metabolic transit of 3-DG in healthy humans is available up to now.

The aim of our study, therefore, was to examine the contribution of dietary 3-DG on the "3-DG-load" of the human body. To obtain information about absorption and metabolism of 3-DG, urinary elimination of 3-DG and its major metabolite 3-DF was analyzed in healthy subjects following a diet containing 3-DG and a diet virtually free from 3-DG. During a 3 day intervention study, the influence of a single dose of honey containing a defined amount of 3-DG on the urinary elimination of 3-DG and 3-DF was observed. For this, a sensitive GC-MS for the simultaneous quantification of 3-DG and 3-DF in human urine had to be developed, and both analytes were synthesized as reference material.

MATERIALS AND METHODS

Materials. Chemicals of the highest purity available were purchased from standard suppliers: 1,1′-thiocarbonyldiimidazole (Sigma-Aldrich, Steinheim, Germany); *n*-hexane, hydroxylamine hydrochloride (Merck, Darmstadt, Germany); *N*,*O*-bis(trimethylsilyl)-trifluoroacetamide, D-fructose, methanol (Sigma-Aldrich); methyl-α-D-galactopyranoside (Acros, Geel, Belgium); pyridine (anhydrous), tributyltin hydride, urease (type C-3, 12KU) (Sigma-Aldrich). Mixed-bed ion exchanger Serdolit MB-2 was from Serva (Heidelberg, Germany), and cation exchanger (Lewatit S100) was from Bayer (Leverkusen, Germany). 3-DG was synthesized as already described[26] with some modifications.[10] [$^{13}C_6$]3-DG was prepared accordingly starting from [$^{13}C_6$]glucose (99%, Euriso-Top, Saint-Aubin Cedex, France). The water used was obtained with a Purelab plus purification system (USFilter, Ransbach-Baumbach, Germany).

Synthesis of 3-Deoxy-D-*erythro*-hexulose (3-Deoxyfructose). Protocols of synthesis were adopted with minor modifications.[27−29] Eighteen grams of D-fructose (**1**, Figure 2) was suspended in 350 mL of acetone containing 0.5% sulfuric acid and mechanically stirred at room temperature (under exclusion of moisture) until the sugar was dissolved (about 1.5 h). Termination of the reaction was carried out by adding 50 mL of ice-cold sodium hydroxide solution (c = 2.75 mmol/L) to the mixture while stirring was continued. Acetone was evaporated in vacuo, and the remaining aqueous phase (reddish brown) was extracted with methylene chloride (3 × 100 mL). The combined extracts were washed with water (2 × 50 mL) and dried over sodium sulfate. After evaporation of the organic solvent, the crude reaction product was recrystallized twice from ethanol/water 1:4 (v/v) and from ether followed by pentane. At 6 °C complete crystallization was achieved overnight. After drying, 5.1 g of long white needles of the diacetal sugar **2** (1,2:4,5-di-*O*-isopropylidene-D-fructopyranose, Figure 2) was obtained (20.2% from compound **1**). Solid 1,1′-thiocarbonyldiimidazole (2.2 g) was added to 1.5 g of the partially protected sugar, dissolved in 30 mL of tetrahydrofuran, and heated under reflux (66 °C) until complete conversion to the *O*-(imidazolylthiocarbonyl) derivative (about 3 h, monitored with thin layer chromtography).[28] The target product was isolated from the evaporated reaction mixture by flash chromatography (stationary phase: silica gel 60, mesh 0.063−0.200 mm) with ethyl acetate/hexane (1:1, v/v) as mobile phase, eluting between 80 and 260 mL.

Drying of the combined fractions yielded 1.9 g of the alkoxythiocarbony1imidazolide derivative (85% from **2**), which was completely employed for the following reduction step. The product was dissolved in 50 mL of anhydrous toluene, which was added dropwise within 30 min to a boiling tributyltin hydride/toluene solution (2.3 g in 200 mL of anhydrous toluene). After completion of reduction (about 1 h), the cooled solvent was evaporated in vacuo, and the dry residue was extracted with hot acetone (3 × 50 mL); the

Table 1. GC-MS Parameters (SIM Mode) for the Determination of 3-Deoxyfructose (3-DF) and 3-Deoxyglucosone (3-DG)

	internal standard	quantifier ion [m/z]	qualifier ion [m/z]	internal standard quantifier ion [m/z]	internal standard qualifier ion [m/z]	dwell time (ms)
3-deoxyfructose	MGP	191	217, 524	204	217, 133	80 (for each measured ion)
3-deoxyglucosone	[$^{13}C_6$]3-DG	347	373, 537	351	379, 543	

combined extracts were washed with hexane (4 × 50 mL) to remove stannous components. Acetone was evaporated, and product isolation was performed by flash chromatography (stationary phase: silica gel 60, mesh 0.063−0.200 mm, mobile phase ethylacetate/hexane 1:1 (v/v), elution between 80 and 170 ml). After recrystallization from pentane, 0.74 g of the reduced diisopropylidene derivative **3** (Figure 2) was obtained as white needles (71% from **2**). ^{1}H nuclear magnetic resonance (NMR) analysis of this product gives a spectrum according to data published in the literature.[28] Distinct signals with chemical shifts of δ = 2.1 for the two protons at C3 indicate the successful reduction at C3 (literature δ = 2.00 and 2.06).[28]

For hydrolysis the complete yield was dissolved in 12.5 mL of acetone and 25 mL of water. Three grams of activated cation exchange resin (Lewatit S100) was added; this mixture was then stirred for 24 h at room temperature. Neutralization was achieved by stirring the solution for another 6 min with the addition of 6 g of a mixed-bed ion exchanger (Serdolit MB-2). The product was purified by flash chromatography (stationary phase as above; mobile phase: methylene chloride/ethanol/water 2:1:0.1 (v/v/v), elution between 80 and 170 mL). The combined fractions were evaporated, and the residue was taken up in water and lyophilized to yield 0.16 g of 3-DF (**4**) (Figure 2; 16% from **2**). After 6 weeks of storage at −18 °C, complete crystallization was accomplished with small, light yellow crystals. The product was characterized by ^{1}H NMR and ^{13}C NMR, and purity was examined via GC-FID. ^{1}H NMR (500 MHz, D_2O) β-pyranose: δ_H 3.43 (s, 2H, H1A/H1B), 1.78 (m, 2H, H3A/H3B), 3.95 (m, 1H, H4), 3.70 (s, 1H, H5), 3.59 (dd, 1H, H6), 3.86 (dd, 1H, H6). ^{13}C NMR (125 MHz, D_2O): δ_C 97.21 (C-2), 67.05 (C-5), 65.21 (C-1), 64.76 (C-4), 63.81 (C-6), 41.29 (C-3).

For purity control of 3-DF, the corresponding trimethylsilyl (TMS) oxime of 3-DF was subjected to GC-FID analysis. Analysis was performed on a Varian 3900 gas chromatograph with a CP-8410 automatic liquid sampler with split injector and flame ionization detection (FID). Separation was performed on a DB-5 capillary column (30 m, 0.25 mm i.d., 1.00 μm film thickness, J&W Scientific, Germany). Helium was the carrier gas with a constant flow at 1.0 mL/min, injector temperature was 250 °C, and injection mode was 1 μL at 1:20 split. The oven temperature program was adopted from the parameters of the GC-MS analysis.

Stock solutions each of 3-DF and D-fructose were prepared in water (c = 1 mM), and calibration curves (0.05−1 mM) of the TMS oximes were recorded with GC-FID. The slope of the calibration curve of 3-DF was compared to the slope of the calibration curve of D-fructose, and the ratio was assumed to indicate the purity/content of synthesized 3-DF.

Intervention Study. Nine healthy, normoglycemic volunteers (ages 24−36 years, 7 women and 2 men, nonsmoking, fasting blood sugar ≤5.5 mmol/L) collected their 24 h urine (8.00 a.m. until 8.00 a.m. the following day) on 2 consecutive days with no dietary restrictions (days 1−2). Furthermore, all nine participants took part in a 3 day intervention study consisting of one wash-out day (day 3), one intervention day (day 4), and one run-out day (day 5). From day 3 to day 5, they followed a "raw food" diet, which implies avoiding heated and fermented foods such as dairy and bakery products, coffee, juices, and beer to ensure a diet virtually free of 3-DG and Maillard reaction products. In the morning of the intervention day (day 4), the participants ingested a single dose of 50 g of honey containing a defined amount of 505 μmol of 3-DG (3-DG concentration of the honey was 1641 mg/kg). The "raw food" diet was continued on the fifth day. Twenty-four hour urine was collected every day of the study as described above. Additionally, a placebo study was performed. Two participants (ages 28 and 31 years, respectively, 1 woman and 1 man, nonsmoking, fasting blood sugar ≤5.5 mmol/L) followed the same 5 day study design as described above, but ingested 50 g of a honey analogue sugar mixture (46.5% D-fructose, 34.5% D-glucose, 1.5% saccharose, and 17.5% water)[30] instead of wild honey in the morning of the intervention day (day 4). Aliquots of collected 24 h urine samples were immediately stored at −18 °C until analysis. 3-DG and 3-DF were analyzed within 2 weeks.

Preparation of Urine Samples for GC-MS Analysis. After the urine thawed, an aliquot of 100 μL was spiked with 10 μL of internal standard solution (containing 1.0 mg/mL methyl-α-D-galactopyranoside[31] and 0.1 mg/mL [$^{13}C_6$]3-DG in water) and was then treated with 30 μL of urease (1 mg/mL in 0.2 M sodium phosphate buffer, pH 7.0) for 10 min at 37 °C in a water bath. Termination of the enzymatic reaction was realized by addition of 900 μL of ice-cold ethanol. After centrifugation (10000g, 15 min), the resulting supernatant was transferred to a new tube and evaporated to dryness under a nitrogen stream. Then the dry residue was incubated with 50 μL of hydroxylamine hydrochloride solution (10 mg/mL in anhydrous pyridine) for 30 min at 80 °C followed by evaporation to dryness. Then 50 μL of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide was added to the residue and vigorously mixed by vortex for 0.5 min and incubated at room temperature for another 2 h. Subsequently, 50 μL of *n*-hexane was added; an aliquot of 80 μL was transferred to a GC vial and was then ready for GC-MS analysis.

GC-MS Analysis of 3-Deoxyglucosone and 3-Deoxyfructose. GC-MS analysis was performed using a HP6890 gas chromatograph, coupled with a HP7683 automatic liquid sampler and a HP5973 mass selective detector equipped with a HP-5MS capillary column (30 m, 0.25 mm i.d., 0.25 μm film thickness; all from Agilent, Germany) and a Zebron Z-guard column (deactivated, 5 m, 0.25 mm i.d.; Phenomenex, Germany). The carrier gas was helium with a constant flow at 1.0 mL/min, the injector temperature was 250 °C, and injection mode was 1 μL pulsed splitless. The oven temperature program started at 80 °C (hold time = 2 min) elevated to 250 °C at 10 °C/min (hold time = 3 min) and finally heated to 300 °C at 30 °C/min (hold time = 3 min), resulting in a complete run time of 25 min. Mass spectrometer was used with electron ionization (70 eV) in scan and SIM modes. In scan mode the recorded m/z area range varied from 50 to 800. For detailed SIM parameters see Table 1.

For external calibration, stock solutions of the analytes in water (0.06−0.6 mM) were pipetted (1−50 μL) to yield appropriate concentrations along with internal standards. Each calibration sample was subjected to the derivatization procedure after evaporation to dryness (see above).

Quantitative evaluation was carried out by the use of the ratio of the area of the most prominent analyte peak and the internal standard peak of the corresponding quantifier ions, despite the occurrence of peaks of *syn*- and *anti*-stereoisomers of the analytes.

The limits of detection (LOD) and quantitation (LOQ) in standard solution and urine were calculated as the concentrations of the analyte necessary to show a peak at signal-to-noise ratios of 3 and 10, respectively. For the determination of the interday repeatability, one urine sample was applied to the sample workup and derivatization procedure five times on different days. The recovery of 3-DF and 3-DG was calculated from the slope of the recovery function after urine had been spiked with three ascending concentrations of the analytes (3-DF, 6−300 μmol/L; 3-DG, 0.6−30 μmol/L) with subsequent sample workup.

NMR Spectrometry. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DRX 500 instrument (Rheinstetten, Germany) at 500 and 125 MHz, respectively. Samples were dissolved in deuterium oxide. Chemical shifts are given in parts per million (ppm), those of protons

relative to the internal HOD signal (4.70 ppm, residual proton), and those of carbon atoms relative to the external standard tetramethylsilane. Assignments of ^{1}H and ^{13}C signals are based on heteronuclear single-quantum coherence (HSQC) and distortionless enhancement by polarization transfer (DEPT) experiments.

Statistical Treatment. Comparisons of means between the daily urinary excretions of the different days were examined using Student's *t* test. *P* values ≤0.05 were considered significant (two-tailed) using OriginPro 8.6.

RESULTS AND DISCUSSION

GC-MS Analysis of Urinary 3-Deoxyglucosone and 3-Deoxyfructose: Method Evaluation. The first aim of our study was to establish a sensitive and selective method for the simultaneous determination of 3-DG and its metabolite 3-DF in urine. As 3-DF is commercially not available, it had to be synthesized as reference material. This was achieved by the preparation of the 1,2:4,5-diacetal of D-fructose, selective reduction at C3 with tri-*n*-butylstannane, and finally hydrolysis of the 3-deoxysugar, according to literature methods (compare Figure 2).[27−29] The ^{1}H NMR spectrum of the final product 3-DF showed several signals due to five tautomeric forms of the deoxysugar in aqueous solution. According to the literature, most signals of the β-pyranoide structure could be assigned, as this is the predominating form of 3-DF in aqueous solution at room temperature. Chemical shifts of the signals are in line with those reported.[29] The chemical shift of the protons at C3 (δ = 1.78) of 3-DF are characteristic for the reduction at C3 and prove the identity of 3-DF along with the other signals. Purity control of the synthesized 3-DF via GC-FID[32] indicated a purity of 99% when compared to D-fructose. The GC-FID chromatogram indicated no impurities of other sugars or sugar derivatives (data not shown).

For the GC-MS analysis of the sugar derivatives, a conversion to volatile compounds is inevitable. The first step of the derivatization is the formation of the corresponding oximes, followed by the conversion to the TMS derivatives (Figure 3).[33] With regard to the 10 isomeric forms of 3-DG[34] and the 5 tautomeric forms of 3-DF,[29] the formation of sugar oximes is advantageous because the oximes exist in open-chain form,[35] leading to only two silylated isomers per aldehyde or keto group, respectively. Compared to the published method[7] for the simultaneous determination of 3-DG and 3-DF, this optimized GC-MS method has the key advantage of higher selectivity. This is accounted for by different retention times of the two analytes and distinct *m*/*z* ratios (compare Figure 2). In the cited method[7] the retention times for both analytes are the same and the *m*/*z* ratio is only 1.

The preparation of the urine samples prior to derivatization consisted of an enzymatic removal of urea for the analysis of carbohydrates in urine.[36] The dry matter of urine contains approximately 23−49% urea,[37] which can consume large amounts of the silylating agent and therefore hamper the silylation of the analytes.[36] The adopted derivatization method[33] was slightly modified in this work, resulting in a reduction of the applied derivatization agents. The application of oxime formation in carbohydrate analysis has been already examined in detail with regard to stability, efficiency, and the number of byproducts formed.[38] The amount of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) was adjusted to 50 μL per derivatization assay, and derivatization was complete after 2 h at room temperature, based on time course studies. The solvent evaporation after oxime formation is time-consuming, and the silylation of the analytes in the dry residue is suboptimal compared to a silylation of the analytes in solution. The drying procedure, however, is necessary to ensure a salt concentration as low as possible in the injected sample solution to minimize contamination and signal suppression in the mass selective detector.

In Figure 4, a selected ion chromatogram of a 3-DF (at *m*/*z* 191) and 3-DG (at *m*/*z* 347) standard solution after derivatization with hydroxylamine hydrochloride and BSTFA to the corresponding TMS oximes is shown. For the TMS

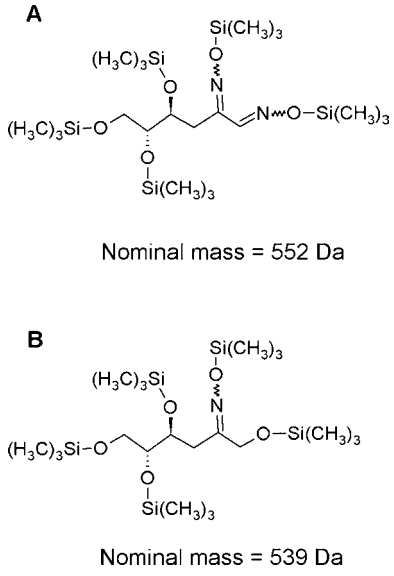

Figure 3. Structures of the trimethylsilyl oxime derivatives of (A) 3-deoxyglucosone and (B) 3-deoxyfructose with their corresponding nominal masses.

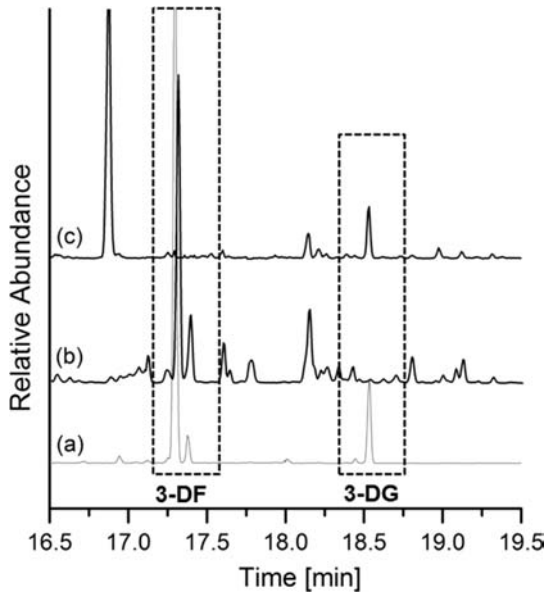

Figure 4. Selected ion monitoring chromatogram of (a) a 3-deoxyglucosone 3-DG)/3-deoxyfructose (3-DF) standard solution (*m*/*z* 347 and 191), (b) a urine sample at *m*/*z* 191, and (c) a urine sample at *m*/*z* 347. All chromatograms were acquired by GC-MS after derivatization with hydroxylamine hydrochloride and *N*,*O*-bis-(trimethylsilyl)trifluoroacetamide to the corresponding trimethylsilyl oximes.

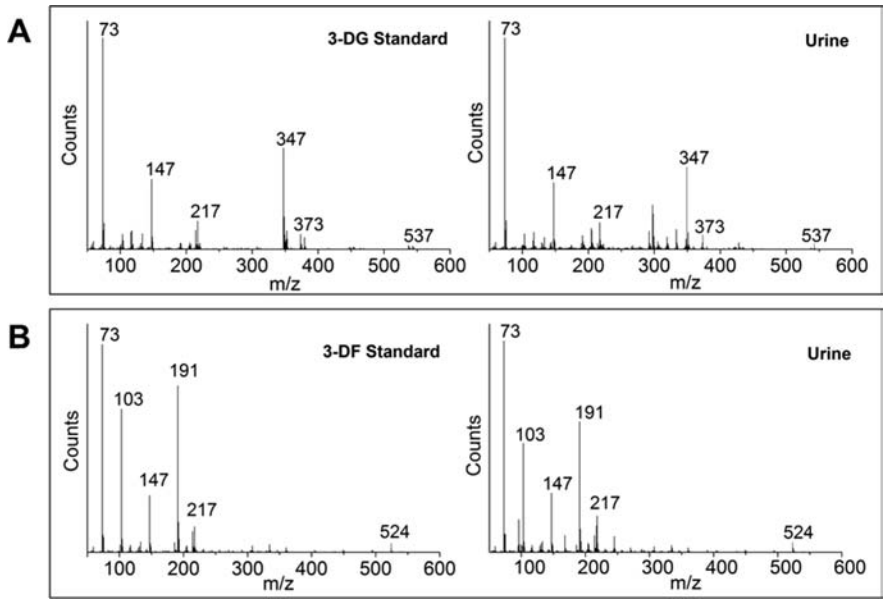

Figure 5. (A) EI-Mass spectra of the peak eluting at 18.5 min of a 3-deoxyglucosone (3-DG) standard solution and a urine sample (scan mode). (B) EI-Mass spectra of the peak eluting at 17.3 min of a 3-deoxyfructose (3-DF) standard solution and a urine sample (scan mode). All spectra were acquired by GC-MS after derivatization with hydroxylamine hydrochloride and *N*,*O*-bis(trimethylsilyl)trifluoroacetamide to the corresponding trimethylsilyl oximes.

Table 2. Performance Parameters of the GC-MS Method for the Determination of 3-Deoxyfructose (3-DF) and 3-Deoxyglucosone (3-DG) in Urine

	R^2	linear range (μmol/L)	interday repeatability[a] (%)	LOD[b] (nmol/L)	LOQ[b] (nmol/L)	recovery[c] (%)
3-deoxyfructose	0.9998	6−300	1.5	52 ± 4	155 ± 11	101.8 ± 3.8
3-deoxyglucosone	0.9980	0.6−30	1.0	20 ± 4	59 ± 13	97.4 ± 4.2

[a]Expressed as relative standard deviation. [b]LODs (limit of detection) and LOQs (limit of quantification) were calculated on the basis of signal-to-noise-ratio. [c]Recovery was determined by addition of various concentrations of 3-DF (60−300 μmol/L, $n = 3$) and 3-DG (0.6−30 μmol/L, $n = 3$) to 100 μL of urine, applying all steps of sample preparation and analysis. The value was calculated from the slope of the recovery function and is given in percent ± SE.

oxime of 3-DF, two peaks are detectable, which arise from its *syn*- and *anti*-isomers due to the derivatization reaction with hydroxylamine hydrochloride. The first peak (17.3 min) is the major peak and can presumably be assigned to the *syn*-form due to steric reasons.[35] The second minor peak (17.4 min) represents the *anti*-form and accounts for <15% of the total peak area. The stable *syn*- and *anti*-anomeric oximes are formed in constant ratio.[33,38] In the present study, the ratio between the *syn*- and *anti*-oximes was about 7:1. Therefore, the quantitation of 3-DF was performed via the ratio of the area of the major 3-DF TMS *syn*-oxime peak and the area of the peak of the silylated internal standard methyl-α-D-galactopyranoside.[31]

The TMS oxime of 3-DG theoretically exists in four different isomeric forms because of the two carbonyl groups, but in the extracted ion chromatogram of a 3-DG standard solution (at m/z 347, compare Figure 4), only one peak was observed. This may be due to steric hindrance preventing the formation of some isomers or the chromatographic system failing to resolve them. The identification of the two analytes in urine was accomplished chromatographically by comparison of the retention times of the target compounds in standard solution and urine as shown in Figure 4 together with the corresponding mass spectra (compare Figure 5).

In Figure 5A, the mass spectra (scan mode) of the peak eluting at 18.5 min in a standard solution and a urine sample are displayed. The two spectra show the same distinct signals at the mass-to-charge ratio of the quantifier ion (m/z 347) and the qualifier ion (m/z 537). The mass spectra (scan mode) of the peak eluting at 17.3 min of a 3-DF standard solution and a urine sample after derivatization to their corresponding TMS oximes are presented in Figure 5B, having consistent signals at m/z 191 (quantifier ion) and at m/z 524 (qualifier ion). Comparison of the mass spectra of the peaks of the two corresponding analytes recorded from a derivatized standard solution and a urine sample allows a doubtless and unequivocal identification of 3-DG and 3-DF in urine.

In Table 2, validation parameters of the method for the determination of 3-DG and 3-DF in urine are summarized. They indicate an accurate sample preparation, a reproducible derivatization procedure, and a reliable GC-MS analysis. On the basis of the relative interday repeatability being <1.5% for both analytes, it can be concluded that all steps from the sample preparation to the evaluation of the obtained chromatograms are precise. They also indicate that the applied internal standards ([$^{13}C_6$]3-DG for 3-DG and methyl-α-D-galactopyranoside for 3-DF) are appropriate.

Monitoring of Urinary 3-Deoxyglucosone and 3-Deoxyfructose. By comparison of the daily dietary intake of 3-DG (0.1−1.0 mmol/day)[11] with the concentrations measured for human plasma (0.04−0.16 μmol/L plasma),[6−9] questions arise concerning the impact of dietary 3-DG on the overall "3-

DG load" of the human body. To the best of our knowledge there is no information about the metabolic fate of dietary 3-DG in healthy, normoglycemic human subjects. Our work was motivated by previous results of a rat study in which orally absorbed 3-DG was eliminated as 3-DF in the urine at a percentage of about 5%.[18]

We therefore applied the developed method to monitor the 3-DG and 3-DF excretion in 24 h urine samples with nine healthy volunteers. During the first 2 days participants followed their own individual diet with no restrictions. In Figure 6 (days 1−2) the results of the urine analysis are displayed. The median 3-DG excretion in 24 h urine was 7.6 μmol on day 1 and 8.9 μmol on day 2, respectively (range = 6.4−15 μmol/day; Figure 6A). The median 3-DF excretion in 24 h urine was 146 μmol on day 1 and 165 μmol on day 2, respectively (range = 91−306 μmol/day; Figure 6B). The urinary excretion of 3-DG and 3-DF did not differ significantly between the two days ($P > 0.05$). 3-DG accounted for 4−8% (mean = 6%) of the summarized 3-DG and 3-DF amounts. This is in line with published data,[7] which show that 3-DF is the main metabolite in urine accounting for >95% of 3-DG. The daily urinary apparent 3-DF excretions are consistent with values published in the literature for healthy subjects (32−92 μmol/g creatinine),[7,26] when a daily excretion of 1.1−1.9 g creatinine is taken as a basis.[37] In the literature, urinary excretion is usually referred to the creatinine elimination for standardization purposes. The results of the urinary elimination in this work are given as the amount present in total 24 h urine. This was mainly because the creatinine excretion is dependent on internal and external factors that lead to a broad fluctuation of the excreted amount.[39]

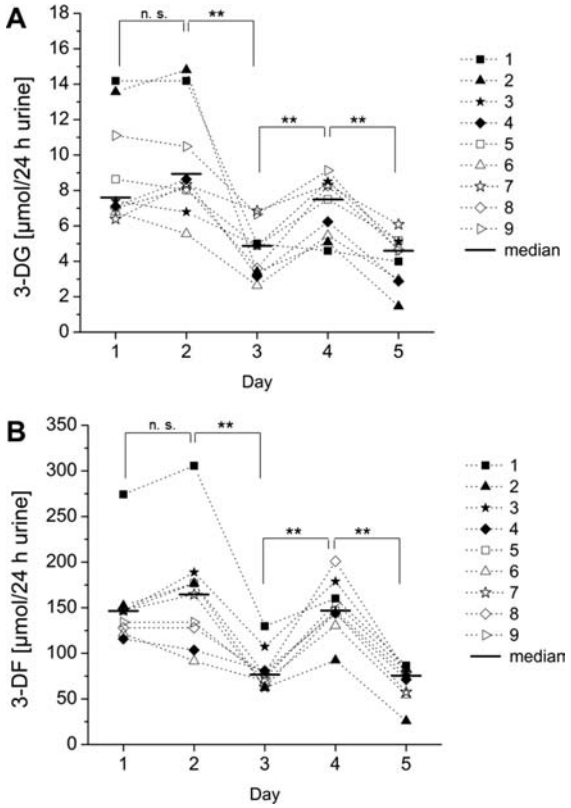

Figure 6. Urinary excretion of (A) 3-deoxyglucosone (3-DG) and (B) the metabolite 3-deoxyfructose (3-DF) in 24 h urine of nine healthy subjects. Days 1−2, participants followed their usual diet without restrictions; days 3−5 (intervention study), participants followed a "raw food" diet; day 3, wash-out day; day 4, intervention day, ingestion of 50 g of wild honey containing 505 μmol of 3-DG in the morning; day 5, run-out day. Comparisons of means were examined using Student's *t* test. n. s., not significant ($P > 0.05$); **, $P < 0.01$ (highly significant).

When the study participants followed a diet virtually free from 3-DG (wash-out day, day 3 in Figure 6), the 24 h urinary excretion of 3-DG and 3-DF significantly decreased ($P_{3\text{-DG}} < 0.001$; $P_{3\text{-DF}} < 0.002$, Figure 6). The median level of renal 3-DG excretion on the wash-out day (day 3, "raw food" diet) was 4.6 μmol/day (from 2.6 to 6.8 μmol/day), and the median level of 3-DF excretion was 77 μmol/day (from 62 to 130 μmol/day). However, the urinary excretion of 3-DG and 3-DF on day 3 can be assumed to be mostly unaffected by dietary 3-DG or other Maillard reaction products such as fructoselysine, which may form 3-DG after ingestion.[9] An important source for urinary 3-DG and 3-DF levels on this day should be endogenously formed 3-DG, which arises from the enzymatic deglycation of protein-bound Amadori compounds.[40] Varying endogenous 3-DG concentrations and, therefore, interindividual differences in the excretions of 3-DG and 3-DF are associated with differences in FN3K activity.[40,41] Because there was no wash-out phase between the days with no dietary restrictions (days 1−2) and the wash-out day (day 3), the 3-DG and 3-DF elimination could also be influenced by dietary 3-DG from the previous days, if it is slowly metabolized.

On the basis of these results it was not possible to make any statement on the bioavailability of dietary 3-DG as the exact amounts of 3-DG ingested with the diet were not quantitated. Furthermore, the influence of other compounds, for example, fructoselysine, of the consumed food could not be evaluated. A postprandial increase of plasma 3-DG in diabetic subjects was discussed to be due to the conversion of the dietary Amadori compound fructoselysine.[9] Recent findings, however, showed that dietary fructoselysine is not transported across intestinal epithelial cell monolayers in vitro and is therefore most presumably not absorbed from food in the human intestine.[42] So far, there is no information about a possible occurrence of 3-DF in foods, especially in fruits. In upcoming studies this is a crucial point to know to address an influence of possible dietary 3-DF.

Therefore, the participants took part in a further study. During a 3 day intervention study (days 3−5, Figure 6), the nine volunteers followed a "raw food" diet virtually free from 3-DG and other Maillard reaction products and consumed 50 g of honey containing 505 μmol of 3-DG on the morning of the intervention day (day 4). On day 5, the run-out day, "raw food" diet was continued. In Figure 6, the daily urinary excretions of 3-DG and 3-DF are shown. Compared to the mean urinary excretion of 3-DG and 3-DF during the two days of the dietary recall without restriction, mean values of both analytes significantly decreased on the wash-out day of the intervention study (day 3, compare Figure 6; $P_{3\text{-DG}} < 0.001$; $P_{3\text{-DF}} < 0.002$).

On the intervention day of the study (day 4), when a defined amount of 3-DG (505 μmol) via wild honey was consumed in the morning, the daily urinary excretion of 3-DG and 3-DF was significantly elevated compared to the wash-out day (day 3; $P_{3\text{-DG}} < 0.002$; $P_{3\text{-DF}} < 0.001$). Median 3-DG and 3-DF excretion increased to 7.5 μmol/day (range = 4.6−9.1 μmol/day; Figure 6A) and 147 μmol/day (range = 92−201 μmol/day; Figure 6B), respectively. With regard to the wash-out day,

the average increase of the urinary 3-DG excretion was 3.0 μmol/day (range = 0.4−3.6 μmol/day) and that of the 3-DF excretion was 70 μmol/day (range = 30−123 μmol/day). This corresponds with approximately 10−15% of the ingested amount of 3-DG being recovered in the urine. Slightly lower excretion rates into urine were observed in rats, but it is obvious that results of animal experiments could be only partly transferred to humans and the study design lasted only 2 h.[18] Median 3-DG and 3-DF excretions on the run-out day (day 5) did not differ significantly from those of day 3 ($P > 0.05$), indicating a rapid elimination of intestinally absorbed 3-DG (compare Figure 6). Despite the intake of a high amount of 3-DG on the intervention day (day 4), the median ratios of the urinary 3-DG/3-DF excretion did not vary significantly compared to the other days (see Supporting Information). In further studies it might be of interest to investigate interindividual differences of the excreted 3-DG/3-DF ratios to have further insights into possible variations of the metabolic handling, for example, during diabetes.

To rule out that the observed increase in urinary excretion of 3-DF on day 4 is due to the high sugar load and a possible formation of 3-DG from glucose or fructose in vivo, a placebo study was performed. Two volunteers consumed 50 g of a honey analogue sugar mixture virtually free of 3-DG instead of 3-DG-containing wild honey on the intervention day (data and figure shown in the Supporting Information). Urinary excretion of 3-DG and 3-DF remained constant, indicating that precursors such as fructose or glucose do not contribute to a measurable 3-DG formation in vivo or an increased urinary 3-DG and 3-DF excretion, respectively. Hence, the elevation of the urinary 3-DF excretion on the intervention day of the intervention study was exclusively due to the 3-DG consumed via the wild honey.

These experimental findings for the first time prove an influence of dietary 3-DG on urinary excretion of 3-DG and 3-DF. The results imply that dietary 3-DG is to some extent taken up from the ingested food in the intestinal tract, metabolized to 3-DF, and eliminated via urine. This allows the conclusion that detoxification systems for endogenously formed reactive aldehydes, such as aldehyde and aldose reductase,[21,22] should also be capable to degrade dietary and therewith exogenous 3-DG. In particular, the recently described small intestine aldose reductase (ALKR1B10), which is described to play a key role in detoxifying dietary and lipid-derived carbonyl compounds,[21,22] should be examined in this context. As only 10−15% of the administered 3-DG is recovered in urine as 3-DG and 3-DF, the question arises about the fate of the remaining 85−90%. Further studies will have to show whether putative 3-DG-specific metabolites such as 3-deoxy-2-keto-gluconic acid or hydroxymethylfurfural (HMF) can be found in the urine. At present, it cannot be excluded that 3-DG is to some extent transformed to HMF due to the low pH value of the stomach. 3-DG may also react with proteins to AGEs in the gastrointestinal tract or in vivo. The analysis of 3-DG and 3-DF in blood plasma plus 3-deoxy-2-keto-gluconic acid and other analytes (i.e., fructoselysine, HMF, pyrraline) of study participants after an oral load of 3-DG would unequivocally reveal if and to what extent 3-DG is absorbed into the systemic circulation and if it is metabolized. On the basis of results of animal experiments, it was concluded that orally ingested 3-DG is absorbed in the intestine to only a minor degree and that the major part remains in the content of the gastrointestinal tract.[18] This finding should be examined in a following study.

In conclusion, it was possible for the first time to reveal differences in urinary 3-DG and 3-DF elimination in healthy human subjects, dependent on the diet. These results are a prerequisite for further studies concerning metabolic pathways of 3-DG in human subjects.

purchased from various producers. A total of 10 samples of extra VOOs, coded F_v, F_N, F_1, Z_v, Z_1, Z_2, C_v, C_1, Cha_1, and Cha_2, were chosen among a sample collection of the laboratory. The samples were kept at −23 °C in dark glass bottles with minimum headspace flushed with N_2 until analysis.

Polar Fraction Preparation. The polar fraction was extracted from 2.5 g of VOO dissolved in 5 mL of hexane using an equal volume of methanol/water (60:40 v/v). The mixture was vortexed for 2 min and centrifuged for 10 min at 3500 rpm. The isolated polar fraction was then used for the determination of total polar phenol content (TPP) colorimetrically[10] and RP-HPLC separation of phenolic compounds prior to and after acidic hydrolysis.[8,9] A second extraction was not necessary as >95% of TPP was obtained in the first extract (n = 5). Repeatability of the process was adequate (CV% = 4.7 for TPP = 7.67 mg caffeic acid/20 g oil, n = 5).

Acidic Hydrolysis according to Mulinacci et al.[8] (Protocol 1). Briefly, an aliquot (200 μL) from the polar fraction was mixed with 200 μL of a 1 M H_2SO_4 solution. The mixture was maintained in a water bath at 80 °C for 2 h. The procedure was carried out in triplicate. Each hydrolysate was then diluted with 200 μL of acetonitrile/water 50:50, v/v. The three replicates were combined to obtain a representative hydrolysate. The latter was filtered through a 0.45 μm pore size regenerated cellulose membrane (Schleicher and Schuell, MicroScience GmbH, Dassel, Germany) before injection into the chromatograph. Method intra- and interday repeatabilities (in two different days) were examined for a VOO sample (n = 5), and the respective CV% values obtained for Htyr and Tyr were 0.9/2.4 and 1.5/2.2. Samples were then analyzed in triplicate.

Acidic Hydrolysis according to Romero and Brenes[9] (Protocol 2). Fifty milliliters of 2 M HCl was added to 2.5 g of VOO in a 100 mL glass bottle that was closed with a polypropylene cap. The mixture was vigorously agitated at 250 rpm in a shaker incubator (model MkX, Stoke Poges, UK) at 25 °C for 6 h in triplicate for each sample. Finally, 2 mL of the aqueous phase was removed by a plastic pipet from each replicate, mixed to form a representative hydrolysate, and filtered through a 0.45 μm regenerated cellulose membrane before injection into the chromatograph. Samples were analyzed in triplicate.

RP-HPLC Analysis. The elution system used for the chromatographic separation of polar phenols on a Nucleosil C_{18} (250 × 4.6 mm, 5 μm) column (Macherey-Nägel, Düren, Germany) consisted of 1% aqueous acetic acid (solvent A) and acetonitrile (solvent B). The gradient was as follows: 0−2 min, 5% B; 2−15 min, 25% B; 15−22 min, 25% B; 22−30 min, 40% B; 30−40 min, 60% B; 40−50 min, 95% B; 50−52 min, 95% B; 52−54 min, 100% B; 54−60 min, 5% B, at a flow rate of 0.5 mL/min and an injection volume of 20 μL. Diode array (UV 6000 LP model, cell volume = 10 μL, Thermo Separation Products, San Jose, CA, USA) and fluorescence (SSI 502 model, cell volume = 8 μL, Scientific Systems Inc., State College, PA, USA) detectors were used in line. Calibration curves were constructed for Htyr and Tyr at appropriate wavelengths[5] [280 nm; exc 280 nm/em 320 nm] (Supporting Information Figure S1). The limit of detection (LOD) and the limit of quantification (LOQ) were estimated for both Htyr and Tyr at 280 nm using the following equations:[11] LOD = 3.3 × σ/S' and LOQ = 10 × σ/S' (where σ is the standard error of the y intercept and S' the slope of the calibration curve). The values obtained were 0.7 and 2.0 ng/μL (Htyr) and 1.9 and 5.9 ng/μL (Tyr), respectively.

RESULTS AND DISCUSSION

First, the stability of Htyr and Tyr and the completeness of oleuropein hydrolysis claimed by Mulinacci et al.[8] were verified. Both compounds were found to be stable, and estimated losses for a solution of 250 mg/L accounted for approximately 6.1% (n = 3) for Htyr and 3% (n = 3) for Tyr using the respective calibration curves. Hydrolysis of an oleuropein solution (250 mg/L) was complete, leading to the sole formation of Htyr. Similarly, the parameter "agitation" of protocol 2 was tested for one VOO sample using two shaker types and was not found to be critical (Table 1). Nevertheless, the yields derived for Htyr and Tyr were half of those obtained using protocol 1, as shown in the same table.

Table 1. Effect of Agitation on the Yield of Htyr, Tyr, and Their Sum according to Protocol 2

hydrolysis conditions, 2 M HCl, 6 h	Htyr[a] (mg/20 g oil)	Tyr[a] (mg/20 g oil)	Htyr + Tyr (mg/20 g oil)
400 rpm[b]	0.66 a ± 0.01	0.31 a ± 0.01	0.97
200 rpm[b]	0.69 ab ± 0.02	0.33 ab ± 0.02	1.02
250 rpm[c]	0.72 b ± 0.01	0.35 b ± 0.01	1.07
isolation of polar fraction/ 1 M H_2SO_4, 2 h, 80 °C[d]	1.63 c ± 0.03	0.69 c ± 0.02	2.32

[a]Data are the mean ± standard deviation (n = 3). Different letters in the columns represent significant differences in concentration (p < 0.05). [b]Bench-top yellow-line orbital shaker (IKA-Werke GmbH & Co. KG). [c]Shaker incubator (model MkX, Stoke Poges, UK). [d]Protocol 1.

On the basis of the above findings the two protocols were applied to a series of extra VOOs varied in TPP levels (Table 2). The superiority of protocol 1 was evident in all cases (2−7-fold higher levels). The trend observed for the total content was also reflected in the ratios of individual phenol levels (data not shown). Subsequent discussion was, consequently, based on the results obtained using protocol 1. None of the extra VOO samples contained the minimum required level of total Htyr and Tyr content (5 mg/20 g oil), although some of them (Z_2, F_v, F_N, C_v) presented a rather high TPP content, unusual for commercial products. Using one standard curve for quantification of both phenols, it was evident that the use of Tyr resulted in higher levels in comparison to those using Htyr due to differences in ε values (see Figure S1A in the Supporting Information). Even so, the required limit was not achieved for any of the VOO samples. Fluorescence detection, which is more sensitive than UV absorption, gave comparable

Table 2. Effect of Acidic Hydrolysis Protocols on the Total Htyr and Tyr Content in Extra VOOs of Various TPP Levels

sample	TPP[c] (mg caffeic acid/20 g oil)	Htyr + Tyr[a,b] (mg/20 g oil) protocol 1	Htyr + Tyr[a,b] (mg/20 g oil) protocol 2	protocol 1/ protocol2

estimations of the total content of Htyr and Tyr (∼1.2−1.4-fold higher) by means of the two calibration curves (see Table S1 in the Supporting Information). Using one standard curve it was shown that Htyr resulted in higher levels of total phenols in comparison to those using Tyr due to differences in their fluorescence response (see Figure S1B in the Supporting Information). Some of the samples reached the required limit (see Table S1 in the Supporting Information).

From the TPP content, RP-HPLC profiles, and levels of Htyr and Tyr of the polar fraction prior to hydrolysis, it was observed that all of the oils were rich in complex forms of Htyr and Tyr. Indeed, the respective ranges prior to hydrolysis were extremely low (Htyr, 0.03−0.5 mg/20 g oil; Tyr, nd−0.43 mg/20 g oil), as expected for fresh oils. At this point we have to stress that calculation on a mass basis introduces a systematic error because the bound forms have a much higher molecular mass compared to those of simple phenols. The mean MW of the 10 most known bound forms of Htyr and Tyr[12] is ∼346 amu. If a correction factor is introduced in the quantification using both standards (Htyr, 2.2; Tyr, 2.5) to account for the differences in mass between Htyr, Tyr, and their complex forms, respectively, then 9 of 10 VOO samples satisfied the health claim using UV detection at 280 nm (5.2 −8.9 mg/20 g oil), and all of them satisfied the health claim when fluorescence was used (5.5−10.6 mg/20 g oil).

In conclusion, after many years of consultation a health claim was finally approved for VOO bioactive phenols, all of them derivatives of oleuropein and ligstroside. Addressing analytical requirements to support this health claim is imperative to ensure consumer protection and avoid unfair competition. Determination of free forms of Htyr and Tyr in the VOO polar fraction hydrolysate and introduction of a correction factor in quantification are needed to have a simple, reproducible, and undisputable analytical protocol.

[a]Values are given in ng/g lw and are presented as mean concentrations. [b]Data from ref 18.

Cambridge Isotope Laboratories Inc. (WI, USA) and were of minimum 97% purity.

Sample Preparation. For meat, egg, dairy products, vegetable oil, and fat samples, the equivalent to one gram of fat was weighed. For fish samples, 20 g was weighed. Each sample aliquot was spiked with d_{18}-labeled α- and γ-HBCD as internal standards. Meat and fish samples were extracted in a Soxhlet apparatus with a mixture of hexane:dichloromethane (1:1). Dairy products were extracted in a separatory funnel with a mixture of ethanol, diethyl ether, and hexane and previous addition of an aqueous potassium oxalate solution. Egg samples were hydrolyzed with concentrated hydrochloric acid, previously extracted with hexane. The treated egg samples were extracted in a separatory funnel with a mixture of diethyl ether:hexane (1:1). Oil and fat samples were dissolved in 10 mL of hexane. After the extraction, lipid content was determined gravimetrically and the resulting extracts were redissolved in hexane. Then, fat was removed by an acid treatment: extracts were cleaned up by the addition of 10 mL of concentrated sulfuric acid. Organic fraction (containing HBCD) was evaporated to 3 mL, and the whole cleanup procedure was repeated until the acid did not turn yellow. Final purification of the extract was carried out in 5 g alumina SPE cartridges. Cartridges were conditioned with 20 mL of hexane and eluted with 30 mL of hexane:dichloromethane (1:2). Purified extracts were concentrated with a gentle nitrogen flow and spiked with d_{18}-labeled β-HBCD as injection standard, and reconstituted to a final volume of 200 μL.[4]

To avoid the presence of interfering substances, glassware was rinsed with acetone and hexane just after its use. After solvent wash, it was also cleaned with water and detergent and purified water. Finally, it was rinsed again with acetone and heated at 300 °C in an oven overnight.

Diastereosiomer Analysis. A Symbiosis Pico (Spark Holland, Emmen, The Netherlands) with a Symmetry C18 column (2.1 mm × 150 mm, 5 μm) preceded by a C18 guard column (2.1 × 10 mm) supplied by Waters (Massachusetts, USA) was used for isomeric HBCD determinations. Experiments were carried out with H_2O:methanol (3:1 v/v) as eluent A and methanol as eluent B, at a flow rate of 0.25 mL/min. The elution program started at an initial composition of 100% A and was ramped to 0% A in the first eight minutes, then eluent A increased to 10% in 17 min, and initial conditions were reached again in 3 min and returned to the starting conditions in 15 min. The injection volume was set at 10 μL.

Mass spectrometric analysis was carried out with a hybrid triple quadrupole/linear ion trap MSD Sciex 4000QTRAPTM (Applied Biosystems, Foster City, CA, USA) instrument equipped with an electrospray (ESI) Turbospray interface, working in negative ionization mode. Data acquisition was performed in selected reaction monitoring (SRM). The $[M - H]^- \rightarrow Br^-$ transitions at m/z 638.7 → 78.9 and 638.7 → 80.9 were monitored for unlabeled HBCDs. The labeled HBCDs were monitored at the 655.8 → 78.9 and 655.8 → 80.9 transitions. The MS−MS detection conditions were optimized to obtain the highest relative intensity: curtain gas at 50 psi, collision gas at 4.5×10^{-5} Torr, temperature of the turbo gas in the TurboIonSpray source at 350 °C, ion source gas 1 at 50 psi, and ion source gas 2 at 10 psi.[8]

Quality Assurance/Quality Control. Method blank samples were performed to check for interferences or contamination from solvents and glassware. No presence of analytes of interest (α-, β-, and γ-HBCDs diastereoisomers) was observed. Spiked samples with native compounds (α-, β-, and γ-HBCD) were analyzed by the described methodology to check recoveries. Recovery values ranged from 79 to 119%, with a relative standard deviation (n = 5) values between 7% and 10%.

The LC−MS−MS identification was based on three main criteria. First of all, simultaneous responses for the two monitored transitions (SRM1 and SRM2) must be obtained at the same retention time than those of available standards. Then, signal-to-noise ratios must be >3. And finally, relative peak intensity ratio must be within ±20% of the theoretical values obtained with standard solutions. Limits of detection, defined as the minimum amount of analyte which produces a peak with a signal-to-noise ratio equal to 3, were 0.03 ng/g for α-HBCD, 0.05 ng/g for β-HBCD, and 0.06 ng/g for γ-HBCD. Limits of quantification, defined as the minimum amount of analyte which produces a peak with a signal-to-noise ratio equal to 10, were 0.11, 0.18, and 0.20 ng/g for α-, γ-, and β-HBCD, respectively.

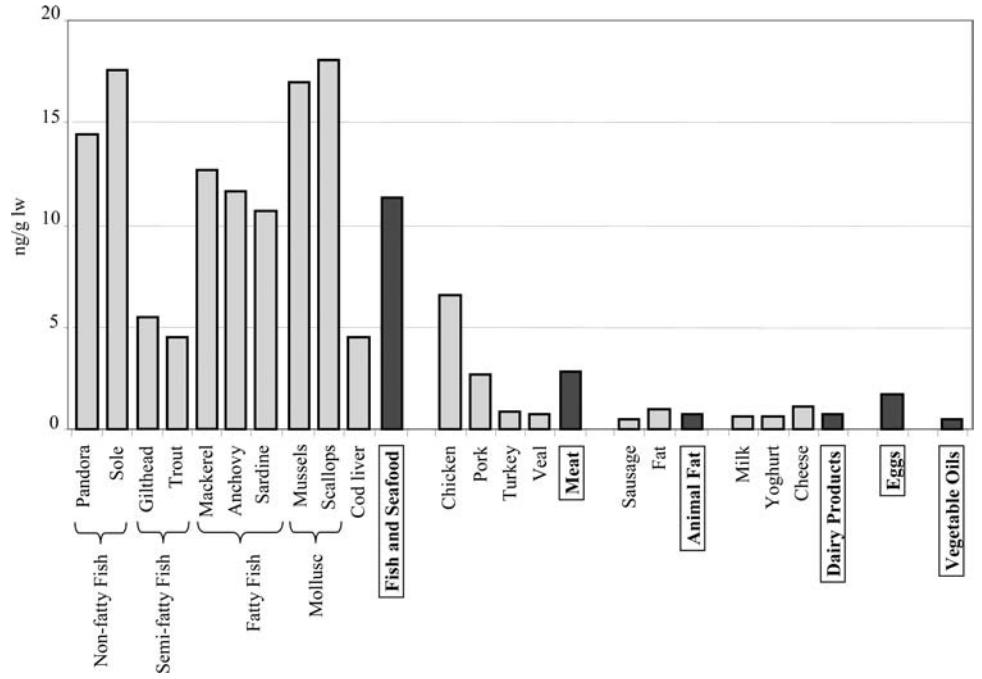

Figure 1. Occurrence of HBCD in Spanish food. Data are mean values (ng/g lw).

Enantiomeric Analysis. A Nucleodex β-PM (4.0 mm × 200 mm × 5 μm) column supplied by Macherey-Nagel (Düren, Germany) was used to perform the enantiomer-specific determination. The separation was achieved using methanol, acetonitrile, and water as mobile phase. Experiments were carried out using 70% water:30% methanol as eluent A and 70% AcN:30% methanol as eluent B, at a flow rate of 0.50 mL min^{-1}. The injection volume was set at 10 μL. The elution program started at an initial concentration of A at 50% decreased to 0% along the first 8 min, and was maintained for 17 min, and initial conditions were reached again in 5 min and maintained for additional 12 min.[9] Mass spectrometric analysis was performed using the same conditions as for diastereoisomer analysis.

Enantiomeric composition was expressed as enantiomeric fraction (EF), which is calculated by eq 1:

$$\mathrm{EF} = \frac{A_+}{(A_+ + A_-)} \quad (1)$$

where A_+ and A_- are the peak areas of eluting enantiomers. It is well-known that ESI is subjected to sample matrix effects that can cause enhancement or suppression of the target analytes' signal and can adversely affect their quantification. In order to avoid this effect that can affect EF calculations, these values are calculated according to eq 2,[10] which makes a correction based on the use of isotopic labeled standards (d_{18}-HBCDs) since d_{18}-labeled enantiomeric analogues behave in an identical manner to their native counterparts:

$$\mathrm{EF}_{\mathrm{corrected}} = \frac{([A_+]/[A_{+\mathrm{d18}}]) \times \mathrm{pg}\, A_{+\mathrm{d18}}}{([A_+]/[A_{+\mathrm{d18}}]) \times \mathrm{pg}\, A_{+\mathrm{d18}} + ([A_-]/[A_{-\mathrm{d18}}]) \times \mathrm{pg}\, A_{-\mathrm{d18}}} \quad (2)$$

where $[A_+]$ and $[A_-]$ are the peak areas of the respective (+) and (−) HBCD enantiomers, $[A_{+\mathrm{d18}}]$ and $[A_{-\mathrm{d18}}]$ are the peak areas of the respective (+) and (−) HBCD d_{18}-labeled standards, while pg $A_{+\mathrm{d18}}$ and $A_{-\mathrm{d18}}$ stand for the noncorrected determined HBCD concentrations.

RESULTS AND DISCUSSION

HBCD Occurrence in Spanish Food Samples. This study is the first to report the concentrations of α-, β-, and γ-HBCDs in different foods in Spain. HBCD levels were analyzed in fish and seafood, meat, animal fat, dairy products, eggs, and vegetable oils since HBCD is a POP and is most likely found in food with fat from animal origin. The results for the 47 products analyzed are shown in Table 1. HBCDs were detected in all analyzed foods. The highest concentrations of HBCD were found in fish and seafood (1.91−23.4 ng/g lw), followed by meat (0.73−12.9 ng/g lw), eggs (0.28−3.42 ng/g lw), dairy products (0.32−1.35 ng/g lw), animal fat (0.27−1.13 ng/g lw), and olive oils (0.18−0.72 ng/g lw). This fact would indicate a higher accumulation of HBCD in fish, similar to other POPs such as PCBs, PCDD/Fs, or PBDEs.

In samples from the meat group, HBCD levels decreased from chicken > pork > turkey > veal. As regards samples from the fish group, molluscs showed the highest levels of contamination (10.5−23.4 ng/g lw), followed by fatty fishes (10.7−14.2 ng/g lw), and then semifat fishes (3.31−7.60 ng/g lw). However, and surprisingly, HBCD levels in sole and pandora, two nonfatty fishes, are among the highest (14.4−17.6 ng/g lw) (Figure 1).

If the concentrations are expressed on fresh weight basis, the highest concentrations were those from products with high fat content: cod liver (1.37−8.44 ng/g ww) and animal fat (0.11−1.11 ng/g ww). Even in this case, fish, and seafood samples showed higher concentrations (mean value of 1.05 ng/g ww) than those detected in animal fat (mean value of 0.53 ng/g ww), vegetable oils (mean value of 0.45 ng/g ww), eggs (mean value of 0.17 ng/g ww), meat (mean value of 0.13 ng/g ww), or dairy products (mean value of 0.07 ng/g ww).

Determined HBCD concentrations were compared to those found in the literature. Most authors reported higher concentrations of HBCD in fish than in the other food categories.[11−15] Our levels in fish and seafood (mean value of 11.6 ng/g lw, or 0.63 ng/g ww) are lower than those detected by Goscinny et al.[11] in Belgium (42 ng/g lw), but higher than those reported by Törnkvist et al.[12] in Sweden (0.15 ng/g ww), Schecter et al.[15] in the US (<0.03−0.35 ng/g ww), and Shi et

dx.doi.org/10.1021/jf405007x | J. Agric. Food Chem. 2014, 62, 2462−2468

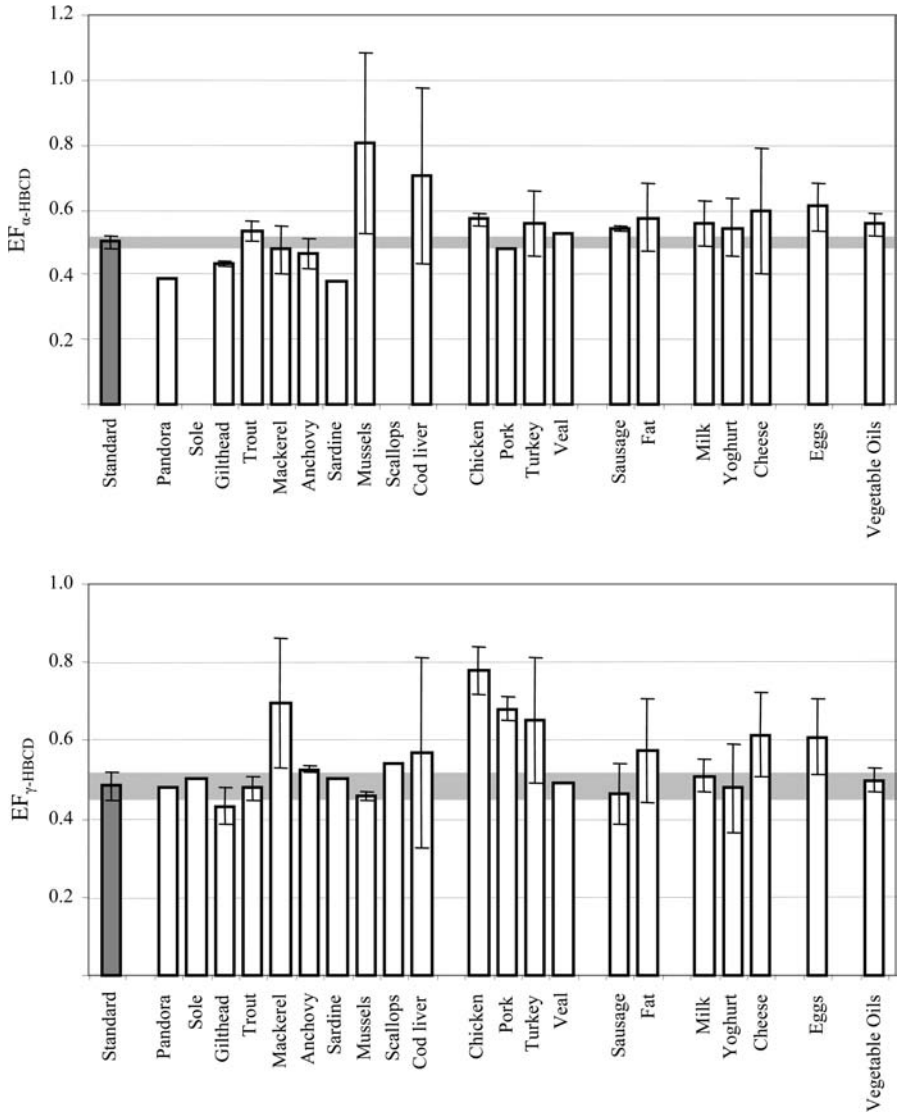

Figure 2. Enantiomeric fraction values (mean ± standard deviation) for α-HBCD and γ-HBCD in Spanish food compared to standards.

al.[13] in China (nd−2.22 ng/g lw). For some specific categories of fish and seafood (mackerel, sole, mussels), HBCD concentrations detected in our study are in the same range as those reported by Van Leeuwen and de Boer[16] in The Netherlands.

Isomeric Patterns. In all the samples, α- and γ-HBCDs were observed, whereas β-HBCD was not detected in any sample. The α- and γ-HBCD contribution was studied for the different groups of food. For fish and seafood samples, the contribution of α-HBCD was greater. In 14 out of 17 fish samples analyzed, α-HBCD concentration was higher than γ-HBCD, with α/γ ratios between 1.2 and 8.7. Similar results were found in the Belgian study, in which α-HBCD was the predominant isomer in fish samples.[11] For most of the other food samples, the trend is the inverse: γ-HBCD concentration was higher than that of α-HBCD. For meat samples, α/γ ratios ranged between 0.34 and 0.99, while for dairy products it ranged between 0.44 and 1.26. Three out of the four egg samples analyzed showed also α/γ ratios lower than 1.

Enantiomeric Fractions. EF values were calculated from the chiral column LC data, and the values were corrected according to eq 2 (Figure 2). In the case of γ-HBCD, it was observed that EF values were between 0.39 and 0.87, whereas EF for α-HBCD ranged between 0.38 and 1. If we compare these EF values with those obtained with standard solutions, in general, no significant differences were detected for γ-HBCD. The EF mean value obtained for standard solutions was 0.49 (with 7.6% of relative standard deviation (RSD)). In general, samples were between the EF value ± RSD range established with standard solutions. However, samples of mackerel (fish) (mean EF value ± SD of 0.70 ± 0.17) and chicken and pork (meat) (mean EF value ± SD of 0.78 ± 0.06 and 0.68 ± 0.03 respectively) presented an increase of EF value compared to standard value, indicating an enrichment of the (+)-γ-HBCD enantiomer in these samples.

In the case of α-HBCD, and for some fish samples (gilthead, pandora, and sardine), results showed a decrease of EF values (EF value of 0.43, 0.39, and 0.38 respectively) with respect to the standards (mean value of 0.50 with 3.6% of RSD). Thus, we can assume that an enrichment of the (−)-α-HBCD enantiomer was observed for these fish samples. Similar behavior was also detected in samples of herring muscle and falcon eggs,[17] and also significant enrichments for (−)-α-

dx.doi.org/10.1021/jf405007x | J. Agric. Food Chem. 2014, 62, 2462−2468

HBCD enantiomer was observed in human breast milk samples.[4]

Daily Intake Estimation. The estimated dietary intake (EDI) of HBCD is based on HBCD data from the present study combined with the consumption data from a Spanish diet model for determining consumer exposure to chemicals.[18] It is also important to note that we analyzed fresh foods, whereas preparation and different cooking methods can influence the levels of contaminants.[19] The Spanish dietary exposure to HBCD was 177 ng day^{-1}. Assuming the average adult body weight as 68 kg, the EDI of HBCD was 2.58 ng $(kg\ bw)^{-1}$ day^{-1}.

Our daily intake through the diet estimation was compared with other assessments in different countries around the world (Table 2). However, this comparison is not easy because there are some differences in sampling strategies, there is a lack of a standardized method for HBCD detection, and there is also a great variety in the number of analyses or different calculation methods for non detects or dietary intake. Once these parameters are taken into account, a comparison is anyway interesting.

Table 2. HBCD Daily Intake Estimation Worldwide

country	food	HBCD levels (ng/g)	daily intake (ng $(kg\ bw)^{-1}$ day^{-1})	ref
		Europe

[a]Wet weight. [b]Not detected. [c]Lipid weight.

Some studies were carried out in different European countries. A median intake of 141 ng of HBCD per day (2.15 ng kg bw^{-1} day^{-1}) was estimated for the Swedish population, with a maximum of 1076 ng per day (21.5 ng kg bw^{-1} day^{-1}).[20] In another study,[21] the EDI was estimated at 1.5 ng kg bw^{-1} day^{-1} for the Dutch population. Later, van Leeuwen and de Boer[16] estimated the fish-related dietary exposure of HBCD for the average Dutch population. The median bound intake in that study was estimated at 8.3 ng day^{-1} for a 70 kg person (0.12 ng kg bw^{-1} day^{-1}). Dietary exposure to HBCD in the Norwegian population was established at 0.3 ng kg bw^{-1} day^{-1}.[22] The estimated adult dietary intake of HBCD arising from the United Kingdom diet resulted on higher levels than those mentioned so far, being in the range of 5.9−7.9 ng kg bw^{-1} day^{-1}.[23] This latter study only considered the intake due to seafood consumption. More recently, the intake of HBCD in Sweden was estimated by Törnkvist et al.[12] to be 0.14 ng kg bw^{-1} day^{-1} (10.2 ng day^{-1}), and Goscinny et al.[11] estimated an EDI of 0.99 ng kg bw^{-1} day^{-1} for the Belgian population. Our results were slightly higher than those reported in these studies for the European population. However, it must be taken into account that most of these studies were carried out a few years ago. It is expected that HBCD consumption has been increasing over the years due to the prohibition of PBDE use.

Few studies refer to EDI values in other continents. In Asia, Shi et al.[13] reported an EDI value in the range of 0.09−1.72 ng kg bw^{-1} day^{-1} for the Chinese population. Murata et al.[14] estimated a dietary HBCD intake of 2.2 and 1.4 ng kg bw^{-1} day^{-1} in 2002 and 2005, respectively. They analyzed 14 different food groups. However, HBCD was only detected in the fish group. In a later study, and based only on fish consumption, Nakagawa et al.[24] estimated an EDI between 1.3 and 3.7 ng kg bw^{-1} day^{-1} for the Japanese population. Higher estimation resulted from the study of Ueno et al.[25] They reported an EDI value between 0.45 and 34 ng kg bw^{-1} day^{-1}, based only on seafood consumption. These EDI values seem to be slightly higher than those reported for European citizens. Given that fish is the food group that provides the highest levels of HBCD contamination, a possible explanation could be the high consumption of fish in Asian diets.

As regards the American population, only two studies have been published dealing with HBCD EDI values. Schecter et al.[15] estimated, for the USA, an EDI value of 0.23 ng kg bw^{-1} day^{-1}, which matched reasonably well with European values. However, Environment Canada[26] established an EDI of 14 ng kg bw^{-1} day^{-1} for the Canadian population.

The calculated contributions of the different food groups to the total EDI of HBCD showed that fish and seafood was a major contributor (56%) for Spanish consumers (Figure 3). Meat (12%) and dairy products (14%) were also important

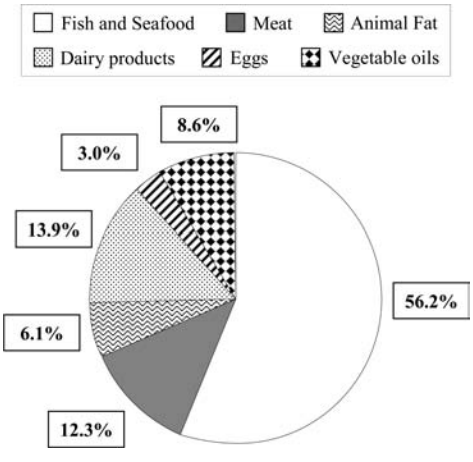

Figure 3. Relative contribution of the different food categories to the dietary intake of HBCD for Spanish consumers.

dx.doi.org/10.1021/jf405007x | J. Agric. Food Chem. 2014, 62, 2462−2468

food groups contributing to the Spanish intake of HBCD. Other studies have also reported fish as the major contributor to the HBCD intake. In the Swedish estimation[12] HBCD mainly came from fish (65%), but also dairy products (24%) and meat (10%) contributed. However, in the Belgian estimation[11] fish accounts for only 7.1% of the EDI, and the meat group was the highest contributor with 43%. This is due to the high consumption of meat and low consumption of fish in Belgium.

Previous studies have been carried out to estimate the human exposure to PBDEs through the diet in Spain. Bocio et al.[27] estimated the dietary intake of PBDEs for the general population living in Catalonia (Spain), and they found a value of 97 ng day^{-1} (1.4 ng kg bw^{-1} day^{-1}). A later study in the same area[28] showed an EDI decrease of 23%, with value of 1.1 ng kg bw^{-1} day^{-1}. An even lower value was reported by Gómara et al.[29] in a study including different locations in Spain, with an EDI value of 39 ng day^{-1} (0.6 ng kg bw^{-1} day^{-1}). However, these differences could be attributed in part to the different consumption data applied in each study, but also to other factors such as the sampling strategy, the way concentrations were given (upper, medium, and lower bound) or the number of PBDE congeners analyzed. In any case, the three values (0.6−1.4 ng kg bw^{-1} day^{-1}) obtained for the dietary intake of PBDEs in Spain were lower than the value obtained in our study for the dietary intake of HBCD (2.6 ng kg bw^{-1} day^{-1}).

Human exposure to HBCD occurs through multiple routes. For non occupationally exposed persons, the major intake of HBCD is probably from food and indoor air or dust. However, the relevance of human HBCD exposure originating from house dust versus food-based HBCD exposure is still unknown. Nondietary exposure, mainly through dust in homes, offices, schools, cars, and public environment can substantially contribute, and in some cases even dominate, the total human exposure to HBCD, especially for toddlers and other children.[30] Our study has focused on the intake of HBCD through the diet. Estimated daily intake of this contaminant for the Spanish population resulted in 2.58 ng $(kg\ bw)^{-1}$ day^{-1}. The main contributor to this intake was fish group, followed by dairy products and meat. Therefore, the exposure of frequent fish consumers could be higher than for the average consumers estimated in our study.

MATERIALS AND METHODS

Chemicals and Reference Compounds. Dichloromethane (99.99%) was supplied by Fischer Scientific (Illkirch, France) and absolute ethanol (99.9%) by Merck (Semoy, France). All of the reference compounds were provided by Sigma-Aldrich (Saint-Quentin-Fallavier, France) [3-methyl-4-octanolide (98%), γ-nonalactone (98%), and eugenol (99%)].

Synthesis of 2-Nonen-4-olide. The lactone was prepared by the reaction of a stabilized vinyl Grignard reagent (isopropyl magnesium chloride, *i*PrMgCl)[20] on hexanal, as described.[21] A flame-dried 500 mL round-bottom flask, equipped with a Teflon-coated magnetic stirring bar, was loaded with 3-iodobut-2-enoic acid ethyl ester[22] (6.9 g, 32.7 mmol) under an argon atmosphere. Tetrahydrofuran (THF; 130 mL) was added and the mixture cooled to −78 °C. *i*PrMgCl solution (16.4 mL, 2 M in Et_2O) was then added dropwise. The mixture was stirred for an additional 2 h at −78 °C. This solution was added through a double-ended needle to a stirred solution of freshly distilled *n*-hexanal (1 equiv) in THF (130 mL) under argon at −78 °C. The reaction was allowed to warm slowly to 0 °C, then quenched with saturated aqueous ammonium chloride, and left to warm to room temperature. Next the reaction mixture was extracted three times with diethyl ether (Et_2O). The combined organic layers were washed with water followed by brine, dried over sodium sulfate (Na_2SO_4), filtered, and concentrated. After purification by flash chromatography over silica gel, using a PuriFlash SI Std IR-50SI (50 μm) cartridge from Interchim (Montluçon, France), 2.6 g (23%) of 2-nonen-4-olide was obtained (purity > 99%). The product exhibited the same spectral data as described by Dai:[23] ^{13}C NMR δ 13.5 (C-5′), 22.0 (C-4′), 24.2 (C-2′), 31.0 (C-3′), 32.7 (C-1′), 83.1 (C (4), 120.9 (C-2), 156.2 (C-3), 172.9 (C-1); GC-MS (EI) *m*/*z* 154 (4, M^+), 125 (72), 84 (100), 83 (19), 55 (15).

Wine Samples. All wines selected are listed in Table 1. These wines were used for various analyses, including semipreparative HPLC and GC-O/MS.

Table 1. All Wines Used in Different Essays through This Experiment, Including Vintage, Producer, Codes, and Appellation

Wine Extraction for HPLC Fractionation. Seven hundred and fifty milliliter wine samples were extracted at room temperature (20 °C) using 60, 60, and then 40 mL of dichloromethane with magnetic stirring (700 rpm) for 10 min each and separated in a funnel. The organic phases were collected, dried over sodium sulfate, concentrated to around 2 mL using a Buchi R-114 rotary evaporator (Buchi, Rungis, France), and then further concentrated under nitrogen flow (100 mL/min) in a graduated glass tube (Atelier Jean Prémont, Bordeaux) to obtain a 750 μL wine extract.

Semipreparative HPLC on Wine Extracts and Sensory Evaluation. Reversed-phase (RP) HPLC was performed on the raw wine extract, using a Novapak C18 column (300 × 7.8 mm internal diameter (i.d.), 6 μm, Waters, Saint Quentin, France) with a guard column of the same phase. The Ultimate 3000 semipreparative HPLC system was from Dionex (Courtaboeuf, France). The procedure was based on the method described by Ferreira et al.,[24] later adapted by Pineau et al.[16] Chromatographic conditions were as follows: flow rate, 1 mL/min; injection volume. 250 μL; gradient, eluent A, microfiltered water, eluent B, ethanol; 0−2 min, 0% B, 2−50 min, 0−100% B. Fifty effluent fractions of 1 mL were collected. Each fraction was diluted into 12% ethanol, then poured into normalized glasses from the Association Française de Normes (AFNOR), and evaluated by three experienced assessors aged 38.6 ± 9.8 [mean ± standard deviation (SD)] years old. The repeatability of the quantitation measurements for specific concentrations (65 μg/L for 3-methyl-4-octanolide, 2.5 μg/L for γ-nonalactone, 2.4 μg/L for eugenol, and 2.0 μg/L for 2-nonen-4-olide) of the considered compounds was calculated after HPLC fractionation of the same wine (i.e., 750 mL), initially extracted with dichloromethane, for 3-methyl-4-octanolide at 6%, for eugenol at 2.6%, for γ-nonalactone at 6%, and finally for 2-nonen-4-olide at 2.6%.

Extracting HPLC Fractions. Each fraction of interest (1 mL) was diluted with ultrapure water (Milli-Q, Millipore, Bedford, MA, USA) to obtain 12% ethanol (v/v) and then re-extracted three times with 1 mL of dichloromethane each time to mimic the wine extraction. The organic phases were combined and concentrated to 250 μL under nitrogen flow before GC-O analysis and heart-cut multidimensional GC-O-MS.

GC-O. GC-O analyses were carried out using a Hewlett-Packard 5890 gas chromatograph (Agilent Technologies, Palo Alto, CA, USA) equipped with a flame ionization detector (FID) and a sniffing port (ODO-1 from SGE, Ringwood, Australia). A 1 μL aliquot of concentrated wine extract was injected by a splitless injector (230 °C; purge time, 1 min; purge flow, 50 mL/min) at an oven of temperature of 45 °C into a type-HP5 capillary column (Agilent; 30 m, 0.25 mm i.d., 0.25 μm film thickness) or a type BP20 capillary column (SGE; 50 m, 0.22 mm i.d. 0.25 μm film thickness). The analysis temperature program was as follows: 45 °C for 1 min, then 3 °C/min to 230 °C, with a 20 min isotherm for both types of columns. The carrier gas was hydrogen (Air Liquide, Floirac, France) with a flow rate of 1 mL/min. Each sample was analyzed in triplicate for 30 min each time and was assessed by three well-experienced assessors. Linear retention indices (LRI) were obtained by simultaneous injection of samples and a series of alkanes (C_7−C_{23}).

Heart-Cut Multidimensional Gas Chromatography−Olfactometry−Mass Spectrometry (MDGC-O-MS). All analyses were performed using a multidimensional gas chromatograph consisting of two independent gas chromatographs (Agilent 6890), interconnected by means of a thermoregulated transfer line kept at 230 °C (West 4400, West Instruments, Gurnee, IL, USA). For chromatograph 1 (GC-1), the 6890 chromatograph (Agilent) was equipped with an FID and an olfactometric port (ODP-3, Gerstel, Mülheim an der Ruhr, Germany), both connected by a flow-splitter to the column exit for simultaneous effluent monitoring. This GC was retrofitted with a pressure-driven switching valve MCS (Multi Column Switching system, Gerstel) to transfer selected heart cuts eluted from the first column directly into the analytical column in the second chromatograph. The carrier gas helium N 60 (Air Liquide) was delivered at a constant flow of 1 mL/min. The pressure ramp program for constant flow was 224 kPa for 1 min, then increased by 1.4 kPa/min to 310 kPa, and maintained at this pressure for 42 min. The column was a 30 m ×

0.32 mm i.d. × 0.5 μm film HP5 (Agilent). An uncoated, deactivated, fused-silica column (40 cm × 0.05 mm i.d.) from Supelco (Bellefonte, PA, USA) was used as an interface between the switching valve MCS to a FID or an olfactometric port. The oven temperature program was as follows: 45 °C for 1 min, then increasing by 5 °C/min to 230 °C, and maintained at 230 °C for 43 min. The injector was maintained at 250 °C (total run time = 83.67 min). A cryotrapping unit (liquid N_2) was mounted between the two GCs for cryofocusing (−50 °C) of the heart-cut fraction at the beginning of the second column. The gas chromatograph 2 (GC-2, Agilent 6890) was coupled to an Agilent HP 5973 mass spectrometer (Agilent). Also, an olfactometric port (ODP3, Gerstel) was set up so that the 2D column exit was split between the MS and ODP3 for simultaneous mass spectrometry and sniffing detection (division 1:1). Two types of columns were used alternately in GC-2 with different polarities. The first column was a 50 m × 0.22 mm i.d. × 0.25 μm [BP20 (SGE)] and the second one a 50 m × 0.22 mm i.d. × 1 μm [BP1 (SGE)]. In GC-2, the column (BP20 or BP1) was connected to the MCS switching valve (situated in the first chromatograph) and routed via a transfer line thermostatically controlled at 230 °C. Two minutes after the heart cut, the oven temperature program (45 °C initially, then 3 °C/min increase to 230 °C) of GC-2 was activated. The pressure ramp program was 224 kPa at midpoint for the first 25 min, then increased at a rate of 1.4 kPa/min to 310 kPa, and maintained at that level for 27 min (total run time = 83.67 min). GC-O port parameters were as follows: GC effluent was combined with humidified air [reconstituted air (nitrogen 80, oxygen 20; v/v), Air Liquide] at a rate of 35 mL/min at the bottom of the glass mask (SGE) to avoid nasal dehydration. The MS parameters were as follows: transfer line at 250 °C; source at 230 °C, and quadrupole at 150 °C, in EI mode at 70 eV. The MS was used in full scan mode (m/z 40−300). MS data were recorded and processed using Chemstation software (version B04.03) from Agilent equipped with an NIST 2008 MS library (U.S. National Institute of Standards and Technology, Gaithersburg, MD, USA). For chemical ionization (CI) with methanol, a similar MDGC configuration with two Agilent 7890A GCs was coupled with a time of flight (TOF) mass spectrometer by JEOL (JEOL Europe, Croissy sur Seine, France).

Quantitation of Higher Aliphatic Lactones and Eugenol by GC-MS. The extraction protocol for quantifying aliphatic lactones and eugenol in wine or in selected HPLC fractions was applied as described by Ferreira et al.[25] Briefly, after solid phase extraction chromatography, the eluent was supplemented with external standard (100 μL of 2-octanol at 10 mg/L in CH_2Cl_2) and concentrated under nitrogen flow (approximately 100 mL/min) to 100 μL. Each extraction was repeated twice. Then, a 2 μL sample of each concentrated wine extract was injected on an Agilent 6890 gas chromatograph in splitless injector mode (injector temperature, 230 °C; purge time, 1 min; purge flow, 50 mL/min) with a Carbowax 20 M type capillary column [BP20, 50 m, 0.25 mm i.d., 0.22 μm film thickness (SGE)]. The temperature program for all analyses was as follows: 45 °C for 1 min, increased by 3 °C/min to 230 °C, followed by a 20 min isotherm. The carrier gas was helium N 60 (Air Liquide) with a constant flow rate of 1 mL/min. The detector was an Agilent HP 5973 mass spectrometer functioning in electron impact (EI) mode (70 eV) and connected to the GC with a heated transfer line at 230 °C (Agilent). The compounds were quantified using selected ion monitoring mode (SIM) on MSD Chemstation software (version B04.03) from Agilent. The external standard, 2-octanol, was detected with m/z 84 and 97 ions and quantified using m/z 84. 3-Methyl-4-octanolide was detected with m/z 99 and 42 ions and quantified with the m/z 99 ion. γ-Nonalactone was detected using the ions m/z 85 and 56 and quantified with the ion m/z 85, and eugenol was detected with ions m/z 164 and 149 and quantified with the ion m/z 164. The repeatability of the quantitation measurements was calculated by the extraction and injection of eight spiked samples (50 mL) with known concentrations of the compounds (100 μg/L for 3-methyl-4-octanolide, 25 μg/L for eugenol and γ-nonalactone). The repeatability values were for 3-methyl-4-octanolide, 5%; eugenol, 2.5%; and γ-nonalactone, 2.3%.

Quantitation of 2-Nonen-4-olide by GC-MS. The extraction protocol for quantifying 2-nonen-4-olide in wine or in selected fractions was similar to that used for 3-methyl-4-octanolide, eugenol, and γ-nonalactone. All quantitative analyses were carried out using an Agilent 6890 GC. One microliter of each concentrated extract (extraction method described by Ferreira et al.[25]) was injected in splitless mode (230 °C; purge time, 1 min; purge flow, 50 mL/min) onto a DB1 capillary column (Agilent, 30 m, 0.25 mm i.d., 0.25 μm film thickness). The temperature program was as follows: 45 °C for 1 min, increasing by 3 °C/min to 130 °C, and increasing again at 40 °C/min until 280 °C, followed by a 10 min isotherm. The carrier gas was helium N 60 (Air Liquide) with a constant flow rate of 1.5 mL/min. The detector was an Agilent HP 5973 mass spectrometer, functioning in EI mode (70 eV), with a transfer line heated to 280 °C. 2-Nonen-4-olide was detected in SIM mode by selecting the m/z 84, and 125 ions and quantified using m/z 84. The external standard, 2-octanol, was detected with m/z 84 and 97 ions and quantified using m/z 84. Measurements were linear in a range of concentrations from 0.5 to 20 μg/L [2-nonen-4-olide, μg/L) = $3.5906x - 0.0323$ (x = ratio of peak area of 2-nonen-4-olide over the peak area of the external standard); $R^2 = 0.9975$]. Repeatability of the measurement of 2-nonen-4-olide for a series of eight extractions and injection of the same wine was assessed at 1.4%. The quantitation limit (0.5 μg/L) was calculated as the minimum concentration that generated a peak signal 10-fold higher than the background noise signal. Recovery was calculated at >80%.

General Conditions for Sensory Analyses. Sensory analyses were performed as described by Martin and de Revel.[26] Samples were evaluated in individual booths, at controlled room temperature (19 ± 1 °C), using covered black Association Française des Normes (AFNOR) glasses[27] containing 50 mL of liquid, coded with random three-digit numbers. Sessions lasted approximately 10 min.

Sensory Panel. The panel consisted of 15 judges, 5 males and 10 females, aged 30.5 ± 4.6 years (mean ± SD). All panelists belong to the enology research laboratory staff at ISVV, Bordeaux University. The judges were selected for their experience in assessing fruity aromas of dessert wines.

Olfactory Thresholds. All analyses were performed in a model solution consisting of twice-distilled ethanol (12%, v/v) and tartaric acid (5 g/L) at pH 3.5 (adjusted using NaOH). For all sensory analyses, the glasses were labeled with three-digit random codes and presented to panelists in random order. All experiments were performed in duplicate.

The detection threshold of the aroma compound was determined in a model solution with an ascending procedure (0.5, 1, 2, 4, 8, 16, 32, 64, 128, and 256 μg/L), using the three-alternative forced-choice presentation method (3-AFC) (ISO 13301 2001).[27] For each concentration, subjects received a set of three glasses; two of them were blank samples (model solution), and one contained the odorant at various concentrations (positive sample). Sensory analyses covered the whole series of dilution sets: each assessor was asked to first sniff each of the three glasses in the prescribed order and then choose the spiked sample.

The detection threshold was defined as the concentration at which the probability of detection was 50%. This statistical value was determined according to an adaptation of the ASTM-E1432 method.[28] The concentration/response function fitted by a sigmoid curve [$y = 1/(1 + e^{(-\lambda x)})$] was designated by a psychometric function reflecting behavior during detection. The detection probability was corrected by the chance factor (one-third for 3-AFC): $(3p - 1)/2$. The software used for graphic resolution and nonlinear regression by ANOVA transform was Sigma Plot version 8 (SYSTAT, San Jose, CA, USA).

Reconstitution and Omission Experiments. For the reconstitution and omission tests, two different types of dessert wines were selected. One was a typical Bordeaux dessert wine (Bordeaux dessert wine 1), with a desirable odor, reminiscent of overripe fruit, particularly orange peel, whereas the other was a nontypical Bordeaux dessert wine (Bordeaux dessert wine 2), with a fresh fruity aroma. Orthonasal typicality was measured by the panel on a nonstructured scale, which was anchored by "bad example" and "good example" on the left and the right ends, respectively. The panel had to respond to the question if a presented sample was considered to be a good or a

bad example for a wine of the category Bordeaux dessert wine, and no further information was asked regarding a sensory profile.[29] After fractionation of each extract by reversed-phase HPLC, the above-mentioned volatile compounds were quantified by GC-MS in selected fractions (Table 2) (experimental protocol in quantitation of higher aliphatic lactone and eugenol, 2-nonen-4-olide). Several reconstitution tests were then performed on the basis of the quantitation results. For each sensory session, samples of aromatic reconstitutions in hydroalcoholic solution (12% vol, pH 3.9) were presented. Names and compositions of the samples are presented in Table 3. The fractions of those Bordeaux dessert wines were pooled to form total aromatic reconstitution (TAR) samples, corresponding to the 50 fractions gathered together. Partial aromatic reconstitution (PAR) samples corresponded to the 50 fractions except fractions 37 + 38, PAR supplemented with the four following volatile compounds, 3-methyl-4-octanolide, eugenol, γ-nonalactone, and 2-nonen-4-olide, at concentrations assayed in specific Bordeaux dessert wine (PAR4C samples), and PAR with three of the four selected volatile compounds.

For each type of dessert wine, a specific sensory session was organized, and each session was performed in duplicate. In practical terms, during a first sensory session, the fractions corresponded to those of Bordeaux dessert wine 1, and the concentrations of the compounds added were related to those assayed in that wine. In a second sensory session, the fractions corresponded to those of Bordeaux dessert wine 2, and the concentrations of the compounds added were related to those assayed in that wine. In a third session, HPLC fractions corresponding to Bordeaux dessert wine 2 without fractions 37 + 38 were supplemented with the volatile compounds corresponding to Bordeaux dessert wine 1. Each sensory session was performed in duplicate on different days. The overripe orange aroma intensity was evaluated in a direct orthonasal way on a 0−10 point nonstructured scale. The scale used was 0 = no odor perceived and 10 = high intensity perceived. Concerning typicality experiments, the scale was 0 = bad example of Bordeaux dessert wine and 10 = good example of Bordeaux dessert wine. For aromatic reconstitutions, fractions were retained and added individually or blended together to reproduce the initial concentrations in the original wines, adding double-distilled ethanol and microfiltered water to obtain an ethanol level of 12% (v/v).

Statistical data were analyzed using R (R Foundation for Statistical Computing, Vienna, Austria, 2011) version 2.15.1 software. Analysis of variance (ANOVA) was performed, the homogeneity of variance was tested with Levene's test, and the normality of residuals was tested using the Shapiro−Wilk test. Statistical significance was set at 5% ($p < 0.05$).

RESULTS AND DISCUSSION

Characterization of Compounds Associated with Key Aromatic Fractions Reminiscent of Overripe Orange

Aromas. Semipreparative HPLC of wine extracts resulted in fractions containing increasing proportions of ethanol in water. It was thus possible to describe their aromatic characteristics without toxic or malodorous solvent. Selected dessert and dry white wine extracts were analyzed by HPLC to constitute fractions with different aromatic descriptors. The comparative sensory evaluation of the fractions revealed clear sensory differences between dessert wine and dry white wine extracts, particularly in the ripe fruit character, but also revealed sensory differences for the typicality appreciation (Table 4). Among others, fractions 37 and 38 in some dessert wine extracts (Liq-Cs 2005, Liq-Cds 2004, and Liq-Cds 2006) were clearly reminiscent of overripe fruits and oranges, which were not detected in the other fractions (Liq-Phd 2010) or in dry white wine extracts (Sec-Cm 2008 and Sec-Bon 2007). To characterize the compounds associated with this aroma, fraction 37, the most significant from a sensory point of view, was re-extracted with dichloromethane, and the concentrated extract was injected on both a polar (BP20) and a nonpolar capillary (HP5) to identify odoriferous zones recalling the above-mentioned descriptors. With the BP20 type capillary, it was not possible to pick out the key odoriferous zones with overripe fruit and orange aromas. However, on HP5, a typical orange aroma lasting 1 min was perceived in a chromatographic zone situated between 1414 and 1443 LRI (Table 5). At this point, MDGC-O-MS was required to analyze this complex matrix and identify the compound(s) associated with this aroma.

Identification and Quantitation of 2-Nonen-4-olide. Using MDGC technology, the odoriferous zone was targeted for its olfactory characteristics on the GC1 olfactometry port. Then, an adequate 3 min cut was performed. The separation of the extract on the analytical column (GC2, BP20 capillary), coupled with both the olfactometry port and the mass spectrometry detector, revealed several odoriferous zones potentially related to the overripe orange odor. Odoriferous zones with coconut, spicy clove, and ripe-fruit aromas corresponding to 3-methyl-4-octanolide, eugenol, and γ-nonalactone, respectively, were identified by mass spectrometry. A fourth odoriferous zone with minty and fruity aromas, corresponding to an unknown compound, was also detected. Coupling the capillary to the MS detector produced a chromatographic peak (Figure 1) with a clear mass spectrum at the retention time of this odoriferous zone, (LRI 2068, BP20 capillary, GC-2). The existence of a similar odoriferous zone associated with the same fragmentation pattern was confirmed by repeating MDGC analysis of fraction 37 extract on a nonpolar capillary BP1 (LRI 1368, GC-2). On the basis of the MS data obtained by EI and CI) which indicated a molecular mass of 154.099 ± 0.05 Da, and the associated chromatographic peak, the unknown odoriferous zone was identified as a lactone: 2-nonen-4-olide or 5-pentyl-5*H*-furan-2-one (CAS Registry No. 21963-26-8). The mass spectra of the 2-nonen-4-olide standard and the wine extract presented the same characteristics (Figure 2). To our knowledge, this was the first time that this compound had been identified in wine.

Odor Characteristics of 2-Nonen-4-olide and Assay in Wines. The perception threshold of (±)-2-nonen-4-olide was calculated at 4.3 μg/L in model solution and at 10.8 μg/L in a dessert wine (Figure 3). The 2-nonen-4-olide molecule has one asymmetrical carbon, indicating the possibility of various enantiomeric ratios between *R* and *S* forms. The perception thresholds and descriptors may change, depending on the ratio of these two isomers, as is the case for other compounds.[30−32] 2-Nonen-4-olide was then quantified in 15 dessert wines from

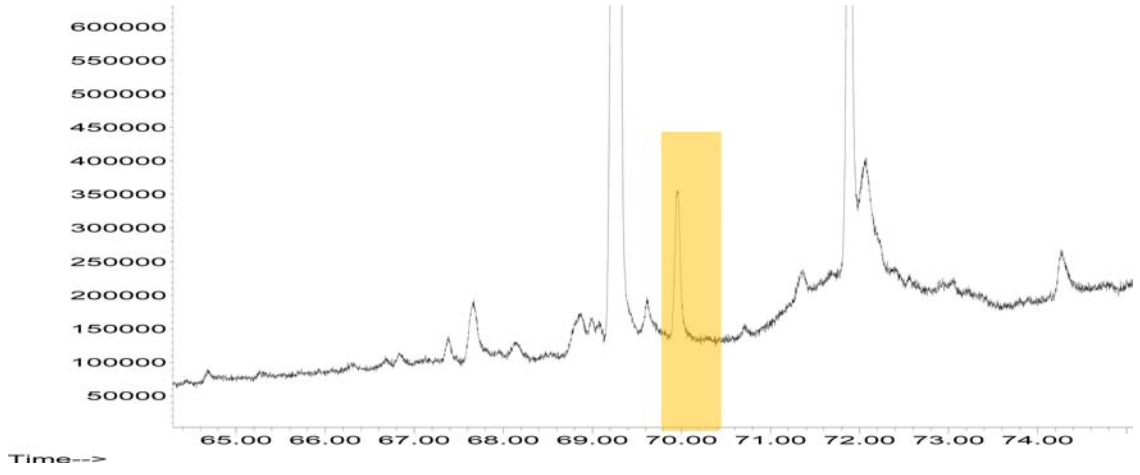

Figure 1. MDGC separation chromatogram from fraction 37 of a dessert wine on a BP1 nonpolar capillary (analysis on GC-2) indicating the peak corresponding to the odoriferous zone.

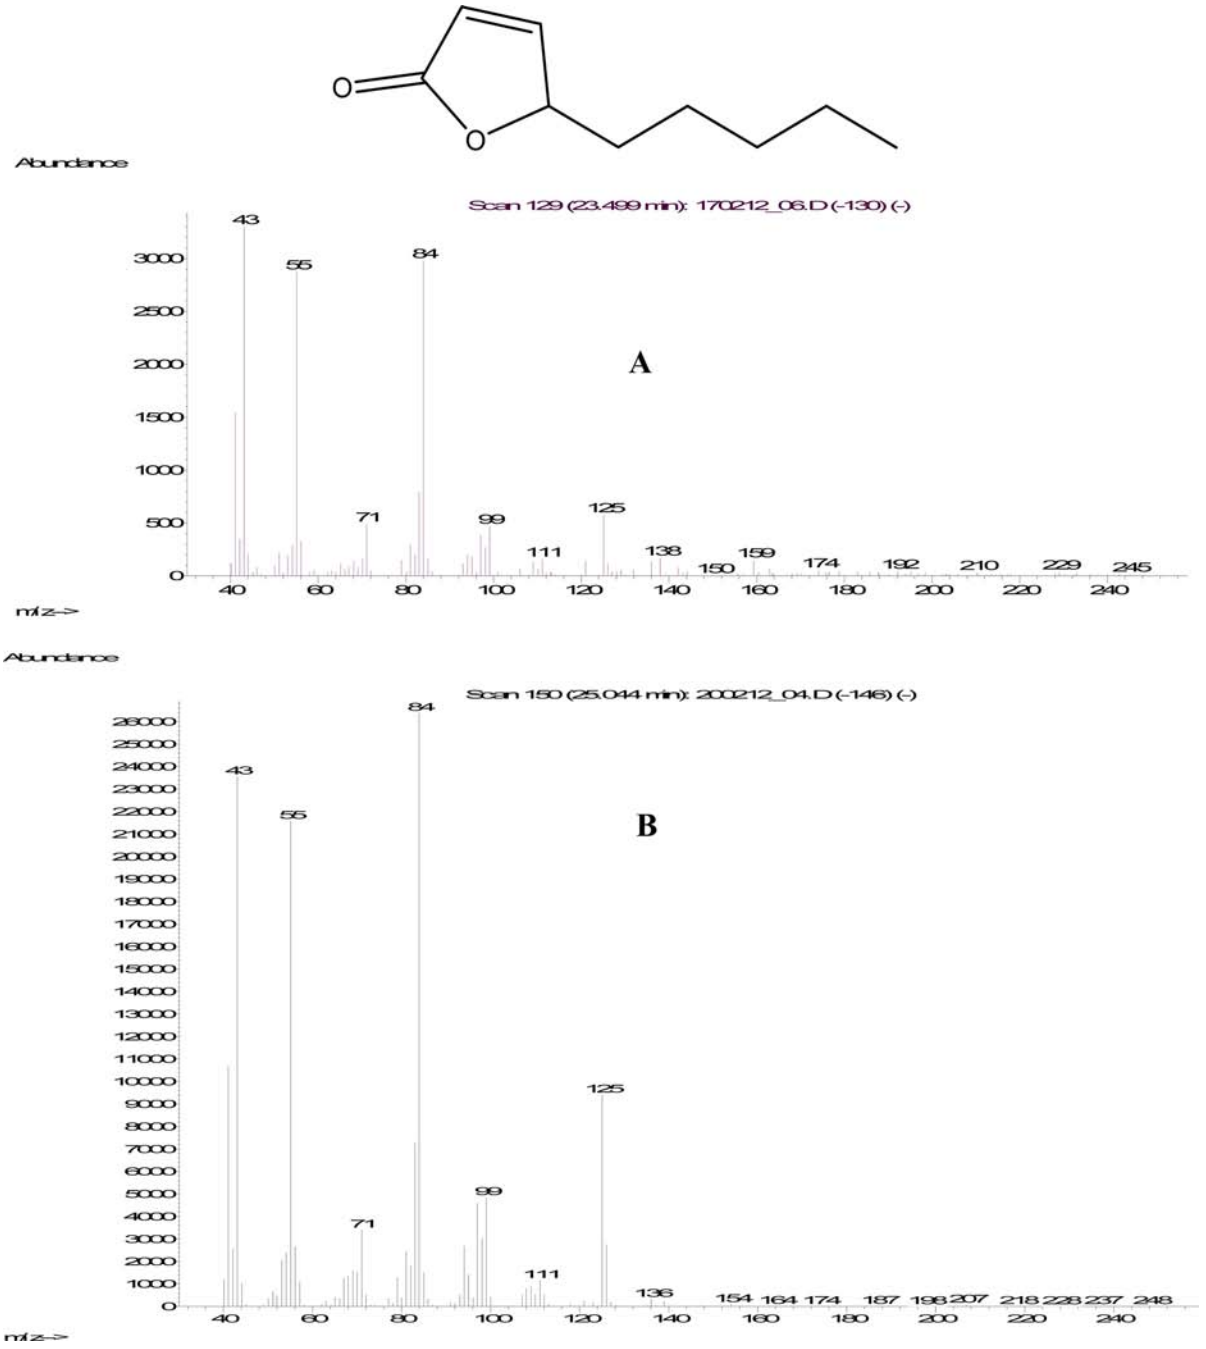

Figure 2. Chemical formula and mass spectra of 2-nonen-4-olide in wine (A) and as pure compound (B).

the Bordeaux region and 8 dry white wines from various appellations in France, including Chablis and Alsace. 2-Nonen-4-olide was not detected in dry white wines, but only in dessert wines obtained from botrytized grapes, thus indicating that this compound is perhaps specific to noble rot dessert wines. Its concentration in dessert wines apparently depends on the vintage, ranging from 2.6 to 18.2 μg/L, that is, values frequently over the olfactory detection threshold in model solution (Table 6). The absence of a specific odoriferous zone related to this overripe orange note suggested that it resulted from perceptual interactions among the above-mentioned volatile compounds (3-methyl-4-octanolide, eugenol, γ-nonalactone, and 2-nonen-4-olide), so relevant sensory analysis protocols were conducted.

Reconstitution and Omission Experiments. These experiments were conducted using two Bordeaux dessert wines presenting different levels of typicality, that is, 6.4 ± 1.4 for dessert wine 1 and 0.9 ± 0.3 for dessert wine 2 (see Materials and Methods). After fractionation of these wine extracts by HPLC, the four above-mentioned specific compounds (3-methyl-4-octanolide, eugenol, γ-nonalactone, and 2-nonen-4-olide) were assayed in HPLC fractions 37 and 38 of these two different wines (Table 2). Then, recombination and omissions tests were organized using selected HPLC fractions, and their sensory impact on the expression of the overripe fruit was studied. In particular, experiments on total aromatic reconstitution, partial aromatic reconstitution without HPLC fractions 37 + 38, or partial aromatic reconstitution

without HPLC fractions 37 + 38 supplemented with the selected compounds were focused on the description of the overripe orange expression and typicality levels.

Preliminary experiments comparing the total (TAR) and partial (PAR) aromatic reconstitutions of Bordeaux dessert wine 1, with PAR supplemented with only one selected compound, revealed significant differences in the intensity of orange aroma. TAR had a mean value of 7.0 ± 0.7, whereas values for PAR and PAR with only one compound did not exceed 4.0 ± 0.7 (Supporting Information). However, a comparison between TAR and PAR supplemented with the four compounds together (PAR4C) at concentrations assayed in Bordeaux dessert wine 1 did not reveal, within two repeated sensory sessions, any significant difference in intensity of the orange descriptor (sensory sessions 1 and 1*, Table 7). The mean values for orange aroma perception in TAR sample were 6.7 ± 0.5 and 6.8 ± 0.9 with repetition, whereas PAR4C presented similar values at 6.2 ± 0.9 and 6.2 ± 0.7 with the repetition, indicating that adding all four compounds produced a sensory appreciation very close to the sample TAR. Thus, clear sensory differences were observed when PAR fractions were supplemented with only one of four selected compounds or with the four compounds together. The 37 + 38 sample presented always the highest values of 7.4 ± 0.4 and 7.5 ± 0.6 for the repetition. Then, sensory tests were conducted to study the impact of each compound omission, with Bordeaux dessert 1 wine, on the overripe aroma register. The mean values for the 37 + 38 sample were 7.6 ± 0.6 and 7.5 ± 0.7 with the repetition, whereas those of TAR were 6.7 ± 0.6 and 6.9 ± 0.6 with the repetition (sensory sessions 1 and 1*, Table 8). Under these conditions, although the mean values for PAR were 3.0 ± 0.6 and 3.3 ± 0.7, the orange aroma was always perceived as much more intense when the sample was supplemented with three of four compounds in PAR fractions. With regard to the omission of the compounds, only sample PAR4C-γN (omitting γ-nonalactone) was not significantly different from the total reconstitution. This contributes to demonstrating the direct effect of 2-nonen-4-olide, eugenol, and 3-methyl-4-octanolide on the overripe orange aroma of Bordeaux dessert wines, whereas γ-nonalactone had only a minor impact on the blend at the concentrations considered. In fact, the association of 2-nonen-4-olide with oak compounds is probably responsible for the new aromatic perception, which may be associated with perceptual blending.

When the sensory reconstitution and omission tests with Bordeaux dessert wine 2, presenting a lower typicality, on the expression of overripe orange aroma were considered, the results were much less significant. When the PAR sample was supplemented with the four above-mentioned compounds at

[a]The asterisk indicates a repetition.

the concentrations found in the dessert wine fractions (Tables 2 and 3), no reproduction of the TAR was achieved under these conditions. PAR4C presented values at 4.5 ± 0.7 and 3.9 ± 0.5 with repetition, nonsignificantly different from PAR at 4.4 ± 0.8 and 3.7 ± 0.7 (sensory sessions 2 and 2*, Table 7). With regard to the sensory experiment with the omission of one compound of four, a significant difference was detected, with fractions from Bordeaux dessert wine 2, between samples 37 + 38 and TAR on one side, and samples PAR, PAR4C-WL, PAR4C-γN, PAR4C-E, and PAR4C-N on the other (sensory sessions 2 and 2*, Table 8). Samples 37 + 38 and TAR had the highest mean values for the overripe orange aroma, 4.5 ± 0.5 and 4.0 ± 0.6, respectively, 3 ± 1.2 and 3.7 ± 0.6 with the repetition, but at lower levels than in the sensory session with Bordeaux dessert wine 1, whereas samples PAR, PAR4C-WL, PAR4C-γN, PAR4C-E, and PAR4C-N had the lowest mean values.

Relatively to typicality appreciation, the results concerning Bordeaux dessert wine 1 indicated no significant difference between 37 + 38, TAR, and PAR4C (values situated between 6 ± 0.6 and 6.2 ± 0.5), whereas PAR presented a lower value (4.5 ± 0.8) (sensory sessions 1 and 1*, Table 9). The results expressed the same level of difference with the repetition of the session (TAR at 6.9 ± 0.5 and PAR4C at 6.5 ± 0.3, but PAR at 3.8 ± 0.7). Omitting fractions 37 + 38 clearly had a negative impact, thus confirming the contribution of the compounds involved in these fractions to wine typicality. When only one compound (3-methyl-4-octanolide, γ-nonalactone, eugenol, or 2-nonen-4-olide) was added to PAR, typicality appreciation was lower (Supporting Information). Relatively to typicality appreciation with Bordeaux dessert wine 2 samples, the addition of the four compounds to sample PAR4C had a minor impact, likely due to the low concentrations used. Whereas the results indicated a significant difference in typicality between the TAR sample and all other samples (sensory sessions 2 and 2*, Table 9), the level of Bordeaux dessert wine typicality was globally lower than with Bordeaux

dessert wine 1 sample. The highest mean values for Bordeaux dessert wine typicality was noted for sample TAR (4.5 ± 1.0 and 4.7 ± 0.7). In fact, both overripe orange aroma and typicality appreciation were limited with Bordeaux dessert wine 2, possibly due to the fact that lower concentrations of the four selected compounds were added. All of these results were confirmed during the replication of the sensory sessions.

At the end, the perception of overripe orange aroma was also studied in the Bordeaux dessert wine 2 matrix, supplemented with the targeted compounds at concentrations determined in Bordeaux dessert wine 1, as previously reported (Tables 2 and 3). Addition of the four compounds to the PAR produced a mean value almost equal to that of the TAR during the two repeated sessions, TAR and PAR4C presenting values of 6.7 ± 1.0 and 6.2 ± 0.5, respectively, much higher than that of PAR 3.3 ± 0.9 (sensory sessions 3 and 3*, Table 7). The same level of significance was confirmed with the repetition. With regard to the omission tests, samples 37 + 38, TAR, and PAR4C-γN had high mean values of 7.6 ± 0.7, 6.6 ± 0.4, and 6.8 ± 0.4, respectively, as previously noted during the sensory session with Bordeaux dessert wine 1 (sensory sessions 3 and 3*, Table 8). Unlike the previous experiment, the omission of eugenol did not significantly affect the sensory appreciation under these particular conditions. Statistical analysis revealed the TAR and PAR4C-E samples received similar intensities in terms of overripe orange fruity aroma (Table 8). In fact, throughout this experiment, when fraction 37 + 38 from Bordeaux dessert wine 1 or the targeted compounds considered at concentrations determined in this wine extract were added to the PAR fraction from Bordeaux dessert wine 2 used in session 2, the overripe orange fruit was much more intense. This emphasized the impact of 2-nonen-4-olide and 3-methyl-4-octanolide concentrations on this aroma perception. For the appreciation of Bordeaux dessert wine typicality, a significant difference was also noted between PAR, PAR4C, and TAR, once again highlighting the four compounds, on the assessment of typicality (sensory sessions 3 and 3*, Table 9).

Finally, all of these results, confirmed by replications of the sensory sessions, contribute to establish the interest of lactones, originating either from wine or oak aging, first, on the orange aroma isolated from Bordeaux dessert wines and, second, on the appreciation of typicality. Lactones are known to be active aroma compounds in many fruits.[33] The correlation between *cis*-3-methyl-4-octanolide concentrations and berry intensity in wines has been highlighted by other authors.[34] Moreover, the impact of 2-nonen-4-olide as an aroma-modifying and -intensifying compound has also been cited.[35] In our experiments, γ-nonalactone, at the concentration considered, which differs from 2-nonen-4-olide only by the absence of a double bond, does not seem to make a similar contribution to the perceptual phenomenon. In summary, through the characterization of molecular determinants for overripe aroma in dessert wines, two lactones, one originating from oak aging, 3-methyl-4-octanolide, and the second associated with noble rot development on grapes, 2-nonen-4-olide, were found to play an important role in the expression of the overripe orange aroma and typicality perceived in fractions obtained by HPLC from Bordeaux dessert wine extracts. In our experimental conditions, eugenol had a less significant effect and γ-nonalactone made a minimal contribution. The various omission and reconstitution tests demonstrated that 2-nonen-4-olide and 3-methyl-4-octanolide particularly contribute to wine aroma through perceptual blending to a synthetic perception. It was also demonstrated that this phenomenon was highly specific, because γ-nonalactone, a saturated form of 2-nonen-4-olide, made a very limited contribution to the perceptual blending. To our knowledge, this type of sensory phenomenon, involving two lactones, had never previously been demonstrated. This opens up new perspectives for interpreting the complexity and typicality of wine aroma.

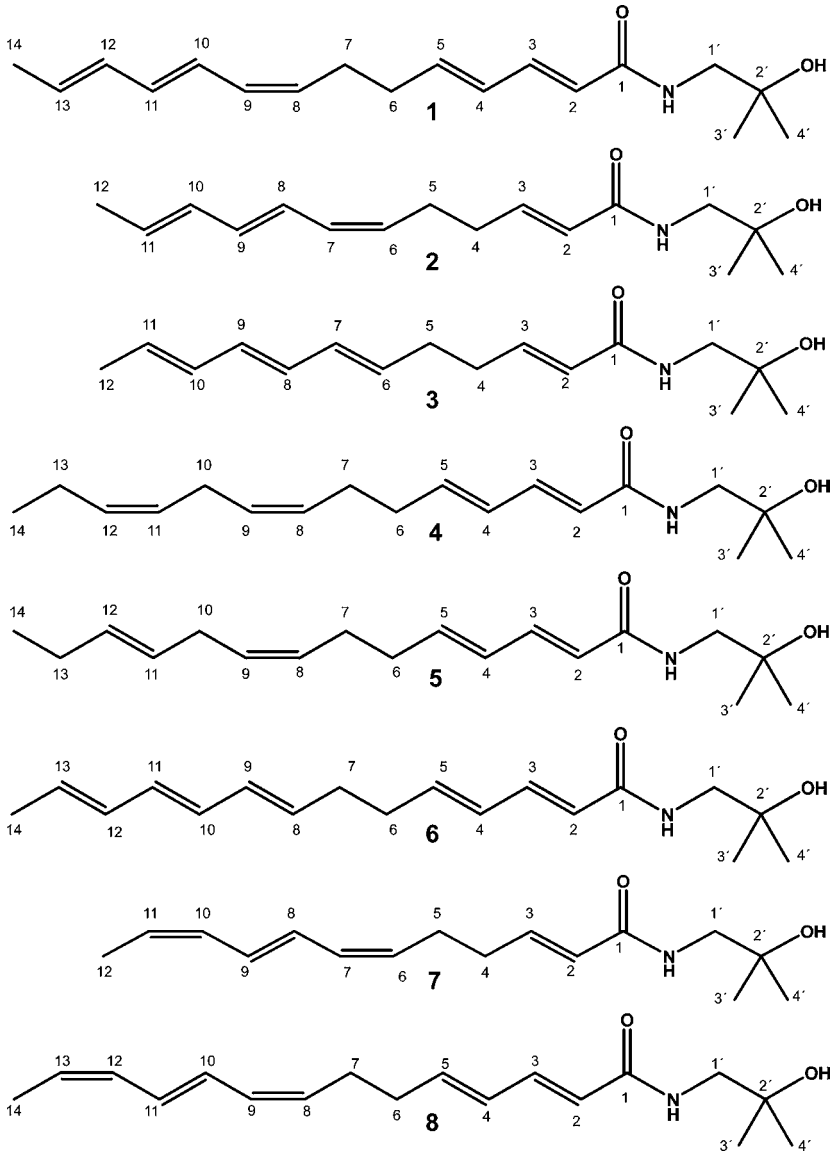

Figure 1. Chemical structures of hydroxy-γ-sanshool (**1**), hydroxy-α-sanshool (2), hydroxy-β-sanshool (**3**), bungeanool (**4**), isobungeanool (**5**), hydroxy-γ-isosanshool (**6**), hydroxy-ε-sanshool (**7**), and hydroxy-ζ-sanshool (**8**).

activate saliva,[15] but the key molecule responsible for this activity is not known yet.

Therefore, the objectives of the present study were to locate and isolate most sensory active phytochemicals from a highly tingling active supercritical fluid (SCF) extract prepared from dried pods of *Z. piperitum* by application of the taste dilution analysis (TDA),[16,17] to validate their chemical structure by means of LC-TOF-MS, LC-MS/MS, and 1D/2D NMR spectroscopy, and to determine human orosensory recognition thresholds as well as salivation-inducing activity of purified chemosensates using an ethanol-free sensory assay.[13]

MATERIALS AND METHODS

Chemicals. The following compounds were obtained commercially: Water for chromatographic separations was purified with an integral 5 system (Millipore, Schwalbach, Germany); *n*-hexane (Merck, Darmstadt, Germany) and solvents used were of HPLC grade (J. T. Baker, Deventer, The Netherlands). Deuterated solvents containing 0.03% trimethylsilane (TMS) were obtained from Eurisо-Top (Gif-Sur-Yvette, France). A supercritical fluid (SCF) extract from dried fruit pods of *Z. piperitum* was obtained from Synthite Industries (Kolenchery, Kerala, India). For sensory analysis, bottled water (Evian, low mineralization = 405 mg/L), sucrose (Sigma-Aldrich, Steinheim, Germany), piperine (Sigma-Aldrich), and capsaicine (Sigma-Aldrich) were used. Filter paper (Rundfilter classic, 94 mm; Melitta, Minden, Germany), cut into a rectangular shape (1 × 2 cm), was used as vehicle for the sensory evaluation of pungent and tingling amides.

Sensory Analyses. *General Conditions and Panel Training.* Twelve volunteers (seven women and five men, ages 25−34 years), who gave their informed consent to participate in the sensory tests of the present investigation and had no history of known taste disorders, were trained in sensory experiments with purified reference compounds at regular intervals for at least two years. The subjects were experienced in evaluating the orosensation of a tingling Szechuan pepper extract (40 μg/1 × 2 cm; Synthite, Kerala, India), isolated from *Z. piperitum* by means of supercritical carbon dioxide extraction and containing hydroxy-α-sanshool and hydroxy-β-sanshool in amounts of 9.1 and 2.5% (HPLC-UV), respectively, and the pungent compounds capsaicine (3 μg/1 × 2 cm) and piperine (20 μg/1 × 2 cm), respectively, by means of a modified half-tongue test using filter paper rectangles (1 × 2 cm) as the vehicle.[13] Panelists were instructed to rinse their mouth after each dilution step with a 3% sucrose solution (15 mL), followed by water (15 mL), and to wait for 2 min between

dx.doi.org/10.1021/jf500399w | J. Agric. Food Chem. 2014, 62, 2479−2488

each sample. Sensory analyses were performed at 19−22 °C in a sensory panel room in three different sessions.

Precaution Taken for Sensory Analysis of Food Fractions and Taste Compounds. To remove solvent traces and buffer compounds from all fractions and compounds isolated from pepper, the individual fractions were suspended in water and, after removal of the volatiles under high vacuum (<5 mPa), were freeze-dried twice. ^{1}H NMR spectroscopic, UPLC-UV-TOF-MS, and ion chromatographic analyses of an aliquot revealed that food fractions treated by that procedure were essentially free of the solvents and buffer compounds used.

Modified Half-Tongue Test. According to a literature protocol,[13] serial 1:1 dilutions of HPLC fractions or purified compounds in ethanol were applied on filter paper rectangles (1 × 2 cm) and the solvent was removed under a stream of nitrogen at 38 °C. As the control vehicle, filter paper rectangles were loaded with ethanol (blank), followed by evaporation at 38 °C. Using a 3% sucrose solution (15 mL) and water (15 mL) as cleansing solutions and an interstimulus interval length of 5 min between sample dilutions, the vehicles loaded with the stimulus in order of ascending concentration were presented to the sensory panel in three independent sessions and were randomly placed on the right or the left side of the anterior tongue together with an anonymized control vehicle (blank) on the other side. For each dilution, the subjects were asked to locate the side of the tongue on which a pungent and/or a tingling sensation was perceivable.

Taste Dilution Analysis (TDA). An aliquot (1.0 g) of the SFC extract prepared from Szechuan pepper was separated by RP-MPLC to give seven fractions, namely, F1−F7, which were freeze-dried twice and dissolved in "natural" concentration ratios, which means the fractions were used in concentrations corresponding to their yields obtained after fractionation. After each fraction had been sequentially diluted 1:1 with ethanol and applied on filter paper rectangles (1 × 2 cm), solvent traces were removed with a nitrogen stream at 38 °C, and the serial dilutions of each of these fractions were presented to the sensory panel in order of ascending concentration. Each dilution was evaluated for tingling activity by means of the half-tongue test detailed above. The dilution at which a sensory difference between the paper rectangle loaded with a Szechuan pepper fraction and a blank vehicle (control) could just be detected was defined as taste dilution (TD) factor.[13] The TD factors evaluated by six trained assessors in two different sessions were averaged. The TD factors between the trained individuals and separate sessions did not differ by more than plus/minus one dilution step.

Recognition Threshold Concentration. Threshold concentrations of the purified compounds were determined by using the half-tongue test and the filter paper rectangles as detailed above. To prevent excessive fatigue, the trials began at a concentration level two steps below the threshold concentration that had been evaluated in preliminary sensory experiments. Whenever the panelist selected incorrectly, the next trial took place at the next higher concentration step. Whenever the panelist selected correctly, the same dilution of the stimulus was evaluated again as a proof of the correctness of the data. The threshold value of the sensory group was approximated by averaging the threshold values of the individuals in three independent sessions. The geometric mean of the two lowest correctly identified concentrations was calculated and taken as the individual recognition threshold. Values between individuals and separate sessions differed by not more than plus or minus two dilution steps; that is, a threshold value of 3.0 nmol/cm^2 for the pungent reference compound piperine represents a range of 0.75−9.0 nmol/cm^2.

Salivation Experiments. Following a literature protocol[15] with some modifications, eight healthy volunteers were asked not to eat and drink for at least 1 h before the experiment started. First, the panelists rinsed the oral cavity with bottled water (8 mL) for 60 s and swallowed. To measure the nonstimulated saliva flow (control), the panelists then took bottled water (2 mL) in the mouth, simulated chewing motions for 30 s, and expectorated into preweighed cups. To measure the stimulated saliva flow, the oral cavity was rinsed again with water (8 mL) for 60 s; thereafter, the panelists took the stimulus solution (2 mL) containing the Szechuan pepper extract (100 mg/100 mL), hydroxy-α-sanshool (100 mg/100 mL), and hydroxy-β-sanshool (100 mg/100 mL), respectively, in the mouth and simulated chewing for 15 s and expectorated into preweighed vessels (stimulus sample). Without swallowing between, the subjects were asked to take water (2 mL) in the mouth, to simulate chewing for 30 s, and to expectorate again (poststimulus sample 1). This step was repeated three times (poststimulus samples 2−4). The saliva flow increase was calculated from the weight difference of the expectorated saliva/water mixture, and the aliquot (2 g) of the aqueous stimulus solution used to collect the stimulus sample and the aliquot (2 g) of water used to obtain the prestimulus sample (control) as well as poststimulus samples 1−4, respectively.

Identification of Chemosensates 1−8. A solution of the Szechuan pepper SCF extract (10 g) in methanol (400 mL) was defatted by *n*-hexane extraction (3 × 400 mL), concentrated under vacuum at 40 °C to about 30 mL, and, after dilution with water (30 mL), separated by medium-pressure liquid chromatography (MPLC) using a Sepacore system from Büchi (Flawil, Switzerland) consisting of a C-620 control unit, three C-605 type pumps, a C-660 fraction collector, a C-635 UV detector, and an injection valve (20 mL). Chromatography was performed using a 40 × 150 mm polypropylene cartridge (Büchi) filled with 25−40 μm LiChroprep RP-18 material (Merck). Monitoring the effluent (40 mL/min) at 265 nm, chromatography was performed with a mixture of aqueous formic acid (0.1% in water, pH 2.5, A) and methanol (B). A gradient was used as follows: 0 min, 65% B; 17 min, 90% B; 22 min, 90% B; 23 min, 100% B; and 28 min, 100% B. Individual fractions were collected, concentrated under vacuum at 40 °C, freeze-dried twice, and used for TDA to locate those fractions inducing a tingling and/or pungent orosensation. Fractions evaluated with high TD factors were further separated by means of preparative HPLC (Jasco, Groß-Umstadt, Germany) equipped with two PU-2087 Plus pumps, an AS-2055 Plus autosampler, a 7725i type Rheodyne injection valve (Rheodyne, Bensheim, Germany), and a MD-2010 Plus diode array detector.

By monitoring the effluent at 265 nm, isolation of amides **2**, **3**, and **7** was performed using a 21.2 × 250 mm, 5 μm, ODS-Hypersil C18 column (ThermoHypersil, Kleinostheim, Germany) using aqueous formic acid (0.1% in water, pH 2.5, A) and acetonitrile (B) as mobile phase (21 mL/min) and the following gradient: 0 min, 40% B; 18 min, 65% B; 22 min, 100% B; 24 min, 100% B; 27 min, 40% B; 30 min, 40% B.

Separation and purification of amides **1**, **4**−**6**, and **8** were achieved on a 21.2 × 250 mm, 5 μm, Varian Pursuit C18 column (Agilent, Waldbronn, Germany), equipped with a 21.2 × 50 mm guard column of the same type, and a mixture of aqueous formic acid (0.1% in water, pH 2.5, A) and acetonitrile (B) as mobile phase (18 mL/min) using the gradient as follows: 0 min, 50% B; 20 min, 70% B; 21 min, 100% B; 23 min, 100% B; 25 min, 50% B; 30 min, 50% B. After the purity of each fraction had been checked by means of analytical RP-HPLC, the isolated phytochemicals were analyzed by LC-MS and NMR spectroscopy, whereas the fractions containing mixtures of individual substances were further purified by HPLC rechromatography. The individual fractions were collected, separated from solvent under vacuum, and freeze-dried to yield the target amides **1**−**7** in a purity of >98%.

The ^{13}C NMR data (125 MHz, d_3-MeOD, HSQC, HMBC) are shown in Table 1.

N-(2-Methyl-2-hydroxypropyl)-tetradeca-(2E,4E,8Z,10E,12Z)-pentaenwamide (hydroxy-ζ-sanshool), **8**, Figure 1: UV−vis (methanol/0.1% aqueous formic acid; 6:4, v/v), λ_{max} = 276, 264 nm; LC-TOF-MS (ESI^+), *m/z* 290.2114 (measured), *m/z* 290.2120 (calcd for $[C_{18}H_{27}NO_2 + H]^+$); MS (ESI^+), *m/z* 290 (100, $[M + H]^+$), 272 (22, $[M + H - H_2O]^+$), 312 (70, $[M + Na]^+$), 328 (33, $[M + K]^+$); MS/MS (DP = +40 V), *m/z* 272 (100), 165 (69), 131 (40), 72 (35), 173 (33), 107 (30), 93 (18), 201 (10); ^1H NMR (500 MHz, d_3-MeOD, COSY), δ 1.18 [s, 6H, H−C(3′,4′)], 1.76 [d, 3H, *J* = 7.1 Hz, H−C(14)], 2.27 [m, 2H, *J* = 7.3, 14.5 Hz, H−C(6)], 2.35 [m, 2H, *J* = 7.4, 14.8 Hz, H−C(7)], 3.26 [s, 2H, H−C(1′)], 5.38−5.46 [m, 1H, H−C(8)], 5.46−5.56 [m, 1H, H−C(13)], 6.00 [d, 1H, *J* = 15.2 Hz, C−H(2)], 6.03−6.17 [m, 3H, H−C(5, 9, 12)], 6.24 [dd, 1H, *J* = 10.6, 14.9 Hz, H−C(4)], 6.43−6.49 [dd, 1H, *J* = 10.2, 14.9 Hz, H−C(10)], 6.49−6.56 [dd, 1H, *J* = 10.4, 15.5 Hz, H−C(11)], 7.12 [dd, 1H, *J* = 10.8, 14.9 Hz, H−C(3)]. The ^{13}C NMR data (125 MHz, d_3-MeOD, HSQC, HMBC) are shown in Table 1.

Ultraperformance Liquid Chromatography−Time-of-Flight Mass Spectrometry (UPLC-TOF-MS). Mass spectra of the compounds were measured on a Waters Synapt G2 HDMS mass spectrometer (Waters, Manchester, UK) coupled to an Acquity UPLC core system (Waters, Milford, MA, USA) consisting of a binary solvent manager, sample manager, and column oven. Analytes were injected into the UPLC-TOF-MS system equipped with a 2.1 × 150 mm, 1.7 μm, BEH C18 column (Waters, Manchester, UK). Operated with a flow rate of 0.4 mL/min at 45 °C, the following gradient was used for chromatography: starting with a mixture (40:60, v/v) of water and acetonitrile, the acetonitrile content was increased to 100% within 4 min and, then, kept constant for 1 min. Scan time for the MS^E method (centroid) was set to 0.1 s. Analyses were performed in the positive ESI and the resolution mode using the following ion source parameters: capillary voltage, +2.0 kV; sampling cone, 30 V; extraction cone, 4.0 V; source temperature, 150 °C; desolvation temperature, 450 °C; cone gas, 30 L/h; and desolvation gas, 850 L/h. Data processing was performed by using MassLynx 4.1 SCN 779 (Waters, Manchester, UK) and the elemental composition tool for determining the accurate mass. All data were lock mass corrected on the pentapeptide leucine enkephaline (Tyr-Gly-Gly-Phe-Leu, *m/z* 556.2771, $[M + H]^+$) in a solution (2 ng/μL) of acetonitrile/0.1% formic acid (1:1, v/v). Scan time for the lock mass was set to 0.3 s, an interval of 15 and 3 scans to average with a mass window of ±0.3 Da. Calibration of the Synapt G2 in the range from *m/z* 50 to 1300 was performed using a solution of sodium formate (5 mmol/L) in 2-propanol/water (9:1, v/v). The UPLC and Synapt G2 systems were operated with MassLnyx software (Waters, Manchester, UK).

High-Performance Liquid Chromatography−Mass Spectrometry (HPLC-MS/MS). LC-MS/MS analysis was performed using an Dionex Ultimate 3000 HPLC system connected to the API 4000QTrap LC-MS/MS (AB Sciex, Darmstadt, Germany) running in the positive electrospray ionization (ESI^+) mode. Zero grade air served as nebulizer gas (45 psi) and as turbo gas (425 °C) for solvent drying (55 psi). Nitrogen served as curtain (20 psi) and collision gas (8.7×10^{-7} psi). Both quadrupoles were set at unit resolution. ESI^+ mass and product ion spectra were acquired with direct flow infusion. For ESI^+, the ion spray voltage was set at +5500 V.

Nuclear Magnetic Resonance Spectroscopy (NMR). ^1H, ^{13}C, DEPT-135, homonuclear $^1H-^1H$ correlation spectroscopy ($^1H-^1H$-*g*COSY), heteronuclear single-quantum coherence spectroscopy (*g*HSQC), heteronuclear multiple-bond correlation spectroscopy (*g*HMBC), and $^1H-^1H$ rotating frame nuclear Overhauser enhancement spectroscopy (phase-sensitive ROESY) NMR measurements were performed on an Avance III 500 MHz equipped with a CTCI probe and an Avance III 400 MHz spectrometer with a BBO probe (Bruker, Rheinstetten, Germany), respectively. Chemical shifts were referenced to the solvent signal. Data processing was performed by

RESULTS AND DISCUSSION

Using the recently developed half-mouth test,[13] orosensory evaluation of paper vehicles loaded with dilutions of the SCF extract prepared from *Z. piperitum* revealed a strong and long-lasting tingling activity in the oral cavity perceived up to a dilution of 1:16384 (data not shown). To locate the most active chemosensates in Szechuan pepper, the SFC extract was dissolved in methanol and extracted with hexane, both fractions were separated from solvent, and dilutions of the hexane extractables as well as the methanol solubles were judged in natural concentration ratios in their tingling activity by means of a TDA. The methanol solubles induced a strong tingling sensation judged with a TD factor of 8192, whereas the hexane extractables showed comparatively low activity judged with a TD factor of only 128. As a consequence, the following investigation on the primary tingling components in Szechuan pepper was focused on the methanol solubles.

Taste Dilution Analysis. To sort out the tingling compounds from the bulk of less taste-active or tasteless substances, the tingling-active methanol solubles of the SFC extract were separated by means of MPLC on RP18 material to give seven fractions, namely F1−F7, which were collected individually, separated from solvent, and used for the TDA using paper disks as vehicles.[13] Fractions F2 and F3 showed by far the highest TD factors of 4096 and 2048, respectively, whereas all other fractions showed only low tingling activity judged with TD factors of ≤128 (Figure 2). Aimed at characterizing the molecular structure of the compounds imparting the most intense tingling sensation of Szechuan pepper, further fractionation and LC-MS as well as NMR experiments were focused on MPLC fractions F2 and F3.

Isolation and Identification of Chemosensates in Fractions F2 and F3. Separation of fractions F2 and F3 by means of preparative RP-HPLC revealed nearly baseline separation of their components, which could be isolated or further purified by means of rechromatography (Figure 3).

LC-MS analysis using electrospray ionization (ESI^+) revealed m/z 264 as the pseudomolecular ion ($[M + H]^+$) and m/z 246 as the main fragment ion for the three main compounds **2**, **3**, and **7** eluting in fraction F2 (Figure 3A). Exemplified for compound **7**, the product ion scan of m/z 264 $[M + H]^+$ revealed the main fragments of m/z 246, 147, 107, and 175 (Figure 4A), indicating the loss of water as well as an alpha and an allyl cleavage, respectively. Moreover, the isobaric compounds **2**, **3**, and **7** were found by LC-TOF-MS to show identical elemental compositions of $C_{16}H_{25}NO_2$. In comparison, the early-eluting compounds **1**, **6**, and **8** in fraction F3 (Figure 3B) showed a pseudomolecular ion ($[M + H]^+$) of m/z 290 and a main fragment ion with m/z 272, well in agreement with the molecular formula of $C_{18}H_{27}NO_2$ as indicated by LC-TOF-MS analysis. The late-eluting compounds **4** and **5** in fraction F3 differed by a mass increment of 2, consistent with an elemental composition of $C_{18}H_{29}NO_2$ (LC-TOF-MS), and showed m/z 292 and 274 as the $[M + H]^+$ and the main fragment ion, respectively.

Unequivocal assignment of protons and carbon atoms could be successfully achieved by means of ^1H, ^{13}C, DEPT-135, $^1H-^1H$-*g*COSY, *g*HMBC optimized for $^2J_{C,H}$ and $^3J_{C,H}$ coupling constants, and *g*HSQC optimized for $^1J_{C,H}$ coupling constants, respectively (Table 1). Comparison of ^1H and ^{13}C NMR data with literature data[1,2] led to the identification of the amides hydroxy-γ-sanshool (**1**), hydroxy-α-sanshool (**2**), hydroxy-β-sanshool (**3**), bungeanool (**4**), isobungeanool (**5**), and hydroxy-γ-isosanshool (**6**), respectively.

dx.doi.org/10.1021/jf500399w | J. Agric. Food Chem. 2014, 62, 2479−2488

The ^{1}H NMR of compound **7** showed eight olefinic protons of the polyunsaturated fatty acid chain, namely, H−C(2), H−C(3), and H−C(6) to H−C(11), resonating in the range of 5.43−6.87 ppm, and six aliphatic protons, which could be assigned to the 2-methyl-2-hydroxypropyl moiety (H−C(1′), H−C(3′), H−C(4′)), the terminal methyl protons H−C(12), and the two methylene groups H−C(4) and H−C(5) of the fatty acid moiety. Unequivocal assignment of all protons and carbon atoms could be successfully achieved by means of 1D/2D NMR spectroscopy, which identified **7** as a geometrical isomer of amides **2** and **3** showing four double bonds at carbons C(2), C(6), C(8), and C(10), respectively. The geometry of the individual double bonds was unambiguously elucidated by comparing the $^3J_{H,H}$ coupling constants of the olefinic protons and the ^{13}C NMR chemical shifts recorded for the individual isomers, as well as by means of ROESY experiments. The protons H−C(2) and H−C(3), both resonating as double triplets, and the two double duplet protons H−C(8) and H−C(9) showed the characteristic *trans*-olefinic coupling constants of 15.2 and 14.8 Hz, respectively. In contrast, the olefinic protons H−C(10) and H−C(11) as well as H−C(6) and H−C(7) showed a $^3J_{H,H}$ coupling constant of ∼10.8 Hz, thus indicating a *cis*-configuration. By comparing the ^{13}C chemical shifts of compounds **2**, **3**, and **7**, the methylene carbon atom C(5) and the methyl carbon C(12), both adjacent to the *cis*-configured double bond, showed a clear upfield shift in **7** when compared to the all-*trans*-isomer **3** (Table 1; Figure 5). The upfield shift of the carbon C(5) from 31.4 to 26.5 ppm in **7** and **2** compared to **3** is well in agreement with a *cis*-shielding effect reported in the literature.[2,7−9] Another fingerprint carbon atom, namely C(12), showed an upfield shift of ∼5 ppm in **7** when compared to its geometric isomers **2** and **3**, respectively (Table 1; Figure 5). The configurations of the double bonds were further supported by means of a ROESY experiment; for example, a ROESY correlation was detected between the methyl protons H−C(12) and methine proton H−C(9). Taking all spectroscopic data into consideration, LC-TOF-MS, LC-MS/MS, and 1D/2D NMR experiments led to the unequivocal identification of compound **7** as *N*-(2-methyl-2-hydroxypropyl)dodeca-(2*E*,6*Z*,8*E*,10*Z*)-tetraene amide (hydroxy-ε-sanshool). which has already been mentioned in the literature,[3,5,6,10] although its chemical structure has not yet been confirmed by means of 1D/2D NMR spectroscopy.

The MS product ion scan of *m*/*z* 290 $[M + H]^+$, the pseudomolecular ion of compound **8**, revealed *m*/*z* 272, 173, 107, and 202 as the main fragment ions (Figure 4B), thus indicating the cleavage of water (*m*/*z* 272), and an alpha cleavage (*m*/*z* 173; *m*/*z* 202), as well as an allyl cleavage (*m*/*z* 107), respectively. The ^{1}H NMR of **8** showed 10 olefinic protons, namely, H−C(2) to H−C(5) and H−C(8) to H−C(13), resonating in the range of 5.38−7.12 ppm, six aliphatic protons assigned to the 2-methyl-2-hydroxypropyl moiety (H−C(1′), H−C(3′), H−C(4′)), the terminal methyl protons H−C(14), and the two methylene groups H−C(6) and H−C(7) of the fatty acid moiety. Assignment of protons and carbon atoms revealed **8** to be a geometrical isomer of the amides **1** and **6**, respectively. The $^3J_{H,H}$ coupling constants of 15.5 and 14.9 Hz of the two double duplets detected for H−C(10) and H−C(11) indicated a *trans*-configuration of this double bond (Figure 6). Moreover, carbon atoms C(7) and C(14) showed an upfield shift of ∼5 ppm in **8** when compared to its geometric isomers **1** and **6** (Table 1; Figure 1), being well in agreement with the expected *cis*-shielding effect.[2,7−9] Taking all spectroscopic data into consideration, the structure of compound **8** was determined to be *N*-(2-methyl-2-hydroxypropyl)tetradeca-(2*E*,4*E*,8*Z*,10*E*,12*Z*)-pentaene amide, coined hydroxy-ζ-sanshool, which to the best of our knowledge has not been reported before.

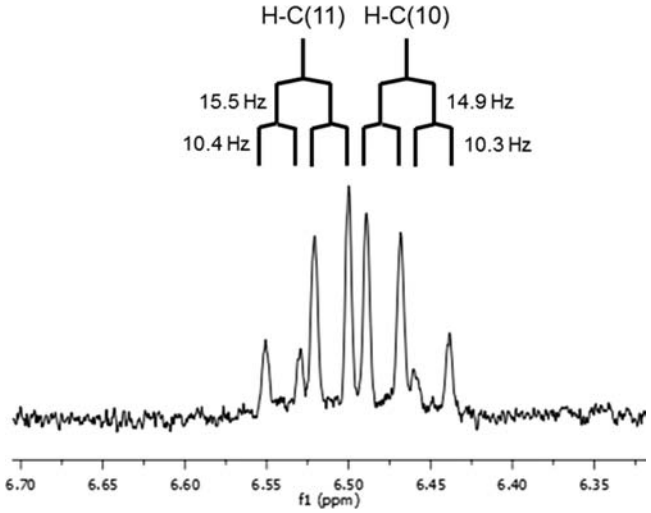

Figure 6. Excerpt (δ 6.3−6.7) of the ^{1}H NMR spectra (500 MHz, d_3-MeOD) of alkylamide **8** showing H−C(10) and H−C(11).

Sensory Evaluation of Pungent and/or Tingling Chemosensates. Prior to sensory analysis, the purity of all compounds was confirmed by LC-MS as well as ^{1}H NMR spectroscopy to be >98%. To determine the human threshold concentrations for the orosensation induced by the individual chemosensates, paper vehicles loaded with the test compounds in serial dilutions were evaluated by means of a half-tongue test.[13] Hydroxy-γ-sanshool (**1**), hydroxy-α-sanshool (**2**), bungeanool (**4**), isobungeanool (**5**), hydroxy-ε-sanshool (**7**), and the previously not reported hydroxy-ζ-sanshool (**8**) were found to elicit an oral tingling and paresthetic sensation above a rather similar threshold concentrations ranging between 3.5 and 8.3 nmol/cm^2, respectively (Table 2). It is interesting to note that the position of the *cis*-configured double bond in **1**, **2**, **4**, **5**, **7**, and **8** did not have a major impact on the tingling threshold concentration of these amides. Interestingly, the absence of a *cis*-double bond, as found for hydroxy-β-sanshool (**3**) and hydroxy-γ-isosanshool (**6**), resulted in a complete loss of the tingling activity. This is well in agreement with earlier studies

Table 2. Orosensory Recognition Thresholds of Alkylamides 1−8

compound[a]	oral sensation	threshold concn[b] (nmol/cm^2)
1	tingling, paresthetic	6.8
2	tingling, paresthetic	8.3
3	numbing, anesthetic	3.9
4	tingling, paresthetic	3.5
5	tingling, paresthetic	3.5
6	numbing, anesthetic	7.1
7	tingling, paresthetic	4.2
8	tingling, paresthetic	7.0

[a]Structures of compounds are given in Figure 1. [b]Orosensory recognition threshold concentrations were determined by means of a modified half-mouth test using paper rectangles (1 × 2 cm) as a vehicle.[13]

on synthetic polyunsaturated alkylamides[10] and those isolated from black pepper;[13] for example, saturation of the double bond in black pepper's tingling compound (2*E*,4*E*,12*Z*)-*N*-isobutyloctadeca-2,4,12-trienamide wiped out the tingling activity of (2*E*,4*E*)-*N*-isobutyloctadeca-2,4-dienamide. Although no tingling activity was detectable for the all-*trans*-configured compounds **3** and **6**, most interestingly, the sensory panelists reported an intense and long-lasting numbing and anesthetic oral impression above threshold concentrations of 3.9 nmol/cm^2 (**3**) and 7.1 nmol/cm^2 (**6**).

To answer the question of whether the tingling and numbing amides differ in their salivating activity, the major amides hydroxy-α-sanshool (**2**, tingling) and hydroxy-β-sanshool (**3**, numbing) were isolated in suitable amounts and aqueous solutions were used to orally challenge a panel of eight healthy volunteers for 15 s; the saliva flow was measured for 120 s using an assay reported recently.[15] A comparative experiment was performed with an aqueous solution of the crude Szechuan pepper extract containing 9.1% hydroxy-α-sanshool and 2.5% hydroxy-β-sanshool. All three stimuli significantly activated a long-lasting saliva flow increase (Figure 7). The tingling

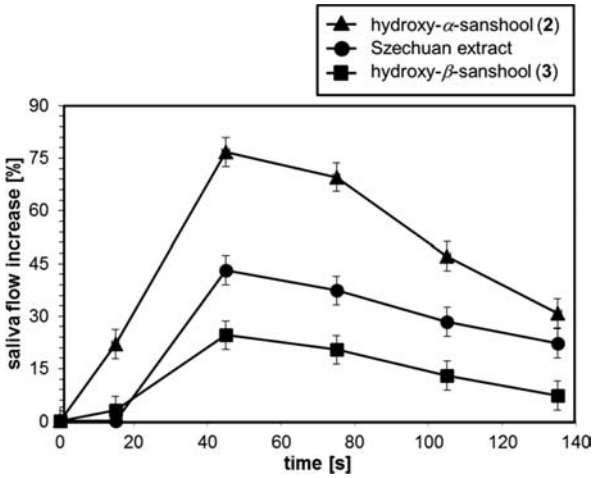

Figure 7. Time course of saliva flow increase induced by an aqueous stimulus solution (2 mL) containing (●) the Szechuan pepper extract (100 mg/100 mL), (■) hydroxy-β-sanshool (100 mg/100 mL), and (▲) hydroxy-α-sanshool (100 mg/mL). Least significant difference is visualized (LSD = 8.263).

hydroxy-α-sanshool induced a massive increase of saliva flow accounting for a maximum of ~75% after 45 s when compared to the control. Also, the Szechuan pepper extract showed a strong increase of saliva flow (~44% after 45 s), whereas the numbing hydroxy-β-sanshool showed only a marginal activity accounting for a saliva flow increase of ~25%. This demonstrates that at least one *cis*-configured double bond is needed for strong salivating activity, being well in agreement with literature data on spilanthol,[14] whereas the all-*trans*-configuration diminishes salivation. As the tingling hydroxy-α-sanshool is the quantitatively predominant amide in Szechuan pepper, this isomer is concluded to be mainly responsible for the tingling as well as the salivation enhancement activity of Szechuan pepper.

The molecular mechanisms by which hydroxy-α-sanshool (**2**) induces the tingling sensation have been a matter of debate. Although this amide is an agonist at the pain-integrating cation channels TRPV1 and TRPA1,[18] newer evidence suggests that neuron activation through a unique mechanism involving inhibition of the pH- and anesthetic-sensitive two-pore potassium channels TASK-1, TASK-3, and TRESK (previously named KCNK3, KCNK9, and KCNK18) is mediating the tingling effect of hydroxy-α-sanshool.[19] The finding that a clear tingling, paresthetic sensation is induced by amides containing at least one *cis*-configured double bond as found in **1**, **2**, **4**, **5**, **7**, and **8**, whereas an intense numbing and anesthetic impression is caused by all-*trans*-configured amides (**3** and **6**), promises the various isomers as valuable molecular probes to test candidate ion channels TASK-1, TASK-3, and TRESK for mediating the tingling effect and to challenge other receptive proteins for mediating the numbing and anesthetic effect. Such experiments will be helpful to deliver a framework for understanding the unique and complex psychophysical sensations associated with the Szechuan pepper experience.

undergo hydrolysis before absorption. Depending upon the glycoside moiety, hydrolysis and subsequent absorption can occur in either the small or the large intestine.[13] The importance of intestinal bacteria for polyphenol metabolism was highlighted by the fact that germ-free or antibiotic-treated animals no longer form the phenolic acid metabolites (ring-fission products) of (+)-catechin, apigenin, myricetin, hesperidin, naringin, rutin, and 3′,4′,5,7-tetra-*O*-*β*-hydroxyethylrutoside.[14] Moreover, the pharmacological effects of the polyphenols might be stronger after being degraded by human intestinal bacteria. For instance, the effect on platelet function of anthocyanins and their metabolites was stronger in combination.[15]

In this study, we attempted to isolate different intestinal bacteria from human feces and carry out research on their abilities and characteristics in the metabolism of isorhamnetin 3-*O*-glucoside. To further clarify the metabolic profile of isorhamnetin 3-*O*-glucoside, rapid and sensitive ultraperformance liquid chromatography/quadrupole time-of-flight mass spectrometry (UPLC/Q-TOF-MS) with automated data analysis (MetaboLynx) was used to analyze its metabolites.[16,17] As far as we know, this was the first research on the metabolites of isorhamnetin 3-*O*-glucoside by human intestinal flora which could provide a powerful analytical methodology for the identification of multiple metabolites of natural products.

EXPERIMENTAL SECTION

Materials. HPLC-grade acetonitrile was obtained from TEDIA Co. Inc. (United States), along with the anaerobic glovebox. AnaeroPack rectangular jars and AnaeroPack-Anaero were purified by Mitsubishi Gas Chemical Co. Inc. (Japan). Formic acid was purchased from Merck KGaA (Germany).

Isorhamnetin 3-*O*-glucoside was obtained from Shanghai Winherb Medical Science Co. (China). Ultrapure water was purified with an EPED superpurification system (China). Other reagents were of analytical grade.

The general anaerobic medium (GAM) used for all fermentation experiments contains 0.3 g of L-cysteine hydrochloride, 0.3 g of sodium thioglycolate, 1.2 g of beef liver extract powder, 2.2 g of beef extract, 2.5 g of KH_2PO_4, 3.0 g of glucose, 3.0 g of soya peptone, 3.0 g of NaCl, 5.0 g of soluble starch, 5.0 g of yeast extract, 10.0 g of tryptone, 10.0 g of proteose peptone, 13.5 g of digestible serum powder, and 1000 mL distilled water. The pH was adjusted to 7.3.

Bacterial Isolation and Culture Conditions. A bacterial suspension of fresh human feces was collected from a healthy female volunteer who had not taken any polyphenols before the experiment. The fecal sample was weighed and homogenized adequately with sterile physiological saline at a ratio of 1:4 (m/v), and then the mixture was centrifuged at 2000*g* for 10 min. The suspension was used as a human intestinal bacterial mixture.

After being diluted in sterile water, the bacterial mixture was spread on GAM agar plates and then incubated in anaerobic gloveboxes under anaerobic conditions at 37 °C for 2 days. As a result of the incubation, about 150 different bacteria colonies were picked up and transferred to GAM agars on an inclined plane.

Bacterial Incubation and Sample Preparation. Each bacterium was inoculated into 1.0 mL of GAM broth after being picked up from the GAM agar plate, followed by the anaerobic incubation of cultures at 37 °C for 24 h. A 0.1 mL sample of the preculture bacteria was inoculated into 0.9 mL of GAM broth with 0.1 mM isorhamnetin 3-*O*-glucoside. Then all samples which had been incubated for 48 h were extracted with ethyl acetate (1 volume of the culture) three times. Finally, the ethyl acetate layer was dried and redissolved in 0.3 mL of methanol.[18] Each supernatant of the sample was used for UPLC/MS analysis.

UPLC Analysis. The analysis of isorhamnetin 3-*O*-glucoside and its metabolites was carried out on a Waters ACQUITY UPLC system, equipped with a Syncronis C 18 column for separation. Acetonitrile (solvent system A) and ultrapure water/0.1% formic acid served as the mobile phase. HPLC was run in gradient mode (solvent system A from 10% to 40% in 0−7.5 min, from 40% to 90% in 7.5−9 min, held at 90% for 9−10 min, and back to 10% in 10−11 min for equilibration of the column) at a flow rate of 0.4 mL/min. The column temperature was set at 35 °C, while the autosampler temperature was maintained at 4 °C.

MS Analysis. Selected incubation supernatants from degradation experiments were applied for the parent and metabolit identification by electrospray ionization mass spectrometry (ESI-MS) in negative mode. Leucine-enkephalin was used as the lock mass to generate an $[M - H]^-$ ion (m/z 554.2615). The source temperature was 120 °C, while the desolvation temperature was maintained at 350 °C. The cone and capillary voltages were 40 V and 3.0 kV. Meanwhile, the gas (N_2) flows of the cone and desolvation were 50 and 600 L/h, respectively. Furthermore, the MS^E experiment was carried out to obtain fragment mass information of the parent and metabolites, which was performed in two scan functions (the mass-scan range, scan time, interscan delay, and collision energy of function 1 and function 2 were m/z 100−1000, 0.5 s, 0.02 s, and 6 V and m/z 50−1000, 0.3 s, 0.02 s, and 15−45 V, respectively). All data collected were analyzed by a Waters Metabolynx (version 4.1) program.

RESULTS

Metabolic Profile of Isorhamnetin 3-*O*-Glucoside by the Isolated Human Intestinal Bacteria. After optimization of the UPLC and MS conditions, negative ion electrospray tandem mass spectrometry and Metabolynx software were used to obtain a general survey of the isorhamnetin 3-*O*-glucoside metabolic profile. As a result of our study, the parent and five metabolites of isorhamnetin 3-*O*-glucoside (Table 1) were detected and identified in the different bacterial samples compared with the blank sample. These metabolites were probably isorhamnetin 3-*O*-glucoside (M1) catabolites: isorhamnetin (M2), kaempferol (M3), quercetin (M4), kaempferol 3-*O*-glucoside (M5), and acetylated isorhamnetin 3-*O*-glucoside (M6). The extracted ion chromatograms (XICs) from the total UPLC/MS chromatograms are shown in Figure 1. What is more, M2 and M3 were found in most of the samples of the isolated human intestinal bacteria, while M5 and M6 were obtained only in the sample of *Escherichia* sp. 12, and M4 existed only in the sample of *Escherichia* sp. 4.

Table 1. Isorhamnetin 3-*O*-Glucoside and Its Metabolites (M1−M6) Produced by Human Intestinal Bacteria Using UPLC/Q-TOF-MS

no.	t_R[a]/min	m/z, calcd	$[M - H]^-$, found	identification	formula
M1	4.75	478.1111	477.0960	isorhamnetin 3-*O*-glucoside	$C_{22}H_{22}O_{12}$
M2	8.58	316.0583	315.0415	isorhamnetin	$C_{16}H_{12}O_7$
M3	8.31	286.0477	285.0374	kaempferol	$C_{15}H_{10}O_6$
M4	6.75	302.0427	301.0359	quercetin	$C_{15}H_{10}O_7$
M5	4.56	448.1006	447.0885	kaempferol 3-*O*-glucoside	$C_{21}H_{20}O_{11}$
M6	6.03	520.1217	519.1136	acetylated isorhamnetin 3-*O*-glucoside	$C_{24}H_{24}O_{13}$

[a] t_R = retention time.

Identification of Metabolites. The characterization of metabolites in the fermentation supernatants was based on their ion fragmentation in ESI^- mode.

Parent. Isorhamnetin 3-*O*-glucoside (M1) was identified by comparing the UPLC retention time (4.75 min), accurate MS at m/z 477.0960 $[M - H]^-$, and MS/MS spectra with those of the authentic standard (Figure 2a).

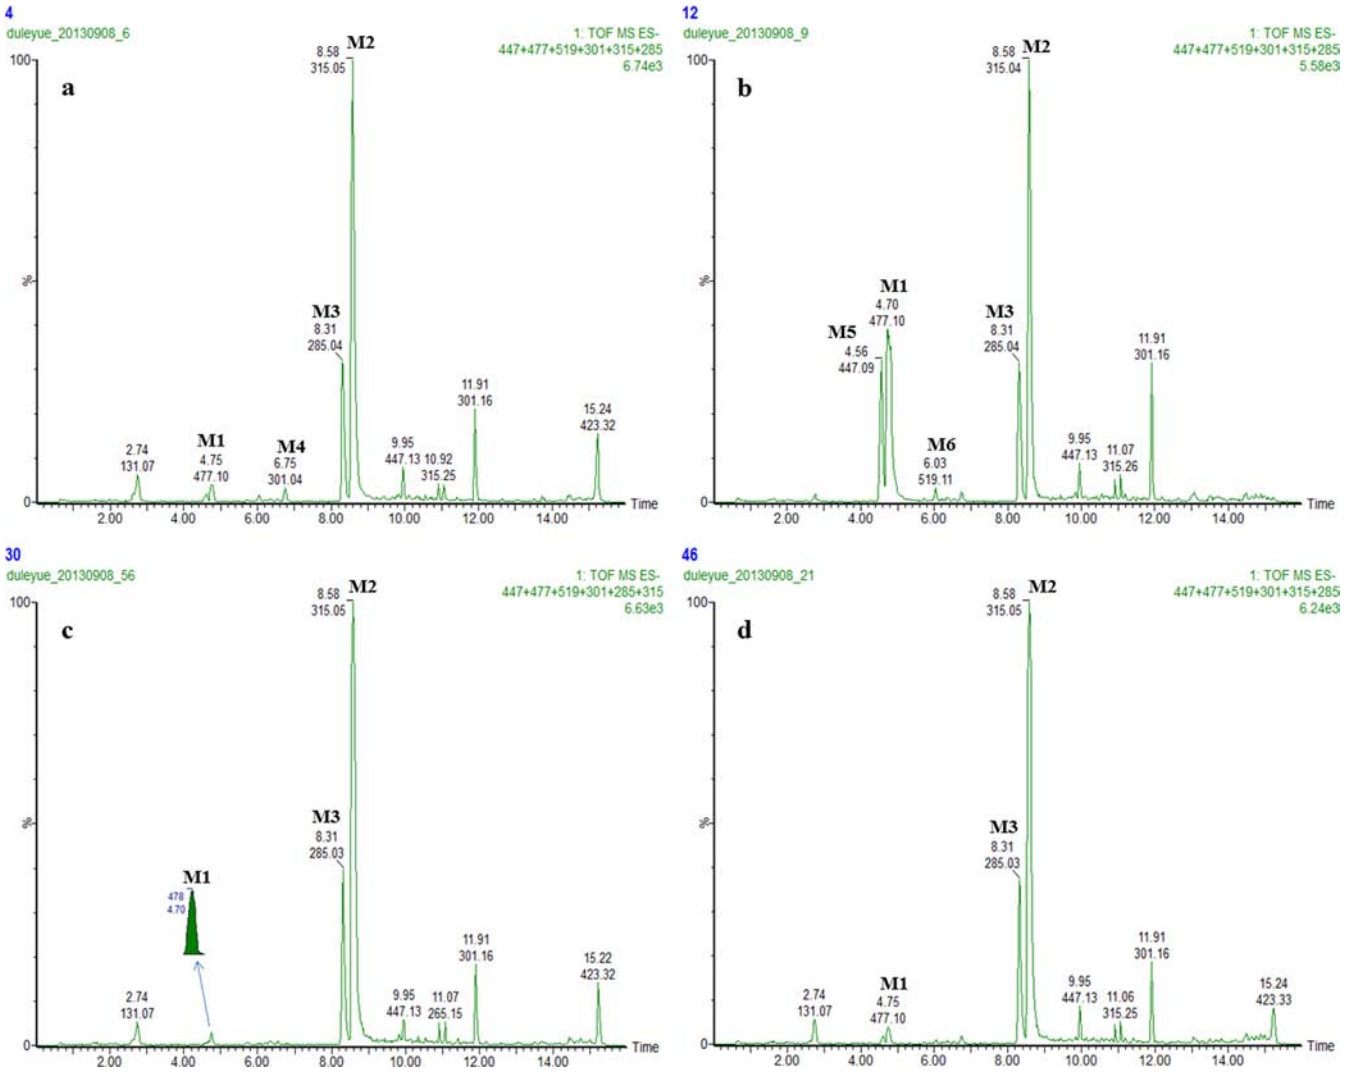

Figure 1. UPLC/MS chromatograms of isorhamnetin 3-*O*-glucoside and its metabolites: (a) strain 4 sample, (b) strain 12 sample, (c) strain 30 sample, (d) strain 46 sample.

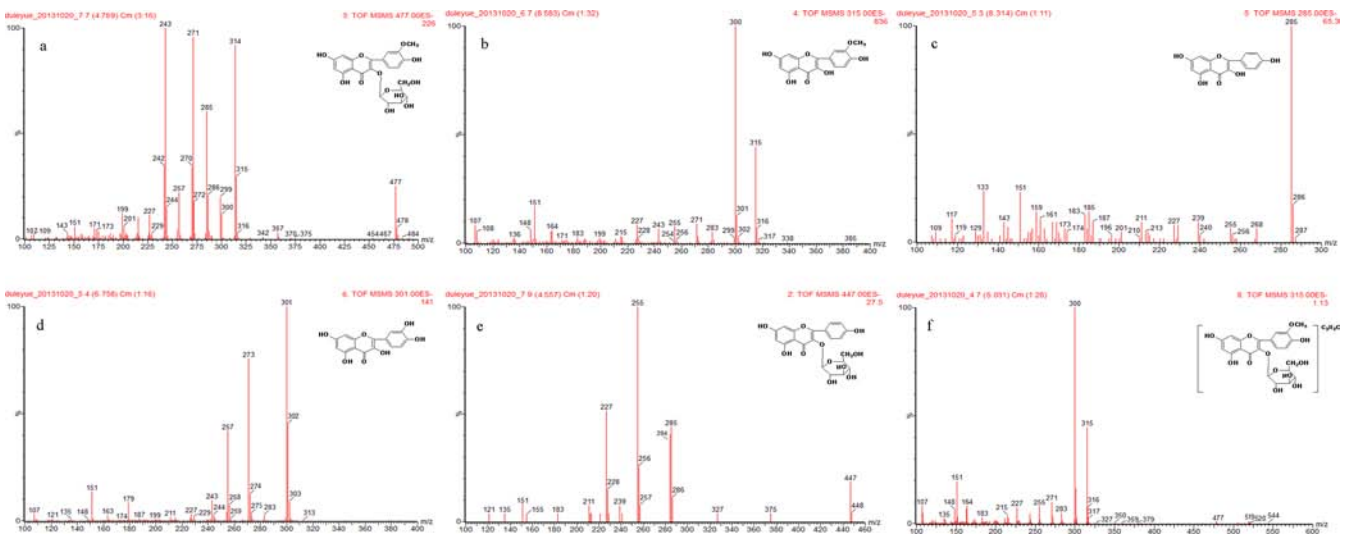

Figure 2. Representative MS/MS spectrum: (a) M1 (*m*/*z* 477), (b) M2 (*m*/*z* 315), (c) M3 (*m*/*z* 285), (d) M4 (*m*/*z* 301), (e) M5 (*m*/*z* 447), (f) M6 (*m*/*z* 519).

dx.doi.org/10.1021/jf405261a | *J. Agric. Food Chem.* 2014, 62, 2489−2495

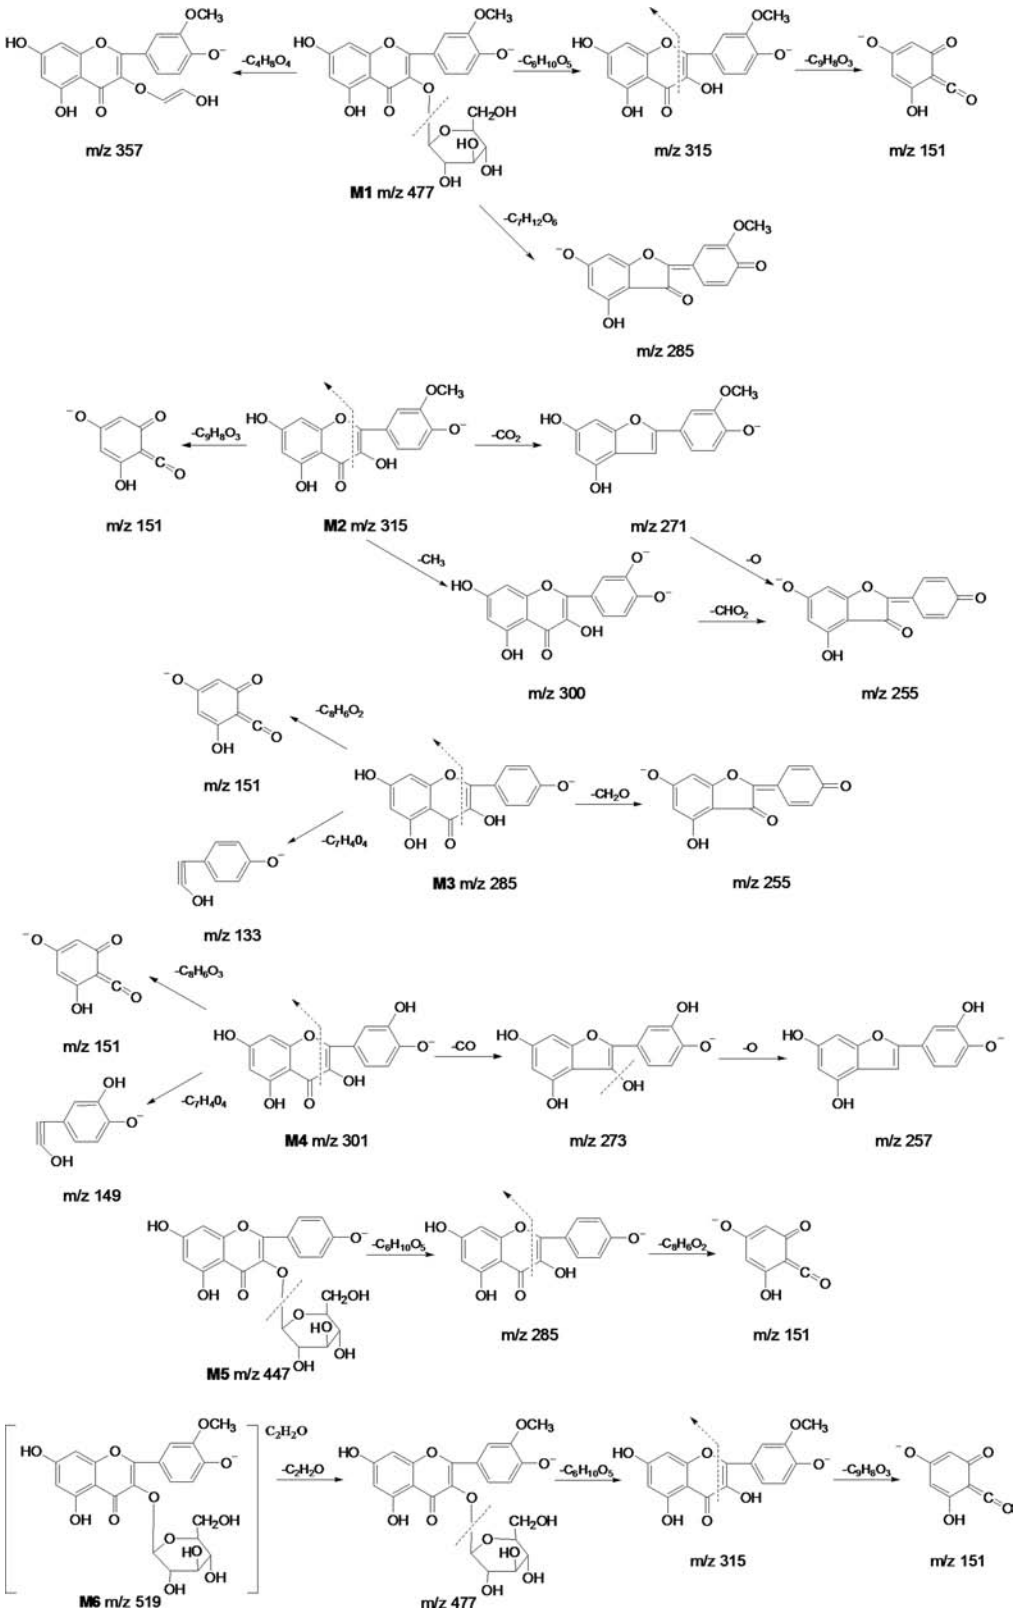

Figure 3. Proposed fragmentation pathways of isorhamnetin 3-*O*-glucoside and its metabolites.

Metabolite M2. According to Figure 2b, the $[M-H]^-$ ion of M2 was at m/z 315 with a retention time of 8.58 min, which was 162 Da lower than that of M1 isorhamnetin 3-*O*-glucoside. The MS/MS spectrum of M2 had product ions similar to those of M1. The high collision energy scan fragment ions were m/z 300, which was produced by the loss of CH_3 from m/z 315, and m/z 255, which was produced by the loss of O from m/z 271. The m/z 151 ion was produced after retro-Diels–Alder (RDA) cleavage. The product ion at m/z 271 was formed by the elimination of CO_2 from m/z 315, and then m/z 271 lost O to form m/z 255

dx.doi.org/10.1021/jf405261a | *J. Agric. Food Chem.* 2014, 62, 2489–2495

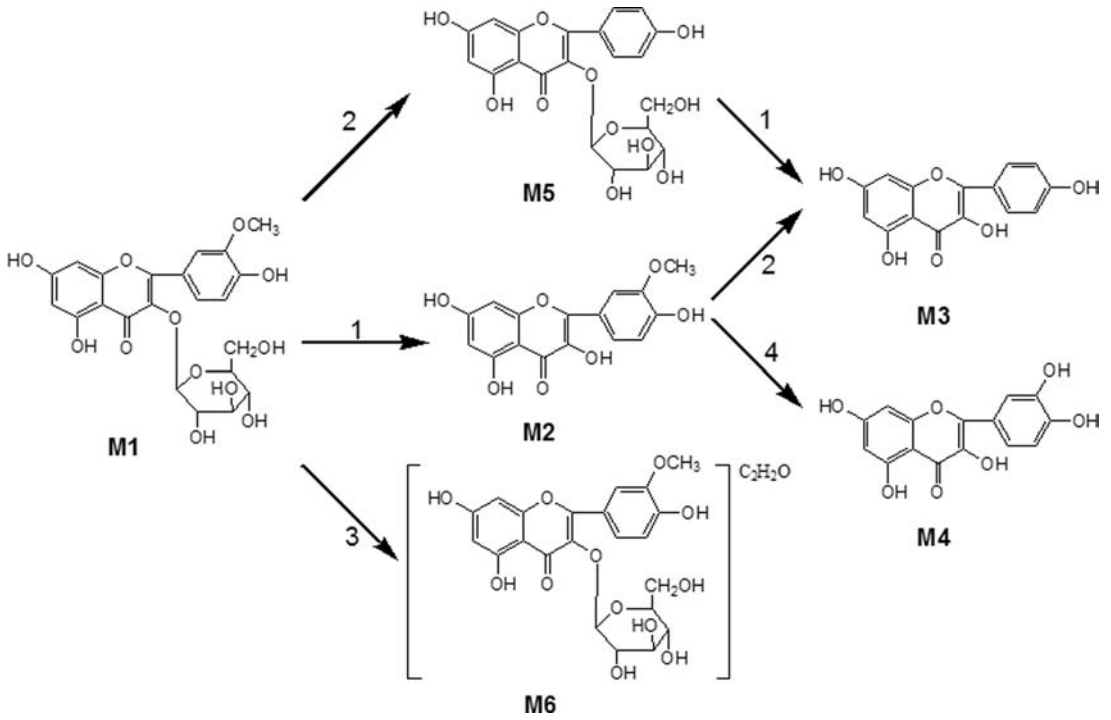

Figure 4. Possible metabolic pathways of isorhamnetin 3-*O*-glucoside by the human intestinal bacteria: 1, deglycosylation; 2, demethoxylation; 3, acetylation; 4, dehydroxylation.

(Figure 3). In view of these results, we identified M2 as isorhamnetin, the deglycosylated product of the parent by loss of a glucose.

Metabolite M3. Metabolite M3 was detected as deprotonated molecular ion $[M-H]^-$ at m/z 285 with a retention time of 8.31 min (Figure 2c). The product ion at m/z 255 was shaped by the elimination of CH_2O from m/z 285 (Figure 3). The characteristic fragment ions were m/z 133 and 151 according to RDA cleavage. On the basis of the MS/MS spectrum, we determined M3 as kaempferol.

Metabolite M4. Metabolite M4 showed a UPLC profile with a retention time of 6.75 min and an MS spectrum which gave an $[M-H]^-$ ion at m/z 301 (Figure 2d). The fragment ion m/z 151 corresponded to RDA cleavage from $[M-H]^-$ at m/z 301. The characteristic product ion at m/z 273 was formed by the elimination of CH_2O from m/z 301, and then m/z 273 lost O to form m/z 257 (Figure 3). These results indicated that M4 was quercetin, which is the demethylated product of M2 isorhamnetin.

Metabolite M5. Metabolite M5 with a retention time of 4.56 min produced a deprotonated molecular ion at m/z 447, a loss of CH_2O (30 Da) from isorhamnetin 3-*O*-glucoside (M1). On the basis of the MS/MS spectrum in Figure 2e, M5 had product ions at m/z 285, 255, and 151, which also emerged in the product ion mass spectrum of M3 kaempferol. The product ion at m/z 151 was formed from the aglycon at m/z 285 by RDA cleavage (Figure 3). Thus, metabolite M5 was tentatively identified as kaempferol 3-*O*-glucoside.

Metabolite M6. Metabolite M6 was found at 6.03 min in the UPLC system, and m/z 519 was its deprotonated molecular ion, which was 42 Da higher than that of isorhamnetin 3-*O*-glucoside. The MS/MS spectrum of M6 (Figure 2f) showed a product ion at m/z 477, which was generated from m/z 519 by loss of acetyl, and then m/z 477 lost a glucose to form the product ion at m/z 315. The other main product ions extracted from M6 were m/z 300 and m/z 151 (Figure 3). From this data analysis, M6 could be identified as acetylated isorhamnetin 3-*O*-glucoside.

Analysis of the Metabolic Pathway of Isorhamnetin 3-*O*-Glucoside by the Isolated Human Intestinal Microflora. According to our experimental results, the metabolic pathways of isorhamnetin 3-*O*-glucoside by the isolated human intestinal bacteria were proposed as displayed in Figure 4. Among all the isolated human intestinal bacteria, the majority of the strains, such as *Escherichia* sp. 12, *Enterococcus* sp. 30, and *Bacillus* sp. 46, could degrade isorhamnetin 3-*O*-glucoside (M1) to large amounts of isorhamnetin (M2) and kaempferol (M3), suggesting that this might be regarded as a common capability of intestinal bacteria. Additionally, *Escherichia* sp. 4 could also metabolize isorhamnetin 3-*O*-glucoside to isorhamnetin, which was further degraded to kaempferol and minor but detectable amounts of quercetin (M4). Isorhamnetin 3-*O*-glucoside was converted to kaempferol 3-*O*-glucoside (M5) and acetylated isorhamnetin 3-*O*-glucoside (M6) only by *Escherichia* sp. 12.

Percentage of the Isolated Human Intestinal Bacteria That Yielded Each of the Metabolites. In terms of proportion, the parent, isorhamnetin 3-*O*-glucoside (M1), was detected in 92% of the isolated human intestinal flora. All of the isolated bacteria could yield the aglycon isorhamnetin (M2), suggesting that deglycosylation was the main metabolic pathway of isorhamnetin 3-*O*-glucoside. A total of 94% of the strains metabolized isorhamnetin-3-*O*-glucoside to kaempferol (M3). The metabolite quercetin (M4) was identified in 7.4% of the strains. However, only one sample of the isolated bacteria could degrade the parent to kaempferol 3-*O*-glucoside (M5) and acetylated isorhamnetin 3-*O*-glucoside (M6). Meanwhile, on the basis of the differences in metabolic ability, 28 samples of the isolated bacteria were identified for their great vitality to metabolic isorhamnetin 3-*O*-glucoside.

DISCUSSION

The metabolites of isorhamnetin 3-*O*-glucoside yielded by human intestinal bacteria and its relevant metabolic process have not been reported in advance. In this study, we established a UPLC/Q-TOF-MS technique to detect and identify the metabolites of isorhamnetin 3-*O*-glucoside produced by the isolated human intestinal microflora. After incubation with different intestinal bacteria, parent isorhamnetin 3-*O*-glucoside and its five metabolites (M1−M6) were tentatively identified in the isolated bacterial samples according to their retention times, accurate molecular masses, and fragment ions. The metabolites were converted by four main metabolic pathways, including deglycosylation, demethoxylation, dehydroxylation, and acetylation. Though the intestinal microflora is composed of massive species, it is possible that a lot of flora conduct the same metabolic steps of isorhamnetin 3-*O*-glucoside.

So far, it has been demonstrated that isorhamnetin could be rapidly absorbed and eliminated in rat plasma after oral administration of mulberry leaf extract. Additionally, double peaks were observed in the curves of mean plasma concentration for isorhamnetin. The first peak appeared at 0.19 h and the second peak at 7.25 h, which might be explained by enterohepatic recirculation.[19] In addition, numerous preclinical studies have indicated that kaempferol possesses a wide range of pharmacological activities, including antioxidant, anti-inflammatory, antimicrobial, anticancer, cardioprotective, neuroprotective, antiosteoporotic, anxiolytic, analgesic, estrogenic/antiestrogenic, and antiallergic activities.[20] Moreover, the metabolism of quercetin was claimed to exert beneficial health effects, including protection against various diseases such as osteoporosis, certain forms of cancer, and pulmonary and cardiovascular diseases, and also protection against aging. Especially the ability of quercetin to scavenge highly reactive oxygen species such as peroxynitrite and the hydroxyl radical was suggested to be involved in these possible beneficial health effects.[21] Some studies also reported that quercetin exhibits antiproliferative, antiatherosclerotic, and neuroprotective activities.[22,23] More importantly, quercetin and isorhamnetin could enhance the oral absorption of each other in rats.[24] We could arrive at a conclusion that the metabolites of isorhamnetin 3-*O*-glucoside such as isorhamnetin, kaempferol, and quercetin might have an impact on its biological effect, which would influence the clinical effects of traditional herbal medicines and medicinal plants. Additionally, these metabolites could improve the bioavailability for absorption of isorhamnetin 3-*O*-glucoside by colonic mucosa due to their lower polarity than that of the parent. It has been reported that the biological activities and bioavailability of flavonoid aglycons are usually higher than those of flavonoid glycosides.[25] Daidzein exhibited more potent antioxidant, antitumor cytotoxic, and estrogenic effects than daidzin.[26] The aglycon quercetin also had stronger anti-inflammatory activity though inhibition of inducible nitric oxide synthase expression and nitrite production and antimicrobial and antioxidant activities than its glycosides.[27−29]

On the other hand, there are massive studies on the microbial metabolism of flavonoids. Moreover, the conversion profile obtained from in vitro incubation with fecal microbiota can elucidate the conversion route. Many flavonoids undergo a ring fission in which the C-ring is degraded; hydroxylated aromatic compounds are formed from the A-ring and phenolic acids from the B-ring. The phenolic acid metabolites of flavonols reflect the hydroxylation pattern of the B-ring structure.[30] The primary metabolite of quercetin is 2-(3,4-dihydroxyphenyl)acetic acid. Further dehydroxylation results in the formation of 2-(3-hydroxyphenyl)acetic acid from both the dihydroxylated derivatives.[31] Other metabolites derived from quercetin include phloroglucinol, 3,4-dihydroxybenzaldehyde, 3,4-dihydroxytoluene, butyrate, and acetate.[32−36] What is more, *Clostridium* and *Eubacterium* genera, which are phylogenetically associated, are other common elements involved in the metabolism of many phenolics. The health benefits from phenolic consumption should be attributed to their bioactive metabolites and also to the modulation of the intestinal bacterial population.[14]

The metabolic pathway and metabolites of isorhamnetin 3-*O*-glucoside produced by isolated human intestinal bacteria shown here are very important for the evaluation of the absorption and metabolism of isorhamnetin 3-*O*-glucoside in vivo. Further research will be performed on the enzyme system which contributes to the bacterial metabolism of isorhamnetin 3-*O*-glucoside.

food products in which sodium has been replaced by other cations.

The effect of salting can also be determined indirectly, for example, by using low-field (LF) ^{1}H NMR to monitor changes in proton relaxation behavior as a result of salt addition. In foods, the NMR proton signals basically originate from small molecules such as water and fat. Changes in tissue microstructure due to salting will affect proton exchange with the surrounding environment. For example, tissue swelling after the addition of salt leads to a more open microstructure, causing higher water mobility. Several studies have been carried out in which LF NMR has been used to monitor changes during fish salting processes.[20−26] However, because none of these studies have dealt with low-salt tissues, it would be of interest to explore the method further as a potential tool for low-salt applications.

The objectives of the present research are to (1) evaluate the application of impedance spectroscopy to monitor physicochemical parameters in salted fish products with and without sodium replacement, (2) establish a fast and consistent method to measure sodium and potassium contents in fish products, and (3) assess the feasibility of employing LF NMR in low-salt tissues.

MATERIALS AND METHODS

Chemicals. Ammonium chloride (NH_4Cl), ammonium hydroxide (NH_4OH), ammonium hydrogen fluoride (NH_4FHF <1%, LD_{50} mg/kg not found), chloroform ($CHCl_3$), ethanol (C_2H_5OH), sulfuric acid (H_2SO_4), potassium sulfate (K_2SO_4), copper sulfate ($CuSO_4$), hydrogen peroxide (H_2O_2), and sodium hydroxide (NaOH) (Scharlau, S.A., or Thermo Fisher Scientific, USA). All chemicals were of analytical-reagent grade.

Experimental Protocol. Experiments using the impedance system were carried out in two phases. In the first phase, the system's capability to distinguish between different types and quantities of salts was evaluated. The second phase evaluated the impedance system for discriminating between fish samples salted with different salt mixtures and quantities of salt.

Phase I: Salt Solutions. Different brines were prepared by using NaCl, KCl, and a mixture of NaCl/KCl (50:50, w/w, %) at different contents. The total salt contents assessed were 0.0, 0.1, 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0% (g salt/100 g distilled water). NaCl and KCl reagents (analytical-reagent grade) were obtained from Panreac Química S.A.U. (Barcelona, Spain). The brines were prepared the day before analysis to ensure that all of the salt was completely dissolved. The parameters measured in brines were a_w, pH, conductivity, and sodium and chloride contents. Sodium content in brines was determined by a Na-selective electrode. All measurements were done in triplicate. Impedance spectroscopy measurements were also carried out on the same brine solutions.

Phase II: Fish Minces. Fresh hake (*Merluccius paradoxus/capensis*) was used as raw material. The fish were caught June 13, 2012, by trawling off the coast of South Africa (FAO fishing area 47, Atlantic Southeast) and were obtained June 19, 2012, from a local supermarket in Valencia (Spain). The fish specimens were placed in styrofoam boxes with ice and transported immediately to the laboratory. Upon arrival at the laboratory, two fish were headed and gutted. Then, the fish were filleted and skinned, and the flesh was chopped with a standard food processor at low speed (Minirobot D81, Moulinex, Group SEB Iberica, Barcelona, Spain). Samples were prepared by mixing the fish mince (fish mince and salt, 200 g total) with an exact amount of salt before homogenization for 1 min in the food processor. The amount of salt added to the fish mince had been preweighed to achieve an exact salt content (NaCl or NaCl/KCl) in the final sample of 0.0, 0.5, 1.0, 2.0, or 3.0% salt (g NaCl or NaCl/KCl/100 g salted fish mince). The homogenized fish minces were divided into five plastic containers (40 g in each). Three of the plastic containers were used for the physicochemical analyses and impedance spectroscopy, whereas the remaining two containers were used for LF NMR measurements. According to the results obtained by Sánchez-Alonso,[27] the mince composition does not suffer significant alterations during the frozen storage period. The samples were stored at −18 °C and thawed to 4 °C during 18 h before analysis. Moisture, lipid, protein, ash, a_w, pH, chloride, sodium, and potassium contents were determined in the same subsamples as were subjected to impedance spectroscopy. The minces assigned for LF NMR analysis were kept frozen for 86 days before the measurements were carried out.

ANALYTICAL METHODS

Physicochemical Analyses. Moisture, lipid, protein, and ash contents were assayed according to AOAC Methods 950.46, 991.36, 928.08, and 920.153, respectively,[28] whereas pH and conductivity of brines were determined by using a multimeter MM 40 (Crison Instruments, S.A., Barcelona, Spain). The pH measurements of fish were carried out using a digital pH-meter micropH 2001 (Crison Instruments) with a puncture electrode (Crison 5231). Water activity was assessed in brines and fish minces with a fast water activity meter (GBX FAst/lab, Romans sur Isère Cedex, France).

The chloride and sodium contents in brines were measured directly in the solutions, using a chloride analyzer (Sherwood model 926, Cambridge, UK) and a Dual Star pH/ISE meter (Thermo Fisher Scientific, Waltham, MA, USA) with a Na-selective electrode (Ross Sodium Ion Selective Electrode, Thermo Fisher Scientific), respectively. Chloride, sodium (by two different analytical methods), and potassium contents of fish minces were measured in an extract of the sample. For preparing the extract, 1.5 g of the mince was homogenized in ultrapure water using an Ultraturrax T-25 (IKA, Labortechnik, Staufen, Germany) at 9000 rpm for 1 min. Then, samples were warmed to 90 °C for 30 min, cooled to room temperature, transferred to a volumetric flask, and diluted to 200 mL with ultrapure water. Finally, samples were filtered through a cellulose filter paper (Whatman no. 1, Whatman International Ltd., Maidstone, UK). For chloride and sodium determinations, an aliquot of the extract was measured at room temperature by using the chloride analyzer and the Na-selective electrode as described above. The Na-selective electrode method was a modification of the Kivikari method.[29] In this study the direct calibration method was used, contrary to the method of Kivikari, where the known addition method was used. A calibration curve was made by using three standards of analytical grade NaCl from Panreac Química S.A.U. Sodium ion strength adjustor (sodium ionic strength adjustor, Thermo Fisher Scientific) was added to all solutions to ensure that samples and standards had similar ionic strengths. Sodium and potassium contents of the samples were determined by ion chromatography (Compact IC 761, Metrohm Ltd., Herisau, Switzerland) by using an ion exchange column (Metrosep C2, 250/4.0, Metrohm Ltd.). The separation was monitored by using a regulated (20 °C) conductivity detector, and IC Net 2.3 (Methrom Ltd.) software was used for data collection and processing. Prior to analysis, samples were filtered through 0.45 μm nylon syringe filters. The isocratic elution was carried out using a solution of tartaric acid (4.0 mM)/dipicolinic acid (0.75 mM) at a flow rate of 1 mL/min. Samples were injected using a 20 μL loop injector. The content of each cation was determined by interpolation in the corresponding calibration curve. The calibration was established using a triplicate set of standard solutions of Na^+ (Fluka, Buchs, Switzerland) and K^+ (Sigma-Aldrich, St. Louis, MO, USA).

Impedance Spectroscopy. The impedance spectroscopy measurement system was developed by the Instituto de Reconocimiento Molecular y Desarrollo Tecnológico (IDM) at the Universidad Politécnica de València (UPV).[18] It consists of a software application that runs on a PC, electronic equipment, and an electrode (for more information see the Supporting Information).

Using the software application, the user chooses the frequencies and the amplitudes of the sinusoidal voltage signals. For each of the frequencies the electronic equipment generates the corresponding sinusoidal voltage waveform to the electrode. The current (I) and

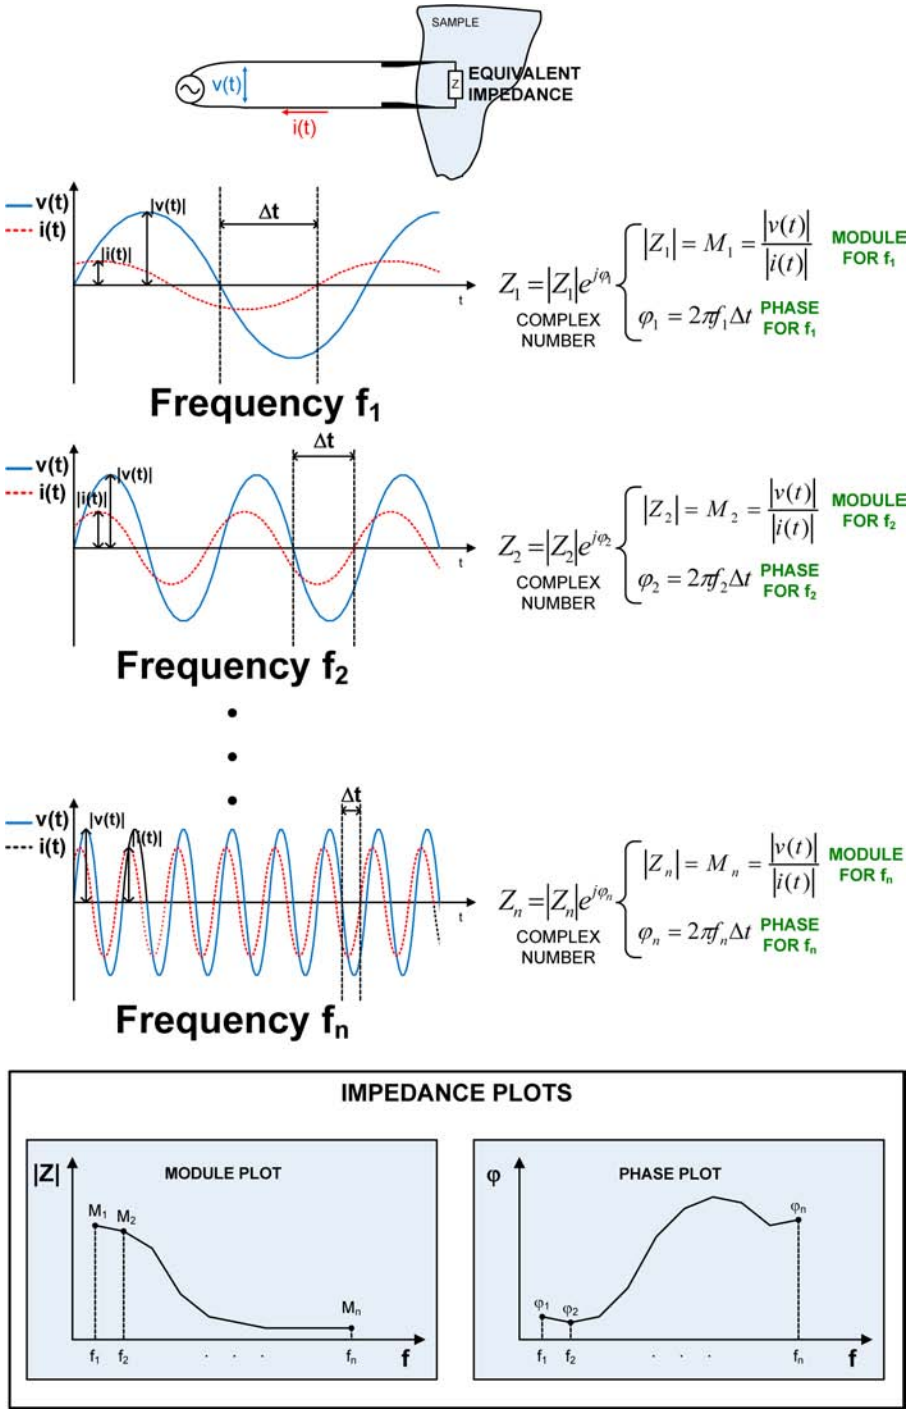

Figure 1. Scheme of impedance measurement and registered signals: module |Z|; phase (ϕ); $v(t)$, voltage signal; $i(t)$, current signal; f, frequency of the signals; Δt, time interval between the zero crossing of the voltage and current signals.

voltage (V) signals at the electrode are then sampled, and the collected data are sent to the PC, where a discrete Fourier transform analysis (DFT) is performed to determine their amplitude and phase. The module |Z| and the phase (ϕ) of the impedance are then calculated using eq 1, where $v(t)$ is the voltage signal, $i(t)$ the current signal, f the frequency of the signals, and Δt the time interval between the zero crossing of the voltage and current signals (Figure 1).

$$Z = |Z|e^{j\varphi}\begin{cases} |Z| = \dfrac{|v(t)|}{|i(t)|} & \text{module} \\ \varphi = 2\pi f \Delta t & \text{phase} \end{cases} \quad (1)$$

The electronic equipment includes a digital processing block based on two CPLDs and three random-access memories (RAM), one digital-to-analog converter, two analog-to-digital converters, and some analog signal adaption circuits.[18]

The sensor employed in this study is a double electrode designed at IDM-UPV. The sensor consists of two steel needles 1.5 cm long and 1 mm in diameter, separated by a distance of 1 cm in a nonconductive frame. This design keeps the separation between both needles constant during measurements.

The impedance measurements were taken by inserting the sensors into the middle of the plastic containers (n = 3) containing the solutions or the fish minces. Ten parallel measurements were

performed in each plastic container. The penetration depth of the electrodes was constant in all analyses (1.5 cm). All measurements were carried out at room temperature.

Preliminary impedance spectroscopy measurements showed that information given by low frequencies was not relevant for this study. Therefore, all of the measurements were carried out in the range of 10 kHz−1 MHz. Seventeen frequencies were chosen in this range; thus, a set of 34 values (17 module values and 17 phase values) was obtained for each sample.

Low-Field ^{1}H NMR. LF ^{1}H NMR measurements were made on all fish minces. After thawing, approximately 2 g samples were taken from each subsample of fish mince (n = 2) and placed in NMR tubes (diameter = 10 mm). There were analyzed in three parallels from each subsample with fish mince in the LF ^{1}H NMR measurements. The tubes were immediately placed in ice and kept there until the NMR measurements were carried out. The measurements were performed using a Bruker minispec mq 20 (Bruker Optik GmbH, Ettlingen, Germany) with a magnetic field strength of 0.47 T corresponding to a proton resonance frequency of 20 MHz. The instrument was equipped with a 10 mm temperature-variable probe. A built-in heating element was connected to the temperature control unit (BVT3000, Bruker Optik GmbH). The temperature in the probe was regulated to 4 °C by blowing compressed air through the sample holder. Transversal (T_2) relaxation was measured using the Carr−Purcell−Meiboom−Gill pulse sequence (CPMG).[30,31] The T_2 measurements were performed with a time delay between the 90° and 180° pulses (τ) of 150 μs. Data from 4000 echoes were acquired from 16 scan repetitions. The repetition time between two succeeding scans was set to 3 s. All even echoes were sampled. The NMR transverse relaxation data were analyzed using two different calculation methods: (1) Biexponential analysis of T_2 relaxation data was performed by fitting of the following equation to the experimental CPMG curves, similar to that reported by Erikson et al.[21] and Lambelet et al.:[32]

$$\text{signal} = A_{21}\, e^{-t/T_{21}} + A_{22}\, e^{-t/T_{22}} \quad (2)$$

T_{21} and T_{22} are the relaxation time components, and A_{21} and A_{22} are the corresponding amplitudes; 4000 data points were used, and the calculations were made using MatLab (The Mathworks Inc., Natic, MA, USA). Because the absolute relaxation amplitudes are proportional to the amount of water and fat in the sample, the relative amplitudes within samples were used. The T_{21} populations are calculated as $A_{21}/(A_{21} + A_{22})$.

For the biexponential fitting, the populations sum to 100%. Three parallel samples from each fish mince (n = 2) were averaged. (2) Multivariate data analysis was performed for all raw relaxation (CPMG) curves. These curves were normalized by setting the first sampled echo to a value of 100 and thereafter scaling the rest of the echo train. The first 600 data points were used for the principal component analysis (PCA).

Statistical Analyses. Statistical treatment of the data was performed using the Statgraphics Centurion (Statpoint Technologies, Inc., Warranton, VA, USA). A multifactor analysis of variance (ANOVA) was conducted for each evaluated parameter to test whether there were significant differences between the samples. These analyses were performed for the salt solutions and fish mince samples (phases I and II); in both cases, the physicochemical parameters were considered as dependent variables in these analyses. The type of cations and salt content, as well as its interaction, were the factors. The Tukey test (least significant difference) was used to test for differences between averages at the 5% significance level.

To evaluate the measurement techniques used in this paper, different multivariate analyses[33] were carried out using the software

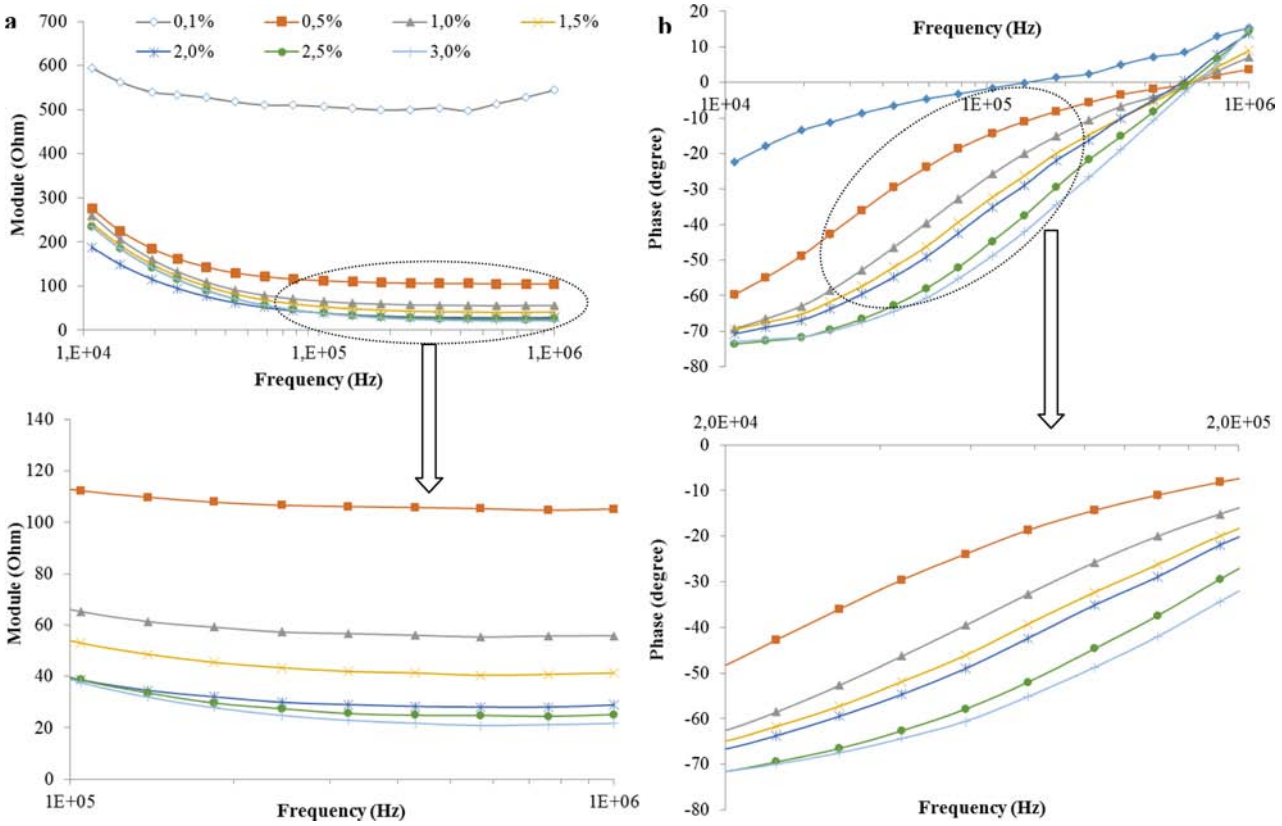

Figure 2. Mean values of modulus (a) and phase (b) of impedance spectra for the KCl solutions with different salt contents (0.1, 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 g salt/100 g distilled water, respectively).

SOLO PLS_Toolbox (eigenvector Research, Inc., Wenatchee, WA, USA).

PCA was used to discriminate the salt content level for NaCl, KCl, and mixtures. Typically, PCA projects a multidimensional data set onto a new coordinate base formed by the orthogonal directions with data maximum variance. The eigenvectors of the data matrix are called principal components (PCs), and they are uncorrelated between them. The PCs are ordered so that PC1 displays the greatest amount of variance, followed by the next greatest, PC2, and so forth. The main features of PCA are the coordinates of the data in the new base (scores plot) and the contribution to each component of the sensors (loads plot).

To create predictive models of physicochemical parameters, partial least square (PLS) regressions were applied to both impedance spectroscopy and NMR measurements. The main objective of PLS is to predict one or more parameters (dependent variables Y) from a set of measured data (independent variables X). First, the set of independent variables is projected onto a new coordinate space by maximizing the covariance between Y and X. The axes of this new space are called latent variables (LVs). The important information that correlates Y and X is contained in the first LVs. Then a prediction model is built by applying a multiple regression to a reduced number of the LVs. PLS prediction models for a_w and Na, K, NaCl, and solute contents (g/100 g) as well as solutes content in the water phase (g solutes/100 g liquid phase) were created using a set of experimental data (calibration set). First, cross-validation was used to select the number of LVs. The model was then validated with a new set of experimental data (validation set).

In the case of impedance measurements PCA and PLS regressions were performed using impedance module and phase values obtained for the 17 frequencies in the range from 10 kHz to 1 MHz. In the case of NMR measurements, the relaxation times for each defined frequency were used.

RESULTS AND DISCUSSION

Phase I: Salt Solutions. *Physicochemical Parameters.* The results of the physicochemical analyses carried out for the salt solutions are shown in Table 1. As expected, the a_w of brines decreased with increasing brine content regardless of type of salt, and the conductivity increased as salt content increased. Conductivity correlates with the total dissolved solids independent of the solute composition. In water, ions pass the electricity from one to another; therefore, the more Na^+, K^+, and Cl^- the solution contains, the more electricity is carried and the higher the conductivity. This explains the fact that the conductivity was affected by the amount of salt but not by the sodium replacement. The initial conductivity of distilled water employed for preparing the salt solutions was 0.025 ± 0.003 mS/cm. The value increased with increasing salt content, from to 2 to 60 mS/cm for the lowest and highest salt contents, respectively. Table 1 also shows the resulting contents of Na^+ and Cl^- after different salt additions to distilled water. In the solution prepared from KCl only, sodium was present in the range of 0.3−2.2 mg/L. The observed differences in chloride content depending on the type of salt are due to the different atomic masses of sodium and potassium (23 and 39 atomic mass units, respectively), owing to the fact that the salts were added equally by weight.

Impedance Spectroscopy. Module and phase impedance spectra of KCl solutions are shown in Figure 2, panels a and b, respectively. Differences in both module and phase of impedance were observed to depend on salt content.

The module of the impedance decreased as the salt content increased, and the values were much higher for the lowest content (0.1% KCl) than for the other contents. Similar

dx.doi.org/10.1021/jf405527t | J. Agric. Food Chem. 2014, 62, 2496−2505

differences between salt contents were observed for NaCl and the mixture of NaCl:KCl (data not shown). These results are in agreement with those observed for the conductivity parameters for the brine (Table 1). The results are in accordance with previous studies on impedance spectroscopy.[16−18] The correlation can be explained by the conductance of an aqueous solution as a function of the ion content of the samples, and in fact impedance measurements are related to the ions' capability of movement under the influence of an electrical field in this aqueous solution. In the present study, the behavior observed for NaCl solutions was similar to what was observed for KCl and NaCl:KCl solutions, which would indicate that impedance values were highly correlated with solute content. These results were confirmed by ANOVAs carried out for each impedance value (module and phase of impedance for each frequency), which established significant differences for solute content ($p < 0.001$) but not for the type of salt ($p > 0.05$) (ANOVA data not shown).

A PCA was performed with the data obtained in the impedance measurements (Figure 3). The statistical analysis

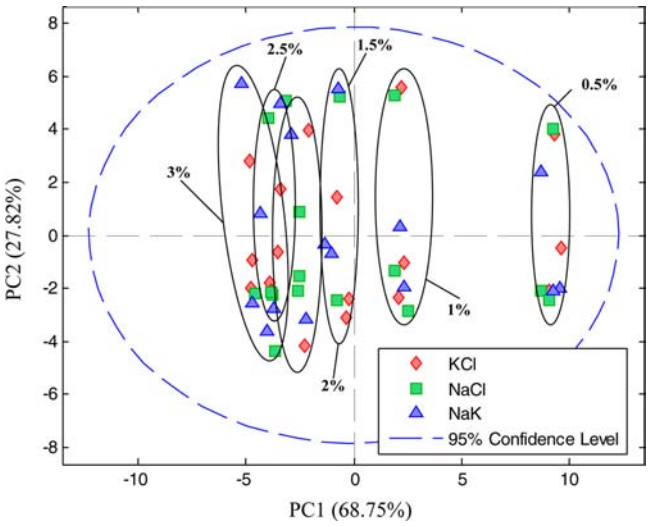

Figure 3. PCA score plot of data obtained from the impedance spectroscopy measurements in solutions with different types of salt (NaCl, KCl, and NaCl:KCl (NaK), 50:50 w/w %) and contents (0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 g salt/100 g distilled water, respectively).

was able to reduce the initial variables (34 variables, 17 values of module and 17 values of phase of impedance) into a set of values of linearly uncorrelated variables called PCs, the number of principal components being less than or equal to the number of original variables. Most of the variation in the sample was explained by PC1 (68.75%) and PC2 (27.82%). According to the results obtained, the impedance spectroscopy method could distinguish between salt contents; however, it was difficult to establish a correct classification of solutions according to the type of salt (Figure 3).

Phase II: Fish Mince. *Physicochemical Analyses.* The composition of the frozen/thawed raw material was determined. Moisture, protein, lipid, and ash contents for unsalted hake were 80.2 ± 0.1 (Table 2), 15.6 ± 1.3, 0.5 ± 0.2, and 1.20 ± 0.02 g/100 g, respectively. These results are similar to those reported in other studies carried out with the same fish species.[27,34]

The results of the physicochemical analyses for salted hake mince are summarized in Table 2. As expected, adding salt to

the mince led to a reduction in moisture, from about 80.2% (mince without additions) to 78.3 and 77.8%, for minces containing sodium and potassium chloride (Na:K) and minces containing sodium chloride (Na), respectively. Due to the increase in mineral contents (up to 3.0 g/100 g mince) the a_w decreased from 0.992 (mince without additions) to 0.974 (Na:K) and 0.969 (Na). The moisture and a_w were significantly lower in minces containing 3.0% salt compared to minces containing less. Both the type of salt and their contents had a significant effect on the a_w, compared to the brines, where the a_w correlates only with the contents of salt. As expected, slightly higher water activities were found in the NaCl:KCl minces than in minces containing NaCl. Water activity decreases with increasing number of colligative units dissolved per volume. As K^+ is a larger ion than Na^+, replacing NaCl with an equal amount by weight of KCl will lead to a lower number of dissolved ions (colligative units) per volume and thus an increase in a_W of the product.

The pH of the unsalted mince (pH 6.97) was reduced after preparation of the mince with different salts (Na) and (Na:K) and contents (Table 2). The pH values of the raw material employed in this study are in accordance with the results obtained in other studies[34,35] for fresh hake. A decrease in pH was observed when salt was added to our minces, a little more pronounced in the case of Na than with most Na:K mixtures. Similar results have been observed in a study by Leroi and Joffraud,[36] indicating that the pH decreases in fish flesh by the addition of salt due to the increase of the ionic strength of the solution inside the cells. Another explanation might be that an increased amount of chloride ions would open the myosin filament and the more dissociable acidic groups would be water-accessible.[37] Samples containing Na exhibited lower pH than the corresponding Na:K samples: pH 6.76 vs 6.81, respectively. Similar results with fish products subjected to partial sodium replacement have also been observed.[38]

The measured contents of sodium, potassium, and chloride are shown in Table 2. The sodium (0.05−0.06 g/100 g) and potassium contents (0.35 g/100 g) of fresh fish mince (Table 2) agree with those reported in another study[39] for deboned hake. The chloride content in mince without additions was 0.21 g/100 g. When only NaCl was added to the minces, the potassium levels remained almost constant at 0.30−0.40 g/100 g, resembling the level in mince without additions.

Table 2 shows a comparison between sodium contents in the different minces as determined by the ion selective electrode and by ion chromatography. Good correlation was observed between the sodium content determined by the ion selective electrode method and ion chromatography, which was confirmed by a simple regression carried out on the data obtained by both methodologies ($y = 1.066x + 7.961$, $R^2 = 0.967$).

Impedance Spectroscopy Measurements. Impedance spectroscopy was used to detect changes in the fish mince by adding different salt contents and types of salt. A PCA was performed on the impedance spectroscopy measurements in fish mince samples with different type of salts.

The discrimination between the different salt contents observed in the PCA plot for fish minces was better than the one obtained for salt solutions (Figure 4). The percentage of variance explained by the first principal component in Figure 4 is 90.17%, whereas in Figure 3 PC1 explains only 68.75% of the total variance. This means that the correlation between impedance spectroscopy data and salt content is stronger in

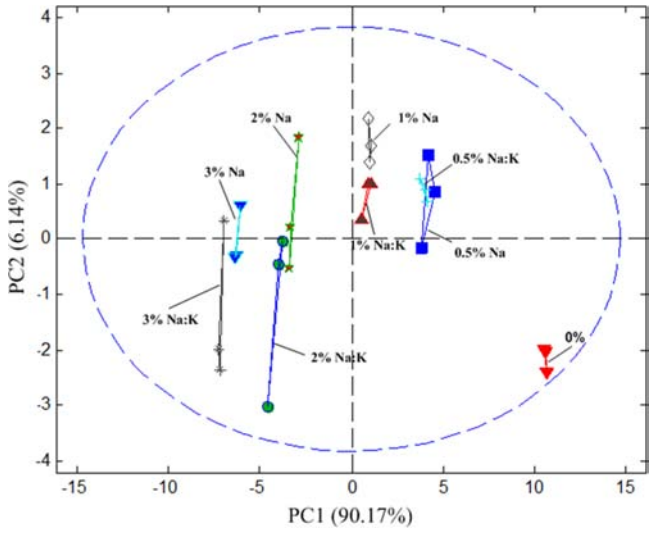

Figure 4. PCA score plot of data obtained from the impedance spectroscopy measurements in hake minces with different salt contents (NaCl (Na) or NaCl/KCl (Na:K) 0.0, 0.5, 1.0, 1.5, 2.0, and 3.0 g/100 g salted mince, respectively).

fish samples than in solutions. A possible explanation for this behavior is the salting-in effects on muscle proteins.[37] At salt contents lower than 0.5 M, the swelling of myofibrils starts and reaches a maximum at 0.8−1 M.[37] This usually causes a decrease in myofibril volume, because the myofibril tends to dissolve. However, in our study, the highest contents in the minces corresponded to 0.65 and 0.55 M for the minces with 3.0% NaCl and NaCl:KCl, respectively. The conformational changes, together with the increase in the conductivity, could be responsible for the different behavior in the IS observed among our hake minces and in the solutions. At some contents, the method also distinguished between types of cations (Na^+ or Na^+/K^+) in the fish mince, a behavior that can be explained by the different effects of sodium (kosmotrope, water-structure maker) and potassium (chaotrope, water-structure breaker) in actin and myosin.[40] Further work is needed to reveal significant differences between cations in the minces.

LF NMR. A LF NMR T_2 relaxation method was used to study the relaxation behaviors in the mince when different types of salt were added to the mince in different amounts. The two transversal relaxation times with corresponding populations obtained from fitting of NMR data are shown in Table 3. In fish muscle, typically two or three relaxation components are reported (ref 41 and references cited therein). The two major ones have relaxation times in the range of 40−60 ms (T_{21}) and 150−400 ms (T_{22}), similar to those of the present research. The mean T_{21} and T_{22} relaxation times for the unsalted hake mince were 54 and 219 ms, respectively. The interpretation of such data has been controversial, but it is now becoming more accepted that the observed changes in relaxation behavior are due primarily to chemical and diffusive proton exchange between water molecules and biopolymers (e.g., proteins).[42,43] A number of studies have nevertheless shown that these processes are linked to the morphology of the sample that in turn can be affected by, for example, processing, such as salting and mincing.[23,25,41]

After addition of 0.5% NaCl or NaCl/KCl to the mince, the proton relaxation times, found by bioexponential fitting, increased to 59−61 ms in the case of T_{21}, whereas the T_{22}

value remained largely unchanged. Addition of more salt led to increases in both T_{21} and T_{22} relaxation times, with mean values of 67−71 and 286−496 ms, respectively.

By comparison, when frozen/thawed Atlantic salmon fillets were salted to 2.7% NaCl in the head part of the fillet, T_{21} increased from 47 ms (unsaltet) to 48 ms (salted), whereas the tail part of the fillet had 2.9% NaCl and T_{21} increased from 47 ms (unsalted) to 50 ms (salted), respectively. No significant changes were observed in T_{22} (140−150 ms (head part) and 140−169 ms (tail part)).[21] Similar values were obtained when fillets of the same species were salted in a 15% NaCl brine.[20] Thus, it seems that the magnitude of change in T_{21} can be similar in highly concentrated brines (whole, lean fillets) as in our lean hake mince. Notably, the mincing of cod fillets does not alter the magnitude of the T_{21} values.[44] A stronger effect of salting of cod was, however, reported,[24] where T_{21} values increased from 51 ms (raw material) to 86−94 ms after presalting by different methods (12% salt).

A PCA score plot of the relaxation time curves is presented in Figure 5. Most of the variation in the sample was explained by PC1 (76.60%) and PC2 (20.54%), and it separates minces with 0, 0.5, and 1.0−3.0% salt. Otherwise, the relaxation data did not reveal any clear trends between the magnitudes of the relaxation times at increasing salt contents above 0.5%. The increase in relaxation times when 0.5% salt was added, reflecting higher water proton mobility, suggests that a more open mince microstructure was formed. This was possibly caused by the binding of chloride ions to myosin filaments, which would induce electrostatic repulsive forces, causing an increase of filament spacing. [37]

In contrast to the increase in T_{21} as a result of the addition of 0.5% salt, the corresponding population (T_{21} pop) did not change accordingly. The T_{21} pop values remained similar to those in the mince without additions (85−87%). With further addition of salt, the values increased to 96−99%, regardless of type and amount of salt (1.0, 2.0, or 3.0% salt) with a corresponding decrease in T_{22} pop. The latter population with high mobility decreased to 1−4%. The changes in T_2 populations reflect a shift of the proton populations, increasing the amount of protons with higher mobility and decreasing the amount of protons with lower mobility. This may be explained by the changes in muscle structure due to the salting-in effect previously discussed.

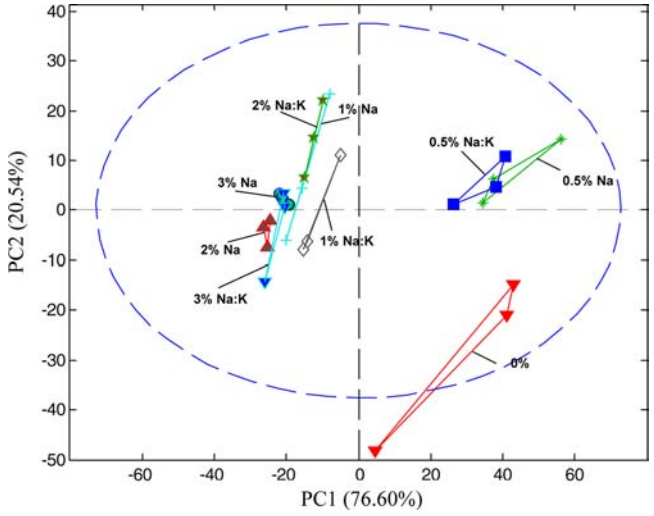

Figure 5. PCA score plot of LF ^{1}H NMR T_2 relaxation data obtained from fish mince with salt content (NaCl (Na) or NaCl/KCl (Na:K) 0.0, 0.5, 1.0, 1.5, 2.0, and 3.0 g/100 g salted mince, respectively).

On the basis of principal component analyses of the NMR T_2 relaxation data, a clear separation between samples with 0, 0.5, and 1.0−3.0% of salt was obtained. However, the LF NMR method was unable to distinguish between minces with different types of cations. In summary, the fact that the most pronounced changes in relaxation behavior occurred at low contents of salt (0−0.5%) indicates that LF ^{1}H NMR can be a suitable tool for indirect studies of structural changes in low-salt systems.[41]

PLS Results. To create predictive models of physicochemical parameters, PLS regression was applied to both impedance spectroscopy and LF NMR measurements. Table 4 shows the values of the determination coefficient (R^2), the root-mean-square error of prediction (RMSEP), and the number of LVs corresponding to the prediction models built for a_w, Na^+ (mg/

dx.doi.org/10.1021/jf405527t | J. Agric. Food Chem. 2014, 62, 2496−2505

Table 4. Parameters of the PLS Models of Physicochemical Parameters from the Impedance Measurements[a]

	LV	R^2	RMSEP
a_w	5	0.886	0.003
	1	0.812	0.003
Na (mg/100 g)	4	0.480	276.154
K (mg/100 g)	4	0.094	269.090
NaCl (g/100 g)	4	0.425	0.730
KCl (g/100 g)	3	0.393	0.628
solute content (g/100 g)	5	0.950	0.210
	1	0.953	0.203
solute content in liquid phase (g/100 g)	4	0.946	0.286

[a]LV, number of latent variables; R^2, coefficient of determination; RMSEP, root mean square error of prediction.

100 g), K^+ (mg/100 g), NaCl (g/100 g), gram salts (g/100 g), and gram solutes/100 g liquid phase using impedance spectroscopy data. Models for a_w, gram salts (g/100 g), and gram solutes/100 g liquid phase show very good behavior with R^2 values close to or higher than 0.9. However, the results obtained for Na^+ (mg/100 g), K^+ (mg/100 g), and NaCl (g/100 g) demonstrate that the proposed technique is not able to discriminate between the different types of salt. As shown in Figure 3, in the PCA plots most of the total variance corresponds to PC1. In the module and phase plots a similar discrimination between the different salt content levels could be obtained considering the module and phase values for all of the frequencies or considering just the module value for one frequency (for example, 1 MHz). On this basis, new PLS models were built for a_w and gram salts (g/100 g) using only one LV. The R^2 values for these new models are similar to those obtained using the number of LVs established by cross-validation. This opens the possibility to limit impedance measurements to the module at a single frequency so that the measurement process would be greatly shortened and the prediction could be made using a simple regression. There were no significant correlations between the LF NMR measurements and the physicochemical results. In conclusion, the PLS models of impedance spectroscopy measurements showed good correlations with R^2 values close to or higher than 0.9 for a_w, solute content, and solute content in the liquid phase. However, the results obtained for Na^+ (mg/100 g), K^+ (mg/100 g), and NaCl (g/100 g) demonstrate that the proposed technique is not able to discriminate between the different types of salt.

In conclusion, good correlations were observed between the sodium content determined by using the ion selective electrode method and ionic chromatography, which was confirmed by a simple regression, carried out using the data obtained with both methodologies. In both salt solutions and fish minces, the impedance spectroscopy measurements could separate between different salt contents down to 0.5%. However, the results obtained for cation determinations demonstrate that the proposed technique is not able to discriminate between the different types of salt. Furthermore, impedance spectroscopy measurements showed good correlations for a_w, solute content, and solute content in the liquid phase. The NMR transversal relaxation time T_2 clearly distinguishes samples with 0, 0.5, and 1.0−3.0% salt, based on PCA. We conclude that LF ^{1}H NMR can be a suitable technique for studies of low-salt products. However, the LF NMR method was unable to distinguish between minces with different types of cations.

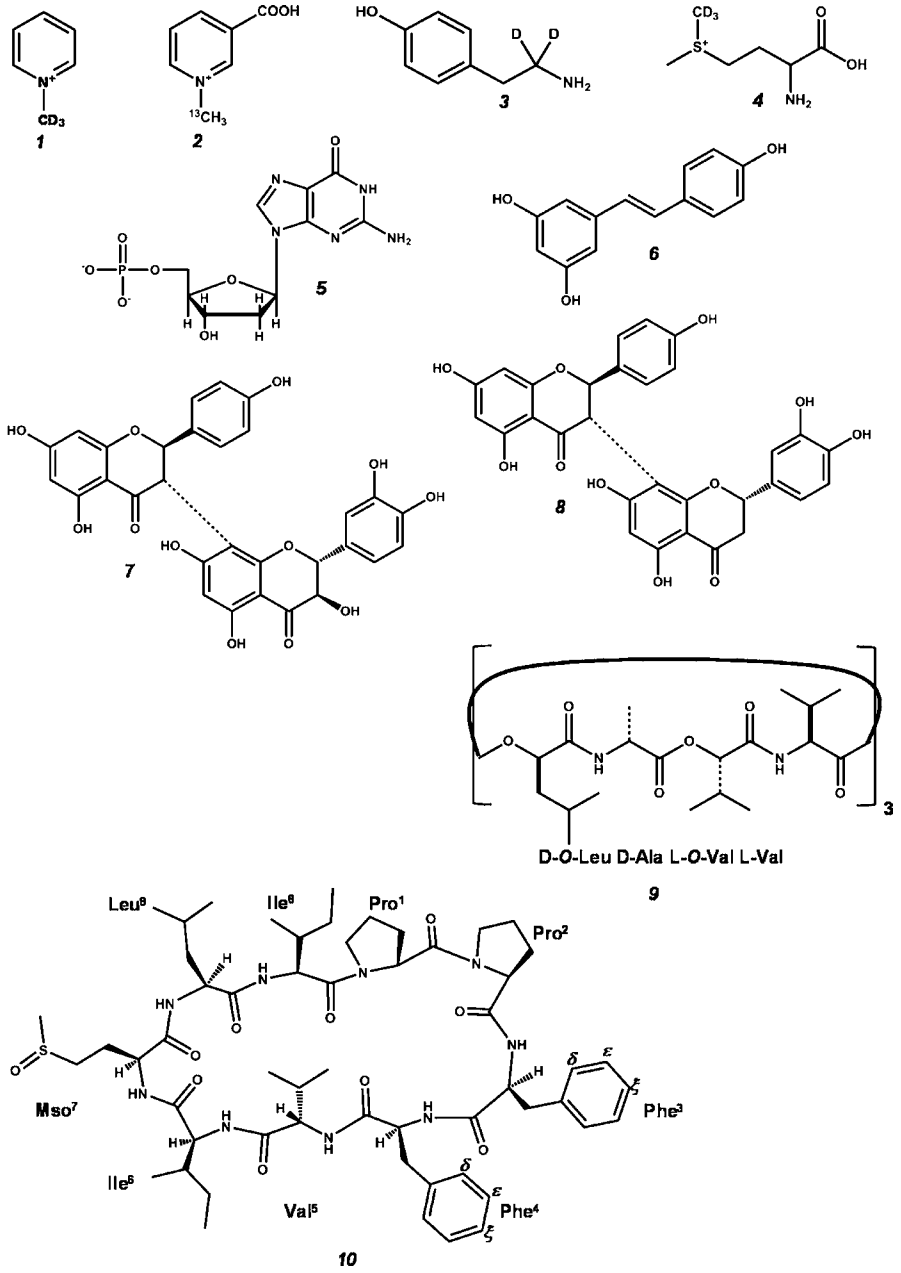

Figure 1. Synthesized and isolated compounds quantitated by qHNMR (NMP-d_3, **1**), trigonelline-$^{13}C_1$ (**2**), tyramine-d_2 (**3**), *S*-methylmethionine-d_3 (**4**), 5′-GMP (**5**), (*E*)-resveratrol (**6**), buchananiflavanone (**7**), GB-2 (**8**), cereulide (**9**), and cyclolinopeptide C (**10**).

basis of the principle of reciprocity, the NMR signal strength for a sample compound in a given coil is inversely proportional to the 90° or 360° pulse length.[19,21]

Compared to applications using internal standards for quantitative determinations, the literature on using external standards for sequential qHNMR analysis of standard and sample is rather poor. The objective of the present investigation was to develop and validate a qHNMR method using small molecules as external standards for a precise quantitation of target compounds in single-compound solutions, compound mixtures, or compounds in fractions without knowledge of their molecular weight.

■ MATERIALS AND METHODS

Chemicals. All chemicals were purchased from Sigma-Aldrich (Steinheim, Germany), solvents were obtained in HPLC grade from Merck (Darmstadt, Germany), and deuterated solvents and deuterium chloride (DCl, 7.6 mol/L in D_2O) were supplied by Euriso-top (Saarbrücken, Germany). d_3-*N*-Methylpyridinium (**1**), ^{13}C-trigonelline (**2**), d_2-tyramine (**3**), and d_3-*S*-methylmethionine (**4**) were synthesized and purified as reported in the literature (Figure 1).[23−26] The following compounds were isolated from natural sources and purified as reported in the literature: guanosine 5′-monophosphate (5′-GMP; **5**) from yeast extract, (*E*)-resveratrol (**6**) from grape berries, buchananiflavanone (**7**) and GB-2 (**8**) from *Garcinia* bark, and cereulide (**9**) from *Bacillus cereus* incubations (Figure 1).[27−30]

Fresh linseed oil was purchased from Ölmühle Solling GmbH (Boffzen, Germany).

Isolation and Structural Characterization of Cyclolinopeptide C (10), Cyclo(Pro-Pro-Phe-Phe-Val-Ile-Mso-Leu-Ile). Linseed oil (50 mL) was dissolved in *n*-hexane (50 mL) and extracted three times with methanol/water (60:40, v/v; 100 mL). The aqueous phases were combined and filtered through a wet filter paper; after removal of the solvent in a vacuum, the residue was dissolved in acetonitrile/water

cyclolinopeptide C	CD_3OD	2.50	1.75	70.0

[a]Recovery based on the external standard caffeine (3.12 mmol/L).

(70:30, v/v; 3 mL) and separated by RP-HPLC. Monitoring the effluent (5.0 mL/min) at 210/280 nm, chromatography was performed using a 250 × 10 mm, 5 μm, phenyl-hexyl column (Luna, Phenomenex, Aschaffenburg, Germany) as the stationary phase and starting with a mixture of formic acid (0.1% in water, pH 2.5) and acetonitrile (40:60, v/v). After isocratic elution for 3 min, the acetonitrile content was increased to 75% within 3 min, kept for 1 min, then raised to 100% within 3.5 min and, finally, maintained for an additional 4 min. The peak eluting at 5.30 min was collected in several runs, concentrated under reduced pressure, and freeze-dried twice to afford cyclolinopeptide C as a white amorphous powder.

Mass Spectrometry. MS analysis was performed using an API 4000 QTrap LC-MS/MS (Applied Biosystems, Darmstadt, Germany) running in the positive electrospray ionization (ESI$^+$) mode. Zero grade air served as the nebulizer gas (45 psi) and turbo gas (425 °C) for solvent drying (55 psi); nitrogen was used as the curtain (20 psi) and collision gas (8.7×10^{-7} psi). For ESI$^+$, the ion spray voltage was set at +5500 V in the positive mode. Solutions of natural product

isolates and synthesized compounds prepared in methanol/water (1:1, v/v) were infused using a syringe pump at a flow rate of 10 μL/min. Data processing was performed by using Analyst 1.4.1 software (AB SCIEX, Darmstadt, Germany). Mass spectra of cyclolinopetide C were measured on a Waters Synapt G2 S HDMS mass spectrometer (Waters, Manchester, UK) coupled to an Acquity UPLC core system (Waters, Milford, MA, USA). HPLC separations were performed using a semipreparative HPLC system (LC-2000 Plus Series, Jasco, Groß-Umstadt, Germany).

Preparation of Sample Solutions for qHNMR. Reference compounds and samples were prepared by weighing all compounds or fractions using three analytical balances (Shimadzu AUW120D, Ohaus DV215CD, Sartorius ED224s) randomly to minimize any potential weighing error. Solutions were prepared in volumetric flasks, providing complete dissolution in the respective solvent (Tables 1 and 2). The stock solutions for the calibration curves benzoic acid (16.30 mmol/L), caffeine (15.90 mmol/L), and L-tyrosine (16.50 mmol/L) were prepared in D_2O, CD_3OD, and D_2O/DCl (90:10, v/v), respectively, and diluted with the corresponding solvent to obtain six different concentrations for benzoic acid (16.30, 8.15, 3.26, 1.63, 0.82, 0.33 mmol/L), caffeine (15.90, 5.30, 2.65, 1.33, 0.66, 0.33 mmol/L), and L-tyrosine (16.50, 8.25, 4.13, 2.06, 0.69, 0.34 mmol/L).

Nuclear Magnetic Resonance Spectroscopy. For structure determination of the isolated materials of 5′-GMP, resveratrol, buchananiflavanone, cereulid, GB-2, and cyclolinopeptide C, H,H correlation spectroscopy (COSY) and ^{1}H, ^{13}C correlated experiments, such as heteronuclear single-quantum coherence (HSQC) as well as the heteronuclear multiple-bond correlation (HMBC), were acquired on a Bruker Avance III 500 MHz system equipped with a cryo-TCI probe (solvent cf. Table 2, 300 K). The spectra were recorded for structure assignment and to check that all chosen integral regions were free of impurities.

^{1}H qHNMR was performed at 298 K using a Bruker AV III system (Bruker, Rheinstetten, Germany) operating at a frequency of 400.13 MHz, equipped with a Z-gradient 5 mm multinuclear observe probe ($BBFO_{plus}$). The samples were dissolved in deuterated solvents (Tables 2 and 3) (Euriso-top, Gif sur Yvette Cedex, France), and aliquots (600 μL) of each sample were analyzed in 5 × 178 mm NMR tubes (USC tubes, Bruker, Faellanden, Switzerland).

To ensure high-quality spectra, the NMR probe was manually tuned and matched to 50 Ω resistive impedance to minimize radio frequency (RF) reflection, with the sample in place. After automatic optimization of the lock phase, each sample was shimmed ($z^1 - z^5$, xyz, $z^1 - z^5$), the receiver gain was set automatically with the *rga* command, and the 90° pulse width was determined individually for each sample using the AU program *pulsecal sn* (Bruker TopSpin 3.0). All spectra were acquired without spinning the sample and referenced to TMS or TMSP. The spectrum quality was verified by analyzing TMS or TMSP signal in terms of peak symmetry, peak width at half-peak height (≤0.8 Hz), and separation of the silicon satellites. All spectra were recorded in the *baseopt* mode (generates a smooth baseline at zero without offset) acquired with a maximum of 16 scans of 64 K complex data points, corresponding to an acquisition time of 3.98 s at a sweep width of 8223 Hz, and a relaxation delay of 40 s. The free induction decay (FID) was multiplied with a 0.3 Hz exponential line-broadening factor and zero-filled prior to Fourier transformation. If the automatic phase correction was not proper enough, a careful manual zero- and first-order phase correction was performed. Baseline correction was performed automatically using the command *absn*. Integration was done manually and whenever required; adjustment of the integrals was performed by the software functions SLOPE and BIAS.

For compound quantitation, defined samples of caffeine (3.55 ppm, s, 3H), benzoic acid (7.90 ppm, m, 2H), and L-tyrosine (7.10 ppm, m, 2H), respectively, were used as external standard, and the specific resonance signals (given in parentheses) were used for analysis. The concentration of each sample solution was calculated by using the ERETIC 2 function of TopSpin 3.0 (Bruker).[31] Initial calibration of the instrument for qHNMR was based on the NIST reference sample benzoic acid (2.98 mmol/L, NIST 350b, purity = 99.9978% ± 0.0044%) for verification of the direct calibrant caffeine (3.12 mmol/L). The qHNMR of the latter was calibrated by a linear response function from six calibration points. Each measurement was preceded by removing the sample from the probe and replacing it again in the spectrometer. After temperature equilibration, the probe was tuned, matched, and shimmed, and the 90° pulse was determined. Intensity of the signal was integrated manually. The T_1 relaxation times of all resonances of interest were determined by using the inversion–recovery pulse sequence, acquiring 10 recovery delays between 0.01 and 15 s, and accumulating 8 scans with an additional relaxation delay of 15 s between the scans. The T_1 time for the individual signals was determined by using TopSpin 3.0 (Bruker). The relaxation delay was set to 5 times the longest T_1 relaxation time in the molecule to ensure complete relaxation.

RESULTS AND DISCUSSION

For a robust and accurate quantitation of target compounds in natural isolates of unknown purity and/or in amounts of <1 mg, a qHNMR method was developed and validated on a 400 MHz system with external standard calibration using ERETIC 2 based on the PULCON (PULse length based CONcentration determination) methodology. The ERETIC 2 tool allows a precise concentration determination by the fact that the 90° pulse is inversely proportional to the NMR signal intensity.[21] If the concentration of a reference sample (C_{ref}) is known and the 90° pulse of all samples has been precisely calibrated, the concentration of the unknown analyte sample (C_U) can be determined using the following equation:

dx.doi.org/10.1021/jf405529b | J. Agric. Food Chem. 2014, 62, 2506−2515

$$C_U = kC_{ref}\frac{A_U T_U \theta_{90}^U n_{ref}}{A_{ref} T_{ref} \theta_{90}^{ref} n_U}$$

A indicates the integral over the resonance line(s), T the sample temperature in Kelvin, θ_{90} the 90° pulse length, and n the number of transients used for the measurement of the reference and the unknown sample. The correction factor k accounts for any experimental variations such as different receiver gains or incomplete relaxation, applied for the measurement of the reference or the unknown analyte sample. The equation is valid when the experiments are performed with the same NMR probe, which is properly tuned and matched.[21] The general working flow is given in Figure 2, and the most critical parameters and practical aspects of this qHNMR method are as follows.

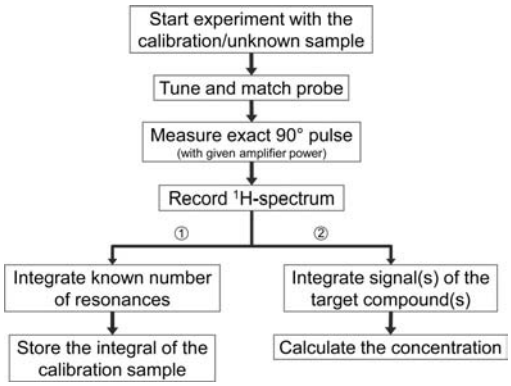

Figure 2. Working procedure for quantitation of target molecules by means of qHNMR using ERETIC 2: ①, calibration of the instrument; ②, concentration measurement according to the literature.[21,31]

Quality of the NMR Tubes. For the most reliable quantitative high-throughput analysis, the NMR tubes need to be as precise as possible to ensure a minimum difference in the active volume of the reference and the target sample. To investigate the error induced by technologically unavoidable differences between NMR tubes, five individual tubes, each containing a stock solution (600 μL) of benzoic acid (6.10 mmol/L) in a certified, highly pure form (NIST 350b, purity = 99.9978 ± 0.0044%), were analyzed using identical instrumental parameters. The experiments revealed a standard deviation of ±1.1% corresponding to the signal area, thus showing a maximum error of <2% caused by variations in the NMR tubes including the error from other sources such as deviations in integration, baseline, and phase correction, respectively.

Use of External Standard. For qHNMR, in principle, each nonvolatile and nonhygroscopic organic compound might be used as external standard if it is soluble and chemically stable in the respective solution and available in high purity. Preliminary studies demonstrated D_2O, D_2O/DCl (90:10, v/v), CD_3OD, DMSO-d_6, C_6D_6, and CD_3CN as the most suitable solvents, whereas volatile solvents such as CD_2Cl_2 and $CDCl_3$, respectively, cannot be recommended due to increasing errors caused by vaporizing effects during preparation of the stock solutions, pipetting, or spectroscopic measurement.

To check the quality of the NIST 350b reference benzoic acid stock solution in terms of precise initial balance, sample preparation, and NMR experiment, the concentrations of solutions of L-tyrosine (3.03 mmol/L, D_2O/DCl) and caffeine (3.12 mmol/L, D_2O), both with a purity >99%, were determined by using benzoic acid (2.98 mmol/L, D_2O) as the external standard. Using the working procedure given in Figure 2 excellent recovery rates of 99.8 and 99.3% were found for caffeine (3.12 mmol/L, D_2O) and L-tyrosine (3.03 mmol/L, D_2O/DCl). To check if caffeine or L-tyrosine was also an appropriate external standard, the spectrometer was calibrated with these compounds. When the spectrometer was calibrated with the caffeine solution (3.12 mmol/L), the recoveries for benzoic acid and L-tyrosine were 99.3 and 99.7% (Table 2). If L-tyrosine (3.03 mmol/L) was used for the calibration of the instrument, the concentration of the caffeine solution (3.12 mmol/L) determined by NMR was found to be 3.09 mmol/L, whereas NMR analysis of the benzoic acid stock solution (2.98 mmol/L) revealed a concentration of 2.95 mmol/L. These data clearly demonstrate each of these three compounds as a suitable calibrant for qHNMR experiments. Due to its low price, high purity, easy handling, and good solubility in a number of deuterated solvents, caffeine was selected as the most adequate candidate and used for the validation of the qHNMR method.

Pulse Sequence, Excitation Pulses, and Spin−Lattice Relaxation Time (T_1). As the qHNMR experiments were performed by using an external standard in a separate NMR tube, it is essential to use the same pulse sequence for the external standard sample as well as for the unknown analyte sample. Assuming full relaxation of all protons of interest, errors in calibration of the pulse length (τ) by an angle θ would reduce the intensity of the resonance signals by a factor of cos θ.[20] In qHNMR analysis with an internal standard, this error should affect all protons comparably, uniform excitation provided. As demonstrated in the literature, no major differences in precision and accuracy of the analytical results are expected when 30°, 45°, or 90° pulses are applied.[7,14,15] The subsequent analysis of a standard solution with a compound of known concentration and a compound to be quantitated requires a separate calibration of the pulse length for both samples, due to the influence of the solvent, concentration, salt content, etc., on the pulse length. Naturally the effect of deviations by calibration of pulses shorter than $\pi/2$ is higher compared to the 90° pulse; for example, a 1° error in a 30° pulse would result in an approximately 1% decrease of the signal intensity, whereas the same error in a 90° pulse causes only an error of <0.02%.[20] For that reason and to maximize sensitivity for all quantitative measurements, 90° pulses were used and, as a consequence, the longer interpulse delay accepted.

If the excitation is performed by a 90° pulse, all equilibrium z-magnetization is converted into detected transverse x,y-magnetization, and depending on the target molecule it is required to insert a long interpulse delay to allow the excited nuclei to re-establish their equilibrium z-magnetization prior to the application of the next pulse. This interpulse delay is generally set to 5 times the longest longitudinal or spin−lattice relaxation time (T_1) to avoid distortion of integrated signal intensity due to relaxation effects. The T_1 for protons in small molecules can range between 0.3 and >10 s and, therefore, accurate determination is fundamental for precise and reliable qHNMR results. T_1 can be determined by an inversion−recovery experiment, or at least estimated via successive prolongation of the relaxation delay until the integrated peak area remains constant compared to the fully relaxed external standard. The spin−lattice relaxation of the methine proton of caffeine resonating at 7.87 ppm via inversion recovery leads to a T_1 of 6.5 s and consequently to a relaxation delay of

approximately 35 s. Plotting the concentration determined by qHNMR against the relaxation delay revealed a constant peak area if the relaxation delay was ≈40 s and matched gravimetric value (data not shown). These data indicate that the inversion−recovery experiment and the successive prolongation of the relaxation delay revealed comparable results. If the calculation was performed by using one of the methyl groups of caffeine, an interpluse delay of 15 s was sufficient to provide fully relaxed signals, thus shortening analysis time by 50%. On the other hand, the individual determination of the T_1 relaxation for each molecule is quite time-consuming and, therefore, a relaxation delay of 40 s, suitable for most small molecules, could be set as a default value for quantitation of all compounds. This value was confirmed by the determination of spin−lattice relaxation for all protons of interest in our compounds via inversion−recovery.

Tuning and Matching. It is essential for obtaining a good signal-to-noise (S/N) ratio and, as a consequence, a high sensitivity that the probe is precisely tuned to the observe frequency and matched to 50 Ω resistive impedance to minimize RF reflection with the sample of interest. On the basis of the reciprocal relationship between excitation and observation, Mo and Raftery proposed that the relative receiving efficiency can be correlated to the 90° pulse (τ_{90}) length, if the probe is perfectly tuned and matched.[32] It is not a prerequisite that the probe is correctly tuned and matched to fulfill the principle of reciprocity, but it is a consequence of the fact that this is the only state which is reproducibly adjustable on each spectrometer. Therefore, we investigated next the influence of automatic tuning and matching versus manual tuning and matching on the precision of the observed analytical data. To achieve this, a benzoic acid solution (6.14 mmol/L in D_2O) was, therefore, measured five times with manual tuning and matching using the *atmm* function of the software and five times with the automatic tuning and matching using the *atma* command. Prior to the acquisition of the spectra, the wobble curve was randomly misadjusted and then readjusted manually (*atmm*) or automatically (*atma*), and the 90° pulse was determined by the command *pulsecal sn*. Manual tuning and matching resulted in an average concentration of 6.10 ± 0.027 mmol/L (τ_{90} = 13.06 μs ± 0.018), whereas automatic tuning and matching revealed a slightly lower average concentration of 5.94 ± 0.043 mmol/L (τ_{90} = 12.86 μs ± 0.149). Independent of the tuning/matching procedure, these results indicate a standard deviation of <2%, thus demonstrating a good precision by the use of both procedures. Comparing the gravimetric data to the averaged NMR experimental data showed a recovery of 96.7 and 99.3%, respectively, when using automatic or manual tuning and matching, thus demonstrating somewhat higher accuracy when the probe was adjusted manually.

Receiver Gain (rg) and Number of Scans (ns). The rg is used to match the amplitude of the FID to the dynamic range of the digitizer. Due to different solvents, residual water, or impurities, the rg values of the calibration and quantitation experiments could be different. Although the Avance III spectrometer is able to balance possible differences in the rg between the external standard sample and the analyte sample, the quality of its linearization was checked by analyzing an L-tyrosine solution (1.01 mmol/L in D_2O/DCl) at different rg values (4, 16, 64, 128, 203, 256, 322, 512, and 912). Plotting the value of the rg against the observed signal area showed an excellent correlation with a linear regression coefficient of r^2 = 0.9995 (Figure 3A). The calculation of the concentration by ERETIC 2 for each value of the rg and the recovery determined by comparison to the gravimetric value was within an error of ±2%.

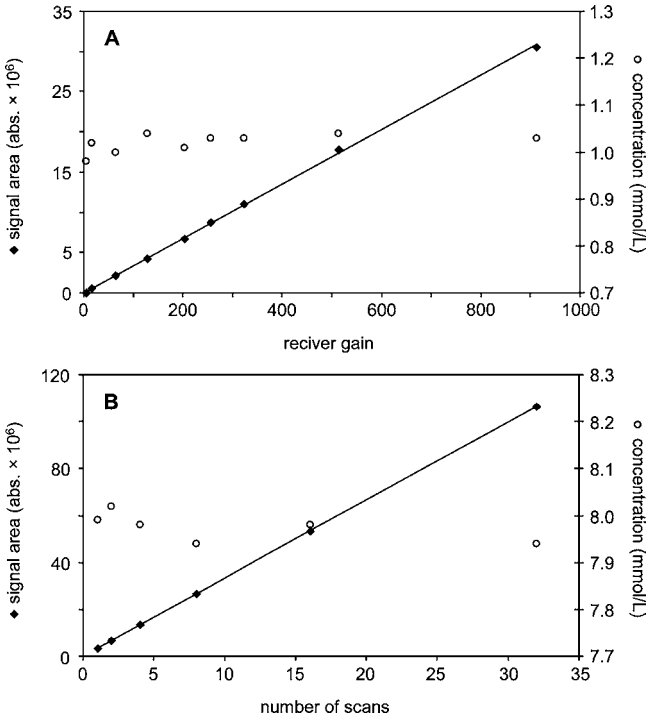

Figure 3. Quantitation of L-tyrosine samples on an Avance III spectrometer using ERETIC 2: (A) correlation between receiver gain (rg) and signal area and calculation of the concentration of L-tyrosine (1.01 mmol/L) at each rg value; (B) correlation between number of scans (ns) and signal area and calculation the concentration of L-tyrosine (8.03 mmol/L) at different ns.

Independent from the ns applied for the calibration experiment, ns applied on the analyte sample could be different. To obtain an adequate S/N ratio in low concentrated analyte samples, the ns has to be increased. In this case ERETIC 2 is able to compensate different ns used for the calibration sample and the sample of interest. To verify the quality of compensation, an L-tyrosine solution (8.03 mmol/L, D_2O) was analyzed with various ns values ranging from 1 to 32. Plotting the ns against the obtained signal area showed a regression coefficient r^2 = 1. Independent from the ns used, the calculated concentration by ERETIC 2 revealed concentrations between 7.94 and 8.02 mmol/L and, therefore, a maximum error of 1.1% (Figure 3B).

Limit of Quantitation (LOQ). As the LOQ depends on the ns, the number of nuclei generating a distinct proton signal, the shape of the signal, and its multiplicity, the LOQ was determined under predefined conditions. At a S/N ratio of 150 for the methyl group (3.55 ppm) of caffeine, obtained by using 16 scans on the 400 MHz instrument equipped with a BBFO probe, the LOQ was determined to be 0.2 mmol/L. The S/N of 150 was recommended in the literature for a target uncertainty of 1%; for an error limit of ±2% a S/N ratio of ≥40 is sufficient.[8] The LOQ can be further increased either by increasing the number of scans or by using higher field instruments equipped with a cryoprobe.

Linearity and Range of the Calibration Curve. To assess the linearity and range of the calibration curves, the

dx.doi.org/10.1021/jf405529b | J. Agric. Food Chem. 2014, 62, 2506−2515

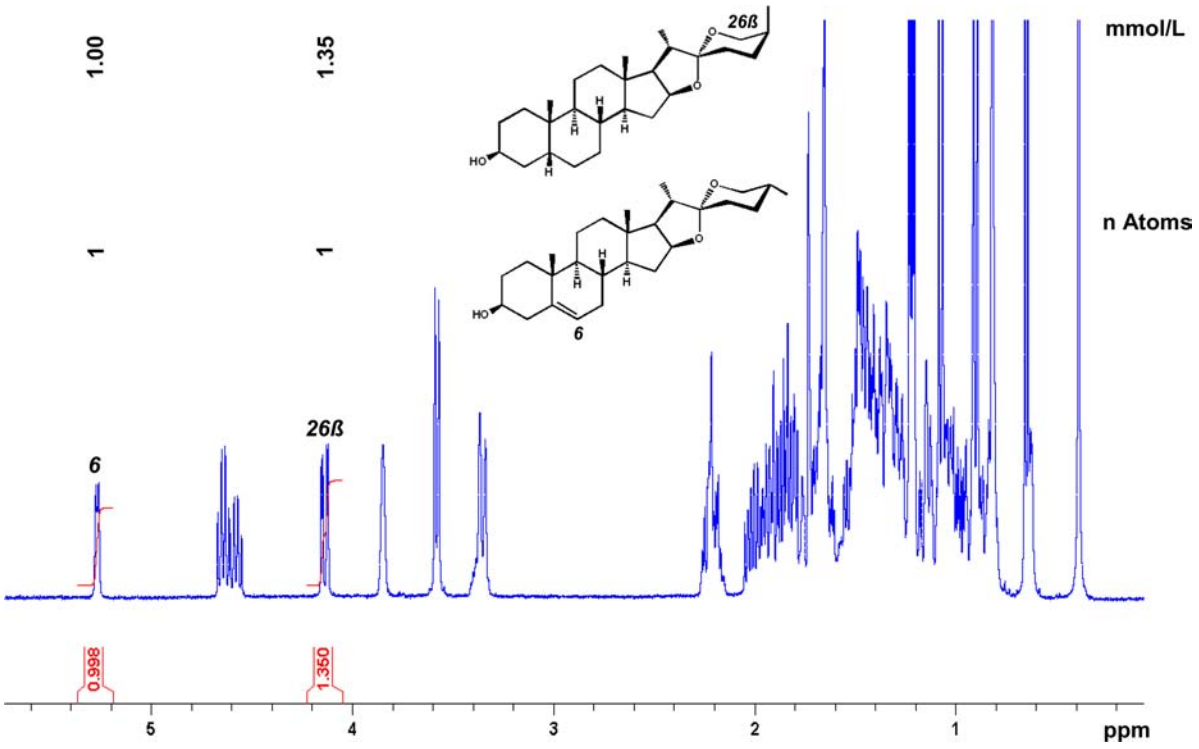

Figure 4. Quantitative ^{1}H NMR spectrum (400 MHz, benzene-d_6, 298 K) of a mixture of the steroidal sapogenins diosgenin and sarsasapogenin. Signal assignment was done according to the literature.[34,35]

reference compounds L-tyrosine (16.50, 8.25, 4.13, 2.06, 0.69, and 0.34 mmol/L), caffeine (15.90, 5.30, 2.65, 1.33, 0.66, and 0.33 mmol/L), and benzoic acid (16.30, 8.15, 3.26, 1.63, 0.82, and 0.33 mmol/L) were analyzed at the six different concentrations given in parentheses. The highest concentration was limited by the solubility of the compounds in the appropriate solvent, and the lowest concentration was somewhat above the limit of quantitation (LOQ). Plotting the experimentally determined data against the gravimetric values revealed linear regression coefficients of 1.00, 1.00, and 0.999 for L-tyrosine, benzoic acid, and caffeine, respectively (Table 3). The recovery of each individual calibration point was within an error limit of ±2%. These data clearly demonstrated an excellent linearity and recovery of the qHNMR method, independent from the compound used.

Accuracy. The accuracy of the qHNMR method was determined by analyzing solutions of benzoic acid (1.72, 6.14, and 16.21 mmol/L) and L-tyrosine (2.73, 7.33, and 9.99 mmol/L) using caffeine (3.12 mmol/L) as external standard and comparing the experimental data to those of gravimetry. The recoveries of benzoic acid were 98.8, 99.6, and 99.2%, whereas L-tyrosine revealed recoveries of 100.6, 100.7, and 100.9% (RSD < 2%).

Inter- and Intraday Precisions. The precision of the qHNMR method was determined by measuring intraday and interday variations of benzoic acid quantitation. Therefore, benzoic acid was analyzed at three different concentrations (5.91, 1.48, and 0.75 mmol/L), each in triplicates, on one day, and the same solutions were analyzed again on three subsequent days. Each measurement was preceded by removing the sample from the probe and replacing it again in the magnet. After equilibration, the probe was tuned, matched, and shimmed, and the 90° pulse was determined. When the measurements were performed at concentration levels of 5.91, 1.48, and 0.75 mmol/L, intraday precision revealed coefficients of variation (CV) of 0.6, 1.6, and 1.7%, respectively, and CVs for interday precision were 0.7, 1.6, and 1.3%.

Stability of Instrument Calibration. To study the long-term stability of the spectrometer calibration, a caffeine solution (2.65 mmol/L, CD_3OD) was used as calibrant and a 1.01 mmol/L L-tyrosine solution (D_2O/DCl) as the analyte solution. The multiplet resonating at 7.11 ppm was used for the quantitation with a S/N ratio of ≥48. Repeated analyses over a period of 6 months with periodically verified calibration prior to qHNMR analysis revealed recovery rates always >98% for the L-tyrosine solution over the entire period. These data clearly demonstrate an excellent long-term stability of the qHNMR analysis.

Influence of Operator on Analytical Robustness and Data Handling. The handling of the data by different operators is considered to be a main factor influencing the quality of qHNMR analyses.[8,11] As phase and baseline correction as well as signal integration are known as the most subjective procedures in qHNMR, three different operators (A−C) were asked to precisely follow the protocol shown in Figure 2 for data acquisition and to analyze a sample of L-tyrosine (4.94 mmol/L) without knowledge of the concentration on the calibrated spectrometer. For processing, automatic phase correction was performed by using *apk0.noe* or *apk*/*apks*. If the phase was not proper enough, a careful manual zero- and first-order phase correction was performed. Baseline correction was carried out using the command *absn*, integration was done manually, and, whenever required, the integrals were adjusted manually with the software functions SLOPE and BIAS. The concentration determined by operator A was 4.95 mmol/L (100.2%), whereas operators B and C found slightly decreased concentrations of 4.89 (99.0%) and 4.86 mmol/L (98.3%), respectively. Although these data

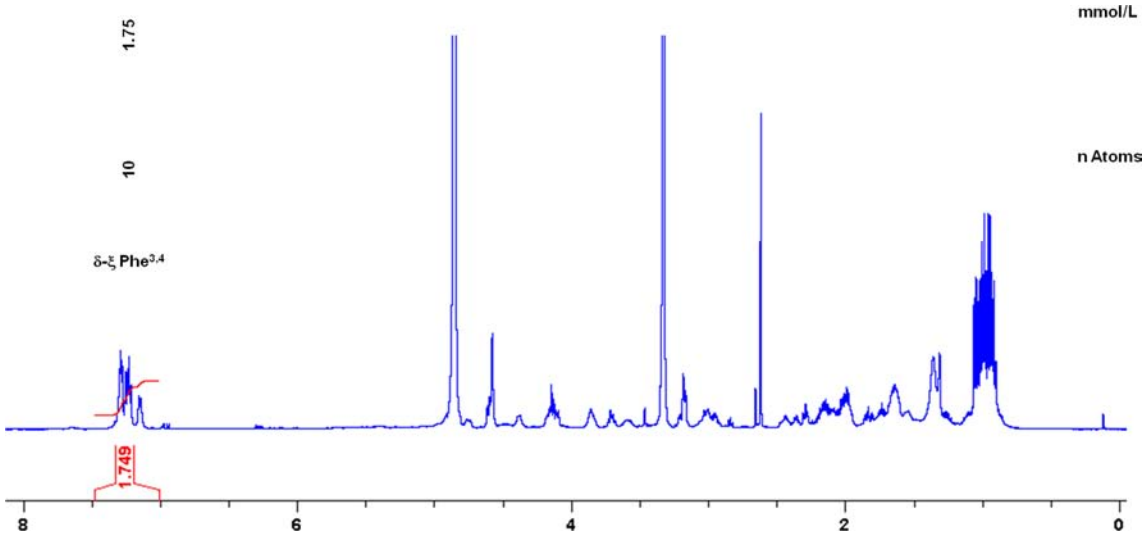

Figure 5. Quantitative ^{1}H NMR (400 MHz, methanol-d_4, 298 K) of cyclolinopeptide C, a cyclic octapeptide isolated from linseed oil. Signal assignment was done according to the literature.[36]

indicate a marginal influence of the operating individual on the qHNMR results, the protocol for acquisition and processing of the NMR data allowed an acceptable interindividual precision of ±2%.

Quantitation of Target Compounds in Reference Materials. To check the performance of the qHNMR method, solutions of a couple of chemical diverse commercial available compounds were prepared with defined concentrations ranging between 1.0 and 27.9 mmol/L in an appropriate deuterated solvent: the nitrogen-containing nicotinic acid, L-tyrosine, tyramine, caffeine, creatinine, and inosine; the polyphenols rutin and (*E*)-resveratrol; the saponins sarsasapogenin and diosgenin; the monoterpenes (−)-neomenthol and (+)-menthol; and the highly volatile odorants acetaldehyde and dimethyl sulfide, as well as the taste compounds sucrose and citric acid. The concentrations of these solutions (by gravimetry) were compared to the results obtained by qHNMR (Table 1). After data acquisition and processing, the recovery of most compounds was found to be between 98.1 and 101.1%, thus demonstrating a small error of ±2% of the method.

Moreover, a mixture of the steroidal sapogenins diosgenin and sarsasapogenin (1.00 and 1.37 mmol/L) was analyzed by qHNMR by integrating the two well-separated proton signals resonating at 5.27 and 4.14 ppm, respectively, representing proton H−C(6) of the olefinic double bond of diosgenin and H−C(26β) of the high-field shifted diastereotopic methylene proton of sarsasapogenin (Figure 4). The analysis showed excellent recovery for both compounds in the mixture (Table 1) with values of 98.5% for sarsasapogenin and 100% for diosgenin.

Compared to the nonvolatile substances, acetaldehyde and dimethyl sulfide showed somewhat lower recovery rates, most likely due to their high volatility during sample preparation. This could be partially overcome by cooling the compounds, NMR solvents, volumetric flasks, and pipets prior to the experiment; for example, the recovery rate for acetaldehyde could be increased from 80 to 93% when the equipment was cooled at 4 °C (Table 1). On the other hand, these data clearly indicate that preparing stock solutions of volatiles by using an analytical balance bears the risk of underestimating the analytical results due to the loss of compound quantity during preparation. This could be overcome by determining the concentration of such prepared solutions by qHNMR and will be helpful to improve the precision of analytical results of high volatiles such as aroma active compounds.

In another set of experiments, the qHNMR method was applied on synthesized stable isotope-labeled reference compounds, namely, *N*-methylpyridinium-d_3 (**1**), trigonelline-$^{13}C_1$ (**2**), tyramine-d_2 (**3**), and *S*-methylmethionine-d_3 (**4**) (Figure 1; Table 2) to be used for quantitative stable isotope dilution analysis (SIDA).[27,33] The purity of these stable isotope-labeled compounds was found to be between 98.0 and 100.5% (Table 2), indicating a high purity and, therefore, an excellent suitability as internal standards for SIDA. The counterion of salts such as *N*-methylpyridinum or trigonelline does not affect the concentration determination via qHNMR. In comparison, the use of an analytical balance for stock solution preparation can cause major errors when the nature of the counterion is unclear, for example, when such ionic compounds were isolated from natural sources such as foods, botanicals, or urine. Additional qHNMR experiments were performed with compounds isolated from natural sources. Solutions of the ribonucleotide 5′-GMP (**5**) isolated from yeast extract, the plant polyphenol resveratrol (**6**) purified form grape berry skins, and buchananiflavanone (**7**) and GB-2 (**8**) isolated from *Garchinia buchananii* bark, the emetic toxin cereulide (**9**) isolated from *Bacillus cereus*, and the cyclic octapeptide cyclolinopeptide C (**10**) from linseed oil were prepared after weighing and dissolving defined amounts of the isolate in NMR solvents. The concentrations of these solutions were compared to the instrumental data obtained by means of qHNMR (Table 2). Whereas the compounds **5**−**10** showed a purity of >95% by means of NMR spectroscopy, the concentrations determined by qHNMR showed in all cases significantly lower values between 70.0% (cyclolinopeptide C) and 91.6% (buchananiflavanone) compared to the concentration expected from the gravimetric preparation of the sample solutions. Although isolates **5**−**10** were freeze-dried twice after chromatographic purification, their ^{1}H NMR spectra showed considerable amounts of residual water (Figure 5) contributing to the initial sample weight and, as a consequence, leading to an under-

dx.doi.org/10.1021/jf405529b | J. Agric. Food Chem. 2014, 62, 2506−2515

estimation of the analytical results when using only the analytical balance for preparation of the stock solution of such a compound. In addition, the presence of inorganic material that is not detectable in the ^{1}H NMR spectrum could contribute to an increased sample weight and, therefore, a lower content of the target molecule in the weighted sample as expected; for example, the cyclic peptides cereulide (**9**) and cyclolinopeptide C (**10**) are known to complex monovalent inorganic cations with high affinity for potassium.

With all of these findings taken into conclusion, the presented qHNMR method is an excellent alternative to the use of previous quantitative NMR techniques using internal standards or artificial electronic signals for quantitative determination and allows a most precise and robust quantitation of organic target molecules in natural isolates and synthetic materials even in the presence of bound water or inorganic residues. As this methodology is able to deliver accurate quantitative data in <15 min per sample, it might be a valuable tool for the quantitation of natural isolates even of unknown molecular weight. This offers the advantage of directly comparing bioactivity data of individual isolates or fractions already in an early stage of bioassay-guided fractionation procedure.

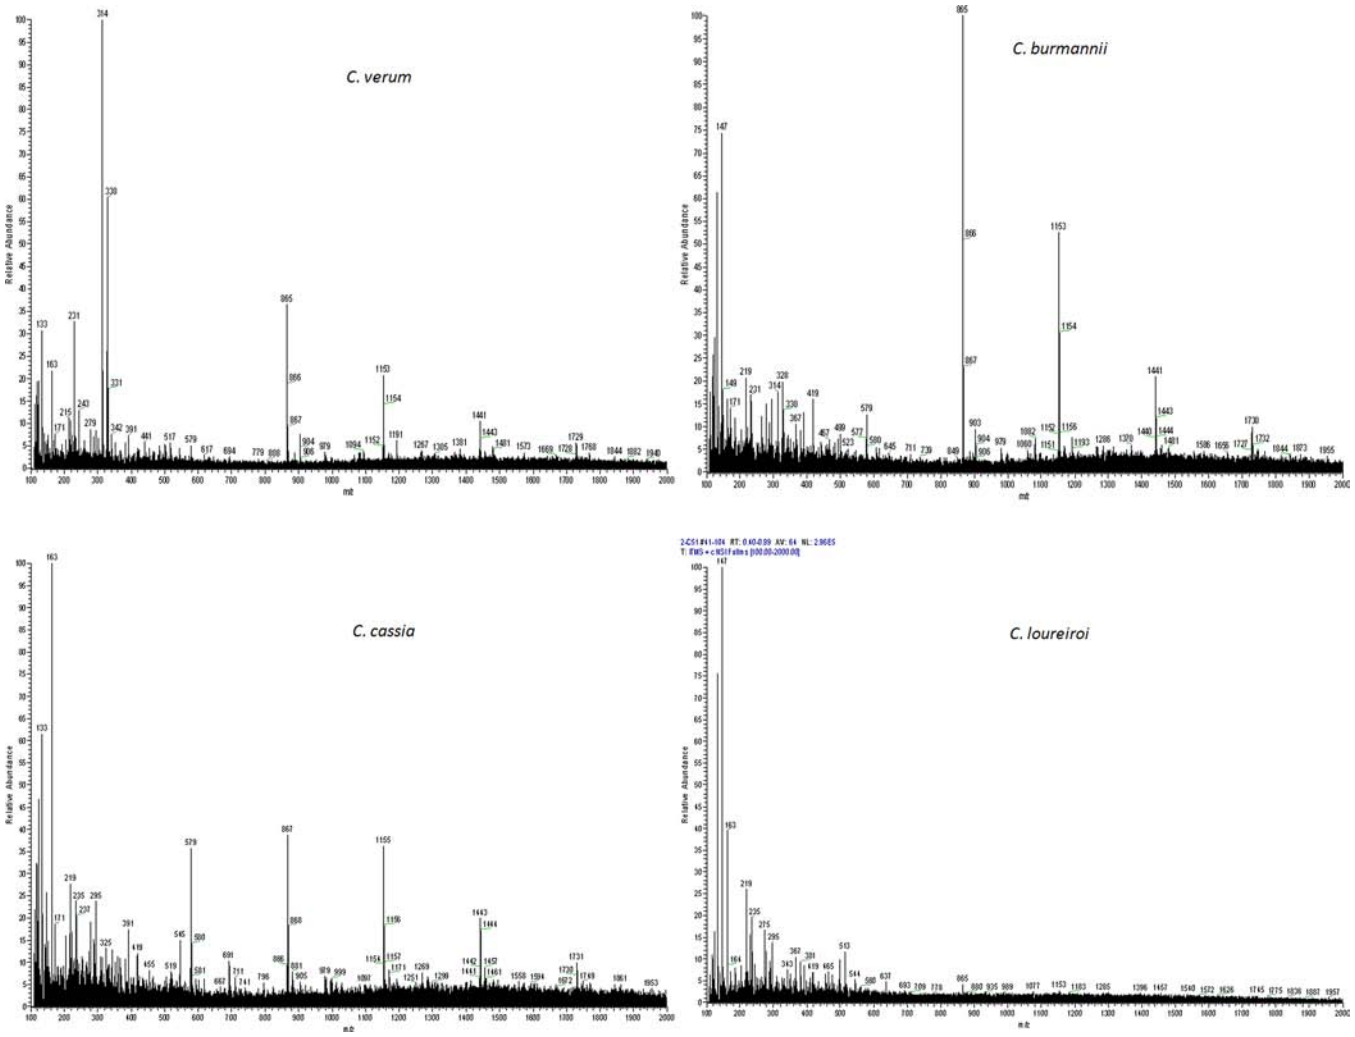

Figure 1. Typical FIMS spectra of the four species of cinnamon.

botanical materials and, consequently, place the technique on a sound statistical base. The patterns of the FIMS fingerprints (spectra with no prior separation) have been successfully used to distinguish plant genera, species, and even farming methods.[14−17] Use of the FIMS fingerprints and principal component analysis (PCA) or analysis of variance (ANOVA) prevents undue reliance on one or two marker compounds, increases the robustness of the analysis, and provides for both visual display and statistical evaluation of the data. Another advantage of the method is the fast method development time (hours) and analysis time (1 min) compared to traditional liquid chromatography−mass spectrometry (LC-MS), which can take days to weeks for method development and up to 1 h or longer for sample analysis of various natural products. A shortcoming of the FIMS technique is that it may not provide all of the information available through a full LC-MS analysis. Therefore, the combination of using both the FIMS fingerprinting technique and LC-MS on selected samples (determined by FIMS) will often be the best approach.

EXPERIMENTAL PROCEDURES

Materials. Fifty authentic cinnamon samples (3 *C. verum*, CV; 2 *C. cassia*, CC; 40 *C. burmannii*, CB; and 5 *C. loureiroi*, CL) and 3 unknown cinnamon samples (CU) were obtained from the library of McCormick & Co., Inc. (Sparks, MD, USA). At the time of the study, cinnamon, typically in the form of bark or chips, was ethylene oxide (ETO) treated and dried if necessary to constant moisture (typically 10−14%) and stored. The samples (collected in 2009−2011) were sourced and vetted through the company's global sourcing division, and the identity of each sample was confirmed by McCormick's internal chemotaxonomic methods. Samples were ground in a Schutte Hammermill (model 24-15-301) or a Brinkman Restch ZM-1 centrifugal mill and passed through a 20 mesh sieve. The ground samples were stored at room temperature in sealed glass jars until use. An additional test cinnamon sample (label claim CL) was purchased in a local supermarket in Maryland.

Water, acetonitrile, and methanol were of Optima grade (Fisher Scientific, Pittsburgh, PA, USA). Formic acid was of mass spectrometry grade (Sigma-Aldrich, St. Louis, MO, USA).

Sample Preparation. All samples were first passed through a 20 mesh sieve. Next, 10 mg of each dried ground sample was mixed with 5 mL of methanol/water (6:4 by volume) in a 15 mL centrifuge tube. All samples were sonicated for 20 min at room temperature. The sample extract was centrifuged at 5000*g* for 15 min (IEC Clinical Centrifuge, Danon/IEC Division, Needham Heights, MA, USA). The supernatant was filtered through a 17 mm (0.45 μm) PVDF syringe filter (VWR Scientific, Seattle, WA, USA). The cinnamon samples were labeled CV01−CV04 for *C. verum*, CC01 and CC02 for *C. cassia*, CB01−CB 40 for *C. burmannii*, CL01−CL05 for *C. loureiroi*, and CU01−04 for unknown and test cinnamon samples.

To avoid errors arising from unexpected degradation of some phenolic compounds, the sample analysis was completed within 24 h of the extraction. The injection volume for all samples was 5 μL. Each

sample was analyzed three times for the FIMS experiment. Representative samples from each species were analyzed one time for the UHPLC-HRMS experiment. Samples were run in randomized order.

Flow Injection Mass Spectrometry. The FIMS system consisted of a LCQ DecaXP ion-trap mass spectrometer (Thermo Fisher Scientific Inc., Waltham, MA, USA) with an Agilent 1200 HPLC system (a quaternary pump with a vacuum degasser, a thermostated column compartment, an autosampler, and a diode array detector (DAD) (Agilent Technologies, Palo Alto, CA, USA). The flow injection was passed through a guard column (Adsorbosphere All-Guard Cartridge, C18, 5 μm, 4.6 × 7.5 mm, Alltech Associates, Inc., Deerfield, IL, USA) to minimize potential contamination for the MS system. Mobile phases consisted of 0.1% formic acid in H_2O (A) and 0.1% formic acid in acetonitrile (B) with isocratic elution at 60:40 (v/v) at a flow rate of 0.5 mL/min for 1.5 min. Electrospray ionization (ESI) was performed in positive ion mode from m/z 100 to 2000 to obtain the FIMS fingerprints. The acquisition mode was centroid. The following conditions were used for the DecaXP mass spectrometer: sheath gas flow rate, 80 (arbitrary units); auxiliary gas flow rate, 10 (arbitrary units); spray voltage, 4.50 kV; heated capillary temperature, 220 °C; capillary voltage, 4.0 V; tube lens offset, 25 V. Spectra were summed from 0.4 to 1.0 min interval required for the sample bolus to enter the MS. Three repeat analyses of the 54 different samples provided 162 spectra.

Data Processing for FIMS Fingerprint. The mass spectrum for each sample consisted of a one-dimensional matrix (ion counts versus mass for m/z 100−2000). The spectra were exported to Excel (Microsoft, Inc., Belleview, WA, USA) from Xcalibur for data preprocessing and then to SOLO (eigenvector Research, Inc., Wenatchee, WA, USA) for PCA. The preprocessing in Microsoft Excel involved combining the 162 spectra, sorting the data by sample names, deleting unnecessary and redundant information (headers, sample information, instrument information, etc.), and aligning the masses (each spectrum was a different length because not all masses appeared in each spectra) using a MS Excel macro written in house. The resulting two-dimensional 162 × 1901 matrix (162 samples versus 1901 masses) was then exported to SOLO for PCA. Preprocessing in SOLO, prior to PCA, consisted of normalization (sum of squares of the counts for a spectra was set to 1) and mean centering.

Ultrahigh-Performance Liquid Chromatography−High-Resolution Mass Spectrometry (UHPLC-HRMS). The UHPLC-HRMS system consists of a Thermo LTQ Orbitrap XL mass spectrometer with an Accela 1250 binary pump, a PAL-HTC-Accela1 autosampler, an Accela 1250 PDA detector, and an Agilent column compartment (G1316A). The separation was carried out on a Thermo Hypersil Gold C18 column (200 μm × 2.1 mm, 1.9 μm) with a flow rate of 0.35 mL/min. The column heater was kept at 50 °C. Mobile phase A consisted of 0.1% formic acid in water, and mobile phase B consisted of 0.1% formic acid in acetonitrile. The elution gradient ranged from 10 to 25% mobile phase B over 0−7 min, from 25 to 40% B over 7−10 min, from 40 to 95% B over 10−12 min, and was held at 95% B for an additional 6 min with subsequent return to initial conditions. Electrospray ionization (ESI) was performed in the positive ion mode to obtain the HRMS data. The HRMS conditions were as follows: sheath gas, 70 arbitrary units; auxiliary and sweep gas, 15 arbitrary units; spray voltage, 4.0 kV; capillary temperature, 300 °C; capillary voltage, 15 V; and tube lens offset voltage, −70 V. The mass range was from m/z 100 to 2000 with a resolution of 15000, isolation width of 1.5 amu, and maximum ion injection time of 500 ms. The most intense ion was selected for the data-dependent scan with a normalization collision energy at 35%.

■ RESULTS AND DISCUSSION

FIMS Fingerprints of the Cinnamon Samples. The first goal of this study was to differentiate the four different species of cinnamon samples without chromatography. No analytical column was used, only a C_{18} reverse-phase guard column as an online filter to protect the MS. The FIMS fingerprint for each sample was obtained as the average of all spectra between 0.4 and 1.0 min. Typical FIMS fingerprints of the four species of cinnamon samples are shown in Figure 1. The differences among the four species of cinnamon are quite obvious visually even though no chromatographic separation was performed. The most notable ions for CV are at m/z 314, 330, 865, and 1153; those for CB are at m/z 133, 147, 865, and 1153; those for CC are at m/z 163, 579, 867, and 1155; and those for CL are at m/z 133, 147, and 163. Some observations from inspection of the spectra are as follows: (1) the ions at m/z 314 and 320 dominate the CV spectrum; (2) the ions at m/z 147 and 865 dominate the CB spectrum; (3) the ion at m/z 163 dominates the CC spectrum; and (4) the CL spectrum has relatively low ion counts for the high atomic mass unit molecular ions.

PCA of the FIMS Fingerprints. The advantage of using PCA to process the MS fingerprints is automation and simplification. It is easy to visually compare the mass spectra of a few samples, but the comparison of hundreds of samples quickly overwhelms our ability to discriminate useful patterns. PCA provides visual patterns that are math-based but still aesthetically and statistically useful, avoiding subjective interpretations of the data.

The PCA score plot showed the 54 cinnamon samples in four different groups (Figure 2). The three CV samples (in triplicate) did not cluster very tightly, occupying a larger area from the right to the middle of the plot, but were still separated from the other groups. The PCA score plot also successfully categorized the unknown samples. For example, three samples were categorized as *C. cassia* (CC) and the remaining sample was identified as *C. loureiroi* (CL), confirming the label claim.

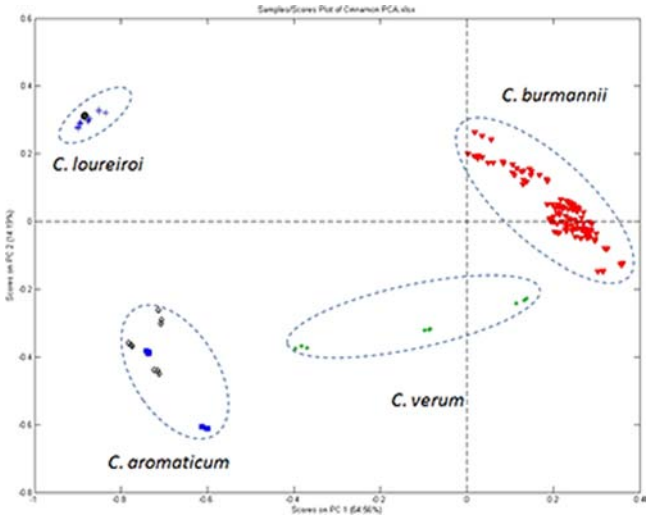

Figure 2. PCA score plot (for FIMS fingerprints) of the four species of cinnamon (▽, CB; ∗, CV; ■, CC; +, CL; ◇, unknown from McCormick; ●, unknown commercial, labeled CL).

PCA Loadings and UHPLC-HRMS Studies. The loading plot of a variable on a PCA reflects how much each of the variables contributed to that PC. The PC1 loading plot of the samples is shown in Figure 3. The plot indicates samples with higher ion counts at m/z 865, 903, 1154, and 1442 would yield a higher PC1 score, leading to positions toward the right of the PCA score plot. The important ions contributing to negative PC1 scores were m/z 133, 147, 275, 381, 465, and 513. This suggests the high molecular weight ions (m/z 865, 904, 1192,

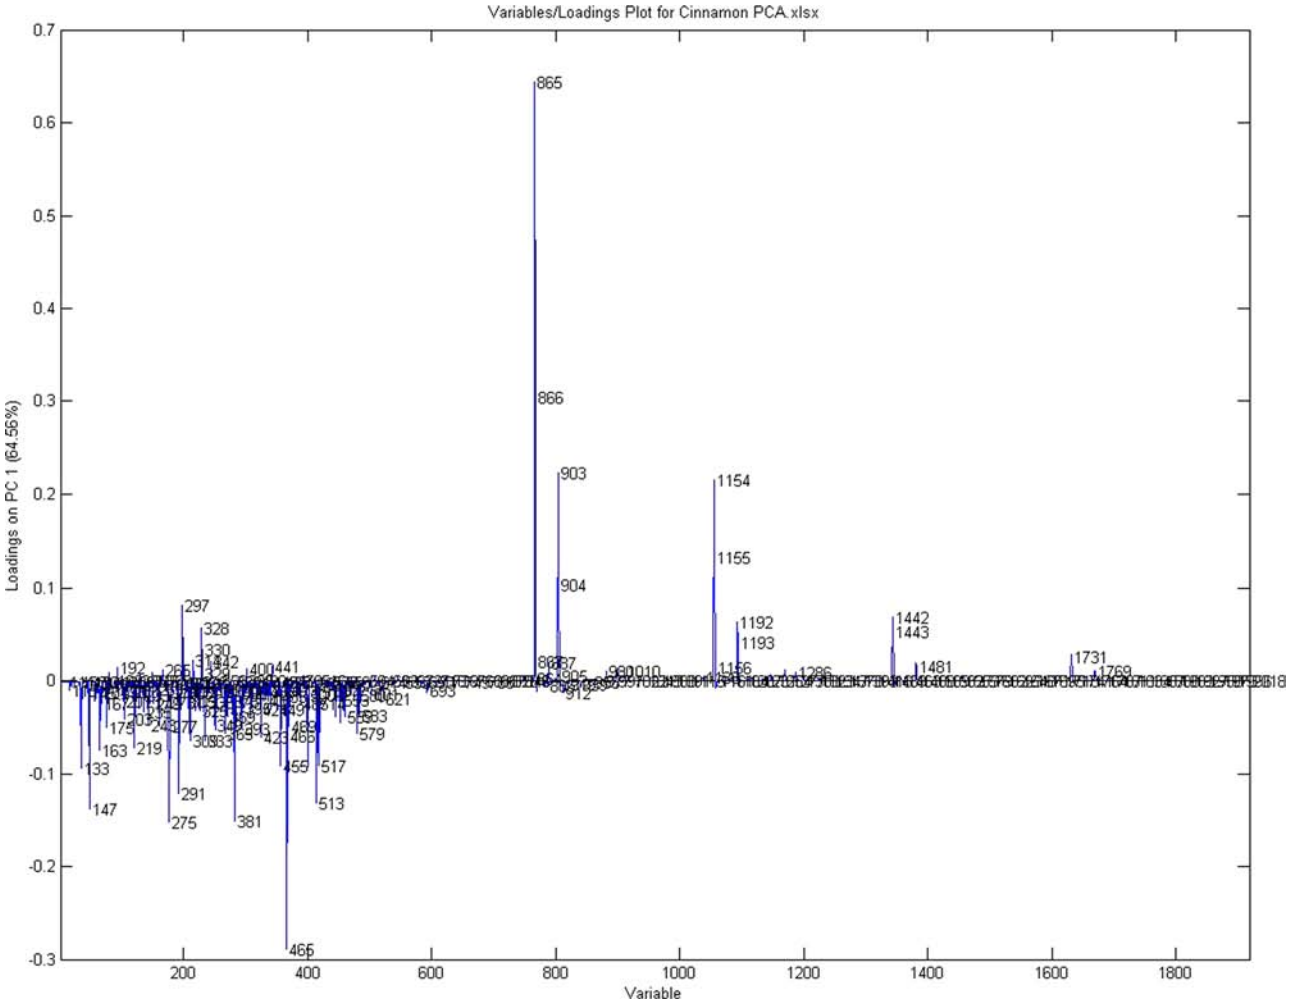

Figure 3. PCA loading plot of PC1 for FIMS fingerprints.

and 1442) tend to position the samples to the right of the PCA score plot, whereas the low molecular weight ions shifted sample positions more to the left side of the plots.

The above-mentioned ions from the PCA loading plot were further studied using UHPLC-HRMS. The HRMS measurements of the ion at *m/z* 865, 1154, and 1442 gave accurate masses of 865.1981 ($C_{45}H_{37}O_{18}$, 0.785 ppm), 1153.2629 ($C_{60}H_{49}O_{24}$, 1.796 ppm), and 1441.3259 ($C_{75}H_{61}O_{30}$, 0.785 ppm). MS^2 and MS^3 experiments were performed on these ions (spectra shown in the Supporting Information). The occurrence of an ion at *m/z* 287 in the MS^2 or MS^3 spectrum is an indication of the doubly linked A-type catechin/epicatechin oligomers, which contain $C_4 \rightarrow C_8$ carbon and $C_2 \rightarrow O \rightarrow C_7$ ether bonds. For example, the ion at *m/z* 865 had MS^2 fragments at *m/z* 533, 713, 453, and 287, in addition to the neutral losses of 286, 288, and 290, indicating it is an A-type trimer proanthocyanin, which has been previously reported.[18,19] Similarly, ions at *m/z* 1153.2629 and 1441.3259 were identified as A-type tetramers and pentamers, respectively. The HRMS measurements of the ions at *m/z* 133 and 147 gave accurate masses of 133.0646 (C_9H_9O, −1.061 ppm) and 147.0439 ($C_9H_7O_2$, −1.061 ppm). A literature paper[20] and our own data from the MS^2 studies (Supporting Information) confirmed these two ions represent the cinnamon components cinnamaldehyde and coumarin.

The PC2 loading plot of the samples is shown in Figure 4. The plot indicates samples with high ion counts at*m/z* 147, 465, 499, 513, and 865 yield a higher PC2 score, which would lead to positioning at the top of the PCA score plot. The ions contributing the most to the negative PC1 score were at *m/z* 579, 867, and 1156. The HRMS measurements of these ions indicate the formulas $C_{30}H_{27}O_{12}$ (*m/z* 579.1501, 0.447 ppm), $C_{45}H_{39}O_{18}$ (*m/z* 867.2134, 0.349 ppm), and $C_{60}H_{51}O_{24}$ (*m/z*1155.2782, 1.721 ppm). Using the *m/z* 579.1501 ion as an example, it fragmented into *m/z* 451, 427, 409, and 291 (17−26%), consistent with the report of procyanidins B_1. Similarly, ions *m/z* 867.2134 and 1155.2782 were identified as a B-type trimer and tetramer, respectively (Figure S2 in the Supporting Information).

These ions were ultimately identified as the dimer, trimer, and tetramers of B-type proanthocyanidins in cinnamon.[13]

To summarize, the coumarin and A-type proanthocyanidins give higher PC2 scores, whereas the B-type proanthocyanidins give lower PC2 scores, thus demonstrating different PCA groupings for the samples containing these profiles.

The ions at *m/z* 465, 499, and 513 are all very small peaks in the UHPLC-HRMS chromatograms. They are only visible using extracted ion mode. Regardless, it is not unusual for a relatively minor component that plays a significant role in PCA to be more visible in the FIMS spectrum than in an UHPLC-HRMS chromatogram.[17]

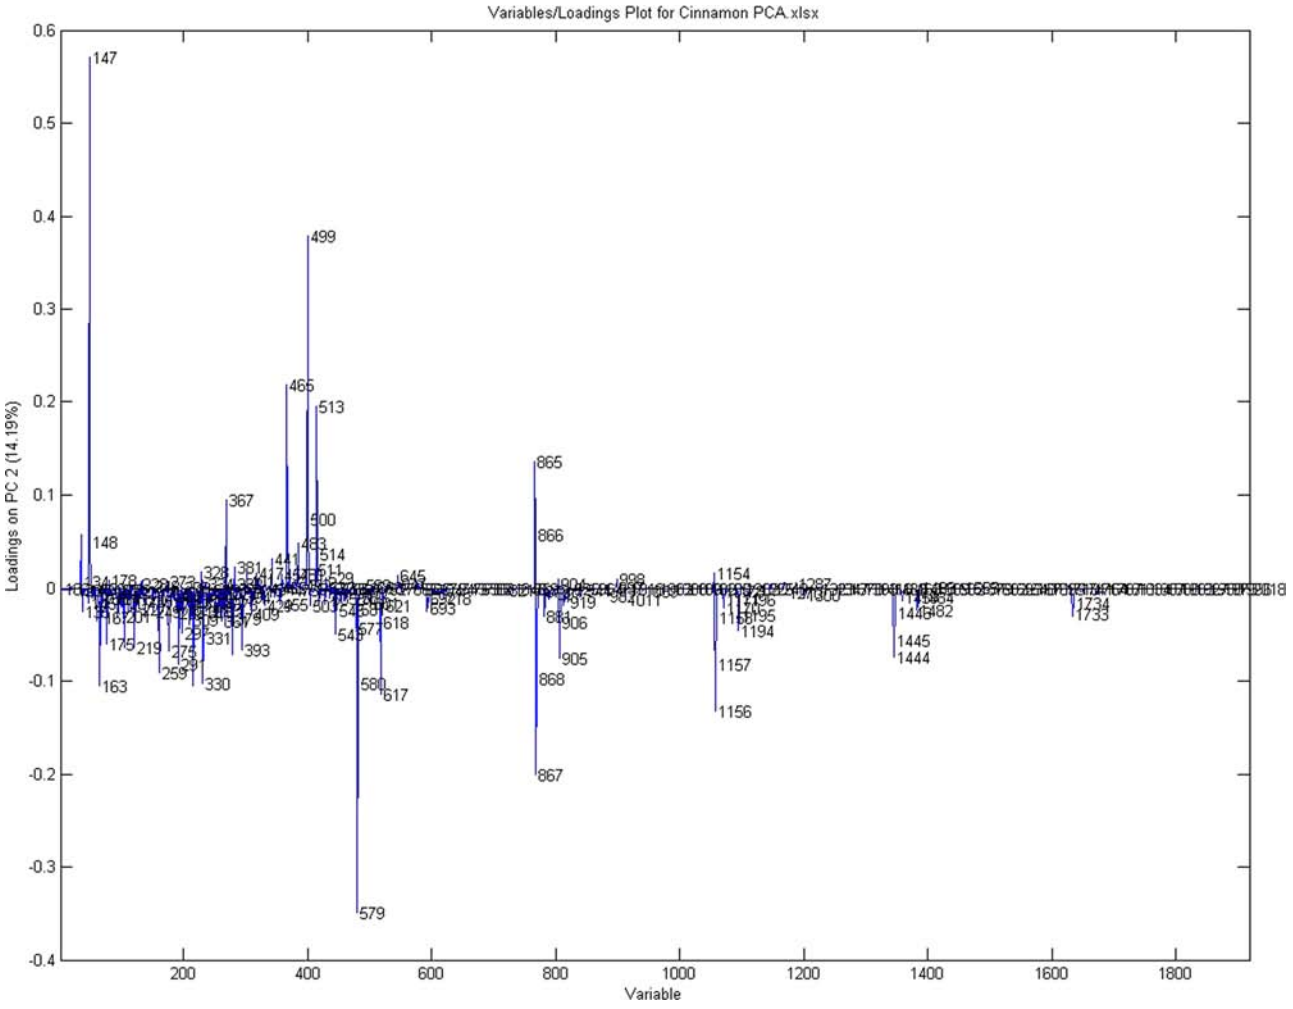

Figure 4. PCA loading plot of PC2 for FIMS fingerprints.

On a further note, it is common to observe that feeding studies and clinical trials involving natural products and their extracts give different or inconsistent test results. Cinnamon studies are no exception. Khan et al. found that cinnamon improves glucose and lipid levels of people with type 2 diabetes.[10] However, Loon's group did not reach this same conclusion.[21] Both groups claimed to use CC in their studies, but neither group attempted to identify the cinnamon samples by source or characterize the composition of the cinnamon samples before administering their respective studies. Thus, it is impossible to tell how different their respective samples are chemically and if the cinnamon used was actually CC or not. Another interesting observation is that the type-A proanthocyanidins isolated from CB were speculated to have insulin-like biological activity.[11] Yet both of the human feeding studies used CC, which contained more type-B than type-A proanthocyanidins. There was no explanation of why CC was chosen for both studies instead of CB or CV, nor were there any reports on the comparison of different cinnamon samples in human studies. The results from the present study clearly show the chemical composition differences between the four species of cinnamon samples. If the assumption is type-A proanthocyanidins have more insulin-like activity, then clearly CB or CV should be expected to perform better in human studies or biological assays, and CL would be the least effective. The results from this study show the importance of analytically determining the chemical composition of the samples when feeding studies are designed.

This study demonstrates a simple, fast, and reliable analytical method that can be used to differentiate four different species of cinnamons. Not only can the method be used for botanical authentication in food supply chains, it also can be used to help design better, more meaningful, and insightful feeding studies or assays, especially when combined with the UHPLC-HRMS method. The data suggested a model system in which the FIMS fingerprinting method is used to screen many samples quickly, whereas representative samples from a group and outlier samples are analyzed using the UHPLC-HRMS method to provide detailed information about a sample's unique chemical composition.

level, without knowing the glycation site(s) and glycation extent per site in the protein. Mass spectrometry, both electrospray ionization mass spectrometry (ESI-MS) and matrix-assisted laser desorption ionization−mass spectrometry (MALDI-MS), allow a detailed analysis of the nature and extent of protein modification at the molecular level.[18−20] The recent technical innovations in mass spectrometry, particularly with the advent of high-energy C-trap dissociation (HCD) and electron transfer dissociation (ETD), have enabled unambiguous characterization of peptides with various modifications.[21,22] HCD allows the detection of the fragments with low mass, which is often not detectable due to the low mass cutoff in ion trap collision-induced dissociation (CID). ETD produces sufficient c and z ions, particularly for those peptides with relatively high mass carrying multiple charges. In addition, ETD can preserve the modification on the amino acid residue, therefore enabling accurate site localization.[23,24]

The purpose of this study was to evaluate the ultrasonic pretreatment effect on the galactose glycation of BSA. We compared the galactose glycation progress of BSA with and without ultrasonic pretreatment in the dry state. The glycation sites of the native BSA and ultrasound-BSA were characterized by the combined HCD and ETD fragmentation approach. The ultrasonic pretreatment on BSA resulted in many more glycation sites and a stronger glycation degree. Our investigation clearly revealed the critical role of ultrasonication in improving the extent of protein glycation.

MATERIALS AND METHODS

Materials. BSA, galactose, trypsin, and iodoacetamide were purchased from Sigma Chemical Co. (St. Louis, MO, USA); DTT was purchased from Thermo Fisher Scientific Inc. (Waltham, MA, USA). All other reagents used were of analytical grade.

Sample Preparation. BSA (0.2 g) was dissolved in 20 mL of 50 mM sodium phosphate buffer at pH 7.4. The solution was split into two aliquots. One aliquot of BSA was used as the control. The other aliquot was treated by probe sonicator (model 550 Sonic Dismembrator, Fisher Scientific, Pittsburgh, PA, USA; 20 kHz) equipped with a microtip probe (1/8 in. = 3.2 mm). In this sonicator setup, the actual minimum ultrasonic intensity was 75 W/cm^2 and the maximum intensity was 150 W/cm^2. The sample tube was kept in the ice bath, and the solution was treated by ultrasound with a 5 s on and 5 s off pulsation at an actual ultrasound intensity of 150 W/cm^2 for 10 min to ensure the temperature of the sample solution is not elevated (lower than 15 °C). One aliquot under ultrasonic treatment was used as the second control without added galactose. To the other aliquot was added the same mass of galactose followed by ultrasonication treatment after mixing.

The equal mass of galactose (10 mg) was added to 1 mL of the native BSA and ultrasonicated BSA solution, separately. After lyophilization, the powders of the native BSA−galactose and ultrasonicated BSA−galactose complex were incubated at 65% relative humidity (saturated potassium iodide solution) and 55 °C for 1 h. The reaction was stopped by transferring the sample tubes into an ice bath. After glycation, the powders were dissolved in cold distilled water, and the free galactose and salts were filtered by a Centricon centrifugal filter unit (10000 Da cutoffs, Millipore, Bedford, MA, USA). The concentration of protein was adjusted to 15 mg/mL and stored at −20 °C for further use. Three replicates were carried out for each sample.

MALDI-TOF Analysis. Mass spectrometry analysis was carried out using a MALDI TOF-TOF mass spectrometer (AB Science, ABI 4800 Proteomics TOF/TOF Analyzer, Foster City, CA, USA) in the positive ion mode. Sinapic acid (5 mg/mL) in 50% acetonitrile with 0.1% TFA was used as the matrix. The proteins were diluted 1:100 by distilled water and mixed 1:1 with the matrix. Mixtures (1.5 μL) were spotted onto the MALDI target and air-dried before analysis. Each sample was spotted on at least three individual target positions, and 80 individual spectra of each spot were averaged to produce a mass spectrum.

The incorporation ratio (IR), that is, the average number of galactose molecules attached to each albumin molecule, was used to evaluate the degree of protein glycation.[25] On the basis of the molecular weight (MW) shift from native BSA to glycated BSA, the IR of galactose to BSA could be deduced as

$$\mathrm{IR} = (\mathrm{MW_{GA}} - \mathrm{MW_{NGA}})/162.0528 \quad (1)$$

where 162.0528 is the MW of galactose attached to albumin, $\mathrm{MW_{GA}}$ is the molecular weight of glycated BSA, and $\mathrm{MW_{NGA}}$ is the molecular weight of nonglycated BSA.

Sample Digestion. Four microliters of the protein and complex solution was added to a 500 μL centrifuge tube containing 90 μL of 50 mM ammonium bicarbonate solution and 9 μL of 100 mM DTT. The sample was incubated at 95 °C for 5 min and then cooled in the ice bath. Eighteen microliters of the alkylation buffer (100 mM iodoacetamide) was added to the tube and incubated in the dark at room temperature for 20 min. Six microliters of 0.1 μg/μL trypsin was added to hydrolyze the protein samples at 37 °C for 4 h. The reaction was then quenched by adding 2 μL of 5% trifluoroacetic acid.

Analysis by HPLC-HCD/ETD-MS/MS. A Shimadzu HPLC (Shimadzu, Kyoto Japan), with two LC-10AD pumps, was used to generate a gradient with a 100 μL/min flow rate. Solvent A was 5% acetonitrile in H_2O, 0.1% formic acid (FA), whereas solvent B consisted of 95% acetonitrile in H_2O, 0.1% FA. For analysis of proteolytic peptides, 40 μL of digested sample was injected onto a 2.0 mm i.d. × 100 mm C18 column (Phenomenex Inc., Torrance, CA, USA). After desalting for 5 min with 5% B, the peptides were eluted at 100 μL/min with a 5−10% gradient for 1 min, 10−40% for 20 min, and 40−95% for 2 min. The effluent was infused into an LTQ-Qrbitrap Velos mass spectrometry (Thermo Fisher Scientific, Waltham, MA, USA) for MS/MS analysis to identify protein glycation. The decision tree methods were enabled for data acquisition. The settings for the decision tree were as follows: ETD was performed instead of HCD if the charge state was 3 and m/z was <650, or if the charge state was 4 and the m/z was <900, or if the charge state was 5 and the m/z was <950. ETD was performed for all precursor ions with charge states >5. The normalized collision energy was set to 28% for HCD. Supplemental activation was enabled for ETD. The signal threshold for triggering an MS/MS event was set to 500 counts. Charge state screening was enabled, and precursors with unknown charge state or a charge state of 1 were excluded. Dynamic exclusion was enabled with an exclusion duration of 90 s.

To further compare the glycation extent of each peptide, the average degree of substitution per peptide molecule of BSA (DSP) was calculated according to the formulation[7,26]

$$\mathrm{DSP} = \frac{\sum_{i-0}^{n} i \times I_{(\mathrm{peptide}+i\times\mathrm{galactose})}}{\sum_{i=0}^{n} I_{(\mathrm{peptide}+i\times\mathrm{galactose})}} \quad (2)$$

where I is the sum of the intensities of glycated peptide and i is the number of galactose units attached to the peptide in each glycated form.

Database Search. Thermo proteome discoverer (ver. 1.4.0.288) was used to generate the mgf. file from mass spectrometric data, and then Mascot Daemon (ver. 2.4.0, Matrix Science, Boston, MA, USA) was used to perform the searches against the NCBInr database. Search parameters were as follows: carbamidomethyl (C) was set as a fixed modification, and glycation (K and R) and oxidation (M) were set as variable modifications. Additional search settings included a maximum of 5five missed cleavages, peptide tolerance of ±10 ppm, and MS/MS tolerance of ±0.2 Da. Peptides with a Mascot ion score >40 were considered to be positive identification or extensive similarity (p < 0.05). Peptides identified with scores between 20 and 40 were considered to be potential positive identifications and were manually validated using the criteria suggested by Chen et al.[27] and Rombouts et al.[28] Only a, b, c, or y and z ions, or associated peaks arising due to water or amine loss, were considered as daughter ions of a parent

peptide. At least five isotopically resolved independent fragment peaks were required to match the theoretical peptide fragments. At least three consecutive fragment ions in the peptide sequence were required for positive identifications. These fragment ions could be either the b or y ion series for HCD fragmentation or the c and z ion series for ETD fragmentation. In addition, for doubly or triply charged ions, only one fragment ion with an intensity higher than one-third of the maximum intensity, an m/z value larger than that of the parent ion while not matching a theoretical peptide fragment, was allowed. For single charged ions, both the b ion or y ion series were required to confirm at least three consecutive amino acid residues in the peptide sequence if the peptide ended with an arginine or lysine residue; either b ion or y ion series were required to confirm at least three consecutive amino acid residues in the peptide sequence for the C-terminal peptide without arginine or lysine residues.

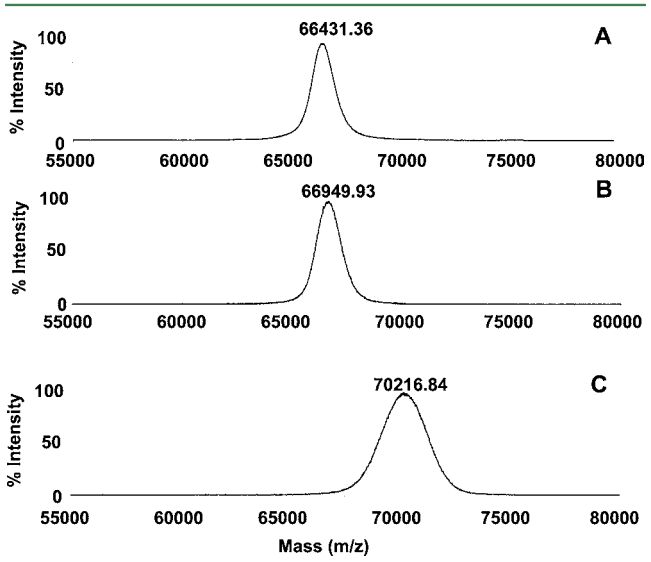

Figure 1. MALDI-TOF-MS analysis of ultrasonicated BSA (A); BSA-galactose before ultrasound (B) and after ultrasound pretreatment (C).

RESULTS AND DISCUSSION

Average Molecular Weight and Incorporation Ratio of Galactose to BSA. Figure 1 shows the MALDI-TOF-MS spectra of BSA−galactose with and without ultrasound pretreatment. The molecular weights of the native BSA and ultrasonicated BSA shifted to 66949.93 and 70216.84 Da (Figure 1B,C), respectively, much higher than the original MW of the native BSA, 66431.36 Da (Figure 1A). The IR of native BSA was calculated as 3.2, whereas that of the ultrasonicated BSA was 23.4. Ultrasonication improved the glycation extent significantly by >7 times. In addition, compared to the native BSA−galactose, the peak width of ultrasonicated BSA was much broader due to the greater incorporation of galactose. With the changes of molecular weight and peak width taken together, MALDI-TOF mass spectra clearly demonstrated that ultrasound pretreatment significantly improved the glycation

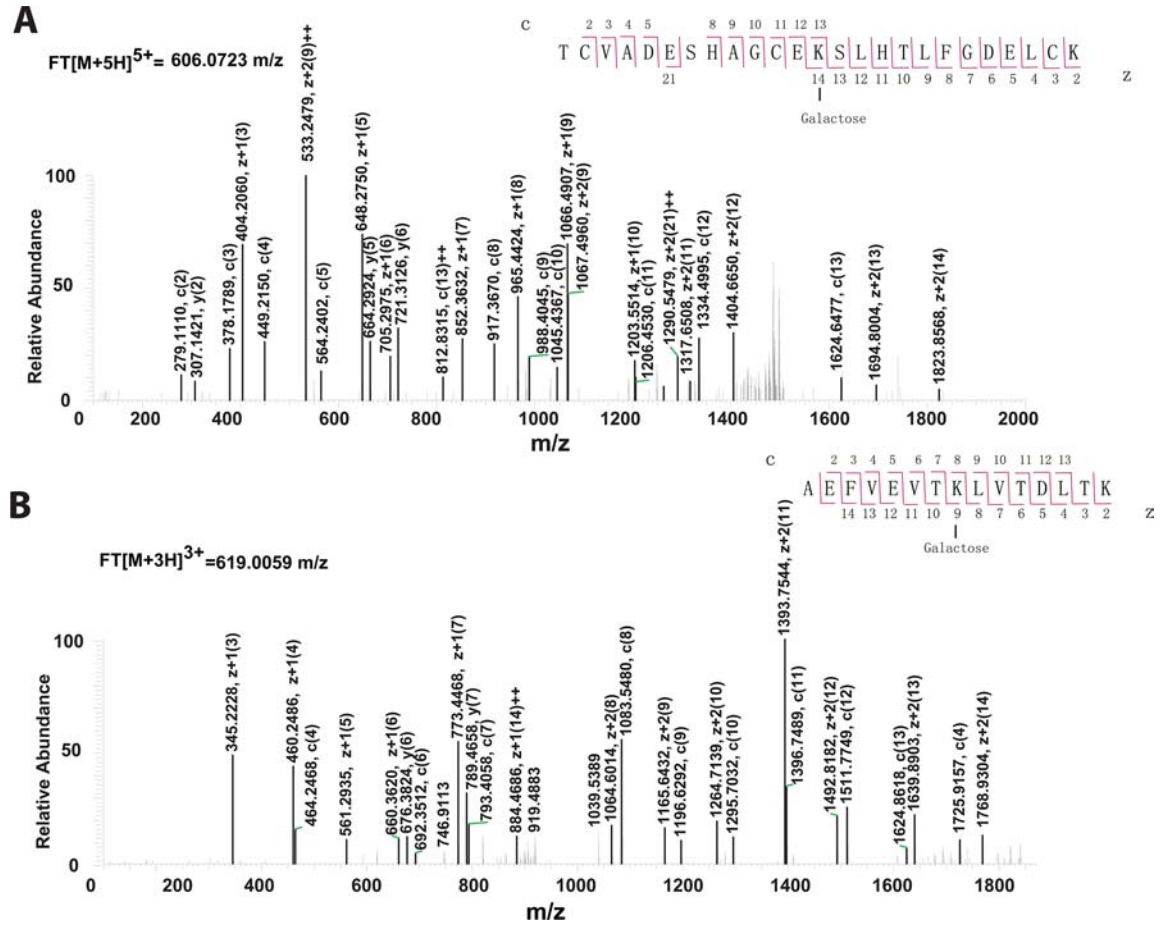

Figure 2. ETD MS/MS spectra of the glycated peptide 52−76 with m/z of 606.0723^{5+} (A) and the glycated peptide 225−239 at m/z of 619.0059^{3+} (B). The sequence of each peptide is shown on top of the peptide. The determined glycation sites are indicated by a line with galactose. The c and z ions are indicated by the numbers and lines.

extent of BSA. To fully understand the effect of ultrasound effect on the glycation extent of BSA, it is essential to obtain a detailed map of the glycation sites of BSA with and without ultrasound pretreatment. Such detailed changes in glycation could not be revealed by MALDI-TOF measurement of the intact molecular weight. To determine glycation sites and glycation extent per peptide, we performed tandem mass spectrometry including HCD and ETD after trypsin digestion.

Glycation Site Determination. Figure 2 shows the determination of glycation sites Lys64 and Lys232 by MS/MS. Both sites were found to be glycated in the native and ultrasonicated BSA. Lys64 is identified in peptide ^{52}TCVADESHAGCEKSLHTLFGDELCK^{76}. The mass of the peptide (3025.3256) matched very well with that of the glycated form (2863.2575 + 162.0528 = 3025.3103), with only a 5 ppm difference. The ETD MS/MS of the peptide generated a series of c and z ions (c1−c13 and z2−z14), unambiguously confirming the sequence of the peptide (Figure 2A). The location of the glycation (Lys64) was obtained by the mass difference between c12 and c13 ions, which is the combined mass of lysine and galactose. It is also confirmed by the mass difference between z12 and z13. Similarly, Lys232 was identified as the glycation site from the ETD fragments of the glycated peptide with m/z of 619.0059^{3+} (Figure 2B). The consecutive c and z ions ensure the positive identification of the peptide sequence and glycation site.

It should be noted that when an arginine or lysine is modified by glycation, trypsin will not be able to cleave at this particular residue, generating a peptide with a miss-cleavage. Therefore, it is common to observe dually and triply glycated peptides, especially when the glycation degree is high. Figure 3A shows the peptide 262−285, which contains three possible glycation sites at lysine 273, 275, and 280, respectively. The m/z before glycation at charge state 5 was calculated as 592.2848; after glycation, three additional ions were found at m/z 624.1098^{5+}, 657.1098^{5+}, and 689.5205^{5+}, representing one, two, and three glycated forms of this peptide, respectively. Similarly, all three potential glycation sites in the peptide 348−377 were also found to be glycated at their respective sites 350, 362, and 375 (Figure 3B).

It is possible for a certain peptide, although exhibiting the mass shift corresponding to monoglycation, to actually contain two (or more) glycated sites. The same modification occurring at different sites generated a mixture of peptides with the same molecular weight. Figure 4 shows one such example. The ion peak with m/z 638.3483^{3+} was found to elute between 4.5 and 5.4 min. The mass of this peptide is calculated as 1912.0201, which is very close to that of the singly glycated peptide ^{218}LSQKFPKAEFVEVTK^{232} (Δm = 0.93 ppm). This peptide contains two possible glycation sites, Lys221 and Lys224. The ETD fragmentation of the ion peak at an elution time of 4.92 min suggests that the glycation occurred on Lys221 with the Mascot score of 55 (Figure 4A). At a little earlier elution time of 4.87 min, an ion peak with m/z 479.0122^{4+} appeared and was selected for ETD fragmentation. The mass of the peptide is 1912.0157, also matching the peptide 218−232 with monoglycation (Δm = −1.34 ppm). The tandem mass spectrum of this ion peak indicates that the glycation mostly occurred on Lys224, instead of Lys221, with the Mascot score of 58 (Figure 4B). The results highlight the importance of the efficient ETD fragmentation on the determination of the modification sites. Due to the high similarity between these two peptides, the two mass spectra are almost indistinguishable except for a few fragment ions. The key fragment ions to distinguish the Lys221 modified peptide from the Lys224 modified peptide are c4 (m/z 636.3538) and z9 (m/z1197.6163). The appearance of a c4 ion in the former peptide

dx.doi.org/10.1021/jf5002765 | J. Agric. Food Chem. 2014, 62, 2522−2530

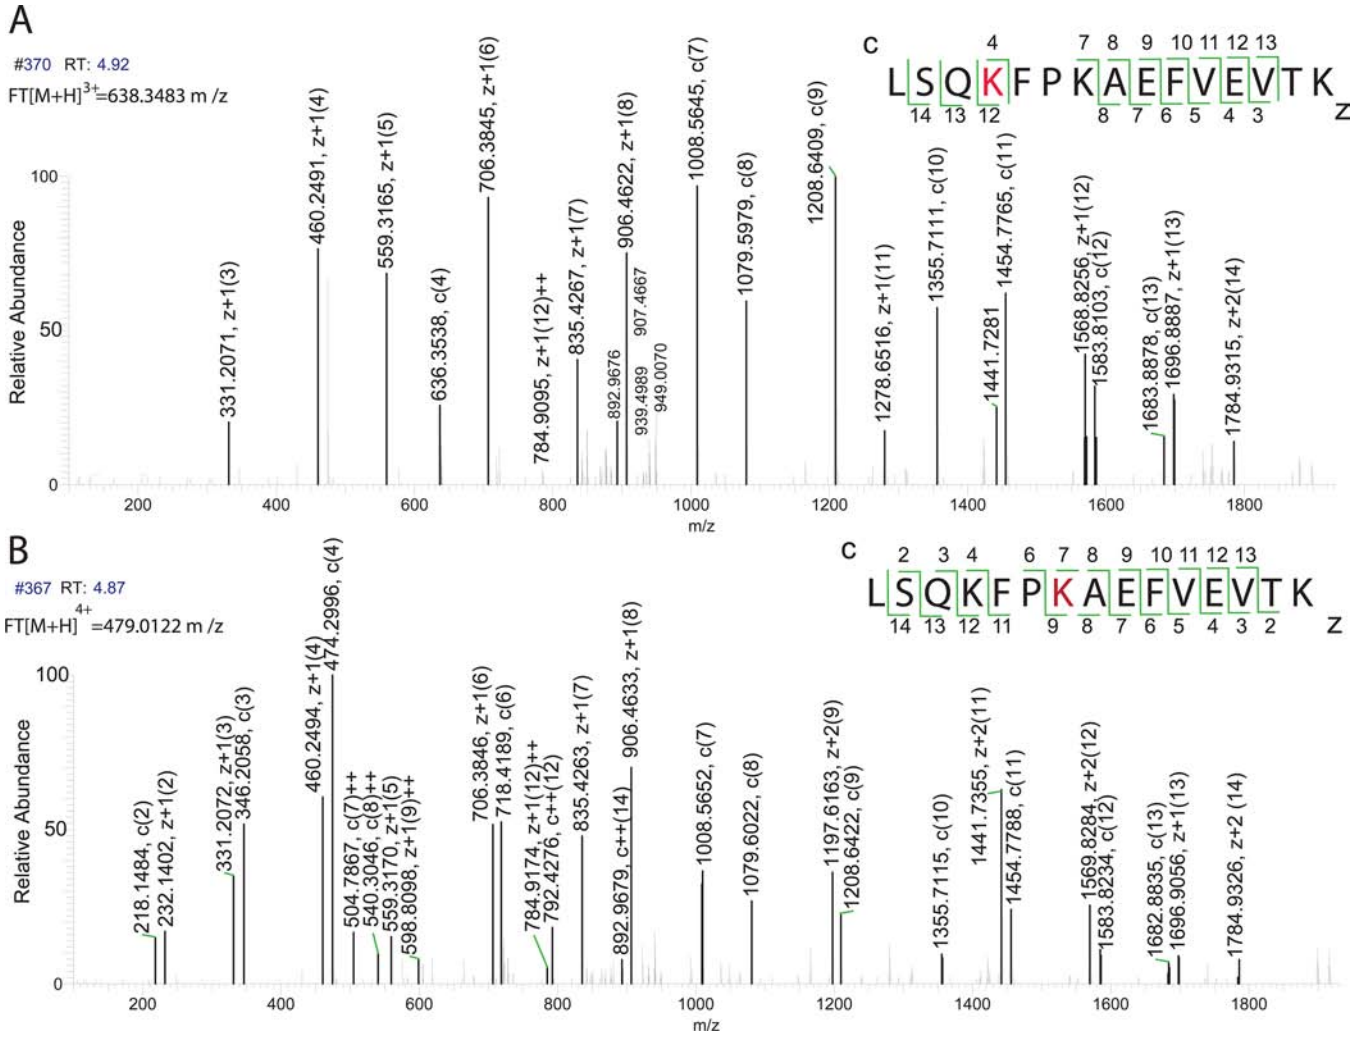

Figure 4. ETD MS/MS spectra of the singly glycated peptide 218−232 at different elution times and charge states: (A) RT = 4.92 min, charge state of 3 with m/z 638.3483^{3+}; (B) RT = 4.87 min, charge state of 4 with m/z 479.0122^{4+}. The MS/MS results indicated these two peptides are not identical, although they showed the same mass. The former is glycated at the position of 221 and the latter at the position of 224 as indicated by the colored lysine residues. The c and z ions are indicated by numbers and lines.

and a z9 ion in the latter provides unambiguous identification of the location of the glycation.

Table 1 shows the sequence and glycation sites of all glycated peptides under both conditions, determined by combined accurate mass and tandem mass spectrometry. BSA contains a total of 82 potential glycation sites including 59 lysines and 23 arginines. Before ultrasonic pretreatment, BSA was found to be glycated at only 12 sites (11K + R), including Lys64, Lys127, K173, Lys204, Lys232, Arg256, Lys280, Lys316, Lys396, Lys439, Lys524, and Lys544. After ultrasonic pretreatment, 42 sites including 39 lysines and 3 arginines were glycated. In addition to the 12 sites in untreated BSA, Lys20, Lys51, Lys76, Lys93, Lys131, Lys136, Lys211, Lys221, Lys224, Lys239, Lys261, Lys273, Lys275, Lys312, Lys322, Lys350, Lys362, Lys375, Lys388, Lys413, Lys465, Lys471, Lys474, Lys499, Lys504, Lys520, Lys523, Lys563, Arg81, and Arg444 were found to be glycated after the ultrasonic pretreatment. The majority of the glycated sites occurred on lysines, as represented by 11 of 59 (19%) and 39 of 59 (66%) lysines in untreated and treated BSA, respectively. In contrast, only 1 of 23 arginines was glycated in native BSA, and only 2 more were found to be glycated after ultrasonication. Given the reduced freedom of the amine group by steric effects from neighboring atoms, it is not surprising to see the much reduced glycation on arginine relative to lysine. Our glycation results are consistent with previous studies in which the glycation predominantly occurred on lysine but not on arginine.[7,8,29] It is worth emphasizing that arginine glycation has not been observed either in our previous study or in the other group's dry-heating of BSA.[8,29] The high-resolution mass accuracy and the versatile fragmentation methods (HCD + ETD) offered by LTQ-Orbitrap are the major contributions for finding the glycation on arginines because it enables unambiguous identification of the glycation sites, especially for those peptides containing multiple glycation sites.

Ultrasonication on the Glycation Extent of BSA. The glycation extent of a protein can be evaluated by (1) the number of the sites that are glycated and (2) the glycation extent per glycation site. When the number of glycation sites is not adequate to assess the glycation extent of the protein, the glycation extent described by DSP can be applied for additional information. In our case, we aim to compare the difference in glycation before and after ultrasonic pretreatment. The effect of this treatment has been clearly demonstrated by the drastically

[a]C* means the cystine residue alkylated by carbamidomethyl. [b]The additional glycation sites after ultrasonic pretreatment are indicated in bold.

increased glycation sites. However, for those sites modified under both conditions, it is necessary to calculate DSP to evaluate the degree of the glycation.

Figure 5 shows mass spectra of the peptides and their corresponding glycated forms before and after ultrasonic pretreatments. The glycated forms of the peptides can be easily determined from the mass difference induced by glycation. Theoretically, if a peptide was monoglycated by galactose, the corresponding m/z peaks with one, two, three, four, or five charges will display a mass increase of 162.0528 Da, with m/z changes of 162.0528, 81.0264, 54.0176, 40.5132, and 32.4106, respectively. For example, the mass spectra of a peptide with a mass of 1356.6357 (m/z 399.2015^{+3}) shown in Figure 5B, the accurate mass and MS/MS determined that it was peptide ^{199}C(carbamidomethyl)ASIQKFGER^{208}. The peak with m/z shift of 54.0178 (m/z 453.2193^{+3}) indicated that one galactose molecule was added to the peptide 199−208, which was again confirmed by MS/MS. The relative abundance of the unglycated form of this peptide was 33.03% before ultrasonication after normalization against the glycated peptide peak. After ultrasonication, the relative abundance decreased to 4.87%, suggesting that the ultrasonication increased the degree of glycation of this peptide. Figure 5C displays another example of this type of ultrasonication effect on the glycation. The accurate mass and MS/MS determined the ion peak with m/z 564.9879^{3+} is the peptide 225−239. An ion peak appeared at the same elution time with the mass addition of 162.0528 Da, indicating one galactose molecule was added to the peptide. The relative abundance of the glycated form of this peptide increased from 25.57 to 100% after ultrasonication, whereas the relative abundance of the unglycated form of this peptide decreased from 100 to 45.99% after ultrasonication. This indicates that the ultrasonication increased the glycation degree of this peptide. Some other peptides containing glycation site(s) without ultrasonic pretreatment are also shown Figure 5, including 115−136 and 538−556 (Figure 5A,D). The mass spectra of these peptides after ultrasonication are shown underneath (purple trace). Comparison of each mass spectral pair depicted the changes of the degree of glycation of each peptide, with all of the peptides showing improved glycation after ultrasonication.

Figure 6 shows the DSP for all of the glycated peptides with and without ultrasonic pretreatment. On the basis of the DSP value, K64 and K204 are the most reactive galactose glycation sites in native BSA with DSP close to 0.8. The ultrasonic pretreatment further increased their DSP to almost full extent at 1.0. For other peptides, most of the DSP values are significantly improved by the ultrasonic pretreatment. It should be

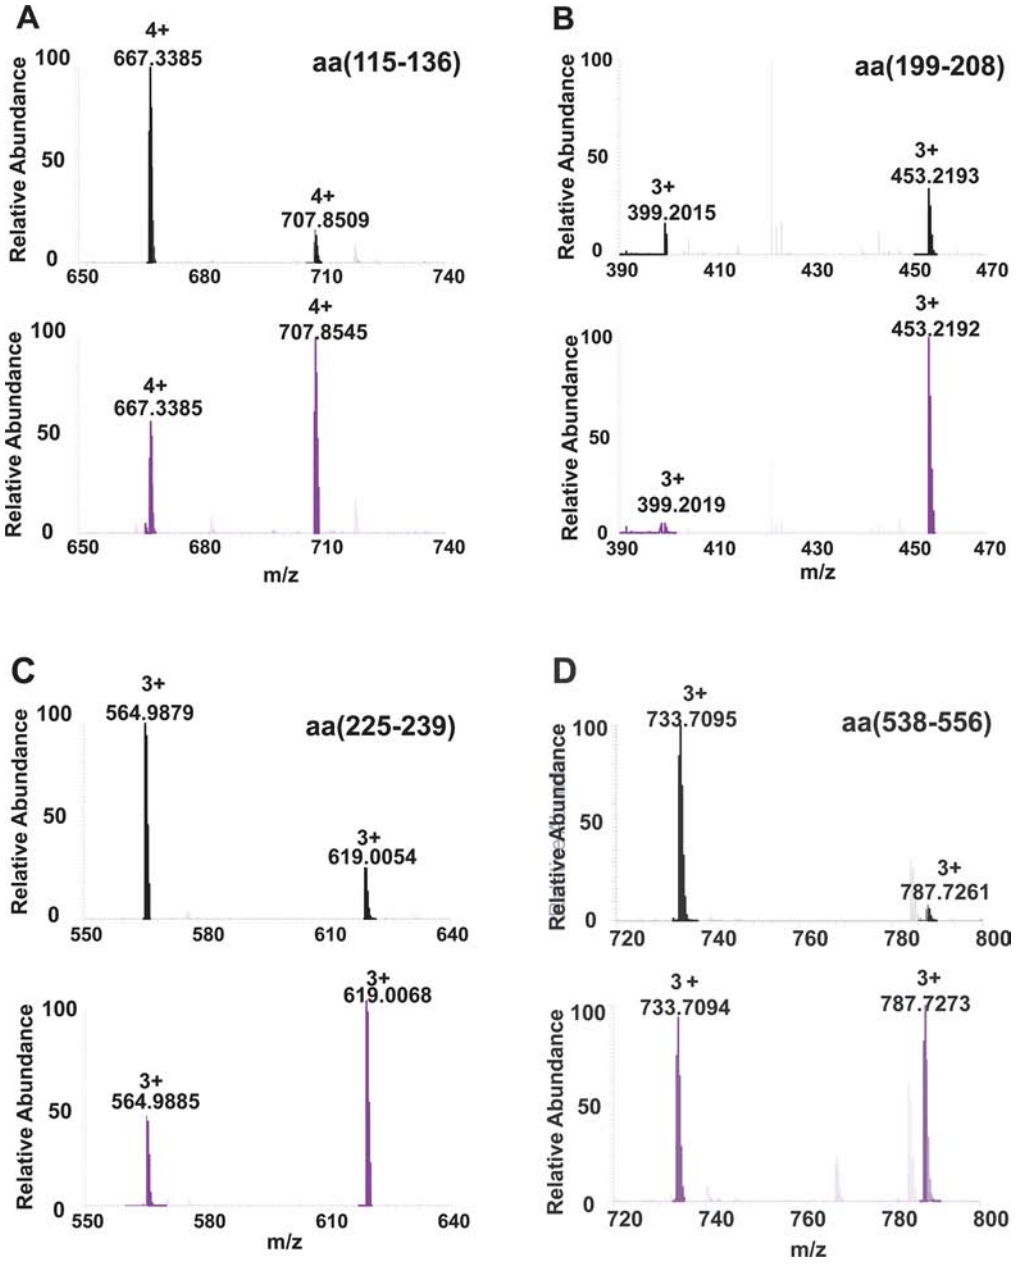

Figure 5. Mass spectra of presentative glycated peptides of BSA after trypsin digestion in both the native and ultrasonicated BSA: peptides 115−136 (A), 199−208 (B), 225−239 (C), and 538−556 (D). Black spectra are the native BSA, and purple spectra are the ultrasonicated BSA.

noted that some peptides, K136 and K474, reached the full glycation with DSP value of 1.0 even though they were not glycated in the native form. This suggests that the protein underwent a structural change under the influence of ultrasonication, exposing some regions of the protein to the solvent and, therefore, gaining more accessibility to the glycation. Because the increased DSP values are distributed all over the protein, this structural perturbation occurred throughout the protein (Figure 6). BSA can be divided into three domains, including domain I comprising residues 1−184, domain II comprising residues 185−377, and domain III comprising residues 378−583.[2] The additional glycation sites induced by ultrasonication occurred in all three domains, including 7 sites in domain I (K20, K51, K76, R81, K93, K131, K136), 12 glycation sites in domain II (K211, K221, K224, K239, K261, K273, K275, K312, K322, K350, K362, K375), and 11 sites in domain III (K388, K413, K465, K471, K474, K499, K504, K520, K523, K563, R444). Taken together, both the increased DSP values and increased glycation sites throughout all three domains suggest that the protein underwent a prevalent structural change in response to ultrasonication. This has been confirmed in a separate conformational study by hydrogen/deuterium exchange and mass spectrometry (data not shown). We have previously performed a similar study on BSA glycation under the influence of DHPM.[29] Under both of these two pretreatments, the glycation sites and glycation extent per glycation site are all significantly improved. Despite the similarity, the conformational changes in response to ultrasonication are actually different from those occurring under the influence of DHPM. The conformational changes induced by DHPM are mainly in domains II and III, but not domain I. In contrast, the ultrasonication-triggered conformational changes are distributed throughout all three

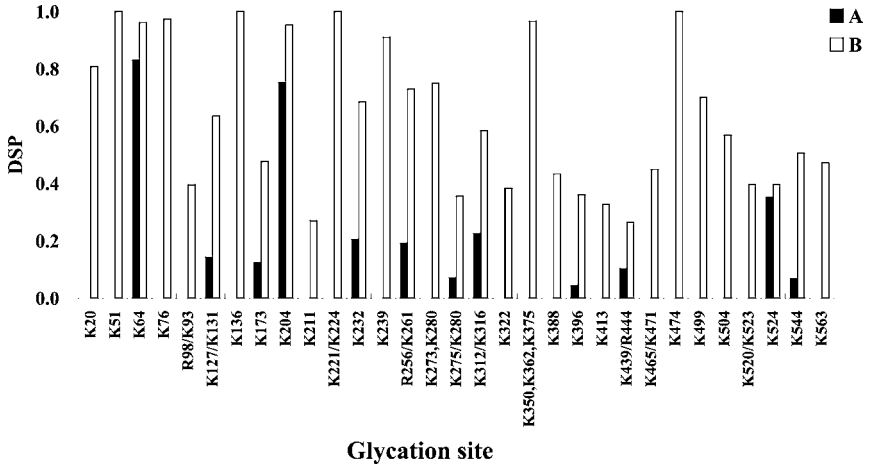

Figure 6. DSP values of glycated sites of native BSA (A) and BSA pretreated by ultrasound (B).

domains. The applications of these two pretreatments are quite similar; both are used in industry to make emulsions and to produce homogenized liquid.[30] The principle of DHPM resides in dividing a pressure stream into two parts, passing each part through a fine orifice, and directing the flows at each other in the microfluidizer interaction chamber. DHPM uses high pressure to guide the flow stream through microchannels in which it generates powerful shear, turbulence, impaction, and cavitation forces that reduce emulsion droplet size.[31,32] The major force responsible for ultrasonically induced effects is cavitation, which is the formation and collapse of vapor cavities in a flowing liquid. It is the collapse of these cavities that causes powerful shock waves to radiate throughout the solution, thereby breaking the dispersed liquid. The major difference between these two methods is that ultrasonication is a high-energy and long process, whereas DHPM is a high-energy but short process. In this work, we applied ultrasound with intensity as high as 150 W/cm^2 on the BSA for 10 min. The calculated energy density (E_v, J/m^3) was 1033 MJ/m^3, much higher than the one applied by DHPM at 100 MPa (~100 MJ/m^3).[26] It is likely that under the higher energy density of ultrasonication, the protein conformation was perturbed to a much higher extent, causing a structural distortion throughout the whole molecule. Consistent with our results, Guzey et al.[33] reported that ultrasound can change the tertiary structure of BSA solution. Ultrasonic pretreatment with temperature control has also been shown to modify the structure of proteins, leading to an increase in surface hydrophobicity.[15,34] It should be noted that in this work, the protein was pretreated with ultrasonication in the absence of sugars. The cavitation effect including the intense heat and pressure generated from ultrasonication will be only applied on the protein, but not directly on the glycation process. The improved glycation after ultrasonic pretreatment was therefore solely contributed from the conformational changes of the protein.

In conclusion, we employed high-resolution Orbitrap mass spectrometry to investigate the ultrasonication effect on the protein glycation. The results demonstrated that ultrasonication altered the protein structure, favoring glycation, indicating ultrasonication is a promising technology for improving protein functionality in the food industry. This approach opens new routes to modify the functionality of proteins in a positive way, providing a way for a better understanding of the structure–function relationship of the glycated proteins.

egg white proteins is rather nonselective. These included ovalbumin, ovalbumin-related protein Y, clusterin, PG D2 synthase, ovotransferrin, lysozyme, and an uncharacterized protein.[15] More recently, ovoinhibitor, extracellular fatty acid-binding protein precursor, and apolipoprotein D precursor were also shown to change in abundance in egg white between day 0 and day 7 of incubation.[18] Additionally, proteomic approaches applied to eggshell membranes from day 1 to day 21 of incubation revealed many proteins exhibiting fluctuation during embryonic development, suggesting a possible specific role according to the embryonic stage.[19] In contrast, there was no similar comprehensive study on yolk protein modification during incubation, although physicochemical properties of yolk are known to change during embryonic development.[20−23]

To investigate the dynamics of egg yolk components in relation to their primary role as a nutritional and physiological support for the embryo during development, we analyzed the proteomic profiles of egg yolk plasma soluble proteins isolated from fertilized and unfertilized eggs at the day of lay and after the first 12 days of incubation (at the end of embryo completion). From the proteomics studies published previously,[7] it seems that the proteins identified in the water-soluble fraction of egg yolk are representative of most of the proteins identified in egg yolk. Indeed the granular fraction is mostly composed of apovitellin, apolipoprotein, and vitellogenin (cleavage products) in high quantities, proteins which are also found in the water-soluble fraction. We believe that the analysis of the water-soluble fraction is more informative than the analysis of the granular fraction. Unfertilized eggs were used as controls to exclude proteins which undergo changes due to storage, such as temperature and automatic reversal, independently of the presence of an embryo. Therefore, this study examines proteomic changes occurring after incubation of fertilized eggs but also as a result of storage/incubation of unfertilized eggs. The results provide a general view on the utilization of egg yolk components by the embryo during incubation but also indicate how storage at high temperature (accelerated aging) can alter the protein profile of egg yolk of unfertilized eggs.

MATERIAL AND METHODS

Preparation of Egg Yolk Plasmas. Nonfertilized eggs (ISA Brown, Hendrix Genetics, St Brieuc, France) and eggs fertilized by artificial insemination (INRA, UE1295 Pôle d'Expérimentation Avicole de Tours, F-37380 Nouzilly, France) were collected at the day of lay and 12 days after incubation (45% hygrometry, 37.8 °C, automatic reversal every hour, INRA, UE1295 Pôle d'Expérimentation Avicole de Tours, F-37380 Nouzilly, France). At day 0 (day of lay) and day 12, egg yolks from eight eggs were independently collected, diluted 1:10 (w/v) in demineralized water, acidified to pH 5 with HCl according to Mann et al., [24] and centrifuged 1 h at 10 000*g*, 4 °C, to pellet the granular fraction of egg yolk. The resulting supernatants were dialyzed against 50 mM Tris-HCl, 50 mM NaCl, pH 7.4 for 24 h at 4 °C. Clarified egg yolks (egg yolk plasmas) were obtained after centrifugation at 4 °C for 1 h at 10 000*g*. All experiments were conducted according to the European legislation on the "Protection of Animals Used for Experimental and Other Scientific Purposes" (2010/63/UE) and under the supervision of an authorized scientist (S. Réhault-Godbert, Authorization no. 37-144).

The protein concentrations of each sample were determined using the Protein Dc Assay (Bio-Rad, Marnes-la-Coquette, France) and bovine serum albumin (Sigma-Aldrich, Saint-Quentin-Fallavier, France) as the standard. All samples were lyophilized and further analyzed by SDS-PAGE under denaturing, but nonreducing, conditions using 12.5% acrylamide-bisacrylamide gels and Coomassie Blue staining.

Preparation of Peptides. Reduction, carbamidomethylation, and enzymatic cleavage of yolk proteins were performed using a modified FASP (filter-aided sample preparation) method.[25] Fifty microgram aliquots of egg yolk proteins were dissolved in 100 μL of 0.1 M Tris, pH 8, containing 6 M guanidine hydrochloride and 0.01 M dithiothreitol (DTT). This mixture was heated to 56 °C for 60 min, cooled to room temperature, and loaded into a Microcon YM-30 centrifugal filter device (Millipore). DTT was removed by centrifugation at 13 000 rpm in an Eppendorf benchtop centrifuge model 5415D for 10 min and washing with 2 × 1 vol of the same buffer. Carbamidomethylation was done in the device using 0.1 M Tris buffer, pH 8, containing 6 M guanidine hydrochloride and 0.05 mM iodoacetamide and incubation for 45 min in the dark. Carbamidomethylated proteins were washed with 0.05 M ammonium hydrogen carbonate buffer, pH 8, containing 2 M urea, and centrifugation as before. Trypsin (1 μg, sequencing grade, modified; Promega, Madison, WI) was added in 40 μL of the same buffer, and the devices were incubated at 37 °C for 16 h. Peptides were collected by centrifugation, and the filters were washed twice with 40 μL of buffer. The peptide solution was acidified to pH 1−2 with trifluoroacetic acid, and peptides were cleaned and concentrated using five successive C18 Stage Tips.[26] The eluate of all five StageTips was combined for mass spectrometric analysis.

Mass Spectrometric Analysis and Evaluation. Peptide mixtures were analyzed by LC_MS/MS using an LTQ Orbitrap Velos mass spectrometer (Thermo Fisher Scientific, Bremen, Germany)[27] as described before.[28] Raw files were processed with MaxQuant (http://maxquant.org/)[29−31] version 1.3.8.1. The initial peptide mass tolerance was set to 20 ppm, and the main search tolerance was set to 6 ppm. The false discovery rate (FDR) for both peptides and proteins was set to 0.01. The maximal posterior error probability (PEP, the probability of each peptide to be a false hit considering identification score and peptide length) was set to 0.01. Carbamidomethylation was set as fixed modification. Variable modifications were oxidation (M), *N*-acetyl (protein), pyro-Glu/Gln (N-terminus), and deamidation (N,Q). The required minimal peptide length was seven amino acids, and two miss-cleavages were allowed. The Requantify and the Label-Free Quantitation (LFQ) option [32] were enabled, together with the Match between runs option using a time window of 2 min. The minimal ratio count for LFQ was set to 2. The database was a *Gallus gallus* subset of UniProt release 20012_8, containing 27 027 entries (http://www.uniprot.org/) combined with the reverse sequences and sequences of common contaminants. In general, only protein identifications with more than two sequence-unique peptides distributed in at least two replicates were accepted. Exceptions were proteins sharing peptides with similar proteins or fragments of the same protein. Label-free quantitation required the presence of 12 (of 16 possible) valid LFQ intensity values in at least one group of replicates belonging together, and the presence of at least two peptides in the razor + unique peptides column. The results of label-free quantitation were analyzed using an ANOVA multiple-sample test and hierarchical clustering provided by Perseus (http://maxquant.org/)[29−31] version 1.3.8.1. Because not all proteins yielded peptides in all replicates, missing intensity values were imputed using values from a suitable Gaussian distribution for minor proteins. One-way ANOVA was done with a permutation-based false discovery rate of 0.01 for truncation. Hierarchical clustering was done after *Z*-scoring to analyze the enrichment among all four samples (Perseus (http://maxquant.org/)).

RESULTS AND DISCUSSION

As a preliminary study, we collected samples of egg yolks at day 0, 4, 8, and 12 of incubation. The first analysis by SDS-PAGE of all our samples, collected and treated under identical conditions, indicated either a high heterogeneity between samples collected at day 4 or 8 and/or no dramatic change as compared with day 0 and day 12, respectively (Figure 1). The

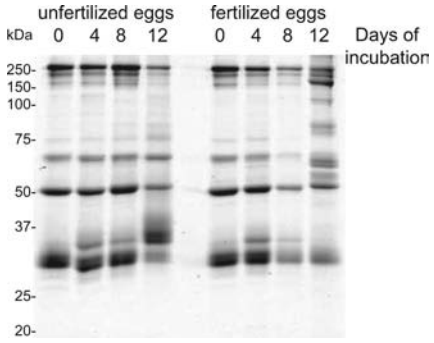

Figure 1. SDS-PAGE analysis of egg yolks from unfertilized and fertilized eggs at 0, 4, 8, and 12 days of incubation. Samples (10 μg) were prepared as described in Material and Methods.

most dramatic changes in protein band pattern were observed between day 0 and day 12 of incubation (Figure 1). From this preliminary study, we decided to compare the proteomes of egg yolk samples from fertilized and unfertilized eggs (as a negative control reflecting the absence of an embryo) at the day of lay and after 12 days of incubation. Of each of the four conditions, eight eggs were used for yolk plasma preparation, and each sample was independently analyzed twice. The resulting 64 raw files were combined for protein identification with MaxQuant. This resulted in the identification of 127 proteins that were distributed into 143 groups by MaxQuant (Supplementary Table S1). The reason for the discrepancy between protein groups and proteins was the occurrence in the database of fragments of the same protein in different entries and entries containing almost identical sequences. These latter may represent variants or isoforms containing possible micro-heterogeneities or may be due to sequencing errors. For these same reasons, the number of identified proteins may not be absolutely correct. Additional information about the protein groups, such as number of proteins in a group, additional accession numbers, peptide counts in different replicates, sequence coverage, and LTQ intensities, is provided in Supplementary Table 2. Peptide sequences and relevant data about peptides, such as distribution among replicates, scores, and posterior error probability (PEP), are contained in Supplementary Table 3. Both files also contain protein identifications not accepted because they did not meet the quality criteria, for instance, identifications with only one unique peptide. Contaminant entries and reverse hits were removed, except for contaminant peptides shared with chicken proteins.

Twenty-one of the protein groups were not identified in yolk in previous proteomic studies (Supplementary Table 1). Ten of these were immunoglobulins, a well-known fraction of the yolk proteome that varies in composition depending on hen environment. Chicken immunoglobulins (IgY) are transferred from the blood of the hen to the yolk by oocyte membrane receptors.[10] During incubation, IgY molecules are exported from the embryomic yolk sac into the blood of the embryo after binding to the chicken yolk sac IgY receptor by a pH-dependent mechanism.[33] This passive immunity is of major importance for the developing embryo because its immune system matures only after hatching. Presence and concentration of IgY molecules depend on the exposure of the mother to pathogenic and nonpathogenic microbes. Because the laying hens used in this study were not bred under controlled or sterile conditions, IgY profiles were not considered as relevant in the following sections. Other proteins, ADP-ribosyl cyclase CD157, gamma-glutamyl hydrolase, apolipoprotein A-IV, 14−3−3 zeta protein and chondrogenesis-associated lipocalin, ovosecretoglobulin, and mucin 5B, were previously identified in other egg compartments[4,5,7,11,16,28,34−37] but were identified for the first time as yolk components in the present study. Only three minor proteins were apparently identified in the chicken egg for the first time. These were α-fetoprotein, a major plasma protein produced by the yolk sac and the liver during fetal life,[38] an uncharacterized peptidase belonging to the C1 family (F1NHB8), and an uncharacterized protein with predicted Chitinase activity (F1NMM2), which is highly expressed in the stomach and the liver of chickens.[39] The presence of this latter protein in the yolk is consistent with the hepatic origin of yolk constituents. Figure 2 shows a typical annotated MS/MS spectrum for each of these new egg proteins.

For label-free quantitation, the protein distribution was analyzed with ANOVA to detect significant differences among the four sets of biological replicates, FE_D0 (fertilized, day 0), FE_D12 (fertilized, day 12), UFE_D0 (unfertilized, day 0), UFE_D12 (unfertilized, day 12). The thresholds defined in section 2.3 left 81 protein groups for quantitation. Seventy-three of these protein groups, likely representing a maximum of 69 individual proteins, showed significant differences among the sets of replicates (Supplementary Table 4).

Hierarchical clustering (Figure 3) of the data was performed to group proteins with similar change in relative abundance according to the nature of the sample (unfertilized or fertilized) and the length of incubation (D0 and D12). Four clusters, C1 to C4, were defined (Figure.3) and will be described in the following sections.

Cluster 1: Proteins with Increased Relative Abundance in Fertilized Eggs after 12 Days of Incubation. Hierarchical clustering revealed five proteins that were significantly enriched in the proteome of yolks of fertilized eggs after 12 days of incubation as compared to other conditions (Cluster 1, Table 1, Figure 3). These were vitronectin, α-fetoprotein, F2/thrombin, apolipoprotein B (distributed over several entries), and apovitellenin-1. One of these proteins, α-fetoprotein (GeneID: 422652, Table 1, bold), was a previously unidentified component of the unfertilized/table egg. α-Fetoprotein may play a role in the development of the avian immune system.[40] It is present in a wide range of chicken embryonic tissues, especially in yolk sac, liver, and connective tissues.[38] The significant increase of α-fetoprotein in yolk plasma of 12 day-old eggs is in accordance to previous evidence of a gradual increase in the yolk sac that is then followed by a decline in its synthesis starting at day 14.[41] Apolipoprotein B and apovitellenin-1 are major proteins of the granular fraction of the yolk and the cell adhesion and cell spreading protein vitronectin is a relatively minor protein of this fraction.[7] Vitronectin is a glycosaminoglycan-binding protein found in serum and tissues, which acts as a cell adhesion and spreading factor. This protein was reported to be a major cell adhesion factor in early chicken embryogenesis.[42] The higher relative abundance of these proteins in yolk plasma after incubation may result from solubilization of these proteins from the granules along with the decrease of yolk pH observed during incubation.[43] Apolipoprotein B fragments and apovitellenin-1 are major components of very low-density lipoprotein (VLDL) particles, and their enhanced appearance in the soluble fraction may reflect degradation of LDL in the course of lipid recruitment by the growing embryo.

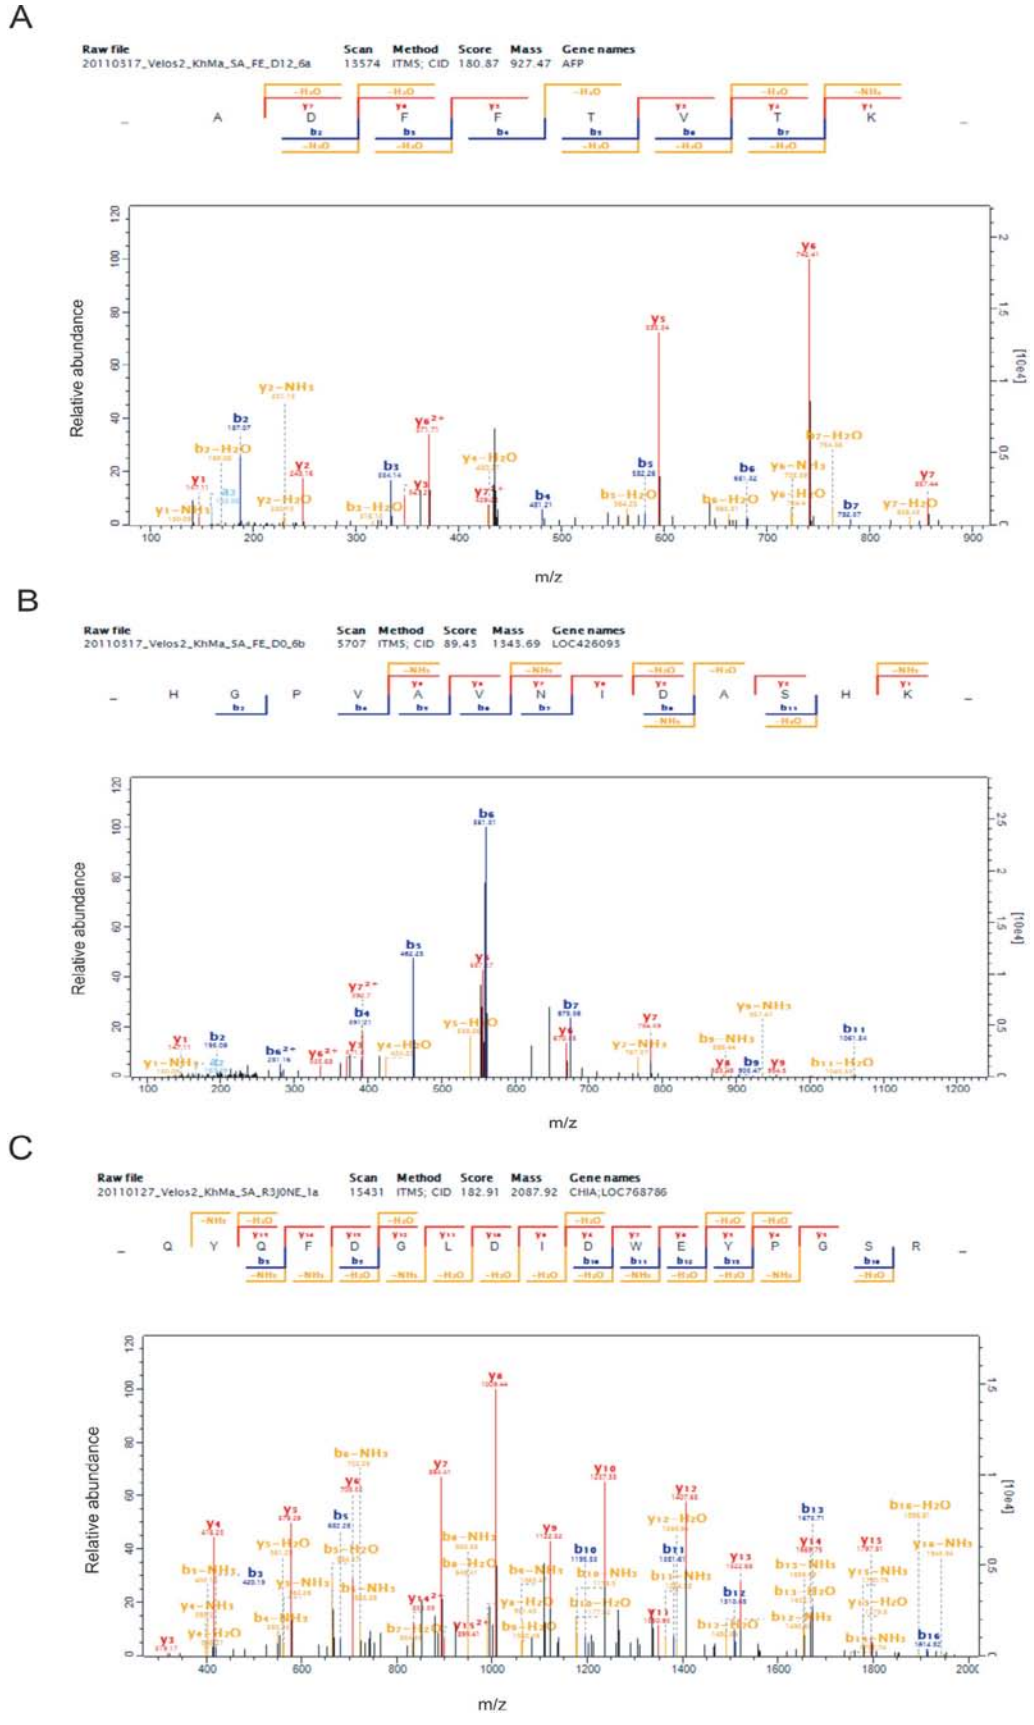

Figure 2. Typical MS/MS spectra of peptides instrumental in the identification of three new minor egg proteins. (A) Spectrum of an α-fetoprotein peptide. This doubly charged peptide was identified with a PEP of 0.0003 and a mass error of −0.75 ppm. (B) Spectrum of a triply charged peptide from F1NHB8_CHICK with a PEP of 0.005 and a mass error of −0.2 ppm. (C) Rather complex spectrum of a long doubly charged peptide of F1NMM2_CHICK with a PEP of 4.9×10^{-31} and a mass error of −2 ppm.

Cluster 2: Proteins with Increased Relative Abundance in Unfertilized Eggs after 12 Days of Incubation. Seventeen proteins of cluster 2 (C2) showed a significant increase in relative abundance in yolks of unfertilized eggs as compared to fertilized eggs after 12 days of incubation (Table 2, Figure 3). Most of these proteins were previously described as major proteins of the egg white and the vitelline membrane,[16,36] but three of them, uncharacterized/ovosecretoglobulin, prostaglandin H2-D isomerase precursor, and mucin 5B, were identified in egg yolk for the first time (Table 2, bold). Several of these proteins were shown to decrease concomitantly in yolk of fertilized eggs upon incubation and may therefore be assimilated by the embryo during its development. These include the two protease inhibitors cystatin and ovoinhibitor, which are likely to regulate the overall proteolytic activity within the yolk compartment, but also ovotransferrin, mucin 5B, and ovoglycoprotein (Figure 3). This group also contains extracellular fatty acid-binding protein (Ex-FABP) and

prostaglandin H2-D isomerase precursor, which belong to the lipocalin protein family and are encoded in genes located within the same genomic locus. Both proteins have been shown to be expressed ubiquitously by embryo tissues with especially high levels of mRNA transcripts in liver and brain.[44,45] Ex-FABP is also associated with heart (GO:0007507) and muscle development (GO:0010831, GO:0045663, GO:0048747), as suggested by Gene Ontology or GO terms (www.geneontology.org). The decreased relative abundance of both proteins in yolks of fertilized eggs after 12 days of incubation may be related to organ development in the embryo.

The observed increase in relative abundance of most of these proteins as compared to proteomes of nonincubated eggs may be due to storage at relatively high temperature (37.8 °C). Deterioration of the perivitelline membrane[46,47] and thinning of egg white upon aging [48] may facilitate the migration of egg white proteins into yolk and thus contribute to the observed increase in relative abundance. To date, the mechanism by which these proteins accumulate in the egg yolk of unfertilized eggs during incubation remains unexplained. No significant relationship between the physicochemical properties of these proteins (molecular mass/pI) and their increased relative abundance in the egg yolk could be found. Approximately 70% of these proteins exhibit an isoelectric point of 5−7 and a molecular weight of 10−50 kDa. However, lysozyme has a pI of about 9, and ovostatin has a molecular weight above 150 kDa (data not shown).

Cluster 3: Proteins with Decreased Relative Abundance in Unfertilized Eggs after 12 Days of Incubation. Cluster 3 contained four proteins exhibiting significant change that were present in both fertilized and unfertilized yolks but decrease in relative abundance specifically in egg yolks of unfertilized eggs during incubation (Table 3, Figure 3). These were a protein similar to the poison toadfish protease natterin, complement factor C3, the junction plaque component plakoglobin, and an uncharacterized protein similar to the desmosomal protein desmoplakin. All four proteins were previously identified as minor yolk components, and their role in egg yolk remains unexplored. Their distribution in yolk replicate groups indicated a loss in unfertilized eggs due to aging.

Cluster 4: Proteins with Decreased Relative Abundance after 12 Days of Incubation of Fertilized and Unfertilized Eggs. Cluster 4 (C4) comprised 43 proteins with a significant decrease in relative abundance after 12 days of incubation in both fertilized and unfertilized eggs (Figure 3, Table 4), including several immunoglobulin chains identified in the egg yolk for the first time. We suspect that the mechanism by which these proteins are decreasing in fertilized versus unfertilized eggs might be different because the presence of an embryo is likely to affect yolk proteins.

If we focus on fertilized eggs, this cluster contained several proteins known to play a role in embryonic development, such as the vitamin-A-binding retinol-binding protein 4.[44,45] Retinol-binding protein 4 has been associated with many biological processes related to embryonic development, [49] including morphogenesis (GO:0048562) and development of heart (GO:0001555; GO:0060347, GO:0007507; GO:0048738,

GO:006004 [50]), lung (GO:0030324), eye (GO:0001654, GO:0060041, GO:0060059), the skeletal system (GO:0048706), the urinary system (GO:0060157), and gonads (GO: 0008584; GO:0048807; GO:0060065; GO:0060068; GO:0060068). Its decrease in yolk of fertilized eggs during incubation suggests that it might be selectively used to for embryonic development. Similarly, we observed a marked reduction in transthyretin abundance in yolk of fertilized egg as compared to other conditions. This protein is known to interact with retinol-binding protein. Our data are consistent with previous observations suggesting a role for transthyretin (previously called prealbumin) in the transport and distribution of thyroid hormone from yolk to embryo prior to establishment of the circulatory system.[50] Yolk riboflavin-binding protein is synthesized by the liver in response to estrogen,[51] secreted into the blood and further transferred to the growing follicles.[52] During incubation, this protein is removed from yolk and egg white and accumulates in embryonic tissues in a complex with riboflavin up to the fourteenth day of incubation.[53] This accumulation in tissues coincides with the disappearance of riboflavin-binding protein from the white and the yolk compartments, [53] which is consistent with the decrease in relative abundance we observed in egg yolk after 12 days of incubation. Superoxide dismutases [Cu-Zn] are known to destroy radicals that are normally produced within the cells and are toxic to biological systems. This antioxidant has been shown to regulate angiogenesis using the model of the chicken embryo chorioallantoic membrane.[54]

Proteins which are decreasing in unfertilized eggs in egg yolk plasma during incubation are mostly "egg-yolk-specific"

dx.doi.org/10.1021/jf404512x | J. Agric. Food Chem. 2014, 62, 2531−2540

proteins (Table 4). The decrease of these proteins in yolk plasma after 12 days of incubation can be explained by at least three hypotheses: (1) endogenous degradation, (2) interaction with lipoproteins and their further relocalization to the granular fraction of the yolk, and (3) diffusion toward the egg white or other compartments. With regard to the first hypothesis, we know that several proteases are present in egg yolk, including aspartic proteases such as "similar to nothepsin",[5,7,55] many proteases involved in inflammatory cascades including thrombin and coagulation factors,[11] and matrix metalloproteinase 2.[56] These various proteases could regulate the activity of some egg yolk proteins and their subsequent degradation. Alternatively, we cannot exclude that the proteins identified in the plasma fraction at the day of lay are not recovered in this plasma fraction after incubation. Indeed, the texture and the chemical modification during incubation might affect the solubility of these proteins, which could then associate with the granular fraction of the egg yolk rather than with the plasma. Another explanation is related to the possible exchange of material between egg yolk and egg white during incubation at 37.8 °C. No significant increase in egg yolk proteins has been reported in the egg white of table eggs (unfertilized eggs) stored at ambient temperature up to 40 days.[48] However, the conditions of incubation used in our assay, a higher temperature together with the control of relative humidity and automatic egg turning, might slightly modify the dynamics of protein exchange and the physicochemical nature of egg proteins.

To our knowledge, this study is the most detailed work available at present on the change of egg yolk protein content occurring during early embryogenesis. In the present study, we have analyzed the effect of fertilization on the yolk plasma proteome after 12 days of incubation and tried to discern changes due to embryonic development from changes due to the aging processes by comparing yolks of fertilized to yolks of unfertilized eggs incubated under the same conditions. The latter results may also be applicable to the storage of table eggs although the conditions used (37.8 °C, constant relative humidity, automatic turning) were not the same as commonly used in supermarkets or homes. We suggest that these conditions may reflect some kind of accelerated aging. It turned out that in many instances, the influence of embryo development and aging overlapped to some degree with most of the identified proteins (Cluster 4). Although the decrease in relative abundance of many proteins in yolks of fertilized eggs may preferentially be attributed to their use by the developing embryo, especially if the decrease is more pronounced in fertilized eggs than nonfertilized eggs, decreases in relative abundance more pronounced in unfertilized eggs (Cluster 3) or increases under certain conditions (Clusters 1 and 2) are more difficult to explain. This analysis performed on the water-soluble fraction of egg yolk (plasma) revealed a likely interaction between yolk plasma and granules, as some proteins might be gradually solubilized from granules during incubation. We also found several proteins, including antiproteases and chelators, that were significantly less abundant after 12 days of incubation as compared to other conditions, providing some clues to study more precisely the kinetics of absorption of some specific egg proteins by the embryo and the regulation of absorption in relation to embryonic stages. Additionally, the study on unfertilized eggs may help to understand possible connections between egg compartments during storage of table eggs and how egg quality can be affected when using inappropriate storage conditions. This work has shown that many proteins initially identified in the egg white and the vitelline membrane increase in relative abundance in the egg yolk after 12 days (Cluster 2). In contrast, decreases in relative abundance could be due either to endogenous degradation by proteases or diffusion of yolk plasma proteins to egg white or the yolk granular fraction upon aging. It is known that the perivitelline membrane not only deteriorates during embryonic development in fertilized eggs but also in stored unfertilized eggs. At the same time, the egg white of unfertilized eggs show the well-known thinning that may be the consequence of reorganization of egg white protein interactions and which could enhance diffusion of proteins to the other compartments. The relatively high temperature used in this study may enhance such processes. Furthermore, the loss of certain proteins may apparently increase the relative abundance of others.

the glucuronidation of resveratrol. Hence, it is important to evaluate the first-pass effect for stilbenes.

In this study, we investigated the absorption and metabolism of piceatannol in rats. We then determined the plasma concentration of piceatannol and identified its metabolites following intragastric administration. Furthermore, the AUC values for intact compounds and their respective metabolites were determined following administration of piceatannol and resveratrol, and the metabolic pathways were compared.

MATERIALS AND METHODS

Chemicals. Piceatannol (>98.0% purity), isorhapontigenin (>95.0% purity), and rhapontigenin (>98.0% purity) were obtained from Tokyo Chemical Industry (Tokyo, Japan). Resveratrol (>98.0% purity) was obtained from Cayman Chemical (Ann Arbor, MI). Sulfatase Type VIII from abalone entrails (EC 3.1.6.1) and β-glucuronidase Type X-A from *Escherichia coli* (EC 3.2.1.31) were obtained from Sigma (St. Louis, MO). All other reagents were purchased from Wako (Osaka, Japan) and Kanto Chemical (Tokyo, Japan), and were used without any other purification.

Animals and Treatments. Eight-week-old male Sprague−Dawley rats (Japan SLC, Shizuoka, Japan) were used in the study. The rats were housed individually in plastic cages in a room with controlled temperature (21−25 °C) and humidity (40−60%). The rats were maintained on a 12 h dark/light cycle with artificial lighting and received AIN-93G (Oriental Yeast, Tokyo, Japan) and water ad libitum. Following a conditioning period that lasted two or three days, the rats were anesthetized with pentobarbital and the right jugular vein was catheterized with silicone tubing (0.5 mm inner diameter (i.d.), 1.0 mm outer diameter). After the catheterization procedure, the rats were allowed a 1 week postoperative recovery period during which they were fed AIN-93G. Following the recovery period, the rats were fasted overnight and were then administered stilbenes. Thereafter, blood samples were collected from the rats. All animal experiments were carried out with strict compliance with the Guidelines for Proper Conduct of Animal Experiments by the Science Council of Japan. The experimental protocols and procedures were approved by the Animal Experimental Committee of Morinaga & CO., Ltd.

Experimental Design. Thirty-six cannulated rats were randomly assigned to six equal groups (n = 6) and transferred to plastic cages with stainless wire mesh floor mats. Each group was administered a different dose of piceatannol or resveratrol to evaluate the dose dependency of their absorption. Stilbene doses were based on the previous study by Marier et al.,[15] which examined resveratrol bioavailability and estimated a maximum concentration (C_{max}) of 6.57 ± 1.55 μmol/L and AUC of 7.1 ± 2.0 μmol·h/L following oral administration of 50 mg/kg (219 μmol/kg). The rats received piceatannol or resveratrol prepared with 50% (v/v) polyethylene glycol 400/saline through direct stomach intubation at doses of 90, 180, or 360 μmol/kg (22.0, 44.0, or 87.9 mg/kg for piceatannol and 20.5, 41.1, or 82.2 mg/kg for resveratrol; 2 mL/kg). Blood samples (0.4 mL) were collected from each rat before piceatannol or resveratrol administration, and at 0.25, 0.5, 1, 2, 4, 8, and 24 h after administration. The samples were collected into heparinized tubes directly from the jugular vein catheter. The rats were transferred to metabolic cages after the 8 h blood collection, where they received AIN-93G. The samples were centrifuged (4 °C, 10 min, 5000*g*), and 1/10 volume of a stabilizer (0.4% ascorbic acid/0.02% EDTA disodium/80 mmol/L sodium phosphate buffer, pH 3.6) was added to the plasma samples. Urine samples were collected using pipettes when urination was observed during the 8 h blood collection period, and 1/10 volume of the same stabilizer used for plasma samples was added to the urine samples. The urine samples were combined every four hours. After blood collection for 8 h, the rats were placed in metabolic cages and urine samples were collected in plastic tubes containing the stabilizer once between 8 and 12 h, once between 12 and 24 h, and once between 24 and 48 h following stilbene administration. Plasma and urine samples were stored at −30 °C until analysis.

In the coadministration study, 6 cannulated rats were given a mixture of piceatannol and resveratrol (each at 180 μmol/kg, 44.0 mg/kg for piceatannol and 41.1 mg/kg for resveratrol) through intragastric administration. Blood samples were collected and plasma samples were stored as described above.

Enzymatic Hydrolysis of Conjugated Metabolites in Biological Samples. We hydrolyzed the plasma samples to determine the total amount of piceatannol and resveratrol. The samples were hydrolyzed according to the method of Maeda-Yamamoto et al.,[21] but with slight modification. Briefly, 5 μL of β-glucuronidase (15.6 units) and 5 μL of sulfatase (1.3 units) were added to 50 μL of plasma samples diluted with 90 μL of sodium phosphate buffer (final concentration of 27 mmol/L; pH 6.5) and incubated at 37 °C for 45 min. The reaction was stopped with 300 μL of ice-cold acetonitrile (ACN) as described below.

Plasma Preparation for High-Performance Liquid Chromatography (HPLC) Analysis. Plasma aliquot samples (50 μL) were extracted with 100 μL of ice-cold ACN and centrifuged at 10000*g* for 10 min at 4 °C. The supernatant was transferred to another microcentrifuge tube, and the precipitate was washed with 100 μL of ice-cold ACN and then centrifuged. Thereafter, the supernatant was combined with the previous supernatant and evaporated to dryness in vacuo. The residue was redissolved in 50 μL of the initial mobile phase and used for HPLC analysis. Appropriate dilutions were performed when concentrations fell outside the analytical range (0.2−10 μmol/L). The mean recovery (at 0.2, 0.5, 1, 5, 10, and 50 μmol/L; n = 3) for piceatannol and resveratrol was 95.9% and 95.0%, respectively.

HPLC Analysis of Stilbenes. The stilbenes were analyzed using a Shimadzu (Kyoto, Japan) Prominence HPLC system equipped with an SPD-M20A photodiode array detector. The data were processed using LabSolutions chromatography workstation software (version 1.21; Shimadzu). Chromatographic separations were performed on a Mightysil RP-18 GP ODS column (150 × 4.6 mm i.d., 5 μm; Kanto Chemical) equipped with a Mightysil RP-18 GP guard column (5 × 4.6 mm i.d., 5 μm; Kanto Chemical) at 40 °C, with 0.1% (v/v) phosphoric acid/water as mobile phase A, and 0.1% (v/v) phosphoric acid/ACN as mobile phase B at a flow rate of 1 mL/min. Sample aliquots (10 μL) were injected into the HPLC system and were eluted with the following gradient conditions: 0−2 min, 14% B; 2−30 min, 14−30% B. The eluate was monitored at 320 nm by the detector. Calibration curves were prepared by supplementation with known concentrations (0.2, 0.5, 1, 2, 5, and 10 μmol/L) of piceatannol, resveratrol, isorhapontigenin, and rhapontigenin in the initial mobile phase. The correlation coefficients evaluated by linear regression analysis were 0.999 or above. The limit of detection (LOD) and the limit of quantitation (LOQ) were defined as the concentrations of the stilbenes spiked into blank plasma and prepared according to the method described in the previous section that produced a signal-to-noise ratio of at least 3 and 10, respectively. The LOD and LOQ for stilbenes were 0.1 μmol/L and 0.2 μmol/L, respectively. The intraday and interday precision of assay were assessed with two concentrations as quality control samples (0.5 and 10 μmol/L stilbenes in blank plasma) in triplicate, with precision estimates ranging from 1.0 to 9.4%.

Identification of Stilbene Metabolites. Major metabolites of piceatannol and resveratrol were fractionated from the rat urine samples using the same HPLC system and column described above. Urine aliquot samples (5 μL) were prepared according to the method used for the plasma samples injected into the HPLC system. Elution was carried out with a mixture of 0.1 mmol/L acetic acid/water and ACN at a flow rate of 1 mL/min at 40 °C. The gradient conditions were as follows: (a) 0−2 min, 10% ACN, and (b) 2−50 min, 10−30% ACN. Each peak was monitored at 320 nm and collected individually. The collected peaks were evaporated to dryness in vacuo and dissolved in 50 μL of 0.1% (v/v) formic acid/10% ACN/water.

The fractionated peak aliquots (10 μL) were injected into a Shimadzu Prominence ultrafast liquid chromatography (UFLC) system equipped with a Kinetex 2.6 μm C18 100 Å ODS column

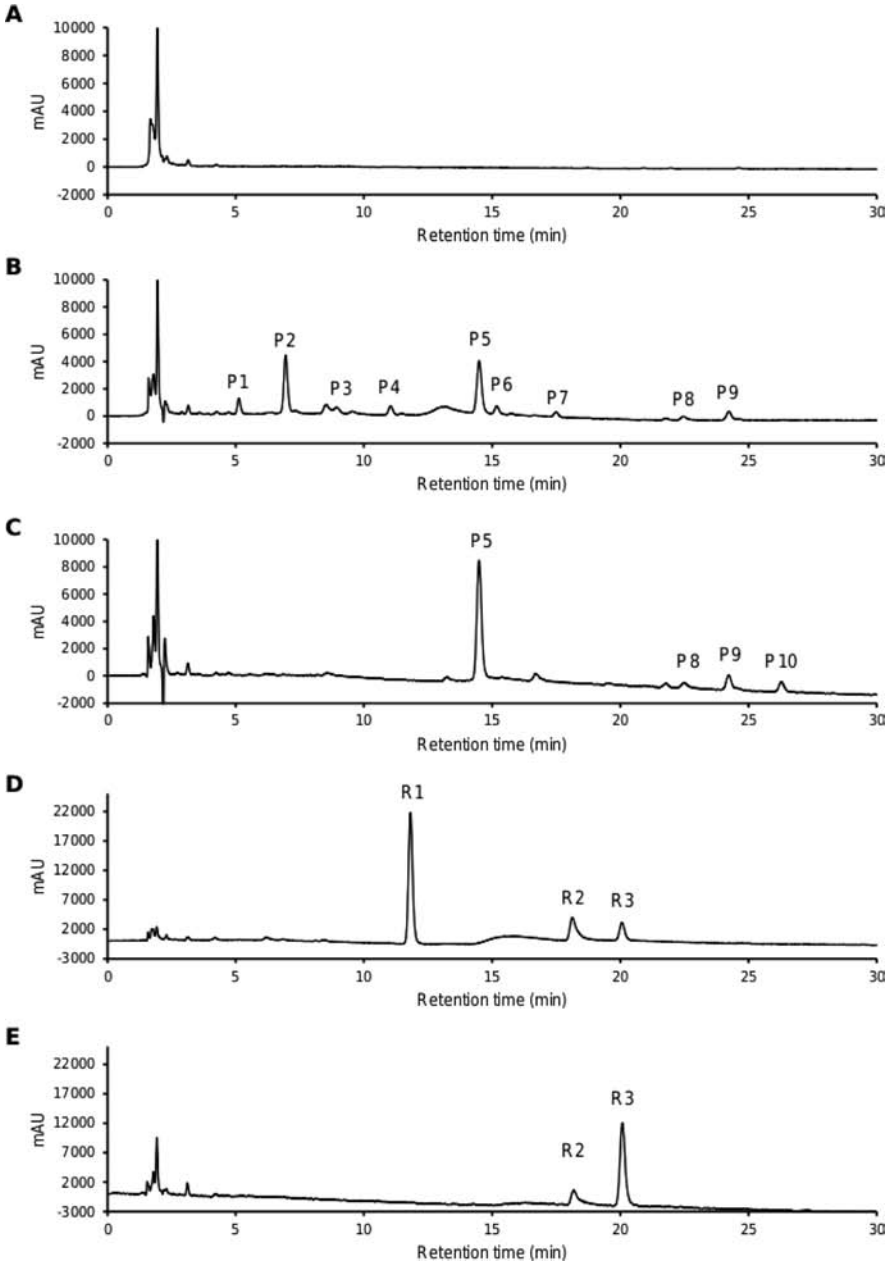

Figure 2. Representative high-performance liquid chromatography (HPLC) chromatograms of rat plasma samples before and 0.5 h after intragastric administration of 360 μmol of stilbene per kg of body weight: (A) before administration; (B) administration of piceatannol; (C) administration of piceatannol, hydrolyzed with enzymes; (D) administration of resveratrol; (E) administration of resveratrol, hydrolyzed with enzymes.

(100 × 2.1 mm i.d.; Phenomenex, Torrance, CA). Elution was carried out at 40 °C, with 0.1% (v/v) formic acid/water as mobile phase A, and 0.1% (v/v) formic acid/ACN as mobile phase B; both were carried out with a flow rate of 0.2 mL/min. The gradient conditions were as follows: (a) 0−2 min, 10% B, and (b) 2−40 min, 10−25% B. The eluate was monitored at 320 nm by using a Shimadzu SPD-M20A. Mass spectrometry analysis was performed using a 3200 QTRAP system (AB SCIEX, Framingham, MA) with an electrospray ionization source. Electrospray ionization tandem mass spectrometry was performed in negative polarity mode with the following settings: curtain gas, 40 psi; nebulizer gas, 50 psi; turbo gas, 80 psi; capillary temperature, 600 °C; ion spray voltage, −4.5 kV; declustering potential, −40 V; and collision energy, −30 V. The full-scan mass spectrum to obtain product ion of the metabolite was collected in the mass range from m/z 100 to 1000.

Data Analysis. Experimental values are expressed as the mean ± SEM. The AUC was calculated using the linear trapezoidal method. The ratio of intact (unmetabolized) compound to total detected signal was calculated by dividing the AUC corresponding to the peak of the intact compound by the total AUC (sum of intact and all metabolites). Linear regression analysis was used to assess the association between the dose and plasma AUC. Statistical significance of differences in mean values between AUC values for piceatannol and resveratrol was evaluated using 2-way analysis of variance (ANOVA) in the individual administration study, and was evaluated by paired sample t-test in the coadministration study. Repeated-measures ANOVA was used to evaluate the time-dependent variation in plasma concentrations between piceatannol and resveratrol for the coadministration study. Student's t-test was used to evaluate the differences in mean AUC values between individual administration and coadministration. Differences were considered statistically significant when $p < 0.05$. All statistical analyses were performed using SPSS version 13.0 J for Windows (SPSS, Tokyo, Japan).

RESULTS

Identification of Piceatannol Metabolites. Figure 2 shows representative HPLC chromatograms of rat plasma samples before and after intragastric administration of piceatannol or resveratrol. No remarkable peak was observed in the plasma before administration (Figure 2A), whereas piceatannol (P5) and several metabolite peaks were detected following piceatannol administration (Figure 2B). Piceatannol and P9 markedly increased together, whereas several peaks (P1, P2, P3, P4, P6, and P7) disappeared when the plasma was hydrolyzed with enzymes (Figure 2C). Moreover, P10 was newly produced after plasma hydrolysis. Resveratrol was undetected in the plasma of any rat that received piceatannol. Following resveratrol administration, a resveratrol peak (R3) was detected in rat plasma with two remarkable hydrophilic peaks (R1 and R2; Figure 2D). When the plasma was hydrolyzed with enzymes, R1 disappeared and R2 only slightly decreased, but resveratrol increased dramatically (Figure 2E). Piceatannol, isorhapontigenin, and rhapontigenin were undetected in the plasma of rats that received resveratrol.

The peaks indicating the metabolites found in rat plasma (P1−P10, R1−R3) were also observed in rat urine (Figure S1 in the Supporting Information); thus, we fractionated the metabolites from urine and identified their mass spectra (Figure S2 in the Supporting Information). Table 1 summarizes the mass spectra for the piceatannol and resveratrol metabolites fractionated from rat urine. As the table indicates, various piceatannol conjugate metabolites were identified. Based on the mass spectra and the disappearance of the peaks after hydrolysis, P1 (m/z 595/419/243) was identified as a diglucuronide metabolite of piceatannol, and both P2 (m/z 419/243) and P4 (m/z 419/243) were identified as monoglucuronide metabolites of piceatannol. Likewise, P3 (m/z 433/257), P6 (m/z 433/257), and P7 (m/z 433/257) were identified as *O*-methyl piceatannol-monoglucuronide metabolites. Although P8 was not hydrolyzed by sulfatase, P8 was considered an *O*-methyl piceatannol-monosulfate metabolite based on the mass spectrum (m/z 337/257). The mass spectra for P9 and P10 were similar to that for *O*-methyl piceatannol. Based on the retention time and the mass spectrum, P9 was identified as isorhapontigenin (3,4′,5-trihydroxy-3′-methoxystilbene; Figure 1) and P10 was identified as rhapontigenin (3,3′,5-trihydroxy-4′-methoxystilbene). In addition to the nine metabolites, other peaks speculated to be piceatannol metabolites were observed in small amounts, but the mass spectra were unidentified. The mass spectra of R1 and R2 fractionated from rat urine after resveratrol administration confirmed that R1 and R2 were conjugate metabolites of resveratrol.

Table 1. Mass Spectra of Metabolites of Piceatannol and Resveratrol

peak	t_R[a]	compound	parent and product ion pairs (m/z)
P1	5.1	piceatannol-diglucuronide	595/419/243
P2	6.9	piceatannol-monoglucuronide	419/243

[a]HPLC retention time.

Plasma Concentration Profiles of Stilbenes. Figure 3 shows the time-dependent plasma concentration profiles for piceatannol and its metabolites following piceatannol administration. Piceatannol and isorhapontigenin were detected in rat plasma, whereas rhapontigenin was undetected at any dose (Figure 3A). Piceatannol reached the C_{max} within 15 min of administration, with the measured C_{max} of 3.3 μmol/L following the 90 μmol/kg dose, 7.5 μmol/L following 180 μmol/kg, and 8.1 μmol/L following 360 μmol/kg. Piceatannol concentration for any dose subsequently declined over time to an undetectable level at 24 h. Isorhapontigenin showed a profile similar to that of piceatannol until 1 h after administration, but at lower concentrations. Isorhapontigenin concentration was almost constant between 1 and 8 h, and trace amounts of isorhapontigenin were detected at 24 h only following 360 μmol/kg administration. The plasma concentration of piceatannol and isorhapontigenin were increased with elevating doses, except the C_{max} of piceatannol between the doses of 180 and 360 μmol/kg.

Conjugate metabolites of intact and *O*-methyl piceatannol were detected in rat plasma after piceatannol administration (Figure 3B). Since P8 was not hydrolyzed, its levels were quantified using the calibration curve for piceatannol and are shown as *O*-methyl piceatannol-monosulfate in Figure 3B. Piceatannol conjugates were the dominant metabolites in plasma up to 2 h after 90 and 180 μmol/kg administration and up to 4 h after 360 μmol/kg administration, but could not be detected at 24 h. Conversely, *O*-methyl piceatannol conjugates were still detectable at 24 h, except for isorhapontigenin conjugates following 90 μmol/kg administration, and *O*-methyl piceatannol-monosulfate following 90 and 180 μmol/kg administration. The plasma concentration of conjugates of intact and *O*-methyl piceatannol was increased with elevating doses.

Plasma concentration reached the C_{max} within 15 min of resveratrol administration, with the C_{max} determined to be 3.8, 3.5, and 5.0 μmol/L following administration of 90, 180, and 360 μmol/kg, respectively (Figure S3 in the Supporting Information). Although the concentration of resveratrol declined within 2 h, secondary peaks appeared at 4 h and were notable following 360 μmol/kg administration, and very small following 180 μmol/kg administration. The plasma concentrations of resveratrol conjugates, including that of R2 quantified using the calibration curve for resveratrol, were much higher than the concentrations of the intact resveratrol. In the analysis of conjugates, notable secondary peaks appeared following 360 μmol/kg resveratrol administration, and, with lower peak AUC, following 180 μmol/kg administration. The concentration of resveratrol and its conjugates tended to increase with higher doses of resveratrol.

The AUC for piceatannol and resveratrol increased in a dose-dependent manner (Table 2). The correlation between AUC and the administered dose was well described by a linear

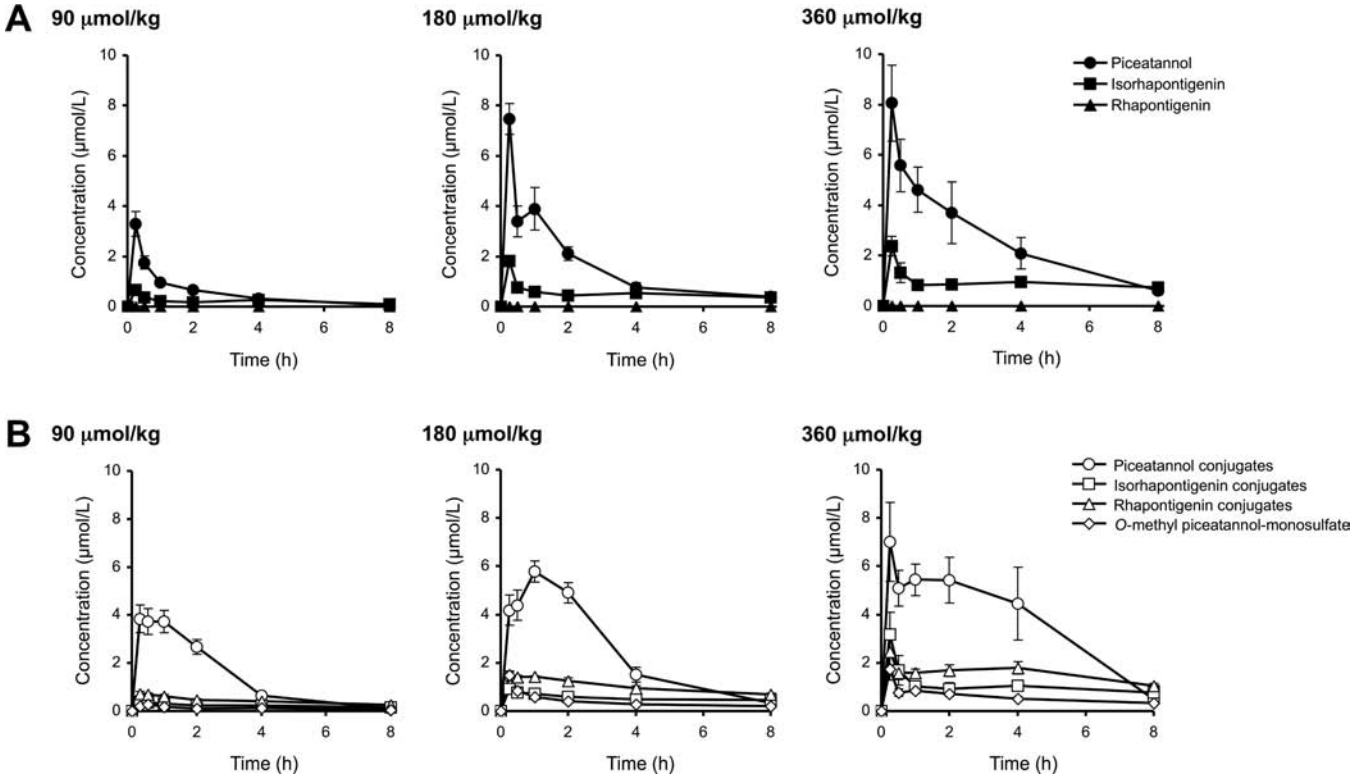

Figure 3. Plasma concentration profiles for piceatannol and its metabolites after intragastric administration of 90−360 μmol of piceatannol per kg of body weight: (A) aglycon and (B) conjugates. Values are expressed as mean ± SEM (n = 6).

regression model, with the coefficients of determination (R^2) for piceatannol and resveratrol estimated as 0.770 and 0.907, respectively. Some correlation between the administered dose and AUC of piceatannol conjugates was detected (R^2 = 0.486), with the AUC increasing with higher doses. The relationship of the AUC with dose for *O*-methyl piceatannol metabolites, resveratrol conjugates, and total piceatannol and resveratrol was good, with R^2 ranging from 0.688 to 0.945. The AUC values for piceatannol were 2.1- to 2.6-fold higher than those for resveratrol, with statistically significant differences found in all comparisons, except for administration of 90 μmol/kg. The total AUC calculated following piceatannol administration was significantly lesser than the AUC calculated for resveratrol. The ratio of intact compound to the total AUC for piceatannol was 3.7- to 4.3-fold higher than the ratio for resveratrol (p < 0.05).

Comparison between Piceatannol and Resveratrol Plasma Concentrations after Coadministration. Plasma concentration was compared between piceatannol and resveratrol after administering a mixture of these two stilbenes (each at 180 μmol/kg). The C_{max} of piceatannol was 4.2 μmol/L at 15 min, whereas the C_{max} of resveratrol was 1.6 μmol/L at 30 min (Figure 4A). Piceatannol concentration was maintained at a level higher than that of resveratrol for up to 8 h following administration. Furthermore, the AUC for piceatannol was 2.1-fold greater than that for resveratrol (p < 0.05; Table 3). In contrast, the total concentration corresponding to piceatannol was less than that associated with resveratrol administration, with statistically significant differences detected at 0.25, 0.5, and 2 h after administration (Figure 4B). Furthermore, the AUC for total piceatannol was significantly less than that for resveratrol. The intact ratio for piceatannol was 3.0-fold higher than that for resveratrol (p < 0.05). The statistically significant differences in AUC values between individual administration and coadministration were detected only for conjugates of isorhapontigenin and rhapontigenin, whereas no significant differences in AUC values of intact compounds or of other metabolites of piceatannol and resveratrol were observed.

DISCUSSION

The focus of our research was to evaluate absorption and metabolism of piceatannol following intragastric administration in rats. Roupe et al. described that only a glucuronide metabolite was evident in rat plasma after intravenous administration of piceatannol.[8] In our study, a monoglucuronide metabolite (P2) was the most abundant metabolite following intragastric administration of piceatannol. However, a number of additional metabolites were also observed in plasma. The difference in the diversity of metabolites identified between the study of Roupe et al. and the current study may be due to differences in the administration routes or, more likely, due to different analytical methods used. In addition to three conjugate metabolites (P1, P2, and P4), four *O*-methyl piceatannol conjugates (P3, P6, P7, and P8) and isorhapontigenin (P9) were identified by liquid chromatography−tandem mass spectrometry (Table 1). In contrast to piceatannol, methylated metabolites were not found with resveratrol. The occurrence of methylation only in piceatannol indicates that the catechol ring of piceatannol was metabolized by catechol-*O*-methyltransferase, as in the case of flavonoids.[22−24] The disappearance of *O*-methyl piceatannol conjugates with plasma hydrolysis was accompanied by an increase in isorhapontigenin and the appearance of rhapontigenin. Therefore, the *O*-methyl piceatannol conjugates (P3, P6, P7, and P8) were considered conjugates of isorhapontigenin and rhapontigenin. The nine piceatannol metabolites shown in Table 1 indicate the major metabolic pathway for piceatannol, involving glucuronidation,

[a]Intact ratio was calculated by dividing the AUC corresponding to the peak of the intact compound by the total AUC, and expressed as a percentage. [b]Values are expressed as mean ± SEM (n = 6). [c]Not detected. [d]Linear regression analysis was used to assess the association between the stilbene dose and plasma AUC. The analysis demonstrated a statistically significant correlation between the dose and AUC for all compounds ($p < 0.05$). [e]Statistical significance of differences in mean values between AUC values for stilbenes was assessed using 2-way ANOVA. When a significant interaction was detected ($p < 0.05$), simple main effect was analyzed for each dose. +, significant difference; −, no significant difference.

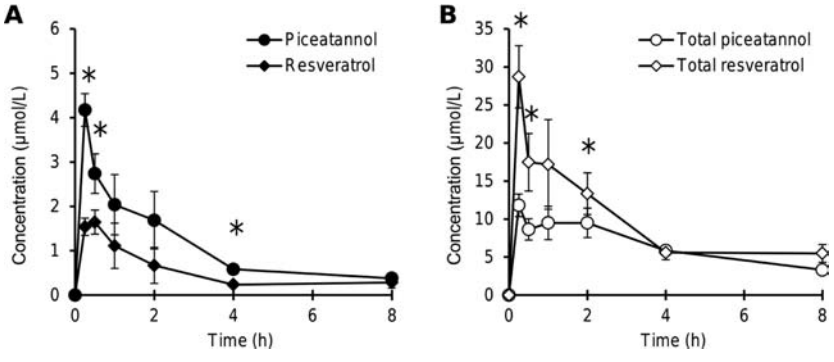

Figure 4. Plasma concentration profiles of piceatannol and resveratrol after intragastric coadministration at 180 μmol per kg of body weight: (A) intact stilbene and (B) total stilbene. Values are expressed as mean ± SEM (n = 6). *Statistically significant differences ($p < 0.05$) between stilbenes were evaluated by using repeated-measures ANOVA.

Table 3. Cumulative Plasma AUCs after Intragastric Co-administration of Piceatannol and Resveratrol to Rats

	AUC_{0-8h}[b] (μmol h/L)	
	piceatannol	resveratrol
intact	8.6 ± 1.3 a	4.1 ± 1.0 b
conjugates	18.8 ± 1.8 a	70.2 ± 5.8 b
isorhapontigenin	4.7 ± 0.6	nd[c]
isorhapontigenin conjugates	6.4 ± 0.8	nd
rhapontigenin	nd	nd
rhapontigenin conjugates	10.2 ± 0.7	nd
O-methyl piceatannol-monosulfate	3.0 ± 0.4	nd
total	51.7 ± 4.4 a	74.3 ± 6.0 b
intact ratio[a] (%)	16.3 ± 1.7 a	5.5 ± 1.3 b

[a]Intact ratio was calculated by dividing the AUC corresponding to the peak of the intact compound by the total AUC, and expressed as a percentage. [b]Values are expressed as mean ± SEM (n = 6). Different letters (a, b) in the same row indicate significant differences ($p < 0.05$) determined using paired sample t-test. [c]Not detected.

sulfation, and methylation. Compared to piceatannol, only two conjugate metabolites (R1 and R2) were detected in the plasma of the rats that received resveratrol. In recent studies, dihydroresveratrol and its conjugates, which are microbiota-derived metabolites, were detected in rat liver, adipose tissue, skeletal muscle, and the colon content following repeated oral administration of 30 and 60 mg/kg resveratrol,[18,20] but not in the plasma.[20] We acquired HPLC chromatograms at 276 nm, the maximal absorbance for quantification of dihydroresveratrol, but no noticeable peak corresponded to a dihydro metabolite of resveratrol. It was not possible at this point to explore the possible presence or absence of the dihydroresveratrol metabolite in rat plasma, because dihydroresveratrol standard was not available. Even though unidentified metabolites of resveratrol were present in the plasma in our study, piceatannol could conceivably have a more complicated metabolic pathway due to the presence of a catechol ring, which enables methylation and increases the number of pathways available for its metabolism. Further studies are required to elucidate piceatannol metabolism.

A remarkable finding was that isorhapontigenin was detected in the intact form as a piceatannol metabolite in rat plasma, whereas, similar to flavonoids,[22,23] rhapontigenin was found only in conjugated forms. Isorhapontigenin has antioxidant, antiarteriosclerosis, and anticancer effects.[25−27] In particular, isorhapontigenin promotes inhibition of cyclooxygenase-1 and cyclooxygenase-2, whereas piceatannol does not.[27] Therefore, piceatannol can exhibit additional biological functions when it is metabolized to isorhapontigenin.

The AUCs for piceatannol and resveratrol increased in a dose-dependent manner after their intragastric administration (Table 2). These results indicate that stilbene absorption was not saturated with doses that ranged between 90 and 360 μmol/kg. Therefore, piceatannol and resveratrol were simultaneously administered at 180 μmol/kg. We had two concerns with the coadministration study. First, previous studies that examined resveratrol metabolism in vitro or in athymic mice found that resveratrol was metabolized to piceatannol.[28−30] In the present study, we did not detect piceatannol in rat plasma or urine after resveratrol administration. The reasons for the disagreement between our results and those of the previous study are unclear. We suspect the disparity might result from the differences between rats and athymic mice, or between in vivo and in vitro conditions. Similar disparities were observed with apigenin metabolism between in vivo and in vitro studies.[31] Therefore, we conclude that the piceatannol measured in rat plasma in the present study was from the administered dose, and not a resveratrol metabolite. Our second concern was that, in some cases, the bioavailability of polyphenols was affected by other compounds ingested simultaneously, and the AUCs for these polyphenols were higher than expected.[32−34] However, in our study, the AUC values for intact and total piceatannol or resveratrol in the coadministration study were similar to those in the individual administration study, and no statistically significant difference was observed between the administration methods. These results indicate that coadministration of piceatannol and resveratrol did not affect the absorption and metabolism of either stilbene. Hence, piceatannol was absorbed at levels that were 2-fold higher than those for resveratrol in the intact form. This finding predicts strong biological activity for piceatannol. In contrast, the total amount of piceatannol absorbed through the gastrointestinal tract into blood circulation (AUC for total) was significantly lower than that for resveratrol. Therefore, these findings indicate that piceatannol is more stable than resveratrol in metabolism.

In conclusion, we determined that the metabolic pathway for piceatannol is more complicated than that for resveratrol; piceatannol metabolism involves conjugation, methylation, or both. Furthermore, we showed that the AUC for intact piceatannol was higher than that of intact resveratrol. A greater AUC for intact piceatannol likely contributes to its important biological functions. Further studies examining the biological fate of piceatannol are required to determine its efficacy, and to determine its biological activity following administration.

MATERIALS AND METHODS

Reagents and Standards. Ethanol, methanol, hexane, chloroform, ethyl acetate, formic acid, hydrochloric acid, acetic acid, sodium carbonate, sodium acetate trihydrate, and anhydrous sodium sulfate were purchased from Merck (Darmstadt, Germany). All chemicals used in the study were of analytical or HPLC grade. Folin−Ciocalteu reagent, 2,2-diphenyl-1-picrylhydrazyl radical (DPPH), 2,2′-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), 2,4,6-tris(2-pyridyl)-*s*-triazine (TPTZ), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), potassium persulfate, iron(III) chloride hexahydrate, iron(II) sulfate heptahydrate, gallic acid, and ellagic acid were purchased from Sigma-Aldrich (St. Louis, MO, USA). The solvents were filtered using a Phenomenex solvent filtration apparatus (Torrance, CA, USA). The water used in this experiment was purified in a Millipore Milli-Q apparatus (Purelab UHQ-PS, Elga).

Material. Geopropolis produced by *Melipona fasciculata* Smith (Figure 1) was collected in November 2008 from the internal parts of

Figure 1. Geopropolis of *Melipona fasciculata* Smith collected in Maranhao state, Brazil.

a beehive located in the municipality of Fernando Falcao, Alto Mearim and Grajau microregion (6°7′30″ S, 44°52′30″ W) (Brazilian savannah), southeastern state of Maranhao, Brazil.

Extraction and Fractionation of Crude Geopropolis Extract. The in natura geopropolis was triturated using a knife mill, and the geopropolis powder (500 g) obtained was extracted by maceration with 1000 mL of 70% ethanol/water (70:30, v/v) for 48 h at a solid to solvent ratio of 1:2 (w/v). The extract was filtered through Whatman no. 1 filter paper (Whatman, Durham, UK) in a Buchner funnel and concentrated to a small volume at 40 °C in a rotary evaporator under vacuum, obtaining the hydroalcoholic extract of geopropolis (HEG).

The geopropolis extract (HEG, 20 g) was dissolved in 100 mL of methanol/water (1:1, v/v) by stirring, and the solution was subjected to fractionation by liquid−liquid partition chromatography using hexane, chloroform, and ethyl acetate. The solutions were filtered (anhydrous Na_2SO_4) and concentrated to a small volume at 40 °C in a rotary evaporator under vacuum, obtaining the hexane fraction (HF), chloroform fraction (CF), ethyl acetate fraction (EAF), and hydroalcoholic fraction (HAF).

Determination of Total Phenolic Content (TPC). The TPC of all samples was determined with the Folin−Ciocalteu reagent and 20% sodium carbonate. The reaction mixture was kept in the dark for 2 h at room temperature, and absorbance was then measured at 760 nm in a Lambda 35 UV−vis spectrophotometer (Perkin-Elmer, Inc., Waltham, MA, USA).[5,7] TPC was calculated from the calibration curve constructed with standard solutions of gallic acid (1.0−30.0 μg/mL) and is expressed as gallic acid equivalent (%). The analyses were carried using three aliquots of each sample, measured in triplicate, and the average value was calculated for each sample.

Determination of Antioxidant Activity. *DPPH Radical Scavenging Activity.* The antioxidant activity of the sample of geopropolis was evaluated by using the DPPH free radical scavenging assay as described by Brand-Williams et al.[16] with modifications. The samples were diluted in methanol at different concentrations (1.0−100.0 μg/mL) and added to a methanol solution of DPPH (40.0 μg/mL). After 30 min of reaction at room temperature in the dark, the absorbance of each solution was read at 517 nm in a Lambda 35 UV−vis spectrophotometer (Perkin-Elmer, Inc.). Methanol was used as the control, and DPPH solution was used as the blank. Standards of gallic acid, ellagic acid, and Trolox were treated under the same conditions as the samples. The percent inhibition was calculated using the formula

$$\text{DPPH scavenging activity (\%)} = 100 - [(A_{\text{sample}} - A_{\text{blank}}) \times 100/A_{\text{control}}]$$

where A_{sample} = absorbance of the sample after 30 min of reaction, A_{blank} = absorbance of the blank, and A_{control} = absorbance of the control.

The percentage of scavenging activity was plotted against the sample concentration to obtain the IC_{50}, defined as the concentration of sample necessary to cause 50% inhibition. All experiments were done in triplicate.

$ABTS^{\bullet+}$ Assay. Antioxidant activity was evaluated by using the $ABTS^{\bullet+}$ method (2,2′-azinobis-3-ethylbenzotiazoline-6-sulfonic acid) as described by Re et al.[17] with modifications. For formation of the ABTS radical, 7 mM $ABTS^{\bullet+}$ solution was mixed with 2.45 mM potassium persulfate solution, and the mixture was stored in the dark for 16 h. The radical was diluted with ethanol PA to an absorbance of 0.700 ± 0.020 at 734 nm. Three different dilutions of the samples (1−20.0 μg/mL) were then added to 3.0 mL of ABTS radical in the dark. Absorbance was read in a Lambda 35 UV−vis spectrophotometer (Perkin-Elmer, Inc.) after 6 min of the reaction using ethanol as a blank. Standards of gallic acid, ellagic acid, and Trolox were treated under the same conditions as the samples. The percent inhibition was calculated using the formula

$$ABTS^{\bullet+}\text{ scavenging activity (\%)} = 100 - [(A_{\text{sample}} - A_{\text{blank}}) \times 100/A_{\text{control}}]$$

where A_{sample} = absorbance of the sample after 6 min of reaction, A_{blank} = absorbance of the blank, and A_{control} = absorbance of the control.

The percentage of scavenging activity was plotted against the sample concentration to obtain the IC_{50}, defined as the concentration of sample necessary to cause 50% inhibition. All experiments were done in triplicate.

Ferric Reducing Antioxidant Power Assay (FRAP). The method described by Benzie and Strain,[18] with some modifications, was used to determine the antioxidant activity based on iron reduction using the FRAP assay. FRAP measures the ferric-reducing ability of a sample in acid medium (pH 3.6), forming an intense blue color as the ferric tripyridyltriazine (Fe^{3+}−TPTZ) complex is reduced to the ferrous (Fe^{2+}) form. FRAP reagent was prepared immediately before analysis by mixing 25 mL of acetate buffer (300 mM, pH 3.6), 2.5 mL of TPTZ solution (10 mM TPTZ in 40 mM HCl), and 2.5 mL of $FeCl_3 \cdot 6H_2O$ (20 mM) in aqueous solution. Different concentrations of 100 μL of the samples (1−100.0 μg/mL) were added to 300 μL of distilled water and 3.0 mL of FRAP reagent, and the mixtures were incubated in a water bath at 37 °C for 30 min. The absorbance of the reaction mixture was read at 593 nm in a Lambda 35 UV−vis spectrophotometer (Perkin-Elmer, Inc.) using FRAP solution as a blank. The calibration curve was constructed using different concentrations of $FeSO_4 \cdot 7H_2O$ (0−2000 μM) (r^2 = 0.9987), and the results are expressed as millimoles of Fe^{2+} per gram of sample. Standards of gallic acid, ellagic acid, and Trolox were treated under the same conditions as the samples.

HPLC/UV−Vis Analysis. HPLC analysis was carried out in a Thermo Finnigan Surveyor Autosampler liquid chromatograph (San Jose, CA, USA) equipped with an injector with a 25 μL loop and a UV detector. A Hypersil BDS C-18 column (250 × 4.6 mm, 5 μm; Thermo Electron Corp., Waltham, MA, USA), protected by a C-18 precolumn (4 × 3 mm, 5 μm, Gemini; Phenomenex), was used. The compounds of the geopropolis extract and fractions were separated at room temperature using a gradient elution program at a flow rate of 1.0 mL/min. The mobile phases consisted of Milli-Q water containing 0.1% formic acid (A) and methanol (B). The following linear gradient was applied: 0−1 min, 5% B; 1−60 min, 5−30% B; 60−90 min, 30−100% B. The column was reequilibrated for 10 min before the next run. The injection volume into the HPLC system was 25 μL, and UV−

vis detection was performed at 254 nm. Before injection into the HPLC system, each extract was dissolved in the same solvent used for extraction (HPLC grade) to obtain a final concentration of about 5 mg/mL and then filtered through a 0.22 μm nylon syringe filter obtained from Allcrom (São Paulo, SP, Brazil).

HPLC-DAD-ESI-MS Analysis. The HEG and EAF fraction were analyzed with an HPLC system (LC-10AD, Shimadzu) equipped with a photodiode array detector, which was coupled to an Esquire 3000 Plus ion-trap mass spectrometer (Bruker Daltonics, Bremen, Germany) using electrospray ionization (ESI). The conditions for dilution of the samples and the mobile phase composition were the same as described above. The ionization conditions were adjusted as follows: electrospray voltage of the ion source of 40 V, capillary voltage of 4.0 kV, and capillary temperature of 320 °C. Ultrahigh-purity helium (He) was used as the collision gas and high-purity nitrogen (N_2) as the nebulizing gas. Nebulization was aided with a coaxial nitrogen sheath gas provided at a pressure of 27 psi. Desolvation was facilitated using a counter current nitrogen flow set at a rate of 7.0 L/min. Analyses were carried out using full-scan mass spectra in the negative ionization mode and data-dependent MS^2 scans from m/z 100 to 3000. The compounds were identified on the basis of the molecular ion mass, fragmentation, UV−visible spectra, or co-injection with standards.

Statistical Analysis. All analyses were performed in triplicate. The results are expressed as the mean ± standard deviation and were analyzed using the GraphPad Prism 5.0 program. One-way analysis of variance (ANOVA) and Tukey's multiple-comparisons test were used to determine significant differences between means. A level of significance of $p < 0.05$ was adopted. Pearson's correlation test was used to evaluate the correlation between TPC (%), DPPH free radical-scavenging activity (IC_{50}), ABTS free radical-scavenging activity (IC_{50}), and ferric-reducing ability (mmol Fe^{2+}/g sample).

RESULTS AND DISCUSSION

Extraction Yields, Total Phenolic Content, and Antioxidant Activity. The HEG yielded 8.80% (44 g) of a black, bitter-tasting, and resin-smelling substance. Fractionation of the HEG yielded the following fractions: HF (0.22 g), CF (2.30 g), EAF (7.44 g), and HAF (9.30 g).

TPC and antioxidant activity of the fractions and extract are shown in Table 1. EAF (57.89%) and HEG (47.78%) had the highest total phenolic content, whereas total phenolic content ranged from 6.32 to 36.0% in the remaining fractions. Abreu et al.,[5] analyzing geopropolis from *Melipona fasciculata* collected in the savannah of Maranhao state, found a TPC ranging from 14.14 to 67.46%. In contrast, Cunha et al.[7] reported total polyphenol levels ranging from 7.36 to 36.95% in hydroalcoholic extracts of geopropolis collected in the Western Lowland of Maranhao.

In the analysis of DPPH and ABTS, a lower IC_{50} value indicates higher antioxidant activity. The EAF exhibited the highest activity among the samples analyzed by the DPPH radical-scaveninging assay, with an IC_{50} value of 3.75 μg/mL. The HEG extract also exhibited antioxidant activity, with an IC_{50} value of 5.24 μg/mL. HAF and CF provided IC_{50} values of 8.81 and 17.86 μg/mL, respectively. The phenolic compounds gallic and ellagic acids, which are strong antioxidants, exhibited the highest DPPH-scavenging activity. The highest antioxidant activity was observed for EAF, which contained the highest levels of total phenols and presented the lowest IC_{50} value and its radical-scavenging activity exceeded that of Trolox (Table 1).

In the ABTS assay, the EAF, which contained the highest levels of phenolic compounds, exhibited the lowest IC_{50} value (1.44 μg/mL), similar to that of ellagic acid, followed by HEG (IC_{50} = 2.56 μg/mL), which presented antioxidant activity similar to that of Trolox. HAF and CF also exhibited antioxidant activity, with IC_{50} values of 4.41 and 16.29 μg/mL, respectively. In the FRAP assay, EAF, HEG, and HAF presented the best ferric-reducing abilities (17.87, 14.70, and 15.06 mmol Fe^{2+}/g, respectively) which were superior to the antioxidant activity of Trolox. No antioxidant activity was observed for HF in any of the antioxidant assays (Table 1). The differences in antioxidant activity between the same samples demonstrated by the different assays, even when the same standard compound was used, can be explained by the reaction mechanisms of the methods.

Correlation between Antioxidant Activity and Total Phenolics Content. The correlations between the results of the DPPH, ABTS, and FRAP methods and TPC are shown in Table 2. A negative correlation was observed for DPPH−TPC (−0.9649), ABTS−TPC (−0.9154), DPPH−FRAP (−0.9670), and ABTS−FRAP (−0.9891), with a low IC_{50} value in the DPPH and ABTS assays being correlated with a high TPC and a high FRAP value and vice versa. The correlation between TPC and FRAP was positive (0.9034) as was that between DPPH and ABTS (0.9866), indicating that a high reducing

Table 2. Pearson Correlation Coefficient between the DPPH, FRAP, and ABTS Methods and Total Phenolic Content[a]

	DPPH	ABTS	FRAP
TPC	−0.9649	−0.9154	0.9034
DPPH		0.9866	−0.9670
ABTS			−0.9891

[a]TPC, total phenolic content; DPPH, 2,2-diphenyl-1-picrylhydrazyl radical; ABTS, 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt; FRAP, ferric reducing antioxidant power.

ability in the FRAP assay is related to the presence of phenolic compounds in the extracts.

The strongest free radical-scavenging activity and reducing ability were observed for the EAF fraction, which presented the

dx.doi.org/10.1021/jf404875v | J. Agric. Food Chem. 2014, 62, 2549−2557

highest TPC. These results suggest that total phenols, particularly hydrolyzable tannins, present in geopropolis were mainly responsible for the antioxidant activity and reducing ability of geopropolis. Other authors also reported important antioxidant activity of geopropolis obtained from the stingless bees *Melipona interrupta* and *Melipona seminigra*[19] and from *Melipona subnitida*,[20] which was correlated with the content of phenolic compounds.

TPC has been shown to be closely correlated with antioxidant activity.[21] Polyphenols have been identified as the most abundant and effective antioxidants in samples of Brazilian propolis produced by *Apis mellifera*.[22−24] In addition, Moreira et al.[25] demonstrated that propolis extracts with the highest concentrations of total polyphenols also exhibit the highest antioxidant activity. In the study of Sawaya et al.,[26] propolis produced by *Scaptotrigona* species, a stingless bee found in the Brazilian states of Maranhao and Sao Paulo, suggested that TPC and antioxidant activity are affected by the chemical composition of propolis, season of collection, and geographic origin.[26]

Identification of Phenolic Compounds. Because EAF and HEG had higher TPC and were more effective against the DPPH radical, the chemical composition of these samples was analyzed by HPLC/UV−vis and HPLC-DAD-MS/MS.

The chromatogram obtained by HPLC/UV−vis (254 nm) for HEG and EAF (Figure 2) revealed similar chemical compositions, with various peaks corresponding to phenolic acids, gallotannins, and ellagitannins on the basis of the analysis of the three-dimensional DAD-HPLC chromatogram of EAF, which established the absorption maxima at 254−363 nm (Figure 3; Figure S1 in the Supporting Information). Gallic acid

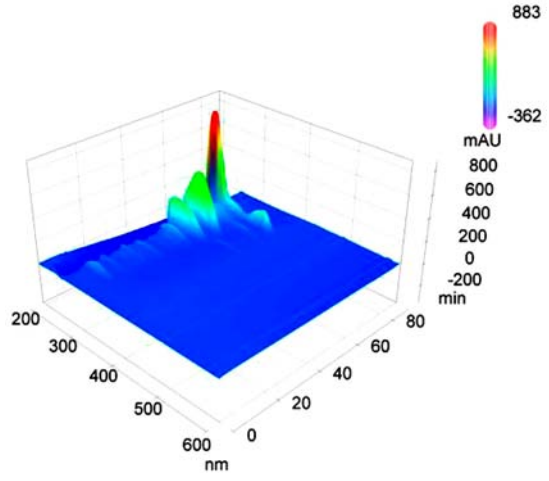

Figure 3. Three-dimensional DAD-HPLC chromatogram of the ethyl acetate fraction of geopropolis. (See also the Supporting Information.)

derivatives exhibit an absorption maximum at 254 nm, whereas ellagitannins show UV spectra similar to that of ellagic acid, with two absorption maxima at λ_{max} 254 and 365 nm. In contrast, gallotannins have only one absorption maximum at 275 nm due to the presence of galloyl and hexahydroxydiphenoyl groups.[27,28]

The compounds **1**−**11** were identified by HPLC-MS/MS as phenolic acids and hydrolyzable tannins (gallotannins and ellagitannins) as indicated by the presence of molecular ions corresponding to gallic acid, ellagic acid, trigallic acid, hexahydroxydiphenic acid (HHDP), and hexahydroxydiphenoyl-glucose (HHDP-glucose). The chemical structures of these compounds are shown in Figure 4.

Table 3 summarizes the tentatively identified phenolic compounds, their retention time, maximum UV−vis absorbance (λ_{max}), molecular weight, molecular ion $[M - H]^-$, and main product ions obtained by HPLC-MS/MS for the 11 fragmentation peaks of HEG and EAF. The compounds were identified by comparing their fragmentation profiles with reference compounds run under the same experimental conditions. When no standards were available, the compounds were identified on the basis of literature data.

The characterization of phenolic compounds is important because these compounds are associated with a variety of health benefits. HPLC with diode array and mass spectrometry detection has proven to be useful for the characterization of individual phenolic compounds, particularly gallotannins and ellagitannins. The results showed losses of 152 and 170 Da from the ion molecule, indicating the presence of galloyl groups, and a loss of 302 Da from the ion molecule, which is characteristic of HHDP groups. Loss of the carboxyl group (44 Da) and water (18 Da) from the ion molecule indicates the presence of a trigalloyl group and C-glucosidic ellagitannins, respectively.[29,30] The presence of ellagitannins was confirmed by the data indicating spontaneous lactonization of HHDP forming ellagic acid, whereas the partial lactonization of HHDP yields a product ion at m/z 319, and subsequent decarboxylation yields an ion at m/z 275 $[M - H - 44]^-$. Furthermore, tannins with molecular masses different by 2 units were observed, which are due to differences in one HHDP group or two galloyl groups.[31]

Phenolic Acids. Compounds **1** and **11** were identified as gallic acid and ellagic acid, respectively, by comparing their retention times, UV−vis spectra, fragmentation pathways observed in MS/MS spectra, and $[M - H]^-$ ions at m/z 169 and 301 with literature data. These peaks were confirmed using an authentic standard.[32,33]

Galloyl Glucose Derivatives and Ellagitannins. Compound **2** was tentatively identified as HHDP-galloylglucose (corilagin). Fragmentation of the molecular ion at m/z 633 $[M - H]^-$ produced ion fragments at m/z 481 (HHDP-glucose), due to the loss of the galloyl group, and at m/z 301, corresponding to the HHDP unit after lactonization to ellagic acid.[33]

Compound **3** showed an $[M - H]^-$ ion at m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and was tentatively identified as HHDP-glucose after the loss of one unit of glucose.[34]

Ellagitannins with $[M - H]^-$ ions at m/z 783 and 785 were at m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and were tentatively identified in the samples analyzed. Compound **4**, a parental $[M - H]^-$ ion at m/z 783 is present, producing ion fragments at m/z 765 (M − 18, loss of water), m/z 481, which correspond to deprotonated HHDP-glucose (M − 302 Da, loss of HHDP), and m/z 301, which corresponds to ellagic acid. These fragments were tentatively identified as di-HHDP-glucose (pedunculagin/casuariin).[28,33]

Compound **5** showed an $[M - H]^-$ ion at m/z 635 and fragments at m/z 483 $[M - H - 152]^-$, m/z 465 $[M - H - 170]$, and m/z 313 $[M - H - 152 - 152 - 18]^-$, indicating the loss of a galloyl group, the loss of gallic acid, and the loss of another galloyl group, water along with cross-ring fragmentation of glucose, and at m/z 301, corresponding to the HHDP unit after lactonization to ellagic acid. This compound was at

[a]RT, retention time; λ_{max}, UV−vis absorption maxima; MW, molecular weight; $[M - H]^-$ molecular ion; HHDP, hexahydroxydiphenic acid. [b]Co-injection of the authentic standard. [c]Compounds identified for the first time in geopropolis.

m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and was tentatively identified as trigalloyl-glucose.[28,33,34]

Compound **6** with m/z 785 $[M - H]^-$ was at m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and was tentatively identified as an HHDP-digalloylglucose isomer (tellimagrandin I) because it contained ions at m/z 633 (loss of a galloyl group), m/z 483 (loss of HHDP), and m/z 313 after the loss of one unit of HHDP, one galloyl group, and water. These two compounds differ from one another by 2 atomic mass units, suggesting that compound **4** could be formed by binding of two adjacent galloyl groups in HHDP-digalloyl-glucose by means of intramolecular oxidation.[30,33,34]

Compound **7** produced $[M - H]^-$ ions at m/z 469 and two main fragments at m/z 425 and 301 due to the loss of CO_2 from the deprotonated molecule and ellagic acid fragment, suggesting the presence of valoneic acid dilactone.[30,35]

Compound **8** showed an $[M - H]^-$ ion at m/z 951, which fragmented to m/z 907, 783, and 301. On the basis of the fragmentation patterns, the peak was at m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and was tentatively identified as the trisgalloyl-HHDP-glucose isomer. UV spectral data and the fragment ion at m/z 783 $[M - H - 168]$ indicate the presence of di-HHDP-glucose. The fragment corresponds to the presence of an additional galloyl residue, but only with a C−C bond to one of the HHDP molecules. The fragment ion at m/z 907 ($[M - H]^- - CO_2$) agrees with the presence of a free unesterified carboxyl group, and ion m/z 301 corresponds to 1 unit of HHDP after the lactonization process to ellagic acid.[28,29,33,36]

Compound **9** showed an $[M - H]^-$ ion at m/z 935, which fragmented to m/z 633 (−302 Da, loss of HHDP), m/z 481 (loss of a galloyl group), and m/z 301, and subsequent decarboxylation yields an ion at m/z 275. This compound was at m/z 481 $[M - H]^-$, followed by an ion fragment m/z 301 (ellagic acid), and was tentatively identified as di-HHDP-galloylglucose (potentillin/casuarictin).[30,32,33]

Compound **10** was tentatively identified as trigalloyl-HHDP-glucose (tellimagrandin II) on the basis of an $[M - H]^-$ ion at m/z 937, followed by ions m/z 785 and 767 (loss of water and a galloyl group, respectively), in addition to the ion fragments m/z 635 (minus one HHDP group), m/z 465 (loss of HHDP and gallic acid groups), and m/z 301, which corresponds to one unit of HHDP after the lactonization process to ellagic acid, followed by decarboxylation producing ion m/z 275. This compound differs from tellimagrandin I by the presence of an additional galloyl unit in the anomeric center of the glucopyranosyl core. Tellimagrandin II is produced by enzymatic transformation of pentagalloylglucose.[30,33]

Bankova et al.[37] demonstrated the presence of gallic acid in geopropolis produced by *Melipona compressipes* collected in the state of Piaui, Brazil. Gallic acid is one of the main compounds found in propolis samples from stingless bees collected in the Brazilian states of Pernambuco, Parana, and Sao Paulo.[38] However, there are no studies in the literature reporting the presence of ellagic acid and hydrolyzable tannins in samples of geopropolis or propolis produced by stinging or stingless bees.

Ellagitannins were the main compounds identified in the HEG and in EAF. These phenolic compounds are esters of HHDP with a polyol, usually glucose, have a high molecular weight, and are soluble in water.[39]

Ellagic acid is a phenolic compound that can occur in free form, glycosylated, or in bound form like ellagitannins. This compound is found in strawberries (*Fragaria ananassa* D.), raspberries (*Rubus idaeus* L.), pomegranates (*Punica granatum* L.), blackberries (*Morus nigra* L.), and eucalyptus (*Eucalyptus globules* L.). Ellagic acid and its derivatives (ellagitannin) have been shown to have antiviral, antioxidant, anticarcinogenic, anti-inflammatory, antifibrotic, and chemopreventive properties,[11] as well as antileishmanial activity.[40]

Antioxidants have attracted much interest because of their protective effect against free radical damage, which is the cause of many diseases, including cancer. In the present study, HEG and its EAF exhibited the highest antioxidant activity. This finding is probably due to the high content of polyphenols, such as gallic acid, ellagic acid, and hydrolyzable tannins. A similar correlation between antioxidant activity and phenolic content has been demonstrated in other studies.[21]

Zahin et al.,[41] studying the antioxidant activity of pomegranate (*Punica granatum*) peel extracts by DPPH free radical scavenging, identified gallic acid, ellagic acid, HHDP-glucose, corilagin, and pedunculagin by HPLC-MS. All of these compounds were detected for the first time in stingless bee products in the present study.

The strong correlation observed between antioxidant activity measurements and ellagitannins indicates that high molecular weight polyphenols were the main contributors of antioxidant activity. This can be attributed to the structure of ellagitannins, which is characterized by the presence of several ortho-hydroxy functions that exhibit a greater ability to donate a hydrogen atom and support the unpaired electron when compared to low molecular weight polyphenols. The antioxidant efficiency of ellagitannins and ellagic acid is directly correlated with their degree of hydroxylation and decreases in the presence of a sugar moiety.[11]

The present results provide further evidence that geopropolis is a rich source of bioactive compounds with potential health benefits, including antioxidant activity, which is related to the presence of phenolic compounds such as phenolic acids, gallotannins, and ellagitannins. Identification of the chemical composition and antioxidant substances is important for the understanding of the biological activity of geopropolis and for the standardization of extracts.

largely degraded by either acids,[12−14] enzymes, or human intestinal bacteria before reaching the circulation system,[15−22] resulting in very low bioavailability of intact ginsenosides (Rb_1, 0.1−4.4%; Rb_2, 3.7%; Rg_1, 1.9−18.4%).[23,24] The degraded ginsenosides have been further proven to traverse membrane more efficiently than the intact ginsenosides.[25,26] Our previous study has shown increased anticancer activity of ginseng extract and total ginsenosides after acidic hydrolysis.[27] All these lead to a transition of study from intact ginsenosides to secondary ginsenosides.

Metabolism of ginsenosides in the large intestine, where ginsenosides are deglycosylated by colonic bacteria, was found to mediate the in vivo activity of ginsenosides and thereby was suggested to be a key step for activation of primary ginsenosides which themselves were regarded as a "pro-drug".[28,29] For example, one of the major intestinal bacterial metabolite compound K (C−K) also called M1 in some papers), which is derived from PPD-type ginsenosides, has been demonstrated to exhibit in vivo and in vitro anticancer activities.[28−30] A metabolic pathway via stepwise cleavage of sugar moieties of ginsenosides with the preference of terminal sugar > inner sugar in intestinal bacteria has been well established, and more than 10 kinds of deglycosylated metabolites have been identified.[31,32] Many kinds of bacteria were suggested to integratively metabolize ginsenosides.[31] However, among the deglycosylated ginsenosides formed in intestine bacteria, only C−K, Rh_1, F_1, Rg_3, and Rh_2 were identified in plasma and urine after oral administration of ginseng,[15,20,33,34] while many other gastrointestinal deglycosylated products were only found in feces.[35] However, as a colonic deglycosylated product produced by gut microflora, C−K appeared in plasma very late (usually 7−10 h after administration) and its plasma level varied greatly in different studies.[20,36] Our previous investigation revealed that P-gP mediated efflux was responsible for the poor absorption of C−K.[37] Because of the delayed and low absorption, the plasma level of C−K is very likely to be out of the range where a significant physiological effect can be expected.

Unlike the metabolism in gut microflora, transformation of ginsenosides in gastric juice occurred early in stomach. The resultant metabolites have great potential to be absorbed within the long transit time in intestine (2−8 h), which is usually a time span during which pharmacological activities were observed.[38] However, although previous study demonstrated the absorption of gastric juice derived metabolites, e.g., Rh_1, into the circulation of human,[33] little information on the extent and time course of this procedure was available. This greatly hindered understanding of the role of gastric juice-catalyzed biotransformation in the holistic metabolism of ginsenosides after oral uptake. Moreover, recent studies have shown that molecular diversity of ginsenosides can be generated under mild acidic condition (AcOH/EtOH 1:1),[39] suggesting that ginsenosides can be metabolized through multiple pathways in addition to the well-known deglycosylation pathway. But there is still no systematic investigation on the identification of metabolites of ginsenosides formed in gastric juice. Because transformation of ginsenosides in gastric juice is the first barrier after being taken orally, and the resulting metabolites then undergo absorption and further metabolism in the gut or liver, it is of paramount importance to investigate the metabolism profile of ginsenosides in gastric juice qualitatively and quantitatively. With this aim, we carried out an in-depth analysis of the metabolites of ginsenosides formed in artificial gastric juice by using ultraperformance liquid chromatography coupled with quadrupole time-of-flight mass spectrometry (UPLC-Q-TOF-MS) and chemical synthesis of speculated metabolites.

MATERIALS AND METHODS

Chemicals and Materials. Ginsenosides R_1, Rb_1, Rg_1, and Re (each purity >98%) were purchased from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China); 20(*S*)-Rg_3, 20(*R*)-Rg_3, 20(*S*)-Rh_2, and 20(*R*)-Rh_2 (Each purity >98%) were purchased from Scholar Bio-Tech (Chendu, China). 20(*S*)-Rg_2, 20(*R*)-Rg_2 (purity >98%), Rk_1/Rg_5, and Rg_6/F_4 were isolated in our lab and identified by HR-MS and NMR spectroscopies, and the ratio of Rk_1:Rg_5 and Rg_6/F_4 was determined to be 2.1:1.0 and 1.9:1.0, respectively, based on ^{1}H NMR. Total ginsenosides of notoginseng (NS-TG), subtotal ginsenosides of protopanaxadiol-type (NS-PPD), and subtotal ginsenosides of protopanaxatriol-type (NS-PPT) were prepared from MeOH extract of notoginseng in our lab by using column chromatography. All chemicals were of analytical grade purity.

Preparation of Hydrolysis Sample of NS-TG, NS-PPD and NS-PPT. Each of NS-TG, NS-PPD, and NS-PPT (30 mg) were accurately weighed into a 50 mL centrifuge tube and 20 mL of 0.1N HCl were added. The solutions were then incubated under 37 ± 0.5 °C with a shaking speed of 100 rpm. At the time points of 0, 0.25, 0.5, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0 h, a 500 μL aliquot of each sample was taken out and neutralized with 10N NaOH, and then diluted 20-fold with 50% MeOH for quantitative analysis.

UPLC-Q-TOF-MS Analysis. UPLC was performed using a Waters ACQUITY UPLC system (Waters Corp., MA, USA) which was equipped with a binary solvent delivery system and a sample manager coupled to Bruker MicroTOF mass spectrometer with an ESI source. All the operations, acquisition, and analysis of data were operated by Hystar software (Bruker).

The chromatography was performed on an Acquity BEH C_{18} column (2.1 mm × 100 mm, 1.7 μm). The mobile phase consisted of 0.1% formic acid in Milli-Q water (A) and acetonitrile containing 0.1% formic acid (B). Two optimized UPLC elution conditions as follows were employed: method I, linear gradient from 15% to 25% B at 0−8 min, 25% to 47.5% B at 8−22 min, 47.5 to 85% B at 22−27 min, and finally 85 to 100% B at 27−29 min; method II, linear gradient from 20 to 40% B within 20 min, then from 40 to 100% B at 20−29 min, and maintained at 100% B for 3 min at a flow rate of 0.35 mL/min. The injection volume was 1 μL for quantitative analysis and 10 μL for metabolites identification.

The ESI-MS data was acquired in negative mode and the conditions of MS analysis were as follows: end plate offset, −500 V; capillary voltage, 4500 V; nebulizing gas (N_2) pressure, 1.5 bar; drying gas (N_2) flow rate, 8.0L/min; drying gas temperature, 200 °C; mass range, *m*/*z* 300−1500. For accurate mass measurement, the TOF mass spectrometer was calibrated routinely using sodium formate solution (0.05 mM NaOH solution with 0.05% formic acid in 90:10 proportion of 2-propanol/distilled water) infused at a flow rate of 2.5 mL/h.

For quantitative analysis, the sample solutions were analyzed by enhanced MS scan. Ginsenosides and its metabolites were quantitatively analyzed by using extracted ion chromatogram (EIC) of the $[M - H]^-$ or $[M + HCOO]^-$ ions. The selected ion for EIC of each ginsenoside was as below: Rb_1, *m*/*z* 1107.5 ($[M - H]^-$); Rc, *m*/*z* 1077.5 ($[M - H]^-$); Rb_2, *m*/*z* 1077.5 ($[M - H]^-$); Rd, *m*/*z* 991.5 ($[M + HCOO]^-$); R_1, *m*/*z* 977.5 ($[M + HCOO]^-$); Rg_1, *m*/*z* 845.5 ($[M + HCOO]^-$); Re, *m*/*z* 991.5 ($[M + HCOO]^-$); 20(*S*)- and 20(*R*)-Rg_3, *m*/*z* 783.5 ($[M - H]^-$); 20(*S*)- and 20 (*R*)-Rh_2, *m*/*z* 667.4 ($[M + HCOO]^-$); Rk_1 and Rg_5, *m*/*z* 765.5 ($[M - H]^-$); 20(*S*)- and 20(*R*)-Rg_2, *m*/*z* 829.5 ($[M + HCOO]^-$); 20(*S*)- and 20(*R*)-Rh_2, *m*/*z* 683.5 ($[M + HCOO]^-$); Rg_6 and F_4, *m*/*z* 811.4 ($[M + HCOO]^-$). Typical calibration curve for quantitation of each ginsenoside in 50% MeOH were shown in Table 1.

Chemical Synthesis of Oxygenated Metabolites. Photosensitized oxygenation products of 20(*S*)-Rg_3, 20(*R*)-Rg_3, 20(*S*)-Rg_2, and 20(*R*)-Rg_2 were synthesized following our protocol described

Table 1. Typical Calibration Curve for Quantitation of Ginsenosides in Incubated Samples of NS-TG, NS-PPT, and NS-PPD

ginsenosides/ notoginsenoside	regression equation	linearity (mg/L)	r^2
R_1	$y = 22754x + 6905.5$	0.035−33.4	0.9976
Rg_1	$y = 37258x + 26583$	0.040−44.3	0.9924
Re	$y = 31852x + 56358$	0.042−76.5	0.9920

Rd	$y = 23118x + 31313$	0.05−58.3	0.9908
20(*S*)-Rg_3	$y = 29880x + 14483$	0.55−28.1	0.9934
20(*R*)-Rg_3	$y = 22808x + 20843$	0.35−52	0.9952
Rk_1	$y = 18966x + 25526$	0.8−121.3	0.9935
Rg_5	$y = 19458x + 20165$	0.8−121.3	0.9955
20(*S*)-Rh_2	$y = 48494x + 5778.5$	0.11−21.3	0.9991
20(*R*)-Rh_2	$y = 51129x + 3367.3$	0.13−20.0	0.9993

previously.[40] Briefly, a solution of the parent compound (200 mg) and Rose-Bengal (20 mg) in MeOH was stirred and irradiated with 400 W lamp under an oxygen atmosphere at room temperature for 10 h. After filtration, triphenylphosphine (40 mg) was added to the filtrate and the solution was stirred at room temperature for another 4 h. The solution was evaporated to dryness in vacuum, then subjected to combinative column chromatographies over silica gel eluted with $CHCl_3$−MeOH (10:0−8:2), MCI-gel CHP 20P, and Bondpack ODS (eluted with 40−100% MeOH) to give individual oxygenated products.

Epoxidation of 20(*R*)-Rg_3 and 20(*R*)-Rg_2 were performed following the procedure described in the literature with minor modifications.[41] Briefly, solution of the selected ginsenosides (100 mg) in acetonitrile (10 mL) was mixed with an aqueous EDTA-Na solution (0.4 μM, 10 mL). The mixed solution was cooled to 0 °C, and then an epoxidation dibetal catalyst solution (ketone, 60 μM in acetonitrile) and the mixture of sodium bicarbonate (155 μM) and oxone (100 μM) were added. The homogeneous solution was stirred overnight and then extracted with *n*-BuOH. The resultant *n*-BuOH layer was applied to column chromatographies over SiO_2 and ODS to afford 20(*R*)-Rg_3 epoxide (compounds **64** and **66**, 21.6 mg) and 20(*R*)-Rg_2 epoxide (compounds **35** and **36**, 15.02 mg) .

Chemical structures of the synthesized metabolites were characterized based on the elucidation of NMR data. ^{1}H- and ^{13}C NMR data were recorded on a Varian Mercury-Plus 300 MHz NMR spectrometer (300 MHz for ^{1}H and 75 MHz for ^{13}C), Varian 400 MHz FT-NMR spectrometer (400 MHz for ^{1}H and 100 MHz for ^{13}C) and Bruker NMR spectrometer (CyroFIT, 600 MHz for ^{1}H and 150 MHz for ^{13}C). Coupling constants were given in Hz and chemical shifts are represented in δ (ppm) relative to Me_4Si as internal standard. HR-ESI-MS was performed on a Q-TOF mass spectrometer (Bruker Daltonics, MA, USA).

Compound **11** [20(*S*)-Rg_2-mo] White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 0.96, 1.01, 1.29, 1.30, 1.41, 1.56, 1.58, 2.16 (3H each, all s), 1.82 (3H, d, J = 6.2 Hz, Me-6″), 3.51 (1H, dd, J = 11.2, 4.6 Hz, H-3), 5.30 (1H, d, J = 6.9 Hz, H-1′), 6.08 (1H, d, J = 15.6 Hz, H-24), 6.37 (1H, ddd, J = 15.6, 9.2, 5.5 Hz, H-23), 6.55 (1H, brs, H-1″). ^{13}C NMR data was given in Table 2.

Compound **12** [20(*R*)-Rg_2-mo]: White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 0.95, 1.01, 1.28, 1.37, 1.39, 1.54, 1.56, 2.10 (3H each, all s), 1.78 (3H, d, J = 6.0 Hz, Me-6″), 3.48 (1H, dd, J = 11.2, 4.8 Hz, H-3), 4.35 (1H, m, H-6), 5.25 (1H, d, J = 6.8 Hz, H-1′), 6.05 (1H, d, J = 15.6 Hz, H-24), 6.32 (1H, ddd, J = 15.6, 9.4, 5.6 Hz, H-23), 6.47 (1H, brs, H-1″). ^{13}C NMR data are given in Table 2.

Compounds **16** and **17** [20(*S*)-Rg_2-mo]: White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 0.93, 0.95, 1.18, 1.34, 1.41, 1.52, 1.53, 1.89, 2.13 (3H each, all s), 1.80 (3H, d, J = 6.2 Hz, Me-6″), 3.49 (1H, dd, J = 11.3, 4.8 Hz, H-3), 4.42 (1H, dd, J = 11.6, 6.7 Hz, H-24), 4.92 (1H, s, H_a-26), 5.27, (1H, s, H_b-26), 5.28 (1H, d, J = 6.8 Hz, H-1′), 6.52 (1H, s, H-1″). ^{13}C NMR data are given in Table 2.

Compounds **21** and **24** [20(*R*)-Rg_2-mo]: White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 0.94, 0.99, 1.24, 1.37, 1.41, 2.15 (3H each, all s), 1.53 (6H, s), 1.82 (3H, d, J = 5.4 Hz, CH_3-6″), 3.49 (1H, dd, J = 11.7, 6.3 Hz, H-3), 4.41 (1H, dd, J = 12.0, 7.0 Hz, H-24), 4.97 (1H, s, H_a-26), 5.30 (1H, d, J = 6.7 Hz, H-1′), 5.31 (1H, s, H_b-26), 6.51 (1H, s, H-1″). ^{13}C NMR data are given in Table 2.

Compounds **35** and **36** [20(*R*)-Rg_2 epoxides]: White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ:0.80, 1.00, 1.20, 1.30, 1.32, 1.40, 1.42, 2.20 (3H each, all s), 1.80 (3H, d, J = 5.4 Hz, CH_3-6″), 4.02 (1H, dd, J = 9.0, 4.0 Hz), 5.10 (1H, d, J = 6.7 Hz, H-1′), 6.50 (1H, s, H-1″). ^{13}C NMR data are given in Table 2.

Compounds **44** and **52** [20(*S*)-Rg_3-mo]: White powder. ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 0.80, 0.95, 0.98, 1.10, 1.29, 1.46 (3H each, all s), 1.89, 1.93 [1.5 H each, s, H-27 of 24(*S*) and 24(*R*)], 3.30 (1H, dd, J = 11.4, 3.9 Hz, H-3), 3.92 (1H, m, H-12), 4.44 (1H, dd, J = 12.0, 4.2 Hz, H-24), 4.91 (1H, d, J = 7.5 Hz, H-1′), 4.93 (1H, s, H-26), 5.25 (1H, s, H-26), 5.37 (1H, d, J = 7.5 Hz, H-1″). ^{13}C NMR data are given in Table 2.

Compound **45** [20(*S*)-Rg_3-mo]: White powder. ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 0.82, 0.95, 1.02, 1.11, 1.29, 1.42 (3H each, all s), 1.56 (6H, s, CH_3-26, 27), 3.26 (1H, dd, J = 11.7, 4.5 Hz, H-3), 3.93 (1H, m, H-12), 4.92 (1H, d, J = 7.2 Hz, H-1′), 5.39 (1H, d, J = 7.5 Hz, H-1″), 6.03 (1H, d, J = 16.4 Hz, H-24), 6.50 (1H, ddd, J = 15.0, 7.2, 5.4 Hz, H-23). ^{13}C NMR data are given in Table 2.

Compounds **46** and **49** [20(*R*)-Rg_3-mo]: White powder. ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 0.83, 0.97, 1.02, 1.14, 1.32, 1.44 (3H each, all s, CH_3-30, 19, 18, 29, 26, 28), 1.95, 1.97 [1.5 H each, s, CH_3-27 of 24(*S*) and 24(*R*)], 3.30 (1H, dd, J = 11.4, 3.9 Hz, H-3), 3.98 (1H, m, H-12), 4.31 (1H, dd, J = 12.6, 4.5 Hz, H-24), 4.97 (1H, d, J = 7.8 Hz, H-1′), 4.98 (1H, s, H_b-26), 5.33 (1H, s, H_a −26), 5.42 (1H, d, J = 7.8 Hz, H-1″). ^{13}C NMR data are given in Table 2.

Compound **50** [20(*R*)-Rg_3-mo]: White powder. ^{1}H NMR (pyridine-d_5, 300 MHz) δ: 0.85, 0.97, 1.06, 1.13, 1.31, 1.45, 1.56, 1.57 (3H each, all s, CH_3-30, 19, 18, 29, 28, 26, 27), 3.30 (1H, dd, J = 11.4, 4.2 Hz, H-3), 3.93 (1H, m, H-12), 4.93 (1H, d, J = 7.2 Hz, H-1′), 5.39 (1H, d, J = 7.5 Hz, H-1″), 6.03 (1H, d, J = 15.6 Hz, H-24), 6.31 (1H, ddd, J = 15.0, 8.4, 5.4 Hz, H-23). ^{13}C NMR data are given in Table 2.

Compounds **64** and **66** [20(*R*)-Rg_3 epoxides]: White powder. ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 0.79, 1.01, 1.22, 1.29, 1.33, 1.45, 1.46, 2.04 (3H each, s), 3.51 (1H, dd, J = 11.0, 5.0 Hz, H-3), 3.74 (1H, m, H-12), 4.09 (1H, dd, J = 9.7, 3.8 Hz, H-24), 4.94 (1H, d, J = 7.2 Hz, H-1′), 5.40 (1H, d, J = 7.5 Hz, H-1″). ^{13}C NMR data are given in Table 2.

Cell Culture and Cytotoxicity Assay of NS-TG, NS-PPD, NS-PPT, and Their Metabolites at Different Time Points. Exponentially growing cells were plated in 96-well microplate (Becton, Dickinson and Company) at a density of 1.5 × 10^4 cells (S_{180}) and 5000 cells (Caco-2 and A_{549}) per well in 100 μL of culture medium and were allowed to adhere for 16 h before treatment (for Caco-2 and A_{549} cells). Serial concentrations of each compound in DMSO (Sigma-Aldrich) were then added (100 μL per well), and the cells were incubated for 48 h (S_{180} and A_{549}) or 72 h (Caco-2) at humidified atmosphere containing 5% CO_2 at 37 °C. The final concentration of DMSO in the culture medium was maintained at 0.3% (v/v) to avoid solvent toxicity. Cell viability was determined using 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl- tetrazolium bromide (MTT) reduction assay. Briefly, MTT solution (10 μL per well, 5 mg/mL solution) were added to each well and incubated for 4 h at 37 °C, and 100 μL of lysing sodium dodecyl sulfate (SDS) were added and kept overnight at room temperature. The optical densities of the resulting solutions were colorimetrically determined at 570 nm using a microplate reader. Dose−response curves were obtained, and the results were expressed

[a]150 MHz for ^{13}C NMR; [b]75 MHz for ^{13}C NMR. The signals were assigned by comparing with those of reference compounds reported previously.[7,40,46,48,66]

as IC_{50} values in μg/mL. Each experiment was carried out for three times. IC_{50} results were expressed as means ± standard deviation.

RESULTS

Identification of Metabolites Formed in Artificial Gastric Juice. A primary study of NS-TG incubated in 0.1 N HCl and artificial gastric juice prepared following "Chinese Pharmacopoeia" give quiet similar profile in both metabolism pathway and metabolism time course. Further examination of NS-TG incubated in pepsin alone revealed that pepsin does not have any effect on the metabolism of NS-TG (Supporting Information). Therefore, 0.1N HCl was employed for simulating gastric condition in the current study to avoid steps for protein removal. To survey the metabolites formed in artificial gastric juice, subtotal ginsenosides of protopanaxadiol-type (NS-PPD), subtotal ginsenosides of protopanaxatriol-type (NS-PPT), and total ginsenosides (NS-TG) incubated for 3 h, the time point when most of the primary ginsenosides were transformed, were analyzed by using UPLC-Q-TOF-MS. In the incubated sample of NS-PPT, four groups of peaks can be easily observed as the major metabolites in the total ion chromatogram (TIC). These major metabolites were easily identified as deglycosylated ginsenosides, corresponding dehydration products, hydration products of primary, and secondary ginsenosides, as well as hydration products of dehydrated ginsenosides (Supporting Information). For NS-PPD (Figure 1B), similarly, the above four groups of metabolites were observed and characterized based on the retention time, quasimolecular ion, and accurate mass. Notably, the metabolites profile of NS-PPD was somewhat different from that of NS-PPT. The relative

Figure 2. Structures of the oxygenated ginsenosides identified by comparing with synthesized authentic compounds.

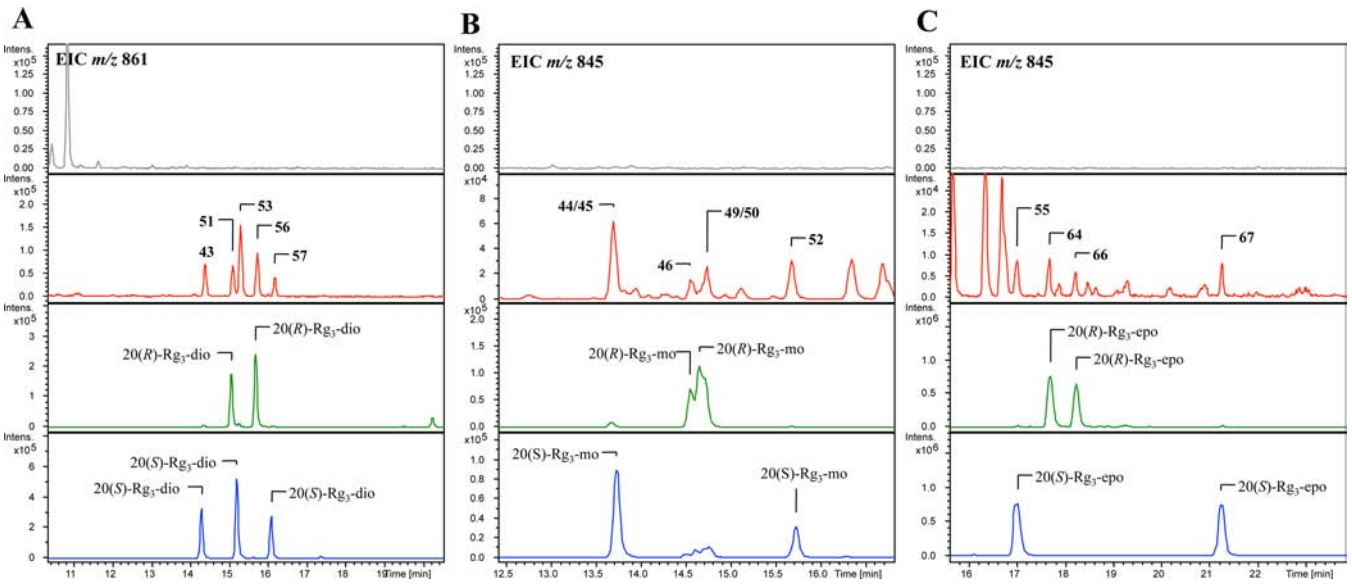

Figure 3. Identification of dioxygenated (A), mono-oxygenated (B), and epoxide metabolites (C) of Rg_3 in NS-TG incubated for 3 h in artificial gastric juice by comparing with synthesized authentic compounds. From top to bottom: NS-TG before incubation, NS-TG incubated for 3 h, and synthesized authentic metabolites of 20(*S*)- and 20(*R*)-Rg_3.

abundance of hydrated metabolites in NS-PPD was much lower than that in NS-PPT, while the intensity of dehydrated metabolites was just the opposite. Takino has reported that PPT-type ginsenosides is easily hydrated in both 0.1 N HCl and rat stomach, whereas PPD-type ginsenosides did not undergo hydration in either medium.[13,14] Our result showed that hydration of PPD-type ginsenosides also occurs in artificial gastric acid, but to much less an extent than that of PPT-type ginsenosides. On the basis of the identification of metabolites of NS-PPT and NS-PPD incubated with artificial gastric juice, metabolites derived from the primary ginsenosides R_1, Rg_1, Re, Rb_1, and Rd in the incubated sample of NS-TG through the above metabolic pathways were characterized or assigned by using the similar approach (Figure 1C).

Because oxygenated ginsenosides were also reported to form in rat stomach (in vivo) or under mild acidic condition except for the above major metabolic pathways.[42] We further screened oxygenated ginsenosides in NS-TG metabolites by using EIC mode in LC-MS. As a result, mono- and dioxygenated Rg_3 and Rg_2 were detected to be the major oxygenated metabolites of ginsenosides in artificial gastric juice. To identify the oxygenated metabolites, we synthesized speculated authentic compounds through photosensitized oxygenation and epoxidation. Chemical structures of the synthesized compounds were confirmed based on spectroscopic evidence. 20(*S*)-Rg_2-mo-I (**11**), a metabolite synthesized by using 20(*S*)-Rg_2 as the starting material, was taken as an example to show the structure elucidation of photosensitized ginsenosides. The proton and carbon signals of aglycone part in the ^{1}H NMR and ^{13}C NMR

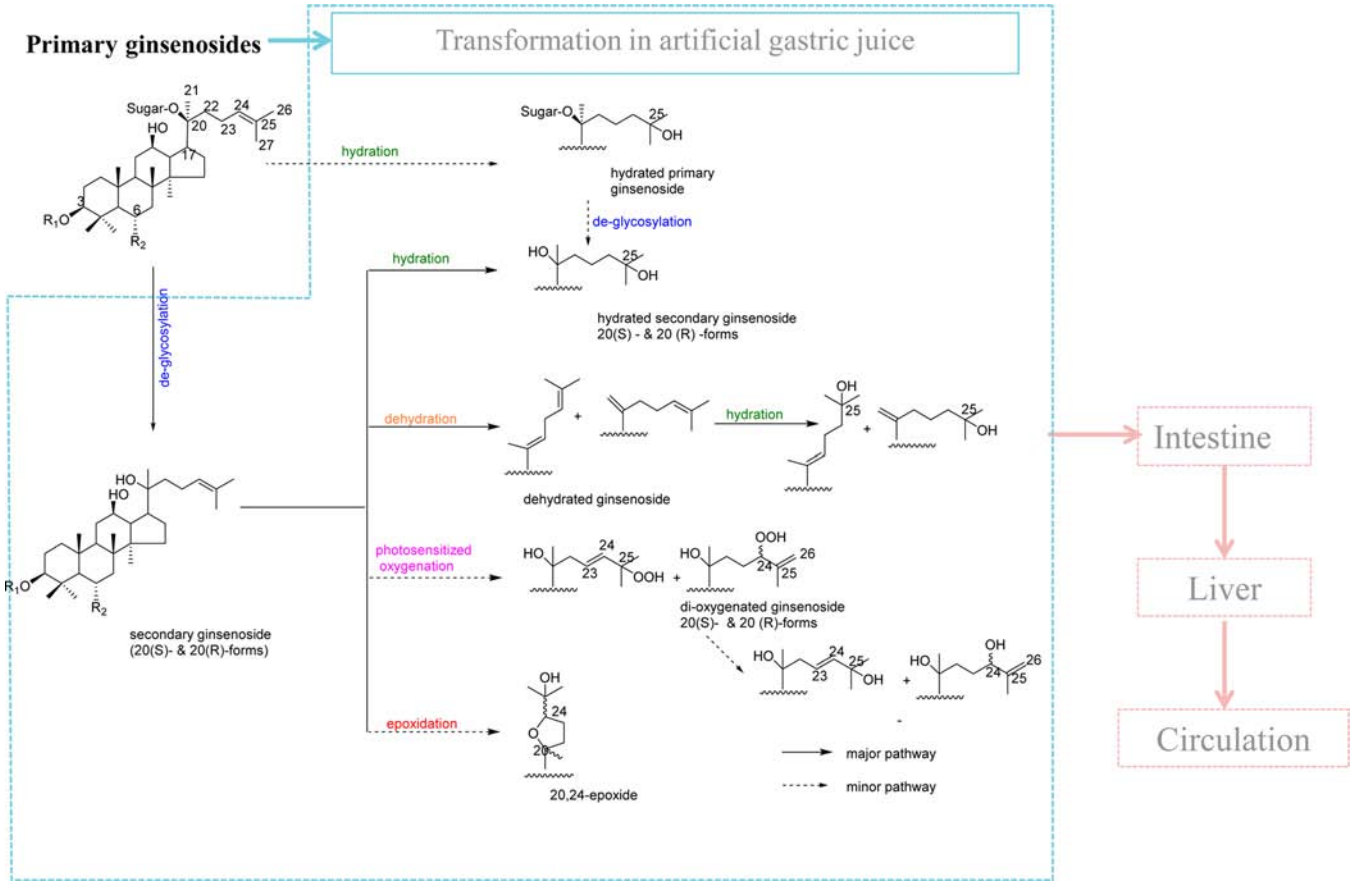

Figure 4. Proposed metabolic pathways of ginsenosides in artificial gastric juice.

23), and δ_C 122.9 (C-23), 141.8 (C-24). The downfield shift of C-22 ($\Delta\delta_C$ = 3.5 ppm), compared to that of 20(*S*)-Rg_2, clearly suggested a translocation of the double bond to C-23 and 24. The oxygenated carbon (δ_C 69.9) assigned to the remaining carbon (C-25) of the side chain indicated the presence of a hydroxyl group at C-25. These evidence revealed the structure of the side chain with a hydroxyl group at C-25 and a double bond at C-23 and C-24, which was supported by the chemical shift comparing with those of related hydroxylated ginsenosides.[7] Thus the structure of **11** was assigned as shown (Figure 2).

Structure characterization of epoxides was shown in example of 20(*R*)-Rg_2-Epo (**35** and **36**). This mixture was synthesized from 20(*R*)-Rg_2 by using epoxidation dibetal catalyst solution which could oxidize 24,25-double bond into 24,25-epoxide. The resulting 24,25-epoxy compounds are quite unstable in the existence of a 20-hydroxy group and immediately changed into 20,24-epoxides.[45] The formation of 20,24-epoxides in **35** and **36** was evidenced by the large downfield shift of C-20 ($\Delta\delta_C$ = 13.3) and C-23 ($\Delta\delta_C$ = 5.3), as well as the displacement of olefinic carbon signals with oxygenated carbon signals [δ_C 87.5(C-24), δ_C 70.9(C-25)] in comparison with that of 20(*R*)-type secondary ginsenosides,[14] and was further supported by comparing the chemical shifts to those of 20(*S*)-epoxides.[46] **35** and **36** were found to be an equivalent mixture of 24(*R*) and 24(*S*)-epimers based on the fact that the signals of C-17,20−27 appeared in pairs in the ^{13}C NMR spectrum (Table 2). On the basis of above evidence, the structure of **35** and **36** was assigned as shown (Figure 2).

By comparing with the synthesized metabolites, the dioxygenated metabolites were identified to be hydroperoxides derivatives of Rg_2 and Rg_3, while the mono-oxygenated metabolites were characterized to be corresponding hydroxides and 20,24-epoxides (Figure 3) of Rg_2 and Rg_3. Hydroperoxides and corresponding hydroxides of Rg_2 and Rg_3, as well as epoxides of 20(*R*)-Rg_2 and 20(*R*)-Rg_3, are new dammarane glycosides which were not reported before. To confirm formation pathway of the oxygenated metabolites, ginsenoside Rg_3 was incubated in artificial gastric juice, resulting in the production of above oxygenated metabolites (data not show), indicating these oxygenated metabolites can be derived from Rg_3 via oxygenation rather than from hydrolysis of hydroperoxides and corresponding hydroxides of primary ginsenosides that have been reported to exist naturally in notoginseng.[47,48]

In summary, totally 83 metabolites were identified in the incubated sample of NS-TG (Table 3). Characterization of these metabolites suggested deglycosylation, dehydration, hydration, and oxygenation as the metabolic pathways of ginsenosides in artificial gastric juice (Figure 4).

Time Course of Transformation of Ginsenosides in Artificial Gastric Juice. The time courses of degradation of primary ginsenosides, as well as the formation of deglycosylation and dehydration metabolites, were plotted by quantitatively determining the content of both parent compounds and metabolites at different time point of incubation (Figure 5). It can be seen that the three primary ginsenosides, N-R_1, Rg_1, and Re, disappeared rapidly. N-R_1 and Re were exhausted at 2 h, while Rg_1 was metabolized thoroughly at 3 h (Figure 5A,B).

dx.doi.org/10.1021/jf405482s | J. Agric. Food Chem. 2014, 62, 2558−2573

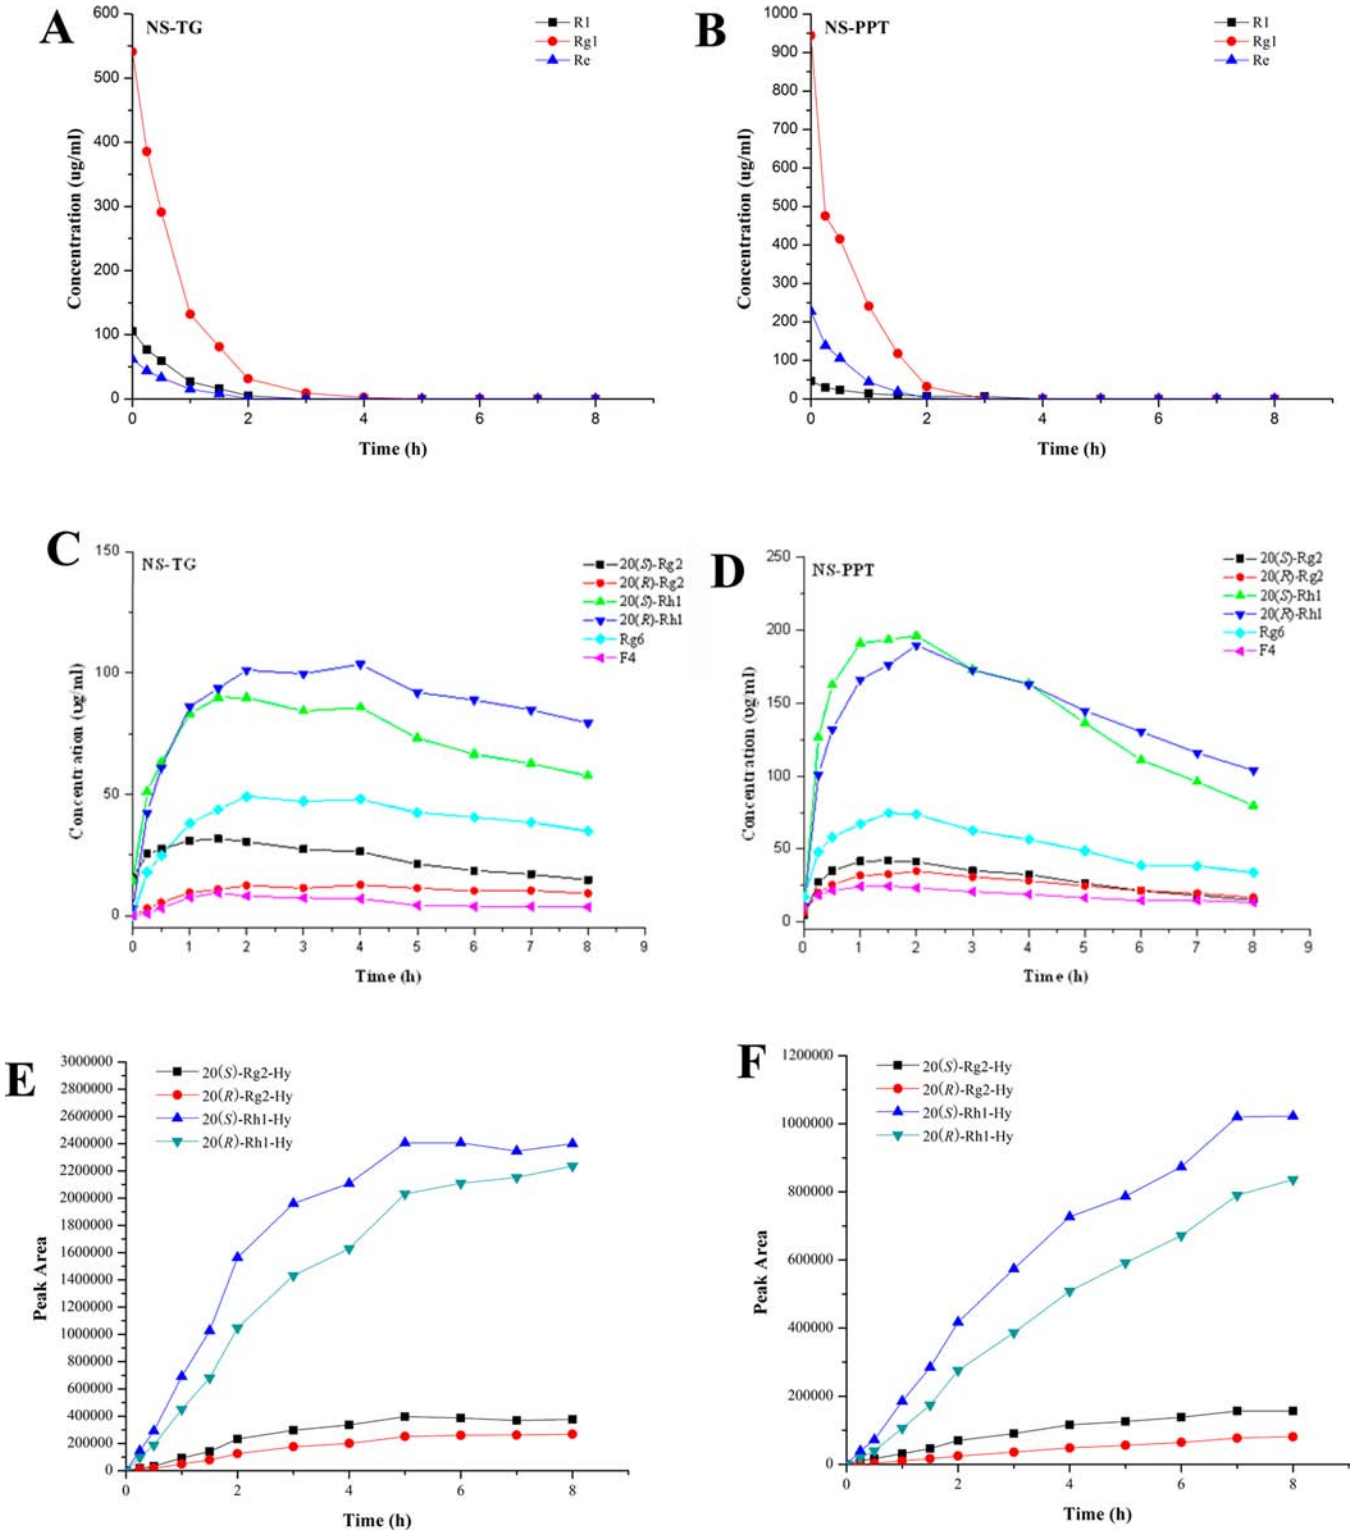

Figure 5. Time course of degradation of primary PPT-type ginsenosides (A,B), formation of deglycosylation, dehydration (C,D), and hydration metabolites (E,F) in incubated NS-TG and NS-PPT. Each sample was analyzed in duplicate, and the average value was employed for plotting.

20(*R*)- and 20(*S*)-Rh_1 were the most dominant metabolites, followed by 20(*S*)- and 20(*R*)-Rg_2 and their dehydration products Rg_6 and F_4. Production of the metabolites peaked at 2 h, and decreased stepwise after 2 h (Figure 5C,D). Decrease of the deglycosylated and dehydrated metabolites might be due to subsequent hydration, which was supported by the increased formation of hydration products after 2 h (Figure 5E,F). Formation of the dehydration products, e.g., Rg_6 and F_4, showed almost identical time course with that of corresponding secondary ginsenosides, and the ratio between them kept the same during 8 h incubation, suggesting that dehydration occurred very quickly after deglycosylation and reached equilibration rapidly. PPD-type ginsenosides showed quite similar time course to that of NS-PPT (Figure 6A–D), but

[a]Abbreviations: PG = sum of primary ginsenosides (N-R_1, Rg_1 Re, Rb_1, Rd); SG = sum of secondary ginsenosides (Rg_2, Rh_1, Rg_3, Rh_2); DH = sum of dehydration products (Rg_6, F_4, Rk_1 and Rg_5).

different from PPT-type ginsenosides, concentration of the metabolites did not decrease at the later period of incubation.

Cytotoxicity of Metabolites of Ginsenosides at Different Time Point to Cancer Cells. Cytotoxicity of ginsenosides

dx.doi.org/10.1021/jf405482s | J. Agric. Food Chem. 2014, 62, 2558−2573

toward a broad spectrum of cancer cell lines have been demonstrated, hence the most widely used cancer cell lines in our lab, S_{180}, A_{549}, and Caco-2 cells, were selected for the assaying cytotoxicity. Among these three cell lines, A_{549} and Caco-2 have been reported for evaluating cytotoxicity of ginsenosides.[49−51] As shown in Table 4, all the ginsenoside samples before incubation exhibited no cytotoxicity (IC_{50} > 2000 μg/mL) or very low cytotoxic activities. With the increase of incubation time in artificial gastric juice, cytotoxicity of all three samples enhanced gradually. Cytotoxicity potential of the ginsenosides were found to be closely related to the ratio between metabolites and primary ginsenosides, indicating that secondary and dehydrated ginsenosides are the major active principles responsible for the cytotoxicity toward cancer cells. However, MTT is a colorimetric assay based on tetrazolium dye reduction catalized by NAD(P)H-dependent oxidoreductase. Therefore, viable but metabolically quiet resting cells like thymocytes and splenocytes reduce very little MTT, leading to a false conclusion. More importantly, although MTT assay is widely used for assaying cell viability, it could not distinguish the effects of cell death or cell growth inhibition, which are important component of biological research. Further studies need to be carried out to evaluate the subtle influence of metabolism on the bioactivity of ginsenosides.

DISCUSSION

Our study revealed multiple metabolic pathways of ginsenosides in gastric juice, including deglycosylation, dehydration, hydration, and oxygenation. The hydration of PPT-type ginsenosides was much more extensive than that of PPD-type ginsenosides, indicating that this pathway is compound type-dependent. Oxygenation, which occurs through both epoxidation and photosensitization, was shown to be a minor metabolic pathway of ginsenosides in gastric juice. These results indicated that molecular diversity of ginsenosides can be generated through transformation in gastric juice, thus creating new chemomes which are more biologically associated with the activity of the herb.

In a previous study, the hydrolytic reaction of ginsenosides under mild acidic condition (AcOH/EtOH 1:1) led to the formation of deglycosylation product, dehydration product, 20-O-alkylated derivatives, 25-OH derivatives, as well as methylation product.[39] In our study, deglycosylation, dehydration and hydration product (25-OH derivatives) were found to be the major metabolic pathway of ginsenosides, suggesting that these pathways are common reaction under acidic condition.

Time course investigation suggested that the primary ginsenosides were decomposed quickly within 2 h, a period required for exclusion of stomach, implying that ginsenosides undergo extensive metabolism in gastric juice before they get into the intestine in vivo. Deglycosylation products, e.g., Rg_3, Rh_2, Rg_2, and Rh_1, were demonstrated to be the major metabolites formed in artificial gastric juice, accounting for 30−40% of the total amount of metabolites. Previous studies have shown that after oral administration significant amount of C−K can be detected in plasma while the primary ginsenosides were poorly absorbed or undetectable.[52,53] Rh_2, a deglycosylated ginsenoside derived from artificial gastric acid, was reported to have an improved intestinal absorption as evidenced by much higher bioavailability (~5% in rat, 15−25% in dog) than its parent ginsenosides Rb_1 and Rb_2 (with bioavailability of 0.78 and 0.08%, respectively), implying an improved absorption with the removal of sugar moiety.[54−56] Moreover, it has been reported that deglycosylated ginsenosides, i.e., F_2, C−K, Rh_2, Rh_1, and F_1 possessed slightly increased membrane permeability than primary ginsenosides, while aglycone, PPD and PPT further showed 1-fold higher permeability than that of deglycosylated ginsenosides in Caco-2 cells.[57] Therefore, deglycosylated metabolites might have great potential to be absorbed into circulation system. This can be exampled by previous report which showed the absorption of gastric juice-derived metabolites of ginsenosides (e.g., Rh_1 and hydrated Rh_1) at early stage (0−4 h) in urine and plasma of human after oral administration of ginseng extract.[33]

Even though, absorption of the deglycosylated ginsenosides into the circulation system could be extremely complicated because of the efflux and stereoselectivity as well as further metabolism. Actually most of the deglycosylated ginsenosides formed in gastric juice were not reported to exist in plasma or only detected in nanomolar levels.[36] A major reason might be the involvement of efflux transport. For example, 20(S)-Rh_2, a major deglycosylated PPD-type ginsenosides formed in gastric juice, was demonstrated to be a substrate of P-gP. Its transport was involved by P-gP and thus resulting in poor absorption.[58] As C-20 epimers of the deglycosylated ginsenosides formed almost simultaneously, stereoselective absorption as well as stereoselective regulation of P-glycoprotein by Rh_2 epimers will result in quite complicated interaction of these two epimers,[59,60] making it difficult to predict their absorption.

An additional issue potentiate the complexity in absorption of the metabolites is the subsequent metabolism in liver after absorption. Recent studies suggested that C-20 hydroxyl group was a determinant for hepatic disposition of ginsenosides,[61] implying that biotransformation of ginsenosides in gastric juice through hydrolysis of C-20 sugar moiety would be a key step for "activating" the subsequent P450-mediated metabolism. Except for the deglycosylated ginsenosides, the corresponding dehydrated and hydrated ginsenosides may also be metabolized in liver to form bulky metabolites. The metabolites resulting from the coupling of gastric juice and hepatic enzyme might be responsible for the unidentified circulating metabolites proposed in previous radioisotope assay, which revealed three times higher serum radioactivity of Rb_2 and its derivatives than Rb_2 level determined by HPLC.[23] It has been proved that intact ginsenosides and deglycosylated ginsenosides exhibited distinct activity on CYP enzymes.[62,63] Therefore, systemic exposure of the deglycosylated and related ginsenosides was quite valuable for evaluating the herb−drug interaction caused by the inhibition of ginsenosides on the CYP's activity.

Although substantial studies have demonstrated in vivo anticancer effect of primary ginsenosides,[64−66] no in vitro evidence of cytotoxicity of primary ginsenosides was available. Our studies showed that primary ginsenosides themselves seems to be "inactive" toward cancer cells but can gain potent cytotoxicity after biotransformation in artificial gastric juice, suggesting that this step may contribute to the observed in vivo anticancer activity of notoginseng. Moreover, both PPD- and PPT-type ginsenosides exhibited increased cytotoxicity after biotransformation and may cooperatively contribute to the activity of NS-TG metabolites. The cytotoxicity of metabolites enhanced along with the increased incubation time and showed good correlation with the ratio of both deglycosylated and dehydrated products to primary ginsenosides. This evidence indicated a major contribution of deglycosylation and dehydration products to the cytotoxicity. However, other

minor metabolites derived from hydration and oxygenation may also have potential activity that needs to be further explored.

visualized by exposure to UV radiation (254 nm), or by spraying first with 10% H_2SO_4 in MeOH and then with 5% phosphomolybdic acid in EtOH, followed by heating at 110 °C for 10 min, or by exposure to iodine vapors. The HPLC system (Shimadzu, Tokyo, Japan) consisted of a series LC-10AdVP pump, FCV-10AlVP valves, SPD-10AVVP spectrophotometric detector, and DGU-14A degasser. The HPLC column used was 250 mm × 4.6 mm i.d., 5 μm, high-density Nucleosil 100-5 RP18 (Macherey-Nagel, Duren, Germany) with a 7.5 mm × 4 mm i.d. guard column of the same material (Alltech, Sedriano, Italy). Water was HPLC quality, purified in a Milli-Q system (Millipore, Bedford, MA, USA). Disposable syringe filters, Anotop 0.2 μm, were purchased from Whatman (Maidstone, U.K.). Fusaric acid was purchased from Sigma (St. Louis, MO, USA).

The methyl esters of **1** and **2** were prepared by diazotization of the corresponding acids as previously reported.[16]

Purification of 9,10-Dehydrofusaric Acid. 9,10-Dehydrofusaric acid, **2** (Figure 1), was purified from fungal culture filtrates of *Fusarium nygamai* as previously described by Capasso et al., 1996.[15] Briefly, culture filtrates were acidified up to pH 2 and exhaustively extracted with EtOAc. The organic extract was purified by combination of column and TLC on silica gel and reverse phase yielding **2** as a homogeneous amorphous solid (121.6 mg/L).

Fungal Strains, Culture Medium, and Growth Conditions. The *Fusarium oxysporum* f. sp. *pisi* race 2 isolates F42 and F69 were kindly provided by Dr. W. Chen (USDA-ARS, Pullman, WA, USA). The *F. oxysporum* f. sp. *pisi* strain CBS 127.73 NRRL36628 (*Fop*1) was provided by CBS-KNAW Fungal Biodiversity Center (Utrecht, The Netherlands). In addition, the strains Pt1 and Arg3 were isolated from wilted pea plants collected at Alvaiázere, Portugal, and Setif, Algeria, respectively. Isolation of fungal colonies on surface-sterilized wilted pea fragments was performed as described previously[3] and maintained as a single-spore colony. They have been deposited in the collection of Institute for Sustainable Agriculture, IAS-CSIC (Córdoba, Spain). The fungal strains were stored as microconidial suspensions at −80 °C in 30% glycerol. For microconidia production, cultures were grown in potato dextrose broth (PDB) (Difco, Detroit, MI) at 28 °C in a shake culture set at 170 rpm.[17] For toxin production, Erlenmeyer flasks (500 mL) containing 200 mL of Czapek−Dox medium (5% glucose, 0.1% yeast extract, 0.05% K_2HPO_4, 0.2% $NaNO_3$, 0.05% $MgSO_4{\cdot}7H_2O$, and 0.001% $FeSO_4{\cdot}7H_2O$), were inoculated with 200 μL of fresh *Fop* microconidia at 10^9 conidia/mL and incubated under shaking at 28 °C for 7 days. The content of the flask was filtered on cheesecloth and centrifuged at 7,000 rpm for 10 min. The supernatant containing the secreted *Fop* toxins was then frozen at −80 °C and lyophilized before further analysis. Morphological characterization of each strain was performed at X40 and X63 magnification with a bright light microscope with Nomarsky filter.

DNA Extraction, PCR Amplifications, and Sequencing. Genomic DNA was extracted from *F. oxysporum* mycelium following a previously reported protocol.[18] Molecular characterization of each *Fop* strain was performed by analysis of the internal transcribed spacers (ITS) and the 5′ intron-rich portion of the elongation factor alpha (EF-alpha). ITS and EF-alpha sequences were obtained by PCR amplification with primers ITS-1/ITS-4[19] and EF-1/EF-2[20] respectively. Each 50 μL reaction mixture contained 50 ng of template DNA, 2 units of BioTaq DNA polymerase (Bioline, London, U.K.), 1× PCR buffer, 2 mM $MgCl_2$, 200 μM dNTPs, and 0.3 μM of each primer. The PCR amplifications were performed on a MyCycler (Biorad, Hercules, CA) thermocycler as follows: (i) for ITS, 94 °C for 2 min, 40 cycles at 94 °C for 1 min, 55 °C for 2 min, and 72 °C for 2.5 min followed by a final step at 72 °C for 10 min; (ii) for EF-alpha, 94 °C for 5 min, 30 cycles at 94 °C for 35 s, 52 °C for 35 s, and 72 °C for 1 min followed by a final step at 72 °C for 10 min. All amplifications were purified with the PCR cleanup kit of QIAgen and cloned in pGEMT vector (Promega, Madison, WI). Two positive clones per amplicon were sequenced by STABVida (Setubal, Portugal) using the pGEMT vector specific primers SP6 and T7.

Sequence Data Analysis. Reads of each sequence were assembled and manually corrected with Chromaspro 1.7.5 (Technelysium Pty Ltd., South Brisbane, Australia). Sequences were used in BLAST[21] searches against the GenBank[22] and Mycobank[23] databases to identify the most similar sequences available in the databases. Pairwise alignments were performed with the Neddleman−Wunsh algorithm (Needle method) implemented at EMBL-EBI webserver.[24] All DNA sequences have been deposited in GenBank (Table S1 in the Supporting Information).

Plant Materials. Assignment of the different strains to a specific race of *F. oxysporum* f. sp. *pisi* was performed by testing the pathogenicity profile of these isolates on a set of differential pea lines (Table 1).[1,3] The comparison of the aggressiveness of each strain was performed on *P. sativum* cv. 'Messire'. To determine the effect of fungal culture filtrates or their corresponding organic extracts, seven pea accessions with a wide range of response to *Fop* race 2 were used including the susceptible accessions JI1213, 'Messire', and P629, the partially resistant accessions JI2480 and P615, and the resistant accessions P42 and P633.

Table 1. List of the Pea Differential Lines for *F. oxysporum* f. sp. *pisi* and Their Susceptibility Response to the New *Fop* Isolates

	expected[a]				observed[b]		
accessions	R1	R2	R5	R6	F42	Arg3	Pt1
'Dark Skin Perfection'	R	S	S	S	S	S	S

[a]Accessions' response to each *Fop* race as described in Kraft and Pfleger[1] and Bani et al.[3] R stand for resistant reaction and S susceptible. [b]Accessions' response to the inoculation with the reference R2 strain F42 and the isolates from Algeria and Portugal obtained in the present study.

For all experiments, germinated pea seedlings were sown in vermiculite and grown in a controlled environment under a 16/8 h light−dark photoperiod at 26 ± 2 °C with 200 μmol/m^2/s of illumination. Plants were watered every three days with tap water.

Pathogenicity Test. To determine the pathogenicity of each *Fop* isolate, seven day old pea seedlings were inoculated with the dip root technique as described previously[3] and maintained in the same growth conditions as above. Disease was then evaluated every three days by estimating the percentage of leaves with symptoms and the area under the disease progression curve (AUDPC).[3] Five plants were used per accession, and each experiment was repeated twice independently.

Extraction and Purification of Fusaric and 9,10-Dehydrofusaric Acids from Fungal Culture Filtrates. Lyophilized *Fop* culture filtrates (200 mL) were redissolved in 1/10 of the initial volume with distilled water. The pH of solutions were adjusted to 2.5 with 1N HCl and extracted with EtOAc (3 × 20 mL). The acidic organic extracts were combined, dried (Na_2SO_4), and evaporated under reduced pressure, yielding brown oily residues (38.9, 101.7, 36.4, 42.7, and 29.5 mg for F42, F69, *Fop1*, Arg3, and Pt1 respectively). The five acidic organic extracts were analyzed by TLC on silica gel [eluent EtOAc−MeOH−H_2O (8.5:2:1, v/v/v)] and on reverse phase [eluent CH_3CN−H_2O (1:1, v/v)], in comparison with authentic standard samples of **1**, **2**, and their methyl esters. To confirm the presence of **1** and **2**, the residue of organic extract of F42 was purified by TLC eluted with CH_3CN−H_2O (1:1, v/v), yielding two pure solid compounds: **1**, R_f 0.50, eluent EtOAc−MeOH−H_2O (8.5:2:1, v/v/v), R_f 0.51 eluent CH_3CN−H_2O (1:1, v/v), and **2**, R_f 0.40, eluent EtOAc−MeOH−H_2O (8.5:2:1, v/v/v), R_f 0.58, eluent CH_3CN−H_2O (1:1, v/v), which were identified as fusaric acid and 9,10-dehydrofusaric acid as described below.

Fusaric acid (1). IR, UV, and ^{1}H NMR spectra were very similar to data reported.[15] ESIMS (+) *m/z*: 381 $[2M + Na]^+$, 202 $[M + Na]^+$. ESIMS (−) *m/z*: 178 $[M - H]^-$. APCIMS (+) *m/z*: 180 $[M + H]^+$.

9,10-Dehydrofusaric acid (2). IR, UV, and ^{1}H NMR spectra were very similar to data reported.[15] ESIMS (+) *m/z*: 200 $[M + Na]^+$. ESIMS (−) *m/z*: 176 $[M - H]^-$.

HPLC Analysis of Acidic Organic Extracts. A method previously reported[16] was optimized and used for analysis. The mobile phases employed were MeOH (eluent A) and 1% K_2HPO_4 adjusted to pH 7.35 with concentrated H_3PO_4 (eluent B). Elution was initially with A:B (50:50), which was transformed using a linear gradient over 20 min to A:B (75:25); the initial conditions were restored using a linear gradient over 5 min, and the column was re-equilibrated under these conditions for 10 min before the next run was initiated. The flow rate was 1 mL/min, and 20 μL aliquots of the samples were injected for analysis. Detection was performed at 268 nm, corresponding to the maximum of absorption of **1** and **2**. The HPLC calibration curves for quantitative determination of **1** and **2** were performed with absolute amounts of standards dissolved in MeOH in the range between 0.2 and 20 μg for each compound, in triplicate for each concentration. HPLC linear regression curves (absolute amount against chromatographic peak area) for **1** and **2** were obtained based on weighted values calculated from seven amounts of the standards in the above range. The samples were dissolved in MeOH and passed through disposable filters, and aliquots (20 μL) were injected into the HPLC instrument. Each sample was assayed in triplicate. The quantitative determination of **1** and **2** was calculated by interpolating the mean area of their chromatographic peaks with the data from the calibration curves.

Recovery Studies. Recovery studies were performed using the best producer isolate F69. Pure fusaric and 9,10-dehydrofusaric acids were added to the culture filtrate from 0.3 to 2.0 mg/L. The samples were prepared as described above and the extracts analyzed by HPLC to determine recovery. Three replicate injections were performed for each concentration. The recovery throughout the range of concentration was higher than 96 ± 2%.

Biological Assays. *Leaf Absorption Assay.* The toxicity of the culture filtrate of *Fop* race 2 isolate F42 was assayed by incubating fully expanded leaves in an F42 culture filtrate. For this, the leaf petiole was immersed into an Eppendorf tube containing 1 mL of one week old fungal culture filtrate before or after autoclaving at 121 °C for 20 min and incubated at room temperature for 24 and 48 h. Four fully developed leaves were used for each pea accession.

Leaf Puncture Assay. A leaf puncture bioassay on pea leaves was performed to evaluate the toxic effect of culture filtrates from all *Fop* race 2 isolates tested. Fully expanded leaves from pea plants were placed on Petri dishes containing water−agar medium and punctured by a sterile needle on the upper surface. Droplets (10 μL) of the culture filtrate or corresponding organic extract in 1% MeOH were applied on the wounded leaves at 2 mg/mL. Plates were then incubated at room temperature under darkness. After 3 days of incubation, the area (mm^2) of the necrotic lesions was measured. Droplets of a pure standard of **1** and **2** at 2 mg/mL were used as positive control reactions while droplets of sterile water, Czapek−Dox medium, or 1% MeOH were used as negative control. The experiments were performed with four replicates for each treatment.

Statistical Analysis. Analyses of variance (ANOVA) were carried out for phytotoxicity records, with the different tested solutions and metabolites as fixed factors of their respective bioassays. One way ANOVA was also performed to test the significance of aggressiveness differences between each strain. Phytotoxicity and percentage of symptoms values were transformed using the square root transformation in order to increase the normality of their distribution. Whenever the ANOVA test was statistically significant ($p \leq 0.05$), a Duncan multiple range test assessing the differences of the means between each treatment was performed. All statistical analyses were performed using Genstat release 11.1 software (VSN International Ltd., Hemel Hempstead, U.K.).

RESULTS AND DISCUSSION

F. oxysporum species complex is composed of many species very closely related morphologically, which makes them difficult to identify. To ensure that all fungal strains corresponded to isolates of the race 2 of *F. oxysporum* f. sp. *pisi*, these isolates were characterized at morphological and molecular levels before further analysis. As expected, all fungal strains showed morphological characteristics of *F. oxysporum* complex species. Amplification of ITS and EF-alpha gave sequences ranging from 544 to 545 bp and 710 to 714 bp long respectively according to the isolate (Table S1 in the Supporting Information). These sequences showed between 99 and 100% identity to *F. oxysporum* sequences from different formae speciales including ff. spp. *pisi*, *ciceri*, *medicaginis*, and *lycopersici* according to the BLAST comparison performed. In addition they share 99.8−100% and 98.6−100% identity to the reference *Fop* race 2 strain F42 respectively (Table S1 in the Supporting Information). This clearly identified them as *F. oxysporum* although it was not possible to identify the ff. spp. to which they belong by these methods, hampered by the potential polyphyletic origin of the isolates and potential horizontal transfer of host-specificity genes.[20] Nevertheless, the in planta pathogenicity test indicated that they corresponded to *F. oxysoprum* f. sp. *pisi*. Indeed, all these strains were pathogenic on the susceptible pea cultivar 'Messire' (Figure 2). Slight differences in aggressiveness were observed between isolates as determined by their AUDPC value ($p < 0.001$). The strain F69 was the most aggressive, reaching AUDPC values of 2388, while the isolates *Fop1* and Arg3 were the least aggressive, reaching AUDPC of only 1678 and 1778.5 respectively (Figure 2A). This difference was rooted to a faster disease development induced by strain F69, which led to complete plant death as early as 12 days post inoculation (dpi) while the Arg3 and *Fop 1* strains required 25 days to induce a similar effect (Figure 2B). This was confirmed by the ANOVA, which revealed significant differences between isolates only up to 15 days post inoculation ($p < 0.001$) while at later stages the differences were not significant ($p > 0.5$). In addition, the inoculation of a set of differential lines[1,3] allowed assigning the new isolates Arg3 and Pt1 to race 2 of *Fop* since accession's response to these isolates followed a similar pattern as for the reference race 2 strain F42. Indeed, no or only mild symptoms were detected on the race 2 resistant accessions while the susceptible accessions 'Dark Skin perfection', P629, and 'Messire' developed characteristic wilt symptoms (Table 1). By contrast, *Fop*1 showed *near wilt* (leaf yellowing) symptoms on most accessions, which impeded a clear classification of this strain to a specific race (data not shown). However, the very close molecular relationship between this isolate and the Algerian (Arg3) isolate as shown by the analysis of EF-alpha sequence (Table S1 in the Supporting Information) together with the *near wilt* symptoms detected would suggest that this isolate also belongs to race 2 of *Fop*.

To characterize further the mechanisms of pathogenicity of *Fop* race 2 isolates that remain largely unknown, the effect of one week old *Fop* culture filtrates was evaluated on pea leaves. Incubation of pea leaves in F42 culture filtrate for 24 h induced leaf withering followed by leaf discoloration that initiated at the central vein and progressed to cover the whole leaf and petiole as early as 48 h of incubation (Figure 3A). Similar effects were detected on all pea accessions tested including on resistant accessions (Figure 3B). The leaf puncture assay also showed a

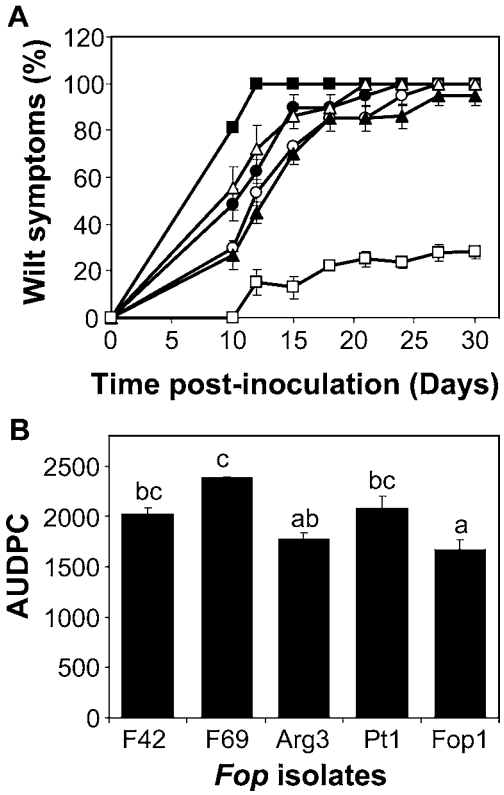

Figure 2. Pathogenicity of the *F. oxysporum* f. sp. *pisi* race 2 isolates on the susceptible pea cultivar 'Messire'. (A) Evolution of *Fusarium* wilt symptoms on the susceptible pea cultivar 'Messire' induced by the *Fop* race 2 isolates F42 (●), F69 (■), Arg3 (○), Pt1 (△), and *Fop1* (▲) respectively, compared to control plants treated with water (□). Disease progression was estimated as percentage of leaf with symptoms over time. (B) Comparison of AUDPC values calculated from the periodic assessment of development of *Fusarium* wilt symptoms. Different letters between each histogram indicate significant difference between the values according to the Duncan multiple range test at $\alpha = 0.05$. Vertical bars are standard error for $n = 5$.

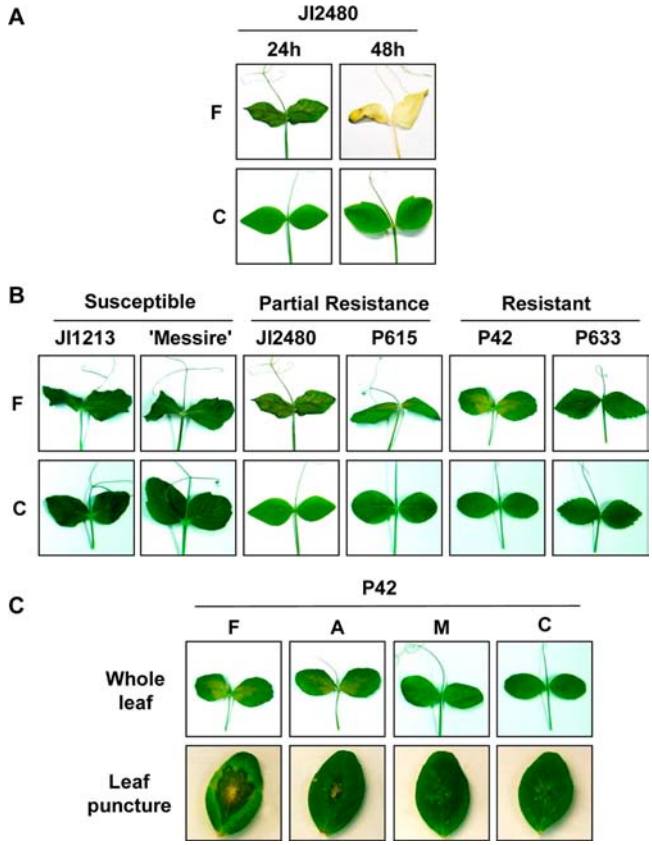

Figure 3. Effect of the culture filtrates of *F. oxysporum* f. sp. *pisi* race 2 isolate F42 on pea leaves. (A) Progression of wilting symptoms induced on the partially resistant accession JI2480 by the culture filtrates after 24 and 48 h of treatment (F) compared to control with sterile water (C). (B) Effect of the culture filtrates after 24 h of treatment on leaves of seven pea accessions differing in their susceptibility to *Fop* race 2. (C) Comparison of the leaf response of the resistant pea accession P42 to culture filtrates (F), autoclaved culture filtrates (A), sterile Czapek–Dox medium (M), and sterile water (C) evaluated with the leaf absorption and the leaf puncture assays.

progressive spreading of necrosis and leaf discoloration after treatment with the fungal culture filtrates while control remained symptomless (Figure 3C). A broad effect of *F. oxysporum* culture filtrates was previously detected for *F. oxysporum* f. sp. *orthoceras* and *F. oxysporum* f. sp. *albedinis*, which extract induced wilting on both host and nonhost species.[25,26] This supports the presence of a nonspecific toxin within these filtrates. In addition it indicated that resistance of the pea accessions tested was not based on toxin detoxification. This was also detected in *F. oxysporum* ff. spp. *melonis*[27] and *cubense*.[28] However, in the present study, only three resistant *Pisum* spp. accessions have been tested. Thus, it may still be possible that the resistance mechanisms of other resistant pea accessions are based on toxin detoxification as detected previously in near-isogenic lines of tomato differing in their susceptibility to *F. oxysporum* f. sp. *lycopersici*.[29] Interestingly, organic extracts of the culture filtrates from all *Fop* race 2 isolates tested were able to induce leaf necrosis on 'Messire' leaves when evaluated with the leaf puncture assay after 3 days of incubation (Figure 4A). However, difference in lesion size could be detected between the strains ($p < 0.001$), in agreement with the difference in aggressiveness of these strains on this pea cultivar (Figure 4B). The lesion size ranged from 16.8 mm^2 for Arg3 to 42.4 and 58.4 mm^2 for F42 and F69 culture filtrate respectively (Figure 4B).

Various pathogenicity factors including cell-wall degrading enzymes, phytoalexin-detoxifying enzymes, and toxins have been shown to mediate *F. oxysporum* virulence.[4] In contrast to a previous study that showed the complete loss of toxic activity after autoclaving culture filtrates,[29] autoclaving only slightly attenuated the toxicity of the filtrate on leaf absorption and puncture assays (Figure 3C). This ruled out that the toxicity is due to proteins and suggested the presence of heat-stable metabolites as found for other isolates of *Fop*[30] and human pathogenic strains of *F. oxysporum*.[31]

To identify the heat-stable metabolite(s) responsible for the toxicity of *Fop* race 2 culture filtrates, the organic extract of culture filtrates obtained from the isolate F42 was fractionated and further analyzed. TLC analysis of these fractions showed that this strain produced two toxins, identified as fusaric acid, **1**, and dehydrofusaric acid, **2**, by comparison with standard samples. Their corresponding methyl esters were not detected. These results were confirmed by purification of **1** and **2** from this organic extract. The ^{1}H NMR spectrum was very similar to those previously reported.[15] The data obtained from ESI MS

spectra further supported the isolation of **1** and **2**. The ESI MS recorded in positive ion mode showed the sodiated dimeric form $[2M + Na]^+$ and the sodium cluster $[M + Na]^+$ at m/z 381 and 202, respectively. In APCI MS it showed the pseudomolecular ion $[M + H]^+$ at m/z 180. When the ESI MS was recorded in negative ion mode, it showed the pseudomolecular ion $[M - H]^-$ at 178. The ESI MS spectrum of **2** recorded in positive and negative ion mode showed the sodium cluster $[M + Na]^+$ and the pseudomolecular ion $[M - H]^-$ at m/z 200 and 176, respectively. Further studies indicated that all *Fop* race 2 isolates investigated produced **1** and **2** but not their related methyl esters. Both toxins have been already identified from cultures of *F. oxysporum* pathogenic to the parasitic plants *Striga hermonthica*.[16,32,33] However, it is the first time that **2** is reported from *F. oxysporum* isolates pathogenic to crops. Other toxins were not found in any of these isolates. Production of toxins showed large qualitative and quantitative variation according to growth conditions including growth medium, temperature, and ambient pH among others.[16,25,34] Thus, it could not be ruled out that these strains may produce additional toxins as described for other *F. oxysporum* strains.[11−14]

Testing these acids with the leaf puncture assay indicated that both **1** and **2** possessed phytotoxic activity and induced necrotic lesion similar to that induced by the F42 culture filtrates (Figure 5B). Comparison of lesion size indicated that **1** (55.8 mm^2) was 2.5 time more phytotoxic than **2** (22.6 mm^2). Many studies demonstrated the function of **1** in pathogenicity, although in several instance no correlation was detected between the concentration of **1** and fungal virulence.[5,7,35] **1** has been shown to alter membrane permeability, inhibit O_2 uptake and ATP synthesis, decrease mitochondrial activity, transpiration rate, and stomatal conductance, and induce cell depolarization,[7,10] suggesting that **1** participates in *F. oxysporum* pathogenicity by decreasing plant cell viability.[7] By contrast, nearly nothing is known about the action of **2**.[15] This compound was previously shown to induce tomato leaf chlorosis and inhibit root elongation to a similar extent as **1**.[15] Here we demonstrated that dehydrofusaric acid was also phytotoxic on pea leaves (Figure 4), indicating that it may also contribute to the pathogenicity of *F. oxysporum*.

To confirm the function of **1** and **2** in *Fop* race 2 pathogenicity, we quantitated the production of both acids by all *Fop* race 2 isolates tested and related it to their level of aggressiveness. For the quantitation, we slightly modified a previously reported HPLC method.[16] The characteristics of the calibration curves, the absolute range, and the detection limits (LOD) of **1** and **2** are summarized in Table S2 in the Supporting Information. Regression analysis suggests that the calibration curves are linear. A representative HPLC chromatogram of the ethyl acetate extract of the culture filtrates of *Fop* F42 is presented in Figure 5A. The metabolite chromatographic peaks (*a* and *b*) in the sample were coincident with the 7.80 and 5.20 min retention times of **1** and **2** standards (Figure 5A). The retention times were highly reproducible, varying less than 0.50 min. For all strains matrix substances absorbing at 268 nm were eluted within the first 20 min. **1** could be quantitatively and reproducibly detected from 0.5 μg, and **2** from 0.2 μg, with lower amounts having poor reproducibility.

Although **1** and **2** were secreted by all isolates of *Fop* race 2 tested, this method allowed detecting quantitative differences between these isolates ($p < 0.001$) for both toxins. Of the strain tested, F69 produced the highest amount of **1** and **2** (258.49 and 243.36 mg/L, respectively) whereas strains Arg 3 and *Fop1* produced the least **1** (9.94 mg/L) and **2** (21.44 mg/L) respectively (Figure 6). The capacity to produce and secrete **1** was significantly and positively correlated with the leaf lesion size ($r^2 = 0.83$; Figure 7A) and slightly correlated with in planta pathogenicity ($r^2 = 0.66$; Figure 7B). Production of **2** was significantly correlated with in planta pathogenicity ($r^2 = 0.8$; Figure 7D) and to a lesser extent with lesion size ($r^2 = 0.66$; Figure 7C). Interestingly, the total toxin production was significantly correlated with both virulence parameters ($r^2 = 0.78$ and 0.76 for leaf lesion size and in planta pathogenicity respectively) (Figures 7E and 7F). This reinforced the important role of **1** in *F. oxysporum* pathogenicity as it was already demonstrated for *F. oxysporum* ff. spp. *carthami*,[36] *lycopersici*,[37,38] *melonis*,[39] and *gladioli*,[40] among others. It also demonstrated that **2** is an important pathogenicity factor acting

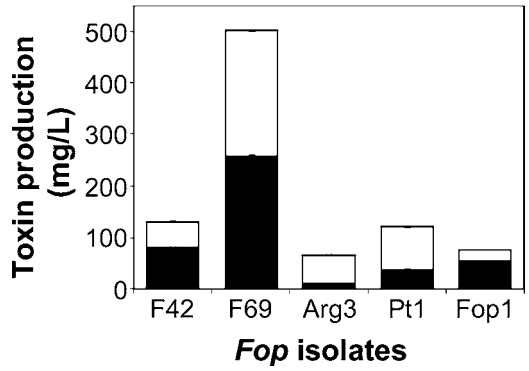

Figure 6. Quantitation of the amount of **1** and **2** produced by the different isolates of *F. oxysporum* f. sp. *pisi* race 2. The histograms show the cumulative production of **1** (black column) and **2** (white column) for each *Fop* race 2 isolate. Vertical bars are standard error for $n = 3$.

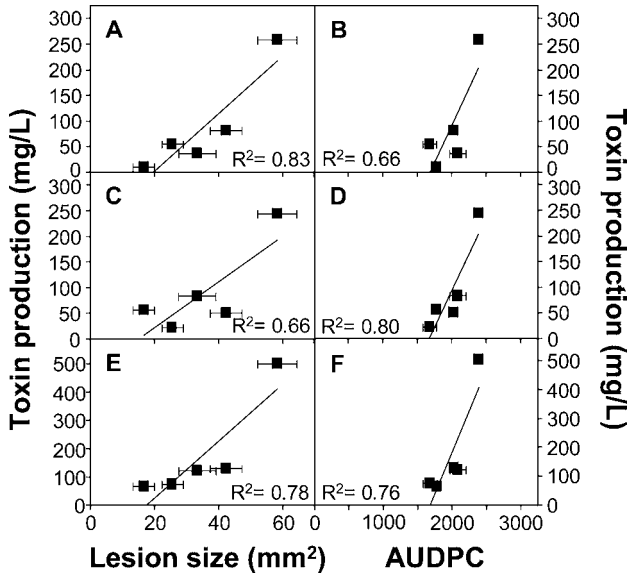

Figure 7. Relationship between toxin production and phytotoxicity. The graphics represent the linear correlation calculated for **1** (A, B), **2** (C, D), and the sum of both toxins (E, F) production by each *Fop* race 2 isolate with the lesion size induced by their corresponding culture filtrate (A, C, E) or their overal aggressiveness on the susceptible pea cultivar 'Messire' estimated by their AUDPC values (B, D, F). Horizontal bars are standard errors for lesion size area or AUDPC values with $n = 4$ and $n = 5$ respectively while vertical bars are standard error bars of toxin content calculated with $n = 3$.

in synergy with **1**, which was not described before for *F. oxysporum* (Figure 7).

In conclusion, it has been demonstrated that *Fop* race 2 isolates produced mainly two toxins that were identified as fusaric and 9,10-dehydrofusaric acids. Both toxins showed high phytotoxic activity on pea when tested on whole leaves and leaf puncture assay. In addition, the amount of both toxins within culture filtrates correlated with strain aggressiveness, which indicates a role of these toxins during *Fop* pathogenicity. Although the importance of fusaric acid in the pathogenicity of *F. oxysporum* is still under debate, the results obtained in the present study strongly indicate that toxin production is an important determinant of *Fop* race 2 pathogenicity.

addition, the binding mechanism of polyphenols with proteins has not been clarified yet, nor has the conjugation site of amino acids of proteins been elucidated.

Therefore, we studied the interaction of catechin and OTF in order to investigate the antioxidant activity of modified protein. Two different conjugating reactions between OTF and catechin were conducted. The identification of catechin was performed by liquid chromatography coupled online to a tandem mass spectrometer (LC−MS−MS). The possibility to graft antioxidant moieties like catechin into a proteic structure represents an interesting innovation that significantly improves the performance of the biomacromolecules, opening up new applications in the nutraceutical and functional food ingredient fields.

2. METHODS AND MATERIALS

2.1. Chemicals and Reagents. Ovotransferrin was provided by Neova Technologies Inc. (Abbotsford BC, Canada), and the purity was >89%. (+)-Catechin was purchased from Sigma (Oakville, ON, Canada), and the purity was >98%, HPLC grade. Asorbic acid, 6-hydroxy-2,5,7,8-tetramethylchromate-2-carboxylicacid (Trolox), ethylenediaminetetraacetic acid (EDTA) were also purchased from Sigma (Oakville, ON, Canada). Fluorescein disodium salt and 2,20-azobis(2-methylpropionamide) dihydrochloride (AAPH) were obtained from Fisher Scientific (Ottawa, ON, Canada). All other chemicals and reagents used in this study were obtained from Sigma and were of the analytical grade.

2.2. Conjugation of OTF and Catechin. Conjugates were prepared either by free radical[16] or alkaline method.[14] To prepare conjugates by the free radical method, in a 100 mL glass flask, 0.5 g of ovotransferrin was dispersed in 50 mL of distilled H_2O, then 1.0 mL of 5.0 M H_2O_2 (5.0 mmol) and 0.25 g of ascorbic acid (1.4 mmol) were added, and the mixture was maintained at 25 °C under atmospheric air. After 2 h, 0.35 mmol of catechin were added to solution to react for 24 h; unreacted catechin was removed by dialysis (dialysis tube with 1000 molecular weight cutoffs) at 4 °C for 48 h with Milli-Q water with eight changes. Conjugate was also prepared by the alkaline method. In the presence of alkaline, catechin is oxidized to its respective quinone. The reaction of this quinone with the nucleophilic side chains of proteins such as lysine, cysteine, methionine and tryptophan leads to a protein-phenol derivative.[14] The alkaline conjugate was prepared in a 100 mL glass flask; 0.5 g of ovotransferrin was dispersed in 50 mL of distilled H_2O, the pH was adjusted to 9.0, and the mixture was maintained at 25 °C under atmospheric air. After 2 h, 0.35 mmol of catechin were added to solution for 24 h with continuous stirring; unreacted catechin was removed by dialysis as above. The resulting solutions were frozen and freeze-dried.

2.3. Determination of Antioxidant Activities. *2.3.1. Oxygen Radical Absorbance Capacity (ORAC) Assay.* The ORAC assay using fluorescein as the fluorescent probe was performed according to Huang et al.[24] The reaction was carried out in 96-well black microplates (96F nontreated, Nunc, Roskilde, Denmark). Samples at different concentrations were mixed with 75 mM phosphate buffer (pH 7.4; 80 μL) and 200 nM fluorescein (50 μL) and incubated at 37 °C for 15 min. Then, 80 mM AAPH solution (50 μL) was added to each well using a dispenser. The fluorescence was recorded every min for 100 min by a microplate reader (Fluoroskan Ascent; Thermo Electron Corp., Vantaa, Finland). The excitation and emission wavelengths were 485 and 538 nm, respectively. Phosphate buffer was used instead of sample solution as blank. The area under curve was calculated by integrating the relative fluorescence curve. The ORAC value was calculated by dividing the slope of sample regression curve by the slope of Trolox regression curve. Final ORAC values were expressed as Trolox equivalents (TE) per mol. All the tests were performed at least in triplicates.

2.3.2. $ABTS^{\bullet+}$ Radical Scavenging Assay. ABTS was performed according to You et al.[25] $ABTS^{\bullet+}$ was produced by mixing 7 mM $ABTS^{\bullet+}$ stock solution with 2.45 mM potassium persulfate. Then the mixture was placed at room temperature in darkness for 17 h to generate radical before use. The $ABTS^{\bullet+}$ working solution was diluted with 5 mM phosphate buffered saline (pH 7.4) to an absorbance of 0.70 ± 0.02 at 734 nm. Radical scavenging activity of samples was measured by mixing 100 μL of the samples with 100 μL of diluted $ABTS^{\bullet+}$. The decline in absorbance was measured at 1 min interval for a total of 10 min. A standard curve was prepared by reacting 100 μL of a series of concentrations of Trolox (0, 2, 4, 8, 12, 16, and 20 μM) with 100 μL of diluted $ABTS^{\bullet+}$ solution. The degree of radical scavenging activity of the samples was calculated on the basis of the Trolox standard curve and was expressed as TEAC (μmol/mg sample).

2.3.3. Reducing Power Assay. The ability of samples to reduce iron(III) was determined by the method of Yildirim, Mavi, and Kara.[26] An aliquot of 1 mL of sample (5 mg/mL) was mixed with 2.5 mL of 0.2 M phosphate buffer (pH 6.6) and 2.5 mL of 1% (w/v) potassium ferricyanide. The mixtures were incubated at 50 °C for 30 min. After incubation, 2.5 mL of 10% (w/v) trichloroacetic acid was added and the reaction mixtures were centrifuged for 10 min at 3000*g*. Finally, 2.5 mL of the supernatant solution was mixed with 2.5 mL of distilled water and 0.5 mL of 0.1% (w/v) ferric chloride solution. After a 10 min reaction time, the absorbance of the resultant solution was measured at 700 nm. Higher absorbance of the reaction mixture indicated higher reducing power.

2.4. Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed in a Mini-PROTEAN tetra cell with a Power Pac Basic electrophoresis apparatus (Bio-Rad Laboratories, Inc., Hercules, CA, U.S.A.) at a constant voltage of 200 V according to Offengenden et al.[27] OTF and OTF-catechin conjugates solutions (2 mg/mL) were diluted in a ratio of 1:1 with Laemmli sample buffer containing 5% β-mercaptoethanol and loaded on 12% Mini-PROTEAN TGX precast gel (Bio-Rad Laboratories, Inc., Hercules, CA, U.S.A.). Loading volume of samples and protein marker "Precision Plus Standards Dual Xtra Protein" (Bio-Rad Laboratories, Inc., Hercules, CA, U.S.A.) was 15 μL. The gel was stained with Coomassie brilliant blue R250 and scanned in an Alpha Innotech gel scanner (Alpha Innotech Corp., San Leandro, CA, U.S.A.) with Fluor Chem SP software.

2.5. Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry (MALDI-TOF−MS). MALDI-TOF−MS was used to determine the molecular weights of OTF and OTF-catechin conjugates. Lyophilized OTF and OTF conjugates were dissolved in 20 μL of distilled H_2O. A 0.8 μL aliquot of sample solution was spotted to an 800 μm Bruker's anchor Chip MALDI target (Bruker Daltonics, Billerica, MA, U.S.A.). A 0.8 μL aliquot of matrix solution was then spotted on top of the sample and left to dry. 2,5-dihydroxybenzoic acid (DHB) was used as the matrix compound. Matrix solution was prepared in 50% acetonitrile at a final concentration of 3.5 mg/mL. MALDI MS was performed on an ultraflex Xtreme TM MALDI-TOF/TOF (Bruker Daltonics, Billerica, MA, U.S.A.) mass spectrometer in positive MS or lift mode.

2.6. Fluorescence. The fluorescence of samples was tested according to Roy et al.[28] with slight modification. The steady-state fluorescence spectra of samples were recorded at an excitation wavelength of 280 nm in a SepctraMax M3 spectrometer (Molecular Devices, Inc., U.S.A.), with 10 nm excitation and 5 nm emission bandwidth, in a 96 well plate. Samples were dissolved in distilled water to make a protein concentration of 10^{-5} M.

2.7. Ultra Performance Liquid Chromatography (UPLC). The hydrophilic/hydrophobic characteristics of OTF, catechin, and OTF-catechin conjugates were studied by reverse-phase chromatography using a UPLC (Waters, Miliford, MA, U.S.A.). In brief, samples were dissolved in double distilled water and filtered through a 0.2 μm nylon syringe filter prior to analyze with a Waters BEH 300 C_{18} column (2.1 × 100 mm). The column was eluted (0.5 mL/min) with a two solvent system: (A) 0.1% Trifluoroacetic acid (TFA) in water and (B) 0.1% TFA in acetonitrile, with a gradient from 0% solvent B to 75% solvent B over 30 min, and then decreased to 0% solvent B in 10 min.

2.8. LC−MS−MS. The identification of the sites of protein-catechin conjugates was performed by LC−MS−MS. Excised gel pieces from above SDS-PAGE containing the samples of interest were digested by

trypsin following the protocol of Offengenden et al.[27] OTF-catechin conjugates were analyzed by a Waters (Micro mass) Q-TOF Premier (Milford, MA, U.S.A.) according to Gu and Wu.[29] Mass was detected through quadrupole time-of-flight (Q-TOF) analyzer operated in a positive ion MS/MS mode. A MS/MS full-scan was performed for each sample. The peptides' sequences were identified from respective monoisotopic mass. Instrumental control and data analysis were performed using Mass Lynx software (Micromass U.K. Ltd.). Peaks Viewer 4.5 (Bioinformatics Solutions Inc., Waterloo, ON, Canada) in combination with manual de novo sequencing was used to process the MS/MS data.

2.9. Statistical Analysis. All sample determinations were performed in triplicate and the results were expressed as mean value ± standard deviation (SD) in this study. The fluorescence decay curves and data figures were prepared using GraphPad Prism Version 5.02 (GraphPad Software, Inc., CA, U.S.A.). Analysis of variance (ANOVA) with Tukey's post hoc test was used to determine statistical differences. Differences were considered significant with p value <0.05.

3. RESULTS AND DISCUSSION

3.1. Antioxidant Activities. Effect of conjugation on the antioxidant activities were evaluated by oxygen radical absorbance capacity assay (ORAC), $ABTS^{\bullet+}$ radical scavenging activity and reducing power as shown in Table 1. The ORAC

Table 1. Antioxidant Activities of Ovotransferrin and Ovotransferrin-Catechin Conjugates

	ORAC (mol Trolox/mol sample)	$ABTS^{\bullet+}$ scavenging activity (μmol Trolox/mg sample)	reducing power (Abs)
ovotransferrin	3.95 ± 0.08d	0.18 ± 0.01d	0.22 ± 0.01d
alkaline conjugates[a]	17.14 ± 1.01b	0.27 ± 0.01c	0.75 ± 0.04c
radical conjugates[a]	22.80 ± 0.63a	0.86 ± 0.04b	1.17 ± 0.06b
catechin	8.03 ± 0.47c	1.67 ± 0.05a	2.48 ± 0.13a

[a]Alkaline conjugates: ovotransferrin grafted with catechin by alkaline method. Radical conjugates: ovotransferrin grafted with catechin by radical method.

method based on a classic hydrogen atom transfer mechanism, and it primarily measured the oxidative degradation of the fluorescent molecule after being mixed with peroxyl radical generator.[30] The ORAC value of OTF was 3.95 mol Trolox/mol sample; after conjugation, these values were increased 4−5 times compared to OTF control. The radical conjugate showed higher ORAC value than the alkaline one. $ABTS^{\bullet+}$ radical scavenging assay and reducing power have been widely used to determine the antioxidant capacities as they require relatively standard equipment and deliver fast and reproducible results.[31] Similar to the ORAC data, the radical conjugates showed stronger $ABTS^{\bullet+}$ radical scavenging activity as well as reducing power than the alkaline one. This is due to the different methods of conjugation. For the radical method, the hydroxyl radicals, generated by the interaction between redox pair components, attack the reactive residues in the side chains of protein chain, producing protein radical. Then the catechin reacted with the radical species on the protein.[16] For the alkaline method, catechin oxidized to its respective quinone and then reacted with protein chain.[14]

Spizzirri et al.[16] also reported the improvement of antioxidant activities of antioxidant-gelatin conjugates. Generally, it is considered that a higher number of hydroxyl group substituents in a phenol structure like catechin results in a superior antioxidant activity.[32,33] The introduction of hydroxyl groups into ovotransferrin was responsible for the improved antioxidant activities of ovotransferrin-catechin conjugates.

3.2. SDS-PAGE. The effect of conjugation on the molecular weight of OTF was carried out by SDS-PAGE (Figure 1). The

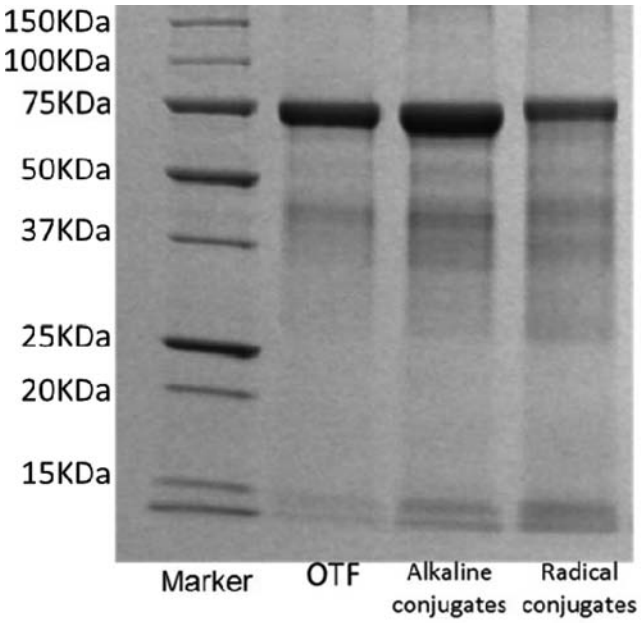

Figure 1. SDS-PAGE of ovotransferrin (OTF) and conjugates of OTF and catechin. Alkaline conjugates: conjugates formed by alkaline method. Radical conjugates: conjugates formed by radical method.

main band in OTF was around 76 kDa.[34] The band of radical conjugates slightly migrated up comparing to the band of OTF, suggesting that the molecular weight of radical conjugates increased resulting from the conjugation. An increase in molecular weight of conjugates after introduction of flavonoid compounds was also reported.[20] However, there was no obvious change in alkaline conjugate. It was reported that phenol-protein complexes could be broken in the presence of SDS,[35] whereas Brunet et al.[11] reported that SDS does not totally break the phenol-protein complex. As the molecular weight of catechin is 290 Da, a lack of change in molecular weight in alkaline conjugate may also be due to a low degree of conjugation.

3.3. MALDI-TOF−MS. Molecular weight change of conjugates was further studied by MALDI-TOF−MS. As shown in Figure 2, the molecular weight of OTF determined by this method was near 76 KDa, agreeing with molecular weight reported by Wu and Acero-Lopez.[7] The molecular weights of both conjugates were increased as shown in the peaks of both alkaline conjugates and radical conjugates. The difference of molecular weight (~400 Da) between OTF and radical conjugates might correspond to the conjugated catechin molecular into OTF monomers. Kim and Cavaco-Paulo[20] pointed out the increase of molecular weight of α-casein-flavonoid conjugates was due to the Michael addition reaction. Similar to results of SDS-PAGE, the difference of molecular weight between OTF and its alkaline conjugates was not obvious. Our MALDI-TOF−MS result further confirmed the possible conjugation of OTF with catechin.

3.4. Fluorescence. A fluorescence study was performed to evaluate changes in structure, as illustrated by the conjugation of OTF with catechin in Figure 3. The maximum emission

dx.doi.org/10.1021/jf405635q | J. Agric. Food Chem. 2014, 62, 2581−2587

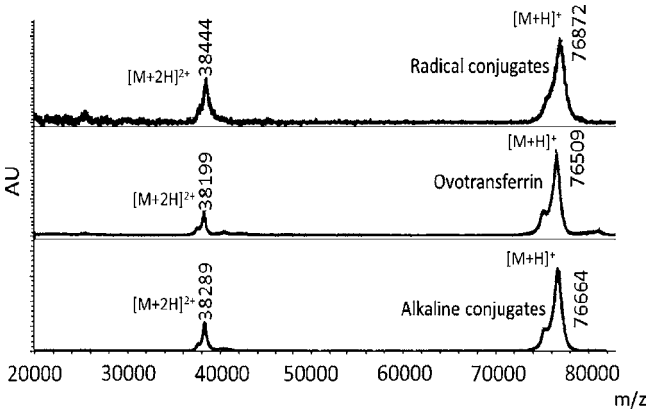

Figure 2. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry of ovotransferrin and ovotransferrin-catechin conjugates. Radical conjugates: ovotransferrin conjugated with catechin by radical method. Alkaline conjugates: ovotransferrin conjugated with catechin by alkaline method.

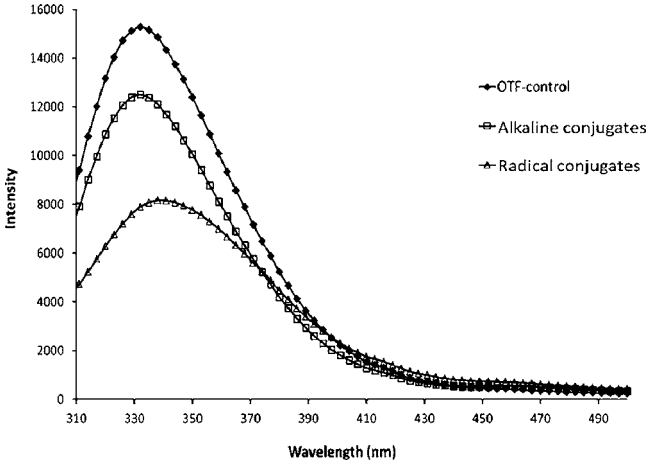

Figure 3. Fluorescence of ovotransferrin (OTF) and conjugates of OTF and catechin. Alkaline conjugates: conjugates formed by alkaline method. Radical conjugates: conjugates formed by radical method.

wavelength for the control OTF was 331 nm (Figure 3), the same as previously reported.[36] There was a red shift of 9 nm after grafted with catechin by radical method, but not the alkaline method. Spizzirri et al.[16] explained that the spectral red shift was due to the covalent conjugation of antioxidants and gelatin. Thus, from the fluorescence result confirmed that catechin was covalently conjugated to OTF by hydrogen peroxide-ascorbic acid pair as radical initiator system. In Figure 3, the fluorescence intensity of OTF-catechin conjugates decreased. Similar results were also observed when grafting flavonoids to soy protein.[37] The interaction of the aromatic ring of the phenolic with aromatic residues such as tyrosine and tryptophan of the protein may be responsible for quenching of fluorescence intensity.

3.5. Ultraperformance Liquid Chromatograph (UPLC). Catechin possesses four −OH phenolic groups located in two benzene rings connected via a nonaromatic ring in which oxygen atom and one more −OH group are present. Therefore, catechin is a well-known hydrophilic antioxidant.[38] A further molecular property of OTF that can be affected by the conjugation of catechin is its hydrophilic/hydrophobic characteristics, which can be illustrated by reversed-phase chromatography. In Figure 4, single peak in each chromatogram of alkaline and radical conjugates were observed, which

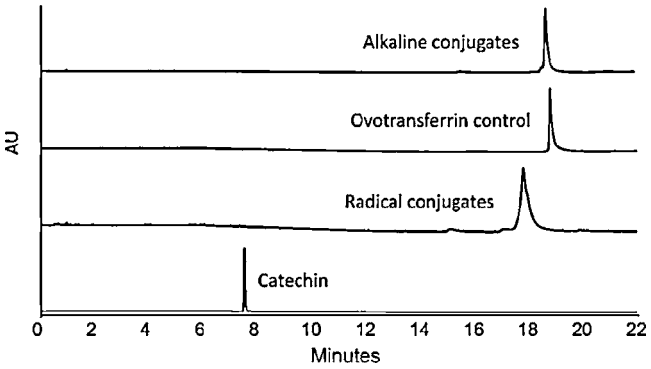

Figure 4. Ultra performance liquid chromatography (UPLC) of ovotransferrin (OTF) and OTF-catechin conjugates. Alkaline conjugates: conjugates formed by alkaline method. Radical conjugates: conjugates formed by radical method, wavelength at 280 nm.

means all the OTF were reacted with catechin. Because alkaline and radical conjugates were dialyzed prior to analysis, the free catechin in OTF-catechin conjugates was completely removed because no peak observed at retention time 7.5 min in the chromatograms of alkaline and radical conjugates (Figure 4). The retention times of OTF and catechin were 19.5 min and 7.5 min, respectively. The retention time of radical conjugate was reduced to 18.4 min, whereas the alkaline conjugate was not changed. In reverse phase chromatography, a decreased retention time indicated reduced hydrophobicity or increased hydrophilicity.[39] The increase of hydrophilicity is related to the introduction of catechin to OTF protein. The interactions between phenolic compounds and proteins would change the net charge in the protein molecules, which in turn affect the hydrophilicity/hydrophobicity of the modified protein.[37] The secondary and tertiary structures of the proteins change as a result of these interactions, influencing the surface properties of the molecules making them hydrophilic in nature.[37] Yuksel et al.[40] also reported that the hydrophobicity of milk proteins was decreased in the presence of low molecular weight phenolics. They explained the decrease in protein hydrophobicity was due to the hydrophobic binding between milk proteins and phenolics.

3.6. LC−MS/MS. LC−MS−MS was conducted in order to identify the possible binding sites of catechin with ovotransferrin. After in gel digestion by trypsin, ovotransferrin and its radical conjugates were analyzed by LC−MS/MS. Figure 5a were the MS spectrum of OTF control and OTF-catechin conjugates, respectively. A high intensity peak in radical conjugate (Figure 5a) was MS ion 597.3. MS/MS data of this doubly charged ion at m/z 597.3 was identified as FMMFESQNK (residues 644−652), which was the same as a triply charged ion at m/z 604.0. Both were part of OTF sequence. Two new MS peaks were identified at 829.5 and 830.5 in Figure 5a as a radical conjugate. Therefore, the MS ions 829.5 and 830.5 were the new ions, which could be the conjugation location. The MS/MS spectrum of these two ions listed in Figure 5b and Figure 5c. The m/z 829.5 was identified as FFSASCVPGATIE-catechin (residues 174−186), and m/z 830.5 was identified as DLLFKDSAIMLK-catechin (residues 316−327). That means catechin was possibly conjugated with the amino acids lysine (residues 327) and glutamic acid

dx.doi.org/10.1021/jf405635q | J. Agric. Food Chem. 2014, 62, 2581−2587

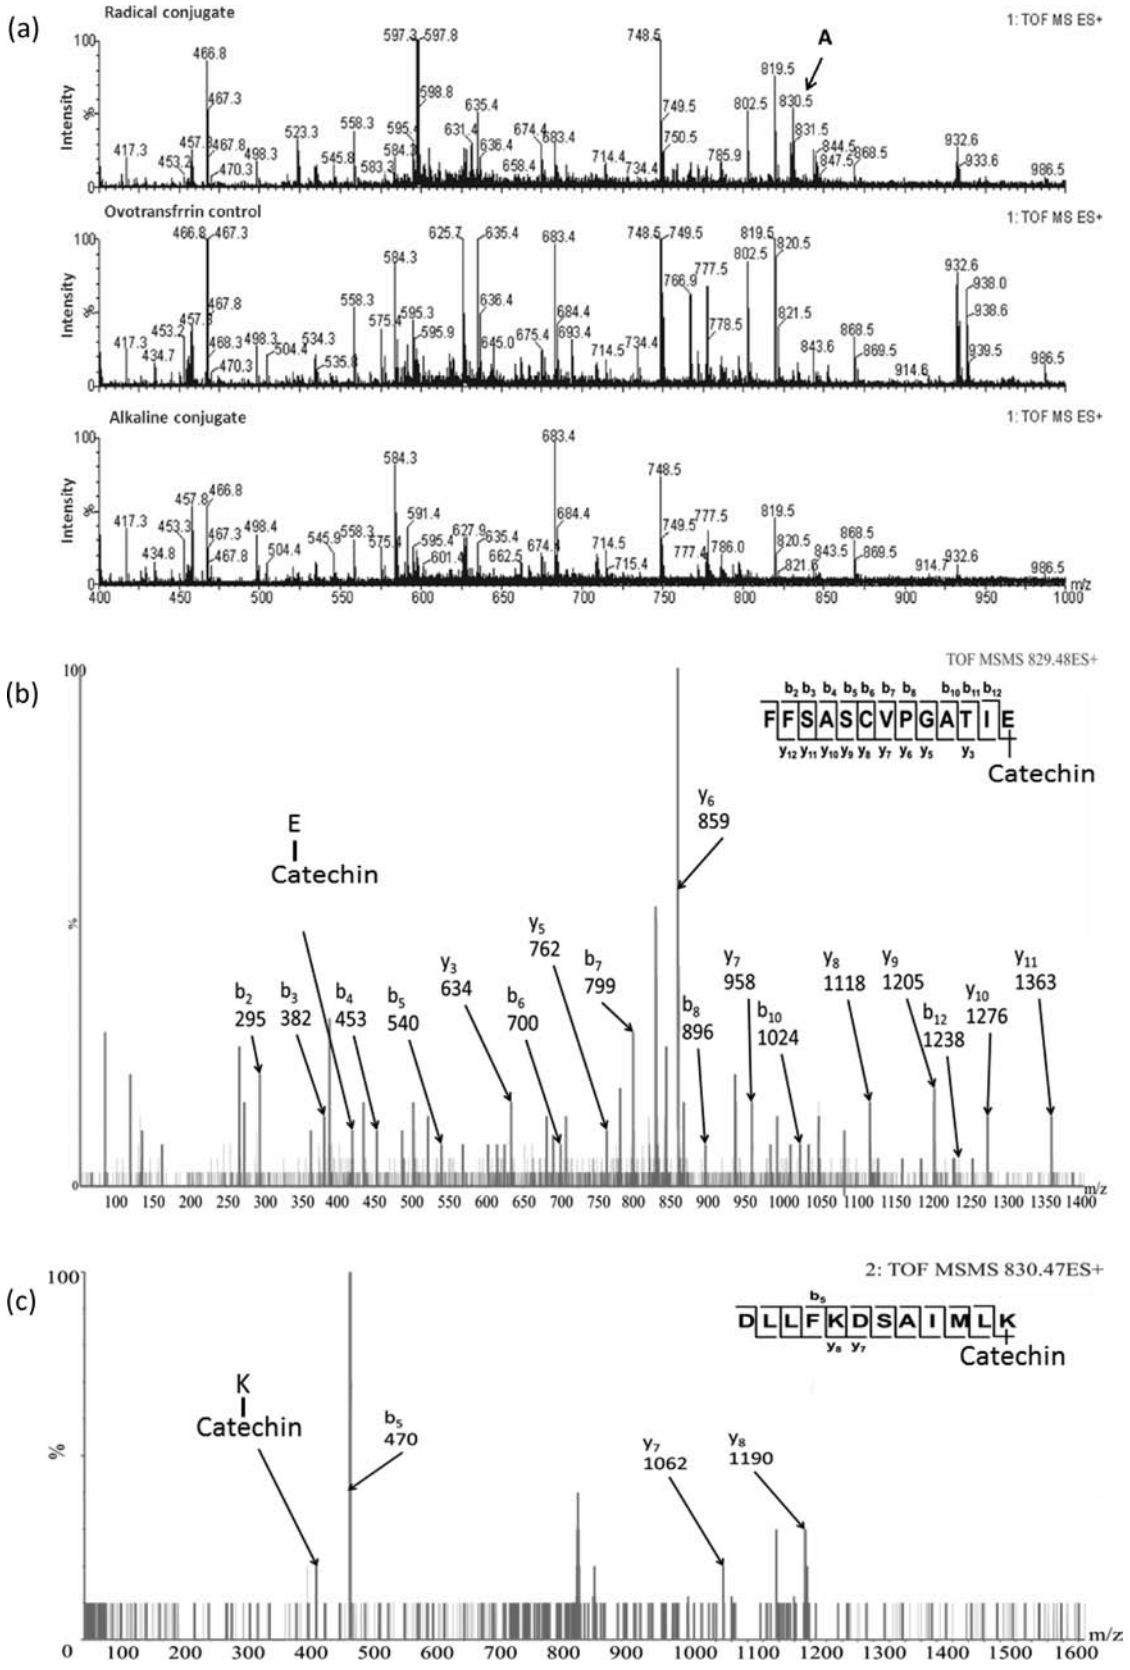

Figure 5. LC-MS-spectra of ovotransferrin (OTF) and OTF-catechin conjugates by radical method and alkaline method; Interpretation of LC−MS/MS spectra of the peak A in (a). Ions at m/z 829.5 (b) and 830.5 (c).

(residues 186) in OTF protein. Catechin is easily oxidized to form a semiquinone that rearranges to an *o*-quinone in the phenolic ring.[41] Several studies on the quinone modifications of various proteins indicate that lysine, histidine, and cysteine residues in the chains are easy to react with quinones.[20] While preparing conjugates using the radical method, as proposed by

dx.doi.org/10.1021/jf405635q | J. Agric. Food Chem. 2014, 62, 2581−2587

Spizzirri et al.,[16] the hydroxyl radicals, generated by the reaction between redox pair components, attack the amino acid in the side chains of ovotransferrin like lysine and glutamic acid, producing radical species on these amino acids. These radical species react with the catechin inducing a catechin-OTF covalent bond. Therefore, by this method, the lysine (residues 327) and glutamic acid (residues 186) in OTF first changed to radical species and then reacted with catechin.

The 3-D structure of ovotransferrin was analyzed by a molecular visualization program, RasMol (Herbert J. Bernstein, NY, U.S.A.), to identify the specific position and the structure of the peptides. RasMol competent Protein Data Bank (PDB Accession code: 1OVT) file was chosen for the analysis.[42] Within the structure of ovotransferrin, we visualized the locations of the covalent bonds (Figure 6). Both peptide DLLFKDSAIMLK and peptide FFSASCVPGATIE belong to the N-lobe.

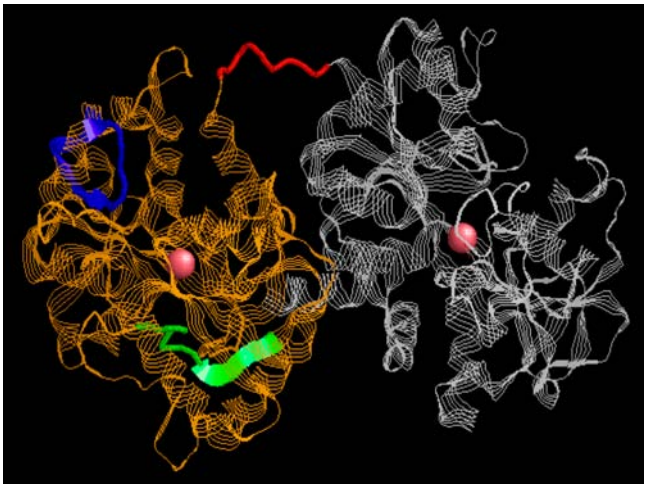

Figure 6. 3-D structure of ovotransferrin was constructed using RasMol molecular graphics software from a protein data bank (PDB) file, accession code: 1OVT. Golden part represents the N-lobe and white part represents C-lobe. Positions of two conjugated peptides FFSASCVPGATIE and DLLFKDSAIMLK were marked by blue and green, respectively.

In conclusion, ovotransferrin-catechin conjuates were successfully prepared using a hydrogen peroxide−ascorbic acid pair as radical initiator system and alkaline method. The data clearly showed that the grafting of ovotrasferrin with catechin is an effective method to improve the oxygen radical absorbance capacity of the protein. Conjugation of catechin with ovotransferrin was studied by fluorescence analyses, UPLC, MALDI-TOF and LC−MS−MS. Catechin was bonded to lysine (residues 327) of DLLFKDSAIMLK (residues 316−327) and glutamic acid (residues 186) of FFSASCVPGATIE (residues 174−186) in ovotransferrin N-lobe. The conjugates can be used as novel protein antioxidants for functional food and food applications.

MATERIALS AND METHODS

Chemicals. All of the flavonoid standards were obtained from Sigma-Aldrich. The purities of the reference substances were determined by gas chromatography (GC) and gas chromatography–mass spectrometry (GC–MS).

Bacterial Strain. *Agrobacterium rhizogenes* A4 strain was taken from the Central Institute of Medicinal and Aromatic Plants, Lucknow, India. The bacterial culture was maintained at 25 ± 2 °C on yeast mannitol broth (YMB) medium (Himedia).

Plant Material and *in Vitro* Culture Establishment. Tomato (*Lycopersicon esculentum*, variety Pusa Early Dwarf) seeds were purchased from the Indian Agricultural Research Institute (IARI), New Delhi, India. Seeds were washed thoroughly with Teepol (10%, w/v), followed by several washings with distilled water. Seeds were kept for 3 h in water prior to being inoculated onto solid Murashige and Skoog (MS) medium with Gamborg's B5 vitamins containing 100 mg/L myoinositol, 30.0 g/L sucrose, and 8.0 g/L agar–agar, which was used for the induction and maintenance of plant cultures through the seeds. All of the cultures were incubated under continuous light of 300 lux at 25 ± 2 °C. The young leaves of 8-week-old plants were used for genetic transformation.

***Agrobacterium*-Mediated Genetic Transformation.** *A. rhizogenes* A4 strain was cultivated at 25 ± 2 °C on YMB. The second and third leaves of *in vitro* grown tomato plants were used to transform, as described previously by Verma et al.[17] Transgenic hairy roots were excised from each wound site and maintained further at 24 ± 2 °C. Transgenic hairy roots were micropropagated on MS medium,[18] supplemented with 100 mg/L Augmentin and 250 mg/L Cefotaxime (Figure 1).

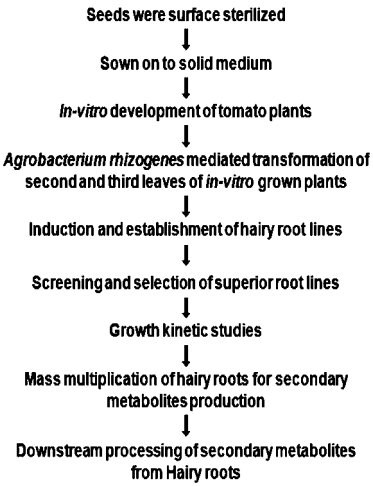

Figure 1. Flowchart of hairy root development in tomato.

Screening of Putative Transformed THRs. DNA was isolated from hairy roots using DNeasy Mini Kit (Qiagen, Valencia, CA). Polymerase chain reaction (PCR) was performed to detect Ri plasmid genes (*rolB*) in putative hairy root lines. Further, any possibility of *Agrobacterium* contamination in THR was ruled out by the amplification of the *virC* gene.

Growth Kinetics of THR. Growth of THR was regularly monitored. The fresh weight of THR was determined every 7 days until 35 days of culture to calculate the growth index (GI) at different time points. At each time interval, samples were harvested, dried on blotting paper to remove unwanted liquid medium, and dried further at 35 ± 2 °C for 7 days, followed by vacuum drying in desiccators until a constant dry weight was obtained. Samples were weighed and stored at −80 °C for further studies.

Extraction of Phenolics. Phenolics were extracted from THRs, and their level was compared to the roots of field grown and *in vitro* grown plants. To extract the phenolics, hairy roots (4 g) were finely powdered in liquid nitrogen, kept overnight in 20 mL of methanol/water (25:75, v/v) at room temperature on a rocking platform, and filtered. The filtrate was collected, and the residue was extracted twice more at 4 h intervals with the same volume of extractant. The filtrate were pooled and extracted with *n*-hexane (3 × 60 mL). The *n*-hexane fraction was discarded, and the methanol–water fraction was further extracted with chloroform (3 × 60 mL). The chloroform fractions were pooled and concentrated on a rotary evaporator.

Further, any residues were removed by freeze-drying. Dry powder (5 mg) was dissolved in high-performance liquid chromatography (HPLC)-grade methanol (1 mL), filtered through a Millipore Sample Clarification Kit (Millx GV, 13 mm, 0.22 N μm), and subjected to HPLC analysis.

Qualitative and Quantitative Analyses of Phenolics. Separation for qualitative and quantitative analyses of phenolics was performed by HPLC–photodiode array (PDA) with a LC-10 (Shimadzu, Japan). Phenolics were separated on a 250 × 4.6 mm (inner diameter), 5 mm pore size RP-C18 column (Merck) protected by a guard column packed with the same matrix. The gradient was prepared from 0.5% (v/v) phosphoric acid in HPLC-grade water (component A) and methanol (component B) in mobile phase. Nylon filters (0.45 μm) were used for filtration of all components and deaerated in an ultrasonic bath. The gradient from 25 to 50% B in 0–3 min, from 50 to 80% B in 3–18 min, from 80 to 25% B in 25 min, and 25% B in 30 min was used for conditioning of the column with a flow rate of 0.8 mL/min. Shimadzu class VP series software was used for data integration, and quantification was carried out by comparison to standard curves, which was constructed according to a previously reported method.[19] All samples and solutions were filtered through 0.45 μm nylon filters (Millipore, Billerica, MA) before analysis by HPLC. A simple mobile phase was used as a control for identification of blank peaks.

Extraction and Quantification of Antioxidant Enzymes. *Extraction of Enzymes from THRs.* Fresh tissue (200 mg) was weighed and ground to a fine powder in liquid nitrogen, allowed to thaw, and then homogenized in 1.5 mL of 0.2 M potassium phosphate buffer (pH 7.8) with 0.1 mM ethylenediaminetetraacetic acid (EDTA). Samples were centrifuged at 15000*g* at 4 °C. The supernatant was collected in a fresh tube and stored at 4 °C for further experiments.

Quantification of Enzymatic Activity. Enzymatic activity of three enzymes, i.e., ascorbate peroxidase (APX), catalase (CAT), and superoxide dismutase (SOD), which play a vital role in the reactive oxygen species (ROS) detoxification pathway, was determined spectrophotometrically, as previously described by Elavarthi and Martin.[20]

Antifeeding Activity of Hairy Root Extract against Chewing Insects. The phenolic compound extract from THRs was tested against two polyphagous insects *Helicoverpa armigera* and *Spodoptera litura*. The insect bioassay was performed as described earlier.[21] The extract of the phenolic compound was mixed with an artificial diet at different concentrations in Petri dishes. The ethanol-mixed diet and only artificial diet were taken as the control and blank, respectively. Petri dishes were kept open overnight at room temperature to let the solvent evaporate. Mortality data were recorded after 6 days. Experiment was performed in triplicate, and data were analyzed by one-way analysis of variation (ANOVA) ($p < 0.05$). Means were compared using Duncan's multiple range test (DMRT) using SPSS software.

RESULTS AND DISCUSSION

Genetic Transformation and Screening of Putative THRs. The second and third leaves of *in vitro* grown tomato plants were infected with *A. rhizogenes* A4 strain, and hairy roots were propagated on MS medium. Hairy roots that did not show necrosis and proliferated well in media were taken for further study. Seven different THRs that showed maximum elongation and branching potentials were selected and screened using PCR. Genomic DNA was isolated from all selected THRs individually, and PCR was performed with a gene-specific primer of the *rolB* gene. An amplicon of ~650 bp was obtained

dx.doi.org/10.1021/jf405695y | J. Agric. Food Chem. 2014, 62, 2588–2594

in THRs that were absent in field grown and *in vitro* grown roots. This confirmed the transformation of THR (Figure 2). *A.*

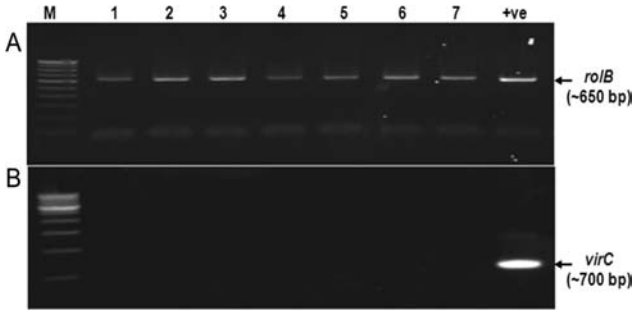

Figure 2. PCR amplification of *rolB* and *virC* genes for confirmation of transformants: (gel A) lane M, 100 bp molecular weight marker; lanes 1−7, different clones of THRs; and lane +ve, positive control and (gel B) lane M, 500 bp molecular weight marker; lanes 1−7, different clones of THRs; and lane +ve, positive control.

rhizogenes-mediated induction of hairy roots has already been reported in a large number of dicotyledonous plants, such as *Atropa, Beta, Brugmansia, Catharanthus, Glycyrrhiza, Hyoscamus, Solanum, Trachelium*, and many others.[22,23] A variety of *A. rhizogenes* strains are available for induction of hairy roots. Different groups have used strain LBA 9402 to initiate hairy roots from tomato to see the response of salt on endogenous levels of jasmonate and octadecanoid,[24] effect of salt on peroxidase activity[25] and for bioremediation of phenol using THRs[26] but we selected A4, which is very commonly used (approximately 22% used worldwide) for biotransformation.[27] *Agrobacterium* contamination in THRs was ruled out by the amplification of the *virC* gene because it was not present between the left and right borders of the Ri plasmid. PCR of THRs with the *virC* primer did not amplify any PCR product. All further studies were restricted to these seven selected THR lines.

Growth Kinetics of Selected THRs. The fact that different root clones differ distinctly, owing to each and every transformation event, has made it mandatory to screen and select the best performing hairy root line to obtain a maximum biomass in a minimum time period. Various independent hairy root clones have been studied in medicinal plants, and variations in the growth level during different growth phases have been noted among hairy root clones of the same origin.[28] Growth of all THRs was regularly monitored during different growth phases, i.e., 7, 14, 21, and 35 days (Figure 3). All THRs showed healthy appearance and lateral branching in liquid media. A gradual increase in the fresh weight up to 28 days of culture could be observed with all of the hairy root clones, which further declined in all lines, except THR-4 (slightly increased after 35 days) and THR-5 (unchanged after 35 days; Figure 4). After 28 days, maximum elongation and branching

Table 1. Activity of ROS Detoxifying Enzymes in THRs

enzyme	field grown roots	*in vitro* grown roots	hairy root
ascorbate peroxidase (mM ascorbate min^{-1} g^{-1})	5.01 ± 0.24	4.50 ± 0.19	7.41 ± 0.30
catalase (mM H_2O_2 min^{-1} g^{-1})	0.79 ± 0.09	0.61 ± 0.06	0.97 ± 0.03
superoxide dismutase (units mg^{-1})	0.87 ± 0.05	0.71 ± 0.03	1.45 ± 0.05

Table 2. Insect Bioassay on an Artificial Diet with *H. armigera* and *S. litura* at Different Concentrations of THR Extract

insect bioassay on an artificial diet with different concentrations of THR extract after 6 days				
	H. armigera		*S. litura*	
extract concentration (μL/g of diet)	percent mortality (%)	percent weight reduction (%) (average weight of larvae, mg)	percent mortality (%)	percent weight reduction (%) (average weight of larvae, mg)
100 μL/g	53.34	85.43 (0.50 ± 0.17)	40.00	86.90 (0.36 ± 0.15)
50 μL/g	30.00	68.93 (1.06 ± 0.15)	26.67	52.38 (1.34 ± 0.15)
10 μL/g	16.67	23.30 (2.63 ± 0.15)	6.67	28.57 (2.00 ± 0.26)
control	3.34	0.97 (3.40 ± 0.20)	0.00	1.19 (2.76 ± 0.15)
blank	0.00	NA (3.43 ± 0.30)	0.00	NA (2.80 ± 0.3)

was observed in THR-7, followed by THR-3 and THR-2. Fresh weight of THR-7 (4.75 ± 0.05 g), THR-3 (4.22 ± 0.09 g), and THR-2 (4.14 ± 0.11 g) was 4.2-, 3.76-, and 3.69-fold higher than non-transformed root (1.12 ± 0.13 g), respectively (Figure 4). The clonal nature of the individually selected hairy root lines resulting from site-specific insertion of Ri T-DNA, and the difference in the incorporated copy numbers might finally be responsible for the interclonal variation in terms of growth.[29] Profuse adventitious root growth was attained after 21 days of growth in various medicinal plants and reached its maximum up to 35 days of culture.[30] Similar observations of decline in growth were observed in *Plumbago zeylanica*, *Plumbago kurroa*, and *Gossypium hirsutum*.[17,30,31] The decline in growth is attributed to the secretion of secondary metabolites and other phenolics in the medium, which hamper the adventitious growth of root hairs.

Qualitative and Quantitative Analyses of Phenolics. Potential of flavonoid production in hairy root cultures of tomato is not yet reported. Most of the studies are on either flavonoid production through tomato fruits or peels.[32] However, some other systems have been explored for flavonoid production through hairy roots. Hairy root cultures of *Psoralea* sp. in different stages displayed more concentrations of daidzein and coumestrol compared to callus cultures from the same plant.[33]

The hairy root line THR-7 showed distinct superiority over other lines in terms of growth indices (after 21 days) and was used to quantify the level of different phenolics. HPLC analysis confirmed the presence of several flavonoid and phenolic acids in hairy roots after 21 days of culture (Figures 5 and 6). Many flavonoids, such as rutin, quercetin, and kaempferol, were present in considerable quantity, along with the number of phenolic acids, such as gallic, protocatechuic, ferulic, colorogenic, and caffeic acids.

AtMYB12 transformed hairy roots of *Fagopyrum esculentum*-produced rutin up to 0.9 mg/g of dry weight, but in the present study, THRs produce up to 20.26 μg/g of rutin.[34] The content of gallic, protocatechuic, chlorogenic, caffeic, and ferulic acids in THR-7 was 34.02 μg/g, 6.11 μg/g, 11.35 μg/g, 29.24 μg/g, and 26.89 μg/g after 21 days. It was 1.4-fold (24.3 μg/g), 1.4-fold (4.32 μg/g), 1.7-fold (6.37 μg/g), 1.3-fold (22.5 μg/g), and 2.49-fold (10.78 μg/g) higher than field grown roots, while 2.5-fold (13.34 μg/g), 3.28-fold (1.86 μg/g), 4.15-fold (2.73 μg/g), 2.94-fold (9.94 μg/g), and 6.22-fold (4.32 μg/g) higher when compared to *in vitro* grown roots (Figures 5 and 6).

Hairy root development has been reported in various plant species. They have a very high growth rate, low maintenance cost, capablity of producing a number of products in a single step, easy recovery and purification of these compounds in biologically active form, and many other benefits. Therefore, it always offers a very good system for producing biological compounds for commercial purposes.

Enzymatic Activity. It was well-established that, when plants were exposed to stress, either biotic or abiotic, the production of ROS increases and can cause significant damage to the cells; therefore, the plant cell produces a number of enzymes, i.e., catalase and ascorbate peroxidase, which can maintain the ROS level.[35,36] Thus, the activities of enzymes involved in the ROS detoxification pathway were analyzed in THR and control samples. The activities of catalase, ascorbate peroxidase, and superoxide dismutase were quantified. The activity of catalase in THRs was 0.97 ± 0.03 mM H_2O_2 min^{-1} g^{-1}, which was 1.22-fold (0.79 ± 0.09 mM H_2O_2 min^{-1} g^{-1}) and 1.59-fold (0.61 ± 0.06 mM H_2O_2 min^{-1} g^{-1}) higher than field grown and *in vitro* grown roots, respectively (Table 1). The activities of ascorbate peroxidase and superoxide dismutase in THRs were 7.41 ± 0.30 mM ascorbate min^{-1} g^{-1} and 1.45 ± 0.05 units mg^{-1}, respectively. These were also 1.47-fold (5.01 ± 0.24 mM ascorbate min^{-1} g^{-1}) and 1.66-fold (0.87 ± 0.05 units mg^{-1}) higher than field grown roots, while 1.64-fold (4.50 ± 0.19 mM ascorbate min^{-1} g^{-1}) and 2.04-fold (0.71 ± 0.03 units mg^{-1}) higher when compared to *in vitro* grown roots (Table 1). The Ri-plasmid-transformed calli of *Rubia cordifolia* showed enhanced expression of catalase, ascorbate peroxidase, and superoxide dismutase genes encoding ROS-detoxifying enzymes.[37] The reason for enhanced activity of catalase, ascorbate peroxidase, and superoxide dismutase was due to bacterial (*A. rhizogenes*) infection. Many hairy root systems, i.e., *Brassica napus*, *Daucus carota*, *Ipomoea batatas*, and *Solanum aviculare*, were available for peroxidase production.[38,39] Peroxidase production was further increased by adding elicitors, such as yeast extract, V_2O_5, and Hg_2Cl_2, which increase phenylalanine ammonia lyase synthesis.[40]

Antifeeding Activity of Hairy Root Extract against Chewing Insects. Many reports suggested that flavonoids in their biological form were toxic to insects. The extract of *Nothofagus dombeyi* and *Nothofagus pumilio* leaves consisted of

triterpenes and flavonoids and showed antifeeding activity against the fifth instar larvae of *Ctenopsteustis obliquana*.[41] The insect-resistant genotype of soybean (*Glycine max* PI 227687) accumulated a high amount of rutin.[42] On the basis of previous findings, we tested the phenolic compounds extracted (PCE) from THR against *H. armigera* and *S. litura*. PCE showed significant mortality against both of the insects, while the surviving larvae showed significant growth retardation and have a very low average weight. At 100 μL/g concentration, PCE caused 53.34 and 40.00% mortality against *H. armigera* and *S. litura*, respectively, after 6 days, whereas no toxicity was observed in a blank diet (Table 2). Surviving larvae of *H. armigera* and *S. litura* on PCE after 6 days showed 85.43 and 86.90% growth retardation, respectively (Table 2). Our HPLC data clearly showed the presence of numerous flavonoids and phenolic acids in PCE; this might be a reason for insect toxicity. Insect mortality also revealed that extracted phenolic compounds were in their biologically active form.

living organisms, this resulted in a lag time in growth, which can be overcome experimentally for some species such as algae and bacteria by adaptation to increasing amounts of D_2O.[6,7] Higher plants have been reported to tolerate 30−70% D_2O, with adverse effects increasing with D_2O concentration. Metabolic responses of plants to higher concentrations of D_2O vary among species. Abnormal morphology and delayed development are noted at concentrations of D_2O above 50% for many species.[7,11] Seed germination and root elongation are adversely affected as D_2O concentrations are increased with wheat,[12] rye,[13] and *Arabidopsis*.[11] To avoid the problems observed at 50% and higher concentrations of D_2O, plants can be cultivated at lower concentrations if sufficient deuterium incorporation can be attained for the intended use such as characterization using neutron scattering studies. Partially deuterated carrots, kale, and spinach were grown hydroponically in solutions of 15−30% D_2O to obtain isotopically labeled vegetables for nutritional studies.[8,9] Despite numerous studies being performed on the effect of deuteration on plant metabolic pathways, the impact of deuteration on individual biomass components for neutron scattering studies has not so far been investigated. In such a scenario, it is important to corroborate the methods for production of deuterated biomass and the chemical characterization of partially deuterated biomass components for progress of biofuel through neutron scattering technologies.

Annual or Italian ryegrass, *Lolium multiflorum*, is a C3 grass widely used across the world as a forage and cover crop. In the southeastern United States, the land area planted in *L. multiflorum* has increased from 1.1 million ha in 2005[14] to 1.3 million ha in 2010.[15] Due to its importance in agriculture, the composition and genetics of annual ryegrass have been extensively studied. In addition to its widespread agricultural use, *Lolium* ryegrass is frequently used for both field and laboratory research to investigate endophytes[16] phytoremediation,[17] pollutant uptake and toxicity,[18−22] morphological responses,[23] herbicide resistance[24] and studies of plasma membranes and associated enzymes such as glucan synthases.[25,26]

In this study, we investigated the effects of D_2O and high levels of deuterium enrichment on the growth and morphology of annual ryegrass (*Lolium multiflorum*), an important and intensively studied forage and cover crop, for future structural studies with SANS applications. The laboratory grown deuterium-labeled annual rye was analyzed for its deuterium incorporation levels by an NMR method.

MATERIALS AND METHODS

Substrate. Annual rye (*Lolium multiflorum*) seeds were obtained from a local gardening supply store. Identification of the species as *Lolium multiflorum*, an amenity and forage grass commonly cultivated in the southeastern United States, was confirmed based on the following characteristics exhibited by plants grown both in open pots in soil and in enclosed hydroponic conditions: plant height 70−80 cm at 60−100 days growth; absence of tillering; inflorescence head formation after 60 days; influorescence stems bare at base; shape of spikelets on influorescence stems; and presence of awns on seeds. The growth medium used for plant cultivation was Schenk and Hildebrandt's basal salts (Phytotechnology Laboratories, Shawnee Mission, KN) dissolved in Milli-Q (Millipore) water. The composition of the Schenk and Hildebrandt's basal salts for plants when prepared at 3.2 g/L in distilled water is given by the manufacturer (Phytotechnology Laboratories) as: 300 mg/L ammonium phosphate monobasic, 5 mg/L boric acid, 151 mg/L anhydrous calcium chloride, 0.1 mg/L cobalt chloride hexahdrate, 0.2 cupric sulfate penthydrate, 20 mg/L Na_2EDTA dihydrate, 15 ferrous sulfate heptahydrate, 195.4 mg/L anhydrous magnesium sulfate, 10 mg/L managanese sulfate monohydrate, 0.1 mg/L sodium molybdate dehydrate, 1 mg/L potassium iodide, 2500 mg/L potassium nitrate, 1 mg/L zinc sulfate heptahydrate, pH 4.2. Before seeding, the seeds were surface-sterilized with 70% ethanol for 2 min and then soaked in Schenk and Hildebrandt's basal salts for plants (S&H salts) in H_2O for 15 min. Initial determination of optimal D_2O concentration was established by germination and growth of seeds in a concentration range of 0 to 99.8% D_2O in jars for 26 days. The Mettler AE200 analytical balance used for weighing the deuterated plants and for weighing reagents has an accuracy of ±0.0001 g. The Ohaus CentOGram triple beam balance that was used to weigh the control ryegrass has an accuracy of ±0.01 g.

Concentration Dependence of Deuteration. The effect of D_2O concentration on growth of annual ryegrass and deuterium incorporation in biomass was initially determined using sealed glass jars with 3-mm glass beads as supports. Growth solutions were Schenk and Hildebrandt's salts (Phytotechnology Laboratories, Shawnee Mission, KS) prepared in 0, 20, 40, 60, 80, and 99.8% D_2O. Ten seeds were used per jar. Germination was scored at 14 days and plants were harvested at 26 days for analysis.

Hydroponic Cultivation in Perfusion Chambers. Deuterium enrichment of plants requires enclosure and perfusion with dried air to limit exchange with ambient water vapor as well as to limit D_2O usage and avoid microbial contamination. Since it was desirable to obtain multiple biomass samples grown at different concentrations of D_2O, a system that allows simultaneous cultivation of several plants in individual isolated chambers was devised. Suitable chambers for long-term cultivation of grasses in D_2O mixtures were constructed from graduated glass cylinders (Figure 1). Standard 1 and 3 L graduated glass cylinders were modified by the in-house glass shop at ORNL by cutting off the top 2 cm to remove the pouring lips followed by glass polishing to enable a tight fit with the rubber stoppers used as closures. The 1 and 3 L chambers were fitted with size 12 two-hole rubber stopper and three-hole size rubber stoppers respectively. Two 20.0 cm

Figure 1. Assembled growth chamber with the labeled component parts.

lengths of 0.6 cm diameter glass tubing with 90-degree bends at 7.6 cm were inserted into the stoppers. Heat-resistant silicone rubber tubing was used to connect the glass tubing to sterile 0.22 μm pore size, 33 mm diameter syringe filters (Millipore Ireland Ltd., Tullagreen, Carrigtwohill, Cork, Ireland) and to connect the tubing to PE drying tubes containing Eagle silica gel desiccant with color indicator. Glass Y-connectors were used to connect multiple chambers using the silicone tubing. Plants were perfused with ambient air from the growth room using Marina 50 and Marina 75 aquarium pumps (Rolf Hagen (USA) Corp., Mansfield, MA) that were connected to the chambers by sterile syringe filters connected to Elite aquarium tubing, with in-line valves for flow rate adjustment. The CO_2 concentration of the ambient air filtered through the silica gel desiccant ranged from 385 to 465 ppm as determined by measurement with an LI-6252 CO_2 analyzer (LI-COR, Lincoln, NE) that was calibrated with analyzed compressed air mixtures (Air Liquide, Oak Ridge, TN). Airflow into each chamber was maintained at 50−100 mL/min as measured with an Alltech Digital Flowcheck HR meter. Due to the small volumes of growth medium used per chamber and to limit evaporation losses, the chambers were perfused from the top and the growth solutions were not aerated. Two types of growth lamps were used: a metal halide lamp mounted on a stand and fluorescent Sylvania Gro-Lamps on a plant cart (Carolina Biological Supply Company, Burlington, NC). The metal halide lamp was mounted in a SunSystem 2 lamp holder (Future Garden, North Lindenhurst, NY) that was suspended from an in-house built lamp stand. Average incident light intensity was 150 μmol photons/m^2/s as measured with a LICOR-250 Light Meter equipped with a quantum sensor (LI-COR, Lincoln, NE) and 8930 lx as measured with a Traceable Light Meter (International LLC, Radnor, PA). Diurnal cycles were 12 h light, 12 h dark. Growth medium was Schenk and Hildebrandt's basal salts (Phytotechnology Laboratories, Shawnee Mission, KN) dissolved in Milli-Q (Millipore) water. Deuterium oxide (99.8%) was purchased from Cambridge Isotope Laboratories (Cambridge, MS). Hydroponic baskets with 5 cm diameter were used to support the rye seeds on 47-mm analytical glass fiber filters during growth and germination. Ambient temperature in the plant growth area was 27 °C during illumination and 21 °C during the diurnal dark period.

Cultivation of Annual Ryegrass in 50% D_2O for Production of Deuterated Biomass. Initial determination of optimal D_2O concentration was established by germination and growth of seeds in a concentration range of 0−99.8% D_2O in jars for 26 days. Deuterium incorporation did not increase above 60% D_2O, while seed germination decreased above 60% (Figure 2). Based on the preliminary tests, a concentration of 50% D_2O was used for scale-up of biomass production in the perfusion chambers. Seeds were germinated and seedling primary roots were established before transfer to the perfusion chambers. The treated seeds (thirty per dish) were germinated in 6-cm diameter polystyrene culture dishes on 47-mm glass filter disks containing 5% acrylic binder (Gelman Sciences/Pall Life Sciences, Ann Arbor, MI) moistened with 4 mL of S&H salts in H_2O. The seeded dishes were incubated in the dark for 24 h, followed by illumination with a metal halide growth lamp on a 12 h diurnal cycle. Dark temperature range was 21 to 22 °C, and light temperature range was 25 to 28 °C. The seeds began germinating at 5 days. The lids were removed from the culture dishes and the dishes holding the seedling plants were transferred to 1 L glass plant jars 6−7 days after seeding. Another 2 mL of S&H salts were added to each dish after transfer to the jars. At eleven days after seeding, the glass filters holding the seedling plant samples #1, #2, and #3 were carefully placed in 5 cm hydroponic plant baskets. Each basket was placed into a 1L perfusion chamber and 12 mL of S&H salts in 50% D_2O, 50% H_2O were added to each cylinder. These plants were watered with S&H salts in 50% D_2O, 50% H_2O once or twice weekly by injection through the perfusion tubing using sterile syringes and syringe filters to ensure that the roots remained covered with solution. Plants appeared to grow normally, with the H_2O-grown rye growing taller and faster than the plants growing in 50% D_2O as expected, yielding several grams of biomass at harvest (Figure 3 and Table 1).

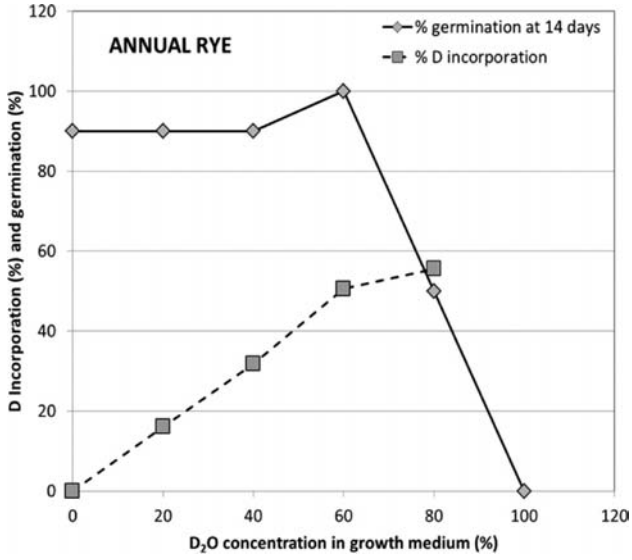

Figure 2. Germination and deuterium incorporation determined for annual ryegrass grown in increasing concentrations of D_2O to establish the optimal cultivation conditions for deuterated biomass production.

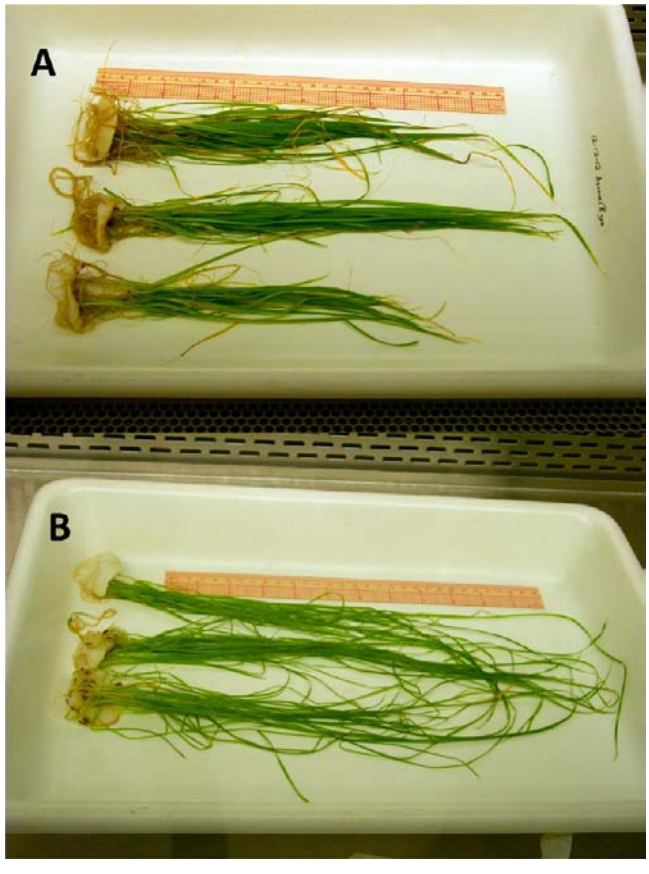

Figure 3. Annual ryegrass plants grown in (A) 50% D_2O under continuous air perfusion and (B) H_2O-grown controls.

The perfusion chamber design reduced evaporation and enabled cultivation for two months with cumulative usage of less than 100 mL solution per chamber. The total amount of hydroponic solution used for the cultivation of the protiated plants was 82 mL per plant, while the total amount of 50% D_2O solution used for the deuterated plants was 88 mL/plant. The total amount of D_2O used per plant for 50 days of growth in the 50% D_2O solution was 44.3 ± 17.5 mL. The seedling

Table 1. Net Biomass Yields from Annual Ryegrass Plants Grown Hydroponically with Perfusion (30 Seeds/Basket)

sample	growth solution	plant stems	wet weight total (g)
#1	start in H_2O, then at 11 days start in 50% D_2O	9	3.55
#2	start in H_2O, then at 11 days start in 50% D_2O	15	6.18
#3	start in H_2O, then at 11 days start in 50% D_2O	13	6.35
#4	H_2O	4	1.18
#5	H_2O	6	1.45
#6	H_2O	4	2.59

samples #4, #5, and #6 were transferred to hydroponic baskets on the twelfth day after seeding, and all three baskets were placed in a 3L perfusion chamber to which 150 mL of S&H salts in H_2O were added. Growth rates of the plants grown in H_2O was observed to double following transfer to the perfusion chambers, while the growth rates of the plants transferred to 50% D_2O in perfusion chambers did not change significantly compared to the initial growth rate in H_2O before perfusion (Tables 2 and 3). At harvest, plants in their baskets were

removed from the chambers, excess hydroponic solution was allowed to drain from the plants in a tray and then the roots and glass fiber supports were blotted with several Kim-Wipe tissues. The protiated control plants (#4, #5, and #6) were harvested at 47 days from seeding and stored at −20 °C until characterization and further use. The plants grown in 50% D_2O (#1, #2, and #3) were harvested at 61 days and used fresh. Plant growth and biomass production of protiated plants and deuterated plants after 47 and 61 days respectively are presented in Tables 1, 2, and 3.

Preparation of NMR Solution for Deuterium Incorporation Studies. Dimethyl sulfoxide (anhydrous, 99.9%), pyridinium chloride (98%), and TFA (reagent grade, 99.0%) were purchased from Sigma Aldrich. Dimethyl sulfoxide (DMSO)-d_6 (99.9% D) and trifluoroacetic acid (TFA)-d (99.5% D) were purchased from Cambridge Isotope Laboratories, Inc. (Andover, MS). Deuterated pyridinium chloride was synthesized according to a literature procedure.[27] Ionic liquid solvent mixture was prepared by mixing vacuum-dried protio pyridinium chloride or deuterated pyridinium chloride with DMSO or DMSO-d_6, respectively in 1:4 ratios in an inert atmosphere. Deuterated ryegrass (10 mg) was then dissolved in a pyridinium chloride−DMSO solvent mixture as described previously.[28] The NMR spectra of homogeneous biomass solution were recorded on a Bruker Avance 400 MHz spectrometer operated at 61.4 MHz for deuterium and 400.1 MHz for proton. ^{1}H NMR spectra were measured at 55 °C with 64 k data points, a 10 s recycle delay, and 16 scans. Deuterium (^{2}H) NMR spectra was recorded at 55 °C with 32 k data points, 10 s recycle delay, and 4000 scans.

Carbohydrates and Klason Lignin Analysis. Samples for carbohydrate and acid-insoluble lignin analysis were prepared using a two-stage acid hydrolysis protocol based on Tappi method T-222 om-88. The sugar solution was analyzed for carbohydrate components by high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD) using Dionex ICS-3000 (Dionex Corp., USA).[29] The standard deviation associated with lignin and carbohydrate analysis was 0.3 to 0.6 and 0.02 to 0.9, respectively.

Cellulose and Hemicellulose Isolation. The extractive-free annual ryegrass samples were delignified using peracetic acid as described previously.[30] Cellulose was isolated from the delignified sample (0.10 g) by extraction with a 17.5% NaOH solution (5.00 mL) at 25 °C for 2 h. The mixture was diluted to 8.75% NaOH solution by addition of 5 mL of deionized water and repeated stirring at 25 °C for an additional 2 h. The isolated α-cellulose samples were then collected by centrifugation, washed with an excess of deionized water and air-dried. For hemicellulose isolation, the filtrate obtained above, was poured into a mixture of ethanol: acetic acid (70:30, v:v). The supernatant was removed by centrifugation and the precipitated hemicellulose was again washed with a mixture of ethanol: acetic acid (70:30, v:v) and air-dried for analysis.

GPC Analysis of Cellulose. The number-average molecular weight (M_n) and weight-average molecular weight (M_w) were determined by GPC after tricarbanilation of cellulose as described previously.[31] The derivatized cellulose was dissolved in tetrahydrofuran (1 mg/mL), filtered through a 0.45 mm filter and placed in a 2-mL autosampler vial. The molecular weight distributions of the cellulose tricarbanilate samples were analyzed on an Agilent GPC Security 1200 system equipped with four Waters Styragel columns (HR1, HR2, HR4, and HR5), Agilent refractive index (RI) detector and Agilent UV detector (270 nm) using THF as the mobile phase (1 mL/min) with injection volumes of 0.02 mL. A calibration curve was constructed based on eight narrow polystyrene standards ranging in molecular weight from 1.5×10^3 to 3.6×10^6 g/mol. Data collection and processing were performed using Polymer Standards Service WinGPC Unity software (Build 6807). Molecular weights (M_n and M_w) were calculated by the software relative to the universal polystyrene calibration curve. Polydispersity index (PDI) was calculated by dividing M_w by M_n.

GPC Analysis of Hemicellulose. The GPC analyses of hemicellulose samples were carried out using an Agilent 1200 series HPLC system consisting of an online degasser and an autosampler, a RI detector and three columns of Ultrahydrogel 120, 250, and 500 (Waters Inc., USA) linked in series. The RI detector was set at 35 °C. The mobile phase was an alkaline sodium hydroxide/acetate solution (0.20 M sodium hydroxide, 0.1 M sodium acetate, pH 12−13) and the flow rate was 0.5 mL/min. The hemicellulose samples were dissolved in mobile phase (~1 mg/mL) and the solution was then filtered with a 0.2 μm filter. The filtered sample (25 μL) was injected into the GPC column system for analysis. Pullulan standard samples were used for the calibration.[32]

Sample Preparation for Solid-State Nuclear Magnetic Resonance for Crystallinity Measurement. The cellulose samples for NMR were prepared from the control protiated and deuterated annual ryegrass from the holocellulose sample (1.00 g) by mild acid 2.5 M HCl hydrolysis as described previously.[33] The isolated α-cellulose samples were then collected by filtration rinsed with an excess of deionized water and dried in a fume hood. For NMR analysis, 4-mm cylindrical ceramic MAS rotors were filled with the isolated α-cellulose. Solid-state NMR measurements were carried out on a Bruker Avance-400 spectrometer operating at a frequency of 100.55 MHz for ^{13}C in a Bruker double-resonance MAS probe at spinning speeds of 10 kHz.

CP/MAS experiments utilizing a 5 ms (90°) proton pulse, 1.5 ms contact pulse, 4 s recycle delay and 4−8 K scans. All spectra were recorded on equilibrated moisture samples (~35% water content).

FTIR Spectroscopy. Annual ryegrass samples were vacuum-dried for 24 h. Infrared (FTIR) spectra were obtained using a Perkin-Elmer 100 Series Fourier transform infrared spectrometer in an attenuated total reflectance (ATR) mode. The spectra were recorded with the accumulation of 128 scans, a resolution of 4 cm^{-1} in the range from 4000 to 500 cm^{-1}. After the baseline correction, the two spectra were scaled with respect to one another, using the C−O stretching of the glucopyranose ring at ~1053 cm^{-1}.

Scanning Electron Microscopy (SEM). Scanning electron microscope images of solvent extracted and holopulps from protiated and deuterated annual rye samples were obtained with a LEO 1530 TFE-SEM microscope operated at 5 kV. The samples were freeze-dried and fixed on carriers with conductive carbon tape. The samples were coated with gold using an ion sputter coater and observed with a thermally assisted field emission (TFE) scanning electron microscope.

Statistical Analysis. Student *t* tests were performed to determine significance between experimental values, where $p \leq 0.05$ is 95% significance (*), and $p \leq 0.01$ is 99% significance (**).

RESULTS AND DISCUSSION

Annual Ryegrass Cultivation in D_2O. From previously reported studies,[34−37] it was apparent that the effects of D_2O on higher plant growth were dependent on species, concentration, and growth stage. The typically observed concentration dependence found little effect at concentrations up to 0.5%, delayed germination and slower growth at 50%, and complete inhibition, or very stunted and abnormal, germination and growth at concentrations higher than 80%. [38] As a result, deuterium enrichment of plants is usually carried out at concentrations less than 50% D_2O using seedlings that have been sprouted and established in H_2O.[9,39] The annual ryegrass (*Lolium multiflorum*) for production of deuterated biomass were grown in enclosed chambers continually perfused with dry air to limit exchange with ambient water vapor while providing a constant supply of CO_2 for photosynthesis and O_2 for photorespiration. Initial screening found that plant germination was severely inhibited in 80% D_2O while deuterium incorporation was not substantially improved (Figure 2). Annual ryegrass germinated in 70% D_2O, but with very low germination rates and a growth rate of 21% of H_2O-grown controls. Germination reached control levels in 50% D_2O, but subsequent growth rates were 45% of H_2O-grown controls (Figure 4). Vernalization, cold treatment of seeds, has been reported to improve growth of winter rye and brome grass at low temperatures.[40] To examine whether vernalization would improve growth under deuterating conditions, seeds were incubated for 24 h at 4 °C followed by 10 days at 10 °C. Germination increased 4-fold in 70% D_2O following vernalization, but growth rate and low biomass yield (less than 10% of controls grown in H_2O) were not improved, so this approach was not further investigated. Growth rates of the plants grown in H_2O were observed to double following transfer to the perfusion chambers, while the growth rates of the plants transferred to 50% D_2O in perfusion chambers did not change significantly compared to the initial growth rate in H_2O before perfusion (Figure 4). The annual ryegrass grown in 50% D_2O was shorter and thicker in appearance than matched protiated controls, but did not appear abnormal in coloration or leaf shape (Figure 3). Possible internal changes in leaf and stem vascularization were not examined. The differences in morphology may correspond to the normal range of adaptations of *Lolium* ryegrass species and related fescue (*Festuca*) grasses to drought, cold, and light conditions,[15,23] but this will need to be confirmed by comparative studies.

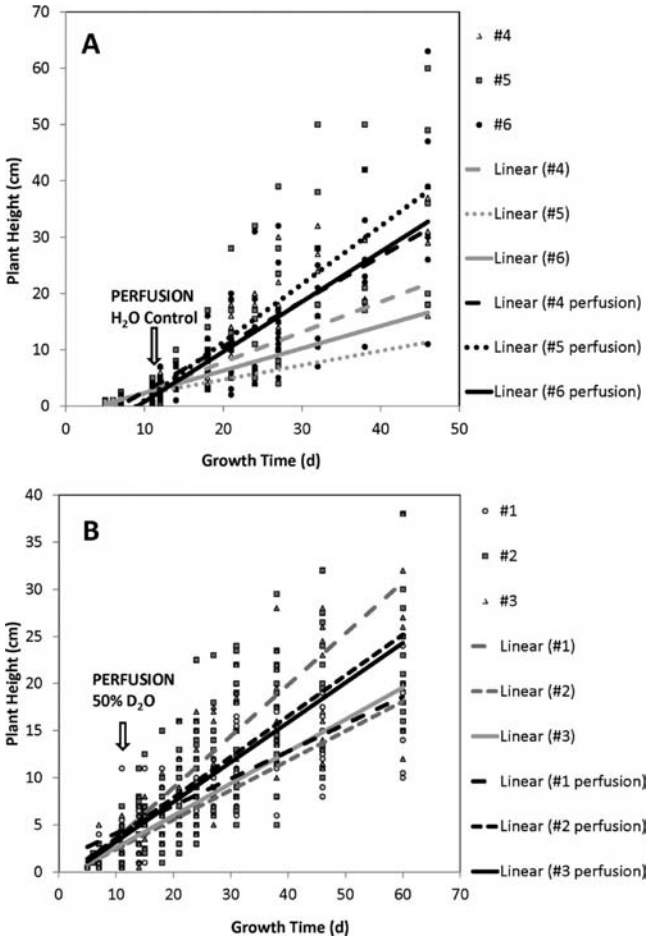

Figure 4. Growth rates determined by linear regression of individual plant heights of (A) three sets of H_2O control seedlings and (B) three sets of seedlings transferred to 50% D_2O.

NMR Analysis. The deuterium incorporation in annual ryegrass samples was examined using the methodology as described previously.[28,41] NMR analysis of annual ryegrass samples grown in increasing D_2O concentrations showed that the deuterium incorporation increased linearly with increasing D_2O concentration up to 60% D_2O, but was not improved significantly for annual rye grown in 80% D_2O, while germination was also inhibited at 80% (Figure 2). Ultimately, based on the effect of D_2O concentration on growth and biomass deuterium incorporation in the preliminary trials, annual rye grown in 50% D_2O was selected for detail structural analysis. ^1H and ^2H NMR experiments were performed in order to determine the deuterium incorporation level in rye grown in 50% D_2O. A standard inversion recovery pulse sequence was used to measure the longitudinal relaxation time for all the resonances and to determine the appropriate recycle delay. Figure 5 illustrates the ^1H and ^2H NMR spectra of annual ryegrass grown in 50% D_2O. The ^2H NMR spectrum of deuterated annual ryegrass shows the poorly resolved group of signals from 3.0 to 5.5 ppm, which is attributable to the cellulosic and other polysaccharides protons in the biomass. The protons from lignin side chain are also present in the described chemical shift range. The signals from 0.5 to 2.0 ppm are due to presence of side chain acetates and some residual

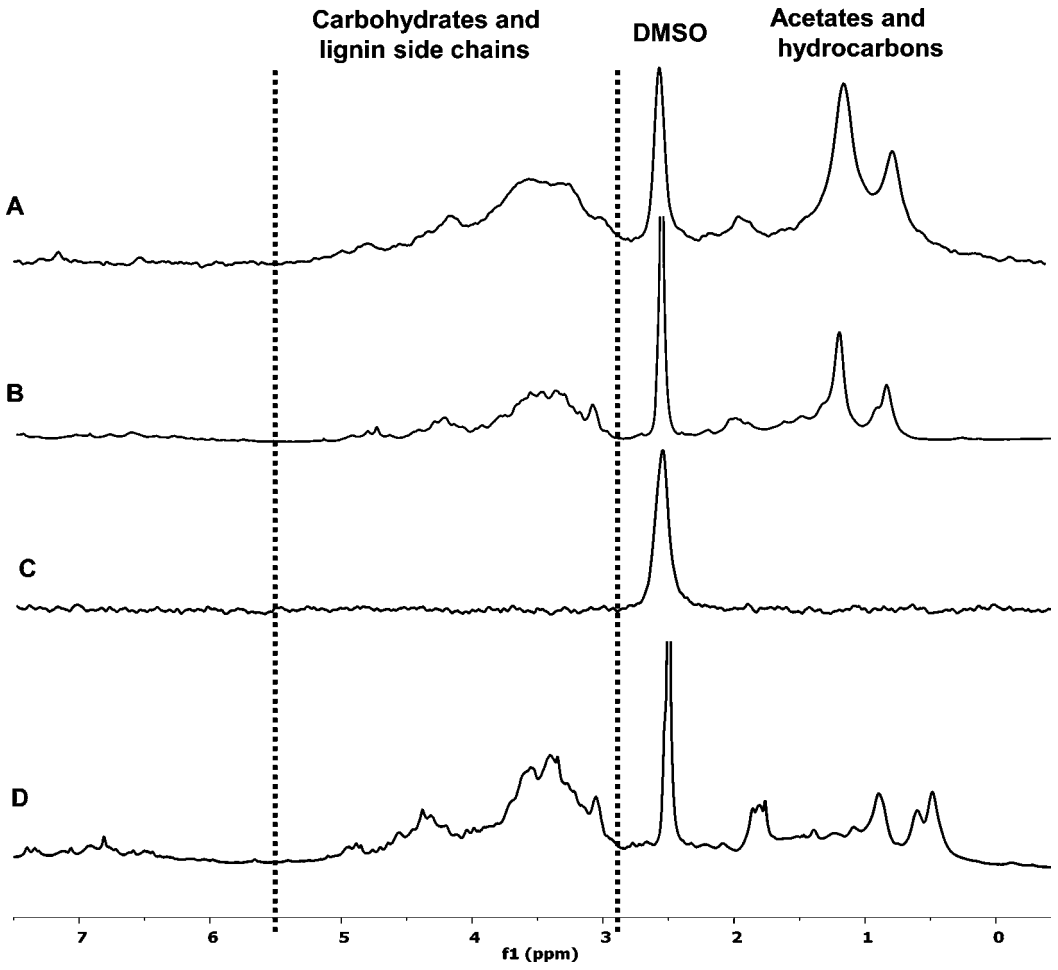

Figure 5. (A) ^{2}H NMR and (B) ^{1}H NMR spectra of deuterated annual ryegrass grown in 50% D_2O; (C) ^{2}H NMR and (D) ^{1}H NMR spectra of control annual ryegrass. The region between two dotted lines represents protons/deuterium mostly from cellulose and some lignin side chains.

Table 4. Compositional Analysis of Annual Ryegrass (Based on Dried Biomass)[a]

	Klason lignin (%)	arabinose (%)	galactose (%)	glucose (%)	xylose (%)	mannose (%)
deuterated ryegrass	10.2 ± 0.6*	5.6 ± 0.02*	3.8 ± 0.03*	66.7 ± 0.9	13.6 ± 0.5	0.0 ± 0.0
protiated ryegrass	12.8 ± 0.3	6.4 ± 0.02	4.4 ± 0.04	58.7 ± 0.7	17.6 ± 0.2	0.0 ± 0.0

[a]Errors are reported in term of standard deviation, * = $P \leq 0.05$.

fatty acids in the biomass. Further, ^{1}H spectrum of deuterated annual ryegrass exhibited the similar group of signals in the region from 3.0−5.5 ppm, while the signals corresponding to lignin aromatic protons were also observed in the ^{1}H spectrum of deuterated annual ryegrass. ^{1}H and ^{2}H NMR spectra of control protiated ryegrass were also obtained to compare and ensure the deuteration (Figure 5C,D). The ^{1}H spectrum of control protiated ryegrass exhibited all of the characteristic signals of biomass in the range of 3.0−5.5 ppm as well as also exhibited the aromatic proton signals corresponding to lignin component while the ^{2}H NMR did not show any corresponding detectable deuterium signals in that range, which confirmed the substantial deuterium incorporation in the rye grown in 50% D_2O. Further, for the quantitative analysis, the concentration of proton nuclei in deuterated ryegrass in deuterated solvent was determined from the ^{1}H NMR spectrum, with respect to an internal standard (TFA/*d*-TFA), while ^{2}H NMR spectrum of the deuterated ryegrass dissolved in a protiated solvent indicated deuteron nuclei concentration with respect to the same internal standard (TFA/*d*-TFA). After normalizing the concentration of deuterated rye in both solutions, the ratio of deuterons to protons ($^{2}H/^{1}H$) was calculated. The $^{2}H/^{1}H$ ratio indicated a deuterium incorporation of 36.9% in annual rye germinated and grown in 50% D_2O. Growth rates of protiated ryegrass plants were doubled following transfer to the perfusion chambers while the growth rates of the plants transferred to 50% D_2O did not change significantly from their growth in H_2O before perfusion. A significant increase in the deuterium incorporation to ∼60% was achieved in the ryegrass that was germinated in H_2O, then transferred to 50% D_2O and grown inside the perfusion chambers. The seedlings started in H_2O before transfer to 50% D_2O appear to better tolerate high D_2O concentrations than the plants grown from germination in 50% D_2O, which could explain the substantially higher ^{2}H incorporation. The current procedure thus offers a method to cultivate annual rye and similar plants to produced deuterated biomass with controlled deuterium incorporation for use in neutron scattering experiments.

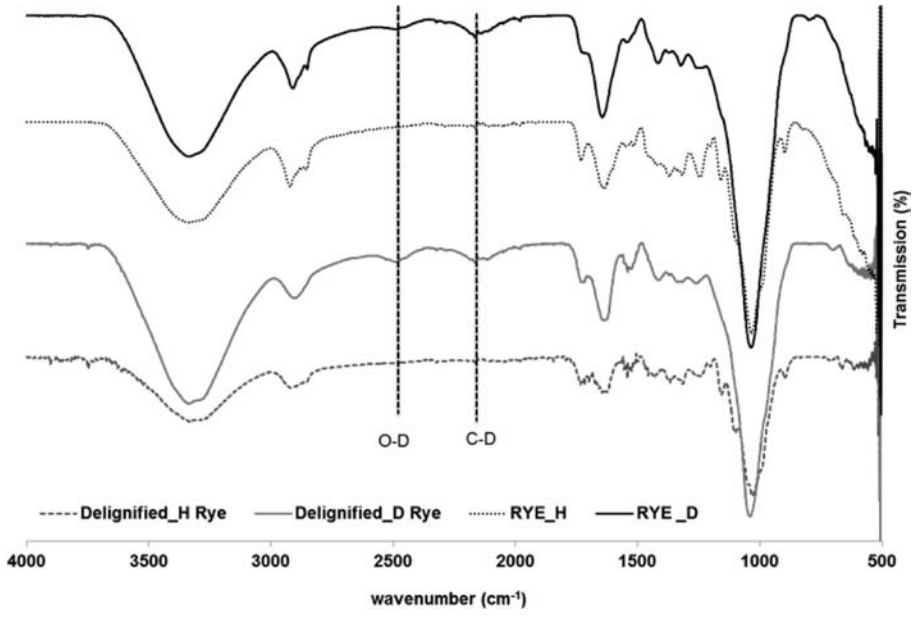

Figure 6. FTIR spectra of deuterated ryegrass, protiated ryegrass and their delignified samples.

Carbohydrate and Klason Lignin Analysis. Table 4 shows the compositional analysis of deuterated and control protiated annual ryegrass samples and is comparable with the literature values.[42] The data presented here are on an oven-dry (105 °C) basis and extractives were removed prior to each measurement. As Table 4 indicates, glucan and xylan were the predominant carbohydrates found in *Lolium* rye. The glucan content was slightly higher in deuterated annual ryegrass compared to that for control protiated annual ryegrass. The major hemicellulose found in ryegrass was xylan; however, small amounts of arabinan and galactan were also present. The total hemicellulose content of the deuterated ryegrass was slightly lower in comparison to that for control ryegrass. The relative klason lignin content was also lesser in the deuterated sample. However, there was not significant variation realized in the overall carbohydrates composition for both samples.

FTIR Analysis. The FTIR spectra of deuterated annual ryegrass, protiated annual ryegrass and their delignified samples are presented in Figure 6. The C−D stretching in deuterated samples at 2139−2251 cm^{-1} indicated nonexchangeable deuterium incorporation in the carbohydrates components of annual ryegrass. The O−D stretching at 2486 cm^{-1} attributed to the proton-deuteron exchange on the biomass surface. The broad and strong peak at ∼3334 cm^{-1} is attributed to the hydroxyl group indicating strong hydrogen bonding. All of the samples exhibited vibrations at 2917−2854 cm^{-1}, attributed to the C−H stretching and at 1378 and 1249 cm^{-1} corresponded to the C−H bending modes. IR bands centered at 1453 and 1118 cm^{-1} can be assigned as C−H symmetrical bending and C−O stretching of cellulose respectively. A nominal isotopic effect was observed in all of the C−D bands in the FTIR of deuterated samples (Table 5). For example, bands at 1375 cm^{-1}, which is characteristic of symmetric C−H deformation of cellulose[43,44] showed a slight shift toward 1326 cm^{-1} in deuterated annual rye sample. Similarly, IR band at 1460 cm^{-1} corresponding to C═C stretching vibration of the aromatic ring[44] also showed an isotopic shift in deuterated annual ryegrass (Table 5). Vibrations at 1053 and 1249 cm^{-1} are mainly attributed to the structural features related to carbohydrates and indicated isotopic shifts in deuterated samples.

Molecular and Morphological Properties. In an effort to determine the effect of growing annual rye in D_2O on the biomass key characteristics related to enzymatic hydrolysis,[45,46] the important molecular properties of deuterated and control protiated ryegrass were compared. The molecular weight of cellulose and hemicellulose and cellulose crystallinity of annual ryegrass grown in 50% D_2O and its protiated control are presented in Table 6. Deuterated rye cellulose had a higher weight average and number average molecular weight compared to its protiated control. Also, it displayed higher polydispersity index than protiated rye cellulose. The difference observed here is clearly attributed to the major deuterium

dx.doi.org/10.1021/jf4055566 | J. Agric. Food Chem. 2014, 62, 2595−2604

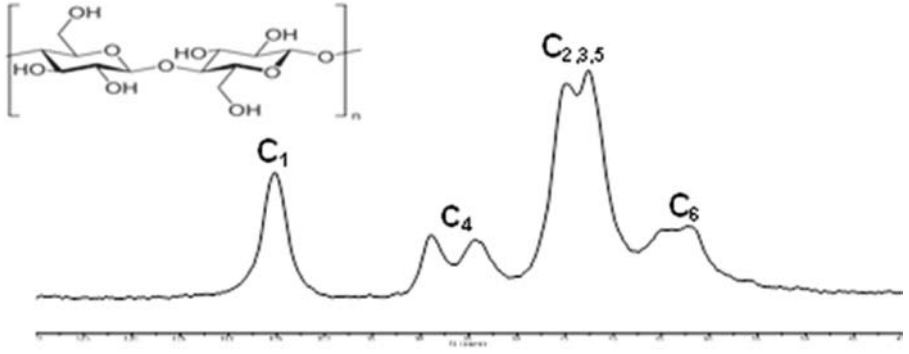

Figure 7. $^{13}C-CPMAS$ spectra of cellulose I isolated from annual ryegrass sample crystallinity index = $\delta_{86-92}/\ \delta_{80-92} \times 100$.

incorporation in the cellulose component of the biomass as also shown by the ^2H NMR spectrum. In contrast, there was no change in the weight and number average molecular weight of hemicellulose isolated from 50% D_2O annual ryegrass. Possibly the ryegrass grown in D_2O may preferentially incorporate deuterium into cellulose compared to other polysaccharides. The crystallinity of cellulose isolated from deuterated ryegrass, as determined by $^{13}CP/MAS$ (Figure 7) was ∼43% which is lower than the cellulose crystallinity of protiated ryegrass. The ^{13}C NMR spectrum of cellulose I isolated from deuterated ryegrass was similar, to that of control; however, at optimal signal-to-noise lower resolution was achieved for cellulose isolated from deuterated ryegrass (not shown). This is probably due to fewer protons available in deuterated ryegrass cellulose in comparison to protiated controls and consequently, the ^{13}C CP/MAS NMR, which is the technique based on the magnetization transfer from protons to carbons, is expected to be less efficient for deuterated substrates than for protonated substrates due to the differences in bond energy between protons and deuterons. Therefore, the subsequent enhancement of the ^{13}C signal will be lessened in 50% D_2O grown rye. Nonetheless, deuteration did not appear to cause any noticeable or significant difference in the cellulose crystallinity.

Morphology of Deuterated Annual Ryegrass. The present paper attempts to study the surface morphology of D_2O grown rye and demonstrates that no major disruption of micro fibrils was observed in the native surface of the rye grown in 50% D_2O compared to its protiated counterpart. The SEM images of control protiated and deuterated annual ryegrass before and after the peracetic acid delignification process are shown in Figure 8A–D. Both the protiated and deuterated rye samples exhibited an elongated and well-ordered surface (Figure 8A,B). The texture was compact and shielded in a thin wax layer commonly found in herbaceous biomass.[47] However, several subtle differences were observed in the deuterated rye leaf such as the deuterated rye leaf exhibited a surface layer with more debris and some noticeable granular structures on the individual fibers. Furthermore, the delignified surface of both samples was examined in an effort to find the effect of deuteration more closely on the morphological

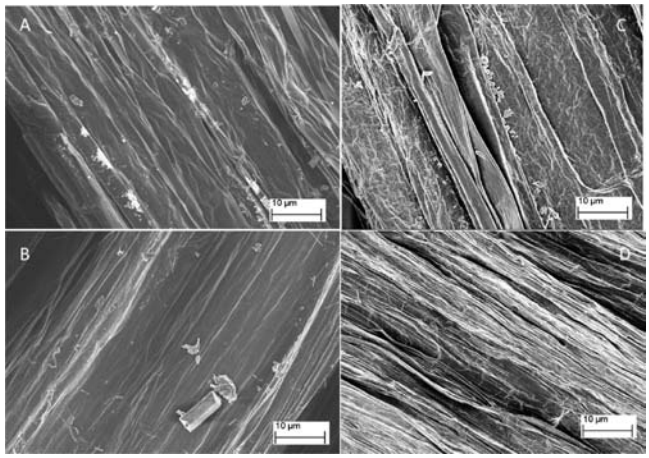

Figure 8. SEM images of (A) deuterated ryegrass, (B) control protiated ryegrass, (C) deuterated ryegrass after delignification, and (D) protiated ryegrass after delignification.

structures in both rye samples. Surface morphology of both samples changed significantly during the delignification process. In both delignified samples the overall structure was disrupted (Figure 8C,D) and the individual fibers were partially separated and dispersed. Peracetic pulping removed most of the surface layer deposits, which were noticed in the native samples and consequently exposed intact cellulose microfibrils. In a delignified deuterated ryegrass, most of the leaf surface was degraded although it showed the cellulose micro fibrils partly embedded in the noncellulosic polymers as revealed by the rough and uneven surface (Figure 8C). The study demonstrates that the leaf morphology appeared to be basically similar for the two annual ryegrass samples, but with certain differences apparent, particularly following delignification. The biomass characterization results indicated some significant changes in the biomass structure with deuteration. There was an increase in the molecular weights of cellulose, whereas hemicellulose molecular weights and cellulose crystallinity remain unaffected with the deuteration. Nevertheless, the results support the development and use of deuterated plant biomass to provide

dx.doi.org/10.1021/jf4055566 | J. Agric. Food Chem. 2014, 62, 2595–2604

crucial supporting characterization for visualization of lignocellulose structure by neutron scattering techniques and computational simulation.

honey − δ^{13}C protein) value, which should be ≤1 in unadulterated samples. However, a recent international laboratory ring test undertaken to assess this potential modification[11] found that filtering and/or centrifuging of honey prior to flocculation to remove insoluble material reduced the apparent C-4 sugar content not only of unadulterated honey but also of intentionally adulterated honeys (up to 15% C-4 sugar) to within acceptable limits, so the proposed filtration modification was not recommended.

More recently, instances have also arisen when pollen filtration did not resolve the anomalously high apparent C-4 sugar content of honey (up to 15%), yet the honey was not derived from hives that had undergone sugar feeding, supporting the theory that some other mechanism was also contributing to more negative δ^{13}C protein values and generating false-positive AOAC 998.12 results.[11]

This study was undertaken to investigate the cause of apparent C-4 sugar fails in New Zealand honey to address increasing concerns raised by border testing agencies in importing countries such as China, the United States of America, Hong Kong, and Europe. The stable carbon isotopes of 1023 New Zealand honeys and their corresponding proteins were analyzed, and apparent C-4 sugars were quantified. Honey floral types prone to AOAC 998.12 failure were investigated to understand which types of fails were real (where the honey is adulterated or contaminated by C-4 sugar) or false positive (contaminated via some mechanism other than sugar), and the mechanisms that may cause false-positive results were explored.

BACKGROUND

Pure and authentic honey derived solely from unique nectar sources should theoretically have similar δ^{13}C honey and δ^{13}C protein values as bees do not substantially fractionate or alter the carbon isotopes of nectar. Previous research has raised the possibility of false-positive AOAC 998.12 C-4 sugar results[9,10,12] via pollen and other insoluble material coextracted with the protein. However, there are several different mechanisms to explain the failure of honey tested under the AOAC 998.12 method.

Excess Cane Sugar Contamination (Genuine Fail). Sugar syrups are fed to bees as a supplementary carbohydrate source in times of winter nectar dearth or to prevent starvation during poor weather. Sugar syrups are also used to retain bees in specific areas such as orchards or fields to provide pollination services or to boost hives into breeding mode several weeks prior to nectar flow. However, supplementary syrup feeding also risks overuse, resulting in bees storing excess sugar syrups into brood boxes, which can later be uncapped and redistributed into collection boxes by the bees as they make more room for brood. Cane sugar (a C-4 plant, with a more positive carbon isotope value than C-3 plants) is the sole bulk sugar product available in New Zealand for commercial beekeepers. Addition or mixing of C-4 sugar syrups (which has a stable carbon isotope or δ^{13}C value of ∼−10‰) with plant nectar will shift the δ^{13}C honey isotope values to more positive isotope values than the δ^{13}C values of available C-3 plant nectar sources, which range from −24 to −27‰.

After-harvest additions of noninverted cane sugar can be readily detected using sugar chemical profiles that measure sucrose content, as there is no opportunity for the sucrose to undergo a reaction with invertase (a bee digestive enzyme), which breaks the sucrose molecule into monosaccharides of fructose and glucose. Codex[13] prescriptively sets limits whereby sucrose should not be present above 5 g/100 g of honey and in some exceptional cases 10 or 15 g/100g of honey (such as ling and lavender).

Pollen Contamination (False-Positive Fail). Protein is extracted from honey as an internal standard; AOAC criteria require $\Delta(\delta^{13}\text{C honey} - \delta^{13}\text{C protein}) \leq 1$. The δ^{13}C protein value may be contaminated by insoluble material (i.e., excess pollen from diverse sources, dust particles, or other hydrophobic components). However, when using the repetitive wash method, the AOAC 998.12 method does not remove this material and it is coextracted with the protein during flocculation. This anthropogenic pollen or dust has been shown to have a different carbon isotope value (ca. −28‰), shifting the final δ^{13}C protein value by up to 1‰ and affecting the calculation of apparent C-4 sugars.[10] In New Zealand honey, significant levels of pollen can occur in honey (in excess of 14,000,000 grains/10 g; personal observation by Rogers). At levels where pollen is >500,000 grains/10 g honey, contamination of protein by concurrently extracted pollen can result in false-positive results.[10] High pollen levels can be introduced into honey due to the robust extraction methods used to dislodge thixotropic honey (such as manuka). Frames often need manual scraping followed by high-speed centrifuging to remove honey. This procedure may dislodge large pockets of pollen stored in the frames, in contrast to gentle "prick and drain" methods employed for runnier honeys, which generally retain the comb structure and associated pollen within the frame.

Supplementary Protein Feeding (False-Positive and Genuine Fails). Supplementary protein feeding can affect δ^{13}C protein values[10] and contaminate nectar-derived protein sources. Common protein supplements include yeast (−24‰), soy flour (−25 to −27.5‰), and pea flour (−28‰),[14−17] which have a range of isotopic values and are similar to the range of honey protein values found in this study (−24.3 to −28.2‰). Although the protein supplements are usually consumed by bees, it is possible small amounts are regurgitated and stored in collections boxes, similar to bee bread and pollen pockets, contributing foreign protein to the honey. Fed at inappropriate times, supplementary feeds might also cause genuine fails due to the practice of mixing sugar syrups with the protein feed to increase palatability and consumption by bees. Issues with using yeast as a protein source were also observed in this study, where honey was more prone to fermentation over time, especially with higher moisture content honey (19−21%) and higher storage temperatures (>22 °C). Hives fed either yeast or sugar syrup inverted with yeast had a tendency to show δ^{13}C honey values that were more positive (−23 to −24.5‰), even if sugar feeding had occurred sparingly (personal observation by Rogers).

Brood Box Contribution (Genuine Fails). C-4 sugar fails may also arise if honey extraction occurs from the brood box. The brood box is where bees store pollen and/or bee bread (key protein sources) as well as nectar and/or sugar syrup, which are converted to honey (key carbohydrate sources) to provide stored sustenance and ensure survival of the colony during food shortages or bad weather. In spring, if bees have filled brood box frames with unconsumed honey, and there is no further room for brood expansion, beekeepers may exchange filled frames for empty frames to allow continued brood expansion. The extraction of honey from brood box frames is generally unacceptable in good beekeeping practices due to the

risk of contamination from winter or prenectar flow hive treatments (i.e., for varroa and other common diseases) and supplementary feeding of sugar or protein.

Unknown (Non C-4 Sugar) Mechanism (False-Positive Fail). New Zealand honey samples exceeding 7% apparent C-4 sugars continue to occur; however, in most instances none of the above causes were cited by participating beekeepers as being possible. Until this study, an unknown mechanism (which is unrelated to C-4 sugar adulteration) has been suspected as being responsible for these failed tests.[10,11] This research aims to investigate and understand false-positive results that were not caused by protein feeding or excess pollen levels in the honey.

MATERIALS AND METHODS

AOAC 998.12 Method and "Apparent" C-4 Sugar Determination. Carbon isotopes (δ^{13}C honey and δ^{13}C protein) and apparent C-4 sugar contents of 1023 New Zealand honey samples (mainly manuka but 14 multifloral and other monofloral varieties also included) were analyzed at the Stable Isotope Laboratory at GNS Science, Lower Hutt, New Zealand, between January 2011 and December 2012. The honeys were harvested between December 2007 and March 2012 and were submitted by honey companies and beekeepers as part of quality assurance requirements to test for apparent C-4 sugars before export.

Honey was submitted blind for testing, and further information was supplied after analysis based on organoleptic (i.e., flavor, odor, and color), physicochemical (i.e., conductivity and thixotropy), and/or pollen count as well as from observations by the beekeepers who target specific nectar flows. Antibacterial activity was also reported if available, including total peroxide activity (PA, caused by hydrogen peroxide which originates from the activity of the enzyme glucose oxidase in honey) or nonperoxide activity (NPA, related to a further amount of antibacterial activity attributed to other bioactive compounds such as methylglyoxal in the product).[18,19] Activity analyses were carried out in commercial testing laboratories by Hills Laboratories, Hamilton, New Zealand, or Eurofins, Hamilton, New Zealand.

Protein Extraction. Protein was extracted from honey using the AOAC 998.12 repetitive wash method whereby 4 mL of distilled H_2O was added to 10−12 g of honey in a clear 50 mL centrifuge tube. The solution was mixed well and heated gently in a water bath to aid dissolution. Two milliliters of 10% sodium tungstate and 2 mL of 0.67 N H_2SO_4 (Sigma-Aldrich) were mixed together and immediately added to the honey solution. The mix was heated at 80 °C in a water bath until a visible protein flocculent formed with clear supernatant, with further 2 mL increments of 0.67 N H_2SO_4 added if no visible flocculent formed after 5 min. The centrifuge tube was filled with water and centrifuged for 5 min at 3500 rpm The supernatant was discarded and the pellet rinsed and centrifuged five times with 50 mL portions of water, thoroughly dispersing the pellet each time. Precipitated protein was dried in an oven overnight at 60 °C. Two manuka honey samples (stored at 4 °C) were routinely analyzed as standards with each batch (18 samples or less) of samples to ensure protein preparation consistency.

Stable Isotope analysis. Approximately 0.5 mg of honey or protein was transferred into 6 × 4 mm tin capsules (IVA-Analysentechnik, Germany) and analyzed for stable carbon isotopes using a Eurovector elemental analyzer coupled to an Isoprime mass spectrometer in continuous flow mode (EA-IRMS). International and working reference standards (IAEA-CH_6, leucine, EDTA, cane and beet sugars), the two honey standards (honey and protein), and blanks were included during each run for calibration.

Isotopic ratios ($^{13}C/^{12}C$) are expressed as isotopic deviations δ defined as

$$\delta\ (‰) = \frac{R_s - R_{ref}}{R_{ref}} \times 1000$$

where R_s is the isotopic ratio measured for the sample and R_{ref} that of the international standards. The δ^{13}C value is relative to the international Vienna Pee Dee Belemnite (VPDB) standard. Results are expressed in δ (‰) versus the specific reference, and analytical precision is within ±0.2‰ for carbon.

Carbon isotopes of the whole honey were compared with their extracted protein and assessed for apparent C-4 cane sugar content using eq 1:

$$\text{apparent C-4 sugar (\%)} = 100 \times [\delta^{13}\text{C(protein)} - \delta^{13}\text{C(whole honey)}] / [\delta^{13}\text{C(protein)} - (-9.7)] \quad (1)$$

The acceptance criteria state that pure honey generally yields a value of apparent C-4 sugars of ≤7%. Some unusual varieties may slightly exceed the range, but will have δ^{13}C values for honey that are in the normal range (more negative than −24.0‰).[7]

Other Analyses. Methylglyoxal (MGO) or NPA and hydroxymethylfurfural (HMF) measurements were supplied by some honey submitters whose honey had already been tested at Hills Laboratories or Eurofins according to their in-house commercial procedures. To complete data sets where MGO and NPA data were not available and perform checks on supplied values, samples were sent to Hills Laboratories for further testing. Due to several bioactive honey measurement systems within New Zealand,[18] the NPA, UMF, and MGO bioactivity values were standardized and reported as NPA according to the UMF Honey Association conversion tool Web site (http://www.umf.org.nz/umf-trademark/methylglyoxal-npa-honey-conversion-calculator).

RESULTS AND DISCUSSION

Which New Zealand Honey Varieties Are Prone to Exceeding 7% "Apparent" C-4 Sugars? Apparent C-4 sugar analysis of 1023 New Zealand honey samples showed that 690 samples had apparent C-4 sugars ≤7% (67% pass rate) and 333 samples had apparent C-4 sugars >7% (33% fail rate) (Figure 1). The apparent C-4 sugar content found in these honeys

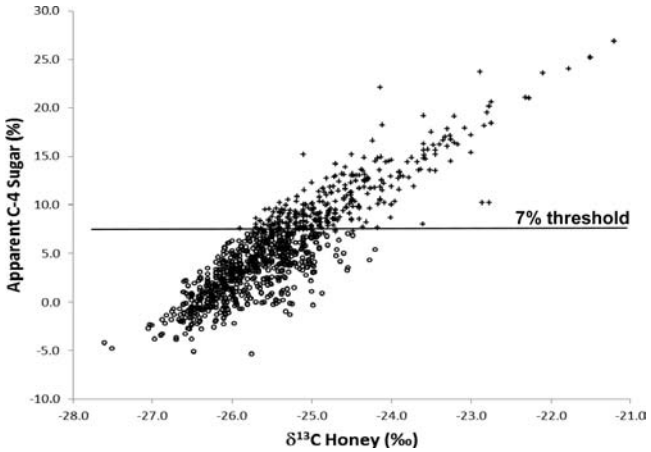

Figure 1. Distribution of δ^{13}C honey isotope values and apparent C-4 sugars for 1023 New Zealand honeys. Circles represent ≤7% apparent C-4 sugars, and crosses represent >7% apparent C-4 sugars. $R^2 = 0.81$, $y = 5.1585x + 136.55$.

ranged between −5.4 and 26.9%; δ^{13}C honey values ranged from −18.5 to −27.6‰, and δ^{13}C protein values ranged from −24.3 to −28.2‰. The average δ^{13}C honey and protein values of the 1023 New Zealand samples were −25.4 ± 0.8 and −26.3 ± 0.4‰, respectively (Table 1). The average δ^{13}C honey and protein values of honeys with apparent C-4 sugars ≤7% were

[a]The range of manuka honey covers both NPA manuka honey and non-NPA manuka honey. It is possible that the floral type of some non-NPA manuka honeys has been misidentified by the beekeeper, resulting in a larger isotopic range than would be expected. However, the overall sample size (n = 757) is sufficient to provide a statistically robust isotopic average for manuka honey. Manuka blend is indicated when manuka components are present but not in sufficient quantities to dominate the floral type (being wholly or mainly as required in Codex).[13]

−25.8 ± 0.5 and −26.3 ± 0.4‰, respectively, whereas honeys with apparent C-4 sugars >7% had average δ^{13}C honey and protein values of −24.6 ± 0.9 and −26.4 ± 0.5‰, respectively. Most samples readily flocculated protein, with some manuka honey samples flocculating on warming, even before addition of the chemicals. It was noted that it was often difficult to flocculate protein from tawari and rata honey, suggesting they may contain lower levels of extractable protein.

Due to the high overall failure rate (33%), honey samples were classified into 15 floral types to investigate how prone each floral type was to failure (Table 1). Four monofloral honey types (manuka, tawari, ling, and kamahi) had samples that exceeded 7% apparent C-4 sugars and failed acceptance criteria, whereas none of the other 11 New Zealand honey varieties exceeded 7% apparent C-4 sugars (Table 1).

Comparison of the carbon isotope values of 690 honeys and their frequency of passes (apparent C-4 sugars ≤7%) to the 333 honeys and their frequency of fails (apparent C-4 sugars >7%) identifies three main regions of interest (Figure 2). In region 1, all honey samples passed and δ^{13}C honey values ranged between −27.6 and −25.9‰; 250 samples were classed as genuine passes with no apparent C-4 sugar adulteration. In region 2, all samples failed the test (apart from a few tawari and multifloral samples) and δ^{13}C honey values ranged between −24.7 and −18.5‰; 59 samples were classed as genuine fails which were attributed to apparent C-4 sugar contamination. In region 3, honey samples could either pass or fail the test and δ^{13}C honey values were between −25.9 and −24.7‰; 440 samples passed, and 274 samples failed. Of interest are the mechanisms that allowed honey samples of similar florality (and hence nectar source) and bulk isotope composition to either pass or fail in region 3 and whether they were genuine fails or false-positive fails. The delineation of region 3 is made specifically for manuka honey, where all manuka honey samples with δ^{13}C honey values more negative than −25.9‰ passed and all manuka honey samples with δ^{13}C honey values more positive than −24.7‰ failed. All samples that failed in region 3 were manuka honey.

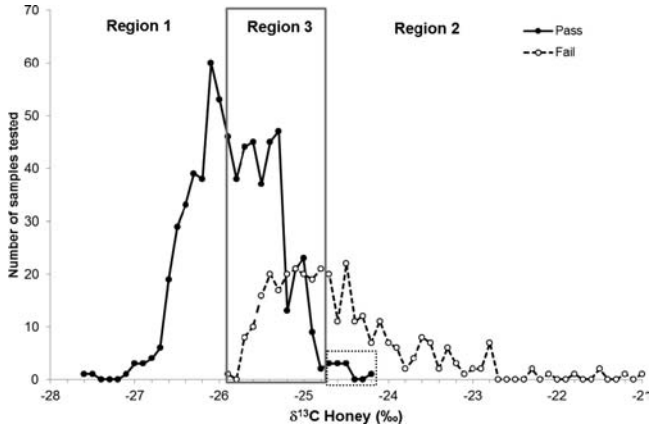

Figure 2. Frequency distribution of 1023 New Zealand δ^{13}C honey values. Region 3 represents honey samples that pass and those resulting in false positives. Several samples encompassed in the dashed box (more positive δ^{13}C honey samples than those in region 3) are tawari, clover, and multifloral samples that had C-4 sugars ≤7%.

In the past, honeys were not considered adulterated with C-4 sugars if their bulk isotope analysis (δ^{13}C honey values) was more negative than −23.5 to −24.0‰.[3,5] Even though 274

New Zealand honeys from region 3 (Figure 2) had δ^{13}C honey values more negative than −24.7‰ (and could therefore be considered as unadulterated on the basis of traditional analyses), these honeys exceeded 7% apparent C-4 sugars and failed the original AOAC 998.12 acceptance criteria.[1] As their δ^{13}C honey values were well within the acceptable range, this suggested that a shift in the δ^{13}C protein values might be affecting the outcome, rather than C-4 sugar adulteration.

An assessment of the δ^{13}C protein values of these 1023 honeys showed that the range of δ^{13}C protein values of honey samples which passed the test (apparent C-4 sugars ≤7%, −24.9 to −27.1‰) is considerably narrower than the range of δ^{13}C protein values that failed the test (apparent C-4 sugars >7%, −24.3 to −28.2‰) (Figure 3). The wide range of δ^{13}C protein values found in these 1023 New Zealand honeys (up to 4‰) may suggest that there is either a diverse isotopic range of pollen (protein source) within New Zealand's honey-producing flora or a distinctive isotope fractionation process occurring in the protein.

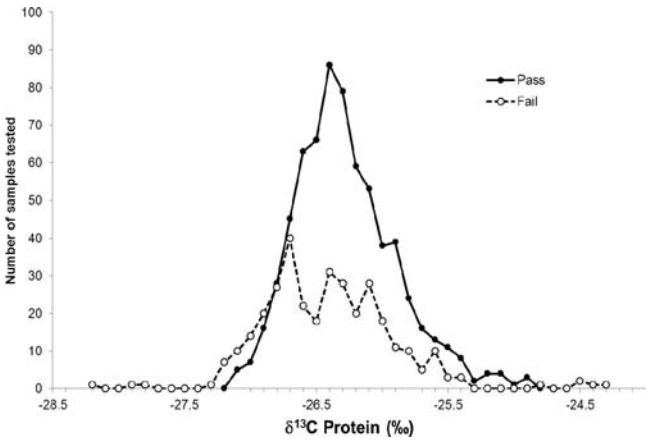

Figure 3. Frequency distribution of 1023 New Zealand δ^{13}C protein values.

Characterization of New Zealand Monofloral Honey Using Carbon Isotopes and "Apparent" C-4 Sugar Content. *Ling.* Ling (or heather) honey has traditionally been identified by Codex[13] as having "special properties" and is allowed higher sucrose contents than other honey (up to 10% w/v). All four ling samples in this study (Figure 4a) failed the AOAC 998.12 method, with apparent C-4 sugars ranging from 8.3 to 22.1%. Three samples (with apparent C-4 sugars between 8.3 and 9.0%) did not originate from hives that were sugar fed by the beekeepers, suggesting that these samples may be false-positive fails. Ling honey δ^{13}C protein values (average δ^{13}C ling protein value of −27.3‰) were up to 1.0‰ more negative than those of other honey proteins in this study (average δ^{13}C total protein value of −26.3‰), whereas the average ling δ^{13}C honey value was −25.2‰ and comparable with the average δ^{13}C total honey value of −25.4‰. One ling sample (circled in Figure 4a) had δ^{13}C honey and protein values of −24.1 and −28.2‰, respectively, which suggested a positive shift in the δ^{13}C honey value, usually associated with C-4 sugar contamination, but also indicated a significant negative shift of δ^{13}C protein values.

Kamahi. One kamahi honey (n = 18) failed the AOAC 998.12 method with an apparent C-4 sugar content of 13.2% (Figure 4b). This sample had a δ^{13}C honey value of −24.5‰ and a δ^{13}C protein value of −26.6‰. The $\Delta(\delta^{13}$C honey-protein) value of this sample was 2.2‰, which is much higher than those of the other kamahi samples in this study (−0.5 to 0.8‰), suggesting the fail was caused by either a significant honey or protein shift or both. This sample was the only sample to fail of 18 samples and was considered to be a genuine fail (most likely due to C-4 sugar) as its δ^{13}C honey value (−24.5‰) was considerably more positive than the average

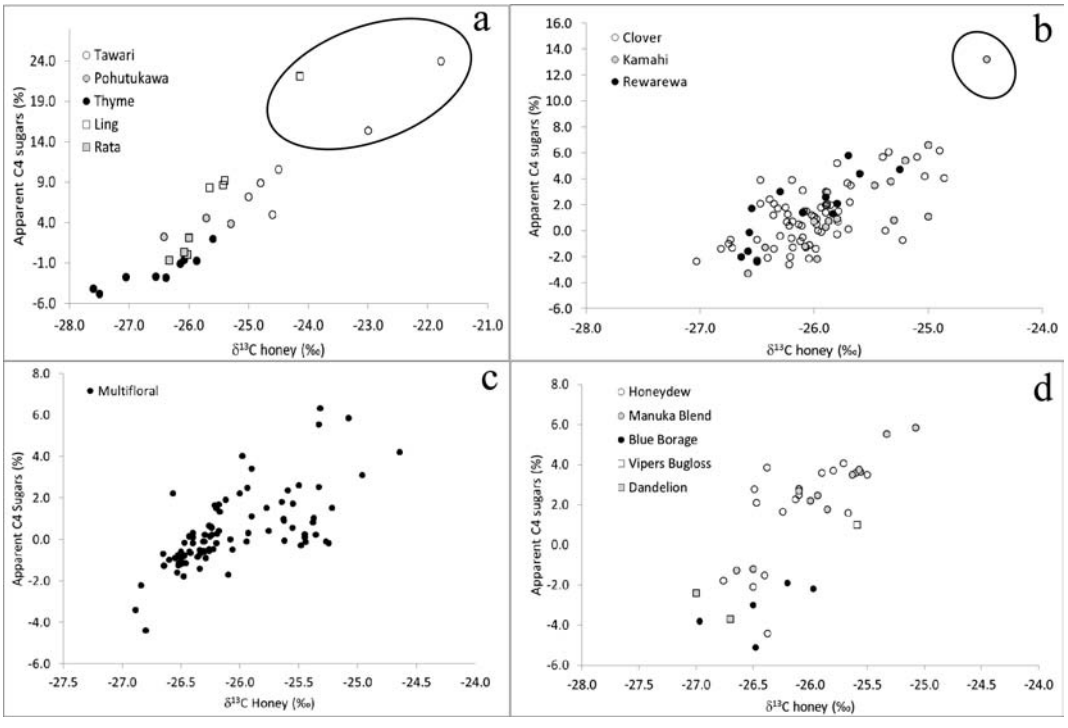

Figure 4. Carbon isotope and C-4 sugar contents of 13 New Zealand mono- and multifloral honeys using AOAC 998.12 method.

δ^{13}C kamahi honey value (−25.6 ± 0.6‰). It was not possible to discount that some other non C-4 sugar contribution may have also occurred due to the more negative δ^{13}C protein value.

Tawari. Four of six tawari honey samples failed the AOAC 998.12 method with apparent C-4 sugars ranging from 7.2 to 24.0% (Figure 4a). Two of these samples (circled in Figure 4a) were reported to have been sampled from hives where some C-4 sugar feeding occurred prior to nectar collection (δ^{13}C honey values of −21.8 and −23.0‰, respectively) and were considered to be genuine fails. The other two tawari honey samples, which had apparent C-4 sugars >7%, had no reported association with C-4 sugar feeding and may represent false-positive results. Although only six samples of tawari honey were studied, the average δ^{13}C tawari honey value (genuine samples) was −24.6‰ (0.8‰ more positive than the average δ^{13}C honey values in this study), even though these four samples were reported by beekeepers to be genuine with no previous sugar feeding history. Six samples of tawari nectar originating from Gisborne (East Coast) were also collected and analyzed for their carbon isotopes. The average δ^{13}C tawari nectar value was found to be −24.5 ± 0.5‰, corresponding to similar δ^{13}C honey values found in tawari honey. Tawari honey was found to have more positive carbon isotope values than any other New Zealand honey floral variety in this study. These positive δ^{13}C honey values are similar to other specialty honeys containing more positive isotope values found elsewhere globally such as citrus and mesquite honeys, which have δ^{13}C honey values averaging −23.8‰.[20]

Clover and Multifloral. A large number of clover (n = 67) and multifloral (n = 93) honeys (sometimes called bush honey due to their mixed nectar source) (Figure 4b,c) were identified and analyzed. In New Zealand, these honeys are the next most popular export honeys after manuka honey. All clover and multifloral honey samples tested in this study had apparent C-4 sugars <7% and passed the AOAC 998.12 C-4 sugar method. The average δ^{13}C clover and multifloral honey values (−26.0 and −26.1‰) were more negative than the average δ^{13}C total honey value (−25.4‰). The average δ^{13}C protein values of clover and multifloral honey (−26.2 and −26.1‰) were similar to the average δ^{13}C total protein values (−26.3‰). Clover and multifloral honeys analyzed in this study had some of the lowest apparent C-4 sugars of all floral types (average 1.1 and 0.4%, respectively). The small isotopic differences between paired δ^{13}C honey and protein values suggested that these honeys were very pure and that both honey and its protein were derived from the corresponding nectar without interference from sugar or other contaminants that may affect their honey or protein isotopes.

Other Monofloral Varieties (Except Manuka and Kanuka). Eight floral varieties (blue borage and vipers bugloss, dandelion, honeydew, manuka blend, pohutukawa, rata, rewarewa, and thyme, n = 58) had average δ^{13}C honey values ≤ −26.0‰ (Figure 4a,b,d) and δ^{13}C protein values between −25.9 and −26.4‰ (Table 1). These honeys all passed the AOAC 998.12 method. Some floral types had negative apparent C-4 sugar contents, which occur when the corresponding δ^{13}C protein value of each honey is more positive than its δ^{13}C honey value. These eight floral types all had apparent C-4 sugars ≤5.8%, although it was recognized that the sample numbers for blue borage and vipers bugloss, dandelion, manuka blend, and rata were not statistically robust (as $n \leq 6$). The floral type with the most negative average δ^{13}C honey value was dandelion (−26.9‰). The floral type with the most negative δ^{13}C honey value in this study was thyme (−27.6‰).

Manuka. The largest group of honeys evaluated in the study comprised manuka honey (757 samples) primarily because these are most frequently tested prior to export. Only 433 of these manuka honeys had apparent C-4 sugars <7% (AOAC 998.12 pass criteria), whereas 324 samples (42.8% of manuka honeys tested) had apparent C-4 sugars exceeding the 7% acceptance criteria. The range of δ^{13}C manuka honey values found in this study was between −21.0 and −27.6‰, with an average honey value of −25.1 ± 0.8‰. δ^{13}C manuka protein values were between −24.6 and −27.3‰, with an average δ^{13}C manuka protein value of −26.3 ± 0.5‰. Apparent C-4 sugars ranged from −3.9 to 26.9%. Manuka honey (161 samples) was found to have apparent C-4 sugars *always* <7% as long as its corresponding δ^{13}C honey value was ≤ −25.9‰ (region 1, Figure 2; Table 1). These samples were considered to be uncontaminated by C-4 sugar and genuine passes. Manuka honey (113 samples) was found to have apparent C-4 sugars *always* >7% as long as its corresponding δ^{13}C honey value was ≥ −24.7‰ (region 2, Figure 2). These samples most likely failed because they contained some C-4 sugar contamination (genuine fail). However, it may be possible these samples are not true fails if they contained honey derived from nectar sources with more positive δ^{13}C values such as tawari or were fractionated (loss of ^{12}C) in some way by yeasts or some further (as yet unknown) mechanism. Manuka honey (483 samples) found in region 3 had δ^{13}C honey values ranging between −24.7 and −25.9 ‰, and had contained apparent C-4 sugars both below and above 7%, although none exceeded 15% apparent C-4 sugar. Of this group from region 3, 272 manuka

Table 3. NPA Rating of 376 Manuka Honey Compared to Carbon Isotopes of Honey and Apparent C-4 Sugars

NPA rating	no. of samples with NPA rating	no. of samples with C-4 sugars >7%	% fail[1a]	no. of samples with δ^{13}C honey ≥ −24.7‰	% fail[2b]
low (4−9.9)	156	17	11	4	3
medium (10−16.9)	129	79	61	44	34
high (17−30)	91	74	81	26	29
total	376	170	45	74	20

[a]% Fail[1] refers to existing criteria where 7% is the fail criteria for apparent C-4 sugars. [b]% Fail[2] refers to new proposed criteria where manuka honey with δ^{13}C honey ≤ −24.7‰ is considered genuine.

honey samples with apparent C-4 sugars below 7% were considered to be genuine passes, whereas 211 manuka honey samples with apparent C-4 sugars exceeding 7% were considered to be false-positive fails.

The lower limit of δ^{13}C honey values for manuka honey (region 3, −24.7‰) is determined by the analysis of pure manuka nectar sampled directly from *Leptospermum* (sp) flowers, which was found to have an average δ^{13}C value of −26.2 ± 0.5‰ (n = 25) (Table 2). It is expected that δ^{13}C protein and δ^{13}C honey of authentic (non-C-4 sugar contaminated) manuka honeys would have similar honey isotope values as the nectar, because the bees do not alter the isotopic values. The average manuka nectar isotope value correlates well with the δ^{13}C honey values of manuka honey, which passed the AOAC 998.12 method in region 1 and false-positive samples from region 3, but may suggest that in some of the samples which are more variable (outliers) that other nectar sources (which contain more negative or positive carbon isotopes) may have a more significant contribution. Alternatively, there may be a small change in the δ^{13}C honey value of some honeys with ripening and maturation. To ensure a statistical safety interval of 3 times the SD (i.e., a confidence level 99.7%), the lowest acceptable value (cutoff) for genuine (unadulterated) manuka δ^{13}C honey value would be −24.7‰ (−26.2‰ − (−1.5‰) = −24.7‰) as suggested by the data in Figure 2. Moreover, of 757 manuka samples analyzed in this study, no manuka samples with δ^{13}C honey value ≤ −24.7‰ (region 2) passed the AOAC 998.12 C-4 sugar method.

False-positive samples from region 3 are also found to have more negative δ^{13}C protein values (average −26.7 ‰) than those from region 2 (average −26.0 ‰, where none of the 757 screened manuka samples passed the AOAC 998.12 and C-4 sugar contamination is known to occur).

Kanuka. Kanuka (*Kunzea ecroides*) honey (19 samples) were analyzed for carbon isotopes and apparent C-4 sugars (Table 1). Flowering concurrently with manuka, examples of pure kanuka honey are not frequently found, as most kanuka honey is collected with, and identified as, manuka honey. It is not possible to distinguish between the two species using pollen identification as they have identical pollen shape and size. In the few identified cases where kanuka nectar sources predominate, the honey is reported to be lighter in color, less intense in flavor, and lower in conductivity and to have little or no thixotrophy compared to manuka honey. Unlike manuka honey, kanuka honey is not reported to have a nonperoxide activity. Kanuka honey exhibits more negative δ^{13}C honey values (average −26.1‰) than manuka (average −25.1‰), although δ^{13}C protein values are similar (average −26.4 and −26.3‰, respectively). All 19 kanuka honeys had apparent C-4 sugars <4.6%, suggesting these honeys are not prone to high apparent C-4 sugar contents, typical of excess C-4 sugar feeding or false-positive fails. As kanuka flowers at a similar time to manuka, this honey would be just as susceptible to excess C-4 sugar fails as manuka honey if sugar syrup feeding was the key reason for high apparent C-4 sugar content in manuka honey.

Could False-Positive Fails Exist for Honey with δ^{13}C Honey Values > −24.7‰? Although some samples with δ^{13}C honey values > −24.7‰ and apparent C-4 sugars >7% (considered to be C-4 sugar contaminated) were confirmed by beekeepers as originating from hives that had been fed some C-4 sugar syrup, other beekeepers stated that some samples included in this group originated from hives which had minimal C-4 sugar syrup feeding. There are several mechanisms other than C-4 sugar that can increase δ^{13}C honey values to become more positive, such as a nectar contribution from another more positive floral source or supplementary protein feeding, which may artificially shift the δ^{13}C honey values toward more positive values if the bee feed has more positive δ^{13}C values and is incorporated into the honey instead of being completely consumed.

The only floral type found in this study with substantially more positive isotope values than the average δ^{13}C honey (−25.4‰) is tawari honey (average δ^{13}C honey −24.0‰), although other types of honey with similar positive δ^{13}C honey values are known.[20] Tawari often flowers just prior to the manuka nectar flow, and brood can build up on this nectar before going directly onto manuka flowers. Tawari nectar has an average δ^{13}C nectar value of −24.5 ± 0.5‰, and if combined with manuka nectar, it may be possible to isotopically shift the overall δ^{13}C honey value to > −24.7‰, without the influence of any C-4 sugars. Other floral sources commonly used in spring built up before the manuka nectar flow are pollination crops such as apple and kiwifruit (minimal nectar) or nectar sources from willows and spring weeds. Analysis of a few commonly available pollen sources that may be consumed by bees prior to manuka nectar flow were undertaken during this study. Kiwifruit pollen had a δ^{13}C pollen value of −24.2 ± 0.3‰, and willow and buttercup (a common weed) had δ^{13}C pollen values of −23.0 ± 0.5‰. Other unknown mechanisms may occur if beekeepers feed sugar syrups or supplements that contain yeast. Further research on the consequential associated fractionation of sugars by yeast may explain more positive apparent C-4 sugar fails, although this study was not aimed at resolving how δ^{13}C honey values could become more positive other than via C-4 sugar contamination. However, it will be an important area to consider in future years for New Zealand's manuka industry if it wishes to eliminate sugar adulteration concerns completely.

Why Does Manuka Honey Have False-Positive Fails Using the AOAC 998.12 C-4 Sugar Method? False-positive manuka honey (211 samples) from region 3 (where δ^{13}C honey values were between −24.7 and −25.9‰ and δ^{13}C protein values were between −25.8 and −27.2‰) had apparent C-4 sugars ranging from 7 to 15.0% with an average apparent C-4

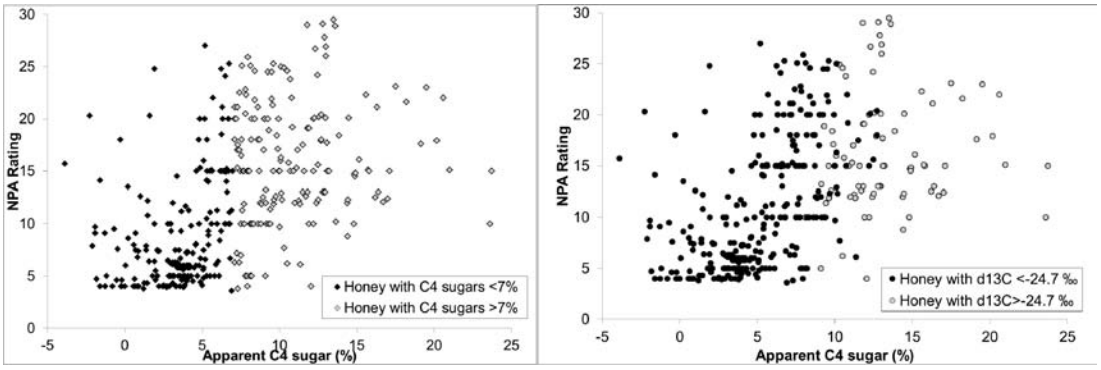

Figure 5. (a, left) Apparent C-4 sugar content versus NPA rating of 376 manuka honeys which fail and pass using (a) the AOAC 998.12 criteria of 7% apparent C-4 sugars and (b, right) the proposed acceptance threshold (from this study) where manuka δ^{13}C honey values < −24.7‰.

sugar content of 8.6 ± 1.3%, although only three samples had apparent C-4 sugars >12%. These samples are all classed as false positives because of a negative shift in δ^{13}C protein values, which artifically increases the $\Delta(\delta^{13}\text{C honey} - \delta^{13}\text{C protein})$ values to >1, whereas the δ^{13}C honey isotope value are < −24.7‰ and traditionally considered unadulterated by C-4 sugars. An assessment of protein isotope values of each region (Figure 2) showed that region 2 (failed samples) had average δ^{13}C protein values of −26.0 ± 0.4‰, region 1 (passed samples) had average δ^{13}C protein values of −26.3 ± 0.3‰, and region 3 (false-positive samples) had the most negative average δ^{13}C protein values of −26.7 ± 0.5‰. A Δ(honey-protein) shift of 0.4‰ (the difference between average δ^{13}C protein values of passed and false-positive samples) equates to an extra 2.8% of C-4 sugar.

A subset of 376 bioactive manuka honeys (Table 3) was selected from the 757 manuka samples, with NPA levels ranging from 4+ to 29.5+ to ensure a minimum level of floral purity (NPA content is considered to be unique to manuka honey and not yet reported in other honey types). From this group, 205 samples had apparent C-4 sugars ≤7% (55%), and 171 samples had apparent C-4 sugars >7% (45%), similar to the overall manuka population screened in this study. These 376 bioactive manuka honeys had δ^{13}C honey values between −21.0 and −26.8‰, δ^{13}C protein values between −24.5 and −27.9‰, and apparent C-4 sugars ranged from −3.9 to 24.5%.

NPA was plotted against apparent C-4 sugar content, and the rate of failure (where apparent C-4 sugars exceed 7%) for high, medium, and low NPA samples was documented in Table 3. Higher NPA honey (17+ to 30+) had the highest apparent C-4 sugar fail rate at 81%, and medium NPA rated honey (10+ to 17+) failed at 61%, whereas only 11% of low NPA rated honey (4+ to 10+) had apparent C-4 sugars >7% (Figure 5a). High rates of failure for high NPA manuka honey were not consistent with excess sugar syrup feeding. High NPA manuka honeys were expected to have the highest nectar purity due to their higher concentrations of methylglyoxal (key active component in NPA manuka honey), which would become diluted if C-4 syrups were fed to bees. The predisposition of high NPA manuka honey to fail and have high apparent C-4 sugar content gives a strong indication toward the cause for false-positive results.

Although the production of methylglyoxal (the compound responsible for high NPA) in manuka honey has been shown to be formed via a conversion pathway of dihydroxyacetone (DHA),[18] the mechanisms and interactions with other compounds that may catalyze the reaction are poorly understood. However, current knowledge suggests that temperature, pressure, humidity, and storage time also have critical effects on manuka honey quality and bioactivity.[21] The issue now becomes one of understanding the effects chemical reactions, which may induce fractionation effects on honey or protein such as the conversion of DHA to methylglyoxal (the chemical reaction that increases NPA) resulting in an increase of the apparent C-4 sugars in higher NPA manuka honey.

These same samples were compared again on the basis of a proposed δ^{13}C manuka honey acceptance threshold of −24.7‰ (suggested by the upper limit of region 3 in this study), where all New Zealand manuka honey with δ^{13}C honey values that are more negative than −24.7‰ are considered genuine, even if they pass or fail (Figure 5b). Of these samples, only manuka honey with apparent C-4 sugars <13% are used (Figure 5b). This value is determined from the range of apparent C-4 sugar values when the proposed δ^{13}C honey value threshold of −24.7 ‰ is applied. Using this carbon isotope threshold, the failure rate of high NPA manuka honeys (17+ to 30+) was significantly reduced with only 29% of these honeys having δ^{13}C honey values > −24.7‰. Medium (10+ to 17+) and low (4+ to 10+) NPA manuka honeys also had significantly reduced failure rates (34 and 3%, respectively) when the proposed carbon isotope threshold was used (Table 3). The failure rate of the entire subset of NPA manuka honey samples was reduced to 20% (where these failed samples had δ^{13}C honey values ≥ −24.7‰). These remaining failed samples may have some C-4 sugar contamination, but currently there is insufficient evidence to provide a robust explanation for some other mechanism contributing toward more positive carbon isotope values. In the future, more research should be conducted to understand mixing of unusual New Zealand nectar sources (tawari with its average nectar values of −24.5‰ is a key example), and/or fractionation effects via some synergistic/reactive mechanism occurring within the honey, which can alter the carbon isotopes to become more positive.

Why Do Some Other (Nonmanuka) Honey Varieties Fail? In this study, ling honey was found to have the most negative δ^{13}C protein values (average −27.3‰). It is likely this thixotropic honey has a chemical reaction or mechanism occurring within the honey that affects its protein isotopic composition similar to manuka honey. Thixotropic honeys such as manuka and ling contain a higher protein content, primarily derived from plant proteins, rather than from bee enzymes typical of many nonthixotropic honeys,[22] suggesting that there may be other thixotropic honey types from elsewhere around

the globe that also behave in a similar fashion and will have a higher tendency to fail the AOAC 998.12 method.

Tawari honey has also been found to have more positive carbon isotope values than all other New Zealand honey floral sources, where the average δ^{13}C honey value was −24.5‰, and also prone to fail C-4 sugar tests. The consequence of a tawari nectar contribution to honey derived from other floral nectars may increase their failure rate, as the resulting δ^{13}C honey values would shift to more positive values. Contamination of manuka honey by tawari nectar may be responsible for some manuka honey fails, especially when δ^{13}C manuka honey values are > −25.1‰ (average manuka δ^{13}C honey value), as concurrent flowering of the two species often takes place in the North Island of New Zealand, where much of the bioactive manuka honey is produced.

Laboratory observations during AOAC 998.12 analysis have shown that tawari honey often contains relatively low levels of extractable protein, so the corresponding protein of a manuka/tawari blend would not exhibit a similar positive shift, and it would appear that the sample contains excess C-4 sugars. An indication of this possible effect has also been observed by the presence of tawari pollen in some failed manuka honeys (personal observation by Rogers). Further studies using tawari and manuka plant-specific chemical markers would also confirm this interaction. Rewarewa and kamahi also have similar flowering times as manuka and kanuka, and it is possible that bees could collect these nectars concurrently with bioactive manuka and/or tawari nectar in sufficient quantities to cause a false-positive fail. In the future, examination of these honey varieties using specific chemical biomarkers, sugar profiles, or pollen counts may clarify mixing.

In conclusion, specific New Zealand floral varieties (blue borage, clover, dandelion, honeydew, kanuka, manuka blend, multifloral, pohutukawa, rata, thyme, and vipers bugloss honeys) do not exceed 7% apparent C-4 sugar when tested using the AOAC 998.12 method. These honeys are not prone to false-positive results, nor would they show apparent C-4 sugar contamination unless excess C-4 sugar feeding has occurred. However, in some cases, sample numbers are not statistically significant, and further isotope characterization of some monofloral varieties would be complementary. It is expected that if beekeepers continue feeding minimal sugar and bees do not rob sugar from other nearby sources (up to a flight radius of 6 km, which is the effective foraging distance for a bee)[23] and if nectar flows are strong and hive management practices are not significantly changed from one season to the next, then these specific floral types will continue to meet current AOAC 998.12 C-4 sugar method criteria.

This study highlights that higher apparent C-4 sugar contents not only occur when the δ^{13}C honey value becomes more positive (by addition of C-4 sugars or another undocumented effect) but also when the δ^{13}C protein value becomes more negative. In the absence of C-4 sugar addition, false-positive results occur where the δ^{13}C protein value becomes more negative during the honey ripening process and artificially elevates the apparent C-4 sugar content of honey. This research shows a strong tendency for manuka honey, particularly higher NPA rated manuka honey (NPA > 10+), which has undergone ripening, to have apparent C-4 sugars that exceed 7% and hence fail acceptance criteria for the AOAC 998.12 C-4 sugar method. Lesser studied honeys such as kamahi, tawari, and ling have also shown a tendency to fail the AOAC 998.12 method. In a subsequent paper, the relationship of apparent C-4 sugar content of manuka honey with NPA > 10+ is discussed. Specifically, the ripening effects of heating and/or storage of higher bioactive manuka honey on apparent C4 sugars are investigated.[21]

To improve the interpretation of the AOAC 998.12 acceptance criteria for New Zealand manuka honey and avoid false-positive fails, the following amendment to the AOAC 998.12 method is suggested:

> *Pure honey (free of corn or cane sugars) yields a value of "apparent" C-4 sugars of ≤7%. New Zealand's manuka honey may exceed this value, but will have honey δ^{13}C values which are in the normal range (more negative than −24.7‰) and an apparent C-4 sugar content no greater than 13.0% (this study and ref 20).*

Table 1. Honey and Protein Carbon Isotopes, Apparent C-4 Sugar Content, DHA Remaining, MGO and HMF Contents, and DHA/MGO Ratio of Honey Inoculated with Various Levels of DHA Incubated at 37 °C for 83 Days[a]

DHA dosage (mg kg^{-1})	δ^{13}C honey (‰)	δ^{13}C protein (‰)	apparent C-4 sugars (%)	DHA (mg kg^{-1})	MGO (mg kg^{-1})	HMF (mg kg^{-1})	DHA/MGO
0 (t = 0)	−26.3	−26.8	2.8	0.0	35.9	64.0	0
0 (t = 83)	−26.3	−26.8	2.8	0.0	39.1	86.0	0
250	−26.4	−26.9	2.8	105.9	87.4	94.6	1.2
500	−26.3	−26.9	3.0	290.4	140.9	86.7	2.1
1000	−26.4	−27.0	3.3	544.0	249.2	95.1	2.2
2000	−26.4	−27.1	3.6	1119.4	477.6	92.9	2.3
4000	−26.4	−27.2	3.9	2196.5	893.4	98.5	2.5
8000	−26.3	−27.3	5.0	4127.3	1649.3	102.2	2.5

[a]Values are reported as an average of three replicates. SDs are within 0.1‰ for isotopes and percentage relative SD of DHA, MGO, and HMF is <5%.

Clover Trial Samples. A 48000 mg kg^{-1} stock solution of DHA, supplied by Sigma-Aldrich, in type I water was prepared and diluted to give final concentrations of 8000, 4000, 2000, 1000, 500, 250, and 0 mg kg^{-1} DHA in honey. HappyBee clover blend honey (60 g) was weighed out, 1 mL of the corresponding DHA stock solution was added, and samples were thoroughly mixed. The control sample (0 mg kg^{-1} DHA) had 1 mL of type 1 water added. Replicate samples were incubated at 37 °C and tested after 83 days.

Manuka Trial Samples. Pure manuka honey samples were selected from four different regions in the southern North Island of New Zealand to see if common patterns existed during the aging of manuka honey. Samples were harvested from December 2011 to January 2012. Samples were held at 20 °C until the study began in October 2012. Replicate splits of each sample were taken in October 2012, with two sample splits (control) being frozen immediately to arrest any chemical transformations and the other paired splits being incubated at 27, 32, and 37 °C; samples withdrawn periodically (t = 21, 63, 151, and 241 days) and immediately frozen. Samples were analyzed for methylglyoxal, dihydroxyacetone, and hydroxymethylfurfural contents and carbon isotope ratios (δ^{13}C) of the honey and extracted protein.[14]

Analysis of DHA, MGO, and HMF. HA (3.34 mg mL^{-1}) was used as the internal standard solution. The PFBHA derivatizing solution (20 mg mL^{-1}) was made up in citrate buffer (0.1M) and adjusted to pH 4 with NaOH (4 M).

A six-point calibration curve was made up for each compound (DHA, MGO, and HMF) using a multicompound standard solution. Standards were made up in an artificial honey matrix (0.20 ± 0.02 g). The artificial honey comprised fructose (41%), glucose (37.5%), sucrose (2.9%), and water (18.6%), and the pH ranged from 3.13 to 3.76, reflecting the pH of honey[12] and so did not need to be adjusted. HA (internal standard, 250 μL), DHA stock (100 μL), and MGO + HMF stock (40 μL) were added, mixed, and left for 1 h. PFBHA derivatization solution (1200 μL) was added and mixed. Samples were left for 1 h to complete derivatization. Acetonitrile (6 mL) was added and the sample mixed until all crystals dissolved; water (2 mL) was added, and the standards were mixed before being transferred to autosampler vials and analyzed. A linear calibration curve was constructed using the HPLC peak area ratios of DHA/HA, MGO peak 1 + MGO peak 2/HA, and HMF peak 1/HA against the mass of the compounds.

Variability of the PFBHA method was determined by analyzing triplicate samples of each manuka honey over 4 days. This introduced real-world variability (such as sample preparation and instrumentation). The percentage relative standard deviation is <5% for all three compounds, and values are reported as averages.

Sample Preparation. Honey samples (0.20 ± 0.02 g) were weighed into test tubes, HA (internal standard, 250 μL) was added, and the sample was mixed and left for 1 h, at which time PFBHA derivatizing solution (1,200 μL) was added, mixed, and left for a further hour. ACN (6 mL) was added and mixed until all crystals were dissolved; water (2 mL) was added and mixed before analysis.

HPLC Method. HPLC to determine DHA, MGO and HMF was performed at the University of Waikato on an HPLC system fitted with two Waters 515 pumps, a 996 photodiode array (PDA) detector (240−400 nm), an autosampler (set at 20 °C), and an Alltech Elite degassing system. A Symmetry shield RP18 column (5 μm, 3.0 × 250 cm) was used for separation of compounds; a 20 μL injection was used. The system was controlled using Waters Empower 2 chromatography software. The system was operated with gradient elution using 30:70 (v/v) ACN/H_2O as mobile phase A and 100% ACN as mobile phase B. The gradient elution was run at a constant combined flow rate of 0.8 mL min^{-1}. Gradient steps were (%B) 0 (10), 2.5 (10), 10.5 (50), 18 (100), 25 (10), and 35 (10). DHA and HA were quantified at 260 nm; HMF and MGO were quantified at 279 and 244 nm, respectively.

C-4 Sugar Determination. δ^{13}C values of honey and corresponding extracted protein were measured using stable isotope analyses according to the internationally used AOAC 998.12 method.[7] Honey and extracted protein (~0.5 mg) were transferred into 6 × 4 mm tin capsules. Samples were analyzed at the Stable Isotope Laboratory at GNS Science, using a Eurovector elemental analyzer coupled to an Isoprime mass spectrometer, for isotopic abundance in continuous flow mode (EA-IRMS). International and working reference standards (IAEA-CH_6, leucine, EDTA, and cane and beet sugars), two honey standards (honey and protein), and blanks were included during each run for calibration. Isotopic ratios (^{13}C/^{12}C) are expressed as isotopic deviations δ defined as

$$\delta\ (\%) = \frac{R_s - R_{ref}}{R_{ref}} \times 1000$$

where R_s is the isotopic ratio measured for the sample and R_{ref} that of the international standards. The δ^{13}C value is relative to the international Vienna Pee Dee Belemnite (VPDB) standard. Results are expressed in δ (‰) versus the specific reference, and analytical precision is within ±0.2‰ for carbon. Apparent C-4 sugar content is calculated by

$$\text{apparent C-4 sugars (\%)} = [\delta^{13}\text{C(protein)} - \delta^{13}\text{C(honey)}]/[\delta^{13}\text{C(protein)} - (-9.7)] \times 100$$

where AOAC 998.12 method interprets pure honey as generally yielding a value of C-4 sugars of ≤7%. Some unusual varieties may slightly exceed the range, but will have δ^{13}C values for honey that are in the normal range (more negative than −24.0‰).[7] It is noted that apparent C-4 sugar is not a direct measurement of actual C-4 sugar levels but an estimation based on the positive δ^{13}C shift that occurs when C-4 sugars (which range from δ^{13}C ~9.7 to 11‰) are added to honey (typically ranging from δ^{13}C ~−24 to −27‰ in New Zealand).[8]

RESULTS AND DISCUSSION

Addition of Synthetic DHA to Clover Honey. Clover honey (which neither displays nonperoxide antibacterial activity nor contains measurable DHA) was used as matrix to investigate the effect of higher levels of DHA and MGO on the apparent C-4 sugar assay. Prior to any addition of DHA, the baseline DHA and MGO contents of the clover honey were tested and were 0 and 35.9 mg kg^{-1}, respectively (Table 1); the MGO result for clover honey is higher than would be expected but may be due to some analytical background interference. Clover honey samples were inoculated with DHA at various concentrations from 0 to 8000 mg kg^{-1} and incubated (37 °C, 83 days) with testing for DHA, MGO, and HMF at 0, 35, and 83 days and for apparent C-4 sugars at 0 and 83 days. At 35 and 83 days clover honeys to which DHA had been added were assayed for MGO content (Figure 1). Results showed

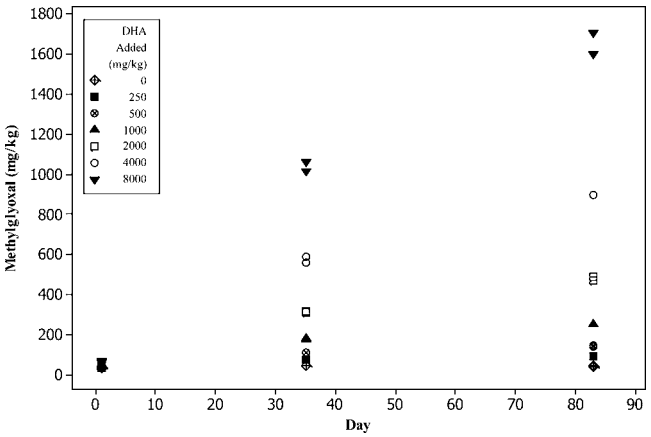

Figure 1. MGO levels (mg kg^{-1}) in replicate clover honey samples after 0, 35, and 83 days of incubation at 37 °C with different additions of DHA (mg kg^{-1}) at 0 days. (Some replicates have excellent repeatability and lie on top of the first point.)

decreased levels of DHA, increased levels of MGO (Table 1), as has been observed previously,[4] and increased levels of HMF. The highest levels of MGO and HMF observed in this trial were 1649 and 102.2 mg kg^{-1}, respectively.

At 0 and 83 days, apparent C-4 sugars were assayed (Table 1; Figure 2). At 0 days, apparent C-4 sugars were 2.8% and were comparable with an average clover honey.[8] After 83 days of incubation, the control sample still measured 2.8% apparent C-4 sugars, but the apparent C-4 sugar content of clover honey with the highest DHA addition (8000 mg kg^{-1}) was 5.0% (a 78.6% increase), the DHA content had decreased (4127 mg kg^{-1}), and the MGO content had increased (1649 mg kg^{-1}) (Figure 2). The ratio of DHA/MGO observed after 83 days was 2.0, similar to that usually observed in mature manuka honey.[15,16]

The HMF level of the clover honey before the trial (at t = 0 days) was 64 mg kg^{-1}, which exceeded recommended Codex limits at the time of purchase. After maturation at 37 °C for 83 days, the clover honey had darkened from a light brown color (at t = 0 days) to a rich caramel color and attained a maximum HMF level (in the DHA, 8000 mg kg^{-1} sample) of 102 mg kg^{-1}. The color and HMF changes are expected given the high temperature and length of incubation. A similar conversion of DHA to MGO might be achieved by using a lower temperature and a longer storage time without the formation of the high

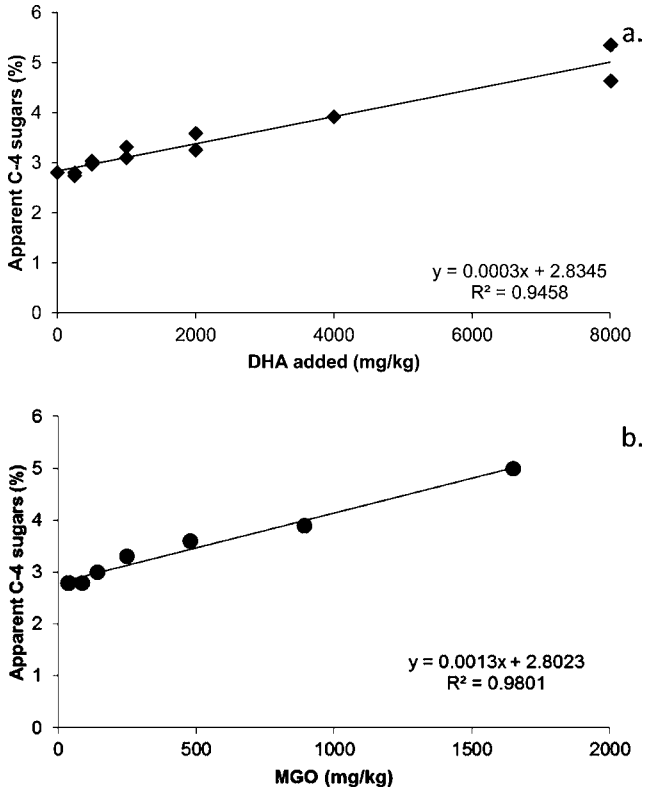

Figure 2. (a) Evolution of apparent C-4 sugars in clover honey after 83 days of incubation at 37 °C after different additions of DHA (mg kg^{-1}) at 0 days; (b) apparent C-4 sugars and corresponding MGO (mg kg^{-1}) evolved in clover honey after 83 days.

levels of HMF because the two reactions, although occurring simultaneously, are not chemically related.

All DHA inoculated clover samples and the clover honey control sample had the same δ^{13}C honey value of −26.4 ± 0.1‰, and these were not found to vary during the trial (Table 1). In contrast, the δ^{13}C protein values, which were unchanged in the control sample between 0 and 83 days, showed an increasing negative trend with increasing initial DHA content; this caused a progressive increase in $\Delta(\delta^{13}$C honey-protein) and apparent C-4 sugars (Table 1). This suggests that freshly harvested honey with a higher initial DHA content would be more likely to fail the AOAC 998.12 C-4 test once maturation had occurred because the chemical reaction converting DHA to MGO was in some way affecting the protein in the honey, causing a false-positive fail. Adams et al.[4] demonstrated that conversion of DHA to MGO was not stoichiometric; that is, not all DHA lost had been converted to MGO, suggesting that DHA and possibly MGO were reacting with other honey components. Other possible reactions that DHA or MGO might undergo include Maillard-type reactions with proteins and/or amino acids. It has been reported that DHA was more reactive with amino acids than glucose; more specifically, basic amino acids (proline, lysine, etc.) were the most reactive with DHA.[17] High concentrations of sugar relative to amino acid and low water activity, both being conditions that pertain in honey, might accelerate the reaction.

MGO is well-known for its capacity to react with and cross-link protein chains.[18] The effect of these Maillard-type reactions would be to reduce the apparent content of amino acids; further cross-linking may also change the solubility and cause

Table 2. Incubation Time, Incubation Temperature, Average DHA, HMF, and MG Contents, and Apparent C-4 Sugar Content of Four Manuka Honeys (Samples 1−4)[a]

aggregation of protein. Such phenomena have been well reported in the production of milk powder.[19−21]

Isotopic enrichment of amino acids in plant seeds and leaves has been studied using LC-IRMS[22] over a range of plant types; the mean $\Delta^{13}C$ values (difference from mean $\delta^{13}C$ for all amino acids) for lysine for leaf and seed were 1.9 and 1.3, respectively. The difference between leaf and seed for lysine was significant, and it might be expected that nectar and hence honey may differ somewhat from these figures. However, it is clear that the loss of an amino acid that makes a positive contribution to the mean would render the mean more negative, similar to the more negative shift seen in clover honey $\delta^{13}C$ protein values (Table 1). A similar positive contribution by lysine was observed in plants in an earlier study.[23] Furthermore, following the demonstrated transfer of essential amino acids including lysine from pollen to eggs of the butterfly *Heliconius charitonia*,[24] it can be assumed that lysine originating from the plant might be transferred to larval bees and hence that contributions from the bee to the honey would have similar

stable isotope values as the plants from which the bee derives pollen.

Manuka Honey. Four manuka honeys with different DHA and MGO contents were selected for storage trials to assess apparent C-4 sugar evolution as DHA, MGO, and HMF evolve at 27, 32, and 37 °C over 241 days (Table 2; Figures 3–6). Initial DHA levels ranged from 1612.4 to 3242.6 mg kg^{-1}. At t = 0, all samples had some MGO content ranging from 178.5 to 315.7 mg kg^{-1} (NPA 7.9+ to 11.2+) as they had been harvested and stored at 20 °C for 10 months prior to the trial.

During the course of incubation, DHA content decreased and MGO content increased (Table 2), as previously demonstrated by Adams et al.[4] The highest MGO contents attained in the study were 459.7 mg kg^{-1} in sample 1, 734.3 mg kg^{-1} in sample 2, 805.4 mg kg^{-1} in sample 3, and 972.1 mg kg^{-1} in sample 4 (which equates to NPA values between 14+ and

dx.doi.org/10.1021/jf404767b | J. Agric. Food Chem. 2014, 62, 2615–2622

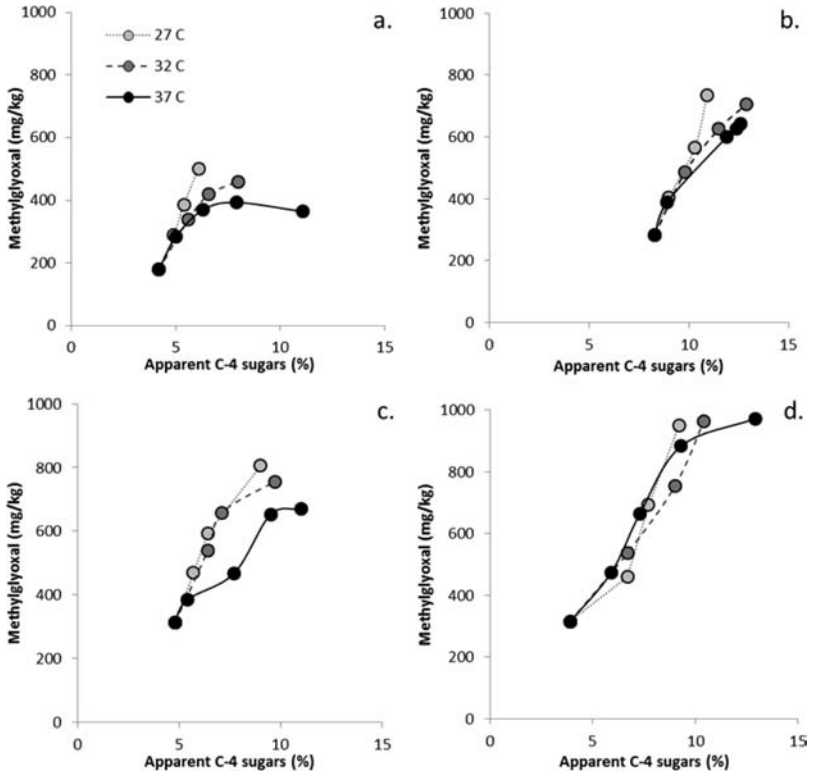

Figure 7. MGO content (mg kg^{-1}) of the four manuka honeys [(a) sample 1; (b) sample 2; (c) sample 3; (d) sample 4] and their corresponding apparent C-4 sugars (%) at 27, 32, and 37 °C.

22+). The highest MGO growth did not always occur in those samples that lost the most DHA (i.e., samples stored at 37 °C for 241 days). After heating at 37 °C, the MGO usually attained a maximum value around 150 days and began to decrease, apart from sample 4, which had a higher initial DHA content than the other samples, so its MGO growth was just attaining its maximum at t = 241 days. At 32 °C, it appeared that all samples except sample 4 were beginning to plateau at a maximum at t = 241 days, whereas sample 4 still had increasing MGO content. At 27 °C, MGO content was still increasing in all samples at t = 241 days, which suggested that at lower storage temperature, MGO content is slower to develop; however, given sufficient time, the MGO content will grow to higher levels than if stored at higher temperatures to accelerate the reaction.

The MGO growth was also accompanied by a similar increasing growth in HMF and apparent C-4 sugars. All four manuka honey samples had initial HMF levels <10 mg kg^{-1}, and by day 241 all but one replicate had exceeded 40 mg kg^{-1} (the Codex recommended threshold), with some in excess of 200 mg kg^{-1}. HMF continued to grow at a much faster rate when the honey was incubated at 37 °C than at 27 or 32 °C.

Apparent C-4 sugars increased with both increasing storage temperature and increasing time. In samples 1, 3, and 4, the apparent C-4 sugars were 4.2, 4.8, and 3.9%, respectively, before incubation, which were well below the permissible AOAC 998.12 C-4 sugar threshold of 7%. Sample 2 had apparent C-4 sugars of 8.3% at 0 days, suggesting a possible apparent C-4 sugar contamination prior to incubation. However, none of these samples were from hives that had undergone sugar feeding prior to nectar collection by bees. Apart from sample 2 at 37 °C, in which apparent C-4 sugars had rapid growth and then remained fairly constant from 63 days onward, all other samples showed steady growth of apparent C-4 sugars over the entire incubation period, and by 151 days, the average apparent C-4 sugars exceeded 7% in all cases regardless of the temperature, suggesting that storage temperatures considerably lower than 27 °C may be a critical factor in retarding the growth of apparent C-4 sugars. A plot of MGO levels and corresponding apparent C-4 sugars of the four manuka honey samples in this study showed that even though MGO growth began to peak and stabilize after t = 150 days, C-4 sugars continued to grow. This phenomenon would explain higher C-4 sugar contents found in older, low NPA or MGO honey (Figure 7). Because DHA and MGO continue to evolve in the jar, even after packaging of honey, the evolution of apparent C-4 sugars would also continue (similar to HMF content) and would be exacerbated when honey is stored at higher ambient temperatures, even for as little as 3 weeks. It is likely that temperatures exceeding 37 °C would increase apparent C-4 sugars at a faster rate.

In this study, the average apparent C-4 sugars of the four manuka honeys after 241 days of storage were 11.1, 12.9, 11.0, and 12.9%, respectively. This research strongly supports the conclusions drawn by Rogers et al.[8] that excess C-4 sugar feeding to bees is not the main cause for C-4 sugars exceeding 7% in New Zealand manuka honey. The key cause is a protein effect, which is activated in the presence of higher levels of DHA and/or MGO found in bioactive manuka honey, which react and cause isotopic fractionation and may also be responsible for other chemical changes.[25] This reaction most likely consumes acidic (^{13}C enriched) amino acids, causing the δ^{13}C protein value to become more negative and thereby generating a bigger Δ (δ^{13}C honey-protein), which artificially enhances the apparent C-4 sugar value as seen after the aging and heating of NPA honey in this study.

dx.doi.org/10.1021/jf404767b | J. Agric. Food Chem. 2014, 62, 2615−2622

When honey is analyzed using the AOAC 998.12 method, unadulterated New Zealand manuka honeys with higher NPA levels (>MGO 260 mg kg^{-1} or > NPA 10+) may have apparent C-4 sugars up to 12.9% (highest C-4 sugar content found in this study), and further increases will occur if the honey is stored for a longer duration at ambient temperature.

We therefore recommend that an exception to the AOAC method 998.12 be considered for all New Zealand manuka honey that has demonstrated DHA and/or MGO levels with the potential to grow beyond MGO > 250 mg kg^{-1}; on the basis of this study and past research,[8] allowable C-4 sugar levels should be at least 13% in manuka honey.

Approved Method 44-15.02.[18] The protein (N × 5.7) content was measured using a Dumas combustion method, adapted from the AOAC Official Method[19] to an automated Dumas protein analysis system (EAS, VarioMax N/CN, Elt, Gouda, The Netherlands).

Gluten Hydrolysis. Gluten was hydrolyzed with porcine pancreatic Try (EC no. 3.4.21.4, Sigma-Aldrich) or Alc 2.4 L FG (EC no. 3.4.21.62, Novozymes, Bagsvaerd, Denmark). An aqueous protein dispersion was prepared by dispersing 6.0 wt % commercial gluten (protein content on dry basis of 83.3%, Syral Belgium, Aalst, Belgium) in water. The dispersion was then heated to 50 °C (Try) or 60 °C (Alc) in a water bath under continuous stirring prior to manual adjustment of the pH by addition of NaOH (1.0 M) to pH 8.0 (Try) or 10.0 (Alc). After the desired temperature and pH conditions were obtained, the peptidase was added and gluten hydrolysis was monitored using the pH-stat method.[20] The degree of hydrolysis [DH, defined as the number of peptide bonds hydrolyzed (h) over the total number of peptide bonds per unit weight present in gluten (h_{tot})] was controlled by varying the hydrolysis time. It was calculated from the amount of base needed during hydrolysis to maintain a constant pH in the hydrolysis reaction medium:

$$\mathrm{DH}\ (\%) = h \times h_{\mathrm{total}}^{-1} \times 100 = (B \times N_{\mathrm{b}} \times 100) \times (\alpha \times M_{\mathrm{p}} \times h_{\mathrm{total}})^{-1}$$

B is base consumption (mL), N_b is the molarity of the base used (1.000 M), α is the average degree of dissociation of the α-NH_2 groups (1.0 and 1.13 for the conditions used for the Alc and Try treatment, respectively), M_p is the mass of the gluten proteins used (in g), h represents hydrolysis equivalents (mequiv/g protein), and h_{total} is the theoretical overall number of peptide bonds per weight unit in gluten protein, that is, 8.3 mequiv/g protein.[20]

At appropriate DH values, the enzyme was inactivated by adjusting the pH to 6.0 using 2.0 M citric acid and subsequent heating to 95 °C for at least 10 min. After cooling to room temperature, the mixture was centrifuged (10000*g*, 20 min, 4 °C) and the supernatant freeze-dried and ground to produce a powder. The gluten hydrolysates produced were coded according to the peptidase used to form them, followed by the DH. For example "Alc3" refers to a gluten sample that was hydrolyzed with Alc to a DH of 3.

Emulsion Preparation. Oil-in-water emulsions were prepared by homogenizing 10 g of corn oil with 90 g of aqueous phase, which was prepared by dispersing powdered gluten hydrolysate (0.11−5.56 wt %) in Tris-HCl buffer (10 mM, pH 9.0, containing 0.02 wt % sodium azide to prevent microbial growth) at room temperature. After stirring for 60 min, the hydrolysate solutions were filtered (grade 4 Whatman filter paper, GE Healthcare, Uppsala, Sweden), and the filtrate was used immediately to produce emulsions. Measurement of the absorbance at 280 nm of the protein solutions before and after filtration indicated that little protein (<5.5% of the total) was lost due to this procedure for all hydrolysates tested. Prior to addition of the oil phase, the aqueous phase of the emulsion, hence, contained hydrolysate levels varying between 0.1 and 5.0 wt % on emulsion weight. A high-speed mixer (Bamix, Biospec Products, Bartlesville, OK, USA) was used to prepare a coarse emulsion, which was then fed into an air-driven microfluidizer (Microfluidics, Newton, MA, USA). The coarse emulsion was passed five times through the microfluidizer at a homogenization pressure of 83×10^6 Pa.

Protein Characterization of Hydrolysate Solutions and Aqueous Phase of Emulsions. Freshly prepared emulsions (2.00 mL) were centrifuged for 20 min in plastic filter units (Centrifugal Amicon Ultra Filter Units, molecular cutoff 100 kDa, Millipore, Cork, Ireland) at 930*g* (CL10 Centrifuge, ThermoScientific, Waltham, MA, USA). The flow-through phase was collected, and the protein content was determined and compared to the protein content of the initial hydrolysate solutions used to prepare the emulsions. Both protein contents were determined using the colorimetric Lowry protein concentration protocol,[21] calibrated with a β-lactoglobulin standard curve (0.0−0.5 mg/mL protein).

Emulsion Characterization. The particle size distribution (area-volume mean diameter d_{32}) of the freshly prepared emulsions was measured by static light scattering (Mastersizer 2000, Malvern Instruments, Malvern, UK). The droplet charge (ζ-potential) was determined by particle electrophoresis (Zetasizer Nano ZS series, Malvern Instruments, Worcestershire, UK). Prior to droplet charge analysis, samples were diluted 100-fold with 10 mM Tris-HCl buffer to avoid multiple scattering effects.

Emulsion Microstructure. The microstructure of the emulsions was visualized using optical and/or confocal scanning laser microscopy with a 60× objective and a 10× eyepiece (Nikon Eclipse 80i, Nikon Instruments Inc., Melville, NY, USA). A small aliquot (about 8 μL) was placed on a microscope slide and covered with a coverslip prior to analysis. Prior to emulsification, the oil and the aqueous phase of the emulsion samples used for confocal microscopy were stained with Nile Red [400 μL of Nile red (0.1% (w/v) solution in ethanol) on 7.5 g of oil] and fluorescein isothiocyanate [FITC, 800 μL of FITC (0.1% (w/v) solution in dimethyl sulfoxide) on 67.5 g of aqueous phase] to visualize lipids and proteins, respectively. The emissions of Nile Red and FITC were detected in the 605 and 515 nm channels, respectively, equipped with long pass filters (HQ 605LP/75 m and HQ 515/30). The microstructure images were analyzed using image analysis software (Nikon).

Emulsion Stability. *Stability to Thermal Processing.* Freshly prepared emulsions were distributed over different glass test tubes and incubated for 30 min in water baths set at different temperatures (30−90 °C). The samples were subsequently allowed to cool to 20 °C, and the particle size distribution was analyzed as described above 24 h and 9 days after the heat treatment.

Stability to Isothermal Storage. Freshly prepared emulsions were distributed over different glass test tubes and immediately incubated for 9 days in temperature-controlled chambers set at different temperatures (4, 20, 37, and 55 °C). Simultaneously, parallel samples containing 150 mM NaCl were stored under the same conditions. The ionic strength was adjusted by the addition of highly concentrated NaCl solution (6.0 M). The final concentration of oil in all of the emulsions was kept constant by adjusting the total volume of the emulsions using water. The particle size distribution of the samples was analyzed as described above 1, 2, 3, 6, and 9 days after preparation.

Stability to Different pH Conditions. Freshly prepared emulsions were distributed over different glass test tubes, and their pH values were immediately adjusted by adding NaOH (1.0 M) or HCl (1.0 M) to obtain values ranging from pH 3.0 to 9.0. The particle size distribution of these samples was determined 24 h and 9 days after adjustment of the pH.

Stability to Different Ionic Strength Conditions. The ionic strength of freshly prepared emulsions was altered by adding a highly concentrated NaCl solution (6.0 M) to produce samples containing 0.0−0.5 M NaCl. The final concentration of oil in all of the emulsions was kept constant by adding water to adjust their total volume. The particle size distribution of these samples was determined 24 h and 9 days after adjustment of the ionic strength.

Statistical Analysis. All measurements were performed on at least three freshly prepared samples (except for the preliminary experiments in which the best-performing hydrolysates were determined) and were reported as means and standard deviations, analyzed using a spreadsheet statistical package (Microsoft Excel 2011). The data were analyzed with Tukey's tests (P value <0.05) using XLStat software (Addinsoft, Brooklyn, NY, USA).

RESULTS

Gluten Hydrolysate Characterization. Gluten was hydrolyzed using Try and Alc to different DH values (DH = 1, 2, and 3 for Try; DH = 3, 6, and 10 for Alc). Alc produced hydrolysates with a higher DH due to its broader specificity relative to Try. The yield (expressed as wt % of the gluten starting material) and moisture and protein contents of the solubilized gluten peptides are listed in Table 1. The hydrolysate yield increased with increasing DH.

Table 1. Characteristics of the Produced Gluten Hydrolysates

sample	yield[a] (%)	moisture content (%)	protein content (% db)
trypsin, DH 1	30.00	4.9 (±0.2)[b]	71.9 (±0.9)[b]
trypsin, DH 2	38.66	3.4 (±0.1)	77.3 (±1.3)
trypsin, DH 3	43.27	4.1 (±0.0)	86.9 (±0.0)
alcalase, DH 3	80.67	3.5 (±0.3)	81.0 (±0.4)
alcalase, DH 6	82.87	4.6 (±0.0)	82.8 (±0.3)
alcalase, DH 10	84.01	2.5 (±0.1)	79.2 (±2.5)

[a]Calculated as the ratio of the weight of the freeze-dried soluble fraction over the total weight of the freeze-dried soluble and insoluble fraction after hydrolysis. [b]The standard deviation values presented here are based on duplicate measurements (n = 2).

Comparison of Emulsifier Properties of Different Gluten Hydrolysate Samples. Preliminary experiments (data not shown) showed that emulsion production at pH 6.5 using gluten hydrolysates did not yield (stable) emulsions with submicrometer droplet diameters. The powdered gluten hydrolysates were then dispersed in an alkaline buffer solution (Tris-HCl buffer, pH 9.0). The actual pH of the emulsion produced, however, was considerably lower (pH ≈7.5) due to citric acid remaining in the freeze-dried hydrolysates. Droplet sizes were determined after 3 h and 7 days to test how the hydrolysates performed as emulsion-forming and -stabilizing agents, respectively. Measurements after 3 h give an indication on how effective a hydrolysate is at forming emulsions with small droplets, whereas measurements after 7 days indicate how effective a hydrolysate is at stabilizing emulsions during storage. Figure 1 shows the mean droplet diameters of emulsions containing 1.0 and 2.5 wt % of the different gluten hydrolysates (i.e., Try1, Try2, Try3, Alc3, Alc6, and Alc10). At the lower hydrolysate concentration (1.0 wt %), Try hydrolysates were significantly better emulsion-forming agents than the Alc hydrolysates. However, at the higher hydrolysate concentration (2.5 wt %), the Try hydrolysates surprisingly displayed significantly worse emulsifying properties than the Alc hydrolysates. A lower concentration of hydrolysate was needed to produce emulsions with similar droplet sizes for Try than for Alc hydrolysates. After 7 days of storage, emulsions prepared using hydrolysates with a DH of 3, that is, 2.5 wt % Alc3 and 1.0 wt % Try3, had significantly smaller droplet sizes as compared to the other hydrolysates, indicating that these were best suited for stabilizing the emulsions (Figure 1). In all other cases, the droplet size drastically increased upon storage. For this reason, the Try3 and Alc3 hydrolysates were focused upon in the following experiments.

Emulsion Formation. Different concentrations of Alc3 (Figure 2a) and Try3 (Figure 2b) hydrolysates were tested for their emulsion-forming properties. All emulsions produced displayed a bimodal size distribution (results not shown), except at the higher hydrolysate concentrations (>3.0 wt %). These higher concentrations, however, did not result in the formation of stable emulsions, and the droplet size increased considerably upon 7 days of storage (>3.0 wt % for Alc3 and >1.0 wt % for Try3). In most cases, the droplet size decreased with increasing hydrolysate concentration until a minimum value was reached (Figure 2a,b), which is in agreement with the behavior expected for emulsifiers during high-pressure homogenization.[22] However, anomalous behavior was observed for the emulsions prepared with high levels of Try3 hydrolysates,

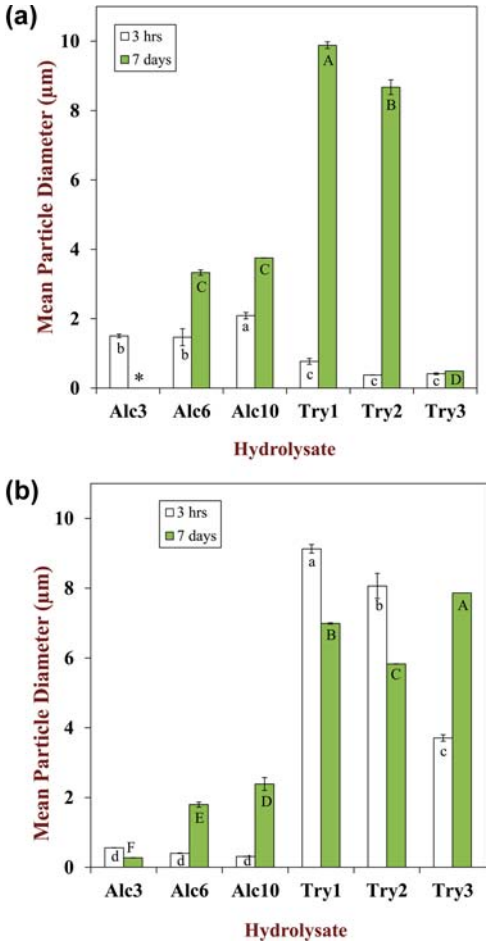

Figure 1. Influence of degree of hydrolysis (DH) on mean particle diameter of emulsions (d_{32}) made with 1.0 wt % (a) and 2.5 wt % (b) of gluten hydrolysates produced with alcalase (Alc) and trypsin (Try). The degrees of hydrolysis of the gluten hydrolysates produced with Alc were 3 (Alc3), 6 (Alc6), and 10 (Alc10), whereas those of the hydrolysates produced with Try were 1 (Try1), 2 (Try2), and 3 (Try3). All emulsions contained 10 wt % corn oil. The reported values were recorded 3 h and 7 days after emulsion production. a–d and A–F represent Tukey groups with $p < 0.05$ for comparison of the particle diameter as a function of peptidase/DH of 3-h- and 7-day-old emulsions, respectively. ∗Upon 7 days of storage, the emulsion produced with 1.0% Alc3 hydrolysate displayed extensive creaming, which hindered droplet diameter measurements.

where a steep increase in particle size was observed at hydrolysate concentrations >2.0 wt %. On the basis of particle size distribution measurements of the fresh and 7-day-old emulsions (Figure 2a,b), 1.0% Try3 and 2.0% Alc3 were selected as the best-performing hydrolysate concentrations in terms of both emulsion formation and stabilization. Microscopic analyses confirmed the bimodal droplet size distribution, as well as flocculation of emulsion droplets produced with higher hydrolysate concentrations (Figure 2c).

To obtain an estimation of the saturation concentration of the hydrolysates at the droplet interface, the protein content in the aqueous phase of the emulsions was determined and compared to the protein content in the aqueous phase prior to emulsification. This ratio was plotted as a function of increasing hydrolysate concentration (Figure 3). It was expected that for the lowest hydrolysate concentrations, no residual protein or very low protein concentrations would be found in the aqueous

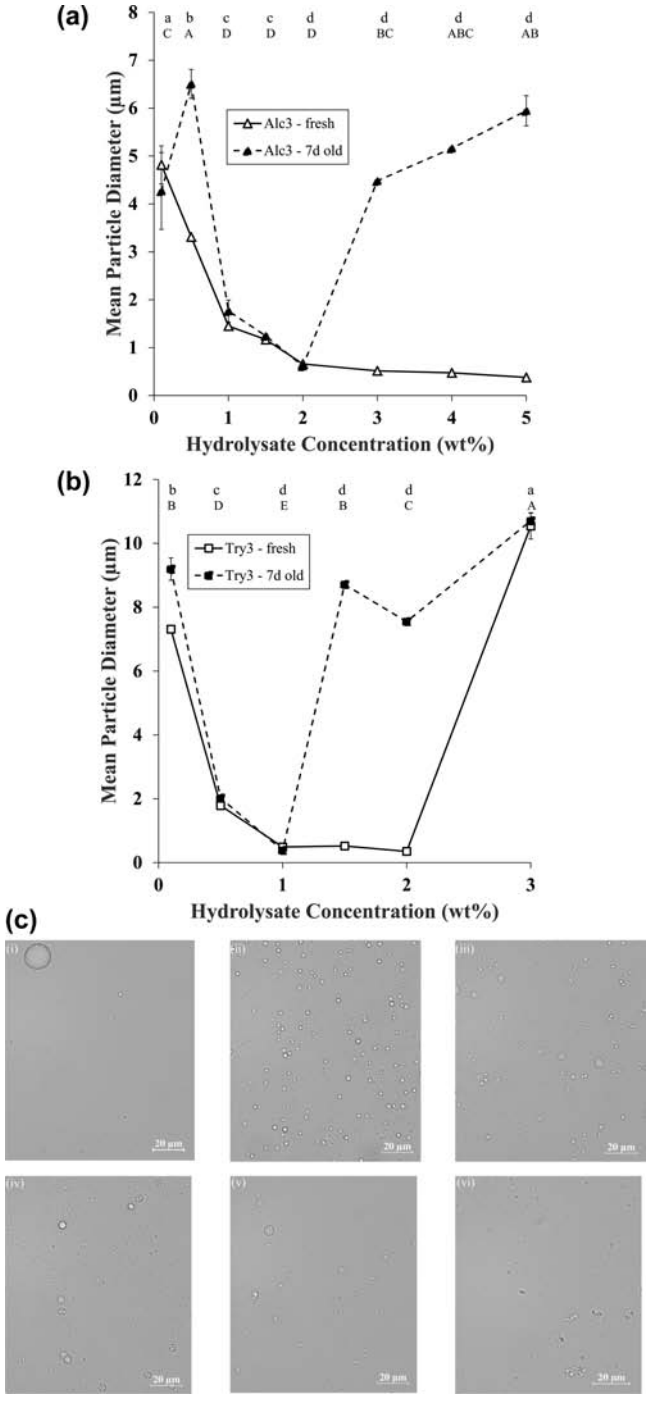

Figure 2. (a, b) Influence of gluten hydrolysate concentration on the mean particle diameter (d_{32}) of 10 wt % corn oil emulsions, freshly prepared and 7 days old. Emulsions were made using gluten hydrolysates with a degree of hydrolysis of 3 produced with alcalase [Alc3 (a)] and trypsin [Try3 (b)]. All emulsions contained 10 wt % corn oil. a–d and A–E represent Tukey groups with $p < 0.05$ for comparison of the particle diameter as a function of hydrolysate concentration of freshly made and 7-day-old emulsions, respectively. (c) Optical microscopic images of emulsions produced with increasing concentrations [i.e., 0.1 (i), 0.5 (ii), 1.0 (iii), 1.5 (iv), 2.0 (v), and 3.0 (vi) wt %] of gluten hydrolysates. The hydrolysates had a degree of hydrolysis of 3 and were produced with Try. All emulsions contained 10 wt % corn oil. The scale bars represent 20 μm.

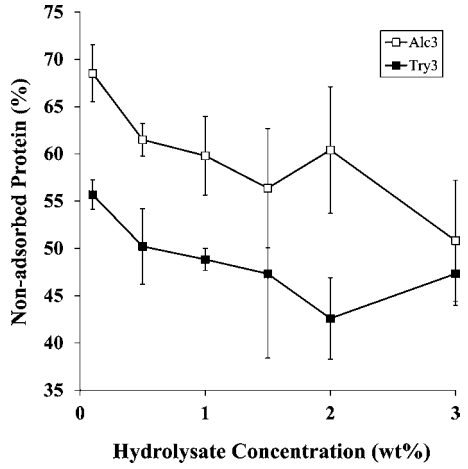

Figure 3. Influence of gluten hydrolysate concentration on the percentage of nonadsorbed proteins found in the aqueous continuous phase of 10 wt % corn oil emulsions. Emulsions were produced using gluten hydrolysates with a degree of hydrolysis of 3 made with alcalase (Alc3) and trypsin (Try3).

phase, and from a critical hydrolysate concentration on the free protein concentration would increase as a function of increasing hydrolysate addition level.[22] However, no such result was obtained (Figure 3). When the protein contents of the continuous aqueous phase of the emulsions were compared to those of the original aqueous phase prior to emulsification, it was clear that about 50 or 60% of the hydrolysates produced with Try or Alc, respectively, were not adsorbed at the droplet interface. This was largely independent of the initial protein concentration (Figure 3). The heterogeneity of the hydrolysate samples in terms of surface activity certainly contributes to this behavior. It is possible that a fraction of the hydrolysates was hydrophobic or surface-active (and therefore became associated with the oil droplets or were even solubilized in the oil phase), whereas another fraction was hydrophilic (and therefore remained in the aqueous phase). Nevertheless, further research using isolated fractions of the hydrolysates would be needed to establish this.

The surface loads of the hydrolysates (i.e., the amount adsorbed per unit surface area) at saturation were estimated to be about 9 and 13 mg/m^2 for Try3 and Alc3 hydrolystates, respectively. These values are on the high end of values typically reported for food proteins (around 1–10 mg/m^2). However, these values should be interpreted carefully for a number of reasons. First, the hydrolysates were a mixture of different types of molecules, rather than a single type, which biases the determination of the exact protein concentration Furthermore, the transfer of part of the hydrolysates to the oil phase cannot be excluded. Second, the mean droplet diameter (d_{32}) used in the calculations assumes that the droplets are not flocculated, although in reality some droplet flocculation may have occurred. For this reason, the surface load for the Try3 hydrolysate was calculated on the basis of the droplet size data at 2.0% of hydrolysate, before extensive flocculation occurred (Figure 2c). Third, there may have been some problems in making reliable protein concentration measurements in the samples due to light scattering by small emulsion droplets or protein aggregates.

Emulsion Stability. Upon 24 h of storage of the original Alc3 and Try3 emulsions, some tendency toward creaming could already be observed. Emulsions containing oil droplets coated by either Try3 or Alc3 hydrolysates were highly sensitive to changes in ionic strength and pH (Figure 4). The electrical

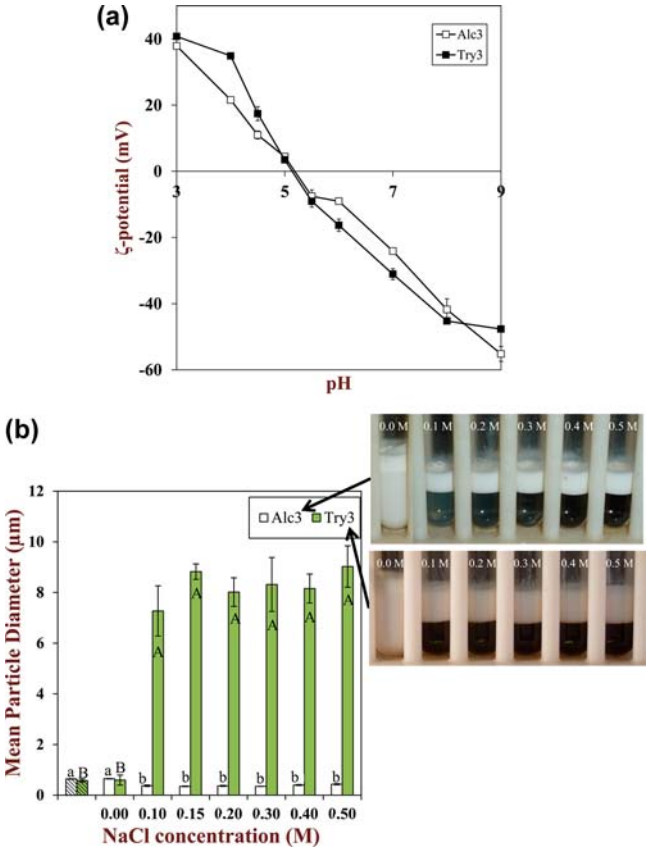

Figure 4. Emulsion characteristics in different pH and ionic strength conditions: (a) influence of pH on the ζ-potential of droplets of emulsions produced with gluten hydrolysates with a degree of hydrolysis of 3 made with alcalase (Alc3) and trypsin (Try3) (reported values were recorded 24 h after pH adjustment); (b) influence of ionic strength on mean particle diameter (d_{32}) (reported values were recorded 24 h after ionic strength adjustment). The shaded bars represent the particle diameter of the freshly made emulsions prior to ionic strength adjustment. The influence of ionic strength on the appearance of the emulsions is shown in the pictures. Extensive creaming occurred at concentrations ≥0.1 M NaCl for the Alc3 and Try3 emulsions. a and b and A and B represent Tukey groups with $p < 0.05$ for comparison of the evolution of the particle diameter in function of ionic strength of Alc3 and Try3 emulsions, respectively.

charge on the hydrolysate-coated oil droplets went from highly positive at low pH to highly negative at high pH, with a point of zero charge just above pH 5 (Figure 4a). At pH values around the isoelectric point of the droplets (pH ≈5), there was a large increase in mean particle size and extensive creaming was observed. At relatively high pH values (pH 8.0 and 9.0), the emulsions were relatively stable to droplet aggregation, maintaining relatively small droplet sizes (d_{32} < 1000 nm) after 9 days of storage (results not shown). At pH 3.0, the particle diameter of the Try3 emulsions remained relatively small, whereas Alc3 emulsions were much less stable and were prone to creaming. All emulsions produced were destabilized by salt addition and displayed extensive creaming behavior. The mean particle diameter of the emulsions produced with Try3 determined by light scattering significantly increased for NaCl ≥ 100 mM, indicating that salt addition promoted droplet aggregation. On the other hand, the particle size measured by light scattering appeared to be relatively small (d_{32} < 1000 nm) for the Alc3 emulsions at all salt concentrations (Figure 4c). However, extensive flocculation was observed in both types of emulsions using optical microscopy analysis. Thus, it is possible that the flocs in the Alc3 emulsions were disrupted during the dilution and mixing stages of the particle size analysis, which highlights the importance of using more than one method for analyzing aggregated systems.

The Alc3 emulsions were relatively stable to droplet aggregation when stored at low temperatures (4 and 20 °C), but they exhibited considerable droplet aggregation behavior when stored at more elevated temperatures (i.e., 37 and 55 °C) (Figure 5a). Conversely, the Try3 emulsions appeared to be stable during isothermal long-term storage at all storage temperatures as no significant changes in particle diameter were observed (Figure 5b). Furthermore, in contrast to Alc3 hydrolysates, Try3 hydrolysates proved to be effective at stabilizing emulsions against droplet aggregation during short-time thermal processing (30 min) (Figure 5c).

Microstructure Analysis. Microscopic analysis of the emulsions not only confirmed the bimodal size distribution of the oil droplets but also showed the presence of intriguing structures within the larger emulsion droplets. We observed smaller droplets enclosed within the larger oil droplets (Figures 2b and 6a). To explore the nature of these smaller subdroplets, the oil and water phases were stained prior to emulsification. The fact that the internal droplets were not stained by either dye suggests that they did not contain lipid or protein and may therefore have been trapped air bubbles (Figure 6b). These air-in-oil-in-water systems could be detected in all emulsions made with hydrolysate concentrations below 3.0 wt %. Above this concentration, no separate oil droplets could be observed. The strong creaming tendency of the emulsions after production is probably partially caused by the more pronounced density difference between the continuous and disperged phase due to the presence of air.

DISCUSSION

Gluten can be divided into the two main storage protein types found in wheat kernels, that is, gliadin and glutenin. In an earlier study, Takeda and co-workers[23] found that unhydrolyzed gliadin and glutenin have different emulsifying behaviors at low pH. Walstra[22] found that peptides formed by hydrolyzing native proteins are more effective emulsifiers than the native proteins themselves, provided that they are not too small, they are water-soluble, and they are amphiphilic. Previous studies have shown the emulsifying capacity of gluten protein hydrolysates using relatively simple homogenization techniques.[3,4,12,14] In most of these studies, however, no information on the droplet size distribution was reported. Linares and co-workers[13] reported oil droplet sizes of about 20 μm for emulsions produced using a high-speed blender, which could be decreased about 10-fold when they were passed through a high-pressure valve homogenizer.[15] In the current study, the average droplet diameter could be decreased into the submicrometer range using a high-pressure homogenizer (microfluidizer) provided the emulsions were prepared at pH conditions sufficiently distinct from the point of zero charge. This is in accordance with what is observed for other proteins.[24−26] The obtained particle diameters are comparable to or larger than those of emulsions made with whey protein isolate (0.27%), β-lactoglobulin (0.05%), or sodium caseinate (0.27%) using similar production parameters.[25−27] The gluten peptides formed by hydrolysis produced electrically charged droplets. The most likely stabilization mechanism preventing droplet

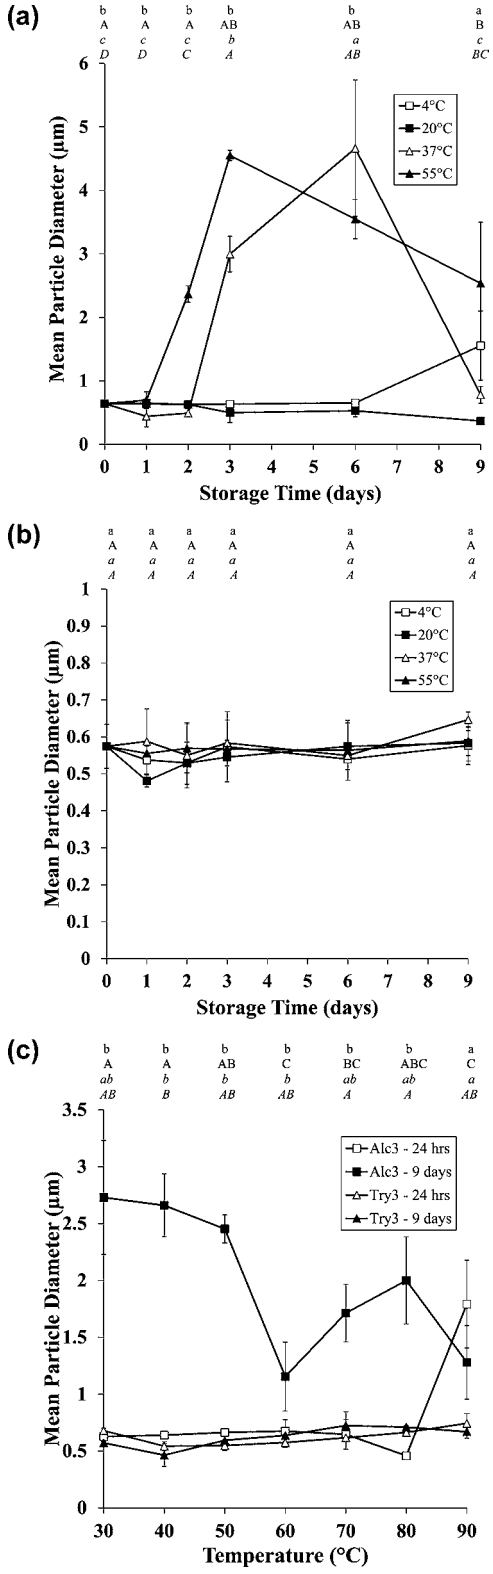

Figure 5. Emulsion stability to isothermal storage and heat processing. (a, b) Influence of isothermal storage on mean particle diameter (d_{32}) of emulsions produced with gluten hydrolysates with a degree of hydrolysis of 3 made with alcalase (a) and trypsin (b). Emulsions were stored for up to 9 days. a, b; A, B; *a*−*c*; and *A*−*D* represent Tukey groups with $p < 0.05$ for comparison of the evolution of the particle diameter in function of storage time of emulsions stored at 4, 20, 37, and 55 °C, respectively. (c) Influence of heat processing on mean particle diameter (d_{32}) of emulsions produced with gluten hydrolysates with a degree of hydrolysis of 3 made with alcalase (Alc3) and trypsin (Try3). Emulsions were heated for 30 min at the indicated temperatures before they were cooled and stored at 20 °C. Droplet sizes shown were recorded 24 h and 9 days after heat processing. a, b and A−C represent Tukey groups with $p < 0.05$ for comparison of the evolution of the particle diameter as a function of treatment temperature of freshly produced and 9-day-old Alc3 emulsions, respectively. *a*, *b* and *A*, B represent Tukey groups with $p < 0.05$ for comparison of the evolution of the particle diameter as a function of treatment temperature of freshly produced and 9-day-old Try3 emulsions, respectively.

aggregation is, hence, electrostatic repulsion.[28−30] For example, at pH 8 and 9, the oil droplets had a strong negative charge (Figure 4a), which would generate a strong electrostatic repulsion that prevents droplet flocculation (Figure 4b). By increasing the ionic strength or decreasing the pH, the net negative charge on the droplets is shielded or decreased and the emulsion is destabilized by flocculation. This is a common phenomenon observed when using proteins as emulsifiers.[31,32] The increase in net particle size due to droplet flocculation then leads to accelerated creaming. At present, a number of nutritional beverages or shakes exist that have a pH value near neutral in which the here-produced emulsion droplets coated by the hydrolysates could be used.

Upon hydrolysis of gluten proteins, a whole range of peptides with largely varying molecular weight, hydrophobicity, and surface activity are created. Previous studies[12,14] indicate that too extensive hydrolysis has an adverse effect on the hydrolysates' emulsifying capacity. Conversely, Linares and colleagues[13] did not find a correlation between degree of hydrolysis and emulsifying properties of solubilized gluten peptides. Previous research on the emulsifying properties of peptides produced from other protein sources, however, showed that there is indeed a minimum size, that is, about 2000 Da (∼20 amino acid residues), required for peptides to display emulsifying potential.[33] However, the molecular weight is not the only factor determining the surface-active properties of peptides. Turgeon and co-workers[33] described that the amphiphilicity of peptides also plays a key role and suggested that the hydrophobic residues should be grouped in discrete patches of at least three to five residues, which are separated by regions containing at least two to three polar residues.

When evaluating the peptides that could possibly be formed by Try and Alc starting from randomly selected gluten protein sequences [i.e., a HMW glutenin subunit (GenBank accession no. ABQ14770.1), a LMW glutenin subunit (GenBank accession no. AAS10192.1), a ω-gliadin (GenBank accession no. AAT01617.1), and a γ-gliadin (GenBank accession no. AAQ63860)] and assuming that Try exclusively hydrolyzes the C-terminal peptide bonds of Arg and Lys[16] and Alc displays a similar specificity on gluten proteins as has been described on casein,[17] it was found that in all cases Try produces more peptides which meet the above listed requirements to be good emulsifiers. Indeed, Alc has a preference to hydrolyze peptide bonds that are N-terminal to hydrophobic residues and C-terminal to, among other residues, Leu and Tyr. As a result, only a small number of peptides containing the above-described hydrophobic patches will be formed from gluten proteins, as these patches, if present in the original protein, are largely cut into pieces during the hydrolysis process by Alc.

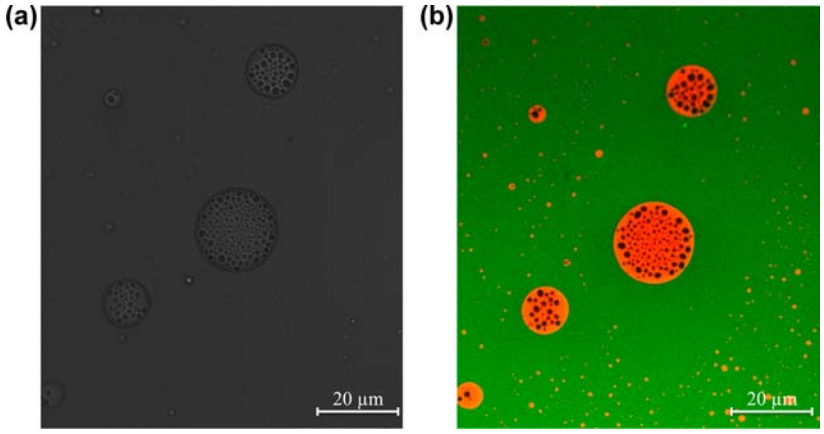

Figure 6. Optical and confocal micrographs of an emulsion made with 0.1 wt % gluten hydrolysate with a degree of hydrolysis of 3 produced with trypsin. The oil phase (red) was stained with Nile Red, whereas the aqueous phase containing the gluten hydrolysates (green) was stained with fluorescein isothiocyanate. The black bubbles inside the oil droplets are assumed to be air. All emulsions contained 10 wt % corn oil.

When the protein contents of the continuous aqueous phase of the emulsions are compared to those of the original aqueous phase prior to emulsification, it is clear that about 50 or 60% of the hydrolysates produced with Try or Alc, respectively, are not adsorbed at the droplet interface. This seems to be largely independent of the initial protein concentration and indeed reflects the above-described difference between the two peptidases and confirms the production of peptides with largely varying surface-active properties. In addition, the higher nonadsorbed protein level for Alc3 emulsions partially explains the higher level of Alc3 hydrolysates relative to the level of Try3 hydrolysates needed to produce emulsions with similar droplet diameters. Furthermore, the high level of nonadsorbed peptides probably induces depletion flocculation at higher hydrolysate concentrations, that is, >1.0 and >2.0% for Try3 and Alc3, respectively. The steep increase in droplet size and creaming tendency as well as microscopic analysis of the emulsions produced with higher hydrolysate concentrations supports this hypothesis.

Regardless of the hydrolysate concentration, all emulsions were relatively sensitive to creaming, which can be partially attributed to the presence of larger air-filled oil droplets (Figure 6). Previous studies already showed that gluten peptides are effective foaming agents.[3,13,34] Furthermore, Takeda and co-workers[23] showed that gluten, similar to one of its functions in dough, also stabilizes the air/water interface. We believe that during the production of the emulsions, air is incorporated into the liquid phase and that the gluten proteins stabilize these air bubbles in the aqueous phase. During homogenization in the microfluidizer, (part of) the air bubbles are forced into the oil droplets. As the interfacial corn oil/air tension (i.e., about 32 mN/m[35]) is lower than the interfacial hydrolysate solution/air tension (i.e., about 45 mN/m[34]), a system that is kinetically stable (but thermodynamically unstable) on the mesoscale (i.e., on the scale of emulsion droplets) is produced. Macroscale stability, however, is reasonably low as the increased density difference promotes creaming of the air-filled oil droplets.

The Try hydrolysates displayed good heat stability, which is not commonly observed with many food proteins. Try and Alc hydrolysates underwent a heat treatment while inactivating the peptidase during their production. Consequently, they were already partially thermally denatured prior to homogenization. This first heat treatment is believed to minimize extensive denaturation of the peptides when adsorbed at the oil droplet surfaces and thus provided better protection against thermal destabilization and creaming of the emulsions upon heating. Furthermore, the heat treatment had probably already converted any free thiol groups on the gluten proteins to disulfide bridges, thereby limiting any additional protein cross-linking at high temperatures.

This study has shown that gluten hydrolysates that display different emulsifying properties can be produced by careful selection of peptidase type and hydrolysis conditions. Of the two peptidases used, Try produced the most promising peptides with a DH of 3. The stability of the emulsions to environmental stresses (such as pH, ionic strength, and thermal processing) also depended on the peptidase type with which the hydrolysates were produced. Gluten hydrolysis may provide a valuable new source of emulsifiers for utilization in the food industry and could add value to byproducts created during starch isolation. The emulsifying properties of these hydrolysates may be further improved by fractionation of the complex peptide mixture. Furthermore, the capacity of the gluten peptides to produce air-filled emulsions holds promise for the production of reduced-fat products and food products with new functionalities. Further research is needed to optimize the conditions in which the latter can be produced.

[a] δ in parts per million, J in hertz. NMR solvent was MeOD.([b]Obtained at 400 MHz. [c]Obtained at 600 MHz.

Plant Material. The green coffee beans of *C. arabica* var. *yunnanensis* were harvested in June 2012 by Tao Zhang and then roasted at 180 °C for 20 min to yield roasted coffee beans. The plant material was identified by Ming-hua Qiu, Kunming Institute of Botany, Chinese Academy of Sciences.

Extraction and Isolation. The powder of roasted coffee beans (200−300 mesh, 23 kg) was extracted with 80% acetone (3 × 50 L) three times (two days each times). The combined acetone extracts were evaporated under reduced pressure; then the 1.8 kg residue was suspended in H_2O and extracted with petroleum ether (PE), ethyl acetate (EtOAc), and *n*-butanol, respectively. The EtOAc layer (500 g) was subjected to silica gel column chromatography (25 × 180 cm) and eluted in a step gradient manner with PE/acetone (20:1, 10:1, 5:1, 1:1, v/v) to yield four fractions: fraction 1 (22 g), fraction 2 (67 g), fraction 3 (310 g), and fraction 4 (60 g). Fraction 4 was decolorized on an MCI gel column (5.0 × 60 cm) eluting with the step gradient of MeOH/H_2O (30−80%, v/v). The 50% MeOH/H_2O fraction (8.2 g) was chromatographed over a second silica gel column (5.0 × 100 cm, eluted with the step gradient manner of $CHCl_3$/MeOH, 15:1 to 3:1, v/v) to yield five fractions (fractions 4-1−4-5). Then fraction 4-1 (600 mg) was chromatographed on a silica gel column (2.0 × 80 cm, eluted with $CHCl_3$/MeOH, 10:1, v/v) to obtain **8** (15 mg), **9** (5.1 mg), and **10** (20 mg). Fraction 4-2 (800 mg) was subjected to chromatography over RP C-18 (3.0 × 50 cm, eluted with MeOH/H_2O, 30−70%, v/v) to give five minor fractions (fractions 4-2-1−4-2-5). Fraction 4-2-2 (50 mg) was separated by preparative thin layer chromatography (P-TLC, eluted with $CHCl_3$/MeOH, 8:1, v/v) to gain **1** (5.7 mg), **2** (20 mg), and **5** (3.0 mg). Using the same methods as for fraction 4-2-2 on P-TLC with $CHCl_3$/MeOH (8:1, v/v), compounds **3** (3.6 mg) and **6** (15 mg) were obtained from fraction 4-2-3 (80 mg). Fraction 4-3 (32 mg) was separated by reverse-phase HPLC (MeOH/H_2O: 30−50%, 25 min, flow rate = 3.0 mL/min, UV 210 nm) to get **4** (2.5 mg, 10.3 min). Fraction 4-5 (600 mg) was chromatographed on a silica gel column (2.0 × 60 cm) with $CHCl_3$/MeOH (10:1, v/v) to afford three

minor fractions (fractions 4-5-1−4-5-3). Fraction 4-5-2 (190 mg) was purified by use of Sephadex LH-20 (1.0 × 200 cm, eluted with MeOH, 100%, 1 L) and divided into two fractions (fractions 4-5-2-1 and 4-5-2-2), and then fraction 4-5-2-2 (160 mg) was isolated by P-TLC ($CHCl_3$/MeOH, 7:1, v/v) to gain **7** (7.1 mg), **11** (12 mg), and **12** (14 mg).

Acid Hydrolysis of Compounds 1−5.[15] Compounds **1**−**5** (each 1 mg) were dissolved in 25 mL of MeOH and refluxed with 1 N HCl (1 mL) for 3 h at 80 °C. The reaction mixture was then evaporated to dryness and diluted with H_2O (10 mL). After being extracted with EtOAc (3 × 10 mL), the aqueous layer was concentrated and compared with reference D-glucose by TLC ($CHCl_3$/MeOH, 2:1, v/v). Then 900 μL of hexamethyldisilazane/trimethylchlorosilane (2:1, v/v) was added in the aqueous layer, and the mixture was stirred at 60 °C for 30 min. The supernatant was subjected to GC analysis. Derivatives of D-glucose were detected from **1**−**5**, which were identified by comparison of their retention times with that of an authentic sample of D-glucose (9.53 min).

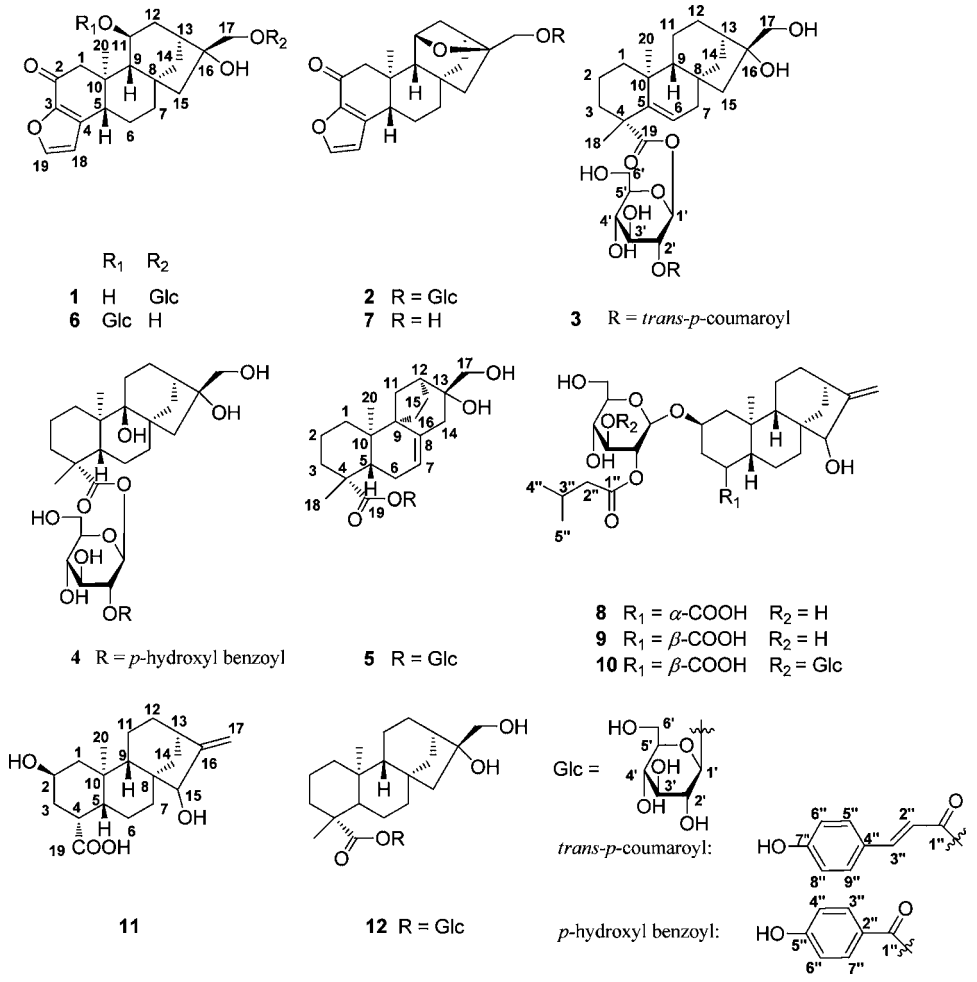

Figure 1. Structures of diterpenoid glucosides isolated from roasted coffee beans.

Cytotoxicity Assays. The cytotoxicities of compounds **1**−**5** were evaluated against HL-60, SMMC-7721, A-549, MCF-7, and SW480 cells by using the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] method.[16] All cells were cultured in RPMI-1640 or DMEM medium (Hyclone, Logan, UT, USA), supplemented with 10% fetal bovine serum (Hyclone) at 37 °C in a humidified atmosphere with 5% CO_2. After seeding of 1×10^5 cells/mL in a 96-well cell culture plate for 12 h before test compound addition, 100 μL of sample or standard agent was placed in each well and incubated at 37 °C for 3 days. After incubation, MTT (100 μg) was added to each well, and the incubation was continued for 4 h at 37 °C. The cells were lysed with 100 μL of 20% SDS−50% DMF after removal of 100 μL of medium. The optical density of the lysate was measured at 595 nm in a 96-well microtiter plate reader (Bio-Rad 680). The IC_{50} value of each compound was calculated by using Reed and Muench's method.[17]

RESULTS AND DISCUSSION

Structure Elucidation. The acetone extract of roasted coffee beans was extracted with ether (PE), ethyl acetate (EtOAc), and *n*-butanol. The EtOAc layer was fractionated by silica gel column chromatography in a step gradient of PE/acetone to yield four fractions, and then fraction 4 (PE/acetone, 1:1, v/v) was further purified successively on silica gel, Sephadex LH-20, and RP C-18 columns, respectively. As a result, the diterpenoid glucosides **1**−**12** were obtained in pure forms (Figure 1), of which **1**−**5** are reported for the first time in this study. Their structures were established by interpretation and full assignments of 1D and 2D NMR spectroscopic data and comparison with literature data.

Compound **1** was isolated as a white amorphous powder. The molecular formula $C_{26}H_{36}O_{10}$ was deduced from the molecular ion peak at m/z $[M]^+$ 508.2308 (calcd for $C_{26}H_{36}O_{10}$, 508.2315) in HREIMS. The IR spectrum indicated that **1** possessed hydroxyl (3418 cm^{-1}) and α,β-unsaturated ketone (1660 cm^{-1}) groups. The ^1H NMR spectrum (Table 1) of **1** displayed characteristic signals for one methyl (δ_H 0.85, s, H-20), two oxymethylenes [δ_H 3.57 (m, J = 7.2 Hz, H-17a), 4.77 (d, J = 7.6 Hz, H-17b); δ_H 3.65 (m, J = 15.6 Hz, H-6′a), 3.87 (d, J = 12.0 Hz, H-6′b)], and five oxygenated methines. The ^{13}C NMR spectrum (Table 2) showed 26 carbon resonances, attributed to a monosaccharide and an aglycone moiety. The monosaccharide was identified as glucose on the basis of comparison of chemical shifts to those found in the literature.[18] Its relative configuration was confirmed as β on the basis of the coupling constant (δ_H 4.28, m, J = 7.2 Hz, H-1′) in the ^1H NMR spectrum. The configuration of glucose was identified as D-form by acid hydrolysis. The other 20 carbon signals of the aglycone moiety were classified by ^{13}C NMR as 1 methyl, 7 methylenes (1 oxygenated), 6 methines (including 1 oxygenated, 2 olefinic), and 6 quaternary carbons (including 1 carbonyl, 2 olefinic, and 1 oxygenated). These data indicated that **1** resembled mascaroside,[19] except that a methylene (δ_C 52.0, C-15) in **1** replaced the oxymethine in mascaroside at C-15, which was further confirmed by the heteronuclear multiple-

dx.doi.org/10.1021/jf500788t | J. Agric. Food Chem. 2014, 62, 2631−2637

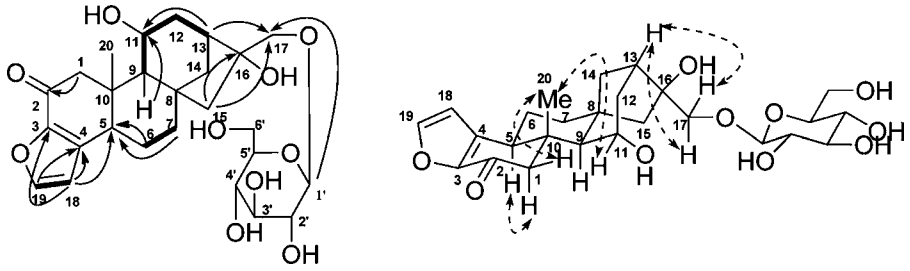

Figure 2. Key HMBC (H→C), ^{1}H–^{1}H COSY (bold), and ROESY (H←- -→H) correlations of **1**.

bond correlations (HMBC) from H_2-15 to C-9, C-13, and C-17 (Figure 2). Meanwhile, the HMBC correlations from H_2-17 to C-13, C-16, and C-1′ suggested the glucose group was coupled to C-17. The relative configuration of **1** was determined by the rotating frame Overhauser effect spectroscopy (ROESY) spectrum. On biogenetic grounds, compound **1** was confirmed as an *ent*-kauranoid with the configuration of H-20 being α-orientated. The key ROESY correlations of H-11/H-20 and H-13/H_2-17 (Figure 2) were assigned H-11 and OH-16 as α-orientated. Thus, the structure of **1** was assigned as mascaroside I.

The HREIMS data for compound **2** indicated a molecular formula of $C_{26}H_{34}O_9$. Analysis of the 1D NMR data of **2** and those of **1** (Tables 1 and 2) revealed that they were comparable. However, the carbon signals of C-11 (δ_C 77.5 for **2**, 66.2 for **1**) and C-16 (δ_C 89.6 for **2**, 82.4 for **1**) were significantly downfield shifted in **2**, and **2** being 18 mass units less than **1** suggested the presence of the ether between C-11 and C-16 in **2**. The HMBC correlations of H-11 with C-9, C-13, and C-16, of H-13 with C-16, and of H_2-15 with C-16 provided important evidence for the above inference. The glucose group was positioned at C-17 on the basis of the HMBC correlation from H_2-17 to C-13, C-16, and C-1′. Furthermore, major correlations of H-20/H-11, H-13/H_2-17 were observed in the ROESY spectrum of **2**, establishing H-11 and H_2-17 as being α-oriented. Therefore, the structure of compound **2** was identified as mascaroside II.

Compound **3**, a white amorphous powder, displayed a $[M]^+$ ion at *m*/*z* 642.3052 (calcd for $C_{35}H_{46}O_{11}$, 642.3040) in HREIMS, consistent with the molecular formula of $C_{35}H_{46}O_{11}$, indicating 13 degrees of unsaturation. IR absorption bands at 3431 and 1630 cm^{-1} were attributed to hydroxyl and double-bond groups. A *p*-coumaroyl group was confirmed by comparison of the MS and 1D NMR data of **3** with those of laevissioside A;[20] its double bond was suggested as *trans* due to the coupling constant (J = 18.0 Hz). The ^{13}C NMR spectrum (Table 2) showed the remaining 26 characteristic carbon signals for diterpenoid and β-glucose. Meanwhile, 20 carbon signals of the diterpenoid were attributed to 2 singlet methyls, 9 methylenes (1 oxygenated), 3 methines (1 olefinic), and 6 quaternary carbons (1 carboxyl, 1 oxygenated, 1 olefinic). These data revealed that **3** was similar to paniculoside IV,[21] except for the presence of two olefinic carbons (δ_C 156.8, C-5, and δ_C 113.5, C-6) in **3**. In the HMBC spectrum, the protons of C-7, C-20, and C-3 all correlated with the sp^2 quaternary carbon (δ_C 156.8, C-5), and the proton of sp^2 methine showed correlations with C-4 and C-10. Therefore, the position of the double bond was between C-5 and C-6. The β-glucose group was confirmed at C-19 by HMBC correlations of H-1′ to C-19. The HMBC correlation from H- 2′ to C-1″ (Figure 3) established that the *trans*-*p*-coumaroyl group was at C-2′. The

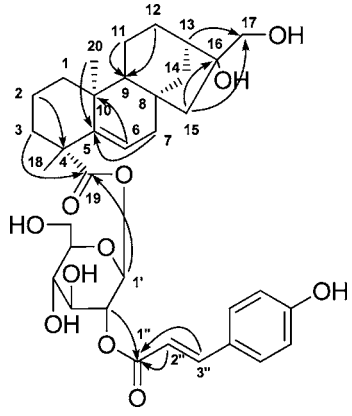

Figure 3. Key HMBC (H→C) correlations of **3**.

ROESY correlation of H-20/H-1′ assigned the relative configuration of CH_3-18 as β. Finally, the structure of **3** was confirmed as paniculoside VI.

The molecular formula of **4**, $C_{33}H_{46}O_{12}$, was determined by HREIMS (*m*/*z* 634.3006, calcd 634.2989). The IR absorption bands at 3424, 2928, and 1610 cm^{-1} suggested the presence of hydroxyl, carbonyl, and double-bond groups. The 1D NMR spectrum shows seven carbon signals (δ_C 166.9, C-1″; δ_C 164.3, C-2″; δ_C 133.7, C-3″; δ_C 133.7, C-4″; δ_C 121.9, C-5″; δ_C 116.4, C-6″; δ_C 116.4, C-7″) and two aromatic signals at δ_H 7.81 (2H, d, J = 6.6 Hz, H-2″ and H-6″), 6.71 (2H, d, J = 12.0 Hz, H-3″ and H-5″), indicating the presence of a *p*-hydroxybenzoyl group. In addition, the ^{13}C NMR spectrum exhibited another 26 carbon signals for diterpenoid and β-glucose. Comparison of the NMR data of the diterpenoid moiety of **4** with those of cofaryloside indicated they were similar.[22] In the HMBC spectrum, correlation from H-1′ to C-19 suggested the β-glucose group was linked to C-19. HMBC correlation from H-2′ (δ_H 3.55) to C-1″ confirmed the *p*-hydroxybenzoyl group at C-2′. The similar ROESY correlations with **3** indicated the relative configuration of CH_3-18 to be β. Therefore, compound **4** was assigned as cofaryloside I.

Compound **5** was obtained as a white powder, and its molecular formula was deduced as $C_{26}H_{40}O_9$ from HREIMS (*m*/*z* 496.2259, calcd 496.2672). The ^{13}C NMR spectrum (Table 2) of **5** displayed 20 carbon signals for diterpenoid, attributed to 2 methyls, 9 methylenes (1 oxygenated), 3 methines (1 olefinic), and 6 quaternary carbons (1 olefinic, 1 oxygenated, 1 carboxyl), suggesting **5** may be analogous to **4**. However, this assignment was in disagreement with HMBC correlations between H-20 and two quaternary sp^3 carbons (δ_C 38.2, C-10 and δ_C 42.4, C-9). Furthermore, comparison of chemical shifts of **5** showed resemblance to villanovane,[23] which was confirmed by the HMBC correlations from H-7, H-11, H-12, H_2-14, H_2-15, and H_2-16 to C-9, and the ^{1}H–^{1}H

dx.doi.org/10.1021/jf500788t | J. Agric. Food Chem. 2014, 62, 2631–2637

correlation spectrometry (COSY) correlations of H-11, H-15/H-12, and H-15/H-16 (Figure 4).

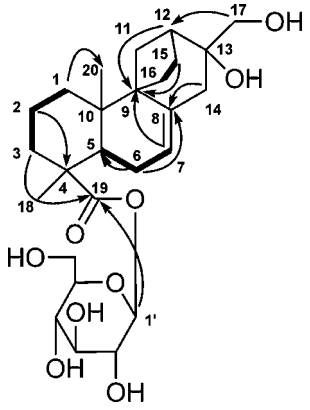

Figure 4. Key HMBC (H→C) and ^{1}H−^{1}H COSY (bold) correlations of **5**.

Comparison of 1D NMR data of **5** with those of villanovane suggested a double-bond and a glucose group were present in **5**, which were consistent with the IR absorption bands at ν_{max} 1631 and 3425 cm^{-1}. The relative configuration of glucose was confirmed as β-based on a coupling constant of 12 Hz for H-1′ (δ_H 6.40). Its position was confirmed at C-19 on the basis of HMBC correlation from H-1′ to C-19. The olefinic group involving C-7 and C-8 was supported by the HMBC correlations from H-5 and H_2-6 to C-7. Furthermore, the key correlations of H-12/H-20 and H-5/H-18 in the ROESY spectrum assigned the relative configurations of C-15, C-16, and C-18 as β. Hence, compound **5** was characterized as villanovane I.

The known compounds isolated were identified by comparison of their NMR data with literature data as mozambioside (**6**),[24] bengalensol (**7**),[25] 19-*norkaur*-16-en-18-oic acid-15-hydroxy-2-[[2-*O*-(3-methyl-1-oxobutyl)-β-D-glucopyranosyl]oxy]-(2β,4α,15α)- (**8**),[26] 19-*norkaur*-16-en-18-oic acid-15-hydroxy-2-[[2-*O*-(3-methyl-1-oxobutyl)-β-D-glucopyranosyl]oxy]-(2β,4β,15α)- (**9**),[26] 19-*norkaur*-16-en-18-oic acid-2-[[3-*O*-β-D-glucopyranosyl-2-*O*-(3-methyl-1-oxobutyl)-β-D-glucopyranosyl]oxy]-15-hydroxy-(2β,4α,15α)- (**10**),[26] 2β,16α,17-trihydroxy-*ent*-kauran-19-oic acid (**11**),[27] and paniculoside IV (**12**).[21]

The evaluation of cytotoxicities of compounds **1**−**12** showed that they were inactive against all test cells.

In conclusion, the present investigation on diterpenoid glucosides has revealed a wide structural diversity and upgrades our knowledge on the composition of roasted coffee. This is the first report about *ent*-atisans from Rubiaceae. Our work lays the chemical foundation for further bioactive research of coffee.

MATERIALS AND METHODS

Reagents and Standards. The standard PAH mixture in 1 mL of acetonitrile (Supelco, Bellefonte, PA, USA) consisted of 10 μg/mL of naphthalene, acenaphthene, acenaphthylene, fluorene, anthracene, phenanthrene, fluoranthene (F), pyrene, B*a*A, Ch, B*b*F, B*k*F, B*a*P, D*b*A, B*g*P, and IP. PAH standard solution was stored in amber flasks at −20 °C.

Ethanol, methanol, acetonitrile, ethyl acetate, hexane, and dichloromethane were of HPLC grade and were provided by Merck (Darmstadt, Germany). 1,1-Diphenyl-2-picrylhydrazyl (DPPH) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Water was purified with a Milli-Q System (Millipore, Bedford, MA, USA). Amber glassware was carefully washed and rinsed with distilled solvent (acetone and hexane) before use.

Marinated Meat Samples and Cooking Conditions. *Preparation of Marinated Meat Samples.* Three different types of beer marinades were tested: Pilsner beer, nonalcoholic Pilsner beer, and Black beer, coded PB, P0B, and BB, respectively. PB contained 5.2% alcohol and was made from water, barley malt, unmalted cereals (maize and barley), and hops; P0B contained 0.5% alcohol and was made from water, barley malt, unmalted cereals (maize), glucose−fructose syrup, flavors, and hops; and BB contained 5.0% alcohol and was made from water, barley malt, sugar, color E150C (ammonia caramel), and hops. All beers were purchased at local supermarkets.

Loin pork steaks were obtained from a local supermarket in Porto, Portugal. Loin pork steaks presented similar dimensions (0.75 cm thick) and weight (about 100 g each). A total of 32 pork loin steaks were used for determination of PAHs: 8 for each marinade and 8 as control samples (unmarinated). Marinade conditions were selected according to previous works:[11,12] marinating time was 4 h at 5 °C, and the proportion of meat amount and marinade volume was 1:1 (g/mL). No other ingredients were added, besides beer. Before cooking, pork samples were removed from the marinade and dried slightly. Four hours of marinating time was selected on the basis of the best beer marinating time for HA inhibition.[11] Recently, Farhadian et al.[14] observed lower PAH concentration in almost all of the analyzed samples with 4 h of marinating.

Cooking Conditions. A bed of charcoal was prepared and ignited in a garden-type grill (35 cm width, 52 cm length, and 15 cm height). When all flames had subsided, pork samples were barbecued at 15 cm distance from the heat source. The grilling temperature was 200−230 °C, and internal temperature reached the minimum 75 °C measured by a digital thermocouple (0560 9260, Testo 926, Lenzkirch, Germany) with a surface probe (0603 1992, Testo 926, Lenzkirch, Germany). Samples were turned once during grilling at half of the total cooking time (10 min). Charcoal was replaced between grilling each type of marinated meat.

After cooking, the eight steaks prepared for each type of marinade were divided in two homogeneous groups of four steaks each. Each group was mixed with a knife mill (Grindomix GM 200, Retsh, Hann, Germany) to obtain a uniform, representative, and homogeneous sample for duplicate analyses. The samples were codified, frozen, and freeze-dried (Cryodos-90, Telstar, Terrassa, Spain). Grilled pork sample codes were as follows: control (unmarinated pork), PBp (pork marinated in Pilsner beer), P0Bp (pork marinated in nonalcoholic Pilsner beer), and BBp (pork marinated in black beer). Average cooking losses were around 54−66 and 50−60% for unmarinated and marinated samples, respectively.

Determination of Marinades Radical-Scavenging in DPPH Reaction. *Extraction of phenolic compounds* of beer marinades was performed according to the method of Zhao et al.[15] and Viegas et al.[12] with some modifications. Marinades were degassed with intensive stirring for 15 min at room temperature. Fifteen milliliters of each sample was extracted during 15 min with 15 mL of ethyl acetate by ultrasound-assisted solvent extraction (FungiLab SA, Barcelona, Spain) and centrifuged at 2000 rpm for 2 min at 20 °C (Eppendorf 5810 R centrifuge, Eppendorf, Hamburg, Germany). The supernatant was collected. Then, 6 g of NaCl was added and the pH was set to 1 (combined pH glass electrode connected to a pH-meter, MicropH 2001, Crison, Barcelona, Spain) using 1 M HCl. The resulting sample was extracted two times more with 15 mL of ethyl acetate. The pooled ethyl acetate extracts were evaporated to dryness under reduced pressure in a rotary evaporator (Rotavapor Büchi RE-111, coupled with a water bath Büchi 461, BÜCHI, Flawil, Switzerland) at 40 °C and redissolved in 10 mL of ethanol 70% (v/v).

Antiradical Activity by DPPH. Extracts of PB, P0B, and BB collected before and after 4 h of marinating were diluted in 96-well microplates (1:2; 1:4; 1:8; 1:16; 1:32; 1:62). A 100 μL amount of 150 μM DPPH and 100 μL of each extract were mixed in the microplates. Absorbances at 517 nm were measured for 2 h until the reaction reached plateau (Biotekmicroplate reader ELX 808, Biotek Corp., USA). For each extract, two readings with DPPH ($A_{extract}$) and one without the radical ($A_{blank\ 1}$) were carried out. DPPH solution were used as control ($A_{control}$), and ethanol 70% was used as blank ($A_{blank\ 2}$). The radical-scavenging activity was expressed as a percentage and calculated by using the following formula:

$$\%\ \text{DPPH scavenging} = 100 - \left(\frac{A_{extract} - A_{blank\ 1}}{A_{control} - A_{blank\ 2}} \times 100 \right)$$

Analysis of PAHs. *Extraction and Cleanup.* PAH extraction and cleanup procedures were performed according to the method of Viegas et al.,[3] with some modifications. Briefly, 2 g of lyophilized meat was weighed into an EPA amber glass vial (40 mL) and was subjected to ultrasound-assisted solvent extraction with 20 mL of *n*-hexane for 1 h at room temperature. The extract obtained was filtered, and the solvent was evaporated nearly to dryness with a rotatory evaporator at room temperature. The residue was redissolved in 3 mL of *n*-hexane and loaded for cleanup in a 5 g silica cartridge (Mega BE-Si, 5 g, 20 mL, from Agilent Technologies) previously washed with 20 mL of dichloromethane, dried completely by vacuum, and conditioned with 20 mL of *n*-hexane. The cartridge was dried by vacuum and eluted with 24 mL of *n*-hexane/dichloromethane (70:30, v/v). The first 5 mL was discharged to reduce the volume of PAH fraction and because no PAHs were detected in this first fraction as described by Viegas et al.,[3] the remaining elution volume was collected in a vial and evaporated to dryness under nitrogen stream at room temperature. The residue obtained was dissolved in 100 μL of acetonitrile.

Chromatographic Conditions. Separation and quantification of PAHs were performed by liquid chromatography with fluorescence detection (HPLC-FLD) according to the method of Viegas et al.[3] A HPLC unit (Jasco, Japan) equipped with a PU-1580 HPLC pump, an AS-950 autosampler with a 20 μL loop, and a FP-920 fluorescence detector was used. PAH separations were performed with a 25 cm × 4.6 mm (length × i.d.), 5 μm particle size, Supelcosil LC-PAH (Supelco, Bellefonte, PA, USA), thermostated at 32.0 ± 0.2 °C. Borwin PDA Controller software (JMBS Developments, Le Fontanil, France) was used. Three solvents were used for mobile phase: 75% methanol in water (A), methanol (B), and ethyl acetate (C) with a flow rate 1 mL/min. The linear gradient program was as follows: 0−18 min, 0−80% B in A; 18−19 min, 80−100% B in A; 19−20 min, 100−90% B in C; 20−28.5 min, 90−82% B in C; 28.5−37.5 min, 82−80% B in C; 37.5−40 min, 80−100% B in C; 40−45 min, 100−0% B in A, followed by rinsing and re-equilibration of the column to the initial conditions. The excitation and emission wavelengths used were 270/390 nm for B*a*A and Ch; 260/430 nm for B*b*F; 290/410 for B*k*F, B*a*P, D*b*A, and B*g*P; and 293/498 for IP. Peak identification in pork samples was carried out by comparing retention times of the peaks with those obtained from a reference standard mixture of PAHs. Quantification of PAHs was performed by standard addition method using nonspiked sample and two fortified levels (10−20 ng/g).[3]

Statistics. The averages of duplicate analyses of two independent experiments were calculated for each PAH. The results were statistically analyzed by analysis of variance. Comparison of mean values was made using the Duncan test. Statistical analyses were all performed with SPSS for Windows version 21 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Antiradical Activities of Beer Marinades. DPPH assay was used to evaluate the antioxidant activity of the marinades under study. The DPPH radical-scavenging activities expressed as percent of inhibition of beer marinades before the addition of meat (T0) and after 4 h of meat marinating (T4) are shown in Figure 1. All beers exhibited radical-scavenging activity. The

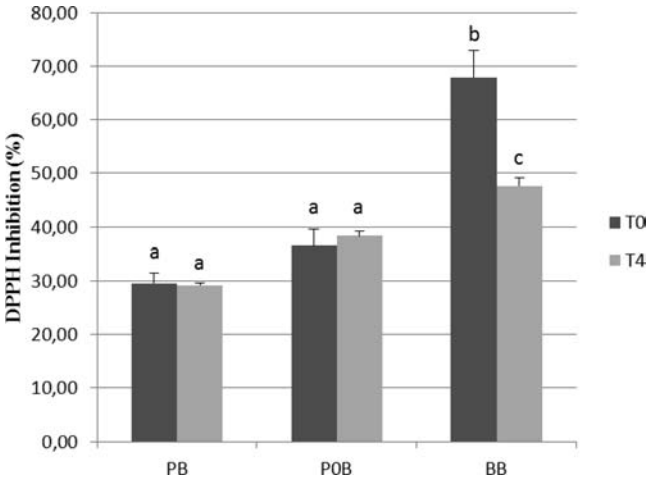

Figure 1. DPPH radical scavenging activity of beer marinades (Pilsner, nonalcoholic Pilsner, and Black beer marinades coded respectively PB, P0B, and BB) before the addition of meat to the marinade (T0) and after 4 h of meat marinating (T4). Results are expressed as percentage of inhibition (%) of DPPH. Error bars represent standard deviation obtained from triplicate experiments. Bars with different letters show significant differences ($p < 0.05$).

results expressed correspond to a 1:8 dilution of beer extracts, necessary to achieve the linearity. As can be seen, at T0, the strongest DPPH-scavenging activity was found in the BB (68.0%), followed by P0B (36.5%) and PB (29.5%). BB exhibited a significantly higher value than others; the slightly higher value of P0B was not significant when compared with PB. These results are in agreement twith those obtained by Tafulo et al.[16] and Polak et al.[17] According to these authors the differences between radical-scavenging activities of the different kinds of beers could be explained by several factors such as the type of fermentation and the presence of food coloring, sweeteners, flavors, and other additives. Ale beers have a higher antioxidant capacity than lager beers.[16] BB is an ale beer in contrast with the rest of the beers studied, which are lager beers. The presence in BB of food coloring (E150C) could be another factor that explains its higher antioxidant activity. In Tafulo et al.,[16] beers with food coloring, including E150C, showed a higher activity antioxidant than ones without it. Nonalcoholic Pilsner beer (P0B) showed a slightly higher antioxidant activity than Pilsner beer (PB). This fact could be explained by the presence in the nonalcoholic Pilsner beer of different additives such as glucose−fructose syrup and flavors. Tafulo et al.[16] also reported that beer samples with sweeteners, flavors, antioxidants, and other additives had a slightly higher antioxidant activity than the samples without it.

After 4 h of meat marinating, no significant changes were observed in radical-scavenging activity of PB and P0B. In our previous work the same behavior was observed for Pilsner beer marinade.[12] However, a significant loss of antiradical capacity was observed in BB after meat marinating. Possible interactions between beer antioxidant compounds and oxidative species of meat surface may occur.

PAH Formation in Charcoal-Grilled Pork. PAH concentrations in charcoal-grilled pork loin are presented in Table 1. All eight PAHs under study were quantified, and their sum was around 21 ng/g wet weight grilled meat. For the quantitative profile, greater contents of Ch > B*a*A > B*bF* > B*a*P were found. B*k*F, D*b*A, B*g*P, and IP were formed in very low concentrations. The four main PAHs formed in charcoal-grilled pork comprise the PAH4. Their contribution to PAH8 was around 80%. Martorell et al.[18] studied 16 PAHs (which include PAH8) in various foodstuffs and also found that lowest PAH levels corresponded to D*b*A, IP, and B*k*F.

Scarce information was found on the individual compounds of PAH4 in grilled meat; several studies describe only B*a*P composition, and few studies mention other PAHs. However, in an EFSA report[2] thousands of food items from several food groups were compared, and the highest mean value was recorded for Ch (3.20 ng/g), followed by B*a*A (1.97 ng/g) and B*b*F (1.48 ng/g); mean contents of these compounds were higher than the mean value for B*a*P (1.02 ng/g). In the present study the PAH4 profile was in agreement with the EFSA statement.

Table 1. PAH8 Formation on Charcoal-Grilled Pork Loin Unmarinated (Control) and Marinated with Pilsner Beer (PBp), Nonalcoholic Pilsner Beer (P0Bp), and Black Beer (BBp)[a]

	PAHs (ng/g wet weight grilled meat)

Chung et al.[5] analyzed seven PAHs of the PAH8 in different pork samples and found a total of 10.18 ng/g in charcoal-grilled ones. B*a*P accounted for 2.90 ng/g. Alomirah et al.[19] screened the concentrations of 16 priority PAHs in 72 grilled and smoked food samples and presented mean results; among the PAH8, Ch (4.88 ng/g) and B*a*A (2.27 ng/g) showed the highest mean values, followed by B*b*F (1.58 ng/g) and B*a*P (1.10 ng/g), and the sum of PAH8 was 11.7 ng/g.

Considering the maximum levels of B*a*P (5 ng/g) and PAH4 (30 ng/g) described in European legislation[8] for meat and meat products that have undergone grilling and barbecuing as heating treatment, the values of B*a*P and PAH4 in control samples, 2.71 and 17.32 ng/g, respectively, were below the maximum levels, indicating that they were cooked to a well-done level appropriate for consumption.

Effects of Beer Marinades on PAH Formation. PAH8 concentrations in charcoal-grilled pork loin marinated during 4

dx.doi.org/10.1021/jf404966w | J. Agric. Food Chem. 2014, 62, 2638−2643

h with different beers are shown in Table 1. As observed for unmarinated meat, PAH8 (B*a*A, Ch, B*b*F, B*k*F, B*a*P, DbA, B*g*P, and IP) were also formed in marinated samples; however, their sum was lower in these samples when compared with control meat. With regard to the three types of beers used as marinades, the less effective in reducing the PAH8 content was PB (17.82 ng/g), followed by P0B (15.50 ng/g). BB had the strongest inhibitory effect on the PAH8 in grilled pork (9.74 ng/g), reducing by more than half the PAH8 content of the control samples. Although not statistically significant, a positive correlation was found between the higher radical-scavenging activity of marinades and a decrease of PAH8 formation (Pearson correlation = 0.606, p = 0.202).

A decrease in antioxidant activity was observed for BB after 4 h; interactions between BB antioxidant compounds and oxidative species of the meat surface may occur, possibly increasing meat resistance to the formation of PAHs.

The exact mechanism of PAH formation is not precisely known; however, it is generally considered that PAHs are formed by condensation of small organic molecules by either pyrolysis or pyrosynthesis.[6,7] At high temperatures these molecules are easily fragmented (pyrolysis) and the free radicals produced recombine to form stable polynuclear aromatic compounds (pyrosynthesis). Because the mechanism of formation of PAHs involves free radicals, it may be possible that antioxidant compounds from beer (especially BB) act as inhibitors in the free radical reaction pathways, through radical quenchers and free radical scavengers activity. Inhibitory effects of different marinating treatments and additives on PAH formation in grilled meat are scarce. Table 2 reports a summary of results from the literature and comparison with the present work. Farhadian et al.[14] evaluated the effect of seven marinade treatments of beef satay on the formation of B*a*P, B*b*F, and F. Inhibitory effects were observed in some marinades; the authors attributed the protective effect due to the presence of spices that are known to have antioxidant activity, emphasizing the sulfur compounds, present in garlic and onion, and their potential to prevent Maillard reactions and then PAH formation. Brady[20] found the highest reduction in samples treated with marinade (from 84 to 92%) followed by spice mixture and garlic paste (from 82 to 90%), spice mixture (from 56 to 80%), and garlic paste (from 31 to 76%) for different cooking methods. However, the charcoal grilling method was not evaluated, and according to EFSA[2] special attention is required for this cooking method because higher PAH content is found in charcoal-grilled products.

Janoszka[21] observed that the addition of onion (30/100 g of meat) and garlic (15/100 g of meat) caused, respectively, average decreases of 60 and 54% of the total content of PAHs (six of the PAH8) in pan-fried pork meat and also connected the effect to the antioxidant effect of polyphenols and sulfhydryl compounds, which can scavenge free radicals and destroy fatty acid hydroperoxides.

In control and marinated samples the PAH8 profiles were quite similar; the predominant PAHs were Ch > B*a*A > B*b*F > B*a*P. However, control samples had greater contents of these PAHs than marinated ones. BB caused a significant decrease these PAHs. B*k*F, D*b*A, B*g*P, and IP were formed in very low concentrations, and no relevant differences between control and marinated were achieved. EFSA[2] concluded that although PAH8 is a suitable indicator of PAHs in food, PAH4 (sum of B*a*P, Ch, B*a*A, and B*b*F) may provide enough information. In fact, the measurement of PAH4 provided a suitable overview of PAH formation and the beer effect on their formation (Figure 2).

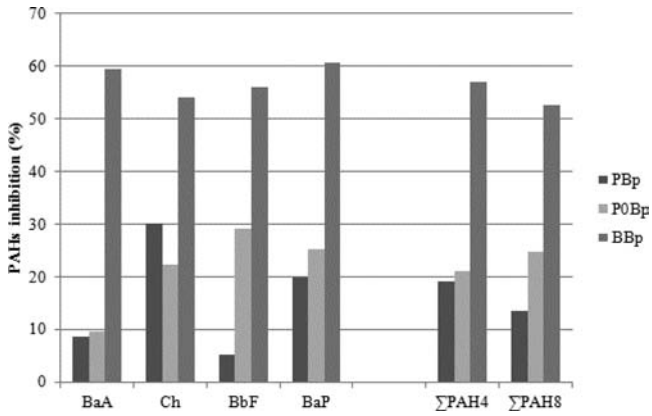

Figure 2. Percentage of inhibition of PAH formation in charcoal-grilled pork loin marinated by different beers (Pilsner, nonalcoholic Pilsner, and Black beer marinades coded respectively PBp, P0Bp, and BBp) versus unmarinated charcoal-grilled loin pork (mean value of quadruplicate analyses). B*a*A, benzo(*a*)anthracene; Ch, chrysene; B*b*F, benzo(*b*)fluoranthene; B*a*P, benzo(*a*)pyrene; ∑PAH4, sum of PAH4; ∑PAH8, sum of PAH8.

With regard to the inhibition of each individual compound, BB showed the highest percentage of inhibition for all with very similar values: 59% of B*a*A, 54% of Ch, 56% of B*b*F, and 61% of B*a*P. P0B and PB presented very similar PAH4 inhibitions, around 20%, but with regard to individual compounds, the inhibitory profile was different. For P0B it was 10% of B*a*A, 22% of Ch, 29% of B*b*F, and 25% of B*a*P. The inhibitory effect of PB was 9% for B*a*A, 30% of Ch, 5% of B*b*F, and 20% of B*a*P.

According to an EFSA report,[2] throughout Europe an exposure of 279 ng/day of PAHs from meat and meat products was estimated on the basis of the occurrence of PAH8 and average consumption of these foods (132 g). Considering an intake of 132 g of grilled pork loin (unmarinated), the uptake of 271 ng of B*a*P and 2057 ng of PAH8 will exceed the overall average dietary exposure of B*a*P (235 ng) and PAH8 (1729 ng) estimated by EFSA. If grilled pork loin marinated in Black beer is consumed, the uptake of 141 ng of B*a*P and 1286 ng in 132 g will not exceed the overall average dietary exposure. Thus, the intake of beer-marinated meat can be a suitable mitigation strategy.

energy input level will be more favorable for producing finer emulsions. Furthermore, the application of a high energy level of emulsification may impart some novel characteristics (e.g., enhanced interdroplet interactions and, subsequently, formation of a uniform and gel-like emulsion) to the emulsions stabilized by these nanoparticles.

Another noteworthy issue is that, for any particle dispersion, interparticle interactions and particle−particle associations (or aggregation) are highly determined by the particle concentration. The concentration of particles may affect their adsorption at the oil/water interface during emulsification, as well as formation of a multilayer-structured interfacial film, since at high particle concentrations, most of the particles with good surface hydrophobicity (e.g., modified silica nanoparticles) are usually present in the aggregated form.[19] Once these aggregated particles are adsorbed at the interface, they could provide supplementary stabilization to the formed emulsions.[19] More importantly, the association or aggregation of particles in the continuous phase (which is more favorable at higher particle concentrations) may lead to formation of a gel-like network in the emulsions, as in the chitin nanocrystal case.[5] The gel-like network formation can thus impart extraordinary stability against creaming to the emulsions. Using steady viscosity and dynamic oscillatory measurements, gel-like network formation has also been confirmed for the emulsions stabilized by preheated SPI or whey proteins at high c values, produced by microfluidization as the emulsification process (e.g., 6% in the continuous phase).[19−21] If the oil fraction is high enough, the gel-like behavior can also be observed for the emulsions stabilized by SPI nanoparticles, produced even by a high-shear mixer with a low-energy input.[21]

In this work we aim to investigate the influence of the emulsification process on the interfacial and emulsifying properties of SPI nanoparticles and the properties of the resultant Pickering emulsions. The SPI nanoparticles were formed by the same process as in our previous work.[12] For comparison, three emulsification processes (I−III) with different energy input levels were applied to formulate the emulsions: (I) only high-shear homogenization; (II) combined applications of high-shear homogenization and ultrasonic treatment; (III) combined applications of high-shear homogenization and microfluidization. It is reasonably hypothesized that increasing the energy input level of emulsification may greatly improve the adsorption of the nanoparticles at the interface and, subsequently, can impart some unique characteristics to the resultant Pickering emulsions, e.g., extraordinary stability against coalescence and creaming and a gel-like emulsion structure.

MATERIALS AND METHODS

Materials. Freeze-dried SPI was the same as that applied in our previous work,[12] the protein content of which was about 91% (wet basis). Soy oil was purchased from a local supermarket in Guangzhou (China). Nile Blue A, Nile Red, and dithiothreitol (DTT) were obtained from Sigma-Aldrich (St. Louis, MO). Bovine serum albumin (BSA) was obtained from Fitzgerald Industries International Inc. (Concord, MA). All other chemicals used were of analytical grade.

SPI Nanoparticle Preparation. The SPI nanoparticles were formed according to the same process described in our previous work.[12] In brief, an SPI solution (6%, w/v) in water, containing 0.02% (w/v) sodium azide, was heated in a bath at 95 °C for 15 min. After being cooled in an ice bath to room temperature, the preheated SPI dispersion was added to the salt powder little by little to a final concentration of 300 mM. Last, the SPI nanoparticle dispersion (6%, w/v), diluted with the same buffer to an appropriate concentration (in the range of 0.01−6.0%, w/v) if needed, was applied to the emulsion preparation.

SPI Nanoparticle Characterization. The particle size (z-average diameter) of nanoparticles in the preheated SPI dispersions was determined using the dynamic light scattering (DLS) technique, using a Zetasizer Nano-ZS instrument (Malvern Instruments Ltd., Worcestershire, U.K.) equipped with a 4 mW He−Ne laser (633 nm wavelength) at 25 °C. The SPI nanoparticle dispersion (6%, w/v) was diluted with the same background buffer (containing 300 mM NaCl) to different individual c values (0.01−1.5%, w/v), and the diluted dispersions were kept at ambient temperature for 30 min, before being subjected to the determination. All the samples were centrifuged at 10000g for 20 min to remove any insolubles in the dispersions prior to the determination. The z-average diameter was obtained with a single-exponential fitting, with each datum reported as the average over three readings.

To unravel the interactive forces involved in the formation and maintenance of the nanoparticle structure, the z-average diameter of the SPI nanoparticle dispersion at c = 0.05% (w/v) in the presence of 6.0 M urea, 0.5% SDS, and 30 mM DTT, alone or in combinations, was also determined according to the same process above.

Dynamic Surface Pressure (π) Measurement. The adsorption kinetics of SPI nanoparticles at the oil/water (pH 7.0, 300 mM NaCl) interface, at varying c values of 0.01−1.5% (w/v), were determined using an optical contact angle meter (OGA-20) with an oscillating drop accessory, ODG-20 (Dataphysics Instruments GmbH, Germany), at 25 °C. The interfacial tension (γ) of the oil/water interface, formed with an oil drop submerged into a cuvette filled with the nanoparticle dispersions, was determined by the drop shape analysis.[22] The surface pressure (π) was calculated as $\gamma_s - \gamma_p$, where γ_s and γ_p are the surface tensions of the aqueous background buffer and the corresponding nanoparticle dispersion (at any test time), respectively. All the measurements with a period of up to 3 h were performed in duplicate. For each sample two consecutive measurements were performed (with the average used for statistics analysis), and each sample was replicated at least two times.

Emulsion Preparation. The SPI nanoparticle dispersions at varying c values of 0.5−6% (w/v), obtained as mentioned above, were applied to form the emulsions, with types I, II, and III corresponding to the three different emulsification processes. All the emulsions were formed at a fixed oil fraction (ϕ) of 0.2. The type I emulsions were prepared as follows: In brief, 16 mL of any SPI nanoparticle dispersion was added to a glass vial, and 4 mL of soybean oil was slowly added to the dispersion, with mixing via an Ultra Turrax homogenizer (model IKA-ULTRA-TURRAX T25 basic, IKA Works, Inc., Wilmington, NC) with a dispersing head operating at 10000 rpm. After all the oil was added, the sample was mixed for an additional 2 min. The type I emulsions were further processed using ultrasonic equipment with a probe at 250 W for 3 min to produce the type II emulsions or homogenized through a microfluidizer (M110EH model, Microfluidics International Corp., Newton, MA) for one pass at a pressure level of 40 MPa to produce the type III emulsions. These resultant emulsions (fresh) were directly subjected to analysis or stored at room temperature for various periods of time for emulsion stability evaluation, e.g., 7 or 40 days for coalescence stability analysis.

Droplet Size Distribution Profiles and Volume-Average Droplet Size ($d_{4,3}$) of Emulsions. Droplet size distribution profiles of various freshly prepared or stored (7 or 40 days) emulsions were obtained with a Malvern MasterSizer 2000 (Malvern Instruments Ltd.). Deionized water or 1.0% (w/v) SDS solution containing 300 mM NaCl was used as the dispersant. The relative refractive index of the emulsion was taken as 1.095, that is, the ratio of the refractive index of soy oil (1.456) to that of the continuous phase (1.33). Droplet size measurements are reported as the volume-average droplet size, $d_{4,3}$ ($=\sum n_i d_i^4 / \sum n_i d_i^3$), where n_i is the number of droplets with diameter d_i. All determinations were conducted on individual samples at least in duplicate.

Flocculation Index (FI, %). The FI (%) of the fresh emulsions was evaluated according to the method described by Castellani and

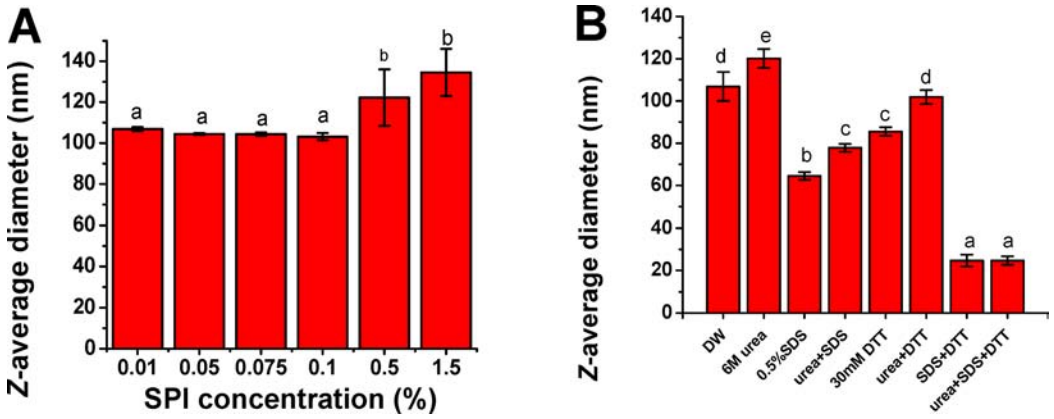

Figure 1. (A) Protein concentration dependence of the *z*-average diameter (D_z) for heat-induced SPI nanoparticles. The nanoparticles were formed by heating the SPI dispersion (c = 6%, w/v) at 95 °C for 15 min and, subsequently, electrostatic screening with addition of 300 mM NaCl. The preheated SPI dispersion was diluted with the same solvent (with 300 mM NaCl) to a specific c value in the range of 0.01−1.5% (w/v). (B) Effects of various protein-perturbing solvents on the D_z of nanoparticles in a preheated SPI dispersion at c = 0.05%. Different characters on the tops of the columns represent the significant difference at the $p < 0.05$ level (n = 3).

others.[23] The emulsions were diluted in deionized water with and without 1% (w/v) SDS, and $d_{4,3}$ of the droplets was determined as described above. The FI was calculated as follows:

$$\text{FI}\ (\%) = [d_{4,3}(\text{in water})/d_{4,3}(\text{in 1\% SDS}) - 1.0] \times 100$$

Microstructure of Fresh Emulsions. The microstructure of the fresh emulsions (types I–III), formed at varying c values of 0.5–6.0% (w/v), was evaluated by confocal laser scanning microscopy (CLSM) using a Leica TCS SP5 confocal laser scanning head mounted on a Leica DMRE-7 (SDK) upright microscope (Leica Microsystems Inc., Heidelberg, Germany). Each fresh emulsion sample (1 mL) was mixed with about 40 μL of fluorescence dye mixtures of Nile Blue (0.1%, w/v) and Nile Red (0.1%, w/v). The mixtures were then placed on concave confocal microscope slides (Sail, Sailing Medical-Lab Industries Co. Ltd., Suzhou, China), covered with glycerol-coated coverslips, and examined with a 100× magnification lens and an argon/krypton laser with an excitation line of 488 nm and a He–Ne laser with excitation at 633 nm, respectively.

Creaming Stability. The creaming stability of various emulsions was assessed visually upon quiescent storage for up to 30 days. Each emulsion (10 mL) in a glass test tube (1.5 cm internal diameter × 12 cm height) was perpendicularly stored at ambient temperature. After different periods of storage, the height of the serum (H_s) and total height of the emulsion (H_t) were recorded. The creaming index (%) was calculated as $(H_s/H_t) \times 100$. Each datum is reported as the mean ± standard deviation of three replicates performed on separated samples.

Rheological Characterization. *Steady Shear Viscosities.* Steady shear viscosities (η) of various fresh emulsions were characterized using a HAAKE RS600 rheometer (HAAKE Co., Germany) with parallel plates (d = 27.83 mm) at 25 °C. The gap between two plates was set to 1.0 mm. After 10 min of equilibration, η of the emulsions was recorded as the shear rate was increased from 1 to 100 s^{-1}.

Dynamic Oscillatory Measurements. The dynamic viscoelastic properties of the gel-like type III emulsions were characterized by the same RS600 rheometer using a small-amplitude oscillatory strain or frequency sweep mode. For the strain sweep experiments, the strain (γ) was varied from 0.002 to 1.0 at a constant frequency of 1.0 Hz, while, for the frequency sweep experiments, the frequency was varied from 0.1 to 100 rad/s at a constant strain of 0.5%. The elastic modulus (G'), loss modulus (G''), and loss tangent (tan δ) were recorded. All the experiments were carried out at 25 °C unless stated otherwise.

Amount of Adsorbed or Entrapped Proteins. The amount of adsorbed or entrapped proteins in the fresh emulsions (types I–III) was evaluated by a centrifugation method. In brief, each fresh emulsion (1.0 mL) was centrifuged at 10000*g* for 30 min at room temperature. After the centrifugation, two phases were observed: a cream layer (or concentrated oil droplets) at the top of the tube and an aqueous phase of the emulsion at the bottom. The cream layer was carefully removed using a syringe, and the subnatant was filtered through a 0.22 μm filter (Millipore Corp.). The protein concentration of the filtrate (C_f) was determined with the Lowry method using BSA as the standard. The percentage of adsorbed proteins (AP) was calculated as $[(C_o - C_f) \times 100]/C_o$, where C_o is the initial protein concentration in SPI aggregate dispersions. The amount of adsorbed proteins (g/100 mL) was calculated on the basis of the total adsorbed protein content per 100 mL of emulsion.

Statistics. An analysis of variance (ANOVA) of the data was performed, and a least significant difference (LSD) with a confidence interval of 95% was applied to compare the means of duplicate or triplicate measurements on separate samples (n = 2 or 3).

RESULTS AND DISCUSSION

SPI Nanoparticle Characteristics. Figure 1 A shows the *z*-average diameter (D_z) of SPI nanoparticles as affected by the c (in the range 0.01–1.5%, w/v) at which the DLS measurements were performed. D_z (about 103 nm) basically remained constant at c values in the range of 0.01–0.1% (w/v), but it significantly increased to 122 nm as c was increased to 0.5% (w/v) (Figure 1 A). A further increase in c to 1.5% (w/v) led to a slight but insignificant increase in D_z. D_z at c = 0.5% (w/v; 122 nm) is basically similar to that (84–112 nm) observed for the glycinin and β-conglycinin mixtures heated at 100 °C for 30 min at the same c value but without 300 mM NaCl.[24] The increases in D_z might be associated with the increased interparticle interactions and subsequent formation of larger particles.[12]

To unravel the pattern of interactive forces involved in formation and maintenance of the nanoparticle structure, we determined the D_z of nanoparticles at c = 0.05% (w/v) in the presence of various protein perturbants, including 6 M urea, 0.5% SDS, and 30 mM DTT, or their combinations, as displayed in Figure 1 B. The results interestingly showed that the presence of 0.5% SDS or 30 mM DTT led to a significant reduction in D_z, with a higher extent of reduction observed in the presence of 0.5% SDS; the presence of both 0.5% SDS and 30 mM DTT led to a considerable decrease in D_z (77% vs 39% in the presence of 0.5% SDS; Figure 1B). On the other hand, the presence of 6 M urea did not decrease D_z, regardless of the presence or absence of 0.5% SDS and/or 30 mM DTT, and in some cases, D_z on the contrary significantly increased (Figure 1

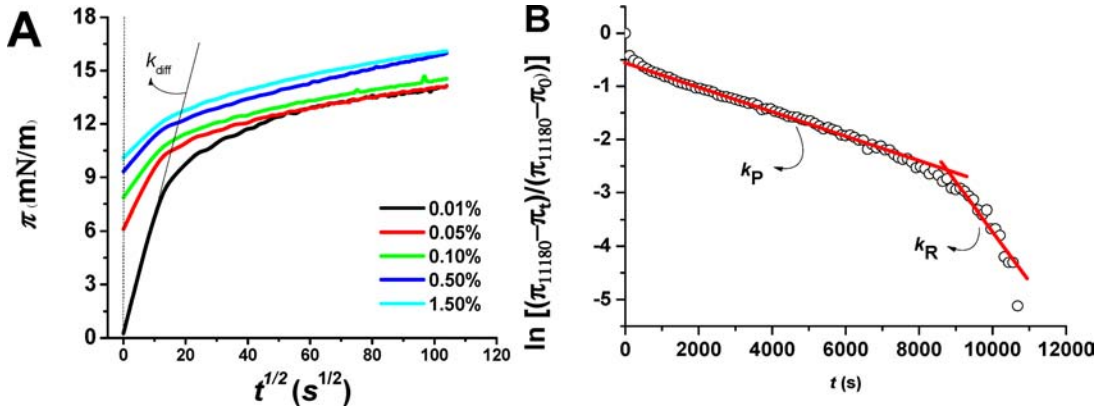

Figure 2. (A) Time evolution of the surface pressure (π) for the adsorption of SPI nanoparticles at the oil/water interface (SPI concentration in solution, 0.01−1.5%, w/v; temperature, 25 °C). (B) Typical profile of the molecular penetration and configurational rearrangement steps at the interface for SPI nanoparticles at c = 0.5%. k_P and k_R represent first-order rate constants of penetration and rearrangement, respectively.

B). Usually, SDS, urea, and DTT mainly disrupt hydrophobic interactions, hydrogen bonding, and disulfide bonding, respectively.[25,26] Thus, the observations suggest that hydrophobic interactions and disulfide bondings are the major intramolecular interactive forces maintaining the internal structure of the nanoparticles, while the hydrogen bonds play a crucial role in their external structure. The interactive force pattern seems to be a bit different from that observed for SPI nanoparticles induced by the calcium ion, where the driving forces for the nanoparticle formation and stabilization were largely attributed to hydrogen bonding and hydrophobic interactions, while disulfide bonding was minor.[27]

Interfacial Adsorption Behavior: Adsorption Kinetics and Structural Rearrangements at the Interface. The interfacial adsorption behavior of the SPI nanoparticles in relation to c was also investigated, with the aim to elucidate the role of the particle concentration in the formation dynamics of the films at the oil/water interface. The surface pressure (π) at the interface for SPI nanoparticles at any test c value (0.01−1.5%, w/v) progressively increased with time (Figure 2A), reflecting protein or particle adsorption at the interface.[22] Due to the consideration that various kinds of emulsifiers (including solid particles, globular proteins, and surfactants) exhibit high similarities in emulsification and emulsion stability,[28] the adsorption kinetics of SPI nanoparticles at the interface can also be described by three main steps: (i) diffusion of particles from the bulk onto the interface, (ii) penetration and structural deformation at the interface, and (iii) rearrangement of adsorbed nanoparticles at the interface and multilayer formation, as has been widely applied to proteins.[29] When the adsorption process is controlled by diffusion, a plot of π against $t^{1/2}$ will be linear and the slope of this plot the diffusion rate constant (k_{diff}).[29] Figure 2 A shows that only at c = 0.01% (w/v) was the adsorption of the nanoparticles at the interface diffusion-controlled, while, at c values of 0.05% (w/v) or higher, the adsorption was more complex. A similar adsorption behavior has been previously observed for native and heat-treated (at 90 or 120 °C for 20 min) SPIs.[30] At c values above 0.01% (w/v), the π value at the beginning of adsorption (0 s; π_0) was far above zero, suggesting that the initial adsorption at these c values was too fast to be detected. However, it can still be observed that π_0 progressively increased from about 0 to 10.2 mN/m as c increased from 0.01 to 1.5% (w/v; Figure 2 A). This observation reflects that increasing the particle concentration progressively accelerated the most initial diffusion and/or adsorption of the nanoparticles from the bulk onto the interface.

The increasing rate of π, or slope for the plot of π against $t^{1/2}$ during initial adsorption (e.g., less than 100 s), gradually decreased with increasing c (from 0.01% to 1.5%, w/v; Table 1), which might reflect the presence of an energy barrier at the interface.[31] On the other hand, π at the end of the adsorption period (11800 s; π_{11800}) was nearly unchanged by variation in c from 0.01% to 0.1%, irrespective of the differences in π changes during initial adsorption; π_{11800} considerably increased from about 14.5 to 16.0 mN/m when c was increased from 0.1% to 0.5% (w/v), and it did not change upon a further increase in c (to 1.5%, w/v) (Table 1). Interestingly, the changing pattern of π_{11800} upon an increase in c is basically the same as that observed for the particle size (Figure 1A), implying that the potential for these nanoparticles to be adsorbed at the interface and participate in interfacial film formation was largely determined by their particle size.

Following the initial adsorption, penetration and subsequent rearrangement of previously adsorbed nanoparticles at the interface occur. These processes can be monitored using a first-

[a]The SPI nanoparticles were formed by heating a 6% (w/v) SPI dispersion at 95 °C for 15 min (and then immediately cooling it in an ice bath to room temperature), followed by addition of 300 mM NaCl. The heated SPI dispersion (containing the nanoparticles) was diluted with pH 7.0 water with the same ionic strength to the required initial *c* value (in the range of 0.5−4.0%, w/v). Emulsifications I−III are the same as in the caption of Figure 3. Each datum is the mean ± standard deviation of triplicate measurements on separate samples. Different online letters (a−d) represent the significant difference at the $p < 0.05$ level due to the difference in *c* (within the same column). [b]The data are the same as in our previous work.[12]

order phenomenological equation: $\ln[(\pi_{11800} - \pi_t)/(\pi_{11800} - \pi_0)] = -k_i t$, where π_{11800}, π_t, and π_0 are the π values at the final time (11800 s) of each step, at any time (t), and at the initial time (t_0), respectively, and k_i is the first-order rate constant.[32] Figure 2 B shows a typical application of the above equation to the adsorption of the nanoparticles at the interface at $c = 0.5\%$ (w/v). In general, the first slope is taken as a first-order rate constant of penetration (k_P), while the next slope refers to a first-order rate constant of molecular rearrangement (k_R) for the adsorbed nanoparticles. The results showed that k_P and k_R for the adsorbed nanoparticles were slightly affected by increasing *c* from 0.01% to 1.5% (w/v) ((−2.41 to −2.65) × 10^{-4} s^{-1} and (−11 to −12) × 10^{-4} s^{-1} for k_P and k_R, respectively; Table 1). At any *c* value, k_R for the adsorbed nanoparticles was considerably higher than k_P, indicating the greater importance of the structural rearrangement of adsorbed nanoparticles at the interface to film formation (than their penetration). The observations suggest that, after initial adsorption, penetration at the interface and subsequent structural rearrangement of adsorbed nanoparticles seem to be slightly dependent on the applied *c* in the range of 0.01−1.5% (w/v).

Emulsifying Properties and Emulsion Characteristics. *Emulsifying Ability or Emulsification Efficiency.* The emulsifying properties of these nanoparticles, including emulsifying ability, flocculated state of a droplet in fresh emulsions, and emulsion stability against coalescence and creaming, were evaluated at varying *c* values of 0.5−6.0% (w/v) and at a fixed oil fraction (ϕ) of 0.2. Three emulsification processes (I−III; see section 2.3) with different levels of energy input were

applied to form the emulsions. Figure 3 shows the typical droplet size distribution profiles of these fresh emulsions, diluted in water or 1% SDS, and the corresponding volume-average diameter ($d_{4,3}$) data are summarized in Table 2. One noteworthy point is that the data for the type I emulsions produced with only a high-shear homogenization have been reported in our previous work,[12] but are still presented herein for comparison between the different emulsification processes. In general, the emulsifying ability of a protein can be reflected in terms of the droplet size of the freshly formed emulsion in the presence of 1% SDS, with smaller sizes indicative of higher emulsifying ability, since SDS can keep individual oil droplets separate in the emulsions.

As expected, the droplet size distribution profiles and the $d_{4,3}$ data (in 1% SDS) were highly dependent on the applied emulsification process and c (Figure 3 and Table 2), indicating that the ability of these nanoparticles to help dispersion of the oil phase into an aqueous phase (at a specific ϕ) might be closely related to the interfacial area of droplets created in the emulsification and the concentration of proteins in the continuous phase. As previously indicated, the type I emulsions exhibited a prominent size distribution peak at around 60−70 μm, with $d_{4,3}$ (in water or 1% SDS) slightly decreasing with an increase in c (from 0.5% to 6.0%) (Figure 3 A,A′ and Table 2). For this type of emulsion, $d_{4,3}$ (in 1% SDS; 52−53 μm) did not significantly change upon an increase of c to 2.0% (w/v), and it progressively decreased as c further increased above 2.0% (w/v; Table 2). This observation suggests that, at c values >2.0% (w/v), the total interfacial area nonlinearly increased with c, due to enough nanoparticles being available to aid formation and stabilization of the newly created interface. The progressive increase in total interfacial area with c (above 2.0%, w/v) is very consistent with the fact that at higher c values the initial adsorption of nanoparticles at the interface was much faster (Figure 2 A), and as a consequence, more interfacial area newly created during the emulsification could be coated and stabilized. When the type I emulsions were further processed by ultrasonic equipment (II) or microfluidization (III), it was observed that, at any specific c, the size distribution profiles in the presence of 1% SDS remarkably shifted toward lower sizes, with a much higher extent of the changes observed for the type III emulsions than the type II counterparts (Figure 3 A′−C′). This can also be reflected in the changes in $d_{4,3}$ data (in 1% SDS; Table 2), confirming that the emulsification efficiency considerably increased with the energy level input order of the emulsification processes: I < II < III.

For the type II emulsions, the droplet size distribution profiles (in 1% SDS) were basically bimodal (Figure 3 B′), reflecting that the additional ultrasonic treatment increased the polydispersity of droplets. In this case, increasing c from 0.5% to 1.0% (w/v) resulted in a shift of the larger size peak toward lower sizes and an increased volume of the smaller peak, and concomitantly, $d_{4,3}$ (in 1% SDS) considerably decreased from 8.6 to 3.9 μm, while a further increase in c to 6.0% (w/v) did not significantly change the size distribution profiles and the $d_{4,3}$ data (Figure 3 B′ and Table 2). In contrast, in the case of type III emulsions, the monomodal size distribution peak (in 1% SDS) progressively shifted toward lower sizes, and $d_{4,3}$ (in 1% SDS) accordingly decreased from 1.76 to about 0.4 μm, as c increased from 0.5% to 4.0% (w/v), though the magnitude of the reduction in $d_{4,3}$ was relatively marginal (Figure 3 C′ and Table 2). The observations suggest that, in both the cases, the amount of nanoparticles at c = 1% (w/v) seemed to be enough to fully cover the newly created interfacial area during the emulsification. The progressive but slight decrease in $d_{4,3}$ upon an increase of c from 1.0% to 4.0% (w/v), in the type III emulsions, reflects that increasing the c of the nanoparticles was favorable for the coalescence stability of newly formed oil droplets during microfluidization. Considering that the initial adsorption of the nanoparticles at the interface was highly related to their concentration, and the adsorption of these nanoparticles was very fast during the initial adsorption, especially at high c values (Figure 2), it can thus be reasonably hypothesized that the droplet size in 1% SDS of the emulsions stabilized by these nanoparticles is mainly determined by the interfacial area created during the emulsification, and increasing c may facilitate the stabilization of newly created oil droplets through an enhanced rate of adsorption during the initial adsorption. In the emulsions stabilized by bare silica, it has been observed that the interfacial area was linearly proportional to the silica content.[18]

Decreases in droplet size with an increase in particle concentration have been similarly observed in emulsions stabilized by modified silica nanoparticles,[18,33] clay particles,[34] and chitin nanocrystal particles.[5] This observation is expected because more particles or nanoparticles are available to stabilize smaller oil droplets. At low c values (e.g., 0.5%, w/v) bridging flocculation and/or coalescence may take place, while, when the SPI nanoparticles are in excess of that needed to fully cover the oil droplet surface, more particles may be adsorbed to form interfacial multilayers or remain dispersed in the aqueous phase.[5,33]

Flocculated State of Droplets in Fresh Emulsions. In the protein-stabilized emulsion system, protein-coated oil droplets may be present in the flocculated form, subsequently affecting the coalescence and even creaming stability of the emulsions. At low c values, bridging flocculation may occur, while, at high c values, the flocculation may be induced by interdroplet attraction interactions (e.g., hydrophobic interactions) between adsorbed proteins on individual droplets. The flocculated state of oil droplets in various fresh emulsions (types I−III) stabilized by SPI nanoparticles was evaluated in terms of the flocculation index (FI, %) by comparison of $d_{4,3}$ between water and 1% SDS (as the dispersant), as included in Table 2. For the type I emulsions, the droplet size distribution profiles without 1% SDS were basically the same as those with 1% SDS (Figure 3 A,A′), indicating a low extent of droplet flocculation in the fresh emulsions. However, it can be still observed that FI progressively decreased from 7.0 to nearly 0 as c increased from 0.5% to 2.0% (w/v; Table 2), suggesting complete inhibition of bridging flocculation at c values above 1.0% (w/v). The decrease in FI with c can be similarly observed in the type II emulsions, where FI progressively decreased from about 84 to near 0 as c increased from 0.5% to 4.0% (w/v; Table 2). This can also be seen from the bimodal droplet size distribution profiles (in water) of this type of emulsion (Figure 3 B), wherein increasing c led to a progressive shift of the larger size distribution peak (toward lower sizes) and, concomitantly, a progressive increase in the volume fraction of the smaller size peak. In contrast, FI at any comparable c value for the type III emulsions was considerably higher than that for the type II counterparts (Table 2), indicating a much higher extent of flocculation. For this type of emulsion, FI on the contrary progressively increased from 1189% to 4672%, as c increased from 0.5% to 2.0% (w/v); when c was above 2.0% (w/v), a contrary trend was observed (Table 2). In this case, the

increasing extent of flocculation upon an increase in c to 2.0% (w/v) might be largely attributed to the enhanced attraction interactions between the adsorbed proteins, while the progressive decrease in FI at c values above 2.0% (w/v) could also be explained to be a result of inhibited flocculation, as in the type I or II emulsions.

The flocculated state of oil droplets in these fresh emulsions can be further corroborated by their CLSM observations, as illustrated in Figure 4. For the type I emulsions, only a portion of the oil droplets at c = 0.5% (w/v) were associated together, while, in the case of the type II emulsions, the microstructural morphology of oil droplets gradually changed from a clustered to a dissociated state as c increased from 0.5% to 4% (w/v; Figure 4, the top two rows). In the latter case, most of the individual oil droplets seemed to be present in the dissociated form, which is well in accordance with the droplet size data (Figure 3 A and Table 2). As compared with the type II emulsions, the extent of droplet flocculation and/or aggregation for the type III emulsions was much higher (Figure 4, middle and bottom rows), indicating a much higher interdroplet interaction of droplets. When c was high enough, e.g., 4% or above, a homogeneous network of the emulsions could be observed, which seems to be in agreement with the decrease in the extent of droplet flocculation (Table 2). On the other hand, the CLSM observations of the contour size of individual oil droplets are basically consistent with the droplet size data (in 1% SDS; Figure 3 C′ and Table 2).

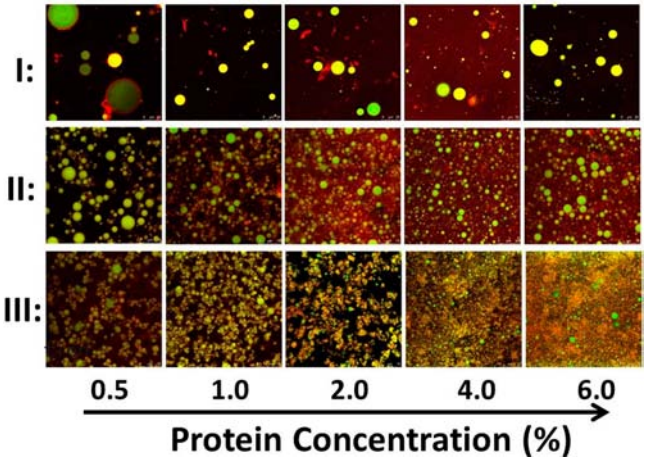

Figure 4. Typical CLSM images of emulsions I–III stabilized by the SPI nanoparticle aggregates at a comparable initial c of 0.5–6.0% (w/v). Emulsions I–III correspond to those produced by the three emulsification processes, as described in the caption of Figure 3.

Coalescence Stability. Extraordinary coalescence stability is one of the most striking features for Pickering emulsions.[33] Table 3 shows the influence of storage after specific periods (7 and 40 days) on $d_{4,3}$ (in 1% SDS) of the various fresh emulsions. In general, we can observe that the coalescence stability of the emulsions was higher at higher c values, or when a higher energy input level of emulsification was applied (Table 3). For the type I emulsions, for example, a minimal c of approximately 1% was needed to keep them stable against coalescence upon storage for 7 days, while a minimal c of 4% (w/v) was needed when the storage was extended to 40 days (Table 3). The type II emulsions, at c values >0.5% (w/v), were basically stable against coalescence upon storage for up to 40 days, though significant but marginal increases in $d_{4,3}$ (in 1% SDS) were observed at c = 1.0% or 2.0% (w/v) after more than 7 days of storage (Table 3). In this case, the emulsion at c = 0.5% (w/v) was unstable against coalescence after 40 days of storage (Table 3). In contrast, all the type III emulsions exhibited extraordinary stability against coalescence upon storage for up to 40 days, even at c = 0.5% (w/v; Table 3).

For particle-stabilized emulsions, the extraordinary coalescence stability can be largely attributed to the effective and irreversible adsorption of particles at the interface, because several thousand kT (k is the Boltzmann constant and T the temperature) of energy might be needed for one particle to desorb from the interface.[35] Besides, the steric hindrance of the particles at the interface,[5,36] as well as a network formation of flocculated particles at the interface or in the continuous phase at high solid concentrations,[5,37] can also contribute to the stability of droplets against coalescence. In the present study, the particle size analyses confirmed that increasing c above 0.1% (w/v) progressively increased the flocculation or aggregation of SPI nanoparticles (Figure 1A), which suggests that the increase in coalescence stability at higher c values might be largely due to the formation of a network involving associated nanoparticles in the system. On the other hand, it should be worth noting that the SPI nanoparticles share some common features of SPI; e.g., once the nanoparticles adsorb at the interface, unfolding or deformation of their structures and subsequent structural rearrangement may occur. This situation may become more distinct at lower c values, e.g., 0.5% (w/v) in the present work. Thus, the differences in coalescence stability at low c values between the different emulsification processes might be to a certain extent attributed to the differences in viscoelasticity and/or intermolecular interactions between adsorbed proteins of interfacial protein films. This can be indirectly corroborated

Table 3. Changes of $d_{4,3}$ (in 1% SDS; μm) of SPI-Nanoparticle-Stabilized Emulsions I–III Formed at Varying c Values of 0.5–6.0% (w/v) upon Storage for up to 40 days[a]

[a]Emulsification processes I–III correspond to those described in the caption of Figure 3. Each datum is the mean ± standard deviation of at least two replicates on separate samples. Different online letters (a–c) represent the significant difference at the $p < 0.05$ level between different storage periods (0–40 days) for a specific emulsion at a specific c value.

by the fact that the microfluidization treatment could improve the surface properties of heat-treated SPI through disruption of initially formed aggregates into smaller ones;[17] the heat-treated SPI with a higher surface activity exhibited a faster increase in surface pressure and dilatational modulus.[30]

Creaming Stability. The creaming behavior of these emulsions upon storage for up to 30 days was evaluated by the visual observation. As reported previously,[12] all the type I emulsions quickly developed into two layers, a creamed layer (top) and a clear serum layer (bottom), within 1 day, but prolonged storage just slightly increased the creaming index (height of the serum layer relative to the total emulsion height) (Figure 5), indicating instability against creaming. In this case, it

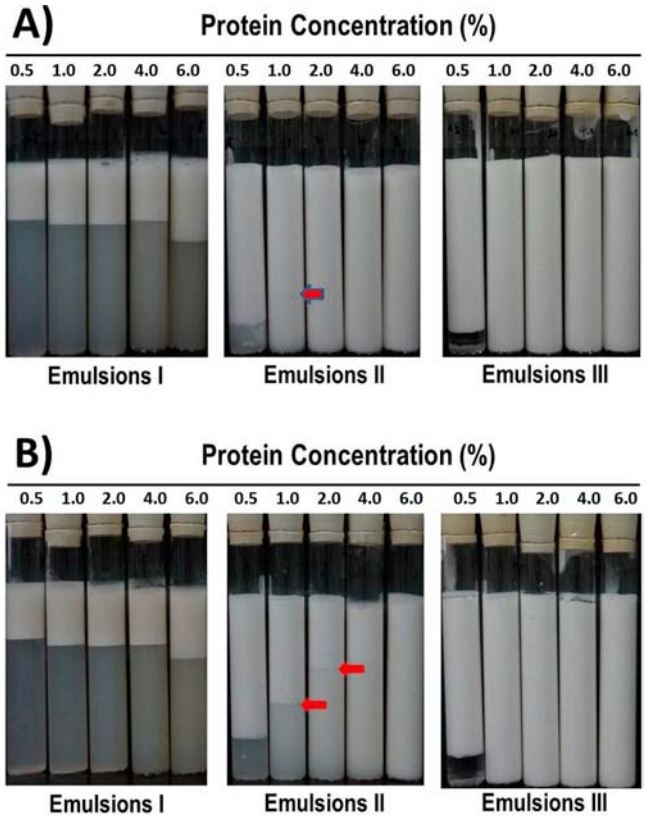

Figure 5. Visual observations of emulsions I–III stabilized by the SPI nanoparticles at varying c values of 0.5–6.0% (w/v) after storage for 1 day (A) and 30 days (B). The arrows within the figure show the position of a distinct creamed layer bottom.

can still be observed that increasing c from 0.5% to 6.0% (w/v) was favorable for the creaming stability; for example, the creaming index at 30 days decreased from about 72% to 60% as c increased from 0.5% to 6.0% (w/v) (Figure 5). The improvement of creaming stability by increasing c can be similarly observed in the type II and III emulsions (Figure 5). For the type II emulsions, no distinct creaming occurred during storage for 7 days at c values of 2.0% (w/v) or above, and when storage was extended to 30 days, a minimal c value of 4.0% (w/v) was needed to completely inhibit the creaming. In the microfluidization case, it is surprisingly observed that no creaming occurred at c values of 1.0% (w/v) or above upon storage for up to 30 days, and even at c = 0.5% (w/v) the creaming index was relatively low (approximately 15%; Figure 5), indicating extraordinary stability against creaming. The improvement of creaming stability by increasing the particle concentration has been observed for the emulsions stabilized by microcrystalline cellulose and modified starch,[3] chitin nanocrystal particles,[5] and zein colloidal particles.[7]

The c dependence of creaming behavior is very consistent with the droplet size data in water (Table 2), reflecting that, within each type of emulsion, the creaming behavior of droplets might still satisfy the Stokes rule. Compared with the type II emulsions, the type III emulsions at any test c value showed much larger $d_{4,3}$ in water but exhibited much higher creaming stability (Table 2 and Figure 5), implying that the creaming behavior in the latter case was predominated by other crucial factors rather than the droplet size in the system. In our previous work, the improved creaming stability for the type I emulsions at higher c or ϕ values has been attributed to the formation of a gel-like network involving server droplet flocculation.[12] This explanation is distinctly applicable to the extraordinary creaming stability of the type III emulsions relative to the type II counterparts, since in the former case the droplet flocculation was much higher (Table 2 and Figure 5). The importance of the gel-like network formation to the creaming stability has also been confirmed in the emulsions stabilized by preheated whey protein or SPI[19,21] and chitin nanocrystal particles.[5]

Rheological Properties of Gel-like Emulsions. To ascertain the formation of a gel-like network in the emulsions, we evaluated the flow behavior and dynamic viscoelastic properties of various freshly prepared emulsions. As expected, all the test emulsions (fresh) exhibited a shear-thinning behavior in the shear rate range of 0.2–100 s^{-1} (Figure 6), mainly reflecting deflocculation of associated droplets in the emulsions.[21,38−40] For the type I emulsions, η at a specific shear rate above 1.0 s^{-1} gradually increased upon an increase in c from 0.5% to 6.0% (w/v) (Figure 6 A), indicating enhanced association or flocculation at higher c values. In this case, all the formed emulsions exhibited a good flow behavior with very low η values, e.g., <0.2 Pa·s at a shear rate of 1 s^{-1}.

When the type I emulsions were further processed by ultrasonic treatment or microfluidization, we observed that the η values were significantly increased, with much greater increases observed for the microfluidized emulsions (type III) (Figure 6). For the type II emulsions, the flow behavior seemed to be independent of c within the c range of 0.5–4.0% (w/v); η was significantly increased only when c was increased to 6.0% (w/v; Figure 6 B). Except the situation at c = 6.0% (w/v), the type II emulsions also exhibited good flow behavior with low η values, e.g., ∼0.5 Pa·s at a shear rate of 1 s^{-1}. By comparison, the flow behavior of the type III emulsions was much poorer than that of the other two types of emulsions, especially at c values of 1.0% (w/v) or above (Figure 6 C). In this case, we can observe that, as c increased from 0.5% to 4.0% (w/v), η at any specific shear rate progressively increased to a maximum, but a further increase in c to 6.0% (w/v) on the contrary led to a considerable decrease in η (relative to that at c = 4.0%, w/v). A similar flow behavior of the type III emulsions has been observed in our previous work,[12] indicating formation of a gel-like network.

The gel-like network formation in the type III emulsions was further evaluated using dynamic viscoelastic measurements. To determine the linear viscoelastic range of measurement, we first performed a strain (γ) sweep experiment on the emulsion at the lowest c value (0.5%) at a constant frequency of 1.0 Hz. From Figure 7 A, it can be seen that the emulsion was mainly elastic in nature at a γ of less than 0.1, and there was

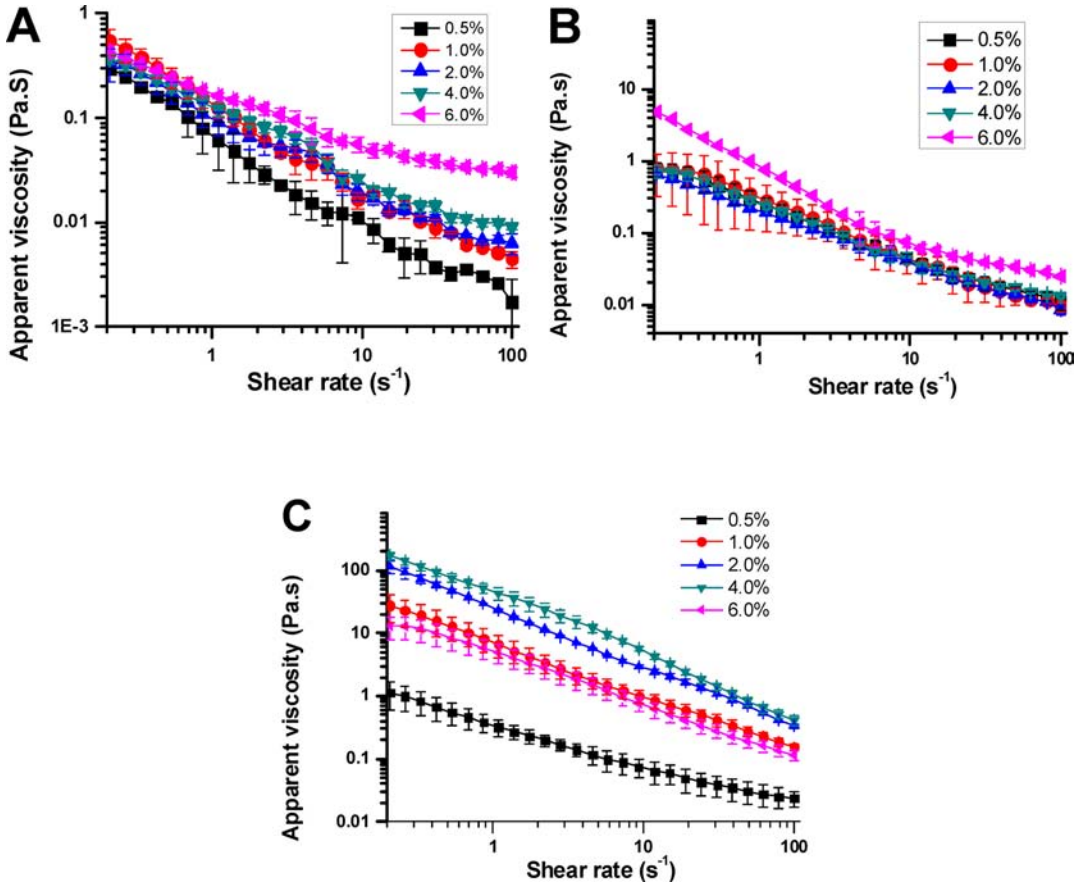

Figure 6. Typical flow behaviors of the fresh emulsions stabilized by the SPI nanoparticles at varying c values of 0.5−6.0% (w/v) formed by emulsification processes I (A), II (B), and III (C). Each datum is the mean ± standard deviation of at least duplicate measurements on separate emulsions. Emulsions I−III refer to those described in the caption of Figure 3.

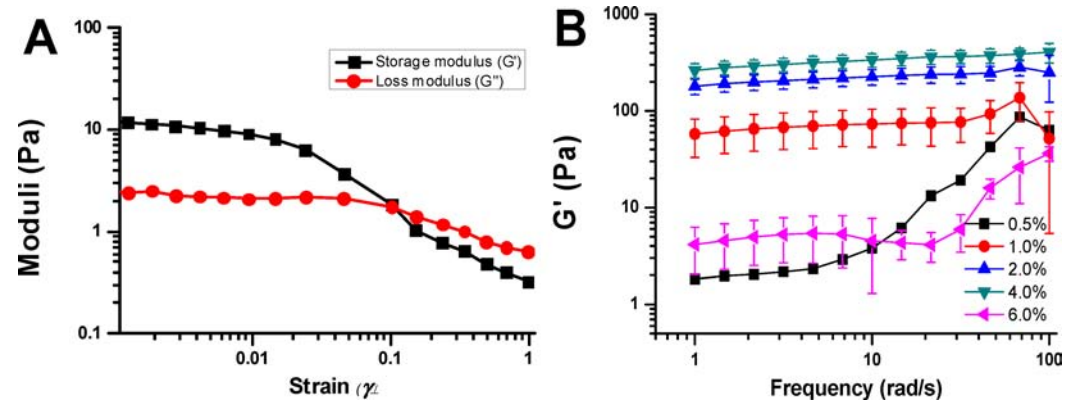

Figure 7. (A) A typical strain sweep of the emulsion stabilized by SPI nanoparticles at a c value of 0.5% (w/v), formed by emulsification III (microfluidization). (B) Frequency dependence profiles of storage moduli (G') for the fresh emulsions stabilized by SPI nanoparticles at varying c values of 0.5−6.0% (w/v), formed by emulsification III. The experiments were performed at a constant frequency of 1 rad/s or a constant strain of 0.5%. Each datum is the mean ± standard deviation of at least duplicate measurements.

approximately a linear viscoelastic range with γ below 0.01, during which the moduli were basically independent of the applied γ. Then, at a constant γ value (0.005) within the linear viscoelastic range, we performed the frequency sweep experiments of the emulsions at varying c values (0.5−6.0%, w/v), and only the storage modulus (G') data are presented in Figure 7 B (the loss modulus, G'', data not provided, due to the consideration of the simplicity within the figure). In all the cases, G' was considerably higher than G' in the low-frequency range, e.g., less than 10 rad/s (data not provided), indicating the formation of predominantly elastic gel-like emulsions. For all the test emulsions, G' progressively increased upon an increase in frequency in the test range of 1.0−100 rad/s. The frequency dependence of G' became less at higher c values (in the c range of 0.5−4.0%); for example, G' at c = 4.0% (w/v) was almost independent of the applied frequency in the test range of 1.0−100 rad/s (Figure 7 B). Similar phenomena for the frequency dependence of the moduli have been observed

for gel-like protein-stabilized emulsions or emulsion gels.[19,21,40] The G' dependence on the frequency can reflect the nature of cross-links in the gel-like network of emulsions or emulsion gels, with less dependence observed for the network consisting of more chemical cross-links.[41] Thus, the observations suggested that, upon an increase in c from 0.5% to 4.0% (w/v), the cross-links in the gel-like network of the emulsions gradually changed from noncovalent "physical" to covalent "chemical" in nature. Like the steady viscosity, the situation for the emulsion at c = 6.0% (w/v) seemed to be an exception, where the frequency dependence of G' became more distinct compared with that at c = 4.0% (w/v; Figure 7 B), indicating a loss of the gel stiffness. The seemingly abnormal loss of the gel stiffness might be largely attributed to the decreased droplet flocculation (Table 2), indirectly confirming the above argument that the gel-like network formation was mainly due to the droplet flocculation.

Amount of Adsorbed Proteins. In the protein-stabilized emulsions, the creaming or rheological behavior is not only related to interdroplet attractive and repulsion interactions, but also affected by interactions between individual proteins in the continuous phase or between the unadsorbed proteins and those adsorbed at the interface. To help unravel the role of these interactions in the rheological or creaming behavior of the emulsions, we evaluated the adsorbed (at the interface) or entrapped (within the gel-like network) protein concentration (g/100 mL of emulsion) of the three types of emulsions (I–III) by a centrifugation method, and the results are presented in Figure 8. In general, for any type of emulsion the concentration of adsorbed or entrapped proteins progressively increased with increasing c from 0.5% to 6.0% (w/v; Figure 8). This is basically consistent with the fact that, at higher c values, more proteins are adsorbed at the interface of the droplets and thus participate in the formation of interfacial protein films.

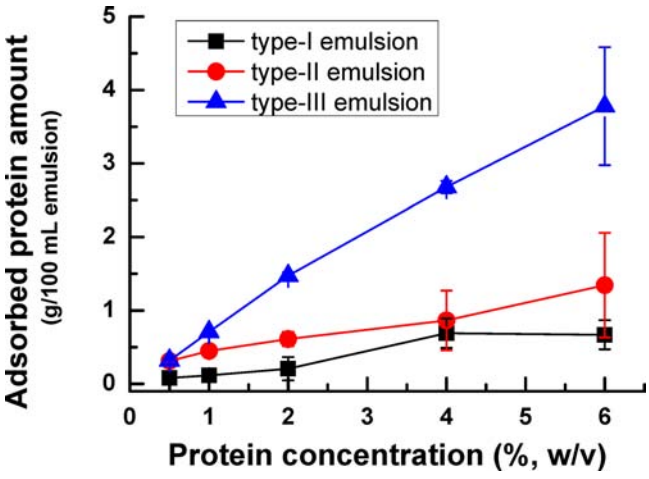

Figure 8. Amount of adsorbed proteins (g/100 mL of emulsion) for emulsions I–III stabilized by the SPI nanoparticles as a function of c (0.5–6.0%, w/v). Each datum is the mean ± standard deviation of triplicate measurements (on separate samples).

However, it can be clearly seen that, for the type I or II emulsions, the concentration of adsorbed or entrapped proteins increased at a much lower rate than that for the type III counterparts upon an increase of c (Figure 8). By calculation, in the case of the type III emulsions, more than 80% of the total proteins were adsorbed at the interface of the droplets or entrapped within the gel-like network, throughout the whole test c range, while, in the type I emulsions, the value was approximately 20%. The situation for the type II emulsions seemed to be a bit different, and in this case, the amount of adsorbed or entrapped proteins progressively decreased from about 80% to 30% with c increasing from 0.5% to 6.0% (w/v; data not shown). At higher c values, e.g., 4% or 6% (w/v), the amount of adsorbed or entrapped proteins for the type II emulsions was slightly but insignificantly higher than that of the type I emulsions (Figure 8). Interestingly, these observations are well in accordance with the rheological and creaming behavior and microstructure of these emulsions at varying c values (Figures 5–7), implying that the rheological and creaming behavior and microstructure of the emulsions stabilized by SPI nanoparticles were mainly related to the amount of adsorbed or entrapped proteins in the system.

In summary, the emulsifying properties of SPI nanoparticles (formed by combined treatments of heat pretreatment and electrostatic screening) and the properties of the resultant Pickering-like emulsions were highly dependent on the emulsification process and c in the continuous phase. In general, increasing c resulted in a progressive reduction in droplet size (in water or 1% SDS) for any type of emulsion. At any test c value, the emulsification efficiency and extent of droplet flocculation increased with an increase in the energy input level. On the other hand, we found that increasing the emulsification efficiency and/or c was favorable for formation of emulsions with higher viscosity and stiffness and greater stability against coalescence and creaming. The rheological and creaming behavior and microstructure of these emulsions were largely determined by the amount of proteins adsorbed at the interface or entrapped within the gel-like network. The results confirmed that the SPI nanoparticles exhibited excellent interfacial and emulsifying properties, as well as a Pickering-like stabilization. With these nanoparticles as the emulsifiers, the application of a high-pressure emulsification technique can produce a kind of Pickering-like emulsion with smaller droplet sizes but a gel-like network structure which exhibits excellent potential to be applied in novel functional food formulations.

chitosan, due to a high degree of deacetylation, allows it to react efficiently with negatively charged groups of proteins.[25] The addition of chitosan resulted in significant inhibition of microbial growth in Greek-style fresh pork sausages[6] and could also improve thermal gelling properties of grass carp gels and delay lipid oxidation.[26] However, the high molecular weights and high viscosity may restrict its uses;[27] the oligomers of chitosan have received considerable attention because they may have a greater biological activity than chitosan and are also water-soluble.[28]

Myosin, as one component of the myofibrillar protein matrix, is a primary gelling protein, which contributes to desirable texture and stabilization of fat and water in processed meat products. The gelation of a single myosin has been studied in detail.[29−31] Many papers have discussed the interaction between myofibrillar protein and polysaccharide,[13,17,19] but the myofibrillar protein system is complex (containing a variety of proteins such as myosin, actin, actomyosin), and it is not clear that the certain protein of the system interacts with polysaccharide. To our knowledge, no investigation has so far been reported regarding the interactions of different ionic types of polysaccharide (KCG, LBG, and water-soluble chitosan (WSC)) with myosin and those interaction-induced effects.

The objective of this study was to investigate the effects of three ionic types of polysaccharide (anionic polysaccharide KCG, neutral polysaccharide LBG, and cationic polysaccharide WSC) on the WHC and hardness of poultry myosin gels. And the changes in the properties of the gels were explained using different instrumental techniques.

MATERIALS AND METHODS

Materials. KCG and LBG were provided by Danisco (China) Co., Ltd. The viscosities of a 1.5% KCG water solution (w/w) and a 1% LBG water solution (w/w) were above 10 and 2400 mPa·S, respectively. WSC was provided by HeFei XinDe Biotechnology Co., Ltd., and the viscosity of 1% water solution (w/w) was 55 mPa·S. The chicken breast meat was purchased from a local supermarket of the Carrefour Group, and the preparations were commenced within 30 min after purchase.

Extraction of Myosin. Myosin was extracted from chicken breast muscle using a modified procedure originally reported by Wang et al.[32] and Hayakawa et al.[33] First, 150 g of minced chicken breast muscle was mixed with 400 mL of a cold solution (0.1 M KCl, 20 mM potassium phosphate, 2 mM $MgCl_2$, 1 mM EGTA, pH 7.0) containing 1 mM dithiothreitol and subsequently ground with a blender (DS-1, Shanghai Yueci Electronic Technology Co., Ltd., China). The mixture was treated with 1% Triton X-100 and homogenized for 3 min at 10000 rpm using a homogenizer (FA25 model, Fluko, China); the material was subsequently centrifuged at 8000*g* for 12 min at 4 °C in a refrigerated centrifuge (CT14RD, Techcomp Co., Ltd., Shanghai, China). The sediment was extracted with 3 volumes of a modified Guba−Straub solution (0.3 M KC1, 0.1 M KH_2PO_4, 50 mM K_2HPO_4, 1 mM EGTA, 4 mM sodium pyrophosphate, 20 mM $MgCl_2$, pH 6.5) and stirred for 15 min at 4 °C with an agitator. The extraction was centrifuged at 5000*g* for 12 min at 4 °C. The supernatant was diluted with 14 volumes of cold 1 mM EDTA−2Na solution and stored for 90 min at 4 °C. After the floating material was removed via siphon, the precipitated protein was collected by centrifugation at 10000*g* for 6 min at 4 °C and suspended using 1 volume of 0.6 M KCl buffer (0.6 M KCl, 150 mM sodium phosphate, pH 6.5). Magnesium chloride and sodium pyrophosphate were added into the protein, reaching final concentrations of 5 mM. The mixture was stirred vigorously for 30 min without foaming at 4 °C and centrifuged at 10000*g* for 20 min at 4 °C. The supernatant was rediluted with 9 volumes of cold distilled water and precipitated for approximately 12 h. The floating material and precipitated protein were re-treated as above. The solution was dialyzed against the 0.6 M KCl buffer (pH 6.5) described above. The resulting supernatant was regarded as the extraction solution of myosin.

The protein composition of the extracted myosin was validated by SDS-PAGE with a gel imaging system (Universal Hood II, Bio-Rad Co., Hercules, CA, USA). The protein concentration in this myosin solution was measured using the biuret method, and the final concentration was adjusted to 20 mg/mL myosin using the 0.6 M KCl buffer (pH 6.5) before test.

Preparation of Myosin−Polysaccharide Sols. Each polysaccharide (KCG, LBG, and WSC) was added to 80 g of myosin solution (myosin 20 mg/mL) at different concentrations (0, 0.25, 0.5, 0.75, and 1%, w/w). Deviations of weight of all ingredients were not in excess of ±0.5%. The mixture of myosin−polysaccharide was stirred for 30 min and homogenized for 1 min at 10000 rpm using a homogenizer (FA25 model, Fluko, China) in a 100 mL beaker and kept overnight (about 12 h) at 4 °C prior to treatment.

Preparation of Myosin−Polysaccharide Gels. Each myosin−polysaccharide sol prepared as described above was added to a beaker of 27 mm in diameter and 35 mm in height. The beaker was heated for 30 min in an 80 °C water bath (an additional 25 min was needed to warm the system from 20 to 80 °C) to form a gel and then immediately cooled in a water bath (about 4−10 °C) and kept overnight (10−12 h) at 4 °C before the WHC, gel hardness, low-field nuclear magnetic resonance (LF-NMR), Fourier transform infrared (FT-IR) spectroscopy, and scanning electron microscopy (SEM) measurements.

Gel Analysis. *WHC.* WHC was determined by a centrifugal method.[34] Approximately 5 g of the gel was centrifuged at 1000*g* for 10 min at 4 °C. WHC was the percentage of the gel's weight retained after centrifugation relative to its initial weight. The experiments were conducted in triplicate.

Gel Hardness. The hardness of the gels was analyzed using a TA-XT Plus Texture Analyzer (Stable Micro System Co., UK) at ambient temperatures (approximately 20 °C). The gel was subjected to a compression test using a cylindrical probe (P/0.5 in., aluminum) at a trigger type button with a 1.5 mm/s pretest speed, a 1.0 mm/s test speed, a 1.0 mm/s post-test speed, a 4.0 mm distance, and a 3 g trigger force. The maximum force of the sustained compression was the gel hardness. The experiments were conducted in six replicates.

LF-NMR Spin−Spin Relaxation Time (T_2) Measurements. The gel sample (2−4g) was placed in a ⌀ 25 mm glass tube. LF-NMR ^1H T_2 measurements were performed using the method described by Han et al.[35] with slight modifications. The data were collected using a Niumag Benchtop Pulsed NMR Analyzer MiniMR-60 (Niumag Electric Corp., Shanghai, China) operating at 23.318 MHz (proton resonances) and a τ value (time between the 90° and 180° pulse) of 200 μs. The data from 12000 echoes were acquired as 32 scan repetitions with 6.5 s between each scan. T_2 was measured in triplicate. The NMR T_2 data were analyzed using Multi-Exp Inv Analysis Software (Niumag Electric Corp.).

FT-IR Spectroscopy. The gel samples were dried for 32 h in an LGJ-12 lyophilizer (Beijing Songyuan Huaxing Technology Development Co., Ltd., China). The spectra of the gels were obtained as previously described[24] and recorded at ambient temperatures (20 °C) using 16 scans. Origin 7.5 software was used to analyze these spectra.

SEM. The gel samples were dried for 15−16 h in an LGJ-12 lyophilizer (Beijing Songyuan Huaxing Technology Development Co., Ltd., China). The SEM observations were performed with a field emission scanning electron microscope (SU8020, Hitachi, Ltd., Japan), according to a reported method.[24] Two fields from each treatment were examined, and one of the two is presented.

Myosin−Polysaccharide Sol Analysis. *Dynamic Rheological Measurements.* The dynamic oscillatory measurements were carried out with a rheometer (Discovery HR-3, TA Instruments Co., USA) in oscillatory mode, as described by Verbeken et al.[36] with a slight modification. A parallel steel plate geometry (60 mm) with a 550 μm gap was used. The samples were heated from 20 to 80 °C at 2 °C/min and cooled from 80 to 20 °C at 4 °C/min. A continuous 0.1 Hz

oscillation and a 2% strain were applied to monitor the storage modulus (G') and tan δ. All experiments were conducted in triplicate.

Statistical Analysis. The analyses of variances, means, and standard errors were determined using Excel 2003 (Microsoft Office Excel 2003 for Windows). A significance level ($P < 0.05$) was used to determine differences between the treatments.

RESULTS AND DISCUSSION

WHC. As shown in Figure 1, all three polysaccharides could improve the WHC of myosin gel, and the improvement by

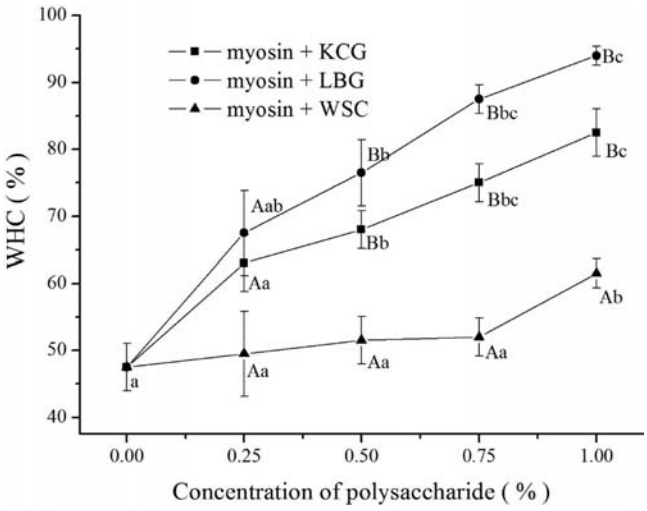

Figure 1. Effects of KCG, LBG, and WSC on the WHC of myosin gels. Different lower case letters (a–c) in the same curve indicate significant difference ($P < 0.05$). Different capital letters (A, B) among the three polysaccharides at the same concentration indicate significant difference ($P < 0.05$).

LBG was the greatest. The increase of KCG or LBG concentrations in the range of 0–1% caused a clear improvement for the WHC of myosin gel, whereas the concentration of WSC in the range of 0–0.75% had no distinctive impact ($P > 0.05$). The difference between the effect of KCG and that of LBG on the WHC was insignificant ($P > 0.05$) at equal concentrations from 0.5 to 1%; however, the addition of KCG and LBG could respectively cause significant increases ($P < 0.05$) of WHC value compared to the WSC at equal concentration. The increase of WHC indicated that more favorable physical entrapment of water occurred in the protein–gum matrices.[13] The results suggested that myosin–KCG or myosin–LBG matrices had a greater ability to entrap water than myosin–WSC matrices.

The effects of KCG, LBG, and WSC on WHC properties shown in our study were consistent with the results of other studies.[7,8,21,36,37] It is well-known that water-binding capacity involves electrostatic, hydrophobic, and hydrogen bonds, etc. LBG has the ability to form hydrogen bonds with water.[7,8] It was found that KCG was present in the interstitial spaces of the protein network, where it bound water and might form gel fragments upon cooling,[36] and thus more water was preserved in the gel network. The WHC improvement of WSC samples was due to the interaction between chitosan and protein.[37] The result suggested that the ability to effectively immobilize water increased in the order myosin–LBG, myosin–KCG, and myosin–WSC.

Gel Hardness. As shown in Figure 2, the hardness of myosin gels increased with the elevated KCG and LBG

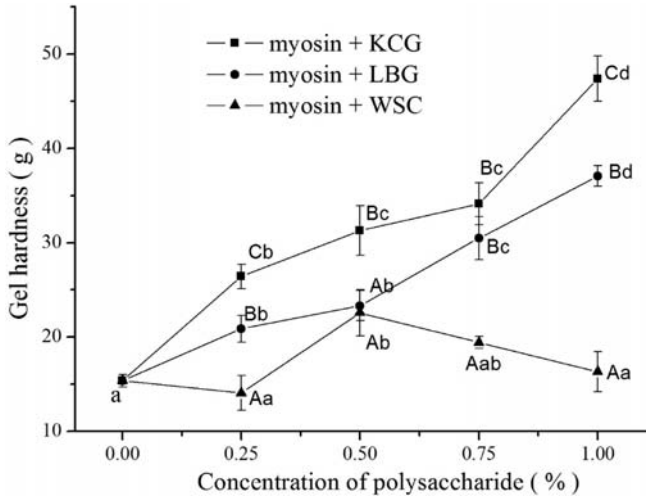

Figure 2. Effects of KCG, LBG, and WSC on the hardness of myosin gels. Different lower case letters (a–d) in the same curve indicate significant difference ($P < 0.05$). Different capital letters (A–C) among the three polysaccharides at the same concentration indicate significant difference ($P < 0.05$).

concentrations, respectively. For the myosin–WSC gel, the change of the gel hardness was insignificant ($P > 0.05$) within the range of 0.25–1.0% addition, except the addition of 0.5% WSC (Figure 2). The increasing effect of KCG in gel hardness was the greatest among the three polysaccharides.

Synergistic effects have been previously observed between carrageenan and proteins, which resulted in much stronger gels compared to protein alone. DeFreitas et al.[21] interpreted the positive influence of carrageenan on the strength of meat protein/carrageenan gels as resulting from the interaction between them. However, Verbeken et al.[36] inferred that KCG did not seem to interact with meat protein in the network formation. Hunt et al.[38] deemed that the increase in gel strength might be caused by electrostatic interactions between sulfate groups of carrageenan molecules, resulting in increased aggregation of the molecular chains of carrageenan. LBG is a nongelling polysaccharide, and Xiong et al.[8] reported that a high hardness of low-fat beef sausages containing LBG was obtained at pH 6.2. In the presence of chitosan, protein–polysaccharide conjugation may be formed between the reactive amino group of glucosamine and the glutaminyl residue of myofibrillar proteins.[26,37] The penetration force of SSMP gels increased proportionally with increasing amount of chitosan incorporated in gels.[37] The breaking force of kamaboko gels increased proportionally with the amount increase of chitosan below 1% addition and then decreased significantly when a higher amount (>1%) of chitosan was added. It was postulated that a higher concentration of chitosan could disrupt the polymerization and aggregation of myofibrils, resulting in a reduced breaking force.[26]

Some researchers reported that KCG, LBG, and WSC would be entrapped as filler ingredients to influence the formation of the continuous gel matrix, modifying the physicochemical properties of the aqueous phase and/or influencing the texture of the final product.[26,36,39] The interactions between polysaccharides and proteins in food systems are largely ascribed to electrostatic association or repulsion. Because myosin would have a negative net charge in myosin/polysaccharide systems at pH 6.5 (isoelectric pH 5.0 of myosin), it was speculated that electrostatic repulsion between the myosin and KCG with the

same charges could be enhanced and thus lead to the changes of the WHC and hardness of myosin−KCG gel. On the other hand, the electrostatic attraction between the protein and WSC with positively charged groups could also be strengthened, and the gel hardness of myosin−WSC should theoretically be increased. However, the present result (Figure 2) revealed that the increase of the myosin−WSC gel hardness was insignificant ($P > 0.05$). Many researchers ascribed the gel hardness to the polymerization of myofibrils inter- or intramolecularly, and the polymerization was relative to the deacetylation degree of chitosan.[37] This insignificant increase might be attributed to the deacetylation degree of WSC, but this mechanism is worth further investigation.

The WHC of myosin gel with LBG was greatest among the three myosin−polysaccharide systems (Figure1), whereas the gel hardness of myosin with LBG was smaller than that with KCG (Figure2). The results were similar to the result of the KCG−/LBG−blue whiting muscle system described by Pérez-Mateos et al.[40] The WHC of myosin gel with KCG was less than that with LBG, because KCG is quite difficult to hydrate within the myosystem.[40] This discrepancy could also be due to the different types of interaction (electrostatic, ionic, etc) between protein and polysaccharide and/or the differences in ability to solubilize or disperse through the protein matrix.

LF-NMR. The distributions of T_2 relaxation times on the gels with myosin−KCG, myosin−LBG, and myosin−WSC are shown in Figure 3. Three relaxation populations of myosin

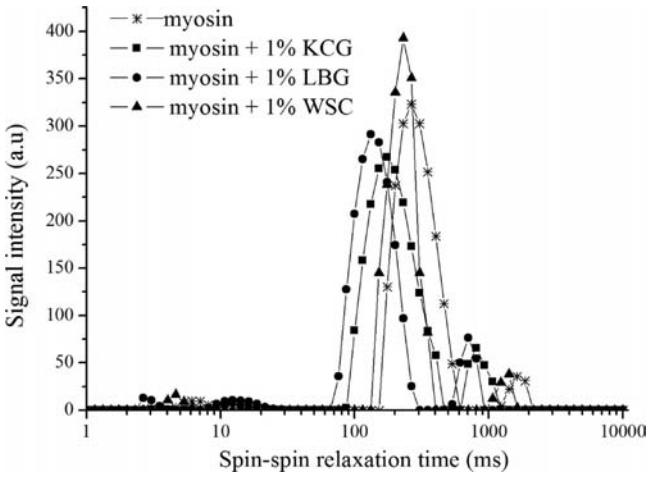

Figure 3. Effects of KCG, LBG, and WSC on the distribution of the T_2 relaxation times of myosin gels.

were centered at approximately 3.05−14.17 ms (T_{21}), 151.99−464.15 ms (T_{22}), and 1232.85−1873.82 ms (T_{23}), revealing bound, immobilized, and free water, respectively, according to the report of Bertram et al.[41] In addition, a broadening of the populations centered at 151.99−464.15 ms (T_{22}) was significant.

The positions of T_{22} and T_{23} clearly shifted toward lower relaxation times with polysaccharide added at 1% concentration (Figure 3). A statistically significant effect was found on the T_{22} and T_{23} ($P < 0.05$) with the addition of gum to myosin (Table 1); the T_{22} and T_{23} decreased in the order myosin−LBG, myosin−KCG, and myosin−WSC, respectively, which is in accordance with the result of WHC. The decrease in nuclear relaxation times indicates an overall decrease of water mobility, and the results are similar to the effect of flaxseed gum added into myofibrillar protein.[42] Hills et al.[43] showed that protein aggregation reduced the water proton relaxation time. This implied that the polysaccharide could stimulate the aggregation of myosin, which was also consistent with the subsequent increase of the storage modulus (G') induced by the addition of the three polysaccharides.

Dynamic Rheological Measurements. The thermodynamic viscoelastic behavior of myosin (Figure 4A) showed that

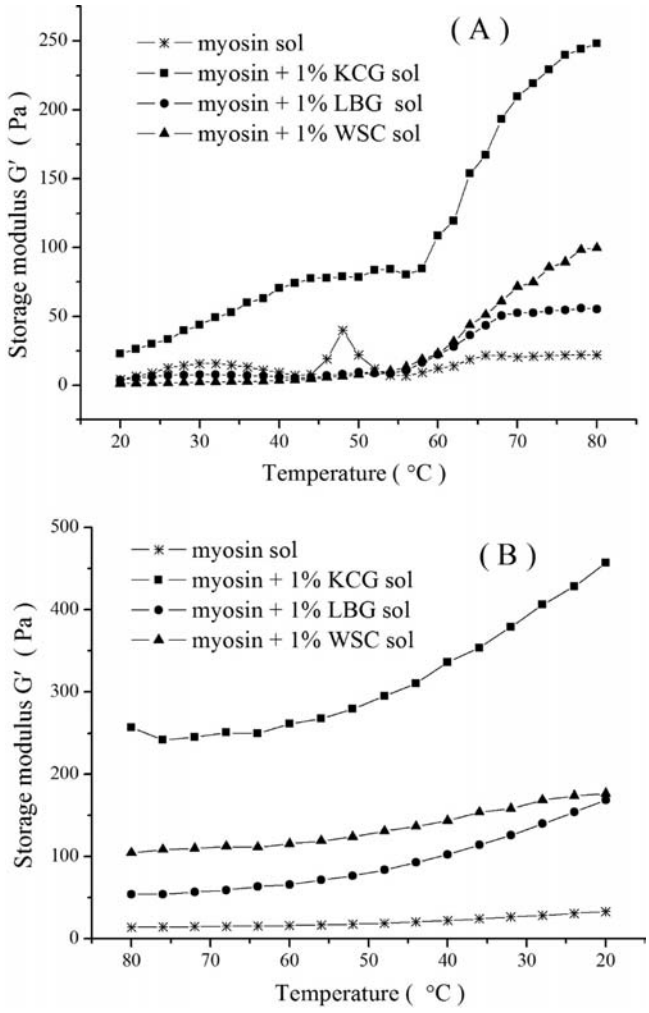

Figure 4. Effects of KCG, LBG, and WSC on the storage modulus (G') of myosin sols during heating (A) and cooling (B).

Table 1. Effects of Three Ionic Types of Polysaccharide on the Spin−Spin Relaxation Times (T_{22} and T_{23}) of Myosin Gels[a]

sample	myosin gel	myosin + 1% KCG gel	myosin + 1% LBG gel	myosin + 1% WSC gel
T_{22}	265.60 ± 17.37d	174.75 ± 13.14b	132.19 ± 0.93a	231.01 ± 0c
T_{23}	1629.75 ± 53.05d	811.13 ± 46.14b	705.48 ± 0a	1417.47 ± 60.9c

[a]Data are expressed as the mean ± SD, $n = 3$. Different letters (a−d) in the same row indicate statistically significant differences at $P < 0.05$.

the G' of the myosin suspension, reflecting the elastic portion of the gel, began to increase from 44 °C and reached a maximum value at 48 °C before declining sharply to a minimum value at 54 °C, after which an ascending curve was exhibited. This rheological transition could be ascribed to the initial association of myosin head as a result of denaturation of the S1 subfragment (42−48 °C) and the disruption of the temporary protein network due to subsequent unfolding of the myosin tail (50−55 °C).[44] Moreover, a similar G' curve was reported during heating of chicken myosin in 0.6 M NaCl at pH 7.0.[45]

The G' of myosin−polysaccharide increased with the increase of temperature, showing differences between different systems (Figure 4A). However, the G' did not decrease during heating at 48 °C. This phenomenon was similar to the effect of β-lactoglobulin added to myosin,[45] and the authors suggested that the relative importance of the various chemical bonds forming the mixed protein gel network might be different from those bonds forming the myosin gel network. The finding in our experiments suggested that the effects of the three polysaccharides were the same as the effect of β-lactoglobulin. The G' values of myosin−KCG mixtures were significantly higher than those of myosin−LBG or −WSC at the same temperature, which meant that the myosin−KCG interaction could lead to a higher elasticity of the sol/gel. These results corresponded with the gel hardness of myosin−KCG, which tended to be higher compared to the gels containing LBG or WSC. The mixtures of myosin with LBG and WSC showed similar G' evolution with heating up to 60 °C, but the myosin−WSC above 60 °C showed higher values of G'.

The G' increase of myosin−polysaccharide suggested the presence of fine gel structure containing polysaccharide sample, because G' is relative to the degree of three-dimensional network formation. Previous observations on protein−KCG systems showed synergistic effects between the two biopolymers on gelation properties at pH above the isoelectric point of proteins.[36,38,46] The main cause of these synergistic effects seems to be thermodynamic incompatibility between the different biopolymers in solution. At low pH values, sulfated polysaccharides and proteins seem to be completely compatible. When the pH increases above the isoelectric point of the protein, the net charge of the protein becomes negative. As a result, electrostatic repulsive forces between protein molecules and sulfated polysaccharides increase, promoting excluded volume effects. This may lead to a mutual concentration of both biopolymers in separate microphases and favor the gelation of the hydrocolloid.[39]

The tan δ of myosin gradually increased until 44 °C and then decreased in subsequent heating. However, the tan δ is <1 throughout heating (Figure 5), indicating that the solution is elastic more than viscous. The tan δ of myosin−KCG is similar to that of myosin−WSC, whereas the myosin−LBG mixtures had higher tan δ at the early stage of heating due to the ability of LBG to give very viscous solution.[47]

Cooling from 80 to 20 °C showed that G' values continued to increase as the temperature decreased (Figure 4B), which indicated an increase in gel hardness as the gels were cooled. Hydrogen bonds have been shown to become stronger as the temperature decreases.[48] The increase of G' is more pronounced ($P < 0.05$) in the presence of KCG and LBG, as indicated by the higher slope of the gelation curve, whereas WSC had no significant effect ($P > 0.05$) on the final elasticity of myosin gels during cooling. This observation suggested the anionic polysaccharide KCG and the neutral polysaccharide LBG could strengthen the cross-linked extent of myosin gel network when the thermal gelling of the myosin was irreversible, whereas the cationic polysaccharide WSC could not.

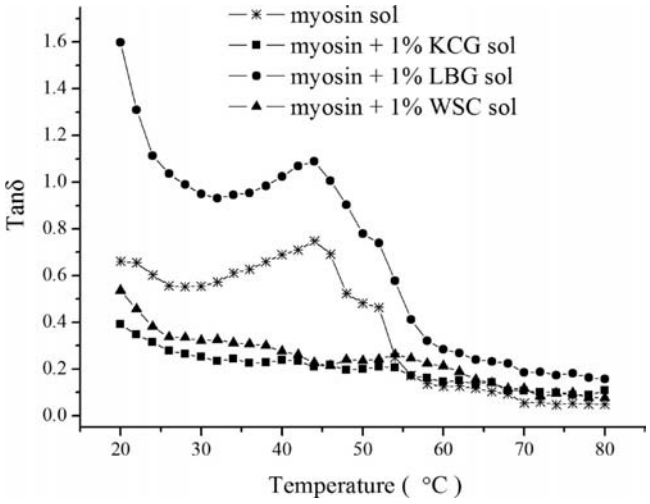

Figure 5. Effects of KCG, LBG, and WSC on the tan δ of myosin sols during heating.

In addition, the G' value is relative to the aggregation of protein[49,50] and the gel strength. Although the changes in G' of myosin−LBG were similar to those of myosin−WSC (Figure 4), the change of gel hardness is not entirely consistent with that of G'. The hardness could be also affected by other factors, such as interactions between protein and polysaccharide, [12] hydrogen bonding, and the microstructure of gels. The different extents of these influences on both hardness and G' might be why the gel hardness of myosin−LBG was much higher than that with WSC (Figure 2).

FT-IR. As shown in Table 2, myosin gel revealed transmittance bands at 3439 cm^{-1} (amide A, N−H or O−H stretching, PK1),[51] 1655 cm^{-1} (amide I, C═O and C═N stretching, PK3), and 1106 cm^{-1} (C−O and C−C stretching, PK4).[52] Among these bands, the amide A band between 3000 and 3500 cm^{-1} is known as the "water region" to assess and estimate the interaction of protein molecules with water,[51] and the amide I band between 1600 and 1700 cm^{-1} is commonly used for secondary structure analysis of proteins.[53]

Table 2. FT-IR Spectra Data for Three Kinds of Myosin−Polysaccaride Gels

		FT-IR spectra numbers (cm^{-1})			
	treatment	PK1	PK2	PK3	PK4
A	myosin gel	3439		1655	1106
B	myosin + 1% KCG gel	3358	3006	1655	1131
C	myosin + 1% LBG gel	3366	3006	1655	1106
D	myosin + 1% WSC gel	3439		1655	1106

The spectra of myosin and myosin−polysaccharide gels indicated similar patterns, which suggested that there was no major change in the functional groups of the myosin with the addition of polysaccharide. The addition of KCG and LBG caused the shift of NH-stretching left peak (PK1) to lower number and the appearance of the NH-stretching right peak (PK2). The shift of PK1 to lower number implied the

enhancement of hydrogen bonding within myosin molecules. A similar shift of this peak caused by interrupting intramolecular hydrogen bonding was also observed by Ma et al.[24] and García-García et al.[7] The enhancement of hydrogen bonding in gels might cause the increase of WHC (Figure 1) and gel hardness (Figure 2), but the effect of WSC on the spectral patterns of myosin gels was not obvious because the spectra did not change (Table 2).

Microstructure. The three-dimensional network structure of gels is an important determiner of sensory texture, rheological properties, and WHC. As shown in Figure 6, distinctive differences among gels were observed, which corresponded to the differences in gel hardness and WHC. The control myosin gels (Figure 6A) appeared slightly porous and consisted of protein aggregates. Cross-linking with KCG−myosin (Figure 6B) or LBG−myosin (Figure 6C) reduced the empty spaces and changed the aggregate gel structure into a fine-stranded gel network. Baeza et al.[39] also suggested that electrostatic cross-links between proteins and KCG might cause a reinforcement of the network structure. The structural difference between the control (myosin gel) and myosin−KCG/myosin−LBG gel may explain why the latter was harder (Figure 2) and more elastic (Figure 4A). On the other hand, Sun et al.[42] proposed that the finer gel network with smaller pore size held the majority of water in myofibrillar structures, and it could be concluded that the increases of the WHC in myosin−KCG and myosin−LBG might be related to a compact and dense myosin gel matrix. Although the added WSC could also cause a compact and dense myosin gel structure (Figure 6D), this addition could induce a more concavo-convex microstructure with larger cavities, a severer phase separation, and a bigger aggregation of myosin, which resulted in the weak gel hardness (Figure 2).

In addition, the amount of meat proteins interacting with polysaccharide (κ-carrageenan) to form complexes/gels increased with the concentration of meat proteins,[54] and the interactions between protein and hydrocolloid were the reason for the increased gel strength; higher protein concentration then affected the interaction by increasing gel strength.[12] These implied that the present results of low myosin concentration (20 mg/mL) could be applicable to the gelation of myosin with higher concentration in meat.

In conclusion, the additions of three polysaccharides could decrease the mobility (reducing the water relaxation time T_{22} and T_{23}) of inner water in myosin gel. The anionic polysaccharide KCG and the neutral polysaccharide LBG could strengthen the cross-linked extent of myosin gel network, thus inducing the increase of G' and forming a compact gel network with fine strands when the thermal gelling of the myosin irreversibly occurred. Moreover, KCG could enhance hydrogen bonding and electrostatic force, and LBG could enhance hydrogen bonding. These efficiencies resulted in the improvement of the WHC and hardness of myosin−KCG and myosin−LBG gels at 0.5−1.0% levels ($P < 0.05$). However, the weak molecular interaction between cationic polysaccharide WSC and myosin had an insignificant effect on the WHC and hardness of myosin−WSC gels ($P > 0.05$). Therefore, it is interesting to search for the anionic polysaccharide and neutral polysaccharide that can substitute for fat in the development of low-fat meat products.

copigmentation cofactors.[15,16] However, to date there are scarce studies about the addition of these natural sources during red winemaking, probably because of the difficulty of performing this process due to the different harvesting dates for white and red grapes. Some of these studies have revealed that the effects on the final quality of the wine are different depending on the winemaking stage and duration of the application and the dose applied as well as the particular phenolic potential of the grapes in the mixture.[7,17−19] Thus, further investigations are needed to better understand the contribution of these incorporated compounds to wine color and color stability.

Generally, white grapes are harvested several weeks before red grapes. Nevertheless, in some Mediterranean regions (such as Andalucía, southwestern Spain, warm climate) red and white grape varieties with similar ripening periods are usually harvested at the same time. In this case, skins and seeds from white grape pomace are available just at the moment they are needed to be added to red winemaking. This winemaking technique may be therefore interesting as an alternative to traditional maceration to improve the quality of red wines from a warm climate as well as to exploit the white winemaking residues.

Therefore, the main objective of this work is to study the impact of adding supplementary amounts of skins and seeds from white grape pomace (var. Pedro Ximenez) during the fermentative maceration on young Syrah wines from a warm climate, especially in terms of their phenolic composition and color stability.

MATERIALS AND METHODS

Vinification Protocols and Samples. *Vitis vinifera* var. Syrah (red grape) and Pedro Ximenez (white grape) grown in the Montilla-Moriles Designation of Origin (Cordoba, southeastern Spain), with the typical climatological conditions of warm climate regions, were used in this study. These cultivars were selected because they have similar periods of ripeness (end of August) and represent the main and more extensively cultivated red and white grape varieties in the region.

Pedro Ximenez grape pomace (PXGP), the main organic vinification byproduct from Pedro Ximenez grapes, was used in the vinification experiments to ferment with Syrah grapes.

About 40 kg of industrially pressed PXGP was provided by La Unión Winery Coop. (Cordoba, Spain). It was collected from the 2012 vintage after Pedro Ximenez grapes were processed for winemaking at optimum technological maturity (density = 13.6 °Baumé). As usual, in traditional white vinifications the grapes are destemmed, so it is assumed that the pomace generated after vinification contains only some stems, which were manually separated. Therefore, the raw material used in the vinification experiments was composed by a mixture of skins and seeds.

Syrah grapes were harvested in 2012 vintage at optimum technological maturity (density = 13.1 °Baumé; total acidity = 5.21 g/L; and pH, 3.61) and good sanitary conditions. About 360 kg of grapes was manually harvested, placed in 15 kg plastic boxes, and transported to an experimental wine production center belonging to the Instituto Andaluz de Investigación y Formación Agraria, Pesquera, Alimentaria y de la Producción Ecológica (IFAPA, Cordoba, Spain).

Nine vinifications were carried out on a pilot scale using 50 L stainless steel tanks. For each vinification, 40 kg of Syrah grapes was processed. Grapes were destemmed and crushed, and the must with solid parts was homogenized and distributed into tanks for maceration. Three types of Syrah wines were elaborated, in three replicates for each one (n = 3), with the following mixtures of Syrah grapes and PXGP: (a) one monovarietal wine elaborate with 100% Syrah grapes (SY); as control; (b) two wines containing the same amount of Syrah grapes and additional 10 and 20% of PXGP (w/w as grapes). Thus, to elaborate PXGP 10% wines, 4 kg of PXGP was added to 40 kg of Syrah grapes in each replicate. In the case of PXGP 20% wines, 8 kg of PXGP was added to 40 kg of Syrah grapes for each replicate. An adequate homogenization among PXGP and Syrah grapes was assured with a gradual addition at crushing.

An identical red winemaking procedure was used for all assays. Enological treatments were adjusted at the same levels for all of the assays: 60 mg/L total sulfur dioxide and 7 g/L of total titratable acidity by adding tartaric acid. Fermentative alcoholic maceration was induced by inoculating *Saccharomyces cerevisiae* selected yeast (TTA, 30 g/hL, 25 °C, Agrovin, Spain) and occurred at controlled temperature (20−25 °C). Fermentation caps were punched down once a day during the on-skin maceration period, which lasted 14 days. After this, the mash was drawn off to remove the skins and other solid parts, and the free-run musts were left to finish the fermentation under the same conditions. To guarantee the development of malolactic fermentation, selected *Oenococcus oeni* lactic acid bacteria (VINIFERM Oe 104, UFC/mL > 10^6; Agrovin, Spain) were inoculated at the rate of 10 mL/hL at the end of alcoholic fermentation. When fermentative processes were finished, the wines were racked in 15 L stainless steel tanks and held for 2 weeks at 4 °C. They were bottled 30 days later and stored at 10−15 °C until analysis.

Must and wine samples (100 mL) were taken at the initial point or grape crushing (I), at the middle of the fermentative alcoholic maceration (FAM), just after the skin removal (SR), at the end of malolactic fermentation (MLF), and 1, 2, 3, 4, and 5 months after fermentative processes were finished (bottled wines).

Enological Parameters. The conventional enological parameters of wines (Table 1) were evaluated according to the official methods established by the European Union.[20]

Table 1. Conventional Analytical Data (Means ± SD, n = 3) of Final Red Wines

	maceration treatment[a]

[a]SY, 100% Syrah grapes; PXGP 10% and PXGP 20%, fermentation of Syrah grapes with PXGP at 10 and 20% (w/w), respectively.

Copigmented and Polymerized Anthocyanin Determination. The contribution of copigmented anthocyanins to the total wine color at pH 3.6 (% copigmented anthocyanins) and the degree of anthocyanin polymerization (% polymeric pigments) were determined following the method proposed by Boulton.[21] The wine sample pH values were first adjusted to 3.6 using 1 M NaOH or HCl.

Total Phenolic Content. Total phenolic content was determined using a modification of the Folin−Ciocalteu method.[22] Absorbance was measured at 765 nm, and the results were expressed as milligrams of gallic acid per liter (mg GAE/L).

Phenolic Compound Analysis by HPLC-DAD. An Agilent 1200 chromatographic system equipped with a quaternary pump, an UV−vis diode-array detector, an automatic injector, and ChemStation software (Palo Alto, CA, USA) was used for the HPLC separation, identification, and quantification of phenolic compounds. Prior to direct injection, the samples were filtered through a 0.45 μm nylon filter (E0034, Análisis Vínicos, Spain). All analyses were made in triplicate.

[a]SY, 100% Syrah grapes; PXGP 10% and PSGP 20%, fermentation of Syrah grapes with PXGP at 10 and 20% (w/w), respectively. Different letters in the same row indicate significant differences ($p < 0.05$). nd, not detected.

The anthocyanin identification was carried out following the method described in Heredia et al.[23] Anthocyanins were separated using a Zorbax C18 column (250 × 4.6 mm, 5 μm particle size) maintained at 38 °C. Acetonitrile/formic acid/water (3:10:87) as solvent A and acetonitrile/formic acid/water (50:10:40) as solvent B were used. The elution profile was as follows: 0−10 min, 94% A−6% B; 10−15 min, 70% A−30% B; 15−25 min, 60% A−40% B; 25−35 min, 55% A−45% B; 35−40 min, 50% A−50% B; 40−42 min, 40% A−60% B; 42−43 min, 94% A−6% B. The flow rate was 0.8 mL/min, and the injection volume was 50 μL. UV−vis spectra were recorded from 200 to 800 nm with 2.0 nm bandwidth. The quantification was made at 525 nm by comparing the areas and retention times with those of the malvidin-3-glucoside standard, and anthocyanin concentration was expressed as milligrams per liter. Sums of glucosides, acetates, and *p*-coumaric derivatives were estimated by summing the content of each member identified by HPLC, respectively, and the sum of anthocyanins was obtained by summing the content of all anthocyanin compounds identified.

The identification of the noncolored phenolic compounds (low molecular weight) was carried out following the method described in Gordillo et al.[14] Individual phenolic compounds were separated using a Zorbax C18 column (250 × 4.6 mm, 5 μm particle size) maintained at 40 °C. Acetonitrile/formic acid/water (3:10:87) as solvent A and acetonitrile/formic acid/water (50:10:40) as solvent B were used. The flow rate was 0.63 mL/min, and the injection volume was 50 μL. UV−vis spectra were recorded from 200 to 800 nm with a bandwidth of 2.0 nm. The quantification was made at 280, 320, and 360 nm by comparing the areas and the retention times with the gallic acid, caffeic acid, (+)-catechin, and quercetin standards, respectively. Phenolic compound concentration was expressed as milligrams per liter. Sums of phenolic acids, monomeric flavanols, and flavonols were also estimated by summing the content of each member identified by HPLC, respectively.

Colorimetric Analysis. Color measurements were made with a Hewlett-Packard UV−vis HP8453 spectrophotometer (Palo Alto, CA, USA), using 0.2 cm path length glass cells and distilled water as reference. The whole visible spectrum (380−770 nm) was recorded (λ = 2 nm), considering the Illuminant D65 and 10° Observer as references. Wine samples were centrifuged (4190*g*, 5 min), and the supernatants were filtered through Millipore-AP20 filters (Bedford, MA, USA) prior to the spectrophotometric analysis.

The CIELAB parameters (L^*, a^*, b^*, C^*_{ab}, h_{ab}) were determined by using the original software CromaLab,[24] following the recommendations of the Commission Internationale de L'Eclairage.[25] The L^* value is the vertical axis and defines the lightness, the property according to which each color can be considered as equivalent to a member of the

gray scale, between black and white, taking values within the range of 0−100, respectively. The a^* and b^* values represent the chromaticity scalar coordinates, which in turn represent opponent red−green and blue−yellow scales.

From L^*, a^*, and b^*, other parameters are defined, such as hue (h_{ab}) and chroma (C^*_{ab}). Hue angle (h_{ab}) is the attribute according to which colors have been traditionally defined as red, green, etc. On the other hand, the chroma (C^*_{ab}) is the attribute that allows each hue to be determined by its degree of difference in comparison to a gray color with the same lightness. Moreover, these colorimetric parameters can be distinguished as quantitative or qualitative color attributes as they indicate a quantitative contribution to color (L^* and C^*_{ab}) or qualitative one (h_{ab}).[26]

Also, the color differences (ΔE^*_{ab}) were calculated between the samples to state the implications of the maceration treatments on the color of the final wines, as well as to assess the color stability. It was calculated as the Euclidean distance between two points in the three-dimensional space defined by L^*, a^*, and b^*: $\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$.

Statistical Analysis. All statistical analyses were performed using Statistica v.8.0 software.[27] Univariate analysis of variance (ANOVA) was applied using the general linear model program to establish whether mean values of the physicochemical data obtained in each studied point differed significantly among the three types of wines (SY, PXGP 10% and PXGP 20%). The means values of each set of samples (n = 3) were compared by the Tukey test at a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Enological Parameters. No statistically significant difference was found among control wines and wines fermented with additional amounts of PXGP for any enological parameter analyzed. These results indicate that the general wine composition was not affected by the maceration treatment applied (Table 1).

The low values found in wines for the reducing sugars and malic acid concentration (<2.0 g/L and <0.01 mg/L, respectively) denoted the correct development of fermentative

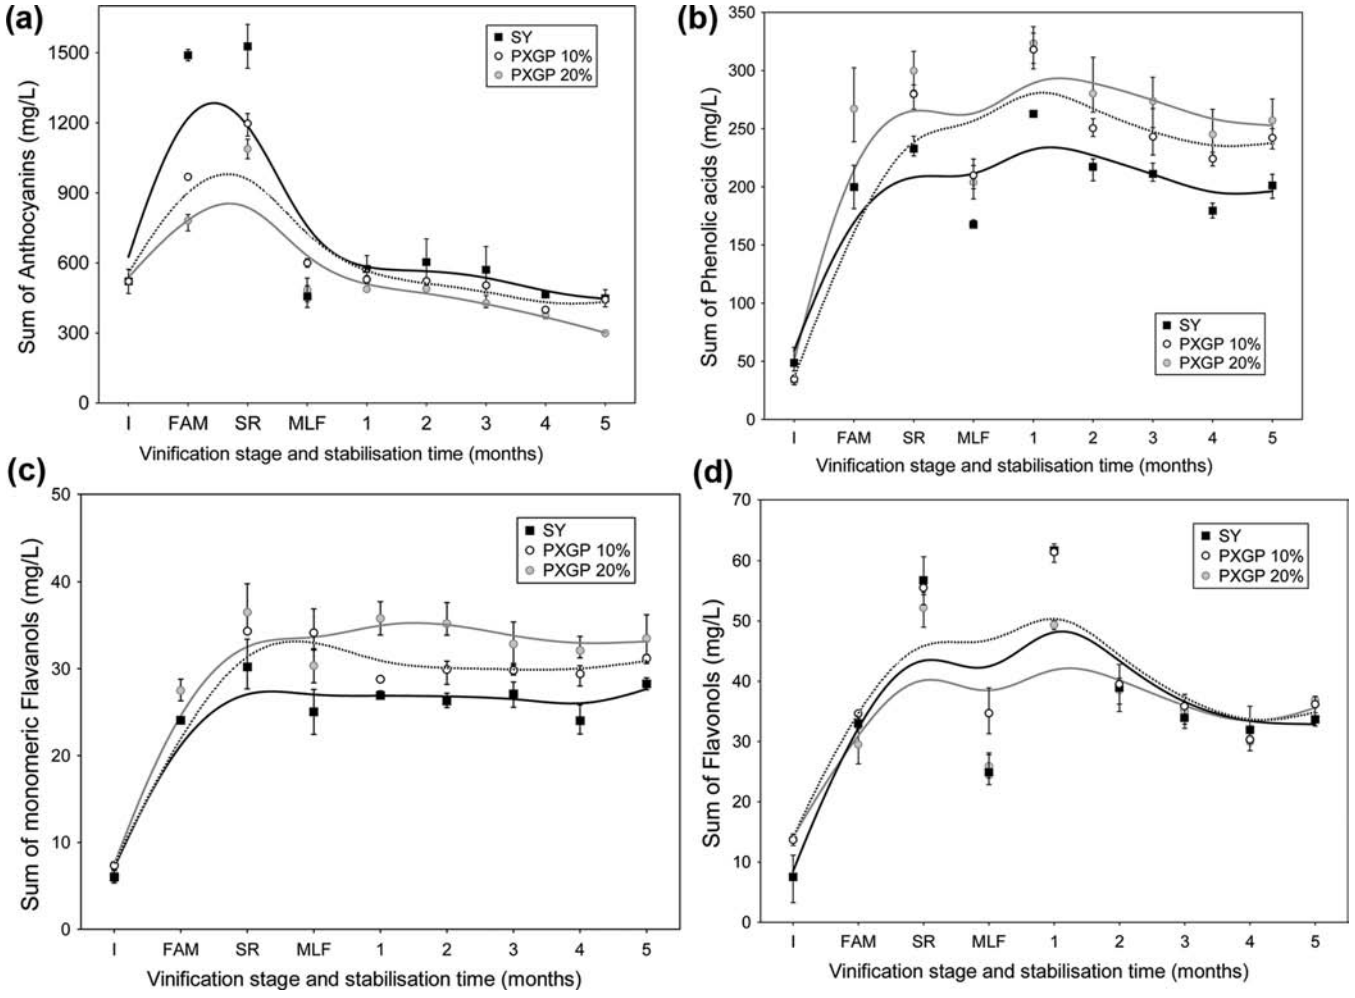

Figure 1. Evolution of the main phenolic families (mg/L ± SD, $n = 3$) in control wines (SY) and wines fermented with PXGP (10 and 20%) during the vinification process: (a) sum of anthocyanins; (b) sum of phenolic acids; (c) sum of monomeric flavanols; (d) sum of flavonols.

processes. The alcohol degree reached when fermentative processes were finished (between 12.9 and 13.2% v/v) was in accordance with the sugar concentration of Syrah grapes at ripeness. The good preservation state of wines was confirmed by the low values of the volatile acidity (around 0.5 g/L). As expected, all finished wines showed very similar values of total acidity (between 5.6 and 5.8 g/L as tartaric acid), pH (around 3.3 units), and free and total sulfur dioxide contents (<10 and between 44.3 and 50.6 mg/L, respectively) because these enological parameters were adjusted at the same levels for all assays.

Phenolic Composition and Changes during Vinification. Twenty-five monomeric phenolic compounds were identified and quantified in wines by HPLC. The comparative chromatographic analysis of samples revealed that control and fermented wines with PXGP did not differ in their phenolic profile in qualitative terms. It included several anthocyanin pigments and colorless phenols belonging to diverse phenolic families: 11 anthocyanins (including nonacylated, acetylated, and *p*-coumaroylated derivatives), 5 phenolic acids (gallic, GRP, *trans*-caftaric, *trans*-coutaric, and syringic), 2 monomeric flavanols ((+)-catechin and (−)-epicatechin), and 8 flavonols (myricetin-3-glucuronide, myricetin-3-glucoside, quercetin-3-glucuronide, quercetin-3-glucoside, laricitrin-3-glucoside, kaempferol-3-glucoside, isorhamnetin-3-glucoside, and syringetin-3-glucoside).

Table 2 summarizes the concentrations for the mentioned anthocyanins (mg/L) together with the percentage of copigmentation and polymerization of wines (mean ± SD, $n = 3$), showing the statistical differences among treatments at the end of the fermentative maceration (skin removal) and after 5 months of stabilization. In the same way, Table 3 summarizes the information relative to the colorless monomeric phenols (mg/L) and the total phenolic content (as mg GAE/L).

Results showed that the addition of PXGP at the beginning of fermentation causes a significant impact on the concentration of the most individual compounds identified and on the physicochemical transformations in which they are involved (copigmentation and polymerization). However, the effect was not the same for the different phenolic families and depended on the proportions of PXGP added. An accurate evaluation of the changes on the total levels of anthocyanins, phenolic acids, monomeric flavanols, and flavonols during the whole process of vinification allowed the stages at which the applied treatments had a greater influence on the chemical quality of wines to be established (Figure 1).

During the period of fermentative maceration, all wines elaborated with supplementary amounts of PXGP had lower levels of anthocyanins than wines elaborated by traditional maceration, although they were richer in phenolic acids and monomeric flavanols. The effect on the flavonols was quite different because additions of 10% PXGP had no significant

dx.doi.org/10.1021/jf405574x | J. Agric. Food Chem. 2014, 62, 2663−2671

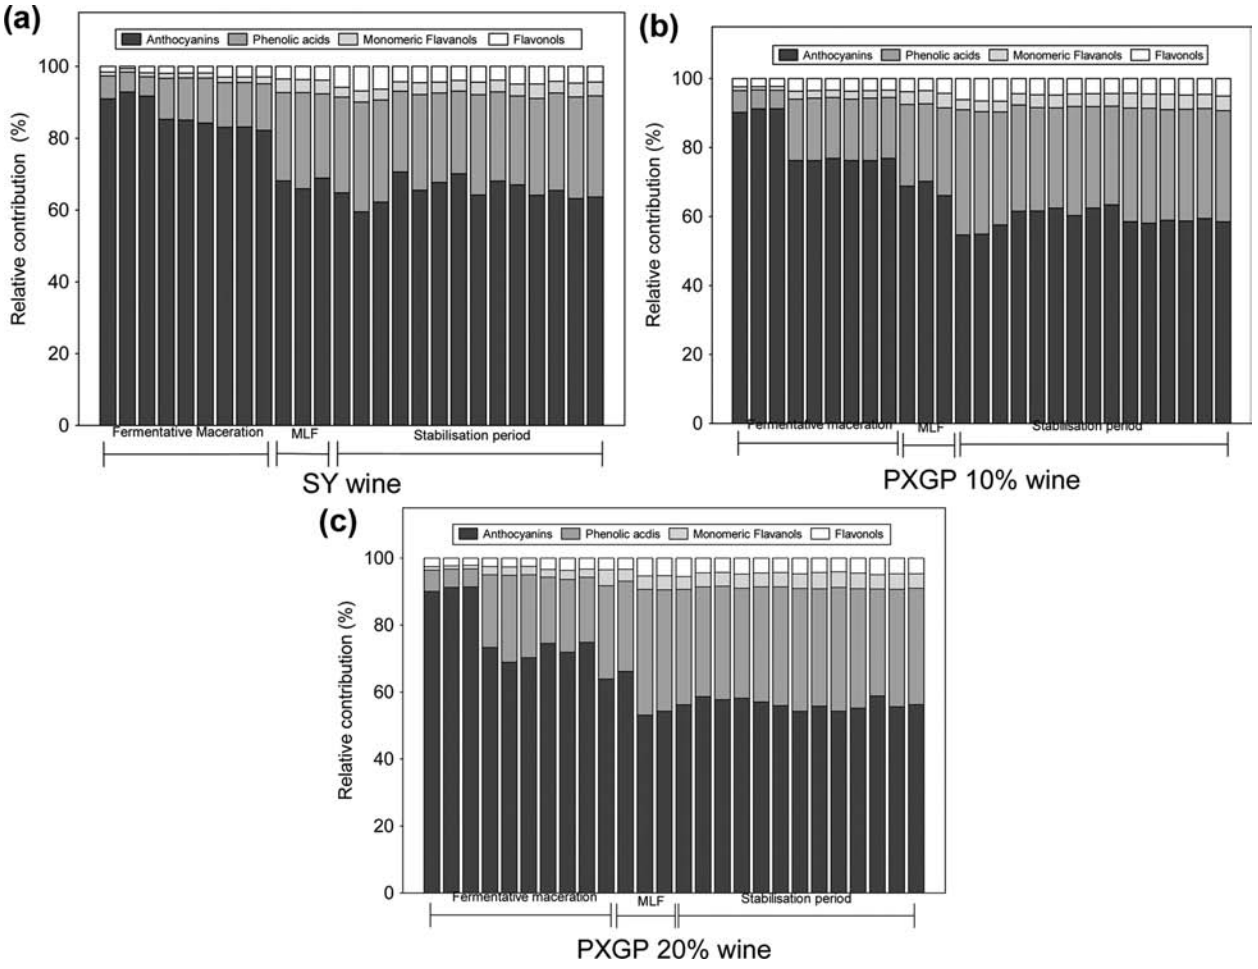

Figure 2. Relative proportion of the different phenolic families during the vinification process, according to the maceration treatment applied: (a) Syrah wines, traditional red wine vinification; (b) PXGP 10% wines, fermentative addition of PXGP at 10% (w/w); (c) PXGP 20% wines, fermentative addition of PXGP at 20%.

effect on the global content, but at higher proportions (20%) it was slightly reduced. Analogous chemical behavior was found by other authors in similar vinification experiments because two competitive effects are expected to occur simultaneously: (1) incorporation of the phenolics contained in the solid parts of grapes enhances the pool of copigmenting cofactors in the wine matrix; and (2) anthocyanin adsorption to the extra amounts of skin and seeds causes loss of color.[9,15,17]

In our winemaking conditions, significantly higher contents of gallic and syringic acids, (+)-catequin, quercetin-3-glucuronide, quercetin-3-glucoside, and syringentin-3-glucoside were found in PXGP wines at the end of the skin contact period, the effect being stronger when 20% was added (Table 3). Thus, adding PXGP at the rates studied favored the enrichment of Syrah wines in specific colorless phenolics, especially those cofactors having limited solubility.[28] Most of these compounds have been described as good copigments,[6] which support the higher grade of copigmentation reached by PXGP wines at skin removal (%CA = 34 and 27 versus 22% in PXGP 20%, PXGP 10%, and control wines).

On the other hand, the lower anthocyanin or flavonol content (only in the case of PXGP 20% wines) suggested the partial adsorption of pigments and even other phenolic compounds by extra amounts of skins and seeds, which could be especially drastic if too high proportions are added to the fermentation mash,[7] as occurred with PXGP at 20%.

Nevertheless, although the initial pigment content clearly differed for the treatments, the differences among them tended to diminish as the stabilization period proceeded (Figure 1a). A gradual decrease of total monomeric anthocyanins after skin removal was observed in the three wines, being more intense for control and PXGP 20% wines. As a consequence, the final values of total anthocyanins were almost the same order of magnitude for control and PXGP 10% wines (448.7 and 431.3 mg/L, respectively), whereas PXGP 20% wines showed the significantly lowest content (298.7 mg/L). Moreover, 10% PXGP addition seemed to protect to a larger extent the presence of bluish forms of anthocyanins (delphinidin-3-glucoside and petunidin-3-glucoside) and some acylated derivatives having chemical characteristics that great affect copigmentation (petunidin-3-acteyl-glucoside and malvidin-3-*p*-coumaroyl-glucoside), because significantly higher contents were found in the final wines.

With regard to the three groups of colorless phenols, wines elaborated with the addition of PXGP maintained the highest levels of phenolic acids (257.8 and 241.9 versus 201.3 mg/L, in 20%, 10%, and control wines, respectively), monomeric flavanols (33.5 and 31.2 versus 28.2 mg/L, respectively), and flavonols (36.2 and 36.1 versus 33.6 mg/L, respectively), and also the final total phenolic content (2346.0 and 2278.2 versus 2036.6 mg/L, respectively).

[a]SY, 100% Syrah grapes; PXGP 10% and PXGP 20%, fermentation of Syrah grapes with PXGP at 10 and 20% (w/w), respectively. Different letters in the same row indicate significant differences ($p < 0.05$).

Furthermore, the contribution of each group of pigments to the total color (copigmented and polymeric pigments) evolved differently depending on the maceration applied, which seemed to be related to the relative proportions of the different phenolic families in each wine (Figure 2). Adding 10% PXGP led to wines with the highest degree of polymerization (%PP = 70.6), meaning a higher proportion of more stable pigments than control wines (%PP = 66.7). Probably, the lower content of pigments in PXGP 10% wines at skin removal could be balanced by the relative highest proportion of copigments extracted in comparison with control wines, resulting in a better pigment/copigment ratio and higher chemical stability. On the contrary, the PXGP 20% wines reached the lowest proportion of polymeric pigments (%PP = 54.1%). This fact shows the difficulty of those wines to convert the earlier copigmentation complexes into more stable pigments despite having important amounts of copigments. Most likely, the significantly lower content of anthocyanins and flavonols from the first steps of vinification was insufficient to achieve higher chemical stability during stabilization.[2,29]

Color Characteristics and Changes during Vinification. The evolution of CIELAB color parameters (L^*, C^*_{ab}, and h_{ab} CIELAB parameters) during the winemaking processes is shown in Figure 3, where the mean value and standard deviation for these variables are included for each set of samples.

As determined from the whole set of data, red wine color evolved in a similar way both in control and in PXGP wines. A net increase of chroma (C^*_{ab}) and decreases of lightness (L^*) and hue (h_{ab}) due to the pigment extraction characterized the fermentative maceration, whereas all of the parameters became gradually stable after the skin contact period because of the stabilization processes.

As can be seen, the maceration treatments applied induced significant differences in the color characteristics of wines and their stability depending on the doses of PXGP added. As expected, the higher color extraction corresponded to control wines, which showed the lowest values of lightness (L^*) and highest values of chroma (C^*_{ab}) at skin removal, indicating darker and more saturated color than PXGP wines (Table 4). These results were consistent with the higher content of anthocyanins in control wines during the fermentative maceration period, which reflects the better balance between the extraction and adsorption of pigments with respect to wines elaborated with higher amounts of pomace than are naturally found in a traditional red wine vinification.

However, it is interesting to note how the particular changes during the stabilization in the phenolic fractions influenced the final color of wines (Table 4), in both quantitative (C^*_{ab} and L^*) and qualitative (h_{ab}) terms.[26] At the end of the stabilization period, the addition of PXGP at 10% led to wines with comparable content in pigments relative to wines elaborated by traditional maceration, but with higher proportions of bluish anthocyanins, copigments, and polymeric pigments, which resulted in lighter wines but with comparable quantity of color (L^* = 60.24 ± 0.67 versus 53.81 ± 1.44 u; C^*_{ab} = 40.49 ± 1.06 versus 41.22 ± 0.91 u) and more notably bluish hues (negative values of hue; h_{ab} = −3.17° ± 0.63 versus −1.66° ± 0.13, in PXGP 10% and control wines, respectively).

The effect on these analytical parameters was the opposite when 20% of pomace from PXGP was added, which can be attributable to the lower phenolic potential during the whole process of vinification. In this case, it was related to significantly lighter wines with less saturated color (L^* = 67.70 ± 0.72 u; C^*_{ab} = 27.40 ± 0.78 u). In terms of total color, the highest color difference values (ΔE^*_{ab}) were found between control wine and 20% PXGP wine (14.38 u) and the least one between control wine and 10% PXGP wines (3.93 u), although in all cases they were visually perceptible (ΔE^*_{ab} > 3.0 CIELAB units).[30]

The assessment of the color differences (ΔE^*_{ab}) occurring from the skin removal to the end of the stabilization period (5 months) allowed evaluation of the color stability of each wine. The lowest values of color difference were obtained for PXGP 10% wines compared to control and PXGP 20% wines (ΔE^*_{ab} = 6.36 versus 9.53 and 8.81 u, respectively), indicating lower color variation and, thus, higher color stability. As can be observed in Figure 3b,c, the chroma decreased and the hue increased toward 0° (redness color) in all wines. This observation means that the color variation that took place during stabilization was due to a decrease of the quantity of color and bluish hue of wines (lower values of C^*_{ab} and higher values of hue). Specifically, these chromatic modifications were less intense in PXGP 10% wines (ΔC^*_{ab} = −5.7 versus −7.7 and −8.6 u; Δh_{ab} = +1.39° versus +1.97° and +2.37° in 10%, 20%, and control wines, respectively). Chemically, this may be explained by the lower loss of monomeric anthocyanins and the higher content in more stable pigments in PXGP 10% wines as a result of the phenolic compounds extracted from PXGP, which favored a better pigmet/copigment ratio and a more effective stabilization of wine color. Thus, it was confirmed that the addition of limited amounts (10%) of skins and seeds of PXGP during fermentation led to wines with more stable color that kept their vivid bluish tonalities for a longer time, and these characteristics are highly appreciated in young red wines. In the case of the higher proportions tested (20%), the adsorption of pigments during fermentation seems to have a stronger effect on the color than the copigmentation (color stabilization) due to the cofactors extracted from PXGP, as reported in the literature.[15]

On the basis of the results, it has been proved that the addition of a limited amount of skins and seeds from white grape pomace during the fermentative step of the winemaking process represents an interesting enological practice to improve the phenolic potential and color characteristic of young Syrah wines from a warm climate. The effectiveness of the fermentative addition was demonstrated by the increase of the concentration of several colorless phenolic compounds (copigments) and intermolecular copigmentation reactions in wines. Potential benefits observed in Syrah wines include greater chemical complexity and higher development of polymerization, as well as better color characteristics and color stability. However, the global effect clearly depends on the proportions of white skins and seeds applied. When too high a proportion of pressed grape pomace (20% w/w) is added to the fermentation mash, it may damage wine quality due to a higher adsorption of phenolic compounds during maceration (pigments and copigments), resulting in a net loss in color in final wines. Thus, not all proportions are acceptable to obtain phenolic and color enhancement effects.

and water phases, have intermediate wettability, and remain intact over the lifetime of the emulsion system.[16] Recently, de Folter et al.[15] have prepared O/W Pickering emulsions with droplet sizes in a range of 10−200 μm by zein colloidal particles through an antisolvent precipitation procedure. The zein-stabilized emulsions were highly unstable to creaming, but possessed long-term stability against coalescence at pH above and below the isoelectric point of zein. Our recent study has shown that incorporation of zein colloidal particles at the surface of rthe oil droplet can act against coalescence during the formation of emulsion-based films by Pickering stabilization.[17]

In practice, there have been multiple challenges for the preparation of Pickering emulsions, including the aggregation of particles in bulk phase, low diffusive mobility that resulted low interfacial adsorption, and limited surface coverage.[16] In our previous study,[18] we have found that soy lipophilic protein (LP), one of the soy storage proteins and a natural complex of hydrophobic membrane protein and biosurfactant phospholipids, self-assembles to form nanoparticles by ultrasonical treatment. These nanoparticles have an improved diffusive mobility to the interface and then form a complex interface of aggregated protein particles and phospholipids, providing the oil droplets with the synergic improvement in coalescence and flocculation stability of emulsion.

Zein, the predominant food grade protein in corn, is a particularly abundant material extracted from corn gluten meal (CGM) and has great potential for commecialization in various industrial applications.[19] Zein with a high proportion (>50%) of hydrophobic amino acids, for example, leucine, proline, and alanine, is insoluble either in water or in oil, but it can be dissolved in a water−ethanol mixture[19] and low molecular weight charged surfactant, such as sodium dodecyl sulfate (SDS) solution.[20,21] Here we describe a method to prepare soluble complexes of hydrophobic corn protein zein colloidal particles and sodium stearate (SS), an anionic surfactant, to overcome problems exhibited by zein particles only and to produce food protein based in a Pickering emulsion with high stability. Moreover, a protein-based Pickering emulsion as a starting template for preparing oil gels without *trans* and saturated fats is also the goal of this study.

MATERIALS AND METHODS

Materials. Zein and SS (>99%) were purchased from Sigma Chemical Co. (St. Louis, MO, USA) without further purification. Low acyl gellan gum available from Kelco (Atlanta, GA, USA) was provided by Berger & Baker Food Industry Co. Ltd. (Guangzhou, China). Polydimethylsiloxane (PDMS, Sylgard184) was purchased from Dow Corning Co. (Midland, MI, USA). All other chemicals used were of analytical grades, and all solutions and dispersions were prepared using Milli-Q water.

Dispersion of Zein Colloidal Particles. Zein (0.5 wt %) was dissolved in water containing SS at concentrations of 2.5, 5, and 10 mM, respectively, under ultrasonic shear (Sonic Ruptor 400 Ultrasonic Homogenizer, OMNI, USA) with the power of 30%. The temperature of the aqueous phase was maintained below 25 °C by using an ice bath under ultrasonic shear.

Particle Size and ζ-Potential Measurements. The measurements of size distribution, ζ-potential, and polydispersity index (PDI) of zein particles were performed using a Nano ZS Zetasizer instrument (Malvern Instruments, Worcestershire, UK). Samples were diluted to 1 mg/mL with water before loading to the cuvette. All measurements were carried out at 25 °C in triplicate. A refractive index of 1.450 was used for zein dispersion and 1.331 for the continuous phase. The apparent hydrodynamic radius (R_h) of protein samples was analyzed by means of the "cumulants" method[22] and Stokes−Einstein equation (eq 1) using Dispersion Technology Software (DTS) (V4.20).

$$D = K_B T/6\pi\eta r \quad (1)$$

D is the diffusion coefficient, K_B is the Boltzmann constant, T is the absolute temperature, η is the medium viscosity, and r is the radius of the particle.

Morphology of Zein Particles Adsorbed at the Oil−Water Interface. The morphology of the zein particle monolayer trapped at the oil−water interface was observed by gel trapping technology (GTT) described by Paunov[23] with modifications. An aliquot of 5 mL of 1.0 wt % gellan gum dispersion in a 10 mL beaker was heated to 50 °C to dissolve and hydrate. Then 0.5 mL zein dispersions modified with different SS concentrations were added into the gellan gum solution, and 2 mL of soybean oil was added to form an oil−water interface. The system was kept at 50 °C for 30 min and stirred mildly with a magnetic stirrer to ensure the sufficient adsorption of zein particles at the oil−water interface. To solidify gellan gum, 2 mM $MgCl_2$ was injected into the aqueous phase with a syringe and the temperature was cooled for 1 h at ambient temperature (25 °C). The top oil phase was removed and then was replaced with 2 mL of PDMS silicone elastomer and cured for 24 h at ambient temperature. The particle monolayer on the PDMS surface could be peeled off from the aqueous gel and imaged with a field emission scanning electron microscope (SEM, LEO 1530 VP, Oberkochem, Germany).

Surface Protein Loading Measurement. The content of protein adsorbed at the oil−water interface was determined according to the method described by Akhtar et al.[24] with modifications. Freshly prepared emulsions (described as below) were centrifuged at $1 \times 10^5 g$ for 30 min at 20 °C using a Himac CS150NX Micro Ultracentrifuge (Hitachi Koki Co. Ltd., Tokyo, Japan) with an S140AT rotor. Five hundred microliters of the supernatant was collected for analysis of the protein in continuous phase. After that, the cream layers and the rest of the supernatant were carefully removed. The precipitate was carefully washed twice with water to remove any residual cream or protein in continuous phase, and after that, the precipitate was heat-dried at 50 °C for 6 h. The composition of protein adsorbed at the oil−water interface was determined using SDS-PAGE. Dispersed protein in aqueous phase was determined by using the micro-Kjeldahl method (N × 5.71) and recorded as M_D (mg), precipitated protein was determined by weighing and recorded as M_P (mg), and the weight of protein added into the emulsions was recorded as M_I (mg), so the weight of adsorbed protein was M_A (mg) = $M_I - M_D - M_P$. The surface loading of protein can be calculated with eq 2

$$\text{surface protein loading (mg/m}^2) = (M_A \times d_{3,2})/(6 \times V \times \Phi_{oil}) \times 10^{-2} \quad (2)$$

where $d_{3,2}$ (μm) is the average droplet size of the emulsions, V (mL) is the volume of emulsions, and Φ_{oil} is the volume fraction of the oil in emulsions.

Contact Angle Measurement. Contact angles of Milli-Q water on solid zein film were measured at 25 °C with the method of sessile drop by a contact angle analyzer (OCA 20 AMP, Dataphysics Instruments, Germany). A droplet of water (constant 4 μL) was deposited on the film surface with a precision syringe. The drop image was recorded immediately just after dropping from the syringe by a video camera, and the profile of the droplet was numerically solved and fitted to the Laplace−Young equation. Ten parallel measurements were performed for each film. Solid zein film was prepared by the method of participation as follows: ultrasonic treated zein dispersion (0.5 wt %) was centrifuged at 10000g for 20 min, and the supernatant was dripped on the cleaved mica and heat-dried at 40 °C for 8 h. To prepare an oil film, soybean oil was spread on the cleaved mica, and then the mica was inclined to allow the redundant oil to flow away.

Preparation and Characterization of Emulsions and Oil Gels. The O/W emulsions were prepared by homogenizing the mixture of 10 wt % soybean oil and 0.5 wt % zein particle dispersion at 10000 rpm for 2 min by using a T25 Ultraturrax homogenizer (IKA, Staufen, Germany). Oil gels were obtained by one-step freeze-drying of the

precursor emulsions (10 mL) over 24 h on a DELTA1-24/LSC freeze-dryer (Martin Christ Gefriertrocknungsanlagen GmbH, Germany) using room temperature in the drying chamber, −60 °C for the cooling unit, and a vacuum of 0.34 mbar. Emulsion droplet size distributions were measured by Mastersizer 2000 (Malvern Instruments Co. Ltd.) at 25 °C. The particle sizes measured are reported as the volume-weighted mean diameter $d_{4,3} = \Sigma n_i d_i^4 / \Sigma n_i d_i^3$, where n_i is the number of droplets with diameter d_i. Refractive indices of 1.46 and 1.33 were used for soybean oil and water, respectively. The microstructure of the emulsion was imaged by a TCS SP5 confocal laser scanning microscope (CLSM, Leica Microsystems Inc., Heidelberg, Germany), using an argon krypton laser having an excitation line of 488 nm and a helium neon laser (He/Ne) with excitation at 633 nm. Aliquots (1 mL) of emulsions were stained with 40 μL of staining solution containing 0.1 wt % Nile Red (for protein) and 0.01 wt % Nile Blue (for oil). Emulsion stability was assessed with the heating−salting test we used previously.[18] Emulsions were heated at 90 °C for 30 min in the presence of 200 mM NaCl and then analyzed for drop size distribution and mean droplet diameters ($d_{4,3}$) described above. The changes in emulsion microstructure were observed by a BX51 light microscopy (Olympus Optical Co. Ltd., Tokyo, Japan).

Statistical Analysis. Unless specified otherwise, three independent trials were carried out, each with a new batch of sample preparation. The results are presented as means ± standard deviations. Analysis of variance (ANOVA) was performed on the data using the SPSS 13.0 statistical analysis system.

RESULTS AND ANALYSIS

Complexes of Zein Particles and SS. The solubilization of zein in SDS solution occurs in two distinct stages. SDS at 4 mM, which is close to its critical micelle concentration (CMC, ≈8 mM), is incorporated into the zein structure, forming zein−SDS complexes, followed by the formation of a complete unfolding chain of zein polypeptides until the concentration of SDS reaches 200 mM.[20,21] In this study we chose SS to stabilize zein protein due to its relatively low CMC value (≈0.4 mM), which should be attributed to its strong binding capacity on the hydrophobic protein.[25]

As expected, the water-insoluble zein agglomerates could be solubilized with SS dispersion above the CMC under ultrasonic shear (Figure 1). The SS dispersions used in this study were around 10 times the CMC (2.5, 5, and 10 mM, respectively), which is predominantly self-assembled micelles with very low monomer concentration (Figure 1B, appeared turbid). Dynamic light scattering (Figure 2) revealed that the hydrodynamic size, polydispersity index (PDI), and ζ-potential of the obtained zein colloidal particles decreased sharply with increasing SS concentration up to 5 mM and then remained constant until 20 mM. Although the zein dispersion without SS had a pH value of 3.7, the addition of SS raised it to a basic range (pH 7.7−8.6) and resulted in a negative charge of the colloids. Moreover, the hydrophobic adsorption of SS also brought about negative charge. Surface charge up to −60 mV at 5 mM SS (Figure 2B) prevented the aggregation tendency of zein in aqueous phase and, therefore, enhanced the solubilization of zein. This critical SS concentration (about 5 mM) suggested the existence of a critical complexation concentration (CCC). When the SS concentration was below the CCC, the natural conformation of zein might not be disturbed. As the SS concentration rose beyond the CCC, the C_{16} alkyl chain of SS might be incorporated into the hydrophobic zein structure, forming the zein−SS complexes with partially unfolded hydrophobic microdomains, which is similar to the structure of zein−SDS (C_{12}) complexes.[20] The hydrodynamic size of the obtained zein−SS particle was 360 ± 21 nm with a PDI of 0.27 ± 0.02, slightly larger than that of zein colloidal particles prepared through antisolvent procedures (with diameters of 200 ± 20 nm and PDI of 0.18, respectively),[17,26] probably due to the structural difference between the two kinds of zein particles. The colloidal behavior of zein−SS particles is likely caused by an increase in anisotropy accompanying partial unfolding of zein proteins, which could be attributed to their large hydrodynamic size and polydispersity.

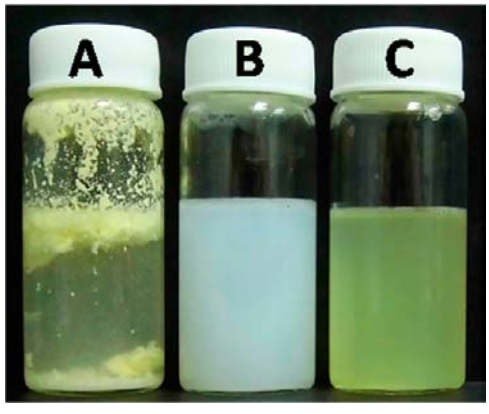

Figure 1. Dispersions of 0.5 wt % zein (A), 10 mM SS (B), and the complex of 0.5 wt % zein and SS (10 mM) (C) in water after ultrasonication.

Interface Adsorption of Zein Particles. The surface hydrophobicity and wettability of silica colloidal particle can be modified through adsorption of low molecular weight charged surfactants.[6,7] Unlike the solid silica particle, the binding of charged surfactant to protein developed from specific electrostatic interactions to nonspecific hydrophobic binding with increasing surfactant concentration, inevitably resulting in the protein unfolding. Using GTT combined with SEM, we inspected the morphology of the adsorbed zein particles monolayer at the oil−water interface (Figure 3), which revealed an enhanced adsorption and accumulation of zein colloidal particles at the interface with increasing SS concentration. In contrast to the zein dispersion in the absence of surfactant SS, an enhanced accumulation of zein particles adsorbed at the oil−water interface was observed for zein modified with 2.5 mM SS that was below the CCC (Figure 3B). The zein particles on the surface of PDMS obtained by GTT for the oil−water interface exhibited intact and isolated microspheres with uniform diameter of 200 nm (determined from the SEM images), very similar to the zein colloidal particles prepared through antisolvent procedures.[17,26] In the case of the zein modified with 10 mM SS (above the CCC), deformable particles and a densely packed layer with significant high surface overlapping at the oil−water interface were observed (Figure 3C), which might be attributed to the partially unfolded zein particles due to the nonspecific hydrophobic interaction with SS that has a concentration above the CCC. It could be concluded that the hydrophobic microdomain of partially unfolded zein molecule triggered the aggregation and the close packing of zein particles with significant high surface coverage at the oil−water interface.

The hydrophobic modification of zein particles by surfactant affects their interfacial wetting properties. We further investigated the wetting properties of zein particles by measuring the water wetting angle on macroscopic solid zein

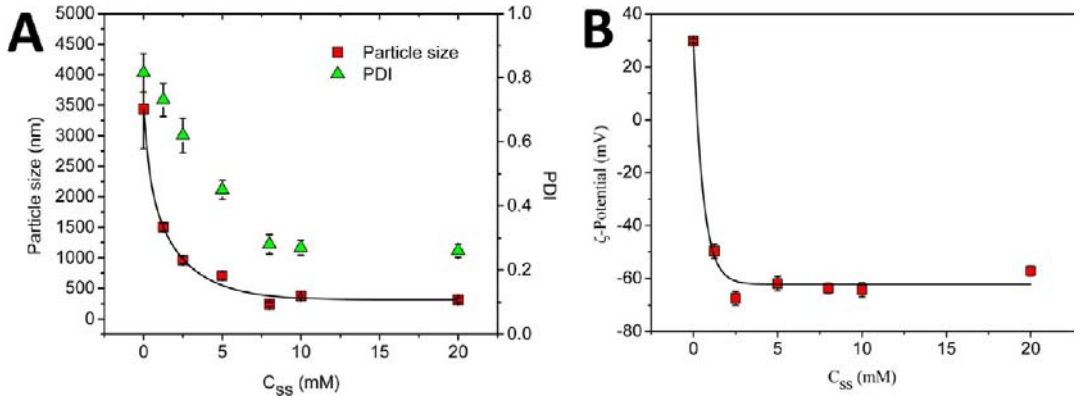

Figure 2. Changes of the particle size (A) and ζ-potential (B) of zein as a function of SS concentration.

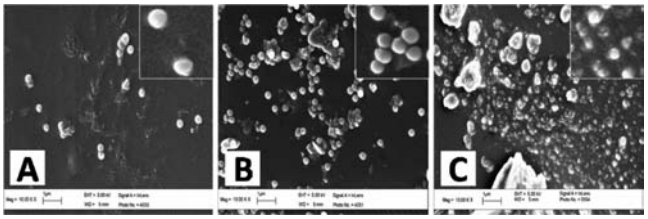

Figure 3. Morphology of the zein adsorbed on oil–water interface obtained by the method of gel trapping technology (GTT) combined with SEM: (A) pure zein; (B) zein with 2.5 mM SS; (C) zein with 10 mM SS. Scale bar = 1 μm.

films (Figure S1, Support Information), which indicated that the wetting angle of water droplets attached to the oil film was about 82°, much higher than that of zein films (60°), suggesting that the bare zein colloidal particles were more hydrophilic and not available to serve as suitable material for interfacial adsorption. de Folter et al.[15] have determined directly the oil-in water three-phase contact angle (θ_{ow}) of bare zein at low pH (pH 4.0) and confirmed the wetting properties of zein strongly favor interfacial particle adsorption with θ_{ow} close to 90°. In this work we estimated roughly the three-phase contact angle of the zein particles that was modified by surfactant SS at the oil–water interface according to GTT described by Paunov.[23] In this method the captured interfacial particle monolayer embedded within the PDMS elastomer surface could be imaged by SEM, and the position of the particles with respect to the PDMS surface has been determined from the SEM images, which gave information on the particle contact angle at the oil–water interface. In the case of bare zein and the zein particles coated by 2.5 mM SS (below CCC) (Figure 3A,B), the spherical zein particles with the average diameter of 200 nm were immersed in the PDMS (representing oil phase) above their equatorial line, protruded into water phase, and actually showed a three-phase contact angle of <90°. For the zein particles modified with 10 mM SS (above the CCC) (Figure 3C), deformed zein particles were immersed in the PDMS below their equatorial line, protruded into oil phase, and exhibited a three-phase contact angle of >90°; therefore, it could facilitate efficient packing of particles and then form a steric barrier at the interface.

We also measured the surface protein loading of the oil droplets as a function of SS concentration (Figure 4A), suggesting a nearly linear enhancement of surface zein loading with increasing SS concentration from 2.5 to 5.0 mM and then reached 9.04 ± 0.43 mg/m^2 at 10 mM. The composition and content of the adsorbed protein at the oil droplet surface was also analyzed by SDS-PAGE (Figure 4B), which revealed a gradually denser band of α-zein (22 and 24 kDa) by increasing SS concentration, further confirming enhancement of interfacial protein loading with increase of surfactant concentration. Thus, it is reasonable to speculate that the formation of zein particles–SS complexes not only improved the diffusive mobility of water-insoluble zein particles but also endowed the particles with equilibrium interfacial wetting properties,

evidently enhanced the surface particle coverage and steric barrier of densely packed layer at the interface, and produced Pickering emulsions with excellent stability against coalescence.

Formation of Zein-Based Pickering Emulsion. de Folter et al.[15] prepared micrometer-sized Pickering emulsions stabilized by zein colloidal particles and studied the effect of particle concentration, pH, and ionic strength on emulsion stability, indicating that under conditions where the particle volume fraction was low (<0.2 wt %) or at low pH, the resulting emulsions were not stable against coalescence. Unfortunately they did not characterize in detail the microstructure of the oil droplets to confirm the formation of Pickering emulsions. In this study we prepared O/W emulsions (Φ = 0.1) stabilized by a mixture of 0.5 wt % zein colloidal particles and surfactant SS at 0, 2.5, 5.0, and 10 mM (Figure 5A). To confirm the formation of Pickering emulsions, we characterized the microstructure of the oil droplets of the obtained emulsions by CLSM (Figure 5B), highlighting the presence of zein particles (labeled in red) adsorbed and covering almost all of the surface of the oil droplet (labeled in green). To our best knowledge, this is the first evident demonstration of the formation of protein zein particle-stabilized Pickering emulsion. In addition, CLSM also showed polydispersed zein aggregates dispersed in the continuous phase, which were further confirmed by droplet size distributions analysis. Unlike Pickering emulsion stabilized solely by particles that possessed long-term stability against coalescence but exhibited severe creaming and macroscopic phase separation,[11−13,15] the emulsion we prepared by zein particle−SS complexes exhibited no creaming and macroscopic phase separation. Binks and co-workers[6] found that synergistic stabilization of O/W Pickering emulsions occurred when positively charged silica nanoparticles were mixed with the anionic surfactant (SDS) in water, and this kind of Pickering emulsion was stable to both creaming and coalescence.

Emulsion Stability and Formation of Oil Gel. Conventionally, a particle-stabilized emulsion typically contains rather coarse droplets (~10 μm diameter or larger). The mean droplet diameter ($d_{4,3}$) of the modified zein particle stabilized emulsions we prepared was about 20−50 μm, depending on the concentration of SS (Figure S2, Supporting Information). A gradual decrease of $d_{4,3}$ and polydispersity of zein particle-stabilized emulsion upon increasing SS concentration was observed (Figure S2; Figure 6B), until a monodisperse Pickering emulsion with narrow size distribution was formed at 10 mM SS. Emulsion microstructure evaluated with an optical microscope revealed dispersed oil droplets covered with adsorbed Pickering-type particles in sample E5, which contained 5 mM SS. Interestingly, the freshly prepared emulsion prepared with 10 mM SS was characterized by unusual microstructure and high oil droplet sizes in the range of 30−40 μm, much like the fat crystals stabilized Pickering emulsion through interfacial crystallization.[14] In the same way, we have monitored the physical stability of emulsion stabilized by zein particles−SS complexes. The heating−salting stability test of emulsions, which were assayed by heating at 90 °C for 30 min in the presence of 200 mM NaCl, was assessed by creaming, mean droplet diameter ($d_{4,3}$), and microstructure with optical microscope observations, given in Figures 6 and 7. After heating−salting treatment, the emulsion stabilized by zein particles with 2.5 mM SS (E2.5, below the CCC) was slightly creamed with an increase of $d_{4,3}$ from 50.1 to 88.3 μm. For emulsions stabilized by zein particles with 5 mM SS (E5, CCC) and 10 mM SS (E10, above the CCC), there was slight flocculation but no coalescence or change of droplet size ($d_{4,3}$) (Figures 6 and 7). In contrast, the emulsion stabilized only by

dx.doi.org/10.1021/jf500005y | J. Agric. Food Chem. 2014, 62, 2672−2678

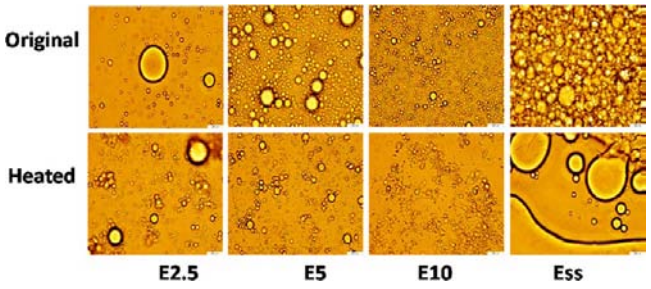

Figure 7. Optical microscope images of emulsions before and after heating–salting treatment (90 °C/30 min, 200 mM NaCl): E2.5, emulsions stabilized with 0.5 wt % zein and 2.5 mM SS; E5, emulsions stabilized with 0.5 wt % zein and 5 mM SS; E10, emulsions stabilized with 0.5 wt % zein and 10 mM SS; Ess, emulsions stabilized with 10 mM SS. Scale bar = 200 μm.

10 mM surfactant SS (Ess) was severely creamed with oil droplet collapse. Thus, it can be concluded that a synergistic improvement in coalescence stability of Pickering emulsion could be derived from a complex of zein particles and charged surfactant SS.

Pickering stabilization is known to require the presence of complete monolayer coverage of closely packed particles against coalescence.[4] The instability of E2.5 emulsion might derive from its low interface protein loading of the droplets (Figure 4) and the limited surface coverage at the oil–water interface (Figure 3B). Correspondingly, the stability of E5 and E10 emulsions against heating–salting induced creaming and coalescence, mainly due to the high interface protein loading and densely packed monolayer created by accumulated and aggregated protein particles at the interface (Figure 3C). To further evaluate the stability of the emulsions, they were freeze-dried to prepare oil gels. Generally, a weak interface of the emulsion droplet stabilized by surfactant and biopolymer could not prevent the severe coalescence between droplets during dehydration processing of freeze-drying, leading to the collapse of the emulsion and oil leakage. Now we found the zein particle stabilized O/W emulsions provided suitable templates for freeze-drying processes to produce oil gels. The appearances of the materials resulting from freeze-drying of the emulsions for surfactant-modified zein particle (E2.5, E5, and E10) and surfactant SS (Ess) stabilized system are shown in Figure 8. For E2.5 and E5 emulsions with SS concentrations between 2.5 and 5 mM, sol-like solids were formed, which had slight oil leakage, confirming the low interfacial loading and insufficient surface particles coverage. For E10 emulsions (containing 10 mM SS), however, a homogeneous and translucent gel without oil leakage was formed, meaning that the oil content entrapped in this matrix was >92% wt %. By contrast, the emulsion stabilized by 10 mM SS yielded a turbid flowing liquid, indicating that freeze-drying failed to produce an encapsulated oil gel only by surfactant SS. The strategy of structuring liquid oils into solid-like oil gels by simply freeze-drying the Pickering emulsion precursor would be meaningful, because until today the most widely used methods used to create fat-structured foods, such as chocolate, ice cream, spreads, and shortening, are given by an underlying colloidal network of polycrystalline fat crystals, which are composed of high-melting saturated or *trans* fatty acids.[27] As we know, excessive consumption of *trans* and saturated fats has been shown to have deleterious health effects including negative effects on lipoprotein profiles and increases in the incidence of heart disease and metabolic syndrome.[28]

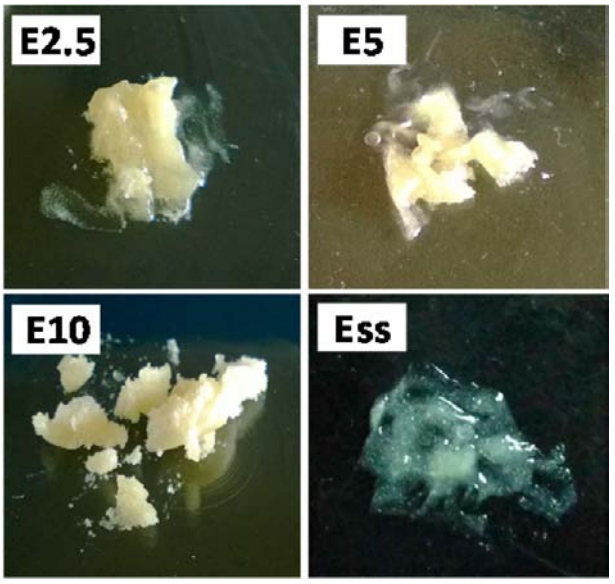

Figure 8. Visual aspect of the freeze-dried emulsions stabilized by zein–SS and sole SS: E2.5, emulsions stabilized with 0.5 wt % zein and 2.5 mM SS; E5, emulsions stabilized with 0.5 wt % zein and 5 mM SS; E10, emulsions stabilized with 0.5 wt % zein and 10 mM SS; Ess, emulsions stabilized with 10 mM SS.

General Discussion. The main challenges to the production of edible Pickering emulsions are the low interfacial adsorption and limited surface coverage due to the aggregation and low diffusive mobility of the food grade colloidal particles.[29] In this study we employed a novel strategy by taking advantage of the properties of the complexes between zein particles and small molecular weight surfactant SS to overcome simultaneously the multiple challenges exhibited by solely colloidal particles, fabricated protein-based Pickering emulsion, and oil gels with superior stability against both coalescence and creaming. For better understanding of the stabilization mechanism of zein particle–SS complexes, we provide a schematic illustrations in Figure 9.

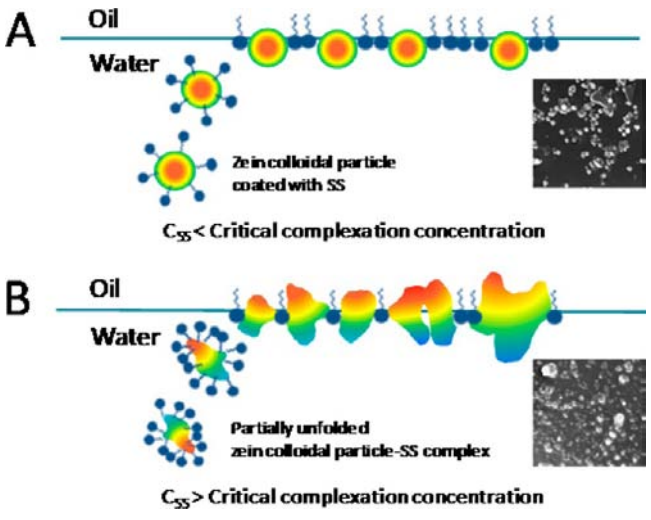

Figure 9. Schematic diagrams showing enhanced adsorption and targeted accumulation of zein particles at the interface with the synergism of SS.

dx.doi.org/10.1021/jf500005y | J. Agric. Food Chem. 2014, 62, 2672–2678

The modification of zein particles through adsorption of ionic surfactant SS affected their interfacial wetting properties. At SS concentration below the CCC (about 2.5 mM) (Figure 9A), the intact and inherently hydrophilic zein colloidal particles migrated to the oil−water interface, resulting in an unsaturated particle monolayer at the interface owing to the inefficient accumulation of particles (low surface protein loading) and weak adsorption on the interface ($\theta_{ow} < 90°$), and thus failed to provide a packed steric barrier of oil droplets against emulsion coalescence and creaming. However, at SS concentration above the CCC (about 10 mM) (Figure 9B), zein particles−SS complexes formed mainly due to nonspecific hydrophobic interaction, resulting in the partial unfolding of zein particles and the exposure of hydrophobic microdomains, not only improved the diffusive mobility of water-insoluble zein particles but also endowed the particles with equilibrium interfacial wetting properties and thus evidently enhanced the surface particle coverage and facilitated efficient packing of zein colloidal particles at the oil−water interface, producing Pickering emulsions with superior stability against both coalescence and creaming.

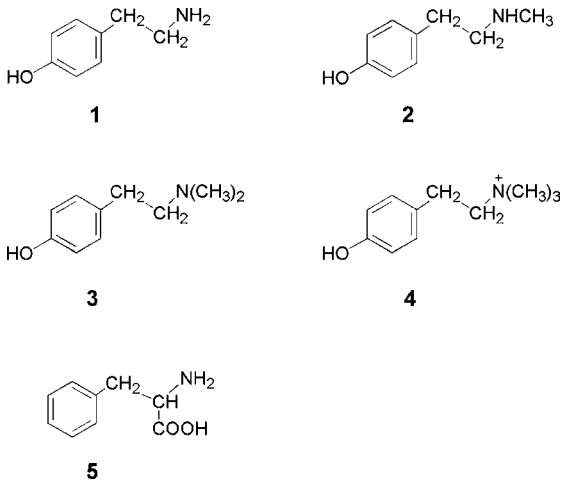

Figure 1. Chemical structures of analyzed compounds: tyramine (**1**), *N*-methyltyramine (**2**), *N,N*-dimethyltyramine (hordenine) (**3**), 2-(4-hydroxyphenyl)ethyl-trimethylazanium (candicine or *N,N,N*-trimethyltyramine) (**4**), and phenylalanine (**5**).

methyl iodide were added. The mixture was stirred at room temperature and the formation of the reaction products *N*-methyltyramine, *N,N*-dimethyltyramine, and *N,N,N*-trimethyltyramine was monitored by liquid chromatography−electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS). The addition of methyl iodide (10 mL) and $KHCO_3$ (1 g) was repeated twice more. Finally, after centrifugation of the mixture, the supernatant was collected and evaporated to dryness at 40 °C in a rotary evaporator. The residue containing *N,N,N*-trimethyltyramine was dissolved in 10 mL of Milli Q-grade water and purified by flash chromatography on SepPac C18 cartridge (Phenomenex, Anzola Emilia, Italy). The sample-loaded column was washed with 100 mL of Milli Q water, and *N,N,N*-trimethyltyramine was eluted from the column by applying 50 mL of a solution of H_2O/acetonitrile (80:20). The eluted product was evaporated to dryness under a stream of air and dried overnight in vacuum over P_2O_5. The yield was 88%.

Preparation of Citrus Leaf Extracts. Citrus leaf samples were obtained from the Research Centre for Citrus Crops and the Mediterranean (CRA-ACM), Arboretum of Reggio Calabria (Italy). Four lots of 100 g were taken from different branches from each citrus plant species. Leaves, in the late development stage, were harvested in January and February. The leaves were washed with distilled water and dried with filter paper. Then 50 g of product, finely chopped, was homogenized in a blender with 100 mL of 0.2% formic acid in Milli Q-grade water and the mixture was stirred for 1 h. In these conditions the extraction yield was higher than 96% for all the analyzed compounds. Finally, the homogenate was centrifuged at 18000*g* for 30 min and the supernatant was stored in 20 mL vials at −20 °C. Citrus varieties included in this study were mandarin, sweet orange, bitter orange, chinotto (*Citrus myrtifolia*), pomelo, citron, grapefruit, bergamot, and clementine.

Preparation of Standards. Standard stock solutions of tyramine, *N*-methyltyramine, *N,N*-dimethyltyramine, and *N,N,N*-trimethyltyramine were prepared at concentration of 2 mg/L and stored at 4 °C. Prior to injection, stock solutions were appropriately diluted with water containing 0.1% formic acid before being used as working solutions. Quantitation was achieved by comparison with calibration curves obtained with the standard solutions. Additional calibration levels (2, 1, 0.5, 0.1, and 0.05 mg/L) were prepared by serial dilution with water containing 0.1% formic acid. The calibration curve was built by use of these standard solutions. The response of the MS/MS detection followed a linear calibration curve between 0.05 and 2 mg/L with a correlation coefficient of 0.99. Detection limits, determined as the compound concentration that gave a peak height 3 times that of background noise, were 0.021 mg/L for tyramine, 0.016 mg/L for *N*-methyltyramine, 0.020 mg/L for *N,N*-dimethyltyramine, and 0.009 mg/L for *N,N,N*-trimethyltyramine.

Flow Injection Analysis and HPLC-ESI-MS/MS Measurements. HPLC-ESI-MS analyses were performed with an HPLC Agilent 1100 series coupled online with an Agilent LC-MSD SL quadrupole ion trap. MS acquisition was performed by using electrospray inonization (ESI) in positive-ion mode. Nitrogen was used at a flow rate of 7 L/min and a pressure of 30 psi as both a drying and a nebulizing gas. The nebulizer temperature was set at 350 °C. The ion charge control (ICC) was applied with a target set at 30 000 and maximum accumulation time at 20 ms. Measurements were performed from the peak area of the extracted ion chromatogram (EIC). Quantitation was achieved by comparison with calibration curves obtained with standard solutions. Optimization of instrumental parameters for analyses of tyramine and its methylated derivatives was performed by continuous infusion [flow injection analysis (FIA)-ESI-MS/MS measurements] of 5 μM standard solution in 0.1% formic acid. Mass cutoff and amplitude were optimized to obtain the most efficient MS/MS transitions from the positively charged precursor ion $[M + H^+]$ to the fragment ions. Multiple reaction monitoring (MRM) was used for quantitation of analytes. The transitions utilized for MS/MS quantitation were 138.1 → 121 for tyramine, 152.1 → 121 for *N*-methyltyramine, 166.1 → 121 for *N,N*-dimethyltyramine, 180.1 → 121 for *N,N,N*-trimethyltyramine, and 166.1 → 120 for phenylalanine. LC-ESI-MS/MS analyses were performed with a 150 mm × 3.0 mm i.d., 5 μm Discovery-C8 analytical column (Supelco). The mobile phase was composed of 0.1% formic acid in water and pumped at 0.1 mL/min under isocratic conditions at room temperature. Volumes of 10−20 μL of standard solutions or samples were injected.

Statistical Analysis. Data are expressed as mean ± std of $n = 4$ determinations, each in duplicate. Differences were assessed by *t*-test, and a p value less than 0.05 was considered to be significant.

RESULTS AND DISCUSSION

Identification of *N,N,N*-Trimethyltyramine in *Citrus* Genus Plants. Recently, we reported the occurrence of secondary metabolites derived from tryptamine in *Citrus* genus plants.[28] Specifically, we described the presence of *N*-methyltryptamine and *N,N*-dimethyltryptamine in all parts of the fruit (peel and edible part) with higher levels in leaves and seeds. Interestingly, we also revealed the occurrence of *N,N,N*-trimethyltryptamine, a metabolite never described before in plants.[28] Subsequently, in several *Citrus* genus plants, we quantitated 5-hydroxytryptamine (serotonin) and its N-methylated forms such as 5-hydroxy-*N*-methyltryptamine, 5-hydroxy-*N,N*-dimethyltryptamine (bufotenine), and 5-hydroxy-*N,N,N*-trimethyltryptamine. In particular, we reported the occurrence of 5-hydroxy-*N,N,N*-trimethyltryptamine, also named bufotenidine or cinobufotenine.[29] It is worth noting that the occurrence of tyramine, *N*-methyltyramine, and *N,N*-dimethyltyramine in *Citrus* genus plants has been known for a long time, whereas the occurrence of *N,N,N*-trimethyltyramine has never been reported so far. Therefore, we sought to verify the occurrence of *N,N,N*-trimethyltyramine in the most common and economically important plants of the *Citrus* genus. Moreover, we also aimed to quantitatively compare, among them, the distribution of tyramine and its N-methylated derivatives. The analysis, performed on a lemon leaf extract and conducted with the same HPLC-ESI-MS/MS methodology previously described,[30,31] showed complete chromatographic separation of all examined metabolites in less than 30 min (Figure 2A). In particular, tyramine eluted at a retention time (T_R) of 12.7 min, followed by *N*-methyltyramine at T_R 15.5 min and *N,N*-dimethyltyramine (hordenine) at T_R 19.5 min. Interestingly, an unknown peak emerged at T_R 23.8 min. Moreover, this peak occurred at m/z 180 and showed a very

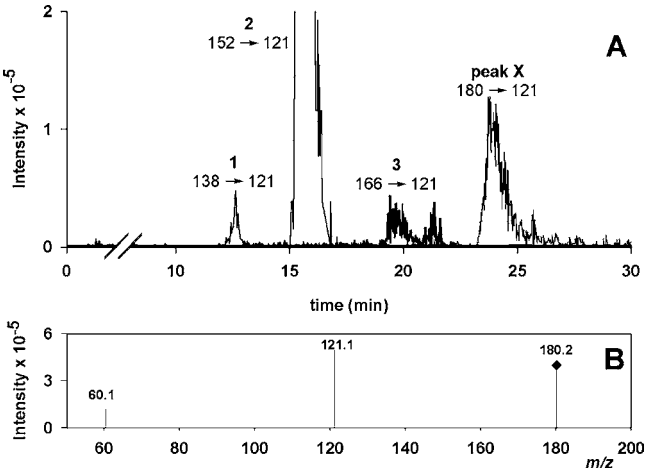

Figure 2. (A) LC-ESI-MS/MS chromatogram of lemon leaf extract. (B) MS^2 fragmentation pattern of the unknown peak (peak X) at retention time of 24 min.

simple MS/MS fragmentation pattern (Figure 2B) with only two fragments at *m/z* 60 and 121, which strongly suggested the possibility that the it might be *N,N,N*-trimethyltyramine.

Synthesis and ESI-MS^n Characterization of *N,N,N*-Trimethyltyramine. With the aim to confirm the presence of *N,N,N*-trimethyltyramine in *Citrus* genus plants, we synthesized the substance according to the method of Chen and Benoiton,[26,27] as it was not commercially available. Under the reaction conditions adopted, the methylation process of tyramine, which was used as starting substrate for the synthesis, was essentially complete in about 6 h at room temperature. Formation of *N,N,N*-trimethyltyramine and the less methylated derivatives (*N*-methyltyramine and *N,N*-dimethyltyramine) was monitored by withdrawing 50 μL of reaction mixture at preset times of 2, 6, 12, and 24 h. Each aliquot was then diluted to a final volume of 1 mL with 0.1% formic acid. Then 20 μL portions of the diluted samples were analyzed by LC-ESI-MS/MS. After 2 h, the reaction mixture contained tyramine and noticeable amounts of *N*-methyltyramine and *N,N*-dimethyltyramine compared to *N,N,N*-trimethyltyramine (Figure 3A). High levels of the desired compound were found in the reaction mixture in 6 h (Figure 3B). Conversely, other N-methylated tyramine derivatives occurred at lower levels. The synthesis was complete in 12 h of reaction, as demonstrated by the presence in the reaction mixture of only *N,N,N*-trimethyltyramine and the disappearance of other components (Figure 3C).

In order to find the optimal instrumental conditions for detection and quantitation, the synthesized *N,N,N*-trimethyltyramine was purified and subjected to mass spectrometric analysis. In particular, amplitude and cutoff, the main parameters for an ion-trap mass spectrometer to achieve the most effective collision-induced dissociation (CID) of the parent ion toward its ion fragments, were optimized. This study was performed in positive-ion mode by direct infusion of 5 μM *N,N,N*-trimethyltyramine solution in 0.1% formic acid. *N,N,N*-Trimethyltyramine showed the highest retention time relative to the less methylated tyramine derivatives and eluted at about 24 min (Figure 4A). It is interesting to note that the MS^2 fragmentation pattern of the synthesized *N,N,N*-trimethyltyramine is essentially constituted by only two ions (Figure 4B). The one at *m/z* 60 corresponds to trimethylammonium ion,

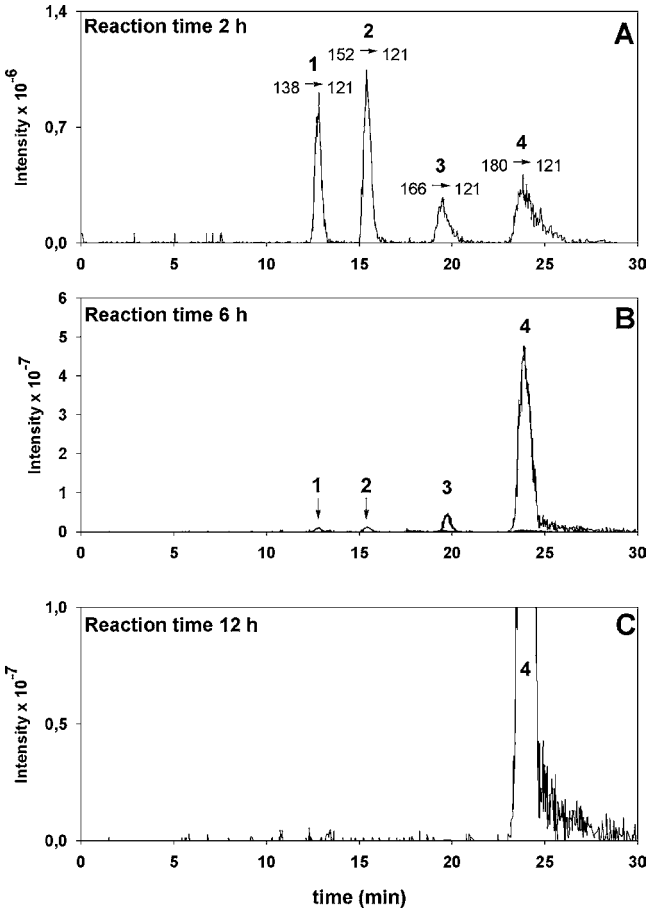

Figure 3. Time course of tyramine methylation performed according to the method of Chen and Benoiton:[26,27] products of tyramine methylation after (A) 2 h, (B) 6 h, and (C) 12 h of reaction. The MS^2 transitions used to monitor tyramine (**1**), *N*-methyltyramine (**2**), *N,N*-dimethyltyramine (**3**), and *N,N,N*-trimethyltyramine (**4**) are also reported.

which is peculiar for most betaines,[30,32] and the other, at *m/z* 121, is formed as a consequence of neutral loss of the trimethylamine moiety[33] from the parent ion. An intense fragment at *m/z* 121 is present also in the MS^2 spectra of tyramine, *N*-methyltyramine, and *N,N*-dimethyltyramine. This fragment was observed for the first time by Cram and Thompson[33] in the solvolysis of 2-arylethyl derivatives and is supposed to have the very stable bicyclo structure shown in the inset of Figure 4B. The fragment is produced from tyramine by neutral loss of ammonia, whereas *N*-methyltyramine and *N,N*-dimethyltyramine produce it by neutral loss of methylamine and dimethylamine, respectively. The MS^3 fragmentation pattern was obtained by isolating the MS^2 fragment at *m/z* 121 of the synthesized *N,N,N*-trimethyltyramine (Figure 4C). The MS^3 fragment at *m/z* 93 likely originated from C_2H_4 neutral loss from the *m/z* 121 parent ion.[33] The identity of the fragment at *m/z* 121 in the MS^2 fragmentation pattern of the synthesized *N,N,N*-trimethyltyramine was further supported by the observation that its MS^3 fragmentation pattern was the same as those of the MS^2 fragments, isolated at *m/z* 121, generated by tyramine, *N*-methyltyramine, and *N,N*-dimethyltyramine.

It is important, from an analytical point of view, to highlight that the stability of the *N*-methylated derivatives of tyramine toward in-source CID is strongly dependent on the degree of

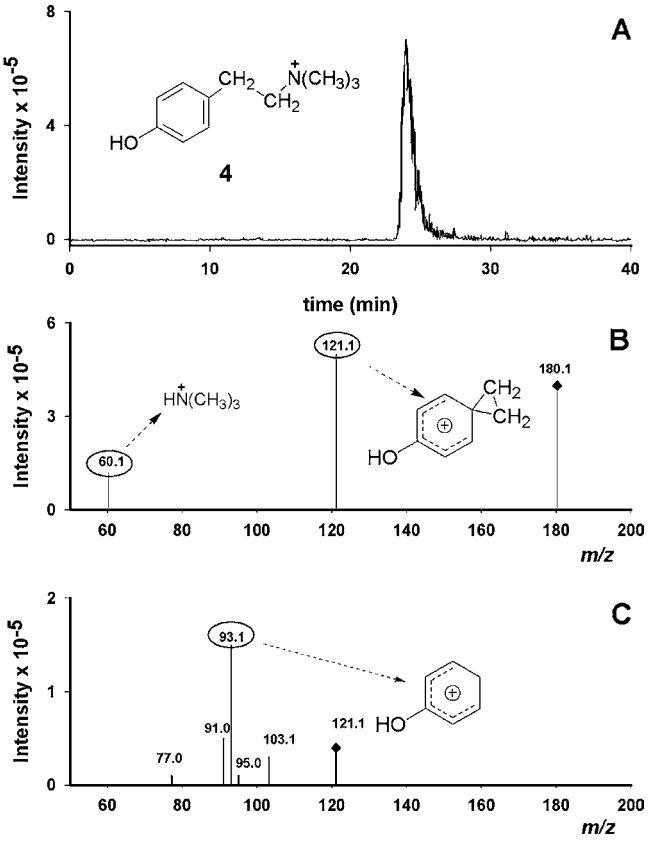

Figure 4. Mass spectrometric characterization of *N,N,N*-trimethyltyramine (**4**) standard solution. (A) Extracted-ion chromatogram at m/z 180.1 from LC-ESI-MS analysis of the synthesized *N,N,N*-trimethyltyramine (**4**) standard solution. (B) MS^2 fragmentation pattern of the peak in panel A. Arrows indicate the structure of the generated MS^2 fragments. (C) MS^3 fragmentation pattern of the peak in panel A, obtained by isolating the MS^2 fragment at m/z 121.1. Arrows indicate the structure of the MS^3 fragment at m/z 93.1, likely generated by C_2H_4 neutral loss.

methylation. In fact, we observed that about 85% of tyramine, 70% of *N*-methyltyramine, and 10% of *N,N*-dimethyltyramine was fragmented by in-source CID. Instead, no in-source fragmentation of *N,N,N*-trimethyltyramine was observed. Therefore, especially for tyramine and *N*-methyltyramine, if needed, more analytical sensitivity can be achieved by selecting the fragment at m/z 121 produced in the ion source than that at the m/z corresponding to the protonated parent molecules.

Distribution of N-Methylated Tyramine Derivatives in *Citrus* Genus Plant Leaves. Analysis of the content of tyramine and its N-methylated derivative in citrus leaf extracts was conducted by HPLC-ESI-MS/MS. From a quantitative point of view, *N,N,N*-trimethyltyramine was most abundant in the leaves of clementine (0.88 ± 0.64 mg/kg), followed by bitter orange and lemon. In contrast, substantially lower levels were found in orange, bergamot, citron, pomelo, and mandarin leaves (Table 1).

In order to unambiguously confirm the presence of *N,N,N*-trimethyltyramine in these matrices, chromatographic and mass spectrometric behaviors of the putative *N,N,N*-trimethyltyramine peak in leaf extracts were compared with those of the synthesized standard. In each case, both peaks showed the same chromatographic retention time. Moreover, under the same instrumental settings of the ion trap, the peaks showed the same fragmentation patterns and the same intensity ratios of main fragments in both MS^2 and MS^3 measurements. On the whole, these results leave no doubt that the compound eluting at about 24 min in the extracts of citrus leaves is *N,N,N*-trimethyltyramine.

Among the other analyzed metabolites, tyramine is well-represented in leaves of citrus plants. Particularly, 49.75 ± 12.16 and 21.63 ± 7.80 mg/kg tyramine were found in leaves of chinotto and clementine, respectively (Table 1), while values of 0.55 ± 0.38 and 0.41 ± 0.33 mg/kg were found in pomelo and bergamot leaves. *N*-Methyltyramine is the tyramine derivative most abundant in citrus leaves. Particularly, leaves of chinotto and clementine contained mean levels above 20 mg/kg of this metabolite, whereas leaves of bergamot, pomelo, citron, mandarin, lemon, bitter orange, and sweet orange contained amounts from a minimum of 0.45 ± 0.31 mg/kg up to a maximum of 6.91 ± 2.04 mg/kg (Table 1).

N,N-Dimethyltyramine was contained in discrete amounts only in the leaves of clementine (0.30 ± 0.19 mg/kg). In all other citrus matrices *N,N*-dimethyltyramine was at levels equal or below 0.07 ± 0.04 mg/kg (Table 1). It is important to point out that phenylalanine, an amino acid well represented in the citrus matrices,[34,35] has the same mass as *N,N*-dimethyltyramine. Fortunately, complete chromatographic separation of all examined tyramine derivatives and phenylalanine was obtained under the chromatographic conditions employed (Figure 5). In particular, phenylalanine, which in all samples examined was always present in much higher amounts than *N,N*-dimethyltyramine, was well resolved from it (Figure 6A). Therefore, phenylalanine did not interfere in the quantitation of *N,N*-dimethyltyramine in the samples examined. It is important to achieve good chromatographic resolution between these two compounds, especially when phenylalanine is much more abundant then *N,N*-dimethyltyramine, despite the fact that phenylalanine and *N,N*-dimethyltyramine seem resolvable by mass spectrometric measurements. In fact, the analytical MS^2 transition employed for *N,N*-dimethyltyramine determination was at m/z 166 → 121, while for phenylalanine it was at m/z 166 → 120. However, besides the intense peak corresponding

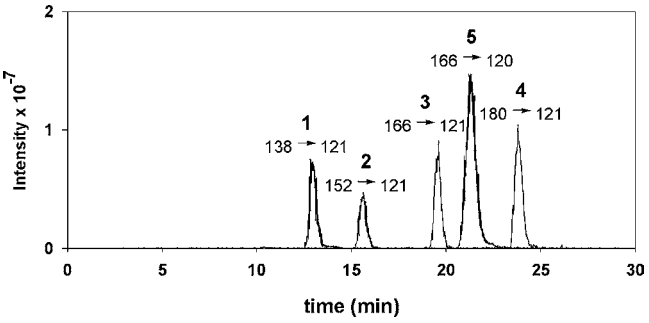

Figure 5. Chromatographic separation of standard solutions of phenylalanine and methylated tyramine derivatives by HPLC-ESI-MS/MS. For each compound, the extracted ion chromatogram (EIC) at the indicated MS^2 transition is reported. (**1**) tyramine (T_R 12.7 min); (**2**) *N*-methyltyramine (T_R 15.5 min); (**3**) *N,N*-dimethyltyramine (T_R 19.5 min); (**5**) phenylalanine (T_R 21.3 min); (**4**) *N,N,N*-trimethyltyramine (T_R 23.8 min).

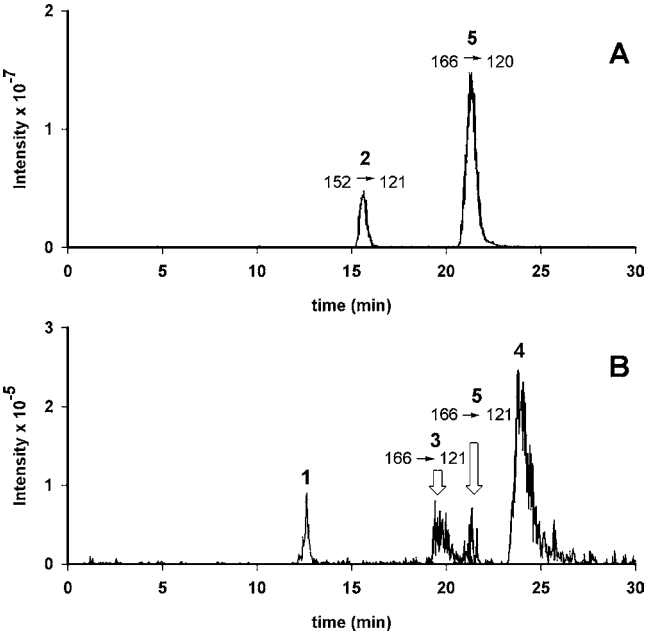

Figure 6. Representative HPLC-ESI-MS/MS chromatogram of lemon leaf extract. (A) Peaks of components present at higher levels: *N*-methyltyramine (**2**) and phenylalanine (**5**) (intensity × 10^{-7}). (B) Peaks of components present at lower levels: tyramine (**1**), *N,N*-dimethyltyramine (**3**), and *N,N,N*-trimethyltyramine (**4**) (intensity × 10^{-5}). The M + 1 peak originating from phenylalanine ^{13}C content, obtained by monitoring the MS^2 transition at 166−121, is also shown in panel B.

to the transition at *m/z* 166 → 120, phenylalanine, being much more abundant than *N,N*-dimethyltyramine in all the samples examined, also showed a peak at *m/z* 166 → 121, arising from a not-negligible ^{13}C contribution, with intensity similar to the peak at *m/z* 166 → 121 of *N,N*-dimethyltyramine. Therefore, without chromatographic resolution, the two compounds would strongly interfere (Figure 6B).

The data reported in Table 1 show that distribution of the biogenic amine tyramine and its other two methylation products, *N*-methyltyramine and *N,N*-dimethyltyramine, is somewhat uneven among the various *Citrus* species. The novelty of this work has been the identification and quantitation of *N,N,N*-trimethyltyramine in *Citrus* plant leaves. The results show that also *N,N,N*-trimethyltyramine is present at very different levels in the various plant species examined. Clementine, lemon, and bitter orange leaves contained the most significant amounts. The highest level was found in clementine leaves (0.88 mg/kg) and the lowest in citron, mandarin, pomelo, and bergamot leaves (0.01 mg/kg) ($p < 0.05$) (Table 1). From a physiological point of view, the simultaneous presence of tyramine and all other N-methylated derivatives in the leaf, a part of the plant highly specialized in biosynthesis, secretion, and accumulation of toxic substances, suggests that these substances are aimed at plant defense. It is well-known that plants under pathogenic attacks respond with the activation of defense mechanisms regulated by several phytohormones. These rapid defensive responses occur through metabolic pathways involving tryptophan, tyrosine, and phenylalanine, leading to the production and accumulation of specific metabolites aiming to prevent or alleviate the action of the pathogens.[36,37] Among the products of these enzymatic activities, an important role is played by tyramine and tryptamine, produced by the actions of tyrosine decarboxylase and tryptophan decarboxylase. These biogenic amines are precursors of many specialized defensive secondary metabolites.[38,39] In this context, the formation of *N,N,N*-trimethyltyramine may be the result of a series of reactions starting from tyrosine decarboxylation and continuing with successive methylation catalyzed by the same or a different N-methyltransferase.[29] This process is likely aimed to increase the plant's defense through formation of a final product with powerful physiological activity. Such a possibility is supported by pharmacological studies reporting that *N,N,N*-trimethyltyramine is a neuromuscular blocker of depolarizing type that possesses muscarine-like and sympathomimetic effects.[22−25] It was demonstrated that in some animals *N,N,N*-trimethyltyramine induces cardiovascular and respiratory disturbances. Furthermore, it has been shown that *N,N,N*-trimethyltyramine is a stimulant of autonomic ganglia and can liberate catecholamines from the adrenal medulla. Finally, the hypothesized defensive role of *N,N,N*-trimethyltyramine could occur in synergy with other biogenic amine derivatives also well-represented in citrus leaves, such as those arising from tryptophan.[29]

Due to the complexity of food samples, analysis of PAH metabolites remains a challenging task. A preconcentration step, which empowers detection of low concentrations and interferent removal, is required and often performed through solid-phase extraction (SPE). Among the analytical methods described in the scientific literature, reverse-phase sorbents, such as C18 cartridges, are the most applied in the analysis of biological, food, and environmental matrices.[12,17,21] Moreover, methods for the simultaneous analysis of different PAH monohydroxy derivatives are quite limited and concern mainly matrices such as foodstuffs,[17,22−25] and none about cephalopod samples. Quantitation usually relies on liquid chromatography with fluorescence detection (LC-FD) or on liquid chromatography with tandem mass detection (LC-MS-MS).[17]

This study provides the first report on the optimal conditions for the simultaneous determination of three monohydroxy derivatives of PAHs, namely, 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene, using SPE-LC-FD, for the analysis of different cephalopod matrices (edible tissues and hemolymph). The developed method was applied to samples of the major cephalopod species consumed worldwide.[26] The developed methodology allows an improved assessment of consumers' PAH exposure, as well as the possibility to explore more deeply the PAH metabolic capacity of marine species and, in particular, of cephalopods.

MATERIALS AND METHODS

Safety Considerations. The toxicity or carcinogenicity of each chemical and reagent used in this method was not precisely defined. However, each one must be treated as a potential health hazard, and exposure to these chemicals should be minimized. Some method analytes have been tentatively classified as known or suspected human or mammalian carcinogens. Pure standard materials and stock standard solutions of these compounds should be handled with suitable protection to skin, eyes, etc.

Standards and Chemicals. The standards of 1-hydroxypyrene, 2-hydroxyfluorene, and 1-hydroxynaphthalene were purchased from Sigma-Aldrich (St. Louis, MO, USA), all with ≥98% purity. Individual stock solutions were prepared at 2 mg/mL in acetonitrile/water (50:50). These solutions were stored at −20 °C, in the dark, for a maximum of 6 months. Individual intermediate standard solutions were prepared at 250, 50, and 5 μg/mL in acetonitrile/water (50:50). Working standard solutions were prepared weekly, kept in amber flasks at −20 °C, and used for calibration, accuracy, and repeatability assays of the validation study.

Given the different fluorescence sensitivity of each compound, mixed standard working solutions were prepared at different concentrations for each compound. For linearity assays, the following concentration levels were used: 750, 850, 1000, 1500, and 2000 ng/mL for 1-hydroxynaphthalene; 30, 40, 50, 60, and 75 ng/mL for 2-hydroxyfluorene; and 150, 175, 200, 250, and 300 ng/mL for 1-hydroxypyrene.

HPLC grade acetonitrile and methanol were obtained from Carlo Erba (Milan, Italy), and ethyl acetate was from Panreac (Barcelona, Spain). Double-distilled water used throughout the experiments was prepared daily from a Milli-Q system (Millipore, Bedford, MA, USA).

Sodium acetate and ascorbic acid were purchased from Merck (Darmstadt, Germany) and Sigma-Aldrich, respectively. Glacial acetic acid was obtained from Panreac, and β-glucuronidase/arylsulfatase from *Helix pomatia* (100,000 Fishman units/mL at pH 4.5 and 38 °C and 800,000 Roy units/mL at pH 6.2 and 38 °C, respectively) was purchased from Roche Diagnostics (Mannheim, Germany).

A solution of sodium acetate buffer at 0.1 M was prepared by dissolving 1.36 g of sodium acetate in 250 mL of distilled water and adjusting the pH to 5.0 with acetic acid. An ascorbic acid solution at 1 mg/mL was prepared in methanol.

Materials and Equipment. Oasis HLB (Merck) solid-phase extraction (SPE) cartridges were used. The LC apparatus consisted of two Gilson pump models 305 and 321 coupled to a Gilson autoinjector, model 234 (Gilson Medical Electronics, Villiers-le-Bel, France). A model 0305 Ultrafluor scanning fluorescence detector (LabAlliance, USA) operated at variable-wavelength program was also used. The results were recorded on UniPoint software (Gilson Medical Electronics). A 250 × 4.6 mm i.d., 5 μm, PAH C18 chromatography column (Waters, Milford, MA, USA) maintained at 30 °C was used. All chromatographic solvents were filtered through a 0.20 μm nylon membrane filter (Whatman, Dassel, Germany) and degassed for 15 min in an ultrasonic bath. All standard solutions and sample extracts were filtered through Durapore PTFE syringe filters, 0.45 μm, from Millipore (Milford, MA, USA).

Sample Collection and Characterization. Fresh squid samples were randomly acquired from November 24 to 30, 2011, at supermarkets in the city of Oporto, Portugal. All samples were *Loligo gahi*, from Argentina Southwest Atlantic Ocean (FAO: 41). After arrival at the laboratory, samples were minced and homogenized. Moreover, hemolymph samples were obtained from *Octopus vulgaris* specimen harvested live from the Northwest Atlantic Portuguese coast. Sample collection, biometric characterization (Table 1), and preparation were performed in accordance with EC regulation no. 333/2007.[27] Moisture of squids was evaluated using 10 g of homogenized sample according to Portuguese Standard NP 2282-1991 and the official AOAC method.[28]

[a]ND, not determined.

Samples were kept frozen, in polycarbonate containers, at −20 °C, until analysis.

Sample Extraction, Hydrolysis, and Solid-Phase Extraction. After defrosting, samples were minced and homogenized, and 1 g was added of 1 mL of ascorbic acid (1 mg/mL) and 6 mL of acetonitrile. Once vortex stirred, the sample was ultrasonicated for 5 min and extracted by centrifugation at 4 °C and 10000*g* for 10 min. The supernatant was collected and concentrated to dryness at 37 °C under a gentle N_2 stream.

For the enzymatic hydrolysis, the extract was redissolved in 4 mL of sodium acetate buffer. Then, 20 μL of β-glucuronidase/arylsulfatase was added and the oxygen atmosphere replaced by nitrogen. After incubation at 37 °C for 45 min, the enzymatic reaction was stopped by

cooling to room temperature, and the extract was centrifuged at 10000*g*, for 10 min, at 4 °C. This supernatant was then loaded into 200 mg Oasis HLB cartridges, previously conditioned with 5 mL of water and 5 mL of methanol. The cartridges were then washed with 5 mL of water and eluted with 10 mL of methanol/ethyl acetate (50:50). Finally, the eluate was evaporated to dryness under a gentle stream of nitrogen, at 37 °C, and the dried extracts were analyzed.

Chromatographic Conditions. Quantitation of the three PAH metabolites was carried out with LC-FD analysis. The dried eluate was dissolved in 1 mL of acetonitrile/methanol (50:50) and microfiltered. A 20 μL injection volume was used with a flow rate at 1 mL/min and a gradient elution of (A) (water) and B (acetonitrile) as follows: 0−5 min, 50% acetonitrile; 5−20 min, a linear gradient from 50 to 100% acetonitrile; 20−25 min, 100% acetonitrile; 25−30 min, a linear gradient from 100 to 50% methanol; and 30−32 min, 50% acetonitrile. A variable excitation/emission wavelength program was optimized to detect the different compounds as follows: 0−6.5 min, 266/348 nm; 6.51−9 min, 266/366 nm, acetonitrile; 9.01−30 min, 346/390 nm.

Validation Assays. To verify that the analytical method complies with criteria for the performance characteristics as established by Commission Decision 2002/657/EC, the following described validation procedures were carried out.

Linearity was evaluated through a calibration curve assembled by plotting each PAH metabolite peak area versus the concentration of standard solutions, at five concentration levels. The concentration levels ranged between 750 and 2000 ng/mL for 1-hydroxynaphthalene, between 30 and 75 ng/mL for 2-hydroxyfluorene, and between 150 and 300 ng/mL for 1-hydroxypyrene. Linearity was also evaluated in matrix-matched samples at 750, 850, 1000, 1500, and 2000 ng/g; 30, 40, 50, 60, and 75 ng/g; and 150, 175, 200, 250, and 300 ng/g 1-hydroxynaphthalene,2-hydroxyfluorene, and 1-hydroxypyrene, respectively.

Detection and quantification limits (LODs and LOQs) were evaluated on the basis of the noise obtained with the analysis of unfortified blank samples (n = 6). LOD and LOQ were defined as the concentration of the analyte that produced a signal-to-noise ratio of 3 and 10, respectively, and were then tested experimentally by spiking blank samples at such levels.

Recovery assays were performed on spiked samples to determine the accuracy and precision of the method, in triplicate, under the same analytical conditions. The accuracy was evaluated through spiking blank matrix at three levels of known concentrations: 750, 1000, and 2000 ng/g 1-hydroxynaphthalene; 30, 50, and 75 ng/g o2-hydroxyfluorene; and 150, 200, and 300 ng/g 1-hydroxypyrene. Precision was evaluated though the RSD (%) of the fortified samples, in within- and between-day assays.

RESULTS AND DISCUSSION

Chromatographic Method Optimization. A gradient reversed-phase LC-FD method was developed for the simultaneous determination of 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene. Different chromatographic conditions such as stationary phase, mobile phase composition, with isocratic or gradient program, flow rate, injection volume, temperature, and wavelength program were optimized for the separation of the selected PAH derivatives. According to the scientific literature, C18 LC columns are the most employed.[19,29,30] A C18 PAH column was chosen given their specificity for the LC analysis of these molecules and, as expected, separation and sensitivity were appropriate.

During the optimization of the chromatographic method, the organic solvents most commonly used for PAH metabolite determination were evaluated. A combination of acetonitrile with water[29,31] or methanol with water[19,32] is reported by most authors, and both of these combinations were tried. In a preliminary study, an isocratic elution system, consisting of methanol or acetonitrile and water (95:5), was attempted. Given that the chromatographic separation achieved was inadequate, a gradient elution system of acetonitrile and water was established. For the simultaneous determination of the three compounds, a variable-wavelength program was optimized on the basis of previous studies.[17,25]

Because PAH metabolites are subject to thermal degradation and photodegradation, antioxidant addition should prevent or at least reduce these processes. Some authors recommended their use in the preparation of the mobile phase and standard solutions to avoid degradation and increase the stability of the analytes. The addition of ascorbic acid at 1 mg/mL to the mobile phase was tried; nonetheless, because no improvement in the standards' stability was observed, this procedure was abandoned in further studies.[9,33] The addition of *tert*-butylhydroquinone (TBHQ), a hydroquinone derivative substituted with a *tert*-butyl group, in the preparation of standard solutions has also been reported to avoid standards' degradation.[17] However, this compound shows fluorescence at the same wavelength as 2-hydroxyfluorene, causing an overload of the photomultiplier tube (PMT) of the detector. Because the aim of this study was to quantitate simultaneously 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene, TBHQ usage was also excluded. To ensure standard stability, degradation studies on working standard solutions were performed during five consecutive days, and it has been concluded that the standard solutions were stable until the third day without antioxidant addition. Representative LC-FD chromatograms of a mixed standard solution and a spiked squid sample are shown in Figure 1.

Extraction Procedure Optimization. Optimization of the extraction, enzymatic deconjugation, and purification/concentration steps was performed with a blank sample (without PAH metabolites).

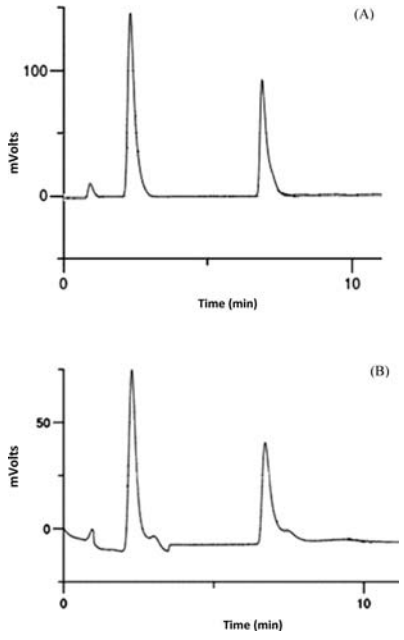

Figure 1. (A) LC-FD chromatogram of a standard solution mixture of (1) 1-hydroxynaphthalene, (2) 2-hydroxyfluorene, and (3) 1-hydroxypyrene at 1000, 50, and 200 ng/g, respectively. (B) LC-FD chromatogram of a spiked sample with (1) 1-hydroxynaphthalene, (2) 2-hydroxyfluorene, and (3) 1-hydroxypyrene at 1000, 50, and 200 ng/g, respectively.

Table 2. Validation Data Obtained for 1-Hydroxynaphthalene, 2-Hydroxyfluorene, and 1-Hydroxypyrene

			recovery (%)			RSD within-day (%)			RSD between-day (%)		
compound	LOD (ng/g)	LOQ (ng/g)	F1[a]	F2[b]	F3[c]	F1[a]	F2[b]	F3[c]	F1[a]	F2[b]	F3[c]
1-hydroxynaphthalene	225.0	750.0	98.7	110.1	107.4	9.5	4.6	15.3	6.8	0.5	12.2
2-hydroxyfluorene	9.0	30.0	70.3	77.6	79.0	6.0	7.2	6.1	1.6	0.1	7.5
1-hydroxypyrene	45.0	150.0	79.9	62.2	67.4	8.6	4.8	3.7	1.9	1.4	0.8

[a]Fortification level 1 = 750/30/150 ng/g of 1-hydroxynaphthalene/2-hydroxyfluorene/1-hydroxypyrene. [b]Fortification level 2 = 1000/50/200 ng/g of 1-hydroxynaphthalene/2-hydroxyfluorene/1-hydroxypyrene. [c]Fortification level 3 = 2000/75/300 ng/g of 1-hydroxynaphthalene/2-hydroxyfluorene/1-hydroxypyrene.

Most of the analytical methods for determining PAH metabolites were developed for human urine samples,[19] blood, and other biological fluids such as fish bile.[34] Although some analytical methods have been optimized for the determination of hydroxylated PAHs in milk and in infant foods,[17] to our knowledge no extraction procedures have been previously reported for their determination in cephalopods.

To optimize the extraction efficiency, different parameters were tested. First, as these compounds are light sensitive and easily degradable, the importance of the addition of an antioxidant to the sample was evaluated. In the present study, the action of two antioxidants, ascorbic acid and TBQH, was assessed. When ascorbic acid was used at a concentration of 1 mg/mL, better recovery rates were achieved when 1 mL of the solution was added to 1 g of sample.

With regard to the extraction solvent, and given that PAH metabolites present high solubility in acetonitrile, this solvent was chosen. Because enzymatic hydrolysis in the following step is active in aqueous media, the extraction organic solvent must be evaporated to dryness. However, the temperature applied during the evaporation step may limit the recoveries of hydroxylated metabolites. Different temperatures were tested (35, 37, 40, and 42 °C) and, in agreement with other studies,[17] the highest temperatures degrade these compounds and, therefore, 37 °C was selected. In addition, to decrease the time of the evaporation step, two volumes of extraction solvent were tested, 6 and 10 mL. Nonetheless, the best recovery results were attained with 6 mL because a reduction in the evaporation time was accomplished. It is worth noting the importance of avoiding light and maintaining a low temperature to minimize metabolite degradation. Good separation between the sample and supernatant was achieved when 10000*g* was applied for 10 min at 4 °C.

Hydrolysis Optimization. Because hydroxy metabolites are biotransformed to phase II metabolites by conjugation with glutathione, glucuronide, or sulfate, an enzymatic reaction with β-glucuronidase is crucial to liberate them and obtain free metabolites. As the enzymatic hydrolysis is a chemical reaction catalyzed by an enzyme that uses water to break molecules, the use of an aqueous buffer solution is essential. It will also keep the pH constant at the optimum value for enzyme activity. Therefore, several experimental conditions, such as pH (4.5, 5.0, and 5.5), buffer concentration (0.05, 0.1, and 0.5 M), enzyme volume, incubation time (40, 45, 50, and 60 min), and temperature (37, 40, and 42 °C) were optimized. In agreement with other authors,[17,35] it was found that 4 mL of a 0.1 M sodium acetate buffer, at pH 5, at 37 °C for 45 min, gave the best results.

On the basis of scientific evidence,[17,19,36] the addition of 20 μL of β-glucuronidase/arylsulfatase from *Helix pomatia* to 4 mL of solution is enough for the reaction to occur extensively, which was tested in this study and revealed to be clearly appropriate. Because the analyzed compounds degrade in the presence of oxygen, it is important to highlight the need to displace the oxygen present in the test tube by a nitrogen atmosphere shortly after the addition of the enzyme.

SPE Optimization. SPE is one of the most employed tools for the cleanup of PAHs[21] and their metabolites.[17,19,37] First, we attempted to choose the best sorbent to obtain higher recoveries. C18 cartridges, reversed phase silica-based sorbents, have several disadvantages such as low breakthrough volumes, instability at some pH values, and the presence of silanol groups, which can result in low recoveries for some polar compounds or lack of precision from column to column, resulting in irreproducible recoveries. PAH hydroxylated metabolites have quite polar characteristic, and it was difficult to extract them with traditional reversed-phase sorbents. Aware that the SPE method, and particularly the C18 cartridges, might impose some variability in PAH hydroxylated metabolite recoveries, hydrophilic polymeric sorbents have been chosen, and best results were obtained with the reversed phase polymeric-based cartridges Oasis HLB, which allow a hydrophilic−lipophilic balance. According to our knowledge, the use of Oasis HLB has never been reported for the analysis of PAH hydroxylated metabolites.

The initial Oasis SPE procedure was based on the C18 SPE procedures previously attempted.[17,19] However, because 1-hydroxynaphthalene and 1-hydroxypyrene metabolites were inefficiently retained, with recoveries of 34 and 32%, respectively, parameters, such as washing and elution steps, were optimized using a mixed standard working solution at 1000, 50, and 150 ng/mL 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene, respectively.

The obtained results suggested that for the washing step water is the more suitable solvent, as it has enough solvent power to remove weakly absorbed interferents without removing the strongly absorbed analytes. Washing solutions containing methanol led to substantial losses and greatly decreased 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene recoveries, from 87, 68, and 75%, respectively, to 66, 40, and 22%, respectively.

With regard to the elution step, to ensure high recoveries of all PAH metabolites, mixtures of solvents are usually recommended.[21] Different solvents and volumes were evaluated, and it was found that the presence of methanol was important; nonetheless, neither methanol nor dichloromethane, alone, eluted efficiently 1-hydroxynaphthalene (recoveries of 15 and 40%, respectively) and 1-hydroxypyrene (recoveries of 32 and 8%, respectively). In agreement with other authors,[17] 10 mL of methanol/ethyl acetate was the best approach to obtain greater recovery.

Method Validation. The developed analytical method complied with criteria for the performance characteristics as established by Commission Decision 2002/657/EC.[38]

The linearity of the method was evaluated in solvent and in matrix-matched solutions. In the working standard solutions, at five concentration levels, correlation coefficients (r^2) were 0.9987 for 1-hydroxynaphthalene and 0.9959 for 2-hydroxyfluorene and 1-hydroxypyrene. In matrix-matched solutions adequate r^2 values of 0.9949, 0.9901, and 0.9903 for 1-hydroxynaphthalene, 2-hydroxyfluorene, and 1-hydroxypyrene, respectively, were obtained.

Because no standard reference material is available for PAH metabolites in cephalopods, for accuracy and repeatability assays, recoveries were determined through a spiking matrix at three different levels, on three different days, and each extract was analyzed three times. Accuracy varied between 62.2 and 110.1%, with within-day and between-day repeatabilities ranging between 3.7 and 15.3% and between 0.1 and 12.2%, respectively (Table2).

Application to Real Samples. The optimized and validated analytical methodology was applied to the analysis of 12 squid samples of *Loligo gahi* species and to 6 hemolymph samples obtained from *Octopus vulgaris* harvested live from the Northwest Atlantic Portuguese coast. *L. gahi* is widely distributed along the Pacific coast of South America. It is the second most important loliginid squid in commercial fisheries worldwide.[39] A small part of the total catch is consumed in Europe, predominantly in Spain.[2] With regard to the selected octopus, it corresponds to the major species consumed worldwide[40] and was recently proposed as a sentinel species for the presence of contaminants in coastal waters.[13]

Of the 18 samples analyzed, 39% (7) were contaminated with 1-hydroxynaphthalene, which was the only PAH metabolite detected, ranging between 786 and 1145 ng/g (Table 3). Naphthalene, a low molecular weight PAH, which is classified as a possible carcinogen to humans (group 2B) by the International Agency for Research on Cancer (IARC), is one the most abundant compounds detected in marine organisms and it is mainly due to petrogenic pollution.[41] None of the squid samples contained detectable amounts of 2-hydroxyfluorene or 1-hydroxypyrene. Also, none of the hemolymph samples exhibited detectable amounts of metabolites, which confirms the lack of (or low) detoxification capacity of the octopus species regarding PAHs.

Table 3. PAH Metabolite Concentrations from the Analyzed Samples

sample	1-hydroxynaphthalene (ng/g)
L18A	830
L18B	786
L10B	788
L10C	<LOQ
L24A	1013
L24B	1145
L24C	<LOQ

Although some publications regarding the contamination of PAHs metabolites in fish[10,11,22−25] have been reported, the comparison with other studies is difficult, because, to our knowledge, there are no reports of the determination of PAH metabolites in mollusks, namely, in cephalopod samples. Nonetheless, the results of the present study are corroborated by a previous work[2] that evaluated the concentrations of 18 PAHs in five commercial squid species in Portugal, with different geographical origins. The results showed that low molecular weight compounds with two and three rings were the most predominant PAHs in all of the species. The detected concentrations in *L. gahi* (from the Atlantic Ocean) may mean additional carcinogenic risks for high cephalopod consumers. Moreover, in a survey that revealed the measurable presence of four low molecular weight PAHs (naphthalene, acenaphthene, fluorine, and phenanthrene) in three commonly consumed and commercially valuable fish species (sardine, chub, and horse mackerel) from the Atlantic Ocean, naphthalene was the most abundant PAH in sardine and horse mackerel, accounting for ca. 55% of the total PAHs.[41]

In contrast to our results, in a study[22] that included the analysis of PAH metabolites in the bile of flounder (*Platichthys flesus*), the major PAH metabolite detected was 1-hydroxypyrene. 1-Hydroxyphenanthrene and 3-hydroxybenzo[*a*]pyrene were also detected in 70 and 24 samples, respectively, of the 87 samples analyzed. However, the concentrations of 1-hydroxyphenanthrene and 3-hydroxybenzo[*a*]pyrene were below or near the LOQ (0.002 mg/mL bile). The bile of flounder samples from the Gulf of Gdansk presented 1-hydroxypyrene concentrations ranging from 0.019 to 0.066 mg/mL.[22]

Rey-Salgueiro et al.[37] also investigated the levels of 3-hydroxybenzo[*a*]pyrene in the bile and plasma of Nile tilapia after waterborne exposure to benzo[*a*]pyrene (10 and 100 mg/L). Metabolites were detected in bile and plasma, and conjugates of 3-hydroxybenzo[*a*]pyrene (glucuronide and/or sulfate conjugates) were the majority forms in both biological fluids, glucuronide 3-hydroxybenzo[*a*]pyrene being the main metabolite in bile. The same research group, in a previous study[17] concerning food safety of commercial milk formulas and infant cereals, reported that no hydroxy PAH metabolites (1-hydroxypyrene and 3-hydroxybenzo[*a*]pyrene) or their conjugates were detected in the analyzed foodstuffs.

With respect to glyceollin, a recent study conducted in rats reported absorption of glyceollins across the gastro-intestinal tract following oral administration of a single 90 mg/kg dose of a mixture of glyceollin isomers I–III.[30] In that study, the average maximum plasma concentration of the three isomers combined was only 160 ng/mL; thus, it seemed plausible that glyceollin may behave similarly to other phytochemicals in being extensively metabolized. Initial characterization of plasma samples taken from the same rats that received the 90 mg/kg dose revealed sulfated metabolites.[17] The purpose of the current work is to extend this initial metabolite profiling through broader characterization of glyceollin metabolites in these same plasma samples and to expand our analyses to urine and feces samples obtained from separate groups of rats that received either a single 90 mg/kg oral dose (urine) or two weeks of daily 90 mg/kg oral doses (feces) of the same glyceollin I–III isomeric mixture used in the initial study.[29]

MATERIALS AND METHODS

Chemicals. High purity grade trifluoroacetic acid (TFA, >99%) and formic acid (>96%) were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO) as was HPLC-methanol solvent. OmniSolv LC-MS acetonitrile was purchased from EMD Millipore (Billerica, MA). A Millipore water purifying system (18.2 MΩ·cm) was used to obtain deionized water.

Extraction of Glyceollin Isomers. Using a procedure developed at the Southern Regional Research Center (SRRC, ARS, USDA, New Orleans, LA), a mixture of glyceollins I, II, and III was obtained.[6] Briefly, after slicing, soybean seeds were inoculated with *Aspergillus sojae*. The *A. sojae* (SRRC 1125) culture was grown at 25 °C in the dark on potato dextrose agar. *Conidia* were harvested from 5-day-old cultures of *A. sojae*. *Conidia* were suspended in 15 mL sterile, distilled H_2O ($1.0–3.0 \times 10^7$ conidia mL^{-1}) and mixed with sliced soybean seeds (1 kg). Three days after exposure to *Conidia*, the glyceollins were extracted from the inoculated seeds with 1 L of methanol. Notably, the process to induce glyceollins in soybean is not a traditional fermentation (soybean seeds are not heated). Typically, there are no glyceollins present in soybean unless the plant or seed was subjected to stress. Under conditions of stress, the soybean seed triggers the production of critical enzymes (phenylalanine ammonia-lyase, PAL) necessary for producing glyceollins. The glyceollins were isolated using preparative scale HPLC employing two Waters (Milford, MA) 25 × 100 mm, 10 μm particle size μBondapak C_{18} radial compression column segments; the column segments were connected in series using an extension tube. HPLC was performed on a Waters 600E liquid chromatograph equipped with a Waters UV–vis 996 detector scanning from 210 to 400 nm. The injection volume was 20 mL; the flow rate was 8.0 mL/min using the following solvent gradient: A = acetonitrile (Sigma-Aldrich), B = water (Millipore system, Billerica, MA) 5% A for 10 min, then 5% A to 90% A in 60 min followed by holding at 90% A for 20 min. The fraction containing the glyceollins was concentrated (≥98% purity) under vacuum and freeze-dried. Confirmation of individual glyceollins was based on HPLC retention times and UV–vis absorbance spectra comparison with those of authentic standards isolated at SRRC. UV–vis spectrophotometry at 285 nm was used to estimate the percentage of the three isomers used in all experiments: glyceollin I (68%), glyceollin II (21%), and glyceollin III (11%).

Glyceollin Dosing of Rats and Plasma Sample Collection. The procedures used for administration of glyceollins to rats and subsequent sample collection have been previously described.[30] Briefly, the mixture of glyceollin isomers I–III defined in the preceding section was dissolved in poloxamer and administered (90 mg/kg) via oral gavage (3 mL) to male ZDSD (Zucker Diabetic Sprague–Dawley) rats (PreClinOmics, Indianapolis, IN) that were subjected to a 12:12 h light/dark cycle. These rats are an obese prediabetic rat model of Type II diabetes.[30] This dose was selected because it was identical to that used in an oral-glucose-tolerance test to evaluate the antidiabetic potential of glyceollins.[29] Rats (approximately 500 g wt) were euthanized at various time points by decapitation; trunk blood was subsequently collected into EDTA-coated tubes supplemented with aprotinin. Plasma samples obtained 3 h after dosage were separated and stored at −80 °C. Upon thawing, 125 μL of plasma was transferred into microcentrifuge tubes to which an equivalent volume of acetonitrile was added. The mixture was vortexed, then centrifuged at 10 000 rpm for 20 min. The supernatant was subjected to mass spectrometric analysis.

Urine Sample Treatment. A urine sample obtained from a 24 h collection period that commenced following a single 90 mg/kg oral dose to a rat was acidified with 1% TFA, vortexed, and centrifuged at 10 000 rpm for 10 min. The supernatant was diluted with 1:1 0.2% formic acid in 10% acetonitrile[31] and stored at −80 °C until the subsequent LC-MS analyses.

Fecal Sample Collection. Rat fecal samples were collected prior to and after the dosage of the mixture of glyceollin isomers I–III (90 mg/kg) once daily for 2 weeks. This study was conducted to assess possible effects of glyceollin administration on the gastrointestinal microbiome, thus necessitating multiple dose administration. Both the pre- and postdosed fecal pellets were weighed, and a 1:2 (pellet weight/vol) ratio of deionized water was added to each group. A smooth paste was created in a glass mortar and pestle. The paste was then transferred to a polypropylene tube and diluted with CH_3CN 1:2 (paste wt/vol). The tubes were centrifuged for 5 min at 1000 rpm. Supernatant was collected and transferred to fresh tubes; then, approximately 0.1 g of ammonium acetate was added progressively with gentle vortexing. Tubes were subsequently centrifuged for 5 min at 1000 rpm. The supernatant (acetonitrile layer) was collected and stored at −70 °C until analysis.

Liver Microsomes Treatment with NADPH or UDPGA Cofactors. Samples were prepared in triplicate for both the control and the experimental group. For the NADPH incubations (phase I oxidation), 168 μL of 100 mM NaH_2PO_4 buffer (pH 7.4), 10 μL of 20 mg/mL rat liver microsomes, 10 μL of 20 mM $MgCl_2$, and 1 mM glyceollins I–III isomeric mixture were added to 1.5 mL Eppendorf tubes, vortexed, and incubated for 3 min at 37 °C. Subsequently, 10 μL of either 10 mM NADPH or buffer (control) was added, and the samples were incubated for 30 min at 37 °C. The incubation was stopped by adding 200 μL of cold acetonitrile, followed by vortexing, and centrifugation for 5 min at 4000 rpm. Supernatant was transferred to fresh tubes and stored at −70 °C until analysis. For the UDPGA conjugation procedure, 134 μL of 100 mM KH_2PO_4 buffer (pH 7.1), 20 μL of 20 mg/mL rat liver microsomes, and 4 μL of 5 mg/mL alamethicin were added to 1.5 mL Eppendorf tubes, vortexed, and incubated on ice for 15 min. Twenty microliters of $MgCl_2$ and 2 μL of 1 mM glyceollins I–III isomeric mixture were then added, vortexed, and incubated for 3 min. Twenty microliters of KH_2PO_4 buffer and 20 μL of 10 mM UDPGA were added to control and experimental groups, respectively. The tubes were incubated for 60 min at 37 °C. Two hundred microliters of cold acetonitrile was added to each tube to terminate the incubation. Tubes were then vortexed followed by centrifugation for 5 min at 4000 rpm. Supernatant was transferred to fresh tubes and stored at −70 °C until analysis.

Liquid Chromatography–Mass Spectrometry. LC-ESI-MS and LC-ESI-MS/MS analyses were conducted on an Agilent 1200 series LC system (Agilent, Santa Clara, CA) coupled to a 3200 QTrap triple quadrupole mass spectrometer (Applied Biosystems/MDS SCIEX, Foster City, CA). Separation was performed on an Agilent Eclipse XDB C18 column (4.6 × 150 mm ID, 5 μm). Ten microliters was injected onto the column held at 25 °C. The binary mobile phase consisted of mobile phase A (water with 0.1% formic acid) and mobile phase B (acetonitrile with 0.1% formic acid). The gradient was 0–44 min 5% B to 45% B; the flow rate was 0.500 mL/min. The UV absorbance detector was set at 285 nm.

For negative ion LC-ESI-MS and LC-ESI-MS/MS analyses, electrospray parameters were set at the following: curtain gas (CUR) of 20 psi, ionspray voltage (IS) of −4500 V, GAS1 of 60 psi, GAS2 of 60 psi, source temperature of 600 °C, CAD gas pressure of 6 psi, entrance potential (EP) of −10 V, and collision cell exit

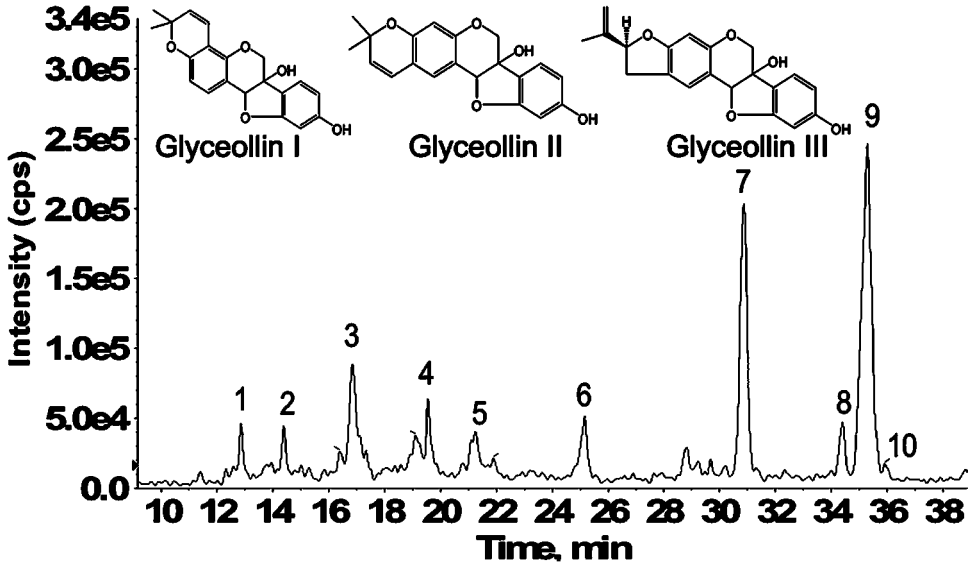

Figure 1. LC-ESI-MS/MS precursor ion scans showing total ion current of all precursors of m/z 148 from feces of rats dosed orally once daily for 2 weeks with 90 mg/kg of the glyceollin isomeric mixture. Isomeric structures of glyceollins I, II, and III are shown above the scans (inset).

potential (CXP) of −3 V. Declustering potential (DP) and collision energy (CE) were optimized to be −55 V and −34 eV, respectively. For positive ion experiments, CUR, IS, EP, CXP, DP, and CE were maintained at 10 psi, 5000 V, 10 V, 5 V, 40 V, and 30 eV, respectively. All other parameters were the same as for negative ion mode. Full scan and precursor ion scans were performed sequentially (scan rate = 1 s/200 Da). In a subsequent LC injection, product ion scans for precursors of interest were added to the sequential acquisitions.

RESULTS AND DISCUSSION

Precursor Ion Scans of *m/z* 148. In our previous work, we proposed a precursor ion scan method to screen for isomeric glyceollins and their metabolites based on a diagnostic radical product ion.[17,29] Higher-energy triple quadrupole (e.g., 34 eV E_{Lab}) CID product ion spectra of glyceollins yield an exceptionally stable radical at m/z 148, which serves as a "signature" common to the three glyceollin isomers.[17] Employing this precursor ion scanning approach, plasma, urine, and feces samples obtained from rats dosed with isomeric glyceollins I, II, and III (structures shown in Figure 1) were screened for the glyceollins and their metabolites by LC-ESI-MS and LC-ESI-MS/MS. The precursor ion scanning of m/z 148 for rat feces samples resulted in the appearance of substantially more metabolites compared to rat plasma and urine samples. Figure 1 shows a representative LC chromatogram of a rat feces sample. All three unmetabolized isomers of glyceollins (m/z 337) were detected. Peaks labeled 9, 8, and 10 on the LC chromatogram correspond to glyceollin I, II, and III, respectively.

Little is known about the metabolism of glyceollins, but our findings from rat feces indicate that extensive oxidation of glyceollins occurred. Peaks 5, 1, and 6 (Figure 1) represent m/z 148 precursors at m/z 353, 371, and 387, respectively. Relative to deprotonated glyceollins (m/z 337), these three metabolites are proposed as products of epoxidation or hydroxylation of glyceollins (m/z 353), diol addition at a double bond (m/z 371), and a combination of these two processes (m/387). Two of the three above-mentioned peaks observed in rat feces (m/z 371, 387) were also detected in rat urine, as was m/z 451 (the latter likely represents glyceollins that are both hydrolyzed and sulfated). Notably, m/z 451 had also been detected in rat plasma, along with m/z 353 and 355 (the latter representing a hydrolysis product).[17] LC-ESI-MS/MS precursor ion scanning of m/z 148 from rat feces showed additional peaks eluting at 14.4 (peak 2), 16.8 (peak 3), 19.3 (peak 4), 30.9 (peak 7), and 35.3 (peak 9) min. These chromatographic peaks correspond, respectively, to glyceollin metabolite precursors at m/z 531, 474, 433, 417, and the deprotonated glyceollin isomers at m/z 337. These five precursors of m/z 148 were also found in rat plasma, whereas m/z 531, 474, and 417 were observed in rat urine (data not shown). Sulfation and sulfation plus an oxygen of glyceollins account for the peaks observed at m/z 417 (peak 7) and 433 (peak 4), respectively, as discussed previously.[17] The two remaining precursor peaks of interest at m/z 474 and 531 were considered as phase II metabolites of glyceollins and were further investigated by tandem mass spectrometry, as discussed in the following section.

Evidence of GSH-Derived Metabolites Obtained by LC-ESI-MS and LC-ESI-MS/MS. A chromatographic peak corresponding to the m/z 531 precursor from feces samples eluted at 14.4 min (Figure 1, peak 2); an identical peak was observed in rat plasma and urine. The NI mode LC-ESI-MS/MS CID product ion mass spectrum of this m/z 531 precursor (Figure 2a) summed across the entire chromatographic peak showed a fragment at m/z 353, which corresponds to a loss of 178 Da. Appearing in Figure 2b is the NI mode LC-ESI-MS/MS CID product ion mass spectrum of m/z 474 corresponding to the chromatographic peak eluting at 17.0 min (Figure 1, peak 3). Similar to the result shown in Figure 2a, the m/z 474 also yields a fragment at m/z 353, indicating this time, a loss of 121 Da. The combined information extracted from Figure 2a,b allows the deduction that glutathione conjugation has occurred in glyceollins and that subsequent metabolic byproducts are present in the three matrices: rat plasma, urine, and feces.[32] GSH is a tripeptide (Glu-Cys-Gly) that, when conjugated to molecules via the thiol function in cysteine, is subsequently metabolized via γ-glutamyltranspeptidase to form cysteinylglycine conjugates. We propose that the loss of 178 Da (Figure 2a) involves loss of intact cysteinylglycine from the m/z 531 precursor that corresponds to a cysteinylglycine conjugate of an oxygenated form of glyceollins. Strongly supporting this

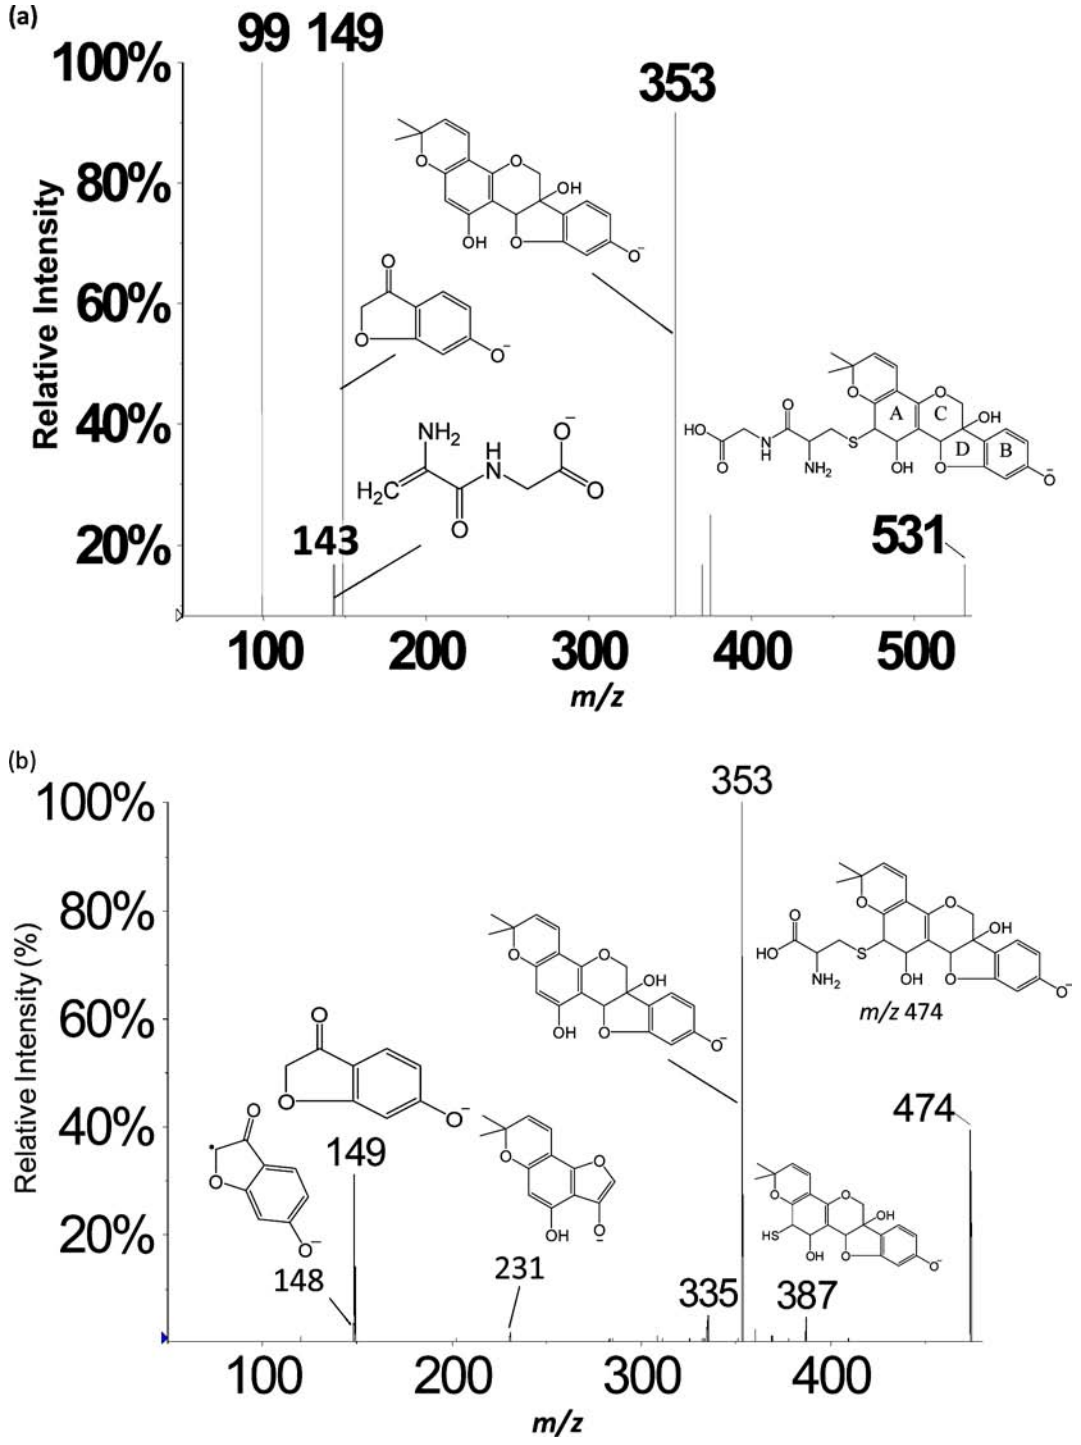

Figure 2. LC-ESI-MS/MS negative ion mode product ion mass spectra of (a) m/z 531 precursor and (b) m/z 474 precursor. One site of hydroxylation and one site of peptide addition are proposed; other isomeric structures may exist (see Scheme 1).

proposition is the appearance of a cysteinylglycine fragment ion at m/z 143 (Figure 2a). To complement this information, the 121 Da loss from the m/z 474 precursor (Figure 2b) is proposed to correspond to intact cysteine. The m/z 474 precursor is thus proposed to represent the cysteinyl conjugate of oxygenated glyceollins, which represents the second step in the metabolism of GSH conjugates via peptidase-mediated hydrolysis of the cysteinylglycine conjugate. Further evidence to support this assignment is given by the appearance of m/z 387 that corresponds to decomposition of the cysteine amino acid (Figure 2b).

The occurrence of GSH conjugation via glutathione S-transferases (GSTs) is often associated with electrophilic compounds or their metabolites.[33] With respect to phytochemicals, this pathway is the principal metabolic route in the metabolism of sulforophane,[34] which is derived from cruciferous vegetables and contains an isothiocyanate-based electrophile. Importantly, sulforophane possesses potent anticarcinogenic and cytoprotective properties[35,36] that are

dx.doi.org/10.1021/jf403498f | J. Agric. Food Chem. 2014, 62, 2692−2700

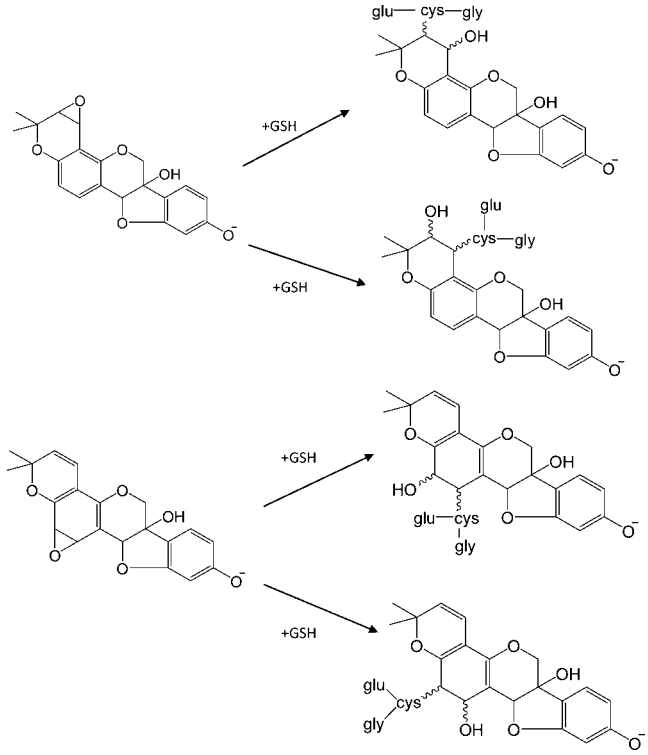
postulated to derive from its ability to induce expression of phase II enzymes, including GSTs.

Evidence obtained from the in vivo studies reported herein indicates that phase I-derived glyceollin metabolites detected in rat plasma, urine, and feces have undergone glutathione conjugation. Although NI mode LC-ESI-MS/MS CID product ion mass spectra of m/z 660 and 644 precursors (corresponding to potential oxygenated and nonoxygenated GSH-glyceollins, respectively) were acquired from rat plasma, urine, and feces samples, no intact glutathione conjugates of glyceollins were detected. This can be attributed to the fast kinetics of enzymatic glutamate cleavage[37] from the GSH–glyceollin complex that produces the cysteinylglyceine conjugate (m/z 531, Figure 2a). As mentioned above, the cysteinylglyceine conjugate can be subsequently metabolized to the cysteine conjugate. The product ion spectrum of the m/z 474 precursor (Figure 2b) corroborates the presence of cysteinyl conjugates of glyceollins. These proposed metabolites are observed in oxygenated forms (i.e., in addition to the cysteinyl sulfur linkage, an oxygen atom has been added). Complementing this finding, a +16 metabolite was also observed via precursor ion scanning following coincubation of 10 μM of the glyceollin isomeric mixture with NADPH in rat liver microsomes (data not shown). We propose that the addition of oxygen precedes the addition of GSH; initial formation of an epoxide would be consistent with this proposition. Enzymatic formation of epoxides followed by glutathione conjugation has been previously documented.[38,39] Epoxide formation at a double bond represents a reactive intermediate that is highly susceptible to GSH complex formation.

The CID product ion mass spectra of m/z 531 (Figure 2a) and 474 (Figure 2b) precursors each yield a fragment at m/z 353 corresponding to the loss of cysteinylglycine or cysteine, respectively, with abstraction of a neighboring hydrogen and double bond (or epoxide) formation on the glyceollins in each case. In addition, Figure 2a,b each shows the presence of m/z 149 (i.e., the B fragment ion formed from decomposition of the glyceollin backbone).[17] In our previous study, the CID product ion spectrum of the sulfated metabolite of glyceollins with an additional oxygen (m/z 433) showed B fragments (m/z 148 and 149) which were the same as those found for unmetabolized deprotonated glyceollins; however, A fragments (m/z 191 and 243) were shifted higher by 16 m/z units. These combined observations allowed the localization of oxygen attachment on glyceollins.[17] For the GSH enzymatic products, the appearance of the m/z 149 fragment suggests that the oxygen and cysteinylglyceine dipeptide or cysteine are not located on the B fragments. More importantly, the A fragment expected at m/z 215[17,40] has been shifted to m/z 231 (Figure 2b), thus indicating that oxygen addition had occurred on the A fragment. On the basis of our evidence for initial epoxidation followed by GSH attachment, combined with the CID data presented above, we conclude that there are four possible attachment sites for the initial oxygenated glutathione conjugates of glyceollins (Scheme 1); the oxygenated cysteinylglyceine and oxygenated cysteinyl–glyceollin conjugates would maintain these same sites of conjugation.

Assignments of oxygenated cysteinylglyceine- (m/z 531 in NI mode) and oxygenated cysteinyl–glyceollin conjugates (m/z 474 in NI mode) were further confirmed by acquiring data in the positive ion (PI) mode. Figure 3a,b show the PI mode LC-ESI-MS/MS CID product ion mass spectra of m/z 533

Scheme 1. Glutathione Conjugation to the Two Most Favorable Epoxide Forms of Glyceollin I



(protonated cysteinylglyceine glyceollins with an additional oxygen) and m/z 476 (protonated cysteinyl glyceollins with an additional oxygen). The appearance of m/z 355 corresponds to the loss of 178 Da from m/z 533 (Figure 3a) and 121 Da from m/z 476 (Figure 3b), indicating a loss of intact cysteinylglyceine or cysteine, respectively, that mirror the losses observed in the NI mode. Proposed fragment ion structures and decomposition mechanisms of oxygenated cysteinyl glyceollin are shown in Scheme 2. Because the CID product ion spectrum of oxygenated cysteinylglyceine glyceollins (m/z 533, Figure 3a) is similar to the CID product ion spectrum of oxygenated cysteinyl glyceollin (m/z 476, Figure 3b), the decomposition mechanisms for the two metabolites appear to be entirely analogous.

Cysteine conjugates can be further metabolized and acetylated, resulting in mercapturic acid conjugates.[41] However, these anticipated conjugates were not detected in precursor ion scans of m/z 148. Consequently, screening for mercapturic acid conjugates of glyceollins was directly performed by product ion scanning. The NI mode LC-ESI-MS/MS CID product ion mass spectrum of m/z 516 (corresponding to the previously detected oxygenated cysteinyl glyceollin, m/z 474, that had potentially undergone acetylation) was performed on rat plasma, urine, and feces samples. Only feces eluted a chromatographic peak corresponding to m/z 516 that appeared at 22.9 min. The NI mode LC-ESI-MS/MS CID product ion mass spectrum of the m/z 516 precursor showed a fragment at m/z 353 corresponding to the loss of mercapturic acid (163 Da), indicating that the precursor was indeed an oxygenated mercapturic acid conjugate of glyceollin. Other fragments similar to those in the CID product ion spectrum of deprotonated glyceollins were detected at m/z 148, 149, and 161; however, for reasons discussed below, in the case of glucuronide conjugation, the signal for m/z 148 was very low.

dx.doi.org/10.1021/jf403498f | J. Agric. Food Chem. 2014, 62, 2692–2700

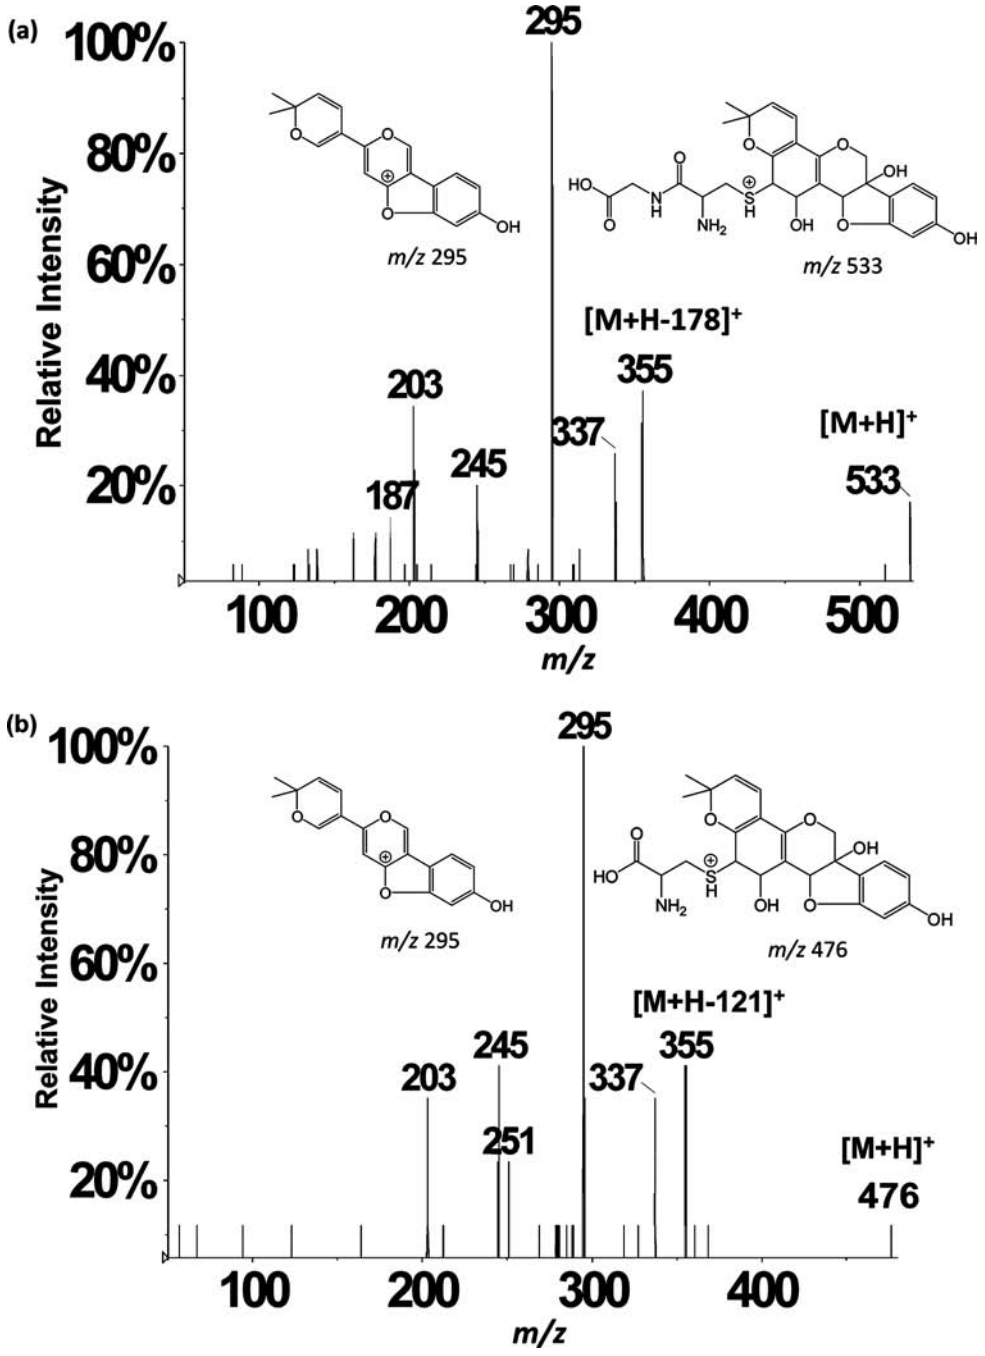


Figure 3. LC-ESI-MS/MS positive ion mode product ion mass spectra of (a) m/z 533 precursor and (b) m/z 476 precursor. Other isomeric forms of the assigned structures may also exist (see Scheme 1).

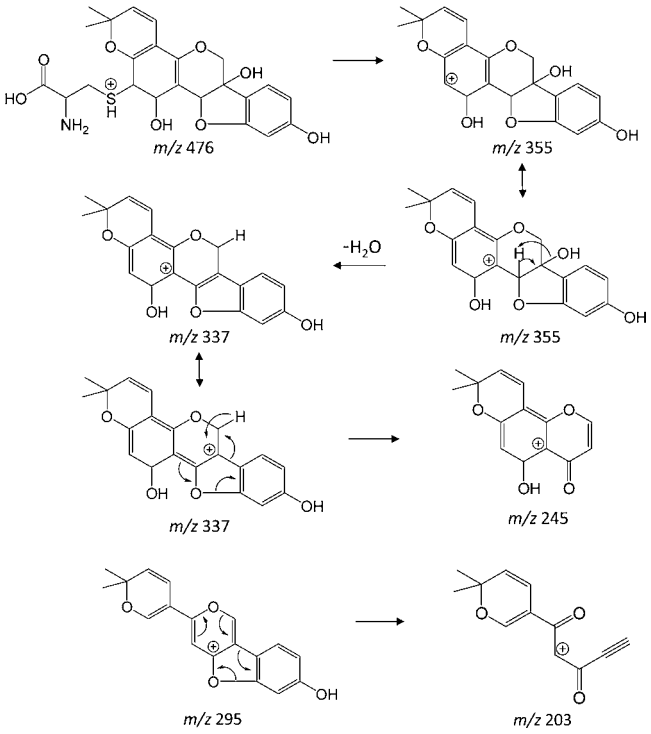
Absence of the mercapturic acid metabolite in plasma and urine may be due to insufficient formation of this metabolite upon a single dose (in contrast to multiple dosing of the rats that provided the source of the feces samples).

Glucuronidation of Glyceollins. Because glucuronide conjugates have been reported for isoflavones,[42−44] the decision was made to screen for glucuronide conjugates of glyceollins by performing product ion scans. In general, an addition of 176 Da in biological medium is well-documented to be characteristic of addition of glucuronic acid.[45,46] Thus, the LC-ESI-MS/MS CID product ion scan of m/z 513 was carried out on rat plasma, urine, and feces samples. A corresponding chromatographic peak appeared at 27.6 min from rat plasma and urine samples only. Absence of the glucuronide conjugate in feces is attributed to high levels of β-glucuronidase in the colon from bacteria.[26] The averaged product ion mass spectrum (Figure 4a) shows a peak at m/z 337 corresponding to deprotonated glyceollins produced after loss of glucuronic acid.[33] In addition, the highest abundance fragment appears at m/z 175. Even though a low abundance product ion at m/z 175 had been observed during CID of deprotonated glyceollins (m/z 337),[17,29] the high abundance of m/z 175 in Figure 4a is better rationalized as release of the glucuronate anion. No fragment ions in Figure 4 are shifted by 176 mass units relative to the product ions in the CID spectrum of m/z 337 (deprotonated glyceollins), indicating that the glucuronide moiety is the most labile

Scheme 2. Proposed Structures and Collision-Induced Dissociation Mechanisms of Oxygenated Cysteinyl Glyceollin I[a]



[a]One isomeric form of m/z 476 is shown, but others are possible (see Scheme 1).

substituent of the m/z 513 precursor. Accordingly, the other CID product ions are assigned as consecutive decompositions of m/z 337, including m/z 319 (water loss) and m/z 149 production. Interestingly, the m/z 148 ion was absent in these scans. This latter product ion is not always observed upon *consecutive* decompositions as it requires relatively high energy CID conditions.[17] That is, owing to the energy consumed in decomposing m/z 513 to m/z 337, less energy remains for m/z 337 to undergo consecutive decomposition, which results in more favorable kinetics for m/z 149 production relative to m/z 148. This also rationalizes the absence of m/z 513 in the scan for precursors of m/z 148.

Glucuronide conjugates of glyceollins for LC-ESI-MS/MS method development are not commercially available. Nonetheless, in vitro glucuronidation is often performed with the aid of uridine diphosphoglucuronosyl-transferase enzymes (UGTs).[27] The UGT enzymes are present in abundance in rat liver microsomes. Using this approach, glyceollins were exposed to rat liver microsomes to generate glucuronide conjugates of glyceollins. LC-ESI-MS/MS analyses were then carried out. The retention time and the similar fragmentation pattern in the product ion spectrum of m/z 513 (Figure 4b) from these in vitro incubations confirmed our assignment of the glucuronidated metabolite of glyceollins from rat plasma and urine samples.

To summarize our findings, LC-ESI-MS/MS analyses were carried out on a triple quadrupole to identify glyceollins and their metabolites from plasma, urine, and feces samples obtained from a 90 mg/kg single oral dose to rats (plasma and urine) or from 90 mg/kg/day for 14 days of dosing (feces). The precursor ion scan of m/z 148 allowed screening for the

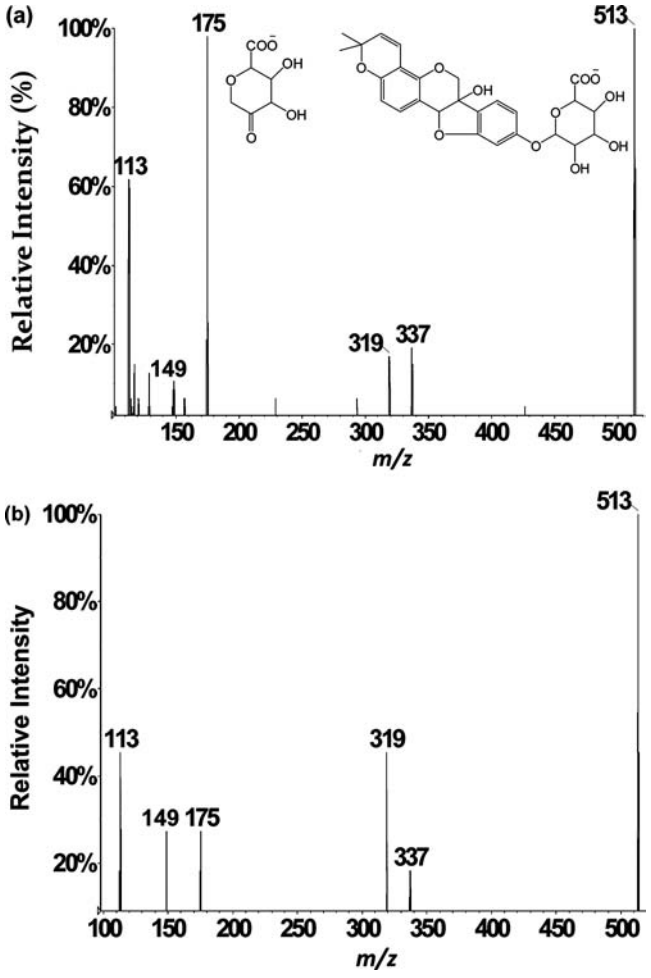


Figure 4. LC-ESI-MS/MS negative ion mode product ion spectrum of m/z 513 precursor corresponding to glucuronic acid conjugates of glyceollins acquired from (a) rat urine and (b) rat liver microsomes.

majority of the glyceollin-related compounds. Table 1 compiles a list of all metabolites found in plasma, feces, and urine of male ZDSD rats. Peaks of interest found at m/z 474 and 531 in all

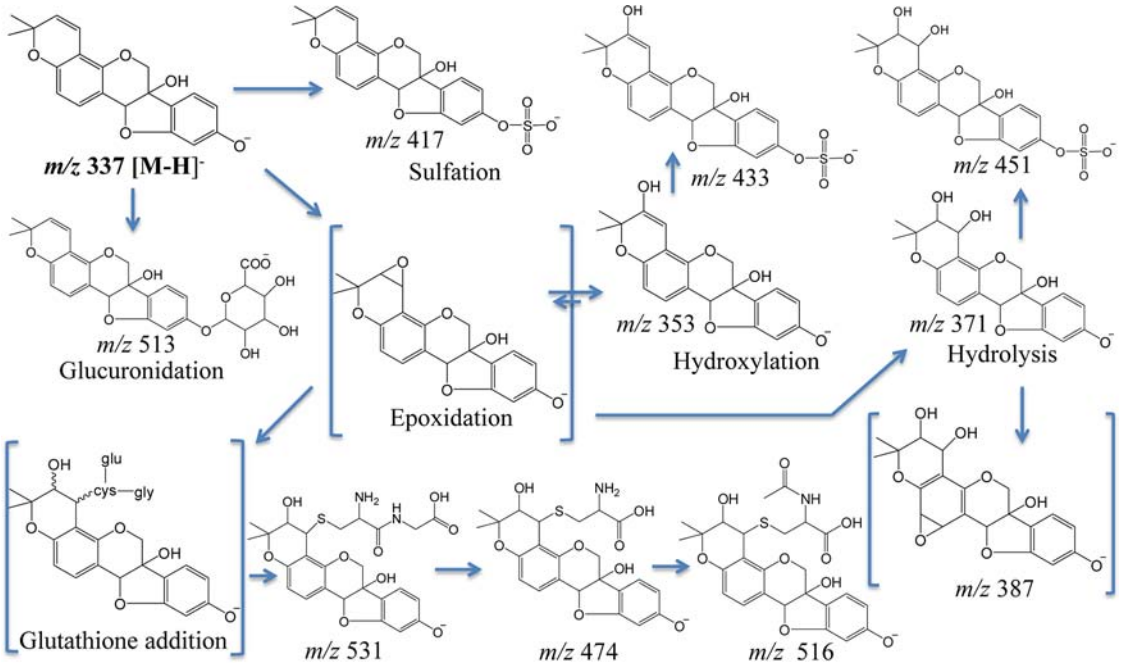
Scheme 3. Summary of Glyceollin Metabolism in Male ZDSD Rats[a]



[a]Brackets surround structures most susceptible to further reaction. Structures proposed in this diagram are not intended to exclude the presence of certain other isomeric forms (see Scheme 1).

three samples were further investigated by product ion scanning. Tandem mass spectra of m/z 474 and 531 acquired in negative ion mode provided evidence for the glutathione conjugation pathway, and these two metabolites were identified as cysteinyl and cysteinylglyceine conjugates, respectively, of glyceollins with an addition of an oxygen. These assignments were substantiated by examining these conjugates in the positive ion mode. On the basis of this thorough analysis of samples derived primarily from in vivo administration of glyceollins, we proposed that the formation of the GSH-derived metabolites is preceded by epoxide formation (phase I metabolism). Four possible isomeric structures of the conjugates are proposed on the basis of tandem mass spectrometry fragmentation patterns (Scheme 1). Oxygenated forms of mercapturic acid conjugates of glyceollins (m/z 516) were found in rat feces but not in rat plasma or urine. Notably, metabolism of another phytochemical (i.e., sulforaphane) via GSH-conjugation is thought to be associated with the potent anticancer activity of this agent via induction of phase II enzymes to remove reactive oxygen species.[34] The possibility that glyceollin's promising antiproliferative effects are similarly derived from an ability to induce phase II enzymes merits exploration. With respect to the glucuronidation pathway, glucuronide conjugates of glyceollins were detected in rat plasma and urine but not in feces. Unlike the GSH conjugation pathway, glucuronidation was independent of phase I oxidation, as confirmed by in vitro glucuronidation of glyceollins by rat liver microsomes. A summary of all metabolic pathways is presented in Scheme 3.

To our knowledge, this is the first study to establish glutathione and glucuronide conjugation pathways of glyceollin metabolism. The scan for precursors of m/z 148 is thus a powerful method allowing the characterization of glyceollin metabolites, which may otherwise be difficult to pinpoint, such as the newly reported oxygenated GSH byproduct conjugates found here. These GSH byproduct conjugates yielded mostly neutral losses of the peptide portion during tandem mass spectrometry. Thus, these conjugates may have been overlooked if they were screened using conventional product ion scans that rely on the appearance of charged peptide fragments. Because the appearance of m/z 148 in precursor ion scans requires optimized CID energies, which may vary according to the particular metabolite, a caveat to this method is that all metabolites may not be detected using a single experimental condition (as was the case of mercapturic acid and glucuronide conjugates in this study). Moreover, if precursor CID does not release a conjugate that has adducted to the B fragment, then the m/z 148 ion may not be observed.

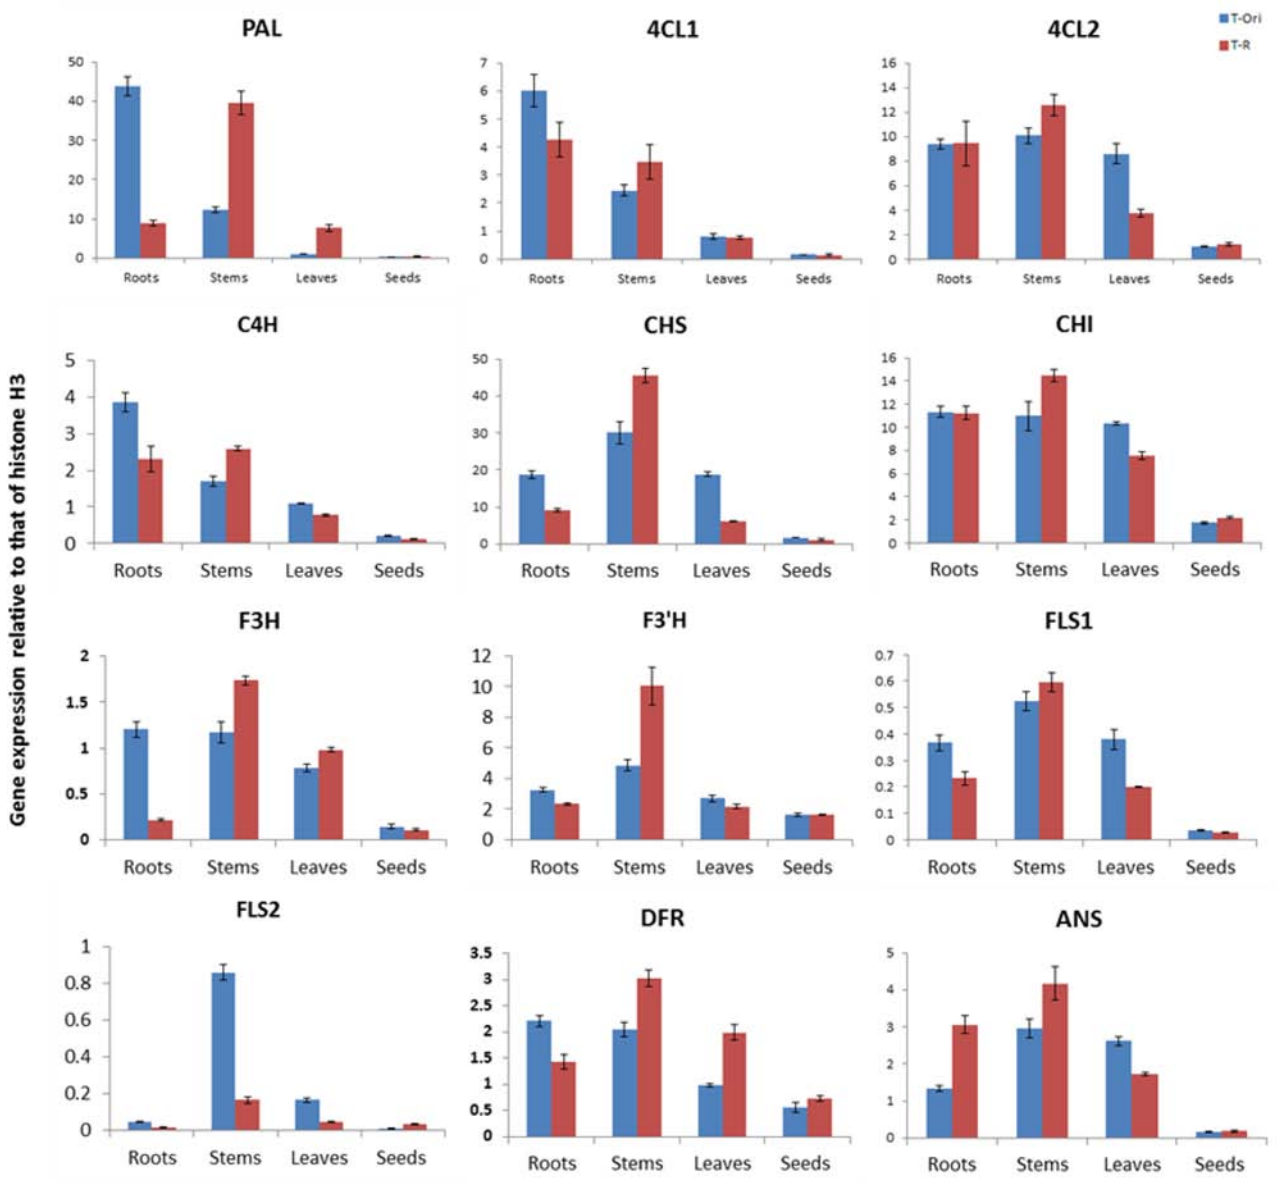

Figure 1. Expression levels of flavonoid biosynthesis genes in two different cultivars of *Fagopyrum esculentum*. T-Ori indicates Tanno-original common buckwheat; T-R indicates Tanno-rutin cultivar. The expression level of each gene is relative to that of the constitutively expressed histone H3 gene. Each value is the mean of three replicates ± SD.

MATERIALS AND METHODS

Plant Materials and Culture Conditions. Two common buckwheat cultivars, 'Tanno-Hiushinai original line' (Tanno-original) and 'Tanno-Hiushinai high rutin line' (Tanno-rutin) were bred by the Hokkaido Agricultural Research Center (Hokkaido, Japan). Seeds of the two buckwheat cultivars were germinated and cultured in a greenhouse (25 °C, 50% humidity) at Chungnam National University (Daejeon, Korea). The various plant organs were harvested when seeds were mature. Samples were rapidly frozen in liquid nitrogen after collection and stored at −80 °C until analysis.

Total RNA Extraction and Quantification of Gene Expression. Total RNA was isolated from samples of *F. esculentum* using an RNeasy Plant Mini Kit (Qiagen, Valencia, CA). For quantitative real-time polymerase chain reaction (qRT-PCR), 1 μg of total RNA was reverse transcribed using the Superscript II First-Strand Synthesis Kit (Invitrogen, Carlsbad, CA) and an oligo$(dT)_{20}$ primer.

Transcription levels were analyzed by qRT-PCR. The gene-specific primer sets were designed for qRT-PCR as described previously.[20] Gene expression was normalized to that of the histone H3 gene as a housekeeping gene.[21] QRT-PCR reactions were performed in triplicate on a MiniOpticon system (Bio-Rad Laboratories, Hercules, CA) with the Quantitect SYBR Green PCR Kit (Qiagen, Valencia, CA). The PCR protocol was as follows: denaturation for 5 min at 95 °C followed by 40 cycles of denaturation for 15 s at 95 °C, annealing for 15 s at 56 °C, and elongation for 20 s at 72 °C. PCR results were calculated as the mean of three replicated treatments.

Extraction of Flavonoids in Buckwheat. Plant materials were freeze-dried and then ground to a powder before extraction using methods described previously with some modification.[22] Powdered samples (0.10 g) were extracted with 5 mL of 80% methanol (MeOH) containing 10% acetic acid (0.1% v/v); this was followed by vortexing for 5 min at room temperature, and then the samples were extracted for 1 h at 37 °C, with 1 min of vortex every 20 min. After centrifugation at 1000 × g for 5 min, the supernatant was filtered and used for analysis.

Quantitative Analysis of Phytochemicals by HPLC. External standards were purchased from Extrasynthese (Genay, France). HPLC-grade methanol (MeOH) was purchased from Wako Pure Chemical Industries (Osaka, Japan). Acetic acid was provided from

dx.doi.org/10.1021/jf4049534 | J. Agric. Food Chem. 2014, 62, 2701−2708

Jun Sei Chemical Co., Ltd. (Kyoto, Japan). For HPLC analysis, extracts were filtered through a 0.45-μm poly filter and diluted 2-fold with MeOH prior to HPLC analysis. Samples were determined using a Futecs model NS-4000 HPLC apparatus (Daejeon, Korea) with a UV−vis detector and autosampler. The analysis was monitored at 280 nm and performed using a C18 column (250 mm × 4.6 mm, 5 μm; RStech, Daejeon, Korea). The mobile phase consisted of a mixture of (A) MeOH/water/acetic acid (5:92.5:2.5, v/v/v) and (B) MeOH/water/acetic acid (95:2.5:2.5, v/v/v); the procedure was described previously.[23] The initial mobile phase composition was 0% solvent B, followed by a linear gradient from 0% to 80% of solvent B in 48 min, then holding at 0% solvent B for an additional 10 min, and the column was maintained at 30 °C. The flow rate was set at 1.0 mL/min, and the injection volume was 20 μL. Quantification of the different compounds was based on peak areas and calculated as equivalents of representative standard compounds. All contents were expressed as microgram per milligram dry weight.

GC-TOFMS Analysis of Polar Metabolites. Polar metabolite extraction was performed as described previously.[24] A total of 20 mg of ground sample was extracted with 1 mL of a mixed solvent of methanol/water/chloroform (2.5:1:1, v/v/v). Ribitol solution (120 μL, 0.2 mg/mL) was added as an internal standard (IS). Extraction was performed at 37 °C with a mixing frequency of 1200 rpm for 30 min, using a thermomixer compact (Eppendorf AG, Germany). The solutions were then centrifuged at 16000 × g for 3 min. The polar phase (0.8 mL) was transferred into a new tube, and 0.4 mL of water was added before centrifugation to separate the nonpolar phase. The mixed contents of the tube were centrifuged at 16000 × g for 3 min. The methanol/water phase containing hydrophilic metabolites was dried in a centrifugal concentrator (CVE-2000, Eyela, Japan) for 2 h, followed by drying in a freeze-dryer for 16 h. Methoxime (MO) derivatization was performed by addition of 160 μL of methoxyamine hydrochloride (20 mg/mL) in pyridine and shaking at 30 °C for 90 min. Trimethylsilyl (TMS) etherification was performed by addition of 160 μL of MSTFA at 37 °C for 30 min. GC-TOFMS was performed using an Agilent 7890A gas chromatograph (Agilent, Atlanta, GA, USA) coupled to a Pegasus HT TOF mass spectrometer (LECO, St. Joseph, MI). Derivatized sample (1 μL) was separated on a fused-silica capillary column (30 m × 0.25 mm id) coated with 0.25 mm of CP-SIL 8 CB low bleed (Varian Inc., Palo Alto, CA, USA). The split ratio was set at 1:25. The injector temperature was 230 °C, and the flow rate of helium through the column was 1.0 mL/min. The temperature program was as follows: initial temperature of 80 °C for 2 min, followed by an increase to 320 °C at 15 °C/min, and a 10 min hold at 320 °C. The transfer line and ion-source temperatures were 250 and 200 °C, respectively. The scanned mass range was 85−600 m/z, and the detector voltage was set at 1700 V. The quantification of each analyte was based on the peak area ratio relative to that of the IS.

Statistical Analysis. Each result shown in the figure or table was the mean of three replicated treatments. Data were expressed as the mean of three independent replicates. The significant differences between treatments were statistically evaluated by the statistical analysis software (SAS), version 8.2. The GC-TOFMS data were subjected to principal component analysis (PCA) (SIMCA-P, version 13.0, Umetrics, Umeå, Sweden) to evaluate similarity/dissimilarity among groups of multivariate data. The PCA output consisted of score plots to visualize the contrast between samples and loading plots to explain the cluster separation. Unit variance scaling was used without transformation of the data.

RESULTS AND DISCUSSION

Expression of Flavonoid Biosynthetic Genes in Buckwheat. The flavonoid biosynthetic pathway is well described in plants. In this study, expression of ten flavonoid biosynthetic pathway genes (*FePAL*, *FeC4H*, *Fe4CL*, *FeCHS*, *FeCHI*, *FeF3H*, *FeF3′H*, *FeFLS*, *FeDFR*, and *FeANS*) was detected in the two cultivars of common buckwheat by qRT-PCR (Figure 1). Most genes, *FePAL*, *Fe4CL1*, *Fe4CL2*, *FeC4H*, *FeCHS*, *FeCHI*, *FeF3H*, *FeF3′H*, *FeDFR*, and *FeANS*, showed higher transcription levels in stems of the high-rutin cultivar compared with the original cultivar. In particular, the PAL gene, which plays a primary role in the flavonoid biosynthetic pathway, showed 3- and 4-fold higher expression in stems and leaves of the high-rutin cultivar. Compared with the original cultivar, *FeC4H*, *FeF3H*, and *FeDFR* also maintained higher transcript level in leaves of the high-rutin cultivar. However, the transcription levels of *FePAL*, *Fe4CL1*, *FeC4H*, *FeCHS*, *FeF3H*, *FeF3′H*, *FeFLS1*, and *FeDFR* were higher in roots of the original cultivar.

Transcription of isoforms or multicopies of CHS, CHI, 4CL, F3H, and FLS has shown the different expression levels on the regulation of the flavonoid biosynthetic pathway in many plants.[25−29] 4CL is involved in lignification and flavonoid biosynthesis; 4CL ligates coenzyme A (CoA) with hydroxycinnamic acids, such as 4-coumaric acid and caffeic acid to form the corresponding CoA thioesters.[30,31] In the present study, two 4CL isoform genes showed different transcriptional levels in buckwheat organs, and both genes exhibited higher expression in the roots and stems of buckwheat than in the leaves and seeds. This result is consistent with the physiological and morphological structures of the buckwheat plant. *Fe4CL2* showed higher activity than *Fe4CL1* in the two buckwheat cultivars (Figure 2); in particular, the highest level of *Fe4CL2* was observed in the stems of the high-rutin cultivar. Overall, our results indicated that the two 4CL isoforms may have the different functions in lignification and flavonoid biosynthesis in buckwheat. FLS is an important enzyme in the synthesis of quercetin, which is the precursor of rutin.[32] Two FLS isoform genes have been reported in tartary buckwheat, which showed differential expression and regulation levels in different buckwheat cultivars and under stress conditions.[32] In the present study, the two FLS isoform genes exhibited differential transcriptional levels in the original and high-rutin common buckwheat cultivars. Our results indicated that expression of *FeFLS2* was obviously higher in seeds of the high-rutin cultivar than seeds of the original cultivar (Figure 2). The expression level of *FeFLS1* in seeds was not significantly different between the cultivars. However, expression of *FeFLS2* in roots, stems, and leaves was 2−4 times higher in the original than in the high-rutin cultivar.

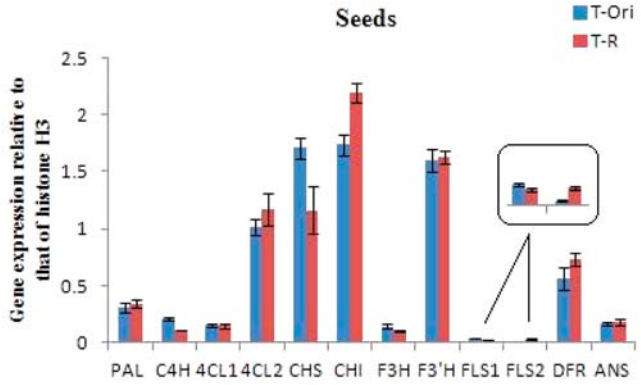

Figure 2. Expression levels of flavonoid biosynthesis genes in seeds of two different cultivars of *Fagopyrum esculentum*. T-Ori indicates Tanno-original common buckwheat; T-R indicates Tanno-rutin cultivar. The expression level of each gene is relative to that of the constitutively expressed histone H3 gene. Each value is the mean of three replicates ± SD.

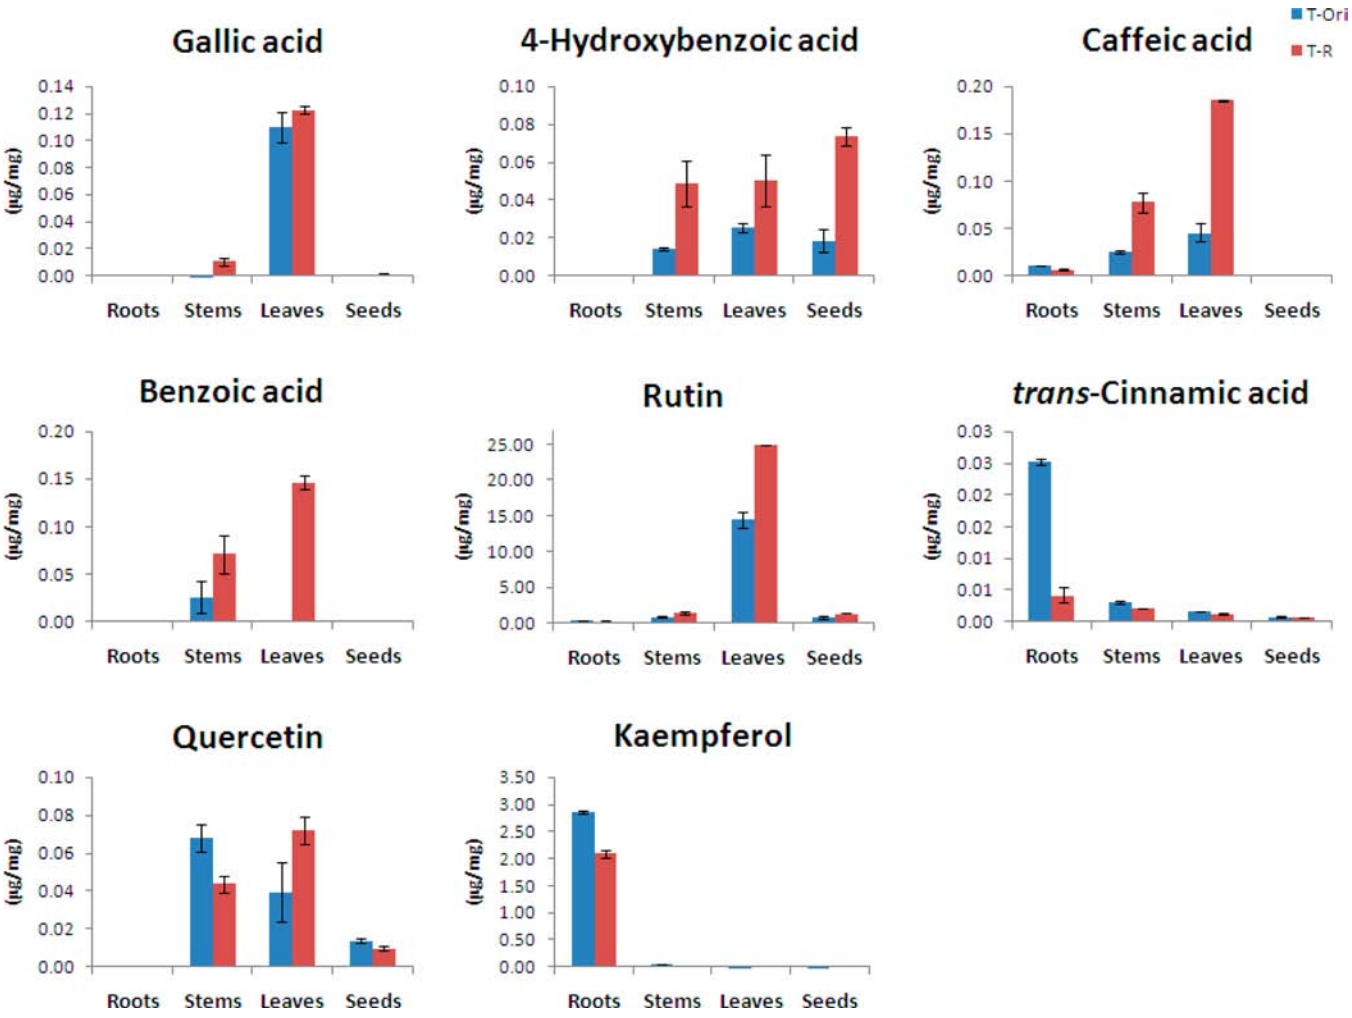

Figure 3. The accumulation of phytochemicals in two *Fagopyrum esculentum* cultivars. The plotted data and error bars indicate the means and variance of duplicate individual experiments. Each value is the mean of three replicates ± SD.

Phytochemical Content in Buckwheat. The compounds gallic acid, 4-hydroxybenzoic acid, caffeic acid, benzoic acid, rutin, *trans*-cinnamic acid, quercetin, and kaempferol were detected by HPLC analysis (Figure 3). Gallic acid, 4-hydroxybenzoic acid, caffeic acid, benzoic acid, and rutin were highly detected in leaves and stems of the high-rutin cultivar. *trans*-Cinnamic acid was 6-fold higher in roots of the original cultivar, and kaempferol was higher in roots than in other organs, particularly in the original cultivar. The primary active component, rutin, showed the highest levels of accumulation in leaves, followed by stems and seeds, and roots contained the lowest levels of this compound. Rutin content in leaves, stems, and seeds of the high-rutin cultivar were 24.86, 1.46, and 1.36 μg/mg, respectively, which was 1.73-, 1.62-, and 1.77-fold higher than that in the original buckwheat cultivar.

Buckwheat is a beneficial and healthy source of dietary rutin, and it has excellent rutin levels compared with those in other crops.[33−36] Rutin content in buckwheat depends on the variety and environmental factors.[37−40] Rutin content has shown significant variations in different growth stages of different *Fagopyrum* species.[37] The results of our study also proved that the quality of buckwheat, especially rutin content could be improved by breeding method. Our results indicated that the higher rutin content in high-rutin cultivar seeds may be directly related to *FtFLS2*, which showed higher expression levels in high-rutin cultivar seeds (Figure 2). However, even the expression pattern of PAL is correlated with its direct product, cinnamic acid, in the roots of buckwheat; this trend was not observed in the stems and leaves of the two buckwheat cultivars. The relationship between rutin content and gene expression of PAL and CHS did not show any obvious positive or negative correlation, this result was not consistent with the finding of a previous study.[37] Our results showed that the levels of flavonoid biosynthetic genes did not clearly correlate with rutin and other flavonoids in buckwheat. Similar results have been reported by previous studies,[32,41−43] which leads us to speculate that these results may be attributable to the dynamic transport of metabolites during physiological and morphological processes in plants. Otherwise, the rutin-degrading enzyme would be another factor that influences the rutin levels in different organs of buckwheat.[44,45] In addition, secondary metabolism in plants is complicated; it could be co-regulated by a complex set of regulatory networks, that is, by not only structural genes but also other classes of genes, including regulators, modifiers, transporters, and elicitors.[38,39,46−48] cDNA amplified fragment length polymorphism (AFLP) has shown that several factors involved in the regulation, metabolism, signaling, and transport of secondary metabolites contribute to the higher rutin content and overall nutritional superiority of rice-tartary over common buckwheat,[48] Study of

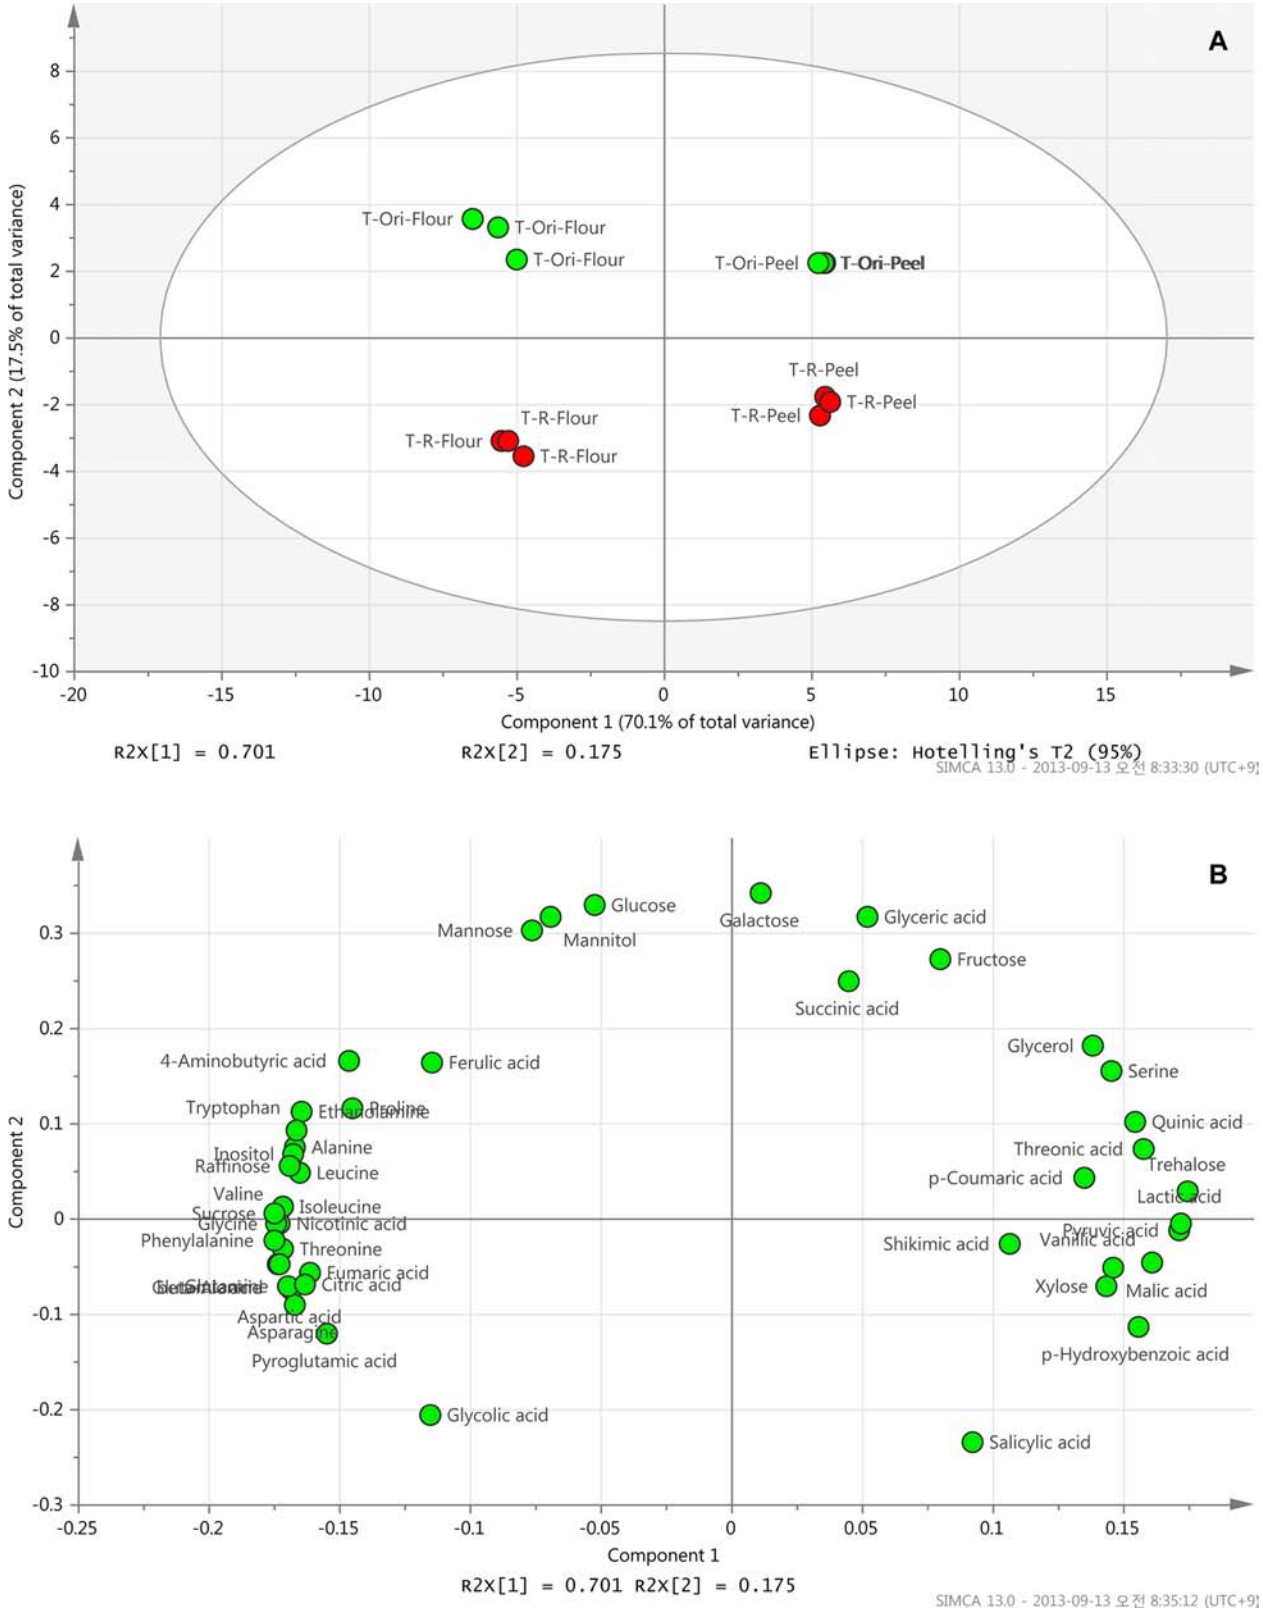

Figure 4. Scores (A) and loading plots (B) of principal components 1 and 2 of the PCA results from polar metabolite data for Tanno-rutin and Tanno-original buckwheat cultivars. T-Ori indicates Tanno-original common buckwheat; T-R indicates Tanno-rutin cultivar.

the differences in rutin or other nutritional content between Tanno-original and Tanno-rutin cultivars may be required.

Metabolic Profiling of Buckwheat. The production of secondary metabolites is strongly associated with primary metabolism pathways. Thus, we conducted comprehensive metabolic phenotyping of the primary metabolism in the peels and flower organs of buckwheat. GC-TOFMS has been one of the most popular metabolomic techniques because it can

dx.doi.org/10.1021/jf4049534 | J. Agric. Food Chem. 2014, 62, 2701−2708

determine the levels of primary metabolites such as amino acids, organic acids, and sugars by using chemical derivatization of these hydrophilic metabolites. In this study, low-molecular-weight molecules from peels and flower organs were identified using GC-TOFMS. The advantages of GC-TOFMS are the relatively high reproducibility and possible adaption for high-throughput analysis because of its rapid spectrum accumulation times. Furthermore, use of mathematical algorithms for deconvolution of closely overlapping peaks is possible because of the high mass-spectrum similarities among peaks. Forty-six metabolites, including 17 amino acids, 17 organic acids, 8 sugars, 3 sugar alcohols, and 1 amine, were detected in the peels and seed flour of two cultivars of *F. esculentum* by using GC-TOFMS (Supplementary Figure S1 and Table S1, Supporting Information). Quantification was performed using selected ions (Supplementary Table S1, Supporting Information).

According to the PCA analysis (Figure 4), the two highest-ranking principal components (PCs) accounted for 87.3% of the total variance within the data set. The first PC (PC1), accounting for 70.1% of total variance, resolved the measured metabolite profiles of buckwheat peels and flour. The second PC (PC2, 17.5% of total variance) differentiated the high-rutin from the original cultivar. There was a clear absence of significant variance within tissues of the same cultivar. PCA enables identification of compounds that exhibit the greatest variance within a population and allows closely related compounds to be identified. In PC2, the variation was mainly attributable to galactose and glucose, for which the eigenvectors were 0.34217 and 0.32803, respectively. The building blocks for secondary metabolites are derived from primary metabolism. Rutin (also called quercetin-3-*O*-rutinoside and sophorin) is the glycoside between the flavonol quercetin and the disaccharide rutinose. Thus, the levels of endogenous glucose may be lower in the high-rutin cultivar than in the low-rutin cultivar because of glycosylation reactions.[49,50] Our results suggest that these metabolites were present in lower quantities in the Tanno-rutin buckwheat than in Tanno-original. Our results showed that buckwheat peels contained amino acids and carbohydrates similar to those in flour. Tanno-original buckwheat contained a particularly high level of carbohydrates (fructose, glucose, mannose, mannitol, and sucrose) in both peels and flour (Supplementary Table S2, Supporting Information).

In this study, metabolites and flavonoid biosynthetic pathway-related genes were compared between Tanno-original and Tanno-rutin, two cultivars of common buckwheat. We found that the Tanno-rutin cultivar generally had higher rutin content in the aerial plant, indicating it could be a good alternative to culture for agricultural usage. Previously, it has been reported that hulls and flour of common buckwheat contained phenolics, flavonols, and procyanidins, and that flavonoids were more abundant in hulls than in flour.[51] The bran is considered a byproduct of buckwheat and has been proven to be a good source of flavonoids with antioxidant and antibacterial activities.[51,52] In this study, we reported the metabolites in peels and flours of the two buckwheat cultivars, which provided nutritional information about the seeds of these cultivars. The hydrophilic metabolite profile is closely related to an organism's phenotype and reveals important nutritional characteristics.[53,54] The differences between these two buckwheat cultivar seeds were identified by PCA results from the metabolite data. Even Tartary buckwheat has a high content of rutin,[3,4] but common buckwheat is cultivated more widely worldwide. This is the first report to present the theoretical basis for the high rutin content in a common buckwheat cultivar by employing the metabolomic method of analysis.

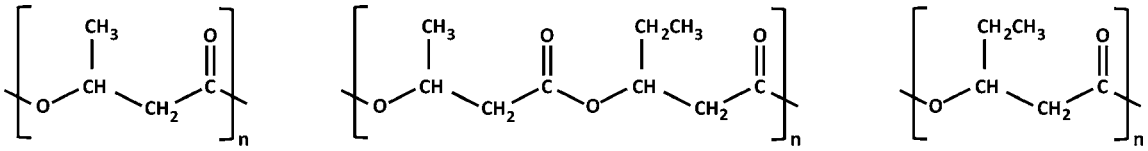

Figure 1. Chemical structures of three different types of PHA, synthesized and accumulated in certain prokaryotes.

Depending on cell needs, the cell is capable of transforming polar lipids into neutral lipids and vice versa due to the different pools present in strategic cellular locations. For instance, polar lipids are pooled and may be mobilized from the different cell membranes. Key membranes involved in the accumulation of lipids include the plasma membrane in both eukaryotes and prokaryotes, and in the case of eukaryotes the endoplasmic reticulum (ER), peroxisome, mitochondrial, plastidial (and their variants, such as apicoplastidial), or even thylakoid membranes, depending on the organism. Key intermediates, such as acetyl coenzyme A (Ac-CoA), malonyl coenzyme A (mal-CoA), acyl coenzyme A (acyl-CoA), and glycerol-3-phosphate (G3P) are also pooled in strategic cellular locations such as the cytosol, plastidial stroma, and mitochondrial intermembrane space. The distribution of the different biosynthetic enzymes plays a key role in achieving the correct lipid traffic toward accumulation. The accumulation of intracellular neutral lipid is a highly reductive process, requiring more NADPH and ATP than the storage of glucose and glucose derivatives.[8]

■ ACCUMULATION OF LIPIDS IN SINGLE-CELL MICROORGANISMS: AN OVERVIEW

Accumulation of lipids is a biological process that fulfills several roles in microorganisms. Storage of lipids contributes to cell growth, cell division, stress response, and as energy storage for survival.[9] In some cases, lipid accumulation plays a role in pathogenity.[7,10−13] Some SCM have the capacity to accumulate lipids >20% of their weight when exposed to an environmental stress, such as the lack of a key nutrient.[14−16] These are referred to as oleaginous SCM (OSCM).[17]

When growing on limiting concentrations of a key nutrient (typically nitrogen) and with sufficient or excess carbon sources, OSCM will stop their replication processes and utilize the available carbon to synthesize and store it in the way of reduced lipids. In the case of TAG and SE, the accumulation process has four main stages. In the first stage, OSCM shift their metabolic machinery to generate a pool of Ac-CoA, as well as NADPH, which is the reducing power driving fatty acid (FA) synthesis forward[18,19] The strategies vary among different classes of OSCM, and details will be discussed in the following sections. In the second stage, Ac-CoA is carboxylated to produce mal-CoA, transferred to acyl carrier protein (ACP), and further transformed into an acyl ACP by sequential turns within the fatty acid synthase (FAS). There are two types of FAS: Type I is an integrated enzyme complex (common in eukaryotic cytoplasm), and type II is a dissociated version in which all subunits are independent (common in prokaryotes and in organelles of prokaryotic origin in primary and secondary endosymbionts, such as plastids and mitochondria). Type I can be subdivided in type IA, present in fungi ($\alpha_6\beta_6$ complex in the cytoplasm), and type IB, present in animals (as cytoplasmic α_2 dimers). For reviews describing type I FAS and type II FAS, the reader is referred to the works of Schweizer and Lu et al., respectively.[20,21] In the third step, depending on the cell's needs and the type of SCM, the acyl chain might end in a specific type of lipid pool, such as membrane lipid (coupling the acyl chain to G3P, Ac-CoA, or other glycerol-based backbone to form PL or other types of polar lipid) or can eventually be incorporated into a neutral lipid droplet core (via the construction of TAG or SE molecules). The nature, location, and dynamics of this stage vary among species and are explained more in detail in the following sections. In this stage, further elongation and desaturation of the acyl chains may also occur, and these phenomena vary throughout the different domains of life. Finally, the fourth stage involves the formation of intracellular lipid droplets (LD). Variations occur depending on the organism and the environmental conditions.

In the case of prokaryotes, accumulation of TAG or SE is less common. In some members of the Gram-positive actinomycete group,[6,22] such as *Mycobacterium*, *Rhodococcus*, *Nocardia*, *Dietzia*, and *Streptomyces*, TAG are readily accumulated. Interestingly, bacterial TAG biosynthesis occurs frequently in the environment because actinomycetes are the most abundant microorganisms in soil.[22] Accumulation of TAG in Gram-negative bacteria has been reported only in species from the genus *Acinetobacter*, but only as a minor component of the neutral accumulated lipid. Wax esters are the main compound stored in these species.[6] For the rest of the Gram-negative bacteria, the main purpose of fatty acid synthesis is to become membrane lipid precursors.[6,18,23−25] However, several studies have successfully transformed model bacteria such as *Escherichia coli* by inserting the required genes to become oleaginous, with remarkable success.[26−28] In addition, TAG have been reported as major components of the neutral lipid of the cyanobacterium *Nostoc commune*, although no indications were obtained for the storage of lipid inclusions in the cells.[6,29] In the case of archaea, TAG accumulation of archaea is yet to be reported.[11]

It is more common in prokaryotes to accumulate PHA, comprising specialized lipids such as poly(3-hydroxybutyrate) (P3HB), polyhydroxyvalerate (PHV), or copolymers such as poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV). Figure 1 shows the structures of such lipids. PHA possess thermoplastic and elastomeric properties and are recyclable materials that can be easily degraded into carbon dioxide and water.[30] The uses and applications of these polyesters have been thoroughly reviewed elsewhere.[30] The most promising are as film formation, paper coating,[31] foils and diaphragms,[32] and multiple-use packages, because the melted polymers have low viscosity, permitting the injection molding of objects with thin walls. The end product is very hard and can be used at temperatures from −30 to 120 °C.[30]

Polyhydroxyalkanoate accumulation in prokaryotes can also be divided into four stages. The first stage involves the generation of a suitable cytoplasmic Ac-CoA pool. The second one involves the synthesis of the hydroxyalkanoate (HA) monomer or monomers, which can change depending on the

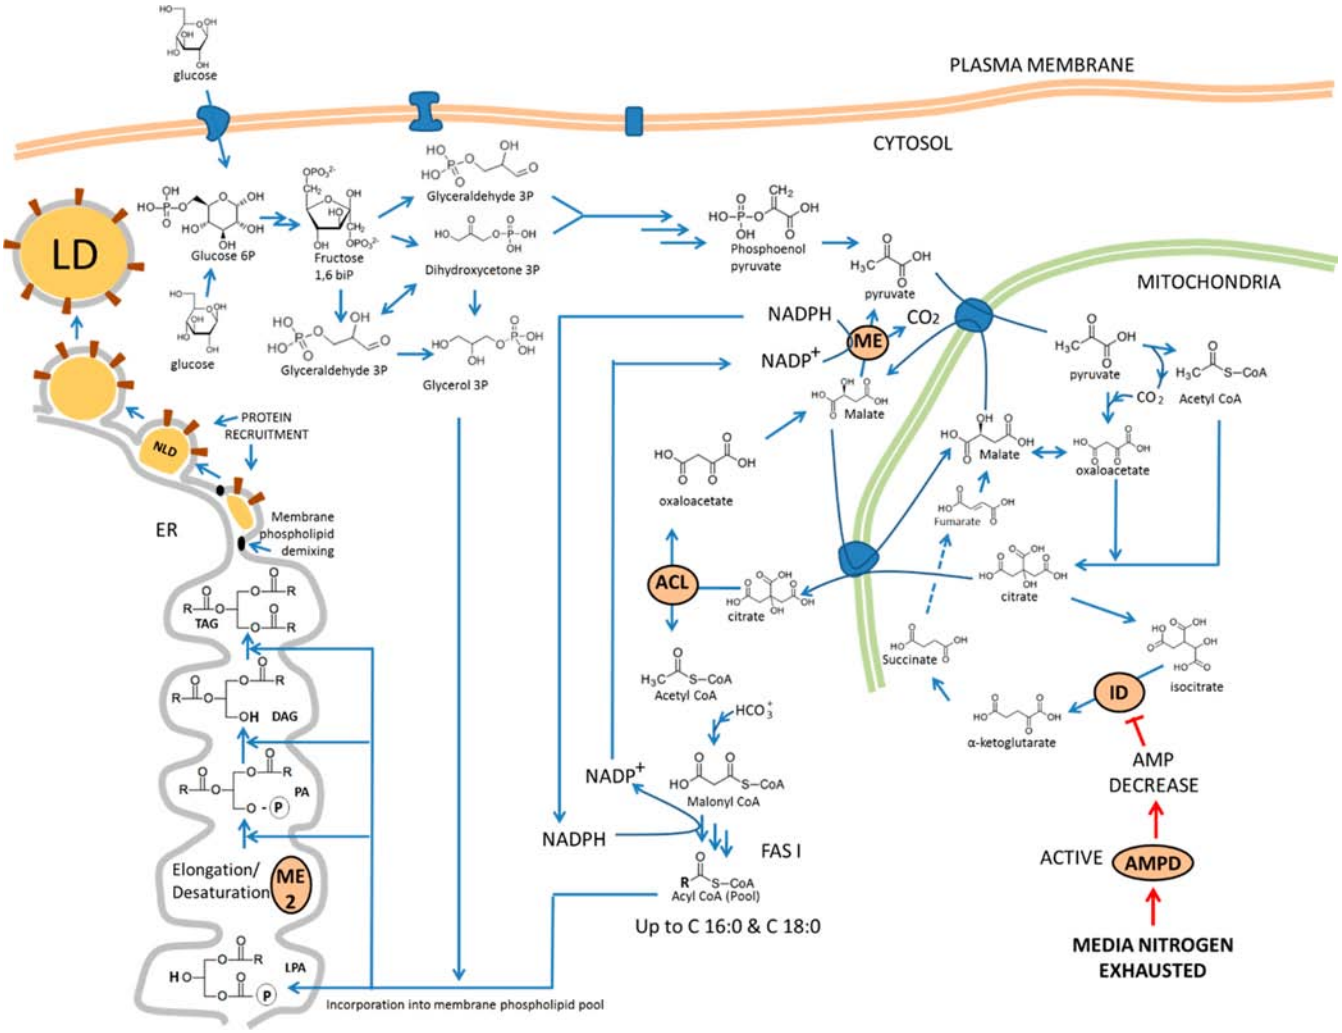

Figure 2. Schematic representation of metabolic steps involved in lipid accumulation in yeasts. The diagram also includes the connection between fatty acid synthesis, triacylglycerol synthesis, and lipid droplet formation. Abbreviations: ME, malic enzyme (cytosolic); ME 2, malic enzyme (ER membrane, responsible for fatty acid desaturation); ACL, ATP:citrate lyase; ID, isocitrate dehydrogenase; NLD, nascent lipid droplet; LD, lipid droplet; ER, endoplasmic reticulum; LPA, lysophosphatidic acid; PA, phosphatidic acid, FAS I, fatty acid synthase I; DAG, diacylglycerol; TAG, triacylglycerol; AMPD, AMP deaminase.

species and substrates. The third stage consists of polymerizing or copolymerizing the monomers into PHA chains, and the fourth one involves the formation of the intracellular PHA LD.

In both prokaryotes and eukaryotes, accumulation of neutral lipids results in the formation of intracellular fat bodies typically called lipid droplets (LD). LD are also called lipid bodies, fat bodies, or adiposomes, and in the case of plants they have also been termed oleosomes, spherosomes,[22,33] or plastoglobules, the latter if their location is inside the plastid.[11] For the present discussion, the term lipid droplet will be used. In most of the eukaryotes LD are intracellular sphere-like particles composed of a core of neutral lipids, such as TAG or SE or both, coated by a monolayer of polar lipids, mainly PL, and decorated with a series of proteins.[11,33−35] The polar heads face the cytoplasm, and the nonpolar tails face the inside, where the neutral lipids reside. The inserted proteins within the polar lipid monolayer play functional, structural, and regulatory roles in the life cycle of LD.[35−37] In the case of polyhydroxyalkanoate-accumulating prokaryotes, they form LD, which are also called lipid granules or carbonosomes.[38,39] In some higher organisms (e.g., humans), lipid droplet interaction with other cellular organelles, and their dynamics is closely related to progression of metabolic diseases, such as obesity, fatty liver, type 2 diabetes mellitus, and atherosclerosis.[36]

Therefore, it has become apparent that LD are not just a static storage compartment in the cell, but rather a dynamic organelle that interacts with other organelles within the cell and actively participates in the intricate cellular processing symphony,[40,41] to the point that some authors consider LD as specialized organelles in cells.[42]

As described in later sections, strategies for lipid accumulation in SCM vary among the different types of SCM, and it is important to understand these differences to improve and/or create productive strategies that can become economically as well as technologically feasible for the generation of biofuels as well as nutritional lipid metabolites such as long-chain polyunsaturated fatty acids (LC-PUFA).

THE CASE OF YEAST

Yeasts are single-cell eukaryotic fungi that display heterotrophic behavior. Thus, they are capable of metabolizing carbon from simple sugars or from other simple compounds such as

dx.doi.org/10.1021/jf4042134 | J. Agric. Food Chem. 2014, 62, 2709−2727

glycerol. When oleaginous yeasts encounter an environmental stress, such as a limiting nutrient (e.g., nitrogen), they shift their metabolic machinery to stop synthesizing proteins and nucleic acids and, thus, begin to allocate the available carbon in the form of reduced lipids. Other examples of limiting nutrients can be phosphorus or magnesium.[6] In practice to date, nitrogen has been extensively used because it seems to yield higher lipid accumulation when compared to other nutrients.[43] The carbon to nitrogen ratio is a useful tool to construct nitrogen-rich or nitrogen-depleted media. For example, it has been shown that for yeasts, poor lipid accumulation occurs in media in which the carbon to nitrogen (C:N) ratio is <20, whereas ideal lipid production occurs in a C:N ratio range of 30−80. The optimal C:N ratio for lipid accumulation varies greatly with the microbial species, strain, and carbon sources present in the growth medium.[44] In yeasts, oleaginicity depends on the ability to produce Ac-CoA, the necessary precursor of fatty acids, in an effective manner.[45,46]

The conversion of 1 mol of Ac-CoA to fatty acids requires the formation of 2 mol of NADPH, which constitutes the reducing power necessary to drive the reaction forward.[45−47] The metabolic steps for lipid accumulation in yeast can be divided into four main stages, as mentioned before (see Figure 2).[18,42,45−48]

Stage 1. Production of Acetyl CoA and NADPH. This stage begins with depletion of nitrogen in the medium. The cell responds by activating AMP deaminase and inducing an acute decrease of cellular AMP content. In mitochondria of oleaginous species, the decrease in cellular AMP levels causes isocitrate dehydrogenase (IDH) activity to decrease or even stop.[19] As a consequence, the production of α-ketoglurarate drops and the tricarboxylic cycle (TCA) is dramatically reduced or even stopped. Therefore, isocitrate will begin to build up inside the mitochondria. To reverse this situation, aconitase transforms isocitrate back to citrate (CIT), leading to an accumulation of CIT in mitochondria. CIT is transported by an antiport protein, known as citrate/malate translocase (CMT), from the mitochondria to the cytoplasm. In the cytoplasm, CIT is cleaved to form oxaloacetate and Ac-CoA, by ATP:citrate lyase (ACL). ACL is an enzyme that is exclusively present in oleaginous species.[18,42,49,50] Cytosolic oxaloacetate is reduced by malate dehydrogenase (MD) to form malate. Cytosolic malate is converted to pyruvate by malic enzyme (ME), encoded by *ME1*. This reaction generates NADPH[51,52] and is coupled to a series of parallel reactions as well. The first is the carboxylation of pyruvate to form oxaloacetate by pyruvate carboxylase inside mitochondria. Mitochondrial oxaloacetate is further reduced to form malate by MD. This malate is then transported outside the mitochondria and decarboxylated by ME. This reaction takes $NADP^+$ and converts it to NADPH. This NADPH is the reducing power required to convert Ac-CoA into fatty acids. Thus, pyruvate carboxylase, MD, and ME are known as the transhydrogenation machinery.[19,42] The resulting pyruvate completes the cycle and goes inside the mitochondria (Figure 2). ME is present in all fungi, but its role in supplying NADPH for de novo lipogenesis is preponderant in oleaginous species.[18] It has been found that, upon nitrogen limitation, ME changes from isoform D to isoform E, which supplies NADPH for de novo lipogenesis.[18]

Stage 2. Biosynthesis of Fatty Acyl Chains. Ac-CoA is converted by acetyl-CoA carboxylase (Acc) to mal-CoA, which is then used to synthesize fatty acids. In yeast, cytosolic Acc is encoded by *ACC1* and mitochondrial Acc is encoded by *HFA1*. The mitochondrial version closely resembles in both its molecular mass and amino acid sequence the cytoplasmic one.[20] Acc uses biotin as a cofactor to transfer CO_2 to Ac-CoA in a two-step process. It is a trifunctional enzyme, harboring a biotin carboxyl carrier protein domain, a biotin−carboxylase domain (where CO_2 binds to biotin), and a carboxyl-transferase domain (where CO_2 is transferred to Ac-CoA to yield mal-CoA).[53] The fatty acyl chain is built in a type I cytosolic fatty acid synthase (FAS I). It is an $\alpha_6\beta_6$ complex encoded by two genes, *FAS1* (β subunit) and *FAS2* (α subunit).[53] It is suggested to contain 6 equivalent sites of FA synthesis with a total of 42 catalytic domains, organized in a ring-like structure.[54] However, variations to this architecture exist and probably may affect the performance in de novo lipogenesis.[42] Loading of substrates to FAS varies among life domains. For example, Ac-CoA is always the basis of FA biosynthesis and is the substrate of β-ketoacyl ACP synthase (KSa) in bacteria.[20,21] Yeasts load Ac-CoA first to KSb through ACP before condensation.[20] The sequence of reactions in yeast FAS II is condensation of Ac-CoA with mal-CoA (via KS), reduction (via ketoacyl reductase, KR), dehydration (via a dehydratase, DH) and further reduction (via enoyl reductase EAR) in a repetitive manner until palmitoyl-ACP is formed. Release of the acyl moiety is a key step that differs from species and is currently a subject of intense research. Yeasts employ malonyl-palmitoyl transacylase (MPT) to transfer the acyl chain from acyl ACP to acyl-CoA.[18,53] In algae, the acyl chain can be released in three ways, depending on the cell's needs. First, it can be hydrolyzed from ACP as a free fatty acid by means of a thioesterase (TE). Second, it can be transferred either to G3P or monoacylglycerol-3-phosphate (MAG3P) through an acyltransferase (AT) in the chloroplast.[8,55,56] Lastly, if the acyl chain is destined to leave the plastid, it can also be released in the acyl-CoA form by acyl-coenzyme A synthetases (ACS).[8,57] It has been found that ACS play a key role in regulating in each compartment the internal acyl-CoA pools by esterification of FA to CoA. The localization of the pools is maintained due to Acyl-CoA's not being able to cross the intracellular membranes. The final fatty acid composition of different types of microalgae is in great part dependent on the activity of these enzymes. For example, microalgal chain length specific TE have been reported, which can release acyl moieties of specific length (e.g., C 12:0 or even C 8:0). This type of fatty acid is more suitable for the production of gasoline and jet fuel.[56]

In contrast, Gram-positive bacteria first form acyl-phosphate from acyl-CoA (via PlsX), which is then transferred onto G3P by PlsY. Gram-negative species use PlsB acyltransferase only to load an acyl group directly onto G3P from acyl ACP.[18,51,58]

Stage 3. Allocation of Acyl Moieties to either Polar or Neutral Lipid Pools. In yeast, acyl-CoAs released from cytosolic FAS I system are channeled to the ER membrane. There, a series of esterifications to a G3P backbone occur, also known as the Kennedy pathway. The first step consists of esterifying the acyl moiety from acyl-CoA to G3P or dihydroxyacetone 3-phosphate via glycerol-3-phosphate acyl transferase (G3PAT), on the sn-1 position. G3PAT is encoded in yeast by *GAT1* and *AYR1*, when the acceptor is G3P or dihydroxyacetone 3-phosphate, respectively.[18] Gat1 does not exhibit a particular preference for acyl-CoA, whereas AYR1 prefers palmitoyl-CoA, thus defining FA composition. A second acyl moiety can be attached on the sn-2 position to generate phosphatidate (PA), catalyzed by acyl-CoA:lysophosphatidic acyltransferase (LPAAT). PA plays a key role in the regulation

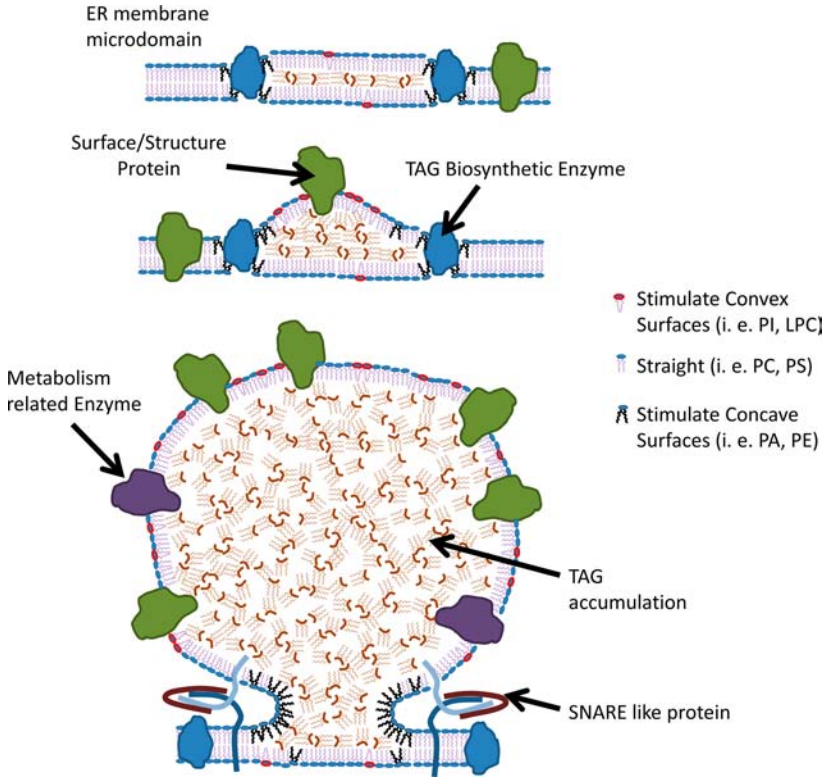

Figure 3. Model of lipid droplet formation in the ER membrane. Adapted from ref 11.

of *ACC1*, *FAS1*, and *FAS2* genes, as it is involved in an autoregulatory loop directed by the concentrations of inositol and choline in the cytosol and PA in the ER membrane.[18,20,53,59−62] Expression of upstream activating sequence (UAS_{INO})-operated genes changes in parallel to PA, inositol, and choline concentrations. In the case when PA is going to be transformed into TAG, it has to be transformed into diacylglycerol (DAG) first. This can happen in two ways. First, the phosphate group can be directly hydrolyzed by a phosphatidate phosphatase (PAP) to create DAG. PAP is encoded by *PAH1* and requires a magnesium ion to perform hydrolysis.[60,62] It is regulated by lipids, nucleotides, and phosphorylation. The second one involves synthesizing cytidine diphosphate DAG (CDP-DAG) from PA, catalyzed by CDP-DAG kinase, encoded by *CDS1*.[18,42] CDP-DAG is the precursor of the different PL in the ER membrane. It thus stays as either phosphatidylcholine (PC), phosphatidylethanolamine (PE), or another type of PL. Eventually, DAG is generated by cleavage of the PL via phospholipase C. Both alternatives are in metabolic interlock with each other. This creates a positive feedback system that channels PA into the TAG pathway if CDP-DAG concentration is higher than DAG concentration or directs PA to the membrane pool in the opposite situation.[18,60−62] Lastly, DAG is transformed into TAG by esterifying an acyl moiety from Acyl CoA catalyzed by an Acyl CoA:DAG acyltransferase (ADAT), encoded by either *DGA1* or *LRO1*,[42] depending on whether DAG is generated directly from PA via PAP or it comes from the ER membrane PL pool, respectively.

Further elongation and desaturation of fatty acids also occur in the ER membrane. Desaturation requires fatty acids to be attached to the ER membrane PL. Here another ME, different from the cytosolic malic enzyme, catalyzes the conversion of malate to pyruvate and the consequent reduction of NADP to NADPH. NADPH then couples to a series of electron transfer reactions involving cytochrome *b*5 reductase and further activating the desaturase, which adds a double bond on the fatty acid chain at the expense of converting 1 mol of oxygen into a mole of water.[3],

Ergosterol is the major sterol present in yeast. For a review in the biosynthesis of ergosterol backbone, the reader is referred to the work of Kristan.[63] Yeast SE are synthesized via transesterification of ergosterol with acyl-CoA.[5] In yeast, two acyl-CoA cholesterol acyltransferase (ACAT) related enzymes, ARE1P and ARE2P (encoded by *ARE1* and *ARE2*), catalyze the reaction. Microscopic localization of green fluorescent protein hybrids and enzyme measurements showed that both ARE1P and ARE2P are localized to the ER.[64] ARE1P esterifies ergosterol and its precursors with nearly equal efficiency with a slight preference for lanosterol, whereas ARE2P uses ergosterol as a preferred substrate.[64] An acyl-CoA-independent pathway for the formation of SEs has not been identified in yeast.

Stage 4. Lipid Droplet Biogenesis. Lipid droplet biogenesis is an area of intensive current research, and there is emerging scientific evidence showing that in yeast it takes place between the two membrane leaflets of the ER.[34,65,66] By mechanisms still not clearly understood there are spots in the ER membrane where there is a concentration of ADATs DGA1 and LRO1. The first one is responsible for TAG synthesis in the outer leaflet of the endoplasmic reticulum, whereas the second is responsible for TAG synthesis in the inner leaflet of the ER.[18,42] The synthesized TAG begin to accumulate, generating a lens-like protrusion and promoting the recruitment of structural proteins. In yeast, PAT proteins (from the initials of perilipin, adipocyte differentiation-related protein, and TIP47)[67] accumulate in the outer leaflet (see Figure 3), whereas in plants this role is played by oleosins. When there is

enough accumulation of TAG between the leaflets, the outer buds off and the lipid droplet is formed (Figure 3).[34,68−70]

There seems to be a functional relationship between the lipid droplet membrane and the ER membrane, because several studies have shown that certain functional proteins can migrate between the lipid droplet and ER membranes by mechanisms that do not require energy expenditure.[71] In yeast, most ER proteins are also detected on the lipid droplet membrane. For example, experiments using yeast mutants unable to synthesize TAG revealed that LD were not formed. However, the proteins that were present in the wild forms in LD were also present in the ER of the yeast mutants, suggesting a relationship between ER proteins and lipid droplet proteins.[68] In some cases, lipid droplet-localized proteins can relocate back to the ER, indicating that some continuity between the two organelles is maintained, even if only transiently, in a way that allows the two-way partitioning of proteins between the two compartments.[33]

In describing the functions of proteins embedded in the droplet monolayers, two mechanisms have been proposed. The first is a hydrophobic helix that interacts with the monolayer. Examples of this strategy are the multifunctional caveolin protein, which has been localized to both the plasma membrane and LD, and DGA1, the major enzyme catalyzing triacylglycerol synthesis.[33] Both have similar topology. Their long internal hydrophobic stretch may enable them to be embedded in either bilayers or monolayers. The second mechanism is best represented by the previously mentioned PAT protein family. They display a four-helix bundle with great similarity to the N-terminal domain of apolipoprotein E.[33,72] Upon binding to lipids, the apoE four-helix bundle opens to expose amphipathic helices that can bind the monolayer surfaces of lipoproteins. In an analogous manner, PAT proteins may bind to lipid droplets by embedding hydrophobic helices into the droplet surface. PAT proteins also share a common structural element: N-terminal 11-mer repeats that have an amphipathic helical structure.[73] Different PAT proteins attach to different-sized LD. It is still unclear why or how they do it.

In the specific case of perilipins (members of the PAT family), there are five groups, and their abundance has been correlated with the abundance of TAG in the lipid droplet as well.[35] Perilipins play crucial roles in regulating triacylglycerol hydrolysis by protein−protein interactions, suggesting physiological and regulatory functions.[35] It is important to mention that perilipin-like proteins are not found in plants. As was already mentioned, functionally similar oleosins and caleosins are present in plants instead.[11]

There is increasing evidence that phospholipid demixing occurs during the birth of LD.[68] The accumulation of lipids that promote concavity decreases the energy burden required for budding. It has been shown that lipid droplet PL contain more lysophospholipids and less sphingomyelin and PA compared to the total membrane.[33,68] In silico studies proposed a packing parameter *S* to quantify the degree of convexity/concavity in PL.[68] Lysophosphatidylcholine and phosphatidylinositol (PI) promote a convex shape where their lipid footprint areas are much smaller than their headgroup areas. Their *S* values are <1. Conversely, PE and PA induce a concave shape. These PL have *S* values >1.[68] Lipids with *S* values <1 adopt a convex surface, favoring lipid droplet formation. This is diagrammed in Figure 4.

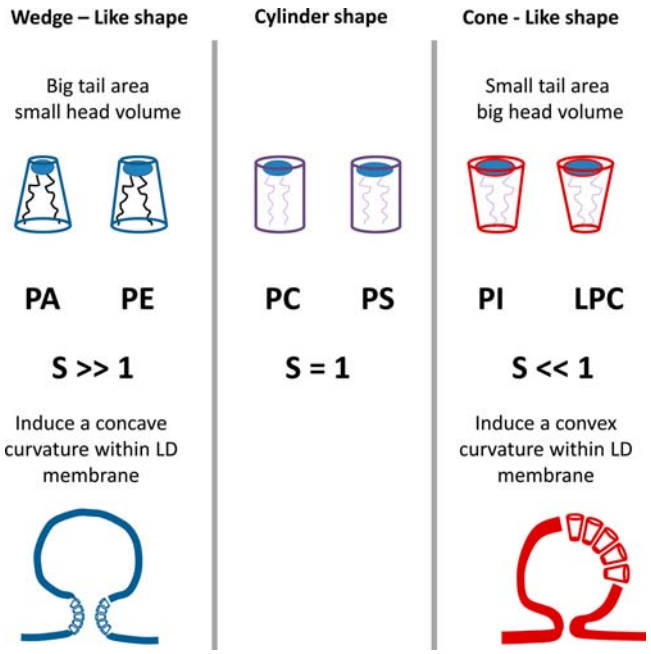

Figure 4. Configurations adopted by different phospholipids, which can affect the curvature during lipid droplet formation.[68]

THE CASE OF MICROALGAE

Eukaryotic microalgae are classified into nine divisions: Glaucophyta, Rhodophyta (red algae), Heterokontophyta, Haptophyta, Cryptophyta, Dinophyta (dinoflagellates), Euglenophyta, Chlorarachniophyta, and Chlorophyta (green algae)[55,74,75] All of these divisions include single-cell strains, which can be either motile, nonmotile, or both. In terms of their nutritional strategies, microalgae can be divided into obligate heterotrophs, obligate photoautotrophs, facultative mixotrophs, and obligate mixotrophs. Most algal divisions contain colorless heterotrophic species that can obtain organic carbon from the external environment either by taking up dissolved substances (osmotrophy) or by engulfing bacteria and other cells as particulate prey (phagotrophy).[75] In most cases, lipid accumulation strategies in microalgae and some single-cell protists (both primary and secondary endosymbionts) follow the four-stage lipid accumulation strategy described for yeast. However, several differences are present in each stage. In addition, further studies are demonstrating that lipid biosynthesis pathways in microalgae are not a simple mirror image of what happens in higher plants, which have been more thoroughly studied.[76,77] It seems likely that regulation of triacylglycerol synthesis and breakdown in microalgae tends to obey a stress response phenomenon, whereas in plants it follows a developmental phenomenon. For a review comparing lipid metabolism between microalgae and plants, see Liu.[4]

Stage 1. Production of Acetyl-CoA and NADPH. Microalgae differ from yeast in the location of the acetyl-CoA pools within the cell. Microalgae display plastidial and cytosolic acetyl-CoA pools, which are key for lipid accumulation. In contrast, yeast's main acetyl-CoA pool used for lipid accumulation is located in the cytosol. There is an additional acetyl-CoA pool present in mitochondria as well as a mitochondrial lipid biosynthesis pathway employing a type II FAS (different from plastidial FAS II) both in algae and in yeasts.[18,76,78−82] They play important roles in different cell processes, such as RNA processing, mitochondrial lipoic acid

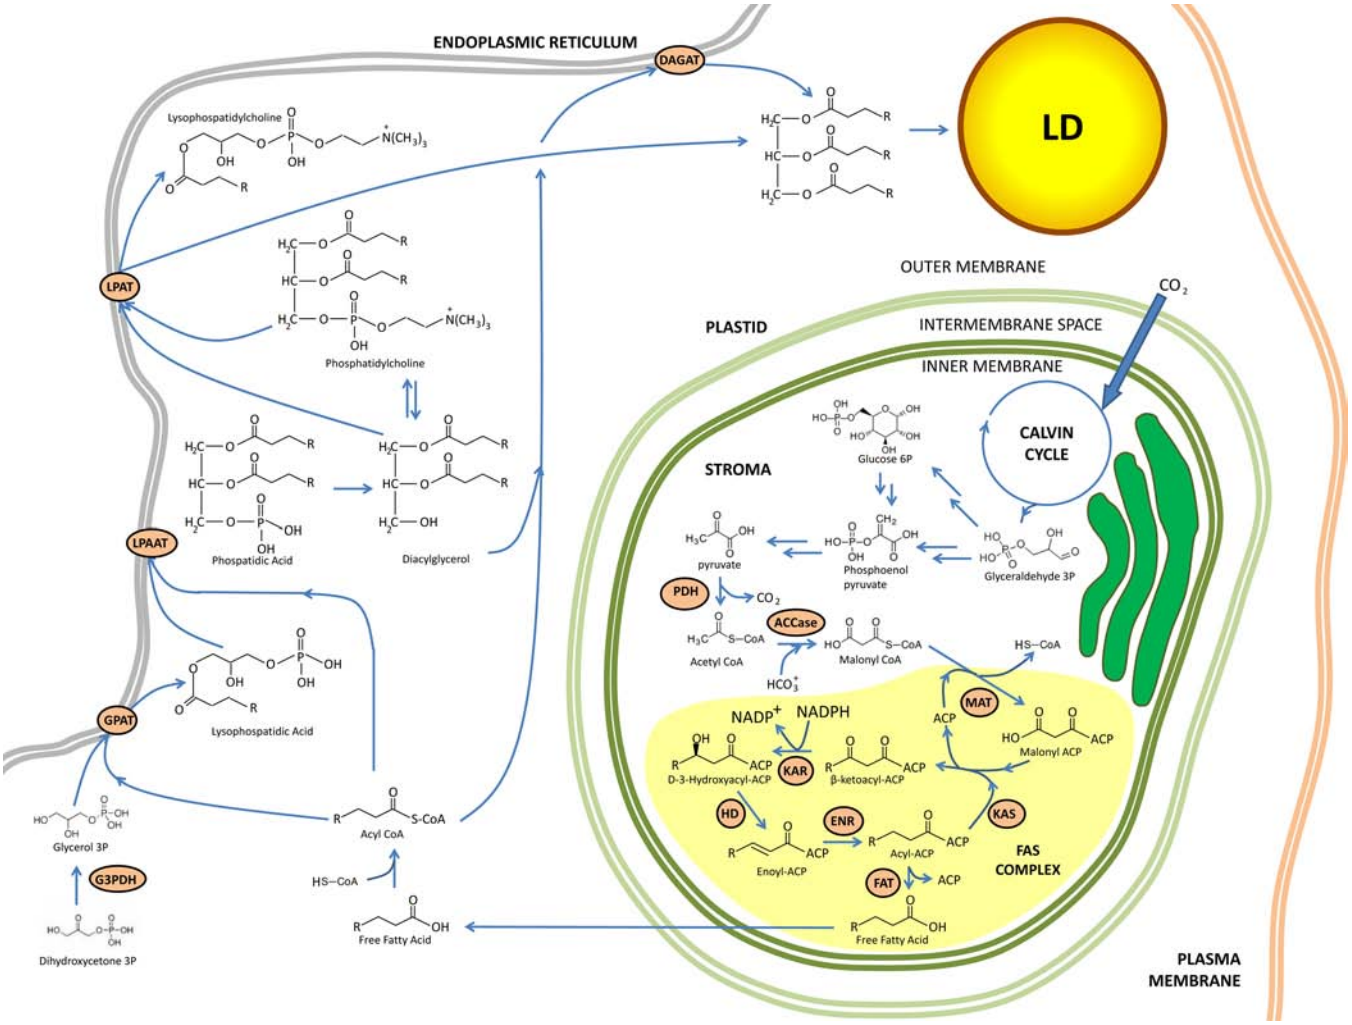

Figure 5. Simplified overview of lipid biosynthesis and lipid droplet formation in photosynthetic algae. Adapted from ref 56. Abbreviations: ER, endoplasmic reticulum; ACCase, acetyl-CoA carboxylase; ACP, acyl carrier protein; DAGAT, diacylglycerol acyltransferase; DHAP, dihydroxyacetone phosphate; ENR, enoyl-ACP reductase; FAT, fatty acyl-ACP thioesterase; G3PDH, glycerol-3-phosphate dehydrogenase; GPAT, glycerol-3-phosphate acyltransferase; HD, 3-hydroxyacyl-ACP dehydratase; KAR, 3-ketoacyl-ACP reductase; KAS, 3-ketoacyl-ACP synthase; LPAAT, lysophosphatidic acid acyltransferase; LPAT, lysophosphatidylcholine acyltransferase; MAT, malonyl-CoA:ACP transacylase; PDH, pyruvate dehydrogenase complex.

synthesis, and protein lipoylation. However, mitochondrial lipid synthesis is not the main avenue for lipid accumulation and will not be covered in the present work. For a review of mitochondrial lipid biosynthesis and its relevance in cell function, the reader is referred to the work of Hiltunen and co-workers.[78−80]

Plastids present in algae play a key role in de novo lipid biosynthesis (for a review of plastid evolution and diversification, see the work of Keeling[83]). In photoautotrophic microalgae, photosynthesis provides an endogenous source of plastidial acetyl-CoA, although more than one pathway may contribute to maintaining the acetyl-CoA pool.[55] For instance, in photoautotrophic microalgae plastidial pyruvate can be sourced via transformation of photosynthesis-derived glyceraldehyde-3-phosphate to phosphoenolpyruvate (PEP). PEP is irreversibly converted to pyruvate (see Figure 5) by pyruvate kinase (PK).[55,84] Finally, the plastidial pyruvate dehydrogenase complex (PDH) catalyzes the oxidative decarboxylation of pyruvate to produce plastidial Ac-CoA, CO_2, and NADH. PDH contains three components: E1 (pyruvate dehydrogenase, composed of E1α and E1β subunits), E2 (dihydrolipoyl acyltransferase), and E3 (dihydrolipoamide dehydrogenase). It is possible that photosynthesis-derived pyruvate is the major contributor to plastidial Ac-CoA for de novo fatty acid synthesis. However, in mixotrophic grown cultures of heterokonts such as *Nannochloropsis* sp., incorporation of acetate directly into lipids occurs.[8,85−88] The acetyl-CoA synthetase (ACSIN) converts acetate to plastidial Ac-CoA. Additionally, a study showed that under nitrogen deprivation *Chlamydomonas* is capable of changing its metabolism from converting acetate to glucose to a more direct incorporation of acetate into fatty acids by down-regulating glyoxylate cycle activity and gluconeogenesis.[4,89]

In microalgae, the cytosolic Ac-CoA pool is mainly fueled by the release of mitochondrial CIT to the cytosol and further cleaved into oxaloacetate and Ac-CoA by ACL. Cytosolic Ac-CoA is the building block used for LC-PUFA elongation in the ER. Concomitant production of NADPH by ME generates the reductive power necessary to drive plastidial de novo fatty acid synthesis forward. Availability of NADPH can increase the reaction velocity of Acc 2 (see stage 2) and ACL.[8] Fatty acid synthesis is an energy-demanding process due to the activity of

dx.doi.org/10.1021/jf4042134 | J. Agric. Food Chem. 2014, 62, 2709−2727

elongases and desaturases. For instance, the formation of a C18 FA requires 54 NADPH from oxygenic photosynthesis.[8] Other functions of malic enzyme in algae may include delivery of CO_2 from the TCA for the plastidial ribulose-1,5-bisphosphate carboxylase (Rubisco). Studies also suggest the existence of a plastidial ME (absent in yeast), which can provide electrons for plastidial FA synthesis.[8,90−92] For a review about plastidial ME see the work of Maier et al.[93]

Some microalgae are capable of accumulating intracellular starch, such as the thoroughly studied microalgal model *Chlamydomonas*. Starch synthesis is an example of how carbon partitioning might play a key role in lipid accumulation. One study showed that in wild-type *Chlamydomonas*, TAG accumulated only after the maximum amount of starch was reached, whereas starchless *Chlamydomonas* mutants initiated TAG accumulation earlier and reached a higher level than wild-type strain.[4,94] Therefore, it is possible to engineer high TAG algal strains by eliminating competing carbon utilization pathways such as starch synthesis to maximize lipid biosynthesis.

Stage 2. Biosynthesis of Fatty Acyl Chains. In algae, de novo fatty acid biosynthesis occurs primarily in the plastid. The committed step in plastidial fatty acid synthesis is the conversion of plastidial Ac-CoA to mal-CoA by Acc1. The three domains of the homomeric Acc1 are located on a multifunctional polypeptide encoded by a nuclear gene.[8,95] It works via biotin carboxylation and subsequent carboxyl transfer to Ac-CoA.[55,96] Some microalgae contain only Acc1, such as *I. galbana*. Others, such as *T. pseudonana* and *P. tricornutum*, contain two homomeric Accases, Acc1 (described above) and a cytosolic Acc (Acc2), which uses cytosolic Ac-CoA to generate mal-CoA. The latter plays a role in LC-PUFA elongation in the ER membrane.[8,97]

FAs are synthesized in microalgae's plastid via a dissociated type II FAS, containing discrete, monofunctional enzymes encoded by distinct genes.[98] In plastidial FAS II mal-CoA is loaded to ACP via malonyl-CoA:ACP transacylase encoded by *FABD*. Malonyl-ACP is used in the cyclic condensation reactions to extend the acyl group to palmitoyl ACP or stearoyl ACP. The acyl ACP can be released from FAS II in several ways: It can be hydrolyzed by a fatty acyl-ACP thioesterase located in the chloroplast envelope, forming a free fatty acid, or it can be transesterified from ACP to CoA via (ACS), or it can even be coupled to either G3P or MAG3P through an AT in the chloroplast.[8,55]

There are some heterotrophic microalgal species that contain a cytosolic type I FAS, synthesized from one or two polypeptides,[8,98] different from plastidial type II FAS. For example, *Aurantiochytrium*[99] contains a type I FAS, which synthesizes saturated C14:0 and C16:0. The synthesized free FAs and the absence of genes homologous to a type II TE may indicate integration of TE activity into the synthase.[100]

Several attempts have been made to overexpress specific enzymes in the lipid biosynthetic pathways. In the cases of Acc and KS (KS III), overexpression failed to increase lipid accumulation.[101]

Stage 3. Allocation of Acyl Moieties to either Polar or Neutral Lipid Pools. The released acyl moieties as free fatty acids destined to stay within the plastid may be further desaturated (typically to hexadecatrienoic acid HDT, C16:3*n*-4) and coupled to a monogalactosyldiacylglycerol (MGDG) backbone. MGDG, along with other types of galactosylglycerides (GG), is a major component of photosynthetic membranes in microalgae and in some cases may be even more abundant than PL.[8,74] In plants, the FA combination of GG can be traced back to their biosynthetic pathways; the so-called eukaryotic molecular species (C18/C18) of GG are synthesized outside the chloroplast in the eukaryotic pathway, and the prokaryotic molecular species (C18/C16) are synthesized in the plastid via the prokaryotic pathway.[8,102] Microalgae differ from plants in that most C20 FAs are synthesized outside the chloroplast and are present in both the eukaryotic-like (C20/C20, C18/C18) and prokaryotic-like (C18/C16, C20/C16) molecular species.[8,74,103,104] Therefore, microalgae's GG are referred to as "C20/C20" or "C20/MLC" (where MLC means medium to long chain) rather than eukaryotic- and prokaryotic-like GG.

When acyl ACP's are esterified to either G3P or MAG3P, they can join the plastidial PL pool. In plants two ATs catalyze these reactions. The first is a soluble enzyme that prefers oleoyl-ACP as substrate. The second one resides on the inner chloroplast envelope membrane and preferentially selects palmitoyl-ACP.[77] In some algal species, such as *C. reinhardtii* and *P. lutheri*, PC is absent in both plastidial and extraplastidial phospholipid pools. Instead, they contain the non-phosphorus betaine lipid diacylglyceryl-*N*,*N*,*N*-trimethylhomoserine (DGTS), which has similar physicochemical properties, as a major membrane component.[105−109] This is a significant difference against higher plants. It has been suggested that DGTS may have a role in lipid droplet formation similar to that of PC in higher plants.[105] However, they contain other types of phospholipids, such as PA, PE, and PI.[8,74]

Acyl ACPs synthesized in plastidial type II FAS can be transesterified with CoA via ACS. These enzymes regulate the acyl pools in different cellular compartments. Thus, stearoyl ACP can leave the FAS II complex via transesterification by a series of ACS responsible for maintaining both intraplastidial and cytosolic acyl-CoA pools.[8,110] In both cases, acyl-CoA is destined to leave the plastid and enter the ER membrane for further oxygen-dependent elongation and desaturation, to become long-chain polyunsaturated fatty acids (LC-PUFA), such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Two types of desaturases can be distinguished in microalgae. The first are front-end desaturases containing an N-terminal cytochrome *b*5 domain and insert the new double bond between the FA carboxyl group and a possible existing double bond. One example is the high substrate specific plastidial-located Δ12 desaturase, identified in *P. tricornutum*, which desaturates palmitoleic acid C16:1*n*-7 to hexadecadienoic acid 16:2*n*-4.[8] The second group comprises the less common *ω*6/*ω*3 desaturases capable of inserting a new double bond between the FA methyl end and a pre-existing double bond.[8,111]

Stearoyl CoA can be desaturated by an ER membrane-bound Δ9 desaturase to oleyl-CoA and then linked to a glycerol backbone for further processing. Some microalgae contain a plastidial Δ9 desaturase, capable of direct desaturation of stearoyl ACP to be then transesterified to CoA and sent to the ER for elongation and desaturation. In most microalgae, *n*-3 LC-PUFA are more abundant than *n*-6 LC-PUFA,[112] whereas in filamentous fungi, such as *mortierella* and *mucor*, *n*-6 LC-PUFA are more common.[3,19] In microalgae the most common pathways for EPA and DHA synthesis are the *n*-3 and *n*-6 pathways, but variations of the theme occur. In the *n*-3 pathway, oleic acid already linked to a glycerol backbone in the ER membrane is desaturated to linoleic acid (LA), via a Δ12

desaturase (encoded by FAD2). A third double bond inserted by an *n*-3 Δ15 desaturase gives α-linolenic acid (LNA), which is further desaturated to produce stearidonic acid (SA) by a Δ6 desaturase. SA is then elongated to C20:4 *n*-3 (eicosatetraenoic acid, EA) and finally desaturated by a Δ5 desaturase to produce EPA. In most DHA-producing microalgae, EPA undergoes an additional elongation and a Δ4 desaturation to create DHA.[112] This is a different, less complicated strategy for DHA synthesis from EPA, compared to the Sprecher pathway, present in mammals, which involves an additional elongation and a β-oxidation. In contrast to the *n*-3 pathway, some microalgae synthesize EPA via the *n*-6 pathway, following Δ6 desaturation of LA to γ-linolenic acid (GLA), elongation to dihomo-γ-linolenic acid (DGLA), creation of a fourth double bond by Δ5 desaturase to produce arachidonic acid (ARA), and a final desaturation to create EPA via a *n*-3 Δ17 desaturase.[112] Some microalgae express Δ9 elongase and Δ8 desaturase, allowing them to synthesize EPA in a different way compared to the *n*-3 and *n*-6 pathways.[112] In a variation of the *n*-3 pathway, LNA is elongated by a Δ9 elongase to eicosatrienoic acid (ETA) and desaturated by the Δ8 desaturase, creating EA. On the other hand, a variation of the *n*-6 pathway using this pair of enzymes involves Δ9 elongation of LA to eicosadienoic acid (EDA) and Δ8 desaturation to DGLA.[74] Thus, microalgae can switch from *n*-6 fatty acids to *n*-3 fatty acids via the *n*-3 Δ15 desaturase and the *n*-3 Δ17 desaturase. In some species of the Thraustochytrids, it is also possible to switch from *n*-6 docosapentaenoic acid (DPA) to DHA, via an *n*-3 Δ4 desaturase.

In addition to these pathways, there is a different *n*-3 LC PUFA biosynthetic pathway present in one of the three genera of heterotrophic Thraustochytrids, namely *Auranthiochytrium*, based on an anaerobic polyketide synthase pathway (PKS).[8,113] A large multifunctional enzyme complex carries out the multitude of individual reactions, utilizing mal-CoA and producing free *n*-3 LC-PUFAs. The major free FAs DPA (22:5*n*-6) and DHA (22:6*n*-3) are then activated to acyl-CoA and incorporated into TAGs.[8,100] Because PKS does not require aerobic desaturation, the pathway is energetically favorable compared to the membrane-bound desaturases and elongases.[114]

TAG synthesis in microalgae follows the Kennedy pathway in the ER in a similar fashion as yeast (see Figure 5). However, an acyl-CoA-independent mechanism for triacylglycerol synthesis in some plants and yeast has been reported.[55,115] This pathway uses PL as acyl donors and DAG as the acceptor, and the reaction is catalyzed by the enzyme phospholipid:DAG acyltransferase.

There are two diacylglycerol acyltransferase families identified in *Chlamydomonas*, involved in the final step of triacylglycerol synthesis: type one (DGAT), encoded by DGAT1, and type two (DGTT), encoded by five DGTT genes, which do not share sequence similarity. Two independent studies showed the expression levels of DGAT1 and DGTT1 increased considerably following nitrogen deprivation.[4,89,116] However, it remains unclear which of these DGATs are primarily responsible for the accumulation of TAGs under this condition or whether individual isoforms have specific roles.

Triacylglycerol synthesis can also occur within the plastid, through a series of acyl-ACP esterifications to plastidial G3P, catalyzed by plastidial ATs similar to the Kennedy pathway in the ER.[117] The involvement of GG (the major polar lipid family in plastidial membranes in several microalgae) in this process remains to be elucidated.

During light−dark cycles, many microalgae initiate triacylglycerol storage during the day and deplete those stores at night to support cellular ATP demands and/or cell division.[56] This cycling has to be taken into account when scaling up processes for production of lipids from algae. This variable may be key to the overall success of an open pond process or a closed photoreactor process.

Stage 4. Lipid Droplet Biogenesis. In contrast to yeast, LD can emerge from plastidial membranes. They can grow facing the cytosol or toward the inside of the plastid, facing the stroma, which is the major aqueous fluid surrounding the thylakoids inside the chloroplast.[4,117] The mechanisms underlying the orientation of lipid droplet growth in plastid membranes are not well understood. When LD grow toward the inside of the plastid (facing the stroma), they can also be called plastoglobules (PTG). PTG can be considered to be functionally equivalent to cytosolic LD, but differ in three major respects. First, they are confined to the stroma. Second, they can assume several different forms including rods, fibers, and globules; and third, they are bound by a specific family of proteins, variously termed plastoglobulins, plastid lipid-associated proteins, and fibrillins.[11] Oleosins (the major lipid droplet proteins present in plants) are not present in green algae, but a major lipid droplet protein was identified by applying proteomics in *Chlamydomonas* and shown to modulate lipid droplet size.[1] Orthologues of the major lipid droplet protein are present in other green algae. A wide variety of parameters affect the abundance of LD in *Chlamydomonas*, and there is ample evidence that turnover of LD plays crucial roles in cellular lipid or carbon homeostasis.[118]

THE CASE OF BACTERIA

In bacteria, the most frequent types of neutral and polymeric lipids synthesized and accumulated are PHA, TAG, wax esters (WE), and, to a lesser extent, SE. This review focuses on the first two. Most bacteria are capable of synthesizing either PHA or TAG. However, a special situation occurs in bacteria such as *Rhodococcus ruber*, and other related bacteria, capable of accumulating both types of lipids from unrelated carbon sources such as glucose.[7,11]

The mechanisms of wax ester accumulation have been reviewed elsewhere.[119,120] In a nutshell, an acyl-CoA is transformed to an aldehyde via an NADPH-dependent acyl-CoA reductase (encoded by *Acr1*), which is then reduced to an alcohol via an also NADPH-dependent fatty aldehyde reductase. The alcohol is then transesterified to an acyl-CoA via an enzyme displaying both wax ester synthase (WS) and acyl-CoA:diacylglycerol acyltransferase (DGAT) activities (abbreviated WS/DGAT).[7]

The only report of the presence of an sterol ester-synthesizing enzyme in prokaryotes was provided by Thornton et al.[121]

Accumulation of TAG in Bacteria. To date, triacylglycerol biosynthesis has been detected only in aerobic heterotrophic bacteria and in cyanobacteria.[6] In most bacteria, accumulation of TAG and other neutral lipids, such as WE, is stimulated by a carbon source present in excess, together with limited nitrogen in the medium.

Biosynthesis of Fatty Acyl Chains. Structurally, fluorescence staining experiments showed that lipid biosynthesis starts at peripheral lipid domains close to the cytoplasm

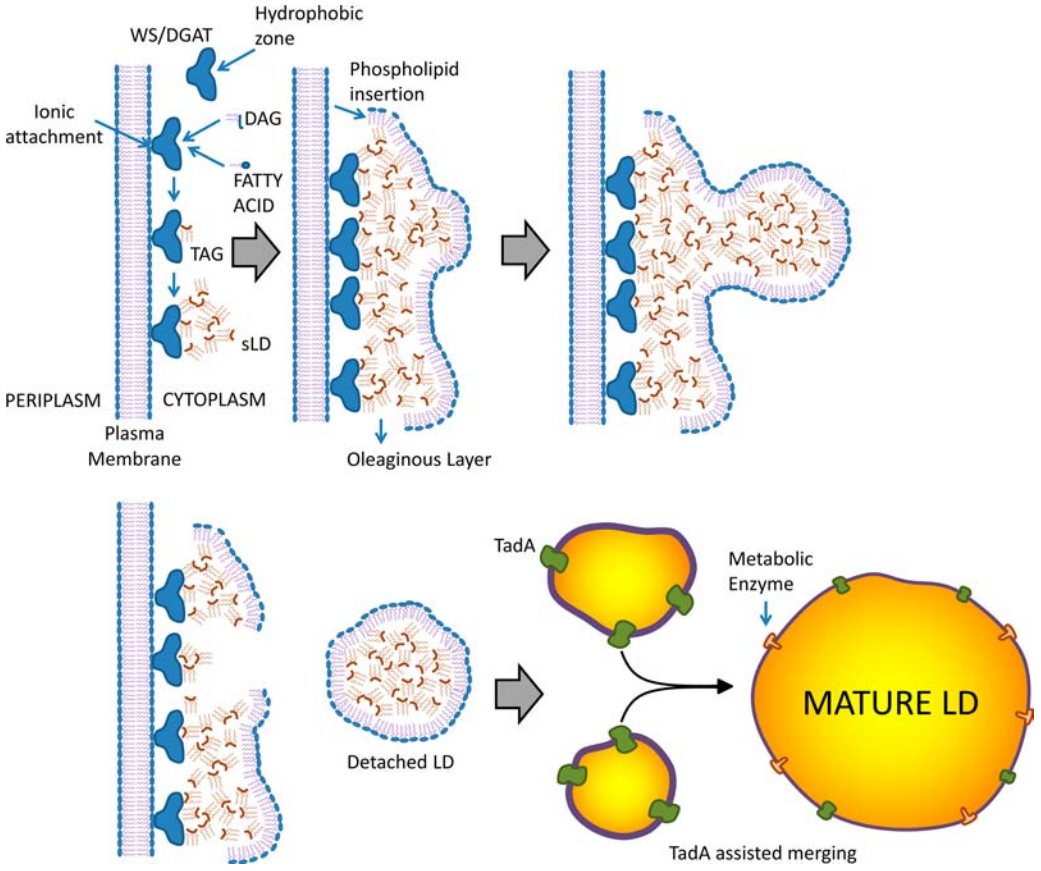

Figure 6. Suggested mechanisms of neutral LD formation in bacteria. Adapted from ref 22.

membrane.[22,122] Biochemically, fatty acid biosynthesis begins in bacteria with Acc, a heterotetrameric enzyme encoded by four genes, *accA*, *accB*, *accC*, and *accD*.[21] Fatty acids in bacteria are synthesized via a dissociated type II FAS. Each monofunctional protein is encoded by a specific gene.

Ac-CoA is converted to mal-CoA and transferred to ACP by malonyl-CoA:ACP transacylase (FabD in bacteria) to form malonyl-ACP. A first condensation of malonyl-ACP with acetyl-CoA by β-ketoacyl-ACP synthase III (FabH) to form β-ketobutyryl-ACP and CO_2 initiates a cycle that can elongate the fatty acyl-ACP by two carbon units for each cycle until a saturated fatty acid of 16 or 18 carbons is made. KSI (FabB) and KSII (FabF) are responsible for the subsequent elongation cycles of the growing acyl-ACP chain.

To balance chain initiation with growth and utilization in bacterial FASII, KSIII, enoyl-ACP reductase (FabI in bacteria), and β-ketoacyl-ACP reductase (Fab G in bacteria) are under negative feedback control by long-chain acyl-ACPs.[18] Long-chain acyl-ACPs directly control reductase activities; consequently, FASII is biased to catalyze forward if these products are withdrawn from the system by any conversion, including phospholipid or triacylglycerol synthesis.

In some bacteria, FAS II yields unsaturated fatty acids, which play a key role in bacterial membrane fluidity and function.[21,123] Unlike ER desaturases present in microalgae or yeast, which introduce double bonds into the completed fatty acid chains at the expense of oxygen, the bacterial FAS II system can also desaturate fatty acids anaerobically, because it does not require molecular oxygen.[21] FabA introduces the double bond at the 10-carbon intermediate, forming *cis*-2-decenoyl-ACP. It additionally isomerizes it into *trans*-3-decenoyl-ACP, which is further elongated by FabB.[18,21] Two genes, *fabA* and *fabB*, are the key players in this pathway and occur together in bacteria that produce unsaturated fatty acids.

Some *Rhodococcus* and *Nocardia* bacteria are capable of incorporating branched or phenylic groups into their intracellular TAG if the corresponding substrate is fed to the medium. For example, *Nocardia globerula* strain 432 accumulated TAG containing the branched fatty acid 4,8,12-trimethyltridecanoic acid after cells were fed pristane (a branched alkane),[6] and TAG with a subfraction containing phenyldecanoic acid residues were detected in cells of *R. opacus* PD630 after phenyldecane was fed as sole carbon source.[6,124]

Allocation of Acyl Moieties to either Polar or Neutral Lipid Pools. The enzymes involved in the esterification of the glycerol moiety probably act via sequential acylation of the sn-1, -2, and -3 positions of G3P, with the removal of the phosphate group occurring before the final acylation step.[6] The first esterification is catalyzed by a G3PAT using either acyl-CoA or acyl ACP to form lysophosphatidic acid. A second acylation to lysophosphatidic acid gives PA, which is the first branchpoint for the synthesis of TAG and PL, because it can be converted to CDP-DAG, the precursor of the different PL species in bacterial membranes. DAG itself is also at a metabolic branchpoint that divides phospholipid and triacylglycerol formations, because it acts as a precursor for TAG, PC, and PE biosynthesis. In addition, DAG can also be derived from PL by the action of phospholipase C[7,125] The distribution of acyl groups on the hydroxyl groups of the glycerol backbone is nonrandom, as has been demonstrated for *R. opacus* PD630.[6,126] The shorter and saturated fatty acids were esterified to the hydroxyl group at position 2, whereas

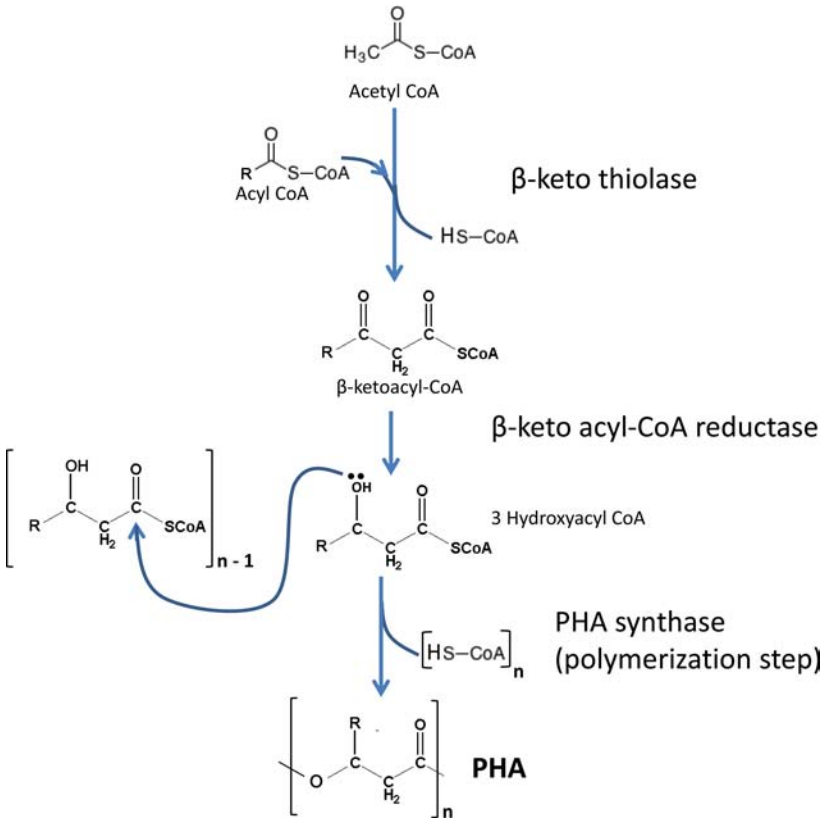

Figure 7. Biosynthesis of PHA.

unsaturated fatty acids were preferentially found at position 3. This distribution in bacterial TAG is different from the TAG of mammals and plants, where the longer unsaturated fatty acids are found at position sn-2.[127]

The final step in wax ester and triacylglycerol biosyntheses in bacteria is catalyzed by WS/DGAT.[7,127] WS/DGAT is encoded by *atfA* and is not related to any known AT involved in the formation of TAG and WE in eukaryotes. It has also been shown that WS/DGAT is localized at the bacterial cytoplasmic membrane, presumably attached to the inner leaflet of the membrane, probably via ionic interactions.[22] For a detailed review about WS/DGAT, the reader is referred to the work of Waltermann et al.[7] Alternative pathways for triacylglycerol synthesis that do not involve DAG in bacteria have also been reported and may involve an enzyme similar to that reported by Dalquist in yeast,[115] which catalyzes the formation of TAG from the transesterification of an acyl donor (e.g., acyl-CoA) to PL.[6] This follows observations that following a double knockout of WS/DGAT genes in *A. borkumensis*, cells were still capable of substantial triacylglycerol accumulation in LD.[11,128]

Triacylglycerol/Wax Ester Lipid Droplet Biogenesis. Triacylglycerol/wax ester lipid droplet biogenesis presumably begins by allocation of newly formed TAG in a hydrophobic zone within WS/DGAT. As time goes by, more WS/DGAT attaches to the membrane, and cumulative synthesis advances, presumably leading to the formation of very small triacylglycerol agglomerates, depicted by Wältermann et al. as small lipid droplets (sLD).[22] sLD apparently recruit PL from the membrane by a mechanism that is still not well understood, forming a layer toward the cytoplasmic side (see Figure 6). The agglomeration of phospholipid-coated sLD appears in microscopy as an oleaginous layer just parallel to the membrane.[22] Then, accumulation of sLD in a given point gives birth to LD, which are coated by PL and detach from the oleaginous layer. These droplets will acquire more TAG and grow. It has been suggested that acquisition of additional TAG is by merging with other LD freshly synthesized from the oleaginous layer via coalescence[22] and/or through a protein identified as TadA.[11] An interesting study by Ding and co-workers[36] examined the proteome of *Rhodococcus* sp. RHA 1 (a Gram-positive bacteria capable of accumulating TAG)[36] grown both in nitrogen-abundant (not favoring lipid accumulation) and nitrogen-depleted conditions (favoring lipid accumulation). Using a combination of techniques, including LC-MS, SDS-PAGE, and immunoblot assays, they reported 228 lipid droplet-associated proteins, which clustered primarily into metabolism-related enzymes, transcriptional regulators, ribosome proteins, and cell division-related proteins. Interestingly, they identified two major proteins, ro02104 and PspA, which constituted about 15% of the total lipid droplet protein. According to their findings, the structure predicted for ro02104 resembles that of apolipoproteins, the structural proteins of plasma lipoproteins in mammals.

Accumulation of PHA in Bacteria. In bacteria PHA comprise a complex class of storage polyesters, with almost 150 different hydroxyalkanoic acids known as constituents.[6] A wide variety of Gram-positive as well as Gram-negative bacteria synthesize PHA. Examples include *Pseudomonas*, *Bacillus*, *Ralstonia*, *Aeromonas*, and *Rhodobacter*, among others. PHA are divided into two groups on the basis of the number of constituent carbon atoms in their monomer units: short chain length PHAs (SCL PHA) and medium chain length PHAs (MCL PHA). Monomers of SCL PHA are 3−5 carbon atoms

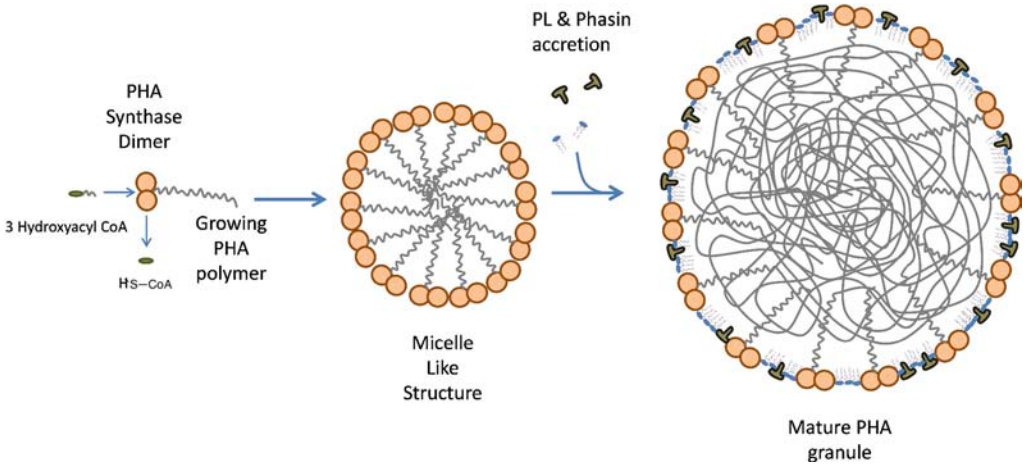

Figure 8. Proposed mechanism of PHA containing lipid droplet formation in bacteria (micelle model). Adapted from ref [22].

long, compared to 6−14 carbon atoms in MCL PHA. In addition, SCL PHA are stiff and brittle with a high degree of crystallinity, whereas MCL PHA are flexible and have low crystallinity, tensile strength, and melting point.[30]

Production of Acetyl-CoA and Synthesis of Hydroxyalkanoate Monomers. Accumulation of PHA starts with the creation of hydroxyalkanoate monomers from three different biosynthetic pathways. The first one involves incorporation of two acetyl-CoAs to form acetoacetyl-CoA, by the enzyme β-ketothiolase.[11,30,129,130] Then acetoacetyl-CoA reductase converts acetoacetyl-CoA into 3-hydroxybutyryl-CoA. This pathway creates hydroxybutyrate (HB) monomers exclusively and is used by bacteria such as *Cupriavidus necator* and *Azotobacter beijerinckii* (see Figure 7).[30,129,130] On a second pathway involving de novo fatty acid biosynthesis, monomers of different lengths can be formed by transesterifying 3-hydroxyacyl-ACP, an intermediate of FAS II to 3-hydroxyacyl-CoA, presumably by the enzyme acyl-ACP-CoA transacylase, encoded by *phaG*. This enzyme is the key link between de novo fatty acid synthesis and polyhydroxyalkanoate biosynthesis.[30,131] This pathway is of biotechnological interest because it helps generate monomers for polyhydroxyalkanoate synthesis from structurally unrelated and simple, inexpensive carbon sources such as glucose or related simple sugars. On a third embodiment, monomers of different lengths can also be sourced from fatty acid β-oxidation pathway either by conversion of 2-enoyl-CoA by an *R*-specific enoyl-CoA hydratase, encoded by *PhaJ*, or by reduction of 3-ketoacyl-CoA, presumably by FabG or PhaB.[30] In this case, the monomer composition is related to the carbon source used.

Polymerization and Copolymerization into Polyhydroxyalkanoate Chains. The resulting *R*-3-hydroxyacyl-CoA monomers are polymerized by polyhydroxyalkanoate synthase. The ability of microorganisms to synthesize a particular form of polyhydroxyalkanoate is mainly due to the substrate specificity of polyhydroxyalkanoate synthases. These enzymes are divided into four classes, depending on their structure and specificity. Class I enyzmes utilize CoA thioesters of 3-hydroxyalkanoates (3-HAs), 4-HAs, and 5-HAs comprising three to five carbon atoms.[132] Species such as *Pseudomonas putida* and *R. eutropha* possess this class of enzymes. Members of class II display major specificity for monomers ranging from 6 to 14 carbon atoms. Enzymes from both classes consist of a single subunit of an average size of 60−70 kDa and are encoded by *PhaC*. In contrast, class III and class IV synthases are encoded by two genes, PhaC/PhaE, and PhaC/PhR respectively, and consist of two subunits. Class III members are capable of polymerizing preferably monomers ranging from three to five carbons, yet can utilize monomers from six to eight carbons as well.[132] Species such as *Allochromatium vinosum* contain class III synthases, whereas class IV has been reported only in *Bacillus* sp.[38] All polyhydroxyalkanoate synthases share a conserved cysteine as a catalytic site to which the growing polyhydroxyalkanoate chain is covalently attached. The active-site cysteine, histidine, and aspartate constitute a catalytic triad similar to esterases.[38] Literature is available for an in-depth analysis of polyhydroxyalkanoate synthases.[133−139]

Polyhydroxyalkanoate Lipid Droplet Biogenesis. Two models currently exist that may explain the formation of in vivo polyhydroxyalkanoate LD (which are also called granules or carbonosomes[38,39]): the micellar and the budding models. The first one is based on the assumption that the polyhydroxyalkanoate synthase is present in the cell as a soluble enzyme, distributed throughout the cytoplasm. Once polymerization of substrate molecules (CoA-thioesters of suitable hydroxyalkanoic acids) starts, the nascent polyester chain converts the initially soluble enzyme into an amphipathic molecule and the increasingly hydrophobic polyhydroxyalkanoate chains aggregate into a micelle-like structure. Polyhydroxyalkanoate synthase remains attached to the surface of the granule and therefore becomes insoluble (see Figure 8). In this model, PL and proteins of the surrounding layer would gradually become incorporated as the self-assembled polyhydroxyalkanoate inclusion increases in size.[38,39] This model requires the polyhydroxyalkanoate granule to be localized in the cytoplasm at all stages of formation. In contrast, the budding model assumes that polyhydroxyalkanoate synthase is associated with the inner face of the cytoplasmic membrane, either inherently or as soon as a polyhydroxyalkanoate chain emerges from the enzyme. In this case, biosynthesis of the polyester would be directed into the intermembrane space where the extending chains would accumulate until eventually the granules detach from the membrane and polyhydroxyalkanoate-specific surface proteins can be attached to the growing granules.[38,39] Although the micelle model is supported by the fact that polyhydroxyalkanoate granules can be produced in vivo in the absence of membranes, most of the recently emerging evidence is in favor of the budding model.[39] The major structural proteins present

in polyhydroxyalkanoate granules are phasins (Phas). Phas may constitute approximately 5% (w/w) of total cellular proteins,[140,141] and they play a main structural role in preventing polyhydroxyalkanoate granules from aggregating and in preventing the nonspecific attachment of other proteins to polyhydroxyalkanoate granules.[140−142] In addition, phasins are presumably involved in the regulation of polyhydroxyalkanoate synthesis, polyhydroxyalkanoate degradation, polyhydroxyalkanoate granule size control,[140,141,143,144] the formation of networks on the polyhydroxyalkanoate granule surface,[145] and the distribution of polyhydroxyalkanoate granules during cell division. Another important group of proteins present in the external granule layer is the depolymerases, which are responsible of catalyzing polyhydroxyalkanoate breakdown. This is a relevant step in the role of polyhydroxyalkanoate accumulation as a survival mechanism in the absence of suitable energy/carbon sources, as was demonstrated many years ago in *R. eutropha*.[146] Two groups have been identified: intracellular (PhaZs) and extracellular depolymerases. PhaZs have been investigated much less than extracellular depolymerases, and the mechanism by which intracellular native polyhydroxyalkanoate granules can be reutilized is still not well understood.[39] Interestingly, the gene coding for PhaZs is located between two copies of *phaC1* and *phaC2* (both polyhydroxyalkanoate synthase genes) in all investigated bacteria that accumulate MCL PHA.[38] In contrast, secreted depolymerases are used by most bacteria to assimilate PHA present in the environment from, for example, other nonliving cells.[147]

Polyhydroxyalkanoate granule synthesis and phasin production are tightly regulated by the effectiveness of the transcriptional regulator PhaR. Genes encoding proteins homologous to PhaR are widely distributed among SCL PHA producing bacteria, indicating an important role in the regulation of SCL PHA biosynthesis.[39,148,149]

THE CASE OF ARCHAEA

The discovery of the Archaea domain in 1977 revealed a novel class of microorganisms encountered in exceptional ecological niches such as high (thermophiles and hyperthermophiles) or low (psychrophiles) temperatures, acidic media (acidophiles an thermoacidophiles), anaerobic atmosphere (methanogens), and high salinity (halophiles).[150,151] The unique chemical structure of their core membrane lipids is in part responsible for their adaptation to such hostile environments. Archaeal membrane lipids, in contrast to those of bacteria and eukaryotes, are made up of saturated chains containing methyl branches, attached to glycerol by ether linkages with a stereochemistry in the 2-position of the glycerol opposite that of conventional mesophilic lipids. (For a review on archaeal ether lipid structures, the reader is referred to the work of Jacquemet et al.[150]) Moreover, Archaea do not synthesize fatty acyl esters, which are the most common constituents of LD; instead, their lipids are based on isoprenoid chains.[11] Therefore, no accumulation of TAG has been reported yet in Archaea. Despite these differences, however, evidence of polyhydroxyalkanoate accumulation was first reported in Haloarchaea back in 1972.[152,153] The strains were called at that time "*Halobacterium* sp. from the Dead Sea", but later identified as *Haloarcula marismortui*.[154] Since then, strains of several other haloarchaeal genera, including *Haloferax*, *Halobiforma*, and *Haloquadratum*, have been found to accumulate PHA.[140,154] As in bacteria, Archaea produce PHA under conditions of nutrient limitation but where carbon is available in excess.[155−161] The mechanisms of polyhydroxyalkanoate accumulation within Archaea are beginning to be understood, and work is underway to elucidate the type of proteins involved in archaeal polyhydroxyalkanoate accumulation. Genes involved in polyhydroxyalkanoate biosynthesis in Haloarchaea were not recognized until recently, when the polyhydroxyalkanoate synthase genes were identified and characterized for *Haloarcula marismortui* and *Haloferax mediterranei*.[156,157,159−163] These archaeal polyhydroxyalkanoate synthases are all composed of two subunits, PhaE and PhaC, and they are homologous to class III bacterial polyhydroxyalkanoate synthases but have a longer C-terminal extension in the PhaC subunit.[162] The close similarity of archaeal and bacterial type III polyhydroxyalkanoate synthase genes and the lack of other polyhydroxyalkanoate gene types in archaea suggest that archaeal PHA originated from the horizontal transfer of an ancestral type III gene from a bacterium.[11] Some authors suggest this transfer to have occurred already before Permian times.[152]

Genome-wide analysis of *H. marismortui* ATCC 43049[162,163] revealed eight paralogues of a short-chain dehydrogenase/reductase, responsible for reduction of acetoacetyl-CoA to (*R*)-3-hydroxybutyryl-CoA (3-HB CoA), a monomer used by polyhydroxyalkanoate synthase to produce polyhydroxybutyrate (PHB). Another study[162] demonstrated that a similar paralogue in *H. hispanica*, namely *fabG1*, encodes a PHA-specific acetoacetyl-CoA reductase responsible for providing 3-HB-CoA for polyhydroxyalkanoate biosynthesis in *Haloarcula* species. The authors concluded that the polyhydroxyalkanoate biosynthesis pathway from Ac-CoA, catalyzed by β-ketoacyl thiolase, acetoacetyl-CoA reductase, and polyhydroxyalkanoate synthase, as distributed in bacteria, likely also exists in the domain of Archaea. Nonetheless, they pointed out that for PHB-accumulating haloarchaeal *Natrialba* strain 56,[157,158] no enzyme activity of acetoacetyl-CoA reductase or β-ketoacyl thiolase was detected in the crude extract, indicating that a different metabolic route toward production of PHB might be employed.

Polyhydroxyalkanoate synthase, putative enoyl-CoA hydratase, and two structural phasin-like proteins have been identified in haloarchaeal polyhydroxyalkanoate granule surfaces.[140] The phasin-like proteins in Haloarchaea share some structural features with bacterial Phas, such as the presence of hydrophobic domains and a high α-helix content.[140,164] After a genome-wide investigation into the 12 Haloarchaea that harbored the PhaP gene, most of these Archaea were found to possess a similar *pha* cluster, with five genes, namely, *maoC-gap12-phaP-phaE-phaC*, having the same organization as that in *H. mediterranei*.[140] The extensive existence of this *pha* gene cluster was suggested as an indication of an evolutionarily conserved *pha* gene cluster unique to Haloarchaea.[140]

A promising approach is to develop archaeal species as industrial scale polyhydroxyalkanoate producers. In particular, several halophilic Archaea have the advantages of utilizing much cheaper carbon sources (including waste materials), as well as having less strict sterilization requirements, plus easier and more efficient methods for polyhydroxyalkanoate extraction.[132]

FUTURE PERSPECTIVES

Microorganisms provide an exciting platform for the development of lipid technologies. In the course of evolution, they have developed elegant pathways to synthesize a wide array of lipids, providing a versatile and cost-effective approach for sourcing

lipids to virtually all sectors of industry. The understanding of the biochemical and cellular mechanisms of lipid production, accumulation, and secretion will provide valuable insights on innovations to overcome the hurdles in microbial lipid utilization.

Ongoing studies using different "omics" approaches will provide a holistic view of flows and interactions between the different metabolic pathways involved in lipid accumulation. Tools such as next-generation sequencing, transcriptome analysis, proteomics, and mass spectrometry are already clearing out the missing links in single-cell lipid biosynthesis. This information will permeate in the creation and scaleup of more efficient processes.

It is thus important to project the potential applications and envision the frontiers to which this valuable toolset can lead the diverse fields of lipid technology. For example, in the field of biotherapeutics, microbial-based approaches have the flexibility to construct platforms to manufacture personalized lipid therapies starting as simply as LC PUFA combinations, appropriate to the metabolic phenotype of each individual[165] and eventually becoming as complex and selective as personalized cancer interventions. This approach of personal medicine will carry improved benefits in the treatment of a range of conditions: in immunological diseases from infections to autoimmunities; in metabolic conditions from diabetes to cardiometabolic diseases; and in microbiota dysbiosis from IBS to IBD. Microbial technologies can also provide an alternative pathway for sourcing promising lipids and fatty acids that are unavailable in the market at present. For example, oil-producing microbes can be considered as appropriate vehicles in which foreign (plant) genes could be cloned for the production of commercially attractive fatty acids such as nervonic acid (C24:1 Δ15) obtained from Honesty (*Lunaria*),[3] which is used in small amounts in the treatment of particular neuropathies. Another example is sterculic acid {ω-(2*n*-octylcycloprop-1-enyl)-octanoic acid},[166] which has been considered as a treatment for certain cancers of the bowel. One more promising example is represented by the non-methylene-interrupted fatty acids (e.g., C20:3 Δ5, Δ11, Δ14), which can be obtained from *Juniperus chinensis* seed oil and is known to reduce the amount of arachidonic acid in certain phospholipid pools and, thus, act to alter eicosanoid signaling.[167]

In the field of energy and biofuels, understanding the mechanisms by which each group of microorganisms generates highly combustible lipids will foster the production of cost-effective fuels through sustainable processing and with improved performance. It is yet to be tested whether the biochemical mechanisms for amphipathic lipid secretion present in some microorganisms would work for the secretion of neutral lipids. This concept, if brought to practice, will significantly reduce the processing costs and render high-quality combustible lipids for the production of biofuels.

In the case of the food industry, a microbial-based approach will allow food companies to expand their core businesses by creating new product portfolios out of their current byproducts. Two promising examples are the production of cocoa butter analogues[3] and the production of high-value oils out of spent agricultural materials.

In the field of biomaterials, microbial lipids are already being used for producing biosurfactants and bioplastics, replacing synthetic analogues due to their improved biodegradability and reduced cost. Companies are now emerging worldwide taking advantage of the microbial lipid toolset. Products such as Metabolix PHA and Biomer are examples on how microbial-derived plastics are gaining momentum in the market.

Microbial biosurfactants are beginning to generate improved results against their synthetic homologues. Their specific modes of action, low toxicity, relative ease of preparation, and widespread applicability are increasing their use in applications such as emulsifiers, wetting and foaming agents, functional food ingredients, detergents in petroleum, petrochemicals, environmental management, agrochemicals, cosmetics and pharmaceuticals, commercial laundry detergents, mining and metallurgical industries (for an overview of microbial surfactant applications, see Mukherjee[168]). The scope of applications goes to such an extent that the petroleum extractive industry is already researching the use of microbial lipid-based biosurfactants for increasing oil recovery yields from subterranean depots.[168,169] The great era of chemistry culminating in the restructuring of the human condition in the 20th century has been defined by the principles of reductionism and simplicity. In contrast, the 21st century heralds the era of complexity for which the inherent biological diversity and information content of microorganisms will be key to adding value to all industrial chains.

A search performed on July 6, 2013, with the terms "microbial lipids" in the U.S. Patent Office "quick search" option retrieved 11905 results. Figure 9 shows a steady increase in U.S. patent publication since 2008, showing the increasing interest in the generation of intellectual property around this area of research.

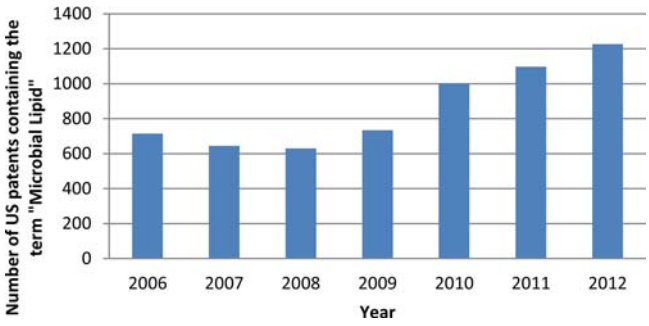

Figure 9. Number of U.S. patents containing the term "microbial lipids" per year.

Notice the increasing trend starting in 2008. The estimated patents by the end of 2013 according to the current trend will be around 1420, almost doubling the number registered in 2009.

The next step in microbial lipid technology is the integration of processes and applications to generate comprehensive, sustainable solutions. The immediate challenge is to combine desired metabolic pathways present in different species or strains to generate superior microbial species. Benefits will include improved yields, targeted lipidomic profiles, and structural features to synthesize in a sustainable and cost-effective way the lipid structures necessary to satisfy the breadth of needs of 21st century industry. For example, an appropriate integration of microbial-based lipid technologies will allow delivery of smart biofuels and even personalized edible oils derived from microorganisms and reporter-equipped biodegradable containers also derived from microorganisms. Currently the most used packaging material for commercial edible oils is polyethylene terephthalate, which is virtually a

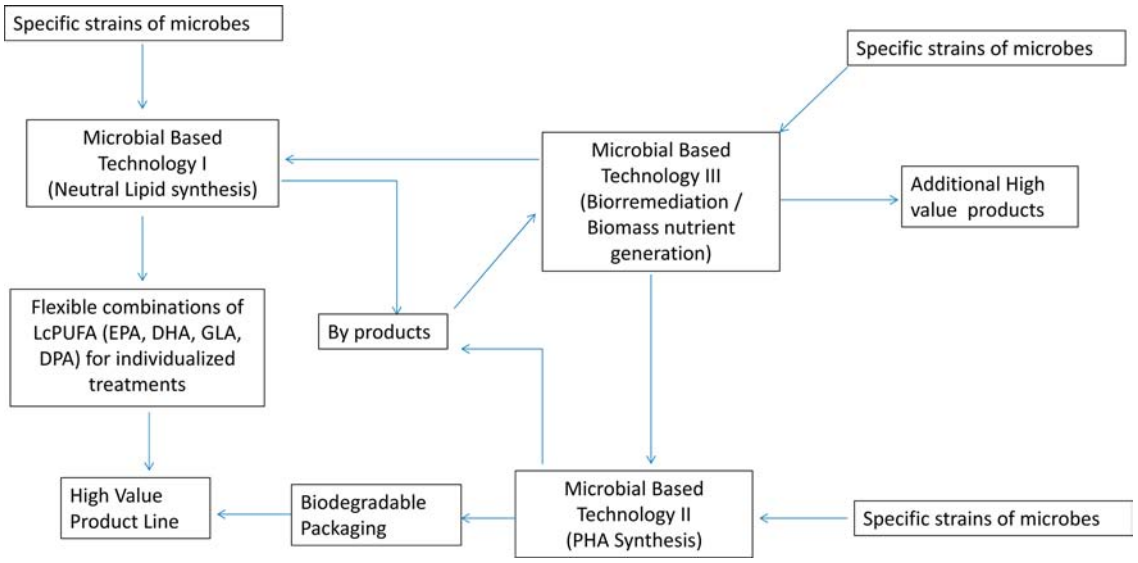

Figure 10. Conceptual flowchart for an integral, sustainable microbial-based edible oil process.

nondegradable plastic. With the appropriate use of microbial PHA, it could be possible to see in the same facility the production of high-value microbial oils (rich in a combination of LC PUFA), along with the production of polyhydroxyalkanoate-based bottles for its commercialization. Furthermore, additional microbial biotechnology platforms will be integrated to transform the byproducts either into biomass nutrients to make the process sustainable or even into another portfolio of high-value products, as a way to increase the business profitability (Figure 10). This would be a proposed example of a sustainable microbial-based industry.

Microbial lipid technologies are a valuable toolset available for the future generation of scientists, which will help them push the boundaries of production solutions ultimately toward a more sustainable society.

(Hymenoptera: Apidae), demonstrating its high virulence and ability to infect multiple bee species.[32] Recent literature reports verify the ubiquitous geographical presence of this invasive pathogen, its presence now being confirmed not only in Europe, Asia, and North America[33] but also in more remote geographical locations such as Australia,[34] South America,[32] and North Africa.[35] Evidence suggests that *N. apis* is gradually being replaced by *N. ceranae* in *A. mellifera*,[18] although *N. apis* remains more prevalent in colder climates.[16,36] Controversy regarding the greater relative virulence of *N. apis* compared with *N. ceranae* remains unresolved, with different results being obtained by different research groups.[18,36−38] Co-infection of *N. apis* and *N. ceranae* commonly occurs in *A. mellifera*[16,20] and has also been reported in *A. cerana*.[39]

N. ceranae infects the bee digestive tract midgut epithelial cells (ventriculus) of adult workers and queens.[17,40] Similar to *N. apis*, the mature spores burst forth by rupturing the epithelial cells and spill into the midgut lumen, followed by defecation with the fecal matter. Infection spreads via a fecal−oral route when adult worker bees contract the infection by cleaning up fecal material originating from infected bees or through trophallaxis of contaminated food.[41,42] Infection with *N. ceranae* has been shown to increase precocious foraging in worker bees, resulting in reduced life expectancy by 9 days on average in cage trials as compared with control groups.[43] Although outward signs of *Nosema* spp. infection cannot typically be seen, the inhibition of pollen digestion caused by the parasites leads to poor nourishment, smaller populations, reduced honey production, and higher winter colony mortality.[44] For more detailed information on the biology of *N. ceranae* as honey bee pathogen, the reader is directed to recently published reviews.[16,17,45]

FUMAGILLIN DISCOVERY AND USAGE IN APICULTURE, HUMAN MEDICINE, AND IN OTHER AGRICULTURE

Fumagillin is a naturally occurring antibiotic compound that was first isolated in 1949 from an *Aspergillus* species, designated H-3[46] and later identified as *Aspergillus fumigatus*.[47] The drug was also discovered to be a potent amebicide.[48] The structure of fumagillin was eventually elucidated[49] through an extensive series of chemical manipulations, including the hydrolysis of fumagillin to yield the alcohol fumagillol (Figure 1).

The importance of fumagillin as a treatment against the microsporidian fungal disease *N. apis* plaguing the European honey bee (*A. mellifera* L.) was soon recognized.[50,51] Fumagillin is also currently the only effective drug treatment available against *N. ceranae*.[52−54] The commercial formulation of fumagillin consists of the dicyclohexylamine (DCH) salt of fumagillin (Figure 2). The significance of the usage of fumagillin in the "salt" form is described under Toxicity of Fumagillin. On the basis of experimentation using cage bioassays, it was nevertheless purported that fumagillin provides only short-term suppression of *N. ceranae*, compared with *N. apis*, and that hyperproliferation of spores of the former results at specific and much degraded concentrations of the drug.[55]

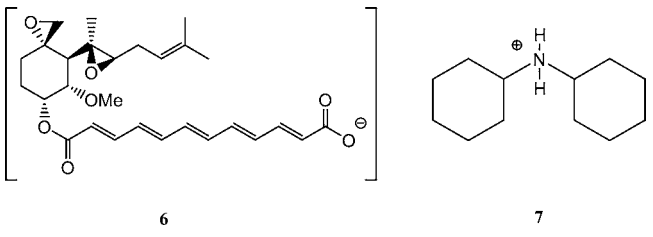

Figure 2. Fumagillin, CAS Registry No. 23110-15-8 (**6**), as the DCH CAS Registry No. 101-83-7 (**7**) salt.

dx.doi.org/10.1021/jf4055374 | J. Agric. Food Chem. 2014, 62, 2728−2737

Fumagillin was also tested for the treatment of microsporidian infections in fish.[56−59]

In human medicine, fumagillin is used as an inhibitor of microsporidian infections in patients with compromised immune systems due to acquired immunodeficiency syndrome (AIDS) or to relieve symptoms of intestinal microsporidiosis that occur after organ transplant procedures.[60−62] More interestingly, though, fumagillin and its analogues are used to treat various cancers by inhibiting the formation of new blood vessels around growing tumors (angiogenesis), thereby limiting their blood supply.[63]

The treatment of cancer tumors by inhibition of angiogenesis was first proposed in 1985.[64,65] The discovery that fumagillin inhibits angiogenesis led to a renewed interest in fumagillin as a therapeutic drug.[63] The mechanism for this activity was not clear, until the discovery of fumagillin binding to the methionine aminopeptidase type 2 (MetAP-2) protein.[66,67] The exact binding of fumagillin to the MetAP-2 enzyme was determined by crystallizing the enzyme with fumagillin covalently bound to the enzyme active site.[68] A crystallographic study then revealed that fumagillin covalently binds to a histidine moiety (His^{231}) of the enzyme, resulting in an irreversible opening of the spiro-epoxide on the cyclohexane core skeleton of fumagillin.[66,68,69]

This result prompted numerous research efforts aimed at modulating the mode of action[70,71] by preparing analogues of fumagillin via modification of the alkene side chain. First, fumagillin was hydrolyzed with a suitable base, thereby removing the side chain to yield fumagillol (Figure 1). Subsequently, a new chemical moiety could be coupled to fumagillol,[70,72,73] resulting in analogues including TNP-470 (Figure 1), which has shown promise as a potential new treatment for malaria.[69,74] Another analogue of fumagillin, named fumarranol, with the spiro-epoxide opened, exhibited an 80−100-fold lower activity than TNP-470 against malaria.[74] The low activity of fumarranol indicates the importance of the intact epoxide for biological activity of the fumagillin family of analogues. A 1000-fold decrease of MetAP-2 inhibition by fumagillin upon the opening of this cyclohexane ring spiro-epoxide was observed.[67,75,76]

Fumagillin binds only to the MetAP-2 enzyme via the epoxide group located on the cyclohexane core ring structure and not to the MetAP-1 enzyme.[66] The other remaining epoxide on the molecule is not crucial for the binding to take place and is therefore dispensable.[76]

MetAP-2 enzymes are found ubiquitously in all organisms.[69] Fumagillin acts against microsporidian as well as mammalian MetAP-2 enzyme, and the low selectivity of fumagillin between human and microsporidian MetAP-2 is the cause of its toxicity to humans as it also inhibits the human MetAP-2 enzyme necessary in protein maturation and post-translation processes.[55,77] A similar observation was recently reported whereby it was shown that fumagillin is active against honey bee MetAP-2 at low concentrations, whereas it has no therapeutic activity at those concentrations against *N. ceranae* MetAP-2.[55] The fact that fumagillin acts against both the disease and bee MetAP-2 may explain the significant bee mortality associated with fumagillin usage.[78] An earlier study supports this increased mortality associated with fumagillin usage.[79] In this study it was observed that fumagillin does not influence the mortality of healthy bees during cage trials, but when *N. apis*-infected caged bees are treated with fumagillin, at concentrations of 25.2−50 mg/L in sugar syrup, increased bee mortality was observed. Even though fumagillin degrades over time,[80,81] the repeated seasonal treatment with fumagillin that is required to control reestablishment of *N. ceranae* infections, which is not necessary for *N. apis* control, ensures that multiple generations of honey bees are exposed to low levels of fumagillin.[54,55] It is postulated that this constant low level of fumagillin in the hive creates conditions conducive to hyperproliferation of *Nosema* spp.[55] The MetAP-2 binding site amino acid sequences between human, honey bees, and *N. apis*, *N. ceranae*, and *Nosema bombi* (nosema infection of bumble bees, *Bombus* spp.) were found to be identical between honey bee and human MetAP-2, whereas the *Nosema* spp. amino acid sequences were identical and exhibited only two differences in the binding site amino acid sequences compared to human and honey bee MetAP-2 sequences.[55] The authors also speculate that the MetAP-2 enzymes may not be the only factor influencing response to fumagillin.

Semisynthetic analogues of fumagillin exhibit different properties from fumagillin regarding their potency, selectivity, and toxicity, and it has been shown that the potency of fumagillin against MetAP-2 depends not only on the covalent interaction with the spiro-epoxide but also on more complex noncovalent interactions necessary for molecular recognition of the target drug by the enzyme.[82]

TOXICITY OF FUMAGILLIN

It is important to note that the key purpose in creating new analogues of fumagillin has been the need to limit the human toxicity associated with fumagillin while retaining or enhancing the beneficial properties of the parent compound, fumagillin.[63,83−86]

Several contradictory findings have been reported in the literature regarding the toxicity of fumagillin. It is important to know that the commercial formulation of fumagillin consists of the dicyclohexylamine (DCH, DCHA) salt of fumagillin in a 1:1 stoichiometric ratio with fumagillin. When the possible adverse effects of a compound are evaluated, any additive or contaminant should also be taken into account, regardless of its concentration, as the contribution to properties such as toxicity or mutagenicity from the additive may be more significant than what is expected.[87] The authors actually used the potential carcinogenicity of DCH contamination in a cyclamate study as an example of such an effect.

It is also interesting to note that most studies on the toxicity of fumagillin itself were conducted using the fumagillin DCH salt as reagent, thereby introducing not only one but two potentially toxic compounds.[85,88−94] Experiments using the fumagillin analogue TNP-470 (AGM-1470) (Figure 1) appear to use only the pure TNP-470 in toxicity testing with no DCH included.[83,85,95−97] In other studies it is unclear whether fumagillin was used as the DCH salt, free acid, or an alternative formulation,[78,98,99] although one study was found that refers to the use of purified fumagillin with no DCH present.[63] It is important to realize this fact when the reported data on the toxicity of fumagillin, or the more frequently employed fumagillin DCH salt, are evaluated.

The toxicity of DCH in isolation has been investigated[100] and was found to induce chromosomal damage in human leucocyte cultures at low concentrations of 10^{-3}−10^{-5} M, over periods ranging from 5 to 25 h. Stoltz et al.[100] also reported that *N*-hydroxycyclohexylamine, a metabolite of DCH, exhibited equivalent toxicity. A study using a *Salmonella typhimurium* strain (TA1535/pSK1002) to verify the genotox-

icity of DCH yielded negative results.[101] Nevertheless, the same study yielded positive results using an in vivo alkaline filter elution test (AFE) with freshwater clams as test subject to detect DNA damage. *Salmonella* mutagenicity tests also proved negative for DCH in an additional study.[102] Similar negative results were reported where DCH exhibited a positive carcinogenic response in only one of six tests.[103] DCH was also reported to be a powerful inhibitor of spermidine synthesis catalyzed by extracts from *Escherichia coli* and *P. aeruginosa* in vitro.[104] A national screening program in Sweden determined that DCH is toxic to rats by several modes of action, but no mutagenic properties were reported.[105] According to the MSDS (Sigma-Aldrich product 185841 v5.0 07/24/2012), DCH exhibits serious immediate toxic effects with an LD_{50} of 373 mg/kg orally (rat). Similar data were reported with an LD_{50} of 200−373 mg/kg.[106] According to the MSDS, the compound is extremely toxic to aquatic life and should not be released into the water system. It is also tumorigenic, causing gastrointestinal and liver tumors (orally) as well as being subcutaneously carcinogenic in mice, causing tumors at the site of application.[107]

Fumagillin toxicity was extensively examined by Stanimirović et al.[88−94] In these papers it is sometimes unclear whether fumagillin DCH or DCH alone was used in their experiments as their use of the terms fumagillin and dicyclohexylamine appear to be equivalent in earlier publications.[88,89] The authors also ascribed the DCH toxicity data[96] as being that of fumagillin,[88,89,93] whereas Stoltz et al.[100] clearly examined only DCH, with no mention of fumagillin ever being made. These inconsistencies, however, should not detract from the value of their research, which is briefly summarized below.

Fumagillin was observed to exhibit significant negative chromosomal aberration effects at 50−75 mg/kg body weight in mice. Concentrations of 25, 50, and 75 mg/kg body weight were administered by gavage.[88] All experimental dosages listed above induced significant antiproliferative and genotoxic potential in mice.[89] Fumagillin exhibited clastogenic activity in human lymphocytes at concentrations equivalent to the therapeutic dose in beekeeping.[92] Genotoxicity to mouse bone marrow cells at concentrations of 10−20 mg/kg body weight administered in vivo to mice by gastric probe (5, 10, and 20 mg/kg concentrations tested), as compared to a control group, was also observed.[93] These results were confirmed with fumagillin-induced chromosomal aberrations at 10−20 mg/kg in mouse bone marrow cells.[94] In summary, the Stanimirović group concluded that fumagillin DCH is a mutagenic formulation, both in vitro and in vivo.

Fumagillin was evaluated in the United Kingdom by the Committee on Mutagenicity in 1999, with the aim of establishing a maximum residue limit (MRL) in honey after a submission by the patent holder, CEVA Animal Health.[108] No MRL recommendation could be made by the Committee on Veterinary Medicinal Products because the available toxicity data at that time were considered to be insufficient to draw any conclusions on the risk. In 2011, it was concluded that fumagillin should be considered as an in vitro mutagen, but not an in vivo mutagen.[109] Fumagillin is still not licensed for general use in beekeeping in Europe except in exceptional circumstances, when a temporary authorization to use it under veterinary supervision will be allowed.[54] Fumagillin is registered for use in the United States and Canada to treat nosema disease. Temporary authorization has been issued in exceptional conditions to use fumagillin in the United Kingdom, Spain, Belgium, Greece, Hungary, and Romania under veterinary supervision.[54]

Although fumagillin is an extremely beneficial compound in human medicine and in apiculture, some undesirable side effects cannot be ignored.[61−63,83,85,86,95] Extended usage of fumagillin over prolonged periods of time, as required by chemotherapy, caused severe body weight loss of >15% from the starting weight in human test subjects.[95] In 1952, it was reported that fumagillin was essentially nontoxic to humans at oral doses of up to 50 mg daily for durations of 2 weeks to treat intestinal amebiasis,[84] although no weight loss was observed in test subjects. A more recent study administered fumagillin orally up to 60 mg daily for 2 weeks to treat microsporidiosis in patients with HIV infection.[61] The authors acknowledged significant bone marrow toxicity of fumagillin with 4 patients of a group of 11 developing severe toxic side effects at the highest dosage administered (60 mg). These effects ceased within days of the treatment being terminated.

Common side effects in human trials in which fumagillin is administered orally are gastrointestinal-related cramping, diarrhea, and significant loss of body weight.[95] This undesirable weight loss side effect prompted recent, perhaps ethically questionable, trial use of fumagillin as a chemical mitigation for obesity.[110,111]

In beekeeping, potential toxic and undesirable consequences of fumagillin treatment have also been examined, with a limited number of effects being documented. For example, unique changes in the ultrastructure of the hypopharyngeal glands have been observed in worker bees after infection with *N. apis* and subsequent treatment with fumagillin.[98] Such alterations may influence protein secretions from these glands, although the role of fumagillin treatment on gland structure and function remain speculative from this descriptive study. Fumagillin was also noted to have a significant influence on mortality during a cage trial experiment in which honey bees (150−200 bees per cage) were fed a sugar syrup solution for 7 days using a total dose of 140 mg of fumagillin per cage, compared with unmedicated controls.[78] In contrast, a later study indicated few to no deleterious effects of fumagillin (50 mg/L fumagillin in sugar syrup) for caged *N. apis*-infected bees, also over a 7 day period.[112] This concentration is also double that currently recommended for the only commercial formulation of the drug registered in North America for apiculture (Fumagilin-B, Medivet Pharmaceuticals Ltd., DIN 02231180). Label directions for this product prescribe 9.5 g of fumagillin DCH base to prepare 380 L of syrup (25 mg/L), which is sufficient to treat 100−110 colonies (86−95 mg/colony) in the spring or 50 overwintering (190.5 mg/colony) colonies in the fall.

The majority of other reported cage experiments that evaluated bee mortality associated with fumagillin usage have found few effects. No statistically observable increase in mortality was observed when sugar syrup was fed at concentrations of 12.6, 25.2, and 50.4 mg/L ad libitum over 17 days to bees not infected by *N. apis*.[79] Field trials on overwintering bee colonies infected with *N. apis* in Ontario, Canada, showed that fumagillin treatments in the fall (25 mg/L, 440 mg/colony) significantly increased colony survival and did not harm bees at the colony level.[79] In a Polish study, fumagillin (56.8 mg/L, 71 mg/colony) increased the unit honey productivity (+19%), brood production (+20%), surplus honey production (+58%), and lifespan of worker honey bees (+20%), with no observable negative effects for *N. apis*-infected colonies in the spring.[113] A study from Alberta, Canada,

recommended fall treatments with fumagillin at increased amounts of fumagillin (22.2 mg/L, 300−400 mg/colony) to effectively treat *N. apis* infection with no noted harmful side effects.[114] Improvements in colony survival were similarly noted for fall sugar syrup treatments containing fumagillin at a lower dosages (26.4 mg/L, 200 mg/colony), also under Canadian wintering conditions.[115] Sugar syrup applications of the drug require a longer period for bees to consume and, hence, have a longer duration of treatment, compared with dusting or pollen patty applications, which are more suitable as spring treatments.[115]

Although previous studies have concluded that fumagillin has suppressed infections and reduced mortality of *Nosema* spp. infected bees in cages[79,112] and colonies,[79,113−115] a recent paper suggests that fumagillin has negative effects on bee health and leads to the hyperproliferation of *N. ceranae* spores.[55] It is, however, difficult to directly compare this with older studies because of differences in methods used to evaluate the effects of fumagillin on the parasites and bees. Previous research has evaluated bee mortality specifically at high therapeutic concentrations of fumagillin using spore counts as an indicator of the efficacy of treatment, while harmful effects on bees have been measured as differential survival of bees or colonies compared with infected, untreated controls. In Huang et al.,[55] deleterious effects on bees were confirmed by alterations in structural and metabolic midgut proteins, notably at concentrations that did not suppress microsporidia reproduction. Although the study did use spore production as a measure of fumagillin efficacy, concentrations at which hypoproliferation of spores were seen were at very low, subtherapeutic levels of fumagillin that were not examined in other studies. Such levels were estimated to represent the degraded concentrations of fumagillin 2−5.5 months after cessation of treatment to a colony.[55] Previous work examining the effects of degraded fumagillin-medicated syrup, after 44 months of storage, showed clear suppression of *N. apis* infections in caged bees with no significant deleterious effects on bee mortality.[116]

The difference between test methods employing controlled environments, as in cage trials, and field trials, where colonies are exposed to other environmental influences, also makes direct comparison among studies difficult. Field trial studies are more prone to the effects of environmental contamination by pesticides, for example, making bees more susceptible to *N. ceranae* infection.[117] Furthermore, synergistic effects exhibited by some pesticides on fumagillin[118] have been observed. The effect of other stress factors[53] and co-infection by pathogens, such as the deformed wing virus, further complicates the interpretation of results.[119] A recent publication that details a comprehensive standard approach to nosema research is of interest, as it will simplify the comparison of results obtained by different research groups.[120]

CHEMICAL ANALYSIS AND STABILITY OF FUMAGILLIN IN THE FIELD AND UNDER LABORATORY CONDITIONS

Mammalian toxicity and mutagenicity of fumagillin are well reported, and therefore it is important that the amount of fumagillin residues in honey intended for human consumption be established. The proposed structures of the main thermal and UV degradation products of fumagillin are shown in Figure 1. UV degradation products involve isomerization and cyclization of the alkene side chain, whereas the epoxide on the main cyclohexane skeleton of the active moiety remains intact.[80,81] Thermal degradation results in the opening of the epoxide situated on the cyclohexane ring. A combination of thermal and UV degradation is also likely to occur. It is important to note that the UV decomposition products of fumagillin retain their biological activity,[81] whereas the thermally degraded fumagillin does not.[54] The hydrolyzed product (fumagillol) also retains some biological activity, albeit only about 10% of that of fumagillin.[121]

Several analytical methods for the detection of fumagillin have been reported. In 1988 a reversed-phase HPLC-UV method was reported to analyze fumagillin in acetonitrile solutions using a UV detection wavelength of 351 nm, which corresponds to the maximum UV absorption of the alkene side chain of the molecule, and a detection concentration range of 0.000−0.035 mg/mL.[122] Interestingly, it was found that 254 nm UV light does not cause fumagillin to degrade, but that 336 and 351 nm UV light (fumagillin λ_{max} 351 nm) and fluorescent room lights do cause degradation. Samples in that study were prepared in acetonitrile, and it is not clear if pure fumagillin, or a salt form of fumagillin, was used. An ELISA method with a limit of detection (LOD) of 20 ng/g and an HPLC UV method (350 nm detection wavelength) with an LOD of 100 ng/g for quantitation of fumagillin and its degradation products in honey were developed.[123] Honey samples were prepared by dissolving first 5.0 g of honey in equal amounts of water (25 mL) and then dilution with acetonitrile (25 mL). Assil and Sporns[123] also describe the isolation of pure fumagillin with the elimination of the DCH and other formulation compounds from the commercial formulation. The authors also identify the UV-cyclized product neofumagillin as a further potential contaminant of honey.

Fumagillin was quantitated in rainbow trout muscle tissue, where it was tested to control myxosporidiae, by using ion-pairing liquid chromatography with UV (351 nm detection wavelength) detection.[124] Fish muscle tissue (1 g) was macerated in the presence of 8 mL of an acetonitrile/water mixture (2:6 v/v) with sample cleanup and concentration done using Bond Elut Octyl C_8 cartridge columns to give a method that has a linear range of 20−1000 ng/g.

The photostability of fumagillin was investigated, and an HPLC method reported using a UV method for detection at 350 nm.[81] The investigators found fumagillin to be extremely unstable when exposed to sunlight or fluorescent laboratory lighting in 50% ethanol solutions, with half-lives of fumagillin determined as being in the range of seconds to minutes. Nevertheless, the activity of UV-irradiated fumagillin in syrup solutions did not reduce its efficacy against nosema disease significantly, with *N. apis* being identified as the microsporidian used in the efficacy experiments.

Fumagillin and its UV and thermal decomposition products were quantitated by LC−diode array−electrospray ionization mass spectrometry.[80] The method that the researchers developed to purify and concentrate fumagillin from the honey matrix using a polymeric solid phase extraction (SPE) technique forms the basis for most of the subsequent published analytical methods.[54] Method detection limits ranging from 1−24 ng/g (for light colored honeys) to 4−45 ng/g for darker colored honeys are reported. The researchers also note that honey samples to be analyzed for fumagillin can be stored at room temperature for 1 month in the dark without influencing the fumagillin results significantly.

A multiclass LC-MS/MS method to determine a variety of antibiotics in honey, including fumagillin, was developed.[125] It

was noted that fluorescent lights and sunlight accelerate fumagillin decomposition and that sodium laboratory lights were preferred for fumagillin analysis. The method LOD for fumagillin was reported as 60 ng/g and was used to determine several other classes of compounds including tetracyclines, fluoroquinolones, macrolides, lincosamides, aminoglycosides, sulfonamides, and phenicols. Sample cleanup was done using the same SPE cartridges described earlier,[80] but sample elution consisted of a very laborious process with multiple elutions of the samples off the SPE cartridges, followed by concentration and reconstitution steps, making this very time-consuming.

A rapid LC-MS/MS method quantitating fumagillin using a QuEChERS (quick, easy, cheap, effective, rugged, and safe) sample preparation technique in conjunction with an Oasis mixed-mode weak anion-exchange SPE cartridge for concentrating fumagillin was reported, with a reported LOQ of 0.1 ng/g.[126] The additional QuEChERS step adds 30 min to the extraction, because it is still followed by an SPE.

The stability of fumagillin under various laboratory and field conditions pertaining to its thermal and UV degradation was reported.[54] It was shown that higher temperatures (40 °C) caused rapid thermal degradation of fumagillin in sugar syrup application solutions, with resulting loss of its activity. Fumagillin was undetectable in sugar syrup solutions after 20 days at this temperature. A stability study of fumagillin under various temperature conditions in the presence and absence of light was also conducted, confirming the sensitivity of fumagillin to light that is amplified by higher temperatures.[54]

The most recent published method of fumagillin analysis in honey by LC-MS/MS[127] is an optimized version of a previously published method.[80] This study provides useful information for laboratory analysis, demonstrating that fumagillin solutions stored in acetonitrile at 4 °C are stable for 6 months.[127] The authors report an LOD of 0.368−0.522 μg/kg and an LOQ of 1.564−1.112 μg/kg in honey, depending on the brand of analytical instrumentation used. They also observed that performing the SPE cleanup and sample concentration step under gravity elution yielded better sample recoveries.

None of the analytical methods for fumagillin published to date recognize the importance of the presence of DCH as a contaminant in honey or other hive products (such as wax), although the presence of DCH in solvent samples originating from the formulation is recognized in a recent paper.[127]

FUTURE OUTLOOK

It could be hypothesized that the mode of action of fumagillin against the two *Nosema* spp. in question is similar to that observed in humans against the MetAP-2 enzyme. It is important to note that fumagillin will also be acting in a similar fashion on the MetAP-2 enzyme of the host honey bee.[55] The intact epoxide on the cyclohexane ring of fumagillin is crucial for its observed activity, but the rest of the molecule is also important for enzymatic recognition. This observation is supported by the studies in the beekeeping literature.[54,81] A potential strategy for the rational design of simpler and more cost-effective compounds that mimic the chemical behavior of fumagillin[128] using the cyclohexane spiro-epoxide as a scaffold for new potential chemical treatments against nosema disease should be considered. The development of new compounds to treat nosema disease in apiculture is of utmost importance, owing to the fact that fumagillin has been extensively employed in human medicine and apiculture almost since its discovery in the early 1950s. Although there is no proof in apiculture to indicate that *Nosema* spp. have developed resistance to fumagillin, it has been reported that *Nosema* spp. infecting diamondback moth, *Pluetella xylostella*,[129] have developed resistance to fumagillin (Fumidil-B), although the identity of the *Nosema* spp. was not established.[129] Given this finding, it can be speculated that *Nosema* spp. resistance to fumagillin in apiculture may develop in the future, owing to the prolonged and intensive utilization of fumagillin dating back to the 1950s.

Numerous different fumagillin toxicity evaluations employing direct in vitro testing against isolated cancer cell lines and in vivo testing in test organisms such as mice and rabbit using the DCH salt form of fumagillin have been reported, as discussed under Toxicity of Fumagillin. In early human trials no observable side effects are noted in some studies, whereas significant weight loss and toxic effects were observed in others. A recent paper[55] proposes that fumagillin may influence the MetAP-2 enzymes in the host and in the pathogen differently due to the slight differences in the amino acid sequence of the binding site portion of the enzymes in *Nosema* spp. as compared to that in honey bees. It remains unclear whether the reduced toxicity of fumagillin and its analogues is due to inherent properties of these analogues themselves or the fact that the toxicity contribution arising from the DCH is not accounted for in studies to date.

It is also important in the evaluation of toxicity studies to take into account the interspecies differences when extrapolating animal and other data to humans.[130] In vitro testing is also not equivalent to in vivo human testing when using human and other cell cultures or bacteria such as *Salmonella* spp. When all of the currently available information is evaluated, it is evident that fumagillin is indeed cytotoxic and mutagenic in vitro and that it has undisputed negative effects in humans such as short-term toxicity, weight loss, and diarrhea. The establishment of an MRL for the presence of fumagillin in honey and other hive products is needed. Caution should be exercised during fumagillin sugar syrup solution preparation, because it could lead to elevated levels of fumagillin and DCH exposure through dermal contact and through breathing in airborne fumagillin dust.

However, a significant concern is not only fumagillin toxicity but also that of DCH, which may be present in equimolar amounts to fumagillin in bee products. As discussed under Toxicity of Fumagillin, it is evident that DCH is at least 5 times as toxic, comparing only the LD_{50} values and disregarding any additional negative effects. All published analytical methods to date evaluate only the presence of fumagillin and, in a few instances, one or two of the major metabolites or degradation products in honey. It is known that fumagillin degrades within days to weeks in honey[54] and that there is a low likelihood of fumagillin being detected in significant quantities in honey if it is applied well before the extraction process.

The contribution of DCH present in the commercial fumagillin formulation to the overall toxicity and resulting food safety implications in products destined for human consumption is definitely not negligible.[87] None of the analytical methods for analyzing fumagillin and metabolites in honey published to date even mention the presence of DCH as an analyte of concern. This is a significant oversight because the potential presence of DCH in hive products is clearly of significance for human health and food safety concerns.

The industrial use of DCH as a corrosion inhibitor and in the rubber industry (vehicle tires) could result in a background level of this compound being present in hive products,

especially in hives located close to main roads and areas of higher vehicle use.[105] This potential background level of DCH contamination needs to be further investigated to determine whether it is a real cause of concern. More importantly, the stability and presence of DCH in bee products such as honey and wax also need to be investigated. There is a clear need for the inclusion of the analysis of DCH relating to the usage of fumagillin in hive products.

Despite all of the potential shortcomings and detrimental aspects relating to fumagillin's usage in beekeeping, and their resulting implications for bee and human health, it is important to note that this is still the only effective chemical treatment currently available to treat nosema disease. The potential contamination by DCH of hive products destined for human consumption could be eliminated by exploring alternative formulation methods of fumagillin or through the development of alternative chemical treatments utilizing the current knowledge regarding the proposed mode of action of fumagillin against *Nosema* spp.

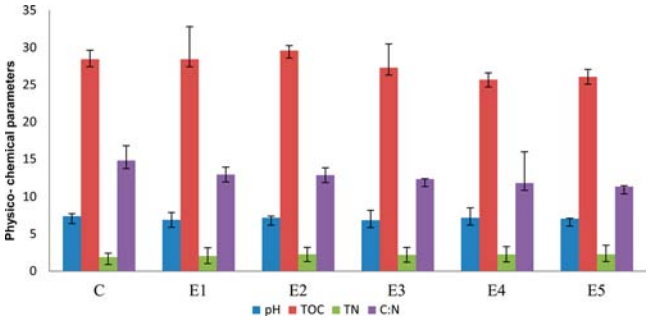

Figure 1. Physicochemical parameters of vermicompost (C, E1−E5).

(E1−E5) were increased significantly compared to control (C); data are presented in Table 1. The higher value of P was recorded at E3, which may be partially due to the earthworm's gut phosphatase and more P discharged by the added phosphobacteria in the substrate. The maximum K level was observed in E5 followed by E2, E3, E4, and E1. A higher value of Ca was observed in E1 and a similar increment of Mg level in E5. The increased level of nutrients in vermicompost was similar to that in the literature.[11,12] The transition metal concentration was decreased in vermicompost samples relative to compost (C) except Zn concentration in E3, which was slightly increased. The decrease in the metal concentration is due to the accumulation of metals (Mn, Zn, and Cu) on the earthworm body.[13] The results of the PCA are given in (Figure 2. Four principal components accounting for 99% of the total variation are retained on the basis of the eigenvalue greater-than-one rule. The first two principal components explain 80.82 and 13.90% of the variance, respectively. The third and fourth principal components are considerably less important, explaining only 3.24 and 1.82% of the variance, respectively. Accordingly, we consider only the first two components, which account for a large proportion of the variation in the data (94% of the variance). It is possible to observe that control and vermicompost treatments are separated into two different groups on the basis of their characteristics. PC1 separates the composts studied in two different groups: group 1A (C, E3) was characterized by high TOC, C:N ratio, and phosphorus; group 1B (E1, E4) was characterized by the lowest value of pH. PC2 included E2 and E5, and it is possible to separate composts that have higher TN contents (2.29%) and reduced level of C:N ratio, 11.39%, respectively. CA was used to detect similar groups to characterize the control and vermicompost samples (Figure 3); it is found that two different groups were ordinated separately from all of the treatments, which confirm PCA.

SEM was used to study the morphological results of the final control and vermicompost samples as shown in Figure 4. In the control sample the cellulose and protein groups were tightly bound with the lignin as an assortment (Figure 4C). Comparison of the micrographs of vermicompost samples E1−E5 suggests that the surface area of compost samples is higher than that of the control. Within the vermicompost samples, the highest proportion of the surface was recorded in

Table 1. AAS Data for Control and Vermicompost Samples

	concentration determined (%)					concentration determined (ppm)			
sample	P	K	Ca	Mg	Na	Fe	Mn	Zn	Cu

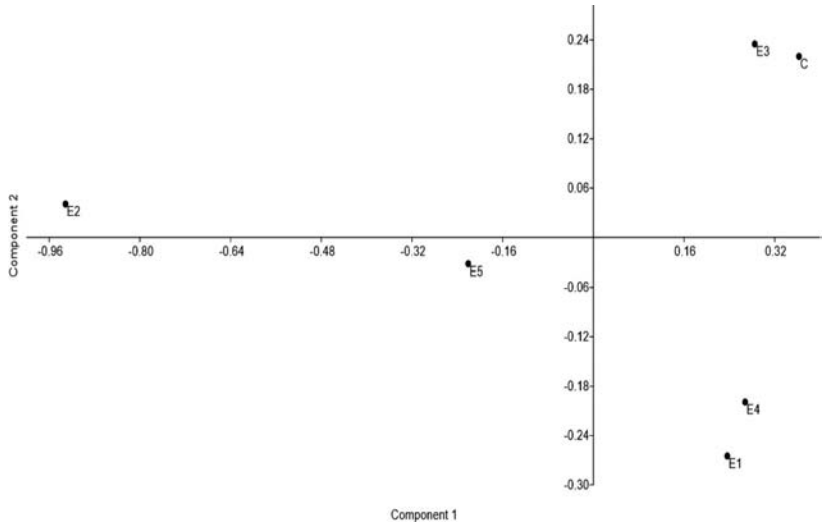

Figure 2. Principal component analysis for control and vermicomposting treatments.

dx.doi.org/10.1021/jf4054403 | J. Agric. Food Chem. 2014, 62, 2738−2741

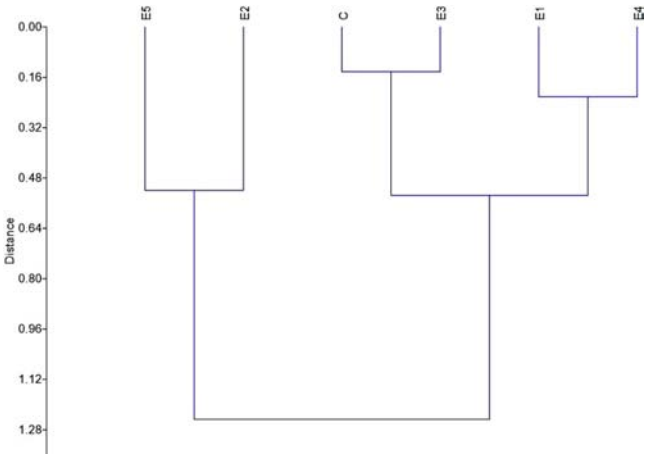

Figure 3. Cluster analysis for control and vermicomposting treatments.

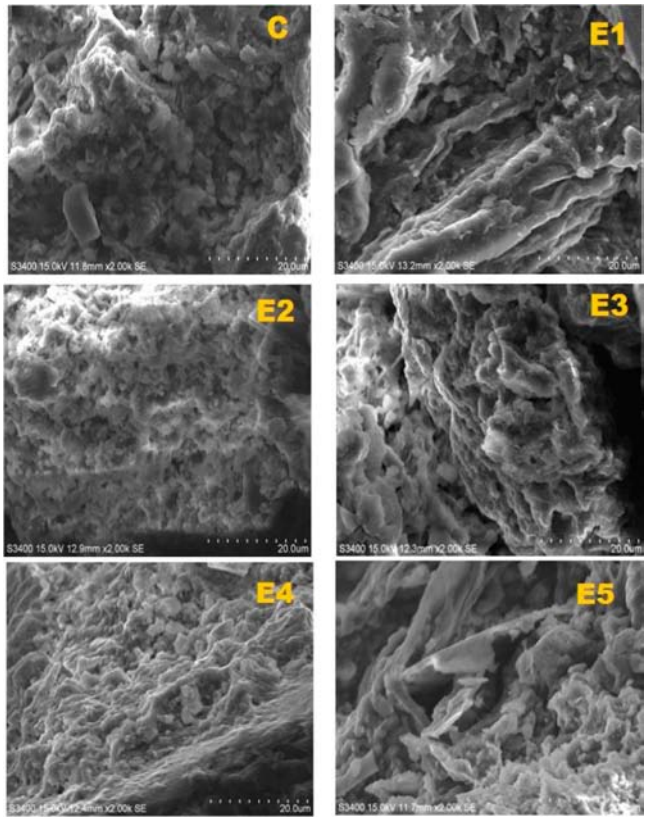

Figure 4. Micrographs by SEM of flower waste vermicompost after 80 days in the following forms: (C) control compost; (E1) vermicompost; (E2) vermicompost + *Azospirillum*; (E3) vermicompost + Phosphobacterium; (E4) vermicompost + blue-green algae; (E5) vermicompost + *Rhizobium*.

E2 followed by E4 and E5. It is observed that the particle size of the vermicompost was smaller than that of control compost. The surface area of vermicompost samples showed single particles packed together to form aggregates. Such aggregation is responsible for the uncertainty about a real surface area of vermicompost because the internal area was not fully accessible. Moreover, different morphological features occurring within vermicompost might be due to their different chemical structures.[5] In addition, in the final vermicompost product (Figure 4, E1−E5), the protein and lignin matrix is disaggregated by earthworms and microbes. The presence of earthworms and microbes shows more numerous surface irregularities that confirm the final compost has attained compost maturity.[7] These images indicate a surface region with an irregular morphology as well as a high number of pores and can corroborate the high CEC value. Similar results were reported for their vermicompost samples.[7,9]

In the past the focus of the application of the chromatography method was on the soil and compost assessment. In contrast to the assessment of soils and composts, there are hardly any methodical works on the evaluation of chromatography pictures of foods.[6,14] The chromatogram of the initial substrate shows three clear zones: (a) an absence of color in the outer zone, which reflects the lack of colloidal substances; (b) a faint brown color indicates the availability of less organic matter; (c) the inner small violet zone indicates the quantity of available minerals, which is clearly observed in E1.[6,8,14] These zones were entirely different from the final substrate in the present study. The final day of samples showed the inner zone with violet radiation confirmed the concentration of the mineralization was increased at the end of the composting process (Figure 5). E2 shows a high level of mineralization process

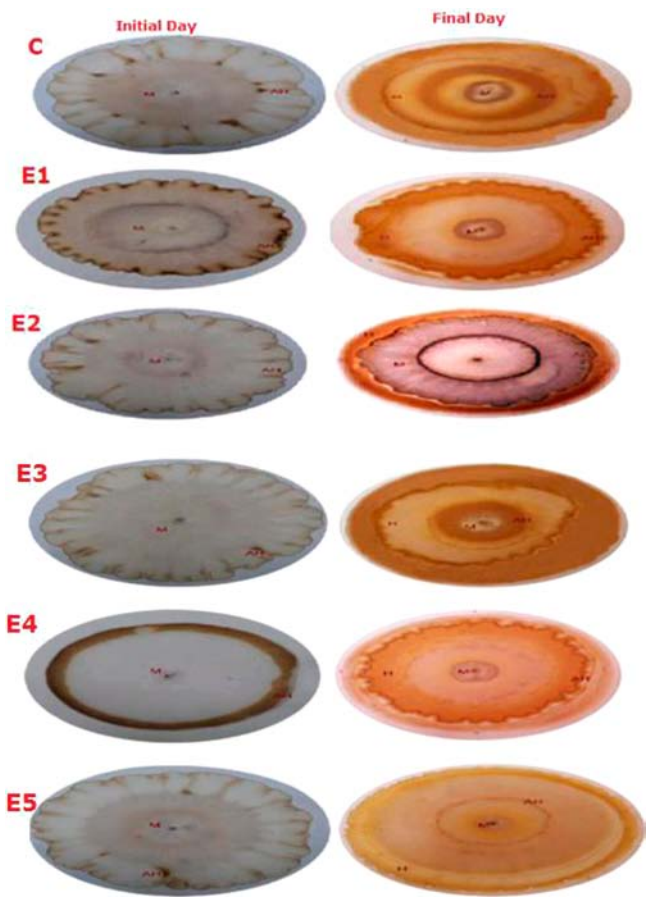

Figure 5. Biodynamic paper chromatography of flower waste vermicompost after 80 days in the following forms: (C) control compost; (E1) vermicompost; (E2) vermicompost + *Azospirillum*; (E3) vermicompost + Phosphobacterium; (E4) vermicompost + blue-green algae; (E5) vermicompost + *Rhizobium*.

followed by E5, whereas in the remaining samples the mineralization process was not clearly visible. All of the final samples showed an evenly distributed brown color in the outer zone that indicates the presence of humus substances in the final

dx.doi.org/10.1021/jf4054403 | J. Agric. Food Chem. 2014, 62, 2738−2741

samples. The existence of humus in all samples around neutral pH values is a sign of maturity of the vermicompost samples. Similar chromatography results of vermicompost samples are reported in the literature.[8,14] The R_f values of different color bands/patterns of all samples are given in Table S1 (see the Supporting Information). In this study, a circular chromatographic method has been used for the purpose of determining differences in the formation of humus in the compost and biofertilizer-enriched vermicompost samples that cannot be determined by chemical analysis.[7]

Vermicomposting led to the drop of pH, decrease in TOC and C:N ratio, and increase in nitrogen content compared to the control sample. The reduction of the C/N ratio was reported from an initial value of 15% in C and to the end of the composting (11.5%) in E5, which indicates organic carbon decomposition in the final vermicompost. However, by the employment of statistical analysis, PCA and CA, it was possible to classify and characterize the vermicompost samples. BPC and SEM techniques proved useful tools to monitor the maturity of vermicompost during the composting process. Critical investigation of our study results indicates that the epigeic earthworm *E. fetida* was capable of decomposing flower waste into nutrient-enriched products and can play a significant role in solid waste management.

N,*N*′-disuccinimidyl carbonate. Activated purified haptens were coupled to bovine serum albumin (BSA), ovalbumin (OVA), and horseradish peroxidase (HRP). The amount of employed activated hapten was adjusted according to the desired final hapten density. Thus, high MRs for BSA conjugates (15 and 17 for FD*c* and FD*n*, respectively) and low MRs for OVA conjugates (2 for both haptens) were obtained as intended. On the other hand, calculated hapten densities of HRP conjugates were 6 and 4 for FD*c* and FD*n*, respectively. Unrealistically high MR values for HRP conjugates (this enzyme contains 3–4 available lysine residues) are probably due to modified molar extinction coefficients of the protein and/or the hapten after conjugation. However, adequate enzymatic activity and hapten coupling was demonstrated by competitive assay.

Antibody Affinity and Selectivity. Competitive assays were performed with FD*c*-type antibodies (obtained with BSA–FD*c* as immunizing conjugate) and FD*n*-type antibodies (from BSA–FD*n* immunized animals), using homologous conjugates (same hapten as the immunizing conjugate) and following the direct and indirect cELISA procedures. Antibody affinity was assessed by checkerboard competitive assays, running a standard curve of Fludioxonil in each microplate column (from 10 pM to 10 μM plus a blank) and assaying diverse antibody and antigen concentrations simultaneously as described in the Supporting Information. The lowest IC_{50} values with homologous

dx.doi.org/10.1021/jf5001716 | J. Agric. Food Chem. 2014, 62, 2742–2744

conjugates were obtained with antibodies from FD*n*-immunized rabbits in both cELISA formats (Tables 1 and 2). Thus, hapten FD*n* behaved better as immunogen than hapten FD*c*, so it was a better mimic of Fludioxonil. Hapten FD*n* keeps unmodified all moieties of the target molecule, and only an N−H bond is substituted by an N−C bond. Comparatively, in hapten FD*c*, the cyano group modification *probably* alters more significantly the electronic properties of the pyrrole moiety (Figures 1 and 2). Moreover, the linker in hapten FD*n* is located further to the bulky aryl moiety than in hapten FD*c*, which probably favors the aromatic portion of this hapten adopting similar conformations to those adopted by the common framework of parent Fludioxonil (see Figure S1 of Supporting Information).

With regard to selectivity, binding of the four antibodies to additional new-generation fungicides that are commonly formulated together with Fludioxonil was assessed, such as cyprodinil, pyrimethanil, mepanipyrim, azoxystrobin, boscalid, and fenhexamid. As expected, no inhibition was observed by any of the studied compounds at a concentration of 10^4 nM with any of the described antibodies.

Competitive Immunoassays. Checkerboard assays were performed with both FD*c*- and FD*n*-type antibodies using also the heterologous conjugates. Concerning the direct cELISAs, antibody FD*c*#1 bound the heterologous tracer HRP−FD*n*, and a moderate IC_{50} value to Fludioxonil was found in this case, improving the IC_{50} value that was obtained with the homologous combination. However, FD*n*-type antibodies recognized only the homologous tracer. Parallel results were observed with the indirect format (Table 2). For a particular antibody/antigen combination, the IC_{50} values stayed in the same order of magnitude in both cELISA formats. Overall, the most sensitive assay was achieved with antibody FD*n*#1 using the homologous combination. The inhibition curve of such an assay is depicted in Figure S2 in the Supporting Information, showing an IC_{50} value for Fludioxonil of 22.9 nM (equivalent to 5.7 μg/L) and an A_{max} of 0.8 absorbance unit.

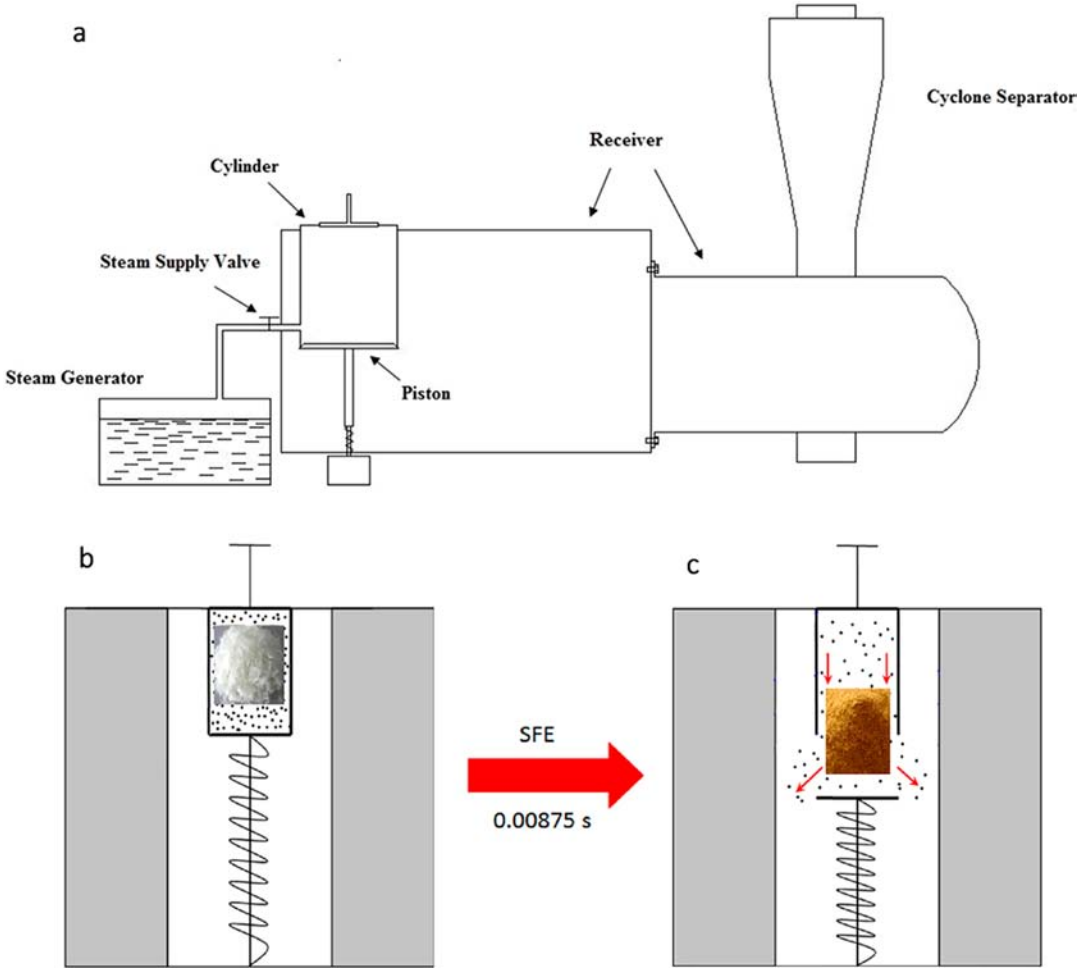

Figure 1. Structural diagram of the QBS-200B SFE test bed: (a) SFE system, (b) status of the piston in the steam boiling phase, and (c) status of the piston in the explosion phase.

pressure decreased dramatically in a very short time (within 0.00875 s). The exploded materials, together with a little water, were recovered in the receiver and frozen at −20 °C until the analyses.

Morphological Characterization. The morphology of feather fibers was observed using scanning electron microscopy (SEM, FEI Quanta 200, Eindhoven, Netherlands). The specimens were mounted on conductive adhesive tape, sputter-coated with gold palladium, and observed using a voltage of 5.0 kV.

Protein Solubility and Pepsin Digestibility. A total of 1 g of ground samples was suspended in 25 mL solutions. The suspensions were shaken in a water bath for 4 h according to the method described by Li and Lee.[16] The mixture was centrifuged at 10000*g* for 20 min at 4 °C. The soluble protein content of the supernatant was then determined using a modified Lowry procedure.[17] The total nitrogen in the original samples was measured by the Kjeldahl method. All analyses were conducted in duplicate.

Pepsin digestibility of each sample was determined by the procedure of the AOAC International using 0.2% pepsin (activity of 1:10 000) in 0.075 M HCl.[18] In this assay, 1.000 g (±0.010 g) of sample was incubated in 150 mL of pepsin solution at 45 °C for 16 h. Protein digestibility was expressed as the difference between the nitrogen content of the sample and the residual nitrogen content after pepsin digestion, divided by the nitrogen content of the sample.

Disulfide−Sulfhydryl Quantification. Disulfide (SS) and sulfhydryl (SH) contents of unexploded and exploded samples were determined according to the method of the solid-phase assay by Chan et al.,[19] with some modifications. For free sulfhydryl content determination, approximately 15 mg of the ground sample with a particle size smaller than 40 mesh was suspended in 0.8 mL of reaction buffer consisting of 8 M urea, 3 mM ethylenediaminetetraacetic acid (EDTA), 1% sodium dodecyl sulfate (SDS), and 0.2 M tris-(hydroxymethyl)aminomethane) (Tris)−HCl (pH 8.0) (buffer A). The reaction mixture was vortexed for various intervals at room temperature. After 2.5 h, 0.2 mL of 50 mM 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB) in 0.2 M Tris−HCl (pH 8.0) (buffer B) was added to each sample, vortexed for 1 h, and then centrifuged at 13600*g* for 10 min at room temperature. Concurrently, a sample was incubated without DTNB as a blank. The supernatant was collected and diluted at a ratio of 1:10. The absorbance of the supernatant was read at 412 nm. An extinction coefficient of 13 600 M^{-1} cm^{-1} was used to calculate the number of thiol-containing groups.

For determination of the total sulfhydryl (SH + reduced SS) content, the assay procedure was as described for the SH assay, except for the use of different reaction buffers. The buffer consisted of 8 M urea, 3 mM EDTA, 1% SDS, and 0.2 M Tris−HCl (pH 9.5), 0.1 M Na_2SO_3, and 50 mM 2-nitro-5-thio-sulfobenzoic acid ($NTSB^{2-}$), synthesized from DTNB according to the procedure by Thannhauser et al.[20] The disulfide group content was calculated as the difference between the thiol group content before and after reduction of disulfide bonds with sulfite. From each replicate of each treatment, three measurements were taken.

Fourier Transform Infrared (FTIR) Spectroscopy. FTIR spectra of the steam-exploded samples, dried at 105 °C for 2 h, were obtained from 4000 to 400 cm^{-1} by a Nexus Thermo Nicolet spectrometer. The KBr pellet sampling method was used to prepare the thin film for testing. All sample spectra were recorded at 128 scans and 4 cm^{-1} resolution, and spectra of two replicate measurements for each sample were averaged. The infrared (IR) spectra were acquired and analyzed

dx.doi.org/10.1021/jf405498k | J. Agric. Food Chem. 2014, 62, 2745−2751

using Thermo Scientific OMNIC software package (version 8.2). Spectra were baseline-corrected, smoothed with a nine-point Savitsky–Golay function, and normalized using the amide I absorption intensity peak. Amide I was shown after band narrowing by Fourier self-deconvolution (FSD) to resolve overlapping IR bands using a half bandwidth of 30.0 cm^{-1} and enhancement factor k = 3.0. Second-derivative spectra were obtained to support the initial identification of band positions by deconvolution. The band positions obtained from the above steps were then used as the initial guess for curve-fitting of the original spectra with Gaussian bands. For the final fits, the positions, heights, and widths of all bands were varied simultaneously. The curve-fitting procedure was calculated on Peakfit version 4.12 software (SeaSolve Software, Inc.).

Statistical Analysis. Data are expressed as the mean ± standard deviation (SD). The difference between groups were tested by analysis of variation (ANOVA) and Duncan's multiple range tests (SPSS version 19.0 for Windows, SPSS, Inc., Chicago, IL). Means were compared and considered significant when $p < 0.05$.

RESULTS AND DISCUSSION

Morphological Changes of Feathers Treated by SFE. The effect of SFE on the morphology of feathers was illustrated in Figure 2. SEM of untreated and treated feathers showed

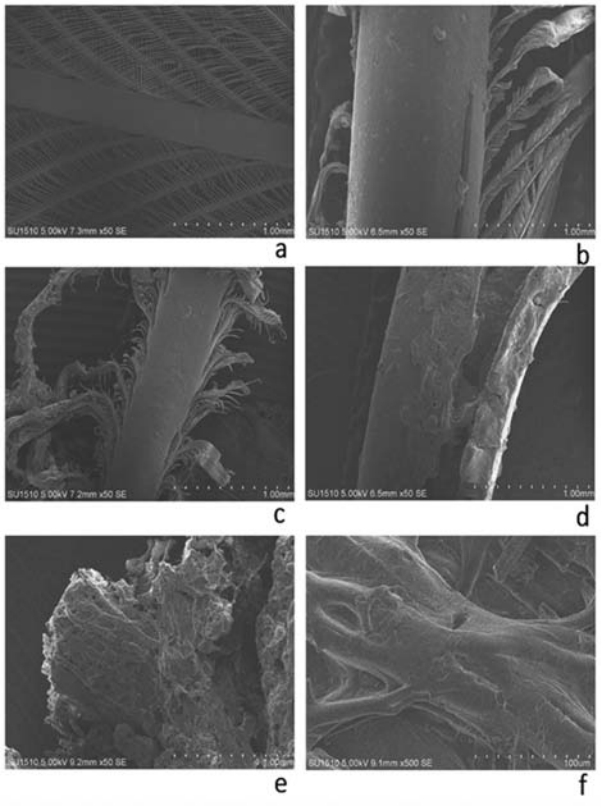

Figure 2. Scanning electron micrographs of untreated and treated feathers by SFE treatment: (a) feather fiber without treatment (50×), (b) steam exploded at 0.5 MPa (50×), (c) steam exploded at 1.0 MPa (50×), (d) steam exploded at 1.4 MPa (50×), (e) steam exploded at 1.8 MPa (50×), and (f) steam exploded at 1.8 MPa (500×).

obvious morphological changes induced by SFE treatment. As shown in Figure 2a, feathers showed a smooth surface and had a hierarchical structure beginning with the level of the central barbs, which grow directly from the quill. These central barbs are tiny "quills" that also grow barbs.[12] At lower steam pressures, feathers showed the regular and compact structure, with shrinkage folds appearing occasionally (panels b and c of Figure 2). As the pressure increased, the central axis of the feather disappeared and the original structure could not be identified. The samples gave cross-interconnected pores, which were sponge-like and had more cracks and cavities (panels d–f of Figure 2).

In SFE treatment, saturated steam with a powerful seepage force penetrates into the fibrous tissues of the materials. The material is maintained at the desired pressure for a short time and undergoes hydrolysis and other chemical processes. At the end of this period, the pressure rapidly decreases to atmosphere and most of the steam in the material will quickly expand. Accordingly, the resulting mechanical effect plays a role in forming the cavities in the surface of feather when the steam rushes out. Yu et al.[14] also demonstrated the mechanical effect of steam explosion through the characterization of the morphological changes of maize stalks in different steam pretreatment methods. We prolonged the time of the feather at 1.8 MPa to 8 min and then carried out SFE, but no additional effect was found on the treatment efficiency, indicating that the mechanical effect played an important role on the exploded feathers.

Protein Solubility and Pepsin Digestibility of Feathers Treated by SFE. Four solvents [0.05 M sodium phosphate buffer (pH 8.0), 0.05 M sodium phosphate buffer (pH 8.0) + 6 M urea, 0.2% potassium hydroxide, and 0.2% pepsin] were used to monitor dissolubility changes of the exploded samples. As shown in Figure 3, the dissolubility of feather meal in all of the

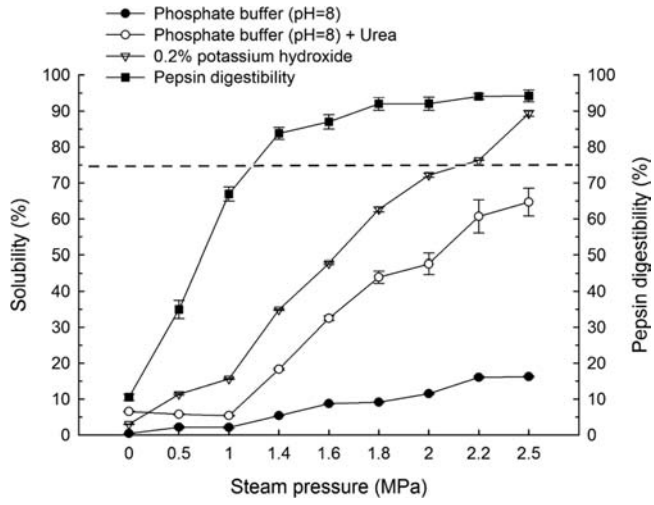

Figure 3. Solubility and pepsin digestibility of feather meal treated by SFE treatment. The dotted line is the minimum digestible protein level recommended as feather meal by the Association of American Feed Control Officials. The data are expressed as the mean ± SD (n = 3).

solvents tested in this study dramatically increased with the increase of steam pressure. The protein solubility in 0.2% potassium hydroxide solution is always the common procedure to evaluate the intensity of treatment.[21] After SFE treatment, the solubility of feather meal could reach 89.3% at 2.5 MPa from only 3.0% in the original sample. The increase may be ascribed to the increasing repulsive forces between surface groups of the exploded sample that mainly exists as the anion form. From the point of view of eco-friendly conversion and utilization of extracted keratins, it is not necessary to use 0.2% potassium hydroxide to extract feather keratins. Figure 3 also

showed that there was 16.2% of the exploded sample soluble in a 0.05 M sodium phosphate (pH 8.0) system and 64.6% of the protein soluble in a 6 M urea system at 2.5 MPa. However, the original feathers are almost insoluble in the above mild solvents. The present work also provides a mild way to extract feather keratin for exploitation of innovative biopolymers.

Feathers are rich in crude protein (90%), while without pretreatment, only 10.5% of feathers could be hydrolyzed by pepsin, because of their intact and compact structures.[4] As shown in Figure 3, pepsin digestibility sharply increased to 91.9% at 1.8 MPa, which was nearly 9 times higher than that of untreated feathers, while it changed not significantly at higher conditions ($p > 0.05$). This result reflects the very high effectiveness of SFE treatment for the improvement of the bioutilization of feather meal. Moreover, only cysteine decreased significantly from 5.07 g/100 g of crude protein for the control to 1.66 g/100 g of crude protein for the exploded sample at 1.8 MPa, while the changes of other amino acids in feather meal were not obvious during SFE treatment (data not shown). Several researchers have employed chemical treatments or screened microorganisms to increase the enzymatic accessibility of feathers.[7,22,23] Obviously, it is not environmentally friendly or requires a long production cycle and tedious preparation. SFE is a physicochemical process, which includes three phases: the steam penetration phase (3−5 s), the boiling phase (1−3 min), and the explosion phase (within 0.00875 s). The total time in high temperatures is very short, and the temperature of materials could decrease to 50 °C or lower immediately after SFE treatment, indicating that SFE treatment is a high-efficiency and environmentally friendly process for production of feather meal.

When steam pressure rose higher than 2.2 MPa, the colors of the samples were dark yellow, indicating degradation and a chemical modification of feather keratin, as demonstrated by Senoz et al.[24] The author suggested that undesired materials formed via cross-linking reactions to provide a high-temperature-resistant nature to the keratin, even when disulfide bonds were broken. In the present work, SFE allowed use of a low steam pressure (1.8 MPa) and short time (1 min) to effectively increase pepsin digestibility of feather meal.

Disulfide Bonds and Free Sulfhydryl of Feathers Treated by SFE. Figure 4 illustrated the quantitative change of the disulfide bond and free SH in feather keratins treated by SFE treatment. Obviously, SFE treatment could significantly decrease the content of the disulfide bond, which is the major factor resistant to proteolytic cleavage. With the increasing severity of the treatment, the disulfide bonds decreased from 330 to 93 nmol mg^{-1}. Because 1 mol of disulfide reacts quantitatively to yield 2 mol of cysteine residues, the free sulfhydryl increase should be accounted for the decreased disulfide cross-linking. However, as shown in Figure 4, the free sulfhydryl significantly ($p < 0.05$) decreased from 10 nmol mg^{-1} for the control to 2 nmol mg^{-1} for the exploded sample (1.0 MPa) and then increased to 31 nmol mg^{-1} at higher steam pressures. Although the sample showed the greatest increase in free sulfhydryl with the greatest decrease in disulfides, the changes were not proportional.

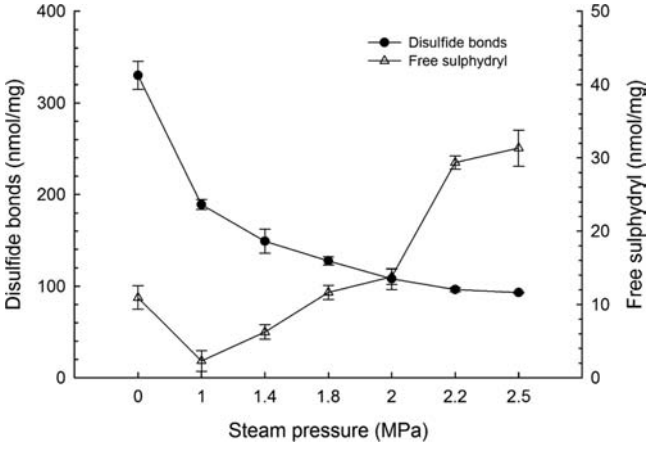

Figure 4. Changes of disulfide bonds and free thiol groups of feather keratins in SFE treatment. The data are expressed as the mean ± SD ($n = 3$).

The decrease in free sulfhydryl content of exploded samples at low pressures and then increases with increasing steam pressures, concomitant with decreases in disulfide bonds, are in general agreement with the findings among extruded samples. These authors showed large reductions in disulfide bond content and slightly increased sulfhydryl content among the extrusion of wheat meal and lentil meal.[25,26] The results indicated that feather keratins containing a high level of cysteine/cystine residues were easily denatured by SFE treatment. It is also likely that some of the free sulfhydryl groups were oxidized to sulfoxyl compounds or formed sulfur-containing volatiles, such as hydrogen sulfide, volatile organic compounds, or flavor compounds, during the process.[27,28] Furthermore, because of the involvement of mechanical force in the explosion phase, cysteine might be more prone to oxidation and then the keratin molecules was susceptible to the extrinsic factors, such as the temperature and humidity.

FTIR Spectroscopy of Feathers Treated by SFE. The secondary molecular structure of feather keratin can be changed under the influence of physicochemical forces, such as mechanical forces or chemical processes.[29] FTIR investigation can be used as an effective tool to assess the structural changes in proteins. Particularly, the amide I band in the range between 1600 and 1700 cm^{-1} and amide II band in the region of 1510 and 1580 cm^{-1} provide useful information. Amide I, the most intense absorption band in proteins, is useful for the analysis of the protein secondary structure and arises mainly from C═O stretching, with a minor contribution from C−N stretching, while the amide II band originates from the N−H bending and C−H stretching vibrations.[30] In Figure 5, the IR spectra of feather keratin are reported. As previously reported[1] and evident from the amide I peak at 1627 cm^{-1}, the feather mainly consists of β-sheet structure. A peak shift of the amide I band was observed as a function of the steam pressure from approximately 1627 cm^{-1} to a strong, broad maximum at approximately 1633 cm^{-1}, which was indicative of decreased amounts of ordered β-sheet structures and the promotion of disordered structures.[1,31]

The amide II band, much less conformationally sensitive than amide I, is related to N−H bending and C−H stretching vibrations. However, it is much more sensitive to the environment of the N−H group. Therefore, the amide II band can be used to deduce changes to the environment of the N−H groups and respond to differences in hydrogen-bonding environments.[32] In general, stronger hydrogen-bonded N−H groups absorb at higher frequencies.[1] In amide II of the steam-exploded samples, it is worth noting a significant decrease in the intensity of the absorption band at 1540 cm^{-1} with respect

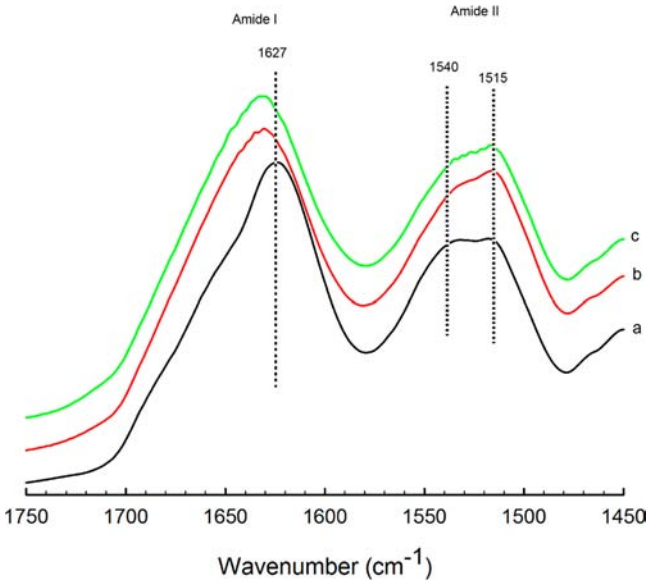

Figure 5. FTIR spectra of (a) feather and samples of the SFE process at (b) 1.0 MPa for 1 min and (c) 2.2 MPa for 1 min. For easier comparison, intensities have been normalized in all spectra. Spectra are offset, and curves are shifted vertically for clarity.

to the component at 1515 cm^{-1}. This means that less hydrogen-bonded peptide groups were contained in the samples resulting from SFE with respect to the original feather, which is in line with the solubility, as shown in Figure 3. Under high temperature and humidity, most of the hydrogen bonds in the feather were broken, as demonstrated by Xu et al.,[33] increasing accessibility of the protein bodies to enzymatic attack.

Effect of Protein Structure Modification on Pepsin Digestibility. A high cystine content (7%) is the most important property that differentiates keratins from other structural proteins, such as collagen and elastin.[34] Feather proteins in their native form are resistant to most proteases when fed to an animal. Thus, destruction of cystines to a certain extent is desirable in production of feather meal. As shown in Figure 6, when steam pressure was below 1.4 MPa, disulfide bonds of feather keratin decreased dramatically and the β-sheet contents changed slightly, with pepsin digestibility increasing

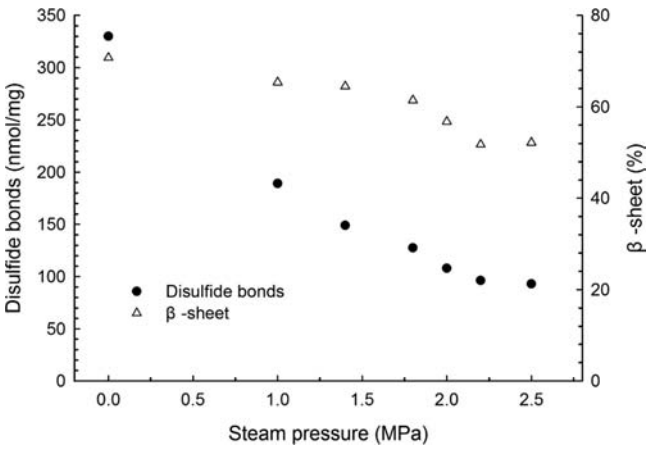

Figure 6. Changes of the relative spectral weights of the β-sheet of feather keratins in SFE treatment.

significantly (83.7%). When the pressure rose higher than 1.4 MPa, β-sheet and disulfide bond contents decreased gradually. Hence, there was a synergistic effect between hydrogen and disulfide bonds on the stability of feather keratin.

Disulfide bonds have the lowest covalent bond energy in proteins, making them the most susceptible for cleavage by thermal effect and mechanical force.[35,36] In the present work, a high negative linear correlation coefficient (R^2 = 0.98) was found between disulfide bond contents of feather keratin and pepsin digestibility, over the full investigated steam pressure range (Figure 7a). Reduction of disulfide bonds caused

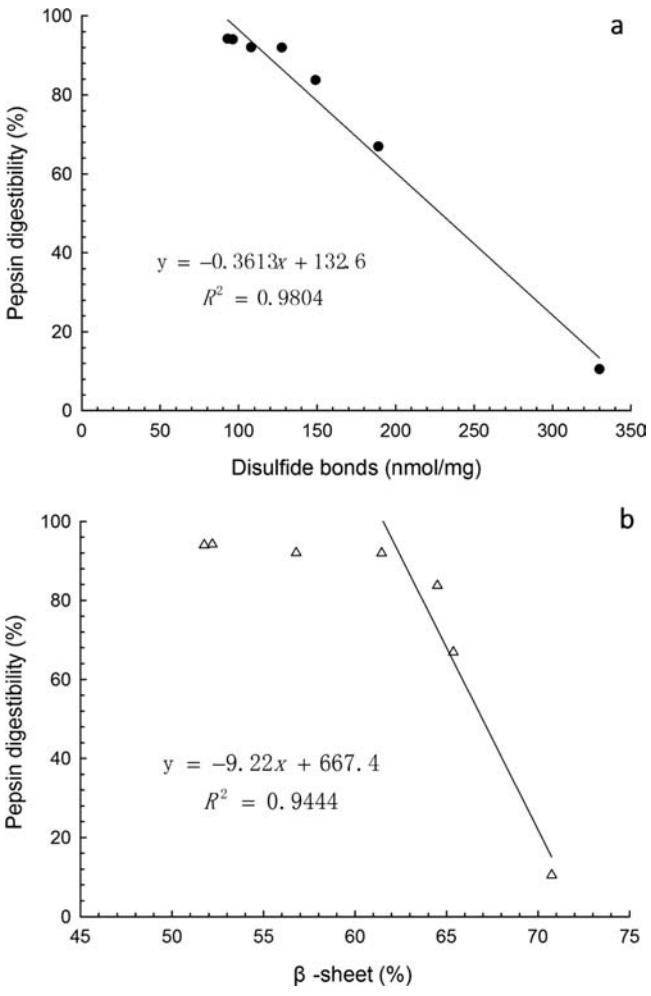

Figure 7. Correlation between pepsin digestibility and (a) disulfide bond content and (b) relative spectral weights of the β-sheet of steam-exploded samples.

disruption of the feather keratin structure and, as a consequence, an enhanced accessibility of sites susceptible to proteolysis. A similar study also found that the degree of hydrolysis by trypsin and pancreatin was strongly correlated to the degree of disulfide reduction of soy flour.[37] In contrast, Figure 7b showed that, at a lower steam pressure, a linear relationship was observed between the relative spectral weights of the β-sheet structures and pepsin digestibility (R^2 = 0.94). As steam pressure increased, the digestibility became independent of the β-sheet contents. The results partly agreed with the findings of Yu et al.,[38] who suggested that the difference in the percentage of protein secondary structure might be responsible for different feed protein digestive behaviors. Obveriously, the

dx.doi.org/10.1021/jf405498k | J. Agric. Food Chem. 2014, 62, 2745−2751

application of heat energy or mechanical energy during SFE breaked hydrogen bonds, which stabilized the β-sheet conformation, and consequently, more protein could disolve in the 6 M urea system (Figure 3). We also observed that a random coil structure was detected among the exploded samples (not shown), suggesting a good amino acid availability from the unordered secondary structure.

SFE equipment with a 5 m^3 chamber has been developed; hence, SFE treatment could be performed on a large scale.[14] Because of the structural features of the catapult explosion mode of SFE, the effective gas deflation passage of the mode has the same area as the cylinder cross-section, which ensures that the deflation time will not be prolonged. Therefore, the treatment efficiency in scale-up applications of SFE can remain consistent with the small equipment. This environmentally friendly technology, requiring little or no chemical input, is a promising route for commercial production of feather meal.

ZnO 800 mg/kg	4.50 ± 0.42ab	30.4 ± 0.74ab	34.9 ± 0.96ab	81.0 ± 2.9b

[a]Data are average of four replicates ± standard deviation.

showed the first evidence that fullerol greatly increased bitter melon water content and fruit yield and improved fruit quality by increasing the phytomedicine content.[12] Servin et al. reported an increase in phosphorus and potassium concentration in cucumber fruit of plants exposed to 750 mg/kg of TiO_2 NPs.[13] In addition, Rico et al. reported that CeO_2 at 500 mg/kg soil modified the quality of rice grains.[14]

Cucumber is one of the very low calorie vegetables. In addition it contains many nutrient elements, including Ca, Fe, Mg, P, K, Na, Mn, S, and Zn. According to USDA National Nutrient Database, 100 g of fresh cucumber provides as much as 147 mg of K, which is an important intracellular electrolyte.[15] In addition, cucumber contains phenolic compounds (*p*-coumaric, caffeic, and ferulic acids and *p*-coumaric acid methyl ester), and those compounds act as protective scavengers against oxygen-derived free radicals and reactive oxygen species (ROS) that play a role in cardiovascular disease prevention and anticancer activity.[16−18] The aim of this study was to study the effect of ZnO and CeO_2 NPs on the nutritional quality of cucumber fruit. Carbohydrates, proteins, antioxidants, and mineral nutrient were analyzed by using several biochemical and spectroscopic techniques.

MATERIALS AND METHODS

Characterization of NPs. The CeO_2 and ZnO NPs (Meliorum Technologies, NY, U.S.) used in this study were obtained from the University of California Center for Environmental Implications of Nanotechnology. According to the supplier, the primary size for those two NPs is 10 nm. The characterization of both NPs, including hydrodynamic size, ζ-potential, and pH, were previously reported by Keller et al.[5] Stock solutions were prepared by adding 1000 mg of nanoparticles to 1.0 L of deionized water. The dispersed nanoparticles were sonicated for 30 min in a water bath and immediately applied to the substrate.

Experimental Design and Growth Conditions. CeO_2 NPs and ZnO NPs were used, separately, at 400 and 800 mg/kg. Pots containing substrate without the addition of NPs were included as a control. Each treatment had four replicate (pots), and each pot contained two plants. More details regarding the experimental design, soil, and greenhouse conditions were introduced in previous a study.[11]

Mineral Content. Dried cucumber fruits were ground to pass a 40-mesh screen (0.425 mm) with a stainless Wiley mill (Thomas Scientific, Swedesboro, NJ). Subsequently, the samples were digested with a mixture of H_2O_2 and plasma pure HNO_3 (v/v: 4:1) using microwave oven (CEM Corp, Mathews, NC, U.S.).[14] The standard reference materials NIST 1547 and 1570a were also digested and analyzed as samples. The recoveries for all elements were between 90 and 99%. The macro- and micronutrient elements were analyzed using inductively coupled plasma optical emission spectrometry (Perkin-Elmer Optima 4300 DV).

Determination of Total Soluble and Reducing Sugars. The total soluble sugars were extracted by the method of Verma and Dubey.[19] One hundred grams of dried cucumber tissue was ground in 10 mL of 80% ethanol and then boiled (80 °C) in a water bath for 30 min. After cooling to room temperature, the extracts were centrifuged at 22000*g* (Thermo Scientific, Soruall T1, U.S.) for 20 min. The extraction was repeated three times, and all the supernatants were combined. Total soluble sugar content was measured following the method of Dubois et al.[20] while reducing sugar content was determined according to the procedure of Nelson-Somogyi.[21] The nonreducing sugar content was reported as the difference between total and reducing sugars.

Determination of Starch in Fruit. The starch extraction was performed following the method of Verma and Dubey.[19] The residue from sugar extraction was dried at 80 °C for 24 h. To the dried residue was added 2 mL of DI water, and the mixture was boiled in a water bath for 15 min. The suspension was cooled to room temperature, and 2 mL of concentrated H_2SO_4 was added. The suspension was stirred for 15 min, and the final volume was adjusted to 10 mL using water. The supernatant was centrifuged at 3000*g* for 20 min, and the extraction was repeated using 50% H_2SO_4. The supernatants were combined and diluted with water to the 50 mL mark. The starch content was quantified following the method of Dubois et al.[20]

Protein Fractionation. Protein extraction and fractionation was conducted according to Chen and Bushak.[22] Dried cucumber fruit (500 mg) was extracted sequentially with 8 mL each of water, 0.5 mol/L NaCl, 70% ethanol, and 0.05 M acetic acid. The extracted protein in each step was labeled as albumin, globulin, prolamin, and glutelin fractions, respectively. The protein content was quantified by the Bradford method.[23]

Total Phenolics and Total Flavonoids. Total phenolic content was determined by the spectrophotometric method followed by Dewanto et al.[24] At room temperature, Folin−Ciocalteu phenol reagent (0.2 mL) was added to each sample (0.1 mL). After 1 min, 3 mL of 5% Na_2CO_3 solution was added to the mixture and the mixture was allowed to stand for 1 h in a dark place. The absorbance was measured at 760 nm using a Perkin-Elmer Lambda 14 UV/Vis Spectrometer (single-beam mode, Perkin-Elmer, Uberlinger, Germany). Total phenolic contents of the sample were expressed on a fresh weight basis as mg of gallic acid equivalent (GAE) g^{-1}.

Total flavonoid content of cucumber fruit was measured using the method of Jia et al.[25] Briefly, to 500 μL of each sample was added 75 μL of 5% $NaNO_2$. After 5 min, to the mixture were sequentially added 150 μL 10% $AlCl_3$, 500 μL 1 M NaOH, and 275 μL of DI water. The absorbance was measured at 510 nm using a spectrophotometer. The total flavonoid content was expressed as catechin equivalents.

Fourier Transform Infrared (FTIR) Spectra Acquisition. The dried cucumber fruits were ground, and the powder was analyzed using FTIR spectroscopy (Perkin-Elmer, Spectrum 100, Universal ATR Sampling Accessory) in a range of 650−3950 cm^{-1}. The second derivative spectrum was collected using Spectrum software (Version 6.0.2.0025, Perkin-Elmer, Shelton, CT). A total of 3 replicates per treatment were used for the analysis.

μ-XRF Analysis. Fruits were carefully washed with DI water to eliminate any surface contaminants. Then, they were transversally cut and frozen in liquid nitrogen for 30 min. The samples were fixed with Tissue Tek (Sakura Finetek USA, Torrance, CA) and sectioned with a cryomicrotome (Triangle Biomedical Sciences, Durham, NC) at −20 °C to a thickness of 30 μm. Subsequently, the samples were mounted onto Kapton tape and freeze-dried for 1 h in a Labconco freeze-dryer (FreeZone 4.5, Kansas City, MO) with operating conditions of −53 °C and 0.140 mBar pressure.

X-ray fluorescence imaging was obtained at beamline 10-2 at the Stanford Synchrotron Radiation Lightsource (Menlo Park, CA). Standard operating conditions were 3 GeV beam energy and 80−

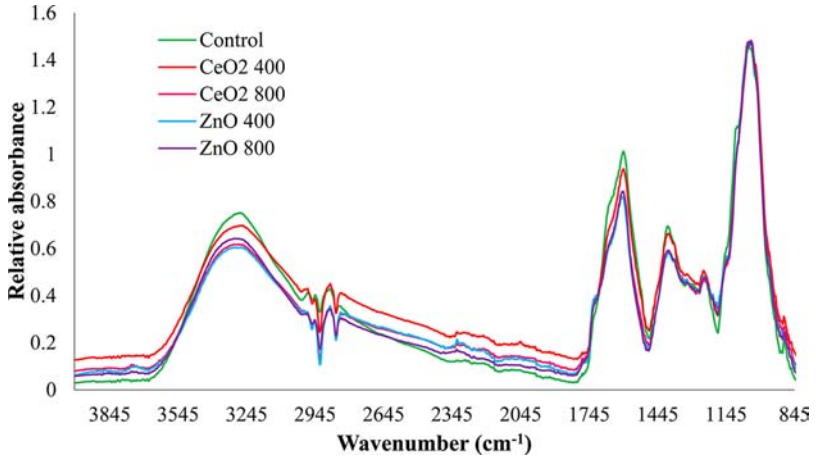

Figure 1. FTIR spectra of cucumber fruit treated with 0, 400, and 800 mg/kg ZnO NPs and 400 and 800 mg/kg CeO_2 NPs. Spectra are means of three replicates.

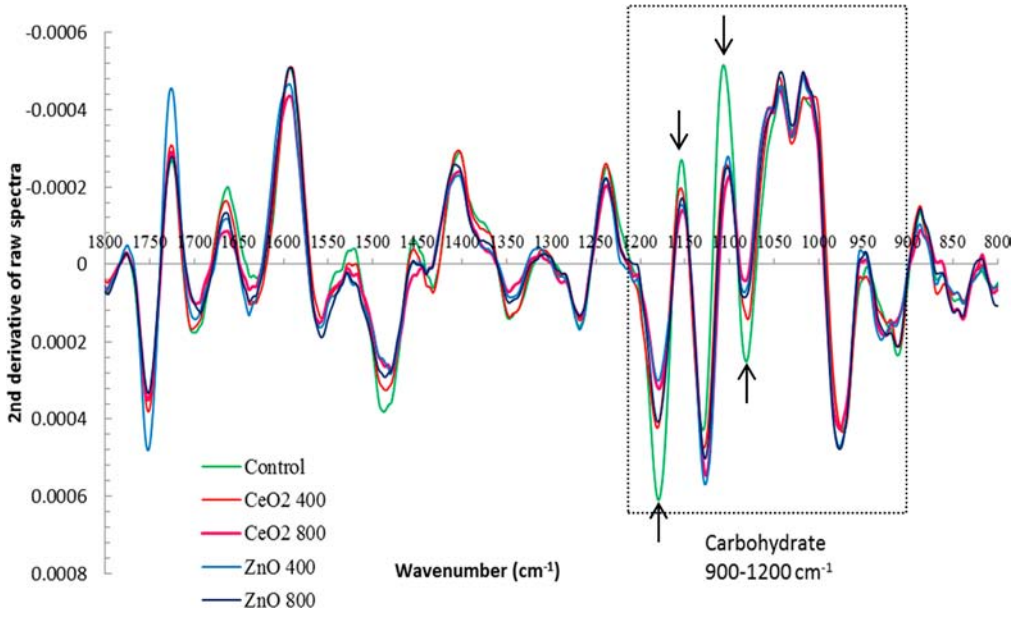

Figure 2. Second derivative of FTIR band in the region of 800−1800 cm^{-1}.

100 mA beam current. Incident X-ray energy was set to 10 keV, and a Si (111) monochromator was used. SMAK[27] software was used for data analyses.

Data Analysis. The treatments from two NPs at two concentrations and four replicate/treatments were allocated in a completely random design. All data including sugars, starch, protein, mineral nutrients, and antioxidant were analyzed by using PROC GLM in SAS software (Version 9.1.3, SAS Institute, Cary, NC).

RESULTS AND DISCUSSION

Effects of NPs on Fruit Carbohydrates (Sugar and Starch) Content. Sugars, starches, and fiber are main components of carbohydrates in cucumber fruit. Among them, "soluble sugars and starch are important parameters to evaluate the quality of fruits."[26,27] As shown in Table 1, reducing sugars (glucose and fructose) were not modified by CeO_2 NPs. This implies that the sweet taste of cucumber fruit was not affected. However, the nonreducing sugar (sucrose) was impacted by CeO_2 NPs. At 400 mg/kg treatment, the content of nonreducing sugars was significantly decreased compared to control, while at 800 mg/kg, the nonreducing sugars content was significantly increased, compared to control. Typically, sugars are a source of carbon and energy.[28] On the other hand, sugars such as glucose, fructose, and sucrose also act as signaling molecules in plant responses under biotic and abiotic stresses.[29,30] Among them, sucrose contributes to stress-related responses.[31] It has been reported that some of the defense-related genes were upregulated in rice leaves when sucrose was fed to the roots.[32] In this study, the upregulation of sucrose by CeO_2 NPs was a possible indicator of stress.

In contrast, ZnO NPs at both concentrations did not impact the reducing and nonreducing sugar contents (Table 1). Leaves are plant's main photosynthetic organs. Sugar and starch are synthesized in the chloroplasts of leaves and are translocated from leaves to fruits. Previous studies reported that reduced photosynthetic rate led to a decrease in the concentration of soluble sugars, and often starch accumulation in leaves.[33] In our study, the photosynthetic rate in leaves was not decreased by ZnO NPs.[11] This explained well that ZnO NPs did not change the carbohydrate composition in fruit.

Starch is another important carbohydrate in fruits. From Table 1, it seems that all NP treatments increased the starch content compared to control, but only at 400 mg/kg ZnO NPs, the difference was significantly increased. Previous reports showed that copper stress induced the overaccumulation of starch and sucrose in cucumber plants.[34] Another report indicates that salinity stress stimulated the starch accumulation in chloroplasts and resulted in increased accumulation of starch and total sugars in *Thellungiella halophile* leaves.[35] This could indicate that starch and sucrose increased in cucumber fruit as a result of stress caused by the NPs.

FTIR Analysis. As a rapid and noninvasive tool, Fourier transform infrared spectroscopy is used to identify changes in functional groups in plant tissues. FTIR spectra of cucumber fruit from plants treated with CeO_2 and ZnO NPs are shown in Figure 1. As seen in this figure, the band area of the carbohydrate region (900−1200 cm^{-1}) was reduced by all NP treatments, compared with the control. Furthermore, the difference between NP treatments and control can be seen in the lignin area (1635 cm^{-1}). The data also showed band differences in control and NP treated plants in the lipid region located between 2840 and 2960 cm^{-1}. In this region, control and 400 mg/kg CeO_2 NP treatments were similar; however, the 800 mg/kg CeO_2 NP treatment and both ZnO NP concentrations reduced this band area. In addition, it was observed that the band areas at 1350−1420 cm^{-1} and 1520−1650 cm^{-1} decreased in all NP treatments. The spectrum at 400 mg/kg CeO_2 NPs was similar to that of the control, while those of the other three treatments were apparently lower than that of the control.

For a better understanding of the fingerprint of carbohydrates, second derivatives of spectra were collected at the 800−1800 cm^{-1} region. The plots of the second derivative spectra are shown in Figure 2. Carbohydrates (glucose, fructose, and sucrose) showed intense characteristic bands in the fingerprint region (900−1400 cm^{-1}).[36,37] It is clear from the spectra that the bands at 1181, 1153, 1106, and 1083 cm^{-1} were lower in the NP treatments, compared to control. According to Duarte et al.,[37] spots 1153 and 1083 cm^{-1} are related to sucrose while 1108 cm^{-1} corresponds to fructose and glucose. Although it is difficult to quantify based on those bands, the spectra revealed that NPs changed the carbohydrate pattern in cucumber fruit.

Effects of NPs on Fruit Protein Fractions and Antioxidant Content. Although cucumber is a low protein vegetable, protein is an important factor contributing to the sweet taste of cucumber fruit.[38] The effect of ZnO and CeO_2 NPs on the four soluble protein fractions is presented in Table 2. Generally, albumin and prolamin fractions are the predominant proteins in cucumber fruit, which represents 84%−92% of the fruit protein. Globulin and glutelin fractions are present to a lesser extent. Results showed that neither CeO_2 nor ZnO NPs significantly affected albumin and prolamin fractions. However, compared to control, globulin content was significantly increased by CeO_2 NPs at 400 mg/kg treatment. Glutelin content was also significantly decreased by CeO_2 NPs at 400 mg/kg. Those results indicated that CeO_2 NPs at 400 mg/kg changed the protein content in fruit. CeO_2 NPs at 800 mg/kg did not affect any of the protein fractions. More studies are needed in order to explain the different response at 400 and 800 mg/kg treatments. ZnO NPs at 400 mg/kg treatment increased globulin content while those at 800 mg/kg treatment increased glutelin content. Du et al. reported that salt stress increased the soluble protein content of cucumber seedlings.[39] Several proteins such as heat shock protein, catalase, and glutathione *S*-transferase are related to stress response.[40] Those proteins were upregulated under abiotic or biotic stress. It is possible that protein increased as a response to NP induced stress.

Phenolic compounds including flavonoids and phenolic acids are the most frequently examined group of antioxidants, and they are highly correlated with the total antioxidant activity.[41,42] This is an important trait in cucumber because phenolic compounds haven been associated with a reduction in breast and prostate cancer risks.[43] As shown in Table 2, none of the CeO_2 and ZnO concentrations impacted flavonoid content. However, CeO_2 NPs at 800 mg/kg significantly decreased the phenolic content. As a result of this treatment there was an increase in total sugar content but a decrease in phenolic content. This indicates that, at this concentration, CeO_2 NP impacted the nutritional quality of the fruit.

Effects of NPs on the Fruit Mineral Composition. The uptake of nutrients by plant roots is affected by abiotic and biotic stressors including soil composition, cation exchange capacity, pH of the soil solution, microorganisms, and metal immobilization in root cell walls, among others.[44,45] Cucumber

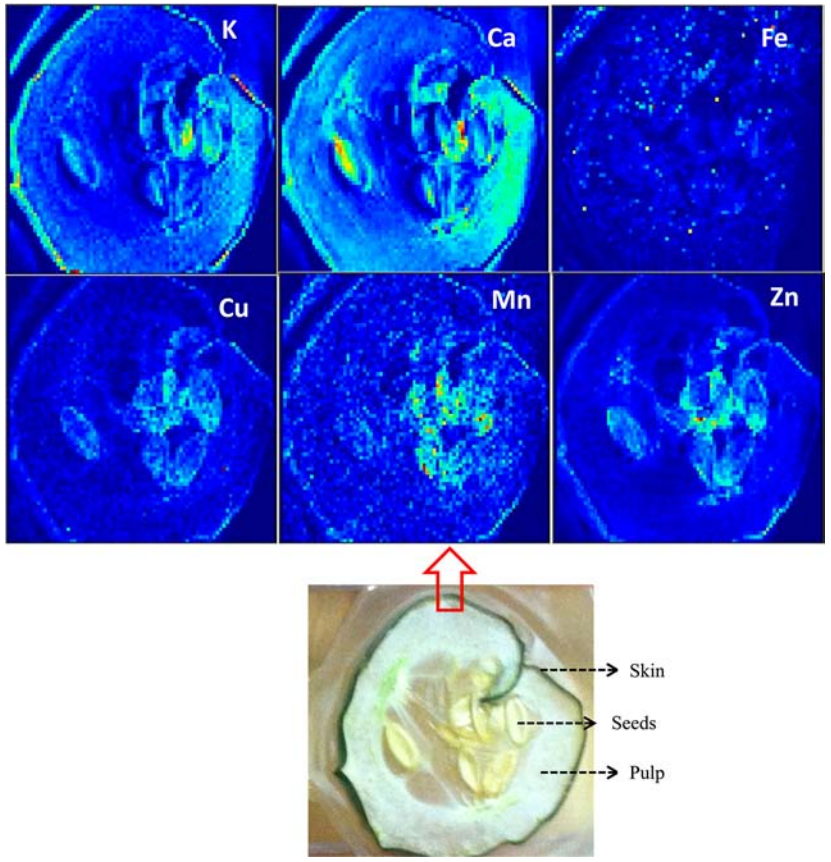

Figure 3. μ-XRF temperature map from a cross cut cucumber fruit showing normalized K, Ca, Fe, Cu, Mn, and Zn intensities. The image corresponds to control fruit. Red represents higher intensity, and dark blue represents the absence of the element.

is a source of vitamins, potassium, magnesium, and phosphorus required for human nutrition.[46] The influence of both the CeO_2 and ZnO NPs on the cucumber fruit mineral content is shown in Table 3. As seen in this table, from all macronutrients analyzed, only Mg showed significant differences in the NP treated plants. At 400 mg/kg, both the CeO_2 and ZnO NPs increased Mg in cucumber fruit by 17% and 18%, respectively ($p \leq 0.05$). Magnesium is an essential element for human health. It is obtained from foods and concentrates in bones and muscle.[47] Magnesium participates in multiple functions including energy production, protein synthesis, cell membranes and chromosomes, ion transport across cell membrane, and cell migration and interacts with protein, fiber, vitamin D, calcium, and zinc.[48] Magnesium is essential in plants as it is the core of the chlorophyll molecule. Mg^{2+} enters the root cortex cells through the apoplast.[49] However, it is not clear how Mg^{2+} enters the symplast and then the xylem apoplast.[50] To this end, we cannot explain why the CeO_2 NPs increased Mg translocation to cucumber fruit. However, other NPs like CuO NPs have been found to increase the production of indole-3-acetic acid in bacteria,[51] and this growth hormone induces the expression of two aquaporins in tomato (*Lycopersicon esculentum* Mill.). Magnesium has been found to be transported through the *rca* channel in wheat root.[52] Thus, it is possible that the CeO_2 NPs promote the expression of aquaporins or other channels, like the MRS2, which is Mg^{2+} transporter to the shoot, enhancing Mg^{2+} uptake.[53]

CeO_2 and ZnO NPs changed the fruit profile of micronutrients Cu, Mo, Mn, and Zn. As expected, Zn was increased at both ZnO NP concentrations. Previous reports have shown that ZnO NPs at 200 mg/kg soil and above increased the concentration of Zn in roots and shoots of corn plants.[54] At all concentrations, both the CeO_2 and ZnO NPs significantly reduced molybdenum concentration in cucumber fruit (Table 3). Reductions were in the range of 57 to 76% for CeO_2 NPs and about 40 to 53% for the ZnO NP treatments. Previous studies have shown that Mo is taken up by plants as MoO_4^{2-}.[55] Reports indicate that Mo uptake is reduced by sulfate and increased by phosphate.[56] In addition, previous work with alfalfa showed that Mo is complexed with malate.[55] As shown in Table 3, P and S were at the same levels in control and NP treated plants; thus, we cannot conclude about the role of P or S in Mo uptake. Perhaps the NPs altered the production of organic acids like citrate or malate, and then, they reduced Mo uptake. Studies about the effects of CeO_2 and ZnO NPs on organic acid production are currently being performed in order to explain the uptake of some micronutrients. The reduction in Mo in CeO_2 and ZnO NPs treated cucumber might not represent a concern to human health as it has been documented that most people in the U.S. consume more than sufficient amounts of this trace mineral in their diets.[48]

Manganese was increased by ZnO NPs at 400 mg/kg. A previous study showed that 34% of Zn/ZnO NPs was bound to Mn−Fe oxides.[57] At this time we cannot explain why this could increase Mn uptake. Additionally, we do not know the effect ZnO NPs produce in Nramp transporters, which are associated with Mn uptake by plants.[58] The increase of Mn in ZnO NPs treatment might not represent a health concern especially in diets that include the consumption of foods high in phytic acid (beans, seeds, nuts, whole grains, and soy products), oxalic acid

Table 4. Comparison of Effects of CeO_2 NPs and ZnO NPs on Cucumber Fruit Quality[a]

	soluble sugar	starch	protein fractionation	phenolic	flavonoid	mineral
CeO_2 NPs 400 mg/kg	−		globulin +; glutelin −			Mg +, Mo −
CeO_2 NPs 800 mg/kg	+			−		Mo −
ZnO NPs 400 mg/kg		+	globulin +			Mg, Mn +; Cu, Mo −
ZnO NPs 800 mg/kg			glutelin +			Cu, Mo −

[a]+ means positive impact; − means negative impact; blank means no impact.

(spinach, cabbage, and sweet potatoes), and tannins (tea), compounds that might slightly inhibit manganese absorption. Intake of minerals including iron, calcium, and phosphorus have been found to limit retention of manganese.[48]

Copper was also reduced by ZnO NPs. Previous studies have shown that ZnO NPs dissociate releasing Zn ions into the medium,[59] and according to Alloway, Zn decreases the uptake of Cu because both metals are taken up by the same transporter.[60] Some experts propose that Cu deficiency rather than excess Cu increases the risk of cardiovascular diseases.[48] More studies are needed in order to understand the effects of CeO_2 and ZnO NPs at the root surface interface and their effect on nutrient uptake by plants.

Micro-XRF Analysis of Mineral Localization in Cucumber Fruit. ICP-OES data only reflect total mineral concentration in cucumber fruit. In order to detect whether NPs altered the mineral distribution pattern, the μ-XRF technique was applied. Because of the limited beam time, only two macronutrients Ca and K and four micronutrients including Fe, Cu, Mn, and Zn were analyzed. The mineral distribution between CeO_2 treated and control plants was very similar. This indicates that CeO_2 NPs did not change the nutrient element distribution in cucumber plant. The micro-XRF intensity map of the cucumber fruit cross-section is shown in Figure 3. In general, K and Ca were localized in skin, pulp, and seeds, while iron was almost evenly distributed in the whole cross section. Figure 3 also shows that Cu, Zn, and Mn were more concentrated in seeds and at lower concentration in the skin.

As revealed by ICP-OES results, Cu concentration was reduced by ZnO NPs. Furthermore, μ-XRF results indicate that Cu is mainly present in cucumber seeds (Figure 3). Therefore, the next generation could also be impacted. Cu is an essential element for plant growth because they participate in many important physiological processes such as photosynthesis and respiration.[61] It has been reported that soaking seeds in Cu sulfate solution may enhance plant growth and development and, even, improve the nutritional quality of fruit.[62] Thus, a reduction in Cu in cucumber seeds suggests that ZnO NPs may have a negative impact on the growth of next plant generation. More studies are needed in order to solve this knowledge gap.

Conclusions. In summary, at the concentration tested, the ZnO NPs did not show negative impact on carbohydrate, protein, and antioxidant contents compared to control. To some extent, ZnO NPs increased starch and protein content, which might result in an increased caloric value of a food that is typically characterized by its low caloric content. However, it is not clear if the increased starch and protein contents are indicators of stress induced by ZnO NPs. Both ZnO NP treatments significantly decreased the concentration of the micronutrients Cu and Mo. Since both Cu and Mo are important minerals in plant tissues and participate in many processes, the quality of fruit in the next generation of cucumber plants may be impacted.

CeO_2 NPs not only decreased Mo concentration, they also altered the nonreducing sugars and phenolic content and they also changed the fractionation of proteins (Table 4). This suggests that CeO_2 NPs impacted the fruit flavor and reduced the antioxidant capacity. Furthermore, as previously reported,[11] the fruits were grouped by size as large, medium, and small and the total weight of each group was recorded. The fresh weight of large cucumbers was reduced by 31.4% by CeO_2 NPs at 800 mg/kg (Table S1 in the Supporting Information). More studies have to be performed in order to determine the effects of NPs on other parameters such as lignin and pectin that can influence fruit weight. The above-mentioned results suggest that, at the concentration tested, both CeO_2 and ZnO NPs impacted the nutritional quality of cucumber.

MATERIALS AND METHODS

Vineyards. In 2012, two cv. Grenache Noir vineyards, site 1 (s1) and site 2 (s2), located in Southern France and frequently subject to drought were studied. The vines in these vineyards are grafted onto the 110 Richter rootstock, trained on a vertical trellis, and pruned as a bilateral cordon. At site 1, plant spacing was 2.25 (between rows) × 0.7 (between plants in a row), giving a plant density of 6350 plants/ha. The rows were aligned in a north/south orientation. At site 2, plant spacing was 2.10 (between rows) × 1.0 (between plants in row), giving a density of 4760 plants/ha. The rows were aligned in an east/west orientation.

Vine Irrigation Treatments. Water was applied with a drip irrigation system, once per week, to generate the various treatments. For irrigated treatments, irrigation was initiated following the first detection of a water deficit. The amount of water supplied depended on the desired intensity of the water deficit. Four different irrigation treatments were applied: irrigation before veraison only (bV), irrigation after veraison only (aV), irrigation before and after veraison (TOT), and no irrigation (DRY). Each irrigation treatment was organized into two rows at s2 and two blocks at s1.

Monitoring of Berry Ripening. Berry ripening was monitored during the last month of maturation. We sampled berries in clusters (200 berries) to ensure that the berries sampled were representative of all cluster positions within the canopy and all positions within the cluster.[17] Fresh berries were analyzed on the day of sampling: pH, sugars (Brix), and titratable acidity. The harvest date for each treatment was determined from these analysis results.

Vine Water Status Measurement. Vine water status was evaluated for each treatment by measuring predawn leaf water potential by the pressure chamber technique.[18] This parameter has been reported to reflect the nature of the soil, climatic conditions, and irrigation. Indeed, it provides information about the water status of the soil layers explored by the roots, because there is an equilibrium between vine water status and soil water status just before dawn.[19] This parameter was monitored from June to September, with at least four replicates for each date. We also determined the carbon isotope composition of grape sugars ($\delta^{13}C$) at maturity.

Sampling, Measurement of Mean Berry Volume, and Preparation of Grape Juices for Aroma and Nitrogen Composition Analysis. Sampling was performed weekly, during the last few weeks of the ripening period, for each treatment. We picked 20 clusters evenly distributed over the two faces of the row, from 20 vines (10 vines from each of the two rows at site 2, and each of the two blocks at site 1). In the laboratory, the clusters were cut into small fragments (each containing between 5 and 10 berries), mixed, and 1 kg of fragments was isolated and stored at −20 °C for grape juice preparation.

Mean berry volume was determined by immersing 100 fresh berries in a graduated cylinder containing water and measuring the displacement of the water. These volumes were used to obtain per-berry measurements, to prevent possible dilution effects due to the irrigation of the vine in some treatments.

Grape juice was prepared from 1 kg of frozen cluster fragments, which were destemmed and defrosted overnight at 4 °C. The berries were then crushed in a blender for 20 s, and the juice obtained was filtered and stored at −20 °C until analysis.

Harvest and Winemaking. At maturity, 100 kg of clusters was picked manually. The vine yield of each treatment was estimated by weighing and counting the clusters present on each of 20 plants.

At site 1, the grapes are used to produce red wines. Clusters were mechanically destemmed and placed in a 1 hL stainless steel tank. SO_2 (3 g/hL) was added to the must, which was then inoculated with yeasts (20 g/hL) (Zymaflore X5, Laffort, France). Alcoholic fermentation and maceration were carried out over a period of 7 days, at temperatures of 24−30 °C. The mixture was pressed, and a malolactic fermentation was performed, with the addition of 1 g/hL of Vitilactic F (Martin Vialatte, France), at 18 °C, before the addition of 4 g/hL SO_2. Tartaric stabilization was then carried out over 15 days at 0 °C, followed by filtration (5 μm pores), before bottling.

At site 2, the grapes are used to produce rosé wines. Clusters were mechanically destemmed and placed in a 1 hL stainless steel tank. SO_2 (3 g/hL) was added to the must, which was allowed to macerate for 24 h at 18 °C before the addition of 2 g/hL SO_2 and pressing. Enzyme (2 g/hL; Lafazym, Laffort, France) was then added, and the mixture was allowed to settle for 18 h at 12 °C. The mixture was clarified and inoculated with 20 g/hL yeast (Zymaflore X5, Laffort, France). Alcoholic fermentation was carried out at 16−23 °C, with monitoring. At the end of the alcoholic fermentation, SO_2 was added to the wine at a concentration of 4 g/hL, before tartaric stabilization for 15 days at 0 °C, filtration (1 and 0.65 μm pores), and bottling.

Analyses. *Analysis of Amino Acids and Ammonium in Grape Juice.* The amino acid content of grape juice was determined with a specific amino acid analyzer (Biochrom 30), according to the protocol used by Crépin et al.[20]

Ammonium was quantified spectrophotometrically in grape juices with an enzyme kit (Enzytec kit, R-biopharm, Germany), according to the manufacturer's instructions.

Dimethyl Sulphide Potential (DMSP) Analysis. Must and wine DMSP were analyzed with a modified version of the protocol described by Ségurel et al.[21] Briefly, the sample (8 mL of must or wine) was mixed with sodium hydroxide (300 mg, to obtain a 1 N solution), sodium chloride (1 g), and DMSPA-d_6 (4.5 μg in aqueous solution as an internal standard). DMSPA-d_6 was synthesized in our laboratory as described by Smith et al.[22] This compound was used as an internal standard, leading to a modification of the protocol suggested by Ségurel et al.,[21] who introduced the standard (DMS-d_6) after heating the sample. We heated the sample at 100 °C for 1 h, resulting in the hydrolysis of DMS precursors and DMSPA-d_6 to generate DMS and DMS-d_6, respectively. Calibration was performed on a model must and wine, according to the same sample preparation protocol, with serial dilutions of SMM. For the model must, SMM concentrations varied between 0 and 2775 μg/L (between 0 and 485 μg/L for wine), and DMSPA-d_6 concentration was 570 μg/L (303 μg/L for wine). Six calibration points were used for each matrix. The resulting curves were linear ($[DMS]/[DMS\text{-}d_6] = 0.8449 \times A_{m/z62}/A_{m/z68} + 0.009$; $R^2 = 0.997$ and $[DMS]/[DMS\text{-}d_6] = 0.9930 \times A_{m/z62}/A_{m/z68} - 0.017$; $R^2 = 0.999$ for wine and grape juice, respectively).

Statistical Analyses. Principal component analysis and Tukey tests were performed with Xlstat software (Addinsoft, France).

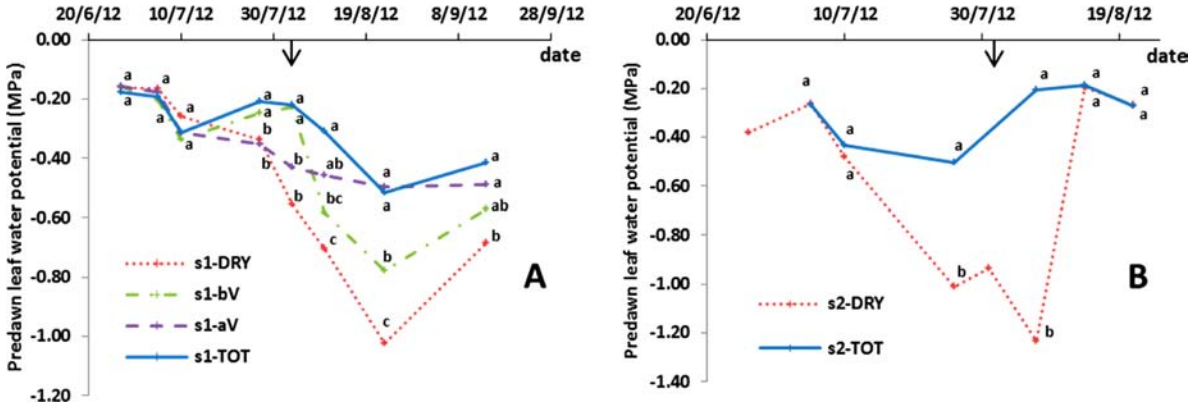

Figure 1. Predawn leaf water potential monitoring for the various irrigation treatments during maturation (site 1 (A) and site 2 (B)). Each point is the mean of at least four replicates. Statistically significant differences in the Tukey test ($p < 0.05$) are indicated by different letters. The arrows on the *x*-axis indicate the dates of veraison.

RESULTS/DISCUSSION

Vine Water Status. The different irrigation treatments presented differed in terms of water status (Figure 1). At site 1 (Figure 1A), the predawn leaf water potential measurements were lowest between August 20th and 30th; there were significant differences between treatments (except for TOT and aV, consistent with the irrigation treatments applied). At site 2 (Figure 1B), predawn leaf water potential was lowest from the end of July to the start of August, with significant differences between treatments. Veraison occurred at about August 3rd at site 1 and August 1st at site 2, and water deficit had no impact on veraison date, as reported by Tregoat.[23]

The carbon isotope composition of grape sugar ($\delta^{13}C$) was used as an integrative indicator of vine water deficit during the ripening period. At site 1, s1-DRY was the treatment associated with the highest degree of stress (−23.16 ‰), followed by s1-bV (−24.15 ‰), s1-aV (−24.42 ‰), and then s1-TOT (−25.34 ‰). At site 2, s2-DRY was the treatment resulting in the greatest water deficit (−22.87 ‰), followed by s2-TOT (−25.22 ‰).

Berry Ripening under Different Water Deficit Conditions. At both sites, sugars accumulated and titratable acidity decreased earlier for the TOT treatment than for the DRY, aV, and bV treatments, consistent with the observations reported by Ojeda.[24] The harvest dates for each treatment were therefore determined on the basis of the results for the monitoring of berry ripening. At maturity, sugar concentrations reached 240 and 247 g/L, and the titratable acidity was 2.8 and 2.5 g (H_2SO_4)/L for s1-DRY and s1-TOT, respectively; sugar concentrations were 190 and 233 g/L, and titratable acidity was 2.75 and 2.5 g (H_2SO_4)/L for s2-DRY and s2-TOT, respectively. Water deficit has been reported to inhibit sugar accumulation in grape berries, by decreasing phloem sugar unloading,[25] potentially accounting for the low sugar concentration of s2-DRY grapes at maturity.

Changes in the Yeast Assimilable Amino Acid Content of Berries during Maturation. Yeast assimilable nitrogen (YAN) consists of ammonium and free primary amino acids;[26,27] secondary amino acids, such as proline and hydroxyproline, are not metabolized by yeast under the conditions usually prevailing during winemaking.[28] Bell and Henschke [16] summarized a large number of published results, showing that amino acid composition varies considerably, according to many factors, including grape cultivar, rootstock, site, seasonal conditions, level of maturity, viticultural practices, soil management techniques, and the health status of the grapes.

We monitored the amino acid content of berries during the last few weeks of maturation (Figure 2). For each irrigation

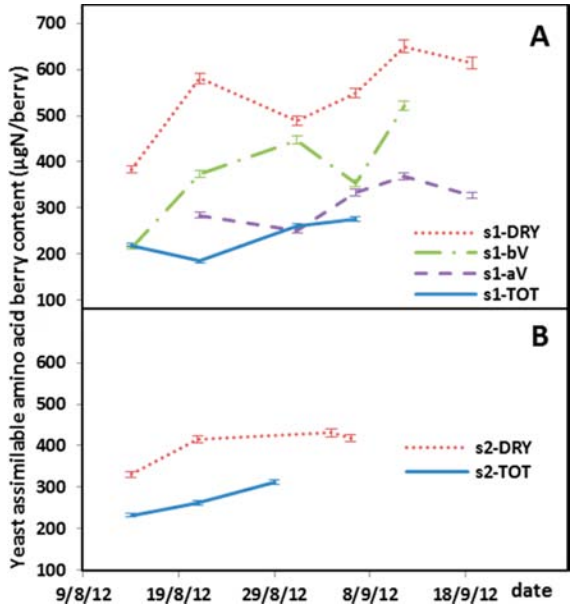

Figure 2. Changes in the yeast assimilable amino acid content of berries during ripening in different water deficit conditions (site 1 (A) and site 2 (B)). The standard deviations indicated are the mean analytical standard deviations.

treatment, the yeast assimilable amino acid content of the berry increased during ripening, this increase being most pronounced for the treatments involving a water deficit (DRY and bV). At maturity, the yeast assimilable amino acid content of berries from vines subjected to the s1-DRY treatment was more than twice that of berries from vines subjected to the s1-TOT treatment (614 and 276 μg N/berry, respectively), and s1-bV and s1-aV displayed intermediate behavior (521 and 327 μg N/berry, respectively) (Figure 2A); the yeast assimilable amino acid content for s2-DRY was 35% greater than that for s2-TOT (418 and 313 μg N/berry, respectively) (Figure 2B). At both sites, greater water deficiencies were associated with the accumulation of larger amounts of yeast assimilable amino

dx.doi.org/10.1021/jf404758g | J. Agric. Food Chem. 2014, 62, 2760−2766

acids in the berry during ripening. The differences were more marked when expressed as concentrations: at site 1, the yeast assimilable amino acid concentrations recorded were 391, 286, 211, and 153 mg N/L for s1-DRY, s1-bV, s1-aV, and s1-TOT, respectively; at site 2, we obtained values of 440 and 209 mg N/L for s2-DRY and s2-TOT, respectively. These observations are consistent with those reported by Morgan, who observed higher levels of solute accumulation in the organs of plants subjected to water deficit than in well-watered plants.[29] Some sugars and amino acids may be recycled to the grape, to sustain ripening.[30] Glutamine and glutamic acid are the only amino acids that decrease in concentration during ripening, this decrease being smaller at higher water deficits (DRY and bV) (data not shown). As reported by Stines,[31] glutamine can act as a precursor for the biosynthesis of other amino acids, potentially accounting for the decrease in glutamine and glutamic acid levels during ripening.

Changes in the Proline/Arginine Ratio during Ripening. Arginine and proline are generally the most abundant amino acids in grapes, together with alanine, gamma aminobutyric acid, and glutamine.[31] The proline/arginine ratio is considered to be a good indicator of the nitrogen nutritional status of the musts from different grape varieties.[16] Indeed, proline cannot be assimilated by yeast, whereas arginine is the most important amino acid for yeast in the must. A lower proline/arginine ratio would therefore be expected to result in a more fermentable must for the same total amino acid concentration. Grenache Noir has been reported to accumulate large amounts of arginine at early stages of maturation (19.7°B) and large amounts of proline when more mature (24°B).[26] In our experiments, the proline/arginine ratio increased during maturation (Figure 3), consistent with the observations of

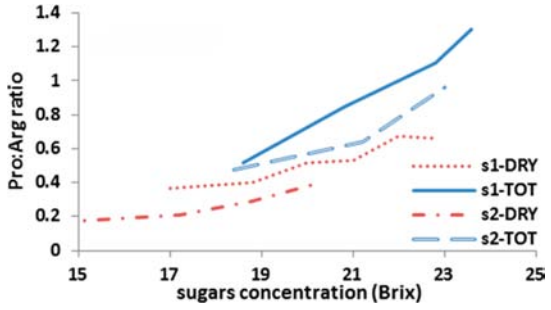

Figure 3. Changes in proline/arginine ratio during maturation as a function of berry sugar concentration, for the DRY and TOT treatments at sites 1 and 2.

Kliewer.[26] The change in this ratio during ripening differed between the DRY and TOT treatments: at the same range of maturity (between 18.8 and 22.8°B), the proline/arginine ratio was lower for the DRY treatment at the two sites, indicating that the amino acid nitrogen fraction was more assimilable by yeast in water-deficient berries. Moreover, the proline/arginine ratio increased more rapidly in the s1-TOT treatment than in the s1-DRY treatment, for the same range of maturity. Water deficiency at the end of the maturation period favored the accumulation of arginine in berries: the arginine content of s1-DRY berries was 2.5 times higher than that of s1-TOT berries at ripeness (363 and 144 μg N/berry for s1-DRY and s1-TOT, respectively; 230 and 173 μg N/berry for s2-DRY and s2-TOT, respectively).

Changes in Berry Ammonium Content during Maturation. Ammonium is the second component of YAN. In our experiments, ammonium levels decreased during ripening, for all irrigation treatments, consistent with previous observations.[16,32] At site 1 (Figure 4A), berry ammonium levels

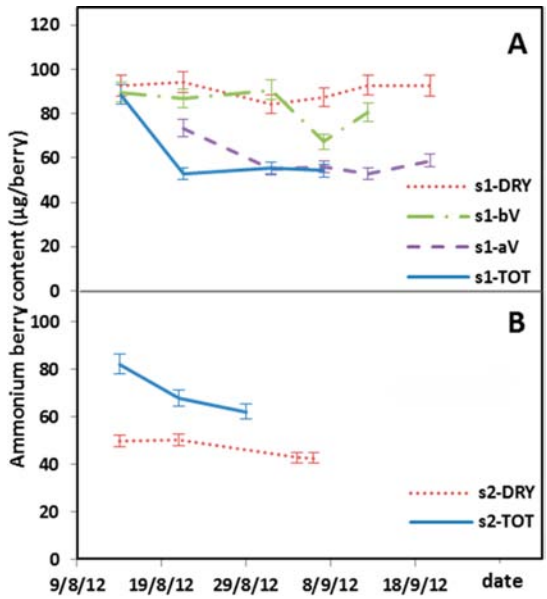

Figure 4. Changes in the ammonium content of the berries during ripening, for the various water deficit conditions (site 1 (A) and site 2 (B)). The standard deviations indicated are the mean analytical standard deviations.

decreased slowly or remained stable in water-deficient treatments (s1-DRY and s1-bV) and were higher than those for the non water-deficient treatments at maturity (s1-aV and s1-TOT). Ammonium, like other solutes, accumulated in larger amounts in water-deficient organs.[29] The higher berry ammonium contents observed in water-deficient treatments may reflect higher levels of transpiration, resulting in a greater uptake of soil water, which contains nutrients such as ammonium.[30] The opposite situation was observed at site 2 (Figure 4B), where s2-TOT berries had higher ammonium contents than s2-DRY berries. Predawn leaf water potential was lower at site 2 than at site 1 (Figure 1B), consistent with a high level of water stress. It is possible that the considerable water deficiency generated by the s2-DRY treatment limited water uptake by the roots more strongly, resulting in lower levels of ammonium accumulation in the berries.

Berries from the water-deficient vines at the two sites had higher ammonium concentrations than berries from irrigated vines: 59, 44, 38, and 30 mg N/L for the s1-DRY, s1-bV, s1-aV, and s1-TOT treatments, respectively, and 47 and 41 mg N/L for s2-DRY and s2-TOT, respectively.

Proportion of the YAN in the Form of Ammonium. The ammonium/YAN ratio decreased during maturation, for all irrigation treatments at both sites. This is not surprising, given the decrease in ammonium levels and the increase in assimilable amino acid levels occurring during ripening. At maturity, the ammonium/YAN ratio varied between 13 and 16% at site 1 and between 9 and 17% at site 2. The lowest ratios were those for s1-DRY and s2-DRY, raising questions about a possible increase in amino acid synthesis or accumulation in the berries of vines subjected to water deficit.

dx.doi.org/10.1021/jf404758g | J. Agric. Food Chem. 2014, 62, 2760−2766

Changes in the DMSP Content of Berries during Maturation. The DMSP content of berries increased during ripening, for all irrigation treatments (Figure 5). In s1-DRY, a large increase in the DMSP content of berries was observed during the last two weeks of maturation, consistent with previous observations showing a large increase in the DMSP content of berries at the end of maturation and over mature[12] (Figure 5A). At maturity, the DMSP content of berries was higher for DRY treatments than for TOT treatments. At site 1, berry DMSP level was 272, 191, 174, 86 ng/berry (173, 105, 112, and 45 μg/L) for s1-DRY, s1-bV, s1-aV, and s1-TOT, respectively; at site 2, berry DMSP level was 238 and 208 ng/berry (250, 139 μg/L) for s2-DRY and s2-TOT, respectively. The smaller difference in berry DMSP content between the two treatments observed at site 2 (Figure 5B) may be due to large differences in maturity.

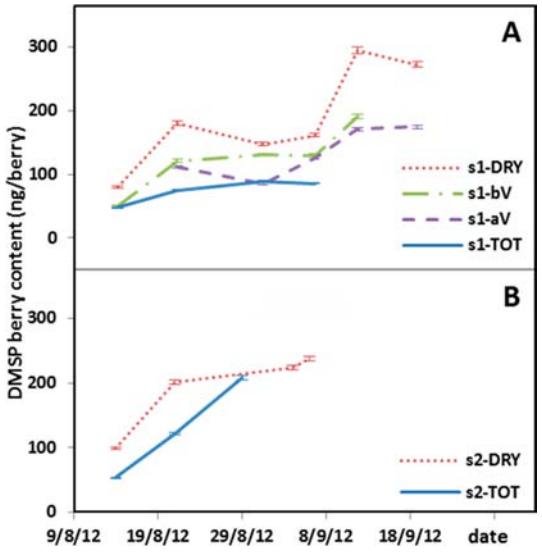

Figure 5. Changes in the DMSP level of berries during ripening under different water deficit conditions (site 1 (A) and site 2 (B)). The standard deviations indicated are the mean analytical standard deviations.

Global Analysis of Grape Juice. At the end of the experiments, 31 samples were available, corresponding to the grape samples for the different irrigation treatments at the two sites collected during the maturation period. We investigated the general impact of vine water stress, by carrying out principal component analysis (PCA) with all the available analytical data: berry ammonium, yeast assimilable amino acid, and DMSP contents (Figure 6). The first axis of this PCA was strongly linked to the variables "yeast assimilable amino acids (YAAA)" and "DMSP" and accounted for 62% of total variability. The second axis was strongly linked to the variable "Ammonium (NH_4^+)" and accounted for 34% of total variability. Amino acid and DMSP contents were found to be correlated (R^2 = 0.85), whereas no correlation could be established between ammonium content and the other two variables. The composition of the DMSP may account for this observation, as the DMSP reflects mostly SMM content in grapes,[13] SMM being an amino acid derivative. Thus, vine water deficit may favor high berry YAN content and concentration and a high berry DMSP.

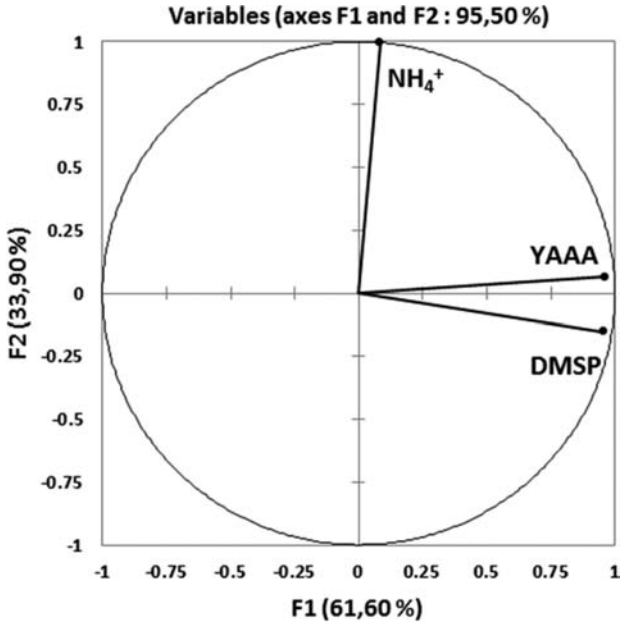

Figure 6. Correlation circle for principal component analysis, based on 31 observations and the ammonium (NH_4^+), the yeast assimilable amino acid (YAAA), and the DMSP levels of berries during maturation, for all irrigation treatments at sites 1 and 2.

Relationship between DMSP and YAN Concentration in Grape Juice at Maturity and Wine DMSP Concentration. The DMSP concentration of must at maturity was greater for water-deficient treatments (DRY) than for the other treatments, at both sites (Figure 7, dark histograms). In the red wines produced from site 1 grapes, DMSP (Figure 7, pale histograms) followed the same pattern as the DMSP of the corresponding grapes. Thus, a higher grape DMSP concentration was associated with a higher DMSP concentration of the wine. For the rosé wines produced from site 2 grapes, wine DMSP concentration was low and similar for the two treatments, despite large differences in must DMSP concentration between the two treatments. This probably reflects the characteristics of the rosé winemaking process, in which there is little extraction from berry skins, the chief source of the DMSP.[14]

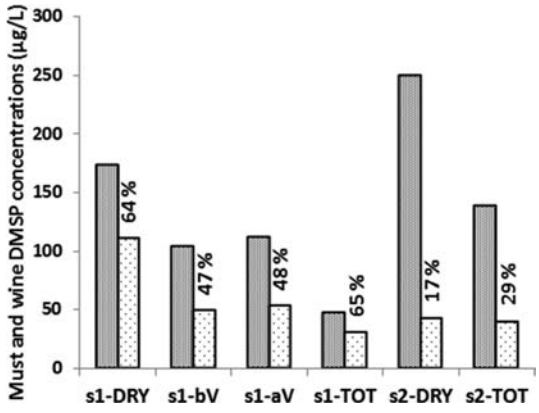

Figure 7. DMSP concentrations in the musts (dark histograms) and wines (pale histograms) and corresponding DMSP preservation rate during fermentation (percentage annotated), for all irrigation treatments at sites 1 and 2.

The wine DMSP/must DMSP ratio provided information about the preservation of DMSP during fermentation. This

dx.doi.org/10.1021/jf404758g | J. Agric. Food Chem. 2014, 62, 2760−2766

ratio was very high for s1-DRY (64%), probably due to the high YAN concentration of the must (450 mg N/L). Indeed, levels of SMM (the main component of DMSP in grapes [13]) have been reported to be better preserved during fermentation with higher concentrations of YAN in model must.[14] The two intermediate treatments, s1-bV and s1-aV, had lower YAN concentrations (330 and 250 mg N/L, respectively) and a lower DMSP preservation rate (47 and 48%, respectively). However, the preservation rate for s1-TOT was high (65%), despite the YAN concentration being lower for this treatment than for the other treatments (183 mg N/L). At site 2 (rosé wines), the wine DMSP/must DMSP ratio was lower than those obtained for the red wines from site 1, for the reasons explained above. This ratio was higher for s2-TOT than for s2-DRY, even though YAN concentration was higher for s2-DRY (s2-DRY: 485 mg N/L; s2-TOT: 250 mg N/L). Therefore, not only YAN concentration impacted DMSP preservation. At both sites, the fermentability of the different musts was satisfactory in terms of their YAN concentrations at maturity.

Thus, generally speaking, water deficit affected both YAN and DMSP levels in grapes, potentially resulting in a better preservation of DMSP during alcoholic fermentation, although DMSP content was variable and depended on the wine considered. One possible consequence of this finding is that "stressed" wines may have a longer aroma shelf life, due to the role of DMS, at the ranges of concentration reported here, in enhancing the fruity notes of Grenache Noir wines.[7] However, further studies are required to confirm these preliminary results.

bromophenol, 2,4-, 2,6-, and 3,5-dibromophenol (99% each), and 2,4,6-tribromophenol were from Sigma-Aldrich (Taufkirchen, Germany), and 3-bromophenol was from Alfa Aesar (Karlsruhe, Germany).

Whisky Samples. A total of 20 whiskies of different origins were analyzed for the content of bromophenols especially in Islay whiskies, which are described in more detail in the following. Three of the nine Islay whisky distilleries on this island, i.e., Laphroaig, Lagavulin, and Ardbeg (not available), reportedly have a significant marine flavor which includes notes of iodine and seaweed. This characteristic note has not been described for two further Islay whiskies analyzed by us, i.e., Bowmore and Bruichladdich. Origins and qualities of non-Islay whiskies will be listed below.

Laphroaig, 10 years. Laphroaig is the southernmost distillery on Islay. The storehouses are directly located at the sea, and during high tide, they are bathed by the ocean.[18] Compared to other distilleries, there is a later cut from spirit collection to feints at Laphroaig, and for this reason it contains more peaty phenolic compounds.[4] It is exclusively aged in American oak barrels. It is known for the strongest marine flavor of all Islay malts.[4] The flavor is described, among others, as peaty, medicinal with nuances of iodine, machine room, and smoky, well-rounded by the sweet flavor of oak.[4,19] The taste includes iodine, smoky, strong distinctive salty taste, and sharp finish.[19] The salty water, the salty marine air, the peaty water, and the peat itself are key factors for the generation of the unique flavor and taste. The malt is known to contain 40 ppm of phenolic compounds.[18] It has been claimed that the nearness to the sea is the reason for the salty character of the spirit and that the exchange of salty air and barrel contribute to the unique flavor.[19]

Lagavulin, 16 years. The Lagavulin distillery is only two kilometers north of Laphroaig.[4] The distillery is also directly located at the sea.[4] The flavor notes include peat, iodine, and flowery while the taste has been reported as smoky, very peaty, salty, full-bodied, and recalling dried seaweed.[4,19]

Bowmore, 12 years. Distillery also located directly at the sea. The flavor includes musk, as well as earthy and nutty notes. Taste attributes are dry, charcoal, moderately peaty, smoky, slightly bitter, and very complex.[19]

Bruichladdich, 10 years. Flavor: nutty, sweet, light, slightly peaty. Taste: mild, smokey, slightly sweet, intense, strong finish.[19]

Non-Islay Whisky. The following samples from Scotland were analyzed: Jura Superstition, Glen Scotia, Johnnie Walker RedLabel, Old Pulteney (12 years), Speyside Single Malt (18 years), The Glenlivet (12 years), Glenfiddich (12 years), Ballantines Gold (12 years), Chivas Regal (12 years), Ballentines Finest, and Glen Garioch (8 years). Samples of other origins were Jameson (Ireland), Jim Beam (USA), Jack Daniels Nr. Seven (USA), the flavored whisky Southern Comfort (USA), and Hohenheimer Whisky (Germany).

Sample Cleanup. The derivatization with acetic acid anhydride/$NaHCO_3$ was performed in a downscaled way according to the procedures reported for benzotriazoles.[20,21] $NaHCO_3$ (40 mg) was weighed into a 2 mL sample vial, and 1 mL of whisky, 10 μL of the internal standard, 3,5-dibromophenol (10 ng/μL in ethanol), and 40 μL of acetic anhydride were added. After the reaction (visible by the development of CO_2), 200 μL of *n*-hexane was pipetted into the vial. After shaking and phase separation, the upper organic phase was separated and used for analysis.

Gas Chromatography with Electron Capture Negative Ion Mass Spectrometry (GC/ECNI-MS). GC/ECNI-MS measurements were carried out with a 7890/5975C system (Agilent, Waldbronn, Germany). Helium (purity 99.9990%) was used as the carrier gas in constant flow mode (1.2 mL/min). A 15 m long ZB-1 column (internal diameter 0.25 mm, film thickness 0.1 μm, Phenomenex, Aschaffenburg, Germany) was used in combination with the following GC oven program: After 1 min at 50 °C, the temperature was raised at 10 °C/min to 250 °C (0 min hold time). Sample solutions (2 μL) were injected splitless into a PTV injector programmed as follows: 80 °C (hold time 0.01 min), then at 500 °C/min to 300 °C. The ion source temperature was set at 150 °C. Methane (purity 99.9995%) was used as moderation gas at an ion gauge pressure of 1.6×10^{-4} Torr. Mass spectra were recorded in the full scan range from m/z 50 to m/z 500. Quantification was carried out in the selected ion monitoring mode using m/z 79 and m/z 81 (Br^- ion isotopes suitable for all organobromine compounds[22]), m/z 250 and m/z 252 (M^- of free dibromophenols and fragment ion of the *O*-acetylated dibromophenols ($[M - C_3H_2O + H]^-$), and m/z 330 and m/z 332 (M^- of free tribromophenols and fragment ion of *O*-acetylated tribromophenols ($[M - C_3H_2O + H]^-$); and m/z 372 and m/z 374 (M^- of *O*-acetylated tribromophenols) were monitored for confirmation throughout the run.

For *O*-acetylated dibromophenols the abundance of M^- was about 7% of m/z 79 while it was ~18% for 2,4,6-tribromophenol. Accordingly, the LOQ would have been higher by ~factor 14 or ~5.5. However, the presence of the verification ions (M^-) along with the retention time was used for verification of the compounds in samples with response to m/z 79 and 81. Vice versa, the absence of di- and tribromophenols in our samples was based on the lack of response to m/z 79 and 81 in the corresponding GC/MS-ECNI-MS chromatograms.

RESULTS AND DISCUSSION

GC/ECNI-MS Method for the Analysis of *O*-Acetylated Bromophenols in Whiskies. Phenolic compounds and especially bromophenols are difficult to analyze in free form by gas chromatography.[7] Especially when present at low amounts (<1 ng injected), GC peaks of bromophenols were characterized by severe peak broadening within a few runs.[23] Only very clean GC/MS systems and frequent instrumental maintenance allowed for the determination of free bromophenols in the low pg range.[23] Moreover, the direct analysis of bromophenols from whisky proved to be difficult. For this reason we chose to convert the bromophenols into *O*-acetylated derivatives according to other studies on halophenols.[5,7,24−26] The protocol followed our recent method for the derivatization of benzotriazoles in dishwasher tabs.[21] This procedure turned out to be easy to perform and resulted in sharp and abundant peaks due to the high sensitivity of GC/ECNI-MS-SIM for polyhalogenated compounds including *O*-acetylated di- and tribromophenols.

The GC/ECNI-MS mass spectra of the *O*-acetylated bromophenols were dominated by the bromide ion isotopes (m/z 79 and 81). For *O*-acetylated 2,4,6-tribromophenol, M^- (m/z 370) was also detected at ~20% of the base peak along with $[M - CH_3CO + H]^-$ at m/z 328 (Figure 2a). The latter fragmentation was also detected in the mass spectrum of *O*-acetylated 2,4-dibromophenol (m/z 250) but at lower abundance (Figure 2b). Other *O*-acetylated dibromophenols showed the same mass spectra except that m/z 250 had even lower abundance than in the 2,4-dibromophenol derivative. While quantification was based on m/z 79 and m/z 81, the mentioned high mass ions were also recorded for verification (see Materials and Methods).

Once these parameters were set up, the method was developed by using 3,5-dibromophenol as internal standard. 3,5-Dibromophenol is not naturally occurring and has only been detected at traces as a transformation product of the anthropogenic polybrominated diphenyl ether congener BDE 196.[23] Initial measurements confirmed that the IS was not present in the whisky samples. Linearity, tested with solutions of bromophenols in ethanol/water (40:60, v/v), was established in the range 20−1,000 pg injected on the column for di- and tribromophenols corresponding to 100−5,000 pg/mL bromophenols in whisky ($R^2 > 0.999$). The signal-to-noise (S/N) approach was used to establish the limit of detection (S/N = 3) and the limit of quantification (S/N = 10). The limit of

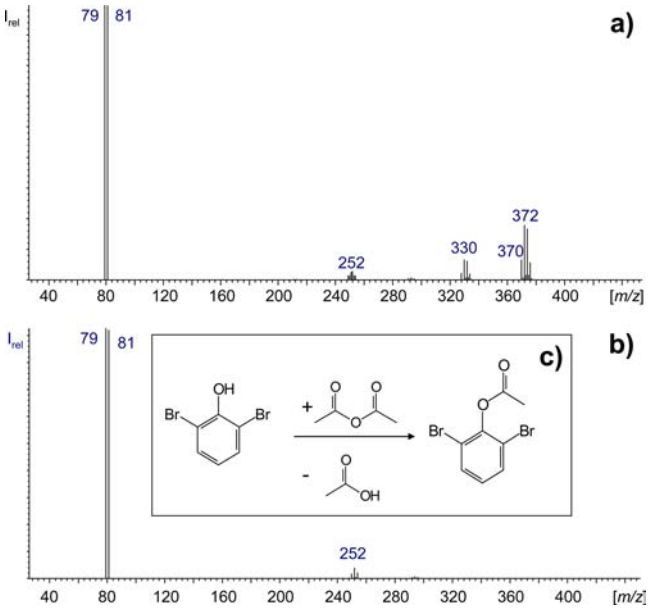

Figure 2. GC/ECNI-MS spectra of *O*-acetylated (a) 2,4,6-tribromophenol and (b) 2,6-dibromophenol along with (c) an inset of the reaction scheme of the *O*-acetylation of 2,6-bromophenol with acetic acid anhydride.

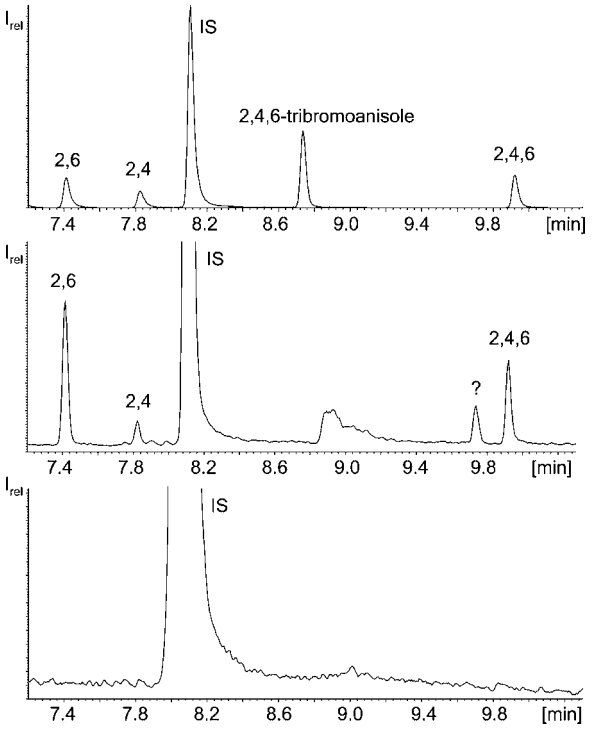

Figure 3. GC/ECNI-MS-SIM chromatograms (m/z 79) of (a) a 50 pg standard solution of *O*-acetylated 2,6-dibromophenol ("2,6"), 2,4-dibromophenol ("2,4"), 3,5-dibromophenol ("IS"), 2,4,6-tribromophenol ("2,4,6"), and 2,4,6-tribromoanisole and a sample of (b) Lagavulin containing *O*-acetylated bromophenols and (c) Jameson (without *O*-acetylated bromophenols). The peak labeled with a question mark ("?") in panel b denotes a yet unknown brominated compound.

quantification of dibromophenols and tribromophenols was estimated at ~2 pg (~10 pg/mL in whisky, i.e., ~40% ethanol in water). However, monobromophenols did not provide the required sensitivity for GC/ECNI-MS determination (limit of detection >100 pg/μL[23]). Samples were analyzed at least in duplicate, and the standard deviation was generally <10%.

Initial experiments on the acetylation procedure demonstrated that this method produced between 95 and 98% of *O*-acetylated bromophenols. This efficiency was in the same range as reported in other studies.[7] More, no enrichment step was used which could reduce the recovery and with the use of the internal standard the results obtained with our method can be considered quantitative. However, the response of the internal standard 3,5-dibromophenol was about 1 order of magnitude lower than the ones of the target analytes. The relative standard deviations of the analyte response factors in the calibration solutions were between 11 and 15%, which represents the accuracy of the method.

The GC/ECNI-MS chromatograms could be well-analyzed and compared with the standard (Figure 3a). In Lagavulin, 2,4- and 2,6-dibromophenols as well as 2,4,6-tribromophenol could be identified (Figure 3b). The most abundant peak originated from 2,6-dibromophenol. Except for the three bromophenols, one further minor peak was detected which eluted slightly before 2,4,6-tribromophenol from the GC column. Due to the low amounts available, the compound gave only response to m/z 79 and m/z 81, so that its identity could not be determined. By contrast, a sample of Jameson (Ireland) did not show the presence of any bromophenols, even after selective zoom into the *y*-axis (Figure 3c). This whisky sample did not indicate the presence of any brominated compound.

Application of the Method of Bromophenol Determination to Whisky Samples. By means of standard compounds we were able to identify the bromophenols in the Islay whiskies (Figure 3). The highest amounts were generally determined for 2,6-dibromophenols. In addition to 2,6-dibromophenol, 2,4-dibromophenol was detected in only three and 2,4,6-tribromophenol in only two samples (Table 1), i.e., those with the highest concentrations of 2,6-dibromophenol (Laphroaig > Lagavulin > Bowmore). The concentration of 2,4-dibromophenol was about 1 order of magnitude lower than that of 2,6-dibromophenol (Table 1). Lagavulin showed the highest level of 2,4,6-tribromophenol (Table 1). The two Islay whiskies with characteristic iodine flavor (Lagavulin and Laphroaig) contained >300 ng/L 2,6-dibromophenol. This concentration is about 3 orders of magnitude higher than the taste threshold of this compound in water.[5] The highest level was detected in Laphroaig, i.e., the sample with the most intense taste and the most distinct marine flavor.[4] Typically, whisky is served in portions of 20 mL, which corresponds with 8 ng of bromophenols per serving (and 1 ng per sample aliquot analyzed).

The sample with the third highest bromophenol content was Bowmore, i.e., another Islay whisky, which reportedly is not characterized by a distinct iodine flavor.[4] Surprisingly, some other whiskies also contained low amounts of bromophenols whose origins remained unclear. However, the measured bromophenol concentrations were generally more than 1 order of magnitude lower than in the two Islay whiskies with distinct iodine flavor (Table 1). These amounts corresponded with <1 ng per serving. Although even these 2,6-dibromophenol levels exceeded the taste threshold concentration for 2,6-dibromophenol in water,[5] the abundance of 2,6-dibromophenol was deemed too low for contributing a "marine" note to the whiskies, which is in accordance with flavor descriptions.[4]

Relevance of the Findings and Potential Origins of the Bromophenols. Assumedly, the ethanolic solutions and

the presence of many other flavor compounds in whisky increase the flavor threshold of 2,6-dibromophenol. For instance, the flavor threshold of 2,6-dibromophenol in prawn meat was 2 orders of magnitude higher than in water (i.e., 60 ng/kg vs 0.5 g/L).[27] Accordingly, the flavor threshold value of 2,6-dibromophenol in prawn meat was at the borderline of whiskies with a distinct iodine flavor and those without.[27] Unfortunately, we were lacking a trained panel with expertise in flavor evaluation. Hence, we could not verify the explicit or additive contribution of 2,6-dibromophenol to the iodine-flavored Islay whiskies. Nevertheless, the low amounts of the possible character impact compound 2,6-dibromophenol required to generate iodine-flavored Islay whiskies suggest that such a marine flavor could be easily imitated (or adjudged) by the addition of only nanogram amounts to the spirits. For this reason a more thorough investigation of the impact of bromophenols on the flavor of whisky should be carried out in the future. Likewise the route by which the bromophenols enter the whisky should be investigated in more detail. The direct uptake of bromophenols from marine air on the one hand and the bromination of existing phenol (40 ppm of phenolic compounds in Laphroaig[18]) on the other hand appear to be the most likely sources.

As we could show in this study, bromophenols could be determined for the first time in Scotch Islay whiskies. Due to the excellent sensitivity of GC/ECNI-MS-SIM, the di- and tribromophenols could be determined without utilization of an enrichment step. Yet, further research will be required to determine the role of monobromophenols which could not be detected with this approach. Such results could be obtained in the future by using purge-and-trap techniques for sample enrichment, which will increase sensitivity and enable the use of GC/EI-MS for analysis.[7] Future sensory evaluation should aim at elucidating the contribution of the bromophenols to the specific flavor of Scotch Islay whiskies. In the positive case, this flavor impression could be imitated by the addition of small amounts to the whiskies. Likewise their natural formation and their point of entrance during the whisky production should be a matter of future research.

There are also some research studies concerning hydrolyzing flavonol glycosides into their corresponding flavonols and determining them in an indirect way.[32] Gallic acid (GA) and chlorogenic acid (CGA), the main phenolic acids and depsides of tea, although quite low in contents relative to other phenolic acids and depsides such as isochlorogenic acid, *p*-coumaric acid, *p*-coumaric quinovic acid, and caffeic acid, were detected by Yin et al.[13] The pretreatment and evolution system of ISO14502-2 ("determination of content of catechins in green tea − using the method of HPLC) is a promising method for routine analysis of catechins in tea. In addition, the determination of caffeine content of tea by HPLC was reported by Lin et al.,[17] Blahova and Lehotay,[21] and Prayong et al.[24]

Previous studies reported that caffeine and polyphenols such as (−)-gallocatechin, (−)-epigallocatechin, (−)-epigallocatechin gallate, (−)-epicatechin, gallocatechin gallate, and (−)-epicatechin gallate in oolong tea, which was obtained from three main production sites in China, that is, Fujian, Taiwan, and Guangdong, were simultaneously determined using HPLC.[20] In addition, five catechins in green tea,[25] catechins and caffeine in green tea leaves,[22] or caffeine and catechins in tea extracts[23] were simultaneously determined using HPLC. However, little information is available on the simultaneous determination of caffeine and polyphenols in Wuyi Rock tea. In this paper, the method of high-performance liquid chromatography coupled with photodiode array detector (HPLC-PDAD) at three different wavelengths [detection wavelength at 278 nm (Det.278 nm), reference wavelength at 360 nm (ref.360 nm); detection wavelength at 330 nm (Det.330 nm), reference wavelength at 380 nm (ref.300 nm); and detection wavelength at 370 nm (Det.370 nm), reference wavelength at 290 nm (ref.290 nm)] for the simultaneous determination of caffeine (CAF), catechins (EGC, C, EGCG, EC, GCG, ECG), and polyphenols (GA, CGA, myricetin, myricetin glycoside, quercetin, quercetin glycoside) in 'Wuyi Rougui' and 'Wuyi Shuixian', the two major cultivars of Wuyi Rock tea, was developed. The objective of this study was to evaluate the tea quality of 'Wuyi Rougui' and 'Wuyi Shuixian' and provide the method for clarifying the cause of "cultivated varieties flavor" of Wuyi Rock tea.

MATERIALS AND METHODS

Samples. Wuyi Rock teas (*C. sinensis* L.), including 10 'Wuyi Rougui' samples and 10 'Wuyi Shuixian' samples, were obtained from Wuyishan Jiejieqing Tea Co., Ltd., in Fujian province, China; Wuyishan Xiangjiang Tea Co., Ltd., in Fujian province, China; Wuyishan Qinpin Tea Co., Ltd., in Fujian province, China; Wuyishan Yanshang Tea Co., Ltd., in Fujian province, China; Wuyishan Huahui Tea Co., Ltd., in Fujian province, China; Wuyishan Mangtingfeng Tea Co., Ltd., in Fujian province, China; Wuyishan Kaimingxuan Tea Co., Ltd., in Fujian province, China; and Wuyishan Qingpao Tea Co., Ltd., in Fujian province, China.

1	1	70	0.5
2	2	80	1.0
3	3	90	1.5

Chemicals. EGC, C, EGCG, E, GCG, and ECG were purchased from Shanghai Ronghe Pharmacy Co., Ltd. (China). Myricetin, quercetin, CGA, and GA were obtained from Chengdu Must Biotechnology Co., Ltd. (China). Caffeine was purchased from Sigma Chemical Co. Ltd. (USA). HCl, acetic acid, vitamin C, and ethylenediaminetetraacetic acid (EDTA) were manufactured by Sinopharm Chemical Reagent Co., Ltd. (China). The above reagents were of analytical grade. Acetonitrile and methanol, of HPLC grade, were the products of Merck Co. Ltd. (Germany). The water used was redistilled and ion free.

[a] Y stands for the area of the peak. X stands for the amount of corresponding compound, mg/L. [b] Signal to noise ratio (S/N) is 10.

Selection of Detection Wavelength. Stock solutions (1000 μg/mL) of each standard were prepared individually by dissolving the required weight of each compound in corresponding solutions. Further diluted solutions (20 μg/mL) of each standard were also prepared individually and then injected into HPLC separately to get their retention time and spectrogram from 200 to 400 nm. After the comparison of each spectrum, the detection wavelength and its reference wavelength were selected.

Elution Program. The analyses of polyphenols and caffeine in tea were carried out by the following HPLC method. An Agilent 1200 series liquid chromatography system (Agilent Corp., USA), comprising a vacuum degasser (part G1322A), a quaternary pump (part G1311A), an autosampler (part G1313A), a column oven compartment (part G1316A), and a photodiode array detector (PDAD) (part G1314A), was used. The column was C18 reverse-phase Zorbax Ecllpse XDB-18 (5 μm, 4.6 mm × 250 mm, P/N 990967-902).

The elution program was according to method ISO 14502-2 with some modifications. Two mobile phases were employed in gradient HPLC elution. Mobile phase A was prepared with 90 mL of acetonitrile, 20 mL of acetic acid, and 2.0 mL of EDTA water solution (10 mg/mL) and subsequently made up to a volume of 1000 mL with water. Mobile phase B was mixed with 800 mL of acetonitrile, 20 mL of acetic acid, and 2.0 mL of EDTA water solution (10 mg/mL) and subsequently made up to a volume of 1000 mL with water. Both mobile phases (A and B) should be filtered through a 0.45 μm filter before use. Column oven temperature was set at 35 °C. The flow rate of the mobile phase was 1.0 mL/min. The injection volume was 20 μL. All of the above paremeters were concordant with the ISO 14502-2 method. To get a better separation, there were some changes in gradient elution program as follows: 100% (v/v) mobile phase A for 10 min, then (over another 10 min) a linear gradient to 80% (v/v) mobile phase A and 20% (v/v) mobile phase B, then (over 5 min) a linear gradient again to 50% (v/v) mobile phase A and 50% (v/v) mobile phase B, held at this composition for 8 min. Finally, it was reset to 100% (v/v) mobile phase A and allowed to equilibrate before the next injection.

Standard Preparation. GA (10 mg), EGC (20 mg), C (20 mg), CGA (10 mg), CAF (15 mg), EGCG (20 mg), E (20 mg), GCG (20 mg), ECG (20 mg), myricetin (10 mg), and quercetin (10 mg) were weighed and mixed together. Then the mixture was dissolved in a 20

mL one-mark volumetric flask with methanol to form the stock mixture solution.

Five milliliters of the stock solution was dispensed to 25, 50, and 100 mL one-mark volumetric flasks, respectively. All of these flasks were diluted with mobile phase to form working standard solutions A, B, and C and then injected into the HPLC. The peak area responses were obtained. Each peak was identified by comparing their retention time and UV spectra with those of the respective standard. A standard graph for each component was prepared by plotting concentration versus peak area.

Extraction Preparation of Sample of Wuyi Rock Tea. The method of extraction from Wuyi Rock tea was used according to the method of ISO 14502-2 with some modifications. Tea leaves (0.2 g) were mixed with 5 mL of 70% (v/v) aqueous methanol at 70 °C by a vortex mixer. After bathing at 70 °C for 10 min, the tube was removed, allowed to cool, and then centrifuged for 10 min at 3500g and 4 °C, and the supernatant was collected. The precipitation was extracted according to the above extraction procedure. The collected supernatants from the above extraction were mixed, then diluted to 10 mL with 70% (v/v) aqueous methanol, and filtered through a 0.22 μm filter. The filtrate was collected for the following analysis.

Method of Hydrolyzing Flavonol Glucosides to Flavonols in Wuyi Rock Tea. As flavonol glucosides present as *O*-glycosides with sugars bound at the C3 position and they can be hydrolyzed into their corresponding flavonols,[32] the quantity of flavonols in the hydrolyzed solution was used to assess the flavonol glucosides in tea sample according to the method of Wang and Helliwell.[32]

There were two steps for preparing the sample of hydrolyzed solution from flavonol glucosides in Wuyi Rock tea. The first step was 5 mL of filtrate of tea sample extraction, which was prepared by using the procedure of Extraction Preparation of Sample of Wuyi Rock Tea above, transferred into a tube, and then mixed with 5 mL of HCl solution at different concentrations on the basis of the following test design. The second step was the mixture bathed with different combinations of temperature and time span according to the following test design and then cooled rapidly to 20 °C, after which 70% (v/v) aqueous methanol was added to 25 mL.

The hydrolysis conditions for flavonoid glycosides including concentration of HCl solution, hydrolysis temperature, and hydrolysis time are shown in the following Single-Factor Test and Orthogonal Experiment. All hydrolyzed solutions should be filtered through 0.22 μm filters before injection into the HPLC.

Single-Factor Test. Effects of different concentrations of HCl solution, hydrolysis temperatures, and hydrolysis times on the content of flavonols and the yield of hydrolysate from flavonol glucosides were conducted, respectively. Specific designs were as follows: the experiment at different concentrations of HCl solution (0, 1.5, 3.0, 4.5, 6.0, 7.5, and 9.0 mol/L) on the flavonol content from the hydrolysis of flavonol glucosides was conducted by hydrolyzing at 80 °C for 1 h, respectively, whereas the experiment of different hydrolysis temperatures (60, 70, 80, 90, and 100 °C) was conducted using 1.5 mol/L HCl solution and hydrolyzing for 1 h, respectively. In addition, the experiment of different hydrolysis times (0, 0.5, 1, 1.5, 2, and 2.5 h) was also conducted using 1.5 mol/L HCl solution and hydrolyzing at 80 °C, respectively.

Orthogonal Experiment. On the basis of the result of the above single-factor test, selection of three factors and three levels of orthogonal experiment is shown in Table 1. The test plan of an orthogonal experiment [$L_9(3)^4$] design for optimizing parameters of hydrolyzing flavonol glucosides to corresponding flavonols in Wuyi Rock tea is shown in Table 4.

Reliability and Quantification of Caffeine and Some Selected Polyphenols in Samples of Wuyi Rock Tea. The UV spectrum of each standard compound after subtraction of the corresponding UV base spectrum was normalized automatically using a computer, and the plots were superimposed.

Peaks were considered to be chromatographically pure when there was exact coincidence to their corresponding UV spectra. Chromatographic peaks in the samples were indentified by comparing their retention times and UV spectra with those of the reference standards. The linear relationship, limit of quantification (LOQ), recovery, and relative standard deviation (RSD) are shown in Tables 2 and 3 to evaluate the quality of this method.

EGC, C, EGCG, EC, GCG, ECG, GA, CGA, myricetin, quercetin, and caffeine were detected and calculated from the sample extraction directly without hydrolysis. The myricetin glycoside and quercetin glycoside were detected in an indirect way by quantitating myricetin and quercetin in sample extraction after hydrolysis.

Statistical Analyses. All statistical analyses, including the design of orthogonal test and independent-sample t test, were carried out with PASW (IBM SPSS Statistics) statistical software (version 19.0).

RESULTS AND DISCUSSION

Chromatographic Performance of Working Standard Solution. HPLC of caffeine and some selected tea polyphenols in their working standard solution at various concentrations was

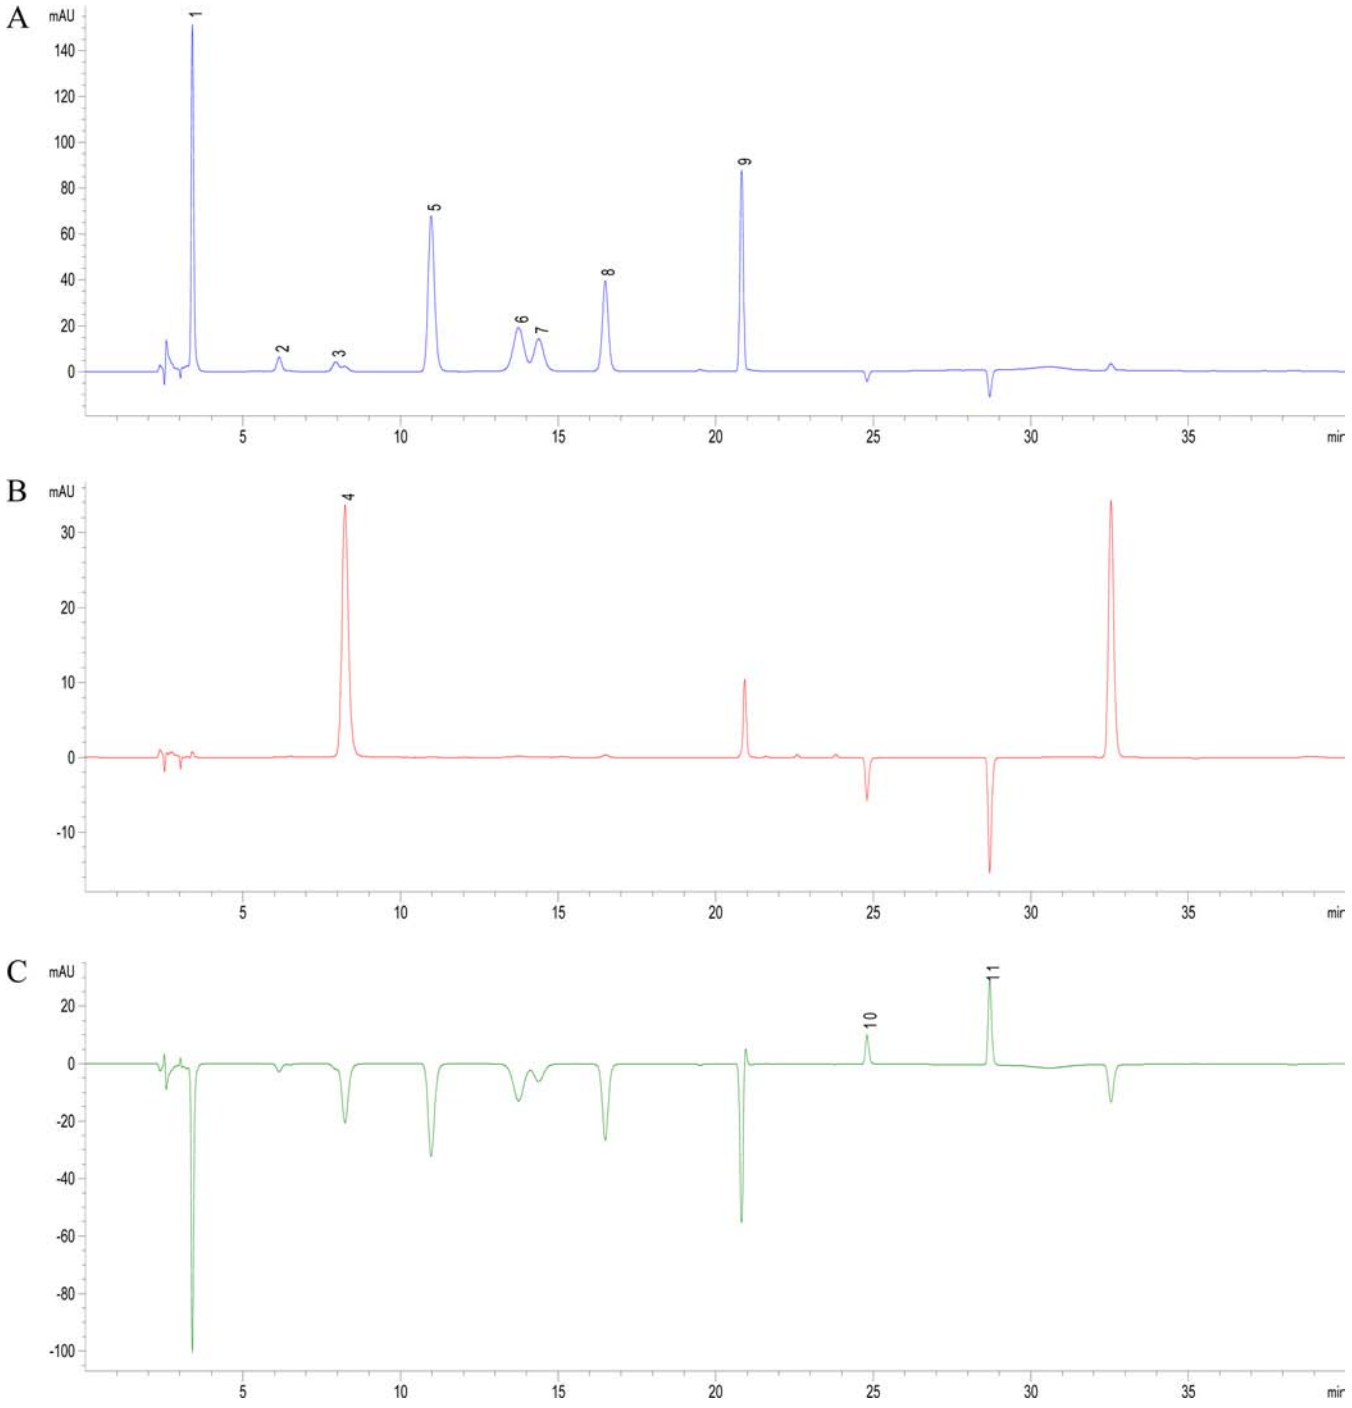

Figure 1. HPLC chromatogram of the working standard solution C mixture containing 25 μg/mL GA (1), 50 μg/mL EGC (2), 50 μg/mL C (3), 25 μg/mL CGA (4), 37.5 μg/mL CAF (5), 50 μg/mL EGCG (6), 50 μg/mL EC (7), 50 μg/mL GCG (8), 50 μg/mL ECG (9), 25 μg/mL myricetin (10), and 25 μg/mL quercetin (11) at different wavelengths under the experimental conditions. (A) GA (1), EGC (2), C (3), CAF (5), EGCG (6), EC (7), GCG (8), and ECG (9) were detected at acquisition wavelength of 278 nm and at reference wavelength of 360 nm. (B) CGA (4) was detected at acquisition wavelength of 330 nm and at reference wavelength of 380 nm. (C) Myricetin (10) and quercetin (11) were detected at acquisition wavelength of 370 nm and at reference wavelength of 290 nm.

recorded. There were negative peaks in a single wavelength. Therefore, it was important to select the proper wavelength for detection. Figure 1 shows the detection wavelength, reference wavelength, and retention time for each compound of standard solution C. These were slightly overlapping near C (3) and CGA (4), EGCG (6), and EC (7), whereas separation of other compounds performed well at corresponding wavelengths. Considering the sensitivity for quantitative determination, GA, C, CAF, EGCG, EC, GCG, and ECG were detected at 278 nm with the reference wavelength at 360 nm. CGA was detected at 330 nm with the reference wavelength at 380 nm. Myricetin and quercetin were detected at 370 nm with the reference wavelength at 290 nm.

Reliability of the Method. The linear range, linear equation of the working curve, coefficient of correlation (r), and LOQ for each standard are shown in Table 2. The results

dx.doi.org/10.1021/jf4056314 | J. Agric. Food Chem. 2014, 62, 2772−2781

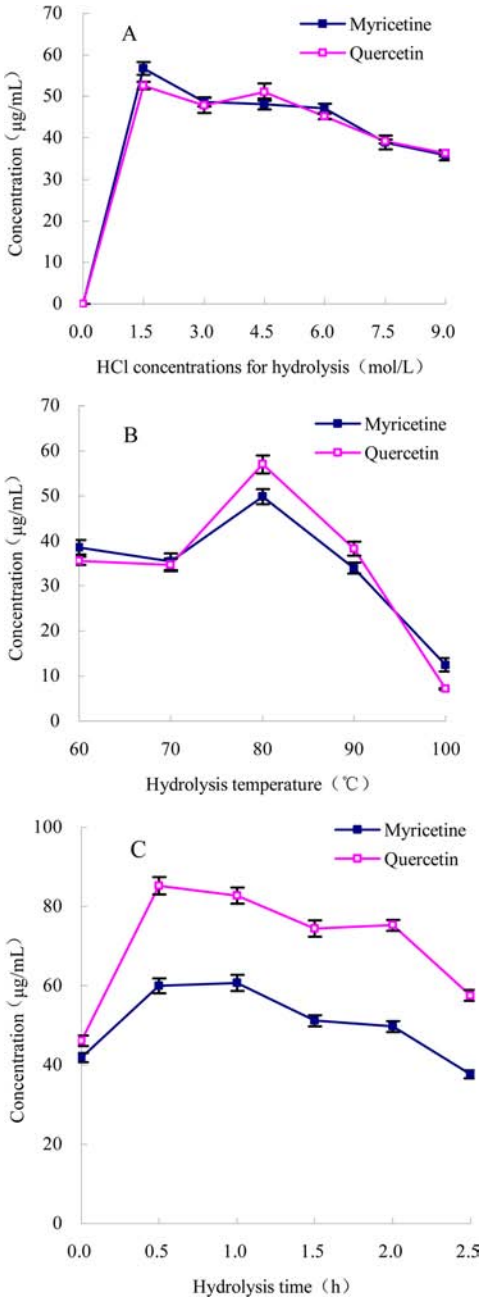

Figure 2. Effect of three factors on the hydrolysis of the flavonols: (A) HCl concentrations for hydrolysis; (B) hydrolysis temperature; (C) hydrolysis time.

indicated that there were low limits of quantification (LOQs) for GA, CGA, CAF, EGCG, EC, GCG, ECG, and quercetin with the range of these being 0.01−0.15 mg/L. Relatively speaking, higher LOQs for EGC, C, and myricetin in the range of 0.30−0.45 mg/L were observed. The correlation coefficient (r) was >0.96 in the analysis of each compound.

As shown in Table 3, recoveries were determined in triplicate in Wuyi Rock tea by spiking pure standards to the extraction solution prior to the sample analysis. The mean recoveries and RSDs of the method for determination of GA, EGC, C, CGA, EGCG, EC, and GCG were 97.5−100.3% and within the range ±3.9% (n = 3), respectively.

The method of indirect determination for the quantification of myricetin and quercetin, which are flavonols, the hydrolysates from flavonol glucosides, could be influenced by hydrolysis. The mean recoveries and RSDs of the method for determination of myricetin and quercetin in Wuyi Rock tea were 82.1−92.1% and within the range of ±4.5% (n = 3), respectively. By multiplying their corresponding recoveries as the correction coefficient with quantificaiton, more reliable results could be obtained.

The above results confirmed that the development of the method in this study was an accurate and precise method for the determination of caffeine and selected polyphenols in Wuyi Rock tea.

Factors Affecting Hydrolysis of Flavonol Glucosides to Flavonols in Wuyi Rock Tea. *Results of Single-Factor Test. 1. Concentrations of HCl Solution.* Figure 2A shows that both myricetin content and quercetin content increased sharply with the concentration of HCl solution from 0 to 1.5 mol/L HCl and reached peak values at 1.5 mol/L HCl, whereas the contents of myricetin and quercetin both decreased gradually with increasing concentration of HCl solution from 1.5 to 9.0 mol/L. These results indicated that the concentration of 1.5 mol/L HCl solution was an appropriate concentration of HCl for hydrolyzing flavonol glucosides to flavonols in Wuyi Rock tea at 80 °C for 1 h.

2. Hydrolysis Temperature. As shown in Figure 2B, contents of myricetin and quercetin in Wuyi Rock tea exhibited a slight change when the hydrolyzing temperature was raised from 60 to 70 °C, whereas both myricetin content and quercetin content increased rapidly with increasing hydrolysis temperature from 70 to 80 °C, reaching peak values at 80 °C and then decreasing sharply with increasing hydrolysis temperature from 80 to 100 °C. These results suggested that 80 °C was a proper hydrolysis temperature for hydrolyzing flavonol glucosides to flavonols in Wuyi Rock tea at a concentration of 1.5 mol/L HCl solution for 1 h.

3. Hydrolysis Time. Quercetin content in Wuyi Rock tea exhibited a sharp increase from 0 to 0.5 h of hydrolysis, a slight decrease from 0.5 to 1 h, a gradual decrease from 1 to 2 h, and a rapid decrease from 2 to 2.5 h (Figure 2C). These results showed that 0.5−1 h of hydrolysis might be a proper hydrolysis time for hydrolyzing flavonol glucosides to quercetin in Wuyi Rock tea at 80 °C and a concentration of 1.5 mol/L HCl solution.

As shown in Figure 2C, myricetin content in Wuyi Rock tea exhibited a rapid increase from 0 to 0.5 h of hydrolysis, but almost no change of myricetin content from 0.5 to 1 h, and then showed a gradual decrease from 1 to 2.5 h. From the above results it could be concluded that 0.5−1 h of hydrolysis might be a suitable hydrolysis time for hydrolyzing flavonol glucosides to myricetin in Wuyi Rock tea at 80 °C and a concentration of 1.5 mol/L HCl solution.

Results of Design of Orthogonal Experiment. The hydrolysis conditions, including concentration of HCl solution, hydrolysis temperature, and hydrolysis time, for flavonoid glycosides to myricetin and quercetin, which were based on an orthogonal experiment $L_9(3)^4$ design, were determined. As shown in Table 4, the order of important factors of the hydrolysis conditions for hydrolyzing flavonoid glycosides to myricetin in Wuyi Rock tea was hydrolysis temperature (factor B), concentration of HCl (factor A), and hydrolysis time (factor C). In addition, Table 4 also shows that hydrolysis at a concentration of 2 mol/L HCl solution and at 70 °C for 1.5 h was the most beneficial hydrolysis condition for hydrolyzing flavonoid glycosides to myricetin in Wuyi Rock tea.

Table 4. Test Plans and Results of Range Analysis Based on an Orthogonal Experiment $L_9(3)^4$ Design for Hydrolyzing Flavonol Glucosides to Corresponding Flavonols in Wuyi Rock Tea

	factors				results

Table 5. ANOVA of Myricetin and Quercetin Output after Hydrolysis

	factor	variance	df	F value	F critical value	signif ($P < 0.05$)
myricetin	concn of HCl	360.3	2	0.575	19.0	
	hydrolysis temp	409.2	2	0.653	19.0	
	hydrolysis time	68.1	2	0.109	19.0	
	error	626.4	2			
quercetin	concn of HCl	1546.3	2	402.0	19.0	*
	hydrolysis temp	221.4	2	57.5	19.0	*
	hydrolysis time	46.2	2	12.0	19.0	
	error	3.8	2			

Table 4 shows that the order of important factors of the hydrolysis conditions for hydrolyzing flavonoid glycosides to quercetin in Wuyi Rock tea was concentration of HCl (factor A), hydrolysis temperature (factor B), and hydrolysis time (factor C). In addition, Table 4 also shows that hydrolyzing at a concentration of 2 mol/L HCl solution and at 90 °C for 1 h might be the best hydrolysis condition for hydrolyzing flavonoid glycosides to quercetin in Wuyi Rock tea.

Further analysis of variance (ANOVA) indicated that there were no significant ($P > 0.05$) differences among different concentrations of HCl solution for hydrolyzing flavonoid glycosides to myricetin in Wuyi Rock tea; the same results were also found among different hydrolysis temperatures or among different hydrolysis times (Table 5). However, there were significant ($P < 0.05$) differences among different concentrations of HCl solution or among different hydrolysis temperatures for hydrolyzing flavonoid glycosides to quercetin in Wuyi Rock tea, whereas there were no significant ($P > 0.05$) differences among different hydrolysis times (Table 5).

From the above results it could be concluded that the best hydrolysis conditions (hydrolyzing at a concentration of 2 mol/L HCl solution and at 90 °C for 1 h) for hydrolyzing flavonoid glycosides to quercetin in Wuyi Rock tea could be considered as the best hydrolysis conditions for hydrolyzing flavonoid glycosides to their corresponding flavonols including quercetin and myricetin in Wuyi Rock tea.

Typical Chromatographic Performance of Wuyi Rock Tea Sample. As shown in Figure 3A,B, a typical chromatogram of tea polyphenols and caffeine in nonhydrolyzed extraction of Wuyi Rock tea sample was observed at different

[a]*, $P < 0.05$.

acquisition wavelengths and at different reference wavelengths. Contents of GA, EGC, C, CAF, EGCG, EC, and ECG were detected at an acquisition wavelength of 278 nm and at a reference wavelength of 360 nm (Figure 3A), whereas CGA content was detected at an acquisition wavelength of 330 nm and at a reference wavelength of 380 nm (Figure 3B).

No target substances (myricetin and quercetin) in nonhydrolyzed extraction of Wuyi Rock tea sample were detected at an acquisition wavelength of 370 nm and a reference wavelength at 290 nm (Figure 3C). In contrast, contents of myricetin and quercetin in hydrolyzed extraction of Wuyi Rock tea sample were detected at an acquisition wavelength of 370 nm and a reference wavelength of 290 nm (Figure 3D). These results indicated that myricetin and quercetin could be detected in hydrolyzed extraction of Wuyi Rock tea sample, which implied myricetin and quercetin might be hydrolyzed from their corresponding glycosides. Thus, the contents of myricetin glycosides and quercetin glycosides could be determined by detecting the content of corresponding myricetin and quercetin.

From the above results it could be concluded that caffeine and some selected polyphenols such as GA, EGC, C, EGCG, EC, ECG, and CGA in nonhydrolyzed extraction of Wuyi Rock tea sample could be simultaneously detected, whereas other polyphenols such as myricetin and quercetin also could be simultaneously detected in hydrolyzed extraction of Wuyi Rock tea sample.

Quantification of Caffeine and Selected Polyphenols in Wuyi Rock Tea Samples. In this effort, the developed HPLC method for simultaneous determination of caffeine and some selected polyphenols was successfully applied in the determination of 20 samples of Wuyi Rock tea, including 10 samples of 'Wuyi Rougui' and 10 samples of 'Wuyi Shuixian'. The results showed that, except for myricetin and quercentin, the other nine kinds of polyphenols (GA, EGC, C, EGCG, EC, ECG, CGA, myricetin glycosides, and quercetin glycosides) and caffeine were all detected in the above 20 samples of Wuyi Rock tea (Table 6).

Until now, the distribution of caffeine and selected polyphenols in two cultivar sets of Wuyi Rock tea was still unclear. The Mann−Whitney *U* test and Kolmogorov−Smirnov test, methods of nonparametric statistics, were used for evaluating the differences of caffeine and selected polyphenols in 'Wuyi Rougui' and 'Wuyi Shuixian', two cultivar sets of Wuyi Rock tea. The results indicated that both the Mann−Whitney *U* test and Kolmogorov−Smirnov test showed significant ($P < 0.05$) differences of ECG, CGA, ECG, and myricetin glycosides in 'Wuyi Rougui' and 'Wuyi Shuixian', which might be credited with causing the different tastes between these two cultivar sets of Wuyi Rock tea. However, there were no significant ($P > 0.05$) differences of GA, C, CAF, EGCG, EC, GCG, and quercetin glycosides in 'Wuyi Rougui' and 'Wuyi Shuixian' (Table 6).

It also could be found from this effort that contents of C, GCG, and CGA in 'Wuyi Rougui' and 'Wuyi Shuixian' were at low levels (Table 6). In addition, some peaks of other unknown substances overlapped slightly with the peak of CGA (Figure 3B). The above observation might result in the accuracy of the quantification of C, GCG, and CGA in Wuyi Rock tea.

In conclusion, due to the very many kinds of flavonoid glycosides in tea and the lack of commercial standards of flavonoid glycosides, it is critical to develop a rapid and cheap method for determining the flavonoid glycosides of tea. The contents of myricetin glycosides and quercetin glycosides in Wuyi Rock tea could be determined by detecting the content of corresponding myricetin and quercetin. Developing the optimized hydrolysis conditions for hydrolyzing flavonoid glycosides to their corresponding flavonols including quercetin and myricetin in Wuyi Rock tea was regarded as a key technology for determining the content of corresponding myricetin and quercetin. In our work, hydrolysis at a concentration of 2 mol/L HCl solution and at 90 °C for 1 h was found to be optimal for hydrolyzing flavonoid glycosides to myricetin and quercetin in Wuyi Rock tea. Caffeine and seven kinds of polyphenols (GA, EGC, C, EGCG, EC, ECG, and CGA) in 20 samples of Wuyi Rock Tea were simultaneously determined using a simple and fast reverse-phase high-performance liquid chromatography procedure coupled with a photodiode array detector (RP-HPLC-PDAD), which was developed in this effort. This work also showed that there were significant ($P < 0.05$) differences of ECG, CGA, ECG, and myricetin glycosides in 'Wuyi Rougui' and 'Wuyi Shuixian', which were credited with causing the different tastes between these two cultivar sets of Wuyi Rock Tea. Therefore, it was suggested that the application of RP-HPLC-DAD, the method developed in this study, might be a promising method for simultaneously determing caffeine and some selected polyphenols in Wuyi Rock tea, evaluating the tea quality of 'Wuyi

Rougui' and 'Wuyi Shuixian', and clarifying the cause of "cultivated varieties flavor" of Wuyi Rock tea. In addition, a simple and fast method for determining the flavonoid glycosides in Wuyi Rock tea, except myricetin glycosides and quercetin glycosides, should be further developed.

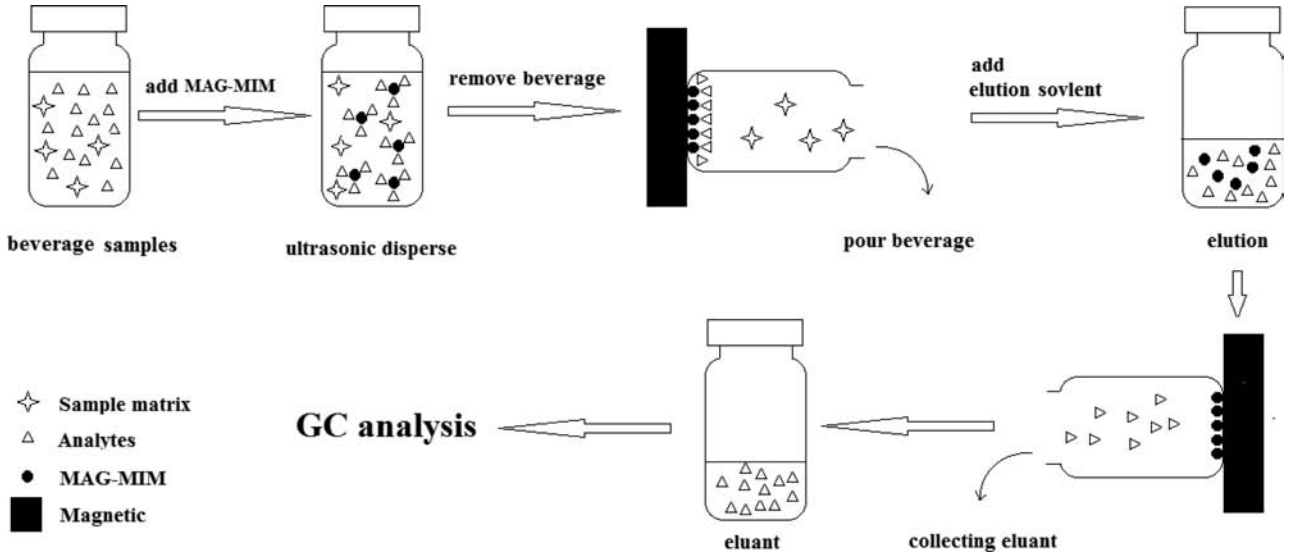

Figure 1. The MAG-MIM-dSPE procedure.

after removal of template molecules from polymers, leaving behind cavities for subsequent rebinding, which can selectively rebind target molecules from a mixture of closely related compounds. Compared with biological macromolecules such as antibodies, receptors, and enzymes, MIPs are much more stable and can be used under more demanding conditions.[36] However, most MIPs suffer from problems of poor recognition in water and template leakage at the present stage.

Furthermore, magnetic particles can be collected and separated from the liquid phase under an external magnetic field, which avoids tedious filtration or centrifugation procedures and allow particles to be easily retrieved at low cost.[37−39] If some magnetic components are encapsulated into MIPs, the resulting composite magnetic MIPs would not only have susceptible magnetic characteristics but also have high selectivity for the target molecule. Composite magnetic MIPs have been prepared, as reported in the literature, and they all exhibited higher recognition selectivity and certain magnetic responses to external magnetic fields.[40−43]

The aim of this work was to develop a new MAG-MIM-dSPE-GC method using composite magnetic dummy molecularly imprinted microspheres (MAG-MIM) as the adsorbents for dSPE in the selective extraction and determination of five phthalates from plastic bottled beverages. The new MAG-MIM adsorbents, which were synthesized by coprecipitation coupled with aqueous suspension polymerization using diisononyl phthalate as the dummy template, improve the poor selectivity of MIPs in a water environment and eliminate the effect of template leakage of MIPs upon quantitative analysis. The MAG-MIM-dSPE-GC method combines the quick separation of magnetic particles, special selectivity of MIM, and high extraction efficiency of dSPE and potentially could be applied to selective screening of phthalates in beverages.

EXPERIMENTAL PROCEDURES

Chemicals and Reagents. Butyl benzyl phthalate (BBP), diethyl phthalate (DEP), dibutyl phthalate (DBP), diisooctyl phthalate (DIOP), diisononyl phthalate (DINP), and dioctyl phthalate (DNOP) were obtained from Crystal Pure Industrial Co., Ltd. (Shanghai, China). Methanol (HPLC grade) was from Xingke Biochem. Co., Ltd. Chloroform, dichloromethane, poly(vinylpyrrolidone) (PVP), and ammonia were purchased from Huaxin Chemical Reagent Co., Ltd. (Baoding, China). Acetone, ethyl acetate, methanol, ethanol, and acetic acid were obtained from Huadong Chemical Reagent Co. (Tianjin, China). Iron(II) chloride tetrahydrate ($FeCl_2{\cdot}4H_2O$), iron(III) chloride hexahydrate ($FeCl_3{\cdot}6H_2O$), oleic acid, 2,2-azobis(isobutyronitrile) (AIBN), methacrylic acid (MAA), and acetonitrile were obtained from Kermel Chemical Reagents Center (Tianjin, China). Ethylene glycol dimethacrylate (EGDMA) was obtained from Sigma-Aldrich (St. Louis, MO). A Nd−Fe−B magnet (80 × 60 × 17 mm) was purchased from a local market in Baoding, China. All the reagents used in this work were of analytical grade (purity ≥99%). Double deionized water was filtered through a 0.45 μm filter membrane before use.

Instrumentation and Conditions. Chromatographic analysis was performed on a Shimadzu GC-2014 system equipped with a split/splitless injector and an FID detector (Shimadzu, Japan). High-purity nitrogen (99.999%) was used as carrier gas. A GH-300 high-purity hydrogen generator and a GA-2000A air pump (Beijing ZXHL Co., Ltd., China) were used to supply hydrogen gas and auxiliary gas (supply oxygen) at the rate of 40 and 400 mL/min, respectively. The capillary column was KB-1 (100% dimethyl polysiloxane as stationary phase, 30 m × 0.25 mm × 0.25 μm, Kromat, Delran, NJ), and its flow rate was set at 1.7 mL/min with a split ratio of 10. An N-2000 workstation (Zheda Zhineng, Hangzhou, China) was used as the data acquisition system. The temperature-programmed mode was as follows: the initial oven temperature was 150 °C for 2.0 min and then increased to 285 °C at the rate of 25 °C/min and held for 10 min. The temperatures of the injection port and FID detector were set at 290 °C and 300 °C, respectively. A Fourier transform infrared (FT-IR) spectrometer (Shimadzu, Japan) was employed to examine infrared spectra of obtained particles. Magnetic properties were measured with a LakeShore 7307 (Lakeshore Cryotronic) vibration magnetometer (VSM) at 300 K. The obtained particles were also characterized by thermogravimetric analysis (TGA, SDTA851E). The morphology of MAG-MIM was characterized by field-emission scanning electron microscopy (FE-SEM), S-4200 (Hitachi, Ontario, Canada). The morphology of Fe_3O_4 magnetite was characterized by transmission electron microscopy (TEM; JEM-100SX, JEOL, Tokyo, Japan).

Preparation of Fe_3O_4 Magnetite with a Hydrophobic Shell. The Fe_3O_4 magnetites with a hydrophobic shell were prepared by the coprecipitation method as follows: $FeCl_2{\cdot}4H_2O$ (0.02 mol) and $FeCl_3{\cdot}6H_2O$ (0.03 mol) were dissolved into 100 mL of deaerated deionized water, 2.0 mL of oleic acid was added dropwise into the solution, and then the mixture was placed in an ultrasonic environment for 20 min under vigorous stirring. Fifteen milliliters of aqueous ammonia was added drop by drop when the temperature of the water bath was elevated to 60 °C. After 30 min, when the temperature was elevated to

dx.doi.org/10.1021/jf4051705 | J. Agric. Food Chem. 2014, 62, 2782−2789

80 °C, another 2.0 mL of oleic acid was added. After 2.0 h, magnetic precipitates were isolated from the solvent by a permanent magnet and washed several times with highly purified deaerated water and ethanol to remove unreacted ferric chloride and oleic acid.

Preparation of MAG-MIM. The MAG-MIM were prepared as follows: Fe_3O_4 magnetite (4.0 mmol), diisononyl phthalate (DINP) (2.0 mmol), and MAA (8.0 mmol) were added into 20 mL of chloroform. After EGDMA (50 mmol) and AIBN (1.2 mmol) were added, the solution was sonicated for 5.0 min to fully dissolve them. Finally, the solution was added dropwise to PVP solution (27 mmol of PVP dissolved into 120 mL of water) by stirring at 600 rpm and heated at 60 °C for 24 h. After polymerization, the obtained MAG-MIM particles were separated, washed with methanol−acetic acid (9:1, v/v) and methanol, respectively, under ultrasound to remove template and unreacted reagents, and then dried under vacuum at 45 °C for 24 h. To verify the effectiveness of the cleaning process, the washing solvent (10 mL) was evaporated, and the sample mixture was redissolved in acetone (0.5 mL) before injection into the gas chromatograph. The magnetic nonimprinted microspheres (MAG-NIM) were prepared and processed similarly as above, except that template was not added.

MAG-MIM-dSPE Procedure. Plastic bottled beverages were obtained from local supermarkets in Baoding, and the MAG-MIM-dSPE procedure was performed as shown in Figure 1. MAG-MIM (100 mg) were added into a 10 mL beverage sample and entirely dispersed by ultrasound at room temperature. After 10 min, phase separation was performed by magnetic separation with a applied magnetic field (Nd−Fe−B magnet) in the bottom of bottle, and then the MAG-MIM were eluted with 7.0 mL ethyl acetate−acetic acid (85:15, v/v) to desorb analytes from the adsorbents. Finally, the eluent was evaporated under a gentle nitrogen stream, and the sample was reconstituted with 0.5 mL of acetone for further GC analysis.

RESULTS AND DISCUSSION

Preparation of MAG-MIM. The preparation of MAG-MIM particles involved the synthesis of hydrophobic superparamagnetic Fe_3O_4 particles, MIM functionalization of the magnetic particles, and removal of the template to generate the recognition sites. Hydrophobic superparamagnetic Fe_3O_4 particles were prepared by a modified coprecipitation method, and the TEM image of the hydrophobic Fe_3O_4 particles showed that their sizes were on nanoscale (Figure 2A). The surface of magnetite was hydrophobic with a coating of oleic acid, which avoided electrostatic agglomeration and ensured the uniform dispersion of magnetic nanoparticles in the polymerization solution and homogeneous embedding. Ultrasound treatment was employed for modification of Fe_3O_4, making the procedure simple, rapid, and easily controlled. This strategy was successful in the fabrication of magnetically susceptible polymer-supported imprinted microspheres. To improve binding capacity, selectivity, and compatibility of MAG-MIM in water, aqueous suspension polymerization was adopted. Moreover, diisononyl phthalate (DINP) was chosen as the template mimic, which eliminated the effect of template leaking during quantitative analysis and demonstrated special recognition ability for the five phthalates.

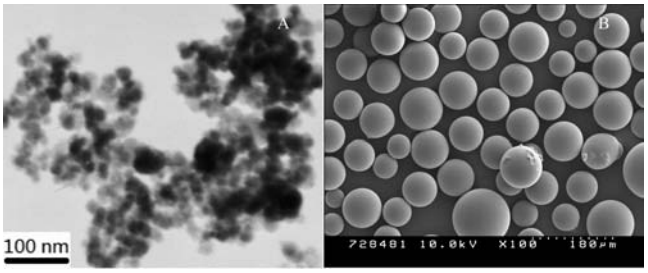

Figure 2. (A) Transmission electron microscopy (TEM) of Fe_3O_4 microspheres and (B) scanning electron microscopy (SEM) of MAG-MIM.

In the oil-in-water suspension polymerization, MAA was a common monomer, and EGDMA as a cross-linker maintained the stability of imprinting sites while making the polymer easier to be handled and processed. Generally, the molar ratios between template and monomer play an important role in the affinity and imprinting effect of MIM toward its template molecule. Therefore, the molar ratios between template and monomer of 1:2, 1:3, 1:4, and 1:6 were investigated, while a molar ratio of 4:25 between monomer and cross-linker was selected to ensure the formation of the defined recognition sites. When porogens had poor hydrogen bonding capacity, the interaction between template and functional monomer was mainly influenced by the dielectric constant of the solvent. The aprotic porogen with a small dielectric constant favored the formation of a higher concentration of template−monomer complexes, which resulted in MIM with high affinity and selectivity.[44] Therefore, taking hydrogen bonding capacity and dielectric constants of porogens into consideration, chloroform and toluene were investigated as porogens for the entire synthetic process. Figure 2B shows that the morphology of MAG-MIM was regular spherical when using chloroform as porogen and a molar ratio of 1:4:25 for template, monomer, and cross-linker. With further consideration to the mechanical strength and special affinity to phthalates, 20 mL of chloroform was chosen as porogenic solvent. Although water was considered to weaken, and even to eliminate, the noncovalent interaction (hydrogen bond, van der Waals force, etc.) between functional monomer and template, the MAG-MIM prepared by aqueous suspension polymerization using PVP as dispersing agent exhibited good recognition performance.

The GC-FID trace of washing solvent after five washes (Figure 8A) proved that methanol can dissolve and wash out DINP,[45,46] allowing MAG-MIM to be cleaned. The preparation method for MAG-MIM applied in this work was aqueous suspension polymerization, and the solvent was water in which methanol can effectively disperse and wash out the DINP template. Moreover, some added acetic acid can destroy the hydrogen bond for imprinting and help methanol wash out the template. Actually, on the basis of the dummy template strategy adopted in this work, residual DINP template on MIM was not washed out and leaked during the extraction procedure but would still not affect the quantitative determination because the leaked template can be fully separated from the analytes during GC separation.

Characterization of MAG-MIM. The products of Fe_3O_4 and MAG-MIM were investigated by FT-IR spectroscopy (Figure 3A). A sharp and strong Fe−O stretching peak (≈584 cm^{-1}) was observed in the trace of Fe_3O_4, while this characteristic peak was not in the trace of MAG-MIM, indicating that Fe_3O_4 magnetite of MAG-MIM was coated with polymers. The band at 1732 cm^{-1} was assigned to the absorption of COOH, and the band at 1233 cm^{-1} was ascribed to stretching vibrations of C−O−C in MAG-MIM. The characteristic bands at 2900 cm^{-1} and 1800 cm^{-1} of diisononyl phthalate still markedly existed in the spectra of MAG-MIM without extraction of the template, but they greatly weakened after extraction. In addition, the GC-FID trace of washing solvent after five washes (Figure 8A) show that MAG-MIM had

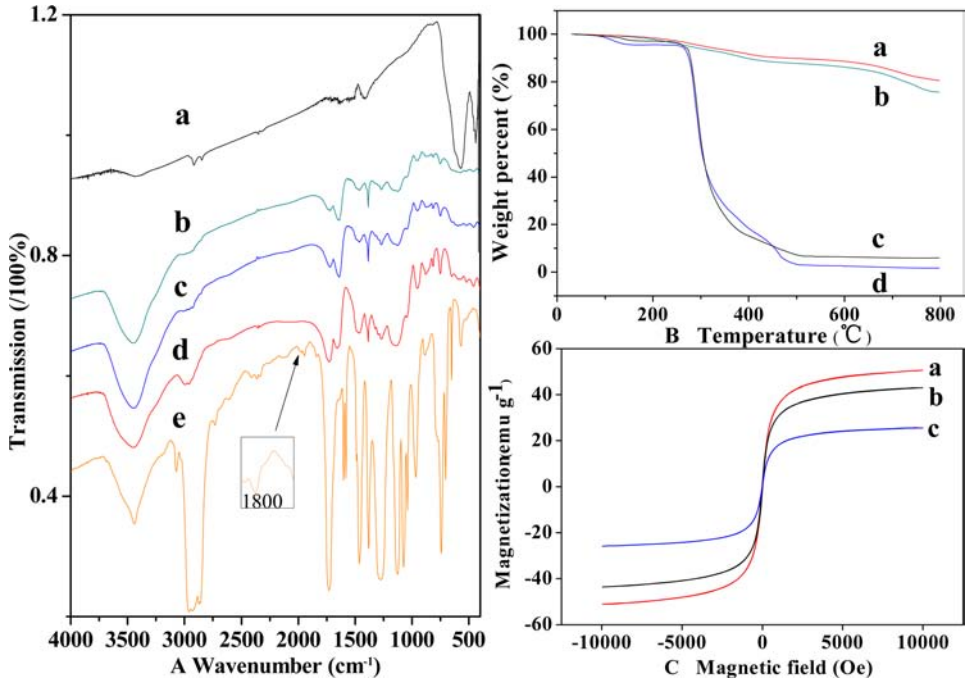

Figure 3. (A) FT-IR spectra of Fe_3O_4 particles (a), MAG-NIM (b), MAG-MIM after extraction of the template (c), MAG-MIM without extraction of the template (d), and diisononyl phthalate (e). (B) TGA of Fe_3O_4 (a), hydrophobic Fe_3O_4 (b), MAG-MIM (c), and MAG-NIM (d). (C) VSM of Fe_3O_4 (a), hydrophobic Fe_3O_4 (b), and MAG-MIM (c).

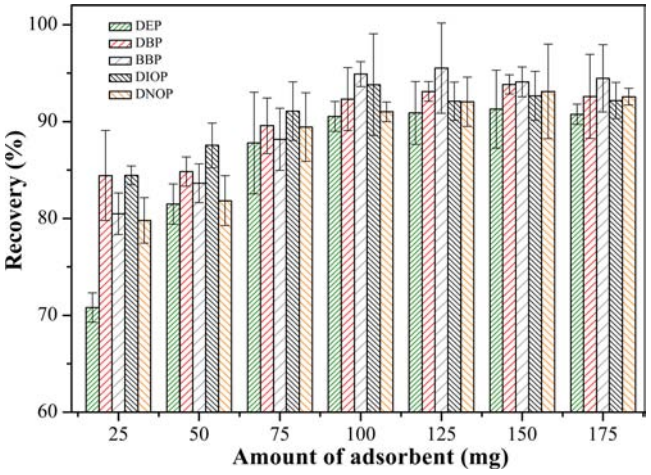

Figure 4. Effect of MAG-MIM amounts in dSPE.

been cleaned. All these observations indicated that MAG-MIM were prepared well.

Figure 3B shows the TGA curve of MAG-MIM and MAG-NIM compared with Fe_3O_4 magnetite and hydrophobic Fe_3O_4 magnetite. There was no dramatic weight loss below temperature of 240 °C, which means that all materials were stable under 240 °C. Significant weight loss occurred from 270 °C to 450 °C owing to the thermal degradation of MIM polymer (c) and NIM polymer (d). The outside layer of beads was a polymer mixture resulting from a different degree of polymerization. This caused the inflection (e.g., at about 10%) and different degradation rates in the TGA trace of MIM (c) and NIM (d). The remaining weight was attributed to the existence of Fe_3O_4 particles, and the quantity of loss of hydrophobic Fe_3O_4 magnetite (b) was more than Fe_3O_4 magnetite (a) without chemical modification, respectively.

The magnetic properties of the obtained materials were analyzed by VSM at room temperature, and the results are illustrated in Figure 3C. It is obvious that there was no hysteresis; both remanence and coercivity were zero, suggesting that the materials were superparamagnetic. The saturation magnetization (M_s) values of Fe_3O_4 magnetite, hydrophobic Fe_3O_4 magnetite, and MAG-MIM were about 51, 44, and 26 emu/g, respectively. The decrease of the M_s value was due to the coating of a hydrophobic layer and an organic polymer shell layer. Although the M_s value of MAG-MIM was reduced to 26 emu/g, they were susceptible to magnetic fields and could be easily separated from a suspension.

Optimization of MAG-MIM-dSPE Procedures. Various factors influencing the MAG-MIM-dSPE extraction effect were investigated, and the results are shown in Figures 4–6. Regarding the MAG-MIM particles that were dispersed in 10 mL of sample solution to rebind the five phthalates during the extraction procedure, the amount of adsorbent used should provide sufficient binding sites for the analytes and achieve good recoveries. Therefore, the minimum amount of MAG-MIM to achieve efficient recoveries was investigated, and Figure 4 shows that the recoveries for the five phthalates were more than 90.5% when 100 mg of MAG-MIM was added to samples, while the recoveries kept constant with a further increase to 175 mg. Therefore, 100 mg of MAG-MIM was selected as the optimal amount of dSPE adsorbent.

When 100 mg of MAG-MIM was dispersed in a sample solution, the analytes should contact the surface of sorbents and attain adsorption−desorption equilibrium in the appropriate time. As shown in Figure 5A, the influence of adsorption time was studied, and extraction equilibria were obtained in a short time. DBP and BBP achieved the largest extraction recoveries in 3 min, while DEP, DIOP, and DNOP needed 10 min to ensure full extraction because the structures of DBP and BBP matched the binding sites of MAG-MIM better than DEP, DIOP, and

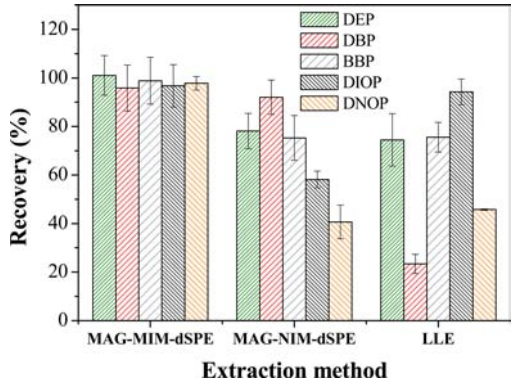

Figure 7. Comparison of MAG-MIM-dSPE, MAG-NIM-dSPE, and simple ethyl acetate extraction.

DNOP. Therefore, the time of adsorption was determined for 10 min.

Generally, an increase in ionic strength decreased the concentration of analytes in sample solution and enhanced the extraction efficiency of MAG-MIM. To evaluate the possibility of a salting out effect, extraction efficiency was studied with an increase in sodium chloride concentration over a range of 0−6% (w/v). As shown in Figure 5B, there was almost constant extraction recovery with an increase of salt concentration from 0% to 1% and then a slight decrease in recovery with a further increase to 6% in salt concentration, which indicated that the ionic strength of the samples hardly interfere with extraction efficiency. Similarly, when the influence of pH was investigated, as shown in Figure 5C, there was no obvious variation in extraction efficiency in a pH range from 3.0 to 9.0 probably because the phthalate structures

dx.doi.org/10.1021/jf4051705 | J. Agric. Food Chem. 2014, 62, 2782−2789

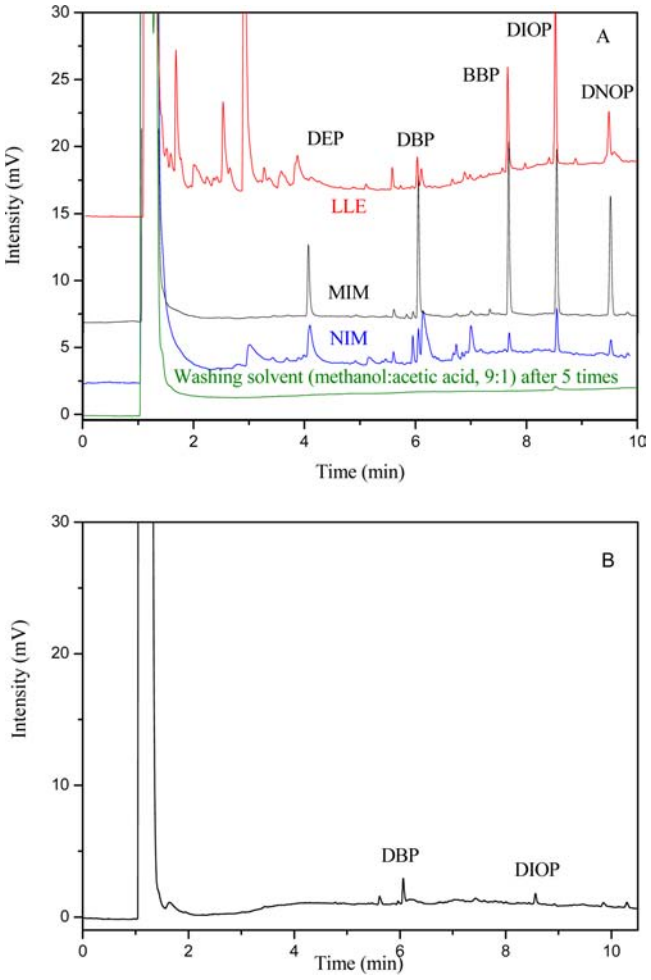

Figure 8. Chromatograms of (A) spiked beverage sample and (B) real sample.

were stable and the MAG-MIM-dSPE extraction procedure was not easily affected by an acid or alkaline environment. Considering that the beverage samples were neutral or slightly acidic, pH was not adjusted for further experiments. The effect of organic matter in the sample matrix was also investigated. The beverage samples used in this work were vitamin drinks, and most of the compounds in the sample matrixes were water-soluble vitamins (such as vitamins B6, B12, and C and niacinamide). These vitamins were hardly absorbed by MAG-MIM in the aqueous matrix, so there was very little effect on the recovery of PAEs (Figure 6A).

After phase separation by an applied magnetic field in the bottom of bottle, the MAG-MIM adsorbent was eluted to desorb the analytes. The phthalates were extracted well by most organic solvents. The solvent molecules were adsorbed easily on the surface of the adsorbent polymer to replace the analyte molecules. A small amount of acetic acid was added to contribute to the destruction of the hydrogen bonds between analytes and binding sites on the adsorbents. Therefore, different kinds and volumes of organic solvents coupled with 15% acetic acid were investigated. Figure 6B shows that 7.0 mL of ethyl acetate−acetic acid (85:15, v/v) was used as the desorption solvent to strip the adsorbed analytes from MAG-MIM.

The time of desorption also investigated as shown in Figure 5D. The new adsorption−desorption equilibria were obtained in a short time. The polarity of DEP can be inferred from its structure, so the extraction equilibrium in strong hydrophobic solvent would take a longer time than that of other analytes. Considering time efficiency, 5 min was selected as the optimum desorption time.

Moreover, the MAG-MIM-dSPE method was compared with MAG-NIM-dSPE in parallel using simple ethyl acetate extraction according to their optimization steps. Recoveries with MAG-MIM-dSPE for phthalates were more than those with MAG-NIM-dSPE or liquid−liquid extraction (LLE), as shown in Figure 7, obtained for spiked beverages (0.040 μg/mL). The chromatograms of MAG-MIM-dSPE, MAG-NIM-dSPE, and LLE are shown in Figure 8A, and the effect of nonselective uptake (interferences) from LLE was worse than that of MAG-NIM-dSPE. The lack of selectivity aggravated the serious inaccuracies in determination. There were many impurity peaks that interfered with the determination of the phthalates as shown in the chromatograms of MAG-NIM-dSPE and LLE. MAG-MIM-dSPE-GC background from the beverage matrix was more or less identical to that of MAG-NIM-dSPE-GC. For example, a peak (≈6 min) was observed in the chromatogram of LLE and MAG-NIM-dSPE-GC, while it did not appear in the chromatogram of MAG-MIM-dSPE-GC. The reason for this may be the effective utilization of functional groups on polyacrylate during the templating process of MAG-MIM, resulting in relatively reduced nonselective binding for the beverage constituents. All aforementioned details indicate that the templating of MIM was successful. In summary, the utility of MAG-MIM-dSPE is reliable for selective screening of phthalates in beverages.

Validation of the MAG-MIM-dSPE-GC Method. To validate the analytical methodology of the MAG-MIM-dSPE-GC method, several parameters such as linearity, recovery,

Table 2. Recoveries in the MAG-MIM-dSPE-GC Method for Spiked Beverage (n = 3)

[a]Not given in the literature. [b]Magnetic solid-phase extraction, the same as dSPE.

reproducibility, limit of detection (LOD), and limit of quantification (LOQ) were evaluated. All parallel experiments were repeated three times, and the results are tabulated in Table 1. The linearity of the MAG-MIM-dSPE-GC method was tested using the areas of chromatographic peaks measured at nine increasing spiked levels in a range of 0.0040−0.40 μg/mL. Good linearities were obtained throughout the concentration range for all analytes with the correlation coefficient (r^2) ≥ 0.9991. Analyses of reproducibility of intraday and interday were carried out for spiked beverage samples (0.08 μg/mL), and RSD values of intraday and interday were less than 6.9% and 7.2%, respectively. The LOD values calculated on the basis of S/N = 3 were in a range of 0.53−1.2 μg/L for all analytes. On the basis of S/N = 10, the LOQ values of analytes were from 1.8 to 4.0 μg/L. Spiked recoveries were determined to validate the method on the basis of the obtained linearity (taking the form of $Y = aX + b$). Recoveries were calculated as:

$$R = \frac{P - b}{a \times C_s} \times 100\%$$

In the equation, R stands for the recovery value, P is the peak area, C_s is the actual concentration, and a and b are two coefficients of the obtained linear equation. The average recoveries for the five phthalates in spiked samples were in a range of 89.5−101.3% (Table 2), which demonstrated that the proposed MAG-MIM-dSPE-GC technique was reliable. The parameters of the present MAG-MIM-dSPE-GC method (such as recovery, LOD, RSD, and estimated time) were justified briefly in comparison with other procedures reported in the literature, indicating that the method is reliable and practical (Table 3).

Real Sample Analysis. To demonstrate the suitability and application of the MAG-MIM-dSPE-GC method for actual samples, five brands of vitamin beverage products collected from local markets in Baoding were pretreated and analyzed under optimal MAG-MIM-dSPE-GC conditions. Figure 8B shows that trace levels of DBP and DIOP at concentrations of 5.7 μg/L and 4.0 μg/L were observed in one of the beverage products, and water-soluble vitamins (such as vitamins B6, B12, and C and niacinamide) (which are the main components in beverage matrixes) did not interfere with the screening of the phthalates.

and *N*-(6-chloro-3-pyridylmethyl)-*N*-ethyl-*N*′-methylformamidine (CPMF)], and a major metabolite of thiacloprid (thiacloprid amide), all of >95% purity, were purchased from Wako Pure Chemical Industries (Osaka, Japan), Dr. Ehrenstorfer (Augsburg, Germany), and Fluka-Sigma-Aldrich (Steinheim, Germany), respectively. Pesticide analysis grade and HPLC grade organic solvents, HPLC grade formic acid, and other analytical grade reagents were obtained from Kanto Chemical Co. (Tokyo, Japan) or Wako Pure Chemical Industries. Pure water for sample preparation and LC-MS/MS analysis was prepared in the laboratory by means of a water purification system (Milli-Q, Millipore Corp., Bedford, MA, USA). ENVI-Carb II/PSA SPE cartridges (500 mg of graphitized carbon black and 500 mg of ethylenediamine-*N*-propyl silica gel) and ENVI-Carb/LC-NH_2 SPE cartridges (500 mg of graphitized carbon black and 500 mg of aminopropyl silica gel) were purchased from Supelco (Bellefonte, PA, USA).

Stock and Working Solutions. Stock solutions of CPMA in water and the other target compounds in methanol were prepared, and the solutions were stored in the dark at 4 and −20 °C, respectively. Multicomponent working solutions (1, 10, and 100 mg/L) were prepared by diluting each stock solution with 20:80 (v/v) methanol/water at every recovery test and LC-MS/MS analyses, and the working solutions were used as calibration standards and for spiking agricultural samples.

Agricultural Samples. Green peppers and tomatoes were used as model agricultural crops. Green peppers and tomatoes were chopped and homogenized by a home food processor (KC-D627, TWINBIRD Corp., Niigata, Japan). For the preparation of spiked samples for recovery tests, green peppers and tomatoes were grown on arable land of the Japan Plant Protection Association (Miyazaki, Japan) without the use of neonicotinoid insecticides. The absence of the target compounds in the vegetables was confirmed by LC-MS/MS prior to each experiment. For the recovery tests, a homogenized sample (5 g) was spiked with 50 μL of the 1, 10, or 100 mg/L multicomponent working solution (0.01, 0.10, or 1.00 mg/kg, respectively). The spiked samples were exposed to the target compounds for 30 min prior to extraction.

In addition to the spike−recovery tests, we also conducted tests on green peppers and tomatoes sprayed with commercial formulations of the target compounds. The plants were grown in a plastic greenhouse on arable land of the National Institute for Agro-Environmental Sciences and, at the harvesting stage, were sprayed with a mixture of four neonicotinoid insecticide formulations: Mospilan (water-soluble powder), containing 20.0% acetamiprid (Nippon Soda Co., Tokyo, Japan); Admire (water-soluble granules), containing 20% imidacloprid (Bayer Crop Science, Tokyo, Japan); Bariard (water-soluble granules), containing 30% thiacloprid (Bayer Crop Science); and Actara (water-soluble powder), containing 10% thiamethoxam (Syngenta Japan K.K., Tokyo, Japan), all diluted with water according to the manufacturers' instructions. The samples were harvested at 1, 3, and 7 days after spraying. After harvesting, the samples were chopped and homogenized by a home food processor.

Sample Preparation. *Proposed Water-Based Extraction Method.* A 5 g aliquot of homogenized sample was weighed into a 100 mL centrifuge tube, and 25 mL of water was added to the tube. The sample was shaken vigorously for 30 min on a shaker (SA-400, Yamato Scientific Co., Tokyo, Japan) and then centrifuged at approximately 1400*g* for 20 min. The sample mixture was suction-filtered through a glass fiber filter (60 mm in diameter, GF-B, Kiriyama Glass Co., Tokyo, Japan), and the solid residue on the filter was washed with 15 mL of water. The volume of the extract was brought to exactly 50 mL with water, and then 2 mL aliquots (equivalent to 0.2 g of sample) were added to 10 mL of acetonitrile. The solution obtained by adding 2 mL aliquots to 10 mL of acetonitrile was cleaned up according to the procedure established by Kobayashi,[16] as follows. The solution was loaded onto an ENVI-Carb II/PSA SPE cartridge preconditioned with 5 mL of acetone and 5 mL of *n*-hexane. The target compounds were eluted with 5 mL of acetonitrile/toluene (3:1, v/v). The eluate was concentrated and evaporated to dryness with a gentle stream of nitrogen. The residue was reconstituted with 1 mL of 20:80 (v/v) methanol/water, and the resulting solution was filtered with a polytetrafluoroethylene membrane syringe-driven filter unit (0.45 μm, GL Sciences Inc., Tokyo, Japan).

Japanese Official Method (Reference Method). To verify the applicability of the proposed water extraction method, we used the

[a]MS-MS transition used for quantification. [b]MS-MS transition used for conformation.

Japanese official method[26] as a reference method as follows. Acetonitrile (50 mL) was added to 20 g of homogenized sample, and the slurry was extracted for 3 min with a high-speed homogenizer (Polytron PT2100, Kinematica AG, Lucerne, Switzerland). The sample mixture was suction-filtered, and the solid residue on the filter was extracted again with 20 mL of acetonitrile. The volume of the combined extracts was brought to exactly 100 mL with acetonitrile, and 20 mL aliquots of the extract (equivalent to 4 g of sample) were mixed with 10 g of sodium chloride and 20 mL of 0.5 M phosphate buffer (pH 7). The resulting mixture was shaken vigorously for 10 min and then allowed to stand for about 10 min. After the aqueous phase was discarded, the acetonitrile phase was dried with anhydrous sodium sulfate and filtered, and the filtrate was concentrated and evaporated to dryness with a gentle stream of nitrogen. The residue was reconstituted in 2 mL of acetonitrile/toluene (3:1, v/v), and the resulting solution was loaded onto an ENVI-Carb/LC-NH_2 SPE cartridge preconditioned with 10 mL of acetonitrile/toluene (3:1, v/v). After the target compounds were eluted with 20 mL of acetonitrile/toluene (3:1, v/v), the eluate was concentrated. The residue was reconstituted in 10 mL of acetone. The resulting solution was concentrated, and 5 mL of acetone was added to the residue. The acetone was evaporated under a gentle stream of nitrogen. After the residue was reconstituted with 1 mL of methanol, the solution was diluted five times with methanol/water (20:80, v/v) and filtered through a polytetrafluoroethylene membrane syringe-driven filter unit.

Evaluation of Matrix Effects. To evaluate matrix effects, we used the proposed water extraction method and the reference method described above to prepare cleaned up extracts of nonspiked samples. The cleaned up extracts were dissolved in 1 mL of methanol/water (20:80, v/v), and then 0.04 μg of each target compound was added to the extracts. Matrix effects were evaluated according to a method described in an earlier paper,[27] and the magnitude of the effects was calculated by means of the following equation:

$$\text{matrix effect (\%)} = \left[\frac{\text{peak area of standards in cleaned up extract}}{\text{peak area of standards in pure solvent}} - 1\right] \times 100$$

LC-MS/MS Analysis. LC-MS/MS analysis was carried out with an HPLC system (Alliance 2695 series, Waters, Milford, MA, USA) equipped with a pump, a degasser, an autosampler, and a column oven. The target compounds were separated on an Atlantis T3 analytical column (50 mm × 2.1 mm i.d., 3.5 μm particle size) fitted with an Atlantis T3 guard column Atlantis T3 (10 mm × 2.1 mm i.d., 3.5 μm particle size), both from Waters. The column oven temperature was kept at 30 °C. The injection volume was 10 μL, and the flow rate was 0.2 mL min^{-1}. Mobile phases A and B were methanol and 5 mM ammonium acetate containing 0.1% formic acid, respectively. A gradient mobile was used, with the A:B ratio varied as follows: 0 min, 20:80; 5 min, 20:80; 10 min, 95:5; 13 min, 95:5; 13.5 min, 20:80; 25 min, 20:80.

The MS/MS system (Quattro Micro API, Micromass, Manchester, UK) was a triple-quadrupole tandem mass spectrometer equipped with an electrospray ionization (ESI) interface. For all compounds, the MS instrument was operated in the ESI positive-ion mode at a desolvation temperature of 350 °C and a source temperature of 120 °C and at an ESI voltage of 3.9 kV. Nitrogen was used as the desolvation gas at a flow rate of 600 L/h. For collision-induced dissociation, argon gas was used as the collision gas at a pressure of 4.5×10^{-3} mbar in the collision cell. Mass spectrometric detection was performed in multiple reaction monitoring mode. The multiple reaction monitoring transitions were selected and tuned by direct syringe pump infusion of a 5.0 mg/L standard solution of each compound prepared in methanol/water 20:80 (v/v) into the spectrometer at a flow rate of 10 μL/min. The dwell time for each transition was 300−600 ms. Optimized MS/MS transitions as well as specific cone voltages and collision energies are summarized in Table 2.

Under the chromatographic conditions described, calibration graphs were constructed by plotting peak areas versus concentrations. Excellent linearity and regression coefficient (r) were achieved for all of the target compounds in this study (Table 2). The limit of detection for each compound was determined as the lowest concentration of each compound that gave a signal-to-noise ratio of at least 3.

RESULTS AND DISCUSSION

Optimization of LC-MS/MS Conditions. To achieve good separation of the target compounds with high sensitivity, we analyzed all samples using a slightly modified version of the LC gradient program reported by Kobayashi.[16] This gradient program resulted in good sensitivity and peak shape for all of the target compounds. We optimized the MS parameters and multiple reaction monitoring transitions for the maximum abundance of fragmented ions under ESI positive-ion mode conditions by infusing standard solutions of the target compounds into the mass spectrometer (Table 2). Full-scan spectra were measured for selection of the most abundant m/z values. For each target compound, the addicted ion $[M + H]^+$ was determined as a precursor ion. The optimal collision energy for each target compound was selected, which yielded the most abundant product ion by dissociation of each precursor ion in the collision cell.

Matrix Effects. Matrix effects have been widely studied and are recognized as a source of error in quantitative LC-ESI-MS/MS analysis of food samples.[28] Matrix effects result from competition between matrix ions and analyte ions in the sprayed solution for access to the droplet.[29] Depending on the environment in which ionization and ion evaporation take place, this competition can either suppress or enhance the efficiency of analyte ion formation.[30]

We evaluated matrix effects on the results of analysis of the target compounds in green peppers and tomatoes by means of the proposed water-based extraction method and the reference method (Figure 1). For all of the target compounds, the

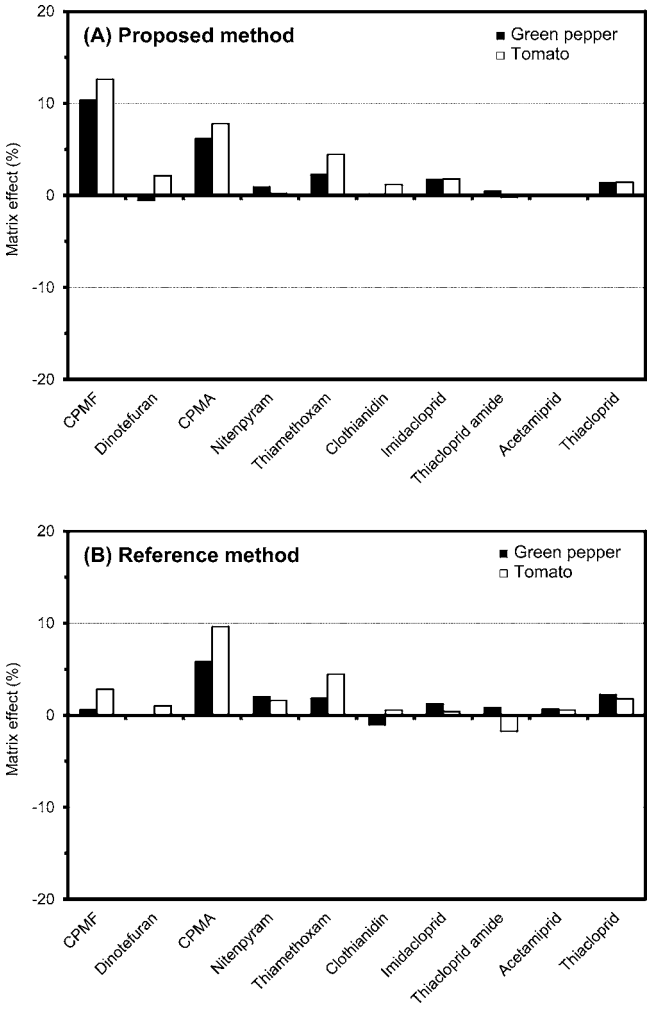

Figure 1. Matrix effects in the proposed water-based extraction method and the reference method.

magnitude of the matrix effect was between −1.7 and +12.6%; this result indicates that for all the combinations of target compounds and matrices in this study, there was no substantial signal suppression or enhancement (matrix effect within ±20%) that interfered with accurate determination by LC-MS/MS analysis according to the criteria explained by Mol et al.[31] On the basis of our results, we performed calibration of the target compounds with external standards diluted with 20:80 (v/v) methanol/water. Some studies[21,32,33] on the QuEChERS method reported that matrix-matched calibration was performed because there was substantial signal suppression and enhancement for the combinations of some pesticides and matrices. On the other hand, matrix effects in the proposed method were not significant; therefore, the target compounds in this study could be analyzed with good precision by calibration with external standards. From the viewpoint of calibration of the target compounds without matrix-matched standards, the proposed method might have an advantage over the QuEChERS method.

Precision and Accuracy of the Proposed Water-Based Extraction Method. We conducted recovery tests on samples spiked with the target compounds at three concentrations (0.01, 0.10, and 1.00 mg/kg; Table 3). The recoveries and relative standard deviations were in the range of 71.2−112.8 and ≤7.5%, respectively, except for the recoveries of imidacloprid (122.3 ± 2.5%) and nitenpyram (121.7 ± 4.9%) in tomato samples spiked at 0.01 mg/kg. For most of the target compounds, the recoveries and relative standard deviations were within the criteria specified in Japanese and European guidelines for validation of pesticide residue analysis methods (70−120 and <20%, respectively).[34,35] These results are indicative of the good precision and accuracy of the proposed water-based extraction method. Although the water solubility and octanol−water partition coefficients of CPMA, CPMF, and thiacloprid amide have not been reported, these metabolites are thought to be at least as hydrophilic as the respective parent compounds. Xiao et al.[20] reported that neonicotinoid insecticides in bovine tissues can be recovered almost completely by means of extraction with pressurized pure water. Our results confirmed that the hydrophilic neonicotinoid insecticides and their metabolites targeted in this study could be extracted into water and recovered, suggesting that the proposed environmentally friendly water-based extraction method is potentially useful for the analysis of hydrophilic pesticides such as neonicotinoid insecticides and related metabolites.

Applicability of the Proposed Method to Samples Sprayed with Commercial Insecticide Formulations. We evaluated the relationship between the analytical results obtained by means of the proposed water-based extraction method and the reference method with green pepper and tomato samples that had been sprayed with four commercial neonicotinoid insecticide

dx.doi.org/10.1021/jf405311y | J. Agric. Food Chem. 2014, 62, 2790−2796

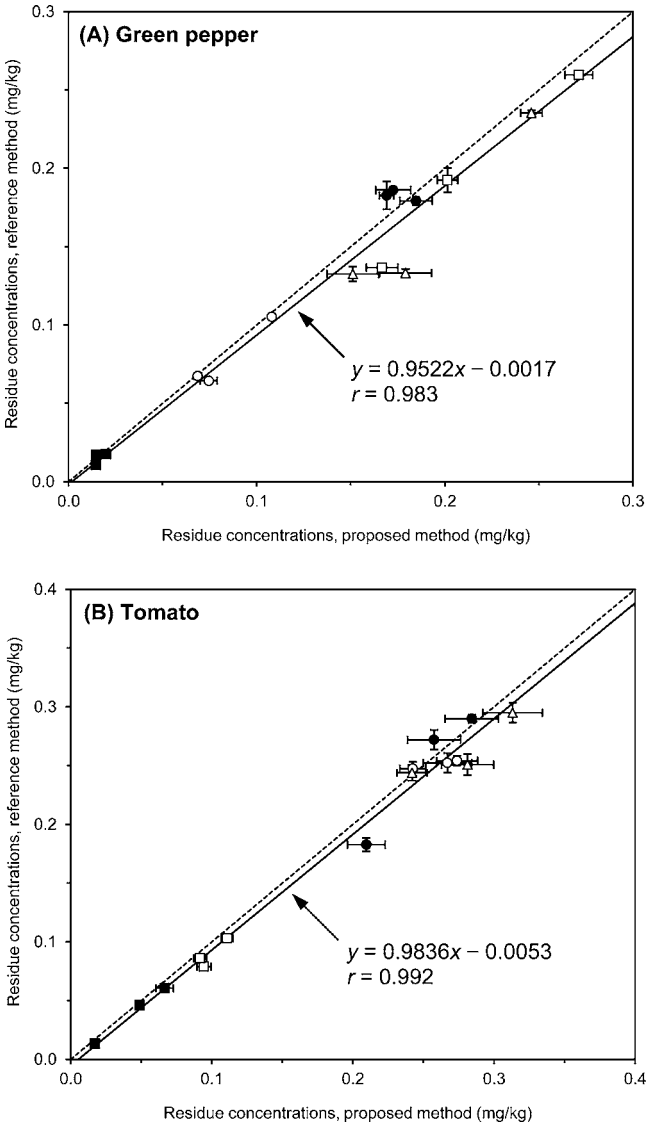

Figure 2. Relationship between residue concentrations in green pepper and tomato samples determined by the proposed water-based extraction method and by the reference method: (○) acetamiprid; (□) clothianidin (a metabolite of thiamethoxam); (△) imidacloprid; (●) thiacloprid; (■) thiamethoxam. Each point is the average of four replicate determinations. The dotted line corresponds to a perfect correlation ($y = x$).

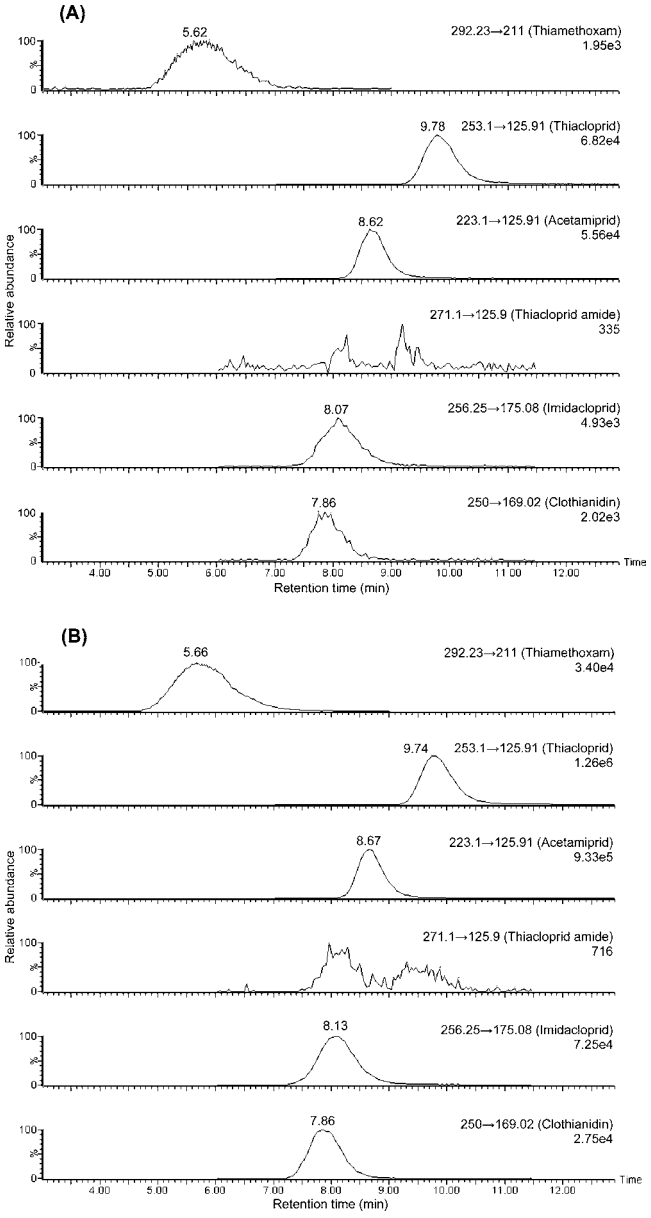

Figure 3. Chromatograms of target compounds obtained from tomato samples harvested 7 days after being sprayed with mixtures of the insecticide formulations by the proposed water-based extraction method (A) and by the reference method (B).

formulations (Figure 2). Acetamiprid, imidacloprid, thiacloprid, thiamethoxam, and clothianidin (a metabolite of thiamethoxam) were detected at >0.01 mg/kg in the samples. The residual concentrations of the target compounds in the green pepper samples determined by means of the proposed method and the reference method were 0.015−0.27 and 0.017−0.26 mg/kg, and those in the tomato samples were 0.017−0.31 and 0.013−0.30 mg/kg, respectively. The residual concentration of thiacloprid amide in the samples was <0.01 mg/kg. Figure 3 shows chromatograms of target compounds obtained from green pepper and tomato samples harvested 7 days after being sprayed with mixtures of the insecticide formulations. The slopes of the simple linear regression equations describing the relationship between the pesticide concentrations detected by means of the proposed method and the reference method were approximately 1; specifically, the slope for the green pepper samples was 0.95 ($r = 0.98$) and that for the tomato samples was 0.98 ($r = 0.99$), indicating that the concentrations detected by means of the two methods were equivalent. Our results suggest that the proposed method can be also applicable for spraying crops and market samples with hydrophilic pesticides.

The proposed environmentally friendly water-based extraction method for agricultural samples here demonstrates that (1) the consumed volume of organic solvent (25 mL per sample) is much less than the volume consumed by the official Japanese multiresidue method (150 mL per sample) and (2) it has simple procedures without liquid−liquid partitioning and can simultaneously and suitably recover hydrophilic pesticides as well as polar metabolites such as CPMA and CPMF that cannot be simultaneously recovered by the official Japanese multiresidue method. To secure food safety, this proposed method could be utilized for regular monitoring of neonicotinoid insecticides and their metabolites in high water content crops, such as green

dx.doi.org/10.1021/jf405311y | J. Agric. Food Chem. 2014, 62, 2790−2796

peppers and tomatoes, and for monitoring before shipment of these crops.

Chinese yellow-rice wine. However, the method needed different excitation and emission wavelengths at different times. After that, Wang et al.[30] developed an HPLC−FLD procedure (λ_{ex} of 234 nm and λ_{em} of 600 nm) to simultaneously detect EC and urea in Chinese yellow-rice wine. The method featured high recovery and good repeatability. However, their report did not provide any spectral information about the analytes. Moreover, the understanding of the derivatization conditions is insufficient, and the detection limit for urea is too high to monitor its variation in the brewing process of some alcoholic beverages. Therefore, in this work, we further studied the HPLC−FLD method and applied it to more alcoholic beverages. First, we systematically investigated the excitation wavelength and emission wavelength of the derivatized analytes. Then, the derivatization and separation conditions of analytes were optimized. Next, the parameters of the developed method were evaluated. Finally, we applied the developed method to the analysis of real samples from the Chinese market.

MATERIALS AND METHODS

Reagents and Solvents. Milli-Q-RG (Millipore, Milford, MA) high-purity water was used for dissolution of chemicals and dilution. Acetic acid, ethanol, hydrochloric acid, 1-propanol, and sodium acetate, purchased from Merck (Darmstadt, Germany), were of analytical grade. Acetonitrile of HPLC grade was purchased from Merck. EC (99%) and urea (99%) were purchased from Sigma Chemical Co. (St. Louis, MO). 9-Xanthydrol (99%) was purchased from Fluka Chemicals Co. (Buchs, Switzerland).

Samples. Red wines, grape brandies, and Chinese rice wines were purchased from the Chinese market. All of the information regarding the samples was obtained from the sample labels. The alcoholic strength of red wines, grape brandies, and Chinese rice wines ranged from 11.5 to 12% (v/v), 38 to 40% (v/v), and 15 to 16% (v/v), respectively. The red wines were made from *Cabernet Sauvignon* grapes grown in the Huaizhuo basin district (Hebei Province, P. R. China); we studied 2008, 2010, and 2011 vintages. The grape brandies were produced by three different manufacturers (namely, Greet Wall, The Dynasty, and Zhang Yu Wine Co. Ltd.) and aged for 3−15 years. The Chinese rice wines were produced by four different manufacturers (namely, Jiashan Youhua, Tapai, Gu Yue Long Shan, and Fuchunjiang Wine Co. Ltd.). All of the companies are from Zhejiang Province, P. R. China. All of the Chinese rice wines were semidry rice wines.

Sample Derivatization. The derivatization reaction was conducted in chromatographic vials as follows: 0.4 mL of the 9-xanthydrol solution (0.02 mol of 9-xanthydrol per liter in 1-propanol) was added to 0.6 mL of a sample or standard, and then 0.1 mL of hydrochloric acid (1.5 mol/L) was slowly added.

To ensure the reaction reached completion, the solution was homogenized and held for 30 min in the dark before being injected into chromatographic system for analysis. Three repeated injections of standard solutions, at six concentrations, were used to generate calibration curves.

HPLC−FLD. The experiments were conducted on an Agilent 1200 series analytical HPLC system equipped with a quaternary solvent delivery system and a G1321A fluorescence detector. The separations were performed on an Agilent Zorbax Eclipse XDB-C18 column (250 mm × 4.6 mm, 5 μm). The flow rate was 1.0 mL/min, the oven temperature 30 °C, and the injection volume 20 μL. The excitation and emission wavelengths were 240 and 308 nm, respectively. Phase A was sodium acetate (pH 7.2, adjusted with acetic acid). Phase B was acetonitrile. Elution was conducted using a gradient program as indicated in Table S1 of the Supporting Information. Quantitation was performed in accordance with an external standard method.

Validation. Method validation was performed following the recommendation of the International Conference on Harmonization.[31] The method was validated for linearity, stability, limits of detection (LOD), limits of quantification (LOQ), precision, and accuracy.

RESULTS AND DISCUSSION

Fluorescence Characteristics. To optimize fluorescence detection, 1 mg/L EC and urea in anhydrous alcohol were derivatized to obtain the three-dimensional spectra of xanthyl EC (XEC) and xanthyl urea (Xurea) (Figure 2). It is evident that XEC and the Xurea have similar fluorescence characteristics, which is consistent with the work of Francis et al.[27] This similarity is caused by their similar molecular structures. The diagonal bands in panels a and b of Figure 2 could be the result of Rayleigh and Raman scattering by solvent molecules. This possibility is supported by the fact that these diagonal signals were present in the contour plot of the blank working solutions. Both XEC and Xurea exhibit maximal fluorescence at 308 nm after excitation at 213 or 240 nm.

For the detection of fluorescence from Xurea, Herbert et al.[26] used excitation and emission wavelengths of 233 and 600 nm, respectively. Francis et al.[27] later verified that the peak at 592

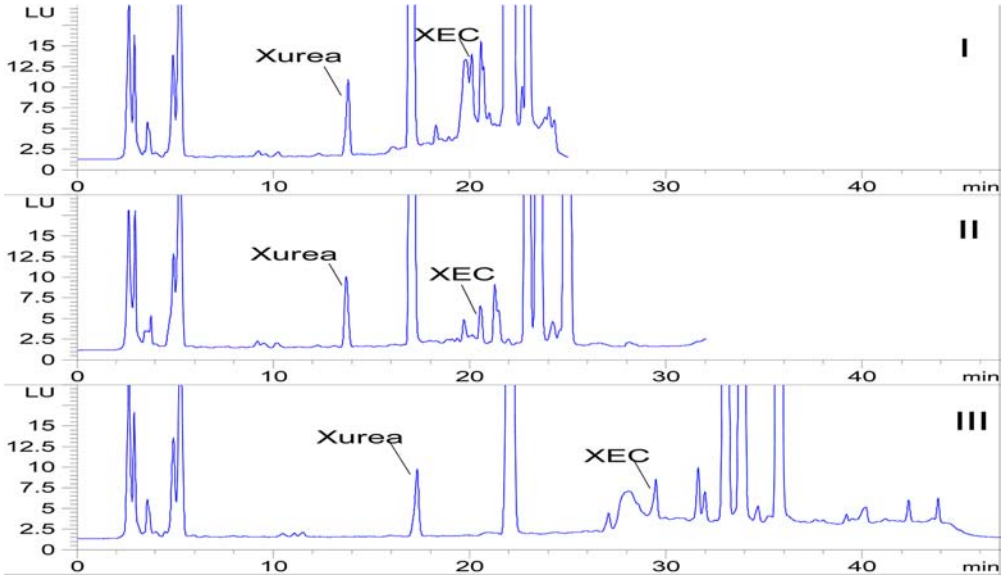

Figure 3. Determination of urea and EC in a 20% alcohol/water mixture using three gradient programs.

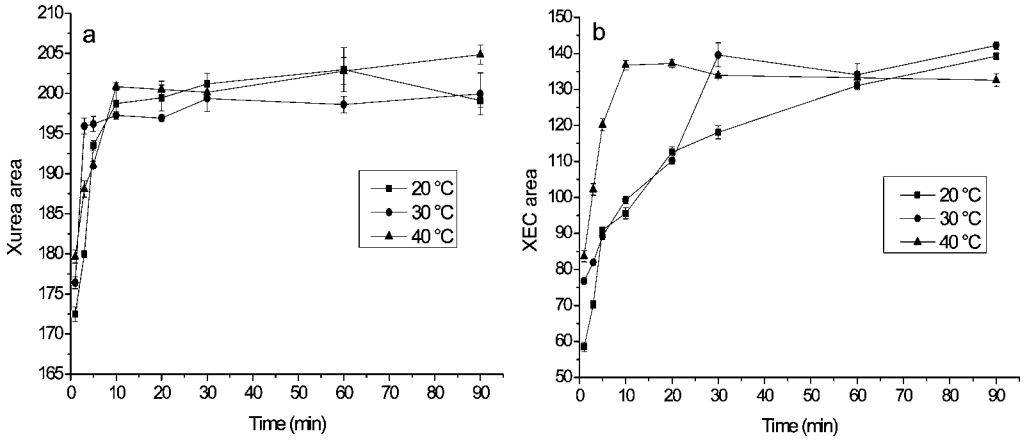

Figure 4. Formation of Xurea (a) and XEC (b) as a function of reaction time and temperature.

nm (corresponding to 600 nm) was actually an artifact of the instrumentation. They observed similar maxima at 211 and 240 nm in the excitation spectrum and 298 nm in the emission spectrum. Our results are consistent with the report of Francis et al.;[27] the slight discrepancies in the emission maxima were due (in part) to the different slit widths used in each instrument.

For the detection of the fluorescence of XEC, Herbert et al.[17] used excitation and emission wavelengths of 233 and 600 nm, respectively. Mihucz et al.[28] later detected XEC at λ_{ex} and λ_{em} wavelengths of 238 and 300 nm, respectively, because they observed that the peak at 300 nm was more intense than that at 600 nm. Our results are consistent with the report of Mihucz et al.

Although wavelengths of 213 or 240 nm could excite the same intense peak at 308 nm, we chose an excitation wavelength of 240 nm and an emission wavelengths of 308 nm for the characterization of XEC and Xurea. This is because high-energy photons will be absorbed by mainly the solvent and can damage the fluorescence spectrophotometer. The use of the same excitation and emission wavelengths allowed the use of HPLC–FLD for the simultaneous determination of XEC and Xurea.

Chromatographic Separation. To achieve successful resolution of XEC and Xurea, three gradient elution programs were tested (Table S1 of the Supporting Information). Figure 3 shows a chromatogram of the derivatized urea and EC in a 20% alcohol/water mixture. An amino group ($-NH_2$) results in Xurea being more polar than XEC, which has an ethoxy group ($-OCH_2CH_3$). This characteristic allowed easy separation of XEC and Xurea. In all cases, we observed insufficient separation of XEC. This may be due to the presence of the 9-xanthydrol derivatives in the reagent, which have polarities that are similar to that of XEC and exhibit strong fluorescence at λ_{ex} and λ_{em} wavelengths of 240 and 308 nm, respectively. Alternatively, the MS detector can provide excellent selectivity for XEC and demonstrate no other interference signal.[34]The best analytical frequency, chromatographic resolution (not satisfactory but acceptable for XEC), and peak shape were obtained adopting gradient program II. Under this condition, XEC and Xurea are detected at 20.6 and 13.8 min, respectively.

Optimization of the Derivatization Condition. The derivatization kinetics was determined by using standard solutions [1 mg/L for both EC and urea in a 40% (v/v) alcoholic solution] reacting at different temperatures. Because a higher temperature can accelerate the reaction of urea to form

dx.doi.org/10.1021/jf405400y | J. Agric. Food Chem. 2014, 62, 2797–2802

EC, the derivatization was conducted at a relatively low temperature (20, 30, or 40 °C). To evalute the stability of the derivatized analytes, a wide reaction time range (5−90 min) was chosen.

It can be observed in Figure 4a that the three curves are almost superimposed, demonstrating that temperature has very little effect on the formation of Xurea. In contrast, the temperature had a strong effect on the formation of XEC (Figure 4b). This is because oxygen is more electronegative than nitrogen. This causes the EC to be less susceptible (than the urea) to nucleophilic attack by the hydroxyl group in 9-xanthydrol. The temperature in this experimental range can provide sufficient activation energy, which ensures the complete formation of Xurea in 10 min. With regard to EC reacting with 9-xanthydrol to form XEC, however, the rate of XEC formation increases with an increasing temperature because of the greater kinetic energy of the reacting molecules. To ensure the complete formation of XEC, the derivative should be held at 40 °C for 10 min, 30 °C for 30 min, or 20 °C for at least 60 min. For simultaneous determination of EC and urea, considering both efficiency and operability, we determined that the derivative reaction should be performed at 30 °C for 30 min. These conditions ensured the completion of the derivative reaction. In addition, the derivatized products were stable in 60 min, with a difference between the maximal signal and the minimal signal of 5% for XEC and 1% for Xurea.

In general, the samples vary in alcoholic strength. To standardize the derivatization and to improve the reproducibility of the method, it is necessary to make the alcoholic strength of the samples uniform. Moreover, in an alcohol/water mixture, the alcoholic strength can have an effect on solubility, stability, and reaction rates. Choosing the appropriate alcoholic strength allows for thermodynamic and kinetic control over a derivative reaction. Thus, the effect of the alcoholic strength on the derivatization response was evaluated. As shown in Figure 5, the alcoholic strength clearly influences the peak area of XEC

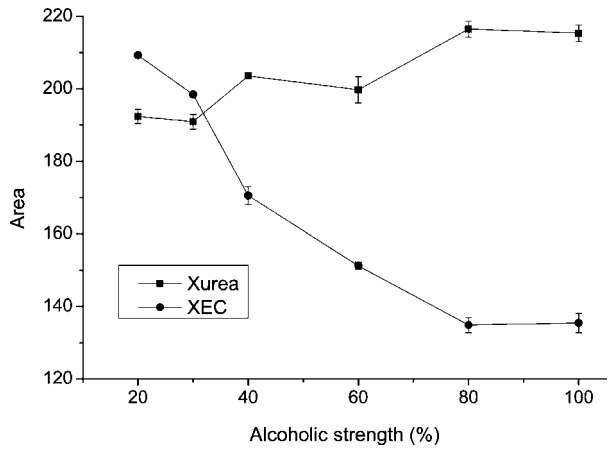

Figure 5. Effect of alcoholic strength on the response of Xurea and XEC (the derivative reaction was conducted at 30 °C for 30 min).

or Xurea. A higher alcoholic strength favors the derivatization of urea but adversely affects the derivatization of EC. The latter result is in agreement with the findings of Roberto et al.,[32] who reported that the extent of EC derivatization decreases with an increasing alcoholic strength. The different responses of urea and EC derivatization can partly be explained by the Hughes−Ingold rules.[33] An alcoholic strength of 20% (v/v) is considered to be more suitable for simultaneous determination of EC and urea in alcoholic beverages. This is true for the three following reasons.

(1) With an increasing alcoholic strength, the response of XEC decreases sharply while that of Xurea increases mildly. Choosing a 20% (v/v) alcohol/water mixture as the solvent can significantly improve the detection sensitivity for EC but slightly decrease that of urea.

(2) Alcoholic beverages generally contain EC and urea at levels of micrograms per liter and milligrams per liter, respectively. Moreover, the response of the fluorescence detector to Xurea is more significant than the response to XEC. Therefore, we must give priority to EC detection sensitivity.

(3) Alcoholic beverages generally contain 10−40% alcohol. Choosing a 20% (v/v) alcohol/water mixture as the solvent results in no dilution or trace dilution of the sample, which can significantly improve the detection limits of EC and urea.

Method Validation. *Linearity, LOD, and LOQ.* Considering the levels of EC and urea normally found in alcoholic beverages, and the maximal or recommended limits set in some countries, the linearity of EC detection was studied in the range from 10 to 500 μg/L, while the linearity of the urea detection was tested in the range from 0.01 to 100 mg/L. The regression equations used for EC and urea determination were $Y = 30.5X + 6.4$ and $Y = 53.3X + 4.3$, respectively. In the equations, Y is the peak area and X is the EC or urea concentration. The correlation coefficients (R^2) of both analytes were >0.999, which indicates excellent linearity over the tested concentration ranges. The LOD (signal-to-noise ratio of 3) and LOQ (signal-to-noise ratio of 10) for both analytes were as follows: 4.8 and 16 μg/L for EC and 0.003 and 0.01 mg/L for urea, respectively.

Precision and Accuracy. To determine the precision and accuracy of the method, intraday and interday repeatability and recovery experiments were performed. To simplify processing, red wine, Chinese rice wine, and grape brandy were chosen for the precision and accuracy experiment because they present more complex compositions and demonstrate greater applicability of the method. Three samples were spiked with EC and urea, at low and high fortification levels, and were analyzed accordingly. The results are listed in Table 1 and show great repeatability for both analytes because the intraday RSD values were <3.7% and the interday values were <4.8%. The data showed satisfactory accuracy of the proposed method as recoveries of all analytes were in the range from 90.7 to 104.8%.

Application of the Method. The new method was applied to alcoholic beverages for the assessment of EC and urea levels. Nine types of red wines, 12 types of Chinese rice wines, and 5 types of grape brandies were analyzed, at least in duplicate, and the results are summarized in Table 2. The levels of EC in red wines, Chinese rice wines, and grape brandies ranged from "detected but not quantified" to 22.4 μg/L, detected but not quantified to 225.0 μg/L, and 44.2 to 78.3 μg/L, respectively. Correspondingly, the levels of urea in these beverages ranged from 1.2 to 2.8 mg/L, 5.1 to 17.7 mg/L, and 0.3 to 0.7 mg/L, respectively. The high level of EC (average value of 76.3 μg/L) in Chinese rice wine may be caused by their special production process, which includes wine boiling, jar filling, and storage. The high standard deviations of the EC and urea concentrations in the Chinese rice wines are the result of the various raw materials and the production processes that are used in their manufacture. A proportion of 8.3% of the Chinese rice wines contained >200 μg/L EC. This is above the Canadian

Table 1. Mean Recoveries and Intraday and Interday Precisions (n = 6) of EC and Urea Measurements from Red Wine, Chinese Rice Wine, and Grape Brandy at Two Fortification Levels

			intraday		interday	
sample	analyte	added concentration (EC, μg/L; urea, mg/L)	RSD (%)	recovery (%)	RSD (%)	recovery (%)
red wine	EC	10	2.1	99.5	3.2	101.0
		500	3.1	100.2	2.8	97.3
	urea	0.01	1.3	101.1	3.1	94.2
		100	1.9	101.7	4.6	104.8
Chinese rice wine	EC	10	2.9	93.8	2.8	103.6
		500	3.1	101.2	4.2	100.0
	urea	0.01	1.2	90.7	2.1	95.8
		100	1.7	101.4	3.7	101.9
grape brandy	EC	10	1.9	98.3	1.0	104.6
		500	1.2	97.8	2.9	103.1
	urea	0.01	2.9	101.2	3.8	103.2
		100	3.7	99.7	4.8	98.3

Table 2. EC and Urea Contents of Alcoholic Beverages

	EC (μg/L)		urea (mg/L)	
samples	range of average values ± the standard deviation		range of average values ± the standard deviation	
red wines	nd[a] to 22.4	13.7 ± 7.6	1.2−2.8	2.1 ± 0.6
Chinese rice wines	nd[a] to 225.0	76.3 ± 75.9	5.1−17.7	8.8 ± 4.5
grape brandies	44.2−78.3	61.3 ± 24.1	0.3−0.7	0.5 ± 0.3

[a]Detected but not quantified.

limits for EC in Japanese sake (200 μg/L). Red wines and grape brandies have the normal EC levels that are within the limits of the Canadian legislation.

The developed method demonstrated good linearity, recoveries, and repeatability for the simultaneous analysis of EC and urea in alcoholic beverages. The advantages of the method presented here are the simplicity of sample preparation and the simultaneous determination of the two analytes within a short period of time. This method is very useful for the study of the kinetics of EC formation from urea in alcoholic beverages during storage. The method will also be helpful for the further investigation of the mechanism of the formation of EC by urea alcoholysis in the brewing process of alcoholic beverages. In addition, this method is compatible with the legal requirements for the maximal limits of EC content in beverages and therefore can be used to screen alcoholic beverages that have EC contents that are higher than the legal limit.

processed, and this presents additional difficulty for morphological identification. The results of this study should ensure the traceability of products to prevent fraud, improve food safety, and assist in implementing initiatives such as appellations of origin.

MATERIALS AND METHODS

Chemicals. The DNA extraction kit was purchased from Bio101 (Vista, CA, USA) and the DNA purification kit from Macherey-Nagel (Bethlehem, PA, USA). The PCR reagents and restriction enzyme were obtained from Fermentas (Massachusetts, USA) and Euro-Clone (Milano, Italy). Clonation DNA was purchased from Promega (Madison, WI, USA). The chemicals were purchased from Sigma-Aldrich (St. Louis, MO, USA) and Bio-Rad (Hercules, CA, USA).

Animal Sampling and DNA Isolation. For the analysis of the 5S rDNA multigene family in the four species of the Engraulidae family, the following were used: fresh samples of *Engraulis encrasicolus* from the Gulf of Cadiz, samples of *Engraulis mordax* from Baja California in Mexico, *Engraulis ringens* from Valparaiso in Chile, and *Engraulis japonicus* from the Sea of Japan. All samples were collected and preserved in absolute ethanol. Total genomic DNA was extracted from 150 mg of muscle sections with FastDNA kit for 40 s, at a speed of 5 m/s, in a FP120 Fastprep instrument (Bio101, Inc., Vista, CA).

PCR Amplification, Cloning, and Sequencing. The 5S rDNA gene was amplified with the two universal primers 5S1F (5′-TACGCCCGATCTCGTCCGATC-3 ′) and 5S2R (5′-CAGGCTGG-TATGGCCGTAAGC-3′).[15] PCR was performed in a final volume of 50 μL containing 4 μL of genomic DNA, 3 mM $MgCl_2$, 200 μM dNTP (Fermentas), 0.2 μM of each primer, 2 units of Taq polymerase (Euro-Clone, Italy), and the appropriate buffer for the enzyme. The reaction was carried out using an initial cycle of 5 min at 94 °C and 35 cycles of 45 s at 94 °C, 45 s at 59 °C, and 1 min at 72 °C and a final extension of 10 min at 72 °C. Products were visualized by agarose gel 2% with ethidium bromide (0.5 μg/mL) after electrophoresis. The PCR products obtained were purified using the NucleoSpin extraction kit (Macherey-Nagel, Inc., Bethlehem, PA) and cloned using the pGEM cloning kit from T Easy Vector Systems (Promega, Madison, WI). The sequencing was carried out using a sequencing kit (BigDye Terminator v 3.1 Cycle Sequencing Kit, Applied Biosystems). Sequencing peaks were analyzed with Chromas 2.0, and the sequences obtained were aligned using the ClustalW and BioEdit programs

Design of Species-Specific Primers of 5S rDNA. Alignment of the 5S rDNA sequences of the four species studied reveals a significant difference in the NTS between *E. encrasicolus* on the one hand and *E. japonicus*, *E. mordax*, and *E. ringens* on the other and a similarity of 83% between *E. encrasicolus* and *E. Japonicus*. Therefore, to differentiate between these species, species-specific primers were designed (Table 1) and located in the NTS using the Primer 3 program.

The multiplex PCR for the simultaneous identification of the different species of anchovy was performed in a final volume of 50 μL containing 2 μL of DNA (80−100 ng), 0.2 μM of each primer, 3 mM $MgCl_2$, 200 mM dNTP, 2 units of the Taq polymerase enzyme, and appropriate buffer for the enzyme. The reaction was carried out under the same conditions as those described above. PCR products were purified and directly sequenced to verify that the amplified products are the same as previously designed. These primers not only indicate the presence or absence of amplification but also allow the product size to be differentiated, which also facilitates the reading of the results.

Sequences of *E. encrasicolus* and *E. japonicus* showed a high degree of similarity, which hinders identification using specific primers. We used the same pair of primers for the two species and were able to distinguish between them using the RFLP restriction enzyme *BspLU11I*. The digestion reaction was carried out in a final volume of 20 μL with 2 μL of PCR product, 1 μL of enzyme, and 2 μL of the appropriate buffer.

RESULTS

In eukaryotes, rDNA (rDNA) is generally arranged in two different gene clusters (multigene families), each composed of

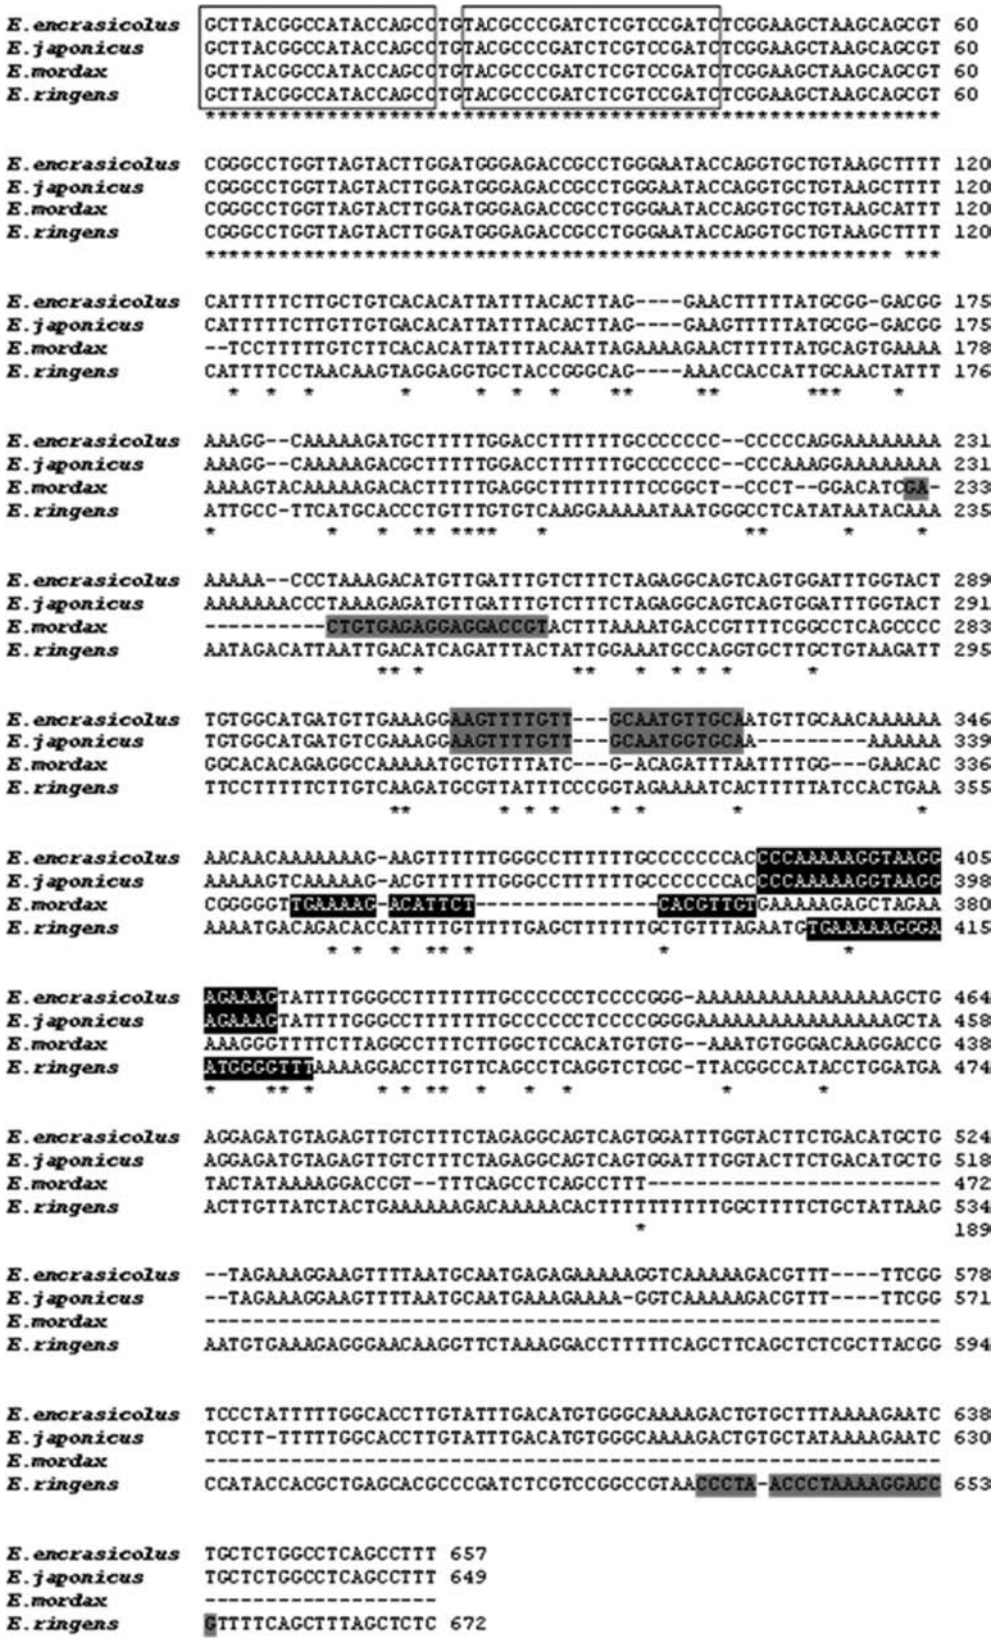

Figure 2. Alignment of the 5S consensus sequences of the four species of *Engraulis*. Consensus sequence were obtained from three individuals of each species (*E. encrasicolus* nine clones, *E. japonicus* eight clones, *E. ringens* 10 clones, and *E. mordax* 12 clones). Sequences of each clone are deposited in GenBank with an access number shown in Table 1. Universal primers (described in Table 1) are framed, and species-specific primers (Table 1) are shaded (Fw sequences shaded in black and Rev sequences shaded in gray).

hundreds to thousands of gene copies, one the major cluster (45S rDNA) and the other the minor cluster (5S rDNA). The 5S rRNA gene consists of one highly conserved sequence of 120 base pairs (bp), which is separated from the next unit by a

dx.doi.org/10.1021/jf405680g | J. Agric. Food Chem. 2014, 62, 2803−2808

nontranscribed spacer (NTS). Although the 5S rRNA gene is highly conserved, the NTSs are variable both in length and in sequence. The fast rate of base substitution, together with gene conversion, should make NTS sequences candidates as markers for species identification.

The aim of this study is to differentiate between four very similar species of the Engraulidae family: *E. encrasocilus*, *E. mordax*, *E. ringens*, and *E. japonicus*, which are of considerable commercial interest in Europe, Asia, and Latin America; reliable differentiation should help to prevent fraud and labeling errors.

Repeat units of 5S rDNA were amplified using universal primers.[15] Several products were obtained among them, which varied depending on the length of the NTS. The coding region of 120 bp showed a high degree of conservation among the four species.

We found many products of 5S rDNA which differed, for example, between *E. encrasocilus*, *E. ringens*, and *E. japonicus* by the length of their NTS, mainly due to the presence of several repeated sequences of poly A, poly C, and poly G or due to fouling by pseudogenes (Figure 1, Table 1).

However, because of the presence of many products and dimer bands, 5S rDNA amplification is not sufficient to differentiate reliably between these species. The high degree of polymorphism observed between the NTS sequences of these four species of *Engraulis*, after aligning their 5S rDNA sequences, means that this characteristic could be useful for differentiating between the species, therefore species-specific primers were designed for the zones of variability (Figure 2, Table 1).

Multiplex PCR was performed with the four pairs of primers designed to discriminate rapidly the four species of *Engraulis*. The results obtained show that these primers indicate not only presence or absence of amplification but also the difference in size of the amplification product, which facilitates reading (Figure 3, Table 1).

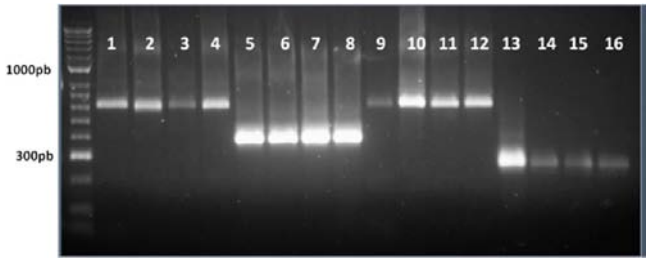

Figure 3. Electrophoretic patterns of multiplex PCR with species-specific primers as described in Table 1 in four independent individuals of each of the four species of *Engraulis*: (1–4) *E. encrasicolus*, (5–8) *E. mordax*, (9–12) *E. japonicus*, and (13–16) *E. ringens*..

In the case of *E. encrasicolus* and *E. japonicus*, it was difficult to design specific primers for each of the species because their sequences are very similar and there were areas where polymorphism is present in the form of sequences of poly A and poly T; consequently, the only solution was to use a restriction enzyme. By analyzing the sequences of all the specific primer clones of the two species, it was found that the enzyme *BspLU11I* allows differentiation to be made between these two species because two different banding patterns were obtained. *E. encrasicolus* has two different alleles for the enzyme *BspLU11I*, whereas *E. japonicus* has one allele with a unique restriction site (Figure 4).

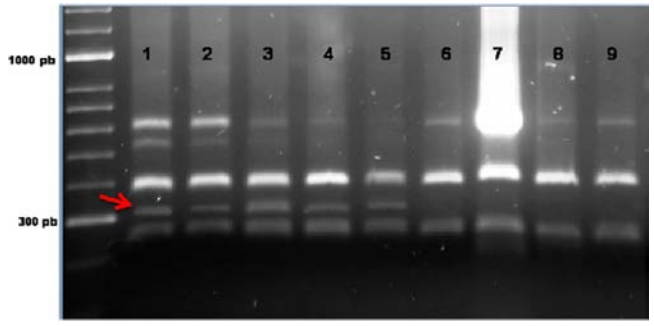

Figure 4. Electrophoretic patterns of digestion with restriction enzyme *BspLU11I* of the PCR products with species-specific primers for *E. encrasicolus* (from 1 to 5) and *E. japonicus* (from 6 to 9). The arrow indicates the differential band. Each lane is from an independent individual.

DISCUSSION

In this paper, we study the identification of four species of anchovy: one European (*E. encrasicolus*), which is in great demand for the European market and for which there has been a significant decrease in the fishing grounds, another Japanese (*E. japonicus*) which is marketed in much of Asia, and two species from the Americas (*E. mordax* and *E. ringens*) that are being imported into Europe in order to increase supply to match the high demand.

Consumers in all markets of the world increasingly expect the seafood industry to devise and implement measures for the safety and traceability of food products to ensure that these products are of sufficient quality, authentic, and properly labeled with all the necessary information. The industry is therefore increasingly seeking fast and reliable techniques for controlling seafood safety and preventing fraud, especially with respect to species of fish that are morphologically similar but very different in commercial value, such as anchovies.

The European anchovy *E. encrasicolus* has been the target of identification studies using PCR-RFLP of cytochrome *b*, versus *Sardinella aurita*,[8] in semipreserved products and in paste.[10] A phylogenetic study has also been made of the Engraulidae family in which the genetic distances between various species is highlighted.[9]

In this study, the repeating units of 5S rDNA have been used as a molecular marker to differentiate rapidly the four species of the Engraulidae family by multiplex PCR . These repeating units showed a 5S rRNA with 120 bp, which is highly conserved among many taxa, separated by NTS noncoding segments of rDNA which evolve much faster than the coding region, and appear to be specific for each species. The 5S rDNA has been widely used as a molecular marker to differentiate closely related species due to the peculiarity of its structure and organization. Thus, in several studies it has been used as a marker to discriminate fish species[16−19] and in one study linked to other genes such U snRNA.[20]

The variations found between the NTS of the different species studied are due to insertions/deletions, repeats, and pseudogenes that have been the main source of variation in the size of 5S rDNA units. These have been characterized in several other organisms and appear to be very useful as markers in the

characterization of species.[21−23] Precise species-specific primers have also been designed for the four species of *Engraulis* which showed considerable differences in the size of the gene (Table 1).

In the four species, amplification with the universal primers gave more than one product; this is probably because the particular organization of this gene appears to be very common in fish. This means that the genes are in different genomic locations and must be independently assessed.[17,24,25]

As in most tandemly repeated multigene families under concerted evolution, our results also revealed homogeneity of the 5S rDNA, but in both *E. encrasicolus* and *E. japonicus*, the elements homogenized by repetition are two widely divergent units, one short NTS I (about 450 bp) and a long NTS II (about 640 bp). Also in *E. encrasicolus* and *E. japonicus*, the duplication observed in NTS II, with base substitutions and insertions/deletions represents most of the difference in length between the two types of NTS. A similar situation has also been described in other genera including *Coregonus*, *Brycon*, and *Leporinus*.[26−28]

However, unlike in other fish species that also have several size classes of 5S rDNA, the comparison between the two classes of NTS revealed that the sequence identity is extremely low in the spacer region.[29]

Unexpectedly, the NTS sequences of the two species *E. encrasicolus* and *E. japonicus* maintain a very high degree of conservation (91% for NTS I and 89% for NTS II) as a result of some particular homogenization mechanism such as gene conversion or unequal crossing;[30] similar results have been found in NTS sequences between two species of shark.[12] The closeness of the genetic distance observed between these two species has also been described by analysis of cytochrome *b* nucleotide divergence, showing values of 0.04, whereas in our study we have obtained a value of 0.045.[31]

The presence of several types of product of 5S rDNA is not sufficient to identify conclusively each species; it can even lead to confusing results. Therefore it was decided to design species-specific primers to give reliable results.

Ultimately, these results should be of great interest for product traceability in the marketing of these species, given the overexploitation of anchovy fisheries in Europe and the continued periods of closure imposed. Imports of other anchovy species have been increasing significantly as suppliers try to alleviate this shortage. These imported products may be frozen or processed, which presents additional difficulties for morphological identification. In conclusion, these results allow anchovy products to be reliably traced, with the object of preventing fraud, improving food safety, and implementing initiatives such as appellations of origin.

column to remove pigments and fatty acids from extracts. To the best of our knowledge, the current report is the first time to present the enantioselective analysis of flutriafol in environment and food samples (cucumber, tomato, grape, pear, wheat, soil, and water). The time-dependent density functional (TDDFT) methodology was applied to predict the electronic circular dichroism (ECD) spectra of flutriafol. The absolute configuration of flutriafol enantiomers was measured through the combination of experimental and predicted ECD spectra. This analytical method developed was validated by its application to the real samples.

MATERIALS AND METHODS

Chemical and Materials. The standard of *rac*-flutriafol (>97.3% purity) was obtained from the China Shanghai Pesticide Research Institute (Shanghai, China). HPLC-grade acetonitrile was purchased from Fisher Scientific (Shanghai, China). Purified water was obtained by using MUL-9000 water purification systems (Nanjing Zongxin Water Equipment Co. Ltd., China). The mobile phase was filtered through a 0.22 μm filter membrane (Tengda, Tianjin, China). Sodium chloride, anhydrous sodium sulfate, acetonitrile, acetone, and hexane of analytical grade were purchased from commercial sources.

A stock solution of racemic flutriafol standard (200 mg/L) was prepared in acetonitrile−water (60/40, v/v). Standard working solutions of *rac*-flutriafol at 0.2, 0.5, 1, 2, 5, 10, and 20 mg/L were prepared in acetonitrile/water (60/40, v/v) from the stock solution by serial dilution. Accordingly, the matrix-matched standard solutions were obtained at 0.2, 0.5, 1, 2, 5, 10, and 20 mg/L concentrations of *rac*-flutriafol by adding appropriate amounts of standards to the control matrix extract. Enantiomers of flutriafol (purity ≥97.0%) were obtained from Daicel (Shanghai, China). Stock standard (500 mg/L) of each enantiomer was prepared in methanol. All solutions were protected against light and stored at −20 °C.

The Cleanert Florisil and Cleanert C18 (500 mg, 6 mL) were purchased from Agela Technologies (Tianjin, China). The samples were comminuted and blended by FeiGe DL-5200B centrifuge (Shanghai, China), Joyoung Soymilk Maker (Hangzhou, China), and Jinyi SK-1 Ultra-Turrax homogenizer (Jiangsu, China).

Apparatus and Chromatographic Conditions. The chromatographic separation of the enantiomers of flutriafol was performed on an Agilent 1200 HPLC system (Agilent, USA) with chiral Lux Cellulose-2 (cellulose tris(3-chloro-4-methyl phenyl carbamate), 250 mm × 4.6 mm id)) (Phenomenex, China) using a mixture of acetonitrile and water (40:60, v/v) as the mobile phase at a flow rate of 0.8 mL/min with the injection volume of 20 μL. The column was kept at 30 °C, with a UV detection at 210 nm. Capacity factor (k), separation factor (α), and resolution factor (Rs) were calculated from the formulas

$$k = (t - t_0)/t_0$$

$$\alpha = k_2/k_1$$

$$\mathrm{Rs} = 2(t_2 - t_1)/(W_1 + W_2)$$

where t is the retention time, t_0 is the void time at given conditions, and k is the retention factor. Parameter k_1 is the capacity factor of the first eluted enantiomer: $(t_1 - t_0)/t_0$. k_2 is the capacity factor of the second eluted enantiomer: $(t_2 - t_0)/t_0$. W_1 and W_2 are the corresponding baseline peak widths for first and second eluted enantiomers. Triplicate determination was made for the measurement of the mean values.

Circular Dichroism Spectroscopy and ECD Calculations. The absolute configuration determination of the flutriafol enantiomers was carried out using a Jasco J815 circular dichroism spectropolarimeter (Tokyo, Japan) at room temperature in methanol. The spectrum was collected over a wavelength range of 200−400 nm at scan speed of 100 nm/min. A quartz cell with a path length of 0.5 cm was used for the scan, and the average of three scans was reported. The geometry of the flutriafol enantiomers was optimized and predicted by Gaussian 09 software using density functional theory (DFT) at a level of B3LYP/6-31+G* in methanol with a conductor-like polarizable continuum model (CPCM) solvent model.[17,18]

Extraction and Cleanup for Water. Water (100 mL) samples spiked at three concentration levels were prepared by the addition of appropriate amounts of standard solutions of racemic flutriafol to tap water. The C18 SPE was preconditioned using 6 mL of methanol followed by 6 mL of purified water. 100 mL of the water sample was slowly uploaded to a SPE cartridge at a flow rate of 2 mL/min, and the effluent was discarded. 10 mL of methanol was used to elute target analytes and collected. The eluate was evaporated to dryness using a rotary evaporator (30 °C). The residue was redissolved in 1 mL of acetonitrile−water (40:60, v/v) and filtered through a 0.22 μm filter membrane for HPLC analysis.

Extraction and Cleanup for Vegetables and Fruits. A 20 g minced sample was added into a 100 mL Teflon centrifuge tube and spiked with different concentrations of flutriafol standard solutions. The tubes containing the spiked samples were vortexed for 30 s and allowed to stand overnight at room temperature to distribute the pesticide evenly. 40 mL of acetonitrile was added to the tube and then homogenized at high speed for 3 min, followed by sonication for 10 min. Subsequently, 6 g of anhydrous magnesium sulfate ($MgSO_4$) and 1.5 g sodium chloride (NaCl) were added. The tube was vortexed vigorously for 2 min and then centrifuged for 5 min at 4,000 rpm. The supernatant acetonitrile (20 mL) was evaporated to dryness and redissolved in 5 mL of a mixture of hexane−acetone (98:2, v/v) followed by cleanup with Florisil-SPE conditioned with 4 mL of hexane. The SPE cartridge was rinsed with 6 mL of hexane−acetone (95:5, v/v) and eluted with 5 mL of hexane−acetone (85:15, v/v) three times sequentially. All eluates were collected and evaporated to dryness under vacuum at 40 °C. The sample was dissolved in 1 mL of acetonitrile−water (40:60, v/v) and filtered through a 0.22 μm filter for HPLC analysis.

Extraction and Cleanup for Wheat and Soil. A 15 g sample of soil or wheat was weighed into a 100 mL Teflon centrifuge tube and spiked with different concentrations of flutriafol standard solutions. The samples were allowed to stand overnight at room temperature. Then, 5 mL of water and 30 mL of acetonitrile were added to the tube and then homogenized at high speed for 3 min, followed by sonication for 10 min. The mixture was homogenized, and 4 g of anhydrous $MgSO_4$ and 1 g of NaCl were added. The tube was vortexed vigorously for 2 min and centrifuged for 5 min at 4,000 rpm. The acetonitrile (15 mL) was concentrated to dryness under vacuum at 40 °C. The residue was transferred with 5 mL of hexane−acetone (98:2, v/v) to a Florisil-SPE column conditioned with 4 mL of hexane. The SPE cartridge was rinsed with 6 mL of hexane−acetone (95:5, v/v) and eluted with 5 mL of hexane−acetone (85:15, v/v) three times sequentially. All eluate was evaporated to dryness with a vacuum rotary evaporator at 40 °C and dissolved in 1 mL of acetonitrile−water (40:60, v/v) for HPLC analysis.

Method Validation. The specificity, linearity, limit of detection (LOD) and limit of quantification (LOQ), matrix effect, accuracy, precision, and stability were applied to evaluate the performance of the method.

A total of 35 blank samples, five samples of each matrix, were applied to verify the absence of interfering substances. The linearity of calibration curves was evaluated based on the peak areas of the standard solutions and the different matrices at seven concentrations ranging from 0.1 to 10 mg/L in triplicate. The linearity was determined by linear regression analysis of both standard solution and matrix-matched calibration curves.

The matrix-dependent LOD and LOQ were determined using the blank and calibration standards of the vegetables, fruits, wheat, soil, and water matrices. The LOD and LOQ for enantiomers of flutriafol were considered as concentrations in a sample matrix resulting in peak areas with signal-to-noise (S/N) ratio of 3 and 10, respectively.

The recoveries were carried out to investigate the accuracy and precision of the method. Soil and water samples from trial plots were located in the Nanjing region in Jiangsu. Other samples were purchased from regional retailers. Five replicates of spiked sample at three different levels from 0.004 to 1 mg/kg were prepared on three consecutive days. The flutriafol was extracted and purified according to the above procedure. The average recoveries and intraday and interday relative standard deviations (RSD) were used to evaluate accuracy and precision.

It has been reported that some kinds of chiral pesticides, such as pyrethroids, could undergo epimerization under certain conditions.[19] Two optically pure flutriafol enantiomers were determined under the same conditions to evaluate the stability of the flutriafol enantiomers during analysis and storage in solvent and matrices. Stability of the stock solutions and the spiked sample matrix-matched standard was tested monthly, and all the samples used in the stability test were stored at −20 °C. The results of the stability tests were compared with those concluded from the freshly prepared samples using Student's t test ($P < 0.05$).

RESULTS AND DISCUSSION

Chromatographic Condition Optimization. A number of the chiral stationary phases (CSPs) were used for chiral separations by HPLC in various chemical fields. The polysaccharide-based CSPs, especially cellulose- and amylase-based polysaccharide columns with higher recognition abilities, are the most used.[20,21] Zhang et al. reported that the two enantiomers of flutriafol could be baseline separated on polysaccharide-based CSPs by reversed-phase HPLC−MS/MS.[22] Ying et al. reported that the flutriafol enantiomers were separated using Chrialcel OD and Chrialcel OJ column by normal phase HPLC.[23] Despite chiral separation, the retention time was not less than 25 min in all reports. In this study, the two enantiomers of flutriafol were completely separated with the Lux Cellulose-2 column under reversed-phase conditions using acetonitrile−water (40:60, v/v) as the mobile phase at a flow rate of 0.8 mL/min with the good resolution factor (Rs) of 1.82. The consumption of solvents was reduced within 20 min.

The methanol and acetonitrile may induce different effects for the separation of the flutriafol on the same column. The flutriafol enantiomers were separated with all Rs higher than 1.54 using a mixture of acetonitrile and water as mobile phase at the rate of 65:35 to 30:70 (v/v). When the percentage of acetonitrile in the eluent increased, a decrease in the retention factors was observed and a worse resolution was obtained. Therefore, a solvent system mixture of acetonitrile−water (40:60, v/v) was used as mobile phase at a flow rate of 0.8 mL/min based on retention time and satisfactory separation (Figure 1). The effect of column temperature on the chiral separation also was evaluated. The result showed a slightly better separation and better peak shape at 30 °C.

The Absolute Configuration and Elution Order Determination of Flutriafol Enantiomers. The each enantiomer was stereochemically determined by circular dichroism (CD) spectroscopy. The two CD curves were almost mirror imaged, and the curves of the predicted ECD and experimental ECD were very similar (Figure 2). The absolute configuration of enantiomers was measured through the combination of experimental and predicted ECD spectra. The configurations of the flutriafol enantiomers that eluted from the

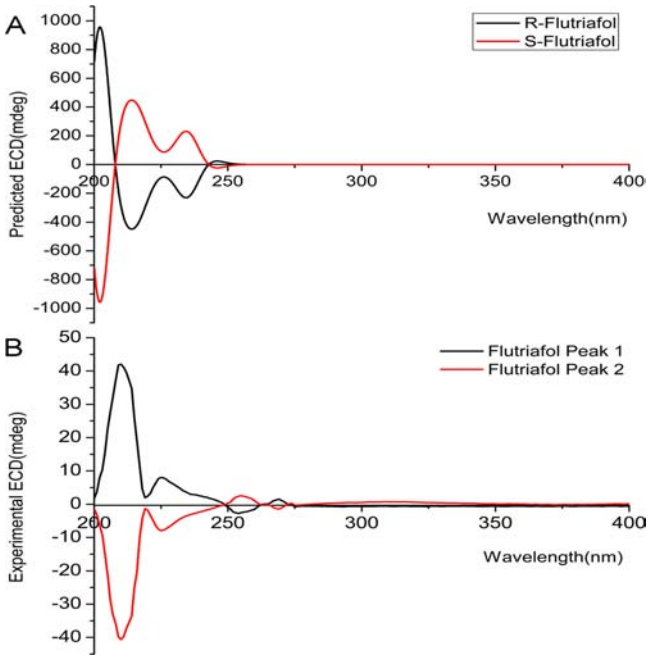

Figure 2. The predicted and experimentally measured ECD spectra of flutriafol enantiomers: (A) predicted ECD spectra; (B) experimentally measured ECD spectra.

HPLC were determined based on the predicted ECD spectra by the TDDFT methodology. Accordingly, peak 1 and peak 2 of the chromatograms shown in Figure 1 were assigned to (*R*)-flutriafol and (*S*)-flutriafol, respectively. Chang et al. had confirmed that (*S*)-flutriafol was (+)-flutriafol and the (*R*)-flutriafol corresponded to (−)-flutriafol.[24] As can be seen from Figure 1, (−)-flutriafol was first eluted under the above conditions, and the mass spectra of the two enantiomers of flutriafol are also provided.

Sample Preparation. The QuEChERS method is a major development for sample preparation in pesticide residue analysis.[25] The magnesium sulfate reduces the water phase and promotes the partitioning of the pesticides into the organic phase.[26] The dispersive cleanup procedure of QuEChERS is faster and easier. However, some food colorings and lipidic soluble materials could not been removed by primary secondary amine (PSA), C18, and graphitized carbon black (GCB). It is not as effective as using SPE columns, and the QuEChERS method has a high requirement in the device.[27−29] Flutriafol was extracted based on the modified QuEChERS method assisted with ultrasound extraction. The flutriafol was concentrated by 10 or 7.5 times, and a further cleanup step was improved using SPE columns.

The Cleanert Florisil, Cleanert NH_2, and Cleanert C18 were used for the cleanup procedure. The pigments and interferences were not efficiently removed and diminished by NH_2-SPE, whereas the C18-SPE was satisfactorily utilized for water sample and the Florisil-SPE could remove the visible pigments of vegetables, soil, and fruits. The chromatograms showed very clean baseline and separation. Methanol was selected as the eluting solvent in Cleanert C18 because of lower toxicity and higher efficiency for the analytes than acetonitrile.[9]

Specificity, Linearity, and Matrix Effect. No interference was detected at the retention time of flutriafol in blank samples of different matrices, and this showed the specificity of the method. Linear regression results of standard solution and matrix-matched calibration curves within the range of 0.1−10 μg/mL for each enantiomer of flutriafol are summarized in Table 1. Table 1 indicates the slopes, *P* values, and correlation

Table 1. Comparison of Matrix-Matched Calibration and Solvent Calibration

calibration (matrix)	calibration range (mg/kg)	regression equation	R^2	*P* value
		(*R*)-Flutriafol		
solvent	0.1−10	$y = 80.27x + 1.11$	0.9999	
soil	0.1−10	$y = 78.271x - 2.5071$	0.9993	0.0579
water	0.1−10	$y = 75.782x - 3.7409$	0.9996	0.823
cucumber	0.1−10	$y = 76.622x - 0.4451$	0.9997	0.0832

coefficients of determination (R^2) of both matrix-matched and standard solution calibration curves. Excellent linearities were observed for the enantiomers ($R^2 \geq 0.9989$), which were adequate for enantiomeric-specific quantitative trace analysis. The response of standard solution and matrix-matched calibration curves were compared to matrix-matched calibration curves using two-tailed paired *t* test with a probability of 95%. Table 1 showed that no significant matrix-induced enhancement or suppression effects were observed for the two enantiomers. The *P* values implied that the data between pure solvent and sample matrices were not significantly different ($P > 0.05$) and the matrix effect could be negligible.

LODs and LOQs. The LODs for both enantiomers were estimated to be 0.001 mg/kg in water, 0.012 mg/kg in grape, cucumber, pear, and tomato, and 0.015 mg/kg in wheat and soil. The LOQs were estimated at 0.003−0.05 mg/kg for the two enantiomers based on five replicate extractions and analyses of seven spiked samples at low concentration levels. The low detection limits indicated that chiral HPLC was capable of the quantitation of flutriafol enantiomers in the food and environmental matrices.

Accuracy and Precision. The analytical precision and accuracy, expressed with the RSD and the recoveries, was evaluated by spiking the blank samples at three different

concentrations with five replications on three consecutive days (Table 2). As shown in Table 2, the method presented satisfactory mean recoveries and precision for both enantiomers. The average recoveries ranged from 83.5% to 101.2% with intraday RSD 2.2−7.3% for (*R*)-flutriafol and ranged from 82.9% to 103.4% with intraday RSD 2.2−7.9% for (*S*)-flutriafol. The chromatograms of the flutriafol in the blank samples and the spiked pear at 0.5 mg/kg are shown in Figure 3. Further statistical analysis using one-way analysis of variance at 95% confidence limit showed no significant difference of interday and intraday assays. The results demonstrated that this method could achieve a satisfactory precision and accuracy for the enantiomeric analysis of flutriafol in food and environmental matrices. In addition, an evaluation of the stability of the two enantiomers was conducted, and no significant difference (P > 0.05) was observed under the solvent and matrix storage treatment as described in Materials and Methods.

Application to Authentic Samples. The effectiveness of this method in measuring trace levels of *rac*-flutriafol was monitored by analyzing seven different samples obtained from field and local market (Nanjing, China). Each kind of sample was analyzed in quintuplicate. The results showed three positive pear samples with flutriafol residues in the range of 0.009−0.019 mg/kg. The enantiomers of flutriafol were not found in other real samples. The typical chromatograms of pear

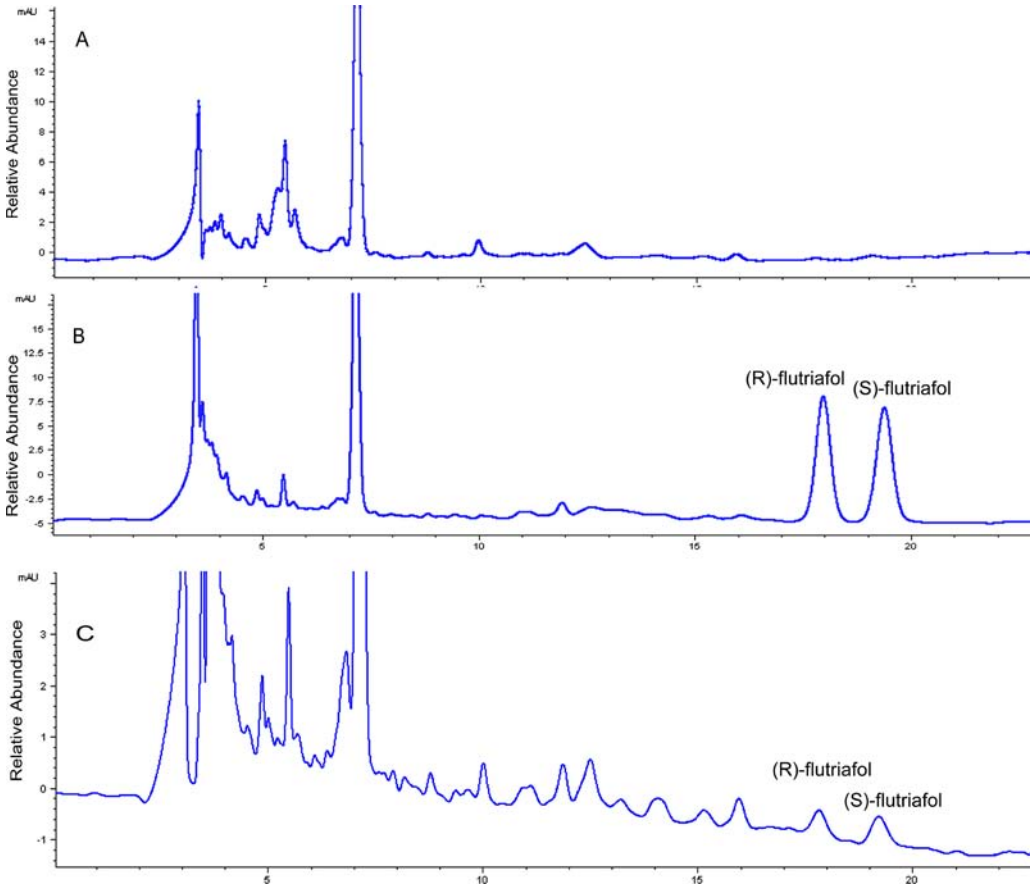

Figure 3. The typical chromatograms of pear sample: (A) blank pear sample; (B) pear sample spiked with 0.5 mg/kg; (C) authentic pear sample.

are presented in Figure 3 with 0.0151 and 0.0158 mg/kg for (*R*)-flutriafol and (*S*)-flutriafol, respectively.

In the present study, a simple and reliable enantioselective method using chiral HPLC for the simultaneous quantitative determination of flutriafol enantiomers in food and environment matrices (cucumber, tomato, grape, pear, wheat, soil, and water) has been successfully established and validated. Target compounds were extracted and purified based on the modified QuEChERS method. In addition, the absolute configurations and elution order of flutriafol enantiomers were determined by a combination of experimental and predicted ECD spectra. Adequate analytical performance characteristics were obtained in terms of linearity range and precision for both enantiomers of flutriafol in seven matrices. Satisfactory results were obtained in the real samples. The purpose of the current work was not only to establish a novel valid chiral HPLC method to separate the two enantiomers of the flutriafol but also to develop a method of quantitative determination of the two enantiomers of flutriafol in the food and environmental samples. The developed chiral HPLC method may be used to facilitate further studies in tracing the different toxicities, bioactivities, metabolism, and environmental behavior of each enantiomer, which could help minimize the hazards posed by flutriafol to humans, animals, and ecological health.

characterization of monoclonal antibody-based direct and indirect cELISAs, samples of strawberries, cucumbers, and tomatoes were fortified with kresoxim-methyl and extracted using the QuEChERS (Quick, Easy, Cheap, Effective, Rugged, and Safe) methodology[14] in order to evaluate immunoassay performance. Validation of the newly developed rapid methods was carried out by comparison with GC−MS through Deming regression analysis and Bland−Altman plots using samples from sprayed crops.

MATERIALS AND METHODS

Reagents and Instruments. The employed monoclonal antibody (KM*o*#117) and the homologous assay conjugates using horseradish peroxidase (HRP−KM*o*) and ovalbumin (OVA−KM*o*) were generated in our lab, and their preparation was as described elsewhere.[13] The affinity to kresoxim-methyl of monoclonal antibody (mAb) KM*o*#117 clearly improves that of a former antibody that we produced some years ago, at the beginning of this project.[12] Rabbit anti-mouse immunoglobulin polyclonal antibody conjugated to peroxidase (RAM−HRP) was from Dako (Glostrup, Denmark). *o*-Phenylenediamine was purchased from Sigma/Aldrich (Madrid, Spain). 96-well Costar flat-bottom high-binding polystyrene ELISA plates were purchased from Corning (Corning, NY, USA). ELISA absorbances were read with a PowerWave HT from BioTek Instruments (Winooski, VT, USA). Microwells were washed with an ELx405 microplate washer also from BioTek Instruments.

Pestanal-grade kresoxim-methyl (methyl (*E*)-methoxyimino[α-(*o*-tolyloxy)-*o*-tolyl]acetate, CAS registry number 143390-89-0, M_w 313.35) was purchased from Fluka/Riedel-de-Haën (Seelze, Germany). Other pesticide standards were also from Fluka/Riedel-de-Haën or from BASF (Limburgerhof, Germany), Bayer CropScience (Frankfurt, Germany), Dr. Ehrenstorfer (Augsburg, Germany), or Syngenta (Basel, Switzerland). Triphenylphosphate (TPP) was from Sigma/Aldrich (Madrid, Spain), and primary−secondary amine (PSA) for dispersive solid phase extraction cleanup was from Scharlab (Barcelona, Spain). Chromatographic determinations were carried out with a 6890N GC apparatus furnished with a 7683 series autosampler, a HP-5MS (30 m × 0.25 mm × 0.25 μm) capillary column, and a quadrupole 5973N mass detector, all from Agilent Technologies (Santa Clara, CA, USA).

Immunoassays. *General Procedures.* Eight-point standard curves, including a blank, were prepared in borosilicate glass tubes by 10-fold serial dilution in PBS starting from a 100 μg/L solution also in PBS. Pesticide concentrated stock solutions (100 mg/L) in anhydrous *N*,*N*-dimethylformamide—kept at −20 °C in amber glass vials—were used to prepare the first standard point. Experimental values were fitted using the SigmaPlot software (Systat Software Inc., Chicago, IL, USA) to a four-parameter logistic equation:

$$y = (A_{max} - A_{min})/[1 + (x/C)^B] + A_{min}$$

were A_{max} is the absorbance that was reached in the absence of analyte, A_{min} is the background signal, C is the analyte concentration at the inflection point of the sigmoidal curve, and B is the slope at the inflection point. Curves were normalized, and average values were calculated from independent experiments.

The concentration of kresoxim-methyl inducing a 50% inhibition (IC_{50}) of the reaction between antibody and hapten conjugate was taken as the key criterion for assay characterization. The limit of detection (LOD) was calculated as the analyte concentration causing a 10% inhibition (IC_{10}) of the immunochemical reaction. Cross-reactivity (CR) was estimated as a percentage value from the quotient between the IC_{50} value for kresoxim-methyl and the IC_{50} for the studied compound, both in molar concentration units.

Antigen-Coated Indirect Competitive ELISA. Microplates were coated by overnight incubation with 100 μL per well of OVA−KM*o* conjugate solution in 50 mM carbonate buffer, pH 9.6. All incubation steps were performed at room temperature with sealed plates, and after each step, microwells were washed four times with washing solution (150 mM NaCl with 0.05% (v/v) Tween 20). The competitive step was carried out during 1 h with 50 μL per well of analyte solution in PBS plus 50 μL per well of a dilution of antibody KM*o*#117 in PBST (PBS containing 0.05% (v/v) Tween 20). Retained mAb was amplified by incubation during 1 h with 100 μL per well of RAM−HRP diluted 1/2000 in PBST. Finally, a signal was generated with 100 μL per well of 0.012% (v/v) H_2O_2 in 62 mM phosphate and 25 mM citrate, pH 5.4 containing 2 g/L of *o*-phenylenediamine. Ten minutes later, enzymatic activity was stopped with 100 μL per well of 2.5 M H_2SO_4. Absorbance was immediately read at 492 nm using 650 nm as reference wavelength.

Antibody-Coated Direct Competitive ELISA. Polystyrene plates were coated by overnight incubation with 100 μL per well of a solution of antibody KM*o*#117 in 50 mM carbonate buffer, pH 9.6. All incubation steps were carried out at room temperature, and after each incubation step, microwells were washed as described above. The competitive step was performed during 1 h with sequential addition of 50 μL per well of analyte solution in PBS and 50 μL per well of a solution of tracer HRP−KM*o* in PBST. Signal was generated and plates were read as before.

Solvent, Detergent, and Buffer Studies. The influence of acetonitrile was evaluated using kresoxim-methyl standard curves in PBS with different solvent contents, whereas antibody or tracer solutions were prepared in PBST. Variation of A_{max} and IC_{50} values due to Tween 20 concentration was also assessed. Moreover, a central composite design was followed for buffer studies, consisting of a two-level full factorial design (α = 1.414) with two factors (pH and ionic strength) and three replicates that included 12 cube, 12 axial, and 15 center points; that is, 39 randomized assays under 9 different buffer conditions (Table S1 in the Supporting Information). The corresponding 9 buffers were set up from a 40 mM citrate, 40 mM phosphate, and 40 mM Tris solution, as described elsewhere.[15] Ionic strength and pH values of each buffer were adjusted using 2 M NaCl and 5 M HCl, respectively. All buffers contained 0.05% (v/v) Tween 20. Kresoxim-methyl was prepared in Milli-Q water, and antibody or tracer solutions were diluted in the studied buffers. A_{max} and IC_{50} values of the 39 resulting curves were fitted as functions of pH and ionic strength using the Minitab software (Minitab Inc., State College, PA, USA).

Sample Treatment and Analysis. Tomatoes, cucumbers, and strawberries were obtained from local supermarkets and extracted using the QuEChERS method.[14] Briefly, 20 g of homogenate was mixed under vigorous stirring with 2 g of sodium acetate and 8 g of anhydrous magnesium sulfate in 20 mL of acetonitrile containing 1% (v/v) acetic acid. The organic phase was separated by centrifugation at 2200*g* during 5 min, and a 10 mL aliquot was cleaned up by vortexing with PSA (500 mg) in the presence of 1.5 g of anhydrous magnesium sulfate. After a second centrifugation step, extracts were filtrated with a Teflon filter (0.2 μm) and stored at −20 °C. Extracts were fortified with kresoxim-methyl, diluted 50-fold in PB (100 mM phosphate, pH 7.4), and analyzed by the developed cELISAs using antibody or tracer solutions prepared in PBT (PB containing 0.05% (v/v) Tween 20). A kresoxim-methyl standard curve in PB was run in each plate.

In order to better simulate real-world situations, greenhouse strawberry crops were sprayed with a nebulizer using a commercial kresoxim-methyl formulation from BASF (Stroby), which was prepared as recommended by the manufacturer (100 mg/L kresoxim-methyl in water containing 20% (v/v) alkyl polyglycol ether). Samples were collected at different days to obtain positive samples covering a wide range of kresoxim-methyl concentrations, homogenized, and stored frozen at −20 °C. Residues were extracted by the described QuEChERS procedure and analyzed by the optimized cELISAs and GC−MS. Immunochemical determinations were performed as described for spiked samples. For chromatographic analysis, one microliter of clean extract containing 500 μg/L of TPP as internal standard was injected in splitless mode at 280 °C, employing helium as carrier with a steady flow of 1 mL/min. The temperature of the oven (110 °C) was held during 1 min; then, it was increased at a rate of 15 °C/min until 280 °C and kept constant at the final temperature during 15 min. Electron impact ionization at 70 eV was

used with the ion source at 225 °C. The employed quantification ions were m/z 116 and 131 for kresoxim-methyl and m/z 325 and 326 for TPP. Retention times were 11.0 and 14.0 min for kresoxim-methyl and TPP, respectively. For method validation, Deming regression and Bland–Altman analysis were applied using the SigmaPlot software (version 12.0).

RESULTS AND DISCUSSION

Assay Selectivity. Two mAb-based immunoassays for kresoxim-methyl were studied. Both assays employed mAb KM*o*#117 and the homologous conjugate but different cELISA formats (for hapten structure, see Figure S1 in the Supporting Information). Immunoassay selectivity with structurally related compounds was assessed toward the main strobilurin fungicides (trifloxystrobin, azoxystrobin, picoxystrobin, dimoxystrobin, metominostrobin, orysastrobin, pyraclostrobin, and fluoxastrobin; see Figure S2 in the Supporting Information). In both cELISA formats, antibody KM*o*#117 was highly selective to kresoxim-methyl (CR values with other strobilurins were below 1%). On the other hand, recognition toward chemicals potentially present in real samples was verified using active principles that are commonly formulated together with kresoxim-methyl, such as boscalid, fenpropimorph, epoxiconazole, propiconazole, tebuconazole, and pyrimethanil, and none of them was noticeably recognized by mAb KM*o*#117.

Tolerance to Solvents and Detergents. QuEChERS methodology for pesticide extraction from food matrices consists of a liquid phase extraction of homogenates with acetonitrile. Hence, tolerance of the described cELISAs to that solvent was appraised. The A_{max} and IC_{50} values of inhibition curves that had been run in the presence of different amounts of acetonitrile (from 0.5% to 10%, v/v) were compared to those obtained in the absence of solvent (see Figure 1). Only a slight influence over the assay signal was observed, and up to 2% acetonitrile was fairly well tolerated by the studied immunoassays.

Immunochemical competitive reactions are usually performed in the presence of different additives. Tween 20 is a common detergent for unspecific binding minimization; however, it has been often shown to exert a negative effect over the analytical parameters of immunoassays for small organic analytes.[16] The relative variation of A_{max} and IC_{50} values in the presence of different concentrations of Tween 20 (from 0% to 0.1%, v/v), taking 0.025% as a reference detergent concentration, is depicted in Figure 1. A similar behavior was observed with the two studied cELISAs, i.e., Tween 20 increased the A_{max} of both assays, but it also increased the IC_{50} value.

Influence of pH and Ionic Strength. The analytical influence of physicochemical conditions such as pH and ionic strength was evaluated. Competitive assays were performed following a biparametric study with composite design in which the center point conditions (pH = 7.5 and I = 175 mM at 25 °C) were similar to those of PBS. A series of buffers were prepared with a mixture of citrate, phosphate, and Tris in order to cover a wide effective pH range. The ionic strength of each buffer was fixed with NaCl, and Tween 20 was added. Figure 2 shows the overlaid contour plots for the responses (A_{max} and IC_{50} values) to pH and ionic strength changes of the two studied immunoassays, taking the results at center point conditions as the reference values. A constricted area for acceptable pH and ionic strength variations (the area stretching changes on A_{max} and IC_{50} values below ±20%; area in white color) was found for the indirect cELISA. With this assay, at pH 7.5, ionic strength values below 150 mM increased both A_{max} and IC_{50} values above tolerable levels (>120%), whereas values over 200 mM decreased excessively the A_{max} (<80%). On the contrary, the direct cELISA was very robust—A_{max} and IC_{50} changes stayed below ±20%—to alterations of either pH or ionic strength conditions (white area in lower graph of Figure 2).

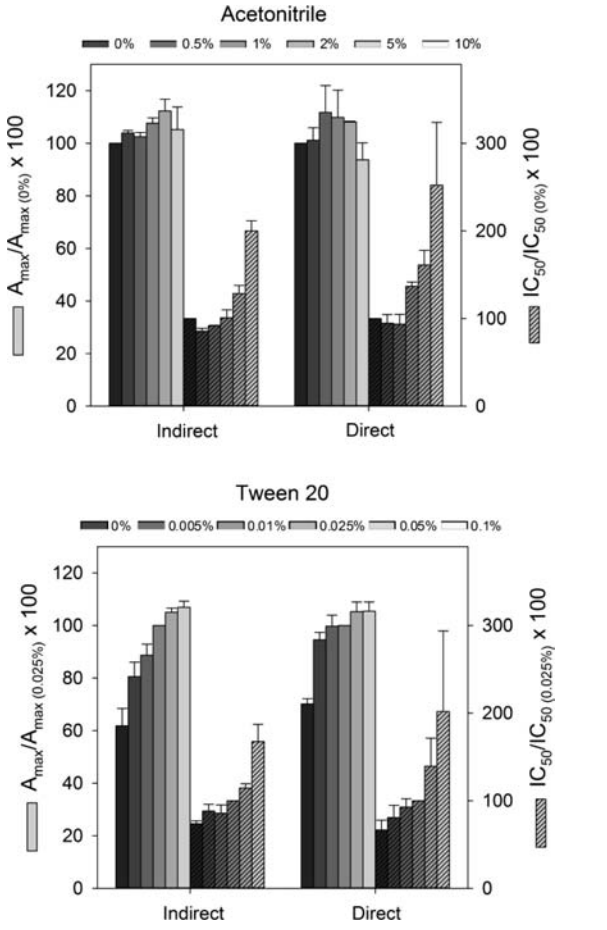

Figure 1. Influence of acetonitrile (upper graph) and Tween 20 (lower graph) contents over A_{max} and IC_{50} values of the studied immunoassays.

Immunoassay Validation. The assays were validated by investigating the LOD, LOQ, trueness, and repeatability. Final assay conditions of the developed cELISAs and the optimized standard inhibition curves can be found in Table 1. Optimum antibody concentrations were 100 and 300 μg/L for the indirect and direct format, respectively, whereas optimum assay conjugate concentrations were 100 μg/L for the former and 30 μg/L for the latter. Signals in the absence of analyte (A_{max}) were high (around 2.0), background signals (A_{min}) were low, and slopes were moderate (between −1.0 and −1.2). Under those conditions, the IC_{50} values for kresoxim-methyl were below 1 μg/L for both cELISAs, and the LODs were around 0.10 μg/L. Attempts to reduce these values by decreasing immunoreagent concentrations just resulted in lower A_{max} without a concomitant effect on assay sensitivity.

To evaluate the trueness and precision, the described immunoassays were applied to the analysis of kresoxim-methyl in diverse fortified foodstuffs. Nowadays, this pesticide is employed against a variety of plant diseases in cucumber,

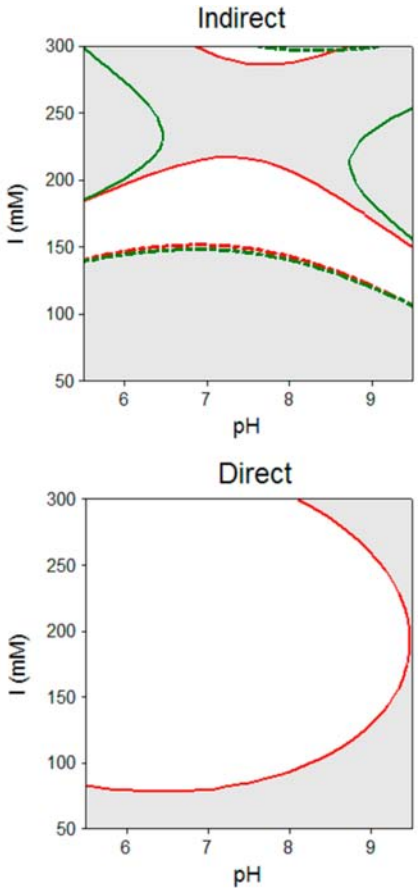

Figure 2. Overlaid contour plots for the A_{max} and IC_{50} dependence upon pH and ionic strength conditions of the studied immunoassays. White areas set the limits of acceptable pH and *I* conditions; those with A_{max} (red) and IC_{50} (green) variations between 80% (solid line) and 120% (dashed line), taking as a reference (100%) the average of the A_{max} and IC_{50} values of the center point conditions of the composite design.

tomato, and strawberry crops. Extracts of those food samples were prepared following a QuEChERS procedure that was essentially based on the AOAC Official Method 2007.01 for pesticide extraction from food matrices.[17] Homogenized foodstuffs were treated with acetonitrile in the presence of buffered saline and $MgSO_4$, and then a cleanup step using PSA was performed. Extracts from kresoxim-methyl-free samples (as judged by GC−MS) were fortified at four concentration levels and analyzed with the optimized immunoassays after a simple dilution in buffer. In general, quantitative recoveries (between 70% and 120%) and good precision values (relative standard deviation below 20%) were retrieved with each cELISA (Table 2), in accordance with the EU validation guidelines for pesticide residue analysis in food.[18] For both immunoassays, the limit of quantification (LOQ) for the studied foodstuffs was set at 0.01 mg/kg, which is lower than the European MRLs for kresoxim-methyl in these food products (0.05, 0.5, and 1.0 mg/kg for cucumbers, tomatoes, and strawberries, respectively).

As further validation of the developed cELISAs, strawberry samples from crops that we had sprayed with a commercial formulation of kresoxim-methyl were employed as model and relevant commodity in order to evaluate the performance of our novel analytical methods under real-like conditions. Fruits were extracted following a QuEChERS procedure and then analyzed

by the optimized immunoassays and by GC−MS (Table S2 in the Supporting Information). Trueness of the developed cELISAs was also assessed by statistical method comparison using the Deming regression, which accounts for errors in observations on both methods. Orthogonal regression analysis showed that the results provided by both cELISAs were statistically comparable to those retrieved by the reference method; i.e., the 95% confidence intervals for the intercept and for the slope included 0 and 1, respectively (Table 3). The corresponding regression lines can be seen in Figure S3 in the Supporting Information. Moreover, good correlation between the studied immunochemical technique and the reference chromatography approach was evidenced by the Bland−Altman plot (Figure 3), as the average values of both methods were randomly distributed around the average difference, and they were mostly inside the limits of agreement (average difference ±1.96 s), meaning that only random deviations occurred.

In summary, two mAb-based immunoassays to kresoxim-methyl—one indirect and one direct cELISA—have been characterized, optimized, and validated using food samples. These assays showed no CR with the most common strobilurin pesticides or a series of fungicides potentially present in relevant foodstuffs. A relative tolerance to acetonitrile contents was observed, and lower influence of pH and ionic strength changes over assay analytical parameters was found with the direct assay. Both immunoassays showed IC_{50} values below 1 μg/L under optimized conditions. The LOQs were fixed at 10 μg/kg from the analysis of fortified tomato, cucumber, and strawberry samples which had been extracted by the QuEChERS method. Overall, good recoveries and precision values were found. Method trueness was also demonstrated by comparison with a reference chromatographic method through statistical analysis using Deming regression and Bland−Altman plot.

casein-stabilized emulsions has been studied,[10] and improved stability against creaming has been reported.[11] However, studies on the oxidative stability of transglutaminase-cross-linked caseinate-stabilized emulsions are inconsistent. Whereas improved oxidate stability of flaxseed oil emulsions was recently reported when caseinate molecules were cross-linked prior to emulsification step,[12] no improvement or decreased oxidative stability was reported for cross-linked caseinate-stabilized fish oil emulsions.[13] In this work, analytical ultracentrifugation was used to gain insight into the state of aggregation in which sodium caseinate existed at the interface. Analytical ultracentrifugation is a versatile tool that can be used in the investigation of polymer size, polymer shape, molecular self-association, and molecular interactions.[14,15] In particular for proteins, analytical centrifugation is one of the classical methods used for the determination of oligomeric states and macromolecular interactions.[9] Due to the relatively large size of these macromolecules, the sedimentation profiles observed under gravitational fields lend this technique a high resolution.[10] The objective of this work was to investigate the oxidative stability of transglutaminase cross-linked caseinate-stabilized fish oil emulsions as a function of homogenization pressure.

MATERIALS AND METHODS

Chemicals. Sodium caseinate powder was provided by Tatua Co-operative Dairy Co. Ltd. (Tatuanui, New Zealand) and used in all experiments except for proton nuclear magnetic resonance (NMR) spectroscopy, in which sodium caseinate (Alanate 180) from New Zealand Milk Products (North America) Inc. (Santa Rosa, CA, USA) was used. Activa transglutaminase-T1 enzyme product, with maltodextrin and transglutaminase declared as main ingredients and with a commercially reported enzyme activity of 100 U/g, was provided by Ajinomoto North America, Inc. (Eddyville, IA, USA). The following were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA): 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) stock solution at 1.8 mM, 2-propanol, 30% hydrogen peroxide, ammonium thiocyanate, barium chloride dehydrate, disodium phosphate, ferric chloride hexahydrate, ferrous sulfate heptahydrate, isooctane, menhaden fish oil, potassium persulfate, sodium chloride, and triple-distilled peppermint oil. The following were purchased from Mallinckrodt Chemicals Inc. (St. Louis, MO, USA): butanol, hexane, and methanol. Ethyl acetate, glacial acetic acid, and sodium acetate trihydrate were purchased from J. T. Baker (Phillipsburg, NJ, USA). Iron powder was purchased from Acros Organics and hexane from EMD Chemicals (Philadelphia, PA, USA). Distilled water was used to prepare all aqueous solutions. Dilute solutions of hydrochloric acid and sodium hydroxide ($\leq$5 N) were used for pH adjustments.

Proton Nuclear Magnetic Resonance Spectroscopy. Proton NMR spectroscopy was carried out using a Varian 300 MHz NMR spectrometer (Varian, Inc., Palo Alto, CA, USA). Two percent (w/v) sodium caseinate solutions were either not treated by homogenization (0 kpsi, 0 MPa) or homogenized at 40 kpsi (276 MPa) under five passes using a Nano DeBEE 45 high-pressure homogenizer (BEE International, South Easton, MA, USA). Both solutions were freeze-dried and subsequently lyophilized from deuterium oxide of 99.9% isotopic purity (Sigma) twice. The samples were then dissolved to 2% (w/v) in deuterium oxide and analyzed. A homogenization pressure of 40 kpsi was selected for NMR studies because this is the highest pressure reached by the homogenizer. It is hypothesized that if protein interactions were promoted in protein solutions by the homogenization pressure, they should become evident after processing at highest homogenization pressures. However, in emulsion-making, a lower pressure (20 kpsi, 137.9 MPa) was selected because at higher homogenization pressures larger particle sizes were observed due to droplet coalescence promoted by the higher temperatures reached at 40 kpsi as compared to 20 kpsi.

Caseinate-Stabilized Emulsion Preparation. *Emulsification via High-Pressure Homogenization.* A 1% (w/v) sodium caseinate solution with 0.05 M sodium chloride and 0.05 M disodium phosphate was prepared at room temperature, during which the mixing time for ensuring complete solvation of the protein was at least 3 h. The pH was eventually adjusted to 7.0. A 4% (v/v) fish oil-in-water coarse emulsion was made using a VirtiShear homogenizer (SP Scientific, Gardiner, NY, USA) at 30000 rpm for 10 s, immediately followed by HPH using a Nano DeBEE 45 high-pressure homogenizer (BEE International) under three or eight passes at either 5 kpsi (34.5 MPa) or 20 kpsi (137.9 MPa). Samples from coarse emulsions were used as controls (~0 kpsi). For temperature control during HPH, a counter-current heat exchanger that was connected to a 2 °C water bath was positioned downstream of the emulsifying cell. Each emulsion sample batch consisted of 100 mL and was prepared in triplicate.

Enzymatic Cross-Linking of Interfacial Protein in Emulsions. The transglutaminase enzyme product was added to emulsion samples prepared at 20 kpsi at different concentrations (0, 5, 10, and 25 mg/mL of emulsion). Fifty milliliters of each emulsion batch added with transglutaminase was incubated for 1 h at 37 °C to avoid acceleration of oil oxidation. The emulsions were then immersed in boiling water for 4 min for enzyme inactivation and quickly cooled in water to room temperature.

Recovery of Interfacial Protein for Analytical Ultracentrifugation Analysis. To analyze the mass distribution of protein at the oil/water interface, emulsions homogenized at 0, 5, and 20 kpsi were made using a volatile oil that could be removed from the emulsion. Thus, peppermint oil was used in place of fish oil. The emulsion samples were ultracentrifuged at 46000*g* for at least 3 h at 2 °C using an Optima XL-I ultracentrifuge (Beckman Coulter, Brea, CA, USA). Immediately after ultracentrifugation, the supernatant was removed with a syringe needle, and then distilled water was added to disperse the residual cream in the centrifugation tube. The dispersed cream was frozen in liquid nitrogen and freeze-dried at −55 °C and 0 mbar using a FreezeMobile freeze-dryer (The VirTis Co., Gardner, NY, USA), during which frozen peppermint oil and water sublimed. After freeze-drying, the residual protein was redissolved in deionized water to a concentration of 2 mg/mL and subjected to overnight dialysis against a buffer of 0.05 M sodium chloride and 0.05 M disodium phosphate, at pH 7, using a Spectra/Por 4 standard regenerated cellulose dialysis membrane of 12−14 kDa molecular weight cutoff (Spectrum Laboratories, Inc., Rancho Dominguez, CA, USA).

Characterization of Oils. The suitability of using peppermint oil to replace fish oil, in the sample preparation of interfacial caseinate for analysis by analytical centrifugation, lies in its similarity in its influence on protein interfacial behavior. Although oil viscosity influences emulsion drop size, it is not the critical factor at issue. Because protein interfacial behavior is influenced by hydrophobicity of oil, it was relevant to gain an understanding about the partition coefficient of peppermint oil and its interfacial tension with water compared with those of fish oil, to validate its appropriateness.

Determination of Logarithm of Partition Coefficient. The solubility of oil in hexane could be determined by UV absorbance measurement.[16] Both fish oil and peppermint oil were assayed. Oil (25 μL) was added to a mixture comprising 20 mL of hexane and 20 mL of deionized water and vortexed for 5 min. The mixture was left to stand for phase separation until both phases became clear. UV absorbance was read at 250 nm on a Beckman Coulter DU 700 series UV−vis spectrophotometer (Beckman Coulter, Brea, CA, USA) for the hexane phase in duplicates, against a standard curve of oil in hexane within a 0−0.125% (v/v) concentration range. The logarithm of the ratio of oil concentrations in hexane and deionized water, log $P_{\text{hexane/water}}$, was calculated.

Measurement of Interfacial Tension with Water. The interfacial tension of fish oil/water and peppermint oil/water interfaces was measured in triplicate by a platinum ring (diameter = 6.1 cm, ratio of radii of ring to wire = 55.6) attached to a CSC DuNouy tensiometer 70545 (CSC Scientific Co., Inc., Fairfax, VA, USA). Each measurement was taken 30 min after layering of oil above the water at room temperature, in a glass dish having inner diameter = 4.7 cm and height

= 2.9 cm). The reading was adjusted by a correction factor read from the manual of the tensiometer.

Ferric Thiocyanate Peroxide Value Assay. To monitor oil oxidation, primary oxidation products were measured by the ferric thiocyanate peroxide value assay. Emulsions from each treatment, cross-linked at various transglutaminase concentrations homogenized at 0, 5, or 20 kpsi, were analyzed. The procedure for the assay was modified from that of Ogawa et al.,[17] and the exact details were reported in our earlier work.[18] Triplicate samples were removed over a period of 12 days for the determination of oxidative stability.

Emulsion Drop Size Measurement. Triplicate emulsion samples were diluted 100-fold with deionized water, and each triplicate was measured twice for particle size (*Z*-average) at 25 °C by dynamic light scattering (DLS), using a Zetasizer Nano ZS90 with optical arrangement at 90° (Malvern Instruments Ltd., Worcestershire, UK). During size measurement, the refractive indices of water and oil were set at 1.33 and 1.46, respectively, whereas the dispersant viscosity was that of water at 25 °C (i.e., 0.89 cP).

According to Thomas,[19] and as previously reported in our earlier work,[18] the average value of *Z*-average (Z_{av}) was converted to the average Sauter mean diameter (d_{32}) as

$$\text{av } d_{32} = Z_{av} \times (1 + Q)^2 \tag{1}$$

where Q was the average experimentally determined polydispersity obtained during particle size measurement.

Intrinsic Rate of Oxygen Depletion Calculation. It must be emphasized that the average emulsion drop size has a strong implication on the total interfacial area per volume subjected to contact with dissolved oxygen in the emulsion. Hence, the intrinsic rate of oxidation, which takes into account the interfacial area, is a more accurate indicator of the rate of oxidation in the average emulsion drop than the change of peroxide value of the emulsion over time. The intrinsic rate of oxidation has an especially strong bearing on the oxidative stability of emulsions with very fine drops, which are often desirable due to the slowing of creaming/sedimentation according to Stokes' law.

The calculation steps were reported in our earlier work.[18] The total rate of oxygen depletion during oxidation of oil was proportional to $(\partial(\text{Abs}_t - \text{Abs}_0))/(\partial t)$ and in turn $(6/d_{32}) \times$ intrinsic rate of oxygen depletion per unit of interfacial area of the emulsion drops, where Abs_0 was the average absorbance reading at 510 nm of an emulsion sample from peroxide value assay corrected by that of the blank at time = 0; Abs_t was the absorbance at 510 nm from peroxide value assay at time = t; and $(6/d_{32t})$ represented the ratio of the total surface area of the emulsion drops to total volume of the drops at time = t.

Hence, the relative intrinsic rate of oxygen depletion per unit of interfacial area of the emulsion drops was calculated as

$$\frac{\partial(\text{Abs}_t - \text{Abs}_0)}{\partial t} \times \frac{d_{32t}}{6} \tag{2}$$

Analytical Ultracentrifugation. Sedimentation velocity experiments were performed in an Optima XL-A ultracentrifuge (Beckman CoulterS). The samples analyzed included protein dissolved directly as it was in buffer, as well as freeze-dried protein recovered from emulsions after the sublimation of peppermint oil and redissolved in buffer. The final protein concentration ranged from 0.5 to 2.0 mg/mL as determined by the Lowry protein assay. Solvent densities and viscosities, along with the partial specific volume, were calculated with SEDNTERP (v. 1.09). The estimation of the partial specific volume ($\bar{v}$) was done according to the method of Cohn and Edsall:[20] $\bar{v} = (\sum \bar{v}_i n_i M_i)/(\sum n_i M_i)$, where n_i is the number of moles of ith component and M is its molecular weight. Solvent densities are extrapolated from the polynomial fit to

$$\Delta\rho_c = a + bC^{1/2} + cC + dC^2 + eC^3 + fC^4 - \rho_{water} \tag{3}$$

where $\Delta\rho_c$ is the density increment at a certain concentration, a–f are coefficients, C is the concentration of the solute, and ρ_{water} is the density of water.[21] Boundary positions were determined using the absorbance (280 nm) and interference (675 nm) optics, with scans taken every 4 min over 8 h at 45000 rpm. The $c(s)$ distributions were calculated using SEDFIT (v. 12.0b).[22] To assess the formation of higher order species, the weighted average sedimentation coefficients of the species was obtained by integration of the entire $c(s)$ distribution. The hydrodynamic movement of a particle can be described by the Svedberg equation: $M = (RTs)/(D(1 - \bar{v}\rho_{solv}))$, where M is molar mass, R is the gas constant, T is the temperature, D is the solute diffusion coefficient, $\bar{v}$ is the partial specific volume of the particle, and ρ_{solv} is the density of the solvent.[23] The sedimentation and diffusion of a particle in a section-shaped cell under a centrifugation field is described by the Lamm equation:

$$\frac{\partial\chi}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left[rD\frac{\partial\chi}{\partial r} - s\omega^2 r^2\chi\right] \tag{4}$$

SEDFIT employs a numerical solution to the Lamm equation that generates a $c(s)$ distribution describing the sedimenting solutes in the solution under a centrifugal field.[24]

Enzymatic Cross-Linking Turbidity Assay. It is expected that an increase in transglutaminase concentration will lead to an increase in cross-linking of caseinate. The turbidity assay was done as a quick qualitative verification of the relative extent of enzymatic cross-linking. Although the Zetasizer instrument may be used to measure particle size distribution in the sodium caseinate solutions to infer turbidity, the credibility of the results from the Zetasizer may be affected by the inherently high polydispersity at 1% (w/v). Hence, turbidity was analyzed by measuring the sample absorbance at 340 nm on a Beckman Coulter DU 700 series UV–vis spectrophotometer at room temperature. The transglutaminase enzyme product was added to 1% (w/v) sodium caseinate solutions (with 0.05 M sodium chloride and 0.05 M disodium phosphate, at pH 7) at 0, 5, 10, and 25 mg/mL and incubated in a 37 °C water bath for 1 h before being boiled for 4 min for enzyme inactivation. Sodium caseinate solutions with 5, 10, and 25 mg/mL of the enzyme product added and boiled immediately without an incubation step were prepared as positive controls. Triplicate measurements of the absorbance of the sodium caseinate solutions were taken. The mean increase in turbidity due to enzymatic cross-linking was reported by the subtraction of the mean absorbance of a positive control from the mean absorbance of the corresponding sample. Statistical analysis for mean comparison was done using the Tukey–Kramer test.

ABTS Decolorization Assay. For the ABTS assay, sample solutions of 1% (w/v) sodium caseinate (with 0.05 M sodium chloride and 0.05 M disodium phosphate, at pH 7) were subjected to enzymatic cross-linking at 5, 10, and 25 mg/mL of the transglutaminase enzyme product (37 °C for 1 h) followed by enzyme inactivation (100 °C for 4 min). Positive controls were added with the corresponding amounts of the transglutaminase enzyme product but subjected only to boiling for 4 min. The negative controls consisted of the native protein solution.

The assay is based on the quenching of the ABTS cationic radical, observed as the loss of blue-green color at 734 nm. The assay could be indicative of the scavenging capability of radicals such as reactive oxygen species or radical species formed from oil oxidation at the oil/water interface. In particular, the assay was chosen because it can be set up such that the sample pH is not altered, and neither does it involve the use of organic solvents. As such, the assay is free of complications from pH- and solvent-induced changes in solubility, structure, and/or state of aggregation of the protein. Although antioxidative mechanisms may be diverse, in the work of Moure et al.[25] involving protein analysis, the assay yielded results that generally agreed with the overall trend in antioxidant properties measured by different methods. The procedure for the assay was modified from that reported by Moure et al.[25] Two parts volume of 1.8 mM ABTS stock solution and five parts volume of 2.45 mM potassium persulfate in 0.02 M disodium phosphate solution were mixed together, adjusted to pH 7, and incubated for 1 h at room temperature in the dark to generate the blue-green ABTS radical cation. Duplicate measurements of radical scavenging capacity were done by mixing 20 μL of the sample or control with 2 mL of the radical solution and, after 15 min, reading the

absorbance at 734 nm on a Jasco V-650 spectrophotometer (Jasco Spectroscopic Co., Easton, MD, USA). The relative antioxidant capacity of the samples was inferred by comparing the mean absorbance values using the Tukey–Kramer method.

RESULTS

Figure 1 shows that the homogenizing pressure in HPH had no effect on the molecular structure of sodium caseinate in

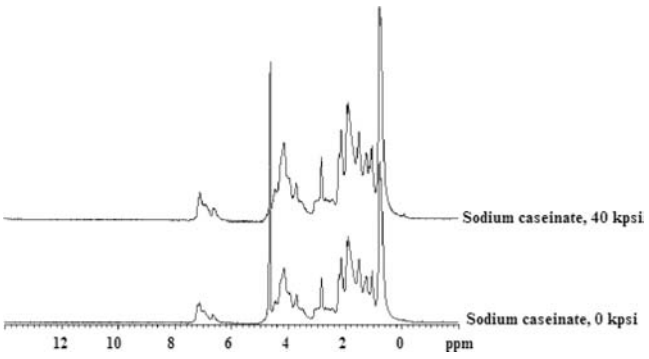

Figure 1. One-dimensional NMR spectra of 2% (w/v) sodium caseinate solutions that were not treated by homogenization (0 kpsi) and homogenized at 40 kpsi under five passes.

solution. Thus, it could be established that during emulsification by HPH, the homogenizing pressure would not exert any influence on the chemical antioxidant property of sodium caseinate in the continuous phase. Despite this, emulsions made by HPH (5 and 20 kpsi) showed slower initial rates of formation of primary oxidation products compared to a coarse emulsion (0 kpsi), as shown by the slope of the oxidation curves in Figure 2. The mean peroxide value (PV) of the coarse

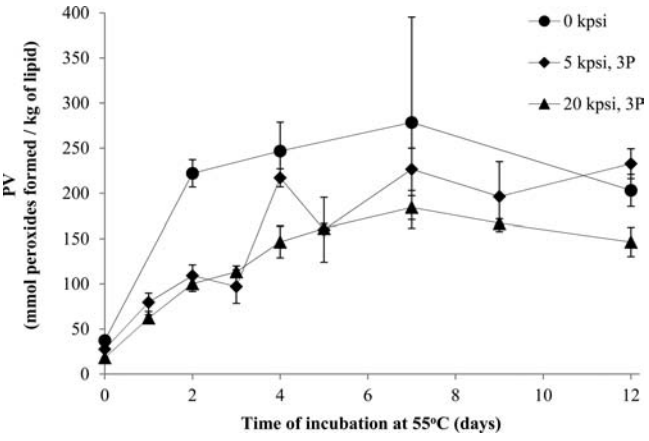

Figure 2. Plots showing the effect of high-pressure homogenization on the peroxide value with increasing incubation time (number of passes = 3) of emulsion samples. A decrease in PV at longer times is due to the conversion of primary to secondary oxidation products. Error bars indicate the standard deviation from the mean of triplicate readings.

emulsion declined considerably at longer incubation time (from days 7 to 12), reflecting further aggravated oil oxidation with the conversion of primary to secondary oxidation products. Between homogenizing pressures, the intrinsic rate of oxidation in emulsions at 20 kpsi was slower than for the emulsions made at 5 kpsi, as shown in Figure 3.1 by a steeper slope of the oxidation curve at 5 kpsi and early incubation times. By day 4 of incubation, emulsions formed at 20 kpsi were at a significantly

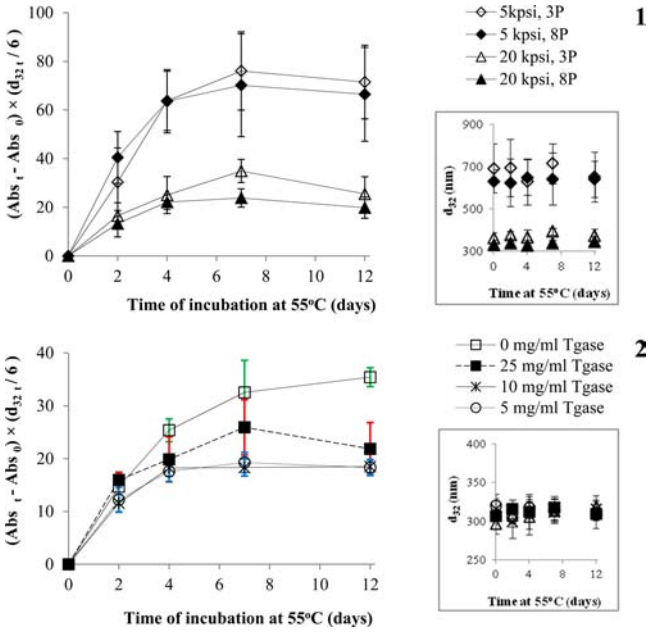

Figure 3. Plots of the relative intrinsic rate of oxygen depletion in fish oil per unit interfacial area, as influenced by (1) homogenization pressure and number of passes (P) and (2) use of different concentrations of the transglutaminase (Tgase) enzyme product at homogenization conditions of 20 kpsi and 3P. Error bars indicate the standard deviation from the mean of oxygen depletion. (Insets) Plots of the variation of the saunter mean diameter d_{32} of emulsions with time, with error bars indicating the standard deviation from the mean of six measurements from triplicates.

lower intrinsic state of oxidation than those formed at 5 kpsi. The difference in the intrinsic rate of oxidation between 5 and 20 kpsi homogenizing pressures is much more pronounced (Figure 3.1) than that in the PV values (Figure 2). This can be explained by the difference in the interfacial area available for oxidation. Compared to emulsions prepared at 5 kpsi, those made at 20 kpsi had significantly ($p < 0.05$) smaller mean d_{32} and thus larger total interfacial area per volume available for reaction with dissolved oxygen.

The addition of transglutaminase to emulsions did not lead to any significant difference in drop size, as shown in the inset of Figure 3.2. No sedimentable aggregates were formed. Even though the total interfacial area per volume was similar, there was improved emulsion oxidative stability at 5 and 10 mg/mL dosage of the enzyme product compared to no dosage. However, when the enzyme product concentration increased further (25 mg/mL), the beneficial effect of the use of transglutaminase apparently decreased. The general trend in the results suggested that there was an optimal enzyme level for emulsion oxidative stability.

Peppermint oil seemed to be a reasonable replacement of fish oil, as suggested by the results displayed in Table 1. From Table 1, the mean logarithm of partition coefficient of the peppermint oil was within 24% difference from that of the fish oil. The mean oil/water interfacial tension of the peppermint oil was within 32% difference from that of the fish oil. Figure 4 shows how homogenizing pressure affected the state of aggregation in solvated and interfacial caseinate. As seen in Figure 4.1, there was a slight increase in the mass of caseinate aggregates in the continuous phase of emulsions with increasing pressure. However, for interfacial caseinate, higher homogenizing pressure led to increased formation of larger species, as

dx.doi.org/10.1021/jf403285z | J. Agric. Food Chem. 2014, 62, 2822–2829

Table 1. Physical Properties of Fish Oil and Peppermint Oil[a]

oil	log $P_{hexane/water}$	oil/water interfacial tension (mN/m)
fish	1.37 ± 0.02 (SD)	12.0 ± 0.2 (SD)
peppermint	1.05 ± 0.04 (SD)	15.8 ± 0.3 (SD)

[a]SD stands for the standard deviation based on duplicate measurements for the logarithm of the partition coefficient, log $P_{hexane/water}$, and triplicate measurements for oil/water interfacial tension.

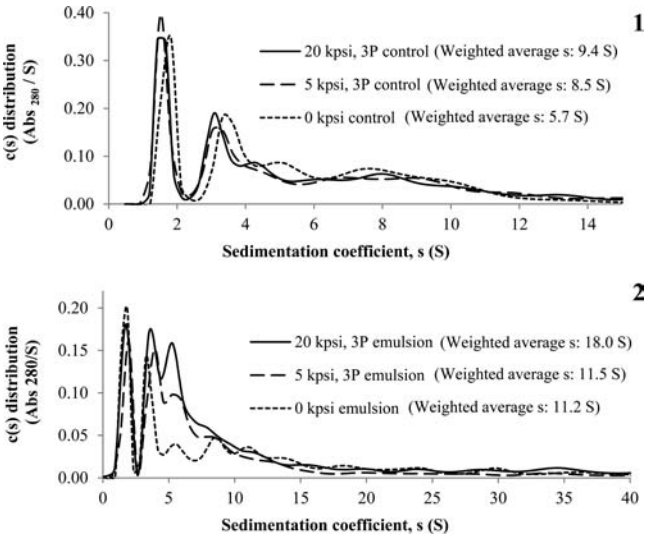

Figure 4. Sedimentation coefficient distribution plots for (1) sodium caseinate solutions homogenized under three passes (P) at 0, 5, and 20 kpsi, which served as controls, and (2) interfacial protein isolated from sodium caseinate emulsions made under three passes at 0, 5, and 20 kpsi. The weighted average sedimentation coefficient, *s*, of each sample is indicated.

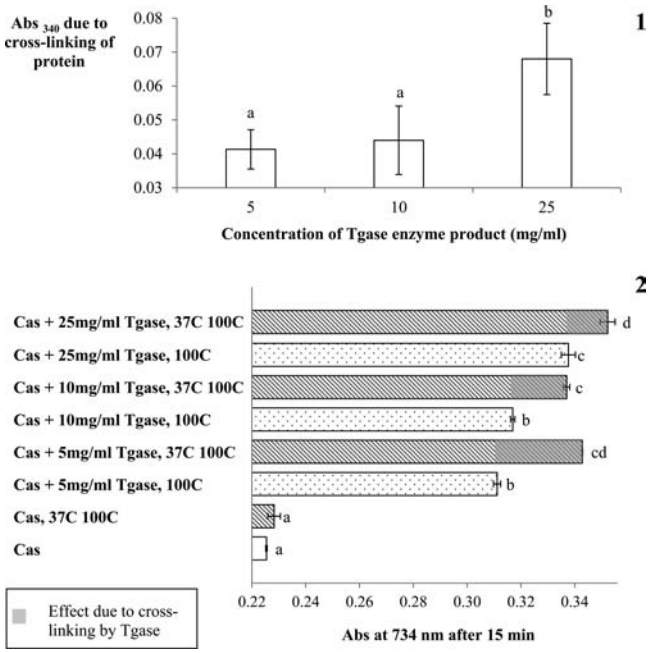

Figure 5. Results of spectrophotometric assays of 1% (w/v) sodium caseinate (Cas) solutions: (1) Turbidity measured at 340 nm as a function of concentration of the transglutaminase (Tgase) enzyme product during enzymatic cross-linking. Error bars indicate the standard deviation from the mean values derived from three measurements. (2) Absorbance measurements at 734 nm in the 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) assay. Prior to the ABTS assay, the samples (which contained Tgase) were subjected to treatment at 37 °C for 1 h followed by 100 °C for 4 min, whereas the positive controls (which also contained Tgase) were subjected to treatment at 100 °C for 4 min. Means with different letters are significantly different from one another at $p < 0.01$, according to the Tukey–Kramer test. Error bars indicate the standard deviation from the mean absorbance values derived from two measurements.

indicated in Figure 4.2 and by an upward shift in the weighted average sedimentation coefficient (from 11.2 S for 0 kpsi to 18 S for 20 kpsi).

Figure 5.1 depicts the results of the turbidity assay, with increase in transglutaminase concentration causing an increase in the cross-linking of caseinate. Figure 5.2 shows the results of the ABTS decolorization assay. The native sodium caseinate solution had the lowest mean absorbance reading at 734 nm, inferring higher antioxidant capacity than any other treated sample. Heat treatment at 37 °C and boiling of the native caseinate solution did not change the absorbance and antioxidant capacity significantly. Boiled protein samples containing the enzyme product had much higher absorbance at 734 nm overall due to the presence of maltodextrin in the commercial product. Generally, the higher the dosage of the enzyme product, the higher was the absorbance. However, at every enzyme product concentration, an additional 60 min of incubation at 37 °C (followed by boiling) led to even higher absorbance, indicating the reduction of chemical antioxidant capacity due to enzymatic cross-linking of caseinate.

DISCUSSION

The poor oxidative stability exhibited by coarse emulsions (0 kpsi) was expected because these emulsions are prone to creaming, due to the large particle size, which causes the oil droplets to become directly exposed to oxygen in the headspace. On the other hand, in emulsions made by homogenization, the increase in interfacial area due to smaller particle size would be expected to increase its susceptibility to react with oxygen present in the continuous phase, when oxygen concentration is not limiting. This was supported by Lethuat et al.,[26] who measured the rate of formation of conjugated diene in sunflower oil emulsions stabilized by bovine serum albumin. However, Let et al.[27] reported that milk-stabilized fish oil emulsions with smaller drops (and therefore larger interfacial area) were less oxidized than emulsions with larger drops. Similarly, higher lipid oxidative stability of caseinate-stabilized emulsion with smaller droplets was also reported by Ries et al.[28] In the present study, oxidative stability increased with decreasing emulsion droplet size. Figure 2 shows that the increase in PV versus time for the 20 kpsi emulsion was not significantly ($p < 0.05$) faster than that for the 5 kpsi emulsion. However, when particle size is taken into account, as shown in Figure 3.1, the lower the homogenizing pressure, the lower was the intrinsic emulsion oxidative stability. From the d_{32} results in the different test scenarios, the varying total interfacial areas per volume of emulsion could be evaluated. It was estimated that regardless of the total interfacial area in each test scenario, there was excessive caseinate at 1% (w/v) to permit maximum protein load at the plateau region of the interfacial adsorption isotherm, which was deduced to be around 3 mg/m^2 oil according to Tornberg's work.[29] As such, the protein load per unit interfacial area in each test scenario

could be reasonably assumed the same. Thus, it was not probable that the more oxidatively stable emulsions had significantly higher protein loads. It was unlikely that they had significantly thicker interfacial layers either, because the thickness of adsorbed caseinate (and casein) was found to be insensitive to adsorption conditions but constant at ∼10−15 nm.[30−32] The next section discusses the disparity in the observed emulsion oxidative stability from a molecular viewpoint (of how cross-linking might alter the chemical antioxidant property) and a physical standpoint (of how cross-linked interfacial caseinate might serve as a physical barrier against oil oxidation).

Analytical Ultracentrifugation Findings Show Higher State of Interfacial Protein Aggregation at Higher Homogenizing Pressure. Sodium caseinate in water at pH 7 is translucent in appearance at as low a concentration of 0.5% (w/v) and thus not completely soluble. Owing to this physical character, attempts to analyze the conformation of interfacial caseinate were met with obstacles. FTIR for studying protein secondary structure was not considered in this case, because the protein in question essentially lacks any defined secondary structure. Khun and Cunha[33] used sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) under non-reducing and reducing conditions to demonstrate the formation of disulfide linkages in interfacial whey protein with increase in homogenizing pressure. This method is, however, not applicable for the study of interfacial sodium caseinate because, first, sodium caseinate does not possess substantial sulfur amino acid residues and, second, the method dissociates any electrostatic and hydrophobic interactions that could have contributed to interfacial caseinate polymerization. In a preliminary experiment, native PAGE assay on a 15% criterion precast Tris-HCl gel (from Bio-Rad) was found not useful for the analysis of sodium caseinate either, as it was impossible to separate sodium caseinate into bands due to the size of molecular aggregates being >200 kDa. In another previous instance, sodium caseinate at pH 7 was found not soluble enough to be analyzed by multiangle laser light scattering-size exclusion chromatography (MALLS-SEC).

To our knowledge, the present study was the first time analytical ultracentrifugation was demonstrated to be a viable method for experimentally examining the state of protein aggregation at an oil−water interface. The analytical ultracentrifugation results of interfacial caseinate elucidated an upward shift in the order of oligomer species and molecular weight, when the homogenizing pressure increased. These results were in agreement with the trend in the high-performance liquid chromatography (HPLC) results published by Lee et al.,[34] which showed dimensionally larger aggregates in interfacial whey protein from emulsions subjected to higher homogenizing pressure. The increased aggregation in interfacial caseinate was an indication of cross-linking in its random coil structure. Slight increases in sedimentation coefficient patterns were observed in homogenized protein solutions, with values gradually increasing with increase in homogenization pressure (Figure 4.1). However, protein recovered for the interface dramatically increased the values for sedimentation coefficient with increasing pressure, presumably due to protein aggregation promoted by interactions between pressure and temperature. Similar observations have been reported for casein micelles subjected to static high-pressure treatments, where aggregation of casein micelles was reported for skim milk exposed to 200 MPa and mild temperature (40 °C), whereas deaggregation was observed at similar pressure levels but lower temperatures.[35]

Cross-Linking of Caseinate Was Associated with Decreased Chemical Antioxidant Property. The samples in the present study were all controlled for the starting level of dissolved oxygen by using the same source of water. To understand how cross-linking of caseinate would influence its inherent antioxidant property, the ABTS decolorization assay at 734 nm was performed on sodium caseinate solution samples dosed with different concentrations of the transglutaminase product, which also contained maltodextrin. When activated, transglutaminase catalyzes the formation of a covalent bond between the free ε-amine group of a protein-bound lysine and the γ-carboxyamide group of a protein-bound glutamine.[36] It was acknowledged that during enzyme inactivation by boiling, the process might cause the removal of dissolved oxygen and/or trigger the Maillard reaction between caseinate and maltodextrin; hence, the impact of boiling was also tested in the ABTS assay.

In all of the samples, absorbance due to turbidity was checked and verified to be negligible at 734 nm and hence would not significantly interfere with true absorbance due to the blue-green ABTS radical. In light of this, Figure 5.2 clearly shows that transglutaminase-induced cross-linking caused a reduction in antioxidant capacity, across the three enzyme product concentrations tested (5, 10, and 25 mg/mL dosage of the enzyme product or 50, 100, and 250 U/g sodium caseinate). Despite this, the emulsion oxidative stability in all three cases was better than without the use of transglutaminase (Figure 3.2). Because the improvement in emulsion oxidative stability could not be explained from a chemical standpoint, the cross-linked interfacial caseinate layer must have played a dominant role in terms of physical barrier property against oxidation. Considering that Kellerby et al.[37] did not observe improvement in the oxidative stability of sodium caseinate-based menhaden oil-in-water emulsions at a transglutaminase activity of 10 U/g protein, the present finding suggests a minimum enzyme activity needed to boost the physical barrier property of interfacial caseinate.

The results in Figure 3.2 also suggested a maximum in emulsion oxidative stability at an optimum transglutaminase activity, similar to the findings of Bao et al.[38] for spray-dried microalgal oil encapsulated by cross-linked sodium caseinate (with transglutaminase) as a function of the cross-linking time. Protein cross-linking could possibly reduce the solvent accessibility of some amino acids with antioxidant activity, such as tryptophan, tyrosine, histidine, methionine, and cysteine; however, the decline in emulsion oxidative stability from 10 to 25 mg/mL dosage of the enzyme product did not seem to be a case of cross-linking induced reduction in solvent accessibility of antioxidant amino acids prevailing over the interfacial physical barrier property. This was because as the dosage of the enzyme product increased, the reduction in antioxidant property owing to cross-linking decreased (see shaded regions in Figure 5.2). There was no significant difference ($p > 0.05$) in the average emulsion drop size between the 10 and 25 mg/mL dosed emulsions (inset in Figure 3.2), thus ruling out the possibility of different interfacial areas for oxygen transfer affecting the oxidation rates. The early stages of milk protein−carbohydrate Maillard reaction had been reported by Calligaris et al.[39] to generate oxidative species. Puscasu and Birlouez-Aragon[40] reported on how intermediary and/or advanced Maillard reaction products formed from milk protein

(α-lactalbumin) and lactose exhibited pro-oxidant property. Albeit scarce, and although the antioxidative property of Maillard reaction products is more widely recognized in general, reports on the pro-oxidant property of milk protein−carbohydrate Maillard reaction products do exist. In Figure 5.2, the increase in absorbance of the boiled-only protein−carbohydrate samples (without the 37 °C incubation) with increasing enzyme product dosage might be attributed to (i) a correspondingly higher formation of pro-oxidant Maillard reaction products and/or (ii) increasing protein−maltodextrin conjugation, leading to lessening solvent accessibility of amino acids with antioxidant activity. Hence, a plausible reason for the decline in emulsion oxidative stability in the 25 mg/mL dosed emulsion was that either or both the aforementioned points started to offset the effect of interfacial barrier resistance to oxygen transfer as a result of greater cross-linking in the interfacial caseinate.

Cross-Linking of Interfacial Caseinate Might Promote Tighter Packing and Hence Enhance Emulsion Oxidative Stability. The influential role of cross-linked interfacial caseinate in improving emulsion oxidative stability, as implied by the results of the ABTS assay on transglutaminase-treated systems, could similarly be inferred when interfacial cross-linking was induced by HPH.

Such a view is substantiated by the works of Lefèvre and Subirade[41] and Lee et al.[34,42] on whey protein adsorbed at the oil/water interface. These authors reported the formation of intermolecular β-sheet, which led to protein aggregation in the interfacial membranes. Lee et al.[34] also detected an increase in intermolecular β-sheet in the interfacial protein of whey protein-stabilized emulsions subjected to higher homogenizing pressure, further demonstrating how HPH could promote condensed interfacial packing that could boost the physical interfacial barrier property against oxidation.

The ability to analyze the density of the HPH-induced interfacial caseinate in situ was met with paramount technical challenge, because the dynamics of conformational behavior accompanying interfacial adsorption during HPH needed to be captured. Neutron scattering and dual polarizing interferometry are both advanced techniques suitable for analyzing the thickness of the interfacial film or the variation of density along the film thickness, but only under static experimental conditions when the film is preformed or immobilized. Molecular dynamics simulations may hold the key to better understanding of the conformational dynamics. The following proposes what might have happened at a higher homogenizing pressure of 20 kpsi as opposed to 5 kpsi, such that it promoted higher emulsion oxidative stability:

For simplicity, sodium caseinate at pH 7 could be molecularly viewed as a polyelectrolyte chain. At 20 kpsi, there was a higher convection rate and thus greater kinetic energy accompanying the turbulence in HPH, which could better overcome the adsorption energy barriers[43] arising from increasing repulsive electrostatic and/or steric interaction forces of protein molecules already adsorbed,[44] whereas free interfacial area continued to diminish. According to the simulation study by Aguilera-Granja and Kikuchi,[45] the polyelectrolyte chains approaching the adsorbent surface experienced such strong electrostatic repulsion that in avoidance they preferentially adsorbed almost as a monolayer with a dominantly high train fraction rather than the loops and tails combined because such a conformation considerably lowered the free energy in the system by exposing hydrophobic functional groups to the oil phase. As such, a tighter packing in the foremost subinterfacial layer to the oil, comprising a higher density of train segments, could be envisioned for HPH at 20 versus 5 kpsi. At sufficiently high surface coverage, the closer local proximity among the train segments could have promoted intermolecular cross-linking and thus led to the analytical ultracentrifugation finding of more interfacial protein oligomers of higher species during HPH at 20 kpsi. The postulated denser subinterfacial layer of train segments probably provided additional resistance to oxygen diffusion from the continuous phase to the oil, thus increasing the physical interfacial barrier property against oxidation. Furthermore, densification of a β-casein cross-linked adsorbed onto polystyrene beads was recently reported by Partanen et al.[46]

polymerase (PARP), and GAPDH were purchased from Cell Signaling Technology, Inc. (Danvers, MA, USA). The antibody against cyclin E was obtained from Santa Cruz Biotechnology (Dallas, TX, USA). Other chemicals and reagents were of high quality and obtained from commercial sources.

Heat-Processing of Ginsenoside Re. Ginsenoside Re was steamed at 120 °C for 3 h using an autoclave as reported previously.[12,13] The reaction was conducted in aqueous solution to contain approximately 5 mM ginsenoside Re. After drying at 50 °C for 3 days, untreated and heat-processed ginsenoside Re at 120 °C were prepared.

Analysis of Ginsenosides. Untreated and heat-processed ginsenoside Re were weighed (10 mg) and completely dissolved in 1 mL of 50% methanol and then filtered through a 0.45 μm syringe filter for high-performance liquid chromatography (HPLC) analysis. The analytical reversed-phase HPLC system consisted of a solvent degasser (Agilent, G1322A), binary pump (Agilent, G1312C), an autosampler (Agilent, G1329B), and model ZAM 3000 evaporative light scattering detector (ELSD) (Young Lin, South Korea). ELSD conditions were optimized in order to achieve maximum sensitivity: temperature of the nebulizer was set for 50 °C, and N_2 was used as the nebulizing gas at a pressure of 2.0 bar. A Phenomenex Luna C18 column (150 × 4.6 mm, 5 μm) was used, and the mobile phase consisted of a binary gradient of solvent A (acetonitrile:water:5% acetic acid in water = 15:80:5) and solvent B (acetonitrile:water = 80:20) at a flow rate of 1.0 mL/min. The gradient flow program was as follows: initial; 0% B, 6 min; 30% B, 18 min; 50% B, 30 min; 100% B. Ginsenosides were identified by the comparison of retention times with those of standard samples. The standard solutions containing 1−50 μg of each ginsenoside were injected into the HPLC, and all calibration curves showed good linearity (R^2 > 0.995). The analysis was repeated two times for the verification of repeatability.

Antiproliferative Effect on Gastric Cancer Cells. The human gastric cancer AGS cell line was purchased from the American Type Culture Collection (ATCC, Manassas, VA, USA). The cells were grown in RPMI1640 medium (Cellgro, Manassas, VA, USA) supplemented with 10% fetal bovine serum (Gibco BRL, Carlsbad, MD, USA), 100 units/mL penicillin, and 100 μg/mL streptomycin and incubated at 37 °C in a humidified atmosphere with 5% CO_2. AGS cells were treated with different concentrations of compounds for 24 h, and cell proliferation was measured using the Cell Counting Kit-8 (CCK-8, Dojindo Laboratories, Japan) according to the manufacturer's recommendations. CCK-8 allows sensitive assays by utilizing the highly water-soluble tetrazolium salt, WST-8, which is reduced by dehydrogenase activities in cells to give a yellow-color formazan dye, which is soluble in the tissue culture media. The amount of the formazan dye, generated by the activities of dehydrogenases in cells, is directly proportional to the number of living cells. Briefly, cells seeded in 96-well plates were treated with various concentrations of compounds. After incubation for the indicated times, 10 μL of CCK-8 reagent was added to each well. Cell proliferation was assessed by scanning with a microplate reader at 450 nm.

Hoechst Staining. Cells in 6-well plates were treated with the indicated compounds and incubated for 24 h at 37 °C. After the cells were washed twice with cold PBS, the cells were then incubated with 1 μg/mL Hoechst 33342 (Sigma-Aldrich, St. Louis, MO, USA) for 15 min in the dark at 37 °C before image acquisition. Stained cells were subsequently examined using an inverted fluorescence microscope.

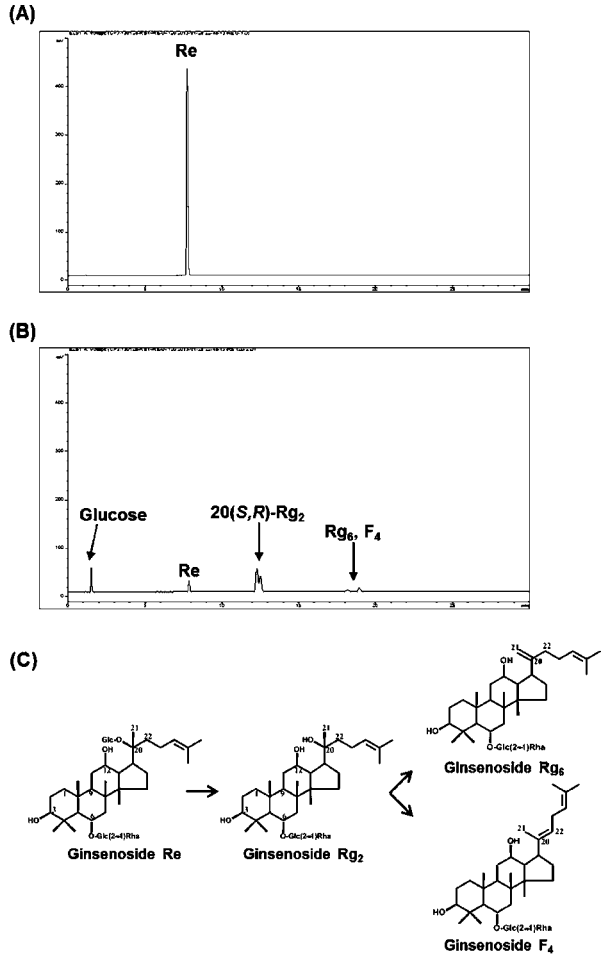

Figure 1. Comparison in the HPLC chromatograms of ginsenoside Re before and after heat-processing at 120 °C. (A) HPLC chromatogram of ginsenoside Re before heat-processing. (B) HPLC chromatogram of ginsenoside Re after heat-processing. (C) Proposed reaction scheme for the heat-treatment of ginsenoside Re. -Glc: D-glucopyranosyl. -Rha: L-rhamnopyranosyl.

Flow Cytometric Assay. To detect changes in cell cycle distribution, the treated cells were collected, washed with cold PBS, and fixed in 70% ethanol at 4 °C for 30 min. The cells were then washed twice with PBS and resuspended in 500 μL of a propidium iodide (PI) staining solution containing 40 μg/mL PI and 20 μg/mL RNase A in PBS. Then, the cells were incubated at room temperature for 30 min in the dark and analyzed with a FACSCalibur flow cytometer (Becton-Dickinson, San Jose, CA, USA) and the ModFit LT V2.0 computer program. Apoptotic cell death was assessed by annexin-V/PI double staining using an Annexin-V-FLUOS Staining Kit (Roche, Penzberg, Germany) according to the manufacturer's recommendations. At least 20,000 events were evaluated in each experiment.

Caspase Activity Assay. Caspase-3, -8, and -9 activities were determined by using caspase-3, -8, and -9 fluorometric assay kits according to the protocol of the manufacturer (BioVison, Milpitas, CA, USA). In brief, a total of 1.6 × 10^6 cells were seeded in 100 mm dishes and incubated for 24 h at 37 °C. Heat-processed ginsenoside Re at 40 and 80 μg/mL and ginsenoside Rg6/F4 mixture at 50 μg/mL were directly added to the dishes and incubated for an additional 24 h. In order to examine the possible effects of ginsenoside on caspase-dependent apoptosis, AGS cells were also pretreated with 50 μM Z-VAD-fmk

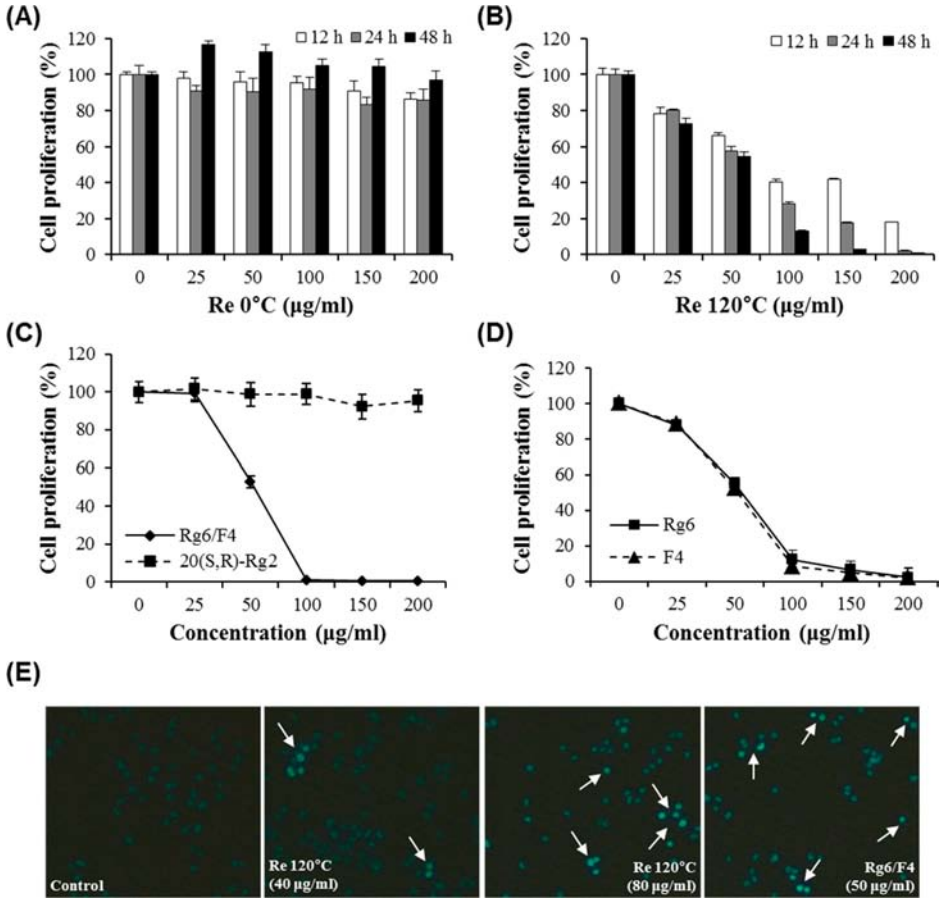

Figure 2. Changes in effects of ginsenoside Re upon heat-processing on AGS cell proliferation. AGS cells were treated with the indicated concentrations of ginsenoside Re (A) and heat-processed ginsenoside Re (B) for 12, 24, and 48 h, and cell proliferation was examined by CCK-8 assay. (C) AGS cells were treated with the indicated concentrations of ginsenosides 20(*S*,*R*)-Rg2 and Rg6/F4 mixtures for 24 h, and cell proliferation was examined by CCK-8 assay. (D) AGS cells were treated with the indicated concentrations of ginsenosides Rg6 and F4 for 24 h, and cell proliferation was examined by CCK-8 assay. (E) AGS cells were treated with the indicated concentrations of heat-processed ginsenoside Re for 24 h, and subjected to Hoechst staining assay. Apoptotic cells (bright blue fluorescent) are indicated with a white arrow. Each value represents the mean ± SEM of three independent experiments.

(pan-caspase inhibitor) for 2 h prior to ginsenoside treatment. The cells (1.0×10^6 cells) were lysed in the supplied 50 μL of lysis buffer and incubated for 10 min in an ice bath. Then, 50 μL of 10 mM dithiothreitol 2× reaction buffer and 5 μL of the 1 mM substrates for caspase-3, -8, and -9 were added to each of the lysed samples and incubated for an additional 1.5 h at 37 °C. Subsequently, caspase activities were measured by comparing relative fluorescent intensities using a Tecan Infinite M1000 plate reader (Männedorf, Switzerland) equipped with a 400 nm excitation filter and 505 nm emission filter.

Western Blotting Analysis. AGS cells (8×10^5 cells) were grown in 60 mm dishes and treated with heat-processed ginsenoside Re at 40 and 80 μg/mL and ginsenoside Rg6/F4 mixture at 50 μg/mL for 24 h. Whole-cell extracts were then prepared according to the manufacturer's instructions using RIPA buffer (Cell Signaling, MA, USA) supplemented with 1× protease inhibitor cocktail and 1 mM phenylmethylsulfonyl fluoride (PMSF). Proteins (whole-cell extracts, 30 μg/lane) were separated by electrophoresis in a precast 4−15% Mini-PROTEAN TGX gel (Bio-Rad, Hercules, CA, USA) blotted onto PVDF transfer membranes and analyzed with epitope-specific primary and secondary antibodies. Bound antibodies were visualized using ECL Advance Western Blotting Detection Reagents (GE Healthcare, U.K.) and a LAS 4000 imaging system (Fujifilm, Japan).

Statistical Analysis. Statistical significance was determined through one-way analysis of variance (ANOVA) followed by a multiple comparison test with a Bonferroni adjustment. *P* values of less than 0.05 were considered statistically significant.

RESULTS AND DISCUSSION

Anticancer effects of several ginsenosides have been identified. In particular, diol type ginsenosides were shown to trigger apoptotic cell death.[21] Ginsenoside Rg3 induces senescence-like growth arrest in human glioma cancer through Akt, which is associated with increased ROS levels and p53/p21-dependent signaling pathways.[22] Ginsenoside Rg3 and Rh2 have also been known to induce apoptosis by the activation of caspase-3 and Bax protein, inhibition of Bcl-2 protein, and production of intracellular ROS in human hepatocellular carcinoma cells.[16] Ginsenoside Rg5 blocks the cell cycle of human hepatoma SK-HEP-1 cells via downregulation of cyclin E-dependent kinase activity.[14] In addition, ginsenoside F2 has been reported to induce apoptosis in breast cancer stem cells by activating the intrinsic apoptotic pathway and mitochondrial dysfunction.[23] However, apart from our previously published investigation, there is no report of positive evidence to show antiproliferative efficacy of ginsenosides Rg6 and/or F4.[24]

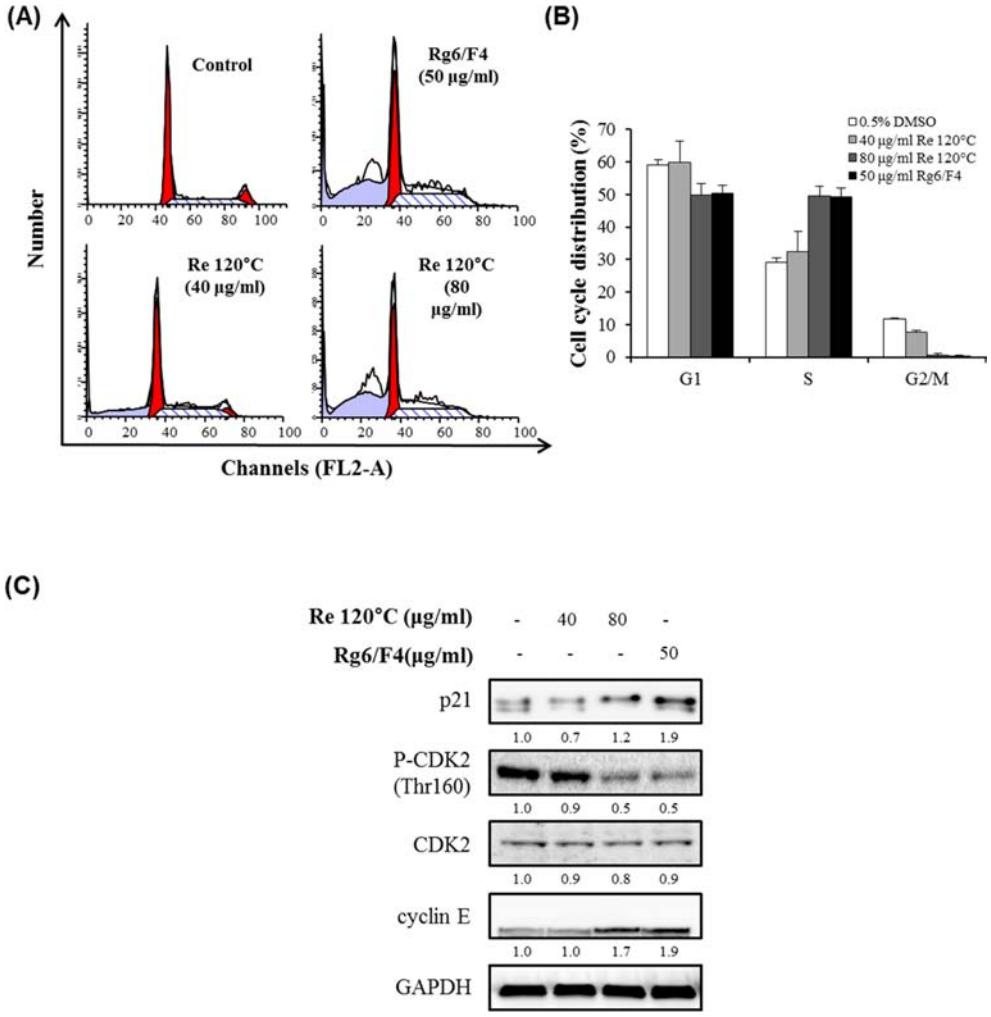

Figure 3. Effects of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures on AGS cell cycle. (A, B) AGS cells were treated with the indicated concentrations of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures for 24 h, and FACS analysis/PI staining was then performed to assess cell cycle distribution. Each value represents the mean ± SEM of three independent experiments. (C) The protein levels of p21, p-CDK2, CDK2, and cyclin E were detected by Western blot analysis using their respective antibodies. GAPDH was used as an internal control. A representative immunoblot of three independent experiments is shown. Density ratios over GAPDH were measured by densitometer.

Figure 1 shows HPLC chromatograms comparing ginsenoside Re before and after heat-processing at 120 °C. Native ginsenoside Re (1000.0 μg/mL) was detected at about 7.8 min (Figure 1A). Following heat treatment, the peak of ginsenoside Re (52.1 μg/mL) decreased, and the peaks of ginsenoside 20(*S*)-Rg2 (168.9 μg/mL), 20(*R*)-Rg2 (125.4 μg/mL), Rg6 (20.7 μg/mL), and F4 (35.4 μg/mL) appeared (Figure 1B). Therefore, we can deduce that ginsenoside Re was transformed into ginsenosides 20(*S*,*R*)-Rg2, Rg6, and F4 by heat-processing (Figure 1C).

Figures 2A and 2B show a comparison of antiproliferative effects of ginsenoside Re and heat-processed ginsenoside Re at 120 °C in AGS cells. Heat-processed ginsenoside Re was found to significantly suppress cell proliferation in a dose- and time-dependent manner, whereas ginsenoside Re had no effect up to 48 h. Because of evident cytotoxicity at 24 h by heat-processed ginsenoside Re (IC_{50}: 79 μg/mL), we pursued the following experiments at this time point. Figure 2C shows the comparison of antiproliferative effects of ginsenosides 20(*S*,*R*)-Rg2 and ginsenoside Rg6/F4 mixtures. The ginsenoside Rg6/F4 mixture strongly suppressed cell proliferation in a dose-dependent manner (IC_{50}: 49 μg/mL), but ginsenosides 20(*S*,*R*)-Rg2 had no effect (IC_{50} > 200 μg/mL). Ginsenosides Rg6 and F4 exhibited almost the same cytotoxic effect against AGS cells (IC_{50}: 49 μg/mL) (Figure 2D) and less cytotoxic activity against normal porcine kidney proximal tubular epithelial LLC-PK1 cells (IC_{50}: 96 μg/mL). As shown in Figure 2E, changes in apoptosis (nuclear pyknosis and chromatin condensation) were observed under a fluorescence microscope. The number of apoptotic cells, displayed with bright blue fluorescence, was also increased after treatments with heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures (Figure 2E).

The effects of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture on the cell cycle distribution at 24 h are shown in Figures 3A and 3B. The population of cells in S phase was increased by treatment with heat-processed Re at 40 and 80 μg/mL in a dose-dependent manner (32.5 ± 6.29 and 49.6 ± 2.99% versus 29.1 ± 1.30%). Ginsenoside Rg6/F4 mixture at 50 μg/mL also promoted similar accumulation of cells in S phase to heat-processed ginsenoside Re (49.4 ± 2.57% versus 29.1 ± 1.30%). During S phase, active CDK2−cyclin E complexes predominate and require phosphorylation of CDK2 at Thr160.[25] Inhibition of CDK2−cyclin E complexes can also be attributed to association with p27 and p21.[26] As shown in Figure 3C,

dx.doi.org/10.1021/jf5000776 | J. Agric. Food Chem. 2014, 62, 2830−2836

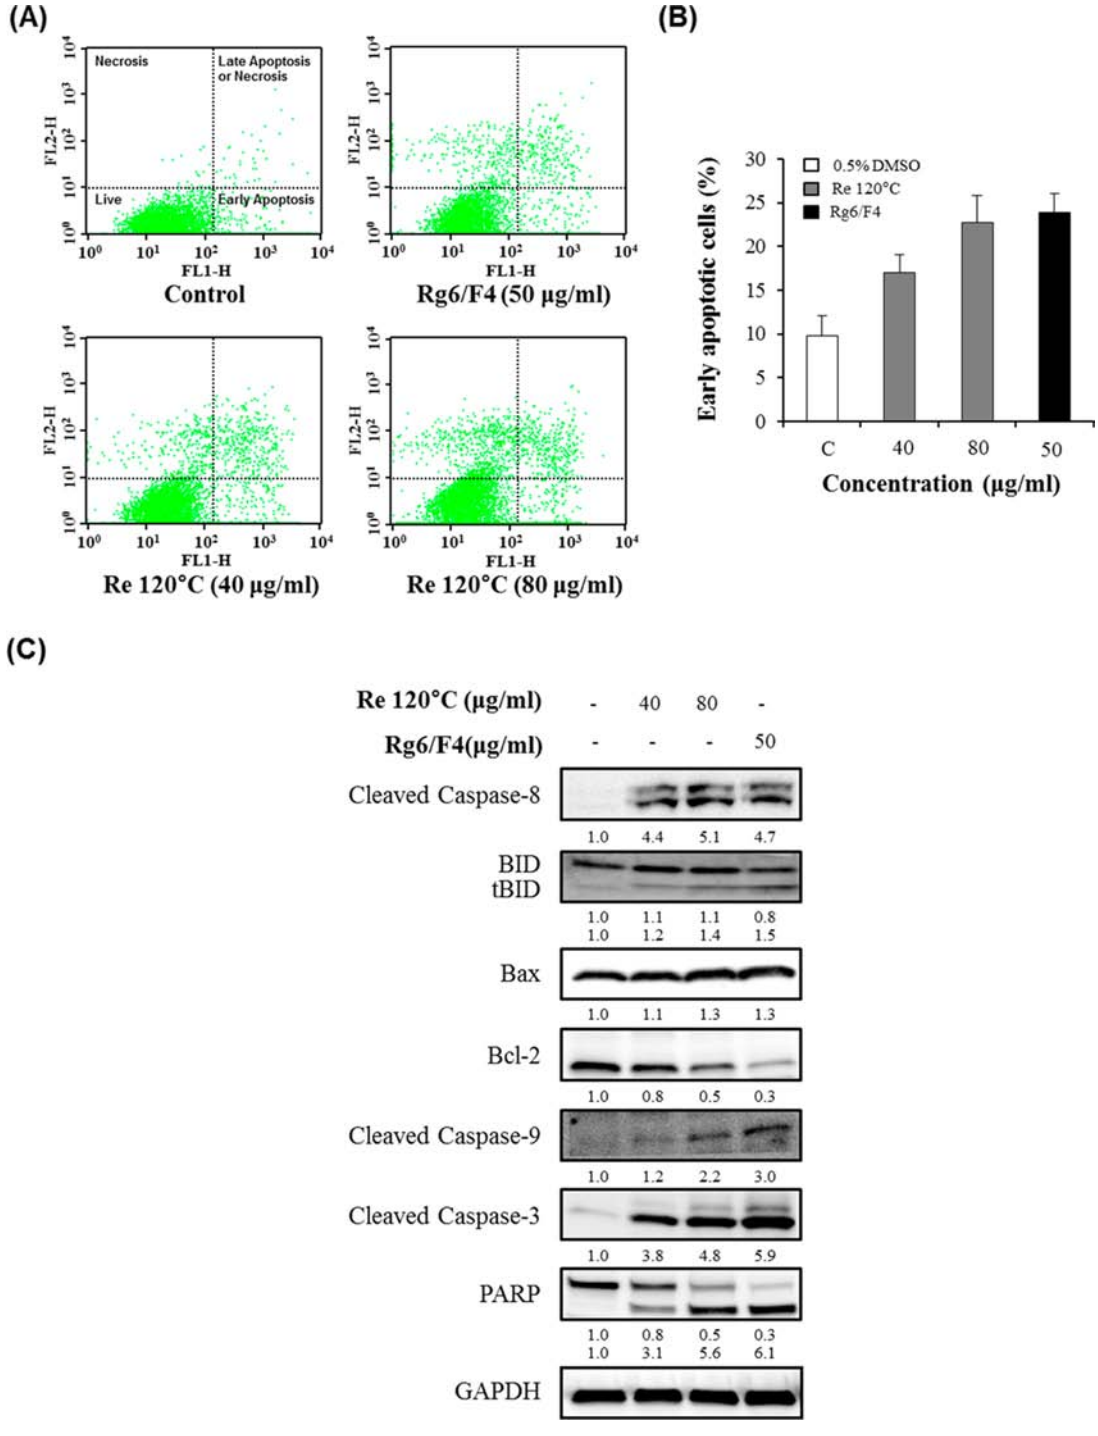

Figure 4. Effects of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures on apoptosis in AGS cells. (A, B) AGS cells were treated with the indicated concentrations of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures for 24 h, and FACS analysis/AV-PI double-staining was then performed to assess apoptotic cell death. Each value represents the mean ± SEM of three independent experiments. (C) The protein levels of cleaved caspase-8, BID, Bax, Bcl-2, cleaved caspase-9, cleaved caspase-3, and PARP were detected by Western blot analysis using their respective antibodies. GAPDH was used as an internal control. A representative immunoblot of three independent experiments is shown. Density ratios over GAPDH were measured by densitometer.

heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture elevated p21 and cyclin E protein levels and inhibited phosphorylation of CDK2 at Thr160. Consequently, both of them induced p21-mediated S phase arrest.

Exposure to heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture resulted in significant apoptosis (Figures 4A and 4B). Heat-processed ginsenoside Re at 40 and 80 μg/mL caused 17.0 ± 2.08% and 22.8 ± 3.01% early apoptotic cell populations, respectively, compared with control value showing 9.7 ± 2.29. Ginsenoside Rg6/F4 mixture at 50 μg/mL also promoted similar induction of apoptosis to heat-processed ginsenoside Re (23.8 ± 2.25% versus 9.7 ± 2.29%). Since apoptosis is one of the mechanisms by which cells undergo death, we also confirmed the molecular mechanisms of

dx.doi.org/10.1021/jf5000776 | J. Agric. Food Chem. 2014, 62, 2830−2836

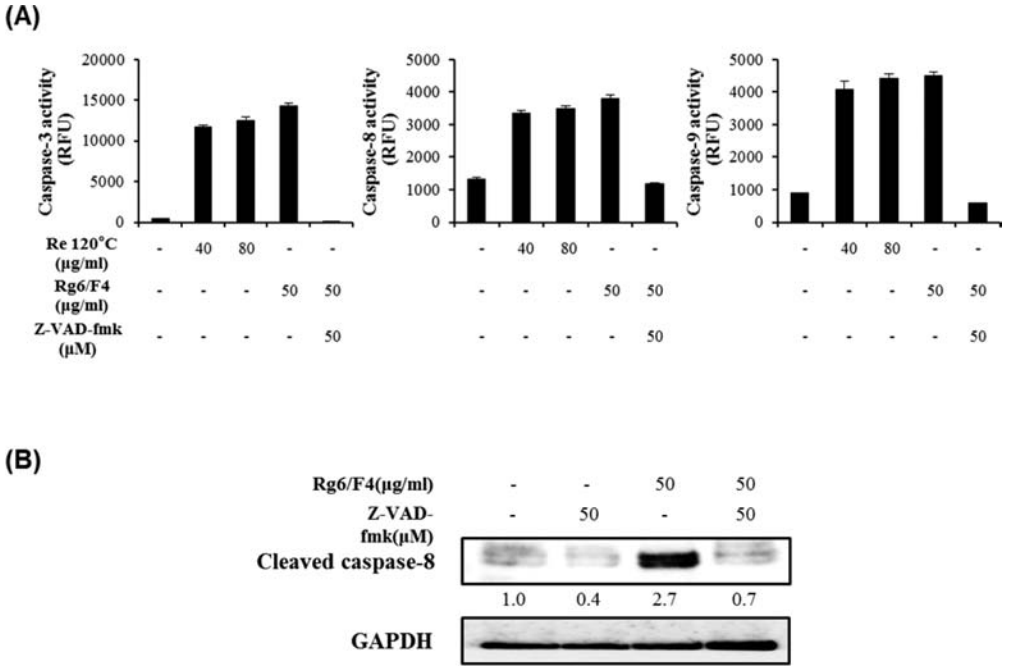

Figure 5. Involvement of caspases in the heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture-induced apoptosis in AGS cells. (A) AGS cells were pretreated with or without 50 μM Z-VAD-fmk for 2 h, followed by exposure to the indicated concentrations of heat-processed products of ginsenoside Re for 24 h, and the activity levels of caspase-3, -8, and -9 were then estimated. Each value represents the mean ± SEM of three independent experiments. (B) AGS cells were pretreated with or without 50 μM Z-VAD-fmk for 2 h, followed by exposure to 50 μg/mL ginsenoside Rg6/F4 mixtures for 24 h, and the protein level of cleaved caspase-8 was detected by Western blot analysis using its respective antibody. GAPDH was used as an internal control. A representative immunoblot of three independent experiments is shown. Density ratios over GAPDH were measured by densitometer.

apoptotic effects by Western blotting. Western blotting results on the protein levels related to caspases and apoptosis are shown in Figure 4C. Treatment of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture increased the level of cleaved caspase-8. While the level of full-length BID (22 kDa) gradually decreased, the level of the active form of tBID (15 kDa) increased after treatment with heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture. The level of proapoptotic protein Bax was slightly increased by treatment with ginsenoside Rg6/F4 mixture, but the level of antiapoptotic protein Bcl-2 markedly decreased by the same condition. Protein levels of cleaved caspase-9 and -3 increased after treatment with heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures. The level of full-length PARP (116 kDa) decreased, whereas the level of cleaved PARP (89 kDa) increased by treatment with heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixtures.

Histograms in Figure 5A show the effect of the pan-caspase inhibitor Z-VAD-fmk on cell proliferation to further confirm the role played by caspases in ginsenoside Rg6/F4 mixture-induced apoptosis. The activities of caspase-3, caspase-8, and caspase-9 were significantly increased by treatment with the products of heat-processed ginsenoside Re and ginsenoside Rg6/F4 mixture. However, Z-VAD-fmk completely inhibited ginsenoside Rg6/F4 mixture-induced caspase activity to near basal levels. As shown in Figure 5B, pretreatment with Z-VAD-fmk completely suppressed the cleavage of caspase-8 by ginsenoside Rg6/F4.

In the present study, we investigated the anticancer effects of heat-processed ginsenoside Re on AGS human gastric cancer cells. Ginsenoside Re was transformed into less-polar ginsenosides, namely, Rg2, Rg6, and F4 by heat-processing. Among them, we discovered that ginsenosides Rg6 and F4 have

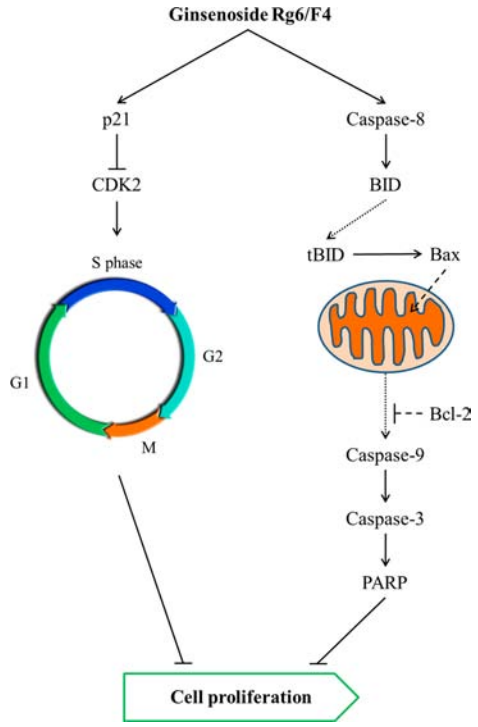

Figure 6. Schematic description of the anticancer mechanism of ginsenoside Rg6 and F4 in AGS cells.

anticancer activity through p21-mediated S phase arrest and caspase-dependent apoptosis (Figure 6). The present study provides a new insight on the mechanism of beneficial effects of heat-processed ginseng on gastric cancer.

Although the antioxidant properties of MR mixtures are well-known and the above-mentioned mechanism for antioxidant properties of reductones is discussed, the antioxidant properties of single compounds are rarely determined. The motivation of the present work was to expend the knowledge about the antioxidant properties of single MR products. 1-DG **3** and GLUC **4** seemed to be a promising starting point, because they are both important intermediates of the MR and possess a structure that should have antioxidant abilities.

Thus, three different methods were used to measure the antioxidant capacity of the two MR intermediates: the spectrophotometric assays TEAC and FCR as well as EPR spectroscopy. In addition, both substances were compared to different MR products and the two reducing carbohydrates D-glucose and D-fructose.

Furthermore, MR model experiments (pH 5 and 8; 80, 100, and 130 °C; with and without L-alanine addition) with D-glucose and D-fructose, as well as with synthesized 1-DG **3** and GLUC **4**, were conducted and investigated in terms of antioxidant abilities, 1,2-dicarbonyl content, and browning.

MATERIALS AND METHODS

Chemicals. 2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), benzoyl hydrazine, ethyl vinyl ether, Folin−Ciocalteu's phenol reagent, D-*arabino*-hexo-2-ulose (GLUC **4**), glyoxal (GO; 40 wt % in water), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (trolox), (−)-2,3-*O*-isopropylidene-D-erythronolactone, potassium nitrosodisulfonate (Fremy's salt), potassium persulfate, and 3-hydroxy-2-methyl-4*H*-pyran-4-one (maltol **2**) were purchased from Sigma-Aldrich (Steinheim, Germany); Dowex 50W X8 and *o*-phenylenediamine (OPD) were purchased from Fluka (Steinheim, Germany); acetic acid, benzaldehyde, ethanol, D-fructose, D-glucose, potassium hydrogen phosphate anhydrate, potassium dihydrogen phosphate anhydrate, phenyl hydrazine, sodium dihydrogen phosphate dihydrate, and *p*-toluidine were purchased from Merck (Darmstadt, Germany); L-alanine was purchased from Roth (Karlsruhe, Germany); methanol was purchased from VWR (Darmstadt, Germany); gallic acid monohydrate was purchased from Serva (Heidelberg, Germany); diacetyl (DA), *tert*-butyllithium, methylglyoxal (MGO; 40 wt % in water), and tetrahydrofuran were purchased from Acros (Geel, Belgium). The quinoxaline standard mix for HPLC was prepared in our working group.[16]

Synthesis of 1-Deoxy-D-*erythro*-hexo-2,3-diulose (1-DG 3). 1-DG **3** was synthesized using the method of Glomb and Pfahler.[17] The purity of the product was >98%.

Synthesis of D-*arabino*-Hexo-2-ulose (GLUC 4). The synthesis of GLUC **4** followed the description of Hellwig et al.[18] as well as Usui et al.[19] with minor modifications. In both syntheses purities of >98% were obtained. The commercially purchased GLUC **4** was used as a reference substance.

High-Performance Liquid Chromatography (HPLC). For HPLC analysis the following system was used: degasser, Knauer Degasys DG-1300; pump, Shimadzu LC-9A; column oven, Shimadzu CTO-10AS VP; guard column, Macherey-Nagel CC 8/4 Nucleosil 120-5 C18; column, Macherey-Nagel EC 250/4.6 Nucleosil 120-5 C18; detector, Shimadzu SPD-M10A; communication module, Shimadzu CBM-10A; software, Shimadzu CLASS-LC10 v1.64A; injection volume, 40 μL; eluent, water/methanol gradient; flow rate, 1 mL/min; oven temperature, 35 °C.

HPLC Analysis of 1,2-Dicarbonyl Compounds. For the determination of 1,2-dicarbonyl compounds, the samples were derivatized with *o*-phenylenediamine (OPD) after the defined reaction time (postderivatization). The resulting quinoxalines were separated via HPLC on an RP-18 column (see above). The mobile phase consisted of water (solvent A) and methanol (solvent B). The gradient started with 20% of solvent B. After 4 min, it was changed to 33% B within 7 min. In the next 8 min B was increased to 65% (held for 7 min). Then the gradient was changed to 100% B in 2 min. Afterward, B was decreased to 0% in 4 min (held for 5 min). In the following 3 min B was increased to 30% (held for 1 min). For equilibration B was decreased to 20% in 4 min (held for 7 min). The identification and quantification (at 318 nm) was carried out with a standard mix of eight 1,2-dicarbonyls (GLUC, 1-DG, 3-deoxyglucosone, 3-deoxypentosone, 1,4-dideoxyglucosone, GO, MGO, and DA) in different dilutions.[16]

Electron Paramagnetic Resonance (EPR) Spectroscopy. EPR measurements were performed with a Magnettech MiniScope MS 100 spectrometer. Potassium nitrosodisulfonate (Fremy's salt) was used as a stabilized radical. The following settings were used: magnetic flux density, 339.700 mT; sweep, 6.983 mT; sweep time, 30 s; modulation, 0.1500 mT; microwave attenuation, 10 dB; gain, 6; measurement interval, 1 measurement in 40 s; measurement time, 30 min.

Recording of EPR Radical Scavenging Kinetics. The solution of Fremy's salt was prepared in phosphate buffer (pH 7.4). One hundred microliters of Fremy's salt solution (1 mmol/L) and 100 μL of sample (diluted with water) were mixed for 10 s. The mixture was filled in a 50 μL capillary and sealed on one side with modeling clay. Solution and modeling clay were separated by an air buffer. The measurement was performed in comparison to a blank sample that consisted of 100 μL of Fremy's salt solution (1 mmol/L) and 100 μL of phosphate buffer (pH 7.4). For the calculation of the antioxidant activity/capacity, the measurement point at 30 min was used (antioxidant activity/capacity after 30 min: AC_{30}/AA_{30}). The antioxidant potential was calculated between 5 and 10 min (AP_{5-10}) as well as between 20 and 30 min (AP_{20-30}).[20]

UV−Vis Spectroscopy. For the browning measurements as well as for the TEAC and Folin−Ciocalteu assays, a Bio-Tek Instruments UVIKON XL photospectrometer was used. Semimicro disposable cuvettes were purchased from VWR.

Browning Measurements. All samples were diluted 1:20 with water, centrifuged (10 min; 20 °C; 14000 rpm), and measured at 420 nm in comparison to water.

TEAC Assay. The reagents and all standards were prepared in PBS buffer (pH 7.2−7.4). Ten trolox standards (0.025−0.45 mmol/L) were used for the calibration. The samples were diluted with water to fit the calibration curve. For the measurement, 500 μL of ABTS solution (0.5 mmol/L), 100 μL of sample, and 200 μL of potassium persulfate solution (10 mmol/L) were mixed in a cuvette. After exactly 6 min, the mixture was measured at 734 nm in comparison to an empty cuvette.

Folin−Ciocalteu Assay. The calibration was performed with five gallic acid standards (10−80 μg/mL). The samples were diluted with water to fit the calibration curve. Two hundred microliters of sample, 1000 μL of Folin−Ciocalteu phenol reagent (diluted 1:10 with water), and 800 μL of sodium carbonate solution (7.5 wt %) were mixed. The mixture was incubated for 15 min at 35 °C and measured at 736 nm compared to a blank sample (water instead of sample). To convert the results from gallic acid equivalents (GAE) to trolox equivalents (TE), different samples of trolox were measured with respect to gallic acid.

Carbohydrate Reaction Mixtures. Model reactions under typical Maillard conditions were conducted. For that purpose aqueous solutions of D-glucose or D-fructose (0.2 mol/L) with or without L-alanine (0.2 mol/L) were prepared. The pH value was adjusted to 5.0 ± 0.1 or 8.0 ± 0.1 with 0.1 N HCl or 0.1 N NaOH. The solutions were sealed in ampules and were thermally treated in a heating block at 80 ± 1, 100 ± 1, or 130 ± 1 °C for a defined reaction time (0−300 min). A part of the sample was trapped with OPD solution (0.5 mmol/L) for the determination of the 1,2-dicarbonyl compounds. The remaining amount of sample was kept underivatized for further analysis (browning measurement, EPR spectroscopy, and FCR assay).

1,2-Dicarbonyl Reaction Mixtures. For 1,2-dicarbonyl reaction mixtures, aqueous solutions of 1-DG **3** and GLUC **4** (0.02 mol/L) with or without L-alanine (0.2 mol/L) were used. The reactions were conducted under the same conditions as the carbohydrate reaction mixtures.

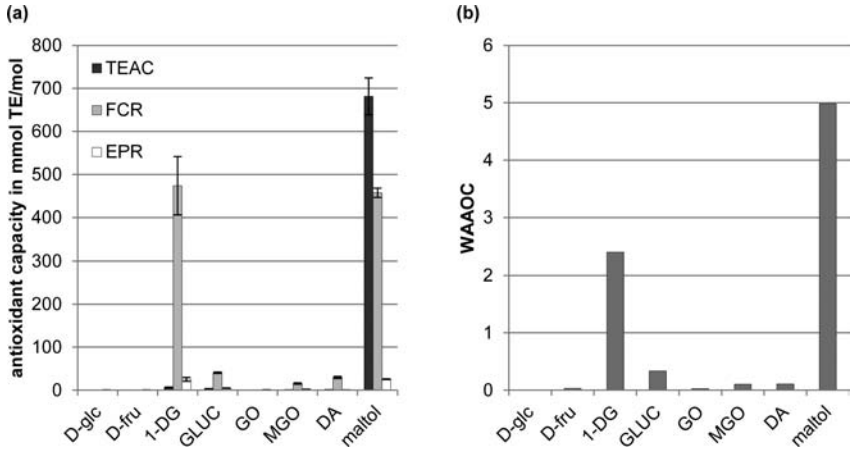

Figure 2. Results of the antioxidant capacity (a) and the WAAOC (b) of the two reductones and six reference substances measured with three different methods. Abbreviations: TEAC, trolox equivalent antioxidant capacity; FCR, Folin−Ciocalteu reagent; EPR, electon paramagnetic resonance; WAAOC, weighted-average antioxidant capacity; D-glc, D-glucose; D-fru, D-fructose; 1-DG, 1-deoxy-D-*erythro*-hexo-2,3-diulose (**3**); GLUC, D-*arabino*-hexo-2-ulose (**4**); GO, glyoxal; MGO, methylglyoxal; DA, diacetyl; maltol, 3-hydroxy-2-methyl-4*H*-pyran-4-one (**2**).

RESULTS AND DISCUSSION

Antioxidant Capacity and WAAOC. The antioxidant capacity of six different MR products, including 1-DG **3** and GLUC **4**, as well as the antioxidant capacity of the reducing carbohydrates D-glucose and D-fructose was measured with three methods (Figure 2a). The results were expressed with respect to trolox as millimoles of trolox equivalents (TE) per mole of sample to allow comparison of the results with other studies.[15] The values of all samples were below 1000 mmol TE/mol in every assay, showing that none of the used substances had an antioxidant capacity that was comparatively as high as the capacity of trolox. Because of the different mechanisms of the various tests, the results for single substances differed strongly. This is a well-known issue, which requires the use of different methods in the first place.[15,21] To generate a single value out of different antioxidant capacities from different assays, the calculation of the weighted-average antioxidant capacity (WAAOC) as described by Tabart et al.[15] was used.

The results of the WAAOC (Figure 2b) showed that the two C6-1,2-dicarbonyls (1-DG **3** and GLUC **4**) had a higher antioxidant capacity than their precursors (D-glucose and D-fructose) as well as their short-chain cleavage products (e.g., glyoxal, methylglyoxal, and diacetyl). The reductone ether maltol **2** showed a higher capacity than the two C6-1,2-dicarbonyls. The reactivities of 1-DG **3** and GLUC **4** differed considerably even though both possess an isomer with reductone structure. The WAAOC of 1-DG **3** was >7 times higher than the WAAOC of GLUC **4**.

EPR Radical Scavenging Kinetics. To allow statements about the velocity and progression of radical scavenging reactions, EPR experiments were conducted. The analysis of EPR kinetics generates two different measures: the antioxidant capacity (AC) and the antioxidant potential (AP), which both are illustrated in Figure 3.[20] According to the definition, the AC is the amount of reduced radical at a specific point in time. The AC is expressed with respect to the used amount of antioxidant (units of AC: moles of reduced radical per mole of defined antioxidant). Many samples contain an unknown type and/or amount of antioxidant or a mixture of different antioxidants; in such cases the antioxidant activity (AA) is mostly used. This measure is expressed with respect to the volume of sample

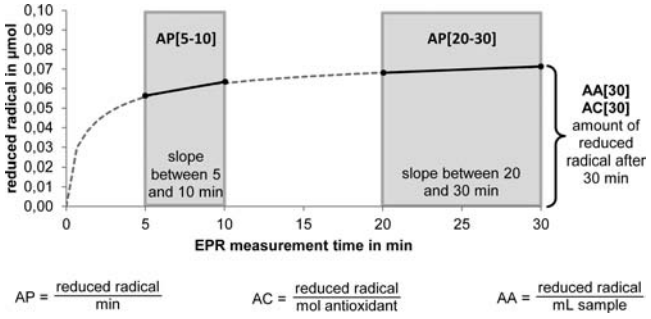

Figure 3. Graphical illustration of the antioxidant activity after 30 min (AA_{30}), the antioxidant capacity after 30 min (AC_{30}), the antoxidant potential between 5 and 10 min (AP_{5-10}), and the antioxidant potential between 20 and 30 min (AP_{20-30}).[20]

solution (units of AA: moles of reduced radical per liter of sample). The AP describes the velocity of the radical scavenging reaction and is expressed in moles of reduced radical per minute. Mathematically this is the slope of kinetics at a specific point in time. In practical terms the slope of a partial regression line can be used to calculate the AP.

All EPR kinetics for this work were recorded in a time frame of 30 min. Fast antioxidants, such as trolox, showed a high AP in the first minutes, followed by a fast decrease of the AP to 0 mol reduced radical/min within several minutes and consequently reached their maximal (final) AC in a short time frame. However, most samples did not deplete their potential to 0 mol reduced radical/min within 30 min, and accordingly their final AC could not be measured. Therefore, the AP and AC of selected points in time are suitable to compare different samples. In this work the AC, the AA after 30 min (AC_{30}/AA_{30}), and the potentials between 5 and 10 min (AP_{5-10}) as well as between 20 and 30 min (AP_{20-30}) were used. With the help of these two potentials, the depletion of the AP of different samples over time could be compared.

From eight tested substances just the two C6-1,2-dicarbonyls and maltol **2** (10 mmol/L solutions) showed a radical reduction of >5% in 30 min (Figure 4a). The used amount of radical in each measurement was 0.1 μmol, and accordingly a radical reduction of 0.05 μmol equals 5%. 1-DG **3** and maltol **2** exhibited similar radical reduction abilities after 30 min: 73 and

dx.doi.org/10.1021/jf404322r | J. Agric. Food Chem. 2014, 62, 2837−2844

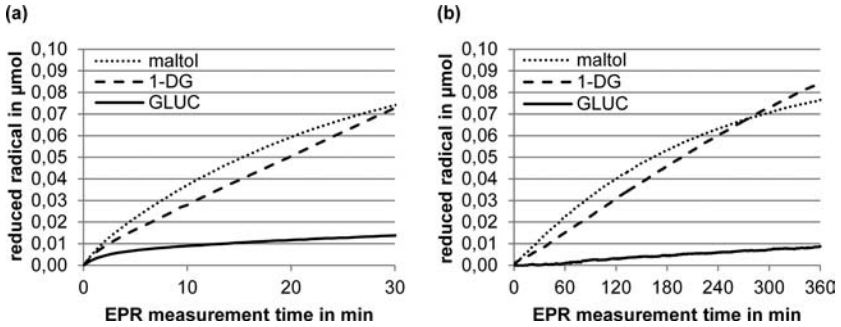

Figure 4. EPR kinetics of GLUC **4**, 1-DG **3**, and maltol **2** as 10 mmol/L solutions (a) and 1 mmol/L solutions (b).

74%, respectively, equaling AC_{30} values of 73 and 74 mmol reduced radical/mol. Within the standard deviation their AC_{30} was identical, but their potentials differed. Whereas the potential of 1-DG **3** was almost constant over 30 min, the AP_{20-30} of maltol **2** decreased about 50% in comparison to the AP_{5-10}. GLUC **4** also showed a constant potential over 30 min but an AC_{30} of only 14 mmol reduced radical/mol.

Measurements over a period of 6 h with 1 mmol/L solutions (Figure 4b) showed identical behaviors of the AP of the three different substances. Additionally, 1-DG **3** showed a higher AC after 360 min as maltol **2**, because of its constant AP. It became apparent that the final AC of 1-DG **3** would be higher than the one of maltol **2**. But even in 6 h the final ACs could not be measured. Therefore, single-point EPR measurements of a 0.25 mmol/L 1-DG solution were performed over a time period of 139 h (Figure 5). The potential decreased slightly in

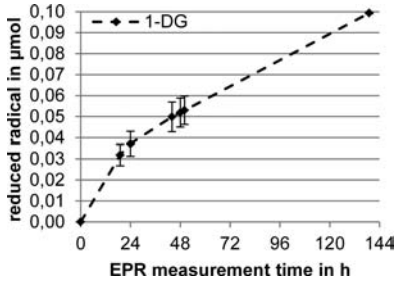

Figure 5. EPR single-point measurements of 1-DG **3** as 0.25 mmol/L solution compared to a blank sample (water and 1 mmol/L Fremy's salt). The radical concentration is depleted after 139 h.

the first 24 h and stayed constant for the next days. After 139 h, the radical concentration was nearly depleted, but the potential of 1-DG **3** was not 0 mol reduced radical/min. Even with a measurement this long, the final AC of 1-DG **3** could not be determined.

The slow reactivity over a long time frame seemed to be characteristic for 1-DG **3** and GLUC **4**. This behavior was the reason for the comparably low AC of the reductones in photometrical assays such as TEAC and FCR, which are designed for fast-reacting antioxidants.

The different radical scavenging behaviors of 1-DG **3**, GLUC **4**, and maltol **2** could be explained by the isomeric composition of each substance. Maltol **2** (Figure 6) reacted relatively rapidly compared to 1-DG **3** and GLUC **4** because only one isomeric form exists in aqueous solution, which is the antioxidative form of this compound. 1-DG **3** and GLUC **4** form different amounts of isomers in aqueous solution, and only the particular reductone isomer is considered to react antioxidatively.

Kaufmann et al.[22] identified up to 15 isomers of 1-DG **3** in aqueous solution. All of them are cyclic hemiacetals that do not possess a reductone structure and thus should not be antioxidative. Solely the enediol tautomer **3b** of the open chain form **3a** (Figure 6) is actually a reductone. But the open chain form **3a** acts only as an intermediate during the rearrangement of different cyclic isomers. The relative quantity of any open chain isomers could not be determined with high-resolution NMR[22] and therefore can be considered as a low percentage (the lowest percentage of a determinable isomer was <3% in this case). A simplified diagram of the equilibria of isomeric forms **3a**−**e** is given in Figure 6. Besides the equilibrium between the open chain isomer **3a** and a specific cyclic isomer such as **3c**, there are equilibria to the particular hydrated forms **3d**/**e**. Thus, the effective reductone concentration of a 1-DG **3** solution equals the undeterminable low relative quantity of the antioxidative enediol tautomer **3b**. The removal of this reductone form from the equilibrium leads, according to Le Chatelier's principle, to the re-formation of this particular form over time. This could explain the low but constant AP of 1-DG **3**.

The even lower potential of GLUC **4** could also be explained by the isomeric composition. Freimund et al.[23] and Kaufmann et al.[24] identified four cyclic isomers of GLUC **4** in aqueous solution, and all of them were hydrates. Thus, a chain opening during a rearrangement of the main isomers leads always to a hydrated open chain isomer **4e**. The quantity of unhydrated open chain isomer **4a** can be estimated lower than in the case of 1-DG **3**. Accordingly, the effective reductone concentration, represented by the relative quantity of the open chain enediol tautomer **4b**, is lower, too.

Antioxidant Properties of the Carbohydrate Reaction Mixtures. The aim of the analysis of the carbohydrate reaction mixtures was to establish a possible correlation between the 1,2-dicarbonyl content, which was determined with HPLC-DAD analysis, and the antioxidant activity, measured with the FCR assay and EPR spectroscopy. However, the results did not show such a correlation. Instead, there was a general correlation between the browning and the antioxidant activity. Both measures increased with the heating time, depending on the used carbohydrate, the amino catalysis, the pH value, and the temperature. The trends of browning and AA (determined with FCR) for the reaction mixture of D-fructose and L-alanine at 130 °C and pH 5/8 are shown in Figure 7. Reaction mixtures with higher temperatures, with pH 8 (instead of 5), with D-fructose (instead of D-glucose), and with L-alanine addition produced a higher antioxidant activity and stronger browning. The absence of a correlation between single 1,2-dicarbonyls and the antioxidant activity could originate in the minor

dx.doi.org/10.1021/jf404322r | J. Agric. Food Chem. 2014, 62, 2837−2844

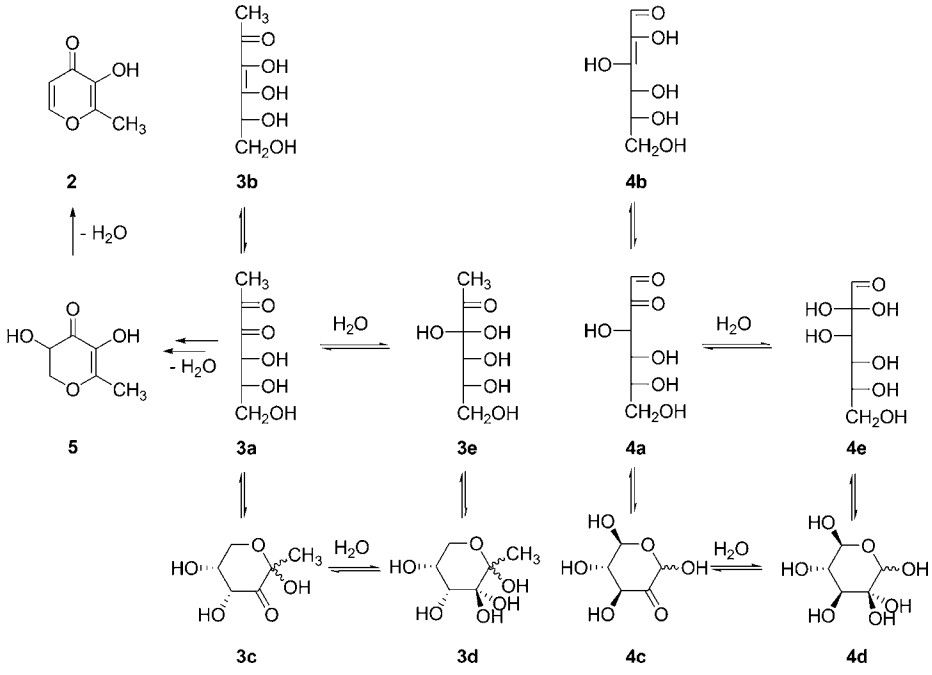

Figure 6. Structures and simplified isomeric equilibria of 3-hydroxy-2-methyl-4*H*-pyran-4-one (maltol **2**), 1-deoxy-D-*erythro*-hexo-2,3-diulose (1-DG **3**), D-*arabino*-hexo-2-ulose (GLUC **4**), and 2,3-dihydro-3,5-dihydroxy-6-methyl-4*H*-pyran-4-one (hydroxydihydromaltol **5**).[22−24,26] **2**, **3b**, **4b**, and **5** show (stabilized) enediol structures of reductones.

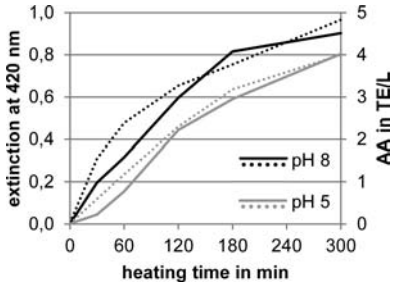

Figure 7. Browning (line) and antioxidant acitivity (AA) determined with FCR (dotted line) of the reaction mixtures of D-fructose and L-alanine at 130 °C and pH 8 (black)/pH 5 (gray) as a function of heating time.

concentrations of these particular substances and in the high amount of different antioxidative substances that were formed simultaneously in the MR. The highest 1,2-dicarbonyl content was detected in the reaction mixture of D-fructose and L-alanine at pH 5 and 130 °C. The summarized concentration of all identified 1,2-dicarbonyls had increased to 1.5 mmol/L within 180 min. In all reaction mixtures of D-fructose (with and without L-alanine addition) at 130 °C (pH 5 and 8), combined concentrations of around 1 mmol/L could be determined. At these concentrations the summarized relative quantity of 1-DG **3** and GLUC **4** was between 17 and 25% (around 0.17−0.25 mmol/L), but the used carbohydrate concentration was 0.2 mol/L, so only around 0.1% of the carbohydrate was degraded to the two 1,2-dicarbonyls. Because of the broad variety of other MR products, the antioxidant activity of this small amount of slowly reacting 1,2-dicarbonyls could easily be overlaid by antioxidative MR products, especially when the formed products were fast-reacting antioxidants.

Antioxidant Properties of the 1,2-Dicarbonyl Reaction Mixtures. To limit the product range of the MR to the direct degradation products of 1-DG **3** respectively, GLUC **4** appropriate reaction mixtures of these single 1,2-dicarbonyls were examined. The decomposition of the 1,2-dicarbonyls was measured with the help of HPLC-DAD analysis.

The results showed that 1-DG **3** decomposed more quickly than GLUC **4** under identical conditions. Furthermore, the degradation of both 1,2-dicarbonyls was faster with the addition

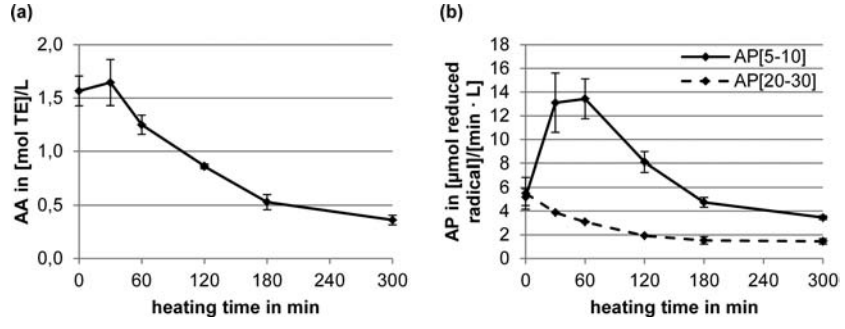

Figure 8. Antioxidant activity (AA) determined with FCR assay (a) and antioxidant potentials (AP) determined with EPR analysis (b) of the 1-DG **3** reaction mixture without L-alanine addition at 130 °C and pH 5.

dx.doi.org/10.1021/jf404322r | J. Agric. Food Chem. 2014, 62, 2837−2844

of L-alanine, and the temperature had a stronger influence than the pH value.

Reaction mixtures of 1-DG **3** (without L-alanine addition) at high temperatures (130 °C) showed a decrease of the AA, which could be determined with the FCR assay (Figure 8a). Nevertheless, a correlation to the remaining 1-DG **3** concentration could not be established. The reaction mixtures of 1-DG and L-alanine did not show such a relationship, possibly because of the much faster degradation of 1-DG **3** and the consequently more rapid formation of fractional antioxidative degradation products.

More detailed information was revealed by the EPR data: the formed antioxidative compounds are mainly fast-reacting antioxidants, and in most cases the low AP of 1-DG **3** was overlaid by the summarized potential of these fast-reacting compounds within the EPR measurement time of 30 min. But, finally, it was possible to establish a correlation between the antioxidant properties and the 1,2-dicarbonyl content in the form of the remaining 1-DG **3** concentration at least for the reaction mixtures without L-alanine.

Figure 8 shows the antioxidant properties and Figure 9 the kinetics of the reaction mixture of 1-DG **3** (without L-alanine addition) at 130 °C and pH 5. Before the heat treatment (0 min), the kinetics of the sample equals the typical nearly linear kinetics of 1-DG (compare to Figure 4). Under heat treatment the AP_{5-10} increased strongly after a short time (30–60 min) and fell after 60 min (Figures 8b and 9). The same trend could be observed for the AA_{30} (Figure 9), but the AP_{20-30} (Figure 8b) was reduced while the AP_{5-10} and the AA_{30} grew. The increase of the AP_{5-10} and the simultaneous decrease of the AP_{20-30} indicated the formation of fast-reacting antioxidants. Their comparably low AC was depleted in a small time frame and was added to the remaining AC of 1-DG **3** in the first minutes of the reaction (Figure 9). The AP_{20-30} equaled the AP of the remaining 1-DG **3** concentration that was increasing over the course of the heating time. In fact, there was a correlation between the relative 1-DG **3** concentration and the relative decrease of the AP_{20-30} for all of the reaction mixtures of 1-DG **3** without L-alanine addition independent from the chosen reaction conditions. Figure 10 shows the correlations for three reaction mixtures at pH 5.

Even though the AP of 1-DG **3** was comparably low, the proof that the antioxidant properties of 1-DG **3** were higher than the antioxidant properties of the corresponding degradation products was possible, at least for a part of the reaction mixtures.

The GLUC **4** reaction mixtures did not show a correlation at all because of the lower AP of GLUC **4** in comparison to 1-DG **3**. The AP of the remaining GLUC **4** concentration in the samples could possibly be determined within an EPR measurement over a longer time frame.

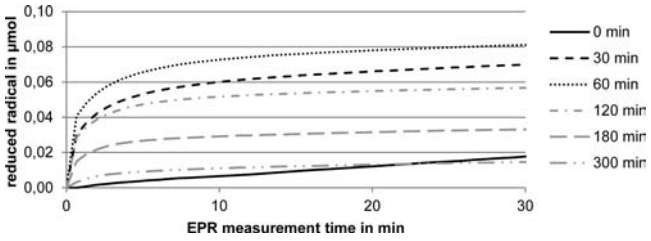

Figure 9. EPR kinetics of the 1-DG reaction mixture without L-alanine addition at 130 °C and pH 5 determined with EPR analysis.

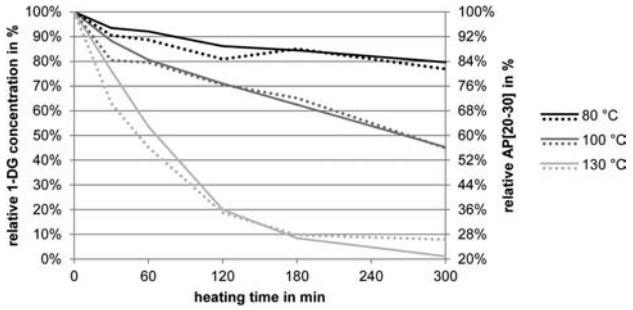

Figure 10. Correlation between the relative 1-DG **3** concentration (line) and the relative antioxidant potential between 20 and 30 min (AP_{20-30}; dotted line) and of the 1-DG **3** reaction mixtures without L-alanine addition at pH 5.

Degradation of 1-DG 3. To measure the 1-DG concentration and to determine the 1,2-dicarbonyl degradation products, 1-DG **3** reaction mixtures were analyzed with HPLC-DAD. The 1,2-dicarbonyl cleavage and elimination products were glyoxal (GO), methylglyoxal (MGO), diacetyl (DA), and 1,4-dideoxyglucosone (1,4-DDG). However, 1,4-DDG and GO could not be detected in all reaction mixtures. 1,4-DDG appeared only in reaction mixtures of 1-DG **3** and L-alanine at pH 5 and, as an exception, in the reaction mixture without amino acid addition at 100 °C and pH 8. The retro-aldol cleavage product GO was detected in all reaction mixtures with L-alanine at pH 8. At pH 5 it was exclusively formed at 130 °C with L-alanine. In Figure 11 the reaction mixture at pH 5 and 130 °C without L-alanine addition is shown. The concentrations of the 1,2-dicarbonyl degradation products suggested that other compounds were formed during the decomposition of 1-DG **3**. These compounds could be secondary products of the 1,2-dicarbonyls or could be formed through independent pathways.[25] However, the short-chain 1,2-dicarbonyls were not antioxidative. Thus, the observed changes of the antioxidant properties of the 1-DG **3** reaction mixtures could not be explained by the formation of short-chain 1,2-dicarbonyl compounds. Possibly degradation products with reductone ether structure were important for the summarized antioxidant properties of the samples. An example for such a substance formed from 1-DG **3** is hydroxydihydromaltol **5**,[13,25] which has strong structural similarities to maltol **2**, and according to Baltes et al.,[26] a small amount of maltol **2** is formed as a degradation product of hydroxydihydromaltol **5** (Figure 6).

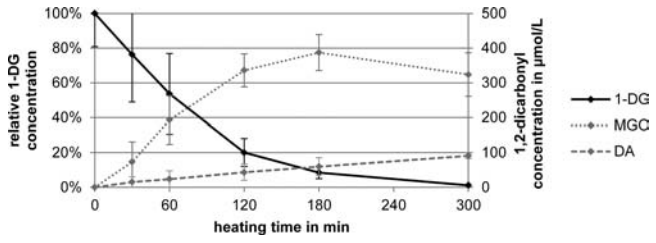

Figure 11. 1-DG **3** degradation (black line, relative 1-DG **3** concentration) and 1,2-dicarbonyl content (gray lines) of the 1-DG **3** reaction mixture without L-alanine addition at 130 °C and pH 5 determined with HPLC-DAD analysis. Abbreviations: MGO, methylglyoxal; DA, diacetyl.

Degradation of GLUC 4. In the corresponding GLUC **4** reaction mixtures the short-chain cleavage products GO, MGO, and 3-deoxypentosone (3-DP) were identified (Figure 12).

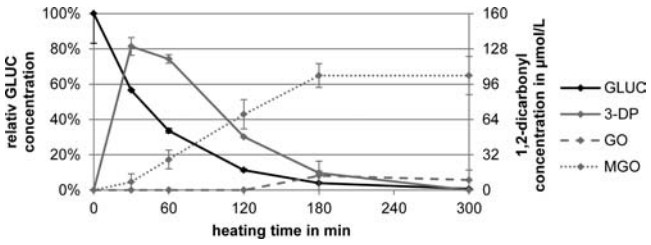

Figure 12. GLUC **4** degradation (black line, relative GLUC **4** concentration) and 1,2-dicarbonyl content (gray lines) of the D-GLUC reaction mixture without L-alanine addition at 130 °C and pH 5 determined with HPLC-DAD analysis. Abbreviations: 3-DP, 3-deoxypentuolose; GO, glyoxal; MGO, methylglyoxal.

These degradation products could be detected under all conditions. Similar to the 1-DG **3** reaction mixtures, the changes of the antioxidant properties were more likely caused by degradation products other than short-chain 1,2-dicarbonyl compounds.

In conclusion, the thermal degradation of 1-DG **3** and GLUC **4** leads to fast-reacting antioxidants, which increase the AP_{5-10} rapidly after short heating times. However, the formed antioxidants are obviously MR products other than the short-chain 1,2-dicarbonyls, because of their lack of antioxidative properties. The reductone ether maltol **2** shows high ACs/APs, and it could be assumed that substances with a related structure play an important part as fast-reacting antioxidants. The antioxidative properties of 1-DG **3** and GLUC **4** are remarkable because of their radical scavenging ability, which is slow compared to other antioxidants but lasts for a longer time (up to 139 h; Figure 5). This behavior causes low results in classical antioxidant assays such as FCR and TEAC, and only EPR measurements could reveal the antioxidant properties of the two reductones and showed their uncommon radical scavenging abilities. The AP of both C6-1,2-dicarbonyls can be measured as soon as the AP of fast antioxidants is depleted. In the case of the 1-DG **3** reaction mixtures without L-alanine addition, the AP_{5-10} could be assigned to the fast-reacting compounds and at the same time the AP_{20-30} could be correlated to the 1-DG **3** concentration.

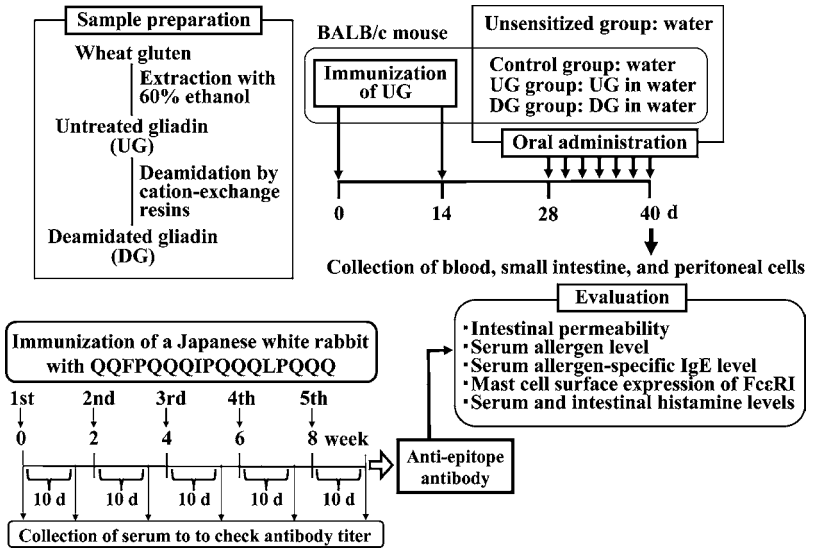

Figure 1. Preparation of deamidated gliadin and evaluation of its in vivo allergenicity by using anti-epitope antibody prepared by immunization with a peptide containing three epitopes.

IgE, and an increase in the level of IgE potently enhances the expression of FcεRI, the high-affinity IgE receptor, on the surface of mast cells.[33−38] Although the deamidated gliadin obtained by cation-exchange treatment has low reactivity with the sera of wheat-allergy patients, retention of its low allergenicity after digestion needs to be confirmed. Therefore, prior to an oral challenge to wheat-allergy patients, we evaluated the allergenicity of deamidated gliadin by measuring the intestinal permeability, serum allergen level, serum allergen-specific IgE level, mast-cell-surface expression of FcεRI, and serum and intestinal histamine levels of gliadin-sensitized mice.

MATERIALS AND METHODS

Deamidation of Wheat Gliadin. Wheat gliadin was extracted from gluten (Nakarai Tesque, Kyoto, Japan) with 60% ethanol. After being concentrated under vacuum, the extract was lyophilized. A cation-exchange resin of the carboxylate type (WK-11, Mitsubishi Chemical Corp., Tokyo, Japan) was washed with 1 N NaOH and then packed into a glass column (5750 × 50 mm, Nippon Flex Co., Aichi, Japan), after which the column was equilibrated with 60% (v/v) ethanol. Then 30 mL of 10 mg/mL undeamidated gliadin (UG) in 60% (v/v) ethanol was loaded onto the column, and the column was eluted with 60% (v/v) ethanol at 5 mL/min. Fractions were collected over 220 min. Deamidated gliadin (DG) obtained as the eluate was concentrated under vacuum and lyophilized.

Degree of Deamidation. The degree of deamidation was obtained from the ratio of amount of acid amide removed by treatment with cation-exchange resin to total acid amide in UG, as described previously.[24,27] Briefly, the acid amides in UG and DG were both completely deamidated by heating in a HCl solution, and the amount of ammonia produced was measured by Conway's micro-diffusion method[39] and the indophenol method.[40] Then the amount of acid amide deamidated was calculated by subtracting the amount of ammonia produced by DG from that produced by UG.

Preparation of Rabbit Anti-Gliadin-Epitope Antibody. As QQFPQQQ, QQIPQQQ, and QQLPQQQ are the major epitope sequences of gliadin, a peptide (QQFPQQQIPQQQLPQQQ) that comprised these three major epitope sequences was synthesized and conjugated to keyhole limpet hemocyanin (KLH). We used the hydrophobic tag-assisted liquid-phase method[41,42] in combination with linker strategy[43,44] to prepare the desired sequence, followed by addition of a cysteine residue to its N-terminus. After deprotection of all protective groups, including the tag, the peptide was conjugated to KLH through the maleimide−thiol reaction.

As shown in Figure 1, Japanese white female rabbits (Nippon Bio-Supply Center, Tokyo, Japan) were subcutaneously immunized with 2 mg of the three-epitope peptide in phosphate-buffered saline (PBS) emulsified with the same volume of Freund's complete adjuvant (Difco Laboratories, Detroit, MI) for the first and second immunization, and Freund's incomplete adjuvant (Difco Laboratories, Detroit, MI) was used for subsequent immunization. Blood was collected from the central artery in the ear 10 days after each immunization to check the antibody titer. Sera containing the anti-gliadin-epitope antibody were collected 10 days after the fifth immunization. This experiment was performed in accordance with the Guidelines for Animal Experiments of the College of Bioresource Sciences of Nihon University (approval no. 09-12).

Binding Capacity of Rabbit Anti-Gliadin-Epitope Antibody. For the identification of IgG-binding sequence in the 17-mer three-epitope peptide, 11 7-mer overlapping peptides with an offset of one amino acid were synthesized. The hydrophobic tag-assisted liquid-phase method was also used to produce these peptides.

Reactivity of the 7-mer overlapping peptides, 17-mer three-epitope peptide, UG, and DG with the anti-gliadin-epitope antibody was measured by use of an inhibition enzyme-linked immunosorbent assay (ELISA) conducted as follows: Either 0.3 mg of peptide (7-mer or 17-mer) in 30 μL of dimethyl sulfoxide or 3 μg of gliadin (UG or DG) in 30 μL of 60% ethanol (v/v) was mixed with 270 μL of rabbit anti-gliadin-epitope antibody or pooled serum from patients RAST-positive to wheat in 0.2% bovine serum albumin (BSA)/phosphate-buffered saline containing 5% Tween20 (PBST), and the samples were incubated for 1 h at 37 °C. Sera were donated from wheat-allergy outpatients (8 females and 12 males, mean age 24.2 years, range 0−53 years, mean total IgE 21 076 IU/mL, range 1030−84 616 IU/mL) who were under treatment at Yokohama City University Hospital after a full explanation of contents of the study. Flat-bottomed microtiter plates were coated with 100 μL of 10 μg/mL gliadin in 60% ethanol at 4 °C overnight and blocked with a 2% BSA/PBST solution for 2 h at 37 °C. The mixture of peptide/gliadin and antibody was added to the wells, and the platers were further incubated for 1 h at 37 °C. Then horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG was reacted for 1 h at 37 °C with the rabbit anti-gliadin-epitope antibody bound to the gliadin that had been coated onto the wells. The wells were washed five times with PBST at every step. As a substrate for HRP, 100 μL of 0.04% *o*-phenylenediamine containing H_2O_2 was added. The reaction was allowed to proceed for 20 min at room temperature and then stopped by adding 100 μL of 2 N H_2SO_4. The optical density of the formazan at 490 nm was measured with a

dx.doi.org/10.1021/jf4034078 | J. Agric. Food Chem. 2014, 62, 2845−2852

microtiter plate reader. The inhibition percent was determined according to the following formula:

$$\text{inhibition (\%)} = \frac{\text{OD}_{490\,\text{nm}}\ \text{without peptide} - \text{OD}_{490\,\text{nm}}\ \text{with peptide}}{\text{OD}_{490\,\text{nm}}\ \text{without peptide}} \times 100$$

Animals. Male BALB/c mice, 5 weeks old, were purchased from Japan SLC Inc. (Shizuoka, Japan). All mouse experiments were performed in accordance with the Guidelines for Animal Experiments of the College of Bioresource Sciences of Nihon University (approval no. AP11B088). Water was made available continuously through automatic ports, and a commercial mouse diet was provided ad libitum.

Sensitization and Intragastric Challenge. As illustrated in Figure 1, mice were sensitized twice, 2 weeks apart, with 50 μg of UG in the presence of 1 mg of aluminum hydroxide (Imject Alum; Thermo Scientific, Kanagawa, Japan) as an adjuvant by intraperitoneal injection. Two weeks after the second sensitization, the mice were orally administered 10 mg of UG or DG in 500 μL of water via an intragastric feeding needle (5202; Fuchigami Instrument Co., Kyoto, Japan) every other day for a total of seven times. Before each intragastric challenge, the animals were deprived of their diet for 4 h. Then 40 min after the final administration, the mice were anesthetized by barbital, and thereafter peritoneal cells, blood samples, and each part of the small intestines were collected. For collection of peritoneal cells, 3 mL of a Tyrode buffer ([10 mM *N*-(2-hydroxyethyl)-piperazine-*N*′-ethanesulfonic acid (HEPES), pH 7.4, containing 130 mM NaCl, 5.6 mM glucose, 1.4 mM $CaCl_2$, 1 mM $MgCl_2$, 5 mM KCl, and 0.1% (w/v) BSA] was injected into the peritoneal cavity, after which the abdomen was gently massaged for about 60 s. The peritoneal cavity was then carefully opened, and the peritoneal cell-containing fluid was aspirated by use of a Pasteur pipet. Blood samples were withdrawn from the postcaval vein, and the sera were separated by centrifugation at 1300*g* and 20 °C for 15 min after clotting. The duodenum, jejunum, and ileum were excised and rinsed with PBS.

Intestinal Permeability. Intestinal permeability was evaluated by the amount of HRP (molecular mass 40 kDa; Wako Pure Chemical Industries, Osaka, Japan) that passed through the wall of the jejunum according to the method of Isobe et al.[45] Briefly, 0.1 mL of 0.1 mg/mL HRP in PBS was injected into the lumen of a closed loop of a 5-cm length of jejunum, and the loop was then placed in 5 mL of PBS and incubated at 37 °C for 30 min. Then 50 μL of the outside solution was collected into the well of a microtiter plate, and the concentration of HRP that had permeated from the lumen through the intestinal wall was measured by adding 100 μL of 0.04% *o*-phenylenediamine with H_2O_2 to the outside solution.

Level of Epitope Absorbed into the Blood. The level of epitope absorbed from the intestinal lumen into the blood was evaluated by performing a competitive inhibition ELISA with the anti-gliadin-epitope antibody as described above. A serum sample in 0.3% BSA/PBST was mixed with the same amount of rabbit anti-gliadin-epitope antibody in 0.3% BSA/PBST, and the mixture was incubated for 1 h at 37 °C for the antigen−antibody reaction to be completed before its addition to gliadin-coated plates.

Level of Gliadin-Specific IgE in Blood. For determination of the level of gliadin-specific IgE in the serum, 100 μL of 5 μg/mL rat anti-mouse IgE antibody (eBioscience, Inc., San Diego, CA) in a 0.05 M sodium carbonate buffer at pH 9.6 was added to a microtiter plate, and the plate was allowed to stand at 4 °C overnight. Nonspecific binding was blocked by with the addition of 200 μL of 2% BSA/PBST and incubation at 37 °C for 1 h. Then 100 μL of test serum diluted 10× with 0.3% BSA/PBST was added to each well, and incubation was continued for 2 h at 37 °C. Biotinylated gliadin, prepared by use of a biotin labeling kit (Dojindo Laboratories, Kumamoto, Japan), was diluted 500× with 0.3% BSA/PBST, and a 100-μL aliquot of it was added to each well, followed by incubation for 2 h at 37 °C. A 100-μL aliquot of HRP-conjugated streptavidin (Funakoshi Co., Tokyo, Japan) diluted 3000× with 0.3% BSA/PBST was added to each well, and incubation was continued for another 1 h at 37 °C. The wells were washed five times with PBST at every step. As a substrate for HRP, 100 μL of 0.04% *o*-phenylenediamine containing H_2O_2 was added to the wells. The reaction was allowed to proceed for 20 min at room temperature and then stopped by adding 100 μL of 2 N H_2SO_4. The optical density was measured at 490 nm with a microtiter plate reader.

Detection of Peritoneal Mast Cells. Mast cells were separated from macrophages and small lymphocytes in the peritoneal cell population by sedimentation at 150*g* for 10 min at room temperature, and the pellet was resuspended in Tyrode buffer. Mast cells, detected by their expression of the high-affinity IgE receptor (FcεRI) and c-kit, were stained with anti-FcεRI (fluorescein isothiocyanate-conjugated) antibody (diluted 1000×) and anti-c-kit (phycoerythrin-conjugated) antibody (diluted 2000×) at 4 °C for 30 min. These antibodies were purchased from eBioscience (San Diego, CA). Flow cytometry was performed with a LSRII flow cytometer (BD Biosciences, San Jose, CA), and data were analyzed with FlowJo 6.4.2 software (Tree Star Inc., Ashland, OR).

Total Histamine in Gut and Free Histamine in Plasma. Total histamine level in the gut, including that in mast cells and basophils, was measured to estimate the inflammatory status of the small intestines. The first 5 cm of the duodenum and ileum, distal from the ligament of Treitz, was collected and flushed with 5 mL of cold 0.9% NaCl solution. After being weighed, the tissue was homogenized with 1 mL of 0.9% NaCl. Then 200 μL of 1.2 N perchloric acid was added to the homogenate, which was subsequently centrifuged for 10 min at 13000*g*. The supernatant was then collected. This procedure was repeated, and the supernatants were pooled and stored at −20 °C until further analysis.

For measurement of the level of free histamine in the plasma, 500 μL of a mouse plasma sample was mixed with the same amount of 1 N perchloric acid, and then centrifuged for 10 min at 13000*g*. The supernatant was collected and stored at −20 °C until further analysis.

The histamine level was measured by fluorometric analysis as described by Komatsu.[46] After 1 mL of each sample had been mixed with 0.135 mL of 1 N NaOH containing 0.75 mg of NaCl, 1.75 mL of a 3:2 (v/v) mixture of *n*-butanol and chloroform was added, and the mixture was stirred for 5 min. After centrifugation at 500*g* for 5 min, 1.5 mL of the organic solvent layer was recovered and mixed with 1.5 mL of *n*-heptane and 0.6 mL of 0.1 N HCl, and the mixture was stirred for 5 min. After further centrifugation at 500*g* for 5 min, 1.5 mL of the HCl layer recovered was mixed with 0.12 mL of 1 N NaOH and 0.1 mL of 0.2% *o*-phthalaldehyde (Wako Pure Chemical Industries, Osaka, Japan). The reaction was allowed to proceed for 40 min at 4 °C and terminated by adding 0.05 mL of 0.5 N H_2SO_4. The fluorescence intensity (excitation at 360 nm and emission at 440 nm) was measured by use of a microtiter plate reader.

Statistical Analysis. All data were expressed as the mean ± standard error of the mean (SEM), and the significance of differences (P values) between groups was evaluated by using Tukey−Kramer test.

RESULTS

Degree of Deamidation. Wheat gliadin was effectively deamidated with the cation-exchange resin of the carboxylate type. The acid amide deamidated amounted to 421.3 μmol/g of protein. As the amount of acid amide in UG was about 1784.8 μmol/g of protein, the degree of deamidation was 23.6%.

Reactivity of Rabbit Anti-Gliadin-Epitope Antibody with Synthetic Peptides. The inhibition rate of synthetic peptides with rabbit anti-QQFPQQQIPQQQLPQQQ IgG is shown in Table 1. The reactivity of QQIPQQQ, one of the major epitope peptides of gliadin, was the highest among the 11 7-mer overlapping peptides synthesized, its inhibition rate being approximately 42%. The reactivity of QFPQQQI and QQLPQQQ was also high, with inhibition rates of 32% and 15%, respectively. The inhibition rate of QQFPQQQ was about 7%. Therefore, rabbit anti-QQFPQQQIPQQQLPQQQ IgG was able to detect the major epitope peptides of wheat gliadin

Table 1. ELISA Inhibition Rate of Synthetic Peptides with Rabbit Anti-QQFPQQQIPQQQLPQQQ IgG

synthetic peptide	inhibition rate[a] (%)	synthetic peptide	inhibition rate[a] (%)
QQFPQQQ	6.94 ± 3.18	QIPQQQL	5.68 ± 3.14
QFPQQQI	32.30 ± 1.52	IPQQQLP	1.19 ± 0.94
FPQQQIP	5.54 ± 0.91	PQQQLPQ	4.95 ± 4.52
POOOIPQ	10.97 ± 0.71	QQQLPQQ	12.95 ± 1.60
QQQIPQQ	3.96 ± 1.32	QQLPQQQ	15.31 ± 2.05
QQIPQQQ	42.35 ± 1.59	full-length	76.07 ± 1.48

[a]Each value is the mean ± SE of seven experiments.

and will be referred to as anti-gliadin-epitope antibody hereafter.

Reactivity of Rabbit Anti-Gliadin-Epitope Antibody and Patients' Serum with UG and DG. The reactivity of anti-gliadin-epitope antibody was compared with that of the patients' serum. Figure 2 shows the reactivity of anti-gliadin-epitope antibody and wheat-allergy patients' serum with UG or DG. The rabbit anti-gliadin-epitope antibody showed reactivity similar to that of the wheat-allergy patients' serum, and the inhibition rate by DG was lower than that by UG.

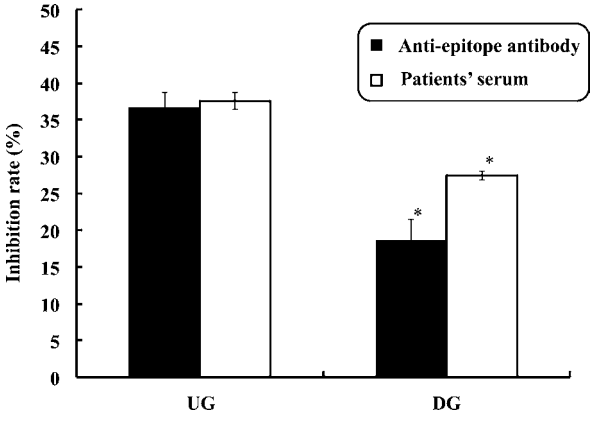

Figure 2. Reactivity of anti-gliadin-epitope antibody and wheat-allergy patients' serum with UG and DG. Asterisk-marked values of DG are significantly different from the corresponding UG value at $P < 0.05$. Each value is the mean of four experiments, with SE shown as a vertical bar.

Intestinal Permeability. Allergic inflammation may enhance intestinal permeability, permitting large molecules such as proteins to be absorbed from the small intestines. Figure 3 presents the permeability of the jejunum from mice orally administered water, UG, or DG after sensitization with UG. The oral administration of UG after sensitization with it greatly enhanced intestinal permeability of HRP. On the other hand, intestinal permeability for the UG-sensitized DG-administered group was almost the same as that of the unsensitized group or UG-sensitized water-administered group.

Level of Epitope Absorbed into the Blood. The low digestibility and high intestinal permeability of proteins may promote the absorption of antigens and epitope peptides into the blood. As shown in Figure 4, the level of epitope in the blood absorbed from the small intestine was much higher for mice orally administered UG after sensitization with it than for those orally administered DG or water. However, orally administered DG and/or its hydrolysates seem to have been absorbed from the small intestines to some extent after 30 min of incubation.

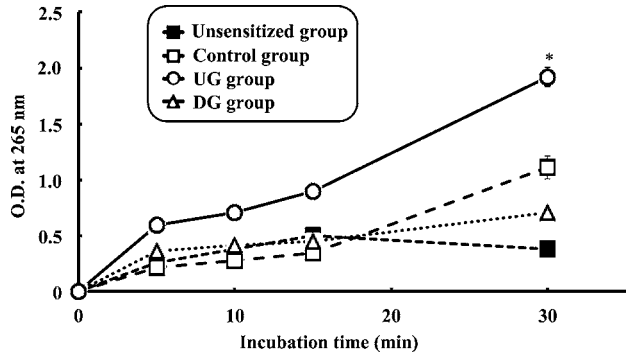

Figure 3. Permeability of small intestines from mice orally administered water, UG, or DG after sensitization with UG. Asterisk-marked values are significantly different from the corresponding values for unsensitized mice at $P < 0.05$. Each value is the mean of seven experiments, with SE shown as a vertical bar.

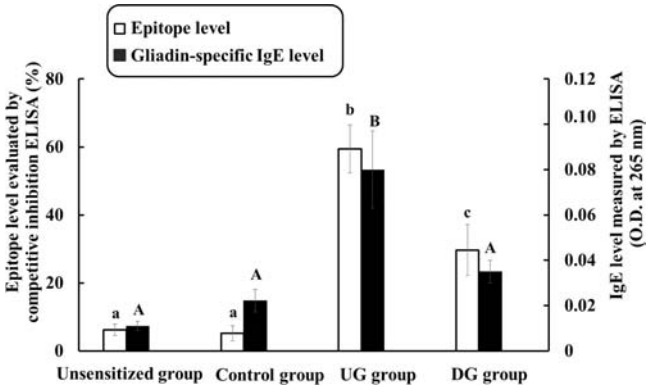

Figure 4. (Open bars) Epitope level and (solid bars) gliadin-specific IgE level in serum. Values with different letters are significantly different at $P < 0.01$. Each value is the mean of seven experiments, with SE shown as a vertical bar.

Gliadin-Specific IgE Level in the Blood. Figure 4 shows the level of IgE specific for gliadin in the blood of mice orally administered UG, DG, or water after UG sensitization. Oral administration of UG after sensitization with it significantly enhanced the level of gliadin-specific IgE in the blood, whereas that of DG scarcely changed it.

Peritoneal Mast Cells. Mast cells, defined as FcεRI+ and c-kit+ cells, play a key role in allergic reactions, and these cells degranulate to release chemical mediators such as histamine when IgE binds to FcεRI on their surface. Figure 5 presents flow cytometric dot plots of FcεRI- and c-kit-expressing cells. The percentage of FcεRI+ and c-kit+ cells in the UG-sensitized orally administered UG group was much higher than in any of the other groups, being approximately 20% of total cells. On the other hand, the percentage of FcεRI+ and c-kit+ cells from UG-sensitized orally administered DG mice was only about 3%. The results are also shown graphically in Figure 5.

Total Histamine in Gut and Free Histamine in Plasma. Figure 6 shows the level of total histamine in the small intestines. This level in the UG-sensitized, orally administered UG group was almost double that in the other groups, whereas the level for the UG-sensitized, orally administered DG group was almost the same as for the unsensitized and control groups.

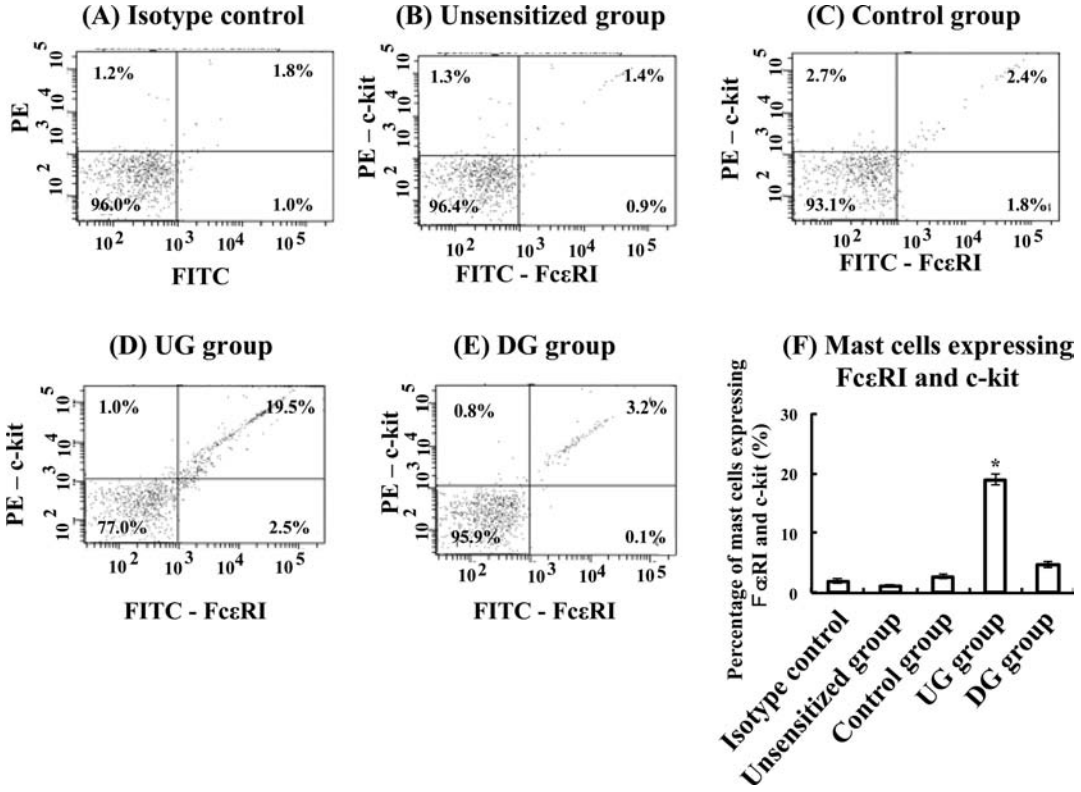

Figure 5. (A–E) Flow cytometric dot plots of FcεRI and c-kit expression on mast cells. (F) Percentage of mast cells expressing FcεRI and c-kit. Asterisk-marked values are significantly different from those of unsensitized mice at $P < 0.05$. Each value is the mean of seven experiments, with SE shown as a vertical bar.

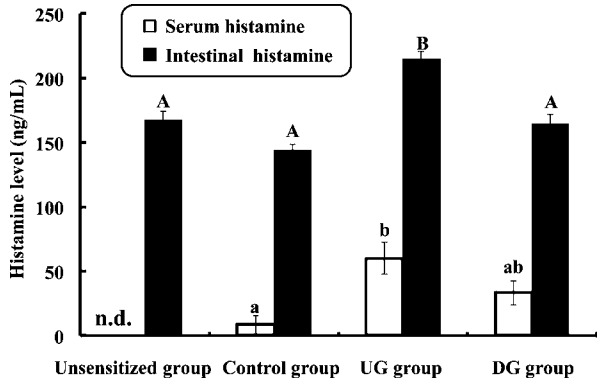

Figure 6. (Open bars) Free histamine level in the serum and (solid bars) total histamine level in the small intestine. Values with different letters are significantly different at $P < 0.01$. Each value is the mean of seven experiments, with SE shown as a vertical bar.

Similarly, oral administration of UG after sensitization with it enhanced the free histamine level in the serum, as shown in Figure 6. The free histamine level in the serum of mice orally administered DG was lower than that of the mice orally administered UG, though there was no significant difference between the two groups.

DISCUSSION

Certain tandem sequence motifs that have glutamine residues in wheat gliadin have been reported to constitute the primary structure of IgE-binding epitopes.[9,14,15] Therefore, deamidation would be an effective means to reduce wheat allergenicity, although it may not be applicable to patients with celiac disease or to those who are sensitive to deamidated proteins.[47−49] Hydrochloric acid treatment has generally been used for deamidation of wheat protein.[50,51,47] However, hydrochloric acid simultaneously causes hydrolysis of peptide bonds, which produces bitter-tasting peptides and reduces the processing properties of wheat such as extensibility and elasticity. The cation-exchange resin treatment used in this study does not cause peptide-bond hydrolysis and rather improves the processing properties.[24,29] Therefore, deamidation by cation-exchange resins will provide proteins with health benefits and enhanced sensory properties.

Deamidation is thus expected to reduce the allergenicity of wheat gliadin. However, gliadin in gluten deamidated to the degree of 36−51% by hydrochloric acid still reacted with the sera of patients suffering from wheat allergy to some extent.[49] Maruyama et al.[50] reported that gluten treated with hydrochloric acid showed reduced reactivity with the sera of patients allergic to wheat and that gluten with more than 50% deamidation showed markedly decreased IgE-binding capacity. Similarly, gliadin with 52% deamidation generated by treatment with hydrochloric acid showed low reactivity with IgE antibody.[51] Yong et al.[23] reported that wheat gluten deamidated by protein glutaminase had low allergenicity when the deamidation degree reached 72%. These findings indicate that more than 50% deamidation is required to reduce the reactivity of gliadin deamidated by acid or enzyme, probably because of the exposure of inner epitope structure to the surface during acidic hydrolysis and enzymatic reaction. On the other hand, 28% deamidated wheat gliadin achieved with cation-exchange resin treatment scarcely reacted with IgE in the sera of patients allergic to wheat.[29] The low reactivity of this deamidated gliadin

dx.doi.org/10.1021/jf4034078 | J. Agric. Food Chem. 2014, 62, 2845−2852

with IgE could be due to the effective deamidation of glutamine residues on the surface of protein by cation-exchange resin.

As shown in our previous study, deamidation increased the solubility of gliadin in water and sodium chloride solutions[25] and enhanced its digestibility by pancreatin.[29] Thus, a further reduction in its allergenicity may occur during digestion. This study was therefore conducted to examine the in vivo allergenicity of DG by using wheat-allergy model mice. Although the degree of deamidation of DG used in this study was only 23.6%, oral administration of DG to mice did not induce allergic reactions. Therefore, the epitope sequences in the inner part of the gliadin structure were assumed to be effectively hydrolyzed during digestion.

When an allergic protein is orally administered to mice after immunization, the protein cross-links IgE molecules, thereby inducing an allergic reaction. Allergic inflammation in the small intestines may enhance intestinal permeability and increase the number of mucosal mast cells and eosinophils in the small intestines.[32,52] Therefore, we examined the permeability of HRP through the jejunum of DG-administered mice. The administration of UG significantly enhanced the intestinal permeability, whereas that of DG scarcely altered it (Figure 3). The considerable rise in serum allergen level after UG administration may be attributed to the increase in intestinal permeability because of probable absorption of large molecules of UG from the small intestines. As the serum allergen level of DG-administered mice was lower than that of UG-administered mice (Figure 4), the epitope structure in DG would have been more extensively hydrolyzed by digestive enzymes in the gut than that in UG. However, the serum allergen level of DG-administered mice was still higher than that of water-administered mice. This result indicates absorption of DG to some extent. The serum IgE level, surface expression of FcεRI, and intestinal histamine level of DG-administered mice were almost the same as those of water-administered mice, indicating that administration of DG did not cause an allergic reaction.

The mechanism of antibody production after immunization with a peptide or protein is not yet completely understood. In this study, a 17-mer peptide (QQFPQQQIPQQQLPQQQ) having three major epitope sequences of gliadin (QQFPQQQ, QQIPQQQ, and QQLPQQQ) was synthesized, and rabbits were immunized with it. The obtained antibody notably recognized QQIPQQQ, one of the major epitopes. Its reactivity with QQLPQQQ was also high. Therefore, these two epitope sequences can be considered to promote antibody production. On the other hand, it recognized QFPQQQI much more than QQFPQQQ, which is another major epitope sequence. The reason for this might be due to differences in the mechanism of antibody recognition between rabbits and human or to the order of connected epitope peptide sequences. However, reactivity of the antibody from rabbits immunized with UG and DG was almost the same as that of patients' serum, indicating that the antibody from rabbit serum can be used for detecting epitope sequences in vivo.

In conclusion, the deamidated gliadin was confirmed to have low allergenicity even in vivo, suppressing the enhancement in intestinal permeability, serum allergen level, serum allergen-specific IgE level, mast-cell-surface expression of FcεRI, and serum and intestinal histamine levels. As deamidated gliadin exhibits a high foaming property,[25] deamidation by cation-exchange treatment with no peptide-bond hydrolysis is a promising technique for production of bread and cakes with low allergenicity and better expansibility.

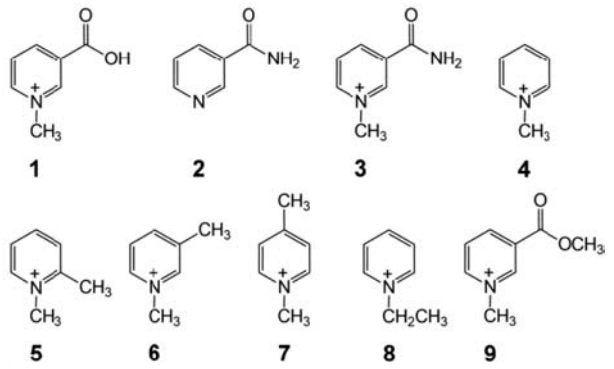

Figure 1. Chemical structures of trigonelline, nicotinamide, 1-methylnicotinamide, methyl derivatives of pyridine, and trigonelline methyl ester.

Therefore, the aim of the present study was to identify pyridinium compounds formed upon coffee roasting and to investigate their influence on experimentally induced arterial thrombosis in rats.

MATERIALS AND METHODS

Animal Studies. Animals were purchased from and housed in the Centre of Experimental Medicine of Medical University in Bialystok according to Good Laboratory Practice rules. Male Wistar rats (180–200 g) were used in all experiments. Animals were housed in a room with a 12 h light/dark cycle, grouped in cages as appropriate, and allowed to have access to tap water and a standard rat chow. All of the procedures involving animals and their care were approved by a local bioethics committee and conducted in accordance with the institutional guidelines that are in compliance with national and international laws and Guidelines for the Use of Animals in Biomedical Research.[24]

Chemicals and Materials. Trigonelline hydrochloride was obtained from Fluka (Steinheim, Germany). Methanol and formic acid (LC-LC-MS grade) were from Sigma-Aldrich (Schnelldorf, Germany). All other reagents were from Sigma-Aldrich, unless noted otherwise, and were of the highest purity available. 1-Methylpyridinium chloride (1-methylpyridine, **4**), 1,2-dimethylpyridinium chloride (1,2-dimethylpyridine, **5**), 1,3-dimethylpyridinium chloride (1,3-dimethylpyridine, **6**), 1,4-dimethylpyridinium chloride (1,4-dimethylpyridine, **7**), 1-ethylpyridinium chloride (1-ethylpyridine, **8**), and trigonelline methyl ester (**9**) (see Figure 1), as standards for chemical analysis and drugs for pharmacological experiments, were synthesized using the methods in the literature. The 6-Keto-$PGF_{1\alpha}$ ELISA kit was purchased from Cayman Chemical Company (Ann Arbor, MI, USA) and rat plasminogen activator inhibitor −1 (PAI-1) ag/activity Zymutest Kits from HYPHEN BioMed (Neuville sur Oise, France), whereas the rat tissue plasminogen activator (t-PA) activity kit was obtained from Innovative Research Inc. (Novi, MI, USA). Reagents to prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen (Fg) level measurements were purchased from Bio-Ksel (Grudziadz, Poland). Moreover, collagen (Chrono-log Corporation, Havertown, PA, USA), pentobarbital (Biovet, Pulawy, Poland), and trisodium citrate (Avantor Performance Materials, Gliwice, Poland) were used in the study. Solid-phase extraction columns Bakerbond CBA, 500 mg and 3 mL (J.T. Baker, Phillipsburg, NJ, USA), were obtained from Witko (Lodz, Poland). The column used was 100 mm × 2.1 mm, i.d., 1.7 μm Acquity UPLC BEH C18 with a 5 mm × 2.1 mm, i.d. guard column of the same material (Waters, Milford, MA, USA).

Coffee Samples. Coffee (*C. arabica*) samples (150 g) were roasted using coffee roaster KN-8828D (Hottop, Cranston, RI, USA) at 220 °C. The roasting process was manually controlled by following audible cues of the beginning of a "first crack" (14.5 min), the beginning of a "second crack" (19 min), and the end of a "second crack" (23 min). Objective color measurements were obtained by a CM-3600d (Konica Minolta, Tokyo, Japan) spectrophotometer in the CIE Lab scale (L^*, a^*, and b^*).[25] The spectrophotometer had a 4-mm diameter viewing area and was equilibrated and calibrated with a standard tile before experiments. The samples were illuminated with standard D_{65} light, and the colorimetric normal observer angle was 10°. Coffee samples were made into pellets (13 × 1 mm) by a hydraulic press at a pressure of 6 tons. Color attributes were measured at six different points of each pellet on white and black backing. Each value reported is the mean of 12 measurements ± SEM. Three different roasting degrees were obtained: light (roasting time 14.5 min, $L^* = 51.62 \pm 0.23$, $a^* = 12.44 \pm 0.08$, and $b^* = 27.09 \pm 0.15$), medium-dark (roasting time 19 min, $L^* = 32.01 \pm 0.29$, $a^* = 9.00 \pm 0.09$, and $b^* = 11.12 \pm 0.16$), and dark roasted coffee (roasting time 23 min, $L^* = 25.98 \pm 0.44$, $a^* = 3.67 \pm 0.08$, and $b^* = 4.24 \pm 0.10$). The coffee samples were ground using a MKM 6003 coffee grinder (Bosch, Stuttgart, Germany).

Extract Preparation. Roasted and ground coffee were prepared using different extraction methods. Ground coffee (1.875 g) was suspended in a final volume of 50 mL of (A) medium temperature water at 60 °C or (B) hot water at 90 °C. Extracts were then cooled down to room temperature, filtered using a paper filter, and centrifuged for 15 min at 5500 rpm and a temperature of 15 °C. The supernatant was brought up to pH 8 with 0.5 M NaOH prior to further purification with the use of solid-phase extraction.

Trigonelline Pyrolysate Preparation. Crystalline trigonelline was ground in a porcelain mortar and placed as a thin layer (2–3 mm) on a Petri dish; the sample was then placed in a laboratory oven LE/4/11/R6 (Nabertherm, Bremen, Germany) and heated in a dry nitrogen atmosphere at 100 °C for 1 h. In the next step, the temperature was raised to 200 °C, and the sample was heated for additional 25 min. Trigonelline pyrolysate was cooled down to room temperature and extracted two times by chloroform. Extracted samples were dried at reduced pressure (0.1 mbar, RT). Samples of 2 mg and 0.2 mg of pyrolysate per 1 mL of Millipore-grade water were used for further analysis.

Solid-Phase Extraction (SPE) of Pyridinium Compounds from Coffee Extracts. Because of the cationic nature of pyridinium compounds, ion exchange chromatography with the use of propylcarboxylic acid Bakerbond CBA columns (J.T. Baker, Phillipsburg, NJ, USA) was chosen as a method of extraction. A portion of supernatant (5 mL) obtained after coffee extract preparation was loaded into a CBA column (500 mg), preconditioned with a methanol and water (each 5 mL). After penetration of column packing by a coffee solution, the column was washed with water followed by methanol (5 mL). The analyte was eluted with 0.2 M formic acid in water (5 mL). This acid fraction was transferred into a glass vial prior to UPLC/MS analyses.

Ultraperformance Liquid Chromatography–Electrospray Ionization Mass Spectrometry of Pyridinium Compounds in Trigonelline Pyrolysate and Coffee Extracts. All analyses of pyridinium compounds in coffee extracts and trigonelline pyrolysate were performed with an Aquity ultraperformance liquid chromatography system UPLC (Waters, Milford, MA, USA) coupled online to a photodiode array (PDA) spectrometer for UV/vis measurements and an LCT Premier XE oa-TOF mass spectrometer (Waters MicroMass, Manchester, UK). Separations were accomplished on 100 mm × 2.1 mm, i.d., 1.7 μm Acquity UPLC BEH C18 column with a 5 mm × 2.1 mm, i.d. guard column of the same material (Waters, Milford, MA, USA) maintained at 40 °C. Samples were eluted using 90% of 2 mM nonafluoropentanoic acid aqueous solution and 10% of methanol solution at a flow rate of 0.3 mL/min. The injection volumes and temperature for both sample and standard solutions were 0.2–2 μL and 4 °C, respectively. The mass spectrometer was operated in "W mode" with lock mass correction. Lock mass solution (leucine-enkephalin, reference mass: $[M]^+$ 556.2771 and $[M+H]^+$ 557.2801) was prepared fresh at a concentration of 0.5 ng/μL in water/acetonitrile (50:50; v/v) and stored at 4 °C until further use. Standards were prepared in Millipore-grade water. Ion chromatograms of pyridine derivative standards obtained at different m/z from mass spectrometer are presented in Figure 2. External calibration curves were established in the concentration range from 0.05 to 5 μM for

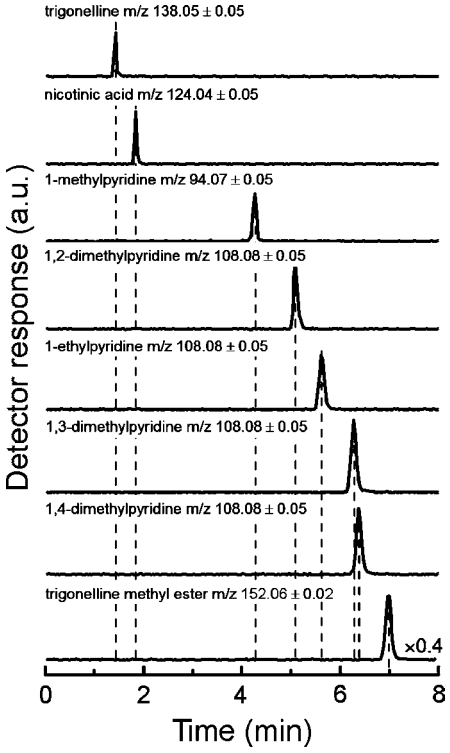

Figure 2. Ion-chromatograms of 500 nM standards of pyridine derivatives obtained at different m/z. Retention times: trigonelline, (**1**, t_R = 1.44 min); nicotinic acid, (**2**, t_R = 1.85 min); 1-methylpyridine, (**4**, t_R = 4.27 min); 1-ethylpyridine, (**8**, t_R = 5.10 min); 1,2-dimethylpyridine, (**5**, t_R = 5.62 min); 1,3-dimethylpyridine, (**6**, t_R = 6.27 min); 1,4-dimethylpyridine, (**7**, t_R = 6.38 min), and trigonelline methyl ester, (**9**, t_R = 7.00 min).

mass spectrometry and 5−1000 μM for UV/vis measurements. Analytes not falling within the given range were adequately diluted with water and reinjected. The amount of the compounds in the samples was calculated from the respective linear regression equation, r^2 > 0.999. Data acquisition and analyses were performed using MassLynx 4.1 data system software (Waters, Milford, MA, USA) and OriginPro 9.0c (OriginLab, Northampton, MA, USA).

Drugs Administration. 1-Methylpyridine (100 mg/kg/d), 1,3-dimethylpyridine (30, 100, 300 mg/kg/d), 1,4-dimethylpyridine (30, 100, 300 mg/kg/d), or vehicle was administered per os once a day for 10 days preoperatively. The animals received the examined drugs dissolved in drinking water or drinking water (vehicle) daily for 10 days via an intragastric probe.

Induction of Arterial Thrombosis. Male Wistar rats were anesthetized by intraperitoneal injection of pentobarbital (40 mg/kg) and placed in a supine position on a heated operation table. Arterial thrombosis was induced by electrical stimulation of the common carotid artery, according to methods previously described.[23,26−28] Briefly, the anode, a stainless steel L-shaped wire, was inserted under the artery and connected to a circuit with a constant current generator. The cathode was a subcutaneous metal needle attached to the hindlimb. The stimulation (1 mA) took 10 min. Forty-five minutes after stimulation, the segment of the common carotid artery with the formed thrombus was clipped at both sides, dissected, opened lengthwise, and the thrombus completely removed, air-dried in 37 °C, and weighed 24 h after the end of the experiment. After the removal of the formed thrombus, blood samples were taken from the heart. Platelet aggregation was assessed in whole blood directly after the experiment. The rest of the blood samples were drawn into 3.13% trisodium citrate in a volume ratio of 10:1, then centrifuged at 3500g in 4 °C for 20 min, and plasma was deep-frozen (−70 °C) in aliquots of 1 mL until further assays could be performed.

Measurement of Platelet Aggregation. Platelet aggregation was assessed in whole blood directly after the experiment by measuring electrical impedance in a Chronolog aggregometer (Chrono-log Corporation, Havertown, PA, USA) according to the method described by Cardinal et al.[29] Blood samples were drawn into 3.13% trisodium citrate in a volume ratio of 10:1. Collagen (5 μg/mL) was added after 15 min of incubation at 37 °C with 0.9% NaCl in a volume ratio of 1:2. Then changes in impedance were registered for 6 min. The results were expressed as percentages using four parameters: maximal extension, slope of platelet aggregation, lag phase, and area under the curve. In addition, in an in vitro study blood samples were mixed with 1,3-dimethylpyridine, 1,4-dimethylpyridine, or vehicle solution before incubation.

Plasma Level of 6-Keto-$PGF_{1\alpha}$, a Stable Metabolite of Prostacycline (PGI_2), Fibrynolysis, and Coagulation Parameters, and Blood Cell Count. Plasma level of 6-keto-$PGF_{1\alpha}$ was measured by ELISA technique in a microtiter plate at 25 °C using a microplate reader (Dynex Technologies, Chantilly, VA, USA) to monitor the changes in absorbance at 405 nm according to the manufacturer's directions. Concentrations of active rat PAI-1 and active rat t-PA were analyzed using ELISA techniques at 25 °C using a microplate reader according to the kit manufacturer's instructions. Both rat PAI-1 and rat t-PA kits were used in a bioimmunoassay for measuring rat PAI-1 and rat t-PA activities in rat plasma collected on trisodium citrate anticoagulant. The stop solutions changed the color from blue to yellow, and the intensity of the color was measured at 450 nm. PT and aPTT were automatically determined with a Coag-Chrom 3003 coagulometer (Bioksel, Grudziadz, Poland) adding routine laboratory reagents to the collected rat plasma. Fg was evaluated according to Clauss method.[30] Blood cell count was assessed by an animal blood counter (ABC Vet, Horiba ABX, Monpellier, France).

Fibrin Generation. Fibrin generation was estimated according to our modification[32,33] of the method of He et al.[31] Briefly, blood samples were drawn from the left ventricle of thrombotic rats, and platelet-rich plasma (PRP) was gained by centrifugation of citrated blood (1:10, 3.13%) at 300g at 4 °C for 20 min. A fibrin generation curve was created by adding thrombin (1 IU/mL) and $CaCl_2$ (36 mM) to the Tris buffer (66 mM Tris and 130 mM NaCl, pH 7.4) and

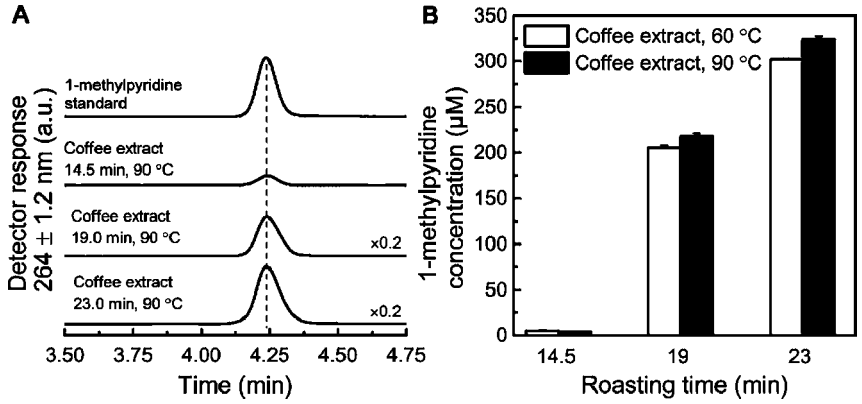

Figure 3. Influence of coffee roasting time and extraction procedure on the concentration of the main trigonelline thermal degradation product, 1-methylpyridine, in the coffee extracts samples. (A) Chromatograms obtained at 264 ± 1.2 nm with the use of a photodiode array detector (PDA) for 50 μM 1-methylpyridine standard and coffee samples of different roasting degrees. (B) Concentration of 1-methylpyridine in the coffee extract.

mixing with the platelet-rich plasma samples directly in the microplate wells. Optical density was measured via a microplate reader (Dynex Technologies, Chantilly, VA, USA) at 405 nm in 1 min intervals for 6 min and expressed as area under the curve (AUC).

Statistical Analysis. The data are shown as the mean ± SEM and analyzed using the nonparametric Mann−Whitney test. P values less than 0.05 were considered significant, less than 0.01 highly significant, and less than 0.001 extremely significant.

RESULTS AND DISCUSSION

The discrepancies between the results of the studies on coffee consumption in relation to the risk of cardiovascular disease and at the same time clear evidence for the beneficial role of coffee drinking from both epidemiologic[34] and experimental studies[11,13] encouraged us to search for new compounds in roasted coffee that could possibly improve endothelial function.

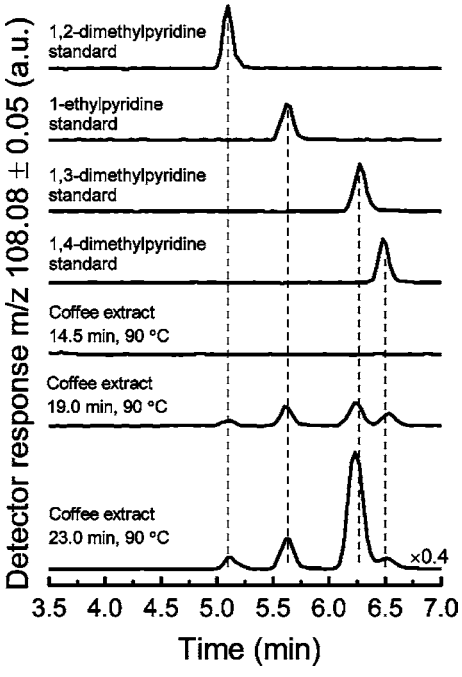

Figure 4. Influence of coffee roasting time on the profile of trigonelline thermal degradation products. Ion chromatograms obtained at m/z 108 ± 0.05 for 500 nM standards of 1-ethylpyridine, 1,2-, 1,3-, and 1,4-dimethylpyridine, and coffee extract samples (roasting time and extraction temperature are as indicated).

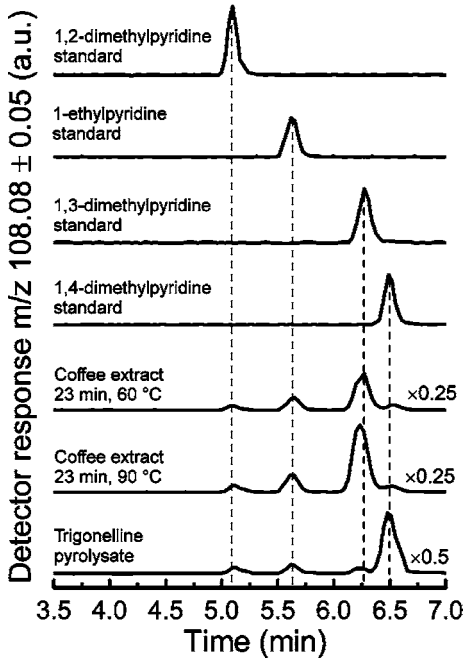

Figure 5. Difference between the profile of trigonelline thermal degradation products in coffee extracts and trigonelline pyrolysate. Ion chromatograms obtained at m/z 108 ± 0.05 for 500 nM standards of 1-ethylpyridine, 1,2-, 1,3-, and 1,4-dimethylpyridine, a dark roasted coffee sample, and trigonelline pyrolysate.

As various factors could be responsible for the conflicting results of the studies on coffee drinking such as daily consumption and the type of coffee[35] or the role of coffee preparation,[36,37] we have focused our attention only on a selected group of compounds, pyridine derivatives (see Figure 1), present in the roasted coffee extracts and formed upon trigonelline pyrolysis.

As was shown previously by Stadler et al.,[19] during the roasting process nonvolatile alkylpyridinium salts are formed. Under a specific physiochemical condition, trigonelline, one of the most abundant compounds in green coffee, undergoes thermal degradation with subsequent formation of 1-methylpyridine and nicotinic acid, as major products, and dialkylpyridinium salts as minor products. There is a lack of information on the adverse effects of alkylpyridinium, especially dialkylpyridinium compounds. Some studies indicate that 1-methyl substituted analogues are less toxic than pyridine itself [38] but may activate cytochrome P450 CYP1A enzyme.[39] However, Szafarz et al.[40] did not observe any changes in basic biological parameters after intravenous administration of 1,4-dimethylpyridine at a dose of 100 mg/kg.

We have monitored the formation of 1-methylpyridine in coffee extracts using a photodiode array detector (PDA) coupled with a liquid chromatograph, by an increase in absorbance at 264 ± 1.2 nm. The concentration of 1-methylpyridine found in coffee extracts, expressed in μmol/L, is presented in Table 1 and Figure 3. Our findings are consistent with the previous results presented by Stadler et al.[19] Decomposition of trigonelline and subsequent formation of 1-methylpyridine increases with roasting time and higher temperature of extraction.

The formation of 1-methylpyridine, as expected, is also accompanied by the formation of dialkylpyridinium compounds as shown in Figure 4. Using a new chromatographic method with the mobile phase modifier, ion-pairing reagent, we were able to differentiate four different isomers with ions of identical m/z 108.08 ± 0.05 (Figure 4). As the formation of three dimethylpyridinium salts is known in the literature, the new entity was characterized and assigned to 1-ethylpyridine, mainly by comparison with its authentic standard. The formation of compounds specified by m/z equals 108.08 was also correlated with the formation of 1-methylpyridine and the degree of coffee roasting. The concentration of dialkylpyridinium compounds

was 2 to 3 orders of magnitude lower than that of 1-methylpyridine. The main dialkylpyridinium compound, which is formed during coffee roasting is 1,3-dimethylpyridine. The concentrations of alkylpyridiniums salts present in the coffee extracts are listed in Table 1. We were not able to quantitate the amount of 1,4-dimethylpyridine due to the high concentration of 1,3-dimethylpyridine present in the extract.

As trigonelline, in contrast to caffeine, undergoes significant thermal degradation upon coffee roasting, including decarboxylation and demethylation (both processes take place in the temperature range typical for coffee roasting), it may be expected that similar products could be formed upon coffee roasting and trigonelline pyrolysis. Indeed, the analysis of trigonelline pyrolysate indicated the formation of similar products. The main dialkylpyridinium product formed from pyrolysis of trigonelline was not, however, as expected 1,3-dimethylpyridine but 1,4-dimethylpyridine, which is shown in Figure 5. The formation of 1-ethylpyridine and trigonelline methyl ester was also observed. The data of quantitative analysis of products formed during pyrolysis of trigonelline are presented in Table 2.

For some reason, the formation of 1,3-dimethylpyridine is favored during coffee roasting compared to pyrolysis of trigonelline itself, probably due to a great variety of other compounds being present in coffee beans. We assume that the formation of 1,3-dimethylpyridine rather than 1,4-dimethylpyridine in roasted coffee might be due to the direct reduction of trigonelline. In the case of thermal decomposition of pure trigonelline, bimolecular reactions might be preferred.

The influence of 1-methylpyridine, and 1,3- and 1,4-dimethylpyridine on the hemostasis and thrombotic processes is not known. To investigate that, we chose the model of experimental arterial thrombosis induced by electrical stimulation of carotid artery of rat. This experimental model enables simultaneous measurement of platelet aggregation and many other coagulation and fibrinolysis parameters. Although thrombus formation was initiated by electrical stimulation producing arterial injury that is unrelated to clinical thrombosis, platelet-rich thrombus morphology suggests that the growth of intravascular thrombotic material in response to electric injury is physiologically relevant.[27] Importantly, in this model platelets make a major contribution to the development of thrombosis as the inhibition of platelet activation by ASA and carbon monoxide or stimulation of endothelial release of PGI_2 by angiotensin-converting enzyme inhibitors or 1-methylnicotinamide afforded pronounced antithrombotic effects.[18,23,25,33,41] The collagen-induced platelet aggregation, and the markers of coagulation and fibrinolysis were also examined ex vivo. We administered these compounds at a dose of 100 mg/kg/d per os for 10 days to rats before the development of arterial thrombosis.

1-Methylpyridine had no effect on thrombus formation. Since we observed rather a trend to enhance the antithrombotic effect of the 100 mg/kg/d dose of 1-methylpyridine (106.3 ± 5.6% of control, for doses of 100 mg/kg/d; ns, Figure 6), other doses of this compound have not been elucidated. Moreover, we did not further evaluate this compound as a potential antithrombotic agent. By contrast, 1,3- and 1,4-dimethylpyridine inhibited arterial thrombus formation. 1,4-Dimethylpyridine at doses of 100 and 300 mg/kg/d decreased thrombus weight to 77.0 ± 5.2% ($p < 0.05$) and 71.3 ± 10.3% ($p < 0.05$), respectively. 1,3-Dimethylpyridine was effective at a dose of 300 mg/kg/d decreasing thrombus weight to 78.4 ± 6.9%. Not only did 1,3- and 1,4-dimethylpyridine appear to inhibit the progress of electrically induced carotid artery thrombosis but also was a more significant effect observed when we administered these pyridines in higher doses. These results indicate a new class of compounds with mild antithrombotic properties which can be found in coffee extracts.

We have further examined possible mechanisms of pharmacological activity of pyridine derivatives formed from trigonelline thermal decomposition. Since we have previously proven an important role of prostacyclin in the effect of many substances influencing endothelial function including structurally related pyridine derivatives such as 1-methylnicotinamide, we tried to elicit the contribution of prostacyclin to the antithrombotic effect of dimethylpyridinium compounds. Prostacyclin is produced in endothelial cells from prostaglandin H_2 by the action of the enzyme prostacyclin synthase and is a potent vasodilator and inhibitor of platelet aggregation.[42] We have found a dose-dependent increase in plasma level of 6-keto-$PGF_{1\alpha}$ (a stable metabolite of prostacyclin) in rats receiving 1,4-dimethylpyridine. 1,4-Dimethylpyridine increased the plasma level of 6-keto-$PGF_{1\alpha}$ to 130.3 ± 14.2% ($p < 0.01$) and 160.2 ± 18.9% ($p < 0.01$), at doses of 100 and 300 mg/kg/d, respectively. 1-Methylpyridine and 1,3-dimethylpyridine showed only a trend to increase the plasma level of 6-keto-$PGF_{1\alpha}$ (Figure 7). Prostacyclin (PGI_2) is thought to be one of the most important prostanoids in regulating the homeostasis of the cardiovascular system.[43,44] It is clear that pharmacological stimulation of PGI_2 in vivo might be beneficial in vascular diseases. So far, prostacyclin or its stable analogues have been widely used in the treatment of pulmonary hypertension[45] and have been proven effective in cases of peripheral arterial disease[46] or liver injury.[47]

We simultaneously measured collagen induced platelet aggregation after thrombus formation in rat arteries. We found that 1,3-dimethylpyridine exerted an antiaggregatory effect, decreasing collagen induced platelet aggregation (Table 3) in thrombotic animals. Both 1,3-dimethylpyridine and 1,4-dimethylpyridine (10^{-5}, 10^{-4}, and 10^{-3} M) did not significantly change platelet aggregation in in vitro experiments (data not shown). Since platelet activation is crucial in arterial thrombosis development, the antiplatelet activity of 1,3-dimethylpyridine could be responsible for its antithrombotic effect. The lack of influence of 1,4-dimethylpyridine on platelets, while stimulating prostacyclin release, was rather surprising and suggests a different mechanism of action. Thus, we performed in vitro experiments in which we incubated whole blood with various concentrations of examined compounds, but they both failed to directly influence platelet aggregation. It seems that the site of 1,3-dimethylpyridine action is not direct or that it acts through active metabolites.

Furthermore, we measured typical coagulation parameters, like prothrombin time (PT), activated partial thromboplastin time (aPTT), and fibrinogen (Fg) level using routine laboratory methods. 1-Methylpyridine and 1,3- and 1,4-dimethylpyridine failed to influence the activity of rat plasminogen activator inhibitor-1 (PAI-1) (Table 3), PT, aPTT, Fg, and blood cell count (data not shown). 1,3-Dimethylpyridine decreased fibrin formation in platelet-reach plasma, but not in platelet-poor plasma (data not shown), while 1-methylpyridine and 1,4-dimethylpyridine produced no effect (data not shown). 1,4-Dimethylpyridine increased slightly tissue plasminogen activator (t-PA) activity only at lowest

dose. 1-Methylpyridine and 1,3- and 1,4-dimethylpyridine at higher doses failed to influence t-PA activity (Table 3).

Inhibition of fibrin generation in platelet-reach but not in platelet-poor plasma by 1,3-dimethylpyridine suggests platelet involvement in the antithrombotic effect of this compound. This effect is in line with the inhibitory effect of 1,3-dimethylpyridine on platelet aggregation in whole blood. According to the fibrinolytic parameters analysis, we may also assume that the fibrinolytic system is not involved in the anithrombotic effect of dimethylpiridinium salts.

In conclusion, we demonstrated here that pyridinium compounds present in roasted coffee possess the antithrombotic prostacyclin releasing (1,4-dimethylpyridine) and platelet inhibiting (1,3-dimethylpyridine) properties. Although they have a cationic chemical nature and their permeability through cell membranes might be difficult, they can reach relatively high dose-dependent concentration in blood.[22] This property would be important for all orally administered formulations. We may hypothesize that 1,3-dimethylpyridine could be a promising agent preventing atherothrombosis development, where the platelets play a crucial role, whereas 1,4-dimethylpyridine could be beneficial in states with impaired prostacyclin endothelial production. Our findings on the novel in vivo biological activity of dimethylpiridinium compounds may have potentially important therapeutic implications and warrant further studies, although low concentration of dialkylpyridinium salts in the roasted coffee probably limits their contribution to the overall antithrombotic functions of coffee beverages.

XXX-3′; this is an adaptor sequence that attaches to the 5′ end of the mRNA template; X stands for undisclosed nucleotides protected by the manufacturer). The RACE ready cDNA was synthesized by a SMARTScribe reverse transcriptase. Then, 3′-RACE PCR was performed using the 3′-RACE Ready cDNA as a template, a Universal Primer A Mix (long, 5′-*CTAATACGACTCACTATAGGGC*AAGCAGTGGTATCAACGCAGAGT-3′; short, 5′-*CTAATACGACTCACTATAGGGC*-3′), and a gene-specific degenerate primer p320 (5′-GGTTACGGTCAATGTATGTGAT-3′) obtained from the PCP N-terminal amino acid sequence. 5′-RACE PCR was performed using the 5′-RACE Ready cDNA as a template, a Universal Primer A Mix, and a gene-specific primer p5-320-2 (5′-ATTGTATGTGAGTTGCATCATGTC-3′) designed on the basis of the sequence of 3′-RACE products. Finally, the complete cDNA sequence of PCP was revealed by combining the product sequences of 3′-RACE PCR and the 5′-RACE PCR. The accession number of the PCP cDNA sequence is JN571084.1.

Primary Cell Acquisition and Cell Cultures. Primary lymphocytes were acquired from murine spleens as previously described.[14] In brief, the total splenocytes were obtained from spleens excised from euthanized mice, and the splenic T cells were either positively or negatively purified using a MACS system with microbeads of anti-CD90, -CD4, -CD8, or anti-B220 antibodies (Miltenyi Biotec, Bergisch Gladbach, Germany), respectively. The purity of the purified T cells used in this study was >95%. The cells were seeded in 96-well flat-bottom plates (Corning, Lowell, MA, USA) at 4×10^6 cells/mL and were stimulated with or without PCP at indicated concentrations, ConA (5 μg/mL) or LPS (1 μg/mL), for 72 h. In some experiments, the purified T cells were seeded in rat anti-mouse CD3/CD28 antibody-coated 96-well plates. All cells were grown in a CO_2 incubator under humidified atmosphere of 5% CO_2 at 37 °C.

Mice and Animal Experiments. Female 6−8-week-old BALB/c were purchased from the National Laboratory Animal Center (Taipei, Taiwan) and used for splenic cell acquisition and in vivo studies.

To assess the in vivo effect of PCP, mice were ip injected with 50 μg/100 μL OVA adsorbed on aluminum hydroxide adjuvant or with adjuvant i alone as a nonimmunized vehicle. The mice were randomly grouped into four (n = 6 each). The first two groups were orally administered by gavage 0.5 mL of PCP solution (2 mg/mL in PBS) at 50 mg/kg body weight (1 mg/mouse) once daily and immunized with OVA or with saline vehicle, respectively. The two other groups were given an equal volume of PBS and immunized with OVA or with saline vehicle, respectively. OVA-immunized mice were immunized on days 0 and 14. Blood samples (100 μL per mouse) were collected from tail veins at various time points (days 0, 10, and 24) after immunization.

To evaluate the potential of PCP to attenuate Th2-dominat allergic response, an OVA-induced atopic dermatitis (AD) murine model, which was developed by Spergel and his collegues,[15] was performed. In brief, female BALB/c mice aged 6−8 weeks were randomly divided into three groups, each consisting of four mice (n = 4). The back skin of all the mice was shaved and tape stripped six times with 3M tape to simulate the skin injury inflicted by scratching in patients with AD. The first group of mice was orally administered daily 200 μL of PBS and sensitized daily in the sensitizing periods with 20 μL of saline vehicle placed on a 1 cm^2 patch of sterile gauze, which is secured to the skin with a transparent bio-occlusive dressing to repel licking by the mice. The other group of mice was administered daily 200 μL of PBS and sensitized with 20 μL of skin-patched OVA (100 mg/mL) in the manner described above. The last group of mice was administered daily 200 μL of PCP (5 mg/mL) and sensitized with skin-patched OVA (100 mg/mL) in the manner described above. There were two sensitizing periods in the AD model; the first period began from day 3 to day 8, and the second period began from day 22 to day 27. Oral administration began on day 0 and terminated on day 32, the end point of the AD model. Blood samples (100 μL per mouse) were collected on day 8 via tail veins of the mice. The lymphocytes of the mice were obtained from the axillary nodes, the brachial nodes, and the inguinal nodes and cultured in the presence or absence of OVA (100 mg/mL) for 48 h. The cell-free culture supernatant was collected for cytokine quantification via ELISA.

Cell Proliferation Analysis by BrdU Incorporation Assay. Cell proliferation was measured using a cell proliferation ELISA BrdU (colorimetric) kit (Roche, Basel, Switzerland) according to the user's manual. Data acquisition was carried out by measuring A_{450} on a Bio-Rad microplate reader (Bio-Rad Laboratories).

Cytokines and Igs Quantification by ELISA. The level of cytokines IFN-γ, IL-2, IL4, IL-5, and TNF-α presented in the cell-free culture supernatants were measured by sandwich ELISA using OptEIA murine IFN-γ, IL-2, IL-4, IL-5, and TNF-α ELISA kits (eBioscience, San Diego, CA, USA), respectively, following the manufacturer's protocols. The levels of the total Igs and the OVA-specific Igs presented in mouse serum were measured by sandwich ELISA using a Mouse MonoAb ID Kit (Invitrogen) and indirect ELISA, respectively, according to the user's manual. Data acquisition was carried out by measuring A_{450} on a Bio-Rad microplate reader. The results were expressed as ELISA units (EU), which were calculated by comparison with mouse IgG standards.

Cytokine Gene Expression Analysis by Quantitative Real-Time PCR. Complementary DNA samples were obtained from T cells treated with or without PCP (100 μg/mL). Gene expression was assessed by quantitative real-time PCR according to the manufacturer's protocol. The results were normalized to endogenous genes (β-actin or GAPDH). The expression level of each target gene was calculated by cycle threshold (Ct) analysis. The sense and antisense primer pairs are β-actin, 5′-GTGGGCCGCTCTAGGCACC-3′ and 5′-CTCTTTGATGTCACGCACGA-3′; G3PDH, 5′-ATGAATACGGCTACAGCA-3′ and 5′-TGGAAATTGTGAGGGAGAT-3′; T-bet, 5′-GGAGAACTTTGAGTCCAT-3′ and 5′-GTAGAAACGGCTGGGAA-3′; GATA3, 5′-CTGCGGACTCTACCATA-3′ and 5′-TTAGCGTTCCTCCTCCA-3′; ROR γ T, 5′-TGAGATTGCCCTCTACAC-3′ and 5′-GCAGAGATGATGATGGAAA-3′; and Foxp3, 5′-TGAGTTTCGCAAGAAGAG-3′ and 5′-GGTTTCCATAGGTACACG-3′.

Detection of Cell Surface Marker and Intracellular IFN-γ by Flow Cytometry. Mouse splenocytes and MACS-purified cells were treated with the indicated samples for 72 h and then collected and suspended in FACS buffer and stained with FITC- or PE-conjugated antibodies specific for CD3, CD4, CD8 (BD Biosciences), CD44, and CD69 (eBioscience) at 4 °C for 0.5 h. Flow cytometry data were acquired on a FACScan (Becton Dickinson and Co., Franklin Lakes, NJ, USA) and analyzed by CellQuest software.

To estimate intracellular production of IFN-γ and granzyme B in T cells by PCP, $CD4^+$ and $CD8^+$ cells isolated from splenocytes by the MACS purification system were incubated with the indicated stimulants or medium alone in the presence of anti-CD3/CD28 antibodies for 72 h. After incubation, brefeldin A (10 μg/mL; eBioscience) was added to block cytokine release. After an additional 6 h, cells were washed, fixed in Fixation Solution (eBioscience), and incubated in the dark at room temperature for 30 min. Then, the cells were permeabilized using the Permeabilization Buffer (eBioscience), stained with PE-conjugated mAbs specific for mouse IFN-γ and granzyme B (eBioscience), and analyzed by flow cytometry.

Immunoprecipitation of STAT4 and STAT6. Isolated $CD90^+$ cells were stimulated with 100 μg per mL of PCP for 4, 8, 16, and 24 h, respectively, in the presence or absence of anti-CD3/CD28 antibodies. Then, the cells were homogenized in RIPA buffer. The homogenate was centrifuged, and the supernatant was collected for total protein detection. The supernatant was immunoprecipitated using the mouse monoclonal antibodies against STAT4 or STAT6 (Santa Cruz Biotechnology, Dallas, TX, USA) overnight with gentle mixing at 4 °C. After incubation with STAT4 or STAT6 antibodies, the lysate was incubated with Protein G plus/Protein A agarose for 3 h with gentle mixing at 4 °C. The solution was then centrifuged, and the pellet was suspended in 20 μL of SDS sample buffer and subjected to SDS-PAGE and Western blot analysis. Blots were incubated with mouse anti-phosphotyrosine antibodies (Merck KGaA) and subsequently detected using a HRP-conjugated anti-mouse IgG (KPL, Gaithersburg, MD, USA). Membranes were washed extensively with Tris-buffered saline with Tween 20. Proteins were detected using the Western Lightning Chemiluminescence Reagent Plus (PerkinElmer, Waltham, MA, USA) and subjected to X-ray autoradiography. In addition, antibodies were

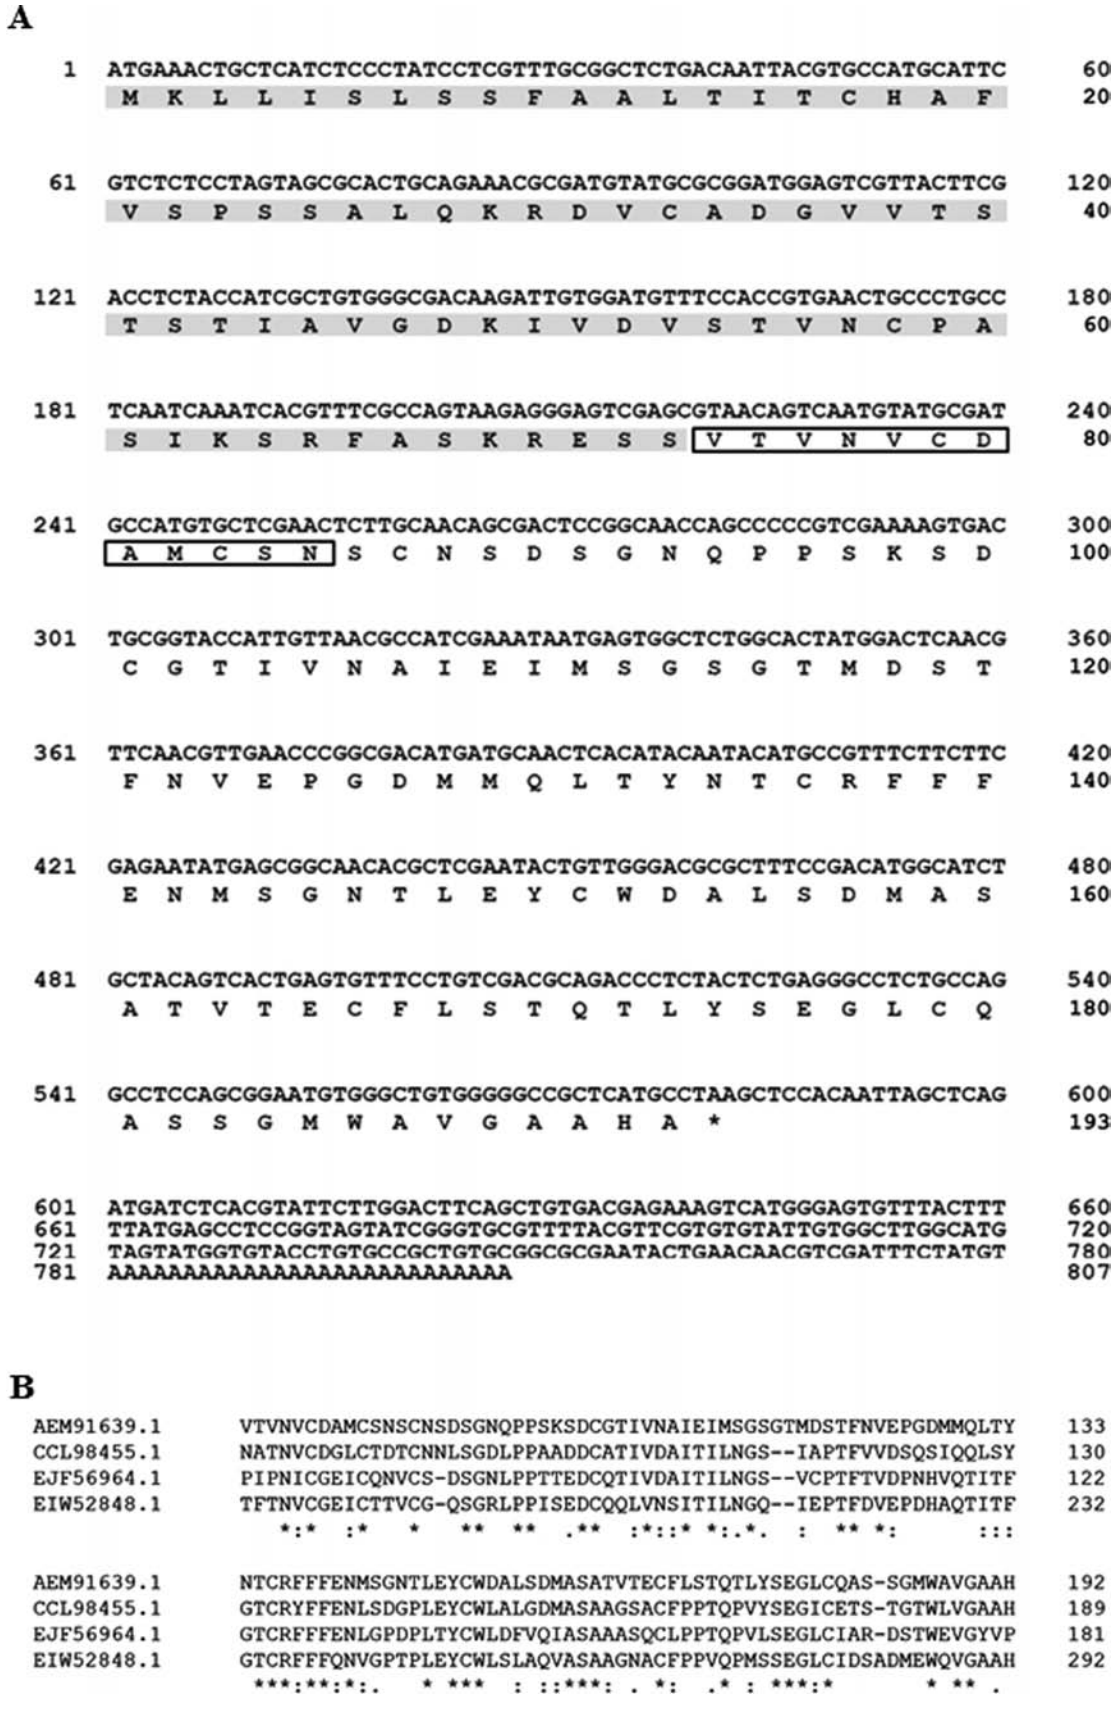

Figure 1. Complete cDNA sequence of PCP gene cloned via RACE PCR. (A) The full-length cDNA sequence of PCP was generated by combining the 3′- and 5′-RACE products. The N-terminal amino acid sequence is boxed, the signal peptide sequence is indicated by a gray background, and the stop codon is indicated by an asterisk. (B) Multiple alignment of PCP amino acid sequence with sequences of proteins from Polyporaceae fungi was performed by ClustalW omega program on the Web site of EMBL-EBI (http://www.ebi.ac.uk/Tools/msa/clustalo/). Identical, highly similar, and similar residues are marked with asterisks, colons, and dots, respectively.

Table 1. Homology Analysis of PCP Amino Acid Sequence with Proteins from Polyporaceae Fungi

species	name	accession no.	length	identity (%)	similarity (%)	gap (%)
P. cocos	PCP	AEM91639.1	193			
F. radiculosa	predicted protein	CCL98455.1	190	49	65	1
T. versicolor	TRAVEDRAFT_31886	EIW52848.1	293	46	60	3
D. squalens	DICSQDRAFT_157655	EJF56964.1	182	43	59	9

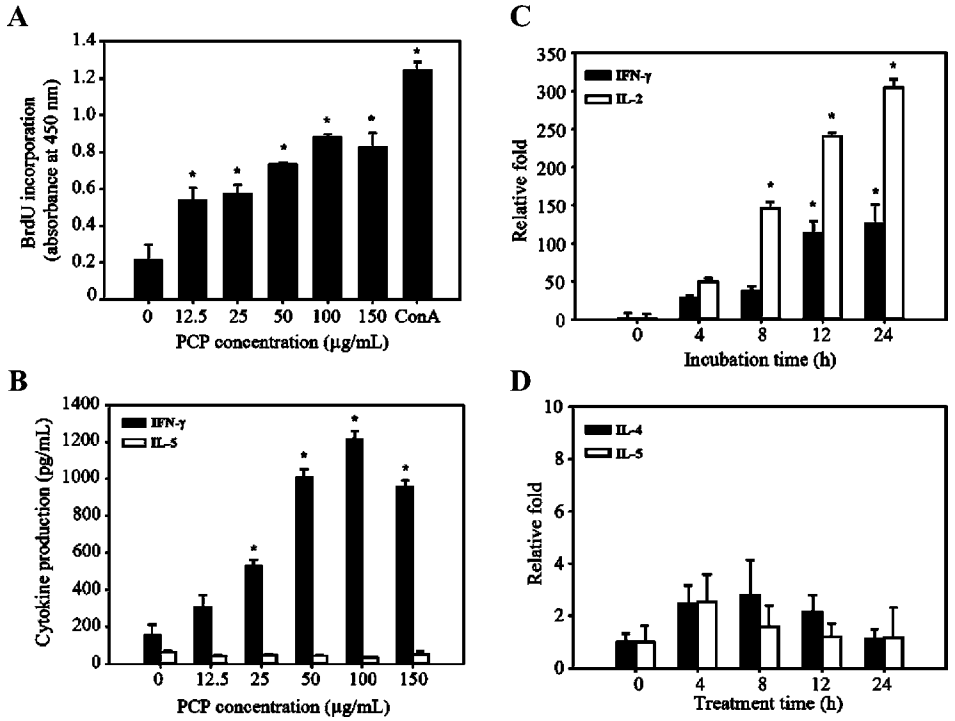

Figure 2. PCP activates murine splenocytes. (A) Mouse splenocytes were incubated with PCP at the indicated concentrations or ConA (5 μg/mL) as a positive control for 54 h. Cell proliferation was determined by measuring BrdU incorporation into DNA for an additional 18 h. (B) Mouse splenocytes were incubated with PCP at the indicated concentrations for 72 h. Culture supernatants were collected to determine their IFN-γ and IL-5 levels by sandwich ELISA methods. Statistical difference was compared to the level in untreated control cells (∗, $P < 0.05$). (C, D) Mouse splenocytes were treated with PCP at each time point. RNAs from treated cells were isolated and subjected to RT-PCR using specific primer sets for mouse Th1-associated cytokines (C; IFN-γ and IL-2), Th2-associated cytokines (D; IL-4 and IL-5), and β-actin. The values were normalized by dividing by the amount of β-actin gene expression in real-time PCR analysis. Each bar of the histogram represents a minimum of three experiments, and data are presented as the mean ± SD (∗, $P < 0.05$ compared to the culture medium control (0 h).

removed by 2% SDS, 62.5 mM Tris, pH 6.8, 100 mM β-mercaptoethanol buffer. The membrane was reprobed with rabbit anti-mouse STAT4 or STAT6 antibodies (Santa Cruz Technology) and detected with HRP-conjugated anti-rabbit IgG (KPL) as a loading control.

Statistical Analysis. All in vitro data are presented as means ± SD of three independent experiments ($n = 3$). All animal experiment data are presented as means ± SE of at least two independent experiments performed in quadruplicate or hexaplicate. Statistical comparison was made by one-way ANOVA followed by a Duncan multiple-comparisons test. Differences were considered as statistically significant when the P values were <0.05.

RESULTS

Cloning the PCP Gene. The N-terminal sequence of PCP was VTVNVXDAMXSN. This sequence was used to design degenerate primers to clone the PCP gene. 3′-RACE was performed using a gene-specific primer p320 (5′-GGTTAC-GGTCAATGTATGTGAT-3′). A 700 bp product, PR320-700, was obtained. This product contained the sequence of the N-terminal sequence of PCP (Figure S1 of the Supporting Information). Another primer, p5-320-2 (5′-ATTGTATG-TGAGTTGCATCATGTC-3′), was made to perform 5′-RACE PCR. A 550 bp product, PR5-320-2-550, was generated. The 83rd to 94th amino acid residues of the translated PR5-320-2-550 sequence were the same as the N-terminal amino acid sequence of PCP (Figure S2 of the Supporting Information). We merged PR320-700 and PR5-320-2-550 to acquire the complete cDNA sequence of PCP (Figure 1A).

It was an 807 bp nucleotide sequence. It had a 579 bp ORF and encoded 193 amino acids. It also had a putative signal peptide at the first 19 amino acid residues as shown in Figure S3 of the Supporting Information. The accession number of this sequence is JN571084.

We also performed sequence homology analysis on PCP using the NCBI protein Blast tool (Figure 1B and Table 1). The sequence of PCP shared 49% identical sequence with a *Fibroporia radiculosa* predicted protein (CCL98455.1), 46% identical sequence with a *Trametes versicolor* hypothetical protein TRAVEDRAFT_31886 (EIW52848.1), and 43% identical sequence with a *Dichomitus squalens* hypothetical protein DICSQDRAFT_157655 (EJF56964.1). Notably, these proteins were all derived from fungi of the Polyporaceae family, suggesting that PCP might be related to a universally expressed fungal protein.

PCP Activates Murine T Cells in the Presence of Co-stimulatory Signals. To determine the induction of PCP on mouse splenocytes, we first estimated the regulation of cell proliferation and cytokine secretion under PCP stimulation measured by using BrdU incorporation and sandwich ELISA methods. As shown in Figure 2A, PCP was able to induce an enhancement of cell proliferation in a dose-dependent manner. Upon stimulation with 100 μg/mL PCP, the maximum BrdU incorporation rate in splenocytes was observed. In particular, PCP induced a 4−5-fold-increased BrdU incorporation as compared to medium alone. Meanwhile, the similarity in cytokine production results showed that PCP markedly activated mouse splenocytes to increase their secretion of IFN-γ in vitro, whereas there was no significant change on IL-5 production (Figure 2B). In the presence of PCP (100 μg/mL), the amount of IFN-γ secreted was up to 1225 pg/mL; however, the incubation of PCP failed to enhance IL-5 production in mouse splenocytes. Because IFN-γ is a cytokine strongly associated with a Th1 response and impedes the development of Th2 responses, we suggested that PCP might up-regulate Th1-mediated immunity. To test this possibility, we further examined the effect of PCP on Th1- and Th2-associated cytokine gene expression. Stimulation of mouse splenocytes with PCP (100 μg/mL) resulted in a time-dependent increase in IFN-γ and IL-2 mRNA expression as measured by quantitative real-time PCR (Figure 2C). In contrast, the mRNA expression of IL-4 and IL-5 in mouse splenocytes was insignificantly increased upon PCP treatment between 4 and 8 h in comparison with those in control untreated cells (Figure 2D). These results suggested that PCP directly enhanced mouse splenocyte activation and promoted Th1-associated cytokine production.

In addition, we tested if $CD4^+$ and $CD8^+$ T cell populations in the spleen were changed through induction of PCP at different concentrations characterized by flow cytometry. CD69 is the earliest activation marker newly synthesized and expressed during T lymphocyte activation.[16] Accordingly, we also investigated the expression of CD69 on $CD4^+$ and $CD8^+$ T cells upon PCP stimulation. Slight increases in $CD4^+$ and $CD8^+$ T cell populations were observed in splenocytes upon PCP stimulation (Figure 3A). However, remarkable increases of CD69-positive cells were seen in both $CD4^+$ and $CD8^+$ T cells after PCP stimulation (Figure 3A).

To further clarify the PCP-induced lymphocyte population, we utilized the MACS system with specific magnetic beads to obtain purified lymphocytes. Because CD28 co-stimulation is also important in T cell activation,[17] $CD90^+$ cells, which are composed mainly of CD4 and CD8 T cell subsets, were isolated from BALB/c mice by positive selection and stimulated in vitro using plate-bound anti-CD3 and anti-CD28 antibodies. Different concentrations of PCP were introduced to the culture system, and cell proliferation was analyzed by BrdU incorporation analysis. PCP treatment increased the proliferation rate of sorted $CD90^+$ cells upon CD3/CD28-mediated activation in a dose-dependent manner (Figure 3B). The maximum response of $CD90^+$ cells was achieved at a concentration of 100 μg/mL of PCP, whereas PCP resulted in a slight increase in cell proliferation of non-$CD90^+$ cells (mainly B cells). $CD4^+$ and $CD8^+$ T cells were isolated from total splenocytes, and the cell proliferation upon PCP stimulation in a combination of anti-CD3/CD28 antibodies was analyzed. The results provided strong evidence for $CD4^+$ and $CD8^+$ T cell proliferation (Figure 3C). These results

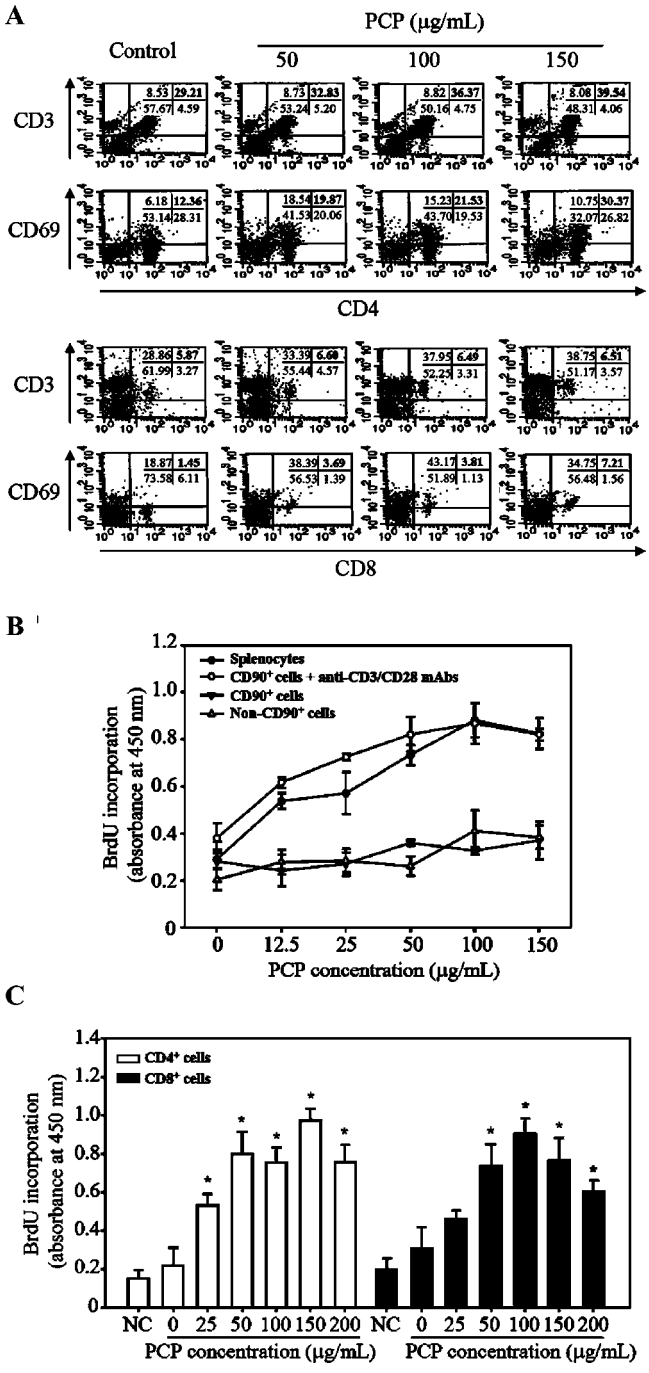

Figure 3. PCP activates murine $CD90^+$ T lymphocytes. (A) Splenocytes were stimulated with PCP (50, 100, and 150 μg/mL), ConA (5 μg/mL), and LPS (1 μg/mL) in combination with anti-CD3/CD28 antibodies for 72 h, and cells were then stained with PE-conjugated anti-CD3 and CD69 antibodies and FITC-conjugated anti-CD4 and CD8 antibodies, respectively. The flow cytometry data are representative of three independent sets of analyses. (B) $CD90^+$ cells were sorted from BALB/c mouse splenocytes using anti-CD90 coated magnetic microbeads. Anti-CD3/CD28 stimulated $CD90^+$ cells, unstimulated $CD90^+$ cells, non-$CD90^+$ cells, and splenocytes were cultured in medium containing various concentrations of PCP for 54 h. (C) Purified $CD4^+$ and $CD8^+$ T cells were activated with anti-CD3/CD28 antibodies in the presence of various concentrations of PCP for 54 h. Cell proliferation was quantified by measuring BrdU incorporation into DNA for an additional 18 h. NC, negative control (medium alone). (*, $P < 0.05$ compared to the anti-CD3/CD28 alone control.)

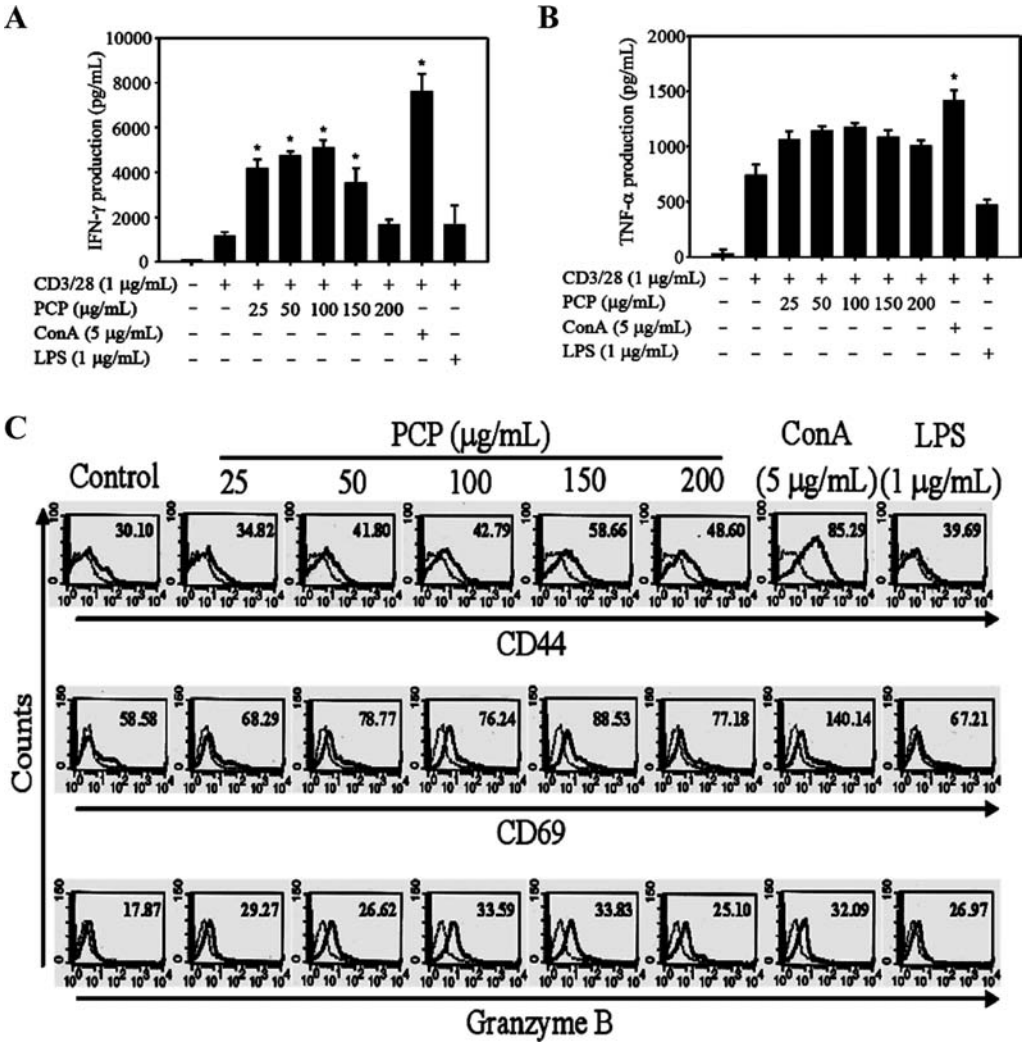

Figure 4. PCP activates murine CD8$^+$ T lymphocytes. (A) Purified CD8$^+$ T cells were activated with anti-CD3/CD28 antibodies in the presence of various concentrations of PCP for 72 h. Culture supernatants were collected to determine the production of IFN-γ and TNF-α measured by sandwich ELISA methods. (B) Purified CD8$^+$ T cells were stimulated with PCP (25−200 μg/mL), ConA (5 μg/mL), and LPS (1 μg/mL) in combination with anti-CD3/CD28 antibodies for 72 h, and cells were then stained with PE-conjugated anti-CD44 and CD69 antibodies and intracellularly stained with PE-conjugated anti-mouse granzyme B antibodies, respectively. The flow cytometry data are representative of three independent sets of analyses. The shaded area shows the unstained control. The solid line indicates the cell surface expression of CD44 and CD69, and intracellular granzyme B level in CD8$^+$ T cells, respectively. The histograms were quantified and represented as mean fluorescence intensity (MFI).

indicated that PCP could enhance the activation of both CD4$^+$ and CD8$^+$ T cells in the presence of a CD3/CD28 co-stimulation signal, demonstrating the up-regulation of cell proliferation and the early activation molecule CD69 expression believed to be involved in transmission of co-stimulatory signals in T cells.

PCP Enhances the Effector Functions of Purified CD8$^+$ and CD4$^+$ T Cells. To clarify whether PCP induced CD8$^+$ T cell activation, we also evaluated distinct cytokine production, the expression of activation markers CD44 and CD69, and the levels of granzyme B on sorted CD8$^+$ T cells. It is well-known that granzyme B is a serine proteinase released by effector CD8$^+$ T cells to kill abnormal cells. CD8$^+$ T cells can also produce cytokines such as TNF-α and IFN-γ. As shown in Figure 4A, PCP exhibited potential activating effects on CD8$^+$ T cells inducing significant increases in the production of IFN-γ and TNF-α secretion; whereas there was no detectable difference in IL-2 levels between the PCP-treated cells and the anti-CD3/CD28 alone control (data not shown). Moreover, we also observed PCP-induced up-regulation of CD44 and CD69 expression on CD8$^+$ T cells in combination with anti-CD3/CD28 antibodies (Figure 4B). A significant increase in intracellular granzyme B levels was also observed in PCP-treated cells when compared to anti-CD3/CD28 control cells. In this study, we demonstrated that PCP was able to activate CD8$^+$ T cells and enhance their effector functions.

To demonstrate that PCP prompted T helper cell development, CD4$^+$ T cells were activated with anti-CD3/CD28 antibodies and cultured in PCP-containing medium at different concentrations to evaluate T helper cell associated cytokine production and transcription factor gene expression. The mRNA levels of respective transcription factors were determined by using a quantitative real-time PCR after various incubation times. PCP treatment (100 μg/mL) increased the mRNA level of T-bet by almost 4.6-fold, whereas it showed only slight fluctuations in relative gene expression levels of

GATA-3, RORγt, and Foxp3 (Figure 5A). To determine whether PCP stimulated phosphorylation of STAT4 (Th1

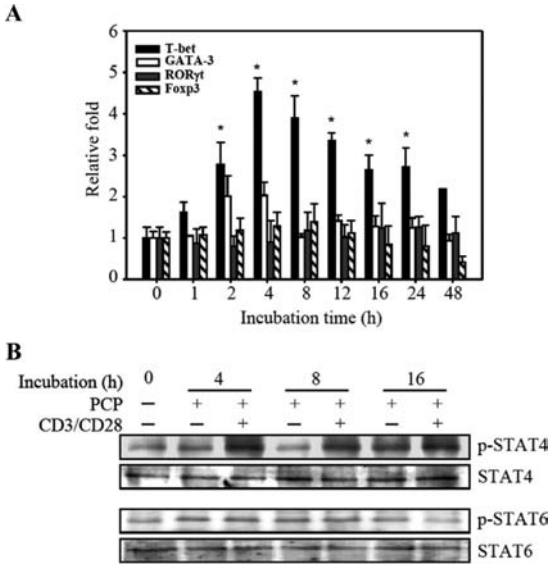

Figure 5. PCP induces the expression of T-bet and the phosphorylation of STAT4 in $CD4^+$ T lymphocytes. (A) Purified $CD4^+$ T cells were treated with PCP in combination with anti-CD3/CD28 antibodies at each time point. RNAs from treated cells were isolated and subjected to RT-PCR using specific primer sets for mouse Th1-associated transcription factor T-bet, Th2-associated transcription factor GATA-3, Th17-associated transcription factor RORγt, Treg-associated transcription factor Foxp3, and β-actin. The values were normalized by dividing by the amount of β-actin gene expression. (∗, $P < 0.05$ compared to the anti-CD3/CD28 alone control (0 h).) (B) Cell lysates from control or PCP-treated $CD4^+$ T cells at the indicated times were immunoprecipitated with anti-STAT4 and STAT6 antibodies and then resolved by SDS-PAGE. Blots were probed with anti-phosphotyrosine (upper panel) or anti-STAT4 and STAT6 (lower panel) antibodies in each group.

transcription factor) or STAT6 (Th2 transcription factor), the cell lysates from control and PCP-stimulated $CD4^+$ T cells with or without combination of anti-CD3/CD28 antibodies were precipitated with antibodies against STAT4 or STAT6. The immunoprecipitates were then detected using either anti-phosphotyrosine or anti-STAT4 or anti-STAT6 antibodies. In the present study, PCP was demonstrated to stimulate STAT4 tyrosine phosphorylation in a time-dependent manner, whereas treatment with PCP (100 μg/mL) had no effect on STAT6 tyrosine phosphorylation compared to anti-CD3/CD28 control cells at indicated time (Figure 5B). In addition, the secretion of Th1-associated cytokines including IFN-γ and IL-2 was dramatically increased under PCP stimulation in the presence of anti-CD3/CD28 antibodies; however, Th2-associated cytokines containing IL-4 and IL-5 were not altered in their secretion levels (Figure 6A). The maximum IFN-γ and IL-2 production was observed at concentrations ranging from 50 to 150 μg/mL of PCP. As shown in Figure 6B, the flow cytometry results also indicated that $CD4^+$ T cells expressed high levels of activation markers CD44 and CD69 after incubation with PCP in the presence of anti-CD3/CD28 antibodies and also increased intracellular production of IFN-γ, but not IL-4 (data not shown). These results implied that PCP specifically primed naive $CD4^+$ T cell differentiation into the Th1 subset.

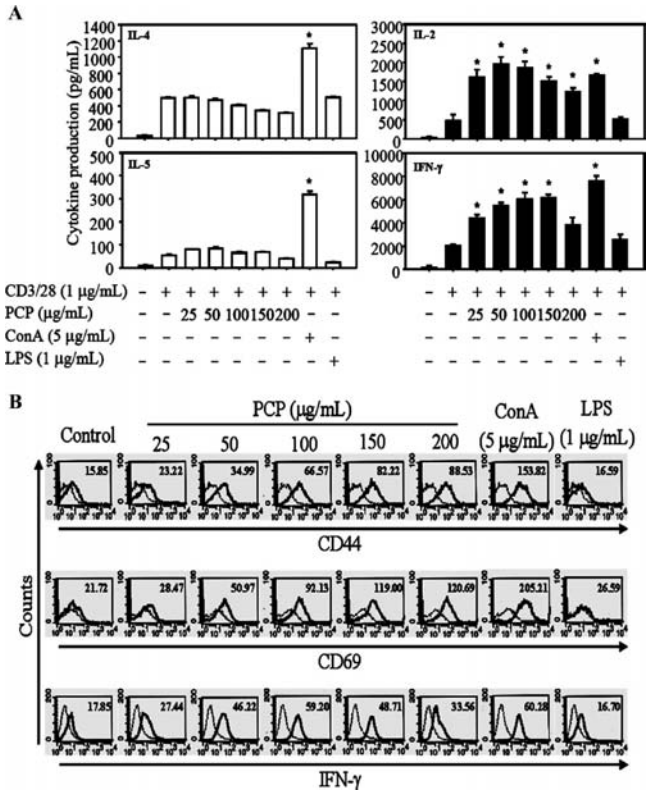

Figure 6. PCP activates murine $CD4^+$ T lymphocytes. (A) Purified $CD4^+$ T cells were incubated with PCP at the indicated concentrations (25, 50, 100, 150, and 200 μg/mL) in combination with anti-CD3/CD28 antibodies for 72 h. Culture supernatants were collected to determine the production of Th1-associated cytokines including IFN-γ and IL-2, and Th2-associated cytokines including IL-4 and IL-5 measured by sandwich ELISA methods. Statistical difference was compared to the level in anti-CD3/CD28 alone control cells (∗, $P < 0.05$.) (B) Purified $CD4^+$ T cells were stimulated with PCP (25−200 μg/mL), ConA (5 μg/mL), and LPS (1 μg/mL) in combination with anti-CD3/CD28 antibodies for 72 h, and cells were then stained with PE-conjugated anti-CD44 and CD69 antibodies and intracellularly stained with PE-conjugated anti-mouse IFN-γ antibodies, respectively. The flow cytometry data are representative of three independent sets of analyses. The shaded area shows the unstained control. The solid line indicates the cell surface expression of CD44 and CD69 and intracellular IFN-γ level in $CD4^+$ T cells, respectively. The histograms were quantified and represented as mean fluorescence intensity (MFI).

Oral Administration of PCP Enhances Th1-Related Immunoglobulin and Cytokine Production by Murine Splenocytes. Sensitization of BALB/c mice with ip injection of OVA protein absorbed to aluminum hydroxide two times as described previously[18] led to the development of an antigen-specific Th2-type response to OVA. The above results suggested that PCP could up-regulate Th1-mediated responses in vitro. Therefore, it was examined whether PCP was involved in the modulation of the Th1 pathway by using the animal model containing the OVA-sensitized murine model to confirm the influence of PCP on $CD4^+$ T cells. In our preliminary study, we fed BALB/c mice varying dosages of PCP (0.5, 1, or 2 mg per mouse) or PBS every day and collected sera on day 7 for the measurement of IFN-γ. We found that the optimal dose was 1 mg per mouse of PCP for maximal induction of IFN-γ in vivo (data not shown); therefore, this dosage was employed for further experiments.

dx.doi.org/10.1021/jf405507e | J. Agric. Food Chem. 2014, 62, 2861−2871

Immunized and nonimmunized mice were orally administered PCP (1 mg per mouse once daily) or an equal volume of PBS as a control for 24 days. As shown in Figure 7A, the production of total IgG1 in sera of PCP-treated mice was suppressed as compared with that of PBS-treated mice, especially in both OVA-immunized and nonimmunized mice on day 24. On the other hand, PCP-treated mice showed a significant increase of total IgG2a levels after administration for 10 days. In OVA-immunized mice, the serum level of OVA-specific IgG1 was significantly decreased when mice were administered PCP, whereas the level of OVA-specific IgG2a was highly increased in a statistically significant manner on day 24. There were a slight decrease on IgE levels and no significant change in IgA and IgG2b after administration of PCP in all situations (data not shown).

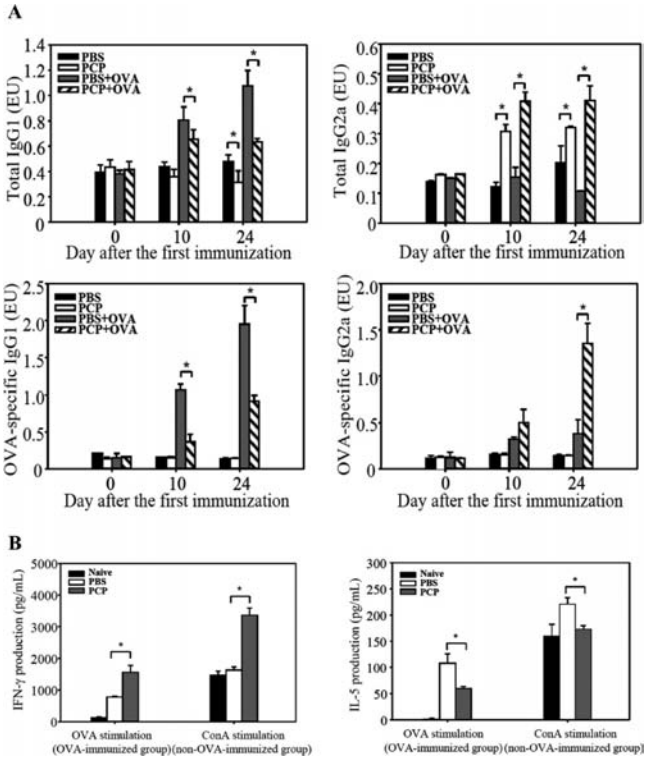

Figure 7. Orally administered PCP activates Th1-associated immunoglobulin and cytokine production in mice. (A) BALB/c mice were injected intraperitoneally with or without OVA under PCP or PBS treatment and their serum total and anti-OVA IgG1 and IgG2a responses determined. Mice administered orally PCP (1 mg per mouse once daily) or PBS were immunized with or without 50 μg of OVA on days 0 and 14, and serum samples were collected on days 0, 10, and 24 after the first immunization. Data represent the mean ± SE, and each group had six mice (∗, $P < 0.05$ among the different groups.) (B) Splenocytes from treated BALB/c mice were prepared on day 24 and incubated with 10 μg/mL OVA or 1 μg/mL ConA for 72 h, respectively. The culture supernatants were collected and used to determine their IFN-γ and IL-5 production. Naive mice had neither additional administration nor immunization with OVA and were used as a negative control. Data represent the mean ± SE ($n = 5$; ∗, $P < 0.05$ among the different groups).

It has been reported that cytokines play an important role in antibody response. Accordingly, we investigated the regulatory effect of PCP on Th1 and Th2 responses in PCP- and PBS-treated mice. On day 24, mice from each group were sacrificed to obtain splenocytes and then incubated in the presence of OVA (OVA-immunized group) and ConA (nonimmunized group) for 3 days, and then culture supernatants were collected to measure the levels of IFN-γ and IL-5. Following in vitro stimulation with ConA, oral administration of PCP increased the IFN-γ level and decreased the IL-5 level compared with oral administration of PBS (Figure 7B, top panel). Moreover, there was no difference in cytokine production by splenocytes stimulated with ConA between PBS-treated and naive mice. In addition, the level of IFN-γ was enhanced by OVA stimulation, and oral administration of PCP further increased the IFN-γ production by splenocytes from OVA-immunized mice. Unlike the induction of IFN-γ, the level of IL-5 significantly decreased in OVA-immunized mice after oral administration of PCP compared with oral administration of PBS (Figure 7B, bottom panel). These results indicated that PCP changed the balance of Th1/Th2 cell immune responses from Th2 dominant to Th1 dominant in OVA-immunized mice.

Oral Administration of PCP Allays IL-4 and IgE Production in a Murine AD Model. To evaluate the potential of PCP to attenuate Th2-dominat allergic response, an OVA-induced AD murine model was performed. The mice were sensitized by OVA and orally administered PCP or saline. At the end of the animal experiment, the lymph nodes were collected for cytokine production quantification and the serum was collected for immunoglobulin measurement. OVA sensitization caused a reduction in IFN-γ production by the lymphocytes; however, PCP administration restored IFN-γ production to normal range found for the control mice that were sensitized by saline (Figure 8A). In addition, OVA

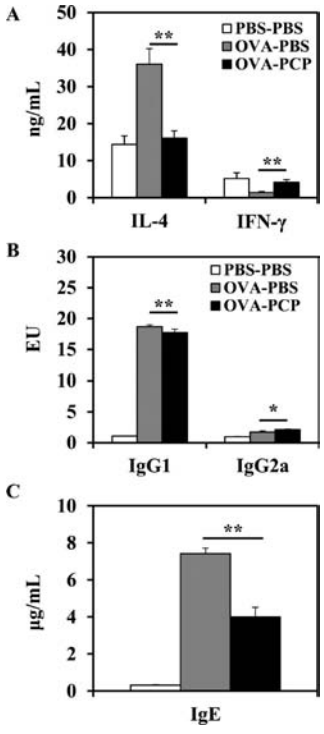

Figure 8. Orally administered PCP alleviates Th2-associated cytokines and immunoglobulin production in mice. (A) IFN-γ and IL-4 production by lymph node cells was detected after 48 h of incubation. ($n = 5$; ∗, $P < 0.05$, and ∗∗, $P < 0.001$, among the different groups.) OVA-specific (B) IgG1 and IgG2a and (C) IgE present in mice serum were detected by ELISA. Data represent the mean ± SE ($n = 5$; ∗, $P < 0.05$ among the different groups).

dx.doi.org/10.1021/jf405507e | J. Agric. Food Chem. 2014, 62, 2861−2871

sensitization also caused a significant increase in lymphocyte IL-4 production, whereas PCP administration restored IFN-γ production to normal range found for the control mice (Figure 8B). The IgE level in serum surged in the mice sensitized with OVA; however, PCP administration significantly reduced this effect by 46% (Figure 8C). In addition, PCP also increased the IgG2a level and reduced the IgG1 level in OVA-sensitized mice (Figure 8D,E). Altogether, oral administration of PCP was capable of alleviating the production of Th2 cytokine and Th2 immunoglobulins.

DISCUSSION

In our previous study we characterized the biochemical features and the TLR4/MyD88-mediated macrophage activating effect of PCP.[6] In this study we determined the complete cDNA sequence of the PCP gene. Taking advantage of the sequence information, we were able to compare the biochemical features that we previously acquired with the sequence-derived biochemical data obtained from bioinformatics tools. The predicted molecular weight (MW) of PCP from the N-terminus to the first stop codon is 12.8 kDa (Figure S4 of the Supporting Information). We previously showed that PCP is a heterodimeric protein consisting of 14.3 and 21.3 subunits. Interestingly, these subunits had identical N-terminal amino acid sequences and the same amino acid composition.[6] This suggested that the difference in MW of the subunits might result from different post-translational modification, such as N- and O-linked glycosylation that was also demonstrated in our previous paper. On the basis of the sequence we obtained in this study, it could be inferred that PCP is composed of two identical 12.8 kDa protein subunits; however, these subunits are asymmetrically modified. It was plausible that the 14.3 and 21.3 kDa subunits were conjugated to a 1.5 kDa glycan and a 8.5 kDa glycan, respectively. Neverthless, further studies are required to clarify these assumptions. The predicted p*I* value of PCP was 3.8 (Figure S4 of the Supporting Information), meaning that PCP carried a negative charge when suspended in the Tris buffer, pH 8.2. This negative charge made it possible for anion-exchange chromatographic purification for PCP. In addition, using YinOYang 1.2 prediction and the NetNGly 1.0 prediction software, we showed that PCP could have O-glycosylation at the 39th and 97th residues and N-glycosylation at the 142nd residue. This finding corresponded well with our previous prediction.[6]

Homology analysis of the PCP amino acid sequence revealed an interesting finding. PCP shared a similar sequence with other fungal proteins from the Polyporaceae family, including *F. radiculosa*, *T. versicolor*, and *D. squalens*. Although *F. radiculoss* and *D. squalens* are mainly studied for their lignin digestion activities, *T. versicolor* is a known for its immunomodulatory and tumor-resisting capabilities.[19] We have recently discovered the critical contribution of *T. versicolor* protein in regard to the immunomodulatory effects of the fungus. The current finding suggested that PCP might be related to a ubiquitously expressed protein conserved in the Polyporaceae family. It would be of great scientific value to investigate the existence and function of such protein in other Polyporaceae fungi.

T lymphocytes play a critical role in the development of adaptive immune response.[20] Recent studies have implicated efficient antigen presentation and T cell priming as being central for the practical implementation of clinical applications. Our results collectively showed a pronounced elevation of MHC class II and CD86 expression on mouse peritoneal macrophages in response to PCP, suggesting PCP had the capability of strengthening APCs that are necessary for T cell activation and proliferation. Accordingly, we further characterized the effects of PCP on $CD4^+$ and $CD8^+$ T cell responses. According to our data, PCP increased cell proliferation and activation marker expression of splenic $CD4^+$ and $CD8^+$ T and induced a predominant IFN-γ response in vitro. Naive T cells are activated antigens presented on APCs.[21] Among PCP-induced $CD8^+$ T cell activation, the increased proliferation of $CD8^+$ T cells was accompanied by differentiation into granzyme B-producing cells. Effector $CD8^+$ CTLs play a pivotal role in the successful clearance of viruses, intracellular microorganisms, and tumors.[22] Therefore, PCP might have a beneficial effect on these circumstances as well. Furthermore, the combined role of PCP as antigen and immunomodulator has led to the suggestion that it might provide an important link between innate and adaptive immune responses.

$CD4^+$ T cells have regulatory functions as helper cells that can initiate and potentiate immune reactions.[23] In this study, we have also shown that PCP is a potent regulator of IFN-γ production and Th1 differentiation in $CD4^+$ T cells. PCP induced IFN-γ and IL-2 production dose-dependently in vitro. To further examine this issue, we systematically evaluated the quantitative and kinetic parameters of PCP-induced activation of T helper lineage-specific transcription factors in $CD4^+$ T cells. T-bet is a transcription factor that stimulates Th1 response while inhibiting Th2 response.[24] We showed that PCP enhanced STAT4 phosphorylation, promoted downstream immune signaling, and increased T-bet expression. In addition, the expression of Th2 signaling proteins (STAT6 and GATA-3) induced by PCP was similar to that of control cells, indicating that PCP had no effect on this pathway. These findings support the point that PCP up-regulates Th1 cell-mediated immune responses.

On the basis of the in vitro data, PCP was demonstrated to be able to regulate Th1 and Th2 balance via Th1 cytokine induction. This effect might result from the activation of T-bet, which induces Th1 transition and IFN-γ synthesis.[25] T-bet can also mediate B-cell IgG2a class-switch recombination and IFN-γ secretion.[26] Accordingly, we showed that PCP down-regulates GATA-3, IL-4, and IL-5 while up-regulating T-bet and IFN-γ.

To clarify the Th1/Th2 modulating abilities of PCP, we examined the effects of oral administration of PCP on antibodies and cytokine production. As a result, we showed that oral PCP increased Th1 response including induction of OVA-specific IgG2a and IFN-γ. On the other hand, oral PCP suppressed OVA-specific IgG1 and IL-5 production. These findings suggested suppression of humoral immune response and antibody class switch recombination.[27] Taken together, PCP might be a regulator of Th1/Th2 balance that favored Th1 response.

We showed in this study that PCP might be a potent antiallergic agent that activates Th1 $CD4^+$ T cells and suppresses Th2 cells, which are the major effectors in allergic responses such as asthma and allergic rhinitis.[28]

Atopic dermatitis is characterized by an itchy, inflammatory skin condition with a predilection for skin flexures. It is also characterized by high serum IgE and a Th2-dominat immune response such as the production of IL-4 and IL-5.[29,30] In this study, we showed that PCP could induce a Th1 response in vitro and in vivo, indicating the potential of PCP to be utilized to regulate T cell response. In addition, we demonstrated the effect of PCP to alleviate Th2 cytokine and IgE production in

an AD murine model. These data exhibited the potential of PCP to be utilized to regulate allergic response.

In conclusion, we cloned the gene of PCP, verified its biochemical characteristics, and demonstrated that PCP is a T cell-activating agent that induces Th1 response in vitro and in vivo. Moreover, PCP could alleviate the Th2-dominant cytokine and IgE production in a murine atopic dermatitis model. These findings showed some unique properties of a newly cloned protein from *P. cocos*, enabling further studies and application.

phase.[20] Excessive macrophage activation is involved in many diseases, such as atherosclerosis. It has recently been suggested that activated macrophages within injured/inflamed arteries are the potential targets of dietary quercetin metabolites.[21] The presence of 50 μM quercetin glucuronide regulates the coronary venular barrier function through improving blood-borne inflammatory mediators and pharmacological tools in a novel microvascular wall model.[22] Taken together, inflamed macrophages may be selected as a good target for evaluating the antiinflammatory potential of quercetin and its metabolites. Changes in pro-/antiinflammatory cytokine secretion levels by target cells may be a good marker for inflammation status.

Cumulative data imply that quercetin (Q) can be absorbed and metabolized into quercetin-3-glucuronide (Q3G) in vivo. However, little is known about the differences in antiinflammatory effects between Q and Q3G administration. To clarify this puzzle, this study investigated the prophylactic or therapeutic effects of Q and Q3G administration on lipopolysaccharide (LPS)-induced inflammation in peritoneal macrophages from female BALB/c mice using ex vivo models. Changes in pro-/antiinflammatory cytokine secretion profiles by macrophages were determined using enzyme-linked immuno-sorbent assay (ELISA) to unravel the possible immunomodulatory or antiinflammatory mechanisms of Q or Q3G.

MATERIALS AND METHODS

Chemicals. Quercetin (Q) is a typical flavonoid existing in many plants. Quercetin-3-glucuronide (Q3G) is a major quercetin metabolite found in the serum in humans. In this study, both quercetin dihydrate ($C_{15}H_{10}O_7 \cdot 2H_2O$; 338.27 g/mol) (Sigma-Aldrich Co., Steinheim, Switzerland) and quercetin-3-glucuronide ($C_{21}H_{18}O_{13}$; 478.37 g/mol) (Carbosynth Limited, Berkshire, UK) were purchased at the highest available purity (>98%, HPLC). The chemical structures of Q and Q3G are shown in Figure 1. Quercetin was dissolved in

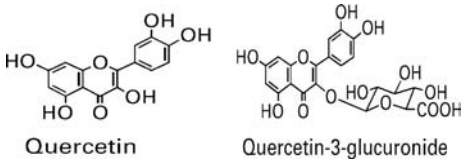

Figure 1. The chemical structures of quercetin and quercetin-3-glucuronide.

dimethyl sulfoxide (DMSO, Wako, Osaka, Japan) to prepare a stock solution at a concentration of 20 mM and sterilized using a filter (Millipore, Carrigtwohill, Cork, Ireland) with 0.2 μm pore size. Quercetin-3-glucuronide (Q3G) was dissolved in phosphate-buffered saline (PBS, 137 mM NaCl, 2.7 mM KCl, 8.1 mM Na_2HPO_4, 1.5 mM KH_2PO_4, pH 7.4, 0.2 μm filtered) to prepare a stock solution at a concentration of 2 mM and sterilized using a filter (Millipore, Carrigtwohill, Cork, Ireland) with 0.2 μm pore size. The stock solution was stored at −80 °C for future use.

Experimental Mice. Female BALB/cByJNarl mice (7 weeks old) were obtained from the National Laboratory Animal Center, National Applied Research Laboratories, National Science Council in Taipei, Taiwan, ROC, and maintained in the Department of Food Science and Biotechnology at National Chung Hsing University, Taiwan, ROC. The mice were housed and kept on a chow diet (laboratory standard diet, Diet MF 18, Oriental Yeast Co., Ltd., Osaka, Japan). The animal room was kept on a 12-h-light and 12-h-dark cycle. Constant temperature (25 ± 2 °C) and relative humidity (50−75%) were maintained. After acclimation for 1 week, the mice were sacrificed to obtain peritoneal macrophages. BALB/c strain mice weighting 20−25 g were used throughout the experiment. The animal use protocol for these experiments was reviewed and approved by the Institutional Animal Care and Use Committee (IACUC), National Chung Hsing University, Taiwan, ROC.

Source of Mouse Primary Peritoneal Macrophages. The primary peritoneal macrophages from mice were collected according to the method described previously.[23,24] Briefly, the adult female BALB/c mice were anesthetized with diethyl ether, bled using a retro-orbital venous plexus puncture to collect blood, and immediately euthanized by CO_2 inhalation. Peritoneal macrophages were prepared by lavaging the peritoneal cavity with 2 aliquots of 5 mL of sterile Hank's balanced salts solution (HBSS) ((50 mL of 10× HBSS (Hyclone Laboratories Inc., South Logan, UT), 2.5 mL of antibiotic−antimycotic solution (100× PSA) containing 10 000 units of penicillin, 10 mg of streptomycin, and 25 μg of amphotericin B per mL in 0.85% saline (Atlanta Biologicals Inc., Norcross, GA); 20 mL of 3% bovine serum albumin (BSA, Sigma-Aldrich Co., St. Louis, MO) in PBS; 2.5 mL of 7.5% $NaHCO_3$ (Wako, Osaka, Japan), 425 mL sterile water)) for a total of 10 mL through the peritoneum. The peritoneal lavage fluid was centrifuged at 400g for 10 min at 4 °C. The cell pellets were collected and resuspended in tissue culture medium (TCM, a serum replacement; Celox Laboratories Inc., Lake Zurich, IL); suspended in a medium consisting of 10 mL of TCM, 500 mL of Roswell Park Memorial Institute (RPMI) 1640 medium (Atlanta Biologicals Inc., Norcross, GA), and 2.5 mL of antibiotic−antimycotic solution (100× PSA). The peritoneal adherent cells (>90% of macrophages) from each animal were adjusted to 2×10^6 cells/mL in TCM medium with a hemocytometer using the trypan blue dye exclusion method.

Mouse Peritoneal Macrophage Cultures with Q and Q3G and Cell Viability Determination. To evaluate the possible cytotoxic effect of the test samples, the cell viability of mouse primary peritoneal macrophages treated with Q or Q3G was determined using 3-(4,5-dimethylthiazol-2-diphenyl)-2,5-tetrazolium bromide (MTT) assay. Briefly, peritoneal macrophages (2×10^6 cells/mL in TCM medium, 50 μL/well) in the absence or presence of Q (0.8, 8, 40, 100, and 200 μM in TCM medium; 50 μL/well), or Q3G (0.8, 1.6, 8, 40, 100, and 200 μM in TCM medium; 50 μL/well), respectively, were cocultured in 96-well plates at 37 °C in a humidified incubator with 5% CO_2 and 95% air for 48 h. An endotoxin and B-cell mitogen, lipopolysaccharide (LPS, Sigma-Aldrich Co., L-2654, St. Louis, MO) at a final concentration of 2.5 μg/mL in culture was selected as a positive control in every individual experiment. Aliquots of 10 μL of 5 mg/mL MTT (Sigma, St. Louis, MO) in PBS were added to each well in the 96-well plate. The plates were incubated for another 4 h. The culture medium was then discarded. The plates were carefully washed with PBS buffer twice. Aliquots of 100 μL of DMSO were added to each well and oscillated for 30 min to extract formed insoluble formazan. The absorbance was measured at 550 nm on a plate reader (ELISA reader, ASYS Hitech, GmbH, Austria). The cell viability was calculated using the absorbance (A) at 550 nm; cell viability (% of control) = $[(A_{\text{sample}} - A_{\text{sample blank}})/(A_{\text{control}} - A_{\text{blank}})] \times 100$. The remaining cell viability showed that Q or Q3G treatments lower than 50 μM did not have cytotoxicity on peritoneal macrophages.

Antiinflammation Assessments of Q and Q3G Administrations Ex Vivo. To verify the antiinflammatory potential of Q and Q3G, Q and Q3G were prepared and administered to mouse primary macrophages in the absence or presence of LPS under two different ex vivo experimental models, including prophylactic and therapeutic models. Dexamethasone (Dex), a potent glucocorticoid drug having antiinflammatory and immunosuppressant functions, was chosen as a positive control in this study.

A Prophylactic Ex Vivo Model. To avoid excessive high concentrations administered in vivo, noncytotoxic concentrations of Q or Q3G at 25 and 10 μM based on the in vitro study were selected to conduct antiinflammation assessments ex vivo. Accordingly, concentrations of 25 and 10 μM Q or Q3G responded to 1×10^6 cells/mL in vitro. On the basis of our preliminary results, we presumed that there are a total of 6×10^6 peritoneal macrophages in a 20 g normal mouse, reflecting its corresponding doses of Q or Q3G were 0.15 and 0.06 μmol/mouse for treating a total of 6×10^6 peritoneal macrophages/mouse in vivo. In our preliminary results, intraperitoneal

administrations with Q or Q3G, even at 0.30 μmol/mouse, over 24 h did not significantly affect the body weight and cause toxic signs in the experimental mice. Each animal received an appropriate concentration of Q or Q3G dissolved in a volume of 100 μL of sterilized PBS using aliquots from a single lot of Q or Q3G (both at 0.06 and 0.15 μmol/mouse), respectively, to evaluate the prophylactic (preventive) Q or Q3G effects on LPS-induced inflammation ex vivo. The negative control animals received the same volume of PBS, and the positive control animals received the same volume of Dex (0.03 μmol/mouse). At 12 h after Q, Q3G, PBS, or Dex injection, all of the experimental animals were sacrificed. The peritoneal macrophages were collected as described previously. The isolated macrophages were cultured in the absence or presence of LPS (Sigma-Aldrich Co., L-2654, St. Louis, MO) at a final concentration of 25 μg/mL in 6-well plates. The plate was incubated at 37 °C in a humidified incubator with 5% CO_2 and 95% air for 48 h. The plates were centrifuged at 400*g* for 10 min. The cell culture supernatants were collected and stored at −80 °C for cytokine assays.

A Therapeutic Ex Vivo Model. We found that administration with an intraperitoneal (i.p.) injection of LPS at a concentration of 10 mg/kg body weight (BW) might induce acute systemic inflammation.[25,26] To obtain inflamed macrophages in vivo, a series of preliminary experiments were conducted to determine the effective LPS dosage for inducing moderate systemic inflammation and inflamed macrophages. We found that mice administered with an intraperitoneal injection of LPS at a concentration of 8 mg/kg BW over 12 h could induce moderate systemic inflammation and inflamed macrophages in mice. Therefore, LPS i.p. was administered at a concentration of 8 mg/kg BW for 12 h to induce inflammation in vivo. We further presumed a total of 6×10^6 peritoneal macrophages in a 20 g normal mouse, reflecting a corresponding concentration about 25 μg/mL LPS to stimulate 1×10^6 peritoneal macrophages/mL in vitro. Dex was found to have antiinflammatory effects to inhibit LPS-induced inflammation in J774 macrophages at 0.1−10 μM in vitro.[27] We adopted 1 μM Dex as a positive control to treat inflamed peritoneal macrophages in vitro. To evaluate the therapeutic (curative) effects of Q or Q3G on LPS-induced inflammation ex vivo, each animal was first challenged with *Escherichia coli* LPS (O127:B8, Sigma-Aldrich Co., L-3129, St. Louis, MO) to induce moderate systemic inflammation to obtain inflamed macrophages in vivo. Mice were given an intraperitoneal injection of LPS from *E. coli* O127:B8 at a dose of 8 mg/kg body weight (BW). Each animal received this dose of LPS in a volume of 100 μL of LPS dissolved in sterilized PBS using aliquots from a single lot of LPS. The negative control animals received the same volume of PBS. At 12 h after LPS or PBS injection, all experimental animals were sacrificed. The inflamed or normal peritoneal macrophages were collected. The isolated inflamed or normal macrophages (1×10^6 cells/mL) were cultured in the absence or presence of Q or Q3G at the indicated final concentrations of 0.4, 0.8, 4, 20, and 50 μM in 6-well plates. Dex (1 μM) was chosen as a positive control. The plate was incubated at 37 °C in a humidified incubator with 5% CO_2 and 95% air for 48 h. The plates were centrifuged at 400*g* for 10 min. The supernatants in cell cultures were collected and stored at −80 °C for cytokine assays.

Proinflammatory and Antiinflammatory Cytokine Level Measurement in Macrophage Cultures Using ELISA. The macrophage culture supernatants in each individual treatment were collected to measure proinflammatory cytokines (TNF-*α*, IL-1*β*, and IL-6) and antiinflammatory cytokine (IL-10) levels using sandwich ELISA kits. The TNF-*α*, IL-1*β*, IL-6, and IL-10 concentrations were assayed according to the cytokine ELISA protocol from the manufacturer's instructions (mouse DuoSet ELISA Development system, R&D Systems, Minneapolis, MN). The sensitivity of these cytokine assays was <15.6 pg/mL.

Statistical Analysis. Values are expressed as means ± SD and analyzed statistically using one-way ANOVA followed using Duncan's New Multiple Range test or followed by unpaired Student's *t*-test. Differences among treatments were considered statistically significant if $P < 0.05$. Statistical tests were performed using SPSS version 12.0.

RESULTS AND DISCUSSION

The differences in antiinflammatory effects between Q and Q3G remain unclear. Normal and inflamed macrophages were collected from mouse peritoneal cavities and cultured with Q and Q3G in prophylactic or therapeutic ex vivo experimental models, respectively, to clarify these therapeutic effects.
