Seedway (Hall, NY, USA)	'Ruby Queen'	garden beet group

[a]Included are table beet (garden beet group), mangel (fodder beet group), or Swiss chard (leaf beet group) cultivars of *Beta vulgaris* ssp. *vulgaris* and one carrot cultivar (*Dacus carota* ssp. *sativus*) grown in three environments for geosmin screening, 2011−2012. [b]Reference 21. [c]Equal mixture of seed from both sources.

market. However, knowledge of geosmin variation among cultivars grown in a single environment does not provide a full picture of how geosmin levels may be influenced by environment. Eleven commercial table beet cultivars and related species were evaluated, including sugar beet [*B. vulgaris* ssp. *vulgaris* (sugar beet group)], Swiss chard [*B. vulgaris* ssp. *vulgaris* (leaf beet group)], and mangel [*B. vulgaris* ssp. *vulgaris* (fodder beet group)], as well as a carrot (*Dacus carota* ssp. *sativus*), which does not contain measurable geosmin, in three different environments over two years for geosmin levels. Environments included a field trial, a greenhouse trial with nonautoclaved soil, and a greenhouse trial with autoclaved soil. The aim of this study was to measure geosmin levels in a collection of *B. vulgaris* cultivars grown in replicated field trials and in nonautoclaved and autoclaved soils. If soil microorganisms contribute to or are responsible for the geosmin content of beets, plants grown in autoclaved soil may have altered geosmin profiles.

MATERIALS AND METHODS

Standards and Reagents. All laboratory chemicals used were of analytical grade. Menthone [(1*R*,4*S*)-*p*-menthan-3-one] and geosmin (2*β*,6*α*-dimethylbicyclo[4.4.0]decan-1*β*-ol)) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Water for analytical analyses was deionized using a Milli-Q water purification system (Millipore, Bedford, MA, USA). Weed control in experimental plots was accomplished using the herbicides Ro-Neet (Stauffer Chemical Co., Westport, CT, USA) and chloridazon (Pyramin) (Nufarm Australia, Victoria, Australia).

Plant Material. Twelve different cultivars, including 11 from the Chenopodiaceae and one from *Daucus*, were analyzed for geosmin levels in this experiment. Seeds used came from six different companies (Table 1). Table beet [*B. vulgaris* ssp. *vulgaris* (garden beet group)], Swiss chard [*B. vulgaris* ssp. *vulgaris* (leaf beet group)], and mangel [*B. vulgaris* ssp. *vulgaris* (fodder beet group)] varieties were used as known geosmin producers, whereas carrot does not produce measurable geosmin and was used as an internal control.

Field Design. The field experiment was conducted at the Arlington Research Farm (University of Wisconsin Arlington Research Farm, Arlington, WI, USA) using a randomized complete block design with three replications. Cultivar was considered the experimental unit. Plant material was direct seeded into 3.7 m long rows spaced 46 cm apart using a cone seeder. This experiment was conducted over two years. The 2011 planting occurred on June 13 and the 2012 planting on June 4. Pre-emergent herbicides cycloate (Ro-Neet; Stauffer Chemical Co.) and chloridazon (Pyramin; Nufarm Australia) were applied to the field at recommended rates before planting. Routine maintenance including hand weeding was conducted. Irrigation was used in 2012 due to drought conditions at the beginning of the season. Experimental plant material was bordered by guard rows of the table beet cultivar Merlin.

Plants were harvested after 72 days on August 23, 2011, and August 14, 2012. Roots from all cultivars were harvested. Ten plants per cultivar per replication were harvested. Roots were bulked. Roots were stored at 5 °C until sampled. Root cores were sampled using a core-borer to remove a cylinder 1 cm in diameter and 2 cm deep. Root samples included skin tissue and were removed from the thickest part of the root. Cylinders were frozen at −20 °C.

Ten roots from a guard row were harvested to conduct an experiment measuring the root-to-root geosmin variation. In 2011, roots were stored at 3−5 °C for 3 weeks until sampled, ground, and frozen at −20 °C, whereas in 2012, roots were at 5 °C for 1 day before they were sampled and frozen at −20 °C until ground and frozen. Samples consisted of half of each root.

Greenhouse Design. The greenhouse experiment was conducted at King Hall Greenhouse, University of Wisconsin, Madison, WI, USA. A randomized complete block design was used and consisted of three replications per treatment, randomized by cultivar. Each cultivar was assigned to a row of six pots, 13.97 cm diameter × 15.24 cm tall. Field soil was removed from the same field where the field experiment was conducted and transported to Madison. Field soil was divided into two treatments, autoclaved and nonautoclaved. Autoclaved soil was autoclaved for 3 h at 103.42 kPa and 220−225 °C. The 2011 planting date occurred on June 2, 2011, and the 2012 planting date on May 31, 2012. Multiple seeds were sown per pot and thinned to the most vigorous seedling per pot. All cultivars were planted in both treatments. Plants were watered daily.

Harvest occurred on August 11, 2011, after 71 days and on August 10, 2012, after 72 days. Roots (minus leaves) were cleaned of all field soil and bulked. Because roots were generally much smaller sized than field-grown roots, whole beets were bulked rather than removing a cylinder of tissue. Samples were kept on ice until frozen at −20 °C.

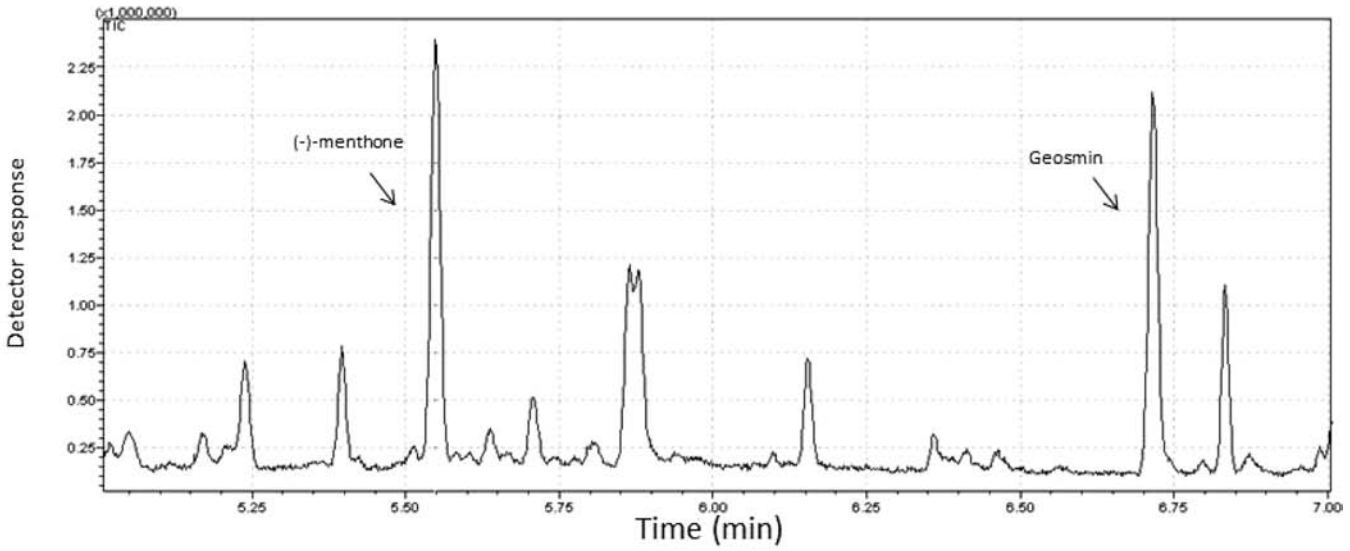

Figure 1. Sample chromatogram of geosmin and internal standard (−)-menthone from table beet. (−)-Geosmin was detected using headspace solid-phase microextraction and gas chromatography−mass spectrometry. Geosmin peak retention time, 6.670 min; (−)-menthone peak retention time, 5.596 min.

Sample Preparation. Samples were removed and thawed at room temperature for 5−10 min. All cores, roots, and leaves were cut into small chunks and blended at a 1:1 ratio of fresh weight grams of tissue/grams of Milli-Q water in an industrial blender for 2 min. All data were expressed on a fresh weight basis. All water used was stored in glass to avoid phthalate contamination. Homogenate was frozen at −20 °C until analyzed.

HSPME Preparation. Preparation occurred similarly to the methods of Lu et al.[15] Frozen samples were thawed in a 28 °C water bath for no longer than 10 min. Samples were stirred, and a 5 g sample was put into a sample glass vial containing 1 g of NaCl. Vials were capped immediately with screwcaps containing a PTFE/silicone septum. Water standards were prepared using 5 g of Milli-Q water. A (−)-menthone internal standard was added to water standards and samples at a concentration of 5.64 μg kg^{-1} (Sigma-Aldrich). Geosmin standard addition to water blanks occurred at concentrations of 21.6, 10, and 5 μg geosmin (kg water)$^{-1}$. Relative recovery rates were assessed using ground beet root samples of cultivar 'Merlin' and additions of geosmin standard at 5, 10, 15, and 21.6 μg geosmin (kg root tissue)$^{-1}$ sample concentrations. Recovery rates were based on the calculation of Lu et al.:[15]

$$\text{relative recovery} = \frac{(\mu\text{g geosmin total} - \mu\text{g geosmin originally in beet})}{\mu\text{g geosmin spiked}} \times 100\%$$

HSPME and GC-MS Analyses. Samples were loaded onto a Shimadzu GC-MS model QP2010SE with an AOC-5000 Shimadzu autoinjector (Shimadzu, Kyoto, Japan). Samples were incubated and agitated for 3 min at 60 °C and 500 rpm, followed by extraction for 10 min in the same conditions using PDMS/DVB fibers conditioned according to manufacturer specifications (Supelco: Sigma-Aldrich, St. Louis, MO, USA). The fiber was thermally desorbed into the GC system at 250 °C for 1 min. Injection mode was split, and a splitless liner was used. The split ratio was 10. The column used was a 30 m SHRXI-SMS with 0.25 mm i.d. and 0.25 mm df (Shimadzu). The temperature program was as follows: 40 °C for 1 min, increase at 35 °C min^{-1} to 300 °C, and hold for 2 min. Total program time was 10.43 min. Between samples, fibers were conditioned at 250 °C for 10 min.

Statistical Analysis. Data were log transformed to meet assumptions of constant variance and were analyzed as a mixed-effects ANOVA using the PROC MIXED procedure of SAS (SAS Institute Inc., Cary, NC, USA). Log-transformed data were used for all statistical analyses. Fixed effects included growth environment (referred to as "environment" in previous sections), cultivar, and the interaction of cultivar and environment. Replicate and replicate within year were considered random effects. Individual cultivars or treatments were compared following significant F tests using pairwise t tests. Values of $P \leq 0.05$ were considered significant.

RESULTS AND DISCUSSION

Relative Recovery. Relative recovery experiments were conducted each year field and greenhouse samples were evaluated to quantitate extraction efficiency. The relative recovery rates averaged over all spiked geosmin levels were 66.86% in 2011 and 47.81% in 2012. Values for field- and greenhouse-grown samples were corrected using each respective year's average relative recovery rate under the assumption that a complete extraction would produce a 100% relative recovery rate.

Root Geosmin Content of Cultivars Grown in Three Environments. *Year Effects.* Table beet and related subspecies cultivar roots were analyzed for geosmin levels using GC-MS over two years (Figure 1). We observed significant effects of both cultivar and environment as well as for the interaction of cultivar × environment (Table 2). A negligible amount of variance was estimated for the effect of year and a very small amount for replicate within year. Data were therefore averaged over year and replicate.

Table 2. Analysis of Variance for Geosmin Levels (Micrograms of Geosmin per Kilogram of Root Tissue) in Table Beet and Related Subspecies Cultivars

source of variation	df numerator	df denominator	P	significance[a]
environment	2	150	0.0141	*
cultivar	10	150	<0.0001	***
cultivar × environment	20	150	<0.0001	***

[a]*, ***, significant at $P \leq 0.05$ or 0.001, respectively.

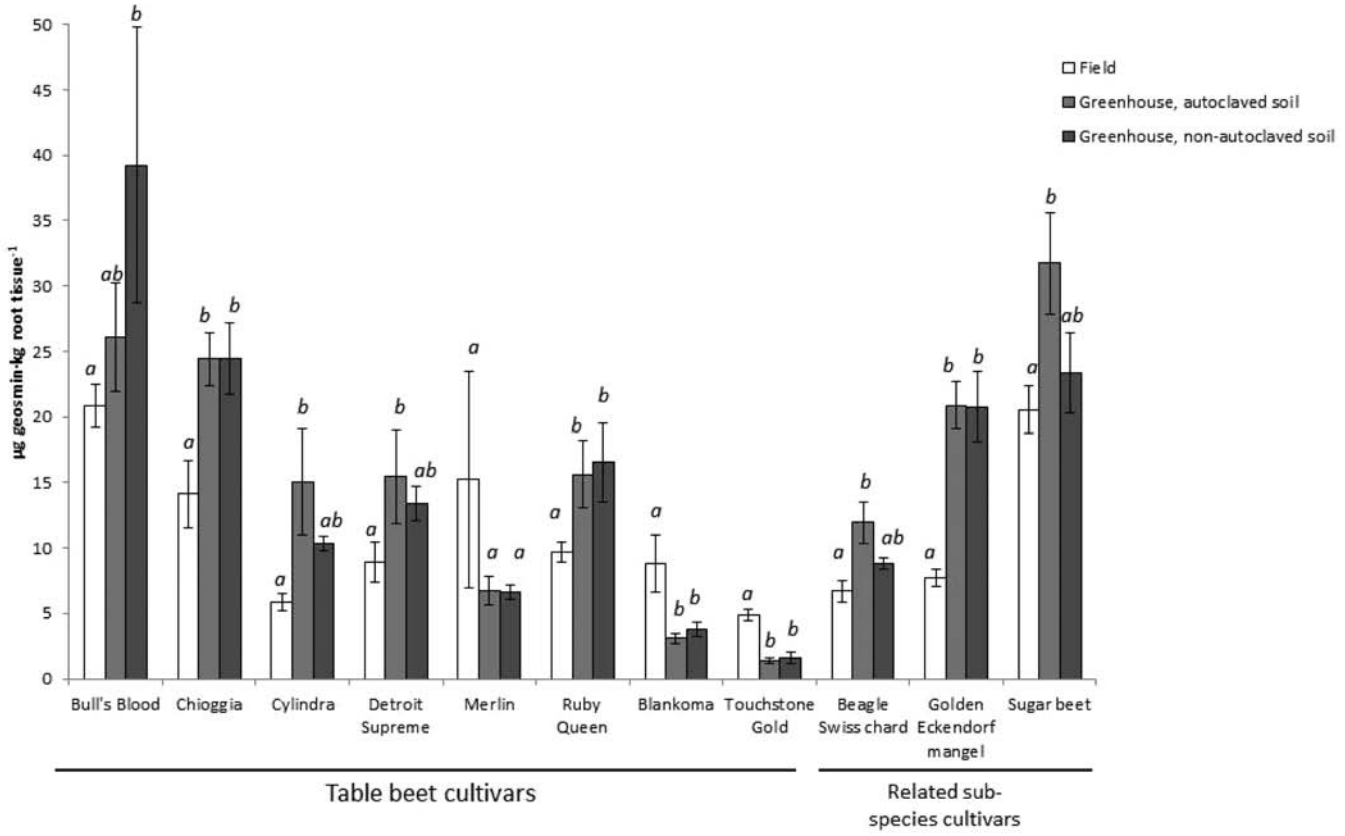

Figure 2. Mean geosmin concentrations of table beet and related subspecies cultivars. Cultivars were grown in field soil (Arlington, WI, USA), in the greenhouse with autoclaved soil, and in the greenhouse with nonautoclaved soil (Madison, WI, USA), 2011−2012. Pairwise comparisons within cultivar use log-transformed data. Means with different letters show significant differences at $P \leq 0.05$.

The lack of variation from year to year raises the possibility that geosmin production in table beet and related subspecies cultivars is endogenously produced. This suggests that a cultivar's geosmin content is a highly characteristic trait of each individual cultivar that may be under genetic control. This is interesting given that field environmental conditions varied from 2011 to 2012. In 2012, average temperatures for June and July were, on average, 2.3 and 1.3 °C higher, respectively, and the area experienced a severe drought. However, the limited irrigation the field environment received in 2012 and the drought tolerance of beet may have helped mitigate the effects of drought and higher temperatures.

Environmental Effects. Mean geosmin concentrations of each cultivar grown in each growth environment are presented in Figure 2. Geosmin concentrations in the field ranged from 4.84 to 20.82 μg geosmin (kg root tissue)$^{-1}$, whereas those in the greenhouse ranged from 1.36 to 31.74 μg geosmin (kg root tissue)$^{-1}$ and from 1.59 to 39.24 μg geosmin (kg root tissue)$^{-1}$ for autoclaved and nonautoclaved soil environments, respectively.

The significant interaction of cultivar × environment was not due to large changes in cultivar rank across environments. Because of this highly significant interaction, additional comparisons between growth environments were performed within a single cultivar (Figure 2). No cultivars exhibited a significant difference between roots grown in the greenhouse in autoclaved soil and those grown in nonautoclaved soil. This is of interest because of the potential for microorganisms to contribute to root geosmin content.[3] A significantly higher geosmin content of roots grown in nonautoclaved soil where the field microbial community has not been subjected to autoclaving might point to a significant association between roots and geosmin-producing microorganisms, such as *Streptomyces* soil bacteria. A consistent pattern of higher geosmin levels was not observed across cultivars tested in nonautoclaved soil, although some cultivars did have higher levels in this environment compared to those grown in autoclaved soil. Geosmin levels from greenhouse-grown plants were in some cases higher than those in field-grown plants. One of the possible explanations for this finding is the smaller size of greenhouse-grown roots, which would possess a higher ratio of root surface tissue to root interior tissue and consequently could be higher in geosmin than an identical genotype with a larger root volume.

Our results are more consistent with the scenario whereby table beet and related subspecies cultivars produce geosmin endogenously. In this instance, a significant difference between roots grown in autoclaved and nonautoclaved soil would not be expected because the microbial community differences would not affect endogenous production. The microbial community was not identified or measured in this study. Assessing the extent that autoclaving affects the soil microbial community over the duration of the growth period could help identify if geosmin-producing soil bacteria and fungi are present. Finding a lack of geosmin-producing microorganisms and no significant difference in geosmin content between roots grown in that environment and nonautoclaved soil with native microorganisms would strengthen the conclusion of endogenous geosmin production.

dx.doi.org/10.1021/jf4047336 | J. Agric. Food Chem. 2014, 62, 2031−2036

Another source of geosmin-producing microorganisms is endophytic bacteria, such as the actinomycetes, which have been observed in beet.[20] However, the geosmin contributions of these bacteria would have to be very substantial to account for the high geosmin content of certain cultivars.

Cultivar Effects. Despite the highly significant interaction of cultivar × environment, some general patterns exist on the cultivar level. Yellow table beet cultivar 'Touchstone Gold' produced the least amount of geosmin in any growth environment. The red table beet 'Bull's Blood' grown in nonautoclaved soil in the greenhouse produced the highest geosmin level measured across all environments, 39.24 μg geosmin (kg root tissue)$^{-1}$. 'Bull's Blood', 'Chioggia' (a table beet containing concentric circles of red pigment), and sugar beet contained the three highest levels of geosmin across all three environments as compared to the remaining cultivars. Besides 'Touchstone Gold', pigmentless table beet 'Blankoma' produced lesser amounts of geosmin in both greenhouse growth environments. In the field, however, 'Blankoma' contained the fifth lowest level. Carrot, used as a vegetable control, had no detectable geosmin for roots grown in any environment.

Mean geosmin concentrations are comparable to those obtained by Lu et al.[15] Cultivar 'Chioggia' has a reported value of 26.7 μg geosmin (kg root tissue)$^{-1}$, which is 12.6 μg geosmin (kg root tissue^{-1}) higher from our measured value of field-grown 'Chioggia', but only 2.3 μg geosmin (kg root tissue)$^{-1}$ higher than greenhouse-grown roots (either soil environment). This similarity is especially interesting given that there was no difference between years in our experiment. It again suggests that on a cultivar level, geosmin production is characteristic and under genetic control. Tyler et al. found levels ranging from 0.6 to 3.7 μg geosmin (kg root tissue)$^{-1}$ for various field-grown beet and related subspecies cultivars, which are considerably lower than our results.[17] However, a different extraction method was used. In their study, Swiss chard had the highest geosmin content, followed by sugar beet, with the lowest measured being beet cultivar 'Nero'. We also found sugar beet to have a high-geosmin-producing cultivar relative to all cultivars studied.

It is interesting that two table beet cultivars, 'Touchstone Gold' and 'Blankoma', that do not contain red pigment have lower geosmin levels, whereas two of the higher producing cultivars ('Bull's Blood' and 'Chioggia') both contain red pigment. Perhaps when these cultivars were developed, plant breeders associated the traditional red pigmentation of table beet cultivars with its traditional earthy flavors. When lighter colored table beets were developed, they may have been selected for different, and perhaps milder, flavors. Regardless of the cause, this information may be of interest to consumers looking for greater or lesser flavor characteristics in this vegetable. Sugar beet produces higher levels of geosmin as well but has not been selected specifically for fresh market palatability, nor has the mangel cultivar 'Golden Eckendorf', which contains midrange geosmin levels. Other red table beets all produce more geosmin than the yellow or white table beet (with the exception of 'Blankoma' grown in the field environment). Beagle Swiss chard produces more than white- or yellow-rooted cultivars tested but is a leaf crop, so root flavor is not an important trait.

Breeding and Interroot Variation. On a cultivar level, geosmin content variation has been identified that could be exploited in breeding for a higher or lower geosmin-containing table beet. Once we established cultivar differences, we began to question what would be the most effective experimental unit on which to base breeding decisions: a cultivar mean or individual root value? If a root with higher geosmin levels was selected and intermated with roots that also contained higher geosmin levels, the mean could increase at a faster rate from generation to generation. If assessing geosmin levels on a cultivar level, the geosmin content for an individual root entering the breeding population is unknown. For example, this could lead to lower geosmin individuals within a higher geosmin-containing cultivar being intermated, which would presumably slow movement of the mean geosmin content if breeding for increased geosmin. If significant interroot variation for geosmin concentration exists in table beet, selecting roots to intermate in a population on a cultivar basis may be less efficient for moving a quantitative trait mean.

To address some of these questions, the magnitude of interroot variation was assessed for a single F1 cultivar, 'Merlin', grown in 2011 and 2102. Two different methods were used to examine geosmin levels in this assessment, and 10 individual roots were examined from this cultivar in each of the two years. Our data revealed that a small but significant amount of variation existed between individual roots from the cultivar 'Merlin' in 2011 and a larger and significant amount of variation existed among individual roots from this cultivar in 2012 (data not shown). More substantial investigation of this point may be useful in establishing a breeding program in which geosmin concentration is a target trait. Although unknown if interroot variation exists within all cultivars, the possibility that interroot variation exists has been demonstrated. When cultivars or lines are evaluted for geosmin content, a decision must be made whether or not it is feasible to select parents on an individual root basis. A trade-off may exist between workload/resource availability and the rate the mean geosmin content of a population is moved up or down.

Geosmin production may be largely endogenous and cultivar specific but not entirely without influence from the growing environment. Further indication of the genetic control of geosmin production was suggested by the lack of significant difference in geosmin levels between roots grown in autoclaved and nonautoclaved field soils in the greenhouse and in the lack of variation between years. For breeding purposes, it is probably most useful to evaluate potential parents on the basis of evaluations of field-grown beets. Beets are grown for market in this way, and despite a significant cultivar × environment interaction, cultivar ranks did not vary widely across growth environments. However, an assessment of feasibility should be performed to determine if selection of breeding parents on an individual root basis is possible or if cultivar means will suffice. Selection of cultivars to assemble a breeding population to begin breeding for beets with higher and lower geosmin levels would be an area for further research. As selection for divergence in geosmin level occurs, perhaps a genetic or pleiotropic relationship will be reveled between genes influencing geosmin production and root pigmentation.

for the conditioning of the column prior to the injection, and (c) a gradient of falling concentrations of acetate and NaOH.

The novel HPAEC-PAD method was to be validated in terms of specificity, repeatability, range, peak resolution, linearity, and the limits of detection (LOD), identification (LOI) and quantification (LOQ). Its accuracy was to be evaluated by comparison with the conventional methods[17] of pectin analysis based on gas chromatography, titrimetry, and colorimetry.

2. MATERIALS AND METHODS

2.1. Chemicals and Sample Material Used. The sodium hydroxide solution (50% w/w; Baker Analyzed reagent) for the eluents was from J.T. Baker (Avantor Performance Materials, Griesheim, Germany). The reference standards, comprising the neutral sugars L-(+)-arabinose (Ara), L-(−)-fucose (Fuc), D-(+)-galactose (Gal), D-(+)-mannose (Man), L-(+)-rhamnose (Rha), and D-(+)-xylose (Xyl), and the uronic acids D-(+)-galacturonic acid (GalUA) and D-(+)-glucuronic acid (GlcUA), were purchased from Sigma-Aldrich (Steinheim, Germany). Unstandardized citrus and apple pectins were made available by Herbstreith & Fox KG (Neuenbürg, Germany). Bovine serum albumin was from Serva Electrophoresis (Heidelberg, Germany), *m*-hydroxydiphenyl (MHDP) from Eastman Kodak (Rochester, NY, USA). All other reagents or solvents (analytical or HPLC grade) were obtained from VWR International (Darmstadt, Germany) or Sigma-Aldrich (Steinheim, Germany).

Hydrochloric acid (HCl) was used to prepare acidic methanol.[18] While ∼150 mL HCl (37% w/w) was heated in a round-bottom flask on a low heat, the gas was slowly flushed for ∼20 min through 100 mL of methanol in a gas-washing bottle, using an uncooled distillation apparatus with gas inlet tube. Subsequently, the molarity of the acidic methanol was determined by titration of an aliquot with 0.25 N NaOH to pH 7.0 (Titrino 716 DMS; Metrohm, Filderstadt, Germany) and then adjusted to 2.0 ± 0.1 M HCl.

2.2. HPAEC-PAD Analyses. The developed HPAEC-PAD method comprised two variants (M_{Dx1}, M_{Dx2}) differing in both the amount of hydrolyzed pectin (section 2.2.1) and the injection volume (section 2.2.2). The first variant (M_{Dx1}) was based on an initial sample weight of 20 μg for hydrolysis at sample/acid ratios of 40 μg mL^{-1}, as recommended by De Ruiter et al.[19] A 5-fold initial amount (100 μg) was used in the second variant M_{Dx2}, where the sample/acid ratios were increased 2.5-fold to ensure an adequate time for the subsequent removal of the acidic solvents by evaporation. In M_{Dx2}, a 5-fold amount of dried hydrolysate was dissolved in a double amount of water to inject only two-fifths (10 μL) of the volume applied in M_{Dx1} (25 μL). Thus, the theoretical absolute amounts of hydrolyzed sample that were injected in both variants were identical.

2.2.1. Hydrolysis of Pectins. According to De Ruiter et al.,[19] the neutral sugar and uronic acid residues were released by methanolysis and subsequent hydrolysis with trifluoroacetic acid (TFA). Each run comprised 6 pectin samples and 3 recovery standards (cf. section 2.2.2) that were treated in parallel. Approximately 20 mg of pectin was exactly weighed into a 20 mL volumetric flask and dissolved in 10 mL of ultrapure water overnight under automatic shaking. After adjusting the volumes, the pectin solution (method variant M_{Dx1}, 20 μL; M_{Dx2}, 100 μL) and the recovery standard (100 μL) were transferred into separate Pyrex tubes (16 × 100 mm). The screw-cap tubes were placed in a Pierce Reacti Therm heating module (30 °C) (Thermo Fisher Scientific, Waltham, MA, USA). The solutions were dried by an airstream that was provided by a Reacti Vap evaporation unit (Thermo Fisher Scientific) comprising nine single-use needles with Luer-Lock hub (⌀ 0.6 × 80 mm; Stericon, B. Braun, Melsungen, Germany). After adding anhydrous 2 M HCl in methanol (M_{Dx1}, 0.5 mL; M_{Dx2}, 1 mL), the tubes were closed and placed on a vortex mixer for stirring and then into a Thermochem CH 2 C heating device (Liebisch, Bielefeld, Germany) for heating (80 °C, 18 h), followed by cooling (5 min) in an ice−water bath. To each tube was added 100 μL of 2-methylpropan-2-ol to improve coevaporation of HCl,[20] when the recooled samples were dried again at 30 °C (heating module) by an airstream. For acidic hydrolysis, 0.5 mL (M_{Dx1}) or 1 mL (M_{Dx2}) of 2 M TFA was added. The tubes were closed and placed into the heating device (121 °C) after stirring on the vortex mixer. After 60 min of heating, the tubes were recooled in the ice−water bath (10 min), and the hydrolyzed samples were dried at 30 °C (heating module) by an airstream. Subsequently, the dry residues were dissolved by adding 0.5 mL (M_{Dx1}) or 1 mL (M_{Dx2}) of ultrapure water into each screw-cap tube. By analogy, 1 mL of ultrapure water was used for the recovery standard that had undergone the hydrolysis procedure (RS_h). The solutions were thoroughly stirred on a vortex mixer and filtered into vials through polyamide membrane filters (0.45 μm).

2.2.2. HPAEC-PAD. An ICS 3000 Dionex System (Thermo Fisher Scientific) with an AS50 Dionex autosampler was used for HPAEC. A 3 × 30 mm AminoTrap column, a 3 × 30 mm CarboPac PA20 guard column, and a 3 × 150 mm CarboPac PA20 column (Thermo Fisher Scientific) were connected in series. For saccharide detection without postcolumn base addition, an ED pulsed-amperometric detector (Thermo Fisher Scientific) with a nondisposable gold working electrode and an Ag/AgCl reference electrode was used, applying the standard carbohydrate quadrupole−potential waveform (Chromeleon software version 6.80). Eluent *A* was ultrapure water (0.055 μS cm^{-1} at 25 °C). According to Garna et al.,[21] eluent *B* contained 170 mM sodium acetate (NaOAc) in 100 mM NaOH, while eluent *C* consisted of 500 mM NaOH. Eluent *B* was prepared by dissolving NaOAc in ultrapure water and subsequent filtration through a Whatman 0.2 μm nylon filter (⌀ 50 mm). The required volumes of ultrapure water and NaOAc solution, respectively, were degassed by flushing them with nitrogen before and during the addition of a 50% (w/w) solution of NaOH. All eluents were kept under nitrogen. After injection (M_{Dx1}, 25 μL; M_{Dx2}, 10 μL), the neutral sugars and the uronic acids were separated in a single run (28 °C), using the eluent gradient profile shown in Table 1 at a flow rate of 0.2 mL min^{-1}.

Table 1. Eluent Composition and Gradient Profile for the Simultaneous Quantitation of Neutral Sugars and Uronic Acids by HPAEC-PAD[a] (28 °C, 0.2 mL min^{-1}) without Postcolumn Base Addition on a CarboPac PA20 Column with Upstream AminoTrap and PA20 Guard Columns

[a]For pulsed amperometric detection (PAD), a nondisposable gold working electrode and the standard carbohydrate quadrupole−potential waveform (Chromeleon version 6.80) were applied. [b]Injection volume: 25 μL (method variant M_{Dx1}); 10 μL (method variant M_{Dx2}).

For each analyte, calibration lines through 6 standard concentrations and the origin were produced by simple linear regression. For method variant M_{Dx1}, the standard solutions covered a range of 1.7−128 μmol L^{-1} for GalUA and 0.28−30.3 μmol L^{-1} for the other

analytes. Standard solutions having the 2.5-fold concentrations were used for M_{Dx2}.

A mixed recovery standard (RS) containing the neutral sugars (100−123 μmol L^{-1}), GlcUA (92 μmol L^{-1}), and GalUA (202 μmol L^{-1}) was used to calculate the relative recovery factors (RRF) according to De Ruiter et al.[19] for each run of method variant M_{Dx1}. The RS used in M_{Dx2} contained the respective 2.5-fold concentrations. The RRF of each analyte was the ratio of the concentration $c(RS_h)$, which was found for the RS after the two-stage hydrolysis procedure according to the respective calibration line, to its initial concentration $c(RS_0)$: RRF = $c(RS_h)/c(RS_0)$. The analyte concentrations of the samples were corrected by multiplying them by the inverse mean RRF of the 3 recovery standards that had undergone the same hydrolysis run like the samples in question. Time-dependent changes in the detector response were minimized by consecutive injection series consisting of the 6 calibration standards, the water blank, 3 samples, the 3 RS_h, and 3 further samples. In this way, each of the pectins was hydrolyzed and analyzed 6 times. The analyte contents of the pectins (in g kg^{-1}) were calculated for the bound monomer units, using the molecular weights of the respective anhydro-monosaccharides. The summated contents of the GalUA and GlcUA anhydro-monomers were considered as the total anhydro-uronic acid content (AUA_{Dx1}, AUA_{Dx2}) of the pectin according to the HPAEC-PAD method variant used, while the sum of the other anhydro-monomer contents represented the total neutral anhydro-sugar content (ANS_{Dx1}, ANS_{Dx2}).

2.3. Validation Experiments. *2.3.1. Determination of the Peak Resolution.* The resolution ($R_{P1,P2}$; eq 1) between two adjacent peaks (P1, P2) was deduced from the retention times of the two analytes (RT_{P1}, RT_{P2}) and the baseline widths (W_{P1}, W_{P2}) resulting from the tangents of the inflection points of each peak[22] by means of the Chromeleon 6.80 software (Thermo Fisher Scientific).

$$R_{P1,P2} = 2(RT_{P2} - RT_{P1})/(W_{P2} + W_{P1}) \quad (1)$$

2.3.2. Evaluation of Repeatability, Range, and Linearity. For the retention times (RT) and the response factors (RF), the day-to-day repeatability was deduced from ten consecutive calibration series to evaluate the stabilities of the separation and the detection systems, respectively, for the method variant M_{Dx1}. These data were also used to determine the ranges and the linearity of M_{Dx1}. For this purpose, mixed standard solutions covering six concentration levels (cf. section 2.2.2) were injected within four days (60 injections). The RF, being the quotient of the response (peak area, nC min) and the respective standard concentration (μmol L^{-1}), was calculated as the mean of 60 single measurements. Linearity was evaluated according to Mandel's fitting test,[23] which involved the comparison of the variances for a linear and a quadratic calibration equation.

To study the precision of the method variants M_{Dx1} and M_{Dx2}, respectively, each of four pectin samples was hydrolyzed and analyzed by HPAEC-PAD (n = 6) based on 2−4 runs that were performed by the same person within 5 days, using the same equipment, chemicals, and standards.

2.3.3. Determination of the Limits of Detection, Identification, and Quantification. The LOD, LOI, and LOQ were identified according to the calibration method of DIN 32645,[24] involving ten consecutive calibration runs (method variant M_{Dx1}) and 7 concentration levels (0.43−17 μmol L^{-1} for GalUA, otherwise 0.06−3.78 μmol L^{-1}) near the bottom end of the ranges. As detailed by Hirsch et al.,[25] the LOD was calculated as the lowest analyte concentration producing the critical minimum response. The latter was deduced from the ordinate intercept of the regression line and the width of its one-sided prediction interval based on the quantile of the one-sided Student's t-distribution (P = 0.05; $f = n - 2$ degrees of freedom). As explained elsewhere,[25] multiplication of the LOD by the factor 2 yielded the LOI, while the LOQ was iteratively calculated for a relative uncertainty of 33.3%, using the standard deviation of the procedure of the regression line and the quantile of the two-sided Student's distribution (P = 0.05; $f = n - 2$).

2.3.4. Evaluation of Accuracy. Being defined as the closeness of the measured value to the true value,[26] the accuracy of the analytical procedure was directly indicated by the RRF of the recovery standards (cf. section 2.2.2). Additionally, significant differences ($P \leq 0.05$) between the carbohydrate contents that different methods yielded for the pectins were identified by multiple pairwise comparisons of means (Duncan's test) with SAS 9.1 (SAS Institute, Cary, NC, USA).

2.4. Reference Methods for the Evaluation of Accuracy. By analogy with the HPAEC-PAD analyses (cf. section 2.2.2), the contents of the neutral sugar and uronic acid residues of the pectins were always calculated for the anhydro-monomers.

The neutral sugars released by two-stage hydrolysis with sulfuric acid (H_2SO_4) were derivatized into the alditol acetates and quantified by gas chromatography with flame ionization detection (GC-FID) (method M_{GC}).[17] Each sample was prepared and injected twice (n = 4). The total contents of neutral anhydro-sugars (ANS_{GC}) were calculated by summing up the individual contents.

The total anhydro-uronic acid (AUA) contents of the pectins (AUA_{MHDP}) were quantified, using the *m*-hydroxydiphenyl assay (method M_{MHDP}) as described by Sirisakulwat et al.[17] Hydrolysis of the pectin with H_2SO_4 (72% w/w) at ambient temperature (60 min) was carried out in duplicate for this purpose. Colorimetric analysis in triplicate followed two times per pectin hydrolysate.

As detailed by Sirisakulwat et al.,[17] the AUA content was also determined titrimetrically (AUA_{titr}) according to the JECFA standard method (M_{titr}), which yielded the degree of esterification (DE) simultaneously.[27] One-fold purification of the pectin was followed by titration in duplicate.

Furthermore, the methyl and acetyl residues were released by saponification of the pectin in duplicate to quantify their contents by HPLC, separating each saponified sample twice (n = 4) on an Aminex HPX-87H column (Bio-Rad Laboratories, Hercules, CA, USA).[17] The degrees of methylation (DMe) and acetylation (DAc) were calculated as the molar ratios of methanol ($MeOH_{HPLC}$) and acetic acid (HAc_{HPLC}), respectively, to the AUA content, which resulted from the HPAEC-PAD method variant M_{Dx2} (AUA_{Dx2}).

2.5. Quantification of Non-Carbohydrate Compounds in Pectin. The total protein contents of the pectins were determined photometrically according to the Bradford assay protocol of Sigma Aldrich for 2 mL.[28] The Bradford reagent was prepared as described elsewhere[29] and used after stirring in an amber bottle overnight and subsequent filtration through a Macherey-Nagel MN 617 ¼ filter. The pectin (~75 mg) was dissolved in ultrapure water overnight under automatic shaking. After the volume had been made up to 20 mL, an aliquot (200−500 μL) was transferred into a cuvette. Ultrapure water was added to complete 1 mL before adding the Bradford reagent (1 mL) and mixing (vortex). After exactly 10 min, the absorbance at 595 nm was measured with a Cary 100 spectrometer (Varian, Mulgrave, VIC, Australia). Each pectin solution was analyzed 6 times versus the water blank. Calibration using bovine serum albumin covered a linear range of 4−10 mg L^{-1}.

The moisture and ash contents of the pectins were determined gravimetrically in duplicate, as described earlier.[17] Their starch contents were quantitated enzymatically in duplicate, using a commercial test kit (R-Biopharm, Darmstadt, Germany).

3. RESULTS AND DISCUSSION

3.1. Specificity and Stability of the Column Performance. All compounds were eluted within 46 min after injection (Figure 1). The total run time was 60 min, including regeneration of the column with 200 mM NaOH and equilibration at 3.4 mM NaOAc in 2 mM NaOH before each injection (Table 1). Directly after the injection, the NaOAc and NaOH concentrations used for equilibration were reduced to 1.7 and 1 mM, respectively, within 30 s by applying a declining linear gradient to induce the predominantly isocratic elution of the neutral sugars (**1**−**7**) at the latter eluent composition (Figure 1). The uronic acids (**8**−**9**) were eluted, after the eluent concentration had sharply been raised to 170 mM NaOAc in 100 mM NaOH[21] and then to 200 mM NaOH (Table 1).

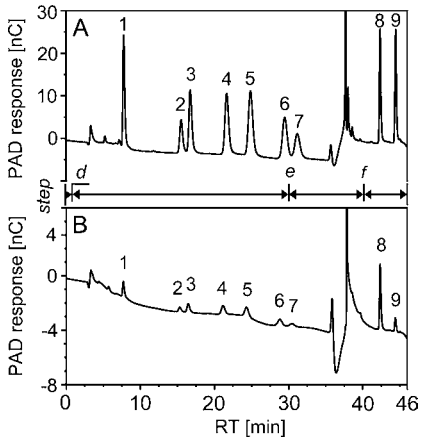

Figure 1. HPAEC-PAD chromatograms of (A) the recovery standard (RS_h) after methanolysis and TFA hydrolysis and (B) the calibration standard at the lowest concentration level (GalUA, 1.7 μmol L^{-1}; GlcUA, neutral sugars, 0.28−0.38 μmol L^{-1}) according to method variant M_{Dx1} (injection volume: 25 μL). For the gradient steps *d*−*f*, cf. Table 1. Peak assignment: **1**, fucose (Fuc); **2**, rhamnose (Rha); **3**, arabinose (Ara); **4**, galactose (Gal); **5**, glucose (Glc); **6**, xylose (Xyl); **7**, mannose (Man); **8**, galacturonic acid (GalUA); **9**, glucuronic acid (GlcUA).

As required for a highly specific method,[26] the gradient profile shown in Table 1 enabled baseline separation of Fuc, Gal, Glc, GalUA, and GlcUA over the calibrated concentration range (**1**, **4**−**5**, **8**−**9** in Figure 1). The resolutions of the adjacent peaks of Rha (**2**) and Ara (**3**) ranged from 1.45 ± 0.15 for the highest standard concentration (Rha, 27.4 μmol L^{-1}; Ara, 30.3 μmol L^{-1}) to 1.67 ± 0.06 for the lowest one (Figure 1B; Rha, Ara: 0.34−0.38 μmol L^{-1}). The peaks of Xyl (**6**) and Man (**7**) showed the poorest, but still satisfactory separation with resolutions between 1.21 ± 0.02 and 1.43 ± 0.05. The time-saving and peak-sharpening effect of the acetate loading before injection, as recommended by Davis[14] for the CarboPac PA1 column, was also observed for the present column generation (CarboPac PA20; data not shown). The peak-sharpening effect was especially of interest regarding the late-eluting neutral sugars Xyl and Man (**6**−**7**), which tended to peak broadening. For PAD detection without the need for postcolumn pH adjustment, the pH was kept above pH 11.5 at 28 °C for the elution of the neutral sugars at minimal alkaline pH and ionic strength. In this way, the response was sufficient, although the pH was sporadically below the recommended value.[30]

Subsequent elution of the uronic acids (**8**−**9**) required a sharp increase of the NaOAc and NaOH concentrations to levels of 170 and 100 mM, respectively, which were chosen according to Garna et al.[21] For this purpose, an appropriate step gradient was started (*e* in Table 1) parallel to the elution of Man (**7**) to bridge the void time, since the resulting acetate signal occurred at retention times of 36−39 min (phase *e*−*f* in Figure 1). However, the high acetate load had to be removed by strongly alkaline rinsing (200 mM NaOH) to ensure proper, reproducible, and time-saving equilibration of the column at a lower acetate concentration before the next injection.

The gradient profile in Table 1 resulted from the optimization of column temperature and acetate loading regarding maximal resolution for each of the critical sugar pairs **2**−**3** and **6**−**7**. Reduction of the column temperature increased the retention times of the neutral sugars and improved the separation of Xyl and Man (**6**−**7**), but the resolution of Rha and Ara (**2**−**3**) got worse. Equilibration (phase *b*−*c* in Table 1) at a higher acetate load and for a longer time, respectively, had the opposite effects. Exemplarily, Figure S1 of the Supporting Information shows the separation of a mixed standard solution for both the gradient profile in Table 1 at 28 °C (chromatogram A) and a modified one at only 16 °C, but with a longer equilibration phase at the 3-fold concentrations of NaOAc and NaOH (chromatogram B). These modifications increased the intervals between the elution of the individual neutral sugars, but induced peak broadening. Consistently, the resolution of Rha (**2**) and Ara (**3**) was higher for chromatogram B (1.88 ± 0.03; n = 3) than for chromatogram A (1.67 ± 0.04, n = 3). Peak overlapping of Xyl (**6**) and Man (**7**) was less pronounced, but the reduced response and peak broadening at the lower column temperature caused a poorer resolution of **6** and **7** (1.29 ± 0.04) compared to the optimized separation conditions (1.41 ± 0.03). Consequently, lower column temperatures may be appropriate for systems that include postcolumn base addition to increase the otherwise lower detector response. The detector sensitivity provided by the brand-new nondisposable electrode (chromatogram C in Figure S1 in the Supporting Information) was not fully restored by manual polishing of this electrode for the first time (chromatogram B), but the latter level was recovered by further manual polishing procedures. According to Schädel et al.,[7] 20 °C was optimal for separating Rha from Ara and Xyl from Man on the CarboPac PA20 column by isocratic elution with water and postcolumn base addition. Also higher temperatures of 40−50 °C were reported to improve the separation of Xyl and Man on the CarboPac 20 column, since an increase in temperature had a stronger retarding effect on Man than on Xyl.[31]

Additional involvement of an AminoTrap column was recommended for protein-rich glycoproteins.[32] However, this precolumn was reported to affect the separation of Rha from Ara and to cause a slight loss in sensitivity.[33] Although interferences of free amino acids may be marginal in view of the low protein contents of citrus (CP1, CP2) and apple (AP1, AP2) pectins (cf. section 3.6), the AminoTrap column was included, since the protein contents of pectic polysaccharides may vary due to the presence of arabinogalactan proteins.[34] A protein content of 5.2 g hg^{-1} was described for sugar beet pectin.[35] Apart from an unknown peak (IP_2, Figure 2D), which was not completely baseline-separated from GlcUA (**9**), all unidentified impurities of hydrolyzed pectin solutions were eluted either prior to 7.6 min (IP_1, Figure 2A) or between 35 and 41.5 min (Figure 2) and were thus baseline-separated from the analytes. Elution of the latter impurities occurred, after the NaOAc and NaOH concentrations had been raised (Table 1).

The separating performance of the column proved to be stable. Irrespective of the standard concentration, the retention times were perfectly repeatable (RT, Table 2), with the relative standard deviations (RSD) being <1%. This was in line with an earlier study[32] comprising 220 consecutive injections of a mixture of six monosaccharides on a CarboPac PA20 column.

Unlike the retention times, the response factors (RF, Table 2) varied more clearly (n = 60), especially those for Glc, Fuc, and Man (5% < RSD < 10%). However, the RSD of the RF for Rha, Ara, Gal, Xyl, GalUA, and GlcUA were below 5% (Table 2). According to the RF−concentration plot of each analyte (not shown), the RF only marginally declined with increasing concentration in the calibration range (by −0.00007 and −0.0046 nC min μmol^{-2} L^2 on average for GalUA and Glc, respectively). However, since incomplete separation of Man from

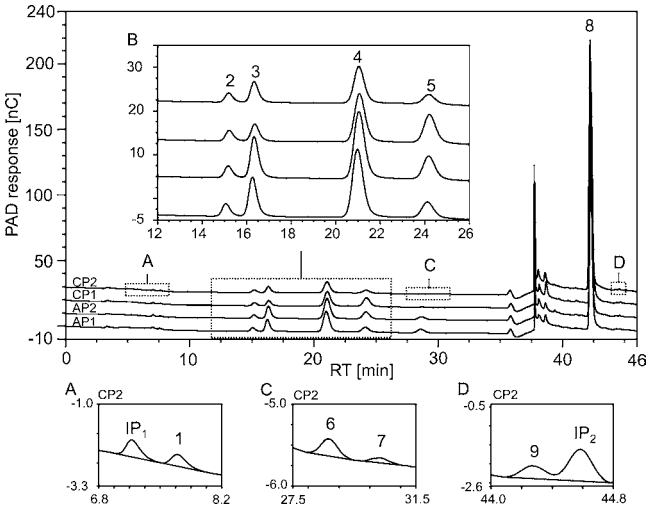

Figure 2. HPAEC-PAD chromatograms obtained for hydrolyzed apple (AP1, AP2) and citrus pectins (CP1, CP2), using method variant M_{Dx2}. For the peak assignment, cf. Figure 1. IP_1, IP_2, impurity peaks.

Xyl was associated with a slightly lower RF at low Man concentrations, the average concentration dependence of the RF was 0.0048 nC min μmol^{-2} L^2 for Man. Degradation of the sugars and changes in the detector response stability may influence the RF repeatability as well. Besides, the response factors of 8 calibration standard solutions, which were stored in the autosampler at 20 °C to compare the RF of each before and after 228 injections of samples, decreased by 1.2 ± 3.6% (GalUA) and 14.7 ± 4.3% (Man) on average within this period. Hence, unknown instabilities of the analytes and the detector response, respectively, were compensated by consecutive injection of hydrolyzed samples and recovery standards (RS_h) of the same hydrolysis series.

3.2. Limits, Range, and Linearity of the Analytical Procedure. As deduced from regression lines for a standard dilution series to infinitesimal levels (Figure S2 of the Supporting Information) according to DIN 32645,[24] the LOD ranged at 179 nmol L^{-1} for GalUA and 30−81 nmol L^{-1} for the other analytes (Table 2). This corresponded to detector loads of 0.8−4.5 pmol. The mixed standard solution representing the bottom end of this series yielded peaks being ∼32 and 7−32 times above the noise level for GalUA (0.43 μmol L^{-1}) and the other analytes (0.06−0.08 μmol L^{-1}), respectively. The RSD of the concentrations that were analytically determined for this solution (n = 10) were 2.5−15.5%, except for glucose (35.8%). The LOQ suggested by the regression approach was ∼3.8 times higher than the LOD and was thus 675 nmol L^{-1} for GalUA and 114−304 nmol L^{-1} for the other analytes (Tables 2), consistent with detector loads of 2.8−16.9 pmol. The recovery rates of the standard levels next to LOQ were 95% for GalUA (0.85 μmol L^{-1}) and 85−102% for the other analytes (0.14−0.38 μmol L^{-1}). For another method on a CarboPac PA20 without postcolumn base addition,[33] estimation according to DIN 32645[24] had indicated slightly lower levels for the LOD (13−54 nmol L^{-1}) and LOQ (35−131 nmol L^{-1}) based on injections of 50 μL, but separation of Rha from Ara and Xyl from Man by 2 mM NaOH without NaOAc had been incomplete.

For the calibration prior to HPAEC-PAD analyses, both linear and quadratic functions had been reported.[5,36] Consistently, large ranges exceeding 30 μmol L^{-1} rather

[a] Analytes **1**−**9** (cf. Figure 1): Fuc, fucose; Rha, rhamnose; Ara, arabinose; Gal, galactose; Man, mannose; Xyl, xylose; GalUA, galacturonic acid; GlcUA, glucuronic acid. RSD, relative standard deviation; M_{Dx1} and M_{Dx2}, method variants designed for injection volumes of 25 and 10 μL, respectively (cf. section 2.2). [b] RT mean ± standard deviation (SD), as deduced from 10 runs of a mixed calibration standard (neutral sugars, glucuronic acid: 11.4−13.7 μmol L^{-1}; galacturonic acid: 71.0 μmol L^{-1}) that was injected every ninth time within the same test series. [c] RF mean ± SD (n = 60), as defined by the average area/concentration ratio of 60 injections within 10 consecutive calibration series covering a range of 1.7−128 μmol L^{-1} for galacturonic acid and 0.28−30.3 μmol L^{-1} for the other analytes. [d] RRF mean ± SD (n = 24), with the RRF = $c(RS_h)/c(RS_0)$ being the concentration ratio of the recovery standard RS after ($c(RS_h)$) and before ($c(RS_0)$) the two-step hydrolysis procedure (cf. section 2.2.2). [e] LOD, LOI, and LOQ as estimated according to the calibration method of DIN 32645[24] (cf. section 2.3.3) on the basis of the means of ten 25 μL-injections per standard solution (m = 1) for 7 concentration levels (n = 7) in a range of 0.43−17 μmol L^{-1} for galacturonic acid and 0.06−3.78 μmol L^{-1} for each of the other analytes.

dx.doi.org/10.1021/jf404626d | J. Agric. Food Chem. 2014, 62, 2037−2048

suggested a second-order function than a linear calibration line for the neutral sugars to cover the whole range by a single equation for injection volumes of 25 μL (data not shown). However, the concentration dependence of GlcUA and GalUA was linear up to 57 and 319 μmol L^{-1}, respectively. Consequently, linearity was evaluated for ranges that were relevant for pectin analysis, but limited by the tolerable upper levels of neutral sugars. The calibration lines (Figure S3 of the Supporting Information) deduced from ten consecutive 6-point calibration series above the LOQ for ranges ≤128 μmol L^{-1} for GalUA and ≤30.3 μmol L^{-1} for Fuc, Rha, Ara, Gal, Glc, Xyl, and GlcUA, respectively, had correlation coefficients >0.999, which are generally considered acceptable.[26] According to Mandel's fitting test,[23] second-order equations did not yield significantly better fits for these analytes. The only exception was Man, for which the correlation coefficient of the calibration line was lower (0.9987), presumably due to the lower peak resolution occurring especially at higher concentrations.

3.3. Accuracy of the Analytical Procedure as Deduced from Recovery Standards. All kinds of hydrolytic processes prior to the glycosyl composition analyses of polysaccharides are known to be compromises between the complete cleavage of differently stable glycosidic linkages and minimal degradation of already released monomers that are also differently acid-resistant.[6,19,37] As suggested earlier,[19] inevitable losses caused by the two-stage hydrolysis were assessed by external recovery standards (RS, cf. section 2.2.2) yielding the relative recovery factors (RRF, Table 2). Methanolysis with HCl followed by TFA hydrolysis had been recommended especially for HPAEC-PAD.[19] Advantages are the evaporability of the acids after each step and the intermediary conversion of monomers into more acid-stable methyl glycosides, including methyl esterification of the carboxyl groups of uronic acid residues. The methyl glycosides are demethylated in the second step.[19,38] The use of TFA had been shown to damage neutral sugars and uronic acids to a smaller extent compared to hydrolysis with H_2SO_4 or HCl under otherwise identical conditions.[6] Due to the marked degradation of free uronic acids with irreproducible lactone formation,[39] hydrolysis with H_2SO_4, being common prior to GC-FID analyses of neutral sugars,[17,40] has been deemed inapplicable for quantitating both neutral and acidic carbohydrate monomers by HPAEC-PAD.[41,42] The selective removal of sulfate ions prior to HPAEC runs is known to be difficult in the presence of uronic acids,[19] but had turned out to be feasible by means of an additional guard column.[42] Methanolysis with subsequent TFA hydrolysis was thus preferred, considering two sample weights by adjusting the procedure to different sample/acid ratios (variants M_{Dx1} and M_{Dx2}).

The acid treatment of the recovery standards caused a loss of neutral sugars by 2−25%, both at the original (M_{Dx1}) and the 2.5-fold (M_{Dx2}) analyte/acid ratio. Consistent with the findings of De Ruiter et al.,[19] the RRF were maximal for Glc and Fuc, but the least stable neutral sugar was Xyl (Table 2). Monosaccharides had been reported to be stable in methanolic HCl (2 M, 85 °C, 24 h), besides a loss of hexuronic acids by 3%.[38] To minimize monosaccharide losses that are known to be large for rotary evaporation of methanolic HCl,[38] the small volumes used in M_{Dx1} (0.5 mL) and M_{Dx2} (1 mL), respectively, were evaporated by an airstream[18] within 20 min at 30 °C, while the removal of HCl was facilitated by adding 2-methylpropan-2-ol.[20]

In contrast, complete removal of aqueous 2 M TFA by an airstream required up to ∼2 h at 30 °C. This long time may lead to additional degradation of monomers, especially for uronic acids that are known to be more sensitive to TFA hydrolysis than hexoses.[19,36] Accordingly, poor but reproducible RRF for GlcUA and GalUA after the two-stage hydrolysis process (Table 2) were the result of losses by 27 and ≥48%, respectively. As expected,[19] corrections based on the RRF of recovery standards that had undergone the same hydrolysis run proved to be indispensable for the analysis of samples.

3.4. Precision and Accuracy as Deduced from Comparative Neutral Sugar Analyses. In addition to the accuracy revealed by the mean RRF of the recovery standards (Table 2, cf. section 3.3) for each HPAEC-PAD method variant (M_{Dx1}, M_{Dx2}), the accuracy of both procedures was also evaluated for 4 unstandardized pectins in terms of the closeness of the measured contents to those yielded by a well-established reference method to include the effectiveness of pectin hydrolysis. As regards the neutral sugar residues, the findings are summarized in Table 3. Determination of neutral sugars by GC-FID of their alditol acetates[43,44] and the trimethylsilyl ethers of methyl glycosides,[4] respectively, is still common due to high sensitivity and resolution, but derivatization[18,40] requires additional time and excludes direct evaluation of the hydrolysis process regarding its effectiveness. Due to less complex chromatograms,[18] GC-FID of alditol acetates has often been preferred and combined with various hydrolysis techniques.[6,19,45] Together with H_2SO_4 hydrolysis,[44,46] it thus served as the reference method M_{GC},[17] despite its inapplicability for uronic acids.

For each of the 4 pectins, the HPAEC-PAD chromatograms indicated good resolution for all neutral sugars (Figure 2). Also the minor compounds (**1**, **6**−**7**), mostly occurring at levels < LOQ (Fuc, Xyl, Man; Table 3), were detected without interference of background noise or impurities. Compared with M_{GC}, M_{Dx1} and M_{Dx2} always yielded the 1.2−1.4-fold Rha contents (Table 3). This significant difference was ascribed to the different hydrolysis modes prior to GC-FID (M_{GC}) and HPAEC-PAD (M_{Dx1}, M_{Dx2}).[6,19] Due to the greater resistance of glycosiduronic acid linkages, hydrolysis of the rhamnogalacturonan I backbone by the treatment with H_2SO_4 might have been incomplete,[6,19,37] while the released rhamnose is more sensitive to H_2SO_4 (M_{GC}) than to TFA (M_{Dx1}, M_{Dx2}).[6] By contrast, 1.02−1.23 times higher Gal contents were obtained by GC-FID (M_{GC}, Table 3). The Xyl and Glc contents were 1.04−2.0 times higher, when M_{Dx1} had been used instead of M_{Dx2}, which involved the 2.5-fold sample/acid ratio but the lower injection volume. As regards the total neutral sugar content (ANS, Table 3), M_{Dx1} yielded the maximal levels (103−112% relative to M_{GC}), but M_{Dx2} came quite close to the reference method (97−105%). Thus, M_{Dx1} resulted either in slight overestimation or in the improved release of neutral sugars due to the lower sample/acid ratio relative to M_{Dx2}. The latter case would consequently imply slight underestimation by the reference method M_{GC} due to incomplete hydrolysis and/or derivatization.

The RSD of mean contents >2 g kg^{-1} were usually ≤2.9% for the GC-FID analyses (n = 4) and ≤4.8% and ≤4.2% for the HPAEC-PAD method variants M_{Dx1} and M_{Dx2} (n = 6), respectively (Table 3). Contents between 0.1 and 2 g kg^{-1} might show greater variation (RSD ≤11.5%, ≤25.4%, and ≤12.6% for M_{GC}, M_{Dx1}, and M_{Dx2}, respectively). Especially the minor sugars, such as Fuc and Man, were determined more precisely by means of M_{Dx2} instead of M_{Dx1}.

3.5. Precision and Accuracy as Deduced from Comparative Uronic Acid Analyses. As expected, analysis

[c]n, number of replications: number of HPAEC injections (1 for each of n hydrolysis runs per pectin) for M_{Dx1} and M_{Dx2}, respectively; number of colorimetric measurements for M_{MHDP}; number of titrations per pectin after one-fold purification for M_{titr}. [d]The content of anhydro-galacturonic acid yielded by these methods actually represents the AUA content. [e]Below the limit of quantification.

of the pectins AP1−CP2 by HPAEC-PAD (M_{Dx1}, M_{Dx2}) confirmed GalUA to be the major carbohydrate residue (621−760 g kg^{-1}, Table 4). Due to the broad linear range for GalUA (Figure S3D in the Supporting Information), all analytes, including those having much lower contents (**1**−**7**, **9**), could be quantitated, using either M_{Dx1} or M_{Dx2} (Figure 2). Minor GlcUA contents < LOQ were also found (Table 4). GC-FID of the trimethylsilyl ethers of methyl glycosides also allows quantitation of both neutral and acidic carbohydrates in a single run.[4,18] Alternatively, the more common acetylation of the reduced monomers may be modified to include the methyl ester alditol acetates or *N*-propylaldonamide acetates of the uronic acids,[47,48] depending on the prior hydrolysis method. However, as regards pectins, the analysis of neutral sugar residues by GC-FID of the alditol acetates has usually been accompanied by separate spectrophotometric quantitation of the total uronic acid residues (AUA) with MHDP relative to GalUA standards,[43,44,46] preferably using an automated assay[49] to ensure fully standardized procedures.[50] HPAEC-PAD analyses of neutral sugars have also been combined with the MHDP assay for AUA.[10,51] Hence, the colorimetric method was included in the comparative pectin analyses as regards the uronic acid residues (M_{MHDP},[17] Table 4). However, since commercial pectins for food applications require a minimum galacturonic acid content of 65% (w/w) on a dried and ash-free basis according to the official titrimetric method of the JECFA (AP1−CP2: 81.2−90.9% w/w),[27] this industrially relevant method not needing pectin hydrolysis served as the reference method for the acidic carbohydrates, but the results were expressed relative to the unpurified pectin samples (M_{titr}, Table 4), by analogy with the other methods.[17] Being unspecific for the type of uronic acid, M_{MHDP} and M_{titr} actually yielded the total AUA contents, but in good approximation of the GalUA contents of pectins (Table 4).

Irrespective of the disparity in the specificity, the reference method M_{titr} and the HPAEC-PAD method variants resulted in almost identical total AUA contents (M_{Dx1}, 98−101%; M_{Dx2}, 95−102%; Table 4), with the differences being mostly insignificant ($P \leq 0.05$). This conformity suggested good accuracy of M_{Dx1} and M_{Dx2} and complete hydrolytic release of the uronic acids prior to HPAEC-PAD. In contrast, AUA contents being significantly higher by the factor 1.03−1.16 indicated overestimation by the method M_{MHDP} compared to M_{titr}, similarly to an earlier report.[17] Both HPAEC-PAD method variants yielded identical GalUA contents for each pectin, but the minor GlcUA contents that were found by means of M_{Dx1} always exceeded those from M_{Dx2} significantly ($P \leq 0.05$; Table 4), as analogously shown above (cf. section 3.4) for various neutral sugars (Table 3).

In conformity with the precision of the HPAEC-PAD results for most of the neutral sugars (cf. section 3.4), the RSD was ≤4.2% for the contents of GalUA and total AUA, respectively, according to M_{Dx1} or M_{Dx2} (n = 6; Table 4). The apparently lower RSD (≤2%) of AUA values resulting from M_{titr} only reflected the precision of the titration procedure (n = 2), without considering the repeatability of the obligatory acidic purification of the pectin prior to titration. Among the methods used to determine the uronic acids, M_{MHDP} comprising nonautomated serial analyses showed the poorest precision (RSD ≤ 6%, n = 12).

3.6. Accuracy of Carbohydrate Analyses as Deduced from Pectin Composition. Although the carbohydrate

[d]Ester residues (as determined by HPLC) relative to AUA_{Dx2}.

composition of the four pectins was largely confirmed by the different approaches used for the comparative pectin analyses (Tables 3 and 4), slight over- or underestimation due to known methodological flaws could not be excluded for individual methods (cf. sections 3.4 and 3.5). Therefore, the carbohydrate results from those methods that yielded the most consistent data were used to calculate the mass balances (TM_1, TM_2) of the pectins for two analytical basic approaches (Table 5). Accordingly, TM_1 was the total based on M_{Dx2}, while TM_2 rested upon M_{GC} and M_{titr}. For this purpose, the ester groups of the pectins and the non-pectin compounds of the four samples were also considered (Table 5). Ranges of 96−103% (w/w) for TM_1 and 98−103% (w/w) for TM_2 indicated successful identification and quantification of all major compounds, irrespective of using the HPAEC-PAD method variant M_{Dx2} or the gas chromatographic/titrimetric approach for carbohydrate analysis. Within these ranges, the mass balances for the two citrus pectins (CP1, CP2) were always higher than those for the apple pectins (AP1, AP2). Due to ∼7−16% lower GalUA levels (Table 4), the two apple pectins displayed lower contents of uronic acids (AUA, Table 5), but were ∼1.8 times richer in neutral sugars (ANS, Table 5), chiefly in Xyl besides Ara and others (Table 3). The notable Xyl and Ara portions of AP1 and AP2 can be ascribed to the presence of xylogalacturonans and arabinans in apple tissue.[34] From an analytical point of view, the relative differences between both sample classes were thus mainly related to the major and one of the minor constituents. However, apart from the Xyl contents of CP1 and CP2, the RSD covered similar ranges for Xyl, Ara, and GalUA (Tables 3 and 4).

Being a key property regarding the gelling behavior and applicability of pectin,[52] the titrimetrically determined degree of esterification (DE, Table 5) should actually be equivalent to the totaled molar percentages of methyl and acetyl ester groups relative to AUA. Unlike the DE values on basis of the titrimetric AUA levels, the chromatographically quantified degrees of methylation and acetylation were expressed relative to the AUA levels resulting from method variant M_{Dx2} (DMe and DAc, respectively; Table 5). Despite different methods, the sum of DMe and DAc came quite close (92−100%) to the DE. Altogether, the four pectins displayed the composition expected for highly esterified apple and citrus pectins,[52,53] as independently confirmed by applying various analytical methods. Hence, acceptable accuracy of the HPAEC-PAD method (M_{Dx2}) was proven.

3.7. Applicability of the Analytical Procedure. Irrespective of the initial sample weight, both HPAEC-PAD method variants could be used for pectin analysis. As deduced from the LOQ and the relative recovery factors (RRF, Table 2) for the variant M_{Dx1}, the sample material should contain GalUA and each of the other 8 analytes at theoretical levels of at least 5.9 and 0.6−1.2 g kg^{-1}, respectively, to yield analyte concentrations ≥LOQ after injection. If necessary, determination of minor compounds might be improved by adding an appropriate solvent volume to the dried hydrolysate in order to adjust the analyte concentrations for HPAEC-PAD. However, the analysis of more concentrated hydrolysates might be hindered by exceeding the upper calibration limits of the major compounds such as Gal (**4**, Figure 2). This may then necessitate two injections at different concentration levels. For this purpose, the variant M_{Dx2}, involving the 5-fold initial sample amount, was introduced to make sufficient amount of hydrolyzed material available for a broader range of optional hydrolysate dilution levels. Besides, M_{Dx2} proved superior to M_{Dx1} because of a more representative sample amount and the

lower RSD observed for the minor compounds in the comparative pectin analyses.

M_{Dx2} was thus recommended for the glycosyl composition analysis of pectins. In terms of accuracy, it proved to be equivalent to the gas chromatographic/titrimetric reference methods, but allowed quantitation of all neutral and acidic analytes in a single run without tedious derivatization. All major carbohydrate constituents ($\geq$1.5 g kg^{-1}) were quantifiable with good day-to-day repeatability (RSD $\leq$ 4.2%). However, hydrolytic losses of 5−27% depending on the analyte (48% for GalUA) required correction by considering concomitantly analyzed recovery standards. According to the effectiveness of methanolysis with subsequent TFA hydrolysis,[19] M_{Dx2} was deemed applicable to pectins, but also to other noncrystalline polysaccharides. By contrast, depolymerization of highly ordered or crystalline polysaccharides requires either treatment with sulfuric acid[4] or methanolysis after enzymatic prehydrolysis of cellulose.[54]

The reproducible and simultaneous separation of Xyl from Man and Rha from Ara proved to be the greatest asset of the suggested HPAEC-PAD method. Elution from the CarboPac PA20 column by means of the suggested NaOAc/NaOH gradient profile ensured their otherwise difficult separation almost to the baseline and detection without postcolumn pH adjustment. Besides the chosen temperature, two factors turned out to be crucial for this purpose: (1) equilibration of the column at an appropriate NaOAc/NaOH level prior to injection; (2) the subsequent short-term linear gradient to the low NaOAc/NaOH level needed for the elution of neutral monosaccharides.

In conclusion, reproducible and accurate determination of 9 neutral and acidic monosaccharides of pectin hydrolysates by HPAEC-PAD in a single run without postcolumn pH adjustment proved to be feasible due to the suggested NaOAc/NaOH gradient. As regards the neutral sugars, the method was deemed equivalent to GC-FID of alditol acetates in terms of repeatability and accuracy. Like HPAEC-PAD, hydrophilic interaction liquid chromatography with evaporative light scattering detection (HILIC-ELSD) also requires no derivatization. Coupled with mass spectrometry, HILIC-ELSD has chiefly been preferred for the analysis of acidic oligosaccharides, because saponification of the methyl esters and acetyl groups is avoided.[55] However, compared with published HILIC-ELSD methods for the analysis of monosaccharides,[56,57] the resolution of the validated HPAEC-PAD method was clearly superior.

dilution of phosphine in nitrogen (74.1 mL/m^3, corresponding to 102.97 μg/L) was used as reference gas (Linde, Unterschleissheim, Germany). Its shelf life is 1 year as stated by the provider. *Caution:* PH_3 is toxic and its gas preparation has to be handled with care and appropriate equipment in a fume hood.

Sample Preparation. Samples with incurred residues were obtained from different supermarkets and companies. They were raw and untreated, except of storage, milling, filling. Samples (about 250 g) were ground using standard laboratory mills, for example, a Grindomix (Retsch, Basel, Switzerland), and homogenized for 1 min using a Turbula-mixer (Willy A. Bachofen AG Maschinenfabrik, Muttenz, Switzerland). Twenty milliliter headspace vials were used for calibration and extraction of samples (BGB Analytik, Böckten, Switzerland). One gram of sample (standard amount) was weighed as such or ground into a headspace vial, and 5% sulfuric acid was added to reach the same level as in the calibration vials. Samples were analyzed in duplicates, and per vial only one injection was made. Powdery samples have to be briefly mixed with a plastic stirrer to avoid enclosure of bubbles and to facilitate mixing. The vials were immediately closed (caps with Teflon septum, Wicom Int., Maienfeld, Switzerland) and vigorously shaken by hand for 5 s to achieve good mixing and wetting before incubation in a heated agitator. If samples foam, 3−4 drops of silicon oil (Merck) can be added.

Calibration. Reference gas was filled into a gastight bag with a septum (Tedlar gas sampling bag, SKC, Dorset, UK). For calibration, appropriate aliquots were taken through this septum using gastight syringes (Hamilton, Bonaduz, Switzerland) and directly added to the headspace of the closed vials containing 15 mL of 5% sulfuric acid. Afterward, the vials were immediately shaken by hand. For screening purposes an external calibration of 0.1, 0.3, 0.5, and 1.0 μg/kg may be used whereby 1, 3, 5, and 10 μL of reference gas are added (on the basis of 1 g of sample). Quantitation is done by standard addition to compensate for the different partitioning of PH_3 over the solvent if sample matrix is present (see below). Thereto, the aliquots of reference gas were added to the headspace of the closed vials containing sample and 5% sulfuric acid prior to incubation. Additions should be approximately 50, 100, and 150−200% of the signal from the unspiked sample, which may be analyzed in duplicate. The content of phosphine is calculated via the regression equation, and the coefficient of determination (R^2) must be ≥0.95. This criterion is somewhat loose but is a compromise between practical feasibility and accuracy and reflects the substantial variation of this analysis (see also Interlaboratory Comparisons).

Instrumentation. Partitioning of phosphine was carried out under acidic conditions with heating and shaking to reach a stable equilibrium. Headspace sampling was followed by gas chromatography (GC) with either pulsed flame photometric detection (PFPD) or MS detection. Incubation of all vials (samples and calibration) was done using an MPS2-Sampler (Gerstel, Sursee, Switzerland) at the following conditions: heating at 65 °C for 20 min with shaking in intervals, 60 s at 750 rpm followed by 90 s without shaking. After incubation, 1000 μL of headspace was injected splitless (1 min) onto a PLOT column (PLOT fused silica, 25 m × 0.53 mm; Coating Poraplot Q, Agilent, Basel, Switzerland) in 2 s using a heated syringe (70 °C, Gerstel). Alternatively, only 500 μL can be injected if sensitivity allows, and headspace or splitless liners (i.d. 2 mm, Agilent) may be used. The syringe was flushed with nitrogen after each injection for 30 s. A GC system (Varian 3800, Zug, Switzerland) with FPD was used. The injector was held at 220 °C, and chromatography was performed isothermally at 50 °C for 15 min with a column head pressure of 10 kPa and hydrogen as carrier gas. A PFPD was used in the P-mode at 300 °C. For system maintenance regular change of the injector septum (about every 30 injections) and regular baking out of the column at its maximum temperature (250 °C) are recommended. For detection by MS (DSQII, Thermo Electron Corp., Austin, TX, USA) helium was used as carrier gas (3 mL/min), and a deactivated fused silica column (BGB, Boeckten, Switzerland) was installed after the PLOT column (2 m, 0.25 mm i.d.) ending in the transfer line (200 °C). To prevent particles from the PLOT column entering the ion source, a press-fit connection with an inner diameter of about 0.1 mm was used. Ionization was done in positive EI mode at 70 eV and 200 °C, and the masses m/z 34 and 33 were monitored. As an alternative injection technique, an automated balanced pressure system (Perkin-Elmer, Boston, MA, USA) was used with the following conditions: pressurization at 190 kPa (helium, 1 min); injection time, 0.2 min; transfer line at 80 °C (deactivated capillary, 2.0 m × 0.32 mm).

Data Interpretation. All calculations were done using Microsoft Excel 2010. For interpretation of the interlaboratory comparison (round 2) the mean of all submitted results except the outlier was chosen as assigned value. The standard deviation for proficiency (σ_p) was derived by the Horwitz equation[15] from the mean.

RESULTS AND DISCUSSION

Method Optimization. The method was optimized for sensitivity, precision, and reliable quantitation. For signal optimization, the sample amount, the volume of 5% sulfuric acid, and the conditions to establish equilibrium (temperature, time, shaking) were investigated using samples with incurred residues only. Signals increased for larger sample amounts for a given volume of acid (Figure 1). However, doubling the sample

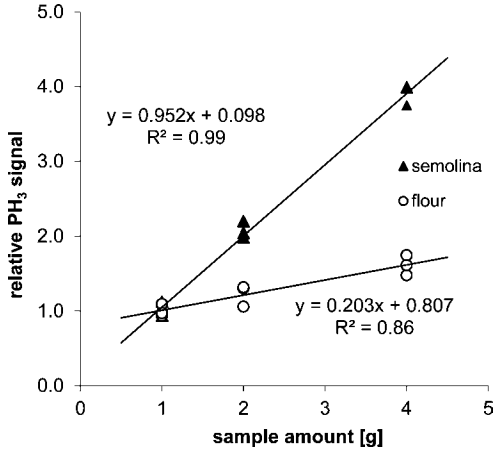

Figure 1. Influence of sample amount on PH_3 signal for wheat flour and semolina. Basis: average peak area for 1 g (n = 3, 15 mL of 5% sulfuric acid).

amount did not result in doubled signals, especially for the flour. Higher sample amounts increased the solubility of phosphine in the sample phase due to stronger interaction with matrix components and changed the viscosity of the sample phase. These effects changed the activity coefficient of PH_3, whereby its concentration in the gas phase did not increase to the same extent as the sample amount. The effect depended on the sample type (see slopes in Figure 1): whereas the signal for semolina almost doubled for doubled sample amounts, the increase was 4.6 times lower for flour. This is explained by their different compositions and interactions with the analyte and by their different viscosities. For larger sample amounts the partitioning strongly changed as compared to pure solvent; that is, the signal per weight decreased. Thus, the sample amount is a critical factor and needs to be carefully controlled and quantitation with external calibration is pointless, especially for more than 1 g of sample (see also below). The two samples were not related to each other and, thus, no direct conclusion can be drawn. However, the effect on viscosity and matrix in solution is expectedly smaller for semolina, which is in line with the usually larger signals in whole compared to ground samples. Small sample amounts such as 1 g are easier to mix and suspend during shaking (see below), and the difference in partitioning as

compared to pure solvent is smaller (see Figures 1 and 4). This allows to draw indicative values from external calibration and facilitates estimating appropriate amounts for standard additions.

Figure 2 shows that the signal of phosphine increased with higher volumes of acid. This can be explained by a smaller

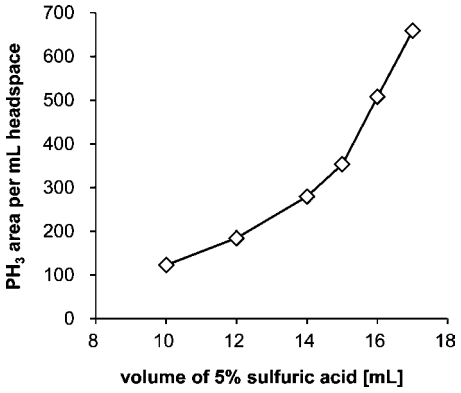

Figure 2. Influence of volume of 5% sulfuric acid on PH_3 signal (wheat flour, 1 g; injection volume = 1 mL).

phase ratio and a lower retention of PH_3 in the more diluted sample phase (i.e., increased activity coefficient).[16] Both effects may have contributed to the increase of signal. Although a small headspace volume has the advantage of larger signals, an intermediate volume of 15 mL acid was chosen as a compromise. Thereby, shaking and suspending were more effective (see below), enough solvent was provided to establish equilibrium faster, and enough headspace was available for needle intrusion and sampling.

Increasing temperature during incubation in the heated agitator gave larger signals (Figure 3) because the partition

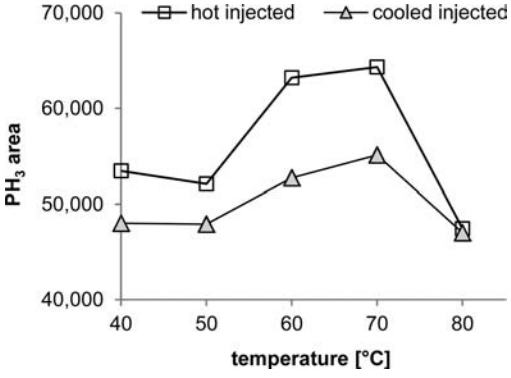

Figure 3. Influence of incubation temperature on PH_3 signal: injection of hot and cooled samples (2 g of wheat flour, n = 2, 15 mL of 5% sulfuric acid).

coefficient depends exponentially on the inverse temperature.[16] At about 70 °C a maximum was observed for both hot and cool injected samples. The influence of temperature was less pronounced for samples cooled before injection, and their signals were generally lower compared to immediate, hot injection. This is because partitioning toward the liquid phase is favored at lower temperatures. Nevertheless, injection after cooling has the advantage of reducing solvent load on the analytical column. Incubation at 80 °C decreased the signal in both hot and cool injected samples, and clumping was more frequent. This decrease may be due to oxidation or other reactions with matrix components. Therefore, an incubation temperature of 65 °C was chosen as a compromise. In the literature, boiling for 20 min in 10% sulfuric acid was described as release condition,[17,18] whereas other methods use longer times.[7] In contrast, Ren et al. found a maximum signal in the headspace after heating wheat at 45 °C for 20 min.[19]

Extraction and partitioning were also checked for the present method as follows: A sample of wheat flour (1 g, 15 mL of 5% sulfuric acid) was analyzed in duplicate. After cooling to room temperature, the vials were opened, flushed with a gentle stream of air for 10 s to remove PH_3 from the headspace, capped again, and reanalyzed including incubation in the heated agitator. The same was done with a calibration standard (0.3 μg/kg, n = 3). The PH_3 signal in the sample reached 23% of the first analysis, whereas in the calibration standard 16% was found. This shows that equilibrium is on the side of the gas phase and that partitioning is the key factor after extraction. Also, it again demonstrates the different partitioning if sample matrix is present (see Figure 4).

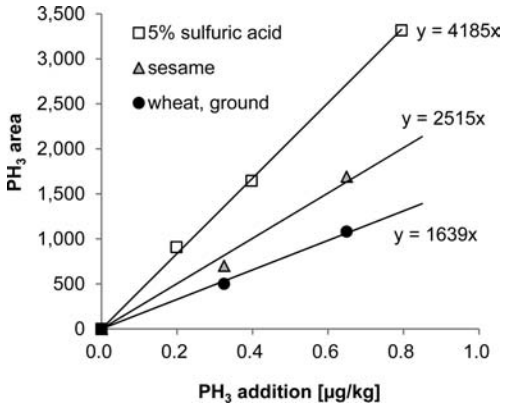

Figure 4. Calibration functions obtained in different matrices. Signal from sample was subtracted (1.5 g of sample, 15 mL of 5% sulfuric acid).

In addition, the influence of shaking on the signal was checked. Samples need to be intensively shaken by hand to achieve good mixing and wetting before incubation in a heated agitator. Thereto, an appropriate ratio of sample and solvent is important, for example, 1 g and 15 mL. Small sample amounts are easier to suspend and swell during shaking and are less prone to form viscous doughs. An intensive (750 rpm on the agitator) and prolonged shaking (20 min) gave best results for a given combination of sample amount, temperature, and volume of acid. Equilibrium was reached for 1 g of wheat flour in 15 mL of solvent after incubation for 20 min, whereas for solvent standards it was established already after 5 min (no data shown). The effect of a more intensive shaking becomes particularly evident for larger sample amounts and for matrices with pronounced swelling. Samples may also be incubated in a GC oven, for example, for 20 min at 65 °C and manual shaking in regular intervals (e.g., every 5 min for 1 min) if a heated agitator is not available. If a classical convection oven is used, a higher temperature (about 80 °C) is recommended because the temperature of the vials is substantially lower due to less efficient heat transfer as compared to a heated agitator or a GC oven. Nevertheless, the use of a heated agitator combined with an autosampler is recommended for practical and reproduci-

Table 1. Characterization of Samples and Results of the Interlaboratory Comparison Tests[a]

	characterization of samples			results of interlaboratory comparison				
	1	2	3	COOP[b]	State Lab[c]			
	(n = 10)	(n = 10)	(n = 3)	(n = 2)	(n = 2)	mean	n	σ_p

bility reasons. Heating and shaking of all vials prior to injection presents an improvement for quantitation as compared to other methods relying on external calibration where partition of phosphine between headspace and liquid phase is not taken into account.[17,18]

Linearity was checked using five concentration levels (n = 1) in 5% sulfuric acid in the range of 0.19−1.95 μg/kg plus a blank. Mandel's test confirmed a linear calibration function (R^2 = 0.98). Linearity was also checked in the range from 0.1 to 10 μg/kg (total of 10 levels, n = 1), and again a linear function was found (R^2 = 0.99). On the basis of 1 g of sample and 15 mL of acid, a limit of quantitation of 0.1 μg/kg was easily achieved without matrix, which corresponds to 0.1 to about 0.4 μg/kg in real samples. This is sufficient to check samples for compliance to residue limits, especially organic samples. In cereal samples, concentrations as low as 0.2 μg/kg were determined by standard addition in our laboratory. The precision, that is, RSD, of results obtained by standard addition accounted for 16% (wheat flour, n = 4, mean = 3.5 μg/kg). This is similar for results obtained with all types of samples analyzed by the two authors' laboratories (COOP and State Lab) in the interlaboratory comparison studies (Table 1). Thus, the method is well reproducible provided that some experience and appropriate equipment are present.

Figure 4 shows that the signal for a given amount of PH_3 was largest in the absence of any sample matrix (5% sulfuric acid only). The effect of sample type (Figure 4) and sample amount (Figures 1 and 5) can vary considerably. Similar effects were also reported in the literature.[9,17] As a consequence, quantitation by external calibration in 5% sulfuric acid mostly leads to an underestimation of phosphine contents and comparability of results may be limited. External calibration using a generic matrix devoid of residues only partially overcomes this problem because of varying effects in different matrices. Therefore, results obtained by external calibration are indicative and not quantitative, especially when large sample amounts are used. Furthermore, recovery experiments and partly also standard additions suffer from the fact that added PH_3 remains largely in the gas phase and poorly sorbs to the matrix.[7] In contrast, incurred residues need to be extracted from the matrix into the liquid phase (diffusion controlled) from where they partition to the gas phase. Standard additions compensate at least for part of these effects, for example, partition between liquid and gas phase, as can be seen from the lower signals from matrices as compared to solvent (Figure 4). Therefore, recoveries in the classical analytical sense cannot be truly determined for incurred residues of phosphine. The key

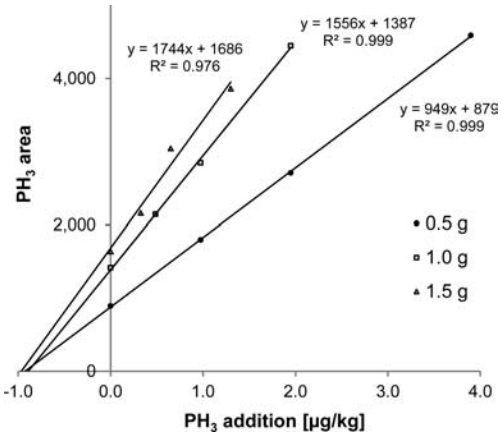

Figure 5. Standard addition experiments with ground cereal risotto using different sample amounts (15 mL of 5% sulfuric acid). Results for different sample amounts: 0.5 g, 0.93 μg/kg; 1.0 g, 0.89 μg/kg; 1.5 g, 0.97 μg/kg.

point is to reach equilibrium under reproducible conditions. A reasonably good correlation in standard addition serves as an indicator for reproducible equilibrium. Recoveries from 50 to 90% were reported, and sample type and amount both affected recovery.[17,20] In this study recoveries from as low as 20 to 140% were found, depending on matrix and sample amount, showing the limited significance of recoveries.

Time is another factor affecting results obtained in screening with external calibration. This was checked with two sets of samples of ground rice (1 g, 15 mL of acid, n = 10 each), of which the first set was directly incubated and analyzed and the other set was left to stand for 2 h before incubation. A significant decrease of 17% of the signal (t test: $p < 0.0001$) was observed for samples left to stand for >2 h. Therefore, long series of samples should be avoided or samples should be prepared batchwise to prevent standing times of >2 h before incubation. The only feasible way to obtain reliable quantitative data is to analyze samples using the standard addition approach. This is preferably done after screening the samples against an external calibration in 5% sulfuric acid to check for the presence of PH_3. In the performance of standard addition experiments, the sample amount is not critical as long as it is within a low range (0.5−1.5 g) as can be seen in Figure 5: very similar results were obtained for the different sample amounts analyzed because the matrix effect was compensated (see slopes in Figure 5).

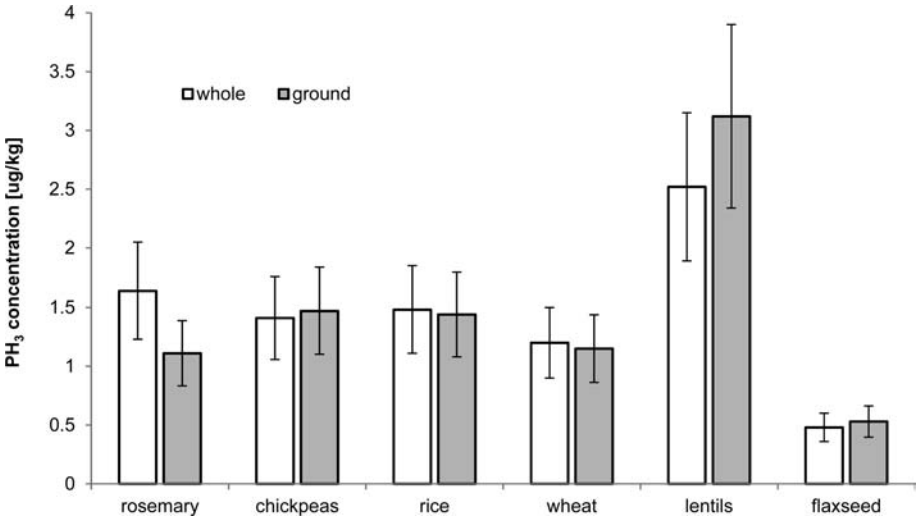

Figure 6. Concentrations of phosphine in whole and ground samples, determined by standard addition. Error bars are ±25% (n = 2, 1 g of sample, 15 mL of 5% sulfuric acid).

Sample homogeneity is critical for standard addition experiments: For heterogeneous samples (e.g., cereal mixtures or Muesli) and for large particles (e.g., cereal grains) the variation of residue per "unit" makes it sometimes impossible to obtain a standard addition with an acceptable R^2. The limited sample amount (usually <2 g) is another factor that contributes to this problem. To overcome this, grinding and mixing of the samples are inevitable. Variation of peak area was substantial for rice as grain (RSD = 28%, n = 10), whereas it was 3 times lower after grinding (RSD = 9%, n = 10). However, grinding is questioned for the analysis of volatile analytes such as PH_3 because losses via evaporation during grinding and mixing have to be considered. Nevertheless, the effect of grinding was tested for different matrices (Figure 6). For all six matrices no significant difference was found between the concentrations of whole and ground samples. Shown error bars present a generic variation of 25%, which is easily achievable with standard addition. Quantitation was done in all cases by standard addition. Thereby, matrix effects were compensated for, which otherwise impair quantitation by external calibration. For example, almost the same result was obtained in the wheat sample of Figure 6: 1.20 μg/kg for whole grain (regression: y = 1962x + 2349) and 1.15 μg/kg for ground wheat (regression: y = 1621x + 1856), but the intercepts and slopes differed because of the different partition. However, sometimes three to four attempts are needed to obtain a standard addition with an $R^2 \geq$ 0.95 for whole wheat kernels or other coarse samples, whereas it usually works straight for ground samples. For many samples it is hard to obtain an acceptable standard addition experiment without grinding. Furthermore, it can be concluded from the data shown in Figure 6 that phosphine is not present in a free gaseous form, which would be readily lost. It is rather sorbed to the sample and may be present in the form of (partially reacted) phosphides or reaction products[21] being released only during incubation in acid. Similar findings are discussed in the literature.[7,8] Some negligible losses during grinding are compensated by a better release of the analyte from the ground matrix. An explanation of previously reported "losses" after grinding or mixing[9] may be due to different partitioning. Ground samples are more easily extracted, and smaller particles have lower resistance to diffusion, whereby equilibrium is established earlier as compared to whole grains.[9,13]

The optimized method differs from the method of Amstutz et al.[6] in several important aspects: Less sample is used (1 vs 5 g), more solvent is added (15 vs 10 mL), quantitation is based on standard additions and not on external calibration without matrix, coarse samples are ground rather than analyzed as such, and longer incubation is performed (10 vs 20 min) to reach equilibrium. Critical points causing variation may be establishing reproducible equilibrium for all sample types and maintaining the same filling levels in the vials.

Interlaboratory Comparisons. To gain data on the variation of PH_3 determination in different laboratories and to characterize and validate the present method, two rounds of an international interlaboratory comparison test were organized in 2011 and 2012. For both tests only samples with incurred, aged residues were used. They were selected from the monitoring samples taken from the market and characterized for stability and homogeneity before sending (Table 1). Analysis 2 took place 15 days after analysis 1 and 1 week before distribution of samples. Analysis 3 was performed after the last results were submitted (about 3 months later). The samples were reasonably homogeneous and stable over the whole test period with the exception of the rice in the first round, where some losses may have occurred after distribution.

In Table 1 the means of results from the two rounds are presented and compared to the results of the two authors' laboratories (COOP and State Lab). In the first round three samples were sent to 10 laboratories without giving detailed advice on the method. Nine of the 10 laboratories returned results. The values reported for the wheat flour ranged from 2.3 to 22.9 μg/kg (factor of 10). Variation of results was considerable and much larger than observed during characterization or between the authors' laboratories (Table 1). Feedback from participants revealed that calibration without any matrix and high sample amounts (3−5 g) were used. This led to some low results, whereas in the authors' laboratories some 20 μg/kg was found. Values varied to a lesser extent for the rice sample (range = 0.48−1.20 μg/kg) but only six participants were able to determine a residue around 1 μg/kg. For semolina merely three results were submitted (range = 0.08−0.26 μg/kg). This shows that for most laboratories a limit of quantitation below 1 μg/kg is not achievable and enforcement of such residues lacks analytical practicability.

z scores for these data set are of limited meaning due to the small number of results and the strong variation, especially for the flour sample. This round simply highlighted the difficulties encountered with this analysis.

For the second round all participants were provided a revised method (as described in the present paper) and were invited to submit results obtained by their own, in-house method (set of "own methods") as well as by this proposed method. Three samples (wheat flour, red lentils, jasmine rice) were sent to 14 laboratories in four European countries, and 13 participants returned results. The participants were asked to analyze the lentils as such and after grinding. Results obtained by a photometric method (e.g., wheat flour, 15.3 μg/kg) were identified as outlier by Grubbs' test and dismissed for all samples. Problems with blanks, as stated by the participant, are a probable explanation of too high values, which were also reported for a similar method.[13]

The mean of all results was 2.9 μg/kg (median = 2.8 μg/kg) for wheat flour, which is slightly below the values obtained during characterization and by the authors' laboratories (Table 1). Figure 7 shows results for wheat flour as a function of the applied method. No significant difference was observed between proposed and the set of own methods. A trend toward lower results is observed for the set of own methods. This may be due to large sample amounts and/or external calibration, which both lead to an underestimation (see Figures 1 and 4). Variation was considerable in all categories for wheat flour, independent of the method and detection (RSD = 45−61%, error bars in Figure 7) but lower as compared to the first round. Providing a method with analytical details to all participants may have contributed to this improvement. Because the majority of participants submitted results based on only external calibration (with or without generic matrix) or standard addition, the interpretation regarding the method of quantitation is limited because of effects mentioned above and the low number of results. Therefore, this aspect cannot be discussed in detail: No significant difference between quantitation types was found (overall and within sets of methods). If only results from laboratories using both types of quantitation were compared, then the mean from standard additions was slightly but not significantly larger than from external calibration (3.6 vs 3.4 μg/kg). Overall, for residues at low μg/kg levels in flour results may vary by some 50% (round 2), irrespective of the method used. Among the 23 results for this sample, 3 were assigned a z score outside the range of $-2 \leq z \leq 2$. The results from MS detectors and (P)FPD detectors were grouped and compared to each other (Figure 7). No significant difference was found between the two different types of detection, which is in line with our own tests (no data shown). Thus, both detectors give equal results and are capable of determining PH_3 residues in the low μg/kg range. The strong overall variation of the methods are rather explained by differences in sample amount, incubation, and method of quantitation than by the applied detector.

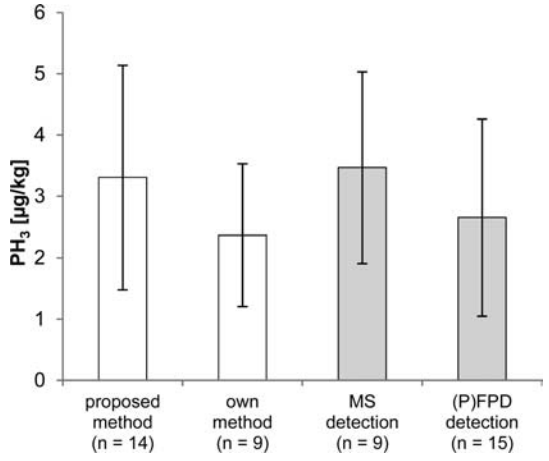

Figure 7. Results of the interlaboratory comparison test for wheat flour, categorized for applied method and used detector (mean values, error bars are ± standard deviation). Outlier was excluded.

For the lentils the sets of proposed and own methods gave similar mean values of 2.4 μg/kg (RSD = 57%) and 2.7 μg/kg (RSD = 48%), respectively. As expected from grinding experiments (Figure 6) no significant difference was found between mean residues of whole (2.5 μg/kg, RSD = 55%, n = 22) and ground lentils (3.0 μg/kg, RSD = 65%, n = 21). This confirms our experimental results and demonstrates that grinding has no discrimination effect. Among the 23 different results obtained for the whole lentils, 3 were assigned a z score outside the range of $-2 \leq z \leq 2$.

Also for the rice sample no significant differences were observed between both types of methods. On average, 13.0 μg/kg was found in the set of own methods (RSD = 54%) and 14.1 μg/kg (RSD = 45%) for the proposed method. Among the 23 results, 5 were assigned a z score outside the range of $-2 \leq z \leq 2$.

Generally, the proposed method gave similar results compared to other methods being used, except the photometric one. Headspace sampling with GC-(P)FPD or GC-MS detection presents a selective and sensitive approach that enables monitoring organic samples for compliance. Because of the mentioned effects of high sample amounts, not more than 2 g should be used and standard addition is necessary for quantitation. Following exactly the proposed protocol gave z scores within the range of $-2 \leq z \leq 2$ for all samples. The variation within a laboratory may account for some 20%, whereas interlaboratory variation is about 50%. Therefore, an extended uncertainty of measurement of roughly 50% is proposed, not including a coverage factor of 2 as is the case in pesticide residue analysis.[22] This value presents a rough estimate derived from RSDs in the comparison test, and it is rather a description of the reality than a precisely calculated value. It is slightly higher than the Horwitz value for concentrations of ≥1 μg/kg. Experiences in pesticide residue analysis are similar, especially at low μg/kg levels. Thus, the determination of phosphine at low concentrations is challenging in practice, and difficulties are revealed only by such interlaboratory comparisons. This substantial variation has to be taken into account when results are compared and checked against maximum residue levels, and it also demands further harmonization and proficiency testing between methods and laboratories. The results from the authors' laboratories differ by no more than 25% from each other (16% on average, Table 1), which demonstrates that the method is robust and delivers results with acceptable variation providing that the proposed protocol is exactly followed. Residues below 1 μg/kg are below the detection limit of many laboratories and can therefore hardly be monitored. However, the present method allows for the detection of residues of about 0.1 μg/kg providing appropriate equipment. Grinding of samples does not lead to lower results and is an important measure to cope with sample

homogeneity. It allows for acceptable standard addition experiments, which are needed to obtain reliable results and which compensate for different partitioning. Screening with calibration in a generic matrix may be an option but suffers from considerably different behavior of seemingly similar samples, which can easily differ by a factor 2 or 3 (Figure 1). This is even more problematic if many different samples have to be analyzed. Therefore, we rather suggest to screen without matrix calibration for the presence of PH_3 whereby only indicative or merely "yes" or "no" results are obtained. Thereafter, any relevant detection of PH_3 is quantified by standard addition. The method was also successfully applied to other matrices such as raw coffee beans, dried mushrooms, spices, chickpeas, tea, dried fruits, and nuts. Because of differences in partitioning between different matrices, sample amounts and also incubation parameters (e.g., time, temperature) may need to be checked individually to ensure equilibrium.

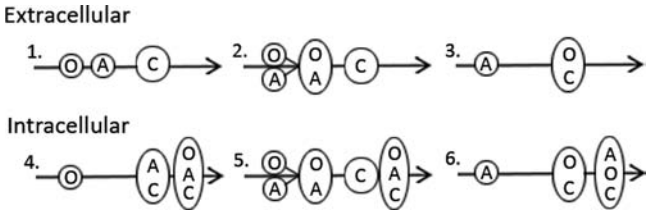

Figure 1. Potential acting position of antioxidants on a cell and possible reaction pathways. A denotes antioxidant, C denotes cell, and O denotes oxidant.

(A denotes antioxidant, C denotes cell, and O denotes oxidant). Extracellular antioxidants that cannot enter cells such as glutathione or ascorbic acid supplement[15,16] have a blocking role against extracellular oxidants (as shown in Figure 1), but their oxidized products can exert some side effects on cells. These potential responses have been reflected in 2, 5, and 6 of Figure 1. Others that can enter the cytoplasm[17] and remain in the cell membrane also must be considered (as shown in 4 of Figure 1). Therefore, this study would reveal the different effects of three sequences for adding antioxidants in the processes of the oxidative hemolysis test on antioxidant evaluation.

MATERIALS AND METHODS

Materials. Hb was purchased from Sigma (USA), L-carosine (L-c) was obtained from Beijing Biotop Technology Co., Ltd. (Beijing, China), reduced glutathione (GSH) was purchased from Shanghai Sangon Biological Engineering (Shanghai, China), L-cysteine (Cys) was purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China), and the synthesized peptide IWHDC was designed by our laboratory and prepared from ChinaPeptides Co., Ltd. (Shanghai, China). Hydrogen peroxide (H_2O_2), trichloroacetic acid (TCA), nitric acid (HNO_3), and perchloric acid ($HClO_4$) were all of analytical grade and were procured from Sinopharm Chemical Reagent Co., Ltd.

Oxidation Test of Erythrocytes. *Preparation of Human Erythrocytes.* Fresh human venous blood was obtained from healthy donors, which was authorized by Yangzhou Blood Center. Blood anticoagulated with citric acid solution (anticoagulant, 4.8 g of $C_6H_8O_7 \cdot H_2O$, 13.2 g of $C_6H_5Na_3O_7 \cdot 2H_2O$, and 14.7 g of $C_6H_{12}O_6 \cdot H_2O$ in each 1000 mL of water) was centrifuged at 625*g* for 3 min and washed three times with 6 mL of cold phosphate-buffered saline (PBS; 145 mmol/L, NaCl, 8.1 mmol/L Na_2HPO_4, and 1.9 mmol/L NaH_2PO_4, pH 7.4) to separate erythrocytes from the white cell layer, plasma, and free Hb released from injured erythrocytes. The packed erythrocytes were diluted with cold Alsever's stock solution (31 mmol/L $C_6H_5Na_3O_7$, 2.9 mmol/L $C_6H_8O_7$, 113.8 mmol/L $C_6H_{12}O_6$, and 71.8 mmol/L NaCl, pH 6.1) to a cell density of 2×10^8 cells/mL. During every trial, erythrocyte solution was saved in a sterile penicillin bottle and stored at 4 °C for not more than 48 h to ensure cell viability and cellular antioxidative level.

Cell Oxidation Induced by H_2O_2. The above erythrocyte solution was treated with different concentrations of H_2O_2 solution at 37 °C for 30 min, and the final concentrations of H_2O_2 were 1.665, 4.995, 16.65, and 166.5 μmol/L, respectively. After centrifuging in 625*g* for 10 min, the hemolytic supernatant was transferred to 96-well plates (NUNC, Thermo Scientific, USA), and the absorbance at 405 nm (hereafter denoted Abs) was detected with the plate reader (Multiskan FC, Thermo Scientific, USA).

Hb Oxidation Induced by H_2O_2. Hb solution was prepared in PBS at a concentration of 20 mg/mL and then reacted with different concentrations of H_2O_2 at room temperature until no bubbles were generated. The reaction solution was transferred to 96-well plates and read at 405 nm with a Multiskan FC plate reader (Thermo Scientific, USA). The same reaction mixture was transferred to a 96-well black plate, and its fluorescent intensity (FI) was read at the excitation wavelength of 355 nm and the emission wavelength of 460 nm with a Fluoroskan Ascent FL plate reader (Thermo Scientific, USA).

Quantitation of Ferric Ions Released from Hb Oxidation by Inductively Coupled Plasma Spectrometry. *Ferric Ion Extraction.* The extraction method was as follows. The Hb reaction mixture was separated through an ultrafiltration membrane (5000 Da) at 4 °C (Vivaflow 200, Sartorius, Goettingen, Germany), and the filtrate was collected. A 10% (v/v) TCA solution was mixed with the Hb reaction solution at 4 °C for 30 min, and then the supernatant was collected. Finally, the Hb reaction mixture was heated in a water bath at 100 °C for 1 h, and the supernatant was collected.

Ferric Ion Detection. Extracted ferric ions were added to a solution of $HNO_3/HClO_4$ (v/v, 4:1). The digestion lasted for 2 h at 140 °C, and the solution was heated again at 190 °C to remove acid. The digested ferric ion solution was diluted with ultrapure water, and then the ferric ions were detected by Elan DRC-e inductively coupled plasma spectrometry (Perkin-Elmer, USA).

Multiple Assessment of Antioxidant Activity with Hemolysis Tests. A 100 μL solution of erythrocytes was treated with H_2O_2 of 166.5 μmol/mL of the final concentration and one antioxidant liquor in each test group. The selected antioxidants were GSH of 1.67 mmol/L, L-c of 1.67 mmol/L, Cys of 1.67 mmol/L, and IWHDC of 0.167 mg/mL, respectively. Both the H_2O_2 and antioxidant were dissolved in PBS and cultured with erythrocytes at 37 °C for several hours. Three different sequences of antioxidant addition were examined in this work. The first kind of reaction consisted of two steps and was denoted R1. The erythrocytes were preincubated with antioxidant for 15 min and then combined with H_2O_2 for 4 h to accomplish hemolysis. The second kind of reaction also included two steps and was denoted R2. Antioxidant and H_2O_2 were fully blended for 15 min prior to dispensing the erythrocytes solution, and the mixture obtained was allowed to sit for 4 h. The third kind of reaction, denoted R3, was slightly different from R1 when H_2O_2 was added. Briefly, H_2O_2 was mixed with the erythrocyte solution to initiate the oxidative stress of cells, and after 5 min, antioxidant was injected immediately to inhibit the oxidative hemolysis, and the mixture was allowed to sit for 4 h. Additionally, H_2O_2-induced hemolysis in the absence of all antioxidants was performed as the injury control group, and the solution was also maintained for 4 h, during which an equal volume of PBS or other solvent was added instead of the antioxidant liquor. All solutions were freshly prepared and used immediately.

Statistical Analysis. Statistical analysis was performed with Microsoft Excel. Statistical significance was tested using the paired-samples *t* test. Significant difference between data sets was assessed by a *p* value of <0.05. Each value shown in this paper represented typical responses from three trials.

RESULTS AND DISCUSSION

Comparison of Hemolysis Tests under Various Concentrations of H_2O_2. Optimization of measurement condition, including cell count, culture time, and temperature, is the first step during the process for evaluating antioxidant activity. In this work, we focused on the effect of H_2O_2 dose on hemolysis to screen a cell model with high sensitivity to oxidative damage.

Erythrocytes were incubated with various final concentrations of H_2O_2 solution (0, 1.665, 4.995, 16.65, and 166.5 μmol/mL; Figure 2). Hemolysis curves were obtained on the basis of the absorbance of Hb in the supernatant. According to the theory that oxidants can induce cell membrane breakage, the absorbance of the hemolysis supernatant should increase as the H_2O_2 dose increases. Hemolysis induced by 1.665 μmol/mL of H_2O_2 appeared to be inhibited, as represented in curves D1 and D2 in Figure 2. This decrease of absorbance suggested that the erythrocytes were not damaged by H_2O_2. These results were unexpected. The decline deserved further research

dx.doi.org/10.1021/jf4049935 | J. Agric. Food Chem. 2014, 62, 2056−2061

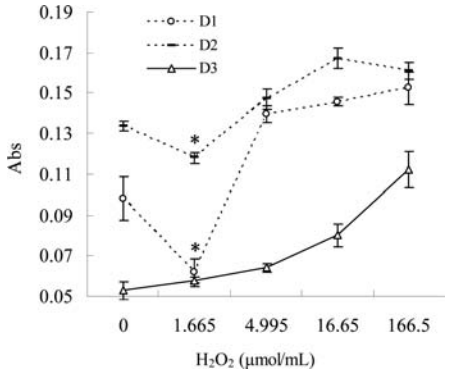

Figure 2. Hemolysis responses to H_2O_2 doses in three donor cell samples (D1, D2, and D3). Erythrocytes were incubated with H_2O_2 at 37 °C for 30 min. Each value is the mean ± SD of three experiments. A line chart is used instead of a scatter graph to more clearly display the trend of each data point. The dashed lines indicate abnormal values at 1.665 μmol/mL of H_2O_2 that are lower than those at 0 μmol/L of H_2O_2. Significant differences are marked by asterisks (∗).

because it generated a negative inference on traditional hemolysis measurements.

Interfering Effect of Free Hb on the Evaluation of Oxidative Hemolysis. MetHb formation occurs during cellular oxidative stress and then promotes membrane leakage through the cross-linking of membrane proteins, leading to intracellular Hb release.[18] However, Figure 3 shows that there

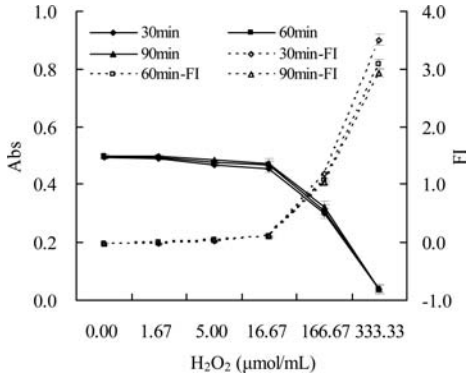

Figure 3. Oxidation of free Hb measured with spectrophotometry (solid line) and fluorometry (dashed line). Hb was incubated with various doses of H_2O_2 for 30, 60, and 90 min.

were other reactions during the oxidation of Hb, for example, color fading. The reducing Abs suggested Hb loss at higher doses of H_2O_2. The decrease of Abs in Figure 2 probably resulted from the further oxidative destruction of MetHb into hemichrome or other degradation products.[14]

Curves D1 and D2 in Figure 2 showed that the Abs values at 0 μmol/L of H_2O_2 were both above 0.1, whereas the Abs at the same abscissa on curve D3 was 0.052 (the supernatant was nearly colorless). This indicated that there was a little free Hb at the beginning of the hemolysis test, and this part of Hb might be attacked first and then degraded by H_2O_2.

To prove whether the initial free Hb presents interferences with the determination of hemolysis, we attempted to add Hb solution to the erythrocyte suspension (the supernatant of this suspension with Abs_{405} of 0.07 was also nearly colorless) before the hemolysis test. The results coincided with the assumption, showing that in the suspension with extra Hb added, Abs at 1.665 μmol/mL of H_2O_2 was lower than that at 0 μmol/L of H_2O_2 (Figure 4). These results suggested that H_2O_2 had

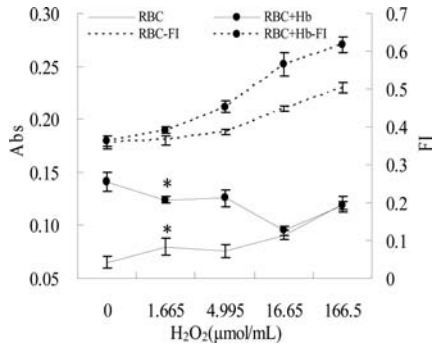

Figure 4. Hemolysis curves for the normal suspension and the suspension with added Hb obtained by absorbance assay (solid line) and fluorescence assay (dashed line). Each hemolysis suspension was cultured at 37 °C for 30 min. Data are the mean ± SD of three experiments. Values with significant difference compared to 0 μmol/L H_2O_2 under addition of Hb are marked by asterisk (∗).

reacted quickly with the extracellular Hb before its entry to cells. Moreover, the trend of the FI data was contrary to the Abs. FI was increasing with the dose of H_2O_2 damage, and all values of FI in the group with Hb added were higher than those without extra Hb (Figure 4). These results suggested that the extra-added Hb had suffered H_2O_2-oxidative damage and the degradation of Hb was along with the hemolysis as well. Therefore, when the degree of hemolysis is determined by spectrophotometry, the degraded Hb by oxidation would be a novel interference in hemolysis evaluation, which could reduce the measurement accuracy.

Degradation of Hb Oxidized by H_2O_2. As shown in Figure 3, the Abs of the Hb solution changed little with the extension of oxidation time, whereas the FI at 333.3 μmol/mL of H_2O_2 decreased clearly, especially at 90 min. This indicated that the initial degraded Hb with fluorescence might be further turned into some nonfluorescing substances during oxidation.

According to previous papers, the reaction time was usually >1 h, and the Hb concentration was at a higher level. Thus, we compared the results of the following tests, one in which the Hb of 0.138 mg was oxidized for 15 min, and the other in which the Hb of 8 mg (H_2O_2 doses were the same as in the first test) was oxidized for 90 min (Figure 5). In Figure 5B, the value of FI declined when the dose of H_2O_2 was higher. However, when the reaction time was extended from 90 min to 24 h, the fluorescent products were found to be stable with no significant variation in the FI value. This revealed that many kinds of fluorescent products were generated during Hb oxidized degradation; some of the products could be further degraded, and some were stable, which would be useful for correcting the Hb absorbance. As shown in Figure 5A, the FI value did not decrease at any dose of H_2O_2, whereas in Figure 5B, a significant decrease of FI was observed at higher doses of H_2O_2. This difference might result from two situations. One was that no sufficient fluorescent products could be further decomposed during Hb degradation so that there was little effect on the FI value, as shown in Figure 5A. The other was that there was not enough time for Hb to completely degrade. Therefore, to better imitate in vivo reaction, the process in Figure 5B would be implemented in the following study.

dx.doi.org/10.1021/jf4049935 | J. Agric. Food Chem. 2014, 62, 2056−2061

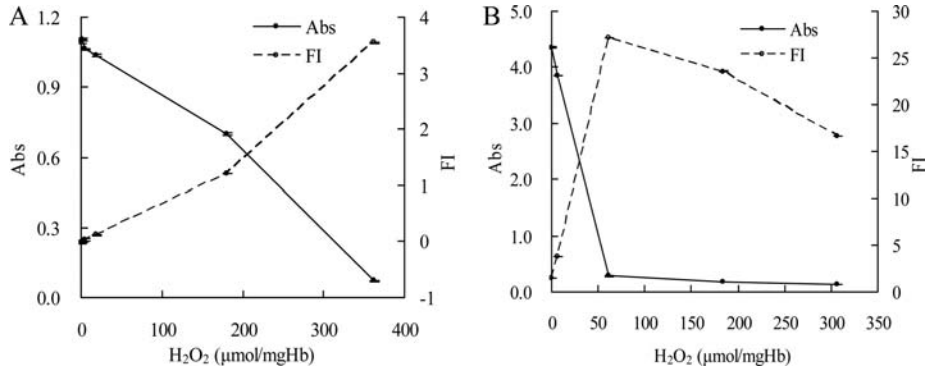

Figure 5. Oxidation curves of free Hb measured with spectrophotometry (solid line) and fluorometry (dashed line). (A) Hb (0.138 mg) was incubated with H_2O_2 for 15 min, and the relative doses of H_2O_2 were 0, 1.81, 5.43, 18.10, 180.98, and 361.96 μmol/mgHb. (B) Hb (8 mg) was incubated with H_2O_2 for 15 min, and the relative doses of H_2O_2 were 0, 6.12, 61.2, 183.64, and 306.07 μmol/mgHb.

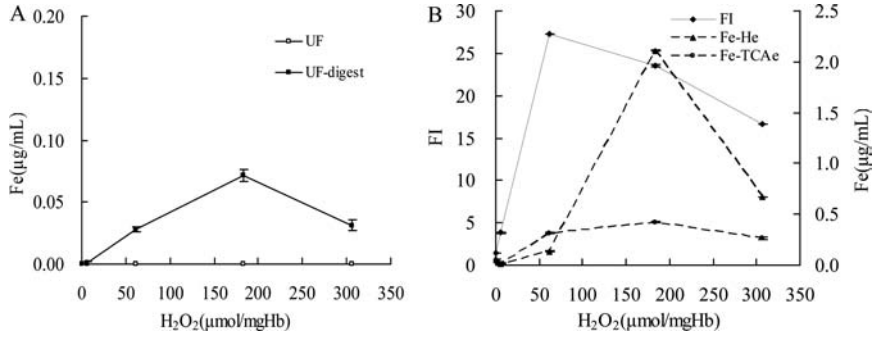

Figure 6. Different assays to extract the ferric ions released from Hb. Hb (8 mg) was incubated with different concentrations of H_2O_2 for 90 min. The ferric ions were extracted by ultrafiltration membrane (A), boiled water bath, and TCA precipitation (B), respectively.

It was found that Hb degradation not only generated fluorescent products but also induced ferric ion release from heme. We studied this release in three different ways (Figure 6). In the ultrafiltration test, the number of ferric ions after digestion was significantly higher compared with nondigestion (Figure 6A), which could indicate that the released ferric ions were binding with other protein substances. The number of released ferric ions extracted by the TCA and heating assays was significantly higher than that extracted by the ultrafiltration assay (Figure 6B). It was possible that some ferric ion conjugates were trapped by the 5000 Da ultrafiltration membrane due to the decrease in flux or that the ferric ions binding to other substances could not be extracted in this way. At the same time, all three assays showed that the highest ferric ion content was obtained when the H_2O_2 concentration was 183.6 μmol/mgHb, which was different from the FI values. This explained coincidentally why the decrease of FI values happened at a higher dose of H_2O_2 (183.6 μmol/mgHb), because there was further degradation.

Correction of Abs in Hemolysis. The above discussion indicated that the oxidative degradation of Hb was the key interfering factor in hemolysis evaluation. The following description was about establishing the model of Hb oxidation and correcting the lost Hb detection beyond the visible spectrum.

Normal erythrocytes contain 95% Hb, so in either in vivo or in vitro hemolysis, the dose of H_2O_2 is relatively little and can be calculated in units of micromoles per milligram of Hb. As shown in Figure 7, the H_2O_2 dose range was between 0 and 61 μmol/mg Hb. Abs and FI showed a good complementary linear relationship. We found that the actual concentration of Hb

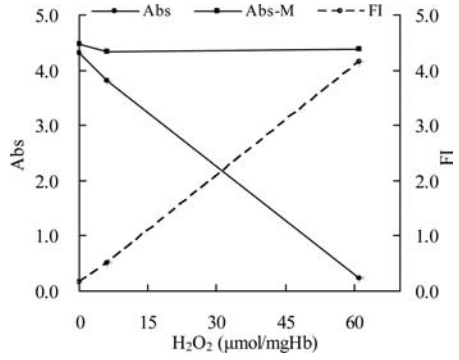

Figure 7. Relationship between Abs and FI in the H_2O_2-induced degradation of Hb.

could be expressed as Hb_{actual} = FI/CC + Abs if FI values divided a constant value (noted as the correction coefficient (CC)). According to the law of conservation of mass, the total Hb content must remain constant before and after degradation. The Abs-M curve in Figure 7 is the calibration curve of Hb with the CC value of 6.436. It can be seen that the Abs of Hb after modification by FI remained close to the initial level with increasing doses of H_2O_2. This confirmed that the correction of absorbance was effective in hemolysis on the basis of the stable fluorescent products.

Effect of the Sequence of Adding Antioxidants on the Assessment of Antioxidant Activity. The previous sections had modified hemolysis measurement, but here we wondered how to improve the protocol of the cell model to imitate the physical oxidation and antioxidation. The widely applied

dx.doi.org/10.1021/jf4049935 | J. Agric. Food Chem. 2014, 62, 2056−2061

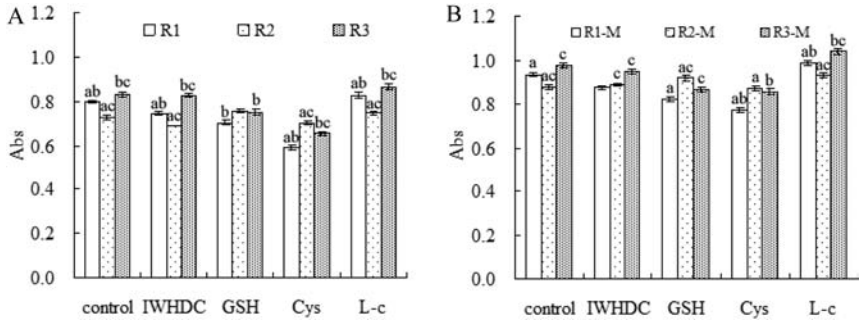

Figure 8. Antioxidant activity of IWHDC, GSH, Cys, and L-c under hemolysis induced by 166.5 μmol/L of H_2O_2: (A) results without modification; (B) results modified by correction factor for FI. Hemolysis reaction was conducted using three different sequences of adding antioxidants (R1, R2, R3), and the control group contained no antioxidant. Each value is the mean ± SD of three experiments. Significant differences are indicated by a, b, and c: a, compared with R1 and R2, $p < 0.05$; b, compared with R1 and R3, $p < 0.05$; c, compared with R2 and R3, $p < 0.05$.

sequence R1, preincubation with antioxidant and erythrocytes,[19,20] reflects the comprehensive activity of exogenous antioxidants because redundant antioxidants can also work outside the cells. Sequence R2, simulating the role of antioxidants on extracellular free radical scavenging, is actually a part of sequence R1 when antioxidants enter the cells.[21] Sequence R3 is also a part of R1[22] and reflects the ability to inhibit free radical chain reaction and repair injury when erythrocytes are in a state of unremitting oxidative stress. These three sequences were tested separately here, but in human blood, they always exist simultaneously and synergistically. Therefore, multidimensional analysis may be better for evaluating antioxidant capacity based on erythrocyte models. Three recognized antioxidants (GSH, Cys, and L-c) and a synthetic peptide (the amino acid sequence IWHDC designed by our laboratory) were evaluated on the basis of their order of addition in this study. First, we compared the difference between the results of unmodified hemolysis (Figure 8A) and those modified by FI (Figure 8B). The antihemolysis activities changed when Abs was modified by FI; therefore, we chose Abs modified by FI for antioxidant activity evaluation.

The three sequences (R1, R2, and R3) showed different hemolysis results not only in the antioxidant groups but also in the control group. The difference observed in the control group may be related to the tolerance of erythrocytes to oxidative stress, whereas the differences observed in antioxidant groups may also be related to the antioxidant mechanism and membrane transfer ability in the samples. As an amino acid antioxidant, Cys showed the highest activity in each of the three evaluation sequences, mainly because the rich disulfide bond provided protection from oxidation. The results of the R3 sequence showed that Cys may have entered the cell and controlled intracellular oxidative damage; the R2 sequence showed no activity, which could be directly related to the lack of scavenging H_2O_2 (data not shown). GSSH generated in the R2 sequence may disrupt the extracellular GSSH/GSH ratio such that the red blood cells exhibit abnormalities of metabolism. The poor performance of L-c in this study may be due to an inappropriate dose. Pentapeptide IWHDC had H_2O_2-scavenging capacity (data not shown) and showed antioxidative capability in the R1 and R3 groups, but not in the R2 group, suggesting that the oxidation products of IWHDC may disrupt cellular metabolism and reduce antihemolytic activity.

On the basis of the modified hemolysis measurement, we investigated how variation in activity assessment if antioxidants were added in three different sequences. The results showed differences in both the control group and the antioxidant groups for all three sequences may be related to cell resistance to oxidation, membrane transport capacity, and the other effect on cellular metabolism. According to the R1, R2, and R3 groups, more activity pathways can be analyzed, and results from them would have considerable value in the initial stage of antioxidant development. In future studies to find the intracellular oxidation level and explain the membrane roles, we will describe the detail mechanisms observed via fluorescent tracer, Western blot, and Fourier transform infrared spectroscopy techniques.

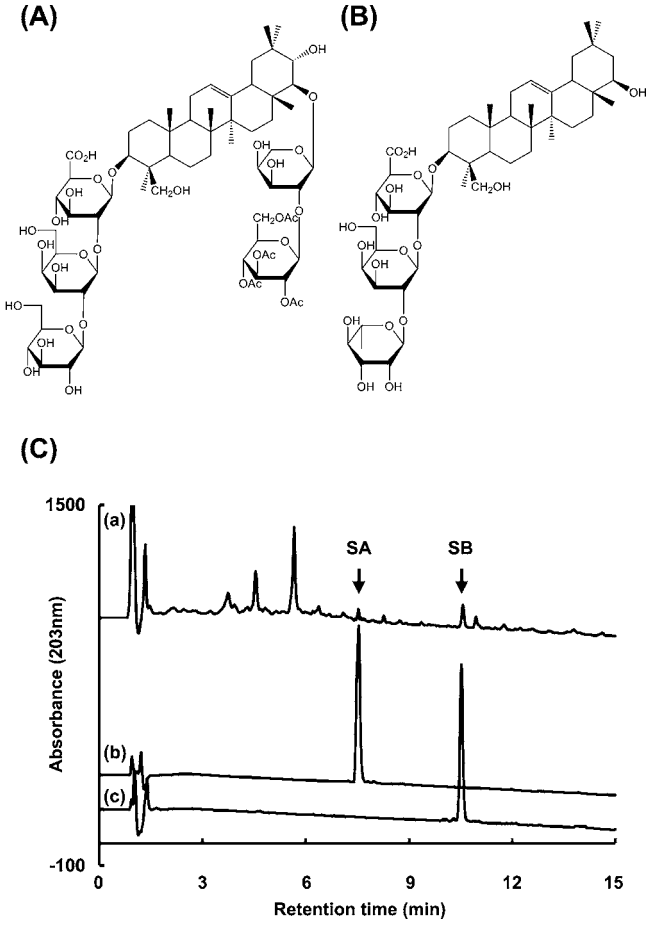

Figure 1. Structures of soyasaponins Ab (A) and Bb (B) Isolated from *Glycine max* Merr and HPLC chromatogram (C) of soybean ethanol extract (a) and isolated SA (b) and SB (c).

^{13}C NMR) analysis, similar to as reported previously.[18−21] The purities of the isolated soyasaponins were assayed by HPLC (Hewlett-Packard 1100 series, Ramsey, MN, U.S.) equipped with Zorbax Eclipse Plus C18 column (4.6 × 100 mm, 5 μm, Agilent Technologies, Santa Clara, CA, U.S.), a HP 1100 series binary pump, a HP 1100 series autosampler, and UV detector (203 nm). The HPLC was done by eluting with a linear gradient of 10% CH_3CN to 60% CH_3CN (flow rate, 1 mL/min) for 15 min. The retention times of soyasaponin Ab and Bb were 9.92 and 12.03 min, respectively.

Soyasaponin Ab. White amorphous powder. FAB-MS: *m*/*z* 1436 $[M - H]^-$.

Soyasaponin Bb. White amorphous powder. FAB-MS: *m*/*z* 941 $[M + H]^+$.

AChE Activity Assay. AChE activity was measured according to the method described by Lee et al.[22] Briefly, a reaction mixture (225 μL) containing 15 mM ATCh (25 μL), 3 mM DTNB (125 μL), 50 mM Tris-HCl (50 μL, pH 8.0), and test agents (25 μL) in a microplate was preincubated for 10 min. AChE (0.226 U/mL, 25 μL) was then added in the mixture, and scanned for 10 min at 405 nm in a microplate reader (Model Biotek μQuant MQX200, Winooski, VT, U.S.). Enzyme activity was indicated as a percentage of the activity when treated with vehicle instead of inhibitors.

Animals. All animal experiment protocols were performed according to the National Institute of Health (U.S.) and Kyung Hee University guidelines for Laboratory Animals Care and Usage and approved by the University Animal Care and Usage Committee of Laboratory Animals in the College of Pharmacy, Kyung Hee University.

Male ICR mice (18−22 g, 5 weeks) were obtained from the Orient Animal Breeding Center, a branch of Charles River Laboratories (Sungnam, Korea). All animals were housed in wire cages under a 12 h light/dark cycle (light on 07:30−19:30) at 20−22 °C and 50 ± 10% humidity and fed standard laboratory chow and water ad libitum.

Passive Avoidance Task. Acquisition and retention of the passive avoidance task was assessed using a two-compartment acrylic box wherein a lighted compartment (20 × 20 × 20 cm^3) was connected to a dark compartment (20 × 20 × 20 cm^3) by an entrance door (5 × 5 cm^2), according to the method of Lee et al.[22] Briefly, the mice underwent acquisition and retention trials. In the acquisition trial, a mouse was initially placed in the lighted chamber, and the entrance door was opened after 10 s. When the mouse entered the dark chamber, the door automatically closed, and a 0.3 mA electrical shock for 2 s was delivered through the grid floor. One hour before the retention trial, the mice were orally administered with soy ethanol extract (SE, 100 and 200 mg/kg), SA or SB (5, 10, 20, and 40 mg/kg), tacrine (10 mg/kg) as a positive control,[23] and vehicle (2% Tween 80, the scopolamine group) as a negative control. Memory impairment was induced by intraperitoneal injection of scopolamine (0.9 mg/kg) 30 min after oral administrations of test agents. The passive avoidance maze task was carried out 30 min after scopolamine treatment. A retention trial was carried out 24 h after the acquisition trial. Thereafter, the mice were placed in the light compartment again and the latency time taken to enter the dark compartment was recorded for each mouse. If the mouse did not enter the dark compartment within 300 s, then we concluded that the mouse remembered the foot shock from the acquisition trial.

Y-Maze Task. Y-maze was used to measure the immediate spatial working memory, which is a form of short-term memory, and was carried out as previously described.[22] A Y-maze is a three-arm horizontal maze symmetrically separated by 120° angles from each other (length, 40 cm; width, 3 cm; and height, 12 cm). The floor and wall of the maze were constructed using dark polyvinyl plastic, as previously reported.[22] During the maze task, the mice were placed inside one arm, and the sequence (i.e., ACCABC, etc.) of arm entries were manually recorded for each mouse for 8 min. An actual alternation was defined as consecutive entries into all three arms (i.e., ABC, CAB, or BAC, but not BAB). Memory impairment was induced by intraperitoneal injection of scopolamine (0.9 mg/kg). To remove mouse odors, maze arms were cleaned between two consecutive tasks. Test agents. i.e., SE (100 and 200 mg/kg), SA or SB (10 mg/kg, p.o.), tacrine (10 mg/kg, p.o.), or vehicle (p.o.) were orally administered 1 h before the maze task. The maze task was carried out 30 min after treatment with scopolamine. The alternation percentage was calculated: alternation percentage = [(number of alternations)/(total arm entries −2)] × 100. The number of arm entries was served as the indicator of locomotor activity.

Morris Water Maze Task. Spatial memory and learning was studied with the Morris water maze task by using a circular pool (diameter, 90 cm; height, 45 cm), according to the method described by Lee et al.[22] First, the pool was filled with water (20 ± 1 °C) up to 30 cm depth, and nonfat milk (500 mL) was mixed with water. A white platform (diameter, 6 cm; height, 29 cm) was centered in one of four quadrants of the milk-filled pool (southwest area) and hidden 1 cm below the water surface. On the first day of the maze task, the mice were given swimming training for 60 s in the platform-free pool. Starting from the second day, the mice were given four swimming training trial sessions per day for four consecutive days. Escape latencies for each mouse were measured and recorded. For each mouse, this parameter was averaged for each trial session. Once the mouse located the platform, the mouse stayed on the platform for 10 s. If the mouse could not search the platform within 60 s, then the mouse was then placed on the platform for 10 s. During this period, a fixed platform was used. After each trial, the animals were taken to the cage and were dried under an infrared lamp. The trial time interval was 30 s. On the last day of training, the mice were underwent a probe trial session after the platform was removed, wherein they were allowed to swim for 60 s. The swimming time spent in platform quadrant section of the pool was recorded. SA or SB (10 mg/kg, *p.o.*), tacrine (10 mg/kg, *p.o.*), or vehicle (*p.o.*) was administered 1 h before the maze task was conducted at every consecutive day. Scopolamine (0.9 mg/kg)

was intraperitoneally administered 30 min after oral administrations of test agents.

Immunoblotting. Mice were sacrificed 30 min after the acquisition trial of the passive avoidance task (2 h after scopolamine treatment). The hippocampi were promptly excised and homogenized in 200 μL of ice-cold RIPA buffer containing a protease inhibitor cocktail. The homogenates were centrifuged for 15 min at 13 000*g*. The resulting supernatants were aliquoted into Eppendorf tubes and stored at −80 °C until required. The expression levels of BDNF, CREB, p-CREB, and β-actin were measured by immunoblotting according to the method of Lee et al.[22] The protein assay was performed using Bradford protein assay kit.

Ex vivo AChE Activity Assay. The mice were randomly divided into 4 groups (n = 4) and were orally administered vehicle (2% tween), SA (10 mg/kg), SB (10 mg/kg), and tacrine (10 mg/kg). The mice were sacrificed 60 min after each administration, and their brains were removed. Their hippocampi were dissected and homogenized in cold RIPA buffer. The homogenates were centrifuged at 10 000*g* for 10 min at 4 °C, and the resulting supernatants were used as enzyme sources. Their AChE activities were measured as triplicates. The protein amount was determined using Bradford protein assay kits (Bio-Rad, Hercules, CA, U.S.). AChE activity per protein amount of the homogenate supernatant (mg) was calculated.

Statistics. All experimental data are expressed as mean ± standard error of mean (SEM).

Distributions in the passive avoidance and Y-maze tasks were depicted by box-plots. A box-plot consists of a box and tails for each group. The horizontal line through the box depicts the median, and the top and bottom of the box mark the upper and lower quartiles, respectively. For passive avoidance task, the significance among data was analyzed by a Kruskal−Wallis nonparametric one-way analysis of variance (ANOVA) test. For the Y-maze, and Morris water maze tasks, the significance was analyzed by ANOVA followed by Student−Newman−Keuls test for multiple comparisons. Statistical significance was set at $p < 0.05$.

RESULTS

SE Protected Scopolamine-Induced Memory Impairment. Preliminary experiment indicated that SE potently prevented scopolamine-induced memory impairment in passive avoidance and Y-maze tasks. The performance of mice treated with SE (200 mg/kg, p.o.) and scopolamine in passive avoidance and Y-maze tasks was 43% (F = 11.97, $P < 0.05$) and 98% (F = 4.84, $P < 0.05$), respectively, of vehicle-treated normal control mice (Figure 2).

Therefore, to understand the possible role of soyasaponins in memory impairment, we isolated the two main soyasaponins SA and SB and identified them by FAB-MS and ^{1}H- and ^{13}C NMR. Isolated SA and SB exhibited soyasponin-specific seven angular methyl singlet signals [δ 0.70 (25-CH_3), 0.86 (26-CH_3), 0.96 (29-CH_3), 0.99 (28-CH_3), 1.23 (27-CH_3), 1.30 (30-CH_3), 1.45 (23-CH_3)] and [δ 0.67 (25-CH_3), 0.90 (26-CH_3), 1.23 (29-CH_3), 1.26 (28-CH_3), 1.33 (27-CH_3), 1.35 (30-CH_3), and 1.41 (23-CH_3)], respectively, in ^{1}H NMR and m/z 1436 $[M - H]^-$ and m/z 941 $[M + H]^+$, respectively, in FAB-MS.

SA and SB Prevented Scopolamine-Induced Memory Impairment. We investigated the preventive effects of SA and SB against scopolamine-induced memory impairment in mice in the passive avoidance task (Figure 3A,B). Both SA and SB significantly prevented scopolamine-induced memory impairment. SB protected memory impairment; however, the effect was more with SB than with SA. SA and SB at a dose of 10 mg/kg (p.o.) restored memory impairment to 86% (F = 85.33, $P <$ 0.05) and 97% (F = 68.10, $P < 0.05$) of untreated normal control mice, respectively. These effects are comparable to that of tacrine (10 mg/kg), a positive control, which restored the step-through latency to 91% of untreated normal control mice. However, no significant differences among the groups treated with SA (10 mg/kg), SB (10 mg/kg), and tacrine (10 mg/kg) were observed. During the acquisition trial, no latency differences were observed among test groups (Figure 3A,B). On the Y-maze task, SA and SB (10 mg/kg) restored spontaneous alteration, which was lowered by scopolamine (Figure 3C). Compared to SA, SB restored memory impairment more potently. SB (10 mg/kg, p.o.) significantly restored the lowered spontaneous alteration induced by scopolamine to 78% of that of untreated normal control mice (F = 35.57, $P <$ 0.05). However, no significant differences between those of SA and SB were observed.

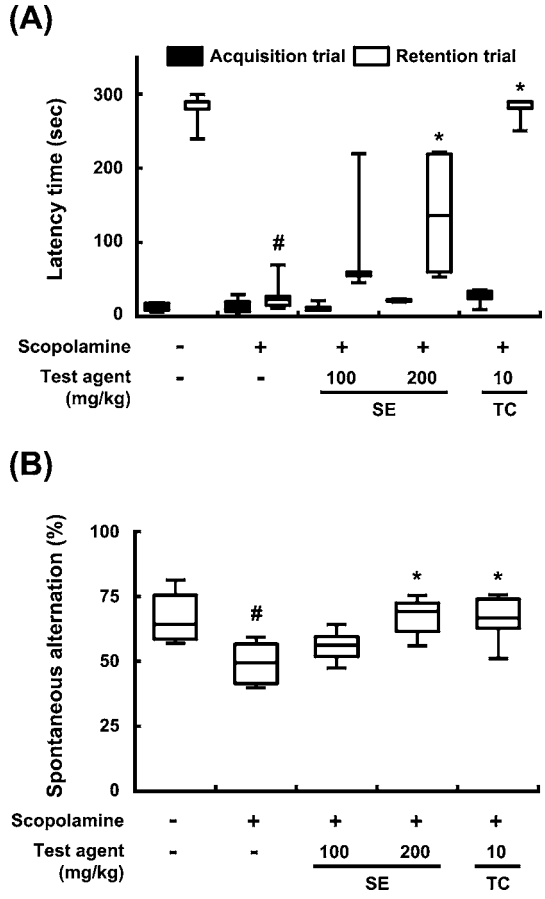

Figure 2. The protecting effect of SE against scopolamine-induced memory impairment in mice. (A) Effect of SE in passive avoidance task. (B) Effect of SE in Y-maze task. SE (100 or 200 mg/kg, p.o.), tacrine (TC, 10 mg/kg, p.o.) or vehicle (the same volume of 2% Tween 80) was administered to mice 1 h before treatment with scopolamine. Memory impairment was induced by scopolamine treatment (0.9 mg/kg i.p.). Normal control mice were treated with vehicle instead of scopolamine. Six different animals were used in each treatment group. Acquisition trials were carried out 30 min after a single scopolamine treatment. Test agents (NOR, none; SCO, scopolamine alone; SE100, 100 mg/kg SE with scopolamine; SE200, 200 mg/kg of SE with scopolamine; closed triangle, 10 mg/kg tacrine with scopolamine) was orally treated 1 h before maze task. Box-plots—To depict a distribution, a box-plot consists of a box and tails for each group. The horizontal line through the box depicts the median, and the top and bottom of the box mark the upper and lower quartiles. #Significantly different from normal mice ($P < 0.05$). *Significantly different from scopolamine-treated control ($P < 0.05$).

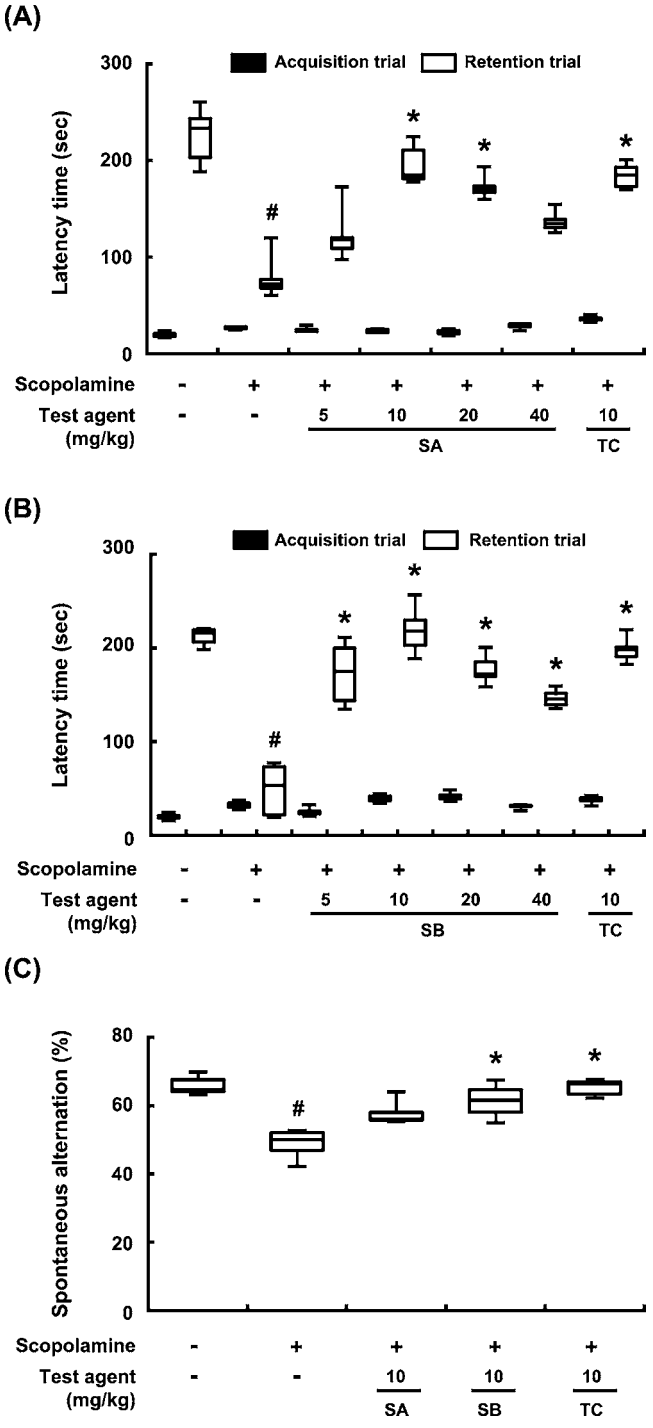

Figure 3. Effects of soyasaponins Ab (SA) and Bb (SB) on scopolamine-induced memory impairment in mice in the passive avoidance and Y-maze tasks. (A) Effect of SA in passive avoidance task. (B) Effect of SB in passive avoidance task. (C) Effects of SA and SB in Y-maze task. Soyasaponins (5, 10, 20, or 40 mg/kg, p.o.), tacrine (TC, 10 mg/kg, p.o.) or vehicle (the same volume of 2% Tween 80) was administered to mice 1 h before treatment with scopolamine. Memory impairment was induced by scopolamine treatment (0.9 mg/kg i.p.). Normal control mice were treated with vehicle instead of scopolamine. Six different animals were used in each treatment group. Acquisition trials were carried out 30 min after a single scopolamine treatment. The retention trials were carried out for 5 min, 24 h after the acquisition trials. Box plot details see Figure 2. #Significantly different from normal mice ($P < 0.05$). *Significantly different from scopolamine-treated control ($P < 0.05$).

We also investigated the effect of SA and SB (10 mg/kg, p.o.) on escape latencies in the Morris water maze task (Figure 4A). Escape latencies were prolonged by scopolamine treatment. SA significantly shortened the escape latencies on the fifth day ($F = 14.51$, $P < 0.05$). However, SB-treated mice showed

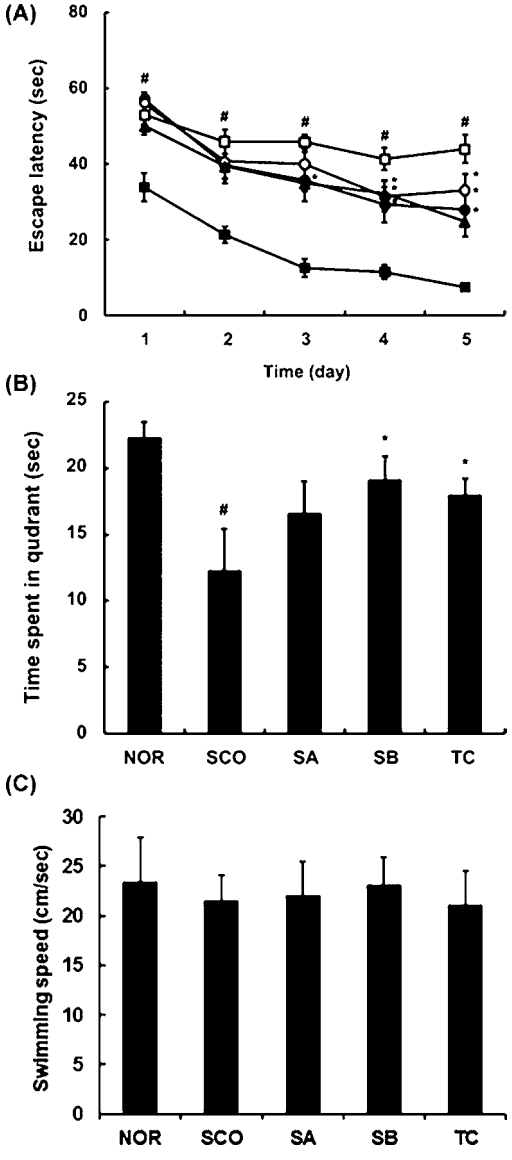

Figure 4. Effects of soyasaponins Ab (SA) and Bb (SB) on scopolamine-induced memory impairment in morris water maze tasks. (A) Effects in escape latencies during training trial sessions. (B) Effects in swimming times spent in target quadrant. (C) Effects in swimming speed. Soyasaponins (10 mg/kg, p.o.) or tacrine (TC, 10 mg/kg, p.o.) was given 1 h before the first trial session at every consecutive day. Memory impairment was induced with scopolamine (0.9 mg/kg, i.p.) at 30 min after treatment with each test agent. Normal group was treated with vehicle instead of scopolamine and test agents. The training trials for 5 days and the probe trial sessions in the last day were performed as described in the Materials and Methods. Open square, group treated with scopolamine; closed square, normal control group; open circle, group treated with scopolamine in the presence of SA; closed circle, group treated with scopolamine in the presence of SB; closed triangle, group treated with scopolamine in the presence of tacrine. Values are expressed as mean ± SEM ($n = 6$). #Significantly different from normal mice ($P < 0.05$). *Significantly different from scopolamine-treated control ($P < 0.05$).

dx.doi.org/10.1021/jf4046528 | J. Agric. Food Chem. 2014, 62, 2062−2068

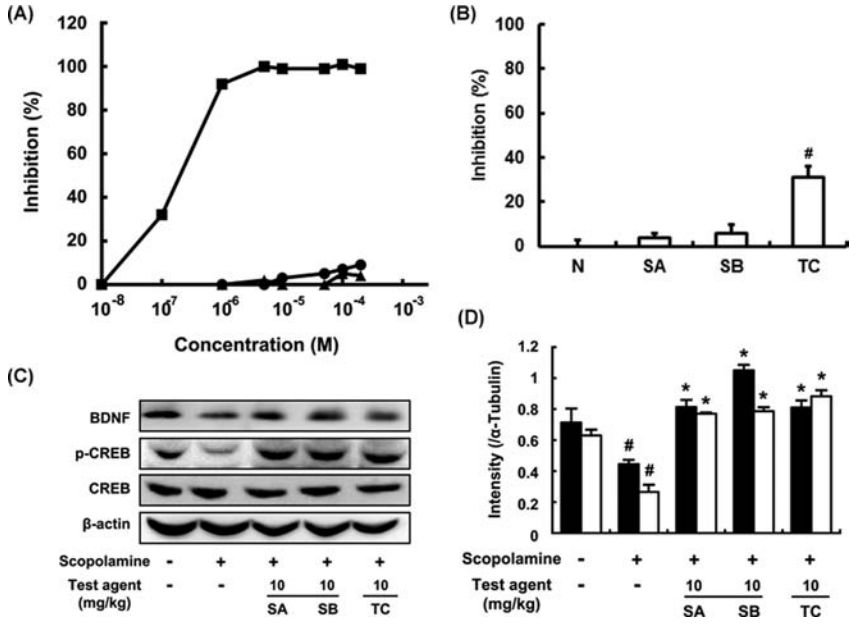

Figure 5. Effects of soyasaponins Ab (SA) and Bb (SB) on aceytlcholinesterase (AChE) activity in vitro and on BDNF expression and CREB phosphorylation in the hippocampus of scopolamine-treated mice. (A) Effect on AChE activity. The inhibitory potencies of SA (closed circle), SB (closed triangle), and tacrine (closed square) against AChE activity were measured in vitro by using electric eel type VI−S AChE. (B) Effect in hippocampal acetylcholinesterase activity. SA (10 mg/kg, p.o.), SB (10 mg/kg, p.o.) or tacrine (TC, 10 mg/kg, p.o.) was orally administered to mice only once and sacrificed 60 min after treatment with test agents and measured hippocampal AChE activity (n = 4). Each sample was measured as triplicates. (C) Effect on BDNF expression. SA (10 mg/kg, p.o.), SB (10 mg/kg, p.o.) or tacrine (TC, 10 mg/kg, p.o.) was orally administered to mice for once. Control group received an equal volume of vehicle for the same period. Memory impairment was induced by scopolamine treatment (0.9 mg/kg, i.p.) 1 h after the administration of each test agent. The normal control group was treated with vehicle instead of scopolamine and test agents. The expression levels of BDNF, CREB, and p-CREB were measured by immunoblotting. (D) Intensity graph showing the quantification of BDNF/β-actin and p-CREB/CREB expression levels measured by densitometry. β-actin was used as an internal control. Values are expressed as mean ± SEM (n = 3). #Significantly different from normal mice (P < 0.05). *Significantly different from scopolamine-treated control (P < 0.05).

significantly shorter latencies from the third day (F = 6.70, P < 0.05) to the fifth day (F = 14.51, P < 0.05). On the day after the last training session, the mean swimming time within the platform quadrant was significantly lower in mice treated with scopolamine alone than in those untreated normal control mice. Soyasaponins increased the swimming time within the platform quadrant (F = 21.52, P < 0.05) (Figure 4B). SB increased the target quadrant swim time more than SA. The effect of SB is comparable to that of tacrine in Morris water maze task. No significant differences in swimming speed within the target quadrant were observed between the groups treated with vehicle alone, scopolamine, and/or test agents (Figure 4C). This demonstrates that scopolamine and soyasaponins have no effect on general locomotor behavior.

Next, we measured the inhibitory effects of these soyasaponins on AChE activity in vitro. These soyasaponins did not inhibit AChE activity (IC_{50}, > 0.2 mM), however, tacrine potently inhibited it (IC_{50} = 0.12 μM) (Figure 5A). We also measured AChE activity in hippocampi of mice orally treated with SA, SB, or tacrine (10 mg/kg). Treatment with SA or SB did not inhibit hippocampal AChE activity, whereas treatment with tacrine inhibited it by 31% (Figure 5B). Next, we investigated the effect of SB on BDNF expression and CREB phosphorylation in the hippocampi of scopolamine-treated memory-impaired mice (Figure 5C,D). Scopolamine significantly reduced BDNF expressions and CREB phosphorylation. However, when SA or SB was administered in these mice, BDNF expression (F = 33.69; P < 0.05) and CREB phosphorylation (F = 91.62; P < 0.05) were significantly increased, as previously reported.[7,12] No significant difference in β-actin level was observed.

DISCUSSION

A decrease in cholinergic function, particularly within the basal forebrain, can decline memory and cognitive function with age.[5] A commercial anticholinergic drug, scopolamine, causes memory impairment in healthy young people, which is the equivalent of memory impairment observed in nondemented drug-free elderly people. Furthermore, several studies have reported that scopolamine is increasingly disruptive with age and declines cognitive function.[7] This is consistent with the previously reported hypothesis that the function of cholinergic neurons decreases with increasing age and dementia.[5,7] In the present study, SE and its constituents SA and SB significantly prevented scopolamine-induced memory impairment in mice in the passive avoidance, Y-maze and Morris water maze tasks. SB rescued memory impairment more potently than SA. However, both SA and SB did not inhibit AChE activity in vitro and ex vivo. Orally administered SA and SB are metabolized to their aglycones by intestinal microbiota of mouse and human feces.[19,24] Therefore, to elucidate the ability of SA, SB, and their metabolites soyasapogenols A and B, their AChE-inhibitory activities were measured. Soyasaponins and their metabolites did not inhibit AChE activity. These results suggest that the amelioration of memory impairment by SA and SB may not be dependent on AChE inhibition. When soyasaponins were orally administered to mice, these compounds might be metabolized to their aglycones soyasapogenols A and B, which are possibly the active

dx.doi.org/10.1021/jf4046528 | J. Agric. Food Chem. 2014, 62, 2062−2068

candidates responsible for preventing memory impairment. However, these metabolisms may not be quickly catalyzed by intestinal microbiota. These results suggest that the effect of SA and SB may be due to parental compounds rather than their metabolites by intestinal microbiota. Nevertheless, both SA and SB prevented scopolamine-induced memory impairment. The memory impairment-ameliorating effect of SB was more potent than that of SA in passive avoidance (5 mg/kg, p.o.) and Y-maze tasks (10 mg/kg, p.o.). However, the effects of SA and SB were not significantly different. Although the AChE-inhibitory effects of SA and SB may be different between in vitro and in vivo studies, these soyasaponins may ameliorate scopolamine-induced memory impairment in mice without the inhibiton of acetylcholinesterase. Furthermore, in the mouse hippocampus, SA and SB potently restored scopolamine-mediated reduced expression of BDNF. BDNF influences neuronal synaptic plasticity by depolarizing neurons as rapidly as glutamate does by activating tyrosine kinase receptors,[25] enhancing glutamatergic synaptic transmission,[26] increasing the *N*-methyl-D-aspartate receptor subunit phosphorylation in the hippocampus, and facilitating hippocampal LTP.[27] Notably, the expression of BDNF in the entorhinal cortex and hippocampus is lower in patients with AD than in healthy male.[8,28] CREB may be the most important transcription factor regulating BDNF expression.[29] Being a cellular transcription factor, CREB regulates the expression of BDNF, tyrosine hydroxylase, and many neuropeptides.[29−31] Several studies have suggested that BDNF and CREB may possess therapeutic potential in patients with AD.[22,32,33] In the present study, we demonstrated that scopolamine inhibited CREB phosphorylation, as previously reported.[22,33] Orally administered SA and SB potently restored scopolamine-mediated reduction of CREB phosphorylation. Overall, compared to SA, SB prevented scopolamine-induced memory impairment more potently. These studies suggest that soyasaponins restore the reduction of BDNF expression and CREB phosphorylation caused by scopolamine and reverse neuronal synaptic plasticity mediated by BDNF, which binds cell surface receptors such as TrkB and low-affinity nerve growth factor receptor. On the basis of these findings, we suggest that soybean, particularly soyasaponins, ameliorates scopolamine-induced memory impairment by increasing BDNF expression and CREB activation.

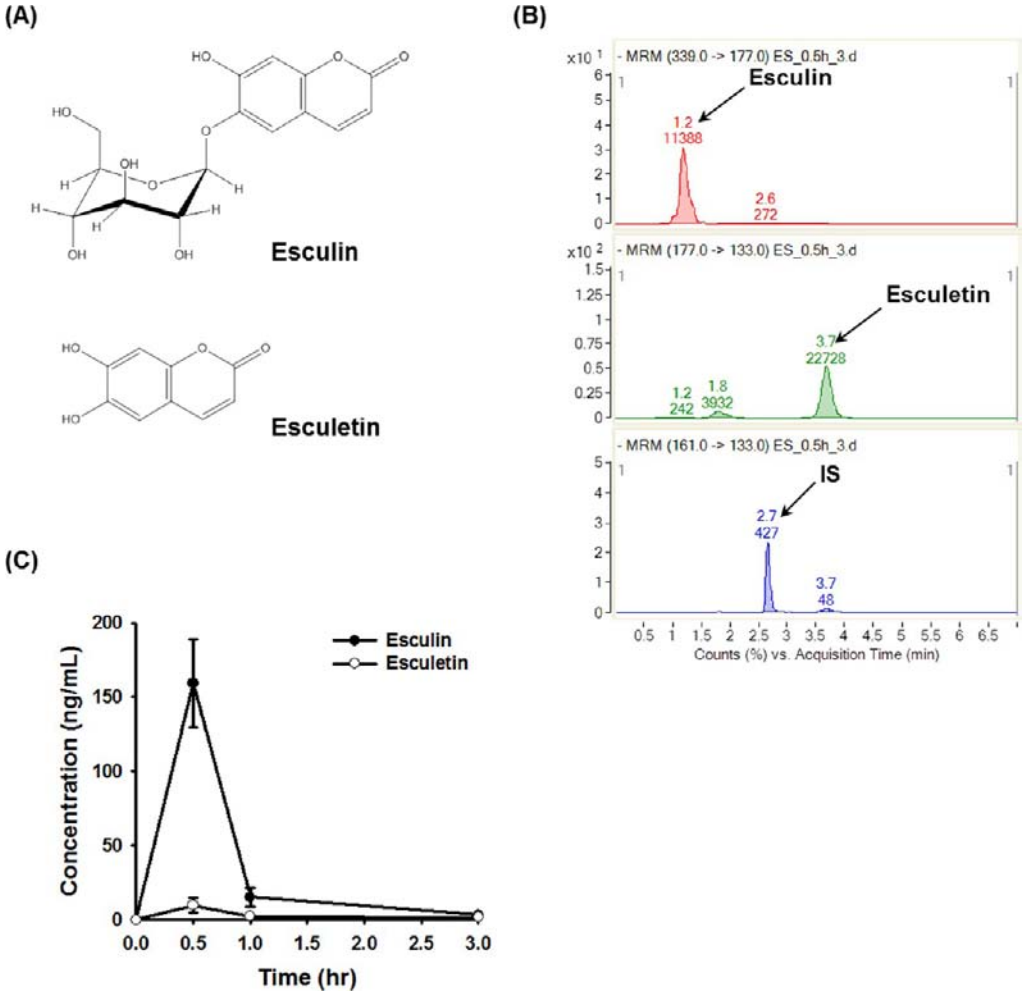

Figure 1. Blood levels of esculin and esculetin after oral administration of esculin in mice. (A) Structures of esculin and esculetin. (B) Representative MRM chromatograms for plasma samples collected after administration of esculin. (C) Blood concentrations of esculin and esculetin in mice.

renal damage are limited. To address this shortcoming, we investigated the effect of esculin, a major active component of ash bark, on glucose metabolism, oxidative stress, and inflammation in diabetic-damaged kidney to identify its effects and mechanism of action in diabetes. Furthermore, the pharmacokinetics of esculin and its metabolite esculetin were simultaneously examined in plasma samples from mice by liquid chromatography-electrospray ionization-tandem mass spectrometry.

MATERIALS AND METHODS

Chemicals. Streptozotocin (STZ), esculin, and esculetin (purity 98−100%) were purchased from Sigma Aldrich (Seoul, South Korea). Antibodies for Akt, phosphor-Ser473 Akt (pS473-Akt), insulin receptor β (IRβ), phosphor-IRβ at Tyr1150/1151 (pY1150/51-IR), glycogen synthase kinase 3β (Gsk3β), phosphor-Ser9-Gsk3β (pS9-Gsk3β), glyceraldehyde 3-phosphate dehydrogenase (GAPDH), cleaved caspase-3, β-actin, and horseradish peroxidase (HRP) conjugated antirabbit antibodies were purchased from Cell Signaling (Boston, MA, USA). Other chemicals and reagents used were of high quality and obtained from commercial sources.

Cell Culture. C2C12 mouse myoblast cell line was obtained from ATCC and cultured in Dulbecco's modified Eagle's medium (DMEM; Invitrogen, Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (FBS; HyClone Laboratories, Logan, UT, USA) and 1% penicillin/streptomycin (Invitrogen) at 37 °C with 5% CO_2 in air.

Myotube Formation and Immunoblotting. C2C12 myoblast were cultured in DMEM until 90% of confluence. Cells were differentiated into myotubes with DMEM containing 2% horse serum for 4 days and then incubated for 16 h in DMEM containing 2% BSA and 10% FBS in the absence or presence of esculin. Subsequently, the esculin-treated cells were stimulated with 100 nM insulin for 10 min. After stimulation, cells were washed twice with PBS and harvested. For Western blotting, antibodies for Akt, phosphor-Ser473 Akt (pS473-Akt), insulin receptor β (IRβ), phosphor- IRβ Tyr1135/1136 IGF-1 Rβ /Tyr1150/1151, Gsk3β phosphor-Ser9-Gsk3β, and GAPDH were used.

2-[*N*-(7-Nitrobenz-2-oxa-1,3-diazol-4-yl)amino]-2-deoxy-D-glucose (2-NBDG) Glucose Uptake Assay. The myotubes, which were obtained from the above procedures, were stimulated with 100 nM insulin for 1 h. After insulin stimulation, the myotubes were incubated with 50 μM 2-NBDG (Invitrogen) for 15 min and then washed with PBS three times to remove free 2-NBDG. The fluorescence intensity of cells containing 2-NBDG was measured on the Infinite M1000 microplate reader (TECKAN) with excitation at 485 nm and emission at 535 nm.

Animal Experiments. The Guidelines for Animal Experimentation, approved by the Korea Institute of Science and Technology, were followed in these experiments. Male ICR mice weighing 30−35 g were used for evaluating the protection of the esculin against STZ-induced diabetic renal damage. The mice were housed under temperature (23 ± 2 °C) and humidity (55 ± 5%) conditions with a standard light (12 h light/dark). The mice were given free access to water and a normal diet (38057, Agribrands Purina Korea, Seongnam, Gyeonggi, Korea)

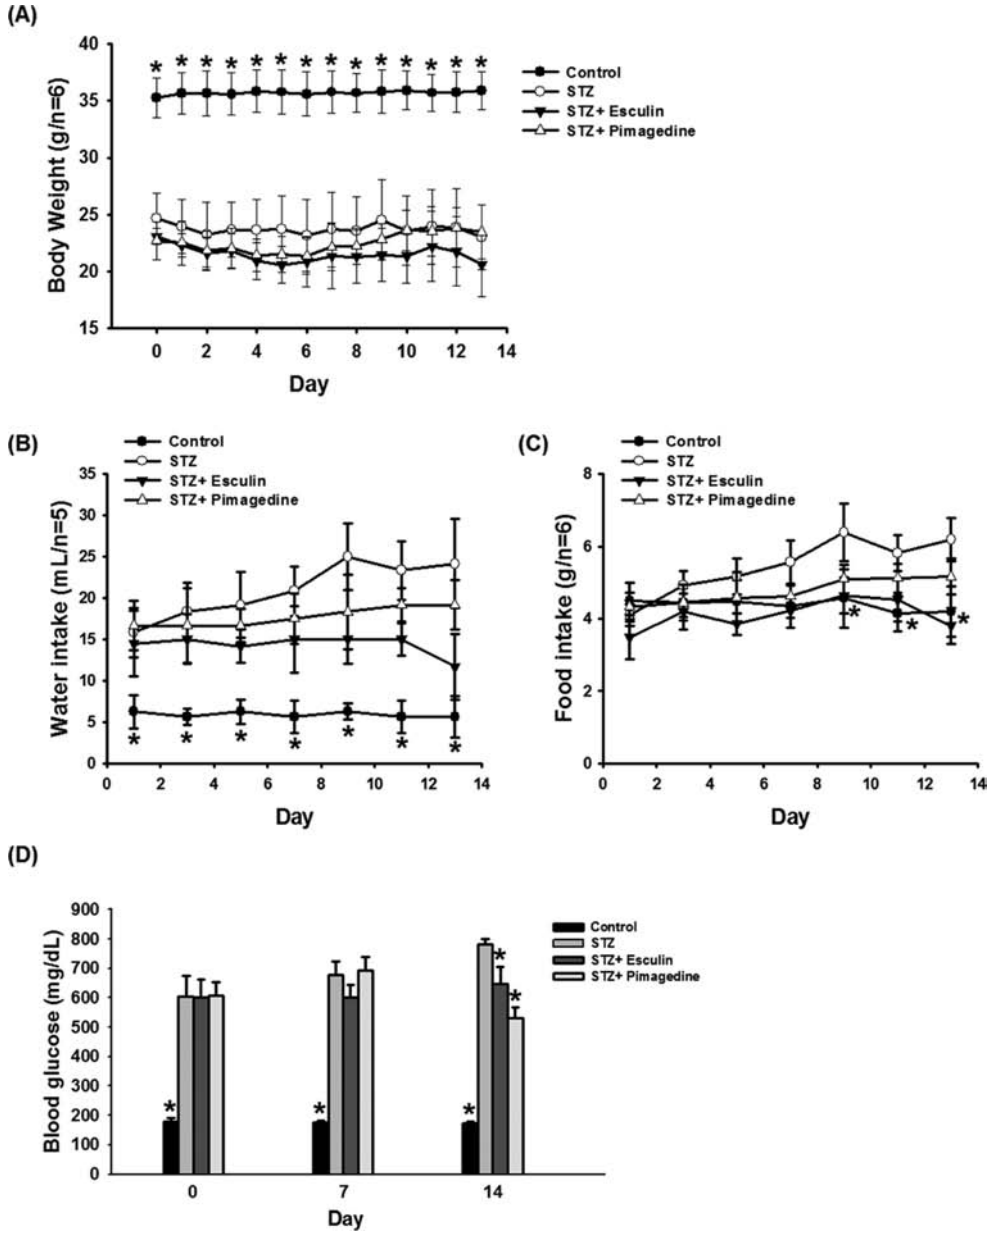

Figure 2. Effects of esculin on physiological parameters in the STZ-induced diabetes model. (A) Changes in body weight. (B) Changes in water intake. (C) Changes in food intake. (D) Changes in blood glucose levels. $p < 0.05$ compared to the STZ-treated control value.

containing 10 kcal % fat for a period of 1 week after arrival. After several days of adaptation, STZ dissolved in citrate buffer (10 mM, pH 4.5) was injected intraperitoneally at a dose of 200 mg/kg body weight following overnight fasting. The mice underwent a sham injection of citrate buffer without STZ and were also used as normal group ($n = 5$). The blood glucose level was determined, and the body weight was measured after 7 days of STZ injection, and to avoid any intergroup differences in these indices, the diabetic mice were divided into three experimental groups: group 1, diabetic mice received water (diabetic control, $n = 6$); groups 2, diabetic mice received 20 mg/kg body weight/day of esculin orally via gavage once a day (diabetic + esculin, $n = 6$); and group 3, diabetic mice received 20 mg/kg body weight/day of pimagedine orally via gavage once a day (diabetic + pimagedine, $n = 6$). The 20 mg/kg of esculin dosage was chosen according to the literature[18] and preliminary experiments. The mice were sacrificed 14 days after sample administration under light ether anesthesia. Blood samples were collected from abdominal aorta, and the serum was separated immediately from the blood samples by centrifugation. Kidneys and livers were removed, quickly frozen, and kept at −80 °C until analysis. All preparations and analyses of various parameters were performed simultaneously under similar experimental conditions to avoid any day to day variations.

Another abbreviated experiment to compare the blood levels of esculin and esculetin at three selected time points (0.5, 1, and 3 h) in mice ($n = 4$) was also conducted. Blood samples were collected from abdominal aorta under light ether anesthesia at 0.5, 1, and 3 h after esculin oral administration (20 mg/kg). The mice were sacrificed in each time point. About 500 μL blood was drawn and collected in a heparin-coated tube, and plasma was obtained following rapid centrifugation and immediately frozen at −80 °C until analysis.

LC/MS/MS Analyses for Esculin and Esculetin in Blood. Plasma samples were analyzed for esculin and esculetin using the LC/MS/MS method reported previously.[19] The LC/MS/MS system consisted of an Agilent 1260 Infinity high-performance liquid chromatography (HPLC) system with an Agilent 6460 triple-quadrupole mass spectrometer (Agilent Technologies, Palo Alto, CA) equipped with a turbo ion spray source. Chromatographic separation was achieved with a BDS Hypersil C_{18} column (50 mm

dx.doi.org/10.1021/jf403840c | J. Agric. Food Chem. 2014, 62, 2069−2076

×2.1 mm ID, 5 μL, Thermo Fisher Scientific Inc., Waltham, MA), and oven temperature was maintained at 40 °C. The mobile phase consisted of 0.1% formic acid (solvent A) and 90% acetonitrile with 0.1% formic acid (solvent B). A gradient program was used for HPLC separation, with a flow rate of 0.25 mL/min the gradient program began with 10% B, which was increased to 90% in 1 min, was maintained to 4 min, and followed by 4 min re-equilibration. Electrospray ionization was performed in negative ion mode. The precursor−product ion pairs monitored in multiple reaction monitoring (MRM) detection were 339→177 for esculin, 177→133 for esculetin, and 161→133 for 7-OH-coumarin (IS). The representative MRM chromatograms are shown in Figure 1B. Calibration curves for analytes were obtained using 9 points in the range 1−500 ng/mL. Calibration curves were generated by plotting the peak area ratio for esculin or esculetin to IS versus the concentration of esculin or esculetin in the standard-spiked plasma by least-squares linear regression. The calibration curve equations are $y = 0.1215x - 0.0368$ ($r^2 = 0.999$) for esculin and $y = 0.0747x - 0.0058$ ($r^2 = 0.999$) for esculetin.

Histological Examination. After fixation of the kidneys with 10% formalin, renal tissues were sectioned and stained with hematoxylin and eosin (HE) reagents for histological examination. Tubular damage in HE-stained sections was examined under the microscope and scored based on the percentage of cortical tubules showing epithelial necrosis: 0, normal; 1, <10%; 2, 10−25%; 3, 26−75%; 4, >75%. Tubular necrosis was defined as tubular epithelial degeneration, interstitial inflammation, and archiectural abnormality as described previously.[20] The morphometric examination was performed in a blinded manner by two independent investigators.

Western Blot Analysis. Frozen kidney tissues were homogenized with a lysis buffer (contents of 1% NP-40, 20 mM Tris-HCl, 150 mM NaCl, 1 mM Na_2EDTA, 1 mM EGTA, 1% sodium deoxycholate, and 100 mM PMSF) and centrifuged at 13 000 rpm at 4 °C for 20 min to obtain the cellular proteins in the supernatant. Differential protein expression patterns were assessed by Western blot following protein quantification by the Lowry and Bradford methods. Equal amounts of proteins from each sample were resolved by SDS-PAGE, transferred to polyvinylidene fluoride (PVDF) membranes for 1 h at semidry, and blocked in blocking buffer for 1 h at room temperature. PVDF membranes were incubated with primary antibody against cleaved caspase-3 (1:1000 dilution), β-actin (1:1000 dilution) overnight at 4 °C, washed three times for 5 min to wash buffer, incubated with HRP-conjugated secondary antibody (1:2000 dilution, antirabbit) for 1 h at room temperature, washed three times, and then detected with ECL solution.

Gene Expression Analysis. Total RNA was isolated from tissue using the TRIzol reagent (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. The RNA concentration of each sample was determined by spectrophotometry at 260 nm; the integrity of each RNA sample was evaluated using the Agilent 2100 BioAnalyzer (Agilent Technologies, SantaClara, CA). cDNA synthesis was performed using 1 μg of total RNA in 20 μL with random primers and Superscript II reverse transcriptase. Quantitative real-time PCR (Q-PCR) analyses were performed with SYBR green fluorescent dye using the 7500 Real-Time PCR System (Applied Biosystem, Foster City, CA). Data analyses were performed using 7500 System SDS software version 1.3.1 (Applied Biosystem). Primer sets used in this study were as follows: glucose 6-phosphatase (G6 Pase), forward 5′-ATGACTTTGGGATCCAGTCG-3′ and reverse 5′- TGGAACCA-GATGGGAAAGAG-3′ and glyceraldehyde-3-phosphate dehydrogenase (GAPDH), forward 5′-TTGTTGCCATCAACGACCCC-3′ and reverse 5′- GCCGTTGAATTTGCCGTGAG-3′.

Statistical Analysis. Statistical significance was determined through analysis of variance (ANOVA) followed by a multiple comparison test with a Bonferroni adjustment. *P* values of less than 0.05 were considered statistically significant.

RESULTS

Blood Levels of Esculin and Esculetin after Oral Administration of Esculin in Mice. After oral administration of esculin to mice (20 mg/kg body weight), there was a rapid and short-lasting increase in plasma esculin and esculetin levels. The concentrations of esculin and esculetin in blood were 159.5 ± 29.8 and 9.7 ± 4.9 ng/mL at 30 min, respectively (Figure 1C). Although a large portion of esculin was detected in the blood, esculetin, which is a deglycosylated metabolite of esculin, was also detected (Figure 1C).

Antidiabetic Effect and Mechanism of Esculin Against STZ-Induced Type 1 Diabetes in Mice. Figure 2 shows the effects of esculin on the changes in physico-metabolic symptoms with diabetes over the 14-day experimental period. The body weight of mice after STZ and STZ + esculin or pimagedine was markedly reduced compared to that of control mice (Figure 2A). In comparison, the intake of water and food were significantly increased in the STZ-treated mice (Figure 2B and 2C). Although no significant amelioration was evident, oral administration of esculin or pimagedine at a dose of 20 mg/kg for 14 days attenuated the diabetes-induced physiological abnormalities. The blood glucose level of diabetic mice was markedly higher than that of normal mice, and it was continuously increased during the experimental period. The elevated glucose level was significantly reduced in diabetic mice given 20 mg/kg esculin or pimagedine (Figure 2D).

As shown in Figure 3A, the plasma alanine aminotransferase (ALT) levels of diabetic mice were significantly increased more than those of normal control mice. However, treatment with esculin led to a significant decrease in plasma ALT levels (Figure 3A). The expression level of G6 Pase gene expression in the liver was significantly increased in diabetic animals. The elevated expression level of G6 Pase was markedly reduced in esculin-treated diabetic mice (Figure 3B), supporting the antidiabetic effects of esculin; however, the effect of esculin was weaker than that of pimagedine (Figure 3B).

Effect of Esculin on Insulin Sensitivity. To ascertain the positive effects of esculin on insulin sensitivity, we first examined glucose uptake in C2C12 myotubes under normal conditions. As shown in Figure 4A, glucose uptake in C2C12 myotubes in the absence or presence of insulin was significantly enhanced by esculin treatment under normal conditions. Correspondingly, esculin (50 μM) application also enhanced the insulin-evoked phosphorylation of IR, Akt, and GSK-3β under normal conditions, indicating a potential for improvement of insulin sensitivity (Figure 4B).

Renoprotective Effect of Esculin Against STZ-Induced Diabetic Renal Damage in Mice. The elevated serum creatinine level of STZ-treated mice was significantly reduced by esculin (Figure 5A). HE staining was performed on renal sections to measure tubular damage. As shown in the representative pictures of renal sections, severe tubulointerstitial injuries including tubular epithelial cell detachments, cystic dilatation of tubules, and inflammatory cell infiltration occurred in kidneys of STZ-treated diabetic mice (Figure 5B). However, the increased tubular damage in STZ-treated mice was reduced by treatment with esculin (Figure 5B). Figure 6A shows the effect of esculin on the cleaved caspase-3 protein expression in STZ-treated mice kidneys. The cleaved caspase-3 protein expression was significantly increased after STZ injection, and cotreatment with esculin afforded significant renoprotection (Figure 6B).

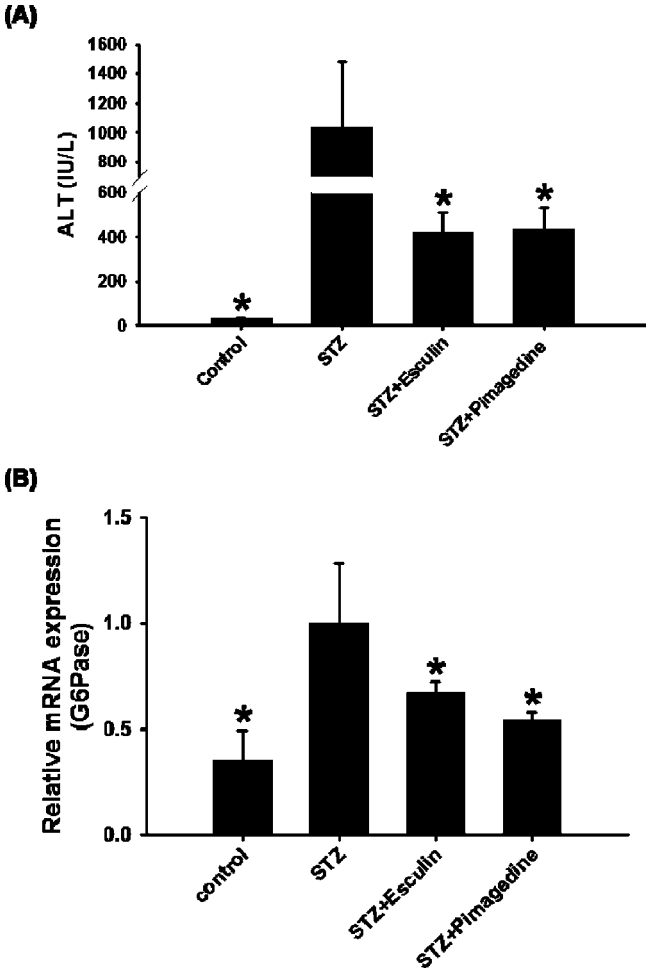

Figure 3. Effects of esculin on serum ALT and hepatic glucose 6-phosphatase levels in the STZ-induced diabetes model. (A) Serum ALT levels. (B) Hepatic glucose 6-phosphatase levels. $p < 0.05$ compared to the STZ-treated control value.

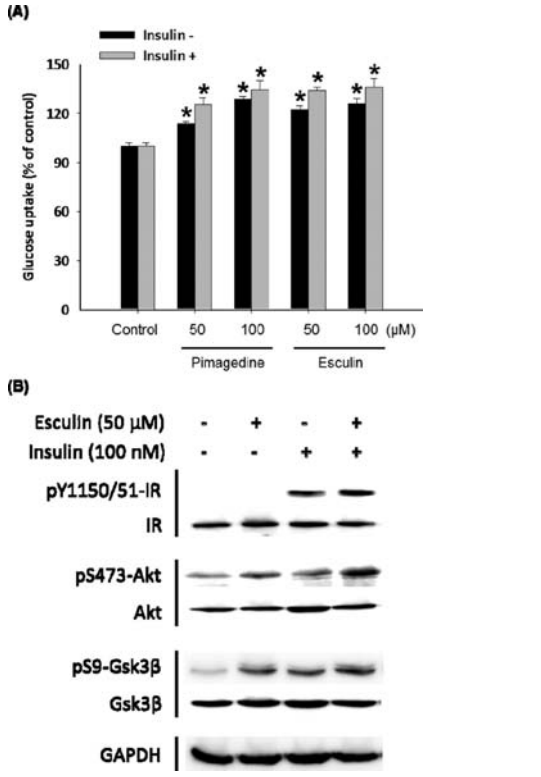

Figure 4. Effects of esculin on glucose uptake and insulin sensitivity in C2C12 myotubes. (A) Basal and insulin-stimulated glucose uptake in pimagedine and esculin-treated C2C12 myotubes under normal conditions. (B) Level of phosphorylation of IR, Akt, and GSK-3β in esculin-treated C2C12 myotubes under normal conditions. Protein levels were analyzed by Western blot. $p < 0.05$ compared to the control value.

DISCUSSION

Many diabetic patients choose complementary and alternative therapies along with mainstream antidiabetic drugs, which has increased demand for alternative therapies for diabetes.[21] In the present study, we investigated the antidiabetic effect and mechanism of esculin, an active ingredient of ash bark, on kidney damage caused by hyperglycemia, oxidative stress, and inflammation to evaluate its possible use in treatment of diabetic renal damage.

To evaluate the effect of esculin on diabetic renal damage, we administered esculin to STZ-induced diabetic mice and monitored plasma glucose levels in each animals. After oral administration of esculin to mice, there was a rapid and short-lasting increase in plasma esculin and esculetin levels. Over the experimental period, the levels of water and food intake were significantly elevated in diabetic mice, indicating the changes in physiological changes that result from the increased blood glucose levels. STZ enters the β cell via a glucose transporter (GLUT2) and liberates toxic amounts of free radicals that cause damage to the DNA. Oxidative inflammation is implicated in pancreatic β-cell injury, leading to development of diabetes mellitus.[22] The pancreatic islet size and blood insulin levels of diabetic mice was markedly lowered than those of normal control mice, but there were no significant ameliorations in islet size or blood insulin levels after esculin treatments (Supplemental Figure 1, Supporting Information). Therefore, the beneficial effect of esculin on blood glucose might be related to other factors than pancreatic damage by STZ. Because hepatic gluconeogenesis gene expression is markedly increased in diabetic animals and contributes to hyperglycemia, expression of G6 Pase, one of the key enzymes in gluconeogenesis,[23] was measured in the liver tissue of diabetic mice. The expression level of G6 Pase was significantly reduced in esculin-treated mice, supporting the antidiabetic effect of esculin.

The tyrosine phosphorylation of IRβ subunit is necessary for insulin signal transduction into the cells. In particular, phosphorylation of tyrosine 1146, 1150, and 1151 is crucial for activation of the IR which initiates further downstream signaling events.[24] Akt regulates glycogen synthesis through phosphorylation within the carboxy terminus at Ser473 and inactivation of GSK-3α and β, which was initially identified as an enzyme that regulates glycogen synthesis in response to insulin.[25] In the present study, esculin increased the uptake of glucose and induced the insulin-evoked phosphorylation of IRβ, Akt, and glycogen synthase kinase 3β in C2C12 myotubes, indicating a potential for improvement of insulin sensitivity.

Hyperglycemia-induced abnormal production of ROS has been implicated in the etiology of diabetic nephropathy, with ROS having critical roles in the development and progression of kidney damage.[26−28] In patients with diabetes and/or renal failure, the level of blood creatinine, which is an effective index for expressing the glomerular filtration rate, increases

dx.doi.org/10.1021/jf403840c | J. Agric. Food Chem. 2014, 62, 2069−2076

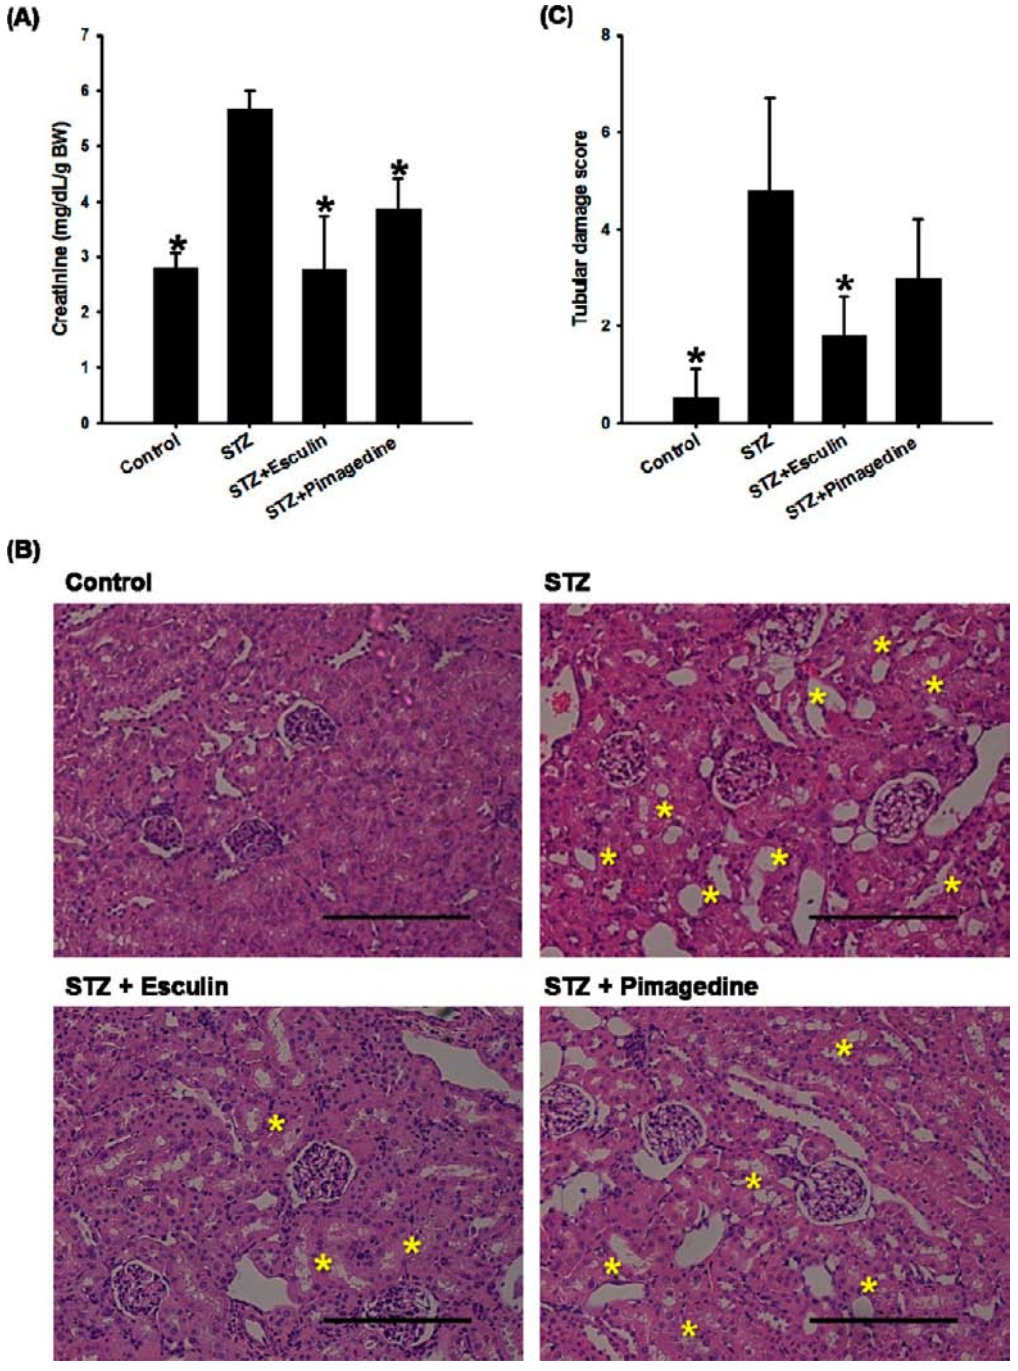

Figure 5. Effects of esculin on renal function and histopathological changes in the STZ-induced diabetes model. (A) Serum creatinine levels. (B) HE staining of representative renal section. (C) Tubular damage score. Yellow asterisks indicate tubular damage. $p < 0.05$ compared to the STZ-treated control value.

exponentially and eventually causes nephritic syndrome.[29] However, the present investigation showed that administration of esculin or pimagedine for 14 days significantly reduced the levels of blood creatinine. Therefore, the diabetic renal dysfunctions of diabetic mice were improved by the administration of esculin.

STZ activates various pro-inflammatory and apoptotic molecules including the caspase-3 and Bax systems.[30−32] Synthetic or naturally occurring caspase inhibitors have the potential to minimize uncontrolled apoptosis in STZ-induced nephropathy.[31,33] For example, the antioxidant compound alpha-lipoic acid can abrogate the oxidative stress induced in mesangial cells and rat kidney by elevated glucose levels.[30] Our results also showed significant increases in cleaved caspase-3 in the kidneys of diabetic mice; the elevated level was significantly reduced after esculin administration. These results imply that esculin may alleviate oxidative stress by preventing caspase-3 activation and related inflammation in the kidney.

Clinical evidence has suggested that the appropriate use of nutraceuticals or herbal medicines can prevent or ameliorate development of diabetic complications.[34,35] However, these medicines usually have an insufficient scientific basis and the exact mechanisms behind their beneficial effects are unknown. This study demonstrates that esculin ameliorates diabetes-

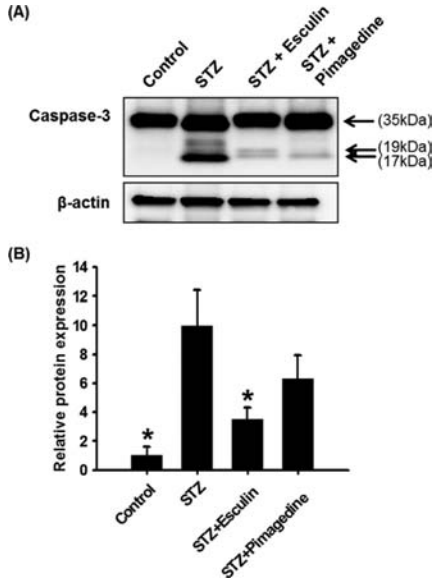

Figure 6. Effects of esculin on renal caspase-3 activation in the STZ-induced diabetes model. (A) Cleaved caspase-3 protein expression and (B) its quantitative data for Western blot analysis of renal cortex tissues. $p < 0.05$ compared to the STZ-treated control value.

induced renal dysfunction by reducing the activation of caspase-3 in the kidney. The current experimental results provide therapeutic evidence of the renoprotective effects of esculin both in vitro and in vivo.

underutilized palm heart species and support the claims of locals with regard to their health potential in treating diabetes, these two vegetables were investigated using related in vitro assays.

MATERIALS AND METHODS

Preparation of Samples. Lalis (*P. geminiflora*) and pantu (*E. insignis*) were purchased at Satok market in Kuching, Sarawak, Malaysia. About 15 kg of each sample was collected and stored in a freezer (−20 °C) and then brought back to the laboratory by flight within 3 days. Voucher specimens of the samples, lalis (SK2276/13) and pantu (SK2277/13), were deposited at the Biodiversity Unit, Bioscience Institute, Universiti Putra Malaysia, Malaysia. The peels of sample were removed, and edible parts were cleaned and chopped into small pieces. Samples were subjected to lyophilization for 72 h using a benchtop freeze-dryer (Virtis, Gardiner, NY, USA). Subsequently, the dried vegetables were ground into fine particles and stored at −40 °C.

Proximate Analyses. The moisture content of the studied vegetables was evaluated through a direct drying method (AOAC method 964.22) using a convection oven (Memmert Universal, Schwabach, Germany). Ash content was measured using a dry ashing method (AOAC method 923.03) whereby the samples were incinerated at 550 °C in a furnace (Furnace 62700, Barnstead/Thermolyne, Dubuque, IA, USA). Lipid content was determined using the Soxhlet method (AOAC method 920.39C), and protein content (N × 6.25) was measured according to the Kjeldahl method (AOAC method 955.04) by Kjeltec instrument (Kjeltec 2200, Foss, Höganäs, Sweden). The above analyses followed AOAC methods.[9] Total carbohydrate was determined using a Clegg anthrone method.[10]

Total (TDF) and insoluble dietary fiber (IDF) contents were measured using a gravimetric method.[11] Dietary fiber analyses were carried out using a Fibertec system (Fibertec System E 1023 filtration module, Sweden). Result was obtained after subtracting the protein and ash contents of residue. Soluble dietary fiber (SDF) was calculated as TDF − IDF value.

Mineral Analysis. The resulting ash sample obtained from the dry-ashing method was dissolved in 100 mL of 1 N hydrochloric acid solution. Subsequently, the ash solution was used in determination of the mineral contents. Minerals (sodium, potassium, calcium, magnesium, iron, zinc, phosphorus, manganese, and copper) were determined using an inductively coupled plasma optical emission spectrometry (ICP-OES) (ICP-OES, PerkinElmer DV2000, Boston, MA, USA) method.[12]

Sample Extraction. The extraction method was according to Liu et al.[13] with slight modification. Four grams of powder extract was mixed with 100 mL of 70% ethanol containing 1.2 M HCl (ratio of 1:25, g/v) and gently shaken at room temperature using an incubator shaker (Heidolph Instruments Incubator1000, Schwabach, Germany) set at 200 rpm for 5 h. After that, sample extracts were filtered through Whatman paper no. 1, and the filtrate was used for total phenolic and flavonoid content determination. The remaining extract was evaporated using a rotary evaporator (Buchi Rotavapor R-200, Essen, Germany) to remove the solvent and then lyophilized. The yield of extracts was subjected to antioxidant and antidiabetic in vitro assays.

Total Phenolic and Flavonoid Contents. Total phenolic content (TPC) of studied samples was determined according to method of Velioglu et al.[14] Results were generated from the standard calibration curve of gallic acid (20−100 μg/mL). Total flavonoid content (TFC) of studied samples was evaluated by an aluminum chloride colorimetric assay[15] with a slight modification. A standard calibration curve was generated using rutin (0.01−0.08 μg/mL).

Phenolic Compounds Analysis. Sample extract was prepared according to a method described by Liu et al.[16] with modifications. Quantification of phenolics in the studied vegetable extracts was performed using a HPLC system consisting of an Agilent 1100 series liquid chromatographic system equipped with an Agilent 1100 series diode array detector (DAD) (Agilent Technologies, Santa Clara, CA, USA) as described by He and Xia.[17] Separation of compounds was implemented using an eclipse XDB-C18 column (250 mm × 4.6 mm i.d.) (Hewlett-Packard, Palo Alto, CA, USA). The mobile phases consisted of 0.5% acetic acid (v/v) (A) and methanol (B). The applied gradient elution composition was a linear increase to 90% B in 20 min, then isocratic for 5 min, and returned to the initial condition in 5 min. Run time and column temperature were set at 30 min and 30 °C, respectively. Flow rate was 0.6 mL/min, and injection volume was 20 μL. The wavelength was set at 280 nm. The compounds in extracts were identified by comparison of their retention times and UV−vis absorption spectra with authentic standards and further confirmed by spiking of extract with authentic standards. External standards with different concentrations (20−100 μg/mL) diluted in ethanol were performed to determine the quantity of identified compounds. This linearity of detector response was assessed using five different concentrations, with three injections for all concentrations. A linear relationship was found between peak area and concentration (20−100 μg/mL). The correlation coefficient ranges from $r = 0.985$ to $r = 0.998$.

After completion of HPLC analysis, the liquid chromatography electrospray ionization mass spectrometry (LC-ESI-MS) analysis was conducted using an Applied TSQ Quantum Ultra-LCMS (Thermo Fisher, San Diego, CA, USA) to check the molecular mass of detected compounds in the HPLC chromatogram. A reversed-phase Lichrospher C18 column (250 mm × 4 mm, i.d., 5 μm; Merck, Damstadt, Germany) was used. Both positive and negative ion modes were used, and optimum resolution used was 3000 Da. The spray voltage was maintained at 3.5 kV. The sheath/auxiliary/sweep gas was 99% pure. The sheath and auxiliary gas pressures were set at 30 and 5 psi, respectively. The capillary temperature was 270 °C. The flush speed was 100 μL/s, and the injection volume was 10 μL. Samples were run using a gradient elution system as described by Hassan et al.[18] Continuous full mass spectral data were achieved by scanning from m/z 100 to 800. Determination of phenolic compounds was carried out by comparing the retention times, UV−vis absorption spectra, and reference standards available.

In Vitro Antioxidant Capacities. *Ferric Reducing Antioxidant Power (FRAP) Assay.* The ability of extract to convert Fe^{3+}/ferricyanide complex to Fe^{2+} ions was assessed on the basis of the method of Benzie and Strain,[19] with some modifications. Concentration of samples was at 0.2 mg/mL. A preliminary test had been carried out to determine the concentration of samples that gave readings within the standard curve range.

Oxygen Radical Absorbance Capacity (ORAC) Assay. The ORAC assay[20] was based on the inhibition of peroxyl radical-induced oxidation initiated by thermal decomposition of 2,2′-azobis(2-methylpropionamidine) dihydrochloride (AAPH). Different dilutions of Trolox (12.5−200 μM) and sample extracts were prepared in phosphate buffer (10 mM, pH 7.4). A concentration of samples was at 0.5 mg/mL. A preliminary test was carried out to determine the concentration of samples that gave readings within the range of Trolox standard curve. Briefly, 10 nM fluorescein (150 μL) was added into a black 96-well plate (Nunc, Roskilde, Denmark) and followed by 25 μL of Trolox, sample, or blank (phosphate buffer). The plate was covered and incubated for 10 min at 37 °C. After incubation, fluorescence measurements (excitation wavelength, 485 nm; emission wavelength, 520 nm) were taken every 90 s to determine the background signal. The fluorescence measurement was performed using microplate reader FLUOstar Omega (BMG LABTECH, Offenburg, Germany). After four cycles, 25 μL of 240 mM AAPH was injected via onboard injector. The test was continued, and fluorescence intensity measurements were taken up to 120 min. ORAC values were calculated on the basis of the difference in area under the fluorescence decay curve between the blank and sample. The antioxidant capacity (ORAC) was calculated according to the following equation:

$$\text{ORAC value} = [(\text{AUC}_{\text{sample}} - \text{AUC}_{\text{blank}})/(\text{AUC}_{\text{Trolox}} - \text{AUC}_{\text{blank}}) \times [\text{Trolox}]\ \text{dilution factor}$$

Inhibition of Lipid Membrane Erythrocytes Oxidation Assay. This assay was done according to the method described by Rodriguez et

al.[21] with some modifications. The blood sample (10 mL) was obtained from a volunteer and collected into EDTA tubes. Then, the tube was immediately centrifuged at 3000 rpm and 4 °C for 10 min. After removal of plasma, the packed red blood cells (RBC) were directly washed three times with 0.9% NaCl (2 mL). After the third wash, packed RBC were gently resuspended in phosphate buffer saline (PBS) (pH 7.4) to obtain a 5% hematocrit in the presence of 1 mM NaN_3 and preincubated at 37 °C for 10 min. Then, the mixture was divided into aliquots (1.6 mL) for each experimental treatment. Concentrations of samples and standard were 0.05 and 0.2 mg/mL, respectively. All treatment groups and BHT (0.2 mL) were challenged with 0.01 M H_2O_2 (0.2 mL). Meanwhile, negative and positive controls were made with solvent and H_2O_2 alone, respectively. After 60 min of incubation at 37 °C, the tube was kept in an ice bath for 1 min.

Malondialdehyde (MDA) produced from membrane lipid oxidation of erythrocyte oxidation was measured using the TBARS method of Buege and Aust,[22] with some modifications. One milliliter of erythrocyte solution was vortexed with 1 mL of TCA/TBA/HCl reagent (15% TCA/0.375% TBA/0.25 mol of HCl) (1:1:1, v/v/v) for 10 s. Then, the mixture was heated in a boiling water for 15 min. Subsequently, the mixture was cooled at room temperature for 10 min and centrifuged at 3000 rpm for 10 min. The absorbance of supernatant was read at 535 nm against a blank of 15% TCA/0.375% TBA/0.25 mol of HCl reagent. The results were expressed as micromolar MDA. The MDA level was calculated using the equation

$$\text{concentration (M)} = \text{absorbance}/(\text{molar extinction} \times \text{length of cuvette used})$$

where molar extinction was $1.56 \times 10^5\ M^{-1}\ cm^{-1}$.

Inhibition of Erythrocyte Hemolysis. Erythrocyte hemolysis was performed on the basis of method of Huang et al.[23] The packed RBC or erythrocytes obtained from previous analysis were diluted in PBS. The suspension of 2% erythrocytes in PBS (1 mL) was mixed with 0.5 mL of the extract. Concentrations of samples and standard were 0.05 and 0.2 mg/mL, respectively. Subsequently, 50 μL of H_2O_2 (100 mmol/L) was added to the mixture. The reaction mixture was incubated at 37 °C for 1 h and then diluted with 8 mL of PBS. The diluted reaction mixture was centrifuged at 1000*g* for 10 min. The absorbance of supernatant was measured at 415 nm. Erythrocytes were treated with 100 mmol/L H_2O_2 and without extract to obtain a complete hemolysis (control). The percentage of inhibition was calculated by using the following equation:

$$\text{inhibition of hemolysis (\%)} = (\text{absorbance of } H_2O_2\text{-induced hemolysis} - \text{absorbance of sample}/\text{absorbance of } H_2O_2\text{-induced hemolysis}) \times 100$$

In Vitro Antidiabetic Properties. *α-Amylase Inhibition Assay.* This assay was performed according to the method of Apostolidis et al.[24] Acarbose (62.5−1000 μg/mL) was used as positive control. The percentage of inhibition was calculated by using the equation

$$\text{inhibition (\%)} = (A_c - A_e)/A_c \times 100$$

where A_c is absorbance of control and A_e is absorbance of sample extracts or standard. Control was using phosphate buffer to replace extracts.

α-Glucosidase Inhibition Assay. The α-glucosidase inhibition assay was carried out according to the method of Kim et al.[25] The α-glucosidase inhibitory activity was expressed as percent inhibition and was calculated as

$$\text{inhibition (\%)} = (\Delta A_c - \Delta A_e)/\Delta A_c \times 100$$

where ΔA_c and ΔA_e are the difference of absorbance before and after incubation of control and sample extracts, respectively. Acarbose (0.125−2 mg/mL) dissolved in phosphate buffer was used as a positive control.

Cell Viability Assay. The viability of the BRIN BD11 cell line in the presence of sample extracts was determined using an MTT (3-(4,5-dimethylthiazol-2yl)-2,5-diphenyltetrazolium bromide) assay.[26] BRIN BD11 cell line was obtained from the Malaysian Institute Nuclear Technology (MINT). Cells were cultivated in T-25 cm^2 culture flasks using Roswell Park Memorial Institute (RPMI)-1640 medium (Gibco BRL Products, Rockville, MD, USA) with 2.0 g/L sodium bicarbonate, antibiotics (100 units of penicillin/mL and 100 μg of streptomycin/mL), and 10% fetal bovine serum (FBS). Cells were maintained in a humidified atmosphere of 5% CO_2 at 37 °C and were harvested at 80−90% confluence to maintain exponential growth. The extracts were dissolved in water and filtered through a sterile 0.22 μm syringe filter.

Insulin Secretion Assay. Insulin secretion activity was evaluated according to the method of Hamid et al.[27] The BRIN BD11 cell line was seeded at a density of 1.0×10^5 cells per well in a 24-well plate cultured in 1 mL of RPMI-1640 culture medium containing 11.1 mM glucose supplemented with 10% (v/v) of fetal bovine serum (FBS) and antibiotics (100 IU mL^{-1} penicillin and 0.1 g L^{-1} streptomycin) to allow attachment overnight prior to the test. Cells were washed three times with Krebs−Ringer bicarbonate buffer (KRBB, pH 7.4) supplemented with 0.5% (w/v) bovine serum albumin (BSA) and 1.1 mM glucose and preincubated for 40 min at 37 °C. The buffer was removed, and cells were then incubated for 30 min with 1 mL of KRBB test buffer supplemented with 0.5% (w/v) BSA and 1.1 mM glucose in the presence of sample extract (0.625−5 mg/mL). Insulin concentration was measured using rat insulin ELISA kit (Mercodia AB, Uppsala, Sweden).

Statistical Analysis. All results were expressed as the mean ± standard deviation (SD) for three replicates unless specified. The data were analyzed by statistical software, SPSS version 20.0 for windows (SPSS Inc., Chicago, IL, USA). One-way analysis of variance (ANOVA) and Tukey's test were performed to determine differences of means among groups. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Nutritional Values of Underutilized Vegetables. The nutritional compositions of the studied vegetables are presented in Table 1. These vegetables were high in moisture content (>87%). The moisture content in the studied vegetables is

Table 1. Nutrient Compositions of Underutilized Vegetables[a]

nutrient composition	lalis	pantu
Macronutrients (g/100 g fw)		
moisture	87.97 ± 0.13b	90.70 ± 0.07a
ash	1.09 ± 0.27a	0.36 ± 0.03b
protein	3.86 ± 0.04a	1.67 ± 0.03b
lipid	0.56 ± 0.04a	0.33 ± 0.02b
total carbohydrate	1.56 ± 0.01b	2.43 ± 0.00a
total dietary fiber (TDF)	4.54 ± 0.01a	3.32 ± 0.26b
soluble dietary fiber (SDF)	0.48 ± 0.01a	0.22 ± 0.25a
insoluble dietary fiber (IDF)	4.06 ± 0.00a	3.10 ± 0.01b
Micronutrients (mg/100 g fw)		
calcium	47.07 ± 2.78a	27.75 ± 4.52b
magnesium	30.62 ± 0.47a	33.57 ± 4.98a
sodium	1.74 ± 0.10a	1.62 ± 0.83a
potassium	343.03 ± 2.19a	236.94 ± 32.09a
iron	0.32 ± 0.01a	0.22 ± 0.03a
copper	0.18 ± 0.00a	0.22 ± 0.01a
zinc	1.76 ± 0.05a	1.08 ± 0.15b
phosphorus	41.18 ± 0.29a	34.96 ± 5.53a
manganese	13.16 ± 0.20a	1.63 ± 0.24b

[a]Values are the mean ± SD ($n = 3$), except for dietary fiber ($n = 2$). Values with different letters are significantly different at $p < 0.05$ within the same row.

Table 2. Antioxidant Contents and Capacities of Underutilized Vegetables[a]

sample	TPC (mg GAE/100 g dw)	TFC (mg RE/100 g dw)	FRAP (μmol Fe^{2+}/100 g dw)	ORAC (μM TE/100 g dw)
lalis	2504.88 ± 61.15a	6.85 ± 0.27b	226.83 ± 14.43b	159.21 ± 19.88b
pantu	1959.70 ± 122.32b	10.63 ± 0.35a	396.83 ± 38.19a	203.58 ± 8.63a

[a]Values are the mean ± SD (n = 3). Values with different letters are significantly different at $p < 0.05$ within the same column.

similar to those of some other Malaysian vegetables such as *Etlingera elatior* (Jack), *Kaempferia galangal* L., and *Apium graveolons* L.[28] Additionally, comparable findings also have been demonstrated in three *Caulerpa* species (82−92%).[29] Lalis contained significantly higher ash, protein, lipid, and dietary fiber compared to pantu, except for total carbohydrate. However, a lower carbohydrate content was found for the studied vegetables compared with the nutrient databank value for raw palm hearts (25.6 g/100 fw).[30]

It was observed that dietary fiber (DF) content was an abundant nutrient in both vegetables, followed by protein value in lalis and total carbohydrate in pantu. A predominant portion of dietary fiber in the vegetables was insoluble DF compared to soluble DF. It was observed that total dietary fiber (TDF) in the samples was higher than their total available carbohydrate content. This may due to a high content of total indigestible carbohydrates in these samples.[18] It was noted that TDF contents of the studied vegetables exceeded the content in common Malaysian vegetables such as bamboo shoot, celery, and *kantan*.[31] The TDF of studied vegetables was considerably higher compared to other nutrients examined in this study, with the ratio of soluble to insoluble within 8.5−14.1. The ratio was higher compared to other vegetables such as seaweed due to more fibrous tissue.[32]

A higher level of potassium, zinc, calcium, phosphorus, and magnesium was observed in the studied vegetables as shown in Table 2. A similar pattern was observed for calcium, magnesium, and phosphorus levels with the same vegetables studied by Voon and Kueh.[33] Interestingly, higher amounts of potassium, magnesium, and phosphorus were found compared to common tomato.[34] It was found that the potassium level was higher than the sodium level, as is ordinary for plant foods. The high potassium content together with low sodium had shown a protective effect toward several diseases.[35] The studied vegetables could be a potential zinc source for daily intake as it contributes about 25% of zinc in the Recommended Nutrient Intake (RNI) of Malaysia.[36]

Antioxidant Properties of Underutilized Vegetables. The total phenolic (TPC) and flavonoid (TFC) contents of studied vegetables are depicted in Table 3. Lalis had significantly higher phenolic content (2505 mg GAE/100 g dw). In contrast, pantu exhibited a significantly higher TFC value (11 mg RE/100 g dw). The TPC values were much higher than those reported in vegetables from Indonesia (440−1143 mg GAE/100 g dw).[37] The studied vegetables showed a comparable TPC content and a lower flavonoid content compared to an ethanolic extract of *Barringtonia racemosa* stem.[38]

As total phenolic and flavonoid levels were determined, further identification and quantification of the polyphenol profile were performed using HPLC-DAD (Figure 1). To confirm the result of HPLC analysis, nine phenolic compounds were determined using LC-ESI-MS. MS data for the compounds are shown in Table 3. From the results, major compounds were detected in ESI(−) mode compared to ESI(+) mode. Seven compounds (protocatechuic acid, catechin, epigallocatechin gallate, chlorogenic acid, methyl gallate, 4-hydroxybenzoic acid, and myricetin) were present in pantu. Meanwhile, a total of five compounds (protocatechuic acid, chlorogenic acid, myricetin, morin, and genistein) were detected in lalis. Due to a lack of availability of standard phenolic compounds, certain peaks cannot be identified. Chlorogenic acid was the most abundant phenolic found in lalis (4.8 mg/g dw) and pantu (16.8 mg/g dw) (Table 4). This content was higher compared to chlorogenic content of commercial vegetables such as carrot, sprout, cauliflower, courgettes, and broccoli (0.01−0.44 mg/g dw).[39,40] The phenolic acid compounds identified in our vegetable extracts are quite similar to those of bamboo shoots.[41] The myricetin content in both of the studied vegetables was higher than the content in vegetables from Indonesia.[37] Comparable protocatechuic acid was found in wild mushroom, *Ramaria botrytis* (0.34 mg/g dw).[42] There is considerable interest as 4-hydroxybenzoic acid functions as a polyester precursor in plants and protocatechuic acid as an antioxidant.[43]

Table 3. Phenolic Compounds Detected in Lalis and Pantu by HPLC-DAD and LC-ESI-MS

compound	t_R (min)	MW	$[M + H]^+$ (m/z)	$[M - H]^-$ (m/z)
protocatechuic acid	15.4	154	nd[a]	153.1
catechin	15.9	290	291.2	nd
epigallocatechin gallate	16.1	458	nd	457.2
chlorogenic acid	16.4	354	nd	353.2
methyl gallate	16.7	184	nd	183.2
4-hydroxybenzoic acid	17.8	138	nd	137.0
myricetin	21.8	318	nd	317.2
morin	22.6	302	nd	301.0
genistein	24.2	270	nd	269.1

[a]nd, not detected above the limit of detection.

Antioxidant activity of extracts was evaluated by measuring the ability to reduce ferric ions in ferric reducing antioxidant power (FRAP) assay. Significant FRAP values of both studied vegetables were observed, as shown in Table 3. The ORAC assay determined the scavenging capacity of vegetable extracts against a peroxyl radical. The ORAC values for lalis and pantu were 159.2 and 203.6 μM TE/100 g dw, respectively (Table 3). In inhibition of lipid membrane erythrocyte oxidation assay (Table 5), the result demonstrated that both vegetables had good protective effects on membrane erythrocyte oxidation. The malondialdehyde (MDA) formation exhibited by lalis and pantu extract is comparable with that of BHT. In addition, pantu exhibited a significantly higher inhibition on erythrocyte hemolysis as compared to standard (Table 5). The inhibition activities of both samples were higher than that of gallic acid.

The FRAP value (226.8−396.8 μmol Fe^{2+}/100 g) was comparable with values reported for pumpkin leaves and butternut (104−744 mmol/L Fe[II]/g extract).[43] However, the studied vegetables showed a lower FRAP valued compared to commercial carrot (680 μmol Fe^{2+}/100 g).[44] Similar findings were found in ORAC values of some commercial vegetables

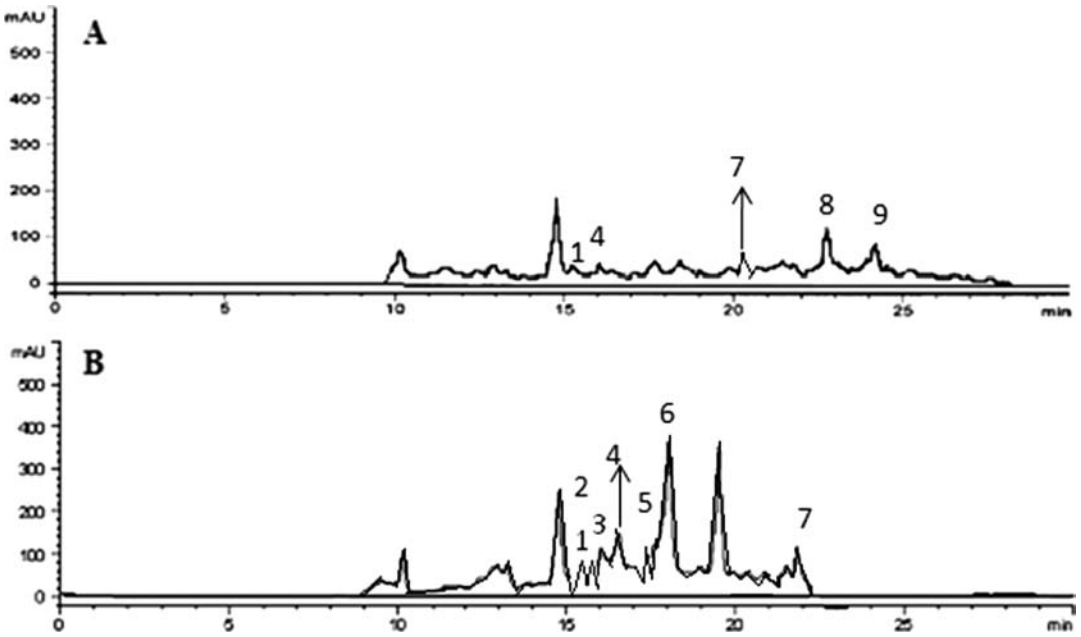

Figure 1. HPLC-DAD chromatograms of phenolic compounds in (A) lalis and (B) pantu. Detection was done at 280 nm. Peaks: (1) protocatechuic acid; (2) catechin; (3) epigallocatechin gallate; (4) chlorogenic acid; (5) methyl gallate; (6) 4-hydroxybenzoic acid; (7) myricetin; (8) morin; (9) genistein.

Table 4. Concentration of Phenolic Compounds in Lalis and Pantu Using HPLC-DAD[a]

peak	compound	lalis (mg/g dw)	pantu (mg/g dw)
1	protocatechuic acid	0.30 ± 0.08	0.79 ± 0.20
2	catechin	nd	0.60 ± 0.14
3	epigallocatechin gallate (EGCG)	nd	1.44 ± 0.27
4	chlorogenic acid	4.80 ± 3.22	16.77 ± 0.30
5	methyl gallate	nd	0.05 ± 0.01
6	4-hydroxybenzoic acid	nd	0.84 ± 0.03
7	myricetin	0.56 ± 0.02	1.45 ± 0.04
8	morin	2.04 ± 0.05	nd
9	genistein	0.17 ± 0.01	nd

[a]Values are expressed as the mean ± standard deviation (n = 3). The calibration coefficients were >0.99. nd, not detected above the limit of detection of phenolic compounds.

Table 5. Antioxidant Capacities of Underutilized Vegetables Using Inhibition Assays on RBC Cell Damage[a]

sample	inhibition of lipid membrane of erythrocyte oxidation (MDA, μM)	inhibition of erythrocyte hemolysis (%)
lalis	0.67 ± 0.02a	48.70 ± 1.47ab
pantu	0.77 ± 0.01a	53.51 ± 1.11a
standard	0.65 ± 0.19α,a	44.96 ± 0.28β,b

[a]Values are the mean ± SD (n = 3). Values with different letters are significantly different at $p < 0.05$ within the same column. α, BHT; β, gallic acid.

such as Brussels sprout, eggplant, and green beans.[45] Furthermore, no significant difference of ORAC values was found among the vegetables and standard. Due to the high hydrophilic phenolic compound content in lalis (Table 4), this may contribute to hinder MDA formation. It was noted that the more polar hydrophilic compounds present in the extract, the greater the ability the extract has to neutralize lipid peroxidation.[46]

Inhibitory Activities of Extracts against Digestive Enzymes. Consumption of foods that contain potential α-amylase and α-glucosidase inhibitors can be dietary solutions for management of type II diabetes. α-Amylase enzyme is able to catalyze the hydrolysis of glycosidic linkages in starch. The α-amylase inhibitors are considered starch blockers as they bind with the reactive sites of amylase enzyme and consequently control the blood glucose level. The studied vegetables showed high inhibition of α-amylase activity (>50%) (Figure 2a). This result was higher than that of wild legume grains (10.6−18.5%)[47] and comparable with those of finger and Proso millets (77−78%).[48]

α-Glucosidase is an enzyme situated in the epithelium of the small intestine and catalyzes the breakdown of disaccharides into glucose for subsequent absorption. An inhibitor of α-glucosidase could delay the glucose absorption rate through the intestine. The impediment of glucose absorption may give a positive effect in controlling the postprandial blood sugar level. In contrast with α-amylase inhibition, the studied vegetables exhibited low levels of α-glucosidase inihibition activity (<45%) (Figure 2b). No IC_{50} was found for either vegetable. However, the inhibition activity of pantu is comparable with wild legume grain inhibition (35.8−49.9%).[47] Low activity at higher concentrations could be due to reduced and no effects of compounds from the extract at higher doses. To our knowledge, this is the first study revealing the enzyme inhibition activity of these underutilized vegetables. On the basis of these preliminary results, the studied vegetables may indicate a potential resource as an inhibitor of α-amylase activity. However, further in vivo research is warranted to confirm its potential value in human subjects.

Effects of Extracts on Cell Viability and Insulin Secretory Activity of BRIN BD11 Cells. Results showed that no cytotoxic effects from either vegetable in BRIN BD11 cells up to a concentration of 2 mg/mL ethanolic extract (data

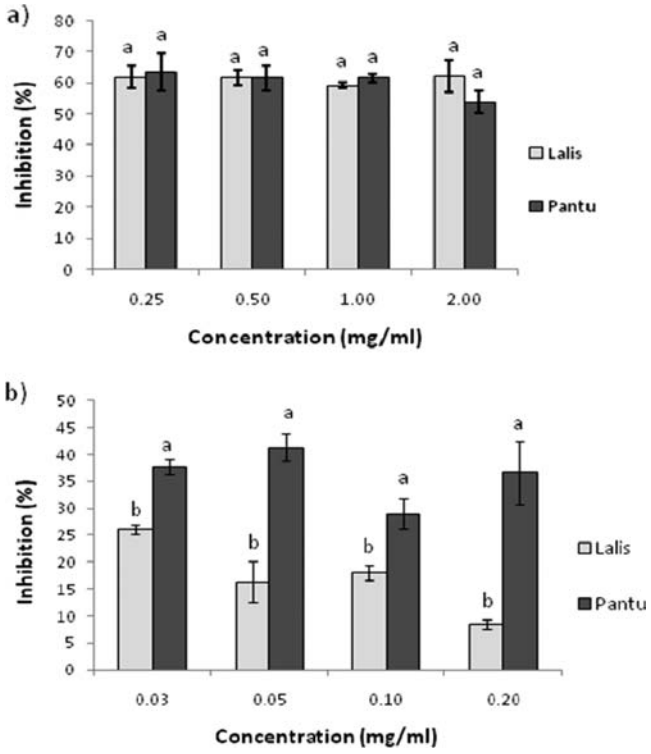

Figure 2. (a) α-Amylase and (b) α-glucosidase inhibition activity of vegetable extracts. Values represent the mean ± standard deviation (n = 3).

not shown). Lesser cell viability, as a sign of reducing blue formazan compound with increased concentrations of both extracts, was observed. In addition, no IC_{50} (inhibition of cell viability at 50%) was found for either vegetable. Hence, the assay did not exhibit toxicity to pancreatic cell line at all doses examined for lalis and pantu after 48 h of incubation.

The insulinotropic activities of vegetable extracts with different concentrations (0.625, 1.25, 2.5, and 5 mg/mL) using BRIN BD11 cells are demonstrated in Figure 3. From the results, no insulinotropic effect was found between the samples and control. This result was in agreement with Hamid et al.,[27] who found *Strobilanthus crispus* extract exhibited no insulinotrophic effect. In contrast, stem bark of *Tinaspora crispa* showed a stimulatory effect on insulin secretion.[27]

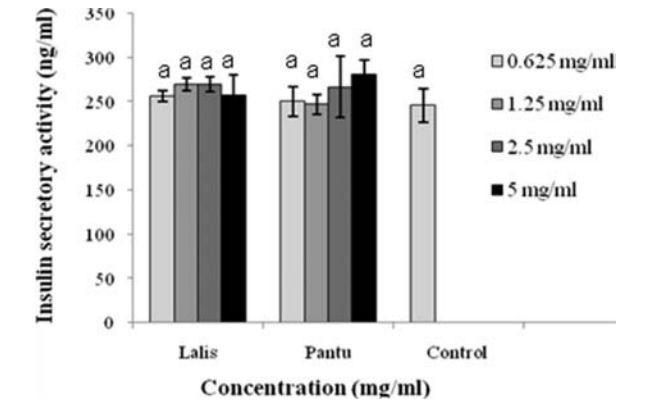

Figure 3. Insulin secretion activity of BRIN BD11 cell lines treated with vegetable extracts. Values are the mean ± SD (n = 3).

In conclusion, this research signifies the initial effort to evaluate the antioxidant and antidiabetic properties of these underutilized vegetables. It is revealed that they are providing valuable sources of dietary fiber, potassium, and zinc contents and exhibited potential antioxidant and antidiabetic properties. Different phenolic acids and flavonoid compounds were found in the studied vegetables such as chlorogenic acid and morin. High inhibition activity (>50%) was exhibited by all samples in α-amylase inihibition assay. Nevertheless, low activity (<50%) of samples was observed in α-glucosidase inhibition assay. In addition, no cytotoxicity effects were found on rat pancreatic BRIN-BD11 cells supplemented with all extracts (0.25−2 mg/mL). Moreover, no significant difference of insulinotrophic activity among the samples with different concentrations was found. It can be suggested these underutilized vegetable palm hearts are interesting indigenous resources to be embraced in local diets.

targeting the intracellular signaling pathway regulating cell cycle progression is an important strategy in lung cancer treatment.[18] The comprehensive reports demonstrate that the mutation in p53 has potency to establish the novel strategies improving the lung cancer prognosis.

The cell cycle is a critical regulation mechanism of cell growth, proliferation, and survival. The dysregulation of the cell cycle leads to uncontrolled cell proliferation and has been demonstrated in many different human cell tumorigeneses.[19] The mammalian cell cycle comprises five sequential stages, quiescent phase G0, G1, S, G2, and mitotic (M) phase. G1 and G2 represent the gap intervals, where cells prepare themselves for the successful completion of S and M phases subsequently. The cells in the S phase receive a signal and faithfully replicate the genetic material, while the M phase portions out the cellular components into two daughter cells.[20] The regulatory molecules of the successive cell cycle progression consist of cyclin and cyclin-dependent kinase (CDK) complexes. Different cyclin−CDK complexes are activated to ensure that cells successfully complete the previous phase and entering the new stage.[21] Furthermore, to ensure genome integrity and chromosomal stability, cell cycle checkpoints are important mechanisms to monitor cells transmitting precise copies of their genome into the next generation. CDK inhibitors (CDKIs) play an important role in checkpoint control of cell cycle progression. CDKIs are divided into two major families, INK4 and WAF/KIP families. The WAF/KIP family, including $p21^{Waf1/Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$, intends to inhibit CDK2 and CDK4/cyclin complex activities via protein−complex association. Moreover, the members of INK4, containing $p16^{INK4A}$, $p15^{INK4B}$, $p18^{INK4C}$, and $p19^{INK4D}$, bind to either CDK4 or CDK6 and inhibit the action of the D type of cyclins.[22] Activation of p53-$p21^{Waf1/Cip1}$ signaling is an important mechanism to prevent cells from G1 entering the S phase.[23,24] It has been shown that garcinol induced G1 cell cycle arrest and apoptosis in pancreatic cancer cells.[25] However, the molecular mechanism of cell cycle progression in p53-mutated lung cancer cells modulated via $p21^{Waf1/Cip1}$ activation with garcinol treatment is still unknown.

The mitogen-activated protein kinase (MAPK) family, a member of serine/threonine protein kinases, is involved in extracellular signal-regulated kinase (ERK), c-Jun-N-terminal kinase (JNK), and p38-MAPK signaling pathways. They mediate a variety of cellular functions through different extracellular stimulations.[26] The ERK pathway has been linked to cell proliferation and growth and is primarily induced by mitogens, while p38-MAPK and JNK are generally activated by cellular stress and inflammatory cytokines.[27] p38-MAPK is also involved in senescence, differentiation, and DNA-damage response.[28] A usual fate of p38-MAPK activation through extracellular stimulation is cell cycle arrest or apoptosis.[28−30] The proliferative role of p38-MAPK has also been reported in several cancers, especially in NSCLC.[31−33] Furthermore, p38-MAPK activation has shown the requirement during some mitogen-stimulated cell proliferation.[34,35] Recently, our group reported that lipopolysaccharide (LPS)-induced COX-2 expression was inhibited by garcinol through p38 inactivation in macrophages.[6] Therefore, it is important to verify the relationship between garcinol and p38-MAPK in tumorigenesis for cancer prevention or treatment.

In this study, we examined antiproliferative effects of garcinol on p53-wild type H460 and p53-null H1299 lung cancer cells. Our data showed that garcinol significantly induced a dose-dependent apoptosis in H460 cells, although a dose-dependent G1 cell cycle arrest was observed in garcinol-treated H1299 cells. We developed an interest in the molecular mechanism of the p53-independent G1 cell cycle in garcinol-stimulated H1299 cells. We found that garcinol downregulated the expression of the D type of cyclins, CDK2, and CDK4, in contrast to upregulating cyclin E and CDK6 protein expression. Garcinol also induced $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ expressions and concomitantly inhibited CDK2- and CDK4-mediated signals. In addition, ERK and p38-MAPK phosphorylations were also downregulated in a time-dependent manner by garcinol treatment. Treatment with p38-MAPK inhibitor enhanced garcinol-induced G1 arrest and cyclin E, p21 $^{Waf1/Cip1}$, and $p27^{KIP1}$ expression in H1299 cells. Our data suggested that the garcinol-induced p53-independent G1 cell cycle arrest might be through downregulation of p38-MAPK phosphorylation, resulting in accumulation of $p21^{Waf1/Cip1}$ protein in H1299 lung cancer cells.

MATERIALS AND METHODS

Reagents. Garcinol (purity = 95%) was purchased from Biomol/Enzo Life Sciences International, Inc. (Plymouth Meeting, PA). Anti-cyclin D1, D3, E, CDK2, CDK4, CDK6, anti-ERK, and anti-p38 antibodies were obtained from Cell Signaling (Beverly, MA). Anti-β-actin antibody was received from Sigma-Aldrich (St. Louis, MO). PD98059 and SB203580 were obtained from Calbiochem (La Jolla, CA). Protein A/G plus agarose was acquired from Santa Cruz Biotechnology (Santa Cruz, CA).

Cell Culture and Cytotoxicity Assay. NSCLC p53-wild type H460 and p53-null H1299 cell lines were obtained from the American Type Culture Collection (Manassas, VA). Both of the cell lines were cultured in RPMI-1640 (Hyclone Laboratories, Logan, UT) supplemented with 5% fetal bovine serum and maintained at 37 °C in a humidified atmosphere at 95% air and 5% CO_2. Cells (1×10^4/well) were cultured in 96-well plates and incubated for 24 h. After the cells were treated with various dosages of garcinol for 24, 48, and 72 h, the incubation media were changed every 2 days during the experiments. At the end of incubation, cell viability was determined by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay.

Cell Synchronization, Drug Treatment, and Flow Cytometric Analysis. Lung cancer cells H460 and H1299 were plating for 24 h. Cells were then synchronized for 24 h. After synchronization, the media were removed and changed to complementary media containing various dosages of garcinol for 24 h. After the treatment, cells were harvested and stained with propidium iodide (50 μg/mL) (Sigma Chemical, MO) and DNA contents were measured using a FACScan laser flow cytometer analysis system (Beckman Coulter, CA).

Western Blot Analysis. Control and garcinol-treated cells were rinsed twice with ice-cold phosphate-buffered saline (PBS) and then lysed in an appropriate RIPA extraction buffer [20 mM Tris−HCl at pH 7.5, 150 mM NaCl, 1 mM disodium salt of ethylenediaminetetraacetic acid (Na_2EDTA), 1 mM ethylene glycol bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), 1% (v/v) NP-40, 1% (v/v) sodium deoxycholate, 2.5 mM sodium pyrophosphate, 1 mM β-glycerophosphate, 1 mM Na_3VO_4, and 1 μg/mL leupeptin] on ice for 30 min. The extracts were then centrifuged at 12000*g* for 30 min. Proteins were loaded at 40 μg/lane and separated by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE). Thereafter, protein was transferred to Immobilon polyvinylidene difluoride membrane (Millipore, MA). Membrane was blocked by blocking buffer (3% bovine serum albumin and 0.5% Tween 20) for 40 min and incubated with different primary antibodies at room temperature for 2 h afterward. After 2 h of incubation, membrane was washed and soaked in horseradish-peroxidase-labeled secondary antibodies at 25 °C for 1 h. The blot was revealed by chemiluminescence (ECL kits, Amersham Pharmacia Biotech, Arlington Heights, IL). Band intensities were quantitated by UVP BioSpectrum Imaging System ChemiDoc-It2

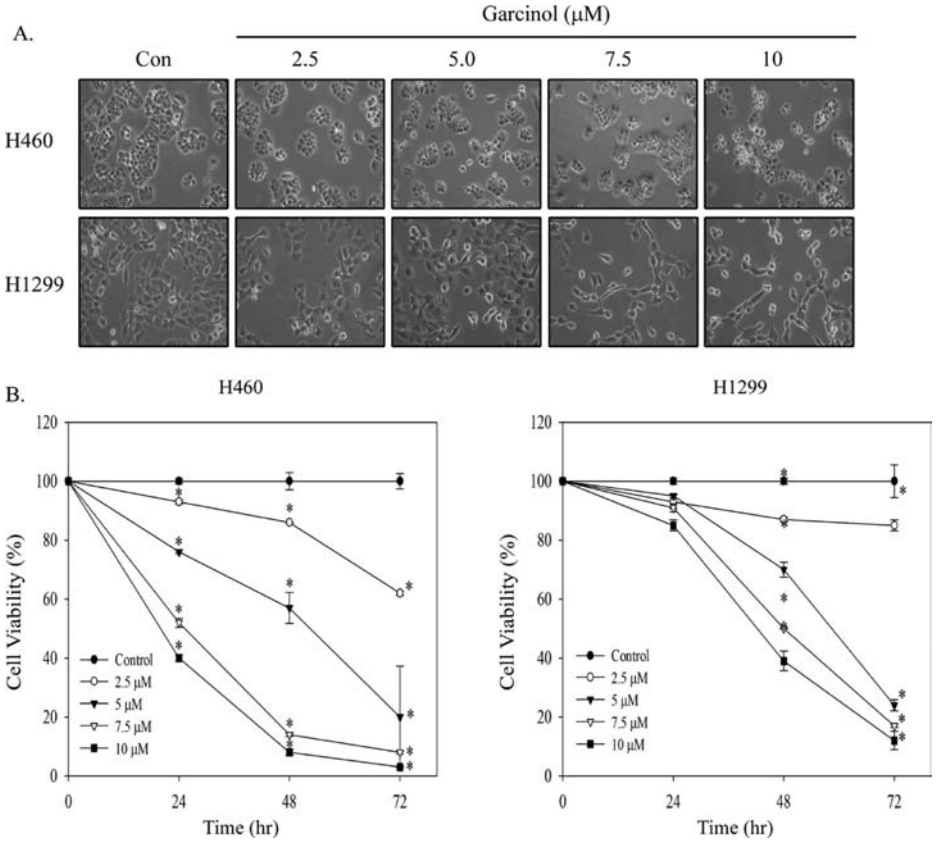

Figure 1. Growth inhibition effect of garcinol in H460 and H1299 lung cancer cells. (A) Morphological changes in garcinol-treated lung cancer cells. H460 and H1299 were treated with various concentrations of garcinol for 24 h. Morphological changes were observed by a microscope at 10 × 10 magnification. (B). Effects of garcinol on cell viability in H460 and H1299 lung cancer cells. H460 and H1299 were maintained in a 96-well plate at a density of 1×10^3/well for 24 h. Cells were then treated with various doses of garcinol for 24, 48, and 72 h. The cell viability was measured using the MTT assay. Data were the mean ± SD of triplicate samples. (*) $p < 0.05$ compared to control cells.

810 (UVP, LLC, Upland, CA). β-Actin was used as the internal control.

Immunoprecipitation. H1299 lung cancer cells were cultured in 100 mm dishes for 24 h, following synchronization. Thereafter, cells were switched to complementary media containing 10 μM garcinol for 24 h. Cells were then harvested and extracted by lysis buffer. The cell lysate was clarified by centrifugation at 12000*g* at 4 °C for 30 min. A total of 250 μg of protein was incubated with anti-CDK2 or anti-CDK4 antibody and protein A/G plus agarose at 4 °C for 18 h. The immunoprecipitate was washed twice with immunoprecipitation buffer [10 mM Tris−HCl at pH 7.4, 1 mM EDTA, 1 mM EGTA, 150 mM NaCl, 0.2 mM sodium vanadate, 0.2 mM phenylmethanesulfonyl fluoride (PMSF), 1% (v/v) Triton X-100, and 0.5% (v/v) NP-40]. CDK2 and/or CDK4 immunoprecipitates were resuspended in 25 μL of RIPA lysis buffer, mixed with protein loading buffer, and separated by SDS−PAGE. After transfer, membranes were blotted with anti-$p21^{Waf1/Cip1}$ and anti-$p27^{Kip1}$ primary antibodies. Blots were then stripped and reprobed with CDK2 and CDK4 as internal controls. The densities of the bands were then expressed as the relative densities compared to controls, which were taken as 1-fold.

Reverse Transcription Polymerase Chain Reaction (RT-PCR). After garcinol treatment, cells were washed in ice-cold PBS and total RNA was isolated by RNA mini kit (Qiagen, Taiwan). cDNAs were prepared from the total RNA (5.0 μg) with high-capacity cDNA reverse transcription kit (Invitrogen, Taiwan) at 42 °C for 60 min. PCR was performed in a final volume of 25 μL containing deoxynucleotide triphosphates (dNTPs) (each at 200 μM), 1× reaction buffer, 2 μL of RT-cDNA products, and 50 units/mL pro Taq DNA polymerase (Promega, WI). PCR primers for $p21^{Waf1/Cip1}$, $p27^{Kip1}$, and GADPH were synthesized according to the following oligonucleotide sequences: $p21^{Waf1/Cip1}$, forward primer, 5′-GGCGCCATGTCAGAACCGGCTG-3′; reverse primer, 5′-ACCCAGCGGACAAGTGGGGAGG-3′; $p27^{Kip1}$, forward primer, 5′-ACGAAGAGTTAACCCGGGACTTGG-3′; reverse primer, 5′-GGGCGTCTGCTCCACAGAACCG-3′; and GAPDH, forward primer, 5′-TGAAGGTCGGAGTCAACGGGTGAGTT-3′; reverse primer, 5′-CATGTAGACCCCTTGAAGAGG-3′.

After an initial denaturation for $p21^{Waf1/Cip1}$ PCR (851 kb) at 95 °C for 5 min, 26 cycles of amplification (95 °C for 50 s, 60 °C for 45 s, and 72 °C for 60 s) were performed and followed by an extension at 72 °C for 10 min. Similarly, for $p27^{Kip1}$ PCR (452 kb), 29 cycles of amplification (95 °C for 50 s, 57 °C for 45 s, and 72 °C for 45 s) were performed and followed by an extension at 72 °C for 10 min. In GAPDH amplification, 29 cycles of reaction (94 °C for 50 s, 60 °C for 45 s, and 72 °C for 120 s) were performed and followed by an extension at 72 °C for 10 min. The PCR products were separated by electrophoresis on 1.8% agarose gel and visualized by SYBR Safe (Life Technologies, Taiwan) staining.

Small Interfering RNA and Dominant Negative p38-MAPK (DN p38-MAPK) Transfection. H1299 cells were cultured to 70% confluence and then transfected with the siRNA duplexes at a final concentration of 10 nM using GenMute siRNA transfection reagent (SignaGen Laboratories, Ijamsville, MD) according to the instructions of the manufacturer. Cellular levels of the $p21^{Waf1/Cip1}$ proteins specific for the siRNA transfection were checked by immunoblotting, and all experiments were performed at 6 h after transfection. DN p38-MAPK plasmid was kindly obtained from Dr. Kuo-Tai Hua. H1299 cells were transfected with DN p38-MAPK using Lipofectamine 2000 transfection reagent according to the protocol of the manufacturer (Invitrogen, Carlsbad, CA).

Statistical Analysis. The results were expressed as the mean ± standard deviation (SD) calculated from the specified numbers of

determination. One-way analysis of variation (ANOVA) was used to compare individual data with the control value. A probability of $p < 0.05$ was taken as denoting a significant difference from the control data.

RESULTS

Cell Viability Inhibition by Garcinol on Human H460 and H1299 Lung Cancer Cells. The cell viability inhibition by garcinol on p53-wild type H460 and p53-null H1299 cells has been examined. Cells were treated with serial dosages of garcinol (0, 2.5, 5, 7.5, and 10 μM) at the time points of 24, 48, and 72 h, respectively. The cell viability was measured by the MTT assay. H460 and H1299 cells were treated with 10 μM garcinol for 24 h, exhibiting morphological changes (Figure 1A). As shown in Figure 1A, the cell shrunk and detachment was observed in garcinol-treated H460 and H1299 cells. In addition, the cell debris was noticed only in garcinol-treated H460 cells. Furthermore, the growth inhibition effect of garcinol was observed in dose- and time-dependent manners in these cell lines (Figure 1B). These results showed that the cell viability was significantly decreased in garcinol-treated H460 cells compared to H1299 cells.

Effects of Garcinol on Cell Cycle Distribution in Human H460 and H1299 Lung Cancer Cells. To further evaluate the hypothesis of the cytotoxic effect of garcinol mediated via alternations in cell cycle development, p53-wild type H460 and p53-null H1299 cells were used. Both H460 and H1299 cells were synchronized for 24 h and immediately treated with garcinol for another 24 h. At the end of treatment, cells were harvested and flow cytometry analysis was performed. As shown in Figure 2, the percentage of cells in the G1 phase increased from 63.7% in the control to 76.0% in garcinol-treated H1299 cells. Up to 13% of the G1 phase was boosted after garcinol treatment in H1299 cells. A sub-G1 fraction increased from 3.3% in the control to 11.2% in a dose-dependent mode in garcinol-treated H460 cells. However, garcinol significantly induced G1 cell cycle arrest in H1299 cells. The results implicated that garcinol possessed different biological activities via distinct p53 statuses.

Expression of Cell Cycle Regulatory Proteins in Garcinol-Treated H1299 Cells. In several studies, it has been demonstrated that garcinol induced apoptosis in many types of cancer cells.[8,9,11,12,25] However, further studies on the G1 arrest molecular mechanism in garcinol-induced p53-null cancer cells are still deficient. Therefore, we focused on the verification of the molecular mechanism of garcinol in H1299 cells. The cyclins and CDKs are two important cell cycle regulatory protein families. It has been well-characterized that D- and E-type cyclins are associated with CDK2 and CDK4/6, which control G1 cell cycle progression.[19,22] To investigate biological pathways of G1 arrest induced by garcinol via the regulatory protein expression, H1299 cells were synchronized and treated with garcinol for 24 h. After 24 h of treatment, the cells were harvested and changes in the expression of cyclin D1, D3, E, CDK2, CDK4, and CDK6 were inspected by western blots. Decreases in the protein levels of cyclin D1, D3, CDK2, and CDK4 were detected in a dose-dependent manner with garcinol treatment, as shown in Figure 3A, while increases in the expression of cyclin E and CDK6 were observed (Figure 3A).

Garcinol Induced G1 Cell Cycle Arrest through the Upregulation of CDK Inhibitors. Previous results showed that CDK activity was inhibited by CDK inhibitors, $p21^{Waf1/Cip1}$ and $p27^{Kip1}$. Furthermore, the activities of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ associated with the complexes of cyclin/CDK were repressed, resulting in cell cycle arrest.[22,23] The effects of garcinol on the expression of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ were characterized by western blot, as shown in Figure 3B. Obviously, the protein levels of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ were upregulated by garcinol treatment in a dose-dependent mode (Figure 3B). The verification of the activities of garcinol-inhibited CDK2 or CDK4 enhanced by $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ was performed by H1299 cell synchronization treated with or without garcinol. The outcomes revealed that the bound

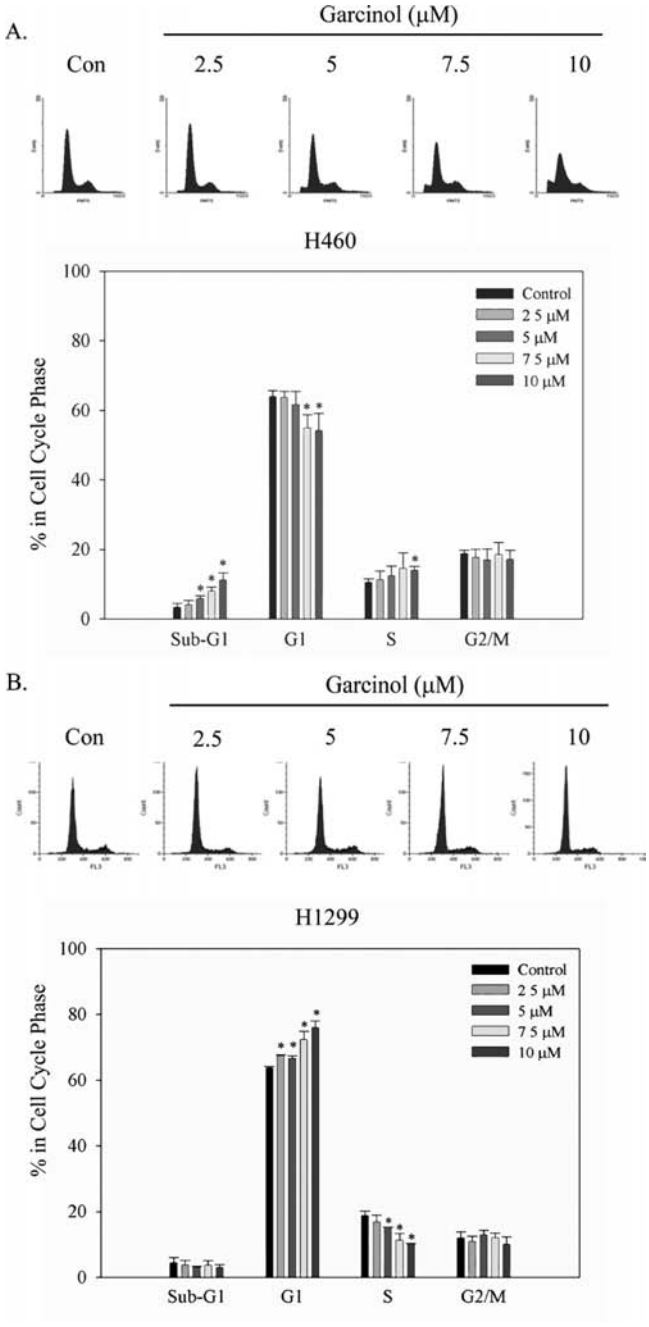

Figure 2. Effects of garcinol on cell cycle distribution in H460 and H1299 lung cancer cells. (A) H460 and (B) H1299 cells were treated with garcinol for 24 h, and then cells were harvested for cell cycle distribution analyses by flow cytometry. Three samples were analyzed in each group, and the results are presented as the mean ± SD. (*) Significant difference was observed from the control group ($p < 0.05$).

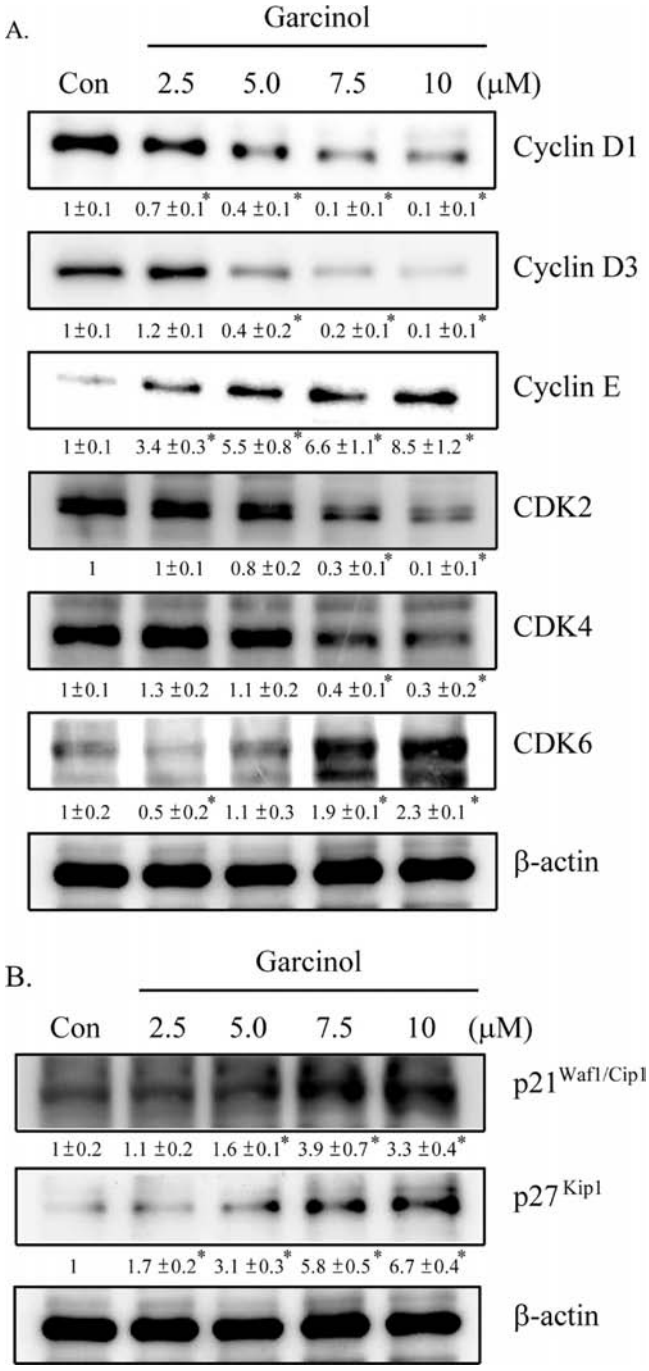

Figure 3. Effects of garcinol on the expressions of cyclins, CDKs, and CDK inhibitors. H1299 lung cancer cells were initially synchronized by serum-free medium and then serum-supplemented medium containing various doses of garcinol (0, 2.5, 5, 7.5, and 10 μM). After the cells were harvested, western blot analyses were performed with (A) anti-cyclin D1, cyclin D3, cyclin E, CDK2, CDK4, and CDK6 and (B) anti-$p21^{Waf1/Cip1}$, $p27^{Kip1}$, and β-actin antibodies. The protein levels in each treatment after normalization with the levels of β-actin are shown in parentheses. Data shown are representative of at least three independent experiments.

protein levels of $p21^{Waf1/Cip1}$ with CDK2 were increased about 3-fold in garcinol-treated cells, otherwise a 5-fold increase in bound protein levels of $p21^{Waf1/Cip1}$ with CDK4 in garcinol-treated cells (Figure 4). Nevertheless, $p27^{Kip1}$, bound with CDK2, was increased about 2-fold in garcinol-treated cells. The results implicated that the garcinol-induced G1 cell cycle arrest might be through upregulation of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ expression, resulting in downregulated CDK activities via enhancing the association.

It has been confirmed that $p21^{Cip1/Waf1}$ expression is regulated by p53-dependent and -independent transcriptional mechanisms.[23] After the cells were treated with garcinol for 12 h, total RNA was collected and RT-PCR was perform to investigate the expression of $p21^{Waf1/Cip1}$ induced by garcinol through transcriptional activation. The $p21^{Waf1/Cip1}$ mRNA expression was increased in a dose-dependent manner. Conversely, the expression of $p27^{Kip1}$ mRNA was declined (Figure 5A). To further verify whether garcinol-induced $p21^{Waf1/Cip1}$ expression in H1299 cells correlated with G1 growth arrest, we knocked down $p21^{Waf1/Cip1}$ expression by siRNA and analyzed the cell cycle distribution in garcinol-treated cells. As shown in Figure 5B, the protein level of $p21^{Waf1/Cip1}$ was dramatically downregulated after specific siRNA transfection. Furthermore, garcinol-induced G1 arrest was completely prevented by transfection with $p21^{Waf1/Cip1}$ siRNA into H1299 cells (Figure 5B). These results suggested that the garcinol-induced G1 arrest in H1299 cells was through upregulation of $p21^{Waf1/Cip1}$ protein.

Garcinol Inhibited ERK and p38-MAPK Activation. To explore the molecular mechanism of garcinol-induced G1 arrest, the phosphorylation of ERK and p38-MAPK, two important molecules in MAPK pathways involving cell cycle regulation, were analyzed in garcinol-treated H1299 cells. The outcomes exhibited that ERK phosphorylation was briefly stimulated between 0.5 and 1 h by serum significantly. Conversely, serum-stimulated ERK activation was repressed with 10 μM garcinol treatment (Figure 6). p38-MAPK was induced at 0.5 h and remained active in serum stimulation for 12 h. With garcinol treatment, the level of active p38-MAPK was diminished in a time-dependent mode (Figure 6). The results implicated that G1 arrest prompted by garcinol might be through ERK and p38-MAPK inhibition in H1299 cells.

p38-MAPK Rather than ERK Involved in Garcinol-Induced G1 Arrest. In the present study, the mechanism of garcinol-induced G1 arrest through $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ activation, following the inhibition of CDK activity, via association with CDKs, was established (Figure 4). Furthermore, ERK and p38-MAPK were activated in garcinol-treated H1299 cells (Figure 6). The pharmacological inhibitors, PD98059 and SB203580, for ERK and p38-MAPK, correspondingly, were used to understand the correlation in the activated pathways between ERK and p38-MAPK and the destination of garcinol-treated cells. H1299 cells were pretreated with 10 μM PD98059 or SB203580 for 30 min before stimulated with 10 μM garcinol for 24 h. Cells were collected for flow cytometry analysis. G1 arrest was observed in H1299 cells treated with ERK and p38-MAPK inhibitors alone (Figure 7). Interestingly, the synergistic effect of the G1 arrest population was detected in combinational treatments with p38-MAPK inhibitor and garcinol unlike in the co-treatment of ERK inhibitor and garcinol. Additionally, H1299 cells were pretreated with p38-MAPK inhibitor before 10 μM garcinol stimulation to verify the cell cycle regulators participated in p38-MAPK signaling when garcinol was supplied. The results showed that the expression of CDK2 was reduced in garcinol-treated cells on western blot (Figure 8A). Moreover, the expression of CDK2 was repressed by the combinational treatment with p38-MAPK inhibitor and garcinol. The

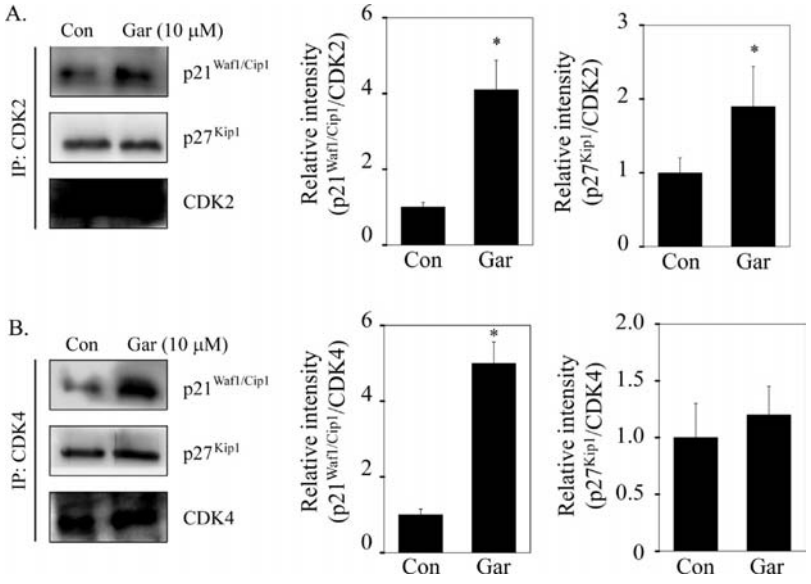

Figure 4. Effects of garcinol on the expressions of CDK−CDKI complexes in lung carcinoma H1299 cells. H1299 cells were treated with 10 μM garcinol for 24 h. Cell lysates were then incubated with protein A/G agarose beads conjugated with (A) anti-CDK2 or (B) anti-CDK4 antibody. The immunoprecipitates were electrophoresed, and the separated proteins reacted against primary antibodies, anti-$p21^{Waf1/Cip1}$, $p27^{Kip1}$, CDK2, and CDK4, to monitor protein interaction by western blot. The bound levels of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ in each treatment normalized with the levels of immunoprecipitation loading control are shown and representative of an experiment performed in triplicate. The density of the band was then expressed as the relative density compared to that in untreated cells (control), which was taken as 1-fold.

expression of cyclin E in the co-treatment of p38-MAPK inhibitor and garcinol was upregulated (Figure 8A). Similarly, the expression of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ in co-treatment with p38-MAPK inhibitor and garcinol was increased, especially in the protein level of $p21^{Waf1/Cip1}$ (Figure 8B). To further evaluate the significance of the p38-MAPK signaling in garcinol-induced $p21^{Waf1/Cip1}$ expression, H1299 cells transiently transfected the DN p38-MAPK. As shown in Figure 8C, ectopic expression of DN p38-MAPK enhanced garcinol-induced $p21^{Waf1/Cip1}$ expression. These results revealed that the garcinol-induced $p21^{Waf1/Cip1}$ expression was through inhibition of p38-MAPK activation.

DISCUSSION

Natural products represent good candidates to downregulate cancer cell growth. Major beneficial effects of these natural components as cancer-preventive agents are their comparative nontoxic effects. These non-nutritive components in a diet have been demonstrated to contribute from their pleiotropic effects, including downregulation of survival signaling and activating the death signaling pathway in cancer cells.[1,2] Garcinol has been indicated to possess numerous biological activities, such as antioxidation, anti-inflammation,[4−6,36] and upregulation of death signaling.[7,9,11,12,25] Although there is countless literature on the anticancer properties of garcinol, the effect of garcinol is still unclear regarding the molecular mechanism of diverse p53 statuses in lung cancer. Here, we have demonstrated that p38-MAPK signaling might be the essential target in p53 mutant lung cancer cell growth via garcinol treatment. Both p53-wild type H460 and p53-null H1299 lung cancer cell growth were inhibited by garcinol treatment. Garcinol significantly induced G1 cell cycle arrest in H1299 but not in H460 lung cancer cells. Furthermore, the D type of cyclin, CDK2, and CDK4 expressions were downregulated, whereas cyclin E and CDK6 expressions were upregulated in garcinol-stimulated H1299 cells. Also, the protein levels of $p21^{Waf1/Cip1}$ and $p27^{Kip1}$ were prompted in garcinol-treated cells, and the upregulation of $p21^{Waf1/Cip1}$ was associated with CDK2 and CDK4, followed by the inhibition of cyclin/CDK complex activity. Meanwhile, the upregulation of $p21^{Waf1/Cip1}$ expression via garcinol stimulation was through transcriptional regulation. The studies indicated that garcinol inhibited ERK and p38-MAPK phosphorylation and merely a combination with the p38-MAPK inhibitor resulted in the enhancement of G1 cell cycle arrest. The expressions of cyclin E, $p21^{Waf1/Cip1}$, and $p27^{Kip1}$ were also boosted after co-treatment of the p38-MAPK inhibitor and garcinol.

Tumor suppressor protein p53 has been shown to participate in numerous cellular processes.[15,24,37] The pivotal roles of p53 are involved in the cell growth arrest and cell death induction in cancer treatment. However, p53 mutations are present in almost half of NSCLC and award chemoresistance and poorer survival prognosis in lung cancer patients.[15,37] The application of disrupting the oncogenic effects is certainly important for the treatment and prevention of lung cancer. One of the advanced strategies for preventive or therapeutic p53 mutant tumors is the probing of active components to restore the p53-regulated pathway in the cells. Garcinol has evaluated its growth inhibition and apoptosis induction in a number of cancer models.[7,9−11,25] However, the role of p53 in garcinol-treated cancer cells is still unclear. We hypothesized that p53 statuses of lung cancer cells might affect the distinct molecular pathways in garcinol-treated cells. The effects of garcinol in p53-wild type and p53-null lung cancer cells were studied to further validate our hypothesis. The results revealed that garcinol induced the morphological changes and decreased the amount of lung cancer cells. Moreover, H460 cells were more active treated with garcinol (Figure 1). To further verify the cytotoxic effects in garcinol-treated cells, the cell cycle distribution was investigated. The outcomes showed that the G1 cell cycle arrest was enhanced by garcinol in H1299 cells (Figure 2). Our results revealed that garcinol induced apoptosis and G1 growth

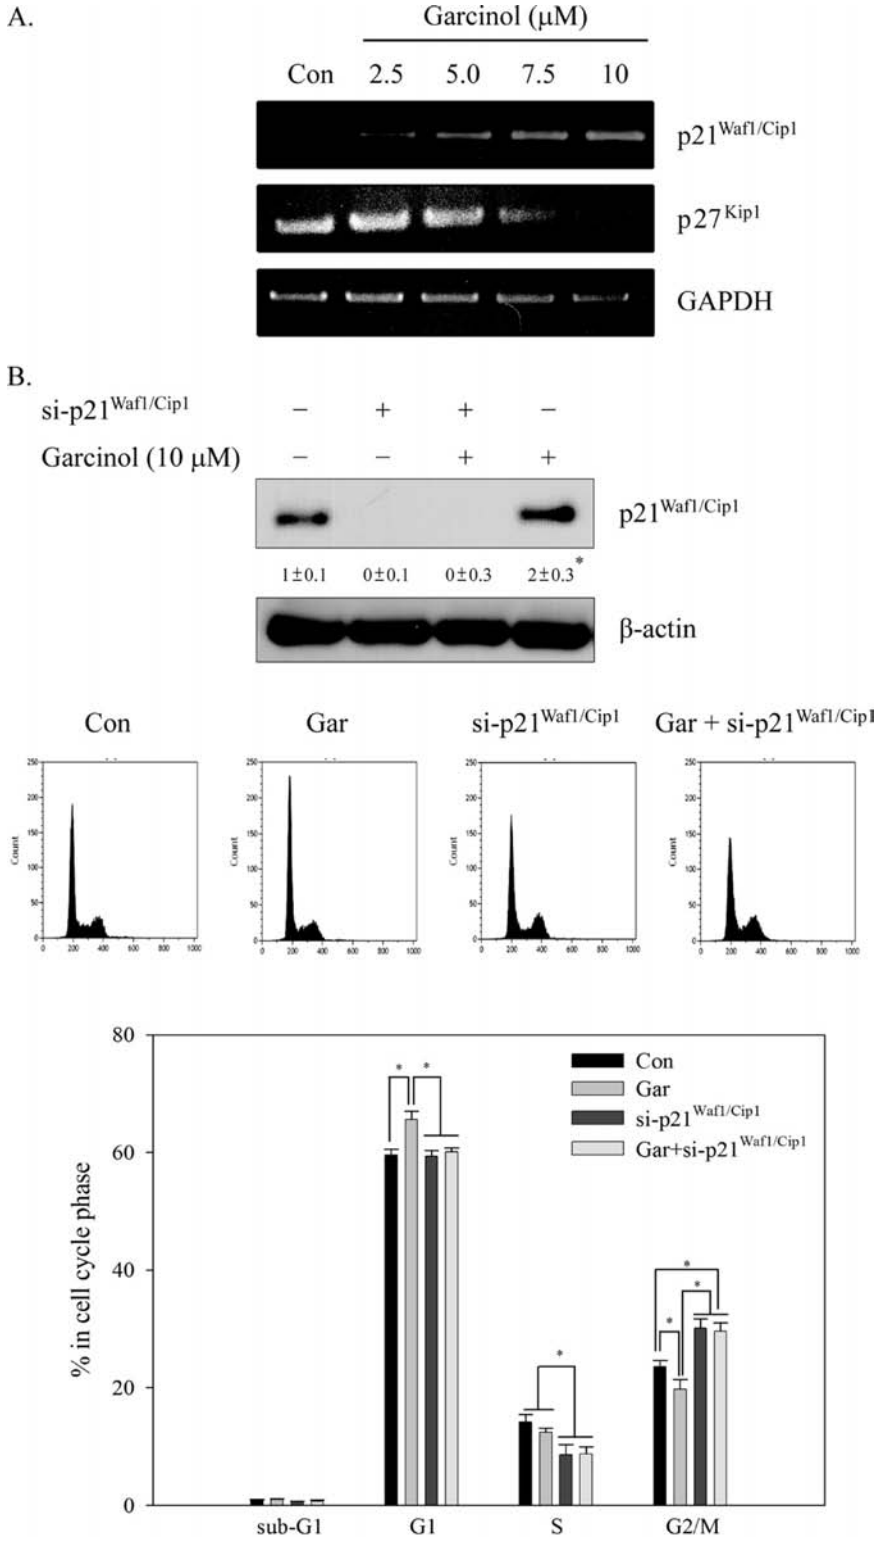

Figure 5. Role of $p21^{Waf1/Cip1}$ in the garcinol-induced G1 cell cycle arrest. (A) H1299 cells were treated with garcinol for 12 h, and total mRNA was extracted afterward. After the extraction of total mRNA, $p21^{Waf1/Cip1}$, $p27^{Kip1}$, and GAPDH RT-PCR were performed, as described in the Materials and Methods. (B) Knock-down $p21^{Waf1/Cip1}$ expression prevented garcinol-induced G1 cell cycle arrest in H1299 cells. H1299 cells were transfected with $p21^{Waf1/Cip1}$ siRNAs as described in the Materials and Methods. After transfection, H1299 cells were synchronized for 24 h and then treated with or without garcinol (10 μM) for an additional 24 h. Cells were harvested for Western blot and cell cycle progression analyses.

arrest in lung cancer cells in different p53 statuses. Tumor suppressor protein p53 might be regarded as a key factor in control cell apoptosis or G1 growth arrest in garcinol-treated lung cancer cells. However, a low concentration (4 μM) of garcinol-treated p53 wild-type A549 cells does not show apoptosis and/or G1 arrest induction.[38] In our study, garcinol-induced significant apoptotic or G1 arrest cell accumulation was observed upper 5 μM garcinol treatment in two cell lines

dx.doi.org/10.1021/jf4037722 | J. Agric. Food Chem. 2014, 62, 2085−2095

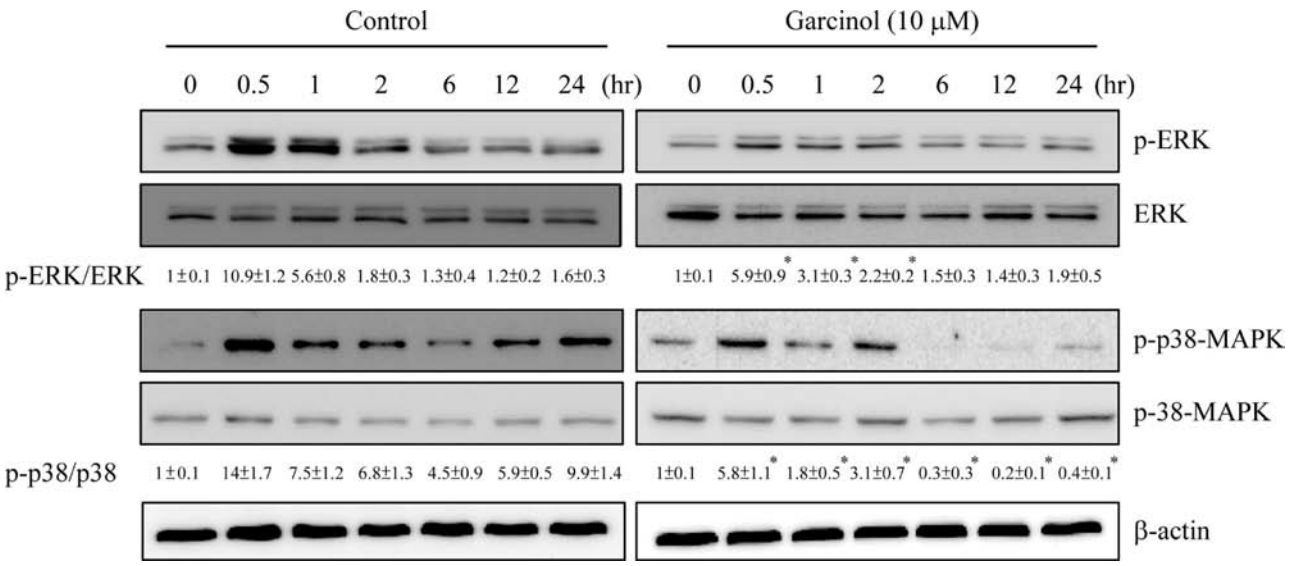

Figure 6. Effects of garcinol on ERK and p38-MAPK expressions in H1299 lung cancer cells. H1299 cells were treated with garcinol (10 μM) for indicated time intervals, and western blot analyses were performed with anti-p-ERK, ERK, p-p38-MAPK, p38-MAPK, and β-actin antibodies. The ratio of phospho-form/non-phospho-form protein in each treatment normalized with the levels of β-actin are shown in parentheses. Data shown are representative of at least three independent experiments. (*) Significant differences were compared to the control and determined by one-way ANOVA ($p < 0.05$).

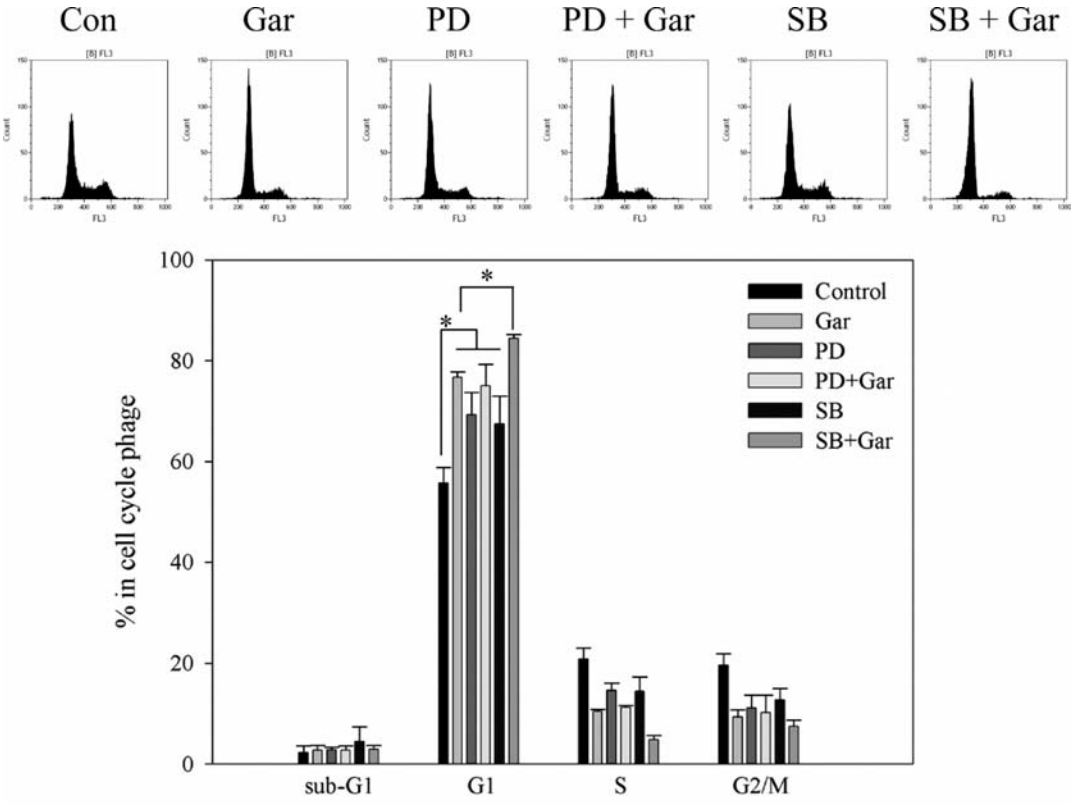

Figure 7. Effect of ERK and p38-MAPK inhibitors on cell cycle distribution in garcinol-treated H1299 cells. H1299 cells were treated with 10 μM PD98059 or SB203580 for 30 min and then stimulated with or without 10 μM garcinol for 24 h. Cells were harvested and stained with propidium iodine subsequently. Cell cycle distribution was determined by FACScan analysis. Three samples were analyzed in each group. (*) Significant differences were determined by Student's t test using the mean ± SD from the control group ($p < 0.05$).

(Figure 2). These results suggested that the effective dosage of garcinol should be carefully concerned in anticancer actions. Furthermore, treatment with a high dosage of garcinol (50 μM) has been demonstrated to induce ROS-dependent apoptosis rather than G1 arrest in p53-negative hepatocellular cancer Hep3B cells.[12] Although treatment with a high dosage of garcinol might induce p53-independnet apoptosis in cancer cells, other side effects might emerge in clinical application.

It has been well-known that garcinol induced the apoptosis of cancer cells through intrinsic and extrinsic pathways.[8,9,11,12]

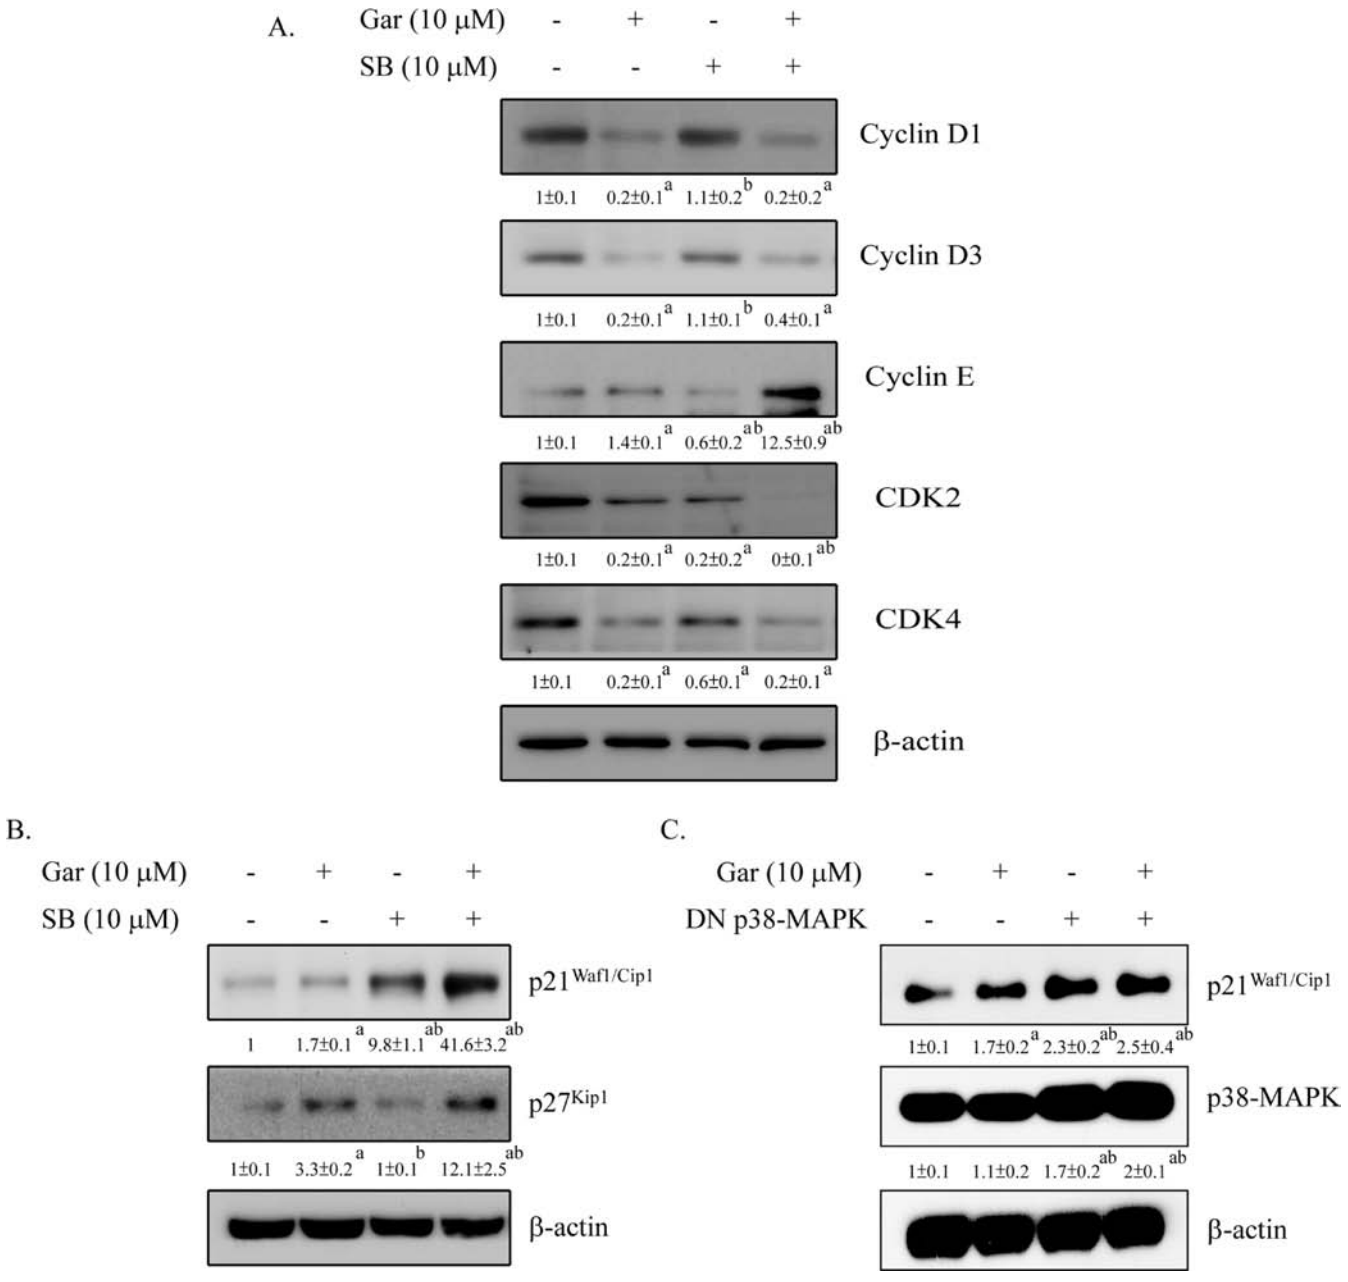

Figure 8. Effects of p38-MAPK inhibitor and garcinol co-treatment on the expressions of cyclins, CDKs, and CDKIs in H1299 cells. H1299 cells were treated with 10 μM SB203580 for 30 min and then stimulated with or without 10 μM garcinol for 24 h. Cells were harvested, and western blot was implemented with (A) anti-cyclin D1, cyclin D3, cyclin E, CDK2, and CDK4 and (B) anti-$p21^{Waf1/Cip1}$, $p27^{Kip1}$, and β-actin antibodies. (C). H1299 cells were transiently transfected with DN p38-MAPK, and then treated with 10 μM garcinol for 24 h. The protein levels of $p21^{Waf1/Cip1}$, p38-MAPK, and β-actin were determined by western blotting. The protein levels in each treatment after normalization with the levels of β-actin were shown in parentheses. Data shown were representative of at least three independent experiments. The significant differences were determined by one-way ANOVA (a) compared to the control ($p < 0.05$) and (b) compared to the garcinol-treated group ($p < 0.05$).

Besides, Collins et al. demonstrated that, with garcinol-induced p53 expression, acetylation accompanied G1 phase population accumulation in breast cancer cells.[39] Additionally, the proliferation of the nicotine-stimulated breast cancer cell is blocked by garcinol, which diminished nicotine receptor signal cascade to mediate cyclin D3 expression and induce p53-$p21^{Waf1/Cip1}$ signaling, resulting in G1 arrest.[10] The reports confirm that garcinol induced G1 cell cycle arrest through p53-related signaling pathways. However, the effects of garcinol in cell cycle regulation on p53-null cancer cells are still mysterious. The results indicated that the D type of cyclins, CDK2, and CDK4 were reduced, whereas the protein level of cyclin E was increased, in garcinol-treated H1299 cells (Figure 3A). The progression of the cell cycle is tightly regulated by the complexes of cyclins and CDKs. In the transition from the G1 to S phase, cyclin D/CDK4/6 and cyclin E/CDK2 control the cycle entry.[19] Furthermore, the activities of cyclin−CDK complexes are modulated through CDK inhibitors. The prominent CDK inhibitors are the WAF/KIP family, including $p21^{Waf1/Cip1}$, $p27^{Kip1}$, and p57 ^{Kip2}.[23] We demonstrated that CDK inhibitors, $p21^{Waf1/Cip1}$ and $p27^{Kip1}$, were enhanced in a dose-dependent manner (Figure 3B). The association between

dx.doi.org/10.1021/jf4037722 | J. Agric. Food Chem. 2014, 62, 2085−2095

$p21^{Waf1/Cip1}$ and CDK2/4 was raised in garcinol-treated cells. However, $p27^{Kip1}$ was only complexed with CDK2 (Figure 4). The data disclosed that the garcinol-induced G1 cell cycle arrest might be through p53-independent upregulation of $p21^{Waf1/Cip1}$ rather than $p27^{Kip1}$, resulting in the inhibition of cyclin−CDK activities via the strengthening binding activity.

It is well-established that $p21^{Waf1/Cip1}$ is necessary and sufficient for p53-dependent repressing of genes regulating cell cycle progression.[23] Post-translational modifications of $p21^{Waf1/Cip1}$, such as phosphorylation, increasing protein stability following cell accumulation at the G1 phase, were acknowledged.[29] In this study, the gene expression of $p21^{Waf1/Cip1}$ was further examined after the treatment with garcinol. The RNA level of $p21^{Waf1/Cip1}$ was considerably increased in a dose-dependent profile (Figure 5A). The data suggested that the garcinol-induced expression of $p21^{Waf1/Cip1}$ might be through transcriptional regulation. Furthermore, to further investigate the relationship between garcinol-induced $p21^{Waf1/Cip1}$ expression and G1 arrest, we knocked down $p21^{Waf1/Cip1}$ expression by specific siRNA before garcinol stimulation. Our results revealed that downregulation of $p21^{Waf1/Cip1}$ by siRNA transfection completely prevented the garcinol-induced G1 arrest (Figure 5B). According to our results, garcinol-induced G1 growth arrest was through $p21^{Waf1/Cip1}$ upregulaion.

MAPK pathways have been demonstrated to play an important role in cell cycle regulation, especially ERK and p38-MAPK.[26,28,30,40] ERK kinases are activated in various cell types as a survival signal through mitogenic and cytokine stimulation. Inhibition of active ERK has been investigated in blockage of cell cycle progression.[26] Moreover, p38-MAPK is generally activated by inflammatory cytokines and cellular stress and then results in G1 arrest, which mediated differentiation.[26−28] Emerging evidence points out the roles of p38-MAPK in cell cycle regulation, proliferation, and metastasis in different cells. The level of active p38-MAPK is higher in 18 analyzed primary NSCLC tumor tissues than normal lung tissue. Active p38-MAPK is discovered in the nucleus and cytoplasm of malignant and dysplastic cells.[33] p38-MAPK has been proven to promote melanoma cell proliferation through ATF-2-meidated upregulation of cyclin D1.[34] Faust et al. indicate that mitogen- and stress-induced activations of p38-MAPK have different functions. The duration of p38-MAPK activation determines the cell's destination, proliferation, or induction of cell cycle arrest.[27] Mitogen stimulation induces a weak and transient p38-MAPK phosphorylation, which is required for the G1−S transition. However, stress induces the strong and sustained p38-MAPK activation, following increasing cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) phosphorylation and cell arrest.[27] Furthermore, our recent report showed that chrysin induced sustained p38-MAPK activation and upregulation of $p21^{Waf1/Cip1}$ expression, following downregulated C6 glioma cell growth.[29] The results also revealed that p38-MAPK phosphorylation was detected at 0.5 h and persisted up to 6 h after serum stimulation. Moreover, serum-stimulated p38-MAPK activation was suppressed by garcinol (Figure 6). Inconclusively, garcinol inhibited serum-stimulated p38-MAPK activation, resulting in the disruption of p38-MAPK-mediated cell proliferation via G1 arrest.

Recent reports show that $p21^{Waf1/Cip1}$ is positively regulated via p38-MAPK phosphorylation and subsequent cell accumulation at the G1 phase.[29,30] Nevertheless, p38-MAPK also affects the cell fate to arrest the G1 phase in the survival cascade of several cancer cell types.[27,32,35] These dual roles of p38-MAPK in cell cycle regulation may depend upon the cell type and other related factors. In our studies, garcinol inhibited serum-stimulated ERK and p38-MAPK activation in a time-dependent profile (Figure 6). The co-treatment of SB203580 and not PD98059 plus garcinol revealed the substantial G1 accumulation compared to garcinol treatment alone (Figure 7). The data suggested that the garcinol-induced G1 cell cycle arrest might be partially proceeded by the means of p38-MAPK inhibition. Also, co-treatment with SB203580 and garcinol enhanced cyclin E and $p21^{Waf1/Cip1}$ expressions compared to garcinol-treatment alone in H1299 cells (Figure 8). Furthermore, transiently transfecting the DN p38-MAPK also enhanced garcinol-induced $p21^{Waf1/Cip1}$ expression (Figure 8C). Therefore, the expression of $p21^{Waf1/Cip1}$ induced by garcinol might be through downregulation of p38-MAPK activity. However, recent evidence reveals that nuclear factor-κB (NF-κB) is a transcription factor regulating cell growth, apoptosis, and inflammation[6,8,41] and also involved in the $p21^{Waf1/Cip1}$-mediated cell cycle arrest of breast and colon cancer cells.[41,42] Knock-down NF-κB expression by siRNA enhances 4-*O*-methylhonokiol, resulting in increasing $p21^{Waf1/Cip1}$ expression in colon cancer cells.[41] Accordingly, NF-κB is a key regulator in the expression of $p21^{Waf1/Cip1}$. NF-κB-mediated proliferative and inflammatory gene expressions have previously been identified through the p38-MAPK signaling pathway.[6,41] In addition, the downregulation of NF-κB via garcinol-augmented cell death has been demonstrated in breast and pancreatic cancer cells.[8,25] It was speculated that p53-independent $p21^{Waf1/Cip1}$ expression induced by garcinol might be as a consequence of the downregulation of p38-MAPK-mediated NF-κB activity. In summary, the G1 cell cycle evoked by garcinol was triggered by p53-independent $p21^{Waf1/Cip1}$ activation by means of the negative regulation of p38-MAPK activation in H1299 lung cancer cells. Our finding revealed that garcinol might become a candidate of the chemopreventive agent for p53-independent lung cancer cells in the future.

inhibition of ROS.[20] In addition, Wang et al. found that Rh2 also acted against the doxorubicin-induced cardiotoxicity.[21] Unfortunately, such good health benefits of ginsenosides including cardiovascular protection shown in vitro attenuated, to some extent, in vivo due to their poor bioavailabilities. To our best knowledge, there is no information on whether the bioactivities of ginsenosides are enhanced or decreased through synthesis of their esterified derivatives.

In this study, first, to exam whether Rh2 ester has better bioavailability than Rh2, the transepithelial transport and absorption mechanisms of Rh2 and its derivative were studied in the Caco-2 system. Caco-2 cell monolayers have been generally accepted as an in vitro model for prediction of drug absorption across the human intestine and for mechanistic studies of intestinal drug transport due to their morphologic and functional similarities to human small intestinal epithelial cells.[22−24] Subsequently, an oxidative injury model was established using human umbilical vein endothelial cells (HUVECs) exogenously exposed to hydrogen peroxide (H_2O_2). The protective effects of Rh2 and its derivative on oxidative injury were evaluated to exam whether Rh2 ester with an enhanced absorption rate had similar or even better pharmaceutical function than Rh2. The present study will provide useful information on the pharmaceutical and preclinical research of ginsenosides and their structure modification.

MATERIALS AND METHODS

Materials and Chemicals. The human colon adenocarcinoma cell line, Caco-2, was purchased from the cell bank of the Chinese Academy of Sciences (Shanghai, China). HUVECs were obtained from the College of Medicine, Nanchang University. Dulbecco's modified Eagle's medium (DMEM), nonessential amino acids (NEAA), penicillin−streptomycin (10000 IU/mL), Hank's balanced salt solution (HBSS), trypsin, and ethylenediaminetetraacetic acid (EDTA) (0.25%/0.02%) in phosphate buffer saline (PBS) were all from Invitrogen Corp. (Carlsbad, CA, USA). Fetal bovine serum (FBS) was obtained from Gibco BRL (N.V. Life Technologies, Paisley, UK). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), mannitol, verapamil, and MK-571 were purchased from Sigma-Aldrich (St. Louis, MO, USA). The Rh2 and its ester derivative Rh2-O were kindly provided by Dr. Yinan Zheng, Jilin Agricultural University China. Transwell cell culture chambers (pore size = 0.4 μM, diameter = 24 mm) and the Millicell-ERS volt-ohmmeter with Ag/AgCl electrodes were purchased from Costar Corp (Cambridge, MA, USA) and from Nihon Millipore (Tokyo, Japan), respectively. The microplate reader was purchased from Thermo Fisher (Thermo Scientific Multiskan MK3, USA).

Culture of Caco-2 Cells and HUVECs. Caco-2 cells were cultured in DMEM supplemented with FBS (10%, v/v), NEAA (1%, v/v), penicillin (100 U/mL), streptomycin (0.1 mg/mL), and glutamine (0.29 g/L). The cells were incubated in a humidified atmosphere of 5% CO_2 at 37 °C. The medium was replaced every 2 days, and the cells were passaged at about 90% confluence using a trypsin/EDTA solution (0.25%/0.02%) at a split ratio of 1:4. Caco-2 cells used in this study were between passage 40 and 60. HUVECs were grown in DMEM containing FBS (10%, v/v), penicillin (100 U/mL), streptomycin (0.1 mg/mL), and glutamine (0.29 g/L). Cultures were maintained at 37 °C in a humidified atmosphere of 5% CO_2 in air.

Cytotoxicity Assay. The cytotoxicity of Rh2 and Rh2-O to Caco-2 cells and HUVECs was quantified using MTT assays.[25,26] The Rh2 and Rh2-O were first dissolved in DMSO and then diluted to desire concentration using PBS (ensuring the concentration of DMSO was <0.5%). Briefly, 0.1 mL of cells was seeded onto 96-well plates with a density of 10000 cells per well in a 96-well plate. The cells were grown in an atmosphere with 5% CO_2 and 95% relative humidity. Following incubation for 24 h, test compounds at different concentrations were added. Thereafter, 0.2 mL of 10% MTT solution was added to each well and incubated for 4 h in the dark. The medium was then removed, and the MTT−formazan crystals were solubilized by incubating with 0.15 mL of DMSO with gentle shaking for 10 min; the absorbance was determined at 490 nm in a microplate reader. Cells incubated without the test compounds were used as controls. In each MTT assay, every sample was tested in five replicates.

Transepithelial Transport Experiments across Caco-2 Monolayer. For transport experiments, Caco-2 cells were seeded onto the 6-well transwell inserts coated with type-I collagen at a density of 4×10^5 cells/well to generate Caco-2 monolayers. Medium was replaced every 2−3 days, and the monolayers used for the experiments were cultured to differentiate for 21−27 days after postseeding. The integrity of the cell layer and the full development of the tight junctions were monitored before every experiment by measurement of transepithelial electrical resistance (TEER) of filter-grown cell monolayers with millicell-ERS equipment. Only a monolayer with a TEER value of >300 $\Omega \cdot cm^2$ was used for the transepithelial transport experiments.

The transport of Rh2 and Rh2-O across Caco-2 monolayers was investigated using the methods described previously with minor modifications.[27] Briefly, the cell monolayers were gently rinsed twice with warm HBSS (pH 7.4, 37 °C) before the experiments. Cell monolayers were then incubated at 37 °C for 30 min in the transport buffer. To measure the apical-to-basolated (AP-BL) transport, 1.5 mL of mixture containing Rh2 or Rh2-O over 10−50 μM (final concentrations) in transport buffer was added to the AP side of the transwell insert and 2.6 mL of HBSS was added to the BL chamber. The plates were then put in an incubator at 37 °C. At a designated time point (30 min interval), 0.4 mL aliquots of solution were collected from the BL side and then replaced with an equal volume of transport buffer. In the direction of BL-AP, Rh2 or Rh2-O dissolved in 2.6 mL of transport buffer over 10−50 μM (final concentrations) was added to the BL side and 1.5 mL of the HBSS to the AP side, and 0.4 mL of the samples was collected from the AP side. All experiments were performed in triplicates.

For ethylenebis(oxyethylenenitrilo)tetraacetic acid (EGTA)-modulated transport experiments, the cell monolayers were pretreated with 2.5 mM EGTA in both AP and BL sides for 15 min at 37 °C after the initial 30 min of preincubation. Cell monolayers were then washed three times with transport buffer. AP to BL transport was initiated in the same way as described above. In the present study, the inhibitory effects of MK-517 and verapamil on Rh2 and Rh2-O flux by Caco-2 monolayers were examined by addition of 100 μM of each inhibitor to the AP side, regardless of where samples were loaded. Thereafter, the transport study was performed according to the method described above.

Superoxide Radical Scavenging Capability of Rh2 and Rh2-O in a Cell-Free System. The superoxide radical scavenging capability of Rh2 and Rh2-O was assayed by a photochemical system (Analytik Jena, Berlin, Germany); the principle of this method was photochemiluminescence (PCL), which is based on the photoinduced autoxidation inhibition of luminol by antioxidants mediated from the radical anion superoxide. The PCL assay was based on the method previously described.[28] Trolox is used as reference compound to evaluate the superoxide radical scavenging capability, and all of the samples were quantified as equivalent units of trolox.

Oxidative Stress Model Induced by H_2O_2. The HUVECs were incubated under the conditions described above. Before H_2O_2 treatment, cells were seeded in 96-well microstate plates at a density of 5×10^3 cells/well and grown to approximately 80% confluence. The plates were incubated at 37 °C for 24 h before further treatments. Then H_2O_2 solutions at various concentrations were added into each well and incubated at 37 °C for 1 h. Cell survival was evaluated by the MTT assay as described above. In this study, the cell survival rate decreased significantly ($p < 0.05$, data not shown) when the H_2O_2 concentration was >100 μM. Therefore, HUVECs treated with freshly prepared 100 μM H_2O_2 for 1 h were used as the oxidative stress model.

Cytoprotective Assay. The HUVECs were seeded in 6-well microstate plates at a density of 4×10^5 cells/well and incubated as

described above before further treatments. After 90% confluence, cells were washed with fresh medium and pretreated with 20 μM ginsenoside for 2 h and then stimulated by 100 μM H_2O_2 for 1 h. The samples were collected for the following analysis. Each sample was assayed in triplicate.

Preparation of Cell Lysates. After completion of the incubation assay, the culture supernatant was collected for analysis of lactate dehydrogenase (LDH) and NO release. The cells were scraped from the plates and extracted with ice-cold lysis buffer (methanol containing 1% Triton X-100), and protein concentration was determined as mentioned above. Aliquots were stored at −80 °C until detection for malondialdehyde (MDA) content and glutathione peroxidase (GSH-Px) and catalase (CAT) activities.

Determination of NO Release. NO release amounts was measured as its oxidative product, nitrite. Briefly, at the end of incubation, 100 μL of supernatant was collected and then reacted with 100 μL of Griess reagent (1 part 1% sulfanilamide and 1 part 0.1% *N*-naphthylethyl-ethylenediamine dihydrochloride (NEDA) in 5% phosphoric acid). Absorbance at 550 nm was measured using a plate reader, and nitrite concentration was caculated using a curve calibrated on sodium nitrite standards.

Determination of LDH Activity. LDH activity released into the medium was detected with an assay kit (Sigma-Aldrich, USA) according to the manufacturer's protocol. Absorbance at 450 nm was detected using a plate reader. One unit of LDH activity is defined as the amount of enzyme that catalyzes the conversion of lactate into pyruvate to generate 1.0 mmol of NADH per minute at 37 °C, and the activity of enzyme was expressed as units per liter.

MDA Assay. Lipid peroxidation in HUVECs was assessed by the thiobarbituric acid (TBA) reaction using a commercial kit (Sigma-Aldrich, USA) following the manufacturer's protocol. Briefly, cells were collected and lysed as described above. Two hundred microliters of cell lysate or MDA standards was incubated with 600 μL of TBA solution at 95 °C for 60 min and then cooled to room temperature in an ice bath for 10 min. Two hundred microliters from each reaction mixture was pipetted into a 96-well plate, and the absorbance was read at 532 nm. Values of MDA level were expressed as nanomoles per milligram of protein.

Determination of GSH-Px Activity. The activity of GSH-Px was determined with commercial assay kits (Sigma-Aldrich, USA) according to the manufacturer's instruction. The GSH-Px activity was calculated indirectly. The assay was based on the oxidation of glutathione catalyzed by GSH-Px, which was then coupled to the recycling of oxidized glutathione back to glutathione utilizing glutathione reductase (GR) and NADPH. GSH-Px was the rate-limiting factor of the coupled reactions. The activity of GSH-Px was indicated by the decrease in NADPH absorbance measured at 340 nm during the oxidation of NADPH to NADP+. In general, 1 unit of GSH-Px was defined as the formation of 1.0 μmol of NADP+ from NADPH per minute in a coupled reaction, and the value of GSH-Px was expressed as units per milligram of protein.

Determination of CAT Activity. The activity of catalase was determined with commercial assay kits (Sigma-Aldrich, USA) according to the manufacturer's instruction. This assay is based on the measurement of the hydrogen peroxide substrate remaining after the action of catalase. The amount of hydrogen peroxide remaining was determined by a colorimetric method, of which the absorbance was measured at 520 nm. One unit of catalase was defined as 1.0 μmol of hydrogen peroxide decomposed to oxygen and water per minute at pH 7.0 at 25 °C at a substrate concentration of 50 mM hydrogen peroxide, and the activity of catalase was expressed as units per milligram of protein.

Effect of Rh2 and Rh2-O on the HUVEC Apoptosis Induced by H_2O_2. Flow cytometry analysis was run using an Annexin V−fluorescein isothiocyanate (FITC) apoptosis detection assay kit to determine H_2O_2-induced cell apoptosis. The assay was performed according to the manufacturer's instruction. Briefly, the cells were collected, centrifuged, and washed several times with PBS. Washed cell pellets were resuspended in fluorochrome solution containing propidium iodide (PI) and Annexin V−FITC for 5 min and analyzed with a BD FACS CaliburFlow Cytometry System (Becton-Dickinson, Franklin Lakes, NJ, USA).

Determination of Caspase-3 Activity. Caspase-3 activity was tested in cells pretreated with or without 20 μM ginsenoside for 2 h in 96-well plates with preseeded cells as previously described and then exposed to 100 μM H_2O_2 for 1 h. Caspase-3 activity was measured with the Promega Apo-ONE homogeneous caspase-3/7 fluorescence assay kit according to the manufacturer's instructions (Fisher, Unionville, ON, Canada). Briefly, after being washed three times with PBS, Apo-ONE homogeneous caspase-3/7 buffer was added to the cells with DMEM at a 1:1 (v/v) ratio. Cells were incubated for an additional 1 h at room temperature prior to recording of the fluorescence with emission and excitation wavelengths of 528 and 485 nm, respectively, in a multiplate reader (PLX 800, Bio-Tek Instruments Inc., Winooski, VT, USA). Values are expressed as relative fluorescence units (RLU) and normalized to untreated control cells from the same aliquot as experimental groups.

Analysis by HPLC. The analysis of ginsenoside Rh2 and Rh2-O was performed according to a previous paper with a slight modification.[29] The HPLC system consisted of an Agilent HPLC series 1100 (Agilent Technologies, Little Falls, DE, USA) with a diode array detector (DAD). The detection wavelength was set at 203 nm. A Hypersil ODS column (150 mm × 3.9 mm, 4.6 μm, Waters, Milford, MA, USA) was used for sample analysis. The mobile phase was acetonitrile/ammonium chloride (90:10, v/v), and the flow rate was 1.0 mL/min. The standard concentrations of Rh2 and Rh2-O were analyzed by HPLC, and peak area measurement was used to generate calibration curves for the quantification of samples. The corresponding standards of Rh2 and Rh2-O for quantification were prepared in methanol solution. The HPLC methods have been validated through accuracy, precision, and recovery experiments. The method had acceptable accuracy (90−110% of true values) and precision (the intraday and interday coefficient variations <15%) over the concentration range (0.10−100 μM). The recovery of samples was between 80 and 120%. The limits of quantitation (LOQ), defined as the minimum concentration that could be determined with acceptable accuracy and precision, were 0.02 and 0.01 μM for Rh2 and Rh2-O, respectively.

Data Analysis. The cumulative quantity of test compound permeated at each time interval was measured and plotted against time. The flux was defined as the amount of compound across the monolayers per square centimeter (nmol/cm^2). The apparent permeability coefficients (P_{app}, cm/s) were calculated using the equation

$$P_{app} = \left(\frac{dQ}{dt}\right)\left(\frac{1}{AC_0}\right)$$

where dQ/dt is the rate of permeability (nmol/s), A is the surface area of the insert (cm^2), and C_0 is the initial concentration (final concentration initially adding to the wells). The efflux ratio (R_e) was determined by calculating the ratio of $P_{app}(B-A)$ versus $P_{app}(A-B)$ as the following equation:

$$R_e = \frac{P_{app}(B-A)}{P_{app}(A-B)}$$

Statistical Analysis. Results are presented as the mean ± SD from three replicates. Student's t test was conducted with a P value of <0.05 as statistically significant. All statistical analysis was carried out using SPSS 13.0 software for Windows.

RESULTS AND DISCUSSION

Cytotoxicity of Rh2 and Rh2-O toward Caco-2 Cells and HUVECs. Prior to investigation of the transepithelial transport of Rh2 and Rh2-O in Caco-2 cell system and whether Rh2 and Rh2-O could protect HUVECs from H_2O_2-induced cell injury, the viability of cells was directly measured using the MTT test to evaluate the cytotoxicity of Rh2 or Rh2-O toward Caco-2 cells. Generally, a cell viability value of <50% of the

controls was considered as the reduction of mitochondrial activity, whereas a higher cell viability of >90% indicated that the compounds at the concentrations were nontoxic to the cells.[30] As shown in Figure 1A, Rh2 and Rh2-O at 50 μM or

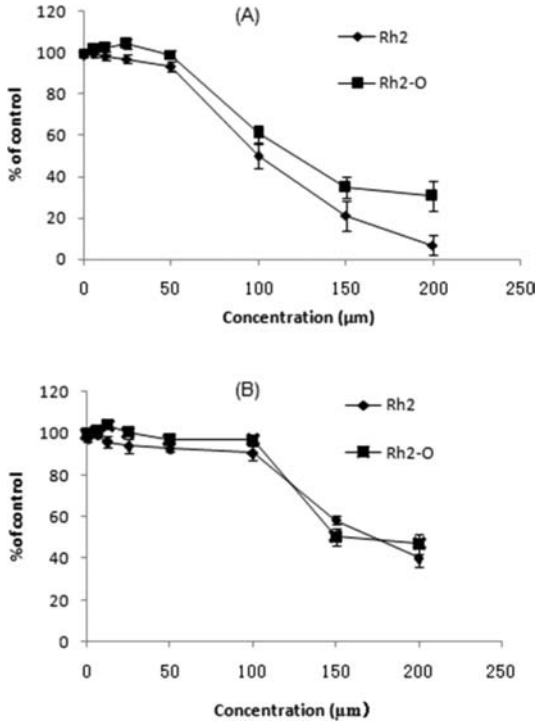

Figure 1. Cytotoxicity of Rh2 (◆) and Rh2-O (■) on (A) Caco-2 cell monolayers and (B) HUVECs using the MTT assay. Data represent the mean ± SD from five replicates.

below were nontoxic to the Caco-2 cells after 2 h of exposure. However, significant inhibition was observed with the rise of concentration to >50 μM. Figure 1B shows that Rh2 and Rh2-O were nontoxic toward HUVECs at concentrations below 100 μM. Therefore, to ensure cell viability, we chose nontoxic concentration of <50 μM Rh2 and Rh2-O in further experiments to examine the transport of Rh2 and Rh2-O across Caco-2 cell monolayer and the protective effect of Rh2 and Rh2-O on H_2O_2-induced cell apoptosis.

Enhancement Effects of Esterification on the Transport of Rh-2 across Caco-2 Cell Monolayers. The results of bidirectional transport of Rh2 and Rh2-O across Caco-2 cell monolayers at 20 μM are shown in Table 1. The apparent permeability coefficient (P_{app}) of Rh2 (20 μM) in BL to AP direction was determined as 3.26×10^{-6} cm/s over 2 h, which was much greater than that of AP to BL direction with efflux ratio (R_e) values of 15.5. This result indicated that an efflux mechanism may be involved in the transport process of Rh2. The flux amounts of Rh2-O in both directions were of similar magnitude and increased linearly over the initial 2 h. As shown in Table 1, the P_{app} value of Rh2-O (20 μM) in the direction of AP-BL was determined as 1.96×10^{-6} cm/s, which was significantly greater than that of Rh2, and $P_{app}(B - A)$ of Rh2-O (20 μM) was 2.08×10^{-6} cm/s. It was reported that there was a close correlation between the permeability across Caco-2 cell monolayers and the absorption of oral administration in vivo.[31] Generally, compounds with P_{app} values of $<1 \times 10^{-6}$ cm/s, between 1×10^{-6} and 1×10^{-5} cm/s, and $>1 \times 10^{-5}$ cm/s were considered to have low (<30%), moderate (30−0%), and high absorption (>70%).[32] According to these criteria, compounds such as Rh2 with a P_{app} value of $<1 \times 10^{-6}$ cm/s in Caco-2 cell monolayers might have poor absorption from the intestine in humans, whereas its ester derivative (Rh2-O) may have moderate absorption. Our results were consistent with a previous study which showed that Rh2 had an extremely low oral bioavailability (approximately 5%) in rats.[10]

Subsequently, the effects of Rh2 and Rh2-O concentrations (10−50 μM) on their transport flux were determined in the directions from AP to BL and from BL to AP (Figure 2A). The AP to BL flux amount of Rh2 was essentially linear up to 2 h and in a dose-dependent manner without any apparent saturation at the selected time points tested. These results indicated that the transport of Rh2 was mainly by passive diffusion in the direction of AP to BL. The corresponding $P_{app}(A - B)$ value (0.21×10^{-6} cm/s) over 10−50 μM had no significant difference and was independent of doses ($P > 0.05$). However, the BL to AP flux of Rh2 was much faster than that of the AP to BL direction and increased with increasing concentrations, with saturation at concentrations >20 μM. The determined $P_{app}(B - A)$ values of Rh2 at different concentrations were significantly greater than those from AP to BL with R_e values of 15.5, 9.7, 8.1, and 6.1 at 20, 30, 40, and 50 μM, respectively. The significant decrease in $P_{app}(B - A)$ values of Rh2 at concentrations >20 μM suggested the saturable flux amount of Rh2 from the BL to AP direction. These results indicated that the permeation mechanism of Rh2 may be passive diffusion with a BL to AP active efflux involved.

Table 1. Transcellular Transport of Rh2 and Rh2-O at 20 μM across Monolayers of Caco-2 Cells in the Absence or Presence of Inhibitors ($n = 3$)[a]

		P_{app} ($\times 10^{-6}$ cm/s)		
sample	inhibitor	AP-BL	BL-AP	efflux ratio (R_e)
Rh2		0.21 ± 0.01 a	3.26 ± 0.25 c	15.5 ± 1.2 b
Rh2	verapamil	2.38 ± 0.29 c	2.41 ± 0.28 b	1.0 ± 0.1 a
Rh2	MK571	0.22 ± 0.02 a	3.59 ± 0.34 c	16.3 ± 1.5 b
Rh2	EGTA	0.19 ± 0.01 a

[a]Values are the mean ± SD, $n = 3$. Values followed by a different letter in the same column are significantly different ($P < 0.05$).

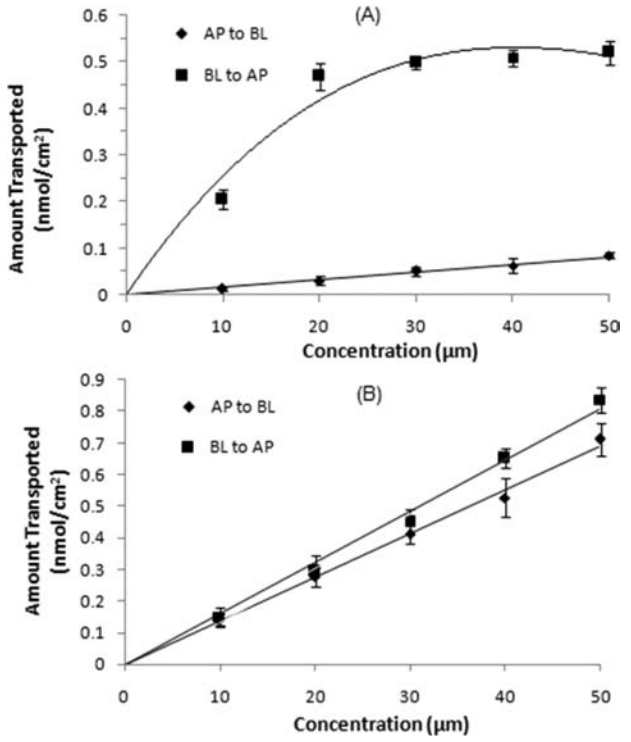

Figure 2. Effects of concentrations on the transport of (A) Rh2 and (B) Rh2-O across Caco-2 cell monolayers in both directions. Data represent the mean ± SD from three replicates.

The flux amounts of Rh2-O in both directions were similar and directly proportional to Rh2-O concentrations over 10−50 μM (Figure 2B). The P_{app} values of Rh2-O (1.96×10^{-6} cm/s for AP to BL and 2.16×10^{-6} cm/s for BL to AP) were not dependent on concentration but of similar magnitude in both directions with R_e values around 1.1. Generally, transport flux of a compound with R_e values >2 was considered as an active efflux. Therefore, the mechanism of permeation for Rh2-O in the translocation across Caco-2 cell monolayers may be passive diffusion with no active efflux involved.

Effects of Various Compounds on Rh2 and Rh2-O Transport. In the present study, EGTA, verapamil, and MK-571 were investigated for their effects on the transport flux of Rh2 and Rh2-O across the Caco-2 cells. The drug molecule can use either a transcellular (passive or active) or paracellular (passive) route to cross intestinal epithelium into systemic circulation after oral administration.[33] Generally, lipophilic molecules might have a significant transport by passive diffusion through the transcellular route, whereas hydrophilic molecules with low molecular weight cross the intestinal epithelium predominantly by paracellular passive diffusion process.[34] Because of much lower surface area available to the molecules entering the intercellular space and tight junctions in the intercellular space, the efficiency of absorption through the paracellular route is lower than that of the transcellular route. Therefore, one of the first transport mechanisms to be determined for studying the processes involved in the absorption of compounds across monolayers was the contribution of the paracellular route. Manipulating tight junction integrity of Caco-2 monolayers, which was performed by a depletion of calcium concentration in the transport medium with a calcium chelator, can be used as an approach to define absorption routes.[35] EGTA, a selective calcium chelator, is known to open the intercellular tight junctions of the Caco-2 monolayers, thus enhancing transport through the paracellular route. Compounds fluxing across Caco-2 monolayers by the paracellular pathway are very sensitive to manipulations of tight junction integrity. The Caco-2 monolayers pretreated with EGTA were employed in transport assay of Rh2 and Rh2-O to characterize the contributions of transcellular and paracellular transports of these two compounds. The $P_{app}(A - B)$ value of mannitol, a compound that is absorbed mainly via the paracellular route, acting as a positive control, was increased significantly after treatment of 2.5 mM EGTA (Table 1), indicating the opening of the tight junctions of Caco-2 monolayers in the experiment. In addition, no significant changes were observed in the P_{app} values for Rh2 and Rh2-O after treatment with 2.5 mM EGTA at 37 °C for 15 min, suggesting that the paracellular route had little contribution to their transport. These results demonstrated that the predominant transport route for both compounds was transcellular.

Verapamil and MK-571 are well-known as inhibitors of P-glycoprotein (P-gp) and multidrug resistance-related proteins (MRP1/2), respectively. Both P-gp and MRP1/2 overexpressing in Caco-2 cells and other cancer cell lines are considered as the most prevalent efflux transporters and possess a high capacity to efflux cytotoxic drugs.[36] To investigate the involvement of active efflux in transport for Rh2 and Rh2-O, the effects of verapamil and MK-571 on the transports of these two compounds were examined. Verapamil and MK-571 showed no significant effects on the P_{app} values of Rh2-O for either AP to BL or BL to AP (Table 1). Similarly, MK-571 did not significantly affect the P_{app} values of Rh2 in both transport directions. However, the treatment of verapamil alone at the apical side was able to completely inhibit the efflux transport of Rh2, and the efflux ratio was decreased to close to 1. As expected, the P_{app} value from the AP to BL was significantly increased by 11-fold and the P_{app} value from the BL to AP was significantly decreased after verapamil treatment, indicating that Rh2 may be the substrate of P-gp. Therefore, our results indicated that the major transport mechanism for Rh2 was passive transcellular diffusion with the involvement of active efflux from the BL to AP flux in Caco-2 cell monolayers. These results were similar to the report by Yang et al., which also found that the permeation mechanism of Rh2 was passive diffusion with an efflux pump (P-gp) involved in the Caco-2 cell monolayers.[37] On the other hand, however, it was reported that Rh2 was not a substrate of P-gp because 10 μM verapamil did not affect the transport of Rh2 in the Caco-2 cell model, which is contradictory to our conclusion.[38] The discrepancy may be due to the difference of P-gp expression levels in Caco-2 cells or inhibitor concentrations used among laboratories. Meanwhile, the mechanism of transport of Rh2-O was determined as passive diffusion with no active efflux involved because there was a lack of effect caused by transporter inhibitors, such as verapamil and MK-571.

Superoxide Radical Scavenging Capability of Rh2 and Rh2-O. PCL assay results showed that the superoxide radical scavenging capabilities of Rh2 and Rh2-O (1 nmol) were equivalent to 0.76 and 0.69 nmol of Trolox (data not shown), respectively. These results indicated that ginsenoside Rh2 and Rh2-O exhibited a relatively higher antioxidant capacity scavenging the superoxide radical in the cell-free systems, and the impact of esterification on superoxide radical scavenging capability of Rh2 was limited.

Effects of Rh2 and Rh2-O on H_2O_2-Induced Apoptosis of HUVECs. Endothelial cell injury caused by ROS plays a critical role in the pathogenesis of AS, and a previous study

reported that AS is characterized by the excessive apoptosis of vascular endothelial cells.[39] Oxidative stress in the vascular wall is closely related to the excessive apoptosis of HUVECs.[40] Therefore, inhibition of the excessive apoptosis of HUVECs may be considered as an efficient route in the prevention and control of AS. In the present study, HUVEC apoptosis was stimulated by H_2O_2, a commonly used oxidant. HUVECs control and pretreated cells were stained with Annexin V−FITC/PI and gated into four quadrants. The cells in the lower right (LR) and upper right (UR) were considered early apoptotic (Annexin+/PI−) and late apoptotic (Annexin+/PI+), respectively, whereas the cells in the lower left and upper left quadrants were considered live and necrotic, respectively. Extent of apoptosis was expressed as the total percentages in LR and UR quadrants. As shown in Figure 3, the apoptosis rate in untreated controls was 2.6 ± 1.1%, whereas the apoptosis rate elevated to 84.9 ± 4.3% after pretreatment with 100 μM H_2O_2-treated cells. In contrast, the apoptosis rates of HUVECs pretreated with 20 μM Rh2 markedly decreased to 63.5 ± 2.2%, and the apoptosis rates of HUVECs pretreated with Rh2-O (69.7 ± 3.9%) have no significant difference from that of pretreated with Rh2. These results demonstrated that both Rh2 and Rh2-O possess similar protective effects against oxidative stress-related cellular apoptosis.

Effects of Rh2 and Rh2-O on the NO, LDH, MDA, GSH-Px, and CAT of HUVECs. The results of effect of Rh2 and Rh2-O on the NO, LDH, MDA, GSH-Px and CAT levels of oxidative injury HUVECs are shown in Table 2. NO has gained recognition as a crucial modulator in vascular disease. It is derived from the action of eNOS and is usually regarded as an endothelial cell survival factor inhibiting cell apoptosis.[41] As shown in Table 2, compared to control group, NO levels in the medium were markedly decreased by exposure to H_2O_2, whereas pretreatment of HUVECs cells with Rh2 or Rh2-O significantly inhibited H_2O_2-induced NO level decrease.

LDH is an oxidoreductase enzyme that catalyzes the interconversion of pyruvate and lactate and is widely used as an indicator for cell damage. As shown in Table 2, LDH release in HUVECs was minimal in the control group (41.39 ± 3.97 U/L), and addition of 100 μM H_2O_2 caused a significant increase (95.25 ± 8.13 U/L). However, pretreatment of Rh2 and Rh2-O significantly attenuated the increase in LDH release induced by H_2O_2. Lipid peroxidation is the degradation of lipids that occurs as a result of oxidative damage and is a useful marker for oxidative stress. Generally, polyunsaturated lipids are susceptible to attack by ROS, resulting in the formation of MDA. Therefore, MDA can be employed as an indicator of lipid peroxidation or oxidative damage in cells.[42] The MDA concentration was 4.58 ± 0.61 nmol/mg protein in the control group (Table 2) and markedly increased to 10.32 ± 1.13 nmol/mg protein after 1 h of exposure to 100 μM H_2O_2. In contrast, the MDA concentration significantly decreased to 7.92 ± 0.69 and 6.11 ± 0.74 nmol/mg protein, respectively, after pretreatment with 20 μM Rh2 and Rh2-O, respectively.

To protect cells from the oxidative damage caused by ROS, organisms have developed several defense mechanisms to remove ROS including antioxidant enzymes GSH-PX and CAT. Both GSH-PX and CAT represent the most important H_2O_2 detoxification system in endothelial cells. GSH-Px enzymes reduce peroxides to alcohols using glutathione, thus preventing the formation of free radical damaging cells, whereas CAT directly catalyzes the decomposition of hydrogen peroxide (H_2O_2) to water and oxygen. As shown in Table 2, the activities

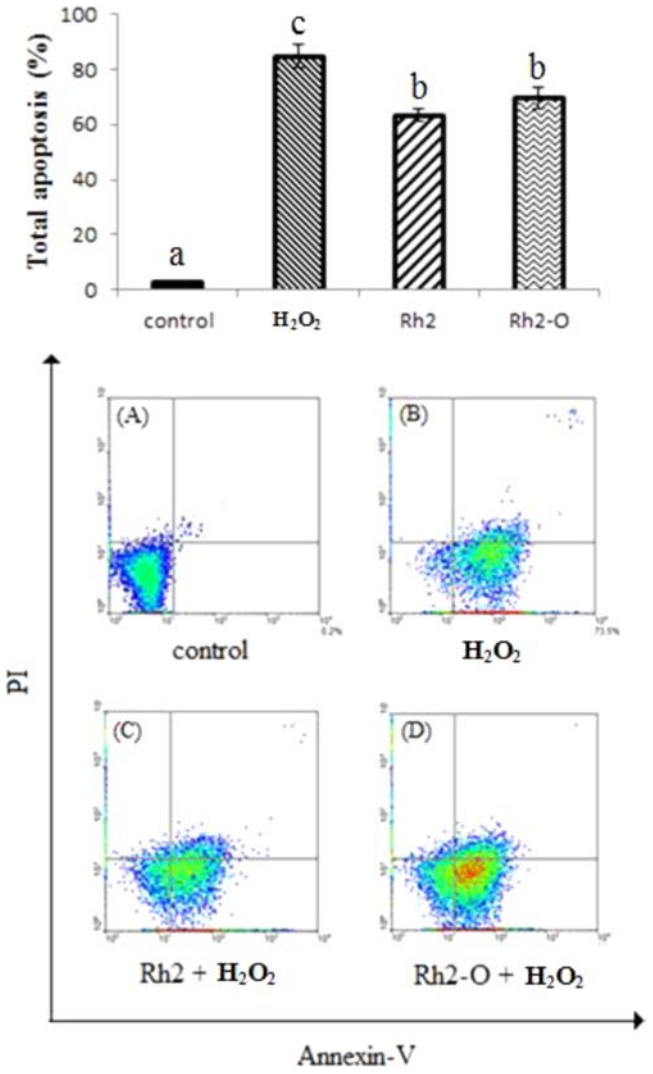

Figure 3. Analysis of HUVEC apoptosis by flow cytometry using Annexin V−FITC and PI. Quadrant analysis of fluorescence intensity of gated cells in Annexin V−FITC and PI channels was from 20000 events. Different letters above the bars present significant difference ($P < 0.05$). (A) Control; (B) H_2O_2 group (100 μM); (C) Rh2 group (20 μM); (D) Rh2-O group (20 μM).

of GSH-Px and CAT significantly decreased in the H_2O_2 group compared to the control, whereas pretreating with Rh2 and Rh2-O significantly increased the GSH-PX and CAT activities in the HUVECs. These results jointly indicated that enhancement of endogenous antioxidant preservation and attenuation of lipid peroxidation may represent major mechanisms of cellular protection against oxidative damage by ginsenoside Rh2 and its derivative Rh2-O. In addition, as depicted in Table 2, no significant difference was observed in the NO, LDH, MDA, GSH-Px, and CAT levels between the Rh2 and Rh2-O groups. These results further indicated that the synthesis of esterified derivative of Rh2 caused little impact on its bioactive protection against HUVEC oxidative damage.

Effects of Rh2 and Rh2-O on Caspase-3 Activation of HUVECs. Cell apoptosis is induced mainly via two pathways, the mitochondrial apoptotic pathway and the death receptor pathway. Both pathways converge at caspase-3 activation. Caspase-3 is one of the downstream effectors of the caspase family and regarded as a major executor caspase that leads to

Table 2. Effect of Rh2 and Rh2-O on the Nitrite, LDH, MDA, GSH-Px, and CAT Activities in HUVECs[a]

group	NO (μmol/L)	LDH (U/L)	MDA (nmol/mg protein)	GSH-PX (U/mg protein)	CAT (U/mg protein)
control	32.58 ± 3.15	41.39 ± 3.97	4.58 ± 0.61	167.92 ± 18.25	40.38 ± 2.68
DMSO	30.36 ± 3.21	42.86 ± 3.52	4.03 ± 0.55	171.35 ± 20.12	46.25 ± 3.14

apoptosis.[16] Caspase-3 activity was expressed as the fold of control group in this study; a lower value means better inhibitory activity. As depicted in Figure S1 (Supporting Information), an increase in caspase-3 activity was obvious in cells incubated with 100 μM H_2O_2 for 1 h. However, when the cells were pretreated with 20 μM Rh2 or Rh2-O for 2 h prior to the addition of 100 μM H_2O_2, the caspase-3 activation was significantly inhibited, which was consistent with the above results that Rh2 and Rh2-O protected HUVECs from oxidative damage and markedly decreased the HUVEC apoptosis. Furthermore, the inhibitory effects on caspase-3 activation had no significant difference between Rh2 and its esterified derivative as well. These studies demonstrated that Rh2 or Rh2-O can effectively restrain cell apoptosis by preventing caspase-3 activation.

In conclusion, the transport of the ginsenoside Rh2 across the intestinal epithelium was evidenced as very poor, whereas its esterified derivative Rh2-O was verified to possess a better absorption in vitro. Because verapamil had a significant effect on the P_{app} values of Rh2 and a negligible effect on that of Rh2-O, the transport mechanisms for both Rh2 and Rh2-O across Caco-2 monolayers were speculated to be transcellular passive diffusion, with an active efflux pump (P-gp) involved for Rh2 and without an active efflux involved for Rh2-O. In addition, both Rh2 and Rh2-O exhibited protective effects against HUVEC oxidative damage stimulated by H_2O_2 and effectively suppressed the activation of caspase-3 and HUVEC apoptosis. Meanwhile, we found that the synthesis of esterified derivative of Rh2 caused an ignorable impact on its bioactivities against HUVEC oxidative injury. Therefore, it is noteworthy that the findings of the present study may provide useful strategy for molecular structure modification of ginsenosides to improve oral absorption of compounds in vitro without affecting their bioactivities against the oxidative injury of HUVECs. Our further work will examine whether the intestinal absorption of Rh2 and its oral bioavailabilities are enhanced in vitro through esterification of Rh2, as well as the effects of structure modification on its bioactivities in vivo.

concentration of charged surface-active components present.[6,21,22] Several studies have shown that lipid oxidation rates in O/W emulsions stabilized with anionic surfactants are much higher due to the electrostatic attraction of cationic transition metals, whereas O/W emulsions stabilized with cationic surfactants oxidize more slowly because of electrostatic repulsion of metals away from the lipids.[23−26] The role of droplet charge has also been demonstrated in the studies of lipid oxidation in protein-stabilized O/W emulsions. In this case, lipid oxidation occurs more rapidly when the pH is above the isoelectric point (p*I*) of proteins and the emulsion droplet is negatively charged.[27−30]

Although a great deal of research has focused on the influence of different emulsifiers on lipid oxidation in O/W emulsions, there are fewer studies on the effects of emulsifiers on lipid oxidation in W/O emulsions. For example, little is known about how emulsifier type (e.g., biopolymers, anionic and cationic small molecular surfactants), concentrations, and aqueous phase pH influence lipid oxidation in W/O emulsions. Preliminary experiments showed that among such lipophilic emulsifiers as polyglycerol polyricinoleate (PGPR), lecithin, and span 60, 65, 80, and 85, PGPR was the only one tested capable of forming a stable W/O. Therefore, in the present work, PGPR was used to form stable W/O emulsions. Dodecyltrimethylammonium bromide (DTAB), sodium dodecyl sulfate (SDS), and polyoxyethylene sorbitan monolaurate (Tween 20) were added as small molecular surfactants that are cationic, anionic, and nonionic, respectively. WPI was used as an example of a biopolymer emulsifier. Experiments were then conducted to determine if these emulsifiers influenced lipid oxidation in PGPR-stabilized W/O emulsions. The knowledge gained from these studies could provide fundamental knowledge that could be used to improve the oxidative stability of oils in W/O emulsions by using different emulsifiers.

MATERIALS AND METHODS

Materials. Walnut oil was purchased from Hain Celestial Group Inc. (Melville, NY, USA) ($C_{16:0}$ = 7.13%; $C_{16:1}$ = 0.11%; $C_{18:0}$ = 3.58%; $C_{18:1}$ = 17.72%; $C_{18:2}$ = 61.91%; $C_{18:3}$ = 9.27%; $C_{20:0}$ = 0.12%; $C_{20:1}$ = 0.24%). Ferrous sulfate, cumene hydroperoxide, hexadecane, $BaCl_2$, SDS, Tween 20, DTAB, and sodium phosphate mono- and dibasic were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). Methanol, *n*-hexane, and 1-butanol were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Polyglycerol polyricinoleate (PGPR, 4175) was gifted by Palsgaard (Morristown, NJ, USA). WPI was obtained from Davisco Food International, Inc. (Eden Praire, MN, USA), and used without further purification. The protein content of WPI was 97.6 wt %. The major protein components of WPI were 55−61% β-lactoglobulin, 19−22% α-lactoalbumin, and 6−8% bovine serum albumin. All of the chemicals used in these experiments were of analytical grade or better. Glassware was placed in 2 M HCl overnight to remove transition metals followed by rinsing with double-distilled water and then drying before use. Double-distilled, deionized water was used for the preparation of all solutions.

Methods. *Emulsion Preparation and Storage Condition.* PGPR-stabilized W/O emulsions were prepared by mixing 0.5 g of PGPR into 100 g of walnut oil. Aqueous phase (2% of a 20 mM phosphate buffer solution at pH 3.0 or 7.0) with different emulsifiers was added to the PGPR−walnut oil blend, and a coarse emulsion was made by homogenization with a hand-held mixer (M133/1281-0, Biospec Products, Inc., Bartlesville, OK, USA) for 2 min. The coarse emulsion was then homogenized with a microfluidizer (Microfluidics, Newton, MA, USA) at a pressure of 12 kbar for three passes. After emulsion preparation, samples were transferred into 10 mL GC vials and sealed with aluminum caps with PTFE/silicone septa and stored at 45 °C in the dark. Three vials of each treatment were taken every day to determine lipid hydroperoxides and hexanal formation. Raw walnut oil also underwent the same emulsification process as the W/O emulsion in the experiment conducted to compare the effect of the existence of water droplet interface on the lipid oxidation.

Measurement of Physical Properties of Emulsions. The particle size of the emulsions was measured at 25 °C using a dynamic light scattering instrument (Zetasizer Nano-ZS, Malvern Instruments, Worcestershire, UK). This instrument measures the rate of electrophoretic diffusion of particles. Samples were appropriately diluted with hexadecane (refractive index = 1.434, viscosity = 3.13 mPa s at 25 °C) according to the method of Choi et al., [20] mixed, and immediately measured by transferring the diluted emulsions into 3 mL plastic curvettes. Particle size was reported as the scattering intensity−weighted mean diameter, *z*-average. The emulsion droplet size ranged from 0.2 to 0.4 μm, and there was no significant change in the droplet size of each emulsion over the course of study (data not shown). Visual observation also showed that there was no phase separation during storage in all treatments. This indicated that the emulsions were stable to droplet coalescence, sedimentation, and phase separation.

Measurement of Lipid Hydroperoxides. Lipid hydroperoxides were measured as the primary oxidation products using a method described by Shantha et al.[31] with some modifications. Emulsions (0.2 mL) were accurately weighed before they were added to a mixture of methanol/butanol (2.8 mL, 2:1, v/v) followed by addition of 15 μL of 3.94 M ammonium thiocyanate and 15 μL of ferrous iron solution (prepared by adding equal amounts of 0.132 M $BaCl_2$ and 0.144 M $FeSO_4$). The solution was vortexed, and after 20 min, the absorbance was measured at 510 nm using a Genesys 20 spectrophotometer (ThermoSpectronic, Waltham, MA, USA). The concentration of hydroperoxides was calculated from a cumene hydroperoxide standard curve.

Measurement of Hexanal. The secondary oxidation product, headspace hexanal, was monitored using a GC-17A Shimadzu gas chromatograph equipped with an AOC-5000 autosampler (Shimadzu, Kyoto, Japan) according to the method described by Panya et al.[32] with some modifications. Samples (1 mL) in 10 mL glass vials capped with aluminum caps with PTFE/silicone septa were heated at 55 °C for 8 min in an autosampler heating block before measurement. A 50/30 μm DVB/Carboxen/PDMS solid-phase microextraction (SPME) fiber needle from Supelco (Bellefonte, PA, USA) was injected into the vial for 2 min to absorb volatiles and was then transferred to the injector port (250 °C) for 3 min. The injection port was operated in split mode, and the split ratio was set at 1:7. Volatiles were separated on a 30 m × 0.32 mm Equity DB-1 column from Supelco with a 1 μm film thickness at 65 °C for 10 min. The carrier gas was helium at 15.0 mL/min. A flame ionization detector was used at a temperature of 250 °C. Hexanal concentrations were determined from peak areas using a standard curve prepared from an authentic standard.

Measurement of Iron-Binding Capacity of WPI. The ability of WPI to bind iron was determined using a modified method of Bincan et al.[33] Dialysis bags (molecular mass cutoff 8 kDa, Shengya Co., Xi'an, China) were cleaned by heating them twice at 80 °C for 30 min in a 2% sodium bicarbonate and 1 mM EDTA solution. The bag was then thoroughly rinsed with deionized water and stored at 5 °C in a 0.1% sodium azide solution. WPI solutions (10% w/v) were prepared with 20 mM phosphate buffer solution at pH 3.0 and 7.0, respectively, using 1.0 M NaOH and HCl to adjust the pH. Two aliquots of 1 mL of WPI solution at pH 3.0 or 7.0 were pipetted into the dialysis bag, equilibrated for 30 min at room temperature in 98 mL of 20 mM phosphate buffer solution at pH 3.0 or 7.0, respectively, and constantly stirred. One milliliter of an 80 μg/mL Fe^{2+} solution (prepared from Fe_2SO_4 in 20 mM phosphate buffer solution at pH 3.0 or 7.0) was then added to the flask so that the final concentration of ferrous outside the dialysis bag was 8 μg/mL. After equilibrium for 24 h, the concentrations of Fe^{2+} outside the dialysis bag were measured by flame atomic absorption spectrophotometer (Sollar-3500, USA).

Statistical Analysis. All analyses were performed on triplicate samples. Oxidation lag phases were defined as the first data point significantly greater than the 0 time value. In all cases, comparisons of the means were performed using Duncan's multiple-range tests. A significance level of $p < 0.05$ was defined as being statistically different.

All calculations were performed using the statistical analysis software SPSS 17 (Statistical Package for the Social Sciences).

RESULTS AND DISCUSSION

Effects of Type and Concentration of Surfactants on the Oxidative Stability of Water-in-Walnut Oil Emulsions. As far as O/W emulsions are concerned, Boon et al.[26] and Haahr et al.[34] have proposed that the oxidative stability of oil-in-water emulsions is determined by the ability of the droplet to attract or repel cationic metals. Emulsion droplet charge is dependent on the type of surfactants (cationic, anionic, or neutral) and the emulsion pH that affects surfactant charge.[7,17] Many studies have confirmed that lipid oxidation was promoted when positively charged transition metals were electrostatically attracted to the surface of the negatively charged emulsion droplets due to close interaction between the lipid substrate and prooxidative transition metals, whereas lipid oxidation was retarded by cationic surfactants that electrostatically repelled metals away from the lipids.[23−30]

In the case of W/O emulsions, to obtain a better understanding of the influence of the type of surfactants on the lipid oxidation, a comparison of oxidation rates as determined by lipid hydroperoxide and headspace hexanal was conducted in walnut oil and 2% water-in-walnut oil emulsions stabilized by PGPR alone or with SDS, DTAB, or Tween 20. Emulsions were incubated at 45 °C for up to 25 days, and the results are shown in Figure 1.

Interestingly, regardless of the type of emulsifier used, all of the emulsions containing 2% water had higher lipid hydroperoxide and hexanal formation rates than the walnut oil alone. The results were different from the observation by Fritsch, who stated that the rates of lipid oxidation in W/O emulsions would be similar to that in bulk oils if the same amount of surface lipid was exposed to air.[35] As stated earlier, the decomposition of lipid hydroperoxides into highly reactive radicals by prooxidants such as transition metals is the main pathway for the promotion of lipid oxidation. Lipid hydroperoxides are surface-active compounds and are thus able to accumulate at the water−lipid interface of emulsion droplets.[19,36] In this way, the higher rates of lipid oxidation in W/O emulsions were possibly due to the large surface area that facilitated interactions between the lipid hydroperoxides and water-soluble prooxidants. Similar phenomena have been observed in O/W emulsions.[16] The results indicated that the presence of a large interface between oil and water in W/O emulsions might also affect the lipid oxidation.

With regard to the type of surfactants, significant differences in oxidation rates were observed among the samples containing different surfactants, suggesting that the type of surfactants in emulsions was an important factor influencing the lipid oxidation in W/O emulsions. However, surprisingly, it could be seen that lipid hydroperoxides increased rapidly in W/O emulsions containing PGPR + DTAB compared to PGPR alone (lag phase 2 and 7 days, respectively), whereas lipid hydroperoxide concentrations were lowest in emulsions containing PGPR + SDS (lag phase 10 days). No differences in lipid hydroperoxide formation were found between the PGPR and PGPR + Tween 20 emulsions (lag phase 7 days). When the secondary lipid oxidation product, hexanal, was measured to monitor lipid oxidation in emulsions containing different surfactants, a similar trend in lipid oxidation rates was observed with PGPR + DTAB > PGPR ≈ PGPR + Tween 20 > PGPR + SDS, indicating that the anionic surfactant again inhibited lipid oxidation, whereas the cationic surfactant promoted lipid oxidation in W/O emulsions.

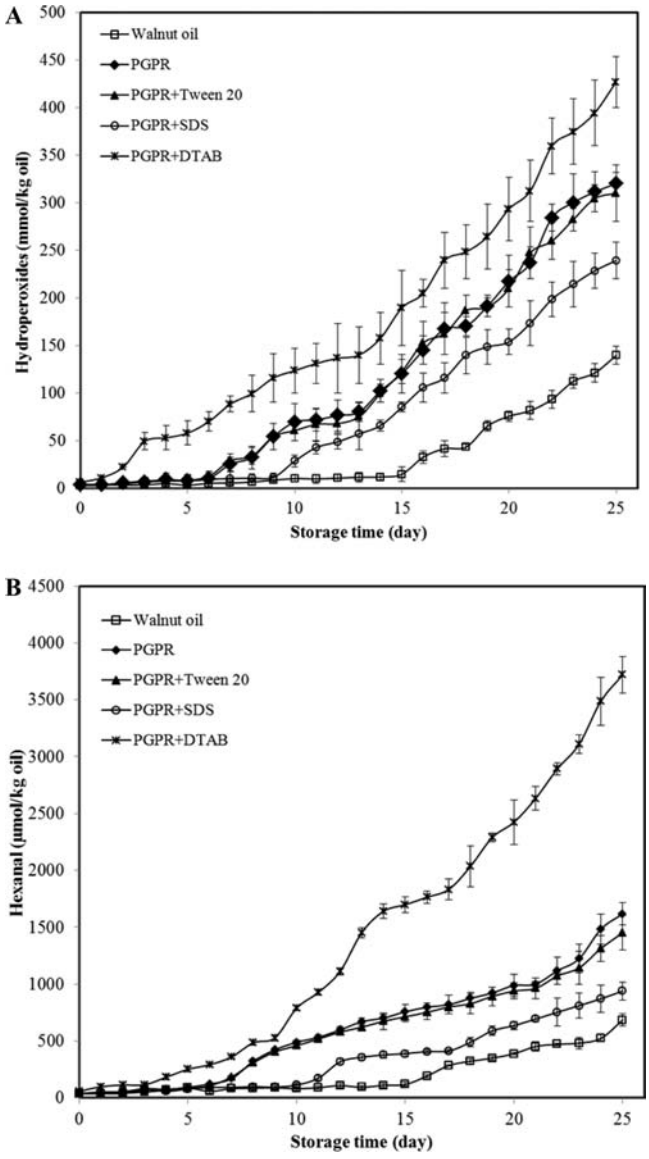

Figure 1. Effects of different surfactants in the aqueous phase (0.1 wt % of emulsions) on the oxidative stability of 2% water-in-walnut oil at aqueous phase pH 7.0 during storage at 45 °C in the dark for 25 days. Lipid oxidation was monitored by measuring hydroperoxides (A) and hexanal (B). Data points and error bars represent means (n = 3) ± standard deviations.

Figures 2 and 3 clearly show that the oxidative stability of emulsions with increasing SDS concentrations did not further increase oxidative stability but increasing DTAB did cause additional promotion of oxidation. These results were completely opposite to the studies in O/W systems by Mei et al.,[23,24] Silvestre et al.,[25] Boon et al.,[26] Hu et al.,[27,28] and Mancuso et al.,[29,30] who found that lipid oxidation was retarded by cationic surfactants and promoted by anionic surfactants, presumably because the surface of the positively charged emulsion droplets containing cationic surfactants repelled metals away from the water−oil interface where lipid oxidation usually occurs, whereas the surface of the negatively charged emulsion droplets containing anionic surfactants attracted metals to the interface.

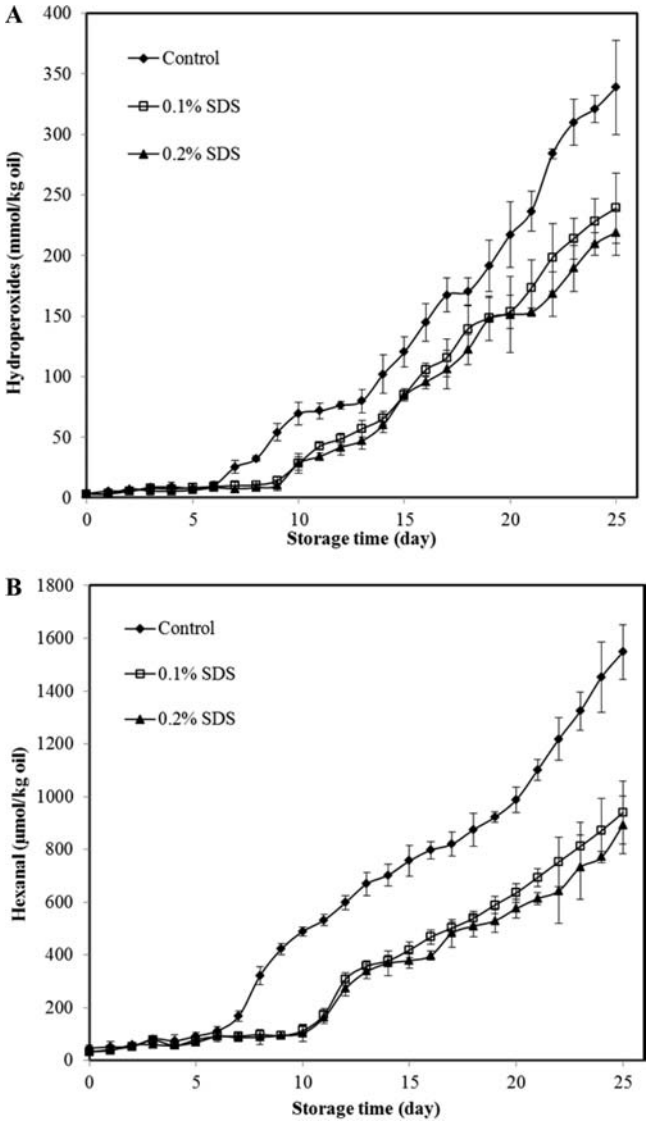

Figure 2. Effects of concentration of SDS in the aqueous phase on the oxidative stability of 2% water-in-walnut oil at aqueous phase pH 7.0 during storage at 45 °C in the dark for 25 days. Lipid oxidation was monitored by measuring hydroperoxides (A) and hexanal (B). Data points and error bars represent means (n = 3) ± standard deviations.

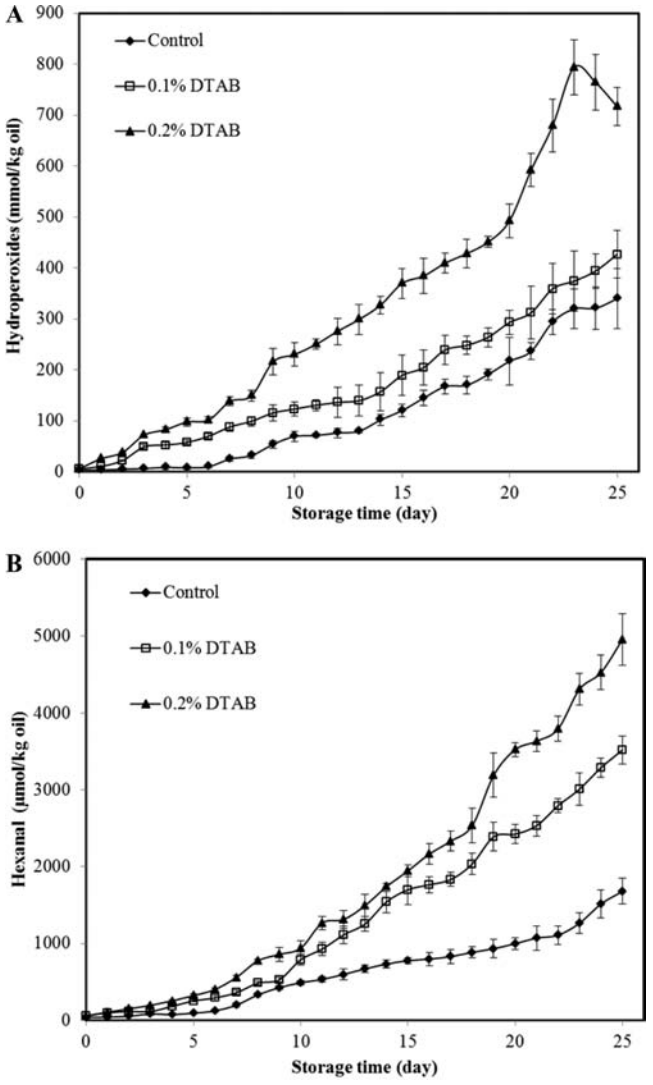

Figure 3. Effects of concentration of DTAB in the aqueous phase on the oxidative stability of 2% water-in-walnut oil at aqueous phase pH 7.0 during storage at 45 °C in the dark for 25 days. Lipid oxidation was monitored by measuring hydroperoxide (A) and hexanal (B). Data points and error bars represent means (n = 3) ± standard deviations.

The reason W/O emulsions containing SDS had higher oxidative stability seemed likely due to the fact that aqueous phase SDS formed negative micelles that were able to electrostatically attract transition metals, thereby reducing the concentration of prooxidants (e.g., transition metals) at the oil−water surface, a location where lipid oxidation reactions primarily occurs (seen in Figure 4). Similar results were found for the hemoglobin-catalyzed oxidation of a safflower oil-in-water emulsion, where the presence of excess anionic surfactant in the aqueous phase of the emulsion increased the oxidative stability.[37] Tween 20 is weakly anionic and thus might not be able to remove metals away from the lipid−water interface. It is unclear why a cationic surfactant such as DTAB would promote oxidation in the W/O emulsion.

Effects of WPI on the Oxidative Stability of Water-in-Walnut Oil Emulsions. Whey protein products such as WPI are commonly used as emulsifiers in O/W emulsions because they have good emulsifying and stabilizing properties.[38,39]

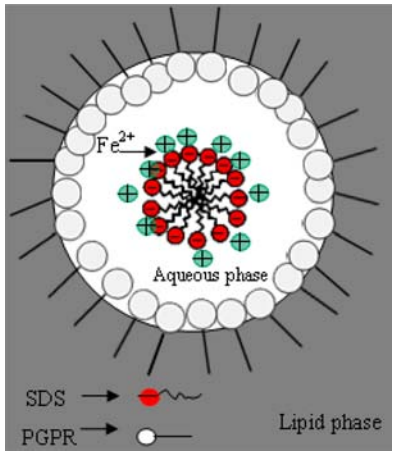

Figure 4. Schematic demonstration of the ability of SDS in the aqueous phase of W/O emulsions to interact with transition metals such as iron and inhibit lipid oxidation.

dx.doi.org/10.1021/jf404593f | J. Agric. Food Chem. 2014, 62, 2104−2111

Moreover, WPI has been shown to possess antioxidative properties in O/W emulsions when they are either at the emulsion droplet surface or in the aqueous phase.[28,40,41] Tong et al.[42] reported that the origin of the antioxidant activity of whey proteins was due to free radical scavenging by sulfhydryl and aromatic amino acids and transition metal chelation. To determine if WPI influenced the oxidative stability of W/O emulsions, the oxidative rates were analyzed by monitoring the formation of lipid hydroperoxides and hexanal. Figure 5 shows

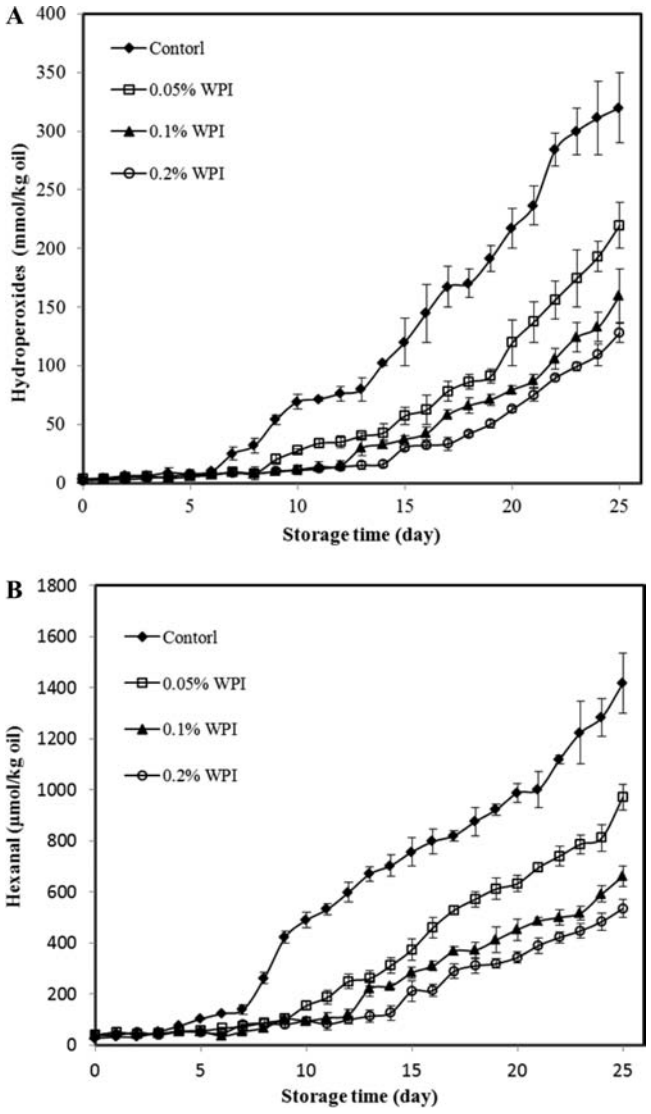

Figure 5. Effects of the concentration of WPI in the aqueous phase on the oxidative stability of 2% water-in-walnut oil at aqueous phase pH 7.0 during storage at 45 °C in the dark for 25 days. Lipid oxidation was monitored by measuring hydroperoxide (A) and hexanal (B). Data points and error bars represent means (n = 3) ± standard deviations.

that increasing concentration of WPI in W/O emulsions at pH 7.0 could decrease lipid oxidation rates. The lag phases of lipid hydroperoxide and hexanal formation in the control (without WPI) were 7 and 8 days, respectively. In the presence of 0.05, 0.1, or 0.2 wt % WPI (of emulsions), the lag phase increased to 9, 13, and 15 days for lipid hydroperoxides, respectively, and 10, 13, and 15 days for hexanal, respectively, suggesting that a higher concentration of WPI in the aqueous phase of W/O emulsions might have contributed to the better oxidative stability.

Hu et al.[27] and Kulmyrzaev et al.[43] have reported that the isoelectric point (pI) of WPI is 5.1, and pH values below or above the pI can dramatically affect the antioxidant activity of WPI. Therefore, further comparisons of oxidation rates as a function of aqueous phase pH were also determined. Figure 6

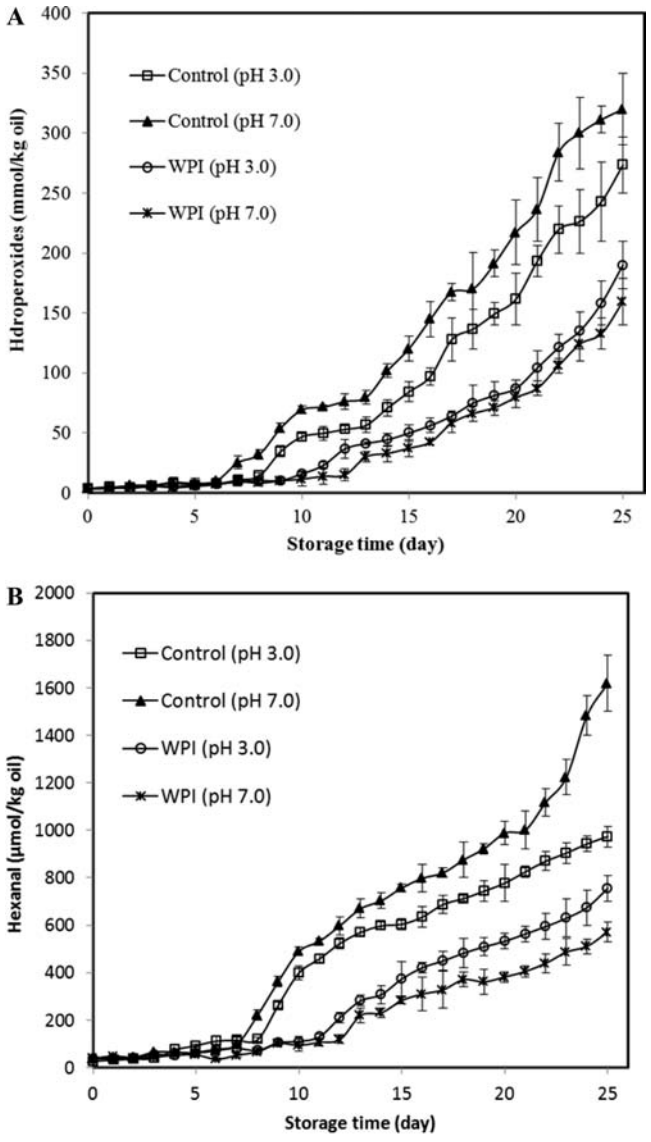

Figure 6. Effects of WPI (0.1 wt % of emulsions) as a function of different aqueous phase pH on the oxidative stability of 2% water-in-walnut oil during storage at 45 °C in the dark for 25 days. Lipid oxidation was monitored by measuring hydroperoxides (A) and hexanal (B). Data points and error bars represent means (n = 3) ± standard deviations.

shows that lipid oxidation of the controls was more rapid when the aqueous phase was pH 7.0 than when it was pH 3.0. At aqueous phase pH 7.0, lipid oxidation of the emulsions occurred slowly with the lag phases of both lipid hydroperoxide and hexanal formation being 7 and 8 days, respectively. The lag phases of lipid hydroperoxide and hexanal formation in the control at aqueous phase pH 3.0 were the same at 9 days of storage. Mancusco et al.[44] also observed that oxidation rates increased with increasing pH in Tween 20-stabilized salmon

dx.doi.org/10.1021/jf404593f | J. Agric. Food Chem. 2014, 62, 2104−2111

oil-in-water emulsion. The same authors proposed that at pH 7.0, low iron solubility resulted in precipitation of metal onto the lipid droplet surface, thereby bringing iron in closer contact with the lipid compared to pH 3.0, where the water solubility of iron is dramatically higher. If the same was true in the W/O emulsions, where iron could precipitate onto the lipid surface, it was not surprising that high pH in the aqueous phase microenvironment promoted lipid oxidation in W/O emulsions. In addition, it was reported that at pH 7.0, free fatty acids in the oil are negatively charged and thus can attract transition metals and increase lipid oxidation rates.[45,46] At pH 3.0 the free fatty acids lose their charge and are less prooxidative. Because all refined oils contain some free fatty acids, it is possible that the decrease in lipid oxidation rates with decreasing pH observed in this study could be due to the presence of free fatty acids.

The ability of WPI to inhibit lipid oxidation in W/O emulsions was greater at pH 7.0 than at pH 3.0 (Figure 6). For example, the lag phase of hexanal formation increased from 8 days (control) to 13 days in the presence of 0.1 wt % WPI at pH 7.0. This compares to an increase the lag phase of hexanal formation from 9 days (control) to 12 days in the presence of 0.1 wt % WPI at pH 3.0. The antioxidant activity of proteins in the continuous phase of O/W emulsions has also been found to be greater at pH values above the p*I* of the protein.[47] The reason for increased antioxidant activity of proteins at pH values above the p*I* is thought to be the increased ability of proteins to bind transition metals when they are negatively charged. For example, WPI bound over 3 times more iron at aqueous phase pH 7.0 than at aqueous phase pH 3.0 (Figure 7).

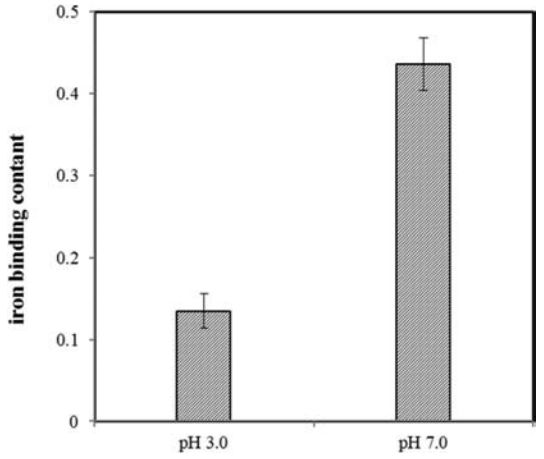

Figure 7. Iron bonding constant per gram WPI during incubation of ferrous ion (8 mg/L) in WPI solution at different pH values for 24 h. Data points and error bars represent means (n = 3) ± standard deviations.

Thus, it was possible that in the microenvironment of the aqueous phase in the W/O emulsions, WPI exhibited better antioxidant activity at pH 7.0 than at pH 3.0 due to binding more transition metals. However, it should be noted that WPI did inhibit lipid oxidation at pH 3.0 when the protein was cationic. This could still be due to its weak chelating activity but also could be due to its free radical scavenging activity.

Effects of WPI and Surfactants Combinations on the Oxidative Stability of Water-in-Walnut Oil Emulsions. Combinations of molecules in emulsion can often interact and synergistically or antagonistically impact lipid oxidation rates.[48] The impact of combinations of between WPI and DTAB or SDS on lipid oxidation rates in the W/O emulsion were tested at both pH 3.0 and 7.0 because the antioxidant activity of WPI was strongly influenced by pH.

The oxidative stability of the controls was observed to be pH dependent, with higher pH increasing lipid oxidation rates in the W/O emulsions as also observed in Figure 6. WPI was again found to be a stronger antioxidant at pH 7.0 than at pH 3.0 as first reported in Figure 6. Table 1 shows that emulsions

Table 1. Effects of the Interaction of WPI with SDS on Lag Phases of Lipid Hydroperoxide and Hexanal Formation in 2% Water-in-Walnut Oil Emulsions during Storage at 45 °C in the Dark for 25 Days

	lag phases[a] (days)	
treatment	hydroperoxide formation	hexanal formation
WPI (pH 3.0)	11	12
WPI (pH 7.0)	13	13
SDS (pH 3.0)	10	10
SDS (pH 7.0)	10	10
WPI + SDS (pH 3.0)	12	13
WPI + SDS (pH 7.0)	15	15
control (pH 3.0)	9	9
control (pH 7.0)	7	7

[a]Oxidation lag phases were defined as the first data point significantly greater than the 0 time value at the level of $p < 0.05$. All concentrations of emulsifiers were 0.1 wt % of emulsions.

containing WPI alone oxidized significantly more slowly than emulsions containing SDS alone, indicating that WPI had stronger antioxidant activity than SDS. From Table 1, it can also be seen that pH had no significant influence on the lag phases of both lipid hydroperoxide and hexanal formation in emulsions containing SDS ($p > 0.05$). The combination of WPI and SDS increased the lag phases of both lipid hydroperoxide and hexanal formation greater than either WPI or SDS alone at both pH 3.0 and 7.0. This increase in antioxidant activity by the WPI/SDS combination could simply due to an increase in the total metal chelating capacity in the emulsion. However, it is also well-known that SDS can induce denaturation of proteins and that exposing amino acids in the core of proteins can increase the ability of proteins to inhibit lipid oxidation.[49,50] The greater inhibition of lipid oxidation by the combination of WPI/SDS at pH 7.0 than at pH 3.0 could be due to WPI's greater antioxidant activity when it is negatively charged.

The influence of interactions between WPI and DTAB on lag phases of lipid hydroperoxide and hexanal formation in W/O emulsions was also investigated (Table 2). DTAB alone consistently promoted lipid oxidation, whereas WPI alone consistently inhibited lipid oxidation in W/O emulsions, similar to the results above (Figures 3 and 6). The combination of WPI and DTAB resulted in lag phases for 5 and 6 days for hydroperoxides and hexanal formation, respectively, at pH 3.0 (Table 2). At pH 7.0, lag phases for hydroperoxides and hexanal formation were 7 and 8 days, respectively, for the DTAB/WPI combination (Table 2). These lag phases are greater than those for DTAB alone but less than for WPI. This is likely because the antioxidant capability of WPI was able to counteract some of the prooxidant activity of DTAB but not to the extent that the lag phases were equal to WPI alone. The lag phases for hydroperoxides and hexanal formation for the WPI/DTAB combination were greater at pH 7.0 than at pH 3.0,

control (pH 3.0)	9	9
control (pH 7.0)	7	7

[a]Oxidation lag phases were defined as the first data point significantly greater than the 0 time value at the level of $p < 0.05$. All concentrations of emulsifiers were 0.1 wt % of emulsions.

which again could be attributed to the increase antioxidant activity of WPI when it is anionic and better able to chelate metals.

In conclusion, the current study shows that formation of a W/O emulsion increased oxidation rates compared to bulk oil. This acceleration of oxidation could be due to the increase in surface area that could facilitate interactions between lipids and water-soluble transition metals. The present work also indicates that Tween 20 had no impact on lipid oxidation rates, whereas DTAB increased oxidation in an unknown manner. SDS and WPI inhibited lipid oxidation in the W/O emulsions, which could be due to metal chelation by these anionic surfactants. WPI was a better antioxidant at pH 7.0 than at pH 3.0 presumably due to its higher transition metal-binding capacity at pH values above the p*I* of the proteins, where the proteins would be anionic. However, WPI was also able to inhibit oxidation at pH 3.0 when it would be cationic, suggesting that it may also be able to inhibit oxidation by scavenging free radicals. Only the combination of WPI and SDS resulted in increased antioxidant activity compared to the individual compounds, which could be due to increased metal chelating capacity or combining both metal chelating and free radical scavenging activities. These results suggest that compounds that chelate transition metal could be used to increase the oxidative stability of W/O emulsions. The ability of WPI to inhibit lipid oxidation in W/O emulsions suggests that it could be used as a natural antioxidant in foods such as spreads.

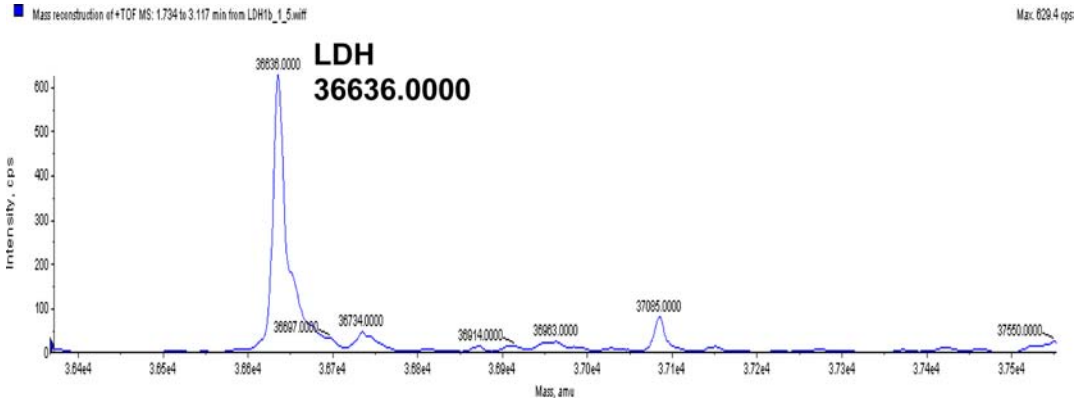

Figure 1. ESI-MS spectrum of bovine LDH control (0.2 mM) at pH 7.4. The *X*-axis indicates mass measured as atomic mass unit (amu) and *Y*-axis indicates intensity measured as counts per second (cps).

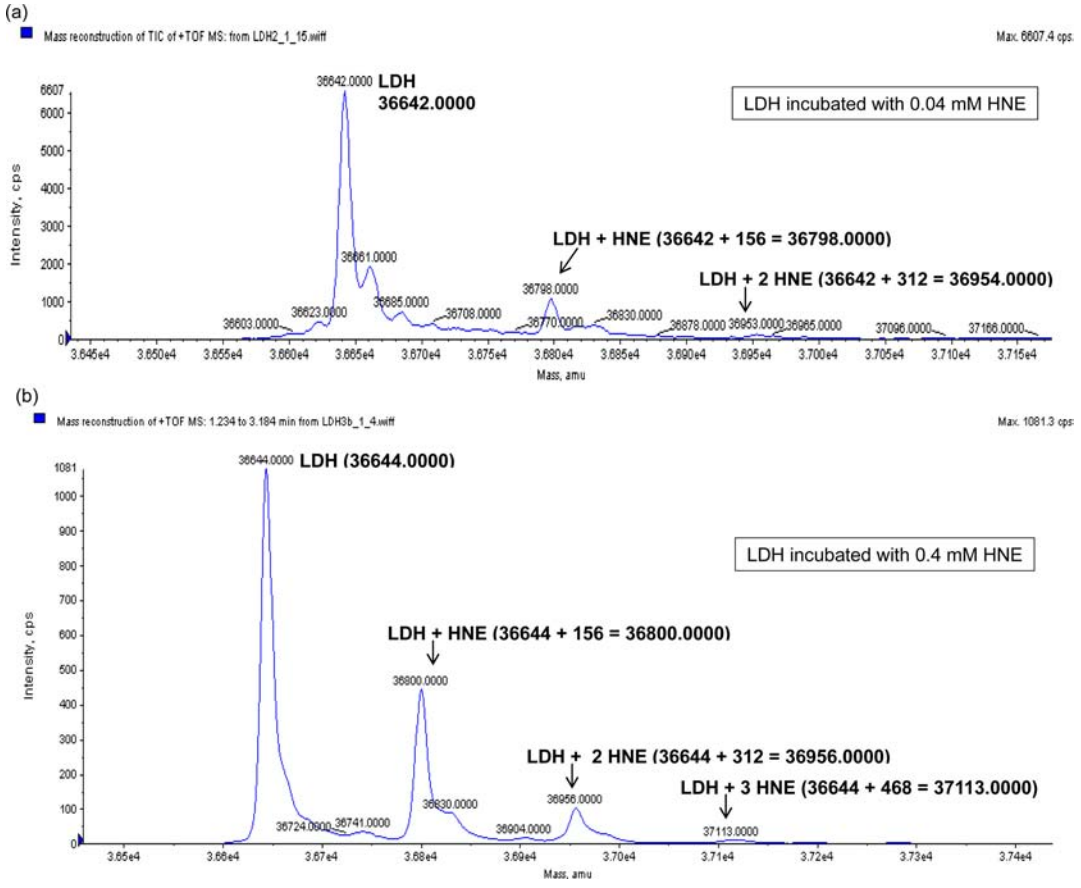

Figure 2. ESI-MS spectrum of bovine LDH (0.2 mM) incubated with (a) HNE 0.04 mM and (b) 0.4 mM at pH 7.4. The *X*-axis indicates mass measured as atomic mass unit (amu) and *Y*-axis indicates intensity measured as counts per second (cps).

Louis, MO). 4-Hydroxy-2-nonenal was obtained from Cayman Chemical Co. (Ann Arbor, MI). PD-10 columns, CM and DEAE cellulose ion exchange chromatography columns were obtained from Pharmacia (Piscataway, NJ). All chemicals were of reagent grade or greater purity.

Myoglobin Isolation and Preparation of Metmyoglobin. Beef myoglobin was purified via ammonium sulfate precipitation and gel filtration chromatography according to Faustman and Phillips.[17] The isolated myoglobin was a mixture of oxy-, deoxy-, and metmyoglobin. To limit the interference with metmyoglobin reduction in the current study, oxidizing agents were not used to convert oxy- or deoxymyoglobin to metmyoglobin. Hence, metmyoglobin was prepared by incubating myoglobin at 37 °C for 24 h. Columns precalibrated with either 50 mM phosphate buffer (pH 7.4) or 50 mM phosphate buffer (pH 5.6) were used to adjust the pH of metmyoglobin solutions. The initial metmyoglobin content was 98.9%, determined according to Tang et al.[18]

Isolation of NADH-Dependent Cytochrome b5 Reductase. Metmyoglobin reductase was isolated according to Hagler et al.[19] and Faustman et al.[20] Aliquots (1 mL) were stored at −80 °C until use.

Effects of HNE on Lactate Dehydrogenase Activity. Commercially purchased purified bovine heart LDH (0.2 mM) was incubated with HNE (0, 0.04, or 0.4 mM dissolved in ethanol) for 5 h at pH 7.4 or for 72 h at pH 5.6 (normal meat pH) in a glass test tube. Lactate dehydrogenase activity was measured as the formation of NADH at 0, 1, 3, and 5 h at pH 7.4 and 0, 24, 48, and 72 h at pH 5.6. Briefly, lactate (50 mM), LDH (0.2 mM), and NAD (0.2 mM) were reacted in incubation buffer (50 mM phosphate buffer) at both pH

values in a quartz cuvette for 3 min. The formation of NADH was measured according to Bergmeyer[21] and Ramanathan et al.,[22] where an increase in absorbance at 340 nm indicates NADH formation. Following determination of LDH activity, a PD column was used to remove unbound HNE and LDH was stored at −80 °C until use.

NADH-Dependent Cytochrome b5 Metmyoglobin Reduction. The methodology according to Reddy and Carpenter[2] was modified to determine NADH-dependent cytochrome b5 metmyoglobin reduction. The assay mixture contained 0.15 mM metmyoglobin in either 50 mM phosphate buffer at pH 5.6 or 7.4, 0.05 mL of 0.2 mM NAD, 0.05 mL of 1 M lactate, 0.1 mL of 5 mM EDTA, 0.1 mL of 3.0 mM potassium ferrocyanide, and 0.03 mL of purified NADH-dependent cytochrome b5 reductase. The reaction was initiated by the addition of LDH at 25 °C according to Ramanathan et al.[15] (0.02 mM LDH in the final reaction mixture; LDH preincubation with HNE or ethanol described in the previous section). Metmyoglobin reduction (nanomoles of metmyoglobin reduced per minute per milligram of reductase) was calculated according to Faustman et al.[20] using the change in absorbance at 580 nm. The protein concentration of reductase was determined using a bicinchoninic acid protein assay.

Mass Spectrometry. Protein masses of native and HNE-treated LDH, including LDH peptide preparation and analysis (Trypsin digestion), were measured according to the method described by Nair et al.[23] For Asp-N and double digestion, 10 μL of LDH solution was dried and digested in 10 μL of 40 mM ammonium bicarbonate +9% acetonitrile containing 0.02 μg (Sigma, St. Louis, MO) proteomics grade endoproteinase Asp-N at room temperature for 4 h.

Statistical Analysis. The experimental design was a completely randomized design with repeated measures, and each experiment was replicated five times (n = 5). Fixed effects for both NADH-dependent

cytochrome b5 reductase and LDH activity include HNE concentration, incubation time, and their interaction. Data was analyzed using the MIXED Procedure of SAS (version 9.1, SAS Institute Inc. Cary, NC), and the Repeated option was used for both NADH-dependent cytochrome b5 reductase and LDH activity measurements. The diff option (LSD at $P < 0.05$ for significance) was used to separate least-squares means from protected F-tests ($P < 0.05$).

RESULTS AND DISCUSSION

Effects of HNE on Covalent Binding on LDH. Characterization of LDH using MS revealed that the mass of protein samples used in the current study matched that of LDH B (isoform predominantly present in cardiac muscle; Figure 1). Mass spectrometric examination revealed that HNE adducted to LDH. Mono-, di-, and triadducts were detected at pH 7.4, whereas only monoadducts were identified at pH 5.6 (Figures 2 and 3). More specifically, MS/MS results indicate that HNE can bind with cysteine residues of LDH at pH 5.6 and 7.4 (Table 1).

Table 2. Active Site Residues in Bovine Heart Lactate Dehydrogenase

active site	position in the sequence	amino acid
NAD binding	100	arginine
substrate binding	106	arginine
NAD/substrate binding	139	asparagine
substrate binding	170	arginine
proton acceptor	194	histidine
substrate binding	249	threonine

Carbon 3 within HNE can covalently bind via Michael addition to histidine residues within myoglobin from all livestock and poultry species and result in increased oxymyoglobin oxidation.[24−27] In addition, HNE adduction makes myoglobin a poor substrate for enzymatic metmyoglobin reduction.[28] Furthermore, covalent binding of HNE to myoglobin can increase heme release.[29]

The active site residues involved in LDH enzymatic activity are summarized in Table 2. Although HNE did not bind to residues within the active sites, the current study suggests that binding to other amino acids can influence enzyme activity. For example, the amino acid sequence of LDH has 7 histidine, 5 cysteine, and 26 lysine residues (Figure 4; www.expasy.org).

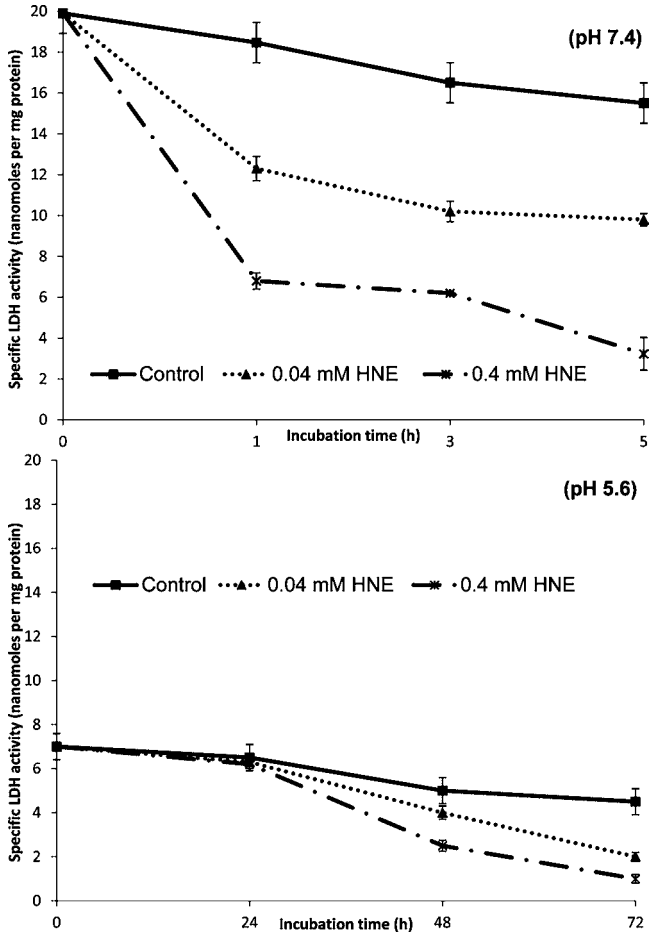

Figure 5. Effect of HNE on LDH activity at pH 5.6 and 7.4. Standard error bars are indicated.

The MS/MS analysis in the current research indicates that HNE binds to cysteine and histidine residues (Table 1). More specifically, at 0.4 mM HNE, four sites of HNE adduction were identified at His-68, Cys-164, Cys-186, and Cys-294 at pH 7.4. However, no histidine adducts were identified at pH 5.6, likely because histidine residues would be expected to have a greater positive charge at pH 5.6 than 7.4, which would reduce reactivity with HNE.[30] The current study is the first to report

dx.doi.org/10.1021/jf404900y | J. Agric. Food Chem. 2014, 62, 2112−2117

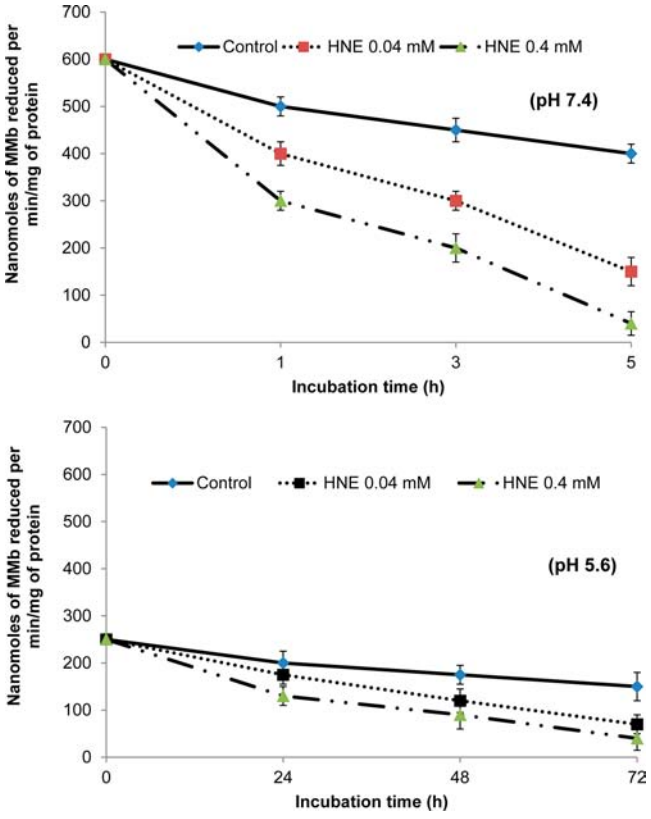

Figure 6. Effect of HNE on LDH-mediated enzymatic metmyoglobin reduction at pH 5.6 and 7.4. Standard error bars are indicated.

that HNE can influence enzymes involved in metmyoglobin reduction.

Previous studies have shown that HNE can covalently bind to enzymes and decrease activity. For example, Hussain et al.[31] reported that HNE decreased rabbit muscle enolase activity in vitro. Covalent binding of HNE to cysteines, histidine, and lysine residues of glyceraldehyde 3-phosphate dehydrogenase and subsequent enzyme inactivation was reported by Uchida and Stadtman.[32] In support, the current study indicates that HNE can bind to cysteine and histidine residues in LDH.

Effects of HNE on LDH Activity and Metmyoglobin Reduction. There was a significant HNE × incubation time interaction for LDH activity (Figure 5). Decreased NADH formation in samples treated with HNE was supported by limited enzymatic metmyoglobin reduction (Figure 6). The effect of HNE on LDH activity was concentration dependent, and HNE had a greater effect on enzyme activity at pH 7.4 than at pH 5.6. Several studies have reported that lipid oxidation and myoglobin oxidation are interrelated. In addition to direct interaction between myoglobin and HNE, the current study indicates that lipid oxidation products decrease meat color stability by influencing enzymes involved in NADH production and metmyoglobin reduction.

In conclusion, HNE can covalently bind to histidine and cysteine residues in LDH and will decrease NADH formation. The results indicate that secondary lipid oxidation products will inactivate enzymes involved in metmyoglobin reduction and, as a result, increase beef discoloration.

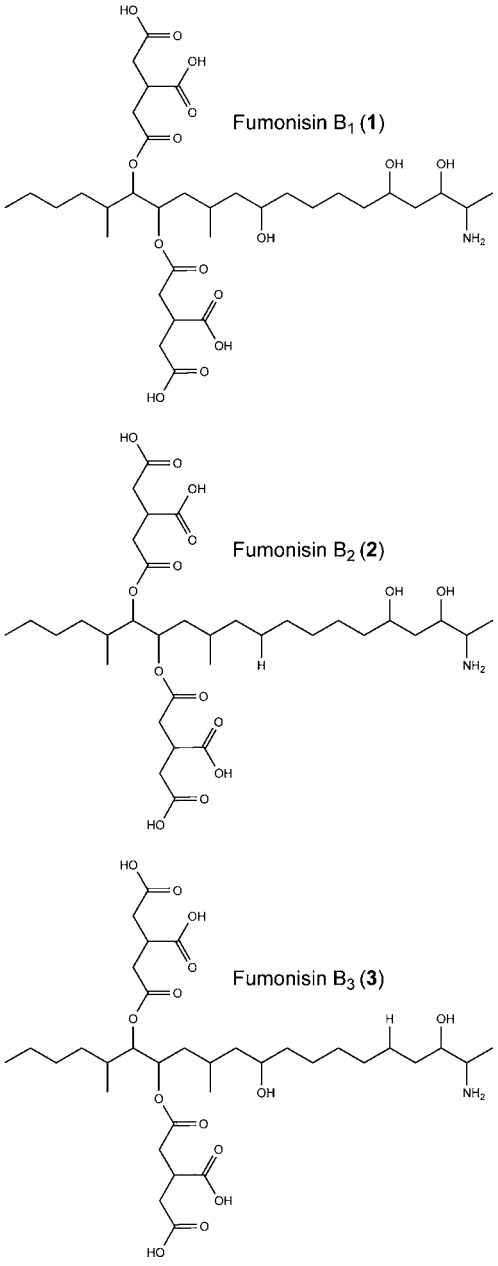

Figure 1. Chemical structures of the B-series fumonisins, FB_1 (**1**), FB_2 (**2**), and FB_3 (**3**).

aerial tissues did analyze the first, second, and third leaves and determined the highest fumonisin accumulation occurred in the first leaf of maize seedlings grown from seed inoculated with *F. verticillioides*.[24] Accumulation of fumonisins in these tissues was noted as containing a significantly higher ratio of FB_1 to FB_2 and FB_3 compared to the observed accumulations in the roots,[24] suggesting a mechanism of greater accumulation of FB_1 over the other analogues by either selective transport or selective production of FB_1 by the fungus colonizing the leaf. Further questions arose about the mechanism of fumonisin accumulation when uninoculated seedlings were watered with FB_1 and FB_2 without detectable accumulation in the leaf tissues,[25] thus suggesting the fungus is essential for accumulation of FB_1 in the leaves. In the current study we address the colonization and fumonisin accumulation discrepancies of why FB_1 does accumulate in leaves infected with *F. verticillioides*, yet does not accumulate in leaves when uninfected seedlings are watered with an aqueous FB_1 solution. Additionally, we also address the potential necessity of conidia for colonization of the seedlings. A holistic sampling strategy was utilized to address the following questions: (i) What is the extent of colonization in maize seedlings when seeds are inoculated with fumonisin-producing and nonproducing strains in combination with wild-type conidiation versus aconidial phenotypes? (ii) What is the resulting fumonisin accumulation in those seedlings? (iii) Are the patterns of fumonisin accumulation and *F. verticillioides* colonization different in fumonisin-insensitive compared to fumonisin-sensitive maize lines? (iv) Does transpiration have a possible role in the movement and accumulation of FB_1?

MATERIALS AND METHODS

Chemicals. Acetonitrile (MeCN) (Burdick & Jackson, Muskegon, MI, USA) and water (J. T. Baker, Phillipsburg, NJ, USA) were of HPLC grade, and formic acid (>95%) (Sigma-Aldrich, St. Louis, MO, USA) was of reagent grade. Fumonisin B_1 (FB_1), fumonisin B_2 (FB_2), and fumonisin B_3 (FB_3) for standard preparation were provided as a gift from Ronald Plattner, National Center for Agricultural Utilization Research, USDA-ARS, Peoria, IL, USA. D-*erythro*-C_{17}-Sphingosine-1-phosphate, D-*ribo*-phytosphingosine-1-phosphate, D-*erythro*-sphingosine 1-phosphate, and D-*erythro*-dihydrosphingosine-1-phosphate were purchased from Avanti Polar Lipids (Alabaster, AL, USA). Phytosphingosine, DL-*erythro*-dihydrosphingosine, and D-*erythro*-sphingosine were purchased from Sigma-Aldrich. D-*erythro*-C_{16}-Sphingosine was from Matreya (Pleasant Gap, PA, USA). Stock solutions, working standards, and internal standards were prepared as previously described.[22] Sucrose (Sigma-Aldrich), Murashige and Skoog basal medium macrosalts and microsalts (Sigma-Aldrich) and Bacto Agar (Difco Laboratories, Inc., Sparks, MD, USA) were utilized for the plant nutrient agar.[26]

Extraction and Analysis of Fumonisins. The procedures for extraction of fumonisins from soil and plant tissues have been reported previously.[24,27] Briefly, lyophilized maize leaf tissues were ground to a powder, spiked with D-*erythro*-C_{16}-sphingosine and D-*erythro*-C_{17}-sphingosine-1-phosphate internal standards (10 μL each at 100 ng/μL) and then extracted with an aliquot of 1:1 MeCN/water + 5% formic acid (1 mL per 10 mg tissue). The filtered extracts (100 μL aliquots) were diluted into the initial mobile phase (900 μL) used for reverse phase high-performance liquid chromatography (RP-HPLC). Air-dried soils were extracted in a similar manner in 1:1 MeCN/water + 5% formic acid (25 mL per 2 g).

All analyses were performed as described previously.[24] Analyses were conducted using a Finnigan Micro AS autosampler coupled to a Surveyor MS pump (Thermo-Fisher, Woodstock, GA, USA). Separation was accomplished using a Cadenza 150 × 2 mm i.d., 3 μm, CW-C18 column (Imtakt, Philadelphia, PA, USA). Column effluent was coupled to a Finnigan LTQ linear ion trap mass spectrometer (MS). The fumonisins, sphingoid bases, and sphingoid base 1-phosphates were analyzed, but only the fumonisin data are reported.

Fungal Strains. The four strains of *F. verticillioides* used in this study were JFL-A04516 (JFL = John F. Leslie, Department of Plant Pathology, Kansas State University, Manhattan, KS, USA), AEG 3-A3-2 (AEG = Anthony E. Glenn, Russell Research Center, USDA-ARS, Athens, GA, USA), AEG 3-A3-5, and MRC826 (Medical Research Council, Tygerberg, South Africa). Both AEG strains are unable to produce conidia.[28] AEG 3-A3-5 produces fumonisins, whereas AEG 3-A3-2 lacks the FUM gene cluster and does not produce fumonisins. Strain JFL-A04516 also does not produce fumonisins due to a point mutation in *FUM1*, a polyketide synthase necessary for fumonisin production.[20] MRC826, as our positive control, is wild type for fumonisin production and conidiation.

Maize Seedling Assay. The maize lines used were Silver Queen (SQ) (Gurney's Seed & Nursery Co., Yankton, SD, USA), a sweet

corn line that is susceptible to *F. verticillioides*-induced maize seedling disease;[23] W23 (The Germplasm Resources Information Network (GRIN), accession no. NSL 30060), a resistant field corn inbred; and B73 (GRIN, accession no. Bc5S4), a moderately resistant field corn inbred. Maize kernels were treated as described previously.[23] Briefly, kernels were surface-disinfected for 10 min in 100% commercial bleach (5.25% hypochlorite), rinsed with sterile water, and allowed to imbibe for 4 h in sterile water. The seeds were then heat shocked by placing them in a 60 °C water bath for 5 min for internal sterilization.[29] Seeds were inoculated with a 10^4 spores/mL suspension and incubated overnight at 27 °C. Three replicates of 10 seeds each were planted in sterile 10 cm plastic azalea pots (Hummert International, Earth City, MO, USA) containing twice-autoclaved commercial potting soil mix (Conrad Faford Inc., Agawam, MA, USA).

The treatments were as follows: SQ/control, SQ/MRC 826, SQ/AEG 3-A3-2, SQ/AEG 3-A3-5, SQ/JFL-A04516, W23/control, W23/MRC826, B73/control, and B73/MRC826. Pots were watered as needed throughout the duration of the assay. Assays were performed under aseptic conditions in a plant growth chamber at 30 °C under a 14 h light (cool-white, high-output fluorescent tubes at an average of 254 μmol/m^2/s) and 10 h dark regimen at 20 °C. Plant tissues were collected for analysis 14 days after planting. During harvest, the shoot portions of the seedlings were separated into first, second, and third leaves (numbered in order of their emergence and expansion) for each replicate pot. Leaves were excised approximately 5 mm from the ligule, such that all portions of the sheath were excluded from the analyses. After removal, a 2−3 cm section of the leaf was sampled and stored for culturing. An approximate 3−4 cm section of the stem between the soil surface and the first leaf was also excised and stored for culturing. Root tissues were also collected and processed as described previously.[23] During root harvest, a section of the mesocotyl (as large as possible) was also sampled and stored for culturing. All tissues removed for culturing were stored briefly at 4 °C. The root and leaf tissues to be analyzed for fumonisins, sphingoid bases, and sphingoid base 1-phosphates were immediately frozen at −20 °C.

In Planta Colonization. Plant tissues reserved for culturing were surface sterilized according to tissue type. Leaves were sterilized in s 10% bleach solution for 10 min followed by a 95% ethanol wash for 5 min. Stems and mesocotyls were sterilized in 20% bleach for 15 min followed by a 95% ethanol wash for 10 min. Tissues were rinsed five times with sterile distilled water (dH_2O) and then plated on potato dextrose agar (PDA) (Sigma, St. Louis, MO, USA) and incubated at 27 °C to assess internally colonizing fungal strains. Tissue infection was observed after 6 days and checked again after 10 days to allow for emergence of any slow-growing fungi. Fungal isolates were identified to genus on the basis of morphological features, including microscopic examination for production of conidia.

Soil Colonization. In the first trial, soil was collected from each individual pot and air-dried for 2 weeks in open plastic bags. After 2 weeks, 1 g of soil was added to 100 mL of autoclaved dH_2O and placed on a 250 rpm rotary shaker for 10 min. A 100,000-fold dilution was made of each soil sample, and 100 μL each of this dilution was plated in triplicate on PDA. Plates were incubated at 27 °C for 4 days. After 4 days, colony-forming units (CFU) were identified as *Fusarium* or other genera. The second trial was quantitated in the same manner, but was performed using wet soil and sampled immediately at the end of the trial to detect fungi that may have been sensitive to desiccation in the first trial. After sampling, the soils from the second trial was air-dried as before.

In Vitro Test Tube Exposure of FB_1. Maize kernels were sterilized and imbibed as described previously.[23] Lines utilized were Silver Queen, W23, and Tama Flint (GRIN, accession no. NSL 217411), a landrace previously noted to be highly insensitive to FB_1.[30] Individual kernels were placed in 25 × 150 mm culture test tubes (Kimble Chase LLC, Rockwood, TN, USA) with 4 mL of plant agar media.[26] Maize seedlings were grown for 7 days under the same growth chamber conditions noted above and culled for fungal contamination. Using a syringe, FB_1 (10 μM), abscisic acid (ABA) (200 μM), or FB_1 and ABA (10 and 200 μM) were injected into the media. Plants were harvested after 24 and 48 h by separating the leaves and stems from the roots. Care was taken not to allow the leaves or stems to have contact with the FB_1-containing agar media. Samples were lyophilized and extracted as mentioned above to assess FB_1 accumulation in the plant.

Statistical Analysis. Statistical analysis was performed using SigmaStat software (Jandel Scientific, San Rafael, CA, USA). For most data sets comparing many groups, one-way analysis of variance was used and ordered by Student−Newman−Keuls test. The maize seedling tissue colonization data were evaluated using the Kruskal−Wallis one-way analysis of variance to determine significant differences between treatments within each tissue type. Except where indicated otherwise, all data were expressed as the mean ± standard deviation, and differences among means were considered to be significant if the probability (P) was $\leq$0.05. All results for plant tissues are expressed as dry weight.

RESULTS AND DISCUSSION

On the basis of our previous work, we hypothesized fumonisin is mobile in planta, accumulates in the leaves, and requires the presence of the fungus in the roots but does not require direct fungal colonization of the leaves. Thus, it should follow that fumonisin accumulation in the leaves is likely via a plant-derived mechanism affected by the fungus in a manner other than direct colonization of the leaves. To assess colonization and colocalization of fumonisin accumulation during seedling infection, the sweet corn cultivar Silver Queen was inoculated with *F. verticillioides* strain MRC826, JFL-A04516, AEG 3-A3-2, or AEG 3-A3-5. Silver Queen is highly susceptible to fumonisin-related seedling blight.[17,23,27] Results are presented separately for the two biological replicates, noted as trial 1 and trial 2, because these data could not be grouped statistically because of significant differences in colonization rates and fumonisin accumulation. Both trials independently show patterns that support the same conclusions despite the significant biological variation. Silver Queen seedlings demonstrated a clear correlation between seed inoculation with fumonisin-producing strains and development of disease symptoms (Table 1). We also assessed the fumonisin-insensitive inbreds W23 and B73 in trial 1 only. These seeds were contaminated with several naturally occurring fungi, such as species of *Acremonium*, *Aspergillus*, *Penicillium*, and *Fusarium*, despite our attempts to sterilize the seed. When inoculated with

Table 1. Characteristics of *Fusarium verticillioides* Strains and Resulting Disease Incidence on Silver Queen (SQ), B73, and W23

			disease incidence[a] (%)		
			sensitive	insensitive	
strain	conidia production	fumonisin production	SQ[b]	B73[c]	W23[c]
water control			0/0	0	0
MRC826	yes	yes	59/92	0	4
JFL-AO4516	yes	no	0/0	ND	ND
AEG 3-A3-5	no	yes	76/87	ND	ND
AEG 3-A3-2	no	no	0/0	ND	ND

[a]Disease incidence is defined as the average percentage of seedlings that exhibit the symptoms associated with disease, such as stunting, leaf lesions, and leaf abnormalities. [b]Disease incidence for trials 1 and 2 of the experiment is reported separately for SQ (trial 1/trial2). [c]B73 and W23 were included only in trial 1 and were inoculated only with MRC826. Disease incidence was not determined (ND) for other strains on B73 and W23.

MRC826, B73 showed no symptoms of seedling blight. Similarly, W23 had very few seedlings with disease symptoms.

Soil analysis was performed to evaluate the ability of the *F. verticillioides* strains to colonize the soil during seedling assays. Colonization of the dried soil from trial 1 was significant for MRC826 and JFL-A04516. In contrast, no colonization was observed for AEG 3-A3-2 and AEG 3-A3-5 (Figure 2A) even at

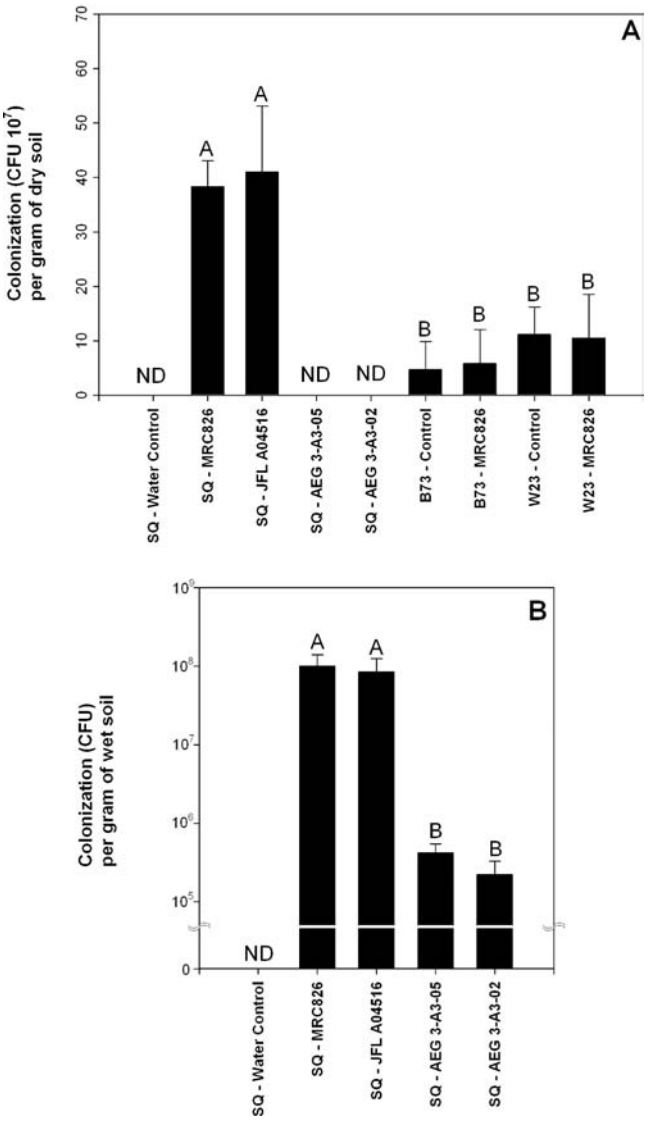

Figure 2. Soil colonization by strains of *Fusarium verticillioides*. Values are the mean ± standard deviation, and letters indicate a statistically significant difference ($P \leq 0.05$, $n = 3$ pots per trial). Trial 1 (A) shows quantification of *F. verticillioides* strains in dried soil at the end of the 14 day experiment involving Silver Queen (SQ) grown from seed inoculated with the strains. Also shown are B73 and W23 water controls and MRC826 inoculations. Trial 2 (B) was similar but based on wet weight of soil. Trial 2 did not include B73 and W23 treatments. ND indicates no *Fusarium* colonies detected.

low serial dilutions. For B73 and W23, soil colonization was observed in both control and MRC826 treatments, which was not surprising given the seed contamination noted above. When performing the second trial, wet soil was sampled to determine if the viability of aconidial strains AEG 3-A3-2 and AEG 3-A3-5 was more susceptible to desiccation effects (Figure 2B). Soil colonization was noted for AEG 3-A3-2 and AEG 3-A3-5, even though the CFU calculations were 250−500-fold less compared to the conidia-producing wild-type MRC826 (Figure 2B). The drying procedure in the first trial apparently did affect the viability of these aconidial strains, likely due to the lack of drought-resistant structures (i.e., spores). Other than this difference in how the soils were sampled for colonization (dry versus wet), all other experimental protocols were identical between trials 1 and 2.

Figure 3 shows fumonisin accumulation in the soil and Figure 4, in the roots. Trials 1 and 2 provided similar results,

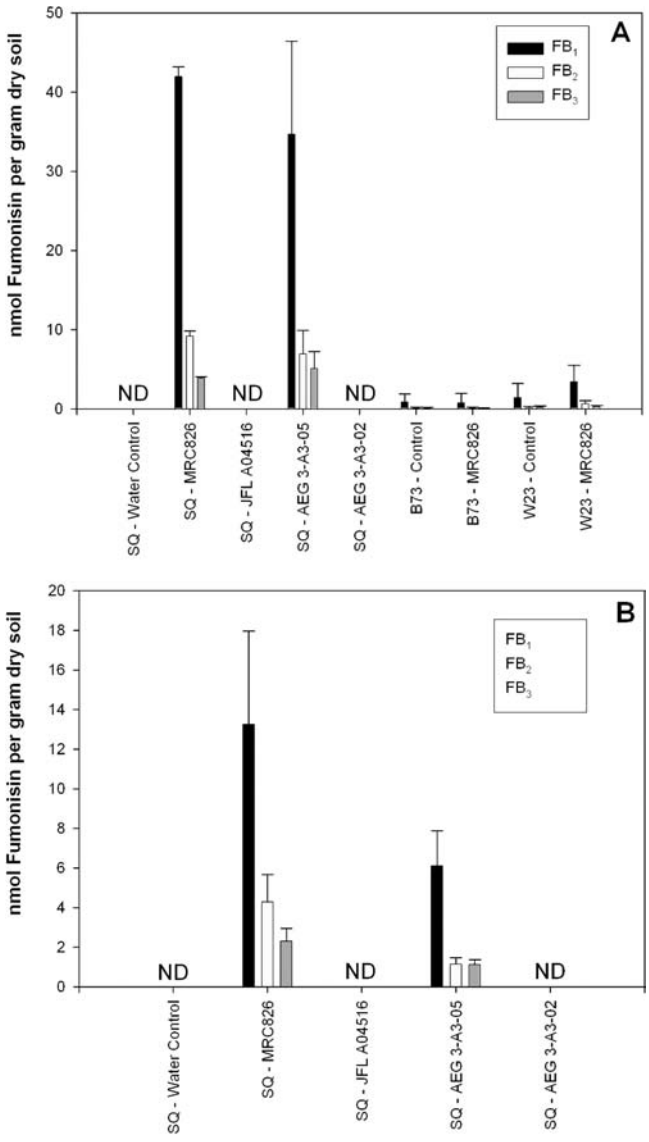

Figure 3. Fumonisin accumulation in soil. Values are the mean ± standard deviation of fumonisin B_1, B_2, and B_3 (respectively, FB_1, FB_2, and FB_3) accumulation in the soil for trial 1 (A) and trial 2 (B) ($n = 3$ pots per trial). ND indicates none detected.

where only fumonisin-producing strains resulted in fumonisin accumulation in the soil or the root tissues. Relatively small amounts of fumonisins were detected in soils from inbreds B73 and W23. Only a small amount of FB_1 (0.34 ± 0.2 nmol/g) was detected in the roots of W23 inoculated with MRC826. Despite the lower soil colonization detected for AEG 3-A3-5, the levels of fumonisin contamination in the soil were not statistically different from MRC826 (Figure 3). A similar trend was noted

dx.doi.org/10.1021/jf5001106 | J. Agric. Food Chem. 2014, 62, 2118−2125

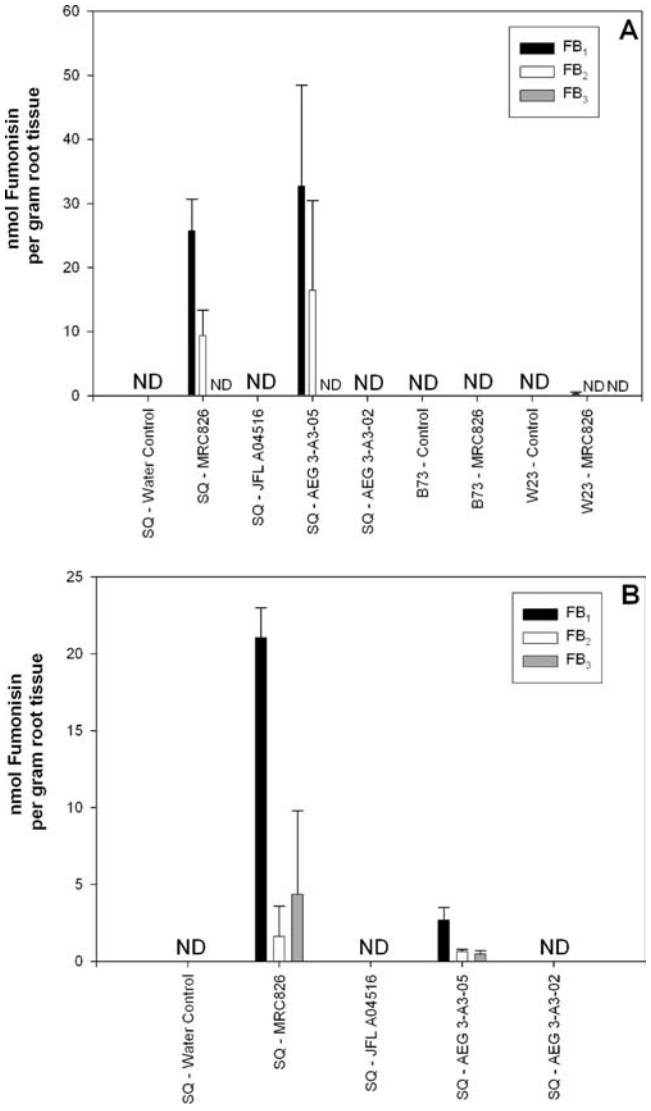

Figure 4. Fumonisin accumulation in root tissue. Values are the mean ± standard deviation of fumonisin B_1, B_2, and B_3 (respectively, FB_1, FB_2, and FB_3) accumulation in the root tissue for trial 1 (A) and trial 2 (B) (n = 3 pots per trial). ND indicates none detected.

for fumonisin in roots (Figure 4). Statistical differences were noted for fumonisin accumulation in roots of MRC826 and AEG 3-A3-5 in trial 2 (Figure 4B).

Tissue colonization by the different strains of *F. verticillioides* is summarized in Table 2. Differences were noted between trials 1 and 2 for frequency of colonization, which suggested that colonization of the plant tissue can be highly variable. Such variability also may explain the differences in fumonisin accumulation in roots noted above. Despite the variability, the Kruskal–Wallis one-way analysis of variance determined that significant differences (P = 0.004) existed between treatments within each tissue type for each trail. Minor colonization of the mesocotyl and stem was observed in Silver Queen uninoculated controls in both trials and may reflect the sensitivity of the test and the difficulties of preventing cross-contamination despite precautionary efforts. It should be noted that despite colonization of the Silver Queen control roots, fumonisins were not detected in the soil or roots, suggesting the background colonization had minimal effects on the parameters we assessed during the course of this study. The AEG 3-A3-2 and AEG 3-A3-5 strains had minimal colonization of the mesocotyl and no colonization of the stem in trial 1, but showed higher colonization rates in trial 2 (Table 2). Neither AEG 3-A3-2 nor AEG 3-A3-5 colonized the leaf tissues in trials 1 and 2. Interestingly, fumonisin accumulation in the leaves (Figure 5) was clearly evident for AEG 3-A3-5 despite the inability to colonize the leaves. In trial 1, only MRC826 colonized the first leaf. In trial 2, colonization was noted for MRC826 and JFL-A04516 in all three leaves at varying rates. Although the trials indicate that leaf colonization is variable, it is clear that the aconidial strains AEG 3-A3-2 and AEG 3-A3-5 are greatly attenuated in their ability to infect the leaves of seedlings.

Only FB_1 was detected in the leaves, FB_2 and FB_3 were not, which supports the observations of Williams et al.[23] and Zitomer et al.[24] Trial 1 (Figure 5A) and trial 2 (Figure 5B) had similar accumulations of FB_1 in the first and second leaves for MRC826 and AEG 3-A3-5 inoculated Silver Queen despite the fact that AEG 3-A3-5 did not colonize leaf tissue (Table 2). B73 and W23 had no detectable FB_1 in the leaves despite higher rates of colonization than in Silver Queen (Table 2). Colonization was counterintuitively higher in the uninoculated control leaf tissues for B73 and W23 compared to the MRC826 inoculated plants. Perhaps inoculation triggered plant defenses, thus lowering colonization frequency. This observation requires further experimentation.

Our data suggest *F. verticillioides* is necessary for accumulation of FB_1 in leaves but that leaf colonization is not required for FB_1 accumulation in these tissues. Further investigations are necessary to understand what mechanism may be responsible for such distal accumulation and how it preferentially targets FB_1. Furthermore, is this mechanism an important component of colonization of the leaves and progression of seedling blight symptom development? Perhaps of most interest is how the resistant inbreds seem to suppress growth of *F. verticillioides* and its capacity for fumonisin production and tissue colonization.

To refine our observations with W23 and eliminate any influence of the fungi contaminating the seed, an experiment was performed on plant nutrient agar in test tubes to quantitate the uptake of FB_1 (10 μM) into the roots and aerial tissues when the FB_1 is added to the agar (Figure 6). Silver Queen and Tama Flint were included as well. The high insensitivity of Tama Flint to FB_1 was noted previously.[30] Germinated seeds were screened to eliminate any samples having fungal contamination.

Analysis of the FB_1 accumulation in the roots revealed a significant difference in root uptake of FB_1 for W23 and Tama Flint compared to Silver Queen. No FB_1 was noted in the aerial tissues in all three maize lines (data not shown). As suggested by the seedling blight assays, the test tube assay indicated the FB_1-insensitive maize lines W23 and Tama Flint absorb less bioavailable fumonisin than does Silver Queen. The mechanism for absorption of fumonisin into the roots may explain differences in the FB_1-sensitive and -insensitive phenotypes. One possibility is that uptake of FB_1 may be driven by transpiration and bulk flow. The hormone abscisic acid (ABA) is known for triggering stomatal closure, thus limiting transpiration.[31] We hypothesized that if FB_1 uptake is dependent on transpiration and bulk flow, then the addition of ABA should limit uptake by closing stomata. To investigate this possibility, Silver Queen was coexposed to ABA and FB_1 in test tube assays. FB_1 absorption was significantly less in ABA coexposed roots after 48 h, suggesting transpiration may have a

[a]Values are presented as the mean ± standard deviation of percent tissue from each treatment per pot (n = 3 pots per trial).

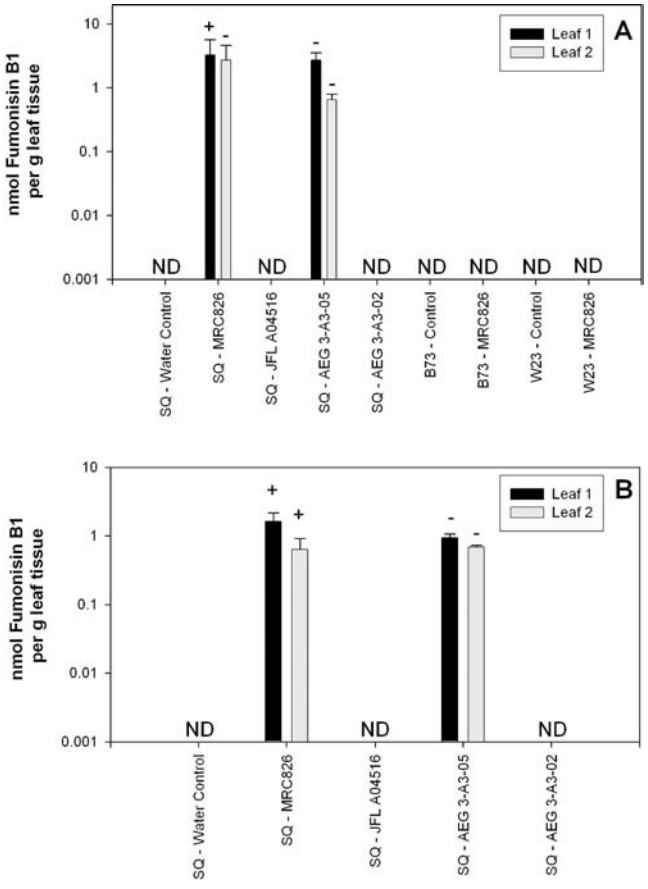

Figure 5. Fumonisin B_1 accumulation in leaves. Values are the mean ± standard deviation of fumonisin B_1 detected in leaves 1 and 2 in trials 1 (A) and 2 (B) (n = 3 pots per trial). Fumonisin B_2 and B_3 were not detected in the leaves. ND indicates not detected, and ± indicates colonization status of the leaf.

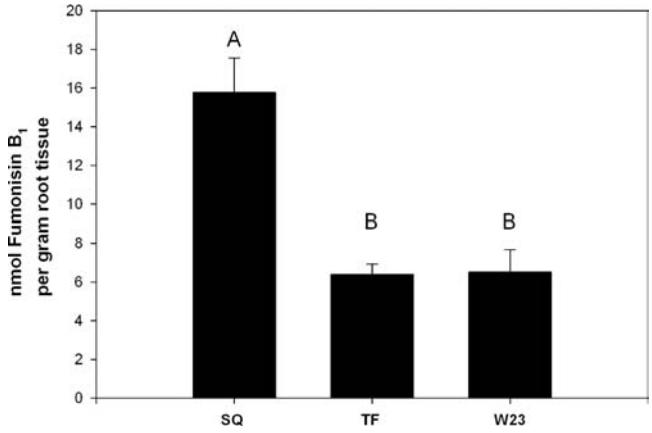

Figure 6. Fumonisin B_1 (FB_1) root accumulation in Silver Queen (SQ), Tama Flint (TF), and W23. FB_1 was spiked into the agar of the test tubes containing the seedling for a final concentration of 10 μM and harvested 48 h after exposure. Accumulation of FB_1 is reported as the mean ± standard deviation from two biological replicates (n = 3 per replicate), and letters indicate a statistically significant difference ($P \leq 0.05$).

role in FB_1 absorption into the roots (Figure 7). Future experiments will evaluate transpiration differences between Silver Queen, W23, and Tama Flint.

In summary, on the basis of our Silver Queen model, local colonization of maize seedling leaf tissue is not necessary for accumulation of FB_1 in those leaves. However, the mechanism for shootward movement of FB_1 into the leaf tissues does require the presence of the fungus in the roots. Such distal movement has been elucidated for other mycotoxins. For example, wheat spikes infected with *Fusarium culmorum* were shown to have trichothecenes migrating beyond the infection hyphae into the xylem and phloem sieve tubes where no fungal colonization was apparent.[32] Our experiments would suggest a similar fate of FB_1 moving ahead of colonization, at least in Silver Queen. Absorption of FB_1 was markedly decreased in the insensitive maize genotypes. The mechanism of FB_1 uptake into the roots is unknown; however, our study suggests ABA might modulate FB_1 uptake and alludes to a possible connection to bulk flow and transpiration. More research on the mechanism for FB_1 accumulation in the roots and how the fungus facilitates movement of FB_1 into the leaves will give us a better understanding of seedling blight disease progression and associated virulence of *F. verticillioides* and perhaps whether such movement contributes to any food safety or exposure concerns. Also, B73 and W23 seem to have inhibitory

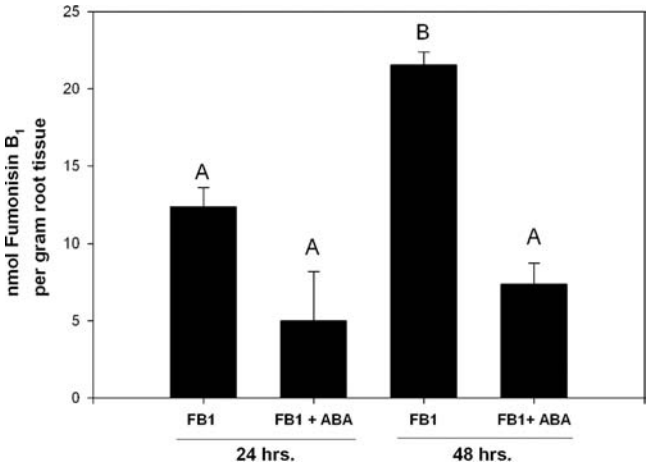

Figure 7. Fumonisin B_1 (FB_1) accumulation in seedlings coexposed with abscisic acid (ABA). Seedlings were assessed after 24 and 48 h of exposure to FB_1 (10 μM final concentration) or FB_1 plus ABA (200 μM). Accumulation of FB_1 is reported as the mean ± standard deviation from two biological replicates (n = 3 per replicate), and letters indicate a statistically significant difference ($P \leq 0.05$).

properties that decrease the growth and fumonisin production by *F. verticillioides* in the soil. This could be due to a range of defense mechanisms expressed by the plant, such as fortifying the cell wall with callose deposits, activation of a hypersensitive response, expression of chitinases and β-1,3-glucanases, and release of phytoprotective compounds such as the cyclic hydroxamic acids (DIMBOA and DIBOA).[33−37] Another possibility is that the fungi naturally inhabiting the seed of B73 and W23, such as *Acremonium zeae*, may be antagonists suppressing the growth of *F. verticillioides*.[38] Future research will investigate the role of plant defense mechanisms and competitive inhibition strategies for the control of *F. verticillioides*.

Plant Materials. Three blueberry species, *V. bracteatum* Thunb. (VB), *V. oldhamii* Miquel. (VO), and *V. corymbosum* L. (VC), were investigated in this study. VB and VO samples were collected from Sanghyo-dong, Seogwipo-si, Jeju Island, South Korea; annual precipitation in this area is approximately 2000 mm, and they are approximately 300 and 500 m above sea level, respectively. VC, which is a common highbush blueberry, was harvested from Sagye-ri, Andeok-myeon, Seogwipo-si, Jeju Island, South Korea. This region is 100 m above sea level and receives 1400 mm of rainfall annually. The blueberry samples were freeze-dried for 5 days and stored at below −70 °C before extraction.

Sample Preparation. Dried samples were homogenized using a mortar and pestle. Each powdered sample (50 mg) was extracted with 1 mL of solvent mixture (methanol/water/chloroform = 2.5:1:1) by using a Retsch MM400 mixer mill (Retsch GmbH & Co, Haan, Germany) at 30 Hz/s for 10 min and centrifuged at 4 °C and 1200 rpm for 5 min. The supernatant (100 μL) was completely dried using a speed vacuum concentrator (Biotron, Seoul, Korea). For gas chromatography−time-of-flight-mass spectrometry (GC-TOF-MS) analysis, two derivatization steps were performed. First, oximation was conducted by dissolving the dried extracts in 50 μL of methoxyamine hydrochloride (20 mg/mL in pyridine) and reacting at 30 °C for 90 min. The samples were then silylated with 50 μL of MSTFA at 37 °C for 30 min. For ultraperformance liquid chromatography−quadrupole-time-of-flight-mass spectrometry (UPLC-Q-TOF-MS) analysis, dried extracts of supernatant (100 μL) were resolved with methanol and filtered through a 0.2 μm PTFE filter. Five biological and two analytical replications were performed using both GC-TOF-MS and UPLC-Q-TOF-MS analyses.

GC-TOF-MS Analysis. An Agilent 7890A GC system (Palo Alto, CA) equipped with an Agilent 7693 autosampler was attached to a TOF Pegasus III mass spectrometer (Leco, St. Joseph, MI, USA), operating in electron ionization (EI) mode (70 eV). A DB-5MS column (30 m length × 0.25 mm i.d. × 0.25 m film thickness, J & W Scientific, Folsom, CA, USA) was used with helium as a carrier gas at a constant flow of 1.5 mL/min. Then, 1 μL of the derivatized sample was injected in a splitless mode. The oven temperature was maintained at 75 °C for 2 min, increased to 300 °C at the rate of 15 °C/min, and then held at 300 °C for 3 min. The acquisition rate was set to 20 scans/s with a mass scan range of m/z 45−1000. The injector and ion source temperatures were 250 and 230 °C, respectively.

UPLC-Q-TOF-MS Analysis. A Waters ACQUITY UPLC system (Waters Corp., Milford, MA, USA) equipped with a binary solvent delivery system, an autosampler, and a UV detector was combined with a Waters Q-TOF Premier MS (Micromass MS Technologies, Manchester, UK) system. Aliquots (5 μL) of each sample were then injected into an ACQUITY BEH C_{18} column (100 mm × 2.1 mm i.d. × 1.7 μm particle size) at a flow rate of 0.3 mL/min. The elution was performed with an acetonitrile/water gradient containing 0.1% formic acid. The gradient was linearly increased from 5% to 100% acetonitrile over 10 min and then decreased to 5% over 2 min. The total run time, including re-equilibration of the column to the initial conditions, was 12 min. The mass spectrometer was operated in both negative and positive ion modes with an m/z range 100−1000. The desolvation gas (nitrogen) was set to 650 L/h at a temperature of 300 °C. The cone gas (nitrogen) was set to 50 L/h, and the source temperature was 80 °C. The capillary and cone voltages were set to 2.3 kV and 30 V, respectively. Data were collected in the centroid mode, with a scan accumulation time of 0.2 s. All analyses were performed using an independent reference spray via the LockSpray interference to ensure accuracy and reproducibility; leucine enkephalin ions were used as the lock mass (m/z 554.2615 [−] and 556.2771 [+]) at a flow rate of 10 μL/min. Accurate mass and elemental composition were calculated using the MassLynx software (Waters Corp.) incorporated in the instrument.

The LC-IT-MS/MS analysis was performed using a 212-LC binary solvent delivery system equipped with a Prostar 410 autosampler and a Prostar 335 photodiode array detector (PDA), which was coupled with a Varian 500-MS ion-trap mass spectrometer equipped with an electrospray interface (Varian Tech., Palo Alto, CA, USA). Aliquots (10 μL) of each sample were then injected into a PurSuit XRs C18 column (100 mm × 2.0 mm i.d., 3 μm; Varian, Lake Forest, CA, USA) with a MetaGuard 2.0 PurSuit XRs C18 guard column (Varian, Lake Forest, CA, USA). The column temperature was set at 40 °C, and the flow rate was 0.2 mL/min. The mobile phase consisted of 0.1% v/v formic acid in water (solvent A) and 0.1% v/v formic acid in acetonitrile (solvent B). The gradient applied was as follows: 10% B from 0 to 2 min, 40% B from 2 to 10 min, 70% B from 10 to 20 min, 90% B from 20 to 30 min, 10% B from 30 to 40 min, and held at 10% B before the next sample injection. Mass spectra were performed in both negative and positive modes through a range of m/z 100−1000. The parameters were as follows: drying temperature, 300 °C; capillary voltage, 70 V; needle voltage, 5 kV; drying gas pressure (nitrogen), 20 psi; and nebulizer gas pressure (air), 40 psi. MS^n analysis was performed using Turbo data-dependent scanning (DDS) under the same conditions used for full scanning. The PDA was set at an absorbance from 200 to 600 nm and managed by Polyview 2000 (version 6.9) (Varian, Walnut Creek, CA).

Data Processing and Statistical Analysis. GC-TOF-MS raw data were converted to netCDF format with ChromaTOF software (LECO). UPLC-Q-TOF-MS raw data were acquired with MassLynx software and converted into netCDF format with Waters DataBridge version 2.1 software. After conversion, the MS data were processed using the Metalign software package (http://www.metalign.nl). The resulting data were exported to Excel (Microsoft, Redmond, WA, USA), and a statistical analysis was performed using SIMCA-P+ 12.0 software (Umetrics, Umea, Sweden). Principal component analysis (PCA) and partial least-squares discriminant analysis (PLS-DA) were used to compare the three blueberry species and to identify the major metabolites in each. The data sets were unit variance scaled in a column-wise manner prior to PCA and PLS-DA modeling. Metabolites with a variable importance projection (VIP) value greater than 0.7 and a p value less than 0.05 were selected as potential metabolites related to different species. Differences in total phenolic content (TP), total flavonoid content (TF), total anthocyanin content (TA), DPPH, and ABTS radical scavenging activities were tested by analysis of variance and Duncan's multiple range test using SPSS version 12.0 software (SPSS Inc., Chicago, IL, USA). Relative contents of significantly different metabolites and antioxidant activities were represented by Pearson's correlation coefficient.

Metabolite Identification and Visualization. After the multivariate statistical analysis, major metabolites were positively identified using standard compounds by comparing both the mass spectra and retention times. When standard compounds were not available, a tentative identification was made based on databases from the NIST05 MS Library (NIST, 2005), published references, and an in-house library. In UPLC-Q-TOF-MS analysis, accurate masses and elemental compositions were calculated using MassLynx software (Waters Corp.). MS^n fragmentation patterns and UV spectra were also used to identify major metabolites with MS workstation software (version 6.9, Varian, USA) in LC-IT-MS/MS. Metabolites were quantified by their m/z peak areas calculated using the software provided with the instrument and by data processing. This quantification aided in making relative comparisons of the metabolites in the three blueberry species. To visualize metabolite profiles, heatmaps were generated using MultiExperiment Viewer software version 4.8 (http://www.tm4.org/), and correlation networks between metabolites and antioxidant activities were constructed with Cytoscape software (http://www.cytoscape.org/).

Determination of Antioxidant Activities by ABTS and DPPH Free Radical Scavenging Activity. For the ABTS assay, we followed the method of Re et al.[21] with some modifications. The stock solutions included 7 mM ABTS solution and 2.45 mM potassium persulfate solution. The working solution was prepared by mixing the two stock solutions in equal quantities and allowing them to react for 1 day at room temperature in the dark. The solution was then diluted until the absorbance reached 0.7 ± 0.02 at 734 nm by using a spectrophotometer (Spectronic Genesys 6, Thermo Electron, Madison, WI, USA). The dried extracts of supernatant were resolved in a solvent mixture and diluted in the ratio of 1:4. Each diluted sample

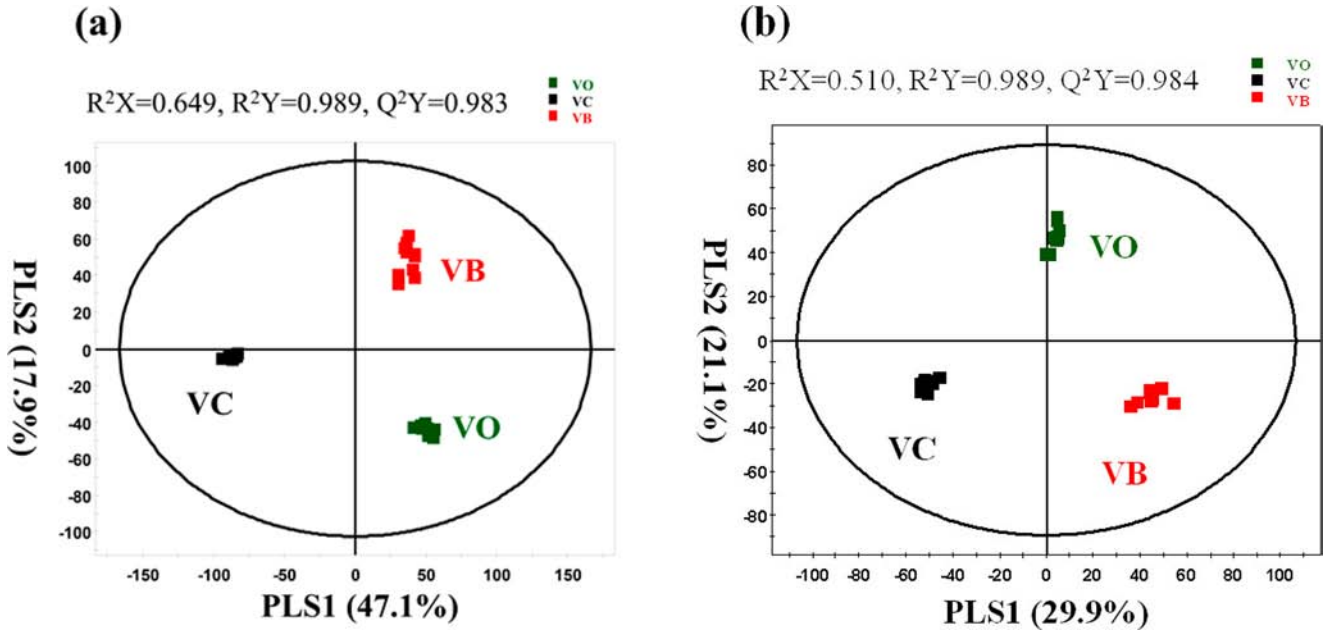

Figure 1. PLS-DA score plots of metabolite profiles in three blueberry species (*Vaccinium bracteatum* Thunb., VB; *V. oldhamii* Miquel., VO; and *V. corymbosum* L., VC). The data sets were obtained using (a) GC-TOF-MS and (b) UPLC-Q-TOF-MS.

of blueberry extract (10 μL) was reacted with 190 μL of the diluted ABTS solution for 7 min in the dark. Absorbance was then measured at 734 nm using a spectrophotometer. The standard curve was linear between 0.0625 and 1 mM Trolox equivalents (TE). Results are expressed in millimolar TE per milligram of dry weight of extract (ext). The DPPH assay was conducted according to the method described by Dietz et al.[22] with some modifications. Diluted samples of blueberry extracts (20 μL) were reacted with 180 μM DPPH solution for 20 min at room temperature. Absorbance was then measured at 515 nm. The standard curve was linear between 0.0625 and 1 mM TE. Experiments were conducted in triplicate.

Total Phenolic Content and Total Flavonoid Content. Total phenolic content (TP) in blueberry samples was determined according to the Folin−Ciocalteu colorimetric method, as modified by Yildirim et al.[23] Briefly, 100 μL of 0.2 N Folin−Ciocalteu's phenol reagent was added to 20 μL of each sample placed in 96-well plates, followed by incubation in the dark for 5 min. After that, 80 μL of 7.5% sodium carbonate solution was added to the mixture and measured at 750 nm using a microplate reader (Thermo Electron, Spectronic Genesys 6, Madison, WI, USA). TP was calculated on the basis of a standard curve with gallic acid (GA) equivalent concentration (ppm). The standard solution concentration curve ranged from 31.25 to 500 ppm. All experiments were conducted in triplicate.

Total flavonoid content (TF) was measured, and 180 μL of 90% diethylene glycol, 20 μL of 1 N NaOH, and 20 μL of each sample were then mixed and incubated for 60 min at room temperature in the dark. Absorbance was measured at 405 nm using a microplate reader (Thermo Electron, Spectronic Genesys 6, Madison, WI, USA). The results are presented as naringin (NG) equivalent concentration (ppm). The standard solution concentration curve ranged from 15.625 to 2000 ppm. All experiments were conducted in triplicate.

Total Anthocyanin Content. Total anthocyanin content (TA) of the blueberry samples was estimated using a microplate reader (Thermo Electron, Spectronic Genesys 6, Madison, WI, USA) by the pH-differential method using two buffer systems, potassium chloride buffer, pH 1.0, and sodium acetate buffer, pH 4.5, as modified by Khanal et al.[24] A diluted sample of 20 μL was mixed with 180 μL of corresponding buffer and read against a blank at 515 and 750 nm. Absorbance was calculated by the following formula: $A = (A_{515\ nm} - A_{750\ nm})_{pH1.0} - (A_{515\ nm} - A_{750\ nm})_{pH4.5}$. Monomeric anthocyanin pigment concentration was expressed as milligrams of cyanidin-3-glucoside: monomeric anthocyanin pigment (mg/L) = $A \times M_r \times DF \times 1000/(\varepsilon \times 1)$, where A is the absorbance, M_r is the molecular weight (449.2), DF is the dilution factor, and ε is the molar absorptivity (26 900). The final concentration of anthocyanins (mg/100 g) was calculated based on the total volume of extract and the weight of the sample.

RESULTS AND DISCUSSION

Multivariate Analysis of *Vaccinium* spp. Using GC-TOF-MS and UPLC-Q-TOF-MS Data. Species-specific metabolite profiling of blueberries (*Vaccinium* spp.) was performed using GC-TOF-MS and UPLC-Q-TOF-MS combined multivariate analysis. Multivariate analysis was used to separate species and to identify species-specific metabolites in three blueberry species. The analysis was performed by both unsupervised PCA and by supervised PLS-DA to identify differences among the three species. Species-specific separation can be observed in the PLS-DA score plots (Figure 1). Similar patterns were found in the PCA analysis (Supporting Information, Figure 1S). As shown in Figure 1a, metabolite profiles of the three species (VO, VB, and VC) were clearly separated by PLS1 and PLS2, and the score plot of GC-TOF-MS data explained 65.0% of the total variability (PLS1: 47.1%; PLS2: 17.9%). VC was separated from VB and VO along PLS1, whereas VB was separated from VO and VC along PLS2. The satisfaction values of X and Y variables were 0.649 (R^2X) and 0.989 (R^2Y), respectively, and prediction accuracy was 0.984 (Q^2Y). PCA and PLS-DA models of metabolites analyzed by UPLC-Q-TOF-MS showed similar patterns as those obtained by GC-TOF-MS analysis (Figure 1b, Supporting Information, Figure 1S). In the score plot of PLS-DA (using positive ion mode data), VC was clearly discriminated by PLS1 (29.9%), and VO was separated by PLS2 (21.1%), with quality parameters of 0.510 (R^2X), 0.989 (R^2Y), and 0.984 (Q^2Y). By using negative ion mode data, VB was separated from VC by PLS1 (27.7%), and VO was separated by PLS2 (15.5%) (Supporting Information, Figure 2S).

Species-Specific Metabolite Profiling of *Vaccinium* spp. Using GC-TOF-MS and UPLC-Q-TOF-MS Analyses.

dx.doi.org/10.1021/jf405272b | J. Agric. Food Chem. 2014, 62, 2126−2133

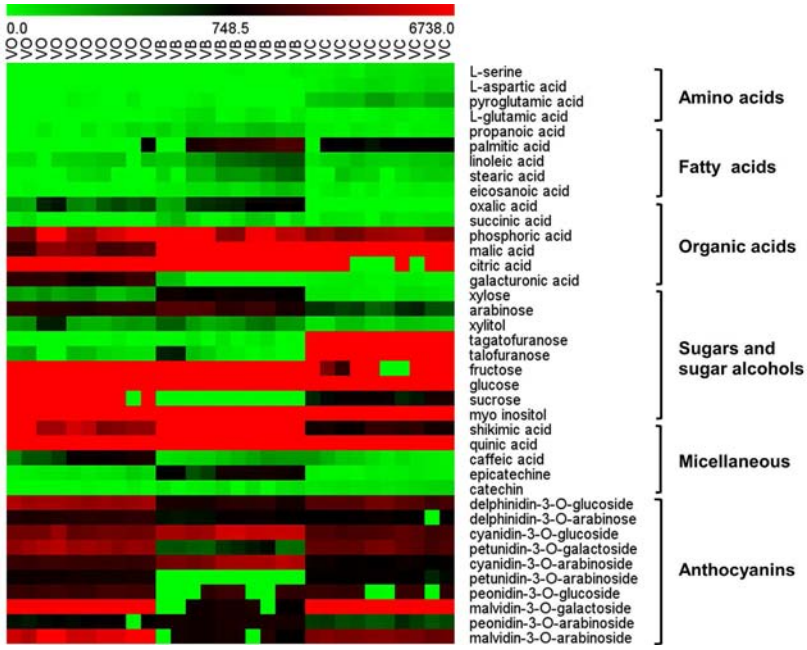

Figure 2. Key metabolites identified using PLS-DA showed a differential pattern in different blueberry species (*Vaccinium bracteatum* Thunb., VB; *V. oldhamii* Miquel., VO; and *V. corymbosum* L., VC). Metabolites (n = 39) that show statistically significant changes among samples (VIP > 0.7 and p < 0.05) are represented using a heatmap, with relative intensities indicated by the heat scale.

Table 1. Differential Metabolites Analyzed Using GC-TOF-MS in Three Species of Blueberry (*Vaccinium* spp.)

[a] t_R is the retention time. [b] iFit is a measure of how well the observed isotope pattern matches the predicted isotope pattern for the formula on that line. A lower score indicates a better fit. [c] Identified metabolites based on variable importance projection (VIP) analysis with a cutoff value of 0.7 and a p value < 0.05. [d] Identification: std, standard compound; ref, references.

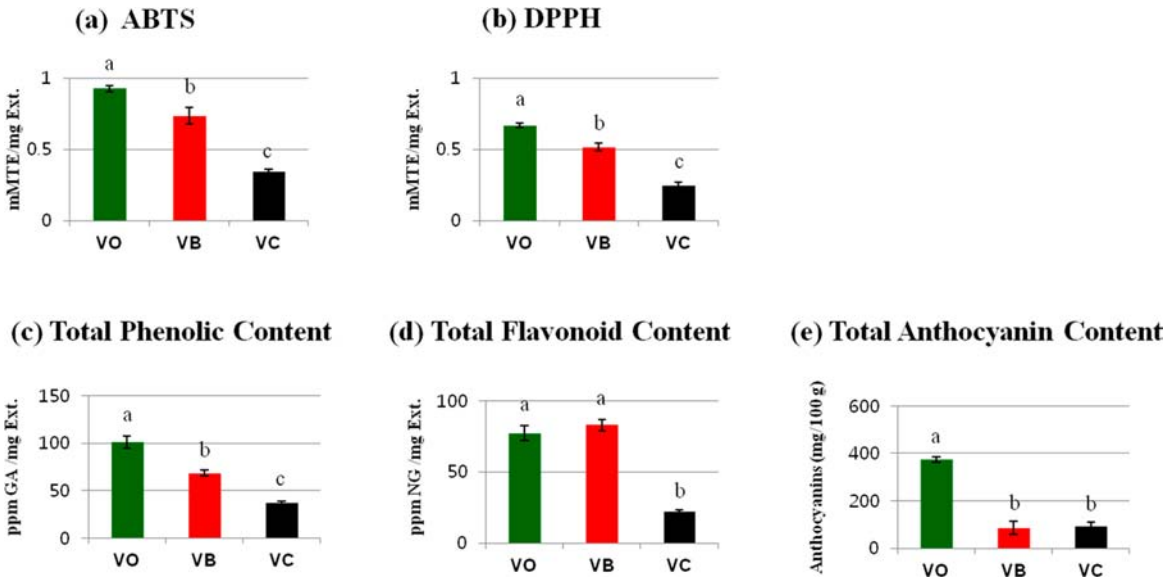

Figure 3. Antioxidant activity tests (a) ABTS and (b) DPPH and (c) total phenolic content, (d) total flavonoid content, and (e) total anthocyanin content of blueberries (*Vaccinium* spp.). Values are the averages of triplicates (n = 3). The same letters are not significantly different by Duncan's multiple range test at the 5% level.

Species-specific separation of *Vaccinium* spp. was observed in the PLS-DA score plots (Figure 1), and their related metabolites were selected based on VIP values (VIP > 0.7) and p values (p < 0.05). The relative differential distribution of selected metabolites is represented by a heatmap (Figure 2). In the GC-TOF-MS analysis, metabolite profiles of the three species were clearly separated by PLS1 and PLS2. In Table 1, 28 metabolites, including amino acids, organic acids, fatty acids, sugar and sugar alcohols, and phenolic acids, were selected as differential variables using VIP values and p values. On the basis of the separation of the three species according to PLS1, we identified oxalic acid, phosphoric acid, xylose, arabinose, xylitol, shikimic acid, citric acid, quinic acid, fructose, and glucose as major metabolites in both VO and VB, while serine, aspartic acid, tagatofuranose, talofuranose, and catechin were associated with VC. In particular, VB contained much higher levels of fatty acids, that is, palmitic acid, linoleic acid, stearic acid, and eicosanoic acid (Figure 2 and Supporting Information, Table 1S). In contrast, citric acid, quinic acid, fructose, glucose, galacturonic acid, caffeic acid, and sucrose were the main metabolites in VO. Organic acids such as oxalic acid, phosphoric acid, and citric acid were associated with both VO and VB, while succinic acid was associated with VB. Malic acid and citric acid are the predominant organic acids related to fruit ripening, and citric acid is the major compound that contributes to the acidity of fruits.[25] Citric acid was most abundant in VO (Figure 2 and Supporting Information, Table 1S). Levels of amino acids such as serine, aspartic acid, and

dx.doi.org/10.1021/jf405272b | J. Agric. Food Chem. 2014, 62, 2126−2133

pyroglutamic acid were higher in VC, while phenolic acids such as quinic acid and caffeic acid, which are related to antioxidant activity, were main components of VO.

In the UPLC-Q-TOF-MS positive ion mode analysis, the three species were separated by PLS-DA, and their related metabolites are listed in Table 2. In total, 10 metabolites were identified as highly differential metabolites contributing to species-specific separation based on VIP values (VIP > 0.7) and p values ($p < 0.05$). Anthocyanins were identified as major metabolites separating the three species. Anthocyanins and their derivatives were identified based on specific MS fragments and UV−vis absorbance (Table 2). Anthocyanins were represented by their specific aglycone cations and showed particular UV absorbance at 520−534 nm. The MS^n fragments of these compounds had characteristic ions at m/z 303, 287, 317, 301, and 331, corresponding to the $[M - \text{sugar}]^+$ product ions of delphinidin, cyanidin, petunidin, peonidin, and malvidin, respectively. The 3-glucoside(s) and 3-galactoside(s) of delphinidin, malvidin, petunidin, cyanidin, and peonidin are the primary anthocyanins that have been identified in blueberries,[1,26] and they were confirmed in this study. Glucoside and galactoside of delphinidin, petunidin, peonidin, and malvidin were mainly detected in VO and VC; in particular, the levels of delphinidin derivatives (delphinidin-3-*O*-glucoside and delphinidin-3-*O*-arabinoside) were high in VO (Figure 2 and Supporting Information, Table 2S). Cyanidin derivatives (cyanidin-3-*O*-glucoside and cyanidin-3-*O*-arabinoside) were mostly identified in VB, and their relative contents were high in this species. In the UPLC-Q-TOF-MS negative ion mode analysis, 11 metabolites, including chlorogenic acid, quercetin-3-*O*-glucoside, and quercetin-3-*O*-rutinoside, were identified as the major metabolites separating the three species (Supporting Information, Figure 2S and Table 3S). Chlorogenic acid is considered a prominent compound in highbush blueberry (*Vaccinium corymbosum* L.),[5] and levels of this compound were also high in VO as well as VC in our study (Supporting Information, Table 3S). Quercetin-3-*O*-glucoside and quercetin-3-*O*-rutinoside are also known compounds in berries.[27] These metabolites showed high levels in VO and VC, respectively.

Correlations between Metabolites and Antioxidant Activities in Different Blueberries. Antioxidant activities (ABTS and DPPH), TP, TF, and TA were measured in the three species. As shown in Figure 3, the wild species (VO and VB) demonstrated significantly higher scavenging activities than VC, which is a commonly cultivated species. TP and TF of VO and VB were also higher than those of VC. In particular, VO showed the highest TP (100.69 ppm GA/mg ext), TA (374.06 mg/100 g ext), and antioxidant activities (ABTS, 0.93 mM TE/mg ext; DPPH, 0.67 mM TE/mg ext) among the three species.

Correlation networks between metabolites and antioxidant activities are illustrated in Figure 4. Pearson's correlation coefficients among all metabolites identified in GC/LC-MS, TP, TF, TA, and antioxidant activity tests (ABTS and DPPH) were calculated (Supporting Information, Table 3S). Selected metabolites, TP, TF, and TA showed positive or negative correlations with antioxidant activities. Correlation coefficients of TP and TF with antioxidant activities were higher than that of TA. In particular, TP was much more strongly correlated with antioxidant activities (DPPH, 0.986; ABTS, 0.978) than was TA (DPPH, 0.766; ABTS, 0.737). Similar results were reported by Koca et al., who found a high correlation between

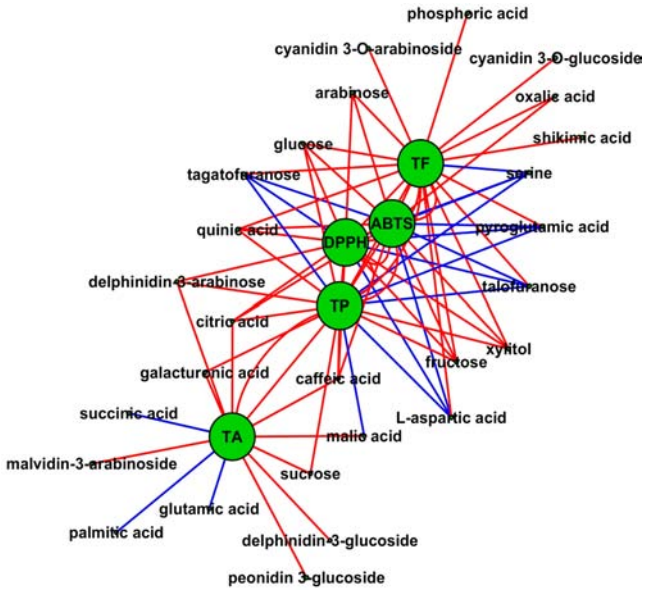

Figure 4. Visualization of the correlation network among metabolite total phenolic content (TP), total flavonoid content (TF), total anthocyanin content (TA), and antioxidant activities (ABTS, DPPH) of blueberries (*Vaccinium* spp.), according to Pearson's correlation coefficient (> ± 0.8). Positive or negative correlations are indicated by connecting red and blue lines, respectively.

total polyphenol content and antioxidant activity in *V. arctostaphylos* (a lowbush species) and *V. coymbosum*.[28]

To construct a correlation network, Pearson's correlation coefficients greater than ±0.8 were selected. TP, TF, and TA were significantly positively correlated with antioxidant activities (ABTS and DPPH). Previous research on antioxidant activity in blueberries has indicated that antioxidant activities are influenced by TP, TF, and TA.[7,29] In Figure 4, nine metabolites (oxalic acid, citric acid, arabinose, xylitol, fructose, glucose, quinic acid, caffeic acid, and delphinidin-3-*O*-arabinose) were highly positively correlated with antioxidant activities, whereas five metabolites (serine, aspartic acid, pyroglutamic acid, tagatofuranose, and talofuranose) showed a negative correlation with antioxidant activities. Some phenolic compounds may be associated with antioxidant activities, and their relative amounts in different blueberry species affect different antioxidant activities. In this study, VO and VB demonstrated significantly higher scavenging activities than VC and had higher levels of quinic acid, caffeic acid, delphinidin-3-*O*-arabinoside, cyanidin-3-*O*-glucoside, and cyanidin-3-*O*-arabinoside. In particular, VO, which showed the highest antioxidant activities, exhibited high contents of quinic acid, caffeic acid, delphinidin-3-*O*-glucoside, and delphinidin-3-*O*-arabinoside. Phenolic acids such as caffeic acid, quinic acid, gallic acid, hydroxybenzoic acid, and chlorogenic acid are the important antioxidants rich in blueberries.[9,30] The antioxidant activities of these phenolic acids are associated to some extent with the number of hydroxyl groups in their molecular structure.[31] In particular, caffeic acid, which exhibited high levels in VO in our study, is an antioxidant found in all plants as a key intermediate in the biosynthesis of lignin.[32] Anthocyanins are a major class of flavonoid phenolics that cause fruit pigmentation, and they are strong antioxidants that contribute to the health-beneficial properties of blueberries.[33] Monoglucosides of delphinidin, malvidin, petunidin, cyanidin, and peonidin are the primary

anthocyanins that have been identified in blueberries.[5−8] Among these, delphinidin and cyanidin, which have more hydroxyl groups, are more active as antioxidants than those with only one hydroxyl substitute, such as pelargonidin, malvidin, and peonidin.[34,35] In particular, VO contained high levels of delphinidin-3-*O*-arabinose, which had a high positive correlation coefficient in the antioxidant activity test results. Although they are not represented in our correlation network (Figure 4), chlorogenic acid and flavonol glycoside were also related to antioxidant activities. Chlorogenic acid, the major nonflavonoid phenolic acid in blueberry,[5] was abundant in both VO and VC. Quercetin derivatives are also well-known antioxidants in plants.[36] Quercetin-3-*O*-glucoside and quercetin-3-*O*-rutinoside levels were high in VO and VC, respectively.

Overall, our results suggest that antioxidant activities are correlated not only with various antioxidants such as phenolic compounds but also with the relative contents of these compounds. *Vaccinium* species rich in phenolic compounds, including phenolic acids, flavonol glycosides, and anthocyanins, represent antioxidant sources that may have potential beneficial effects on human health.

dealing with the grapefruit furanocoumarin metabolites has been conducted in humans.[13] Authors reported that the consumption of 900 mL of commercial GFJ led to urinary excretion of BT and its conjugated forms, which were evaluated by enzymatic hydrolysis. Although this procedure allowed for the quantification of metabolites as BT equivalents, information about structures, concentration profiles, and overall distribution of metabolites was lost.

Thus, the main objective of the present study was to provide a further qualitative and quantitative characterization of furanocoumarin metabolites in urine after GFJ consumption. Identities of main metabolites of GFJ furanocoumarins were elucidated by accurate-mass measurements and multi-stage mass experiments (MS^n) using high-resolution/accurate-mass (HR/AM) hybrid linear trap quadrupole-Orbitrap mass spectrometry (LTQ-Orbitrap). To improve the detection limits for the determination of the identified metabolites, a rapid and sensitive methodology based on solid-phase extraction (SPE) and ultraperformance liquid chromatography coupled to triple quadrupole-tandem mass spectrometry (UPLC−QqQ-MS/MS) was developed. Finally, to demonstrate the applicability of the proposed method and the potential of furanocoumarin metabolites as specific biomarkers of GFJ consumption, urine samples of five volunteers were analyzed after intakes of moderate doses of different citrus fruit juices: grapefruit, lemon, and orange juices.

MATERIALS AND METHODS

Reagents and Materials. BT, BMT, and bergapten were purchased from Extrasynthese (Genay, France), whereas DHBMT was supplied by Cayman Europe (Tallinn, Estonia). The internal standard 4-methylumbelliferone (4-MU) was obtained from Sigma (Madrid, Spain). Formic acid (∼98%) and sodium hydroxide (≥98%) were purchased from Panreac (Barcelona, Spain). Ammonium hydroxide (32%, w/w), acetic acid glacial (100%), hydrochloric acid (37%, w/v), sodium acetate anhydrous, acetonitrile, acetone, and methanol were obtained from Merck (Barcelona, Spain). Solvents were high-performance liquid chromatography (HPLC)-grade, and all other chemicals were analytical-reagent-grade. Ultrapure water was obtained from a Milli-Q gradient water purification system (Millipore, Bedford, MA). Individual stock solutions of each analyte and a mixture of them were prepared in methanol. Working standard solutions were made by appropriate dilution in 80% methanol in water acidified with 0.1% formic acid and then stored in amber glass vials at −20 °C.

Sweet orange (*Citrus sinensis* L. Osbeck, cv. Navelate), lemon (*Citrus limon* L., cv. Fino), and grapefruit (*C. paradisi* Macfad., cv. Star Ruby) of different Spanish cultivars were purchased from a local market at maturity.

Subjects and Study Design. Five healthy Caucasian male volunteers, ranging between 20 and 35 years old, were recruited for this study. The participants had no history of cardiovascular, hepatic, or renal disease and had stable alimentary habits. They had not adhered to any special diet for at least 4 weeks prior to the consumption; therefore, the obtained results can be attributed to a normal dietary pattern. The study protocol was approved by the Ethics Committee of Clinical Investigation of the University of Barcelona (IRB00003099). The study was explained to subjects through verbal and written instructions, and written informed consent was obtained from all participants.

Before each intervention, participants followed a 7-day wash-out period, in which they were requested not to consume citrus fruit or their processed products. After this period, subjects collected their blank urines. The feeding study consisted of three interventions, involving the consumption at dinner of a glass of juice (250 mL) of orange, lemon, and grapefruit. Fresh juices were prepared on the day of each intervention using a home juicer machine. Participants were asked to collect the first morning urine, 10 h after juice intake. All samples were collected in 100 mL random coded sterile specimen containers and immediately stored at 4 °C. Upon receipt of each sample, four aliquots of 1.0 mL were transferred to individual 1.5 mL capped Eppendorf tubes and stored at −80 °C until the analyses.

Because of the lack of commercial standards of furanocoumarin metabolites, a pooled urine sample, prepared by mixing equal volumes of urine from two volunteers after GFJ consumption, was employed for the method development. To ensure concentration levels high enough to allow for the determination of major and minor metabolites, the two volunteers drank a rather large volume (1 L) of freshly prepared GFJ.

Sample Preparation. On the day of the analysis, the urine samples were thawed on ice, vortexed for 1 min, and centrifuged at 15000*g* for 5 min at 4 °C. Supernatants (990 μL) were then spiked with 10 μL of the internal standard solution (4-MU, 30 μg/mL in methanol) and 175 μL of 2 M sodium acetate buffer (pH 4.80) and vortexed for 30 s.

Sample cleanup was carried out by SPE using Oasis WAX 96-well plates (30 mg, 30 μm). The optimized protocol involved conditioning the cartridges with 1 mL of methanol, equilibrating with 1 mL of 300 mM sodium acetate buffer (pH 4.80), loading 1 mL of urine sample, washing with 1 mL of 300 mM sodium acetate buffer (pH 4.80) followed by 1 mL of 15% methanol in 300 mM sodium acetate buffer (pH 4.80), and then eluting the analytes with 1.5 mL of 2.5% (v/v) ammonium hydroxide in methanol. The eluate was brought to dryness under a nitrogen flow and then reconstituted with 200 μL of 0.1% formic acid in water. The extract was passed through a 0.20 μm polytetrafluoroethylene (PTFE) syringe filter and analyzed by UPLC−QqQ-MS/MS. All samples were analyzed in triplicate.

UPLC−MS Analysis. Sample analyses were performed on a Waters Acquity ultraperformance liquid chromatography (UPLC) system (Waters, Milford, MA) consisting of a binary pump, a vacuum degasser, an autosampler, and a thermostatted column compartment. Chromatographic separation was performed on a reversed-phase column Acquity UPLC BEH C18 (50 × 2.1 mm, 1.7 μm) also from Waters, maintained at 25 °C. Mobile phases A and B were 0.1% formic acid in water and 0.1% formic acid in acetonitrile, respectively. The following linear gradient was used: 0 min, 25% B; 0.20 min, 25% B; 3.5 min, 65% B; 4.0 min, 100% B; 4.20 min, 100% B; 4.80 min, 25% B, and 6.0 min, 25% B. The flow rate was set to 550 μL/min, and the injection volume was 10 μL.

For qualitative characterization of the GFJ furanocoumarin metabolites, the UPLC system was coupled to a linear trap quadrupole-Orbitrap mass spectrometer LTQ-Orbitrap Velos from Thermo Fisher Scientific (San Jose, CA) equipped with an electrospray ionization (ESI) source. The ESI was operated in both polarity modes under the following specific conditions: spray voltage, −3.5 kV for negative mode and +3.8 kV for positive mode; sheath gas, 40 arbitrary units; auxiliary gas, 10 arbitrary units; sweep gas, 10 arbitrary units; and capillary temperature, 320 °C. Nitrogen (>99.98%) was employed as sheath, auxiliary, and sweep gas. The scan cycle used a full-scan event at a resolution of 60 000 (at m/z 400) and three data-dependent MS/MS events acquired at a resolving power of 30 000. The most intense ions detected in the full-scan spectrum were selected for data-dependent scan. Parent ions were fragmented by high-energy C-trap dissociation (HCD) with a normalized collision energy of 45% and an activation time of 100 ms. Additionally, MS^3 experiments were performed on the most intense MS/MS fragments of each metabolite using collision-induced dissociation (CID) with a normalized collision energy of 35%. Instrument control and data acquisition were performed with Xcalibur 2.0.7 software (Thermo Fisher Scientific). An external calibration for mass accuracy was carried out the day before the analysis according to the guidelines of the manufacturer.

Quantification was carried out on a triple quadrupole mass spectrometer API 3000 (Applied Biosystems, Foster City, CA) equipped with a TurboIonspray ionization source. The mass spectrometer was operated in the negative ESI mode under the following specific conditions: ion spray voltage (IS), −4.5 kV; source temperature (TEM), 350 °C; curtain gas (CUR), 12 arbitrary units; nebulizer gas (NEB), 10 arbitrary units; entrance potential (EP), −10 V; cell exit potential (CXP), −15 V; focusing potential (FP), −200 V; and collisionally activated dissociation (CAD) gas, 4 arbitrary units. Nitrogen (>99.98%) was employed as curtain, nebulizer, and collision gas. The detection was performed in the multiple reaction monitoring (MRM) mode. Analyst v1.4 software (Applied Biosystems) was used for data acquisition and control of all system components.

Statistical Analysis. Statistical calculations were made using the software package GraphPad Prism, version 5.0 (GraphPad Software,

San Diego, CA). Unless otherwise specified, data are presented as the mean ± standard deviation (SD). Statistical significance was determined by one-way analysis of variation (ANOVA) followed by Dunnett's multiple comparison tests when comparing more than two groups and two-way ANOVA followed by Bonferroni's test when comparing two factors.

RESULTS AND DISCUSSION

Characterization of GFJ Metabolites by HR/AM Mass Spectrometry. To elucidate the chemical structures of the main GFJ metabolites, a pooled urine sample was collected 10 h after the intake of 1 L of freshly prepared GFJ and analyzed by UPLC coupled to a LTQ-Orbitrap mass spectrometer. Taking advantage of the HR/AM of this MS instrument, main GFJ metabolites could be tentatively identified with mass measurement errors below 4.5 ppm (Table 1). Combining HR/AM measurement and MS^n increased the confidence of the proposed metabolites. Thus, the availability of chemical formulas for the precursor and product ions generated from high-resolution data-dependent accurate-mass analysis allowed for the speed up of structural elucidation of metabolites.

After the intake of GFJ, a major metabolite was found at 1.10 min, showing a $[M-H]^-$ ion at m/z 377.0513. Its MS/MS fragmentation produced a base ion at m/z 201.018 (M − H − 176, loss of glucuronic acid moiety), which corresponds to the deprotonated molecule of BT (Figure 1a). Thus, this compound was tentatively identified as a glucuronide metabolite of BT (BT-glcU). Another main metabolite with $[M-H]^-$ ion at m/z 280.9763 eluted at 1.27 min, yielding again a MS/MS base ion at m/z 201.018 produced by the loss of 80 Da (Figure 1b). This characteristic loss of a sulfate group indicated that this metabolite might be the sulfoconjugate of BT (BT-SO_3). On the basis of data obtained by enzymatic hydrolysis, Messer et al. [13] proposed BT glucuronide and sulfate as main GFJ furanocoumarin metabolites in humans. To the best of our knowledge, these metabolites have been identified for the first time in the present work using a mass spectrometry approach. Free BT could also be positively identified in urine after GFJ consumption, which is in agreement with the results previously reported.[13] As shown in Figure 1c, the fragmentation by HCD of the $[M-H]^-$ ion at m/z 201.0187 produced characteristic ions at m/z 173.023, 145.028, and 117.033. Glucuronide metabolite of DHBMT (DHBMT-glcU) was also tentatively identified (Δm = −0.78 ppm) at 2.32 min with a $[M-H]^-$ ion at m/z 547.1820. Its MS/MS spectrum (Figure 1d) showed fragment ions at m/z 371.148 (M − H − 176, loss of glucuronic acid), which corresponds to the deprotonated molecule of DHBMT, m/z 345.154 (M − H − BT), and also m/z 201.018. In the study conducted by Messer et al.,[13] no DHBMT could be detected after enzymatic hydrolysis of urine, which authors mainly attributed to the possible transformation into free BT during its metabolism. An explanation to this disagreement might rely on the hydrolysis step used by the authors, because enzymatic efficiency greatly depends upon the structure of the metabolites.[18] Two isomeric forms of another metabolite could also be detected at 2.66 and 2.79 min with a $[M-H]^-$ ion at m/z 530.1787. Its fragmentation yielded an ion at m/z 353.138, corresponding to the loss of a glucuronic acid moiety, and also the characteristic ion of BT at m/z 201.018. This pattern suggested that these metabolites might be glucuronides of a hydroxybergamottin-like compound (HBMT-glcU) (Figure 1e). To the best of our knowledge, this study provides for the first time evidence of the existence in urine of glucuronides of DHBMT and HBMT as GFJ furanocoumarin metabolites. No free furanocoumarins, other than BT, could be detected (in both polarity ESI modes) in urine after the GFJ consumption, which indicated that they are mainly metabolized to the reported forms.

In addition to these furanocoumarin metabolites, naringenin (NAR) and its glucuronide and sulfate conjugates were also identified in urine (Table 1), which is in agreement with previous studies dealing with the metabolism of GFJ flavonoids.[19,20]

SPE Optimization. Once the main furanocoumarin metabolites present in urine were identified, the research was focused on the development of an analytical method sensitive enough to allow for their detection after the consumption of a low regular dose of GFJ. To this end, an approach based on the use of SPE and UPLC coupled to triple quadrupole mass spectrometry was performed. The specific MRM conditions for quantification and confirmation are detailed in Table 2.

As known, the sorbent type and solvent composition for washing and elution steps are crucial parameters for the

optimization of any SPE procedure. Taking into account the ionizable nature of major furanocoumarin metabolites, mainly glucuronide and sulfate derivatives, it was hypothesized with the use of an ionic-exchange mechanism. Glucuronide metabolites can be easily ionized because of the presence of the carboxylic group on the glucuronic acid moiety, which usually shows pK_a values around 3,[21] whereas sulfate conjugates carry a permanent negative charge (pK_a < 1). Therefore, a mixed-mode weak anion-exchange (WAX)/reversed-phase polymeric sorbent was evaluated for the extraction and preconcentration of furanocoumarin metabolites from urine. As a result of their dual properties, this kind of sorbent has been used to efficiently retain both neutral and acidic metabolites from biological samples.[22] Stramm et al.[23] were able to selectively retain glucuronides and sulfate conjugates of steroids using Oasis WAX SPE cartridges.

To obtain maximal retention, it is necessary to deprotonate glucuronides while maintaining the piperazine anion-exchange groups of sorbent positively charged (pK_a ∼ 6). Thus, urine was buffered to pH 4.8 prior to the loading step, which guarantees a deprotonation rate of glucuronides higher than 98%. Working under these pH conditions, different percentages of methanol (0−15%) were tested, aiming to improve the cleanup step (Figure 2). This study may be especially critical for the neutral compounds, such as the BT, because they are only retained by a reversed-phase mechanism. No reduction in the amounts of any of target metabolites was observed in the studied range; therefore, 15% methanol was finally selected.

Another critical step is the selection of a suitable phase for the quantitative elution of the retained compounds. When dealing with weak anion-exchange mechanisms, two different approaches are usually possible to achieve the elution. The most common one consists of the protonation of the acidic compounds by using an elution solvent with a pH low enough. Nevertheless, sulfoconjugates are no able to elute under these

dx.doi.org/10.1021/jf405701a | J. Agric. Food Chem. 2014, 62, 2134−2140

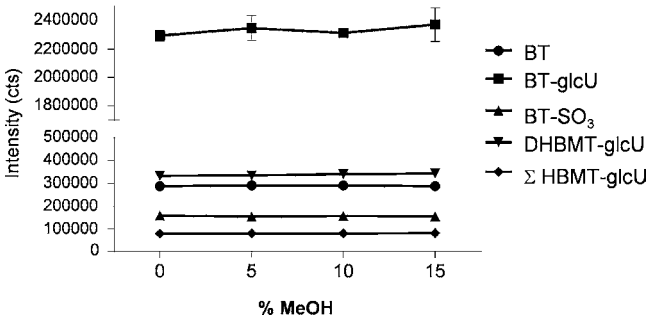

Figure 2. Effect of the proportion of methanol during the SPE washing step.

conditions, because they are not prone to neutralization. Therefore, elution could only be carried out by neutralizing the piperazine anion-exchange function of the sorbent. Three different proportions of NH_4OH in methanol were evaluated for the elution of furanocoumarin metabolites (Figure 3). Whereas no differences were observed between the use of 2.5 and 5% NH_4OH, the amounts of metabolites eluted were statistically lower when using 1% NH_4OH. The only exception to this behavior was found for BT, which is the only metabolite retained exclusively by the reversed-phased mechanism. Consequently, its elution should not be pH-dependent. Therefore, 2.5% NH_4OH in methanol was chosen for the elution of furanocoumarin metabolites from the WAX sorbent.

Because of the lack of commercial standards for the furanocoumarin metabolites, the recovery of the SPE procedure could only be evaluated for BT. A blank urine sample was spiked at concentrations of 50, 500, and 5000 ng/mL, and the recovery was calculated by dividing the difference between the measured concentrations for spiked and non-spiked samples by the added concentrations. Quantitative recoveries, in the range of 94−102%, were obtained for all concentration levels. The precision of the method was evaluated by calculating the relative standard deviation (RSD) at the same three concentration levels. Satisfactory results were obtained with RSD values below 7% in all cases. Limits of detection (LODs), calculated for a signal-to-noise ratio (S/N) of 3 using the less sensitive MS/MS transition, were in the range of 0.9−1.5 ng/mL.

Feeding Study. The proposed method was applied to the analysis of urine samples from five volunteers (U1−U5) after the consumption at dinner of a glass (250 mL) of freshly prepared juice of orange, lemon, and grapefruit. Because no standards were available, only BT could be accurately quantified in the urine samples. For the rest of the metabolites, concentrations were estimated as equivalents of BT, which provide semi-quantitative information about their levels in urine.

The subjects were requested not to consume citrus fruits or derivatives during the 7 days previous to each intervention. First morning urines were collected the day before the intake and in the morning following the intervention, 10 h after juice consumption. No furanocoumarin metabolites were detected in the urine samples after the wash-out periods or after the consumption of orange and lemon juices. Nevertheless, important concentrations of metabolites were found in the urine samples of all of the volunteers after the intake of a glass of GFJ (Table 3). Figure 4 shows the MRM chromatograms for the quantification MS/MS transitions obtained for U2 after the intake of 250 mL of GFJ.

The concentration of BT showed considerable variation among the five volunteers, ranging from 382 to 2670 ng/mL (median of 595 ng/mL). Messer et al.[13] found BT in free and conjugated forms, as the only furanocoumarin excreted in urine within 6 h after consumption of 900 mL of GFJ. On the basis of results of enzymatic hydrolysis, they suggested that the majority of BT was excreted as conjugate forms. Our data suggest a similar pattern with estimated concentrations for the total BT in conjugate forms between 30- and 130-fold higher than those of free BT. Among the furanocoumarin metabolites, BT-glcU was in all cases the major urinary metabolite, showing a median concentration around 33 μg/mL (Figure 5). BT-SO_3 and DHBMT-glcU were also found at concentrations in the microgram per milliliter level. As shown, the glucuronides of HBMT were the least abundant conjugates, with a median concentration of 621 ng/mL.

Our findings suggest that GFJ furanocoumarins are mainly excreted as glucuronide and sulfate conjugates, whereas a lower

amount is excreted as free BT. The proposed method for the determination of these metabolites might be useful for studying the grapefruit–drug interactions in dietary studies. In addition, these results demonstrate that these metabolites can be selective enough to be considered as potential biomarkers of GFJ consumption, because they were not detected in urine after the wash-out periods or after consumption of orange and lemon juices.

Pyraclostrobin is used to control a wide range of plant pathogens. For example, pyraclostrobin applications limited the growth and disease severity of *Rhizoctonia* species related to rice (*Oryza sativa*).[10] Reported plant dissipation rates are rapid, with pyraclostrobin DT_{50} of <2 days in corn (*Zea mays*) plants[11] and 11 days in peanut (*Arachus hypogaea*) plants.[12] However, pyraclostrobin is reported to dissipate relatively slowly in soil, with an average half-life (DT_{50}) of 32 days.[13] Slightly more rapid soil dissipation has been reported as well in a sandy loam (DT_{50} = 29 days) and a sandy clay (DT_{50} = 22 days).[14] Dissipation of pyraclostrobin in sterilized soil was 47 days, indicating that biotic processes, while dominant, may not be the only loss mechanism.[14] Photodegradation of pyraclostrobin [by ultraviolet (UV) lamp irradiation] was rapid, with reported DT_{50} values as low as 39 min and as high as 128 min for a 5.9 μmol L^{-1} solution.[15] Thus, multiple loss mechanisms are possible. The high *n*-octanol/water coefficient (log K_{ow} = 3.99)[16] and very high adsorption coefficient (log K_{oc} = 3.96) [16] further suggest that, although it is somewhat immobilized in soil, it still has potential for runoff into surface water.

Characterization of pyraclostrobin in sugarcane and the soil in which it is grown is not reported in the literature because of its recent U.S. EPA Emergency Use Label addition for sugarcane. Degradation rates of active substances in crop protection products are important parameters for assessing environmental exposure. Therefore, the purpose of this study is to investigate the dissipation rate of pyraclostrobin in sugarcane soil and the retention of the fungicide to sugarcane leaves when subjected to wash-off conditions.

MATERIALS AND METHODS

Pyraclostrobin Stock Solution Preparation. The pyraclostrobin stock solution used for amending soil samples was prepared from commercial Headline SC [BASF, 250 g of active ingredient (a.i.) L^{-1}] by adding 1 mL of Headline SC to 10 mL of 18 MΩ deionized (DI) water that was acidified with 0.3 mL of 12 M HCl. Pyraclostrobin was then extracted by liquid−liquid extraction with 3 × 10 mL of ethyl acetate in a separatory funnel. The extracts were filtered and concentrated to a final volume of 10 mL and analyzed by high-performance liquid chromatography (HPLC), as outlined below under the Instrumental Analysis section. The resulting concentration was determined to be 1250 μg mL^{-1} based on calibration with standards made from a 100 μg/mL pyraclostrobin standard solution.

Soil Sample Preparation. Cancienne silt loam (fine silty, mixed, superactive, non-acid, hyperthermic Fluvaquentic Epiaquepts) was collected from the United States Department of Agriculture (USDA)−Agricultural Research Service (ARS) Sugarcane Research Unit's Ardoyne Farm in Schriever, LA (29° 38′ 09.37″ N, 90° 56′ 25.79″ W). The soil was collected from a depth of 0−15 cm, transported to the laboratory, sieved to pass a 2 mm screen, and stored at 4 °C until the experiment commenced. The soil was collected from a field with no history of pyraclostrobin application. The water content was estimated by oven-drying at 90 °C for 1 h. An air-dried sample was characterized by Brookside Laboratories in New Bremen, OH. The cation-exchange capacity (CEC) was 18.10 cmol kg^{-1} of soil; the soil pH (1:1 soil/water) was 6.10; and the organic matter (by loss on ignition) was 1.61%. The estimated nitrogen release (calculated by loss on ignition) was 58 kg ha^{-1}. Mehlich III extractable nutrients in the soil were 8 mg kg^{-1} of sulfur, 32 mg kg^{-1} of phosphorus, 2087 mg kg^{-1} of calcium, 467 mg kg^{-1} of magnesium, 121 mg kg^{-1} of potassium, 25 mg kg^{-1} of sodium, 0.56 mg kg^{-1} of boron, 286 mg kg^{-1} of iron, 122 mg kg^{-1} of manganese, 5.97 mg kg^{-1} of copper, 4.33 mg kg^{-1} of zinc, and 501 mg kg^{-1} of aluminum. The total carbon (C) and nitrogen (N) by dry combustion were 1.01 and 0.11%, respectively, with a C/N ratio of 9.2.

For the laboratory incubation, the soil moisture was adjusted to 0.20 g of water g^{-1} of soil using distilled water. A total of 50 g (dry weight equivalent) of soil was placed each into a series of 28 Erlenmeyer flasks (250 mL) along with 0.2 g of pyraclostrobin-spiked sand. The spiked sand was prepared by the addition of pyraclostrobin stock solution (1250 μg mL^{-1}) to sterilized fine-grain sand, followed by evaporation of the ethyl acetate solvent, giving a calculated concentration of 1000 μg g^{-1}. The pyraclostrobin-spiked sand was added to each flask, and the contents were mixed and sealed with a rubber stopper. The initial concentration of pyraclostrobin was calculated to be 3.3 μg g^{-1}. Flasks were incubated in the dark at 22 °C and sampled in triplicate at 0, 4, 11, 14, 28, 42, and 63 days. Four control flasks containing only 0.2 g of spiked sand were stored and sampled in duplicate at 0 and 63 days. Flasks were removed from incubation and stored in a freezer at −20 °C.

Extraction Method Optimization. Two extraction methods were adapted and compared for this experiment: a method designed by BASF and provided by the U.S. EPA[17] and a method using dispersive solid-phase extraction (dSPE) quick, easy, cheap, effective, rugged, and safe (QuEChERS).[18] Both adapted methods assayed pyraclostrobin levels using HPLC with ultraviolet−visible (UV−vis) detection (HPLC−UV). Briefly, 50 g of soil sample along with 50 mL of acetonitrile was shaken for 30 min at 200 rpm. The sample was then vacuum-filtered through a medium-porosity filter, and the supernatant was collected and evaporated to dryness. The residue was redissolved in 1.0 mL of acetonitrile and analyzed by HPLC. For the QuEChERS method, 15 g of soil was placed into a 50 mL polytetrafluoroethylene (PTFE) centrifuge tube with 15 mL of acetonitrile and vortexed for 1 min. The sample was then centrifuged for 5 min at 5000 rpm, after which 1.0 mL of the resulting supernatant was added to a 2.0 mL QuEChERS tube containing 150 mg of $MgSO_4$, 50 mg of primary−secondary amine sorbent (PSA), and 50 mg of C18 material. This tube was vortexed and centrifuged as above. The supernatant was removed and filtered through a 0.22 μm nylon filter and analyzed by HPLC.

Wash-off Studies. Commercial Headline SC fungicide was applied according to the label instructions (14 g of a.i. ha^{-1}) to three rows of variety "HoCP 96-540" commercial sugarcane using a three-row spray boom calibrated to deliver 280 L ha^{-1}. At the time of application, the plant-cane crop was infected with brown rust. Five plants were randomly selected and harvested at 0.5, 6, 24, 48, and 72 h after application of the fungicide. Replicates (n = 3) were obtained by harvesting one five-plant sample from each of the front, middle, and back of the field. Upon harvesting, the whole green leaves of all five plants were removed at the dewlap, submerged in 2 L of room-temperature tap water, and agitated on a shaker at 100 rpm for 30 min. The leaves were removed from the water, dried for 1 week at 60 °C, and weighed, and the aqueous extract was filtered through a filter under vacuum, collected in 1 L polypropylene bottles, and frozen at −20 °C. The contents in the bottles were later thawed and concentrated by passing through a methanol-conditioned (10 mL) Oasis hydrophilic−lipophilic balanced (HLB) 6 mL (200 mg, 30 μm particle size) cartridge (Waters, Taunton, MA) under vacuum until dry. The cartridges were immediately stored at −20 °C until the recovery for analysis by HPLC. The pyraclostrobin extracted from the wash water was then recovered from each cartridge by eluting with 10.0 mL of HPLC-grade acetonitrile (EMD Millipore, Billerica, MA). A total of 1 mL of each sample was filtered through a 0.22 μm nylon filter and assayed for pyraclostrobin by HPLC, as outlined below.

Instrumental Analysis. The method developed for the analysis of strobilurins in tomato residues[19] and the method D9812/1 submitted to the U.S. EPA by BASF for product registration were adapted into this study.[17] Analysis was performed using a Hitachi HPLC system (Hitachi LaChrome Elite L-2310, Dallas, TX) with a UV−vis detector L-2420 and a column oven (Hitachi model L-2350) and a manual injector from Rheodyne model 7725 (Rohnert Park, CA). A 20 μL sample was injected onto a C18 ZORBAX Eclipse PAH, 5 μm, 4.6 × 150 mm (Agilent, Santa Clara CA), and eluted isocratically [70:30 acetonitrile (ACN)/0.1% formic acid solution] at a flow rate of 1.0 mL min^{-1} at 40 °C. The pesticide was detected at 275 nm. Standards ranging from 1 to 10 μg mL^{-1} were prepared in ACN using a 100 μg

mL^{-1} stock solution from AccuStandard (New Haven, CT). The resulting calibration line had a R^2 of 0.9989, and the detection limit for the analysis was 0.01 $\mu g\ mL^{-1}$.

The recoveries of the extraction method were determined by spiking three unamended soil samples and two control flasks with pyraclostrobin stock solution to a final concentration of 3.17 $\mu g\ g^{-1}$ and performing the extraction procedure as described above. The spike recoveries were calculated to be 97% (±6%), comparable to soil recoveries using QuEChERS by Zhang et al.[12]

Data Analysis. The major goal of this study is to investigate the dissipation rate of pyraclostrobin and predict its persistence in sugarcane soil. On the basis of different dissipation pathways, various kinetic models can be derived, which can subsequently be used to model the pesticide and estimate the DT_{50} and DT_{90} end points. For the selection of the kinetic model that best describes the dissipation results, FOCUS work group guidance recommendations were followed.[20]

Dissipation data were fitted to four models: simple first-order (SFO) kinetics model ($C = C_0e^{-kt}$), Gustafson−Holden[21] or first-order multi-compartment (FOMC) model ($C = C_0/((t/\beta) + 1)^{\alpha}$), hockey-stick (HS) model ($C = C_0e^{-k_1t_b}e^{-k_2(t - t_b)}$ for $t > t_b$ and $C = C_0e^{-k_1t}$ for $t \leq t_b$), and bi-exponential or double-first-order in parallel (DFOP) model ($C = C_0(ge^{-k_1t} + [1 - g]e^{-k_2t})$),[20] where C is the fungicide soil concentration in $\mu g\ g^{-1}$ at time t, C_0 is the initial concentration of fungicide, k_x values are degradation rate constants, α and β are shape and location parameters (FOMC model), respectively, t_b is the point where the rate constant changes (HS model), and g is the fraction of C_0 applied to compartment 1 (DFOP model). DT_{50} and DT_{90} values were determined using analytical equations described by the FOCUS work group; however, for the DFOP model, an analytical solution for the DT_{50} and DT_{90} values does not exist. Instead, the values must be determined graphically by finding the time at which only 50 and 10% of the initial amount of pesticide remains.

For each model, the goodness of fit was determined through visual observation of the residual plot and the χ^2 significance test using Microsoft Excel with the solver add in package.[20] Because the coefficient of determination (R^2) applies to linear data, model efficiency (EF) was determined to assess agreement of measured and calculated data. Pyraclostrobin levels in each soil sample at each time point were calculated on a $\mu g\ g^{-1}$ soil basis. Wash-off data were normalized to the gram of dry leaf biomass for each sample. Data for both pyraclostrobin levels in soil and on leaves were analyzed for analysis of variation (ANOVA) using Proc Mixed in SAS,[22] with time after fungicide treatment as the fixed effect and replicate as the random variable. Means were separated at the $p < 0.05$ level using the Saxton Macro.[23]

RESULTS AND DISCUSSION

The BASF extraction method resulted in interfering peaks possibly because of polar molecules from the extraction matrix, which introduce error in the integration of peak areas; however, interfering peaks were reduced, and integration of pyraclostrobin peak area was significantly improved using the adapted QuEChERS method[18] (Figure 2). The QuEChERS data were used for subsequent analysis and modeling. Pyraclostrobin percent recovery from soil was determined to average 97% (±6%) by comparing the day 0 samples to non-treated controls from the same period. Data were not corrected for this minor amount. Similar recoveries from soil were reported previously.[12] The purity of the pyraclostrobin peak was checked by analyzing an extracted soil sample and pyraclostrobin standards using two different HPLC methods that employed columns of different polarity.

Pyraclostrobin degraded under laboratory-controlled soil conditions over the duration of the experiment (63 days) to levels that were about 50% of the initial amended level (Table 1). Initial pyraclostrobin levels measured in soil (3.17 $\mu g\ g^{-1}$) were significantly lower by 4 days (2.45 $\mu g\ g^{-1}$) and continued to decrease, with significant differences detected at 28 days (2.10 $\mu g\ g^{-1}$), 42 days (1.70 $\mu g\ g^{-1}$), and 63 days (1.55 $\mu g\ g^{-1}$).

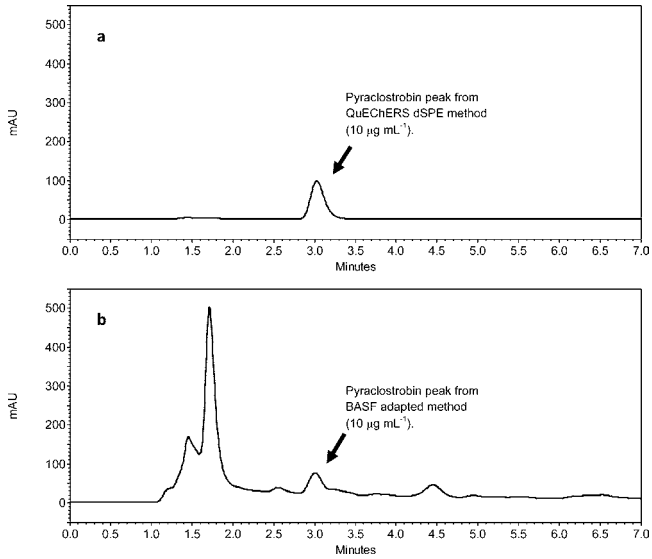

Figure 2. Chromatograms of pyraclostrobin in soil extract using (a) QuEChERS method or (b) BASF adapted method. The retention time for pyraclostrobin is 2.95 min. Note the decrease in intensity of the interfering peaks at 1.0−2.5 min using the QuEChERS method.

Table 1. Amount of Pyraclostrobin Extracted from Exposed Soil as a Function of the Exposure Time[a]

time (day)	concentration ($\mu g\ g^{-1}$ of soil)	total pyraclostrobin (μg)	fraction remaining
0	3.17 a[b]	190	1.00
4	2.45 b	147	0.77
11	2.20 b	133	0.70
14	2.22 bc	133	0.70
28	2.10 cd	123	0.65
42	1.70 de	105	0.55
63	1.55 e	93	0.49

[a]Each value is the mean of three replicates. [b]Means with the same letter are not different at the $p < 0.05$ level.

The results showed an initial rapid degradation, followed by a slower dissipation rate after several days (Figure 3). The results were fit to each of the four different models (Table 2). Although the SFO model does an adequate job of approximating the DT_{50} value at 65 days (similar to the experimentally determined value), the goodness of fit as measured by inspection of the residual plot is poor (Figure 4) and the model efficiency (EF) (0.8139) is unsatisfactory (Table 3). The dissipation kinetics appears to be biphasic, which is commonly characterized by a rapid decrease in the concentration, followed by a slower rate of decrease. This may be due to a reduction in substrate availability because of adsorption onto soil organic matter. In addition to the SFO model, three biphasic models (FOMC, HS, and DFOP) were used to model the data.[20] The HS and DFOP models have the best fit graphically, with acceptable residual plots (Figure 4). The χ^2 values are lowest for these two models (7.815 for both), and the model EFs are 0.9946 and 0.9945, respectively (Table 3), suggesting that they have the best agreement with the data. However, it should be noted that the HS model is not commonly used for modeling soil degradation kinetics because

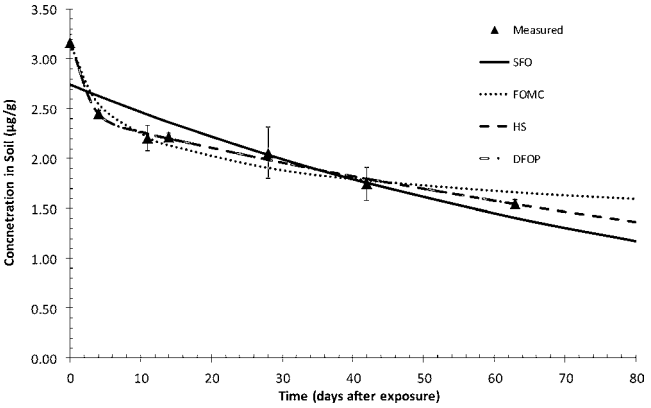

Figure 3. Degradation of pyraclsotrobin in amended soil under controlled conditions at an initial concentration of 3.17 μg mL^{-1}. Measured values are the mean (n = 3) ± standard deviation. The best-fit data for the models: (a) simple first-order kinetics model (SFO), (b) Gustafson−Holden multi-compartment model (FOMC), (c) hockey-stick model (HS), and (d) bi-exponential model (DFOP).

Table 2. Calculated Parameters for the Four Models: (1) Simple First-Order Kinetics Model (SFO), (2) Gustafson−Holden Multi-compartment Model (FOMC), (3) Hockey-Stick Model (HS), and (4) Bi-exponential Model (DFOP)

parameter	SFO	FOMC	HS	DFOP
C_0[a] (μg g^{-1})	2.74	3.15	3.17	3.17
k_1[b] (day^{-1})	0.0106		0.0640	0.5421
k_2[c] (day^{-1})			0.0072	0.0072
g[d]				0.2310
a[e]		0.1765		
b[f] (day^{-1})		1.7233		
t_b[g] (day)			4.6300	

[a]C_0 = concentration at t = 0. [b]k_1 = rate constant until $t = t_b$. [c]k_2 = rate constant from $t = t_b$. [d]g = fraction of C_0 applied to compartment 1. [e]a = shape parameter. [f]b = location parameter. [g]t_b = breakpoint (time at which the rate constant changes).

Table 3. Comparison of the Calculated End Points, DT_{50} and DT_{90}, Model Efficiency (EF), and the χ^2 Test with the Four Models: (1) Simple First-Order Kinetics Model (SFO), (2) Gustafson−Holden Multi-compartment Model (FOMC), (3) Hockey-Stick Model (HS), and (4) Bi-exponential Model (DFOP)[a]

	SFO	FOMC	HS	DFOP
DT_{50} (day)	65	86	59	60
DT_{90} (day)	217	797030	282	282
m (degree of freedom)	5	4	3	3
visual (residual plot)	not good	fair	good	good
χ^2 calculated (0.05, m)	11.07	9.488	7.815	7.815
model efficiency (EF)	0.8139	0.9676	0.9946	0.9945

[a]Models 1, 3, and 4 are similar in their predictions.

it offers no advantage over the other two biphasic models.[20] Calculated DT_{50} and DT_{90} values were 59 and 282 days, respectively, using the HS model and 60 and 282 days, respectively, using the DFOP model. The DT_{50} values are in agreement with the experimentally determined DT_{50} value of 63 days. The FOMC has an appreciable model efficiency of 0.9676, but visual inspection of the fit shows that the model is not appropriate for pyraclostrobin dissipation modeling. While the residual plot is fair, it is not as accurate as the HS and DFOP models.

The value obtained for DT_{50} here (63 days) was higher than other reported values. Reddy et al.[14] found DT_{50} range from a low of 9.2 days (sludge-amended soil) to 47 days (sterilized soil), with an average of 28 days. Zhang et al.[12] found DT_{50} in peanut field soil to be 13−17 days. Footprint[13] lists "typical" DT_{50} of 32 days. The slower dissipation of pyraclostrobin observed in the present study was similar to dissipation of another strobilurin, axozystrobin, in soil amended with compost (DT_{50} = 73 days).[24] However, varied rates of azoxystrobin dissipation are also common. Wang et al.[25] reported a range of azoxystrobin DT_{50} in soil used to cultivate bananas of 8.8−13 days. The rate of pyraclostrobin should minimally impact dissipation, as Reddy et al.[14] showed similar DT_{50} (28 days) for soil amended with either 1 or 10 μg g^{-1}. The slow dissipation may be related to the field not having a prior history of pyraclostrobin application. Additional applications may lead to enhanced dissipation, as reported for the fungicide tebuconazole in agricultural soil.[26] Repeated applications during one growing season resulted in DT_{50} decreases from 43 to 5 days.[26] The recommended split applications of pyraclostrobin may result in a similar scenario. Indeed, in a field trial, only low levels of pyraclostrobin were detected (≤0.20 μg g^{-1}) in soil following four applications at higher than label rates (112.5 g of a.i. ha^{-1}).[12] Organic components of the soil are also likely to affect the dissipation rate in soil. The log K_{oc} for pyraclostrobin is 3.96,[16] which is moderately high, indicating strong adsorption to the soil. However, the low organic matter content of the soil (1.61%) most likely significantly reduces this effect.

Because pyraclostrobin is primarily applied to leaves to control brown rust, a wash-off study was conducted to determine if a time period existed after application when precipitation would most likely result in pyraclostrobin wash-off onto the soil surface. By taking 57 000 stalks ha^{-1},[28] a rainfall event of 2.28 mm would need to occur to obtain the equivalent of 2 L of wash-off water per 5 stalks sampled. Daily rainfall amounts of at least 2.28 mm were recorded on May 1, 2, 10, 11, 22, and 23, 2013, and June 2, 8, 9, 11, 14, 23, and 29, 2013 at the Ardoyne Farm. The timing of these rains coincided with the highest incidence of brown rust.[1] However, yearly weather patterns will dictate brown rust severity. Additionally, rainfall events exceeded 2.28 mm at 75 and 47% of the time for May and June 2013 at the study site, respectively. Thus, wash-off of pyraclostrobin onto the soil surface is a legitimate environmental fate for pyraclostrobin in Louisiana sugarcane fields. Initial measurements prior to pyraclostrobin application indicated no presence of the chemical (Figure 5). Significant pyraclostrobin in the wash was observed at 30 min after application, with a value of over 35 μg g^{-1} dry leaf tissue. Significant decreases in pyraclostrobin wash-off were observed at each subsequent sample time, with a 38, 32, 57, and 52% reduction at 6, 24, 48, and 72 h, respectively (Figure 5). The amount recovered at 72 h was not statistically different from the control. The data are in good agreement with the product label that lists a rain fastness of 48 h for Headline SC.[27]

The QuEChERS method allowed for better baseline chromatogram linearity as well as shortened analysis time per sample. The DT_{50} for pyraclostrobin in this study was 63 days. The value is higher than previously reported DT_{50} and indicates that pyraclostrobin is moderately persistent to persistent in Louisiana sugarcane soil. Modeling suggests that the degradation of the pesticide follows biphasic kinetics. Wash-off studies

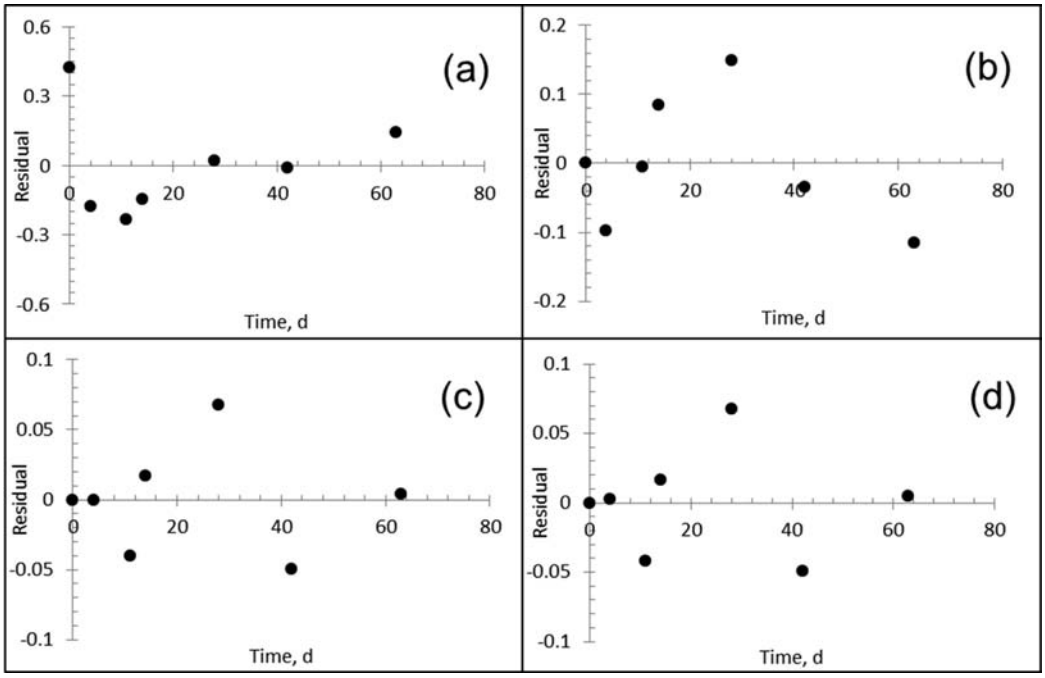

Figure 4. Residual plots for the best-fit data for the models: (a) simple first-order kinetics model (SFO), (b) Gustafson−Holden multi-compartment model (FOMC), (c) hockey-stick model (HS), and (d) bi-exponential model (DFOP).

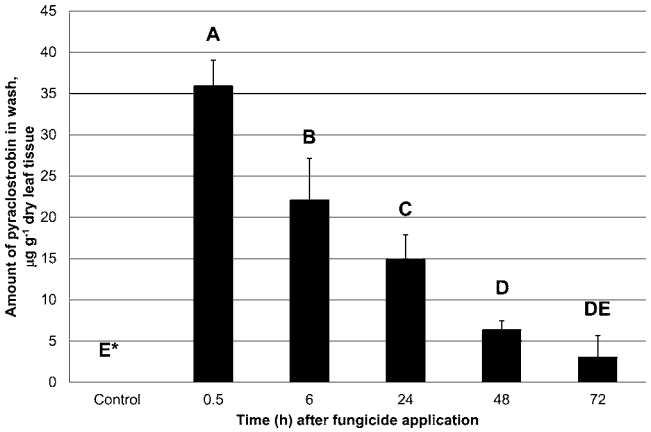

Figure 5. Appearance of pyraclostrobin in the wash-off after application to sugarcane leaves. No rainfall occurred during the period of the study. (∗) Bars with the same letter are not different at the $p < 0.05$ level.

indicate that application of Headline SC within 48 h of a rainfall event may result in significant transport of pyraclostrobin off of leaf surfaces. With the resurgence of brown rust and discovery of orange rust, applications of pyraclostrobin and other strobilurin and triazole fungicides will remain a necessity. Prudent spray timing designed to miss rainfall events will improve chemical effectiveness and sugarcane yields.

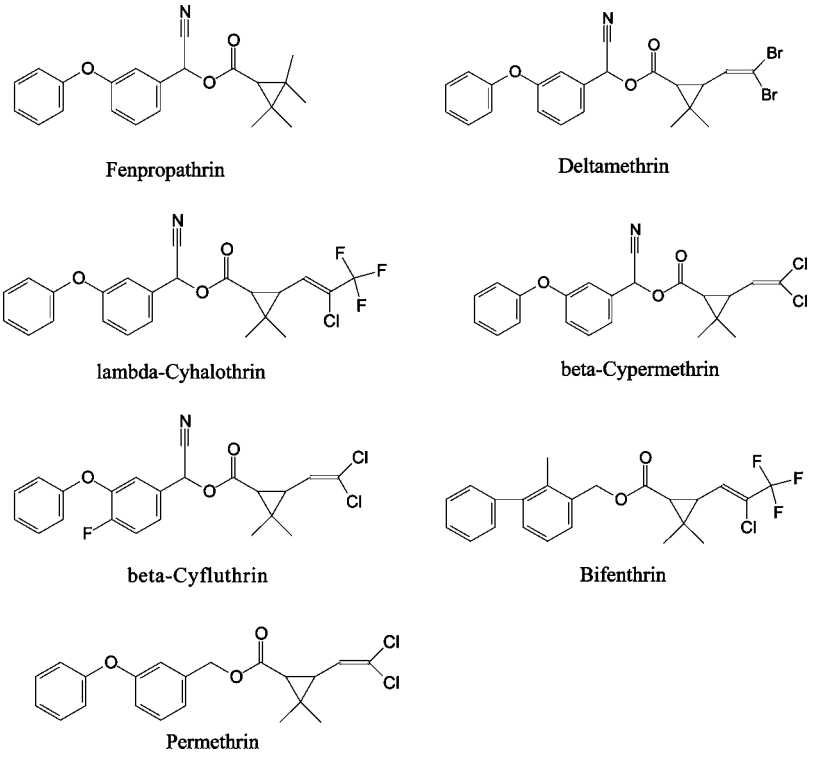

Figure 1. Molecular structures of SPs.

xenobiotic compounds can be successfully eliminated by diverse microorganisms belonging to different taxonomic groups.[25−29] Recently, Cycoń et al.[24] reported that *Bacillus* sp. TDS-2 isolated from sandy soil successfully removed thiophanate-methyl (100 mg kg^{-1}) from soils within 24 days. Chen et al.[26] reported that about 80% of the initial dose of *β*-cypermethrin (50 mg kg^{-1}) was removed from the sterilized soils by *Streptomyces aureus* HP-S-01 within 10 days. A few bacterial species, including *Sphingobium* sp. JZ-2,[30] *Sphingobium* sp. JQL4-5,[31] *Clostridium* sp. ZP3,[32] and *Ochrobactrum trtici* pyd-1,[33] have been reported for the degradation of fenpropathrin. However, these isolates commonly degraded only a couple of pyrethroid insecticides, which may limit their use in bioremediation as various regions are usually contaminated by multiple pyrethroid compounds.[3,4,9−11] Furthermore, little is known about the biodegradation pathway and catalytic mechanisms of fenpropathrin.

In our previous study, *Bacillus* sp. DG-02 was isolated from the pyrethroid-manufacturing wastewater treatment system.[34] In the present study, we demonstrated that strain DG-02 was capable of degrading not only fenpropathrin but also other related SPs. The aims of this study were to investigate the biodegradation kinetics and to determine the bacterial metabolic products of fenpropathrin. Finally, our findings highlight the promising potentials and advantages of *Bacillus* sp. DG-02 for bioremediation of pyrethroid-contaminated environments.

MATERIALS AND METHODS

Chemicals. Deltamethrin (98%), fenpropathrin (93%), *λ*-cyhalothrin (95%), *β*-cypermethrin (94.8%), *β*-cyfluthrin (95%), bifenthrin (98%), and permethrin (95%) were obtained from Zhongshan Aestar Fine Chemical Inc., Ltd., China. The chromatographic grade acetonitrile were purchased from Sigma-Aldrich, USA. The chemicals were dissolved in dimethyl sulfoxide (DMSO) or acetone at a stock concentration of 10 g L^{-1}, and stored in dark bottles at 4 °C prior to use. The stock solutions were sterilized by membrane filtration and rationed into medium to get the desired concentrations. At high concentrations, polysorbate 80 was used as emulsifier to disperse the possible precipitate in the liquid medium. All other chemicals and solvents used in this study were of analytical grade.

Bacterium Used in This Study. The mineral salt medium (MSM) containing (g L^{-1}) $(NH_4)_2SO_4$, 2; $MgSO_4{\cdot}7H_2O$, 0.2; $CaCl_2{\cdot}2H_2O$, 0.01; $FeSO_4{\cdot}7H_2O$, 0.001, $Na_2HPO_4{\cdot}12H_2O$, 1.5; and KH_2PO_4, 1.5, was used for the isolation of potential degrading strains. The final pH was adjusted to 7.5. The bacterial strain DG-02, which was deposited in the China Center for Type Culture Collection (collection no. CCTCC M 20111382), was isolated from a pyrethroid-manufacturing wastewater treatment system using an enrichment culture technique.[34] In this study, the bacterium was further identified by API 50 CHB systems (bioMérieux Inc., France) according to the instructions of the manufacturer.

Inoculum Preparation. The bacterial strain was stored in 15% glycerol at −80 °C. Before each experiment the strain was thawed and grown in 250 mL Erlenmeyer flasks containing 50 mL of sterile Luria−Bertani (LB) medium (containing tryptone, 10 g L^{-1}; yeast extract, 5 g L^{-1}; NaCl, 10 g L^{-1}). At 30 °C, the flasks were placed on a platform shaker at 180*g*. The bacterial cells in the late-exponential growth phase were harvested by centrifugation (5 min, 4000*g*) at 4 °C and washed twice in 0.9% normal saline (N-saline) before inoculation. Unless otherwise stated, the densities of strain DG-02 were adjusted with sterile N-saline to approximately 1.0×10^8 colony-forming units (CFU) mL^{-1}. One percent of this suspension was used as the inocula for the subsequent studies.

Growth and Degradation Experiments. For the growth and degradation experiments, triplicate cultures were grown in MSM supplemented with 50 mg L^{-1} of fenpropathrin as the sole carbon source at 30 °C and 180*g* on a rotary shaker. A noninoculated culture served as a control. Samples were collected periodically from the cultures. The bacterial growth was monitored by counting the CFU per liter of serial dilutions, and the amount of residual fenpropathrin was determined by high-performance liquid chromatography (HPLC) as described below.

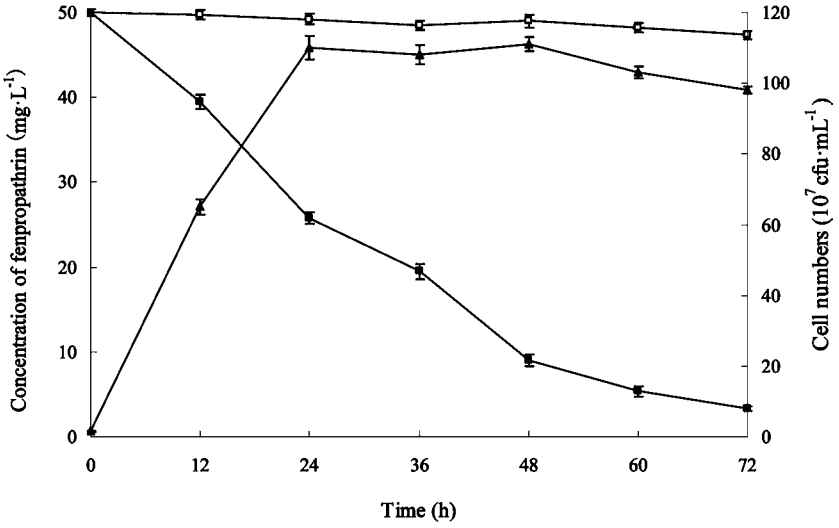

Figure 2. Degradation and utilization of fenpropathrin (50 mg L^{-1}) during growth of strain DG-02: (□) fenpropathrin control; (■) fenpropathrin degradation by strain DG-02; (▲) cell growth. Error bars indicate the standard deviation of three replicates.

The mineral salt media containing different final concentrations of fenpropathrin (25, 50, 100, 200, 400, 600, 800, 1000, and 1200 mg L^{-1}) were inoculated respectively with strain DG-02 and incubated at 30 °C and 180*g* on a rotary shaker. Each treatment was performed in triplicate, and fenpropathrin residues were measured at an interval of 12 h.

Identification of Metabolites during Fenpropathrin Degradation. The metabolic products of fenpropathrin in cell-free filtrates of strain DG-02 cultures containing different concentrations of fenpropathrin (50, 100, and 200 mg L^{-1}) were extracted and identified by gas chromatopraphy−mass spectrometry (GC-MS) (Agilent 6890N/5975, USA). The cell-free filtrates were taken at an interval of 12 h. The same bacterial culture supernatants lacking fenpropathrin were used as a negative control, and noninoculated control containing the same amount of fenpropathrin was included as well. The metabolites were extracted with ethyl acetate from the cell-free filtrates after acidification to pH 2 with 2 M HCl. The organic layer was dehydrated, dried, and redissolved in methanol.[30,35] After filtration with a 0.45 μm membrane (Millipore, USA), the samples were subjected to GC-MS as described below. The metabolites identified by mass spectrometry analysis were matched with authentic standard compounds from the National Institute of Standards and Technology (NIST, USA) library database.

Degradation Kinetics of Various SPs. To determine its ability to degrade various SPs, strain DG-02 was inoculated into fresh MSM supplemented with 50 mg L^{-1} deltamethrin, λ-cyhalothrin, β-cypermethrin, β-cyfluthrin, bifenthrin, and permethrin, respectively. Triplicate cultures were grown in MSM at 30 °C. Degradation measurements were carried out periodically as described above.

Biodegradation of Fenpropathrin in Soils. The soil samples were collected from the top 0−20 cm from a farm in South China Agricultural University, Guangzhou, southern China, that had never been treated with fenpropathrin or organic and inorganic fertilizers. The detailed physicochemical properties of the soils were (g kg^{-1} of dry weight): organic matter, 10.5; total N, 0.5; total P, 0.4; total K, 18.2; and pH, 6.9. The soils have a sandy loam texture (sand, 65.0%; silt, 28.0%; clay, 7.0%).[34] In the laboratory, the soils were gently air-dried to the point of soil moisture suitable for sieving. After sieving to a maximum particle size of <2 mm, the soils were used in the bioremediation experiments.

The bioremediation experiment with strain DG-02 was performed in sterile and nonsterile soils. In the first case, soils were sterilized by autoclaving for 1 h at 121 °C. The stock solution of fenpropathrin was sprayed on the surface of 200 g of sterile and nonsterile soils.[24] The applied dose of insecticide corresponded to a soil concentration of 50 mg kg^{-1}. After thorough mixing, the bacterial suspension was introduced in triplicate into the soils by drip irrigation to give a final bacterial count of approximately 1.0×10^8 CFU g^{-1} of soil. The triplicate samples of sterile and nonsterile soils without strain DG-02 were kept as controls, respectively. The same amount of pesticide was applied to these soils. The water contents were adjusted to approximately 40% of water-holding capacity by the addition of sterile deionized water.[24] All of the soil samples were incubated in a darkened thermostatic chamber maintained at 30 °C for 15 days. Soil treatments (20 g) were removed aseptically at 0, 3, 6, 9, 12, and 15 days for the determination of fenpropathrin concentrations.

Chemical Analyses. Pyrethroid quantification was performed on an Agilent 1100 HPLC equipped with a ternary gradient pump, programmable variable-wavelength UV detector, column oven, electric sample valve, and C_{18} reversed-phase column (Hypersil ODS2 5 μm × 4.6 mm × 250 mm) with array detection from 190 to 400 nm (total scan) based on retention time and peak area of the pure standard. The samples were performed using a mobile phase of 90:10 acetonitrile/water. Sample injection volume was 10 μL, and mobile phase was programmed at a flow rate of 1 mL min^{-1}.[36,37]

The metabolites of fenpropathrin were confirmed on an Agilent 6890N/5975 GC-MS system equipped with an autosampler and on-column, split/splitless capillary injection system, with a HP-5MS capillary column (30.0 m × 250 μm × 0.25 μm) with array detection from 30 to 500 nm (total scan). The operating conditions were as follows: the column was held initially at a temperature of 90 °C for 2 min, then raised at 6 °C min^{-1} to 150 °C for 1 min, at 10 °C min^{-1} to 180 °C for 4 min, and finally at 20 °C min^{-1} to 260 °C for 10 min. The temperatures corresponding to the transfer line and the ion trap were 280 and 230 °C, respectively, and the ionization energy was 70 eV. The injection volume was 1.0 μL with splitless sampling at 250 °C. Helium was used as a carrier gas at a flow rate of 1.5 mL min^{-1}.[38]

Kinetics Analyses. The substrate inhibition model (eq 1) was used to fit the specific degradation rate (q) at different initial concentrations of fenpropathrin.

$$q = \frac{q_{max} S}{S + K_s + (S^2/K_i)} \quad (1)$$

q_{max} is the maximum specific fenpropathrin degradation rate (h^{-1}), K_i is the substrate inhibition constant (mg L^{-1}), K_s is the half-saturation constant (mg L^{-1}), and S is the inhibitor concentration (mg L^{-1}).

The disappearance of fenpropathrin and other pyrethroids in MSM or soils was fitted to the first-order kinetic model (eq 2).

$$C_t = C_0 \times e^{-kt} \quad (2)$$

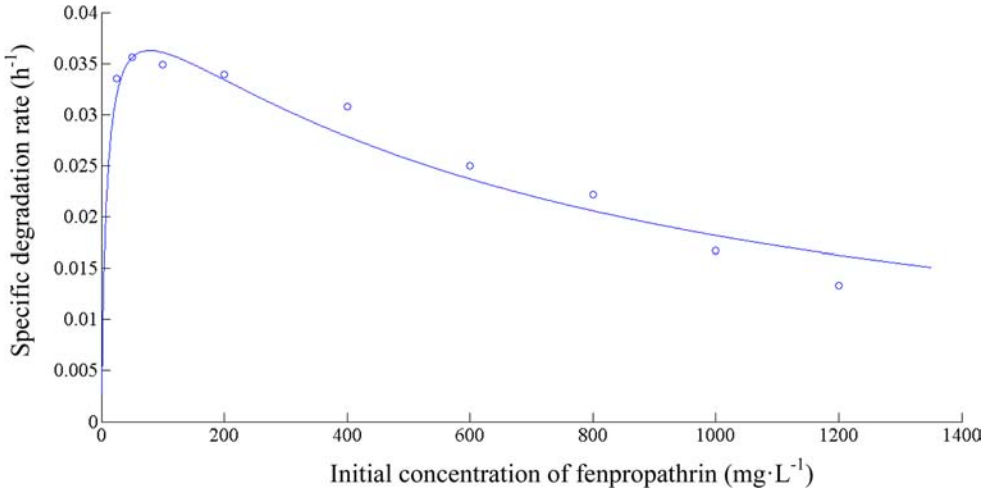

Figure 3. Relationship between initial fenpropathrin concentration and specific degradation rate by strain DG-02.

C_0 is the amount of substrate at time zero, C_t is the amount of substrate at time t, and k and t are the degradation rate constant (h^{-1}) and degradation period in hours, respectively.

The algorithm as expressed in eq 3 was used to determine the theoretical half-life ($t_{1/2}$) values of fenpropathrin and other pyrethroids.

$$t_{1/2} = \frac{\ln(2)}{k} \tag{3}$$

ln 2 is the natural logarithm of 2, and k is the rate constant (h^{-1}).

RESULTS AND DISCUSSION

Identification of Strain DG-02 Using API Systems. In our previous studies, stain DG-02 was tentatively identified as *Bacillus* sp. based on the morphology and 16S rDNA gene analysis.[34] In this study, the bacterium was further classified as *Bacillus cereus* by API 50 CHB systems (bioMérieux Inc., France) according to the instructions of the manufacturer, with good identification (95.3%). It was positive in tests such as glycerol, maltose, ribose, trehalose, adonitol, cellobiose, gluconate, and *N*-acetylglucosamine. It was negative in tests such as erythritol, sannose, sorbose, rhamnose, melibiose, 5-keto-D-gluconate, and methyl α-D-mannoside. Detailed biochemical properties of strain DG-02 are presented in Table S1 in the Supporting Information.

Utilization of Fenpropathrin as a Growth Substrate by Strain DG-02. The growth of strain DG-02 on fenpropathrin and the ability of this bacterium to degrade fenpropathrin are shown in Figure 2. Strain DG-02 degraded fenpropathrin rapidly with about 82% of the initial dose being eliminated within 48 h. During this time, the number of strain DG-02 cells was increased to its maximum level. After incubation for 72 h, approximately 93.3% of the added fenpropathrin was degraded by strain DG-02 when fenpropathrin was used as the growth substrate. It is worth mentioning that partial bacterial strain DG-02 perhaps utilize their dead cells for growth. Finally, the residual amount of the pesticide was not detectable by HPLC at 120 h post incubation (data not shown). In contrast with previous studies, the current study showed that the strain DG-02 could efficiently degrade fenpropathrin, suggesting this isolate may be an ideal candidate for bioremediation of a fenpropathrin-contaminated environment. In the control test, no significant change in fenpropathrin concentration was observed in the uninoculated medium.

Biodegradation of Fenpropathrin with Different Initial Concentrations. To test the effect of fenpropathrin concentration on its degradation, strain DG-02 was inoculated to the media containing various initial fenpropathrin concentrations ranging from 25 to 1200 mg L^{-1} (Figure S1 in the Supporting Information). Strain DG-02 rapidly degraded and utilized the added fenpropathrin up to the concentration of 1200 mg L^{-1}, and a lag period was observed at higher fenpropathrin concentrations. At a concentration of 25 mg L^{-1}, the residual level of fenpropathrin could not be detected in just over 72 h. Further loading of the organic compound in subsequent experiments demonstrated that strain DG-02 was capable of degrading about 93.3 and 90.4% of fenpropathrin at a dose of 50 and 100 mg L^{-1} in 72 h, respectively, and the strain completely degraded the added doses in approximately 120 h. When the concentration was increased to 200, 400, and 600 mg L^{-1}, respectively, about 87.6, 84.7, and 80.5% degradations of this compound were observed in 72 h, respectively, and complete degradation occurred after a prolonged culture. Over this time period the cells could utilize only 75.8, 67.2, and 61.2% of fenpropathrin when it was given 800, 1000, and 1200 mg L^{-1}, respectively. These findings suggest that increased concentration of fenpropathrin has a slight effect on biodegradation performance of strain DG-02 with a modest increase in the duration of lag phase, but did not lead to complete inhibition or cell death. Previous studies showed that the pyrethroid-degrading strains usually transform the added pesticides with a concentration lower than 200 mg L^{-1}.[39,40] At higher concentrations, however, the metabolic activity of the reported pyrethroid-degrading strains was subject to complete catabolite repression.[41] Noticeably, our results suggest this particular isolate could tolerate and degrade fenpropathrin up to a concentration as high as 1200 mg L^{-1}. This feature gives the pesticide degrader a competitive advantage in variable environments, as they could survive and utilize the pollutants even exposed to a high concentration.[42]

The decrease in fenpropathrin degradation rate following an increase in the initial fenpropathrin concentration implies that fenpropathrin may act as a partial inhibitor to strain DG-02. To address this possibility, the substrate inhibition model (eq 1) adapted from Luong was used to fit the specific degradation rate (q) at different initial concentrations.[43] The relationship between q and S is shown in Figure 3. The kinetic parameters of strain DG-02 determined from nonlinear regression using

Table 1. Chromatographic Properties of Metabolites of Fenpropathrin during Degradation by Strain DG-02

Compound	RT (min)	*m/z*	Chemical structural formula in NIST library	Name
A	17.293	349		Fenpropathrin
B	15.919	218		2,2,3,3-Tetramethyl cyclopropanecarboxylic acid phenyl ester
C	11.034	154		3,4-Dihydroxy benzoic acid
D	9.744	228		3-Phenoxybenzoate
E	9.576	154		3,4-Dimethoxy phenol
F	8.025	198		3-Phenoxybenzaldehyde
G	7.907	225		α-Hydroxy-3-phenoxy-benzeneacetonitrile
H	4.392	94		Phenol

matrix laboratory (MATLAB) software package (version 7.8) were q_{max} = 0.05 h^{-1} and K_s = 9.0 mg L^{-1}. The inhibitory effect of fenpropathrin was considered to occur in a linear manner at K_i = 694.8 mg L^{-1}. The critical inhibitor concentration (S_m) was established to be 78.9 mg L^{-1} by calculating the square root of $K_i \times K_s$. The coefficient of determination (R^2) was 0.9549, which indicates that the experimental data were well correlated with the model. As shown in Figure 3, when the initial concentration of fenpropathrin was <78.9 mg L^{-1}, the q value was gradually increased. At higher concentrations, inhibition by fenpropathrin became substantial and the q value was proportionally decreased in a dosage-dependent manner. This reveals that the fenpropathrin degradation activity of strain DG-02 could be partially inhibited at a high concentration of fenpropathrin but may not lead to a complete repression.

Degradation Products and Degradation Pathway of Fenpropathrin. The predicted chemical structures, retention times (RT), and characteristic ions of the mass spectra (m/z) are summarized in Table 1. Compound **A**, with a RT of 17.293 min, showed a prominent protonated molecular ion at m/z 349, which is similar to the characteristic parental ion of fenpropathrin (Figure 4a). Additionally, compound **A** also has the same RT as the authentic fenpropathrin. Therefore, compound **A** was identified as fenpropathrin. Along with the degradation process, compound **A** disappeared concomitantly with formation of seven new compounds (Figure 4b–h). The changes in fenpropathrin peak area over time are shown in Figure S2 in the Supporting Information. The seven compounds were characterized as 2,2,3,3-tetramethylcyclopropanecarboxylic acid phenyl ester, 3,4-dihydroxybenzoic acid, 3-phenoxybenzoate, 3,4-dimethoxyphenol, 3-phenoxybenzaldehyde, α-hydroxy-3-phenoxybenzeneacetonitrile, and phenol, respectively, on the basis of the similarity of their fragment retention times and molecular ions to those of corresponding authentic compounds in the NIST library database (Figure S3 in the Supporting Information). Among these products, 3-phenoxybenzaldehyde, 3-phenoxybenzoate, and 3,4-dimethoxybenzoic acid were also reported during the degradation of fenpropathrin in previous studies,[30,33] but the other four metabolic products of fenpropathrin were detected for the first time in this study. These metabolite concentrations were very low. We also noted that these metabolites were transient, suggesting that fenpropathrin was completely degraded by the strain DG-02 without any noncleavable metabolites at the end of the experiment. In the negative control lacking fenpropathrin, none of these metabolites was detected. In the noninoculated control containing the same amount of fenpropathrin, only fenpropathrin was detected (Figure S4 in the Supporting Information).

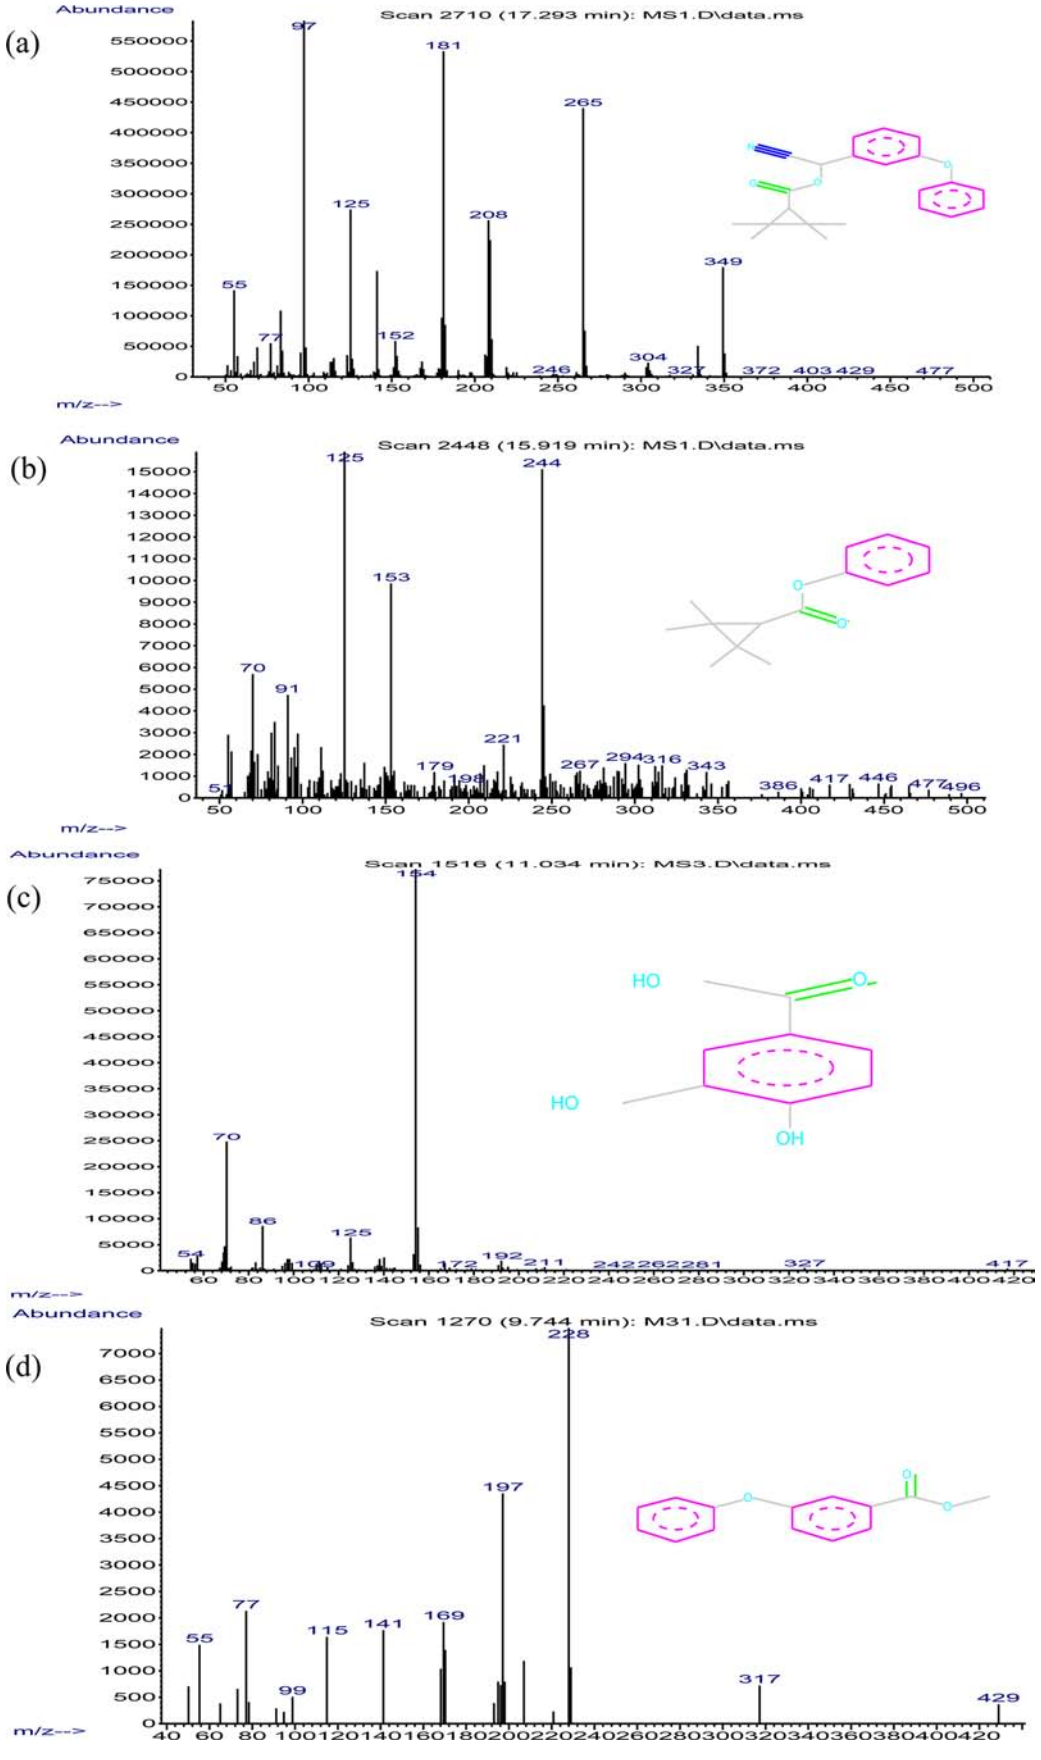

Figure 4. continued

dx.doi.org/10.1021/jf404908j | J. Agric. Food Chem. 2014, 62, 2147−2157

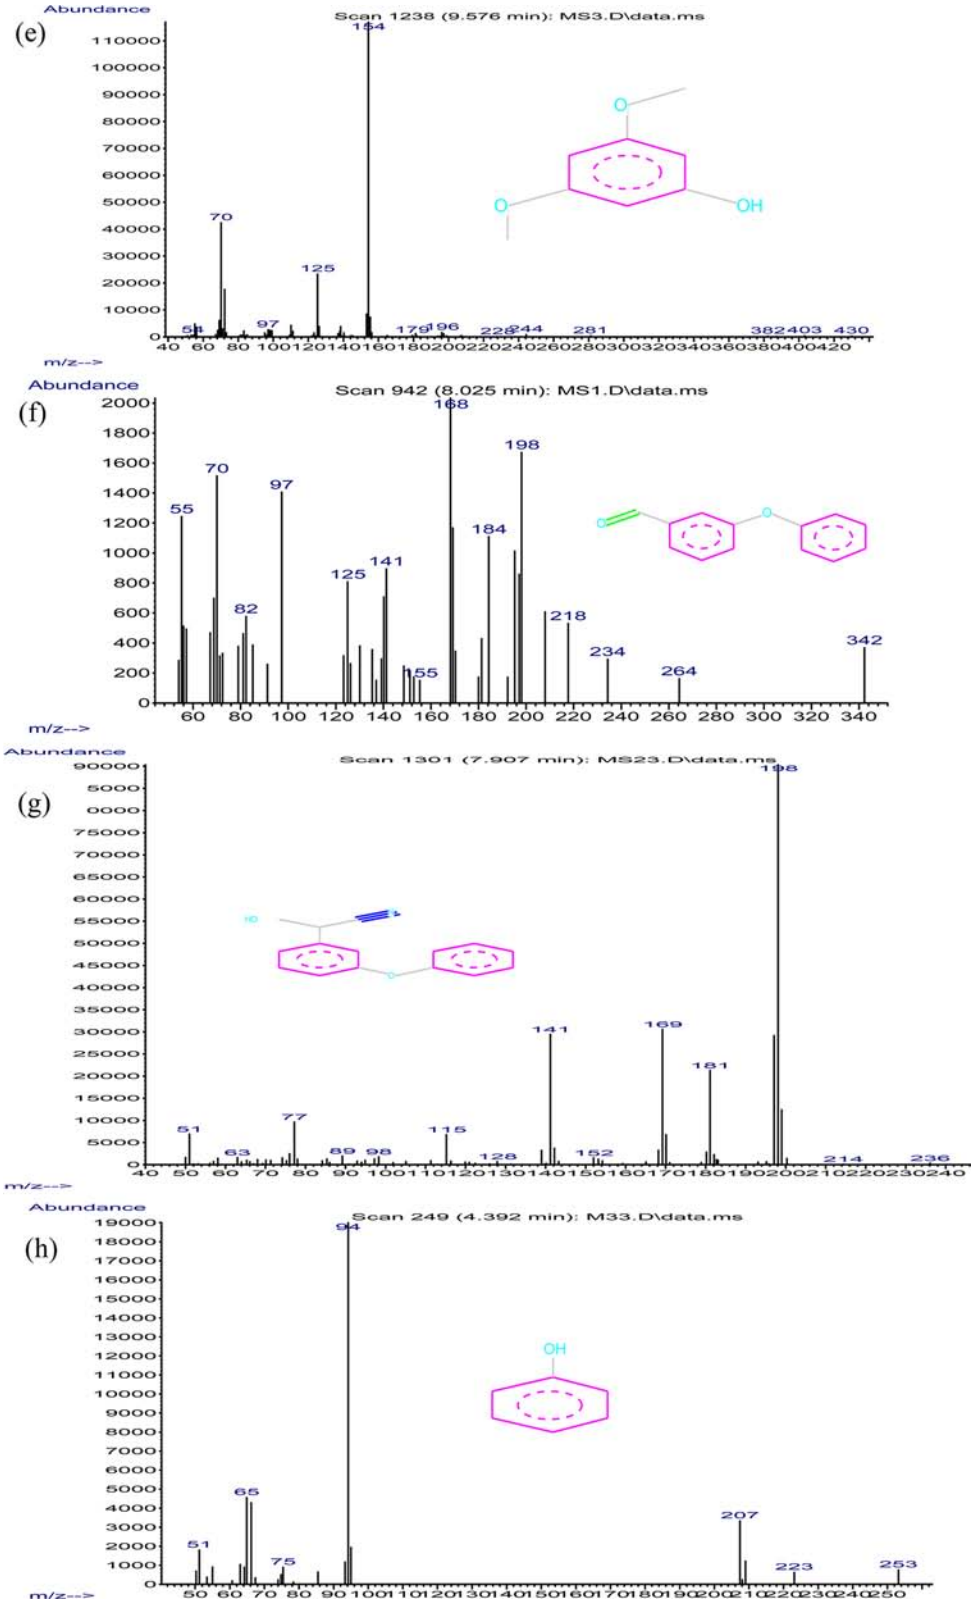

Figure 4. GC-MS analysis of the metabolites produced from fenpropathrin degradation by strain DG-02. (a–h) Characteristic ions of compounds **A–H** in GC-MS. The retention times of the compounds were 17.293, 15.919, 11.034, 9.744, 9.576, 8.025, 7.907, and 4.392 min, respectively, which were identified as fenpropathrin, 2,2,3,3-tetramethylcyclopropanecarboxylic acid phenyl ester, 3,4-dihydroxybenzoic acid, 3-phenoxybenzoate, 3,4-dimethoxyphenol, 3-phenoxybenzaldehyde, α-hydroxy-3-phenoxybenzeneacetonitrile, and phenol, respectively.

On the basis of the chemical structures of fenpropathrin and the metabolic products formed during fermentation, we propose a degradation pathway of fenpropathrin in strain DG-02 (Figure 5). According to this pathway, fenpropathrin was initially hydrolyzed by cleavage of the carboxylester linkage to produce α-hydroxy-3-phenoxybenzeneacetonitrile and

dx.doi.org/10.1021/jf404908j | J. Agric. Food Chem. 2014, 62, 2147–2157

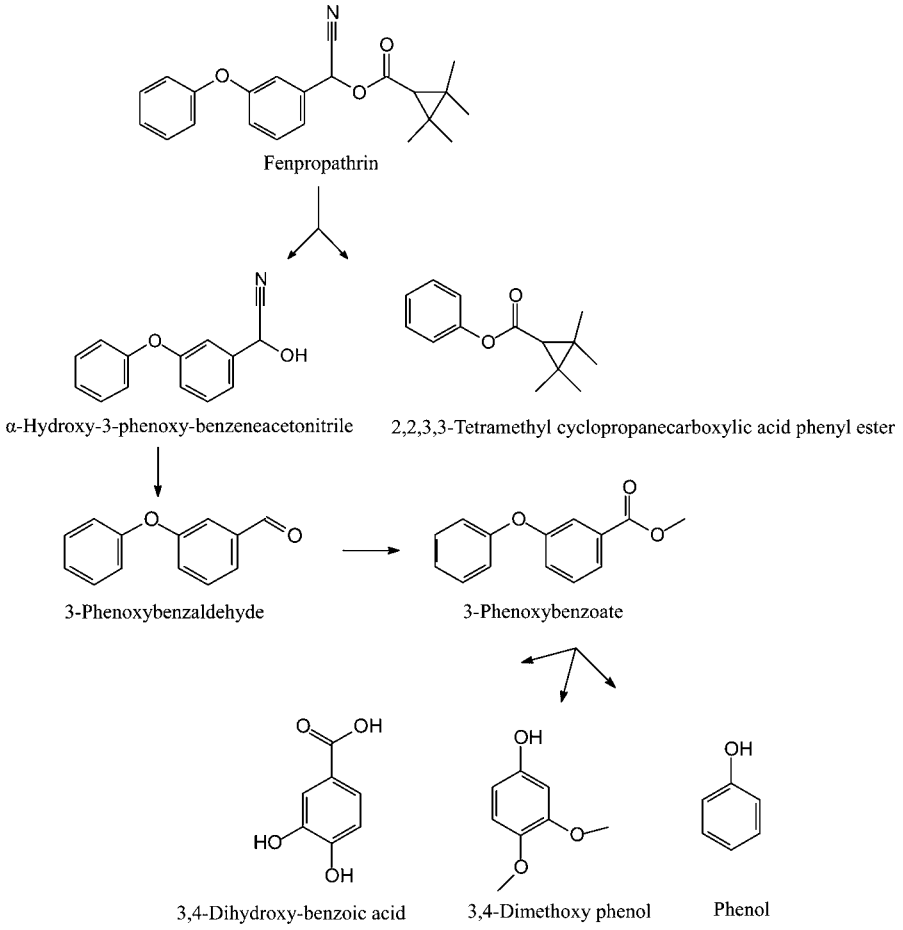

Figure 5. Proposed pathway for degradation of fenpropathrin in strain DG-02.

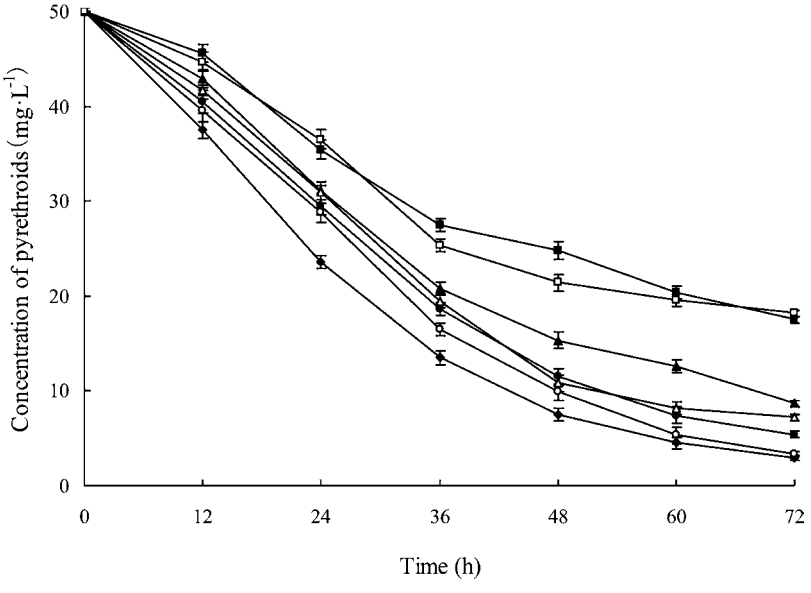

Figure 6. Degradation kinetics of various SPs by strain DG-02: (◆) deltamethrin; (◇) fenpropathrin; (●) *β*-cypermethrin; (△) *β*-cyfluthrin; (▲) *λ*-cyhalothrin; (□) permethrin; (■) bifenthrin. Error bars indicate the standard deviation of three replicates.

2,2,3,3-tetramethylcyclopropanecarboxylic acid phenyl ester. The intermediate product *α*-hydroxy-3-phenoxybenzeneacetonitrile was unstable in the environment, which was spontaneously converted to 3-phenoxybenzaldehyde. Subsequent oxidization of 3-phenoxybenzaldehyde yielded 3-phenoxybenzoate, which was then subject to diaryl cleavage, resulting in the formation of 3,4-dihydroxybenzoic acid, 3,4-dimethoxyphenol, and phenol. However, these compounds were transient. Eventually, no persistent accumulative product was detected by GC-MS analysis, indicating that these compounds under-

dx.doi.org/10.1021/jf404908j | J. Agric. Food Chem. 2014, 62, 2147−2157

went aromatic ring cleavage and further metabolism. Very interestingly, in our previous studies we demonstrated that strain DG-02 also degraded 3-phenoxybenzoic acid to give 3,4-dihydroxybenzoic acid, 3,4-dimethoxyphenol, and phenol.[34] Clearly, the bacterial strain appears to harbor a complete metabolic pathway for degradation and metabolism of fenpropathrin, indicating that the isolate could be an ideal candidate for bioremediation of the environments contaminated by fenpropathrin and the related pyrethroid insecticides.

It was evident from the results that strain DG-02 degrades fenpropathrin by first cleavage of the carboxylester linkage and diaryl bond of fenpropathrin. Similar findings were also observed in biodegradation of other pyrethroid insecticides such as cyfluthrin and cypermethrin.[38,42] However, our results were very different from the previous findings of Zhang et al.,[32] who reported that *Clostridium* sp. ZP3 degraded fenpropathrin with an oxidization process to yield 3,5-dimethylamphetamine, benzenemethanol, and benzyl alcohol. It was generally regarded that ester hydrolysis via carboxylesterases was the primary degradation pathway of various pyrethroids in a multitude of species, from mammals to insects to microorganisms.[30,40,44,45] The fenpropathrin degradation pathway in strain DG-02 appears to be similar to the initial steps of most environmental isolates in pyrethroid biodegradation processes, in which pyrethroids were converted to 2,2,3,3-tetramethylcyclopropanecarboxylic acid and 3-phenoxybenzoic acid through hydrolysis of the carboxylester linkage.[30,35,39] Unfortunately, however, it is not clear whether these microorganisms are capable of further metabolism of pyrethroids. In this study, we showed that strain DG-02 could further metabolize the intermediate 3-phenoxybenzoate by cleavage of the diaryl bond (Figure 5), leading to complete degradation of the pesticide, which is rarely seen in other pyrethroid-degrading strains.

Degradation Kinetics of Various SPs. The abilities of strain DG-02 to degrade various pyrethroids are shown in Figure 6. The strain was capable of utilizing all of the pyrethroids tested. As shown in Figure 6, degradation of all tested compounds started rapidly at the beginning of incubation with no apparent lag period. Deltamethrin and fenpropathrin were the most preferred substrates, with degradation rates of 94.1 and 93.3% within 72 h of incubation, respectively. β-Cypermethrin, β-cyfluthrin, and λ-cyhalothrin were degraded relatively more slowly than deltamethrin and fenpropathrin, with degradation rates of 89.2, 85.6, and 82.7%, respectively. Bifenthrin and permethrin were the most persistent; only 65.1 and 63.6% of the added substrates were degraded under the same experimental conditions, suggesting that absence of the cyano group may cause a substantial reduction in the hydrolysis rate. These results contrast with the previous findings that degradation reduction in pyrethroid compounds with a cyano group is due to its toxic effect.[33] Our results provide a strong endorsement to the previous view that different capacities of various microorganisms to utilize pyrethroid compounds could be attributed to a number of factors, including the differences in substrate transportation, enzyme specificity, and molecular structures of these compounds.[34]

Several papers on the microbial degradation of fenpropathrin have been published. *Sphingobium* sp. JZ-2 could use fenpropathrin as the sole carbon source in MSM and could degrade >80% of the added pesticide at a concentration of 50 mg L^{-1} after 4 days of incubation.[30] A genetically engineered microorganism named JQL4-5-*mpd* was also able to simultaneously degrade methyl parathion and fenpropathrin in MSM.[31] *Clostridium* sp. ZP3 was reported to be capable of degrading fenpropathrin in liquid medium with the presence of an extra carbon source (glucose).[32] One recently isolated fenpropathrin-degrading strain, *O. trtici* pyd-1, could also utilize fenpropathrin as a growth substrate and degrade approximately 90% of 100 mg L^{-1} of the pesticide in 72 h in liquid culture.[33] However, these strains either could degrade only a limited number of pyrethroids or showed a low degradation efficiency, which limits their use in bioremediation of environments contaminated with multiple pyrethroids. It is noteworthy that strain DG-02 could degrade not only fenpropathrin but also other pyrethroids, which is rarely seen in other microorganisms.

Previous papers suggest that the bacterial isolates from *Bacillus* genus could be the most metabolically active microorganisms, as they are capable of degrading a wide variety of xenobiotic aromatic compounds, including thiophanate-methyl,[24] chlorpyrifos,[29] and 4-chloro-2-nitrophenol.[46] The results from this study further expand the metabolic list of the *Bacillus* species. In our previous studies, strain DG-02 was found to be highly efficient in degrading 3-phenoxybenzoic acid.[34] 3-Phenoxybenzoic acid is a major product common to most of the pyrethroids.[47] Degradation of this compound by the same strain that degrades pyrethroids is very important because 3-phenoxybenzoic acid is generally antimicrobial, and it would be accumulated if not degradable, which prevents further degradation and may cause growth arrest.[37] Importantly, the ability of strain DG-02 in degrading a wide range of pyrethroids suggests that this particular isolate has promising potentials and advantages as a bioremediation organism in removing pyrethroid residues from various environments as most contaminated regions were affected by multiple pyrethroid compounds.[3,4,9−11]

To predict the ability of strain DG-02 in biodegradation of various substrates in environment, the degradation process was fitted to the first-order kinetic model (eq 2). The kinetic parameters for all runs calculated from the equations are presented in Table 2. In these studies, the degradation rate and the substrate concentration were in direct proportion, and the degradation process corresponded to the first-order kinetic model, with an R^2 ranging from 0.9564 to 0.9826, indicating that the experimental data were well-correlated with the model. The degradation process was characterized by a k ranging from 0.0160 to 0.0355 h^{-1} and a $t_{1/2}$ varying from 19.5 to 43.3 h (Table 3). Given that the reported $t_{1/2}$ values for various pyrethroids in water or soil are usually between 17 and 600 days,[1] addition of strain DG-02 significantly shortened the $t_{1/2}$ for pyrethroids, suggesting that this strain is suitable for the efficient and rapid degradation of pyrethroid residues and cleanup of contaminated environments.

Table 2. Kinetic Parameters of Degradation of Various SPs by Strain DG-02

treatment	regression eq	k (h^{-1})	$t_{1/2}$ (h)	R^2
deltamethrin	$C_t = 52.0e^{-0.0355t}$	0.0355	19.5	0.9826
fenpropathrin	$C_t = 52.3e^{-0.0315t}$	0.0315	22.0	0.9735
β-cypermethrin	$C_t = 54.8e^{-0.0286t}$	0.0286	24.2	0.9657
β-cyfluthrin	$C_t = 53.2e^{-0.0277t}$	0.0277	25.0	0.9688
λ-cyhalothrin	$C_t = 51.9e^{-0.0234t}$	0.0234	29.6	0.9564
bifenthrin	$C_t = 52.0e^{-0.0155t}$	0.0155	44.7	0.9574
permethrin	$C_t = 50.7e^{-0.0160t}$	0.0160	43.3	0.9718

Table 3. Kinetic Parameters of Degradation of Fenpropathrin in Sterile and Nonsterile Soils Inoculated with Strain DG-02

treatment	regression eq	k (day^{-1})	$t_{1/2}$ (days)	R^2
sterile soils + fenpropathrin	$C_t = 49.8e^{-0.0098t}$	0.0098	70.7	0.9791
nonsterile soils + fenpropathrin	$C_t = 49.9e^{-0.00187t}$	0.0187	37.1	0.9913
sterile soils + fenpropathrin + DG-02	$C_t = 51.6e^{-0.0981t}$	0.0981	7.1	0.9849
nonsterile soils + fenpropathrin + DG-02	$C_t = 51.0e^{-0.1281t}$	0.1281	5.4	0.9916

Biodegradation of Fenpropathrin in Soils. The abilities of strain DG-02 to degrade fenpropathrin in sterile and nonsterile soils were investigated, respectively. The kinetic parameters for all treatments are presented in Table 3. Kinetic data showed that the degradation process corresponded to the first-order model and was characterized by k ranging from 0.0098 to 0.1281 day^{-1}. The coefficient of determination R^2 was determined to be 0.9791−0.9916, showing that the experimental data are well-correlated with the model. Without strain DG-02, the $t_{1/2}$ values were 70.7 and 37.1 days for fenpropathrin in sterile and nonsterile soils, respectively. In contrast, the $t_{1/2}$ values for fenpropathrin in sterile and nonsterile soils inoculated with strain DG-02 were shortened, giving $t_{1/2}$ values of 7.1 and 5.4 days, respectively. Our results confirmed previous observation made by Khan et al.[48] indicating that biodegradation is the main mechanism of SP dissipation in soils, whereas its abiotic breakdown is less important. Studies on other SPs have shown that microorganisms which can degrade them in culture conditions also perform their degradation in soils.[26,49] In our bioremediation experiment, strain DG-02 efficiently degraded fenpropathrin in soils, suggesting that strain DG-02 may be ideal for bioremediation of soils contaminated with fenpropathrin.

In conclusion, *Bacillus* sp. DG-02 was found to be highly efficient in degrading fenpropathrin in different contaminated soils and water resources. This strain was able to utilize fenpropathrin as the growth substrate and rapidly degraded the pesticide in a concentration as high as 1200 mg L^{-1}. This is an important feature of a microorganism to be employed for bioremediation of variable environments. Moreover, we presented evidence that the bacterium harbors the metabolic pathway for complete degradation and metabolism of fenpropathrin. The strain could degrade both the carboxylester linkage and the diaryl bond of fenpropathrin, which plays a key role in the fenpropathrin biogeocycle. Another important feature which is worth mentioning is that this particular strain was capable of degrading a wide range of synthetic pyrethroids, suggesting that the isolate has promising potentials and advantages as a bioremediation organism in removing pyrethroid residues from water, soils, or crops.

(3NT).[13] Skibsted[1] recently postulated the potential facile conversion among ROS and RNS in cured meat systems assisted by other additives, such as ascorbate. However, the connection between oxidative and nitrosative reactions and the impact of protein nitration on the quality of cured muscle foods are poorly understood. Already 35 years ago, Cassens et al.[14] reported that almost half of the inorganic nitrite added to a meat product is bound to proteins, while only 10% corresponds to the addition of nitrite to myoglobin to form nitrosylmyoglobin. A full comprehension of the fate of reactive nitrite and its implication in the formation of specific protein oxidation and nitration products requires a second look to the chemistry of curing agents using innovative methodologies. The understanding of the redox chemistry of nitrite and ascorbate will enable, in turn, the identification of the real impact of these reactions on meat proteins and cured muscle foods.

This study was planned to elucidate the impact of nitrite and ascorbate on the chemical changes suffered by myofibrillar proteins in a pro-oxidative environment.

MATERIALS AND METHODS

Chemicals and Raw Material. All chemicals, reagents, and high-performance liquid chromatography (HPLC)-grade solvents were purchased from Panreac (Panreac Química S.A., Barcelona, Spain), Merck (Merk, Darmstadt, Germany), and Sigma Chemicals (Sigma-Aldrich, Steinheim, Germany). The water used was purified by passage through a Milli-Q system (Millipore Corporation, Bedford, MA). Porcine meat (muscle longissimus dorsi) was obtained from a local slaughterhouse.

Synthesis of α-Aminoadipic Semialdehyde (AAS) Standard Compound. *N*-Acetyl-L-AAS was synthesized from *Nα*-acetyl-L-lysine using lysyl oxidase activity from an egg shell membrane following the procedure described by Akagawa et al.[15] Briefly, 10 mM *Nα*-acetyl-L-lysine was incubated with constant stirring with 5 g of egg shell membrane in 50 mL of 20 mM sodium phosphate buffer at pH 9.0 at 37 °C for 24 h. The egg shell membrane then was removed by centrifugation, and the pH of the solution was adjusted to 6.0 using 1 M HCl. The resulting aldehydes were reductively aminated with 3 mmol of *p*-aminobenzoic acid (ABA) in the presence of 4.5 mmol sodium cyanoborohydride ($NaBH_3CN$) at 37 °C for 2 h with stirring. Then, ABA derivatives were hydrolyzed by 50 mL of 12 M HCl at 110 °C for 10 h. The hydrolysates were evaporated at 40 °C *in vacuo* to dryness. The resulting AAS−ABA was purified using silica gel column chromatography and ethyl acetate/acetic acid/water (20:2:1, v/v/v) as the elution solvent. The purity of the resulting solution and authenticity of the standard compounds obtained following the aforementioned procedures have been checked using mass spectrometry (MS) and proton nuclear magnetic resonance (^{1}H NMR).[15,16]

Extraction of Myofibrillar Proteins (MPs). MPs were extracted from 10 g of porcine meat according to the method described by Utrera and Estévez,[8] with slight modifications. Meat was weighed, chopped finely with a knife, and treated with 4 volumes of 10 mM potassium phosphate buffer at pH 7. The mixture was homogenized in the ULTRA-TURRAX for 30 s and then centrifuged at 670*g* for 15 min. Then, the supernatant was carefully removed, and 4 volumes of 10 mM potassium phosphate buffer at pH 7 was added again. The vials were shaken vigorously and centrifuged under the aforementioned conditions, and the supernatant was removed. A total of 4 volumes of 0.1 M NaCl was added, and the samples were stirred and centrifuged as in the previous steps. This procedure was repeated 3 times. Before the last centrifugation, the solution was filtered by passing through a gauze. The pH of this solution was adjusted to 6 with 0.1 N HCl, and the vials were centrifuged. Finally, the supernatant was carefully withdrawn and added to 200 mL of 100 mM sodium phosphate buffer at pH 7 with 0.6 M NaCl and 8 M urea to obtain a concentration of MP of 4 mg/mL.

Experimental Setting. MP suspensions (4 mg/mL) were oxidized for 4 days in screw-capped vials using a hydroxyl radical generating system [25 μM Fe(III) and 2.5 mM H_2O_2, final concentrations]. A previous kinetic study was undertaken to set the concentration of pro-oxidants and the length of the assay. The headspace of the vials was generously flushed with nitrogen and immediately transferred to an oven to induce oxidation at 37 °C and constant stirring. Dependent upon the addition of sodium nitrite (N; 0, 75, and 150 mg/L) and sodium ascorbate (A; 0, 250, and 500 mg/L), nine different reaction units were prepared in triplicate (n = 3) according to a total factorial design. Upon completion of the oxidation assay, samples were analyzed for the concentration of tryptophan, AAS, SBs, and 3NT.

Analysis of AAS. A total of 400 μL of protein suspension were dispensed in Eppendorf tubes and treated with a cold 10% trichloroacetic acid (TCA) solution. Each Eppendorf tube was vortexed and then subjected to centrifugation at 2000*g* for 30 min at 4 °C. The supernatant was removed, and the pellet was treated with a cold 5% TCA solution. A new centrifugation was performed at 5000*g* for 5 min at 4 °C. The supernatant was removed, and the pellets were incubated with the following freshly prepared solutions: 0.5 mL of 250 mM 2-(*N*-morpholino)ethanesulfonic acid (MES) buffer at pH 6.0 containing 1% sodium dodecyl sulfate (SDS) and 1 mM diethylenetriaminepentaacetic acid (DTPA), 0.5 mL of 50 mM ABA in 250 mM MES buffer at pH 6.0, and 0.25 mL of 100 mM $NaBH_3CN$ in 250 mM MES buffer at pH 6.0. The tubes were vortexed and then incubated in an oven at 37 °C for 90 min. The samples were stirred every 15 min. After derivatization, samples were treated with a cold 50% TCA solution and centrifuged at 5000*g* for 10 min. The pellet was then washed twice with 10% TCA and diethyl ether/ethanol (1:1). Finally, the pellet was treated with 6 N HCl and kept in an oven at 110 °C for 18 h until completion of hydrolysis. The hydrolysates were dried *in vacuo* in a centrifugal evaporator. The generated residue was reconstituted with 200 μL of Milli-Q water and then filtered through hydrophilic polypropylene GH Polypro (GHP) syringe filters (0.45 μm pore size, Pall Corporation, Port Washington, NY) for HPLC analysis.

A Shimadzu "Prominence" HPLC apparatus (Shimadzu Corporation, Kyoto, Japan), equipped with a quaternary solvent delivery system (LC-20AD), a DGU-20AS online degasser, a SIL-20A autosampler, a RF-10A XL fluorescence detector, and a CBM-20A system controller, was used. An aliquot (1 μL) from the reconstituted protein hydrolysates was injected and analyzed in the above-mentioned HPLC equipment. AAS−ABA was eluted in a Cosmosil 5C18-AR-II RP-HPLC column (5 μm, 150 × 4.6 mm) equipped with a guard column (10 × 4.6 mm) packed with the same material. The flow rate was kept at 1 mL/min, and the temperature of the column was maintained constant at 30 °C. The eluate was monitored with excitation and emission wavelengths set at 283 and 350 nm, respectively. Standards (0.1 μL) were run and analyzed under the same conditions. Identification of both derivatized semialdehydes in the fluorescence detection (FLD) chromatograms was carried out by comparing their retention times to those from the standard compounds. The peak corresponding to AAS−ABA was manually integrated from FLD chromatograms, and the resulting areas were plotted against an ABA standard curve with known concentrations that ranged from 0.1 to 0.5 mM. Results are expressed as nanomoles of carbonyl compound per milligram of protein.

Analysis of TRP. The decrease of TRP fluorescence in MP suspensions was measured on a Perkin-Elmer LS 55 luminescence spectrometer (PerkinElmer, Beaconsfield, U.K.). The emission spectra were recorded from 300 to 400 nm with the excitation wavelength established at 283 nm. Emission spectra of the buffer were recorded under the same conditions and used as background spectra. Excitation and emission slit widths were set at 10 nm, and the speed of data collection while scanning was of 500 nm/min. The TRP content was calculated from a standard curve of the analogous *N*-acetyl-L-tryptophanamide (NATA). The linearity (R^2 = 0.9955; $p < 0.05$) between the NATA concentration (ranging from 0.1 to 0.5 μM) and fluorescence intensity was statistically significant. Results were expressed as milligrams of NATA equivalents per gram of protein. The percent loss of TRP was calculated as $[(T_0 - T_4)/T_0] \times 100$, where T_0 is the concentration of TRP in samples at day 0 and T_4 is the remaining concentration at the end of the oxidation assay (4 days). The effect of nitrite and ascorbate against TRP oxidation was calculated as $[(T_C -$

$T_T)/T_C] \times 100$, where T_C is the concentration of TRP in the control sample and T_T is the percent of TRP loss for each treated sample.

Analysis of SBs. The formation of SBs was assessed in myofibrillar protein isolates (MPIs) using a LS-55 Perkin-Elmer fluorescence spectrometer (PerkinElmer, Beaconsfield, U.K.). Prior to the analysis, reaction mixtures were diluted (1:20) with 8 M urea in 100 mM sodium phosphate buffer at pH 7. SBs were excited at 350 nm, and the emitted fluorescence was recorded at 450 nm. The excitation and emission slit widths were set at 10 nm, and the speed of data collection while scanning was of 500 nm/min. The height of the peaks corresponding to SB spectra was recorded. After the applied dilutions were taken into consideration, the results were expressed as fluorescence units.

Analysis of 3NT. The extent of protein nitration was evaluated by calculating the nitrosation degree (ND), which is defined as the average number of 3NT residues divided by the total number of tyrosine residues in a protein molecule. 3NT was quantified by spectrophotometry according to the procedure recently described by Yang et al.[17] Briefly, 5 mL of MP suspension was treated with 10% cold TCA and then centrifuged at 670*g* for 5 min. Protein pellets were reconstituted with 1 mL of 8 M urea in 100 mM sodium phosphate buffer at pH 3.5. Tyrosine and 3NT were assessed at 280 and 357 nm, respectively.

Statistical Analysis. Data from the analysis ($n = 3$) were collected and subjected to statistical analyses. To assess the effect of the different concentrations of nitrite and ascorbate, an analysis of variance (ANOVA) was applied (SPSS, version 15.5). A Tukey test was applied when ANOVA found significant differences between treatments. The statistical significance was set at $p < 0.05$. Response surface analysis was also carried out using the Unscrambler program (version 10.1).

RESULTS AND DISCUSSION

Effect of Nitrite and Ascorbate against TRP Oxidation. Table 1 shows the residual amounts of TRP in the suspensions of MP treated with curing agents after the *in vitro* oxidation assay. The initial concentration of TRP in the protein suspensions (~13 mg/g of protein; no significant differences between experimental units) significantly decreased as a result of the pro-oxidant action of the hydroxyl-radical-generating system. The loss of TRP ranged from 51 to 80% depending upon the treatment applied to the MP suspensions. These results are consistent with previous studies aimed to assess the oxidation of TRP by systems emulating the Fenton chemistry.[18,19] A decrease of the TRP fluorescence denotes chemical changes on the TRP residue typically attributed to oxidative deterioration.[5] Simat and Steinhart,[20] Salminen and Heinonen,[21] and Utrera and Estévez[19] attributed the oxidative degradation of TRP to the action of hydroxyl radicals and the subsequent reaction between these radicals and the pyrrole ring or the phenyl moiety of the TRP residue. The depletion of TRP in processed muscle foods has also been ascribed to oxidative stress and regarded as a relevant nutritional loss.[22,23]

Table 1. Concentration of TRP (mg of NATA/g of Protein) in MPIs with Added Nitrite (N) and Ascorbate (A) (Mean ± Standard Deviation)[a]

	0 mg/L N	75 mg/L N	150 mg/L N	p^b
0 mg/L A	3.32 y ± 0.37	2.63 y ± 0.70	2.59 y ± 0.22	0.369
250 mg/L A	4.01 y ± 0.49	4.45 x ± 0.58	4.47 x ± 0.44	0.500
500 mg/L A	6.35 x ± 1.46	4.85 x ± 0.71	5.58 x ± 0.99	0.986

[a]Means with different letters (x and y) within a column were significantly different ($p < 0.05$) in a Tukey's test subsequent to ANOVA. [b]Significance value of ANOVA for the effect of added nitrite. [c]Significance value of ANOVA for the effect of added ascorbate.

The addition of nitrite had no influence on the residual amount of TRP in the experimental units. In opposition to our initial hypothesis, nitrite displayed neither antioxidant nor pro-oxidant actions on TRP residues. Among the antioxidant properties attributed to nitrite, authors have reported the ability of nitrite to sequester oxygen and to chelate metals and, hence, block their pro-oxidant actions.[1,2] Oxygen was removed from the headspace of the experimental units, and its role in the oxidation events described in the present study may have been negligible. On the other hand, the chelation of iron, given its role in the Fenton chemistry and the metal-catalyzed oxidation of proteins,[6] would have been a hypothetical mechanism for nitrite to inhibit TRP oxidation. In fact, the chelation of transition metals by phenolic compounds has been reported to be behind the antioxidant action of various phytochemicals on TRP residues.[19,21,24] Whereas the ability of nitrite to chelate iron in the conditions of the present experiment remains indefinite, it is obvious that this mechanism was not effective to inhibit TRP oxidation. The potential pro-oxidant effect of nitrite on TRP residues was not found, even though RNS, such as peroxynitrite, were actually found in the present samples (data not shown). TRP residues are known to be sensitive to both ROS[20] and RNS.[25] Because TRP depletion was independent of the nitrite concentration, it is reasonable to conclude that RNS contributed to neither the oxidation nor the nitration of TRP, because both nitrite-mediated modifications would have led to the loss of TRP fluorescence. Consistently, Ito et al.[26] reported that, even at the most favorable conditions of acidic pH and protein conformation, nitrite weakly reacts with TRP in myosin to form nitrosated species. Additional insight on the nitration of protein residues will be provided in the 3NT section.

Ascorbate had a significant effect on the residual amounts of TRP (Table 1). Regardless of the concentration of nitrite, MP suspensions treated with 500 mg/L of ascorbate had significantly higher concentrations of TRP than the control counterparts. The effect of the combination of both curing agents as displayed in the response surface (Figure 1A) is similar to that of the ascorbate alone. The potential pro-oxidant effect of ascorbate in the presence of transition metals via the Fenton reaction (reaction 2) was obviously not observed in the present study. On the contrary, these results reflect an antioxidant effect of ascorbate against the oxidation of TRP residues. Ascorbate has been highlighted as an efficient scavenger of hydroxyl radicals,[27] and this ability may explain the present results. The ascorbyl radical formed as a result of the electron donation finds stability in the form of the dehydroascorbic acid, which does not yield further reaction species.[27] In medical research, Frei et al.[28] already described as "outstanding" the antioxidant activity of ascorbate in human plasma. Unfortunately, the authors reported the antioxidant effect on plasma lipids, while the effect on other plasma components, such as proteins, was not assessed. While the food science literature on this topic is scarce, studies on medical research often varied and, at times, provided contradictory results on the effect of ascorbate on TRP. Some authors highlight the pro-oxidant action of ascorbate under physiological conditions,[29,30] while others described the ability of ascorbate to inhibit and even revert oxidation and nitrosation of TRP residues.[31] The present results show that ascorbate offers antioxidant protection to TRP in MP as a likely consequence of scavenging hydroxyl radicals.

Effect of Nitrite and Ascorbate on AAS Formation. As expected, the hydroxyl-radical-generating system induced efficiently the formation of AAS in MP (Table 2). The

[a]Means with different letters within a row (a and b) and column (x and y) were significantly different ($p < 0.05$) in a Tukey's test subsequent to ANOVA. [b]Significance value of ANOVA for the effect of added nitrite. [c]Significance value of ANOVA for the effect of added ascorbate.

abstraction of an electron from a susceptible protein-bound lysine residue by radical species leads to the formation of a carbon-centered radical, which is followed by the formation of a carbonyl compound upon the catalytic action of a transition metal, such as iron.[16] The concentration of AAS in this study is consistent with previous studies, in which MPs were oxidized *in vitro* using a combination of hydrogen peroxide, iron, copper, and myoglobin.[8,16,31] The addition of nitrite, alone, had no significant effect on the formation of AAS (Table 2). As aforementioned for TRP oxidation, the mechanisms ascribed to the antioxidant properties of nitrite (oxygen sequestering and metal chelation) may not be applicable to protein carbonylation. The formation of protein carbonyls takes place in the absence of oxygen,[7] which was, furthermore, removed from the headspace of the present reaction mixtures. Iron catalyzes the oxidative deamination of lysine residues to yield AAS,[7] and therefore, the chelation of this metal has been reported to be a likely mechanism to control protein carbonylation in muscle proteins.[31,32] Once again, either nitrite was unable to chelate iron or this mechanism was not efficient to inhibit protein carbonylation. Considering the present results, the antioxidant properties of nitrite, usually reported on lipids, may involve specific mechanisms that may not be applicable to proteins, such as the physicochemical stabilization of unsaturated fatty acids proposed by Igene et al.[33]

As for TRP oxidation, nitrite and its reactive derivatives were not able to promote protein carbonylation. Similar results were found by Bian et al.[34] in bovine serum albumin and biological samples oxidized by a combination of nitrite, hydrogen peroxide, and heme/non-heme iron. According to these authors, carbonylation of BSA had no relationship with the nitrite concentration. Apparently, RNS may not be able to initiate the carbonylation pathway from lysine residues in the conditions of the present experiment. The same conclusions came from Vossen et al.,[4] who found no effect of nitrite on the formation of protein carbonyls in cured liver pâté. The present experiment do not allow for the statement of whether the reason for the lack of pro-oxidant action of RNS is qualitative (the type of RNS did not react with lysine residues) or quantitative (the amount of RNS was insufficient to produce a significant effect).

[a]Means with different letters within a row (a–c) and column (x–z) were significantly different ($p < 0.05$) in a Tukey's test subsequent to ANOVA. [b]Significance value of ANOVA for the effect of added nitrite. [c]Significance value of ANOVA for the effect of added ascorbate.

In contrast to nitrite, ascorbate had a significantly and quantitatively remarkable effect on the formation of AAS (Table 2). The protection of ascorbate against protein carbonylation was already significant at 250 mg/L. Increasing its concentration to 500 mg/L did not lead to a significant improvement. As aforementioned, ascorbate is known to be an efficient scavenger of the hydroxyl radical, which was the likely initiator of protein carbonylation in the present experiment. In agreement with the TRP results, the present study confirms that ascorbate also protects proteins against protein carbonylation induced by a hydroxyl-radical-generating system. In line with the enthusiastic description made by Frei et al.[28] on the antioxidant capabilities of ascorbate in plasma, the protective effect of ascorbate against AAS formation in MP is considerably higher than that displayed by plant phenolics and other phytochemicals in previous studies.[24,31,32]

Measured as percent inhibition, the effect of ascorbate against carbonylation was more intense than that against TRP oxidation (~90 versus ~50%). Consistent with the present results, the rate constants for the reaction of the hydroxyl radical with TRP and ascorbate are comparable (~1×10^{10} L mol^{-1} s^{-1}) and notably higher than that between the hydroxyl radical and lysine (~3.4×10^8 L mol^{-1} s^{-1}).[35] Additionally, TRP residues are typically buried in the hydrophobic protein core, while hydrophilic lysine residues are usually exposed on the surface. The accessibility of the oxidation promoters and the curing agents to the protein residues may also have had an influence on the present results.

The response surface in Figure 1B shows the combined effect of nitrite and ascorbate on AAS formation. Interestingly, the lowest concentration of AAS was found in reaction mixtures with 500 mg/L ascorbate and 75 and 150 mg/L nitrite. The present results suggest that the presence of ascorbate enabled an antioxidant action of nitrite. This antioxidant effect may be attributed to the nitric oxide likely formed as a result of the reaction already described between nitrite and ascorbate (reaction 3). This finding is of great technological interest because nitrite and ascorbate are commonly combined at these concentrations in cured meat products to guarantee color stability and inhibit microbial growth.[2] The present results confirm that this arrangement is also successful to control protein carbonylation. Given that carbonylation is considered to be responsible for an impaired functionality of MPs and loss of nutritional value,[7,8] the combination of curing agents in the aforementioned proportions may be recommended to improve the quality of muscle foods.

Effect of Nitrite and Ascorbate on SB Formation. Table 3 shows the SBs found in protein suspensions treated with curing agents after 4 days of *in vitro* oxidation. The formation of SBs, already described in oxidized protein isolates, is attributed to the reaction between protein carbonyls and lysine residues.[7] AAS is the most reactive of the protein carbonyls,[7] and therefore, the formation of SBs is interpreted as an advanced oxidation product of lysine through the carbonylation pathway.[8,22,32] This advanced expression of the oxidative damage to proteins is independent of hydrogen peroxide and only requires the timely proximity between AAS and lysine residues.[7] Consistently, the SB results are comparable to those reported above for the AAS, reflecting the connection between both oxidation products. Nitrite had no influence on the concentration of SBs, while ascorbate significantly inhibited the formation of these structures in MPs. Once again, no significant differences were found between 250 and 500 mg/L ascorbate. As reflected in the corresponding response surface (Figure 1C), no interaction between both curing agents was found. The effect of ascorbate against the formation of SBs may be a reflection of the protective role of this compound on lysine residues. A reduced concentration of AAS in experimental units treated with ascorbate may reasonably lead to a lower formation of SBs in these samples compared to the control counterparts. SBs have been described to be responsible for an impaired functionality of MPs because SBs compromise the solubility and worsen the aggregation and the gelling capacity of MPs.[8] Therefore, the positive effect of ascorbate against the formation of SBs may be regarded as a beneficial outcome of its antioxidant properties in muscle foods, where the functionality of MPs plays a major role (i.e., meat emulsions).

Effect of Nitrite and Ascorbate on 3NT Formation. As shown in Table 4, 3NT was found in MPs incubated in the absence of nitrite, which is consistent with the basal levels usually reported for proteins in living systems derived from the physiological nitrosative stress.[13] The present study confirms that the ND increases in the presence of nitrite in a highly oxidative environment. The reaction between RNS, including peroxynitrite and nitrogen dioxide, and tyrosyl residues in proteins results in a number of tyrosine modifications, of which

the formation of 3NT is one of the most investigated.[34] The formation of 3NT is usually linked to the formation of peroxynitrite via reaction between nitric oxide and superoxide radical[36] (reaction 5).

$$NO^{\bullet} + O_2^{\bullet -} \rightarrow {}^{-}ONOO \quad (5)$$

Peroxynitrite reacts with CO_2 to produce metastable nitrating, nitrosating, and oxidizing species as intermediates, including the 3NT.[36] Considering the oxidizing conditions of the present experiment, the most plausible pathway for the formation of 3NT in MPs may involve the reaction between the hydroxyl radical and nitrite to yield the nitrogen dioxide radical (reaction 6), which is eventually able to bind to tyrosyl residues in proteins.[37]

$$OH^{\bullet} + NO_2^{-} \rightarrow NO_2^{\bullet} + OH^{-} \quad (6)$$

Among biotargets that can react directly with peroxynitrite and other RNS, heme-containing proteins, such as hemoglobin, seem to react particularly rapidly.[12,36] This also applies to heme-containing muscle proteins, such as myoglobin.[2] Because Woolford et al.[38] reported the formation of 3NT in non-heme muscle proteins, few studies have aimed to describe the occurrence and impact of protein nitration in muscle foods.[39,40] According to the present results, other major muscle proteins, such as MPs, may also be susceptible to nitrosative stress. Whether ROS and RNS may be formed simultaneously, the different behaviors of nitrite on the oxidative and nitrosative damage to meat proteins suggest that protein oxidation and protein nitration seem to be two independent and distinguishable processes. The same conclusion came from Bian et al.,[34] who studied the heme-iron-mediated nitration of tyrosyl residues in proteins.

The addition of ascorbate inhibited efficiently the nitrosation of MPs. A dose-dependent anti-nitrosation effect was observed at 75 and 150 mg/L nitrite. The ND in MP suspensions treated with 150 mg/L nitrite and 500 mg/L ascorbate was similar to the basal level (Figure 1D), which means that ascorbate completely inhibited the nitrosation damage to MPs. The anti-nitrosative effect of ascorbate could also be ascribed to the radical scavenging activity of ascorbate on the hydroxyl radical and, in this case, also RNS, such as the nitric dioxide radical. As far as the authors know, this study originally provides scientific evidence of the ability of ascorbate to inhibit the nitrosation of MPs.

The present paper provides novel insight into the interaction between curing agents and meat proteins. These chemistry fundamentals may be helpful to fully understand the role of nitrite and ascorbate on cured muscle foods and optimize formulation to design muscle foods with enhanced quality traits. However, the occurrence of these reactions in cured muscle foods and their consequences on food quality and human nutrition and health require further investigations.

data generated.[19−22] Additionally, in modern GC-TOF MS methods using the recently revived atmospheric pressure chemical ionization source (APCI), the investigation of target compounds is easier and more efficient. This is due to the soft ionization that takes place under APCI in comparison with the high fragmentation observed in the widely used electron ionization (EI) source. Thus, working with APCI, the molecular ion ($M^{+\bullet}$) or the protonated molecule ($[M + H]^+$) is commonly presented in the mass spectrum (in most cases as base peak), which improves both selectivity and sensitivity of the screening detection.[23] Also, the availability of a QTOF instrument allows MS/MS and/or MS^E experiments to go further in the identification of compounds detected due to the structure information given by the fragmentation pathways.

The aim of the present work is to complement a previously developed screening based on liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS).[22] By combination of GC-HRMS and LC-HRMS we pursue one of the main challenges in food safety and toxicology: advancing toward the ideal "universal" screening whereby all types of analytes, independently of their polarity and volatility, would be detected in the analysis. A QuEChERS-based sample treatment has been applied, with some modifications. A critical stage was to validate the GC-QTOF MS method for both pesticides and PAHs, establishing the screening detection limit (SDL) in complex aquaculture samples. The validated method has been applied for screening pesticides and PAHs in commercially and experimentally available real samples.

MATERIALS AND METHODS

Reagents and Chemicals. Individual pesticide reference standards were purchased from Dr. Ehrenstorfer (Scharlab, Barcelona, Spain) with purity between 93 and 99%. Stock standard solutions (around 500 mg/L) were prepared in acetone and were stored in a freezer at −20 °C. Nineteen mixtures of pesticide standards (individual concentration of each pesticide around 50 mg/L) were prepared by dilution of stock individual solutions in acetone. A working standard solution containing all pesticides at 1 mg/L was prepared by dilution of mixtures with acetone. In our target list, ethoxyquin is included as a preservative. It is mainly considered as a synthetic preservative, but it is also used as a pesticide (under the commercial name as "Stop-Scald") to prevent oxidation in vegetable and fruit samples.

Benzo[*j*]fluoranthene, 5-methylchrysene, benzo[*c*]fluorene, dibenzo[*a,e*]pyrene, dibenzo[*a,h*]pyrene, dibenzo[*a,i*]pyrene, dibenzo-[*a,l*]pyrene, and cyclopenta[*c,d*]pyrene individual standard solutions and mixture PAH MIX 9 containing naphthalene, acenaphthylene, acenaphthene, fluorene, phenanthrene, anthracene, fluoranthene, pyrene, benzo[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, benzo-[*k*]fluoranthene, benzo[*a*]pyrene, indeno[1,2,3-*cd*]pyrene, dibenzo-[*a,h*]anthracene, and benzo[*g,h,i*]perylene at10 mg/L were purchased from Dr. Ehrenstorfer. A working standard solution containing all compounds at 1 mg/L except for cyclopenta[*c,d*]pyrene, which was at 0.5 mg/L, was prepared by combining the standard mixtures and diluting in *n*-hexane.

Acetone (pesticide residue analysis quality), *n*-hexane (ultratrace quality), acetonitrile (reagent grade), toluene (for GC residue analysis), and glacial acetic acid were purchased from Scharlab. Anhydrous magnesium sulfate (extra pure) and anhydrous sodium acetate (reagent grade) were purchased from Scharlab. The QuEChERS commercial products composed by 2 mL microcentrifuge tubes for d-SPE containing 50 mg of primary−secondary amine (PSA), 150 mg of anhydrous $MgSO_4$, and 50 mg of C18 were purchased from Teknokroma (Barcelona, Spain). This was the kit selected in our recommended procedure. Moreover, another QuEChERS kit with the same composition together graphitized carbon black (GCB, 50 mg) was also purchased from Teknokroma. It was also studied in the optimization of the method (Scharlab).

Samples. Feed ingredients that are either used or tested and aquafeeds were directly purchased or provided from manufacturers. Protein feed ingredients were pea protein (2 samples), pea (1), wheat (3), wheat gluten (4), corn gluten (3), soy protein (4), sunflower meal (1), rapeseed cake (1), fish meal (2), krill meal (1), and fish protein (1). Oil ingredients such as rapeseed oil (5), palm oil (2), linseed oil (1), and fish oil (2) were also studied. With regard to feed, five different aquafeeds were analyzed that had different compositions of marine ingredients and plant ingredients. Three fish species (Atlantic salmon (*Salmo salar*), sea bass (*Dicentrarchus labrax*), and sea bream (*Sparus aurata*)) were directly purchased from supermarkets. Sea bream fillets (3) and one fish liver from other growing experiments were also collected from IATS facilities.

GC-QTOF MS Instrumentation. The GC system (Agilent 7890A, Palo Alto, CA, USA) was equipped with an autosampler (Agilent 7693) and coupled to a hybrid quadrupole-orthogonal acceleration-TOF mass spectrometer (XEVO G2 QTOF, Waters Micromass, Manchester, UK), using an APCI source (APGC by Waters Corp.). A fused silica DB-5MS capillary column (30 m long × 0.25 mm i.d. × 0.25 μm df) (J&W Scientific, Folsom, CA, USA) was used for GC separation. The injector was operated in splitless mode, injecting 1 μL at 280 °C. The oven temperature was programmed as follows: 90 °C (1 min), raised at 5 °C/min to 315 °C (5 min). Helium was used as carrier gas at 2 mL/min. The interface temperature was set to 280 °C using N_2 (from liquid N_2) as auxiliary gas at 150 L/h and as cone gas at 16 L/h and N_2 (from gas cylinder quality 99.9990%) as makeup gas at 320 mL/min. The APCI corona pin was operated at 1.8 μA, and the cone voltage was set to 20 V. The ionization process occurred within a closed ion volume, which enabled control over the protonation/charge transfer processes. The water, used as modifier when working under proton-transfer conditions, was placed in an uncapped vial, which was located within a specially designed holder placed in the source door. In these conditions, the most critical separation was between benzo[*b*]-fluoranthene, benzo[*j*]fluoranthene, and benzo[*k*]fluoranthene, by one side, and between dibenzo[*a,i*]pyrene and dibenzo[*a,h*]pyrene, by the other side, the results of which should be treated as primary data.

For MS^E experiments, two acquisition functions with different collision energies were generated. The low-energy (LE) function, selecting a collision energy of 4 eV, and the high-energy (HE) function, with a collision energy ramp ranging from 10 to 40 eV to obtain a greater range of fragment ions.[23] It should be noted that all of the exact masses shown in this work have a deviation of 0.55 mDa from the "true" value, as the calculation performed by the MassLynx software uses the mass of hydrogen instead of a proton when calculating $[M + H]^+$ exact mass. However, as this deviation is also applied during mass axis calibration, there is no negative impact on the mass errors presented in this paper. MS data were acquired in centroid mode and were processed by the ChromaLynx XS application manager (within MassLynx v4.1; Waters Corp.).

Recommended Analytical Procedure. Before analysis, ingredients and feed samples were thawed at room temperature and ground using a Super JS mill from Moulinex (Bagnolet Cedex, France). Fish tissues were also thawed at room temperature and processed in a crushing machine (Thermomix, Vorwerk España M.S.L., S.C., Madrid, Spain). As a result, homogenized samples were obtained in both cases. Five grams of sample was accurately weighed (precision = 0.1 mg) into centrifuge tubes (50 mL) and mixed in a vortex with 10 mL of acetonitrile (Figure 1). Then, 4 g of $MgSO_4$ was added, and the tube was again shaken in a vortex during 30 s. The extract was centrifuged at 4500 rpm for 5 min (Consul centrifuge, Orto-Alresa, Madrid, Spain), and the upper layer of the extract was transferred to a new centrifuge tube (15 mL) and stored overnight in a freezer to precipitate proteins and fix lipids to the tube walls (freezing cleanup). Afterward, 1 mL of the extract was carefully transferred to the cleanup QuEChERS vial (50 mg of PSA + 150 mg of $MgSO_4$ + 50 mg of C18), and it was shaken for 30 s and centrifuged at 12000 rpm for 5 min. After this cleanup, 0.5 mL was transferred to a new Eppendorf vial with the addition of 0.1 mL of hexane. The extract was concentrated to

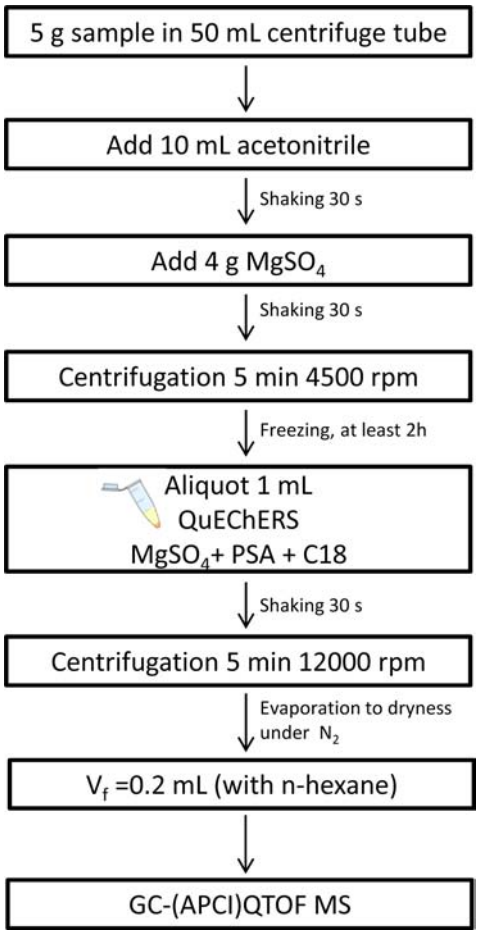

Figure 1. Sample treatment applied in the GC-(APCI) QTOF MS screening method.

dryness at 30 °C (to remove acetonitrile) under a gentle stream of nitrogen, reconstituted with 0.2 mL of *n*-hexane, and finally transferred to a vial for GC injection. The samples were run twice, using water as modifier to favor in-source protonation and without the addition of water for those compounds for which no protonation was observed.

Method Validation. Validation of the screening method was performed for qualitative purposes on the basis of European analytical guidelines.[24,25] Twenty different samples (details under Samples) were spiked with over 133 pesticides and 24 PAHs at two levels, 0.01 and 0.05 mg/kg (0.005 and 0.025 mg/kg for cyclopenta[*c*,*d*]pyrene), and analyzed together with their nonspiked samples ("blanks"). Additionally, two method blanks were analyzed to ensure that no laboratory contamination was introduced during the procedure. The SDL was set up as the main validation parameter to estimate the threshold concentration at which detection becomes reliable. SDL was established as the lowest concentration tested at which a compound was detected in at least 95% of 20 spiked samples under study (i.e., detected in at least 19 samples at each concentration level) independent of its recovery and precision. The detection was made by using the most abundant ion measured at its accurate mass (typically the protonated molecule). This means that, at least, one peak (SDL) had to be observed in the respective narrow-window extracted ion chromatogram (nw-XIC) at the same retention time (tolerance of ±0.5% with respect to standard) and measured at accurate mass (mass error < 5 ppm). Tables 1 and 2 show the results obtained at each spiked level.

RESULTS AND DISCUSSION

Feed ingredients, feed compositions, and fish tissues are complex matrices that contain a large number of interferences that may hamper detection and identification of undesirable compounds. To investigate the presence of any GC-amenable organic contaminant in this kind of sample, cleanup steps are normally applied to improve sensitivity and selectivity.[4,7,12−15,18] However, when the screening is focused on different chemical families of compounds, the situation is more problematic because analytes have rather different chemical and physical properties, and the analytical strategy should be suitable for all of them.[22,26] In this work, the screening was focused on many different pesticides and PAHs in a single analysis. As the objective was the detection and subsequent identification of the compounds detected in samples, no recoveries and precisions were calculated in this work.

Sample Treatment Optimization. One of the goals of a wide screening method is to minimize the possible analyte losses along sample treatment, so any restrictive step should be carefully studied. Acetonitrile solvent was selected because it is not highly amenable with lipid content and offers good recoveries for many GC-amenable compounds. In addition, to reduce the amount of extracted interferences, different conditions were tested, such as (1) the addition of water, (2) the addition of toluene and/or hexane together with acetonitrile for the extraction, and (3) the addition of sodium acetate.

1. The addition of water did not offer better results than the use of only acetonitrile. Thus, many compounds could not be detected at the lowest spiked level. Although some authors reported that water incorporation to fatty samples improves the determination of many pesticides,[27] in the samples under study the addition of water did not represent a relevant improvement for pesticides.

2. The use of organic solvents such as hexane or toluene reduced the coextractives in the acetonitrile layer but also the presence of several nonpolar compounds, such as DDTs, heptachlors, and HCH isomers, in the sample extract, as they have more affinity to the hexane or toluene layer.[27,28]

3. The addition of sodium acetate seemed not much favorable because it generated a turbid extract. Although this situation does not represent a great disadvantage as reported by other authors,[29] in our case, better results were obtained without using sodium acetate.

One of the easiest ways to reduce the amount of matrix interferences is to store the organic extract in a freezer. Thus, the solution obtained is rather clean as most proteins and lipids are fixed on the bottom and walls of the tube, respectively. As previously reported, the application of low temperature before d-SPE cleanup substantially reduces the amount of coextractives.[13,14] Moreover, improved chromatographic peak shapes, reduced signal suppression, and minimized retention time shifts were observed for some compounds, as supported by the bibliography.[13,14] After the freezing, an aliquot can be easily taken and centrifuged to improve the solid−liquid separation.

The d-SPE cleanup step was also studied by using two commercially available QuEChERS kits (d-SPE with 150 mg of Mg_2SO_4, 50 mg of PSA, and 50 mg of C18; and d-SPE with 150 mg of Mg_2SO_4, 50 mg of PSA, 50 mg of C18, and 50 mg of GCB). The kit containing GCB was tested to try to improve the removal of matrix that hampers the detection.[12,27] After using these cleanup cartridges, several pesticides, such as HCB and DDTs, were not detected at the spiked levels. GCB seems to properly remove additional matrix components from vegetable extracts, but it also tends to retain certain pesticides,

[a]PAHs were measured as $[M + H]^+$ after the addition of water in the APCI source. [b]SDL, screening detection limit. [c](−) The evaluation of the SDL was not feasible due to the presence of the analyte in the samples used for validation. [d]Cyclopenta[*c*,*d*]pyrene was spiked at 0.005 and 0.025 mg/kg, respectively.

such as terbufos, thiabendazole, HCB, and other planar-ring analytes.[12] Finally, the QuEChERS kit without GCB was selected for sample cleanup.

APCI. Ionization in GC-(APCI) MS occurs by charge transfer and/or proton transfer, resulting in the formation of the molecular ion, protonated molecule, or both. By deliberately introducing water in the source, this protonation can be promoted (details on this issue can be found in recent publications).[23,30] Thus, many compounds, including most pesticides and PAHs, gave higher response when water was used as modifier and the protonated molecule was measured. On the contrary, halogenated hydrocarbons without any other heteroatoms, such as some organochlorine pesticides, showed better response under charge-transfer conditions, the molecular ion being the diagnostic ion. In the latter case, better response was obtained without the addition of water in the source. However, in some cases, this behavior was observed to show some irreproducibility over time. This might be due to the fact that humidity present in the atmosphere is an uncontrolled parameter that may affect differently those compounds ionized under charge-transfer conditions. Also, for those compounds that show a tendency to protonation, ambient humidity might be even better than the saturation conditions reached after the deliberate introduction of water in the source. Under these circumstances, the fact of adding or not adding water would affect mainly the sensitivity, particularly for a few selected compounds. Consequently, samples were run twice (with and without intentional use of water as modifier), which allowed the optimum conditions to be reached for each compound.

QTOF MS Data Processing. The acquired data files from the GC-QTOF MS were processed by using ChromaLynx software. A *txt* file with the list of the molecular formulas for representative ions was collected together with the retention time per compound. This information was available when the reference standard was injected and was used to search the recorded masses for each file. The software searches for $[M + H]^+$, $M^{+\bullet}$, and/or fragment ions at a prefixed retention time (target approach).

When the reference standard was not available, the only information was that either the molecular ion or the protonated molecule would be expected upon GC-(APCI) QTOF MS analysis. In this case, both ions were included in the processing screening method, as the behavior in the APCI source could not be previously evaluated for these compounds. Any detection being made in this way would indicate the potential presence of the compound, and more information would be required for further identification (e.g., MS/MS experiments). Obviously, as no reference standard was injected, no experimental data on the behavior of the compound during sample preparation and GC-MS sensitivity were available. The acquisition of reference standard and injection in the GC-QTOF MS system would be needed for unequivocal confirmation of the tentative identification.

Qualitative Validation of the Screening Method. First, different samples of each matrix were injected to find the lowest contaminated matrix for spiking. In this previous analysis, we found some matrices positive for several target compounds. It is noteworthy that ethoxyquin and light PAHs were present in the wide majority of samples analyzed. The lowest contaminated samples for each type of matrix were then spiked with a mixture of pesticides and PAHs at concentrations of 0.01 and 0.05 mg/kg for each analyte (0.005 and 0.025 mg/kg for cyclopenta-[*c*,*d*]pyrene). One hundred and thirty-three pesticides and 24

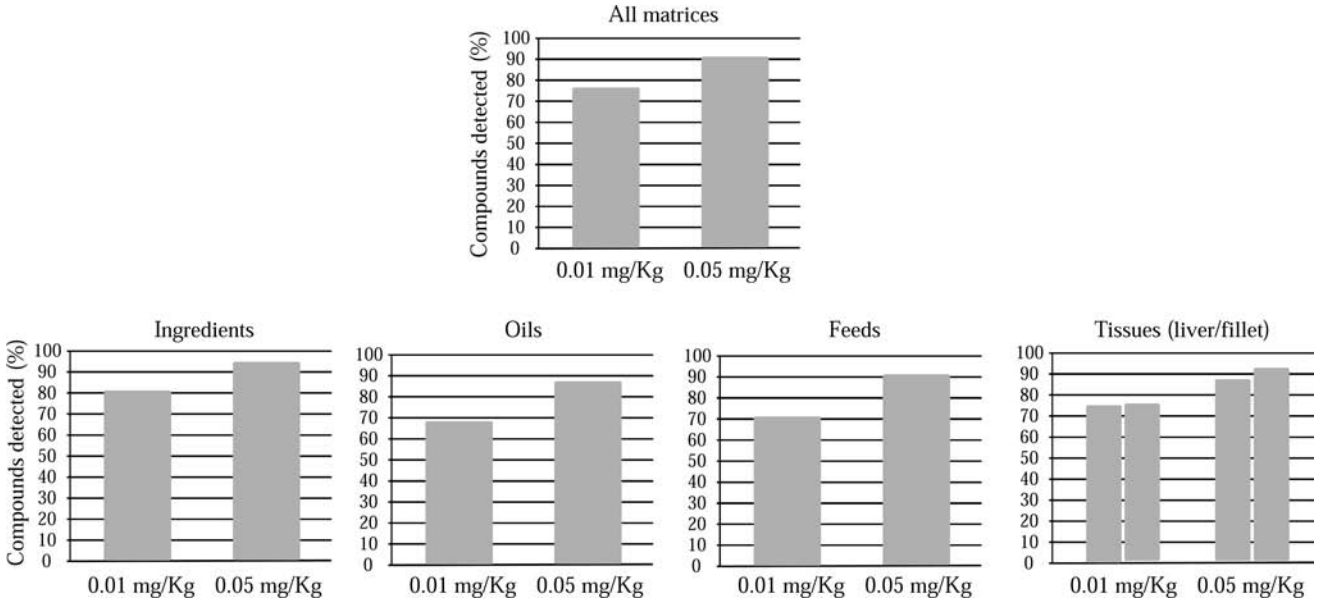

Figure 2. Validation results: number of pesticides detected at 0.01 and 0.05 mg/kg in different types of samples.

PAHs were selected to qualitatively validate the screening by GC-QTOF MS. Twenty different samples of interest for marine seafood were used for validation experiments. Tables 1 and 2 show the number of positive/negative findings for pesticides and PAHs, respectively, at each spiked level in the samples studied. At 0.01 mg/kg, 76% of pesticides and 83% of PAHs were detected. At the highest level validated (0.05 mg/kg), these values improved to 91% of detected pesticides and to 100% of PAHs. Figure 2 shows the percentage of detections for the different matrices studied. As can be seen, oils were the most problematic matrices followed by feeds and tissues, whereas feed ingredients represented lower difficulty for detections. With regard to fish tissues, liver was trickier than fish fillets.

Figure 3 shows different examples of the qualitative validation at the 0.01 mg/kg level. Four groups are illustrated, attending at the samples studied: (A) ingredients, (B) oils, (C) feeds, and (D) fish tissues. The bottom of each figure shows the nw-XIC for the nonspiked sample, and the top shows the nw-XIC for the spiked sample at 0.01 mg/kg with the most abundant ion used for detection, measured at accurate mass (mass error in ppm is also given). In the case of ingredients (Figure 3A), HCH isomers were properly detected at 0.01 mg/kg in fish meal. These compounds were satisfactorily validated in all samples at 0.01 mg/kg except for oils, so a SDL at 0.05 mg/kg was finally proposed (Table 1). Dibenzo[*a*,*l*]pyrene, dibenzo[*a*,*e*]pyrene, dibenzo[*a*,*i*]pyrene, and dibenzo[*a*,*h*]-pyrene were validated at 0.05 mg/kg because they could not be detected in at least 95% of samples at the lowest level, despite that in corn gluten these isomers were detected at 0.01 mg/kg. The figure for oils (Figure 3B) illustrates the validation for benzo[*a*]pyrene, a toxicity reference, at 0.01 mg/kg. The validation of chlorpyrifos methyl was of relevance because it is widely used as an insecticide. In both cases, the detection at 0.01 mg/kg was feasible in oils within low mass errors below 5 ppm. In the case of feeds (Figure 3C), the widely known DDTs, included in the target list due to their common presence in marine resources as part of the larger group of fat-soluble POPs that readily accumulate along the marine food chain, were satisfactorily validated at 0.01 mg/kg for ingredients, feeds, and tissues but not for oils, so a SDL at 0.05 mg/kg was finally proposed. The herbicide carfentrazone ethyl is used in many crops such as wheat, corn, or soy. Therefore, it was included in the target list and also because subproducts from these crops are commonly incorporated in feed compositions (wheat gluten, corn gluten, soy protein). A SDL at 0.01 mg/kg was achieved in all samples studied for this compound. Finally, in fish tissues (Figure 3D), the nw-XICs illustrate the presence of phenanthrene and anthracene in the nonspiked samples, a fact that was also observed in other types of samples, supporting the ubiquity of light PAHs in many environmental and food samples. The same occurred for ethoxyquin, a synthetic preservative widely used in fatty compositions to prevent lipid oxidation. The presence of at least two representative ions for each compound at the expected retention time with accepted mass errors (<5 ppm) allowed the reliable identification in positive samples.

Screening of Real Samples. The validated screening was applied to different types of samples, searching for the target list of validated compounds. After the detection of any compound in the samples, the reliable identification was required to avoid reporting false positives. Although the presence of a m/z ion (commonly $[M + H]^+$), measured at accurate mass with low mass error, and the agreement in retention time, gives confidence to the analysis, we followed strict criteria for confirmation, which was based on the presence of, at least, another representative m/z ion (commonly fragment ion) with low mass error.[23] This is feasible working in the QTOF MS instrument that allows the use of MS^E mode (details in GC-QTOF MS instrumentation).

Figure 4 shows different positive findings in oils, proteins, and feeds commonly used in animal farming. As shown, at least two representative m/z ions were necessary to unequivocally identify the presence of the compound in the sample, at the expected retention time (deviation $\leq \pm 0.5\%$, in comparison to standards) and measured at accurate mass within acceptable mass deviation ($\leq$5 ppm). The main pesticides found were chlorpyrifos methyl and pirimiphos methyl, which were detected in several vegetable samples. Ethoxyquin, the use of which is currently authorized in feed ingredients, was also

dx.doi.org/10.1021/jf405366n | J. Agric. Food Chem. 2014, 62, 2165−2174

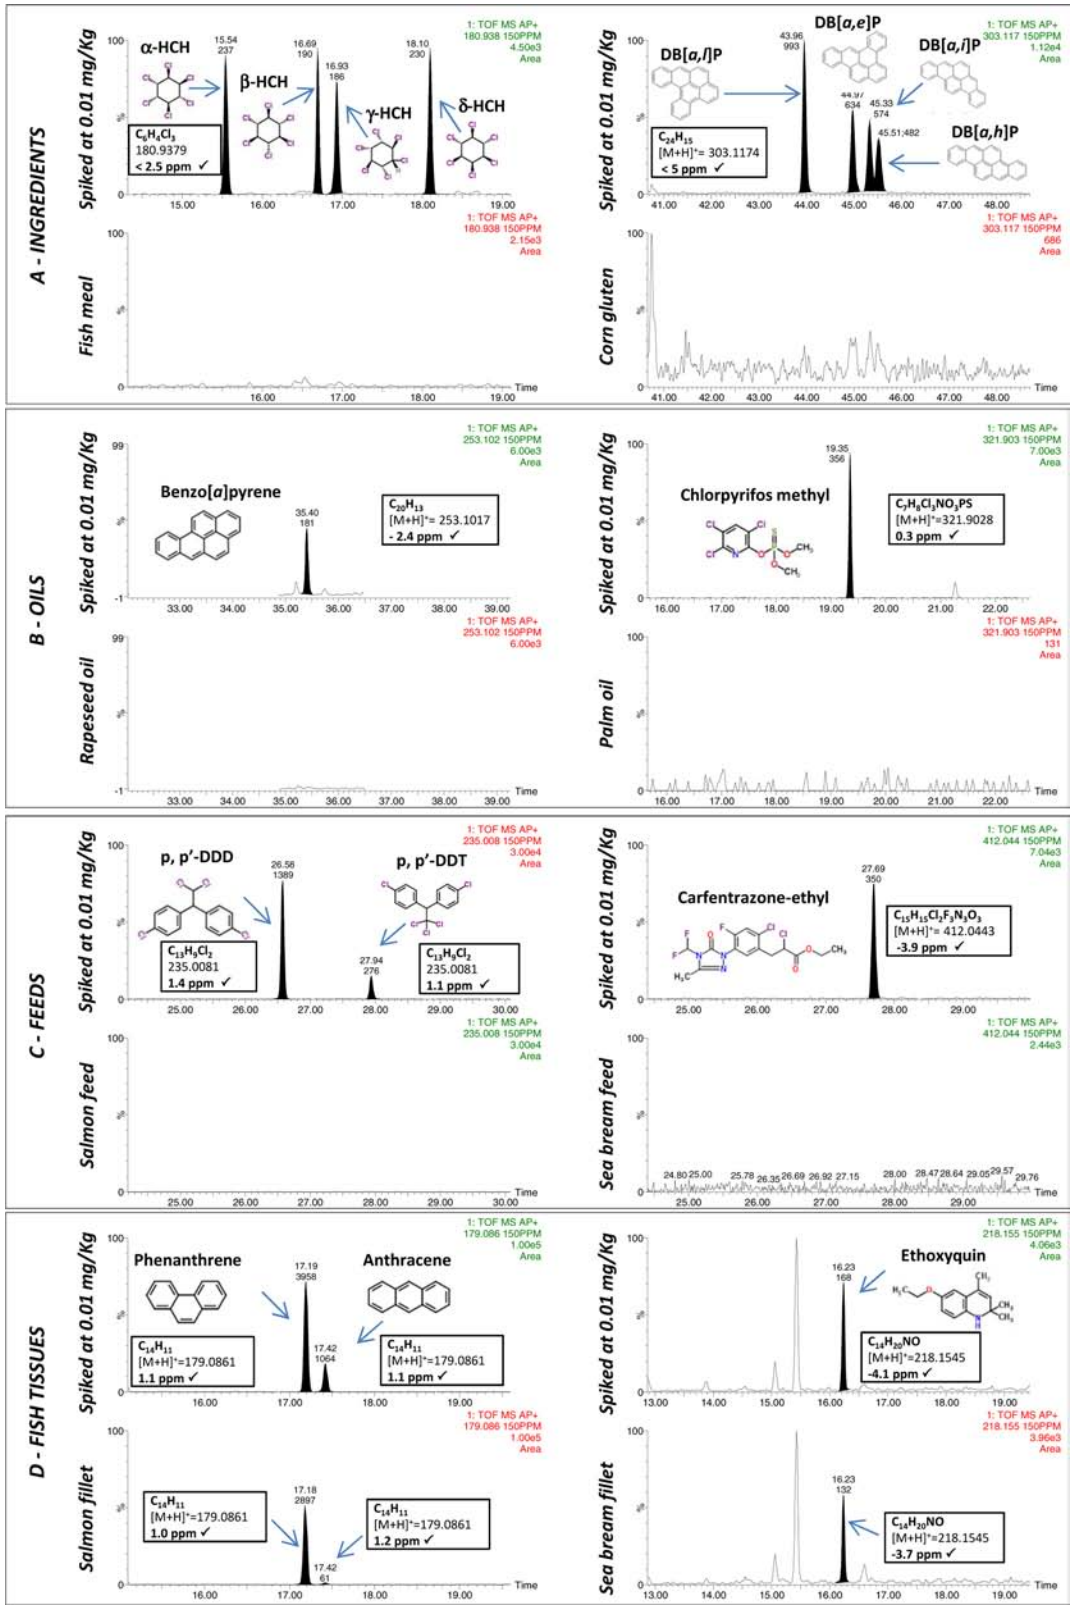

Figure 3. Validation: nw-XICs for the diagnostic m/z ion in samples spiked at 0.01 mg/kg (top) and nonspiked samples (bottom). Diagnostic ion corresponds to $[M + H]^+$ except for HCH isomers and DDTs, for which it corresponds to a fragment ion: (A) α-, β-, γ-, and δ-HCH isomers and dibenzo[*a*,*l*]pyrene, dibenzo[*a*,*e*]pyrene, dibenzo[*a*,*i*]pyrene, and dibenzo[*a*,*h*]pyrene in feed ingredients; (B) benzo[*a*]pyrene and chlorpyrifos methyl in oils; (C) *p*,*p*′-DDD, *p*,*p*′-DDT, and carfentrazone-ethyl in feeds; (D) phenanthrene, anthracene, and ethoxyquin in fish tissues. (Check mark) Accurate mass deviations within tolerance limits.

found in feeds but, additionally, it was identified in the edible part of several commercial fish samples. It seems that this synthetic preservative (and possibly its transformation products) can reach consumers. Earlier studies also reported the

dx.doi.org/10.1021/jf405366n | J. Agric. Food Chem. 2014, 62, 2165−2174

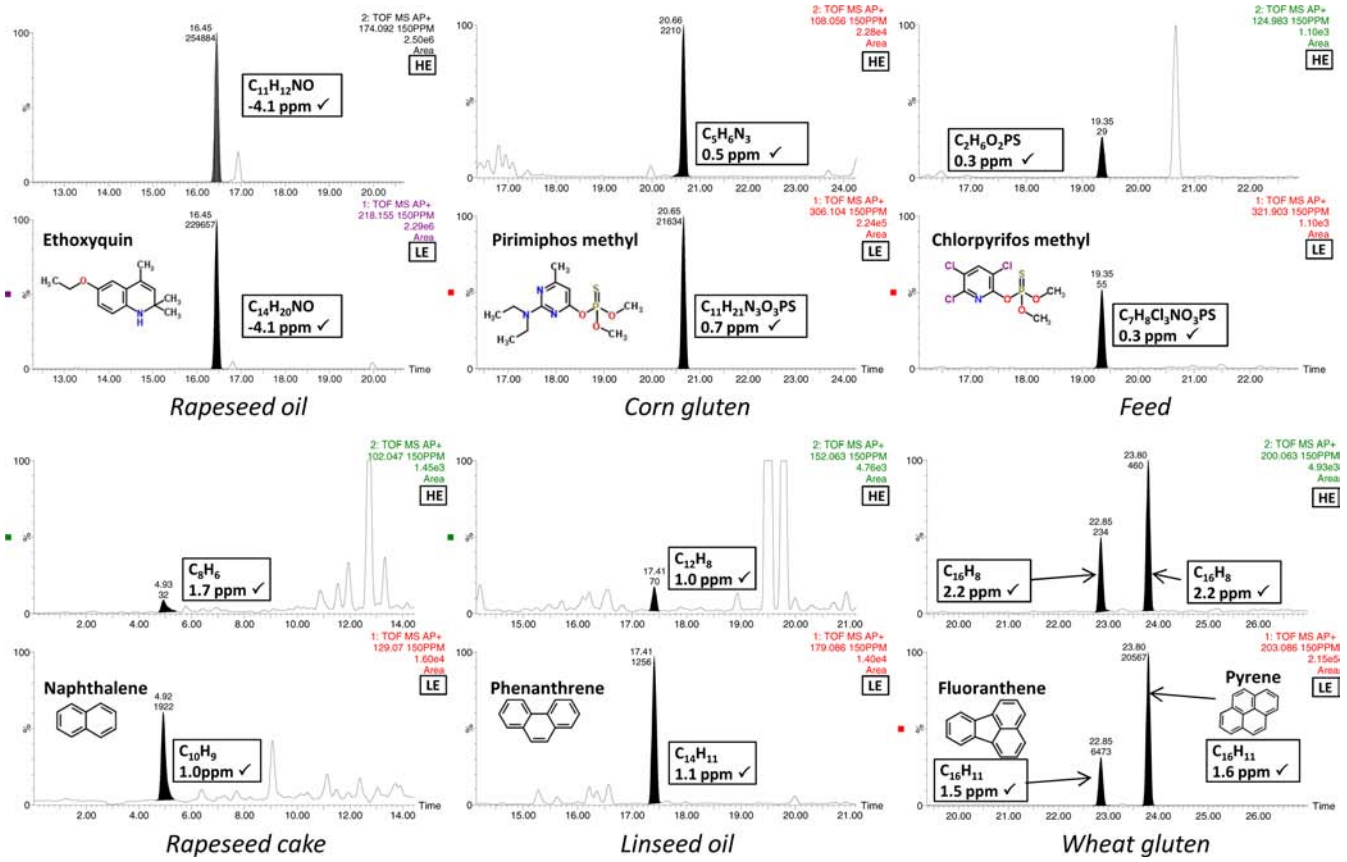

Figure 4. Real-world samples: nw-XICs for identified compounds in oils, proteins, and feeds. For each matrix, the LE function (bottom) and HE (top) are shown to illustrate the presence of the protonated molecule (LE) and fragment ions (HE). (Check mark) Accurate mass deviations within tolerance limits.

overall presence of synthetic antioxidants, such as ethoxyquin, in several commercially important species of farmed fish, namely Atlantic salmon, halibut, cod, and rainbow trout, and their aquafeeds,[31] as well as the carry-over from feed to fillet.[32] Therefore, quantitative methods directed toward this compound and its derivatives will surely be necessary in the near future.

With regard to PAHs, "light" PAHs (e.g., phenanthrene, pyrene) were in nearly all samples analyzed. Although they are not carcinogenic PAHs according to EFSA, they are contaminants that can give (noncarcinogenic) toxic reactions in fish.[33] PAHs present poor MS fragmentation, a fact that makes their identification troublesome. In this work, after evaluation of the presence of the protonated molecule in the LE function, collision-induced dissociation (CID) fragments, or characteristic isotopic ions, were also evaluated for positive samples to achieve a proper identification. As illustrative examples, at the bottom of Figure 4, positive findings for light PAHs are presented for samples of rapeseed, linseed, and wheat.

After the first screening for which reference standards were available, we focused our screening to find any other pesticides for which reference standards were not available in our laboratory. Although tentative detection for some of these pesticides occurred, based on the presence of $[M + H]^+$ and/or $M^{+\bullet}$ in the LE function, further investigation of fragment ions, from the LE and/or HE function, did not allow us to confirm their identity, so they could not be reported as positive identifications.

With this work, we pursued the achievement of an essential tool in food safety and toxicology: the use of wide-scope screening for the detection and identification of a large number of compounds. The combination of GC-HRMS and LC-HRMS is nowadays the closest approach to the ideal "universal" screening. The GC-QTOF MS screening developed has been qualitatively validated for a notable number of pesticides and PAHs in complex samples from aquaculture activities, allowing the detection of these compounds in a rapid and efficient way at the low SDL established. This method in combination with the LC-QTOF MS screening previously developed allows searching for many undesirables of different polarities and volatilities in distinct sample matrices.[22,34,35]

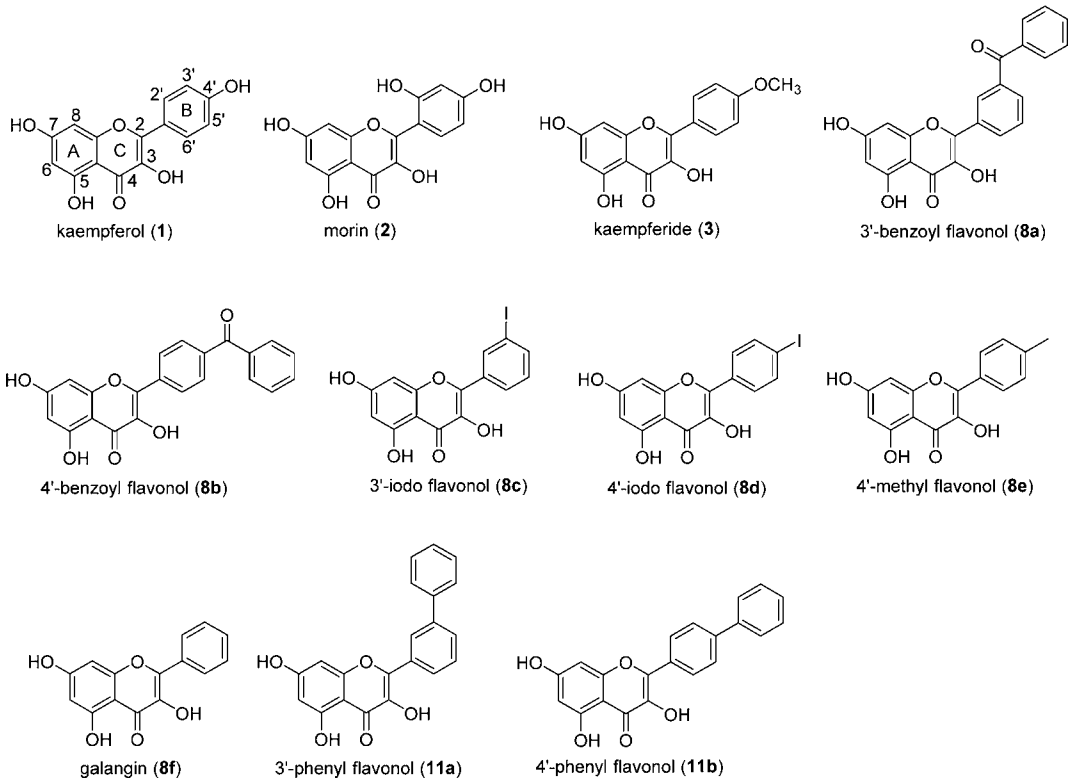

Figure 1. Structures of natural and synthetic flavonols.

General Procedure for the Synthesis of the Flavonol Analogues. Synthesis of the Flavonol Methyl Ethers. Methoxyphloroacetophenone (50 mg, 2.53 mmol) was placed into a round-bottom flask and dissolved in 1,2-dichloroethane (5 mL), and 4 mL was distilled to remove water. The carboxylic acid (3.54 mmol) and the acid chloride (8.33 mmol) were then added, followed by triethylamine (5 mL) and dimethylformamide (DMF) (15 mL). The solution was stirred at room temperature under argon for 3 h before being heated to reflux for an additional 12 h. The triethylamine and DMF were then removed under vacuum. The residue was dissolved in 3.8 mL of ethanol and heated to reflux. A solution of KOH (1.0 g) in H_2O (1.4 mL) was then added, and the mixture was refluxed for an additional 60 min. The solvents were removed under vacuum. The solid was dissolved in water (30 mL) and the crude product was precipitated out of solution by the addition of 10% HCl until the solution reached pH 5. The crude precipitate was extracted into chloroform (5 mL) and rinsed with saturated aqueous sodium bicarbonate (10 mL × 2). Because the desired product was only partially soluble in chloroform, these last two steps must be repeated several times (6−10 times until the chloroform extractions are no longer yellow). The chloroform was removed under vacuum. The crude product was then dissolved in a minimal amount of acetone (~0.5 mL/10 mg of flavonol). The solution becomes cloudy upon the addition of hexanes (10 mL) and was filtered through a pipet packed with glass wool. The filtrate contains the desired yellow product. The filtrate was evaporated under vacuum and set aside. Because some of the product remained in the precipitate, the precipitate on the glass wool in the pipet was dissolved in acetone, the acetone was evaporated, and trituration with acetone (~0.5 mL)/hexanes (10 mL) was repeated (2−4 times until the filtrate is no longer yellow). The NMR spectrum confirmed that all of the product was removed from the crude precipitate.

Deprotection. The methyl ether flavonol (20 mg, 0.06 mmol) was placed into a round-bottom flask and dissolved in acetic acid (16 mL). HBr (48% aqueous solution, 2 mL) was added via a syringe. The solution was heated to reflux for 24 h. Water (150 mL) was then added, resulting in a cloudy solution. The precipitate was isolated by filtration. This crude product was dissolved in chloroform (10 mL) and rinsed with saturated aqueous sodium bicarbonate (3 × 10 mL). The chloroform was evaporated under vacuum. The crude product was dissolved in a minimal amount of acetone (0.5 mL), and an excess of hexanes (10 mL) was added. The filtrate was collected, and the process was repeated several times. The filtrate was dried under vacuum to give a yellow precipitate.

*2-(3-Benzoylphenyl)-3,5,7-trihydroxy-4H-chromen-4-one (**8a**):* data was consistent with previous papers.[24]

*2-(4-Benzoylphenyl)-5,7-dihydroxy-3-methoxy-4H-chromen-4-one (**7b**).* 62% yield (121 mg, 0.312 mmol); ^{1}H NMR (300 MHz, acetone) δ 12.10 (s, 1H), 8.28 (ddd, 2H, J = 1.8, 3.6, 8.4 Hz), 7.96 (ddd, 2H, J = 1.8, 3.6, 8.7 Hz), 7.85 (m, 2H), 7.71 (dddd, 1H, J = 1.7, 3.4, 7.4, 14.7 Hz), 7.60 (dddd, 2H, J = 1.6, 3.2, 7.4, 14.7 Hz), 6.56 (d, 1H, J = 1.8 Hz), 6.31 (d, 1H, J = 1.8 Hz), 3.96 (s, 3H); ^{13}C NMR (75 MHz, acetone) δ 195.09 (C), 178.84 (C), 164.77 (C), 162. 46 (C), 157.29 (C), 154.27 (C), 140.27 (C), 139.30 (C), 137.38 (C), 134.31 (C), 132.95 (CH), 129.98 (CH), 129.95 (CH), 128.72 (CH), 128.52 (CH), 105.47 (C), 99.03 (CH), 94.04 (CH), 60.14 (CH_3).

General Procedure for the Synthesis of Aryl Flavonol Ethers through Suzuki−Miyaura Cross-Coupling Reactions. The procedure developed by Molander and Biolatto[30] was used with minor modifications. The organotrifluoroborate (0.073 mmol), the iodo flavonol methyl ether (20 mg, 0.049 mmol), potassium carbonate (20 mg, 0.146 mmol), and $Pd(OAc)_2$ (1 mg, 0.004 mmol) were placed in a round-bottom flask. These compounds were dissolved in 4 mL of methanol and heated to 65 °C overnight (16 h) with stirring. The solution was cooled to room temperature, and 10% HCl was added until the solution reached pH 5. The resulting precipitate was isolated by filtration. The precipitate was extracted with acetone until the extracts were no longer yellow and then the acetone was removed under vacuum. The crude product was dissolved in a minimal amount of acetone (0.5 mL), and excess hexanes (10 mL) were added. The precipitate was isolated by filtration, and this process was repeated several times. The filtrate was dried under vacuum to give a yellow precipitate. Deprotection of the flavonol ethers was achieved as described earlier.

*2-([1,1′-Biphenyl]-3-yl)-5,7-dihydroxy-3-methoxy-4H-chromen-4-one (**10a**):* 68% yield (30 mg, 0.083 mmol); ^{1}H NMR (500 MHz, MeOH) δ 8.28 (dd, 1H, J = 1.5, 3.0 Hz), 8.02 (ddd, 1H, J = 1.0, 1.5, 7.5 Hz), 7.79 (ddd, 1H, J = 1.0, 2.3, 7.5 Hz), 7.67 (m, 2H), 7.63 (t, 1H, J = 8.0, 16.0 Hz), 7.49 (m, 2H), 7.39 (ddd, 1H, J = 1.5, 3.5, 7.5 Hz), 6.43 (d, 1H, J = 2.5 Hz), 6.21 (d, 1H, J = 2.0 Hz), 3.83 (s, 3H); ^{13}C NMR (125 MHz, MeOH) δ 180.10 (C), 163.20 (C), 158.78 (C), 157.35 (C), 143.07 (C), 141.67 (C), 140.73 (C), 137.50 (C), 132.39 (C), 130.69 (CH), 130.34 (CH), 130.10 (CH), 128.91 (CH), 128.28 (CH), 128.13 (CH), 127.99 (CH), 105.97 (C), 100.26 (CH), 95.12 (CH), 60.97 (CH_3).

Biological Reagents and Plant Material. Kaempferide, kaempferol, and morin were purchased from Indofine (Hillsborough, NJ, USA). Pollen germination assays were conducted using flavonol-deficient transgenic petunia plants. The procedure for growing and collecting the flavonol-deficient petunia pollen has been previously described.[12,31] Conditionally male fertile (CMF) transgenic V26 petunias were grown on a 16/8 h photoperiod, newly dehiscent anthers of flowers lacking pigmentation were collected, and the pollen from these anthers was suspended in germination media (GM).

Pollen-Rescue Assay. These assays were performed using the method developed by Mo et al.[12] in which PEG 4000 GM was used in the suspension of petunia pollen grains at a density of (1−2) × 10^4 grains/mL. Stock solutions were prepared by dissolving the flavonols (0.001−4000 nM) in dimethyl sulfoxide (DMSO) and then adding them to the GM for a final concentration of 0.2% DMSO per well. Unreported results from our laboratory show that 0.5% v/v DMSO and below are not toxic to pollen and did not activate the pollination sequence. The assays were performed in triplicate by adding flavonols, at various concentrations, to the pollen in GM in 96-well plates. Control samples were incubated without flavonols, but in the presence of DMSO. The plates were incubated at 25 °C and gently rotated (150 rpm) for 4 h at room temperature before germination was assessed. A pollen grain was scored as germinated when the length of the pollen grain tubes was greater than one diameter. The EC_{50} values were calculated by finding the maximum and minimum for each flavonol and determining the midpoint between these two concentrations. A minimum of seven concentrations were selected for each experiment.

Competition Assay. The stock solutions were prepared identically to those in the pollen-rescue assay. The competition assays were run under two sets of conditions. The first assay studied the effects of keeping the concentration of kaempferol constant (500 nM) and varying the concentrations of flavonol analogues (0−4000 nM). The second assay compared the reverse conditions, varying the concentration of kaempferol (0−4000 nM) and keeping the concentrations of the flavonol analogues (500 nM) constant. Pollen germination was assessed as described for the pollen-rescue assay.

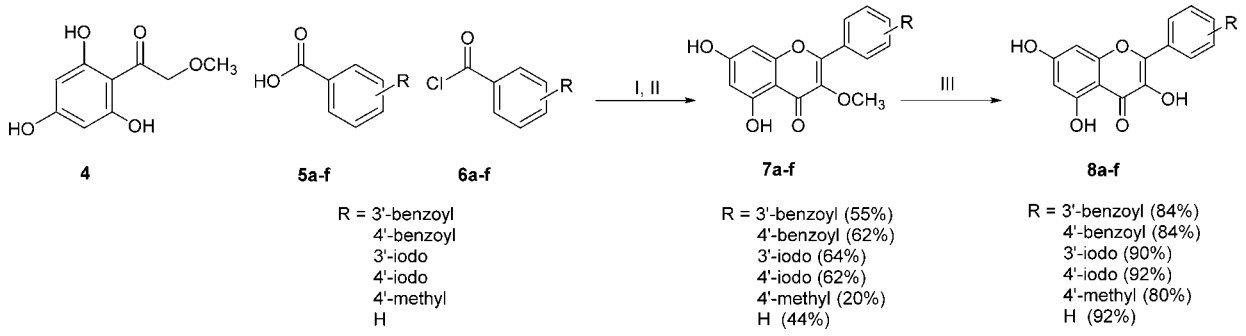

Figure 2. Synthesis of flavonol analogues. Reagents and conditions: (I) Et_3N, DMF, **5**, **6**, reflux; (II) KOH/H_2O, ethanol, reflux; (III) HBr, acetic acid, reflux.

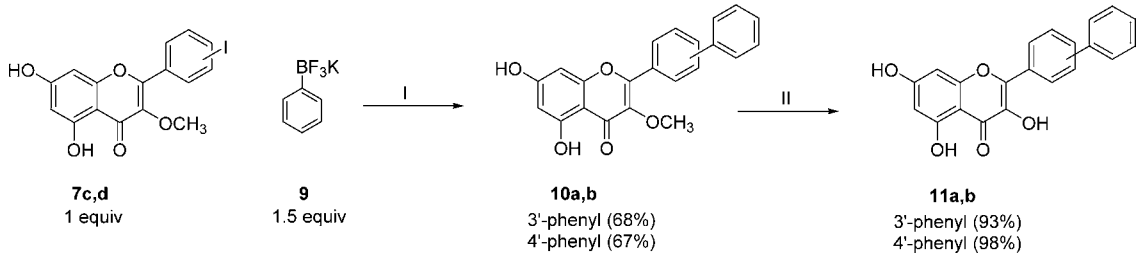

Figure 3. Synthesis of biaryl flavonol analogues. Reagents and conditions: (I) $Pd(OAc)_2$, K_2CO_3 (3 equiv), MeOH, 65 °C; (II) HBr, acetic acid, reflux.

Table 1. Potency and Efficacy of Natural and Synthetic Flavonols on Pollen Germination[a]

	pollen-rescue assay		
flavonols[b]	potency EC_{50} values (nM)	flavonols[b]	efficacy maximal response (% G[c])
3′-phenyl flavonol (**11a**)	0.849 ± 1.32 a	kaempferol (**1**)	60.51 ± 2.18 A
kaempferol (**1**)	161.54 ± 0.81 b	galangin (**8f**)	52.71 ± 0.93 B
galangin (**8f**)	181.04 ± 14.97 b	morin (**2**)	46.00 ± 1.33 B
kaempferide (**3**)	333.74 ± 85.96 c	4′-methyl flavonol (**8e**)	35.40 ± 1.61 C
morin (**2**)	1152.89 ± 60.66 d	kaempferide (**3**)	30.58 ± 0.50 C
4′-methyl flavonol (**8e**)	1840.76 ± 79.51 e	3′-phenyl flavonol (**11a**)	12.39 ± 1.48 D
3′-iodo flavonol (**8c**)	N/A	3′-benzoyl flavonol (**8a**)	4.84 ± 0.39 E
4′-iodo flavonol (**8d**)	N/A	3′-iodo flavonol (**8c**)	4.10 ± 0.09 E
4′-phenyl flavonol (**11b**)	N/A	4′-benzoyl flavonol (**8b**)	3.43 ± 1.37 E
3′-benzoyl flavonol (**8a**)	N/A	4′-iodo flavonol (**8d**)	3.27 ± 0.20 E
4′-benzoyl flavonol (**8b**)	N/A	4′-phenyl flavonol (**11b**)	2.48 ± 0.405 E
DMSO (control)	N/A	DMSO (control)	1.98 ± 1.24 E

[a]Values are the mean ± SEM of two independent experiments, done in triplicate, except for 4′-methyl flavonol and kaempferide in which the mean reflects three independent experiments. Tukey's multiple-comparison tests determined statistical differences between the EC_{50} values (lower case letters) and the maximal responses (upper case letters) of each flavonol after ANOVA ($P < 0.05$). N/A, not statistically different from the control. Statistical analysis was performed using the software Origin. [b]Concentration ranges: 0.001−4000 nM. [c]Percent germination.

Statistical Analysis. The EC_{50} values and maximal responses of the flavonols in each cell line were analyzed by Tukey's multiple-comparison tests after one-way analysis of variance (ANOVA). Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Chemistry. Flavonol analogues were synthesized through a "one pot" procedure described by Ichikawa et al.[32] in which the ω-methoxyphloroacetophenone **4** was esterified by the acid chloride **6a−f** to produce a triester intermediate, which then proceeded to cyclize (Figure 2). Ester hydrolysis of this intermediate resulted in the synthesis of the flavonol methyl ethers, compounds **7a−f** ((3′-benzoyl (55%), 4′-benzoyl (62%), 3′-iodo (64%), 4′-iodo (62%), galangin (44%), and 4′-methyl (20%) flavonol methyl ethers). Demethylation of the flavonol methyl ethers **7a−f** was attempted using BBr_3 in chloroform[33] or sodium sulfide in DMF.[34] Only partial demethylation occurred with BBr_3, and no demethylation was observed with sodium sulfide. A disadvantage to the first method is that BBr_3 is water sensitive and thus difficult on a small scale. In the second method, it is believed that deprotection of **7a−f** did not occur because the phenolic hydrogen atoms were deprotonated, making the ring more electron rich, causing the methoxy group to become unreactive. Complete deprotection and high yields were achieved using HBr in acetic acid to give the desired flavonols, compounds **8a−f** (3′-benzoyl (84%), 4′-benzoyl (84%), 3′-iodo (90%), 4′-iodo (92%), galangin (92%), and 4′-methyl (80%) flavonols).[35]

The 3′- and 4′-phenyl flavonols were synthesized via an organotrifluoroborate chemistry developed by Molander et al.

dx.doi.org/10.1021/jf405688d | J. Agric. Food Chem. 2014, 62, 2175−2181

(Figure 3).[30] This method utilized a palladium-catalyzed Suzuki−Miyaura cross-coupling reaction. Good yields were achieved in the synthesis of both the 3′-phenyl **10a** (68%) and 4′-phenyl **10b** (67%) flavonol methyl ethers. These yields are noteworthy for the lack of reactivity of the cross-coupling reaction to the redox active flavonols. High yields were achieved in the demethylation of these intermediates to the 3′-phenyl **11a** (93%) and 4′-phenyl **11b** (98%) flavonols. All synthetic flavonols (galangin, 3′- and 4′-benzoyl, 3′- and 4′-iodo, 3′- and 4′-phenyl, and 4′-methyl flavonols) were identified through spectroscopic and spectrometric data (NMR and IR spectroscopy and high-resolution MS).

Pollen-Rescue Assays. In vitro pollen-rescue assays were conducted to explore which naturally occurring flavonols (kaempferol, kaempferide, galangin, and morin) and flavonol analogues (3′- and 4′-benzoyl, 3′- and 4′-phenyl, 3′- and 4′-iodo, and 4′-methyl flavonols) were the most effective at activating the pollination sequence and, thus, were the most efficient agonists (Table 1 and Figure 4). DMSO has been shown to have no significant effect in activating the pollination sequence at concentrations of <0.6% and was used as a vehicle control at concentrations of 0.2%.[12] The use of a DMSO blank served as the negative control. The effectiveness of these agonists was determined on the basis of two criteria, potency (EC_{50}) and efficacy (maximal response). An ideal agonist has high potency (low EC_{50}) and high efficacy. The natural products kaempferol, galangin, and kaempferide had the highest potencies. Morin, as well as the flavonol analogue 4′-methyl flavonol, were somewhat less potent. A different trend was observed in the efficacy of the flavonols. The natural product, kaempferol, had the highest efficacy, whereas galangin and morin were partial agonists. Kaempferide and the flavonol analogue 4′-methyl flavonol had the lowest efficacy, achieving half the maximal response. The remaining hydrophobic flavonol analogues (3′- and 4′-benzoyl, 3′- and 4′-phenyl, and 3′- and 4′-iodo flavonols) gave minimal or no response when tested in concentrations up to 4 μM when compared to the negative control. These results show that kaempferol is the best agonist among the flavonols tested and that the hydrophobic analogues (3′- and 4′-benzoyl, 4′-phenyl, and 3′- and 4′-iodo flavonols) do not act as agonists.

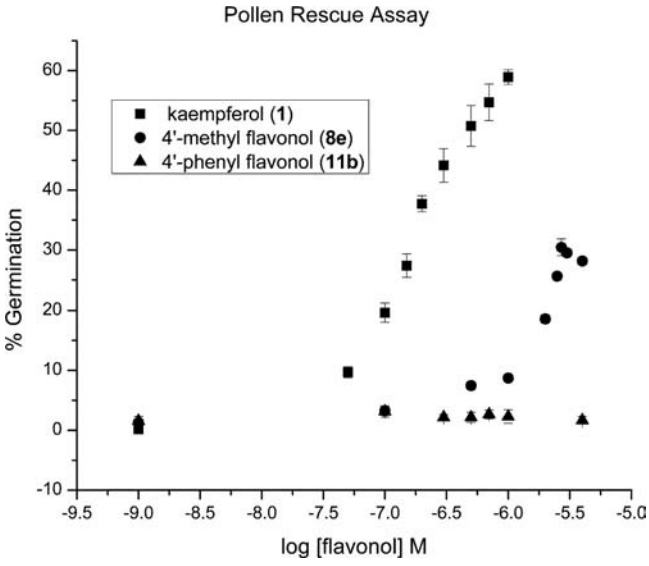

Figure 4. Comparison of a fully (kaempferol, 4′-OH), partially (4′-methyl flavonol), and minimally (4′-phenyl flavonol) active flavonol to induce pollen germination.

Competition Assays. Possible antagonists were identified by comparing the potency and efficacy of kaempferol in the presence and absence of the flavonol analogues (Table 2 and Figure 5). Thus, in vitro competition assays were run between

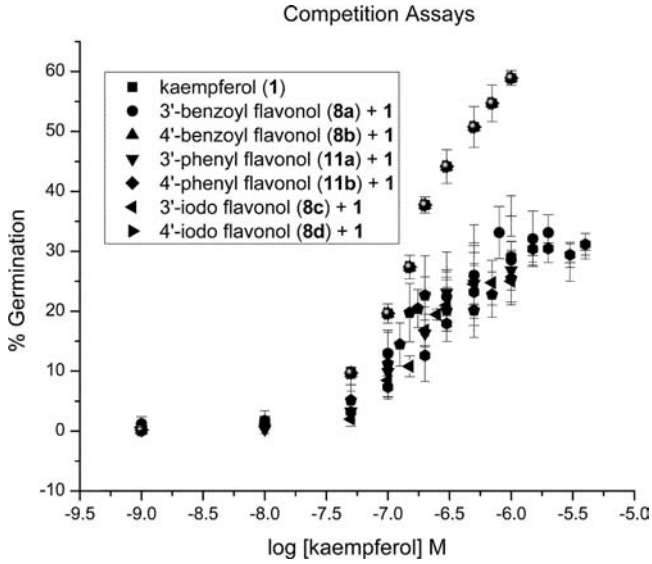

Figure 5. Comparison of kaempferol (**1**) in the presence and absence of flavonol analogues to activate the pollination sequence.

Table 2. Potency and Efficacy of Kaempferol in the Presence and Absence of Flavonol Analogues on Pollen Germination[a]

	competition assay		
flavonols[b]	potency EC_{50} values (nM)	flavonols[b]	efficacy maximal response (% G[c])
kaempferol (**1**), control	162 ± 1 a	kaempferol (**1**), control	61 ± 2 A
3′-iodo flavonol (**8c**) + **1**	103 ± 2 a	3′-benzoyl flavonol (**8a**) + **1**	33 ± 2 B
4′-iodo flavonol (**8d**) + **1**	114 ± 26 a	4′-phenyl flavonol (**11b**) + **1**	32 ± 0 B
3′-phenyl flavonol (**11a**) + **1**	156 ± 31 a	4′-iodo flavonol (**8d**) + **1**	30 ± 1 B
3′-phenyl flavonol (**11a**) + **1**	157 ± 31 a	4′-benzoyl flavonol (**8b**) + **1**	29 ± 2 B
3′-benzoyl flavonol (**8a**) + **1**	169 ± 26 a	3′-phenyl flavonol (**11a**) + **1**	26 ± 3 B
4′-phenyl flavonol (**11b**) + **1**	250 ± 59 a	3′-iodo flavonol (**8c**) + **1**	25 ± 3 B

[a]Values are the mean ± SEM of two independent experiments done in triplicate. Tukey's multiple-comparison tests determined statistical differences between the relative EC_{50} values (lower case letters) and maximal responses (upper case letters) of each flavonol after ANOVA ($P < 0.05$). [b]Concentration ranges: flavonol analogues (**8a−d** and **11a,b**), 0−4000 nM; kaempferol (**1**), 500 nM. [c]Percent germination.

the model agonist, kaempferol, and the minimally activating flavonols (3′- and 4′-benzoyl, 3′- and 4′-phenyl, and 3′- and 4′-iodo flavonols). A classical antagonist decreases the potency (increased EC_{50}) and efficacy of a full agonist such as kaempferol. From these assays, we found no difference between the potency of kaempferol in the presence or absence of these minimally activating flavonols; however, the efficacy of kaempferol was diminished by half. Kaempferol was unable to increase the percent germination above half its maximal response in the presence of these flavonols, even at high concentrations (>1 mM). In other words, the flavonols caused kaempferol to act as a partial agonist. On the basis of this information, all of the hydrophobic flavonol analogues (3′- and 4′-benzoyl, 3′- and 4′-phenyl, and 3′- and 4′-iodo flavonols) inhibited kaempferol action in a noncompetitive manner. Additional studies are needed to determine the mechanism by which flavonols are acting as noncompetitive inhibitors in pollen germination.

Structure–Activity Relationship Comparisons. The effects of hydrophilicity, hydrophobicity, steric bulk, hydrogen bonding, and planarity in the B ring of flavonols were studied to determine which characteristics activated (agonist) or inhibited (antagonist) the pollen germination sequence. Previous research has shown that the best flavonol agonists were flavonols with a more hydrophobic, less hydroxylated B ring.[11,12] For example, flavonols with one (kaempferol) B-ring hydroxyl group were 10 times more potent than flavonols with two (quercetin) and 100 times more potent than flavonols with three (myricetin) B-ring hydroxyl groups. We observed this trend between kaempferol and the 2′,4′-dihydroxy flavonol, morin.

Flavonols with a B-ring substituent capable of hydrogen bonding also appear to make better agonists. Substituting a 4′-hydroxyl group (kaempferol, 162 nM and 61% G) with a methoxy group (kaempferide, 334 nM and 31% G) decreased both its potency and efficacy by 50%. Substituting the 4′-hydroxyl group (kaempferol, 162 nM and 61% G) with a methyl group (4′-methyl flavonol, 1841 nM and 35% G) lowered the potency 11-fold and decreased the efficacy by 50%.

Another interesting, but not completely understood, observation was that the more hydrophobic 3′-phenyl flavonol (0.849 nM and 12% G) was the only flavonol analogue that appeared to act as an agonist. All other hydrophobic flavonol analogues (3′- and 4′-benzoyl, 3′- and 4′-iodo flavonols), including the isomeric 4′-phenyl flavonol, acted as apparent antagonists. A plausible explanation is that there is a size restriction on the flavonol binding site and only smaller less sterically hindered compounds, such as kaempferol and galangin, and/or compounds with small planar groups at the C3 position of ring B (3′-phenyl flavonol) are able to fit into the binding site. Flavonols with bulky groups (4′-phenyl, 3′- and 4′-benzoyl, 3′- and 4′-iodo flavonols) likely bind to a different site, an idea supported by the fact that the flavonol analogues appear to be inhibiting the action of kaempferol in a noncompetitive manner. Additionally, steric bulk could explain why the more hydroxylated flavonols (quercetin, morin, and myricetin) were not as efficient at activating the pollination sequence as kaempferol. The decrease in efficiency might be a consequence of more hydrophobic, less hydroxylated flavonols' inability to fit into the flavonol binding site rather than a preference for more hydrophobic flavonols or a combination of both characteristics.

Structure–activity relationship studies have shown that efficacy is not as simple as the previously proposed idea that more hydrophobic, less hydroxylated flavonols make the best agonists.[11,12] Of the flavonols tested, only the smaller, less sterically hindered compounds (kaempferol, galangin, kaempferide, morin, and 4′-methyl flavonol) were found to act as agonists, whereas the larger more hydrophobic flavonols (4′-phenyl, 3′- and 4′-benzoyl, 3′- and 4′-iodo flavonols) had no agonist activity, but interfered with the action of kaempferol. This action could involve receptor-mediated events such as noncompetitive antagonism or could represent a form of functional antagonism. Our results suggest that the most important factor in determining if a flavonol will function as an agonist is its size, with hydrogen bonding and/or planarity appearing to improve the potency and efficacy of the agonist as long as it is not sterically hindered. Further studies are needed to identify the biologically relevant receptor of flavonols in plants to better understand the biological mechanism(s) by which flavonols activate pollen germination, possibly through the use of benzoyl flavonols as photoaffinity reagents.[36] Irreversible binding of benzoyl flavonols to the receptor could allow isolation of the complex. These findings also provide important information for the exploitation and use of flavonoids in the development of new agrichemicals.

although its effectiveness remains controversial.[15,16] Therefore, new drugs for RSV treatment and prevention are urgently needed.

Natural products serve as an important source of potential antiviral agents based on their traditional uses.[17] In the present study, we reported the supercritical fluid extract of "Guangchenpi" possessing *in vitro* antiviral activity against RSV. Therefore, the objectives of the present study were to investigate the anti-RSV constituents of the supercritical fluid extract of "Guangchenpi" and to probe the possible mechanism of the most active constituent in the extract.

MATERIALS AND METHODS

Plant Material. The mature pericarps of *Citrus reticulata* 'Chachi' were collected in Xinhui city, Guangdong Province, China, and then were oven-dried at 80 °C for 4 h. The plant was authenticated by Prof. Guang-Xiong Zhou, College of Pharmacy, Jinan University. A voucher specimen with accession No. 20090226 was deposited in the Herbarium of the College of Pharmacy, Jinan University.

General Apparatus and Chemicals. Supercritical CO_2 fluid extraction was performed in a HA-121-50-02 supercritical fluid CO_2 extraction apparatus (Jiangsu Nantong Huaan Supercritical Fluid Extraction Inc., Jiangsu, China). Optical rotations were measured in a JASCO P-1030 automatic digital polarimeter. IR spectra were determined using a JASCO FT/IR-480 plus infrared spectrometer with KBr pellets. NMR spectra were performed on a Bruker Avance 400 MHz spectrometer with TMS as the internal standard. Chemical shifts were expressed in δ values (ppm) with reference to the solvent signals. ESI-MS data were recorded on a Finnigan LCQ Advantage Max ion trap mass spectrometer. Silica gel (200−300 mesh, Qingdao Marine Chemical Inc., China) and Sephadex LH-20 (Pharmacia, Sweden) were used for column chromatography (CC). Thin-layer chromatography (TLC) was performed on precoated silica gel plates (GF254, Yantai, China). Analytical high-performance liquid chromatography (HPLC) was performed on a Dionex chromatograph equipped with a P680 pump, a PDA-100 photodiode array detector, and an Agilent Zorbax SB-C_{18} reversed-phase column (4.6 mm × 250 mm, 5 μm). Preparative high performance liquid chromatography (HPLC) was carried out on a Varian Postar 210 chromatograph equipped with a Varian-306 pump and a Varian UV/vis-152 detector with a C_{18} reversed-phase column (Cosmosil, 10 mm × 250 mm, 5 μm). All reagents were purchased from Tianjin Damao Chemical Company (Tianjin, P. R. China).

Extraction and Isolation. The supercritical fluid extract of "Guangchenpi" was prepared with the method described in a previous report.[14] Briefly, supercritical fluid extraction was conducted at a pressure of 25 MPa and a temperature of 35 °C for 2 h, and the flow rate of CO_2 was 20 L/h. Supercritical fluid extract (46.2 g) passed through a normal-phase silica gel column chromatography (10 cm × 40 cm, 300 mesh, 1 kg) eluted with petroleum ether, petroleum ether−acetone gradients (99:1, 98:2, 97:3, 95:5, 93:7, 90:10, 85:15, 80:20, 70:30, and 60:40, v/v) and finally pure methnol to obtain 12 fractions (A−L) based on TLC analysis. Fractions D−G were subjected to further isolation due to their anti-RSV activity. Fraction D (3.5 g) was purified by repeated silica gel column chromatography (4 cm × 30 cm, 300 mesh, 100 g) eluted with cyclohexane−ethyl acetate (300:1 → 1:1, v/v), and recrystallized from cyclohexane to yield compound **3** (218.5 mg). Compound **2** (517.8 mg) was isolated from fraction E (3.3 g) by a silica gel column (4 cm × 20 cm, 300 mesh, 85 g) eluted with cyclohexane−ethyl acetate (200:1 → 1:1, v/v), and recrystallization from cyclohexane. Compounds **4** (9.4 mg) and **5** (11.7 mg) were obtained from fraction F (1.3 g) by repeated silica gel column chromatography (3 cm × 12 cm, 300 mesh, 30 g) eluted with cyclohexane−ethyl acetate (200:1 → 1:1, v/v) and then sephadex LH-20 column chromatography (2.5 cm × 75 cm, 50 g) using chlorofrom−methanol (2:1, v/v) as eluent. Fraction G (3.2 g) was separated by silica gel column chromatography (4 cm × 30 cm, 300 mesh, 100 g), eluted with chloroform−methanol (100:1 → 1:1, v/v), and further purified by preparative HPLC column [RP-18 (10 × 250 mm, 5 μm)], using methanol−water (85:15, v/v) as the mobile phase to obtain compound **1** (82.5 mg).

HPLC Analysis. The contents of the active compounds **2** (tangeretin) and **3** (nobiletin) in the supercritical fluid extract of "Guangchenpi" were analyzed by a Dionex chromatograph equipped with a P680 pump and a PDA-100 photodiode array detector using an Agilent Zorbax SB-C_{18} reversed-phase column (4.6 mm × 250 mm, 5 μm). Compounds **2** and **3**, obtained from the isolation, were well separated from other peaks with relative abundance in the supercritical fliud extract as displayed in their HPLC profiles (Figure 2). In the experiment, compounds **2**, **3**, and the supercritical fluid extract of "Guangchenpi" were dissolved in methanol and filtered through a 0.22 μm PTFE syringe filter before injection into the HPLC. The column temperature was set to 25 °C. The mobile phase consisted of A (water with 0.5% acetic acid) and B (acetonitrile). Gradient elution conditions were 0−15 min, isocratic 49% B, and 16−25 min, 100% B. The flow rate was 1.0 mL/min. The injection volume was 10 μL. The analytes were monitored at 330 nm.

Cell and Virus. Human larynx epidermoid carcinoma (HEp-2, ATCC CCL-23) cells and RSV A2 (ATCC VR-1540), Long (ATCC VR-26), and B (ATCC VR-955) strains were purchased from Medicinal Virology Institute, Wuhan University, China. The RSV strains were grown and titered in HEp-2 cells. The HEp-2 cells were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco, USA) plus 100 U/mL penicillin and streptomycin solution, 2 mM L-glutamine, and 10% fetal bovine serum (FBS; Sijiqing Biological Engineering Company, China), which is designated as growth medium (GM). Virus-infected cells were maintained in DMEM with 100 U/mL penicillin and streptomycin solution, 2 mM L-glutamine, and 2% FBS (Maintenance Medium, MM). Virus titers were determined by the 50% tissue culture-infective dose ($TCID_{50}$) method and plaque reduction assay. Ribavirin (Sigma, USA) was used as a positive control in the anti-RSV tests. All of the cells were cultured at 37 °C in a 95% humidified atmosphere supplied with 5% CO_2. The RSV strains were stored at −80 °C until use.

3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyl Tetrazolium Bromide (MTT) Assay. The cytotoxicity of the supercritical fluid extract and the compounds on HEp-2 cells was detected by MTT assay in 96-well plates (Corning, USA).[18] In brief, sample was added to confluent HEp-2 cell monolayers, and MM without the sample was used as cell control. The cells were incubated for 72 h, then MTT solution (Sigma, USA) was added. The plate was further incubated for 4 h to form formazan crystals. The optical density (OD) values were measured with an enzyme immunoassay (EIA) reader (Thermo Labsystems Multiskan MK3) at 570 nm. The 50% cytotoxic concentration (CC_{50}) of the sample was calculated by regression analysis of the dose−response curve generated from the OD values. The maximal noncytotoxic concentration (MNCC) of the sample on the cells was also calculated through the OD values.

Cytopathic Effect (CPE) Reduction Assay. CPE reduction assay was adopted to evaluate the anti-RSV activity of the supercritical fluid extract and compounds against A2, Long, and B strains.[19] The anti-RSV activity of each sample was tested using MNCC as the beginning concentration. Briefly, HEp-2 cells were seeded in 96-well plate. Cell monolayers were inoculated with the mixture of a serial 2-fold dilution of sample and virus suspension (100 $TCID_{50}$). Virus suspension and MM without sample were added as virus and cell controls, respectively. The plate was incubated for about 3−4 days. The virus-induced CPE was observed under light microscopy. The concentration that reduced 50% of CPE with respect to virus control was estimated from the plots of the data and was defined as the 50% inhibitory concentration (IC_{50}) of the tested sample. The selective index (SI) value was calculated from the ratio CC_{50}/IC_{50}.

Plaque Reduction Assay. The anti-RSV activity of tangeretin (compound **2**, the most active compound in the extract) was further determined by plaque reduction assay.[20] HEp-2 cells were seeded in 24-well plates for 24 h. The virus suspension with 60−80 plaque forming units (PFUs) and a serial 2-fold dilution of tested sample were added to the confluent cell monolayer. Virus suspension and the MM

without sample were added as the virus and cell controls, respectively. The plate was incubated in 5% CO_2 at 37 °C with intermittent shaking at 15 min intervals for 2 h, and the medium was aspirated. The cell monolayers were washed with PBS twice and then overlaid with agarose overlay medium. After the agarose solidified, samples with different concentrations and MM were added to the corresponding and virus control wells, respectively. The plates were then incubated for 4−5 days to allow the formation of RSV plaques. The cells were fixed with 10% formalin and stained with 1% crystal violet, and the number of plaques was counted. Half of the maximal concentration inhibiting the RSV-induced plaque formation by the sample was defined as the IC_{50} value in the assay.

Plaque reduction assay was also adopted to investigate the inhibitory effects of tangeretin on the RSV extracellular and intracellular replication as described in the previous report.[21] In conventional RSV assays, the time allowed for virus attachment and penetration (extracellular replication phase) is about 2 h. In this experiment, the sample was added to the confluent HEp-2 cells at three different infection phases: (1) during the extracellular replication phase (sample present first 2 h of infection) only, (2) during the whole infection phase (sample present throughout the experiment), or (3) during the intracellular replication phase (sample present after 2 h postinfection) only. The plate was incubated for 4−5 days to allow for the formation of plaques. After fixation and coloration, the number of plaques was counted. The plaque inhibition (%) was calculated as follows: [(mean number of plaques in virus control) − (mean number of plaques in sample)/(mean number of plaques in virus control)] × 100%.

Attachment Inhibitory Assay. The attachment inhibitory effect of tangeretin against RSV Long strain was also determined with plaque reduction assay.[22] HEp-2 cell monolayers in a 6-well plate were prechilled at 4 °C for 1 h, and then the medium was aspirated. Cell monolayers were infected with 60−80 PFU RSV Long strain in the absence (as virus control) or presence of a serial dilution of the tested sample at 4 °C for 2 h. Afterward, the unabsorbed virus was removed, and the cell monolayer was washed with ice-cold PBS twice, covered with overlay medium, and incubated for further 4−5 days at 37 °C under 5% CO_2 to allow the formation of RSV plaques.

Penetration Inhibitory Assay. Penetration inhibitory effect of tangeretin against RSV Long strain was also tested with plaque reduction assay.[23] HEp-2 cell monolayers grown in 24-well plate were prechilled at 4 °C, and infected by 60−80 PFU RSV Long virus (diluted in cool MM) for another 2 h at 4 °C to allow virus attachment to the cells. The unabsorbed viruses were aspirated, and cells were washed with PBS twice. The plate was then covered with a serially diluted sample or only MM (as virus control) and shifted to 37 °C to allow time for virus penetration into the cells. After 2 h of incubation, the cells were treated with PBS at pH 3 for 1 min to inactive the unpenetrated RSV and then treated with an equal volume of PBS at pH 11 for neutralization. The cells were overlaid and incubated for 4−5 days. After fixation and coloration, the number of plaques was counted.

Quantitative Real-Time PCR Assay. Quantitative real-time PCR assay was conducted to determine how tangeretin regulated mRNA expression of RSV proteins relating to RSV intracellular replication.[24] HEp-2 cell monolayers in a 6-well plate were infected with RSV Long strain (MOI = 1) at 37 °C for 2 h, followed by adding tangeretin. After incubated for another 14 h, the plate was washed with PBS twice, replenished with MM, and further incubated until 24 h postinfection. Total RNA was extracted using TRIzol reagent (Invitrogen, USA), purified by calculating OD_{260}/OD_{280}, which was between 1.8 and 2.2, quantified according to the dilution ratio and the value of OD_{260}, and stored at −80 °C until use. Relative quantitation of the expression of selected genes was performed by the Light Cycler 480 (Roche, USA) system. The primer pairs for PCR are shown in Table 1. The cycling conditions were 95 °C for 5 min, followed by 40 cycles of 95 °C for 10 s, 57 °C for 10 s, and 72 °C for 10 s. A dissociation curve was generated by a cycle of 95 °C for 5 s, 67 °C for 1 min, and 97 °C for 15 s. Results were normalized using GAPDH as a reference gene.

Confocal Assay. HEp-2 cells were infected with RSV Long strain (MOI = 1) for virus absorption. After removing the free virus, the infected cells were overlaid with tangeretin, and then incubated at 37 °C for 24 h. The cells were fixed, permeabilized, and immunostained with the anti-RSV phosphoprotein antibody (Abcam, UK) and then the secondary goat antibody. The cell nuclei were visualized with DAPI (Sigma, USA). Fluorescence was recorded in a confocal laser scanning microscope LSM 510 (Zeiss, Germany).

Western Blot Assay. HEp-2 cells were seeded in 100 mm culture dishes (Corning, USA) and cultured for 24 h at 37 °C. RSV Long strain (MOI = 1) was added to confluent cell monolayers. After 2 h postinfection, the cells were washed with PBS twice and treated with tangeretin until 24 h postinfection. Cells were detached from culture dishes by trypsinization with 0.25% Trypsin−EDTA and then transferred to centrifuge tubes, followed by centrifugation at 800*g* for 3 min. Cell pellets were washed three times with ice-cold PBS, lysed in RIPA buffer containing 0.5 M DTT, 0.1 M PMSF, and 20 × phosphatase inhibitor for 30 min on ice, and then centrifuged at 12000*g* at 4 °C for 15 min. The supernatant containing total cellular proteins was collected and stored at −80 °C until use. Protein concentration was determined by the BCA protein assay kit (Thermo, USA). Protein was subjected to SDS−polyacrylamide gel electrophoresis (SDS−PAGE), after SDS−PAGE proteins were blotted onto a PVDF membrane. The membranes were probed with the anti-RSV phosphoprotein antibody (Abcam, UK) and the secondary goat anti-mouse IgG antibody labeled with horseradish peroxidase (HRP; CST, USA). With the ECL plus Western Blotting reagent pack (Thermo, USA), specific bands were detected.

Statistical Analysis. Data were reported as the mean ± SD for triplicate determinations. The IC_{50} values were estimated from the graphic plots of the data by Origin 8.0. Statistical analysis was performed using Graphpad Prism 5.0 by one-way ANOVA and Tukey post hoc test.

RESULTS AND DISCUSSION

Anti-RSV Activity and Constituents of the Supercritical Fluid Extract of "Guangchenpi". CPE reduction assay showed that the supercritical fluid extract of "Guangchenpi" possessed *in vitro* anti-RSV activity against RSV A2, Long, and B strains with IC_{50} values of 12.5−25.0 μg/mL, whereas its aqueous extract was not active against these RSV strains even at the concentration of 100.0 μg/mL. Based on the observation, polymethoxylated flavonoids found in "Guang-

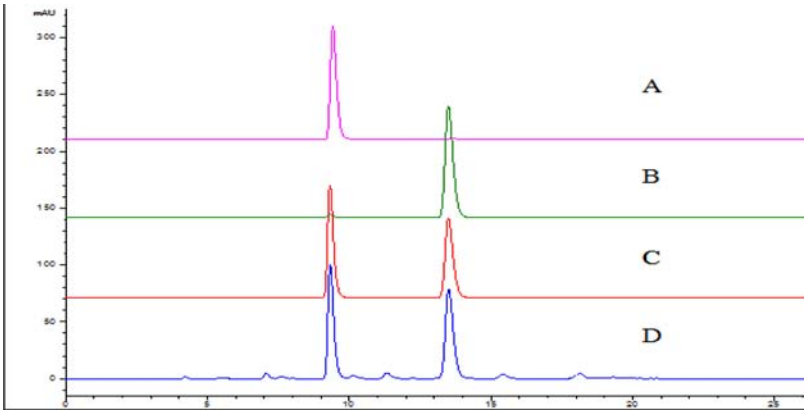

Figure 2. HPLC chromatograms of (A) compound **3**, (B) compound **2**, (C) a mixture of compounds **3** and **2**, and (D) the supercritical fluid extract of "Guangchenpi". The chromatograms were generated using a HPLC column (Agilent Zorbax SB-C_{18}, 4.6 mm × 250 mm × 5 μm) at 330 nm. The mobile phase consisted of A (water with 0.5% acetic acid) and B (acetonitrile). The elution programs were 0−15 min, 49% B, and then 16−25 min, 100% B. The flow rate was 1.0 mL/min. The injection volume was 10 μL.

chenpi" were speculated to be the major anti-RSV constituents.[14] Bioassay-guided isolation of the supercritical fluid extract and spectroscopic identification with published literature comparison found five polymethoxylated flavones, namely, 5-*O*-demethylnobiletin (**1**),[25] tangeretin (**2**),[25] nobiletin (**3**),[25] 6-demethoxytangeretin (**4**),[25] and sinensetin (**5**)[25] (Figure 1A). Moreover, the structure of compound **5** was further confirmed by X-ray diffraction analysis (Figure 1B) of yellow block crystals, $C_{20}H_{20}O_7$, M_r = 372.36, monoclinic, space group $P2_1/n$, a = 14.9739(4) Å, b = 8.2788(2) Å, c = 15.1899(4) Å, β = 110.994(3)°, V = 1758.03(9) Å^3, Z = 4, d_x = 1.407 Mg/m^3, $F(000)$ = 784.0, μ(Cu Kα) = 0.896 mm^{-1}. Data collection was performed on a Gemini S Ultra using graphite-monochromated radiation (λ = 1.54184 Å) with 2799 unique reflections collected to θ_{max} = 62.70°, where 2468 reflections were observed [$F^2 > 2\sigma(F^2)$]. The structure was solved by direct methods (SHELXS 97) and refined by full-matrix least-squares on F^2. The final R = 0.0366, R_w = 0.0985, and S = 1.035. Crystallographic data of this structure is first reported in this paper and has been deposited at the Cambridge Crystallographic Data Centre under the reference number CCDC 950510.

These five polymethoxylated flavones (**1**−**5**) were screened for their *in vitro* anti-RSV activity with CPE reduction assay. All of them were active against RSV A2, Long, and B strains to different extents (Table 2). Both tangeretin (**2**) and nobiletin (**3**) displayed better activity compared with the positive control ribavirin. It is noteworthy that only two compounds (**2** and **3**) out of the five have four methoxyl groups in the A ring of flavone, which may be important to their anti-RSV activity. Polymethoxylated flavonoids (PMFs) are an interesting group of bioactive compounds in *Citrus* plants. Although PMFs have

been reported to possess antiviral activity against influenza virus[26] and HIV,[27] their anti-RSV activity was reported in the present study for the first time.

Contents of Tangeretin and Nobiletin in the Supercritical Fluid Extract. The HPLC chromatograms (Figure 2) recorded the areas of the active compounds **2** and **3** in the supercritical fluid extract. The HPLC method showed a good baseline resolution of compounds **2** and **3** with sharp symmetrical peaks. The calibration curves of the two compounds have a good linearity over the full range tested. As shown in Figure 2, both compounds **2** and **3** were two major polymethoxylated flavones in the supercritical fluid extract. Their contents (w/w %) in the supercritical fluid extract were calculated to be 11.28% and 11.12%, respectively (Table 3).

Table 3. Linearity Studies of Compounds Tangeretin and Nobiletin

compounds	contents (%)	regression equation[a]	R^2	injection amount (μg)
tangeritin (**2**)	11.28	$y = 3.6691 \times 10^3 x - 4.0437 \times 10$	0.9998	1.2−6.6 μg
nobiletin (**3**)	11.12	$y = 3.4918 \times 10^3 x + 3.9858 \times 10$	0.9999	1.36−7.48 μg

[a] y, peak area count; x, injection amount (μg).

In our previous study, UV method with tangeretin as a standard was used to test for the total contents of PMFs in both the supercritical fluid extract and the aqueous extract of "Guangchenpi". Results showed that the total PMF content in the supercritical fluid extract was much higher than that in the aqueous one.[14] The present study demonstrated that both tangeretin (**2**) and nobiletin (**3**), the two more active polymethoxylated flavones, have higher content in the supercritical fluid extract. Overall, supercritical CO_2 fluid extraction can effectively enrich the anti-RSV constituents in "Guangchenpi".

Anti-RSV Activity of Tangeretin with Plaque Reduction Assay. As a most active constituent in the supercritical fluid extract of "Guangchenpi", tangeretin was further investigated for its anti-RSV activity with plaque reduction assay. In Figure 3, tangeretin could dose-dependently inhibit the RSV-induced plaque formation on HEp-2 cells. Its IC_{50} and SI values against RSV A2, Long, and B strains were 7.0 ± 1.5, 5.6 ± 1.5, and 5.4 ± 0.9 μM and 59.6, 73.8, and 75.5, respectively. Meanwhile, the corresponding values for ribavirin were 10.6 ± 1.2, 10.2 ± 1.5, and 10.2 ± 1.2 μM and 24.1, 25.1, and 25.1, respectively.

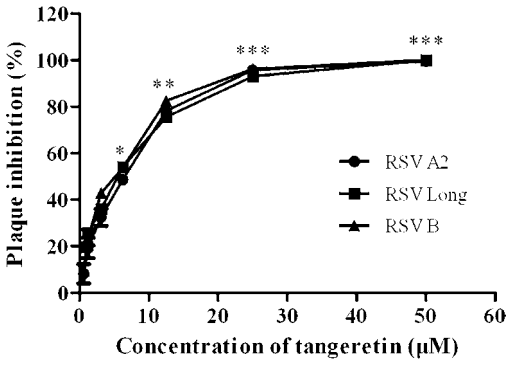

Figure 3. Results of different concentrations of tangeretin against different RSV strains (A2, Long, and B) with plaque reduction assay. Results were expressed as plaque inhibition of control (mean ± SD) from three independent experiments. Significant differences between tangeretin and virus control at $P < 0.05$ (*), $P < 0.01$ (**), $P < 0.001$ (***).

Subsequently, the inhibitory effects of tangeretin on the RSV extracellular and intracellular replication using plaque reduction assay were assessed. At the concentration of 12.5 μM, tangeretin inhibited both extracellular and intracellular replication of RSV by 15.9% and 68.8%, respectively (Figure 4). Ribavirin inhibited intracellular replication of RSV by 56.2%.

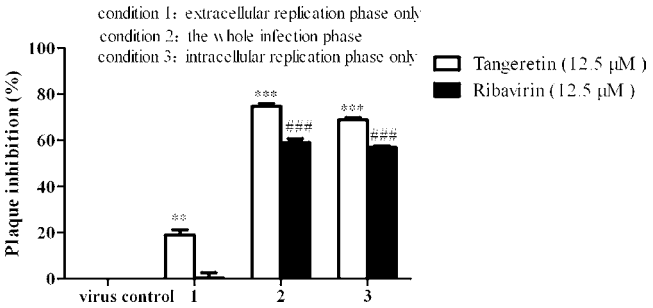

Figure 4. Antiviral activity of tangeretin and ribavirin (positive control) under different virus phases. Results were expressed as plaque inhibition of control (mean ± SD) from three independent experiments. Significant difference between tangeretin and virus control at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***); significant difference between ribavirin and virus control at $P < 0.05$ (#), $P < 0.01$ (##), and $P < 0.001$ (###).

However, no significant plaque inhibition (%) was observed when ribavirin was present only in the extracellular replication phase (Figure 4), and this result was the same as reported previously.[21]

Effects of Tangeretin on RSV Attachment and Penetration. Generally, attachment and penetration are two important stages in the extracellular replication of virus. In the attachment inhibitory experiment, tangeretin did not show any effect on the RSV absorption to the HEp-2 cells even at the concentration of 100.0 μM, similar to ribavirin (data was not shown). On the other hand, it inhibited 50% RSV entry into HEp-2 cells at the concentration of 43.5 μM, while its plaque inhibition (%) on RSV penetration was 67.9% at the concentration of 100.0 μM (Figure 5), which is much higher than that of the control, ribavirin. These results suggested that the efficacy of tangeretin to interfere with the RSV extracellular

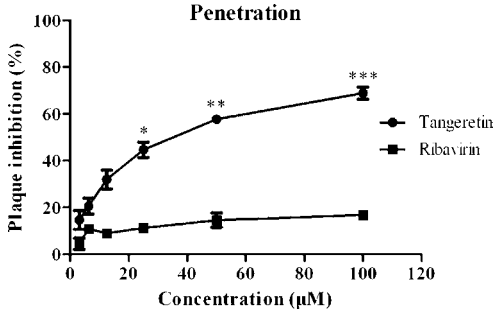

Figure 5. Results of penetration inhibitory assay. Results were expressed as plaque inhibition of control (mean ± SD) from three independent experiments. Significant difference between tangeretin and virus control at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***).

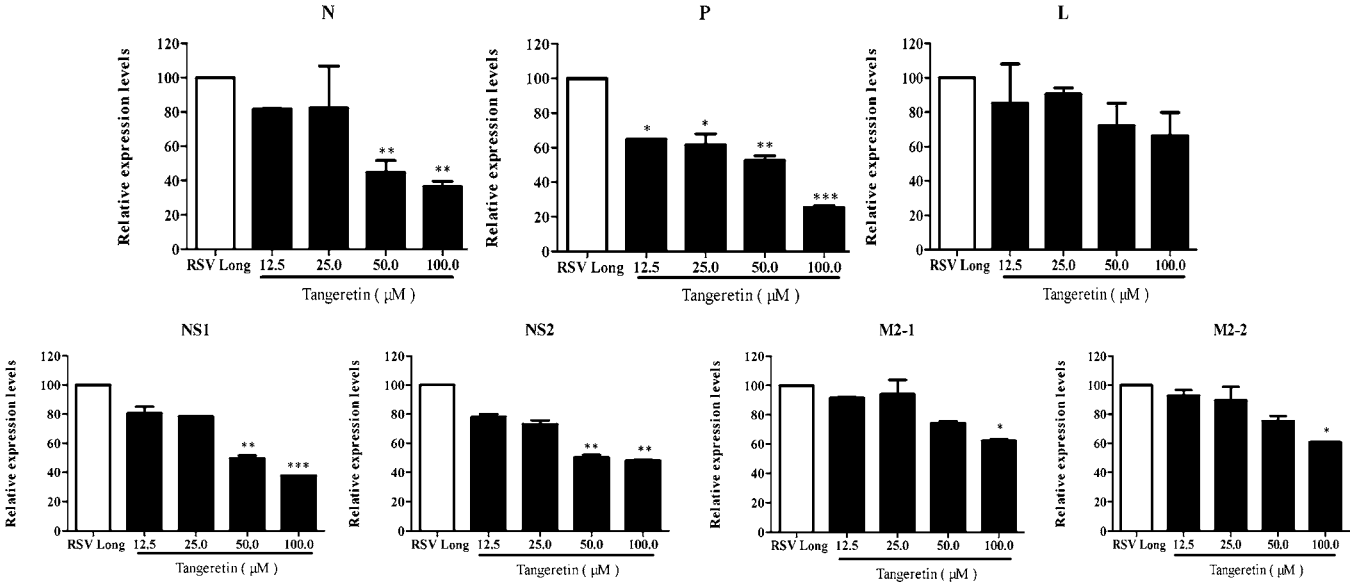

Figure 6. The effects of tangeretin on the mRNA expression levels of RSV proteins (N, P, L, NS1, NS2, M2-1, and M2-2). Results were expressed as relative expression levels (mean ± SD) by three independent experiments. Significant difference between tangeretin and virus control at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***).

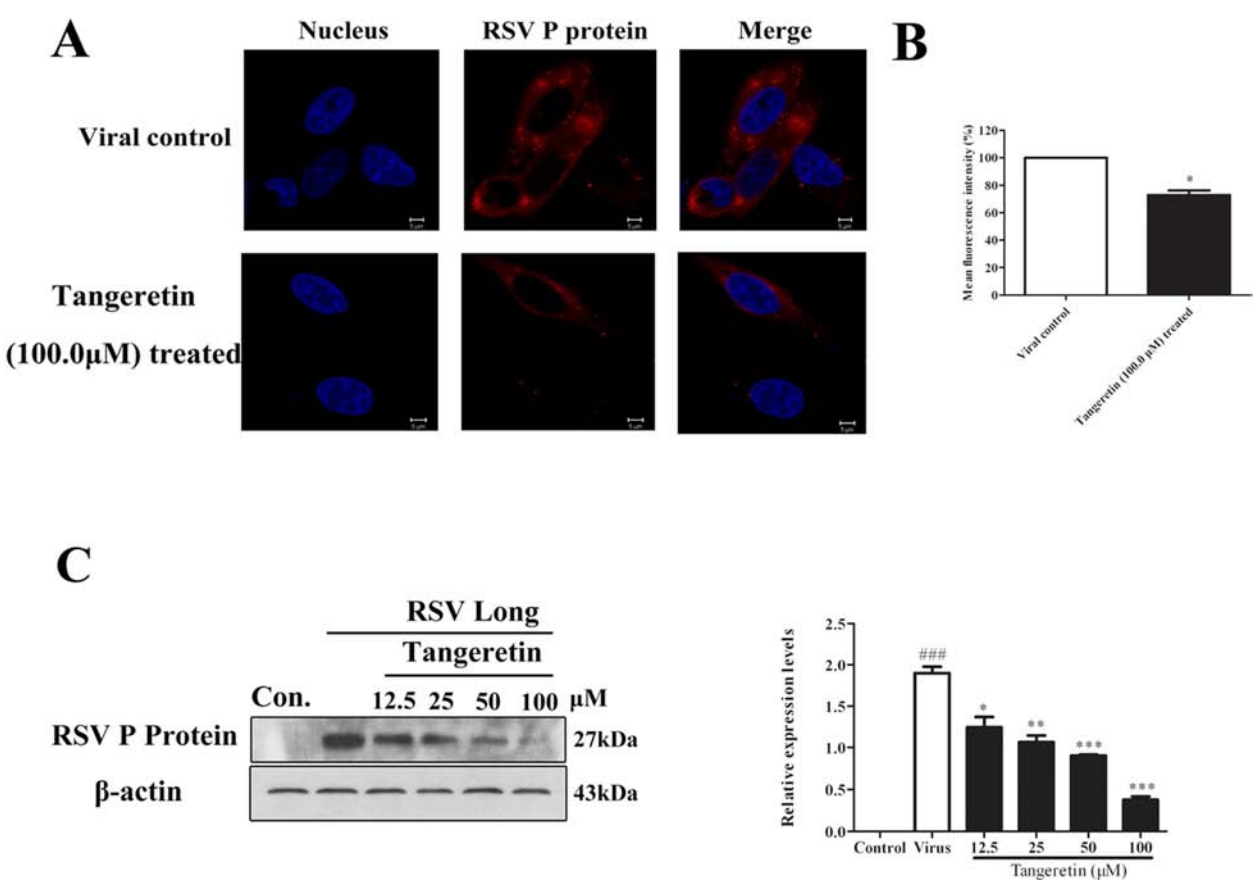

Figure 7. Results from the confocal and Western blot assays: (A) representative images (scale bar, 5 μm) and (B) densitometric analysis for the confocal assay and (C) representative images and densitometric analysis for the Western bloat assay. Results were expressed as relative expression levels (mean ± SD) by three independent experiments. Significant difference between tangeretin and virus control at $P < 0.05$ (*), $P < 0.01$ (**), and $P < 0.001$ (***); significant difference between control and virus group at $P < 0.05$ (#), $P < 0.01$ (##), and $P < 0.001$ (###).

replication was likely contributed by the inhibition of RSV penetration. RSV fusion (F) protein is a glycoprotein that is associated with the RSV penetration.[28] This protein interacts with toll-like receptor 4 (TLR4), and triggers the nuclear factor-κB (NF-κB) signaling pathway.[29] NF-κB is a critical regulator of the immediate early pathogen response, playing an important role in the RSV infection.[30] It has been reported that tangeretin inhibited the activation of the NF-κB pathway.[31]

dx.doi.org/10.1021/jf404310y | J. Agric. Food Chem. 2014, 62, 2182−2189

Therefore, we speculate that tangeretin may directly or indirectly inhibit the NF-κB pathway and interfere with RSV entry into the host cells.

Effect of Tangeretin on the mRNA Expression Levels of RSV. Quantitative real-time PCR analysis was carried out to evaluate the effect of tangeretin on the mRNA expression levels of proteins related to RSV intracellular replication. HEp-2 cell monolayers were first infected with RSV Long strain (MOI = 1), then treated with different concentrations of tangeretin. Total RNA was extracted from the infected cells, and the changes in mRNA expressions of RSV amplicons nonstructural (NS1, NS2), regulatory (M2-1, M2-2), nucleocapsid (N), phosphoprotein (P), and polymerase (L) proteins were analyzed. As shown in Figure 6, tangeretin significantly inhibited the mRNA expression of RSV nonstructural proteins NS1 and NS2 at the concentration of 50.0 μM. It also reduced the RSV regulatory proteins M2-1 and M2-2 at the concentration of 100.0 μM. Interestingly, tangeretin decreased the mRNA expression levels of RSV nucleocapsid-associated proteins N, P, and L to different extents. This compound downregulated the mRNA expression level of RSV P protein with inhibition rates of 49.3% and 74.5% at the concentrations of 50.0 and 100.0 μM, respectively.

Effect of Tangeretin on RSV P Protein. In the present study, confocal assay was used to investigate the influence of tangeretin on RSV P protein. All cells in each group (about 5000 cells) were calculated for the mean fluorescence intensity by the Array Scan Infinity (Thermo, USA). As shown in Figure 7A, almost all the infected cells (control) were observed to emit the red fluorescence from P protein under confocal laser scanning microscopy, whereas fewer cells with tangeretin treatment showed red fluorescence. Apparently, tangeretin significantly decreased the expression of RSV P protein (Figure 7B).

Furthermore, the influence of tangeretin on RSV P protein expression was evaluated by Western blot assay. RSV P protein expression was significantly decreased by tangeretin in a dose-dependent manner (Figure 7C). These results further confirmed the inhibition effect of tangeretin on the expression of RSV P protein.

Based on the results of the present study, tangeretin mainly affected the intracellular replication of RSV. Quantitative real-time PCR results showed that tangeretin mainly down-regulated mRNA expression of RSV P protein, while both confocal and Western blot assays exhibited that tangeretin could attenuate the expression of RSV P protein, suggesting that RSV P protein might be one of the anti-RSV targets of this compound. RSV P protein in combination with RSV L, N, M2-1, and M2-2 proteins (ribonucleoproteins) has been reported to be involved in viral transcription and replication processes.[32,33] Therefore, tangeretin may influence RSV transcription and replication through inhibiting the expression of RSV P protein. Further study on the anti-RSV mechanism of tangeretin is currently in progress in our group.

As a broad-spectrum antiviral agent, ribavirin can potentially act via inhibiting various stages of the virus replication cycle, including viral translation, genome or transcript capping, RNA synthesis, and progeny virus spread, which belong to the intracellular replication of virus.[34,35] Apparently, the anti-RSV mechanism of tangeretin is different from that of ribavirin.

In summary, our work demonstrated that the supercritical fluid extract of "Guangchenpi" possessed *in vitro* anti-RSV activity and that its active constituents were polymethoxylated flavones. Tangeretin and nobiletin were two major polymethoxylated flavones found in the supercritical fluid extract of "Guangchenpi", and they had potent anti-RSV activity comparable to the positive control ribavirin. The anti-RSV mechanism of tangeretin was different from that of ribavirin. Tangeretin mainly affected the intracellular replication of RSV and could inhibit RSV entry into HEp-2 cells. RSV P protein might be one of the anti-RSV targets of this compound. These results suggest that the supercritical fluid extract of "Guangchenpi" and tangeretin may have good potential to be used in the treatment and the prevention of RSV infection.

NOTE ADDED AFTER ASAP PUBLICATION

There was an error in the Quantitative Real-Time PCR Assay section in the version of this paper published February 28, 2014. The correct version published March 12, 2014.

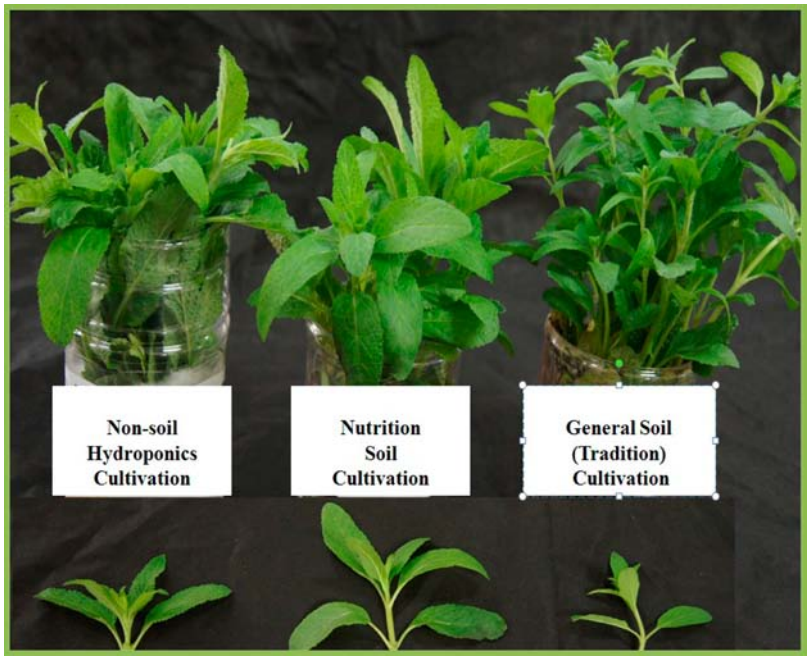

Figure 1. Plebeian herba cultivated in three different conditions.

Kyungpook National University (Daegu, Korea). Soil fertility was enhanced with 15.2 ± 0.2 g/kg organic matter, 1.0 ± 0.1 g/kg total N, 0.25 ± 0.03 g/kg total P, and 100.9 ± 1.8 g kg total K. In this study, Plebeian herba cultured in nutrition hydroponics, nutrition plus soil, and general soil (non-nutritive solution) are referred to as NHC, NSC, and GSC, respectively (Figure 1).

Measurement of Leaf Chlorophyll Content. Fresh leaves were sampled for determining the chlorophyll content. Plebeian herba leaves (0.8 g) were homogenized in 5 mL of 80% acetone. The absorbance of the leaf extract was determined spectrophotometrically at 663, 645, 505, and 453 nm.[17] The concentrations of the pigments were calculated using the following formulas and were expressed per leaf fresh weight (mg/g FW):

$$\text{chlorophyll } a = 0.999 \times \text{Abs}_{663} - 0.0989 \times \text{Abs}_{645}$$

$$\text{chlorophyll } b = -0.328 \times \text{Abs}_{663} + 1.77 \times \text{Abs}_{645}$$

$$\beta\text{-carotene} = 0.216 \times \text{Abs}_{663} - 1.22 \times \text{Abs}_{645} - 0.304 \times \text{Abs}_{505} + 0.452 \times \text{Abs}_{453}$$

Preparation of Extract. Leaves were pulverized with a grinder after drying at 40 °C. Extraction was carried out using 1 g of plant mixed with 20 mL of 100% ethanol and extracted at 50 °C for 3 h. The extraction was repeated twice until the extracts became colorless. The extract was filtrated through Whatman no. 2 paper and then evaporated in a vacuum at 45 °C by using a rotary evaporator (JP/N 1000S-W; Eyela, Japan) and water bath (Digital Water Bath SB-651; Rikakikai, Tokyo, Japan) to remove the ethanol. The final samples were dissolved in dimethyl sulfoxide (DMSO) for analysis of antioxidant and enzyme inhibitory effects. On the other hand, the evaporated extract was dissolved in methanol (HPLC grade) and filtered through a 0.45 μM membrane filter prior to HPLC analysis.

Extraction of Soluble Free and Bound Phenolics. For the extraction of soluble free phenols, the prepared methanol extract was homogenized further using a Polytron homogenizer for an additional 3 min to obtain a thoroughly homogenized sample. After centrifugation, the supernatant was saved. The remaining precipitate was rehomogenized and centrifuged as above. The two supernatants were combined.[18] To determine bound phenolics in the methanol extract, the residues from the above soluble free extraction were drained off and hydrolyzed directly with 20 mL of 4 M NaOH at room temperature for 1 h with shaking. The mixture was acidified to pH 1 with concentrated hydrochloric acid and extracted five times with ethyl acetate. The ethyl acetate fraction was finally evaporated to dryness at 45 °C. The residues were dispersed in 50 mL of 4 M NaOH and stirred for 4 h under nitrogen. The solution was then acidified to pH 1 and centrifuged, and the bound phenolics were extracted with diethyl ether/ethyl acetate (1:1, v/v) as described for esterified phenolics. Free and bound phenolic extracts were dried to a powder and stored at −70 °C until use.

Analysis of Total Phenolics and Flavonoid Content. Total free phenolics were estimated using the Folin−Ciocalteu reagent,[19] and the absorbance was recorded at 725 nm with a UV−vis spectrometer (Power Wave XS, Bio-Tek Instrument, Winooski, VT, USA). On the basis of the standard curve prepared with gallic acid (0−40 μg/mL), the amount of total phenolics in the extract was calculated and expressed in milligrams of gallic acid equivalents (GE) per gram of sample on a dry weight basis (mg GE/g DW). The content of total flavonoids was determined using the previous method.[18] Briefly, 100 μL of tested sample solution was mixed with 7.5 μL of 10% aluminum trichloride ($AlCl_3$) and 7.5 μL of 5% sodium nitrate solution (in DW). After 6 min, 100 μL of 1 N sodium hydroxide and 25 μL of distilled water were added. The total flavonoid content was determined using a standard curve with quercetin (Sigma-Aldrich Chemie, Steinheim, Germany) (0−40 μg/mL) as the standard. The mean of three readings at 415 nm was used and expressed as milligrams of naringin equivalents (NE) per gram of dry weight (mg NE/g DW).

HPLC Analysis of Ascorbic Acid and Phenolic Compounds. The phenolic compounds were determined by using HPLC (Waters, Milford, MA, USA) on a Zorbax Eclipse XDB-C18 (4.6 cm × 250 mm, 5 μm, Agilent, Santa Clara, CA, USA) column, associated with a UV−visible detector (Jasco, Tokyo, Japan) . The column was operated at a temperature of 25 °C.

For determination of ascorbic acid, the mobile phase consisted of methanol/distilled water (50:50, v/v) with 0.5% of phosphoric acid (A) and methanol (100%) with 0.25% of phosphoric acid (B). The gradient program was as follows: 0−6 min, 50% A; 6−10 min, 20% A; 10−20 min, 0% A; 20−22 min, 10% A; 22−25 min, 40% A; 25−40 min, 50% A. The UV detection was carried out at 230 nm.[19] The phenolic compounds were determined using methanol/water (50:50, v/v, pH 2.5 with trifluoroacetic acid) as mobile phase and UV detection of 345 nm.[20]

The flow rate of the mobile phase was 0.7 mL/min, and the injection volumes were 10 μL of the standards and sample extracts. All phenolic compounds and capsaicins were quantified using the external standard method. Quantification was based on peak area. Calibration curves of the standards were made by diluting stock standards in methanol.

DPPH Scavenging Activity. The DPPH radical scavenging activity of ethanolic extract was analyzed by following our previous method.[21] The ethanolic extract (10 μL) was added to 190 μL (0.025 mg/mL) of DPPH solution. After 30 min of standing in darkness, the absorbance was recorded at 517 nm. Gallic acid solution (50 μg/mL) was used as a positive control.

ABTS Scavenging Activity. The total antioxidant activity was measured by the $ABTS^+$ radical cation decolorization assay.[22] Distilled water was used to dissolve ABTS to 7 mM concentration, and the ABTS radical cation ($ABTS^+$) was produced by reaction with 2.45 mM potassium persulfate; the mixture was left in darkness at room temperature. After 12 h, the absorbance was adjusted to 0.70 ± 0.05 at 734 nm by adding absolute ethanol. To determine the scavenging activity, 190 μL of ABTS reagent was mixed with 10 μL of extracts, and absorbance was measured after 6 min of reaction at room temperature, using trolox as a control.

Nitric Oxide Radical Scavenging Activity. NO generated from sodium nitroferricyanide dihydrate (SNP) was measured by the Griess reagent, as described previously.[18] Each 25 μL of sample or quercetin was mixed with 25 μL of 10 mM SNP in PBS (pH 7.4) and incubated at 25 °C for 150 min, and then 50 μL of Griess reagent (2% sulfanilamide in distilled water and 0.2% naphthylethylenediamine dihydrochloride in 4% phosphoric acid) was added. DMSO was used instead of test samples as a control. The absorbance of the chromophore formed during the diazotization of nitrite with sulfanilamide and subsequent coupling with naphthylethylenediamine was read at 540 nm and referred to the absorbance of standard solutions of sodium nitrite treated in the same way with Griess reagent. The plot between the concentration of nitrite and incubation time exhibited the best incubation time for nitrite production from SNP.

Superoxide Dismutase (SOD) Activity. The SOD activity was determined according to our previous study.[18] Extract samples were mixed with tris(hydrochloric acid) buffers and 7.2 mM pyrogallol solution. The reaction was stopped by the addition of 30 μL of 1 N hydrochloric acid. Absorbance of the mixture was determined at 420 nm against a blank. This assay was replicated three times. The inhibition was calculated as

$$\%\ \text{inhibition} = 100 - [\{(A - B)/C\} \times 100]$$

where A is absorbance of sample with reagent, B is absorbance of sample without reagent, and C is absorbance of the control

α-Glucosidase Inhibition Assay. This assay was performed according to our previous study.[23] In brief, 50 μL samples were diluted with 100 μL of 100 mM phosphate buffer (pH 6.9) in a 96-well microplate and incubated with 50 μL of α-glucosidase (0.76 U/mL in same buffer) at 25 °C for 5 min. Fifty microliters of 5 mM *p*-nitrophenyl-α-D-glucopyranoside (prepared in the same buffer) was added to each well in time intervals after pre-incubation. In both cases before and after incubation, absorbance was recorded at 405 nm and compared to a control that had 50 μL of buffer solution in place of the extract.

Statistical Analysis. All results were obtained with means ± SD of three parallel measurements. Data were subjected to an analysis of variance (ANOVA), followed by mean comparisons by Duncan's multiple-range test at $p < 0.05$.

RESULTS AND DISCUSSION

As shown in Table 1, chlorophyll *a*, chlorophyll *b*, water content, and extraction yield were similar in NHC, NSC, and GSC of Plebeian herba. The highest levels of β-carotene and ascorbic acid were found in NSC. Kimura and Rodriguez[24] showed that the hydroponic leafy vegetables had significantly

lower lutein and β-carotene contents than the conventionally produced plants. A significant difference ($p < 0.05$) in β-carotene content was observed between hydroponic and soil cultivation, whereas for ascorbic acid content, a significant difference ($p < 0.01$) between the two treatments was observed for products cultivated in nutrition (NHC and NSC) and non-nutrition (GSC). In comparison to field studies, Plebeian herba plant grown in the nutrition cultured systems had a higher amount of ascorbic acid than previously reported in the literature for wild-harvested salvia plant.[25,26]

Content of Total Phenolics and Flavonoids. The free, esterified, and insoluble-bound phenolics in the extracts of Plebeian herba are shown in Table 1. The results revealed that the free phenolic contents were significantly higher than the bound and esterified phenolics content in each sample. It can be observed that the NSC extract contained the highest amount of phenolics (20.5 mg GE/g DW) among all of the extracts analyzed. The NHC and GSC had a comparatively lower presence of phenolics content at 13.4 and 14.4 mg GE/g DW, respectively. Free phenolics contributed approximately 76, 80, and 72% in NHC, NSC, and GSC extracts, respectively. The bound phenolics ranged from 13 to 19%, whereas esterified phenolics contributed 6−8% to the total.

Phenolics Content. Phenolic compounds are known as high-level antioxidants because of their ability to scavenge free radicals and active oxygen species such as singlet oxygen, superoxide anion radical, and hydroxyl radicals.[21] The highest flavonoid content was also found in NSC extract, contributing 10.5 mg/g DW. Free flavonoids content ranged from 3.4 mg/g DW (GSC) to 8.0 mg/g DW (NSC), whereas bound flavonoids ranged from 0.8 mg/g DW (NHC) to 1.8 mg/g DW (GSC). The contribution of bound flavonoids to NSC was <16%, whereas the contribution of esterified flavonoids was much higher as compared to that of NHC and GCS. Bound flavonoids in the GSC contributed 2.5 and 2.1 times more to the NHC and NSC, respectively. In the study of Grinder-Pedersen et al.[27] the growing conditions of fruits and vegetables (conventional vs nutritional) affect the content of flavonoids, resulting in differences in the urinary excretion of major dietary flavonoids, such as quercetin. It is well-known that variable agronomic and environmental factors such as climate, soil type, light intensity, irrigation, nutrient supply, pest control, weather, growing location, cultivation methods, and time of harvest can affect the phytochemical profile.[28,29] The effects of organic and conventional cultures on total phenolics and antioxidant activity in blueberry fruit were studied,[30] and the results showed that fruit produced following nutrition procedure showed a higher content of phytochemicals with respect to conventionally grown plants. The contents of flavonoids and ascorbic acid in these extracts were in the order NSC > NHC > GSC extracts; moreover, phenolics contents (mg/g DW) were in the order NSC > GSC > NHC extracts.

Antioxidant Activity. Plebeian herba containing high levels of phytochemicals can contribute to antioxidant activity, which is a promising component in decreasing the risk of degenerative diseases.[5] DPPH is a stable free radical that accepts the hydrogen radical to become a stable diamagnetic molecule: yellow-colored diphenylpicrylhydrazine.[31] The scavenging activities of Plebeian herba leaf extracts on the DPPH radical are shown in Figure 2A. All of the tested extracts reacted directly with DPPH radicals and quenched them to different degrees, with increasing activities at higher concentrations. Overall, the extract of NSC showed the highest scavenging

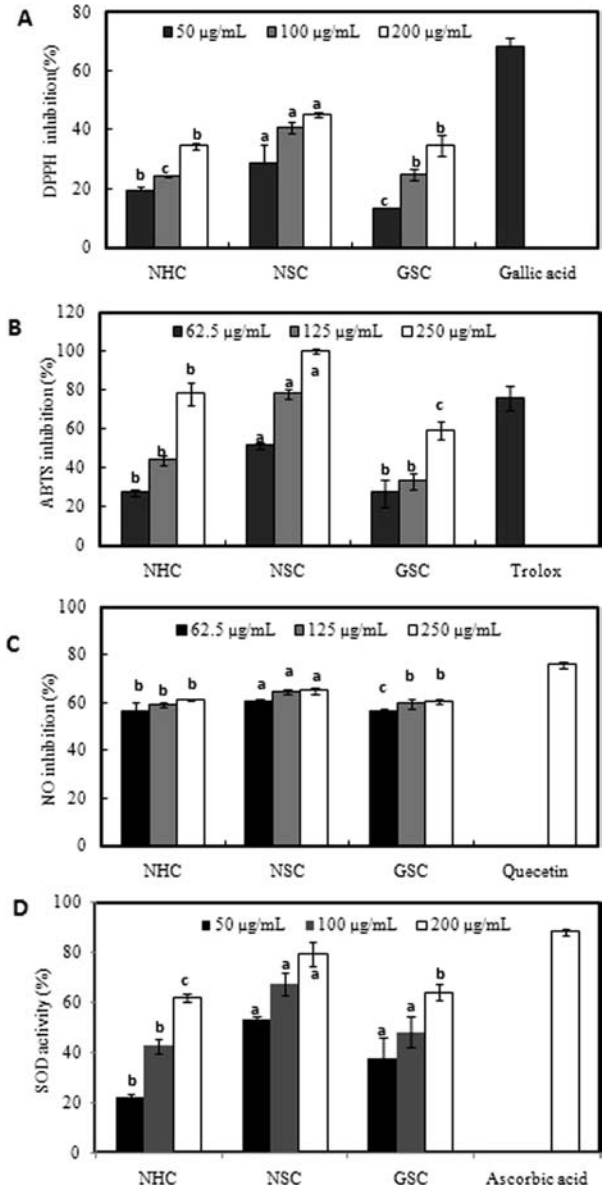

Figure 2. Antioxidant activities of Plebeian herba leaf extracts at different concentrations: (A) DPPH radical inhibition; (B) ABTS radical inhibition; (C) NO inhibition; (D) SOD activity. Different letters indicate a significant difference by Duncan's multiple ranges at $p < 0.05$.

activity. At 200 μg/mL, the scavenging activity of NSC extract reached a plateau of 45.2%. There was no significant variation between NHC (34.6%) and GSC (34.8%) extract, at the same concentration. Scavenging of DPPH radical allows evaluation of the hydrogen-donating potency of phenolic compounds. Plants of the *Salvia* genus mainly contain essential oil and phenolic compounds such as flavonoids, phenolic acids, and phenolic diterpenes.[4] As previously observed on *S. plebeia* extracts,[32] 6-methoxyluteolin-7-glucoside, β-sitosterol, and 2′-hydroxy-5′-methoxybiochanin were demonstrated to be responsible for their strong antioxidant activities. Earlier studies on the antioxidant activity of *Salvia officinalis* reported it to be attributed mainly to the presence of phenolic compounds, such as carsonic acid, rosmarinic acid, and salvianolic acid.[32,4] Therefore, these phenolic compounds in the extracts could be

responsible for the antioxidant activity found in the present study.

The ABTS radical scavenging activities of extracts were measured at three concentrations, ranging from 62.5 to 250 μg/mL. Of all the tested samples, NSC showed an outstanding scavenging activity with an inhibition value of 99.8% at 250 μg/mL concentration; NHC (78.4%) and GSC (59.3%) were found to have significantly weaker activity, at the same dose (Figure 2B). Determination of the antioxidant capacity by ABTS assay of nutrition cultured *S. plebeia* R. Br. plant was the first approach in this study. The term "antioxidant capacity" used in this assay corresponds to the measure of the moles of a given free radical scavenged by a test solution, independent of the antioxidant activity of any antioxidant present in the mixture.[33]

Because of the complex nature of plants, extracts cannot be evaluated by single methods. In this study, we additionally adopted in vitro NO inhibitory methods to determine the ability to inhibit free radicals. Figure 2C shows the NO radical scavenging activity of Plebeian herba leaf extract. All of the tested extracts inhibited the degradation of NO efficiently. A similar plateau to scavenge NO radical at 250 μg/mL is reached for NSC extract already at a concentration of 125 μg/mL. No significant difference between NHC (61.4%) and GSC (60.7%) extract was found at the same concentration. To the best of our knowledge, the antioxidant activity of NO free radical scavenging activity of nutrition hydroponics and soil cultured Plebeian herba has not been investigated.

SOD is a class of enzymes that catalyze the dismutation of superoxide into oxygen and hydrogen peroxide. The results of this study showed a concentration dependency in the SOD activity in the extracts of NHC, NSC, and GSC (Figure 2D). At a concentration of 200 μg/mL, the NSC extract showed the strongest SOD activity (79.4%), followed by GSC (64.0%) and NHC (62.1%) extracts.

To shed light on the contribution of phenolics to antioxidant activity, the antioxidant capacities of the free, esterified, and bound phenolics were analyzed (Table 2). The concentration of NSC to inhibit 50% of DPPH was 233.7 μg/mL. To obtain the same IC_{50} scavenging activity of NHC and GSC, the concentrations needed for NHC and GSC were 342.9 and 345.3 μg/mL, respectively. In the DPPH assay, bound phenolics exhibited the strongest scavenging capacity with IC_{50} values ranging from 113 to 127 μg/mL. Again, the IC_{50} values of ABTS in the bound phenolics were much lower than those exhibited by free and esterified phenolics. The highest inhibition of NO was exhibited by bound phenolics, whereas free phenolics exhibited the weakest antioxidant effect. The IC_{50} inhibition of NO of bound phenolics varied from 170.4 to 190.8 μg/mL. Consistent with the results obtained from these

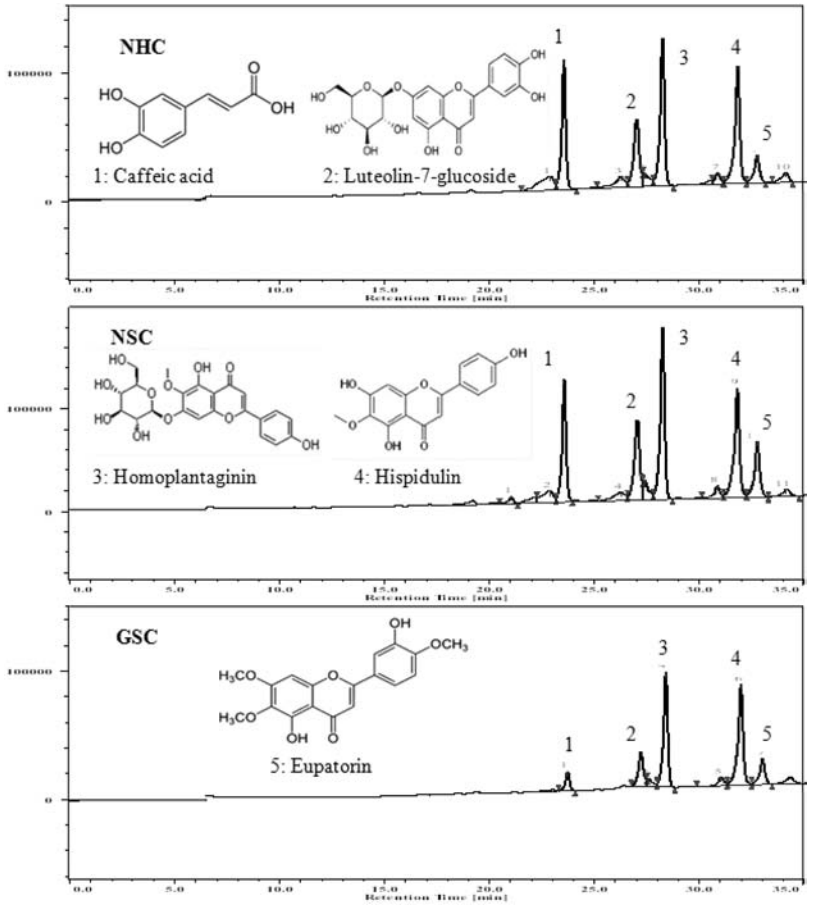

Figure 3. HPLC profiles of methanolic extracts from Plebeian herba. Peaks: caffeic acid (1); luteolin-7-glucoside (2); homoplantaginin (3); hispidulin (4); and eupatorin (5).

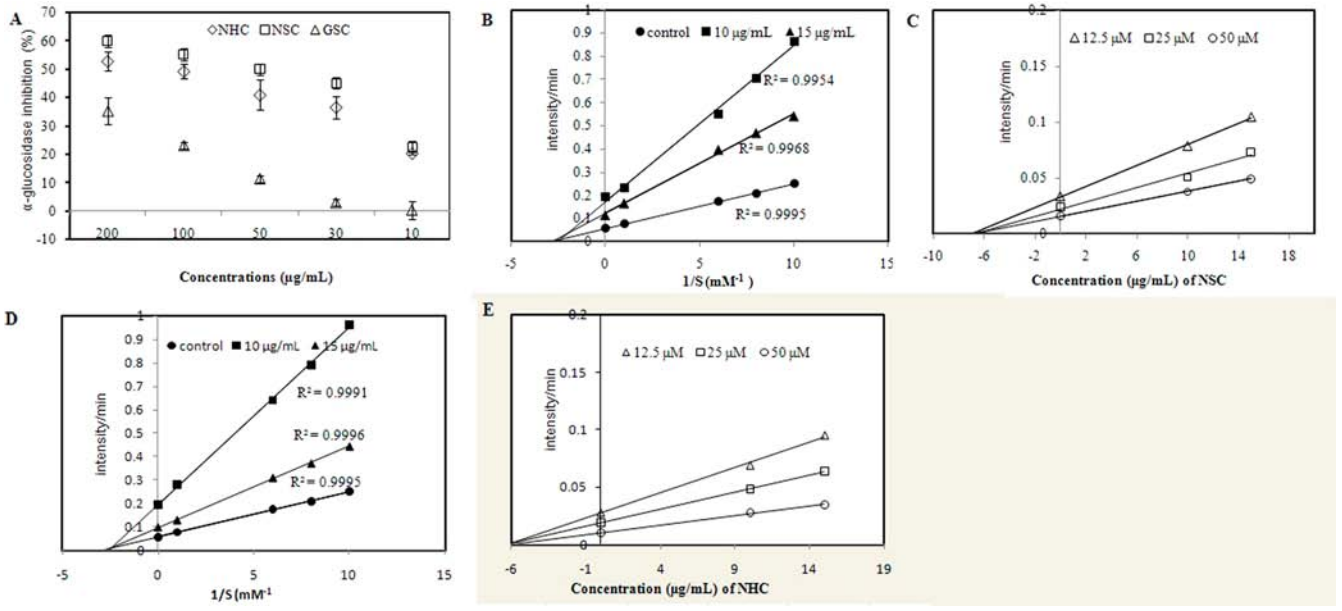

Figure 4. α-Glucosidase inhibition (A) by extracts of Plebeian herba at different concentrations. Data represent the mean of three independent experiments, each performed in duplicated samples. Lineweaver−Burk plot of kinetic analysis of α-glucosidas inhibition by NSC (B). α-Glucosidase was treated with various concentrations of PNP-glycoside (0.125−0.5 mM) in the absence or presence (C) of NSC at two different concentrations (10 and 15 μg/mL). (D) α-Glucosidase was treated with various concentrations of PNP-glycoside (0.125−0.5 mM) in the absence or presence (E) of NHC at two different concentrations (10 and 15 μg/ML) The enzyme reaction was performed by incubating the mixture at 37 °C for 15 min.

assays employed in this study, the same trend of the phenolic-dependent SOD activity values was observed. The extract from NHC, NSC, and GSC, which had the highest content of free phenolics among all varieties tested, exhibited the highest antioxidant activity.

Phenolic Constituents. Different phenolic compounds normally possess specific chromatographic behavior and UV−visible spectral characteristics. Major phenolic compounds in Plebeian herba tested in this study were preliminarily and systematically identified using RP-HPLC with UV by comparison with authentic phenolic standards and relative literature data.[10,34] Major chemical classes and representative constituents of phenolic compounds identified in this study are summarized in Table 3. Figure 3 shows the HPLC profiles of the phenolic standards and leaf extracts of Plebeian herba. Peaks 1−5 in Figure 3 was identified as caffeic acid (1), luteolin-7-glucoside (2), homoplantaginin (3), hispidulin (4), and eupatorin (5). Although some peaks were not completely identified by the relative authentic standards, they could be other phenolic diterpenes, flavonoids, and aromatic volatile compounds, which were confirmed by our chromatographic and UV spectral data and by the analytical characteristics of phenolics reported by Jin et al.[10] Table 3 shows that caffeic acid, homoplantaginin, and hispidulin were the most common phenolics in the analyzed samples, whereas the contents of these three compounds remained low in the GSC. Very high levels of homoplantaginin (5.08 mg/g DW) and caffeic acid (4.17 mg/g DW) were found in the NSC. A previous study also reported the presence in Plebeian herba of hispidulin, homoplantaginin, luteolin-7-glucoside, and caffeic acid.[9] The precision for the 10 analyses was described as the relative standard deviation (RSD), and the test results are given in Table 3. The overall precision in Plebeian herba ranged from 1.3 to 3.1%. The recovery test was determined by standard addition method. Phenolic compounds were spiked into the samples and then extracted, processed, and quantified in accordance with the previous procedures (preparation of extract). The average recoveries of the five phenolic compounds were 93.8−102.4%. This indicated that the method was precise, accurate, and sensitive enough for simultaneous quantitative evaluation of these phenolic compounds in Plebeian herba.

α-Glucosidase Inhibition. As shown in Figure 4A, all of the extracts of Plebeiaen herba had the ability to inhibit α-glucosidase. The inhibitory activities of α-glucosidase increased proportionally to the concentration of the extracts. At a concentration of 200 μg/mL, NSC had the highest inhibitory activity (60.4%) followed by NHC (53.0%) and GSC (35.4%). The extracts of NHC had low phenolic content and had a relatively lower α-glucosidase inhibition. A recent study indicated that a polyphenolic extract of black cumin containing a mixture of phenolic compounds[35] showed significant inhibition of intestinal α-glucosidase activity. The inhibition mode against α-glucosidase activity was analyzed using Lineweaver−Burk plots ($1/V$ vs $1/S$). NSC showed the most significant inhibition; α-glucosidase was treated with NSC (10, 15 μg/mL) using PNP-glycoside (0.125−2 mM) as the substrate to determine the inhibition type. Double-reciprocal plots of enzyme kinetics demonstrated a noncompetitive inhibition of α-glucosidase activity (intersected at a nonzero point on the x-axis ($-K_i$)) (Figure 4B). The data revealed that NSC as the inhibitor is only bound to the enzyme−substrate complex in this model. The inhibition kinetics was also analyzed by Dixon plots, ($1/V$ vs [I] with various concentrations of substrate) (Figure 4C). The K_m value of PNP-glycoside for α-glucosidase was 1.21 mM (data not shown), and a higher V_{max} (0.05 M/min) in the presence of NSC was obtained, as compared to the control. Paneld D and E of Figure 4 show Lineweaver−Burk plots of α-glucosidase inhibitory activities in the presence of NHC at the same dose with NSC and in the absence of the inhibitor with different substrate concentrations of PNP-glycoside. With increasing NHC concentration, the vertical axis intercept ($1/V_m$) increased; however, the horizontal axis intercept ($\lfloor 1/K_m$) remained the same. These results indicate that the velocity of the reaction catalyzed by α-glucosidase was slowed with increasing NHC concentration, and the K_m value of α-glucosidase was not affected, which was correlated with the classical pattern of noncompetitive inhibition and indicated that NHC and the substrate did not bind to α-glucosidase at the same site.

The results presented here show that phenolics, flavonoids, and ascorbic acid highly existed in extracts of Plebeian herba. This investigation provides a strong rationale for further studies on Plebeian herba as a strategy to prevent type 2 diabetes. Furthermore, horticultural production is increasingly oriented toward high-quality products, in particular for the contents of antioxidants including ascorbic acid and phenolics. Thus, the production of high-quality plant tissues requires optimization of the growth environment for consistent production of specific metabolites, such as phenolics and flavonoids.

MATERIALS AND METHODS

Apparatus. ^{1}H nuclear magnetic resonance (NMR, 600 MHz), ^{13}C NMR (150 MHz), ^{1}H−^{1}H correlation spectroscopy (^{1}H−^{1}H COSY), heteronuclear single quantum coherence, heteronuclear multiple bond correlation (HMBC), and rotating-frame overhauser enhancement (ROE) spectroscopy spectra were recorded on a Bruker AV600 instrument (Bruker Biospin GmbH, Rheinstetten, Germany); chemical shifts are given in δ (ppm) relative to the solvent signal (CD_3OD, δ_H 3.31; δ_C 49.01, 300, or 243 K). Electrospray ionization (ESI) time-of-flight mass spectrometry (TOFMS) was carried out on a QSTAR Elite system (AB Sciex, Tokyo, Japan). All chromatographic experiments were carried out on an high performance liquid chromatography (HPLC) system (Hitachi, Tokyo, Japan), which consisted of an L-7150 pump, a 7161 injector (Rheodyne, loop capacity: 10 mL), an L-7455 diode-array detector (DAD, optical path length of a flow cell: 0.2 mm), and an SF-2120 fraction collector (Advantec, Tokyo, Japan). Chromatograms were recorded on a personal computer using D-7000 chromatography data station software (Hitachi). HSCCC experiments were carried out using an HPLC system (Hitachi) equipped with a type-J coil-planet centrifuge (J-CPC) (Easy-PREP 320, Kutsuwa Sangyo, Hiroshima, Japan) between the 7161 injector and L-7455 DAD. The J-CPC apparatus contains three multilayer-coil separation columns placed symmetrically at a distance of 7 cm from the central axis of the centrifuge. Each separation column was fabricated by directly winding a single piece of polytetrafluoroethylene (PTFE) tubing (1.6 mm i.d. × 50 m length) onto each column holder. The total capacity of the three columns is about 320 mL. Optical rotations were measured with a P-2200 polarimeter (JASCO, Tokyo, Japan). UV data were measured with a U-2900 spectrophotometer (Hitachi). All solvents (high or HPLC grade) for extraction and chromatographic separation were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

Plant Material and Sample Preparation. In this study, the spray-dried powder of the polyphenol-rich extract from hop bracts (HBP; food additive grade in Japan) was used as a raw material. The factory-scale preparation method for HBP is described in previous papers.[2,4] To describe it briefly, HBP was prepared from the crude hop bract extract supplied by Simon H. Steiner Hopfen GmbH (Germany). The extract was produced by extracting 101 t of the female inflorescence of hop bracts with 50% aqueous ethanol (100 kL, 50 °C, 10 h), centrifuging the material to remove solids, and evaporating ethanol. The bracts were obtained to crush hop cones (cropped in Hallertau, Germany, in 2003) and to remove the lupulin glands by sifting. Next, the crude extract from the 101 t of hop bracts was dissolved in distilled water and passed through a SEPABEADS SP-850 column (150 cm i.d. × 230 cm, Mitsubishi Chemical Corporation, Tokyo, Japan). The column was washed with distilled water (12 kL) and eluted with 50% aqueous ethanol (12 kL). After concentrating the eluting fraction, the concentrated fraction was spray-dried to obtain 2 t of HBP powder (yield: 2.0%). In this study, a small portion of HBP powder (25 g) was used for the following HSCCC separation.

HSCCC Conditions. The HSCCC separation of HBP was carried out using a two-phase solvent system composed of methyl *t*-butyl ether (MTBE)−acetonitrile−0.1% aqueous trifluoroacetic acid (TFA) (2:2:3) in the NP partition mode (initial mobile phase: organic upper-phase (UP) solvent; stationary phase: aqueous lower-phase (LP) solvent). First, the three-coil PTFE columns (capacity: 320 mL) of J-CPC were entirely filled with the LP solvent as a stationary phase. Then, the columns were rotated at 1000 rpm (112*g*), while the UP mobile phase was pumped into the columns in the tail-to-head direction at a flow rate of 4.0 mL/min. After hydrodynamic mixing between the two phases in the columns reached equilibrium, 10 mL of sample solution (5 g of HBP dissolved with 5 mL each of the UP and LP solvents) was injected, and the hydrophobic constituents of the HBP sample were separated using the UP mobile phase. Following elution using UP for 120 min, the mobile phase was switched to LP, which completely eluted the polar constituents retained on the column, and elution was performed using LP for 100 min. During HSCCC separation, the UV absorbance of the eluate was monitored by a DAD. The eluate (12 mL) was collected every 3 min by a fraction collector, and each collected fraction was evaporated and lyophilized. For treatment of 25 g of HBP, HSCCC separation was repeated five times.

HILIC Conditions. The lyophilized HSCCC fractions were further separated by HILIC using an amide column under the following conditions. HILIC separation was carried on a TSKgel Amide-80 column (21.5 mm i.d. × 300 mm, 10 μm, Tosoh, Tokyo, Japan) protected with a guard column (21.5 mm i.d. × 75 mm). The mobile phase consisted of eluent A (90% aqueous acetonitrile) and eluent B (50% aqueous acetonitrile). A multilinear gradient was applied from 100:0 (A:B) to 80:20 over 20 min, and then it was changed to 50:50 over 60 min. The flow rate was maintained at 13 mL/min, and the sample solution (a maximum of 200 mg of a lyophilized HSCCC fraction dissolved in a maximum of 10 mL of eluent A) was injected through a sample loop. During HILIC separation, the UV absorbance of the eluate was monitored by a DAD. The eluate (13 mL) was collected every 1 min by a fraction collector, and each collected fraction was evaporated and lyophilized.

RP-HPLC Conditions Using ODS Column. The lyophilized HILIC fractions were further separated by RP-HPLC using an ODS column under the following conditions. The RP-HPLC separation was carried out on a Mightysil RP-18 GP column (10 mm i.d. × 250 mm, 5 μm, Kanto Chemical, Tokyo, Japan) protected with a guard column (10 mm i.d. × 10 mm). The mobile phase consisted of eluent A (10% aqueous acetonitrile) and eluent B (50% aqueous acetonitrile). An isocratic elution of 100:0 (A:B) was started for 20 min, and then a linear gradient was applied from 100:0 to 50:50 over 40 min. The flow rate was maintained at 13 mL/min, and the sample solution (a maximum of 100 mg of a lyophilized HILIC fraction dissolved in a maximum of 5 mL of eluent A) was injected through a sample loop. During RP-HPLC separation, the UV absorbance of the eluate was monitored by a DAD. The eluate (13 mL) was collected every 1 min by a fraction collector, and each collected peak fraction was evaporated and lyophilized.

RP-HPLC Conditions Using Phenyl Column. When the isolation of a pure compound by the above RP-HPLC method was unsuccessful, a further RP-HPLC separation step using a phenyl column was performed under the following conditions. The RP-HPLC separation was carried out on an Inertsil Ph-3 column (10 mm i.d. × 250 mm, 5 μm, GL Science, Tokyo, Japan) protected with a guard column (10 mm i.d. × 10 mm). The isocratic elution of a mobile phase with aqueous acetonitrile (an appropriate volume ratio was applied on a case-by-case basis) was performed at a flow rate of 13 mL/min. The sample solution (a maximum of 100 mg of a lyophilized RP-HPLC fraction obtained from step 3 dissolved in a maximum of 5 mL of the mobile phase) was injected through a sample loop. During RP-HPLC separation, the UV absorbance of the eluate was monitored by a DAD. The eluate (13 mL) was collected every 1 min by a fraction collector, and each collected peak fraction was evaporated and lyophilized.

Ultrafiltration. For the purification of high-molecular-weight compounds (proanthocyanidins) in HSCCC fraction J, ultrafiltration was performed under the following conditions. A portion of the lyophilized powder of fraction J dissolved in 50% methanol was applied to an Amicon ultra filter device (exclusion molecular weight limit: 3000 Da, Millipore) and centrifuged (14000*g*, 30 min). The concentrated solution containing highly oligomeric proanthocyanidins (over 20-mers) was washed with the dissolving solvent twice and was evaporated and lyophilized for further NMR analysis.

RESULTS AND DISCUSSION

HSCCC Separation and Fractionation of Hop Bract Extract. In this study, the spray-dried powder of HBP was used as raw material. HBP contains various types of polyphenolic compounds,[4] but the phenolic composition of HBP has yet to be fully elucidated. First, the constituents of HBP were fractionated by HSCCC using a two-phase solvent system composed of MTBE−acetonitrile−0.1% aqueous TFA (2:2:3) in the NP partition mode (initial mobile-phase: organic UP

solvent; stationary phase: aqueous LP solvent). Ten milliliters of sample solution (5 g of HBP dissolved with 5 mL each of the UP and LP solvents) was injected into the HSCCC column (capacity: 330 mL). To treat 25 g of HBP, HSCCC separation was repeated 5 times. Figure 1 shows the NP-HSCCC

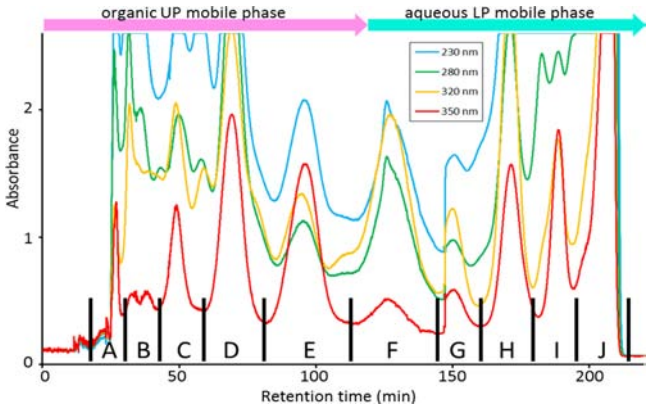

Figure 1. HSCCC separation and fractionation profile of HBP (5 g). Separation was carried out using a two-phase solvent system composed of MTBE–acetonitrile–0.1% aqueous TFA (2:2:3) and NP partition mode (initial mobile phase: organic UP; stationary phase: aqueous LP). Flow rate: 4 mL/min. Retention % of stationary phase: 65%. Other chromatographic conditions: see Materials and Methods. All eluates were collected and divided into 10 fractions (fractions A–J).

chromatogram of HBP (5 g) separation. In the separation profile, hydrophobic constituents of HBP were quickly eluted with the organic UP mobile-phase solvent within 145 min, whereas the polar/hydrophilic constituents were strongly retained on the aqueous LP stationary phase in the HSCCC column. Then, the mobile-phase solvent was switched from UP to LP at 120 min after HBP injection, and then the remaining polar/hydrophilic constituents eluted through the column by 215 min. As shown in Figure 1, all eluates were collected and divided into 10 fractions (fractions A–J). The weights and yields of the fractions are listed in Table 1. The total yield of HBP from the HSCCC method (5 g × 5 times) was calculated to be 90.4%. The yield reveals that almost all of the constituents of HBP are recovered with no loss due to HSCCC treatment because the moisture content of the spray-dried HBP powder is about 5–10%. Among all the HSCCC fractions, the weight and yield of fraction J were the highest—13.5 g, 54.0%. Fraction J was the most hydrophilic fraction, and it contained a wide variety of oligomeric proanthocyanidins (details of the characterization of the fraction J constituents are described below). Furthermore, the moderate hydrophobic polyphenols of the above HSCCC fractions (except for hydrophilic fraction J and hydrophobic fractions A and B) were sequentially separated by conventional HPLC. Unfortunately, the sequential separation for the fractions A and B were incomplete in the present study because the constituents in the both fractions were too hydrophobic for next HILIC separation.

Sequential Chromatographic Isolation of Polyphenolic Constituents of the HSCCC Fractions of HBP. The phenolic constituents of the HSCCC fractions C–I were further separated by HILIC using an amide column followed by RP-HPLC using ODS and phenyl columns. The schemes for sequential HPLC separation of HSCCC fractions C–I are shown in Figure 2. As a result of comprehensive HPLC separation, 102 types of single-peak compounds were isolated and recovered with amounts ranging from 0.1 mg to 40 mg. Furthermore, the structures of the compounds were elucidated on the basis of their spectroscopic data including ESI-TOFMS and 1D/2D NMR.

Structural Analyses of the Isolated Compounds. Among the isolated compounds described above, 35 known compounds, 1 known compound identified for the first time in plants, and 3 new compounds were found. As shown in Table 2, the structures of the 35 known compounds (**5**–**39**) were identified by comparing their LC retention times, MS, NMR, and other spectroscopic data with those of experimental and literature values of standard compounds. They included 2-(2-methylbutyryl)phloroglucinol-1-*O*-*β*-glucopyranoside (**5**);[16] 2-isobutyrylphloroglucinol-1-*O*-*β*-glucopyranoside (**6**);[16] 3-*O*-caffeoylquinic acid (**7**);[17] 4-*O*-caffeoylquinic acid (**8**);[17] 5-*O*-caffeoylquinic acid (**9**);[17] 4-*O*-*β*-glucopyranosyl-*p*-coumaric acid (**10**);[18] *trans*-3-*O*-*p*-coumaroylquinic acid (**11**);[19] *cis*-3-*O*-*p*-coumaroylquinic acid (**12**);[19] 4-*O*-*p*-coumaroylquinic acid (**13**);[20] 3-*O*-feruloylquinic acid (**14**);[21] 4-*O*-feruloylquinic acid (**15**);[21] kaempferol-3-*O*-*β*-glucopyranoside (**16**);[22] quercetin-3-*O*-*β*-glucopyranoside (**17**);[22] kaempferol-3-*O*-*β*-rutinoside (**18**);[22] kaempferol-3-*O*-*β*-neohesperidoside (**19**);[22] quercetin-3-*O*-*β*-neohesperidoside (**20**);[22] quercetin-3-*O*-(2″-*O*-*α*-rhamnosyl-6″-*O*-malonyl)-*β*-glucopyranoside (**21**);[22] myricetin-3-*O*-*β*-glucopyranoside (**22**);[22] kaempferol-3-*O*-*β*-(6-*O*-malonyl)-glucopyranoside (**23**);[23] quercetin-3-*O*-*β*-(6-*O*-malonyl)-glucopyranoside (**24**);[23] procyanidin B1 (**25**);[24] epicatechin-(4*β*-8)-epicatechin-(4*β*-8)-catechin (**26**);[25] epicatechin-(4*β*-6)-epicatechin-(4*β*-8)-catechin (**27**);[25] tryptophan (**28**); 2-(3-hydroxy-2-oxoindolin-3-yl)acetic acid (**29**);[26] 1,2,3,4-tetrahydro-*β*-carboline-3-carboxylic acid (**30**);[27] 1-methyl-1,2,3,4-tetrahydro-*β*-carboline-3-carboxylic acid (**31**);[28] pinoresinol-4″-*O*-*β*-glucopyranoside (**32**);[29] isolariciresinol-3*α*-*O*-*β*-glucopyranoside (**33**);[30] lariciresinol-4-*O*-*β*-glucopyranoside (**34**);[31] (3*S*)-*O*-*β*-glucopyranosyl-6-[3-oxo-(2*R*)-butenylidenyl]-1,1,5-trimethylcyclohexane-(5*R*)-ol (**35**);[32] dihydrovomifoliol-3′-*O*-*β*-glucopyranoside (**36**);[33] 5-*O*-*β*-xylopyranosylgentisic acid (**37**);[34] 4-*O*-*β*-glucopyranosyl-*p*-hydroxybenzoic acid (**38**);[35] and (2*E*,4*E*)-8-*β*-glucopyranosyloxy-2,7-dimethyl-2,4-decadiene-1,10-dioic acid (**39**).[36] The 20 compounds (**10**–**15**, **21**, **22**, **27**, **29**–**39**) have not been reported from hops.

The spectroscopic data of compounds (**1**–**4**) are also shown in Tables 2–4. Compound **1** was obtained as a yellow amorphous powder. Its TOFMS signal (*m*/*z* 431.2273 [M + H]$^+$) confirmed that its molecular formula was $C_{21}H_{34}O_9$. The ^{1}H NMR spectrum of **1** showed two *trans*-coupled olefinic signals ($^3J_{H\text{-}4,H\text{-}5}$ = 15.6), a singlet olefinic signal, an oxygen-

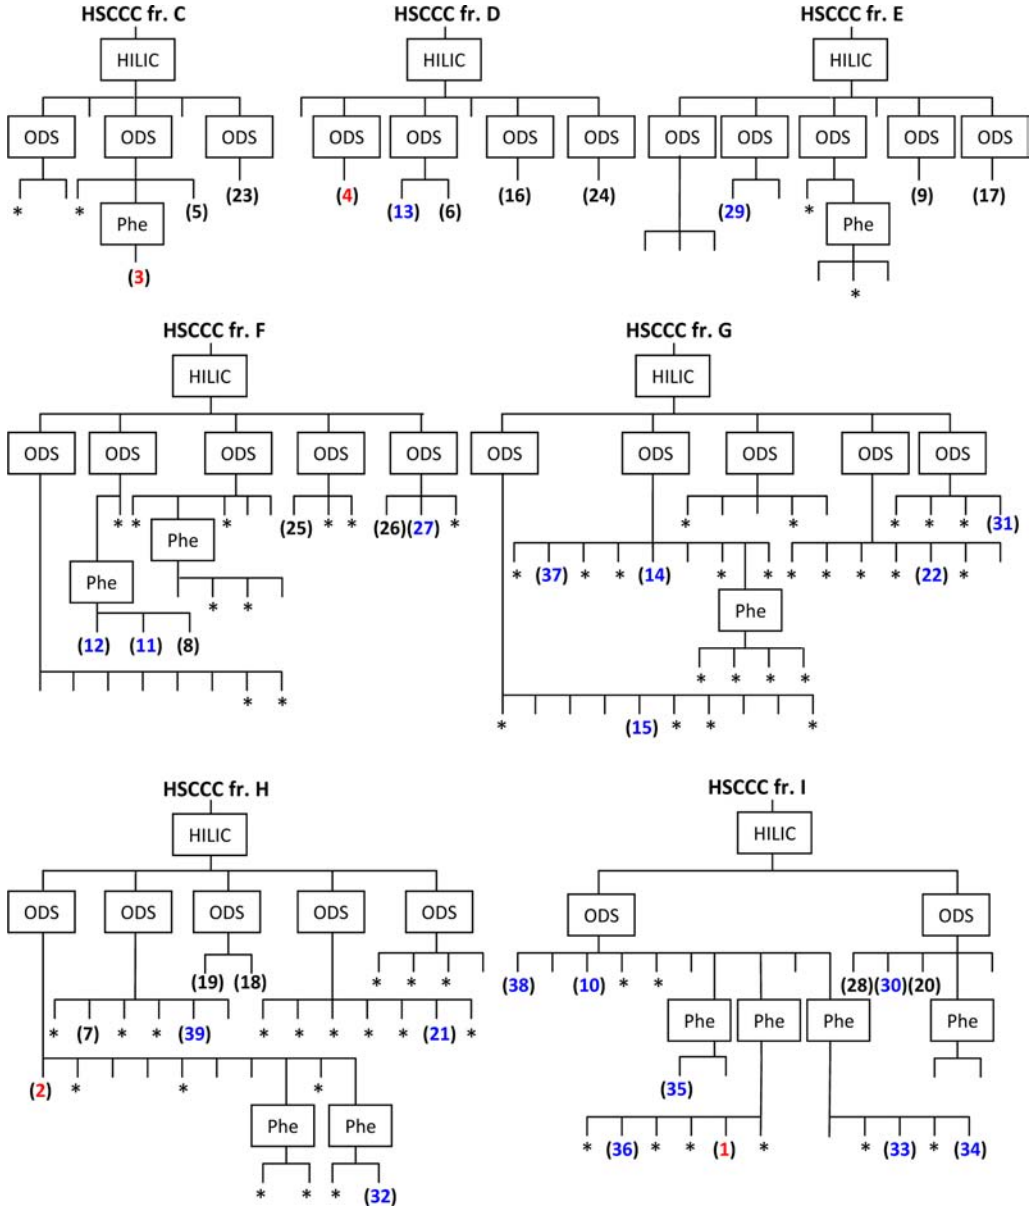

Figure 2. Schemes of sequential HPLC separations of HSCCC fractions C–I. Numbers in red indicate new compounds and a known one, which has been identified for the first time in plants. Numbers in blue indicate known compounds that have not been reported from hops. Asterisk (*) indicates isolated compounds whose structures could not be determined in this study.

bearing methine signal, a sugar moiety, four methylene signals, a methine signal, a secondary methyl group, two tertiary methyl groups, and an olefinic methyl group (Table 3). The $^{1}H-^{1}H$ COSY correlation from H-4 to H-5 and the HMBC correlations from H-2 to C-1 and from H-6 to C-2, C-3, and C-4 indicated the presence of the 3-methyl-2,4-pentadienoyl group (Figure 3). The proton connectivities of H-7′, H-2′, H-3′, H-4′, and H-5′ assigned by $^{1}H-^{1}H$ COSY and the HMBC correlations from H-2′ax, H-3′eq, H-5′eq, H-8′, and H-9′ to C-1′ and from H-5′ax, H-5′eq, H-8′, and H-9′ to C-6′ supported the presence of the 1,4-dihydroxy-2,6,6-trimethylcyclohexane moiety (Figure 3). The HMBC correlation between H-5 and C-1′ indicated that the acyl group was attached at C-1′, suggesting that **1** has 2′,3′,4′,4′-tetrahydroabscisic acid as the aglycon portion (Figure 3).[37] The ROE correlations from H-2′ax to H-4′ax and H-8′ and from H-5 to H-3′ax and H-5′ax supported the chair conformation. The ROE between H-2 and H-6 indicated the *cis* orientation of H-2 with respect to H-6 (Table 3). Coupling constants in ^{1}H NMR and chemical shifts in ^{13}C NMR supported the presence of the *O*-*β*-glucopyranosyl moiety (Table 3). The HMBC correlation between H-Glc1 and C-1 confirmed that the sugar moiety was attached at C-1. Therefore, the structure of **1** was confirmed to be 1-*O*-(2′,3′,4′,4′-tetrahydroabscisoyl)-*β*-glucopyranose (Figure 4).

Compound **2** was obtained as a yellow amorphous powder. Its TOFMS signal (*m*/*z* 142.0497 $[M + H]^{+}$) confirmed that the molecular formula was $C_6H_7NO_3$. The ^{1}H and ^{13}C NMR spectra of **2** were consistent with those of a known chemical synthetic intermediate, (*R*)-4-methylene-5-oxopyrrolidine-2-carboxylic acid.[38] The absolute configuration of the structure was expected to have the 2*S*-form because of positive optical rotation, the sign of which was reversed compared to the literature value of the above compound, and this was consistent with L-pyroglutamic acid in methanol. On the basis of these

[a]Not detected.

data, **2** was determined to be (*S*)-4-methylene-5-oxopyrrolidine-2-carboxylic acid, which was identified for the first time in plants (Figure 4).

Compounds **3** and **4** were obtained as yellow amorphous powders. Their molecular formulas were determined to be $C_{15}H_{16}O_8$ and $C_{16}H_{18}O_9$ (*m*/*z* 325.0912 $[M + H]^+$ and 355.1007 $[M + H]^+$), respectively, by TOFMS analyses. The ^{1}H NMR spectrum of **4** was similar to that of **3**, except for the presence of a methoxy signal and the integral values of the olefinic signals. The ^{13}C NMR spectra of **3** and **4** supported the presence of the *p*-coumaroyl group (*δ* 127.1, 131.2, 116.8, 161.4, 116.8, 131.2, 147.0, 114.8, and 168.9) in **3** and the feruloyl group (*δ* 127.7, 111.8, 149.4, 150.7, 116.5, 124.2, 147.3, 115.1, 168.8, and 56.4) in **4** (Table 4). The ^{1}H and ^{13}C NMR spectra of **3** and **4** indicated that they contain the same sugar moiety; it was identified to be galactono-1,4-lactone[39] by coupling constants ($^3J_{H\text{-}2,H\text{-}3}$ = 8.7, $^3J_{H\text{-}3,H\text{-}4}$ = 8.7, $^3J_{H\text{-}4,H\text{-}5}$ = 2.4, $^3J_{H\text{-}5,H\text{-}6}$ = 6.0, 6.9, and $^3J_{H\text{-}6,H\text{-}6}$ = 11.1 in **3** and $^3J_{H\text{-}2,H\text{-}3}$ = 8.1, $^3J_{H\text{-}3,H\text{-}4}$ = 8.1, $^3J_{H\text{-}4,H\text{-}5}$ = 2.4, $^3J_{H\text{-}5,H\text{-}6}$ =5.7, 7.5, and $^3J_{H\text{-}6,H\text{-}6}$ = 11.1 in **4**), the HMBC correlation between H-2 and C-1, and the isotopic shifts of C-2, C-3, and C-5 in the H−D exchange experiments (CD_3OH and CD_3OD); the moiety was confirmed by a comparison of experimental values with a standard compound (Table 4). The HMBC correlation between H-6 and C-9′ confirmed that the sugar moiety was attached at C-9′. The absolute configuration of the sugar moiety in **4** was expected to have the L-form because of positive optical rotation, which was consistent with L-galactono-1,4-lactone in methanol. The absolute configuration of **3** was expected to have the same form, although the optical rotation of **3** could not be observed because of its small amount. Therefore, the structures of **3** and **4** were determined to be 6-*O*-*p*-coumaroyl-L-galactono-1,4-lactone and 6-*O*-feruloyl-L-galactono-1,4-lactone, respectively (Figure 4). To our knowledge, compounds **1**−**4** have been identified for the first time in plants.

Structural Characterization of Hydrophilic Proanthocyanidins in HBP. As shown in Figure 1 and Table 1, the constituents of HSCCC fraction J were a mixture of the most

abundant and hydrophilic compounds in HBP. Further LC separations (HILIC and ODS) of the fraction J constituents were incomplete because both chromatograms showed an unresolved broad peak (data not shown). It was noted that hops contain an abundance of proanthocyanidins with different degrees of polymerization (DP),[40] and the hydrophobicity of oligomeric proanthocyanidin significantly decreases as its DP value increases.[41] Furthermore, in our preliminary examinations, the acid hydrolysis of the fraction J constituents resulted in the production of a large amount of red pigments (anthocyanidins), and the gel-permeation chromatogram of fraction J showed a broad and large peak, which was attributed

to the existence of high-molecular-weight compounds (over 3000 Da). These results revealed that the main constituents of fraction J are highly oligomeric proanthocyanidins. Then, for the further purification of the high-molecular-weight compounds (proanthocyanidins) in fraction J, ultrafiltration was performed. In our previous study,[3] highly oligomeric proanthocyanidins (over 20-mer) were purified and concentrated by this treatment. As shown in Figure 5, the ^{1}H NMR spectrum of the highly purified oligomeric proanthocyanidins from fraction J showed broad peaks at δ 6.3−7.2 (H-2′, H-5′, and H-6′), 5.7−6.2 (H-6 and H-8), 5.1 (H-2), 4.2−4.8 (H-4 in interflavan linkages), 3.5−4.0 (H-3), and 2.3−2.7 (H-4) that matched catechin or epicatechin units (Figure 5). The ^{13}C NMR spectrum also showed broad peaks at δ 156 (C-5, C-7, and C-8a), 146 (C-3′ and C-4′), 132 (C-1′), 119 (C-6′), 115 (C-2′ and C-5′), 107 (C-6 or C-8 in interflavan linkages), 97 (C-4a, C-6, and C-8 that are not used in interflavan linkages), 77 (C-2), 73 (C-3), 38 (C-4 in interflavan linkages), and 30 (C-4), indicating that the proanthocyanidins in the hop bract extract are B-type procyanidins, with flavan-3-ol units that are linked through C-4 to C-8 (or C-6) interflavan bonds (Figure 5).[25]

In the present LC separation scheme of the hop bract extract, HSCCC using a two-phase solvent system was highly effective, resulting in high-recovery separation and in the considerable reduction of the amount of extract utilized. The comprehensive

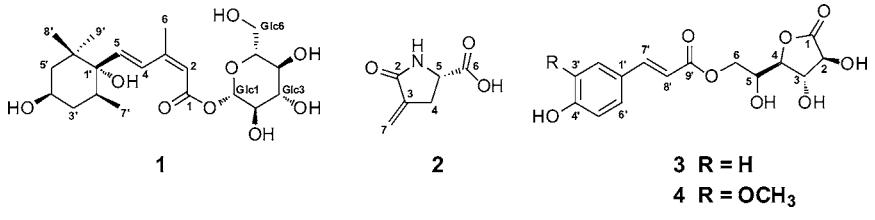

Figure 4. Structures of 1−4.

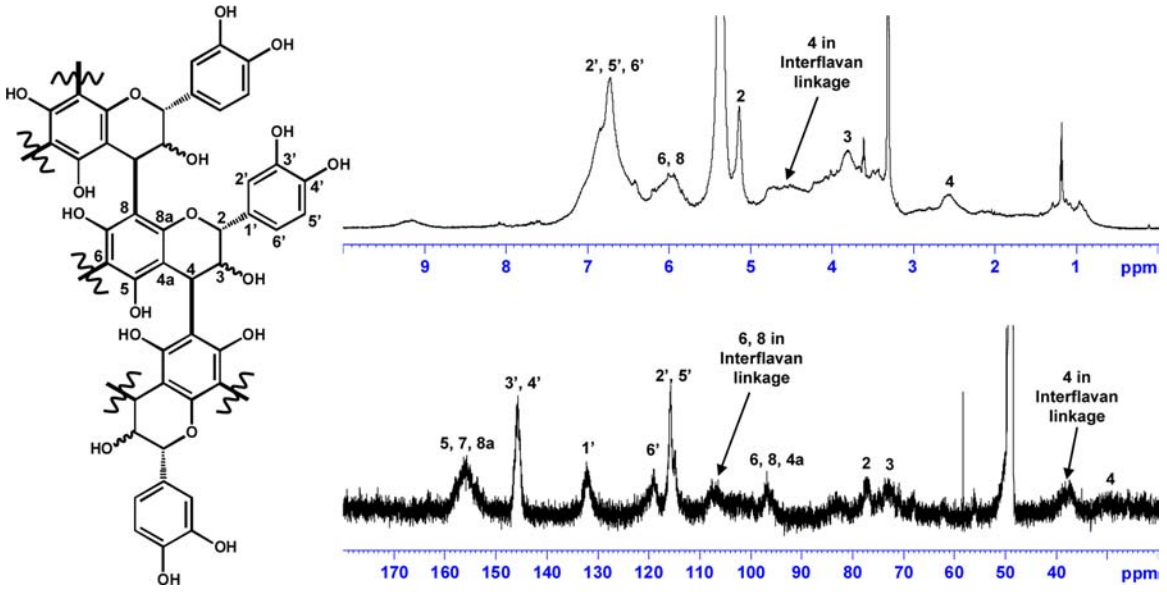

Figure 5. ^{1}H and ^{13}C NMR spectra of high-molecular-weight proanthocyanidins in HBP.

separation and structural analyses resulted in four compounds that have been identified for the first time in plants, and 20 compounds that have not been reported from hops were also identified. Most of the compounds were hydrophilic glycosylated and/or esterified analogues of abscisic acids, hydroxycinnamic acids, flavonols, lignans, hydroxybenzoic acids, or carotenoid. In addition, large amounts of highly oligomeric proanthocyanidins were found in the hop bract extract. They were easily separated from the hydrophilic fraction (fraction J) by the first HSCCC fractionation following ultrafiltration. Furthermore, the ^{1}H and ^{13}C NMR spectra revealed that hop proanthocyanidins have B-type procyanidin structures, which is in agreement with previous studies.[24,42] Hereafter, biological studies of all isolated compounds are needed for the elucidation of the various physiological activities of hop compounds and the industrial uses of hop bracts.

1-*O*-(2′,3′,4′,4′-Tetrahydroabscisoyl)-*β*-glucopyranose (1). NOTE ADDED AFTER ASAP PUBLICATION

This paper was published ASAP on February 26, 2014, with Figures 3 and 4 incorrectly cited, and an error to Figure 5. The corrected version was reposted on February 28, 2014.

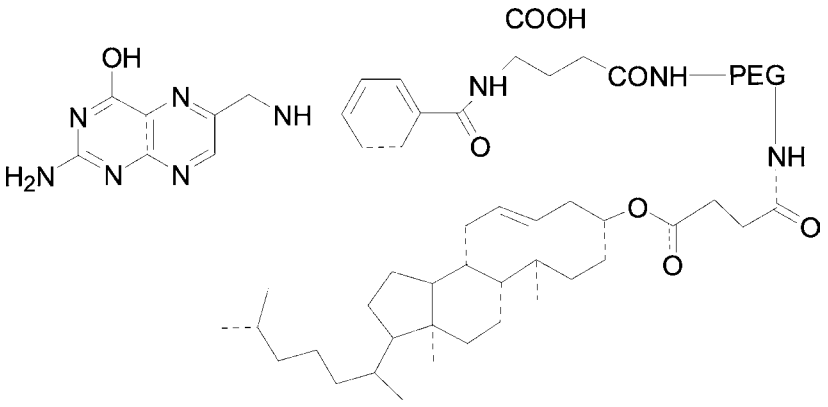

Figure 2. Molecular structure of folate-PEG-CHEMS.

novel lipophilic folate derivative; its amide and ester linkages are certainly more resistant to hydrolysis than other lipophilic derivatives, such as folate-PEG-DSPE and folate-PEG-cholesterol.[31] We examined tumor cell uptake performance of this folate conjugate. Then, we used the thin-film dispersion method to prepare folate-targeted liposomal UA (FTL-UA) and determined its mean diameter, zeta potential, entrapment efficiency, and stability. We investigated in vitro cellular cytotoxicity, apoptosis, cell cycle analysis, in vivo pharmacokinetic studies, and antitumor efficiency on KB xenografts.

MATERIALS AND METHODS

Materials. UA and folate-PEG-CHEMS were obtained from the pharmacy school of Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China (purity > 95%). Hydrogenated soybean phosphatidylcholine (HSPC) was purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA). Monomethoxy polyethylene glycol 2000-distearoyl phosphatidylethanolamine (mPEG-DSPE2000) was obtained from Lipoid GmbH (Germany). Cholesterol (CHOL) was purchased from Acros Organics. Calcein was obtained from Aladdin Chemistry Co. Ltd. Folic acid was purchased from Sinopharm Chemical Regent Co., Ltd. All solvents and reagents were of analytical or HPLC grade and used without further purification.

RPMI 1640 media and Hoechst 33258 (product B 2883) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). Annexin V/PI apoptosis kits were purchased from MultiSciences Biotech, Hangzhou, China. Methylthiazolyl-diphenyl-tetrazolium bromide (MTT), cell cycle and apoptosis analysis kit, penicillin−streptomycin solution, and trypsin solution were purchased from Beyotime Institute of Biotechnology, Jiangsu, China. Fetal bovine serum (FBS) was purchased from Zhejiang Tianhang Biological Technology Co., Ltd., Hangzhou, China. Human oral cancer KB cell line has been identified as being derived from the human oral epidermoid carcinoma cancer and obtained from a cell bank (Wuhan University, Hubei, China).

Female Kunming mice (25 g, 6−8 weeks old) and female Balb/c nu/nu mice (20 g, 6−8 weeks old) were obtained from Beijing Huafukang Bioscience Technology Co. (Beijing, China; license SCXK (jing) 2009-0004).

Preparation of Liposomes. The thin-film dispersed hydration method was used to prepare liposomes encapsulating UA.[32] The lipid compositions of the nontargeted PEGylated liposome (PL-UA) and the FR-targeted liposome (FTL-UA) were HSPC/CHOL/mPEG-DSPE2000 at a molar ratio of 63:32:5 (at weights of 48, 12, and 16.7 mg) and HSPC/CHOL/mPEG-DSPE2000/F-PEG-CHEMS at a molar ratio of 63:32:4.5:0.5 (at weights of 48, 12, 13.4, and 5 mg), respectively. UA to lipid ratio is 1:20 (w/w). Liposome colloidal suspensions were prepared by dissolving the lipid mixture (about 78 mg) in chloroform and dried to form a thin lipid film in a pear-shaped glass flask on a rotary evaporator under reduced pressure at 40 °C. Traces of residual solvent were eliminated overnight at room temperature by using a glass drying oven connected to a vacuum pump. The resulting lipid film was hydrated in 4 mL of phosphate-buffered saline (PBS, pH 6.8) and incubated at 60 °C for 30 min. The suspension of lipids was then extruded five times through a 0.2 μm pore size polycarbonate membrane to produce unilamellar vesicles distributed more uniformly with a Lipex Extruder (Northern Lipids Inc., Vancouver, BC, Canada) driven by pressurized nitrogen (0.5−1.0 MPa) at 60 °C.

Determination of Entrapment Efficiency. The entrapment efficiency of the liposome was evaluated after removal of the free UA (low-speed centrifugation at 3000*g* for 10 min at room temperature to separate the free UA; liposome was dispersed in the supernatant liquid). UA concentration in the liposome was determined by HPLC measuring absorption at 210 nm following liposome lysis in methanol. The amount of UA entrapped in liposome was determined as a difference between the amount of UA initially added during liposome preparation and the amount of the entrapped UA present in the supernatant liquid following lysis. The drug loading efficiency was calculated using the following equation:[33]

$$\text{entrapment efficiency (\%)} = \frac{\text{amount of encapsulated UA in liposome}}{\text{amount of UA initially added}} \times 100$$

Characterization of Liposome. The size distribution of the liposomes was determined by dynamic light scattering on a DelsaNano series (Beckman Coulter, Inc., Fullerton, CA, USA). All particle size data refer to volume-weighted distributions, and liposomes were diluted to appropriate concentrations and measured at 25 °C. The zeta potential of the liposome indicates the charge on the surface of liposome, which was measured by Zeta PALS (Zeta Potential Analyzer, Brookhaven Instruments Corp., Holtsville, NY, USA) at 25 °C.

Cell Culture. Human oral cancer KB cell line was cultured in folate-free RPMI 1640 media supplemented with 100 U/mL penicillin, 0.1 mg/mL streptomycin, and 10% fetal bovine serum (FBS). Cells were maintained in a humidified atmosphere containing 5% CO_2 at 37 °C.

Uptake of FR-Targeted Liposome Assay. KB cells in logarithmic phase were suspended with trypsin and collected in Eppendorf tubes. The cell suspension was centrifuged at 1000*g* for 5 min. The supernates were discarded, the precipitants were resuspended with folate-free RPMI-1640 media, and KB cells treated with various drugs were incubated for 1 h at 37 °C. The various drugs were nontargeted liposomal calcein (L-calcein) and FR-targeted liposomal calcein (F-L-calcein). To determine the role of FR binding, 0.1 mL of folate (10 mM) was added to the media in the FR blocking group. After incubation, the cells were washed three times with cold PBS to remove unbound liposomes. Then, for quantification analysis, resuspended cells in PBS were analyzed by flow cytometry using a BD-LSRFortessa flow cytometer (BD Biosciences, USA), with an

excitation wavelength of 488 nm, with results expressed as mean fluorescence intensity.

Cytotoxicity Assay. The cytotoxic effects of free UA or UA liposomal formulations were evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. KB cells grown in folate-free RPMI 1640 medium were placed in 96-well tissue culture dishes at 6×10^4 cells/mL, cultured for 24 h, and then incubated with various concentrations (6, 12.5, 25, 50, 100, and 200 μM) of the UA sample including free UA, PL-UA, FTL-UA, and FR blocking group for an additional 48 or 72 h. Then, 20 μL of MTT (5 mg/mL) was added to each well, and the 96-well plate was incubated for 4 h at 37 °C. Medium was removed and replaced with 150 μL of DMSO to dissolve the blue formazan crystals produced by live cells. The plates were then read on an ELISA reader (Thermo Labsystems, Shanghai Co. Ltd., Vantaa, Finland), and the cell viability ratio was determined from the absorbance measured at 492 nm.

Nuclear Staining with Hoechst 33258. The nuclear morphology of cells was evaluated using the cell-permeable DNA dye, Hoechst 33258, which is a DNA-specific fluorescent dye. It is an apporpriate fluorochrome for chromosome analysis, because it penetrates cell membranes significantly. The KB cells were seeded in 24-well plates and were divided into four groups at the concentration of 1.0×10^5 cells/mL. Twenty-four hours after seeding, the cells were treated with PBS, 50 μM PL-UA, 50 μM FTL-UA, and 50 μM FR blocking group, repectively, and further incubated for 24 h at 37 °C. The cells were fixed for 10 min in 1 mL of 4% paraformaldehyde at 4 °C and washed with ice-cold PBS (2 × 1 mL). Hoechst 33258 (1 mL) was added at a final concentration (5 μg/mL) and incubated for 10−20 min at 37 °C. Hoechst 33258, which was not ingested by KB cells, was removed by ice-cold PBS (2 × 1 mL washes). To examine the degree of cell apoptosis, the stained cells were observed under the inverted fluorescence microscope equipped with an Olympus color digital camera (exposure factor was 30).

Cell Cycle Analysis. To determine the proportion of apoptotic sub-G1 hypodiploid cells, we conducted cell cycle assay by flow cytometry. The KB cells were placed in 6-well plates, divided into four groups at the concentration of 4.7×10^5 cells/mL, and, 24 h after plating, the cells were treated with PBS, 50 μM PL-UA, 50 μM FTL-UA, and 50 μM FR blocking group, respectively. Then, after 24 h, the cells were digested by trypsin, washed with ice-cold PBS (1 × 1 mL), and fixed for 24 h in 1 mL of 70% ethanol at 4 °C. The KB cells were washed with ice-cold PBS (2 × 1 mL) and were treated in 0.5 mL of propidium iodide (PI) staining buffer from the 3 mL staining buffer containing 150 μL of PI and 60 μL of RNaseA for 30 min in the dark at 37 °C. Flow cytometric analysis was conducted using flow cytometry. The effects on cell cycle assay were demonstrated by differences in the percentage of cell distribution at each phase of the cell cycle.

Cell Apoptosis Assay. The KB cells were divided into four groups at a concentration of 4.7×10^5 cells/mL in 6-well plates and cultured for 24 h. After treatment with PBS, 50 μM PL-UA, 50 μM FTL-UA, and 50 μM FR blocking group for 24 h at 37 °C, KB cells were harvested and washed with ice-cold PBS (1 × 1 mL). The harvested cells were incubated for 5 min in the binding buffer containing 5 μL of Annexin V-FITC and 10 μL of PI at room temperature in the dark and then were washed twice with ice-cold PBS. Afterward, the stained cells were analyzed by flow cytometer, and then were defined as follows: upper left quadrant (Q_1), primary necrotic cells (Annexin V−/PI+); upper right quadrant (Q_2), late apoptotic cells (Annexin V+/PI+); lower left quadrant (Q_3), living cells (Annexin V−/PI−); lower right quadrant (Q_4), early apoptotic cells (Annexin V+/PI−) .

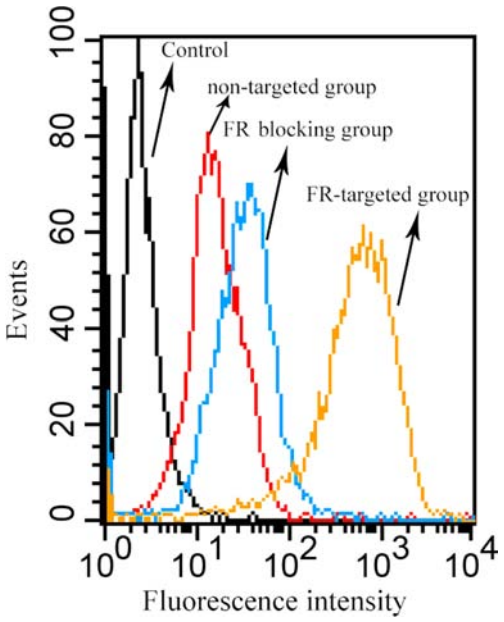

Figure 3. Uptake of calcein-loaded liposome by KB cells measured by flow cytometry. KB cells were treated with PBS (control), L-calcein (nontargeted group), F-L-calcein (FR-targeted group), and F-L-calcein plus 1 mM folate (FR blocking group) for 1 h at 37 °C.

Pharmacokinetic Studies. Animal experiments were carried out in agreement with the principles and procedures outlined by the ethics committee of Huazhong University of Science and Technology (IACUC no. 303). Female Kunming mice (25 g, 6−8 weeks old) were used for pharmacokinetic studies. Free UA, PL-UA, and FTL-UA (20 mg/kg, respectively) were injected (300 μL) through the tail vein (each group of four animals). Blood samples (100 μL) were taken from the mouse eyeball at various times (10 min and 0.5, 1, 2, 4, 8, 12, and 24 h) and placed in Eppendorf tubes containing 20 U of heparin sodium. The samples were centrifuged (5000*g*, 5 min) at room temperature and supernatants collected. Methanol (200 μL) was added to plasma samples to precipitate plasma proteins. Ethyl acetate (400 μL) was added to plasma samples, which were vortex-mixed and then centrifuged (12000*g*, 10 min) at 4 °C. The supernates were collected in Eppendorf tubes, and the ethyl acetate (400 μL) extraction, vortexing, and centrifugation were repeated. The supernates were combined and evaporated to dryness under nitrogen flux at 60 °C (thermostated water bath) and stored at −20 °C. Before the HPLC analysis, the residue was resuspended in methanol (100 μL, HPLC grade) and then centrifuged at 12000*g* for 10 min at 20 °C. The supernate from each sample was collected and placed in HPLC glass vials for the analytical determination. Analysis was performed by using an HPLC system (Waters, Milford, MA, USA) consisting of a 600 binary pump, a 717 plus autosampler, a thermostated column compartment, and a Waters 2487 dual-absorbance detector. Data were acquired and processed with Empower chromatography manager software (Waters). Chromatographic separation was carried out at 20 °C using a Sapphire RP C_{18} column (4.6 × 250 mm, 5 μm particle size, Sepax, USA). The mobile phase consisted of methanol (HPLC grade), ultrapure water, and triethylamine hydrochloride (90:10:0.03 v/v/v) and with glacial acetic acid to adjust the pH to 7.2. The flow rate

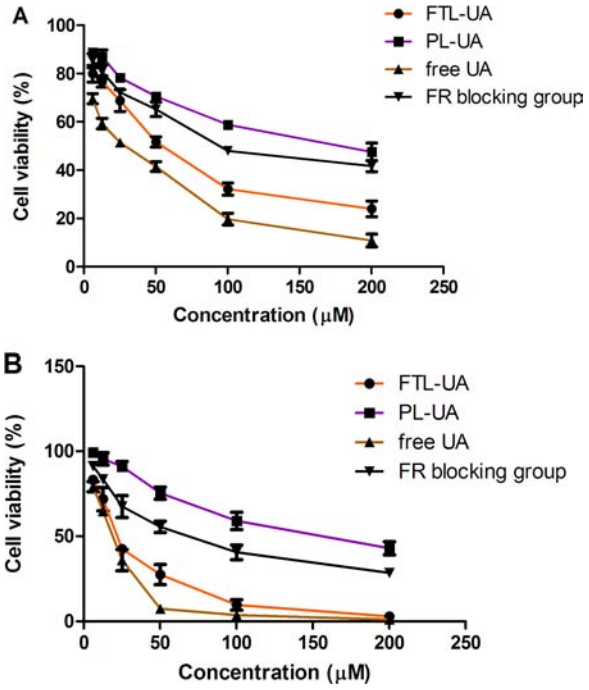

Figure 4. In vitro concentration and time-dependent antitumor effects induced by free UA, PL-UA (nontargeted group), FTL-UA (FR-targeted group), and FR blocking group: (A) 48 h; (B) 72 h. Cytotoxic analysis was performed by MTT assay. $P < 0.05$.

was 1.2 mL/min, and UV detection was performed at 210 nm. The sample and the standards were injected at a volume of 20 μL. The UA quantification was carried out by using an external standard curve in the linear concentration range between 0.4 and 200 μg mL^{-1}. UA was identified by comparison of concentrations (μg mL^{-1}) and peak areas from the chromatograms.

In Vivo Antitumor Assay. KB cells (3.6×10^6), resuspended in 150 μL of 0.9% physiological saline, were inoculated subcutaneously in the right hind flank of each female Balb/c nu/nu mouse (20 g, 6−8 weeks old). On day 7 after tumor implantation, the mice were raised on a folate-free diet for 1 week and maintained on the special feed throughout the study. Mice were randomly distributed into four treatment groups (control, free UA, PL-UA, and FTL-UA) of 6 mice per group. On day 7 after feeding folate-free diet, the tumors were about 60−150 mm^3. Mice (six per group) were given an intravenous injection via the tail vein of different UA formulations at the dose of 4.5 mg/kg every other day for five doses. We chose this total dosage (23 mg/kg) on the basis of the multiple-dose PK study in which 98 mg/m^2 was administered.[14] Then the dosage was calcuated (human body surface area A (m^2) = 0.0061 × height (cm) + 0.0128 × weight (kg) − 0.1529; and animal body surface area formula A (m^2) = $K \times (W^{2/3})/10000$, mice (K value) = 9.1). During the administration, the weight of nude mice and the size of xenografts were measured regularly. Tumor volume was determined by measuring the tumor in three dimensions with calipers and calculated using the formula tumor volume = (width^2 × length)/2. At the end, animals were killed when their tumors reached 2 cm in diameter. Survival cycle was calculated from the first day of treatment until the day of killing. All data analysis was performed using GraphPad Prism version 5.01.

RESULTS AND DISCUSSION

Characterization of Liposomes. In a typical preparation, liposomes were prepared by thin-film dispersion followed by high-pressure extrusion. Mean size distributions of PL-UA and FTL-UA were 150−160 nm. The mean entrapment efficiency of UA was about 87% at the drug/lipid ratio of 1:20 (w/w). The size distribution of the colloidal dispersion (dispersity index) indicates the formation of a colloidal system with a suitable homogeneity (Table 1). The zeta potentials of PL-UA and FTL-UA were −23.15 and −21.24 mV, respectively. The negative zeta potential of the formulations was due to the presence of the negatively charged lipid mPEG-DSPE;[31,34] the

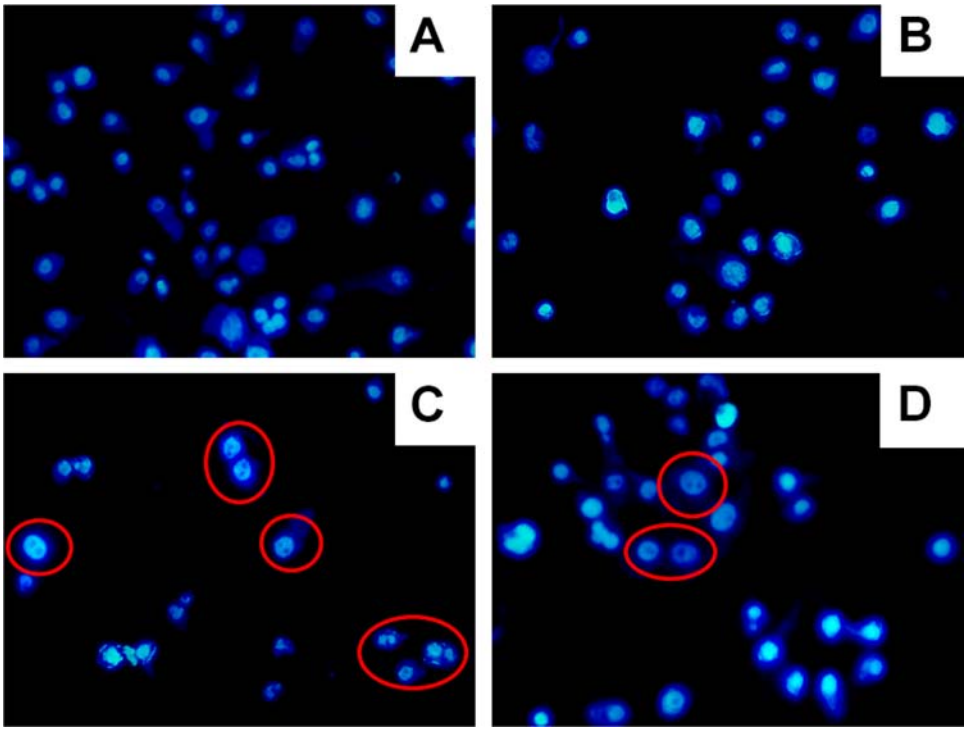

Figure 5. Induction of UA loaded liposome on apoptotic body formation in KB cells: (A) control; (B) nontargeted group (PL-UA); (C) FR-targeted group (FTL-UA); (D) FR blocking group (FTL-UA plus 1 mM folate), containing 50 μM UA, respectively. KB cells stained with Hoechst 33258 were visualized for apoptotic bodies (circled in red) under inverted fluorescent microscope (40×, exposure factor was 30).

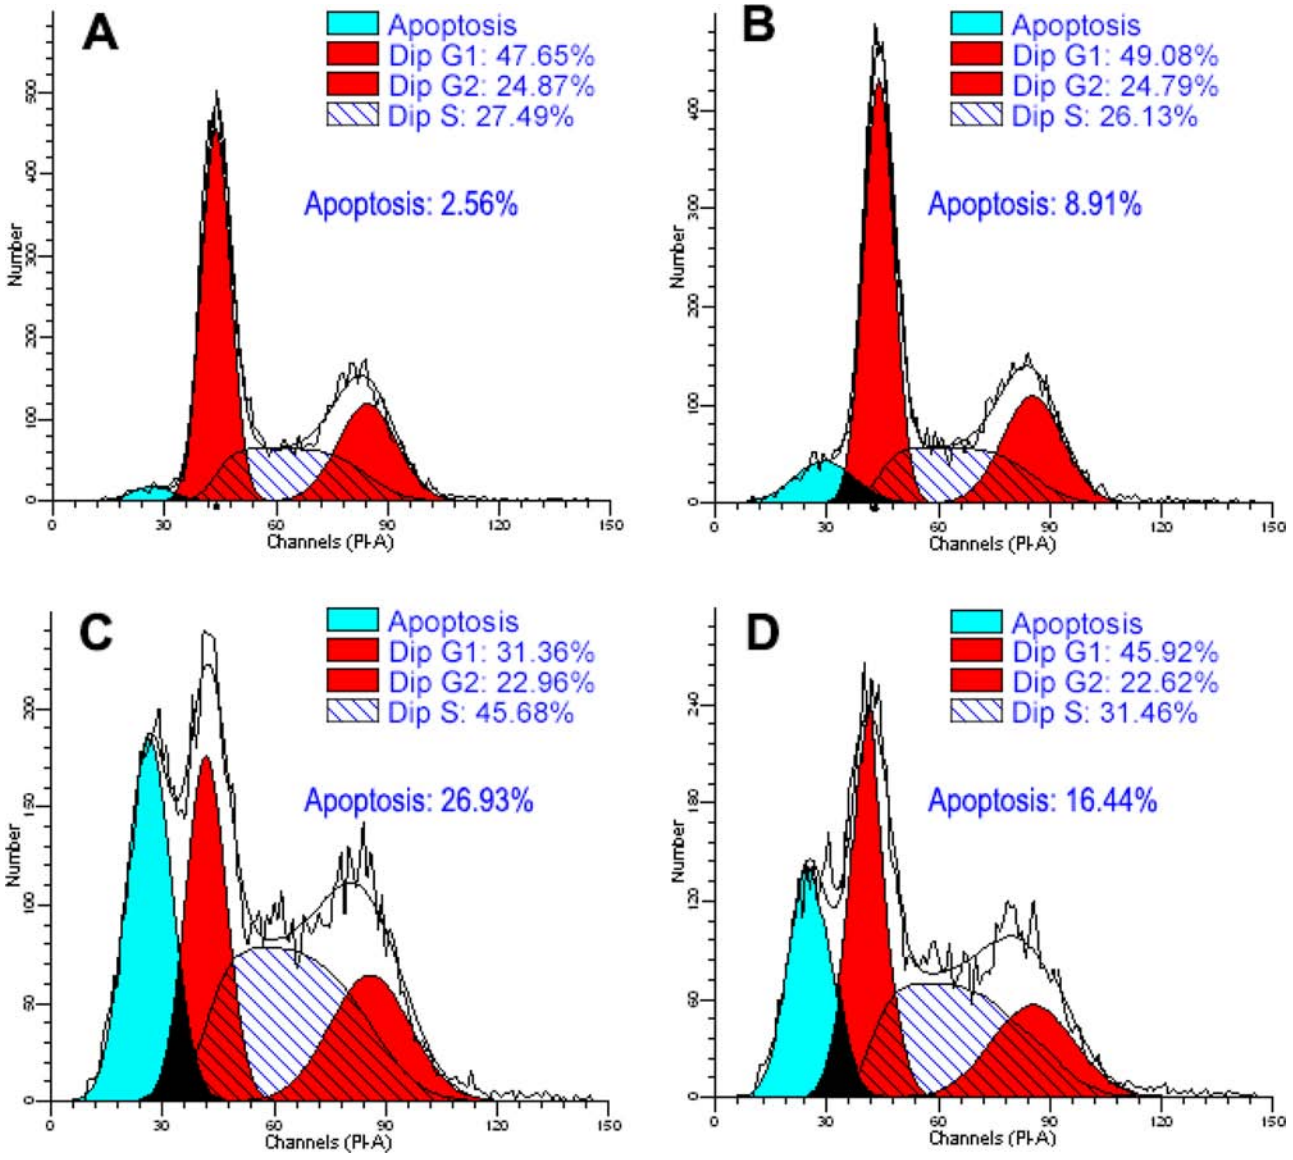

Figure 6. Effect of UA loaded liposome on cell cycle pattern and apoptotic cell proportion in KB cells: (A) control; (B) nontargeted group (PL-UA); (C) FR-targeted group (FTL-UA); (D) FR blocking group (FTL-UA plus 1 mM folate), containing 50 μM UA, respectively. Apoptotic sub-G1 DNA content was detected by flow cytometry after propidium iodide staining.

high negative potential made the particles repel each other. Thus, interparticle aggregation can be avoided, and stability can be maintained for a long period of time.[35] The liposomes showed good stability when stored in PBS at 4 °C. After 3 months in storage, the mean particle size increased from 156 to 177 nm and UA release from the liposomes was <10% (Table 1).

Cellular Uptake Assay. Uptake of FR-targeted liposome by KB cells was analyzed by flow cytometry. Calcein as the fluorescent indicator was entrapped into the liposome aqueous phase. As shown in Figure 3, the fluorescence intensity of F-L-calcein was about 31 times higher than that of L-calcein, and the intensity decreased when 1 mM free folic acid was added. (The mean fluorescence intensities of L-calcein, F-L-calcein, and FR blocking groups were 20.09, 628.14, and 36.28, respectively.) The results indicated that more folate-linked particles were actively taken up by FR-positive cells than the nontargeted particles, and the uptake could be blocked by 1 mM folic acid. These data show that FR-targeted liposomes could effectively target KB cells through the FR-mediated pathway.

In Vitro Evaluation of Cell Viability. Cell viability of free UA and UA loaded liposomes was assayed on KB cells and was compared with the untreated cells. This was carried out to evaluate both the concentration response and the incubation time effect. We first analyzed the effect of different concentrations of free UA, PL-UA, FTL-UA, and FR blocking groups on the inhibition of KB cancer cells. As shown in Figure 4, the cytotoxic effect was observed after 48 and 72 h of incubation of different groups. FTL-UA induced significant time- and dose-dependent effects, and a lower IC_{50} value of FTL-UA versus PL-UA was achieved at 72 h (22.05 vs 146.3 μM). The IC_{50} value of FTL-UA was lower than that of the FR blocking group for KB cell lines (22.05 vs 65.66 μM). These data were consistent with the results from the above-described cellular uptake assay and showed that FTL-UA is potentially useful as a therapeutic agent.

Free UA exerted great efficacy with IC_{50} of 16.49 μM (72 h). Lower IC_{50} values of the free UA in comparison with PL-UA and FTL-UA can be explained by the fact that the conjugates

dx.doi.org/10.1021/jf405675g | J. Agric. Food Chem. 2014, 62, 2207−2215

on the surface of the liposome enter the cells via the slower endocytosis pathways. Therefore, the higher IC_{50} observed for PL-UA and FTL-UA is likely explained by their slower drug release rate and hindered structure, the cytotoxic activity being present only after the drug is released from the liposome.[36]

Nuclear Morphological Analysis. In the qualitative study of inducing cell apoptosis, KB cells were stained with the cell-permeable DNA dye Hoechst 33258 and visualized by inverted fluorescent microscopy (Olympus Corp., Japan). Apoptosis is characterized by typical cellular morphology changes and biochemical features including cell shrinkage, chromatin condensation, cytoplasm vacuolization, mitochondrial degradation, DNA fragmentation, and cellular breakdown into apoptotic bodies.[37] As shown in Figure 5A, an image of untreated cells featuring round intact nuclei was observed. In contrast, the PL-UA-treated cells showed bright staining, however, there is no evidence of apoptotic bodies (Figure 5B). The typical morphological changes mentioned above were apparent in FTL-UA and FR blocking group samples. Apoptotic bodies and DNA fragmentation in FTL-UA group were readily visible (Figure 5C). There were some brighter stained cells in the FR-blocking group, but the number of cells did not decrease (Figure 5D). On the basis of morphologic observation, it is suggested that FTL-UA induced KB cell death via a mechanism involving apoptosis.

Analysis of Cell Cycle and Quantitative Percentage of Apoptotic Cells. The cell cycle distributions of KB cells were investigated by flow cytometry. As shown in Figure 6A, the sub-G1 hypodiploid cells number percentage was 2.56% in the controlled group. However, as demonstrated in Figure 6B–D, PL-UA, FTL-UA, and FR blocking group treatments of the KB cells induced significant differences in the proportions of apoptotic cells, which were reflected by the subdiploid peak (8.91, 26.93, and 16.44%). These results demonstrate that FTL-UA-induced cell death was caused principally by apoptosis induction, which mainly caused S cell cycle arrest. This result was consistent with the assessment of apoptosis induction by UA on human ACC-83 tumor cells, by cell cycle arrest in S phase.[38]

Apoptosis Analysis. Annexin V-FITC/PI double staining was carried out to determine whether FTL-UA demonstrated greater apoptotic effects than PL-UA. The KB cells were treated with various drugs at the same concentration of 50 μM UA for 24 h, subjected to simultaneous staining with Annexin V-FITC and PI, and then analyzed by flow cytometry. As shown in Figure 7, compared to the control group, the percentage of viable cells decreased significantly and apoptotic cells increased markedly when KB cells were exposed to FTL-UA. The results suggest that FTL-UA in activation of apoptosis (the percentage of late-apoptotic cells was 36.2%) was more effective than PL-UA (the percentage of late-apoptotic cells was 8.8%). Moreover, FTL-UA enhanced activation of apoptosis of KB cells, especially in the late stage of apoptosis. The number of apoptotic cells at the early and late stages increased in a dose-dependent manner. The percentage of apoptotic cells at late stage of apoptosis increased from 12.7 to 36.2% when the dose was changed from 20 to 50 μM. The activation of apoptosis of the blocking group (21.4%) was not better than that of FTL-UA group; it is demonstrated once again that the apoptosis-promoting activity of FTL-UA can be blocked by folic acid and that it induces apoptosis of KB cells through the FR-mediated pathway.

Pharmacokinetic Studies. Pharmacokinetic parameters were determined using the software DAS 2.1.1 (Drug and Statistics, China), and noncompartment open model was used to fit data.

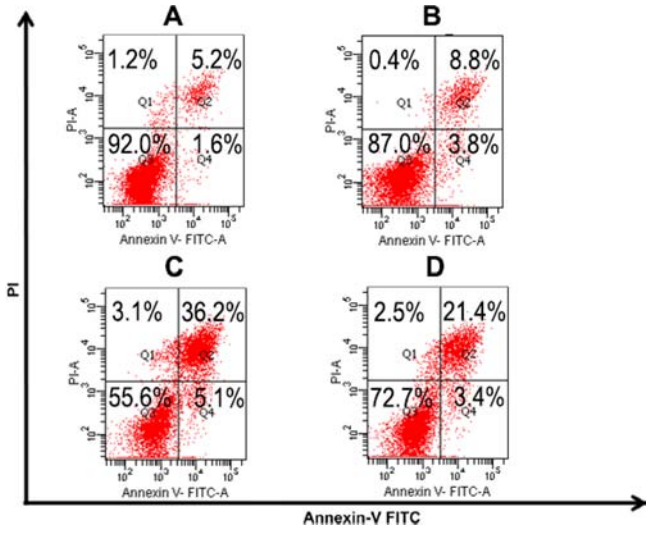

Figure 7. Effect of apoptosis of Annexin-V FITC and PI double staining assay: (A) control; (B) nontargeted group (PL-UA); (C) FR-targeted group (FTL-UA); (D) FR blocking group (FTL-UA plus 1 mM free folate), containing 50 μM UA, respectively.

The chromatographic method provided a suitable separation of the peaks of UA and other plasma components. Plasma concentration profiles of free UA, PL-UA, and FTL-UA and a summary of the major pharmacokinetic parameters are compared in Figure 8 and Table 2, respectively. As expected,

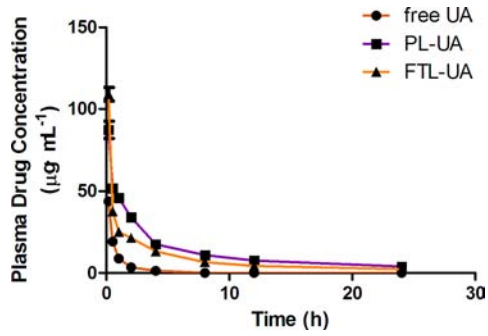

Figure 8. Pharmacokinetic profiles of free UA, PL-UA, and FTL-UA in Kunming mice (6–8 weeks old) following iv administration (20 mg/kg per mice). Data represent the mean ± standard deviation (n = 4). The UA loaded liposome profile was significantly different from that of free UA. $P < 0.005$.

free UA disappeared rapidly from plasma probably due to metabolic conversion or distribution to other organs. However, when free UA was entrapped in liposomes, significant differences in the pharmacokinetic profile and parameters were observed. UA liposome was slowly removed from blood circulation following intravenous administration. The AUC value of FTL-UA (218.32 mg/L·h) was 6-fold higher than that of free UA (36.88 mg/L·h). The MRT and $t_{1/2z}$ value of FTL-UA (MRT = 5.54 h, $t_{1/2z}$ = 7.61 h) showed improvements of 7.2- and 9.8-fold with respect to free UA (MRT = 0.77 h, $t_{1/2z}$ = 0.78 h). Meanwhile, PL-UA formulations showed much longer circulation times. FTL-UA was observed to be cleared from circulation more rapidly than PL-UA, and this result is consistent with a previous study on liposomes containing folate–polyethyleneglycol–distearoylphosphatidylethanolamine (F-PEG-DSPE).[39] It might be due to increased uptake of the liposomes

Table 2. In Vivo Pharmacokinetic Parameters of UA and Its Liposome after a Single Intravenous Administration at a Dose of 20 mg/kg in Kunming Mice[a]

	units	free UA	PL-UA	FTL-UA
AUC	mg/L·h	36.88 ± 2.16	316.11 ± 3.48	218.32 ± 12.73
AUMC	mg/L·h^2	28.23 ± 1.00	1987.11 ± 82.99	1210.01 ± 85.41
MRT	h	0.77 ± 0.04	6.29 ± 0.27	5.54 ± 0.14
Clz	L/h/kg	0.531 ± 0.037	0.056 ± 0.003	0.084 ± 0.009
Vz	L/kg	0.591 ± 0.228	0.737 ± 0.133	0.9 ± 0.237
$t_{1/2z}$	h	0.78 ± 0.33	9.25 ± 2.05	7.61 ± 2.41
C_{max}	mg/L	43.82 ± 4.49	87.15 ± 10.48	109.03 ± 8.30

[a]AUC, area under curve; AUMC, area under mean curve; CLz, clearance; $t_{1/2z}$, plasma half-life; MRT, mean residence time; Vz, distribution volume during elimination phase; C_{max}, maximum plasma drug concentration (n = 4 animals for each group).

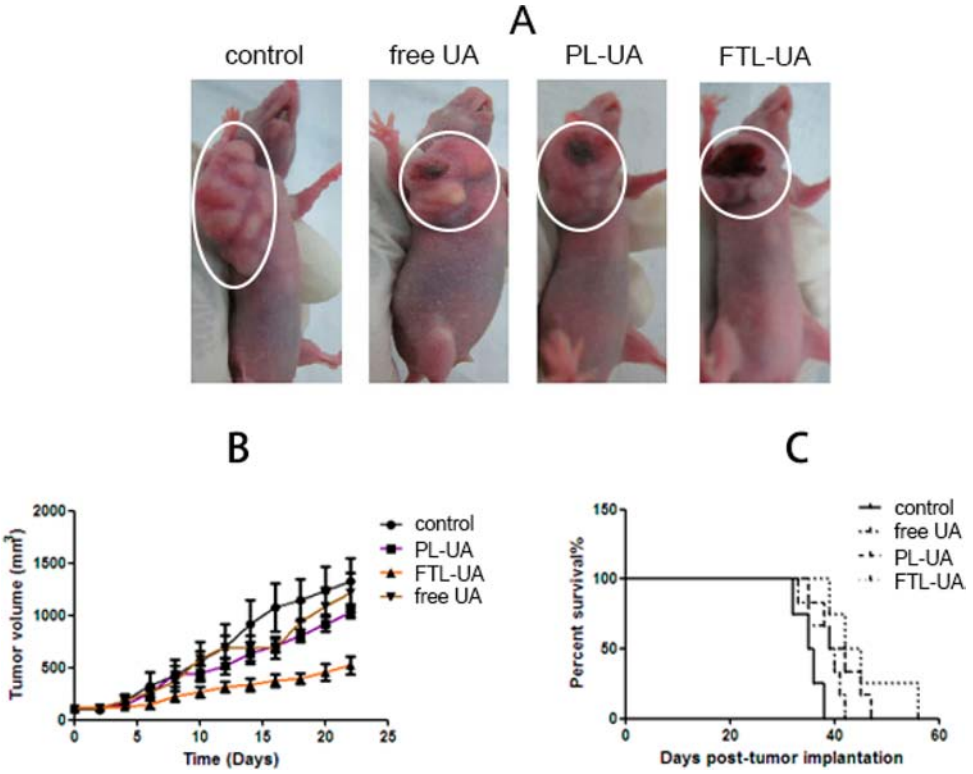

Figure 9. In vivo antitumor efficacy of KB tumor-bearing female Balb/c nu/nu mice treated with PBS, free UA, PL-UA, and FTL-UA (n = 6): (A) representative photographs of each group's female Balb/c nu/nu mice; (B) tumor growth curve ($P < 0.001$); (C) survival curves. $P < 0.02$.

by the phagocytic cells of the reticuloendothelial system (RES), which express a low level of FR-β.[40] The explanation is supported by the finding that the accelerated clearance of FR-targeted liposomes was blocked by free folic acid.[41] Pharmacokinetic and plasma stability studies clearly show that FTL-UA offers optimal conditions to treat KB tumor: (1) it is stable in plasma; (2) it remains in plasma with a long half-life and high AUC without rapidly diffusing into the tissues.

Pharmacodynamic Studies. PL-UA and FTL-UA were tested for antitumor efficacy using the human KB tumor xenograft model in female Balb/c nude mice. During our experiment, each group of nude mice was in good spirits and had freedom of movement. They had good appetite for food and water, and excretion was normal. It is obvious from Figure 9A that there were necrosis voids on the surface of the KB tumor xenograft in each mouse of the FTL-UA group. There was just a little necrosis in the surface of KB tumor xenograft in other groups. From the beginning of the administration, the tumor volume was measured once every 2 days for 24 days. The tumor growth curve was plotted. The data of tumor growth curves are shown in Figure 9B, which demonstrates very significant tumor growth inhibition in response to treatment with FTL-UA compared to other groups. One-way analysis of variance (ANOVA) was performed to demonstrate the difference among the volumes. Tumor-bearing mice treated with FTL-UA had about 55% reduction in tumor volume compared with PBS-treated mice ($P < 0.05$). For the negative control (PBS-treated) group, tumor growth is most evident and maintained a level of rapid growth. In contrast, free UA did not decrease tumor growth compared with the control group. The survival curves of each group were estimated by using the Kaplan−Meier method, and the difference of the median survival times was assessed by the log-rank test.[42] All of the untreated mice (control group) were killed because their tumors reached about 2 cm in diameter within 39 days following implantation, and free UA- or PL-UA-treated mice died within 42 and 47 days, respectively. However, the tumor-bearing mice treated with FTL-UA were alive for

dx.doi.org/10.1021/jf405675g | J. Agric. Food Chem. 2014, 62, 2207−2215

56 days (Figure 9C). Pharmacodynamic experimental results confirmed that FTL-UA slows tumor growth and that tumor volume was smaller compared to other groups. This demonstrates that FTL-UA has played a significant role in the efficacy of anti-KB tumor activity.

In recent years, plant-derived compound UA has attracted public attention because of its beneficial effects in the treatment of diseases. However, UA is poorly bioavailable and has suboptimal phamacokinetics that largely confine its broad application. Some researchers entrapped it in different formulations to curtail its limitations. Both et al. synthesized UA liposome to maintain ceramide and collagen content in human skin cells.[43] Most liposomes including liposome-anchored PEG molecules are for passive targeting. In view of this, we synthesized FR-targeted liposomal UA, the active-targeting formulation, to improve the poor availability that limits the utility of free UA. In 1995, Lee et al. first prepared folate-targeted liposomes, which were incorporated by a folate-PEG-DSPE construct into the lipid bilayer and were loaded with doxorubicin (DOX), an anticancer drug. Uptake of folate-PEG-liposomal DOX by KB cells was 45-fold higher than that of nontargeted liposomal DOX.[44] Folate-targeted liposomes as a mature preparation technology developed rapidly for nearly 20 years. So far, there is no literature reporting the synthesis of FR-targeted liposomal UA.

In this study, we encapsulated UA in FR-targeted liposomes. This formulation largely enhanced the solubility and bioavailability of UA. The cytotoxicity, apoptosis assay, pharmacokinetic, and plasma stability studies clearly show that FTL-UA offers the possibility to treat KB tumor cells. In the pharmacodynamic study, FTL-UA showed obvious antitumor advantage over the other treatment groups. These results provide the experimental basis for preclinical research and clinical development for the treatment of KB patients. Future work will be needed to evaluate the antitumor efficacy of our UA-loaded liposome in other tumor xenografts or in combination therapy to provide an effective basis for wide clinical applications in the treatment of cancers.

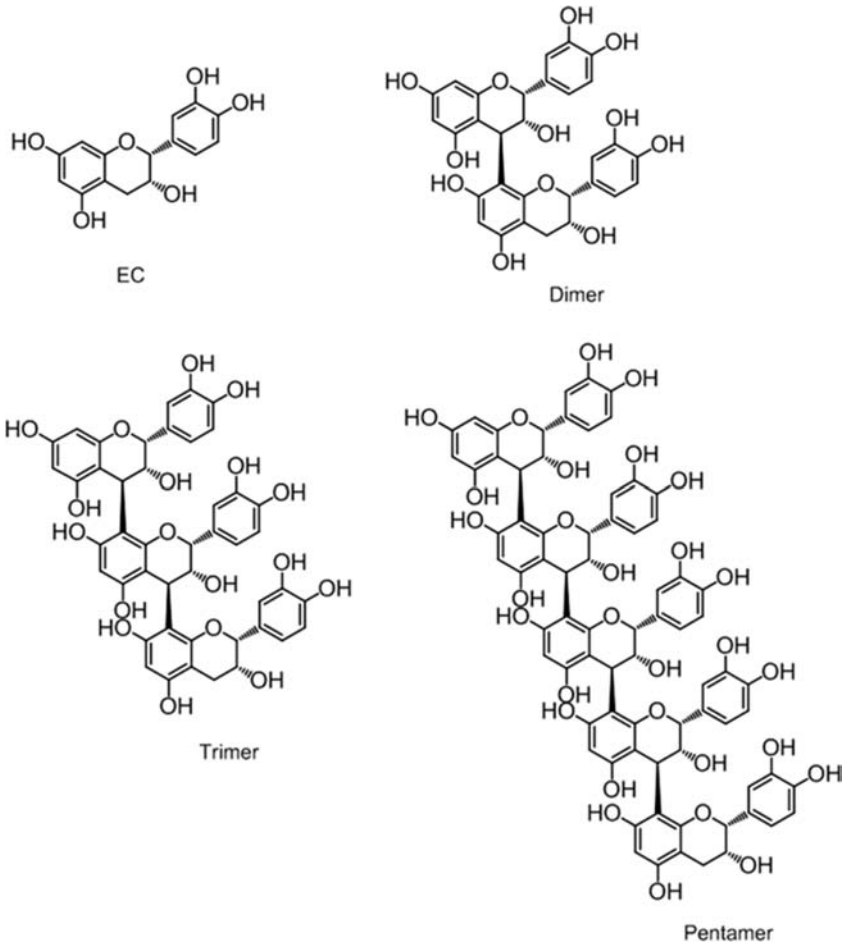

Figure 1. Structures of representative cocoa flavan-3-ols: EC and select oligomers.

between the catechin monomers (C, EC) and the PCs (oligomers and polymers), all of which are present in cocoa. EC and cocoa procyanidins have been shown to possess antiobesity and antidiabetic properties.[25−27] Emerging data suggest that these bioactivities may be highly correlated to flavanol DP.[28−30] Recently, Yamashita et al.[31] demonstrated that a tetrameric cocoa flavanol significantly improved insulin secretion in mice compared to monomeric, dimeric, and trimeric flavanols (EC, PC B_2, and PC C_1, respectively).[31] Furthermore, cinnamtannin A_2 significantly increased glucagon-like peptide-1 (GLP-1) secretion. These results suggest that insulin secretion and glucose homeostasis could be dependent on flavanol DP. Aside from this study, data on the antiobesity and antidiabetic activities of cocoa flavanols with distinct DPs in vivo are notably lacking. To our knowledge there has not been a long-term feeding study to examine the impact of chronic exposure to cocoa flavanols of distinct sizes on the onset of obesity and impaired glucose tolerance.

The objective of this study was to compare the effects of long-term dietary exposure to cocoa flavanol monomers, oligomers, and polymers on obesity and impaired glucose tolerance. This was done by fractionating cocoa flavanols into matrices with different mDP values and then evaluating the ability of each fraction to prevent obesity, insulin resistance, and impaired glucose tolerance after chronic administration in mice fed a high-fat (HF) diet. We hypothesized that the ability of cocoa flavanols to inhibit weight gain and the onset of insulin resistance and impaired glucose tolerance during an animal model of HF feeding was dependent upon flavanol DP.

MATERIALS AND METHODS

Chemicals and Standards. (±)-C, (−)-EC, epigallocatechin [(−)-(EGC)], epicatechin gallate [(−)-ECG], and epigallocatechin gallate [(−)-(EGCG)] were obtained from Sigma (St. Louis, MO, USA). PC dimer B_2 and trimer C_1 were obtained from ChromaDex (Irvine, CA, USA). Purified PC dimer B_1, dimer B_2-gallate, dimer B_5, trimer T_2, tetramer A_2, and pentamers (DP5) through decamers (DP10) were obtained from Planta Analytica (Danbury, CT, USA). Solvents for extraction, fractionation, and normal-phase HPLC were of ACS grade or better (Fisher, Pittsburgh, PA, USA; or VWR, Radnor, PA, USA). Solvents for UPLC-MS/MS were of LC-MS grade (VWR).

Cocoa Flavanol Extraction and Fractionation. A flavanol-rich cocoa extract (CE) was produced following the methods of Adamson et al.[32] and Robbins et al.[1] with modifications. For methodological details, see the Supporting Information. CE was fractionated by solid phase extraction to produce three fractions with different mDP values (monomers, oligomers, and polymers) according to the method used by Sun et al.[33] with modifications. The total polyphenol composition of the fractions was quantified by the Folin−Ciocalteu assay. For methodological details, see the Supporting Information.

Estimation of mDP by Thiolysis. Thiolysis was employed to determine the mDP of the flavan-3-ols that comprised each fraction on the basis of the methods described by Guyot et al.[34] and Gu et al.[35] with modifications. For methodological details, see the Supporting Information.

Normal-Phase HPLC and UPLC-MS/MS of Cocoa Procyanidins. Cocoa fractionation was further evaluated by normal-phase HPLC profiling (n = 1)[36] and UPLC-MS/MS (n = 3) to quantify

individual monomer and PC species up to decamers. For methodological details, see the Supporting Information.

Animals. Animal experiments were approved by the Institutional Animal Care and Use Committee at Virginia Polytechnic Institute and State University (protocol 13-099-FST). Male C57BL/6J mice (N = 54, ~25 g) were obtained from Jackson (Bar Harbor, ME, USA). Following arrival, mice were maintained on standard rodent chow for 2 weeks under standard housing conditions (3 mice/cage, 12 h light/dark cycle, 30−70% relative humidity, 20−26 °C) to acclimatize to the vivarium environment. To reduce coprophagy, bedding was changed twice per week throughout the study. Mice were provided food and water ad libitum unless otherwise specified.

Diets. Mice were assigned to one of six diet/treatment combinations (n = 9/group) (Table 1). Animals were fed one of two diets from the diet-induced obesity model series (Research Diets, Inc., New Brunswick, NJ, USA): a low-fat diet (LF, D12450J) with 10% kcal from fat or a high-fat diet (HF, D12492) with 60% kcal from fat (diets were sucrose-matched). LF and HF diet formulas are displayed in Table 2. The HF diet was provided alone or supplemented with one of the four cocoa fractions. The diets containing CE or cocoa fractions provided doses of 25 mg/kg body weight (BW)/day (262.53 mg/kg diet) based on an estimated daily food consumption of 95.23 g food/kg BW/day for male C57BL/6J mice from previous studies in our laboratory (data not shown). Diets were maintained at −20 °C throughout the study to prevent degradation of lipids or cocoa compounds. To maintain freshness and prevent degradation of fat or cocoa compounds, food was replaced twice per week for all cages. Animals were maintained on diets for 12 weeks.

Table 1. Description of Mouse Diet and Treatment Groups

abbreviation	basal diet	cocoa treatment	n
LF	LF	LF control	9
HF	HF	HF control	9
HF+CE	HF	cocoa extract	9
HF+M	HF	monomers	9
HF+O	HF	oligomers	9
HF+P	HF	polymers	9

Food intake for each cage was measured twice per week by weighing the food provided to the cage and then weighing the leftover food prior to its replacement with fresh food. Food intake for each cage was calculated as the difference between fresh food and leftover food weights and then divided by the number of animals per cage. To minimize food waste and inherent inaccuracies in food intake measurements for powdered diets, food was placed in metal feeding cups with a small opening at the top. Additionally, food inside the cups was covered with a metal grate. These measures reduced, but did not completely eliminate, food waste.

Body Weight and Body Composition. Mice were weighed weekly throughout the study. Mouse body composition was measured during weeks 1, 5, 8, and 11 in duplicate using a Bruker LF90 NMR analyzer (Billerica, MA, USA) as described in the manufacturer's instructions.

Glucose Tolerance and Insulin Tolerance Tests. Glucose tolerance tests (GTTs) were performed during week 10. Mice were fasted for 12 h and administered glucose (USP-grade, Hospira, Inc., Lake Forest, IL, USA) via intraperitoneal (ip) injection (1 g glucose/kg BW in saline). Blood was collected from the tail at 0 min (baseline) and 30, 60, 90, and 120 min following glucose administration. The tail tip was removed with surgical scissors, and a droplet of blood was obtained for glucose measurement. Glucose was measured using One Touch Ultra Blue test strips (LifeScan, Inc., Milpitas, CA, USA) and a glucometer. During week 11, mice underwent insulin tolerance test (ITTs). Mice were fasted for 4 h and injected with insulin ip (Humulin R, Cardinal Health, Dublin, OH, USA; 0.65 U insulin/kg BW in saline), and a droplet of blood was expressed from the tail at 0 min (baseline) and after 15, 30, 45, and 60 min. Blood collection and glucose measurement were performed as described for GTT.

[a]Research Diets D12450J. [b]Research Diets D12492. [c]Cocoa extract or the monomer-, oligomer-, or polymer-rich fractions were added to the HF diet at 262.53 mg/kg. [d]Lard contributed 72 mg cholesterol/100 g lard. The cholesterol contents of the LF and HF diets were 51.6 and 279.6 mg/kg, respectively.

Euthanasia and Necropsy. At the end of week 12, mice were fasted overnight and euthanized by CO_2 (following AVMA Guidelines on Euthanasia) followed by bilateral pneumothorax. Blood was immediately collected by cardiac puncture (with 1 cm^3 tuberculin syringes and $^1/_2$ in. 26 gauge needles) and clotted for 30 min at room temperature in BD Vacutainer serum separation tubes with Clot Activator. Clotted blood was centrifuged (15 min, 4 °C, 1500g), and the resulting serum was stored at −80 °C.

Fasting Serum Insulin and Endotoxin. Insulin in serum was measured using a murine insulin ELISA assay kit (Millipore, Billerica, MA, USA) in duplicate. Endotoxin in serum was determined using PyroGene Recombinant Factor C Endotoxin Detection assay kits (Lonza Walkersville, Inc., Walkersville, MD, USA).[37] Limulus Amebocyte Lysate assay plates and reagent water and pyrogen-free tubes (all from Lonza) were employed to minimize exogenous endotoxin contamination. Assays were performed in triplicate on 100 μL of diluted serum (50 μL of serum + 50 μL of LAL water). Fluorescence was quantified using a BioTek Synergy 2 plate reader (Winooski, VT, USA), and data were processed using Gen 5 software (v1.08, BioTek).

Data and Statistical Analysis. Outliers were identified and removed using Dixon's Q test at the α = 0.05 level if necessary. Data were analyzed by one-way ANOVA to determine the overall significance of treatment. If significance was detected, a Fisher's LSD post hoc test was then performed to compare all treatment means. Significance was defined as $P < 0.05$.

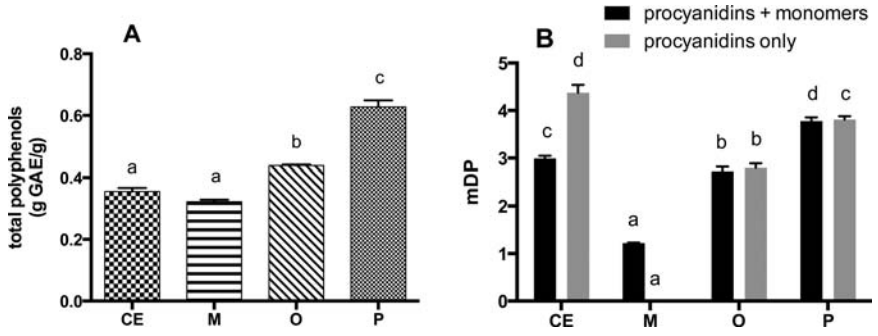

Figure 2. (A) Total polyphenols content [expressed as g gallic acid equivalents (GAE)/g of material] of CE and individual cocoa fractions as quantified by the Folin−Ciocalteu assay. Values are the mean ± SEM of $n = 3$ replicate analyses. Statistical comparisons were performed using one-way ANOVA with Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different. (B) Actual mDP values of CE and individual cocoa fractions as determined by thiolysis. Values are presented on the basis of including procyanidins only (DP ≥ 2, i.e., the thiolysis value) or procyanidins + monomers (all flavanols) in the calculation. Values are the mean ± SEM of $n = 5$ replicate analyses. Statistical comparisons between fractions were performed separately for procyanidin values and values including both procyanidins + monomers values using one-way ANOVA with Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different within each value type. Note that for the monomer (M) fraction, the procyanidin-only value is presented as 0 as the thiolysis value for this fraction was negative due to the poor suitability of thiolysis for characterizing monomer-rich matrices. CE, cocoa extract; M, monomer-rich fraction; O, oligomer-rich fraction; P, polymer-rich fraction.

[a]Treatments with different letters for the same compound (or sum of compounds) are significantly different. [b]Data are reported as the mean ± SEM from $n = 3$ replicate analyses. [c]Cocoa extract. [d]Likely procyanidin dimers B_3, B_4, and either B_6, B_7, or B_8.

RESULTS AND DISCUSSION

Cocoa Fractions. The total amounts and yields of CE and the cocoa fractions produced for this study are displayed in the Supporting Information (Table S3). As shown in Figure 2A, the total polyphenol contents (on a w/w basis) of the CE and the fractions were P > O > M = CE. As shown in Figure 2B, the mean mDP values of the PCs for each fraction were significantly different (CE > polymer > oligomer > monomer). As thiolysis measures the mDP of only dimers and above, an additional calculation was required to factor in the monomer content (see the Supporting Information). The mDP values accounting for both monomers and PCs were also significantly different (polymer > CE > oligomer > monomer). It should be noted that thiolysis is a qualitative procedure likely approximates relative differences between fractions as opposed to representing absolute mDP values. This measure indicates that the four fractions had significantly different average flavanol sizes. The polymer fraction was enriched for the larger species and therefore had a larger mDP than CE, whereas the monomer and oligomer fractions were enriched for distinct subsets of the smaller species and had smaller mDP values than CE.

Reverse-Phase UPLC-MS/MS Analysis. The levels of native monomers and specific PCs that were detected in the CE

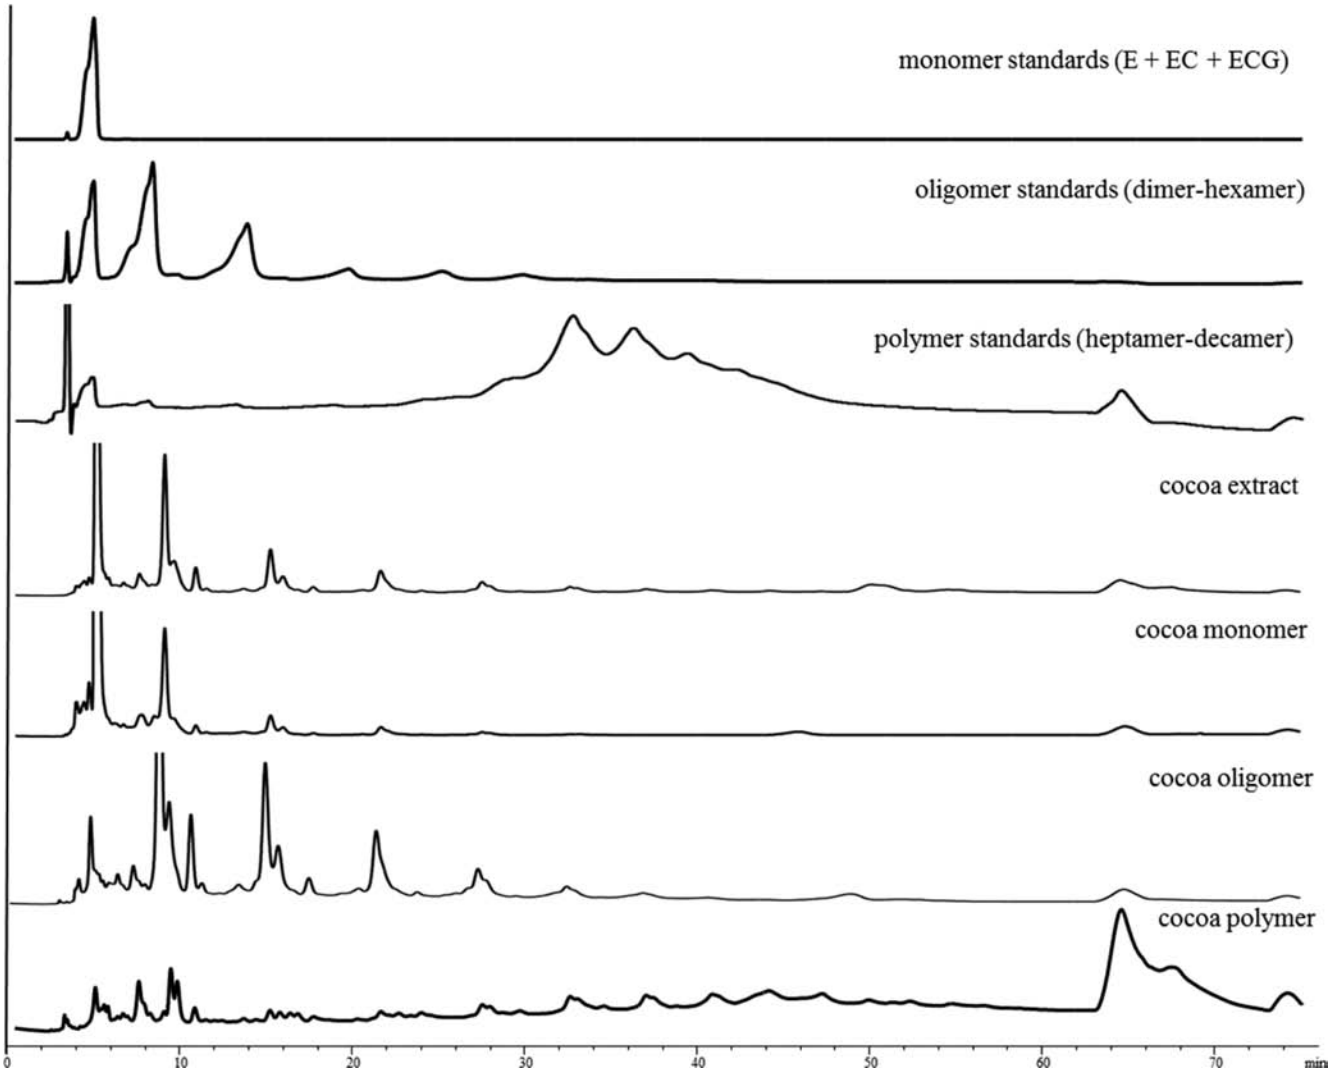

Figure 3. Fluorescence profiles of normal-phase HPLC chromatograms of authentic standards [monomers, oligomers (DP 2−6), and polymers (DP 7−10)] and the profiles of the cocoa extract, monomer, oligomer, and polymer fractions used in the mouse diets. Note that the scale is different for each chromatogram (chromatograms were scaled/cropped to emphasize relative peak heights within each trace). The scale for each chromatogram in fluorescence units (LU) is as follows: monomer standards, 740 LU; oligomer standards, 72 LU; polymer standards, 46 LU; CE, 230 LU; monomer-rich fraction, 160 LU; oligomer-rich fraction, 150 LU; polymer-rich fraction, 40 LU.

and cocoa monomer, oligomer, and polymer fractions are presented in Table 3. CE was composed of large amounts of monomers, dimers, and PCs with DP 3−6 and 7−10. It should be noted that CE had roughly the same amount of PC C1 as the six dimers combined, whereas dimers typically predominate over trimers in cocoa by a factor of 1.5−3 times. The reasons for this could include variations in the extraction conditions, the sensitivity of our instrument, or variations in the cocoa raw material. The monomer fraction was highly enriched for monomer species compared to CE and was slightly enriched for dimers compared to CE, but was somewhat reduced in PCs of DP 3−6 and depleted of PCs DP 7−10 compared to CE. The oligomer fraction was highly depleted of monomers compared to CE, but was greatly enriched for dimers and PCs DP 3−6 compared to CE and was slightly enriched for DP 7−10 compared to CE. Finally, the polymer fraction was highly depleted for monomers, dimers, and PCs DP 3−6 compared to CE and was slightly enriched for PCs DP 7−10 compared to CE. As the reverse-phase UPLC analysis quantified PCs only up to DP 10, the composition of larger PCs that make up a large portion of CE and the majority of the polymer fraction (see Figure 3) is not reflected in the total composition values in Table 3.

Normal-Phase HPLC Analysis. Normal-phase HPLC flavanol profiles of CE and cocoa PC fractions are shown in Figure 3. Analysis of standards showed that retention time roughly correlated to DP (larger species eluted later, top three chromatograms in Figure 3). CE appeared to have a wide range of early- and late-eluting flavanol species. By comparing relative peak heights within each chromatogram (bottom four chromatograms in Figure 3), the monomer, oligomer, and polymer fractions appeared to be enriched for early-, mid-, and late-eluting flavanol species, respectively. Figure 3 shows that the polymer fraction was relatively enriched for late-eluting large polymers compared to CE and the monomer- and oligomer-rich fractions, although these were not quantifiable by UPLC-MS/MS (see Table 3). It should be noted that fluorescence chromatograms do not accurately represent relative PC composition, as relative response factors for fluorescence detection decrease rapidly with increasing DP.[1]

Taken together, four separate measures of PC composition provide evidence to support that fractions designated "monomer", "oligomer", and "polymer" were indeed relatively enriched for flavanol monomers, oligomers, and polymers, respectively, compared to CE and each other. It should be noted that Table 3 reflects quantities of flavanol compounds only for which authentic standards were available. The Folin data (Figure 2A) show that the CE and the fractions were predominantly composed of polyphenols, as the gallic acid equivalents (GAE) were >30%. Although there were differences in the total polyphenols as measured by GAE between the fractions, structural differences may account for some of these differences.

Food Intake. Food intakes at weeks 3, 6, and 9 of the feeding study are presented in Figure 4. The average weekly food intake per animal was consistent across all groups in the HF diet (one-way ANOVA indicated no overall effect of treatment on food intake within the HF diet). This supports the conclusion that supplementation of the HF diet with CE or cocoa fractions did not affect food intake, which excludes reduced food intake as the mechanism by which cocoa fractions modulated weight gain, obesity, or glucose homeostasis in this experiment. The differences in measured food intake between the LF and HF diets may be due to differences in caloric density[38] (Table 2) and/or differences in consistency (LF was a powder, whereas HF was mealy/doughy), which may have affected diet wasting due to the ability of the mice to remove feed from the feed cups without eating it. Lack of apparent increases in food intake with weight gain may be due to the inherent difficulties in accurately measuring intake of powdered diets.

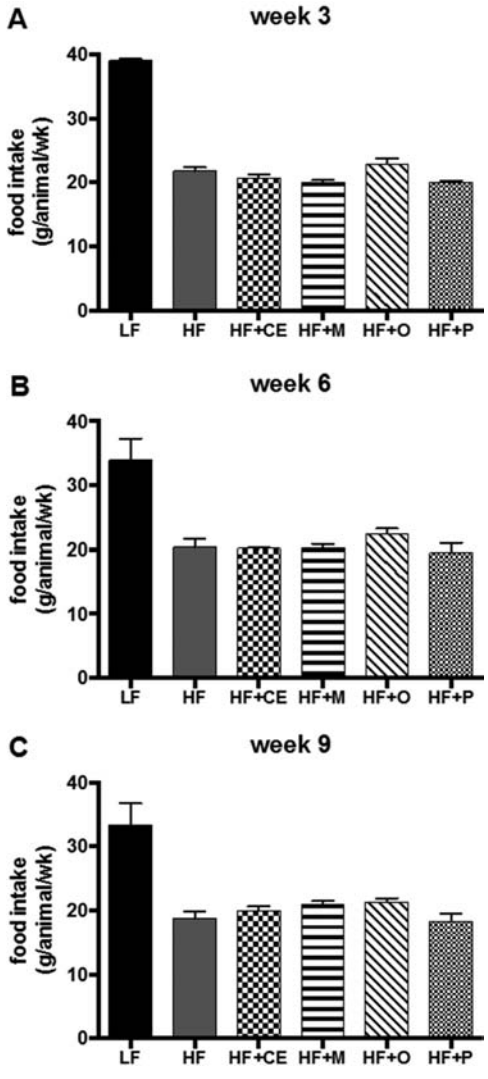

Figure 4. Calculated food intake values at weeks 3 (A), 6 (B), and 9 (C) of the feeding study. Data shown are the mean ± SEM of $n = 3$ replicate cages/treatment ($n = 3$ mice/cage). One-way ANOVA indicated no overall effect of dietary treatment on food intake ($P = 0.1439$, 0.0792, and 0.0541 for overall diet effect at 3, 6, and 9 weeks, respectively). Therefore, post hoc test for significance between treatment means was not performed. LF, low-fat control diet; HF, high-fat control diet; HF+M, high-fat control diet + monomer-rich fraction; HF+O, high-fat control diet + oligomer-rich fraction; HF+P, high-fat control diet + polymer-rich fraction.

Weight Gain and Body Composition. Weight gains during the feeding study are displayed in Figure 5A. HF feeding caused a significantly greater weight gain compared to the LF control group. Mice fed HF diets supplemented with cocoa monomers and oligomers did not gain a significantly different amount of weight compared to mice fed a LF control diet. However, within the HF diet, only the HF+O group was significantly different from the HF control. Changes in fat mass during the feeding study are displayed in Figure 5B. Mice from the HF control group gained significantly more fat mass than did mice in the LF control group. Supplementation of the HF diet with cocoa oligomers inhibited a significant increase in fat mass compared to the LF control, whereas supplementation of

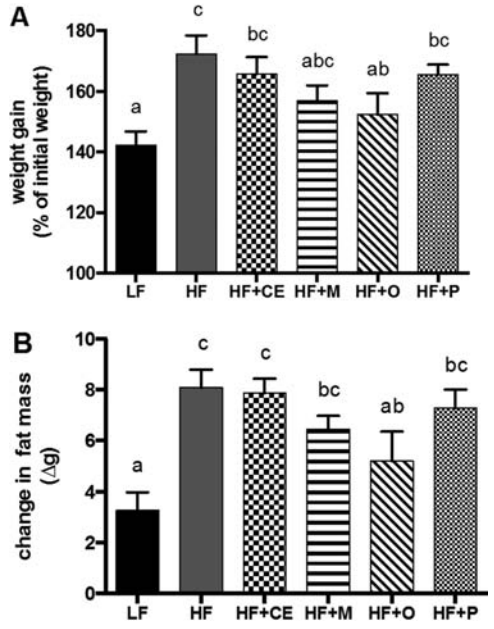

Figure 5. (A) Weight gains (final weights expressed as a percentage of initial weight) after 12 weeks of feeding; (B) changes in total body fat mass (difference between final and initial fat masses) after 11 weeks of feeding. Data shown are the mean ± SEM of $n = 9$ animals/treatment ($n = 8$ for the HF+M group due to loss of one mouse from this group during the feeding study). Significance between treatments was determined with a one-way ANOVA and Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different. LF, low-fat control diet; HF, high-fat control diet; HF+M, high-fat control diet + monomer-rich fraction; HF+O, high-fat control diet + oligomer-rich fraction; HF+P, high-fat control diet + polymer-rich fraction.

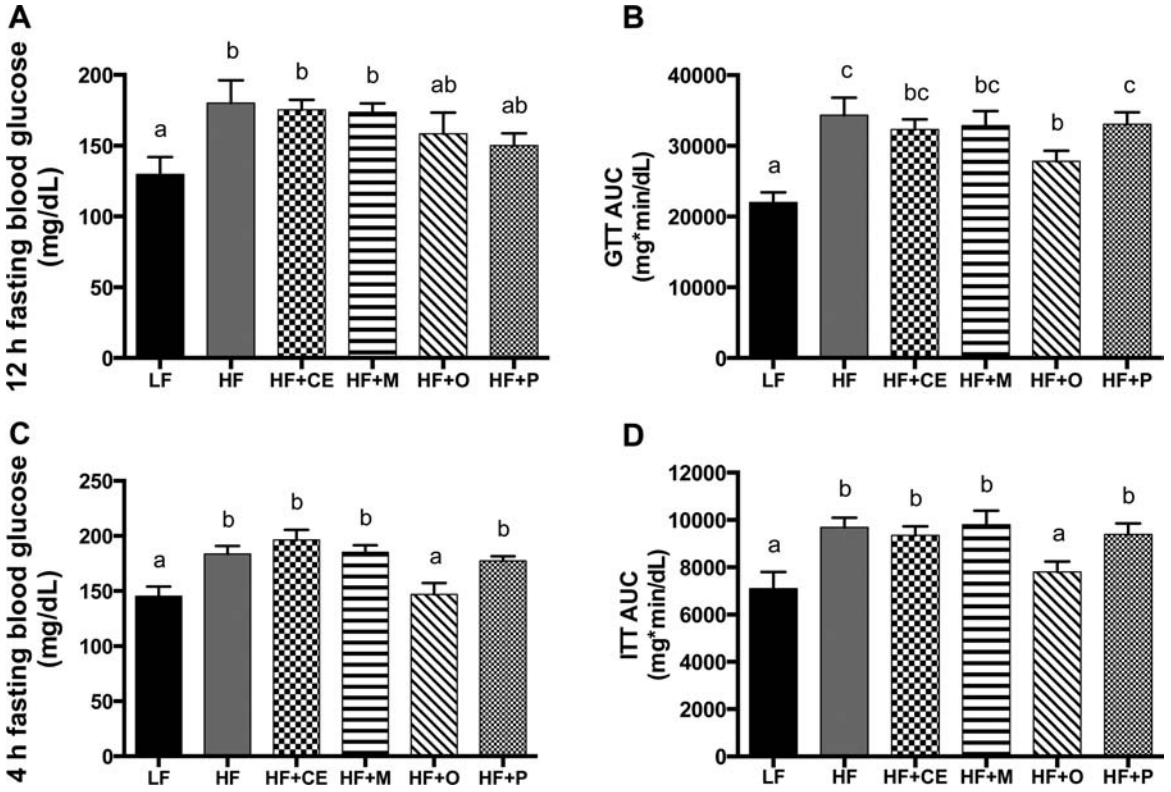

Figure 6. (A) Fasting (12 h) blood glucose levels at week 10; (B) glucose tolerance test (GTT) area under the blood glucose concentration curve (AUC) at week 10; (C) fasting (4 h) blood glucose levels at week 11; (D) insulin tolerance test (ITT) AUC at week 11. Data shown are the mean ± SEM of $n = 9$ animals/treatment ($n = 8$ for the HF+M group due to loss of one mouse from this group during the feeding study). Significance between treatments was determined with a one-way ANOVA and Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different. LF, low-fat control diet; HF, high-fat control diet; HF+M, high-fat control diet + monomer-rich fraction; HF+O, high-fat control diet + oligomer-rich fraction; HF+P, high-fat control diet + polymer-rich fraction.

the HF diet with CE, monomers, and polymers did not significantly inhibit increases in fat mass compared to the LF control. Within the HF diet, supplementation with cocoa oligomers significantly inhibited increases in fat mass compared to CE but not compared to monomers or polymers.

Glucose and Insulin Tolerance. Fasting (12 h) blood glucose levels at week 10 are displayed in Figure 6A. Mice fed a HF control diet had significantly elevated fasting glucose levels compared to the LF control group. Fasting glucose levels of the HF + CE and HF + monomer groups were also significantly elevated compared to the LF control. Supplementation of the HF diets with cocoa oligomers and polymers resulted in intermediate fasting glucose levels that were not statistically different from those of either the LF or HF control groups. Figure 6B displays the GTT data as measured by the area under the curve (AUC) of the blood glucose levels over time following glucose administration. The HF control exhibited significantly higher AUC (i.e., impaired glucose tolerance) compared to a LF diet. Supplementation of the HF diet with oligomers resulted in an intermediate GTT AUC that was significantly lower than that of the HF control but also significantly higher than that of the LF control. Supplementation of the HF diet with CE, monomers, and polymers did not lower GTT AUC compared to the HF control.

Fasting (4 h) blood glucose levels at week 11 are shown in Figure 6C. Mice fed the HF control diet had significantly elevated 4 h fasting blood glucose levels compared to mice fed the LF control diet. Supplementation of the HF diet with cocoa oligomers inhibited increased fasting blood glucose compared to LF control. Supplementation of the HF diet with CE, cocoa monomers, or polymers did not inhibit increased 4 h fasting blood glucose levels, as these treatments had levels significantly higher than the LF control and not significantly different from the HF control. Figure 6D displays the ITT data as measured by the blood glucose AUC over time following insulin administration. The ITT data closely mirrored the 4 h fasting glucose data. Mice fed the HF control diet had significantly elevated ITT AUC values compared to mice fed the LF control diet. Supplementation of the HF diet with cocoa oligomers inhibited increased ITT AUC compared to LF control. Supplementation of the HF diet with CE, cocoa monomers, or polymers did not inhibit increased ITT AUC values, as these treatments had values significantly higher than the LF control and not significantly different from the HF control.

Fasting Insulin. Fasting serum insulin levels are presented in Figure 7. The HF diet significantly elevated fasting serum insulin levels compared to the LF control. Supplementation of the HF diet with CE did not significantly inhibit increases in fasting serum insulin, as this treatment was not significantly different compared to the HF diet alone but was significantly higher than the control LF diet. Supplementation of the HF diet with monomers, oligomers, and polymers resulted in fasting insulin levels that were significantly lower than those with the HF diet and not significantly different from those of the control LF diet.

Endotoxin. Fasting serum endotoxin levels are presented in Figure 8. HF feeding did not significantly increase fasting serum endotoxin concentrations compared to the LF diet. Supple-

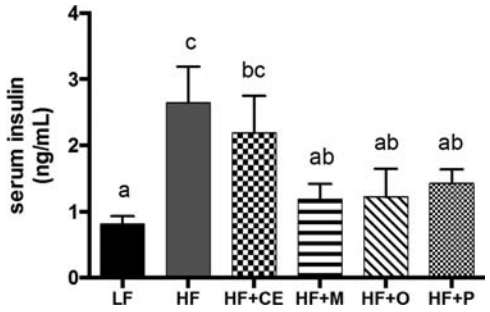

Figure 7. Fasting serum insulin levels following the 12 week feeding study. Data shown are the mean ± SEM of $n = 9$ animals/treatment ($n = 8$ for the HF+M group due to loss of one mouse from this group during the feeding study; $n = 6$ for the HF+M group and $n = 7$ for the HF+P group due to loss of samples during preparation for the ELISA assay). Significance between treatments was determined with a one-way ANOVA and Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different. LF, low-fat control diet; HF, high-fat control diet; HF+M, high-fat control diet + monomer-rich fraction; HF+O, high-fat control diet + oligomer-rich fraction; HF +P, high-fat control diet + polymer-rich fraction.

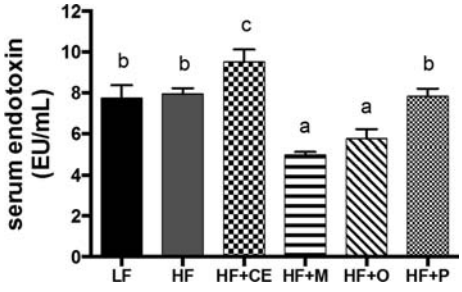

Figure 8. Fasting serum endotoxin levels following the 12 week feeding study. Data shown are the mean ± SEM of $n = 9$ animals/treatment ($n = 8$ for the HF+M group due to loss of one mouse from this group during the feeding study). Significance between treatments was determined with a one-way ANOVA and Fisher's LSD post hoc test ($P < 0.05$). Treatments with different letters are significantly different. LF, low-fat control diet; HF, high-fat control diet; HF+M, high-fat control diet + monomer-rich fraction; HF+O, high-fat control diet + oligomer-rich fraction; HF+P, high-fat control diet + polymer-rich fraction.

mentation of the HF diet with CE significantly increased endotoxin compared to the LF and HF controls. Conversely, supplementation of the HF diet with monomers and oligomers significantly decreased endotoxin compared to LF and HF controls. Supplementation of the HF diet with polymers did not significantly affect endotoxin levels compared to LF and HF controls.

Discussion. We believe this to be the first long-term feeding study to examine the correlation between flavanol PC size (individual species DP and overall mDP of the matrix) and the ability to inhibit the deleterious effects of a HF diet. Our results indicate that a cocoa fraction enriched in oligomeric PCs likely possess enhanced bioactivity compared to other flavanols as well as the composite CE itself. It should be noted that the oligomer-rich fraction had significantly greater total polyphenol content (GAE, w/w) than both CE and the monomer-rich fraction (Figure 2A). However, it also had significantly less total polyphenol content than the polymer-rich fraction. The fact that bioactivity was not correlated with total polyphenol content supports our observations that structure and mDP contribute to flavanol biological activity.

Our results generally agree with the few previous studies of the impact of flavanol DP on obesity and glucose homeostasis. Gu et al.[39] demonstrated that PC DP was generally proportional to inhibitory activity against digestive enzymes, suggesting that larger PCs may more effectively control glucose release. Yamashita et al.[40] showed that larger PCs (DP ≥ 4) more effectively inhibited intestinal α-glucosidase than smaller PCs (DP ≤ 3), although smaller PCs more effectively stimulated glucose uptake and AMP-activated protein kinase phosphorylation in rat skeletal muscle cells. Yamashita et al.[31] further demonstrated that PC oligomer cinnamtannin A_2 more effectively stimulates insulin secretion and activation of insulin signaling in skeletal muscle than smaller PCs and EC. Montagut et al.[41] also demonstrated that PC oligomers can activate insulin signaling and stimulate glucose uptake.[41] Whereas these studies suggested various relationships between PC size and specific bioactivities, our data suggest that the overall effect on diet-induced obesity and impaired glucose tolerance is optimal for intermediate size values.

It should also be noted that, although all three flavanol fractions effectively inhibited hyperinsulinemia (Figure 7), only the oligomer-rich fraction effectively improved glucose tolerance compared to the HF diet (Figure 6B), inhibited increases in 4 h fasting glucose compared to the LF control (Figure 6C), and inhibited the development of insulin resistance (Figure 6D). Therefore, only the oligomer-rich fraction effectively prevented development of a prediabetic phenotype. Studies[42,43] suggest that flavanols decrease lipid accumulation in β-cells and subsequent glucose-stimulated insulin production under hyperlipidemic conditions. However, studies in healthy animals suggest that flavanols may actually increase insulin secretion by increasing levels of glucagon-like peptide-1 (GLP-1), which is a hormone secreted from gut L-cells in response to carbohydrate ingestion that stimulates insulin secretion.[31] In vitro and animal studies also suggest that PCs improve insulin sensitivity in skeletal muscle and adipocytes, thus decreasing the need for insulin secretion.[40,44] These studies and our data highlight the fact that the effects of flavanols on mechanisms related to glucose homeostasis are highly context dependent. Distinct mechanisms of action may be involved in the prevention of obesity and insulin resistance versus the amelioration of existing obesity and insulin resistance.[45] Furthermore, flavanols may improve insulin and blood glucose levels by distinct mechanisms in the acute postprandial state (gut mechanisms such as inhibiting macronutrient digestion/absorption, increased GLP-1 and insulin secretion)[31,39] versus chronic effects in the fasted state (peripheral tissue mechanisms such as decreased insulin secretion and improved insulin sensitivity).

Our finding that an oligomer-rich fraction was generally more effective than a monomer-rich fraction is intriguing, as the absorption and systemic bioavailability of PCs are generally regarded to be inversely proportional to size.[46−48] This suggests that oligomers, which are largely unabsorbed in their native form, may act primarily through a mechanism located in the gut. This hypothesis is supported by the fact that PCs appear to improve glucose tolerance and increase insulin secretion when glucose is administered orally but not by ip injection.[49] Potential mechanisms by which unabsorbed PCs may act in the gut to inhibit the onset of obesity and impaired glucose tolerance include inhibition of macronutrient digestion and

absorption,[39,40] stimulation of GLP-1 secretion and GLP-1 driven insulin secretion,[31] and inhibition of GLP-1 degradation by dipeptidyl peptidase-IV.[49] In the present study, cocoa oligomers appear to more effectively control 4 h fasting glucose levels versus 12 h fasting glucose levels (Figure 6A,C). These data indicate that oligomers more effectively modulate postprandial blood glucose control as opposed to blood glucose levels after longer periods of fasting, suggesting that oligomers may primarily exert acute postmeal effects while the compounds are still in the upper gastrointestinal tract, as opposed to chronic systemic effects.

Another possible mechanism for cocoa PC action in the gut is the inhibition of metabolic endotoxemia. Low-grade inflammation has been shown to impair insulin signaling and induce metabolic derangements in skeletal muscle.[50,51] A key mediator of this inflammatory state is endotoxin, the major glycolipid component of the outer membrane of Gram-negative commensal bacteria in the gut. Circulating endotoxin activates the Toll-like family of pathogen-associated molecular pattern recognition receptors that initiate an inflammatory signaling response via NF-κB activation.[52] HF feeding induces a chronically elevated endotoxin state.[53] Research in mice and humans has linked chronically elevated endotoxin to the development of obesity and insulin resistance via activation of Toll-like receptor (TLR) 4 in skeletal muscle. PCs are well-known to reduce inflammation,[54] and control of the chronic low-grade inflammatory state resulting from high-fat feeding may represent a mechanism by which dietary PCs prevent and/or ameliorate metabolic syndrome. PCs may inhibit metabolic endotoxemia and the resulting metabolic derangements (including insulin resistance) by reducing epithelial permeability to endotoxin,[55,56] or by blunting TLR4 stimulation[57] and induction of inflammation by circulating endotoxin.[58,59] Gu et al.[60] demonstrated that cocoa reduces circulating endotoxin, improves gut barrier function, and reduces systemic inflammation induced by HF feeding. Although these activities have all been demonstrated separately for PCs, inhibition of endotoxemia has yet to be shown as the mechanism by which cocoa PCs improve skeletal muscle insulin signaling and systemic glucose tolerance. Data definitively linking improved regulation of inflammatory tone to prevention of insulin resistance would represent a novel mechanism by which PCs prevent metabolic syndrome. The present data indicated that HF feeding did not significantly elevate fasting serum endotoxin compared to the LF diet (Figure 8). However, this lack of difference may be due to the prolonged (12 h) fast, as increases in circulating endotoxin are generally observed in the postprandial (fed) state.[53] Circulating endotoxin was measured in the 12 h fasting state in recently euthanized animals, as opposed to the postprandial state, as this was a post hoc assay. Nevertheless, supplementation of the HF diet with both monomers and oligomers significantly reduced fasting endotoxin concentrations. This suggests that these fractions warrant further consideration for prevention of metabolic endotoxemia. The potential mechanisms by which monomers and oligomers reduce serum endotoxin concentrations include reduced endotoxin production in the gut (by gut microflora) and/or reduced paracellular permeability of the gut to endotoxin (by increased gut junction protein expression). Additional studies are required to determine the impact of cocoa flavanols on postprandial serum endotoxin profiles.

Potential antiobesity and antidiabetic activities of cocoa flavanols that require absorption and distribution of PCs to target tissues, such as direct stimulation of pancreatic β-cell function[43,61] and insulin signaling in skeletal muscle,[41] likely play a complementary role to the gut-mediated activities that we have identified due to the poor bioavailability of PCs. Further research is required to determine the relative importance of the gut activities of unabsorbed PCs versus the systemic activities (in the pancreas, liver, adipose tissue, skeletal muscle, etc.) of absorbed PCs. Additionally, the microbial metabolites of these compounds may play a role in systemic activities of poorly absorbed native compounds.

It is important to note the low doses employed in the present study. We employed CE and cocoa fractions at 25 mg/kg BW/day [0.02625% (w/w) in the diet]. This is considerably lower than doses used in the majority of previous feeding studies of cocoa or cocoa extracts (Supporting Information). Previous studies have employed doses of 600 mg/kg body weight/day or 0.5−12.5% (w/w) in the diet (although the higher percentage compositions in the diet were cocoa powder, which is ∼2−5% flavan-3-ols by weight).[17−23] The doses employed in previous studies may be on the extreme end of what is feasible for translation to human dietary dosing. However, we have demonstrated here that cocoa extracts or fractions can be effective at lower doses, which translate to more reasonable human doses [25 mg cocoa flavanols/kg BW/day in a 20 g mouse is equivalent to 2.03 mg/kg cocoa flavanols in a human[62]]. Therefore, our data suggest that moderate doses of cocoa flavanols or cocoa powder have the potential to be more effective in human clinical trials than previously thought. This concept was proposed previously by Castell-Auvi et al.,[42] who demonstrated that high doses had no effect on hyperinsulinemia and lower doses (5−15 mg/kg BW) actually worsened hyperinsulinemia, whereas 25 mg/kg BW improved hyperinsulinemia. It is also important to note that this dose did not alter food intake in our model, whereas the higher doses in previous studies may have inhibited the onset of diet-induced obesity and insulin resistance by significantly altering food intake (and, hence, macronutrient intake) due to poor palatability or other factors (however, this is unknown as food intake is rarely reported).

One factor in our study design that warrants mention was that mice were fed equivalent doses of the CE and cocoa fractions on a mg/kg BW basis. Due to differences in average molecular weight (MW) of the species in each treatment, mice were therefore fed different concentrations on a mol/kg BW basis. However, the oligomer fraction was still the most effective treatment despite the fact that the mice on the monomer treatment received significantly greater doses than mice on the oligomer treatment, on a mol/kg BW basis. This further reinforces the conclusion that oligomers possess enhanced bioactivities. Furthermore, attempting to formulate the diets on an equivalent mol/kg BW basis would have been problematic due to the fact that thiolysis is only an estimation of MW, and there may be components not accounted for by the assays used to characterize CE and cocoa fractions (normal-phase HPLC, which was qualitative, and UPLC, which measured only up to DP 10). Therefore, formulation on a mg/kg BW basis was determined to be the preferred approach.

Oligomeric PCs appear to possess the greatest antiobesity and antidiabetic bioactivities of the flavanols in cocoa, particularly at the low doses employed for the present study. The extraction and fractionation methods employed here are capable of producing gram quantities of flavanol fractions from complex matrices for long-term feeding studies, thus over-

coming a major limitation in experimental design. Additional studies of prolonged feeding of flavanol fractions in vivo are needed to further identify the fractions with the highest bioactivities and therefore the greatest potential for translation to human clinical applications at reasonable doses.

The results of this study suggest several future directions. First, isolation of individual compounds in the oligomer fraction for long-term feeding studies are needed to further refine our understanding of which cocoa flavanols possess the greatest potential for activity in humans. Second, additional studies are needed to determine the relative importance of the gut activities of unabsorbed PCs versus the systemic activities of absorbed PCs (or absorbed microbial metabolites) in the oligomer fraction. Identification and localization of the mechanistic target will guide design of the most effective delivery strategies for human interventions. Third, mechanistic studies are needed to identify the primary mechanism(s) by which PC oligomers inhibit the onset of obesity and impaired glucose tolerance during HF feeding. The majority of studies (including the present study) simply observe biomarkers that are improved during supplementation with PCs. Although useful for hypothesis generation, mechanistic experiments are needed that specifically inhibit and/or stimulate putative mechanistic targets to isolate and definitively identify the specific mechanisms of action. Identification of specific mechanisms essential for PC bioactivities will facilitate the design of human interventions with appropriate mechanistic targets. The most promising mechanisms appear to be located in the gut: inhibition of macronutrient digestion/absorption, GLP-1/DPP4 activity, and inhibition of endotoxin production and/or uptake. Finally, studies are required to determine whether the antiobesity and antidiabetic effects of PC oligomers are primarily acute postprandial activities due to oligomers in the upper gastrointestinal tract or systemic effects due to circulating PCs and colonic metabolites.

serum (FBS) was from Invitrogen. The microsomal triglyceride inhibitor BMS212122 was a kind gift from Bristol-Meyers Squibb; a 200 μmol/L stock solution of it was prepared in DMSO. The antibody against SR-BI was purchased from Novus Europe (UK). The ELISA kit ab46044 for determining IL-6 was from Abcam (UK). Red wine and dealcoholized red wine were kind gifts of Bodegas Torres (Barcelona, Spain), and their phenolic composition can be found in Chiva-Blanch et al.[14] Green tea (a kind gift of Bonomelli s.p.a., Bologna, Italy) was fully characterized[15] and was freshly prepared on the day of the experiment by brewing loose-leaf tea (2 g/100 mL) for 3 min in just-boiled water. A fully characterized (Supplementary Table 1) cocoa extract was a kind gift from Kraft Foods.

Methods. Caco-2 cells were grown on 100 mm plates and were subcultured onto microporous membranes inserted into Transwells. Cells were grown with DMEM supplemented with 10% FBS, penicillin, and streptomycin. Media in the Transwell cultures was replaced every other day, and cultures were used for experimentation at least 10 days postconfluence, to ensure differentiation. Only the apical compartment contained phenol red, and monolayer integrity was assessed by measuring the appearance of phenol red in the basolateral compartment. This method was shown to be equivalent to measuring TEER[16] with the added benefit that the phenol red analysis is done once the experiment is ended and, therefore, there is no risk of puncturing the monolayer with electrodes. The concentration of phenol red was determined spectrophotometrically at 560 nm, in aliquots of basolateral media containing 5% 1 N NaOH as previously reported.[16]

The different sources of polyphenols (red wine, green tea, or cocoa extracts) or ethanol were administered to Caco-2 monolayers to the apical compartment containing DMEM + 10% FBS. The amounts added to each well corresponded to a final concentration of 50 μM total polyphenols (calculated as gallic acid equivalents), which approximates the intestinal concentrations that can be attained after ingestion.[1] The final concentration of ethanol in all samples was 0.2%, corresponding to the same amount contained in red wine.

Cholesterol Efflux and HDL Functionality. For experiments in which basolateral cholesterol efflux and HDL functionality were measured, the basolateral compartments of the Transwells were incubated with DMEM without phenol red and the apical compartments with BMS212122 (0.05 μmol/L) in DMEM + 10% FBS for 3 h prior to the apical addition of polyphenols (DMSO did not exceed 0.05%). BMS212122 is an inhibitor of the microsomal triglyceride transfer protein (MTP), which completely inhibits the assembly and secretion of apolipoprotein B-containing lipoproteins, that is, chylomicrons;[17] therefore, all of the cholesterol secreted basolaterally from the Caco-2 monolayers was HDL-associated. Polyphenols from red wine, dealcoholized red wine, green tea, or cocoa were added apically to a final concentration of 50 μM (gallic acid equivalents) total polyphenol. The antibody against SR-BI (aSR-BI) was added to the basolateral compartment (1:1000 dilution) for experiments in which HDL functionality was determined.

Determination of Free and Total Cholesterol. Free cholesterol and esterified cholesterol were determined as previously described.[16] Briefly, 2 mL of basolateral medium was collected after 24 h, and 5 μL of the internal standard ergosterol (1 mg/mL in EtOH) and 4 mL of EtOH were added. The mixture was thoroughly vortexed. Lipids were then extracted with 2 mL of methyl *tert*-butyl ether (MTBE) and 6 mL of hexane. After vigorous shaking, the lower aqueous phase was discarded and the upper organic phase was separated in two glass tubes (approximately 4 mL each); the first tube was evaporated under nitrogen, and the residue was silylated using pyridine and BSTFA + 1% TMCS (1:1) to measure free cholesterol. The second tube was evaporated under nitrogen, and the residue was suspended in 1 mL of methanolic KOH (1 mL of 3 N KOH + 9 mL of MeOH) and incubated at 80 °C for 1 h to allow for saponification. Samples were then neutralized with 50 μL of 6 N HCl, and 3 mL of hexane was added to extract the lipids: the lower aqueous phase was discarded, the upper organic phase was evaporated, and the residue was silylated using pyridine and BSTFA + 1% TMCS (1:1) to measure total cholesterol. Esterified cholesterol was determined by subtracting the amount of free cholesterol to the amount of total cholesterol. Cholesterol and ergosterol were quantified by GC-MS using selective ion monitoring, as described previously.[16]

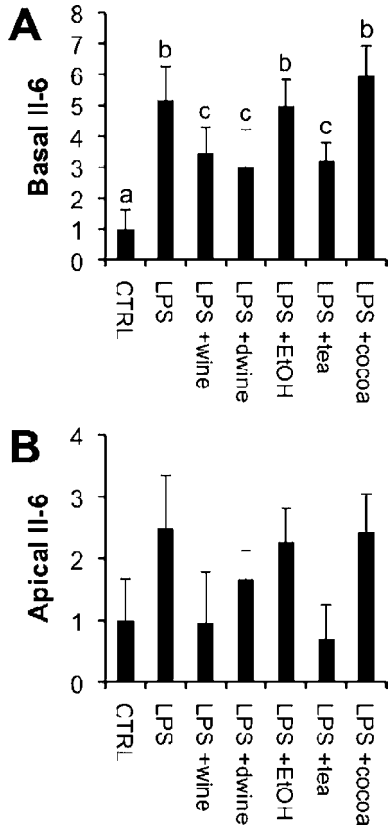

Figure 1. Red wine and green tea polyphenols reduce IL-6 secretion by Caco-2 cells. Cells were treated apically with the indicated polyphenolic extracts from red wine, green tea, or cocoa for 4 h. Freshly dissolved LPS was then added where indicated at a concentration of 10 μg/mL. After 2 h, IL-6 was determined in apical and basolateral media. Basal, basolateral; Ctrl, controls; LPS, lipopolysaccharide; dwine, dealcoholized wine. Treatments without a common letter differ, $p < 0.05$.

IL-6 Determination, RNA Extraction, and Quantitative PCR. The IL-6 high-sensitivity human ELISA kit (ab46044) was used according to the manufacturer's instructions to determine IL-6 in apical and basolateral compartments.

For gene assays, cells were washed twice with cold 0.9% NaCl and were scraped off the microporous membrane. RNA was extracted with Qiazol according to the manufacturer's instructions. cDNA synthesis was performed with Superscript III following the manufacturer's instructions. Primers (available upon request) were designed and, for each primer set, the melting curves were verified to make sure that a single product was amplified. PCR amplification was performed with a 7900 real-time PCR system (Applied Biosystems) in 384-well plates. SYBR Green was used in 10 μL reactions with 30 ng of total RNA input and 500 μM of each primer. GAPDH was used as reference gene, and fold change in expression levels was determined as $2^{-\Delta\Delta Ct}$. Results were normalized to control treatments.

Statistical Analyses. For every experiment each treatment was performed at least in triplicate, and the same experiment was performed at least twice. Results are expressed as the mean ± standard deviation of at least two separate experiments. Statistical analysis was performed using the SAS Statistical Analysis Systems (version 9.2, SAS Institute Inc., Cary, NC, USA). One-way ANOVA with the Bonferroni post hoc analysis was performed to determine the effect of the different treatments. A $p < 0.05$ was considered significant.

RESULTS AND DISCUSSION

Wine and Tea Polyphenols Reduce IL-6 Secretion by Caco-2 Cells. The secretion of IL-6 by controls was greater

dx.doi.org/10.1021/jf500348u | J. Agric. Food Chem. 2014, 62, 2228−2232

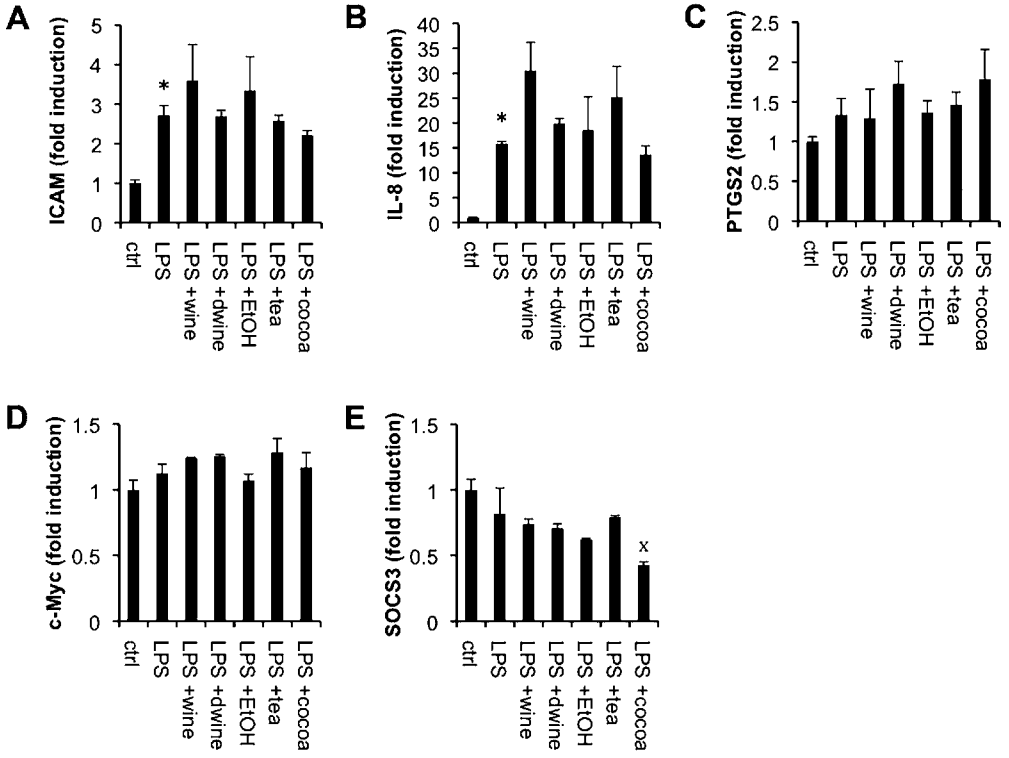

Figure 2. Effects of polyphenols on intestinal inflammatory gene expression. Caco-2 monolayers grown in Transwells were treated apically with the indicated polyphenolic extracts from red wine, green tea, or cocoa for 4 h. LPS was then added where indicated at a concentration of 10 μg/mL. After 2 h, cells were collected and gene expression was determined by qPCR. Ctrl, controls; LPS, lipopolysaccharide; dwine, dealcoholized wine. (*) $p < 0.001$ as compared with control cells, $x < 0.03$ as compared with LPS treatment.

basolaterally (0.16 ± 0.08 pg/mL) than apically (0.09 ± 0.08 pg/mL). IL-6 secretion by LPS-treated cells was significantly ($p < 0.03$) greater basolaterally (0.48 ± 0.02 pg/mL) than apically (0.29 ± 0.07 pg/mL), suggesting that intestinal inflammation leads to the release of inflammatory cytokines into the circulation. Polyphenols from red wine and green tea, but not those from cocoa, significantly reduced basolateral IL-6 secretion from Caco-2 monolayers grown on Transwells and challenged with LPS (Figure 1A). A similar effect was seen on apical secretion, although it was not significant, perhaps due to the very small quantities of IL-6 secreted apically (Figure 1B). Even though red wine and green tea polyphenols significantly inhibited IL-6 production, the absolute effect was moderate and we observed a high variability between experiments.

To further investigate the effect of polyphenols on induced inflammation, we determined, by qPCR, the expression of selected inflammation genes. *IL-8*, *ICAM*, and *PTGS2* (*COX-2*) mRNA expressions were significantly increased by LPS by approximately 15-, 3-, and 1.3-fold, respectively (Figure 2). Unfortunately, IL-6 quantification by qPCR was not feasible due to an elevated Ct. However, polyphenols from either source did not decrease the expression of *IL-8*, *ICAM*, or *PTGS2* in LPS-treated cells (Figure 2), casting some doubt on the factual anti-inflammatory actions of polyphenols at the intestinal level and at dietary concentrations. Indeed, emerging evidence suggests that, rather than direct anti-inflammatory actions, polyphenols affect the intestine by modulating the microbiota.[1]

As the IL-6 signaling pathway involves STAT3 activation, we measured the expressions of c-MYC and SOCS3, which are induced by STAT3. c-MYC was increased by LPS and even more so by red wine and green tea polyphenol supplementation (Figure 2). Conversely, SOCS3 (which acts as a feedback inhibitor of the JAK/STAT signaling pathway) expression was reduced by LPS treatment. Wine and tea polyphenols had no effect, but the cocoa extract significantly reduced SOCS3 expression relative to LPS treatment ($p < 0.03$, Figure 2), confirming that polyphenols have limited intestinal anti-inflammatory activities when used in concentrations that approximate dietary intakes. Nutraceuticals and supplements provide pharmanutritional[19] doses that might, conversely, produce beneficial effects.[20]

HDL Secretion and Functionality. As mentioned in the Introduction, several human studies report an association between polyphenol intake and circulating HDL-c concentrations. Therefore, much research is concentrating on investigating the mechanism(s) behind this arguably positive piece of evidence. In addition to the putative protective role of HDL in cardiovascular disease, cholesterol efflux from macrophages is predictive of cardiovascular risk,[21,22] even though this notion needs further confirmation.[23] HDL functionality is generally assessed by its capacity to efflux cholesterol from macrophages. Indeed, some polyphenols have been shown to increase macrophage cholesterol efflux ex vivo.[24−26] However, we believe that HDL functionality should be assessed not only by its capacity to efflux cholesterol from macrophages but also by its capacity to deliver cholesterol via SR-BI because this is the last step in reverse cholesterol transport.[13,27] Therefore, both aspects must be considered to determine HDL functionality. If the HDL particle can induce efflux from macrophages, but cannot deliver cholesterol properly via SR-BI, then cholesterol will accumulate in plasma as associated with HDL. We treated Caco-2 monolayers with different polyphenols and measured HDL functionality determined as the capacity of HDL to deliver cholesterol to cells via SR-BI (measured as the percent cholesterol

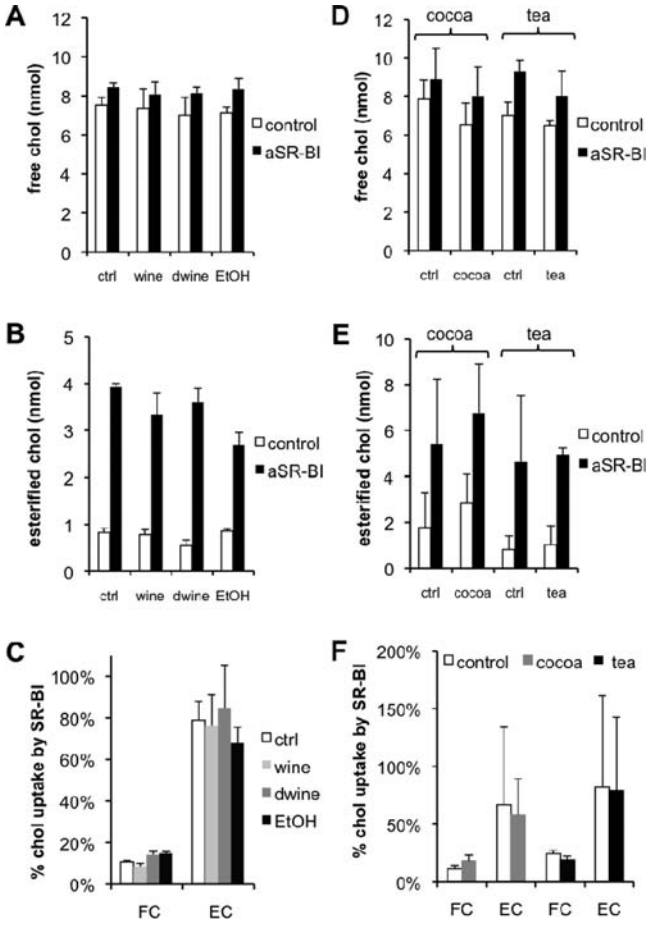

Figure 3. Red wine, green tea, or cocoa polyphenols do no alter intestinal cholesterol efflux or HDL functionality. Caco-2 monolayers were pretreated apically with the microsomial trygliceride transfer protein inhibitor BMS212122 for 3 h. At time 0, basolateral medium was replaced with fresh DMEM without phenol red in the presence or absence of aSR-BI, and polyphenols or EtOH was administered apically. At 24 h, free (A, D) and esterified cholesterol (B, E) were measured and HDL functionality (C, F) was determined. Chol, cholesterol; FC, free cholesterol; EC, esterified cholesterol; aSR-BI, antibody against SR-BI; dwine, dealcoholized wine.

taken up by SR-BI: (1 − cholesterol in the absence of aSR-BI/cholesterol in the presence of aSR-BI) × 100%.[16] Cholesterol can be secreted basolaterally by Caco-2 monolayers associated with HDL or to chylomicrons. Because we were interested only in looking at cholesterol secretion associated with HDL and HDL functionality, we used the microsomal triglyceride transfer protein inhibitor BMS212122 to inhibit chylomicron secretion. We did not record an effect on cholesterol secretion or cholesterol uptake by SR-BI when cells were treated for 24 h with polyphenols from red wine (Figure 3A−C), cocoa (Figure 3D,F), or green tea (Figure 3E,F). We then assessed HDL functionality in an inflamed state by LPS induction: similarly, we did not see a difference in cholesterol secretion (results not shown) or cholesterol uptake by SR-BI (Supplemental Figure 1). Taken together, these data suggest that polyphenols (at least those from red wine, cocoa, and green tea) administered at a dietary dose neither increase cholesterol secretion by intestinal cells nor enhance HDL functionality. It should be noted that Yasuda et al. explored a different pathway of HDL synthesis as influenced by cocoa polyphenols in Caco-2 cells[28] by measuring apolipoprotein A1 (apoA1) secretion. They report increased apoA1 production as a result of up-regulation of mature form SREBPs and increased LDL receptor activity induced by cocoa polyphenols. However, it should be noted that these authors used undifferentiated Caco-2 cells instead of confluent monolayers as we did, and metabolism is very different in these cells. Lipoproteins are secreted only by differentiated Caco-2 monolayers and not by undifferentiated cells. Therefore, issues of concentrations and pathways of HDL production should be further addressed to elucidate this matter. Further studies are also warranted to ascertain whether the positive associations between polyphenol consumption and HDL-c concentrations are the result of confounding factors or are, indeed, due to these secondary metabolites.

Another cautionary note concerns the ApoE effects on cholesterol secretion. In this respect, Caco-2 cells possess the most commonly found ApoE3/E3 genotype[29] and, therefore, our results should be applied to the general population. However, the intestines of genotypically different individuals might react differently to polyphenol exposure. Finally, cell cultures are very useful to study mechanisms, but in vivo conditions such as pH, osmolarity, microbiota, and mucus might evidently differentially modulate the effects we report.

In conclusion, by using human intestinal cells supplemented with physiological concentrations of polyphenols from three different sources, we confirm their limited anti-inflammatory visceral actions and report that they do not directly affect cholesterol secretion or HDL functionality.

dients allows vegetable oils to perform as base oil and as additive(s). The additive function depends on the chemical nature of the group introduced into their structure. For example, introduction of branching through synthetic conversion will allow the vegetable oil to also take on the role of a pour point depressant additive because it will result in lowered pour point and cloud point properties.[12,16] Thus, such multifunctional characteristics make it unnecessary to incorporate, analyze, and control pour point depressant in the formulation, which is a big cost savings for the lubricant user. This study was designed to enzymatically synthesize, purify, identify, and characterize crude and purified lipoyl glyceride product mixtures for extreme pressure and other tribological properties.

MATERIALS AND METHODS

Materials. α-Lipoic acid (D/L racemic mixture, **1**) and 2-methyl-2-butanol were purchased from Sigma-Aldrich (St. Louis, MO, USA). Novozym 435 (*Candida antarctica* lipase B immobilized on acrylic beads) was purchased from Novozymes North America (Franklinton, NC, USA). High-oleic sunflower oil (81% oleic acid, **2**) was purchased from Columbus Foods (Des Plaines, IL, USA). Refined, bleached, and deodorized soybean oil, **3**, was obtained from Pioneer Hi-Breed International (Des Moines, IA, USA). Polyalphaolefin with a viscosity of 6 cSt at 100 °C (PAO6), known under the trade name Durasyn 166, **4**, was a free sample from Ineos Oligomers (League City, TX, USA). Di-*tert*-dodecyl polysulfide, $(t\text{-}C_{12}H_{25})_2S_5$, known under the trade name TPS-32, was a free sample supplied by Arkema Canada Inc. (Burlington, ON, Canada).

Synthesis of Lipoyl Glycerides. Lipoic acid, **1** (20.6 g; 0.10 mol), high-oleic sunflower oil, **2** (133 g; 0.15 mol), and 2-methyl-2-butanol (46 g) were treated with Novozym 435 (15.4 g; 10:1 substrate to enzyme ratio) for 24 h at 60 °C in an orbital shaker. The reaction mixture was then placed under partial vacuum (250 mbar) for 6 h at 60 °C using a rotary evaporator, which served to slightly increase the generation of lipoyl glycerides. The enzyme was separated from the product by filtration through a 20 μm nylon Spectra/Mesh (Cole-Parmer, Vernon Hills, IL, USA) and washed with acetone (200 mL) to increase product recovery. Solvent was removed under reduced pressure at 60 °C, and 133 g (89% yield) of the crude lipoyl glyceride product was obtained.

Solvent Fractionation of Lipoyl Glycerides. The reaction product was extracted with methanol (2 × 300 mL) to remove lipoic acid and free fatty acids. The oil phase was freed of residual solvent under reduced pressure at 60 °C to give 93 g, 61% isolated yield, of purified lipoyl glyceride product.

HPLC Analysis. Analyses were performed using a Thermo Separation Products (San Jose, CA, USA) HPLC system consisting of a Spectra System AS3000 autosampler, a Spectra System P4000 pump, a Spectra System UV6000LP detector, an Alltech (Deerfield, IL, USA) 500 evaporative light-scattering detector, and a 250 mm × 4.6 mm i.d., 5 μm, Luna Phenyl-Hexyl column (Phenomenex, Torrance, CA, USA). The column was eluted isocratically with 95% acetonitrile/5% acetone/0.05% acetic acid (v/v/v) at a flow rate of 1.5 mL/min, with UV detection at 340 nm. Injection volumes were 10 μL.

LC High-Resolution Mass Spectroscopy Analysis. Structural confirmation of derivative structures was obtained by high-resolution mass spectrometry using a Thermo Scientific Accela UHPLC system (autoinjector, PDA detector, and a 1250 quaternary pump) coupled with an LTQ Orbitrap Discovery mass spectrometer (MS), with an Ion Max electrospray ionization (ESI) source, all running under Thermo Scientific Xcalibur LC-MS software. The MS was run with the ESI probe in the positive mode. The source inlet temperature was 350 °C; the sheath gas rate was set at 10 arbitrary units; the auxiliary gas rate was set at 2 arbitrary units; and the sweep gas rate was set at 2 arbitrary units. The maximal mass resolution was set at 30000, the spray voltage was set at 3.0 kV, and the tube lens was set at −100 V. Other parameters were determined and set by the calibration and tuning process. The column (Luna Phenyl-Hexyl; 5 μm, 250 mm × 4.6 mm) was eluted isocratically with 95% acetonitrile/5% acetone containing 0.1% formic acid at a flow rate of 1.0 mL/min, with UV detection at 340 nm.

Solubility in Petroleum-Based Oils. The solubility of lipoyl glyceride product mixtures in **4** at room temperature was determined gravimetrically, using visual inspection for any changes in oil transparency, and is expressed as a percentage of the total weight.

Surface Tension. Equilibrium surface tension at room temperature (23 ± 2 °C) was measured using the axisymmetric drop shape analysis method[17] on the FTA 200 automated goniometer (First Ten Angstroms, Portsmouth, VA, USA), using previously reported procedure.[18]

Density, Viscosity, and Viscosity Index. Density and dynamic and kinematic viscosity as a function of temperature were measured on a Stabinger SVM3000/G2 viscometer (Anton Paar GmbH, Graz, Austria). Viscosity index was calculated from kinematic viscosity data at 40 and 100 °C following the procedure outlined in ASTM D 2270-93.[19]

Pressurized Differential Scanning Calorimetry (PDSC). PDSC tests were conducted on a Q20P pressure differential scanning calorimeter (TA Instruments−Waters LLC, New Castle, DE, USA) fitted with a computer and appropriate software to allow for data acquisition and analysis. All tests were conducted with the cell pressurized with pure oxygen to 500 ± 25 psig in dynamic mode, that is, with a positive oxygen flow rate of 100 ± 10 mL/min. In a typical experiment, an oil sample of 1.2−2.0 mg was placed onto an aluminum pan, which was then hermetically sealed; a small pinhole was punched on the top cover, and the pan was placed in the instrument cell. The cell was then pressurized to 500 ± 25 psig and the temperature allowed to equilibrate to 50 °C. Oxygen was then allowed to flow at 100 ± 10 mL/min. Once the desired oxygen pressure, flow rate, and initial cell temperature were attained, the cell temperature was ramped up to 250 °C at a rate of 10 °C/min. The resulting heat flow versus temperature data were plotted and analyzed using the instrument computer and software to determine onset temperature and peak temperature. Duplicate runs were conducted, and average values are reported.

Four-Ball (4-Ball) Instrument and Test Specimen. The 4-ball tests were conducted on a model KTR-30L 4-ball tribometer equipped with TriboDATA software (Koehler Instruments, Bohemia, NY, USA). The specification and detailed description of the instrument hardware and software have been given before.[6] Test balls used in 4-ball experiments were obtained from Falex Corp. (Aurora, IL, USA), and their specifications have also been given before.[6]

4-Ball Antiwear Test. The 4-ball antiwear tests were conducted according to the procedure outlined in ASTM D 4172-94.[20] The coefficient of friction for each test was calculated from the corresponding torque and load data using the procedure outlined in ASTM D 5183-95.[21] The wear scar diameters of the balls used in the test were measured using a wear scar measurement system comprising hardware and ScarView software (Koehler Instruments). The wear scar diameters along and across the wear direction of the three balls were used to calculate the average wear scar diameters for the test. Each test lubricant was used in at least two antiwear measurements, and average coefficient of friction and wear scar diameters values were reported.

4-Ball Extreme Pressure Test. The 4-ball extreme pressure test was conducted according to the procedure outlined in ASTM D 2783-88.[22] The test comprises a series of 10 s tests at increasing loads until welding of the four balls is observed. The load at which welding is observed is the weld point and is a characteristic extreme pressure property of the lubricant tested. For tests below the weld point, the average wear scar diameter of the three balls, measured in accordance with ASTM D 4172-94,[27] is recorded as a function of the test load.

RESULTS AND DISCUSSION

Lipoic Acid Basics. Lipoic acid, **1**, is a naturally occurring cellular cofactor that has a cyclic disulfide moiety.[23] Sulfur is

one of several elements known to provide extreme pressure properties to lubricants.[24] This makes derivatives of lipoic acid potential candidates for application in extreme pressure lubrication. Lipoic acid is an ingredient in dietary supplements and cosmetics.[25,26] In addition, lipoic acid exhibits beneficial effects in the therapy of many diseases. In the past few years, several papers have described its chemical modifications to improve pharmacological properties.[27] The solubility of lipoic acid in lubricating oils is very low but can be significantly improved with appropriate modifications. Novel conjugates of 1,3-dioleoyl-glycerol and lipoic acid have been already described in the literature.[28] The enzymatic route described in this paper is a green synthesis approach that is readily scalable to high production volumes through proven continuous packed-column technology[29] and does not rely on single-use catalysts described in the literature[28] procedure.

Synthesis and Characterization of Lipoyl Glycerides. A schematic for the enzymatic synthesis of lipoyl glycerides is given in Figure 1. A detailed description of the synthesis, purification, and characterization of lipoyl glycerides has been given previously.[30]

Various glycerides of lipoic acid (**1**) were obtained by a lipase-catalyzed transesterification reaction between high-oleic sunflower oil (**2**) and **1** (Figure 1). A 1:1.5 molar ratio of **1** to **2** was used. Application of excess **2** in the reaction helped ensure that a large proportion of **1** was incorporated into the glyceride species. The reaction product was a complex mixture of unreacted starting materials (**1** and **2**) as well as various structures of lipoyl glycerides and free fatty acids (**9**). Some of the structures in the reaction product mixture are depicted in Figure 1.

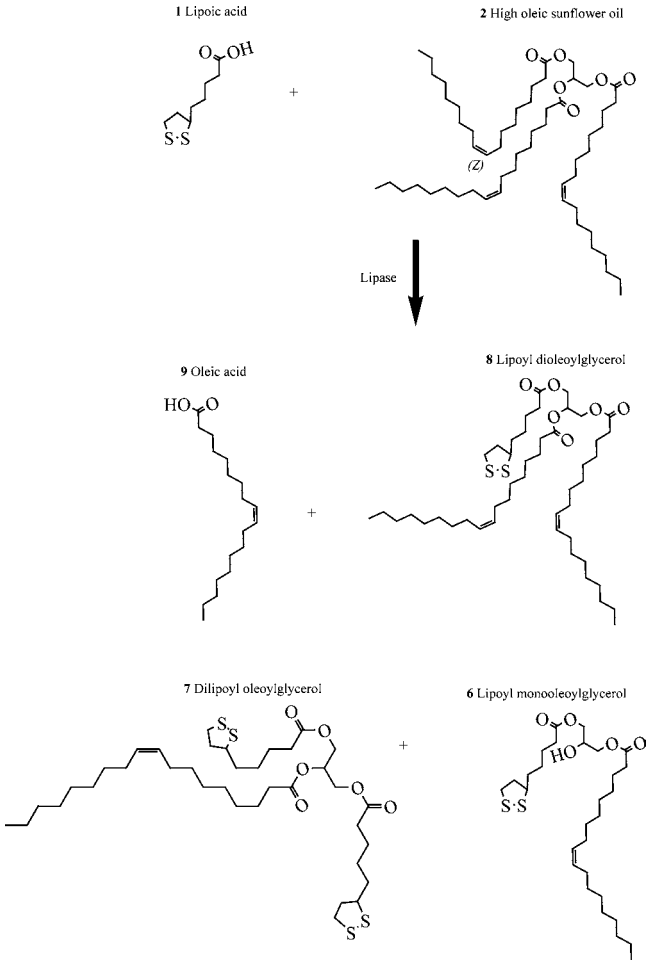

Figure 1. Schematic of the transesterification reaction of lipoic acid with high-oleic sunflower oil.

HPLC and LC-MS analyses were used to identify and quantitate **1** and the various lipoyl products in the product mixture. The following principal lipoyl reaction products were observed: lipoyl glycerol (**5**), lipoyl monooleoylglycerol (**6**), dilipoyl oleoylglycerol (**7**), and lipoyl dioleoylglycerol (**8**). The mass spectra of these entities are shown in Figure 2. In all cases, the parent compound was identified in a complex with a metal ion (K^+ or Na^+) or formate resulting from the MS ionization process. Multiple complexes were observed, including dimers. The fact that the principal products are oleoylglycerides is consistent with the fatty acid composition of **2**, which is mainly (81%) oleic acid (Table 1).[31] As expected, small quantities of similar lipoyl derivatives of other fatty acids of **2** were also observed.

The analysis of the lipoyl product mixture showed that 72 mol % of the original **1** participated in the transesterification reaction to produce a variety of lipoyl products, whereas 28 mol % did not react at all (Table 2). The relative molar composition of reacted **1** in the crude product mixture decreased in the order **8** > **7** > **6** > **5** (Table 2).

The crude product mixture containing lipoyl glycerides was extracted with a polar solvent, methanol. The resulting purified mixture was analyzed using the same procedures used to analyze the crude product mixture. Table 3 compares the composition (% w/w and mol/mol) of the major species in the crude versus purified product mixtures. As expected, extraction with methanol completely removed the more polar species from the crude product. As a result, the purified product was free of unreacted **1** and **9** generated by the transesterification reaction. These two species are the most polar components in the crude product mixture. Their removal resulted in an increase in the relative proportion of the less polar components **2**, **8**, and **7** in the purified product mixture (Table 3). Thus, the crude and purified product mixtures represented two different compositions and were evaluated for their physical and tribological properties.

Density. The densities of neat soybean oil (**3**), **2**, crude and purified product mixtures, and blends at 40, 75, and 100 °C are compared in Table 4. As expected, the densities of all the oils investigated decreased with increasing temperature. The data in Table 4 show that the crude and purified product mixtures had higher densities than the starting **2**, which had lower density than **3**. The higher density of the product mixtures over **2** can be attributed to the insertion of the heavier sulfur atoms during transesterification. The density results also show a slightly higher value for the crude than for the purified product mixture. However, for all practical purposes, the two product mixtures can be considered to have similar densities. The data in Table 4 also show that the blends have higher densities than the neat vegetable oils (**2**, **3**), and the density increases proportionately with increasing concentrations of the product mixtures in **2** and **3**. An important observation in Table 4 is the relative density of the crude product mixture blend in **2** versus that in **3**. The density of the blend in **3** is greater than that in **2** at 40 and 75 °C but is reversed (**2** > **3**) at 100 °C. This could be due to a higher propensity of crude product mixture to decompose in **3** than in **2** at 100 °C, which is close to the melting point of sulfur.

Table 1. Fatty Acid Composition of High-Oleic Sunflower (2) and Soybean (3) Oils

fatty acid name	fatty acid structure	**2**, % w/w[31]	**3**, % w/w[5]
palmitic	C16:0	5	10.6
stearic	C18:0	4	4.0
oleic	C18:1	81	23.2
linoleic	C18:2	9	53.7
linolenic	C18:3	0.5	7.6

Viscosity and Viscosity Index. The kinematic and dynamic viscosities of neat **2**, **3**, crude and purified product mixtures, and blends are compared in Table 4. As with density, the viscosities of the transesterification products were higher than that of the starting **2**, which was more viscous than **3** (Table 4). The increased viscosity of the two product mixtures relative to **2** can be attributed to the increased polarity of the molecules after transesterification. The increased polarity will increase the intermolecular interactions between the molecules and thereby retard oil flow. Table 4 also shows that the purified product mixture is more viscous than the crude, which is the reverse of the relative densities between these two product mixtures. This could be due to the higher average molecular weight of the purified product mixture relative to the crude. The data in Table 4 also show that the kinematic and dynamic viscosity of blends in **2** or **3** increased with increasing concentrations of product mixtures in the blend.

The viscosity indices of neat **2**, **3**, crude and purified product mixtures, and blends are also given in Table 4. Transesterification resulted in slightly lowering the viscosity index of **2** from about 200 to 178−185. Despite this lowering, the viscosity index range for the neat product mixtures was much higher than the best petroleum-based and polyalphaolefin (**4**) oils. Blending of lipoyl glyceride product mixtures in **2** and **3** caused a slight reduction in the viscosity index of these two vegetable oils. As shown in Table 4, the viscosity index decreased with increasing concentration of the two product mixtures in the vegetable oils.

Surface Tension. The surface tensions of the neat oils and blends are compared in Table 5. As shown in Table 5, within one standard deviation, transesterification did not cause any change in the surface tension of **2**. The surface tension of **2**, which is slightly higher than that of **3**, remained more or less the same. However, as shown in Table 5, blending of the crude product mixtures into **3** increased the surface tension of **3** by almost 1 dyn/cm to the value of the neat product mixtures.

Solubility in Polyalphaolefin Oil (4). Application of lipoyl glycerides as lubricant additives requires that they be soluble

not only in biobased base oils such as **2** and **3** but also in petroleum-based oils such as **4**. Solubility investigation showed that both product mixtures are highly soluble in **2** and **3**. The results of the solubility study in **4**, which has a viscosity close to that of **3**, are also summarized in Table 5. As shown in Table 5, the crude product mixture was found to be insoluble in **4**,

whereas the purified product mixture was highly soluble. The difference in the solubility of these two product mixtures is a reflection of the difference in their compositions. As shown in Table 3, the crude contains almost 48% mol/mol of polar or hydrophilic components (**1**, **5**, **9**), whereas the purified contained a mere 2.9% mol/mol. As a result, the crude mixture is hydrophilic and insoluble in the lipophilic **4**, whereas the purified mixture is lipophilic and highly soluble in **4**, as shown in Table 5.

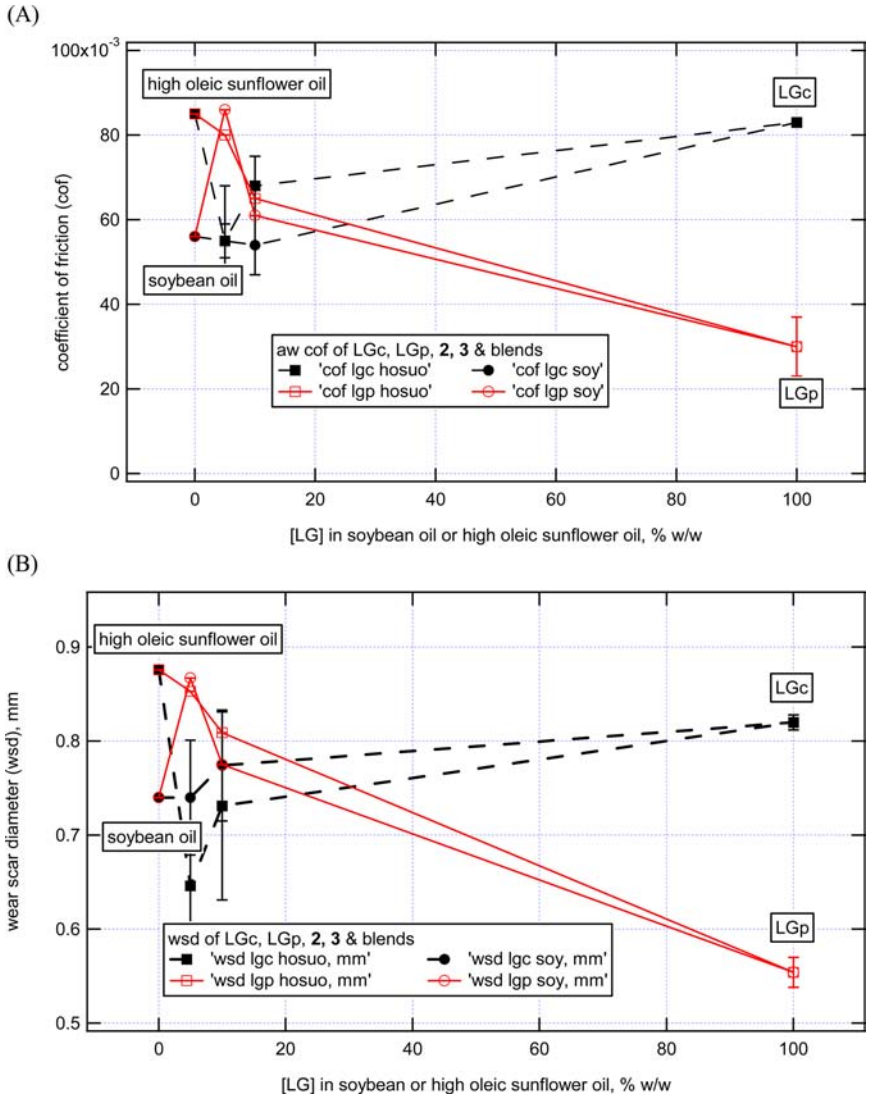

Figure 4. Antiwear properties of **2**, **3**, crude (LGc) and purified (LGp) lipoyl glyceride product mixtures, and blends: (A) coefficient of friction (COF); (B) wear scar diameter (WSD, mm).

Oxidation Stability. Oxidation stability was investigated using PDSC. In this procedure, the oils are heated at a fixed rate (°C/min) under a pressurized oxygen atmosphere until oxidation is detected due to changes in heat flow. The temperatures at which the oxidation begins, called the onset temperature, and maximum oxidation occur, called the peak temperature, are used to compare the oxidation stability properties of oils. Onset and peak temperatures correlate very well, and either or both values can be used to compare the oxidation stability of vegetable oils. The higher the onset and peak temperatures, the more stable the oil is toward oxidation.

The oxidation of vegetable oils has been attributed to the presence of allylic and bis-allylic protons in their structures.[2,15] Thus, the relative abundance of mono- and polyunsaturated fatty acids in the respective triglycerides of the vegetable oils has a strong influence on oxidation stability properties. The higher the degree of unsaturation, the less oxidatively stable the oil.

Table 1 compares the fatty acid compositions of **2** and **3** and provides data about the structure of the fatty acid as it relates to the number of double bonds as well as the relative fraction of each fatty acid in the triglyceride mixture in the oil. The data in Table 1 can be used to estimate the degree of unsaturation or unsaturation index (UI) for the vegetable oils as[32]

$$\mathrm{UI} = 100 \times [\Sigma(d_i \times w_i)] \quad (1)$$

where d_i is the number of double bonds on a fatty acid and w_i is the weight fraction of the fatty acid in the vegetable oil.

According to eq 1, the larger the number of double bonds in the fatty acid and the larger its weight fraction among the fatty acids in the triglyceride, the higher the UI value and the less oxidatively stable the oil will be. Application of eq 1 to the data in Table 1 gave UI values of 100.5 and 153.4 for **2** and **3**, respectively. Thus, eq 1 predicts that **2** will have a lower UI and, hence, will be more oxidatively stable than **3**.

Figure 3 compares the PDSC results for neat **2**, **3**, crude and purified product mixtures, and their blends. The data for the neat vegetable oils shows higher onset and peak temperatures for **2** than for **3**, as was predicted by eq 1. The data in Figure 3 also show that the neat crude and purified product mixtures have significantly higher oxidation stability than either vegetable oil. It also shows that the addition of small amounts of the crude or purified product mixture to the vegetable oils resulted in significant improvement in their oxidation stability. The

dx.doi.org/10.1021/jf404289r | J. Agric. Food Chem. 2014, 62, 2233−2243

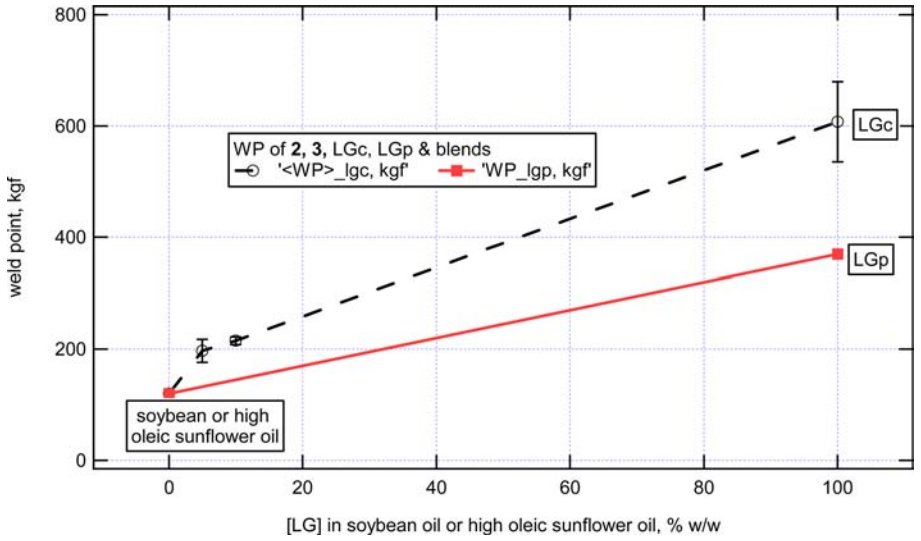

Figure 5. Weld points (WP) of **2**, **3**, crude (LGc) and purified (LGp) lipoyl glyceride product mixtures, and blends (kgf).

onset and peak temperatures of the vegetable increased with increasing concentration of crude and purified product mixtures in the blend.

There are two possible reasons for the improvements in the oxidation stability of **2** after the transesterification reaction with **1**. The most obvious reason is the replacement of fatty acids with mono- or polyunsaturation by **1**, which has zero unsaturation. A second possible reason is the antioxidant property of the sulfur moiety in the crude and purified product mixtures. Improvements in the oxidation stability properties of oils with sulfur moieties have been reported previously and have been attributed to the antioxidation property of the sulfur group.[16,33,34]

Examination of Figure 3 shows slightly higher onset and peak temperatures for the crude than for the purified product mixture, which corresponds to a slightly better oxidation stability for the crude product mixture. This difference cannot be attributed to differences in sulfur content between the two products, because they are about equal (Table 3). However, it might be due to other properties related to compositional differences. As discussed before, two types of lipoyl glyceride species were generated after transesterification: hydrophilic (polar) and lipophilic (nonpolar). As shown in Tables 2 and 3, almost 50% of the species in the crude mixture are hydrophilic, whereas the corresponding value in the purified mixture is <3%. The improved oxidation stability of the crude product might be an indication of a better antioxidant characteristic for the hydrophilic than for the lipophilic lipoyl glyceride species.

Cold-Flow Properties. Cold-flow properties correspond to temperatures below which the oils cease to flow. It is an important property of lubricating oils that dictates the seasons and geographic locations where the oils can be applied. Pour point and cloud point are used to quantify cold-flow properties. Table 5 compares the pour points and cloud points of crude and purified product mixtures, along with those of **2** and **3**. As shown in Table 5, improvements in pour point and cloud point have been observed as a result of the transesterification reaction. Both the crude and purified product mixtures displayed improved cold-flow properties over those reported for the parent **2**[9] or for **3**.[5] Improvements in cold-flow properties are usually associated with the introduction of branching to the triglyceride chains, which is not the case here. Two possible reasons are replacement of long-chain fatty acids (C_{16} and higher) in the starting triglycerides, which causes crystallization and solidification at lower temperature, by the shorter chain (C_8) **1** during transesterification (see Figure 1 and Table 1), and production of a much more complex product mixture after transesterification than that of the starting **2**, which will result in depressed melting temperatures.

Antiwear Properties. 4-Ball friction and wear properties under antiwear conditions (40 kgf, 1200 rpm, 75 °C, 60 min) are compared in Figure 4. The test provides two parameters: coefficient of friction and wear scar diameter. Neat **2** showed a higher coefficient of friction and higher wear scar diameter than neat **3**. This result is contrary to expectation based on the relative viscosities of these two vegetable oils (Table 4). Antiwear tests are conducted under mixed film conditions where both the viscosity and chemical properties of the oils will have an effect. In oils with similar chemical properties, viscosity becomes the dominant predictor of antiwear results. In this particular case, however, viscosity effects were overwhelmed by chemical effects. This indicates major differences in chemical properties between these two vegetable oils, far beyond what is quantified by the fatty acid composition shown in Table 1.

Comparison of the antiwear results for the two product mixtures showed a different result from that between **2** and **3**. Here, the two product mixtures have similar chemical origins. Both are transesterification products of **1** and **2**, which means they have similar chemical species in their mixture. However, because of the differences in purification procedures, they comprise different proportions of the same species. The consequence of this, as discussed previously, was differences in lipophilicity and viscosity. The crude mixture was found to be less viscous and less lipophilic than the purified (Tables 3 and 4). As a result, the crude mixture, because of its hydrophilic properties, was found to be insoluble in the lipophilic base oil **4** (Table 5). The consequence of viscosity is illustrated in Figure 4, where the lower viscous crude product displayed a poorer coefficient of friction and wear scar diameter. Such a result is expected in mixed film test conditions of oils with similar chemical properties but different viscosities.[24]

Extreme Pressure (EP) Properties. Extreme pressure tests are conducted to determine if the oils are capable of providing lubrication at very high pressures and/or temperature

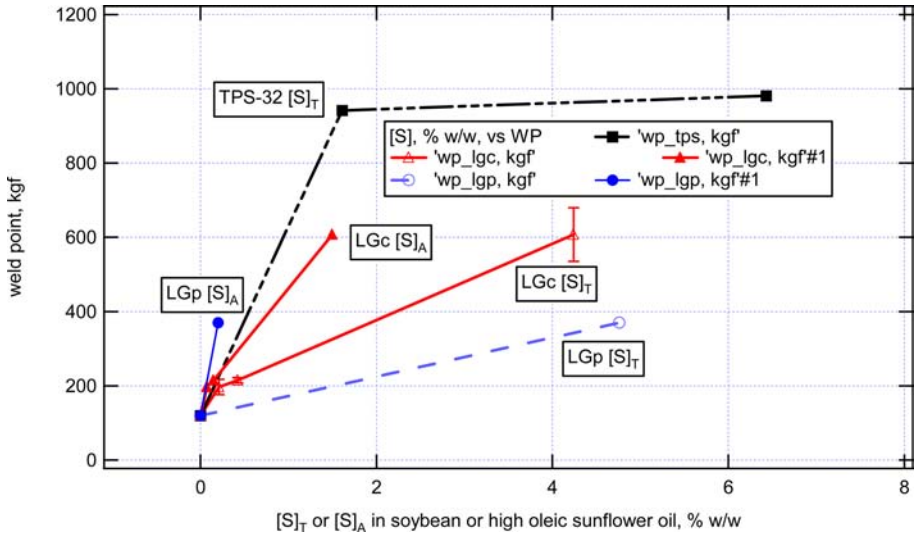

Figure 6. Effect of total versus active sulfur concentration on weld point (WP) for the commercial additive TPS-32 and crude (LGc) and purified (LGp) lipoyl glyceride product mixtures in the vegetable oil **2** or **3** (kgf).

conditions. To do so, the oils must be capable, under the lubrication conditions, of participating in a tribochemical reaction with the friction surfaces and in situ generating tribofilms that[24] reduce friction and separate the friction surfaces so they do not damage each other. Such properties have been observed in oils that contain certain elements including sulfur, phosphorus, and halogens. Therefore, it was of interest to investigate if the lipoyl glyceride mixtures, which contain disulfide moieties in their structures, could undergo tribochemical reactions under EP conditions and in situ produce tribofilms with beneficial properties. In the 4-ball extreme pressure test, a series of 10 s tests are conducted at 1760 rpm and room temperature, with the load progressively increasing until lubricant failure is observed due to the welding of the four balls. The load at which welding occurs is called the weld point and is the characteristic EP property of the oil. The higher the weld point, the better the extreme pressure property of the oil.

Neat vegetable and mineral base oils have weld point values of around 100 kgf and are considered not to have beneficial EP properties. Improving the EP properties of such oils is accomplished with the blending of additives that have one or more of the elements listed above.

The 4-ball extreme pressure test results on **2**, **3**, crude and purified product mixtures, and their blends are summarized in Figure 5. Similar weld point values of about 120 kgf were observed for **2** and **3**. As mentioned before, this value is expected and not high enough to be considered a beneficial extreme pressure characteristic. On the other hand, the crude and purified product mixtures displayed weld point values that were 4−6-fold higher (Figure 5). These results are considered a substantial improvement over the value of the neat vegetable oils and an indication of beneficial extreme pressure characteristic. The improved extreme pressure results of neat product mixtures indicates that the disulfide moieties in these products did participate in tribochemical reactions with the metal surfaces in situ during the test. The result of such tribochemical reaction is the generation of tribofilms that lower friction, prevent surface damage, and allow the lubrication process to proceed under the extreme conditions. In fact, small additions of the crude mixture to **2** or **3** resulted in increased weld point for the blends (Figure 5). This observation indicates that lipoyl glyceride product mixtures can also be used as extreme pressure additives to improve the EP pressure properties of vegetable oils.

Close examination of the data in Figure 5 shows big differences in the extreme pressure performance of neat crude product relative to neat purified product mixture. As it turns out, the hydrophilic crude product mixture was significantly more effective than the lipophilic purified product mixture in improving the EP properties of transesterified **2**. As mentioned previously, these two products are mixtures of species of similar chemical structures. However, they differ in the proportion of the chemical species. The crude mixture contains about equal molar quantities (% mol/mol) of hydrophilic and lipophic species, whereas purified mixture contains very little hydrophilic and almost all lipophilic species (Table 3). As a result, the crude mixture is soluble in polar vegetable oils but insoluble in lipophilic petroleum-based base oils. The purified product, on the other hand, is soluble in both polar and nonpolar base oils. It is also more viscous than the crude product, but viscosity has no contribution to EP properties.[24] Thus, understanding the difference in the extreme pressure performance of these two product mixtures will require closer examination of the relative composition of the species in their product mixture and of their solubility.

Effect of Chemical Structure. To better understand the difference in the EP properties of the crude and purified product mixtures, we compared the results with that of a commercial polysulfide extreme pressure additive, TPS-32, which has been described as di-*tert*-dodecyl polysulfide, $(t\text{-}C_{12}H_{25})_2S_5$, with five sulfur atoms per molecule.[35] In conducting the comparison, we assumed that TPS-32 has the single structure shown above and that all five sulfur atoms are active and participate in tribochemical reactions under EP conditions. On the other hand, crude and purified products comprise mixtures of lipophilic and hydrophilic structures with sulfur atoms for which relative tribochemical activity under extreme pressure conditions is unknown.

The weld points of the crude and purified products from this work were compared with the published weld point of TPS-32[35] as a function of the concentration of sulfur (% w/w) in

dx.doi.org/10.1021/jf404289r | J. Agric. Food Chem. 2014, 62, 2233−2243

each mixture. The concentrations of sulfur in the crude and purified product mixtures were estimated and are given in Table 3. The concentration of sulfur in TPS-32 was estimated by assuming that the material contains a single structure, $(t\text{-}C_{12}H_{25})_2S_5$. Two types of sulfur concentrations were used in the comparisons: total sulfur or $[S]_T$, the weight fraction of sulfur in all components in the material; and active sulfur or $[S]_A$, the weight fraction of sulfur in all of the components that participate in the tribochemical reaction. For TPS-32, because it is assumed that there is only one component in the mixture, $[S]_T = [S]_A$. However, for crude and purified product mixtures, $[S]_T$ is different from $[S]_A$. The value of $[S]_T$ was calculated from the contributions of all sulfur-containing components in each mixture, which is detailed in Table 3. However, $[S]_A$ values for the crude and purified mixtures were obtained from the contributions of the sulfur-containing hydrophilic components in the mixture, namely, **1**and **5** in Table 3.

This type of analysis was selected to test the hypothesis that the better extreme pressure performance of the crude product was an indication of preferential tribochemical reaction by the sulfur atoms of the hydrophilic species in the mixture. According to this hypothesis, the hydrophilic species will have lower solubility in the lipophilic **2** and will preferentially adsorb onto the hydrophilic metal surface rather than stay in solution in the lipophilic oil. In other words, the equilibrium between surface versus solution concentration is different for the hydrophilic and lipophilic species. The hydrophilic species will preferentially concentrate on the surface, whereas the lipophilic species will preferentially stay in solution. As a result, in the case of the crude product, there will be a higher concentration of sulfur atoms on the surface to participate in the tribochemical reactions with the metal surface and produce in situ the tribofilms responsible for the favorable extreme pressure outcome.

Figure 6 compares the weld points of TPS-32 and crude and purified products as a function of $[S]_T$ and $[S]_A$. Weld point values as a function of $[S]_T$ increased in the order purified $\ll$ crude $\ll$ TPS-32. On the other hand, weld point values as a function of $[S]_A$ displayed the following order: purified $\approx$ TPS-32 $\approx$ crude. Of course, this analysis is not proof of the mechanism for the extreme pressure performance of the crude and purified product mixtures. It is one of the many possible explanations for the observed differences in the EP properties between the two products. Further work is needed to verify the validity of this and alternative mechanisms.

Farm-based products provide a sustainable, abundant, safe, and environmentally friendly raw material base for many consumer and industrial products currently manufactured from petroleum. However, successful replacement of petroleum with farm-based raw materials will require solving a number of inherent weaknesses in natural products. In this work, enzymatic transesterification was applied to improve the lubrication properties of high-oleic sunflower oil. The enzymatically modified oil displayed improved oxidation stability and cold-flow properties relative to the unmodified oil. It also displayed highly improved extreme pressure properties that were comparable to those of a commercial extreme pressure additive widely used in various lubricant formulations currently on the market.

based on the release of specific compounds present in the polymer formulation with controlled kinetics in particular environments.[16] It is known that the addition of active agents to polymer matrices avoids food degradation processes improving the quality, safety, and health properties of foodstuff.[17] In this sense, the combination of active technologies, such as the addition of antioxidant and/or antimicrobial agents to packaging materials, with the use of nanocomposites can synergistically lead to formulations with balanced properties and functionalities.[8,18] Regarding the development of active films based on PCL, Salmieri et al.[19] incorporated oregano, savory, and cinnamon essential oils (EOs) at 1% (w/w) as natural antioxidants to alginate/PCL-based films. Their results confirmed the plasticizing effect of EOs in addition to their bioactive role, with the oregano-based films demonstrating the most effective antiradical systems. β-carotene is another widely available natural antioxidant, and it has been reported that the addition of low amounts of this compound to PCL resulted in a significant plasticization of the matrix improving its ductile properties.[20] In this sense, the use of hydroxytyrosol (3,4-dihydroxyphenylethanol, HT), a compound with the highest antioxidant effect among the various polyphenols present in olives,[21] could be a promising approach from an economical point of view, because it would turn agricultural residues into higher added-value active food packaging additives. In previous studies, certain decrease in thermal properties of natural antioxidants has been observed for compression molded packaging materials at high temperatures.[22] However, hydroxytyrosol showed a good performance in polypropylene materials acting as antioxidant, and it might be considered as a promising alternative to use in active packaging formulations.

The novelty of this work lies on the use of HT as natural antioxidant combined with a commercial nanoclay to develop films for active packaging based on PCL. The addition of the nanoclay could help to improve the intrinsically poor PCL barrier properties. Also, the use of HT is justified to improve shelf life of foodstuff by the antioxidant performance of this compound. At the best of our knowledge, there is no evidence in scientific literature of PCL-based packaging systems where the poor thermal resistance and barrier properties of PCL are overcome. In this way, this study is focused on the development and full characterization of new nanocomposites based on PCL, HT, and a commercial MMT (Cloisite30B, C30B), with high potential to improve thermal and barrier properties in biopolymers.[23] Active nanobiocomposite films were obtained by melt-blending followed by compression molding, which were further characterized on their thermal, structural, mechanical, and functional properties. In addition, the release of HT from these nanobiocomposites at different times was also evaluated.

MATERIALS AND METHODS

Materials. Poly(ε-caprolactone) (PCL, CAPA6800) commercial grade (pellets) was kindly supplied by Perstorp Holding AB (Sweden). Hydroxytyrosol (98% purity) (HT) was kindly supplied by Fine & Performance Chemicals Ltd. (Middlesbrough, U.K.). The commercial organo-modified montmorillonite used in this study was Cloisite30B (C30B), and it was supplied by Southern Clay Products (Austin, TX). This nanoclay was synthesized by replacing sodium ions in different silicate layers by methyl bis(2-hydroxyethyl) tallow alkyl ammonium cations by ion exchange.

Nanobiocomposites Preparation. PCL nanocomposites were processed by melt blending in a Haake Polylab QC mixer (ThermoFischer Scientific, Waltham, MA) at 80 °C for 5 min at 100 rpm. Before processing, PCL and C30B were left in an oven at 50 °C for 20 h and 100 °C for 24 h, respectively, to eliminate moisture. Both additives were introduced in the mixer once the polymer was in the melt state in order to avoid unnecessary losses. The 50 cm^3 mixing chamber was filled with 50 g of total mass. Eight different formulations were obtained by adding different amounts of HT and C30B in concentrations ranges of 5−10 wt % and 2.5−5 wt %, respectively (Table 1). An additional sample without any additive was also prepared and used as control (PCL0).

Table 1. PCL Nanobiocomposites and Thickness (Mean ± SD, n = 5)

formulation	HT (wt %)	C30B (wt %)	thickness (μm)
PCL0			204 ± 3
PCL/HT5	5		202 ± 6
PCL/HT10	10		206 ± 6
PCL/C30B2.5		2.5	191 ± 4
PCL/C30B5		5	198 ± 3
PCL/HT5/C30B2.5	5	2.5	196 ± 5
PCL/HT10/C30B2.5	10	2.5	201 ± 3
PCL/HT5/C30B5	5	5	191 ± 2
PCL/HT10/C30B5	10	5	198 ± 4

Films were obtained by compression-molding at 120 °C in a hot-plate hydraulic press from Carver, Inc., model 3850 (Wabash, IN). Materials were kept between the plates at atmospheric pressure for 5 min until melting, and then they were successively pressed under 2 MPa (1 min), 3 MPa (1 min), and lastly 5 MPa (5 min) to liberate the trapped air bubbles. The average thickness of the obtained films was around 200 μm, as measured with a 293 MDC-Lite Digimatic Micrometer (Mitutoyo, Japan) at five random positions (Table 1), after 48 h of conditioning at 50% relative humidity (RH) and 23 °C. The final appearance of the films was completely homogeneous.

Nanobiocomposites Characterization. *Differential Scanning Calorimetry (DSC).* Tests were conducted in triplicate by using a TA DSC Q-2000 instrument (New Castle, DE) under inert N_2 atmosphere. Samples (3 mg) were introduced in aluminum pans (40 μL) and were submitted to the following thermal program: heating from −90 to 160 °C (3 min hold), cooling to −90 °C (3 min hold), and heating to 160 °C, all steps at 10 °C min^{-1}. The crystallization and melting parameters were determined from the second heating scan. The crystallinity at room temperature (χ_c) of each material was evaluated by using eq 1:

$$\chi_c = \left(\frac{\Delta H_m}{\Delta H_m^0 \left(1 - \frac{\%\,wt_{clay}}{100}\right)} \right) \times 100 \quad (1)$$

where ΔH_m is the specific melting enthalpy of the sample, and ΔH_m° is the melting enthalpy of the 100% crystalline PCL matrix (142.0 J g^{-1}).[10]

Thermogravimetric Analysis (TGA). Thermogravimetric analysis was performed in a TGA/SDTA 851e Mettler Toledo thermal analyzer (Schwarzenbach, Switzerland). Samples (5 mg) were weighed in alumina pans (70 μL) and were heated

Table 2. DSC Results Obtained for All Formulations in Nitrogen Atmosphere (Mean ± SD, n = 3)[a]

PCL/HT5/C30B5	28 ± 2^a	56 ± 2^b	51 ± 2^{ab}	63 ± 2^a	47 ± 2^b
PCL/HT10/C30B5	27 ± 3^a	55 ± 1^a	49 ± 1^{ab}	60 ± 4^a	48 ± 1^b

[a]Different superscripts within the same column indicate statistically significant different values ($p < 0.05$).

from 30 to 700 °C at 10 °C min^{-1} under N_2 atmosphere (flow rate of 50 mL min^{-1}). Analyses were repeated three times for each sample.

Tensile Tests. Tensile tests were carried out by using a 3340 Series Single Column System Instron Instrument, LR30K model (Fareham Hants, U.K.) equipped with a 2 kN load cell. Tests were performed in rectangular probes (100 × 10 mm^2), an initial grip separation of 60 mm, and a crosshead speed of 25 mm min^{-1}. Before testing, all samples were equilibrated for 48 h at 50 RH %. Tensile strength, elongation at break, and elastic modulus were calculated from the resulting stress−strain curves by following the ASTM D882-09 standard.[24] Tests were carried out at room temperature. Five repetitions were performed for each film composition, and mean values were reported.

Oxygen Transmission Rate (OTR). Oxygen transmission rate was determined with an oxygen permeation analyzer (8500 model Systech, Metrotec S.A, Spain). Tests were carried out by introducing O_2 (99.9% purity) into the upper half of the diffusion chamber while N_2 was injected into the lower half, where an oxygen sensor was located. Films were cut into 14 cm diameter circles for each formulation, and they were clamped in the diffusion chamber at 25 °C. Tests were performed in triplicate and were expressed as oxygen transmission rate per film thickness (OTR·e).

Scanning Electronic Microscopy (SEM). Micrographs were obtained for surfaces and cross sections of cryo-fractured films with a JEOL JSM-840 microscope (Peabody, MA) running at 12 kV. Samples were coated with gold layers prior to analysis to increase their electrical conductivity. Images were registered at magnifications of 100× and 500×.

Transmission Electron Microscopy (TEM). Transmission electron microscopy tests were performed by using a JEOL JEM-2010 microscope (Tokyo, Japan) operated at 100 kV. Films were previously ultramicrotomed to obtain slices of 100 nm thickness (RMC, model MTXL).

X-ray Diffraction (XRD). X-ray diffraction patterns were recorded at room temperature in the 2.1−40° (2θ) range (step size = 0.01°, scanning rate = 8 s step^{-1}) by using filtered Cu Kα radiation (λ = 1.54 Å). A Bruker D8-Advance diffractometer (Billerica, MA) was used to determine the interlayer spacing of clay platelets.

Color. Color changes on the films' surfaces due to the additives were analyzed with a KONICA CM-3600d COLOR-FLEX-DIFF2 colorimeter, HunterLab (Reston, VA). The L^*, a^*, b^* system (CIELab) was employed; the L^* axis represents the lightness from black ($L^* = 0$) to absolute white ($L^* = 100$), the a^* axis varies from green (−) to red (+), and the b^* axis varies from blue (−) to yellow (+). These parameters were measured at five different locations on each specimen, and average values were calculated. The total color difference, ΔE^*, between the control PCL film and nanocomposite films was calculated by using eq 2:

$$\Delta E* = [(\Delta L*)^2 + (\Delta a*)^2 + (\Delta b*)^2]^{1/2} \quad (2)$$

where ΔL^*, Δa^*, and Δb^* are the difference between initial and final values (before and after the additives addition) of L^*, a^*, and b^*, respectively.

HT Release from Films. The evaluation of the release rate of HT from each film at different times was carried out for 4 cm^2 samples immersed in 100 mL of methanol. The extracts were periodically taken and further analyzed by UV−vis spectroscopy with a Shimadzu Spectrophotometer 2450 (Kyoto, Japan). Spectra were obtained on extracts directly inserted in the cell compartment, and they were studied over the 200−300 nm wavelength range, which includes the maximum absorption wavelength of HT at 281 nm. Spectra were acquired each minute for 1 h to ensure that the release of the active agent to the methanol solution had reached a maximum value. In order to quantify the amount of HT released, the specific extinction coefficient, ε (mg^{-1} L cm^{-1}), for HT in methanol was calculated to be 0.0124 mg^{-1} L cm^{-1}, through the measurement of the absorbance A at 281 nm of a set of HT standard solutions with concentration, c (mg L^{-1}), and by using the Lambert−Beer law equation:

$$A = cl\varepsilon \quad (3)$$

where l = 1 cm. In all experiments, temperature was kept constant at 25.0 °C with a Multistirrer 6 thermostatic bath from Velp Scientifica (Usmate, Italy). During HT release experiments, composite-containing solutions were stirred at ∼220 rpm.

Statistical Analysis. Statistical analysis of results was performed with SPSS commercial software (Chicago, IL). A one-way analysis of variance (ANOVA) was carried out. Differences between average values were assessed on the basis of confidence intervals by using the Tukey test at a $p \leq 0.05$ significance level.

RESULTS AND DISCUSSION

Thermal Characterization. DSC tests were performed to elucidate the effect of the nanoclay and HT addition on the thermal properties of the PCL matrix. Four parameters were determined: crystallization temperature, T_c; melting temperature, T_m; crystallization enthalpy, ΔH_c; and melting enthalpy, ΔH_m. These results are summarized in Table 2. It should be highlighted that the melting temperature of neat PCL was lower than that obtained for the rest of the materials formulated in this study. This result gives an indication of the lower

[a]Different superscripts within the same column indicate statistically significant different values ($p < 0.05$).

crystallinity of neat PCL when compared to nanobiocomposites, as it has been reported by other authors.[11]

Regarding crystallinity values, this parameter increased with the addition of HT ($p < 0.05$) due to the interaction between the polymer matrix and the additive molecules, which can show some plasticizing effects. On the other hand, the addition of the polar C30B to the polyester matrix also resulted in a significant increase ($p < 0.05$) of the crystallization rate and could modify the PCL crystalline structure due to the ability of the nanoclay particles to heterogeneously nucleate the crystallization of the polymer matrix, as it has been well-documented for a wide range of nanocomposites.[25] Similar results were obtained by Persico et al. in LDPE nanocomposite films containing carvacrol, where differences in crystallinity values were considered a consequence of two main factors: the presence of heterogeneous nucleation sites and changes in chain mobility. In this sense, they reported that clay platelets could act as nuclei for the initial heterogeneous nucleation and subsequent growth of crystallites. Furthermore, they hypothesized that the increase in chain mobility promoted by carvacrol enhanced the ability of the polymer to crystallize.[26]

However, no significant differences ($p > 0.05$) were observed in crystallinity values for films containing 2.5 and 5 wt % of nanoclay (Table 2). Similar results were found for the ternary nanobiocomposites containing the same amount of C30B ($p > 0.05$), and a decrease was noted for those with 5 wt % of nanoclay, although without significant differences ($p > 0.05$). In this sense, it was reported that the variations in the crystallinity by the addition of nanoclays can be accounted for by two factors: nucleation that increases crystallinity and reduction in the flexibility of polymer macromolecular chains that impedes their rearrangement into ordered crystalline structures, reducing crystallinity. Both factors are related to nanoclay dispersion and content, and different results should be obtained depending on the prevailing effect.[11] Furthermore, the addition of HT enhanced polymer chain mobility, promoting its self-nucleation and crystallinity. In conclusion, the neat crystallinity observed for materials with both additives (HT and C30B) can be attributed to the superposition of all these contributions. The reduction in chain mobility as the result of the nanoclay addition can be considered an important factor in controlling the final properties and structure developed by the material.

TGA results indicated that the thermal degradation of PCL in inert atmosphere took place through the rupture of the polyester chains via ester pyrolysis reaction with the release of CO_2, H_2O, and carboxylic acids. In the case of polyesters, such as PCL, pyrolysis results in chain cleavages randomly distributed along the macromolecular chains. It was reported that when two pyrolysis reactions occur with neighboring ester functions, 5-hexenoic acid is one of the reaction products.[13] TGA curves obtained for all the studied PCL nanobiocomposites just showed one main degradation step. The initial degradation temperatures (T_{ini}) determined at 5% weight loss and maximum degradation temperatures (T_{max}) obtained for all formulations are shown in Table 3. The incorporation of the active compound and the nanoclay brings about a significant effect on the thermal stability of the obtained nanobiocomposites ($p < 0.05$). In this sense, the addition of 10 wt % HT to PCL resulted in a 18 °C reduction in T_{ini}. This result could be explained by the plasticizing effect of HT to PCL, as already stated in the DSC study. In this sense, it was reported that the addition of plasticizers to biopolyesters, such as PLA, results in some decrease in the polymer thermal stability.[27] On the other hand, the addition of the nanoclay also produced some significant decrease ($p < 0.05$) in the PCL thermal stability, but this decrease was not enough to result in PCL degradation at processing temperatures. It was reported that layered silicates could catalyze PCL pyrolysis by a catalytic action played by the nanoclay due to the presence of Lewis acidic sites, created upon organic modifier degradation.[13]

Mechanical Properties. The addition of low nanoclay content (less than 10 wt %) to polymers is expected to improve mechanical properties, particularly when effective nanoclay exfoliation occurs.[22,1] The enhancement in mechanical properties of polymer nanocomposites can be attributed to the high rigidity and aspect ratio of nanoclays together with the good affinity through interfacial interaction between polymer matrix and dispersed nanoclay.[28]

In this study, tensile tests were performed to evaluate the influence of the addition of the nanoclay and/or the active additive on the mechanical properties of PCL-based nanobiocomposites. Results are shown in Table 3, where the elastic modulus E (MPa), elongation at break ε_B (%), and tensile strength TS (MPa) were determined in all materials. The addition of HT to PCL resulted in some modification in E and ε values ($p < 0.05$), whereas no significant differences were observed in TS ($p > 0.05$). In this sense, an increase in the HT concentration caused an increase in ε and a decrease in E values compared to the neat polymer. This behavior could be explained by the plasticizing effect of HT resulting in the increase in ductility of the polymer, and it is consistent with results obtained by other authors with the addition of similar additives to biopolymer matrices.[20,29] In this sense, it should be noted that the physical state of HT is a viscous liquid, with the consequence of the intimate mixture of HT molecules within the macromolecular chains, permitting the enhancement on the internal movement and consequently on ductile properties.

On the other hand, the addition of the nanoclay caused a significant increase in both the elastic modulus and elongation at the break of nanobiocomposites ($p < 0.05$). Concomitantly, a decrease (~40%) of tensile strength ($p < 0.05$) was observed when the amount of the nanoclay in the film increased from zero to 5 wt %. The constrained polymer model developed by Beall can be used to explain some of the general phenomena observed in polymer/clay nanocomposites, including changes in mechanical properties, such as modulus improvement and increased elongation at break. In this sense, the constrained polymer region could be viewed as temporary cross-links, which certainly contribute to increase moduli but when strained can break and reform as the stress and strain increase. In examining the crazes formed in composites that exhibit this increase in elongation at break, it has been observed that fibrils form where the clay plate align along the direction of the fibril length. This gives a convenient platform for the polymer to break the temporary cross-links and then reattach along the clay platelets.[30] For the ternary nanobiocomposites and regarding the *E* values, it was observed that the effect of the nanoclay was predominant for C30B5 ternary composites, resulting in a clear increase in *E* values ($p < 0.05$), although a superposition of the influence of both additives (i.e., nanoclay and HT) should be taken into account to explain results obtained for C30B2.5 materials. In fact, the ultimate behavior observed in mechanical properties can be considered as the result of several factors, such as crystallinity, polymer plasticization, filler−matrix interface, all of which affect the stress−strain properties in a complex way.[26] Although there are difficulties in considering antagonist effects by HT and C30B in ternary composites, it could be concluded that the addition of the nanoclay induced reinforcement effects provided by the high aspect ratio and surface area of silicate layers. The improvement in these properties could be considered a clear indication of the high dispersion of the nanoclay through the polymer matrix and their high compatibility.[31]

Morphological Study. SEM micrographs of films (not shown) showed a featureless and nonporous morphology, indicating a good dispersion of C30B and HT in the PCL matrix; that is, no phase separation was observed.

The morphological characterization of these materials was completed by transmission electron microscopy (TEM), allowing a qualitative evaluation of the dispersion degree of the nanoclay in the PCL matrix. TEM micrographs of PCL nanocomposites containing C30B showed partial exfoliation, because swollen and single dispersed clay layers were observed (Figure 1). Complete exfoliation of nanoclays into individual platelets is not often achieved in nanocomposites, and consequently, a mixed morphology consisting of intercalated and exfoliated structures is usually obtained.[1]

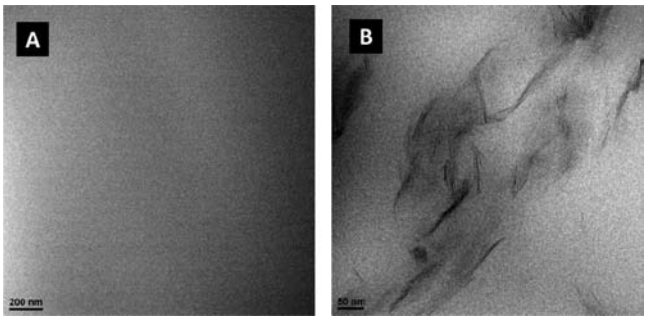

Figure 1. TEM images of neat PCL (A) and PCL/HT5/C30B2.5 (B) nanobiocomposite.

In general terms, TEM tests suggested the good dispersion of C30B in the PCL matrix, because no aggregates were observed. These results could be attributed to the strong interactions between polymer and nanoclay, which are caused by the hydrogen bonding between the carbonyl group in the polymer structure and the hydroxyl groups of the organo-modified nanoclay.[1]

XRD Analysis. The dispersion of clays in nanocomposite films was studied by using X-ray diffraction (XRD). The XRD pattern of PCL was characterized by the presence of two distinct peaks at $2\theta = 24.9°$ and 27.5° corresponding to the (110) and (200) planes, respectively, suggesting a semicrystalline structure.[14] No noticeable differences were found from the XRD patterns for all formulations in this angle range, suggesting that the polymer matrix structure was not influenced by the presence of the filler and/or HT.

The most important variations in XRD patterns of these PCL-based nanobiocomposites were found in the low angle range (below 10°), which gives an indication of the clay dispersion into the polymer matrix (Figure 2). C30B was characterized by a single diffraction peak at $2\theta = 4.8°$, corresponding to the (001) basal reflection,[14] accounting for the 18.6 Å interlayer distance. A shift of the clay diffraction peak to lower angles in these nanobiocomposites was observed, indicating a good interaction of the nanoclay with the polymer matrix, showing an increase in the interlayer distance up to 32.7 Å for PCL/C30B5 due to the intercalation of PCL macromolecular chains into the clay galleries. Ludueña et al. reported similar results for PCL/C30B nanocomposites showing a final d_{001} spacing value increased to 33.1 Å (79% from the initial value).[32] These results could be correlated as well with those obtained for oxygen barrier properties, because an inverse correlation between *d*-spacing and oxygen transmission rate was apparent.[28] However, there was no shift in the interlayer distance in nanobiocomposites with different clay content, suggesting that clay load did not affect the clay platelets' intercalation. Similar results were found by Ahmed et al. for PCL/C30B films with nanoclay compositions ranging from 2.5 to 10 wt %.[12]

In addition, some decrease in the C30B peak intensity was observed, in particular when the active additive was introduced in the formulation. Because C30B is characterized by the presence of free hydroxyl groups, the short alkyl chains of the C30B organic modifier would make these groups available for interactions with the polymer macromolecules and HT reactive functional groups, resulting in higher dispersion degree of the nanoclay in the polymer matrix.[14] On the other hand, the basal diffraction around 5.2° in nanobiocomposites' XRD patterns may correspond to a fraction characterized by a different alkylammonium chain arrangement in the interlayer space or to a small amount of unmodified C30B.[26]

Barrier Properties. Barrier to oxygen is one of the main issues in the design of materials for food packaging applications. The high sensitivity of many food products to oxygen degradation, microbial growth stimulated by moisture, and aroma retention needed for keeping the food quality requires the improvement in biopolymers barrier properties to gases, vapors, and aromas.[1] In general, permeability of a polymer to oxygen or water vapor is dependent on some inter-related factors, including polarity, hydrogen bonding between side

chains, molar mass and polydispersity, cross-linking, processing methodology, and crystallinity.[33]

Results obtained for the oxygen transmission rate per film thickness (e), OTR·e, for all the studied materials are shown in Table 4. Films containing nanoclay showed a slight decrease in OTR·e (p > 0.05) due to the nanoclay intercalation into the PCL structure. On the other hand, some increase in OTR·e was observed for samples with HT (p > 0.05). This effect could be due to the plasticizing effect of HT resulting in the increase in the mobility of PCL chains.[34] A significant improvement in oxygen barrier (p < 0.05) was achieved for ternary nanobiocomposites containing C30B and 10 wt % HT, rendering more competitive materials for oxygen-sensitive products. This result also suggests that the incorporation of the active additive could promote the intercalation of the nanofiller into the PCL matrix by improving the dispersion of the nanoclay in the PCL matrix and finally improving oxygen barrier properties. A similar effect was observed in nanobiocomposites based on plasticized PLA containing C30B.[23] This improvement in barrier properties may be explained by the theory developed by Nielsen,[35] based on the tortuous pathway that gas molecules should follow to diffuse through the polymer. This tortuosity is produced by the good dispersion in the matrix of the layered silicates platelets and the consequent longer diffusion pathway increasing the diffusion time and decreasing permeability.[33−36] According to Duncan,[35] barrier properties are not only influenced by tortuosity but also by changes in the polymer matrix at the interfacial regions. In the case of favorable interactions between polymer and nanofiller, polymer strands close to each nanoparticle can be partially immobilized, working against the gases' diffusion. In this sense, the Beall[30] model states that the polymer region around the clay affecting diffusion is the constrained region, characterized by lower free volume and diffusion coefficient.

Regarding the nanofiller content, no significant differences were observed by comparing OTR·e results for films containing 2.5 and 5 wt % of nanoclay (p > 0.05), suggesting a possible filler agglomeration in films with higher amounts of C30B. In this sense, Sánchez et al. found that composites containing 5 wt % of different nanofillers exhibited the highest oxygen barrier performance, and that the addition of larger amounts of nanoclays (10 wt %) to various biopolyesters did not result in further oxygen barrier improvements.[1] These results suggest that there should be a balance between the filler content, the nanocomposite morphology, and the possibility of permeability deterioration caused by filler agglomeration.[22]

Colorimetric Analysis. Color is an important factor to be considered for some industrial applications. Colorimetric analysis of films was carried out to evaluate the effect of the presence of the studied additives (Table 4) in this important property. Significant differences in color were observed as the result of the HT and/or C30B addition to PCL (p < 0.05). In this sense, neat PCL showed the highest L^* value, with a significant decrease in the presence of additives, especially for the ternary nanobiocomposites, indicating a significant darkening of these films. ΔE^* values increased in ternary nanobiocomposites. A significant improvement in a^* and b^* values was also found for these films (p < 0.05), resulting in a

slightly amber color. Similar color changes were reported for polypropylene stabilized with hydroxytyrosol,[22] contributing to strengthen the color of the obtained films. Rhim[37] also reported a decrease in L^* values and an increase in b^* and ΔE^* values in films produced by blending agar with C20A and C30B, suggesting that differences in color might be attributed to the dispersion of the nanoclays in the polymer matrix.

Release of HT from PCL Nanobiocomposites. The combination of active additives and nanocomposites can synergistically lead to materials with balanced properties and functionalities for food packaging applications. The formulation of novel antioxidant nanobiocomposites based on PCL and HT can be considered as a way to control solubility and release of the antioxidant agent to foodstuff. In this sense, phenolic compounds from virgin olive oil, such as HT, are known to play an antioxidant role in preventing damage to biomolecules. One of the most abundant components of olive oil is an oleuropein derivative named oleacein (dialdehydic form of decarboxymethyl elenolic acid linked to HT).[38] The evaluation of equilibrium and kinetic properties of hydroxytirosol in these nanobiocomposite films was carried out with methanol as release media. It is known that the tendency of HT (and other phenols) to be solubilized, transferred, or diffused into a given solvent is governed by thermodynamics. One of the primary thermodynamic factors describing this tendency is the activity coefficient,[39] which increases as solubility decreases. Although methanol is not commonly used as food simulant, the activity coefficient of HT at 25 °C in this solvent (0.20) is between those shown in ethanol (0.027) and water (0.91),[40] thereby allowing the exploration of broader applications of these nanobiocomposites.

Figure 3a shows the HT release for the three obtained nanobiocomposite films containing HT 10 wt %. As indicated,

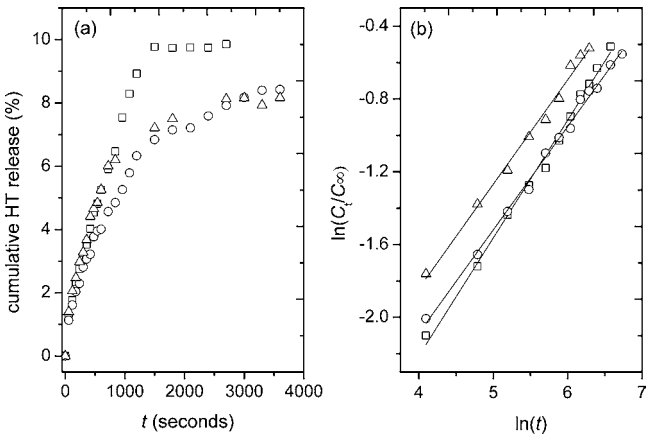

Figure 3. (a) Desorption release profiles (a) and short-time range ($C_t/C_\infty < 0.6$) desorption kinetics (b) of HT from PCL/HT10 (□), PCL/HT10/C30B2.5 (○), and PCL/HT10/C30B5 (△) films; solid lines (b) represent the fitting of eq 4 to desorption kinetic experimental data.

desorption equilibrium was reached after ∼1 h from the beginning of the process. It is important to note that the release experiment was very aggressive, because materials were completely immersed in methanol. The presence of the nanoclay leads to the decrease in the HT release, with cumulative release values of 7.9 and 7.7% for C30B2.5 and C30B5, respectively (Table 5). This behavior could be probably related to interactions between C30B and HT. In this sense, Sánchez et al. found an enhancement in thymol solubility in PCL nanocomposites due to the presence of nanoplatelets, possibly due to the retention of the active agent over their surface.[1] They also found a decrease in the thymol diffusion coefficient with the addition of nanoclays, as the result of the tortuous path imposed to the diffusion of the active agent through the nanocomposite bulk. These results suggest that it is possible to control the release of natural agents with interest in the design of novel active films and coatings through incorporation of laminar nanoclays into bioplastics, such as PCL. A similar behavior was found for Pereira et al. for urea−montmorillonite nanocomposites, showing slower release when compared to pure urea.[41] This profile was probably related to the fact that, as a consequence of some interaction between montmorillonite and urea, this compound would need to adsorb in montmorillonite platelets after its dissolution; this also shows the importance of exfoliation in the controlled release.

The assessment on the release mechanism was performed by using the power law Korsemeyer−Peppas equation[42]

$$C_t/C_\infty = kt^n \tag{4}$$

where C_t and C_∞ are the cumulative concentrations of HT released at time t and at infinite time, respectively, and k and n are fitting parameters, giving the later useful information on the release mechanism. The validity of eq 4 is restricted to $C_t/C_\infty < 0.60$.[43]

Figure 3b shows the fitting of eq 4 to the experimental data, and the computed fitting parameters are summarized in Table 5. It was observed that the desorption mechanism of HT in PCL/HT10 is non-Fickian ($0.5 < n < 1$), which is indicative of coupling diffusion and relaxation mechanisms. However, for nanobiocomposites, n values were approximately 0.5, showing that HT desorption is diffusion-controlled (so-called Fickian). In this case, the apparent diffusion coefficients, D_{ap}, can be computed directly from k, by using the following equation

$$k = (4/l)*(D_{ap}/\pi)^{0.5} \tag{5}$$

where l is the film thickness (cm). The calculated diffusion coefficients for HT desorption from PCL/HT10/C30B2.5 and PCL/HT10/C30B5 were 2.9 (±0.5) × 10^{-10} cm^2 s^{-1} and 4.5 (±0.6) × 10^{-10} cm^2 s^{-1}, respectively. These values show that the release of HT under these conditions is very slow and also suggests that the diffusion follows the trend of the O_2 permeation; that is, an increase in the nanoclay content leads to an increase in O_2 permeation and HT diffusion. Taking into account these data, it is evident that the transport mechanism is rather complex and the reasons behind that are not yet well understood.

In conclusion, the effect of the addition of HT and C30B on properties of PCL-based nanobiocomposites was evaluated by using several analytical techniques. In this sense, some decrease in elastic modulus was observed for films containing HT, suggesting some plasticizing effect in the polymer matrix. On the other hand, the incorporation of C30B resulted in some decrease in thermal stability and a significant enhancement in oxygen barrier and tensile properties, due to the successful intercalation of the nanofiller into the matrix. Slight differences in color with the addition of the additives for all films were also observed. Nanobiocomposites showed slow release for HT, which is an important result for its potential application as PCL-based active films and coating systems, with eventual

Table 5. Concentration of HT Released in the HT 10 wt % Formulations

		eq 4

substitution of common synthetic antioxidants used in packaging materials. The obtained PCL-based nanocomposites have shown improved functional properties and can be regarded as potentially interesting materials for active packaging applications within the food manufacturing and agricultural sectors. To complete these investigations, further tests are to be carried out in order to evaluate the migration and antioxidant performance of these nanobiocomposites by contact with food.

diacylglycerols on fat crystallization in oil-in-water emulsions.[16,17] Herrera's group studied the effect of different additives on the crystallization behavior of bulk lipids.[18−22] Radujko et al. studied the influence of different emulsifiers on the physical and crystallization characteristics of edible fats.[14] Basso et al. studied the effect of monoacylglycerols as modifiers in the crystallization of palm oil.[24] The main effects of these additives in the crystallization of fats occur during the stages of nucleation and growth of the crystalline network, changing physical properties such as crystal size, solid fat content, and microstructure. The issue of promoting or inhibiting crystallization, however, is still debatable. In general, studies indicate that emulsifiers with acyl groups similar to those of the crystallized fat accelerate this process.[23]

For the above reasons, two semisolid fats were selected (palm olein and coconut oil), which have great potential for use as fat ingredients in the food industry. This paper aims to study of changes in the crystallization behavior of palm olein and coconut oil after the addition of commercial emulsifiers containing predominantly MAGs.

MATERIALS AND METHODS

Materials. Palm olein was obtained from Agropalma S/A (Pará, Brazil) and coconut oil from Copra Alimentos Ltd.a. (Alagoas, Brazil). The emulsifiers were provided by DuPont Nutrition & Health (São Paulo, Brazil) and are constituted mainly by monoacylglycerols (EM1 >90.0% MAGs produced from edible vegetable oil; EM2 >52.0% MAGs produced from refined fully hydrogenated vegetable fats). The fatty acid compositions of these fats, emulsifiers, and their blends were determined by gas chromatography and are presented in Table 1. The fats were stored at 0 °C prior to use. All other reagents and solvents were of analytical or chromatographical grade.

Sample Preparation. Commercial emulsifiers (1.0 and 3.0% w/w) were dispersed in the melted coconut oil and palm olein and stirred with a magnetic stirrer at 70 ± 0.5 °C until a homogeneous sample was obtained.

Fatty Acid Composition. The fatty acid composition was determined after conversion of fatty acids into their corresponding methyl esters (FAMES) using the method described by ISO method 5509.[25] Analyses of FAMES were carried out in a Varian gas chromatograph (model 430 GC, Varian Chromatograph Systems, Walnut Creek, CA, USA), equipped with a CP 8412 autoinjector. Galaxie software was used for quantification and identification of peaks. Injections were performed into a 100 m fused silica capillary column (i.d. = 0.25 mm) coated with 0.2 μm of polyethylene glycol (SP-2560, Supelco, Bellefonte, PA, USA) using helium as the carrier gas at an isobaric pressure of 37 psi; linear velocity of 20 cm/s; makeup gas, helium at 29 mL/min at a split ratio of 1:50; and volume injected, 1.0 μL. The injector temperature was set at 250 °C, and the detector temperature was set at 280 °C. The oven temperature was initially held at 140 °C for 5 min, then stepped to 240 °C at a rate of 4 °C/min, and held isothermally for 30 min. Pure oils and theirs blends were analyzed in triplicate, and reported values represent the average of the three runs.

Medium-chain saturated fatty acids (MCSFAs) are expressed as the sum of the amounts of caprylic, capric, and lauric acids. Long-chain saturated fatty acids (LCSFAs) are expressed as the sum of the amounts of myristic, palmitic, and stearic acids. Saturated fatty acids (SFAs) are expressed as the sum of the amounts of caprylic, capric, lauric, myristic, palmitic, and stearic fatty acids. Unsaturated fatty acids (USFAs) content is expressed as the sum of the amounts of oleic, linoleic, and linolenic acids. Monounsaturated fatty acids (MUFAs) content is expressed as the amount of oleic acid. Polyunsaturated fatty acids (PUFAs) content is expressed as the sum of the amounts of linoleic and linolenic acids.

Triacylglycerol Composition. Triacylglycerol composition was analyzed in a Varian gas chromatograph (model 3400CX, Varian Ind. Com. Ltd.a., São Paulo, Brazil). A DB-17HT Agilent (catalog no. 122-1811) capillary column (50% phenyl-methylpolysiloxane, 15 m in length × 0.25 mm bore and containing 0.15 μm film). The conditions were as follows: split injection, ratio, 1:100; column temperature, 250 °C; programmed to 350 °C at 5 °C/min; carrier gas, helium, at 1.0 mL/min flow rate; injector temperature, 360 °C; detector temperature, 375 °C; injection volume, 1.0 μL; sample concentration, 100 mg/5 mL of hexane.[26] All samples were analyzed in triplicate, and the reported values are the average of three runs. TAG profiles were followed throughout the reactions by plotting the percents of the areas of carbon number peaks groups.

Regiospecific Distribution of Fatty Acids. A proton-decoupled ^{13}C NMR was used to analyze the positional distribution of fatty acids on the triacylglycerol backbone. Lipid samples (250 mg) were dissolved in $CDCl_3$ (0.5 mL) in 5 mm NMR tubes, and NMR spectra were recorded on a Bruker Advance DPX spectrometer operating at 300 MHz. The ^{13}C spectra of the lipid samples were acquired with a spectral width of 2332.090 Hz, pulse of 10.2 μs, and a relaxation delay of 30s. Determination of ^{13}C was performed at a frequency of 75.8 MHz with a multinuclear probe of 5 mm operating at 30 °C, using the method described by Vlahov.[27] The results showed the compositions of saturated fatty acids, oleic acid, and linoleic plus linolenic acids in *sn*-2 and *sn*-1,3 positions. All samples were analyzed in triplicate, and the reported values are the average of three analyses.

Polarized Light Microscopy. Samples were melted at the temperature of 70 °C in an oven and, with a capillary tube a drop of sample was placed on a glass slide preheated at a controlled temperature (70 °C) and covered with a cover glass. Samples were kept in the stove at the analysis temperatures (10, 15, and 20 °C) for 24 h. Crystal morphology was evaluated by means of the polarized light microscope (Olympus, model BX 50) coupled to the digital video camera (Media Cybernetics). Glass slides were placed on a hot plate LTS 32; heating and freezing stages were operated by a TP93 temperature programmer (Linkam Scientific Instruments Ltd., Surrey, UK). The images were captured using Image Pro-Plus software version 7.0 for Windows (Media Cybernetics) using polarized light and amplified up to 100 times.

For each glass slide, three visual fields were focused, of which only one was chosen to represent the observed crystals. The evaluation parameter selected for quantitative image analysis was the mean diameter of crystals and was measured by the Image Pro-Plus software, version 7.0 for Windows (Media Cybernetics).[28]

Differential Scanning Calorimetry (DSC). DSC curves were obtained by DSC (DSC 4000, Perkin-Elmer Corp., Norwalk, CT, USA), under a dynamic atmosphere of He (20 mL/min) and a cooling rate of −10 °C/min and heating at 5 °C/min, at temperatures ranging from 80 to −60 °C for cooling with isothermal time of 10 min at 80 °C with an isothermal of 10 min at −60 °C (AOCS Cj 1-94, 2009), using sealed aluminum capsules containing sample mass between 5 and 10 mg. The temperature and heat of melting were calibrated with indium (initial temperature of 156.6 °C). Curves were processed in the program Pyris, and melting and crystallization curves were analyzed for the onset (T_{onset}, °C) of melting and crystallization, peak crystallization and melting temperatures (T_{pc} and T_{pm}, °C), and crystallization and melting enthalpies (ΔH_c and ΔH_m, J/g). The samples were analyzed in triplicate.[29]

Statistical Analysis. Results were expressed as the mean ± SD in triplicate. Differences between the samples (melting and crystallization behavior, diameter of crystals, and fatty acids composition) during the experimental period were statistically analyzed using one-way analysis of variance (ANOVA), followed by post hoc Tukey test, taking on $p > 0.05$. Statistical analysis was performed using Statistica 11.0 software.[30]

RESULTS AND DISCUSSION

Fatty Acid Composition. The fatty acid composition is very important because it is directly related to the properties of each fat, such as melting point and crystallization characteristics.

Table 2. Triacylglycerol Composition (Grams per 100 g) of Coconut Oil (CO) and Palm Olein (PO)

[a]CN, carbon number.

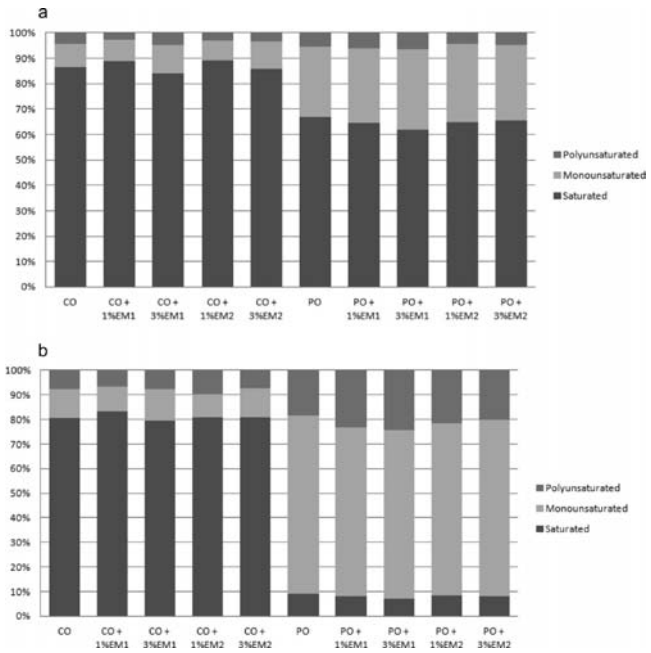

Figure 1. Regiospecific distribution of fatty acids in *sn*-1,3 positions (a) and *sn*-2 position (b) in triacylglycerols of coconut oil, palm olein, and their mixture with the two commercial emulsifiers.

Fatty acid compositions of the individual fats and their mixtures with the two commercial emulsifiers are presented in Table 1. Fatty acid compositions of palm olein and coconut oil are in accordance with the results published in the literature.[31,32] Saturated fatty acids are predominant in coconut oil ($p < 0.05$),

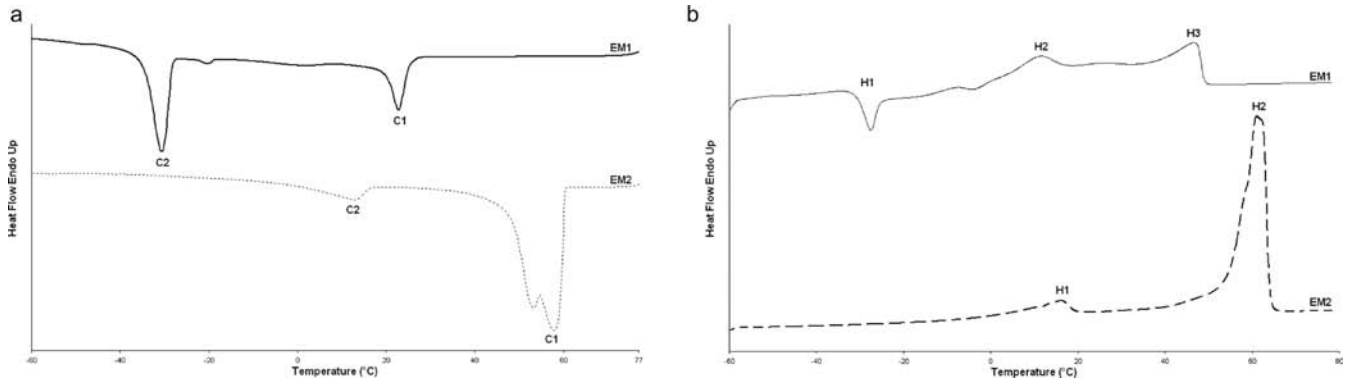

Figure 2. DSC crystallization (a, c) and melting (b, d) curves of the two commercial emulsifiers.

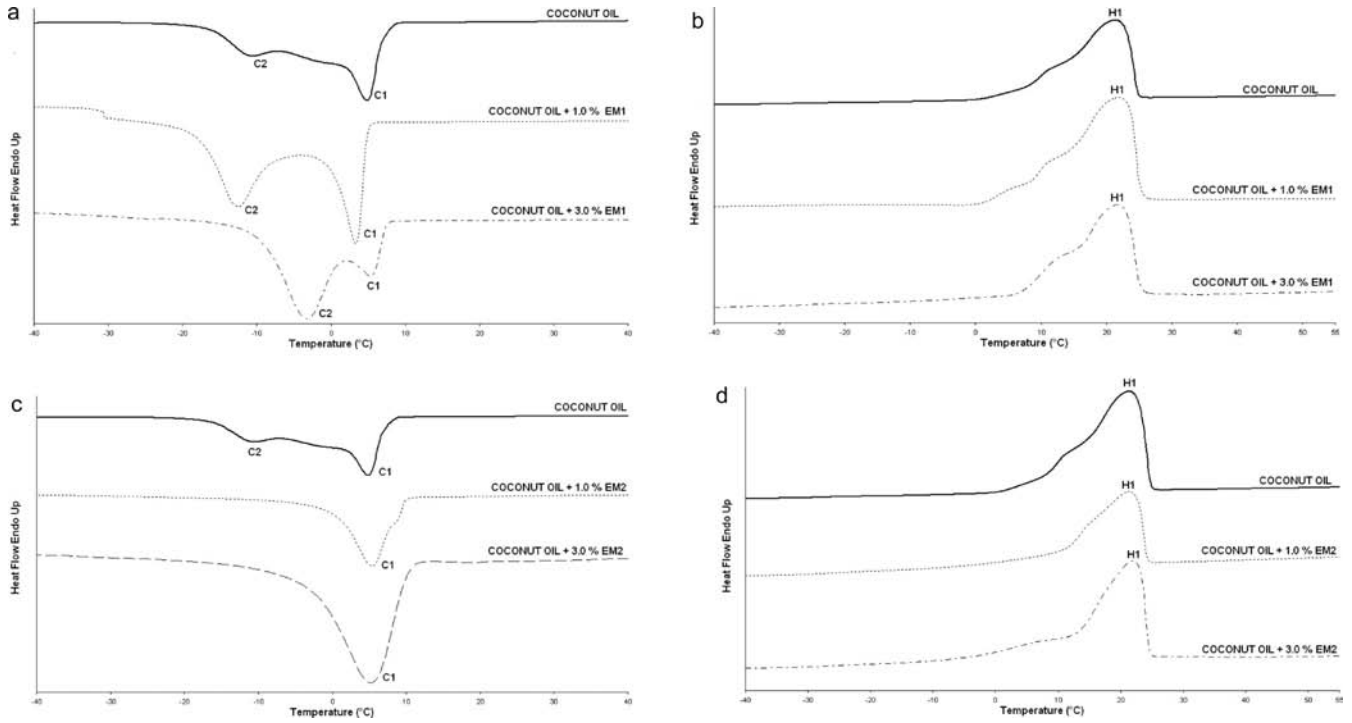

Figure 3. DSC crystallization (a, c) and melting (b, d) curves of coconut oil and its mixture with the two commercial emulsifiers.

mainly lauric, miristic, and palmitic acids, respectively. Palm olein showed predominance of unsaturated fatty acids ($p > 0.05$), mainly oleic acid, and at the same time has high amounts of palmitic acid (36.9 ± 0.5%). Unsaturated fatty acids are predominant in EM1, mainly linoleic acid, and EM2 showed the highest content of saturated fatty acids, mainly stearic acid (Table 1).

The addition of EM1 and EM2, in both proportions, showed no significant differences ($p < 0.05$) in the composition of fatty acids in coconut oil and palm olein.

Triacylglycerol Composition. TAG composition is responsible for providing specific physical properties of lipids. In a processed food that contains significant fat content, the product's behavior may depend on the triacylglycerol composition of that fat.[28] Oils and fats are considered complex samples, because they are composed of a large number of triacylglycerols. Thus, the identification of triacylglycerols becomes a difficult process, in which the number of possible structural forms is very large compared to the number of fatty acids.[33] TAG compositions of the individual fats are presented in Table 2.

In palm olein, four triacylglycerol groups were identified and were similar to those reported by other authors.[34] Palm olein has triacylglycerols ranging from C48 to C54, mainly C52 (48.2%) and C50 (37.7%).

The high diversity of TAGs in coconut oil ranged from C28 to C54. The triacylglycerol profile of coconut oil showed 14 triacylglycerol groups; TAGs C32 (CCLa, 12.8%), C34 (CLaLa, 16.1%), C36 (LaLaLa, 16.6%), C38 (LaLaM, 12.9%), and C40 (LaMM, 10.5%), where C = capric acid, La = lauric acid, and M = myristic acid, were the major mainly saturated TAGs (84.5%). The triunsaturated triacylglycerols in coconut oil were only 0.2%. The triacylglycerol species identified in the coconut oil samples were similar to those reported by other authors.[35]

Regiospecific Distribution of Fatty Acids. Regiospecific distribution of fatty acids in triacylglycerols has implications for the nutritional quality and technology of oils and fats.

Analysis of the regiospecific distribution of fatty acids in triacylglycerols by NMR is desirable, as it does not require hydrolysis by pancreatic lipase, further separation of partial acylglycerols by thin layer chromatography, and finally analysis of fatty acids by gas chromatography.[36] The NMR technique shows that the signal of the spectra corresponding to the *sn*-2 position is always equivalent to around 33.3 g/100 g (an acyl group of three), whereas the signal corresponding to *sn*-1,3 positions is always equivalent to around 66.6 g/100 g (two acyl groups of three).

Results for fatty acid composition by NMR were similar to those obtained by gas chromatography of most samples of this study to saturated fatty acids, 18:1 cis and trans and 18:2 + 18:3.

Figure 1 shows the regiospecific distribution of fatty acids in *sn*-1,3 positions (a) and *sn*-2 position (b) in triacylglycerols of coconut oil, palm olein, and their mixture with the two commercial emulsifiers. Saturated fatty acids were found mainly in the *sn*-1,3 positions, and polyunsaturated fatty acids were found mainly in the *sn*-2 position, a typical feature of vegetable oils.[37]

Coconut oil was composed by 86.5% saturated fatty acids, 8.9% monounsaturated fatty acids, and 4.6% polyunsaturated fatty acids at the *sn*-1,3 positions, whereas 80.7% saturated fatty acids, 11.6% monounsaturated fatty acids, and 7.7% polyunsaturated fatty acids were found at the *sn*-2 position.

Palm olein was composed by 67.0% saturated fatty acids, 27.3% monounsaturated fatty acids, and 5.5% polyunsaturated fatty acids at the *sn*-1,3 positions, whereas 18.5% polyunsaturated fatty acids, 72.3% monounsaturated fatty acids, and 9.1% saturated fatty acids were found at the *sn*-2 position.

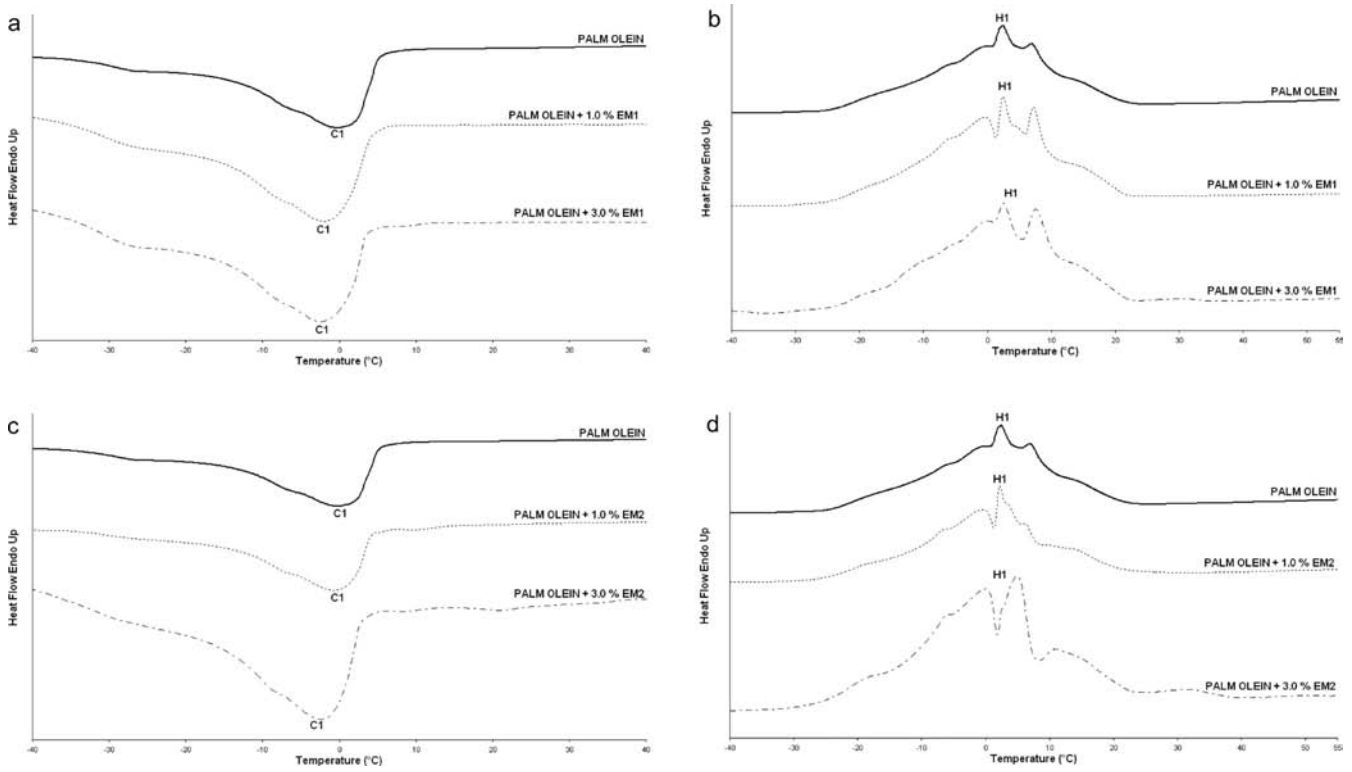

Figure 4. DSC crystallization (a, c) and melting (b, d) curves of palm olein and its mixture with the two commercial emulsifiers.

According to Hayes and Khosla,[38] palm olein is composed by 85% oleic acid and 10% palmitic acid at the *sn*-2 position. These authors also claim that saturated fatty acids are found in higher proportion at the *sn*-2 in highly saturated fats such as coconut oil.

The addition of EM1 and EM2, in both proportions (1 and 3%), to coconut oil and palm olein did not change the regiospecific distribution of fatty acids compared to pure oils.

Differential Scanning Calorimetry. Figure 2 shows the melting and crystallization curves obtained by DSC of two emulsifiers. Figure 3 shows the changes in crystallization profiles of coconut oil crystallized with and without the addition of EM1 (a) and EM2 (b).

Coconut oil showed two distinct but overlapping exothermic peaks, one minor exothermic peak at −11.0 ± 0.2 °C (C2) and a second peak at 4.7 ± 0.2 °C (C1). These slightly different temperatures from those reported by Marina et al.[39] and Mansor et al.[40] can be attributed to the different nature of preparation of the coconut oil, the growing condition of the coconut, cultivar type, and maturity of the coconut.[40] The existence of the two major exothermic peaks in coconut oil is related to crystallization to the saturated and unsaturated TAGs.

The addition of EM1 in two different ratios (1.0 and 3.0% w/w) changed the crystallization behavior of coconut oil (Figure 3). The enthalpy of crystallization of the peak related to the unsaturated TAGs (C2) was significantly increased ($p < 0.05$) with 1.0 and 3.0% (w/w) EM1; this is due to the composition of the emulsifier being predominantly unsaturated. For this reason, the first peak of coconut oil referring to saturated TAGs was reduced with the addition of 3.0% (w/w) EM1.

In many investigations, the first thermal effect during the crystallization process is considered the start of nucleation.[41] However, in DSC thermograms, for example, a minor component may affect the initial, minor peak, whereas the later crystallization peak (representing the bulk of crystallization) may not be affected.[41]

On the basis of the data plotted in Figure 3 and the values obtained for T_{onset} (°C) and T_{pc} (°C), it is possible to observe that the addition of 3% EM1 in coconut oil affected the second stage of the crystallization, the crystal growth, and this effect is probably due to the presence of the emulsifier containing 90% MAGs. Basso et al.[24] also observed this effect with the addition of 1% MAGs to palm oil. According to Fredrick,[42] MAGs accelerate the polymorphic transition to stable forms.

The addition of EM2 also accelerated the process of crystallization but, otherwise, crystallization was affected at the beginning of the first peak (T_{onset}, °C); it may be stated that the addition of this emulsifier affected the nucleation of crystallization.

The onset temperatures (T_{onset}, °C) were significantly higher ($p > 0.05$), 9.1 ± 0.5 °C for 1.0% (w/w) of addition and 11.3 ± 0.2 °C for 3.0% (w/w), compared with pure coconut oil that showed an onset temperature (T_{onset}, °C) of 6.7 ± 0.3 °C. With the addition of EM2 (1.0 and 3.0% w/w) was not observed the formation of the second crystallization peak for the coconut oil.

Tables 3, 4, and 5 show the parameters regarding the crystallization curves of coconut oil, palm olein, and their mixture with the commercial emulsifiers.

The enthalpy of crystallization was also changed, with higher values observed in total ΔH_c of crystallization for all mixtures. The greatest variation in enthalpy of coconut oil occurred with the addition EM2, which shows significant difference from coconut oil ($p > 0.05$). The enthalpy of crystallization shows a significant difference between the peaks ($p > 0.05$), indicating that more crystals are present in these samples.

The melting curves for coconut oil and mixtures with EM1 (b) and EM2 (d) are shown in Figure 3. Tables 3, 4, and 5 show the

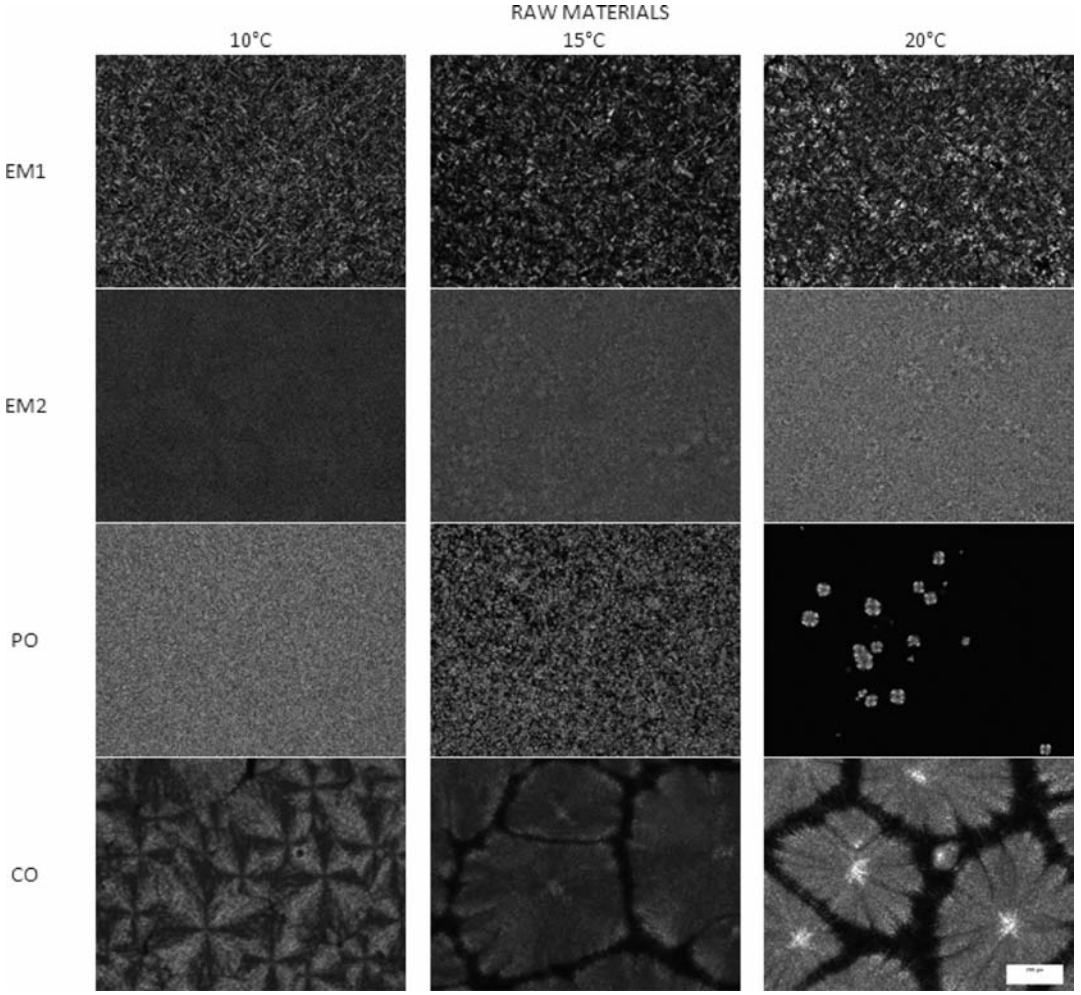

Figure 5. Images of the crystallization of individual commercial emulsifiers, pure coconut oil, and palm olein. The bar represents 200 μm.

parameters regarding the melting curves of coconut oil, palm olein, and their mixture with the commercial emulsifiers.

The addition of EM1 produced a few changes on the melting temperatures (T_{onset} °C) for coconut oil, and mixtures demonstrated close values in a range that varies from 9.9 ± 0.1 to 12.4 ± 0.2 °C with no significant difference ($p > 0.05$). On the other hand, enthalpy of melting was significantly affected ($p < 0.05$) mainly by adding the EM1, in which there was an increase of total ΔH_m in both proportions.

The crystallization curves of palm olein with added EM1 (a) and EM2 (b) are shown in Figure 4. The formation of only one peak crystallization in mixtures with the two commercial emulsifiers was observed.

The addition of emulsifiers (EM1 and EM2) changed the crystallization profile of palm olein, showing significant difference ($p > 0.05$) in the crystallization temperature (T_{onset}, °C). The addition of 1.0 and 3.0% (w/w) EM2 showed crystallization temperature (T_{onset}, °C) lower than observed in pure palm olein and EM1, indicating that the addition of EM2 delayed the crystallization of this oil.

Increasing the crystallization temperature (T_{onset}, °C) by the addition of EM2, rich in saturated MAGs, in coconut oil and palm olein is in agreement with the results of studies by Man et al.[43] and Basso et al.,[24] in which the crystallization peaks (T_{onset}, °C) of the compounds containing more saturated triacylglycerols moved to the region of higher temperatures.

The enthalpy of crystallization (ΔH_c) suffered the most relevant effects, with an increase of 35.1 ± 0.8 J/g in the energy released. Similar results were observed with the addition of 3.0% (w/w) EM1, which increased the energy delivered to the crystallization peak to 40.4 ± 0.8 J/g. This indicates that adding EM1 to the palm olein has an effect on energy released in the crystallization.

On the other hand, the addition of the emulsifier in a proportion of 1.0% (w/w) of EM2 produced no significant ($p < 0.05$) effect on the enthalpy of crystallization (ΔH_c), showing a decrease of 3.0 ± 0.2 J/g in the energy released when compared to the pure olein. A great increase in the release of heat during the crystallization process may be detrimental, because it may result in elevated temperatures that will cause the dissolution of already-formed crystals.[24]

The melting curves of mixtures showed melting peaks very close to that of palm olein, but the enthalpies of melting (ΔH_m) were significantly higher for EM1 and for EM2 added in a proportion of 3.0% (w/w) and also did not present significant differences for EM2 at 1.0% (w/w).

In summary, the emulsifiers modified the DSC melting properties of the coconut oil and palm olein that are ascribed to the influences of the emulsifiers on the crystallization properties. The melting profiles were different, indicating that interactions between TAGs changed due to emulsifier addition.

Polarized Light Microscopy. The study of crystalline microstructure of fat systems has become increasingly important because the functional properties of many foods depend on knowledge of their fine structure. Microstructure is dependent on the composition of a fat, as well as its crystallization behavior, including polymorphism, and the characteristics of the microstructure in turn determine the physical properties of the fat. Success in the measurements requires several stages including obtaining a truly representative image of material, analyzing that image properly, and interpreting the resulting data.[44]

The anisotropic solid phase lattice in the analysis under polarized light refracts light differently from the isotropic liquid phase. The liquid phase appears in the images in black and solid phase in white or grayscale.[45] The "crystals" seen by light microscopy in natural fats are actually clusters of many individual crystals. Fast cooling rates create smaller crystals and slow cooling rates create larger visible crystals, respectively. Thus, the conditions of process determine the size of the clusters, but not the size of the crystals.[46]

The samples were crystallized at 10, 15, and 20 °C. An image was taken directly after 24 h of formation of the fat crystal network, as can be seen in Figures 5, 6, and 7. Crystal mean diameter values of coconut oil, palm olein, and their mixture with the commercial emulsifiers are shown in Table 6.

Figure 5 shows the individual commercial emulsifiers, pure coconut oil, and palm olein. The EM1 sample, which has a composition with high unsaturated fatty acids content, gives a network of small needle-shaped and granular crystals, which can possibly be explained by the crystallization of a β'-polymorph.[47] The increasing of the temperature did not affect the microstructure of EM1.

EM2, which has a high content of saturated fatty acids, showed a dense structure of very small crystals. This is probably due to conditions of cooling that affect the crystallization of higher saturated emulsifier. Even at the highest temperature of crystallization (20 °C) the grain structure maintained crystallization.

Coconut oil at 10 °C showed a dense structure of large crystals; the image showed very compact spherulites type, with no empty space between them, and low birefringence, but with good definition. At 15 and 20 °C this oil shows extra-large spherulites, the nucleus had higher birefringence, and the edges showed little needles. In coconut oil as the temperature was increased to 15 °C the microstructure of this oil was sharply affected. Temperatures up to 20 °C increased the voids between spherulites, which consequently decrease the crystallized area.

Palm olein (Figure 7) showed a dense structure of very small crystals with instantaneous and homogeneous crystallization, which is observed in a large number of small crystals and with the increase in temperature (20 °C) had reduced the total spherulites.

From the observation of microscope images it is possible to affirm that the use of these pure fats (coconut oil and palm olein) has many limitations for applications in those foods that require higher storage temperatures because the temperature of 20 °C formed extra-large spherulites type (coconut oil) or hardly

PO + EM2 (3.0% w/w)	2.5 ± 0.6a	1.8 ± 0.5a	6.6 ± 0.9b

crystallized (palm olein), and these microstructures are not suitable for application in foods.

Figure 6 shows the coconut oil addition with 1.0 and 3.0% (w/w) of EM1 and EM2.

The addition of EM1 to coconut oil changed the crystallization pattern. The spherulite size was significantly lower when added 1.0 and 3.0% (w/w) of EM1 were added at temperatures of 10 and 15 °C (Table 6). At 20 °C the addition of EM1 in coconut oil produced large spherulites that extrapolated the visual field of the slide; therefore, for statistical purposes a maximum value of the visual field has been estimated as 1250 μm.

The addition of EM2 to coconut oil considerably changed the behavior of this oil. The spherulites after the addition of 1.0 and 3.0% (w/w) were significantly smaller in size (Table 6) than the pure coconut oil and that with EM1 added. The addition of 3.0% (w/w) also maintained the large number of spherulites even at higher temperatures (20 °C), which makes this percentage addition a more interesting technological standpoint.

Figure 6 shows the palm olein addition with 1.0 and 3.0% (w/w) of EM1 and EM2.

In palm olein, the addition of 1.0% (w/w) EM1 did not alter the microstructure of this fat at any of the temperatures, but the increase in this ratio to 3.0% (w/w) of this emulsifier altered the pattern of crystallization of this fat. With the increased temperature occurred a reduction of crystallized area, and at 20 °C no crystallization occurred even after 24 h.

These results for microstructure with addition of EM2 are consistent with the findings of Basso et al.,[24] who described that the addition of saturated monoacylglycerols leads to the formation of a greater number of crystallization seeds, possibly more stable to the effect of temperature. During the crystallization process, a crystalline network is formed that allows for greater interaction between triacylglycerol molecules, between which intermolecular attractive forces such as the van der Waal's forces can act, which may promote greater intermolecular attraction, leading to a decrease in system

dx.doi.org/10.1021/jf405221n | J. Agric. Food Chem. 2014, 62, 2253−2263

solubility, more evident at high temperatures, contributing to the crystallization process.

According to Herrera et al.,[48] fats for food product applications should have crystal diameters of <30 μm to prevent grainy mouthfeel. The crystal dispersion of fats with a large number of small crystals can provide desirable properties such as good spreadability. In this study, the addition of emulsifiers with monoacylglycerols induced the formation of large numbers of small crystalline nuclei, in agreement with that described by Foubert et al.,[49] who reported an increase in the amount of crystallization seed and in the number of crystals formed and a decrease in the induction period, due to the influence of existing partial acylglycerols. The minimum diameter values, 3.2 μm for coconut oil and 1.1 μm for palm olein, were much lower than those obtained for these oils in the absence of monoacylglycerols.

From the results presented in polarized light microscopy and DSC it was possible to observe great coherence between them, the addition of emulsifiers affecting the crystallization of both oils, but this modification acts at different times of crystallization (nucleation and crystal growth). The addition of EM1 to coconut oil affects the second stage of crystallization crystal growth, and this behavior can be observed both in the DSC curve (Figure 3) and in the microscope images (Figure 6), where the addition of the emulsifier led to crystallization of fewer cores of larger diameters. Although the effects of adding EM1 were more effective in coconut oil, it also affected the crystallization of the palm olein. Furthermore, the results of the DSC crystallization curve with respect to the addition of EM2 indicated that the addition of the emulsifier affected the nucleation; this behavior can be observed in Figures 3 and 4 for the DSC curves, and also can be viewed in Figures 6 and 7, in which the nucleation density was retained even at high temperatures.

On the basis of the DSC and microstructure, the coconut oil and palm olein crystallization process was modified by adding the commercial emulsifiers. Several conclusions can be drawn from this study: (a) The crystallization behavior of fat blends strongly depends on the type of emulsifier used and the chemical composition of the sample. (b) The addition of emulsifiers affects not only the type of crystals formed (fractionation) but also the amount of crystals obtained (enthalpy), inducing or delaying the crystallization process. Higher crystallization rates decrease process costs and would make it possible to use this oil in the production of food that requires high rates of crystallization, such as candy coatings and cookie fillings, conserving the desired coconut oil and palm olein characteristics such as its plasticity.

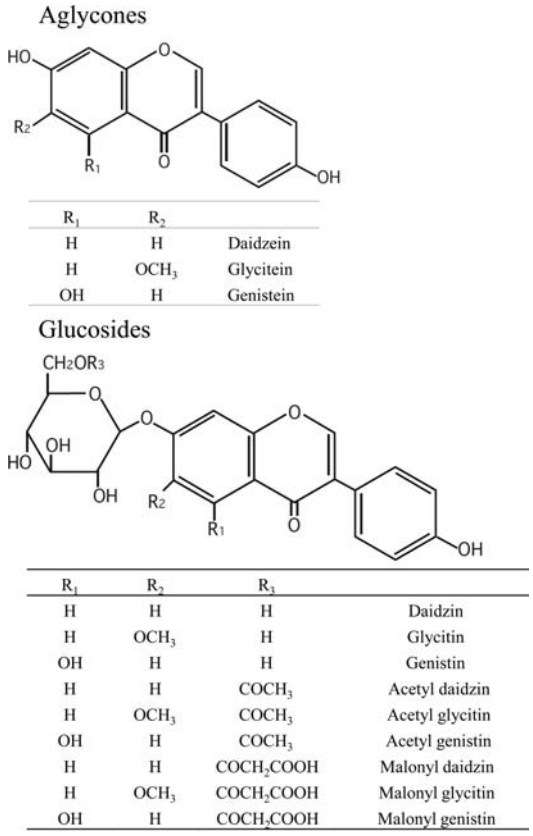

Figure 1. Chemical structures for isoflavone aglycones, isoflavone glucosides, acetyl isoflavone glucosides, and malonyl isoflavone glucosides.

information regarding the absorbability of M-Iso. The aim of the present study was to define the intestinal absorption characteristics of malonyl daidzin stratified according to the molecular structure and water solubility. First, we used soybean hypocotyls to generate isoflavone preparations rich in malonyl daidzin and then compared the absorption of M-Iso and nonmalonyl isoflavone glucosides (G-Iso) in different sections of the intestinal tract. Finally, we determined the enteric site of hydrolysis of each glucoside substance to aglycones.

MATERIALS AND METHODS

Materials. Isoflavone standards were purchased from Fujicco Co. (Hyogo, Japan), and equol was obtained from Funakoshi Co. (Tokyo, Japan). M-Iso were produced by first adding soybean hypocotyls to 70% (v/v) ethanol. After extraction for 12 h at 25 °C, the solvent was removed and dried. The concentrate was loaded onto a column (DIAION HP-20, Mitsubishi Chemical Co., Tokyo), eluted with 25% (v/v) ethanol, and the isoflavone-rich elute dried to yield a powder. G-Iso (Isomax-80) was purchased from Tokiwa Phytochemicals (Chiba, Japan). The isoflavone composition of M-Iso and G-Iso is shown in Table 1.

Measurement of Plasma Isoflavone Concentration in Rats. Female Wistar rats (9 weeks old) were purchased from Charles River Laboratories Japan Inc. (Kanagawa, Japan) and maintained under a 12−12 h light−dark cycle with free access to water and food. All rats were fed a soybean-free diet (F2PLD1; Oriental Yeast, Tokyo) for 1 week, and food was removed overnight. Because the compositions of isoflavones in M-Iso and G-Iso were different, the dosage was adjusted to 25 mg/kg of daidzein family. Therefore, 2.29% (w/w) M-Iso and 1.00% (w/w) G-Iso dissolved in distilled water were administered orally at 6.78 mL/kg. This was followed by extraction of 300 μL of blood from the tail vein at 0, 1, 3, 6, 10, 24, 34, and 48 h

Table 1. Isoflavone Composition of Each Substance and Dosages

	composition[a] (%)		dose (mg/kg body wt)	
	M-Iso[b]	G-Iso[b]	M-Iso	G-Iso
daidzin	4.2	66.6	1.7	24.6
glycitin	2.3	29.9	0.9	11.1

postadministration. The blood samples were centrifuged at 12000 rpm for 5 min, and 150 μL of plasma was transferred into a microtube and kept at −80 °C until analysis.

Analysis of Isoflavones and Metabolites by HPLC and LC-MS/MS. Quantitative analysis of isoflavones by HPLC was performed using the method described by Kudou et al.[9] To analyze the plasma concentration of isoflavones and metabolites, β-glucuronidase (Nippon Biotest Laboratories Inc., Tokyo) diluted in 0.1 M acetate buffer (pH 4.5) was added to 200 μL of each plasma sample. After mixing, each solution was incubated overnight at 38 °C. After incubation, ethyl acetate was added and the solution vigorously shaken and then centrifuged for 5 min at 1000 rpm. The organic solvent layer was transferred to a clean tube and evaporated under a nitrogen gas stream. The dried sample was dissolved in 0.01 M NaOH, and the solution was centrifuged at 10000 rpm for 5 min. The upper layer was injected into LC-MS/MS. The samples were separated on a PEGASIL ODS column (5 μm 4.6 × 150 mm, Senshu Scientific Co., Tokyo) at 22 °C using a linear gradient consisting of methanol/water/acetonitrile/acetic acid (43:41:16:0.007; v/v/v/v) and methanol/acetonitrile/acetic acid (73:27:0.007; v/v/v) at a flow rate of 0.4 mL/min. The column elute was detected using a photodiode array detector monitoring 200−650 nm and ion trap MS (Quattro Ultima, Waters, MA, USA) fitted with an electrospray interface operating in negative ion mode.

Transport Experiments in Caco-2 Cells. We performed transport experiments using Caco-2 cells for the four isoflavone materials. M-Iso, G-Iso, and their aglycones were hydrolyzed fully with commercial almond β-glucosidase (Oriental Yeast, Tokyo, Japan). The Caco-2 cell line, from human colorectal carcinoma, was obtained from Dainippon Sumitomo Pharma Co. (Osaka, Japan). Experiments were performed using the protocol described by Steensma et al.[17] with some modifications. After determination of the integrity of the monolayers, the transport experiment was performed at 37 °C in an atmosphere of 5% CO_2 and 95% relative humidity in Hanks balanced salt solution, with the apical side at pH 6.5 and the basolateral side at pH 7.4. Transport of the test compound across cells was expressed as the amount transferred to the basolateral side.

Hydrolysis of Glucoside Substances by Rat Intestinal Homogenates. This experiment was performed following the protocol described by Ioku et al.[18] Intestinal tissue samples were prepared from 10-week-old female Wistar rats fed a soybean-free diet (F2PLD1) for 1 week and fasted prior to the experiment. After sacrifice by cervical dislocation, duodenum, jejunum, ileum, and colon were dissected and fixed at both ends with clips. Each was rinsed with 0.1 M potassium phosphate buffer (pH 7.0) and homogenized in 3 volumes of 0.1 M maleic acid buffer (pH 6.0). Supernatants were obtained by centrifugation (20000 rpm for 30 min at 4 °C). The mean value (n = 3) of β-glucosidase in the four intestinal solutions was as follows: duodenum, 0.007 U; jejunum, 0.015 U; ileum, 0.031 U; and colon, 0.006 U. Substrates (M-Iso or G-Iso) were prepared by dissolving each in 80% methanol to a concentration of 2000 mg/L. One hundred microliters (200 μg as aglycone) of the substrate solution and 500 μL of enzyme solution were added to a tube, and 0.1 M phosphate buffer solution, pH 7.0, was added up to 1.5 mL. All tubes were incubated at 37 °C and samples removed at 0, 1, 3, 6, and 24 h. Prior to HPLC analysis, the enzyme reaction was stopped by the addition of up to 5 mL of 80% methanol.

Statistical Analysis and Ethics Approval. Results are expressed as the mean ± SEM. Two-way ANOVA was used to determine the effects of isoflavone substances (S), time course of changes (T), interactions (T × S) with respect to plasma isoflavone concentration and the amount of transported substrates from M-Iso and G-Iso. Fischer's least significant difference (LSD) test was used for post hoc analysis of comparison of means within a factor after one-way ANOVA. Dunnett's test was also used as another post hoc analysis for comparisons of baseline values (0 h) and each time point value after one-way ANOVA. The effect of isoflavone absorption calculated from the area under the curve (AUC) for the plasma concentration time course was examined by Student's unpaired t test and the equality of variance determined using Levene's test. Differences were considered significant at $P < 0.05$. Statistical analysis was performed using SPSS II (version 11) for Windows (SPSS Inc., Chicago, IL, USA).

All animals were treated in accordance with guidelines established by the Japanese Society of Nutrition and Food Science (Law 105 and Notification 6 of the Japanese government).

RESULTS

Water Solubility of Isoflavone Compounds. The water solubility of M-Iso and G-Iso was measured by a spectrophotometer set to a wavelength of 660 nm. Compounds were dissolved in distilled water at various concentrations as aglycone (5−50 mg/mL). The G-Iso solution showed a concentration-dependent increase in turbidity (0.5 mg/100 mL, 0.023; 5 mg/100 mL, 0.460; 50 mg/100 mL, 2.767), whereas the M-Iso solution remained clear throughout the test (<0.001).

Changes in Plasma Isoflavone Concentrations after Substance Administration. Figure 2 shows the serial changes in plasma isoflavone concentration after ingestion of G-Iso and M-Iso. The plasma concentration of daidzein 1 h after administration of G-Iso was significantly higher than that after administration of M-Iso. However, the concentration of daidzein 3 h after administration of M-Iso was significantly higher than that after administration of G-Iso (Figure 2A). We also evaluated isoflavone absorption by comparing AUCs spanning from 0 to 48 h (Figure 3). The AUC of daidzein using M-Iso was significantly greater than that with G-Iso. The plasma equol concentration after administration of M-Iso tended to increase after 24 h compared with G-Iso (Figure 2B). The AUCs of equol showed a trend similar to that of daidzein (Figure 3). The plasma concentration of genistein was significantly higher after administration of M-Iso compared with G-Iso (data not shown). This finding is due to the larger amount of genistein family in M-Iso relative to that in G-Iso.

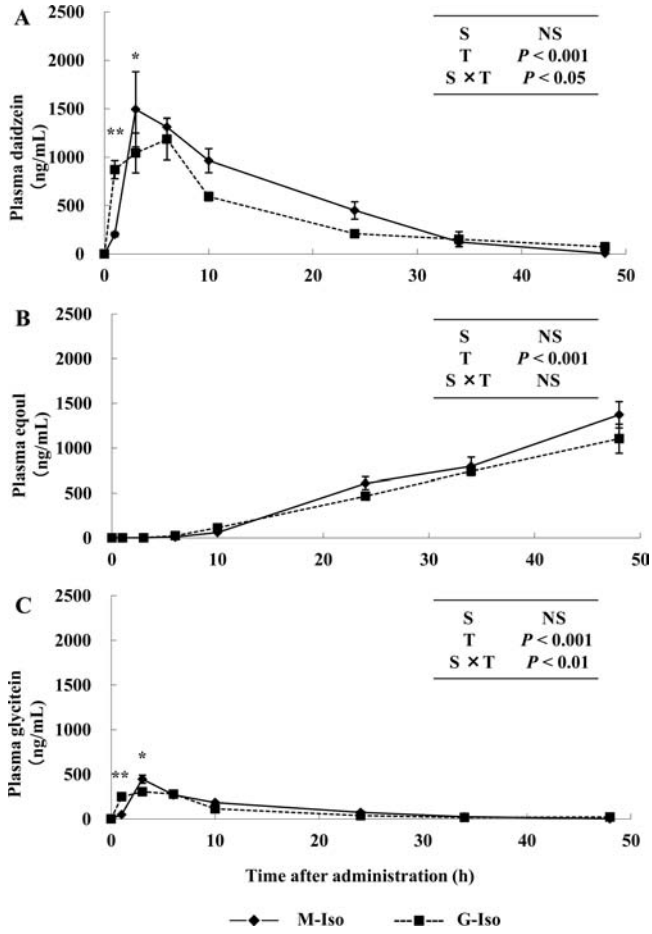

Figure 2. Plasma concentrations of daidzein (A), equol (B), and glycitein (C) after oral administration of M-Iso and G-Iso in rats. Data are expressed as the mean ± SE (n = 5). Because the compositions of isoflavones in M-Iso and G-Iso were different, the dosage was adjusted to 25 mg/kg of daidzein family. Therefore, 2.29% (w/w) M-Iso and 1.00% (w/w) G-Iso dissolved in distilled water were administered orally at 6.78 mL/kg. Plasma concentrations of isoflavones and equol were measured by HPLC and LC-MS/MS. Two-way ANOVA was used to determine the main effects of isoflavone substances (S), time course of changes (T), and interactions (S × T) with respect to isoflavonoid concentrations in plasma. LSD test was used for comparison of means within a factor. Significant difference between the M-Iso group and the G-Iso group at a particular time point; (∗) $P < 0.05$ and (∗∗) $P < 0.01$. NS, not significant. For abbreviations, see Table 1.

Similar changes were noted in plasma glycitein concentration following the administration of G-Iso and M-Iso, although the levels were small in both substrates (Figure 2C).

Transport Experiments Using Caco-2 Cells. Figure 4 shows the results of the transport experiments on M-Iso, G-Iso, and their hydrolysates (M-Iso-hydrolysate and G-Iso-hydrolysate). Negligible transportation of the two glucosides (from the apical side to the basolateral side) was observed in M-Iso and G-Iso, whereas their aglycones were transported to the basolateral side. In addition, only aglycones were detected on the basolateral side (data not shown).

Enteric Specificity of Isoflavone Glucoside Hydrolysis from Rat Intestinal Homogenates. Figure 5 shows the substrate specificity of isoflavone glucoside hydrolysis in the four intestinal segments. Malonyl daidzin in M-Iso was hydrolyzed to aglycone only after treatment with colonic

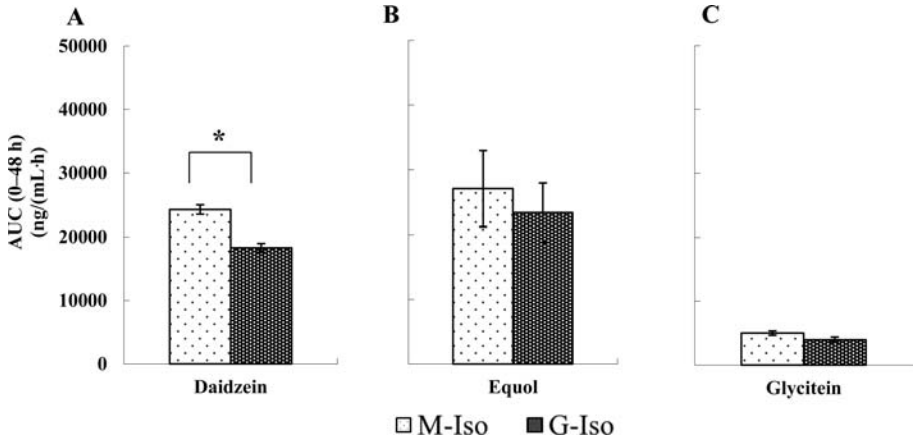

Figure 3. AUCs for daidzein (A), equol (B), and glycitein (C), calculated for each plasma isoflavone from 0 to 48 h on the basis of the initial baseline value. Data are the mean ± SEM (n = 5). Significant difference between M-Iso and G-Iso by Student's unpaired t test after Levene's test for equality; (*) $P < 0.05$. For abbreviations, see Table 1.

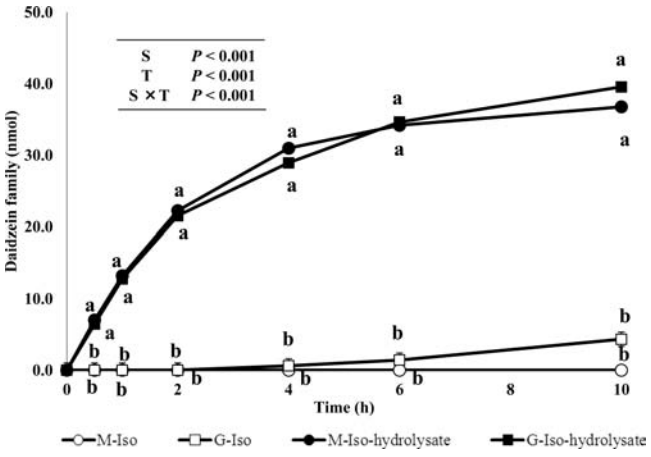

Figure 4. Transport of M-Iso, G-Iso, and their hydrolysates in Caco-2 cells. Initial substrate amounts were 65 nmol of daidzein family for M-Iso, G-Iso, M-Iso-hydrolysate, and G-Iso-hydrolysate. Hydrolyzation of M-Iso and G-Iso was performed using commercial almond β-glucosidase. Data are expressed as the mean of triplicate measurements. Two-way ANOVA was used to determine the main effects of isoflavone substances (S), time course of changes (T), and the interactions (S × T) with respect to isoflavonoid concentrations in plasma. LSD test was used for comparison of means within a factor after one-way ANOVA. Different letters denote significant differences at a particular time point; $P < 0.05$. For abbreviations, see Table 1.

homogenate (Figure 5D), and hydrolysis was barely observable following processing by duodenal, jejunal, and ileal homogenates (Figure 5A–C). Malonyl daidzin content was decreased and daidzin content increased following processing by colonic homogenates up to 6 h and then decreased until 24 h in M-Iso (Figure 5D). These findings suggest that M-Iso are hydrolyzed to aglycone via nonmalonyl glucosides from malonyl glucosides. On the other hand, daidzin in G-Iso was hydrolyzed to the aglycone by jejunal, ileal, and colonic homogenates (Figure 5F–H), but not duodenal homogenate (Figure 5E). A steady increase in daidzein was observed following treatment with colonic homogenate, and the majority of daidzin was hydrolyzed to aglycone within 24 h in G-Iso (Figure 5H). Treatment of G-Iso, however, with jejunal and ileal homogenates promoted rapid hydrolysis until 6 h, but this process slowed after 6 h (Figure 5F,G). With M-Iso treatment by colon homogenates, the amount of daidzein after 24 h was almost identical to the initial malonyl daidzin amount (Figure 5D). However, the total amount of daidzein was decreased with G-Iso (Figure 5H).

DISCUSSION

In this study, we demonstrated that M-Iso were mainly hydrolyzed and absorbed in colon and that absorption properties differed between M-Iso and G-Iso.

The transport experiment showed that M-Iso and G-Iso were barely transported across the Caco-2 monolayer, whereas their aglycones prepared by glycoside hydrolase were transported (Figure 4). These results suggest that conversion of glycosides to aglycones is necessary for intestinal absorption.

We evaluated characteristics of isoflavone hydrolysis dependent on the localization in rat intestine (Figure 5). M-Iso were hydrolyzed only in colon homogenate (Figure 5A–D), whereas aglyconization of G-Iso occurred in homogenates of jejunum, ileum, and colon (Figure 4E–H). These results indicate that the degree of isoflavone hydrolysis differed by the intestinal section. Upon M-Iso hydrolysis in the colon homogenate, the glycoside increased after 6 h and then decreased (Figure 5D). This result suggests that M-Iso were hydrolyzed to aglycone via nonmalonyl glycoside. Hydrolysis curves of G-Iso were somewhat different on the basis of intestinal localization (jejunum, ileum, or colon). In the colon, G-Iso was linearly hydrolyzed and most glucosides were aglyconized within 24 h (Figure 5H). In the jejunum and ileum, however, G-Iso was rapidly aglyconized within 6 h, with the reaction then slowing (Figure 5F,G). In accordance with these data, Ismail and Hayes[19] reported that the hydrolysis property of β-glucosidase varies on the basis of the type of isoflavone. The different hydrolysis patterns of M-Iso and G-Iso in the four intestinal segments likely reflects the substrate specificity of different β-glucosidases in the intestine. In addition, our data seem to indicate that malonyl and acetyl glucosides are hydrolyzed in the distal regions of the gut having very high bacterial concentrations.[20] The amount of daidzein after 24 h of treatment of M-Iso by colonic homogenate was almost identical to the initial amount of total daidzin (Figure 5D). However, with G-Iso, the amount of daidzein at 24 h was decreased compared to the initial daidzin (Figure 5H). G-Iso may be transformed to other metabolites, for example, O-desmethyl

dx.doi.org/10.1021/jf404378r | J. Agric. Food Chem. 2014, 62, 2264–2270

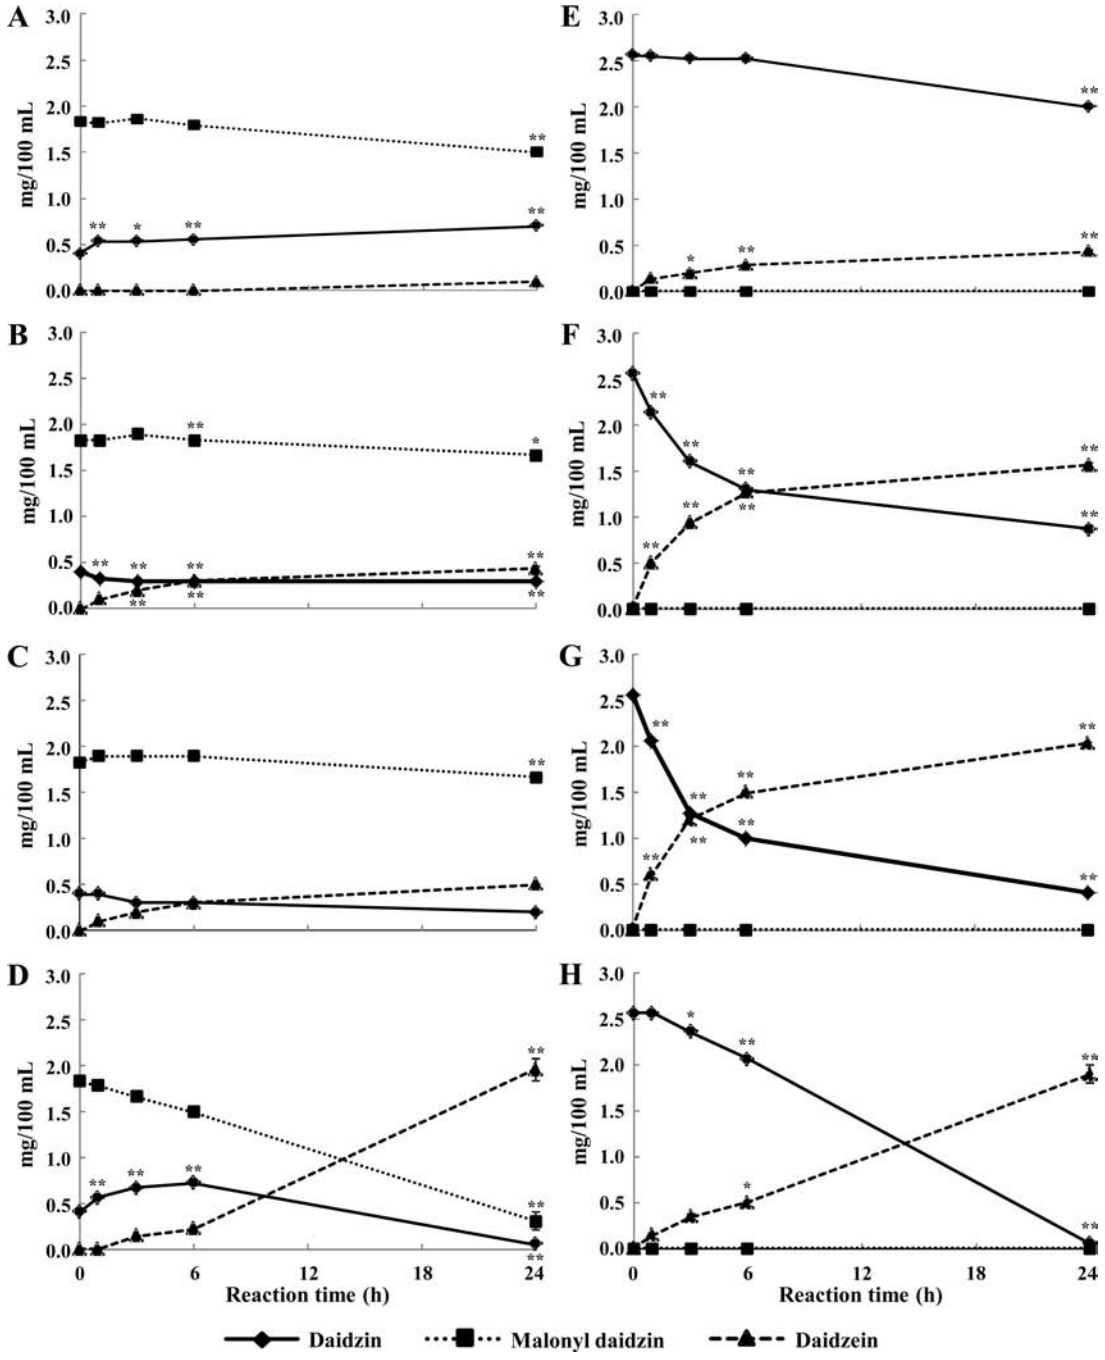

Figure 5. Hydrolysis of M-Iso and G-Iso in four intestinal homogenates: (A) M-Iso treated with duodenal homogenate; (B) M-Iso treated with jejunal homogenate; (C) M-Iso treated with ileal homogenate; (D) M-Iso treated with colonic homogenate; (E) G-Iso treated with duodenal homogenate; (F) G-Iso treated with jejunal homogenate; (G) G-Iso treated with ileal homogenate; (H) G-Iso treated with colonic homogenate. Measurements of isoflavones were performed by HPLC. Each isoflavone concentration is shown as the aglycone equivalent. Data are the mean ± SEM (n = 3). Significant difference from the baseline value (0 h) at a particular time point by Dunnett's test as a post hoc test after one-way ANOVA; (*) $P < 0.05$ and (**) $P < 0.01$. For abbreviations, see Table 1.

angolensin (*O*-DMA), or degradation products of daidzein, which were not measured in the present study.

Plasma daidzein and glycitein concentrations measured within 1 h of G-Iso administration increased more rapidly than with M-Iso; however, concentrations measured 3 h after M-Iso administration were higher than those with G-Iso (Figure 2). As well, M-Iso AUCs were greater than that of G-Iso (Figure 3). Plasma equol concentration after ingestion of M-Iso or G-Iso was also similar to plasma daidzein and glycitein; equol concentration after M-Iso tended to be lower than after G-Iso up to 10 h, but tended to increase thereafter, and it is likely that AUCs of equol would increase after 48 h. These results signified important differences between M-Iso and G-Iso in hydrolysis and absorption. Further studies are necessary to confirm these results. In addition, other metabolites, such as dihydrodaidzein and *O*-DMA, were not measured as they are minor metabolites in the blood of rats fed a diet supplemented with daidzein.[21]

Hydrolysis of isoflavone glucosides in the four intestinal segments suggests that G-Iso is hydrolyzed more quickly in the

upper small intestine than in the large intestine. The results also indicate that plasma concentration was higher in G-Iso than in M-Iso in the early stages (Figure 2). Andlauer et al.[22] investigated intestinal absorption and metabolism of isoflavones from tofu and demonstrated that the major aglycones (e.g., genistein and daidzein) in the small intestine originated from glucosides. Furthermore, aglycones that are absorbed from the intestinal tract are rereleased as glucuronides in the intestine.[22] This suggests that at least part of aglycones derived from glucosides are absorbed into the blood through the intestine, whereas the remaining components are rereleased into the intestinal tract. Wang et al.[23] investigated the effects of structural differences on isoflavone metabolism in the intestine. Using an intestinal perfusion model, they found significant differences in absorption and excretion between isoflavones and their respective glucuronides. The glucuronides were mainly excreted in the small intestine, with very little in the colon. As discussed above, non-malonyl glucoside-rich isoflavones were hydrolyzed to aglycones and absorbed from the small intestine and thus were rereleased again as glucuronide into the intestine.[24] On the other hand, isoflavones rich in malonyl forms, which are not hydrolyzed in the small intestine, would reach the colon and be absorbed effectively after hydrolysis (Figure 6).

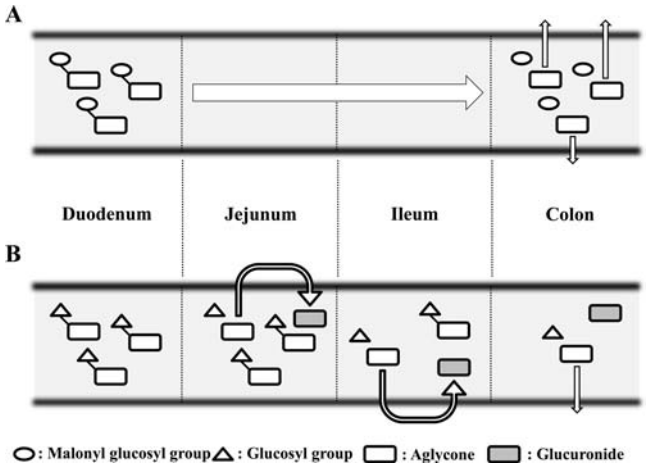

Figure 6. Schematic diagram of the hydrolysis and absorption processes of M-Iso (A) and G-Iso (B) in the intestine.

Yamada et al.[25] evaluated the absorbability and degradability of hesperidin, which is dependent on conjugation with glucosides in the intestine. Their results showed that glucosyl hesperidin is absorbed more rapidly and efficiently than hesperidin alone, due to its high water solubility. The water solubility of M-Iso in the present study may have also contributed to the absorbability.

In conclusion, our data suggest that M-Iso, which are not hydrolyzed in the small intestine, reach the colon and are hydrolyzed there. Effective absorption of malonyl-rich isoflavone aglycones in the colon likely contributes to the significant increase in plasma isoflavone levels. Furthermore, intake of malonyl isoflavone aglycones may be superior in regard to the production of equol, as they are more likely to reach the colon.

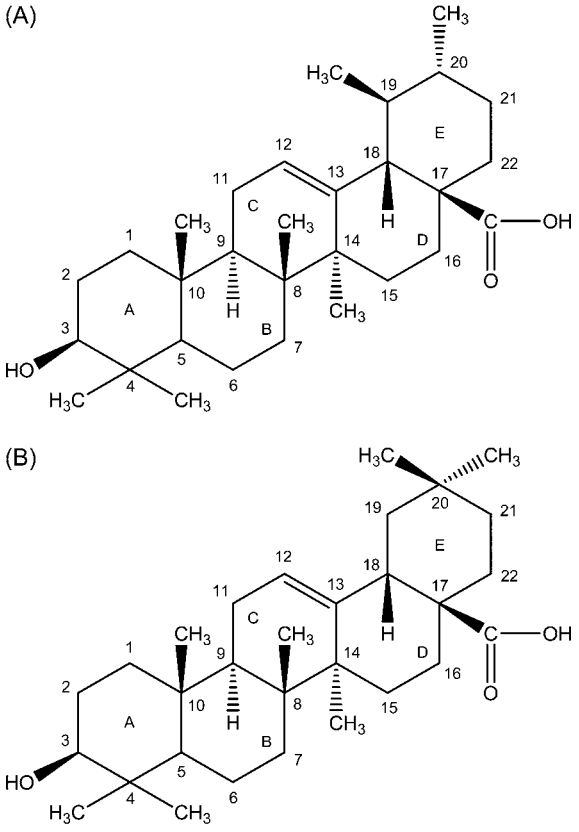

Figure 1. Molecular structure of (A) ursolic acid and (B) oleanolic acid.

production in mitochondria upon incubation with 5.0 ng mL^{-1} ursolic acid occurred. Therefore, they considered that mild mitochondrial uncoupling evoked through pharmacological concentrations (1.6−5.0 ng mL^{-1}) of ursolic acid as discovered in some herbal preparations may be helpful in cardioprotection.

In another study, oleanolic acid was found to obstruct lipopolysaccharide-intervened secretion of high-mobility group box 1 protein by endothelial cells as well as high-mobility group box 1 protein-mediated proinflammatory responses, which creates a decline in monocyte adhesion and migration.[8] Oleanolic acid also deterred high-mobility group box 1 protein-interfered nuclear factor-κB and tumor necrosis factor-α production, which are the most principal inflammatory mediators. These discoveries could offer that oleanolic acid may be utilized as an anti-inflammatory ligand for vascular inflammatory infirmity medication. Owning to its easily obtainable, low-cost material and various biological roles, humankind in many cultures, as well as animals globally, have been reliably consuming these triterpenoids, e.g., ursolic acid and oleanolic acid, in their victual, or have been utilizing them for curative objects, for numerous centuries without marked disease actions.[9,10] Accordingly, an exponential growth in the amount of information about bioactive ursolic acid and oleanolic acid or other triterpenoids over the early decade mirrors the increasing core in their concealed cosmeceutical, nutraceutical, and medicinal applications.

Unfavorably, the demerit of applying ursolic acid and oleanolic acid, indeed, is the toxicity related to their hemolytic and cytostatic character.[4] In a more recent examination, Jilani et al.[11] described that contact of leukocyte depleted erythrocytes for 48 h to Ringer's solution containing ursolic acid (0.5−10 μM) and diminished forward scatter, a result arriving statistically significantly at 5.0 μM, revealing cell shrinkage. Also, activation of Ca^{2+} entry, ceramide shaping, eliciting phospholipid scrambling and to a lesser extent hemolysis in human erythrocytes have been perceived upon addition of ursolic acid. These consequences were ascribed to frank evidence of the ursolic acid influencing erythrocytes from flowing blood and exciting the suicidal demise of erythrocytes, with a consequent generation in anemia. For all of these, the episteme of the existence and biological functions of these natural triterpenoid chemicals, in particular those derived from edible and pharmaceutical herbaceous plants, are of enormous relish.

Blood plasma includes many proteins or other substances such as enzymes that are eagerly bound with ligands especially drugs and, consequently, impress the pharmacodynamics and pharmacokinetics of many drugs, but most investigations on the binding of drugs to assorted proteins in blood have evidently displayed that likely the most significant protein is albumin.[12] Even though albumin has a net negative charge at the pH of blood, pH = 7.4, it binds both positively and negatively charged ligands, such as tetracyclines, digitoxin, salicylates, sulfonamide, phenylbutazone, barbiturates, acid dyes, vitamins C, uric acid, histamine, bilirubin, etc.[13] Pharmacologically, albumin protein recognition is a weighty factor of pharmacokinetics as it decides how much of a drug will be accessible in its free state for therapeutic utility, nontarget effectiveness (side effects), toxicity, and circulation into other human body cabins.[14] Drugs that are greatly bound to albumin protein generally have a low proportion of distribution and could be smaller promptly swept from the body as just the free section is usable for renal elimination. Depending on the expected target of a drug and the hopeful period of action, a high extent of albumin protein binding may or may not be an attractive characteristic.[15] An in vitro albumin protein recognition forecasts the degree to which an objective chemical will be recognized by albumin protein in the same species in vivo.

In arousing pharmacological and toxicological responses, drugs mostly connect either reversibly or irreversibly with target sites on intrastitial biopolymers or organelles, and therefore bring about changes of physicochemical or biochemical procedures in the living organism.[16,17] As has been shown, although drugs can bind to different proteins in blood, the chief plasma and tissue protein which is typically chargeable for the broad spectrum binding of most drugs is albumin. Despite a large quantity of literature, there is little consolidated knowledge obtainable on the kinetic and physiological dispersal of albumin−triterpenoids in the human body. It is thereby proper to contemplate the function of albumin in influencing triterpenoid binding and pharmacokinetics. The objective of the present study was to inspect the molecular recognition as well as the solution structure of the complexes fashioned between the triterpenoids ursolic acid and oleanolic acid and the protein bovine serum albumin (abbreviation: BSA, Figure 2), by means of computer-aided molecular modeling, steady state and time-resolved fluorescence, site-specific ligands, and hydrophobic 8-anilino-1-naphthalenesulfonic acid displacement. Furthermore, the conformation of BSA protein upon complexation was monitored by circular dichroism (CD) and synchronous fluorescence along with three-dimensional fluorescence measurements. These clues stated here can probably be useful when exploiting new synthesized drugs, which have analogous configuration with triterpenoids, whether the

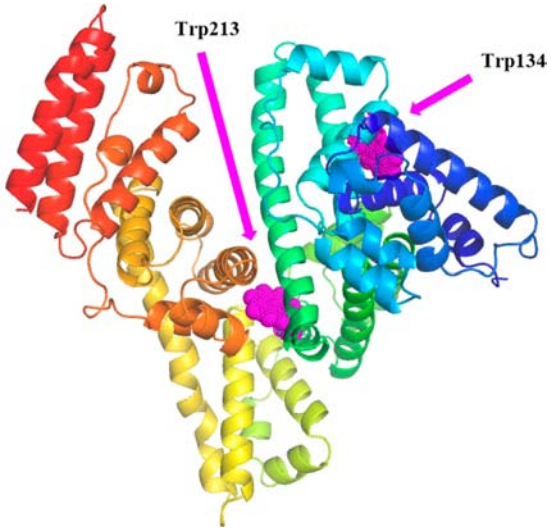

Figure 2. The ribbon model of the BSA derived from X-ray diffraction crystallography (PDB: 4JK4) and the tryptophan (Trp) residues located in domain I and II. This diagram was fabricated using PyMOL on the basis of the atomic coordinates accessible at the Brookhaven Protein Data Bank (http://www.rcsb.org/pdb).

intention is to utilize their depot role or to avoid binding to BSA.

EXPERIMENTAL SECTION

Materials. Albumin from bovine serum (A7030, lyophilized powder, fatty acid free, globulin free, ≥98%), ursolic acid (U6753, ≥90%), oleanolic acid (O5504, ≥97%), and 8-anilino-1-naphthalenesulfonic acid (A1028, ≥97%) were received from Sigma-Aldrich (St. Louis, MO) and used without further purification, and deionized water was obtained from a Milli-Q Ultrapure Water Purification System from Millipore (Billerica, MA). Tris (0.2 M)−HCl (0.1 M) buffer of pH = 7.4, with ionic strength 0.1 in the presence of NaCl, was used, and the pH was measured with an Orion Star A211 pH Benchtop Meter (Thermo Scientific, Waltham, MA). Dilutions of the BSA stock solution (10 μM) in Tris−HCl buffer were prepared immediately before use, and the concentration of BSA was checked spectrophotometrically using $E^{1\%}_{1cm}$ = 6.6.[18] All other reagents employed were of analytical grade and purchased from Sigma-Aldrich.

Molecular Modeling. Molecular modeling of the BSA−triterpenoid complexes was operated on an SGI Fuel Visual Workstation. The crystal structure of BSA (entry codes 4JK4), determined at a resolution 2.65 Å, was retrieved from the Brookhaven Protein Data Bank (http://www.rcsb.org/pdb). After being imported in the program Sybyl Version 7.3 (http://tripos.com), BSA structure was carefully checked for atom and bond type correctness assignment. Hydrogen atoms were computationally added using the Sybyl Biopolymer and Build/Edit menus. To avoid negative acid/acid interactions and repulsive steric clashes, added hydrogen atoms were energy minimized with the Powell algorithm with 0.05 kcal mol^{-1} energy gradient convergence criteria for 1500 cycles; this procedure does not change positions to heavy atoms, and the potential of the three-dimensional structure of BSA was assigned according to the AMBER force field with Kollman all-atom charges. The two-dimensional structure of triterpenoid was downloaded from PubChem (http://pubchem.ncbi.nlm.nih.gov), and the initial structure of the molecule was produced by Sybyl 7.3. The geometry of triterpenoid was subsequently optimized to minimal energy (tolerance of 0.5 kcal mol^{-1}) using the Tripos force field with Gasteiger−Hückel charges, and the lowest energy conformer was utilized for the docking analysis. The Surflex-Dock program which employs an automatic flexible docking algorithm was applied to analyze the possible conformation of the ligand that binds to BSA, and the program PyMOL (http://www.pymol.org) was finally used for visualization of the molecular docking results.

Steady State Fluorescence. Fluorescence emission spectra were obtained with a 1.0 cm path length quartz cell using a F-7000 spectrofluorimeter (Hitachi, Japan) equipped with a thermostatic bath. The excitation and emission slits were set at 5.0 nm each, intrinsic fluorescence was carried out by exciting the continuously stirred protein solution at 295 nm to favor tryptophan (Trp) excitation, and the emission spectra were read in the wavelength range of 300−450 nm at a scanning speed of 240 nm min^{-1}. The reference sample consisting of the Tris−HCl buffer of triterpenoid in corresponding concentrations was subtracted from all fluorescence measurements.

Time-Resolved Fluorescence. Time-resolved fluorescence was examined with a FLS920 spectrometer (Edinburgh Instruments, U.K.), using the time-correlated single photon counting system with a hydrogen flash lamp excitation source, in air equilibrated solution at ambient temperature. The excitation wavelength was 295 nm, and the number of counts gathered in the channel of maximum intensity was 4,000. The instrument response function (IRF) was gauged exploiting Ludox to scatter light at the excitation wavelength. The data were analyzed with a nonlinear least-squares iterative method utilizing Fluorescence Analysis Software Technology, which is a sophisticated software package designed by Edinburgh Photonics for the analysis of fluorescence and phosphorescence decay kinetics; IRF was deconvoluted from the experimental data, and the resolution limit after deconvolution was 0.2 ns. The value of χ^2 (0.9−1.2), the Durbin−Watson parameter (greater than 1.7), and a visual inspection of the residuals were used to assess how well the calculated decay fit the data. Average fluorescence lifetime (τ) for multiexponential function fittings were from the following relation:[19]

$$I(t) = \sum_i A_i \, e^{-t/\tau_i} \quad (1)$$

where τ_i are fluorescence lifetimes and A_i are their relative amplitudes, with i variable from 1 to 2.

Site-Specific Ligand. Binding location studies between BSA and triterpenoid in the presence of four typical site markers (phenylbutazone, flufenamic acid, digitoxin, and hemin) were executed using the fluorescence titration approach. The concentrations of BSA and site markers were held equimolar (1.0 μM), and then triterpenoid was added to the BSA-site marker mixtures. An excitation wavelength of 295 nm was chosen, and the fluorescence emission wavelength was acquired from 300 to 450 nm.

Hydrophobic ANS Displacement. In the first series of experiments, BSA concentration was kept fixed at 1.0 μM, triterpenoid/ANS concentration was varied from 5.0 to 45 μM, and BSA fluorescence was gained (λ_{ex} = 295 nm, λ_{em} = 341 nm). In the second series of experiments, triterpenoid was added to solutions of BSA and ANS held in equimolar concentration (1.0 μM), the concentration of triterpenoid was also varied from 5.0 to 45 μM, and the fluorescence of ANS was recorded (λ_{ex} = 370 nm, λ_{em} = 465 nm).

CD Spectra. Far-UV CD spectra were collected with a Jasco-815 spectropolarimeter (Jasco, Japan) equipped with a microcomputer; the apparatus was sufficiently purged with 99.9% dry nitrogen gas before starting the instrument, and then it was calibrated with d_{10}-camphorsulfonic acid. All the CD spectra were obtained at 298 K with a PFD-425S Peltier temperature controller attached to a water bath with an accuracy of ±0.1 °C. Each spectrum was performed with use of a precision quartz cuvette of 1.0 cm path length and taken at wavelengths between 200 and 260 nm, which provides a signal extremely sensitive to small secondary conformational distortions. Every determination was the average of five successive scans encoded with 0.1 nm step resolution and recorded at a speed of 50 nm min^{-1} and response time of 1 s. All observed CD data were baseline subtracted for buffer, and the estimation of the secondary structure elements was obtained by exploiting Jasco Spectra Manager II, which computes the different designations of secondary structures by comparison with CD spectra, determined from distinct proteins for which high-quality X-ray diffraction data are available.[20]

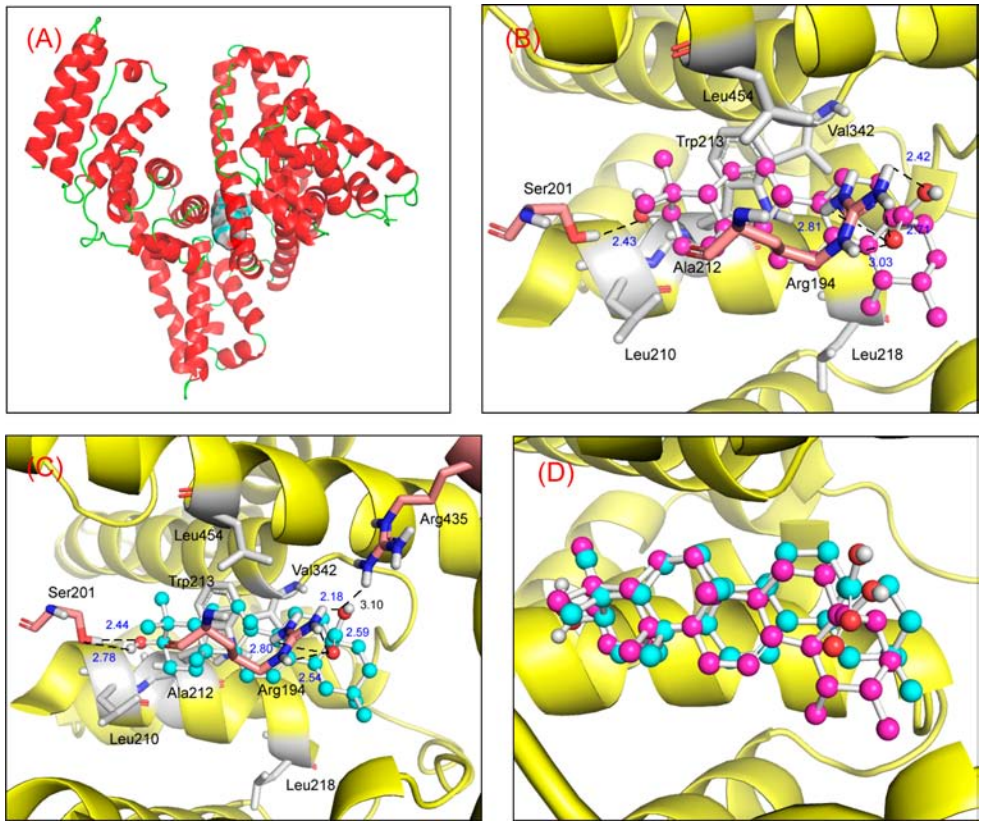

Figure 3. Molecular modeling of triterpenoids docked to BSA. Panel A shows docked triterpenoids in BSA at subdomain IIA, BSA displayed in surface colored in red, to triterpenoids, colored as per the atoms and endowed with opaque surface of electron spin density. Panels B and C indicate the amino acid residues involved in binding of triterpenoids. The ball-and-stick model represents triterpenoids, colored as per the atoms, and the pivotal amino acid residues around triterpenoids have been described in stick model; salmon stick model portrays hydrogen bonds between Arg-194, Ser-201 (B) and Arg-194, Ser-201, Arg-435 (C) residues and ursolic acid and oleanolic acid, respectively; white stick model narrates hydrophobic interactions between Leu-210, Ala-212, Trp-213, Leu-218, Val-342, Leu-454 (B) and Leu-210, Ala-212, Trp-213, Leu-218, Val-342, Leu-454 (C) residues and ursolic acid and oleanolic acid, respectively. Panel D interprets the conformational superposition of ursolic acid (magenta) and oleanolic acid (cyan) in the subdomain IIA of BSA.

Three-Dimensional Fluorescence. The emission wavelength was reaped between 200 and 500 nm, the initial excitation wavelength was set to 200 nm with increment of 10 nm, the number of scanning curves was 16, and the other scanning parameters were identical to those for the steady state fluorescence above.

Principle of Fluorescence Quenching. Fluorescence quenching refers to any process that decreases the fluorescence intensity of a sample. A variety of molecular interactions can result in quenching, such as excited state reactions, molecular rearrangements, energy transfer, ground state complex formation, and collisional quenching. Fluorescence quenching is described by the well-known Stern−Volmer equation:[21]

$$\frac{F_0}{F} = 1 + k_q\tau_0[Q] = 1 + K_{SV}[Q] \quad (2)$$

In this equation, F_0 and F are the fluorescence intensities in the absence and presence of quencher, respectively, k_q is the bimolecular quenching constant, τ_0 is the lifetime of the fluorophore in the absence of quencher, [Q] is the concentration of quencher, and K_{SV} is obtained by linear regression of a plot of F_0/F versus [Q].

Calculation of Recognition Ability. When ligand molecules bind independently to a set of equivalent sites on a macromolecule, the equilibrium between free and bound ligand molecules is given by the following relation:[22]

$$\log\frac{F_0 - F}{F} = \log K + n\log[Q] \quad (3)$$

In this equation, F_0 and F are the fluorescence intensities in the absence and presence of quencher, respectively, K and n are the association constant and the number of binding sites, respectively, and [Q] is the concentration of quencher. Thus, a plot of $\log(F_0 - F)/F$ against log [Q] can be used to calculate K and n. Moreover, the fluorescence intensities were corrected for absorption of the exciting light and reabsorption of the emitted light to decrease the inner filter effect by using the following relationship:[21]

$$F_{cor} = F_{obs} \times e^{(A_{ex}+A_{em})/2} \quad (4)$$

where F_{cor} and F_{obs} are the fluorescence intensities corrected and observed, respectively, and A_{ex} and A_{em} are the absorption of the systems at the excitation and the emission wavelength, respectively. The fluorescence intensity utilized in this work is the corrected intensity.

Statistical Analysis. All assays were executed in triplicate, and the mean values, standard deviations, and statistical differences were estimated using analysis of variance (ANOVA). The mean values were compared using Student's *t*-test, and all statistic data were treated using the OriginPro Software (OriginLab Corporation, Northampton, MA, USA).

RESULTS AND DISCUSSION

Molecular Modeling. The purpose of ligand−receptor docking is the ability to prefigure the preponderant recognition patterns of a ligand with an acceptor such as protein or nucleic acid of established three-dimensional crystal structure. We first

dx.doi.org/10.1021/jf4049512 | J. Agric. Food Chem. 2014, 62, 2271−2283

used this computational modeling technique to visually look over the binding modes between the BSA and the triterpenoids. Majorek et al.[23] and Bujacz et al.[24,25] in the first place declared a structure of albumin from bovine serum to 2.70 Å and 2.47 Å, severally, derived from tetragonal crystals obtained from defatted commercial BSA. The tertiary structure of BSA received from these X-ray diffraction measurements is a heart-shaped molecule, and it includes 583 amino acid residues and has 9 loops formed by 17 disulfides. The three-dimensional configuration is composed of three homologous domains (I, II, and III), each domain in turn is the spawn of two subdomains (A and B), which are largely helical and widely cross-linked through several disulfide bridges. Besides, the 6 subdomains partake of a joint helical motif, and the motif mainly corresponds to the amino acids surrounded within the double disulfide bonds 1, 3, 4, 6, 7, and 9. Two tryptophans (Trp), namely, Trp-134 and Trp-213, situated in domain I and domain II, respectively, and Trp-134 residue are lying in a hydrophilic circumstance, close to the protein surface, while Trp-213 residue is encircled by a hydrophobic surrounding within a protein patch.[12,26,27] The best docked energy conformation is shown in Figure 3; it was clear that both ursolic acid and oleanolic acid binding sites are located within subdomain IIA formed by six-helices (Figure 3A), but the recognition ability of subdomain IIA with the latter is higher, compared with the former.

For the BSA−ursolic acid mixture, the oxygen atoms of the carbonyl group and the oxygen atom of the hydroxyl group in ursolic acid can make hydrogen bonds (Figure 3B) with the hydrogen atoms of the amino group in Arg-194 and the hydrogen atom of the hydroxyl group in Ser-201 residues; the bond lengths are 2.42 Å, 2.71 Å, 2.81 Å, 3.03 Å, and 2.43 Å, respectively. For BSA−oleanolic acid complex, the oxygen atoms of the carbonyl group, the oxygen atom of the hydroxyl group, the hydrogen atom of the hydroxyl group, and the oxygen atom of the hydroxyl group can form hydrogen bonds with the hydrogen atoms of the amino group in Arg-194, the hydrogen atom of the hydroxyl group in Ser-201, the oxygen atom of the hydroxyl group in Ser-201, and the hydrogen atom of the amino group in Arg-435 residues; the bond lengths, respectively, are 2.18 Å, 2.54 Å, 2.59 Å, 2.80 Å, 2.44 Å, 2.78 Å, and 3.10 Å (Figure 3C). On the basis of surface modification of the amino acid residues composed of subdomain IIA, we may ascertain a hydrophobic region of subdomain IIA composed of Leu-210, Ala-212, Trp-213, Leu-218, Val-342, and Leu-454 residues, the skeleton of 22 carbon atoms organized into five rings toward the domain, which implied that hydrophobic interaction was exerting a heavy effect between them.

Apparently, ursolic acid and oleanolic acid have greatly close molecular structures but have only disparate sites of methyl group on the E-ring; if the methyl group at C_{19} of ursolic acid is shifted to C_{20}, it turns to oleanolic acid. To elaborate the divergence of binding mode between ursolic acid and oleanolic acid, the optimized conformations of ursolic acid and oleanolic acid have been overlapped in the subdomain IIA (Figure 3D). It was effortlessly seen that the dissimilarities of both locality and conformation between ursolic acid and oleanolic acid were tiny. Therefore, we could speculate that the different position of one methyl group on the E-ring might give rise to moderately disparate affinities of triterpenoids. In comparison with these noncovalent interactions, particularly hydrogen bonds residing in the BSA−triterpenoid conjugation, we may obtain some beneficial information regarding this distinction. Chemically, although hydrogen bond energies may seem small, on the order of 4.0−25.0 kJ mol^{-1}, it should be remembered that they commonly occur as a system of interconnections; thus they are additive and donate considerably to the comprehensive stability of systems such as the polypeptide polymer and protein or nucleic acid.[28,29] It was evident at first glance that the hydrogen bonds between BSA and triterpenoids look very alike to one another, for example, the carbonyl group in triterpenoids could generate a hydrogen bond network with the Arg-194 residue in BSA, but they do have at least two differences between the two systems. The first is the number of hydrogen bonds. Careful examination of Figure 3B and Figure 3C shows that oleanolic acid may form two strong hydrogen bonds with Ser-201 residue, whereas only one hydrogen bond can be yielded for ursolic acid. Furthermore, another hydrogen bond could be formed between oleanolic acid and the Arg-435 residue. A second theme is the differentiation between these hydrogen bonds. Intuitively, the lengths of hydrogen bonds between ursolic acid and the Arg-194 residue are larger than the oleanolic acid; this means that oleanolic acid has greater affinity than the ursolic acid. These distinctions mentioned above macroscopically behave in the diverse affinities between triterpenoids and BSA, i.e., $K = 1.419 \times 10^4$ M^{-1} (ursolic acid−BSA) and $K = 1.811 \times 10^4$ M^{-1} (oleanolic acid−BSA), respectively.

It is well testified that the biological activities of ursolic acid and oleanolic acid may be related to the methyl group on the E-ring. Ovesná et al.[30] conducted an in vitro study to scrutinize the protective effects of ursolic acid and oleanolic acid in leukemic cells. They lucidly revealed that in murine leukemia cells L1210 and K562 cells, the antioxidant activity of oleanolic acid measured by single cell gel electrophoresis was notably better in contrast with the antioxidant activity of ursolic acid. But for HL-60 cells, the percentage of ursolic acid protective outcome was 63.8%−61.6% at the concentration range of 2.5−10 μM, and the antioxidant effect of oleanolic acid was reasonably inferiorly collated with the activity of ursolic acid; however, the inconsistency between the protective activity of ursolic acid and oleanolic acid was not remarkable. In a recent study, ursolic acid and oleanolic acid were found to be powerful inducers of apoptosis in four human liver cancer cell lines involving mitochondrial dysfunctions.[31] Interestingly, the anticancer activities of the two triterpenoids were not uniform; ursolic acid at tantamount volume was larger than oleanolic acid in suppressing Na^+-K^+-ATPase activity in HepG2 cell; ursolic acid at 8.0 μM induced more DNA destruction than oleanolic acid in HepG2 and Hep3B cells, yet oleanolic acid at 8.0 μM stimulated more mitochondrial membrane latent decrease than ursolic acid in Huh7 and HA22T cells. The computational analyses quoted above, as a result, corresponded absolutely closely with these depictions found in the reference, i.e., the position of substituting group ($-CH_3$) on the E-ring may quite likely have an effect on the noncovalent interactions between triterpenoids and the amino acid residues in BSA, and result in different affinities between these triterpenoids. Moreover, the significant driving forces in the BSA−triterpenoid conjugation are hydrogen bonds and hydrophobic interactions; we also presume that the three-dimensional spatial structure of BSA may be perturbed due to the triterpenoids operating on the amino acid residues in a polypeptide chain by noncovalent bonds. Consequently, the information manifested in solution experiments expatiated below, as deduced from steady state and time-resolved fluorescence, competitive ligand

displacement, CD spectra, synchronous fluorescence, and three-dimensional fluorescence techniques, was applied to affirm upper molecular modeling corollaries.

Photochemical Properties of BSA−Triterpenoids. The molecular recognition of triterpenoids by BSA was evaluated by the assessment of intrinsic fluorescence of Trp residues, and Figure S1 (Supporting Information) conveys the raw data for quenching of BSA fluorescence at pH = 7.4 by addition of triterpenoids. It will be noticed that BSA arose to have a fluorescence peak at 341 nm, following an excitation at 295 nm. In BSA, the three aromatic amino acid residues Phe, Tyr, and Trp are all fluorescent, but emission of BSA is controlled by Trp residues, which absorbs at the longest wavelength and exhibits the largest extinction coefficient.[12,26,27] Clearly, a regular shortening of the Trp residues' fluorescence intensity was perceived from Figure 4 accompanied by growth in the

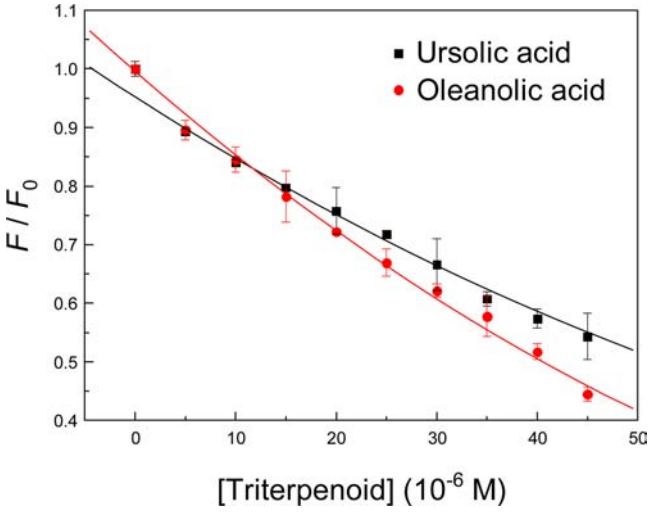

Figure 4. Trp residue fluorescence quenching of BSA (1.0 μM) at pH = 7.4 and T = 298 K, plotted as expunction of fluorescence intensity (F/F_0) *against* triterpenoid concentrations: 0, 5.0, 10, 15, 20, 25, 30, 35, 40, and 45 μM. The fluorescence intensity was read at λ_{ex} = 295 nm and the λ_{em} maximum obtained at 341 nm. All data were corrected for quencher fluorescence, and each point was the mean of three independent observations ± SD ranging from 0.38% to 4.44%.

concentration of triterpenoids. Under the present conditions triterpenoids displayed no fluorescence emission in the range 300−450 nm, which did not affect BSA intrinsic Trp residues' fluorescence. These phenomenon explained plainly that there were association reactions between BSA and triterpenoids and the ligand was localized in the region where Trp residues located within or near the fluorophores.[32] Further, the fluorescence quenching effect of oleanolic acid was better than that of ursolic acid, which denotes that oleanolic acid has a good affinity to complex with BSA, and this result is almost totally in agreement with the affinity imparity that branched from molecular modeling simulations. A similar finding has also been illustrated by Bourassa et al.[33] for the molecular recognition of antioxidant polyphenols resveratrol, genistein, and curcumin by milk α- and β-caseins.

Normally, quenching mechanism research can be employed to expose the localization of fluorophores in proteins and may also signify the dispersal of quenchers over middling large distances comparable to the dimension of proteins.[21] In order to expound the essence of fluorescence quenching of BSA by triterpenoids, the data were dissected according to the Stern−Volmer eq 2, and the corresponding results fitted from Stern−Volmer plots (Figure 5) are collected in Table 1. Usually, a

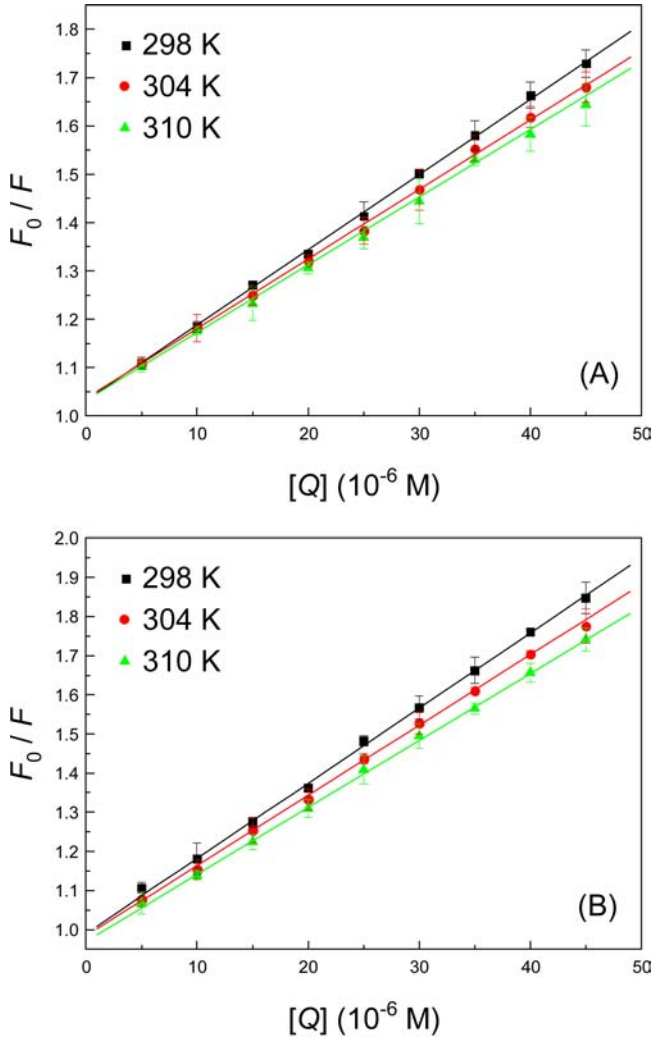

Figure 5. Stern−Volmer plot depicting Trp residue quenching of BSA (1.0 μM) at pH = 7.4 in the presence of 5.0, 10, 15, 20, 25, 30, 35, 40, and 45 μM ursolic acid (A) and oleanolic acid (B). Each data was the average of three separate determinations ± SD ranging from 0.62% to 4.64%.

linear Stern−Volmer plot is exhibitive of a single kind of fluorophore, all equivalently attainable to quencher. The Stern−Volmer plots for triterpenoids are apparently linear,

	310	1.704	2.969	0.9996

[a] R is the correlation coefficient.

dx.doi.org/10.1021/jf4049512 | J. Agric. Food Chem. 2014, 62, 2271−2283

which hints that just one type of quenching reaction exists. Simultaneously, the Stern−Volmer quenching constant K_{SV} is contrarily connected with temperature and the value of k_q is 100-fold greater than the biggest feasible value of bimolecular quenching constant in aqueous solution (1.0×10^{10} M^{-1} s^{-1}), demonstrating that the probable quenching mechanism for BSA fluorescence emission by triterpenoids is a static type, because higher temperature will classically result in the dissociation of weakly bound complexes, and thus lesser quantities of static quenching.

One consideration to bear in mind is that static and dynamic quenching can be discerned by their differing reliance on temperature or viscosity, but preferably by fluorescence lifetime measurements, which can discriminate between static and dynamic processes straightly.[21] To further acquire direct proof of the nature of the BSA−triterpenoid recognition, the representative fluorescence decay figures of BSA at different molar ratios of triterpenoids in Tris−HCl buffer, pH = 7.4, are displayed in Figure S2 in the Supporting Information, and the fluorescence lifetime and their amplitudes are summarized in Table 2. Obviously, the decay curves fitted well to a biexponential function, and the relatively fluorescence lifetimes being exhibited are τ_1 = 3.68 ns and τ_2 = 6.95 ns of BSA, whereas in the maximum concentration of ursolic acid or oleanolic acid, the lifetimes are τ_1 = 2.89/3.03 ns and τ_2 = 6.07/5.99 ns, respectively. Considering Trp residues are known to show multiexponential decays, a transparent allotment of the observed individual fluorescence lifetime constituents to the dissimilar fluorescent Trp residues is tough for a multiple Trp residue protein such as BSA. Therefore we have not sought to assign the separate components; on the contrary, the average fluorescence lifetime has been employed in order to capture a qualitative analysis. The mean fluorescence lifetime of BSA did not change obviously, just from 5.74 ns to 5.53/5.43 ns, at different ursolic acid or oleanolic acid concentrations, indicating evidently that fluorescence quenching is truly a static mechanism. The results match our previous discussion based on molecular modeling and steady state fluorescence that quenching is static in nature, triterpenoids binds in the vicinity of Trp residues in subdomain IIA, and BSA−triterpenoid complexes are formed between fluorophore and the triterpenoids, which is nonfluorescent. Recent research by Abou-Zied et al.[22] also found similar phenomena when BSA from human serum recognizes with anticancer agents 6-hydroxyquinoline, 7-hydroxyquinoline, and 8-hydroxyquinoline.

Table 2. Fluorescence Lifetime Data of BSA as a Function of Concentrations of Triterpenoids

samples	τ_1 (ns)	τ_2 (ns)	A_1	A_2	τ (ns)	χ^2
free BSA	3.68	6.95	0.37	0.63	5.74	0.99
BSA + ursolic acid (1:1)	3.45	6.31	0.29	0.71	5.48	1.02
BSA + ursolic acid (1:2)	3.21	6.12	0.19	0.81	5.57	1.05
BSA + ursolic acid (1:4)	2.89	6.07	0.17	0.83	5.53	0.98
BSA + oleanolic acid (1:1)	3.29	6.42	0.31	0.69	5.45	1.07
BSA + oleanolic acid (1:2)	3.54	6.19	0.22	0.78	5.61	0.99
BSA + oleanolic acid (1:4)	3.03	5.99	0.19	0.81	5.43	1.03

Frequently, drugs possess some specificity for the binding site on the acceptor like target protein; if the specificity is lower, it alludes binding affinity is lower, and a bigger potion of drug will be needed, which is related with some side effects.[34,35] Therefore the efficacy of a drug depends on its binding strength for the binding site as well as its binding affinity to generate the desired effects. In order to reckon the binding strength of triterpenoids to BSA, eq 3 was applied to estimate K and n by linear regression of a plot of the $\log(F_0-F)/F$ versus $\log [Q]$ (Figure S3 in the Supporting Information), and the results are also displayed in Table 3. The affinity K reduced with rising temperature, showing the destabilization of the BSA−triterpenoid complex; likewise, the affinity of BSA with oleanolic acid is greater than that of ursolic acid, and this corroborates perfectly our preceding results found on molecular modeling that the strength of ursolic acid with BSA is lower than that of oleanolic acid. According to Dangles and Dufour[36] and united with the recent reports on the subject of protein−ligand recognition, such as piperine, bile acids, hydroxyquinoline derivatives, retinol, retinoic acid, and folic acid,[37−41] it is fairly plain that the recognition of triterpenoids by BSA belongs to intermediate affinity. In addition, the value of n is properly 1, which may infer the presence of just one sort of binding site in BSA for triterpenoids. This fact also overlaps the foregoing molecular modeling and further agrees with the following site-specific ligands and hydrophobic 8-anilino-1-naphthalenesulfonic acid displacement experiments.

It is should be mentioned that the binding intensity of circulating triterpenoids for albumin is moderately small, but the physiological concentration of albumin is in all probability roomy enough (~640 μM) to allow triterpenoids vast binding. Albumin binding may effectually prolong the in vivo half-life of triterpenoids, and the concentration of triterpenoids ordinarily accumulated in some organs such as brain, heart, kidney, liver, and plasma, which is in logical harmony with the in vivo experiments in healthy volunteers and different animals specified somewhere. For example, Song et al.[42] and Xia et al.[43] administrated healthy volunteers with single doses of oleanolic acid and ursolic acid and found that the peak plasma

concentration (C_{max}) and time to peak concentration (T_{max}), respectively, are 12.12 ng mL^{-1} and 5.2 h for oleanolic acid and 3404.6 ng mL^{-1} and 4.0 h for ursolic acid. These results distinctly proved that oleanolic acid and ursolic acid were distributed to an immense degree out of the blood chamber or accumulated in some tissues. In a study with Sprague−Dawley rats, the C_{max} and T_{max} were found to be 1.10 μg mL^{-1} and 0.42 h, and the dispersion order of ursolic acid in various organs was detected as follows: lung > spleen > liver > cerebrum > heart > kidney.[44] This in vivo study hence concluded that ursolic acid was mostly distributed in ample blood furnishing tissues such as lung, spleen, and liver, and the spreading depended chiefly upon the blood flow and perfusion rate of the organ. In another very recent pharmacokinetic study, Yin et al.[45] announced that triterpenoids were assimilated, metabolized, and stored in tissues which in reverse exerted their regional and systemic activities. In this experiment, male C57BL/6 mice were fed triterpenoids for approximately 8 weeks, and it can unmistakably be heeded that the liver not only had the utmost bioavailability for triterpenoids paralleled with other tissues but also was the outstanding organ for triterpenoid reposition and metabolism. In light of the above experimental observations, we could obviously view that the bioavailability and deposit of triterpenoids such as ursolic acid and oleanolic acid in the human body relied mainly upon the blood circulation, or rather plasma protein binding. Consequently, more attention should be paid to this issue, because albumin can usually act as an important vector for nearly all endogenous and exogenous ligands in human plasma to deliver the triterpenoids to the target organs, where it brings forth its pharmacological and toxicological effect.

Thermodynamic Analysis. As noted earlier, molecular recognition commonly show a striking level of specificity and high-affinity. Basically, binding transpires only when it is linked with a negative Gibbs free energy of binding (ΔG°), which may have differing thermodynamic symbols, changing from enthalpy to entropy driven. Therefore, the apprehension of the acting forces running the recognition and interaction request a detailed recountal of the binding thermodynamics, and a relationship of the thermodynamic functions with the structures of interacting mates.[46] To attest the noncovalent interactions between BSA and triterpenoids, supposing the enthalpy ΔH° do not vary clearly over the temperature range studied, the three thermodynamic functions are related by the following equations:

$$\ln K = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \quad (5)$$

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad (6)$$

where K is the affinity constant for a given association reaction under a definite set of experimental conditions, R is the gas constant, and T is the absolute temperature. A linear plot (Figure 6) of ln K versus $1/T$ produces ΔH° and ΔS°, and the data fitted from Figure 6 also shown in Table 3. Ross and Subramanian[47] generalized the signs and magnitudes of the thermodynamic parameters associated with different solitary kinds of interactions that might settle in protein association processes, as recounted below. For classic hydrophobic interactions, both ΔH° and ΔS° are positive, while they are negative for van der Waals forces and hydrogen bonds shaping in low dielectric medium. Furthermore, concrete electrostatic interactions between ionic species in aqueous solution were

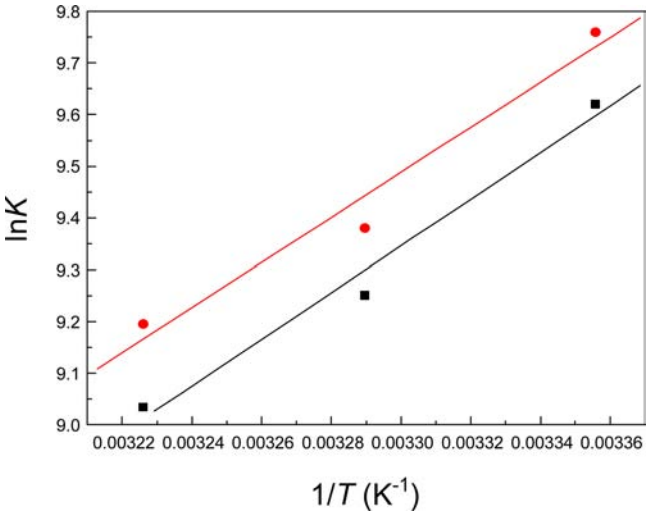

Figure 6. van't Hoff plot for the molecular recognition of ursolic acid (■) and oleanolic acid (●) by BSA in Tris-HCl buffer, pH = 7.4.

defined by a positive value of ΔS° and a negative ΔH° (almost zero). A negative ΔH° is observed whenever there is a hydrogen bond in the process. In the current instance of BSA−triterpenoid system, ursolic acid and oleanolic acid involve several hydrophobic cyclic systems (6-membered ring) and these cyclic systems dominantly function with amino acid residues of BSA to generate hydrophobic interactions; therefore, one could reasonably proclaim that hydrogen bonds, van der Waals forces, and hydrophobic interactions all weigh heavily in the molecular recognition of triterpenoids by BSA. Moreover, the BSA−triterpenoid recognition process is an unprompted exothermic reaction owing to the negative value of ΔG°; the experimental data ΔG° (298 K) is also greatly close to the theoretical data ΔG° = −23.69 kJ mol^{-1} and ΔG° = −24.29 kJ mol^{-1} for ursolic acid and oleanolic acid, respectively, confirming the reliability of the results of steady state fluorescence.

Identification of Binding Domain. As we have seen, both ursolic acid and oleanolic acid were located in subdomain IIA (Sudlow's site I) by building on the results of molecular modeling and eq 3. To further clarify this aspect, site-specific ligand experiments between the triterpenoids and the other ligands that specifically bind to a known site or domain were executed. The curious feature of albumin to bind various substances is predominantly dependent on the existence of two foremost binding sites, that is, Sudlow's site I and site II, which are situated within particular regions in subdomains IIA and IIIA,[48,49] respectively. Site I is known as the warfarin−azapropazone site and formed as a cave in subdomain IIA, the residue Trp-213 of BSA in this patch. The internal wall of the pocket is formed by hydrophobic side chains, whereas the entry to the cavity is enveloped by positively charged residues. The unusual quality of this site is the binding of the ligand which is a bulky heterocyclic anion with a negative charge localized in the middle of the molecule, such as warfarin, phenylbutazone, 3,5-diiodosalicylic acid, and azapropazone.[25,27] Site II corresponds to the hole of subdomain IIIA and is renowned as the indole−benzodiazepine site, which is almost equal in size to site I; the interior of the domain is composed of hydrophobic amino acid residues, and the external pocket existed two basic amino acid residues (Arg-410 and Tyr-411).[23−25] Ligands binding to site II are aromatic carboxylic

acids with a negatively charged acidic group at the end of the molecule, e.g., ibuprofen, flufenamic acid, diflunisal, and diazepam. Subsequently Brodersen et al.[50] proposed that digitoxin binding in albumin is autonomous from Sudlow's site I and site II, and perch on what was nominated as site III. In the present work, the competitor used involved phenylbutazone, a typical marker for site I, flufenamic acid for site II, digitoxin for site III, and hemin for domain I. According to eq 3, the affinity constants were fitted from raw fluorescence data and found to be $0.1967 \times 10^4/0.1538 \times 10^4$ M^{-1}, $1.459 \times 10^4/1.522 \times 10^4$ M^{-1}, $1.461 \times 10^4/1.653 \times 10^4$ M^{-1}, and $1.384 \times 10^4/1.619 \times 10^4$ M^{-1} for ursolic acid and oleanolic acid, respectively, in the presence of phenylbutazone, flufenamic acid, digitoxin, and hemin. The outcomes advocate triterpenoids having the same site with phenylbutazone in BSA, and authorize the simulation of molecular modeling putting the triterpenoids at subdomain IIA and is also in agreement with 8-anilino-1-naphthalenesulfonic acid displacement below.

Fluorescence dye 8-anilino-1-naphthalenesulfonic acid (ANS) is accepted to bind to hydrophobic patches of proteins and can serve as a perceptive announcer of conjugation in the vicinity of protein Trp residues; thereby it has been employed to specify all the hydrophobic sites of proteins.[51] For the purpose of further ensuring the property of the molecular recognition of triterpenoids by BSA, binding studies were carried out in the presence of ANS under unanimous conditions. Based on the protocol designed above, the relative fluorescence intensity (F/F_0) *against* ligand concentration ([Ligand]) plots is indicated in Figure 7. Vividly, at a ligand concentration of 45 μM, both triterpenoids and ANS dribble Trp-213 residue fluorescence, but the pitch of quenching by triterpenoids was to some degree lower than ANS; ANS could extinguish about 69.05%, whereas ursolic acid and oleanolic acid, respectively, could just slake 46.16% and 54.01% of Trp-213 residue fluorescence. In a much earlier report, Stryer[52] imprimis asserted that the quantum yield of ANS is approximately 0.002 in aqueous buffer, but near 0.4 when bound to protein, with almost no contribution from the unbound probe. When triterpenoids are added to the ANS−BSA mixture, it can compete with ANS for its hydrophobic domain, and the fluorescence would trim. The valid explanation for this is that ANS is virtually nonfluorescent when in aqueous solution, but it will become highly fluorescent in nonpolar solvents or when it is bound to proteins. As can be seen in Figure 7, ANS−BSA fluorescence faded about 30.87% and 35.87% in the presence of ursolic acid and oleanolic acid, respectively, pronouncing that triterpenoids may contend against ANS moderately for its binding site. Although still partially debatable, consensus prevailed today that there are five discrepant binding sites for ANS associated with BSA, but preferentially at a site close to the Trp-213 residue.[53] In this context, ANS powerfully stifles the fluorescence of BSA, which justifies that the binding position for ANS in this high-affinity site comes near to Trp-213; about 30.87% and 35.87% displacement of ANS fluorescence illustrates that triterpenoids and ANS likely participate at a conjunct site in BSA, viz., the site is located next to the residue Trp-213. An analogous consequence has also been transmitted by Sen et al.[54] for the binding of gold nanoparticle to albumin from human serum.

Structure and Stability of BSA. Conformational changes in acceptors upon binding ligands are possibly key in a number of biomedical systems, and frequently a conformation change in the receptor would noticeably be a mechanism for cooperativity.[55] In terms of molecular modeling, we deduced that the conformation of BSA has changed after the triterpenoid conjugation. To verify this point, the circular dichroism (CD) spectra of BSA in the absence and presence of triterpenoids are displayed in Figure S4 in the Supporting Information, and the secondary structure components calculated based on raw CD data are pooled in Table 4. The CD curves of BSA exhibited

Fluorescence quenching silhouettes of BSA and BSA−ANS mixture; binding isotherm of (A) ursolic acid (■) and (B) oleanolic acid (■) and ANS (●) provoked quenching of BSA fluorescence and quenching of BSA−ANS complex fluorescence by (A) ursolic acid (▲) and (B) oleanolic acid (▲); pH = 7.4, T = 298 K. Each data was the mean of three individual measurements ± SD ranging from 0.23% to 4.82%.

Table 4. Secondary Structure Constituents of BSA Recognition with Triterpenoids at pH = 7.4 Appraised by Jasco Spectra Manager II Software

samples	secondary structure components (%)			
	α-helix	β-sheet	turn	random
free BSA	61.3	8.1	11.9	18.7
BSA + ursolic acid (1:2)	57.8	8.7	12.6	20.9
BSA + ursolic acid (1:4)	52.1	9.9	14.2	23.8
BSA + oleanolic acid (1:2)	56.4	8.9	12.8	21.9
BSA + oleanolic acid (1:4)	49.2	10.1	14.4	26.3

dx.doi.org/10.1021/jf4049512 | J. Agric. Food Chem. 2014, 62, 2271−2283

two negative peaks in the far-UV CD region at 208 and 222 nm, characteristic of α-helical structure of BSA. The rational elucidation is that the negative bands between 208 and 209 nm and 222 and 223 nm are both contributed by the $\pi \rightarrow \pi^*$ and the n $\rightarrow \pi^*$ transition for the peptide bond of α-helix.[56] Free BSA has 61.3% α-helix, 8.1% β-sheet, 11.9% turn, and 18.7% random coil; upon complexing with ursolic acid and oleanolic acid, a decline of α-helix was detected from 61.3% free BSA to 52.1%/49.2% BSA−triterpenoid complexes, while elevation was detected in β-sheet, turn, and random coil from 8.1%, 11.9%, and 18.7% free BSA to 9.9%, 14.2%, and 23.8% BSA−ursolic acid and 10.1%, 14.4%, and 26.3% BSA−oleanolic acid at a molar ratio of BSA to triterpenoids of 1:4. The decrease of α-helix with an increment in the β-sheet, turn, and random coil explained triterpenoids bound with amino acid residues of the polypeptide chain and giving rise to the destabilization of the BSA spatial structure,[57] i.e., some degree of BSA destabilization upon triterpenoid complexation.

Another testimony of structural changes of BSA after complexing with triterpenoids was represented by synchronous fluorescence spectra. It involves simultaneously scanning of the excitation and emission monochromators while retaining a stable wavelength interval ($\Delta\lambda$) or fixed increment of energy ($\Delta\nu$) between them.[58] Fuller and Miller[59] suggested that if the D-value ($\Delta\lambda$) between excitation and emission wavelengths was riveted at 60 nm, the synchronous fluorescence states the idiosyncratic clue of Trp residues. Figure 8 displays the synchronous fluorescence of BSA in Tris−HCl buffer in the presence of different amounts of triterpenoids. A faint red shift can be noted from Figure 8, which sustained that the hydrophobicity around the Trp residue was abated and the hydrophilicity expanded.[60] Moreover, it has been frankly shown in Figure 9 that the slope was higher for the BSA−oleanolic acid mixture, interpreting that the quenching effect of Trp-213 residue fluorescence by ursolic acid was definitely frailer than that of oleanolic acid.

To procure more exhaustive information on the conformational alterations of triterpenoid complexes with BSA, three-dimensional fluorescence of BSA and BSA−triterpenoid complex is scanned in Figure S5 in the Supporting Information, and the corresponding parameters are also filed in Table 5. Peak 1 (λ_{ex} = 280.0 nm, λ_{em} = 360.0 nm) chiefly unravels the spectral trait of Tyr and Trp residues, because when BSA is excited at 280.0 nm, it principally shows the intrinsic fluorescence of Tyr and Trp residues, and the Phe residue fluorescence can be trifling.[21] Besides peak 1, peak 2 mainly exposits the fluorescence spectral action of polypeptide chain backbone structure C═O. The fluorescence intensity of peak 2 alleviated a lot after the addition of triterpenoids, which delivered that the peptide chain structure of BSA was changed and this espouses far-UV CD spectra. Analyzing from the fluorescence intensity variations of the two peaks which decreased tangibly, but to an unequal tune: the intensity of peak 1 has been receded of 40.29% and 50.32%, while peak 2 of 18.4% and 21.16% for BSA−ursolic acid and BSA−oleanolic acid, respectively, evincing that the molecular recognition of triterpenoids with BSA begot the conspicuous destabilizing of the polypeptide chain of protein, which augmented the unwrapping of some hydrophobic patches that had been entombed before.[61] All of the above inspections and analyses verified that the conjugation of triterpenoids with BSA evoked spatial structure changes in protein, which may be associated with its physiological function. This phenomenon is also in

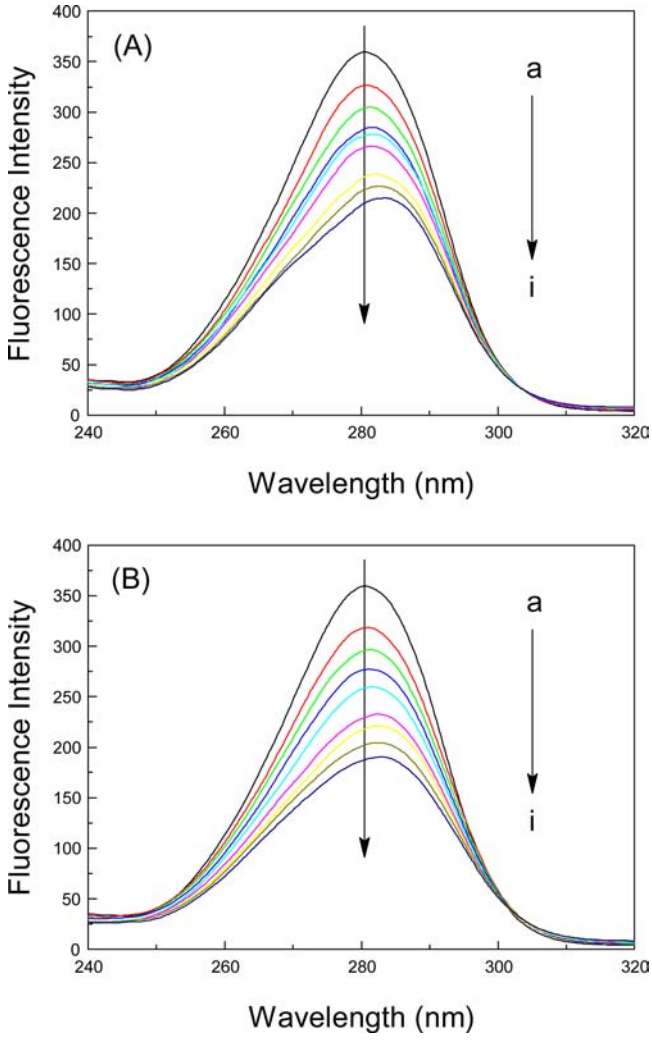

Figure 8. Synchronous fluorescence spectra ($\Delta\lambda$ = 60 nm) of BSA (1.0 μM) in the presence of 0, 5.0, 10, 15, 20, 25, 30, 35, and 40 μM ursolic acid (A) and oleanolic acid (B); pH = 7.4 and T = 298 K.

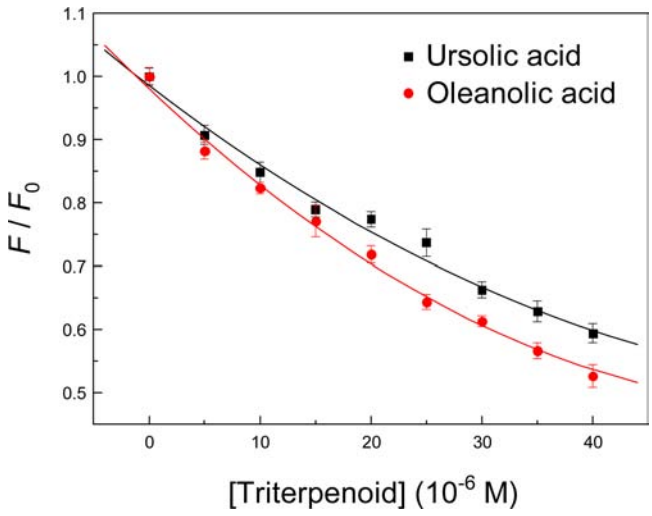

Figure 9. Synchronous fluorescence quenching ($\Delta\lambda$ = 60 nm) efficiency of BSA (1.0 μM) at pH = 7.4 and T = 298 K, plotted as elimination of fluorescence intensity (F/F_0) versus triterpenoid concentration. Each point was the average of three independent experiments ± SD ranging from 0.87% to 2.49%.

Table 5. Three-Dimensional Fluorescence Spectral Distinctive Parameters of BSA and BSA−Triterpenoid Complex

system	peak 1 ($\lambda_{ex}/\lambda_{em}$)	$\Delta\lambda$ (nm)	intensity F	peak 2 ($\lambda_{ex}/\lambda_{em}$)	$\Delta\lambda$ (nm)	intensity F
BSA	280.0/360.0	80.0	788.5	230.0/362.0	132.0	326.1
BSA + ursolic acid	280.0/364.0	84.0	470.8	230.0/363.0	133.0	266.1
BSA + oleanolic acid	280.0/367.0	87.0	391.7	230.0/366.0	136.0	257.1

accordance with the inference based on UV/vis absorption spectra introduced by Rada et al.,[62] and then, the extent of α-helical content changes induced by ursolic acid was smaller than that by oleanolic acid, which gave indirect proof to the affinity of human serum protein (mainly albumin) with oleanolic acid being larger than that with ursolic acid.

In a word, we have decoded the molecular recognition of two naturally bioactive triterpenoids, ursolic acid and oleanolic acid, by protein BSA under physiological conditions, which were dissected by blending with molecular modeling, steady state and time-resolved fluorescence, and CD spectra. The results explained that both ursolic acid and oleanolic acid are fastened in subdomain IIA, Sudlow's site I of albumin, substantially by the noncovalent interactions such as hydrogen bonds and van der Waals and hydrophobic interactions, but the strength of oleanolic acid with BSA is better, compared with ursolic acid, which are related to the position of methyl substituting group in the molecular structure of triterpenoids. Further assays will be performed to earn integrative information concerning the stereochemistry and different position of methyl group substitutions on the E-ring meddled with their affinity toward protein albumin by using nuclear magnetic resonance and molecular dynamics simulation, and the work is now in process. Steady state and time-resolved fluorescence endorse that the quenching of BSA Trp residue fluorescence resulted from a static mechanism, or rather the nonfluorescent BSA−triterpenoid complex formation with a comparatively modest intensity of 10^4 M^{-1}. Furthermore, the conformation of BSA was proved to be moderately disturbed upon the addition of triterpenoids with a shrinkage of α-helix accompanied by a rise in β-sheet, turn, and random coil, counseling a partial disruption of protein. All the data gathered herein fit well with the fact that the molecular recognition of triterpenoids by albumin may also be coherent with the pharmacological or toxicological style of the hugely utilized natural pentacyclic triterpenoids ursolic acid and oleanolic acid, as the biological effect of natural products is, assumedly, regulated through cellular diffusion bound to the most copious plasma protein.

$$\frac{(F_0 - F)F_\infty}{(F_0 - F_\infty)F} = \frac{[O_2]}{[O_2]_\infty} \quad (2)$$

which removes the need to know K_D;[16] the subscript "∞" means the fluorescence intensity and concentration when the material has reached oxygen equilibrium. The challenge in oxygen solubility and transfer studies is often the interference of atmospheric oxygen and the need to reliably remove oxygen prior to measurement to obtain F_0. Measuring the process of oxygen transfer across an emulsion interface is very challenging due to the need to create the initial conditions such that oxygen is saturated in the aqueous phase but the fast process of diffusion across an interface with nanometer scale thickness has not yet occurred. Considering Einstein's formula $h \approx (Dt)^{1/2}$, the time a molecule needs to leap across the distance, h = 10 nm is of the order of 1 μs if $D = 10^{-6}$ cm^2/s or 1 ms if $D = 10^{-9}$ cm^2/s. Within the oil droplet oxygen diffusivity is of the order of 10^{-5} cm^2/s. Hence, if the droplet radius is of the order of 100 nm, it reaches steady state in 10 μs.

As a result, it is improbable that the fluorescence technique is able to capture such fast kinetics, unless the diffusivity in the droplet film is extremely low, on the order of $<10^{-14}$ cm^2/s. Moreover, the collective response of an emulsion sample does not truly represent the situation in an individual droplet. We applied the fluorescence technique for various emulsions based on milk proteins and other food emulsifiers to verify our assumption described above. The detailed results are not reported within this paper, but the experimental details, the modeling applied, and the overall results are briefly presented in the Supporting Information.

After considering the fluorescence technique, we decided to approach the problem by using a planar air−water interface, which although different from the o/w emulsion interface is still considered to be a good model of such systems.[5] The aim of the present work was to investigate whether scanning electrochemical microscopy (SECM) combined with a Langmuir trough is a suitable method for measuring oxygen permeability of protein interfaces. Similar setups have been used previously for oxygen permeability studies across phospholipid and octadecanol monolayers.[17−20]

MATERIALS AND METHODS

Materials. β-Lactoglobulin (L3908) and β-casein (C6905) were obtained from Sigma (Steinheim, Germany). Twenty-five millimolar phosphate buffer (pH 7) was prepared with $NaH_2PO_4 \cdot H_2O$ and Na_2HPO_4 from J. T. Baker (Deventer, The Netherlands). All solutions were prepared with MQ water. Molar masses used in the calculation of mean molecular area were 18400 g/mol for β-lactoglobulin and 24100 g/mol for β-casein, respectively.

Procedure. In an SECM experiment, a microelectrode tip is biased at a potential where the reaction of interest is occurring, and tip current is recorded as a function of distance from the interface (Figure 1). A Langmuir trough is used for forming a protein film at the air−water interface under controlled conditions. A compressed layer was studied because a protein film at an emulsion interface is expected to consist of a compact layer. As the method is based on induced transfer beginning at equilibrium conditions, the presence of atmospheric oxygen and the short time scale of the transfer process do not have a critical impact on the measurement.

An inverted ultramicroelectrode was placed in the water subphase within the well of a Langmuir trough, and the protein film was formed on the water surface (Figure 1). The tip was biased at a potential where oxygen is reduced, resulting in a current-distance response (so-called approach curve) that provides information on the oxygen permeability of the interface. Close to a permeable interface, the current is higher than in the bulk solution as the electrode reaction drives the transfer of oxygen from the phase that has a higher concentration of oxygen. Close to an impermeable surface, the current is lower than in the bulk due to hindered diffusion of oxygen to the electrode. The response can be modeled by solving the diffusion equation for the axisymmetric cylindrical SECM geometry, taking into account the kinetics of the interfacial oxygen transfer, finally yielding the rate constant for oxygen transfer.

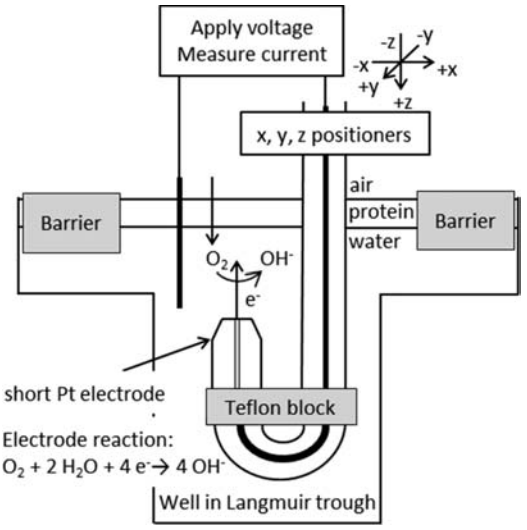

Figure 1. Schematic of the measurement setup (not to scale). An inverted ultramicroelectrode is used to measure the rate of oxygen transfer. SECM is used to control the potential and position of the electrode while recording the current.

SECM measurements were performed with a CHI900 instrument (CH Instruments, Austin, TX, USA) in a Langmuir trough with a well (195 cm^2, KSV Instruments Ltd., Helsinki, Finland). Phosphate buffer was used to counter the local shift in pH due to the formation of hydroxide ions as well as acting as the supporting electrolyte. The trough was filled with the buffer solution and thermostated to 23.5 °C. The interface was cleaned with a suction pipet with the barriers closed. Barriers were opened, and a homemade inverted Pt ultramicroelectrode with a radius a = 12.5 μm and RG = 10 (ratio of the radii of the insulating glass sheath and the electrode) was positioned in the well of the Langmuir trough. Ag wire acted as the counter and quasi-reference electrode. The current versus distance curves, or approach curves, were recorded at 0.5 μm/s with respect to the clean air−water interface to ensure that the response corresponded to a diffusion-controlled transfer with no kinetic limitations (pure positive feedback) for a clean interface. Prior to each approach curve measurement, the working electrode was activated by cycling 10 times from −0.35 to 1.2 V followed by a cyclic voltammogram (3 cycles) for oxygen reduction from 0.5 to −0.8 V.[21] This pretreatment together with the use of a buffer solution resulted in stable and reproducible voltammograms and approach curves. Approach curves for the oxygen reduction were recorded by biasing the electrode at −0.75 V, where oxygen reduction occurred at a diffusion-controlled rate.

After reproducible pure positive feedback was obtained for a clean interface, 200 μL of refrigerated protein solution (0.1 mg/mL in 25 mM, pH 7, phosphate buffer) was evenly spread on the subphase using a Hamilton syringe. The surface was stabilized for 30 min, and a surface pressure−area isotherm was recorded at a compression speed of 5 mm/min. Approach curves were then measured at the end point of the compression.

RESULTS AND DISCUSSION

Simulation of Theoretical Approach Curves. Theoretical approach curves were simulated for the system with

dx.doi.org/10.1021/jf5008715 | J. Agric. Food Chem. 2014, 62, 2284−2288

concentrations, diffusion coefficients, and dimensions as outlined in Figure 2.

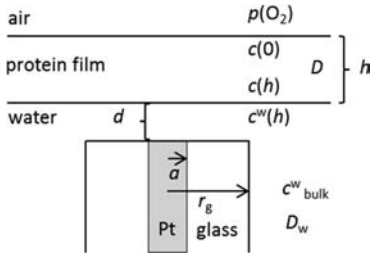

Figure 2. Outline of the system (not to scale). Film thickness = h, electrode-interface distance = d, electrode radius = a, radius of the glass sheath = r_g. D is the diffusion coefficient of oxygen in the film and D_w that in water. Oxygen concentrations: $c(0)$ at the air–film interface, $c(h)$ in the film, $c^w(h)$ in water at the film–water interface, and c^w_{bulk} in the bulk water phase.

Approach curves were simulated using the Finite Element Method in Comsol Multiphysics. The diffusion equation in axisymmetric circular cylindrical geometry using dimensionless variables is

$$\frac{\partial C}{\partial T} = \frac{\partial^2 C}{\partial R^2} + \frac{1}{R}\frac{\partial C}{\partial R} + \frac{\partial^2 C}{\partial Z^2} = 0 \quad (3)$$

The steady state solution gives the concentration profile in the system. The dimensionless variables are defined as $Z = z/a$, $R = r/a$, $L = d/a$, $C = c/c_{bulk}$, $T = D_w t/a^2$, and RG = r_g/a.

Current response is obtained from the concentration profile as the integral at the electrode surface:

$$\frac{I}{I_{bulk}} = \frac{\pi}{2}\int_0^1 \left(\frac{\partial C}{\partial Z}\right)_{Z=0} R\ dR \quad (4)$$

To calculate the concentration profile, a boundary condition to describe the kinetic limitation provided by the protein film at the interface is derived by using the oxygen flux across the interface from the concentrations in the aqueous phase. Similar situations have been considered previously,[17−20,22,23] but the theory is briefly presented below. Using the concentrations defined in Figure 2, oxygen solubility in water and in the protein film is described according to Henry's law as

$$c^w_{bulk} = \frac{p_{O_2}}{K_H},\ c(0) = \frac{p_{O_2}}{K_H^m} \quad (5)$$

where K_H is the Henry constant for oxygen solubility in water and K_H^m is that in the protein film. The partition between water and the film, P, is therefore

$$\frac{c(0)}{c^w_{bulk}} = \frac{K_H}{K_H^m} = P = \frac{c(h)}{c^w(h)} \quad (6)$$

That is, partition equilibrium naturally applies also at the water–film interface. Oxygen flux across the film is according to Fick's first law

$$j_{O_2} = \frac{D}{h}[c(0) - c(h)] = \frac{D}{h}c(0)\left[1 - \frac{c^w(h)}{c^w_{bulk}}\right] \quad (7)$$

by applying eq 6. The flux can be written in the dimensionless form as

$$J_{O_2} = K[1 - C(L)];\ K = \frac{D}{D_w}\frac{a}{h}P \quad (8)$$

The simulated approach curves for different values of the dimensionless rate constant, K, between 1000 for an ideally permeable interface and 0 for an ideally impermeable interface are presented in Figure 3. It is worth noting that the sensitivity

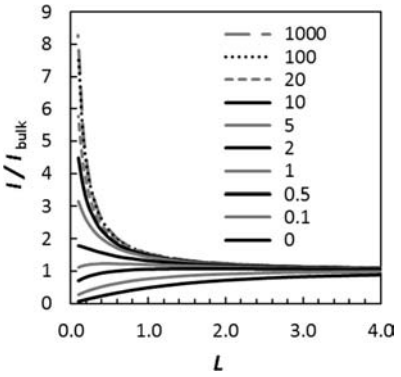

Figure 3. Simulated approach curves with the dimensionless rate constant, K, ranging from K = 1000 (highest curve, positive feedback) to K = 0 (lowest curve, negative feedback).

of the method at the limit of large K decreases and the curves for K = 1000 and K = 100 nearly overlap. When K > 5, the curves start to differ only below L = 1, whereas for lower K, the deviation from positive feedback is already evident at greater distances from the interface.

The distance of closest approach is obtained for each measurement from the approach curves to clean interface and is taken to be the point at which the current starts to level out and deviate from the ideal positive feedback. From the measurements, the criteria of $I > 5I_{bulk}$ and $L < 0.15$ were chosen as the point for an acceptable response for a clean interface. The distance of closest approach can never reach zero due to the roughness of the electrode surface, and it is assumed to remain the same for the approach to the protein-modified interface as has been previously supposed with octadecanol and phospholipids.[17,19,20,22,23] The nanoscale thickness of the interface is unlikely to have an effect on the distance of closest approach, which is on the order of micrometers.

Compression Isotherms and Experimental Approach Curves. Surface pressure–area isotherms for protein films are shown in Figure 4, and the isotherms were found to be highly reproducible for each protein. At the end point of the

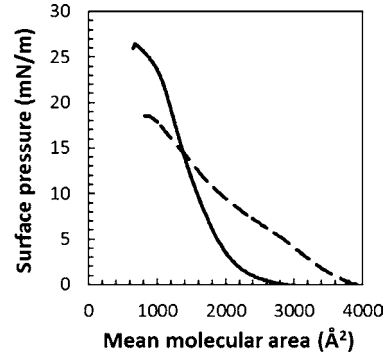

Figure 4. Langmuir compression isotherms for β-lactoglobulin (solid line) and β-casein (dotted line).

dx.doi.org/10.1021/jf5008715 | J. Agric. Food Chem. 2014, 62, 2284−2288

compression, the trough area is 40 cm^2 and the theoretical maximum surface mass concentration of the protein is therefore 5 mg/m^2. The corresponding mean molecular areas for β-casein and β-lactoglobulin are 820 and 650 $Å^2$, respectively. When β-casein was adsorbed on polystyrene beads, saturation of the layer was found to occur around this concentration,[24,25] and it is also in the same order of magnitude (1−3 mg/m^2) of the concentration at which the layer thicknesses for both proteins have been determined by neutron reflectivity.[10]

Typical experimental approach curves to an air−water interface without protein and to an interface modified with β-lactoglobulin and β-casein at surface pressures at the end point of the compression, 26.5 mN/m for β-lactoglobulin and 18.5 mN/m for β-casein, are shown in Figure 5.

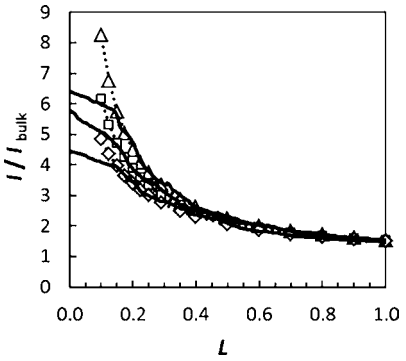

Figure 5. Experimental approach curves for the air−water interface (from top to bottom) without a protein fitted for K = 1000 (△), with β-casein film fitted for K = 25 (□), and with β-lactoglobulin film fitted for K = 12 (◇). Low K indicates low permeability to oxygen.

The response for an air−water interface without a protein fits the theoretical curve of K = 1000 corresponding to ideal positive feedback with no kinetic limitation at the interface as expected. The response for β-lactoglobulin fits the theoretical curve of K = 12 and β-casein to K = 25. Using a diffusion coefficient of oxygen in water of $D_w = 2.0 \times 10^{-5}$ cm^2/s and a film thickness of 3.1 nm for β-lactoglobulin or 5.4 nm for β-casein,[5] we obtain the product PD from eq 8 as 0.6×10^{-7} cm^2/s for β-lactoglobulin and 2.2×10^{-7} cm^2/s for β-casein, showing that β-lactoglobulin provides a better barrier to oxygen transfer. A possible explanation is the more compact structure of the β-lactoglobulin film originating from stronger intermolecular interactions as previously demonstrated by surface rheological measurements.[26] For β-lactoglobulin, 3-fold dilatational elasticity could be determined. In contrast, for β-casein, the determination of stress strain curves in surface shear measurements was not possible due to the weakness of the film.

Oxygen solubility in the protein film can be assumed to be smaller than in water due to the free volume effect. Therefore, even though the solubility in the film is not known, the *lowest limit* for the diffusion coefficient can be obtained by assuming that $c(0) = c^w_{bulk}$, that is, P = 1, and the value PD directly corresponds to the diffusion coefficient. Compared to the diffusion coefficient of oxygen in solid polymers (10^{-8} cm^2/s), the obtained values are in a reasonable range.

Even though β-lactoglobulin is known to form thinner films, it was less permeable to oxygen than β-casein under the conditions applied here and demonstrates the inhibition of oxygen transfer in β-lactoglobulin. To the best of our knowledge, this is the first study that allows independent characterization of oxygen permeability of protein interfaces. We demonstrated that oxygen permeabilities of interfacial layers of β-casein and β-lactoglobulin can be distinguished with this setup. The results of the oxidation studies by Berton et al.[27,28] comparing these proteins suggest, however, that the difference in oxygen permeability may not be enough to determine the rate of oxidation in emulsions as β-casein was shown to be more effective in protecting the lipid from oxidation. Due to the extremely thin, nanometer size, interface, oxygen permeability is unlikely to be the limiting step in controlling lipid oxidation in emulsions having the time scale of the oxidation reactions on the order of days, unless oxygen transfer is practically blocked. As the size of an oxygen molecule is on the ångstrom scale, it is unlikely that the surface coverage of any protein interface would be sufficient to completely block the oxygen transfer. Our results, however, clearly indicate that for decreased oxygen permeability, a globular structure forming a viscoelastic layer is more effective than a fluid-like structure.

Applying SECM for liquid−liquid interfaces would be an interesting step toward a more realistic model of the emulsion interface as, in contrast to air−liquid interfaces, proteins are reported to be more firmly attached to liquid−liquid interfaces.[25] For attempts to develop better interfaces with highly improved oxygen blocking efficacy, the SECM method provides an excellent tool to characterize and compare the blocking properties of different interfaces.

granules, thus producing starch with unimodal granule size distribution.

MATERIALS AND METHODS

Plant Material. A collection of 142 barley (*Hordeum vulgare* L.) genotypes of diverse origins (Table 1) were analyzed for starch granule size distribution. Seven widely grown Canadian barley varieties CDC Dolly (Canadian Food Inspection Agency (CFIA), Ottawa, Ontario, Canada, Variety registration Office (VRO) registration certificate # 3967), CDC Clyde (CFIA registration certificate # 2103), CDC Kendall (CFIA registration certificate # 0298), CDC Copeland (CFIA registration certificate # 1100), CDC Battleford (CFIA registration certificate # 1104), CDC Meredith (CFIA registration certificate # 3942), and AC Metcalfe[26] and Harrington were also evaluated. Plants from the barley germplasm collection were grown in a growth chamber at 18 °C under 16 h photoperiod (200 μmol m^{-2} s^{-1} photosynthetic photon flux density) until maturity. Plants in the field were grown in rows or small plots at three locations on the University of Saskatchewan farm near Saskatoon, Saskatchewan, Canada (52° 8′ N/106° 38′ W). Single heads of mature plants were collected for eventual analysis of the grain.

Starch Granule Size Determination. All starch analyses were conducted on grain collected from the middle section of spikes. Starch samples for microscopic imaging were prepared and analyzed (≥5000 starch granules) as described.[27] Samples to be analyzed by laser diffraction (Mastersizer 2000, MAL 1030346, Malvern Instruments, Malvern, England) were prepared using a modified starch extraction procedure as follows: A sample of coarsely ground barley grain (1 g) was steeped overnight at 4 °C in 2 mL of 0.02 N HCl. Starch granules were separated from cell wall and protein matrix by digestion at 37 °C for 3 h with 15 units *Streptomyces griseus* type XXV proteinase (Sigma), 2 units lichenase (Megazyme), and 8 units *Thermomyces lanuginosus* β-xylanase (Sigma), as described.[28] Digested grain samples were mixed using a glass rod, filtered over 100 μm nylon filter, and centrifuged for 10 min at 3000*g*. The crude starch granule preparation was purified by cesium chloride density gradient centrifugations as described.[29] The purified starch granules were suspended in water to 40 mg/mL concentration and briefly dispersed by sonication prior to analysis. Laser diffraction analysis of starch was done using Mastersizer 2000 and initiated by adding 0.5 mL starch suspension to sample handling unit (Hydro 2000SA, Malvern Istruments, Malvern, England) held under constant mixing (pump speed 1700 rpm). During sample addition, laser obscuration was maintained between 12% and 14%, and readings were obtained using refractive indices of 1.31 for water and 1.52 as standard. A measurement time of 12 s with 12 000 measurement snaps was used for data analysis with measuring range from 0.02 to 96.86 μm. Grains from two biological replicates for each genotype were used for starch granule preparations. From each starch sample two aliquots were separately analyzed twice, and the average of the two measurements was used for statistical analysis. Volume based calculations were derived from Mie theory as described.[30]

Total Starch Concentration. Barley grain (10 g) samples were finely ground in a UDY mill (UDY Corporation, Fort Collins, CO) to pass through a 0.5 mm sieve. Total starch concentration in the meal was determined by an enzymatic hydrolysis method[31] using a commercial kit (Megazyme International Ireland, Wicklow, Ireland). In this method, 100 mg of meal was digested for 8 min in boiling water bath with 300 U α-amylase in 3 mL of 50 mM 3-(*N*-morpholino) propanesulfonic acid (MOPS) pH 7.0 buffer followed by addition of 4.0 mL of 200 mM sodium acetate buffer pH 4.5 and 20 U amyloglucosidase followed by incubation for an additional 30 min at 50 °C. Released glucose was determined using glucose oxidase/peroxidase assay by measuring absorbance at 510 nm. Starch concentration was calculated as described.[32]

Determination of Amylose Concentration. Samples of extracted starch (10 mg) were suspended in 10 mL of water, gelatinized for 5 min by boiling followed by debranching using *Pseudomonas* sp. isoamylase (Megazyme) as described.[33] Thereafter, long (amylose) and short (amylopectin) glucan chains in 1 mg of debranched starch

[a]Italicized values are lower than 70%. [b]Low B-type granule content subject to environmental influences. [c]Stable low B-type granule content in multiple environments.

were separated by high performance size exclusion chromatography (HPSEC) employing a Waters HPLC system (Waters Corporation, Milford, MA) equipped with a Phenogel 5 μm guard column (30 mm × 4.6 mm) attached to Phenogel 300 mm × 4.6 mm i.d. column (Phenomenex, Torrance, CA) and a refractive index detector. Debranched waxy barley starch was used as amylopectin standard in the analysis.

Statistical Analysis. The analysis of variance (ANOVA) of the means and Pearson's correlation was performed with SPSS multivariate analysis (SPSS Inc. version 17). Multiple means comparisons were determined with the Duncan's multiple range test at $p < 0.05$ confidence level.[34]

RESULTS

Screening of Barley Genotypes for Altered Starch Granule Size Distribution. All starch samples prepared from 139 barley genotypes showed bimodal distribution when analyzed by light microscopy of starch granule sizes (Table 1). The average diameter for A-type starch granules among the genotypes was 19.3 (16.51−22.23) μm. The number of B-type small starch granules (≥10.0 μm in diameter) in the samples was on average 84.6% (53.4−95.9%), and their diameters were on average 5.43 (4.72−6.20) μm (Table 1). Five genotypes (Etu, Heartland, Kinai-Kyoshinkai 2 (KK-2), Mensury, and Oac21) showed B-type starch granule number that were unusually low (<70.0%; Table 1). Since reduced number of small starch granules could be caused by environmental conditions, the five genotypes were selected for additional studies. Repeated trials

with the genotypes grown under greenhouse conditions consistently confirmed reduced small granules content for genotype KK-2, but not for the remaining four genotypes, which were excluded from further analysis.

KK-2 Barley Produces Starch with Reduced Number of Small Starch Granules. To test if the starch phenotype observed for genotype KK-2 grown under green house could be repeated in the field, the genotype was grown at three different locations in Saskatoon, Canada. Included in the trial were also the Canadian cultivars CDC Battleford, CDC Dolly, and Harrington, which all produce normal starch. A microscopic image analysis of starch prepared from the three normal starch genotypes showed an average number of B-type starch granules ranging from 77.5% to 90.6%. In contrast, KK-2 produced a significantly ($p < 0.01$) lower number of small starch granules (60.2−67.5%) at all three locations (Table 2, Supporting Information Figure 1). Thus, the low number of B-type starch granules seen for KK-2 was concluded to be relatively stable across different environments.

Table 2. Microscopic Analysis of Starch Granules of Field Grown Plants[a]

barley genotype	B-type starch granules at location			
	Kernen	Preston	seed farm	av
CDC Battleford	80.9	88.6	77.5	82.3 ± 8.6[b]
CDC Dolly	86.7	90.6	81.2	86.2 ± 6.2[b]
Harrington	78.8	82.3	84.4	81.8 ± 4.5[b]
Kinai Kyoshinkai-2 (KK-2)	60.2	67.5	65.3	64.3 ± 3.1[a]

[a]Values followed by same letter are not significantly different ($p < 0.05$).

The relative starch volume contributed by the different size classes of starch granules was determined using laser diffraction analysis, which in contrast to microscope image analysis is more efficient and reliable for screening a large number of genotypes. Similar to granule size distribution by microscope image analysis (Figure 1A), the laser diffraction analysis showed a bimodal distribution of starch granule volumes (Figure 1B). The starch granule volume distributions among the Canadian barley varieties showed similar profiles with a low point around 5−6 μm separating the very small C-type starch granule volume from the larger granule population. For KK-2, the starch granule profile showed a low point around 5 μm, an increased volume for starch granules with 5−15 μm diameter range, and reduced volume for A-type starch granules (Figure 1B). The starch granule volume distribution profile suggested the increase to the 5−15 μm granule fraction in KK-2 occurred at the expense of the largest A-type starch granules. On the basis of three classes, the ratio between A-type, B-type, and C-type volume percentages for KK-2 starch was 7.5:7.1:1, and the corresponding ratio for normal starch was 7.1:3.3:1 (CDC Kendall, Table 3).

Introgression of Altered Starch Granule Size Trait into a Canadian Cultivar. To introgress the reduced number of small starch granules in a Canadian malting barley genotype, KK-2 was crossed with spring-type malting barley cultivar CDC Kendall. The F_2 population of 112 lines showed variation for starch granule size with transgressive segregation seen at both ends of the starch granule size volume distribution (Figure 2A). There were 21 lines that showed higher A-type starch granule volumes than CDC Kendall and five lines that produced lower small starch granules volumes than KK-2 (Figure 2A). None of the lines in F_2 population showed significantly reduced large

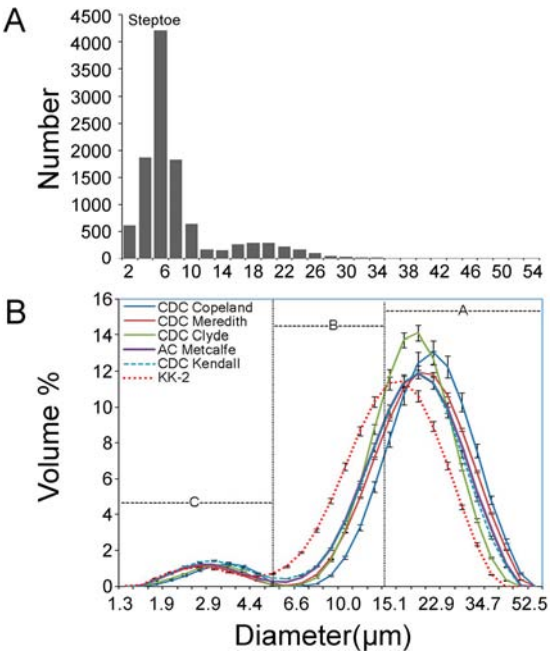

Figure 1. Starch analyses by microscope and laser diffraction particle sizing. (A) Distribution of starch granules in barley cv. Steptoe based on size and number as determined by microscope. (B) Distribution of starch granule volumes as determined by laser diffraction analyses. The granule volume profiles of five Canadian barley lines with normal granule sizes and Japanese barley line KK-2 are shown. Each data points represent mean of two replicates with SD.

A-type starch granule volume percentage than KK-2, and 80 lines produced significantly higher volume percentage of the medium size B-type starch granules than CDC-Kendall; thus, an overall increase in the average size of starch granule population was seen for the F_2 population. To study the inheritance of the starch phenotypes, the F_2 population was advanced to the F_5 generation for further starch analysis.

A total of 154 F_5 lines were selected for analysis of starch granule size distribution. As compared to the F_2 population, the F_5 lines showed on average a higher volume of A-type starch granules (54.3% versus 49.6%), similar volumes of B-type starch granules (38.1% versus 39.6%), and lower volume of C-type starch granules (7.6% versus 10.9%) (Figure 2). Five of the F_5 lines distinguished themselves as producers of 5−13% higher volume of A-type starch granules as compared to CDC Kendall (LSD = 2.74, $p < 0.05$), 24 lines showed lower C-type starch granules volume than KK-2 (LSD = 1.26, $p < 0.05$), and 10 lines had higher B-type (5−15 μm) starch granule volume than KK-2 (Figure 2B). Among the low C-type starch granule phenotype extremes were six lines with near zero concentration of C-type starch granules, and hence, a unimodal distribution curve for starch granule volume was observed for these lines (Figure 2). However, only three F_5 lines 116, 144, and 168 showed unimodal starch granule size distribution across several environments (Figure 3).

Reduction in C-Type Starch Granules Affects Grain Characteristics. The total starch concentration for barley F_5 lines 116, 144, and 168 with unimodal starch granule size ranged from 40.8% to 46.5% (Table 3) and were similar to KK-2 (48.5 ± 2.0%) but lower than normal barley starch (57.8 ± 5.0%). A normal amylose concentration was observed in starch extracted from lines 116, 144, 168 and both the parental genotypes (24−26.8%). Thousand grain weight (TGW) in the

[a]Determined by laser diffraction particle size. Values for starch granule volume are the mean of eight replicate samples for parental lines and four replicate samples for F_5 lines. TGW, % starch, and % amylose were determined from two replicate samples. Values followed by same letter are not significantly different ($p < 0.05$). [b]Concentration (%) in total starch. [c]F_5 lines with unimodal distribution. [d]Lines with increased A-type starch granule volume than CDC-Kendall.

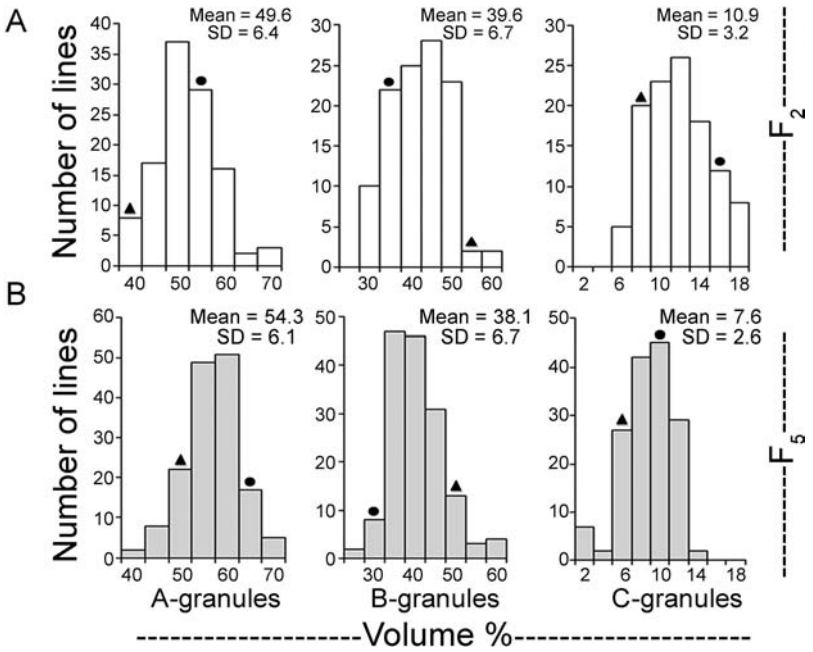

Figure 2. Distribution of starch granules volume fractions in F_2 and F_5 generation from a CDC Kendall × KK-2 cross. A total of 112 F_2 (A) and 154 F_5 (B) lines were analyzed. The volumes (%) of each granule fraction for KK-2 (▲) and CDC Kendall (●) are indicated.

three selected lines (21.4−27.8 g) was also significantly less compared to CDC Kendall (45.9 ± 0.6 g), but slightly higher than KK-2 (18.3 ± 0.1) (Table 3). Overall, the grain characteristics of barley lines with unimodal starch granule size distribution were more similar to KK-2 than CDC Kendall.

In contrast to F_5 lines 116, 144 and 168, lines 75 and 82 with larger A-type granule volumes produced grain with slightly higher TGW and total starch concentration than normal starch (Table 3). Starch granules in these lines showed granule volume distribution profiles similar to CDC Kendall. Amylose concentration in the selected F_5 lines and parent genotypes was not significantly different which indicates starch granule size distribution trait is independent of amylose concentration in CDC Kendall × KK-2 population. However, total starch concentration showed weak but significant ($r^2 = 0.226$, $p < 0.01$) interaction with amylose and thousand grain weight ($r^2 = 0.437$, $p < 0.01$) (Table 4).

Correlation among Granule Distribution Parameters. The distribution curve obtained from starch granule volume size distribution analysis obtained from Malvern mastersizer can also be analyzed by the values of d0.1, which infer 10% of volume distribution is below this value, d0.5, where 50% distribution is above and 50% below, and d0.9, where 90% of the volume distribution is below this value. The average value of d0.1 in CDC Kendall was 7.6 ± 0.2 and in KK-2 was 6.9 ± 0.5. Median value for diameter or d0.5 was 17.5 ± 0.7 in CDC Kendall and 14.8 ± 0.5 in KK-2. Maximum diameter occupied by only 10% of starch granule population shown as d0.9 was 29.9 ± 1.02 in CDC Kendall and 25.49 ± 0.99 in KK-2. Pearson two tail correlation analyses among starch granule population parameters revealed significant influence of A- and B-type starch granule volume on their ratio shown as A/B ($r^2 = 0.9$, $p < 0.01$). Small size C-type starch granules volume (%) affect distribution by significantly affecting d0.1 ($r^2 = 0.8$, $p < 0.01$) and having a minor impact on A/B %

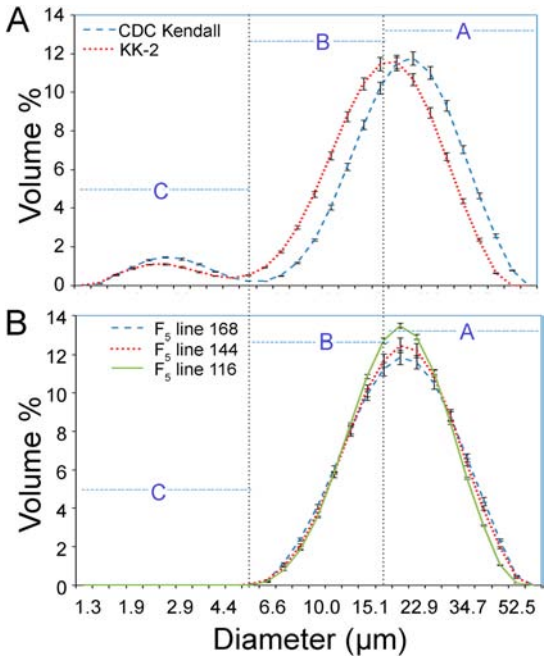

Figure 3. Unimodal starch granule size distribution in CDC Kendall × KK-2 progeny. (A) Starch granule volume distribution in parental lines and (B) three F_5 breeding lines as determined by laser diffraction particle analysis. Each data point represents a mean of three replicates with SD.

($r^2 = 0.14$, $p < 0.05$). A- and B- type starch granules volume (%) significantly ($p < 0.01$) affected d0.5 and d0.9 (Table 4). Among all parameters under study, d0.9 has strongest influence on A/B%. (Table 4). Grain filling represented as TGW is significantly ($r^2 = 0.241$, $p < 0.01$) affected by C-type starch granules volume (Table 4).

DISCUSSION

The analysis presented in this study supports division of barley grain starch granules into three types: large lenticular A-type (>15 μm), small oval B-type (5−15 μm), and very small irregularly shaped C-type (<5 μm) granules. Similar allocation of granule types is present in wheat endosperm starch.[7,8,13] In normal barley starch, the volume distribution of the three types is approximately 7:3:1, but the relative ratios can be genetically altered as shown in this study. The apparent discrepancy between Malvern mastersizer laser light scattering and microscopy analysis (shifting of peak split) could be due to differences in shape based calculation differences. The microscope image analysis observes surface view; hence, there is only one dimension. Mastersizer 2000 used in this study calculates volume distribution based on Mie theory which assumes particles to be spherical and is more realistic than the Fraunhofer approximation used in other laser light scattering based instruments.[30] In microscope image analysis, volume is calculated on the basis of the shape observed for a particle to give more accurate data, but it is based on a very small fraction of starch granule population. It is also very tedious and resource demanding to screen a large number of genotypes or breeding lines.

Initial microscopic screening of 139 barley starches suggested 10 of the 139 genotypes which produced starch with reduced number (<70%) of small starch granules (Table 1). However, repeated studies of these lines confirmed reduced number of small starch granules only in genotype KK-2. This inconsistency in starch granule size for the nine lines was likely caused by environmental effects on starch traits in one experiment. As observed earlier, the heritability for starch granule traits is low to intermediate on single plot basis, but more accurate data can be obtained if starch traits are analyzed over multiple environments.[35]

Various environmental effects on starch deposition and composition are known for wheat[36] and often affect the ratio between A-type and B-type starch granules size, A-type starch granule surface area, granule volumes, and contribution to total starch.[35] Growth conditions affecting wheat grain starch concentration are often related to stresses such as high temperature or drought.[36,37] Heat-sensitive wheat cultivars are known to produce 18−23% fewer B-type starch granules as compared to heat-tolerant wheat cultivars.[38] Similarly, the drought sensitive wheat cultivar Cappelle Desprez accumulates fewer small B-type starch granules when compared to drought tolerant cultivar Plainsman V.[37] Heat stress reduces starch accumulation in barley grain and results in a reduction in number of starch granules, but not granule size.[39] As the A-type, B-type, and C-type starch granules populations are initiated at different time points during grain development, a sudden stress during the later stages of grain filling has a larger effect on the number of small starch granules than large starch granules and may lead to abnormal ratios between large and small starch granules. These indirect effects of environment might be responsible for the inconsistency of starch granule size distribution phenotype of some of the barley genotypes initially selected in this study (Table 1).

[a]Data analyzed was derived from 154 F_5 derived lines from CDC Kendall × KK-2 cross. The analyses of A (>15 μm), B (5−15 μm), C (<5 μm) granules volume %, total starch, amylose %, and thousand grain weight (TGW) were determined on duplicate samples. [b]Correlation is significant at $p < 0.05$ level (2-tailed). [c]Correlation is significant at $p < 0.01$ (2-tailed).

Analysis of progeny derived from the cross between KK-2 × CDC Kendall cross showed a large diversity in starch granule size distribution. Indeed, starch granule size phenotypes not seen in the parental genotypes were obtained by the three F_5 lines lacking C-type starch granules. These lines showed more extreme skewing of C-type and A-type starch granule fractions toward the 5−15 μm starch granules population than the parent KK-2, thus giving a near unimodal starch granule size distribution (Table 3, Figure 3). The study suggests KK-2 carries more than one gene affecting primarily the production of C-type starch granules, where a certain gene combination led to lines producing unimodal starch granule size. However, the correlation analysis in this study indicated A/B-type granule volume ratio is not much influenced (r^2 = 0.14, $p < 0.05$) by C-type starch granules volume % (Table 4). Therefore, other combinations of KK-2-derived genes likely caused the higher A-type starch granule size volume observed in five F_5 lines (Table 3). Genetic mapping studies of starch granule size and volume traits in barley have identified quantitative trait loci (QTL) on chromosomes 2H, 4H, and 5H,[20] but the underlying genes are unknown. In wheat, a QTL on chromosome 4B affects the ratio of A- and B-type starch granules[40] and another QTL on 4DS affects starch granule size.[41] In the wild wheat *Aegilops*, a QTL for small starch granules has been identified on chromosome 4S, and the locus is postulated to stimulate starch granule initiation.[42] Whether any of the barley lines developed in this study carry genes corresponding to identified QTLs in wheat or barley needs to be investigated.

The barley lines with unimodal starch granule size distribution showed reduced grain weight and starch concentration as compared to CDC Kendall (Table 3); hence, they are not optimal for production of malting barley grain. However, lines with increased A-type starch granule volumes did not indicate any effect on TGW or starch production and may be better suited for development of improved malting varieties. The F_5 barley lines with variant starch granule size distribution characterized in this study will be valuable to study the relationships between grain yield, starch concentration, and starch granule size distribution. The characterized barley lines will also be valuable to understand the genetics of starch granule size initiation and growth in barley and other triticeae members. It will also enable researchers to alter starch granule size distribution in triticeae cereal members to meet the specific needs of industries.

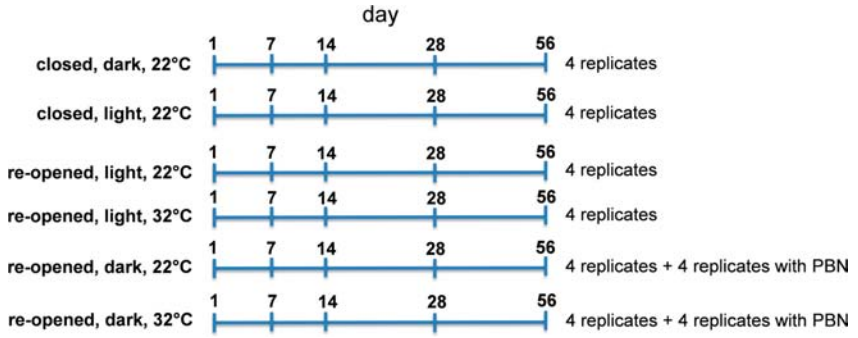

Figure 1. Study design. Soybean oil was stored under different conditions for 56 days. Samples for analyses were drawn on days 1, 7, 14, 28, and 56. Four replicates were performed for each sampling time and condition. For measurement of lipid radicals, four separate replicates were incubated with 20 mM PBN on day 1.

surface of the oil, the degree of saturation of the oil, and the presence of antioxidants, metals, and enzymes have been identified to influence the process of lipid oxidation in vegetable oils.[4,5,11,12] The environmental factors, temperature, light, and oxygen, have also been demonstrated to play a pivotal role in the deterioration of edible oils.[12−14] However, the individual contribution of each environmental factor, under mimicked household conditions, to the oxidative status of soybean oil, one of the most commonly used vegetable oils to supply developing countries with vitamin A,[15] has not been demonstrated so far. The aim of the current study was to identify the major inducer of lipid oxidation in soybean oil stored at household conditions with regard to the oxygen volume, storage temperature, and cold fluorescent light. In addition, several lipid oxidation products were analyzed to identify the most reliable method for assessing the oil quality under retail and household storage conditions.

MATERIALS AND METHODS

Chemicals. Hexanal-d_{12} (98.5 atom % D) was purchased from C/D/N Isotopes Inc., Quebec, Canada. α-Phenyl-*tert*-butylnitrone (PBN) was obtained from Enzo Life Sciences. All-Rac-Tocol was delivered by Matreya LLC, Pleasant Gap, PA, USA. All other chemicals were ordered from Sigma-Aldrich Austria or Carl Roth Germany.

Oil Samples and Study Design. The refined soybean oil was purchased from Henry Lamotte Oils GmbH (Bremen, Germany). Soybean oil was delivered in dark containers and was subjected to peroxide value (POV) analyses, which revealed a mean content of POV of 1.43 ± 0.24 meq O_2/kg. Aliquots of 460 ± 0.1 g were transferred upon arrival into 0.5 L transparent PET bottles, which were kindly provided by Rauch Fruchtsäfte GmbH (Rankweil, Austria). The oil-containing bottles were closed and stored under different conditions for 56 days (Figure 1). To study the individual effects of temperature and cold fluorescent light on the oxidative status of the oil, the bottles were shortly reopened for sampling after 7, 14, 28, and 56 days and were stored in the dark or exposed to cold fluorescent light in a cycle of 12 h light, alternating with 12 h darkness, at 22 ± 1 °C or 32 ± 1 °C. For each oil sample stored under a certain condition, 20 oil-containing bottles were needed to draw samples from four replicates on day 1, 7, 14, 28, and 56. As the light source, lamps (Philips Tornado cool daylight, 1450 lm corresponding to a 103-W incandescent light bulb, Philips, Eindhoven, The Netherlands) were used. These lamps emit cold fluorescent light designed to mimic the 5000 K blackbody spectrum of natural daylight. The distance between the light source and the head of the bottle was set up to be 34 cm, while the distance between the bottles was 15 cm. To study the effect of oxygen on the lipid oxidation of the oil, the bottles, which were kept in the dark at 22 ± 1 °C, remained closed or were shortly reopened for sampling after above-mentioned days. Before sampling, the bottles were mixed to exclude inhomogeneity. The samples were frozen at −80 °C until analyses. To detect the free lipid radicals by electron spin resonance (ESR) spectroscopy, four additional bottles were required due to the inhibiting effect of the spin trap PBN on the lipid oxidation.[16] On day one, PBN was added at a concentration of 20 mM. Bottles were stored in the dark and reopened as described above.

Calculation of Oxygen Volume in Headspace. The headspace of the bottles at the beginning of the study was calculated by the difference of the total volume of the bottle and the sample volume of 460 ± 0.1 g of soybean oil. After each withdrawal of sample, the headspace increased accordingly. As the surrounding air consists of approximately 21% O_2, the amount of O_2 in the headspace was calculated for each sampling day (Table 1).

Table 1. Calculated Oxygen Volume [mL] and Amount [mmol] in the Headspace of PET Bottles after Sampling on Specific Days

sampling day	calculated oxygen volume in headspace [mL]	calculated oxygen amount in headspace at 300 K [mmol]	headspace volume [mL]
0	14.0	0.57	67.0
1	24.8	1.01	118
7	33.7	1.37	161
14	42.6	1.73	203
21	50.3	2.04	240
28	59.2	2.40	283

Quantification of Fatty Acid Composition by GC/FID. The fatty acid composition was quantified according to Lall et al.[17] Briefly, 500 μL of heptadecanoic acid methyl ester (1%) was added as an internal standard to 100 mg oil sample. The mixture was dissolved in 2 mL of toluene. Afterward, a total of 100 mg of pyrogallol was added to protect from oxidative deterioration. To achieve derivatization of fatty acids, 4 mL of sodium methoxide in methanol (0.5 M) was added to the reaction mixture. The mixture was purged with nitrogen for 2 min and heated up to 50 °C for 10 min. After the mixture was cooled down to room temperature, 200 μL of glacial acetic acid, 5 mL of double distilled water, and 5 mL of *n*-hexane were added for extraction. The hexane extracts were dried with Na_2SO_4 and filtrated (0.45 μm) prior to GC/FID analyses. Fatty acid methyl esters (FAMEs) were separated on a ZB-WAX Zebron capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Phenomenex, Aschaffenburg, Germany) using the Shimadzu GC-2010 Plus (Shimadzu, Vienna, Austria) which was equipped with a flame ionization detector (FID). The hexane extracts were injected (1 μL) with a split ratio of 1:20 at 220 °C. Helium was used as a carrier gas with a column flow rate of 3 mL/min. The FID detector needed synthetic air and nitrogen as makeup gas with a flow of 30 mL/min, hydrogen gas with a flow of 40 mL/min, and synthetic air with a flow of 400 mL/min. FAMEs were separated using a temperature gradient starting at 60 °C for 2 min. The temperature was increased at 13 °C/min to 150 °C and then at 2

°C/min to finally yield 240 °C. The fatty acid composition of the study oil under different storage conditions was quantified by external calibration. The recovery was determined to be 115 ± 7.23%. Table 2 depicts the LOD and LOQ of the respective FAMEs.

Table 2. Limit of Detection and Limit of Quantification of Fatty Acid Methyl Esters

FAME	LOD [μg/mL]	LOQ [μg/mL]
methyl palmitate (C16:0)	34.8 ± 0.05	123 ± 0.18
methyl stearate (C18:0)	38.2 ± 0.04	130 ± 0.15
methyl oleate (C18:1)	36.8 ± 0.29	120 ± 0.15
methyl linoleate (C18:2)	36.4 ± 0.05	127 ± 0.18
methyl linolenate (C18:3)	39.2 ± 0.05	127 ± 0.15
methyl arachidate (C20:0)	59.4 ± 0.09	190 ± 0.28

Analyses of Fatty Acid Composition by NMR. ^{1}H NMR spectra were recorded with a Bruker Avance III 500 MHz instrument at 500.32 MHz at ambient temperature. The oil samples (0.2 g) were dissolved in deuterated chloroform. Spectra were acquired from oil samples on day 1 and after storage of 56 days under different conditions. The number of protons was determined by integration of the signals. The aliphatic-to-olefinic ratio was calculated by assigning the signals as described earlier.[18]

Soybean oil: δ (ppm) 0.87 [m, 3 H, CH], 0.96 [t, 3 H, CH], 1.27 [m, 2 H, CH], 1.60 [m, 2 H, CH], 2.02 [m, 2 H, CH], 2.29 [m, 2 H, CH], 2.77 [m, 2 H, CH], 4.13 [dd, 2 H, CH], 4.29 [dd, 2 H, CH], 5.25 [m, 1 H, CH], 5.34 [m, 1 H, CH].

UV-Spectrometric Analyses of Conjugated Dienes. The measurement of conjugated dienes was performed as described previously.[19] Briefly, 0.01 g of oil was dissolved in isooctane, and the UV-absorbance was detected at 233 nm. The concentration of conjugated dienes in oil sample was calculated using the absorption coefficient of linoleic acid hydroperoxide (2.525×10^4 M^{-1} cm^{-1}).

Determination of the Peroxide Value. The POV was determined according to AOCS official method Cd 8-53.[20] Briefly, samples of 5.0 g of soybean oil were dissolved in a mixture of 30 mL of glacial acetic acid and chloroform (3:2, v/v). A total of 0.5 mL of a saturated potassium iodide was added to the oil solution and vortexed for 1 min. After addition of 30 mL of distilled water, iodine was reduced by 0.1 N sodium thiosulfate, and few drops of a starch solution were used to indicate the end point of the titration. The peroxide value was calculated using the following equation:

$$\mathrm{POV\ (meq/kg)} = ((\mathrm{Va} - \mathrm{Vb})N \times 1000)/W$$

where Va is the volume (mL) of sodium thiosulfate needed for the reduction of iodine in the oil sample, Vb is the volume (mL) of sodium thiosulfate needed for the reduction of potential iodine in the blank sample, N is the normality of the sodium thiosulfate solution, and W is the weight of the oil sample (g). The POV was expressed as percent value, setting the results of the first day to zero.

ESR Measurements of Lipid Radicals. Oil samples (500 μL) were thawed and transferred into ESR flat cell (ER 160 FC-Q). The ESR flat cell was positioned in a rectangular TE102 microwave cavity to acquire ESR spectra at room temperature by means of a Bruker ESP300 operating at 9 GHz with 100 kHz modulation frequency. Spectra were recorded every 84 s, averaging every 5 consecutive spectra. ESR measurements were performed by applying the following settings: center field, 3490.6 G; sweep width, 70 G; sweep time, 83.9 s; modulation amplitude, 1.32 G; microwave power, 20 mW; conversion time, 81.9 ms; time constant, 81.9 ms; resolution 1024 points. The receiver gain was adjusted for each sample and considered in the calculations. The first derivative of the microwave absorption was double-integrated to calculate the area under the curve. ESR spectra were simulated to obtain the hyperfine coupling constants with the public EPR software tools from the National Institute of Environmental Health Sciences. The hyperfine coupling constants were calculated to be 14.81 and 2.00 G, which are characteristic for the coupling of the free electron with adjacent nitrogen and hydrogen nucleus. However, due to line broadening effects of the viscous oil samples, the hydrogen splitting could not be observed, resulting in a triplet rather than the expected triplet of doublets. The spin trap, PBN, was chosen to predominantly detect carbon-centered radicals.[16]

HS-GC/MS Analyses of Hexanal. The sample preparation was performed with slight modifications according to Giuffrida et al.[21] Headspace vials (20 mL) for Combi Pal were filled with 2.5 g of sample oil and 2.72 mL of water/methanol (3:1). The sample mixture was spiked with 4 μg/mL hexanal-d_{12}. The headspace vials were sealed with magnetic screw caps silicone/PTFE (La-Pha-Pack, Langerwehe, Germany) and preheated at 70 °C with an agitator speed set to 750 rpm for 15 min on a CTC Combi Pal (CTC Analytics AG, Zwingen, Switzerland). After incubation, 1000 μL of headspace was injected by a 90 °C preheated gastight syringe on a ZB-Wax Zebron capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness) using a split ratio of 1:5 at 250 °C. GC/MS analysis was performed on a Shimadzu GCMS-QP 2010 Ultra (Shimadzu, Vienna, Austria) using helium as a carrier gas at a column flow rate of 1.31 mL/min. The initial oven temperature of 35 °C was held for 2 min before it was increased at a rate of 15 °C/min to 65 °C. Then, the oven was heated up to 80 °C at 2 °C/min and finally yielded 230 °C at a rate of 30 °C/min to hold the temperature for 5 min. The temperature of the ion source was set to 200 °C, and the acquisition parameters applied were full scan mode, scan range 40−600 m/z, scan speed 3333 u/s, SIM mode for 56 m/z and 72 m/z (specific for hexanal) and 64 m/z and 80 m/z (specific for hexanal-d_{12}). Labeled and unlabeled hexanal were identified by comparing the mass spectra with the NIST 11 mass spectral library and retention times with reference standards. Hexanal-d_{12} eluted at 5.13 min, whereas hexanal eluted at 5.21 min. Stable isotope dilution analysis was performed using the fragment ions 80 m/z (hexanal-d_{12}) and 72 m/z (hexanal), as described recently.[22] The response factor was calculated to be 1.09 ± 0.08. The LOD and LOQ of hexanal were determined to be 0.03 ± 0.02 μg/mL and 0.10 ± 0.00 μg/mL, respectively.

Quantification of Tocopherols. The analyses of tocopherols in soybean oil samples were performed with slight modifications according to Gliszczynska-Swiglo and Sikorska.[23] A total of 0.05 g of soybean oil was dissolved in 1 mL of 2-propanol, and 5 μg/mL tocol was added as internal standard. After syringe filtration with a nylon filter (0.2 μm), 5 μL was injected into a Dionex Ultimate 3000 LC system (Thermo Fisher Scientific, Vienna, Austria) equipped with a diode array detector. UV chromatograms were recorded at 295 nm. The tocopherols were separated at 25 °C on a PFP Kinetex C18 column (100 × 2.10 mm, 1.7 μm, Phenomenex, Aschaffenburg, Germany) with a flow rate of 0.5 mL/min. The mobile phase consisted of bidestilled water and methanol and with an initial ratio of 25:75 (v/v) which increased to 100% methanol within 10 min. α-, β-, γ-, and δ-Tocopherols were eluted at 6.71, 6.10, 6.24, and 5.59 min, respectively. Total tocopherols were calculated by the sum of tocopherol isomers. Each tocopherol isomer was quantified by external calibration. The recovery of total tocopherols was 94 ± 12.1%. The LOD for α-tocopherol, γ-tocopherol, and δ-tocopherol was 0.24 ± 0.02 μg/mL, 0.04 ± 0.01 μg/mL, and 0.02 ± 0.01 μg/mL, respectively.

Statistical Data Assessment. Statistical analyses were conducted with SigmaPlot 11 (Systat software Inc., Chicago, Illinois). All experiments consisted of four bottles and two technical replicates. All data were subjected to the Nalimov outlier test and are presented as mean ± standard deviation. Normal distribution of the data was assessed by the Shapiro-Wilk test. ANOVA was performed to analyze statistically significant differences ($p < 0.05$) between day 1 and the other sampling days. The Dunnett's post hoc test and in case of heterogeneity of variance the Dunn's post hoc test were applied to identify the differences, which are indicated with an asterisk in the graphs. To analyze statistically significant differences between oils stored under different conditions, the area under the curve (AUC) was determined after data were normalized by the value obtained on day 1. Statistical significant differences ($p < 0.05$) between the AUCs were calculated by means of the Student's t test. In the case of heterogeneity of variance, the Mann−Whitney−Wilcoxon test was applied.

Correlation coefficients were determined to detect relationships between two variables ($p < 0.05$). The Pearson product-moment correlation coefficient was calculated for normally distributed data, whereas the Spearman's rank correlation coefficient was calculated if the data did not show a normal distribution.

RESULTS AND DISCUSSION

The purpose of the current study was to study the oxidative stability of soybean oil stored in transparent PET bottles under household conditions. Soybean oil, which belongs to the four most commonly consumed vegetable oils worldwide, with a production of 35.7 million tonnes in the year 2008/09,[24] is usually sold and stored in transparent PET bottles at ambient temperatures of 22−32 °C. Withdrawal of oil by the consumer leads to an increased headspace and oxygen availability. We aimed to identify the contribution of each of these environmental factors, such as oxygen, temperature, and cold fluorescent light under household conditions on the oxidative status in refined soybean oil. Although literature data demonstrate that each of these environmental factors is attributed to the promotion of oxidative deterioration in vegetable oils,[12−14] it has not been demonstrated so far which of these environmental factors chiefly contributes to lipid oxidation in refined soybean oil stored at household conditions.

Effects of Increasing Headspace Volume at Atmospheric Pressure on the Formation of Hydroperoxides in Soybean Oil. To study the impact of oxygen on the deterioration of soybean oil, we determined the POV in oil stored under constant and increasing oxygen volume at 22 °C and atmospheric pressure for one month. To mimic consumer handling of the oil bottles, the closed PET bottles filled with soybean oil were shortly reopened for sample drawings. The short reopening and sampling resulted in an increased headspace volume and supply with atmospheric oxygen (Table 1). As expected, increasing oxygen volume caused a rise of the POV by 91.0 ± 1.09%, whereas constant oxygen volume led only to an increase of the POV by 46.6 ± 4.65% (Table 3). Thus, the increasing headspace volume at atmospheric pressure had a significant impact on the oxidative stability of soybean oil. However, the air-exposed area-to-mass ratios have also been shown to play an essential role in lipid oxidation of olive oil.[25] When different masses of olive oil were stored in brown glass vials with 20 mm i.d. at 38 °C in the dark in the presence of air-derived oxygen, a high area-to-mass ratio with 1.25, 2.5, and 3.5 g olive oil resulted in a POV of at least 50 meq O_2/kg after 700 h of storage, whereas a low area-to-mass ratio with 7 g olive oil did not lead to a POV of greater than 30 meq O_2/kg after 1400 h of storage. The results of the current study are also in accordance with findings reported by Chung et al.,[13] showing that 5 g of soybean oil exposed to light at 55 °C for 24 h absorbed 54.6 μmol of oxygen.[13] We, therefore, conclude that enhancing the headspace oxygen volume by reopening the bottles, as a common household practice, promotes oxidative rancidity of the oil. The impact of increasing headspace oxygen introduced by intermittent bottle-opening was obvious after 28 days of storage, as demonstrated by an accelerated POV increase compared to nonopened bottles. Consecutive experiments included the more severe condition of intermittent bottle openings for 56 days, which is also of greater practical relevance for consumer handling.

Table 3. Increase of POV [%] in Soybean Oil Stored in Permanently Closed Bottles under Constant O_2 Volume or in Reopened Bottles under Increasing O_2 Volume at 22°C for 28 Days[a]

	increase of POV [%]	
time [days]	constant O_2 volume (permanently closed)	increasing O_2 volume in headspace (reopened)
1	0	0
7	36.6 ± 13.0[a]	50.1 ± 16.5[a]
14	29.0 ± 6.35[a]	63.3 ± 1.20[b]
28	46.6 ± 4.65[a]	91.0 ± 1.09[b]

[a]Data are expressed as mean ± SD ($n = 4$). All POVs were normalized to the POV on day 1. Different letters in a row indicate statistically significant difference between the POV in oil stored under constant and variable O_2 volume, as calculated by the Student's t test.

Effects of Temperature and Cold Fluorescent Light on the Formation of Primary and Secondary Lipid Oxidation Products in Soybean Oil. For studying the effect of temperature on the lipid oxidation, a storage temperature of 22 and 32 °C was chosen to imitate widely common room temperatures. To investigate the influence of cold fluorescent light, bulbs were chosen that emit electromagnetic irradiation in the cold fluorescent range thereby mimicking the storage condition in a typical household.

Autoxidation of vegetable oils rich in polyunsaturated fatty acids is known to lead to the formation of conjugated dienes, which strongly absorb UV irradiation at around 233 nm.[26] In this study, the closed PET bottles, which were filled with soybean oil and stored in the dark or exposed to cold fluorescent light, were reopened for sampling throughout the study at 22 and 32 °C. Figure 2A shows that the formation of conjugated dienes on day 1 and 56 remained unchanged in the study oil stored in the dark, independent of the storage temperature. The minimal decrease in the formation of conjugated dienes on day 7 and 14 might be explained by a higher decomposition than production rate of conjugated dienes. By exposing the soybean oil to cold fluorescent light for 56 days, the concentration of conjugated dienes increased from 19.5 ± 3.50 μM to 26.2 ± 0.15 μM, and to 29.0 ± 1.14 μM at 22 and 32 °C, respectively (Figure 2B). In the presence of cold fluorescent light, a statistically significant difference could be observed between the oils stored at the two distinct temperatures with regard to the content of conjugated dienes. At these household-mimicking conditions, cold fluorescent light was demonstrated to play a pivotal role in the oxidation of soybean oil in the presence of air-derived oxygen at atmospheric pressure, whereas temperature in the range of 22 and 32 °C did not influence the oxidation process in the absence of cold fluorescent light. Thus, the rate of photo-oxidation dominates the rate of autoxidation at household conditions. The light-induced lipid oxidation might be promoted by photosensitizers, such as chlorophylls. Natural pigments were demonstrated to be responsible for photo-oxidative deterioration of extra virgin olive oil stored at 27 ± 1 °C in the presence of cold fluorescent light for up to 72 h.[27] A POV of 153 meq/kg was obtained after a 36 h storage of extra virgin olive oil, while a POV of less than 13 meq/kg was measured after 72 h of storage, when chlorophyll and other minor components had been removed during the stripping process. Khatoon and Krishna[28] reported elevated concentrations of conjugated dienes in refined safflower oil which was subjected to static heating at 180 °C for 8 h in an open pan. Because of the high temperature and surface area, the

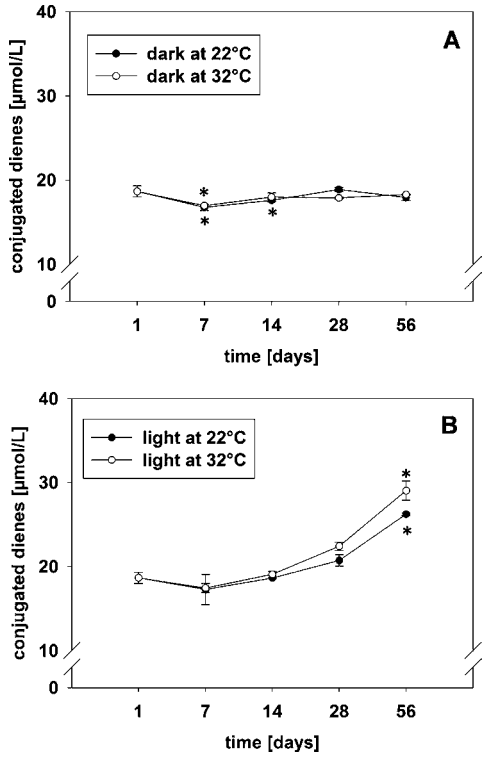

Figure 2. Changes of the formation of conjugated dienes in soybean oil stored in the absence (A) or in the presence of cold fluorescent light (B) at 22 or 32 °C in reopened bottles during storage for 56 days. Data are expressed as mean ± SD (n = 4). The concentrations of conjugated dienes on days 7, 14, 28, and 56 were normalized to the concentration of conjugated dienes on day 1. Asterisks indicate statistically significant differences compared to day 1 ($p < 0.05$).

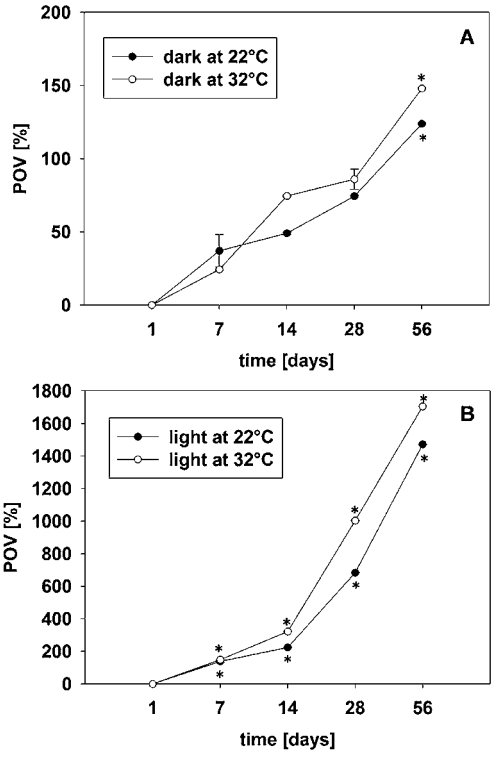

Figure 3. Changes of POVs in soybean oil stored in the absence (A) or in the presence of cold fluorescent light (B) at 22 or 32 °C in reopened bottles during storage for 56 days. Data are expressed as mean ± SD (n = 4). POVs were normalized to the individual POV on day 1. Asterisks indicate statistically significant differences compared to day 1 ($p < 0.05$).

concentrations of conjugated dienes were increased from approximately 0.5 g/L to 4.1 g/L. However, studies that investigate the effects of temperature and light at household conditions on the generation of conjugated dienes are lacking.

Because of the suitability of the POV and its wide acceptance,[26] we also analyzed the amount of peroxides formed during storage of soybean oil in reopened PET bottles at the two distinct temperatures in the presence or absence of cold fluorescent light to mimic household conditions. As expected, the POV in the soybean oil was enhanced after storage for 56 days, independent of light exposure and the temperature applied (Figure 3). Because the POV results indicated a significant increase of the lipid oxidation in oils stored in the dark, which was not demonstrated by quantitative data for conjugated dienes, the suitability of the POV analyses for assessing the early stages of lipid oxidation in vegetable oils can be confirmed. Similar to the results obtained for concentrations of conjugated dienes, exposure of the oil to cold fluorescent light had a pronounced impact on the POV. While the POV in the oil stored in the dark for 56 days increased by 124 ± 0.62% and 148 ± 0.70% at 22 and 32 °C, respectively, the POV in the oil exposed to cold fluorescent light rose by 1473 ± 1.79% and 1706 ± 0.79%, respectively. A similar effect of light on the POV in soybean oil stored in open glass bottles at 30 °C for 30 days was demonstrated by Naz et al.[29] In their study, the POV in soybean oil stored in the dark was significantly ($p < 0.01$) lower than that of oil samples exposed to daylight. However, open glass bottles filled with oil do not mimic typical household conditions. Chung et al.[13] could demonstrate a significant impact of light exposure of a 200-W tungsten lamp to soybean oil stored at 55 °C for 24 h in 45 mL serum bottles sealed with septa and caps, thereby also not mimicking household conditions. While the POV in the oil stored in the dark only reached 1.80 meq O_2/kg, the presence of light caused a marked increase of the POV to yield 12.4 meq O_2/kg. However, a traditional household incandescent light bulb is characterized by a consumption of 40−100 W, which has been considered in the current study.

Besides mimicking the household conditions by exposing oil to fluorescent light, the ambient temperatures of 22 and 32 °C were chosen to study the effects of household temperatures on the oxidative stability of soybean oil. No difference with regard to the POV was observed between the two distinct temperatures of 22 and 32 °C when the study oil was stored in the dark (Figure 3A). In contrast, a statistical significant difference was obtained when the oil was exposed to cold fluorescent light in a cycle of 12 h light alternating with 12 h darkness (Figure 3B). Abramovic and Abram[30] also investigated the effect of two different temperatures on the POV of camelina oil stored in glass bottles in the dark. It could be shown that the POV of the oil stored in the dark at room temperature for 30 days increased from 2.38 meq O_2/kg to 8.12 meq O_2/kg, while the POV of the oil stored in the dark at 8 °C for 30 days remained almost constant. As we could not determine any difference with regard to the concentration of conjugated dienes and the POV between the soybean oils stored in the dark at 22 and 32 °C, this prompted us to reinvestigate the oxidative stability of the soybean oil kept in dark at the two distinct temperatures by means of ESR, a method with higher sensitivity.[16]

dx.doi.org/10.1021/jf405736j | J. Agric. Food Chem. 2014, 62, 2297−2305

ESR is regarded as a more sensitive method to study early lipid oxidation reactions, since free radicals were detected in canola oil, sunflower oil, and fish oil stored at 40 °C in the dark in a desiccator with P_2O_5 before POV increased.[16] The current study investigated, for the first time, the effect of retail and household storage conditions of soybean oil in the dark at 22 and 32 °C on the formation of lipid radicals (Figure 4A). After storage for 28 days, the formation of lipid radicals was significantly increased at both temperatures. Albeit not detectable by iodometric measurements, applying ESR spectroscopy revealed a more pronounced increase of the formation of lipid radicals in the study oil stored in the dark at 32 °C than in the oil stored at 22 °C. Thus, ESR spin trapping technique proved to be a suitable method to detect early stages of lipid oxidation in vegetable oils. However, the signal intensity of the PBN adducts was shown to correlate well with the POV in soybean oil stored in the dark at 32 °C for 56 days with a correlation coefficient of 0.938 ($p < 0.05$) (Figure 4B), implying that ESR spectroscopy might be a reliable method to monitor the oxidative status in vegetable oils. Even a moderate increase of temperature from 22 to 32 °C induced the formation of lipid oxidation in soybean oil, independent of the exposure to light. However, if the impact of light on lipid oxidation is to be studied by ESR spectroscopy, a nonlight sensitive spin trap, such as 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), has to be used.

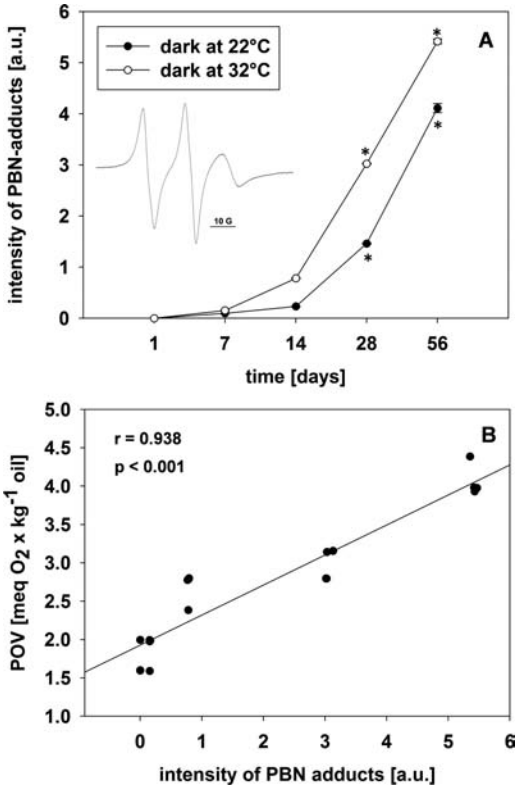

Figure 4. Changes of the formation of lipid radicals in soybean oil stored in the dark at 22 or 32 °C in reopened bottles during storage for 56 days (A). Correlation between POV and the intensity of the PBN adducts in soybean oil stored in the dark at 32 °C in reopened bottles for 56 days with a coefficient of 0.938, $p < 0.05$ (B). Data are expressed as mean ± SD ($n = 4$). All POV were normalized to the POV on day 1. Asterisks indicate statistically significant differences compared to day 1 ($p < 0.05$).

In this study, the effect of temperature and cold fluorescent light was also studied by quantifying the fatty acid composition of soybean oil stored in bottles with increasing headspace for 56 days. Although no significant changes of the fatty acid profile of the soybean oil were expected due to the moderate household storage and handling conditions, the fatty acid profile was analyzed to characterize the soybean oil. The predominant fatty acids in soybean oil, C16:0, C18:0, C18:1, C18:2, C18:3, and C20:0, were quantified on day 1 and 56 (Table 4). Linoleic acid was identified as the dominant fatty acid in soybean oil, reaching a concentration of 499 ± 29.6 mg/mL. The fatty acid profile obtained at day 1 was in accordance with results obtained by Ivanov et al.[31] However, our results did not indicate any significant changes of the fatty acid concentrations in soybean oil after storage for two months independent of the storage conditions chosen. Though a decrease of unsaturated fatty acids and a corresponding increase of saturated fatty acids might be conceivable in oil undergoing lipid oxidation, the degree of saturation remained unchanged. There is no comparable study that investigated the effects of light, temperature, and oxygen at household conditions on the fatty acid profile of soybean oil. Crapiste et al.[32] observed a marked decrease of unsaturated fatty acids in sunflower oil after storage for 55 days at a higher temperature of 67 °C. It could be shown that the oleic acid to linoleic acid ratio increased from 0.334 to 0.568 in pressed sunflower oil. However, the results presented here indicate that the fatty acid composition analyzed by GCMS might not be a reliable and sensitive method for assessing early stages of lipid oxidation of vegetable oils during household storage conditions.

Studying the changes in the proton absorption of the fatty acids in the differently stored soybean oil by NMR confirmed the GCMS results. The aliphatic-to-olefinic ratio of the oil was 10.6 ± 0.05 and 10.5 ± 0.06 on day 1 and 56, respectively, independent of the storage condition. There is no literature available showing the impact of temperature, light, and oxygen at household conditions on the aliphatic-to-olefinic ratio of

Table 4. Fatty Acid Composition in Soybean Oil Analyzed by GC/FID on Day 1 and 56 after Different Storage Conditions[a]

		dark at 22 °C		dark at 32 °C		light at 22 °C		light at 32 °C

vegetable oil. Wanasundara et al.[33] showed that the aliphatic-to-olefinic ratio of soybean oil stored at nonhousehold conditions in open flasks at high temperature of 65 °C in the dark increased from approximately 10 on day 1 to approximately 13 on day 30. NMR spectroscopy is commonly used to characterize the degree of saturation in oils treated at high temperatures.[18,34] However, the application of NMR to evaluate the oxidative status in vegetable oil stored under household conditions might not lead to noteworthy results.

Next to the primary reaction products of lipid oxidation, the decomposition products of fatty acid hydroperoxides are commonly used markers for assessing lipid oxidation in vegetable oils.[35] One of the most reliably used biomarkers for evaluating the oxidative status is hexanal. Hexanal is known to be a decomposition product from linoleic acid, which is the predominant fatty acid of soybean oil.[36] In the current study, we also determined the impact of temperature and light at household conditions on the formation of hexanal. As a result, hexanal concentration remained constant upon the storage conditions applied (Figure 5). This suggests a singlet oxygen-

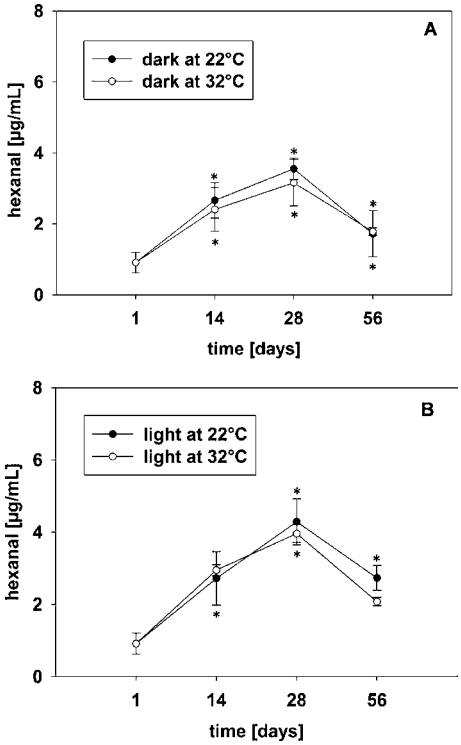

Figure 5. Changes of hexanal formation in soybean oil during storage for 56 days in reopened bottles in the absence (A) or presence (B) of cold fluorescent light at 22 and 32 °C. Data are expressed as mean ± SD (n = 4). Asterisks indicate statistically significant differences compared to day 1 (p < 0.05).

derived peroxidation of linoleic acid by a nonpropagating two-electron "ene" mechanism without the initiation of lipid peroxidation chain reactions.[37,38] Singlet oxygen has no impact on the stability of peroxides, whereas metals, which initiate radical chain reactions, lower the stability of peroxides.[5] However, there is a lack of studies investigating the effect of temperature and light at household conditions on the formation of hexanal in soybean oil. Sanches-Silva et al.[39] investigated the hexanal content in potato crisps stored in the dark and in the presence of natural light. It could be shown that the hexanal content did not change in potato crisps stored in the dark, whereas the storage in the presence of natural light led to an approximately 10-fold significant rise of the hexanal content. This high amount of hexanal might be explained by the frying conditions of the potato crisps in olive oil but also making the effect of light more prominent.

The peak concentration of hexanal analyzed on day 28 in the current study indicates higher decomposition rate than formation rate of hexanal, leading to a decrease of hexanal concentration after storage of the oil for 1 month accompanied by an increase of POVs.

Effects of Temperature and Cold Fluorescent Light on the Stability of Tocopherols in Soybean Oil. Tocopherols have been shown to exert antioxidative as well as pro-oxidative effects in different vegetable oils, by donating hydrogen to the lipid radical and by being converted to a more stabilized radical. The stabilized radical, if not regenerated by antioxidants, contributes to the propagation of lipid radicals.[40,41] Thus, the total tocopherol content of a vegetable oil is crucial for its oxidative stability. In the current study, soybean oil contained 489 ± 34.6 ppm total tocopherols, which is less than the tocopherol content of 1546 ppm found in refined soybean oil, as described elsewhere.[42] The lower amount of tocopherols detected in the beginning of the current study might be due to different processing steps during production of the soybean oil. Tocopherols also act as a marker for reflecting the oxidative deterioration of the oil. Many studies have shown an association between the decrease of the content of tocopherols of a vegetable oil and the progress of the lipid oxidation.[43−45] In this study, a decrease of all tocopherol isomers in oil stored for 56 days, independent of the storage conditions, was demonstrated (Table 5). The most pronounced loss of α-, β-,

Table 5. Percent Decrease of Tocopherol Isomers [%] in Soybean Oil Stored under Different Conditions for up to 56 Days[a]

			decrease [%]	
tocopherol isomer			day 28	day 56
α	dark	22 °C	34.3 ± 8.49[a]	48.9 ± 3.55*[a]
		32 °C	37.4 ± 0.67[a]	49.3 ± 0.33*[a]
	light	22 °C	39.6 ± 4.27[a]	58.0 ± 1.50*[b]
		32 °C	42.9 ± 4.52[a]	60.2 ± 2.40*[b]
γ	dark	22 °C	40.7 ± 2.71[a]	69.4 ± 2.10*[a]
		32 °C	40.2 ± 1.62[a]	62.1 ± 6.38*[a]
	light	22 °C	43.6 ± 14.4[a]	77.3 ± 3.52*[c]
		32 °C	41.2 ± 6.89[a]	85.4 ± 4.11*[d]
δ	dark	22 °C	−1.36 ± 12.7[a]	15.8 ± 6.85[abc]
		32 °C	1.55 ± 0.56*[a]	10.2 ± 0.91*[b]
	light	22 °C	8.50 ± 10.1[a]	23.4 ± 0.67*[abc]
		32 °C	7.51 ± 8.11[a]	24.6 ± 0.82*[c]

[a]Data are expressed as mean ± SD (n = 4). Distinct letters indicate statistically significant difference within the same column and isomeric compound (p < 0.05). The asterisk indicates statistically significant difference with regard to day 1 (p < 0.05).

and γ-tocopherol by 60.2 ± 2.40%, 85.4 ± 4.11%, and 24.6 ± 0.82%, respectively, was obtained in oil samples exposed to light and stored at 32 °C for 56 days. This high loss of total tocopherols correlated significantly with an increase in the POV (r = −0.900; p < 0.05). Thus, monitoring the decrease of tocopherols might be a reliable marker to evaluate lipid oxidation in vegetable oils. Others reported dramatic loss of α-,

β-, and γ-tocopherol by 100%, 47.1%, and 31.2%, respectively, in soybean oil heat-treated at 95 °C for 1 day.[45] In agreement with the POVs from our soybean oil study, a more pronounced decrease ($p < 0.05$) of the most abundant tocopherol isomer (128 μg/mL γ-tocopherol on day 1) was observed in the study oil exposed to cold fluorescent light (77.3 ± 3.52% at 22 °C and 85.4 ± 4.11% at 32 °C) compared to the oil stored in the dark (69.4 ± 2.10% at 22 °C and 62.1 ± 6.38% at 32 °C) (Table 5), indicating that cold fluorescent light has the most pronounced impact on lipid oxidation and tocopherol stability at the conditions chosen in this study. Khan et al.[46] also showed that the photooxidative effect of chlorophyll dominated the antioxidative effect of tocopherols as evident by a significant higher POV of 28.3 ± 0.11 meq/kg of nonstripped borage oil compared to the POV of 11.6 ± 0.03 meq/kg of stripped borage oil after storage at 27 ± 1 °C in the presence of cold fluorescent light for 48 h.

Taken together, we could demonstrate that increasing (i) the oxygen containing headspace volume from 67 to 283 mL, (ii) the ambient temperature from 22 to 32 °C, and (iii) adding the exposure to cold fluorescent light contributes to the oxidative status of soybean oil in transparent PET bottles, albeit the extent of the contribution differs. The most pronounced effect with respect to promoting lipid oxidation in soybean oil stored in transparent bottles at household conditions with increasing oxygen volumes was attributed to cold fluorescent light. The higher ambient temperature at 32 °C as well as the increasing headspace oxygen volume up to 283 mL throughout the study, mimicking consumer handling, showed only little effects on the oxidative deterioration of the study oil. For studying the lipid oxidation of vegetable oils stored in the dark, the detection of lipid radicals by ESR spin trapping technique using PBN as a spin-trap proved to be a suitable method to detect early stages of lipid oxidation in vegetable oils. Cold fluorescent light has been proven to be the predominant inducer of oxidative deterioration of soybean oil stored under household conditions, suggesting the use of nontransparent bottles accompanied by consumer education.

present, e.g., their solubility and molecular geometry.[17] A number of low-energy approaches have been developed to form nanoemulsions, including spontaneous emulsification (SE), emulsion inversion point (EPI), phase inversion temperature (PIT), and phase inversion composition (PIC) methods.[17−20] These methods are currently not widely used in the food industry, and where they are used, there is a relatively poor understanding of their physicochemical basis and the major factors impacting their performance.[17,21] Low-energy approaches may have advantages over high-energy approaches for certain applications: they are often more effective at producing very fine droplets; they have lower equipment and energy costs; and they are simpler to implement. On the other hand, there are also some potential drawbacks of low-energy methods, including limitations on the types of oils and surfactants that can be used to form stable nanoemulsions and the fact that relatively high surfactant/oil ratios (SORs) are typically needed to produce them.[19,20,22]

In the current study, we examine the potential of using an isothermal low-energy method (spontaneous emulsification) for producing transparent orange oil nanoemulsions suitable for utilization in foods and beverages. In general, this method involves titrating an organic phase (containing oil and surfactant) into an aqueous phase with continuous mixing, which leads to the spontaneous formation of ultrafine droplets because of rapid diffusion of the surfactant from the organic phase into the aqueous phase.[18,21,23] This method allows for nanoemulsions to be fabricated at room temperature using simple stirring rather than expensive homogenization equipment. This approach may therefore be particularly suitable for utilization within certain sectors of the food and other industries.

To the best of our knowledge, the formation of orange oil nanoemulsions by spontaneous emulsification has not yet been reported. Previous studies in spontaneous emulsification have shown that the size of the droplets generated using the spontaneous emulsification process depends upon many factors, including the type and concentration of surfactant and oils used, stirring conditions, and injection conditions.[4,23−25] The purpose of the present study was to investigate the major factors influencing the formation and stability of orange oil nanoemulsions. The results of this study have important implications for the design and utilization of nanoemulsions as delivery systems in the food and other industries. In particular, they may be useful for implementation in beverage emulsions, where only low concentrations of oil and surfactant are present in the final product.[26]

MATERIALS AND METHODS

Materials. Orange oil (1× fold; lot SC020295) was obtained from International Fragrances and Flavors (Union Beach, NJ). The nonionic surfactants (Tween 20, 40, 60, 80, and 85 and Span 20) were purchased from Sigma-Aldrich Co. (St. Louis, MO). Medium-chain triglyceride (MCT) oil (Miglyol 812) was purchased from Sassol Germany GmbH (Witten, Germany). The manufacturer reported that the fatty acid composition of MCT was 50−65% caprylic acid (C8:0) and 30−45% capric acid (C10:0). The aqueous phase used to prepare the emulsions was citrate buffer solution (5 mM; pH 3.5), which was chosen to mimic the acidic conditions in certain soft drinks and other beverages. Double-distilled water was used in the preparation of all solutions and emulsions.

Emulsion Preparation. Nanoemulsion formation was carried out using a method based on a spontaneous emulsification procedure described previously, with some minor modifications.[21] In brief, spontaneous emulsification was performed by titration of an organic phase (containing different amounts of orange oil, MCT, and nonionic surfactant) into an aqueous phase (5 mM citrate buffer at pH 3.5) while continuously stirring (500 rpm) the system with a magnetic stirrer at ambient temperature (≈25 °C). Unless otherwise stated, the experiments were carried out using standardized conditions: a total oil phase (orange oil + MCT) content of 10 wt %, surfactant content of 20 wt %, and aqueous phase content of 70 wt %. In these samples, the oil (10 g) and surfactant (20 g) were first mixed together and then the mixture was titrated into 70 g of aqueous phase at a rate of 2 mL/min. In some experiments, systems with different surfactant/emulsion ratios (SERs) were prepared by varying the amount of surfactant in the overall system. For example, a system with SER = 10% contains 10 g of surfactant in 100 g total (surfactant + oil + buffer).

Particle Size Measurements. The particle size distributions and mean particle diameters (Z averages) of nanoemulsions were measured using a dynamic light scattering instrument (Zetasizer Nano ZS, Malvern Instruments, Malvern, U.K.). This instrument determines the particle size from intensity−time fluctuations of a laser beam (633 nm) scattered from a sample at an angle of 173°. Each individual measurement was an average of 13 runs. To avoid multiple scattering effects, samples were diluted before the particle size measurements using citrate buffer solution (5 mM, pH 3.5).

Nanoemulsion Thermal Stability Measurements. The thermal stability of the nanoemulsions was determined by measuring their turbidity (600 nm) during heating and cooling using a temperature-scanning spectrophotometer (Evolution Array, Thermo Scientific). The turbidity was measured as the temperature was increased from 20 to 90 °C at a rate of 1 °C/min and then decreased back to 20 °C at the same rate. A citrate buffer solution (5 mM, pH 3.5) was used as a blank.

Statistical Analysis. All experiments were carried out 2 or 3 times using freshly prepared samples, and the results are reported as the calculated mean and standard deviation of these measurements. Means were subjected to Duncan's test, and a p value of <0.05 was considered statistically significant.

RESULTS AND DISCUSSION

Effect of the Oil Composition on the Particle Size. Initially, we examined the influence of oil-phase composition on the size of the droplets formed in nanoemulsions produced using spontaneous emulsification. Oil-phase composition was varied by combining different mass ratios of orange oil and MCT prior to emulsification. Otherwise, the system composition was standardized: oil content (orange oil + MCT) = 10 wt %; surfactant content = 20 wt %; and surfactant = Tween 80.

Oil-phase composition (orange oil/MCT ratio) had a major effect on the formation of emulsions and nanoemulsions by spontaneous emulsification (Figure 1). Orange oil alone was not able to form stable nanoemulsions: the emulsions produced were extremely unstable and inhomogeneous (data not shown). Transparent nanoemulsions containing fine droplet ($d \approx 25$ nm) could only be produced if the orange oil was mixed with a certain amount of MCT carrier oil (Figure 1). When the orange oil level in the lipid phase decreased to <30 wt % or increased to >50%, there was an appreciable increase in the mean particle diameter and no transparent nanoemulsions could be formed, although the droplet sizes in most of the systems were still relatively small ($d < 100$ nm) (Figure 1). We observed a similar phenomenon when another essential oil (carvacrol) was used to spontaneously form nanoemulsions.[6] The large particle sizes observed at high orange oil contents can be attributed to emulsion instability caused by Ostwald ripening and/or coalescence. The large particle sizes observed at higher orange oil contents may be due to changes in the phase behavior of the surfactant−oil−water system at certain compositions.[20] The

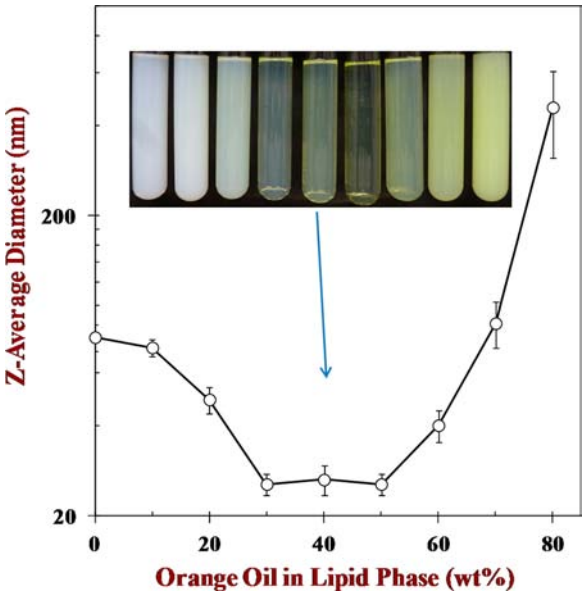

Figure 1. Effect of the oil-phase composition (wt % of orange oil in the oil phase) on the mean particle diameter of emulsions and nanoemulsions produced by spontaneous emulsification. Emulsions and nanoemulsions were prepared using 10 wt % oil (orange oil + MCT), 20 wt % surfactant (Tween 80), and 70 wt % water (pH 3.5 citrate buffer solution) at a stirring speed of 500 rpm at ambient temperature (≈25 °C). From left to right, the photograph shows orange oil concentrations in the lipid phase of 0, 10, 20, 30, 40, 50, 60, 70, and 80 wt %, respectively.

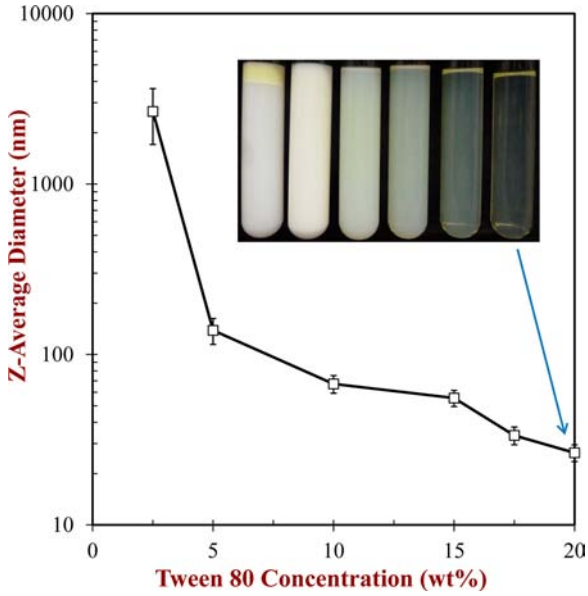

Figure 2. Effect of the surfactant concentration on the mean particle diameter and physical stability of emulsions produced by spontaneous emulsification. The surfactant (Tween 80) concentration in emulsion varied from 2.5 to 20 wt %, as indicated. Oil phase = 4% orange oil + 6% MCT.

physicochemical mechanisms governing the size of the droplets produced by spontaneous emulsification are still not clearly understood, and further research is still required in this area.

It should be noted that the type of carrier oil was also critical for the formation of ultrafine droplets by spontaneous emulsification. We could not form stable orange oil nanoemulsions at any oil-phase composition when long-chain triglycerides (e.g., corn and canola oils) were used as carrier oils rather than MCTs (data not shown). These experiments indicate that both the type and amount of carrier oil used to form nanoemulsions using the spontaneous emulsification method is critical.

Effect of the Surfactant Concentration on the Particle Size. The effect of the surfactant concentration on the particle size was investigated by preparing a series of emulsions with a fixed oil-phase composition (4% orange oil + 6% MCT) and surfactant type (Tween 80) but different SERs. Here, SER equals the mass of surfactant divided by the mass of the overall emulsion expressed as a percentage: SER = 100 × m_S/m_E. The amount of surfactant present had a pronounced influence on the size of the droplets produced, with the smallest droplets being formed at the highest surfactant concentrations, i.e., SER from 5 to 20 wt % (Figure 2). For example, at SER = 2.5 wt %, the emulsions formed contained relatively large droplets (d > 2000 nm) and phase separation occurred quickly. On the other hand, at SERs = 5, 10, 15, 17.5, and 20 wt %, the mean particle diameter decreased to 139, 67, 56, 34, and 25, respectively (Figure 2). In addition, the systems became optically transparent at the highest surfactant levels. Thus, it was possible to make clear colloidal delivery systems that contained very small droplets at high SERs.

This phenomenon is in agreement with earlier studies[21] and can be attributed to a number of physicochemical mechanisms. Higher surfactant concentrations at the oil−water boundary cause a large reduction in the interfacial tension, which may lead to a highly dynamic interface that spontaneously generates fine droplets through interfacial turbulence.[27] Second, higher surfactant concentrations mean that a larger oil−water interface can be stabilized, which means that smaller droplets can be produced.[11]

It should be noted that one of the major disadvantages of the low-energy approach of forming orange oil nanoemulsions is that a high surfactant level is required. However, in many cases, the concentration of the oil phase required in final food and beverage products is very low, and therefore, nanoemulsions will be highly diluted after formation. For example, the flavor oils used in soft drinks and waters are often appreciably less than 0.1% of the final product, and therefore, the surfactant level is also low.[26]

Effect of the Surfactant Type on the Particle Size. The impact of non-ionic surfactant type on the size of the droplets formed in the nanoemulsions was also investigated. A series of nanoemulsions with fixed oil composition (4% orange oil + 6% MCT) was prepared using the same surfactant concentration (20 wt %) but different surfactant types (Tween 20, 40, 60, 80, 85, and Span 20). The type of non-ionic surfactant had an appreciable impact on the mean particle diameter of the emulsions formed (Figure 3). Transparent nanoemulsions containing very fine droplets were formed in the systems prepared from Tween 40, 60, or 80 (d ≈ 25 nm), whereas opaque emulsions containing relatively large droplets that were unstable to gravitational separation were formed using Tween 20 or 85 or Span 80 (Figure 3). These results suggest that surfactants with too high hydrophilic−lipophilic balance HLB numbers (Tween 20, HLB = 16.7) or too low HLB numbers (Tween 85, HLB = 11; Span 80, HLB = 8.6) were unsuitable for the formation of nanoemulsions using the oil phase used in this study (Figure 3). On the contrary, surfactants with intermediate HLB numbers seemed to be more suitable for the

dx.doi.org/10.1021/jf500160y | J. Agric. Food Chem. 2014, 62, 2306−2312

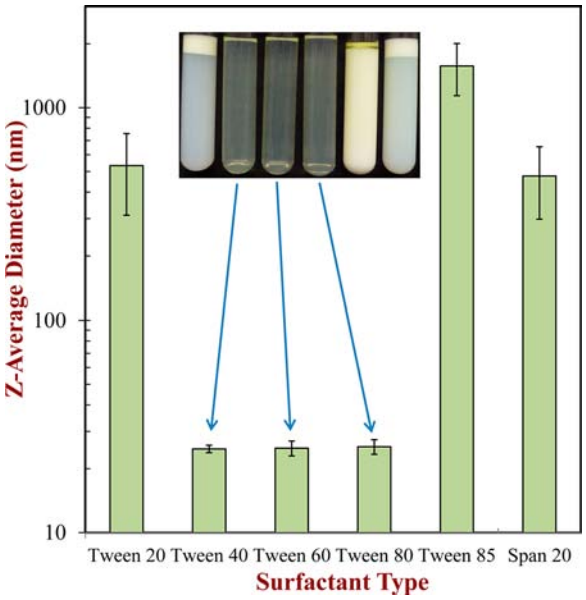

Figure 3. Effect of the surfactant type on the mean particle diameter and physical stability of emulsions produced by spontaneous emulsification. Oil phase = 4% orange oil + 6% MCT. Surfactant was 20 wt % in the system.

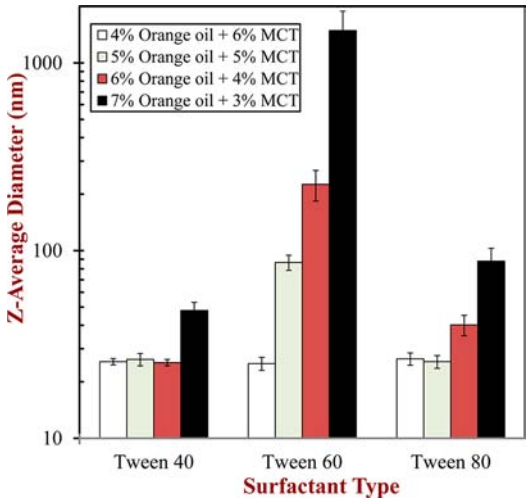

Figure 4. Effect of the surfactant type and oil-phase composition on the mean particle diameter of emulsions produced by spontaneous emulsification. The oil-phase composition (varying ratio of orange oil/MCT; total oil = 10 wt %) was indicated in the legend. The surfactant was 20 wt % in system. The results indicate that Tween 40 can load the most amount of orange oil (6%), producing transparent nanoemulsions with very small particle sizes ($d \approx 25$ nm), while Tween 60 can load the least amount of orange oil (4%), and Tween 60 is in the middle (5% orange oil). Other types of surfactants cannot produce transparent orange oil nanoemulsions, regardless of the oil phase.

formation of orange oil emulsions, because Tween 40, 60, and 80 (with HLB numbers 15.6, 14.9, and 15.0, respectively) were able to form clear nanoemulsions that were stable for separation (Figure 3). There are a number of possible reasons why surfactants with intermediate HLB values may favor the formation of ultrafine orange oil nanoemulsions. The spontaneous formation of ultrafine droplets at the oil–water boundary may require a very low interfacial tension to stimulate interfacial turbulence. Surfactants with intermediate HLB numbers might be expected to form monolayers with low interfacial tensions. If the HLB number is too low, then the surfactant will remain in the oil phase rather than moving into the water phase. If the HLB number is too high, then the interfacial tension and optimum curvature of the surfactant monolayer may be too high to form very fine oil droplets.

Effect of the Different Surfactant Types and Oil-Phase Compositions on the Particle Size. Having established that Tween 40, 60, and 80 could all form transparent orange oil nanoemulsions, we further investigated the effect of oil-phase composition on the size of the droplets produced using only these surfactants. Our aim was to establish which surfactant was most effective at producing small droplets and high orange oil loading capacities. In these experiments, the total surfactant concentration (20 wt %) and oil-phase concentration (10 wt %) were held constant, while the mass ratio of orange oil/MCT in the oil phase was varied. Our results indicated that surfactant type had a major influence on the formation of nanoemulsions with high loading capacities (Figure 4): Tween 40, 60, and 80 were capable of incorporating 6, 4, and 5% orange oil while still maintaining ultrafine droplets, i.e., $d < 30$ nm. At higher orange oil levels, there was an appreciable increase in the mean particle diameter. There are a number of possible reasons for the observed increase in the particle size at higher orange oil levels, which are associated with either emulsion formation or emulsion stability. During emulsion formation, there may be an optimum surfactant and oil-phase composition that leads to an ultralow interfacial tension and spontaneous droplet formation at the oil–water boundary. After emulsion formation, droplet growth may occur because of Ostwald ripening or coalescence processes, which depend upon surfactant type and the composition of the oil phase. In particular, Ostwald ripening has been shown to occur rapidly in oil-in-water emulsions containing flavor oils because of their relatively high water solubility.[28,29] The addition of water-insoluble oils (such as MCT or long-chain triglyceride) to flavor oils has been shown to inhibit this form of droplet growth, which has been attributed to an entropy of mixing effect that opposed Ostwald ripening.[29] Thus, there may be a minimum amount of MCT that has to be present in the emulsions to prevent rapid droplet growth from occurring after emulsion formation.

Thermal Stability of Selected Orange Oil Nanoemulsions. Emulsified flavor oils may be subject to thermal treatments (such as pasteurization) during food processing. We therefore examined the thermal stability of selected orange oil nanoemulsions (10% oil phase and 20% surfactant) by measuring the change in sample turbidity during a controlled heating–cooling cycle. Nanoemulsions with three different oil-phase compositions were examined: 4 wt % orange oil + 6 wt % MCT, 5 wt % orange oil + 5 wt % MCT, and, 6 wt % orange oil + 4 wt % MCT. The nanoemulsions were heated from 20 to 90 °C and then cooled to 20 °C at a heating/cooling rate of 1 °C/min. The turbidity of all of the samples before and after heating is summarized in Figure 5. The full turbidity–temperature profiles during heating and cooling of selected samples are shown in Figure 6.

Tween 40. The nanoemulsions with three different oil compositions were all initially transparent ($\tau \approx 0$ cm^{-1}), but they all became highly turbid ($\tau > 0.6$ cm^{-1}) after the heating–cooling cycle, which is indicative of temperature-induced droplet growth (Figure 5). A representative turbidity–temperature profile for the 5% orange oil + 5% MCT system is shown

dx.doi.org/10.1021/jf500160y | J. Agric. Food Chem. 2014, 62, 2306–2312

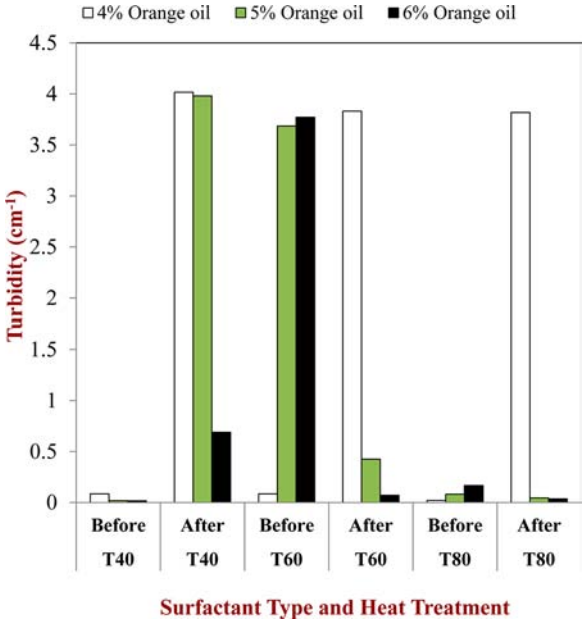

Figure 5. Turbidity of representative orange oil emulsions/nanoemulsions before and after heating. The samples were heated from 20 to 90 °C at a rate of 1 °C/min and then cooled to 20 °C at the same rate. In the figure, "before" means the turbidity (at 600 nm) of samples before the heat−cooling circle and "after" means the turbidity after the heat−cooling treatment.

in Figure 6a. This system was initially transparent. During heating, the turbidity remained close to zero from 20 to 63 °C, increased to a maximum around 77 °C, and then decreased to close to zero again around 80 °C. We postulate that the increase in turbidity observed around 75 °C was due to droplet coalescence as the system approached the PIT. The decrease in turbidity at higher temperatures is attributed to the formation of a clear microemulsion around the PIT. Upon cooling, the turbidity increased steeply around 74 °C and the system remained opaque at lower temperatures, which was attributed to rapid droplet coalescence at temperatures just below the PIT.

Tween 60. Before heating, nanoemulsions containing 4 wt % orange oil were transparent ($\tau \approx 0$ cm^{-1}), whereas those containing 5 or 6 wt % orange oil were opaque ($\tau > 3$ cm^{-1}) (Figure 5). Conversely, the nanoemulsions containing 4 wt % orange oil became opaque after heating, whereas those containing 5 or 6 wt % orange oil were much lower. A representative turbidity−temperature profile for the 5% orange oil + 5% MCT system is shown in Figure 6b. This system initially appeared optically opaque ($\tau > 3$ cm^{-1}). During heating, the turbidity remained high from 20 to 75 °C, then decreased steeply, had a value close to zero from 79 to 85 °C, and then increased steeply around 86 °C. We postulate that the decrease in turbidity observed around 75 °C was due to the formation of a clear microemulsion phase around the PIT, while the steep increase at 86 °C was due to the formation of a water-in-oil (W/O) emulsion containing relatively large water droplets at temperatures well above the PIT. Upon cooling, there was a steep decrease in turbidity around 83 °C until the system became transparent from around 77 to 66 °C, which was attributed to the formation of a clear microemulsion around the PIT. Upon further cooling, the turbidity of the system increased somewhat, which was attributed to some droplet coalescence at temperatures just below the PIT.

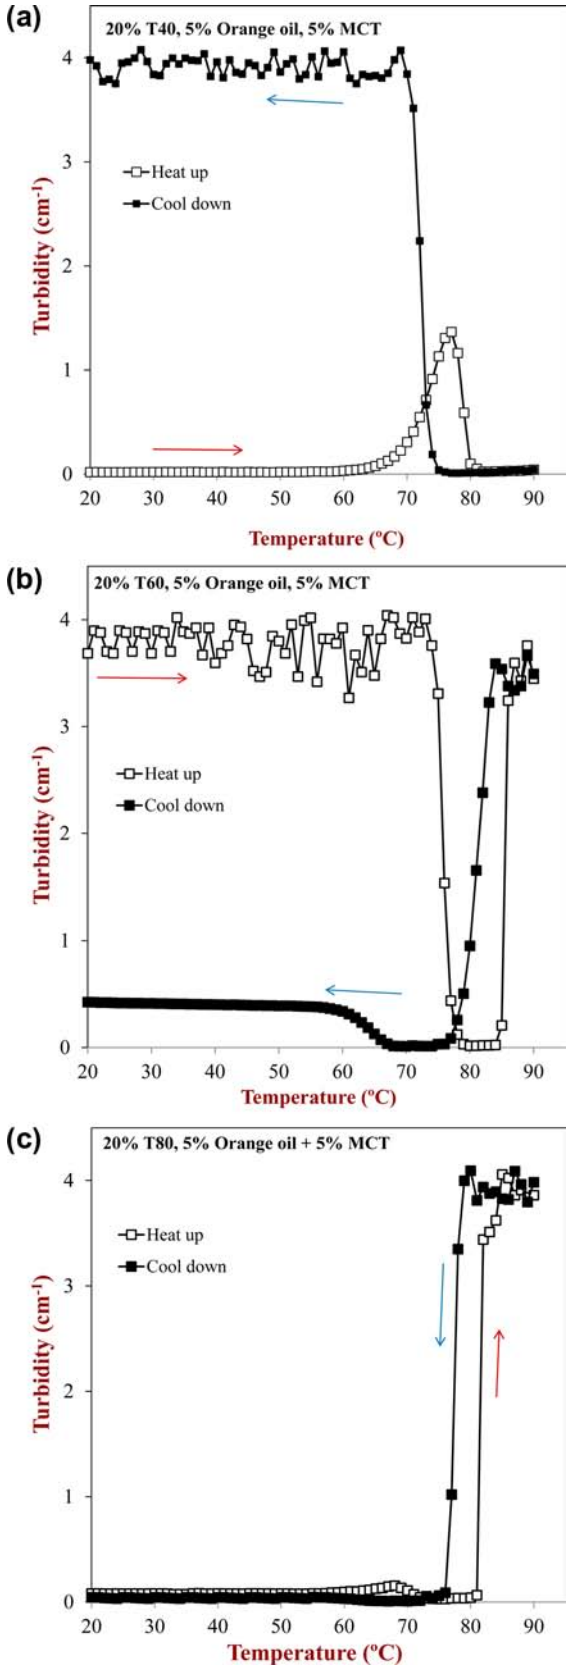

Figure 6. Turbidity−temperature profiles during heating and cooling of selected orange oil emulsion/nanoemulsion samples. Oil compositions and surfactants are shown in the legend. (c) Nanoemulsion containing 20% Tween 80, 5% orange oil, and 5% MCT was temperature-reversible (i.e., remaining transparent after heating and cooling).

dx.doi.org/10.1021/jf500160y | J. Agric. Food Chem. 2014, 62, 2306−2312

Tween 80. Prior to heating, all of the nanoemulsions had relatively low turbidities, but after heating, the systems containing 4 wt % orange oil became opaque, whereas those containing 5 or 6 wt % orange oil were clear (Figure 5). A representative turbidity–temperature profile for the 5% orange oil + 5% MCT system is shown in Figure 6c. This system initially had a relatively low turbidity. During heating, the turbidity remained close to zero from 20 to 60 °C, increased to a slight maximum around 66 °C, decreased close to zero from 72 to 80 °C, and then increased steeply around 81 °C until the system became opaque ($\tau > 3$ cm^{-1}). We postulate that the increase in turbidity observed around 66 °C was due to droplet coalescence as the system approached the PIT. We attribute the low turbidity from 72 to 80 °C to the formation of a microemulsion around the PIT and the large increase in turbidity above 81 °C to phase inversion to a W/O emulsion containing large water droplets that scatter light strongly. Upon cooling, the turbidity of the system decreased rapidly below 78 °C, which was attributed to the formation of a clear microemulsion again around the PIT and a nanoemulsion at lower temperatures.

These results clearly show that the temperature dependence of orange oil nanoemulsions is complex and depends upon the nature of the surfactant and oil phase used to fabricate them. In some cases, clear nanoemulsions formed at ambient temperatures by spontaneous emulsification remain stable after thermal treatment, whereas in other cases, they do not. In other cases, unstable opaque emulsions formed at ambient temperatures by spontaneous emulsification revert to clear nanoemulsions after thermal treatment, whereas in other cases, they remain unstable. We postulate that the most important factor determining droplet growth after heating is their coalescence stability near the PIT. Some systems underwent rapid droplet growth during cooling, whereas others did not.

Storage Stability of the Spontaneously Emulsified Orange Oil Nanoemulsions. For most commercial applications, it is important that nanoemulsion-based delivery systems remain physically stable throughout their shelf life; i.e., there is little change in their particle size during storage. We therefore examined the influence of storage time on the stability of a representative nanoemulsion: 5% orange oil + 5% MCT and 20 wt % Tween 80. This system was selected because it was the only one that formed transparent nanoemulsions at ambient temperature after spontaneous emulsification and was also stable to heating and cooling (see previous section). There was an appreciable increase in the mean droplet diameter from around 25 to 46 nm during storage for 40 days at ambient temperature (Figure 7), which suggests that some droplet growth occurred because of either coalescence or Ostwald ripening. Nevertheless, when the nanoemulsion was diluted 10 times in aqueous solution (5 mM citrate buffer at pH 3.5), the rate of droplet growth was appreciably reduced; i.e., the diameter only increased around 25–32 nm after 40 days of storage at ambient temperature (Figure 7). It should also be noted that, after a certain time, the droplet diameter remained relatively stable; e.g., after 19, 26, and 40 days, the particle size of the diluted nanoemulsions was 31, 32, and 32 nm ($p > 0.05$). Practically, the concentration of essential oil required in a final food product is usually very low, and therefore, nanoemulsions will be highly diluted after formation. Consequently, they should remain relatively stable in commercial applications.

The fact that the stabilities of the nanoemulsions improved after dilution suggests that the instability of the undiluted

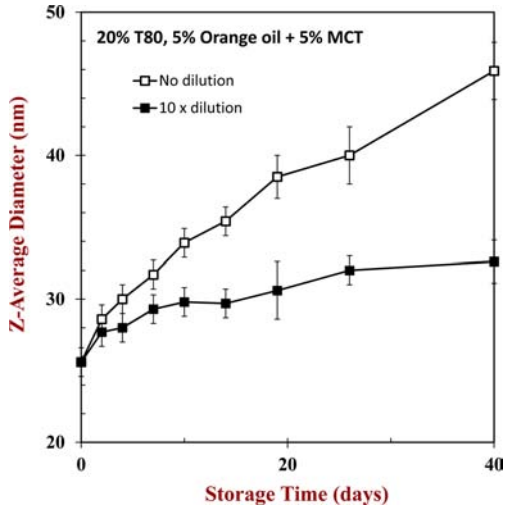

Figure 7. Increase in the mean particle diameter of selected nanoemulsions during 40 days of storage at room temperature. Nanoemulsions were prepared using 10 wt % oil (5% orange oil + 5% MCT), 20 wt % surfactant (Tween 80), and 70 wt % water (pH 3.5 citrate buffer solution) at a stirring speed of 500 rpm at ambient temperature (≈25 °C). This nanoemulsion was selected because it was transparent with very small sizes ($d \approx 25$ nm) and temperature-reversible (remaining to be transparent after heating–cooling circles). The nanoemulsion was either undiluted or diluted 10 times by citrate buffer. The results indicated that the size of the nanoemulsion increased over storage, but this effect was much reduced if the nanoemulsion was diluted.

emulsion may have been due to the relatively high amount of surfactant present (SER = 20 wt %). At relatively high surfactant levels, there may have been appreciable amounts of free surfactant micelles present that could transfer oil molecules between droplets through Ostwald ripening or promote droplet aggregation through depletion,[30,31] which is in accordance with results that we reported previously on essential oil nanoemulsions.[20]

In this paper, we have described the influence of surfactant and oil composition on the fabrication and stability of orange oil nanoemulsions formed by spontaneous emulsification. We found that oil-phase composition (orange oil/MCT ratio), surfactant type, and surfactant concentration all had an appreciable impact on the particle size and nanoemulsion stability. Clear nanoemulsions could be formed under certain system compositions: 20% Tween 40, 60 or 80 and 4–6% orange oil with 6–4% MCT). Surfactant type and oil-phase composition also affected the thermal stability of the nanoemulsions. Only nanoemulsions containing 20% Tween 80, 5% orange oil, and 5% MCT remained clear after heating and cooling. The droplet size of these nanoemulsions increased over time during storage at ambient temperature. Nevertheless, the rate of droplet growth could be retarded by dilution of the nanoemulsions in aqueous solutions prior to storage.

These nanoemulsion preparation methods described in this study could be implemented by the food and beverage industries. Under the optimized conditions established in this study, physically stable and transparent orange nanoemulsions could be formed by simple mixing. The fabrication of nanoemulsions by spontaneous emulsification has a number of potential advantages: simplicity of implementation, no expensive equipment required, and lower energy and operating costs. Additionally, in comparison to high-energy methods (e.g.,

high-pressure homogenization), spontaneous emulsification can produce nanoemulsions with smaller droplet sizes, making them particularly suitable for application in clear beverages. The major disadvantage of this method is that high amounts of synthetic surfactant are required, but this may not be a problem where the oil concentration required in a final product is relatively low, e.g., beverage emulsions.

However, the mechanisms for the hyperaccumulation of F and Al in tea leaves remain unknown. We hypothesize that the localization of F and Al in tea plants plays an important role in their detoxification. On one hand, F and Al may be immobilized by pectin and hemicellulose in the apoplasts of cell walls, limiting their movement through membranes, prohibiting them from entering symplasts, and thus reducing their toxicities to cells. On the other hand, F and Al are captured and compartmentalized by vacuoles after entering protoplasts, reducing their contacts with organelles in symplasts. However, the mechanisms controlling the subcellular localization of F and Al in tea plants are not fully understood.

To test our hypothesis that the subcellular localization contributes to the detoxification of F and Al in tea plants, different subcellular fractions such as those of the cell wall rich, pellet, and soluble fractions of tea leaves and roots were separated using the differential centrifugation and osmotic lysis methods. Then the concentrations of F and Al in these subcellular fractions were analyzed using ion chromatography and atomic absorption spectrometry, respectively. Finally, the distribution of F and Al in different subcellular fractions was examined to test our hypothesis.

MATERIALS AND METHODS

Tea Plants and Growth Conditions. Tea seeds (Shuchazao, *Camellia sinensis* L.) were collected from the High-tech Demonstration Garden (E117°38′, N31°43′) of the Anhui Agricultural University. The seeds were immersed in water for 2 days. Afterward, the healthy ones were chosen and planted in the trays containing moist quartz sand (particle size of 0.3 cm), and then the trays were placed into automatic climate chambers (50% humidity, 12 h light/dark cycle, 550 μE m^{-2} s^{-1} illumination, and day and night temperatures of 25 and 20 °C, respectively). The seeds were irrigated with 5 mM F (NaF) and 2.5 mM Al [$Al(NO_3)_3$] for 6−8 days until the first trifoliate leaves had just expanded. Finally, the roots and leaves were washed several times with deionized water, and the water on the surfaces of roots and leaves was wiped up with filter paper.

Isolation of Cell Wall, Organelle, and Cytoplasm Fractions from Tea Leaves and Roots. The fractions of the cell wall, organelle, and cytoplasm of tea roots and leaves were isolated according to the methods proposed by Weigel and Jager.[22] In brief, 100 pieces of 10 mm tea root tips or 2.0 g of tea leaves was homogenized using a mortar and pestle in a medium containing 250 mM sucrose, 50 mM Tris-HCl (pH7.5), and 1 mM dithiothreitol. All the steps were performed at 4 °C. The resulting debris was strained through eight layers of cheesecloth, and the liquid was filtered through the cheesecloth, with the residue left on the cheesecloth. The residue on the cheesecloth was washed twice with the grinding medium. The pooled washes, together with the first filtrate, were centrifuged at 300*g* for 30 s (Z36HK, Hermle). The resulting pellet combined with the residue on the cheesecloth contained mainly cell walls and cell wall debris and was designated as the cell wall rich fraction. The supernatant from the first centrifugation step was then centrifuged at 20000*g* for 45 min to sediment cell organelles. The sediment on the bottom of the centrifugal tube mainly contained organelles, and organelle debris was considered as the pellet fraction (20000*g*). The resultant supernatant solution in the centrifugal tube was termed the soluble fraction. The purity of each fraction was tested by examining activities of cytochrome *c* oxidase (the marker for mitochondria) and glucose-6-phosphate dehydrogenase (the marker for cytosol), as described in Enzyme Assays.

Preparation of Protoplasts. The protoplast fraction of tea roots and leaves was prepared following the method described by Yoo et al.[23] The surfaces of healthy fresh leaves were sterilized with 70% alcohol. The leaves were cut into 0.5−1.0 mm pieces from intercostal tissue using a sharp razor blade. Two grams of leaf pieces was quickly and gently transferred into 5 mL of a 2-morpholinoethanesulfonic acid (MES) enzyme buffer solution (20 mM, pH 5.7) containing 1.5% cellulase, 0.4% macerozyme, 0.4 M mannitol, 20 mM KCl, 10 mM $CaCl_2$, and 0.1% bovine serum albumin (BSA). The leaf pieces were incubated in a vacuum container for at least 3 h at room temperature (25 °C) in the dark. The MES enzyme solution turned green after a gentle swirling motion, indicating the release of protoplasts, which was checked under a microscope (400×, Motic B5, Motic, Shanghai, China).

Five milliliters of the enzyme/protoplast solution was diluted with 5 mL of a 2 mM MES buffer solution containing 154 mM NaCl, 125 mM $CaCl_2$, and 5 mM KCl to achieve the release of protoplasts before filtration to remove undigested leaf tissues. The enzyme solution containing protoplasts was filtered through a 75 μm mesh nylon filter. The filtrate was centrifuged at 100*g* for 2 min to sediment the protoplasts in a 50 mL round-bottom centrifugal tube. The supernatant was completely removed, and the protoplast pellet was resuspended with 10 mL of a 2 mM MES buffer solution. An aliquot of 5 mL of 0.6 M sucrose containing 20 mM MES (pH 5.7) was put on the bottom of the tube that was centrifuged at 150 rpm for 15 min. The protoplasts were suspended on the sucrose layer and collected with a 5 mL syringe. Then the collected protoplasts were suspended in 30 mL of suspension medium. An additional 5 mL of the sucrose solution (0.6 M) was injected below the suspended protoplasts, and the tube was centrifuged at 100*g* for 15 min. The washing procedure was repeated twice, and the protoplast pellet was suspended in 2.5 mL of 0.6 M mannitol. The green layer between the sucrose interfaces contained purified protoplasts.

Preparation and Identification of Vacuoles. The vacuoles of protoplasts of tea roots and leaves were separated using the osmotic lysis method.[24−26] The protoplast suspensions (2.5 mL) were lysed by being mixed with 12.5 mL of 60 mM K_2HPO_4 (pH 8.0) containing 12% (w/v) Ficoll and 1 mM dithiothreitol (DTT). The mixture was gently blended by repeatedly inverting the tube for 5 min. Then 5 mL of 0.6 M mannitol, 50 mM potassium phosphate (pH 7.0), and 1 mM (Na^+) EDTA were layered on the top of the lysate and centrifuged at 1000*g* for 15 min. During centrifugation, the vacuoles migrated toward the top and were recovered in the top 4 mL of the Ficoll layer. The concentrations of protoplasts and vacuoles were determined by using a hemocytometer.

Enzyme Assays. The α-mannosidase activities in isolated protoplast and vacuole fractions were assayed by measuring the liberation of *p*-nitrophenol from PNP-α-mannopyranoside substrates according to the method of Boller and Kende.[27] Briefly, a 0.5 mL assay mixture containing 50 μL of α-mannosidase (usually 1−5 μg of protein and 0.1−0.5 unit of activity) and 50 μM succinic acid was adjusted to pH 5.0 with NaOH, and 0.3 μmol of the PNP-α-mannopyranoside substrate was also added. The reaction was started by the addition of 0.3 μmol of the PNP-α-mannopyranoside substrate and stopped after 60 min by adding 0.8 mL of 1 M Na_2CO_3. The α-mannosidase activities were determined at 405 nm using a spectrophotometer.

Cytochrome *c* oxidase (the marker for mitochondria) was assayed at room temperature (25 °C) by following the oxidation of cytochrome *c*.[28] The 3 mL reaction mixture contained 10−50 μg of protein, 15 μM cytochrome *c* reduced with sodium dithionite, 10‰ digitonin, and 50 mM phosphate buffer (pH 7.5). The activities of cytochrome *c* oxidation were determined at 550 nm using a spectrophotometer. Glucose-6-phosphate dehydrogenase (the marker for cytosol) was determined spectrophotometrically.[29] An assay contained 800 μL of 0.1 M triethanolamine buffer (pH 7.6), 70 μL of 0.1 M $MgCl_2$, 30 μL of 35 mM glucose 6-phosphate, and 30 μL of 11 mM $NADP^+$, in a total volume of 1 mL. The reaction was started by the addition of 70 μL of different homogenized subcelluar fractions of tea leaves and roots and measured at room temperature at 340 nm using a spectrophotometer.

Isolation of Pectin and Hemicellulose from Cell Walls. The crude cell walls of tea roots obtained from the procedures described in Isolation of Cell Wall, Organelle, and Cytoplasm Fractions from Tea Leaves and Roots were washed in a 15 mL centrifugal tube with two aliquots of 3.5 mL of ice-cold 75% ethanol and kept undisturbed for 20 min in an ice−water bath. The homogenates were then centrifuged for

10 min at 1000*g* and the pellets washed three times with 5 mL of ice-cold acetone, a methanol/chloroform mixture [1:1 (v/v)], and methanol.[30] The supernatant of each wash was discarded, and the final deposits were freeze-dried overnight. The dry deposits were weighed and considered crude cell walls that were then used for further removal of pectin and hemicellulose components.

The pectin and hemicellulose were removed from the crude cell walls following the method of Mort et al.[31] In brief, an aliquot of 0.2 g of crude cell walls was transferred into a 50 mL plastic centrifuge tube with 30 mL of a 0.5 M imidazole/acetate solution (pH 7.0). To remove pectin, the cell walls were shaken for 24 h on a shaker at 400 rpm (25 °C) after the centrifugal tubes had been sealed with a stopper and aluminum foil. Afterward, the homogenates were separated by centrifugation for 15 min at 20000*g*, and the pectin in the supernatant was transferred to a 50 mL test tube for further analysis. The same procedure was performed to remove alkaline pectin with 50 mmol of $NaCO_3$ per liter. The procedures for isolating pectin fractions were repeated three times. To remove hemicellulose, the residues (cell walls without pectin) in the centrifugal tube were mixed with 5 mL of 4% KOH and then 8% KOH in sequence containing 0.1% $NaBH_4$, shaken for 8 h at 200 rpm, and centrifuged for 15 min at 20000*g*. The hemicellulose in the supernatant was transferred into the 50 mL test tube for further analysis. The final residues in the centrifugal tube were the cell walls without pectin and hemicellulose. Triplicate experiments were performed for each extraction step. All the extracts from cell walls were stored in a freezer before the determination of Al levels, digested by HNO_3, and then analyzed using atomic absorption spectrometry (ZEEnit700, Analytik Jena AG).[19] Whole cell walls, cell wall residues without pectin, and cell wall residues without pectin and hemicellulose (most were cellulose) were freeze-dried prior to adsorption experiments.

Al Adsorption in Different Fractions of Cell Walls. Batch experiments were conducted to determine the adsorption of Al on different components of cell walls in tea roots; 0.5 g of whole cell walls, cell wall residues without pectin, or cell wall residues without pectin and hemicellulose were introduced into 250 mL centrifugal tubes, and then 200 mL Al solutions in 5 mM were also added. The ionic strength in the centrifugal tubes was adjusted using 0.1 mM KNO_3, and the pH was kept at 6.0 using 0.1 M NaOH and 0.1 M HCl. The Al mixtures were shaken on a shaker at 200 rpm (25 °C) after the centrifuge tubes had been sealed with a stopper and Teflon film. At the end of the 2 h adsorption equilibrium time, the Al mixtures were subsequently centrifuged at 20 °C for 10 min at 1000*g*. The concentrations of Al in the supernatant were determined using atomic absorption spectrometry (ZEEnit700, Analytik Jena AG).[19]

The mass of Al adsorbed on the whole cell walls and their residues was obtained by the difference between the mass of Al originally added and that from the solution phase at the end of adsorption experiments. The amount of Al adsorbed was calculated by the equation

$$Qa = (C_0 - C_e) \times V/M \quad (1)$$

where Qa is the amount of Al adsorbed (milligrams per gram), C_0 is the initial concentration of Al (millimoles per liter), C_e is the equilibrium concentration of Al at the end of the adsorption experiment (millimoles per liter), V is the volume of the solution (liters), and M is the mass of the whole cell walls or their residues (grams).

Extraction and Determination of Levels of F and Al in Tea Samples. The fluoride that accumulated in tea plants was extracted according to the method optimized by Zhang et al.[32] Briefly, root or leaf samples were weighed, placed into 50 mL centrifugal tubes that contained 30 mL of redistilled water, and extracted at 100 °C for 30 min in water. The extraction mixtures were cooled to room temperature and then centrifuged at 2500*g* for 10 min at 20 °C to separate the supernatant. The F concentrations in root, leaf, protoplast, and vacuole fractions were determined by ion chromatography (ICS-1100, Dionex), equipped with an Ionpac AS23 anion-exchange column (4 mm × 50 mm) coupled with an IonPac AG23 Guard column (4 mm × 50 mm). The separation of F was performed with a mixed solutuion of 4.5 mM Na_2CO_3 and 0.8 mM $NaHCO_3$ at 30 °C. The flow rate was 1.0 mL/min, and the injection volume was 25 μL.

For Al determination, the protoplast and vacuole fractions as well as the root and leaf samples were weighed and digested with HNO_3 as described by Shen et al.[19] The Al concentrations in the protoplasts, vacuoles, roots, and leaves were determined by atomic absorption spectrometry (ZEEnit700, Analytik Jena AG).

Statistics. The contents of F and Al in different subcellular fractions (the cell wall rich, pellet, and soluble fractions) of tea roots and leaves were expressed as micrograms per gram on a fresh weight basis. The contents of F and Al in protoplasts and vacuoles were calculated as micrograms of F and Al per 10^6 protoplasts and vacuoles, respectively. The experiments were repeated in triplicate for statistical analysis. The experimental data were subjected to one-way or two-way analysis of variance (ANOVA) to analyze the contents of F and Al in the different parts of tea roots and leaves. Fisher's least significant differences (LSDs) followed by Duncan's multiple range tests were performed to compare the means of F and Al in different fractions of tea roots and leaves. The data in the tables are presented as means ± the standard deviation. For statistical analysis, SAS version 9.0 and SPSS version 13.0 for windows were employed.

RESULTS

Subcellular Localization of F and Al in Tea Roots and Leaves. The purity of subcellular fractions, including the cell wall rich, pellet, and soluble fractions of tea leaves, was tested by examining the activities of marker enzymes. Mitochondria were widely distributed in most of the plant cells and selected as the representative of the organelle fraction. Cytochrome *c* oxidase and glucose-6-phosphate dehydrogenase are primarily present in mitochondria and cytosol and therefore considered as marker enzymes of mitochondria and the soluble fraction of tea leaves, respectively. The activities of both cytochrome *c* oxidase and glucose-6-phosphate dehydrogenase were undetectable in the cell wall rich fraction, indicating no contamination of the cell wall rich fraction by the pellet and soluble fractions (Table 1). Therefore, the Al and F detected in the cell wall rich fraction derived from the retention and accumulation of Al and F, rather than from the release from the pellet and soluble fractions. The activity of glucose-6-phosphate dehydrogenase (the marker for cytosol) in the pellet fraction was 1.4 nmol/min, which was 5.2% of that in the soluble fraction (26.7 nmol/min). This revealed that the level of contamination of the pellet fraction by the soluble fraction was very low, and Al and F examined in the pellet fraction that originated from Al and F contaminated by the soluble fraction were trivial (~5%). The activities of cytochrome *c* oxidase (the marker for mitochondria) in the pellet and soluble fractions were 39.6 and 5.6 nmol/min, respectively, indicating that 12.3% of the pellet fraction may be released into the soluble fraction. Therefore, levels of Al and F measured in the soluble fraction

Table 1. Selected Enzyme Activities in Different Fractions of Tea Leaves[a]

total/recovery[R]	162.1	95.5[R]	213.0	95.7[R]

[a]The means within the columns followed by a−c were significantly different ($p < 0.05$) among Al concentrations in the cell wall rich, pellet (20000g centrifugal force), and soluble fractions in tea roots and leaves. [b]The means within the lines followed by A and B were significantly different ($p < 0.05$) among Al concentrations in the cell wall rich, pellet, and soluble fractions between tea roots and leaves.

possibly from the release from the pellet fraction during the homogenization were relatively low (approximately 12.3%), but this barely affected the results for Al and F. This result showed that the purity of the cell wall rich, pellet, and soluble fractions isolated from tea leaves was good for Al and F determination.

The total concentration of F in tea roots was 22.4 μg/g, and those in the cell wall rich, pellet, and soluble fractions of tea roots were 5.2, 4.9, and 11.1 μg/g, respectively, accounting for 24.6, 23.1, and 52.3% of that of the total fluoride that accumulated in tea roots, respectively (Table 2). The total concentration of F in leaves was 31.5 μg/g, and those in the cell wall rich, pellet, and soluble fractions of tea leaves were 5.6, 2.8, and 21.4 μg/g, respectively, which account for 18.9, 9.3, and 71.8% of that of the total fluoride that accumulated in tea leaves, respectively (Table 2). The amounts of F in the cell wall rich, pellet, and soluble fractions were 94.6% of those in intact roots and leaves.

Total Al concentrations in tea roots and leaves were 162.1 and 213.0 μg/g, respectively (Table 3). The concentration of total Al in tea leaves was 31.4% higher than that in tea roots. The concentrations of Al in the cell wall rich, soluble, and pellet fractions were 108.1, 34.6, and 12.1 μg/g, respectively, accounting for 69.8, 22.4, and 7.8% of that of the total Al that accumulated in tea roots, respectively (Table 3). In tea leaves, Al concentrations in the cell wall rich, soluble, and pellet fractions were 160.2, 37.7, and 15.1 μg/g, respectively, accounting for 75.2, 17.7, and 7.1% of that of the total Al found in tea leaves, respectively (Table 3). The sums of Al detected in the cell wall rich, pellet, and soluble fractions were 95.5 and 95.7% of that of the total Al measured in intact roots and leaves, respectively (Table 3). More than 70.0% of the total Al in tea roots and leaves was present in the cell wall rich fraction, suggesting that the cell wall rich fraction may immobilize more Al than the pellet and soluble fractions.

F and Al Concentrations in Protoplasts and Vacuoles. Vacuoles were isolated from protoplasts by the lysis of protoplasts and the subsequent purification process. α-Mannosidase is almost exclusively present in vacuoles and therefore considered as a marker enzyme of vacuoles.[27] The purity of vacuoles was examined under a light microscope and by the activity of α-mannosidase. The protoplasts separated from tea leaves were uniform in size (diameters from 15 to 30 μm), and the vacuoles were clearly observed, indicating that the vacuoles were successfully isolated from protoplasts (Figure 1).

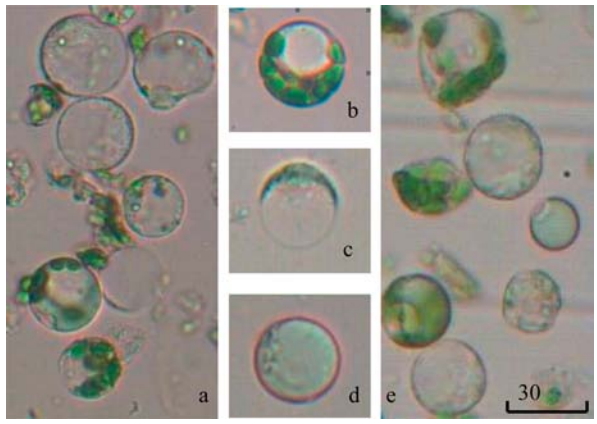

Figure 1. Light micrographs of protoplasts and vacuoles of tea leaves (400×): (a) mixture of protoplasts and vacuoles released from tea leaf pieces, (b) unvacuolated protoplasts, (c) swollen vacuoles, (d) intact vacuoles, and (e) protoplasts and vacuoles on a hemocytometer.

Assuming only one vacuole was released from each protoplast, the activities of α-mannosidase measured in 10^6 protoplasts and 10^6 vacuoles were approximately the same.[33] The activity of α-mannosidase in the vacuoles of the protoplasts of tea leaves was 7.7 nmol/min, accounting for 99.1% of that of the total α-mannosidase (7.6 nmol/min) in protoplasts (Table 4).

To detect the contamination of the vacuoles during the isolation of vacuoles from the protoplasts, extravacuolar marker enzymes, including glucose-6-phosphate dehydrogenase and cytochrome c oxidase, were measured in protoplasts and vacuoles (Table 4). The activities of glucose-6-phosphate dehydrogenase (the marker for cytosol) and cytochrome c oxidase (the marker for mitochondria) in vacuoles were 2.4 and

Table 4. Selected Enzyme Activities in Protoplasts and Vacuoles of Tea Leaves

enzyme	per 10^6 protoplasts (nmol/min)	per 10^6 vacuoles (nmol/min)	relative activity in vacuoles (%)[b]
α-mannosidase	7.7 ± 1.5 a[a]	7.6 ± 1.8 a	99.1
glucose-6-phosphate dehydrogenase	42.3 ± 3.9 a	1.0 ± 0.2 b	2.4
cytochrome *c* oxidase	65.4 ± 5.1 a	1.2 ± 0.3 b	1.8

[a]The averages within the lines followed by a and b represent significant differences ($p < 0.05$) among selected enzyme activity in 10^6 protoplasts and 10^6 vacuoles in tea leaves. [b]The ratio of activity in 10^6 vacuoles to that in 10^6 protoplasts.

1.8% of those detected in the protoplasts, respectively. This result indicated that the level of contamination of the vacuoles by cytosol and mitochondria from protoplasts was very low.

The amounts of F in 10^6 protoplasts and 10^6 vacuole rich fractions were 29.7 and 29.1 μg (fresh weigh), respectively, indicating that the vacuole rich factions contained 98.0% of the total F present in the homogenates of protoplast fractions (Table 5). The amounts of Al were 19.5 and 17.2 μg (fresh weigh) per 10^6 protoplasts and vacuole rich fractions, respectively (Table 5). Approximately 88.0% of the total Al in protoplasts was stored in the vacuole rich fractions. This result indicated that most of the F and Al was localized in the vacuole rich fractions of protoplasts after entering the cytoplasm.

Table 5. Amounts of F and Al in the Protoplasts and Vacuoles of Tea Leaves[a]

	F (μg)	Al (μg)
per 10^6 protoplasts	29.7 ± 3.6 a	19.5 ± 2.7 a
per 10^6 vacuoles	29.1 ± 4.2 a	17.2 ± 1.9 a
% in vacuoles	98.0	88.3

[a]The same letter in each row represents no significant difference ($p > 0.05$) among F and Al concentrations in 10^6 protoplasts and 10^6 vacuoles in tea leaves.

Distributions of Aluminum in Different Fractions of Tea Roots. The total concentration of Al in the whole cell walls was 108.1 μg/g, but the Al concentrations were reduced to 52.1 and 29.0 μg/g, respectively, after the pectin fractions and pectin and hemicellulose fractions had been removed (Table 6). This indicated that pectin and hemicellulose fractions immobilized 51.8 and 21.4% of the total Al, respectively, in the whole cell walls.

The adsorption experiments revealed that the quantities of Al adsorbed on the whole cell walls, cell wall residues without pectin, and cell wall residues without pectin and hemicellulose were increased by 41.0, 6.7, and 9.4%, respectively, as the adsorption time increased from 1 to 2 h (Table 6) . At each adsorption time, the amounts of Al adsorbed on the whole cell walls were significantly larger than those on the cell wall residues without pectin and the cell wall residues without pectin and hemicellulose. The amounts of Al adsorbed on the cell wall residues without pectin were reduced by 28.0 and 54.6% compared with those on the whole cell walls after adsorption for 1 and 2 h, respectively. When both pectin and hemicellulose were removed from the cell walls, the amounts of Al adsorbed on the residual fractions were reduced by 72.5 and 82.0% compared with those on the whole cell walls after adsorption for 1 and 2 h, respectively. These results indicated that pectin and hemicellulose in cell walls may immobilize large amounts of Al in the apoplasts of tea roots.

Table 6. Concentrations and Adsorption of Al in Different Fractions of Tea Roots

		Al adsorption (mg/g)	
	[Al] (μg/g)	1 h	2 h
whole cell walls	108.1 ± 5.8 a[a]	20.4 ± 0.6 aB[b]	34.6 ± 1.2 aA
cell wall residues without pectin	52.1 ± 0.4 b	14.7 ± 0.5 bA	15.7 ± 0.9 bA
cell wall residues without pectin and hemicellulose	29.0 ± 0.8 c	5.6 ± 0.3 cA	6.2 ± 0.7 cA

[a]The means within the columns followed by a–c were significantly different ($p < 0.05$) among Al concentrations or quantities of Al adsorbed on the whole cell walls, cell wall residues without pectin, and cell wall residues without pectin and hemicellulose of tea roots. [b]The means within the lines followed by A and B were significantly different ($p < 0.05$) among Al quantities adsorbed on the whole cell walls, cell wall residues without pectin, and cell wall residues without pectin and hemicellulose of tea roots between 1 and 2 h adsorption times.

DISCUSSION

Tea plants have been found to contain concentrations of Al and F higher than those of many other plants[34] without showing any signs of toxicity, suggesting that Al and F may be detoxified in tea plants. The detoxification by means of compartmentalization at the subcellular level is a common characteristic of hyperaccumulator plants. Sequestration in vacuoles has been suggested to be responsible for heavy metal tolerance in hyperaccumulator plants.[20] For instance, in hyperaccumulator *Thlaspi caerulescens*, Zn is primarily localized in the vacuoles.[21] More than 80% of the total Al in buckwheat leaves was present in the protoplasts, and most Al was localized in the vacuoles, demonstrating that Al was sequestered in the vacuoles of the leaves of plants in which Al accumulates.[19] This study shows that most of the F and Al were present in the soluble fractions of tea roots and leaves, and vacuoles contained 98.0% of the total F and 88.3% of the total Al measured in the protoplasts of tea leaves. This result suggested that internal detoxification of Al and F in the tea roots and leaves may be achieved by their sequestration into vacuoles.[35] In the vacuoles, Al may be chelated with citrate, oxalate, and other organic acids, because the Al–citrate and –oxalate complexes are the stable, less toxic forms of Al, reducing the toxicity of Al in vacuoles.[36] Free fluoride ion (F^-) can also be chelated with cations such as Al^{3+}, Fe^{3+}, and Ca^{2+}. Because the toxicity of AlF_n^{3-n} (such as AlF^{2+}, AlF_2^+, AlF_3, and AlF_4^-), Fe_n^{3-n} (such as FeF^{2+}, FeF_2^+, FeF_3, and FeF_4^-), and CaF_2 complexes is lower than that of F^-, the toxicity of F^- in tea plants can thus be reduced.

Compartmentalization in cell walls may be another major mechanism responsible for Al detoxicification. Root apoplastic spaces, including cell walls and intercellular spaces, are the first compartments of roots that make contact with the potentially toxic Al, and most of the Al that accumulates in roots corresponds to Al in this apoplastic space.[37] Our results demonstrate that cell walls contained 69.8 and 75.2% of the total Al detected in the tea roots and leaves, respectively. This is supported by the observations of Tolra et al.,[38] who indicated that Al was mainly localized in the cell walls of the leaf epidermal cells in tea plants. Carr et al.[39] found that Al in both

young and old tea leaves preferentially accumulated in the cell walls and that the Al concentration in this compartment increased with time. Because cell walls are regarded as a pivotal site for metal storage in plants,[40,41] the deposition of metals in cell walls is considered to be a crucial mechanism for improving heavy metal tolerance. Taylor et al.[35] pointed out that the cell wall is the major site of Al accumulation, and the immobilization of Al in cell walls was one of the crucial exclusion mechanisms for Al detoxification.[16] Wang et al.[42] revealed that more than 85% of the Al absorbed in maize roots was localized in cell walls. In plant cell walls, pectin is a polysaccharide containing galacturonic acids with high electronegativity, which can easily chelate with Al and thus immobilize the Al in cell walls. It was found that both the contents and methylation of pectin contributed to the tolerance of maize to Al toxicity.[43] These results indicate that when pectin was removed from the cell walls of tea roots, the Al concentrations were reduced by 51.8%, and the adsorption of Al in the cell wall residues also significantly declined. These findings suggested that the pectin fractions in the cell walls of tea roots may fix the Al in apoplasts and thus reduce the toxicity of Al to tea plants.

The positive correlations between F and Al concentrations in tea plants have been observed, leading to the hypothesis that the uptake of F and Al were somewhat linked.[44] Free fluoride ions (F^-) can be chelated with aluminum ions (Al^{3+}) in the forms of AlF^{2+}, AlF_2^+, AlF_3, AlF_4^-, etc.[34] F and Al in the forms of Al−F complexes were readily taken up and transported in the xylem of tea shoots.[13,45] Al−F complexes such as AlF_2^+ and AlF^{2+} were less toxic than hydroxy and Al^{3+} forms such as Al^{3+}, $Al(OH)_2^+$, and $Al(OH)^{2+}$.[46] These findings suggested that the forms of F and Al also determined their toxicity to tea plants. F and Al complexes could be in the form of AlF^{2+}, AlF_2^+, AlF_3, AlF_4^-, etc., or their combinations. However, the exact forms of F and Al complexes in the different subcellular fractions of tea plants are still unclear. Consequently, further studies are needed to understand the chemical species of Al−F complexes in different parts of tea plants to determine the mechanisms of the tolerance of tea plants to F and Al toxicity.

This led researchers to monitor stable isotope labeled anthocyanins in grapes cultured in vitro at high and low temperatures, demonstrating that high temperatures resulted in anthocyanin degradation.[15] Increased temperature has been shown to alter the profile of anthocyanins, resulting in an increase of trihydroxylated as well as acetylated and coumarylated moiety proportions.[16,17] At present, a clear understanding of temperature's influence on individual anthocyanin regulation and/or degradation is still lacking.

The perceived quality of red grapes for winemaking is highly dependent on the resulting pigmentation of the final wine.[18] Although color is not the only factor, red grapes grown in warm growing regions such as the central valley of California, Riverlands in Australia, or Languedoc in France have only moderate color and command prices that are significantly lower than those grown in cooler regions. With an increased understanding of how warm climates affect anthocyanin concentrations, it may be possible to improve the pigmentation of warm-region grapes. An understanding of the mechanisms that control color loss as suggested below may lead to treatments to preserve color in warmer climates.

To address the need for following the metabolic pathway of anthocyanins in grape berries, a method was recently reported that utilizes a distinct isotopic label.[19] Tracing this label can provide a means to follow the appearance and loss of substances in the phenylpropanoid pathway as well as how environmental factors may influence the pathway. Anthocyanin turnover has been shown in *Brunfelsia calycina* flowers and in mustard seedlings;[20,21] however, the prevention of anthocyanin degradation has only recently been targeted for color improvement in agricultural crops.[22] Anthocyanin degradation in grapes has been demonstrated, but only using an in vitro model on Petri dishes.[15] The current study utilizes L-phenyl-$^{13}C_6$-alanine (Phe^{13}) as a tracer to investigate flavonoid metabolism and catabolism in *V. vinifera* cv. Cabernet Sauvignon berries on the vine throughout maturation during two growing seasons to begin to address the color issue in warm-climate grapes.

MATERIALS AND METHODS

Sample Collection and Tracer Addition. This research utilizes a method that was recently developed and is briefly described below. Grape samples came from self-rooted Cabernet Sauvignon, Clone 8, vines in the Hopkins experimental vineyard at the University of California, Davis, CA, USA. Grape maturation studies were conducted during the summers of 2010 and 2011 on clusters selected from contiguous vines within a single row. Grape berry clusters were soaked in Phe^{13} for 48 h while remaining on the vine at two different stages of maturity: unripe green grapes and ripening red grapes.

In 2010, the grape clusters were treated with tracer on July 29 and August 31 for green and red treatments, respectively. In 2011, grape clusters received tracer on July 7 and August 22 for green and red treatments, respectively. For each treatment, 4 clusters received the tracer, and 3 individual grapes from each cluster were harvested for each time point, yielding 12 berries per time point. The excised berries were frozen at −80 °C and stored until extraction.

Extraction and LC-DAD-MS/MS Analysis. Individual, lyophilized grape berries without their seeds were extracted in 60% acetone for 24 h. The supernatant was then centrifugally evaporated and reconstituted in water. The resulting extract was stored at −80 °C until analysis by HPLC-DAD-MS/MS. Analysis of grape extracts was conducted using an Agilent series 1200 instrument in line with an Agilent 6430 triple-quadrupole mass spectrometer with electrospray injection (Agilent Technologies, Santa Clara, CA, USA). A binary gradient of 10% formic acid in water versus pure acetonitrile was used to separate phenolics on an Agilent Zorbax SB-C18 Rapid Resolution HT small-particle column (4.6 mm × 100 mm, 1.8 μm) with a precolumn filter. The diode array detector (DAD) monitored four wavelenths: 280, 316, 365, and 520 nm. The mass spectrometer acquired data using "dynamic MRM" mode so it was possible to measure positively and negatively ionized isotopomers during the same run. Specific retention times and MRM transitions for each isotopomer can be found in our previous publication.[19] Quantitation of total phenolic levels was achieved through external standardization by UV−vis absorbance using representative standards for each class of compounds (caffeic acid for hydroxycinnamates, rutin for flavonols, and malvidin-3-glucoside for anthocyanins). The total concentration was then multiplied by the ratio of labeled to unlabeled phenolics to determine their respective concentrations. External standards of Phe and Phe^{13} were used for quantitation by LC-MRM-MS (166.3 → 120 and 172.3 → 126, respectively). The graphical heatmaps in Figures 2 and 3 were created using the open source Excel add-in imDev.[23]

Statistical Analysis. Comparisons of each metabolite over time were analyzed using R (version 3.0.2). A one-way ANOVA with p values adjusted for multiple hypothesis testing at $q = 0.05$ was used to determine significant changes over time for each metabolite in red and green berries from 2010 and 2011.[24]

RESULTS AND DISCUSSION

Using our recently developed technique to incorporate stable isotopic label into grape flavonoids in situ, we sought to probe the evolution and turnover of grape phenolics throughout maturation.[19] Multiple classes of Phe-derived phenolics were monitored throughout the maturation process over two vintages, providing a rare glimpse of overall phenolic metabolism. Furthermore, using the Phe^{13} tracer, we hoped to shed light on several facets of grape phenolic metabolism: the disappearance of hydroxycinnamates, the different patterns of flavonol biosynthesis, and the turnover or degradation of anthocyanins. Although our tracer did not perform exactly as we had expected, the deviations from our expectations suggest there are even more mysteries in phenolic substrate regulation.

Levels of grape phenolics were monitored throughout the 2010 and 2011 growing seasons starting on July 29 and July 7, respectively. In addition, the stable isotopic tracer L-phenyl-$^{13}C_6$-alanine was introduced to berry clusters on the vine two times during each season to observe the incorporation of label at two stages of maturity: green preripened and red ripening grapes. Following each of the four treatments, the concentrations of both unlabeled and labeled phenolic metabolites were monitored throughout the ripening season. Berry variability was generally below 15, 20, or 15% (relative standard error) for unlabeled hydroxycinnamates, flavonols, and anthocyanins at concentrations above 10 nmol/berry, respectively (Supporting Information file 1).

Phenylalanine Tracer. Phenylalanine levels ranged from 7.3 to 57.2 nmol/berry in 2010 and from 12.0 to 112.2 nmol/berry in 2011 in the red and green grape trials (Figure 1b). After the treatment of the clusters, Phe^{13} was readily found in the grape berries, and its gradual decline typically followed within 2 weeks. However, in all four trials a steady, but very low, level of Phe^{13} persisted until the end of the season, in one case 89 days after the treatment was concluded (Figure 1b). In both years more Phe^{13} was absorbed into red berries, although we cannot explain why this occurred.

Phenolic Metabolites during Maturation. Hydroxycinnamate tartrate esters were already present in green grapes prior to treatment and declined precipitously after the onset of ripening. Caftaric, *cis*-coutaric, and *trans*-coutaric acids dropped to <10% of their initial values over the course of the

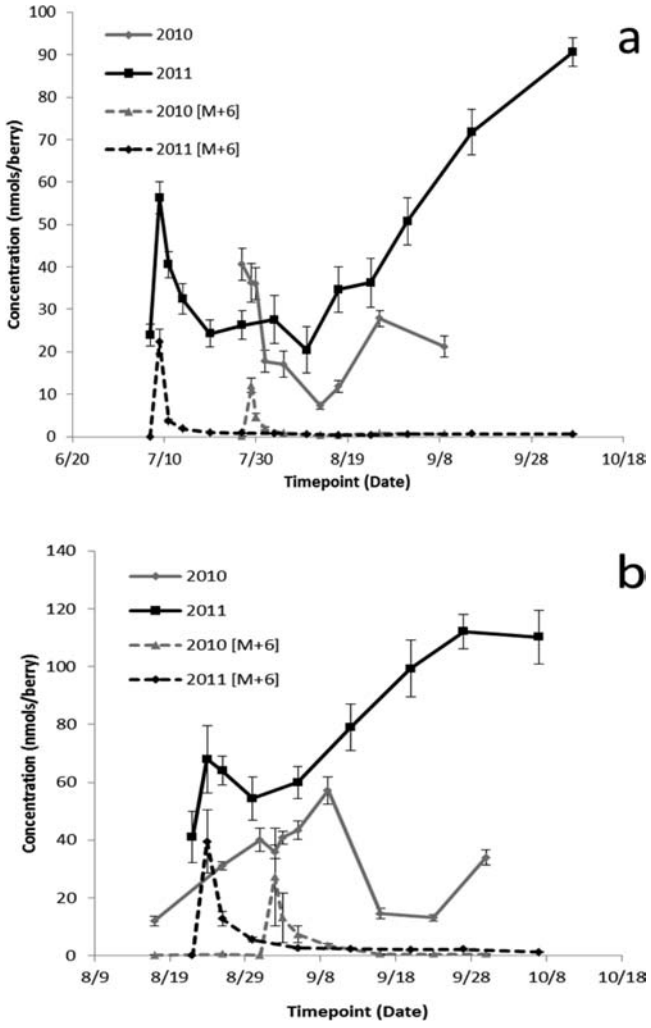

Figure 1. Average phenyalanine concentration ± standard error (nmol/berry) in labeled and unlabeled grape berries following treatment with Phe[13] in (a) green and (b) red grapes.

experiments (Supporting Information file 1), consistent with previous studies.[3−5] Although miniscule amounts of labeled *cis*-coutaric and *trans*-coutaric acids were detected at a few time points from green grapes in 2010 and 2011, their quantities were below the limit of quantitation (data not shown). Label was never found in caftaric acid or in any of the hydroxycinnamates in treated red grapes. The tiny, or nonexistent, labeling of these phenylpropanoids could be a result of the hydroxycinnamic−tartrate ester pool having already been amassed with no further biosynthesis or from the label not entering the pulp of the berry, where these compounds are synthesized and stored.

Flavonols, with the exception of quercetin-3-*O*-glucuronide, were not present in great quantity per berry prior to the onset of ripening. After the onset of ripening, levels steadily increased for 3−4 weeks until reaching a semisteady state. Quercetin-3-*O*-glucuronide, on the other hand, was present at the beginning of each experiment, and its level did not appear to be strongly influenced by maturity. Incorporation of tracer into flavonols depended on grape maturity at the time of treatment. Green grapes that were treated produced detectable levels of myricetin, quercetin, laricitran (2011 only), and kaempferol moieties, whereas quercetin was the sole flavonol found in treated red grapes. With the exception of quercetin, each of the labeled flavonols did not appear until after the onset of ripening. Ultimately, labeled flavonols were present in very minute amounts, most likely due to the dominance of anthocyanin production occurring simultaneously (Supporting Information file 1).

The entire anthocyanin data set is represented in four graphical heatmaps standardized by the relative quantities of each metabolite (Figures 2 and 3). With the exception of the malvidin moieties, anthocyanin ripening profiles generally followed a consistent pattern regardless of substitutions on the 3-*O*-glucose. Concentrations tended to peak in mid to late August but declined in 2010 and remained stagnant in 2011 during the remainder of the season. Malvidin moieties, on the other hand, climbed steadily throughout maturation and often continued to accumulate (Figure 4a), especially the acetylated and coumarylated varieties, until the end of the trial.

Although previous studies consistently indicate that comparative higher temperatures tend to increase the proportion of hydroxylated and methylated anthocyanin B rings,[16,17] many studies have not commented on the change in profile over the ripening process. Our results indicate that moieties of malvidin and, to a lesser extent, peonidin tend to increase during late-stage ripening, whereas cyanidin and dephinidin decrease (Figures 2a and 3a). A previous study also showed cyanidin to decrease during late-stage ripening; however, in the same study delphinidin continued to increase.[10] In our study, it is unclear whether the decrease of di- and trihydroxylated anthocyanins represents anthocyanin degradation or if the shift represents continued metabolism by anthocyanin *O*-methyltransferase (AOMT), which may be the dominant pathway in grapes.[25,26] Acylated anthocyanins also showed similar trends during ripening during 2010 and 2011; however, AOMT has shown no affinity for coumarylated anthocyanins,[27] and no studies to our knowledge have assessed the enzyme's activity with acetylated anthocyanins.

Overall, the total quantity of incorporated label per berry varied depending upon the time of incorporation (Supporting Information file 1). The sum of incorporated label detected in all of the labeled metabolites reached 46, 7, 16, and 13% of the maximum concentration of Phe[13] measured in 2010 and 2011 green and 2010 and 2011 red berries, respectively. The large difference between 2010 and 2011 green incorporation percentages reflects the addition of tracer at the onset of ripening in 2010 versus tracer addition 2−3 weeks prior to veraison in 2011. These data illustrate that adding tracer immediately prior to veraison resulted in the greatest recovery of label.

Labeled Anthocyanins during Maturation. Labeled anthocyanins were typically present at 0.1−1% of their unlabeled counterparts, depending on how recently the grapes were treated in green grapes or the stage of maturity in red grapes. The variability of labeled anthocyanins within 12 replicate berries was generally below 30% in red-treated grapes and below 20% (relative standard error) in green-treated grapes (Supporting Information file 1). Labeled metabolites in red grapes from 2011 tended to have higher variation and resulted in only a select few labeled metabolites varying significantly over time (Figure 3b). Labeled cyanidin and delphinidin moieties tended to increase rapidly after tracer incorporation in red grapes or after the onset of ripening in green grapes but began to decrease shortly thereafter, with the exception of red grapes labeled in 2010, which experienced a slight surge in late September. After rising rapidly, labeled petunidin tended to

level off and remain constant during ripening. Labeled peonidin profiles appeared erratic, whereas malvidin was the only labeled anthocyanin to regularly increase in concentration throughout ripening (Figure 4b). However, both malvidin and peonidin

dx.doi.org/10.1021/jf402229u | J. Agric. Food Chem. 2014, 62, 2321−2326

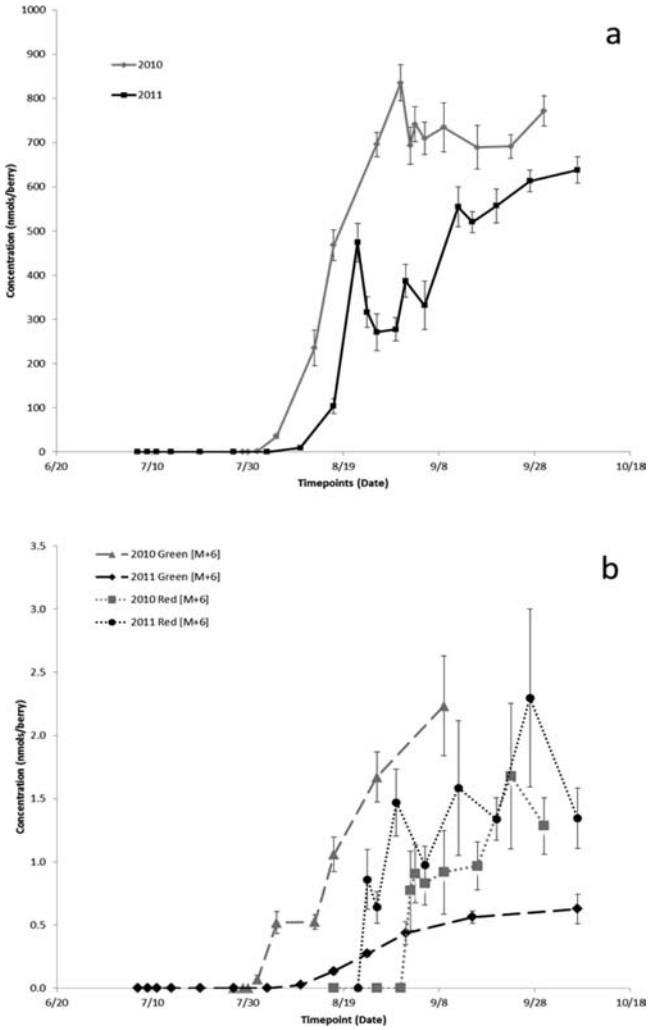

Figure 4. Average malvidin-3-glucoside (M-3-G) concentration ± standard error (nmol/berry) during the 2010 and 2011 growing seasons: (a) ripening profile of unlabeled M-3-G throughout ripening; (b) labeled M-3-G in grape berries following Phe^{13} addition to green and red grapes. Each metabolite varied significantly due to the influence of date with the exception of labeled M-3-G in red 2011 grapes.

had consistently higher percentages of label (labeled/unlabeled) as compared to delphinidin, petunidin, and cyanidin in red grape treatments. When considered alongside the development profiles, this may indicate that AOMT activity is active throughout the metabolism of anthocyanins and acts upon compounds typically considered final metabolites (i.e., delphinidin, cyanidin, petunidin), whereas flavonoid-3′,5′-hydroxylase does not.

A notable intricacy of anthocyanin metabolism in grapes is the production of coumarylated anthocyanins. When Phe^{13} is present, three labeled isotopomers become possible: a labeled anthocyanidin (antho^{13}-cou), a labeled *p*-coumaroyl group (antho-cou^{13}), and a molecule that contains both the labeled anthocyanidin and a *p*-coumaroyl group. The relative incorporation of label between these different isotopomers can provide information on pathway regulation. In our study, when red grape berries were treated with Phe^{13}, there was an increase in the proportion of antho-cou^{13} as compared to antho^{13}-cou. However, this trend was not observed when green grapes were treated; the antho-cou^{13} and antho^{13}-cou isotopomers of malvidin had the same proportions as compared to the unlabeled moiety. This trend indicates that coumarate may be esterified to anthocyanin glucosides well after their initial biosynthesis. Under this hypothesis, when label is added to red grapes, labeled coumaryl groups are conjugated to existing, unlabeled anthocyanins in addition to newly produced, labeled anthocyanins, whereas when the label was added to green grapes, the label formed a uniform pool that was distributed equitably between the two possible positions after the onset of ripening.

Persistence of Label and Implications. Perhaps the most interesting result of the study is the production of labeled anthocyanins as late as 1 month after tracer addition (Figures 1a and 2a) in green grapes incubated in 2011. Whereas the concentration of Phe^{13} dropped to, and remained less than, 1 nmol/berry by July 20, anthocyanins did not begin to be produced until August 10, 2011. Despite the apparent low levels of Phe^{13}, labeled malvidin-3-glucoside continued to accumulate until September 15, 2011. In fact, in all treatments, levels of Phe^{13} dropped to <1 nmol/berry but remained persistent throughout ripening (Supporting Information file 1). This holdover of label indicates that there may be an intermediate pool of label held sequestered in grape berries until the onset of ripening when phenylpropanoid metabolism is ramped up. We suspect that the large in-flux of Phe^{13} is readily converted into a storage form and is subsequently released as needed during maturation. The most obvious candidate for the hypothetical pool of stored label is in the form of phenolamides. Phenolamides are known to exist in grape berries[28] and have been recently suggested as serving as intermediates for phenolic metabolism.[29] Phenolic metabolism has long been assumed to occur directly from phenylalanine, but mounting evidence supports the theory that there is an intermediate substrate pool that may be accumulated and further metabolized under demand. Ultimately, further research must be completed to confirm and identify the hidden source of labeled Phe^{13} that seems apparent here.

Using the longstanding model of phenylpropanoid metabolism, our experiment was designed to follow the lifetime of individual anthocyanins after they were labeled with stable isotopic tracer. Our results demonstrated the expected accumulation of anthocyanins and the direction of label almost exclusively to those flavonoids. However, under this design, we hoped to estimate the turnover of anthocyanins in grape berries in situ. However, the unexpected persistence of labeled substrate prevented a fair assessment of turnover because we continued to see biosynthesis of labeled metabolites well after each treatment. This persistence of label presents new evidence that there may be an intermediate pool of phenolic substrate in grape berries, perhaps stored in anticipation of the onset of ripening. Future studies to uncover the intermediate pool as well as to compare tracer incorporation and turnover between warm- and cool-climate grapes are underway.

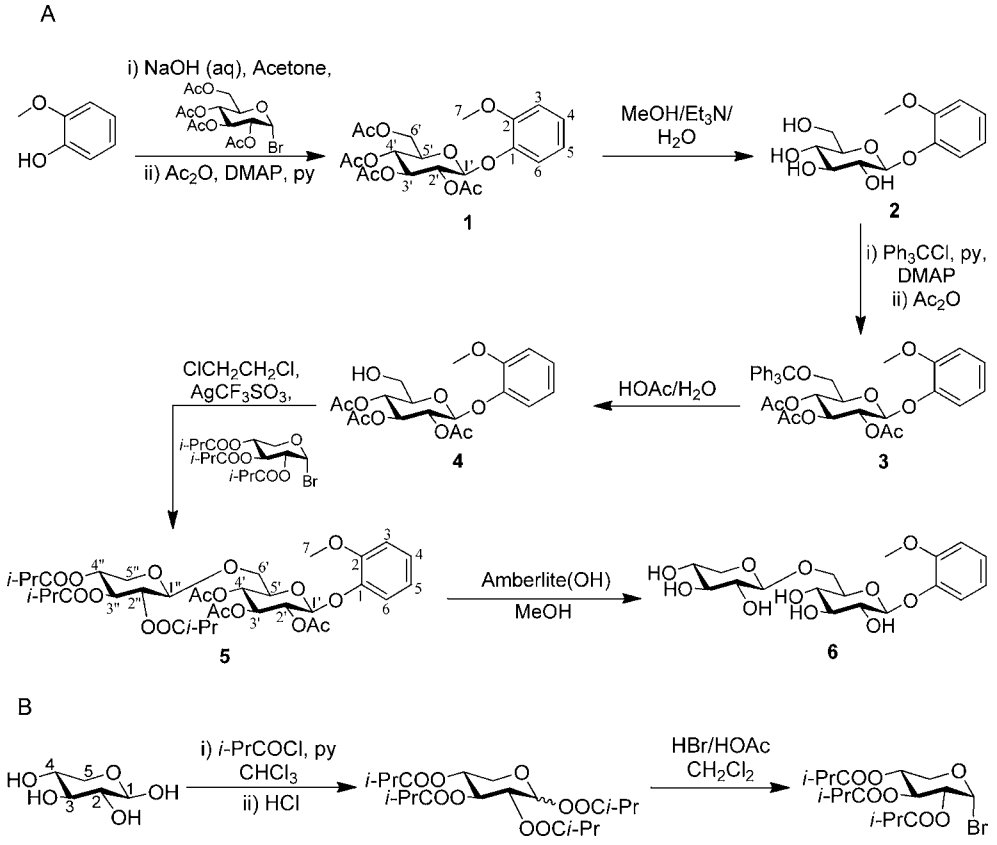

Figure 1. Synthesis of (A) guaiacyl β-D-primeveroside (6) and (B) tri-*O*-isobutyryl-α-D-xylopyranosyl bromide.

bushfires that occurred in the period 7 February−14 March 2009. These fires, particularly those in the period of 7 February, were of extremely high intensity, causing extensive loss of vineyards and winery buildings in the Yarra Valley, and can be considered one of the worst fire events in Australia's history. Smoke was present in the area for an extended period as a result. Smoke-exposed grapes and wines made from smoke-exposed grapes were obtained from producers who identified these as showing clear smoke flavor.

Materials. Guaiacol, 4-methylguaiacol, *o*-cresol, *m*-cresol, *p*-cresol, syringol and 4-methylsyringol, and d_7-*p*-cresol were purchased from Sigma-Aldrich (Castle Hill, Australia). d_3-Guaiacol and d_3-4-methylguaiacol had been previously synthesized in-house.[9,10] d_3-Syringol was prepared according to the method of Aihara et al.,[11] and syringol β-D-glucoside and syringol β-D-gentiobioside were synthesized in house, as previously reported.[7] All chemicals were analytical-reagent-grade unless otherwise stated. Water was obtained from a Milli-Q purification system (Millipore, North Ryde, Australia).

Guaiacol-β-D-Primeveroside (2-methoxyphenyl-6-*O*-(β-D-xylopyranosyl)-β-D-glucopyranoside) Synthesis. All chemicals were analytical-reagent grade. Guaiacyl β-D-primeveroside (**6**) was synthesized using a procedure (Figure 1A) based on a method employed previously by our group to prepare d_3-syringyl β-D-gentiobioside.[12] Briefly, guaiacyl-2′,3′,4′-tri-*O*-acetyl-β-D-glucopyranoside (**4**) was prepared in four steps by coupling guaiacol and tetra-*O*-acetyl-α-D-glucopyranosyl bromide, followed successively by glucose deprotection, tritylation, and acetylation, and finally detritylation. The protected disaccharide was prepared using synthesized isobutyryl-protected xylopyranosyl bromide as the glycosyl donor (Figure 1B) to avoid excessive orthoester byproduct formation during coupling. Deprotection with Amberlite(OH) resin gave the disaccharide **6**.

Instrumentation. Proton (^{1}H) and carbon (^{13}C) Nuclear Magnetic Resonance (NMR) spectra were recorded with a Bruker spectrometer operating at 400 or 600 MHz for proton and 100 or 150 MHz for carbon nuclei, respectively. Chemical shifts were recorded as δ values in parts per million (ppm). Spectra were acquired in chloroform-*d* or deuterium oxide (D_2O) at ambient temperature, and resonances were assigned by routine 2D correlation experiments. For ^{1}H NMR spectra, the peak as a result of residual $CHCl_3$ (δ 7.26) or the CH_3 peak of acetonitrile (δ 2.06), added when D_2O was the solvent, was used as the internal reference. For ^{13}C NMR spectra, the central peak of the $CDCl_3$ triplet (δ 77.16) or the CH_3 peak of acetonitrile (δ 1.47), added when D_2O was the solvent, was used as the internal reference. High-Resolution Mass Spectrometry (HRMS) spectra were obtained on a Bruker microTOF-Q II with electrospray ionization (ESI) or atmospheric-pressure chemical ionization (APCI) in positive mode. Samples dissolved in water or methanol at concentrations of approximately 1−2 mg/L were analyzed by flow injection. Specific optical rotations were recorded with a PolAAr 21 polarimeter, referenced to the sodium D line (589 nm) at 20 °C, using the spectroscopic-grade solvents specified and at the concentrations (*c*, g/100 mL) indicated. The measurements were carried out in a cell with a 1 dm path length. Melting points were measured with a Buchi Melting Point B-540 unit and were uncorrected.

Synthesis of Tri-O-isobutyryl-D-xylopyranose. Isobutyryl chloride (51 g, 480 mmol) in $CHCl_3$ (100 mL) was added dropwise to a stirred solution of D-(+)-xylose (10 g, 68 mmol) in anhydrous pyridine (49 mL, 610 mmol) at 0 °C under N_2. The yellow mixture was stirred at room temperature for 18 h. The resultant orange mixture was diluted with a further 200 mL $CHCl_3$ and washed with 2 M HCl (3 × 150 mL), saturated $NaHCO_3$ (3 × 150 mL), water (2 × 50 mL), and brine (3 × 50 mL). The organic layer was dried (Na_2SO_4), filtered, and concentrated in vacuo. The oily reaction product was purified by silica gel column chromatography eluted with 15% EtOAc/hexane to give a colorless oil as a 97:3 mixture of α/β epimers (29 g, 99%). R_f 0.33 (15% EtOAc/hexane). $[\alpha]_D$ + 65.4 (*c* 0.67, CH_2Cl_2). ^{1}H NMR for α epimer (600 MHz, $CDCl_3$): δ 6.27 (1H, d, J = 3.7 Hz, H_1); 5.52 (1H, t, J = 9.9 Hz, H_3); 5.06 (1H, dd, J = 9.9, 3.7 Hz, H_2); 5.05 (1H, dd, J = 11.1, 9.9 Hz, H_4); 3.91 (1H, dd, J = 11.0, 5.8 Hz, H_{5eq}); 3.68 (1H, app t, J = 11.0 Hz, H_{5ax}); 2.70−2.41 (4H, m, C*H*Me$_2$); 1.24−1.07 (24H, m, Me). ^{13}C NMR (150 MHz, $CDCl_3$): δ 176.10−175.10 (C═O); 89.16

Synthesis of Tri-O-isobutyryl-α-D-xylopyranosyl Bromide. Under an N_2 atmosphere with NaOH pellets in a trap, 33% HBr/HOAc (12 mL, 66 mmol) was added to a stirred solution of tetra-*O*-isobutryl-D-xylose (97:3 *α*:*β*, 6.2 g, 14 mmol) in CH_2Cl_2 (30 mL) at 0 °C. After 20 h, CH_2Cl_2 (200 mL) was added, and the reaction mixture was successively washed with sat. aq. $NaHCO_3$ solution (2 × 100 mL), H_2O (100 mL), and brine (100 mL). The organic layer was dried (Na_2SO_4) and concentrated in vacuo (5.8 g, 95%). A portion was recrystallized from EtOH for characterization purposes to afford tri-*O*-isobutyryl-*α*-D-glucopyranosyl bromide as white crystals.

R_f 0.73 (1:4:95 petroleum ether/Et_2O/CH_2Cl_2), mp 54.1−54.7 °C. $[\alpha]_D$ + 179.2 (*c* 0.94, $CHCl_3$). ^1H NMR (400 MHz, $CDCl_3$): *δ* 6.57 (1H, d, *J* = 4.1 Hz, H_1); 5.62 (1H, t, *J* = 9.8 Hz, H_3); 5.06 (1H, td, *J* = 10.3, 5.9 Hz, H_4); 4.78 (1H, dd, *J* = 9.8, 4.1 Hz, H_2); 4.03 (1H, dd, *J* = 11.2, 5.9 Hz, H_{5eq}); 3.87 (1H, app t, *J* = 11.2 Hz, H_{5ax}); 2.56 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 2.53 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 2.50 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 1.17−1.10 (18H, m, $(CH_3)_2CH$). ^{13}C NMR (100 MHz, $CDCl_3$): *δ* 176.04−175.73 (*C*=O); 87.97 (C_1); 70.81 (C_2); 69.22 (C_3); 67.84 (C_4); 62.78 (C_5); 34.04−33.93 ($CHMe_2$); 19.04−18.78 (6 × $(CH_3)_2CH$). APCI-HRMS (m/z): $[M-Br]^+$ Calcd for $C_{17}H_{27}O_7^+$ 343.1751; Found, 343.1757.

*Synthesis of Guaiacyl 2′,3′,4′,6′-tetra-O-acetyl-β-D-glucopyranoside (**1**).* Under N_2, a solution of tetra-*O*-acetyl-*α*-D-glucopyranosyl bromide (3.9 g, 9.4 mmol) in acetone (20 mL) was added via cannula into a stirred solution of guaiacol (1.2 g, 9.5 mmol) in 0.3 M NaOH (31.5 mL, 9.5 mmol). The resultant orange reaction mixture was stirred under N_2. The pH was monitored and maintained at 12 over a 5 h period using 1 M NaOH. The solution was acetylated with Ac_2O (8.5 mL, 90 mmol) and 4-dimethylaminopyridine (DMAP) (10 mg, 0.08 mmol) in pyridine (9 mL, 110 mmol) and stirred overnight at room temperature. The flask was concentrated in vacuo to give a syrup. Et_2O/CH_2Cl_2 (4:1, 150 mL) was added, and the suspension was filtered then washed successively with 0.2 M HCl (2 × 75 mL), water (3 × 50 mL), and brine (3 × 50 mL). The organic layer was dried (Na_2SO_4), filtered and concentrated in vacuo. The crude product was purified by silica gel column chromatography using 0→5% Et_2O/CH_2Cl_2 giving a white solid. This was recrystallized from EtOH to give 1.4 g (34%) of **1** as white crystals. R_f 0.33 (10% Et_2O/CH_2Cl_2). ^1H NMR data agreed with the literature.[13]

*Synthesis of Guaiacyl β-D-glucopyranoside (**2**).* A suspension of **1** (1.4 g, 3.2 mmol) was stirred in a mixture of MeOH/Et_3N/H_2O (8:1:1, 25 mL) overnight at room temperature. Additional MeOH/Et_3N/H_2O (8:1:1, 5 mL) was added, and the solution was stirred for a further 5 h. The resultant clear solution was concentrated in vacuo, H_2O was added, and the solution was concentrated again. This procedure was repeated several times until the solid reached a constant weight. This crude solid was recrystallized from EtOH to give **2** as a white crystalline solid (820 mg, 90%). ^1H NMR data agreed with the literature.[8]

*Synthesis of Guaiacyl-2′,3′,4′-tri-O-acetyl-6′-O-trityl-β-D-glucopyranoside (**3**).* Anhydrous pyridine (2.2 mL, 27 mmol) was added via syringe to **2** (0.63 g, 2.2 mmol), DMAP (8 mg, 0.07 mmol), and Ph_3CCl (1.1 g, 3.8 mmol) under a N_2 atmosphere. The mixture was stirred at 50 °C for 9 h, and then stirred overnight at room temperature. Ac_2O (2.2 mL, 23 mmol) was added, and the reaction was stirred for a further 90 min. The flask was placed on ice, MeOH (2.5 mL) was added, and the resultant mixture was stirred for 30 min. The solvent was removed in vacuo, and the crude solid was dissolved in CH_2Cl_2. This solution was washed sequentially with 0.2 M HCl, water, and brine. The organic layer was dried (Na_2SO_4), filtered, and concentrated in vacuo. The crude material was purified by silica gel column chromatography eluted with 3→10% Et_2O/CH_2Cl_2 to give a white solid (800 mg, 56%). R_f 0.24 (3% Et_2O/CH_2Cl_2). mp 90−95 °C. $[\alpha]_D$ +13.8 (*c* 0.44, $CHCl_3$). ^1H NMR (600 MHz, $CDCl_3$): *δ* 7.45 (6H, dt, *J* = 7.7, 1.6 Hz, *ortho* CPh_3); 7.36 (1H,, dd, *J* = 7.9, 1.4 Hz, H_6); 7.28 (6H, tt, *J* = 7.7, 1.6 Hz, *meta* CPh_3); 7.22 (3H, tt, *J* = 7.2, 1.6 Hz, *para* CPh_3); 7.09 (1H, td, *J* = 7.9, 1.4 Hz, H_4); 6.93 (1H, dd, *J* = 7.9, 1.4 Hz, H_3); 6.90 (1H,td, *J* = 7.9, 1.4 Hz, H_5); 5.36 (1H, dd, *J* = 9.3, 8.0 Hz, $H_{2'}$); 5.24 (1H, app t, *J* = 9.3 Hz, $H_{3'}$); 5.20 (1H, app t, *J* = 9.5 Hz, $H_{4'}$); 4.97 (1H, d, *J* = 8.0 Hz, $H_{1'}$); 3.84 (3H, s, H_7); 3.62 (1H, ddd, *J* = 9.5, 5.4, 2.2 Hz, $H_{5'}$); 3.22 (1H, dd, *J* = 10.4, 2.2 Hz, $H_{6b'}$); 3.15 (1 H, dd, *J* = 10.4, 5.4 Hz, $H_{6a'}$); 2.08 (3H, s, $COCH_3$); 2.02 (3H, s, $COCH_3$); 1.74 (3H, s, $COCH_3$). ^{13}C NMR (150 MHz, $CDCl_3$): *δ* 170.56 (C=O); 169.69 (C=O); 169.14 (C=O); 150.81 (C_2); 146.42 (C_1); 143.67 (*ipso* CPh_3); 128.78 (*ortho* CPh_3); 127.94 (*meta* CPh_3); 127.13 (*para* CPh_3); 124.68 (C_4); 121.04 (C_5); 120.49 (C_6); 112.71 (C_3); 101.07 ($C_{1'}$); 86.73 (CPh_3); 73.65 ($C_{5'}$); 73.00 ($C_{3'}$); 71.53 ($C_{2'}$); 68.82 ($C_{4'}$); 61.88 ($C_{6'}$); 56.12 (C_7); 20.86 (2 × $COCH_3$); 20.51 ($COCH_3$). APCI-HRMS (m/z): Calcd for $C_{38}H_{42}NO_{10}^+$ ($[M + NH_4]^+$), 672.2803; Found, 672.2791.

Compound **3** (390 mg, 0.59 mmol) was dissolved in HOAc/H_2O (4:1, 3.9 mL), and the solution was stirred under N_2 at 60 °C for 4 h. The reaction mixture was cooled, toluene (3 mL) was added, and the solution was concentrated in vacuo. This step was repeated twice, and the crude material was purified by silica gel column chromatography eluted with 20% Et_2O/CH_2Cl_2 to give **4** as a white solid (200 mg, 83%). R_f 0.18 (15% Et_2O/CH_2Cl_2). mp 160.6−160.8 °C. $[\alpha]_D$ = −30.8 (*c* 0.55, CH_2Cl_2). ^1H NMR (600 MHz, $CDCl_3$): *δ* 7.08 (1H, dd, *J* = 7.8, 1.2 Hz, H_6); 7.06 (1H, td, *J* = 7.8, 1.2 Hz, H_4); 6.90 (1H, dd, *J* = 7.8, 1.2 Hz, H_3); 6.87 (1H, td, *J* = 7.8, 1.2 Hz, H_5); 5.32 (1H, app t, *J* = 9.5 Hz, $H_{3'}$); 5.26 (1H, dd, *J* = 9.5, 7.8 Hz, $H_{2'}$); 5.10 (1H, app t, *J* = 9.5 Hz, $H_{4'}$); 5.02 (1H, d, *J* = 7.8 Hz, $H_{1'}$); 3.81 (3H, s, H_7); 3.74 (1H, ddd, *J* = 11.9, 8.2, 2.0 Hz, $H_{6b'}$); 3.63 (1H, dd, *J* = 11.9, 5.9 Hz, $H_{6a'}$); 3.59 (1H, ddd, *J* = 9.5, 5.0, 2.0 Hz, $H_{5'}$); 2.35 (1H, dd, *J* = 7.8, 5.9 Hz, *OH*); 2.07 (3H, s, $COCH_3$); 2.05 (3H, s, $COCH_3$); 2.03 (3H, s, $COCH_3$). ^{13}C NMR (150 MHz, $CDCl_3$): *δ* 170.45 (C=O); 170.13 (C=O); 169.54 (C=O); 150.71 (C_2); 146.12 (C_1); 124.80 (C_4); 121.02 (C_5); 119.96 (C_6); 112.82 (C_3); 100.84 ($C_{1'}$); 74.46 ($C_{5'}$); 72.63 ($C_{3'}$); 71.48 ($C_{2'}$); 68.74 ($C_{4'}$); 61.45 ($C_{6'}$); 56.07 (C_7); 20.79−20.77 (3 × $COCH_3$). *Synthesis of Guaiacyl-2′,3′,4′-tri-O-acetyl-2″,3″,4″-tri-O-isobutyryl-β Primeveroside (**5**).* Under a N_2 atmosphere at −15 °C, anhydrous 1,2-dichloroethane (2.6 mL) was added to $AgCF_3SO_3$ (0.12 g, 0.48 mmol), activated 4 Å molecular sieves (0.23 g), tri-*O*-isobutyryl-*α*-D-xylopyranosyl bromide (190 mg, 0.45 mmol) and **4**·(93 mg, 0.23 mmol). The slurry was stirred for 10 min, then 2,6-di-*tert*-butyl-4-methylpyridine (93 mg, 0.45 mmol) was added, and the mixture was stirred overnight at room temperature. The reaction mixture was diluted with CH_2Cl_2, filtered through diatomaceous earth, and concentrated to dryness. The resulting crude material was purified by silica gel column chromatography, eluting with 95:4:1 petroleum ether/Et_2O/CH_2Cl_2 to give **5** as a white gummy solid (160 mg, 91%). R_f = 0.22 (95:4:1 petroleum ether/Et_2O/CH_2Cl_2). $[\alpha]_D$ = −51.8 (*c* 0.55, $CHCl_3$). ^1H NMR (400 MHz, $CDCl_3$): *δ* 7.11 (1H, d, *J* = 7.8 Hz, H_6); 7.10 (1H, td, *J* = 7.8, 1.6 Hz, H_4); 6.98 (1H, td, *J* = 7.8, 1.6 Hz, H_5); 6.93 (1H, dd, *J* = 7.8, 1.6 Hz, H_3); 5.26 (1H, app t, *J* = 9.4 Hz, $H_{3'}$); 5.22 (1H, dd, *J* = 9.4, 7.6 Hz, $H_{2'}$); 5.13 (1H, app t, *J* = 9.0 Hz, $H_{4''}$); 4.97 (1H, d, *J* = 7.6 Hz, $H_{1'}$); 4.96 (1H, app t, *J* = 9.4 Hz, $H_{4'}$); 4.92 (1H, app t, *J* = 9.0 Hz, $H_{3''}$); 4.89 (1H, dd, *J* = 9.0, 7.2 Hz, $H_{2''}$); 4.53 (1H, d, *J* = 7.2 Hz, $H_{1''}$); 4.05 (1H, dd, *J* = 11.6, 5.4 Hz, $H_{5eq''}$); 3.83 (3H, s, H_7); 3.73 (2H, m, $H_{6'}$); 3.70 (1H, ddd, *J* = 9.3, 5.4, 2.8 Hz, $H_{5'}$); 3.22 (1H, dd, *J* = 11.6, 9.3 Hz, $H_{5ax''}$); 2.50 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 2.48 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 2.33 (1H, sept, *J* = 7.0 Hz, $CHMe_2$); 2.07 (3H, s, $COCH_3$); 2.03 (3H, s, $COCH_3$); 2.01 (3H, s, $COCH_3$); 1.12 (6H, d, *J* = 7.0 Hz, $(CH_3)_2CH$); 1.11 (6H, d, *J* = 7.0 Hz, $(CH_3)_2CH$); 1.09 (6H, d, *J* = 7.0 Hz, $(CH_3)_2CH$); 1.08 (6H, d, *J* = 7.0 Hz, $(CH_3)_2CH$); 1.01 (6H, d, *J* = 7.0 Hz, $(CH_3)_2CH$). ^{13}C NMR (150 MHz, $CDCl_3$): *δ* 175.99 (Me_2CHC=O); 175.96 (Me_2CHC=O); 175.45 (Me_2CHC=O); 170.39 (CH_3C=O); 169.73 (CH_3C=O); 169.51 (CH_3C=O); 150.81 (C_2); 146.18 (C_1); 125.02 (C_4); 121.54 (C_5); 120.41 (C_6); 113.05 (C_3); 100.83 ($C_{1'}$); 100.76 ($C_{1''}$); 74.53 ($C_{5'}$); 72.70 ($C_{3'}$); 71.43 ($C_{2'}$); 71.36 ($C_{4''}$); 70.47 ($C_{2''}$); 69.07 ($C_{4'}$); 68.84 ($C_{3''}$); 67.23 ($C_{6'}$); 62.47 ($C_{5''}$); 56.20 (C_7); 34.01 ($CHMe_2$); 33.99 ($CHMe_2$); 33.91 ($CHMe_2$); 20.77 (3 × $COCH_3$); 19.01 (2 × $((CH_3)_2CH$); 18.96 (2 × $((CH_3)_2CH$);

Isolation of Glycosides from Smoke Affected Grapes. Ten kg of smoke-tainted grapes were homogenized using a knife mill (Grindomix GM 200, Retsch GmbH, Germany) centrifuged at 4000 rpm for 5 min, and the supernatant was slowly (over 20 h) passed through a low-pressure column (capacity 600 mL) of an absorbent polymer resin (Amberlite FPX66, The Dow Chemical Company, Camberwell, Victoria, Australia). After removal of nonabsorbed material with water (5 L) and removal of volatiles with pentane (2.5 L), the glycosidic fraction was eluted from the column with food grade ethanol (2 L), concentrated on a rotary evaporator to dryness, then redissolved in 50 mL of ethanol, and stored at −20 °C until required. The glycosides were quantified as previously reported.[14] For the reconstitution study, an aliquot of the ethanolic solution was added directly to the base wine.

Chemical Analyses. Standard chemical analysis and quantification of free volatile phenols for all wines were conducted by Commercial Services at the Australian Wine Research Institute (AWRI, Adelaide, Australia), as reported elsewhere.[7]

Sensory Analysis. The reconstitution and the smoke affected wine sensory studies were conducted several months apart in mid-2011, with the sensory protocols being very similar. Ten panelists were used for the smoke affected wine study (six female), while 11 were used for the reconstitution study (seven female), all were part of the AWRI trained descriptive analysis panel with experience in wine descriptive analysis studies (age range, 32−60), and recruitment and training criteria as previously described.[4] All data were collected in accordance with standard institutional procedures, including risk assessment and informed consent, and all samples were expectorated. For both studies, the assessors had three training sessions: two 2 h discussion sessions to generate and define attributes by consensus though assessment of pairs of wines, followed by one practice rating session in isolated booths, where a subset of the samples was presented in duplicate and performance was assessed. For the smoke affected wine study, the assessors rated six aroma (*overall fruit*, *vanilla*, *oaky*, *earthy/dirty*, *smoky/burnt*, and *band-aid*) and 11 palate attributes (*overall fruit flavor*, *vanilla flavor*, *oaky flavor*, *burnt/charred flavor*, *bandaid flavor*, *bitterness*, *astringency*, *hotness*, *ashy aftertaste*, *acid aftertaste*, and *burning aftertaste*). For the reconstitution study, ten aroma (*overall fruit*, *red fruit*, *dark fruit*, *fresh green*, *musty/dusty*, *woody*, *earthy*, *smoky*, *medicinal*, and *alcohol*) and eight palate attributes (*overall fruit flavor*, *woody flavor*, *smoky flavor*, *burnt rubber flavor*, *medicinal flavor*, *bitterness*, *astringency*, and *burnt/ashy aftertaste*) were rated. For attribute definitions and reference standards used, see SI Tables S4 and S5.

The intensity of each attribute was rated using an unstructured 15 cm line scale from 0 to 10, with indented anchor points of "low" and "high" placed at 10% and 90%, respectively.

Samples were assessed at 22−24 °C in three or five formal sessions, lasting a maximum of 2 h, under sodium lighting in isolated ventilated tasting booths. Assessors were presented with 15 (smoke affected wines) or 16 (reconstitution study) samples per session, in sets of three or four for the two studies, respectively, with 90 s rest breaks between each sample. Assessors were instructed to rinse their mouths after each evaluation with aqueous citrus pectin solution (1 g/L, Fluka), followed by two rinses of water. There was a forced rest of at least 10 min between each of the sets of three or four samples. Samples (30 mL) were presented in a random and balanced order across the assessors, in coded, covered International Organization for Standardization tasting glasses. Two replications of each of the 20 samples for the smoke-affected wine study and three replications of the 20 reconstitution samples were assessed. FIZZ software (Version 2.46, Biosystemes, France) was used for the collection of all data.

Experimental Design of the Reconstitution Study. Different volatiles, singly and in combination; an isolated glycoside fraction from smoke-affected grapes; and synthesized glycosides were added at different concentrations to a red base wine, as specified in Table 1. The red base wine was a relatively low flavor bag-in-box commercial Shiraz wine with negligible or not detected concentrations of volatile phenols. The concentrations of the compounds added were chosen with regard to measured concentrations in a smoke-tainted wine (Wine 15, SI Table S2). Two smoke-affected wines were also included. Wine 15 was not included due to volume limitations. Stock solutions of all compounds were prepared using 96% v/v food grade ethanol (Tarac Technologies, South Australia, Australia) and stored at 4 °C during the experiment, with appropriate volumes added directly to the base red wine 1 h prior to testing.

Table 1. Samples for Sensory Analysis with Details of Concentrations of Each Compound Added to a Base Wine[a]

sample code	details
base wine[a]	no addition
all Ph	all volatile phenols[b]
Gu	guaiacol 79 μg/L
all Cr	*o*-cresol 20 μg/L, *p*-cresol 10 μg/L, *m*-cresol 16 μg/L
m-Cr	*m*-cresol 16 μg/L
o-Cr	*o*-cresol 20 μg/L
p-Cr	*p*-cresol 10 μg/L
Syr	syringol 148 μg/L
Gu+4-Me	guaiacol 79 μg/L, 4-methylguaiacol 43 μg/L
Gu+all Cr	guaiacol 79 μg/L, *o*-cresol 20 μg/L, *p*-cresol 10 μg/L, *m*-cresol 16 μg/L
low Gly[c]	low glycoside-isolate addition (equivalent to 500 μg/L SyrGG)
high Gly	high glycoside-isolate addition (equivalent to 1500 μg/L SyrGG)
high Gly + all Ph	high glycoside-isolate and all volatile phenols in combination[b]
low Gly + all Ph	low glycoside-isolate and all volatile phenols in combination[b]
Gu + Gu-Glu	guaiacol 79 μg/L and guaiacol glucoside 500 μg/L
Gu-Glu	guaiacol glucoside 500 μg/L
m-Cr-Glu	*m*-cresol glucoside 500 μg/L
Syr-Glu-Glu	syringol gentiobioside 500 μg/L
wine 18[d]	smoke-tainted wine 2007, Pinot Noir, Yarra Valley
wine 19	smoke-tainted wine 2009, Shiraz, Yarra Valley

[a]Base wine: 2010 Merlot bag-in-box wine (2L). [b]Volatile phenols matching the concentration of phenols of smoke tainted wine (Shiraz, 2007): Guaiacol 79 μg/L, 4-Methylguaiacol 43 μg/L, Syringol 148 μg/L, Methylsyringol 38 μg/L, *o*-Cresol 20 μg/L, *p*-Cresol 10 μg/L, *m*-Cresol 16 μg/L. [c]Glycoside fraction isolated from smoke affected grapes. [d]For details of wines 18 and 19, see SI Table S1.

Sample Preparation. *Saliva Collection and Incubation.* Saliva was collected from healthy nonsmoking volunteers, with normal

salivary flow and olfactory and gustatory function from within the staff of the AWRI, and selected from prior knowledge that they could consistently perceive smoke flavor from tasting glycosides. Samples were taken in duplicate at different days at different times. Note that these subjects were not members of the sensory panels.

The salivary flow was increased by chewing Parafilm (Pechiney Plastic Packaging) for approximately 10 min and collected in a test tube through expectoration. At each collection period, saliva (3.0 mL) was transferred to a 22 mL amber vial with screw cap Teflon seal. A standard condition was used with guaiacol monoglucoside added (6.32 μg in 1 mL water) incubated in a water bath (37 °C) and stirred for 30 min on a magnetic stirrer. The reaction was stopped by adding saturated aqueous $CaCl_2$ (2 mL), and the free volatiles quantified. In a single study using a single subject different conditions were examined with standard conditions involving 3 mL saliva, 6.32 μg guaiacol monoglucoside in 2 mL saturated tartaric acid pH 3.5, 0% v/v alcohol, 0 g/L glucose, and no mouthwash, with variables studied involving pH (adjusted using 2 M NaOH or 2 M tartaric acid); temperature; ethanol concentration; glucose concentration; and chlorhexidine mouthwash rinsing (0.2% w/v chlorhexidine gluconate, GlaxoSmithKline Consumer Healthcare GmbH&Co., Stuttgart, Germany). The latter was investigated following thorough rinsing for one minute with saliva collected immediately after rinsing and after five minutes.

Volatile Phenol Analysis. For analysis of the released volatiles by solid-phase microextraction (SPME), deuterated standards (d_3-guaiacol, d_3-4-methylguaiacol, d_7-*p*-cresol, and d_3-syringol) were added to the saliva samples in the 22 mL amber vials, after the reaction was stopped. A Gerstel autosampler (MPS) was fitted with a 85 μm PA (polyacrylate) fiber assembly (Supelco) to sample the headspace above the stirred wine sample for 30 min at 50 °C, immediately prior to instrumental analysis. Instrumental analyses were carried out with a Hewlett-Packard (HP) 6890 gas chromatograph and a HP 5973 mass selective detector (Agilent Technologies, Forest Hill, Australia) fitted with a Gerstel autosampler (MPS).

The gas chromatograph was fitted with a 60 m × 0.25 mm J&W fused silica capillary column DB-WAX, 0.25 μm film thickness. The carrier gas was helium, linear velocity was 33 cm/sec, and flow rate was 1.4 mL/min. The oven temperature was started at 40 °C, held at this temperature for 2 min, increased to 240 °C at a 10 °C/min rate, and held at this temperature for 10 min. The injector temperature was 220 °C, and the transfer line was held at 280 °C. For quantification, mass spectra were recorded in Selective Ion Monitoring (SIM) mode. The ions used for quantification in SIM runs were m/z 127 for d_3-guaiacol; m/z 124 for guaiacol; m/z 141 for d_3-4-methylguaiacol; m/z 138 for 4-methylguaiacol; m/z 115 for d_7-cresol; m/z 108 for cresol; m/z 157 for d_3-syringol; and m/z 154 for syringol.

In Mouth Measurements with SBSE (Stir Bar Sorptive Extraction). This method was modified from the BOSS System, developed by Buettner et al.[15,16] A SBSE bar (film thickness 1.0 mm, 20 mm length, Gerstel, Germany) was held in the mouth for 5 min, by attaching it to a very thin spatula and rotating it by the subject. The lips and velum were kept closed, and the spatula was moved carefully within the oral cavity. After equilibration, the SBSE bar was removed from the oral cavity, dipped into water, briefly dried with lint-free tissue, and placed in individually sealed glass liners in the autosampler tray for analysis. Thermodesorption of the samples was performed by inserting the glass liners in a thermodesorption unit (TDU, Gerstel GmbH) in combination with a CIS-4 PTV injector (Gerstel GmbH), which allows cryofocusing of the analytes. The sampling parameters were as follows: splitless thermal desorption was performed with the TDU set at 40 °C for 0.2 min and then heated with a rate of 100 to 240 °C for 5 min. Cryofocusing was performed with liquid nitrogen at −100 °C. Injection was performed with a ramp of 12 °C/s from −100 to 240 °C (5 min). The gas chromatographic conditions were as for the SPME analysis.

Gas Chromatography-Olfactometry (GC-O). GC-O was performed using an Agilent 6890 gas chromatograph, equipped with a Gerstel MPS2 multipurpose sampler and coupled to an Agilent 5973N mass selective detector. The GC was also fitted with a Gerstel olfactory detection port (ODP) and the flow was split between MS and ODP in a 1:1 ratio. The instrument was controlled with Agilent G1701DA ChemStation software with the Maestro software integrated version 1.3.3.51/3.3. The GC column and oven program was as described for GC-SPME analysis.

Data Analysis. Sensory descriptive data for each attribute were analyzed using an analysis of variance (ANOVA) testing for the effects of sample, judge and replicate and their two-way interactions, treating judge as a random effect. Tukey's HSD was applied as a means comparison test. Principal component analysis (PCA) and partial least-squares regression (PLS) were carried out using The Unscrambler 10.2 (CAMO Technologies Inc., Woodbridge, NJ). All PLSR analyses were carried out using standardized data, using the PLS2 algorithm with full cross-validation, with the y data set being the sensory attribute scores, and the x data being the chemical compositional data. Following ANOVA of the reconstitution study, contrast tests were performed to assess significant differences between particular pairs of samples.

RESULTS AND DISCUSSION

Sensory Investigations. The importance of nonvolatile glycoconjugates of phenols relative to volatile phenols to the in-mouth characteristics of smoke-affected wines was assessed in two ways, first with an examination of wines made from grapes affected by bushfire events, and second by a reconstitution study with volatiles and nonvolatiles added to a base wine.

An initial study was aimed at confirming the importance of volatile phenols and their glycosides on the sensory of smoke-affected wines, which was shown in an earlier investigation,[4] using wines with a wider range of phenol concentrations, and to allow selection of a wine with known composition as point of reference for the subsequent reconstitution study. While some wines made from potentially smoke-affected grapes had comparable concentrations of volatile phenols and glycosides of phenols to the control wines (see SI Tables S2 and S3), there were many wines with concentrations substantially higher, with differences much greater than the analytical error (coefficient of variation of less than 15%[7,12]). Generally, there was a high degree of correlation among the phenolic compounds, with Pearson coefficients above approximately 0.8 for almost all-pair wise correlations, and all being statistically significant ($P < 0.05$, $r > 0.44$, $n = 20$), with the exception of the gentiobioside glycoside of phenol (Ph-GG), which was only weakly and insignificantly related to the other analytes. Wine 15 was highest in almost all the compounds measured. This indicates that smoke exposure gives consistent concentrations of the range of volatile phenols.

From the ANOVA of the sensory descriptive analysis data, there were significant differences among the wines for all sensory attributes rated. Considering the fact that these were commercially produced wines with varied extent of oak treatment and of different vintages, and because it was of greatest interest to assess the relationship of the smoke related sensory attributes with the phenol compounds measured for each wine, the fruit and oak related attributes were not considered in subsequent analysis. A partial least-squares regression (PLS) analysis (Figure 2) showed that the smoke related attributes *bandaid* and *smoky burnt* aroma, and *bandaid*, *burnt/charred*, and *ashy aftertaste* (palate) were associated strongly with most of the volatile phenols and their glycosides, being rated highest in the wines 15 and 17. The *burning aftertaste* attribute was strongly associated with the alcohol concentration of the wines, and was not related to the smoke-related attributes. Three factors were considered important to the model, with the third component showing a separation of the *bandaid* attributes from the other smoke related attributes, and *bandaid* was more associated with the three cresols (data not shown). There was a good ability to model the smoke related sensory attributes with the chemical data (76% of the variance of the sensory data explained), with the coefficients of determination for predicted versus measured (calibration) being from 0.71 to 0.86 for each of the smoke-related palate attributes. The validation values were also similarly high (0.61 to 0.66), indicating the predictive ability of the model for new samples, not included in the model, was good.

Regarding the key in-mouth attribute ashy aftertaste, using a model including only the volatiles (two-factor model, 72% of the variance of the sensory data explained) gave slightly poorer R^2 values for this attribute compared to the complete model (R^2 predicted vs measured: calibration, x, validation y), while a model including glycosides only (one-factor model, 59% of the variance of the sensory data explained) also gave slightly poorer R^2 values for the ashy aftertaste (R^2 predicted vs measured: calibration, 0.63, validation 0.59), indicating that both volatile phenols and nonvolatile precursors are contributing to this attribute. While almost all volatile and glycoside conjugates of phenols were important to the model, the analytes with greatest positive contribution were 4-methyl guaiacol, guaiacol, the three volatile cresols, as well as phenol rutinoside (Ph-RG), methylguaiacol rutinoside (MGu-RG), guaiacol rutinoside (Gu-RG), and cresol rutinoside (Cr-RG). The free volatile compounds syringol and 4-methyl syringol had small negative or negligibly positive regression coefficients.

The results of this study confirmed the results of the previous work,[4] that multiple volatile phenols and nonvolatile glyco-conjugates were together associated with smoky off-flavor. The

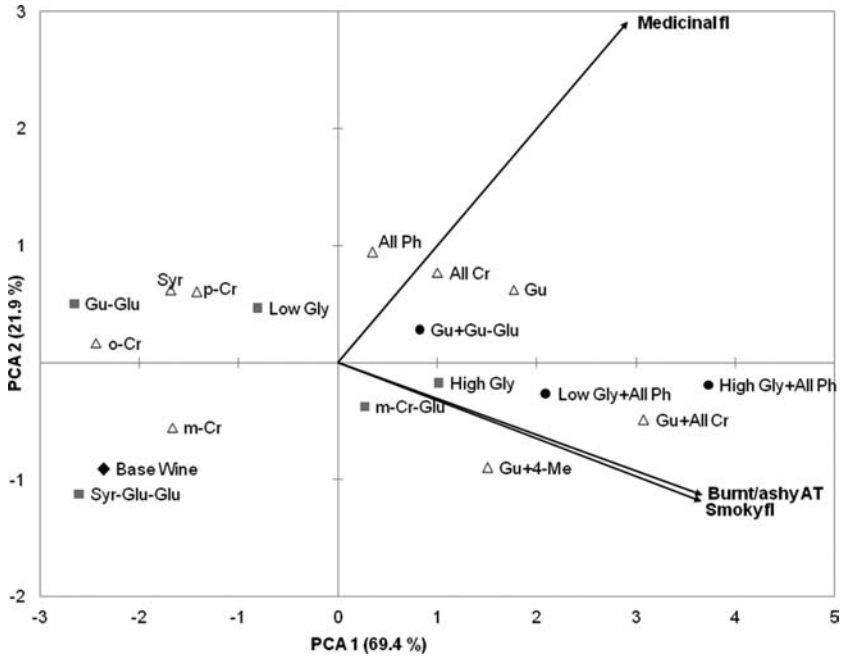

Figure 3. Principal component analysis biplot of the flavor sensory attribute mean values for wines with added volatiles (△), glycoconjugates (■), or both (●).

composition of the wine 17 was used as the basis for a confirmatory study using a reconstitution approach to further assess the sensory significance of the volatile phenols and the nonvolatile glycosides.

Reconstitution Sensory Study. Descriptive sensory analysis was used to characterize differences in the flavor attributes of a red wine, after addition of volatiles, synthetic glycoconjugates, fractions containing glycoconjugates isolated from smoke-affected grapes, or combinations thereof. The combinations used were based on hypotheses based on results of the initial sensory correlative study and a previous study,[4] so that the relative influence of individual volatile phenols and combinations, notably guaiacol, 4-methyl guaiacol and the cresols, were investigated at concentrations that were found in the smoke-affected wine 17 (see SI Table S1). Also included in the sensory descriptive analysis study were two smoke-affected wines (wines 18 and 19, see SI Table S1) as reference samples. Table 1 provides details of the 20 samples included.

From an inspection of the data for the 20 samples, it was noted that the smoke-affected wines (Wines 18 and 19) were rated highly in several attributes, including "woody" and "fresh green", which were not evident in the reconstitution samples or the base wine, and these two wines (Wines 18 and 19) were rated substantially higher for the smoke related attributes. To assess the various additions, the two wines made from smoke-affected grapes were excluded, and ANOVA was conducted for the remaining 18 samples listed in Table 1. Aroma attributes were rated for the samples as well as in-mouth attributes, and from the ANOVA there were no significant differences between any of the glycoside samples with no addition of volatiles (that is Low Gly, High Gly and *m*-Cr-Glu, and Syr-Glu-Glu and Gu-Glu) and the base wine in the *smoke* and *medicinal* aroma attributes, as determined by contrast tests. The concentration of free volatile phenols in the glycoside samples was also found to be negligible, and below the detection limit of the analytical method. Accordingly, only the palate attributes were investigated further.

From the ANOVA, the attributes *medicinal flavor*, *smoky flavor*, and *burnt ashy aftertaste* were rated significantly different across the samples. The attributes *smoky flavor* and *burnt ashy aftertaste* were highly correlated (r = 0.74, n = 18). Figure 3 shows the PCA for the significant flavor attributes. The major separation along PC1, which accounted for close to 70% of the variance in the sensory data, related to differences in ratings for *burnt ashy aftertaste* and *smoky* flavor. Separation along PC2 was related mainly to differences in *medicinal* flavor. The base wine, plotted to the lower left quadrant of the figure, was rated low in each of these attributes. The addition of syringol and the individual cresols (*o*-, *m*-, and *p*-cresol) had only a small effect on the flavor properties of the base wine, while the base wine with the three cresols added together (All Cr) was shifted strongly to the right and to the upper half of the figure, demonstrating an additive effect of the three compounds together, giving higher *medicinal* and *smoky* flavor. The samples with guaiacol alone (Gu) and guaiacol with 4-methyl guaiacol (Gu+4-Me) were rated higher again in *burnt/ashy* and *smoky* flavor, with the Gu+4-Me wine being lower in the *medicinal* flavor score. The combination of guaiacol and cresols (Gu + All Cr) had a very high rating in the *smoky* attributes. Interestingly, the All Ph sample, was rated lower in the *burnt/ashy* and *smoky flavor* attributes than the Gu and all Cr samples, indicating a suppressing effect of the other phenols in the mixture. Assessing statistical significance for these two attributes, there was a trend (P = 0.097) for the All Ph sample to be rated lower in *burnt/ashy aftertaste* than the Gu sample, while other pairwise comparisons for All Ph, Gu, and All Cr were not significant.

Regarding the glycosides, the wine with added syringol gentiobioside (Syr-Glu-Glu) was rated very similarly to the base wine, while the Gu-Glu sample was rated significantly higher only for the *medicinal* attribute. The *m*-cresol glucoside was rated substantially higher in *burnt/ashy* and *smoky*, at a similar intensity to the free guaiacol alone. Importantly, for the glycoside fraction isolated from the smoke affected grapes,

there was a perceptible flavor effect for the low Gly sample, being rated significantly higher in *medicinal* (P = 0.05) compared to the base wine, while the high Gly was rated significantly higher in *smoky* flavor compared to the base wine (P = 0.02).

As expected, the glycoside samples with volatile phenols added were rated higher in the smoky attributes than their counterparts with no volatiles added, so that the (Gu+Gu-Glu) wine was rated moderately highly in the smoke related attributes, at a concentration similar to that of the guaiacol addition alone, and the high Gly+ All Ph sample was overall rated as most different from the base wine, being situated to the far right of Figure 3, and substantially and significantly higher in scores for these attributes than the (All Ph) wine, confirming that the glycoside fraction contributed flavor.

Breakdown of Glycoconjugates with Incubation of Saliva. Results from the reconstitution study confirmed a direct sensory effect of glycosidically bound volatiles on smoke related flavor attributes. In addition, previous studies had demostrated that monoglucosidically bound volatiles in a model wine system or water could give rise to a smoky flavor in-mouth and that the respective volatiles were released.[4] These investigations from Parker et al.[4] indicated that the release of volatiles is highly variable across individuals.

A series of investigations were conducted to gain a better understanding of the variability between individuals and to assess factors responsible for differences in release of phenols through of glycoside hydrolysis.

Table 2 presents a summary of a set of experiments aiming to assess release of guaiacol from incubation with saliva from four individuals. Subject A had a mean release of guaiacol from its monoglucoside of 17% (release range of 9.7−25%). A comparison across the four different subjects showed that person D had a greater, and more consistent, activity to release guaiacol than the other subjects. The wide variation among individuals may be due to differing mouth biota and will be investigated in future studies.

Table 2. Release of Guaiacol from Guaiacol Monoglucoside Following Incubation with Saliva Obtained from Four Subjects in Vitro[a]

subject	mean release (standard deviation) %	minimum release (%)	maximum release (%)	number of replicates
A	17 (6)	9.7	25	6
B	31 (13)	21.0	52	9
C	12 (8)	3.8	20	4
D	63 (5)	57.0	68	4

[a]30 min incubation, 37 °C.

For this study, the glucosides, dissolved in water, were added directly to human saliva. When the glycosides were added to a model wine (pH 3.5, 12% v/v alcohol) and added to the saliva, the release was strongly reduced, so that there was a complete inhibition if saliva was mixed with model wine in a 3:2 ratio. A series of samples were examined to assess the influence of the model wine system on the release, in a single replicate for each condition from a single subject. Replication was not possible due to limitations in quantity of the guaiacol glucoside, but the results are comparable across treatments to provide screening data of the most important variables influencing release. As expected, the release decreased with lowering of the pH, with a total inhibition at a pH of 3.5 (Table 3). The release of guaiacol was lower when incubated at room temperature and nearly totally inhibited when incubated at 0 °C in comparison to body temperature (37 °C).

Table 3. Percentage Release of Guaiacol from Guaiacol Monoglucoside Following Incubation with Saliva in Vitro From One Subject[a] with Each Value Obtained As a Single Replicate As a Function of Temperature, pH, Alcohol Concentration, Glucose Concentration, and Time after Rinsing with Chlorhexidine Antibacterial Mouthwash[b]

[a]Subject A from Table 1. [b]Unless otherwise stated, conditions were 30 min incubation, 3 mL saliva, 6.32 μg guaiacol monoglucoside in 2 mL saturated tartaric acid pH 3.5, 37 °C, 0% v/v alcohol, 0 g/L glucose, no mouthwash. [c]Not detected.

The alcohol concentration was found to have a strong effect on the release of guaiacol (Table 3), with the release decreasing from 39% to 6.3% with increasing ethanol concentration. However, the presence of alcohol did not lead to a complete inhibition of the guaiacol release. The same effect could be seen for a high glucose concentration, with 3 g/L of glucose leading to a strong decrease in the guaiacol release from 55% to 5%. Another inhibiting effect of the release could be seen by using antibacterial mouthwash. The use of chlorhexidine mouthwash completely inhibited the release of guaiacol from the glucoside for up to 2 h after application. These results are in agreement with the findings that bacterial microorganisms in saliva are the agents for release.[17]

Beside guaiacol, monoglucosides of syringol and *m*-cresol were also investigated. The mean release of six measurements for each glycoside was determined (Table 4). The proportion of both compounds released was high, similar to that of guaiacol glucoside.

Most volatile phenols in grapes and wine are found as disaccharide glycosides, and some in relatively high concentrations.[7] Therefore, the interaction of these glycoconjugates with saliva is of great interest. The degradation of syringol gentiobioside (2,6-dimethoxyphenyl-1-*O*-*β*-D-glucopyranosyl-(1→6)-*β*-D-glucopyranoside) and guaiacol primeveroside (2-methoxyphenyl-6-*O*-(*β*-D-xylopyranosyl)-*β*-D-glucopyranoside) was studied, and the results are shown in Table 4. The syringol gentiobioside reacted with the saliva in a similar way to its

Table 4. Release of Guaiacol, Syringol and *m*-Cresol from Mono- and Disaccharide Glycosides Following Incubation with Saliva in Vitro[a]

glycoside	release (standard deviation) %

guaiacol primeveraside	3 (2.4)

[a]30 min incubation, two subjects, 37 °C, mean of three replicates per subject.

monoglucoside, with a mean of six measurements giving 27% release. A much lower mean release of 3% resulted for the guaiacol primeveroside, indicating that the active principle in saliva, presumably bacterial enzyme activity, is able to hydrolyze both mono- and disaccharides, with evidence for variability in activity according to the nature of the sugar and the aglycone.

In addition, the release of free volatiles was confirmed in vivo, by placing SBSE bars in mouth after holding the glycoside solution in mouth. Surprisingly, free guaiacol and syringol could be detected, by means of GC-olfactometry, up to 15 min after spitting out the glycoside solution

In conclusion, monoglucosides and disaccharide glycosides can be released by the activity of saliva, with a great dependency on the glycoside and the individual. The release is greatly affected by a low pH, alcohol, and glucose concentration. Considering the buffering properties and alcohol dilution of saliva, as well as rapidly elevated temperature following ingestion, hydrolysis of glycosides is likely to continue as long as there is residual wine in the oral cavity. The decrease in release following chlorhexadine mouth wash, as observed previously in studies on flavonoid glucosides,[7] provides further evidence that it is in-mouth bacteria that play a role in the hydrolysis, with previous studies indicating the presence of gram-positive cocci in tetrads and gram-negative diplococci,[7] although oral epithelial cells may also be involved.[7] The reconstitution study clearly showed that the glycosidically bound volatiles have a direct impact on perceived smoke flavor, including aftertaste, and together with the data from the in vitro experiments, it is apparent that the breakdown of glycosides in mouth, including disaccharide glycosides, is an important mechanism of flavor perception in wine.

FPIAs can be performed in microtiter plates (MTPs) or cuvettes with different instrumental configurations. Generally, the assays performed in cuvettes are faster for individual sample measurements (approximately 2 min), but up to 20 or 30 samples can be measured simultaneously within 10 min in MTPs.[18] The missing (enzymatic) amplification step can lead to a lower overall sensitivity of the assay; for example, the EIA for the determination of the herbicide simazine yielded a 30 times lower detection limit than the FPIA using the same antibody.[19] Usually working ranges in the micrograms per liter to milligrams per liter range are observed for FPIAs;[20] for example, the detection limit of the herbicide chlorsulfuron was 10 μg/L.[17] FPIAs have been used for high-throughput screenings of small-molecule analytes such as the mycotoxins ochratoxin A (OTA), zearalenone, and deoxynivalenol in food-safety control within the following ranges: 5−200, 500−5000, and 100−2000 μg/L, respectively.[20]

Here, we present and compare two novel FPIAs for the fast, easy, and cost-effective determination of caffeine in beverages and cosmetics, one performed with a multimode plate reader, the other in a spectrometer especially developed for FPIA measurements. The concentrations obtained with these assays were verified with LC tandem mass spectrometry (LC−MS/MS) and ELISA using TMB as substrate. Additionally, the applicability of quality criteria from heterogeneous to homogeneous immunoassays was tested.

MATERIALS AND METHODS

Reagents and Materials. All solvents and chemicals were purchased from Sigma-Aldrich (Taufkirchen, Germany), Merck KGaA (Darmstadt, Germany), Serva (Heidelberg, Germany), and Mallinckrodt Baker (Griesheim, Germany) in the highest available quality. 5-(Aminoacetamido)fluorescein was obtained from Invitrogen (Carlsbad, CA, U. S. A.). The enzyme HRP (EIA grade) was obtained from Roche (Mannheim, Germany). The synthesis of the caffeine HRP conjugate was described before.[13] To obtain ultrapure reagent water for the preparation of buffers and solutions, a Synthesis A10 Milli-Q water purification system from Millipore (Schwalbach, Germany) was used.

All MTPs with 96 flat-bottomed wells were purchased from Greiner Bio-One (Frickenhausen, Germany). Black nonbinding MTPs were employed for fluorescence polarization measurements, whereas clear Microlon 600 MTPs were used for ELISAs. The caffeine reference standard used for the preparation of the calibrators was obtained from Sigma-Aldrich (Cat. no. C1778-1VL). The anti-mouse IgG whole molecule antibody (polyclonal, sheep, lot 21481) was purchased from Acris Antibodies (Herford, Germany). The anti-caffeine antibody (monoclonal, mouse IgG2B, clone 1.BB.877, lot L2051502M) was obtained from United States Biological (Swampscott, MA, U. S. A.). The beverages, coffees, tea, and cosmetics were purchased in a local supermarket.

Synthesis and Characterization of the Caffeine Fluorescein Conjugates. The synthesis of a caffeine spacer derivative (CafD) 7-(5-carboxypentyl)-1,3-dimethylxanthine was described elsewhere.[13] For the FPIA application in MTPs, the following protocol was used to synthesize the caffeine fluorescein conjugate: 2.42 mg of CafD were dissolved in *N*,*N*-dimethylformamide (DMF) and a small amount of *N*,*N*′-disuccinimidyl carbonate was added. *N*-Hydroxysuccinimide and *N*,*N*-dicyclohexylcarbodiimide were both dissolved in DMF, and each was added to the CafD solution in a molar excess of 1.2 compared to the amount of CafD. The mixture was shaken for 18 h at 21 °C (750 rpm). Then the reaction mixture was centrifuged for 10 min. The solution containing the activated NHS caffeine ester was mixed with the 5-(aminoacetamido)fluorescein (dissolved in 0.27 mol/L sodium dihydrogencarbonate) in a molar ratio of 1.5:1. After shaking for 18 h at room temperature, the chemical identity of the reaction product was confirmed with high-resolution mass spectrometry (Orbitrap Exactive, Thermo Scientific, Schwerte, Germany; ESI negative). A mass peak of m/z = 679.22 showed that the caffeine fluorescein conjugate had formed.

The product was cleaned by HPLC (Series 1200, Agilent Technologies, Waldbronn, Germany; column: Phen 250 × 3 mm, Sepserv, Berlin, Germany). The oven temperature was set to 40 °C, the flow rate was 0.4 mL/min, and the pressure was 170 bar. The solvents were ultrapure water (A) and methanol (B) containing 10 mmol/L ammonium acetate and 0.1% acetic acid. At the beginning, 80% solvent A was used. After 3 min, the percentage of solvent B was linearly increased to 95% within 17 min. After 28 min, the percentage of solvent B was decreased to 20% within 1 min. Then the composition was kept constant until the end of the run (40 min). The fraction containing the main peak was evaporated to dryness under a current of nitrogen and dissolved in methanol.

For the fluorescein conjugate for the application in cuvette, CafD was coupled to aminopropylamido carboxyfluorescein. This conjugate was obtained from *aokin* AG (Berlin, Germany).

Sample Preparation. The soft drink, energy drink, and caffeine-containing beer were degassed by shaking, followed by approximately 15 min in an ultrasonic bath. One bag of caffeine powder for soft drinks (2 g, containing 120 mg caffeine) was dissolved in 250 mL water. One bag of tea (Ceylon-Assam black tea, 1.75 g per bag) was brewed with 250 mL of boiling water allowing an infusion time of 10 min. The cosmetic sample (caffeine-containing shampoo) was prepared by dissolving 5.05 g in 1 L ultrapure reagent water. The espresso was prepared in a capsule espresso machine (Nespresso, Ristretto capsule). The instant coffee was prepared by dissolving 2.50 g of the instant coffee granulate in 200 mL boiling water.

A total of 7.00 ± 0.05 g of ground coffee powder per sample (three different types of 100% arabica ground coffee (1, 2, and 3 (decaffeinated), and one 100% robusta ground coffee) were brewed with 250 mL of boiling water. Different preparation methods for all coffees were employed; however, the same masses of ground coffee and water were always used. (i) A filter coffee machine was used. (ii) In a French press, an infusion time of 5 min was allowed. (iii) A Turkish coffee was prepared by pouring hot water on the ground coffee. When the coffee cooled down, it was filtered. (iv) For the preparation of the Italian espresso, an electric espresso machine (De'Longhi, Italy) was used.

For arabica 1, one other preparation method was used: the ground coffee was boiled with water and then refilled gravimetrically with water. Three different approaches were used for this preparation method: 5.00 g of coffee was boiled with 400 mL of water for 10 min, or 7.00 g of coffee was boiled with 250 mL of water for 10 or 30 min. The reference standard for decaffeinated coffee was obtained from FAPAS (Sand Hutton, Great Britain) and prepared as Turkish coffee (iii).

FPIA in Cuvettes (FPIA 1). The FPIA 1 was performed in the filter-based *aokin* spectrometer FP 470 (*aokin* AG), that was developed especially for FPIA measurements. All reagents were

pipetted with the *aokin* Liquid Handling Workstation directly into the round glass cuvette within the spectrometer. The system was controlled by the *aokin* software mycontrol v. 3.4.3.1. The excitation wavelength was set to 470 nm, and the emission was measured at 520 nm. The fluorescence intensities at perpendicular and parallel polarizer settings were measured simultaneously and constantly (kinetic measurement). First, 2.2 mL of reaction buffer (phosphate buffered saline based buffer) were pipetted into the cuvette that contained a stir bar. An ∼1 g/L methanolic stock solution of caffeine was prepared gravimetrically, and calibrators were obtained by sequential dilution with ultrapure water. A total of 200 μL of the calibrator (0−1000 μg/L) or sample dilution were added, followed by the addition of 100 μL of the caffeine fluorescein conjugate dilution (*aokin* AG). Afterward, 100 μL of the anti-caffeine antibody dilution (*aokin* AG) were added. The caffeine concentrations were determined by the software over a defined time range (40−80 s after the antibody was added). The degrees of polarization (in millipolarization units mP) for the calibration curve were determined 60 s after the antibody was added. The degrees of polarization were corrected by the background signal and G-factor (0.979). All samples and calibrators were measured in triplicate.

The degrees of polarization were subjected to a Grubbs outlier test ($\alpha = 0.01$). The mean values of the calibrators were fitted to a four-parameter logistic function with the parameters A (upper asymptote), B (slope at the test midpoint), C (concentration at test midpoint), and D (lower asymptote)[21] using the Origin 8G software (OriginLab, Northampton, U. S. A.).[22] Standard deviations of the mean signals were used to obtain the precision profile according to Ekins by calculating the relative error of each calibrator caffeine concentration.[23] The accordingly determined range with a relative error of the concentration below 30% was assigned the measurement range of the assay.

FPIA in MTPs (FPIA 2). All pipetting steps were carried out with 8-channel pipettes from Eppendorf (Hamburg, Germany). A total of 300 μL of TRIS buffer (10 mmol/L tris-(hydroxymethyl)aminomethane, 150 mmol/L sodium chloride, pH 8.5) with 0.01% Triton X-100 and 1% methanol were pipetted into each well. After adding 20 μL of the calibrators in triplicate (0−1000 μg/L) and sample dilutions (6-fold), a background measurement was performed on the monochromator-based multimode reader SpectraMax M5 (Molecular Devices, Biberach an der Riss, Germany) with the following settings: excitation at 492 nm, emission at 520 nm (at parallel and perpendicular polarizer settings), and a cutoff filter at 515 nm. A total of 10 μL of caffeine fluorescein conjugate, diluted in TRIS buffer, was added to each well, followed by 10 μL of the anti-caffeine antibody (1.37 mg/L in TRIS buffer). After shaking for 10 min on the plate shaker Titramax 101 from Heidolph (Schwabach, Germany; 750 rpm), the fluorescence was measured with the settings described above. The perpendicular and parallel intensities resulting from the background measurement were subtracted from the respective values. These background-corrected values were then used for the calculation of the degree of polarization. The values were corrected by the G-factor (0.946) of the instrument. The background corrected intensities and the degrees of polarization were subjected to a Grubbs outlier test. The assay was repeated four times, yielding a 6 × 4 determination of the caffeine concentration for each sample. The calibration curve was fitted as described above. A calibration curve with 8 calibrators was used to determine the caffeine concentrations of the samples. These calibrators were measured on each MTP. The measurement range was determined as described above with 16 calibrators in triplicate.

Reference Methods. Caffeine determination with the reference methods HRP TMB ELISA and the LC−MS/MS were performed with the same instruments and methods as described before by Grandke et al.[14]

RESULTS AND DISCUSSION

Comparison of the Caffeine FPIAs and Applicability of Quality Criteria. The FPIA in cuvettes (FPIA 1) is a kinetic assay where the degree of polarization can be measured as a function of time (Figure 1); here, no incubation step is required as it is a continuous process. One time point was chosen at which the values for the calibration curves and precision profile were determined (60 s after the antibody was added). The caffeine concentrations for real samples were determined over a time range (40−80 s). In contrast, the degrees of polarization for the FPIA in MTPs (FPIA 2) were determined after a defined time of 10 min (end point measurement). The incubation time in MTPs is prolonged compared to measurements in the cuvettes, as it takes longer to reach the equilibration because the circulation is much faster when a stir bar is used than on a plate shaker.

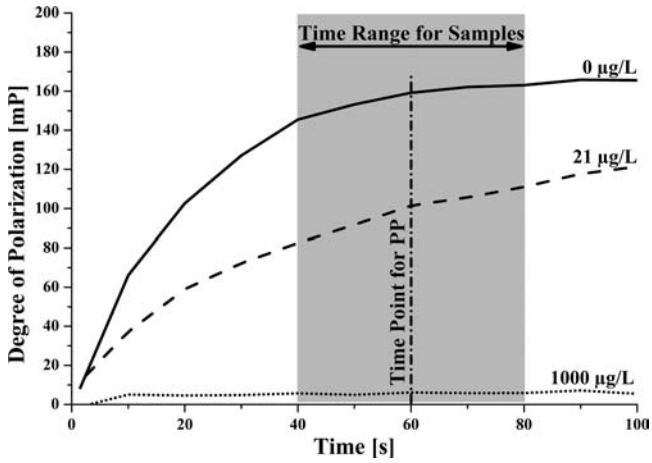

Figure 1. Kinetic measurement of the degree of polarization after antibody addition shown for three caffeine calibrators (0, 21, and 1000 μg/L) measured with the FPIA in cuvettes. The time range for the determination of caffeine concentrations in samples (40−80 s, gray background) and the time point (60 s, dash-dotted line) at which the values for the calibration curve and the precision profile (PP) were determined are highlighted.

The FPIAs were optimized in regard to the parameters buffer basis, buffer additives, anti-caffeine antibody concentration, and caffeine fluorescein conjugate concentration. Additionally, different types of MTPs (nonbinding and untreated MTPs, different manufacturers) were tested for FPIA 2. Calibration curves with precision profiles for the FPIAs were determined under optimized conditions. Quality criteria for the assessment of caffeine EIAs in respect of the calibration curves (4-PL) had been previously defined and applied to a series of heterogeneous EIAs.[14,24] The applicability of these criteria to FPIAs was to be evaluated in this study.

The sensitivity in terms of the test midpoint C of the calibration curve was determined to 27.4 μg/L for FPIA 1

(Figure 2) and is approximately three times higher than that obtained for FPIA 2 with 9.9 μg/L (Figure 3). Therefore, FPIA

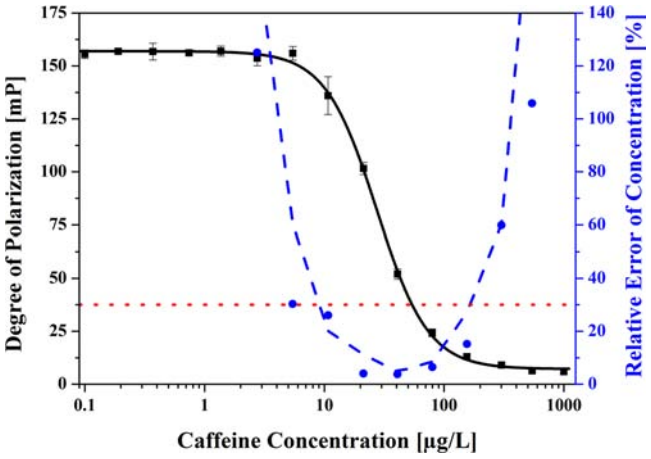

Figure 2. Calibration curve (black squares and solid line), precision profile (blue circles and dashed line), and measurement range (intersection points at 30% relative error of concentration, dotted red line; 8.94−164 μg/L) were determined for FPIA 1 in cuvettes (A = 157 mP; B = 2.02; C = 27.41 μg/L; D = 7.20 mP; R^2 = 0.999; RDR = 0.96).

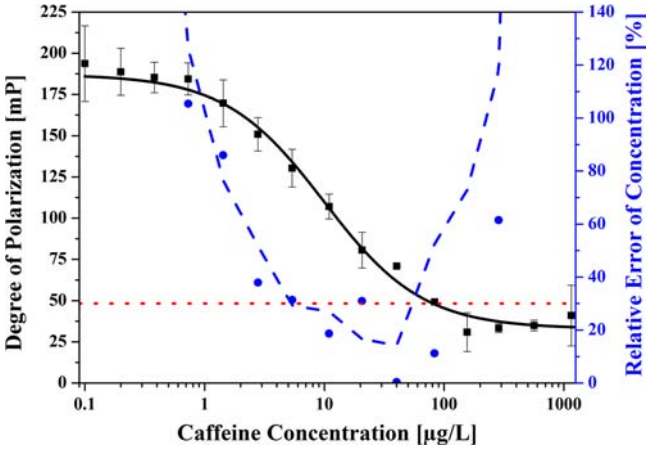

Figure 3. Calibration curve (black squares and solid line), precision profile (blue circles and dashed line), and measurement range (intersection points at 30% relative error of concentration, dotted red line; 5.19−55.5 μg/L) were determined for FPIA 2 in MTPs (A = 187 mP; B = 1.05; C = 9.93 μg/L; D = 33.0 mP; R^2 = 0.986; RDR = 0.82).

2 is more sensitive than FPIA 1. Compared to that of the ELISA (C = 95 ng/L),[14] the test midpoint of FPIA 2 is relatively high. FPIAs for other analytes showed higher test midpoints: 207 μg/L for butachlor and 165 μg/L for melamine.[25,26] Hence, the sensitivity of our caffeine FPIAs is comparatively good. Similar dynamic ranges were observed for FPIA 1 and 2 (150 mP and 154 mP, respectively). The relative dynamic ranges (RDRs) were on a normalized scale 0.96 for FPIA 1, and 0.82 for FPIA 2. Accordingly, only FPIA 1 fulfilled the predefined required threshold of 0.90. The calibration curve of FPIA 1 showed a slope B at the test midpoint of 2.02. The slope of the calibration curve for FPIA 2 was 1.05. The coefficient of determination R^2 is a measure for the goodness of fit. FPIA 1 showed a good R^2 value of 0.999, whereas FPIA 2 (R^2 = 0.986) did not reach the required value of 0.990. Additionally, the standard deviations of the measured values were analyzed. The highest standard deviation for FPIA 1 was 9.94 mP, whereas the highest standard deviation for FPIA 2 was 22.95 mP. Overall, a better goodness of fit was obtained for FPIA 1 compared to FPIA 2. Measurement ranges of 8.94−164 μg/L and 5.19−55.5 μg/L were determined for FPIA 1 and FPIA 2 according to the precision profiles. Neither of the ranges covered 3 orders of magnitude, even though the measurement range than that of FPIA 1 was three times wider than FPIA 2. Other FPIAs had shown comparable measurement ranges: 5−200 μg/L for OTA,[20] 32.0−1220 μg/L for the herbicide butachlor.[25] Therefore, a critical assessment of the requirement for this criterion should follow for homogeneous assays. In summary, FPIA 1 fulfilled all quality criteria for the calibration curve with the exception of the measurement range.

Assay Evaluation for Different Matrixes. The most common matrixes of caffeine occurrence were selected to compare the suitability of the FPIAs for caffeine determination (Figure 4). For the kinetic FPIA 1, the measurement for one

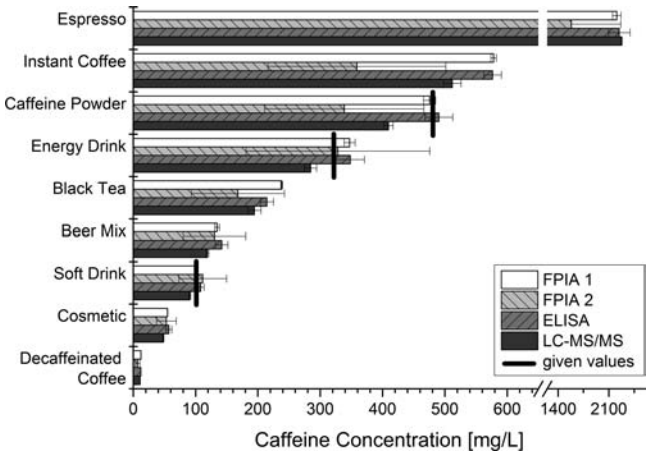

Figure 4. Caffeine concentrations of beverages and cosmetics determined with FPIA 1 and 2, ELISA, and LC−MS/MS. Furthermore, the values provided by the manufacturer are depicted for three samples (black lines). For better comparability, the caffeine concentrations are given in milligrams per liter.

sample takes approximately 2 min. This assay is automated, and eight samples can be measured in triplicate with the liquid handling workstation in one run. FPIA 2 allows a 6-fold determination of eight samples within 20 min, including all pipetting, incubation, and measurement steps. Smaller sample volumes are required for FPIA 2 than for FPIA 1. Additionally, all samples were measured by ELISA and LC−MS/MS.

Beverages with high caffeine concentrations (>150 mg/L) need to be labeled as required by Commission Directive 2002/67/EG.[27] Here, a direct comparison is possible between the values provided by the manufacturer and the determined values. The closest agreement for the energy drink was found with 328 mg/L for FPIA 2 compared to the given value of 320 mg/L. The values for ELISA and FPIA 1 were higher with 348 mg/L and 347 mg/L, respectively, whereas the concentration obtained with LC−MS/MS was lower with 285 mg/L. One bag of the caffeine powder (dissolved in 250 mL water) should contain 120 mg caffeine. The caffeine contents calculated from the results of ELISA and FPIA 1 were 122 mg and 119 mg, respectively, and were therefore very close to the value given by

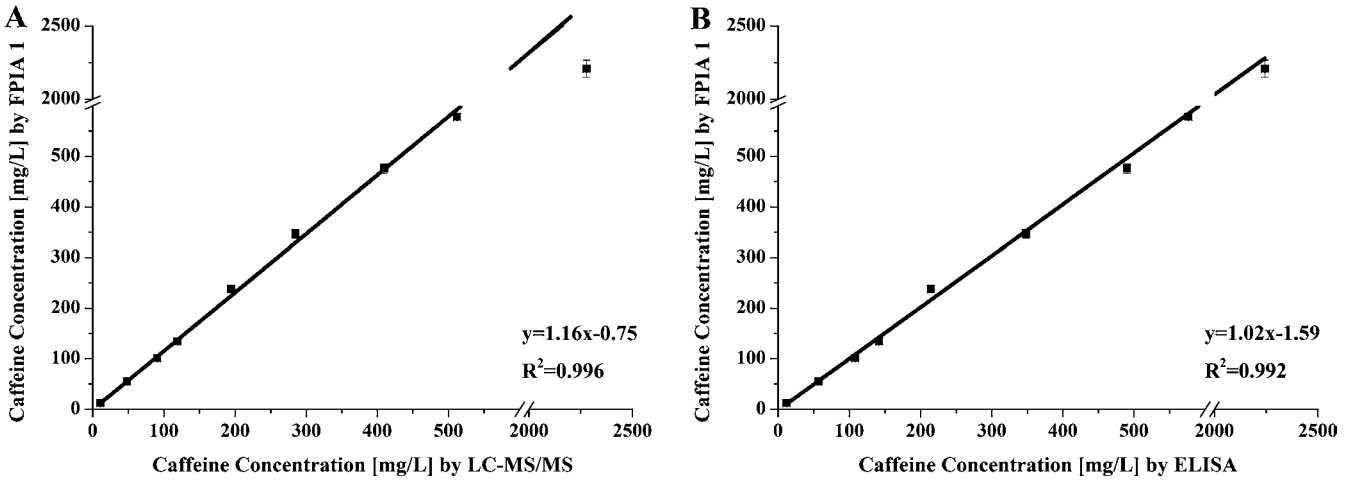

Figure 5. Correlation between FPIA 1 and LC−MS/MS (A) and ELISA (B) for caffeine-containing beverages and cosmetics.

Table 1. Caffeine Concentrations (FPIA 1) and Coefficients of Variation (CVs) for Several Preparation Methods (Filter Coffee, French Press, Turkish Coffee, Italian Espresso) Determined for Different Types of Coffee (Robusta, Arabica 1, 2, and 3 (Decaffeinated))

	filter coffee		French press		Turkish coffee		Italian espresso	
	concn [mg/L]	CV [%]	concn [mg/L]	CV [%]	concn [mg/L]	CV [%]	concn [mg/L]	CV [%]
robusta	742 ± 15	2.0	825 ± 6	0.7	761 ± 15	2.0	848 ± 17	2.1
arabica 1	487 ± 4	0.9	387 ± 4	0.9	454 ± 8	1.7	490 ± 4	0.9
arabica 2	452 ± 4	1.0	512 ± 6	1.1	471 ± 10	2.2	465 ± 4	0.9
arabica 3	16.2 ± 0.4	2.7	14.7 ± 0.1	0.9	14.6 ± 0.5	3.4	17.1 ± 0.2	0.9

the manufacturer. FPIA 2 and LC−MS/MS led to underestimations. FPIA 1 with 101 mg/L, led to the best agreement for the soft drink compared to the expected value of 100 mg/L. Slight overestimations were observed with ELISA (108 mg/L) and FPIA 2 (112 mg/L). LC−MS/MS showed lower concentrations for all three samples than the expected values. The caffeine contents of the shampoo determined with the different methods were all very similar: 9.56 (LC−MS/MS), 11.3 (ELISA), 10.9 (FPIA 1), and 10.5 mg/g (FPIA 2) based on the amount of shampoo. These data correlate well with the values obtained by Carvalho et al.[13]

A decaffeinated reference standard was investigated. All determined concentrations were within the satisfactory range of 193−606 g/kg. The closest agreement to the assigned value of 399 mg/kg was found for LC−MS/MS with 390 mg/kg. FPIA 1 (438 mg/kg) and ELISA (428 mg/kg) led to higher values, whereas FPIA 2 led to a lower caffeine concentration (246 mg/kg).

The concentrations determined with FPIA 2 for the energy drink, beer mix, soft drink, and cosmetic showed a good correlation with the data determined for ELISA and FPIA 1. For the other samples (espresso, instant coffee, caffeine powder, black tea, and decaffeinated coffee), a large underestimation was observed compared to the other immunoanalytical methods. The coefficients of variation (CVs) for the FPIA 2 were very high. The CVs for LC−MS/MS, ELISA and FPIA 1 were below 6%, 9%, and 4%, respectively. High precision corresponding to low CVs and the applicability to many different matrixes is desired. Therefore, FPIA 2 is not suitable for the quantitative determination of caffeine in these consumer products yet. This method can be used for fast semiquantitative analysis of many samples.

The intra- and interplate variations of concentrations of real samples as a measure for precision were proposed by Grandke et al. to assess the applicability of EIAs.[14] For the FPIAs performed in cuvettes, no intra- and interplate variations could be determined. The FPIAs performed in MTPs showed very high CVs for the real samples, which evidently exceed the desired values of 10% for the intraplate and 20% for the interplate variation. All in all, the parameters for intra- and interplate precision are not applicable.

Additionally, the correlation with LC−MS/MS as reference method was proposed as a measure for accuracy.[14] However, the cross-reactivity of the antibody toward other alkaloids can cause overestimations compared to instrumental methods. Therefore, the HRP TMB ELISA using the same monoclonal antibody was used as immunoanalytical reference method to render the correlation independent of cross-reactivity. For FPIA 1, the following correlation parameters were determined: slope $m = 1.16$, intercept $n = -0.75$, and coefficient of determination $R^2 = 0.996$ for LC−MS/MS and $m = 1.02$, $n = -1.59$, and $R^2 = 0.992$ for ELISA (Figure 5). The parameters n and R^2 show similar results for both linear regressions and are in agreement with the required values ($R^2 > 0.95$, n near 0). However, the crucial slope parameter m is significantly better (requirement: 1.00 ± 0.05) for the correlation with ELISA.

For FPIA 2, the parameters for the correlations with LC−MS/MS ($m = 1.90$, $n = -2.03$, $R^2 = 0.933$) and ELISA ($m = 0.80$, $n = -1.98$, $R^2 = 0.954$) did not fulfill all requirements, especially because the slope parameter differed significantly from unity. A notable underestimation was observed for the correlation with ELISA, although the same monoclonal antibody was used. Altogether, the best correlation was found for FPIA 1 and ELISA, resulting in a highly accurate assay.

Applicability of FPIA for Different Ground Coffees and Preparation Methods. The caffeine concentration of different types of ground coffee (arabica and robusta) and preparation methods (filter coffee, French press, Turkish coffee, and Italian espresso) were measured with the newly developed FPIA methods. On the basis of the previous findings, only the results obtained for FPIA 1 are discussed (Table 1). Generally, the coffees made of robusta beans showed higher caffeine concentrations (740−850 mg/L) than arabica beans, in agreement with Casal et al.[3] The arabica coffees 1 and 2 showed similar caffeine concentrations (390−510 mg/L), and for arabica 3, the decaffeinated coffee, caffeine concentrations in the range of 15−17 mg/L were determined. For all samples, no preconcentration steps were necessary; on the contrary, the decaffeinated coffee samples had to be diluted as well.

Comparing the various preparation methods, the French press method revealed opposing results for the different arabica coffees (arabica 1 and 2) because, here, the highest and the lowest caffeine concentrations were determined. All other preparation methods led to relatively similar results. For the robusta coffee, the highest caffeine concentrations were found for the French press and Italian espresso preparation method. No clear correlation between the preparation method and the caffeine concentration could be concluded for different ground coffees.

In addition to the four preparation methods, the influence of the boiling time and the ratio of coffee to water on the extracted caffeine amount was investigated (Table 2). A higher ratio of coffee to water yielded lower extracted caffeine amounts (based on the mass of coffee). Moreover, the extracted caffeine amount from ground coffee increased from 12.9 to 14.1 mg/kg with longer boiling times (30 min instead of 10 min). These results confirm the conclusions made by Bell et al.[28] The results obtained for the coffee samples with FPIA 1 are precise as indicated by the good CVs, which are all below 4%.

Table 2. Caffeine Contents and Coefficients of Variation (CVs) Determined for Different Ratios of Ground Coffee to Water and Different Boiling Times of Arabica 1

mass of arabica 1 [g]	volume of water [mL]	boiling time [min]	concn [mg/kg]	CV [%]
5.0	400	10	13.5 ± 0.2	1.5
7.0	250	10	12.9 ± 0.5	3.5
7.0	250	30	14.1 ± 0.5	3.8

Two caffeine FPIA formats (FPIA 1 in cuvettes and FPIA 2 in MTPs) were developed and carefully optimized. In contrast to previously developed instrumental methods, neither FPIA requires sample preparation steps, which are typically time- and cost-intensive. Also, the measurement time for each sample is much lower for homogeneous assays compared to instrumental methods; for example, the caffeine determination in one sample takes 40 min using LC−MS/MS instead of 2 min with FPIA 1 or 20 min for the measurement of up to 24 samples simultaneously using FPIA 2. Additionally, the instruments for immunoanalytical methods are usually less expensive than equipment needed for instrumental methods like LC−MS/MS. Compared to heterogeneous immunoassays (e.g., ELISA) the FPIA is a mix-and-read assay, so no time-consuming incubation or washing steps are necessary. This makes the homogeneous assay a fast and easy screening method with sufficient sensitivity (but lower than ELISA) for almost all caffeine-containing beverages.

Both FPIAs were assessed with quality criteria previously defined for heterogeneous assays.[14,24] FPIA 2 did not fulfill the requirements for the quality criteria and showed high coefficients of variation for the caffeine determination in real samples. Because of its high throughput, FPIA 2 is a good screening tool for semiquantitative caffeine determination. FPIA 1 fulfilled almost all quality criteria for the calibration curve. A variety of matrixes were analyzed and led to reliable and accurate caffeine concentrations with FPIA 1. This homogeneous assay represents an automatable method for the fast and easy quantification of caffeine in consumer products.

gas chromatography mass spectrometry (GC−MS), methylation analysis, nuclear magnetic resonance (NMR) spectroscopy (^{1}H,^{13}C, H−H COSY, HSQC, TOCSY, and NOESY), and atomic force microscopy (AFM). In addition, in vitro antioxidant activity was investigated by the reducing power, superoxide anion scavenging activity, and the DPPH radical scavenging activity assays.

MATERIALS AND METHODS

Materials and Reagents. The 6-month-old *Achatina fulica* (China white jade snails) with an average shell size of 3−5 cm were supplied by the Huzhou Fenren Company (Zhejiang, China). Table 1 shows the composition of *A. fulica* soft body in this study.

Table 1. Composition of *Achatina fulica*

composition	wt % in *A. fulica* soft part
carbohydrate[b]	25.75 (0.527)[a]
protein[b]	71.58 (0.871)
lipid[b]	3.76 (0.136)
moisture[c]	78.15 (1.673)
ash[b]	5.04 (0.362)

[a]Data were shown as mean (SD), n = 3. [b]Dry weight. [c]Fresh weight.

Monosaccharide standards and disaccharide lactose were purchased from Sigma (St. Louis, MO, USA). Papain (1200 U g^{-1}) and L-cysteine hydrochloride (Cys) were purchased from Fluka (Seelze, Germany). The derivatization reagent 1-phenyl-3-methyl-5-pyrazolone (PMP) was from Sinopharm Chemical Reagents (Shanghai, China). 2,2-Diphenyl-1-picryl-hydrazyl (DPPH), ferrozine, nitroblue tetrazolium (NBT), phenazine methosulfate (PMS), reduced nicotinamide adenine dinucleotide (NADH), and vitamin C were purchased from Sigma-Aldrich Co. All the other reagents used were of analytical grade.

Composition Analysis of *Achatina fulica* Soft Body. The whole soft body of *A. fulica* was oven-dried to constant weight (102 °C for 18−24 h) to determine moisture contents. Lipids were extracted in baths of diethyl ether,[16] and protein contents were determined by the Lowry method.[17] Ash contents were determined by combusting extracted samples in a muffle furnace at 550 °C for 8 h, and carbohydrates were analyzed using the phenol sulfuric acid method of Dubois et al.[18,19]

Isolation and Purification of AFPS-IB. Polysaccharides were isolated using a previously described procedure with some modifications.[8] The shell of *A. fulica* was removed, and fresh muscle was freeze-dried and ground to a powder, which was then defatted using acetone for 24 h. Five grams of defatted powder was suspended in 50 mL of 0.1 M sodium carbonate buffer (pH 6.0). The suspension was shaken for 24 h at 200 rpm and 60 °C after the addition of papain (250 mg), EDTA (73.1 mg), and Cys (39.4 mg). The supernatant was precipitated with four volumes of ethanol at 4 °C overnight and then centrifuged (Beckman Model J-21B centrifuge, Beckman Inst, Inc., Palo Alto, CA, USA) for 30 min at 8000 × g. The precipitate was washed sequentially with alcohol and acetone and then dissolved in 10 mL of ice-cold distilled water. The digestion mixture was cooled to 4 °C, and trichloroacetic acid was added to a final concentration of 5% (w/v). The sample was mixed, allowed to stand for 1 h, and then centrifuged for 20 min at 8000 × g. The supernatant was recovered by decanting before mixing with three volumes of ethanol. The suspension was stored overnight at 4 °C and then centrifuged for 30 min at 8000 × g. The precipitate was washed with absolute ethanol, dissolved in water, and dialyzed against 100 volumes of water. The dialyzate was freeze-dried to obtain crude polysaccharide AFPS.

AFPS was dissolved in distilled water, applied to a DEAE-Sephacel column (2.6 cm ×30 cm, Whatman, Brentford, UK), and eluted with distilled water, followed by 0.1 M NaCl and 0.5 M NaCl, respectively. Each fraction of 5 mL was collected at a flow rate of 30 mL h^{-1} and monitored by the phenol-sulfuric acid method at 490 nm.[19] The collected fractions were further chromatographed on a Sephacryl S-300 HR gel filtration column (1.6 cm × 100 cm, Amersham Biosciences, Uppsala, Sweden) eluted with distilled water; fractions were collected and lyophilized to give a white powder consisting of polysaccharides designated AFPS-IA, AFPS-IB, and AFPS-IC. AFPS-IB was subjected to subsequent analyses. The whole procedure is shown in Figure S1.

Homogeneity and Molecular Weight Determination. The homogeneity and molecular weight of AFPS-IB were determined by high performance size exclusion chromatography (HPSEC) on a TSK-Gel G4000 PWXL column (300 mm × 7.5 mm, Tosoh Biosep, Japan), with a column temperature of 40 °C. The polysaccharides were eluted with 0.2 M NaCl at a flow rate of 1.0 mL min^{-1} and detected by a refractive index detector (Water 2414). Preliminary calibration of the column was performed using dextrin in a range of molecular weights measured in kDa (500, 66.9, 48, 20, 5; Showa-Denko, Japan).

Monosaccharide Composition Analysis. The monosaccharide composition was determined using a PMP-HPLC method.[20] In brief, polysaccharides (typically 1 mg) were hydrolyzed with 2 M trifluoroacetic acid (TFA) at 110 °C under nitrogen for 8 h with lactose added as an internal standard. The monosaccharide hydrolysate was dried under vacuum and then derivatized with 450 μL of 1-phenyl-3-methyl-5-pyrazolone (PMP) solution (0.5 M, in methanol) and 450 μL of 0.3 M NaOH at 70 °C for 30 min. The reaction was stopped by neutralization with 450 μL of 0.3 M HCl before extraction with chloroform (3 × 1 mL). HPLC analyses were performed on an Agilent ZORBAX Eclipse XDB-C18 column (5 μm, 4.6 mm × 150 mm) at 25 °C and UV detection at 250 nm. The mobile phase was 0.05 M KH_2PO_4 (pH 6.9) with 15% (solvent A) and 40% (solvent B) acetonitrile in water. A gradient of B from 8% to 19% in 25 min was used. Sulfate content was determined by the $BaCl_2$/gelatin method and ion-exchange chromatography.[21]

Methylation Analyses. The polysaccharide fraction (0.5 mg) was dissolved in DMSO (0.5 mL) and *O*-methylated using two consecutive cycles of NaOH−MeI.[22] The per-*O*-methylated product showed no band in the region of 3600−3300 cm^{-1}. It was then hydrolyzed with 45% (v/v) formic acid at 100 °C for 15 h. The hydrolyzed product was evaporated to dryness, and the residue was then reduced with $NaBH_4$ and acetylated with acetic anhydride to obtain a mixture of partially *O*-methylated alditol acetates. Qualitative and quantitative analyses were conducted by gas chromatography−mass spectrometry (GC-MS) (Finnigan trace, Thermo Electron Finnigan Co. Ltd., USA) with helium as the carrier gas (2 mL min^{-1}). A capillary column of OV1701 (30 m × 0.25 mm ID, 0.25 μm film thickness; Supelco) was held at 150 °C during the injection and then programmed to increase at 3 °C min^{-1} to 250 °C (constant temperature). The resulting partially *O*-methylated alditol acetates were identified by their typical retention times and electron impact spectra.

UV, IR, and NMR Analyses. The UV−vis absorption spectra were recorded using a UV-2550 spectrophotometer (Shimadzu, Japan) in the wavelength range of 200−800 nm. The FT-IR spectrum (KBr pellets) of the polysaccharide (2 mg) was recorded on a Nicolet 5700 FT-IR (Thermo Electron, Madison, WI, US) in a range of 400−4000 cm^{-1} at room temperature.

For NMR analysis, polysaccharide-containing fractions (about 50 mg) were lyophilized in D_2O (99.8%) twice and dissolved in 500 μL of high-quality D_2O (99.96%) containing 0.1 μL of acetone. ^{1}H, ^{13}C NMR experiments were carried out at 600 MHz on a Bruker Avance III 600 spectrometer (Bruker BioSpin Corporation, Fallanden, Switzerland). Spectra were recorded at 60 °C to place the HDO signals with minimal disturbance to carbohydrate protons. The observed ^{1}H chemical shifts were reported relative to the internal acetone (2.23 ppm). Standard homo- and heteronuclear correlated 2D techniques were used for general assignments of the polysaccharide (AFPS-IB): COSY, TOCSY, NOESY, and HSQC.[23] Spectra were also carried out at 60 °C.

Atomic Force Microscopy (AFM). AFPS-IB was imaged using AFM according to the method described by Sun and Zhang (2006).[24] A stock solution (10 mg mL^{-1}) was prepared by adding some AFPS-IB into double-distilled H_2O. The solution was diluted to a final

concentration of 1 μg mL^{-1}. Approximately 5 μL of diluted AFPS-IB solution was dropped on the surface of a mica sample carrier, allowed to dry, and then imaged in air at room temperature. Scanning probe microscopy images were obtained using a Nano Scope III atomic force microscope (Digital Instruments, Santa Barbara, CA, USA) and collected by tapping mode atomic force microscopy (TmAFM). All measurements were performed in air at ambient pressure and 30−40% relative humidity (RH).

Reducing Power Assay. The reducing power was determined using the method of Li, Zhou, and Li (2007), with some modifications.[25] Samples of 1 mL of different concentrations (2−12 mg mL^{-1}) in phosphate buffer (0.2 M, pH 6.6) were mixed with 1 mL of potassium ferricyanide (1%, w/v) and incubated at 50 °C for 20 min. The reaction was terminated by the addition of 1 mL of TCA (10%, w/v), the solution was then mixed with 0.2 mL of ferric chloride (0.1%, w/v), and the absorbance was measured at 700 nm. Increased absorbance of the reaction mixture indicated greater reducing power. Vitamin C was used as reference material. Reducing power was expressed as a percentage of the activity of a 1 mM solution of vitamin C.

Superoxide Radical Scavenging Capacity. The superoxide radical scavenging activity assay was performed using the photoreduction of the NBT (nitroblue tetrazolium) method as described by Li, Zhou, and Han (2006), with some modifications.[26] Superoxide radicals were generated in 3 mL of phosphate buffer (0.1 M, pH 7.4) containing 156 μM NADH (reduced form), 52 μM NBT, 20 μM phenazin methosulfate, and varying concentrations of AFPS-IB (2−12 mg mL^{-1}). The color reaction of superoxide radicals and NBT was detected by monitoring the absorbance at 560 nm. Vitamin C was used as reference material. In the essential control, NADH was substituted with phosphate buffer. The inhibition percentage was calculated using the following formula: Scavenging effect (%) = $(A_{\text{Control 560}} - A_{\text{Sample 560}})/A_{\text{Control 560}} \times 100$, where A is the absorbance.

DPPH Radical Scavenging Capacity. The DPPH radical scavenging activity was measured using the method reported by Li, Zhou, and Han (2006) with slight modifications.[26] Briefly, 0.2 mL of DPPH· solution (400 μM in dehydrated alcohol) was added to 1.0 mL of sample solution, and then 2.0 mL of water was added. The mixture was shaken vigorously for 2−3 min and allowed to stand at room temperature in the dark for 30 min. The absorbance was measured at 517 nm against a blank (water instead of sample and DPPH solution). Vitamin C was used as reference material. The scavenging percentage was calculated by the following equation: Scavenging effect (%) = $(A_{\text{Control 560}} - A_{\text{Sample 560}})/A_{\text{Control 560}} \times 100$, where A is the absorbance.

Statistical Analysis. Data were reported as the mean ± standard deviation (SD) (n = 3) and evaluated by one-way analysis of variance (ANOVA) followed by the Student's t-test. Differences were considered to be statistically significant if $P < 0.05$. All statistical analyses were carried out using SPSS for Windows, Version 16.0 (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

Isolation, Purification, and Composition of AFPS-IB. The nutritional ingredients of *Achatina fulica* (China white jade snail) are shown in Table 1. Twenty to thirty percent of carbohydrates are included in *A. fulica*. The crude polysaccharides (AFPS) were isolated from *A. fulica* soft body with a yield of 15.54% (dry weight), which were further separated by ion exchange chromatography on a DEAE-52 column. The polysaccharide fractions (AFPS-I) were pooled and further purified by Sephacryl S-300 HR gel-permeation chromatography (Figure 1a). Three major water-soluble factions, AFPS-IA, AFPS-IB, and AFPS-IC, were collected with yields of 1.12, 5.23, and 2.76% of the dry material, respectively (Figure 2b).

Fraction AFPS-IB, which exhibited a larger peak area in the elution profile, was collected for further study. The homogeneity and average molecular weight of AFPS-IB were analyzed by the HPSEC method (Figure 2c). AFPS-IB appeared as a single peak on the HPSEC molecular weight profile, corresponding to an average molecular weight of 128 kDa.

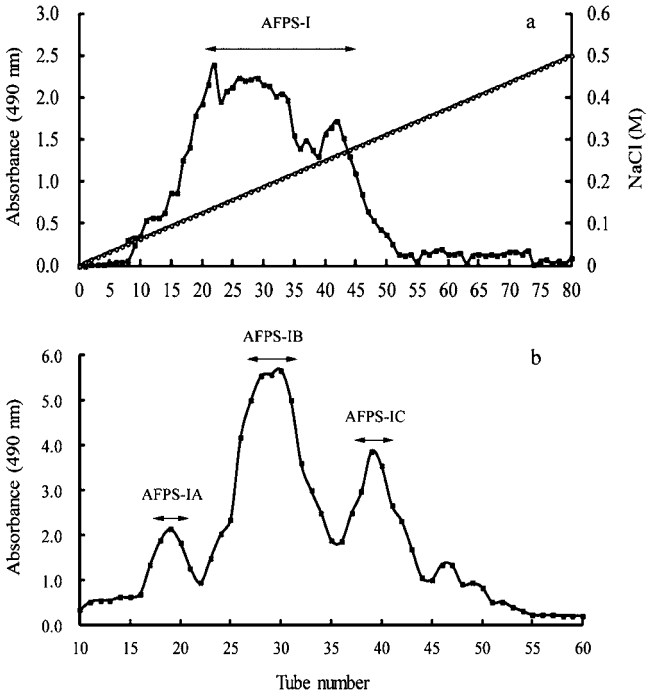

Figure 1. Purification of AFPS-IB. (a) The crude extract was fractionated on a DEAE ion-exchange column and (b) the collected fractions were further purified by gel filtration chromatography on a Sephacryl S-300 HR column.

Monosaccharide composition analysis of AFPS-IB showed that it consisted of Glc, Fuc, Rha, Man, and Gal in a molar ratio of 189:2:1:1:2, respectively. The presence of glucose as the main monosaccharide indicated that AFPS-IB was a glucan. The sulfate content of AFPS-IB was estimated at 2.7% (Table 2).

UV and IR Spectrum of AFPS-IB. The polysaccharide AFPS-IB showed negative response to the Lowry test and no absorption at 280 or 260 nm in the UV−vis spectrum, indicating the absence of protein and nucleic acids. Figure 3 shows the IR spectra of the polysaccharide fraction AFPS-IB of *A. fulica*. The bands in the region of 3428 cm^{-1} were assigned to the hydroxyl stretching vibration of the polysaccharide, and those in the region of 2929 cm^{-1} were due to C−H stretching vibration. A strong band between 950 and 1160 cm^{-1} in the FT-IR spectrum of AFPS-IB was attributed to the stretching vibrations of the pyranose ring. Absorptions at 917 cm^{-1} were typical for D-glucose in the pyranose form.[27] A characteristic absorption band at 843 cm^{-1} was also observed, indicating the α-configuration of the sugar units as described previously.[28]

Structure Data from Methylation Analysis. AFPS-IB was methylated and hydrolyzed to form alditol acetate derivatives, which were prepared and analyzed by GC−MS. As shown in Table 3, the analysis identified 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methyl-D-glucitol, 1,4,5-tri-*O*-acetyl-2,3,6-tri-*O*-methyl-D-glucitol, and 1,4,5,6-tri-*O*-acetyl-2,3-di-*O*-methyl-D-glucitol in a molar ratio of 1:10:1, which indicated the presence of nonreducing-end D-glucopyranosyl, (1→4)-linked D-glucopyranosyl, and (1→4,6)-linked D-glucopyranosyl. The high proportion of (1→4)-linked D-glucopyranosyl indicated AFPS-IB mainly consisted of a (1→4)-linked D-glucopyranosyl backbone. The same proportion of nonreducing-end D-glucopyranosyl and (1→4,6)-linked D-glucopyranosyl indicated the appearance of a

Structure Data from NMR and AFM. To make clear the chemical structures and chain conformations of polysaccharides is important to understand their biological activities. Combination of NMR spectroscopy and atomic force microscopy (AFM) is useful to obtain more information about the structure and properties of polysaccharides. The ^{1}H NMR spectrum of AFPS-IB in D_2O at 60 °C is shown in Figure 4a. The anomeric region (δ_H 4.3−5.6 ppm) contained three signals. The three sugar residues in AFPS-IB were arbitrarily labeled as X, Y, and Z, respectively, in a molar ratio 10:1:1. On the basis of their

observed chemical shifts, X1 at δ_H 5.35 ($J_{H\text{-}1,H\text{-}2}$ = 4.3 Hz), Y1 at δ_H 4.98 ppm ($J_{H\text{-}1,H\text{-}2}$ = 4.7 Hz), and Z1 at δ_H 4.48 ppm ($J_{H\text{-}1,H\text{-}2}$ = 8.0 Hz), the residues X, Y, and Z were designated as α-, α-, and β-hexapyranosyl residues, respectively. The ^{13}C NMR spectra in Figure 4b show three signals in the anomeric region (δ_C 90–105 ppm); the signals were assigned to residues Z (δ_C 102.3 ppm), X (δ_C 100.8 ppm), and Y (δ_C 98.8 ppm) from the downfield to the high field, respectively, which were confirmed by cross-peaks in the $^1H,^{13}C$ HSQC spectrum (Figure 5).

The detailed proton signals (Table 4) of these three systems from H-1 to H-6 were assigned using the $^1H/^1H$ homonuclear

correlation (^{1}H−^{1}H COSY) (Figure S2) and TOCSY experiments (Figure S3). The carbon signals were assigned based on the assignment of the protons, using ^{1}H,^{13}C HSQC spectrum (Figure 5). For example, the anomeric carbon signal at δ 100.8 ppm for unit X was assigned by the correlation signal of X-H1/C1. The other signals from C2−C6 were similarly assigned as 74.5 (C-2), 75.6 (C-3), 80.1(C-4), 76.1 (C-5), and 63.4 (C-6 ppm). Similarly, the down-shift of the C-4 in unit X was a 4-linked Glc residue, whereas the down shift in the C-4 and C-6 indicated the appearance of the 4,6-linked Glc (Unit Y).

The sequence of the glycosyl residues was determined on the basis of a 2D-NOESY NMR experiment (Figure S4, Table 5). The H-1 of residue X has a strong interresidue NOE contact to H-4 of residue Y in addition to intraresidue NOE contacts to H-3, H-4, H-5, H-6a, and H-6b, it is evident that residue X is linked to the 4-position of residue Y. Similarly, residue Y has a strong interresidue NOE contact to H-4 of residue X which indicates that residue Y is linked at the 4-position of residue X. The H-1 of residue Z has a strong interresidue NOE contact to H-6a and medium to H-6b of residue Y in addition to intraresidue NOE contacts to H-2, H-3, and H-4, evidenced that residue Z is linked at the 6-position of residue Y. Based on the above results, we concluded the AFPS-IB was an association of the 4-linked α-glucan chains with (1→6)-β-linked branches. However, the NMR results do not contain information about how the chains are associated, which should be further investigated by AFM studies.

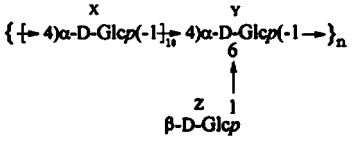
Atomic force microscopy (AFM) is a powerful technique for direct observation of the conformation of individual macromolecules, including polysaccharides.[24] The persistence length can be determined from statistical analysis of the change in the tangent direction of polymer chain as a function of segment separation of the chain trajectory.[29] The AFM image of AFPS-IB is shown in Figure 6. The fiber-like structure and small branches of the AFPS-IB molecule can be observed. The chain length of the backbone was approximately 1140−1540 nm and the height was 20−40 nm. The fiber-like structure of AFPS-IB revealed by AFM was consistent with the results of NMR. NMR spectroscopy can provide useful information about the molecular conformations of polysaccharides. In some cases it is possible to directly confirm the presence of these conformations by AFM imaging of the polysaccharide.[30] Thus, the sequence of AFPS-IB was proposed below:



Antioxidant Activity. Figure 7 shows the antioxidant activities of AFPS-IB determined by the DPPH radical, reducing power and superoxide radicals (O_2^-) assays. Vitamin C was used as reference material. As shown in Figure 7a, AFPS-IB

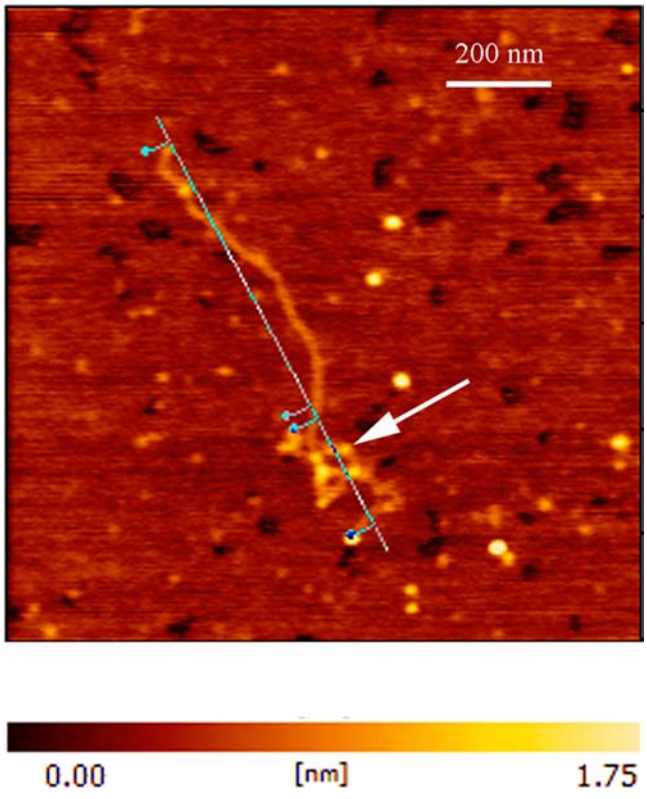

Figure 6. Atomic force microscopy (AFM) image of AFPS-IB. The AFPS-IB concentration was 1 μg mL^{-1}.

showed the ability to scavenge DPPH free radicals. The scavenging effects of the polysaccharide increased with increasing concentrations. The IC_{50} value of AFPS-IB for DPPH free radicals was 6.34 mg mL^{-1}. The maximum value of AFPS-IB reached 85.1% that of vitamin C at 12.0 mg mL^{-1}. Figure 7b depicts the reducing power of the tested sample. Reducing capacity was expressed as a percentage of the activity of a solution (1 mM) of vitamin C. In the tested sample AFPS-IB, the reducing capacity was positively correlated with sample concentration. The maximum value of AFPS-IB reached 65.6% that of vitamin C. Figure 7c shows the O_2^- scavenging ability, which indicates that the radical scavenging activity of the samples increased in a concentration dependent manner. The IC_{50} value of AFPS-IB for O_2^- radicals was 7.83 mg mL^{-1}. The maximum value of AFPS-IB reached 73.4% that of vitamin C.

Glucans, as a source of bioactive macromolecules, have diverse pharmaceutical activities which are dependent on the structural characteristics. The glycosidic linkage and configuration are two main factors determining the bioactivity. AFPS-IB, isolated from *A. fulica*, is a novel water-soluble glucan composed of (1→4)-α-D-glucose residues in the main chain with (1→6)-β-linked branches at glucose residues. The structure of AFPS-IB is similar to that of starch isolated by Baldwin et al.[31] from potato, except for the (1→6)-D-Glc*p* in AFPS-IB was β-configuration. It is also similar to a glucan characterized by Maity et al.[32] from the fruit bodies of an edible hybrid mushroom PCH9FB, except for different molar ratio of (1→4)-α-D-Glc*p* and (1→6)-β-Glc*p* residues. Antioxidation tests performed in vitro showed that AFPS-IB had higher DPPH radical and superoxide anion (O_2^-) scavenging activities than that of potato starch, which showed very poor antioxidant activity, and similar to the glucan from the fruit bodies of an edible hybrid

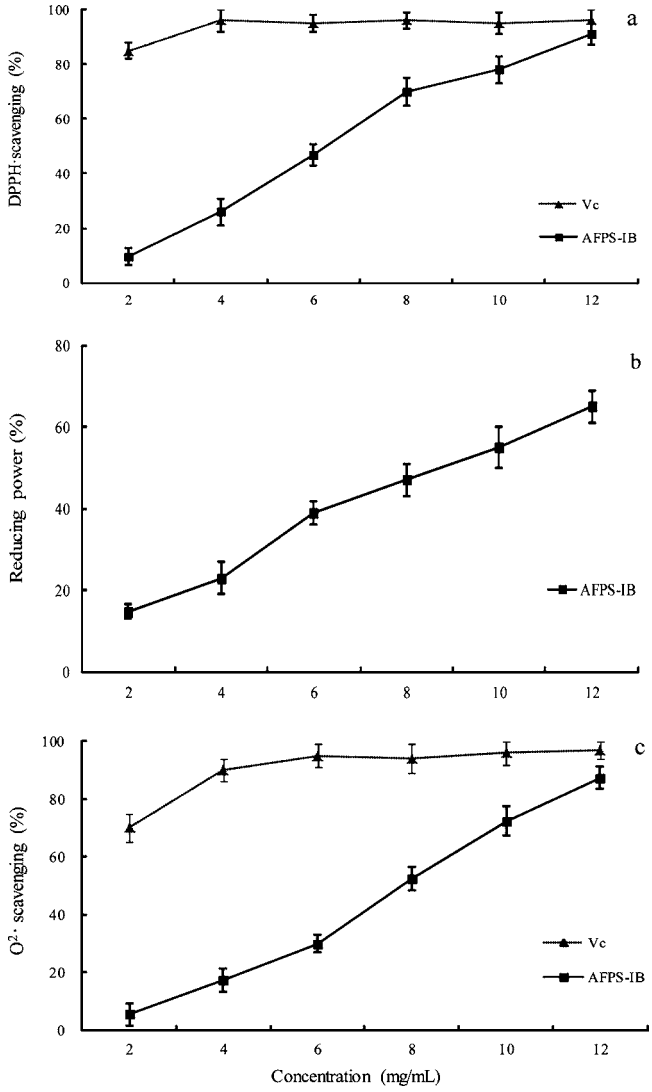

Figure 7. Antioxidant activity of the polysaccharide AFPS-IB and Vc in vitro. (a) The scavenging effect on DPPH radicals; (b) Reducing power was expressed as a percentage of the activity of vitamin C; (c) The scavenging effect on superoxide radicals. Vitamin C was used as reference material. Values are means ± SD of three separate experiments.

mushroom PCH9FB with an IC_{50} value of 5.00−7.00 mg mL^{-1}.[32] The antioxidant mechanism of glucan is not clear, nor is it clear why glucans with different glycosidic linkages and configurations have different free radical scavenging capabilities. The most pronounced hypothesis is that free radicals can abstract hydrogen atoms at all ring C−H bonds of aldoses, uronic acids, and other sites on carbohydrates. The abstraction of hydrogen atom will generate carbon-center radicals. The radicals at carbons which form glycosidic bonds will undergo a β-scission reaction resulting in the breakdown of polysaccharide chains.[33] Some free radicals have lone-pair orbitals antiperiplanar to the alkylidene C−H bond. Therefore, glycosidic linkages with different conformations can have different reaction rates with these free radicals, allowing for selectivity in cleaving β-D-linkages of polysaccharides.[34] A (1→6)-β-D-glucan and (1→4)-α-D-glucan complex isolated from mushroom has been found to have strong antioxidant activities.[35] The responses to such glucans are likely to be regulated by different conformations of glycosidic linkages. Therefore, it can be hypothesized that the

dx.doi.org/10.1021/jf403896c | J. Agric. Food Chem. 2014, 62, 2344−2352

conformation of (1→6)-β-D-Glcp residues may be responsible for its antioxidant activity.

In summary, this study isolated and characterized a novel water-soluble glucan (AFPS-IB) from the soft body of *Achatina fulica*. AFPS-IB was composed of Glc, Fuc, Rha, Man, and Gal in a molar ratio of 189:2:1:1:2, with a molecular weight of 128 kDa. The backbone of AFPS-IB was composed of (1→4)-α-D-glucose residues, which occasionally branched at O-6, and terminated with 1→)-β-glucose. Antioxidation tests performed in vitro showed that AFPS-IB had remarkable DPPH radical and superoxide anion (O_2^-) scavenging activity and high reduction potential. The information of this work and published literature have demonstrated that glucan has a key role for health functions of *Achatina fulica*. AFPS-IB could be regarded as a potential natural antioxidant. Further studies on other activities of the polysaccharide are currently in progress.

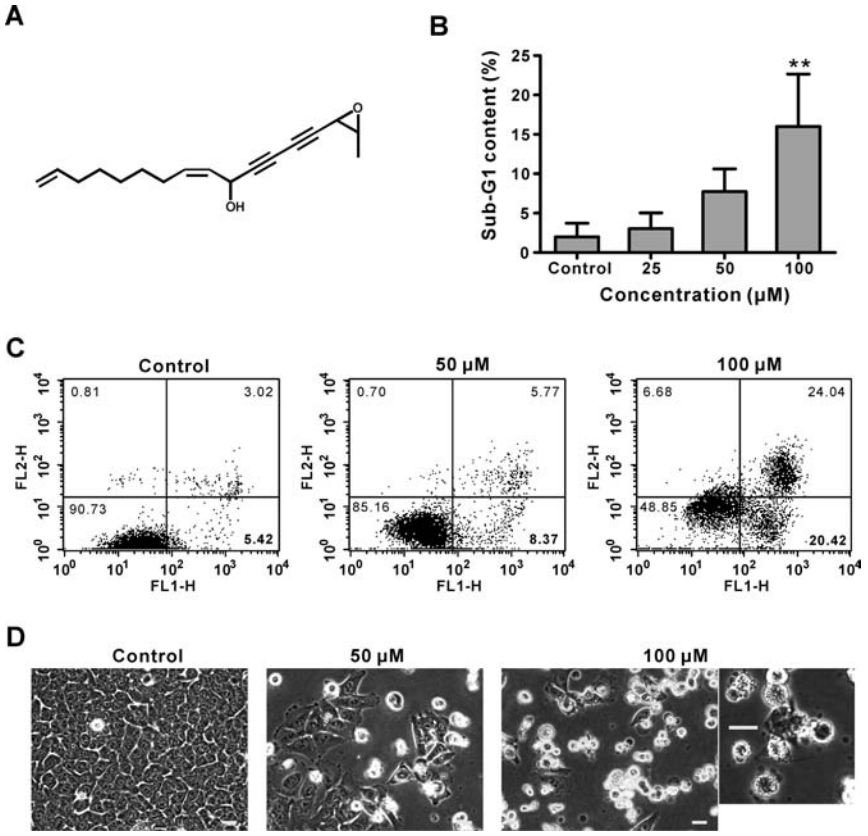

Figure 1. Induction of apoptotic cell death by GKB in HCT116 cells. HCT116 cells were treated with GKB (25−100 μM) for 24 h. (A) Chemical structure of GKB. (B) The sub-G1 content (%) was measured by flow cytometric DNA content analysis. The values represent the mean ± SD of three independent experiments. $^{**}p < 0.01$, compared with the control. (C) The externalization of phosphatidylserine was detected by flow cytometric analysis after annexin V−fluorescein and PI staining. The percentage of the cell population in each quadrant is shown. The lower right quadrant represents an early apoptotic cell population, and the percentage of cells in this quadrant is indicated in bold numbers. (D) Changes in cell morphology. The images are representative of at least three independent experiments (bar = 20 μm).

programmed cell death, including apoptosis and necroptosis, and investigated the overall cellular signaling pathway underlying the GKB-induced cancer cell death using flow cytometry, Western blot analysis, and proteomic approaches. For this task, we preferentially analyzed the secreted proteome using LC−MS/MS technology because secreted proteins play crucial roles in many of the biological processes of cancer cells. To our knowledge, this study is the first report analyzing the secreted proteome from cancer cells undergoing phytochemical-induced apoptotic cell death.

MATERIALS AND METHODS

Reagents. GKB was isolated from *G. koraiensis* as previously described.[15] Its chemical structure is shown in Figure 1A. HPLC grade LC−MS/MS solvents, including acetonitrile (ACN) and water, were purchased from Burdick and Jackson (Morristown, NJ). Trypsin was purchased from Promega (Madison, WI), and formic acid was purchased from Merck (Darmstadt, Germany). JC-1 dye was purchased from Biotium (Hayward, CA). Dithiothreitol, iodoacetamide, ammonium bicarbonate, propidium iodide (PI), z-VAD-fmk, necrostatin-1, *N*-acetylcysteine (NAC), bovine serum albumin, and all other reagents were purchased from Sigma (St. Louis, MO). Antibodies against cleaved caspase-3, cleaved caspase-8, cleaved caspase-9, PARP, Cyclin D1, AIF, BID, Bax, and Bcl-xL were purchased from Cell Signaling Biotechnology (Beverly, MA). Antibodies against Bcl-2 and β-actin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA).

Cell Culture. HCT116, Caco-2, HT-29 human colorectal cancer, and HepG2 human hepatoma cells were obtained from the American Type Culture Collection (ATCC; Rockville, MD). HCT116 and HT-29 cells were cultured in minimal essential medium (MEM) supplemented with 10% fetal bovine serum (FBS), 1 g/L D-glucose, 100 units/mL penicillin, and 100 μg/mL streptomycin. Caco-2 cells were cultured in MEM supplemented with 10% heat inactivated-FBS, 1 mM sodium pyruvate, 100 units/mL penicillin, and 100 μg/mL streptomycin. HepG2 cells were cultured in DMEM supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin. For the secretome analysis, HCT116 cells were cultured in conditioned media, which are described in detail below. These cells were maintained at subconfluence in a 95% air and 5% CO_2 humidified atmosphere at 37 °C.

Cell Viability Assay. HCT116, Caco-2, HT-29 cells (5000 cells per well), and HepG2 cells (1×10^4 cells per well) were seeded in a 96-well plate and incubated for 24 h. The cells were then treated with GKB for 24 or 48 h. Cell viability was determined by measuring mitochondrial dehydrogenase activity as previously described.[21,22]

Observation of Morphological Changes. The cellular morphology was observed by phase contrast microscopy as previously described.[21]

Flow Cytometric Analysis of DNA Content and Phosphatidylserine Externalization. The sub-G1 content (%), which is an indirect measure of apoptosis, was determined using flow cytometric DNA content analysis as previously described.[21,22] The externalization of phosphatidylserine, which is a precise marker of apoptotic cell death, was detected using flow cytometric analysis of cells stained with annexin V−fluorescein and PI, as previously described.[21]

Measurement of Reactive Oxygen Species. Cellular reactive oxygen species (ROS) levels were quantified using the 2′,7′-dichlorodihydrofluorescein diacetate (H_2-DCFDA) assay as previously described.[13,23]

Measurement of Mitochondrial Membrane Potential. Mitochondrial membrane potential ($\Delta\Psi_m$) was measured using flow cytometry after JC-1 dye staining. After treatment of GKB, both floating and adherent cells were harvested by trypsinization. The cells (1×10^6 cells) were washed with Dulbecco's phosphate-buffered saline (DPBS) and incubated with JC-1 (5 μM) at 37 °C for 15 min. Then, the green and red fluorescence was measured using a flow cytometer. The percentage of cells that emit the green fluorescence (JC-1 monomer) was used to quantify the alteration in mitochondrial membrane potential induced by GKB.

Evaluation of Cell Surface Expression of Fas and TNF-R1. The cell surface expression of the death receptors Fas (CD-95) and TNF-R1 was evaluated using flow cytometric immunofluorescence analysis. After treatment of GKB, both floating and adherent cells were harvested by trypsinization. The cells (1×10^6 cells) were fixed in 4% paraformaldehyde at 4 °C for 5 min and incubated in DPBS containing 0.5% bovine serum albumin (100 μL) and FITC-conjugated monoclonal antibodies (20 μL); mouse monoclonal antibody against CD95 (Becton Dickinson, San Jose, CA) and Armenian hamster monoclonal antibody against TNF-R1 (Santa Cruz Biotechnology) at 4 °C for 50 min. FITC-conjugated normal mouse and Armenian hamster isotype control antibodies (Santa Cruz Biotechnology) are used, respectively, for the check of background fluorescence. Then, fluorescence was measured using a flow cytometer. Mean values of FITC fluorescence (FL1-H) was calculated by using histogram statistics tool of CellQuest Pro software (Becton Dickinson) to quantify relative expression of Fas and TNF-R1.

Western Blot Analysis. HCT116 cells (5×10^5) were seeded on 60 mm dishes, incubated for 24 h, and then treated with GKB for 24 h. Total cell lysates were prepared and Western blot analysis was performed as previously described.[22,24]

Preparation of the Secreted Proteins. For the analysis of the secreted proteome, we used cells grown in the conditioned media for secretome analysis (CMS), which contained additional supplements instead of FBS to minimize cell death induced by serum deprivation. The CMS contained MEM supplemented with 3 g/L D-glucose, 2 mM L-glutamine, 0.1 mM L-alanine, 0.1 mM L-asparagine, 0.1 mM L-aspartic acid, 0.1 mM L-glutamic acid, 0.1 mM glycine, 0.1 mM L-proline, 0.1 mM L-serine, 100 units/mL penicillin, and 100 μg/mL streptomycin; FBS and phenol red were excluded from the media. HCT116 cells (1.5×10^7 cells) were seeded in 150 mm dishes and were incubated in normal MEM containing 10% FBS for 24 h. The cells were washed twice with DPBS and once with CMS to remove any residual FBS. Then, the cells were cultured in CMS containing GKB (0 or 50 μM) for 24 h. The media and cells were harvested by cell scraping, and the supernatant was collected twice by centrifugation at 850*g* for 5 min at 4 °C. The samples were prepared from three independent experiments. The supernatants were filtered through 0.2 μm syringe filters and concentrated using a centrifugal filter device (Vivaspin 20, GE Healthcare, Uppsala, Sweden) with a 10 kDa cutoff membrane according to the manufacturer's instructions. The protein concentrations were determined using the Bradford assay (Thermo Fisher Scientific, Rockford, IL).

One-Dimensional SDS−PAGE and In-Gel Digestion. Three replicates of freshly prepared concentrated protein samples (15 μg) were separated on a 12% SDS−PAGE gel and stained with colloidal Coomassie blue.[25] Each gel lane was excised into 11 sections, and the gel slices were washed twice with distilled water. The gels were subjected to a conventional in-gel digestion procedure with minor modifications.[26] The detailed procedures are described in the Supporting Information, Materials and Methods.

LC−MS/MS analysis. The prepared peptide samples were analyzed using a LTQ XL linear trap mass spectrometer (Thermo Scientific, San Jose, CA) equipped with a nano-HPLC system (Eksigent, Dublin, CA). The peptide sample (5 μL) was injected and loaded onto a C_{18} trap column (2.5 cm × 100 μm, Upchurch Scientific, Oak Harbor, WA) using an autosampler. The trapped samples were eluted and separated using an in-line, homemade reverse-phase C_{18} micro column, which was packed in a fused-silica nanospray tip (column dimension, 10 cm × 100 μm; particle size, 5 μm; pore size, 300 Å; Nanobaume, Wildomar, CA). The detailed elution gradients and parameters for the MS are described in the Supporting Information, Materials and Methods.

Protein Identification through Database Searching. All MS/MS samples were analyzed using Sorcerer-SEQUEST (version 3.5, Sage-N research, Milpitas, CA). SEQUEST was set to search the IPI human database (final version 3.86, 91522 entries), with up to 2 missed trypsin cleavage sites. Scaffold 3 (version 3.6.2, Proteome Software Inc., Portland, OR) was used to validate the MS/MS-based peptide and protein identifications. The detailed information concerning the parameters of the database search and the peptide/protein filtering criteria are described in the Supporting Information, Materials and Methods.

Computational Analysis of the Expression and Interaction of the Secretory Proteins. To evaluate the changes in protein expression, we exploited the spectrum counting method using the Quantification analysis tool of Scaffold 3. Because the total protein yield of the control group was less than that of the GKB-treated group but the same amount of prepared peptide samples was injected, the quantification values of the control group were corrected by multiplying by the dilution factor, 0.117. Using the corrected data, the fold-change ratio (Rsc) was calculated to compare the relative abundance of each protein. Rsc was calculated using the following formula (eq 1).

$$R_{sc} = \log_2(n_2/n_1) \quad (1)$$

where, for each protein, R_{sc} is the $\log_2$ ratio of the protein abundance between the GKB-treated and the control-treated group, and n_1 and n_2 are the normalized spectral counts of the control group and the GKB-treated group, respectively. For proteins whose spectral counts were 0 for either the control group or the GKB-treated group, the R_{sc} values were expressed as ∞ or $-\infty$, respectively. Proteins with an R_{sc} above 1.0 or below −1.0, with a minimum spectral count of 1, were selected and further analyzed for statistical significance using Student's *t*-tests.

The secretory proteins were analyzed based on their cellular compartment Gene Ontology (GO) terms using the Scaffold software and the DAVID proteomics tool.[27] Proteins were selected for further analysis if they were annotated with at least one of the following GO terms: secretory granule, extracellular matrix part, extracellular region part, extracellular matrix, proteinaceous extracellular matrix, extracellular space, external side of plasma membrane, or extracellular region.

To visualize the interactions among the identified proteins, a network was generated using the STRING tool (version 9.0).[28] The interaction network of the identified secretory proteins was exported along with the evidence score. The exported data were then imported into Cytoscape (version 3.0.1)[29] as a network file. The expression level of the identified proteins and the number of interacting partners, which were determined using the STRING tool, were also imported as 'attributes' of the interaction network.

ELISA of ADAM9, SERPINB5, and IL18. To verify the results of the LC−MS/MS analysis, we also performed ELISA to measure the actual concentration of the secreted proteins present in the media. ELISA kits were purchased from R&D Systems (Minneapolis, MN) for ADAM9, Wuhan EIAab Science (Wuhan, China) for SERPINB5, and eBioscience (Vienna, Austria) for IL18. The ELISA was performed according to the manufacturer's instructions.

Statistical Analysis. The data are expressed as the means ± SD. Statistical analyses were performed using one-way analysis of variance followed by the Dunnett's multiple comparison test or the Tukey's multiple comparison test using the GraphPad Prism 5 software (GraphPad Software, Inc., La Jolla, CA), excluding the LC−MS/MS data. $p < 0.05$ was considered statistically significant.

RESULTS

Antiproliferative Activity of GKB in Human Cancer Cells. The antiproliferative activity of GKB against mouse leukemia cells has already been reported.[11] In this study, we examined the antiproliferative activity of GKB on other human cancer cells, including human colorectal cancer. As a result, we found that GKB also inhibited the proliferation of HCT116,

Caco-2, and HT-29 human colorectal cancer cells and HepG2 human hepatoma cells (Table 1). We selected HCT116 cells, which have wild type p53, as a model cell line to study the molecular mechanisms underlying the suppression activity of GKB against human colorectal cancer.

Table 1. Antiproliferative Activity of GKB in Human Cancer Cells

	IC_{50}[a] (μM)			
	GKB		Etoposide	
cell line	24 h	48 h	24 h	48 h
HCT116	66.2 ± 14.1	53.8 ± 9.2	189.9 ± 5.3	25.6 ± 2.0
Caco-2	68.8 ± 5.7	57.2 ± 4.0	>200	32.1 ± 4.7
HT-29	58.8 ± 0.9	53.4 ± 7.6	38.1 ± 5.9	12.9 ± 1.7
HepG2	43.8 ± 4.5	43.2 ± 1.6	>200	82.8 ± 4.8

[a]The concentration that inhibits cell proliferation by 50%.

Proapoptotic Activity of GKB in Human Cancer Cells. Next, we measured the biochemical and morphological properties of HCT116 cells relating to apoptosis to examine whether this antiproliferative activity of GKB was due to apoptotic cell death. First, we measured the sub-G0/G1 content (%) using flow cytometric DNA content analysis. GKB potently induced an increase in the sub-G0/G1 content (Figure 1B). Second, we also found that GKB induced the translocation of phosphatidylserine from the cytoplasm to the cell surface using the annexin V–fluorescein and PI staining assay (Figure 1C). Third, GKB induced apoptotic morphological changes, such as the formation of apoptotic bodies (Figure 1D) and chromatin condensation (data not shown). Taken together, we concluded that GKB induced apoptotic cell death in p53-proficient HCT116 cells. GKB also induced apoptotic cell death in p53-mutated human colon cancer cells, including Caco-2, SW480, DLD-1, and HT-29 cells. In these cells, the induction of apoptotic cell death was inferred from an increase in the sub-G0/G1 content and the observation of morphological changes, such as the formation of apoptotic bodies and chromatin condensation (data not shown). Therefore, we speculated that GKB induced apoptosis in human colon cancer cells in a p53-independent manner. In addition to

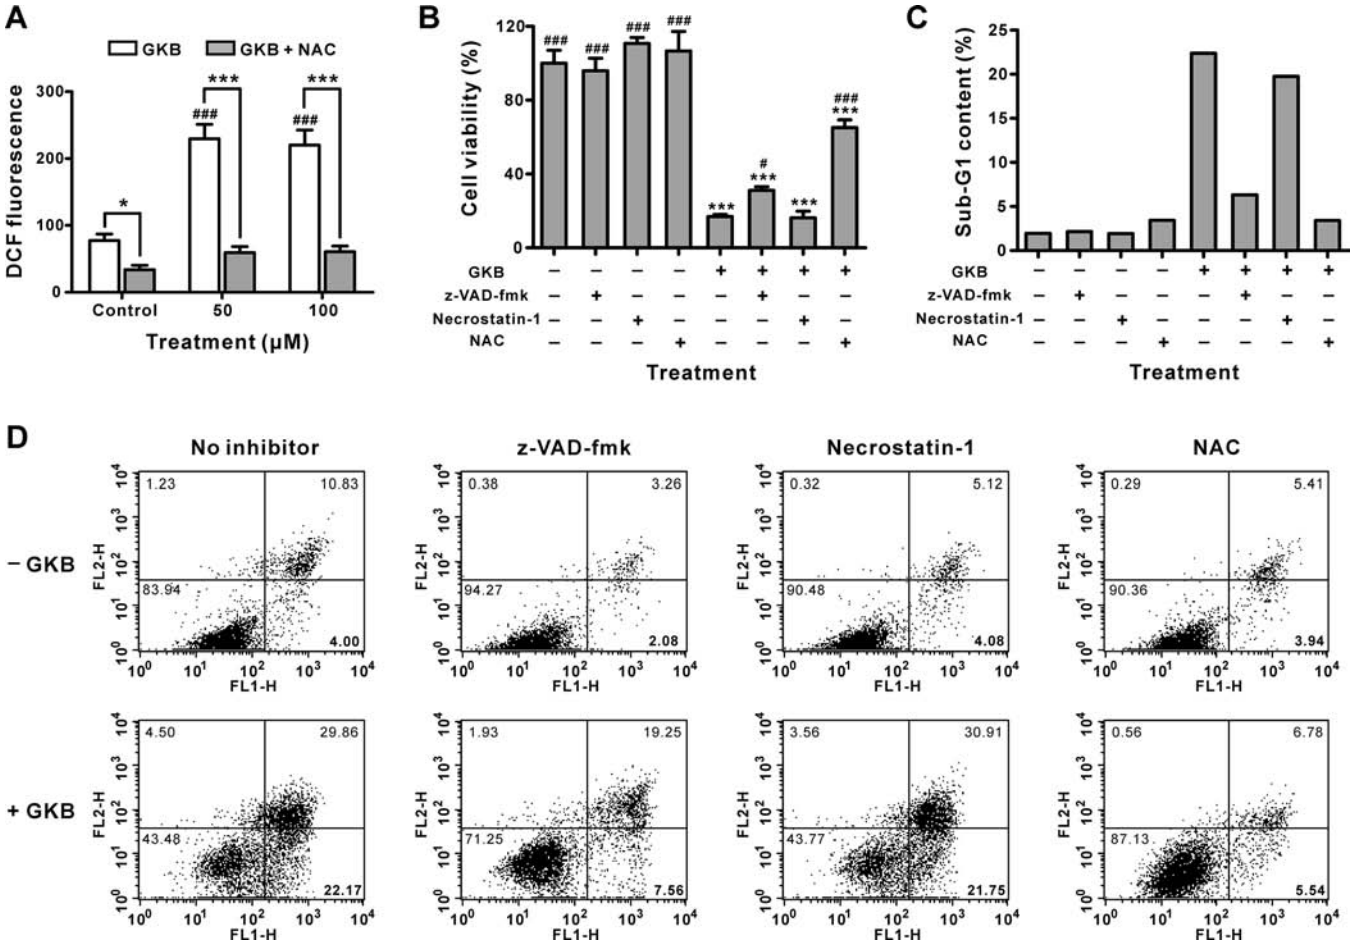

Figure 2. Effects of chemical inhibitors on the GKB-induced HCT116 cell death. (A) Effects of GKB on the intracellular accumulation of reactive oxygen species (ROS). HCT116 cells were treated with GKB (50 or 100 μM) and *N*-acetylcysteine (NAC, 10 mM) for 6 h. The values represent the mean ± SD of triplicate experiments. $^{###}p < 0.001$, compared with the control. $^{*}p < 0.05$ and $^{***}p < 0.001$, compared to the presence and absence of NAC, respectively. (B) HCT116 cells were treated with GKB (0 or 100 μM) and cell death inhibitors (20 μM z-VAD-fmk, 50 μM necrostatin-1, or 10 mM NAC) for 24 h. Then, cell viability was determined by measuring the mitochondrial dehydrogenase activity. The values represent the mean ± SD of triplicate experiments. The graph is representative of three independent experiments. $^{***}p < 0.01$, compared with the control. $^{#}p < 0.05$ and $^{###}p < 0.001$, compared with the GKB single-treatment group in the absence of cell death inhibitors. (C, D) HCT116 cells were treated with cell death inhibitors (20 μM z-VAD-fmk, 50 μM necrostatin-1, or 10 mM NAC) for 1 h and were then treated with GKB (0 or 100 μM) for 24 h. Then, (C) the sub-G1 content (%) and (D) the externalization of phosphatidylserine were measured using flow cytometry.

dx.doi.org/10.1021/jf404047z | J. Agric. Food Chem. 2014, 62, 2353−2363

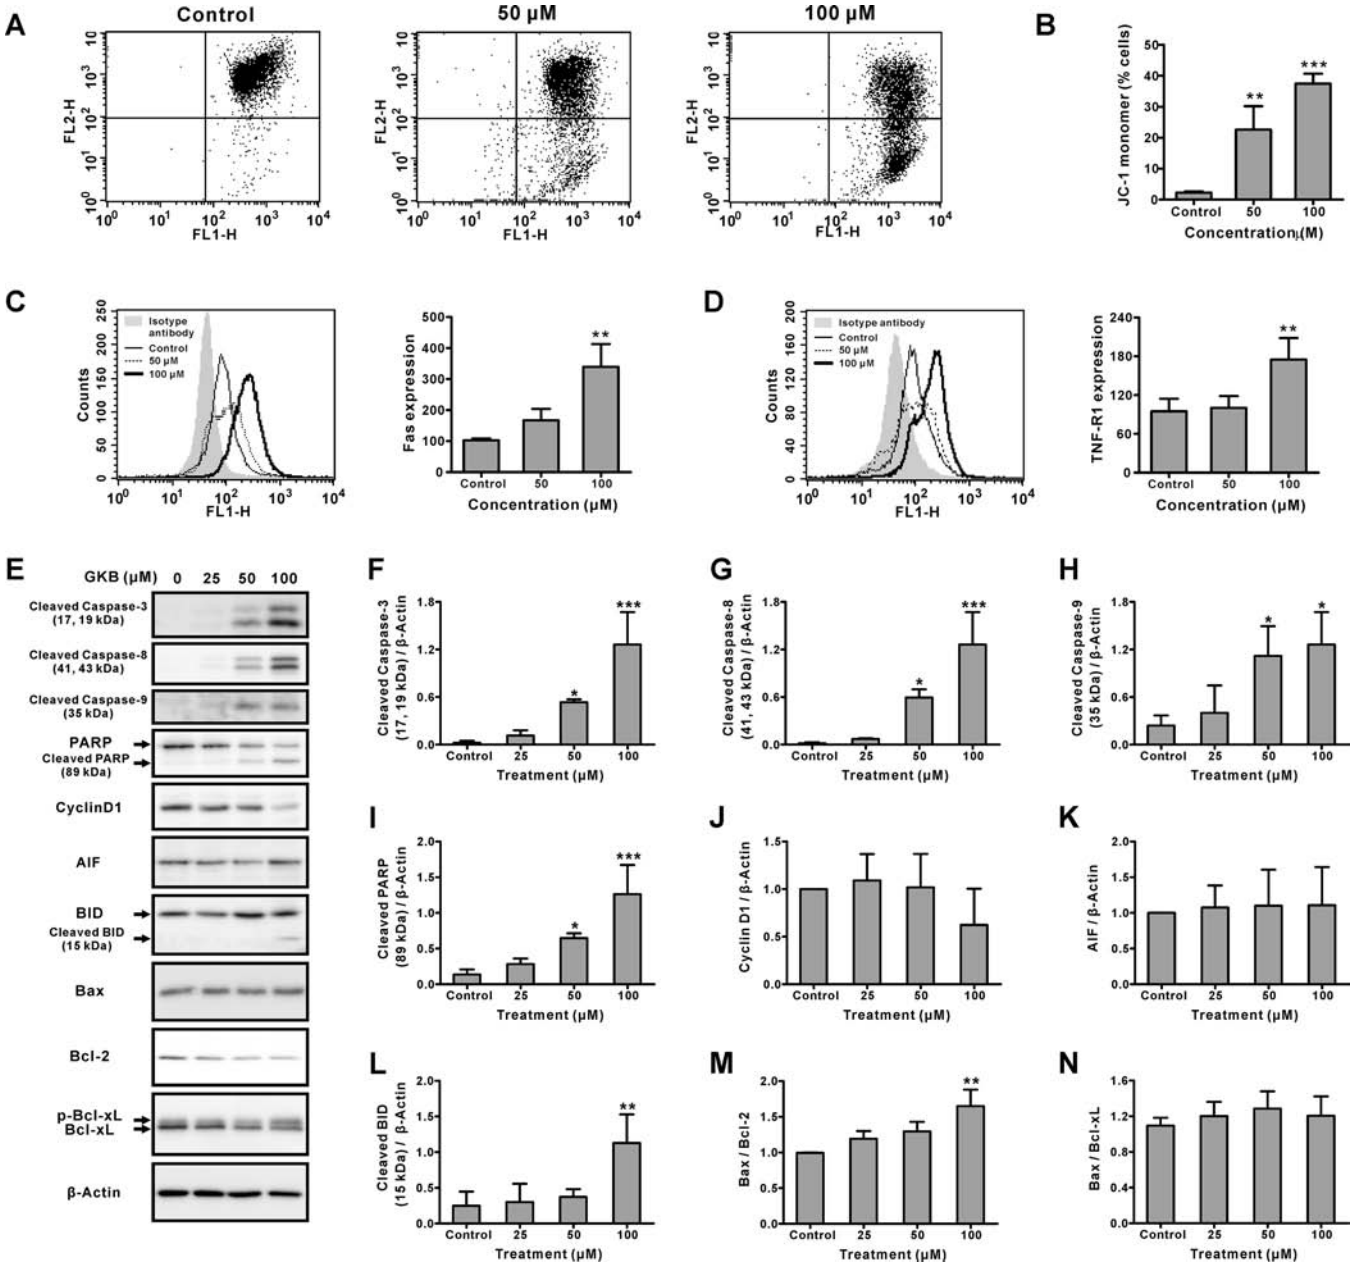

Figure 3. Effects of GKB on the intrinsic and extrinsic apoptotic signaling pathway in HCT116 cells. HCT116 cells were treated with GKB (25−100 μM) for 24 h. (A, B) Effect of GKB on the mitochondrial membrane potential, which was evaluated by flow cytometric analysis after JC-1 staining. (C, D) Effect of GKB on the cell surface expression of death receptors Fas and TNF-R1. Their expression was measured by flow cytometric immunofluorescence analysis. (E−N) The expression of apoptosis regulatory proteins was measured by Western blot analysis. (E) The Western blots shown are representative of three independent experiments. The relative expression of (F) cleaved caspase-3/β-actin, (G) cleaved caspase-8/β-actin, (H) cleaved caspase-9/β-actin, (I) cleaved PARP/β-actin, (J) Cyclin D1/β-actin, (K) AIF/β-actin, (L) cleaved BID/β-actin, (M) Bax/Bcl-2, and (N) Bax/Bcl-xL was determined by densitometry. The values represent the mean ± SD from three independent experiments. *$p < 0.05$, **$p < 0.01$, and ***$p < 0.001$, compared with the control.

colorectal cancer, GKB also induced apoptotic cell death in HepG2 (p53-proficient) human hepatoma cells (Supporting Information, Figure S1).

Effects of Chemical Inhibitors on the Programmed Cell Death Induced by GKB in HCT116 Cells. Because we hypothesized that ROS accumulation might be involved in the initiation of apoptotic cell death by GKB, we measured the accumulation of intracellular ROS using the H_2-DCFDA assay. GKB (50 or 100 μM) significantly induced an accumulation of intracellular ROS, and this accumulation was completely abrogated when the cells were cotreated with the antioxidant NAC (a precursor of glutathione) (Figure 2A).

Next, we investigated the effects of cell death inhibitors, including z-VAD-fmk (an apoptosis inhibitor), necrostatin-1 (a necroptosis inhibitor), and NAC (an antioxidant), to determine what effects necroptosis, another cell death pathway, may contribute the antiproliferative activity of GKB and to elucidate the relevance of the ROS accumulation in the GKB-induced programmed cell death. First, treating cells with z-VAD-fmk or NAC significantly recovered the cell viability that decreased following treatment with GKB; on the other hand, necrostatin-1

dx.doi.org/10.1021/jf404047z | J. Agric. Food Chem. 2014, 62, 2353−2363

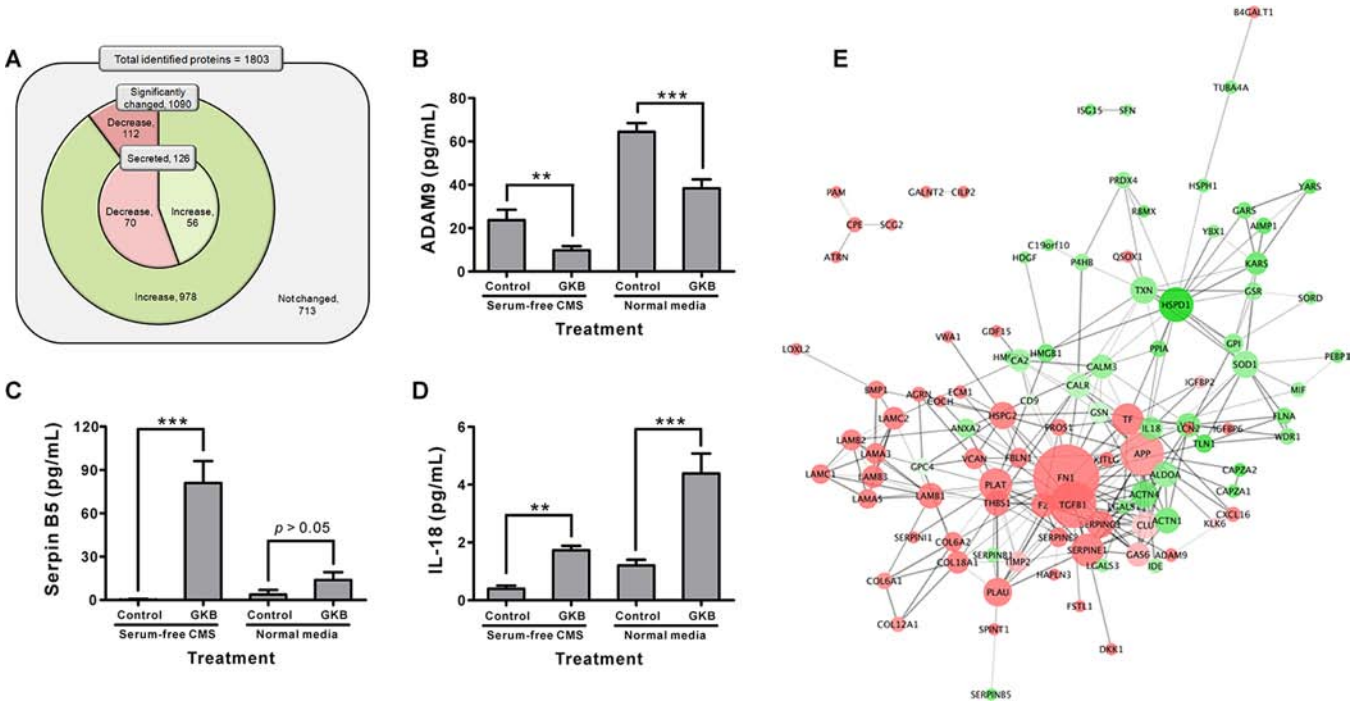

Figure 4. Effect of GKB on the expression and interaction of the secreted proteins in HCT116 cells. (A) Expression and the Venn diagram summarizing the total identified proteins and secretory proteins analyzed in this study. The relative protein expressions were analyzed using the spectrum count method, and the proteins that significantly changed following GKB treatment were determined. From these proteins, the secretory proteins were further separated based on the Gene Ontology (GO) analysis. (B–D) Confirmation of the expression levels of secreted (B) ADAM9, (C) SERPINB5, and (D) IL18 using ELISA. HCT116 cells were cultured in conditioned media for secretome analysis (CMS) supplemented with GKB (50 μM) or in normal medium supplemented with GKB (100 μM) for 24 h. The values represent the mean ± SD of three independent experiments. $^{**}p < 0.01$ and $^{***}p < 0.001$, compared with the control. (E) The protein–protein interactions of the secretory proteins that were significantly altered in response to GKB treatment. Each circular node indicates an identified protein. Proteins that were up- or downregulated are colored in green or red, respectively. The size of the protein node indicates the number of interactions; larger nodes indicate more interactions. The thickness of the connecting lines indicates the overall confidence score of the interaction, as calculated by the STRING tool; thicker lines indicate a higher degree of confidence.

did not affect the antiproliferative activity of GKB (Figure 2B). Second, z-VAD-fmk and NAC recovered the sub-G1 content (%), which was increased following treatment with GKB. The sub-G1 contents of HCT116 cells treated with GKB, GKB + z-VAD-fmk, GKB + necrostatin-1, and GKB + NAC were 22.38, 6.32, 19.75, and 3.41, respectively; while the sub-G1 content of the vehicle control cells was 1.94 (Figure 2C). Third, z-VAD-fmk and NAC also abrogated the externalization of phosphatidylserine, which was induced by treatment with GKB. The early apoptotic cell populations (%, annexin V–fluorescein positive and PI negative) of HCT116 cells treated with GKB, GKB + z-VAD-fmk, GKB + necrostatin-1, and GKB + NAC were 22.17, 7.56, 21.75, and 5.54, respectively, while that of the vehicle control cells was 4.00 (Figure 2D).

Based on these data, we speculated that apoptosis might be the main programmed cell death mechanism of the antiproliferative activity of GKB, not necroptosis. Additionally, intracellular accumulation of ROS was important in triggering apoptotic cell death in response to GKB treatment because ROS scavenging via cotreatment with NAC severely abrogated the GKB-induced apoptotic cell death observed in HCT116 cells.

Effect of GKB on Intrinsic and Extrinsic Apoptotic Signaling Pathways in HCT116 Cells. In addition to biochemical and morphological data, Western blot analysis showed that GKB induced the cleavage of caspase-3 and PARP, which are representative makers of apoptosis, in a dose-dependent manner (Figure 3E,F,I).

We further elucidated the cellular signaling pathway relating to the apoptotic cell death induced by GKB. To determine whether the intrinsic mitochondrial pathway was involved in the GKB-induced apoptotic cell death, we measured the mitochondrial membrane potential ($\Delta\Psi_m$) using the JC-1 dye staining method. As a result, we observed that GKB significantly disrupted the mitochondrial membrane potential (Figure 3A). GKB induced an increase in cell populations (%) with green fluorescence (JC-1 monomer), in a dose-dependent manner (Figure 3B). In addition, GKB also induced the cleavage of caspase-9 (Figure 3E,H) and the increase of Bax/Bcl-2 ratio (Figure 3E,M), which are representative markers of the intrinsic apoptotic pathway.

We also investigated the effect of GKB on the extrinsic death receptor pathway. For this purpose, we measured the cell surface expression of the death receptors Fas and TNF-R1 using flow cytometric analysis of immunofluorescence. As a result, we observed that GKB induced an increase in the expression of Fas and TNF-R1, in a dose-dependent manner (Figure 3C,D). In addition, GKB significantly induced the cleavage of caspase-8, which is a precise marker of extrinsic pathway (Figure 3E,G). We also discovered that the GKB induced the cleavage of BID (Figure 3E,L). BID is known to be activated via the proteolytic cleavage by caspase-8 in the Fas signaling pathway, and it induces cytochrome *c* release from mitochondria.[30] These data implied that GKB also activated the extrinsic death receptor pathway.

Taken together, we concluded that the GKB-triggered apoptotic HCT116 cell death was mediated through both intrinsic mitochondrial and extrinsic death receptor pathways.

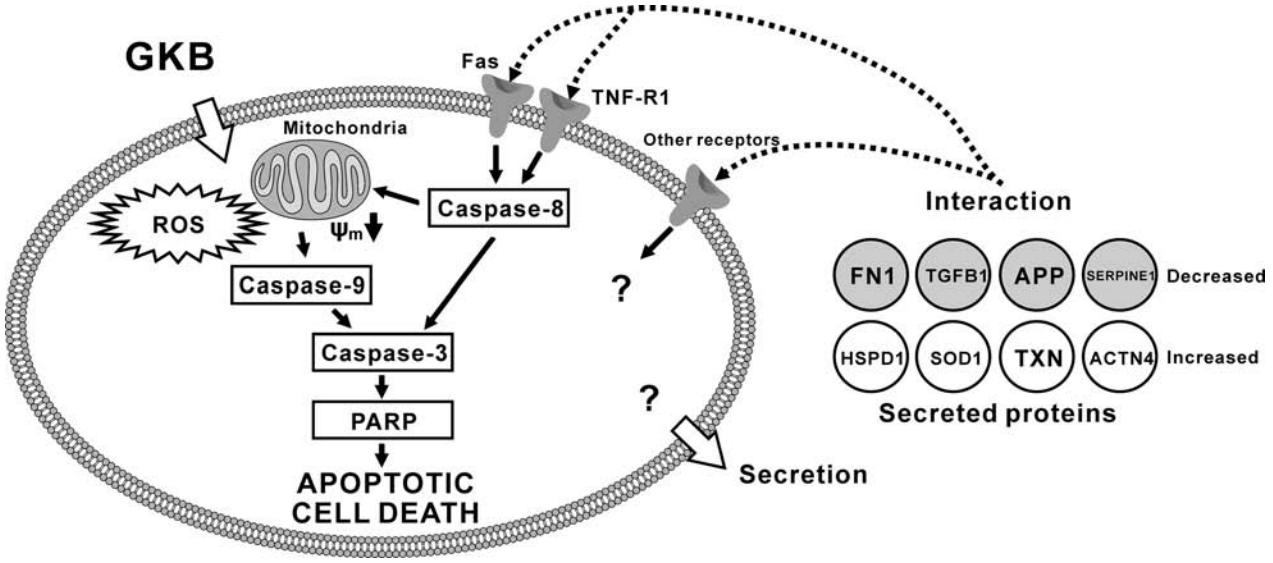

Figure 5. Schematic summary of the present study.

Comparative Analysis of the Secreted Proteome between the Control-Treated and GKB-Treated HCT116 Cells. As shown in Supporting Information, Figure S2, the conditioned media of the control-treated and GKB-treated HCT116 cells were collected for the secretome analysis. Because the IC_{50} value (29.43 ± 1.10 μM) of GKB was relatively lower when HCT116 cells were cultured in CMS, compared to normal medium, the HCT116 cells were treated with 50 μM GKB for 24 h for the LC−MS/MS analysis. As a result of the LC−MS/MS analysis, a total of 1803 proteins were identified, and all identified proteins were found in both the control and GKB-treated groups.

The fold changes in protein expression between the control-treated and GKB-treated groups and their statistical significances were analyzed using the spectral counting method. The identified proteins were further selected based on their GO term analysis. As shown in Figure 4A, among the 1803 identified proteins, 1090 proteins showed statistically significant fold changes in their expression ($p < 0.05$; Rsc >1 or Rsc < −1). Within those proteins, 126 (7.0% of the total identified proteins) proteins were annotated as secreted proteins by GO term analysis. Among those, 70 proteins were downregulated, and the other 56 proteins were upregulated based on the spectral counting method. We suggest that these 126 proteins are crucial secreted proteins related to the GKB-induced apoptotic cell death of HCT116 cells. The complete lists of proteins are shown in the Supporting Information: Table S1 (downregulated) and Table S2 (upregulated).

Validation of the Secreted Protein Expression by ELISA. The expression levels of three representative proteins, ADAM9, SERPINB5, and IL18, in the culture media were further validated using ELISA (Figure 4B−D). We selected these proteins because they have already been reported as secretory proteins that are involved in growth inhibition and the programmed cell death of various cancer cells.[19,31−33] Our results showed that the expression levels revealed by ELISA were similar to those calculated using the LC−MS/MS spectral count method. Specifically, the protein expression of IL18 and SERPINB5 was increased following GKB treatment, whereas ADAM9 expression decreased; these results were the same in both the normal and conditioned media (CMS). Therefore, based on these data, we could assume the reliability of the spectrum counting method used in this study for the relative quantitation of the secreted proteins.

Interaction among the Secreted Proteins Whose Expression Was Altered by GKB Treatment. To identify the highly interactive proteins within the secretome, the protein network was analyzed using the STRING tool (Figure 4E). Of the 126 secretory proteins, 104 proteins were found to interact with at least 1 protein. Because the size of the circle in Figure 4E indicates the number of interacting partners, we can infer that proteins such as FN1, TGFB1, APP, HSPD1, and SERPINE1 have a large number of interacting partners. For example, FN1, which had 37 interactions, was found to be the most interactive protein, followed by TGFB1 and APP, which had 24 and 22 interactions, respectively. HSPD1 (16 interactions) was the most interactive protein among the upregulated proteins. SERPINE1, PLAT, TF, and PLAU also showed relatively high degrees of interaction. A total of 15 proteins were found to interact with more than 10 partners. These highly interacting proteins are listed in Supporting Information, Table S3. We also list the 22 proteins that did not have any reported interaction partners in the STRING database (Supporting Information, Table S4).

■ DISCUSSION

Here, we present evidence that GKB, a model polyacetylene compound derived from wild vegetables, inhibited the proliferation of various human colorectal cancer cells through the intracellular accumulation of ROS and the consecutive induction of apoptotic cell death. The GKB-induced apoptotic cell death was triggered through both the intrinsic mitochondrial and extrinsic death receptor pathways. GKB induced the activation of initiator caspases, caspase-8 and caspase-9, as well as executioner caspase, caspase-3. We also elucidated the secreted proteins and the theoretical interaction network underlying the GKB-induced apoptotic HCT116 cell death using LC−MS/MS and bioinformatics analyses. The summarized schematic diagram depicting the GKB-induced apoptotic cell death in HCT116 cells and the potential secretory proteins are shown in Figure 5. To the best of our knowledge, this study is the first report describing the molecular mechanism and analyzing the secretory proteome of dietary polyacetylene-induced apoptotic cancer cells.

Secreted proteins play pivotal roles in many biological phenomena, including cancer biology, and the secreted proteome has often been analyzed using LC−MS/MS technology. However, until now, few investigations of the secreted proteome from apoptotic cancer cells induced by bioactive chemicals have been reported.[18,20] We think that this scarcity is due to several key limitations. First, serum-free medium is usually used during the analysis of the secretome to minimize the background protein signals that arise from the serum. However, serum starvation can often affect apoptotic cell death, and unwanted cell death is triggered even in the vehicle control cells.[16,34] This phenomenon can make it difficult to discriminate which secreted proteins came from the apoptotic cells. Second, as apoptotic cell death progresses, the plasma membrane integrity is gradually destroyed, and nonspecific cytosolic proteins are abundantly found along with the proteins that are actively excreted from the apoptotic cancer cells.[35,36] Until now, isotope labeling or cyanine dye staining methods have been used to compare the differential secretome profiles between the control cells and the apoptotic cells. However, these methods require expensive and cumbersome labeling procedures.

In the present study, we successfully analyzed the secreted proteome of GKB-induced apoptotic cancer cells without the use of conventional labeling methods. Our method consisted of two main strategies. First, we optimized the conditioned media for secretome analysis (CMS). To minimize unwanted cell death induced by serum deprivation, we supplemented the medium with glucose and amino acids, as glucose and amino acid deprivation are known to induce apoptosis in various cancer cells.[37−40] When HCT116 cells were cultured in CMS, the apoptotic cell population was significantly lower than the population of cells that were cultured in MEM that did not contain serum and additional nutrients, such as glucose and amino acids (data not shown). We confirmed that the changes in the protein expression of ADAM9, SERPINB5, and IL18 were well correlated between the LC−MS/MS spectral counting analysis and the ELISA both in the serum-free CMS and in the serum-containing normal medium. Although the tendencies of changes in protein expression were identical between ELISA and LC−MS/MS analysis results, the exact fold change values were somewhat different. These differences might have arisen by differences in dynamic range of the two experiments: higher sensitivity of ELISA and low dynamic range in LC−MS/MS analysis.[19] Second, we further analyzed the secretory proteins using GO term analysis to exclude the cytosolic proteins that were nonselectively excreted due to the loss of plasma membrane integrity. Before the GO term screening, most of the significantly changed proteins were classified as increased (89.7%; 112 decreased, 978 increased); on the other hand, after screening, only 44.4% of the significantly changed secretory proteins were classified as increased (70 decreased, 56 increased, Figure 4A). These data implied that many of the false positive proteins, which were thought to be the nonselectively excreted proteins due to the loss of the plasma membrane, could be excluded by the GO term analysis. We report here that the secretory proteome of chemically induced apoptotic cancer cells could be successfully analyzed without the use of the isotope or cyanine dye staining. We hope that our approaches can be used to analyze other secretomes to elucidate the molecular mechanisms underlying apoptotic cell death induced by various bioactive chemicals.

In this study, we discovered a total of 125 secretory proteins whose expression significantly changed after treatment with the dietary polyacetylene, GKB. These proteins may be involved in the apoptotic cell death of cancer cells. Therefore, their functions in the programmed cell death of cancer cells deserve to be studied. This list of candidate proteins can be narrowed down to a smaller number based on their feasibility and probability. Here, we suggest a priority list of the secretory proteins involved in the programmed cell death of human colorectal cancer cells triggered by the chemical. We analyzed the possible interactions between the secreted proteins whose expression significantly changed following treatment with the dietary polyacetylene using the STRING tool. We speculated that the highly scored or interactive proteins might have stronger influences on the apoptotic cell death of cancer cells. We suggest that the high-scored proteins, such as FN1, TGFB1, APP, HSPD1, and SERPINE1, belong in the priority group. All 15 proteins that have more than 10 interacting partners are shown in Supporting Information, Table S3. As we speculated, almost half (7 proteins) of the high-scored proteins had GO terms related to apoptosis.

We further searched the functions of these highly interactive proteins (Supporting Information, Table S3). Here we list some representative proteins. First, for decreased proteins, FN1 was reported to induce programmed cell death in human hematopoietic cell by interacting with very late antigen 5 (VLA5).[41] TGFB1 induces B lymphoid cell apoptosis by first blocking cells at the G1/S transition, followed by apoptosis.[42] APP was overexpressed during neuronal apoptosis which was induced by the treatment of *N*-methyl-D-aspartate (NMDA). [43] SERPINE1 (also known as plasminogen activator inhibitor type 1) overexpression was associated with decreased apoptosis in neoplastic cells.[44] Second, for increased proteins, HSPD1 exerted both negative and positive effect on apoptosis.[45] Proteins SOD1 and TXN were antiapoptotic in ischemic renal epithelial cells and murine skin, respectively.[46,47] ACTN4 increased rate of apoptosis by interacting with and activating DNase Y during apoptosis.[48] In some proteins, it was surveyed that the expression level and their function may not correlate with each other. However, as we could see in the case of HSPD1, proteins were found out to be both negative and positive on apoptosis. Further investigation should be needed in order to assign the accurate function of the proteins.

In addition, we believed that some proteins may be involved, but their functions and interactions may not have been reported yet, and thus they might have low scores according to the STRING analysis. These proteins may be novel because they have not yet been investigated in relation to apoptosis. For these reasons, low-scored proteins also deserve consideration. Thus, we selected 22 proteins that did not have any interacting partners among the secreted proteins found in our study (Supporting Information, Table S4). Among them, only 2 proteins had GO terms related to apoptosis. The functional study of these high- and low-scored proteins will help us understand the programmed cell death of cancer cells induced by the bioactive chemicals, and these studies should be applied to the development of novel cancer therapeutic agents. Therefore, further studies elucidating the genetic and biochemical functions of these secretory proteins are needed.

Here, we also propose that GKB, a dietary polyacetylene, is a potential cancer chemopreventive agent. In the present study, we demonstrate that the antiproliferative activity of GKB against various human cancer cells originated from the induction of apoptotic cell death, not from necroptosis. In addition to the induction of apoptotic cell death, GKB induces phase II detoxification enzymes, including quinone reductase, via the Nrf2 signaling pathway in cultured colon and liver cells.[13] A

recent animal study reported that GKB attenuated inflammation and colon carcinogenesis in the azoxymethane/dextran sodium sulfate mouse model.[12]

However, in order for GKB to be a promising chemopreventive agent, the bioavailability and stability issues have to be resolved. There are a number of studies regarding bioavailability of polyacetylenes. They include in vivo studies[49] as well as Caco-2 cell uptake assays.[50,51] In those studies, it is demonstrated that a few polyacetylenes, which appear to be hydrophobic, are bioavailable.[50] Additionally, polyacetylenes are reported to be unstable.[6,52]

To overcome these stability and bioavailability issues, various techniques may be applied. Among them, we expect that nano- or microencapsulation, a technique which is widespread throughout the food engineering and pharmaceutical industries, could be a promising solution.[53−55] Many studies have shown that the parameters of pharmacokinetics and pharmacodynamics can be improved upon nanoencapsulation of classical drugs.[53] We expect that further in-depth study including the bioavailability assessment of GKB and the application of GKB nanoencapsulation may serve as a milestone for the development of GKB as a cancer chemopreventive agent.

In summary, we demonstrated that the suppression activity of GKB against HCT116 human colorectal cancer cells was due to the induction of apoptotic cell death, which was dependent on intracellular ROS accumulation and was triggered through both mitochondrial and death receptor pathway. We also suggested possible secretory proteins that may be involved in the GKB-induced apoptotic cell death of cancer cells using LC−MS/MS and bioinformatics analyses. Our approach and data might be applied to the functional study of apoptosis-related genes, as well as to the development of novel cancer chemopreventive agents.

PSPAs can scavenge oxygen free radicals, reduce lipid peroxides in blood and liver, and prevent liver damage induced by dimethylnitrosamine (DMA), *tert*-butyl hydroperoxide (T-BHP), and acetaminophen (APAP).[16−18] However, the pathological process of liver damage induced by chemicals is not the same as that induced by alcohol consumption and thus could not simulate the process of ALD. Besides, there is still no study of the preventive effect of PSPAs on acute and subacute ALD. Therefore, we carried out righting reflex loss and recovery experiments of mice under alcoholic intoxication to investigate the potential dealcoholic effect of PSPAs. In addition, to investigate the preventive effect on acute and subacute ALD of PSPAs, we tested the liver function index, lipid peroxidation degree, antioxidase activity, and liver histopathology in the body of mice treated by PSPAs by establishing acute and subacute ALD mice models.

MATERIALS AND METHODS

Plant Materials. PSP (cultivar 'YAN No. 176') was obtained from the Academy of Agricultural and Forestry Sciences in Hebei Province. They were harvested at the beginning of October 2011 and immediately kept at 10−14 °C. Within 2 weeks, the harvested PSPs were washed thoroughly, sliced, and freeze-dried. All samples were ground using a domestic grinder and stored in sealed aluminum foil bags at −20 °C prior to extraction. The proximate composition of the obtained PSP powder, which was already published by us, was as follows: moisture, 10.82 ± 0.12% (w/w); starch, 65.35 ± 1.25% (w/w); protein, 8.21 ± 0.14% (w/w); fat, 0.7 ± 0.02% (w/w); ash, 3.89 ± 0.02% (w/w); and crude fiber, 4.87 ± 0.09% (w/w).[19]

Preparation of PSPAs. Anthocyanins were extracted from PSP according to published methods.[19] Briefly, the dried PSP powder, ammonium sulfate, deionized water, and ethanol were mixed according to the quality proportion of 2:4:11:5, and the mix mentioned above was blended well and then kept still to form two phases completely. The formed aqueous two-phase system was kept in a dark place for 30 min at room temperature and then centrifuged at 4 °C and 5000*g* for 10 min. A separating funnel was used to separate the above-mentioned two phases. The upper phase was concentrated in a rotary evaporator, adsorbed by macroporous resin (AB-8), and eluted by 70% of ethanol solution at an elution flow rate of 1 mL/min. The effluent was collected, concentrated, freeze-dried, and stored at −20 °C in sealed aluminum bags.

Total Anthocyanin Quantification. A pH-differential method was used to determine the total anthocyanin content.[20] Briefly, 0.0125 g of the extract was dissolved in 1 mL of distilled water. Two water solutions were carried out on the sample. Potassium chloride (0.025 M) and sodium acetate (0.4 M) were used to set the pH values of the two solutions at 1.0 and 4.5, respectively. The two solutions were diluted to make the absorbance at 520 nm <1.2. The diluted solutions were equilibrated for 15 min, and then absorbances at 520 and 700 nm were recorded using an UV−vis spectrophotometer model UI-trospec 2000 (Amersham Pharmacia Biotech, Dubendorf, Switzerland). Absorbance was calculated as $A = (A_{510\ nm} - A_{700\ nm})_{pH1.0} - (A_{510\ nm} - A_{700\ nm})_{pH4.5}$, and total anthocyanin content was calculated using the following formula and expressed as milligrams of cyanidin 3-glucoside equivalent (CGE)/100 g PSPAs:

$$C = (A/eL) \times M \times D \times (V/W) \times 100$$

C is total anthocyanin content (mg CGE/100 g PSPAs), A is the absorbance mentioned above, e is the molar absorbance of cyanidin 3-glucoside (26900 L/cm/mol), L is cell path length (1 cm), M is the molecular weight of cyanidin 3-glucoside (432 g/mol), D is dilution multiple, V is the final volume (mL), and W is the sample weight (mg).

HPLC-ESI-MS/MS Analysis of Anthocyanins. The anthocyanins in purple sweet potato extract were analyzed using an Agilent 1200 series high-performance liquid chromatography (Agilent Technologies, Palo Alto, CA, USA) connected to an Agilent 6410 triple-quadrupole mass spectrometer. The column used was an Agilent Zorbax SB-C18 column (250 mm × 4.6 mm i.d., 5 μm). The operating conditions were as follows: flow rate, 0.5 mL/min; injection volume, 20 μL; and column temperature, 25 °C. The elution solvents were (A) 0.1% v/v trifluoroacetic acid in water and (B) acetonitrile. The gradient was as follows: from 5 to 30% B from 0 to 5 min; from 30 to 45% B from 5 to 45 min; from 45 to 90% B from 45 to 50 min. Spectra from 200 to 600 nm were scanned, and anthocyanins were detected at 254 nm. To identify PSP anthocyanins, electrospray ionization (ESI) was run in the positive ion mode in the mass range from 400 to 2000 (m/z) and under the following conditions: flow rate, 8.0 L/min; drying gas temperature, 350 °C; nebulizer pressure, 40 psi; and capillary voltage, 4500 V.[19]

Experimental Animals and Growth Conditions. Seven-week-old male inbred (C57BL/6) mice were obtained from Vital River Laboratories (VRL) (Beijing, China). The animals were kept under controlled conditions at 18−26 °C and 40−70% relative humidity with a 12 h dark−light cycle and acclimated for 2 weeks prior to use. Feed pellets and disinfected tap water were provided for cafeteria feeding. Experiments were carried out on the basis of the regulations of the Experimental Animal Welfare and Ethics Committee, Chinese Association for Laboratory Animal Sciences (CALAS).

Alcoholic Intoxication Experiments. For the righting reflex loss experiment of alcoholic intoxication, C57BL/6 mice were separated into four groups, 10 animals in each group: control group (same volume of saline), low-dose group (50 mg PSPAs/kg body weight), middle-dose group (125 mg PSPAs/kg body weight), and high-dose group (375 mg PSPAs/kg body weight). All groups were fasted for 12 h, and then PSPAs in saline were administered intragastrically. Thirty minites later, mice were treated with 50% ethanol solution (18 mL/kg body weight). Duration of the ethanol-induced loss of righting reflex was recorded. Judgment standard of lost righting reflex was as follows: the ethanol-treated mice were placed back down, and the righting reflex was judged as lost if the above pose was maintained for >30 s.

For the righting reflex recovery experiment of alcoholic intoxication, the grouping method was the same as that used in the righting reflex loss experiment of alcoholic intoxication. All groups were fasted for 12 h and then treated with 50% ethanol solution (18 mL/kg body weight). Thirty minutes later, all groups were administered intragastrically PSPAs in saline once. The duration of recovery of righting reflex was recorded.

The righting reflex for each control or treatment mouse was performed in triplicate. The duration of ethanol-induced loss of righting reflex and the duration of recovery of righting reflex for each mouse were recorded as means of three experiments.

Acute and Subacute ALD Mice Models. For the prevention experiment of PSPAs on acute ALD, C57BL/6 mice were divided into five groups of 12 animals: negative control (without anthocyanins and ethanol treatments), acute ALD mice model group (with ethanol treatment only), low-dose group (50 mg PSPAs/kg body weight), middle-dose group (125 mg PSPAs/kg body weight), and high-dose group (375 mg PSPAs/kg body weight). The same volumes of saline were administered intragastrically for the negative control and acute ALD mice model group, whereas PSPAs were administered intragastrically for low-, middle-, and high-dose groups once daily for 30 consecutive days; food and water intakes of mice were recorded once a day. Four hours after the last administration, the negative control group was fed by gavage using an equal amount of purified water, whereas the other groups were treated with a 50% ethanol solution (12 mL/kg body weight). All groups were fasted for 16 h, and then anesthesia was carried out by injecting 60 mg/kg body weight pentobarbital sodium into the abdominal cavity of the mice. Blood was sampled from the abdominal aorta to determine activities of serum aspartate aminotransferase (AST), alanine aminotransferase (ALT), triglyceride (TG), total cholesterol (TCH), low-density lipoprotein cholesterol (LDL-C), and lactate dehydrogenase (LDH). Livers were weighed and cut into slices, some of which were kept in buffered formalin for histological observation, and 10% of liver tissue homogenates was obtained from the remaining liver sections and stored at −75 °C.

For the prevention experiment of PSPAs on subacute ALD, the grouping method was the same as that used in the prevention experiment of PSPAs on acute ALD. The same volumes of saline were administered intragastrically for the negative control and acute ALD model group, whereas PSPAs were administered intragastrically for low-,

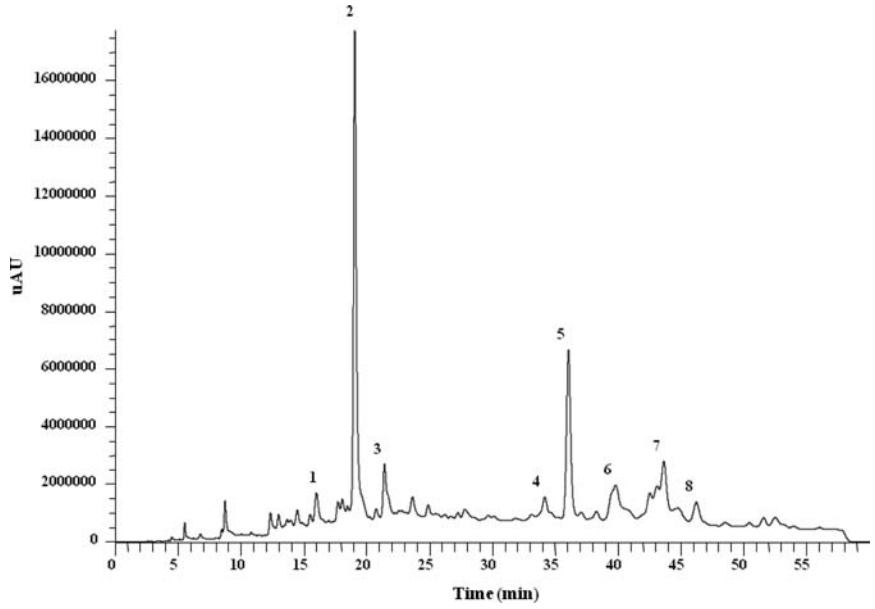

Figure 1. HPLC chromatogram of purple sweet potato anthocyanin compounds detected at 254 nm. Peak numbers refer to Table 1.

Table 1. Mass Spectrometric Data and Identification of Purple Sweet Potato Anthocyanins

peak	retention time (min)	$[M^+]$ (m/z)	major fragment ion (m/z)	identification	ref
1	16.02	471	448, 297	cyanidin-3-glucoside	22

5	36.07	1111	949	peonidin 3-(6″,6‴-dicaffeoyl sophoroside)-5-glucoside	23
6	39.83	949	787, 463, 301	peonidin 3-caffeoyl sophoroside-5-glucoside	23
7	43.66	1069	907, 447, 301	peonidin 3-caffeoyl-*p*-hydroxybenzoylsophoroside-5-glucoside	23
8	46.26	1125	963, 463	peonidin 3-(6″-caffeoyl-6‴-feruloylsophoroside)-5- glucoside	23

middle-, and high-dose groups once daily for 30 consecutive days. A 30% ethanol solution was fed by gavage at 10 mL/kg body weight once a day to the model group and anthocyanins groups for 14 days before the finish of this experiment, and the duration between the administration of saline or anthocyanins and the administration of ethanol was >4 h. All groups were fasted for 4 h, and then anesthesia was carried out by injecting 60 mg/kg body weight pentobarbital sodium into the abdominal cavity of mice. Blood was sampled from the abdominal aorta to determine the activities of serum ALT, AST, LDH, TCH, TG, and LDL-C. Livers were weighed and cut into slices, some of which were kept in buffered formalin for histological observation, and 10% of liver tissue homogenates were obtained from the remaining liver sections and stored at −75 °C.

Determination of Liver Index. The liver index of mice was calculated according to the following equation: liver index = liver weight/body weight × 100%.

Determination of Serum ALT, AST, LDH, TCH, TG, and LDL-C Activities. Activities of serum ALT, AST, LDH, TCH, TG, and LDL-C were determined using the corresponding kits (Nanjing Jiancheng Bioengineering Institute, Nanjing, China).

Determination of Hepatic MDA, SOD, GST, and ADH Levels. Mice liver samples were blended with 30 mM cold phosphate buffer and 1% TritonX-100 and ground in a tissue grinder. The supernatant was obtained for assay of malondialdehyde (MDA), SOD, GST, and alcohol dehydrogenase (ADH) according to the instructions of corresponding kits (Nanjing Jiancheng Bioengineering Institute).

Histopathological Observation. Mice liver sections were fixed for 24 h in 10% formalin buffer, embedded in paraffin for hematoxylin and eosin staining, and then observed using a light microscope. The magnification was 100 times, and at least 10 areas of each tissue slice were observed.

Statistical Analysis. Experiments were performed in at least triplicate. The results were expressed as means ± SD (standard deviation). Statistical analysis was carried out with SAS software (version 8.1, SAS Institute Inc., Cary, NC, USA). Significant differences were decided at $p < 0.05$.

RESULTS AND DISCUSSION

Total Anthocyanins and Identification of PSPAs. On the basis of the result of the pH-differential method, the total anthocyanin content was 3.02×10^4 mg cyanidin 3-glucoside equiv/100 g PSPAs, and the yield of PSPAs corresponded to 0.93% of the PSP powder. Figure 1 shows the HPLC chromatogram of PSPAs. Eight constituents were separated. From the UV−visible spectra, LC-ESI/MS spectra, and some literature sources (Table 1 and Supporting Information Figure 1), seven constituents were identified. Peaks 1 and 4 were tentatively identified as cyanidin-3-glucoside and peonidin-3-methoxyglucoside, respectively.[21] Peaks 3, 5, 6, 7, and 8 were tentatively identified as peonidin 3-*p*-hydroxybenzoyl sophoroside-5-glucoside, peonidin 3-(6″,6‴-dicaffeoyl sophoroside)-5-glucoside, peonidin 3-caffeoyl sophoroside-5-glucoside, peonidin 3-caffeoyl-*p*-hydroxybenzoyl sophoroside-5-glucoside, and peonidin 3-(6″-caffeoyl-6‴ -feruloyl sophoroside)-5-glucoside, respectively.[22] Peak 2 was a new discovery, which will be further investigated.

Alcoholic Intoxication Experiments. The loss of righting reflex indicates that mice have become drunk, whereas the recovery of righting reflex means that mice have sobered up.[23]

Table 2 shows the effect of PSPAs on durations of ethanol-induced loss and recovery of righting reflex. Compared with control, intake of PSPAs extended the duration of ethanol-induced loss of righting reflex significantly ($p < 0.05$), especially for the high-dose PSPAs group ($p < 0.01$), where the duration of ethanol-induced loss of righting reflex was extended to 13.69 ± 2.75 min [2.29 times control (5.97 ± 2.83 min)], indicating that PSPAs may have potential prevention effect on alcoholic intoxication. Besides, in middle- and high-dose PSPA groups, the durations of the recovery of the righting reflex were both shortened significantly ($p < 0.05$), indicating that PSPAs may have a potential curative effect on alcoholic intoxication.

Table 2. Effect of PSPAs on the Durations of Ethanol-Induced Loss and Recovery of Righting Reflex[a]

treatment group	duration of loss of righting reflex (min)	duration of recovery of righting reflex (min)
control	5.97 ± 2.83	445.55 ± 24.87
low-dose PSPAs	10.22 ± 3.16#	423.51 ± 15.12
middle-dose PSPAs	11.77 ± 2.10#	383.76 ± 13.22#
high-dose PSPAs	13.69 ± 2.75##	382.73 ± 18.08#

[a]Values are the mean ± standard deviation of 10 determinations. Compared with control #, $p < 0.05$; ##, $p < 0.01$.

Growth and Liver Index of C57BL/6 Mice. The liver index can partly reflect the level of ALD.[24] Table 3a shows the effects of PSPAs on original body weight, final body weight, liver weight, and liver index of mice in the acute ALD experiment. No significant difference was found for the changes of body weight between different treatment groups, and no significant difference was found for the final body weight between the different treatment groups, either. Compared with control, acute alcohol intake resulted in a significant increase of liver weight (1.27 ± 0.12 g) and liver index (5.92 ± 0.17%) ($p < 0.01$), which were 117.59 and 123.08% of control (liver weight and liver index were 1.08 ± 0.10 g and 4.81 ± 0.22%, respectively). Compared with the model, liver weights in the low-, middle-, and high-dose groups were reduced by 3.15, 3.15, and 11.81%, respectively, and the liver indices in the low-, middle-, and high-dose groups were reduced by 6.25, 7.09, and 7.60%, respectively. However, even in the high-dose PSPA group, the liver weight (1.12 ± 0.07 g) and liver index (5.47 ± 0.12%) were still 3.70 and 13.72% higher than those of the control. Our result was in agreement with that reported by McKim et al.,[25] who found that antioxidants such as cocoa flavonoids could reduce acute ALD.

Table 3b shows the effects of PSPAs on original body weight, final body weight, liver weight, and liver index of mice in the subacute ALD experiment. Compared with control, the body weight of mice in the model group (20.82 ± 0.78 g) was reduced significantly by 6.68% ($p < 0.05$). The possible reason was that the metabolism of alcohol changed the digestive function of the stomach and intestine, resulting in changes of food consumption. The liver index can partly reflect the severity of ALD. Compared with control, subacute alcohol intake resulted in a significant increase of liver weight (1.16 ± 0.09 g) and liver index (5.57 ± 0.33%) ($p < 0.01$). Compared with model, liver weights in the middle- and high-dose PSPA groups were reduced significantly ($p < 0.01$) by 2.59 and 4.31%, respectively, and the liver indices in the middle- and high-dose PSPA groups were reduced significantly ($p < 0.01$) by 9.87 and 11.13%, respectively. Particularly, no significant difference was found between the liver index of the high-dose PSPA group and that of control.

Serum ALT, AST, and LDH Activities. The change of serum biochemical indices is an important symbol of liver damage. Serum transaminases (i.e., ALT and AST) are essential catalysts in human metabolic process. Increasing ALT is a mark of liver cell membrane damage, and increasing AST is a mark of liver cell mitochondria damage. When damages such as inflammation and necrosis happen to liver cells, ALT and AST are released into the blood, causing an increase of serum transaminase.[26] The effect of PSPAs on the activity of serum ALT and AST of the acute ALD mice is shown in Figure 2a. Compared with control, the activities of ALT and AST in the model group increased significantly ($p < 0.01$), indicating that acute alcoholism caused damages of liver cell membrane and mitochondria. Compared with the model group, the activity of ALT in low-, middle-, and high-dose groups of PSPAs decreased by 47.28, 35.15, and 45.04%, respectively, and the activity of AST decreased by 17.67, 28.39, and 30.21%, respectively, indicating that PSPAs had a preventive effect on acute ALD. Our result was similar to the effect of genistein on ALD.[27] Figure 2c shows the effect of PSPAs on the activity of serum ALT and AST of the subacute ALD mice. Compared with control, the activity of AST in the model group increased, but not

significantly, indicating that the intake of alcohol had caused slight damage of liver cell membrane and mitochondria. Compared with the model group, the activity of ALT in low-, middle-, and high-dose groups of PSPAs decreased by 11.11, 12.70, and 21.30%, respectively, and the activity of AST decreased by 13.60, 13.94, and 17.73%, respectively, indicating that PSPAs had a preventive effect on subacute ALD.

Besides, under normal circumstances, LDH contained in living cells could not penetrate the cell membrane; when cells were affected by outside poisonous substances, the cell membrane would be damaged, and the permeability of the cell membrane would be changed; thus, the intracellular LDH would be released into extracellular fluid, resulting in the increase of LDH activity.[28] The effect of PSPAs on the activity of serum LDH of the acute ALD mice is shown in Figure 2b. Compared with control, the LDH level of the model group showed a significant increase ($p < 0.01$). Intake of PSPAs in advance could inhibit the increase of LDH, especially in the high-dose group, for which the activity of LDH (386.80 ± 14.94 U/L) was 10.21% lower than that of model (430.80 ± 37.75 U/L), and no significant difference was found between the LDH level of the high-dose PSPAs group and that of control (394.20 ± 24.94 U/L) ($p > 0.05$). The effect of PSPAs on the activity of serum LDH of the subacute ALD mice wis shown in Figure 2d. Compared with control, the LDH level of the model group showed a significant increase ($p < 0.01$), indicating that intake of alcohol caused damage to the cell membrane. Intake of PSPAs in advance could inhibit the activity of LDH, especially in middle- and high-dose groups, as there was no significant difference between the LDH activities of the middle-dose (293.60 ± 39.29 U/L) and high-dose (281.00 ± 18.51 U/L) groups and that of control (286.40 ± 38.88 U/L) ($p > 0.05$). Our result was in agreement with that reported by Tang et al.,[29] who studied the effect of quercetin on ALD and found that quercetin could alleviate the release of liver-specific aminotransferases induced by ethanol. The possible reason is that anthocyanins and quercetin are both flavonoids, which possess strong antioxidant activity (Supporting Information Figure 2), and one of the mechanisms of alleviating ALD is inhibiting the increase of oxidative stress.

Serum TG, TCH, and LDL-C Levels. At the primary phase of alcoholic liver disease, TG and TCH will accumulate massively, which is a sensitive indicator of reflecting lipometabolism. LDL-C is endogenous TG, and excessive intake of alcohol will cause the increase of synthesis of LDL-C. The effect of PSPAs on serum TCH, TG, and LDL-C levels of acute ALD mice is shown in Figure 3a,b. Compared with control, the levels of TCH and TG in the model group increased by 4.39 and 12.96%, respectively. Compared with the model group, the levels of serum TCH in low-, middle-, and high-dose anthocyanin groups decreased by 11.34, 13.03, and 20.59%, respectively, and the levels of serum

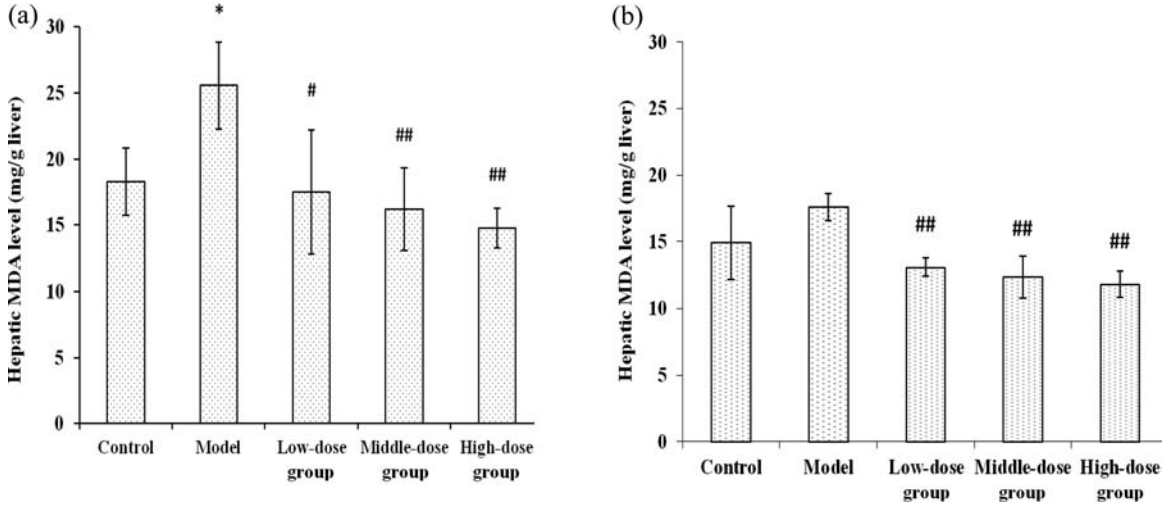

Figure 4. Effect of PSPAs on the hepatic MDA level of the ALD mice: (a) effect of PSPAs on hepatic MDA level of acute ALD mice; (b) effect of PSPAs on hepatic MDA level of subacute ALD mice. Compared with control: *, $p < 0.05$; **, $p < 0.01$. Compared with model: #, $p < 0.05$; ##, $p < 0.01$.

TG in low-, middle-, and high-dose PSPA groups decreased by 19.67, 21.31, and 19.67%, respectively. Moreover, the level of TCH in the high-dose PSPA group was 17.11% lower than control ($p < 0.05$), and no significant difference was found between the levels of TG in all PSPA groups and control. These results indicate that intake of PSPAs can alleviate alcohol-induced accumulation of TCH and TG. Our results were in accordance with those reported by Zhang et al.,[6] who found

dx.doi.org/10.1021/jf405032f | J. Agric. Food Chem. 2014, 62, 2364−2373

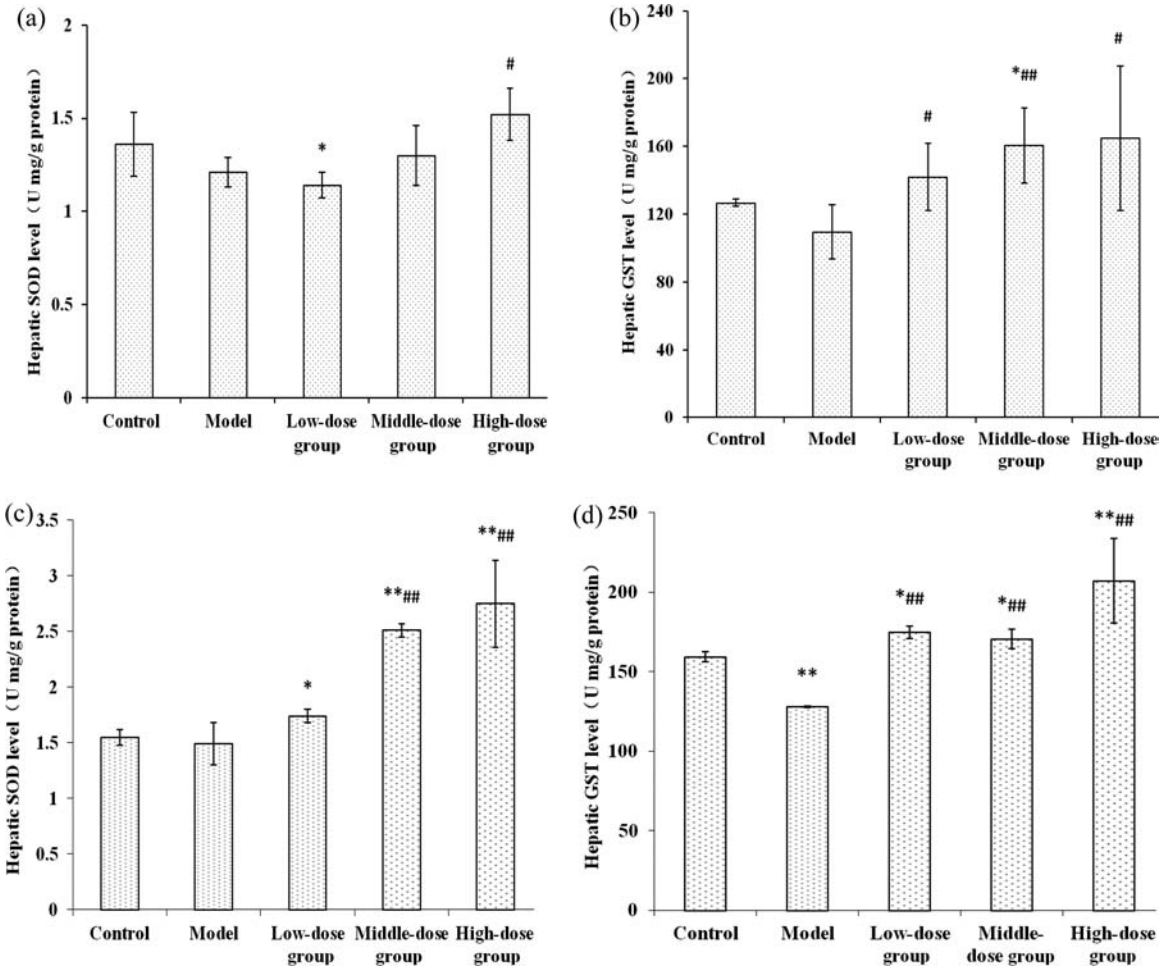

Figure 5. Effect of PSPAs on the hepatic SOD and GST levels of the ALD mice: (a) effect of PSPAs on hepatic SOD level of acute ALD mice; (b) effect of PSPAs on hepatic GST level of acute ALD mice; (c) effect of PSPAs on hepatic SOD level of the subacute ALD mice; (d) effect of PSPAs on hepatic GST level of subacute ALD mice. ostruthin could inhibit the increase of TCH, TG, and LDL-C induced by alcohol and alleviate acute alcohol intoxication and hepatic lipid metabolism. The possible reason was that anthocyanins and ostruthin both belong to flavonoids and possess strong antioxidant activity (Supporting Information Figure 2).

Studies showed that long-term intake of alcohol would increase the NADH/NAD^+ ratio, up-regulate lipogenesis, and down-regulate transport capacity of fatty acid, causing hepatitis.[30] Therefore, chronic intake of alcohol is often accompanied by the increase of blood lipids, but antioxidants can reduce this trend. Taurine[31] and fermented barley[32] could reduce the increase of blood lipids induced by ALD significantly because of their antioxidant activity. Our result was similar to reported results. Subacute intake of alcohol increased the levels of serum TCH and TG by 14.17 and 51.69%, respectively. Compared with the model, the levels of serum TCH in low-, middle-, and high-dose PSPA groups were decreased by 5.32, 9.57, and 13.48%, respectively, and the levels of serum TG in low-, middle-, and high-dose PSPA groups were decreased by 26.67, 34.81, and 39.26%, respectively. Furthermore, there was no significant difference between the serum TCH and TG levels of low-, middle-, high-dose PSPA groups and control (Figure 3c,d).

Hepatic MDA Level. After a lot of alcohol intake in a brief period, alcohol is metabolized in the liver, producing some aldehyde compounds, which can combine with protein, release a large amount of reactive oxide species (ROS), and increase internal oxidative stress level and lipid peroxidation. MDA is the main product of lipid peroxidation induced by ROS, and the content of MDA can reflex the oxidative stress level of liver.[33]

Figure 4a shows the effect of PSPAs on the hepatic MDA level of the acute ALD mice. Compared with control, MDA in the model group increased significantly ($p < 0.05$) by 39.69%, indicating that alcohol intake increased the oxidative stress level of liver. Compared with the model group, MDA levels in low-, middle-, and high-dose PSPA groups decreased significantly ($p < 0.05$) by 31.55, 36.56, and 42.31%, respectively, and no significant difference was found between all PSPA groups and control. The possible reason is that PSPAs possess strong antioxidant activity. Our result was similar to the result of Bharrhan et al.,[34] who found that catechin could decrease MDA in alcohol-induced damaged liver of rats.

Figure 4b shows the effect of PSPAs on the hepatic MDA of the subacute ALD mice. Compared with control, MDA in the model group increased by 17.97%. Pretreated by PSPAs, lipid peroxidation of mice was inhibited significantly, and thus MDA was decreased significantly ($p < 0.01$) by 25.47, 29.73, and 32.75% for low-, middle-, and high-dose PSPA groups,

low-dose PSPAs	hepatocyte edema ++	hepatocyte edema +	hepatocyte edema ++
middle-dose PSPAs	hepatocyte edema +	–	–
high-dose PSPAs	hepatocyte edema +	–	–

[a]"–" indicates no lesion; "+", minor lesion; "++", mild lesion; "+++", moderate lesion; "++++", severe lesion.

respectively. Particularly, the MDA level in the high-dose PSPA group was 20.66% lower than that in control. This can be attributed at least partly to the capacity of eliminating active oxygen radicals of anthocyanins. Our result is in agreement with the findings of You et al.[35] and López et al.,[36] who found that the antioxidants in taraxacum and amaranth had some preventive effects on ALD.

Hepatic SOD and GST Levels. In recent years, people are paying more attention to the effect of oxidative stress and lipid peroxidation on ALD. Alcohol can produce a large amount of radicals during its metabolism in the liver, for example, O_2^-, H_2O_2, and OH^-. When the radicals go beyond the elimination ability of human body, liver cells will be damaged.[37] GST and SOD are important internal antioxidases, which can alleviate oxidative stress caused by alcohol. Some studies have already showed that intake of antioxidants such as vitamin E and vitamin C in advance could alleviate alcohol-induced liver damage.[38]

The effect of PSPAs on the hepatic SOD level of the acute ALD mice is shown in Figure 5a. SOD activity in the model group (1.21 ± 0.08 U mg/g protein) was 11.03% lower than that in control, indicating that the elimination ability of mice on O_2^- was weakened by alcohol intake. Compared with the model, SOD activity in the high-dose PSPA group was increased significantly ($p < 0.05$) by 25.62% and was even 11.76% higher than normal level (control, 1.36 ± 0.17 U mg/g protein); thus, the ability to eliminate O_2^- was also improved, and the liver damage was alleviated.

Intake of alcohol will increase the internal oxidation products, and GST can eliminate oxygen free radicals effectively, prevent oxidative stress, and inhibit lipid peroxidation. Acetaldehyde is an alcohol metabolite, which can combine with GST, resulting in changes of membrane permeability and fluidity; thus, the structure and function of cells are damaged. Moreover, when the structure and function of cells are damaged, free radicals will not be eliminated; thus, liver damage will be aggravated. At present, the decrease of GST content is considered to be one of the mechanisms of ALD. Figure 5b shows the effect of PSPAs on the hepatic GST level of the acute ALD mice. Compared with control, the GST level in the model group decreased by 13.67%, indicating that the liver cell membrane was damaged. The GST content in anthocyanin groups was increased significantly in a dose-dependent relationship, and the GST contents in low-, middle-, and high-dose PSPAs groups were even 11.89, 26.62, and 30.08% higher than that in control, indicating that PSPAs could alleviate alcohol-induced oxidative stress, thus alleviating alcohol-induced liver damage. Our result is in agreement with that reported by Tang et al.,[29] who found that taurine could decrease alcohol-induced dyslipidemia and oxidative damage.

The effects of PSPAs on hepatic SOD and GST levels of the subacute ALD mice are shown in Figure 5c,d. Compared with control, the SOD and GST levels in the model group decreased.

dx.doi.org/10.1021/jf405032f | J. Agric. Food Chem. 2014, 62, 2364−2373

Intake of PSPAs in advance increased the SOD and GST activityies significantly ($p < 0.01$) to normal levels, and the SOD and GST levels in the high-dose group were 77.42 and 29.94% higher than those in the control group.

Hepatic ADH Level. ADH is a metalloenzyme existing in liver cell cytoplasm and mitochondria, which can transform ethanol into acetaldehyde and then oxidize acetaldehyde into acetic acid. In mitochondria, some acetic acid can enter into the tricarboxylic acid cycle and be oxidized into CO_2 and H_2O, which are removed from the body.[39] The effect of PSPAs on the hepatic ADH level of the acute ALD mice is shown in Figure 6a. Compared with control, the ADH level of the model group decreased significantly ($p < 0.01$) by 59.56%, indicating that a large amount of alcohol could not be metabolized into CO_2 and H_2O, causing hepatotoxicity easily. Compared with the model group, ADH activities in low-, middle-, and high-dose PSPA groups were increased by 34.31, 46.76, and 62.14%, respectively. However, the ADH activity in the high-dose PSPA group was still 34.43% lower than in the control group.

The effect of PSPAs on the hepatic ADH level of the subacute ALD mice is shown in Figure 6b. Compared with control, ADH activity in the model group decreased significantly ($p < 0.01$). Compared with the model group, ADH activity of anthocyanin groups increased significantly ($p < 0.05$). However, ADH activity of high-dose PSPA group was still 45.59% lower than that of the control group.

Histopathological Analysis. Table 4a and supplement Figure 3 showed the effect of PSPAs on the histopathology of the acute ALD mice. The liver cells of C57BL/6J mice in control group had complete structure, similar size, tight arrangement, uniform staining, and no liver pathological changes. In model group, the mice liver cells showed pathological changes, e.g. loose arrangement and cellular edema. In anthocyanins low-dose group, the pathological changes of mice liver cells were similar to that in model group, e.g. disordered arrangement of cells and cellular edema, but the degree thereof was reduced. In anthocyanins middle and high-dose groups, no pathological changes was observed, and the cellular morphology thereof was close to that of control group.

The effect of PSPAs on the histopathology of subacute ALD mice is shown in Table 4b and Supporting Information Figure 3f–i. Compared with control, pathological changes such as liver cell swelling and fatty degeneration happened to mouse liver in the model group, which included mice that were treated with alcohol continuously. After the intake of PSPAs, liver cell swelling was alleviated significantly, and the improving pathological effect showed a dose-dependent relationship. Liver tissue morphology after high-dose anthocyanin treatment was similar to that after normal treatment.

Noni (*Morinda citrifolia*) is native to lands from Southeast Asia to Australia and is also cultivated in Polynesia, India, the Caribbean, South America, and southern Taiwan.[16]

Noni can inhibit various pathogens, such as *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Proteus morgaii*, *Bacillus subtilis*, *Escherichia coli*, and different strains of *Salmonella* and *Shigella*.[17,18] Noni juice also provides an anti-inflammatory effect to relieve locally acute inflammation and selectively inhibits COX-1 and COX-2 expression.[16,19] A previous study has shown that noni fruit contains abundant polyphenols and alkaloids.[16]

Noni exhibits various biological activities, but its effect on *H. pylori* are still unknown. This study determines the effect of noni fruit extracts on the adhesion of *H. pylori* and *H. pylori*-induced inflammation.

MATERIALS AND METHODS

Preparation of Ethanol and Ethyl Acetate Extracts. One hundred grams of noni fruit powder was extracted with 1 L of 95% ethanol or 99% ethyl acetate for 24 h at room temperature. The residues were removed by filtration, and the extracts were evaporated to dryness, under vacuum, at 37 °C. The dried extracts were transferred into airtight amber bottles and stored at −80 °C. The phenolic compounds of both extracts were measured using high-performance liquid chromatography (HPLC).

HPLC Analysis of Phenolic Compounds Present in Noni Fruit Extracts. The phenolic compounds were separated using HPLC with a binary gradient intelligent pump (L6200A, Hitachi) and a UV−vis detection system (L4250, Hitachi). A Lichrospher 100 RP-18e (Merck) column (5 μm, 25 cm × 4 mm i.d.) and security guard RP-18e (5 μm, 4 × 4 mm i.d.) were used. The mobile phase consisted of 2.5% (v/v) acetic acid water solution (solvent A) and acetonitrile (solvent B). The gradient program consisted of 3% B, initially, changing to 21% B after 4 min, was maintained at 21% B until 10 min and raised to 22% B after 11 min, was maintained at 22% B until 15 min and raised to 35% B after 16 min, was maintained at 35% B until 35 min and raised to 100% B after 36 min, and was maintained at 100% B until 40 min and then reduced to 3% B after 45 min. The injection volume for all samples was 20 μL. Simultaneous monitoring was performed at 266 nm, and the flow rate was 0.8 mL/min.

Isolation and Culture of *H. pylori*. *H. pylori* was isolated from gastric ulcer patients. The gastric mucus of gastric ulcer patients was collected after executed gastroscopy. The *H. pylori*-positive tissues were detected by a urease rapid test. The gastric mucus (*H. pylori*-contained) was seeded in *H. pylori* selection medium (10 mg/mL vancomycin, 2.5 U/mL polymyxin B, 5 mg/mL trimethoprim, and 2 mg/mL amphotericin B in 22 g/L brucella broth) in an anaerobic pack at 37 °C for 72 h. The activity and purity of the *H. pylori* was determined using morphology, urease, and oxidase test (genotype belong to CagA and urease positive strains). *H. pylori* was stored in 30% glycerin-containing medium at −80 °C.

Cell Line and Culture. Human gastric cancer cell lines (AGS cells, BCRC 60102) were cultured using F12 nutrition mixture medium containing 10% FBS fetal bovine serum and 1% penicillin−streptomycin at 37 °C in a humidified incubator containing 5% CO_2.

Cell Viability Assay. The effect of extracts on cell viability was studied using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT). AGS cells were seeded in a 96-well plate with 200 μL (5×10^5/mL) of cells in each well and left overnight. The cells were treated with various concentrations of noni extracts (200, 400, 600, or 800 μg/mL) or *H. pylori* and 0.05 mg/mL amoxicillin at 37 °C for 24 h. The medium was replaced by fresh medium, containing 0.5 mg/mL MTT, and cultured at 37 °C for 4 h. One hundred microliters of isopropanol was added to each well to dissolve the crystals. The optical density of each sample was read at 630 nm against the blank prepared from the cell-free well.

Bacterial Drug Sensitivity Test. The *H. pylori* suspension (optical density = 0.3 at 600 nm for 1×10^8 CFUs/mL) was treated with various concentrations of noni extracts (0.05, 0.096, 0.189, 0.375, 0.75, 1.25, 2.5, 5, or 10 mg/mL) cultured in an anaerobic pack, at 37 °C for 24 h. One hundred microliters of suspension was detected using ELISA at 600 nm for the minimum inhibitory concentration (MIC) test. One hundred microliters of suspension was mixed with 100 μL of urease reagent (3 mM PBS, pH 5.8; and 2% urea and 7 μg/mL phenol red, pH 5.0) at 37 °C for 4 h, and the minimum bactericidal concentration (MBC) was measured at 560 nm.

Antiadhesion Assay. AGS cells were seeded in a 24-well plate with 5×10^5/mL cells, and 400 μL of medium was added to each well overnight. The *H. pylori* suspension (15 μL) and samples (200, 400, or 600, or 800 μg/mL) were added to each well. After 6 h, nonadherent bacteria were washed off, using PBS. The amount of adherent bacteria was estimated using urease reagent and *H. pylori* antibody−FITC (no. GTX36341, GenTex, USA). The suspension was collected to determine the amount of nonadherent bacteria at 600 nm and to measure the bacterial viability in the urease reagent at 560 nm.

Determination of IL-8 Protein. The level of IL-8 protein from the cell-cultured medium was measured using a commercial enzyme-linked immunosorbent assay kit (no. K0031216, Koma Biotech Inc., Korea).

CagA, iNOS, and COX-2 Protein Expression Assay. AGS cells were seeded in a 10 cm dish with 1×10^5/mL. *H. pylori* suspension was added and cocultured with the extracts for 6 h. All cells were collected and disintegrated by using cell lysis buffer (no. 9803, Cell Signaling, USA). Cell proteins were collected after centrifuged (6708*g*) for 10 min at 4 °C. CagA, iNOS, and COX-2 protein expression were detected by Western blot.[20]

The protein was resolved in 10% SDS−polyacrylamide gels and electroblotted on a polyvinylidene difluoride (PVDF) membrane. The membrane was blocked in 5% fatfree dried milk, dissolved in TBS buffer (25 mM Tris, pH 7.4, 150 mM NaCl, 0.3% Tween-20).

The membrane was soaked with anti-COX-2 polyclonal antibody (ab52237, Abcam, UK), anti-iNOS polyclonal antibody (ab3523, Abcam, UK), or anti-CagA monoclonal antibody (ab90490, Abcam, UK) overnight at 4 °C. The removed antibody and membrane were soaked with an appropriate HRP-conjugated secondary antibody (ab6721, Abcam, UK) for 1 h at room temperature. The reacted bands of the target proteins were revealed by enhanced chemiluminescence, using an enhanced chemiluminescence (ECL) commercial kit (Amersham Pharmacia Biotech, Piscataway, NJ, USA).

Neutrophil Isolation. Whole blood was collected from a human, mixed with 4.5% dextran, and left to subside for 40 min at 37 °C (the ratio of whole blood to 4.5% dextran was about 4:1). An upper layer was obtained, which contained neutrophils and residual red blood cells (RBCs), and this was then mixed with Ficoll hypaque and centrifuged at 400*g* for 10 min at 25 °C. The leukocytes pallet was mixed with Ficoll hypaque (the ratio of pallet to Ficoll hypaque was about 2:1) at 400*g* for 10 min at 25 °C, and the upper layer was removed. RBC lysis buffer was added for 5 min to remove erythrocyte (the ratio of pallet to RBC lysis buffer was about 1:4). After centrifuging at 250*g* for 10 min at 25 °C, the cell residue was mixed with RPMI medium (containing 15% FBS) and cultured at 37 °C for 24 h. Cell viability and morphology were determined by MTT and Giemsa stain (no. 32884, Sigma, Germany).[21]

Neutrophil Chemotaxis Assay. Neutrophil chemotaxis was determined by two-chamber techniques. Thirty microliters of supernatant of *H. pylori* cocultured with AGS cells or various concentrations of extracts were poured into the lower layer. The IL-8 protein (1000 pg/mL) was used as a positive control. Fifty microliters of neutrophils (2×10^5/mL) was added to the upper layer. A PVP-free membrane was placed between the lower and upper layers and cultured for 1 h at 37 °C. The degree of migration of neutrophil was calculated by Giemsa stain.[22]

Statistical Analysis. All results are presented as the mean ± SD (n = 6). The difference in the results for this study was assessed using a one-way ANOVA of SPSS (version 12.0; SPSS Inc.). A significant difference is identified for $p < 0.05$.

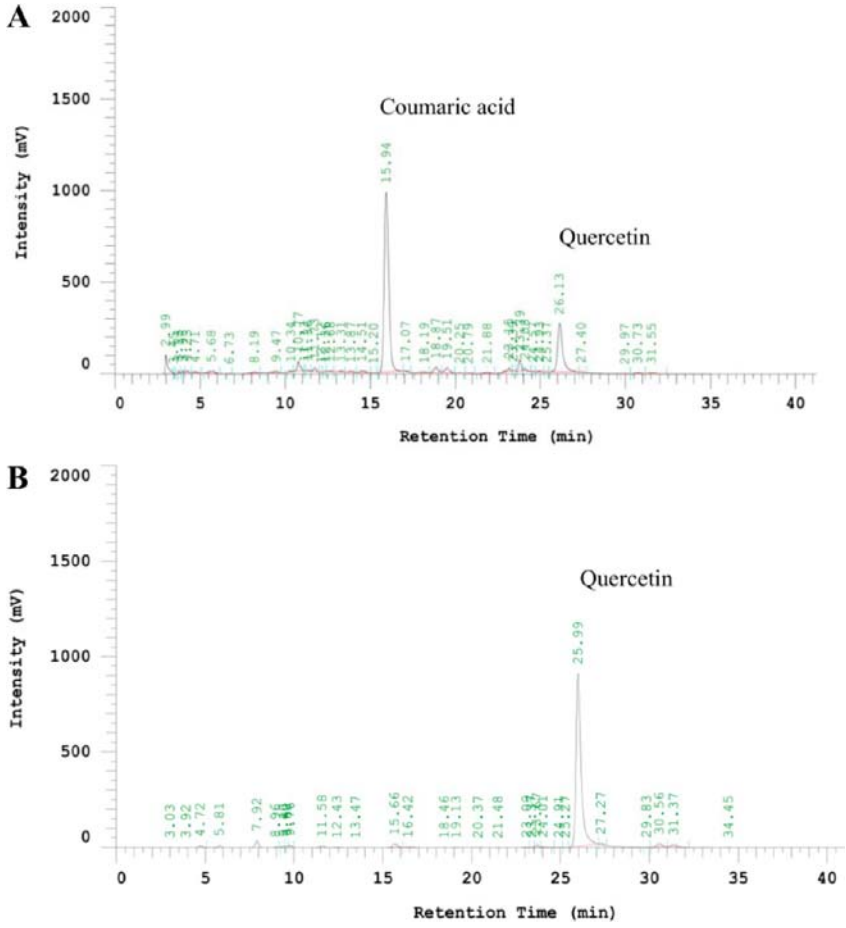

Figure 1. HPLC profiles of phenolic compounds present in ethanol (A) and ethyl acetate (B) extracts of noni fruit.

RESULTS AND DISCUSSION

Phenolic Profile of Both Extracts. Phenolics have manifold bioactive effects, such as antibacterial, antiadhesion, and anti-inflammation, in animal or cell models.[23,24] Noni fruit has been found to contain several phenolics and flavonoids.[25]

Ethanol extract contained 48.81 ± 7.06 mg/g total phenolics and 40.91 ± 1.17 mg/g total flavonoids. Ethyl acetate extract contained 68.82 ± 4.62 mg/g total phenolics and 39.38 ± 0.44 mg/g total flavonoids. Ethanol extract contained 2.8 ± 0.02 mg/g and ethyl acetate contained 6.9 ± 0.06 mg/g condensed tannins. The ethyl acetate extract was more abundant in phenolics, flavonoids ,and condensed tannins than the ethanol extract.

The phenolic profiles of ethanol and ethyl acetate extracts were measured by HPLC. Large amounts of coumaric acid and quercetin were found in the ethanol extract (23.8 and 4.4 mg/g extract), whereas the ethyl acetate extract contained abundant quercetin (28 mg/g extract) (Figure 1).

Effect of Noni Fruit Extracts on *H. pylori*. Ethanol and ethyl acetate extracts of noni fruit showed poor inhibition on the density of *H. pylori* at lower doses (0.04−2.5 mg/mL) (Figure 2A). Similar results were also found for bacterial viability (Figure 2B). The ethanol extract had a better MIC (5 mg/mL) than the ethyl acetate extract (10 mg/mL). Both extracts had the same MBC (10 mg/mL), but it was much poorer than that for amoxicillin (0.04 mg/mL). Amoxicillin is widely used to eradicate *H. pylori*; it was deemed a positive control.[26] Noni fruit extracts showed bactericidal activity at high concentrations (Figure 2B). The effects of noni fruit extracts on the growth of *H. pylori* were weak, even though both extracts contained abundant coumaric acid and quercetin (Figure 1).

Actually, *H. pylori* could resist fractional antibiotics, such as macrolides, metronidazole, tetracycline, and quinolones.[27] It is difficult to eradicate *H. pylori* from humans using antibiotics. In this study, a moderate way to prevent the colonization of *H. pylori* was demonstrated.

Antiadhesion of *H. pylori* to Gastric Epithelial Cells. *H. pylori* adhesion clearly influences local inflammation and disease formation. Thus, the adhesion of *H. pylori* on AGS cells was measured after treatment with both extracts. First, the cell viability of noni fruit extracts and appropriate ratio of *H. pylori* to AGS cells were determined. Both extracts had no effect on cell viability (200−800 μg/mL) after 24 h of culture. The appropriate ratio of *H. pylori* to cells was 300:1 (data not shown).

Panels A and B of Figure 3 show the antiadhesion activity of both extracts on *H. pylori*, which appeared to be dependent on concentration. Nonadhering *H. pylori* was detected in the cocultured suspension (Figure 3C,D). The viability of *H. pylori* in the suspension remained unchanged after treatment with both extracts except for amoxicillin (Figure 3E,F).

Noni fruit extracts showed weak inhibition of bactericidal activity on *H. pylori*, but greatly reduced its adhesion to epithelial cells. Adhesion is an important step for the growth, colonization, and transportation of bacteria pathogen-associated molecules to the host cell. The CagA protein is transported to

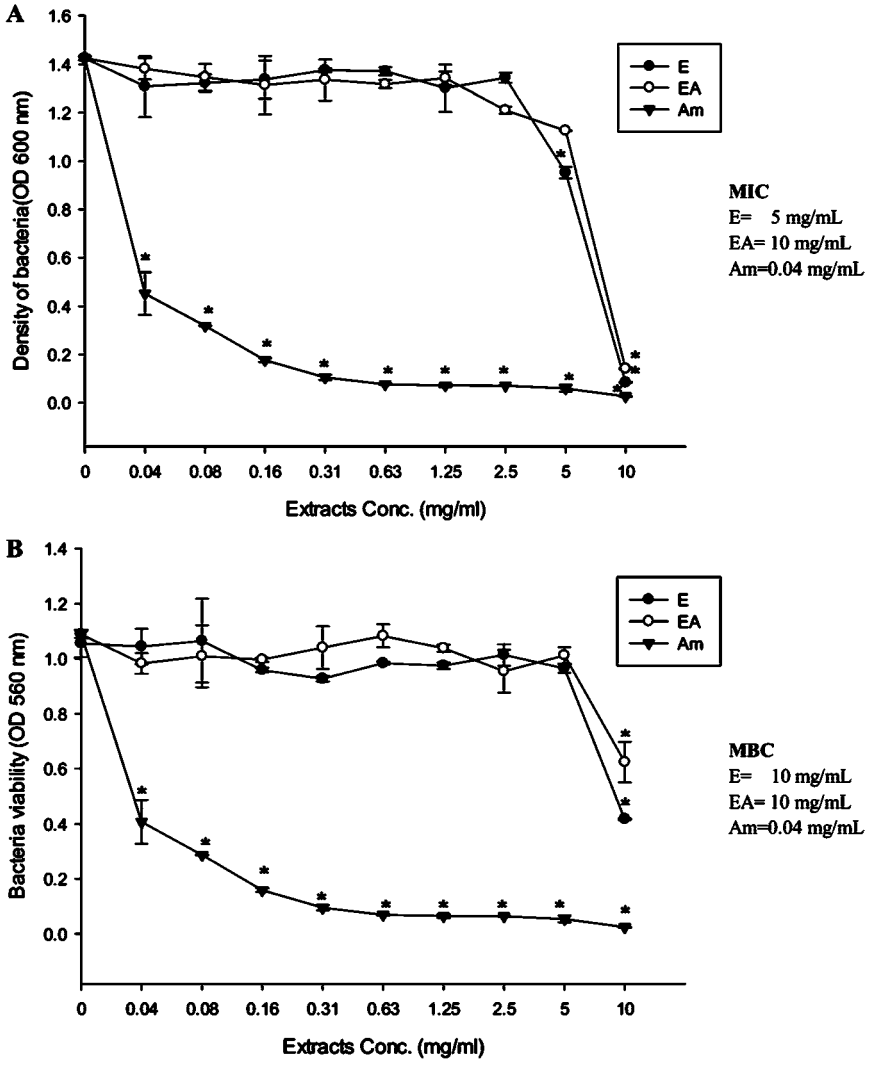

Figure 2. Density (A) and viability (B) of *H. pylori* after noni fruit extract treatment. *H. pylori* was cultured with extracts for 24 h. The MIC and MBC of treatments were measured. (∗) Significantly different as compared with 0 mg/mL. E, ethanol extract; EA, ethyl acetate extract; Am, amoxicillin.

the host cell via a T4SS after *H. pylori* adheres to the gastric epithelial cell.[28] Therefore, the inhibition of the adhesion of *H. pylori* may relieve the inflammation and decrease the risk of gastric diseases.

Inhibition on IL-8 and CagA. *H. pylori* induces inflammation and releases cytokines from host cells or immune cells. IL-8 is an important factor in the development of gastric diseases during *H. pylori* infection.[2] IL-8 protein allows neutrophil infiltration, which causes severe inflammation and tissue disruption and further leads to gastritis, gastric ulcer, and gastric cancer.[8]

CagA, iNOS, COX-2, and IL-8 proteins were induced during *H. pylori* infection. Time-dependent increases of CagA, COX-2, iNOS, and IL-8 protein production were found, and these molecules reached the maximum at 6 h (data not shown). Indeed, the production of IL-8, iNOS, and COX-2 on AGS cells was not changed during both extract treatments separately (data not shown).

Furthermore, the effects of noni fruit extracts on *H. pylori*-induced inflammatory response were determined. Ethanol extract significantly inhibited intercellular CagA protein, but there was a difference among 200, 400, 600, and 800 μg/mL (Figure 4A). Ethyl acetate extract inhibited CagA protein at concentrations >400 μg/mL (Figure 4B). Similar results also appeared on the IL-8 production; both extracts significantly inhibited IL-8 secretion (Figure 4C,D).

CagA protein is produced by *H. pylori*, which is transported into host cell via a T4SS. CagA can induce IL-8 protein secretion, and it also regulates transcription factors via CagA phosphorylation or phosphorylation-independent pathways.[5,6] The intracellular CagA protein was determined to ascertain the severity of *H. pylori* infection. These results showed the change of CagA and IL-8 resulted in antiadhesion for *H. pylori*, which prevented CagA transportation and modified IL-8 production.

Inhibition of COX-2 and iNOS. *H. pylori* induces the expressions of iNOS and COX-2 proteins, which causes tissue damage. Furthermore, iNOS and COX-2 increase the risk of gastritis, gastric ulcer, and gastric cancer. Therefore, the effect of noni fruit extracts on inflammation of *H. pylori*-induced on AGS cells was evaluated.

The expression of COX-2 protein was significantly lower for both extract treatments than with *H. pylori* infection only (Figure 5A,B). The ethanol extract did not affect the expression

of iNOS protein. Ethyl acetate extract showed significant inhibition at concentrations >400 μg/mL (Figure 5C,D).

The expression of COX-2 and iNOS protein in gastritis, gastric ulcer, or gastric cancer patients with *H. pylori* infection is higher than in *H. pylori*-negative patients.[29] The overexpression of COX-2 protein causes host cell invasion, proliferation, and apoptosis, which increase the risk of tissue lesions.[30] The iNOS protein induces the secretion of IL-8 protein and increases tissue inflammation.[31] Interestingly, the ethanol extract demonstrated antiadhesion, but did not restrain the expression of iNOS at 200−600 μg/mL (Figures 3A and 5C). This result showed that iNOS expression may not be relevant to the adhesion of *H. pylori*.

The inhibition of COX-2 and iNOS expression by noni extracts probably proceeded via antiadhesion and regulates the inflammatory signal in the host cell during *H. pylori* infection.

dx.doi.org/10.1021/jf405199w | J. Agric. Food Chem. 2014, 62, 2374−2383

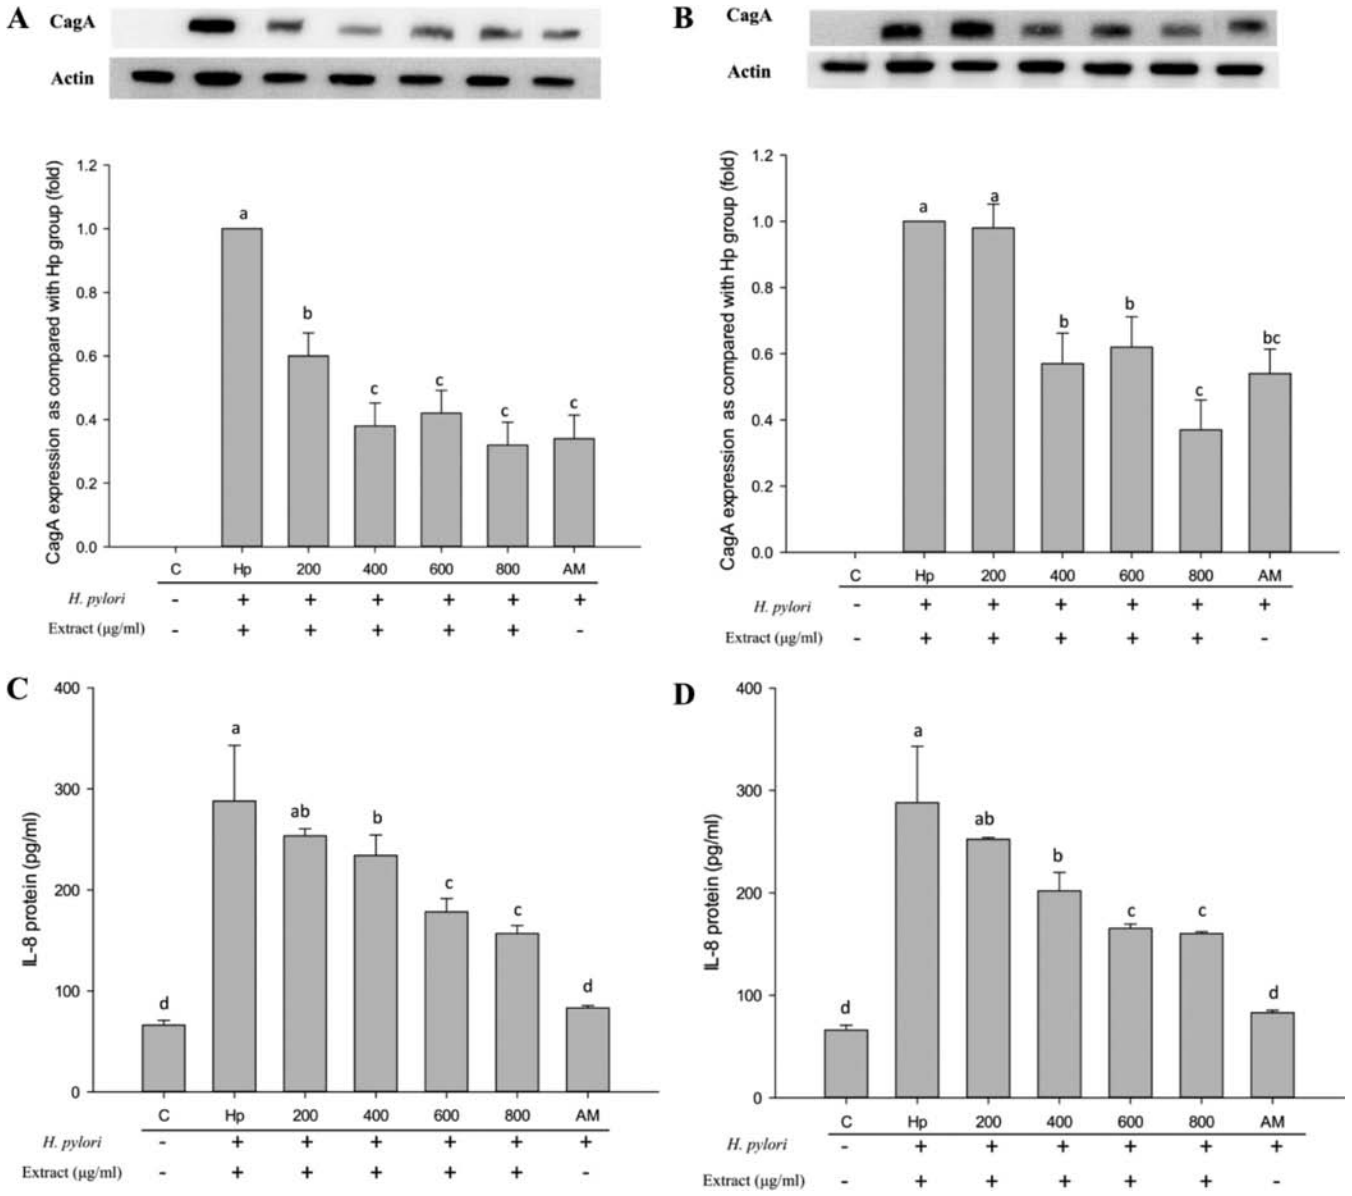

Figure 4. Transportation of CagA on AGS cells induced by *H. pylori* after ethanol (A) and ethyl acetate extract (B) treatment and expression of IL-8 induced by *H. pylori* after ethanol (C) and ethyl acetate extract (D) treatment. Extracts and *H. pylori* were cocultured with AGS cells for 6 h. Different letters above bars indicate significant difference. C, control, non-*H. pylori*; Hp, *H. pylori* cocultured only; Am, amoxicillin.

Moreover, noni root extracts are found to reduce the expression of COX-2, iNOS, and TNF-α in LPS-induced cells and animal models, and a similar composition is found in both root and fruit.[32] The ethyl acetate extract of noni fruit suppresses the expression of COX-2 and iNOS on LPS-induced macrophages.[19] The high polar extract of noni fruit also inhibits iNOS and COX-2 expression of gastric ulcer rat.[33] These results indicated that noni fruit extracts could regulate the *H. pylori*-induced inflammation.

Inhibition of Neutrophil Chemotaxis on *H. pylori* Infection. IL-8 plays a crucial role in neutrophil chemotaxis.[8] Noni fruit extracts showed inhibition on IL-8 during *H. pylori* infection (Figure 4C,D). To further demonstrate that the chemotaxis of neutrophil was relieved by noni fruit extracts, the cultured medium was collected after both extracts (800 μg/mL) and *H. pylori* (the ratio of *H. pylori* to AGS cells was the same as that for the antiadhesion assay) were cocultured with AGS cells for 6 h. The cultured medium was added to the lower layer, and the neutrophil isolated from human peripheral blood was seeded in the upper layer. Undeniably, IL-8 protein caused numerous migrations of neutrophils, and *H. pylori* groups also induced neutrophil chemotaxis (Figure 6). This result indicated that both extracts inhibited neutrophil migration (significantly different as compared with the *H. pylori* group) from a coculture medium. The ethanol extract showed powerful inhibition of neutrophil migration (significantly different to the antibiotic group) (Figure 6B).

Neutrophil is attracted during *H. pylori* infection, but the *H. pylori* cannot be eradicated. Long-term neutrophil infiltration causes tissue damage and local structural failure. The abundant infiltration of neutrophil is thought to increase the development of gastritis, gastric ulcer, or gastric cancer and to cause recurrence of gastric disease.[34] Therefore, the prevention of IL-8 secretion and neutrophil chemotaxis may decrease the risk of gastric disease.

Expression of COX-2 on AGS cells induced by *H. pylori* after ethanol (A) and ethyl acetate extract (B) treatment and expression of iNOS induced by *H. pylori* after ethanol (C) and ethyl acetate extract (D) treatment. Noni fruit extracts and *H. pylori* were cocultured with AGS cells for 6 h. Different letters above bars indicate significant difference. C, control, non-*H. pylori*; Hp, *H. pylori* cocultured only; Am, amoxicillin.

Contribution of Phenolic Compounds to Antiadhesion. Many studies demonstrate antiadhesion on various bacteria for plants or natural products, such as cranberry, green tea, and isolates of red wine.[35−37] The active ingredients are caseinoglycopeptides, fucosylated saccharides, glycoprotein, oligosaccharides, sialylgalactosides, proanthocyanidins, and other phenolic compounds.[37,38] Previous studies indicate that condensed tannins (such as proantocyanidin) show antiadhesion of *H. pylori*.[35,36,39,40] The contents of condensed tannin were scarce in both extracts of noni fruit, and their role in antiadhesion of *H. pylori* needs to be determined.

To confirm the importance of the phenolics on antiadhesion of *H. pylori* from noni fruit extracts, polyvinylpyrrolidone (PVP) was mixed with both extracts separately to precipitate phenolics. Both extracts lost the antiadhesion of *H. pylori* when the phenolics were removed (E-PVP and EA-PVP groups) (Figure 7). Accordingly, the phenolics of noni fruit extracts may play key role on antiadhesion of *H. pylori*. However, the effects of quercetin and coumaric acid on antiadhesion of *H. pylori* remain unknown.

To replicate the extracts, pure coumaric acid and quercetin were conversed to levels of each extract and were used to evaluate the effect on the antiadhesion of *H. pylori* infection. The group of equivalent contents of coumaric acid (19.04 μg/mL) in 800 μg/mL ethanol extract (E-C) provided antiadhesion on *H. pylori* (significant difference as compared with the Hp extract group), but the effect was weaker than the ethanol extract group (Figure 7). The group of equivalent contents of coumaric acid (19.04 μg/mL) and quercetin (3.52 μg/mL) in 800 μg/mL ethanol extract (E-CQ) demonstrated

dx.doi.org/10.1021/jf405199w | J. Agric. Food Chem. 2014, 62, 2374−2383

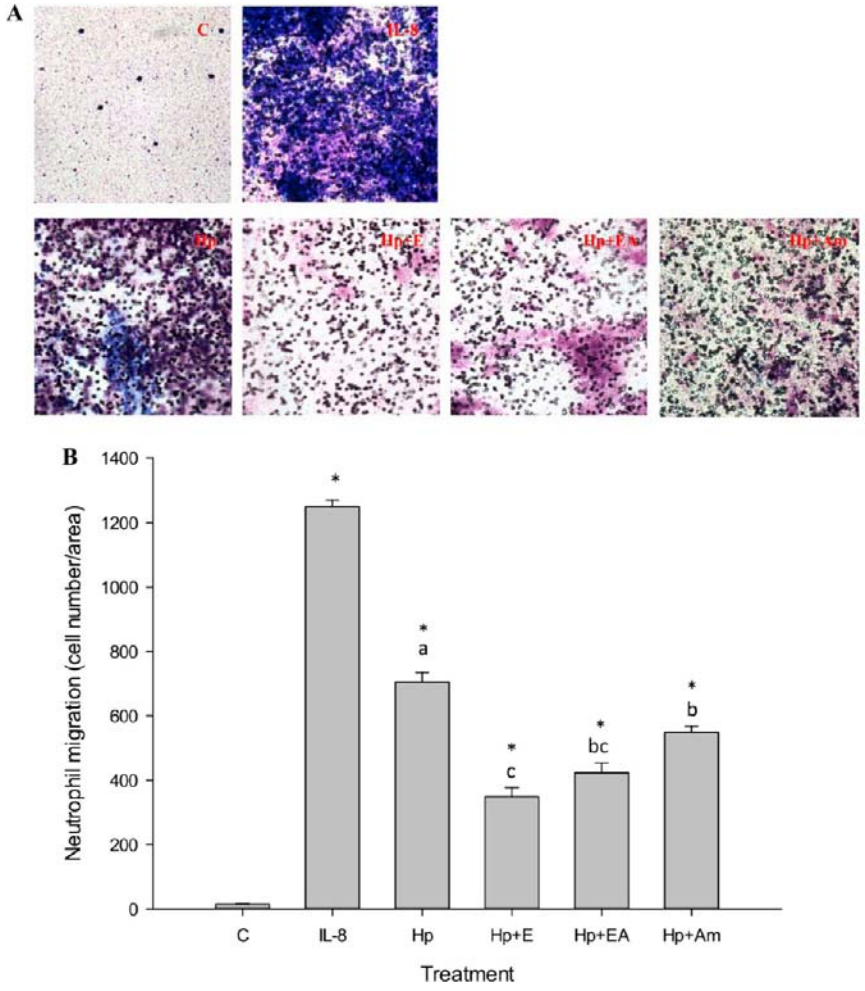

Figure 6. Effect of noni fruit extracts on neutrophil chemotaxis (A) and quantification (B). Different letters above bars indicate significant difference. (*) Significantly different as compared with the control. C, control, non-*H. pylori*; IL-8, IL-8 protein as positive control, 1000 pg/mL; Hp, *H. pylori* cocultured only; Hp+E, *H. pylori* and ethanol extract cocultured; Hp+EA, *H. pylori* and ethyl acetate extract cocultured; Hp+Am, *H. pylori* and amoxicillin cocultured.

great inhibition on adhesion (significant difference as compared with the Hp extract group) but was lower than that of the ethanol extract group (Figure 7). On other hand, the group of equivalent contents of quercetin (22.4 μg/mL) in 800 μg/mL ethyl acetate extract (EA-Q) provided inhibition on adhesion (significant difference as compared with Hp extract group) (Figure 7).

These results confirmed that quercetin and coumaric acid played key roles in the antiadhesion of *H. pylori* infection. However, the equivalent contents of coumaric acid showed weaker than ethanol or ethyl acetate extracts, respectively (Figure 7). Interestingly, the ethanol extract showed excellent inhibition on CagA transportation and antiadhesion at low dose (200 μg/mL) (Figure 4A). Thus, there are unknown components in ethanol extract of noni fruit that contribute to the antiadhesion and blocking CagA signal of *H. pylori*.

Coumaric acid can inhibit intestinal inflammation in dextran sulfate sodium (DSS)-induced rats by obstructing the COX-2 signal, but its effect on the expression of COX-2 and iNOS is weak.[41] Coumaric acid showed weak capability in prevention for *H. pylori* owing to no effect on growth of *H. pylori*.[42] In this study, the coumaric acid group (E-C) showed significant inhibition on the adhesion of *H. pylori* even though that was weaker than the ethanol extract group (Figure 7). The coumaric acid-rich ethanol extract also inhibited the expression of IL-8 and COX-2 proteins induced by *H. pylori* (Figures 4C and 5A). Coumaric acid probably interacted with other compounds to regulate inflammation during *H. pylori* infection. These results indicated that coumaric acid showed the potential to prevent formation of gastric diseases.

Undoubtedly, quercetin has a key role in the ethyl acetate extract against adhesion and inflammation during *H. pylori* infection. Quercetin is confirmed to selectively activate pro-inflammation signals, such as PGE_2 and NO production, to relieve inflammatory responses, and also to promote wound healing in animal models.[43,44] Quercetin also reduces inflammation and lipid peroxidation in *H. pylori* infection of gastric mucosa.[45]

The effect of quercetin on the adhesion of bacteria to AGS cells is still unknown. The mechanisms for the antiadhesion on bacteria are multifarious, such as target coating, adhesin inhibition, receptor inhibition, and receptor competitive inhibition.[46] The particular flavonoids, such as catechin, proanthocyanins, and anthocyanins, have been shown to change the surface modification and biofilm detachment to cause bacterial adhesion failure.[47,48] Thus, quercetin probably suppresses the adhesion of *H. pylori* via the similar pathway of catechin or proanthocyanin. The chemical structure of

dx.doi.org/10.1021/jf405199w | J. Agric. Food Chem. 2014, 62, 2374−2383

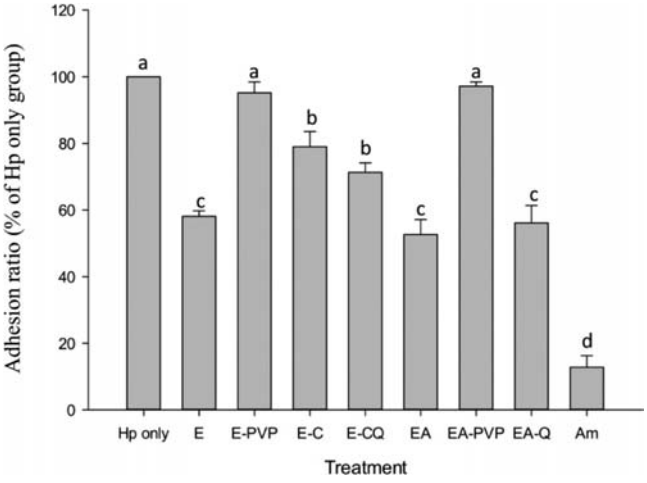

Figure 7. Contribution of phenolic compounds on antiadhesion. Different letters above bars indicate significant difference. C, control, non-*H. pylori*; Hp, *H. pylori* cocultured only; E, ethanol extract; EA, ethyl acetate extract; E-PVP, ethanol extract reacted with PVP before treated; EA-PVP, ethyl acetate extract reacted with PVP before treated; E-C, equivalent contents of ethanol extract; E-CQ, equivalent contents of coumaric acid and quercetin of ethanol extract; EA-Q, equivalent contents of quercetin of ethyl acetate extract; AM, amoxicillin.

coumaric acid is different from that of quercetin, and this could dominate the capacity of antiadhesion of bacteria.[42,43]

In this study, quercetin not only contributed to anti-inflammation but also inhibited the adhesion of *H. pylori*. It probably represented a new way to prevent or inhibit inflammation or pathogenesis that was caused by microorganisms. Indeed, the ethyl acetate fraction of noni fruit contains other phenolic compounds, such as scopoletin and rutin.[19] In this study, quercetin was found to be the major phenolic compound in ethyl acetate extract (Figure 1B). This was probably due to the variety of noni or sample extraction.

On the other hand, abundant coumaric acid and quercetin were found in the ethanol extract of noni fruit (Figure 1A). The group of equivalent contents of coumaric acid and quercetin in 800 μg/mL of ethanol extract showed weaker antiadhesion of *H. pylori* than that of ethanol extract treatment (Figure 7). This indicated that some other substances in the ethanol extract could contribute to the antiadhesion. Previous studies verify the various components in noni fruit, such as asperulosidic acid and anthraquinones, that may have the potential to affect the adhesion and inflammation for bacterial infection.[49,50] Moreover, the condensed tannin was found in ethanol extract. The antiadhesion of *H. pylori* disappeared in the E-PVP group (Figure 7). Accordingly, the high-polar condensed tannin probably played a critical role in the antiadhesion of *H. pylori*. Further studies are required.

Phenolics provide antioxidant, anti-inflammatory, or bactericidal activity and are rarely studied for their antiadhesion for bacteria. In this study, the phenolics of noni fruit were shown to regulate inflammation by impeding the attachment of *H. pylori* to the host cells. These results showed that coumaric acid and quercetin inhibited inflammation by reducing the adhesion of *H. pylori*.

Conclusion. Ethanol and ethyl acetate extracts of noni fruit showed excellent antiadhesion and anti-inflammation for AGS cells from *H. pylori* infection and decreased the risk of gastric diseases. Coumaric acid, quercetin, and unknown components probably played key roles. Further works to identify the unknown components are needed.

Noni fruit is an agent or supplement that prevents *H. pylori* adhesion or related diseases. Further work is required to confirm the actual mechanism for antiadhesion.

interferon-γ (IFN-γ) was purchased from PharMingen (San Diego, CA, USA). The AMV reverse transcriptase and dNTP mixture were obtained from Takara Bio (Kyoto, Japan). PCR primers were custom-synthesized and purified by Bioneer (Daejon, Republic of Korea). Analytical reagents were purchased from Sigma Aldrich (St. Louis, MO, USA) and used without further purification.

Preparation of Bioprocessed Polysaccharide (BPP). The isolation and characterization of BPP is described in our recent publication.[2] The amount of β-glucan in each extract was determined using a Mixed-Linkage-β-glucan Kit (Megazyme Intern Treland Ltd., Wicklow, Ireland).

Bacterial Strain and Culture Condition. *Salmonella enterica* subsp. *enterica* ser. Typhimurium (*S.* Typhimurium) ATCC 140 was obtained from the American Type Culture Collection (Manassas, VA, USA) and kept as frozen glycerol stock. Cells in frozen stock were streaked onto NA medium to produce cell colonies, from which a single colony was transferred to nutrient broth (NB) medium. For preparation of inocula, cells were grown for 20 h at 37 °C in NB. For infection, cultured bacterial cells were recovered by centrifugation at 13,000 rpm for 30 s and then washed with and resuspended in PBS. The turbidity of the cell suspensions was measured. The cell suspensions were diluted with PBS to the desired concentration of bacteria using a standard curve of optical density versus bacterial number determined as colony-forming units (CFU).

In Vitro Bactericidal Assay. *S.* Typhimurium cells were diluted with PBS to a density of 2×10^4 CFU/mL, treated with three concentrations of BPP (1, 10, and 100 μg/mL), and incubated at 37 °C for 0, 2, 4, and 8 h. After incubation, the diluted culture (100 μL) was plated onto NA medium to assess bacterial CFU.

Mammalian Cell Culture. Murine macrophage cell line RAW 264.7 from the American Type Culture Collection (Manassas, VA, USA) were cultured in RPMI 1640 medium supplemented with 10% heat-inactivated FBS containing 100 U/mL penicillin and 100 μg/mL streptomycin. The cells were cultured at 37 °C in humidified air containing 5% CO_2.

Morphologic Changes in Macrophages. RAW 264.7 cells were grown in the presence of BPP (100 μg/mL) in 24-well cell culture plates with coverslips for 8 h. The coverslips were examined under a microscope (100×) to observe morphologic changes in macrophages. Cells were selected in six blindly chosen random fields, and the morphologically changed cells were then counted and recorded. This assay was performed for at least three individual experiments.

Determination of Bacteria in Macrophages. To measure internalization and intracellular survival of bacteria in macrophages, RAW 264.7 cells were infected with *S.* Typhimurium following the method of Lu et al.[8] For analysis of macrophage bacterial uptake efficiency, inoculum (10 μL) containing 1×10^4 CFU was added to RAW 264.7 macrophage cells (1×10^4 cells) pretreated with three concentrations of the BPP (1, 10, and 100 μg/mL) and incubated for 30 or 60 min in a 5% CO_2 atmosphere. Cells were washed once with RPMI 1640 medium after incubation at 37 °C and then treated with the same medium containing 10% FBS and gentamicin (30 μg/mL) for 30 min to kill extracellular bacteria. For viable cell counting, the infected macrophage cells were washed three times and then lysed with distilled water. Aliquots of lysates were plated onto NA medium to measure bacterial CFU.

To measure intracellular survival, *S.* Typhimurium cells (1×10^4 CFU) were added to serially diluted BPP-treated macrophage sample for 4 h. The samples were incubated at 37 °C for 1 h, followed by washing once with medium and subsequent treatment with RPMI 1640 medium containing 10% FBS with gentamicin (30 μg/mL) for 2, 4, and 8 h. Cell washing, lysis, and plating procedures onto NA medium were carried out following the same protocol as for the analysis of bacterial uptake efficiency.

Mice and Treatments. The protocol for the mouse studies was approved by the Ethics Committee for Animal Care and Use, Ajou University, Republic of Korea. All experiments were performed in compliance with the relevant laws and institutional guidelines. Six- to eight-week-old female BALB/c mice were purchased from Orient Bio Inc. (Seongnam, Korea), and were hosted under a 12 h light/dark cycle at 20−22 °C and relative humidity of 50 ± 10%. The mice were fed freely a pelletized commercial chow diet obtained from Orient Bio Inc. (catalog no. 5L79) and sterile tap water during the entire period. After acclimation for 1 week, the mice were then divided into three groups (n = 10), avoiding any intergroup difference in body weight. BPP was dissolved in water, and given to mice via the dietary (oral) or the intraperitoneal (ip) route. Two groups were given BPP, whereas one was given only water. The dose of the BPP was adjusted to 10 mg/kg body weight for both routes. After administration of the BPP for 14 consecutive days, the mice were infected ip with sublethal or lethal doses of *S.* Typhimurium (1×10^4 CFU or 1×10^5 CFU). Collection of blood samples and excision of organs including liver and spleen were carried out for further experiments.

In Vivo Bactericidal Assay. After administration of BPP (10 mg/kg) for 14 consecutive days, mice were infected ip with a sublethal dose of *S.* Typhimurium (1×10^4 CFU). Two days later, the mice were sacrificed by CO_2 asphyxia, and the abdominal cavities were opened and repeatedly washed with a total PBS (10 mL) as described by Kodama et al.[9] Bacterial counts in the pooled PBS wash were determined by plating technique to measure CFU levels described above.

Serum Nitrite and Nitrate Levels. Serum nitrite and nitrate levels were measured primarily following the method of Misko et al.[10] with some modification. Blood samples collected by cardiac puncture were left at 37 °C for 20 min to obtain the serum, followed by filtration of the serum through an Ultrafree-MC microcentrifuge filter unit (Millipore, Bedford, MA, USA) for 1 h at 14,000 rpm to remove the hemoglobin released by cell lysis. The serum (50 μL) was incubated in a reaction mixture [(40 mM Tris Cl, 40 μM reduced β-nicotinamide adenine dinucleotide phosphate, 40 μM flavine adenine dinucleotide, and nitrate reductase (0.05 U/mL)] at pH 7.9 at 37 °C for 15 min. Reduced samples were incubated with an equal volume of Greiss reagent [1% sulfanilamide and 0.1% *N*-(1-naphthyl)-ethylenediamine dihydrochloride in 5% phosphoric acid] at room temperature for 15 min. The absorbance was read at 570 nm using a microplate reader (model 550, Bio-Rad, Hercules, CA, USA). Total nitrate/nitrite levels were determined by comparison with a reduced $NaNO_3$ standard curve.

Mitogen-Induced Lymphocyte Proliferation. Spleen cell suspensions were prepared by gentle pressing the spleen through a stainless steel mesh as described by Teixeira et al.[11] Thereafter, the cells were suspended in RPMI 1649 medium supplemented with 5% FBS and seeded into 24-well culture plates in the presence of concanavalin A (Con A, 2.5 μg/mL) to stimulate T cells. After stimulation for 72 h at 37 °C in 5% CO_2, cell proliferation levels were determined at 490 nm on a microplate. Cell numbers were determined using MTS [(3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium)] assay in the form of the CellTiter 96 aqueous nonradioactive cell proliferation assay kit (Promega, Madison, WI, USA) following the manufacturer's instructions. The increase of cell growth was determined by setting as 1 the growth of spleen cells from pathogen-free mice in FBS-supplemented RPMI 1640 medium without Con A.

ELISA of Cytokines. Th1 and Th2 cytokines (IL-1, IL-2, IL-6, and IL-12 vs IL-4, IL-5, and IL-10) in the culture supernatant of spleen cells from infected or mock-infected mice without Con A were determined by ELISA kits (Life Technologies, Carlsbad, CA, USA). The ELISA kit for IFN-γ was the product of Biosource Int. (Camarillo, CA, USA). After reactions, the absorbance of the final solution at 420 nm was read in a microplate reader (model 550, Bio-Rad, Hercules, CA, USA).

Mice Salmonellosis Study. The salmonellosis assay was carried out by the method of Kim et al.,[12] with some modification. Three groups of 10 mice each (water-treated control and BPP-treated experimental groups via ip and oral routes) were used for bacterial infection. Mice were infected ip with a lethal a dose of *S.* Typhimurium (1×10^5 CFU). After infection, the mice were treated with BPP (10 mg/kg) via the ip or oral routes every 24 h during the entire experimental period. To determine the survival rate, mice were observed for an additional 28 days after bacterial infection.

Histology of Liver Tissue. For histological analysis, the liver tissue of the mice was fixed with 4% paraformaldehyde in 0.5 M phosphate buffer (pH 7.4). The tissues were rinsed with water, dehydrated with ethanol, and embedded in paraffin. The liver tissue was sectioned into 4 μm samples and mounted onto glass slides. The sections were then dewaxed using xylene and ethanol and stained with hematoxylin and eosin Y (H&E) to reveal the hemorrhagic necrosis in the liver. Histological changes were observed under a light microscope at 100× magnification.

Reverse Transcription Polymerase Chain Reaction (RT-PCR) of Cellular RNA. Total cellular RNA was prepared following acid phenol guanidium thiocyanate−chloroform extraction.[13] For reverse transcription, total RNA (1 μg) was incubated with AMV reverse transcriptase (5 U) and oligo (dT18) as primer (100 ng). DNA amplification was then primed in a reaction mixture containing dNTP mix (400 μM), *Taq* polymerase (2.5 U), and primer sets (20 μM each) representing target genes as follows: inducible nitric oxide synthase (iNOS) sense primer, 5′-ATGTCCGAAGCAAACATCAC-3′; iNOS antisense primer, 5′-TAATGTCCAGGAAGTAGGTG-3′; β-actin sense primer, GTGGGGCGCCCCAGGCACCA-3′; β-actin antisense primer, 5′-GTCCTTAATGTCACGCACGATTTC-3′. PCR was conducted using a thermocycler (model PTC-200, MJ Research Inc., Reno, NV) with one cycle for 5 min at 94 °C, followed by 30 cycles for 30 s at 94 °C, 45 s at 58 °C, and 45 s at 72 °C, and finally one cycle for 5 min at 72 °C. All amplified PCR products were subjected to 1.5% agarose gel electrophoresis and visualized with a UV illuminator. The intensity of the separated bands of DNA was quantified using a gel documentation system (model LAS-1000CH, Fuji Photo Film Co., Tokyo, Japan).

Western Blot Analysis of Cell Proteins. The BPP-treated RAW 264.7 cells were lysed and extracted using RIPA buffer (50 mM Tris Cl, 150 mM NaCl, 1% NP-40, 0.5% sodium deoxycholate, 0.1% SDS, and 1 mM EDTA, pH 7.4). Protein concentrations were determined by the Bradford method using a Bio-Rad Protein kit. Bovine serum albumin (BSA) was used as standard. The cell extract containing proteins (30 μg) was separated on 10% SDS−polyacrylamide gels and electrophoretically transferred onto nitrocellulose membrane (Millipore, Billerica, MA, USA). After blocking with 5% skim milk, the membrane was incubated with rabbit anti-mouse iNOS polyclonal antibody (Cell signaling Tech., Danvers, MA, USA) or anti-mouse β-actin monoclonal antibody (Millipore), followed by HRP-conjugated anti-IgG antibodies. Blots were developed using the ECL detection kit (Pierce, Rockford, IL, USA). The intensity of separated protein bands was quantified using a gel documentation system (model LAS-1000CH, Fuji Photo Film Co., Tokyo, Japan). At least three separate replicates were determined for each experiment.

Statistical Analysis. Results are expressed as the mean ± SD of three independent experiments. Significant differences between means were determined by ANOVA test using the Statistical Analysis Software package SAS (Cary, NC, USA). $p < 0.05$ is regarded as significant.

RESULTS AND DISCUSSION

Structure of BPP. The method we used to prepare the polysaccharide is widely used for the isolation and purification of glucans. Results from our previous study,[2] and in the present study (Table 1), suggest that BPP has a beta-glucan structure. Additional observations showed that the sharpness of the HPLC peak depends on the amount of the sample loaded on the chromatographic column. We observed sharper peaks with smaller amounts (results not shown). We cannot rule out the possibility that components other than glucan, possibly a bound protein as observed by Sanzen et al.[14] in a related study, may contribute to the observed immunostimulation described below.

Table 1. β-Glucan Content of BPPs[a]

sample	β-glucan (% of dry wt)
BPP from culture with black rice bran	0.75 ± 0.02 a
BPP from culture without black rice bran	0.40 ± 0.01 b
black rice bran only	0.03 ± 0.00 c

[a]Values expressed as means ± SD ($n = 3$) in the column with the same letters are not significantly different at $p < 0.05$.

Effect of BPP on in Vitro Growth of *Salmonella*. To find out whether BPP has antibacterial activity against *S.* Typhimurium, bacteria were incubated with serially diluted extracts in PBS (1, 10, and 100 μg/mL) at 37 °C for 0, 2, 4, and 8 h. Figure 1 shows that bacteria treated with the extracts at each concentration for different incubation times showed no significant bactericidal activities until 8 h incubation compared to that of vehicle (PBS). The data show that BPP did not kill bacteria directly. We observed similar results with *Hericium erinaceus* mushroom extracts.[5]

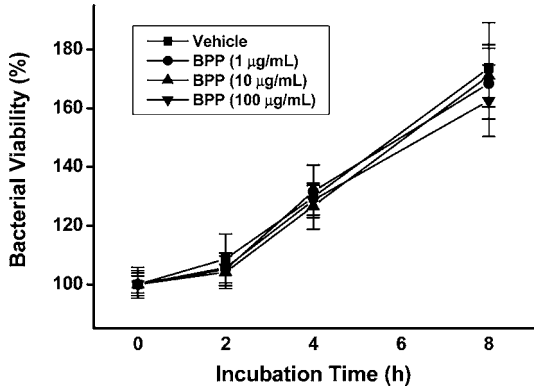

Figure 1. Effects of BPP on growth of *S.* Typhimurium. Serially diluted BPP (1, 10, and 100 μg/mL) was incubated with *S.* Typhimurium (2×10^4 CFU) for 2, 4, and 8 h. Plotted values are mean ± SD of triplicate experiments.

Induction of Morphologic Changes in Macrophages. To determine whether BPP can induce changes in the morphology in the macrophage cells, RAW 264.7 cells were cultivated in the presence of the extract (100 μg/mL) for 2, 4, and 8 h. The microscopic observation of cell morphology revealed that the cells treated with BPP changed to dendrite-like cells (Figure 2), reaching up to 3.6-, 10.3-, and 12.4-fold increases corresponding to the incubation times. Dendritic morphologic changes were not observed with PBS-treated controls regardless of incubation times.

Phagocytotic Stimulatory Effects of BPP. To examine whether BPP enhances phagocytotic activity, RAW 264.7 cells were cultivated in the presence of three concentrations (1, 10, and 100 μg/mL) for 4 h before infection. Thereafter, the *S.* Typhimurium cells were incubated for 30 and 60 min before they were lysed and contents enumerated for bacteria. Figure 3 shows that, after 60 min of incubation, the internalization of bacteria into the macrophage cells increased in a dose-dependent manner. The bacterial uptake rates of macrophages treated with 1, 10, and 100 μg/mL BPP were about 1.4-, 2.4-, and 3.5-fold greater than that of macrophages treated with the PBS control. The phagocytotic stimulatory effect of BPP was also evaluated in vivo in a mouse model. As described in Table 2, administration of the BPP via both oral and ip routes, respectively, elicited higher bactericidal effects than that of

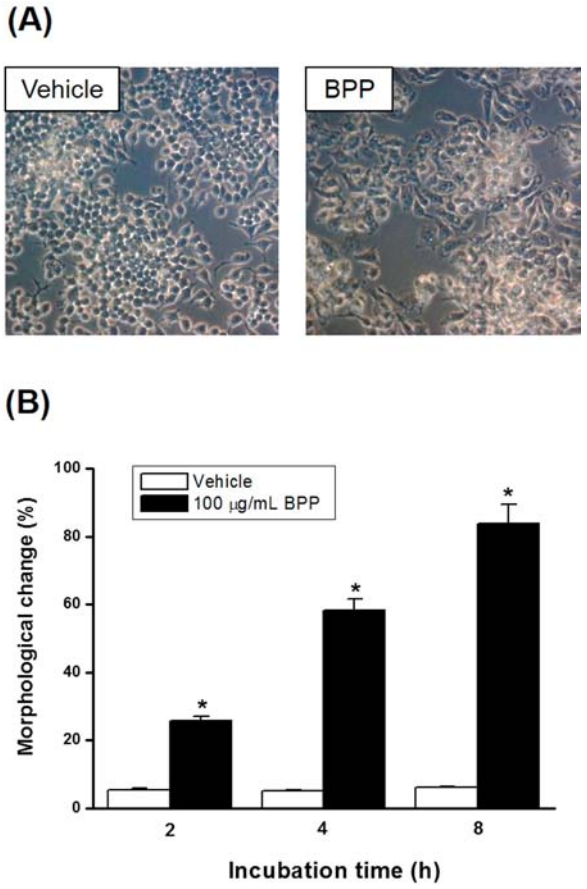

Figure 2. Effects of BPP extract on morphologic changes in macrophages. Murine macrophage cell line RAW 264.7 cells were cultured in the presence of BPP (100 μg/mL) for 2, 4, and 8 h. (A) After 8 h incubation, the morphologic changes were photographed at 100× magnification. (B) One hundred cells in five blindly chosen random fields were examined per coverslip, and the rates of morphologically changed cells were scored. Data are expressed as the mean ± SD of triplicate experiments. Asterisks indicate statistical difference at $p < 0.05$, compared to each vehicle (PBS)-treated control.

vehicle (about 48 and 44% decreases in bacterial CFU by ip and oral administration, respectively).

Effects of the BPP on Intracellular Bacterial Survival. To examine whether the BPP affects *S.* Typhimurium survival within macrophage cells, RAW 264.7 cells were treated with three concentrations of the extract (1, 10, and 100 μg/mL) for 4 h and then infected with the bacterial for 1 h. After removal of bacteria from the culture medium, infected macrophages were incubated for another 2, 4, or 8 h in the presence of gentamicin. Figure 4 shows that, 2 h after infection, the intracellular growth of *S.* Typhimurium within the cells treated with 1, 10, and 100 μg/mL BPP was about 6.9, 45.0, and 87.8% greater than that of the PBS-treated control, respectively. However, 8 h after infection, marked decreases in intracellular bacteria were observed in the cells treated with each concentration of BPP (about 12.2, 52.7, and 65.0% decreases by 1, 10, and 100 μg/mL BPP treatments, respectively) compared with the PBS-treated control.

The apparent discrepancy might be due to the fact that at 2 h after bacterial infection, the amount of bacteria in BPP-treated cells was greater than in vehicle-treated cells due to enhanced engulfment of bacteria by the BPP treatment. In contrast, at 4 h and 8 h postinfection, bacteria cell levels in BPP-treated cells were markedly reduced compared with vehicle-treated cells, probably because of time-dependent enhancement of intracellular bacteriolysis by the BPP treatment through activation of Th1 immune reaction.

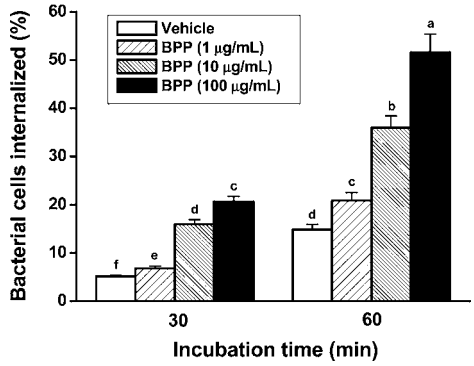

Figure 3. Changes in phagocytotic stimulatory effects of BPP on *S.* Typhimurium-infected macrophages. Murine macrophage cell line RAW 264.7 cells (1×10^4) were incubated with three concentrations of BPP (1, 10, and 100 μg/mL) for 4 h, and then infected with *S.* Typhimurium (1×10^4 CFU). Incubation continued at 37 °C for the indicated periods. After incubation, bacteria-infected macrophages were then cultured in the presence of gentamicin (30 μg/mL) for 30 min. Bacterial internalization efficiency by macrophages was determined by evaluating the protection of internalized bacteria from bactericidal action of the antibiotic gentamicin. Data are expressed as the mean ± SD of triplicate experiments. Bars sharing a common letter are not significantly different at $p < 0.05$.

Table 2. Effect of BPP on the Growth of *S.* Typhimurium Inoculated into Mouse Peritoneal Cavity[a]

treatment	colony numbers (×10^2 CFU/mL)
vehicle	5.02 ± 0.15 a
BPP ip (10 mg/kg)	2.59 ± 0.08 c
BPP oral (10 mg/kg)	2.83 ± 0.11 b

[a]Values are expressed as the mean ± SD of triplicate experiments. Values with the same letters in the column are not significantly different at $p < 0.05$.

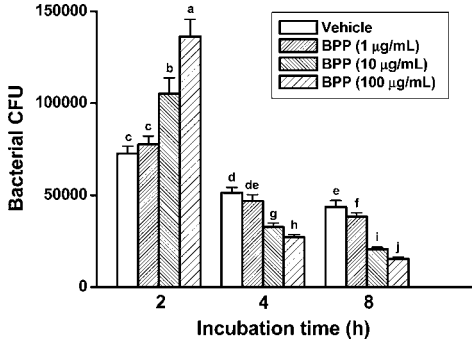

Figure 4. Survival and/or proliferation of *S.* Typhimurium within the BPP-treated macrophages. Murine macrophage cell line RAW 264.7 cells (1×10^4) were incubated with three concentrations of the BPP (1, 10, and 100 μg/mL) for 4 h and then infected with *S.* Typhimurium (1×10^4 CFU) at 37 °C for 1 h. The cells were washed and then further incubated in the presence of gentamicin (30 μg/mL) for the indicated periods. At each time point, the cells were lysed and the number of viable intracellular bacteria counted. Data are expressed as the mean ± SD of triplicate experiments. Bars sharing a common letter are not significantly different at $p < 0.05$.

Salmonella–Immune System Relationships. To facilitate understanding the results and interpretations of the present study, we will briefly mention reported studies designed to define the role of the immune system following infection by *Salmonella* that complement our related studies with mushroom, herbal, and liquid rice hull extracts.

- The innate host defense against intracellular pathogens seems to involve signaling pathways by which macrophages inhibit replication of *Salmonella* Typhimurium by triggering the MEK kinase cascade and NADPH oxidase activity.[15]
- Dendritic cells (DCs) link innate and adaptive immunity by recognizing pathogen-associated molecular patterns (PAMPs) to specialized receptors on their surface. *Salmonella* have developed molecular mechanisms based on virulence proteins to alter DC function and suppress the immune response to cause infection in the host.[16]
- A mechanism also exists that prevents virulent *Salmonella* from evading cell uptake, thus enhancing DC immunogenicity, bacterial degradation, and induction of innate and adaptive immune pathways.[17,18]
- Feeding mice a cornstarch-based diet with added fructo-oligosaccharide (FOS) or xylo-oligosaccharide (XOS) increased the translocation of *S.* Typhimurium SL1344 to internal organs, whereas feeding 10% apple pectin increased the intestinal and fecal content of this pathogen, suggesting that the mentioned prebiotics increased the severity of the *Salmonella* infection.[19]

The results of the present study indicate that the macrophage cells associated with the immune system seem to have a strong affinity for *Salmonella* bacteria, and that the BPP treatment induced internalization of the bacteria in the cells. Our results are consistent with the above-mentioned observations in the literature on the interactions of *Salmonella* with the immune system.

Effects of BPP on Leukocyte Activation in Infected Mice. To evaluate whether BPP activates leukocytes in *S.* Typhimurium infected mice, we also determined mitogen-induced splenic lymphocyte proliferation and IFN-γ levels in sera. As shown in Table 3, administration of BPP markedly induced splenic lymphocyte proliferation by Con A stimulation (about 46.3 and 34.9% increases by the treatment by ip and oral routes, respectively). Serum IFN-γ level in *S.* Typhimurium-infected mice was also increased by the treatment with BPP (about 32.0 and 21.3% increases by ip and oral treatment, respectively). As anticipated, the treatment through the ip route was more effective than oral administration to induce IFN-γ production, most probably by more effective peritoneal macrophage stimulation.

Table 3. Effect of BPP on Spleen Lymphocyte Proliferation and Serum IFN-α Levels in *S* Typhimurium Infected Mice[a]

treatment	lymphocyte proliferation (fold-increase)	IFN-γ (pg/mL)
vehicle	1.49 ± 0.11 b	309 ± 18 b
BPP ip (10 mg/kg)	2.18 ± 0.15 a	408 ± 21 a
BPP oral (10 mg/kg)	2.01 ± 0.12 a	375 ± 15 a

[a]Values are expressed as the mean ± SD of triplicate experiments. Values with the same letters in the column are not significantly different at $p < 0.05$.

Because NO generation by iNOS is an index of macrophage activation, RT-PCR was used to examine whether the BPP treatment elicited inducible NO synthase (iNOS) gene expression in RAW264.7 murine macrophage cells. Figure 5A shows that, for 8 h, iNOS expression by BPP-treated cells was ~3.4-fold greater than in the cells infected with *S.* Typhimurium without BPP. The BPP treatment without *S.* Typhimurium infection induced iNOS expression to the same level in the bacteria-infected cells with BPP treatment (~3.5-fold increase). Western blot analysis shows that the iNOS protein expression profile was similar to that of the mRNA expression (Figure 5B).

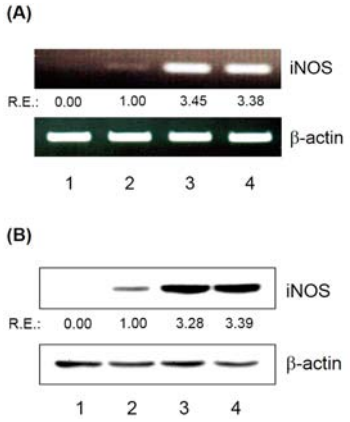

Figure 5. Effects of BPP on iNOS gene expression in *S.* Typhimurium-infected macrophages. (A) iNOS mRNA expression profiles assessed by RT-PCR. Murine macrophage cell line RAW 264.7 cells (1×10^6) were cultured with or without BPP (100 μg/mL) for 8 h. Then, *S.* Typhimurium (1×10^4 CFU) was added to RAW 264.7 cells for 8 h. After incubation, total RNA was purified and iNOS mRNA expression was determined using RT-PCR analysis. Lanes: 1, PBS-treated without bacterial infection; 2, bacterial infection alone; 3, BPP-treated without bacterial infection; 4, BPP-treated with bacterial infection. (B) iNOS polypeptide expression profiles assessed by Western blot. RAW 264.7 cells (1×10^6) treated with BPP (100 μg/mL) for 24 h and subsequent infection of *S.* Typhimurium were lysed and iNOS protein in the cell lysate was identified by Western blot using anti-mouse iNOS polyclonal antibody. Lanes: 1, PBS-treated without bacterial infection; 2, bacterial infection alone; 3, BPP-treated without bacterial infection; 4, BPP-treated with bacterial infection. The relative proportions of iNOS mRNA and polypeptide are expressed as the R.E. (relative expression) values calculated from iNOS gene/β-actin gene expression. Figures represent results from at least three individual experiments.

Effect of BPP on Th1 and Th2 Cytokine Production. To examine whether BPP has the capacity to regulate the differentiation pathway of CD4 T cells, changes in Th1 and Th2 cytokine production profiles were determined by ELISA assay. Table 4 shows that BPP administration (10 mg/kg) through both peritoneal and oral routes significantly increases Th1 cytokine production including IL-1β, IL-2, IL-6, and IL-12 from splenocyte in *S.* Typhimurium-infected mice. In contrast, BPP administration did not lead to the enhanced Th2 cytokine production including IL-4, IL-5, and IL-10 in the bacterial infected mice (Table 5).

The results imply that BPP can differentiate native CD4 T cells into Th1 cells, thereby potentiating cell-mediated immunity,[20] presumably by the above-described mechanisms.

Table 4. Effect of BPP on the Th1 Cytokine Production from Splenocytes in Mice[a]

	cytokines (pg/mL)			
treatment	IL-1β	IL-2	IL-6	IL-12
	Salmonella (−)

Effects of BPP on Histopathology of Mouse Livers. To examine whether BPP can ameliorate liver injury induced by salmonellosis, mice were treated ip or orally with BPP (10 mg/kg) every 24 h for 2 d after intraperitoneal infection of a sublethal dose (1×10^4 CFU) of *S.* Typhimurium. Figure 6 shows that extensive liver necrosis and hemorrhage were present in the tissues from *Salmonella*-infected control mice. However, liver tissues from bacteria-infected mice treated with BPP showed minimal damage, regardless of the administration route. These results show that BPP protected the livers against *Salmonella*-induced hepatic necrosis.

Effects of BPP on Mortality of Infected Mice. To determine possible therapeutic effects of BPP on murine salmonellosis, mice were infected with lethal doses (1×10^5 CFU) of *S.* Typhimurium and assessed for mortality. Each group of 10 mice was treated with BPP (10 mg/kg) ip or orally every 24 h during the entire experimental period. Figure 7 shows that the mortality rate in the PBS-treated control group was 100% on day 7. However, the groups treated with BPP survived until at least day 23 or longer. Ip administration of BPP was more effective in prolonging the lifespan of the mice than administration by the oral route. These observations demonstrate the potential of BPP to protect mice against the

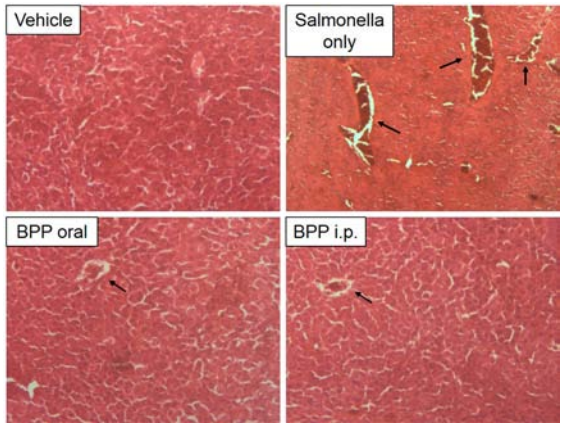

Figure 6. Effect of the BPP on the formation of pathological lesions in liver of *S.* Typhimurium-infected mice. Liver specimens from BPP-treated mice (10 mg/kg) infected with *S.* Typhimurium (1×10^4 CFU) were fixed with 4% paraformaldehyde. The sections were then stained with hematoxylin and eosin (H&E). Magnification 100×. Arrows indicate representative hemorrhagic necrosis. Figures represent results from at least three individual experiments.

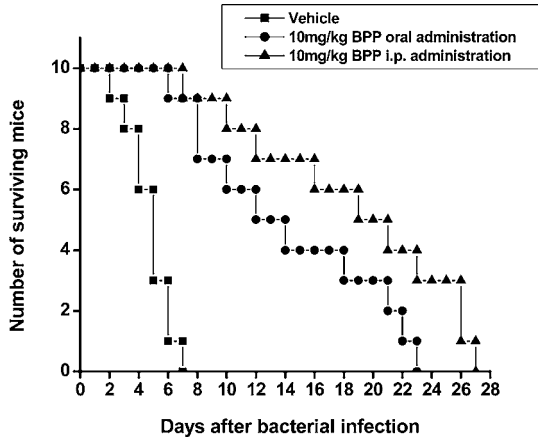

Figure 7. Histogram showing effect of BPP on *S.* Typhimurium infection-induced lethality. Balb/c mice (10 mice per group) were infected with lethal doses of *S.* Typhimurium (1×10^5 CFU) through the intraperitoneal route. Then, the extract (10 mg/kg) was intraperitoneally or orally administered every 24 h during the entire experimental period. PBS was used as the vehicle in the control group. Plotted values are mean values of triplicate determinations.

lethal effects of the bacteria, presumably via Th1 cell-mediated macrophage stimulation of the immune system.

Beta-glucan might be the active component that induces Th1 cell-mediated macrophage stimulation. This suggestion is supported by the finding that β-glucan content was highest in BPP prepared from *L. edodes* mycelial culture with black rice bran compared with that from mycelia or black rice bran only (Table 1).

Related Studies on Immunoprevention of *Salmonella* Infections. Here, we briefly mention several additional reported studies on the in vivo inhibition of *Salmonella* by natural compounds and plant extracts.

- Beta-glucan acted as an immunomodulator of the innate immune response in immature chickens that decreased organ invasion of *S. enterica*.[21]
- A safety evaluation of a mushroom β-glucan showed that the compound was not mutagenic and exhibited no

dx.doi.org/10.1021/jf405223q | J. Agric. Food Chem. 2014, 62, 2384−2391

observed adverse effect level (NOAEL) in rats at the highest dose of 2000 mg/kg/bw/day tested,[22] suggesting that BPP, which also seems to have a β-glucan structure, might also be safe.

- A study of the effect of an aqueous extract of the roots of the Indian herbal plant *Withania somnifera* on T helper (Th) immunity in mice using flow cytometry indicated selective Th1 upregulation, suggesting its use for selective Th1/Th2 modulation.[23]
- A water extract of the herb *Houttuynia cordata* extended the lifespan of mice infected with a lethal dose of *S.* Typhimurium in a dose-dependent manner, suggesting that the extract has the potential to be used in the treatment of bacterial infection.[12]
- A water extract of the roots of the Indian medicinal plant *Asparagus racemosus* containing steroidal saponins exhibited immunoadjuvant potential, as indicated by significant upregulation of Th1 (IL-2, IFN-γ, and IL-4) cytokines, suggesting its mixed Th1/Th2 adjuvant activity.[20]

It would be of interest to find out whether combinations of BPP with the above-mentioned natural compounds and plant extracts would exhibit additive or synergistic health-promoting effects.

Summary and Research Needs. We evaluated the natural biopolymer, previously shown to protect mice against *Salmonella* lipopolysaccharide-induced endotoxemia, to protect mice against *S.* Typhimurium-induced sublethal and lethal infections. Administration of BPP by ip injection or by the oral route protected the mice against both liver necrosis and lethality. BPP administered by ip was more effective than that delivered by oral feeding. The protective effect was accompanied by stimulation of innate immune cells, as demonstrated by a series of in vitro and in vivo assays. Because the previous and present studies show that BPP can protect against both endotoxemia and infection without any adverse side effects in mice, it seems that the novel biopolymer has the potential to serve as a multifunctional food.

Our observations suggest the need for additional studies that might further enhance the health-promoting characteristics of BPP. These include the following possibilities.

- Because outbreaks and exposures associated with *Salmonella enterica* occur worldwide,[24−26] it would be of interest to find out whether human consumption of BPP as part of a normal diet would protect indigenous populations and travelers against infection by *Salmonella*.
- Because *Salmonella* is a major foodborne pathogen that develops resistance to medical antibiotics,[27−29] it would be of interest to find out whether BPP would also protect against antibiotic-resistant *Salmonella* and other pathogens such as *Escherichia coli, Listeria monocytogenes, Staphylococcus aureus,* and *Vibrio cholerae*.
- It would be of interest to determine whether herbal or liquid rice hull extracts would also stimulate the production of BPP in mushroom mycelia.

Because exposure of contaminated food to natural antimicrobials might be only partly effective in inactivating virulent foodborne pathogens[30−32] and toxins[33−38] produced by the pathogens and by plants, it would also be worthwhile to determine whether adding BPP to food would protect animals and humans against residual levels of pathogens and toxins after consumption via stimulation of the immune system.

ampholyte-free preparative isoelectric focusing, which is referred to as autofocusing, using the method described by Hashimoto et al.,[12] using an autofocusing apparatus with 10 sample compartments (75 mm in length × 80 mm in width × 85 mm in height for each compartment). The water extract was placed in sample compartments 5 and 6. The other compartments were filled with deionized water. Autofocusing was carried out at 500 V for 18 h. The autofocusing fractions were freeze-dried.

The autofocusing fraction that exerted antihyperuricemic activity after alcalase digestion was subjected to preparative reversed-phase liquid chromatography. YFLC gel C18 (particle size of 40 μm in diameter, Yamazen, Osaka, Japan) was packed into a column (250 × 15 mm inner diameter) and equilibrated with 10% (v/v) acetonitrile in the presence of 0.1% TFA. A total of 2 g of the dried active autofocusing fraction without alcalase digestion was dissolved in 100 mL of the equilibrium solvent and loaded into the column using a MPLC system (Yamazen) at 10 mL/min. After loading of the sample, the column was washed with 100 mL of the equilibrium solvent. After elution of the non-absorbed components, the absorbed components were eluted with a linear gradient of acetonitrile from 10 to 80% in the presence of 0.1% TFA over 20 min. Fractions were collected every 1 min. Elution was monitored by absorbance at 280 nm.

Alcalase Digestion. Prior to conducting the animal experiment, an aliquot of each fraction was digested with alcalase. The sample was dissolved in water to yield 8% (w/v) and adjusted to pH 8.0 by the addition of NaOH or HCl. Alcalase (liquid form) was added at a ratio of 0.04% (v/v) to the reaction mixture and reacted at 60 °C for 4 h. The reaction was terminated by heating to 85 °C for 10 min. The reaction product was freeze-dried and stored at −20 °C until use.

Animal Experiment. Male Wistar rats were purchased from Charles River Laboratories Japan (Yokohama, Japan). All diet pellets were purchased from Oriental Yeast (Tokyo, Japan). All animals were housed (temperature, 22−24 °C; humidity, 40−60%) in the same building under a 12 h light−dark cycle and given free access to diet pellets and filtered water. The rats were allowed to adapt to the environment for 1 week before the start of the experiment. This study was conducted in accordance with the standards established by the Guide for the Care and Use of Laboratory Animals of Maruha Nichiro Holdings Central Research Institute (Tsukuba, Japan).

The test components were suspended in distilled water at an appropriate concentration and administered at a constant volume of 5 mL/kg of body weight to the rats via a stomach sonde. The doses of fractions (mg/kg of body weight) are shown in the figures. The rats in the control group were administered the same volume of distilled water (vehicle). In some cases, test components were dissolved in saline and injected into the tail vein. Before the injection, the sample was sterilized by passing through a filter (0.45 μm pore size, GL Sciences, Tokyo, Japan). At 1 h after the administration of test components, rats received a potassium oxonate solution (250 mg/2 mL of 3% gum arabic saline/kg of body weight) by intraperitoneal injection to elevate their blood uric acid level.[9,10,13] At 1 h after the oxonate injection, blood samples were collected from the caudal artery under pentobarbital anesthesia. Rats were starved for more than 12 h before their blood was drawn.

Isolation of Peptides from the Alcalase Digest of the Active Fraction. Peptides were obtained from the alcalase digest of the active fraction by preparative reversed-phase liquid chromatography and were resolved by size-exclusion chromatography (SEC) and reversed-phase high-performance liquid chromatography (RP-HPLC). A total of 1 mg of the alcalase digest of the active fraction was dissolved in 200 μL of 30% acetonitrile in the presence of 0.1% TFA and loaded into a Superdex peptide 10/30 HR (GE Healthcare, Buckinghamshire, U.K.), which had been equilibrated with 30% acetonitrile in the presence of 0.1% TFA at a flow rate of 0.5 mL/min. Fractions were collected every 1 min. The SEC fractions were dried under vacuum and dissolved in 200 μL of 10% acetonitrile in the presence of 0.1% TFA and further fractionated using a Cosmosil 5C18-MS-II (250 × 4.6 mm inner diameter, Nacalai Tesque, Kyoto, Japan). Elution was performed using a linear gradient of acetonitrile from 10 to 80% in the presence of 0.1% TFA for 30 min at a flow rate of 1 mL/min. Absorbance at 214 nm was monitored. The column was maintained at 40 °C.

Other Analytical Methods. The protein content was evaluated by amino acid analysis after HCl hydrolysis. Amino acid analysis was performed according to the method described by Bidlingmeyer et al.,[14] with slight modifications.[15] The peptide sequence was analyzed using the Edman degradation procedure using a PPSQ-21 (Shimadzu, Kyoto, Japan). Chondroitin sulfate was determined by the carbazole sulfate method using shark cartilage chondroitin sulfate C as a standard.[16]

The xanthine oxidase assay was performed according to the method by Osada et al.,[13] with slight modifications.[10] Xanthine was dissolved in 50 mM Tris−HCl buffer at pH 7.4 to give 15 mM. Xanthine oxidase was resolved in the same buffer to give 0.1 mU/mL. The sample was dissolved in the same buffer to give a suitable concentration. The substrate (40 μL), enzyme (10 μL), and sample solution (1950 μL) were mixed and incubated for 10 min at 37 °C. The reaction was terminated by the addition of 50 μL of 3.2% (v/v) perchloric acid. Absorbance at 292 nm was measured. Allopurinol and the buffer were used as positive and negative controls, respectively. Inhibitory activity is expressed as the remaining activity against the negative control (%). For the evaluation of the effect of ingestion of Tyr-Leu-Asp-Asn-Tyr on the serum xanthine oxidase inhibitory activity, 100 μL of serum from the rats that received the peptide, vehicle, or allopurinol were mixed with the buffer (1850 μL) and used as sample solution.

Statistical Analysis. Data are presented as the mean ± standard deviation. Statistical significance ($p < 0.05$ and 0.01) was analyzed by one-way analysis of variance followed by Scheffe's post-hoc test using StatView 4.11 (Abacus Concepts, Inc., Berkeley, CA).

RESULTS

As shown in Figure 1, the intact water extract did not show significant antihyperuricemic activity. However, the alcalase digest showed significant uric acid lowering activity to the oxonate-induced hyperuricemic rat by oral administration at 1 g/kg of body weight, indicating that peptides produced from the parent proteins in the water extract by alcalase digestion are responsible for the antihyperuricemic activity. The intact water-soluble components of the shark cartilage were fractionated on the basis of their isoelectric points by autofocusing. As shown in Figure 2, acidic (fraction numbers 1−5), weakly acidic (fraction numbers 6−7), and basic (fraction numbers 8−10) fractions were collected. Solid components were recovered from the acidic, weakly acidic, and basic fractions at 66, 24, and 10%, respectively. The acidic and weakly acidic fractions consisted of protein and chondroitin sulfate. In contrast, the basic fraction predominantly consisted of protein. The three fractions were digested with alcalase, and the digests were orally administered

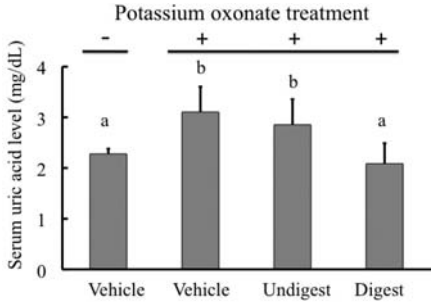

Figure 1. Effect of supplementation of the water extract of shark cartilage (undigest) and its alcalase digest (digest) on serum uric acid levels of rats treated with potassium oxonate. Data present the mean ± standard deviation ($n = 6$). Data points marked with different letters indicate significant differences ($p < 0.01$).

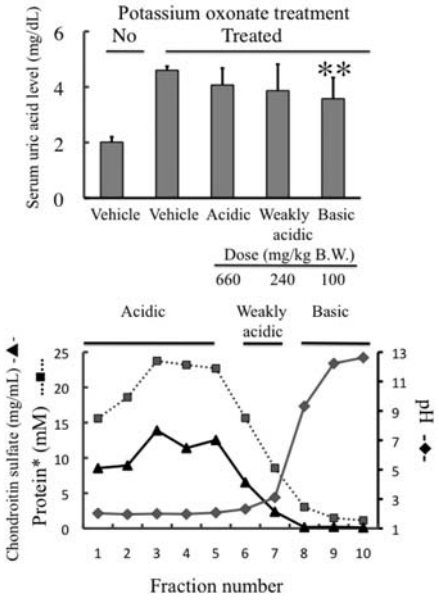

Figure 2. First purification of the protein that produces peptides with antihyperuricemic activity after alcalase digestion using ampholyte-free preparative isoelectric focusing (autofocusing). The water extract of shark cartilage without alcalase digestion was fractionated by autofocusing (lower panel). Acidic, weakly acidic, and basic fractions were collected as indicated by bars. (∗) Protein content is expressed as the sum of the constituting amino acids in the HCl hydrolysate. An aliquot of each fraction was evaluated for antihyperuricemic activity after alcalase digestion (upper panel). Dosages were determined by the following equation: (ratio of each fraction to the start material) × 1 g/kg of body weight. Data present the mean ± standard deviation (n = 6). Data marked with ∗∗ are significantly different from the cntrol group treated with potassium oxonate at $p < 0.01$.

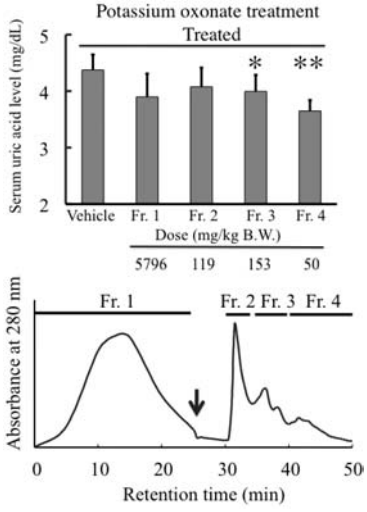

Figure 3. Second purification of the protein that produces peptides with antihyperuricemic activity after alcalase digestion by preparative reversed-phase chromatography. The basic fraction shown in Figure 2, without alcalase digestion, was used (lower). The arrow represents the start of gradient elution. Effluents were collected every minute and gathered to fractions 1−4, as shown. An aliquot of each fraction was evaluated for antihyperuricemic activity after alcalase digestion (upper). Data present the mean ± standard deviation (n = 6). (∗ and ∗∗) Significant differences from the control group (vehicle) treated with potassium oxonate at $p < 0.05$ and 0.01, respectively.

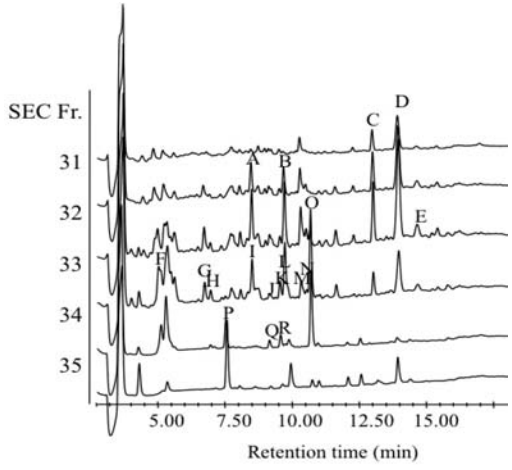

Figure 4. Isolation of peptides from the alcalase digest of the hydrophobic fraction (fraction 4 in Figure 3). The alcalase digest was first subjected to SEC. Fractions were collected every 1 min. SEC fractions (fractions 31−35) were further fractionated by RP-HPLC. Peaks marked with large characters were collected and subjected to sequence analysis. Sequences of the identified peptides are summarized in Table 1.

to the oxonate-induced hyperuricemic rats. The dose of each fraction was determined on the basis of the recovery percentage. Only the alcalase digest of the basic fraction significantly reduced the serum uric acid level at 0.1 g/kg of body weight, which is less than that of the water extract (1 g/kg of body weight) or the other fractions.

The proteins in the basic fraction were further fractionated by preparative reversed-phase liquid chromatography without alcalase digestion. As shown in Figure 3, three peaks (fractions 2−4) were eluted by gradient elution after elution of the unabsorbed components (fraction 1). These fractions were also digested with alcalase and evaluated for their antihyperuricemic activity. The dose of each fraction was determined on the basis of the recovery percentage. Only the alcalase digest of fraction 4 showed significant antihyperuricemic activity by oral administration at 50 mg/kg of body weight.

The peptides in the alcalase digest of fraction 4 were first resolved by SEC. Fractions were collected every 1 min. The SEC fractions eluted between 29 and 35 min were subjected to analytical RP-HPLC. As shown in Figure 4, the two-dimensional HPLC provided excellent resolution of the constituent peptides. The peptides marked with large characters were collected and subjected to sequence analysis. The obtained sequences are summarized in Table 1. All peptides contained aromatic amino acids: tyrosine, phenylalanine, and tryptophan. On the basis of the sequence data, all peptides were chemically synthesized and evaluated for antihyperuricemic activity. As shown in Figure 5, Tyr-Leu-Asp-Asn-Tyr (YLDNY) and Ser-Pro-Pro-Tyr-Trp-Pro-Tyr (SPPYWPY) showed significant antihyperuricemic activity by intravenous injection at 5 mg/kg ($p < 0.01$ and 0.05, respectively). However, Asp-Phe-Trp-Arg-Tyr (DFWRY) and other peptides did not show significant antihyperuricemic activity (data not shown). Oral administration of Tyr-Leu-Asp-Asn-Tyr also significantly reduced serum uric acid at 50 mg/kg of body weight (Figure 5), while Ser-Pro-Pro-Tyr-Trp-Pro-Tyr did not show significant activity by oral ingestion. Oral administration of Tyr-Leu-Asp-Asn-Tyr also significantly increased serum inhibitory activity against xanthine oxidase at the same dose (Figure 6). The

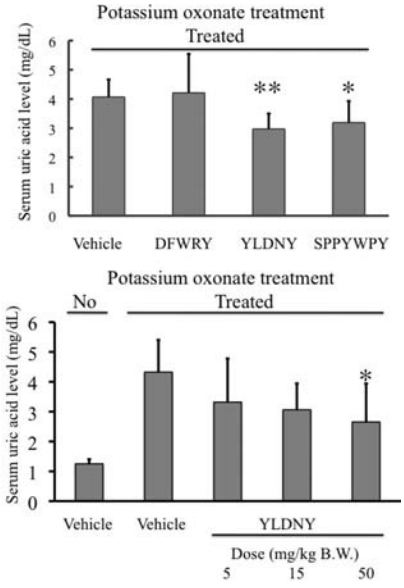

Figure 5. Antihyperuricemic activity of the synthetic peptides. Asp-Phe-Trp-Arg-Tyr (DFWRY), Tyr-Leu-Asp-Asn-Tyr (YLDNY), and Ser-Pro-Pro-Tyr-Trp-Pro-Tyr (SPPYWPY) were injected into the tail vein (5 mg/kg of body weight) (upper panel). YLDNY was also orally administered (lower panel).

xanthine oxidase inhibitory activity of Tyr-Leu-Asp-Asn-Tyr and possible fragment peptides is shown in Table 2. Asp-Asn, Leu-Asp-Asn, Asp-Asn-Tyr, and Leu-Asp-Asn-Tyr showed inhibitory activity, while Tyr-Leu-Asp-Asn-Tyr and constituting amino acids did not show the inhibitory activity. The IC_{50} values of these fragment peptides were 13−23 times higher than that of allopurinol.

DISCUSSION

Over the last few decades, numerous studies have demonstrated that ingestion of food protein hydrolysates has significant biological effects, such as moderation of hypertension, hypertriglyceridemia, hypercholesteremia, etc. The active peptides

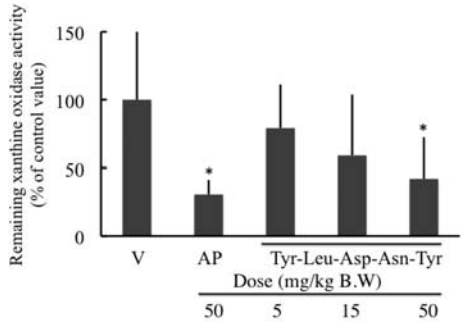

Figure 6. Inhibitory activity against xanthine oxidase by serum from the rat that had ingested vehicle (V), allopurinol (AP), and Tyr-Leu-Asp-Asn-Tyr. Data present the mean ± standard deviation ($n = 6$). (*) Significant difference from the control group (V) at $p < 0.05$.

have been identified using activity-guided fractionation based on *in vitro* assay systems using enzyme reactions and cell culture systems. Using this approach, many peptides have been apparently identified as active compounds. However, unlike other functional ingredients, proteins and peptides are further degraded into smaller peptides and constituent amino acids during digestion and absorption. As a result, the peptides in food may lose the potential biological activity detected by *in vitro* assays. Therefore, the *in vitro* activity of the peptides in the food cannot be directly linked to their biological activity after ingestion. To resolve these questions, the biological activity of potentially active peptides should be evaluated by feeding experiments using animal models. However, this approach requires relatively large amounts of peptide in comparison to the *in vitro* assays. For this approach, we have developed large-scale ampholyte-free preparative isoelectric focusing, referred to as autofocusing, which can process peptide samples up to 50−500 g.[12] Coupled with preparative reversed-phase chromatography, the parent protein, which produced antihyperuricemic peptides after alcalase digestion, was recovered from the basic and hydrophobic fractions (Figures 2 and 3). The alcalase digest of the final fraction exerted significant uric acid lowering activity at a $^1/_{20}$ dose in comparison to the crude digest. All peptides identified in the digest consisted of aromatic amino acids. Similarity research analyses using FAST and BLAST protocols revealed that these peptide sequences are similar to mammalian hypothetical proteins, of which the function is unknown. Using peptides synthesized on the basis of the sequence data, two peptides were identified, which exerted antihyperuricemic activity by intravenous injection at 5 mg/kg of body weight. Among these peptides, oral administration of Tyr-Leu-Asp-Asn-Tyr at 50 mg/kg of body weight exerted antihyperuricemic activity, which indicates that this peptide plays a significant role in the antihyperuricemic activity of shark cartilage extract. However, the dose of Tyr-Leu-Asp-Asn-Tyr necessary for the significant antihyperuricemic activity by oral ingestion was comparable to the required dose of the alcalase digest of the final fraction (fraction 4 in Figure 3). The presence of other peptides in the digest may enhance the antihyperuricemic activity of Tyr-Leu-Asp-Asn-Tyr by oral ingestion.

Our previous study demonstrated that ingestion of a protease digest of shark cartilage increases serum inhibitory activity against xanthine oxidase, a key enzyme for uric acid synthesis, whereas the digest has no *in vitro* xanthine oxidase inhibitory activity. Tyr-Leu-Asp-Asn-Tyr also had no *in vitro* xanthine

oxidase inhibitory activity (Table 2), whereas it increased serum xanthine oxidase inhibitory activity by ingestion (Figure 6). It has been demonstrated that most of the food-derived peptides in blood are tri- and dipeptides even after ingestion of larger peptides.[17−19] Then, Tyr-Leu-Asp-Asn-Tyr may be further degraded into smaller peptides with xanthine oxidase inhibitory activity and absorbed into the blood system. Indeed, some di- and tripeptides, which could be potentially derived from Tyr-Leu-Asp-Asn-Tyr, show xanthine oxidase inhibitory activity. The Asp-Asn motif is contained in all xanthine oxidase inhibitory peptides. These facts suggest that these fragment peptides might be absorbed in the blood and exert antihyperuricemic activity by inhibition of xanthine oxidase. Alternatively, the degradation peptides may induce endogenous xanthine oxidase inhibitors. Further studies on the metabolic fate of Tyr-Leu-Asp-Asn-Tyr and other peptides in the active fraction and on the identification of increased endogenous or food-derived xanthine oxidase inhibitors in serum after ingestion of these peptides are currently in progress to elucidate the mechanism of the antihyperuricemic activity.

The active peptide Tyr-Leu-Asp-Asn-Tyr in the alcalase digest of crude shark cartilage can be separated from chondroichin sulfate and other high-molecular-weight components by a simple selective precipitation technique using 75% ethanol, which can decrease dose to exert antihyperurecemic activity by ingestion.[17] Therefore, the peptide concentrate has potential as a functional food ingredient with antihyperuricemic activity.

the process of enzymatic degradation. Negative-ion ESI-MS and CID MS/MS were employed for structural analysis and sequence of hydrolysates.

MATERIALS AND METHODS

Materials. Purified food-grade κ-carrageenan was purchased from Lubao Biochemistry Co., Ltd. (Jinjiang, China). *Pedobacter hainanensis* 13-Q^T was a strain gifted from the laboratory of Dalian Institute of Chemical Physics (Dalian, China). 3-Amino-9-ethylcarbazole (AEC), sodium cyanoborohydride ($NaBH_3CN$), and albumin of chicken egg white were purchased from Sigma-Aldrich (St. Louis, MO, USA). Bio-Gel P-2 Gel (45−90 μm wet bead size) and Bio-Gel $P\overline{4}$ Gel (90−180 μm wet bead size) were purchased from Bio-Rad Laboratories, Inc. (Hercules, USA). Molecular weight protein markers (PageRuler Unstained Protein ladder) were purchased from Fermentas Scientific Inc. (Vilnius, Lithuania). Water was purified by a Milli-Q ultrapure water purification system from Millipore (Burlington, MA, USA). All other chemicals used in the experiments were of analytical reagent grade.

Methods. *Bacterial Strains and Culture Conditions.* 50 μL of *Pedobacter hainanensis* 13-Q^T bacteria glycerol stock was inoculated into 10 mL of medium containing the following: κ-carrageenan (5 g/L), peptone (3 g/L), $NaNO_3$ (1 g/L), NaCl (20 g/L), $K_2HP_4{\cdot}3H_2O$ (1 g/L), $MgSO_4{\cdot}7H_2O$ (0.5 g/L), and $CaCl_2$ (0.1 g/L), dissolved in 1 L of distilled water, pH 7.5, and then incubated at 30 °C on a rotary shaker at a speed of 200 rpm overnight.[31] Cells were subcultured by transferring 200 μL of the cell culture into 40 mL of the above-described culture medium prior to incubation on a rotary shaker overnight (200 rpm) at 30 °C. The bacterial cells were cultured and grown to OD_{600} of 0.6−1.0 to reach the maximum output of κ-carrageenase.

Purification of κ-Carrageenase. The culture medium (100 mL) was centrifuged at 8000 rpm for 30 min. Subsequently, 80% ammonium sulfate was added to the supernatant and left overnight. The precipitates were collected by centrifugation at 8000 rpm for 50 min and then dissolved in 5 mL of 0.05 mol/L Tris-HCl buffer (pH 7.0). The clear supernatant containing κ-carrageenase was collected by centrifugation at 5000 rpm for 30 min and evaluated for enzymatic activity, where its protein content was estimated by the Bradford method.[32] Then the purified κ-carrageenase was applied to a Bio-Gel $P\overline{4}$ column (120 cm × 2 cm), equilibrated in 0.05 mol/L Tris-HCl buffer (pH 7.0), and eluted with the same buffer. Fractions were collected by continuous monitoring of the activity of κ-carrageenase. The pooled fraction was assayed for its total enzymatic activity and protein content. In order to protect the activity of κ-carrageenase, all the aforesaid steps were carried out at 4 °C.

κ-Carrageenase Assays. The determination of enzymatic activity was assayed by measuring the increase in the concentration of reducing sugar ends formed by enzymatic digestion, using the dinitrosalicylic method of Miller.[33,34] Boiled enzyme was used as a blank. 100 μL of the enzyme solution was added to 900 μL of 0.2% (w/v) κ-carrageenan in 0.05 mol/L Tris-HCl buffer (pH 7.0), and the mixture was incubated at 40 °C for 20 min. After incubation, 750 μL of modified 3,5-dinitrosalicylic acid reagent was added to the solution, and the mixture was heated for 5 min in a boiling water bath and then cooled in ice water. When the sample was cooled, 5 mL of deionized water was added and the absorption at 520 nm was measured in a (NewCentury-T6) spectrophotometer (Purkinje General Instrument Co., Ltd., Beijing, China). The amount of released sugar was estimated using a D-galactose calibration curve (0.2 to 0.8 mg/mL), and one unit of κ-carrageenase activity was defined as the amount of enzyme that produces the equivalent of 1 μmol of D-galactose from κ-carrageenan per minute under the above-described condition.

Molecular Weight Determination. The molecular weight determination of κ-carrageenase was analyzed using SDS−PAGE with a 5% (w/v) polyacrylamide for the stacking gel, a 10% (w/v) polyacrylamide for the running gel, and 0.1% (w/v) SDS. One milligram of enzyme was denatured by heating at 100 °C for 10 min in 200 μL of protein denaturation solution containing 5% SDS and 6.2% DTT. The loading amount of protein samples was 10 μg. Electrophoresis was carried out at 80 V in stacking gel and 120 V in separating gel for 4 h using an electrophoretic buffer consisting of Tris-glycine with 0.1% SDS (pH 8.3). The gels were stained with staining buffer containing 1% (w/v) Coomassie Blue-R250, 40% aqueous ethanol, and 10% aqueous acetic acid for 30 min and subsequently destained with 40% aqueous ethanol and 10% aqueous acetic acid. Visualization of the proteins was carried out using ImageQuant 350 (GE Healthcare, Piscataway, NJ, USA).

Preparation of κ-Carrageenan Oligosaccharides. κ-Carrageenan was enzymatically digested with κ-carrageenase. A 10-unit aliquot of enzyme solution was added to 100 mL of 0.2% (w/v) κ-carrageenan in 0.05 mol/L Tris-HCl buffer at pH 7.0, and the solution was incubated at 40 °C. 5 mL of the sample was taken out at intervals (i.e., 0.5 h, 1 h, 2 h, 4 h, 8 h, 12 h, 16 h, 20 h, 24 h, 28 h, 32 h, 48 h, 72 h, and 96 h) and boiled in a 100 °C water bath to stop the reactions. The products were concentrated and desalted using gel-filtration chromatography on a Bio-Gel P-2 column (40 cm × 2 cm). The column was eluted with distilled water using a pump with a flow rate of 0.8 mL/min, and fractions of 4 mL were autocollected. The elution was monitored by the phenol−sulfuric acid method.[35] Fractions containing sugar were pooled together and lyophilized for further analysis.

TLC Analysis of κ-Carrageenan Hydrolysate. Each 2 μL aliquot of 2 mg/mL reaction mixture was loaded onto a 20 cm × 20 cm plastic TLC plate precoated with 0.2 mm silica gel (Macherey-Nagel, Düren, Germany) and developed with a solvent system consisting of *n*-butanol:formic acid:water (4:7:1, v/v/v) at 25 °C. The developed plate was stained by spraying with orcinol−sulfuric acid reagent (0.2 g of orcinol, 20 mL of 98% H_2SO_4, 100 mL of methanol) and heated at 150 °C until the bands were obviously visible.[36]

3-Amino-9-ethylcarbazole (AEC) Labeling and HPLC Analysis of κ-Carrageenan Hydrolysate. Five milligrams of κ-carrageenan oligosaccharides obtained at different intervals was dissolved in 500 μL of deionized water. Two hundred microliters of 0.2 mol/L AEC in methanol, 25 μL of 0.5 mol/L aqueous sodium cyanoborohydride ($NaBH_3CN$), and 50 μL of acetic acid were added successively. The mixtures were incubated at 70 °C for 1 h.[37] These labeling reactions were then terminated by neutralization with 100 μL of 1.0 mol/L NaOH. The aqueous phase was extracted with 500 μL of dichloromethane to remove excess AEC, and then centrifuged at 8000 rpm for 3 min. The aqueous phase was taken out for chromatographic analysis. HPLC separation was performed on a Shimadzu LC-2010AHT (Tokyo, Japan). The column used was a 250 mm × 4.6 mm i.d., 5 μm, Sinochrom ODS-BP, with a 4 mm × 4 mm i.d. guard column of the same material (Elite Analytical Instruments Co., Ltd., Dalian, China). Data were collected and processed through Shimadzu Labsolutions software, version 5.51. The labeled oligosaccharides were analyzed by UV detection at 254 nm. Injection volume was 10 μL. The separation was performed at 40 °C in a linear gradient mode from 20% to 40% acetonitrile in 10 mmol/L ammonium acetate aqueous solution (pH 4.5) over 60 min. The flow rate was 0.5 mL/min.

Preparation of κ-Carrageenan Oligosaccharide Alditols. A 0.5 mL aliquot of 4% (w/v) aqueous sodium borohydride ($NaBH_4$) solution was added to 2 mg of the freeze-dried sample, and the mixture was incubated at 25 °C for 2 h.[38] The reaction was terminated by neutralization with 50 μL of acetic acid to destroy excess $NaBH_4$. Boric acid was removed by repeated coevaporation with 0.1% anhydrous methanol/HCl (v/v) three times. The oligosaccharide alditols were analyzed by CID MS/MS.

ESI-MS and CID MS/MS Analysis. The κ-carrageenan oligosaccharides were analyzed using a LTQ-XL ion-trap mass spectrometer equipped with an electrospray ion source and a HPLC system (Thermo-Fisher, Waltham, MA, USA). Data acquisition and processing were performed through the Xcalibur software. Aqueous samples (1 mg/mL) were injected via a 2 μL Rheodyne loop, and taken into the electrospray ion source by a stream of 50% aqueous methanol at a flow rate of 200 μL/min from the pump of HPLC system. For the electrospray ion source, the spray voltage was set at 4 kV, with a sheath gas (nitrogen gas) flow rate of 30 arbitrary units, an

auxiliary gas (nitrogen gas) flow rate of 5 arbitrary units, a tube lens voltage of −250 V, a capillary temperature of 350 °C, and a capillary voltage of −48 V. Scan rate was normal, and the type was full, with a microscan number of 3, searching for a mass range of m/z 200−2000. When CID MS/MS was carried out, helium (He) was used as the collision gas, and the collision energy was set at 25−30% with an isotope width of m/z 3.00.

RESULTS AND DISCUSSION

Purification of κ-Carrageenase. After incubation, the cells were removed by centrifugation and 100 mL of crude culture supernatant was obtained. The original κ-carrageenase activity was 5.72 units/mg protein, which was set as a 1-fold purification. The proteins were then precipitated by ammonium sulfate, resulting in enzymatic activity of 60.46 units/mg of protein with a 10.57-fold purification from the crude culture supernatant. Afterward, the proteins were redissolved in Tris-HCl buffer and concentrated to 5 mL of solution. The enzymatic activity reached to 107.25 units/mg protein with a 18.75-fold purification. The proteins were further purified on a Bio-Gel $P\overline{4}$ column, which separated two peaks (B and C) of proteins with κ-carrageenase activity. Peak B, containing higher κ-carrageenase activity, was combined, and peak C was omitted due to a lesser amount of protein and lower activity. Furthermore, peak B was concentrated and the solution was applied for rechromatography on Bio-Gel $P\overline{4}$. According to the rechromatographic pattern, peak B was found to have only one active peak. It was further confirmed by SDS−PAGE where only a single protein band was observed (Figure 1). Overall, after the four steps of purification, the κ-carrageenase activity increased from 5.72 units/mg of protein to 700.53 units/mg of protein, leading to a 122.47-fold purification from the crude culture supernatant. The degree of purification is shown in Table 1. With references to the reported data, it can be concluded that the purified enzyme has much higher activity than those of some enzymes from other different sources. Khambhaty et al.[24] have reported the purification of κ-carrageenase from *Pseudomonas elongate*, exhibiting maximum enzymatic activity of 426.19 units/mg of protein. Sarwar et al.[39] have reported a characterized κ-carrageenase from *Cytophaga* spp. having enzymatic activity of 5.0 units/mg of protein.

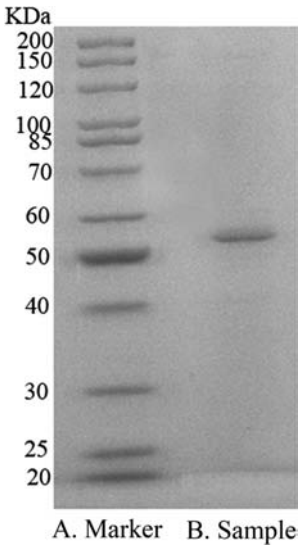

Figure 1. SDS−PAGE analysis of κ-carrageenase purified from *Pedobacter hainanensis* 13-Q^T.

Molecular Weight of κ-Carrageenase. The molecular weight of κ-carrageenase was determined by SDS−PAGE. As presented in Figure 1, the protein band of κ-carrageenase appeared as a single one between 50 kDa and 60 kDa standard molecular weight markers. The results indicated that the κ-carrageenase has an apparent molecular weight of ∼55 kDa.

TLC Analysis of κ-Carrageenan Oligosaccharides Hydrolysis by κ-Carrageenase. TLC analysis is a potent method to detect various oligosaccharides of different polymerization degrees.[40] The presence of sulfate groups in sulfate oligosaccharides has an effect on migration and resolution of these oligosaccharides on TLC plates.[41]

With molecular mass information obtained by ESI-MS analysis, the κ-carrageenan oligosaccharides were observed and monitored on TLC plates (Figure 2). Lanes a, b, c, and d,

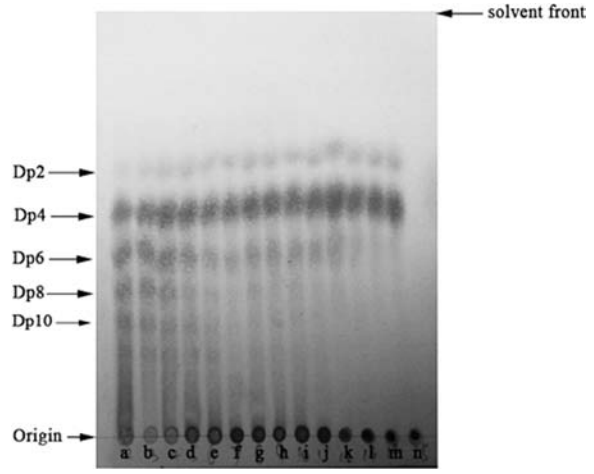

Figure 2. TLC analysis of κ-carrageenan oligosaccharides prepared through κ-carrageenase at pH 7.0 and 40 °C of a−n represented for samples of 0.5 h, 1 h, 2 h, 4 h, 8 h, 12 h, 16 h, 20 h, 24 h, 28 h, 32 h, 48 h, 72 h, and 96 h, respectively.

the product mixtures mainly containing oligosaccharides with various polymerization degrees between disaccharide (Dp 2) and decasaccharide (Dp 10), were observed as distinctive

Table 1. Purification of κ-Carrageenase from *Pedobacter hainanensis*

no.	step	total vol (mL)	total act.[a] (units)	total protein[a] (mg)	sp act.[b] (units/mg)	purifn[c] (-fold)

[a]Values are expressed as means ± SD (n = 3). [b]Specific activity = average of total activity/average of total protein. [c]Purification fold = specific activity/5.72 (units/mg); the value of 5.72 was original specific activity, designed as a 1-fold purification.

dx.doi.org/10.1021/jf500429r | J. Agric. Food Chem. 2014, 62, 2398−2405

separated bands on the TLC plate. After hydrolysis for 12 h, the spots of oligosaccharides at Dp 10 and higher polymerization degrees became faint, indicating that κ-carrageenan was effectively degraded. The reaction mixtures loaded on lanes i, j, k, l, m, and n corresponding to 24−96 h digestion mainly contained oligosaccharides ranging from disaccharide to hexasaccharide, of which tetrasaccharide was the dominant component.

HPLC Analysis of κ-Carrageenan Oligosaccharides Hydrolysis by κ-Carrageenase. To quantitatately assess the yield of oligosaccharides of different Dps, each sample was labeled by reductive amination with AEC and analyzed by HPLC. Some chromatographic data of the reaction products of enzymatic hydrolysis for 0.5 h, 12 h, 24 h, and 96 h are depicted in Figure 3. The peaks corresponding to Dp 2, Dp 4, Dp 6, and Dp 8 were clearly detected. Over 96 h, the area of the peaks of higher molecular weight fractions gradually decreased. The quantitative data of Dp 2, Dp 4, Dp 6, and Dp 8 are summarized in Figure 4. Obviously, typical oligosaccharides were obtained at different time courses. According to the peak area of these oligosaccharides, Dp 4 was the dominant component. The content of Dp 4 was low at the beginning, higher in the middle, and lower at the end of the reaction, and the highest yield of Dp 4 was about 70% of total oligosaccharides until 24 h. The curve of Dp 6 was similar to that of Dp 4. In contrast, the area curve of Dp 8 was in a quite different trend. The content of Dp 8 reached the highest point in the beginning and then decreased continuously to the end. During the process of enzymatic hydrolysis, the content of Dp 2 gradually increased. However, Dp 2 had a relatively low yield.

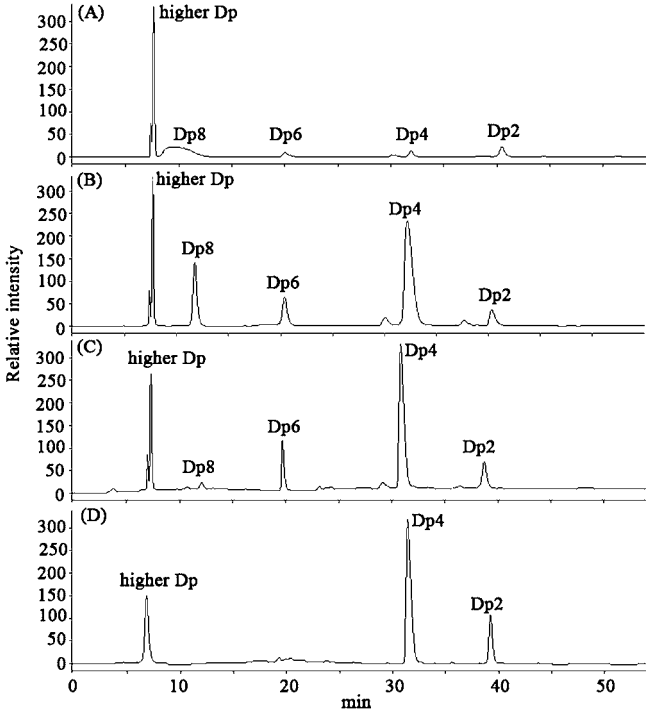

Figure 3. HPLC analysis of κ-carrageenan oligosaccharides obtained by κ-carrageenase at pH 7.0 and 40 °C (A) for 0.5 h; (B) for 12 h; (C) for 24 h; (D) for 96 h.

ESI-MS Analysis of κ-Carrageenan Oligosaccharides Hydrolysis by κ-Carrageenase. Due to the presence of sulfate groups on the oligosaccharides, all MS experiments were performed in negative-ion mode.[42] The mass spectra of the oligosaccharide mixtures obtained at 12 h, 24 h, and 96 h are depicted in Figure 5.

The mass spectra exhibited signals of multiply charged molecular anions, including singly, doubly, and triply charged

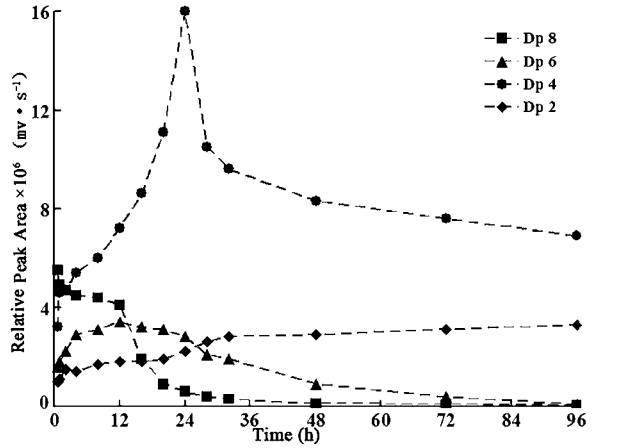

Figure 4. The yield curve of Dp 2, Dp 4, Dp 6, and Dp 8 obtained with different time courses analyzed by HPLC.

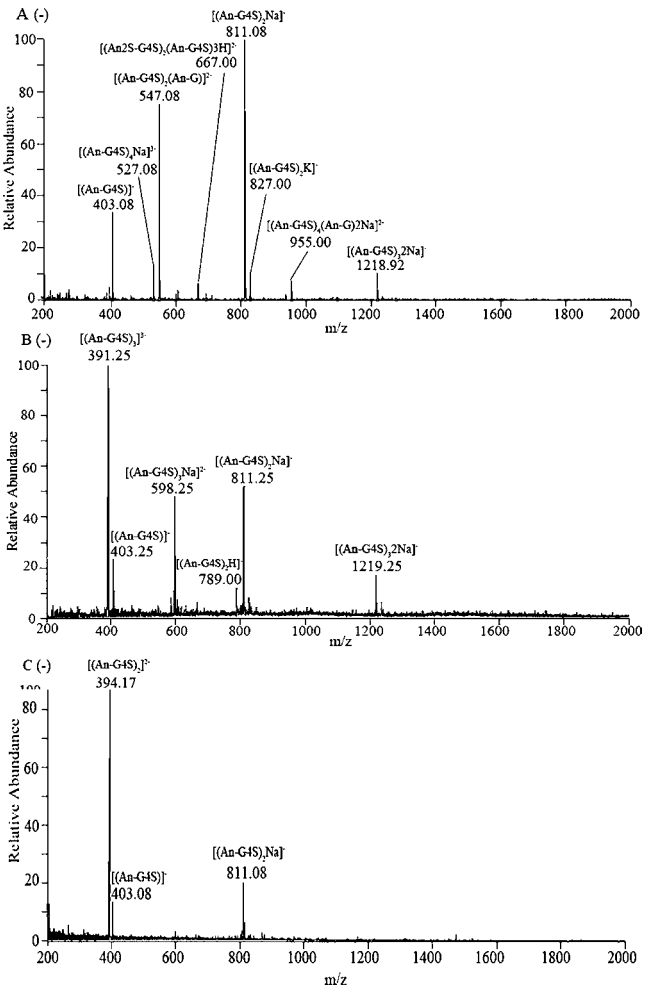

Figure 5. The ESI-MS analysis of κ-carrageenan oligosaccharides prepared by κ-carrageenase at pH 7.0 and 40 °C (A) for 12 h; (B) for 24 h; (C) for 96 h.

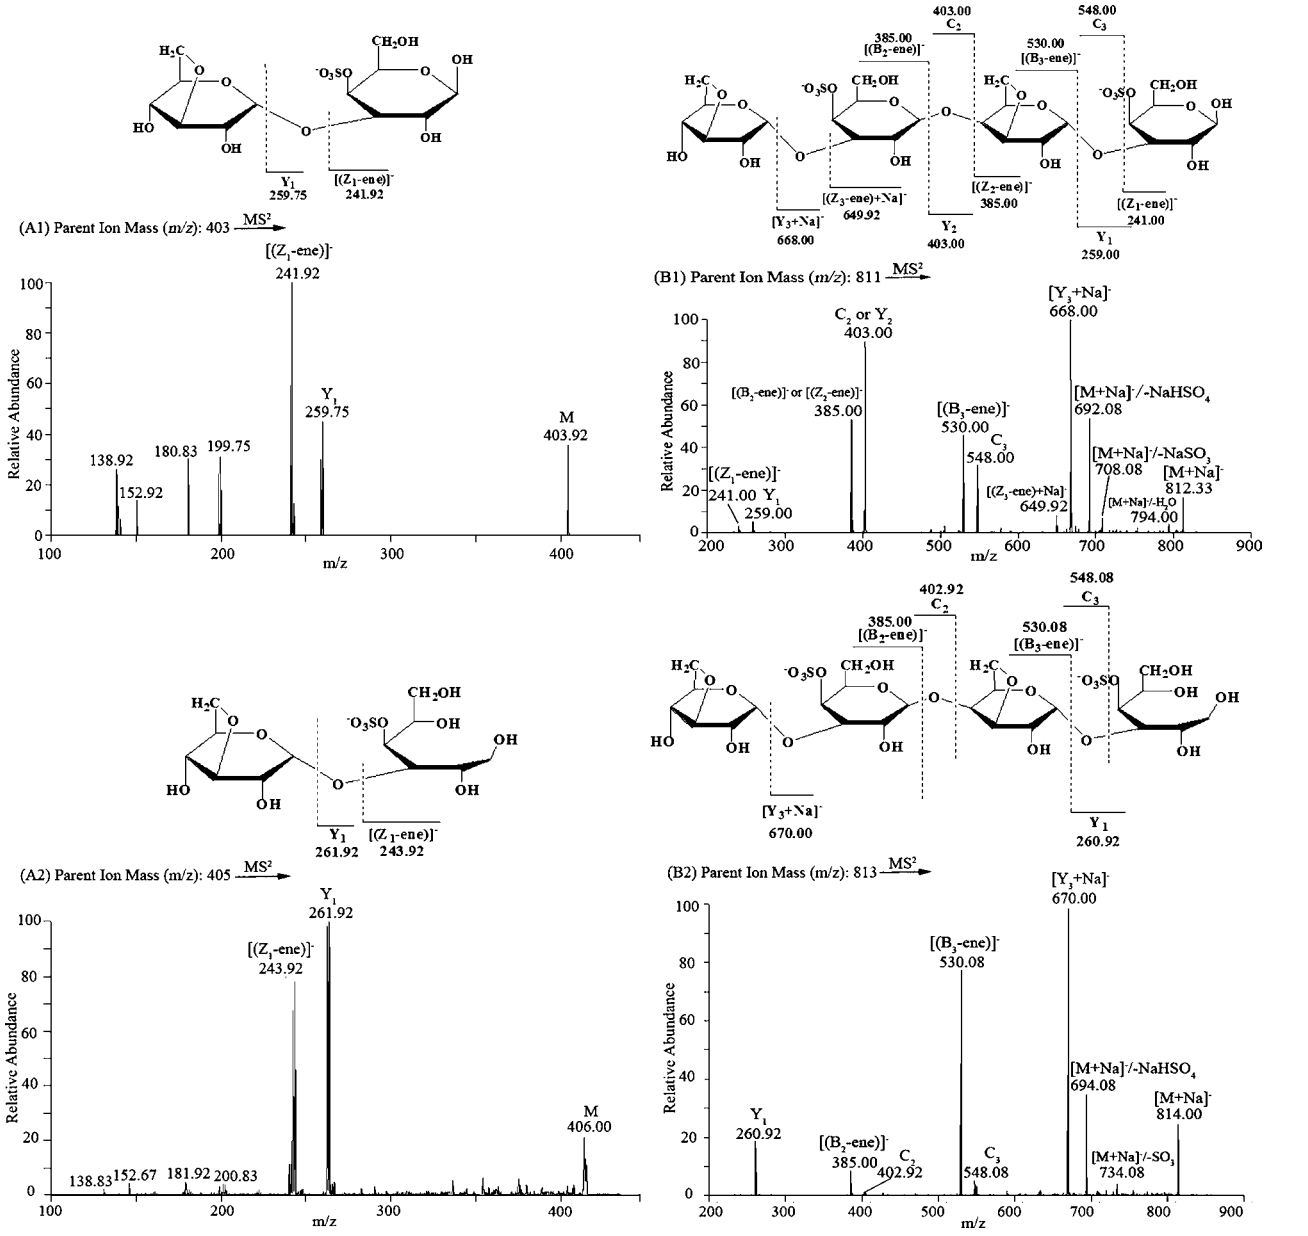

Figure 6. The CID MS/MS analysis of κ-carrageenan oligosaccharides and oligosaccharide alditols degraded by enzymatic hydrolysis. (A1) disaccharide vs (A2) disaccharide alditol, and (B1) tetrasaccharide vs (B2) tetrasaccharide alditol. Note the different fragments present in each spectrum, arising from the different linkages.

ones. As shown in Figure 5A, the sample prepared in 12 h contained a series of κ-carrageenan oligosaccharides, including disaccharide, tetrasaccharide, hexasaccharide, octasaccharide, and decasaccharide. The peak at m/z 403.08 is assigned to disaccharide $[(G4S\text{-}An)]^-$ carrying one sulfate group. The peaks corresponding to molecular anion as sodium salt $[(G4S\text{-}An)_2Na]^-$ (m/z 811.08) and potassium salt $[(G4S\text{-}An)_2K]^-$ (m/z 827.00) are assigned to tetrasaccharide carrying two sulfate groups. The base peak found at m/z 1218.92 is likely to be representative of hexasaccharide with three sulfate groups bearing two sodium ions $[(G4S\text{-}An)_3 2Na]^-$. The peak at m/z 547.08 corresponds to doubly charged desulfated hexasaccharide anions $[(An\text{-}G4S)_2(An\text{-}G)]^{2-}$ carrying two sulfate groups. This desulfation could be formed in the mass spectrometer due to high cone voltage.[42] The peak found at m/z 667.00 is assigned to the doubly charged anion $[(AnG2S\text{-}G4S)_2(An\text{-}G4S)3H]^{2-}$. The oversulfated disaccharide units of AnG2S-G4S are attributed to inclusion of ι-carrageenan, a common impurity in commercial κ-carrageenan.[42,43] The peak found at m/z 527.08 corresponds to the triply charged octasaccharide anion $[(An\text{-}G4S)_4Na]^{3-}$. The peak found at m/z 955.00 corresponds to doubly charged desulfated decasaccharide anions $[(An\text{-}G4S)_4(An\text{-}G)2Na]^{2-}$.

The κ-carrageenan oligosaccharides obtained by digestion using κ-carrageenase for 24 h are mainly between Dp 2 and Dp 6, and their MS profile is depicted in Figure 5B. We found that the peaks at m/z 811.00 and m/z 789.00 correspond to molecular anions as sodium salt $[(An\text{-}G4S)_2Na]^-$ and hydrogen salt $[(An\text{-}G4S)_2H]^-$, respectively. In the mass spectra of hexasaccharide, the base peak at m/z 1219.25 corresponds to the molecular anion with two sodium atoms ($[(An\text{-}G4S)_3 2Na]^-$); while the peaks found at m/z 391.25 and

dx.doi.org/10.1021/jf500429r | J. Agric. Food Chem. 2014, 62, 2398−2405

598.25 correspond to triply and doubly charged anions $[(An\text{-}G4S)_3]^{3-}$ and $[(An\text{-}G4S)_3Na]^{2-}$, respectively.

After enzymatic digestion for 96 h, tetrasaccharide was the major product, as shown in Figure 5C. The peak at m/z 394.17 corresponds to doubly charged tetrasaccharide anion $[(An\text{-}G4S)_2]^{2-}$.

These results showed enzymatic properties of the κ-carrageenase, for which the cleavage group was An-G4S unit, resulting in a series of neocarrabiose oligosaccharides with the code of An-G4S.

Sequencing of κ-Carrageenan Oligosaccharides by CID MS/MS. Glycosidic cleavages provide information on constituent monosaccharide sequence and branching, whereas cross-ring cleavages can be used to define linkages. The cross-ring cleavage ions are generally less abundant when compared with the glycosidic cleavage ions.[44−46] A nomenclature for describing these fragment ions was proposed by Domon and Costello[47] and widely accepted.

The detailed structures of κ-carrageenan oligosaccharides obtained by enzymatic hydrolysis were elucidated by CID MS/MS. In order to differentiate fragment ions with identical masses arising from glycosidic cleavages, the oligosaccharide mixture was reduced by $NaBH_4$ to obtain oligosaccharide alditols. Due to the reduction, the reducing terminal fragment ions showed an increase of 2 Da in CID MS/MS analysis. Therefore, the difference of reducing and nonreducing terminal fragments can be easily identified from each other.[48,49]

In the obtained MS profiles, all the oligosaccharide molecular ions showed 2 Da increase after the reduction treatment (data not shown). During the CID MS/MS analysis, disaccharide (m/z 403.25) and its alditol (m/z 405.08) form, together with tetrasaccharide (m/z 811.25) and its alditol (m/z 813.00) form, were taken as the precursors to determine the structure of κ-carrageenan oligosaccharides. The CID MS/MS spectra are depicted in Figure 6, and the assignment data are shown in Table 2.

In the MS/MS profiles of the disaccharide (Figure 6A1) and its alditol form (Figure 6A2), both glycosidic and cross-ring fragments are found. The two major glycosidic fragment ions derived from the disaccharide alditol corresponding to the peaks at m/z 243.92 and 261.92 (Figure 6A2) are 2 Da increased from the peaks at m/z 241.92 and 259.75 (Figure 6A1). In the CID MS/MS spectra of the disaccharide and its alditol, Y- and Z-type glycosidic cleavage fragments are considerably more abundant than the cross-ring cleavage fragments. The cross-ring cleavage fragment ions at m/z 152.92, 199.75, 138.92, and 180.83 are derived from the sulfated disaccharide precursor ion. The ions at m/z 152.92, 180.83, and 138.92 are assigned to $^{3,5}A_2$-, $^{2,5}A_2$-, and $^{2,4}A_2$-type fragments, respectively. The peak at m/z 199.75 is assigned to $^{1,3}X_1$-type.

In the CID MS/MS spectra of tetrasaccharide (Figure 6B1) and its alditol (Figure 6B2), mainly glycosidic cleavage fragment ions as sodium adducts are observed but no cross-ring cleavage fragments are found in the spectra. Minor desulfation occurs, as indicated by the presence of weak signals at m/z 692.08, 694.08 (−120 Da, equivalent to the loss of $NaHSO_4$), 708.08 (−103 Da, equivalent to the loss of $NaSO_3$), and 734.08 (−80 Da, equivalent to the loss of SO_3). The peaks at m/z 260.92 and 670.00 (Figure 6B2) show a 2 Da shift compared with the peaks at m/z 259.00 and 668.00 (Figure 6B1). These peaks are assigned to the reducing side fragments produced by glycosidic cleavages. The peaks at m/z 530.08 and 548.08 (Figure 6B2) observed here remain the same as the peaks at m/z 530.00 and 548.00 (Figure 6B1). These peaks are derived from cleavages at the nonreducing side of both tetrasaccharide and its alditol, determining that sulfated G4S are at the reducing terminal residue. Therefore, according to the spectral feature of glycosidic fragments from nonreducing (B- and C-type ions) and reducing sides (Y- and Z-type ions), the sequence of κ-carrageenan oligosaccharides prepared by κ-carrageenase could be readily deduced as $(An\text{-}G4S)_n$, which would give rise to oligosaccharides with terminal G4S residue.

According to ESI-MS and MS/MS analysis, the enzymatic products were a homologous series of even-numbered sulfated oligosaccharides with $(An\text{-}G4S)_n$, of which An is at the nonreducing end and G4S is at the reducing end. This result indicates that the κ-carrageenase of *Pedobacter hainanensis* cleaves at the internal β-1,4 linkages of κ-carrageenan (Figure 7).

Table 2. Fragment Ions Observed in the CID MS/MS Spectra of Disaccharide, Tetrasaccharide, and their Alditols as Precursors

	obsd fragment ion (m/z) of enzymic products $(An\text{-}G4S)_n$ and Their Alditols			
	disaccharide		tetrasaccharide	
fragment ion type	403	405	811	813
$^{2,4}A_2$	138.92	138.83

The purified κ-carrageenase isolated from *Pedobacter hainanensis* is a novel enzyme acting as a β-hydrolyase to produce κ-carrageenan oligosaccharides with An-G4S-type, yielding tetrasaccharide as the main end product. The action pattern of this enzyme was quite different from those of other κ-carrageenases reported earlier. Ma et al.[50] have reported a κ-carrageenase isolated from *Pseudoalteromonas* sp. They indicated that the main end products were dimers of different neocarrabioses, e.g., disaccharide, tetrasaccharide, hexasaccharide, octasaccharide, and decasaccharide. Potin et al.[26] have reported a κ-carrageenase purified and characterized from *Cytophaga* strain Dsji. They showed that tetrasaccharide and hexasaccharide were the major end products and the purified enzyme was not capable of hydrolyzing tetrasaccharide and hexasaccharide. Enzymatic activity, hydrolytic products, and various characteristics showed that the κ-carrageenase from *Pedobacter hainanensis* could be an alternative resource to produce better quality carrageenan with commercial value.

carbohydrates, and the thermoplastics could therefore have better properties.

In this research, we have grafted sorghum DDG with three different types of methacrylates (methyl, ethyl, and butyl methacrylates) and the grafting conditions have been optimized. The influence of grafting conditions on the grafting parameters, properties of the grafted DDG and the thermoplastics developed from the grafted DDG have been studied.

MATERIALS AND METHODS

Materials. Sorghum DDG was obtained from an ethanol producer in Kansas, U.S.A. The three methacrylates, methyl methacrylate (99.8%, TCI America, Portland, OR), ethyl methacrylate (98%, Alfa Aesar, Ward Hill, MA), and butyl methacrylate (99%, Acros Organics, New Jersey) and the initiator (Potassium persulfate, TCI America, Portland, OR), reducing agent (sodium bisulfite, Sigma Aldrich, St. Louis, MO), and other chemicals required for the study were reagent grade and used as-received.

Grafting. Grafting was done in a four-necked flask under nitrogen atmosphere. A schematic of the grafting process is shown in Figure 1.

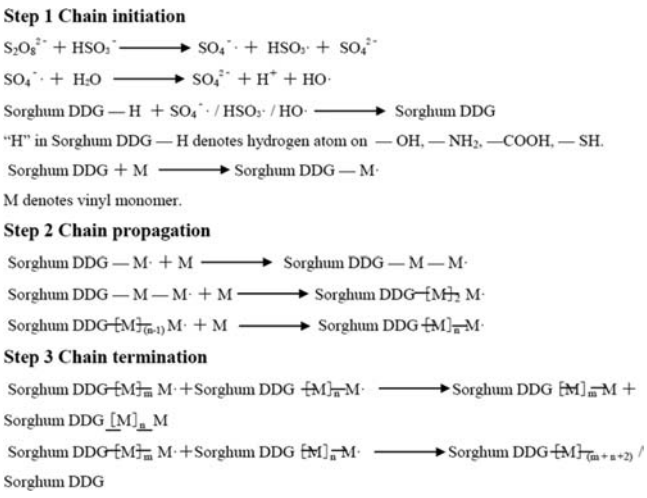

Figure 1. Schematic of the grafting process.

Sorghum DDG was dispersed in water and the monomer concentrations ranging from 20 to 180% on weight of the DDG were added into the flask, along with the required amount of initiators and reducing agents. Grafting was done by heating the flask to 70 °C for 2 h. Paradioxybenzene (2%) was added into the flask to terminate the grafting reaction and the grafted DDG was collected. Any unreacted monomers were removed by thoroughly washing the grafted DDG with water. The amount of DDG obtained after grafting was weighted and used to calculate the % grafting and other grafting parameters. The grafting parameters that were determined include % monomer conversion, molar grafting ratio, % grafting, and % homopolymers using the equations given below.[12] In this report, % grafting describes the % by weight of the monomers grafted on to the meal, grafting efficiency (%) indicated the weight % of monomers grafted to the initial weight of the monomers used and includes both the grafted polymers and the homopolymers.

$$\%\ \text{monomer conversion} = \frac{W_1 - W_2}{W_1} \times 100 \quad (1)$$

$$\%\ \text{grafting} = \frac{W_1 - W_2 - W_3}{W_0} \times 100 \quad (2)$$

$$\%\ \text{grafting efficiency} = \frac{W_1 - W_2 - W_3}{W_1 - W_2} \times 100 = \frac{\%\ \text{grafting}}{\%\ \text{monomer conversion}} \times \frac{W_0}{W_1} \times 100 \quad (3)$$

where W_b and W_a were the weight of the products before and after the extraction, respectively; W_3 and W_0 were the weight of the homopolymer and feathers, respectively, and $W_3 = W_b - W_a$.

Extracting Homopolymers. Since homopolymers affect the thermoplasticity and the properties of the products developed, the grafted samples used for compression molding were extracted with acetone to remove the homopolymers. Grafted samples were Soxhlet extracted in acetone for 24 h until all the homopolymers were removed.[12] Samples were later dried and conditioned before using for compression molding.

Characterizing Grafted DDG. *Thermal Analysis.* Grafted DDG was examined using a differential scanning calorimeter (DSC) (Mettler Toledo D822e, Columbus, OH) to observe the melting behavior. DSC studies were done by placing the samples in sealed aluminum pans and heating them up to 240 °C at a rate of 20 °C/min.

^{13}C NMR. Solid state ^{13}C NMR studies were done on a Bruker Avance 400 MHz spectrometer (Bruker Daltonics Ins, Fremont, CA) consisting of a $^1H/^{13}C/^{15}N$ triple-resonance, 3.2 mm magic angle spinning probe. Spectra were collected at room temperature using a standard cross-polarization experiment with high-power ^1H-decoupling, and spinning the samples at 20 kHz.

Developing Thermoplastic Films. Grafted DDG with and without any homopolymers was compression molded to form films. About 10 g of the grafted samples were placed between aluminum foils and compression molded in a Carver Press (Carver Inc., Wabash, IN) at 360 °F for 5 min at 40 000 PSI. After compression molding, cold water was run-in to cool the press and the samples were removed. Films obtained were conditioned under standard atmospheric conditions of 21 °C and 65% relative humidity for at least 24 h before being tested. At least 8 films were compression molded and samples were cut from the films and randomly selected for testing. Thickness of the films varied from 0.3 to 0.7 mm depending on the extent of grafting and type of monomer used.

Wet stability of the films was tested by immersing the films in 21 °C water for 30 min. After 30 min in water, the samples were immediately tested for their tensile properties according to ASTM standard D 882. Film strips measuring 15 ×1.5 cm^2 were tested on an MTS tensile tester (Model Q test 10, Eden Prairie, MN) using a gauge length of 5 cm and crosshead speed of 50 mm/min. At least 25 samples were tested for each condition and the average and ± one standard deviation are reported.

RESULTS AND DISCUSSION

Influence of Monomer Concentration on % Monomer Conversion. Figure 2 reveals that the % of monomers that were converted into polymers increased with increasing concentration of the monomers used during the reaction. Monomer conversion was considerably lower at monomer concentration of 20% but substantially increased to about 95% when the monomer concentration was increased to 60% or higher. Further increase in monomer concentration did not show any significant increase in the monomer conversion, and the monomer conversion was very similar for all three monomers studied. At low monomer concentration (20%), the molecules have a lower chance of reacting with each other and with the DDG and form polymers, and therefore had a low % conversion. Increasing monomer concentrations above 60% would result in excessive monomers that react with each other and form homopolymers. Since excessive concentration of monomers would add to the cost and does not substantially

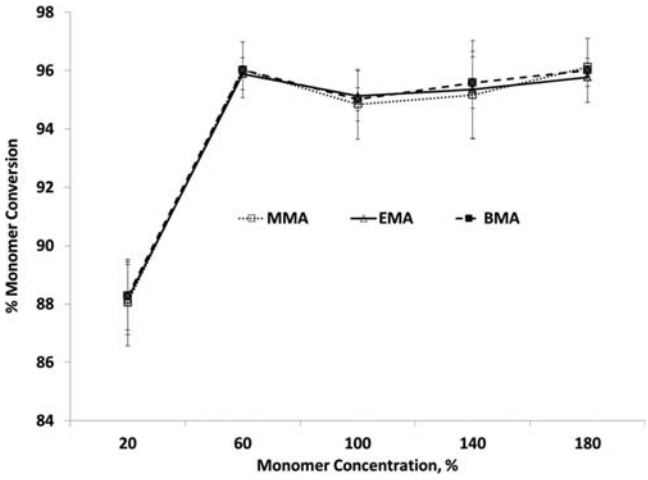

Figure 2. Influence of monomer concentration on the % monomer conversion. Grafting reaction was done at 70 °C for 120 min.

increase monomer conversion, a monomer concentration of 60% would be sufficient to get good % grafting and lower % homopolymers.

Influence of Monomer Concentration on % Grafting Efficiency. Grafting efficiency was substantially lower at high monomer concentrations as seen from Figure 3. At monomer

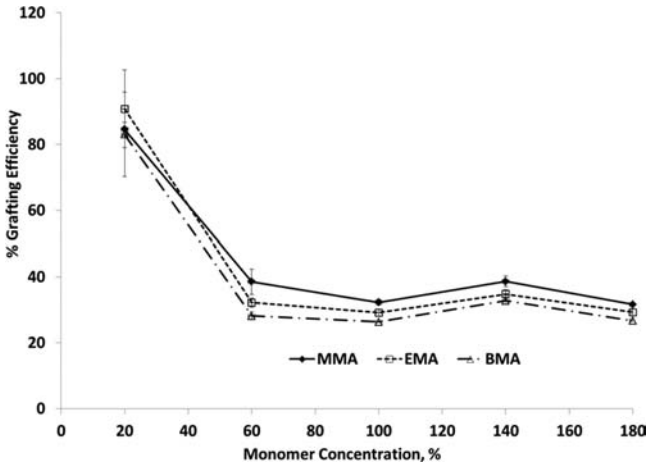

Figure 3. Influence of monomer concentration on the % grafting efficiency. Grafting reaction was done at 70 °C for 120 min.

concentrations of 20%, the grafting efficiency ranged from 66 to 91%, with the % grafting efficiency being highest for MMA, followed by EMA and BMA. Monomers containing longer side chains are more difficult to penetrate into DDG and attach onto the grafting sites. In addition, longer alkyl chains offer stearic hindrance and are more difficult to react with the DDG compared to a shorter chain monomers such as MMA. Therefore, BMA had a lower % grafting than MMA or EMA as seen from Figure 2. Changes in % grafting efficiency with increasing monomer concentration are consistent with observations made for the same monomers when grafted onto starch, soyprotein and corn DDG.

Influence of Monomer Concentration on % Grafting. Monomers (%) grafted onto DDG showed an opposite trend to the % grafting efficiency, as seen from Figure 4. Increasing monomer concentration steadily increased the % of polymers grafted onto DDG for all the monomers studied. When

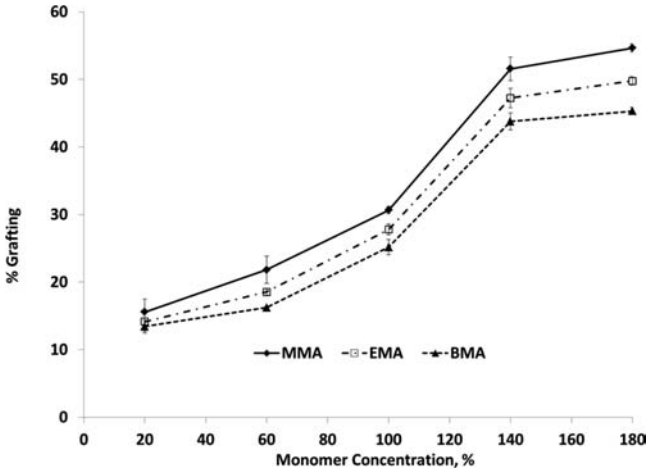

Figure 4. Increase in % grafting with increase in monomer concentration when grafted with the three monomers at 70 °C for 120 min.

monomer concentration was increased, the probability of the monomers reacting with themselves and with the DDG increased. This led to an increase in the amount of grafted chains on DDG and therefore the % grafting also increased. As seen with % grafting efficiency, MMA showed a higher % grafting than EMA and BMA because MMA are shorter polymers and readily reacted with the DDG and themselves. Longer polymer chains formed by EMA and BMA cannot penetrate easily into DDG and attach themselves to the grafting sites. Therefore, BMA had the lowest % grafting compared to the other two monomers. Molar grafting ratio data also showed that MMA had higher amounts of grafted monomers than EMA or BMA due mainly to the shorter chain length and lower stearic hindrance of MMA.

Influence of Monomer Concentration on % Homopolymers. Amount of homopolymers formed increased linearly with increasing monomer concentration as seen from Figure 5. At any particular monomer concentration, MMA had the lowest % homopolymers compared to EMA or BMA. Since MMA could react more easily with DDG, it had a lower chance to react with itself and form homopolymers. Increasing the

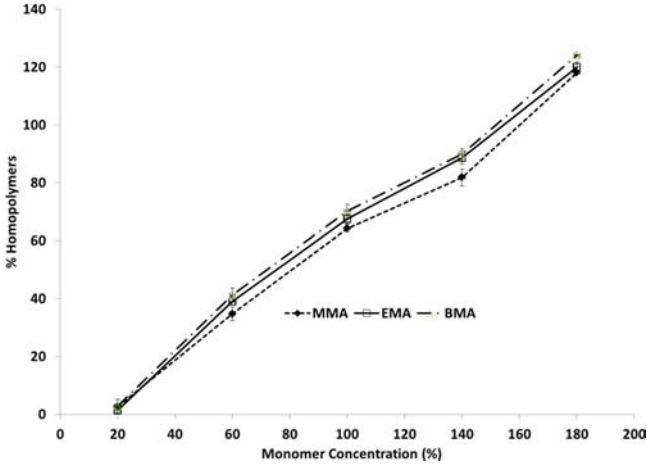

Figure 5. Changes in the amount of homopolymers formed with increasing ratio of monomers when the grafting was done at 70 °C for 120 min.

dx.doi.org/10.1021/jf405499t | J. Agric. Food Chem. 2014, 62, 2406−2411

concentration of monomers increased the reaction between the monomers and led to the formation of higher amounts of homopolymers. At monomer concentrations above 50%, the monomers predominantly form homopolymers than graft onto the DDG. Saturation of grafting sites in DDG that are accessible to the monomers decreased and that would also make the monomers to form homopolymers.

Nuclear Magnetic Resonance. NMR spectra of ungrafted and DDG grafted with EMA show distinct differences as seen from Figure 6. Since sorghum DDG contains about 25−45%

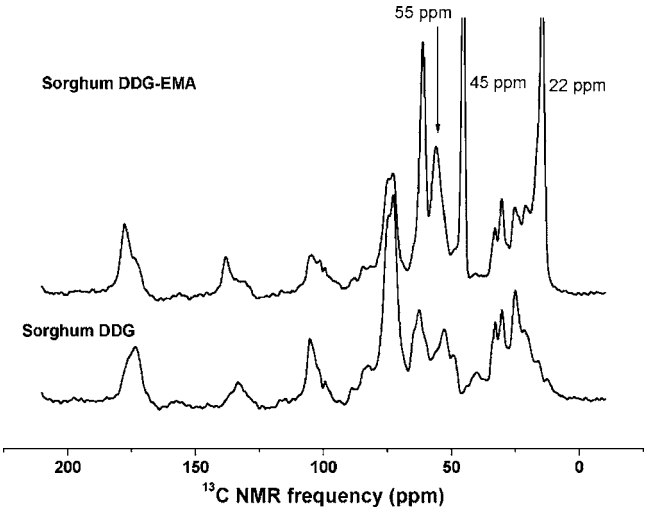

Figure 6. NMR spectrum depicting the differences between the ungrafted DDG and DDG grafted with EMA.

protein, 20% hemicellulose and 9−16% cellulose, the NMR spectra of sorghum DDG displayed major peaks belonging to the proteins, hemicellulose and cellulose. In sorghum DDG, the peak at about 175 ppm reflected amino group in protein,[13] the peak at about 75 ppm and 105 ppm represented C4 and C1 in cellulose and hemicellulose, respectively.[14,15] After EMA grafting, peaks at 22 ppm reflecting methyl groups ($-CH_3$), 45 ppm representing tertiary carbon and 55 ppm representing methoxy group ($-OCH_3$) in methacrylate are seen. The difference between the two spectra clearly indicated that EMA has been successfully grafted onto sorghum DDG.

Thermal Behavior of Grafted DDG. Figure 7 shows that the ungrafted and DDG grafted with the three monomers had distinct melting peaks. The peak at 130 °C seen in the ungrafted DDG should be due to the melting of the proteins. MMA grafted DDG had a broad melting peak suggesting poor thermoplasticity. Compared to MMA, the EMA- and BMA-grafted DDG showed considerably sharp melting peaks at 205 °C. BMA grafted DDG had an additional melting peak at about 180 °C, most likely due to the different melting behaviors of the proteins and carbohydrates in the DDG. As can be inferred from Figure 7, BMA grafted DDG had the highest melting enthalpy of 108 J/g, compared to 80 and 55 J/g for EMA and MMA, respectively. DSC curves clearly suggested that BMA imparted better thermoplasticity to DDG than MMA and EMA. Although the melting peaks for EMA and BMA were observed at 205 °C, the grafted DDG could be compression molded into films at 190 °C under pressure.

Tensile Properties of Grafted DDG films Without Homopolymers. Tensile properties of the films made from the grafted DDG after extraction of the homopolymers shown

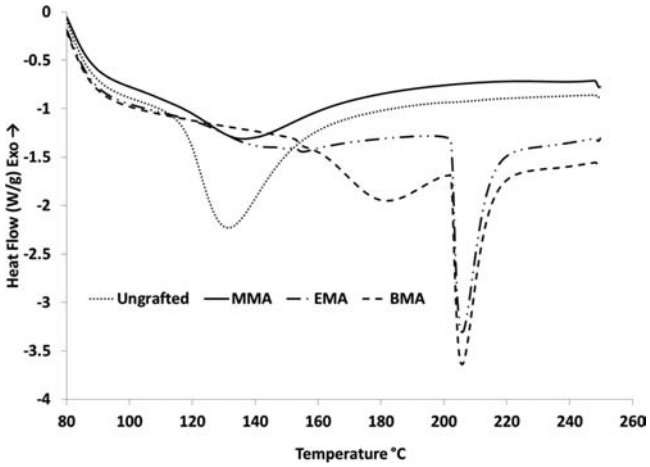

Figure 7. Differential scanning calorimetry curves for the ungrafted and DDG grafted with the three monomers shows that EMA and BMA provided better thermoplasticity compared to MMA.

in Tables 1−3 reveal some interesting features. For all three monomers, increasing the grafting ratio increased strength, except for DDG grafted with 53% BMA, where the strength decreased compared to the films obtained at 40% BMA grafting. At a grafting ratio of about 23%, films made from all three monomers had strengths between 2 and 2.3 MPa but films grafted with longer lengths of carbon chains had higher elongation. For instance, MMA-grafted films had an elongation of 0.5% compared to 1.1% for BMA grafted films. Increasing the grafting ratio from 23 to 30% more than doubled the strength and elongation of the MMA-grafted films, whereas the EMA and BMA grafted films showed a marginal increase in strength. Further increase in the grafting ratio to 40% and above led to increased strength of the films. MMA-grafted films had the highest strength but low elongation compared to EMA and BMA films, whereas BMA grafted films had higher elongation than the MMA and EMA films. The modulus of the films was highest for MMA-grafted DDG, followed by EMA- and BMA-grafted DDG. Tensile properties of the films mainly depend on the thermoplasticity of the grafted DDG. At low grafting ratios, the DDG partially melts, and the films contain considerable amounts of proteins and carbohydrates that do not melt leading to poor tensile properties. Increasing grafting ratio improves the thermoplasticity, and therefore the films have higher strength and elongation. Monomers with longer chains offer higher extensibility and better thermoplasticity. Therefore, the EMA- and BMA-grafted films had higher elongation than the MMA grafted films. Since the EMA- and BMA-grafted films are more flexible, the modulus is lower than that of the MMA films.

Wet tensile properties of the films showed a different trend than the dry properties of the films grafted with the three monomers. Films grafted with MMA showed strength retention ranging from 43 to 59% compared to 33−69% for EMA and 15−61% for BMA with increasing grafting ratio resulting in higher strength retention. Although there was no particular trend in the wet strength retention with the increasing chain length of the monomers, elongation of the films was considerably higher for BMA followed by EMA and MMA. MMA- and EMA-grafted films did not show significant change in the wet elongation but the BMA-grafted films had at least 100% increase in elongation when wet. Increasing the grafting ratio adds higher amounts of the hydrophobic polymer onto

DDG, and therefore the wet stability increased with increasing grafting ratio. Water acts as a plasticizer and allows the molecules to move more freely therby increasing the elongation. Although increasing chain length should increase hydrophobicity and improve wet tensile properties, BMA-grafted films had similar or lower strength retention than the MMA or EMA films. This should be due to the lower amounts (molar weight) of BMA on the films compared to MMA and EMA, although the % grafting ratios were similar.

Tensile Properties of Grafted DDG Films with Homopolymers. Since homopolymers are formed during the grafting reaction and the homopolymers are part of the grafted DDG, we investigated the properties of DDG films containing homopolymers. As seen from Table 4, the dry tensile properties of the films containing homopolymers were slightly different but there were considerable variations in the wet strength of the films compared to those developed from the same monomers but without the homopolymers. For instance, at 40% grafting, EMA grafted DDG without homopolymers had dry strength of 4.4 MPa compared to 6.3 MPa with homopolymers and the % elongation was 1.5% compared to 1.8%. Addition of homopolymers will increase the thermoplasticity and the hydrophobicity of the grafted DDG leading to increased strength and elongation. Also, the properties of the homopolymers will influence the properties of the DDG films. Our previous research has shown that films made from homopolymers with longer carbon chains have lower strength but higher elongations. BMA films with a dry strength of 4.8 MPa and elongation of 3.1% show excellent wet strength and elongation retention and could be useful for various applications.

Table 4. Tensile Properties of Sorghum DDG Films Grafted with MMA, EMA, and BMA under the Optimum Grafting Conditions and Including the Homopolymers[a]

	breaking strength, MPa		breaking elongation, %	
	dry	wet	dry	wet
MMA	4.5 ± 1.2	3.2 ± 1.0	1.4 ± 0.1	1.3 ± 0.4
EMA	6.3 ± 1.1	4.7 ± 1.1	1.8 ± 0.1	2.3 ± 0.2
BMA	4.8 ± 1.0	1.8 ± 0.4	3.1 ± 0.6	8.1 ± 1.2

[a]Grafting % for the three monomers was about 40% and homopolymers (%) were 54, 58 and 28% for MMA, EMA, and BMA, respectively.

Sorghum DDG grafted with methacrylates could be used to develop films with good dry and wet tensile properties. Changing the concentration of monomers resulted in higher grafting ratios and a higher percentage of homopolymers. Also, increasing grafting ratio generally increased the strength and elongation of the films. Similarly, the wet strength of the films was also higher at higher grafting ratios. Films containing homopolymers exhibited better tensile properties compared to films made from the same monomers but without the homopolymers. It was also observed that increasing the length of the alkyl chain resulted in films with lower strength but higher elongation since the monomers with longer chains are more flexible. Among the three monomers studied, BMA-grafted DDG had better thermoplasticity and also formed films with good dry and wet tensile properties. Grafting appears to be a more viable approach to develop thermoplastics from DDG compared to other common types of chemical modifications.

Currently, researchers are still on the lookout for some new and simpler methods of D-tagatose production. From a commercial point of view, a single-step or single-pot biosynthesis of D-tagatose from lactose is very much desired. Technically, however, it is hard to achieve because the producing strains of isomerase and hydrolase have incompatible fermentation conditions, especially the optimal pH. In the present study, we attempted to develop an efficient single-step method for the D-tagatose production from lactose. The ECAI-Q299K mutant, whose optimal conditions approached that of β-D-galactosidase, was obtained before. A recombinant strain (*E. coli*-ZY) was constructed to coexpress β-D-galactosidase and ECAI-Q299K at a fairly high level. With this *E. coli*-ZY strain, D-tagatose was successfully generated in a single step for the first time and, later, separated, purified, and crystallized to give pure powder with a high yield. The results are believed to lay down the foundation for industrialized D-tagatose production.

MATERIALS AND METHODS

Materials, Bacterial Strains, and Media. Ex-Taq DNA polymerase, restriction enzymes, T4 DNA ligase, ampicillin, and isopropyl-β-D-thiogalactopyranoside (IPTG) were purchased from Takara Biotechnology Co., Ltd. (Dalian, China). The pETDuet-01 expression vector was bought from Novagen (Darmstadt, Germany). The high-performance liquid chromatography (HPLC) and Rezex RCM-Monosaccharide Ca^{2+} columns were purchased from Agilent (Wilmington, DE) and Phenomenex (Guangzhou, China), respectively. Other reagents were of analytical grade and purchased from commercial sources. The hosts of *E. coli* BL21 (DE3) were purchased from Merck (Darmstadt, Germany). Different *E. coli* strains were cultured in Luria-Bertani (LB) medium. The *E. coli* strain and *Saccharomyces cerevisiae* NX-3 were stored at the laboratory.

Construction of the Coexpression Plasmids. As previously reported,[28] we found that alternations at Q299 of ECAI can significantly influence the optimal pH of the enzyme. Using directed evolution mutagenesis, it was found that the optimal pH of ECAI-Q299K was 6.5. The *araA*′ gene from the recombinant *E. coli* of L-arabinose isomerase Q299K and the *lacZ* gene from *E. coli* W303 were amplified using polymerase chain reaction (PCR). The up- and downstream oligonucleotide primers of the *araA*′ gene (Table 1) were *araA*′-up and *araA*′-down, respectively. The template for this PCR was the genome from recombinant *E. coli* of L-arabinose isomerase Q299K. The PCR fragment was subsequently cloned into the *EcoR* I–*Hind* III restriction sites of pETDuet-01 to generate the recombinant plasmid pETDuet-*araA*′.

The up- and downstream oligonucleotide primers of the *lacZ* gene (Table 1) were *lacZ*-up and *lacZ*-down, respectively. The template for this PCR was the genome from *E. coli* W303. The PCR fragment was subsequently cloned into the *Bgl* II–*Xho* I restriction sites of pETDuet-*araA*′ to generate the recombinant coexpression plasmid pETDuet-*araA*′-*lacZ*. The recombinant plasmid was identified by PCR and single restriction enzyme digestion (*Hind* III). The correct plasmid was sent to GenScript Biotech Co. (Nanjing, China) for DNA sequencing. The ECAI-Q299K and β-D-galactosidase coexpression plasmid were constructed successfully.

Expression of Recombinant Coexpression Plasmid in *E. coli* Strain BL21 (DE3). Expression studies were carried out using *E. coli* BL21 (DE3). Transformation was performed according to the pET system manual. The vectors of pETDuet-*araA*′-*lacZ* were transformed. A single colony from freshly transformed cells was inoculated in 5 mL of LB medium containing 50 mg/mL ampicillin and incubated for 8–10 h at 37 °C. Then, 2 mL of cell suspension was inoculated to 25 mL of LB medium supplemented with 50 mg/mL ampicillin and 1 mM isopropyl-β-D-thiogalactopyranoside (IPTG) to OD_{600} of 0.6; the culture was cultivated at 25 °C to induce protein expression; and cells were harvested by centrifugation after 22 h. The induced cells were collected by centrifugation at 5000*g* for 5 min, and the cell density was adjusted to OD_{600} = 1 using normal saline. The cells were disrupted by sonication in an ice bath. The expression of target genes was assessed by total cell protein analysis using sodium dodecyl sulfate–polyacrylamide gel electrophoresis[29] (SDS–PAGE) and Coomassie Blue staining.

Assay of Recombinant Enzymatic Activities. The preparation of crude enzyme is as follows: the *E. coli*-ZY strain liquid (1 mL) was harvested by centrifugation (10000*g* for 20 min), suspended by 1 mL of 0.1 M sodium phosphate buffer (pH 6.5), and disrupted by sonication (400 W; working time, 3 s; interval, 3 s; and cooling temperature, 4 °C). The crude enzyme supernatant was obtained by centrifugation (16000*g* for 40 s at 4 °C).

The L-arabinose isomerase activity of crude enzyme was measured by determining the amount of formed D-tagatose after a 20 min reaction with 1 mL of 100 mM D-galactose. The generated D-tagatose was determined by the cysteine–carbazol–sulfuric acid method, and the absorbance was measured at 560 nm.[30] D-Tagatose was also determined by HPLC. Lactose, D-galactose, D-glucose, and D-tagatose concentrations were determined by HPLC, using a Rezex RCM-Monosaccharide Ca^{2+} column at 80 °C with distilled water as the mobile phase at an elution rate of 0.3 mL/min. All components were analyzed with a refractive index detector RI-101. The generated D-tagatose concentration from the reaction was calibrated on the basis of the standard linear graph prepared using different D-tagatose concentrations. One unit of L-arabinose isomerase activity was defined as the amount of enzyme catalyzing the formation of 1 μmol of D-tagatose/min under optimal conditions.

The β-D-galactosidase activity of crude enzyme was measured by the *o*-nitrophenyl β-D galactopyranoside (ONPG) method. The hydrolytic activity of ONPG by β-D-galactosidase was determined by measuring the release of *o*-nitrophenol (ONP). The reaction was carried out with continuous agitation in an assay volume of 4.0 mL containing 0.5 mL of 0.1 M sodium phosphate buffer (pH 6.5), 0.5 mL of the suitably diluted crude enzyme, and 3 mL of 10 mM ONPG at 37 °C for 20 min. The reaction was stopped by adding 2.0 mL of 0.5 M sodium carbonate solution, and ONP formation was measured spectrophotometrically at 420 nm.[31] One unit of β-D-galactosidase activity was defined as the amount of enzyme catalyzing the formation of 1 μmol ONP/min under optimal conditions.

Effects of the Temperature, pH, and Metal Ions on Recombinant Enzyme Activities. To optimize the operating conditions, the effects of the temperature, pH, and metal ion were investigated. The effect of the temperature on enzyme activity was analyzed by assaying the *E. coli*-ZY cell samples over a range of 15–45 °C. The optimal pH of the recombinant enzyme was determined using the standard assay conditions with three buffer systems, namely, sodium acetate (pH 4.0–6.0), phosphate (pH 6.0–8.0), and Tris–HCl (pH 8.0–9.0). To determine the influence of metal ions on enzyme activities, 1 mL of *E. coli*-ZY liquid was used under standard conditions in the presence of several metal ions ($CoCl_2$, $MnCl_2$, $FeCl_2$, $MgCl_2$, $NiCl_2$, $CaCl_2$, $ZnCl_2$, and $CuCl_2$) at a final concentration of 1 or 10 mM. The measured activities were compared to enzyme activity without additional ions under the same conditions.

Effects of Cell Dosage and Substrate Concentration. The effects of cell dosage and substrate concentration were investigated to obtain the optimal conversion conditions. Preparative-scale production of D-tagatose was performed in a 1 mL reaction system containing a final concentration of 100 mM lactose, 10 mM Mn^{2+}, 1 mM Fe^{2+}, and 10 mM phosphate buffer (pH 6.5). The *E. coli*-ZY wet cells were centrifuged from 0.5, 1, 3, 5, 7, and 9 mL of fermentation broth, which was converted into wet cell weight (WCW) using the relation of 100 mL of fermentation broth = 2.4 g of WCW. To determine the influence of the substrate concentration on the conversion rate, a final concentration of 5, 10, 30, 50, 70, and 90 g/L lactose was combined with the cells centrifuged from 3 mL of fermentation broth in a 1 mL reaction system. Other investigations were performed as previously mentioned.

Biotransformation Amplification of Lactose to D-Tagatose with Borate Addition and Yeast Cell Processing. The 100 mL biotransformation system contained a final concentration of 50 g/L lactose, 10 mM $MnCl_2$, 1 mM $FeCl_2$, 100 mM phosphate buffer (pH 6.5), 235 mM borate, and the *E. coli*-ZY cells centrifuged from 300 mL of fermentation broth (6.2 g of wet cells). The reaction conditions were 34 °C and 200 rpm for 36 h. Samples (0.5 mL) were obtained at 4 h intervals for HPLC analysis. *S. cerevisiae* NX-3 was cultured at yeast extract−peptone−dextrose (YPD) medium and conditions of 30 °C and 200 rpm. The *S. cerevisiae* NX-3 cells were harvested during log phase by centrifugation at 10 000 rpm for 10 min and washed twice with sterile water. For every 100 mL of reaction syrup, 2 g of yeast cells was added. Fermentation conditions have been determined through a series of experiments; finally, fermentation was carried out in an incubator at 37 °C with shaking at 100 rpm. Samples (0.5 mL) were withdrawn at proper time intervals and analyzed.

D-Tagatose Separation, Crystallization, and Characterization. After *S. cerevisiae* NX-3 fermentation, the cells were disposed by centrifugation. Borate was separated from syrup according to DTF-01 Ca^{2+} cation-exchange chromatography, and the optimal Ca^{2+} cation-exchange chromatography conditions were investigated. D-Tagatose solution was concentrated to 20 g/L at 55 °C using rotary vacuum evaporation. Anhydrous ethanol (40 mL) was added to D-tagatose solution upon reaching room temperature; the solution became muddy and then was heated above 60 °C for dissolution. A total of 10% of total D-tagatose was added as crystal seed, while the solution was cool. The solution was refrigerated at 4 °C for 4−8 h, and 20 mL of anhydrous ethanol was added with stirring. Bulk crystallization was observed after 40 h; the crystals were harvested by centrifugation (5000 r/min for 15 min). Then, 20 mL of anhydrous ethanol was added to the resulting crystals with continuous stirring. D-Tagatose crystals were dried in a suction flask and vacuumed at 25 °C. Infrared spectroscopy and proton nuclear magnetic resonance (^{1}H NMR) were used to characterize D-tagatose production.

RESULTS

Gene Cloning and Construction of Recombinant Coexpression Plasmid pETDuet-*araA′*-*lacZ*. The successful amplification of the *araA′* gene of ECAI-Q299K and the *lacZ* gene by PCR resulted in 1.5 kbp DNA fragments (Figure 1A) and 3.07 kbp DNA fragments (Figure 1B), respectively. The *araA′* and *lacZ* genes were successively ligased with pETDuet-01 to construct the recombinant coexpression plasmid pETDuet-*araA′*-*lacZ* (Figure 2A). With the coexpression plasmid as a template, Figure 2B shows that *araA′* and *lacZ* were successfully amplified by PCR and single restriction enzyme digestion (*Hind* III). DNA sequencing results also demonstrate that a correct coexpression plasmid pETDuet-*araA′*-*lacZ* was obtained.

Coexpression of Two Enzymes and Preliminary Survey of Activities. The recombinant coexpression plasmid pETDuet-*araA′*-*lacZ* was transformed into *E. coli* BL21 (DE3). The obtained positive clones were used for the coexpression of the two enzymes. When the culture conditions were optimized,

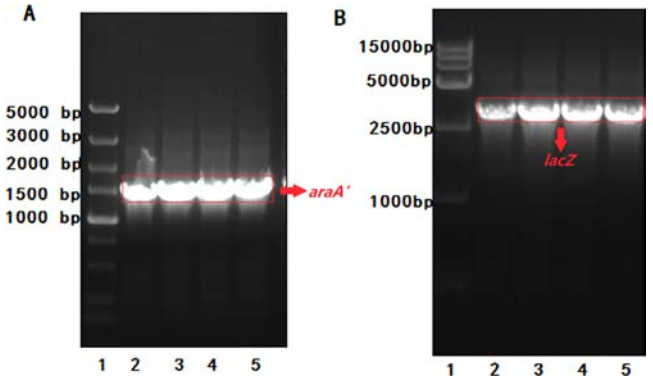

Figure 1. (A) Cloning of the *araA′* gene from the recombinant *E. coli* of L-arabinose isomerase Q299K by PCR. Lane 1, DL5000 marker; lanes 2−5, *araA′* gene. (B) Cloning of the *lacZ* gene from *E. coli* W3110 by PCR. Lane 1, DL15000 marker; lanes 2−5, *lacZ* gene.

the following conditions were obtained: 10 g/L lactose, 10 g/L NaCl, and 10 g/L yeast extract at 25 °C after 22 h. The results of SDS−PAGE analysis of recombinant protein coexpression were showed in Figure 3. It proved that the recombinant *E. coli* BL21 (DE3) strain was constructed successfully, which simultaneously expressed the *β*-D-galactosidase and ECAI-Q299K in soluble form after induction with lactose. The stripe characteristics were observed at approximately 112 and 56.2 kDa, in accordance with the previous reports for the two enzymes. This recombinant *E. coli* BL21 (DE3) strain was named *E. coli*-ZY. The enzymatic activity of ECAI-Q299K for D-galactose isomerization was 7.8 units within 1 mL of *E. coli*-ZY fermentation broth, whereas that of *β*-D-galactosidase for lactose hydrolysis was 56.3 units.

Optimal Conditions of D-Tagatose Production by the Recombinant Coexpression Cell. At an optimal pH of 6.5, the highest conversion rate for lactose to D-tagatose by the recombinant coexpression cell was 20.1%. At pH 5.0, 6.0, 7.0, and 8.0, they exhibited 27, 66, 83, and 43% of highest conversion rate, respectively (Figure 4A). The optimal temperature for D-tagatose production was 34 °C, as shown in Figure 4B. Recombinant enzyme activity was measured in the presence of 1 or 10 mM metal ions (Table 2). The enzyme activity was not stimulated by Mg^{2+} or Ni^{2+}, but Co^{2+}, Ca^{2+}, and Cu^{2+} significantly inhibited recombinant coexpression enzyme activity. However, Zn^{2+}, Fe^{2+}, and Mn^{2+} enhanced enzyme activity. Mn^{2+} (10 mM) and Fe^{2+} (1 mM) increased enzyme activity by 56.6 and 32.1%, respectively; both appeared to be required for the catalytic activity of the recombinant coexpression cell. The maximum production rate was obtained at pH 6.5 and 34 °C in the presence of 10 mM Mn^{2+} and 1 mM Fe^{2+}.

The added amount of recombinant cells was a factor in the efficient production of tagatose. Cell dosage and lactose concentration effects were investigated, and the results are shown in panels A and B of Figure 5. The optimal dosage of cells was determined to be the amount centrifuged from 3 mL fermentation broth, and the optimal lactose concentration was 50 g/L. On that condition, we obtained the highest production rate of 38.1 g L^{-1} h^{-1} and the nearly highest conversion rate of 25.4%.

Production and Purification of D-Tagatose. The time course study revealed that the conversion reached its equilibrium within 24 h (Figure 6A), the substrate lactose almost completely hydrolyzed, and the conversion rate of D-

of prepared *S. cerevisiae* NX-3 cells. Figure 6B shows that during *S. cerevisiae* NX-3 fermentation, the consumption of D-galactose and D-glucose was nearly completed at 4 h and exhausted at about 12 h, whereas no changes were observed in D-tagatose. These results indicate that D-galactose and D-glucose in the mixture were selectively used by *S. cerevisiae* NX-3. The cell pellet was disposed by centrifugation, and borate was separated from syrup by DTF-01 Ca^{2+} cation-exchange chromatography. The optimal DTF-01 Ca^{2+} cation-exchange chromatography conditions were as follows: column temperature, 70 °C; input volume, 20 mL; and flow velocity, 1.0 mL/min. The recovery of D-tagatose was 83%, and its purity reached 98%.

dx.doi.org/10.1021/jf4042485 | J. Agric. Food Chem. 2014, 62, 2412−2417

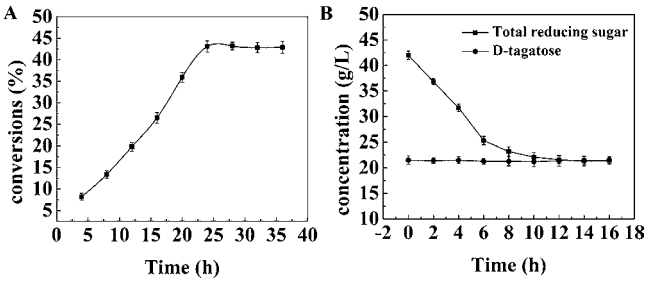

Figure 6. (A) Effect of the reaction time. (B) Time of D-tagatose syrup fermentation by yeast cells.

In short, the maximum conversion of 43% was achieved at pH 6.5 and 34 °C in the presence of 10 mM Mn^{2+}, 1 mM Fe^{2+}, and 235 mM borate. These conditions are suitable for industrial application because it would reduce byproduct formation and save energy.

D-Tagatose Crystallization and Characterization. The crystallization rate reached 58%. The crystals were confirmed to be D-tagatose by infrared spectroscopy (see Figure S1 of the Supporting Information) and ^{1}H NMR (see Figure S2 of the Supporting Information).

DISCUSSION

The aim of this work was to investigate the possibility of producing D-tagatose from lactose with the recombinant *E. coli* cells harboring β-D-galactosidase and ECAI-Q299K. As described previously, the recombinant *E. coli* BL21 (DE3) strain was successfully constructed andD-tagatose is produced in high levels by the recombinant *E. coli* with lactose as the substrate. Most previous studies reported that L-AIs are active at neutral or alkaline conditions. However, lactose is commonly hydrolyzed by β-D-galactosidase under an acidic pH. Thus, we previously modified ECAI through directed evolution to shift its optimal pH to 6.5, the same as that of β-D-galactosidase.

The D-tagatose yield of 74% was obtained in the presence of borate at 60 °C and pH 9.0 with a purified L-AI mutant from *Geobacillus thermodenitrificans* as the catalyst; this yield was 24% higher than without borate.[20] In the current work, the *E. coli*-ZY cells containing β-D-galactosidase and ECAI-Q299K were used for D-tagatose production in borate buffer. The conversion of 43% was achieved at 34 °C in the presence of approximately 235 mM borate (pH 6.5).

D-Glucose and D-galactose can be consumed by *S. cerevisiae*.[32] The paper also presents the purification and crystallization of D-tagatose. *S. cerevisiae* NX-3 was prepared by screening according to the use of D-glucose and D-galactose. Crystallization of D-tagatose was reported for the first time.

This study is the first report for developing the efficient single-step production of D-tagatose from lactose by the recombinant cells. The single-step method reduces both the time and cost in D-tagatose preparation, in comparison to the processes involving the hydrolysis of lactose and separation of D-galactose from a mixture of D-glucose and D-galactose prior to isomerization. The single-step production of D-tagatose from lactose and full-blown crystallization methods demonstrate potential for commercial applications.

The conversion rate from D-galactose to D-tagatose by the recombinant cells is lower than that by some thermophiles, such as *Thermotoga neapolitana*, *Thermotoga maritima*, *Anoxybacillus flavithermus* TC-06, etc. (Table 3). To overcome these difficulties, the following solutions were considered: (1) coexpression of β-D-galactosidase from *E. coli* and other original L-AIs and (2) modulation of the expression volume of the coexpression system to allow for the key enzyme ECAI to obtain higher activity.

The objective of this study was to characterize fibrillar aggregates made using pea proteins and to assemble formed fibrils into protein-based gels to study the rheological behavior of these gels. The results described in this paper include the characterization of fibrils made using pea proteins with the use of thioflavin T (Th T) assay, circular dichroism (CD), and transmission electron microscopy (TEM), and the rheological evaluation of protein-based fibrillar gels. To the best of our knowledge, this is the first report addressing the assembly of pea proteins into fibrils at low pH, the subsequent assembly of fibrils in spatial networks, and the mechanical characterization of formed gels.

MATERIALS AND METHODS

Materials. Predried dehulled commercial green pea seeds with a protein content of 22 g/100 g (dry weight basis) were purchased from a local supermarket. Whey protein isolate (WPI) Bipro was obtained from Davisco Food International, Inc. (Le Sueur, MN, USA). Soy protein isolate was extracted from defatted soy protein flour provided by Cargill BV (Amsterdam, The Netherlands). Soy protein extraction was carried out according to a previously described protocol[21] with slight modifications, in which acid precipitation was carried out at pH 4.5, instead of pH 4.8, and the final soy protein isolate was not freeze-dried. GDL, *o*-phthaldialdehyde (OPA), *N*,*N*-dimethyl-2-mercaptoethyl-ammoniumchloride (DMA), disodiumtetraborate decahydrate (Borax), sodium dodecyl sulfate (SDS), urea, dithiothreitol (DTT), trifluoroacetic acid (TFA), acetonitrile, and uranyl acetate were purchased from Sigma-Aldrich (Steinheim, Germany). Th T was obtained from Acros Organics (Geel, Belgium). All reagents were of analytical grade and used without further purification.

Pea Protein Extraction and Characterization. Pea protein isolate was extracted from commercial green peas by isoelectric precipitation. Extraction of pea protein was based on a previously described procedure,[6] with modifications. Pea protein flour was milled from dried peas in a Waring commercial blender (New Hartford, CT, USA). Milling was performed in the presence of liquid nitrogen to prevent excessive heating that may lead to heat denaturation of the proteins. Milled pea flour was dispersed in Milli-Q water in the ratio of 1:10 (g/mL) to make a protein slurry. The pH of the slurry was adjusted to pH 8.0 with 1 M NaOH and incubated at room temperature (20 ± 2 °C) for 1 h. The slurry was then centrifuged at 10000*g* (20 °C, 25 min) to remove insoluble materials. The supernatant was collected and the pH readjusted to pH 4.8 using 1 M HCl. The supernatant was then incubated at 20 °C for 2 h under continuous stirring and subsequently centrifuged at 10000*g* (20 °C, 25 min). Following this, the supernatant containing albumins and sugars was discarded. The pellet was collected and redispersed in Milli-Q water in the ratio of 1:10 (g/mL). The redispersed suspension at a pH of 4.8 was centrifuged at 10000*g* (20 °C, 25 min) and the pellet resuspended in Milli-Q water in the ratio of 1:3 (g/mL) to remove remaining sugars and albumins. The pH of the resuspended pellet was set to pH 8.0 using 2 M NaOH, and the solution was incubated at room temperature (20 ± 2 °C) for 1 h, followed by centrifugation at 10000*g* (20 °C, 25 min) to remove remaining traces of insoluble materials. The supernatant was collected and the pH measured and adjusted to a final pH of 8.0 using 2 M NaOH if necessary. The pea protein was then stored at 4 °C in the presence of 0.02% sodium azide to prevent microbial growth. The pea protein solution extracted in this way will be referred to as "native" pea protein. The protein content of native pea protein was determined using Dumas (NA 2100 Protein, CE Instruments, Milan, Italy) using a factor of 5.52[27] and was found to be about 87 ± 0.1 mg/mL. The dry matter content of native pea protein was 94 mg/mL, and the purity of pea protein extract was 92 ± 1%. Pea proteins showed a typical denaturation temperature around 77 °C as demonstrated by calorimetric measurements at a heating rate of 2 °C/min for 87 mg/mL pea protein solution (results not shown).

The protein composition of native, unheated, and heated pea protein at an approximate concentration of 10 mg/mL was analyzed using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions. A MOPS-SDS (20×) buffer was used as a running buffer. Electrophoresis conditions were 200 V and 10 mA throughout at 25 °C and 50 min running time. Following separation, the proteins were fixed and stained using the Simply Blue Safe stain and developed to obtain a suitable background color. The apparent molecular weights of the present proteins were determined by comparison to the molecular weight standard (Sigma wide range molecular weight markers, 6−200 kDa) applied into a separate lane. The gels were scanned, and the acquired images were analyzed by Image Master software. SDS-PAGE was also carried out on pea protein solutions heated for different periods at pH 2.0.

Pea Protein Solutions Preparation and Fibril Formation. Native pea protein solutions were diluted to 40 mg/mL in Milli-Q water adjusted to pH 2.0 using HCl. The obtained solutions were then centrifuged at 15000*g* for 30 min at 4 °C to remove any traces of insoluble material that could arise following pH readjustments. The supernatant was collected and filtered through a 1.2 μm (Millex-SV, Millipore Corp., Bedford, MA, USA) filter. The final pH of the sample was adjusted to pH 2.0 using 6 M HCl. Determined protein concentrations after centrifugation and filtration showed that negligible protein losses occurred during these processes.

Fibril preparation using pea protein was carried out according to a previously described protocol.[21] In summary, aliquots of 20 mL protein solutions prepared as described above were incubated at 85 °C for 20 h in a temperature-controlled water bath equipped with a stirring device and continuously stirred with a magnetic stirring bar at 300 rpm. After the heat treatment, samples were cooled in an ice bath and stored at 4 °C until further use, typically within 2 weeks.

Fibrils made using 40 mg/mL soy protein were prepared in a similar way as previously described[21] except for soy protein being heated in a water bath equipped with a stirring device and continuously stirred with a magnetic stirring bar at 300 rpm, instead of being heated using a shearing device, whereas fibrils made using whey protein were prepared according to a previously described protocol.[26]

Characterization of Fibrils Made Using Pea Protein. Determination of the number of primary amines present following the hydrolysis of pea proteins into peptides was carried out using the chromogenic OPA assay as previously outlined.[28] Reversed phase high-performance liquid chromatography (RP-HPLC) (Shimadzu, Kyoto, Japan) was used according to a method adapted from a previously described procedure[29] to determine how much of the protein was hydrolyzed into peptides. All samples were analyzed in aqueous solutions containing 4 M urea and 0.3% DTT. RP-HPLC was carried out using 2 M 6000A pumps in combination with a high-sensitivity accessory block (Waters), an ISS-100 injector (Perkin-Elmer, Uberlingen, Germany), a Waters model 680 gradient controller, and a Kratros 783 detector (Kratos Analytical, Ramsey, NJ, USA). A 250 × 4.6 mm Aeris wide-pore C18 column (Phenomex, The Netherlands) was used with a KrudKatcher Ultra HPLC column in-line filter (Phenomex) as a guard column. A 10 μL pea protein sample was injected onto a wide-pore C18 analytical column thermostated at 40 °C. Samples were eluted at a flow rate of 0.40 mL/min with a linear gradient of 0.10 v/v % trifluoroacetic acid (TFA) in 98 v/v % water and 2 v/v % acetonitrile to 0.10 v/v % TFA in 10 v/v % water and 90 v/v % acetonitrile. The equipment was linked to a data acquisition and processing system (Turbochrom, Perkin-Elmer). Data analysis was done with Chromeleon software version 7.1 (ThermoFisher Scientific).

Determination of the degree of conversion of peptides into fibrils was carried out on heated samples according to the previously described procedure.[21] In summary, heated pea protein solutions at pH 2.0 were diluted to 2 mg/mL. The solutions were divided into six centrifugal tubes containing filters with a molecular weight cutoff (MWCO) of 100 kDa and centrifuged in four consecutive steps (3000*g*, 30 min, 15 °C) yielding four filtrates (F1−F4). The obtained volumes were in this way sufficient to determine the protein content of each centrifugation step as determined by Dumas (NA 2100 Protein, CE Instruments) with a protein factor of 5.52.[27] The degree of conversion of monomers to fibrils was determined using eq 1

$$C = P - (F_1 + F_2 + F_3 + F_4) \times 100\% / P \quad (1)$$

where C is the conversion factor (%), P is the initial protein content (g) in the solution, F_1 is the protein content (g) in filtrate 1, F_2 is the protein content (g) in filtrate 2, F_3 is the protein content (g) in filtrate 3, and F_4 is the protein content (g) in filtrate 4.

The Th T fluorescence assay was used to evaluate the formation of β-sheet structures based on a previously described principle.[30] After fibril preparation, a volume of 48 μL of heated pea protein samples was mixed with 4 mL of filtered (0.2 μm, Schleicher and Schuell) 60 μM Th T solution in a phosphate buffer (10 mM phosphate, 150 mM NaCl at pH 7.0) and incubated for 10 min at 25 °C. Fluorescence intensity was measured using a fluorescence spectrophotometer (Perkin-Elmer LS 50 B) at an excitation wavelength of 460 nm (slit width = 2.5 nm) and an emission wavelength from 465 to 550 nm (slit width = 2.5 nm). Controls included the fluorescence intensity of Th T solution without the addition of protein solution and unheated pea protein solutions.

Spectroscopic and Microscopic Analyses. Determination of the hydrodynamic diameters of the protein aggregates was carried out using dynamic light scattering (DLS) (Zetasizer Nano ZS, Malvern Instruments, Worcestershire, UK). Changes in aggregate size during the heating of 5 mg/mL pea protein solutions at 85 °C for 20 h were recorded as a function of time at pH 2.0. Reported values are the average hydrodynamic diameters of the largest intensity peak, as found in the distribution analysis using Malvern DTS 5.03 software. The particle size distribution from DLS was derived from a deconvolution of the measured intensity autocorrelation function of the samples using a non-negatively constrained least-squares (NNLS) fitting algorithm. Duplicate measurements were performed for this analysis.

Far-UV circular dichroism (CD) was used to investigate the secondary structure of native and fibrillar pea protein solutions. Far-UV CD spectra of ∼0.2 mg/mL native and fibrillar pea protein solutions were obtained and recorded at 25 °C in the spectral range from 190 to 260 nm with a Jasco J-715 spectropolarimeter (Jasco Corp., Japan), using a quartz cuvette with an optical path of 0.1 cm. The spectral resolution was 0.5 nm, and the scan speed was 100 nm/min, with a response time of 0.125 s at a bandwidth of 1 nm. Twenty scans were accumulated and averaged, and the spectra were corrected for that of a protein-free sample.

Near-UV CD was used to investigate the tertiary and/or quaternary structure of native and pea protein fibrillar solutions. Near-UV spectra of ∼2 mg/mL native and fibrillar pea protein solutions were obtained and recorded at 25 °C in the spectral range from 250 to 350 nm with a Jasco J-715 spectropolarimeter (Jasco Corp., Japan), using a quartz cuvette with an optical path of 1 cm. The spectral resolution was 0.5 nm, and the scan speed was 100 nm/min, with a response time of 0.125 s at a bandwidth of 1 nm. Twenty scans were accumulated and averaged, and the spectra were corrected for that of a protein-free sample.

Fibrillar solutions made using pea protein were prepared for TEM by negative staining according to a previously described protocol.[26] A 10 μL aliquot of 0.25 mg/mL fibrillar solutions made using pea protein was deposited onto a carbon support film on a copper grid (Aurion-Immuno Gold Reagents and Accessories, Wageningen, The Netherlands). The excess fibrillar solution was removed after 30 s using a filter paper (Whatman no. 1, 512-1002, VWR International Europe BVBA, Leuven, Belgium). A droplet of 2% uranyl acetate at pH 3.8 was added for 30 s to improve the contrast. Excess uranyl acetate was removed by use of a filter paper. Electron micrographs were obtained using a Jeol JEM1011 transmission electron microscope (Tokyo, Japan) operating at 80 kV.

Rheological Characterization of Protein-Based Fibrillar Gels. Gelation of fibrillar aggregates made using pea protein was carried out by acid-induced cold gelation using GDL. Before gelation was initiated, the pH of the fibrillar solutions made using pea protein at pH 2 was adjusted to pH 7. The concentrations of GDL added to the samples to induce gelation were determined using the empirical relationship (% GDL (w/w) = 0.0065 × $C_{protein}$ (g/L) + 0.045).[31] GDL was added to fibrillar solutions made using pea protein with a protein concentration ranging from 40 to 160 mg/mL to induce gelation at 25 °C. For gelation at a protein concentration as high as 160 mg/mL, pea protein fibrillar solutions prepared at 40 mg/mL were concentrated by ultrafiltration using Merck Millipore Amicon stirred cell fitted with 30 kDa MWCO membrane (Darmstadt, Germany). Several trials were carried out using calculated GDL concentrations, and a final GDL concentration range of 0.3−1% was chosen to get to a final pH of about pH 5 at the end of gelation time. The pH of all samples was determined as a function of time during 15 h of incubation at 25 °C. A stress-controlled rheometer (ARG2, TA Instruments, Leatherhead, UK) with a concentric cylinder geometry (C14: cup diameter = 15.4 mm; bob diameter = 14.04 mm) was used to determine storage modulus (G') and loss modulus (G'') as a function of time (frequency, 1 Hz; temperature, 25 °C; % strain, 0.05, 15 h). After 15 h of incubation, an oscillation amplitude sweep was performed (frequency, 1 Hz; temperature, 25 °C; % strain, 0.001−100). Duplicate measurements were carried out for each protein concentration within the linear region, which was between aa strain of 0.001 and 10%.

RESULTS AND DISCUSSION

Characterization of Fibrils Prepared Using Pea Protein. *Hydrolysis of Pea Protein into Peptides.* It has been reported that the fibril formation process in β-lactoglobulin is initiated following the hydrolysis of proteins at pH 2 into peptides, some of which assemble into fibrils.[32] Heat-induced hydrolysis of protein at pH 2 has been shown to play a significant role in fibril assembly of soy 7S/11S globulin.[22] To study whether this phenomenon plays a role in fibril assembly using pea protein, the degree of hydrolysis as quantified by the number of primary amine groups available following heating of pea protein was determined by chromogenic OPA assay. The chromogenic OPA assay results showed that about 30% of primary amines could be detected after heating 40 mg/mL pea protein at pH 2.0 and 85 °C for 20 h. Assuming an average lysine content of about 8% per protein, this would correspond to an ensemble-averaged degree of hydrolysis of about three fragments generated from every protein.

SDS-PAGE was carried out on pea protein solutions to study the molecular weight degradation (Figure 1). Figure 1A (lane B) shows that the isolated pea protein used in this study

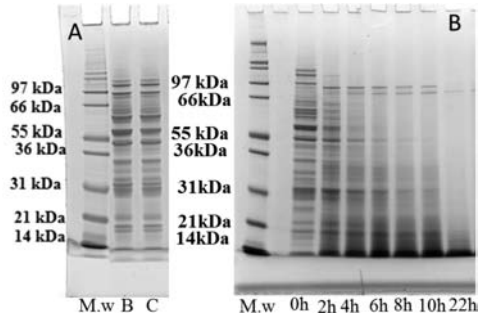

Figure 1. (A) Molecular weight degradation of pea proteins during fibril formation: SDS-PAGE electrophoretograms for standard marker (M.w), native pea protein at pH 8 (B), and pea protein at pH 2 prepared for fibril formation but not heated (C). (B) SDS-PAGE electrophoretograms for time-dependence heating of pea protein at pH 2.0 for up to 22 h. The band marked M.w is the standard marker; 0 h, 2 h, 4 h, 6 h, 8 h, 10 h, and 22 h represent heating of the samples for up to 22 h. The dominant bands at ∼70, 50, 33−14 kDa are vicilin/convicilin fraction subunits, whereas the less dominant bands at ∼40 and 20 kDa represent the legumin fraction subunits.

dx.doi.org/10.1021/jf4055215 | J. Agric. Food Chem. 2014, 62, 2418−2427

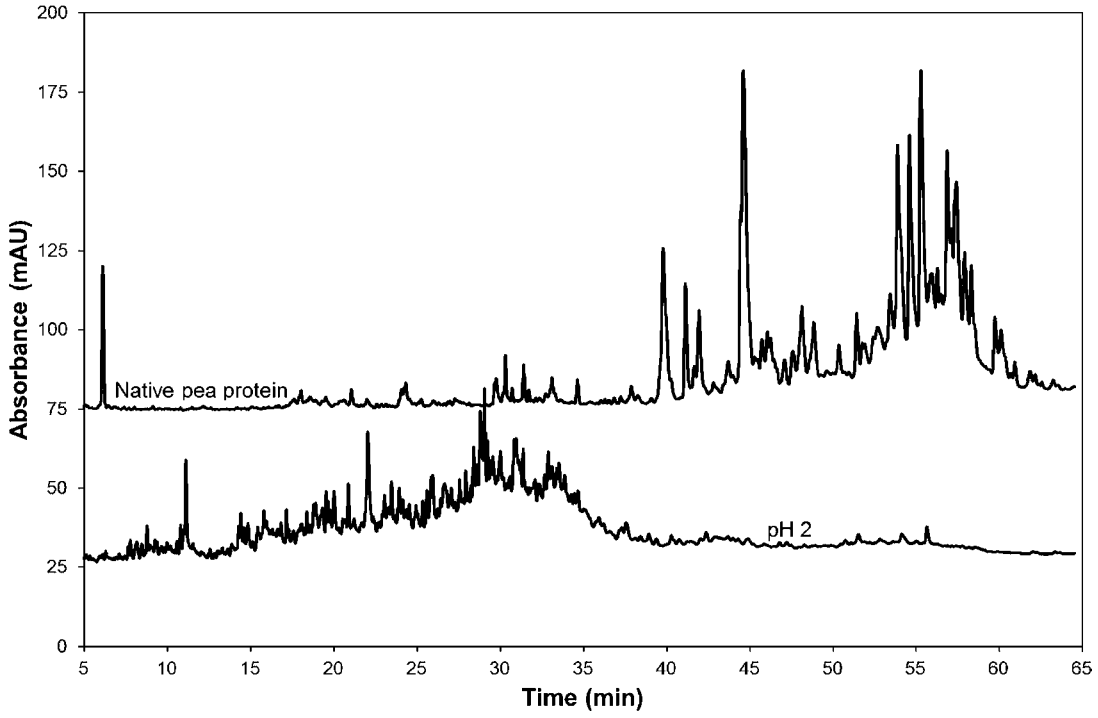

Figure 2. Hydrolysis of native pea proteins into peptides: reversed phase high-performance liquid chromatography (RP-HPLC) chromatograms for native pea protein and heated pea protein at pH 2.0.

contains both legumin (less dominant bands at ∼40 and ∼20 kDa) and vicilin/convicilin (dominant bands at ∼70, ∼50, and ∼33−14 kDa). Native pea protein at pH 8.0 (Figure 1A, lane B) showed similar bands as pea protein at pH 2.0 before heating (Figure 1A, lane C; and Figure 1B, lane 0 h). This shows that both vicillin/convicilin and legumin fractions were still present in the samples before heating. SDS-PAGE was also carried out on pH 2.0 samples as a function of heating time (h) as shown in Figure 1B. The results show that with heating of the samples for 2 h, bands of molecular weights above 97 kDa disappear. Heating the sample for longer than 10 h causes the bands above 21 kDa to disappear (Figure 1B), suggesting that progressive hydrolysis occurs during prolonged heating of pea protein at pH 2.0. There were persistent bands of between 66 and 97 kDa that remained dominant over all heating times at 85 °C (Figure 1B). The bands at around 70 kDa are convicilin polypeptides, whereas the bands around 97 kDa that seem to fade off at heating times exceeding 10 h could be traces of lipoxygenase.[4]

RP-HPLC analysis of the protein solutions following heating at pH 2.0 in comparison to native pea protein (Figure 2) showed that all proteins were degraded to different degrees from the native form. This confirms that hydrolysis of all proteins present occurs following the heating of pea proteins at pH 2.0 (Figure 2). The findings on the study of molecular weight degradation of pea protein suggest that (i) hydrolysis of pea protein into peptides which can assemble into fibrils is a process that requires prolonged heating of the samples at a pH away from the IEP, at low ionic strength, combined with heating temperatures above the denaturation temperature of the protein; (ii) gradual degradation of pea proteins occurs over incubation time (h); and (iii) hydrolysis of pea protein to peptides which assemble into fibrils follows the generic fibrillization mechanism similar to that of other globular proteins such as whey proteins,[23] soy proteins,[21] and lysozyme.[33]

Degree of Conversion of Peptides into Fibrils Made Using Pea Protein. To determine the degree of conversion of peptides into fibrils, a centrifugal filtration method was used as described before.[12] No protein was found by the Dumas method in the fourth washing step, which indicates that at this stage of the procedure, the obtained fibril solution was free from nonaggregated peptides. It was found that about 50% of the initial protein was present in the form of fibrils in pea proteins.

Th T Fluorescence Assay. Heated pea protein was checked for the presence of β-sheet aggregates as a typical characteristic for fibril assembly. Figure 3 and Table 1 show the results of Th T assay as a function of heating time (Figure 3) and pH (Table 1). The use of Th T to evaluate the formation of β-sheets in

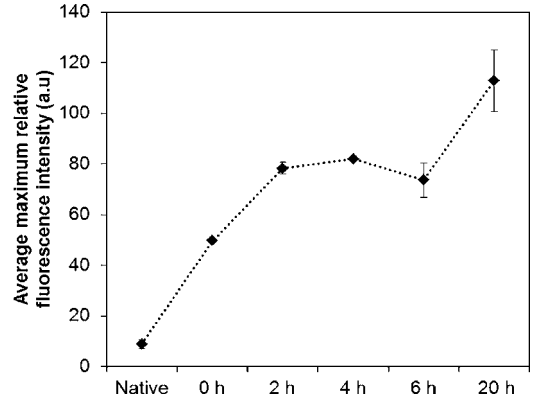

Figure 3. Formation of β-sheet aggregates as detected by Th T: average relative maximum fluorescence intensities as a function of heating time at a protein concentration of 40 mg/mL.

Table 1. Comparison of Maximum Relative Fluorescence Intensity for Native Pea Protein, Heated Pea Protein at pH 2.0 during the Study of Aggregate Assembly Kinetics, Heated Pea Protein at pH 2 Prepared Following Heating of 40 mg/mL of Pea Protein at 85 °C for 20 h, Heated Pea Protein at pH 7, Heated Soy Protein at pH 2, and Heated Whey Protein at pH 2.0

protein sample	pH	max rel fluorescence intensity (au) ± SD
native pea protein	8	9 ± 0.1
pea protein	2 (aggregate assembly kinetics)[a]	10 ± 0.5
pea protein	2[b]	113 ± 1
pea protein	7	62 ± 0.5
soy protein	2	121 ± 3
whey protein	2	349 ± 5

[a]Represents samples used in the study of fibril assembly kinetics that were followed over time using dynamic light scattering (aggregate size results are shown in Figure 4). [b]Represents heated pea solutions at (40 mg/mL, pH 2.0) after which the pH of the samples was adjusted to pH 7.0 for gelation to be induced using GDL.

proteins following the heating of protein solutions at low ionic strength and pH 2.0 for a prolonged time has been described in detail elsewhere.[30] Native pea protein had the lowest fluorescence intensity (Table 1). Following the incubation of pea protein solutions at pH 2.0, an increase in maximum fluorescence intensity was observed within the first 2 h of incubation (Figure 3). After 2 h of incubation, an initial gradual reduction in maximum fluorescence intensity was observed, suggesting that fibrils were formed during heating.[11] The gradual reduction in maximum fluorescence intensity after 2 h of heating coincided with the disappearance of bands of molecular weights above 66 kDa as observed in SDS-PAGE electrophoretograms (Figure 1B). A further slight decrease in maximum fluorescence intensity was observed at an incubation time of between 5 and 6 h followed by a steady increase in maximum fluorescence intensity. Such a reduction in fluorescence intensity has been attributed to the partial disruption of the highly ordered structure by further polypeptide hydrolysis.[11]

Progressive increase in fluorescence intensity was observed following heating of the samples for >6 h of incubation (Figure 3), whereas following heating of the sample for >10 h, bands of molecular weights above 21 kDa disappeared as observed in SDS-PAGE electrophoretograms (Figure 1B). An increase in the fluorescence intensity in heated samples at pH 2.0 for incubation periods above 6 h confirms the presence of β-sheets to which Th T reagent could bind. Following subsequent readjustment of the pH from 2.0 to 7.0, the fluorescence intensity of the pea protein sample was shown to decrease to almost half (Table 1). The decrease in fluorescence intensity could be as a result of partial disruption of the β-sheet fibrillar structure as previously reported for other types of fibrils.[34] The pH adjustment to pH 7.0 is essential to enable acid-induced gelation as described under rheological characterization of protein-based fibrillar gels. The findings show that thioflavin T can also bind to the β-sheets present in fibrils made using pea protein.

Changes in Structural Properties during Fibril Assembly. *Aggregate Assembly Kinetics.* Typical particle size distribution profiles of up to 12 h (by intensity) of heating of pea protein are presented in Figure 4. A concurrent increase in particle size was observed over time. This increase in particle

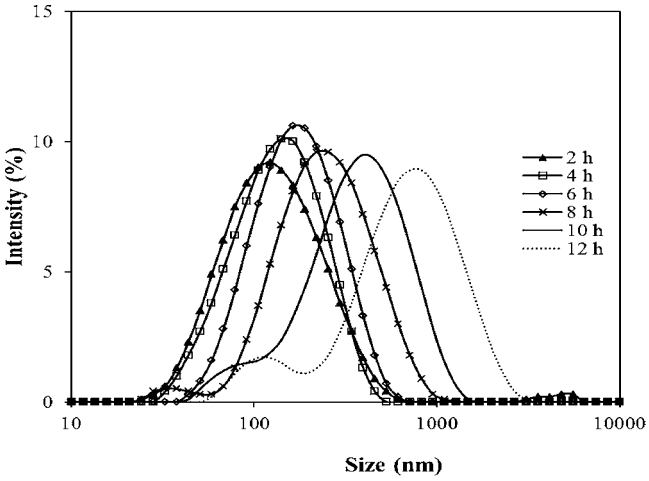

Figure 4. Hydrodynamic radius of aggregates is increased upon fibril formation: changes in aggregate size over time for 5 mg/mL pea protein heated at pH 2 and 85 °C monitored by the use of dynamic light scattering.

size is associated with thermal denaturation of the protein and subsequent aggregation. For heating periods below 6 h, predominant monomodal contributions were observed. When the heating period exceeded 6 h, the contributions became bimodal, and the distribution peaks shifted toward much higher aggregate sizes above 150 nm (Figure 4). The shift in the distribution peaks toward higher sizes coincided with a further increase in Th T binding after 6 h of incubation (see Figure 3). Bimodal contributions indicate that the fibril assembly (especially elongation of fibrils) occurred only after heating with enough incubation periods. The results show that the formation of pea protein β-sheet aggregates occurred following heating over incubation periods >6 h. The Th T assay performed on this sample following heating also showed the presence of some β-sheet aggregates (Table 1).

Secondary Structure. To probe the secondary conformational changes, far-UV CD spectra were recorded of native pea protein, heated pea protein at pH 2.0, and heated protein at pH 7.0 as shown in Figure 5A. The spectrum of native pea protein showed two minima around 222 and 208 nm and a zero crossing at 204 nm, indicative of a secondary structure that is highly predominated by α-helical and some β-sheet contributions.[35] Upon heating of pea protein at pH 2.0, a shift at the zero crossing to 197 nm was observed, illustrating a considerable loss of β-sheet strands. Substantial amounts (about 20%) of β-sheet were, however, still present in pea protein heated at pH 2.0 when the far-UV CD spectra were analyzed by the method previously described.[36] Following adjustment of the sample pH from pH 2.0 to 7.0, the CD spectrum showed a predominance of random coil elements. The predominance of random coil gives an indication of a further unfolding of the polypeptides upon adjustment of the pH of fibrillar solutions formed using pea protein at pH 2.0–7.0. Far-UV CD results were in agreement with the Th T assay as a reduction in Th T intensity occurred when the pH was adjusted from pH 2.0 to 7.0 (Table 1). Similarly, conformational changes to random coil from β-sheet structures occurred with pH adjustment (Figure 5A).

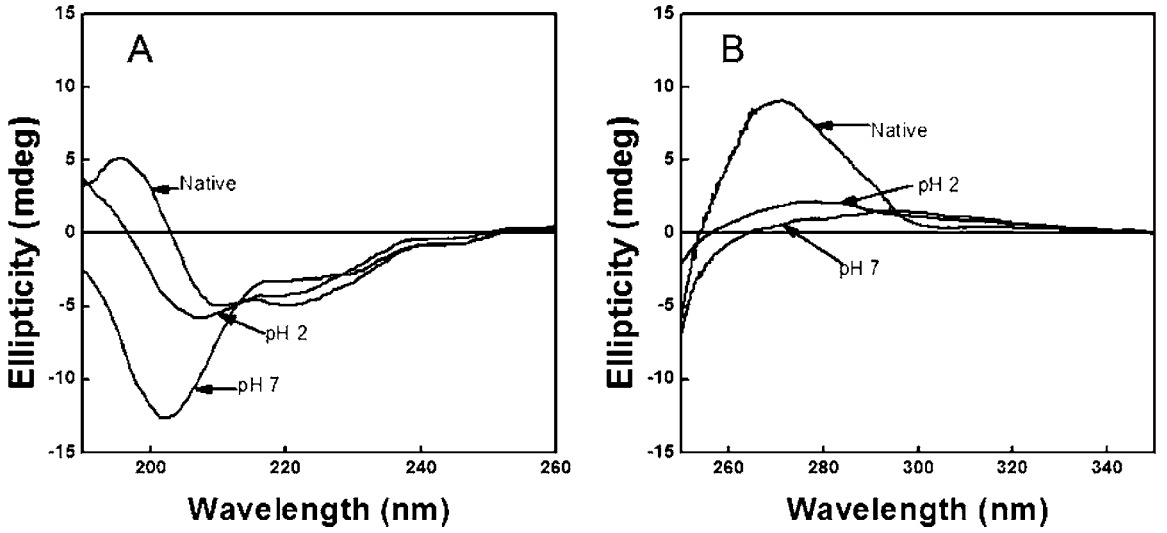

Figure 5. Changes on secondary, tertiary, and, to some extent, quaternary structural levels upon fibril formation: analysis of secondary structural elements by far UV-CD of native pea protein, heated pea protein at pH 2.0, and heated pea protein at pH 7.0 (A); near UV-CD spectra of these samples (B).

Tertiary and/or Quaternary Structure. To probe the tertiary and to some extent quaternary conformational changes, near UV-CD spectra were recorded of native pea protein, heated pea protein at pH 2.0, and heated pea protein readjusted to pH 7.0 (Figure 5B). The actual shape and magnitude of the near-UV CD spectrum of proteins depend on the number of aromatic amino acids restrained in their mobility, typically caused by spatial packing of the polypeptide.[37] Unheated native pea protein was shown to exhibit a prominent positive dichroic band at 270 nm, which is a typical contribution of tyrosine residues.[38] The magnitude of this contribution decreased substantially following heating, illustrating that the protein loses its tertiary packing constraints, resulting in the formation of a less well-defined structure. The decrease in the dichroic intensity may also reflect progressive exposure of tyrosine residue to the aqueous phase, as a result of heat-induced protein structural unfolding as well as polypeptide hydrolysis.[11] Readjustment of the pH from pH 2.0 to 7.0 did not result in major changes in tyrosine residues, implying that the protein tertiary structure remains unfolded. The results suggest that adjustment of the pH from pH 2.0 to 7.0 following heating of the protein at low pH destabilizes the secondary structure of the protein/peptides, whereas changes in tertiary structure could not be observed.

TEM. To analyze the formed pea protein fibrils on a microscopic scale, TEM pictures of the samples were taken (Figure 6). At pH 2.0 following the prolonged heating of pea protein, linear, but curly, fibrils having a worm-like appearance can be observed. The appearance of fibrils made using pea protein was comparable to that of the fibrils prepared using soy β-conglycinin at pH 2.0 and 80 °C,[11] but different from fibrils made using whey protein β-lactoglobulin.[23] Similarities between fibrils made using pea proteins and soy proteins, which are both predominantly oligomeric multidomain proteins, could be related to similarities in the thermal aggregation mechanisms of these proteins. Differences in the morphology of pea protein and whey protein fibrils could be attributed to inherent differences between plant storage and animal proteins as well as differences in the quaternary structure of the protein and its solubility, which may have a considerable influence on the aggregation behavior of the proteins.

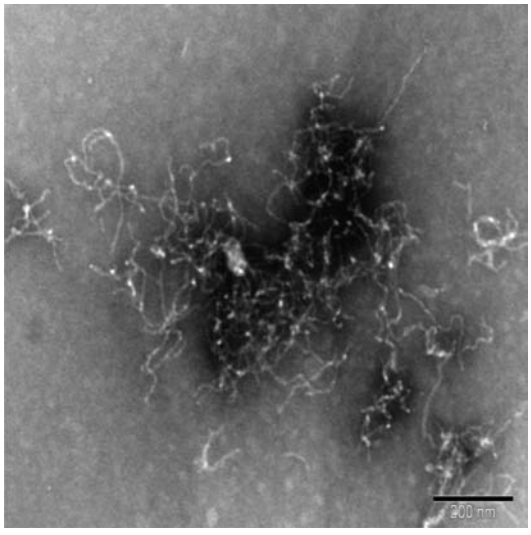

Figure 6. Morphology of pea protein fibrillar aggregates: transmission electron micrographs (TEM) of 0.25 mg/mL pea protein fibrils prepared at pH 2.0 following prolonged heating at 85 °C. Scale bars represent 200 nm.

Comparison between Fibrils Made Using Pea Proteins and Soy Proteins. Past research has shown that fibrils can be obtained using other plant storage proteins.[11,22] To compare fibrils made using pea proteins and soy proteins, characterization of fibrils prepared using soy proteins was carried out. Fibrils made using pea proteins showed a comparable ability to bind to Th T fluorescent dye as those made using soy protein (Table 1). Moreover, the characterization of fibrils assembled using pea proteins as a function of heating time also showed a similar increase in size compared to soy β-conglycinin.[11]

During the assembly of peptides from soy β-conglycinin to fibrils, an initial increase in maximum relative fluorescence intensity was observed as a function of time. A gradual decrease in the maximum fluorescence intensity following incubation periods of about 8 h was observed.[11] A similar observation was

dx.doi.org/10.1021/jf4055215 | J. Agric. Food Chem. 2014, 62, 2418−2427

recorded for fibrils made using pea protein, although the decrease in maximum fluorescence intensity occurred 2 h earlier in pea protein than in soy β-conglycinin. Fibrils formed from soy protein were found to have an approximate contour length of 1 μm, a persistence length of 2.3 μm, and a thickness of a few nanometers.[21] Fibrils made using soy protein were described as being more branched and curly than those made using whey protein,[21] which was also confirmed in our laboratory (results not shown). Comparisons of TEM micrographs of fibrils made using pea protein and soy protein showed that fibrils made using both pea proteins and soy proteins exhibited similar characteristics of being highly flexible, worm-like, and curly.

Progressive and remarkable changes in the secondary conformation as a result of fibril formation using pea proteins were observed in this study, similar to those reported for soy β-conglycinin and glycinin.[22] An increase in particle size during fibril assembly in pea proteins was also observed in this study, similar to that reported for soy proteins.[22] The results show that (i) pea proteins can be assembled into fibrils that have structural characteristics comparable to those of soy proteins and (ii) plant proteins show similar characteristics in fibril formation and, hence, pea proteins can effectively be used as a potential substitute for other plant proteins such as soy proteins.

Comparison between Fibrils Made Using Pea Proteins and Whey Proteins. The characterization of fibrils prepared using whey protein has been extensively carried out in the past[14,18,39] and also confirmed in our laboratory.[26] Considering the inherent differences in the structure and composition of pea proteins and whey proteins, it was expected that the characteristics of fibrils made using pea proteins would vary from those made using whey protein. β-Lactoglobulin (β-lg), the major fraction of WPI, has been reported to have a typical conversion factor of about 50%.[12] In this study, fibrils made using pea proteins also had a conversion factor of about 50%.

The use of Th T to compare the formation of β-sheet aggregates in pea proteins and whey proteins was also carried out. The results showed that Th T can bind to the β-sheets present in both pea proteins and whey proteins, although β-sheets in whey proteins exhibited a higher maximum relative fluorescence intensity compared to those of pea proteins (Table 1). This could give an indication of the presence of fewer β-sheet aggregates in pea proteins compared to whey proteins, with a similar incorporation in fibrillar aggregates.

Using TEM to analyze the microstructure, fibrils made using whey proteins were found to be longer and to have a thickness of a few nanometers and a length of 1 μm.[40] Fibrils prepared using whey proteins were also described as being semiflexible.[39] The characterization of fibrils made using pea protein, on the other hand, showed that the fibrils were highly flexible, more branched, and curly (Figure 6). However, depending on several conditions such as ionic strength, pH, protein concentration, and whether the protein solutions were stirred during heating or not, whey protein has been reported to be capable of forming curly fibrils that are as flexible[39] as fibrils made using pea proteins.

Rheological Characterization of Protein-based Fibrillar Gels. Fibrils have been shown to form gels at relatively low protein concentration.[41] To study the ability of fibrils made using pea protein to form gels at low protein concentrations compared to conventional cold- or heat-induced gelation of pea protein,[10] gel formation in fibril solutions made using pea protein was initiated using GDL, after fibrillar solution pH was adjusted to pH 7.0. During the adjustment of pH from 2.0 to 7.0, gelation of the fibrillar solutions did not occur, although the samples became increasingly turbid at pH 5. GDL was added to the samples at pH 7.0 to allow for slow acidification toward the isoelectric point of the sample (around pH 5). Changes in the storage modulus (G') and loss modulus (G'') were followed as a function of time after the addition of GDL (Figure 7A,B). Gelation was assumed to have occurred when the tan δ of the solution was <1 ($G' > G''$).[42]

In all gelation experiments G' values were higher than G'' at the beginning of all measurements (Figure 7A,B), whereas tan δ values were <1 at the end of all gelation experiments (Table 2). With increasing protein concentrations, G' values obtained after 15 h of gelation increased. Increasing the protein concentration to 160 mg/mL resulted in an increase in the G' with a high G' (350 Pa) being observed even at time 0 h, although self-supportive gels (gels that are firm and can retain their shape without support) could not be formed by the fibrils even at protein concentrations as high as 160 mg/mL. The inability of fibrils made using pea protein to form self-supportive gels even at relatively high protein concentrations may be related to the flexibility of the fibril rods as seen in Figure 6. The flexibility of the fibril rods could have an influence on the ability to form stronger gels at higher protein concentrations. Furthermore, an increase in protein concentration at a low ionic strength could result in a high electrostatic interaction making it difficult to form cross-links between fibrils, resulting in high percolation concentrations[43] that could influence the strength of the gels. Additionally, the analysis of steady-state birefringence by use of rheo-optic measurements as previously described[44] in fibrillar solutions made using pea protein did not show typical decay curves, and no birefringence domains were observed (results not shown). This suggests that short and/or flexible aggregates are formed using pea proteins which do not easily form strong gels.

The final pH of the samples upon the addition of GDL in this study was pH ∼5, which is close to the reported IEP of 4.8 for the legumin pea fraction but below the IEP of 5.5 for the vicillin fraction.[45] The resultant gels at pH 5 were turbid due to the final pH being close to the IEP, as opposed to the transparent gels that were prepared from pea protein isolated using ammonium sulfate at a more acidic pH using citric acid.[45]

For comparison, gels were also prepared from fibrils made using soy protein and whey protein as indicated by the dashed lines in Figure 7A (G') and Figure 7B (G''). Gels prepared from fibrils made using pea protein were comparable in strength to gels prepared from fibrils made using soy protein at the same protein concentration (Figure 7A). This may be attributed to similarities in flexibility of the rods. Pea protein-based fibrillar gels were, however, weaker than whey protein-based fibrillar gels as about 6 times more pea protein fibrils was needed to derive a G' comparable to that of whey protein-based fibrillar gels. The differences in gel strength between pea protein and whey protein may be attributed to the fact that fibrils made using whey protein may have the ability to form networks with higher efficiency compared to those made using pea protein, due to differences in the flexibility of the fibril rods.

To analyze the deformability of the gels prepared from fibrils made using pea protein, soy protein, and whey protein, an amplitude sweep was performed on protein-based fibrillar gels as a function of applied strain. Pea protein, soy protein, and whey protein-based fibrillar gels were all still within the linear

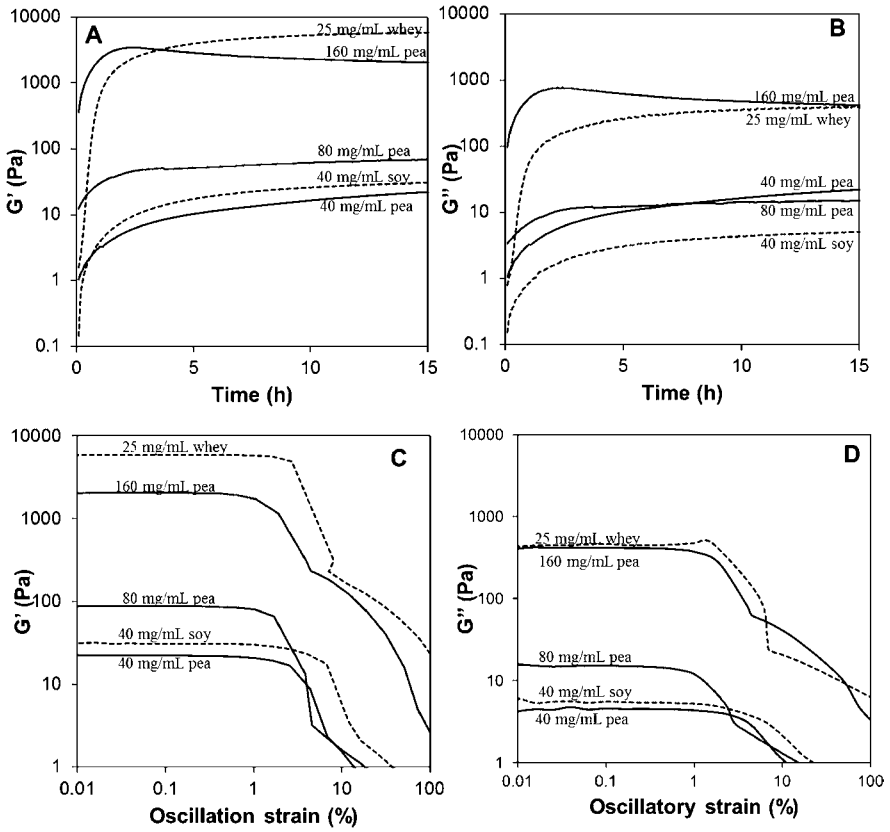

Figure 7. Changes in G' (Pa) (A) and G'' (Pa) (B) over time for 40, 80, and 160 mg/mL pea protein fibril solutions prepared at pH 2.0 and pH adjusted to pH 7.0 before initiation of gelation using GDL. The gelation was compared with 40 mg/mL of soy protein prepared at pH 2.0 and 85 °C for 20 h and 25 mg/mL of whey protein fibrils prepared at pH 2.0 and 80 °C for 20 h. Changes in oscillation strain (%) as a function of G' (Pa) (C) and G'' (Pa) (D) for 40, 80, and 160 mg/mL pea protein, 40 mg/mL soy protein, and 25 mg/mL whey protein-based fibrillar gels following slow acidification toward the isoelectric point using GDL.

region of percent strain between 0.001 and 10, at a frequency of 1 Hz, following deformation as a function of applied strain (Figure 7C,D). With an increase in oscillation strain above 10%, pea protein-based fibrillar gels prepared at a lower protein concentration (40 and 80 mg/mL) fractured earlier compared to pea protein-based fibrillar gels at a higher concentration (160 mg/mL), soy protein-based fibrillar gels (40 mg/mL), and whey protein-based fibrillar gels (25 mg/mL) (Figure 7C). The findings suggest that the fracture properties of pea protein-based fibrillar gels at a high concentration were comparable to those of soy protein and whey protein-based fibrillar gels, although pea protein- and soy protein-based fibrillar gels were generally weaker compared to whey protein-based fibrillar gels.

In conclusion, it can be stated that fibril assembly using pea protein was successfully carried out at pH 2.0. Fibrils made using pea protein were more flexible, branched, and curly compared to fibrils made using whey protein, but comparable to fibrils made using soy protein. Fibrils made using pea protein were assembled into gels that had a strength comparable to that of soy protein-based fibrillar gels but were weaker than whey protein-based fibrillar gels. The findings show that the fibril formation mechanism in plant storage proteins seems to be generic as pea protein fibrils were comparable to soy protein fibrils. Thus, pea protein can effectively be used as a possible replacement for other globular proteins such as soy protein as a structural food ingredient in protein-based fibrillar gels. These findings contribute to the existing knowledge on fibril assembly in globular protein, and the information on the rheological behavior of protein fibrils enhances the understanding of rheological behavior of pea protein-based fibrillar gels.

Table 2. Final G' and tan δ Values for Different Fibrillar Solutions Made Various Using Concentrations of Pea Protein, 40 mg/mL Soy Protein, and 25 mg/mL Whey Protein[a]

protein sample	final G' (Pa) ± SD	final tan δ ± SD
40 mg/mL pea	22 ± 2.3	0.18 ± 0.01
80 mg/mL pea	70 ± 5.01	0.22 ± 0.001
160 mg/mL pea	2058 ± 3.4	0.20 ± 0.02
40 mg/mL soy	31 ± 4.0	0.17 ± 0.01
25 mg/mL whey	5845 ± 22.0	0.07 ± 0.002

[a]The values were obtained after 15 h of gelation following addition of GDL to the fibrillar solutions at 25 °C.

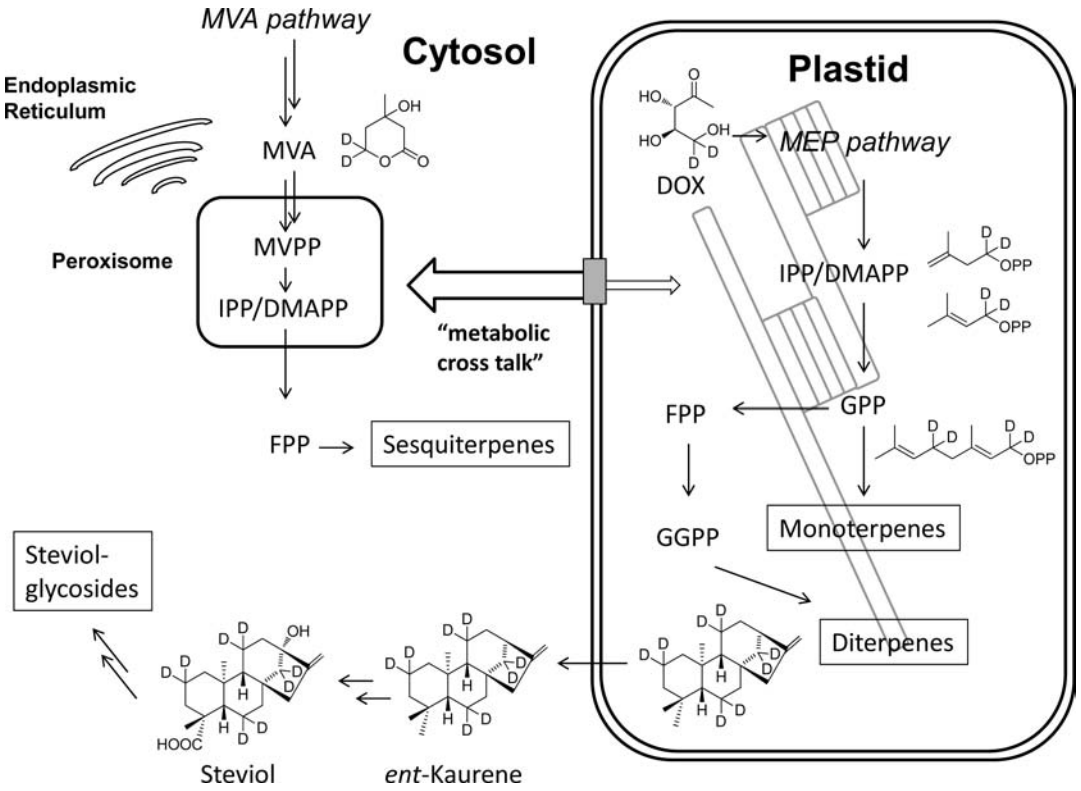

Figure 1. Proposed simplified scheme for the compartmentalization of terpene biosynthesis via MEP and MVA pathways in *Stevia rebaudiana*. Metabolic cross talk is mediated by a yet unidentified metabolite transporter, which is represented by a gray-shaded rectangle inserted into the plastid membrane. IPP, isopentenyl diphosphate; DMAPP, dimethylallyl diphosphate; FPP, farnesyl diphosphate; GGPP, geranylgeranyl diphosphate; MEP, methylerythritol phosphate; MVA, mevalonic acid; MVPP, 5-diphosphomevalonate.

rhamnose and xylose in, for example, dulcoside A and rebaudiosides C and F cannot be explained until now[10] due to lacking information about the participating enzymes.

This study aims to reinvestigate the biosynthesis of steviol glycosides by feeding experiments using the labeled precursors of the MEP and MVA pathways, namely, [5,5-$^2H_2$]-1-deoxy-D-xylulose (d_2-DOX) and [5,5-$^2H_2$]-mevalonic acid lactone (d_2-MVL), respectively. Two analytical methods were applied to detect the incorporation of the labeled intermediates: gas chromatography–mass spectrometry (GC-MS) and liquid chromatography–electrospray tandem mass spectrometry in negative ion mode (LC-(ESI)-MS/MS).[11] This experimental design is fundamentally different from the one that was chosen by Totté et al. in the aforementioned study. We chose to feed labeled precursors of the isoprenoid pathways and used the more sensitive mass spectrometry to detect the incorporation of labeled precursors. Moreover, we investigated in parallel the incorporation of the precursors into essential oil isoprenoids that were generated in glandular trichomes of *Stevia* leaves.

A comprehensive investigation of the chemical composition of leaf extracts of *S. rebaudiana* revealed that its essential oil contains numerous mono-, sesqui-, and diterpenes.[12] An appropriate technique for the analysis of such volatile organic compounds (VOC) is headspace solid phase microextraction (HS-SPME) in combination with GC-MS.[13] It has been recently employed for the study of the pathway utilization in the sesquiterpene biosynthesis of grape berries.[14] Hence, analyses of the leaf and stem volatiles of *S. rebaudiana*, including mono-, sesqui-, and diterpenes, were performed by HS-SPME-GC-MS as well to gain further insight into the pathway utilization in glandular trichomes.

MATERIALS AND METHODS

Reagents. HPLC grade acetonitrile was obtained from VWR International (Leuven, Belgium). Purified water was purchased from TKA Genopure-UV system. [5,5-$^2H_2$]-Mevalonic acid lactone (d_2-MVL) was prepared according to the method of Simpson et al.,[11] and [5,5-$^2H_2$]-1-deoxy-D-xylulose (d_2-DOX) was prepared according to the method of Meyer et al.[15] Spectral data of the labeled compounds were in all cases in good agreement with the data given in the references cited above. Stevioside, rebaudioside A, and isosteviol with purities of ≥99.0 and 98.0%, respectively, were obtained from Wako Chemicals (Neuss, Germany). Steviol with a purity of ≥98% (HPLC), α-terpineol (≥96%), β-caryophyllene (≥80%), and pyridine (anhydrous ≥99.8%) were purchased from Sigma-Aldrich (Taufkirchen, Germany). *N*-Methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) in 1 mL ampules was obtained from CS-Chromatographie Service (Langerwehe, Germany), diisopropyl ether, ACS (≥99%), and linalool were obtained from Roth (Karlsruhe, Germany), anhydrous sodium sulfate EMSURE ACS and sulfuric acid (90–91%) were obtained from Merck (Darmstadt, Germany), and sulfuric acid (1 mol/L) was obtained by diluting 90–91% sulfuric acid, respectively.

Safe-lock tubes, 2.0 mL, were purchased from Eppendorf (Hamburg, Germany).

Standard Solutions. To prepare stock solutions, the steviol glycosides were dried to constant weight at 103 °C, cooled, and stored in a desiccator until use.

For LC-MS, 10 mg of dried steviol glycosides was dissolved in water (10 mL). Solutions of stevioside and rebaudioside A were prepared by diluting the respective steviol glycoside with acetonitrile/water (8:2 v/v) to obtain final concentrations of 10 μg/mL and were used for tuning the mass spectrometer.

For isosteviol identification by GC-MS, stock solutions of isosteviol (0.1 mg/mL in anhydrous pyridine) were prepared.

Plant Material and Incubation. *S. rebaudiana* plants of the genotype Gawi were obtained from the Institute of Crop Science and

dx.doi.org/10.1021/jf500270s | J. Agric. Food Chem. 2014, 62, 2428–2435

Resource Conservation (INRES), Chair of Horticultural Sciences of the University of Bonn. Shoot tip cuttings of plants with four leaves were placed in vials containing 11 mL of autoclaved half-strength MS[16] nutrient medium (solution without solidifying agar) containing each 30 mg of d_2-MVL or 30 mg of d_2-DOX or only half-strength MS medium as control. Incubation was performed in a culture cabinet at 25 °C and 80% humidity under 16 h per day reduced light conditions of 150 $\mu E \cdot m^{-2} \cdot s^{-1}$ photosynthetic active radiation. After 5 days, leaves and stems were harvested. The leaves were grouped in "old" leaves (leaves that were almost fully expanded prior to incubation) and "new" leaves (leaves that were expanding during incubation). In 2012, orienting incubations were performed with d_2-DOX, and in 2013 with d_2-DOX and d_2-MVL, respectively. In addition to the leaves, stems were sampled and analyzed separately.

Leaves and stems were ground in a mortar in the presence of some milliliters of fluid nitrogen. After the evaporation of the nitrogen, the dried leaf/stem powder was stored immediately at −20 °C prior to analysis.

Sample Extraction. *Headspace−Solid-Phase Microextraction.* The analysis of the leaf and stem volatiles was performed with the plant material of 2013. Approximately 1 cm^2 of the freshly harvested leaves or stems was placed into 10 mL headspace vials without further preparation. The subsequent measurement of the leaf and stem volatiles was performed with a polyacrylate fiber, 85 μm (Supelco, Bellefonte, PA, USA). The equilibration time of the samples was 30 min at a temperature of 45 °C; afterward, the SPME fiber was exposed to the sample headspace for a further 10 min and was subsequently thermally desorbed in the injection port of the GC.

Aqueous Extraction of Diterpene Glycosides. Freeze-dried *Stevia* leaves (25 mg) were weighed in a 2 mL Safe-lock tube and extracted three times with portions of 0.5 mL of water in a heating block set at 102 °C for 30 min. Each extract was cooled to room temperature and centrifuged (15 min, 6866*g*). The aqueous phases were transferred to a weighed tube and filled to 1.5 mL (weight correction) after the last extraction step. Recovery was 93% for rebaudioside A calculated by measuring a known sample in duplicate according to earlier investigations.[17]

Hydrolyis of Steviol Glycosides. To convert the extracted steviol glycosides to isosteviol, 100 μL of the *Stevia* extract was mixed with 4 mL of sulfuric acid (1 mol/L) and heated for 60 min at 102 °C. After cooling, the solution was extracted three times with 2 mL of diisopropyl ether each time. The combined ether phases were dried with sodium sulfate and evaporated to dryness after filtration.

Silylation. Trimethylsilyl (TMS) ethers were prepared by adding 300 μL of anhydrous pyridine and 150 μL of MSTFA to the dried samples or to an aliquot of the isosteviol stock solution, for example, 25 μL. This mixture was heated for 15 min at 60 °C. After cooling, 1 μL was injected into the GC.

Sample Preparation for LC-ESI-MS/MS Detection. *Stevia* extract was diluted with acetonitrile/water mixture (8:2 v/v) to obtain a final concentration of 0.01 mg/mL. Ten microliters was injected into the LC.

GC-MS Analysis. *HS-SPME-GC-MS Analysis.* GC-MS analysis was performed on a Varian 450 GC coupled to a Varian 240 MS ion trap spectrometer (Varian, Darmstadt, Germany). The injection port was set to 220 °C. A splitless injection was used, and the split valve was opened after 3 min. Separation was achieved on a 30 m × 0.25 mm i.d. × 0.25 μm film thickness DB5 column (Varian, Darmstadt, Germany). The carrier gas (helium 5.0) was set to 1 mL/min as constant flow. The column temperature started at 35 °C for 3 min and was increased to 230 °C at a rate of 5 °C/min. The transfer line temperature was set to 260 °C and the ion source to 150 °C. The spectrometer operated in the electronic impact (EI) mode at 70 eV scanning the m/z 50−350 range at a rate of 0.64 s/scan. Acquisition was done using Varian MS Workstation 6.9.2. The analytes were identified by comparison of the retention times and mass spectra with standard substances or were identified by their mass spectra and Kovats retention indices using the Massfinder library available from Dr. Hochmuth (Hamburg, Germany).

GC-MS Analysis of Steviol Glycosides. The GC-MS system and basic settings were the same as mentioned above. The following settings were changed for steviol glycoside analysis: The injection port was set to 250 °C, and injections were made in the split mode with a ratio of 1:20. The column temperature program started at 180 °C and was kept at this temperature for 1 min. Then it was increased to 300 °C during 10 min at a rate of 8 °C/min. Mass spectra were recorded in a range of m/z 50−450 at a scan rate of 0.82 s/scan. Isosteviol was identified by comparison of its retention time and mass spectra with the standard substance.

HPLC-(-ESI)-MS/MS Analysis. Liquid chromatography analysis was performed on a binary LC-20AD system (Shimadzu, Duisburg, Germany) equipped with an SIL-20A autosampler, a Spark Mistral column thermostat and a four-channel degasser. The HPLC system was coupled to an API2000 triple-quadrupole detector (AB Sciex, Darmstadt, Germany) equipped with an ESI source used in the tandem MS mode with multiple reaction monitoring (MRM). Analyses and data processing were performed using Analyst 1.6.1 software. The instrument operated in the negative ion mode with the following source adjustments: ion spray voltage, −4200 V; curtain gas, 20 psi; gas 1 and 2, 50 psi; capillary temperature, 400 °C. The compound-dependent parameters were for both stevioside and rebaudioside A a declustering potential of −151 V, a cell entrance potential of −42 V, a collision energy of −30 V, a focusing potential of −340 V for stevioside and of −260 V for rebaudioside A, an entrance potential of −12 V for stevioside and of −7.5 V for rebaudioside A, and a cell exit potential of −22 V for stevioside and of −26 V for rebaudioside A.

The MRM method involved the precursor/product transitions m/z 803−811 to m/z 641−649 for stevioside/d_8-stevioside and m/z 965−973 to m/z 803−811 for rebaudioside A/d_8-rebaudioside A.

For HPLC separation, a YMC-Triart Diol-HILIC column (250 × 4.6 mm, particle size = 5 μm, YMC, Dinslaken, Germany) equipped with the corresponding guard column (4 × 3.0 mm) was used. The mobile phase consisted of acetonitrile/water mixtures. The column temperature was maintained at 40 °C, and the flow was set to 0.4 mL/min. The sample injection volume was 10 μL. The solvent gradient started with 20% water for 20 min, increased linearly to 40% water over 5 min, and then decreased back to 20% water. Column reequilibration was set at 5 min.

Incorporation Rates. In all cases, incorporation rates (%) were calculated by dividing the peak area of the completely labeled compound by the peak area of the genuine compound multiplied by 100.[14]

RESULTS AND DISCUSSION

***Stevia* Plants.** Cuttings of the *S. rebaudiana* genotype Gawi were tested together with other genotypes as plant material for the feeding experiments and proven to be the most robust with the best leaf production during the investigation period. The total sweetener content is about 10%, with stevioside being the most abundant (6−7%) and rebaudioside A with a content of about 3%.[18] The feeding and incubation procedure was carried out according to the method of Totté et al.[5] but without the chloramine T supplementation. Nevertheless, no microbial infestation was observed. For a better understanding of the distribution of labeled steviol glycosides, the leaves were harvested separately and divided into "old" and "new" leaves and stems (for a description, see Plant Material and Incubation).

Analysis of Glandular Trichome Volatiles. Prior to the determination of the steviol glycosides, the plant material was analyzed by HS-SPME-GC-MS without further preparation. This method allows the selective detection of volatiles that are stored in the subcuticular space of glandular trichomes and released into the headspace.[19,20] In the foliar, 10-celled lipophilic glandular trichomes of *S. rebaudiana*, the six secretory

[c]Tentatively identified by mass spectrum and retention index.

cells form three pairs of head cells. To form the secretory sheath, the cuticular membrane detaches from the outer walls of the apical secretory cells along a line that appears to be the pectin layer.[21] For a typical HS-SPME-GC/MS chromatogram, see the Supporting Information (Figure S1). The trichome volatiles are dominated by mono-, sesqui-, and diterpenes. The identified volatiles are in agreement with those identified in previous studies on *S. rebaudiana* volatiles and also known as common headspace volatiles of other plant species.[12,22−25] The analysis of the incubated cuttings provides a comprehensive insight into the pathway utilization of the different terpene glandular trichomes. After administration of the labeled precursors, genuine terpenoid volatiles were detectable in all samples. However, contents of volatiles in old leaves were 100 times lower than those in new leaves or stems (data not shown), which can be explained by a reduced biosynthetic activity in old leaves or a reduced density of trichomes per leaf area unit.[26] Nevertheless, deuterium incorporation was detected in terpenoid volatiles in all investigated tissues. Labeled and genuine terpenes can be chromatographically separated due to the inverse isotopic effect in gas chromatography.[27] Monoterpenes are formed by two units of IPP/DMAPP, sesquiterpenes by three units, and diterpenes by four units, respectively. Because $^2H_2$-MVL and $^2H_2$-DOX are metabolized to $^2H_2$-IPP and/or $^2H_2$-DMAPP, up to four deuterium atoms can be incorporated into monoterpenes, six into sesquiterpenes, and eight into diterpenes. Deuterium incorporation, molecular ions, and ion traces used for data evaluation are given in Table 1. Results obtained in the feeding experiments for both precursors in all plant tissues are given in Table 2. d_2-DOX was incorporated into volatile mono-, sesqui-, and diterpenes and d_2-MVL mainly into sesquiterpenes with similar incorporation rates for both precursors. However, incorporation of d_2-MVL into mono- and diterpenes was barely detectable or 10−100 times lower than that obtained for d_2-DOX.

Analysis of Steviol Glycosides. Two independent analytical methods were used for determining the incorporation of deuterium into steviol glycosides. For GC-MS analysis, the steviol glycosides were hydrolyzed, yielding the aglycon steviol, which was converted to isosteviol and detected after silylation as a sum parameter. In the second method, the diterpenes were separated by LC and detected as individual steviol glycosides with (ESI)-MS/MS.

GC-MS Analysis. The hydrolysis of steviol glycosides to steviol and its conversion to isosteviol were carried out with diluted sulfuric acid in the water extract of the labeled leaves according to the method of Nowotny.[28] As the genuine steviol content in the leaves never exceeds 0.003% (w/w), its determination was omitted.[29] The detection as TMS-ester via GC-MS was performed according to the method of Ohta[9] with some modifications. The proposed derivatization reagents hexamethyldisilazane and trimethylchlorosilane tended to block the injection needle of the autosampler and were therefore substituted by MSTFA. For a typical chromatogram of isosteviol as TMS-ester, see the Supporting Information (Figure S2). In the total ion chromatogram (TIC), labeled and unlabeled isosteviol can be clearly separated due to the inverse isotope effect[27] with retention times of 12.21 min for the

unlabeled and 12.13 min for the labeled component. The corresponding MS spectra revealed a characteristic fragmentation pattern (Figure 2) with m/z 390 (molecular ion), m/z 375 (loss of a methyl group at $COOSi(CH_3)_3$), m/z 300 (loss of $HO\text{-}Si(CH_3)_3$), and m/z 272 (subsequent loss of CO at C4) for the genuine component and mass shifts of up to seven atomic mass units for deuterium-labeled isosteviol. A retrobiosynthetic analysis predicts that a maximum of eight deuterium atoms will be incorporated into steviol because the building block of diterpenes, GGPP, is assembled by four IPP/DMAPP molecules attached to each other, each containing two deuterium atoms (Figure 1). Interestingly, we observed a maximum of seven labeled protons incorporated into isosteviol, whereas steviol glycosides, analyzed by LC-MS, exhibit eight deuterium atoms. By treatment with sulfuric acid all steviol glycosides are hydrolyzed to steviol, which undergoes rapidly a Wagner–Meerwein rearrangement to isosteviol, containing an *ent*-beyerene skeleton. After this reaction, the two labeled

dx.doi.org/10.1021/jf500270s | J. Agric. Food Chem. 2014, 62, 2428–2435

protons at C14 are at the *exo*/*endo*-position to the carbonyl group at C16 implying keto−enol tautomerism and the interchangeability of the deuterium ion preferentially at the *exo*-position (Figure 3).[30,31]

LC-(ESI)-MS/MS. The diluted water extract of the labeled leaf samples was injected into the HPLC system without further cleanup. The observed fragmentation pattern in ESI-MS/MS was the same as reported earlier.[32] As expected, a maximum of eight deuterium ions were incorporated into each steviol glycoside. No shift in retention times could be observed, and all labeled compounds had the same retention times as the unlabeled compound. For LC-MS data, see the Supporting Information (Figure S3). The incorporation rate was calculated for stevioside and rebaudioside A, respectively.

Incorporation Rates. For each terpene under study the maximum numbers of deuterium labels introduced from the respective precursors were considered. Incorporation rates were then calculated on the basis of the mass peak intensity representing the fully labeled compound in comparison to the intensity of the peak representing the unlabeled compound. However, labeled terpenes, which have not acquired the maximum number of deuterium labels, but a fraction therefrom (for example, by combination of a labeled IPP with an unlabeled DMAPP), were also detectable. These peaks were not dominant and were therefore not considered for the calculation of incorporation rates.

Tables 3 and 4 report the incorporation rates into isosteviol, stevioside, and rebaudioside A after d_2-DOX and d_2-MVL feeding using different analytical protocols.

Table 3. Incorporation Rates of Deuterium-Labeled Precursors into Isosteviol after Feeding with $^2H_2$-DOX and $^2H_2$-MVL, Respectively, Analyzed by GC-MS (n = 2)

sample	$^2H_2$-DOX incorporation rate (%)	$^2H_2$-MVL incorporation rate (%)

stems (2013)	4.6 ± 2.3	1.0 ± 0.6	0.2	0.1

The incorporation rates for labeled DOX were high in all leaf samples, but in 2012, they were lower in old than in new leaves. This is in agreement with recent results of Kumar et al.[33] They demonstrated that gene expression of enzymes involved in the steviol glycoside biosynthesis (including enzymes of the early steps in isoprenoid biosynthesis) is at maximum in leaves at the first node (apical position). Only gene expression of 1-deoxy-D-xylulose 5-phosphate reductoisomerase (DXR) and kaurene oxidase (KO) showed highest expression at the third node. In 2013, some young leaves showed necrosis and produced less biomass. This could explain the reduced incorporation rate when compared to those in 2012. Nevertheless, no incorporation could be detected after feeding with d_2-MVL.

Table 4 gives the incorporation rates of individual steviol glycosides after LC-MS analysis. The same pattern as detected by GC-MS analysis could be observed in 2012 and 2013. In contrast to GC-MS, deuterium incorporation could be detected also in stems and even some labeling after d_2-MVL feeding. Totté et al.[5] reported after feeding experiments with [1-^{13}C]-glucose that only the plastidial methylerythritol-4-phosphate (MEP) pathway and not the cytosolic acetate-mevalonic acid (MVA) pathway is involved in the early steps of steviol biosynthesis. Glucose enters the MEP pathway by being converted to pyruvate and glyceraldehyde-3-phosphate. In contrast to Totté et al.,[5] we used an indirect intermediate of the MEP pathway, namely, d_2-DOX, which should be directly incorporated and transformed to 2-*C*-methyl-D-erythritol 4-phosphate after phosphorylation[34,46] with little diversion to other pathways. Due to remarkably high incorporation rates of about 10−30% into steviol gylcosides in leaves during the feeding period, we could confirm the results of Totté et al.[5] We verified this finding by another feeding experiment using a direct intermediate of the MVA pathway, d_2-MVL, which is transformed to mevalonate phosphate and directly incorporated.[7] No significant incorporation of deuterium using this intermediate could be detected, which confirms that the MEP pathway is the dominant route for diterpene biosynthesis in leaves. It is noteworthy that feeding glucose and feeding the specific precursors DOX and MVL yield the same results. Both approaches are not free of criticism because exogenous substrates can change the physiological conditions in the plant.[35] However, the consistent results show that at least a large part of diterpene biosynthesis is fueled by the MEP pathway, whatever the exact percentage might be under physiological conditions. For our experiments we used two different analytical methods to detect labeled precursor incorporation. We hydrolyzed all steviol glycosides to steviol/isosteviol in the gas chromatographic method and determined the incorporation rate as a sum parameter. Hence, it was not possible to report the incorporation into each steviol glycoside. In addition, we performed LC-MS-MS, which enables us to evaluate the incorporation into stevioside and rebaudioside A separately. By this approach, it could be clearly shown that the incorporation rates were significantly different for stevioside and rebaudioside A, respectively, due to successive glycosylation. This is in agreement with the reported biosynthetic sequence where stevioside is the direct precursor of rebaudioside A.[8] Three different uridine diphosphate-dependent glycosyltransferases (UGTs) contribute to the glycosylation of steviol to build steviolmonoside, steviolbioside, stevioside, and finally rebaudioside A. As expected, the incorporation rates detected by GC-MS represented the mean of the rates of the single steviol glycosides detected by using the LC-MS protocol (except for old leaves in 2012, Tables 3 and 4).

The HS-SPME-GC-MS measurements confirm the results obtained for the steviol glycosides. d_2-DOX served as the main precursor for the generation of diterpenes. d_2-MVL was incorporated into diterpenes as well, but mainly into sesquiterpenes. The labeling data provide evidence that mono- and diterpenes are almost exclusively formed by plastidial IPP/DMAPP, whereas sesquiterpene biosynthesis uses both cytosolic and plastidial IPP/DMAPP. Hence, the results indicate an export of plastidial isoprenoid intermediates into the cytosol and corroborate recent studies about the mixed biosynthetic pathway of the sesquiterpene artemisinin.[36] This model of a unidirectional pathway utilization was demonstrated by Bick and Lange with isolated chloroplasts of spinach, kale, and Indian mustard[38] and has been proposed for the first time by Arigoni and Schwarz.[37] For sesquiterpene biosynthesis it was recently confirmed in grape berries and leaves,[14,39] carrot roots and leaves,[40] snapdragon flowers,[41] and lima bean leaves.[42,43]

The relatively high incorporation rates for mono-, sesqui-, and diterpenes in glandular trichomes of *Stevia* are surprising if compared to rates obtained in other studies in which exogenous DOX was used to label trichome-derived terpenes. Monoterpenes in glandular trichomes of mint showed labeling degrees below 1%,[44] and the diterpene salvinorin A in glandular trichomes of Maria Pastora sage showed similar low labeling degrees when treated with labeled DOX.[45] Low incorporation rates of DOX have been reported to be the result of poor phosphorylation rate of exogenous DOX, partial degradation of DOX into acetate, limited active transport of DOX into plastids, and limited membrane permeability of DOX (refs 36 and 45 and references cited therein). The comparatively high incorporation rates obtained for terpenes in glandular trichomes on *Stevia* leaves and stems might be explained by their ultrastructure: Plasmodesmata, in moderate number, occur more frequently in transverse walls of the secretory head cells, as well as in those between cells of the second subapical pair and stalk cells and between the latter and basal cells. Plasmodesmata connect mesophyll cells and basal cells.[21] Thus, exogenous DOX and MVL may be easily translocated from the cut stem via mesophyll cells to the secretory cells, where the biosynthesis of terpenes is located.

The results of the feeding experiments indicate that both the MEP and the MVA pathways contribute to the biosynthesis of sesquiterpenes, whereas mono- and diterpenes, in particular, steviol glycosides, are almost exclusively formed by the MEP pathway. However, a full understanding of the interplay between the two pathways requires knowledge of the mechanisms of exchange between their respective compartments. The nature of the transporters participating and the true extent of exchange occurring in plants under natural growing conditions are still open questions.[3]

Over the last 20 years, these concerns and the discovery of variability in the level of ODAP concentration have led to the setting up of germplasm and breeding programs which aim to select those genotypes with the lower ODAP levels.[10−12,24,25] In fact, the most common quantitative ranges for the two isomers are 0.07−7.52 and 0.05−0.79 g/dry kg for β and α isomers (Figure 1), respectively.[26−30]

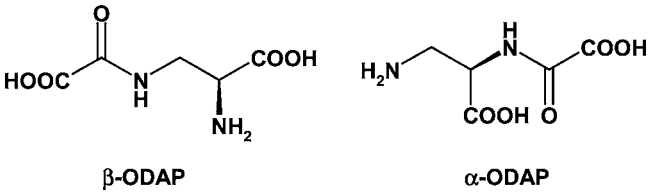

Figure 1. The two non-protein amino acids, α- and β-ODAP, of *L. sativus*.

With this in mind the present paper has the purpose of exploring agronomic, qualitative, and chemical traits of ten Sicilian accessions of grass pea in order to identify those varieties which merge high productive traits with low ODAP concentration.

MATERIALS AND METHODS

Field Trial and Plant Material. The trial was carried out in the experimental field of the University of Catania (Sicily, Southern Italy, 10 m a.s.l.) in 2006−2007 using 10 accessions of grass pea taken from farmers' collections (Table 1).

The seeds were sown on the 30th November into ploughed soil fertilized with 100 kg/ha of P_2O_5. The experiment was arranged in a complete randomized block design with plots of 4 × 3 m, replicated three times. A sowing rate of 60 plant/m^2 with rows 1.0 m far was adopted. Seeds were collected at the end of June 2007 and immediately processed for the analyses.

No irrigation was used, and weeds were managed mechanically. The soil was a clay-loam soil with pH 8.1 and medium nutrient status. During the trial rainfall and temperature were recorded. Average temperature ranged from 10 °C in January to 25 °C in June while the minimum never went below 5 °C and maximum reached 32 °C at the end of the crop cycle. Total rainfall was 495 mm, 50% of which fell in December. Temperature and rainfall data did not differ significantly from the thirty-year values.

In the field the following parameters were measured: plant height at flowering, pods per plant, seeds per pod, 1000 seed weight, seed yield, seed dimension (three-dimensional parameters: longitudinal, transversal, and thickness). Seed protein content was calculated as: (Kjeldahl nitrogen content × 6.25).

Qualitative Analyses and Isolation of α- and β-ODAP. 10 g of dried seeds was milled and extracted with water (50 mL) for 12 h at room temperature and under continuous stirring. The mixture was centrifuged (20 min, 4000 rpm) and the supernatant charged on a column filled with Dowex-50W-8% cross-linked, dry mesh 200−400 (20 mL) in acid (H^+) form. The elution was carried out using water, and the fractions were analyzed by thin layer chromatography (TLC, cellulose, acetone:butanol:water:formic acid 7:7:4:4), spraying with ninhydrin (isomer α reacts in pale rose, isomer β in pale blue). All positive fractions were pooled, and the solvent was removed at reduced pressure. The mixture was analyzed by HPLC-ELSD and NMR

HPLC Analyses. The previous mixture was analyzed by HPLC in the following conditions: HPLC model P580 (Thermo Fisher Scientific, Waltham, MA, USA), reverse phase column Luna C_{18} 250 mm × 4.6 mm i.d. × 5 μm (Phenomenex, Torrance, CA, USA), kept at 20 °C in a model TCC-100 thermostated oven (Thermo Fisher Scientific, Waltham, MA, USA). The elution was performed using a mixture of 0.13% formic acid in water; flow 0.5 mL/min; detector, model Alltech 3300 evaporative light scattering detector (ELSD) (Grace, Deerfield, IL, USA); drift tube temperature 52 °C, nebulizer gas nitrogen, gas flow 1.5 L/min. Retention times of α-ODAP and β-ODAP: 3.40 and 3.63 min, respectively.

^{1}H NMR Analyses. 5 mL of the previous mixture was evaporated to dryness and the residue dissolved in 2 mL of a 0.1 N solution of DCl in D_2O. The mixture was submitted to nuclear magnetic resonance (^{1}H NMR) in the following conditions: spectrometer model Avance 400 (Bruker Corp., Billerica, MA, USA) with 5 mm probe and Z gradient at 400.13 MHz (^{1}H), pulse power for 90°, −1.1 db; 90° pulse length, 8.0 μs; measurement temperature, 299 K; pulse angle, 90°; preacquisition delay, 6.5 μs; acquisition time, 7 min; relaxation delay, 50 s; scan number, 8; sweep width, 12 ppm; number of FID points, 32K; number of frequency points, 64K; line broadening, 0.3 Hz.

α-ODAP: ^{1}H NMR, CH_2, 3.47 H_α dd (13.4, 5.2 Hz), 3.28 H_β dd (13.4, 8.4 Hz); CH, 4.60 dd (8.4, 5.2 Hz).[31,32]

β-ODAP: ^{1}H NMR, CH_2, 3.76 H_α dd (14.8, 3.8 Hz), 3.67 H_β dd (14.8, 6.8 Hz); CH, 4.03 dd (6.8, 3.8 Hz).[31,32]

Isolation of β-ODAP. 10 mL of the previous mixture of α- and β-ODAP coming from the chromatographic separation was dried and the residue dissolved in distilled water and left at room temperature for 24 h. A white precipitate was separated by filtration and analyzed with the HPLC-ELSD and NMR procedures previously described. The resulting compound was pure β-ODAP, which was used to build the calibration curves for the quantitative analyses of the two amino acids in the HPLC analyses, and for the calibration methods in the NMR analyses.

Quantitative Analyses. *Sample Treatments.* 1 g of plant material (seeds of grass pea) of the ten samples in this study was extracted according to the procedure previously described. A 260 mL fraction coming from the Dowex column, containing the two neurotoxins, was

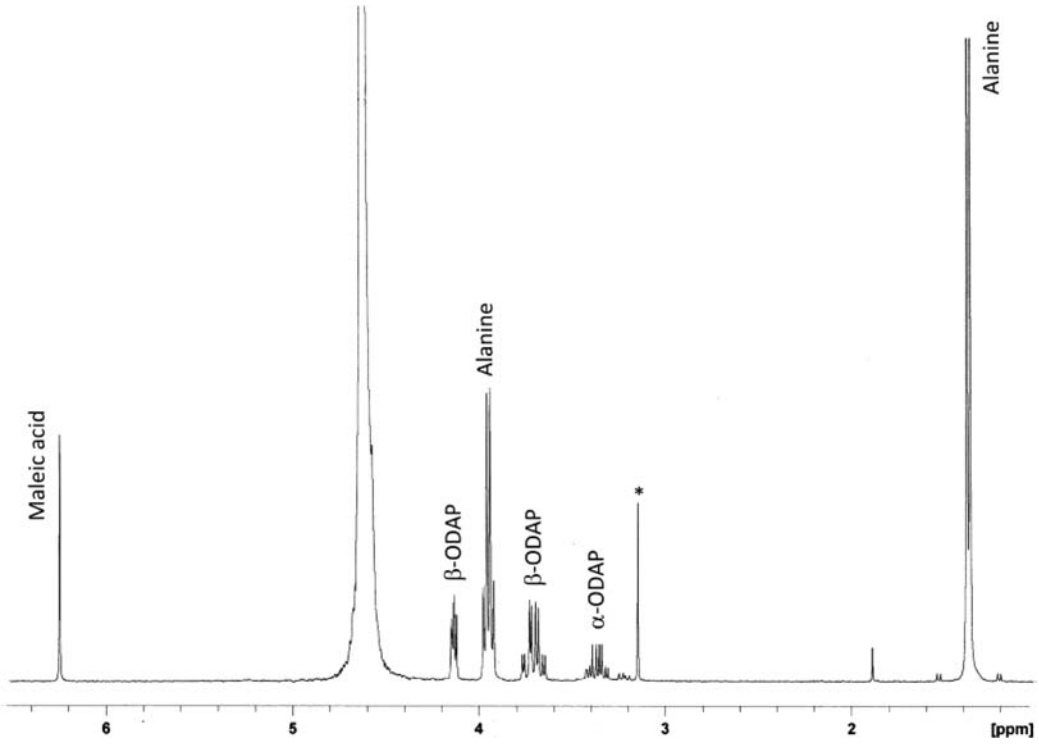

Figure 2. ^{1}H NMR quantitative determination of β- and α-ODAP, with the use of maleic acid and alanine as standards (* solvent impurity).

dried out. The final residue was dissolved in 25 mL of distilled water, and the solution was analyzed for its content of α- and β-ODAP adopting the two analytical procedures previously described, namely, HPLC-ELSD and NMR.

HPLC-ELSD Analyses. 5 mL of the previous solution was diluted (9:1) with 0.1 N HCl. 10 μL was analyzed by HPLC-ELSD in the conditions previously described. Each analysis was carried out in triplicate. For the quantitation of both amino acids the pure β-ODAP, previously purified, was used to build two calibration curves in the amount comprising between 2140 and 778 ng ($y = 0.5493x + 486.43$, $R^2 = 0.9997$) for β-ODAP and between 476 and 214 ng ($y = 0.9639x + 164.51$, $R^2 = 1$) for α-ODAP.

NMR Analyses. 20 mL of the same solution was concentrated, and each residue was dissolved in 2 mL of 0.1 N DCl in D_2O. 500 μL of the resulting solution was then submitted to nuclear magnetic resonance (^{1}H NMR) in the previously described conditions, performing four measurements every 10 min. For the calculations alanine (56 μL of a solution 0.068 M in D_2O) and maleic acid (56 μL of a solution 0.069 M in D_2O) were used as standards. Phase and baseline corrections were performed manually, as were the signal integrations. In the case of improper baseline corrections the BIAS and SLOPE functions were activated for the integral calculation. The ^{1}H NMR signals selected for the quantification of α-ODAP and β-ODAP were at 3.28 and 4.03 ppm, respectively.[31,32] The reference signals of the standard compounds were the methyl group of alanine at 1.55 ppm and the vinyl protons of maleic acid at 6.31 ppm (Figure 2).

Validation and Calibration Procedures. For the validation and intercomparisons three model mixtures were prepared gravimetrically. Mixture NMR-1 with the following molar ratio: β-ODAP (85.42 mol/mol %), alanine (8.50 mol/mol %), maleic acid (6.08 mol/mol %). Mixture NMR-2: β-ODAP (1.97 mol/mol %), alanine (95.73 mol/mol %), maleic acid (2.30 mol/mol %). Mixture NMR-3: β-ODAP (21.44 mol/mol %), alanine (7.94 mol/mol %), maleic acid (71.62 mol/mol %).

In order to check the linearity of the method, 13 model solutions containing β-ODAP were prepared in different molar ratios (from 2.02 to 99.04 mol/mol) solved in DCl/D_2O. Figure 3 shows the experimentally determined molar ratios for β-ODAP and experimental value versus estimated experimental value.

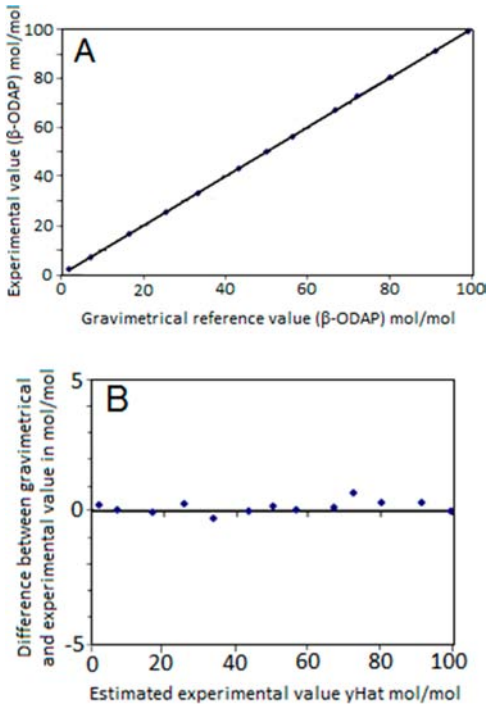

Figure 3. Tests of linearity. Theoretical and experimental molar ratios of the 13 model mixtures, calculated for β-ODAP. Correlation coefficient: 0.99996 (A). Difference between gravimetric and experimental value vs estimated experimental value yHat (with yHat =1.003x, where x represents the gravimetric value) (B).

In order to explore the relationships between the parameters, a Pearson correlation was performed.

RESULTS AND DISCUSSION

Morphological, Productive, and Qualitative Traits. Studied accessions did not differ in relation to phenological stages. For all the accessions seed emergence occurred 24 days after sowing, flowering began in the second week of February, pod set in the second week of March, and pod maturity at the end of June, period in which seeds were harvested.

Plant height, detected at the beginning of flowering, was about 31 cm for all the studied accessions, with the exception of 'Corleone' and 'Mineo', where heights were 26 cm (Table 1). This was lower than values reported by other authors,[33,34] but it can be explained by the wide inter-row distance adopted to facilitate measurements and harvest.

Grain yield was 1.07 t/ha on average; the best results were achieved by accessions 'Troina', 'Aidone 2', and 'Aidone 3' (1.86, 1.48, and 1.40 t/ha, respectively). The lowest yield was recorded in 'Corleone' with 0.69 t/ha. The remaining accessions showed values between 0.81 and 0.98 t/ha. The production of the best accessions is in agreement with those reported previously as 1.7−2.6 t/ha,[35] 1.2−1.6 t/ha,[11] and 1.6−2.0 t/ha.[5]

As regards yield components, on average the number of pods per plant was 10.5, with a coefficient of variation of 20.9%. The highest number of pods per plant was found on 'Aidone 1' (17.1), while the lowest was recorded in 'Licodia Eubea' (5.9). The number of seeds per pod was of 2.3 on average with a limited range of variability (9.44%). On the contrary, weight of the 1000 seeds was quite variable (19.83%) with an average value of 247.1 g ranging from 181.4 to 345 g. For this parameter the accessions 'Corleone' and 'Mineo' (345.1 and 307.5 g, respectively) significantly differ from the others (Table 1).

The boxplot in Figure 4 summarizes results for seed morphological data. With regard to longitudinal section, the accession 'Aidone 3', 'Corleone', and 'Mineo' revealed the highest median values equal to 11 mm with data skewed to the right, although the skew is more prominent in the last. The accessions 'Aidone 3' and 'Mineo' showed 50% of the readings within 10 and 11 mm, whereas 'Corleone' showed the highest interquartile extent, ranging from 10 to 12 mm. When the transversal section was taken into account, accession 'Corleone', in accordance with the longitudinal data, showed the median value (11 mm) higher than the 90th percentile of all the other accessions. No valuable differences were observed in thickness.

The protein content of grass pea accessions was on average of 26.6% with a CV of 2.9. It ranged from 25.4 of genotypes 'Aidone 3' and 'Corleone' to 27.4% of genotypes 'Troina' and 'Mineo' (Table 1). These values are in agreement with those reported in the literature,[12,36] comparing several samples from eleven different accessions, which found an average value of 27.2%, and with that described by Yan et al.,[28] which reports values between 25.6 and 27.3%. It must be emphasized that this value of grass pea protein content is in general higher than those of field pea, chick pea, and fava bean, which are, instead, much more commonly consumed.

Chemical Analyses. The contents of α- and β-ODAP in the ten accessions of Sicilian grass pea were listed in Table 2. It must be emphasized that the two analytical methodologies here used were applied for the first time in the determination of α- and β-ODAP in *L. sativus*. Compared to the usual methods used for the determination of the two ODAP isomers, the instrumental tools adopted here do not require any derivatization procedure,[37−39] so they are relatively much more simple. The two procedures gave comparable results, as shown in Table 2, with some differences observed in the determination of the minor component, α-ODAP.

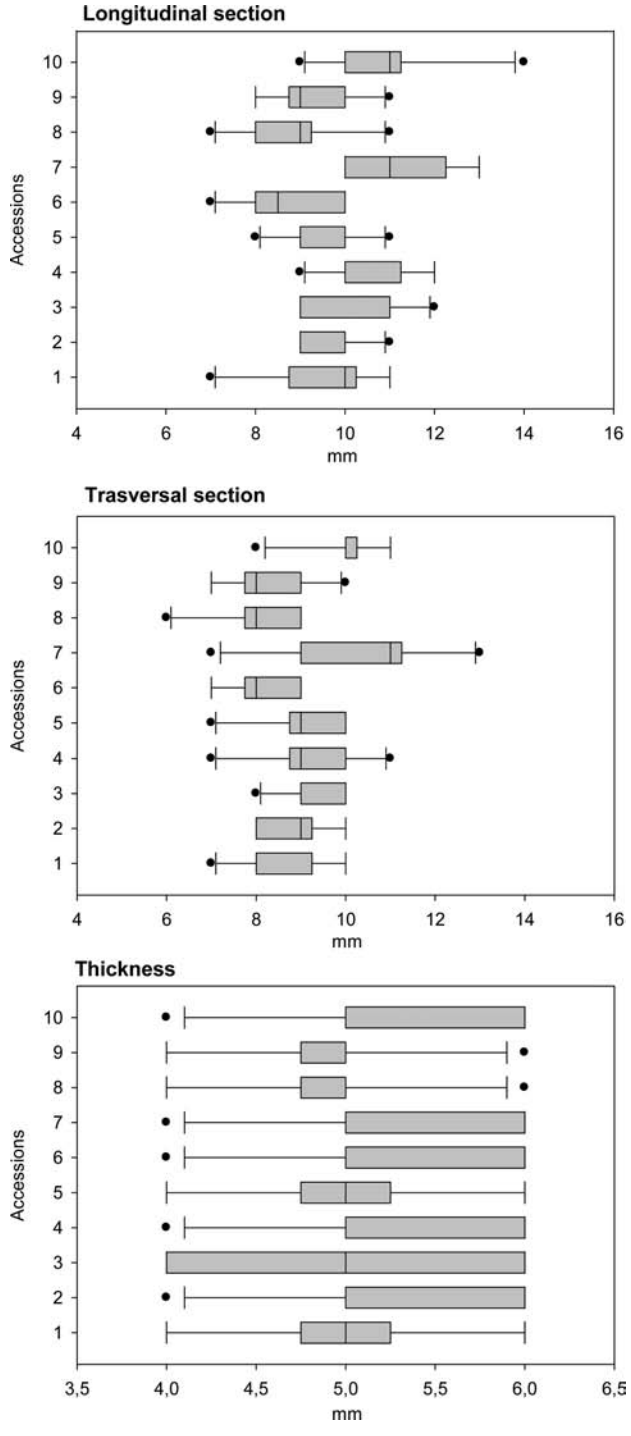

Figure 4. Distribution of the seed dimensions. In the boxes plot, each representing the distribution of 25 data, the lowest and highest boundaries indicate the 25th and 75th percentile, respectively, and the black line within the box marks the median. Whiskers on the right and left of the box indicate the 90th and 10th percentiles, respectively. Dark circles represent the 95th and the 5th percentiles.

The content of the two isomers falls in the range normally reported for these compounds.[26−30] In particular, the accessions 'Aidone 3' and 'Corleone' show the lower amount

of β isomer, whereas the samples 'Aidone 2' and 'Maletto' had a higher content of the same isomer, as shown by the NMR and HPLC-ELSD evaluations (Table 2). For the α isomer a slightly more complex situation is observed: from the NMR analyses the content of this isomer is lower in the accessions 'Aidone 3' and 'Corleone', as for the β isomer, instead the higher amount is reported for the samples 'Bronte' and 'Maletto'; by the HPLC analyses the accessions 'Aidone 3' and 'Mineo' show the lower amount, whereas six samples, namely, 'Aidone 2', 'Aidone 1', 'Licodia Eubea', 'Corleone', 'Maletto', and 'Piana degli Albanesi', show a comparable and higher amount of α isomer. These results are confirmed by the ANOVA analysis of the aforesaid quantitative results, which shows significant differences for the β isomer in the two analytical approaches (NMR and HPLC), whereas for the α isomer a less significant difference by NMR analyses and no differentiation by HPLC are observed (Table 2).

A remarkable chemical aspect of β-ODAP, which could affect the quantitative determination of this compound and its isomer in grass pea, is its spontaneous isomerization into the nontoxic isomer. This reaction is strongly influenced by the pH of the aqueous solution and, mainly, by heating, giving an equilibrium with about 40% of α-form.[28,31,40−42]

In order to verify if the aforesaid isomerization took place during the experimental procedures (extraction, analytical determinations, etc.) used in this study, pure β-ODAP was left in water at neutral pH and running ^{1}H NMR spectra at the initial time (t_0), after 24 h (t_1), four days (t_2), one week (t_3), two weeks (t_4), six weeks (t_5), and sixteen weeks (t_6). Only after one week an appreciable amount of α isomer was recorded (ca. 5% with respect to β isomer), whereas in the last experiment (t_6) a 6:4 ratio between β and α isomers was observed. It was noted that in this last experiment also an appreciable amount of 2,3-diaminopropionic acid (DAPRO) was recorded (see Supporting Information); the latter is the hydrolysis product of β- and α-ODAP, confirming that a competition between the isomerization and hydrolysis occurs in these conditions.[31] Therefore, if on one hand the β isomer isomerizes to the α isomer, on the other hand the process is very slow and cannot occur during the experimental procedures (mainly extraction step) adopted in this study, thus confirming that those detected are the real amounts of the two isomers in the Sicilian grass pea.

Pearson Correlation. Interesting relationships were found between agronomic and chemical parameters (Table 3). One expected negative correlation was found between the number of pods per plant and the 1000 seed weight (−0.586, $p < 0.045$). This is commonly measured in grain crops since increasing number of pods means that the weight of seeds decreases. Another interesting significant correlation is the one between 1000 seed weight and β-ODAP determined both with the NMR method and with the HPLC method (−0.651, $p < 0.041$, and −0.677, $p < 0.032$, respectively). In this case the β-ODAP seems negatively related with the seed weight. This observation is in agreement with Tadesse and Bekele,[43] who found negative association between seed size and ODAP content on fifty grass pea land race accessions. However, it is in contrast with the findings reported by Dahiya,[44] who, when analyzing eighteen genotypes of grass pea with a paper-chromatography technique, found that smaller seeds contain lower concentrations of ODAP.

Another valuable correlation was found between the β-ODAP content determined with HPLC and NMR and the altitude from where the seeds were collected (0.709, $p < 0.021$,

and 0.733, $p < 0.015$, respectively). From this relation, it emerges that seeds from environments with higher altitudes show a higher content of β-ODAP. On the contrary, a recent study carried out on nine grass pea genotypes in five different environments in Ethiopia showed a negative correlation between altitude and β-ODAP content;[45] therefore, the mechanism of this relation is not yet clear and needs to be fully elucidated. In agreement with Tadesse and Bekele,[43] no association was found between ODAP and protein content, indicating that ODAP is synthesized independently of protein content.

The last significant correlation refers to chemical parameters: β-ODAP HPLC is highly positively correlated to β-ODAP NMR (0.995, $p < 0.001$), testifying that the two methods are comparable and equally usable. The application of two well consolidated analytical methodologies, namely, NMR and HPLC-ELSD, gives comparable results in the quantitative determination of the two amino acids, showing at the same time some operative advantages with respect to the more complex and time-consuming analytical procedures adopted in this field up to now.

Accessions 'Aidone 2', 'Aidone 3', and 'Troina' showed a high seed yield and a valuable protein content; namely, 'Aidone 3' showed also a low β-ODAP content and so represents good material for a future breeding program. Moreover, correlations revealed that accessions with heavier seeds and those coming from low altitude environments have a lower β-ODAP content.

In conclusion, the results of this study show that the Sicilian grass pea accessions do not present very high amounts of the neurotoxic β-ODAP. In any case, taking into account the very low consumption of this species and relatively low level of the neurotoxins, its sporadic presence in the human diet does not represent a real health risk. In this view, Sicilian grass pea can be considered a niche product strongly characterizing local cultural and gastronomic traditions.

$^a U$, measurement uncertainty. ^{b}SD, standard deviation.

mineral elements.[21−24] The representative studies were carried out by the team of Baralkiewicz. In 2008, Madejczyk et al.[12] determined 12 elements in 30 rape and honeydew honey samples from various locations within Poland by ICP-MS. Cluster analysis (CA) of the honey data revealed that the origins of honey samples are correlated with their chemical composition. Subsequently, Chuazinska et al.[25] studied 13 elements (Al, B, Ba, Ca, Cd, Cu, K, Mg, Mn, Na, Ni, Pb, and Zn) in 55 honeydew, buckwheat, and rape honey samples by ICP-MS. CA and PCA were applied to classify honey according to the profiles of minerals. On the basis of their previous research, Chuazinska et al.[26] studied 15 elements (Cr and Sr were added) in 140 honey samples including honeydew, buckwheat, and rape honeys from 16 areas of Poland using ICP-MS. Linear discriminant analysis (LDA) and calibration and regression tree (C&RT) were performed for the whole data set to discriminate and classify honey samples according to their botanical and geographical origins. The above studies have suggested that chemometric analysis of elemental profiles in the honeys determined by various analytical techniques may be an alternative way for evaluating the honey classes on the basis of the geographic or botanical origins of honey.

Chinese honey is very popular worldwide and holds a large proportion of the world market. Unfortunately, to the best of our knowledge, no research has been carried out to classify the botanical origins of Chinese honeys on the basis of mineral elements. At the same time, few researchers have attempted to test their developed model by reference samples.

The aim of this work is to analyze the mineral elements in Chinese honeys by ICP-MS and construct a statistical model for their botanical origin. Moreover, this study is the first to test the validation of the developed model by 42 reference samples with well-known information.

MATERIALS AND METHODS

Honey Samples. This study was carried out on 163 honey samples, including 4 kinds of honey: linden (*Tilia amurensis* Rupr.), vitex (*Vitex negundo* var. *heterophylla* Rehd.), rape (*Brassica campestris* L.), and acacia (*Robinia pseudoacacia* L.). They were collected directly from beekeepers with guaranteed origin in Heilongjiang (39 linden honey samples), Beijing (27 vitex and 25 acacia honey samples), Hebei (23 vitex and 18 acacia honey samples), and Shaanxi (19 rape and 12 acacia honey samples) regions of China from April to July 2013. All samples were unprocessed and stored in plastic containers at 4 °C until analysis.

Sample Preparation. The honey sample was liquefied at 50 °C and homogenized in an ultrasonic bath for at least 30 min prior to analysis.

Honey samples were prepared according to the following procedure: 1.0 g of honey sample was accurately weighed and placed into a PTFE digestion vessel, and 5 mL of nitric acid (65%, w/w, MOS grade) and 3 mL of hydrogen peroxide (30%, w/w, MOS grade) were added. In each set of digestion, one reagent blank solution and CRM sample were prepared in the same way. Sample was digested using a MARS 6 microwave reaction system (CEM Corp., USA) according to a previous study.[17] After the vessels were cooled, the digests were transferred to a volumetric flask and diluted to 50 mL with deionized water.

Sample Analysis. The elements standard solutions for ^{23}Na, ^{24}Mg, ^{31}P, ^{39}K, ^{43}Ca, ^{55}Mn, ^{56}Fe, ^{63}Cu, ^{66}Zn, ^{85}Rb, ^{88}Sr, and ^{137}Ba were prepared by multielement calibration standards solutions (Agilent Technologies, USA). An Agilent 7700x ICP-MS (Agilent Technologies, Japan) fitted with a standard glass concentric nebulizer, a quartz double-pass spray chamber, and nickel sampler and skimmer cones was used. The operating conditions and measurement parameters were referred to those reported in our previous study.[17]

Method Assurance. The method performance for determination of 12 mineral elements in honey samples was evaluated by limits of detection and quantification (LOD and LOQ, respectively), reference sample measurement, spiking recovery, and precision (see Table 1). Because there is no matching CRM for honey, the analytical quality control was routinely validated using a tea reference material, GSB-7-tea (GBW10016, China). As shown in Table 1, the LOQ of the major elements and trace elements are at sub parts per million and parts per billion levels, respectively. The certified and measured values of 12 mineral elements in GSB-7-tea are in good coincidence. The spiking recoveries for these 12 elements in honey samples range from 85.9 to 109.8%, with measuring precision within 10%. This suggests that the performance of the method allows accurate measurement of the levels of these elements in the honey samples.

Data Sets and Chemometric Techniques. Basic statistical and multivariate analyses were carried out using Mass Profiler Professional (MPP) software (version B. 12.05, Agilent Technologies, Santa Clara, CA, USA). Chemometric approaches such as principal component analysis (PCA), PLS-DA, and BP-ANN were performed for all of the data to discriminate and classify honey samples according to their botanical origin.

PCA is an unsupervised pattern-recognizing technique, which reduced the number of dimensions and provided a partial view and trends of the data in space.[27] It is often used to examine the relationships between the variables and the types of samples.

PLS is a well-known regression tool applied to chemometrics by Wold.[28] PLS-DA, an extension of PLS, is used to predict a set of

variables and identify them as functional classes from a large number of independent variables.

ANN has been widely used in chemometrics as a supervised pattern recognition technique, which comprises a set of interconnected processing algorithms working in parallel to mimic the processes of the human brain.[29] In this study, the neural network implementation in MPP software is the multilayer perception trained using the BP-ANN. It normally consists of three layers, the input layer, intermediate layer, and output layer; the input layer features rows to be classified that are fed into this layer, and the output layer has an output node for each class in the data set.

RESULTS AND DISCUSSION

General Features of Elements. The contents of 12 elements for all of the honey samples and each botanical origin of honey samples are listed in Table 2. According to the mean value of elements in all honeys, they were divided into three groups: abundant major elements, minor elements, and trace elements.

The first group was composed of K, Ca, P, Na, and Mg with contents of >10 mg/kg. First, it is obvious that the most abundant element in all of the honeys was K, with a mean value of 552.15 mg/kg. This finding agrees with many previous results.[12,18,24] The mean value of K in linden honey was 1426.75 mg/kg, which was 4.4−8.8 times higher than in other honeys. The highest mean value of Ca was found in linden honey, whereas the mean values of Ca in rape and acacia honeys are close to each other. The mean value of P in all honey samples was 39.55 mg/kg, and the acacia and linden honeys had the highest and lowest values of P, respectively. Na and Mg have similar mean contents in all honey samples with mean values of 12.73 and 12.87 mg/kg, respectively. Except for the linden honey, the mean values of Na in vitex, rape, and acacia honeys have similar levels. Mg was higher in linden and rape honeys than others, whereas the lowest mean value of it was found in vitex honey.

Fe and Zn displayed mean values within the range of 1−10 mg/kg (1.72 and 1.02 mg/kg, respectively) in all honey samples, and both were taken as minor elements. It was also found that Fe and Zn had similar mean values in various honeys with a difference of <0.35 mg/kg except in acacia honey samples. In addition, vitex and acacia honey samples had equal mean values of Fe, whereas linden honey had the lowest mean values of Fe and Zn.

The third group, including Mn, Cu, Rb, Sr, and Ba, had mean values lower than 1 mg/kg. In this group, the mean values of Rb were higher than those of other elements in different honey samples, whereas Cu was the lowest element. As shown in Table 2, the highest mean values of Mn, Rb, Sr, and Ba were all found in linden honey samples, especially Rb and Ba. Vitex, rape, and acacia honey samples had equal mean contents of Rb within the range of 0.41−0.43 mg/kg, and the range of Ba in them was 0.03−0.05 mg/kg. For Cu, similar mean values were found in linden and vitex honeys and rape and acacia honeys, respectively.

On the basis of the above analysis, the contents of the 12 studied elements were different in various botanical origins of honeys. Some of the honeys had their own characteristic elemental profile, especially the linden honey. However, there are variations within the same origin of the samples as demonstrated by the large difference between the minimum and maximum values in Table 2; therefore, chemometric methods are required to evaluate the tendency of sample clustering based on clustering factors such as botanical origin.

Chemometric Analysis. *PCA.* PCA is widely used to find the relationships between variables and types of samples. Here the data set was first subjected to statistical analysis using ANOVA. With the p value of <0.05, 10 elements, Na, Mg, K, Ca, Mn, Fe, Cu, Rb, Sr, and Ba, displayed statistically significant values among the honey samples from different botanical origins. The levels of these significant elements in 163 honey samples were subjected to PCA algorithm in the MPP software, and 10 elements as variables were reduced to four principal components (PCs). The four PCs could explain 93.06% of the total variance. As shown in Table 3, the first PC (PC1) accounts for 62.61% of the variance and the other three PCs (PC2, PC3, and PC4) represent 19.77, 5.96, and 4.72%, respectively. Examining the loading of variables demonstrated the contribution by each element to the four PCs. As shown in Table 3, the PC1 is basically a function of Sr, Ba, K, Ca, Mn, and Rb, PC2 was associated with Na and Fe, and PC3 and PC4 were mainly related with Cu and Mg, respectively.

Table 3. Loadings of the Variables for the Four PCs

element	component 1 (62.61%)	component 2 (19.77%)	component 3 (5.96%)	component 4 (4.72%)
Na	−0.177	**0.574**	0.082	0.077
Mg	0.300	0.316	−0.215	**-0.622**
K	**0.374**	−0.045	0.241	0.330
Ca	**0.373**	0.119	0.038	−0.264
Mn	**0.364**	0.089	−0.091	−0.212
Fe	−0.095	**0.570**	0.609	0.081
Cu	0.191	0.440	**-0.644**	0.513
Rb	**0.360**	−0.138	0.088	0.319
Sr	**0.383**	0.008	0.221	0.018
Ba	**0.381**	−0.097	0.190	0.107

Obviously, PC1 and PC2 are the main components, representing 82.38% of the variables. Analysis of the loadings plot of variables for PC1 and PC2 (Figure 1) demonstrated that Na and Fe were negatively correlated with PC1, whereas Mg, K, Ca, Mn, Cu, Rb, Sr, and Ba were positively correlated with PC1. On the other hand, K, Ba, and Rb were negatively correlated with PC2, and the others were positively correlated with PC2. The loading plot of samples for PC1 and PC2 (Figure 2) shows a clear separation between linden honey and other samples. The close position of the other three types of honey samples in Figure 2 suggested that the separation of these three types of honeys did not depend on the major variables in PC1 and PC2. At the bottom right of Figure 2, the linden honey samples were positively correlated with PC1. Combined with Figure 1 and Table 3, this suggested that the linden samples have the highest values of K, Ca, Mn, Rb, Sr, and Ba, which coincides with the general feature of the data demonstrated above.

The results obtained by PCA confirmed that PCA could reduce the multivariable to four components simply and partly revealed a correlation between the elements and honey samples. The linden honey samples could be classified clearly from others with K, Ca, Mn, Rb, Sr, and Ba as their elemental markers. Although PCA could provide a visual graph on how the samples are clustered, it could not provide information on how good the clustering is and the confidence on such clustering. Hence, other chemometric tools were further explored to classify the honeys.

Classification and Prediction. To better classify the honey samples with elemental profiling, PLS-DA and BP-ANN models were built on the basis of 10 elements measured in 121 honey samples (75% of honey samples of each botanical origin randomly selected from the total samples) from different botanical origins.

PLS-DA. PLS-DA with four components was first selected for building a model to predict the botanical origins of honey samples. The model was evaluated in terms of recognition and prediction ability, which are summarized in Table 4. The recognition ability was represented by the percentage of honey samples correctly classified during the model training process, and the overall accuracy was 90.9%. Linden and rape honey samples could be classified clearly with accuracies of 100%, whereas the accuracies for vitex and acacia honey were 91.9 and 80.5%, respectively. The prediction ability was represented by the percentage of the honey samples correctly classified using a typical N-fold cross-validation procedure. The whole process was repeated 10 times with 3 folds. The overall accuracy of prediction was 88.4%, with the accuracies of vitex (89.2%) and acacia (75.6%) honey slightly lower than those in model training.

BP-ANN. To further improve the classification accuracy, a BP-ANN model was examined. In this study, a three-layer BP-ANN was built and applied to classify the honey samples on the basis of their botanical origins. Both the input and output layer have one neuron, whereas the number of neurons in each hidden layer is 15. The learning process is continued with a

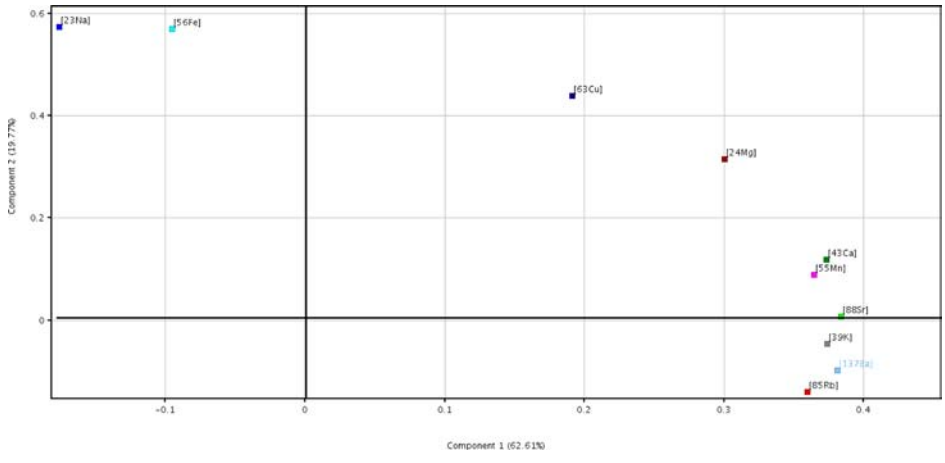

Figure 1. Two first-component loadings plot of variables.

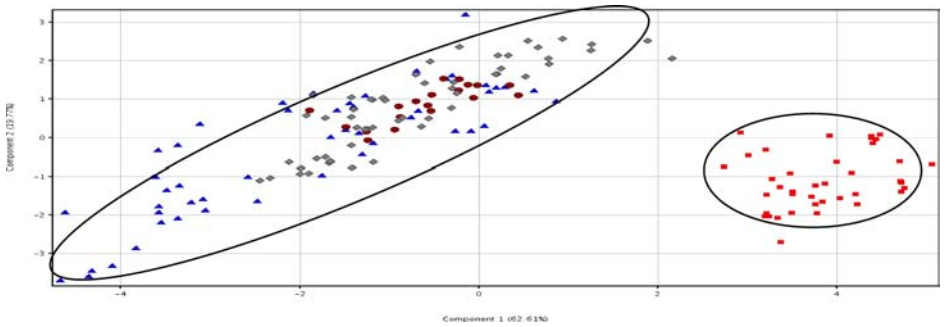

Figure 2. Two first-component scores of honeys from different botanical origins: linden (■), vitex (▲), rape (●), and acacia (◆) honey.

Table 4. Model Training and Cross-Validation Results by PLS-DA Model

	linden	vitex	rape	acacia	accuracy (%)
model training					
linden	29	0	0	0	100.0
vitex	0	34	0	3	91.9
rape	0	0	14	0	100.0
acacia	0	8	0	33	80.5
recognition ability (%)					90.9
model cross-validation					
linden	29	0	0	0	100.0
vitex	0	33	0	4	89.2
rape	0	0	14	0	100.0
acacia	0	8	2	31	75.6
prediction ability (%)					88.4

learning rate of 0.7 and the number of iterations (epochs) of 100. The model was also evaluated in terms of recognition and prediction ability. As demonstrated in Table 5, all honey samples can be successfully classified into four groups representing corresponding botanical origins during model training process. "Leave one out" was selected during the model cross-validation procedure to evaluate the robustness of the developed model. As shown in Table 5, the prediction ability of linden honey was 100% during model cross-validation. The overall accuracy of the prediction ability was slightly lower (92.6%) with the accuracies for vitex, rape, and acacia honeys of 86.5, 85.7, and 95.1%, respectively.

Table 5. Model Training and Cross-Validation Results by BP-ANN Model

	linden	vitex	rape	acacia	accuracy (%)
model training					
linden	29	0	0	0	100.0
vitex	0	37	0	0	100.0
rape	0	0	14	0	100.0
acacia	0	0	0	41	100.0
recognition ability (%)					100.0
model cross-validation					
linden	29	0	0	0	100.0
vitex	0	32	0	5	86.5
rape	0	0	12	2	85.7
acacia	0	0	2	39	95.1
prediction ability (%)					92.6

Prediction of Test Set by BP-ANN. Compared with the PLS-DA method, the performance of the BP-ANN model is more accurate. To further test the stability of the model developed for prediction, the independent test set of the remaining 42 honey samples with well-known sample information was classified using the constructed model. The results in Table 6 showed that 41 of 42 honey samples could be predicted into the four groups correctly, except that one acacia honey was wrongly classified into rape honey. The overall prediction accuracy is 97.6%, indicating the applicability of the proposed BP-ANN model.

Table 6. Model Prediction Results by BP-ANN Model

	predicted group				
test set	linden	vitex	rape	acacia	accuracy (%)
linden	10	0	0	0	100
vitex	0	13	0	0	100
rape	0	0	5	0	100
acacia	0	0	1	13	92.3
prediction ability (%)					97.6

Food source tracing has been a critical issue in recent years, especially for high-valued food products. Simply relying on anticounterfeiting labeling is insufficient to exclude faked or adulterated products from the market. However, many high-valued food products do have characteristic features depending on their chemical components. As demonstrated above, multiple elemental profiling by ICP-MS technique combined with chemometric tools can reliably classify honey samples according to their botanical origins. The developed prediction model has the advantage of high accuracy and robustness, relying little on human factors, and thus is promising for application in food classification and group assignment, especially in the field of food source tracing and adulteration studies, where elemental contents vary with food origin.
