargonidin malonylglucoside. The level of ellagic acid conjugates in the BC3 selections was not increased compared to the parents, although the overall profile of individual compounds was retained. Increases for the BC2 selection

AN07,003,59 were due to the unexpected high level of methylellagic deoxyhexoside, an ellagic acid conjugate totally absent in all other selections and parents, that probably originated from FVG but could be easily lost in backcrossing considering that it had already been lost in fruit of BC3 selections. Ellagitannins were enhanced in AN07,003,59 and one of the BC3 selections (AN07,216,57) compared to 'Romina', but the overall profile was maintained. Flavan-3-ol levels were not increased in the selections compared to 'Romina'.

The approach used for breeding strawberry nutritional quality is appropriate for (a) screening large populations by using spectrophotometric parameters (TPH, ACY, and TAC) and (b) characterizing the phytochemical content of the new selections chosen from those with the highest spectrophotometric values. With such an approach it is possible to concentrate effort on the characterization of fruit phytochemical content of only the more interesting selections. Wild FVG can make an important contribution to improving strawberry fruit content of important health-related phytochemicals combined with high values of sensorial traits. However, a well-defined backcross program is needed to conserve such improvements in fruit nutritional quality while recovering the other agronomic traits (in particular yield, size, and firmness) that are lost when the *Fragaria* × *ananassa* × FVG interspecific cross is performed. The HPLC-PDA-MS compositional study performed on the three BC selections enabled the characterization of bioactive compounds responsible for the improvement of the nutritional value of their fruit. They all had increased levels of flavonols and anthocyanins, two selections had enhanced ellagitannin contents, and the BC2 selection had increased content of ellagic acid conjugates (due to methylellagic deoxyhexoside, detected only in this selection), compared to the cultivated parent, 'Romina'. Furthermore, it is interesting to note that at least the contents of total flavonols and ellagitannins in all selected selections and respective parents are higher compared to the commercial variety 'Elsanta'. The knowledge now available for the three new selections, intensely characterized for their fruit compositional content, will be used to better define their use as breeding lines in future breeding programs or even for the release of the best ones as commercial varieties. In conclusion, it has been demonstrated that the progenies obtained from two half-subcross combinations of cultivated strawberry 'Romina' and wild-derived selections AN94,414,52 and AN00,239,55 have productive, sensorial, and, in particular, nutritional qualities, and it is encouraging that breeding programs can be utilized to ameliorate the characteristics of such fruits. In particular, the breeding of cultivated with wild genotypes has generated progenies with a commercial production much higher than the wild parents, but with sensorial, nutritional characteristics, and polyphenolic content much higher than those of the cultivated cultivar.

restoring the inhibitory κB (IκB) and inhibiting cytokine expression.

MATERIALS AND METHODS

Materials. 'Sheolhyang' strawberry (*Fragaria* × *ananassa* Duch.) cultivated in Asan, South Korea, was purchased in May 2012 and used for the multisolvent extraction. Elliagic acid, chlorogenic acid, *p*-coumaric acid, kaempferol, quercetin hydrate, quercetin 3-*O*-glucoside, (+)-catechin hydrate, pelargonidin 3-*O*-glucoside, pelargonidin 3-*O*-rutinoside, cyanidin 3-*O*-glucoside chloride, and formic acid were obtained from the Sigma-Aldrich Corp. (St. Louis, MO, USA). Ethyl acetate, methanol, and acetonitrile were from DUCKSAN (Ansan, South Korea), SAMCHUN (Yeosu, South Korea), and Burdick & Jackson (Muskegon, MI, USA), respectively.

Metabolite Extraction. Strawberries were cleaned immediately after harvest and freeze-dried, and dried powders were stored at −80 °C until extraction. Polyphenols in the strawberry were prepared by multisolvent extraction with ethyl acetate and methanol according to the method of Määttä-Riihinen et al. with modification.[27] Freeze-dried strawberry powders (2.5 g) were mixed with 10 mL of ethyl acetate and stirred for 30 min at room temperature, and the supernatant was collected. The supernatant was divided in two groups as fraction 1 (SF1), and the other part was washed with 0.1 M sodium acetate (pH 7.0) and distilled water and prepared as fraction 2 (SF2). Solvents in SF1 and SF2 were evaporated and resuspended with methanol for LC-MS/MS analysis. The residue of ethyl acetate extraction was extracted with acidic methanol, and the supernatant was divided into two groups. Supernatant was indicated as fraction 3 (SF3), and fraction 4 (SF4) was prepared after acidic hydrolysis of fraction 3. The residue after acidic methanol extraction was further treated with acidic methanol, and the supernatant was collected as fraction 6 (SF6); then fraction 5 (SF5) was prepared after more acidic hydrolysis of the residues.

LC-MS/MS Analysis. Samples were analyzed using an Accela HPLC system with a PDA detector (Accela 80 Hz PDA detector) and an LTQ-Velos ion trap mass spectrometer fitted with a heat electrospray ionization interface (Thermo Fisher Scientific, San Jose, CA, USA). Separation was carried out using an UPLC BEH C18 column (1.7 μm, 100 × 2.1 mm i.d., Acquity, Waters, Milford, MA, USA). The elution gradient was carried out with a binary solvent system consisting of 0.1% formic acid in water (phase A) and 0.1% formic acid in acetonitrile (phase B) at a constant flow rate of 0.3 mL/min. The linear gradient profile was as follows: 5−10% B over 5 min, held at a 10% B over 5 min, 10−40% B over 20 min, 40−90% B over 10 min, then returned to the initial conditions (5% B) in 5 min and conditioning at 5% B over 10 min, finished at 55 min. The column temperature was 36 °C, and the UV spectra were measured between 180 and 800 nm. Acquisition was performed in the negative and positive modes by electrospray ionization (ESI) source, and the *m*/*z* range was 100−1000 Da. The capillary temperature was 275 °C, and the source voltage was set to 5 kV for ionization.

Data Processing and Metabolite Identification. Peak detection, alignment, and identification were performed using SIEVE software (Thermo Fisher Scientific, Waltham, MA, USA). The MS/MS fragmentation patterns were used for informative nontargeted metabolic profiling of LC-MS data. The acquired LC-MS/MS spectrum was identified after comparison with those proposed by the Massbank database (www.massbank.jp), KEGG database (www.kegg.co.jp), Metlin (http://masspec.scripps.edu), and related reports.

Statistical Analysis. Samples were run in five replicates. All of these statistical analyses were performed using SIMCA (Umetrics, Sweden). Unsupervised multivariate statistical analysis was used to detect possible differences among groups by PCA, and the S-plot generated by OPLS-DA was applied to detect maximal separation of distinctive metabolites in each fraction. For cell proliferation assay, Western blot, and quantitative RT-PCR, the Student *t* test was used.

Cell Culture. RAW 264.7 cells were obtained from the Korean Cell Line Bank (Seoul, Korea) and were cultured in DMEM supplemented with 10% fetal bovine serum, 1% penicillin/streptomycin, and 1% HEPES at 37 °C, 5% CO_2. The RAW 264.7 cells were stimulated with LPS (100 ng/mL) and treated with different fractions (SF1−SF6) or ellagic acid at the concentrations as shown in the figure captions.

Cell Proliferation Assay. RAW 264.7 cells were plated (1×10^4 cells/well) in a 96-well plate overnight and then treated with different concentrations of strawberry fractions (20, 50, and 100 μg/mL) for 72 h in the growth medium. Before 4 h of harvest, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma) solution (200 μL) was added to each well. The dark blue formazan crystals formed were dissolved in DMSO, and the absorbance was measured with an ELISA reader at 570 nm (Molecular Devices, Sunnyvale, CA, USA). Cell proliferation was described as the relative cell viability compared to the control.

Western Blot Analysis. After RAW 264.7 cells were cultured overnight, they were treated with strawberry fractions and ellagic acid for 15 min or 24 h. The cells were washed with PBS and then harvested with radioimmunoprecipitation assay (RIPA) buffer (10 mM Tris-HCl, 5 mM EDTA, 150 mM NaCl, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, 0.1 mM Na_3VO_4, 1% phenylmethanesulfonyl fluoride, 1% protease inhibitor) to extract the cellular proteins. After

dx.doi.org/10.1021/jf4038503 | J. Agric. Food Chem. 2014, 62, 3954−3962

centrifugation at 12000*g* for 15 min, the same amount of protein (30 μg) was loaded in 10% polyacrylamide gel and electrophoretically separated and transferred to a polyvinylidene difluoride membrane (Millipore, Billerica, MA, USA). The primary antibodies against iNOS, COX2, IκBα, JNK (Santa Cruz Biotech, Santa Cruz, CA, USA), phospho-ERK, phospho-p38, phospho-JNK, phospho-Stat1 (Cell Signaling Technology, Boston, MA, USA), β-actin (Sigma), and secondary antibodies (Santa Cruz) were used. The expression levels of proteins were visualized with EZ capture MG (ATTO, Tokyo, Japan) and quantified with CS Analyzer (ver.3.0, ATTO).

RNA Extraction and Quantitative RT-PCR Analysis. RAW 264.7 cells (7×10^5 cells/10 cm dish) were treated with strawberry fraction (SF4) and ellagic acid for 15 h. Total cellular RNA was isolated by Trizol reagent (Sigma) and reverse-transcribed to cDNA using a RevertAid First Strand cDNA Synthesis Kit (Theromo Scientific, Lafayette, CO, USA) in a 96-well format Atlas Thermal Cycler (Astec, Fukuoka, Japan). The cDNA was amplified using TaqMan Fast Advanced Master Mix (Applied Biosystems, Foster City, CA, USA) on an ABI Prism 7500 real-time PCR system (Applied Biosystems). The temperature cycling conditions used for amplification were one cycle of 50 °C for 2 min, one cycle of 95 °C for 20 s, and 40 cycles of 95 °C for 3 s and 60 °C for 30 s. Labeled TaqMan primers including tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), interleukin-6 (IL-6), and glyceraldehydes-3-phosphate dehydrogenase (GAPDH) were purchased from Applied Biosystems. The relative quantification of target mRNA was calculated using the comparative $2^{-\Delta\Delta CT}$ method after normalization with the internal control, GAPDH.

RESULTS

Metabolomic Phenotyping of Multistep Solvent Extracts from Strawberry. Through multisolvent extraction, strawberry metabolites were fractionated into six groups. Fractions 1 (SF1) and 2 (SF2) were extracted with ethyl acetate, and fractions 3−6 (SF3−SF6) were prepared by methanol extracts. The yield of each fraction from SF1 to SF6 was determined as 0.01, <0.01, 10.93, 59.54, 3.63, and 1.00%, respectively. Unsupervised multivariate analysis (PCA) implied that multisolvent extraction successfully classified the target metabolites into different groups. In negative mode, vector 1 (explaining 32.7% of the total variance) discriminated the metabolite profiles by different solvents, whereas vector 2 explained 27.0% of the total variance. The ethyl acetate group (SF1, SF2) was clearly separated by methanol groups (SF3−SF6) as depicted in Figure 1. In positive mode, metabolites in each fraction were discriminated by principal components 1 (explaining 32.6% of the total variance) and 2 (14.6% of the total variance), and a similar pattern was found in negative mode. The PCA score plots demonstrated the distinctive metabolite phenotypes induced by the multisolvent extraction. Metabolites contained in each fraction were identified and summarized (supplementary Tables 1 and 2 in the Supporting Information).

Strawberry Fraction 1 (SF1). As an ethyl acetate extract, SF1 would contain less polar compounds such as hydroxycinnamic acid derivatives, flavan-3-ols (contain catechin), and dimeric and trimeric proanthocyanidins and flavonol glycosides. In the present study, (+)-catechin hydrate (RT 5.42, *m/z* 289.69), *p*-coumaroyl-glucoside (RT 5.90, *m/z* 325.19), kaempferol 3-*O*-acetyglucoside (RT 18.86, *m/z* 489.17), galloylglucoside (RT 6.38, *m/z* 331.97), proanthocyanidin dimer (EC-4,8-C) (RT 4.71, *m/z* 557.30), ferulic acid hexose derivative (RT 8.16, *m/z* 449.26), and dicoumaroyl hexose (RT 28.72, *m/z* 471.25) were identified as the main compounds in negative ion mode. Pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25), (+)-catechin hydrate (RT 2.12, *m/z* 291.13), 4′-*O*-methylglucoliquiritigenin (RT 9.27, *m/z* 433.18), pelargonidin 3-*O*-(6-*O*-malonyl-β-D-glucoside) (RT 14.66, *m/z* 519.29), and quercetin malonylhexose (RT 20.68, *m/z* 551.31) were mainly found in positive ion mode.

Strawberry Fraction 2 (SF2). SF2 was washed SF1, and epicatechin (RT 5.42, *m/z* 289.69), baicalein-7-*O*-glucoside (RT 8.16, *m/z* 431.33), and proanthocyanidin B4 (RT 4.71, *m/z* 577.30) were found in negative ion mode, whereas pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25), (+)-catechin hydrate (RT 5.37, *m/z* 291.06), luteolin (RT 19.10, *m/z* 287.73), kaempferol (RT 20.65, *m/z* 287.80), and 1-*O*-galloyl-β-D-glucose (RT 13.83, *m/z* 333.17) were identified under positive ion mode.

Strawberry Fraction 3 (SF3). SF3, as a simple methanol extract, proanthocyanidin dimer (RT 4.71, *m/z* 577.30), (+)-catechin hydrate (RT 5.42, *m/z* 289.69), ellagitannin (RT 10.93, *m/z* 935.22), kaempferol coumaroyl hexose (RT 22.41, *m/z* 593.29), quercetin 3-*O*-glucuronide (RT 15.42, *m/z* 477.16), and *p*-coumaroyl glucoside (RT 5.90, *m/z* 325.19) were identified in negative ion mode. Pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25) and pelargonidin 3-*O*-(6-malonyl-β-D-glucoside) (RT 14.66, *m/z* 519.29) were found in positive ion mode.

Strawberry Fraction 4 (SF4). SF4 was prepared through the acidic hydrolysis step of SF3. In negative mode of analysis, pelargonidin 3-*O*-glucoside (RT 6.91, *m/z* 431.16), delphinidin (RT 15.29, *m/z* 301.67), ellagic acid (RT 13.16, *m/z* 301.73), quercetin 3-methyl ether 7-rhamnoside (RT 3.35, *m/z* 461.16), and 5,2′-dihydroxy-6,7,8,6′-tetramethoxyflavone (RT 18.22, *m/z* 373.27) were found, whereas pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25), pelargonidin (RT 15.90, *m/z* 271.64), gallic acid (RT 14.17, *m/z* 171.32), and petunidin (RT 14.24, *m/z* 317.14) were identified in positive ion mode.

Strawberry Fraction 5 (SF5). Delphinidin (RT 15.29, *m/z* 301.67), kaempferol 7,4′-dimethyl ether 3-*O*-sulfate (RT 26.06, *m/z* 393.18), bis-HHDP-glucose (RT 2.94, *m/z* 739.42), and ellagic acid (RT 13.16, *m/z* 301.73) were detected in negative ion mode, whereas pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25), pelargonidin (RT 15.90, *m/z* 271.64), and diosmetin and (RT 13.51, *m/z* 301.18) were found in positive ion mode.

Strawberry Fraction 6 (SF6). Ellagic acid (RT 17.302, *m/z* 301.66), delphinidin (RT 15.29, *m/z* 301.67), and cyanidin 3-glucoside-7-rhamnoside (RT 24.75, *m/z* 593.31) were the main compounds in negative ion mode. Pelargonidin 3-*O*-glucoside (RT 7.89, *m/z* 433.25), pelargonidin (RT 12.52, *m/z* 271.53), diosmetin (RT 13.51, *m/z* 301.18), and cyanidin 3-*O*-(6-*O*-*p*-coumaroyl)-glucoside (RT 22.02, *m/z* 595.25) were identified in positive ion mode of analysis.

Strawberry Fractions Exerted Anti-inflammatory Activity in RAW 264.7 Cells without Cytotoxicity. To evaluate the cytotoxic effect of strawberry, RAW 264.7 cells were treated with different concentrations (20, 50, and 100 μg/mL) of strawberry fractions (SF1−SF6), and cell viability was determined by the MTT assay. As shown in Figure 2A, none of the strawberry fractions showed significant cytotoxicity at the concentrations tested. To investigate the regulatory activity of strawberry fractions on inflammation, we evaluated the expression level of the well-known inflammatory markers, iNOS and COX-2, after the induction LPS. The murine macrophage RAW 264.7 cells were treated with the strawberry fractions (20 μg/mL) for 24 h. Among the fractions, SF4 exerted the strongest inhibition of iNOS protein expression,

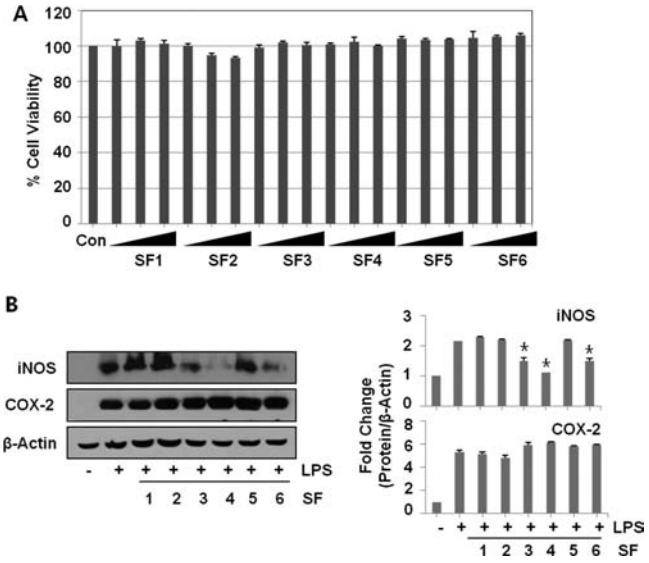

Figure 2. Effects of 'Seolhyang' strawberry fractions (SF1−SF6) on cell viability and expression level on iNOS and COX-2 protein in RAW 264.7 cells. (A) The cells (10000 cells/well in 96-well plate) were treated with strawberry fractions (SF1−SF6; 20, 50, 100 μg/mL) for 72 h, and cell viability was determined by MTT assay. (B) The cells (7×10^5/well in 60 mm dish) were treated with strawberry fractions (SF1−SF6; 20 μg/mL) with LPS (100 ng/mL) for 24 h. The level of protein expression was determined by Western blotting and normalized with β-actin. Statistical significance was determined by Student's t test compared to the LPS-treated group (∗, $P < 0.05$).

followed by SF4 and SF6, although the COX-2 level was not affected (Figure 2B). Next, we selected the potent fractions, SF3, SF4, and SF6, for further study to determine the concentration dependency in regulating iNOS. As shown in Figure 3A, all fractions at concentrations of 20, 50, and 100 μg/mL were found to suppress iNOS expression in a dose-dependent manner, among which SF4 possessed the most potent efficacy. However, we also confirmed that there was no regulatory activity in COX-2 expression by strawberry fractions up to 100 μg/mL.

SF3 and Especially SF4 Regulated the Inflammatory Mediators Inhibitory κB and ERK in LPS-Stimulated RAW 264.7 Cells. The inflammatory mechanism induced by LPS has been suggested to be from transducing the intracellular signaling through nuclear factor κB (NFκB) and mitogen-activated protein kinases (MAPKs) including extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38.[28] Here, we determined whether the strawberry fractions showing iNOS inhibitory activity might regulate the NFκB and MAPKs signaling pathways. Inhibitory κBs (IκBs) preventing translocation of NFκB into the nucleus are known to be degraded by proteasome after the inflammatory stimulation by LPS, and we found that SF3 and especially SF4 exerted significant restoration of IκBα. In addition, the phosphorylation of ERK induced by LPS was blocked more significantly by SF4 (Figure 3B). These results suggest that the strawberry fractions, especially SF4, may contain active metabolites playing important roles in suppressing inflammation induced by LPS in RAW 264.7 cells.

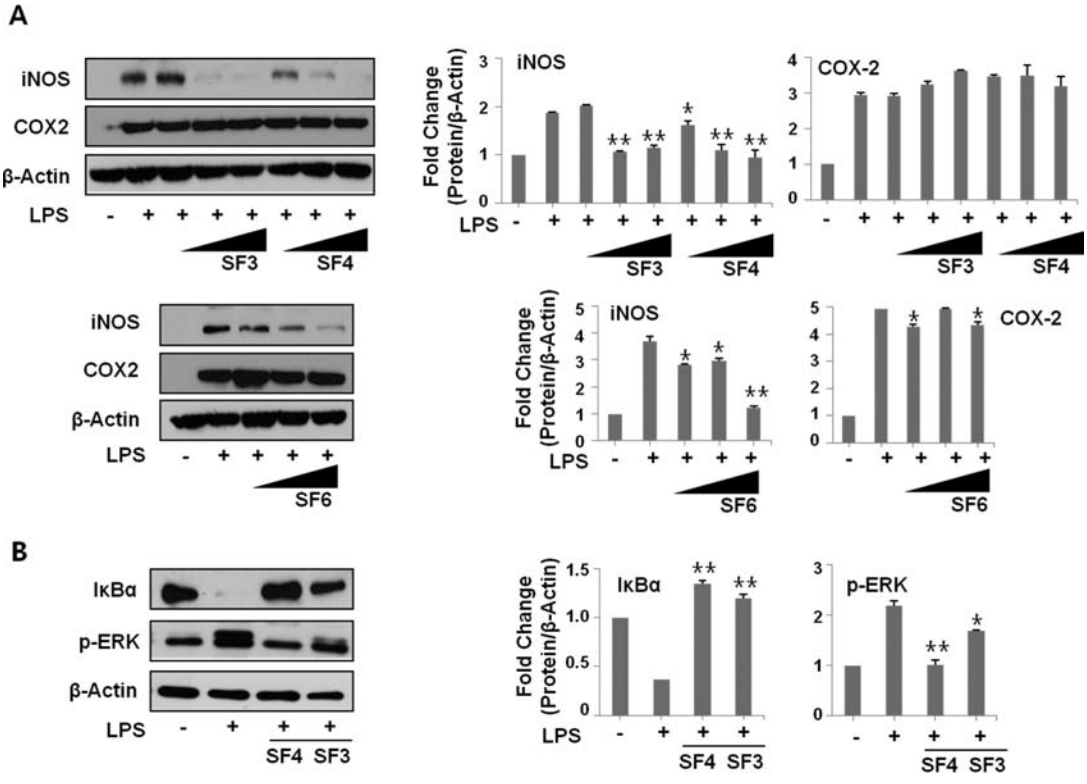

Figure 3. Effects of SF3, SF4, and SF6 on LPS-induced iNOS, COX-2, IκBα, and p-ERK protein expression in RAW 264.7 cells. (A) The cells (7×10^5/well in 60 mm dish) were treated with SF3, SF4, and SF6 (20, 50, 100 μg/mL) with LPS (100 ng/mL) for 24 h. The level of protein expression was determined by Western blotting and normalized with β-actin. (B) The cells were treated with SF3 and SF4 (100 μg/mL) with LPS (100 ng/mL) for 15 min. The level of protein expression was determined by Western blotting and normalized with β-actin. Statistical significance was determined by Student's t test compared to the LPS-treated group (∗, $P < 0.05$; ∗∗, $P < 0.01$).

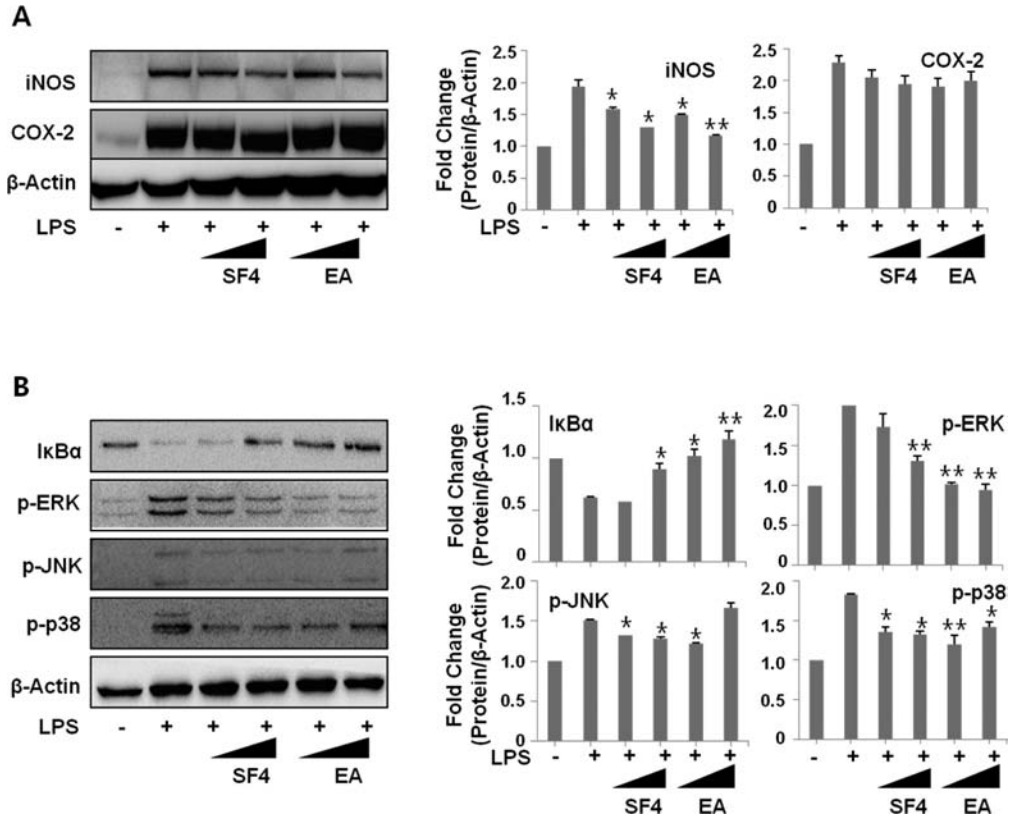

Figure 5. Effects of SF4 and ellagic acid on LPS-induced phosphorylation of MAPKs, LPS-mediated IκBα degradation, and iNOS and COX-2 protein expression in RAW 264.7 cells. The cells (7×10^5/well in 60 mm dish) were treated with SF4 (50, 100 μg/mL) and ellagic acid (0.3, 1.0 μM) with LPS (100 ng/mL) for 24 h (A) and 15 min (B). The level of protein expression was determined by Western blotting and normalized with β-actin. Statistical significance was determined by Student's *t* test compared to the LPS-treated group (∗, $P < 0.05$; ∗∗, $P < 0.01$).

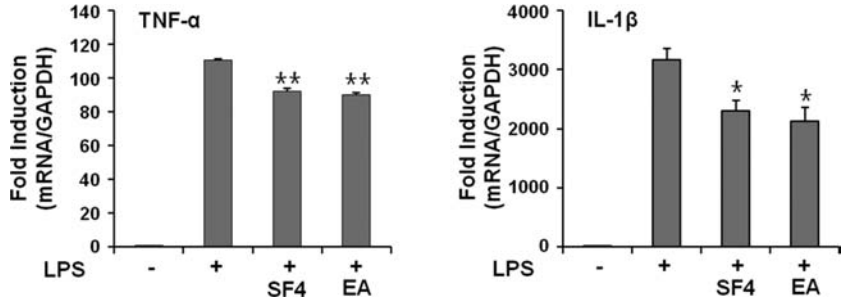

Figure 6. Effects of SF4 and ellagic acid on mRNA expression of cytokines, TNF-α, and IL-1β in LPS-induced RAW 264.7 cells. The cells (7×10^5/well in 60 mm dish) were treated with SF4 (100 μg/mL) and ellagic acid (0.3 μM) with LPS (100 ng/mL) for 15 h. The mRNA levels of TNF-α and IL-1β were measured by quantitative RT-PCR. Statistical significance was determined by Student's *t* test compared to the LPS-treated group (∗, $P < 0.05$; ∗∗, $P < 0.01$).

profiles of SF3 and SF4 were analyzed by OPLS-DA, and an S-plot clearly visualized the different variables between SF3 and SF4 (Figure 4). Anthocyanin families such as cyanidins, pelargonidin, and quercetin were found in both fractions; however, ellagic acid was significantly higher in SF4 compare to SF3 ($P < 0.01$, Table 1).

Ellagic Acid and SF4 Regulated the Same Inflammatory Mediators in LPS-Stimulated RAW 264.7 Cells. The contents of ellagic acid in strawberry are different across cultivars,[29] and the average amount of it was calculated as 1.24 mg/100 g FW.[30] We also determined the amount of ellagic acid in SF3 and SF4 and found that SF4 contained about 25-fold more ellagic acid than SF3 (data not shown). On the basis of those studies, we chose the concentrations of ellagic acid for treatment, 0.3 and 1.0 μM, to compare the inflammation regulatory effect with SF4. As shown in Figure 5, SF4 (50 and 100 μg/mL) and ellagic acid (0.3 and 1.0 μM) exerted similar activities in regulating the LPS-induced inflammatory mediators through inhibiting iNOS protein expression, blocking IκBα degradation, and suppressing phosphorylation of ERK, JNK, and p38, without affecting COX-2 expression. These results suggest that SF4 and ellagic acid regulate iNOS expression via suppressing NFκB and MAPK signaling pathways, and ellagic acid might be an active component in strawberry fraction, SF4, showing anti-inflammatory effect.

Ellagic Acid and SF4 Reduced the Level LPS-Induced Pro-inflammatory Cytokines. Pro-inflammatory cytokines including TNF-α, IL-1β, and IL-6 play important roles in the

dx.doi.org/10.1021/jf4038503 | J. Agric. Food Chem. 2014, 62, 3954−3962

inflammatory process.[31] To investigate the regulatory activity of the representative cytokine expression by SF4 and ellagic acid, we performed quantitative RT-PCR. Here, we confirmed that ellagic acid and SF4 showed significant suppression of LPS-induced TNF-α and IL-1β mRNA expression at similar levels (Figure 6). However, the mRNA level of IL-6 was not affected by either ellagic acid or SF4 (data not shown). These results also suggest that ellagic acid may be the key metabolite in SF4 possessing the inflammation regulatory effect in macrophage cells.

DISCUSSION

The metabolomics approach is an efficient way to open a whole set of metabolites and define unique metabolomic phenotyping through various statistical analyses along with subsequent annotation of the features. Although different techniques have been used to characterize and quantify active compounds in the berry family, just simple comparison and characterization have been attempted due to the complexity of the constituents and their dependence on the extraction methods.[32] Major bioactive compounds in strawberry can be classified into five groups including phenolic acids, stilbenes, flavonoids, tannins, and lignans, and different features of each group make it difficult for the multidimensional characterization of bioactive compounds in a single step of analysis. However, successful application of metabolomics on the characterization of black raspberry demonstrated that the screening of bioactive compounds from strawberry would be possible through the correlation of metabolomic data with activity evaluation in vitro.[33]

In this study, we prepared six different fractions (SF1−SF6) of strawberry 'Seolhyang' using ethyl acetate and methanol, profiled the whole metabolites with HPLC-ESI-ion trap MS/MS (Figure 1), and compared the inhibitory effects on iNOS protein expression (Figures 2 and 3). Among them, we chose the most active fractions, SF3 and SF4, and found the statistically unique components, kaempferol 7-*O*-glucoside and quercetin 3-*O*-glucoside in SF3 and ellagic acid in SF4, using OPLS-DA (Table 1). These results indicate that ellagic acid in SF4 may act as one of the key constituents exerting health beneficial efficacy when SF4 shows more significant physiological activities than SF3.

Inflammation is the systematic process of the host defense mechanism to eliminate harmful stimuli such as bacterial infection and tissue injuries, and chronic inflammation is well-known to be associated with the development of different chronic diseases including obesity, cardiovascular diseases, diabetes, and cancer.[31] The cellular stimulus of the inflammation activated Toll-like receptors (TLRs), which transduce the signal through IKK/NFκB or MAPK/AP-1 signaling pathways and enhance gene expression of pro-inflammtory cytokines, iNOS, and COX-2.[31,34] Strawberry juice, phenolic extracts, and polysaccharides in strawberry were reported to show anti-inflammatory effects through reducing pro-inflammatory cytokines such as IL-1β, IL-6, and TNF-α, as well as enhancing the anti-inflammtory cytokine IL-10.[3,35,36] However, it has not been demonstrated which active component plays a key role in regulating inflammation in those studies. To investigate the role of strawberry fractions on regulating the inflammation and identify the crucial components in the fractions, we used murine macrophage RAW 264.7 cells, which have been widely applied and suggested as a useful model for the evaluation of inflammation and immune-related kinetics.[37] In LPS-induced RAW 264.7 cells, SF4 exerted a more significant effect in regulating the inflammatory markers including iNOS suppression, IκB restoration, and ERK inhibition than SF3 (Figure 3). Because ellagic acid was identified as the most significantly different compound in SF4 compared to SF3, we concluded that ellagic acid is one of the key constituents exhibiting anti-inflammatory activity in SF4.

The effect of ellagic acid on inflammation has been studied using in vitro and in vivo models. In animal studies, dietary supplementation of ellagic acid in trinitrobenzenesulfonic acid (TNBS)-induced rat colitis and in dextran sulfate sodium-induced mouse colitis exerted anti-inflammatory activities through commonly regulating iNOS and COX-2 expression caused by inhibiting the MAPK and NFκB signaling pathways.[38−40] In addition, ellagic acid was reported to show suppression of LPS-induced inflammatory markers such as COX-2, microsomal PGE synthase-1, and cytosolic phospholipase 2Aα in human monocytes.[41] Lee et al. also evaluated the anti-inflammatory role of ellagic acid in oxidized low-density lipoprotein-mediated endothelial dysfunction.[42] Our results also support the role of ellagic acid present in SF4 in inhibiting LPS-induced inflammation via blocking the MAPK and NFκB signaling pathways in RAW 264.7 murine macrophage cells.

However, in the above in vitro studies evaluating the effect of ellagic acid on inflammation, the treatment concentration from 5 to 30 μM of ellagic acid is too high to reach by strawberry consumption.[41,42] Ellagic acid has been identified in different cultivars of strawberry ranging from 0.41 to 4.10 mg/100 g FW,[27,29,43] and its average amount is 1.24 mg/100 g FW.[30] To calculate the amount of ellagic acid in SF4, we first confirmed the yield of SF4 from freeze-dried strawberry powder, which was 59.4%. On that basis, the final concentration of ellagic acid in SF4 (100 μg/mL) was determined to be approximately 0.3 μM if we assumed that the whole ellagic acid (4.10 mg/100 g FW) was separated into SF4. We also analyzed the contents of ellagic acid in SF4, and its concentration was determined to approximately 7.99 mg/100 g FW (data now shown). The higher concentration of ellagic acid compared to the previous studies might be from the acidic conditions in SF4. Therefore, we treated ellagic acid at 0.3 and 1.0 μM and compared to SF4 treatment at 100 μg/mL in LPS-stimulated RAW 264.7 murine macrophage cells. As shown in Figure 5, we confirmed that SF4 and ellagic acid exhibited similar efficacy in regulating iNOS expression, blocking the degradation of IκBα, decreasing the phosphorylation of ERK, JNK, and p38, and suppressing pro-inflammatory cytokines TNF-α and IL-1β (Figures 5 and 6), suggesting the active component in SF4 responsible for anti-inflammation may be ellagic acid.

The absorption and metabolism of ellagic acid in vivo system is another factor we need to consider. Ellagitannins are demonstrated to release ellagic acid under physiological conditions in the digestive system using human colon adenocarcinoma Caco-2 cells and a monogastric Iberian pig model close to the human gastrointestinal tract.[44,45] In addition, >2-fold of ellagic acid was recovered in the ileal fluid from volunteers with an ileostomy after raspberry consumption, indicating the role of the stomach and/or the small intestine for the release of ellagic acid from ellagitannins.[46] In our study, ellagitannins in SF3 and ellagic acid in SF4 were detected because a more acidic condition was applied in SF4. These results suggest that the extraction conditions of SF4 may mimic the physiological conditions of the gastrointestinal tract in terms of the hydrolysis of ellagitannins.

After the finding that neither ellagitannins nor ellagic acid was detected in urine,[47] many studies have supported that ellagic acid is metabolized into urolithins, especially urolithin A and urolithin B,[44,46,48,49] raising the question of whether ellagic acid can reach the target organ where the macrophage exists as its original form. Although it is a critical issue to identify the actual potent phytochemicals that can act in vivo system, most metabolites produced from colonic microflora or hepatic system are not frequently present in the natural resources. To overcome this hurdle, the process of metabolism of natural active components must be elucidated and the correlation of in vitro and in vivo physiological efficacies validated.

Taken together, we employed the metabolomic approach to identify the key constituent showing physiological efficacy, that is, inflammation in this study. Ellagic acid was the significantly different component in SF4, compared to SF3, and we confirmed that ellagic acid possesses similar activity with SF4 in regulating NFκB and MAPK signaling pathways, which led to the reduction of cytokines (TNF-α and IL-1β) and iNOS expressions. These results demonstrate that ellagic acid from the strawberry 'Seolhyang' is the major component involved in suppressing inflammation. In addition, metabolomic analysis can be applied to determining the critical ingredients having biological functions in a complicated food matrix. It is, however, necessary to keep expanding the database to cover the whole metabolites in the mixture to reduce the possibility of missing potent unknown compounds.

MATERIALS AND METHODS

Diet. Freeze-dried highbush whole blueberry powder (50:50 blend of Tifblue and Rubel) was received from the U.S. Highbush Blueberry Council (Folsom, CA, USA). This blend contains 38 mg/g total phenolics and 21 mg/g total anthocyanins. AIN-93 M diet and AIN-93 M diet supplemented with 2.5 and 5% BB were prepared in pellet form by Harlan-Teklad (Madison, WI, USA) and stored at 4 °C in vacuum-sealed bags until use. BB diet was customized to have the same calorific value as AIN-93 M.

Animal Study. Animal experiments were executed in agreement with an approved protocol from the Institutional Animal Care and Use Committee at the University of Louisville. Female ACI rats (5−6 weeks old) were purchased from Harlan Sprague−Dawley, Inc. (Indianapolis, IN, USA). After a week of acclimation, animals were randomized into seven groups (Table 1). Groups 1, 4, and 7 were provided with AIN-93 M diet, and groups 2 and 5 were fed a diet supplemented with BB (2.5% w/w). Groups 3 and 6 received diet supplemented with 5% BB. After 2 weeks of experimental diet intervention, groups 4−7 were implanted subcutaneously with a 1.2 cm silastic implant containing 9 mg of 17β-estradiol (E_2) as described.[16] Group 7 received control AIN-93 M diet for 14 weeks and then was changed to BB diet (5% w/w) after the appearance of first palpable tumor in control group. As the BB diet in group 7 started after the appearance of tumors, this was considered as therapeutic intervention. Body weight and diet consumption were recorded weekly until euthanasia. Starting from 12 weeks of E_2 treatment, animals were palpated weekly for tumor incidence and multiplicity. When the palpable tumors reached >90% in group 4, animals in all groups were euthanized by CO_2 asphyxiation. Blood was collected by cardiac puncture to isolate serum and plasma. Lung, liver, brain, mammary tissue, and pituitary gland were collected, weighed, and snap frozen for further analysis. Mammary tumor size was measured by a Vernier caliper. Small pieces of mammary tissue and pituitary gland were fixed in 10% formalin for histopathological analysis.

Table 1. Experimental Design

group	treatment	no. of animals
1	untreated	8
2	2.5% BB diet	5
3	5% BB diet	5
4	E2 + control (AIN-93 M diet)	24
5	E2 + 2.5% BB diet	20
6	E2 + 5% BB diet (preventive)	20
7	E2 + 5% BB diet (therapeutic)	20

Histopathology. To assess the presence of microscopic tumors and pathological changes in the mammary glands of rats treated with E_2 for 12 weeks, 5 μm mammary tissue sections (n = 21) from multiple previous studies were stained with hematoxylin and eosin and analyzed by a board-certified veterinary pathologist.

Immunohistochemistry. Tissue sections from five randomly selected animals from each group were stained for proliferating cell nuclear antigen (PCNA) using a PCNA staining kit (Life Technologies, Grand Island, NY, USA) following the manufacturer's protocol. Five to six different sites in each slide were scored for deeply stained epithelial nuclei by two cytopathologists and represented as percent deeply stained cells.

Plasma Prolactin. Plasma prolactin levels were quantified using a Rat Prolactin ELISA Immuno-assay kit (Alpco, Salem, NH, USA) following the manufacturer's instructions. Briefly, plasma samples (n = 5) from E_2-treated groups were diluted 100- or 200-fold, and plasma from groups that did not receive E_2 was diluted 2-fold prior to the analysis. The samples were added to a 96-well plate incubated with rat prolactin sample buffer followed by enzyme-labeled anti-rat prolactin antibody. Then samples were incubated with 3,3′,5,5′-tetramethylbenzidine (TMB) and substrate solution (provided in the kit) followed by measurement of the optical density at 450 nm immediately after the addition of stop solution. About 25 μL of diluted plasma samples was measured against various concentrations of calibrator samples ranging from 5 to 80 ng/mL of prolactin levels.

Western Blot Analysis. Western blot analysis was done as described elsewhere.[14] Briefly, whole-cell lysates were prepared from mammary tissues using radioimmunoprecipitation assay (RIPA) lysis buffer (Santa Cruz Biotechnology Inc., Dallas, TX, USA), and protein concentrations were measured by using the bicinchoninic acid (BCA) method. Proteins were separated on MES-SDS-Bis-Tris 4−12% gradient gel (Invitrogen, Carlsbad, CA, USA). The proteins were transferred to PVDF membranes and probed for cyclin D1, PCNA, estrogen receptor-alpha (ER-α), c-myc, and progesterone receptor (PR). Equal loading of the protein was confirmed by β-actin.

Total RNA Isolation and qRT-PCR Analysis. Total RNA from frozen mammary tissues was isolated using Trizol reagent (Invitrogen). RNA concentrations were measured by NanoDrop (N2000c, NanoDrop Corp., Wilmington, DE, USA). qRT-PCR was performed with 100 ng of RNA using a qScript One-Step SYBR Green qRT-PCR Kit (Quanta Biosciences, Gaithersburg, MD, USA) with 500 pmol of forward and reverse primers for each gene. The genes and primer sequences are as follows: CYP1A1 (forward, 5′ GGGATA-TAGAAGCCATTCAGACTTG 3′; reverse, 5′ TGGAGACCTTCC-GACATTCAT 3′); ER-α (forward, 5′ GGCACATGAGTAACAAAG-GCA 3′; reverse, 5′ GGCATGAAGACGATGAGCAT 3′); 18S (forward, 5′ GGGAGGTAGTGACGAAAAATAACAAT 3′; reverse, 5′ TTGCCCTCCAATGGATCCT 3′). Quantitative PCR was carried out on a 7500 Fast-Real Time PCR instrument (Applied Biosystems, Green Island, NY, USA), following the manufacturer's guideline. The gene expressions were calculated by relative quantification method ($2^{\Delta\Delta Ct}$) comparing with control and normalizing to 18S RNA.

Small RNA Isolation/miRNA Analysis. Small RNAs (<200 bp) were isolated from mammary tissues using a mirVana microRNA isolation kit (Invitrogen) following the manufacturer's instruction. The concentration of the small RNA was quantified by Bioanalyzer (Agilent Technologies, Santa Clara, CA, USA). qPCR analysis of miR-18a, miR20a, miR25, and miR-34c was performed using a TaqMan miRNA Reverse Transcription Kit and TaqMan gene-specific miRNA assays (Applied Biosystems, Foster City, CA, USA) according to the manufacturer's instructions. Relative changes in miRNA expressions were quantified by comparison with the control and normalization to 5S RNA.

Toxicity Analysis. Whole blood was collected at the time of euthanasia to analyze serum chemistry and hematological parameters, as described previously.[17] Liver functions were analyzed by measuring the levels of aspartate transaminase, alanine aminotransferase, alkaline phosphatase, γ-glutamyl transpeptidase, and amylase in serum. Kidney functions were analyzed by measuring blood urea nitrogen, creatinine, and various electrolytes in serum. Various hematological parameters such as white blood cells (WBCs), red blood cells, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, and platelet count were analyzed from whole blood. Five random samples from each group were analyzed.

Statistical Analysis. All statistical comparisons between controls and E_2-treated groups were made using an unpaired one-tailed Student's t test. Tumor latency was analyzed using a nonparametric log-rank test. Diet consumption was analyzed using an unpaired two-tailed Student's t test, and body weight was analyzed by two-way ANOVA. All statistical analyses were done in GraphPad prism software, version 4.3 (San Diego, CA, USA). A p value of $\leq$0.05 was considered significant.

RESULTS

Food Consumption and Body Weight. There was no significant difference in diet consumption among groups receiving either control diet or AIN-93 M diet supplemented with 2.5 and 5% BB, in the absence of E_2 treatment. The diet consumption, however, increased in E_2-treated animals fed control diet or BB-supplemented diets (Figure 1A). The

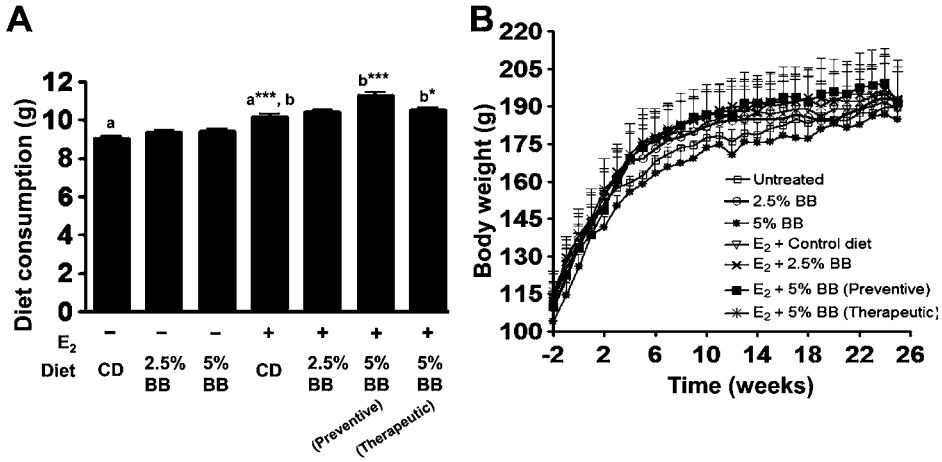

Figure 1. Average diet consumption and body weight:. (A) Average diet consumption by ACI rat per day fed with AIN-93 M diet and diet supplemented with 2.5 and 5% BB in the presence and absence of E_2. Values denote mean ± SD of diet consumption over a period of 25 weeks. Asterisk (a) indicates significant difference of E_2 control from untreated control ($p = 0.0001$). Asterisk (b) indicates significant difference of BB diets from E_2 control ($p = 0.001$ and 0.044). (B) Average body weight of rats receiving either AIN-93 M or BB diet. One-way ANOVA analysis showed that there was no significant difference in body weight after 25 weeks of E_2 treatment.

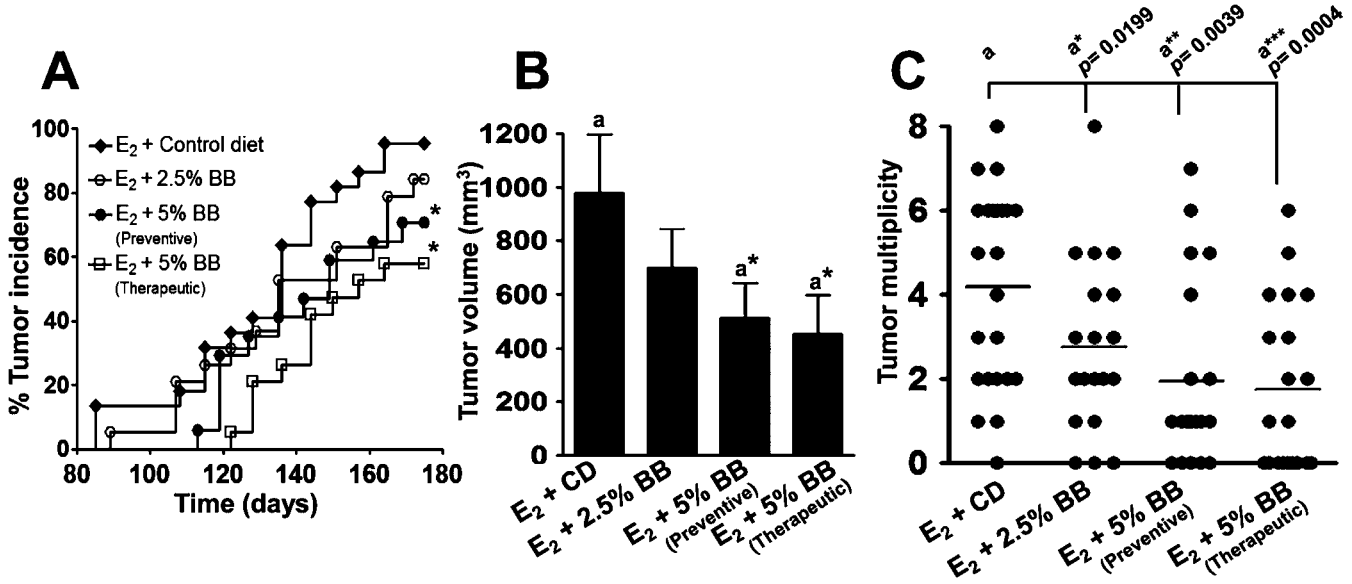

Figure 2. Effect of blueberry diet on (A) tumor incidence, (B) tumor volume, and (C) tumor multiplicity. (A) Tumor incidence was calculated from the weekly palpation report and analyzed using a nonparametric log-rank test. Asterisk indicates significant difference of 5% BB diet [preventive ($p = 0.0109$) and therapeutic mode ($p = 0.0021$)] from E_2-treated control. (B) Tumor volume and multiplicity were calculated at the time of euthanasia and analyzed using unpaired one-tailed Student's t test. Asterisk indicates that the tumor volume of both 5% BB diets ($p = 0.0398$ and $p = 0.0106$) was significantly different from E_2-treated control.

increase was significant in animals receiving the 5% BB diet in both preventive and therapeutic mode; the increase was insignificant in the 2.5% BB diet group. At the end of the study (25 weeks), one-way ANOVA analysis showed no significant difference in body weights among the control and E_2-treated animals (Figure 1B).

Tumor Incidence, Multiplicity, and Volume. BB diet was highly effective in favorably modulating the various tumor indices (latency, incidence, multiplicity, and burden). BB diet dose dependently delayed the tumor latency. The groups receiving 5% BB diet in both the chemopreventive and therapeutic modes had a significant delay with the first tumor appearance in the control group by 28 and 37 days, respectively, as compared to the age-matched control animals (Figure 2A). The group that received 2.5% BB diet also had delayed tumor latency but only slightly, about 7 days. At the end of the study, the control group developed palpable mammary tumors in 96% animals, whereas animals provided with the 5% BB diet in chemopreventive and therapeutic groups had palpable tumors only in 60% ($p = 0.0109$) and 55% ($p = 0.0021$) of animals, respectively; the 2.5% BB diet also showed some (11%) but insignificant reduction in tumor incidence compared to the control group. Tumor volume and multiplicity were measured after the animals had been euthanized. Animals receiving control diet had an average tumor volume of 979 ± 218 mm^3, whereas animals on the 5% BB diet had significant reductions, 512 ± 130 mm^3 ($p = 0.0398$) and 452 ± 144 mm^3 ($p = 0.0106$), for chemopreventive and therapeutic mode, respectively (Figure 2B). Animals on the 2.5% BB diet showed a modest but insignificant

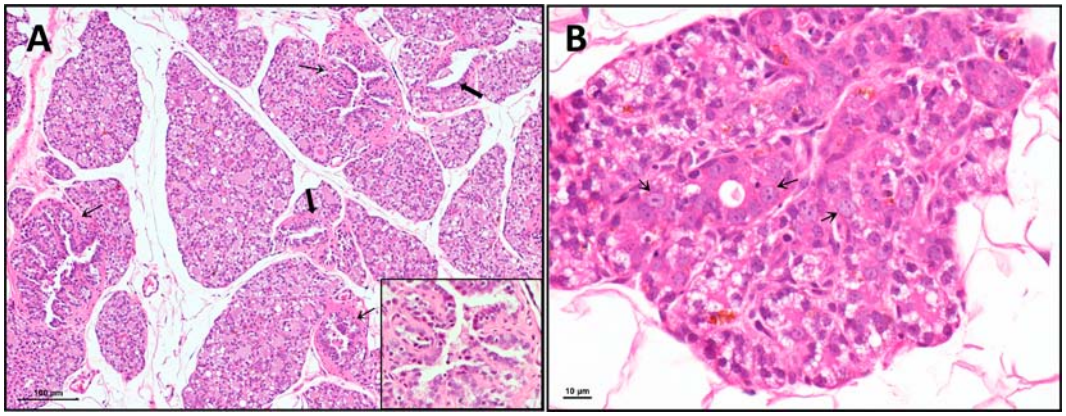

Figure 3. Presence of epithelial dysplasia and ductular papillomas from mammary tissue of rats treated with E_2 implant for 12 weeks. (A) Image of mammary section at 40× magnification showing long papillary projections from ductular walls (thin arrows) and ducts lined with hyperplastic epithelium with two or more layers (bold arrows). Inset shows 400× magnification of papillary projections. (B) Mammary section at 600× magnification with nuclei showing karyomegaly, which are hyperchromatic containing one to three distinct nucleoli (thin arrows).

(0.1435) reduction with an average tumor volume of 698 ± 145 mm^3. Tumor multiplicity in control animals was 4.17 ± 0.48 per animal, and it was reduced to 2.17 ± 0.52 (p = 0.0039) and 1.75 ± 0.45 (p = 0.0004) by the 5% BB diet given in chemopreventive and therapeutic mode, respectively (Figure 2C); the 2.5% BB diet also showed a significant reduction in tumor multiplicity, 2.75 ± 0.45 (p = 0.0199).

Liver, Mammary, and Pituitary Weights. At the end of the study, the liver, mammary, and pituitary tissue weights were not significantly different among the groups without E_2 treatment. However, the differences were significant with E_2 treatment. Mammary tissue weight with 5% BB diet in chemopreventive mode was modestly offset (p = 0.0486) from E_2-treated control. There was a 4−5-fold increase in the pituitary weight in E_2-treated animals; however, this was significantly offset with the 5% BB diet in preventive (33.9 ± 5.6 mg vs 42.2 ± 10.7 mg; p = 0.0031) and therapeutic (34.4 ± 5.3 mg; p = 0.0031) modes (Table 2). Pituitary weights in animals receiving the 2.5% BB diet also showed significant decrease (34.4 ± 8.0 mg; p = 0.0070).

Histopathology. In all animals that were treated with E_2 for 12 weeks (n = 21), there was expansion of mammary tissue with proliferation of terminal buds that differentiated into acini. The acinar epithelial cells were frequently vacuolated, and the acini contained amphophilic inspissated secretory material filling the lumina (Figure 3A). Concomitantly, there was proliferation of ductules and ducts with variable grades of epithelial dysplasia (n = 13). The ductular epithelial cells were cuboidal with distinct cell borders and moderate amounts of eosinophilic cytoplasm. Often (n = 4), the nuclei showed karyomegaly and were hyperchromatic, containing one to three distinct nucleoli (Figure 3B). Mitotic figures were not present in the sections examined. In >50% of cases (n = 11), the ducts were ectatic and lined by hyperplastic epithelium that formed two or more layers (Figure 3A). Ductular adenomas (n = 3) were characterized by the development of a 100−250 μm long papillary projection from the ductular walls that narrowed the lumina (Figure 3A, inset). The neoplastic cells contained scant cytoplasm and round nuclei with one to three distinct nucleoli. In all cases, desquamated epithelial cells were present within the ductular lumina. Prominent periductular fibrosis was a feature of all adenomas. Multifocal perivascular mast cell infiltration correlated with the severity of the lesion in all cases. In addition, the ductular epithelial dysplasia correlated with the size of expansion of the terminal bud.

Cell Proliferation Index. Cell proliferation was analyzed by staining tumor and adjacent mammary tissue for PCNA protein markers using antibody-based assay. After 25 weeks, there was no significant difference in cell proliferation among animals receiving either control or 2.5 and 5% BB diets. However, the E_2 treatment increased the cell proliferation to nearly 6-fold (p = 0.0095) (Figure 4). This increase in the cell proliferation was

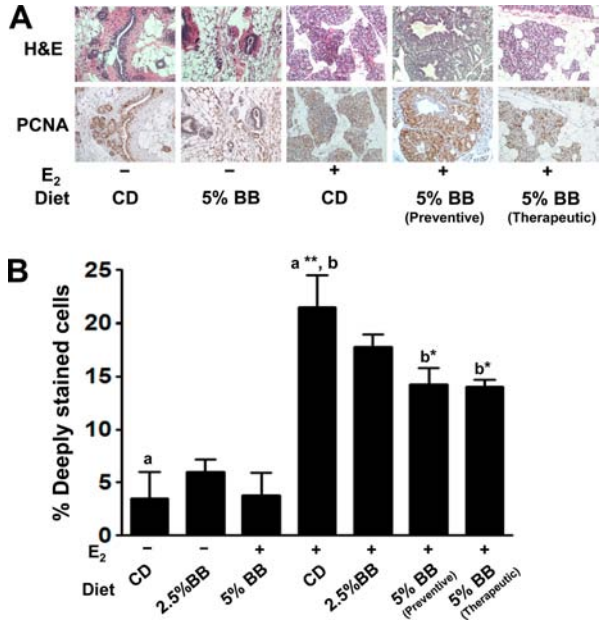

Figure 4. Proliferative index and effect of blueberry diet with or without estrogen (E_2) treatment. (A) Immunohistochemical staining for proliferating cell nuclear antigen (PCNA). Representative photomicrographs are 20× magnification of normal and hyperplastic mammary tissue. (B) Graph denotes the percentage of deeply stained cells for PCNA in mammary tissues (n = 5). [a] Statistically significant from untreated control (p = 0.0095). [b] Statistically significant from E_2-treated control (p = 0.0373 and p = 0.0251).

significantly offset by 34 and 35% with 5% BB diet administered in chemopreventive and therapeutic mode, respectively (Figure 4); the effect was insignificant with the 2.5% BB diet.

Plasma Prolactin. No significant difference was observed in the levels of plasma prolactin between untreated groups and BB diet groups. On the other hand, there was a substantial increase (p = 0.0035) in prolactin levels with E_2 treatment (6973 ± 2443 ng/mL) compared to untreated control (11.8 ± 1.8 ng/mL). After 25 weeks, animals provided with 5% BB diet in chemopreventive (2205 ± 438 ng/mL; p = 0.05) and therapeutic mode (1950 ± 285 ng/mL; p = 0.01) demonstrated significant reduction in the elevated levels of plasma prolactin (Figure 5). A modest but insignificant reduction in prolactin levels (4193 ± 1509 ng/mL) was also observed with the 2.5% BB diet.

Modulation of Estrogen-Specific Genes. There was a pronounced effect of E_2 on the expressions of cytochrome CYP 1A1 and ER-α at the mRNA levels. All groups were compared against the untreated control, and the fold change was expressed as mean ± standard error. E_2 treatment up-regulated the CYP 1A1 mRNA levels by 60-fold. The 5% BB intervention provided in chemopreventive and chemotherapeutic modes both significantly offset the E_2-associated increase in CYP1A1 to 28.3 ± 6-fold (p = 0.0011) and 27.6 ± 10.3-fold (p = 0.0102), respectively. Similarly, the mRNA expression level of ER-α in E_2-treated animals was up-regulated by 19.7 ± 2-fold compared to untreated control, and this increase was also significantly offset by the 5% BB diet, chemopreventive mode (14.2 ± 2-fold; p = 0.0201) and therapeutic mode (11.1 ± 4-fold; p = 0.05) (Figure 6A). Western blot analysis showed that E_2 treatment up-regulated both cyclin D1 and PCNA. Intervention of 5% BB diet in both preventive and therapeutic modes down-regulated cyclin D1 and PCNA at protein levels.

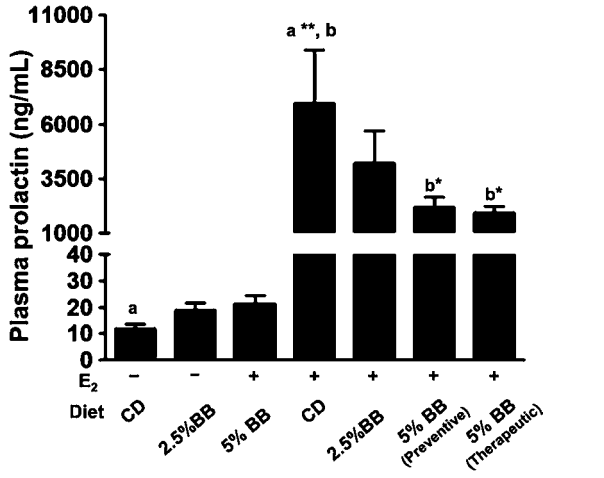

Figure 5. Circulating plasma prolactin levels among rats receiving either control diet or diet supplemented with 2.5 and 5% BB. Values represent the average of six samples ± SE done in duplicates. [a] Statistically significant from untreated control (p = 0.0035). [b] Statistically significant from E_2-treated control (*, p = 0.05; **, p = 0.01).

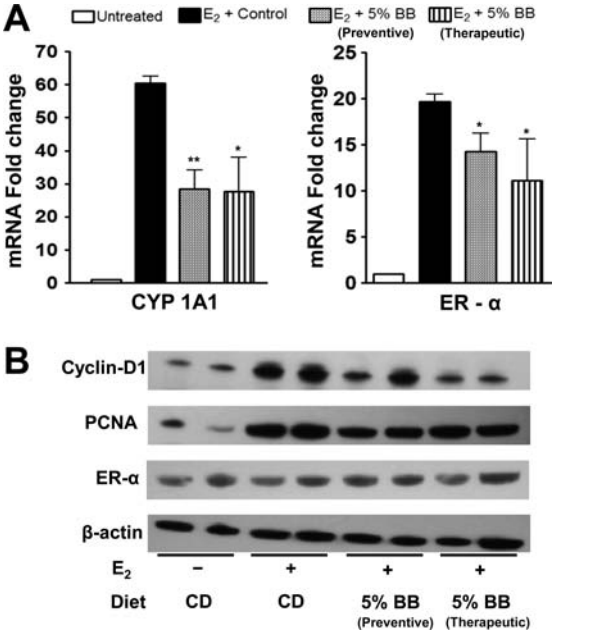

Figure 6. (A) mRNA expression of CYP1A1 and ER-α in mammary tissues. The total RNA isolated from the mammary tissue was analyzed by qPCR. Data represent the average of four animals ± SE. Asterisk represents significant difference from E_2-treated control (p = 0.0011 and 0.01). (B) Protein expression of cyclin D1, PCNA, and ER-α in mammary tissue. The total cellular lysate isolated from the mammary tissues was analyzed by Western blot.

However, ER-α protein level was not modulated with either E_2 treatment or administration of BB diet.

Modulation of Estradiol-Specific miRNAs. We analyzed four E_2-specific miRNAs (miR-18a, -20a, -25, and -34c) on the basis of our previous study in this animal model[18] to determine the effect of BB treatment on their modulation. All four miRNAs were significantly up-regulated under the influence of E_2 intervention in agreement with our previous findings. miR-18a and miR-34c were up-regulated about 13- and 11-fold, respectively, compared to untreated control. The effect of E_2 on

dx.doi.org/10.1021/jf403734j | J. Agric. Food Chem. 2014, 62, 3963−3971

miR-18a and miR-34c was reduced to 6.4-fold (p = 0.0013) and 4.9-fold (p = 0.0033), respectively, with the 5% BB diet in therapeutic mode (Figure 7). Berry diet given in chemo-preventive mode also offset these two elevated miRNAs, but the effect was not as pronounced. There was no significant effect of BB treatment on the up-regulated miR-20a and miR-25 expression levels.

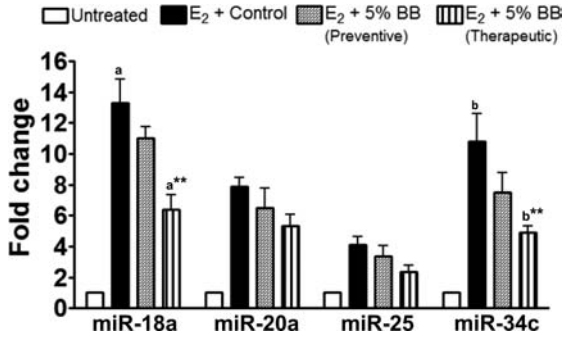

Figure 7. Expression of miRNAs 18a and 34c in mammary tissues. The small RNA was isolated by mirVana microRNA kit and quantified by Bioanalyzer. qPCR analysis was performed using a TaqMan microRNA Reverse Triscription Kit and TaqMan gene-specific MicroRNA assays. Graph represents the average of four rats ± SE done in duplicates. Asterisk indicates significant difference from E_2-treated control (p = 0.0013 and 0.0033).

Effect of Dietary Blueberry on Serum Chemistry and Hematological Parameters. Analysis of serum for liver enzymes such as aspartate transaminase, alanine aminotransferase, alkaline phosphatase, γ-glutamyl transpeptidase, amylase, and lipase indicated that they were within the normal range, and no difference was found with E_2 or BB diet or in combination compared to control, suggesting that berry diets had no toxic effects (Table 3). Serum was analyzed for plasma proteins (albumin and globulin), glucose, cholesterol, and triglycerides (Table 3). Analysis of blood urea nitrogen, creatinine, and various electrolytes showed no significant changes, indicating normal kidney functions with BB treatment (Table 3). Whole blood from all of the groups was analyzed for hematological parameters such as white blood cells, red blood cells, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, and platelets. No difference in any of the hematological parameters was found in any group compared to aged-matched control animals (Table 3). The levels of

neutrophils and lymphocytes measured in whole blood showed no significant difference among all groups (Table 3).

DISCUSSION

Cancer chemopreventive agents are either natural products or their synthetic analogues, which inhibit the transformation of normal cells to premalignant cells or the progression of premalignant cells to malignant cells.[19] It is believed that chemopreventive agents can inhibit oncogenic pathways, inhibit growth, and induce apoptosis in cancer cells.[20] Conventional chemopreventive agents are administered long-term and believed to block or delay the progression of transformed cells by modulating cell proliferation or differentiation.[21] They also prevent activation of carcinogen, trap carcinogen before reaching the active site, and enhance detoxification systems.[21] On the other hand, standard therapeutic drugs are toxic to both cancer and normal cells, which results in therapeutic activity and side effects to normal cells. Cytotoxicity to normal cells may lead to secondary tumors.[20]

This study was conducted to test both the chemopreventive and therapeutic potential of Tifblue and Rubel blueberry blend against E_2-mediated mammary tumorigenesis. We had previously reported on the chemopreventive effect of Berkley blueberry on mammary tumorigenesis.[15,22] This is the first study of its kind in which the therapeutic potential of blueberry has been shown. We also confirmed the microscopic tumors and precancerous conditions by histological evaluation of mammary gland sections from rats treated and necropsied at 12 weeks of E_2 treatment. Variable ductular epithelial changes including dysplasia, hyperplasia, and adenoma formation were found, suggesting various stages of carcinogenesis. In addition, periductular fibroplasia as well as mast cell infiltration positively correlated with degree of dysplasia.

Similar to our earlier studies[15,22] this Tifblue−Rubel blueberry blend at 2.5 and 5% given in the chemopreventive mode was highly effective in increasing the tumor latency by 7 and 28 days, respectively. The administration of 2.5% BB diet showed significant reduction in tumor multiplicity and pituitary weight. In our earlier studies, 2.5% BB diet made from the mixture of three blueberries was not effective against E_2 treatment; this could be because the E_2 implant size was 3 cm long containing 27 mg of E_2.[22] In another study with a similar 9 mg E_2 implant, a 2.5% diet showed protective effects that were in the same vicinity as reported by us previously.[23] In both studies, the 2.5% BB diet had only modest effect and did not significantly reduce the tumor volume, tumor latency, and molecular markers investigated. The higher dose of BB (5%) administered in chemopreventive mode was highly protective in reducing tumor volume and tumor multiplicity and increased tumor latency to 28 days, in agreement with our previous findings.[15] However, the protective effect of blueberry was slackened after 20 weeks of E_2 treatment, likely due to the exponential growth rate of the cells to reach the malignant stage. For the first time BB diet was administered after 12 weeks of E_2 treatment to determine the therapeutic effect against precancerous and microscopic adenomas. When compared with animals that received 5% BB diet in chemopreventive mode, the therapeutic group showed a significantly enhanced effect by reducing tumor volume and multiplicity and increasing the tumor latency to 37 days, that is, 9 days more than the preventive groups. Even when the BB diet was initiated after 14 weeks of E_2 treatment, the therapeutic group elicited protective effects. The therapeutic potential of BB anthocyanidins has been shown by others against human prostate cancer[24] and by us against lung cancer xenograft.[14] However, there is no study for direct comparison in E_2-induced mammary tumorigenesis. Interestingly, the present data also suggest that BB diet can be started in the postinitiation stage of tumorigenesis and still elicit a response similar to that of chemopreventive mode.

Bioavailability of anthocyanins in vivo is crucial for their biological effects. Anthocyanins are absorbed intact in the glycosidic form.[25,26] They are rapidly absorbed from the stomach and jejunum.[27,28] Yet >50% of the ingested anthocyanins are found in the cecum,[29] implying poor absorption. Anthocyanin structure exists as a flavilium cation in acidic conditions, which is stable, but converts to unstable quinoidal or carbinol structure at neutral or alkaline conditions.[30] However, it has also been shown that anthocyanins are stabilized by flavanols and ascorbic acid present in the food matrix.[31,32] This may explain the higher bioavailability of anthocyanins when given as a whole fruit powder relative to individual anthocyanins,[33] indicating strong synergism occurs in absorption between coexisting molecules in fruit. Furthermore, in a study with healthy subjects with ileostomy, nearly 40% of anthocyanins were recovered in the ileal fluid, indicating that despite the difference in pH, the anthocyanins were stable and large amounts will pass from the small intestine to the large intestine.[34] Yet, all of the bioavailability studies were done with bolus doses of pure anthocyanins or fruit powder/extracts.[35] Anthocyanins were not detected in the plasma of animals fed a diet mixed with sources rich in anthocyanins or the pure compound.[29] However, lack of detection of anthocyanins in the plasma does not indicate lack of tissue bioavailability. When anthocyanins were delivered intravenously, a biphasic decay of plasma levels was observed, indicating tissue distribution.[33] In a parallel publication in this issue, we have discussed in detail the bioavailability of anthocyanins and its levels in lung tissue.[12] We have demonstrated the presence of all five anthocyanidins, delphinidin, cyanidin, peonidin, petunidin, and malvidin, in lung tissues. Thus, anthocyanins are bioavailable and bioaccumulate in non-gastrointestinal tissues.

In agreement with our previous studies, the effect of E_2 was reflected in the body, liver, mammary, and pituitary weights of the animals.[15] The transitory increase in body weight and organ weight is majorly due to the E_2 and may not be due to the diet consumption. Moreover, control AIN-93 M diet and diets supplemented with 2.5 and 5% BB were isocaloric. Although there was no effect of BB diet on body weight gain and organ weights, it was found to significantly offset E_2-associated elevation in the weight of pituitary tumors. The pituitary weight was affected due to the increase in plasma prolactin levels induced by E_2, resulting in pituitary prolactinomas.[36] However, the E_2-mediated mammary tumor model was well studied and standardized to reduce the side effect to the pituitary gland.[16] Earlier studies have shown that prolonged supply of E_2 increases the production of prolactin in E_2-sensitive rat strains.[37,38] High circulatory levels of prolactin in serum are one of the major reasons for animals to develop E_2-induced mammary tumors.[39] Berry diet at 2.5 and 5% significantly offset the prolactin levels elevated by E_2.

E_2 also induces the production of phase I enzyme, CYP1A1. It catalyzes the conversion of E_2 into its metabolites ($2E_2$ and $4E_2$), which further undergo redox cycle leading to the formation of reactive oxygen species.[40] In this study, we

showed that BB diet significantly reduced the expression of CYP1A1, suggesting its protective role against mammary carcinogenesis. Studies have shown that cyclin D1 and E_2 receptors have important roles in regulating proliferation of breast epithelial cells.[41,42] It is well established that E_2 via ER-α elicits rapid signals driving cancer cells to proliferation. This biological effect of E_2-mediated by ER-α was reduced significantly in 5% BB diet provided in therapeutic mode. Regulation of cyclin D1 gene expression has been associated with changes in the proliferation rate of breast cancer cells.[43] Induction of cyclin D1 expression occurs rapidly and is a critical feature of the mitogenic action of E_2. The expression of cyclin D1 was down-regulated by 2−2.6-fold with 5% BB diet in chemopreventive and therapeutic modes, respectively. Investigation of PCNA in nuclear proteins revealed that dietary BB reduced the expression levels significantly. PCNA was shown to interact with ER-α both in the absence and in the presence of DNA, to enhance the interaction of ER-α with ERE-containing DNA, and associate with endogenous E_2-responsive genes.[44] These findings clearly indicate that BB diet could modulate major E_2-associated proliferation markers that lead to protective effects against mammary tumorigenesis in animals treated with E_2.

Another interesting finding in this study is from the analysis of miRNAs related to the ER-α family. Aberrant miRNA expression is implicated in E_2-related breast, uterine, and ovarian cancer development and progression.[7] Hormones play a crucial role in regulating miRNAs by both genomic (transcriptional) and nongenomic mechanisms.[45] Lorio et al. identified miRNAs having expression correlated with specific breast cancer biopathologic features, such as E_2 and progesterone receptor expression, tumor stage, vascular invasion, or proliferation index.[5] Targeting specific miRNAs for inhibiting specific stages of a cancer[46] is being explored. Several miRNAs that regulate ER are involved in synchronized feedback mechanisms as a component of ER activation. Many of these ER-regulating miRNAs therefore are either E_2-inducible (miR-18a and let-7) or subject to E_2-mediated repression (miR-206, miR-221/222, and miR-145).[47] This laboratory has recently identified miRNAs that modulated under the influence of E_2 in this animal model and report aberrant changes in miRNA expression profile as early as 3 weeks of E_2 treatment.[48] We chose four miRNAs, miR-18a, -20a, -25, and -34c, on the basis of our previous study where these miRNAs were up-regulated with E_2 to understand the influence of BB diet on their modulation. Increases in miR-18a and miR-20a mature forms were observed after E2 stimulation.[18] In this study, BB diet administered in therapeutic mode significantly reduced miR-18a and miR-34c, whereas chemopreventive mode showed modest but significant reduction. These findings provide initial insights of BB diet in decreasing the E_2-induced miRNA levels. However, the BB diet failed to modulate miR-20a and -25 expression levels, which remain the subject of further investigation.

In the chemopreventive mode, the rats are fed BB diet as young as 6−7 weeks old. The relative enhanced effect observed with the therapeutic approach could be due to the adaptive response of the rats to the BB phytochemicals in the chemopreventive mode. For example, the CYP1A1 mRNA level in mammary tissue was highest at 3 weeks after E_2 implant and gradually decreased with time.[15,23] The effect of the BB phytochemicals was more pronounced in the inhibition of conversion of normal cells to precancerous or precancerous frank tumors, but were not as effective once the tumors reached the exponential growth rate. Thus, by the time the mammary cells started exhibiting precancerous conditions, the efficacy was better when BB phytochemicals were introduced into the system than when they were already in the circulation. Nevertheless, both approaches were effective in delaying the onset and growth of palpable tumors.

In summary, this is the first demonstration indicating that BB diet is highly protective even in preinitiated E_2-mediated mammary tumors in ACI rats through its effects by modulating cell proliferation and molecular targets. Thus, the consumption of BB can be used as an effective strategy for the treatment of E_2-associated breast cancer and possible prevention of its relapse and metastasis. Our study demonstrates the chemopreventive and therapeutic potential of blueberry and advances our understanding of the working mechanisms in search of potential future drugs.

Table 1. Macronutrient Composition of Low-Fat and High-Fat Lard-Based Diets[a]

% kcal from	10 kcal% fat diet[b]	60 kcal% fat diet[b,c]
protein	20.5	18.4
carbohydrate	69.1	21.3
fat (lard)	10.4	60.3
kcal/g	3.6	5.1

[a]Values are calculated from ingredient analysis or manufacturer data. The LF diet (10 kcal% fat) is TD.08806, which is a Teklad Custom Research Diet from Harlan. The HF diet (60 kcal% fat) is TD.06414, and it also from Harlan. [b]For the 4% BB diets, 40 g of Tifblue powder replaced 25 g of starch, 6 g of cellulose, and 9 g of corn starch. [c]Approximate fatty acid profile (% of total fat): 37% saturated, 47% monounsaturated, 16% polyunsaturated.

was made by freeze-drying whole Tifblue blueberries, and it was supplied by the U.S. Highbush Blueberry Council (Folsom, CA, USA).[15] Tifblue is a rabbiteye variety of BB (*Vaccinium ashei*) and phenolic acid, flavonol, anthocyanin profiles, as well as the nutritional composition of fresh and frozen BB, have been quantified previously.[16−18]

Animals. Sixty-four 9-month-old male C57Bl/6 mice (Jackson Laboratories, Bar Harbor, ME, USA) were individually housed and maintained on a 12 h light/dark cycle. The mice were given food and water ad libitum and given 2 weeks to adjust to their new environment, after which time they were weight-matched (no initial difference in body weight between the four groups: $F_{3,56} = 0.071$, $p = 0.97$, one-way ANOVA) and placed on one of four diets (Teklad Lab Animal Diets) for 5 months ($n = 16$/diet): LF, LFBB, HF, or HFBB. Food intake was assessed over two 24 h periods. All animals were weighed at least weekly and observed daily for clinical signs of disease. Animals were utilized in compliance with all applicable laws and regulations as well as principles expressed in the National Institutes of Health *Guide for the Care and Use of Laboratory Animals*. This study was approved by the Jean Mayer Human Nutrition Research Center on Aging at Tufts University Institutional Animal Care and Use Committee. During the 5 month period on the diets, the animals underwent behavioral tests designed to examine object recognition learning and memory and spatial learning and memory. Behavioral testing was performed on $n = 14−16$ mice per group because 1 mouse died ($n = 1$ LF) and 4 mice were removed from the study because of rapid weight loss ($n = 2$ HF, $n = 1$ HFBB) and cataracts ($n = 1$, HFBB).

Novel Object Recognition Test. Mice were tested with the novel object recognition test[19] after 2, 3, and 4 months on the diets (test sessions 1, 2, and 3, respectively). The novel object recognition test measures the ability to remember an object by observing reaction to the introduction of a novel object compared to a previously viewed object; animals with intact recognition memory will spend more time exploring a novel object than a familiar one. The test was performed similarly to the methods of Carey et al.[20] Animals were habituated to an empty testing chamber for 10 min (plastic rectangular cage, 16 × 24 × 12 cm). Next, mice were given three 10 min trials with 10 min intertrial intervals (Figure 3A). In trials 1 and 2 (training trials), mice explored the testing chamber containing two identical objects that were centered across from each other, 2 cm away from the walls. In trial 3 (testing trial), one of the objects was replaced with a novel object. For every trial, the time that the mice spent attending to each object was recorded with stopwatches. Attending to the object was defined as the duration of time the mouse spent in physical contact with the object using any body part other than the tail or whenever it was engaged in active exploration (e.g., sniffing or manipulating). In test session 1 (when mice had been on diets for 2 months), the objects used in testing were dice and marbles, in test session 2 (when mice had been on diets for 3 months) Eppendorf tubes and binder clips were used, and in test session 3 (when mice had been on diets for 4 months) chess pawns and 15 mL tube caps were used. The novel and familiar objects were counterbalanced within a test session so that, for example, in test session 1 half the mice had a marble as the novel object and dice as familiar objects and the other half of the mice had the die as the novel object and marbles as familiar objects.

Morris Water Maze. Mice were tested for 4 days in the MWM after 5 months on the diets similar to previous methods.[21] This paradigm requires the mouse to use spatial memory and distal cues in the testing room to find a hidden white platform 1 cm below the surface of a circular pool of water (colored opaque with white nontoxic paint) and to remember its location from the previous trial. The mice were given 60 s to find the hidden platform during each acquisition trial. There were five acquisition trials on day 1 and four acquisition trials on days 2 and 3. The platform remained in the same position during acquisition trials, but start locations were varied. On day 4, a reversal test was performed during which the platform was moved to the opposite quadrant, thereby requiring the mouse to retain the learned escape strategy but to quickly learn the new escape position. A 60- s probe trial was performed during the fifth and last trial on days 2−4, during which the platform was removed. Performance was monitored with image tracking software (HVS Image, UK).

Data Analysis. Data are represented as the mean ± SEM and were analyzed using IBM SPSS Statistics 21 (IBM, Armonk, NY, USA) and Systat (Systat Software, Inc., Chicago, IL, USA). Significance was set at $p \leq 0.05$. Food intake, caloric intake, and percent increase in weight were analyzed with two-way ANOVA (factors: fat percentage and presence of blueberry). The novel object recognition test data are presented as a percent recognition index (RI) for object B: RI = (time attending to object B/time attending to object A + B) × 100 (Figure 3A). As there were no differences between the two training trials within each diet group, those data were combined for further analysis ($p > 0.05$, training trial 1 versus training trial 2, Wilcoxon signed ranks test). Novel object recognition was analyzed by comparing the RI of the training trial to the RI of the testing trial with the nonparametric Wilcoxon signed ranks test for paired samples. Testing trial performance was further analyzed by comparing RIs to chance performance (50% RI) with one-sample t tests. Morris water maze latency was analyzed with univariate ANOVA (factors: fat, BB, and day for acquisition learning or trial for reversal learning), and probe trial data were analyzed with independent sample t tests.

RESULTS

Mouse Weights and Food Intake. An average of two 24 h food intake measurements indicated that the mice that consumed HF diets ate fewer grams of food than the mice that ate LF diets ($F_{1,58} = 4.00$, $p \leq 0.05$, main effect of fat percentage, two-way ANOVA, Figure 1A). There was no effect of BB on food intake ($F_{1,58} = 0.003$, $p = 0.96$). Although the mice on HF diets ate less, they consumed more calories on average. An analysis of caloric intake based on the food intake measurements and calories in the diets (from Table 1) indicated that mice that consumed the HF diets consumed more calories than mice on the LF diets ($F_{1,58} = 12.41$, $p = 0.001$, main effect of fat percentage, Figure 1B). Furthermore, after 5 months on the diets, mice consuming HF diets gained significantly more weight than the mice on LF diets ($F_{1,56} = 60.32$, $p < 0.001$, main effect of fat percentage, Figure 2).

Novel Object Recognition Test. Analysis of novel object RI indicated that after 2 months on the diets, mice on LF and LFBB diets showed a significant increase in time spent on the novel object (object B, Figure 3A) in the testing trial compared to time on object B in the training trial ($p < 0.05$ Wilcoxon signed ranks test, Figure 3B). The mice on HF and HFBB diets did not spend more time on the novel object (object B) in the testing trial (versus training trial, $p = 0.59$ and $p = 0.72$, respectively). After 3 months on the diets, mice on LF and LFBB diets continued to demonstrate intact novel object recognition (training versus testing trial RI, $p < 0.05$, Figure

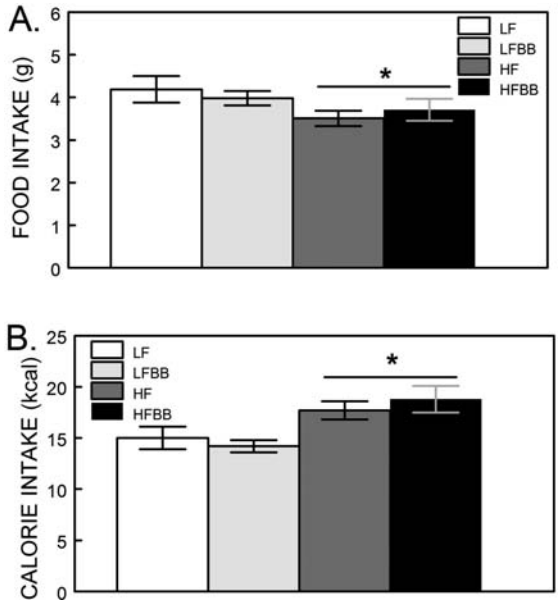

Figure 1. Food (A) and caloric (B) intake. An average of two 24 h food intake measurements indicated that overall the mice that ate HF diets consumed less than the mice that ate LF diets. However, mice on HF diets consumed significantly more calories than those on LF diets. (* $p < 0.05$, significant difference from LF diets, two-way ANOVA.)

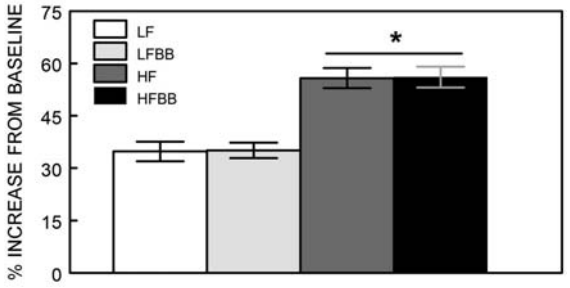

Figure 2. Percent increase in weight after 5 months on diets. Mice on HF diets gained significantly more weight than mice on LF diets. Blueberry had no effect on weight. (* $p < 0.05$, significant difference from LF diets, two-way ANOVA.)

3C), whereas mice on the HF diet continued to show impaired performance ($p = 0.65$). However, mice on the HFBB diet demonstrated a trend toward a difference between RIs in the training and testing trials ($p = 0.056$). After 4 months on the diets, mice on LF and LFBB diets demonstrated intact novel object recognition (testing versus training trial, $p < 0.05$, Figure 3D), whereas mice on the HF diet did not spend more time on the novel object in the testing trial ($p = 0.92$). Mice on the HFBB diet showed a significant increase in time spent on the novel object in the testing trial compared to object B in the training trial ($p < 0.05$).

Another method of examining performance in the novel object recognition task is to compare testing trial performance to chance performance (50% RI). A mouse with intact novel object recognition will spend >50% of its time on the novel object in the testing trials. The LF and LFBB diet-fed mice performed at levels greater than chance during all test sessions ($p < 0.05$, one-sample t test, Figure 4). Mice fed the HF diet did not perform above chance in any test session ($p > 0.05$). The HFBB-fed mice did not perform above chance after 2 months on the diet ($p = 0.23$), but after 3 months on the diet there was a trend ($p = 0.15$), and after 4 months on the diet, the mice demonstrated performance that was significantly greater than chance ($p = 0.02$).

There were no differences between diet groups in the overall amount of time mice explored the objects during novel object recognition testing, indicating that differences in RI were not influenced by differences in general exploration of the objects (effect of diet: $F_{3,164} = 0.930$, $p = 0.93$; diet × test session: $F_{6,165} = 0.507$, $p = 0.80$, two-way ANOVA, data not shown).

Morris Water Maze. There was a trend toward a main effect of fat percentage on the average acquisition day latencies in the MWM ($F_{1,165} = 3.53$, $p = 0.062$, univariate ANOVA), but no effect of BB or interaction of fat percentage × BB on acquisition latency (data not shown). There was no effect of diet on reversal learning latency (data not shown). However, there were differences in passes through the platform location during the probe trials. On the day 2 probe trial, mice that were on the HF diet passed through the platform location significantly less often than the mice on the LFBB diet ($p < 0.05$, t test, Figure 5) and there was a trend from the LF diet (HF versus LF, $p = 0.14$). On the day 3 probe trial, there was a trend that suggested fewer passes through the platform by mice on the HF diet compared to mice on both LF diets (LF, $p = 0.16$; LFBB $p = 0.13$). On all probe trials, there were no differences in the number of passes through the platform location between the HFBB-fed mice and either group of LF-fed mice. There were no differences in probe trial performance during the reversal day between any groups.

DISCUSSION

In this study, middle-aged mice were fed HF or LF diets with and without BB supplementation for 5 months. Mice that were fed HF diets gained significantly more weight than those fed LF diets. This is congruent with the fact that the mice on HF diets were consuming more calories on a daily basis. BB supplementation did not prevent or augment weight gain. This corroborates previous research. BB has been shown to decrease weight gain induced by a HF diet when combined with defatted soybean flour.[22] However, whole BB in the diet has not been shown to prevent weight gain from a 45 or 60% HF diet, although feeding isolated anthocyanins from BB has been demonstrated to decrease weight gain and body fat when fed in conjunction with a HF diet.[23]

Mice fed the HF diet showed impaired novel object recognition performance when tested after 2, 3, and 4 months of consuming the diet. A recent study demonstrated that a HF diet, similar to the diet employed in this study (60% calories from fat), did not impair novel object recognition memory in mice that were approximately 8.5 months old.[7] The mice in our study were 11−13 months of age during novel object recognition testing; thus, the impaired memory demonstrated by the mice in the current study may be due to an interaction of HF diet and age. Mice that were fed the HFBB diet initially showed impaired performance, but their performance improved over subsequent test sessions and, after 4 months on the diet, their performance was no longer impaired. This suggests that over time BB may be able to reverse some of the impact a HF diet may have on certain types of learning and memory. It is unclear why the effect of BB in the current study is time dependent and why the BB did not prevent the initial impairment of novel object recognition associated with consumption of a HF diet. One possible explanation is that there is a threshold level of fat-soluble antioxidants in BB, such

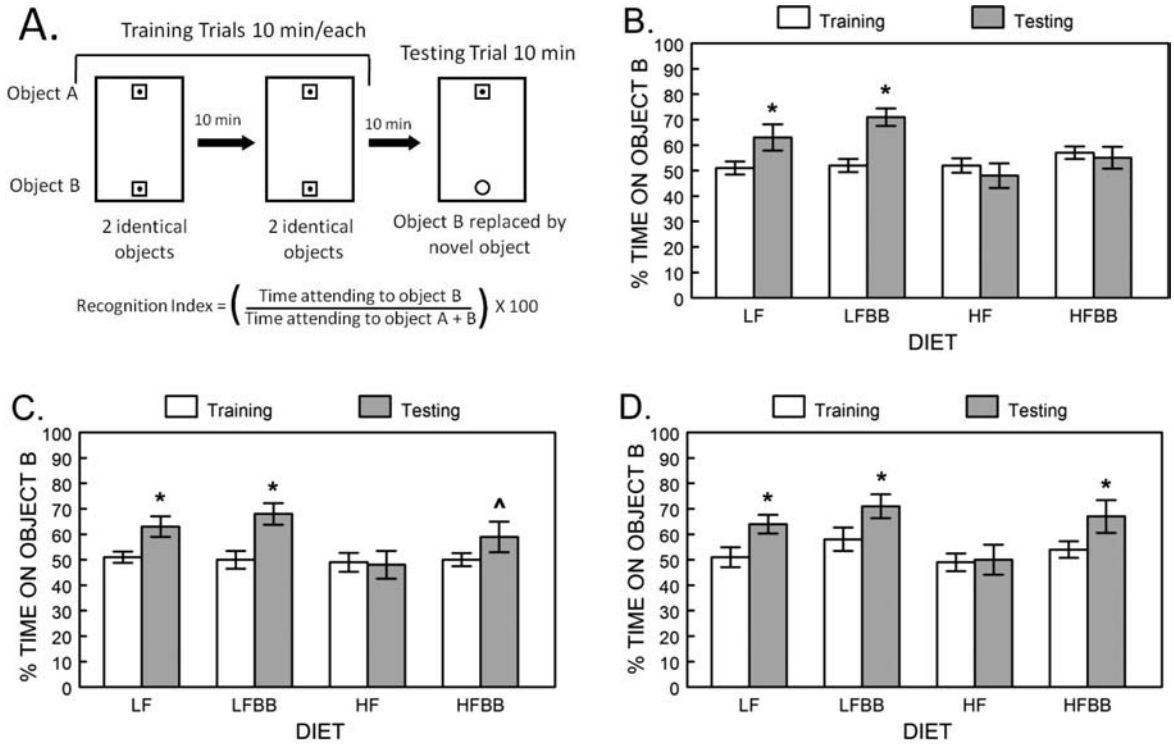

Figure 3. Novel object recognition performance after 2 (B), 3 (C), and 4 (D) months on the diets. (A) The schematic represents testing cages as they were arranged in each trial of testing. (B) After 2 months on the diets, mice on LF and LFBB diets showed a significant increase in RI in the testing trial compared to the training trial, suggesting intact object recognition learning/memory. Mice on HF and HFBB diets did not demonstrate an increase in RI in the testing trial, suggesting impairment. (C) After 3 months on the diets, mice consuming HFBB diet showed a trend toward an increase in RI in the testing trial ($\hat{p} = 0.056$). (D) After 4 months on the diets, mice on LF, LFBB, and HFBB diets showed a significant increase in RI in the testing trial compared to the training trial, whereas the mice on the HF diet did not. ($* p < 0.05$, testing trial is different from training trial, Wilcoxon signed ranks test.)

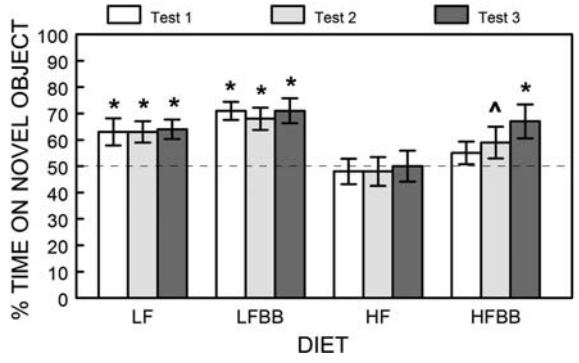

Figure 4. Testing trial performance in the novel object recognition task over three test sessions. The LF- and LFBB-fed mice, but not the mice fed the HF diet, performed at levels greater than chance when tested after 2, 3, and 4 months on the diets (chance is 50% time on the novel object and is indicated by the dotted line). The HFBB-fed mice demonstrated a trend ($\hat{p} = 0.15$) after 3 months on the diet, and after 4 months on the diet, the mice demonstrated performance that was significantly greater than chance. ($* p < 0.05$, one-sample t test compared to a mean of 50%.)

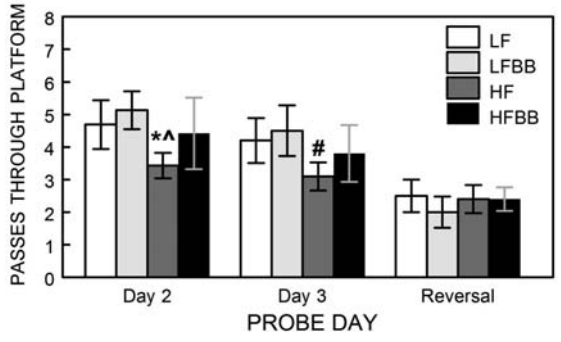

Figure 5. Morris water maze probe trials. On days 2 and 3 of the probe trial, mice that were on the HF diet passed through the platform location less often than the mice on the LF diets. On all probe trials, there were no differences in the number of passes through the platform location between the HFBB-fed mice and either group of LF diet-fed mice. ($* p < 0.05$ from LFBB diet, $\hat{p} = 0.14$ trend from LF, # trend from LF ($p = 0.16$) and LFBB ($p = 0.13$), t test.)

as vitamin A, that must accumulate in the brain to alleviate memory impairment, similar to the "threshold hypothesis" discussed by Malin and colleagues.[24] The time-dependent manner in which novel object recognition memory is rescued by BB supplementation in mice on a HF diet may be attributed to the time course of accumulation of BB fat-soluble antioxidants in the brain, although this remains to be directly tested.

The diets did not have considerable effects on the performance of mice in the MWM; however, during the probe trials, the mice on the HF diet showed deficits in performance. Notably, the probe trial performance of the mice on the HFBB diet did not differ from the mice on the LF diets. The lack of profound effects on latency to find the hidden platform during acquisition learning or reversal learning could potentially be due to a floor effect in which the middle-aged

dx.doi.org/10.1021/jf404565s | J. Agric. Food Chem. 2014, 62, 3972−3978

mice showed age-related deficits that were not significantly worsened by the HF diet or prevented by the BB diet. A recent study found a decline in MWM performance (i.e., path length to the hidden platform) in middle-aged rats, but no further decline due to being on a HF diet.[25] Previous research has demonstrated that BB is able to prevent or reverse age-related performance deficits in spatial mazes such as the MWM,[26] which may suggest that we should have observed improved performance in the LFBB mice. However, the study by Joseph et al.[26] tested old rats in the MWM, whereas our study tested middle-aged mice, so differences in rodent, age, or both, could be a reason for the discrepancy in results.

It is more likely that the lack of more significant differences between groups in this test is due to the possible lack of sensitivity of the MWM to alterations in mouse learning and memory or the diets having different effects on different types of memory (object recognition versus spatial). Water-based mazes such as the MWM were initially developed for rats, which swim in their natural environment, but may not be as ecologically valid for mice that evolved on dry land.[27] For example, mice are more likely to passively float, which could obscure deficits or enhancements in learning and memory. Furthermore, research suggests that object recognition memory may be largely mediated by the perirhinal cortex in the medial temporal lobe,[28] whereas spatial memory is associated with the intact functioning of the hippocampus.[29] Thus, the behavioral results may suggest possible differential effects of the diets in different brain regions.

The mechanisms by which blueberry can modulate the effects of a HF diet were not evaluated in this study. One possibility is that the memory impairment is due to HF diet-related oxidative stress. Morrison et al. found that a HF diet fed to aged mice impaired memory retention in the 14-unit T maze, increased oxidative stress in the brain, and impaired NF-E2-related factor 2, which may play a role in the body's endogenous antioxidant response.[3] BB has been found to reduce oxidative stress in vivo[26] and in vitro.[30,31] Also, BB may have reduced the inflammation elicited by consumption of a HF diet; consumption of a HF diet has been demonstrated to increase the inflammatory cytokines TNFα and IL-6.[4] In studies of aging, BB has been shown to reduce overexpression and overproduction of these inflammatory factors.[32,33] It has also been shown that resveratrol, a component of blueberry, reduces indices of oxidative stress (4-hydroxynonenal) and inflammation (TNFα and ionized calcium binding adaptor molecule 1 expression) in the hippocampus of mice fed a HF diet.[14] A HF diet also has been demonstrated to decrease neurogenesis in the mouse hippocampus,[5] whereas BB has been demonstrated to increase neurogenesis in aged rodents.[34] Furthermore, HF diet consumption has been linked to reductions in brain-derived neurotrophic factor (BDNF) in both the cortex and hippocampus of mice,[5,35] areas crucial for recognition and spatial memory. In contrast, BB has been known to increase BDNF, and this increase was correlated with spatial memory improvements.[36] BDNF is important for hippocampal synaptic plasticity because it can promote morphological changes that support synaptic efficiency and thus influence hippocampus-mediated behaviors, such as spatial learning and memory.[37] There is also the possibility that BB and fat acted synergistically, with dietary fat enhancing the absorption of fat-soluble vitamins such as vitamin A. Vitamin A and its derivatives have been shown to improve memory deficits in aged mice,[38] but the possible interaction between fat and BB intake in the absorption of nutrients necessitates further study.

The Tifblue powder used in this study is made from a rabbiteye variety of BB (*Vaccinium ashei*). Rabbiteye BB has been shown to reduce DNA damage in mouse hippocampus and cortex, areas important for recognition and spatial memory.[39] HPLC analysis of rabbiteye BB has shown it to contain high levels of flavonoid anthocyanidins and anthocyanins.[40] In fact, Li and colleagues found nine different anthocyanins in rabbiteye BB using HPLC-DAD-MS^n, including delphinidin-3-glucoside and petuidin-3-glucoside.[41] Flavonoids have been shown to modulate neuronal signaling pathways that influence synaptic plasticity and neurogenesis, which ultimately can have an effect on learning and memory.[42,43] Flavonoids also can promote neuronal viability and suppress inflammation by inhibiting c-jun N-terminal kinase, apoptosis signal-regulating kinase-1, and p38 pathways, thus preventing neurodegeneration.[42] Therefore, it is likely that the effects of BB are attributable, at least in part, to the biological activities of flavonoids. Flavonoids have been shown to cross the blood−brain barrier,[44] and specifically anthocyanins have been shown to accumulate in the brains of aged rats fed a BB-supplemented diet.[9] A recent study found that aged rats fed diets supplemented with anthocyanins in amounts similar to that found in BB showed increased BDNF in the hippocampus as well as improvements in cross-maze spatial memory performance.[8] Recently, delphinidin-3-glucoside, a component of rabbiteye BB, has been found to reduce the release of proinflammatory mediators from brain microglial cells;[45] thus, the anthocyanin components of BB may be reducing inflammation induced by a HF diet. Furthermore, another component of BB, cyanidin-3-glucoside, has been shown to reduce spatial recognition memory impairment by possibly reducing oxidative stress.[46]

This study supports that adding BB to a HF diet could reverse some of the behavioral deficits associated with consumption of a HF diet, specifically deficits in object recognition memory. It is important to find ways to prevent or reverse the effects that a HF diet may have on the brain and behavior, as the incidence of obesity is increasing worldwide, and consumption of a HF diet has been implicated as a factor in the development of obesity and obesity-related diseases. The purpose of this study was not to encourage consumption of a HF diet, but rather to suggest that making small changes to a putative unhealthy diet, such as incorporating more nutrient-dense foods, could provide some level of protection against cognitive deficits attributed to that diet. This is an important finding that requires further study in both animal models and humans. Furthermore, it is not known the exact mechanism(s) by which BB may be modulating the effects of a HF diet, but research suggests a multitude of probable mechanisms; however, this topic also calls for further study.

Processing of the Blueberry-Containing Baked Product. Wild blueberries (*Vaccinium angustifolium* Aiton) were obtained from the Wild Blueberry Association of North America as a freeze-dried powder, which was stored at −20 °C. The novel blueberry-containing product was composed of 40 g of dough and 20 g of filling and was produced via standard procedures. The dough contained the following ingredients: white flour, freeze-dried blueberry, egg, butter, yeast, salt, skimmed milk powder, sugar, and water, whereas the filling contained freeze-dried blueberry, sugar, salt, evaporated milk, corn flour, and eggs (Table 1). Dough ingredients were combined in a mixer and moistened with water, and finally yeast was incorporated (Figure 1). Dough proving (the step when dough is allowed to rise) was carried out in a prover for 1 h at 30 °C. Filling ingredients were mixed, plastic sealed, and then cooked in a water bath until the temperature reached 90 °C. Following this, 40 g of dough was injected with 20 g of filling, and a second proving step was conducted at 30 °C for 1 h. Finally, the proven bun was baked at 180 °C for 12 min. Sampling was conducted after each stage (Figure 1), and samples were freeze-dried for 4 days prior to powdering and storage at −20 °C until analysis. The proved and baked buns were freeze-dried as a whole and then mixed and powdered together. Homogeneous samples were taken for analysis, representative of both the dough and filling.

Table 1. Blueberry-Containing Bun Formulation

ingredient (% w/w)	dough	filling
blueberry powder	12.4	31.8
egg	5.9	28.7
salt	0.5	0.1
sugar	7.7	22.2
white flour	46.4	
butter	5.9	
yeast	1.1	
skimmed milk powder	4.6	
evaporated milk		12.6
corn flour		4.6

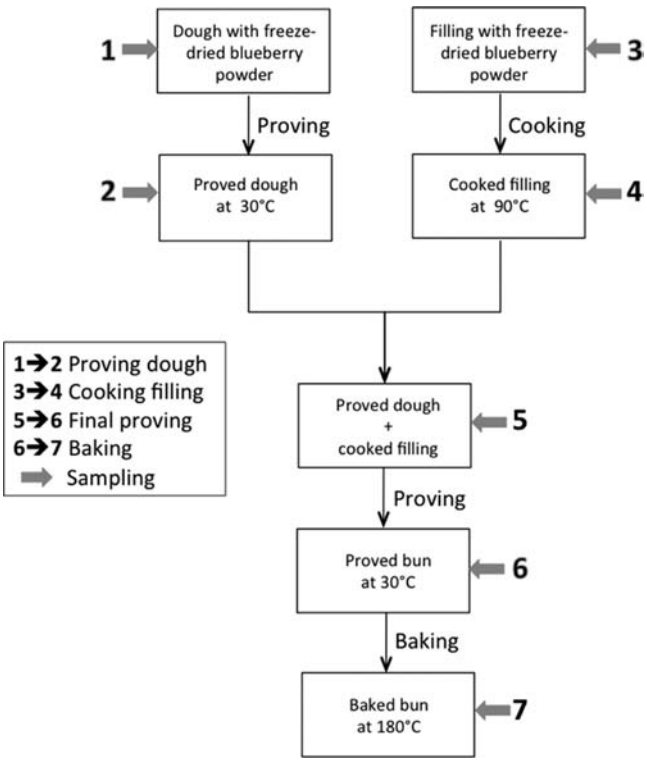

Figure 1. Diagram of the blueberry-containing baked product processing with sampling points indicated: 1 and 2, proving of the dough; 3 and 4, cooking of the filling; 5 and 6, final proving; 6 and 7, baking.

The changes in (poly)phenol content reported at each stage were calculated as changes between the initial (poly)phenol content of dough (in the proving of the dough stage), the initial (poly)phenol content of the filling (in the cooking of the filling stage), the (poly)phenol content of the dough and filling together after proving and cooking (in the final proving stage), and the (poly)phenol content of the final proved bun (in the baking stage) before and after the specific stage investigated (Figure 1). The total changes in (poly)-phenol content were calculated as changes between the initial content of dough and filling together before any processing was carried out and the final content in the baked product. All of the samples analyzed were weighed before and after freeze-drying, and the results were compensated for moisture loss during processing. The results are reported as milligrams per fresh bun.

Extraction of Flavonoids and Phenolic Acids. Extraction of anthocyanins and procyanidins from freeze-dried samples (0.2 g) was performed as previously described.[1] Briefly, anthocyanins were extracted three times with 5 mL of acidified methanol (0.1% HCl in MeOH). Pelargonidin-3-*O*-glucoside was added to the samples as a recovery standard (300 μL, 1 mM). Samples were vortexed for 5 min, sonicated for 5 min in an ultrasonic bath (Fisher Scientific, Loughborough, UK), and centrifuged at room temperature for 15 min at 1800*g*. The supernatants were combined, and 3 mL was mixed with 3 mL of 5 M HCl and heated at 90 °C for 1 h for anthocyanin hydrolysis, in order to cleave all anthocyanins to anthocyanidins. A 50 μL aliquot of filtered sample was injected into the HPLC for analysis.

Procyanidins were extracted from freeze-dried samples (0.5 g) with 5 mL of acetone/water/acetic acid (70:29.5:0.5; v/v/v). Tubes were vortexed for 2 min, sonicated at 50 °C for 5 min, and vortexed again for 1 min. Samples were then centrifuged for 5 min at 2567*g* at room temperature, and the supernatant was retained and passed through a Strata SCX solid phase extraction cartridge (55 μm, 70 Å, 500 mg/3 mL; Phenomenex, Torrance, CA, USA). Conditioning of the SPE packing bed was performed using 5 mL of deionized water on a vacuum (0.2 bar) manifold (24-position, Phenomenex). After conditioning, 2 mL of the supernatant was loaded into the SPE cartridge, and approximately half of the loaded sample was discharged from the cartridge to ensure that the sample was not diluted with the water used to condition the cartridge. A 0.45 μm PTFE filter was placed at the end of the cartridge, and approximately 1 mL was filtered and transfer to an HPLC vial. Five microliters was injected in the HPLC.

Phenolic acids and chlorogenic acid were extracted three times with 5 mL of 10% formic acid in water (v/v). HPPA was added to the samples as recovery standard (50 μL, 10 mM). Samples were vortexed for 1 min, sonicated for 5 min in an ultrasonic bath, vortexed for a further 1 min, and centrifuged for 15 min at 2000*g* at room temperature. The combined supernatants (15 mL) were vortexed, and a 50 μL aliquot was filtered through a 0.22 μm filter prior to transfer to HPLC amber vials. Quercetin was extracted and hydrolyzed to aglycone as follows: Freeze-dried blueberries or samples at different stages of processing (0.2 g) were added to 8 mL of water/methanol (1:1) and vortexed for 1 min to facilitate dissolution. To this extract was added 2 mL of HCl (5 M), and the mixture was vortexed and left to heat on a steam bath at 90 °C for 1 h. After that, the extract was allowed to cool, and 3 mL of mixture was added to 3 mL of methanol. The samples were sonicated, filtered, and injected. Kaempferol-3-*O*-glucoside (50 μL, 10 mM) was used as the recovery standard, after it had been confirmed that this compound was not present in the freeze-dried blueberry samples tested.

HPLC Analysis of Anthocyanidins, Procyanidins, Phenolic Acids, and Quercetin. Samples were analyzed for anthocyanidins, chlorogenic acid, caffeic acid, ferulic acid, and quercetin content as previously described[1] using an Agilent 1100 series HPLC system (Agilent Technologies, Palo Alto, CA, USA) equipped with a diode

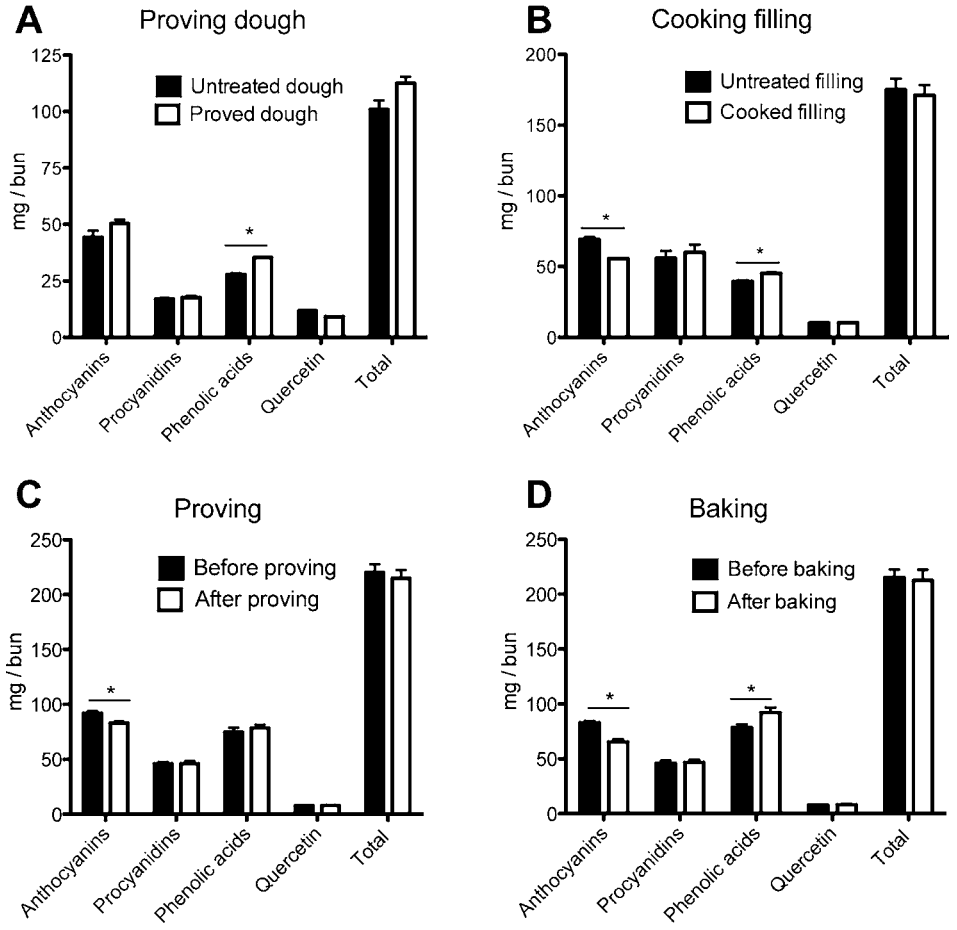

Figure 2. Changes in total anthocyanin, procyanidin, phenolic acid, quercetin, and total (poly)phenol contents during the different stages of processing of a blueberry-containing bun: (A) proving of the dough; (B) cooking of the filling; (C) second proving; (D) baking. Results are expressed as mg/bun ± SEM (n = 3). ∗, $p < 0.05$, significant differences before and after processing.

array detector. The column was a Nova-Pak C_{18} column (250 × 4.6 mm; 4 μm particle size; 30 °C; Waters Ltd., Elstree, UK). The mobile phase consisted of (A) methanol/water/5 M HCl (5:94.9:0.1; v/v/v) and (B) acetonitrile/water/5 M HCl (50:49.9:0.1, v/v/v) and was pumped through the system using the following gradient profile (min/% mobile phase B): 0/5, 5/5, 40/50, 55/100, 59,9/100, and 60/5 with a flow rate of 0.7 mL/min. The eluent was monitored by photodiode array detection at 320 nm (chlorogenic acid) and 520 nm (anthocyanidins) with spectra of products obtained between 220 and 600 nm. Calibration curves were obtained using authentic standards.

For procyanidins, a normal phase HPLC method with fluorescence detection was used as previously described.[1] A Develosil Diol 100 column (250 × 4.6 mm; 100 Å pore size; 5 μm particle size; 35 °C) together with a Cyano Guard column (4 × 3 mm) (Phenomenex) was used for separation. The mobile phase consisted of (A) acetonitrile/acetic acid (98:2; v/v) and (B) methanol/water/acetic acid, (95:3:2; v/v/v)/ and the following gradient system was used (min/% mobile phase B): 0/7, 3/7, 60/37.6, 63/100, 70/100, and 76/7 with a flow rate of 1 mL/min. UV data were collected at 280 nm, and fluorescence detection was conducted with an excitation wavelength of 230 nm and emission at 321 nm. Procyanidins were quantified using external calibration curves obtained using a mix of flavanol oligomer standards (DP1−DP10) isolated from cocoa (Mars, Inc., Hackettstown, NJ, USA). Flavanol polymers (DP > 10) were not quantified.

Statistical Analysis. All results are expressed as means ± SEM of three replicates. The statistical evaluation of the results was performed by one-way analysis of variance (ANOVA) followed by Tukey's post hoc test using GraphPad Prism version 5.0 (GraphPad Software, Inc.). Significance was defined as $p < 0.05$.

RESULTS

Changes in Anthocyanin Content during Processing. Changes in anthocyanin content were evaluated throughout the various steps in the processing chain (Figure 1). The total loss in anthocyanin content throughout all of the processing stages was 42%, with significant decreases in total anthocyanin content observed during cooking of the filling (20%, $p < 0.05$, Figure 2B), second proving (10%, $p < 0.05$, Figure 2C), and baking (21%, $p < 0.05$, Figure 2D). Individual anthocyanin losses ranged from 36% (malvidin) to 48% (peonidin) (Figure 3), and significant decreases were observed after cooking of the filling (malvidin, 18%; delphinidin, 25%; and petunidin, 21%, $p < 0.05$; Figure 3B), after proving (delphinidin, 16%; cyanidin, 13%; and petunidin, 10%, $p < 0.05$; Figure 3C), and during baking (malvidin, 24%; petunidin, 26%; and peonidin, 24%, $p < 0.05$; Figure 3D).

Changes in Procyanidin Content during Processing. No significant differences in total procyanidin content were observed during the different stages of bun processing (Figure 2). However, for the whole process, dimer and trimer levels significantly increased by 36 and 28%, respectively ($p < 0.05$), whereas nonamers and decamers disappeared completely ($p < 0.05$; Figure 4). In the individual stages of processing, significant increases in dimers after cooking of the filling (18%, $p < 0.05$; Figure 4B), second proving (10%, $p < 0.05$; Figure 4C), and baking (9%, $p < 0.05$; Figure 4D) were found; an increase was also observed in trimers after cooking of the

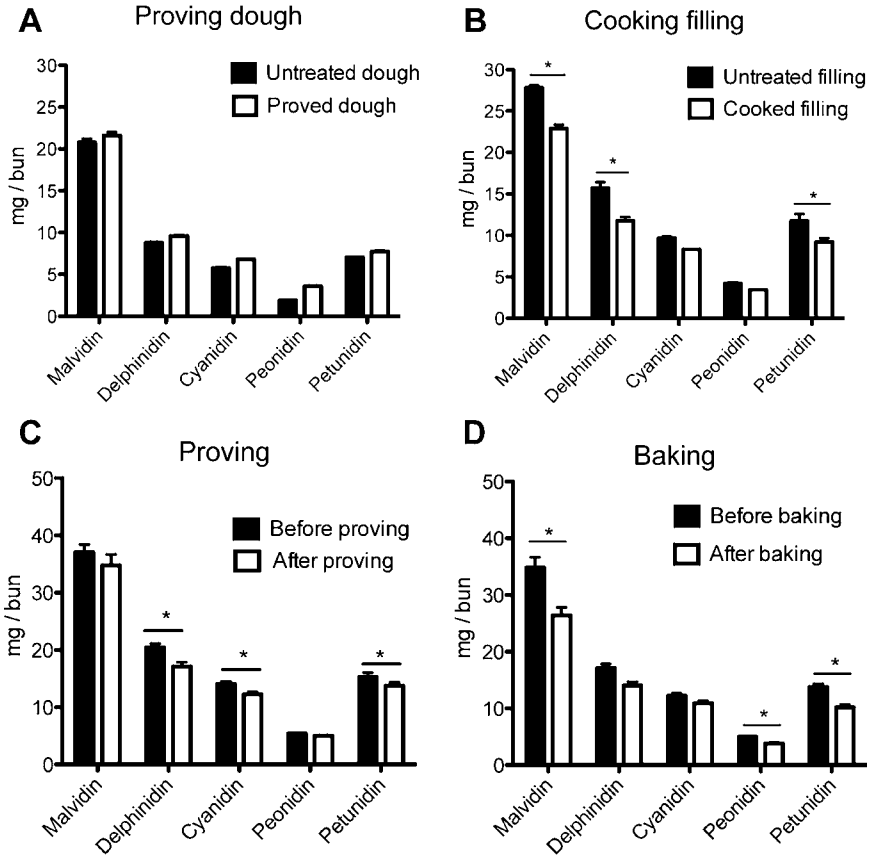

Figure 3. Changes in total malvidin, cyanidin, delphinidin, peonidin, and petunidin contents during the different stages of processing of a blueberry-containing bun: (A) proving of the dough; (B) cooking of the filling; (C) second proving; (D) baking. Results are expressed as mg/bun ± SEM (n = 3). *, $p < 0.05$, significant differences before and after processing.

filling (19%, $p < 0.05$; Figure 4B). In contrast, nonamers and decamers disappeared completely after baking and second proving, respectively (Figure 4C,D).

Changes in Phenolic Acid Content during Processing. For the whole process, a 27% increase in total phenolic acid content was observed. In the individual stages, increases during proving of the dough, cooking of the filling, and baking was found (27, 14, and 17%, respectively, $p < 0.05$; Figure 2A,B,E), which corresponded mostly with increases in 5-*O*-caffeoylquinic acid (chlorogenic acid) (31, 14, and 18% increases after proving dough, cooking filling, and baking, respectively, $p < 0.05$; Figure 5A,B,D), as caffeic and ferulic acid levels did not change through any of the stages of processing.

Changes in Quercetin Content during Processing. Quercetin levels did not significantly change during the whole process or in any of the stages of processing (Figure 2).

Changes in Total (Poly)phenolic Content during Processing. Evaluation of the total (poly)phenol content in the different stages of processing revealed no significant differences in any of the stages (Figure 2).

DISCUSSION

Because of their perishable nature and seasonal availability, berries are often processed and stored prior to consumption. Unfortunately, during handling, processing, and storage of the berry-based products, their (poly)phenols are prone to oxidation, degradation, and polymerization processes. Then, it is not surprising that in the past 10 years considerable research effort has been carried out to preserve as much as possible these compounds from deterioration.[12]

Our findings show that the anthocyanin content of blueberry decreased during cooking, proving, and baking. Cooking of the filling was carried out in a water bath at temperatures lower than 90 °C for 1 h, proving at a constant temperature of 33 °C for 1 h, and baking at 180 °C for 12 min. The total anthocyanin losses in those stages were 20, 10, and 21%, respectively. The magnitudes of the changes were similar to previous work, in which baking frozen blueberries at 175 °C for 15 min reduced anthocyanin levels by 16%[26] and heating at 100 °C for 20 min produced a 32% loss in anthocyanins from blueberry juice.[21] Several studies have investigated the impact of baking on anthocyanin-rich muffins with a formulation similar to that of the one reported here. A decrease in anthocyanin content (approximately 20%) was observed after baking of a raspberry-containing muffin at 177 °C for 25 min.[27] However, baking of a purple wheat bran-enriched muffin at 177 °C for 7−12 min led to a complete loss of anthocyanins,[29] whereas 75−80% losses in cyanidin-3-galactoside were reported after baking of a muffin incorporated with dried skin apple at 175 °C for 20 min.[30] A major difference between the formulations of the muffins was the use of different leavening agents. Rosales-Soto et al.[27] used double-action baking powder as the leavening substance, whereas the two studies in which major anthocyanin losses occurred used baking soda[29] and baking powder.[30] It has been suggested that leavening agents can dramatically affect the polyphenol content of baked products, with baking soda (sodium bicarbonate) producing the biggest losses in

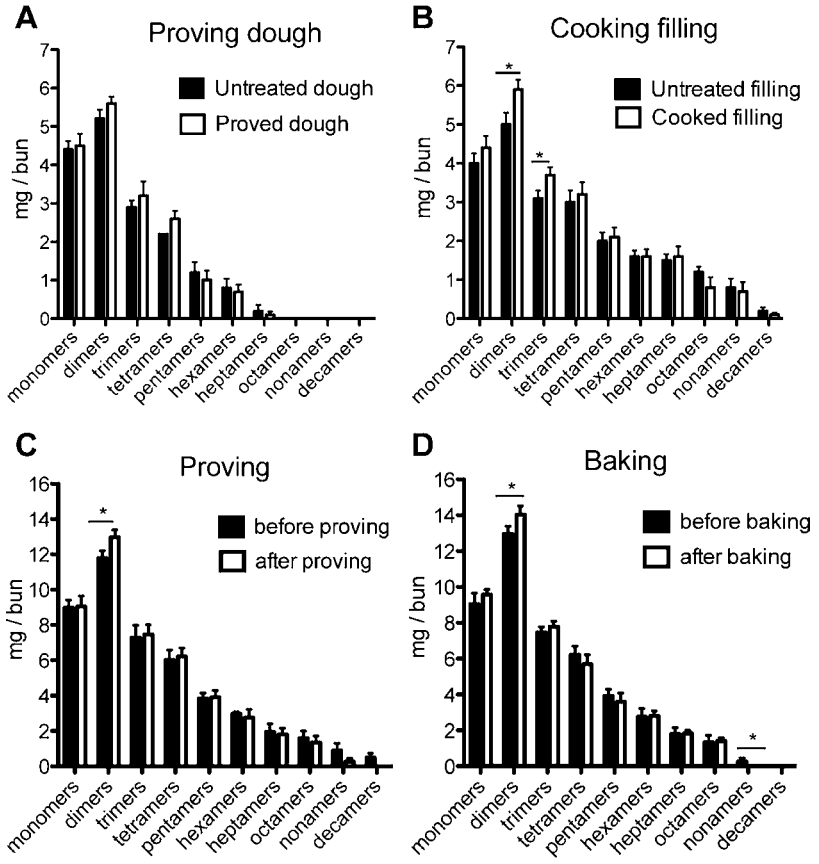

Figure 4. Changes in individual procyanidin (monomers, dimers, trimers, tetramers, pentamers, hexamers, heptamers, octamers, nonamers, and decamers) contents during the different stages of processing of a blueberry-containing bun: (A) proving of the dough; (B) cooking of the filling; (C) second proving; (D) baking. Results are expressed as mg/bun ± SEM (n = 3). *, $p < 0.05$, significant differences before and after processing.

polyphenol content.[31] Indeed, it has been reported that ingredients that induced alkalinity, such as sodium bicarbonate and baking powder, increased the pH of a biscuit dough and decreased the stability of green tea catechins.[32] Furthermore, addition of acidulants such as citric or lactic acid increased the anthocyanin content of blue corn cookies prepared with baking soda by decreasing the pH of the dough and the cookies.[28] Double-action baking powder contains two types of acids, one that acts quickly in a wet mixture with baking soda at room temperature and a slow-acting acid that will react later when heated in an oven. It is thus possible that the use of double-action baking powder retained better the polyphenols by producing a greater acidic pH for longer time. In the present study, we used yeast as leavening agent. Yeast reduces the pH of the dough by producing small acidic compounds such as lactic or acetic acid when fermenting, which could explain the good retention of anthocyanins observed here. Yeast has been recently suggested to be a good vehicle to prevent polyphenols from degradation,[33] and incubation of an anthocyanin-rich Maqui berry juice with yeast led to an increase in anthocyanin concentration.[33] This is in agreement with the work of Wang et al., which showed that baking bread enriched with a green tea extract using yeast led to good retention of green tea catechins (83–91%).[34]

In this work, the total amount of blueberry procyanidins remained constant during processing; however, an increase in lower molecular weight oligomers and a decrease in higher molecular weight oligomers were observed. The greatest increase was found in dimers and trimers, whereas nonamers and decamers completely disappeared. This is consistent with the increase in flavanol monomers in comparison with procyanidins reported after the baking of chocolate cakes[31] and the increase in procyanidin monomers, dimers, and trimers after a freeze-dried blueberry pomace had been subjected to extrusion at 180 °C, with higher oligomers decreasing considerably after extrusion.[35] Processing of blueberries into juiced, canned, and pureed products also resulted in greater retentions of monomers and dimers than of larger oligomers in all products.[24] A plausible explanation for the effects shown in our baked product could be that large oligomers bonded to dough ingredients, for example, proteins, via hydrogen bonding and hydrophobic interactions and resisted extraction more than the smaller oligomers and monomers.

Another major finding of this work is that chlorogenic acid levels increase significantly after dough proving, cooking, and baking. It has been reported that baking frozen blueberries for 15 min at 175 °C did not significantly change their chlorogenic acid levels.[26] However, an increase in phenolic acids including chlorogenic acid after heat treatment has been reported in tomatoes, green beans, pepper, broccoli, and potatoes.[36−41] In baked products where alkalinizing agents such as baking soda or baking powder were used, baking led to a decrease in chlorogenic acid and total phenolic content,[29,30] whereas when yeast was used, increases in phenolic acids were observed after baking.[42] Thus, the increases in chlorogenic acid shown here may be due to a combination of the effects of yeast, which may have improved the retention of chlorogenic acid as in the

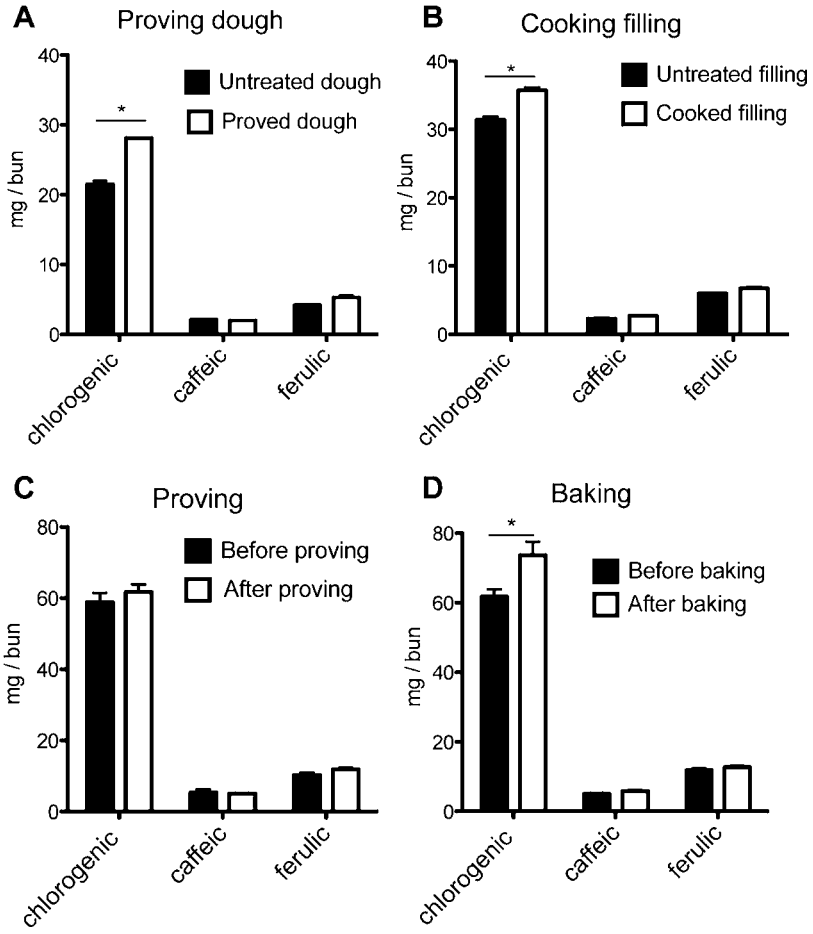

Figure 5. Changes in chlorogenic, ferulic, and caffeic acid contents during the different stages of processing of a blueberry-containing bun: (A) proving of the dough; (B) cooking of the filling; (C) second proving; (D) baking. Results are expressed as mg/bun ± SEM (n = 3). *, $p < 0.05$, significant differences before and after processing.

case of anthocyanins, and heating, which may have disrupted the blueberry−dough matrix, facilitating further extraction.

In summary, procyanidins, flavonols, and phenolic acids were found to be more stable than anthocyanins during the different stages of processing. Cooking of the filling and baking were the processes that resulted in the most degradation of anthocyanins, mainly due to the instability of these compounds at higher temperatures. The choice of leavening agents may be a critical factor for the stability of (poly)phenols during baking, with yeast being more suitable than baking powders to improve the retention of these compounds in baked products. Lower molecular weight procyanidins seemed to increase in the process, probably due to the higher molecular weight degradation and conversion into lower molecular weights. This is of particular importance, as it has recently been shown that procyanidins are not absorbed in the small intestine and only monomers and, to a very limited extent, dimers are absorbed.[43] However, higher oligomers and polymers can be metabolized by the microflora in the lower gut into small molecules such as phenolic acids, and the absorption of these compounds from the colon may still impart health benefits.[44,45] The effects of processing and storage on the bioactive properties of berry-based products have been scarcely investigated, and those studies that have been carried out (thermal versus nonthermal treatments, storage time, etc.) just evaluated the antioxidant capacity, not their effects on relevant markers of chronic disease. In this study we provide further information regarding the impact of processing on the (poly)phenol content of blueberry, which may be of relevance to epidemiological and human intervention studies aiming at understanding the health benefits of this (poly)phenol-rich food.

Table 2. Phenolic Acids Analyzed in Urine with Common Names, Abbreviations, MRM Transition Ion Pair Used for Quantification, and Retention Time (Rt) on Chromatographic Column

phenolic acid	common name	abbreviation	MW	ion pair	Rt (min)
4-hydroxybenzoic acid		4HBA	138	137.4/93.1	11.6
3-hydroxybenzoic acid		3HBA	138	137.4/93.1	14.7
3,4-dihydroxybenzoic acid	protocatechuic acid	3,4HBA	154	152.5/109.2	6.7
3,4,5-trihydroxybenzoic acid	gallic acid	GA	170	169.2/124.9	3.6
2,5-dihydroxybenzoic acid	gentisic acid	2,5HBA	154	153.3/107.9	12.4
3-methoxy-4-hydroxybenzoic acid	vanillic acid	VA	168	166.7/122.7	13.7
3,4-dihydroxyphenylacetic acid	homoprotocatechuic acid	3,4HPAA	168	166.7/122.7	6.5
1,3,4,5-tetrahydroxycyclohexanecarboxylic acid 3-(3,4-dihydroxycinnamate)	chlorogenic acid	CGA	354	353.0/191.0	12.0
3-methoxy-4-hydroxyphenylacetic acid	homovanillic acid	HVA	182	180.8/136.7	12.7
3-hydroxyphenylacetic acid		3HPAA	152	150.7/106.9	14.0
4-hydroxyphenylacetic acid		4HPAA	152	150.7/106.9	12.9
3,4-dihydroxycinnamic acid	caffeic acid	3,4HCA	180	179.0/134.7	14.4
3-hydroxyphenylpropionic acid	phloretic acid	3HPPA	166	164.8/120.9	19.8
4-hydroxyphenylpropionic acid	hydrocinnamic acid	4HPPA	166	164.8/120.9	22.2
4-hydroxycinnamic acid	*p*-coumaric acid	4HCA	164	162.7/118.8	22.0
3-hydroxycinnamic acid		3HCA	164	162.7/118.8	25.7
4-hydroxy-3-methoxycinnamic acid	ferulic acid	FA	194	192.8/133.8	23.6
benzoylaminoacetic acid	hippuric acid	HA	179	178.3/134.0	10.3

both of which were provided fresh on a weekly basis. Cages were changed weekly. The experimental animal protocol was approved by the Animal Care and Use Committee of the University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Chemicals and Phenolic Acid Standards. All chemicals used in the study were of HPLC grade or higher and were obtained either from Fisher Scientific (Hampton, NHm USA), Sigma-Aldrich (St. Louis, MO, USA), or SynerMed (Monterey Park, CA, USA). Standards for phenolic acids were obtained from Sigma-Aldrich, and their names and abbreviations are listed in Table 2 with primary structures depicted in Figure 1.

Urine Collection. Between days 30 and 40 of the experiment, six rats from each treatment were transferred to individual metabolic cages to monitor urine output over a period of 48 h during steady state, chronic consumption of the berry diets. Urine output was recorded, samples were collected in 15 mL conical tubes and centrifuged at 1000*g* for 15 min, and the supernatant was stored at −70 °C until further analysis.

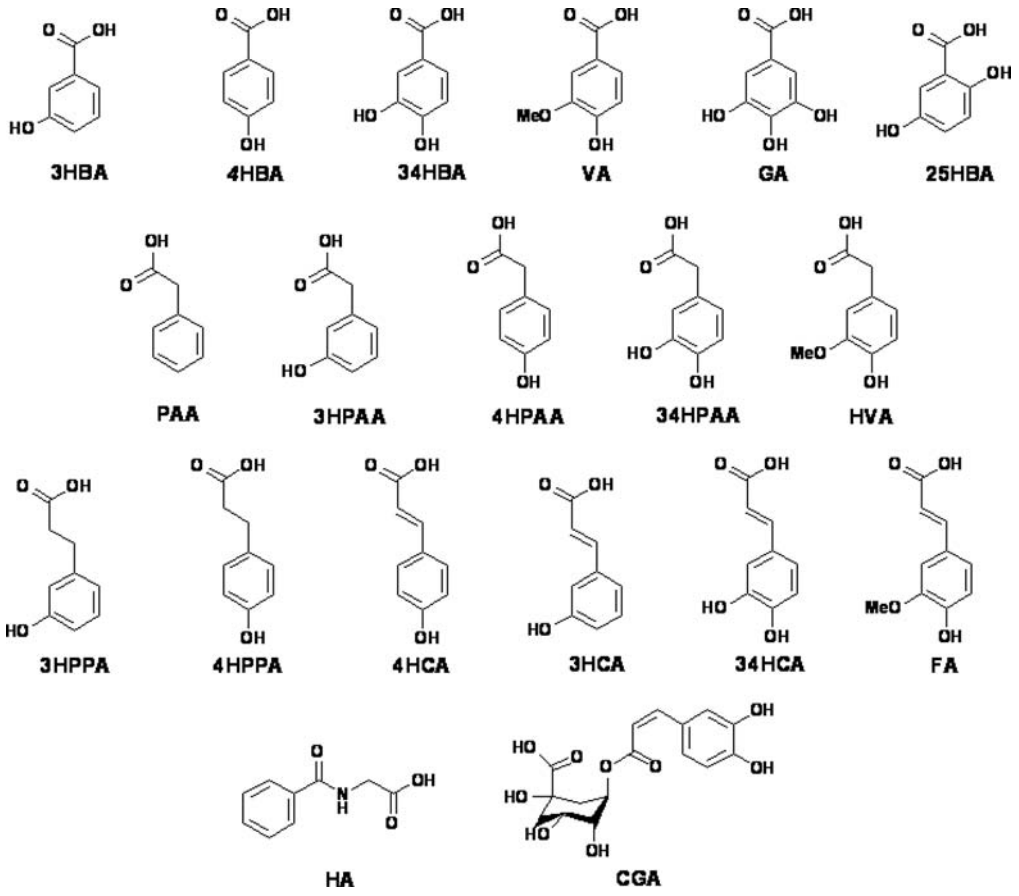

Figure 1. Chemical structures of phenolic acids investigated in the current study. Names and symbols of all phenolic acids are listed in Table 2.

Urine Treatment for Phenolic Acid Analysis. For analysis of free phenolic acids, urine samples were purified by solid phase extraction (SPE) using a Waters Sep-Pak Vac RC (500 mg) C_{18} cartridge. The column was washed with 3 mL of 100% MeOH and then equilibrated with 3 mL of 0.2% formic acid in H_2O. Thawed urine (200 μL) was loaded onto the column and then washed with 3 mL of 0.2% formic acid in H_2O. The sample was eluted with 2 mL of 0.2% formic acid in MeOH, and the solvents were evaporated with nitrogen to <1 mL. Samples were adjusted to 1 mL in volumetric flasks with 0.2% formic acid in MeOH. Extraction was carried out in duplicate.

For analysis of total phenolic acids, 200 μL of thawed urine was added to 1.8 mL of enzyme solution containing 1 M ammonium acetate, 0.5 mM ascorbic acid, and 110 U sulfatase (*Helix pomatia*; Sigma, S9626) in a screw-cap glass tube. After incubation for 2 h at 37 °C, 100 μL of acetic acid was added to each tube. The same SPE procedure mentioned above was used for purifying total phenolic acids; 200 μL of the enzyme-treated urine sample was added to the column in place of the 200 μL of urine. The quantities of conjugated PA were calculated by subtracting the free phenolic acid from the total phenolic acid obtained following enzyme treatment.

Analysis of Phenolic Acids. Total, free, and conjugated PA were analyzed using an LC-MS/MS consisting of an Agilent 1100 high-performance liquid chromatography (HPLC) system equipped with a diode array detector (Agilent Technologies, Santa Clara, CA, USA) coupled to a 4000 QTRAP mass spectrometer (Applied Biosystems, Forest City, CA, USA). Separation was performed on a Phenomenex Synergi Max-RP column (150 × 3.00 mm, 4 μm) using a flow rate of 0.4 mL/min. The mass spectrometer used an electrospray interface in negative ionization mode. Electrospray ionization tandem mass spectrometry (ESI-MS/MS) was conducted using a QTRAP quadrupole-linear ion trap (QLIT) instrument equipped with a Turbo Ion Spray (TISP) interface (Applied Biosystems/MDS Sciex, Concord, ON, Canada). The whole LC-MS system was controlled by Analyst software (v. 1.4.1, Applied Biosystems/MDS Sciex). Multireaction monitoring (MRM) mode scan was performed to selectively monitor the compound to be identified and quantified with a specific parent mass and its unique fragment ion (Table 2). The solvent consisted of (A) 0.2% formic acid in water and (B) methanol. The 35 min linear gradient was as follows: 0−2−20−21−29−30−35 min with 20−20−35−40−60−70−20% B, followed by a 6 min re-equilibration of the column before the next run. Further details about the HPLC as well as the operating conditions on the mass spectrometer and recoveries of the phenolic acids have been described previously.[11] Molecular weights, MRM transition pairs, and retention times of PA are provided in Table 2.

Extraction of Phenolic Acids in the Berries. For analysis of the free forms of the PA, approximately 250−400 mg of sample was weighed directly into a glass culture tube with a threaded end. Eight milliliters of methanol/water (50:50; v/v, MeOH/H_2O) was added to each sample. Tubes were capped tightly and incubated for 2 h at 90 °C with vortexing every 30 min. Samples were cooled overnight at −20 °C and centrifuged at 4 °C for 15 min at 3600*g*. The supernatant was adjusted to 10 mL in a volumetric flask with 100% MeOH and aliquoted to HPLC vials after syringe filtration with a 0.22 μm filter. Samples were stored at −20 °C until analysis.

Analysis of Procyanidins and Anthocyanins in Berries. The berries included in the diet were analyzed for their procyanidin and anthocyanin profiles using HPLC. Separations based on degree of polymerization (DP) were conducted using a Develosil Diol column (250 × 4.6, 5 μm, Phenomenex, Torrence, CA, USA). Details about the procyanidin extraction, HPLC conditions, mobile phase, gradient, standards, and peak identification have been described previously.[12,13]

Anthocyanins were extracted from the freeze-dried berry powders using methanol/water/acetic acid (MWA) (85:15:0.5, v/v) as described previously.[14] Sample (1 g) was weighed and put into a 15 mL screw-cap tube and extracted with 15 mL of MWA, then vortexed

3-hydroxyphenylpropionic acid (3HPPA)	4.2	1.8	ND

[a]ND = not detected. [b]DP = degree of polymerization of monomeric catechin/epicatechin units. [c]3-Hydroxyphenylacetic acid, 3,4-dihydroxyphenylacetic acid, 3-methoxy-4-hydroxyphenylacetic acid, 2,5-dihydroxybenzoic acid, 3-hydroxycinnamic acid, 4-hydroxyphenylpropionic acid, and hippuric acid were not detected in any of the berry powders used in this study.

for 30 s followed by sonication for 5 min. The tube was then centrifuged at 4550*g* for 10 min and the supernatant removed. The sample was extracted one more time with 10 mL of MWA using the same procedure, and the supernatants were combined. The combined supernatant was transferred into a 25 mL volumetric flask, and MWA was added to make up the final volume to exactly 25 mL. The solution was further diluted appropriately and filtered using a 0.22 μm Teflon syringe filter for analysis. A Zorbax Stablebond Analytical SB-C18 column (4.6 × 250 mm, 5 μm, Agilent) was used for separating anthocyanins with diode array detection as previously described.[12]

Statistical Analysis. Data were analyzed using one-way analysis of variance in SigmaPlot (Systat Software Inc., San Jose, CA, USA) and are presented as means ± SEM. Post hoc mean separation was performed using Holm−Sidak method whenever appropriate.

RESULTS

Major Dietary Free Polyphenols in Berries. The three berries included in the diets in this study had significant differences in their polyphenol profiles. Only 10 of the 18 phenolic acids studied in the current study were detected in the free form in the berries, with BRB containing only 8 phenolic acids (Table 3). 3-Hydroxyphenylacetic acid, 3,4-dihydroxyphenylacetic acid, 3-methoxy-4-hydroxyphenylacetic acid, 2,5-dihydroxybenzoic acid, 3-hydroxycinnamic acid, 4-hydroxyphenylpropionic acid, and hippuric acid were not detected in free form in any of the berry powders used in this study, although they were present in some of the urine samples from the different diet treatments.

Whereas chlorogenic acid was the primary phenolic acid present in BB and CB, it was present only in small amounts in BRB, where 3,4-dihydroxybenzoic acid was the major dietary phenolic acid followed by 4-hydroxycinnamic acid. A majority of the free phenolic acids present in the berries was present in rather small amounts (<10 μg/g). Although only a small amount of 4-hydroxycinnamic acid was detected in CB, it was a major phenolic acid present in BB and BRB. BRB contained small amounts of procyanidins (0.103 mg/g dry weight, Table 3), but high amounts of anthocyanins (70.5 mg/g dry weight) that were predominantly cyanidin derivatives (>95% of the total; Table 3). Cranberry, on the other hand, contained small amounts of anthocyanins (5.3 mg/g dry weight), but much larger amounts of procyanidins. The total procyanidin content of BB was similar to that of CB, but BB had lower amounts of dimers and trimers. The anthocyanin profile of BB contained 32 anthocyanins, but none of the individual anthocyanins were present in concentrations >5 mg/g DW compared to BRB, which contained high levels of cyanidin-3-rutinoside (40.4 mg/g DW) (Table 3).

Phenolic Acid Excretion. Steady-state quantities of free, total, and conjugated phenolic acids excreted in the urine over a 24 h period are presented in Table 4. Of the 18 PA investigated, all phenolic acids, except 3-methoxy-4-hydroxybenzoic acid, were detected in the urine of rats across treatments in free form, albeit at low concentrations for some. Free 3-methoxy-4-

Table 4. Excretion of Free Phenolic Acids (Mean ± SEM, μg/day) from Rats Fed a Control Diet, High-Fructose Diet (HF), and High-Fructose Diets with Cranberry (HF + CB), Blueberry (HF + BB), and Black Raspberry (HF + BRB)[a]

[a]Diets contained 5% of the respective whole berries on dry weight basis. Means without a common letter differ; $p < 0.05$, one-way ANOVA. Means without a common letter differ and represent six observations per treatment. ND = not detected. Values in bold represent phenolic acids that were excreted in largest amounts of the three berry treatments.

hydroxybenzoic acid was not present in the urine of animals fed the polyphenol-free control and HF diets, but was present in the urine in conjugated form.

Inclusion of berries in the diet increased the urinary excretion of seven phenolic acids (Table 4). Total excretions of 3,4-hydroxybenzoic and 2,5-hydroxybenzoic acids were increased by <10 μg/day (Table 4), but berry treatments significantly increased the total excretion of 3-hydroxybenzoic (Figure 2), 3-hydroxycinnamic (Figure 3), 3-hydroxyphenylpropionic (Figure 4), and 3-hydroxyphenylacetic acids (Figure 5) by 25−420 μg/day (Table 4) and that of hippuric acid by 2000−6400 μg/day compared to the control dietary treatments (Table 4).

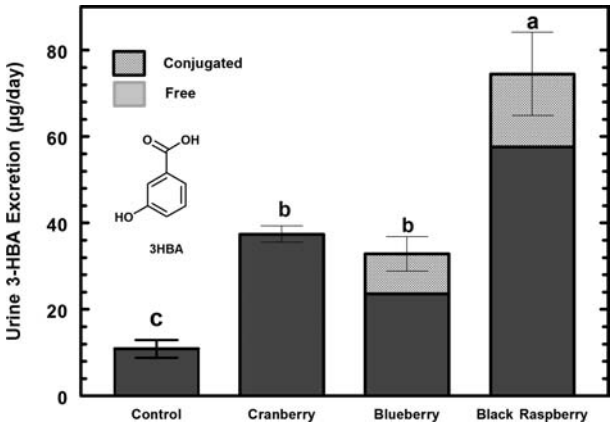

Figure 2. 3-Hydroxybenzoic acid (3-HBA) excretion in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. The fructose-fed group is presented in the "control" bar. 3-Hydroxybenzoic acid was not present in any of the diets (Table 3). 3-Hydroxybenzoic acid was not present in conjugated form in the urine of control or cranberry treatment groups. Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic ($n = 6$/group).

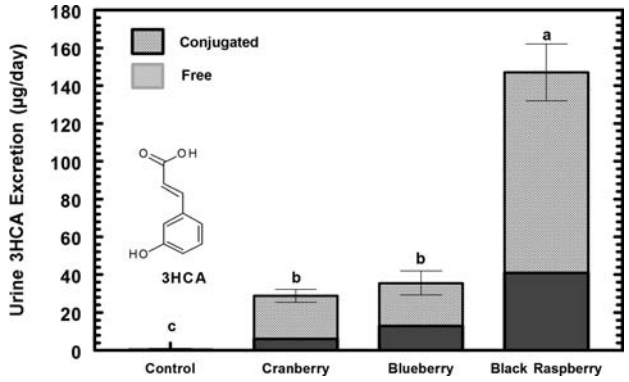

Figure 3. 3-Hydroxycinnamic acid (3-HCA) excretion in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. The fructose-fed group is presented in the "control" bar. 3-Hydroxycinnamic acid was not present in any of the diets (Table 3). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic ($n = 6$/group).

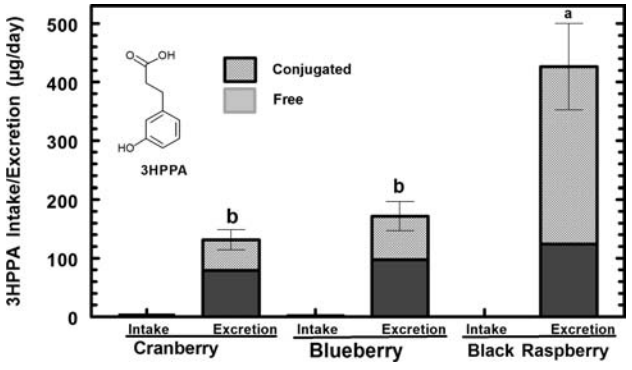

Figure 4. 3-Hydroxyphenylpropionic acid (3HPPA) consumed in the diet and excreted in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. 3HPPA was not present in the control or HF diets and was excreted in the urine in low quantities in these diets, which were significantly lower than any of the berry treatment groups (Table 4). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic acid ($n = 6$/group). Intake column represents the free phenolic acid consumed (μg/day), which was present in the berry powder in the diet.

There were specific phenolic acids for which urinary excretion was uniquely altered by the different berries. Feeding CB significantly increased urinary excretion of total 4-hydroxycinnamic acid (Table 4; Figure 6) and 3-methoxy-4-hydroxyphenylacetic acid (Table 4; Figure 7) by >180 μg/day and that of hippuric acid by >6000 μg/day relative to the control dietary treatments (Table 4). With BB feeding, total excretion of chlorogenic acid, ferulic acid, and 3,4-dihydrox-

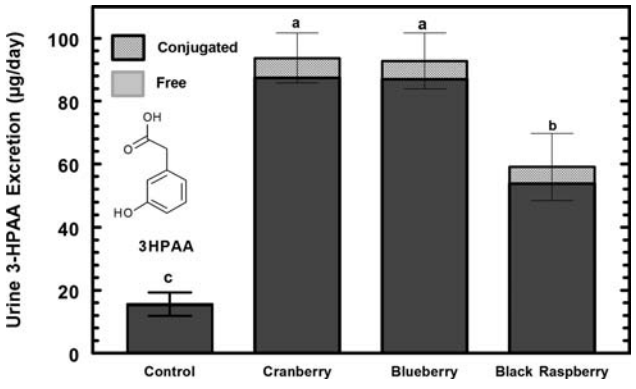

Figure 5. 3-Hydroxyphenylacetic acid (3HPAA) excretion in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. The fructose-fed group is presented in the "control" bar in the figure. 3HPAA was not present in any of the diets (Table 3). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic acid ($n = 6$/group).

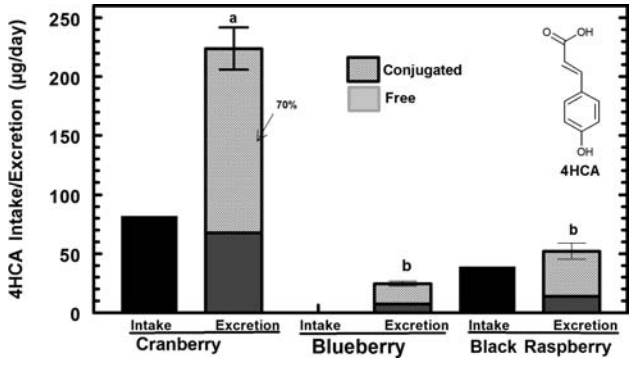

Figure 6. 4-Hydroxycinnamic acid (4HCA) consumed in the diet and excreted in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. 4-Hydroxycinnamic acid was not present in the control or HF diets and was excreted in the urine in low quantities in these diets (Table 3). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic acid ($n = 6$/group). 4-Hydroxycinnamic acid excretion in the HF control group was not significantly different from the blueberry treatment group (Table 4). Intake column represents the free phenolic acid consumed (μg/day) which was present in the berry powder.

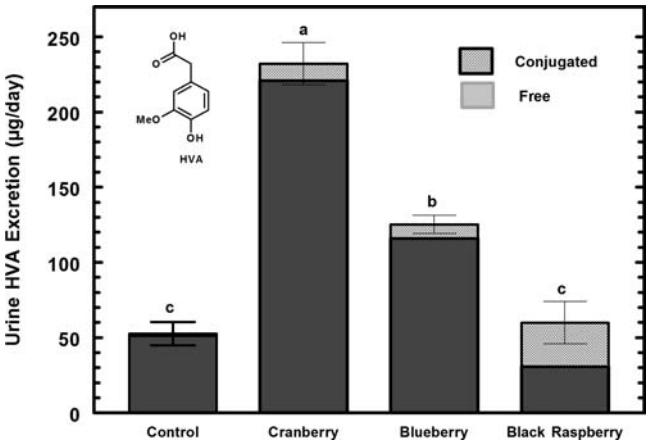

Figure 7. 3-Methoxy-4-hydroxyphenylacetic acid (HVA) excretion in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. The fructose-fed group is presented in the "control" bar. HVA was not present in any of the diets (Table 3). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic ($n = 6$/group).

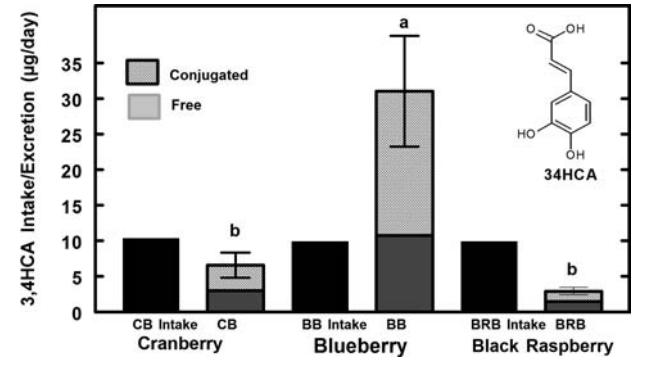

Figure 8. 3,4-Dihydroxycinnamic acid (3,4HCA) consumed in the diet and excreted in the urine of rats fed cranberry, blueberry, or black raspberry in the diet. 3,4-Hydroxycinnamic acid was not present in the control or HF diets and was excreted in the urine in low quantities in these diets, which was not significantly different ($p > 0.001$) from the cranberry or black raspberry treatment groups (Table 4). Bars with different letters above are significantly different ($p < 0.001$). SEM above bar represents variation in the total (free plus conjugated) phenolic acid ($n = 6$/group). Intake column represents the free phenolic acid consumed (μg/day), which was present in the berry powder.

ycinnamic acid (Figure 8) was elevated relative to the CB and BRB dietary treatments (Table 4). Ferulic acid was present in the largest amount in the BB and BRB diets (Table 3). With BRB feeding, the excretion of total 3-hydroxybenzoic, 3-hydroxycinnamic, and 3-hydroxyphenylpropionic acids were elevated relative to the CB and BB dietary treatments (Table 4). Hippuric acid was excreted in the highest amounts, and its quantity exceeded all the other phenolic acids combined, particularly in the free and total forms.

Between the two polyphenol-free diets, the excretion pattern of all the phenolic acids was similar irrespective of their form between the control starch-containing diet and the high-fructose diet except for ferulic acid and 4-hydroxycinnamic acid, which could have been present in the starch that was used in the starch control diet.

Twelve of the 18 phenolic acids investigated in the current study were also detected in their conjugated forms, proportions (% of total) that have been presented in Table 5. Phenolic acids that were either not detected in the urine or excreted in small amounts in their conjugated forms include 3-hydroxyphenylacetic, 4-hydroxyphenylacetic, 3,4-dihydroxyphenylacetic, gallic acid, 2,5-dihydroxybenzoic, chlorogenic, and 4-hydroxyphenylpropionic acids, none of which changed significantly ($p > 0.1$) with the inclusion of berries in the diet when expressed as percent of total excreted in the urine (Table 5). However, for some of these the extent of conjugation was rather small (0–12%) relative to the total amount excreted. Excretion of conjugated forms of 4-hydroxybenzoic, 3,4-dihydroxybenzoic, 3-hydroxycinnamic (Figure 3), 4-hydroxycinnamic (Figure 6), and 3,4-dihydroxycinnamic acids (Figure 8) were either close to or >50% irrespective of the dietary treatments. Excretion of ferulic and 3-methoxy-4-hydroxybenzoic acids in their conjugated forms was 85% or higher in the berry-treated animals.

DISCUSSION

Diet can be a major factor contributing to the phenolic acids excreted in the urine because phenolic acids can be produced not only by colonic microflora from a number of polyphenolic compounds, such as procyanidins and anthocyanins but also endogenously from different amino acids, such as glycine, tyrosine, and phenylalanine. This study was aimed at understanding the conjugation and excretory pattern of phenolic acids after feeding whole freeze-dried powders of polyphenol-rich cranberry, blueberry, and black raspberry in the diet and to determine if there is a unique pattern for each berry. The amount of freeze-dried powder used in this study (50 g/kg diet) would be equivalent to consumption of approximately 300 g (2−3 cups) of fresh berries in a 70 kg human.

With the feeding of CB in this study, increased excretion of total 4-hydroxycinnamic acid was uniquely specific to CB compared to BB or BRB (Table 4; Figure 6). Although there was appreciable intake of 4-hydroxycinnamic acid in the CB (Figure 6), the excretion of 4-hydroxycinnamic acid was nearly 3 times that consumed. Although there was a significant but lesser intake of 4-hydroxycinnamic acid from black raspberry, this did not result in a large increase in the total urinary 4-hydroxycinnamic acid excretion.

There was no specific phenolic acid for which increased excretion was totally unique to BRB but excretion of 3-hydroxybenzoic (3HBA) (Figure 2), 3-hydroxycinnamic (3HCA) (Figure 3), and 3-hydroxyphenylpropionic (3HPPA) (Figure 4) acids was increased with BRB feeding relative to CB and BB. BRB contains appreciable levels of ellagitannins, and thus the excretion of urolithins might be expected to be increased with BRB feeding,[15] although they were not analyzed in this study. Increased excretion of 3-hydroxybenzoic acid (3HBA) (Figure 2) and 3-hydroxycinnamic acid (3HCA) (Figure 3) with all three berry treatments occurred even though neither of these phenolic acids was detected in the berries (Table 3) and thus are likely metabolites of 3,4-hydroxybenzoic and 3,4-hydroxycinnamic acids, respectively. Increased excretion of chlorogenic acid was unique to the BB treatment (Table 4), but the increase was small relative to the amount of chlorogenic acid in BB and CB (Table 4). In a previous study using a concentrated cranberry powder in the diet (33 g/kg diet),[11] increases in urinary excretion of 3-hydroxycinnamic (Figure 3), 4-hydroxycinnamic (Figure 6), and 3-hydroxyphenylacetic (Figure 7) were proportional to the amount of cranberry concentrate in the diet. The amount of concentrate used in the previous experiment[11] would have provided more polyphenolics in the diet than the 50 g/kg of whole berry powder used in the present study.

Phenolic acids excreted in the highest amounts were hippuric, 3-methoxy-4-hydroxyphenylacetic, 4-hydroxycinnamic, 3-hydroxycinnamic, 4-hydroxybenzoic, and 4-hydroxyphenylacetic acids, with or without berries in the diet. Hippuric acid, also called benzoylglycine, can be produced by conjugation of benzoic acid with the amino acid glycine. Benzoic acid can be produced as a degradation product of both polyphenols and phenolic acids as well as by phenylalanine metabolism in the gut. Whereas considerable amounts of hippuric acid are excreted in the urine of animals fed polyphenol-free diets,[11,16] its urinary excretion increases with the ingestion of polyphenols in humans as well as other animals.[17−19] Furthermore, its urinary excretion in rats has been shown to increase dose dependently with increasing amounts of procyanidins from a diet containing sorghum bran, which is rich in procyanidins.[17] Whereas CB and BB contained similar amounts of total procyanidins, BB contained proportionately greater amounts of the higher oligomers and polymers than CB, and excretion of hippuric acid was greater with BB feeding than with CB. BRB contained only small amounts of procyanidins and hence had the lowest amount of hippuric acid excreted in the urine among the three berry-fed animal groups. Irrespective of the diet, hippuric acid was excreted primarily in the free form. 4-Hydroxybenzoic, 3-methoxy-4-hydroxybenzoic, 3-methoxy-4-hydroxyphenylacetic, and 4-hydroxyphenylacetic acids can originate from dietary amino acids, primarily tyrosine and phenylalanine.[17,20,21] As a result, although their presence in the urine could be expected irrespective of the dietary presence of polyphenols, their forms and amounts may differ depending on the type and amount of polyphenols in the berries.

In rats fed the polyphenol-free diet, no free 3-methoxy-4-hydroxybenzoic acid was detected in animals, indicating that the relatively small amounts of free forms excreted in the urine with berry feeding originated from the polyphenols in the berries (Table 4). However, there was no change in the total or conjugated 3-methoxy-4-hydroxybenzoic acid excretion in the urine, suggesting that all of the conjugated and a majority of the total 3-methoxy-4-hydroxybenzoic acid originated from dietary amino acids. Tyrosine can be converted into 3,4-hydroxybenzoic acid, which can then be methylated to form 3-methoxy-4-hydroxybenzoic acid. Previous studies have demonstrated increased urinary excretion of free 3-methoxy-4-hydroxybenzoic

acid after polyphenol consumption, which was also increased in the current study when berries were included in the diet.[17]

Although studies on comparison of the berries or their polyphenol profile contributing to the differences in the excretion of phenolic acids are limited, previous paper indicate that ferulic, 3-hydroxyphenylacetic, 3-methoxy-4-hydroxyphenylacetic, hippuric, and cinnamic acid derivatized phenolic acids are increased when diets rich in procyanidins are fed,[16,17,22] which was usually the case in the current study. Higher excretion of 4-hydroxycinnamic acid in animals fed CB may simply be the result of their higher concentration in the berry and thus intake from the diet (Table 3). However, the intakes of 3,4-hydroxycinnamic acid in the diet are similar with the three berry treatments (Figure 8), but the total excretion of 3,4-hydroxycinnamic acid is 3−4-fold higher in the BB compared to the CB or BRB treatments (Figure 8; Table 4). This could be the result of metabolism of the chlorogenic acid to 3,4-hydroxycinnamic acid in the BB treatment group.

The differential effect of the three berries on the excretory pattern of some of the phenolic acids may be attributable to the differences in their polyphenol profiles. It should be noted that anthocyanins are present in high amounts in BRB (primarily as cyanidins) and procyanidins in CB and BB (Table 3). There are also some differences in the free phenolic acids (Table 3) present in the three berries. 3,4-Hydroxybenzoic acid (protocatechuic acid), a major metabolite of cyanidin-3-glycosides, which would include cyanidin-3-rutinoside[23,24] that was present in high amounts in BRB, was excreted in greatest quantities in animals fed BRB (Table 4). Removal of a hydroxyl group at the C-4 position from 3,4-hydroxybenzoic acid during the metabolic processes may have contributed to the highest amounts of urinary excretion of 3-hydroxybenzoic acid (Figure 2) in animals fed BRB. 4-Hydroxybenzoic acid and 3,4-dihydroxybenzoic acid were present in higher amounts in the BRB powder than in BB or CB powders (Table 3). Although our own data and some other previous studies have suggested 3-hydroxyphenylpropionic acid as a metabolite primarily of procyanidins,[11,17,25−27] the current study suggests that it may also possibly be a metabolite of anthocyanins as well, given that BRB-fed animals excreted the highest amounts of 3-hydroxyphenylpropionic acid in all forms. 3-Hydroxyphenylpropionic acid was not detected in the BRB powder. Although not in the highest amounts, Wu et al.[28] observed increased concentrations of 3-hydroxyphenylpropionic acid throughout the entire gastrointestinal tract of pigs following ingestion of BRB. It needs to be determined whether 3-hydroxyphenylpropionic acid is also a metabolite of ellagitannins, another polyphenol present in appreciable amounts in BRB, but not CB or BB.

Contribution of the conjugated PA to the total amount present in the urine was often >50%, with values as high as ≥85% in several cases. The cinnamic acids, 3-hydroxycinnamic (Figure 3) and 4-hydroxycinnamic (Figure 6), were conjugated to a greater extent than the phenylacetic acid derivatives (Table 4) (3-hydroxyphenylacetic acid, Figure 5; 3-methoxy-4-hydroxyphenylacetic, Figure 7). The benzoic acid derivatives vary in extent of conjugation depending upon the structure (Tables 4 and 5). A previous study has also shown the urinary excretion of several phenolic acids in conjugated forms in humans after consumption of a diet containing strawberries.[29] Although it is not clear whether and how much is contributed by the conjugation of phenolic acids to their overall health effects and bioactivity, estimating just the free forms may not be a true indicator of the amounts of phenolic acids excreted in the urine.

In addition to urinary excretion, some phenolic acids may also be excreted through the biliary route. Urine is the primary route for mostly smaller nonconjugated and monoconjugated phenolic acids, but extensively conjugated ones may find their way in the bile. However, literature on this aspect is very limited, and no attempt was made to investigate it in the current study.

In summary, hippuric, 4-hydroxphenylacetic, 3-methoxy-4-hydroxphenylacetic, and 4-hydroxybenzoic acids were excreted in highest amounts irrespective of the dietary treatments. Urinary excretion of a majority of the phenolic acids analyzed in the current study was increased by the inclusion of berries in the diet, with a slight reduction only in 4-hydroxyphenylacetic acid excretion. Depending on the berry dietary treatment, the largest increase in the urinary excretion of phenolic acids was observed with hippuric, 3-hydroxyphenylpropionic, 4-hydroxycinnamic, 3-methoxy-4-hydroxyphenylacetic, 3-methoxy-4-hydroxybenzoic, ferulic, and 3-hydroxyphenylacetic acids. A majority of the phenolic acids were also detected in conjugated form in considerable amounts, with some exceeding 80% of the total excreted in the urine. Thus, measurement of just the free form may not accurately reflect the amount excreted, and future studies investigating the health effects, bioactivity, or bioavailability of parent polyphenols should also consider their metabolites, not just the parent compound(s). Furthermore, parent compound(s) as well as their metabolites may also be methylated or conjugated, which may affect the bioactivity of many of these polyphenols.

plasma and urine of subjects consuming pomegranate juice or BRB powder in water.[19,21] For nectar formulation, the addition of stabilizer (such as pectin, xanthan, and agar) to the juice would increase viscosity and thus aid in the suspension of particles such as fruit pulp and seeds.[22]

Aside from the formulation, the processing and storage need to be considered carefully to ensure minimal effect on the levels of berry bioactives in products. For example, the manufacturing and storage of berry jam, juice, and puree as well as canning yielded a decrease in anthocyanins and flavonoids, whereas ellagitannins content remained heat stable and more influenced by the processing related to seeds exclusion.[23−25] Formulation and processing of a food delivery system for a human clinical trial and subsequent scale up require consistency of ingredients and final product as well as quality and bioactive retention during storage. As such, the objective of the current study was to assess the consistency, quality, and shelf stability of BRB pectin confections and nectar developed for clinical trials and demonstrate their acceptability among men enrolled in a prostate cancer clinical trial.

MATERIALS AND METHODS

Standardization of All Ingredients and Adjustment of Formulations from Laboratory-Scale to Large-Scale Production. To ensure the homogeneity of the food products for the clinical trial, all ingredients were purchased in a single lot: corn syrup (Gordon Food Service, Springfield, OH, USA), sugar (U.S. Food Service, Cincinnati, OH, USA), and pectin (RS 400, Danisco, USA Inc., New Century, KS, USA). Pectin (CF 130 B) from Danisco was previously used in the laboratory scale for both confections and nectars; however, due to the lack of availability for the scale-up production, RS 400 pectin was applied. Freeze-dried BRB powder was obtained from both Stoke Raspberry Farm (Wilmington, OH, USA) (cultivar 'Jewel') and BerriProducts LLC (Corvallis, OR, USA) (cultivar 'Munger'). Mixed BRB powder (Ohio:Oregon = 2:3) was blended using a mixer (Day mixing, 1608, Federal Equipment Co., Cleveland, OH, USA) in the Food Pilot plant in the Parker Food Science Building at The Ohio State University (OSU). After mixing, the powder was separated into 4 kg/bag, sealed by using a vacuum sealer (MC-30 computer control, Sipromac, Houston, TX, USA), and kept at −40 °C, avoiding light, until use. According to Stoner et al.,[11] the levels of 26 nutrients in BRB remained within 10−20% of the original measurements for at least 2 years in the freeze-dried form stored at −20 °C. Scale-up production of confections and nectars required reformulation due to ingredients' change and processing parameter adjustments with the goal of retaining bioactives and quality. Final selected formulations are shown in Table 1.

Scale-up Production of BRB Products. *Confection Production.* Confections were prepared in 1 kg batches, and formulations adjusted from laboratory scale as shown in Table 1. In the preparation, water, sugar, corn syrup, and pectin were mixed and then stirred and heated on a hot plate (PC-620 D, Corning, Tewksbury, MA, USA) until a final temperature of 95 °C and °Brix from 65 to 68 were reached, which was determined by a hand-held refractometer (Fisher Scientific Japan Ltd., Tokyo, Japan). These processes were the same as laboratory scale and achieved within 45 ± 3 min. When the mixture had cooled to 78 °C at room temperature, freeze-dried BRB powder was added and mixed into the gel. The mixture was deposited at 65 °C with a pastry bag into molds (2115-1521 Truffles, Wilton, Columbus, OH, USA). Confections equilibrated at room temperature (21 ± 2 °C), avoiding lights for 24 h before packaging. All of the products was prepared in the OSU Pilot Plant in the Parker Food Science Building with relative humidity (RH) of 0.1−3.5% and temperature of 22 ± 1 °C. Random samples (n = 3) from each batch (83 ± 4 pieces) were obtained to evaluate their water activity, water content, and pH. Four random batches were chosen to track the stability of bioactives with HPLC (n = 6 per batch), rheological (n = 6 per batch), and textural properties (n = 10 per batch).

Table 1. Adjusted Formulations of BRB Confections and Nectars from Laboratory-Scale to Large-Scale Production

	confections		nectars (two BRB doses)	
composition (%)	lab scale	large scale	lab scale	large scale
BRB powder	20.0	20.0	4.0/8.0	4.0/8.0
sugar	35.0	29.5	3.0	3.0
corn syrup	12.0	11.0	1.0	1.0
water	29.5	37.8	90.2/86.2	91.2/87.2
pectin	1.5	1.2	1.8	0.8
50% (w/w) citric acid	2.0	0.5		
total	100	100	100	100

Low-Dose BRB Nectar Production. Nectar with 10 g of BRB dose was produced in MicroThermics, Inc. (Raleigh, NC, USA) in a 120 kg batch according to the large-scale formulation shown in Table 1. In the preparation, pectin, sugar, corn syrup, and water were first mixed and heated to 95 °C with a UHT/HTST Lab Direct and Indirect Processing System (MicroThermics Inc.), and then the premix was kept in an extended hold cabinet to maintain a temperature above 60 °C. BRB powder was added into the premix, and an adjustable speed drive (Leeson Electric Corp., Grafton, WI, USA) was used for mixing. The mixture was then pumped into a sterilized UHT/HTST Lab Direct and Indirect Processing System with 3 L/min flow rate and pasteurized at 75 °C for 15 min according to a method adapted from Silva and Gibbs to inactivate enzymes and the majority of molds.[26] Nectar was then cooled to 25 °C and filled into 250 mL Nalgene PETG sterilized bottles (Thermo Fisher Scientific Inc.) in a Clean Fill Hood with sterile product outlet (MicroThermics Inc.). Nectars were stored at 4 °C until use. Random bottles (n = 9) were selected to evaluate the pH, Brix, water activity, viscosity, and bioactive compounds with HPLC.

High-Dose BRB Nectar Production. Nectar with 20 g of BRB dose was produced in the OSU Pilot Plant in the Parker Food Science Building because Microthermics equipment was unable to process such high-viscosity nectar. A 100 kg batch of nectar was prepared with the large-scale formulation shown in Table 1. In the preparation, pectin, sugar, corn syrup, and water were first mixed well and heated in a steam-jacketed kettle (A5132-1 ATMOS, Hamilton Kettles, Cincinnati, OH, USA). Once the temperature reached 95 °C, BRB powder was added and mixed well. Temperature was kept at 95 °C for 15 min to pasteurize, a method adopted from the production of BRB puree and strawberry nectar.[24,27] After heating, nectar was cooled to 75 °C and filled into 250 mL Nalgene PETG sterilized bottles (Thermo Fisher Scientific Inc.) with a volumetric piston filler (Simplex, AS-1, Napa, CA, USA). A fixed volume of nectar (8 oz) was controlled to fill into bottles. After cooling, nectars were stored at 4 °C until use. Random bottles (n = 9) were selected to evaluate the pH, Brix, water activity, viscosity, and bioactive compounds with HPLC.

Phenolic Analysis of BRB Products. *Extraction.* One gram of BRB powder or confection/nectar containing 1 g of BRB was fully dispersed into water containing 5% (v/v) formic acid and adjusted to a final volume of 50 mL. Aliquots of 2 mL were immediately removed from the well-mixed solution and then mixed with 8 mL of acetone containing 5% (v/v) of formic acid, followed by bath sonication for 1 min in an FS3OH Sonicator (Fisher Scientific, Fair Lawn, NJ, USA) and then centrifuged at 2000g for 10 min with a IEC HN-SII centrifuge (Damon Corp., Needham Heights, MA, USA). Supernatant was removed to a clean 22 mL glass vial (Fisher Scientific, Pittsburgh, PA, USA) with a disposable glass pipet (Fisher Scientific, Pittsburgh, PA, USA). Solvent of acetone/water (80:20, v/v) containing 5% formic acid was used to extract the pellet twice more until the pellet was colorless. A Speedvac concentrator (SPD 131DDA-115, Thermo Fisher Scientific, Waltham, MA, USA) was used to dry sample extracts.

Identification. A Waters 2695 HPLC with a Waters 996 photodiode array detector (Waters, Milford, MA, USA) combined with a Waters

Q-Tof Premier (Micromass MS Technologies, Manchester, UK) was used for the identification of phenolic compounds. Dried extracts were dissolved in acetone/water (20:80, v/v) containing 5% formic acid and filtered through PTFE filters (Fisher Scientific, Pittsburgh, PA, USA; 0.2 μm, 13 mm diameter) before injection. Separation was carried out on a Symmetry C18 (75 mm × 4.6 mm i.d, 3.5 μm particle size) reversed phase column (Waters). The mobile phase for separation consisted of 1% (v/v) formic acid in water (A) and 1% (v/v) formic acid in acetonitrile (B). Initial mobile phase composition, 100% A and 0% B, was followed by a linear gradient to 80% A at 10 min, 70% A at 12 min, 50% A at 14 min, 0% A at 16 min, and returned to 100% A at 16.1 min and re-equilibrated through 20 min. Column temperature was kept at 35 °C, and flow rate was 1.3 mL/min. HPLC flow was split 1:10 prior to MS. The MS analysis was performed in positive and negative ion modes and calibrated with sodium formate in the range of m/z 50−3000. Leucine enkephalin was used as lockspray mass with m/z at 556.2771$^+$/554.2615$^-$. Capillary voltage was at 2.8 kV in negative mode and 3.2 kV in positive mode. Dry gas flow was at 700 L/h, cone voltage at 35 V, and desolvation gas temperature at 480 °C. For MS/MS analysis, the same instrumental parameters were used except that collision energy was set to 25 eV. Standards of cyanidin 3-gucoside, cyanidin 3-sambubioside, cyanidin 3-rutinoside, ellagic acid, and rutin were run to support peak identification.

Quantification. BRB confections and nectars were analyzed by HPLC to quantify anthocyanins, ellagitannins, and ellagic acid content. Freeze-dried BRB powder was quantified to determine the changes of BRB bioactives during production and subsequent storage in products. Quantification in all BRB samples was carried out using an Agilent 1100 series (Agilent, Waldbronn, Germany): G 1322A degasser, G 1328A manual injector, G 1311A quaternary pump, and G 1365A MWD controlled by the ChemStation software (Agilent). Chromatographic separation was performed with the same column and method as those in the identification step. Samples were injected with a volume of 20 μL. Absorbance at 260, 355, and 520 nm wavelength was recorded. Anthocyanins were quantified as one peak at 520 nm with cyanidin 3-glucoside as external calibrant[24] with concentrations ranging from 3.125 to 100.0 μg/mL. Ellagic acid was used as the external standard to quantify free ellagic acid and ellagic acid derivatives under 260 nm with a range of 0.25−4.0 μg/mL. Ellagic acid and ellagic acid derivatives were represented as total ellagic acid. Ellagitannin quantification was following the method of Gasperotti et al.,[28] in which (sanguiin H-6) $\varepsilon_{260\ nm}$ = 63615 M^{-1} cm^{-1} and (ellagic acid) $\varepsilon_{260\ nm}$ = 28266 M^{-1} cm^{-1} in 88% acetonitrile and 12% 1% formic acid in water (v/v) were reported. The standard curve of sanguiin H-6 was derived from the ellagic acid standard curve using a calculated factor (28266/63615 = 0.44).

Retention of Anthocyanins, Ellagitannins, and Total Ellagic Acid in BRB Products. The retention rate of these compounds from BRB confections and nectars was calculated using the formula

$$\text{retention}\ (\%) = \frac{C_{\text{phenolics}}}{C_{\text{BRB}} \times C_{\text{phenolics}}'}$$

where $C_{\text{phenolics}}$ = concentration of anthocyanins or ellagitannins in products, C_{BRB} = percentage of BRB in products after processing, $C_{\text{phenolics}}'$ = concentration of anthocyanins or ellagitannins in freeze-dried BRB powder. $C_{\text{phenolics}}$ and $C_{\text{phenolics}}'$ were obtained from HPLC quantification, and C_{BRB} was obtained from products' preparation.

Characteristic Consistency of the BRB Products. BRB delivery dosage, water activity (Aqua Lab Water Activity Meter series 3, Pullman, WA, USA), pH, and soluble solid (°Brix) were determined to check the consistency of BRB products needed for the clinical trials. A SevenMulti pH conductivity meter (Mettler Toledo Inc., Columbus, OH, USA) was used to measure the pH of the confection (mashed into a paste) and nectar. °Brix was measured by hand-held refractometers with ranges of 0−32° and 58−90° (Fisher Scientific Japan Ltd., Tokyo, Japan). Water content of confections was obtained from thermogravimetric analysis (TGA) (Q5000, TA Instrument, New Castle, DE, USA) by heating 15−20 mg samples at 5 °C/min from 25 to 160 °C. Moisture content was calculated as described in Siegwein et al.[29]

Rheological Consistency of BRB Products. Confections were analyzed with an AR 2000ex Controlled Stress Rheometer (TA Instruments) with a 20 mm diameter probe. Dynamic strain sweep (0.01−10%) at 25 °C and different frequencies (0.1, 1, 10, 100 Hz) were first tested to determine the linear viscoelastic region (LVR), and all samples exhibited a linear response for strain values up to 0.15%. Dynamic frequency sweep (0.1−100 Hz) tests were then carried out at 25 °C with 0.1% strain to obtain viscoelastic behavior of confections. Storage modulus (G'), loss modulus (G''), and complex viscosity (η^*) were recorded and compared. Changes of apparent viscosity (η) in nectars with a 40 mm diameter probe were recorded with increasing flow shear rate (0.001−1000 s^{-1}) at 1 Hz and 25 °C. Random samples from scale-up production were also analyzed. Texture profile analyses (TPA) of confections were obtained with an Instron 5542 Universal Testing Machine (Instron Corp., Canton, MA, USA) with Bluehill 2 Materials Testing Software (Instron Corp., Norwood, MA, USA) with 40% compression at 1 mm/s rate by 35 mm diameter probe. Hardness, cohesiveness, springiness, and chewiness were obtained according to the methdod of Peleg.[30]

2-Month Storage of BRB Products. A 2-month shelf life required for BRB products to allow for recruitment and clinical intervention was studied. Both confections and nectars were packaged; plastic 2 oz cups with lids (Gordon Food Service, Springfield, OH, USA) were for confections, and amber bags were used for each nectar bottle; the samples were kept in the dark at 4 °C for 2 months. Fresh samples and samples at 4, 6, and 8 weeks were collected to evaluate the storage stability of bioactive compounds and textural properties in the products. The number of samples used for analysis was the same as those in fresh samples described earlier.

Scale-up Production Design for a Prostate Cancer Clinical Trial. This clinical trial was approved by the OSU Clinical Scientific Review Committee (CSRC) first and subsequently by the Institutional Review Board (IRB) with approval numbers OSU-12125 and 2012C0096, respectively. In total, 56 patients newly diagnosed with resectable prostate cancer (average age = 61.6 ± 1.02 years) were recruited into this study, 32 of which were in BRB functional food intervention groups and 24 in dietary assessment groups (control). Only BRB intervention groups were focused on and discussed in this study. Design of intervention groups in this clinical trial, BRB dosage in products, and total amount of processed products are shown in Figure 1. All patients signed written informed consent forms before participation. The BRB intervention period for each patient lasted 20−30 days depending on the scheduled surgery day. Extra products were given to participants in case of a need to delay surgery. Only the sensory acceptability of the products tested in this study will be discussed herein.

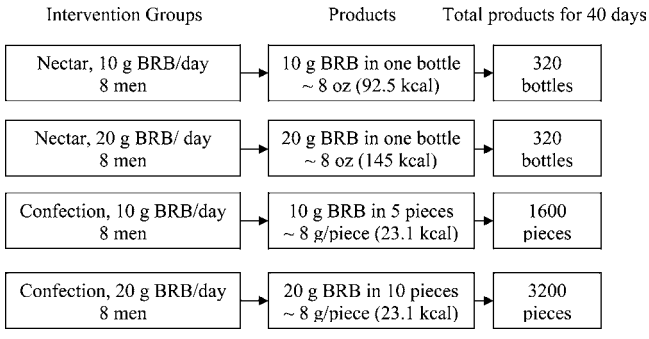

Figure 1. BRB delivery dosage and total BRB products in a prostate cancer clinical trial.

Sensory Evaluation. To obtain the overall acceptability of BRB products, a sensory evaluation survey was developed and approved by the IRB (2012C0096). At the end of the clinical trial, sensory tests were conducted using a nine-point hedonic scale (1, dislike extremely;

2, dislike very much; 3, dislike moderately; 4, dislike slightly; 5, neither like nor dislike; 6, like slightly; 7, like moderately; 8, like very much; 9, like extremely) to evaluate the overall acceptability and acceptability of aroma, flavor, sweetness, texture, and grittiness.[31]

Statistical Analysis. A one-way analysis of variance (ANOVA) and Tukey's post hoc test were used with SPSS 20.0 (Chicago, IL, USA) to determine the significance in the characteristics between confection batches. The means of rheological properties and contents of bioactive compounds in BRB confections and nectars during storage were compared as well. An independent t test compared differences between laboratory-scale and large-scale products with Minitab 15 statistical software (Minitab Inc., State College, PA, USA). A $p \leq 0.05$ was considered to be significantly different.

RESULTS AND DISCUSSION

Formulation Adjustment of BRB Products from Laboratory-Scale to Large-Scale Production. Formulations of pectin-based confection and nectar (Table 1) were adjusted from the laboratory scale to achieve similar textural properties as well as a lower caloric content for clinical subjects. Pectin RS 400 used in large-scale production had a higher degree of esterification (70%) compared to CF 130 B used in laboratory scale (31% esterification and 19% of amidation); therefore, pectin was decreased from 1.5 to 1.2% in BRB confection to reach similar rheological properties as indicated by similar G', G'', and η^* values (Figure 2). Sugar in BRB confection and citric acid were both decreased in scale-up versions to achieve the desired lower calorie content (from 29.3 to 23.1 kcal/piece confection). Calorie control was essential so as not to induce weight gain during intervention. For the nectar, calorie adjustment was not required, but pectin addition was decreased from 1.8% in laboratory scale to 0.8% for clinical trial so as to reach similar rheological end points during scale up (Figure 3).

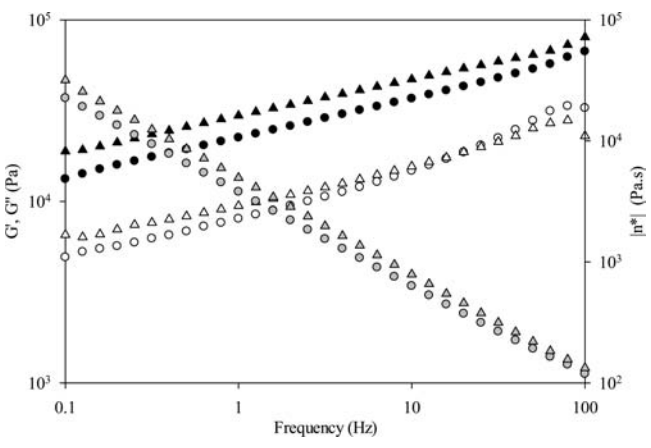

Figure 2. Frequency sweep of laboratory-scale confection (circles) and large-scale confection (triangles): (solid symbols) storage modulus G'; (open symbols) loss modulus G''; (gray symbols) complex viscosity $|\eta^*|$.

Identification and Quantification of Phenolics. Phenolics in BRB powder were identified with a combination of HPLC-MS/MS, accessible standards, UV–vis, and reported mass. HPLC chromatograph and peak identification information for phenolics are shown in Figure 4 and the accompanying table. Peaks 1a,b and 1c,d coeluted in the HPLC but were identified by MS as cyanidin 3-glucoside, cyanidin 3-sambubioside, cyanidin 3-xylosylrutinoside, and cyanidin 3-rutinoside with a characteristic fragment of cyanidin aglycon $[M - H]^-$ at

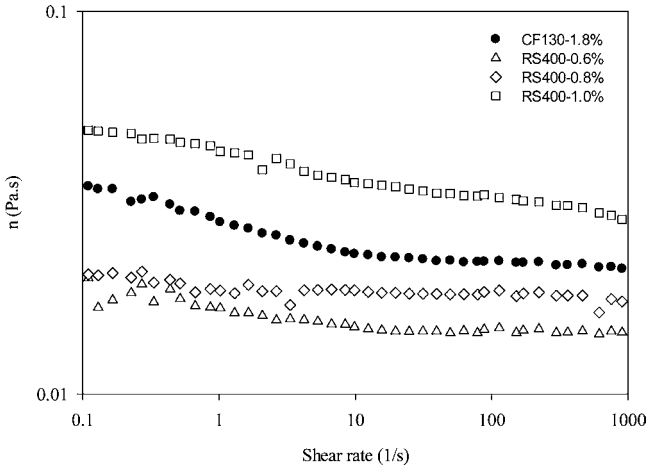

Figure 3. Viscosity of nectar premix with different concentrations of large-scale RS 400 pectin compared to CF 130 B pectin used in laboratory scale.

m/z 285 and other reported fragment ions.[32] In this study, pelargonidin 3-rutinoside was detected in a very low content with MS; thus, only the four major cyanidin glycosides were quantified as anthocyanins in BRB powder and the processed products. This HPLC method was not developed to separate each anthocyanin well due to other phenolics including ellagitannins and quercetin glycoside. Peaks shown with a retention time of 7.4–8.6 min were unknown but considered as possible anthocyanin-related compounds due to absorbance at 480 nm and MS $[M - H]^-$ m/z 651 and MS/MS m/z at 285 and 593.

Peak 2 was tentatively identified as quercetin xylosylrutinoside with $[M - H]^-$ m/z at 741 and MS/MS m/z 301.036 and 355 nm UV–vis. Peak 3 was identified as sanguiin H-6 with MS $[M - H]^{2-}$ m/z at 934; MS/MS m/z at 935, 633, and 301 with UV–vis featured at 260 nm and comparison with previous reports.[33−35] Lambertianin C with MS $[M - H]^{2-}$ m/z at 1401 and a true mass of 2803 was identified according to Hager et al.,[35] but it was detected in a minor peak at 8.57 min and coeluted with some unknown anthocyanin degradation compounds in this HPLC method. However, lambertianin C was reported as one of the major ellagitannins (>32%) besides sanguiin H-6 (>42%) in six raspberry (*Rubus idaeus* L.) cultivars.[28] Several ellagitannins eluted before anthocyanins with MS of 783, 933, and 633, which were likely pedunculagin isomer, castalagin/vescalagin isomer, and galloyl-HHDP glucose isomer according to Hager et al.[35] In this study, sanguiin H-6 was the most abundant ellagitannin detected and thus quantified as ellagitannin and compared during processing and storage. In peaks 4–6, rutin, ellagic acid, and quercetin hexuronic acid were identified with a combination of available standards (rutin and ellagic acid), accurate MS, MS/MS, UV–vis, and reported data.[36] Methyl-ellagic acid-pentose, acetyl-ellagic acid-pentose, malonyl-methyl-ellagic acid-pentose, and acetyl-methyl-ellagic acid-pentose were identified according to the accurate masses of their molecular ions and fragment m/z (MeEA $[M - H]^-$ m/z at 315, EA at 301) by MS/MS in peaks 7–10.[28,33]

Changes of Phenolics during Laboratory-Scale and Large-Scale Processing. HPLC profiles of BRB confections and nectars were the same as that of BRB powder, but in some cases were present at different concentrations due to the effect

	large (95 °C, 15 min)	69.0 ± 2.8b	91.0 ± 3.6a	127.9 ± 6.2b

[a] Values represent means ± standard error ($n = 24$ for confections and $n = 9$ for nectars). Means with different letters in the same column within each BRB product are significantly different ($p \leq 0.05$).

of processing. Anthocyanins, ellagitannin, and total ellagic acid in BRB products were quantified according to the identification above and then were compared to that of laboratory scale to ensure similar delivery of these bioactives for the clinical trial. Retention rates of phenolics in both laboratory-scale and large-scale products are shown in Table 2. Confections contained 6.8 mg/g of anthocyanins and proved to have the highest anthocyanin retention rates (94%) after processing. In addition, there were no distinct changes of anthocyanins and ellagitannin between laboratory-scale and large-scale confections, demonstrating consistency in the processing steps ($p > 0.05$). This was mainly due to the low mixing temperature of the pectin gel with freeze-dried BRB powder (78 °C). For the nectars with 10 g of BRB dosage, 86% of anthocyanins were retained after large-

dx.doi.org/10.1021/jf404566p | J. Agric. Food Chem. 2014, 62, 3997−4006

scale processing, whereas only 69% were left in the 20 g of BRB dose. This was related to the different processing conditions of the low and high dose of BRB nectars: 75 °C for 15 min and 95 °C for 15 min, respectively. Higher temperature and longer heating time were required to pasteurize the 20 g of BRB dose nectars. Both anthocyanin retention rates in large scale were significantly lower than those in the laboratory scale ($p < 0.05$), mainly due to the longer mixing time of 10 g BRB powder with premix at 60 °C in the hold cabinet and higher heating temperature for the 20 g dose nectar in the large-scale production. Anthocyanin degradation is known to follow first-order reaction kinetics, and processing at lower temperature for shorter time improves the retention rates.[37] In addition, multiple processing steps influence the retention of anthocyanins. Significantly lower retention of monomeric anthocyanins was found in nonclarified and clarified juices (31 and 27%) than in BRB puree (63%) and berries canned in water (58%).[24] The comparatively higher retention rates of anthocyanins in BRB confections and nectars (69−94%) may be due to the use of whole BRB powder and single mixing and/or heating steps. Other factors such as the presence of oxygen, light, enzymes, and pH fluctuations may also influence the loss of anthocyanins.[38]

Ellagitannins were retained at 95 and 91% after processing of confection and nectar with the 20 g of BRB dose in large-scale production. Nectar with lower BRB dose had 66% of ellagitannin retention rate, which was significantly lower than those of confection and nectar with 20 g of BRB as well as that of laboratory scale ($p < 0.05$). This may be due to partial seed sedimentation in the Microthermics flow processing system because higher BRB dose nectar would cause blockage of the system, which resulted in the higher BRB dose nectar being processed in the OSU pilot plant. This was consistent with previous results where BRB ellagitannins were retained in higher quantities in purees (65%) and berries canned in water or syrup (79%) but not juice (only 31−33% retained), where the exclusion of seeds accounted for the significant loss.[39] Similar results were also found in blackberry processing, where 30 and 18% of ellagitannins were recovered in nonclarified and clarified juices, respectively, whereas canning and pureeing had little effect.[25]

All BRB products demonstrated above 100% ellagic acid retention rates. Ellagic acid increased in raspberry juice after heat processing due to better extraction from the cell matrix.[40] It was possible that the heat treatment of BRB products in this study may have improved ellagic acid extraction compared to the BRB powder.[25] Additionally, increased ellagic acid may result from hydrolysis of ellagitannins during processing.

Consistency of Scale-up Production of BRB Products. Characteristics of BRB confections from different batches and nectars from randomly selected bottles were measured to evaluate the production consistency (Table 3). Confections were prepared within 4 weeks; 50 batches (83 ± 4 pieces per batch) totaled 4162 pieces. The average weight of the confections was 8.42 ± 0.35 g with a BRB concentration of 24.95 ± 0.48%. Dosage of BRB was within 5% of desired concentration (Table 3). Physical properties such as pH and water activity also showed consistency in the products (Table 3).

Rheological properties of confections from different batches (randomly selected) were evaluated (Figure 5A,B). There were no distinct differences in G', G'', and η^* between different batches at 0.1, 1, 10, and 100 Hz ($p > 0.05$), suggesting the

Table 3. Characteristics of BRB Confections and Nectars in Scale-up Processing[a]

characteristic	BRB confections (per piece)	nectar, 10 g of BRB (per bottle)	nectar, 20 g of BRB (per bottle)
BRB dosage (g)	2.10 ± 0.09	10.48 ± 0.31	20.22 ± 0.45
pH	3.44 ± 0.02	3.64 ± 0.02	3.56 ± 0.02
A_w	0.72 ± 0.02	0.95 ± 0.00	0.95 ± 0.00

[a]Values represent means ± standard error (n = 3 per batch for confections and n = 9 for nectars).

Table 4. Concentration and Daily Delivery of Phenolics in Fresh BRB Products

	products for BRB delivery[a]			
	confections (5 pieces/day)	confections (10 pieces/day)	nectar, 10 g of BRB (one bottle/day)	nectar, 20 g of BRB (one bottle/day)
concentration				
anthocyanins (mg/g)	6.8 ± 0.1	6.8 ± 0.1	1.0 ± 0.03	1.6 ± 0.1
ellagitannins (μg/g)	593.0 ± 12.1	593.0 ± 12.1	66.4 ± 3.5	182.2 ± 9.3
total ellagic acid (μg/g)	113.7 ± 3.5	113.7 ± 3.5	19.6 ± 3.1	44.1 ± 2.1
estimated daily amount of delivery[b]				
anthocyanins (mg)	285.6	571.2	253.7	399.2
ellagitannins (mg)	24.9	49.8	16.8	45.5
total ellagic acid (mg)	4.8	9.6	5.0	11.0

[a]Average weight of products: confections, 8.4 g/piece; nectar, 10 g of BRB, 253.7 g/bottle; nectars, 20 g of BRB, 249.5 g/bottle. [b]Estimated daily amount of delivery was obtained from the average weight of confections/nectars; thus, no SD was provided.

confections were made with consistent textural properties. Viscosity of samples from 10 and 20 g of BRB nectar was measured with shear flow tests, and results are shown in Figure 5C. With increased shear rate, viscosity showed smaller difference between replicates. Nectars with 10 and 20 g of BRB had 0.15 ± 0.02 and 0.72 ± 0.13 Pa·s viscosity at 1.00 s^{-1} shear rate, respectively.

Stability of Phenolics during Storage. Concentration and daily delivery amount of anthocyanins, ellagitannins, and total ellagic acid in fresh products are shown in Table 4. Confections delivered higher daily amount of anthocyanins and ellagitannins than nectars for equivalent BRB doses due to higher initial value of these bioactives in confections (Table 2). The retention rate of these phenolics in BRB products during storage is shown in Table 5. During storage, anthocyanins in confections decreased significantly from 94 to 87% in 4 weeks but were fairly constant (no statistically significant change) up to 8 weeks of storage. A similar trend was observed for the anthocyanins in the low nectar dose, whereas the 20 g dose had no significant change until 8 weeks of storage. The depletion of anthocyanins in the confections may be a consequence of residual enzymatic activity, as was observed in processing of blueberry and storage of strawberry nectar.[27,41] Gössinger et al. reported that enzymes were not fully inactivated even after a heat treatment of 90 °C for 60 min.[27] Therefore, to promote retention of anthocyanins, a balance may need to be reached between initial heat processing to achieve enzyme inactivation (high heat for longer time results in lower anthocyanin concentration) and stability during storage (higher heat initially applied, less degradation during storage). Additionally, storage conditions may also play an important role in the stability of anthocyanins. Refrigerated storage resulted in lowering of the polymeric color percentage of blueberry juice[42] and reducing the rate of anthocyanin degradation[43] compared to room temperature.

Table 5. Retention of Phenolics in BRB Products during 2 Months of Storage at 4 °C[a]

product	storage time (weeks)	anthocyanins (%)	ellagitannins (%)	total ellagic acid (%)
confection	0	94.4 ± 1.0a	95.6 ± 1.9a	106.4 ± 3.3a
	4	87.0 ± 1.0b	94.4 ± 2.7a	101.4 ± 7.3a
	6	84.5 ± 1.6b	95.7 ± 4.8a	100.0 ± 1.4a
	8	83.4 ± 2.5b	93.6 ± 4.5a	106.9 ± 6.9a
nectar, 10 g of BRB	0	86.1 ± 2.7a	66.4 ± 3.5a	113.6 ± 6.8a
	4	78.9 ± 3.6b	59.6 ± 1.3b	105.0 ± 2.3a
	6	77.9 ± 3.2b	57.2 ± 2.6b	103.2 ± 7.0a
	8	76.3 ± 2.7b	60.2 ± 1.7b	104.1 ± 4.8a
nectar, 20 g of BRB	0	69.0 ± 2.8a	91.0 ± 4.6a	128.0 ± 6.2a
	4	68.5 ± 3.2ab	91.4 ± 3.7a	129.4 ± 3.0a
	6	66.3 ± 1.0ab	89.9 ± 3.1a	125.3 ± 2.5a
	8	65.1 ± 3.3b	93.3 ± 2.4a	127.8 ± 3.3a

[a]Values represent means ± standard error (n = 24 for confections and n = 9 for nectars). Means with different letters in the same column within each BRB product are significantly different ($p \leq 0.05$).

Retention of ellagitannins was not significantly changed in confection and 20 g of BRB nectar during storage ($p > 0.05$). Ellagitannins in the 10 g of BRB nectar decreased significantly, but the change was <10% after 8 weeks of storage. The high stability of ellagitannins in confections and nectar during storage was consistent with those previously reported in other berries.[25,39] Total ellagic acid concentration remained stable during storage of all products ($p > 0.05$). This was consistent with previous reports in which ellagic acid derivatives were not affected by thermal processing and remained stable during storage in red raspberry jams.[23]

Textural Stability during Storage. Rheological properties of BRB confections showed no significant change in complex viscosity η^* (Figure 6) during storage with similar trends for G' and G'' (data not shown). Texture profile analysis (TPA) showed significant decrease ($p < 0.05$) in cohesiveness and springiness but not in hardness and chewiness after 2 months of storage (data not shown). Chewiness is the combined results of hardness, cohesiveness, and springiness. This indicated that minor changes in cohesiveness and springiness of BRB confections did not influence chewiness. Water content was 27.85 ± 0.55% at day 1 and did not significantly change during 8 weeks of storage ($p > 0.05$). However, water activity (A_w) increased significantly from 0.72 ± 0.02 to 0.76 ± 0.02 after 8 weeks of storage ($p < 0.05$). This increase in water activity indicated water migration in the gel structure, which resulted in changes of cohesiveness and springiness but no other textural properties. Nectars with both BRB doses showed no significant changes in viscosity during storage at 4 °C ($p > 0.05$).

Sensory Acceptability of BRB Products during Dietary Intervention. Sensory evaluation was obtained from 15 of 16 subjects in the BRB nectar group and from 12 of 16 in the BRB confection group. Results are shown in Table 6. Nectar and confections scored 7.27 and 7.08 in overall acceptability (7, like moderately on a 9-point hedonic scale). Both products scored

dx.doi.org/10.1021/jf404566p | J. Agric. Food Chem. 2014, 62, 3997−4006

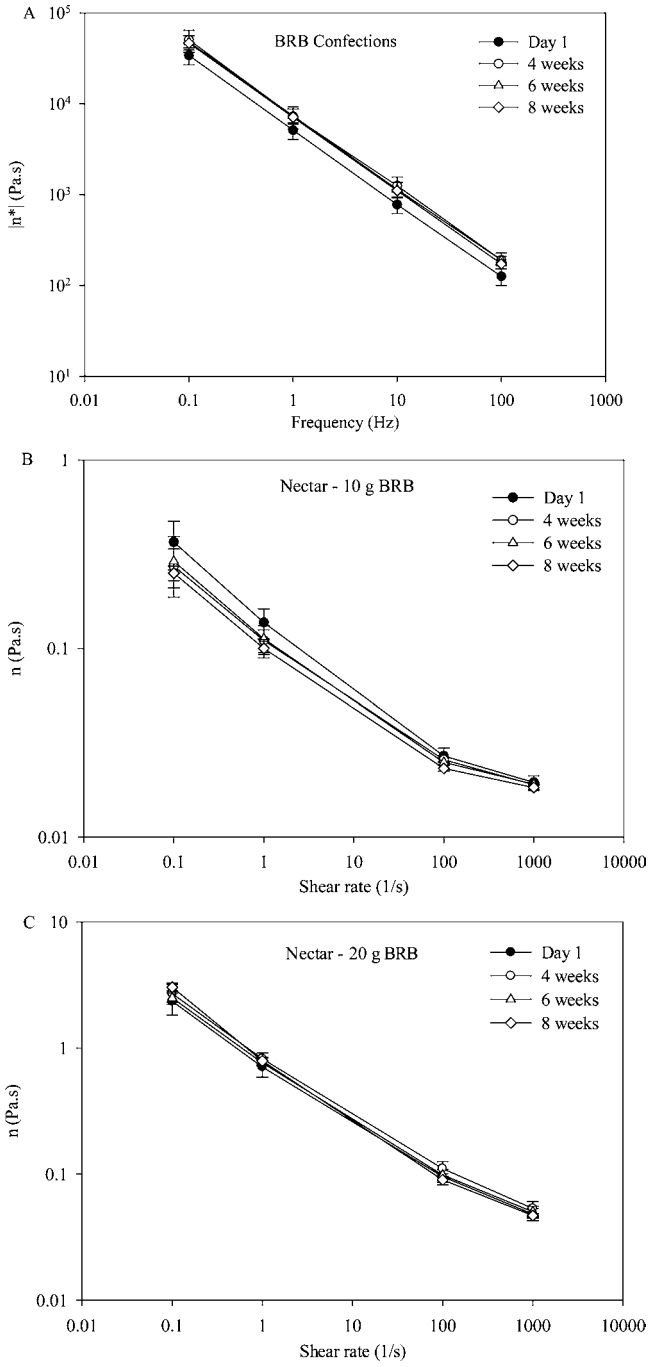

Figure 6. Viscosity of BRB scale-up products during storage at 4 °C: (A) confections, $|\eta^*|$; (B) nectar, 10 g of BRB dosage, η; (C) nectar, 20 g of BRB dosage, η.

above 6 on flavor, aroma, sweetness, and texture. Grittiness was below 6 (like slightly) in nectars, likely due to the seeds in the whole freeze-dried BRB. Grittiness may influence the overall liking score of both products. When subjects were asked in the surveys what factors contributed to or hindered the consumption of BRB products, 33% in the nectar group and 20% in the confection group mentioned grittiness. Other factors such as dose frequency in confection may have influenced the overall liking (40% mentioned that high dose frequency, 10 pieces per day, was a hindrance).

In this study, both BRB confections and nectars were formulated successfully to deliver a specific dose of bioactives in a consistent manner. After scale up, rheological properties did not vary within a product category, and ellagitanin and ellagic acid proved to be more heat stable and consistent than anthocyanins. During 8 weeks of storage, high-dose nectar showed the least changes in bioactives. Final products were well accepted (>like moderately) by men enrolled in a prostate cancer clinical trial. Thus, this study demonstrates that two different BRB delivery vehicles consisting of different matrices can be formulated to meet quality standards and bioactive stability and successfully scaled up for a human clinical trial. The use of these food products can prove to be instrumental in studying the efficacy of BRB bioactives in the prevention of or as adjuvant therapy in a variety of cancers (prostate, esophageal, oral, etc.).
