JOURNAL OF AGRICULTURAL AND FOOD CHEMISTRY

Editorial

pubs.acs.org/JAFC

New Features and Expanded Coverage for *Journal of Agricultural and Food Chemistry*

Publishing in *JAFC* has never been more inviting. With ACS Publications Division support and the support of the Divisions of Agrochemicals and Agricultural and Food chemistry, in 2013 the *Journal* launched two ***Research Article of the Year*** awards, one slanted toward agrochemicals and the other toward food chemistry. It was difficult to decide on the winners, but with so many excellent candidates from 2012 published manuscripts two were chosen. In the Agrochemical category, award winners were John Grabber, Dino Ress, and John Ralph for "Identifying New Lignin Bioengineering Targets: Impact of Epicatechin, Quercetin Glycoside, and Gallate Derivatives on the Lignification and Fermentation of Maize Cell Walls" (*J. Agric. Food Chem.* **2012**, *60* (20), 5152−5160). In the Food Chemistry category, authors Caroline Hellfritsch, Anne Brockhoff, Frauke Stähler, Wolfgang Meyerhof, and Thomas Hofmann received the award for "Human Psychometric and Taste Receptor Responses to Steviol Glycosides" (*J. Agric. Food Chem.* **2012**, *60* (27), 6782−6793). Both Research Articles of the Year were the topics of presentations made at the National Meeting of the American Chemical Society in Indianapolis, by corresponding authors John Grabber and Thomas Hoffman (Figure 1).

Figure 1. JAFC Managing Editor Matt Hotze (left) and Editor Jim Seiber (right) congratulate 2013 Research Article of the Year Lectureship awardees John Grabber (left middle) and Thomas Hofmann (right middle) during their lecture session at the Fall ACS National Meeting in Indianapolis in September 2013.

JAFC also launched a **new category, Targeted Metabolomics Applied to Agriculture and Food** (for details, see the author guidelines at http://pubs.acs.org/page/jafcau/submission/authors.html). Associate Editors Peter Schieberle and Russ Molyneux and I will describe the new category in an upcoming Perspective (in process), which includes the prospects for this exciting new field and its many applications in agricultural and food chemistry. Metabolomics is one of the new endeavors that is cross disciplinary in scope and can involve biotechnology, analytical chemistry, sensory science, toxicology, nutrition, and many other fields important to *JAFC*. As the Perspective states, "*JAFC* will limit the section on Targeted Metabolomics to those manuscripts that at least attempt to characterize the differing compounds in order to draw substantive conclusions, for example, on pathways or mechanisms of formation or modification."[1]

Got something new and exciting that can be described in 2000 words and 4 graphics or less? Then check out the new **Letters category** launched in September 2013 and also described at the author guidelines link, above. Letters are being accepted that are brief, timely, and urgent. The first Letters submissions are undergoing peer review and are expected to be published as JAMs and ASAP soon.

Two other *JAFC* categories have enjoyed significant growth in numbers of publications received and published in 2013. Reviews and Perspectives, both standing categories for several years, had their best years ever, with 10 Perspectives and 45 Reviews published as of this writing. Table 1 lists the Perspectives published in 2013. Our hats-off to the authors who responded to the call for manuscripts, or volunteered topics themselves, and to several of our Associate Editors (Russ Molyneux played a major role) and Managing Editor Matt Hotze for stimulating the pipeline in these two categories.

We have also been active with new **ACS Selects** (formerly called Virtual Issues) covering the fields of **gut microbiota** and the **health implications of nanotechnology** in agricultural and food chemistry. Our guest editors for the Microbiota issue, Associate Editors Francisco Tomás-Barberán and Yoshinori Mine, worked with Managing Editor Matt Hotze to select manuscripts published during 2011−2013 that best represented the field from the *JAFC* perspective, and then worked with an international cadre of authors to publish additional new content on this topic.

Similarly, Guest Editor Hongda Chen, National Program Leader for USDA-ARS, worked with editors from four ACS journals (*JAFC*, *ACS Nano*, *ES&T*, and *ACS Sustainable Chemistry and Engineering*), to assemble a consensus choice of representative manuscripts published in the fast developing field of **nanotechnology**. This new ACS Selects will roll out soon. You can view all of the ACS Selects/Virtual Issues that *JAFC* has participated in at the JAFC Selects webpage (http://pubs.acs.org/page/jafcau/vi/index.html)

Continually refreshed with new science and new features, it is no surprise that *JAFC* retained its leadership as **the most cited journal in three ISI categories**, Agriculture, Applied Chemistry, and Food Science and Technology. The journal is blessed with an outstanding group of **Associate Editors (Hanne Christine Bertram, Zhen-Yu Chen, John W. Finley, Chi-Tang Ho, Yoshinori Mine, Russell J. Molyneux, Peter**

Targeted Metabolomics, a New Section in the *Journal of Agricultural and Food Chemistry* (JAFC)
J. N. Seiber, R. J. Molyneux, P. Schieberle
J. Agric. Food Chem. 61, DOI: 10.1021/jf4046254

Schieberle, **Takayuki Shibamoto**, **Veronika Somoza**, **Francisco Tomás-Barberán**, **Elizabeth Waters**, and **Liangli (Lucy) Yu**) and strong support from ACS Publications Division and the ACS technical divisions of Agricultural and Food Chemistry and Agrochemicals.

We take this opportunity to congratulate Associate Editor Taka Shibamoto for receiving the Award for the Advancement of Application of Agricultural and Food Chemistry from the Division of Agricultural and Food Chemistry of the ACS at the Indianapolis meeting (Figure 2.) Professor Shibamoto has identified Maillard browning reaction chemicals in several foods and beverages. Recently, we had occasion to congratulate another strong supporter of *JAFC*, Lucy Sun Hwang, at a symposium held in her honor during the 2013 International Society for Nutraceuticals and Functional Foods (ISNFF) in Taipei, Taiwan, in November. Lucy has been a strong advocate for agricultural and food chemistry in Asia and worldwide (Figure 3). Also in 2013, I had the opportunity to serve as

Figure 2. Associate Editor Takayuki Shibamoto received the 2013 Award for the Advancement of Application of Agricultural and Food Chemistry from the Division of Agricultural and Food chemistry of ACS at the Indianapolis meeting.

Figure 3. The *Journal* salutes the distinguished Career of Professor Lucy Hwang (left middle) at the Annual Conference of the International Society For Nutraceuticals and Functional Foods, held November 5−9, 2013, in Taipei, Taiwan. Associate Editors Chi-Tang Ho (right middle), who made the presentation on behalf of the *Journal*, Associate Editor Zhen-yu Chen (far right), and Advisory Board member Gow-Chen Yen (far left) are pictured.

Thematic Chair for the ACS National Meeting in New Orleans, Louisiana, under the theme banner of "Energy and Food". Almost half the divisions organized symposia within the theme. Associate Editor Peter Schieberle gave an excellent plenary address titled "Chemistry of food flavors: simply pleasure or beyond?", and Associate Editor John Finley arranged a symposium on "The Interconnected World of Energy, Food and Water."

This was also a year filled with travel by several of us to attend **international meetings** on several continents. Some of the meetings we attended will culminate in manuscript clusters, cutting edge Research Articles or Letters, Perspectives, and Reviews published in issues of *JAFC*. It is important for the *Journal* to be represented at meetings such as these, where a broad cross section of new authors can be encouraged to publish their best work in *JAFC*. Over the past year we have had the opportunity to publish work presented at six meetings as symposium clusters in special issues— Advances in Food Allergen Detection, IX Italian Congress of Food Chemistry, Florida Pesticide Residue Workshop 2012, Safety of GM Crops: Compositional Analysis, ISMR11 − 100 Years of the Maillard Reaction, and Human Health and Transgenic Crops. An upcoming meeting of particular note is the **13th IUPAC Congress of Pesticide Chemistry**—Crop, Environment, and Public Health Protection Technologies for a Changing World, to be cosponsored by IUPAC and ACS AGRO and held August 10−14, 2014, in San Francisco, California, in conjunction with the Fall National Meeting of the ACS. I look forward to seeing many of you at these meetings.

On behalf of the *JAFC* team, our Associate Editors, Editorial Advisory Board members, ACS staff, and editorial assistants, I take this opportunity to thank all of our authors and reviewers (a list of our 2013 reviewers follows this editorial) and editorial staff who contributed to our successes in 2013. I extend our **best wishes for a successful, healthy and prosperous 2014!**

Jim Seiber, Editor

REVIEWER LIST 2013

The Editor and Associate Editors gratefully acknowledge the following scientists for reviewing manuscripts during 2013. Many of these individuals reviewed several manuscripts. We thank all of the reviewers for their contributions of time and talent. Note: this list reflects reviews received between November 13, 2012, and November 10, 2013.

JOURNAL OF AGRICULTURAL AND FOOD CHEMISTRY

Perspective

pubs.acs.org/JAFC

Targeted Metabolomics: a New Section in the *Journal of Agricultural and Food Chemistry*

James N. Seiber,[†] Russell J. Molyneux,[§] and Peter Schieberle*[,#]

[†]4143 Meyer Hall, Department of Environmental Toxicology, University of California, Davis, California 95616, United States

[§]Daniel K. Inouye College of Pharmacy of Hawaii at Hilo, 34 Rainbow Drive, Hilo, Hawaii 96720, United States

[#]Deutsche Forschungsanstalt für Lebensmittelchemie, Lise-Meitner-Straße 34, 85354 Freising, Germany

Starting in 2013, *JAFC* initiated a new section "Targeted Metabolomics Applied to Agriculture and Food" for manuscripts describing applications of metabolomics related to research topics in agriculture, food, and nutrition, in particular, metabolite-targeted analysis and progress in the development of analytical platforms for metabolomics methodologies. This description was expanded somewhat in the Journal's Scope, Policy, and Instructions for authors (revised April 2013) with the additional statement:

"A metabolome is the complete quantitative set of small molecules (metabolites) in a biological system, i.e., a food, which varies continuously with time. Also metabonomics studies, focused on changes in a given metabolome, e.g., induced by environmental conditions or diseases, fall into this category. Metabolic profiling or metabolomics fingerprinting correlated with multivariate or data-mining methods are acceptable, if presented in a targeted way".

This Perspective is meant to further explain the types of studies/topics that might fall within the scope of the new targeted metabolomics section of the *Journal of Agricultural and Food Chemistry* and to encourage authors to submit manuscripts to this section of *JAFC*.

Due to the rapid development in the sensitivity and/or selectivity of analytical equipment, such as NMR, GC×GC-MS, or LC-MS (i.e., UHPLC-Q-TOF) as well as the option to handle large data sets by new software, metabolomics has developed and expanded largely in the past 15 years. A symposium, "Applications of Metabolomics in Agriculture", was held at the American Chemical Society Spring meeting in 2005 covering information to that date, and a Perspective was subsequently published summarizing the content of the symposium, which included papers on understanding metabolic pathways, food and environmental safety, and nutrition, diet, and health.[1] The Perspective particularly pointed out the challenges and opportunities which lay ahead for this exciting field.

Metabolomics is a very promising approach of the postgenomics era aimed at facilitating our understanding of the dynamics of biochemical composition within living systems. It is fundamental to understanding systems biology in its efforts to integrate DNA, RNA, protein, and metabolite analyses in phenotypic, morphological, clinical, food, and other biological contexts. Metabolomics can also be quite useful as a guide to optimizing trait development in agricultural products[2] or in improving food-processing conditions by comparing changes in the food's metabolome.[3] The analytical tools of most use in metabolomics (NMR spectroscopy, mass spectrometry, and others) can yield massive data sets when following changes in the metabolome of often hundreds of metabolites simultaneously over time, for example, in relation to nutritional status, environmental changes, etc. Thus, it provides a more complete picture of composition than generally seen with traditional plant biochemistry and natural product analyses.

The literature differentiates between two concepts of metabolomics: untargeted and targeted methodologies.[4] Untargeted methods are intended to analyze as many compounds as possible of the entire set of chemical compounds in a given sample, that is, a food at different stages of fermentation/processing or a body fluid after ingestion of a certain diet, including unknowns. Usually the raw data on the analyzed set of molecules occurring in a minimum of two samples are compared and, after data alignment, compounds occurring in one of the samples are visualized by application of bioinformatics approaches, that is, dedicated software. The untargeted approach is, thus, unbiased and tries to differentiate/compare samples by statistical means, that is, chemometrics, to find discriminant metabolites whether the structure was known or is unknown. It must, however, be kept in mind that the set of compounds analyzed depends on several parameters, in particular, on the conditions of compound isolation from the insoluble matrix. Furthermore, a sufficient number of samples must have been analyzed to allow statistical calculations.[5] In contrast, targeted metabolomic approaches aim at measuring defined groups of previously identified metabolites that are biochemically relevant. The targeted approach is designed to first confirm the structures of specific compounds by using reference compounds or reliable library data, and the "targeted" marker metabolites are then commonly compared on the basis of quantitative results, including concentration changes over time or condition. The number of analytes considered is usually high in both approaches, although target approaches must be limited to compounds representing, for example, food quality or that are markers of a biological phenomenon. A recent paper explains well the term metabolomics and the differences between a targeted and an untargeted approach.[4]

Nevertheless, there is a close relationship between the two approaches, because an untargeted approach should be done first to show differences in the set of analytes in the samples under investigation, that is, to help annotate those compounds

that are likely to be most relevant to addressing the research plan or question. If marker compounds are pinpointed from such "untargeted" comparisons, a library search must follow to establish whether a compound is already known. This process is commonly known as dereplication.[6,7] If the structure is not yet described, the study must then be focused on the identification and quantitation of the marker compounds according to standards set forth in previous *JAFC* perspectives.[8,9] However, whereas in conventional studies these standards require complete identification of compounds under investigation, it is obvious that in a targeted metabolomics study, dealing with tens or hundreds of compounds, it is almost impossible to conform to such requirements. Nevertheless, when claims are made for specific compounds as metabolic markers, such compounds should be fully characterized. In an ideal situation this will require that both NMR and MS techniques be concurrently applied (together with others that might be definitive), because the former tends to lack sensitivity and the latter, selectivity.

Researchers who follow an untargeted approach are strongly encouraged to undertake further characterization of those compounds showing differences in given samples. *JAFC* will limit the section on targeted metabolomics to those manuscripts that at least attempt to characterize the differing compounds to draw substantive conclusions, for example, on pathways or mechanisms of formation or modification. An untargeted approach alone is primarily descriptive and may not be driven by a scientific concept and experimental design and, therefore, generally will not fall within *JAFC*'s scope. Because *JAFC* is primarily a chemistry journal, it is important for authors to include in their manuscripts examples of their spectroscopic/spectrometric data sets, so that readers can evaluate the ability of the techniques to discriminate between the numerous compounds that may be present.

JAFC has already published a number of good examples translating the metabolomics approach into food chemistry, which illustrate the breadth and depth of this field.[1,3,10−14] Also, guidelines for minimum standards in conducting metabolomics studies published by, for example, the Metabolomics Standard Initiative (MSI) or the COSMOS (Coordination of Standards in Metabolomics), should be consulted.[15,16]

With the boundaries defined in this Perspective, we leave it to authors, reviewers, and readers of the Journal to populate and comment on the development of targeted metabolomics applicable to agricultural and food chemistry.

Volunteer Stratification Is More Relevant than Technological Treatment in Orange Juice Flavanone Bioavailability

ABSTRACT: The effect of two technological treatments on orange juice flavanone bioavailability in humans was assessed. Processing affected flavanone solubility and particle size of the cloud. Volunteers were stratified in high, medium, and low urinary excretion capabilities. Flavanones from high-pressure homogenized juice showed better absorption than those of conventional pasteurized juice in high excretors. These differences were not observed in medium and low excretors. High flavanone excretors took advantage of the high-pressure homogenization juice attributes (smaller cloud particle size) and showed an improved absorption/excretion. Stratification of the individuals by their excretion capability is more relevant than technological treatments in terms of flavanone bioavailability. This stratification should be considered in clinical studies with citrus juices and extracts as it could explain the large interindividual variability that is often observed.

KEYWORDS: *bioavailability, flavanones, orange juice, technological treatments, volunteer stratification*

INTRODUCTION

Hydrostatic high pressure and pulsed electric fields have consolidated as alternatives to conventional citrus processing, as these mild treatments produce juices with quality characteristics similar to those of fresh juice.[1] Although the impact of these novel technologies on orange juice bioactives has been studied,[2] their effect on flavanone bioavailability in humans has not been studied to the same extent.

Conventional processing leads to flavanone precipitation from the soluble fraction to the cloud.[3] As flavanone solubility is a key factor for their bioavailability,[4] there is an interest in developing new technologies that increase orange juice flavanone solubility. High-pressure homogenization with moderate heat treatment is able to reduce orange juice particle size (micrometer scale), leading to microsuspensions of the cloud that might increase flavanone bioavailability.[5]

The systemic health effects of citrus flavanones depend on their absorption. Hesperidin is not absorbed in the small intestine, and it reaches the colon, where it is hydrolyzed by gut microbiota to release hesperetin that is then absorbed.[4,6] Depending on the gut bacterial composition of the different volunteers, they can have different levels of rhamnosidase activity and therefore different capabilities to absorb and excrete hesperetin.[7,8] Due to the large interindividual variability in flavanone absorption and excretion, a previous stratification of volunteers by their absorption/excretion capability was suggested to be desirable in nutritional studies.[4]

The aim of this study was to evaluate the effect of the high-pressure homogenization versus conventional pasteurization on citrus juice flavanone bioavailability in humans. This will be assessed by taking into account the stratification of volunteers in different flavanone absorption/excretion levels.

MATERIALS AND METHODS

Orange Juices. Fruits from a *Citrus* hybrid between mandarin and sweet orange (*Citrus sinensis* L. var. 'Ortanique') were harvested at optimal maturity index during the season 2011−2012 from an orchard located in Lliria (Valencia, Spain) and kept at 8 °C before being processed. Fresh hand-squeezed juice was prepared using a hand-squeezer (Braun MPZ22, Madrid, Spain) and then was filtered using a 2 mm steel sieve. The juice was immediately consumed after preparation. High-pressure homogenized (HPH) juice was previously tempered at 31 °C in a steam-jacketed kettle and homogenized at 150 MPa in a high-pressure homogenizer (NS3015H model, GEA Niro Soavi S.p.A., Parma, Italy). During homogenization, the juice was heated at 68 °C for 10 s, and when it reached the outlet section of the system, it was immediately cooled at 7 °C in a plate heat-exchanger (model junior, APV Ibérica S. A., Madrid, Spain). Samples were bottled also in 1 L glass jars with twist-off lids (both previously sterilized with fluent steam). Conventional pasteurization (CP) of samples was carried out using a plate heat-exchanger (model Junior, APV Ibérica S.A) fed at 1 L/min, where the juice was heated at 92 °C for 40 s and finally cooled at 7 °C, and aseptically bottled in 1 L glass jars with twist-off lids (both were previously sterilized with fluent steam).

Qualitative and Quantitative Analyses of Juice Flavanones. These were carried out as reported previously by HPLC-DAD-MS.[4] The different flavanones were quantified as hesperidin.

Volunteer Stratification and Intervention Study. Volunteers' (n = 18) flavanone absorption/excretion capability after the intake of orange juice had been characterized in previous studies.[4] All volunteers had a consistent behavior over the past two years regarding their individual capability for flavanone excretion after orange juice consumption. High, medium, and low excretors were identified. High (flavanone excretion values >10% of the ingested flavanones), medium (excretion values between 5 and 10%), and low excretors (excretion values < 5%) were characterized. A crossover study (10 males and 8 females; 20−50 years old) was carried out as reported previously.[4] The volunteers ingested 400 mL of the juices. Flavanone intake was quoted as hesperetin and naringenin equivalents.

Analysis of Flavanone Metabolites in Urine. Volunteers collected 24 h urine, and samples were stored and processed as reported previously.[4] Phase II metabolites of flavanones were identified and quantified by a UPLC 1290 Infinity series (Agilent Technologies) equipped with a triple-quadrupole mass spectrometer (6460 Jet Stream series, Agilent Technologies).

A Poroshell 120 C18 column (100 × 3.0 mm i.d., 2.7 μm) (Agilent, Palo Alto, CA, USA) was used at room temperature, and the injected volume was 3 μL. Gradient elution was carried out using water/formic acid (99:1, v/v) and acetonitrile at a constant flow rate of 0.5 mL/min. The gradient used was [t (min), % acetonitrile v/v] (0, 1), (10, 40), (12, 90), and (15, 1).

The optimum mass spectrometer parameters for detection of hesperetin and naringenin aglycones, hesperetin 7- and 3′-glucuronide,

[a]Values are expressed as mg/100 mL. [b]Standard deviation (n = 3). Means followed by the same letter are not significantly different according to Duncan's test (P < 0.05).

naringenin 7- and 4′-glucuronide, and hesperetin 7- and 3′-sulfate (50 μM) were optimized, connecting directly the column to the Jet Stream. Pure standards were synthesized by Villapharma (Murcia, Spain).

Source parameters were as follows: capillary voltage, −3500 V; charging potential, −500 V; nebulizer pressure, 40 (psi); auxiliary gas, heated to 275 °C and introduced at a flow rate of pure nitrogen, 9 L/min. The multiple reaction monitoring (MRM) method monitored five transitions for each analysis: hesperetin, m/z 301→164; hesperetin glucuronide, m/z 477→301; hesperetin diglucuronide, m/z 653→(477)→301; hesperetin sulfoglucuronide, m/z 557→(477)→301; hesperetin sulfate, m/z 381→301, with a dwell time for each transition of 8 ms. Concentrations of hesperetin diglucuronide and hesperetin sulfoglucuronide metabolites were estimated by synthesized hesperetin glucuronide calibration curves (20, 10, 5, 2.5, 1 μM). For naringenin, metabolites were as follows: naringenin, m/z 271→113; naringenin glucuronide, m/z 447→271; naringenin diglucuronide, m/z 623→(447)→271; naringenin sulfoglucuronide, m/z 527→(447)→271; naringenin sulfate, m/z 351→271, with a dwell time for each transition of 8 ms. Concentrations of naringenin diglucuronide and naringenin sulfoglucuronide metabolites were estimated by synthesized naringenin glucuronide calibration curves (20, 10, 5, 2.5, 1 μM).

Limits of quantification (LOQs) were 80, 50/80, and 40/50 nM for hesperetin, hesperetin 7- and 3′-glucuronides, and hesperetin 7- and 3′-sulfates, respectively. Limits of detection (LODs) were 30, 20/30, and 15/20 nM, respectively. In the case of naringenin metabolites, LOQs were 30 and 70/500 nM for naringenin and naringenin 7- and 4′-glucuronides, and LODs were 10 and 20/200 nM, respectively.

The intraday repeatability of the UPLC-QqQ method was assessed from 10 consecutive chromatographic runs using a standard solution with 2.5 μM of every standard in MeOH/0.1% (v/v) formic acid. The interday repeatability of the method was assessed by analyzing the same standard solution for two consecutive days. The relative standard deviation (RSD) for peak area was in the range of 0.5−4.7% in the intraday test and 1.3−3.5% in the case of the interday test. Finally, an analysis of variance (ANOVA) was carried out, and means were separated by Duncan's test (P < 0.05%).

RESULTS AND DISCUSSION

Table 1 shows that both pasteurized (CP) and homogenized (HPH) juices had similar flavanone contents with slight differences in the soluble and cloud fractions. The particle size, however, was much smaller in the homogenized juice (Figure 1). The flavanone content of fresh hand-squeezed orange juice was considerably lower than those of thermally processed juices, consistent with the milder extraction process and the lack of a cloud fraction in the fresh juice. However, flavanones were mainly in the soluble phase.

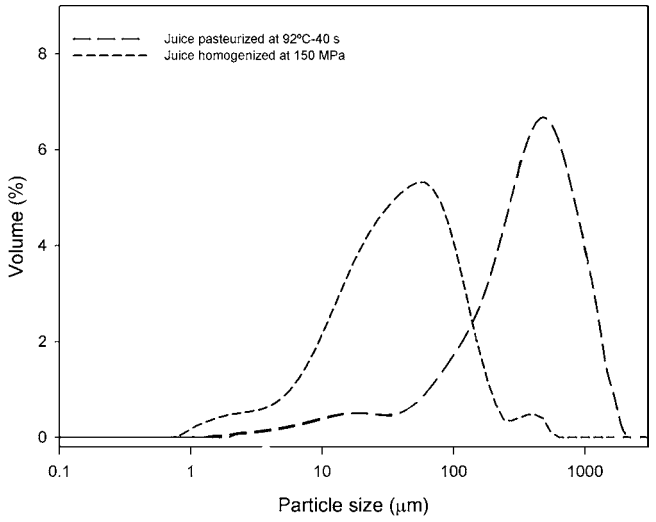

Figure 1. Representative particle size distribution of citrus juices produced by conventional pasteurization (CP) and high-pressure homogenization (HPH).

After juice intake, either hesperetin 7-sulfate or 7-glucuronide was the most abundant urinary metabolites. Their isomers in the 3′-position were found in lower concentrations (between 2 and 5 times). Hesperetin sulfoglucuronide and hesperetin diglucuronide were minor metabolites. The same trend was found for naringenin metabolites.

Volunteers were stratified after the intake of fresh orange juice, and high excretors showed mean excretion values of 15% of the flavanone intake; medium excretors, 9%; and low excretors, 3%, after fresh juice intake (Figure 2).

Homogenization and pasteurization led to a decrease in the percentage of ingested flavanones that were excreted with regard to hand-squeezed juice (Table 2; Figure 2A). This decrease was not observed when only the soluble flavanones were considered.

The total excretion percentage of fresh hand-squeezed orange juice reached mean values of 8.1 and 11.0% for hesperetin and naringenin, respectively (Table 2). Those values were in the range of previous papers.[9,10]

High flavanone excretors showed no significant differences in flavanone excretion (% ingested dose) after the intake of fresh

hand-squeezed orange juice and that of HPH juices, whereas differences with fresh juice persisted for both medium and low excretors (Figure 2B). High excretors must have a gut microbiota very active in releasing hesperetin from hesperidin, and therefore they take advantage of the smaller cloud particle size in the HPH juice with more hesperidin available to interact with the gut bacteria than in pasteurized juice. Meanwhile, the lower levels of the appropriate microbiota to hydrolyze rutinosides in the medium and low excretors did not allow enhanced flavanone bioavailability when the flavanone accessibility was improved, and no significant differences between HPH and pasteurized juices were found (Figure 2).

Although pasteurized juice showed the lowest absorption and excretion rates, high excretors were able to maximize flavanone absorption up to 49 and 57% higher than those of the low excretors for both hesperetin and naringenin, respectively (Table 2).

The results show that high flavanone excretors have the appropriate microbiota and the intestinal transporters necessary to efficiently absorb and excrete flavanones after orange juice intake and can better benefit from improvements in flavanone solubility and accessibility than low excretors who do not respond in the same way.

The amounts of hesperetin glycosides present in the soluble fraction of the three juices obtained were quite similar, ranging between 9.1 mg/100 mL for fresh hand-squeezed and 12.1 for the HPH juice (Table 1). Thus, the relative urinary excretion expressed as percentage of the soluble intake was calculated. This ranged for all excretors from 7.7% for the pasteurized juice to 10.1% for the homogenized juice with no statistically significant differences among treatments (Table 2). The same trend was found for naringenin equivalents present in the soluble fraction. Therefore, the intake of similar amounts of soluble flavanones leads to similar relative urinary excretion of metabolites. However, significant differences in excretion were found when volunteers were stratified for their excretion capabilities. Thus, the differences observed for flavanone excretion after the intake of HPH and CP juices by high excretors clearly indicated that other juice characteristics, such as particle size, can also be relevant for absorption in addition

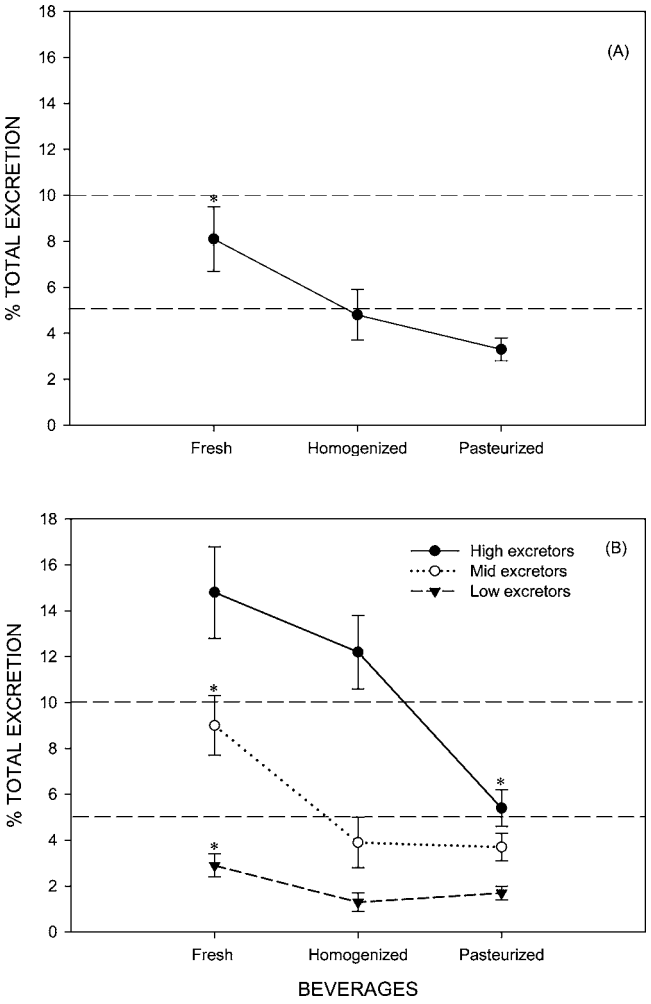

Figure 2. Urinary excretion of hesperetin after the intake of juices produced by different technological treatments in volunteers stratified as high, medium, and low excretors: (A) mean values for all volunteers (n = 18); (B) stratification in high (n = 4), medium (n = 7), and low (n = 7) excretors. Error bars are standard errors. Values are percentage of the total hesperetin intake excreted in urine. *, $p < 0.05$, significantly different according to Duncan's test.

to flavanone solubility, in agreement with previous results on carotenoid bioavailability.[11]

These results suggest that volunteer stratification for flavanone excretion should be considered in future studies to evaluate the bioavailability and health effects of citrus flavanones.

Supporting Information

ABSTRACT: Regarding their relevance for the fungal resistance of mangoes in long supply chains, the alk(en)ylresorcinols (AR) were quantitated in peel and mesocarp throughout storage (27 days, 14 °C, ethylene absorption). The 12 'Chok Anan' and 11 'Nam Dokmai #4' lots picked between 83 and 115 days after full bloom (DAFB) had different harvest maturity indices. The development of dry matter and fruit growth indicated physiological maturity ~100 DAFB. During storage, all fruits ripened slowly, mostly until over-ripeness and visible decay. The total AR contents always ranged at 73 ± 4.5 and 6.4 ± 0.7 mg hg^{-1} of 'Chok Anan' and 'Nam Dokmai #4' peel dry weight, respectively, but only at 6.7 ± 0.7 and 0.9 ± 0.1 mg hg^{-1} for the corresponding mesocarp ($P \leq 0.05$). These narrow concentration ranges were contradictory to the decreasing fungal resistance. Accordingly, the alk(en)ylresorcinols have not been a deciding factor for the fungal resistance.

INTRODUCTION

Prevalent plant diseases in mango crops such as anthracnose and black spot disease, which are caused by *Colletotrichum gloeosporioides* (Penz.) Penz. & Sacch. and *Alternaria alternata* (Fr.) Keissl., respectively, remain quiescent after fungal infection of the fruit on the tree until the onset of ripening after harvest.[1] The diseases are controlled by preharvest application of fungicides and postharvest hot-water dipping baths, which may include added fungicides. Consideration of the natural defense system might contribute to avoiding the use of fungicides, which are unacceptable in some destination areas.[1] Among the antimicrobial compounds of the mango fruit,[2,3] alk(en)ylresorcinols[4] (AR) are thought to restrain the development of anthracnose and *Alternaria* rot[5,6] and may be an alternative to synthetic fungicides.[7,8] Termination of fungal quiescence by the onset of fruit ripeness coincided with a significant decline of the AR contents in the peel.[1,5,6,9] Cultivar-specific resistance to anthracnose and infections by *A. alternata* were related to the AR contents of the mango peel[5,9] and more recently to those of the mango sap.[10]

The AR presumably play different roles as barrier-forming allelochemicals and phytoanticipins[11] in a mango-specific plant defense system.[12] The latter involves a longitudinal multilayered network of branching resin ducts in the outer region of the mango pericarp with a cultivar-specific mean number of ducts per cross-section area that has been correlated with the resistance to fruit flies.[13] This network of resin ducts pervades the fruit and thus also occurs in the inner mesocarp regions and the base.[14] Epithelial cells secreting the lipophilic sap fraction,[15] which displays cultivar-specific profiles of monoterpenes[16] as bioactive ingredients[17] besides AR,[10] were distinguished from those releasing a mucilaginous sap fraction.[18] This hydrophilic fraction contains several enzymes[19] as typical defense proteins,[12] especially a laccase-type polyphenol oxidase (PPO)[20,21] and peroxidase (POD).[21] Conventionally, the commercial harvest time is before the onset of mango ripening on the tree, when sap flow is still occurring.[22] Because the abscission zone of mangoes is penetrated by two separate duct systems (i.e., that of the fruit and that of the stalk),[14] irritant sap spurting and oozing from the abscission point may cause sapburn, which is prevented in fresh-fruit marketing by postharvest desapping of the fruit.[10]

Being phenolic lipids, the AR consist of a resorcinol moiety that is linked to an alk(en)yl chain, by analogy with the catechol-based urushiols of other Anacardiaceae species.[23] The chain varies in length, mostly between C_{15} and C_{19}, and in the degree of unsaturation. Among a range of AR homologues in *Mangifera indica* L., heptadecenyl- ($C_{17:1}$), heptadecadienyl- ($C_{17:2}$), and pentadecylresorcinol ($C_{15:0}$) are prevalent.[9,10,24−26] Due to their amphiphilic nature,[27] their numerous biological activities, for example, antimicrobial, antiparasitic, anticancer, anti-inflammatory, and cytotoxic properties, chiefly involve effects on the structure and function of membranes as well as the interaction with proteins, including effects on membrane-related enzyme activities.[23,28] Via the analogous interaction with cytoplasmic membranes of epidermal cells, the AR of mangoes act as haptens, causing allergic contact dermatitis after sensitization. Cross-sensitivity between AR and urushiols may occur,[24,29] but the resorcinol moiety of AR needs initial hydroxylation for subsequent *o*-quinone formation.[23]

Consistent with a notable susceptibility of 'Nam Dokmai' fruit to anthracnose,[7,30] extremely low AR contents had been reported for this cultivar.[9,10,26] With regard to the suitability of 'Chok Anan'[31] and 'Nam Dokmai #4'[32] fruit for long supply chains, we have recently described the impacts of different maturity stages at harvest on the properties of the mangoes during postharvest storage for up to 27 days at 14 °C under ethylene absorption. Apart from their different sensitivities to chilling injury[33] and the preferential distribution channels,[34,35] the two cultivars differed in their characteristic harvest maturity criteria and in their suitability for storage.[31,32] In the present follow-up study, the AR profiles were specified for both the peel and the mesocarp of these fruits[31,32] as a function of harvest time, maturity stage at harvest, and postharvest quality and ripeness during cold fruit storage, respectively. The aim was to identify the relevance of the AR for the shelf life of the fruit in long supply chains concerning options for their control by appropriate timing.

MATERIALS AND METHODS

Plant Material. As detailed previously,[31,32] fresh 'Chok Anan' (C) and 'Nam Dokmai #4' (N) mango fruits (*M. indica* L.) were obtained from research orchards in Mae Jo and San Sai (northern Thailand), respectively, during the main harvest season in April−May 2008. For both cultivars, the usual commercial harvest time (UCH) is ∼100 days after full bloom (DAFB) in this region.[31,36] Picking of the fruit every 6 days around the expected UCH of each cultivar resulted in five harvest days between 83 and 107 DAFB for 'Chok Anan' (C1−C5, Figure 1) and between 91 and 115 DAFB for 'Nam Dokmai #4' (N1−N5), respectively.[31,32] Each time, ∼300 fruits were picked from 10 trees at different positions within the canopy. To specify their maturation times on the tree, the average DAFB until each of the 10 harvest dates was estimated, because DAFB-precise harvest of individual fruits would have required tagging of the flowers and continuous evaluation of the field temperature. After their transportation to Chiang Mai University under passive-air cooling, they were washed to remove leaked sap. To minimize sap exudation during transport and subsequent sapburn during storage,[14,22] the fruits had been severed ∼10 cm above the stem end of the pedicel, which was cut back to 1 cm just before washing. Being nonuniform batches, the fruits of each harvest day were sorted into two or three categories *A*−*C* (Figure 1) according to their peel color that was rated visually, on the basis of the RHS color chart.[31,32] Because the measured peel color varied significantly within each category across the harvest period in similar ranges as it did across the three categories on each harvest day, the 12 'Chok Anan' and 11 'Nam Dokmai #4' fruit lots that resulted from the five harvest dates per cultivar were explored as individual variants of specific harvest maturity (C1*A*−C5*C* and N1*A*−N5*C*, respectively; Figure 1).[31,32]

The fruits of each variant were stored in cardboard boxes for up to 27 days at 14 °C and 50−60% relative humidity (RH) in the presence of ethylene absorbers ($KMnO_4$) to delay ripening (Figure 1).[31,32] Rotten fruits were removed immediately. To complete the previously reported characterization of the variants after 1, 10 ± 1, 18 ± 1, and 27 days of storage[31,32] by AR analyses, three fruits without visible defects were manually peeled per variant with a stainless steel mango peeler on each of those days for the sampling of peel and mesocarp (Figure 1). The latter was cut into cubes (∼1 cm^3). The strip-shaped peel samples (∼1−2 mm thickness) represented the skin plus residual pulp, which was attached to the skin after fruit peeling. For the AR analyses, these peel and mesocarp samples were ultrarapidly frozen in liquid nitrogen, freeze-dried, vacuum-packed in polyethylene pouches, and stored at −80 °C until airfreight transport (∼ −40 °C) to Hohenheim University. There, the freeze-dried samples were pulverized in a laboratory blender (Waring, Torrington, CT, USA) after immersion into liquid nitrogen. The powders were vacuum-packed in polyethylene pouches and stored (−20 °C) until analysis.

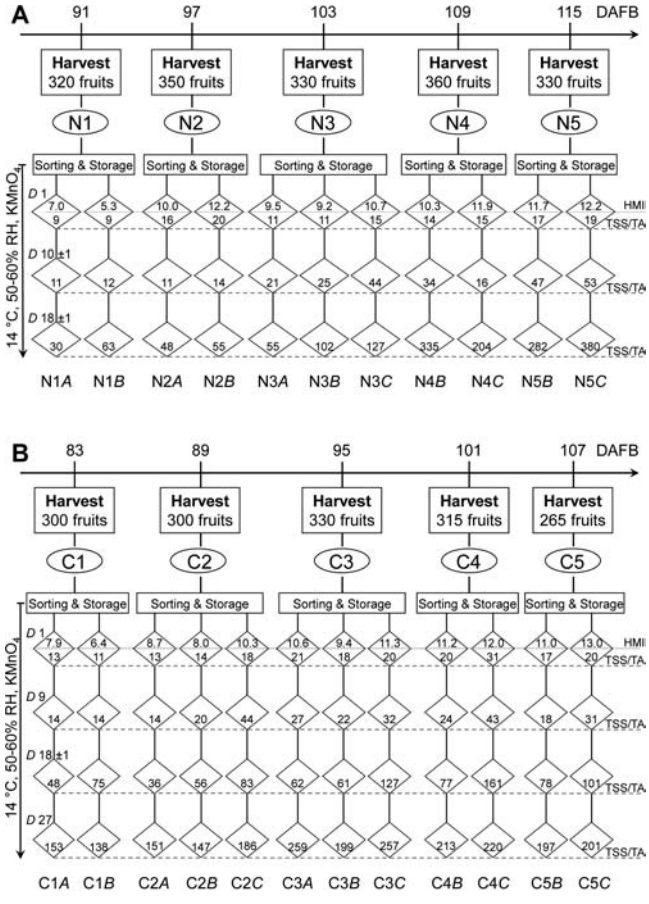

Figure 1. Experimental design, based on (**A**) 'Nam Dokmai #4' (N) and (**B**) 'Chok Anan' (C) fruits that were picked on five days between 91 and 115 days and between 83 and 107 days after full bloom (DAFB), respectively. Sorting of the fruits of each batch (N1−N5, C1−C5) into the categories *A*−*C* directly after the harvest yielded the variants N1*A*−N5*C* and C1*A*−C1*C*, respectively, which were immediately stored at 14 °C (50−60% RH, $KMnO_4$).[31,32] Each variant was composed of 110−180 fruits for 'Nam Dokmai #4' and 57−213 for 'Chok Anan'. On several days (*D*) of storage (rhombs), aliquots of each variant were used for the analysis of alk(en)-ylresorcinols and a range of attributes reported earlier,[31,32] such as the reproduced sugar/acid ratios (TSS/TA), which rose disproportionately with increasing fruit ripeness. On day 1, each variant was also specified by the harvest maturity index (HMI, Tables 4 and 5), which rose with increasing maturity.

Sample Preparation for the Analysis of Alk(en)ylresorcinols. Alk(en)ylresorcinol extraction from the pulverized peel was performed in duplicate. The method of Knödler et al.[25] was slightly modified to facilitate the procedure. Aliquots of 2.5 g of peel powder were extracted with 50 mL of dichloromethane in a capped 100 mL glass bottle by continuous stirring at room temperature for 1 h under a N_2 atmosphere. Centrifugation[25] was replaced by filtration through a Büchner funnel with filter paper no. 4 (Whatman, Maidstone, UK) to separate the solids from the crude extract. The residue was extracted with 50 mL of dichloromethane for 30 min.[26] Evaporation of the combined filtrates in vacuo at 30 °C left a residue that was dissolved in 10 mL of dichloromethane. Its solid-phase extraction (SPE) on polyamide (2 g, 0.05−0.16 mm; Carl Roth, Karlsruhe, Germany), filled in Econo-Pac columns (Bio-Rad, Munich, Germany), followed, after the sorbent had successively been conditioned with 20 mL of methanol and 25 mL of dichloromethane. The peel extract was applied to the column, the latter was washed with 25 mL of dichloromethane, and the AR were recovered by elution with 50 mL of methanol. After evaporation of the eluate in vacuo (30 °C), the dried residue was

dissolved in 0.5 mL of methanol and membrane-filtered (0.45 μm) into vials for HPLC and LC-MS analyses, respectively.[25]

The mesocarp powder was initially extracted in the same way to identify the AR homologue profile by LC-MS analysis. Because only the three major AR homologues **3**–**5** (Table 1) were quantifiable in the pulp (cf. Figure 2), a simpler and faster method without SPE and the hazardous dichloromethane was developed for the AR quantitation in the pulp samples. Comparative application of both extraction methods to two or three pulp samples of each cultivar showed no significant effects on the analytical results ($P \leq 0.05$; data not shown).

dx.doi.org/10.1021/jf4028552 | J. Agric. Food Chem. 2014, 62, 28–40

The carotenoids, which were present in the crude mesocarp extract without SPE on polyamide, did not interfere with the quantifiable AR compounds **3**–**5** during HPLC analysis. Only the quantitation of the minor compounds **6**–**8** (Table 1), traces of which were otherwise maximally detectable in the pulp, would have been affected by coelution of a few of the carotenoids. Hence, the mesocarp powder was finally analyzed in duplicate by extracting each aliquot (2.5 g) with 50 mL of ethyl acetate in a capped 100 mL glass bottle by continuous stirring at room temperature for 1 h under a N_2 atmosphere. The extract was filtered through a Büchner funnel with Whatman filter paper no. 4. The residue was extracted with 50 mL of ethyl acetate (30 min). Evaporation of the combined filtrates to dryness in vacuo (30 °C) left a residue that was dissolved in methanol (0.5 mL) and membrane-filtered (0.45 μm) into vials for HPLC analysis.

HPLC and LC-MS Analyses of Alk(en)ylresorcinols. Each extract was analyzed by the injection of 10–75 μL into a HPLC system described elsewhere.[25] The AR were separated on a 150 mm × 3.0 mm i.d., 3 μm, C18 Aqua column (Phenomenex, Torrance, CA, USA) with a 4.0 mm × 2.0 mm i.d. C18 ODS guard column. Gradient elution at 25 °C and a flow rate of 0.6 mL min^{-1} involved the eluents A (100% redistilled water) and B (100% methanol). To remove the chlorophylls of pigment-containing extracts from the column completely, the gradient program of Knödler et al.[25] was amended as follows: from 17 to 9% A (20 min), 9% A isocratic (10 min), from 9 to 0% A (5 min), 0% A isocratic (15 min), from 0 to 17% A (0.1 min), 17% A (5 min). The total run time was 55 min. Detection of the AR was at 275 nm, while their UV–vis spectra were recorded in the range of 200–600 nm.

The same HPLC system was connected to an Esquire 3000+ ion trap mass spectrometer with an APcI source (Bruker, Bremen, Germany) for the LC-MS analyses, which were performed as detailed elsewhere.[25] The AR of the extracts were separated under the HPLC conditions described above. Positive ion mass spectra of the column eluate were recorded in the range of m/z 100–500.[25] Nitrogen served as the drying gas at a flow rate of 5 L min^{-1} and as the nebulizing gas at a pressure of 65 psi.

By analogy with Knödler et al.,[25] the individual compounds were identified by their retention times and their UV and mass spectra. The AR contents in the peel of each cultivar and in 'Chok Anan' pulp were calculated from linear seven-point calibration curves of the respective reference standards (5–1000 mg L^{-1} for 5-pentadecylresorcinol; 10–2100 mg L^{-1} for 5-heptadecylresorcinol) at 275 nm. Due to the very low alk(en)ylresorcinol contents of 'Nam Dokmai #4' pulp, five-point calibration curves of 5-pentadecylresorcinol (0.78–78 mg L^{-1}) and 5-heptadecylresorcinol (0.75–75 mg L^{-1}), respectively, were used for those samples. Because no reference standards were available for the unsaturated compounds, the calibration curve of the corresponding saturated standard substance was used in these cases, together with a molecular weight correction factor (CF; Table 1).[37] The contents of 5-nonadecenyl- and 5-nonadecadienylresorcinols were analogously obtained from the calibration curve of 5-heptadecylresorcinol. The two reference standards (HPLC purity ≥ 95%; S1 and S2 in Table 1) were from Sigma-Aldrich (St. Louis, MO, USA). All reagents and solvents were of analytical or HPLC grade (VWR, Darmstadt, Germany).

Statistical Analyses. Multiple pairwise comparisons of means (Tukey's tests), using SAS 9.1 (SAS Institute, Cary, NC, USA), yielded the significant differences between the variants ($P \leq 0.05$).

RESULTS AND DISCUSSION

Characteristic Alk(en)ylresorcinol Homologues in Mango Peel and Pulp. Because the available reference standards included only 5-pentadecylresorcinol (S1: $C_{15:0}$) and 5-heptadecylresorcinol (S2: $C_{17:0}$), the identity of the alk(en)ylresorcinol homologues occurring in the peel and mesocarp of both cultivars had to first be confirmed by HPLC-DAD-MS^n (Table 1). For this purpose, two or three samples of peel and pulp, respectively, were examined per cultivar. Purification of their dichloromethane extracts by solid-phase extraction excluded potential interference of coextracted carotenoids. The UV spectrum of each alk(en)ylresorcinol homologue showed the typical absorbance maxima of the 1,3-dihydroxybenzene chromophore at 275 and 280 nm (Table 1). By the presence of the latter maximum as a shoulder of the first one, the AR were clearly distinguishable from alkylcatechols.[38]

Eight alk(en)ylresorcinol homologues were found in all peel samples (Figure 2A,B) and in 'Chok Anan' mesocarp (Figure 2C), but only five of them in the pulp of 'Nam Dokmai #4' fruit (Figure 2D). Regardless of the cultivar and the part of the fruit, the main compound (Figure 2) was confirmed[9,10,24–26] to be 5-heptadecenylresorcinol (**5**; $C_{17:1}$), producing a $[M + H]^+$ ion of m/z 347 (Table 1). The second most important one was 5-heptadecadienylresorcinol (**3**; $C_{17:2}$; m/z 345). Oka et al.[24] had isolated the two AR from mango peel to describe their contact allergenic activities. After localization of the double bonds by 1D and 2D NMR, Knödler et al.[28] assigned their structures to 5-(11′*Z*-heptadecenyl)resorcinol and 5-(8′*Z*,11′*Z*-heptadecadienyl)resorcinol, respectively. The third major compound (Figure 2) was again[26] 5-pentadecylresorcinol (**4**; $C_{15:0}$; m/z 321) that yielded a stable fragment at m/z 111 (Table 1) due to protonation of the aromatic system. The latter is typical of saturated AR.[25] In addition, compound **4** had the same characteristics that the reference standard S1 revealed for the $C_{15:0}$ homologue (Table 1). Unlike 'Chok Anan' mesocarp, 'Nam Dokmai #4' pulp contained only traces of **4** (Figure 2D).

The other alk(en)ylresorcinol homologues were the minor compounds **1**, **2**, and **6**–**8** (Table 1). Quantitation of all five was feasible only for 'Chok Anan' peel (Figure 2A). The quantifiable minor alk(en)ylresorcinol homologues of 'Nam Dokmai #4' peel were restricted to **1** and **8**, because those samples contained merely traces of **2**, **6**, and **7** (Figure 2B). In all of the mesocarp samples, none of the minor compounds could be quantitated, because only traces of them were found, either for all five ('Chok Anan', Figure 2C) or simply for **1** and **2** ('Nam Dokmai #4', Figure 2D). The minor compounds included the second saturated alk(en)ylresorcinol homologue. Consistent with Knödler et al.,[25] it occurred in a number of samples (Figure 2) and proved to be 5-heptadecylresorcinol (**7**; $C_{17:0}$; m/z 349). Its identity was confirmed by the reference standard S2 (Table 1). The monounsaturated minor compounds were 5-pentadecenylresorcinol (**2**; $C_{15:1}$) and 5-nonadecenylresorcinol (**8**; $C_{19:1}$), which implicated $[M + H]^+$ ions of m/z 319 and 375, respectively. Like the main compound **5** ($C_{17:1}$), they showed a single characteristic fragment at m/z 123 (Table 1) due to the formation of the 1,3-dihydroxytropylium ion by β-cleavage of the alkyl chain.[25] In contrast to the saturated and monounsaturated alk(en)ylresorcinol homologues, the di- and polyunsaturated ones (**1**, **3**, **6**; Table 1) chiefly yielded product ions at m/z 123, 137, 149, 163, and 177 in the MS^2 experiment. As detailed elsewhere,[25] this overall indicated unsaturated hydrocarbon chains for the major compound **3** ($C_{17:2}$) mentioned above and the minor compounds **1** and **6**. The latter two were 5-heptadecatrienylresorcinol ($C_{17:3}$; m/z 343) and 5-nonadecadienylresorcinol ($C_{19:2}$; m/z 373), respectively (Table 1).

On the whole, the same three major and five minor alk(en)ylresorcinol homologues that were reported earlier for the peel and pulp of other cultivars[26] were also found in these two varieties. However, the minor compounds of their pulp were unquantifiable ('Chok Anan') or, for the majority of them, even undetectable ('Nam Dokmai #4').

Alk(en)ylresorcinol Contents Observed after Different Harvest Times. Because the sap flow is known to vary with

the stage of maturation at harvest,[7,22] the occurrence of AR in the sap[10] might suggest analogous changes in the alk(en)ylresorcinol contents of the fruit. To test this hypothesis, the alk(en)ylresorcinol contents found 1 day after harvest were to be related to the fruit development stages observed at harvest between 83 and 115 DAFB (Tables 2 and 3). The 11 'Nam Dokmai #4' (N1*A*−N5*C*; Table 2) and the 12 'Chok Anan' fruit variants (C1*A*−C5*C*; Table 3), which were distinguished per cultivar by their on-tree maturation periods (DAFB) plus the assigned category *A*−*C* (Figure 1), also differed in the dry matter (DM) of the pulp[31,32] and in the fruit mass (Tables 2 and 3), which were recorded 1 day after harvest and on the picking day, respectively. Local experience had shown that the fruit in this growing region can generally be expected to be fully mature ∼100 DAFB, being the usual commercial harvest time (UCH).[31,36] Accordingly, the seed development as well as fruit growth and the accumulation of dry matter should be completed then, being a prerequisite for the full potential of subsequent ripening. Consequently, physiological maturity may be identified retrospectively by the onset of the plateau levels that fruit size and dry matter should have reached within the constraints of the surrounding conditions.[8] DM had thus been recommended as a maturity indicator to distinguish mature from immature fruit.[39]

For the 'Nam Dokmai #4' fruit, the growth phase ended ∼97 DAFB (N2) according to the DM plateau shown by all variants picked 97−115 DAFB (N2−N5) (Table 2).[32] The fruit mass increased from the first (N1, 91 DAFB; 268−270 g) to the last harvest (N5, 115 DAFB; 349−353 g), but the differences were insignificant between 97 and 109 DAFB (N2−N4; 291−307 g) (Table 2). The mass of the N1 fruit was equal to the relatively small size reported by Vásquez-Caicedo et al.[34] for ripe fruit of this cultivar (271 g), but the cited value might also be due to the influence of the fruit load of the tree. A decrease by 0.14 g for every extra fruit was stated for 'Kensington Pride' mangoes.[40]

Because the development of the 'Chok Anan' fruit on the tree was overall less uniform (in terms of peel color[32] and fruit mass), the stage of physiological maturity was less evident. The fruit masses of the 'Chok Anan' variants tended to increase from 179 g (C1*A*) 83 DAFB to 277 g (C5*C*) 107 DAFB (Table 3). However, the fruits of each harvest day greatly varied in size, which always rose from category *A* to *C* (Table 3). Within each of the categories *B* and *C*, the fruit size was constant for 'Chok Anan' between 95 and 107 DAFB (C3−C5). In addition, these latter seven variants and a few of the C2 lots (89 DAFB) presented a constant maximal DM (19−23 g hg^{-1}; Table 3).[31] The end of the 'Chok Anan' growth phase was thus deemed to be 95 DAFB (C3). Similarly, an increase in fruit size from 227 to 239 g between 84 and 100 DAFB[41] and an average fruit mass of 275 g at the ripe stage[34] were reported earlier for 'Chok Anan' fruit of the study area, whereas fruits below 200 g are usually considered unmarketable.[42]

For both cultivars, the end of the growth phase 95−97 DAFB (N2, C3) was thus indeed just before the estimated UCH (100 DAFB), which was just before the 'Nam Dokmai #4' harvest N3 (103 DAFB) and coincided with C4 (101 DAFB) for 'Chok Anan'. However, ethylene production was not yet detectable 1 day after harvest for any of the 23 variants.[31,32]

According to the alk(en)ylresorcinol levels of the peel ($c_{AR,p}$) 1 day after harvest, the variants of each cultivar could be separated into two $c_{AR,p}$ classes that clearly depended on the harvest time. For the peel of 'Chok Anan' fruit that was already picked 83−101 DAFB (C1−C4; i.e., until UCH), $c_{AR,p}$ usually amounted to 67−88 mg hg^{-1} of dry weight (DW). By contrast, the peel of the two C5 variants, which were picked last (107 DAFB; i.e., clearly after UCH), showed $c_{AR,p}$ levels of merely 51−58 mg hg^{-1} (Table 3). Only variant C2*C* (fruit of the category *C* from the harvest C2 89 DAFB) insignificantly differed in the $c_{AR,p}$ from the two C5 variants (C5*B*, C5*C*). On average, the peel of the 10 'Chok Anan' variants forming the C1−C4 group had a $c_{AR,p}$ of 76 ± 8.9 mg hg^{-1} of DW (Table 3). It significantly differed ($P \leq 0.05$) from that of the C5 group (55 ± 5.5 mg hg^{-1}). However, compared to the 95% confidence interval (CI) of the mean for the former group (±6.4 mg hg^{-1}), that of the latter was high (±49 mg hg^{-1}).

For 'Nam Dokmai #4' peel, $c_{AR,p}$ (Table 2) reached only ∼one-ninth of the contents in 'Chok Anan' peel. Approximately until UCH, elevated $c_{AR,p}$ levels of 8.4−11.4 mg hg^{-1} of DW occurred between 91 and 97 DAFB (N1−N2; Table 2). Again, the fruit picked afterward (N3−N5, 103−115 DAFB) showed lower alk(en)ylresorcinol contents (3.3−7.6 mg hg^{-1}). Almost all last-mentioned 'Nam Dokmai #4' variants significantly differed from the first group ($P \leq 0.05$). The $c_{AR,p}$ group mean amounted to 9.4 ± 2.2 mg hg^{-1} of DW for the "until-UCH" group N1−N2, but dropped to the significantly ($P \leq 0.05$) lower average of 5.8 ± 1.3 mg hg^{-1} for the "post-UCH" group N3−N5 (Table 2). These ranges were met by the alk(en)ylresorcinol levels, which were reported for peel of the same cultivar by Knödler et al.[26] (79.33 mg kg^{-1} of DW) and Hassan et al.[9] (∼10−19 μg g^{-1} of FW; i.e., ∼5.0−9.5 mg hg^{-1} of DW, assuming 20% DM). Desapping, which was applied by Hassan et al.,[9] might lower the alk(en)ylresorcinol contents due to losses via the released resin. However, the data presented in Tables 2 and 3 referred to peel samples that were obtained without desapping of the fruit. They suggested that the $c_{AR,p}$ levels significantly fell after UCH.

Thus, cultivar-specific "until-UCH" ranges above ∼8 and ∼60 mg hg^{-1} of DW for the peel of 'Nam Dokmai #4' and 'Chok Anan', respectively, could be distinguished from "post-UCH" ranges below that limit. The time when the $c_{AR,p}$ drop was noticed (N3, 103 DAFB; C5, 107 DAFB) corresponded to the stage 3−6 days after UCH (i.e., 6−12 days after the onset of the DM and fruit mass plateaus 95−97 DAFB; Tables 2 and 3). However, because the fruit was picked only every 6 days, the significant decline of $c_{AR,p}$ might already have started up to 5 days earlier.

Nevertheless, the total alk(en)ylresorcinol contents of the mesocarp ($c_{AR,m}$) ranged rather uniformly at 0.6−1.6 mg hg^{-1} of DW around a grand mean of 1.0 ± 0.2 mg hg^{-1} for all 'Nam Dokmai #4' variants (Table 2) and at 5.5−9.8 mg hg^{-1} of DW around an average of 7.5 ± 1.0 mg hg^{-1} for all 'Chok Anan' lots (Table 3), regardless of the on-tree maturation time (91−115 and 83−107 DAFB, respectively). Consideration of DM resulted in the equivalent alk(en)ylresorcinol contents of the fresh mesocarp ($c_{AR,fm}$), being 0.1−0.3 mg hg^{-1} of fresh weight (FW) for 'Nam Dokmai #4' (Table 2) and 0.9−2.3 mg hg^{-1} for 'Chok Anan' (Table 3). The levels reported by Droby et al.[6] (1.5−2.1 mg hg^{-1} of FW) and Knödler et al.[26] (2.6−18.7 mg hg^{-1} of DW) for the pulp of various cultivars were comparable to those of 'Chok Anan' flesh. On a dry weight basis, the alk(en)ylresorcinol amounts in the pulp represented only ∼$^1/_{10}$ of the total AR contents in the peel (Tables 2 and 3), as already implied in Figure 2 for each cultivar.

Alk(en)ylresorcinol Contents of Fruits Differing in Harvest Maturity. Because the physiological maturity had been ascribed to the stages 95−97 DAFB (N2, C3) within the 24 days of examined on-tree maturation up to 115 DAFB, a clearer distinction of individual harvest maturity stages was of interest with respect to beginning ripening on the tree and its

[a]Similar HMI values indicated similar maturity stages among the 12 variants specified in Table 3. The variants comprising the most mature fruits 1 day after harvest were identified by the maximal HMI. [b]PC1 accounting for 41.4% of the variance represented the maturity on the first day (14 °C) after harvest by combining the contributions of the following mesocarp attributes *x* (Pearson correlation coefficients between PC1 and *x* in parentheses; $P \leq 0.05$, *; $P \leq 0.01$, **; $P \leq 0.001$, ***; $P \leq 0.0001$, ****):[31] contents of titratable acids (−0.92****), dry matter (0.83***), all-*trans*-*β*-carotene (0.62*), chlorophyll *b* (−0.47), chlorophyll *a* (−0.15), and total soluble solids (0.14), as well as mesocarp firmness (−0.47) and mesocarp color, the latter in terms of the yellow (b^*_m; 0.88***) and green (a^*_m; 0.74**) CIE values. [c]For the most relevant attribute (TA, mesocarp contents of titratable acids) and for the PC1 scores ($S_{PC1,C}$) converted into the HMI, the values stated earlier[31] are indicated.

possible impact on the alk(en)ylresorcinol contents. As detailed earlier,[31,32] the 11 'Nam Dokmai #4' and the 12 'Chok Anan' variants had been examined regarding similar maturity stages 1 day after harvest by principal component analysis (PCA) on the basis of characteristic pulp attributes (cf. footnotes of Tables 4 and 5). The effect of the maturity stage at this point was represented by the first principal component (PC1).[31,32] The content of titratable acids (TA) always contributed most to PC1, while low TA levels indicated advanced stages of maturity (Tables 4 and 5).[31,32] Whereas DM and the fruit mass were useful to estimate the point of full physiological maturity (Tables 2 and 3), TA and other pulp attributes had turned out to be even more relevant to distinguish the maturity stages 1 day after harvest by PC1 (Tables 4 and 5).[31,32] Because the PC1 score of a fruit variant ($S_{PC1,N}$ for 'Nam Dokmai #4'; $S_{PC1,C}$ for 'Chok Anan') thus characterized the maturity stage of that variant best,[31,32] it was converted into a cultivar-specific harvest maturity index (HMI) > 0 (Tables 4 and 5) to compare the variants of each cultivar more conveniently.

As already suggested by the TA contents that greatly varied within ranges of 0.55−1.09 g hg^{-1} for 'Nam Dokmai #4' (Table 4) and 0.39−0.9 g hg^{-1} for 'Chok Anan' (Table 5), the 11−12 variants of each cultivar had proven to differ widely in their maturity stages 1 day after harvest.[31,32] For each cultivar, the HMI roughly doubled from the least mature to the most mature variant (Tables 4 and 5). Due to the uneven development of the fruits, the variants, which corresponded to different categories *A*−*C* on a particular harvest day, differed in their maturity stages, especially in the case of 'Chok Anan'. However, all variants that were harvested after they had reached full maturity (N2−N5, 97−115 DAFB; C3−C5, 95−107 DAFB) displayed quite similar HMI levels (≥73% of the maximal HMI).

Most importantly, the variants of the above "post-UCH" groups with reduced alk(en)ylresorcinol contents of the peel (N3−N5, Table 2; C5, Table 3) and the fully mature N2 and C4 variants that were harvested just before the $c_{AR,p}$ drop had almost identical HMI values. Moreover, the marked changes of the mesocarp,[31,32] which were expressed by the increasing HMI (Tables 4 and 5), had no impact on the overall constant alk(en)ylresorcinol contents of the pulp ($c_{AR,m}$, Tables 2 and 3). The alk(en)ylresorcinol contents were thus independent of the mesocarp changes[31,32] that were associated with the maturation on the tree according to the fruit analyses 1 day after harvest. As discussed above, the two $c_{AR,p}$ classes of each cultivar on day 1 rather suggested an effect of the harvest time, which appeared to be related to the point of completed seed development.

Despite the great quantitative AR differences between the two cultivars, the fruits always displayed similar ratios of peel mass to mesocarp mass (Tables 2 and 3). Consequently, $c_{AR,p}$ was not influenced by the peel percentage of the fruit. The peel uniformly constituted 11.2 ± 1.4 and 12.2 ± 1.4 g hg^{-1} of the fruit mass for 'Nam Dokmai #4' and 'Chok Anan', respectively

dx.doi.org/10.1021/jf4028552 | J. Agric. Food Chem. 2014, 62, 28−40

(Tables 2 and 3), regardless of the on-tree maturation time and the maturity stage 1 day after harvest. It has to be taken into account that the peel consists of the fruit skin and adhering pulp. Together with the layer of the main vascular bundles, mesocarp firmness thus affects the peel thickness, which is chiefly defined by the ability of being peeled easily. The uniform peel percentages were consistent with the firmness that was reported earlier for the mesocarp of the fruit 1 day after harvest.[31,32] It also varied only slightly among all the variants of each cultivar, although the most mature variants N5*C* and C5*C* always proved to be the softest fruits within the narrow firmness ranges.[31,32]

Alk(en)ylresorcinol Contents Observed during Low-Temperature Fruit Storage. The findings of Droby et al.[5] regarding an AR drop from fungitoxic to nontoxic levels at adequate fruit ripeness after postharvest ripening may suggest that refrigeration can improve the AR retention during long-distance transports due to minimized respiration and ripening. In the cited study,[5] the total AR contents of the peel ($C_{17:1}$, $C_{15:0}$) insignificantly varied around 202 ± 13 μg g^{-1} of FW (~101 ± 6.5 mg hg^{-1} of DW, assuming 20% DM) within a period of 55 days before and 12 days after harvest for 'Tommy Atkins' fruit, which had been inoculated with *A. alternata* spores after picking. The authors noted a dramatic development of black spot symptoms at the ripe stage after 17 days, when the total alk(en)ylresorcinol content of the peel dropped by 50% to 103 μg g^{-1} of FW (~52 mg hg^{-1} of DW).[5] Alk(en)ylresorcinol contents in the latter order of magnitude were also shown by the 'Chok Anan' variants picked last (C5*B*/*C*, Table 3), but already 1 day after harvest. For noninoculated fruit of different varieties, Droby et al.[5] found 154−232 μg g^{-1} of FW (~77−116 mg hg^{-1} of DW) in the peel at the green-mature stage at harvest, but only 74−125 μg g^{-1} of FW (~37−63 mg hg^{-1} of DW) at the ripe stage, when disease symptoms developed in inoculated fruit after postharvest ripening. Such low alk(en)ylresorcinol levels (76 μg g^{-1} of FW) were also shown by the peel of ripe 'Tommy Atkins' fruit after ripening on the tree.[5] Hassan et al.[9] observed a significant postharvest drop of the predominant 5-*n*-heptadecenylresorcinol only between the "harvest" and the "sprung" stages.

By contrast, the 11 'Nam Dokmai #4' and 12 'Chok Anan' variants were not exposed to ripening conditions after the harvest, but stored at 14 °C (Figure 1) to test the above hypothesis by mimicking basic conditions of long supply chains. However, the application of ethylene absorbers and the minimum temperature, which was also tolerated by green-mature fruit without chilling injury, did not preclude slow ripening during storage, even though the ripening rates differed among the variants, as detailed earlier.[31,32] Accordingly, the TA contents always declined significantly, in addition to parallel softening and an increase in the total soluble solids (TSS), all-*trans*-β-carotene, and mesocarp yellowness (b^*_m).[31,32] As previously shown by multivariate analyses for each cultivar,[31,32] the quality that was reached by a few of the variants after a short time (e.g., N5*B*/*C* after 10 ± 1 days)[32] was also shown by others after longer storage (e.g., N2*A*/*B* after 18 ± 1 days).[32] The ripening rate of each variant could be described by the characteristic development of well-established ripeness indicators,[31,32] such as the disproportionately rising sugar/acid ratio (TSS/TA) and the postharvest ripeness index (RPI_{KS}),[43] which declines linearly after a possible lag phase. These two variables are compiled in the Supporting Information for the 'Nam Dokmai #4' (Table S1) and the 'Chok Anan' (Table S2) variants to compare the AR contents found after different storage times with the particular ripeness of each sample. A total increase of TSS/TA from 9 to 380 for 'Nam Dokmai #4' within 18 ± 1 days and from 11 to 259 for 'Chok Anan' within 27 days, while the RPI_{KS} overall declined from 11 to 3.4 and 4.3, respectively, indicated marked changes in ripeness.[31,32] In total, the 33 'Nam Dokmai #4' and 48 'Chok Anan' lots of all the sampling days represented a great number of different ripeness stages (Tables S1 and S2).

Unacceptably high TSS/TA ratios ≥102 indicated over-ripeness or decay on day 18 ± 1 for N3*B*/*C* and all N4−N5 variants (Table S1), which were previously deemed to be semi-fast-ripening and fast-ripening, respectively, and together constituted >50% of the 'Nam Dokmai #4' variants.[32] After this storage time, microbial spoilage of individual fruits had been observed among those variants.[32] For this cultivar, postharvest storage with parallel AR analysis was thus only feasible until that time. For 'Chok Anan', the variants comprising fruit of category *C* showed this fast-ripening behavior (C2/3/4/5*C*, Table S2), whereas over-ripeness and notable decay of individual fruits were noted on day 27 for all 12 variants.[31] However, the variants that were harvested as soon as their pulp had adopted predefined values for a range of key attributes just before UCH ripened only moderately during storage[31,32] and thus proved to be most suitable for long supply chains. These were the two 'Chok Anan' variants C2*A* and C2*B* that were picked 89 DAFB (Table 3) at a stage of mesocarp attributes,[31] which corresponded to a HMI of ~8−9 (Table 5). For 'Nam Dokmai #4', such storage behavior was shown by N2*A* and N2*B*[32] that were harvested 97 DAFB (Table 2). The storage behavior of this cultivar depended on the on-tree maturation time rather than on the HMI-related pulp properties.[32] One day after harvest, the variants N2*A* and N2*B* even had HMI levels (~10−12) in the upper range (Table 4).

Despite the great changes in fruit ripeness, the total AR contents of peel ($c_{AR,p}$) and mesocarp ($c_{AR,m}$) always varied within ranges, which were already found 1 day after harvest (Tables S1 and S2). They were not correlated with the ripeness indicators. The Pearson correlation coefficients between $c_{AR,p}$ and RPI_{KS}, for example, were only 0.23 for 'Nam Dokmai #4' (n = 33) and −0.15 for 'Chok Anan'(n = 48).

For the aforesaid "until-UCH" group of 'Nam Dokmai #4' (N1−N2), the elevated mean AR content of the peel 1 day after harvest (9.4 ± 2.2 mg hg^{-1} of DW, Table 2) significantly fell by 38% during storage to an average level of 5.8 ± 0.9 mg hg^{-1} for the days 10−18 ($P \leq 0.05$). This decline seemed to correspond to the AR drop by 50% that was mentioned above for 'Tommy Atkins' peel after 12 days of ripening at 20 °C.[5] After 10−18 days, the four N1−N2 variants thus showed the same mean $c_{AR,p}$ level that was found for the seven variants of the "post-UCH" group (N3−N5) both 1 day after harvest (5.8 ± 1.3 mg hg^{-1}, Table 2) and throughout storage (6.2 ± 1.2 mg hg^{-1} for days 10−18), despite the deviant behavior of variant N4*B* (Table S1). However, the apparent outlier N4*B* implied that $c_{AR,p}$ of 'Nam Dokmai #4' peel actually varied around a grand mean of 6.4 ± 0.7 mg hg^{-1} ($P \leq 0.05$) within the total postharvest storage time (Table 6). In the large "until-UCH" group of 'Chok Anan' (C1−C4) comprising 10 variants, the elevated $c_{AR,p}$ mean 1 day after harvest (76 ± 6.4 mg hg^{-1} of DW, Table 3) did not change during storage (73 ± 6.2 mg hg^{-1} for days 9−27). The $c_{AR,p}$ means of the two "post-UCH" variants C5*B*/*C* after 1 (55 ± 49 mg hg^{-1}, Table 3) and 9−27 days (74 ± 18 mg hg^{-1}) were not distinguishable from each other in view of the small number of variants in this group.

[a]Alk(en)ylresorcinol homologues **1**–**8** (cf. Table 1 and Figure 2) in % of the total content in peel and mesocarp respectively. [b]For the data of the individual samples, cf. the Supporting Information. [c]SD, standard deviation; 95% CI, confidence interval ($P \leq 0.05$). [d]Mean content ± 95% CI (DW, dry weight). [e]tr, traces. [f]In the mango mesocarp, only traces of the minor compounds were found (Figure 2).

On the whole, it proved debatable whether the harvest time (Tables 2 and 3) and the ripeness stage[5,9] have causal effects on the postharvest alk(en)ylresorcinol levels in the peel during the low-temperature storage. Even for the peel of over-ripe 'Chok Anan' fruits, no postharvest drop of $c_{AR,p}$ to non-fungicidal levels[1,5] was observed. The findings rather suggested a variation of $c_{AR,p}$ around a grand mean of 73 ± 4.5 mg hg^{-1} ($P \leq 0.05$) for 'Chok Anan' peel between harvest and day 27 of storage (Table 6).

Concurrently, the alk(en)ylresorcinol levels in the mesocarp of this cultivar ranged around 6.7 ± 0.7 mg hg^{-1} of DW (Table 6), regardless of the harvest time or the period of low-temperature storage. The analogous average content of 'Nam Dokmai #4' mesocarp (0.9 ± 0.1 mg hg^{-1} of DW, Table 6) confirmed an earlier report for 'Nam Dokmai' pulp (0.496 mg hg^{-1}).[26] Although the peel was richer in AR, there was no stage at which 'Nam Dokmai #4' peel reached the alk(en)ylresorcinol levels that had been deemed fungitoxic.[5]

Cultivar-Specific Alk(en)ylresorcinol Profiles. The alk(en)ylresorcinol pattern that was found 1 day after harvest for all variants per cultivar remained unchanged during storage (Tables S1 and S2 of the Supporting Information). On average, the homologue profile in 'Chok Anan' peel thus comprised 54% $C_{17:1}$, 29% $C_{17:2}$, 11% $C_{15:0}$, 2.9% $C_{17:3}$, 1.0% $C_{15:1}$, 0.9% $C_{19:1}$, 0.5% $C_{17:0}$, and 0.5% $C_{19:2}$ (Table 7). Consistent with the ~11 times lower $c_{AR,p}$ mean of 'Nam Dokmai #4' peel compared to that of 'Chok Anan' peel (Table 6), the number of quantifiable compounds (**1**, **3**–**5**, and **8**; Table 1) was also smaller. The portions of the homologues $C_{17:1}$ (56%), $C_{17:2}$ (30%), $C_{15:0}$ (8.0%), $C_{19:1}$ (3.5%), and $C_{17:3}$ (2.2%) (Table 7) were similar to those stated earlier for the peel of this cultivar,[26] except for the compounds $C_{15:1}$ (**2**), $C_{17:0}$ (**7**), and $C_{19:2}$ (**6**), which could not be quantitated in the present study (Figure 2B). The three major homologues ($C_{17:1}$, $C_{17:2}$, and $C_{15:0}$) uniformly constituted 94.3% of the AR amount in the peel for each cultivar (Table 7). Their peel AR patterns differed most in the portion of compound **8** ($C_{19:1}$), which was the prevailing minor homologue in 'Nam Dokmai #4' peel (Table 7).

On the whole, the relative homologue composition in the peel was comparable to the profiles of several other cultivars,[26] chiefly in terms of the major compounds that were considered exclusively in some studies.[5,9,24] Accordingly, the variety had little influence. Solely for some Chinese cultivars, the $C_{17:2}$ portions slightly exceeded those of $C_{17:1}$, which was otherwise prevailing.[26] However, the location and seasonal conditions of cultivation and postharvest procedures such as desapping had turned out to be further influencing factors.[9,10] Nonetheless, the large number of data in the Supporting Information, which are summarized in Table 7, showed that the alk(en)ylresorcinol profile was independent of the maturity stage.

dx.doi.org/10.1021/jf4028552 | J. Agric. Food Chem. 2014, 62, 28–40

In the 'Chok Anan' pulp, the relative portions of the alk(en)ylresorcinol homologues $C_{17:2}$ (29%) and $C_{15:0}$ (9.9%) were almost equal to the respective percentages in the peel (Table 7). Only the $C_{17:1}$ portions of the mesocarp AR (61% for 'Chok Anan', 67% for 'Nam Dokmai #4') exceeded those of the peel (54 and 56%, respectively) because the latter were lower in favor of the quantifiable minor compounds.

Relevance of the Alk(en)ylresorcinol Contents for the Mango Defense System. The high similarity of the AR profiles among the cultivars, especially regarding the major homologues (Table 7), was consistent with the concept of a mango-specific defense system.[12,26] Differences chiefly existed in the average alk(en)ylresorcinol levels (Table 6) and in the profiles of minor compounds (Table 7), but both cultivars had equal mass percentages of peel (Tables 2 and 3). The variety showing an overall higher susceptibility to ripening and decay during low-temperature storage[32] had extremely low alk(en)ylresorcinol contents (Table 6).

The strikingly narrow ranges within which the alk(en)ylresorcinol contents of peel and pulp varied per cultivar regardless of maturity and ripeness (Table 6) supported the assumed role of the amphiphilic AR as phytoanticipins,[11] which occur in the biphasic sap[10] of a defense system that is based on resin ducts.[12] These resin ducts act as a reservoir and routes for the fast transport of preformed defense compounds to the points of attack, where the phytoanticipins are efficacious due to transiently high local concentrations.[12] Hence, the functionality of such compounds does not require their accumulation until reaching fungitoxic contents[5] in the peel and pulp. Consistent with the prevalence of the resin ducts in the exocarp,[13,14] 7−11 times higher AR contents occurred in the peel compared to the pulp (Table 6).

Although the sap itself was not isolated and analyzed, the findings of Tables 2−7 must be ascribed to the AR of the sap that was included in the samples. This was mainly suggested by the scarce average contents in the peel and pulp of 'Nam Dokmai #4' (Table 6). As shown by Hassan et al.,[10] the alk(en)ylresorcinol content of 'Nam Dokmai' sap[10] was ∼10 times higher than in the peel of this cultivar[9] and met the fungicidal levels stated earlier for the peel of other cultivars,[5] although it was much lower compared to the sap of AR-rich varieties.[10] Due to the temporary local accumulation at the site of attack as a result of the fast sap transport via the resin ducts, the production of small amounts of defense substances is already enough.[12] According to Konno,[12] resin-duct-based defense is deemed most effective against tiny herbivores, which may be coated completely by the released sap and faced with particularly high concentrations relative to their own size. Likewise, the sap with its concentrated membrane-active AR severely irritates the skin locally,[20,22] but the pulp, containing the sap and its AR in a highly diluted form, can usually be eaten by mango-sensitive people suffering from contact dermatitis, if someone else peels the fruit.[29] Because the strongest binding to proteins had been stated for AR with C_{19} chains,[23] the notable percentage of the $C_{19:1}$ homologue among the minor AR compounds in 'Nam Dokmai #4' may slightly contribute to compensate the scarce total amounts (Tables 6 and 7) through a specific affinity to enzyme proteins.

Consistent with the mobility of the sap and possible defense-related local concentration changes, the alk(en)ylresorcinol contents of the peel ($c_{AR,p}$) were not correlated with those of the pulp ($c_{AR,m}$; Tables S1 and S2). The resin ducts in the mesocarp might have served as a reservoir. According to Joel,[13] the thickness of the layer containing 90% of the ducts in the outer portion of the peel significantly differed between resistant and susceptible cultivars, but no correlation between peel thickness and the resistance of the fruit to fruit flies or between the thickness of the peel and that of the duct layer was observed.

The significantly lower alk(en)ylresorcinol contents, which were noted 1 day after harvest within the narrow concentration range of each cultivar for the peel of the fruit picked after UCH (Tables 2 and 3) or for other peel samples after some time of postharvest ripening,[5,9] might have been caused by a gradually decreasing sap production, sinking sap mobility in the resin ducts, and/or stronger multiple attack by pathogens after UCH.[7,12,22] Kumpoun et al.[7] obtained the maximum amount of the alk(en)ylresorcinol-containing lipophilic sap fraction from 'Mahajanaka' fruit, when the latter was picked at the commercial harvest time (98−105 DAFB). When on-tree maturation was extended for up to 126 DAFB, the total amount of sap released from the harvested fruit and the lipophilic fraction declined continuously.[7]

The alk(en)ylresorcinol production appeared to be influenced by the complex interaction of various environmental factors,[9,10] which may include the UV-light-induced resistance to diseases[44] such as anthracnose.[8,10] Furthermore, the activities of various sap enzymes, including PPO and POD, were shown to change during maturation[19] and ripening.[20] However, according to the Tables S1 and S2 of the Supporting Information, maturity and ripeness had no impact on the AR amounts, which could not prevent the occurrence of anthracnose symptoms in the over-ripe fruits of each cultivar after long low-temperature storage.[31,32] Indeed, the effectiveness of the defense system at this low temperature might be different from that during usual postharvest ripening, which was covered by other AR studies.[5,9] For example, peeling-associated injury was reported to induce notable AR accumulation in the outermost flesh layers, when the peeled fruit was left at ≥15 °C, but not ≤10 °C.[6] As detailed earlier for the variants studied,[31,32] the slow ripening during storage at 14 °C until over-ripeness (Tables S1 and S2) and decay involved chlorophyll degradation to undetectable levels, but only a poor development of the pulp color and the carotenoids. Similarly, the low temperature might have delayed or prevented any changes in the sap composition during storage,[45,46] or it may have affected physical sap properties,[12] such as its flow properties.[22] Altogether, this suggests a follow-up study of the cultivar-specific appearance of the resin duct system[13] together with the parallel examination of the other sap components in addition to the AR.

In conclusion, the AR proved to be present in the peel and the pulp within narrow concentration ranges that were typical of the cultivar and the part of the fruit, but independent of maturity and ripeness. As supported by the cited findings, the observed occurrence of the AR in peel and pulp could be explained by the presence of AR in the sap portions contained therein. The previously recommended harvest just before UCH involved the best protection of the fruit during storage due to moderate ripening at low temperature,[31,32] but the natural AR reserves proved irrelevant for the storage behavior and could not prevent the decay of over-ripe fruits. In view of their activity toward membranes and proteins,[23,28] the AR thus appear to be involved in protection against anthracnose, but in a complex way together with other factors of the sap-based defense system.

ABSTRACT: The present work aimed to assess the effect of the following treatments on the medicinal potential (β-glucan content) and agronomical performance (yield) of *Agaricus subrufescens*: five different fungal strains, three cultivation substrates (compost), four casing layers, and four cultivation environments. Two experiments were performed, and the results indicate that the greatest contribution to the variation in β-glucan content was the strain (35.8%), followed by the casing layer (34.5%), the cultivation environment (15.7%), and the type of compost (9.9%). On the other hand the variation in yield was affected most by the cultivation environment (82.1%), followed by the strain (81.3%), casing layer (49.1%), and compost type (15.2%). These findings underscore the importance of developing a production protocol that employs specific cultivation practices for improving mushroom yield as well as β-glucan content.

KEYWORDS: *almond mushroom, medicinal potential, strain, compost, yield*

INTRODUCTION

The incidence of cancer is gradually increasing, and more types of diseases associated with cancer are reported each year.[1] In addition to radiotherapy and chemotherapy, immunotherapy and biotherapy are also regarded as important tools for cancer treatment.[2]

Immunotherapy and biotherapy include several different approaches, such as biological response modifiers, cytosines, lymphocyte transplant, and genetic therapy, along with the use of medicinal plants and alternative medicines, such as mushrooms.[3] Clinical trials for these therapies continue to be widely performed, and there is increasing evidence to support the efficacy of these approaches; however, the underlying mechanisms remain poorly understood.[1,4,5]

Agaricus subrufescens, which is synonymous with *Agaricus blazei* ss. Heinemann and *Agaricus braziliensis*, is a basidiomycete fungus commonly referred to as "almond mushroom" or "medicinal mushroom". Its medicinal properties (namely, tumor-inhibitory activity) have been attributed to the presence of β-glucan polysaccharides.[6]

There is some controversy in the literature regarding the medicinal substances present in *A. subrufescens*. Camelini et al.[7] reported that the quality of the extracts depends on the chemical composition of the mushrooms and the β-glucan content, in particular. Other chemical components, such as steroids,[8,9] lectin,[10] and several polysaccharides,[1] have also been extensively studied.

Although the scientific community is increasingly concerned with the identification of the active substances present in mushrooms with medicinal properties, important agronomical and physiological characteristics have been overlooked. These factors are critical in production processes, and they may influence the chemical characteristics of mushrooms.

Eira[11] highlighted the importance of using samples of registered origin for experimental procedures. The same publication further described how factors such as cultivation conditions, substrate composition, and the strain used may interfere with the results. In other words, the results obtained using generic samples of unregistered origin are not conclusive. Accordingly, factors such as these should be controlled in any experiment that aims to compare the nutritional and functional properties of *A. subrufescens*.

In a study comparing the basidiocarp β-glucan contents of field and greenhouse mushrooms from Brazil and greenhouse mushrooms from Japan, Park et al.[12] observed lower β-glucan contents for *A. blazei* mushrooms grown in greenhouses (7.6 ± 2.8 g 100 g^{-1} mushroom dry weight grown in Japan and 8.4 ± 0.9 g 100 g^{-1} mushroom dry weight grown in Brazil) than for those grown in the field (10.1 ± 2.1 g 100 g^{-1} mushroom dry

weight). However, the authors did not indicate whether all of the basidiocarps analyzed were of the same strain.

Firenzuoli et al.[13] previously noted the lack of studies with data for specific cultivation characteristics, as well as the agronomical and physiological behavior of *A. blazei* strains used in pharmacological, biochemical, and medicinal research.

The cultivation practices used for *A. subrufescens* in Brazil derive from the practices used for *A. bisporus* production and incorporate some of the management techniques from recently published studies.[14−17] At a national and international level, there is still no cultivation protocol or guide that addresses how certain practices influence the presence of active substances in harvested mushrooms and the agronomical performance of *A. subrufescens* as well as how the cultivation of this species may be rendered viable and sustainable.

In the present study, two experiments were performed to assess how various cultivation practices (different strains, compost materials, casing layers, and cultivation environments) affect the final β-glucan content of the cultivated basidiocarps and agronomical outcomes (yield, number and weight of basidiocarps, precociousness, and time to first harvest).

MATERIALS AND METHODS

Two experiments were performed. The first experiment tested the effect of different strains and compost formulations. The strains and formulations that yielded the best results in the first experiment were subsequently used in the second experiment, which assessed the effect of different casing layers and cultivation environments.

Spawn. For the first experiment, five commercial *A. subrufescens* strains that have been deposited at the Mycotec of the Módulo de Cogumelo FCA/UNESP were used. The main characteristics of the strains are listed in Table 1. Strain ABL 99/30 was selected for the second experiment. The spawns used in both experiments were produced according to the methodology described by Zied et al.[18]

Composting (Phases I and II). The three composts used in the first experiment were produced according to the "traditional" composting method. Phase I (26 days total) consisted of 7 days of prewetting and 19 days of fermentation. The composts were turned six times. Phase II of composting lasted 9 days (8 h at 59 ± 1 °C pasteurization and 8 days at 47 ± 2 °C conditioning). The three composts were prepared simultaneously. The materials used on each compost and their chemical composition at the end of phase II are listed in Table 2. The initial C/N ratio of the compost at the moment the pile was set up was previously calculated for 33-37/1.

The compost containing sugar cane bagasse and oat straw was used for the second experiment and produced in the same manner as described for the first experiment. At the end of phase II, the chemical characteristics of the compost were as follows: 1.66% N content, 0.45% P_2O_5, 0.26% K_2O, 5.53% Ca, 0.23% Mg, 0.98% S, 65% organic matter (OM), 36.2% C, 300 mg kg^{-1} Na, 10 mg kg^{-1} Cu, 3300 mg kg^{-1} Fe, 128 mg kg^{-1} Mn, 28 mg kg^{-1} Zn, a C/N ratio of 22/1, and a pH of 6.83.

Compost Inoculation and Spawn Run. In both experiments, the respective strains were mixed with the composts after pasteurization and conditioning and were then placed into plastic boxes containing 12 kg of compost and 120 g of spawn. The composts were subsequently incubated for 21 days in the dark in a climate-controlled chamber with a compost temperature of 28 ± 1 °C, at 75 ± 5% relative humidity, and without ventilation. The spawn growth of the strains during this period was periodically monitored, and the cultures were checked for compost contamination by mold and other microorganisms.

Casing Layer. In the first experiment, a mix of soil and charcoal (4:1, v/v) was used. Calcitic lime was added for pH correction, followed by pasteurization for 12 h at 58 °C. When the mycelia were fully developed, the compost was pressed and leveled to facilitate the addition of the casing layer to a height of 5 cm. A 12.5 L volume of

casing was added to each plastic box containing 12 kg of compost. The boxes were placed in a greenhouse (with a low-density polyethylene milky plastic film 150 μm thick; E.L.V. Leitoso, Electro Plastic, São Paulo, Brazil) with partial control of temperature, relative humidity, and aeration. During the cultivation, the air temperature ranged from 10 to 40 °C, the compost temperature ranged from 18 to 32 °C, and the relative humidity was between 35 and 100%.

In the second experiment, four casing layers were used: soil + charcoal (4:1, v/v), soil + coconut fiber (4:1, v/v), soil + composted pine bark (4:1, v/v), and soil + sphagnum peat moss. The soil used was the same as in the first experiment. Prior to the addition of the casing layer, calcitic lime was added to the soil, which was subsequently wetted and mixed with the organic materials (charcoal, coconut fiber, composted pine bark, and sphagnum peat). The main physicochemical properties of the casing layers are listed in Table 3.

After homogenization, the casing layers were pasteurized and placed over the compost as described for the first experiment. The boxes containing the four casing layers were then placed under four different cultivation environments: a climate-controlled chamber (length × width × height: 12 × 2.3 × 2.3 m) (Model Dalsem Mushrooms Container, Horst, The Netherlands); an experimental greenhouse (length × width × height: 8 × 4 × 2.5 m) with a low-density polyethylene Duplalon double-sided (black/white) plastic film 120 μm thick (E.P.B. Estufa Preto e Branco, Electro Plastic, São Paulo, Brazil); an experimental greenhouse (length × width × height: 8 × 4 × 2.5 m) with a low-density polyethylene milky plastic film 150 μm thick (E.L.V. Leitoso, Electro Plastic); and an experimental greenhouse (length × width × height: 8 × 4 × 2.5 m) with a low-density polyethylene transparent plastic film 150 μm thick (E.L.V. Difusor M36, Electro Plastic).

Primordial Induction. In the first experiment, the primordial induction occurred naturally, according to the weather conditions of the day or week. The total production time was 120 days, with some primordial growth observed after 21 days. Depending on the strain and compost used, the number of harvest flushes during cultivation ranged from two (strain ABL 99/30 inoculated on compost 1) to seven (strain ABL 03/44 inoculated on compost 3).

In the second experiment, the environmental conditions varied for each cultivation environment (compost and air temperatures, relative humidity, and light intensity). The environmental conditions during production for the different cultivation environments are listed in Table 4.

In all three greenhouse environments (Duplalon, milky, and transparent plastic film), the primordial induction occurred naturally, according to the weather conditions of the day or week. In the climate-controlled chamber, the environmental variables (temperature, relative

humidity, and aeration) were manipulated according to the methodology described by Zied and Minhoni[19] to control the production and to obtain five flushes.

The total production time was 120 days, with some primordial growth observed after 21 days, in the climate-controlled chamber and in the greenhouses with Duplalon or milky plastic film. Depending on the casing layer and cultivation environment used, the number of harvest flushes during cultivation ranged from two (casing layer with charcoal grown in a greenhouse with Duplalon plastic film) to five (casing layer with charcoal grown in the climate-controlled chamber).

Harvest. The basidiocarps were harvested manually, followed by the scraping of the bottom of the stalk to remove casing layer residues. The analysis was subsequently performed to quantify yield, time to first harvest, precociousness, basidiocarp weight, and the number of basidiocarps.

Experimental Design. For the first experiment, a double-factorial design was used, with five *A. subrufescens* strains (ABL 99/28, 99/30, 03/44, 04/49, and 06/59) and three composts (Massai and sugar cane bagasse, oat straw and sugar cane bagasse, and Aruana straw and sugar cane bagasse) in a completely randomized design. A double-factorial design was also used for the second experiment, with four casing layers

Figure 1. Yield (%) and β-glucan content (g 100 g^{-1} mushroom dry weight) for the five fungal strains, three composts, four casing layers, and four cultivation environments tested.

(soil + charcoal, soil + coconut fiber, soil + composted pine bark, and soil + sphagnum peat moss) and four cultivation environments (climate-controlled chamber, experimental greenhouse with Duplalon plastic film, experimental greenhouse with milky plastic film, and experimental greenhouse with transparent plastic film) in a completely randomized design. For both experiments, eight replicates were performed for each treatment, with each replicate consisting of a box containing 12 kg of compost.

Analyzed Variables. The following data were measured and analyzed as previously described by Pardo et al.,[20] and Zied et al.:[16] yield (basidiocarp fresh weight divided by the compost fresh weight multiplied by 100 and expressed as a percentage); the number of basidiocarps (count of the harvested basidiocarps); basidiocarp weight (basidiocarp fresh weight divided by the number of basidiocarps, expressed in grams); precociousness (yield over the first half of the total harvest time divided by the yield over the total harvest time multiplied by 100 and expressed as a percentage); and time to first harvest (number of days between casing and harvesting of the first flush). The β-glucan content of the basidiocarps was determined using the methodology of the Foundation of Japanese Food Analysis Center[21] and the modifications proposed by Prosky et al.[22] as described by Park et al.[12]

Statistical Analyses. The means of each variable analyzed were compared using Tukey's test ($p \leq 0.05$) and SAS JMP software. Sigma Stat 3.5 software was used to calculate linear correlations among the values for yield, number, and weight of basidiocarps, precociousness, time to first harvest, and basidiocarp β-glucan content.

RESULTS AND DISCUSSION

Experiment 1. The ABL 99/30 strain had the highest yield and number of mushrooms, whereas the ABL 06/59 strain had the lowest yield and number (Table 5). However, the mushrooms of the ABL 06/59 strain had greater weights (not statistically significant). One possible explanation for this finding is that yield was positively correlated with the number of basidiocarps (r = 0.993) and negatively correlated with basidiocarp weight (r = −0.742). When analyzed separately, the type of compost used had no effect on the yield or the number of mushrooms produced.

These results are in contrast with the findings of González Matute et al.,[23] who observed an effect of substrate composition on yield. The authors used sunflower seed hulls, spent compost, vermiculite compost, peat moss, and brewery waste, with C/N ratios between 40:1 and 71:1.

Although correlations between the yield and the number and weight of basidiocarps were observed, basidiocarp weight was not significantly different among the various strains or composts. The lack of statistical significance was due to the high coefficients of variation obtained for yield (64%), the number of basidiocarps (80.47%), and basidiocarp weight (37.65%).

The average values of the yield and number of basidiocarps for strains ABL 99/30, 03/44, and 04/49 were higher than the

overall average for all of the treatments (9.81% and 73.35 u). The average basidiocarp weight values for strains ABL 99/29 and 06/59 were higher than the overall average for all of the treatments (18.07 g).

In a study analyzing three different composts and two strains, Kopytowski Filho[24] observed no significant differences in yield for the interaction of the two factors (i.e., compost versus strain). However, when the two factors were analyzed separately, ABL 99/30 was found to have a higher yield than ABL 04/49, and the use of organic compost was found to have a higher yield than synthetic and semisynthetic composts.

dx.doi.org/10.1021/jf403584g | J. Agric. Food Chem. 2014, 62, 41−49

In the present study, strains ABL 06/59 and 99/30 had the highest values of precociousness, which were markedly higher than the overall average for all treatments (53.85%). These values indicate that for these two strains, most of the production occurred during the first 47 days of harvest following primordial formation. It should be noted that precociousness values were positively correlated with basidiocarp weight (0.835), indicating that under the tested conditions, the mushrooms produced during the first half of the cultivation cycle had higher weights.

Zied et al.,[25] studied Tifton (T)- and oat (O)-based composts and the following casing layers: acrylamide gel (gel), soil + coal (c), and soybean meal supplement (s). They reported the following precociousness values: Tgel (75%) > Oc (61%) > Ogel (58%) > Os (57%) > Ts (53%) > Tc (51%). In another study using strain ABL 04/49,[25] a higher precociousness value was obtained than that observed in the present study for the same strain cultivated with oat-based compost and soil + charcoal casing (37.95%). This discrepancy may reflect differences in the environmental conditions in a given week or month.

The shortest times until the first harvest were observed for strains ABL 99/30, 03/44, and 06/59 regardless of the type of compost used, with the following exception: the time until first harvest increased when strain ABL 03/44 was grown with Massai straw and sugar cane bagasse. The type of compost used also influenced the time to first harvest. In addition to reducing the values of yield and precociousness, the application of Aruana straw and sugar cane bagasse compost to strain ABL 99/28 increased the time to first harvest.

The basidiocarp β-glucan content was not affected by the yield, the number of basidiocarps, basidiocarp weight, precociousness, or the time to first harvest. However, the β-glucan content was affected by the strain and the type of compost used. For example, significant differences in β-glucan content were observed when strains ABL 99/30, 03/44, and 04/49 were grown with Aruana straw and sugar cane bagasse compost.

The average β-glucan content observed for the tested treatments (5.19 g 100 g^{-1} mushroom dry weight) can be used to establish an acceptable level of β-glucan in basidiocarps for export. The strain alone is responsible for 35.8% of the variation in the β-glucan values, whereas the type of compost used is responsible for 9.9% of the variation (Figure 1). Thus, the strain used is of the utmost importance, and it should be selected in accordance with the type of raw material used in the compost.

Wang et al.[26] tested six different substrate formulations for the production of *A. blazei*, with the final N contents of the compost ranging between 1.2 and 1.55%. The authors used asparagus straw, cottonseed hull, cow manure, soybean cake, and gypsum as the raw materials for the compost production and did not find any significant differences in the final polysaccharide content of the basidiocarps.[26]

Experiment 2. The highest yield values were obtained in the climate-controlled chamber (Table 6) and were not affected by the type of casing layer used (Tukey, $\leq$0.05). However, the type of casing layer had a significant effect on yield in the greenhouses with partial climate control regardless of the type of plastic film used. The more open casings (soil + charcoal and soil + composted pine bark) resulted in a higher yield.

When the different casing layers and cultivation environments were compared, a positive correlation between yield and the number of basidiocarps (r = 0.81) and a negative correlation between the number of harvested basidiocarps and respective unit weights (r = −0.695) were observed. No correlations were observed for precociousness, time to first harvest, or basidiocarp β-glucan content.

Similar results were reported by Zied et al.,[18] who observed that the number of harvested basidiocarps was negatively correlated with the water-holding capacity of the casing layer and positively correlated with the total density and porosity of the casing layer. Pardo et al.[27] reported that a porous casing layer resulted in an earlier first flush for *A. bisporus* and an increased number of mushrooms, albeit with reduced weight.

The treatments that resulted in a higher yield also resulted in a higher number of harvested basidiocarps and reduced weight. The only treatment for which this trend was not observed was the soil + pine bark casing layer in the climate-controlled chamber. In this case, a significantly higher weight was observed (Tukey's test at a 5% significance level). These findings indicate that factors such as porosity are less important in the casing layer material in a controlled environment.

The environmental variables resulted in lower yields in the greenhouses with plastic films (Table 4). Zied and Minhoni[19] previously recommended 27 ± 2 °C compost temperature, 25 ± 2 °C air temperature, and 90 ± 2% relative humidity during the initial 12 days following the addition of the casing layer and during the intervals between flushes. For primordial induction, the compost temperature should be lowered to 20 ± 2 °C, the air temperature to 18 ± 2 °C, and the relative humidity to 85 ± 2%.

No statistically significant differences in precociousness were observed, although the values observed were higher than those observed in the first experiment. Precociousness exceeded 50% during the first half of the harvest period in approximately 93% of the recorded cases (Table 6), which indicates a more concentrated cultivation during the first days of growth. This result may permit shorter cultivation cycles, especially for the following combinations: soil + charcoal/climate-controlled chamber, soil + charcoal/greenhouse with Duplalon film, soil + composted pine bark/greenhouse with Duplalon film, and soil + composted pine bark/greenhouse with milky film.

It should be noted that casing layers with higher porosity and lower water-holding capacity (soil + charcoal and soil + pine bark) have been associated with precociousness. For instance, Colauto et al.[17] observed that casing layers with high porosity (lime schist and Santa Catarina peat) had a higher biological efficiency than less porous casing layers (soil + coal and São Paulo peat).

The soil + pine bark casing layer in the climate-controlled chamber and the soil + charcoal casing layer in the greenhouse with milky film resulted in the shortest times to first harvest. The only casing layer that significantly affected the time to first harvest in relation to a particular cultivation environment was soil + pine bark under greenhouse conditions, which resulted in a later first flush.

The basidiocarp β-glucan content was not significantly affected by the type of casing layer or cultivation environment. This finding is in contrast with the results of Park et al.,[12] for a study comparing the basidiocarp β-glucan content of mushrooms grown in Brazil and Japan. They compared field-grown and greenhouse mushrooms that were produced in Brazil with mushrooms produced in greenhouses in Japan and found that *A. blazei* grown in greenhouses had lower β-glucan contents (7.6 ± 2.8 g 100 g^{-1} mushroom dry weight grown in Japan and

8.4 ± 0.9 g 100 g^{-1} mushroom dry weight grown in Brazil) than *A. blazei* grown in the field (10.1 ± 2.1 g 100 g^{-1} mushroom dry weight). The differences from the present study in terms of the β-glucan content may reflect differences in the types of compost and the strains used.

The average values of β-glucan content obtained in the present study for the tested treatments (4.99 g 100 g^{-1} mushroom dry weight) can be used to establish an acceptable level of β-glucan in basidiocarps. The casing layer and cultivation environment were responsible for 34.5 and 15.7%, respectively, of the variation in β-glucan content (Figure 1). Thus, the choice of casing layer is important for producing basidiocarps with desired physical characteristics.

Production Protocol. The spatial variability of the β-glucan content and yield as affected by the tested factors (fungal strain, compost, casing layer, and cultivation environment) are presented in Figure 1. These values may be used as indicators for the adoption of production practices and the creation of a protocol of good cultivation practices that can be used by producers wishing to export *A. subrufescens*.

The factor with the greatest contribution to the variation in β-glucan content was the strain (35.8%), followed by the casing layer (34.5%), the cultivation environment (15.7%), and the type of compost (9.9%). The variation in yield was affected most by the cultivation environment (82.1%), followed by the strain (81.3%), casing layer (49.1%), and compost type (15.2%).

The present findings indicate that standard values can be set to 5 g 100 g^{-1} mushroom dry weight for β-glucan content and 10% for yield. The following cultivation practices are also proposed:

- Strains ABL 99/30, ABL 03/44, and ABL 04/49 should be used because of their good agronomical performance and reasonable β-glucan contents.
- Compost prepared from sugar cane bagasse and wheat or Massai straw can be used by Brazilian growers. An adequate formulation of the substrate is of central importance in obtaining high yields, as balanced compost (C/N ratio of 33−37:1) minimizes variation in the yield and β-glucan content.
- The casing layer is determinant of the yield and β-glucan content of basidiocarps, which varied greatly in the present study depending on the treatments used. The casing layer should be selected according to the desired physical characteristics of the harvested basidiocarps (e.g., number and weight of basidiocarps). At the same time, the use of pine bark and charcoal as a supplement to the soil is recommended due to the low cost of these materials in Brazil (1:4, v/v).
- The cultivation environment is another determinant of yield. The large variation in yield throughout the year caused by seasonal weather changes is one of the main reasons growers abandon commercial cultivation. Cultivation in climate-controlled chambers is therefore recommended because it is not affected by variations in external environmental conditions and does not directly influence the β-glucan content of the harvested basidiocarps.

Reduced Herbicide Leaching by in Situ Adsorption of Herbicide–Micelle Formulations to Soils

Haim Katz[†] and Yael G. Mishael*

Department of Soil and Water Sciences, The Robert H. Smith Faculty of Agriculture, Food and Environment, Hebrew University of Jerusalem, Rehovot 76100, Israel

ABSTRACT: Aiming to reduce herbicide leaching, "in situ" adsorption of herbicide–micelle formulations to soils was explored. Sulfentrazone or metolachlor were solubilized in cationic micelles, and these herbicide–micelle formulations were applied to sandy and alluvial soils. Sulfentrazone adsorption to the soils was negligible; however, its adsorption via its solubilization in micelles and their adsorption to the soil was significant and in good agreement with the Freundlich and Langmuir models. Adsorption of solubilized herbicide to the sandy soil was higher than to the alluvial soil. The low ratio between the surfactant concentration and the cation exchange capacity (CEC) of the alluvial soil brought upon micelle decomposition and reduction in herbicide adsorption. Therefore, an optimized ratio between surfactant and soil CEC was chosen to maximize herbicide retention. Even upon adding relatively low loadings of surfactant (0.075–0.3% w/w soil), herbicide leaching through the soils was significantly reduced (2–5-fold) in comparison with the commercial formulations.

KEYWORDS: *reduced leaching, slow release formulations, surfactants, sulfentrazone, metolachlor*

INTRODUCTION

Herbicides provide substantial agronomic and economic benefits. However, introducing bioactive molecules to the environment poses environmental issues including their leaching and surface migration, which may cause soil, surface, and groundwater contamination.[1,2] Furthermore, migration and leaching reduce herbicide concentration at the topsoil which reduces weed control efficacy. Herbicide leaching in the soil is governed by several factors, such as soil characteristics, chemophysical properties of herbicides, the effect of climatic conditions, and tillage methods.[1,3]

In the current study the extensive leaching of sulfentrazone and metolachlor, which have been detected in groundwater,[4−6] is addressed. Sulfentrazone (water solubility of ∼280 ppm) is an anionic herbicide (pK_a = 6.56), its mobility enhances with the increase in soil pH, and its adsorption to the soil especially at alkaline pHs is negligible.[7] Metolachlor, although nonionic, is relatively soluble in water (490 ppm),[8] and its sorption to soils is considered not high.[9]

The main approaches to reduce herbicide leaching are herbicide dose optimization, site specific weed management, and nonchemical weed control such as mechanical and thermal. Another approach widely pursued in the past few decades is developing slow release formulations,[10−33] many of which are based on organically modified clay minerals[10,12,15−17,19,24,26−35] including organoclays,[11,15,16,19,31,32,34,36] polymer–clays,[23,24,29,30,33] and micelle–clays.[20,25,28,35] Several of these formulations were tested and found to reduce leaching through soil columns; however, their preparation is inefficient since it entails large water volumes, loss of active ingredient, drying, grinding the formulation and resuspending the powdered formulations, etc.

Therefore, an alternative approach of in situ formation of organo–clay sorbents for herbicide retention, by adding the organic cations to the soil, was developed.[37−39] A few studies have reported the enhanced adsorption of herbicides (and other organic contaminants) in soils treated with surfactants.[40−42] However, these reports did not include leaching studies nor did they address herbicide solubilization in micelles, since surfactant concentrations were below the critical micelle concentration (CMC).

The phenomenon of solubilization, increasing the solubility of an insoluble or poorly soluble organic substance in a surfactant solution, has been widely studied for many decades and is well-established in different fields such as medicine, cosmetics, detergency, and environment.[43−48] For example, studies on soil remediation by "enhanced pump and treat" have addressed the issue of surfactant concentration below and above their CMC and indicated that upon formation of micelles in the solution pollutant mobility was enhanced.[49,50]

In previous studies on micelle–clay slow release formulations,[25,26,35] we demonstrated that herbicides (sulfumeturon and sulfosulfuron) adsorption to the clay is enhanced when the surfactant is adsorbed as micelles (vs monomers). In a later study we described the mechanism of sulfentrazone and metolachlor solubilization in octadecyltrimethylammonium (ODTMA) micelles and characterized the herbicide–micelle adsorption to the clay. The percent of active ingredient (sulfentrazone and metolachlor) in clay formulations based on solubilization of the active ingredient in micelles is 4-fold higher than in organo–clay formulations.[11]

These clay based formulations have been tested and found to reduce leaching through soil columns; however, their application in the field is problematic due to inefficient preparation as described above.

In the current study, we suggest designing herbicide−micelle−clay formulations in which the clay is not an external ingredient but rather part of the target soil. The herbicide is solubilized in micelles, the herbicide−micelle formulation is directly applied to the soil, and herbicide leaching through the soil is suppressed due to its sorption, via micelle adsorption, to the soil. The herbicide and micelles are applied to the soil at the same time, in comparison to the two step application in other reports (soil modification and then herbicide application) which is advantageous. Furthermore, an "in situ" mode increases the percent of active ingredient, and since there is no clay in the employed formulation, preparation and application in the field is simplified.

MATERIALS AND METHODS

Materials. Wyoming Na-montmorillonite (SWy-2) (cation exchange capacity, 0.76 mmol/g; surface area, 700 m^2/g) was obtained from the Source Clays Repository of the Clay Mineral Society (Columbia, MO). Octadecyltrimethylammonium bromide (ODTMA) and Triton X-100 were purchased from Sigma-Aldrich (Stenheim, Germany). Acetonitrile and water, high-performance liquid chromatography (HPLC) grade, were purchased from Merck (Darmsradt, Germany). Sulfentrazone N-[2,4-dichloro-5-[4-(difluoromethyl)-4,5-dihydro-3-methyl-5-oxo-1*H*-1,2,4-triazol-1-yl[phenyl]methane-sulfonamide technical (purity 91.3%) was received from FMC (Princeton, NJ). Boral is a commercial formulation of the ai sulfentrazon (75% ai, water dispersible granular) 480 g ai/L liquid), metolachlor 2-chloro-*N*-(6-ethyl-*o*-tolyl)-*N*-[(1*RS*)-2-methoxy-1-methylethyl] acetamide technical (purity 98.6%), and commercial metolachlor (Dual-Gold 915 g ai/L liquid), which were obtained from Agan Chemicals (Ashdod, Israel). Rehovot sandy soil[51] was collected from the faculty's experimental farm. An Alluvial soil was collected from fields located a few miles east of the faculty's experimental farm (Na'an). The soil samples were air-dried and sieved through a 2 mm screen. The soils characteristics are shown in Table 1.

Table 1. Soil Characterization

soil	sand %	silt %	clay %	pH	OM %	CEC [mequiv/100 g]
alluvial	43.3	14.9	41.8	7.6	1.05	48.5
sandy	95.5	3.3	1.2	7.5	0.2	6.0

Methods. *Preparation of Herbicide−Micelle Formulations and Micelle−Clay and Herbicide−Micelle−Clay composites for Zeta Potential Measurements.* Throughout the study, the preparation of ODTMA micelles included heating the solutions to exceed the Krafft temperature, T_K point (40 °C) and reach a clear solution. Sulfentrazone (0.75−4.2 mmol/L) was added to an ODTMA solution (2.8 mM) which was stirred for 24 h. Micelle−clay and herbicide−micelle−clay composites were prepared by adding 2 g/L montmorillonite to the micelle solution (2.8 mM ODTMA) in the presence or absence of the herbicide (2.1 mM sulfentrazone) in the solution and stirred for another 24 h.

Zeta Potential Measurements of Micelle and Herbicide−Micelle Solutions and Clay and Composite Suspensions. The samples were allowed to settle for approximately 1 h, and a few milliliters of the suspension (of the clay, micelle−clay, and herbicide−micelle−clay composites) or the solution (of micelle and herbicide−micelle solutions) from the top of the flask was measured. ξ was measured using a Zetasizer Nanosystem (Malvern Instruments, Southborough, MA), where the ξ was deduced from the mobility of the particles using the Smoluchowski equation.

Micelle Size Measurements. Micelles and mixed micelles solutions were prepared by addition of ODTMA (2.8 mM), Triton X-100 (1.5 mM), or both surfactants (2.8 mM ODTMA and 1.5 mM Triton X-100) (by weight) to a stirred Erlenmeyer flask with distilled water, overnight. Size measurements were made after sample filtration (0.2 μm) by Zetasizer Nanosystem (Malvern Instruments, Southborough, MA). The corresponding apparent hydrodynamic radii were calculated as

$$R_{app} = \frac{kT}{6\pi\eta D}$$

where k is the Boltzmann constant, T is the absolute temperature, D is the diffusion coefficient, and η is the solvent viscosity in poise. The micelle size is expressed as apparent diameter $2R_{app}$.

Adsorption−Desorption of Commercial Herbicides and Herbicides Solubilized in Micelles to Soils. Sulfentrazone (300, 600, or 900 mg/L) was solubilized in ODTMA (2.8 mM), Triton X-100 (1.5 mM), or both surfactants (2.8 mM ODTMA and 1.5 mM Triton X-100) and stirred overnight. An alluvial soil was added to the herbicide−micelle solutions, reaching 67 g/L. The tubes were kept under continuous agitation, reaching equilibrium (for 24 h). Supernatants were separated by centrifugation at 15 000*g* for 20 min, and the herbicide concentrations in supernatants were measured by HPLC (see below).

Adsorption isotherms (adding 0−12 mg sulfentrazone/g soil) on a sandy or an alluvial soil (67 g/L) of sulfentrazone (0−800 mg/L) as is or solubilized in an ODTMA solution (3.36 mM) were obtained. The experiment was conducted in Teflon centrifuge tubes which were kept under continuous agitation for 24 h. Supernatants were separated by centrifugation at 15 000*g* for 20 min, and herbicide concentrations in supernatants were measured by HPLC (see below). Herbicide desorption was measured after 24 h by resuspending the precipitate (reaching 67 g soil/L) with distilled water. Supernatants were separated after 24 h of agitation by centrifugation, and the concentration of the desorbed herbicide in the supernatant was measured by HPLC. Sample analyses were performed in triplicate.

Herbicides Release and Leaching through Thin Soil Layers. Herbicide−micelle formulations were prepared by adding 800 mg/L herbicide (sulfentrazone or metolachlor) to ODTMA solutions (3.36−12.9 mM for the sulfentrazone and 3.36 mM for the metolachlor) and stirred overnight.

The release and leaching of sulfentrazone and metolachlor from herbicide−micelle formulations and from the commercial formulations was measured by applying the formulations on a thin sandy or alluvial soil layer (200 g and approximately 2 cm) deposited on a filter paper (Whatman 1442-125) in a Buchner funnel (area of 7.85×10^{-3} m^2). A second filter paper was placed on top of the soil to ensure uniform water distribution and to minimize disruption of the soil surface. No herbicide adsorption was obtained on the filter paper. Sulfentrazone leaching was also studied from the alluvial soil after washing it (10 pore volumes) to remove the dissolved organic matter. The herbicide−micelle and commercial formulations (Boral for sulfentrazone and Dual-Gold for metolachlor) were applied as solutions at a rate of 10.2 mg ai per funnel, equivalent to 1300 g/ha. Water was applied as a control. Soil pore volume was measured. The funnels were irrigated 8−14 times with 50 mm of water (40 mL per funnel) at uniform intervals between irrigations. The leachates were collected after each irrigation, and herbicide concentrations were measured by HPLC. Each treatment was performed in triplicate.

Herbicide Analysis. Supernatants were filtered with acrodisc (polypropylene) filters (Pall Corp., MA) of 0.45 μm pore diameter. The herbicides were analyzed by HPLC (Agilent Technologies 1200 series) equipped with a diode array detector set at 254 and 225 nm for sulfentrazone and metolachlor, respectivly. The HPLC column was a LiChroCARTR 250-4 PurospherR STAR RP-18 (5 μm) (Merck), operating at flow rate of 0.8 mL min^{-1}. For sulfentrazone detection, the mobile phase was 50% acetonitrile and 50% water with trifluoroacetic acid, pH ∼ 3. For metolachlor detection, the mobile phase was 70% acetonitrile and 30% water.

RESULTS AND DISCUSSION

Sulfentrazone Solubilization in Micelles. Zeta potential (ξ) of montmorillonite, ODTMA micelles, and an ODTMA−clay composite and ξ of ODTMA micelles as a function of sulfentrazone solubilized were monitored (Table 2). The ξ

dx.doi.org/10.1021/jf403456m | J. Agric. Food Chem. 2014, 62, 50−57

Table 2. Zeta Potential of ODTMA Micelles (2.8 mM) and Micelles Solubilized with Sulfentrazone (2.1 mM), Montmorillonite (2 g/L), and Montmorillonite-ODTMA Composite with and without Sulfentrazone (2.1 mM)

sample	ζ potential (mV)
ODTMA	46 ± 5
ODTMA + SFZ	44 ± 3.6
clay	−39 ± 0.6
ODTMA + clay	51 ± 1.2
ODTMA + SFZ → clay	48 ± 4.5

measured for montmorillonite, ODTMA micelle, and ODTMA−clay composite are in agreement with previous studies.[52] ODTMA micelle adsorption on the clay was complete and exceeded the CEC of the clay, resulting in charge reversal of the clay (51 ± 1.2 mV).[52] Surprisingly the positive ξ of ODTMA−clay composite did not decrease (less positive) upon adsorption of anionic sulfentrazone (48 ± 4.5 mV) with a 0.75 sulfentrazone/ODTMA mol/mol ratio. Furthermore, the positive ξ of ODTMA micelles did not decrease upon solubilization of anionic sulfentrazone at herbicide/surfactant mol at a ratio of 0.25−1.5 mol/mol.

Previously, we studied sulfentrazone solubilization in ODTMA micelles at a ratio of 0.1−0.5 mol/mol and found that upon increasing sulfentrazone concentrations solubilization in the micelles decreased from 72 to 60%, respectively.[11] Sulfentrazone solubilization in ODTMA micelles was explained by two mechanisms: 1. The cationic ODTMA micelles enhance sulfentrazone dissociation resulting in anion formation which binds electrostatically to the cationic micelles.[28] 2. Sulfentrazone molecules can interact with the hydrophobic micelle core (solubilized into the micelle). On the basis of the suggested mechanisms, we concluded that an increase in sulfentrazone concentration in the micelles decreases the positive charge on the micelles, resulting in lower affinity of sulfentrazone to the micelle.

However, our current results demonstrate that ξ of ODTMA micelles does not decrease upon sulfentrazone solubilization. Both mechanisms suggested above may take place and do not contradict the current ξ findings, when considering sulfentrazone solubilization mainly in the micelle core (Figure 1B)

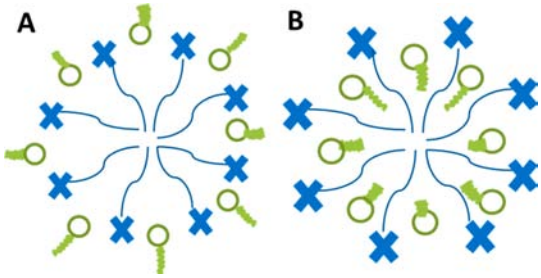

Figure 1. Suggested configurations of sulfentrazone solubilization in ODTMA micelles: (A) solubilization in the micelle shell and (B) solubilization in the micelle core.

and not at the surface (Figure 1A). Penetration into the core can explain (a) the decrease in solubilization upon increase in sulfentrazone concentration (solubilization limit and repulsion of excess positive changes in the micelles) and (b) the negligible changes in ξ of ODTMA micelles upon sulfentrazone solubilization. This implies that the suggested mechanisms[11] may be sequential with electorstatic attraction first and then sulfentrazone penetration into the micelles.

Adsorption−Desorption of Sulfentrazone Solubilized in Micelles to Soils. To maximize sulfentrazone adsorption to the soil via its solubilization in micelles which adsorb to the soil, two reactions, solubilization and micelle adsorption, need to be optimized. Herbicide solubilization may be increased by employing nonionic micelles with a lower CMC (than ODTMA) and which have high solubilization properties such as TX 100.[49,50,53−55] Many studies report the synergistic effect of mixed micelles.[56−61] Supporting these studies, the mixed micelles were found to have the largest micelle size (obtained from size measurements) which may enable higher solubilization due to larger core volume. The measured apparent micelle diameters of TX 100 micelles, ODTMA micelles, and the mixed micelles were 8.5, 7.5, and 9.5 ± 0.2 nm, respectively. Although sulfentrazone solubilization in TX100 micelles or in the mixed system may be higher than in ODTMA micelles, the latter's adsorption to the soil is predicted to be higher due to electrostatic attraction. To test the trade-off between solubilization and adsorption, sulfentrazone (300, 600, and 900 mg/L) adsorption to an alluvial soil was studied upon its solubilization in TX 100, ODTMA, and in mixed micelles of the two surfactants (Figure 2).

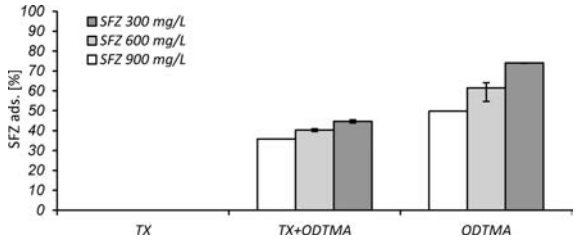

Figure 2. Adsorption of sulfentrazone (SFZ) (300, 600,900 mg/L) solubilized in micelles ODTMA (2.8 mM), TX 100 (1.5 mM), and mixed micelles of both surfactants to an alluvial soil (67 g/L).

Sulfentrazone adsorption to the soil upon its solubilization in TX 100 micelles was negligible, which demonstrates the poor adsorption of these micelles to the soil. Intermediate adsorption was obtained for the mixed micelles, and the highest adsorption was reached with the pure ODTMA micelles. These results indicate that although solubilization may be enhanced by the nonionic surfactant its adsorption to the soil is poor (lower than the adsorption of ODTMA micelles), causing lower sulfentrazone adsorption. Therefore, further adsorption and leaching studies of sulfentrazone were conducted with ODTMA micelles.

The adsorption of sulfentrazone (technical grade and Boral) and sulfentrazone (50−800 mg/L) solubilized in micelles (3.36 mM) to the sandy soil and to the heavy alluvial soil was studied (Figure 3). The adsorption of sulfentrazone, technical grade and Boral, to both soils, sandy or alluvial, was negligible. At the pH values of the soils 7.5 and 7.6, respectively, the herbicide is deprotonated, i.e., in its anionic form explaining the low adsorption to the soils and supporting reports on its high leaching.

The adsorption isotherms of sulfentrazone via its solubilization in ODTMA micelles have an L-shape and were in good agreement (R^2 > 0.986 or >0.972) with the Freundlich and Langmuir models, respectively (Table 3).

dx.doi.org/10.1021/jf403456m | J. Agric. Food Chem. 2014, 62, 50−57

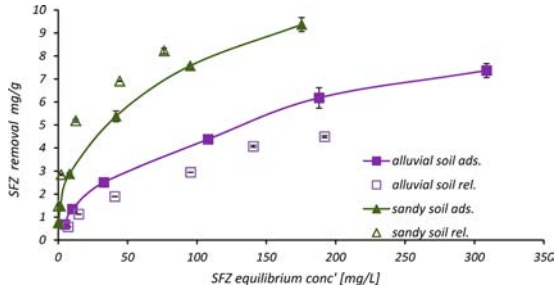

Figure 3. Adsorption/removal and desorption of Sulfentrazone (SFZ) (50–800 mg/L) solubilized in ODTMA micelles (3.36 mM) on/from soils (67 g/L).

Table 3. Adsorption Coefficients of Sulfentrazone Solubilized in ODTMA Micelles (3.36 mM) to Soils (67 g/L)

	Langmuir			Freundlich		
soil	X_m [mg/g]	K_L [L/mg]	R^2	K_f [L/mg]	n	R^2
sandy	9.8	0.057	0.972	1.11	0.42	0.994
alluvial	8.13	0.014	0.972	0.34	0.53	0.986

Higher adsorption of sulfentrazone (solubilized in ODTMA–micelles) to the alluvial soil was expected since the percent of clay in this soil is approximately 35 times higher than in the sandy soil and sulfentrazone adsorption to the soil is via the electrostatic adsorption of ODTMA micelles to the clay fraction. Surprisingly sulfentrazone affinity and loading to/on the sandy soil were higher than to the alluvial soil as indicated by the affinity coefficients which are 3–4 times higher for the sandy soil (for both models) and by X_m (Langmuir loading coefficient) which is higher for the sandy soil. Furthermore, the desorption from the sandy soil presents a normal hysteresis. However, the desorption from the alluvial soil exposes suspicious excessive desorption (inverse hysteresis).

The high adsorption of sulfentrazone on the sandier soil and the high desorption from the heavier soil can be explained by analyzing the molar ratio between the surfactant and the soil CEC. Mishael et al.[26] investigated sulfosulfuron adsorption to montmorillonite via its solubilization in ODTMA micelles. They found that the optimum ODTMA/CEC (mol/mol) ratio was ~1.5. Above this ratio not all the micelles adsorbed, resulting in herbicide solubilized in unadsorbed micelles, and below this ratio (i.e., high clay concentration) ODTMA adsorbed as monomers (which have a higher affinity to the clay than the micelles) causing decomposition of micelles and release of solubilized herbicide to the solution. The adsorption of sulfentrazone on the monomer–clay complexes is much lower than on the micelle–clay complexes as reported for sulfentrazone[28] and sulfometuron.[25]

The ODTMA/CEC mole ratio for the adsorption experiment with the sandy and with the alluvial soil were 1 and 0.12, respectively, which explains the higher adsorption to the sandy soil (ratio close to optimum ratio) and perhaps can explain precipitation of sulfentrazone in the experiment with the heavier soil due to the high clay concentration releasing sulfentrazone above its water solubility from the micelles. During the desorption experiment the unadsorbed sulfentrazone is released to the solution, resulting in excessive release. This implies that not all of the sulfentrazone (in the case of the alluvial soil) adsorbed but rather precipitated; therefore, the Y axis denoted sulfentrazone removal and not adsorption.

These results emphasize the importance of selecting an optimal surfactant/CEC ratio.

Sulfentrazone and Metolachlor Release and Leaching from Micelle Treated and Nontreated Soils. *Sulfentrazone Release and Leaching from Micelle Treated and Nontreated Soils.* We suggest that the cationic micelles solubilized with sulfentrazone adsorb to the soil which in turn inhibits both herbicide release from the micelles and leaching through the soil without compromising weed control.[11] To test the reduction in sulfentrazone leaching when applied to that solubilized in micelles, Boral, sulfentrazone (800 mg/L) solubilized in ODTMA micelles (3.36–13 mM), and water (control) were applied to a thin layer of the sandy or alluvial soil, and the soils were irrigated with 0–8 pore volumes; also, sulfentrazone concentrations in the leachates were measured (Figures 4). Sulfentrazone

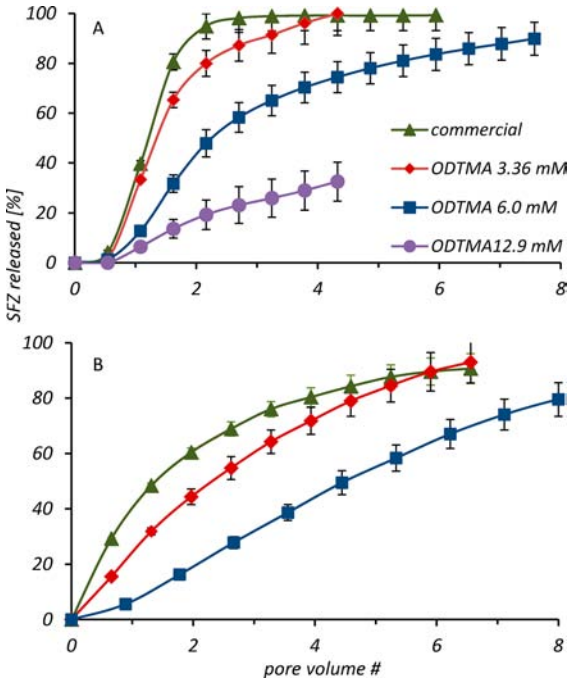

Figure 4. Sulfentrazone (SFZ) release and leaching applied as a commercial Boral or sulfentrazone–micelle formulations applied on thin layer of soil (A) alluvial or (B) sandy.

leaching from the commercial formulation was higher than from the herbicide–micelle ones, through both soils. For the alluvial soil, after 2.7 pore volumes irrigations (equivalent to 300 mm of rain), 98% of the sulfentrazone from the commercial formulation (Boral) leached through the soil layer, whereas 87, 58, and 23% leached from the 3.36, 6.0, and 12.9 mM ODTMA formulations, respectively. In the sandy soil, after 2.6 pore volume irrigations (equivalent to 200 mm of rain), 69% of the SFZ from the commercial formulation leached through the soil layer, whereas 54 and 27% leached from the 3.36 and 6.0 mM ODTMA formulations, respectively.

The decrease in sulfentrazone leaching upon the increase in surfactant concentration emphasizes the contribution of the adsorbed micelles to the inhibited leaching.

Effect of Soil on Sulfentrazone Release and Leaching from Micelle Treated and Nontreated Soils. In agreement with the adsorption/desorption results (Figure 3), sulfentrazone leaching (applied solubilized in micelles) through the alluvial soil

dx.doi.org/10.1021/jf403456m | J. Agric. Food Chem. 2014, 62, 50–57

was higher than through the sandy soil (Figure 4b). An irrigation of 2.6 pore volumes resulted in 87% and 48% leaching of sulfentrazone applied to the alluvial and sandy soils, respectively. The enhanced leaching from the alluvial soil can be explained by micelle decomposition caused by "excess" clay in the alluvial soil as described and calculated in the adsorption experiments. For the leaching experiments it is problematic to estimate the volume of soil the micelles can access, since the micelle solution is applied on top of the soil and not in a batch array. Therefore, the micelle/CEC mol/mol ratio was not calculated, but the enhanced leaching from the alluvial soil implies that the optimal ratio was exceeded.

The enhanced leaching of sulfentrazone from the commercial formulation through the alluvial soil, obviously, cannot be explained by a low micelle/CEC mol/mol ratio (Figure 4a). Four alternative explanations were raised and examined.

1. High adsorption of sulfentrazone to iron oxides, common in this sandy soil (Hamra), which could explain inhibited leaching. It is well documented that herbicides have high affinity to oxides.[62−64] However, sulfentrazone (technical and as Boral) adsorption experiments to iron oxides resulted in negligible adsorption, excluding this mechanism.
2. Transport of herbicides via their interaction with the dissolved organic matter (DOM) may also be considered. Indeed, the percent of DOM in the alluvial soil was higher than in the sandy soil. To test this hypothesis the DOM was washed from the alluvial soil and the leaching experiment was repeated with the washed soil; however, no significant differences were observed (Figure 5) indicating that in this case the DOM had a minor role in sulfentrazone transport (not surprising since both are negatively charged).

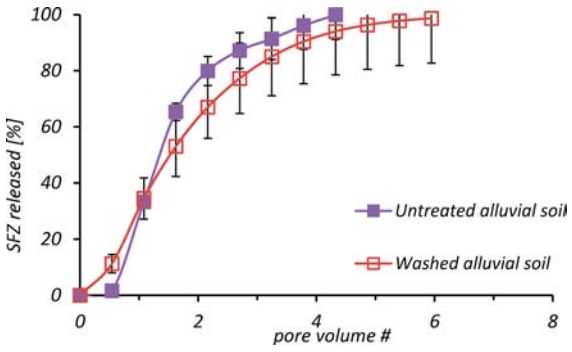

Figure 5. Sulfentrazone release and leaching from a sulfentrazone−micelle (3.36 mM ODTMA) formulation applied on a thin soil layer of an untreated alluvial soil and on a thin soil layer of alluvial soil in which the DOM was washed.

3. The well aggregated structure of the alluvial soil (in comparison to the sandy soil) may decrease the accessible soil adsorption sites, enhancing sulfentrazone leaching. If so, the leaching pattern, higher leaching through the alluvial soil, of other herbicides should be the same. As seen in Figure 6, metolachlor leaching through the two soils is not very different, and when plotted as a function of number of washes the leaching through both soils is nearly the same. In contrast, upon plotting the leaching of sulfentrazone as a function of number of washes the leaching from the alluvial soil remained higher (plot not shown). This suggests that the soil structure and that the kinetics are not the governing factors.
4. Finally, the repulsion of anionic sulfentrazone from the alluvial soil with a high clay concentration may explain the enhanced leaching through this soil. Metolachlor which is nonionic would not be as repelled from the heavy soil, and indeed its leaching through the sandy and heavy soils is not very different (Figure 6).

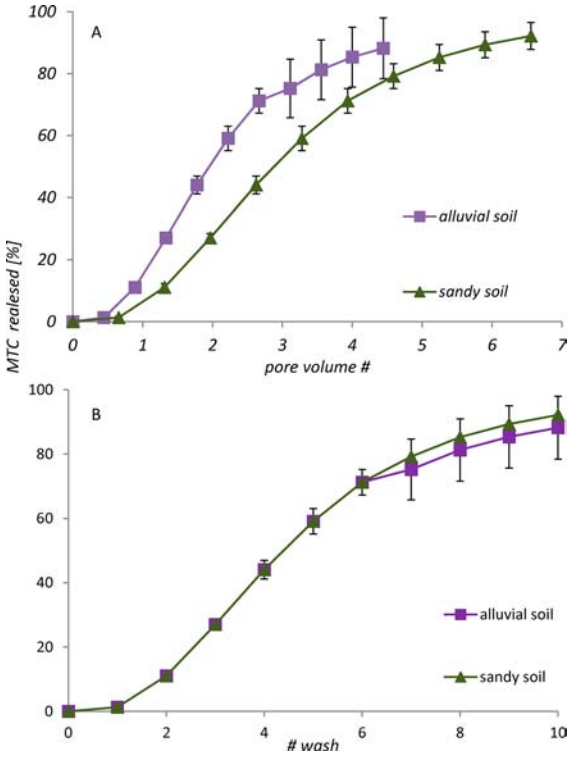

Figure 6. Metolachlor (S-dual gold) release and leaching from a thin layer of alluvial soil as a function of (A) irrigation pore volume and (B) number of irrigations.

Metolachlor Release and Leaching from Micelle Treated and Nontreated Soils. Leaching of metolachlor (solubilized in 3.36 mM ODTMA or as the commercial formulation, S-Dual Gold) through the alluvial soil was tested, in order to demonstrate that employing herbicides in micelles reduces their leaching is valid not just for sulfentrazone (Figure 7).

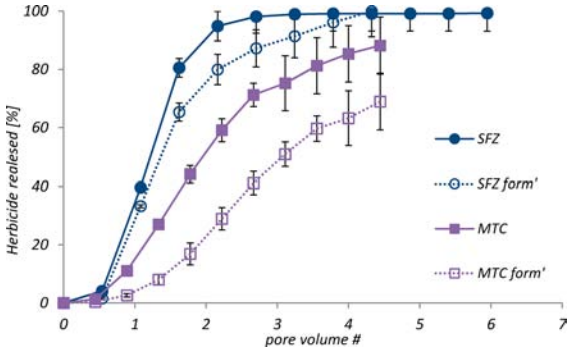

Figure 7. Herbicide release from commercial and herbicide−micelle (ODTMA 3.36 mM) formulations applied on thin layer of alluvial soil.

dx.doi.org/10.1021/jf403456m | J. Agric. Food Chem. 2014, 62, 50−57

Metolachlor leaching in both cases applied as the commercial or as a micelle formulation was restricted in comparison to sulfentrazone leaching. After irrigating 2.7 pore volumes, 98 and 87% of the sulfrentrazone leached from the commercial and from the micelle formulation, respectively, whereas metolachlor leaching after irrigating 2.7 pore volumes reached only 71 and 41% of the applied herbicide as the commercial or micelle formulation, respectively. As expected, leaching of anionic sulfentrazone was higher than the leaching of nonionic metolachlor.

Metolachlor leaching was inhibited when employed solubilized in micelles. Furthermore, metolacher leaching was inhibited to a higher degree (~50%) than that of sulfentrazone (~16%).

As discussed above due to a low surfactant/CEC mol/mol ratio in the alluvial soil micelle decomposition and monomer adsorption are expected. Nevertheless, metolachlor (unlike sulfentrazone) has high affinity to organo−clay complexes [34] which explains its high inhibition even under conditions of micelle decomposition.

Metolachlor leaching, when applied solubilized in micelles (3.36 mM ODTMA), was reduced by up to 2-fold, and sulfentrazone leaching, when applied solubilized in micelles (13 mM ODTMA), was reduced by up to 5-fold. These reduction rates are much higher than values previously reported for in situ slow release formulations.[39,65]

Gamiz et al. reported a reduction in fluometuron leaching of 1.25 upon adding 12.5% (surfactant (w)/soil (w)).[39] Rodriguez-Cruz et al. studied the retention of three pesticides in soil columns modified with ODTMA (w/w ratio of 2.5%). The leaching of linuron, atrazine, and metalaxyl through the soil treated with ODTMA was 3−4-fold less than from the nontreated soil.[65] In the current study, for sulfentrazone, not only were ODTMA doses much lower but herbicide reduction rates were higher. Sulfentrazone leaching was reduced by 5-fold upon adding only 0.3% ODTMA, and metolachlor leaching was reduced by 2-fold upon adding only 0.075% ODTMA.

The current study demonstrated four advantages when comparing the leaching retention to other reports on in situ soil modification: (1) Upon adding low loadings of ODTMA (0.075−0.3% w/w), herbicide leaching is significantly reduced. (2) ODTMA has been reported as toxic to microbial soil processes.[66] However, surfactant concentrations employed in this study are below the reported limit (1−10% w/w). (3) The herbicide is solubilized in the micelles as a formulation and both are applied to the soil at the same time, in comparison to the two step application in other reports (soil modification and then herbicide application). (4) An optimized surfactant/soil CEC mol/mol ratio is taken into account to maximize herbicide retention via micelle adsorption.

To conclude, herbicides were solubilized in micelles, and these formulations were applied to soils, for reduced herbicide leaching. This mode of application is more efficient than the common two step application, soil modification, and then herbicide application. Sulfentrazone (as Boral or technical) adsorption to a sandy or alluvial soil was negligible; however, its adsorption via its solubilization in ODTMA micelles was significant and in good agreement with the Freundlich and Langmuir models. An optimized surfactant/soil CEC mol/mol ratio was taken into account to maximize herbicide retention via micelle adsorption. Even upon adding low loadings of surfactant (0.075−0.3% w/w soil) herbicide leaching was significantly reduced.

Supporting Information

ABSTRACT: Bovine milk is known to contain naturally occurring peptides, but relatively few of their sequences have been determined. Human milk contains hundreds of endogenous peptides, and the ensemble has been documented for antimicrobial actions. Naturally occurring peptides from bovine milk were sequenced and compared with human milk peptides. Bovine milk samples from six cows in second-stage peak lactation at 78−121 days postpartum revealed 159 peptides. Most peptides (73%) were found in all six cows sampled, demonstrating the similarity of the intramammary peptide degradation across these cows. One peptide sequence, ALPIIQKLEPQIA from bovine perilipin 2, was identical to another found in human milk. Most peptides derived from β-casein, α_{s1}-casein, and α_{s2}-casein. No peptides derived from abundant bovine milk proteins such as lactoferrin, β-lactoglobulin, and secretory immunoglobulin A. The enzymatic cleavage analysis revealed that milk proteins were degraded by plasmin, cathepsins B and D, and elastase in all samples.

KEYWORDS: *peptidomics, bovine milk, bioactive peptides, protease*

INTRODUCTION

The peptides that are naturally occurring in bovine milk have not been completely identified, nor have they all been investigated for biological activity. In this study, breakthroughs in the analytical chemistry of peptides have enabled us to perform a peptidomic profiling of the endogenous peptides in bovine milk.

Human milk contains hundreds of naturally occurring peptides released by plasmin and other milk proteases within the mammary gland.[1,2] Eighteen percent of the peptides in human milk had >50% homology with known functional peptides.[2] Most of these peptides matched known antimicrobial peptides. Assays demonstrated that an isolated ensemble of endogenous human milk peptides inhibited the growth of *Escherichia coli* and *Staphylococcus aureus*. As *S. aureus* and *E. coli* are common causative agents in human mastitis, these peptides may be a mechanism of maternal resistance to mastitis. This previous work in human milk demonstrated that naturally occurring milk peptides may influence the health of the mother and the infant.

The presence of active proteases—plasmin[3−5] (as well as tissue-type and urokinase-type plasminogen activators[6,7]) and possibly active cathepsin B and cathepsin D[8−10]—in non-mastitic bovine milk suggested that naturally occurring peptides would also be present in bovine milk. The appearance of low molecular weight bands in gel electrophoresis experiments has suggested that naturally occurring peptides exist in healthy bovine milk, typically referred to as the proteose peptone fraction.[11] The proteose peptone fraction has been separated into components and, for some, their sequences have been determined, typically with gel electrophoresis and amino acid sequencing.[12−14] That research showed this fraction to be composed of casein degradation products and some whey proteins.[15,16] A previous analysis of bovine milk peptides isolated by immobilized metal affinity chromatography and analyzed using matrix-assisted laser desorption/ionization tandem time-of-flight (MALDI-TOF/TOF) mass spectrometry identified 15 peptides but only 2 complete sequences, both from α_{s1}-casein.[17] Eleven naturally occurring phosphorylated peptides and one nonphosphorylated peptide from bovine milk β- and α_{s2}-casein were identified with MALDI-TOF/TOF and ultrahigh-pressure liquid chromatography electrospray ionization mass spectrometry.[18] In another paper, 21 peptide sequences were identified in healthy bovine milk by LC-MS/MS.[19]

This research analyzed naturally occurring peptides in bovine milk by a shotgun nanoliquid chromatography quadrupole time-of-flight tandem mass spectrometry approach. The cleavage sites were matched to cleavage patterns of known milk enzymes to determine which were likely responsible for protein cleavages in the mammary gland.

MATERIALS AND METHODS

Sample Collection. Bovine milk samples were collected from the University of California—Davis Dairy Barn in the winter from six Holstein cows. All six cows were deemed mastitis-free on the basis of the following criteria: (1) prior to milking, each teat was checked to ensure there was no abnormal milk (e.g., watery (serous) milk, flakes, or clots) or issues in the quarter (e.g., swelling, redness); (2) after milking, each pretank filter was checked to ensure no abnormal milk entered the tank; (3) milk weights were recorded, and any cows with low milk production were checked again for mastitis. None of the cows used in this study had abnormal milk, udder swelling, or low milk production. In addition, samples from the milk tank were cultured raw

for total bacteria and coliform bacteria counts and then laboratory-pasteurized for thermophilic bacterial counts. All bacterial counts were normal. All cows sampled were lactating for the second time (second lactation period). Milk samples represented a range of days postpartum: 78−121 days. Animals were kept in free stall housing and fed a total mixed ration (a mixture of grain (barley and corn), alfalfa, cottonseed, almond hulls, oat hay, added minerals and salts, beet pulp, and canola meal) and had access to water ad libitum. Cows were milked twice daily, at 4 a.m. and 4 p.m. in a milking parlor managed according to American Association for Accreditation of Laboratory Animal Care guidelines. Samples employed in this study are all from 4 p.m. milkings. Cows were milked with automated milking machines (Metatron, GEA Farm Technologies) from all four quarters at once. The resulting stream of milk was split from delivery to the bulk tank throughout the pumping process to provide samples representative of each cow's individual milk for this study. Before the pumps were attached, all four teats were washed first with water and then with an antiseptic solution (Chlorhexidine Active Mastitis Prevention) with 0.5% chlorhexidine gluconate, a chemical antiseptic, as the active ingredient. The time from initiation of suction to end of milking was 5.5−6.5 min. The cows produced from 41 to 52 lbs of milk. After pumping, milk was immediately placed in a 100 °C water bath for 4 min to deactivate the milk proteases. Samples were then transferred to a −20 °C freezer.

Sample Preparation. Samples were removed from the freezer and allowed to thaw at room temperature. Then, they were vortexed for 3−4 min each. Peptides were extracted according the procedure of Dallas et al.[2] but adapted to a 96-well plate format for increased sample preparation speed, reproducibility, and throughput. Briefly, 50 μL of each milk sample was added to the 96-well plate with 150 μL of nanopure water followed by pipet mixing. The 96-well plates were centrifuged at 2800*g* for 30 min at 4 °C, and 160 μL of the infranate (skim milk) was removed from the upper lipid layer by multichannel pipet and added to a second 96-well plate. Proteins were precipitated with addition of 160 μL of 200 g/L trichloroacetic acid (TCA). A plate cap was added, and the samples were vortexed for 5 min. After centrifugation at 2800*g* for 30 min at 4 °C, the peptide supernatant was collected. The peptide supernatant was cleaned up on a C18 solid phase extraction column plate to remove salts, sugars, and TCA. Columns were prepared with 99.9% acetonitrile (ACN)/0.1% trifluoroacetic acid (TFA) (v/v), followed by 1% ACN and 0.1% TFA (v/v). The peptide samples were then added. Three column volumes (200 μL) of 1% ACN and 0.1% TFA (v/v) were added to remove sugars, salts, and TCA. Then, 3 column volumes of 80% ACN and 0.1% TFA (v/v) were used to elute peptides. Solvents were passed through the columns by centrifugation for 30 s at 2800*g* without heating. Peptides were dried in the plate by centrifugal evaporation. Peptides were resolubilized in 20 μL of nanopure water with 5 min of sonication and 30 min of plate vortexing. Samples were then centrifuged at 16000*g* for 30 min to pull down any remaining solids. Supernatants were transferred to sampling vials for Q-TOF analysis.

Mass Spectrometry. Peptides were analyzed by mass spectrometry according to the procedure of Dallas et al.[2] Samples were injected on the Agilent 6520 (Santa Clara, CA, USA) nano-LC-chip-Q-TOF MS/MS (Chip-Q-TOF) with an Agilent chip C18 column. Changes to the procedure in Dallas et al.[2] include using a drying gas flow rate of 3 L/min and a spectral acquisition rate of 1 spectra/s. The gradient elution solvents were (A) 3% ACN/0.1% FA (v/v) and (B) 90% ACN/0.1% FA (v/v). The gradient employed was ramped from 0 to 8% B from 0 to 5 min, from 8 to 26.5% B from 5 to 24 min, and from 26.5 to 100% B from 24 to 48 min, followed by 100% B for 2 min and 100% A for 10 min (to re-equilibrate the column). Ion polarity was set to positive. The peak collection thresholds were set at 200 ion counts or 0.01% relative intensity for MS spectra and 5 ion counts or 0.01% relative intensity for MS/MS. Automated precursor selection based on abundance was employed to select peaks for tandem fragmentation with an exclusion list consisting of all peptides identified in previous analyses in this study. The acquisition rate employed was 0.63 spectra/s for both MS and MS/MS modes. The isolation width for tandem analysis was 1.3 m/z. The collision energy was set by the formula (slope) × (m/z)/100 + offset, with slope = 3.6 and offset = −4.8. Five tandem spectra were collected after each MS spectrum, with active exclusion after 2 MS/MS for 2 min. Precursor ions were selected only if they had at least 1000 ion counts or 0.01% of the relative intensity of the spectra.

Spectral Analysis. Spectra were analyzed by database search according to the procedure of Dallas et al.[2] Briefly, data were exported from Agilent MassHunter in .mgf format and imported into the offline search engine X!Tandem.[20] X!Tandem searches were against a bovine milk library compiled from previous bovine milk proteome studies.[21−23] Peptides were accepted if e-values were ≤0.01, corresponding to a 99% confidence level. Masses were allowed 20 ppm error. No complete (required) modifications were included, but up to four potential modifications were allowed on each peptide. Potential modifications allowed were phosphorylation of serine, threonine, and tyrosine; oxidation of methionine and tryptophan; and deamidation of asparagine and glutamine. A nonspecific cleavage ([X]|[X]) (where 'X' is any amino acid) was used to search against the protein sequences. Because the instrument did not always select the monoisotopic ion for tandem fragmentation, isotope errors were allowed (allowing up to one C13). No model refinement was employed in X!Tandem.

Library Search. X!Tandem peptide results were used to construct a peptide library from all samples. Duplicates with the same sequence, protein, and modifications were removed. In addition, all peptides that were the same except for the position of the modification were reduced to a single entry for each. The library information consisted of neutral mass, retention time, and a peptide ID. Compounds were identified from MS-only runs of all six samples by the "Find by Molecular Feature" function in Agilent MassHunter Qualitative Analysis version 6. The target data type was small molecule (chromatographic). Retention time was restricted from 3.5 to 36 min (the range of library peptides). Only peaks with at least 1000 ion counts were selected. The selected charge carrier was "protons". The isotope model was "peptides", and the maximum assigned charge was 7. After compounds were extracted, they were matched to the peptide library by mass and retention time to identify peptides. The database match employed a mass error tolerance of 40 ppm and a retention time tolerance of 1 min. Each exact peptide mass in the library was converted to an m/z for all charge states from 1 to 7 for the search. All amino acid sequence ranges expressed throughout this paper will include the signal sequence.

Enzyme Analysis. A custom program written in Python was used to estimate the activity of selected enzymatic systems. This program works with the output from the peptide library from an individual trial. Each peptide is assigned a location within a protein on the basis of the unique sequence to determine the sequence context of the peptide. After assigning context, both termini of each peptide are compared to a selected set of proteolytic enzyme rules. As a measure of simplification, rules were assumed to only act on P1 and P1′. P1 is the amino acid directly before the cleavage site, and P1′ is the amino acid directly after the cleavage site, where the protein N-terminus is on the left and the C-terminus is on the right. Enzymatic cleavage rules were derived from a list published on ExPASy.[24] The enzyme specificity patterns used in the algorithm for evaluating cleavages are shown in Table 1. Peptides having termini that pass a comparison to an enzymatic rule have their mass spectral intensity (peak volume)

Table 1. Enzyme Cleavage Specificity Rules Used for Enzyme Analysis[a]

enzyme	P1	P1′
plasmin	R, K	any
cathepsin B	G, A, M, Q, T	F, G, I, V, L
cathepsin D	A, V, L, I, P, M, F, W	A, V, L, I, P, M, F
elastase	A, V, L, I, G, R	G, P, A, L, F

[a]Specificity rules were derived from PeptideCutter as described in ref 24.

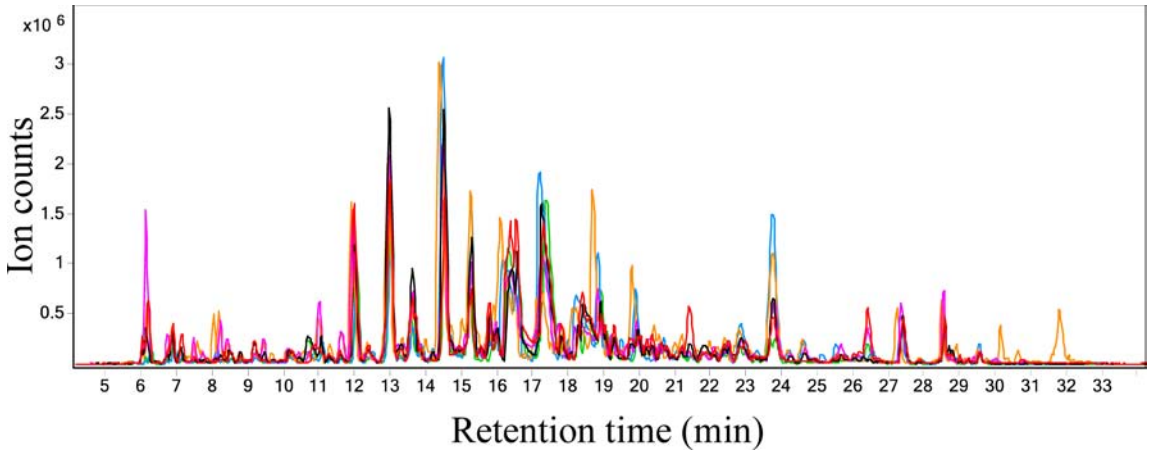

Figure 1. Base peak chromatograms of all six bovine milk samples overlapped.

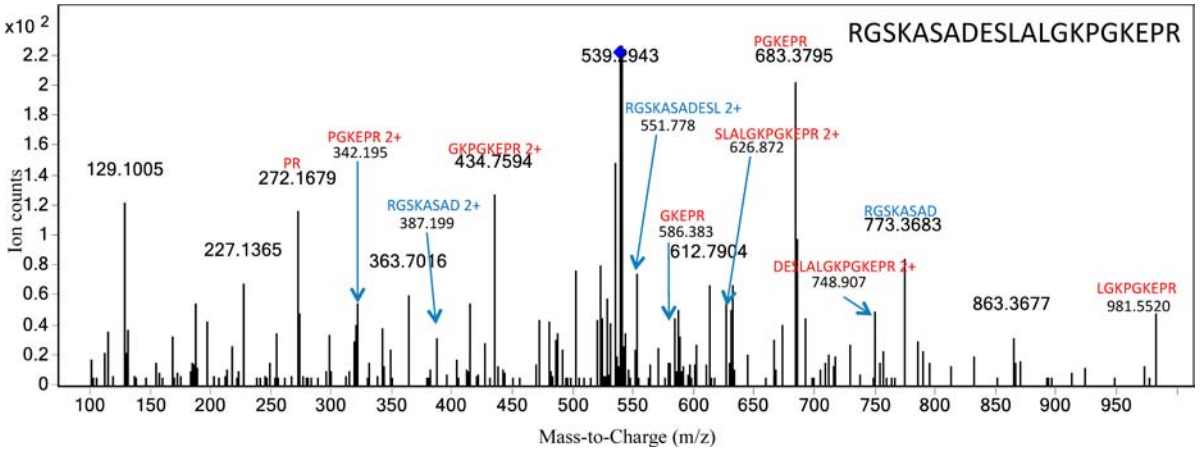

Figure 2. Tandem fragmentation of m/z ($z = 4$) 539.29 at one time point within its 8.3−8.8 min retention time with y-type ions in red, b-type ions in blue, and the precursor ion denoted by a blue diamond. The tandem fragmentation analysis confirms the presence of peptide RGSKASADESLALGKPGKEPR from fibroblast growth factor-binding protein 1.

added to the sum of the respective enzyme. In the case that a peptide matches multiple rules simultaneously, the full intensity of that peptide is added to both enzymatic sums; thus, the intensity value output represents potential activity rather than uniquely specific activity. Peptides failing all enzymatic comparisons have their intensity added to a list of remainders, the purpose of which is to assist in the identification of new enzymatic systems.

Homology Searches for Comparison of Bovine and Human Milk Peptides. Sequences identified in the bovine milk samples were searched for homology against endogenous peptides previously identified in human milk.[2] This search was performed with protein−protein BLAST. For each query, matches were retained only if peptides shared at least 50% identity (at least 50% of the amino acids were the same and in the same positions).

RESULTS AND DISCUSSION

The base peak chromatograms from all six samples (shown in Figure 1) have a substantial number of overlapping peaks. The large degree of overlap is interpreted to indicate that release of peptides in the mammary gland is thus similar across the six cows measured. The annotated tandem spectrum in Figure 2 demonstrates how peptide identifications were verified in an automated process in X!Tandem, in this case, confirmation of the presence of RGSKASADESLALGKPGKEPR from bovine fibroblast growth factor-binding protein 1 in all six samples from 8.3 to 8.8 min retention time.

The nano-LC Q-TOF and database searching methodologies developed for peptidomic analysis identified 159 endogenous peptides in the six bovine milk samples. All 159 peptide sequences are shown in Supplementary Table 1 in the Supporting Information. Previous research on endogenous bovine milk peptides revealed fewer peptides. One study employing MALDI-TOF/TOF identified two peptides sequences, both from α_{s1}-casein.[17] Another study employed MALDI-TOF and LC-MS to identify 11 phosphopeptides and 1 nonphosphorylated peptide.[18] Mansor et al. identified 21 peptide sequences from healthy bovine milk by LC-MS/MS.[19] The increased number of peptides identified in the present research is likely due to improved identification methods.

Six of the peptides found in Mansor et al. were identified in the present research (identified in Supplementary Table 1). Most of the other peptides in the work of Mansor et al. matched segments of the proteins identified here but were not identical sequence matches. The two bovine milk peptides found in Meltretter et al. were not found here, but overlapping peptides were identified in the present data.[17] Of the 12 peptides found in Baum et al.[18] 3 were identical to those found here (2 phosphorylated, 1 nonphosphorylated) (see Supplementary Table 1), 4 overlapped but were incomplete matches,

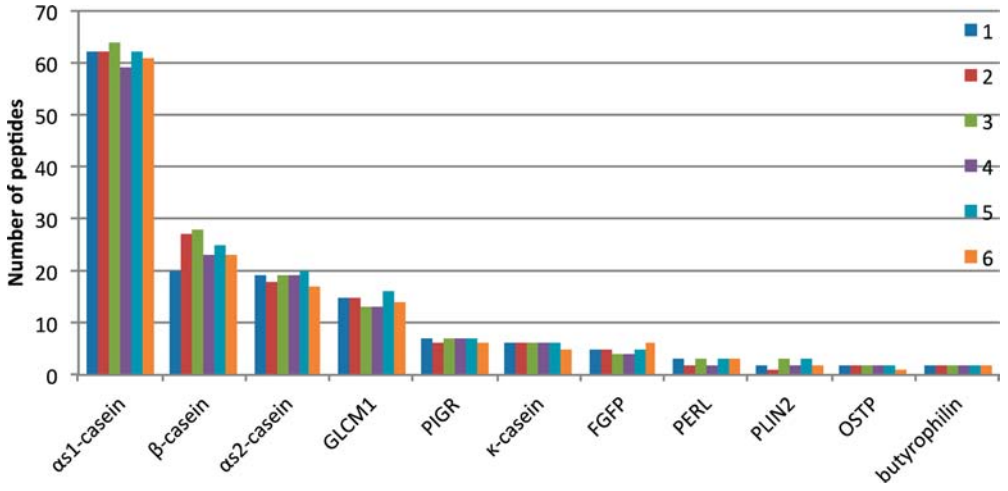

Figure 3. Number of peptides identified for each protein by each sample. GLCM1, glycosylation-dependent cell adhesion molecule 1; PIGR, polymeric immunoglobulin receptor; FGFP, fibroblast growth factor-binding protein 1; PLIN2, perilipin-2; PERL, lactoperoxidase; OSTP, osteopontin.

and 5 matched by sequence but had a lower degree of phosphorylation in the present paper.

The peptides identified ranged in charge states from 1 to 6. Peptide sequence length ranged from 8 to 45 amino acids. The average number of amino acids in a sequence was 16.7. Peptide mass ranged from 784.4 to 4416.2 Da. The average peptide mass was 1938.8 Da.

The majority of identified peptide sequences (73%) were present in all six samples. Sixteen percent were found in five of the six samples; thus, 89% of peptides identified were found in at least five of the samples. This data set was interpreted to indicate that the degradation processes within the mammary gland are relatively similar across these six healthy Holstein cows in second-stage peak lactation. Analysis of more cows would be necessary to extend this interpretation to healthy Holstein cows in general, as the cows examined had similar feed and climate.

The parent proteins for all peptides identified are present in healthy bovine milk as protein fragments and as intact proteins. Gel electrophoresis implied the presence of these intact milk proteins.[25] In the present research, 15 proteins gave rise to endogenous milk peptides, including α_{s1}-casein, α_{s2}-casein, β-casein, κ-casein, glycosylation-dependent cell adhesion molecule 1, polymeric immunoglobulin receptor, fibroblast growth-factor-binding protein 1, lactoperoxidase, perilipin-2, butyrophilin, and osteopontin. Previous research by Meltretter et al. identified only α_{s1}-casein-derived peptides.[17] The work of Baum et al. identified peptides only from α_{s2}-casein and β-casein.[18] Mansor et al. identified peptides from most of the proteins identified in the present research, but did not identify peptides from polymeric immunoglobulin receptor, perilipin-2, and butyrophilin.[19] The increased number of protein precursors identified in the present research compared to previous research is likely due to more exhaustive tandem fragmentation of peptide precursors and searching against the large in-house library of milk proteins with X!Tandem.

However, other high-abundance milk proteins including lactoferrin, β-lactoglobulin, and secretory IgA (sIgA) did not produce peptides. These proteins were also not present as peptides in human milk.[2] One peptide from β-lactoglobulin was found in healthy bovine milk in Mansor et al., but, like the present research, they detected no peptides from lactoferrin or sIgA.[19] Likewise, these peptides were not identified in milk in the previous works of Meltretter et al.[17] and Baum et al.[18]

This variation in which proteins are degraded in the mammary gland could be due to protein structural differences. Milk enzymes may more easily degrade the looser three-dimensional structure of the caseins[2] than the more rigid, compact, globular structures of lactoferrin, β-lactoglobulin, and sIgA.[2] The type and position of glycan post-translational modifications on lactoferrin and sIgA may also influence resistance to protein degradation.

Forty percent of all peptide sequences were derived from α_{s1}-casein. The number of peptides found for each protein is shown in Figure 3. In human milk, the majority of peptides identified in mothers studied were derived from β-casein,[2] whereas α_{s1}-casein peptides were present but less abundant. The number of peptides identified from each protein were similar across the six bovine milk samples (Figure 3). These data are interpreted to indicate that protein degradation in the cow mammary gland is well regulated and controlled across cows. However, evaluation of more milks is necessary to confirm this interpretation, as these cows were exposed to identical feeding and climate conditions. This similarity of peptides released across bovine milk samples was mirrored in the results showing that human milk peptide profiles are highly similar between mothers.[2]

Each sample had between 35 and 37 phosphorylated peptides. The total number of phosphorylated peptides for all six samples combined was 38 (24% of all peptides identified by count). The number of phosphopeptides identified here is higher than the 11 identified in Baum et al.[18] Research by Meltretter et al. and Mansor et al. did not identify any phosphopeptides.[17,19] The high number of phosphorylated peptides detected in the present research is not surprising as most of the phosphorylated peptides come from the four casein proteins, which are all known to be multiply phosphorylated.[18] Some of these phosphopeptides contained multiple phosphorylations: two had three phosphorylations, and four had two phosphorylations. This is less phosphorylation than found in the work of Baum et al.: they identified nine peptides with four phosphorylations.[18] The presence of phosphorylations on caseins is known to allow formation of organophosphate salts for minerals, especially calcium.[26] Peptides containing multiple phosphorylation sites may bind calcium and aid in calcium

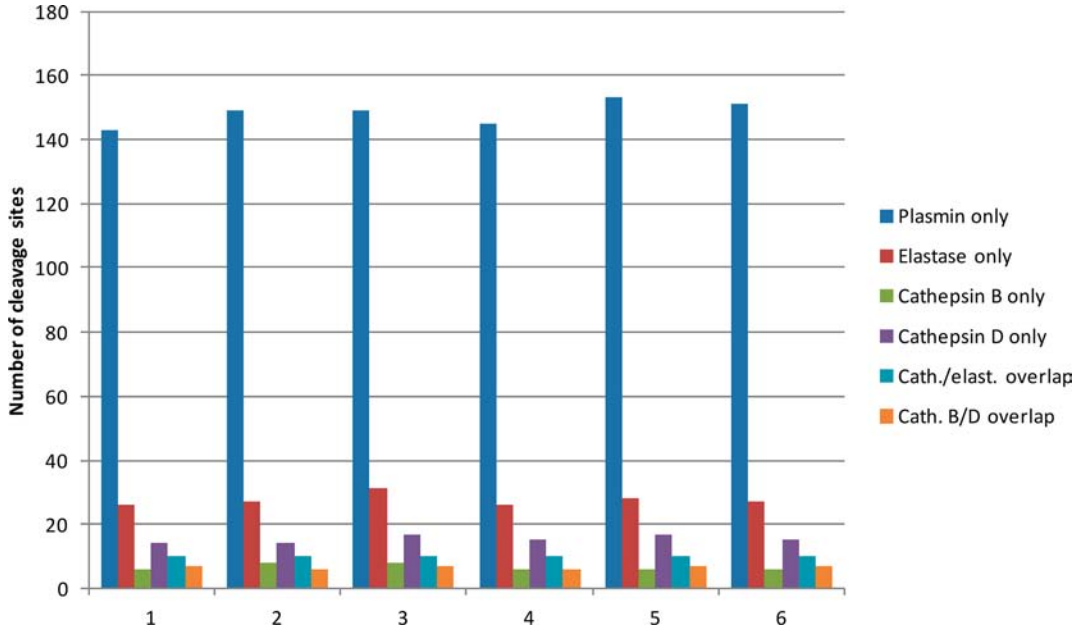

Figure 4. Cumulative intensities for all assigned cleavage sites for each bovine milk sample.

delivery.[27] Other modifications found include methionine oxidation, deamidation of glutamine, N-terminal acetylation, and pyroglutamination of glutamine. No glycosylated peptides were searched for with the methodology employed; therefore, no glycopeptides were identified.

Only one bovine milk peptide sequence matched exactly a known endogenous peptide in human milk: ALPIIQKLEPQIA from human and bovine perilipin 2 (amino acids 65−77 in both species, including the signal sequence). This peptide was not identified in milk peptide profiles in Mansor et al.,[19] Meltretter et al.,[17] and Baum et al.[18] No function has been ascribed to this peptide sequence. Although many bovine milk peptides derived from the same proteins as peptides found in human milk,[2] the amino acids within these sequences differed, presumably due to evolutionary changes.

All six cows released peptides from the same locations within each protein (α_{s1}-, α_{s2}-, β-, κ-casein, osteopontin, and glycosylation-dependent cell adhesion molecule 1), but with various levels. None of the protein fragments were derived from the protein signal sequence of any of the proteins.

Enzyme Cleavage. Plasmin (EC 3.4.21.7) was interpreted by computation to be a major agent of cleavage in the bovine mammary gland (see Figure 4). Plasmin is a serine protease that cleaves on the C-terminal side of arginine or lysine.[28] Cleavage after arginine or lysine accounts for the majority of released peptides by count. Plasmin and trypsin cannot be differentiated with these methods, because both cleave after arginine or lysine; however, no evidence for trypsin in bovine milk exists.[29] Plasmin is known to be present and active in bovine milk.[30] Plasmin is thought to enter milk from the blood,[30] and this interpretation is supported by the lack of mRNA for plasminogen in bovine mammary epithelial cells.[31] The remaining cleavage sites are interpreted to be created by elastase and cathepsins B and D (Figure 4) on the basis of their match to the cleavage specificity of the remainder of cleavages. More cleavages were attributed to cathepsin D than to cathepsin B for all milks. A separate column shows that many peptide cleavage sites could not be differentiated between cathepsins B and D. Likewise, several peptide cleavages were assigned to elastase in each milk sample, and a substantial number of cleavages could not be differentiated between the cathepsins and elastase. Cathepsin D (3.4.23.5), cathepsin B (EC 3.4.22.1), and elastase (EC 3.4.21.36) have been proven to exist in milk via either sequencing or antibody recognition.[32] Other cathepsins (i.e., cathepsins L (EC 3.4.22.15) and G (EC 3.4.21.20)) may also be present in milk, but their presence has not been confirmed.[32] Therefore, in this analysis, only plasmin, cathepsin B, cathepsin D, and elastase were assessed. Not all cleavage sites were matched to these enzymes: on average, 237.6 cleavage sites for each milk sample were assigned to plasmin, cathepsin B, cathepsin D, or elastase. However, on average, another 108.3 cleavage sites could not be assigned to these enzymes. This finding suggests that other enzymes not assessed here (nor proven to exist in bovine milk) are active in the bovine mammary gland. Further research to determine which enzymes are responsible is warranted.

***α_{s1}*-Casein.** Isracidin, a peptide derived from α_{s1}-casein (RPKHPIKHQGLPQEVLNENLLRF, 16−38) was identified in the bovine milks. Isracidin is known to be active against *S. aureus* and the yeast *Candida albicans*.[33] The signal sequence of α_{s1}-casein is amino acids 1−15, so in the terminology of this paper, the position would be 16−38 (which includes the signal sequence). This paper is the first to identify isracidin as a naturally occurring peptide in bovine milk. Previously, isracidin was identified after digestion with chymosin.[33]

α_{s1}-Casokinin-5 (FFVAP, 38−42) a known angiotensin converting enzyme inhibitory peptide,[34] is found within the sequences of three identified peptides (38−49 **FFVAP**FPEVFGK, 38−51 **FFVAP**FPEVFGKEK, 38−54 **FFVAP**FPEVFGKEKVNE). Whether the FFVAP sequence will exhibit identical actions within a longer sequence is unknown. A closely overlapping peptide with these, α_{s1}-casein (39−52), was previously found in Mansor et al.[19]

α-Casein exorphin (RYLGYLE, 105−111), a known opioid agonist peptide[35] from α_{s1}-casein, is found within three sequences found (95−115 HIQKEDVPSE**RYLGYLE**QLLR, 95−117 HIQKEDVPSE**RYLGYLE**QLLRLK, 95−119 HIQKEDVPSE**RYLGYLE**QLLRLKKY). It is not known whether

dx.doi.org/10.1021/jf4040964 | J. Agric. Food Chem. 2014, 62, 58−65

these longer sequences will retain the opioid inhibitory function. RYLGYLE has naloxone-inhibitable opioid-like properties.[36] RYLGYLE is a δ-selective opioid receptor ligand.[35] Opioid receptors are found in the digestive tract and the brain.

α_{s1}-Immunocasokinin-6, TTMPLW (208−214) from α_{s1}-casein, which has angiotensin-converting enzyme inhibitory[36] and immunomodulatory function,[37] is present within two sequences (187−214, 191−214). α_{s1}-Immunocasokinin-6 is known to decrease proliferation of lymphocytes,[38] decrease proliferation of human peripheral blood mononuclear cells,[39] increase antibody formation and macrophage phagocytosis,[40] and decrease *Klebsiella pneumoniae* infection in mice.[41,42]

Caseicin B (EVFGKEKVN, 45−53) from α_{s1}-casein inhibits the growth of *E. sakazakii* of α_{s1}-casein and is found within the sequence identified 40−54. Whether this longer sequence has antimicrobial function is unknown.

β-Casein. Peptide 16−39 from β-casein (RELEELNVPGEIVESLSSSEESIT) is a known caseinophosphopeptide that binds to calcium with its phosphorylation sites.[37] This binding of peptides to calcium hinders calcium phosphate precipitation in the milk, increasing the bioavailability of this mineral.[43] This peptide is present within the sequences of five peptide sequences found in this data set (16−40, 16−43, ranging from one to three phosphorylations).

Casoparan (41−45, INKKI)[44] is present within one larger sequence detected in β-casein: **INKKI**EKFQSEEQQQTEDELQDK (41−63). Casoparan activates macrophages to increase their phagocytic activity and peroxide release. Casoparan also acts as a bradykinin-potentiating peptide (i.e., increasing the duration or magnitude or bradykinin's vasodilatory effects).[44] Whether casoparan is functional within this larger sequence is unknown.

Casohypotensin (129−136, YPVEPFTE),[45] another bradykinin-potentiating peptide and a competitive inhibitor of angiotensin converting enzyme, is present within longer sequences in the identified β-casein protein fragment: HKEMPFPK**YPVEPFTE**SQSL (121−140). Whether casohypotensin is functional within this larger sequence is unknown.

β-Casokinin-7, an ACE inhibitor[46] from β-casein AVPYPQR 192−198, is present in several larger peptides in bovine milk but missing the initial alanine as 193−201 **VPYPQR**DMP and 193−204 **VPYPQR**DMPIQA. Whether the missing alanine is important to function as an ACE inhibitor is unknown. In addition, β-casein (193−209) in previous literature has been shown to have bitter taste perception.[47] β-Casein (193−204) found here may also have bitter taste.

Casecidin-15 YQEPVLGPVRGPFPI (208−222) from β-casein has been shown to be antimicrobial toward *E. coli*[48] and is present in the identified peptide sequences but lacking two amino acids: β-casein (210−222). A similar peptide, casecidin-17 YQEPVLGPVRGPFPIIV (208−224) that is also antimicrobial toward *E. coli*,[48] is also present but missing two amino acids: β-casein (210−224).

α_{s2}-Casein. A known antihypertensive peptide from α_{s2}-casein (TKVIP, 213-217) was present within an identified peptide sequence α_{s2}-casein (**TKVIP**YVRYL, 213−222). Whether this longer sequence will have antihypertensive function is unknown.

As endogenous milk peptides could be released by a variety of proteases, a nonspecific cleavage pattern was necessary for the X!Tandem searches. Searching X!Tandem with a nonspecific cleavage (rather than the typical tryptic cleavage employed for proteomic studies) against the full bovine proteome with modifications allowed resulted in a failed search because the search space was too large for the program. Therefore, to reduce the search space, a smaller list of proteins compiled from all proteins identified in proteomic studies of bovine milk was used. This restriction of the protein library used may have affected the results. Improvements in database searching speed would allow more thorough analysis of nonspecifically cleaved peptides.

Some endogenous milk peptides may be glycosylated. However, peptides with unknown glycosylation cannot be identified currently with X!Tandem. In addition, identification of glycopeptides with our approach is difficult as CID leads to mostly glycosidic cleavages rather than peptide chain cleavages.[49] This pattern allows identification of the glycan but not the peptide. The use of an alternate fragmentation strategy, such as electron transfer detection, which fragments both the glycan and peptide moieties,[49] could resolve this problem. In addition, glycopeptides ionize poorly in comparison with peptides,[49] thus making them difficult to detect without prior fractionation to increase their abundance. Identification of nonspecifically cleaved naturally occurring glycopeptides from a complex biological mixture remains a major challenge in glycobiology.[50]

The results of these healthy cow's milk are likely to differ from milks of cows with mastitis, an inflammation of the mammary gland. As somatic cell counts were not measured in these milks, we cannot rule out the possibility that some of these cows had subclinical mastitis, which could affect the results. Milks from cows with mastitis are known to have upregulated plasmin, cathepsin, and elastase[32,51,52] as well as urokinase-type plasminogen activator.[7] In addition, invading bacteria present in mastitis are also known to release exogenous enzymes into the milk, including elastase.[53] Previous work has shown that mastitic milks, compared to healthy milks, significantly differ in relative abundance of 33 identified peptide sequences.[19] All six of the peptides identified in this work that matched those identified in Mansor et al. were found in both healthy and mastitis cows but at different levels. As absolute quantification is employed for neither the work of Mansor et al. nor the present research, the abundances of peptides between these cows and the mastitic cows in the previous work are not comparable.

Impact of the Nonvolatile Wine Matrix Composition on the *In Vivo* Aroma Release from Wines

Carolina Muñoz-González, Pedro J. Martín-Álvarez, M. Victoria Moreno-Arribas, and M. Ángeles Pozo-Bayón*

Instituto de Investigación en Ciencias de la Alimentación (CIAL) (CSIC-UAM) C/Nicolás Cabrera 9, 28049 Madrid, Spain

ABSTRACT: The impact of the nonvolatile wine matrix composition on the retronasal aroma release of four volatile compounds added to different types of wines has been evaluated. For this purpose, a tailor-made retronasal aroma trapping device (RATD) was used to entrap the exhaled breath of six panelists previously trained in a specific consumption procedure. Five wines of different composition (white wine, sparkling white wine, young red wine, aged red wine, and a sweet wine) were evaluated. Prior to the evaluation, with the exception of the sweet wine, the wines were adjusted to the same ethanol content and aromatized with a mixture of four target volatile compounds. Aroma release data were submitted to multivariate statistical analysis in order to relate wine chemical composition and aroma release during wine drinking. Results showed interindividual differences and a clustering of panelists among lower and higher aroma releasers, which was in agreement to the differences in their breathing capacity. A significant influence of the matrix composition in the low aroma releasers group during wine consumption was observed. The consumption of red wines provoked a significantly higher aroma release than the consumption of white and sweet wines. From the chemical composition determined in the wine samples (pH, total acidity, total polyphenols, neutral polysaccharides, residual sugar, and nitrogenous compounds), the amount of total polyphenols was better correlated with the observed effect.

KEYWORDS: *wine, nonvolatile wine matrix, retronasal aroma, in vivo aroma release, wine drinking*

INTRODUCTION

The hedonic behavior behind wine consumption is greatly influenced by wine aroma, which is one of the most outstanding characteristics in explaining wine quality. Wine aroma is composed of hundreds of volatile compounds which depending on their concentration and chemical structure will have a higher or lower impact on the overall flavor profile of a wine.[1,2] The characterization of these compounds and the elucidation of their sensory relevance for wine aroma have been the focus of many interesting works,[3−5] and taking into account the magnitude of this task, it is likely these works will continue in the future.

However, we already know that only the characterization of the overall flavor composition of a food (for example: the headspace profile) does not directly correlate with the perceived sensations during consumption.[6] The process of aroma release during food consumption is a sequential process, which starts when the food is smelled (orthonasal aroma) and continues during the processing of the food in the mouth. Within the oral cavity, volatile compounds are released from the food and from here breathing flow carries them to the olfactory region where they are perceived. This is a dynamic and complex process known as retronasal aroma, in which not only the physicochemical characteristics of the compounds, but other physiological factors such as breathing flow, the presence of saliva, and tongue movements are also involved.[6,7] For liquid foods, such as wine, although the processing in the mouth could not be as critical, there are some factors such as the formation of a coating on the pharyngeal mucosa, the flow rates, temperature, etc., that should be considered as important aspects for modulating the aroma released available for the olfactory receptors during consumption.[7−10]

In spite of the facts that retronasal aroma is directly related to flavor perception and it is a key modulator for food consumption and food preferences, there are not many scientific works directed toward understanding aroma release during wine consumption. This type of study would need new analytical approaches based on monitoring aroma release during drinking.[1] One possible approach is the use of artificial devices to simulate the drinking process. Following this *in vitro* approach, Genovese and collaborators[11] studied the influence of saliva on wine aroma release. Although, undoubtedly, the use of artificial devices has considerable advantages (better control of the variables of the study, many experimental repetitions, no requirements of human subjects avoiding ethical considerations, etc.), they cannot mimic the real situation during wine consumption; therefore, they do not take into consideration all the physiological factors involved in aroma release (such as swallowing), making their correlation with sensory perception difficult. Other approaches to monitor aroma release during *in vivo* food consumption, such as the use of real time monitoring (breath by breath analysis) using mass spectrometric techniques such as atmospheric pressure ionization or proton transfer reaction mass spectrometric techniques (API-MS and PTR-MS, respectively),[12,13] or the use of aroma trapping devices of exhaled breath during consumption,[14−16] which are

often employed to study aroma release in many types of liquid and solid foods, have not been often applied in the wine field. Only Lasekan et al.,[17] applied an exhaled odor trapping device to investigate the aroma compounds released during the consumption of palm wine.

On the other hand, in recent years, the influence of the nonvolatile matrix composition has been highlighted as an outstanding factor influencing wine aroma release.[18−24] Using specific wine nonvolatile components[19,22−24] or the whole wine matrix composition[20,21] it has been possible to determine the interaction effect between wine compounds and specific wine volatiles. Even the effect of these interactions on the sensory characteristics of wines has been shown.[25,26] Most of these analytical studies have been carried out in static conditions, which, although very valuable, do not represent the retronasal aroma delivery of volatiles during a real wine consumption situation.

Therefore, the objective of this work was to determine the impact of the nonvolatile wine matrix composition on the *in vivo* aroma release during the consumption of different types of wines. To achieve the objective of this work, a tailor-made retronasal aroma trapping device (RATD) was used to trap the exhaled breath of six panelists previously trained in a specific consumption procedure. Five wines of different composition were aromatized with a mixture of volatile compounds at the same concentration and the aroma release data were submitted to multivariate statistical analysis in order to relate wine chemical composition and aroma release during wine drinking.

MATERIAL AND METHODS

Wine Samples. Five commercial Spanish wines representative of different winemaking technologies and with different matrix compositions were selected for this study: a young Verdejo white wine (**WH-W**), a young Tempranillo red wine (**YR-W**), a 4-year old (16 months in oak barrels) Tempranillo red wine (**AR-W**), a Cava white wine (Spanish sparkling wine manufactured by the traditional method) (**SP-W**), and a sweet biologically aged wine made from Pedro Ximénez grapes (**SW-W**).

In order to minimize the effect of ethanol on the volatility of aroma compounds, all the wines, except the sweet wine that was kept at its initial concentration (15% v/v) were adjusted to the same ethanol content (13.5% v/v). All the wines were spiked with four *food-grade* aroma compounds from Sigma-Aldrich (Steinheim, Germany) characterized by presenting different physicochemical properties (Table 1). To do that, four independently aroma stock solutions in ethanol absolute were prepared and from here, each aroma compound was added to the wines to obtain a final concentration of 50 mg/L. The initial concentration of these aroma compounds in the original wines was also previously determined in the five types of wines (Rodriguez-Bencomo et al., 2011[20]) showing that endogenous aroma represent a 5% of the aroma added to the wines, except for β-phenyl ethanol, which concentration corresponded to 15%. The considerably lower amount of these compounds in the original wines compared to the higher amount of the exogenously added aroma should not interfere on the solubility or volatility properties of the added aroma compounds as has been previously shown (Athes et al., 2004[27]).

Retronasal Aroma Trapping Device (RATD). A tailor-made retronasal trapping device (RATD) was employed for this study. This glass device allowed the trapping of exhaled breath after wine consumption into a Tenax trap thanks to a nosepiece coupled to a hollow tube in which the trap was fitted. A vacuum pump connected to a rotameter allowed a steady flow through the trap. Finally, a flowmeter allowed us to know the exact flow through the trap. In preliminary experiments, an optimization and validation of the effectiveness of this device for the purposes of this study was performed. The retention time, ion of quantification, the range of concentration assayed for each volatile compound and regression lines, together with the values of the residual standard deviation (s) and the determination coefficient (R^2), which are estimators of the adequacy of the regression models, are presented in Table 2. In addition, the inter- and intratraps variability is presented. Adequate relative standard deviation between analysis, very low values of s and satisfactory values for the regression coefficients were obtained for the assayed compounds: isoamyl acetate (R^2 = 0.964), ethyl hexanoate (R^2 = 0.991), linalool (R^2 = 0.985), and β-phenylethanol (R^2 = 0.978).

Retronasal Aroma Trapping Procedure during Wine Consumption. Six volunteers (2 males and 4 females) between 26 and 34 years old previously trained in the retronasal aroma trapping procedure participated in this study. They were instructed not to eat, drink, or smoke 2 h before the experiments. They had no known illnesses and had self-reported normal olfactory and gustatory functions. Before each experiment, the panelists had to clean their mouths and rinse with a bicarbonate solution. The monitoring of the oral cavity of the panelists for the four compounds of interest was performed before each analysis.

The drinking procedure consisted in mainly two steps. In the first one, 20 mL of wine contained in a syringe were provided to the panelist, who had to keep it in the mouth for 10 s with the lips closed. After this time, the panelist had to swallow and breath normally through the nose into the glass nosepiece for 20 more seconds. During the experiment, a relatively small amount of wine, typically consumed with a meal (100 mL) was provided. Two repetitions of the same wine were performed on the same day but on different sessions (leaving at least 2 h between replications). The same procedure was followed with the original control wines (without aroma added), so that we could find out the amount of aroma initially present in the wines that could be trapped with this device. These results were used to correct the aroma release data.

Analysis of Volatile Compounds. The aroma compounds from the expiration of breath by the nose and trapped onto the Tenax cartridges were desorbed with 6 mL of a hexane/diethyl ether solution (1:1). Thirty microliters of an internal standard (3-octanol) were added, and the sample was then concentrated using a nitrogen stream to a final volume of 200 μL and analyzed in the GC-MS. A volume of 8 μL of the concentrated breath extract was injected in a cool injection system unit (CIS), (Gerstel, Mülheim an der Ruhr, Germany) in the solvent vent mode. The injector temperature ranged from −80 to 270 °C.

The identification of volatile compounds was carried out with a Gas Chromatograph Agilent 6890N coupled to a quadrupole Mass Detector Agilent 5973. After injection on the CIS, volatile compounds were separated on a Supra-Wax polar capillary column (60 m × 0.25 mm i.d. × 0.50 μm film thickness) from Konik (Barcelona, Spain). Helium was used as the carrier gas at a flow rate of 1 mL/min. The oven temperature was initially held at 50 °C for 2 min, then increased at 8 °C/min to 240 °C and held for 15 min.

For the MS system (Agilent 5973N), the temperatures of the transfer line, quadrupole, and ion source were 270, 150, and 230 °C, respectively. Electron impact mass spectra were recorded at 70 eV ionization voltages, and the ionization current was 10 μA. The acquisitions were performed in Scan (from 35 to 350 amu) and SIM

[a]RT = Retention time (minutes). [b]Ion Q = quantification ion. [c]Linear regression parameters = intercept (a), slope (b), residual standard deviation (s), and determination coefficient (R^2); [d]Repeatability is expressed as an average of 5 assays performed in the same conditions

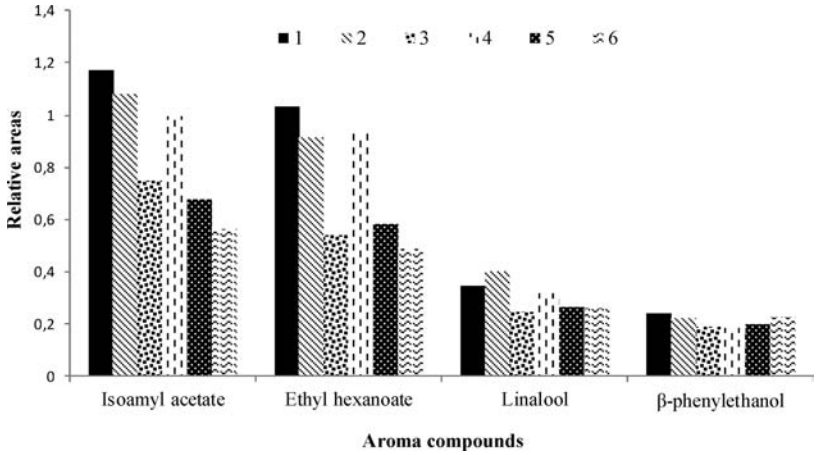

Figure 1. Average values of aroma release (relative peak areas) obtained for each panelist during wine consumption considering the five different wines (**WH-W**, **SP-W**, **YR-W**, **AR-W**, and **SW-W**) and two repetitions of the same wine. For better comparison, data for β-phenylethanol are multiplied by a factor of 10. Different background patterns mean different panelists.

modes. The identification of compounds was based on the comparison of retention times and mass spectra. The mass spectra were compared with those from NIST 2.0 database. Relative peak areas (RPAs) were obtained by calculating the relative peak area in relation to that of the internal standard. The use of RPAs data to express aroma release was sufficient for this type of analysis as the aim of the work was to compare the extent of aroma release between wine samples.

Wine Matrix Composition. Nitrogen compounds (total nitrogen, free amino acids, and peptides), neutral polysaccharides and residual sugars, total polyphenols, total acidity, and pH were determined in the five types of wines following the procedures previously described in Rodriguez-Bencomo et al., 2011.[20]

Statistical Analysis. The statistical methods used for data analysis were linear regressions to establish the regression parameters for each aroma compound released after wine drinking and the lack of fit test to judge the adequacy of the linear models: cluster analysis (the square Euclidean distance was taken as a measure of the proximity between two samples and Ward's method was used as linkage rule) to check the grouping of panelists depending on their aroma release performance; one-way ANOVA to test the influence of matrix composition on aroma release and to test compositional differences between wines; least significant difference (LSD) test for mean comparison; principal component analysis (PCA) to examine the relationship between compositional parameters and wine matrices; and correlation analysis to determine the existence of correlations between each of the compositional variables and the aroma release data of the four aroma compounds. The STATISTICA program for Windows Version 7.1 was used for data processing (StatSoft, Inc., 2005, www.statsoft.com).

RESULTS AND DISCUSSION

***In Vivo* Aroma Release from Wines.** Different published works have shown that wine matrix might play an important role on aroma release in static headspace conditions.[18−21,28,29] However, the relevance of this effect on a real wine consumption situation has not been evaluated so far. In this work, we have focused on the "in vivo" release (during wine consumption) of some target aroma compounds added to five wines with different matrix composition. We monitored, the so-called 'expiration breath', since it might be a good representation of the aroma compounds which interact with the olfactory system.[14] The type of aroma compounds (isoamyl acetate, ethyl hexanoate, linalool and β-phenylethanol) represented a wide range of physicochemical properties and the concentration was selected in order to make an easy-to-drink wine, preventing the possible tiredness and rejection of the wine by the panelists and avoiding analytical problems (sensitivity). To overcome the effect of ethanol, which has been shown, might significantly affect the partition coefficient of the aroma compounds,[19,30−33] all the wines, except the sweet wine were adjusted to the same ethanol concentration (13.5% v/v). The differences in ethanol content between the sweet wine (15% v/v) and the rest of the wines were of 1.5% (v/v), which is unlikely to exert a significant difference on the release of the aroma compounds. [33] Wines were consumed following a systematic procedure in order to minimize interindividual differences. Previous training sessions were performed with the panelists to familiarize them with the procedure. As it was described in Material and Methods, a tailor-made breathing trapping device, previously optimized and validated for this purpose was employed. Although this type of device did not allow us to monitor the retronasal aroma release in real time such as the breath by breath analysis using mass spectrometric techniques (PTR-MS; APCI-MS), other important advantages such as the unequivocally identification of the compounds of interest, the possibility of having a concentrated breath

extract,[14] and the facility to adapt it to any laboratory with a relatively low economical investment make it very interesting for the purposes of this type of study.

The average data (relative peak areas) corresponding to each of the aroma released by the six panelists, independent of the type of wine, is depicted in Figure 1. Previously, the same consumption procedure was employed to evaluate the five wines without spiked aromas, and only traces of the four aroma compounds were detected. However, all the release data were corrected taking into consideration these results. As can be observed in the figure, in spite that all the panelists followed a strict consumption procedure, for each single aroma compound, large differences in the released patterns between individuals were found. Interestingly, these differences seemed to be constant toward the same type of compound. For example, the interindividual release pattern of the two esters, isoamyl acetate and ethyl hexanoate, was quite similar; panelist #1 released the highest amount of these compounds, while panelist #6 always released the lowest. However, when considering a more chemically different compound, such as linalool, and β-phenylethanol, this pattern was different. For instance, linalool was more greatly released by panelists #1, #2, and #4, while the rest of subjects released almost the same amount. In addition, depending on the type of compound, differences between panelists were less pronounced, and for example, the release of β-phenylethanol was more or less the same for all of them. The existence of interindividual differences on aroma release patterns during food consumption have been extensively described, both in solid[34−36] and liquid food-matrices[6,8,9,37] and could be attributed to anatomical and physiological differences between panelists (respiratory flows, saliva composition, oral and pharyngeal mucosa, etc.).

To further investigate whether there was a trend in the aroma release pattern, a cluster analysis with the data corresponding to the aroma released by the 6 panelists during the consumption of the five different wines was performed. Figure 2 shows the dendrogram obtained from this analysis in which two groups of aroma releasers can be clearly observed. A first group formed by panelists #1, #2, and #4, and a second comprising of panelists #3, #5, and #6. Both groups could be called higher and lower releasers, respectively. A similar trend on flavor release was observed during the consumption of liquid emulsions,[37] and these differences between higher and lower releasers were also in agreement with previous works.[34,35] Although a higher number of individuals might be needed to confirm this trend, the preliminary results derived from this study indicated two behaviors on the aroma release during wine consumption.

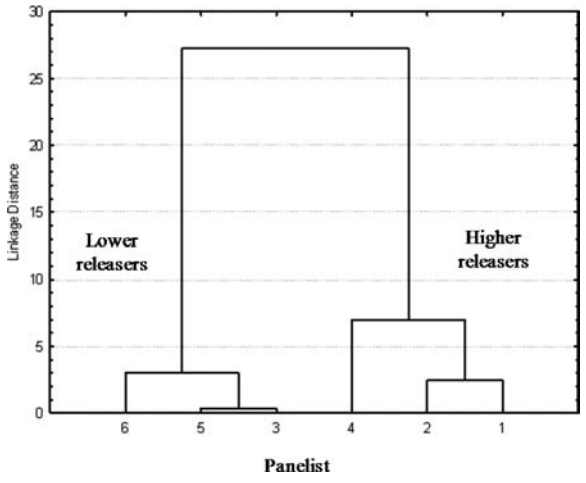

Figure 2. Dendrogram showing the grouping of panelists depending on their aroma release performance during the consumption of the five different types of wine.

Among the anatomical and physiological differences between panelists that might be responsible for the differences in the observed trends on aroma release, the variations in the flow rates between subjects might be an explanation. It has been suggested that a greater respiratory rate could contribute to bringing more volatiles to the upper airways, and consequently, more volatiles could be present in the expired air of the panelists.[36−38] However, in another study performed *in vivo* and *in vitro*, Well et al.[10] showed that an increase in flow rate resulted in a decrease in the aroma release.

To determine whether the breathing capacity might have an influence on the grouping of panelists in higher and lower releasers, two breathing related parameters corresponding to the vital capacity (VC) and forced vital capacity (FVC) were calculated. The vital capacity (VC) can be defined as the volume of air breathed out after the deepest inhalation,[39] while the forced vital capacity (FVC) is the determination of the vital capacity from a maximally forced expiratory effort.[40,41] In fact, FVC is the most basic maneuver in spirometry tests.[40,41] Both parameters were estimated considering different individual physiological variables such as age, sex, ethnic group, and height of the panelists. These data are shown in Table 3. As can be seen, the highest predicted FVC and VC values did indeed correspond to panelists from the first group (higher releasers), while the second group, the lower releasers, also showed the lowest FVC values. These results suggest that although other physiological variables might also affect the rate of aroma release during the consumption of wine, in the experimental conditions of this study, we have found a direct relationship between respiratory rate and aroma compounds in the expired air of the panelists, which might influence the sensory perception of wine aroma.

Table 3. Predicted Forced Vital Capacity (FVC) and Vital Capacity (VC) Values Calculated for the Panelists[a]

	FVC		VC	
panelist	predicted value (L)	SD	predicted value (L)	SD
1	4.75	0.43	4.47	0.13
2	5.63	0.86	5.75	0.12
3	4.12	0.43	3.90	0.13
4	5.72	0.86	5.65	0.12
5	4.52	0.43	4.28	0.13
6	4.00	0.43	3.81	0.13

[a]FVC and VC estimated using Dynamic Measurement Technologies software (www.dynamicmt.com) based on Hedenström et al., 1985−1986[40,41] and Langhammer et al., 2001,[39] respectively. SD: ± standard deviation.

Effect of Wine Matrix Composition on Aroma Release.

Considering the two types of behaviors between panelists regarding the aroma release during wine consumption (higher and lower releasers), release data (relative peak areas) obtained from both groups of panelists were separately treated and submitted to one-way ANOVA in order to know if the nonvolatile wine matrix composition could have a significant effect on aroma release during wine consumption. Surprisingly, we noticed that the effect of wine matrix was different

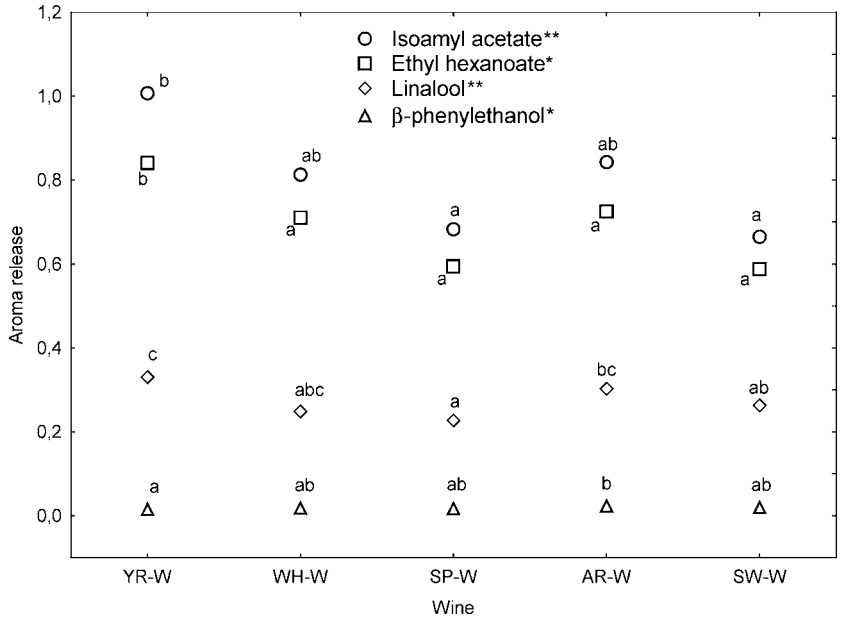

Figure 3. Results of the aroma release during the consumption of the five different types of wine for the lower releaser group. Significant differences on aroma release depending on matrix composition are indicated with * $0.05 < P < 0.1$ or ** $P < 0.05$. Different letters across the different wines denotes statistical differences after the application of LSD test.

Table 4. Mean ± Standard Deviation (SD) Values ($n = 3$) of the Chemical Composition of the Five Matrices: White Wine (WH-W), Sparkling Wine (SP-W), Young Red Wine (YR-W), Aged Red Wine (AR-W), Sweet Wine (SW-W)[a]

	WH-W		SP-W		YR-W		AR-W		SW-W	
	mean	SD	mean	SD	mean	SD	mean	SD	mean	SD

[a]Different letters across the different wines denotes statistical differences after the application of LSD test. [b]This data is indirectly determined as the difference between the analytical determination of amino acids plus peptides and free amino acids, therefore SD values are not included in the table.

depending on the group of panelists. For the higher releaser group, only the release of linalool was influenced by matrix composition ($0.05 < P < 0.1$). This result seemed to be related to some analytical constraints of the trapping device, such as the possible saturation of the Tenax trap during the experiment with higher releasers, which could have masked the wine matrix effect. However, considering the lower releaser group, all the compounds were significantly influenced by matrix composition; these results are shown in Figure 3 together with the results corresponding to the application of the LSD test with the five types of wine matrices. It is important to highlight that the differences on aroma release also depended on the type of aroma compound considered (e.g., we observed more differences on the release of linalool toward the different wines that on the release of β-phenylethanol); however, independently on the type of aroma compound considered, there was a clear trend, in which higher aroma release was always observed during the consumption of the two red wines (**YR-W** and **AR-W**) compared to the consumption of white wines (**WH-W** and **SP-W**) and the sweet wine (**SW-W**). As can be seen in Figure 3, the highest release of isoamyl acetate, ethyl hexanoate, and linalool was during the consumption of young red wine, while β-phenylethanol was more released during the consumption of aged red wine.

Therefore, in spite of the interindividual differences between panelists, the influence of wine matrix composition on the amount of aroma released during wine consumption was evidenced. This finding is in agreement with previous studies in the literature which have already demonstrated using static conditions, the existence of interaction between nonvolatile wine matrix components and aroma compounds, which might affect the release of aroma compounds into the headspace.[20,22−24,28] Moreover, the effect of wine matrix on aroma release has been shown in *in vitro*- dynamic conditions,[11] being this the first time that this effect is proven in an *in vivo*, real consumption situation.

In order to try to determine which component/s from the wine matrix were more involved on aroma release during wine consumption, the chemical characterization of the nonvolatile matrix composition of the five wines consumed by the panelists

was performed and it is shown in Table 4 together with the results of the LSD test. As can be seen, the five wines exhibited significant differences in their composition. As expected, the sweet wine (**SW-W**) was the most different, showing the highest pH (4.12), the lowest value of acidity (3.68 mg tartaric acid/L), and the highest content of neutral polysaccharides (171 g mannose/L) and residual sugars (310 g/L). In addition, this wine showed the highest levels of nitrogen compounds (total nitrogen, amino acids, and peptides). In spite of its *a priori*, higher matrix complexity, during the consumption of this wine, we did not observe a significant effect on aroma release, which was more similar to that experienced during the consumption of white wines (**WH-W** and **SW-W**). The lack of a clear interaction effect of this type of wine with typical wine aroma compounds is in agreement with previous results performed in static conditions.[20] It seems, at least, in static conditions, that the higher content of some small molecules in this wine, such as mono- and disaccharides or free amino acids[18,42] could be responsible for a "salting out" effect, which might compensate the retention effect exerted by other higher molecular weight compounds (such as polyphenols or proteins)[18,20] or by an increase in the solution hydrophobicity because of the presence of a large amount of hydrophobic sugars such as fructose.[33]

The consumption of the two white wines (**WH-W**, **SP-W**) provided in general, a lower aroma release. These wines exhibited the highest values of acidity (5.6−5.29 mg tartaric/L) and therefore lowest pH values (2.99−3.07), although these differences did not seem enough to explain the differences observed on aroma release compared with the aroma release during red wines consumption. In addition, white and sparkling wines showed the lowest values of the majority of nonvolatile compounds determined in the samples (polyphenols, polysaccharides, residual sugars, and nitrogen compounds). However, compared with red wines, the group of compounds that was dramatically different between the two types of samples was the content of total polyphenols. Red wines showed ten times more of these compounds (2010 and 1860 mg gallic acid/L for **YR-W** and **AR-W**, respectively) compared to white wines (211 and 173 mg gallic acid/L for **WH-W** and **SP-W**, respectively).

To better envisage the compositional differences between the five types of wines, a principal component analysis (PCA) was performed with the data from Table 4. Two principal components were obtained. The first one (PC1) was negatively related (|loadings| > 0.82) with all the compositional parameters (pH, neutral polysaccharides, residual sugars, nitrogen compounds) except total polyphenols and positively correlated with total acidity (0.92). The PC2 was positively correlated with the total polyphenol content (0.97). Figure 4 shows the representation of the wines on the plane defined by PC1 and PC2. Clearly, PC1 could distinguish between sweet wines, with high and negative values for this component from white and sparkling wines with high and positive values for PC1. Red wines appeared together between sweet and white wines. On the other hand, PC2 clearly separated red wines from the rest. This component was only defined by the polyphenol content, which clearly, as was previously commented, was much higher in these wines than in the rest.

Many works in the literature performed in static conditions have shown the existence of specific interactions between polyphenols and aroma compounds resulting in a reduction of the aroma released into the headspace.[22,28,33] For instance, it

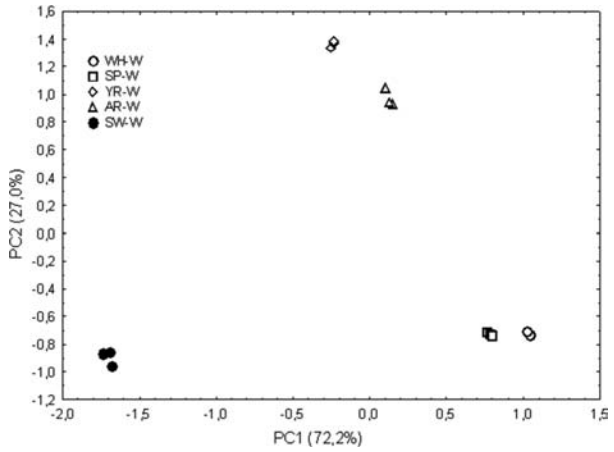

Figure 4. Representation of the wines on the plane defined by PC1 and PC2 obtained with the nonvolatile matrix composition data (Table 4).

has been shown that monomeric polyphenols, abundant in young red wines, can interact with terpenes in ethanolic solutions provoking a lower aroma release in *in vitro* conditions.[22] Other interactions that have been described involved the galloyl ring of some phenolic compounds and the aromatic ring of some aroma compound.[28,43] Moreover, the type and polymerization state, which is related with the polyphenol origin (from seed or skin), might be involved in different interaction with aroma molecules (Mitropoulou et al., 2011;[44] Lorrain et al., 2013[45]). Anyway, in dynamic real drinking conditions, as we have used in this study, aroma release seems to be enhanced by the presence of polyhenols. One possible explanation could be that after swallowing, these types of compounds could specifically interact with pharyngeal and/or esophageal mucosa contributing to the formation of a product coating on the throat and pharynx, which could increase the contact area between air and product, favoring aroma release.[8] In fact, some works in the literature have already suggested interactions between aroma compounds and oral/esophageal mucosa to explain a delay on aroma release, which to an extent might be dependent on product composition.[9,46] Another explanation, could be the formation of polyphenol−aroma complexes in the surface coating, acting as aroma reservoirs and resulting in a greater concentration of aroma molecules ready to be released by the expiration flows. In fact, in *in vitro* systems (static headspace), using reconstituted wine samples, Mitropoulou and co-workers[44] suggested the possible formation of a protein-polyphenol-carbohydrate complex able to encapsulate hydrophobic aroma molecules.

Although obtaining straightforward relationships between the aroma release behavior during wine drinking and the effect of wine matrix components is a difficult task not only because of the differences in compositional parameters but also because of the physicochemical characteristics of the aroma compounds and the physiological parameters affecting retronasal aroma release, a correlation analysis between compositional parameters (from Table 4) of all the wines of the study and the average values of aroma release considering the data from all the panelists was performed. Results showed that the matrix components, which better correlated with the aroma release where the total polyphenol content, which were positively correlated with the release of isoamyl acetate (r = 0.81), ethyl

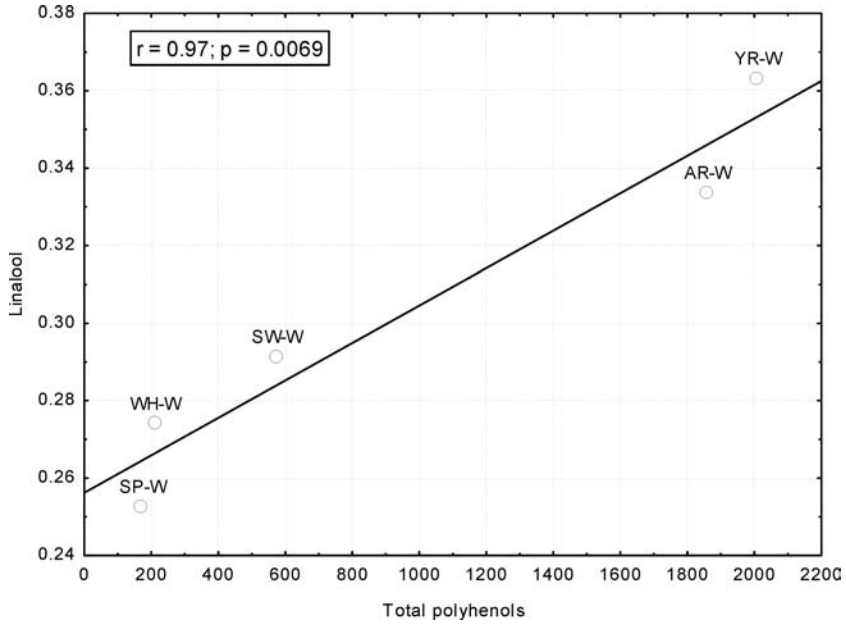

Figure 5. Correlation between the retronasal release of linalool during wine consumption and the polyphenol content in the five types of wines.

hexanoate (r = 0.80), and linalool (r = 0.97). Figure 5 shows this correlation, where it is possible to see how red wines showed the highest aroma release values, while the wines with the lowest polyphenol content showed the lowest aroma release for this compound. In spite of the greater aroma release that was observed by β-phenylethanol during the consumption of **AR-W**, the release of this compound did not correlate with the total polyphenol content or any other compositional parameter analyzed in the samples. This suggests that its release could be more affected by other chemicals of different nature or by specific interaction with different types of polyphenols more characteristic of aged wines (polymerized polyphenols), which will require further studies.

In conclusion, results of this work show that in spite of the interindividual differences due to certain physiological characteristics of the individuals (such as the breathing capacity), there is an influence of the wine matrix composition on the *in vivo* aroma release from wines and therefore in the amount of aroma available for the olfactory receptors. Among the different major wine matrix components, polyphenols, seem to enhance aroma release during wine drinking, which could be due to the involvement of these compounds on the formation of a wine coating after swallowing, which might increase the contact area between exhaled air and product and/or because of the formation of polyphenol−aroma complexes on the surface coating acting as a reservoir of aroma molecules ready to be released by the expiration flows. Ongoing work is directed to study the nature of these interactions and their meaning for the sensory characteristics of the wines.

ABSTRACT: Acrylamide detection still represents one of the hottest topics in food chemistry. Solid phase cleanup coupled to liquid chromatography separation and tandem mass spectrometry detection along with GC-MS detection are nowadays the gold standard procedure for acrylamide quantitation thanks to high reproducibility, good recovery, and low relative standard deviation. High-resolution mass spectrometry (HRMS) is particularly suitable for the detection of low molecular weight amides, and it can provide some analytical advantages over other MS techniques. In this paper a liquid chromatography (LC) method for acrylamide determination using HRMS detection was developed and compared to LC coupled to tandem mass spectrometry. The procedure applied a simplified extraction, no cleanup steps, and a 4 min chromatography. It proved to be solid and robust with an acrylamide mass accuracy of 0.7 ppm, a limit of detection of 2.65 ppb, and a limit of quantitation of 5 ppb. The method was tested on four acrylamide-containing foods: cookies, French fries, ground coffee, and brewed coffee. Results were perfectly in line with those obtained by LC-MS/MS.

KEYWORDS: *acrylamide, Orbitrap, high-resolution mass spectrometry, Maillard reaction*

INTRODUCTION

Acrylamide has been a hot topic in food science, and in particular in Maillard chemistry,[1,2] since the first report highlighted its presence at high concentration in French fries, cereals, and coffee.[3] On the one hand, with regard to acrylamide toxicological and exposure outcomes,[4−6] a huge variety of papers dealt with the chemical and analytical insights of acrylamide determination. The chemical aspects of acrylamide formation have been studied more intensively in several pivotal papers: the determination of precursors,[7−9] the detection of a key intermediate,[10] the mechanism in heated food[11] and the kinetic modeling of formation.[12] On the other hand, in the past decade several methods for quantitative determination have been reviewed.[13,14] Generally, acrylamide analysis can be characterized by three steps: sample preparation including extraction, spiking with labeled internal standard with or without derivatization,[15] cleanup, chromatographic separation, and detection. With regard to the first step several techniques have been developed providing satisfactory results: pressurized liquid extraction (PLE) cation-exchange cartridges, hydrophilic−lipophilic balanced cartridges, and C-18 cartridges.[16−19] The chromatographic separations should take into consideration several drawbacks; among them the acrylamide high polarity as well as the poor retention, matrix effect, and solvent interferences,[20−22] that can be ruled out through derivatization procedures with mercaptobenzoic acid or through the use of the "bromination" method.[23−25] For the detection step the analytical techniques of choice were tandem mass spectrometry (MS/MS) acquisition performed by selected reaction monitoring (SRM) or multiple reaction monitoring (MRM), choosing the characteristic transitions m/z 72→55, 72→54, and 72→27,[26−28] Fourier transform infrared (FT-IR)[8] analysis, or time-of-flight mass spectrometry (TOF/MS),[29] or by fluorescence method.[30] To obviate the matrix effect and the poor retention of acrylamide and in addition to the above-mentioned analytical methods, many official institutions standardized and published their full validated methods for the determination of acrylamide, most of which focused on LC-MS/MS analysis and isotope dilution with ^{13}C or ^{2}H (Swiss Federal Office of Public Health; U.S. Food and Drug Administration).[28]

In this paper the performances of ultrahigh-pressure liquid chromatography coupled to Orbitrap high-resolution mass spectrometry (U-HPLC-HRMS) have been evaluated and accurately compared to the HPLC tandem mass spectrometry method (LC-MS/MS) to build a fast and sensitive procedure that can avoid the cleanup step as well as obtain a high mass accuracy.

MATERIALS AND METHODS

Chemicals. Methanol and water for U-HPLC-HRMS and LC-MS/MS determination were obtained from Merck (Darmstadt, Germany). Formic acid (98%), acrylamide, [2,3,3-d_3]-acrylamide, and Orbitrap calibration solution standards were purchased from Sigma (St. Louis, MO, USA). All of the samples were filtered through a 25 mm diameter and 0.22 μm pore size nylon filter using a 2.5 mL syringe (BD, Franklin Lakes, NJ, USA) equipped with a PTFE adapter (Phenomenex, Torrance, CA, USA). Carrez reagent potassium salt and Carrez reagent zinc salt were purchased from Carlo Erba (Milano, Italy).

High-Resolution Mass Spectrometry (HRMS). Acrylamide separation was performed on a U-HPLC Accela system 1250 (Thermo Fisher Scientific, San Jose, CA, USA) consisting of a degasser, a quaternary pump, a thermostated autosampler, and a column oven. Mobile phase A was 0.1% formic acid, and mobile phase B was 0.1%

formic acid in methanol. Four chromatographic columns were tested: Synergi Hydro (150 × 2.0 mm, 4.0 μm) Kinetex PFP (50 × 2.0 mm, 2.6 μm), Luna HILIC (150 × 2.0 mm, 3.0 μm), and Kinetex C18 (100 × 3.0 mm, 2.6 μm), all from Phenomenex. In all cases the binary gradient (min)/(% B) (0/5), (2/5), (4/80), (5/80), (6/5), (7/5) was used, and the flow rate was 0.2 mL/min, except for the C18 column, with which the flow rate was 0.3 mL/min, and HILIC column, for which the mobile phases consisted of (A) 0.1% formic acid in acetonitrile and (B) 0.1% formic acid in water. Volumes of 10 μL were injected using the thermostated autosampler at 18 °C. The separation temperature was set at 30 °C, and the autosampler needle was rinsed with 500 μL of a mixture of methanol/water 50:50 before each injection.

To set up the optimal condition, a water solution of acrylamide (concentration = 250 μg/mL) at a flow rate of 5 μL/min was pumped using a 500 μL syringe pump directly into the LC stream entering in the HRMS (6.25 μg/mL final concentration, according to the chromatographic flow rate that was 0.195 mL/min). The U-HPLC was coupled to an Exactive Orbitrap MS (Thermo Fisher Scientific) equipped with a heated electrospray interface operating in the positive mode and scanning the ions in the m/z range of 50−400. The resolving power was set to 50000 full width at half-maximum (fwhm, m/z 200), resulting in a scan time of 1 s. The automatic gain control was used to fill the C-trap and gain accuracy in mass measurements (ultimate mass accuracy mode, 5×10^5 ions); maximum injection time was 50 ms. The interface parameters were as follows: spray voltage, 4.5 kV; capillary voltage, 42.5 V; skimmer voltage, 14 V; capillary temperature, 300 °C; heater temperature, 250 °C; sheath gas flow, 40 (arbitrary units); and auxiliary gas flow, 6 (arbitrary units).

Before the acrylamide determination was run, the instrument was externally calibrated by infusion with a calibration solution that consisted of caffeine, Met-Arg-Phe-Ala (MRFA), Ultramark 1621, and acetic acid in a mixture of acetonitrile/methanol/water (2:1:1, v/v/v). Several reference masses (lock masses) were tested for the mass analyzer recalibration: methanol ($[M_2 + H]^+$, exact mass = 65.05971); methanol/water ($[A_2B_2 + H]^+$, exact mass = 101.08084); sodium adduct of methanol/water ($[A_2B_2 + Na]^+$, exact mass = 123.06278); [2,3,3-d_3]-acrylamide ($[M + H]^+$, exact mass = 75.06322); and diisooctyl phthalate ($[M + H]^+$, exact mass = 391.28429).[31] To optimize the HRMS conditions and the mass accuracy, 200 μL of the above-mentioned calibration solution was spiked with 10 μg of [2,3,3-d_3]-acrylamide and the scanning window was set in the m/z range of 70−1400 for the initial calibration procedure.

Preparation of Standard Solutions. A stock solution of acrylamide was prepared by dissolving 10 mg of standard in 1 mL of water. This solution was diluted and stored at −20 °C until use. A calibration curve was built in the range of 5−500 ng/mL according to the limit of detection (LoD) and the limit of quantitation (LoQ). Three replicates of the 0.5 ng/mL solutions were injected into the U-HPLC/HRMS system to verify the lowest concentration for which the signal-to-noise ratio was >3. Concentrations of <1 ng/mL resulted in no signal. The LoQ was 5 ng/mL for the standard solution, and the r^2 value was always >0.99 in the above-mentioned range. Reproducibility of the method was evaluated through the intraday and interday assay. The slope among the three subsequent calibration curves showed a % RSD of <7%. The same calibration points used for the above-mentioned curve were spiked with 1.25 μg of [2,3,3-d_3]-acrylamide to evaluate the potential differences in the presence or absence of the internal labeled standard.

Sample Preparation. *Cookies.* Model cookies (height = 3 mm, diameter = 30 mm) were prepared according to AACC Method 10-54 (AACC, 2000) as previously described.[32] Cookies were baked at 200 °C for 13 min in a forced-air circulation oven (Memmert, Schwabach, Germany).

French Fries. Ten pieces (5 cm × 0.7 cm × 0.7 cm, total amount = 50 g) were fried in 1 L of olive oil for 5 and 7 min. At the end of the cooking process the French fries were freeze-dried and stored until the acrylamide extraction.

Brewed Coffee and Ground Coffee. Ground coffee was purchased in a local market; an aliquot was directly analyzed without further preparation; instead, 15 g was brewed with 100 mL of water (100 °C for 15 min) under continuous stirring. Solid particles were removed through a paper filter, and 50 mL was stored at −20 °C until the analysis.

Acrylamide Extraction. French fries and cookies were ground in a knife mill Grindomix 200 (Retsch, Haan, Germany), and 100 mg were weighed in a volumetric flask; along with 4.8 mL of deionized water, 100 μL of Carrez reagent potassium salt and 100 μL of Carrez reagent zinc salt were added to each sample. The same protocol was followed for ground coffee. For coffee liquid samples 500 μL was diluted in 1 mL of deionized water. Each replicate of the different samples was prepared in two different ways: one was spiked with 125 μg of [2,3,3-d_3]-acrylamide, whereas the other was without the internal standard. All samples were vortexed for 10 min at 800 rpm at room temperature, and after centrifugation (2500 g, 4 °C, 10 min), 1 mL of the aqueous layer was accurately filtered and collected into a glass vial.

Tandem Mass Spectrometry (MS/MS). To validate the HRMS method, all of the above-mentioned samples were analyzed through LC-MS/MS according to the method of Gökmen et al.[16] Two grams of the freeze-dried French fries, cookies, or coffee powder were weighed; 8.9 mL of deionized water was added in a 15 mL centrifuge tube along with 500 μL of Carrez reagent potassium salt, 500 μL of Carrez reagent zinc salt, and 100 μL of internal standard [2,3,3-d_3]-acrylamide (final concentration = 90 ng/mL). For brewed coffee 1 mL was mixed along with 8.9 mL of water, 500 μL of both Carrez reagents, and 100 μL of internal standard. The tubes were shaken vigorously for 1 min, and the resulting mixture was centrifuged at 2500 g for 10 min at 4 °C. Then supernatant were collected in a 20 mL volumetric flask, and two further extractions were performed using 5 mL of deionized water, except for brewed coffee that was filtered and injected. Finally, the pellets were discarded, and the supernatants were filtered through a 0.45 μm nylon filter. One milliliter of supernatants was collected and passed through an Oasis HLB cartridge (Waters, Milford, MA, USA) previously activated with 1 mL of methanol and 1 mL of deionized water; 20 μL of the final solution were injected onto the LC column for quantitation by MS/MS. Identification and quantitative determination of acrylamide and [2,3,3-d_3]-acrylamide were carried out using an API 2000 triple-quadrupole mass spectrometer (Applied Biosystems, Carlsbad, CA, USA) coupled to an ion spray interface, equipped with an HPLC binary micropump series 200 (Perkin-Elmer, Waltham, MA, USA). Chromatographic separation of acrylamide and [2,3,3-d_3]-acrylamide was achieved through an Inertsil column, 250 × 4.6 mm, 5 μm (GLSciences, Torrance, CA, USA); the mobile phases were (A) 0.1% formic acid and (B) 0.1% formic acid in methanol, and the gradient elution (min)/(% B) (0/0), (3/0), (8/93), (12/0), (15/0) was applied at a flow rate of 0.8 mL/min, whereof 0.2 mL were split into the ion source. Quantitation was carried out in multiple reaction monitoring (MRM) mode at m/z ratios of 72 and 75 for acrylamide and [2,3,3-d_3]-acrylamide, respectively. Specific molecular fragments corresponding to m/z 55 and 44 for acrylamide and m/z 58 and 44 for [2,3,3-d_3]-acrylamide were also monitored. The daughter ions were obtained through fragmentation with the following conditions: the source temperature was set at 350 °C, nitrogen was used as nebulizer gas at a flow rate of 12 L/h, and the needle and cone voltages were set at 3.0 kV and 100 V, respectively. Under the above-mentioned chromatographic conditions the acrylamide and its corresponding deuterated standard eluted at 7.4 min. For LC-MS/MS analysis acrylamide was quantified using a linear calibration curve built in the range of 50−500 ng/mL, the LoD and LoQ were 10 and 20 ng/mL for acrylamide and [2,3,3-d_3]-acrylamide, respectively, and the coefficient of determination, r^2, was >0.99.

Statistical Analysis. All of the analyses were performed in triplicate for both HRMS and MS/MS; the results were reported as nanograms per gram of samples for cookies, French fries, and ground coffee or as nanograms per milliliter for brewed coffee or acrylamide solution. For HRMS, data were recorded using Xcalibur software version 2.1 (Thermo Fisher Scientific). For MS/MS data, Analyst version 1.4.2 (Applied Biosystems) was used.

RESULTS AND DISCUSSION

Method Development. Despite recent developments in acrylamide analysis, improvements in high-throughput quantitative procedures for its determination are still requested. The key point of this paper was to evaluate the potentialities of HRMS in the detection of this small amide in a complex mixture riding out the problems associated with the solid phase extraction and, possibly, to the use of internal standard.[13,14]

The first step of the work dealt with the optimization of chromatographic separation of acrylamide in combination with HRMS detection. It is well-known that acrylamide is a very polar molecule with poor retention ($k' < 2.0$) in conventional liquid chromatography reversed phase sorbents.[16,33] Four columns with different selectivities were tested by evaluating chromatographic performances, including retention time and reproducibility. Among the tested columns, including HILIC phase, pentafluorophenyl phase, and a core shell C18 phase, a polar end-capped stationary phase was selected to get a good reproducibility and avoid the interferences of the solvent, matrix, and unretained compounds that eluted along with the solvent front. A typical chromatogram of acrylamide standard is presented in Figure 1. Along with the polar end-capped column, the use of a core shell C18 phase can ensure a significant reproducibility for several subsequent injections even if the k' was always 1. From the chromatographic separation point of view, relevant results were obtained with HILIC phase, even if the use of acetonitrile interfered with the ionization of acrylamide.

Although the retention time was rather short (2.85 min), it ensured separation from the first eluting impurities; the peak shape was maintained, and the deviation of retention time was <0.1 min among assays of calibration standards, real samples, and recovery samples.

The following step of the experimental work was the HRMS optimization downstream the U-HPLC separation. Specifically, the use of auxiliary gas coupled to a capillary voltage higher than 4.0 kV caused the fragmentation of acrylamide in source. As a consequence it was decided to use an auxiliary gas flow rate of 6 AU to avoid undesired fragmentation of the molecules and the formation of the typical fragment (72→55).[26−28,34] The lens voltage was optimized by setting the mass on 72.0 by manual tuning. This procedure was repeated in two different conditions: direct infusion of the acrylamide standard solution in the ion source and its infusion in the liquid chromatography flow to evaluate the interferences of the solvents. The heater temperature and the capillary temperature were optimized to ensure the best solvent nebulization. Under the stated conditions in Materials and Methods, the Orbitrap MS analyzer showed the best compromise between selectivity and quantitative performance.

Method Performance. The method performance was tested against quality parameters such as specificity, carry-over, linearity of the calibration, coefficient of correlation (r^2), limit of quantitation, limit of detection, precision, accuracy, and recovery. The first point was checking for the absence of any contaminants with an exact mass similar to the one of acrylamide by injecting several times pure water. Subsequently, a calibration curve was built after determination of the LoD and LoQ. The LoD was calculated according to the method of Armbruster et al.[35] After 20 replicates, the limit of blank was 0.5 ppb, the limit of detection was 2.65 ppb, and the limit of quantitation was 5 ppb. Two different series of calibration curves were prepared: one spiked with the deuterated internal standard; another one without internal standard. For both series the linearity was achieved in the range of 5−500 ng/mL and the r^2 was always >0.99. Each point was injected three times each day and for three consecutive days. After each replicate, a blank sample (pure water) was injected in order to verify the absence of carry-over effect. The precision of the two methods was verified in the linearity range through the evaluation of the slope of three different calibration curves; the results, reported as %RSD, were <8% for both calibration curves; the accuracy of the method, calculated through the ratio observed amount/specified amount × 100, was always >90%. The recovery test was performed using two different concentrations of [2,3,3-d_3]-acrylamide (100 and 253 ng/mL final concentration, $n = 6$ for each matrix) to verify the matrix effect and the ion suppression. First, the ionization performance

dx.doi.org/10.1021/jf404205b | J. Agric. Food Chem. 2014, 62, 74−79

of [2,3,3-d_3]-acrylamide was evaluated through the injection of the pure standard dissolved in water, and then the recovery was calculated as the ratio between the area of the internal standard and the area of spiked samples. The results ranged from 90 to 99% and are shown in Table 2. In Figure 2 the recovery of

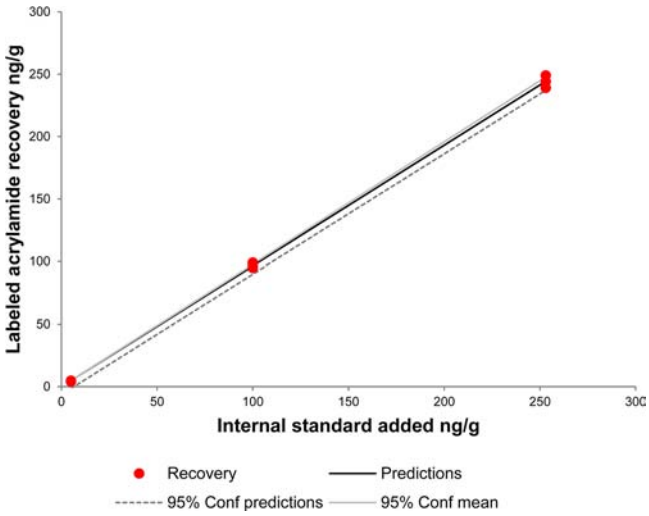

Figure 2. Recovery of internal standard spiked in French fries. The dotted lines represent the 95% confidence intervals calculated on the predictions and on the mean (n = 3).

internal standard spiked in French fries is presented. The setup of the condition for mass accuracy optimization was one of the prominent points of the paper. In a first set of fine-tuning trials several lock masses were used to recalibrate the instrument and reduce the mass error,[31] and the mass to charge ratio of some contaminants or interference ions was evaluated (Table 1), such as methanol ($[M_2 + H]^+$, exact mass = 65.05971); methanol/water ($[A_2B_2 + H]^+$, exact mass = 101.08084); and sodium adduct of methanol/water ($[A_2B_2 + Na]^+$, exact mass = 123.06278). Then, 1 μL of [2,3,3-d_3]-acrylamide solution ($[M + H]^+$, exact mass = 75.06322) was directly infused in the liquid chromatography flow with a final concentration of 3 μg/mL. The former trials gave unsatisfying results with a mass accuracy around 5 ppm, whereas the latter, which used deuterated acrylamide straight in the calibration solution, reduced the mass accuracy to −0.7 ppm. The calibration mixture was spiked with 10 μg of [2,3,3-d_3]-acrylamide to set the instrument for the optimal detection of small molecules with m/z <80. The presence of [2,3,3-d_3]-acrylamide in the calibration solution determined the reduction in the discrepancies between the observed mass ($[M + H]^+$, exact mass = 72.04434) and the theoretical mass of acrylamide ($[M + H]^+$, exact mass = 72.04439).

Measurement of Acrylamide Content in Foods. As described above, three of the most commonly consumed acrylamide-containing foods, French fries, coffee, and cookies, were selected to test the performance of the developed method. The determination of acrylamide in these food matrices showed different requirements in terms of extraction and cleanup before chromatographic separation.[14] Up to now acrylamide was detected through solid phase extraction along with liquid chromatography and tandem mass spectrometry detection,[28,34,36−38] by LC-MS after derivatization with 2-mercaptobenzoic acid,[15] by direct gas chromatography coupled to mass spectrometry,[39] and by pyrolysis GC-MS.[40] The extraction procedure used in this paper was exactly the same for cookies, French fries, and ground coffee, whereas for brewed coffee only a dilution in water was performed. The recovery test and the LoD were evaluated in the different matrix, with satisfactory results as presented in Table 2, where the LoD and LoQ in the

Table 2. LC-HRMS Performances for Acrylamide Detection in Three Different Foods[a]

	RT (min)	LOD (ppb)	LOQ (ppb)	recovery (%)	% RSD	% RSD*[a]	linearity
French fries	2.85	2.65	5	97	8	9	
brewed coffee	2.83	3	5	90	7	9	
ground coffee	2.85	3	5	90	7	5	
cookies	2.85	2.65	5	92	6	5	
standard	2.83	2.65	5		<7	<5	>0.99

[a]%RSD* indicates the set of samples performed with labeled internal standard.

tested foods and in standard solutions were almost similar. In Table 3 acrylamide concentrations obtained on the various foods with and without the use of internal standard are reported, and they were compared not only with those present in the literature but also with the results obtained by LC-MS/MS on the same samples. For French fries the value ranged from 270 ± 12.1 ng/g (254 ± 4.6 ng/g for internal standard analysis) to 424 ± 10.3 ng/g (490 ± 10.0 ng/g for internal standard analysis) according to the processing time (5 and 7 min, respectively).[41] These values were very similar to the ones obtained through LC-MS/MS as reported in Table 3.[27,42,43] For cookie samples two different typologies of cookies prepared de novo according to two recipes, already used in a previous paper from our group, were used for acrylamide determination.[32] The value varied from 276 ± 3.5 ng/g (cookies with 0.65% sodium chloride) to 317 ± 9.2 ng/g (cookies without 0.65% sodium chloride). The use of the internal standard resulted in similar values: 262 ± 4.0 and 340 ± 5.6 ng/g for cookies with and without sodium chloride, respectively. These data clearly showed the substantial agreement between the U-HPLC/HRMS method and the SPE LC-MS/MS method (Table 3).

Table 3. Acrylamide Concentration in the Tested Foods, through LC-HRMS (with and without Labeled Internal Standard), through LC-MS/MS and Literature Data

food	no labeled standard	labeled standard	LC-MS/MS	literature data	ref
cookies (different formulations)	276 ± 3.5 ng/g	262 ± 4.0 ng/g	286 ± 15.3 ng/g	278−313 ng/g	32
	317 ± 9.2 ng/g	340 ± 5.6 ng/g	325 ± 9.3 ng/g	451−510	15
French fries (different frying times)	270 ± 12.1 ng/g	254 ± 4.6 ng/g	280 ± 18.8 ng/g	253−2688	42
	424 ± 10.3 ng/g	490 ± 10.0 ng/g	409 ± 11.1 ng/g	150−1200	43
				50−1800	27
brewed coffee	12 ± 0.1 ng/mL	15 ± 0.2 ng/mL	13 ± 0.2 ng/mL	6−16 ng/mL	46
				5−12	44
				14−21	45, 49
ground coffee	140 ± 3.6 ng/g	159 ± 8.1 ng/g	145 ± 3.2 ng/g	45−374 ng/g	46
				267; %RSD = 0.5	47

The method performances were tested also in brewed coffee sample and in ground coffee. In this case the acrylamide contents were 12.1 ± 0.1 ng/mL and 140 ± 3.6 ng/g for brewed coffee and ground coffee, respectively, and the previous results were fully confirmed,[44−47] even if with the use of [2,3,3-d_3]-acrylamide small differences were present: 15 ± 0.2 ng/mL and 159 ± 8.1 ng/g for brewed coffee and ground coffee, respectively. The key points for brewed coffee were the LoD and the recovery that were 3 ppb and 90%, respectively. Acrylamide detection in coffee is characterized by several drawbacks due to the matrix effect and the roasting of coffee beans.[44] For this reason for LC-MS/MS the use of internal standard is a key point that can be easily overcome thanks to the HRMS. This is presented in Table 3, where the analysis performed through HRMS or MS/MS showed similar results.

The results obtained with the developed methods were in any case in line with those present in the literature.[48,49] From the analytical point of view the use of [2,3,3-d_3]-acrylamide increased the robustness of the method, in particular, the variability due to the ion suppression or to the matrix effect was eliminated for each analysis. Interestingly, without the use of labeled internal standard the results were still satisfying, and the differences between the two methods were <14% in solid foods, thus suggesting that in the cases not requiring high precision the use of the HRMS method could theoretically allow also avoidance of the use of external standard.

A huge variety of papers have been published on quantitation procedures for acrylamide in foods. The method here developed using U-HPLC Orbitrap HRMS proved to be very effective as it negated the matrix effect and time consumption due to solid phase extraction. Moreover, the use of a modified calibration solution allowed the optimal set of the instrument and it improved enormously the mass accuracy for acrylamide detection. Also, the use of internal standard could be theoretically avoided with a negligible loss in method accuracy. From the analytical standpoint the performances were satisfactory: the relative standard deviation was <7%, the recovery in the three different matrix was always >90%, and the limit of detection was comparable to the ones of tandem mass spectrometry.

Supporting Information

ABSTRACT: An interlaboratory comparison of a multipesticide residue analytical method is reported. The goal of the comparison was to evaluate the potential for liquid chromatography/high resolution mass spectrometry along with a specific automated screening procedure to allow the determination of the presence or absence of a set of targeted compounds without additional manual review. The method utilized an off the shelf QuEChERs based extraction followed by analysis with an orbitrap mass spectrometer with the data evaluated by ToxID. The method was tested at three laboratories, with three produce matrices (spinach, carrots, and oranges), and three levels of spiked pesticides with all analyses in triplicate. A series of 247 compounds were tested, and it was found that the three laboratories produced consistent data; however, manual review was still necessary. The data was shown to have no false negatives for 211 compounds in the three produce matrixes at 200 ppb. Of these 211 compounds, 189 had no false negatives at 50 ppb, and 129 had no false negatives at 10 ppb. The HRMS method was shown to be robust with similar data being achieved by all three laboratories and detectable concentrations only slightly above the range shown for triple quadrupole MS/MS.

KEYWORDS: *QuEChERs, pesticide residue, interlaboratory comparison, high resolution mass spectrometry*

INTRODUCTION

It has become evident that there are a multitude of potential contaminants in foods. The vast numbers of compounds include hundreds of different pesticides, mycotoxins, industrial compounds, and their byproducts. Insuring food safety therefore increasingly requires the use of methodologies that can monitor for hundreds of chemicals at the same time. These multiresidue methods combine a single extraction technique with analytical instrumentation capable of determining numerous compounds. Screening methods that can relatively quickly examine hundreds of compounds at relevant concentrations (i.e., below tolerance levels) have their place along with more rigorous quantitative methods. It has been noted that for screening to be effective for hundreds of compounds automated library based procedures will need to be implemented.[1]

Extraction protocols for multiresidue methods have been investigated by many researchers, with much of the recent efforts focused on modifications to the QuEChERS procedure as originally described by Anastassiades et al.[2] Versions with various buffers have been compared by Lehotay et al.[3] and a modified QuEChERS version was compared with aqueous acetonitrile extraction and pure acetonitrile extraction by Lacina.[4] Both groups report that the various different versions of QuEChERS perform reasonably well for most pesticides with the differences between the various procedures most pronounced for a couple of pH dependent pesticides.

The extracts produced in these multiresidue techniques have been commonly used along with liquid chromatography tandem mass spectrometry. These combined techniques lead to reports of the determination of pesticide residues in produce, wine, mango, watermelon, tea, and many other foods.[5−10] These quantitative methods require that the mass spectrometric procedures be targeted for a specific set of pesticides prior to analysis, so that the scan functions can be optimized for the selected reaction monitoring of each individual pesticide. One drawback of this optimization can be a limitation on the number of pesticides monitored at similar retention times due to the duty cycle of the instrument (the number of different scan functions that can be cycled through while still getting sufficient points across each chromatographic peak) Untargeted compounds will not be determined.

More recently the use of high resolution mass spectrometry (HRMS) rather than tandem mass spectrometry has been explored. Various instrumental configurations have been used: an orbitrap for the analysis of 350 pesticides in honey;[11] pesticide residues in fruits and vegetables with an orbitrap[12,13] and a quadrupole orbitrap;[14] organic contaminants in foods using a quadrupole time-of-flight MS;[15] a report of pesticide residues in ginseng and spinach using several different HRMS

configurations.[16] One focus has been on how much mass resolution is necessary. Recent efforts have postulated that complex matrices require resolution greater than 50000 ($m/\Delta m$),[1] and in a comparison of HRMS to tandem MS, it was shown that above 50000 resolution, the selectivity of HRMS is greater than standard tandem MS.[17] In a later report, Kaufmann et al. stated that while "sensitivity was slightly inferior ... HRMS has advantages that will most likely never be met by MS/MS".[18] Among the advantages is the nontargeted nature of full-scan data acquisition. Signals for virtually all ions within the selected mass range are acquired as opposed to only those targeted for acquisition as occurs with multiple reaction monitoring in MS/MS. This makes it possible to analyze data retrospectively for analytes that were not considered at the time of acquisition. Potential drawbacks of the orbitrap based methods are some ion suppression issues that can occur in the c-cell of these instruments[12,19] and the need for robust automated methods to handle the abundance of data produced.[1,13]

Many of these recent efforts utilizing both time-of-flight and orbitrap platforms have been reviewed with the conclusion that these systems are "attractive for residue analysis in food".[20] It is, however, important to show that these methods are robust and rugged with results that agree across different users. This robustness can be best shown by comparing results on the same samples from different laboratories. We report here on such an interlaboratory comparison using an orbitrap HRMS to screen for pesticide residues in three diverse food matrices: spinach, a leafy green; oranges, watery fruit; and carrots, a root crop. The goal of the project was not the development of a full quantitative method but rather an examination of the utility of HRMS along with an automated data processing program to relatively quickly screen produce for the presence of pesticide residues. Our intent was not to investigate the method but to evaluate current procedure. We therefore chose to only utilize the 100000 resolution achievable by the orbitrap. As mentioned previously there are many versions of the QuEChERs extraction protocol, all of which do reasonably well for most compounds. We therefore chose to mimic a recently published validation of a QuEChERS LC-tandem mass spectrometric procedure[10] using the same matrices and extraction protocols. These choices would allow us to examine the utility of the HRMS screening procedure without going through optimization of the extraction or analysis protocols. To further examine the utility of the procedure, we chose to use a commercially available set of 247 pesticides, none of which were preselected to be amenable to the chosen QuEChERS procedure and LC-MS. Although this set of pesticides was not the same as the procedure that we were mimicking there was a sufficient overlap that we could compare our HRMS results with their tandem MS results. All samples were prepared at a single laboratory, frozen, and shipped to the other two laboratories. At each laboratory, the samples were spiked with the set of standards, extracted using the modified version QuEChERs, and analyzed by LC/HRMS on an orbitrap mass spectrometer.

MATERIALS AND METHODS

Reagents. The three laboratories in this study may have had different suppliers for some of the reagents so these are listed by specification. Water was supplied as 18.2 MΩ water from a Millipore Milli-Q source or purchased as HPLC grade. Acetonitrile was HPLC grade. When used for the mobile phases, the water and acetonitrile were either fortified at 0.1% with ACS reagent grade formic acid or purchased as prefortified HPLC grade reagents.

Materials. Prefilled QuEChERs extraction tubes containing 4 g of $MgSO_4$ and 1 g of NaCl (part no. ECMSS50CT, UCT, Bristol, PA) and prefilled QuEChERs extraction tubes containing 50 mg of PSA and 150 mg of $MgSO_4$ (part no. CUMPS2CT, UCT).

Standards. A mixed pesticide standard set was obtained from Accustandard (part no. S-21974-set, New Haven, CT). This set consists of 13 1 mL ampules each containing 16−22 pesticides at 100 μg/mL, for a total of 247 compounds. The stock standard was prepared by combining 400 μL from each of the ampules in a single 10 mL volumetric flask, and the final volume was brought to 10 mL with acetonitrile for a final concentration of 4 μg/mL. A diluted stock solution was prepared by bringing 2.5 mL of the stock solution to 10 mL with acetonitrile for a final concentration of 1 μg/mL. A 5 ppm solution of triphenylphosphate and d-6 malathion in acetonitrile was prepared as an internal standard.

Sample Preparation. Three different matrices were prepared. One pound or more of carrots, oranges, and spinach were chopped in a Hobart food chopper without peeling. The mixture was then thoroughly blended in a Robot Coupe, model R2 equipped with a 3 quart stainless steel bowl. The sample homogenate was frozen in 18 ounce Nasco whirl-pak bags with each bag containing about 250−300 g each. Bags of each matrix were shipped overnight to the other two laboratories for all subsequent work. At each laboratory, 12 10 g samples of each homogenized commodity were placed into 50 mL centrifuge tubes. Three tubes were left as unspiked matrix samples, three were spiked with 100 μL of the diluted stock standard (10 ppb in produce), three with 500 μL of the diluted stock standard (50 ppb in produce), three with 500 μL of the stock standard (200 ppb in produce). All were spiked with 100 μL of the internal standard solution. A reagent blank consisting of 10 mL water was also prepared. Acetonitrile was added to each of the tubes so that the total volume of acetonitrile added (spikes plus acetonitrile) was 10 mL. A ceramic stone was added to each tube, and the sample was vigorously shaken for 1 min. A UCT salt packet containing 4 g of $MgSO_4$ and 1 g of NaCl was then added, and again the samples were shaken for 1 min. The sample was centrifuged for 5 min at ≥3000 rpm. A 1 mL aliquot was transferred to a tube containing 50 mg of PSA and 150 mg of $MgSO_4$. The sample was shaken for 1 min. The sample was centrifuged for 5 min at ≥3000 rpm. A 0.5 mL aliquot was diluted with 0.5 mL of the aqueous mobile phase (water with 0.1% formic acid), and the sample was filtered into a microvial for LC-HRMS analysis.

Instrumental Analysis. Samples were analyzed using an Agilent (Santa Clara, CA) 1200 series rapid resolution liquid chromatograph interfaced to a Thermo Fisher Scientific (West Palm Beach, FL) Exactive orbitrap mass spectrometer. The LC was operated using a Thermo Fisher Scientific Hypersil Gold aQ C-18, 100 mm × 2.1 mm, 1.9 μm column held at 40 °C. The mobile phase flow rate was 0.25 mL/min, going from 99% water with 0.1% formic acid to 95% acetonitrile with 0.1% formic acid from 1 to 10 min followed by a 5 min hold at 95%, with a 5 min re-equilibration step for a total run time of 21.5 min. Three microliters of extract was injected. HRMS data was acquired in the positive electrospray mode using a metal needle at 3.5 kV, a source capillary temperature of 300 °C and mass resolution of 100000 (as specified in the tune page), the balanced mass accuracy setting, and an injection time of 20 ms. Data was acquired over the mass range of m/z = 75−1500. Prior to analysis, the mass spectrometer was tuned by infusion of azoxystrobin into the system. The tube lens, skimmer, and other parameters were adjusted so that the relative abundance of m/z 372 compared with m/z 404 was less than 10%. This tuning step was performed in order to ensure that any fragmentation of analytes through the tube lens and skimmer was minimized. A single tune file from each laboratory was used for the entire set of analyses though a mass calibration was performed prior to the analysis of each sample matrix.

It should be noted that the final extract concentration was 0.5 g sample/mL extract. At the 10 ppb concentration using a 3 μL injection, this would result in a total of 15 pg on column. While these low levels may help reduce ion suppression, they also can be a challenge to detect.

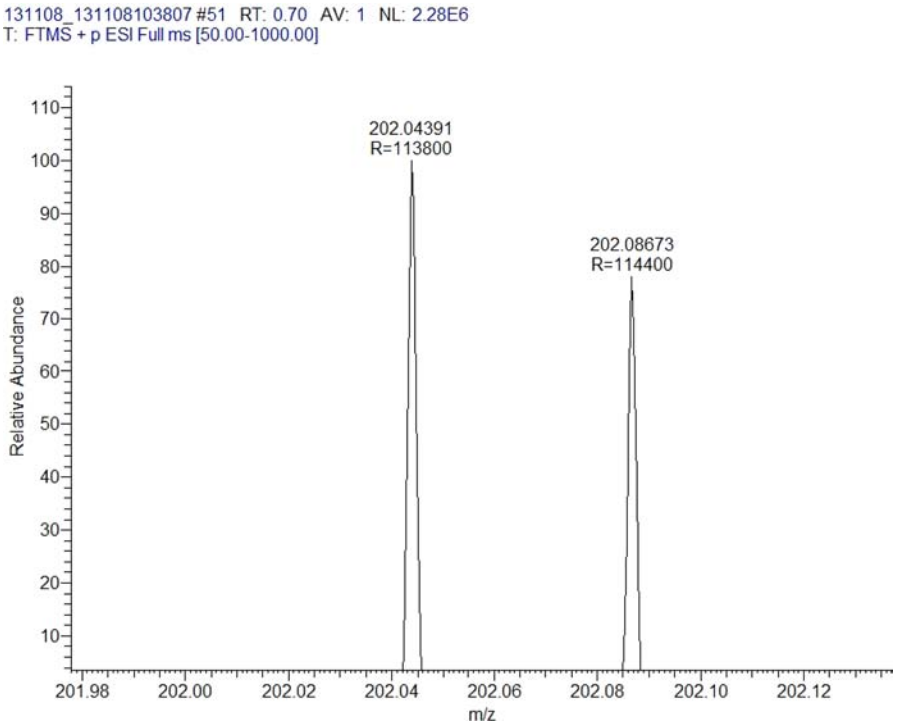

Figure 1. Mass profile for an infusion of thiobendazole and carbaryl on the orbitrap mass spectrometer at a resolving power of 100000. The theoretical m/z of the $(M + H)^+$ ions are 202.04334 and 202.08626, respectively.

Data Analysis. The raw pesticide data from the instrument was analyzed using the ToxID software package (Thermo Scientific). This program required an input file listing the molecular formula for each pesticide of interest, along with its expected retention time. During the setup of the method, the stock solution of 247 standards was injected on the instrument to determine retention times. Five compounds had distinctively split peaks and were entered into the input file twice (with separate retention times), while six compounds were not detected in the positive electrospray mode, thus in total there were 246 entries in the input file used for these tests. During operation of the software, the raw exact mass data for each entry was compared with the theoretically expected data (as computed from the entries molecular formula) for each of the individual pesticides in the input file. User parameters were set for detection at an elution time of ±0.25 min with a mass accuracy of ±5 ppm. The response threshold was set by each laboratory and had a slight variability depending on instrument but was in the range of 1000- 5000 counts. The ToxID data output for samples, spiked samples, and method blanks were reviewed to determine if analytes were found correctly and identified in amounts significantly greater (3x) than that observed in the method blanks.

Safety. Pesticides are considered hazardous materials. In accordance, all laboratory procedures were conducted with good chemical handling practices, and waste was disposed of as per the laboratory's hazardous waste plan.

RESULTS AND DISCUSSION

Specificity. Individual pesticide residues were identified in samples through two fundamental characteristics of the pesticide. The first was that the retention time for the pesticide must have been within 0.25 min of the time observed for an authentic standard of that pesticide. The second and more important characteristic was that the exact m/z of the pesticide must have been within 5 ppm of the calculated theoretical value.

As an example of the specificity that is provided by an exact mass instrument consider the case of the two pesticides, carbaryl and thiabendazole. Although carbaryl ($C_{12}H_{11}NO_2$) and thiabendazole ($C_{10}H_7N_3S$) have the same nominal mass of 201, the theoretical exact m/z's of their $(M + H)^+$ ion are 202.08626 and 202.04334, respectively. While these ions would be indistinguishable on unit resolution mass spectrometers, they are easily differentiated under high resolution conditions with a required resolution ($m/\Delta m$) of only 4700. This is clearly demonstrated in Figure 1, which shows the infusion (no chromatography) of these two compounds into the orbitrap system used in the current work. The protonated molecular ions of the two compounds are quite distinct. The work herein described was performed at a mass resolution of 100000. Isomeric compounds, having identical formulas, cannot be distinguished by differences in the exact mass of the molecular ion. However, these compounds can often still be distinguished by differences in relative retention time through the chromatographic system. Alternatively they can be differentiated by collisional fragments generated in the HCD cell of the instrument. These experiments could be conducted on the described instrumentation, but that is the subject of future work.

Interlaboratory Comparison. Data was reviewed for each individual pesticide at each level in each matrix. The number of detections (out of three samples) for each combination (matrix−pesticide−level) was recorded. All data from the three laboratories is included in the Supporting Information. The number of detections for the same combination was then compared across the three laboratories and is shown in Table 1. As can be seen in the table, the three different laboratories were very consistent in their ability to detect the pesticides. At the lowest level over 70% of the time either all three laboratories found a pesticide the same number of times in a particular matrix or did not see it at all in that matrix. By the highest concentration level the consistency in the data was almost at 90%. Clearly the entire method showed good consistency across the three laboratories.

dx.doi.org/10.1021/jf405128y | J. Agric. Food Chem. 2014, 62, 80−87

Reagent Blanks. With each set of samples, a reagent blank (using clean water and all other reagents including the internal standards) was analyzed. These samples were processed using the same ToxID protocol as used for all samples. A total of 43 of the compounds on the entry list were reported as a positive hit in at least one reagent blank sample by the ToxID software. Upon further inspection almost all of these "detections" appeared to be the result of software integrating noise. This points out the need for user accessible data integration parameters (other than intensity threshold) in the ToxID software. In addition, this also indicates that there needs to be a manual review of data.

Table 1. Comparison of the Percentage of Times That the Different Laboratories Agree on the Detection (Or Nondetection) At the Specified Concentration Level

concn level	% 0 of 3 agree	% 2 of 3 agree	% 3 of 3 agree
10	5.65	22.6	71.8
50	2.0	14.6	83.3
200	1.6	9.5	88.8

Table 2. The Number of Pesticides with the Specified Number of False Positive Hits in Each Matrix[a]

matrix	1 hit	2 hits	3 hits	4 hits	5 hits	6 hits	7 hits	8 hits	9 hits
oranges	13	6	11	3	1	4	0	1	1
carrots	5	2	10	3	0	0	0	0	1
spinach	11	6	13	3	1	2	0	0	1

[a]Each unspiked matrix was analyzed three times by each laboratory so the maximum number of hits is nine.

Unspiked Matrix. The analyzed samples were purchased at the supermarket with no *a prioi* knowledge of pesticide use. Therefore, the unspiked matrix samples were examined for the presence of any of the pesticides in the spiked mixture. Each laboratory extracted a set of three samples of each matrix without any spikes other than the internal standards. Three incurred residues were identified in the oranges (imazalil, pyriproxifen, and thiadendazole); two residues in the spinach (imidacloprid and spinosad), and none in the carrots. For these residues, in all cases there were good distinct peaks that appeared to be real in all nine samples analyzed of the unspiked matrix. There were a number of additional compounds tentatively identified by ToxID in the unspiked matrix that on closer inspection did not look like real peaks. These pesticides would be considered as false positves and are summarized in Table 2. There are two ways to consider the false positive rate: either (number of pesticides seen at least

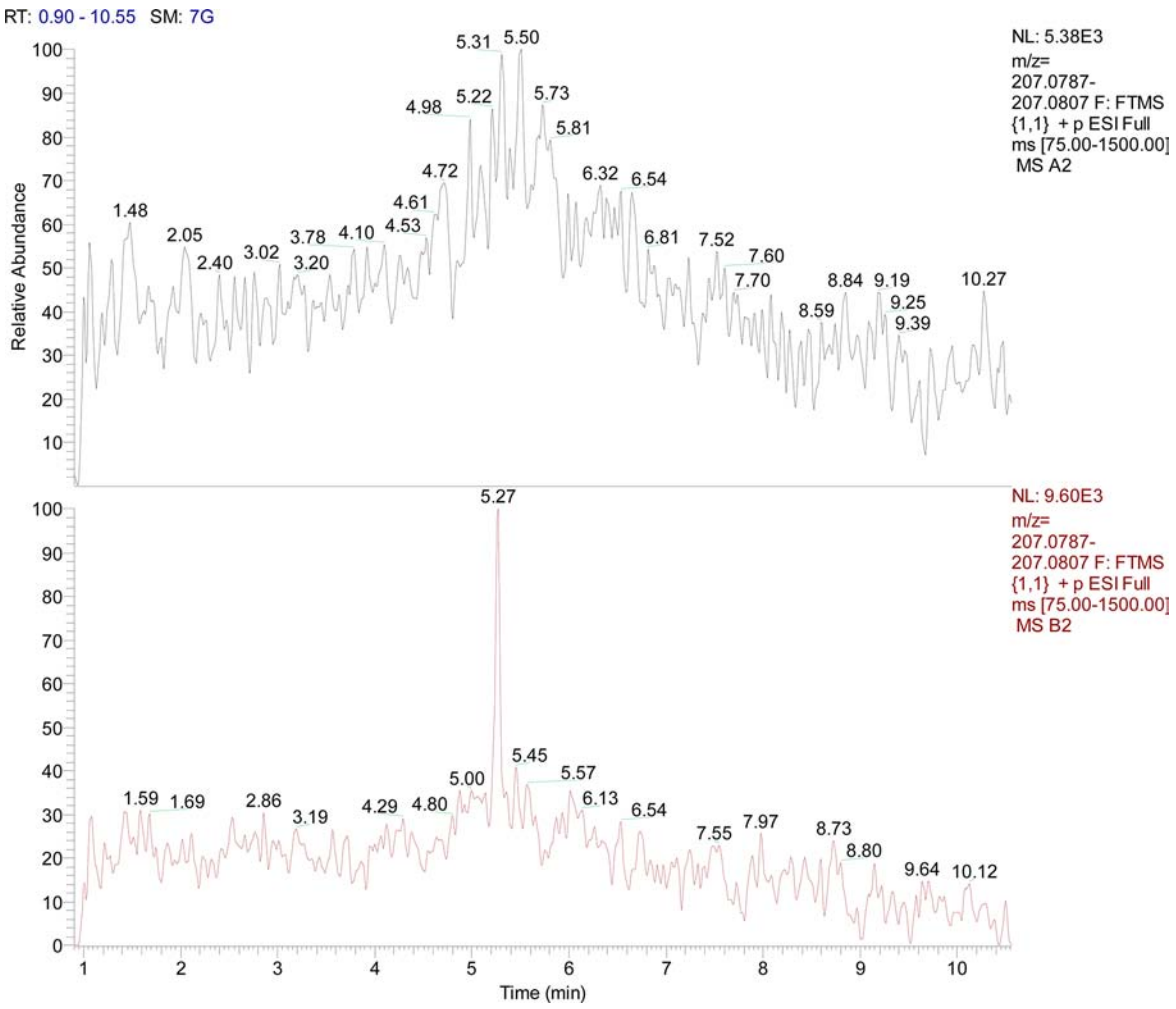

Figure 2. Selected ion chromatogram (5 ppm window) around $(M + H)^+$ ion for aldicarb sulfoxide spiked into oranges at 10 ppb (top) and 50 ppb (bottom). ToxID identifies a peak in both samples; however, the compound was not considered to be identified in the upper sample upon review.

dx.doi.org/10.1021/jf405128y | J. Agric. Food Chem. 2014, 62, 80−87

once)/(the total number of pesticides, 247) or (the total number of hits)/(total possible hits, 2223). Thus, the false positive rates for the three matrixes are as follow: oranges 16% and 5.2%, carrots 9% and 2.7%, spinach 15% and 4.5%. Although these rates are low, they again point to the need for additional data review beyond the library program.

False Negatives. A false negative occurs if a residue that should be reported was missed. To give a true assessment of the false negative rates, the data needed to be adjusted for positive detections based on the integration of noise. To do this, any pesticide that had a ToxID reported detection in either an unspiked matrix or reagent blank was carefully examined in the lowest spiked samples. In a few cases, the ToxID program integrated a noise peak at the 10 ppb level and then identified the compound as having been found. An example of this noise integration is shown in Figure 2 (top); however, in all of these cases, when the compound was examined at the 50 ppb level, the peak was present at sufficient signal-to-noise ratio to be correctly identified, Figure 2 (bottom). In these cases, the detections for the 10 ppb sample were manually changed to nondetects prior to the analysis of false negatives.

The false negative rate for each pesticide at each concentration level is defined by eq 1, where F is the false negative rate, N is the number of missed detections at a given concentration, and D is the number of possible detections at a given concentration. For most pesticides, D is 27, but for those pesticides for which there was an incurred residue, the data was adjusted to only use the matrixes without that incurred residue (D = 18 in those cases).

$$F = 100 \times N/D \quad (1)$$

The false negative rate for each pesticide at each concentration is included in the Supporting Information. The data is summarized in Table 3 showing the number of pesticides within a specified false negative percentage range. The method was tested with a mixed pesticide standard containing 247 different pesticides along with two internal standards. Seven compounds did not respond on the LC/MS system while five others gave split peaks creating a total of 246 distinct ToxID entries to examine for false negatives. At the 10 ppb spiking level, just over half (129) of the pesticides were seen in all spiked samples, with this number increasing to about 75% (189) at 50 ppb, and 85% (211) at 200 ppb. This table also shows that there were only a couple of truly problematic compounds that had false negative rates of over 50% at the higher concentration level. Several of these compounds also had poor (though) detectable response in the standards so likely lacked sensitivity to be detected at lower concentrations in matrix. It is also possible that a couple of these pesticides may have had problems with the chosen extraction procedure, though this was not evaluated. It should be noted that this version of QuEChERS has an overall dilution of the sample by a factor of 2. Some of the other versions of QuEChERs result in

Table 3. Number of Pesticides with the Specified False Negative Rate Using the ToxID Software at Each Concentration

concn	0%	0−25%	25−50%	50−75%	75−100%
10	129	34	30	16	37
50	189	18	16	14	9
200	211	9	13	11	2

[b]Never reached, there was always at least one false negative.

concentration of the extract by a factor of 2−5. It is possible that using one of these other versions would further reduce the false negative rate and improve the overall sensitivity of the method at the possible cost of increasing false positives.

It is useful to compare the overall performance of this HRMS method with that of the triple quadrupole MS/MS reported by Sack et al. for these same three matrixes using the same extraction scheme but with multiple reaction monitoring tandem mass spectrometry as the detection method.[10] This comparison is shown in Table 4. It should be noted that the Sack et al. data were reported using operating conditions that were optimized for each individual pesticide, whereas the current data was collected using a single scan function on the mass spectrometer. Furthermore, the Sack data are actual reported MDLs, while the current data only report on the minimum concentration in this screening project that had no false negatives; for many compounds, the detection limit is likely lower because there were many pesticides with strong signals at the lowest tested level. Nevertheless, the current data show a robust response with the minimum detection limits; over 50% of these 161 pesticides had a zero false positives at a concentration on the same order of magnitude as the reported MDL (i.e., minimum concentration of 10 vs an MDL of 5). There were clearly some pesticides that worked much better on the tandem MS system; further investigation is needed to see what is causing this to occur. Furthermore, the current methodology can easily be expanded to include many other pesticides (and other toxic organic contaminants). All that is necessary is the knowledge of the chemical formula of the compound; it can then be easily added to the screen (provided it extracts and is detectable by the LC/HRMS system). In fact, because the instrumental conditions do not change, items can be added to the list retroactively. This is one item that the triple quadrupole system could not do because it needs to have screened for a specific (and preset) transition.

It is also useful to examine the validated level in terms of what detection level is actually needed. This can be done by comparing the validated level to the tolerance for a particular pesticide in a given matrix as determined by the EPA and listed in the Code of Federal Regulations.[21] Table 5 compares the

minimum validated levels with the tolerances for those compounds for which a tolerance has been established. Examination of this table shows that in almost all cases the minimum validated level is below (and in most cases, well below) the United States tolerance and for many compounds meets the 10 ppb default detection limit of Europe. Thus, use of the reported screening method would succeed in observing the pesticides at the levels where they would need to be found. This being a screening method, follow-up would be required to determine whether they are below tolerance when found. Overall, there clearly is utility in the HRMS screening procedures, though improvements still need to be made in the software for dealing with these large multiresidue screens.

Effect of Cyclolinopeptides on the Oxidative Stability of Flaxseed Oil

Oyunchimeg Sharav,[†] Youn Young Shim,*[,‡] Denis P. Okinyo-Owiti,[‡] Ramaswami Sammynaiken,[§] and Martin J. T. Reaney*[,†,‡,⊥]

ABSTRACT: Polar compounds present in flaxseed oil increase its oxidative stability. Flaxseed oil becomes less stable to oxidation when filtered with silica. This observation may be linked to antioxidant compounds present in flaxseed oil. Flaxseed oil was passed over a silica adsorbent column to remove polar compounds. The polar compounds were then eluted from the silica absorbant using a series of increasingly polar solvents. The polar fractions from flaxseed oil were then added back to silica-treated flaxseed oil to determine the impact of fractions containing polar compounds on oxidative stability (induction time) at 100 °C. A polar fraction containing mainly cyclolinopeptide A (CLA, **1**), but also containing β/γ- and δ-tocopherol increased the induction time of silica-treated flaxseed oil from 2.36 ± 0.28 to 3.20 ± 0.41 h. When oxidative stability was determined immediately after addition of the polar fractions other flaxseed fractions and solvent controls did not affect oil stability. However, when the oxidative stability index (OSI) test was delayed for three days and oil samples were held at room temperature after the addition of the polar fractions to the flaxseed oil, it was observed that the control oil treated with silica had become highly sensitive to oxidation. A polar fraction containing a mixture of CLs (**1**, **5**, **7**, **9**, **11**), improved the oxidative stability of peptide-free oil with respect to the control when the OSI measurement was made three days after adding the fraction. In addition, effects of **1** on the oxidative stability of peptide-free oil containing divalent metal cations was investigated.

KEYWORDS: *Linum usitatissimum L., cyclolinopeptide, flaxseed, antioxidant, oxidative stability*

INTRODUCTION

Flaxseed (*Linum usitatissimum* L.) is an oilseed adapted to cool northern climates. Whole flaxseed contains 41% fat, 28% dietary fiber, and 21% protein having an amino acid profile comparable to that of soybean meal.[1] Flaxseed is one of the richest dietary sources of α-linolenic acid (ALA), having high levels of polyunsaturated fatty acids (73%).[2] Food and Agriculture Organization statistics show that global flaxseed production has been stable at ∼2 000 000 tonnes between 2008 and 2012 with the majority of the crop being produced in North America, Asia, and Europe.[3] Flaxseed oil is used predominantly as drying oil but it is increasingly being used as a source of dietary omega-3 fatty acids.[4]

Whereas the high content of unsaturated fatty acid present in flaxseed is important to its purported health benefits, its chemical structure makes it vulnerable to oxidation. Oxidation of flaxseed oil during improper processing and storage reduces its nutritional value and causes the development of undesirable flavors.[5,6] Despite its distinctive unstable oil content, flaxseed produces antioxidants that protect the meal in storage.[7−9] Flaxseed contains several known bioactive compounds, including lignans, phenolic acids, anthocyanin pigments, flavonols, flavones, and phytic acid, all of which may contribute to the seed's antioxidant capacity.[10] The concentration of these antioxidants in flaxseed oil depends on the extraction procedure and the treatment of the oil. Moreover, refining may also reduce minor compounds that have an effect on oil shelf life. The unrefined oil may have higher nutritional value and longer shelf life than refined flaxseed oil.[11] On the other hand, cold-pressing procedures do not involve heat or chemical treatments and the oil is extracted under mild conditions.[12] Siger et al.[11] reported several antioxidant compounds in cold-pressed flaxseed oil, including flavonoids (12.7−25.6 mg/100 g), phenolic acids (76.8−307.3 mg/100 g), α-tocopherols (0.55−9.11 mg/100 g), γ-tocopherols (10.56−15.00 mg/100 g), and plastochromanol-8 (3.37−5.53 mg/100 g). However, tocopherols are considered the main antioxidants in flaxseed oil. Some authors report weak[13] or no relationship between flaxseed oil oxidative stability and the content of tocopherols or phenol compounds in the oil.[14] Therefore, it is possible that other minor oil soluble compounds play a role in slowing the oxidation of flaxseed oil.

Cyclolinopeptides (CLs) are hydrophobic compounds present in flaxseed oil with polarity comparable to known natural antioxidants (Table 1 and Figure 1), but the antioxidant activity of these compounds has not been studied. The oxidative stability of CLs in vegetable oil was reported by Brühl et al.[6] while the stability of CLs in partially defatted flaxseed products was reported by Aladedunye et al.[7] The first discovered CL, CLA (**1**), was characterized in 1959.[15] Its unique structure induced researchers to investigate its

[a]Peptides are named according to references where they are first described. [b]The first and third positions of amino acid sequences are highlighted in Figure 1. Abbreviations are Met for methionine and MetO for methionine *S*-oxide. [c]From reference and ESI-MS data obtained as described in supplemental file by Gui et al.[27]

bioactivity. Recent studies show that peptides possess a wide range of biological activities and can act as anticancer[16] and antimicrobial[17] agents. Peptides have also demonstrated immunomodulatory and antioxidant activities. Moreover, some peptides produced in living cells act as antioxidants. Well-known examples of such antioxidants include hormones (melatonin,[18] angiotensin, oxytocin, and enkephalin[19]) and skeletal muscle peptides carnosine and anserine.[20] The antioxidative mechanism of peptides is not well understood. Some authors suggest that peptides that contain aromatic residues (tyrosine, histidine, tryptophan, and phenylalanine) are able to stabilize reactive oxygen species (ROS) through electron transfer.[21] Peptides are also well-known metal chelators and this property may contribute to antioxidant properties. The antioxidant activity of peptides produced by protein digestion is often greater than that of the intact proteins and the amino acid order and structure affect antioxidant activity.[22]

In accelerated oxidation tests of lipids, the oxidation rate is normally low until natural antioxidants are consumed and then the rate of oxidation increases. The time required for the increase in oxidation rate is called the induction time. The active oxygen method (AOM) accelerates lipid oxidation by applying both elevated temperatures and oxygen to an oil. The oxidative stability index (OSI) is an accelerated oxidation assay that determines production of volatile organic compounds produced during oil oxidation. The main criticism of this assay is that the oxidation mechanism at high temperatures is not necessarily similar to the mechanism encountered under normal storage conditions. Nevertheless, it is reported that the shelf life of the sample at ambient conditions can be predicted based on OSI at elevated temperature.[23,24] In general, lipid oxidation is the result of many complex chemical processes and interactions. The reaction between unsaturated fatty acid groups in lipids and ROS created in different ways is important to the stability of lipids containing unsaturated fats.[25]

The presence of CLs in flaxseed oil has led us to hypothesize that these compounds may contribute to the stability of crude flaxseed oil. The purpose of this study is to isolate polar fractions present in flaxseed oil, including CLs, to determine if these fractions increased the oxidative stability of flaxseed oil that has been treated to remove polar compounds. The effect of CL-containing fractions obtained from crude flaxseed oil were tested for their effects on the oxidative stability of peptide-free flaxseed oil. Subsequently the effects of enriched CLs on the oxidative stability of flaxseed oil in the presence of metal cations were determined. Analysis of the compounds present in fractions that contribute to oxidative stability may reveal compounds contributing to the antioxidant mechanism in flaxseed oil. There are no previous reports of the antioxidant activity of CLs in flaxseed oils.

MATERIALS AND METHODS

General. Cold-pressed crude flaxseed oil was donated by Biorginal Food and Science, Inc. (Saskatoon, SK, Canada), and stored at 4 °C. Canola oil was purchased from a retail supplier (Saskatoon, SK, Canada). Silica gel 60 (particle size 0.040−0.063 mm, 230−400 mesh) was purchased from EMD Chemicals Inc. (Gibbstown, NJ, USA). High-pressure liquid chromatography (HPLC) and column chromatography solvents were HPLC grade and purchased from Fisher Scientific (Pittsburgh, PA, USA) unless otherwise noted. A Milli-Q system (Millipore, Bedford, MA, USA) was used to prepare deionized water for all mobile phases. Metal stearates (Zn^{2+}, Ni^{2+}, and Co^{2+}) were obtained from Sigma-Aldrich Canada Ltd. (Oakville, ON, Canada). CL **1** was prepared by reverse phase chromatography of a silica gel solid phase extraction of flaxseed oil according to Reaney et al.[26] and Gui et al.[27] At the time of this study highly enriched CL **1** was available in relatively large quantities while other peptides were not available in quantities sufficient to conduct similar studies.

Silica Gel Flash Column Chromatography. A cotton ball was placed in the bottom of the glass column (2.5-cm i.d.) which was then packed with silica gel (80 cm^3). A sand layer (1-cm; 50−70 mesh) was placed on top.[27] Flaxseed oil (400 mL) was introduced into the column at a ratio of 5:1 (v/v, oil to silica gel) and was allowed to elute through the column under gravity to yield peptide-free oil.[27] The column was eluted with 400 mL of 100% hexane (A), 250 mL of 20% (v/v) ethyl acetate (EtOAc) in hexane (B), 250 mL of 50% (v/v) EtOAc in hexane (C), 250 mL of 100% EtOAc, and (D) finally 250 mL of 10% (v/v) methanol (MeOH) in dichloromethane (DCM, E) (Figure 2). Each of the fractions B−E (~230 mL each) were collected in volumetric flasks and diluted to a final volume of 250 mL. Samples of each fraction (B−E; 20 mL each) were taken and concentrated under vacuum pressure at 40 °C using a Buchi Rotavapor R-200 evaporator (9000 Pa, Brinkman Instruments, Inc., Westbury, NY, USA) and the resulting residue was subjected to HPLC and HPLC-MS analysis.

HPLC Analysis. HPLC analysis was conducted using an Agilent 1200 series HPLC systems (Agilent Technologies Canada Inc., Mississauga, ON, Canada) equipped with a quaternary pump, an autosampler, and a variable-wavelength diode array detector (DAD,

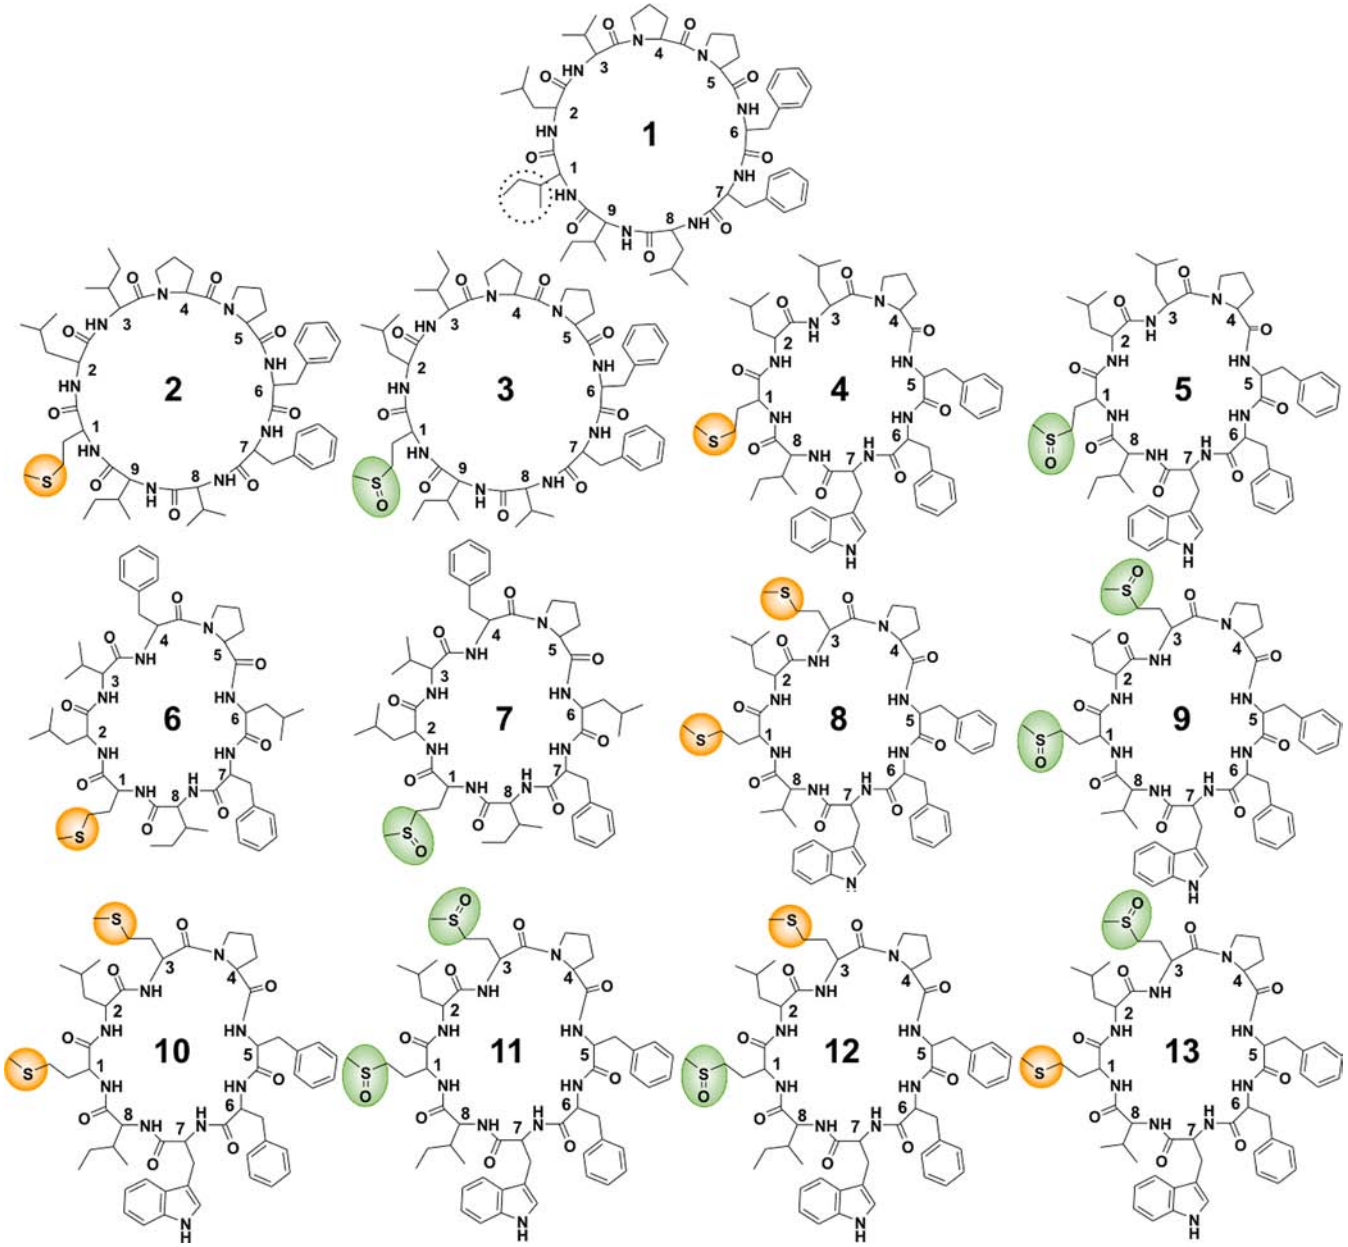

Figure 1. Structures of CLs. Met and MetO in the first and third positions of amino acid sequences are highlighted in CLs.

190−300 nm). The samples were separated on a ZORBAX Eclipse XDB-C18 column (150 × 4.6 mm i.d., 5 μm, Agilent Technologies Canada Inc.) with an in-line filter. The mobile phase consisted of a linear gradient of water−acetonitrile and a flow rate of 2 mL/min.[27] The injections of silica extracts onto the HPLC column were conducted to show if compounds were present and were not meant to be quantitative. Chromatograms of peptide extracts had peaks that exceeded an absorbance of 2.5 AU. With this strong absorbance quantative analysis of peptides was not possible.

Mass Spectrometry. Tocopherols in fraction D were separated using a Chromolith FastGradient RP-18e column (50 × 2.0 mm i.d., 3 μm, Merck KGaA, Darmstadt, Germany). An Agilent HPLC (1200 series) equipped with a quaternary pump, an autosampler, DAD (190−300 nm), and a degasser directly connected to a Bruker micrOTOF-Q II Mass Spectrometer (Hybrid Quadrupole-TOF MS/MS; Bruker, Bremen, Germany) with Apollo II ESI ion source (operated with Nebulizer gas at 4.0 bar and dry gas temperature held at 200 °C) was used in HPLC MS analysis. The mobile phase consisted of a linear gradient of 0.1% (v/v) formic acid in water and 0.1% (v/v) formic in acetonitrile (60:40 for 2 min, to 10:90 in 8 min, to 60:40 in 0.5 min, to equilibration for 5.5 min) and a flow rate of 0.40 mL/min.

OSI Analysis. *Effect of Polar Fractions on Oxidation of Silica-Treated Flaxseed Oil.* Eluate from each fraction (B−E; 30 mL) was added to 30 mL of silica-treated flaxseed oil, and the mixture was concentrated under vacuum at 40 °C using a Buchi Rotavapor R-200 evaporator (9000 Pa) to remove organic solvent. Control samples were prepared by adding the same solvent used to elute the column to silica-treated flaxseed oil and concentrating under vacuum pressure as described above. Crude and silica-treated flaxseed oil samples were kept under vacuum pressure in a desiccator for 24 h prior to OSI analysis (as described below).

Effect of the Concentration of Polar Fraction on the OSI of Silica-Treated Flaxseed Oil. Fractions D and E (200 mL) were collected from a silica gel flash column and concentrated as described above. The concentrate was added to 30 mL of silica-treated flaxseed oil and stored in a desiccator that was sealed and connected with a vacuum system for 24 h. The OSI of these samples was determined as described below.

dx.doi.org/10.1021/jf4037744 | J. Agric. Food Chem. 2014, 62, 88−96

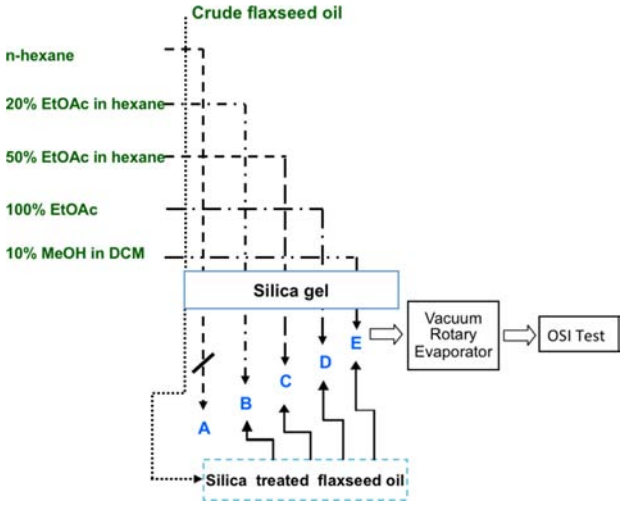

Figure 2. Flowchart for isolation of CL-containing fractions and sample preparation for OSI.

Effect of CL **1** *and Divalent Metal Cations on the OSI of Flaxseed Oil.* Stock solutions of metal stearates (Ni^{2+} and Zn^{2+}; 1.25 mM) and **1** (2.5 mM) were prepared in silica-treated flaxseed oil. The stock solutions were then added to silica-treated flaxseed oil to achieve the desired final concentrations of metal stearate (0.125 mM) and **1** (0.25 mM). The OSI of these samples was determined as described below. In a separate study, stock solutions of zinc stearate (1.0 mM) and **1** (1.0 mM) were prepared in canola oil. Subsequently, **1** (1 mL, 2 mL, 3 mL) and zinc stearate (4 mL) stock solutions were added to 23 mL of silica-treated flaxseed oil. The mixture volume was increased to 30 mL by the addition of canola oil. The final concentration of **1** was 0.03–0.09 mM and that of Zn^{2+} was 0.12 mM. The OSI of these samples was determined as described below. In a third study, stock solutions of **1** (0.625 mM) and cobalt stearate (0.625 mM) were prepared in canola oil. The canola oil along with metal-stearate-treated canola oil were added to 25 mL of silica-treated flaxseed oil until the volume of the oil was 32 mL. The addition of treated canola oil produced mixed oils with final concentrations of 0.04 or 0.12 mM **1** and/or 0.02 mM cobalt stearate. The OSI of these samples was determined as described below.

Measurement of OSI. OSI was measured with an OSI instrument (Omnion, ADM, Rockville, MD, USA) using AOCS official method Cd 12b-92.[28] Samples (5.0 ± 0.05 g) were taken in a glass test tube and then placed in the preheated (100 °C) OSI instrument. Air was bubbled through each sample (130 mL/min flow rate) during heating. Technical replicate samples (n = 4) were analyzed in each experiment. Crude oil and silica-treated flaxseed oil were taken as reference samples. OSI values were calculated using the Omnion OSI v 8.18 software, which detects the end point mathematically by determining the maximum of the second derivative of conductivity plotted against time.

Statistical Analysis. All analyses were performed using SPSS 13.0 software (SPSS Inc., Chicago, IL, USA) and data are presented as mean ± standard deviation (SD) (n = 4). Differences between mean values were evaluated using one-way analysis of variance (ANOVA) followed by a posthoc least significant difference (LSD) test, or an unpaired Student's t test. Statistical significance was accepted at $p < 0.05$.

RESULTS AND DISCUSSION

CL Isolation and Identification. UV absorbance indicated the presence of carotenoids in the oil. In the present study, CLs (**2**, **3**, **5**, and **7**) containing polar fractions from silica were prepared by flash column chromatography of cold-pressed flaxseed oil, and the solvent was removed from the fractions by concentrating under vacuum. The yields of the extracts obtained by silica gel flash chromatography are presented in units of g/100 mL of flaxseed oil (Table 2). Silica-treated flaxseed oil, with a clear yellow color, was obtained by passing fresh crude flaxseed oil through a silica gel column. Using an approach analogous to that applied in this study, Abuzaytoun and Shahidi[29] analyzed fractions obtained by passing cold-pressed hempseed and flaxseed oil through a column packed with two adsorbents (activated silicic acid and activated charcoal) and eluting the compounds with a series of organic solvents. They observed that after absorption on silica and carbon, the oil was essentially free of tocopherols and lacked light absorbance at 550–710 nm, which would indicate a loss of chlorophyll molecules as well. CLs were identified by their standard HPLC retention times as described by Gui et al.[27] The crude flaxseed oil was rich in **1**–**13** (Table 3 and Figure 3). HPLC analyses of fractions B–E revealed the presence of CLs in fractions D and E. Fraction D contained CLs (**1**–**8**, **10**, **12**), whereas fraction E contained a mixture of CLs (**1**–**13**) (Figure 4C and D). Peptides containing methionine (Met) group (**2**, **4**, **6**, **8**, and **10**) were decreased, and CLs (**9** and **11**) were not apparent in the HPLC chromatograms of polar compounds isolated from flaxseed oil. Oxidation of the Met group of CLs into methionine *S*-oxide (MetO) is observed regularly with the exposure of flaxseed oil to oxygen during oil extraction.[30] Most of the peptides were observed in fractions D and E. In addition, mass spectrometric analysis of fraction D indicated the presence of γ-tocopherol (Figure 5), β- and δ-tocopherols (data not shown).

Oxidative Stability Test. To determine the presence of antioxidant substances, the OSI values were determined at 100 °C on crude pressed flaxseed oil, silica-treated flaxseed oil, and silica-treated flaxseed oil with polar fractions (B–E) added (Table 4). Adding solvents to silica-treated flaxseed oil and subsequently evaporating them was conducted to act as a control. The OSIs of solvent-treated control oils, ranging from 2.03 to 2.65 h, were not significantly different from that of silica-treated flaxseed oil (Table 4). An effect of the addition and removal of solvents was observed with solvent D treated oils having lower stability (Table 4). This was not explored further. Crude flaxseed oil had higher oxidative stability than silica-treated flaxseed oil, indicating that some of the chemical constituents that were removed by silica gel play a significant role in reducing the rate of flaxseed oil oxidation. OSI times of crude and silica-treated flaxseed oils varied from 3.00 to 4.30 h and 1.15 to 2.75 h, respectively (Table 4). Abuzaytoun and Shahidi[26] observed that passing flaxseed oil over a silicic acid/charcoal column reduced markers of oxidation, thiobarbituric acid-reactive substances and conjugated dienes of cold-pressed flaxseed oil from 6.01 to 4.54 μM/g and from 1.65 to 1.09 μM/g, respectively. However, the oils were more susceptible to

oxidation with continued storage. Several natural antioxidant compounds have been determined in flaxseed oil and the quantity of these compounds depends on cultivar, growing conditions, and processing method. According to the study of Choo et al.,[12] cold-pressed flaxseed oil purchased in New Zealand, including locally produced and imported oil, contained 76.8−307.3 mg/100 g phenolic acid, 12.7−25.6 mg/100 g flavonoids, 3.4−5.5 mg/100 g plastochromanol-8, and 11.1−24.5 mg/100 g tocopherols. In addition, cold-pressed flaxseed oil may contain up to 150 mg/100 g CLs.[27] Therefore,

reduced oxidative stability observed with silica treatment may be related to the removal of any or all of these polar compounds. The presence of other minor compounds and synergistic interaction among substances should be considered.[12,29] Addition of fraction D to silica-treated flaxseed oil increased its stability to oxidation when compared to silica-treated flaxseed oil and solvent treated control oil (Figure 6, Table 4). However, oils treated with fractions B, C, or E were not significantly different from solvent-treated oil controls (Table 4). Fraction D contained **1** and trace amounts of γ-, β-, and δ-tocopherols. These compounds could potentially contribute to the observed increase in oxidative stability.

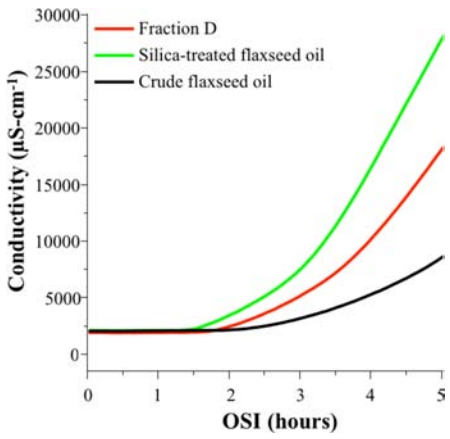

Figure 6. OSI of flaxseed oil and CLs-containing fractions.

Fractions B and C did not affect oxidative stability of silica-treated flaxseed oil when compared with appropriate controls. Fraction E contained more polar CLs than Fraction D (Table 4). The effect of silica treatment on other compounds such as phenolics and flavonoids with known antioxidant properties[31,32] was not investigated, but these compounds were not evident in extracts and may remain bound to the silica column.

Reports of the presence of phenolic compounds in flaxseed[11,12,33] are based on the use of colorimetric methods that employ low specificity reagents. For instance, the Folin–Ciocalteu reagent was used to determine the flavonoid content of cold-pressed flaxseed oil,[12] but this reagent may also react with a broad range of reducing substances including nitrogen-containing compounds such as indole derivatives.[34] D/L-tryptophan produces a strong absorbance at 745 nm when reacted with Folin–Ciocalteu reagent.[34] As indicated in Figure 4, fraction E contains **5**, **9**, and **11**. Each of these peptides contains tryptophan and MetO residues. It is possible that these substances reduce the Folin–Ciocalteu reagent, giving a false indication of the presence of phenolic compounds in flaxseed oil.

Many studies have revealed that polar fractions obtained from various vegetable oils contain phenolic compounds that contribute to antioxidant activity. For instance, Zhang et al.[35] contacted parsley essential oil with silica gel and conducted a stepwise solvent elution of the silica with EtOAc, EtOAc/MeOH (1:1, v/v), and MeOH. This study revealed that the antioxidant activity of the fractions increased with the polarity of the solvent used to elute that fraction from the silica. Phenolic compounds are also reported in fractions exhibiting

dx.doi.org/10.1021/jf4037744 | J. Agric. Food Chem. 2014, 62, 88–96

the strongest antioxidant activity. In comparison to fraction D and the solvent control, fraction E has little or no effect on flaxseed oil oxidation in spite of its higher polarity (Table 3). It is possible that fraction E does not contains phenolic compounds. Elevated induction time may be linked to specific CLs abundant in fraction D but are absent or less abundant in fraction E, or synergic activity of the peptides with tocopherols detected in fraction D. The dose−response and time-dependent activity of fractions D and E were studied after 10 months storage at 4 °C in a refrigerator (Table 4 and Figure 7). The

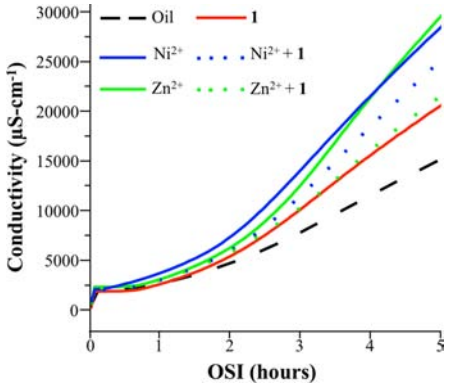

Figure 7. OSI of flaxseed oil and CL **1** + M^{2+}.

induction time of crude flaxseed oil decreased from 4.30 to 3.07 h during the 10-month storage period. Guseva et al.[36] observed that the peroxide value of cold-pressed flaxseed oil increased from 1.8 to 2.9 after six months storage at 10 °C, while Yildirim[34] reported that over 126 days storage at 4 °C, the peroxide value increased from 3.01 to 6.73. In addition, the fatty acid and antioxidant contents in crude flaxseed oil changed significantly over the first seven months of storage, after which no further changes were observed.[37] In this study the OSI times were measured over three days (Table 4) after removal from storage at 4 °C and maintaing the sample at room temperature. The oxidative stability of silica-treated flaxseed oil decreased significantly, by over 50%, after the temperature was increased, while oil subjected to other treatments was more stable. Silica-treated flaxseed oil with added fractions D and E decreased in induction period by 20% after three days removal from storage. Therefore, both fractions D and E have antioxidant properties that may be effective for long storage periods at low temperatures. It is important to note that the largest impact of fractions D and E was observed only after long storage followed by removal from storage for three days.

Influence of CL 1 on Metal Cation Induced Oxidation of Flaxseed Oil. Crude cold-pressed vegetable oil contains small amounts of metals. The quantity of trace metals varies depending on genetics, environmental conditions during plant growth, and processing methods used for oil extraction.[38,39] These metals potentially act as lipid oxidation catalysts. In this study, transition metal ions (Zn^{2+}, Co^{2+}, and Ni^{2+}) were added to flaxseed oil to determine their effects on the rate of oil oxidation. Also, if **1** binds to metals in flaxseed oil it may affect the rate of oil oxidation. Metal binding with **1** has been reported. Balasubramanian et al.[40] reported that **1** binds weakly to Ca^{2+} ions in MeOH. Moreover, Chatterji et al.[41] detected **1**:Tb^{3+} complexes stabilized by the f orbital of the lanthanide. Although binding of both ions with **1** was stabilized by Phe residues, the interaction with Ca^{2+} did not involve charge.

Silica gel adsorption readily removes divalent metal ions with high efficiency from different substrates.[42−44] Hence, silica-treated flaxseed oil is likely greatly reduced in, or free from. divalent metal ions. We observed that transition metal ions Zn^{2+} and Ni^{2+} accelerated the oxidation rate of silica-treated flaxseed oil (Table 5). Induction times of silica-treated flaxseed oil in the presence of these metals at 0.25 mM concentration were reduced by over 0.8 h when compared with controls without added metal. Whereas **1** had no effect on the oxidation of oil when added alone, **1** slowed oxidation induction by Ni^{2+} and Zn^{2+} by 17 and 37%, respectively (Table 5). The is the first study describing the impact of a CL on the rate of oil oxidation in the presence of a transition metal (Zn^{2+}, Ni^{2+}, and Co^{2+}). The observed results may be attributed to **1** binding with metal soaps, making them unavailable for oil oxidation. In addition, zinc ion is abundant in flaxseed (4 mg/100 g) and this study revealed that **1** could potentially interact with zinc. Additional experiments were focused on the dose-dependent interaction of zinc with **1**.

The effects of **1** and zinc ion on oxidation of silica-treated flaxseed oil at mole ratios of 1:4, 1:2, and 1:1.3 of **1** to Zn^{2+} were explored (Table 6). Canola oil was used as a more stable oil to dissolve metal stearates and **1** as dissolving these compounds in flaxseed oil led to unacceptably rapid oxidation (not shown). The addition of canola oil increased overall oil stability (from 2.35 h up to 3.5−8 h) and, hence, OSI times are not comparable to those in other studies. This agrees with other studies where blends of flaxseed oil with sesame, milk thistle,[36] and olive oil[37] have superior oxidative stability when compared to unblended flaxseed oil. This phenomenon occurs with other oils. For example, Isbell et al.[45] reported that adding just 5% of crude meadowfoam oil to triolein enhanced its stability by 35%.

The addition of canola oil modified the impact of zinc on oil OSI. Zinc soaps did not lower the OSI of blends of canola and flaxseed oil. It is possible that antioxidant compounds are present in canola oil that inhibit zinc oxidation pathways. Canola oil is rich in tocopherols; commercial canola oil contains up to 700 mg/kg tocopherols. Moreover, during refining processes, especially after bleaching and deodorizing, metal cations would have been almost cleared from the commercial oil used in this study.[46]

CL **1** improved the oxidative stability of canola/flax blends when added alone to the oil. However, the presence of zinc reduced the antioxidant effect of **1** (Table 6). At 0.12 mM concentration, **1** enhanced the induction time by 11.4 and 6.7% when canola oil was present at 26.0 and 16.6%, respectively. An interaction of **1** with zinc on oxidative stability was also observed in this study. As shown in Table 6, the OSI times of a

3.41 ± 0.13[b]a	3.55 ± 0.16a	3.05 ± 0.15c	3.10 ± 0.14b	3.11 ± 0.15b

[a]Values are mean ± SD (n = 4). Means in a horizontal row followed by the same letter are not significantly different at $p < 0.05$. [b]Content of canola oil is 28.5% for volume canola oil.

the canola/flax blend with **1** is similar to that of the blend with highest ratio of **1** to Zn^{2+} studied (1:1.3). Addition of smaller amounts of **1** did not counteract the effect of Zn^{2+} on OSI. It is possible that CLA almost completely binds Zn^{2+} at this ratio. In contrast, oil with **1** and Zn^{2+} added at a molar ratio of 1:4 oxidizes at the same rate as oil in the presence of metal soaps with no **1** added. This likely indicates that the presence of excess amounts of metal ion exceeds the metal binding capacity of **1**. In addition, the effect of Co^{2+} ions on the oxidation of silica-treated flaxseed oil was studied. However, **1** had no effect on the rate of oil the oxidation in the presence of cobalt as there was no influence of **1** on OSI in the presence of cobalt stearate. Because cobalt has a strong redox potential it may be able to initiate oxidation. It cannot be determined if binding to **1** has occurred (Table 7).

In conclusion, crude flaxseed oil has higher oxidative stability than silica-treated flaxseed oil, indicating that some of the chemical constituents removed upon treatment with silica gel play a significant role in protecting flaxseed oil from oxidation. Fractions containing **1** and tocopherols (fraction D), and a mixture of CLs (**1**−**13**) (fraction E), improved the oxidative stability of peptide-free oil, suggesting the significant role played by these compounds in protecting oil from oxidation. CLs have their own role in the strong antioxidant system of flaxseed oil. They may behave as antioxidants or pro-oxidants depending on concentration and environment. Dose- and time-dependent antioxidant properties of these peptides were observed. CL **1** is able to interact with metals selectively. Further studies are required to determine if **1** inhibits oil oxidation processes by binding metals or other mechanisms. Although, the OSI test was able to illuminate an approximate picture of oxidation in the presence of CLs, possible trace compounds in the studied fractions prevented the conclusive demonstration of the direct role of CLs as antioxidants. Further research should be conducted with simplified model systems to definitively show the interaction of pure CLs with antioxidants and radicles.

Evaluation of Liquid Chromatographic Behavior of Lumazinic Derivatives, from α-Dicarbonyl Compounds, in Different C18 Columns: Application to Wine Samples Using a Fused-Core Column and Fluorescence Detection

María del Carmen Hurtado-Sánchez, Anunciación Espinosa-Mansilla, María Isabel Rodríguez-Cáceres, and Isabel Durán-Merás*

Department of Analytical Chemistry, University of Extremadura, 06006 Badajoz, Spain

ABSTRACT: Several C18 columns, packed with totally porous particles of different sizes and shell thicknesses, have been compared for simultaneous determination of α-dicarbonyl compounds, previous derivatization to lumazinic derivatives. Chromatographic conditions for the separation have been optimized for each column, and chromatographic parameters have been calculated and exhaustively compared. A core−shell C18 column provided the best results, and a HPLC method with fluorimetric detection has been proposed. The developed method has been validated in terms of linearity, precision, and sensitivity. Detection and quantification limits obtained were comprised between 0.02 and 0.30 and 0.07 and 1.0 ng mL^{-1}, respectively, while RSD values obtained were lower than 6% and 5% in intraday and interday repeatability studies, respectively. The method has been applied to analysis of the α-dicarbonyl compounds in different types of wines. The higher levels of the total α-dicarbonyl compounds were found in sweet wines and the lower levels in white wines.

KEYWORDS: *α-dicarbonyl compounds, lumazinic derivatives, C18 columns, fluorescence detection, wine samples*

1. INTRODUCTION

α-Dicarbonyl compounds are reactive intermediates formed in physiological systems by lipid peroxidation of polyunsaturated fatty acids[1,2] and biological systems through the Maillard reaction by degradation of sugars.[3,4] In processed foods, these compounds are formed from carbohydrates during thermal processing in the course of the Maillard reaction, and they are also important compounds present in food products obtained by fermentation processes, such as wine. In this matrix, α-dicarbonyl compounds are formed as a consequence of the malolactic fermentation, a process that can occur after or simultaneously with alcoholic fermentation. During malolactic fermentation decarboxylation of L-malic acid takes place, and in consequence, acidity levels are reduced and several compounds related with the aroma and flavors are formed.[5,6] Among the identified formed compounds, dicarbonyl compounds with a short chain such as diacetyl (DIA), glyoxal (Gly), methylglioxal (MGly), 2,3-pentanedione (2,3-Pen), and phenylglyoxal (PhGly) are included.[5−7] These compounds are present in all types of wines, with levels higher in red wines,[8] and these concentrations are increased during age.[9] They play an important role in wines because they have a great influence on flavor and sensory characteristics. Specifically, DIA and 2,3-Pen are the most important compounds in the aroma of wines, and DIA is responsible for the buttery flavor of certain wines.[10] In addition, α-dicarbonyl compounds present reactivity with other components, which contribute to the loss of nutritional quality and increment production of toxic compounds in the wine.[11]

Glucosones, such as glucosone (GS) and 3-deoxyglucosone (3-DG), are α-dicarbonyl compounds with a C-6 backbone, which can be also formed from hexoses through monosaccharide autoxidation.[12] To date, to our knowledge, no data about the quantities of these compounds in wines have been reported.

A number of methods have been developed for determination of α-dicarbonyl compounds in several matrices such as biological samples and processed and fermented foods, and the prelabeled HPLC method is the most common. The more frequent derivatization reaction is formation of quinoxaline derivatives, and different diaminobenzenes have been proposed as derivatizing reagents: 2,4-dinitrophenylhydrazine,[13] 1,2-diaminobenzene,[14] and 1,2-diamino-4,5-dimethoxybenzene.[15,16] Other reagents used have been 6-hydroxy-1,2,3-triaminopirimidine,[17,18] 2,3-diaminonaphthalene,[19] or 5,6-diamino-2,4-hydroxypyrimidine.[20]

For analysis of these compounds in wine samples, methods such as gas chromatography with a mass-selective detector (GC-MS)[21] or a thermoionic detector (GC-NPD)[22] have been proposed as alternative techniques. However, the methodology more frequently used is based on formation of quinoxaline derivatives and analysis by RP-LC with photometric detection.[22−24] All HPLC methods employ C18 columns with particles of 5 μm for chromatographic separation of the corresponding derivatives.[25]

In this point, development of packed columns with smaller particle diameter to work in reverse phase could improve analysis in terms of separation efficiency and also in terms of reduction of the analysis time, which is an important factor to

take into account. In this way, columns packed with core−shell and totally porous sub-2 μm particles have been most frequently employed in qualitative and quantitative analysis.[26] The efficiency of a packed column is described by the Deemter's plate height model,[27] which explains the variation of this parameter with the linear velocity. The key concept of porous shell (or fused-core) particles is to increase both efficiency and separation velocity by reducing the mass transfer (C term in the van Deemter curve).[28] This is possible because it has a silica core that allows keeping their diameter large enough to avoid pressure limitations at high linear velocities. This type of column is constituted by a solid silica core of 1.7 μm in size with a porous outer layer 0.5 μm thick and a total particle size of 2.7 μm. On the other hand, packing of columns with porous sub-2 μm particles consist of derivatized, high-purity porous-silica microspheres having reproducible bonded monolayers. The rigidity and extremely narrow particle-size distribution of totally porous particles allow high-resolution and fastest analysis since operation at high flow rates is possible. However, this column has the disadvantage that usually an ultra-high-pressure liquid chromatography (UPLC) system is required to achieve the best results, while a fused core column allows fast separation on a conventional LC system, without significant loss in efficiency or resolution.[29] In the past decade, comparative studies about the separation of compounds in columns with different particle size, such as pharmaceutical compounds[30] or aflatoxins,[29] among others, have been realized by several authors, and in all cases, they concluded that columns with small particle size achieve major separation efficiency and improve the analytical method developed. On the other hand, core−shell columns have been compared with sub-2 μm porous particles columns in pharmaceutical compound analysis,[31] and a higher capacity of the core−shell columns to accomplish better separation efficiency under the same operation conditions was demonstrated.

The present paper is focused in two ways: first, to investigate the chromatographic behavior, in different packed columns, of the lumazinic derivatives formed from α-dicarbonyl compounds, in order to explore the advantages of columns with core−shell and minor particle size in analysis of these compounds; second, apply the obtained results in development of a simple, rapid, and competitive method to determine these compounds in different types of wines.

2. MATERIALS AND METHODS

2.1. Chemicals, Standards, and Samples. DIA, 2,3-Pen, and PhGly, all of 97% purity, and aqueous solutions of Gly and MGly, 40% purity, were purchased from Sigma-Aldrich (Madrid, Spain). GS (98%) and 3-DG (95%) were obtained from Santa Cruz Biotechnology (California, USA). Stock standard solutions of 3-DG (100 μg mL^{-1}), GS (400 μg mL^{-1}), and PhGly (135 μg mL^{-1}) were prepared by dissolving in ultrapure water adequate amounts of the powder presentation of each compound. Stock solutions of DIA (600 μg mL^{-1}), 2,3-Pen (150 μg mL^{-1}), Gly (50 μg mL^{-1}), and MGly (70 μg mL^{-1}) were prepared by weighting and dilution of the adequate aliquots in ultrapure water. Stock analyte solutions were prepared separately and stored at 4 °C. Working standard mixture solutions were daily prepared by suitable dilution of stock analyte solutions with ultrapure water. 5,6-Diamino-2,4-hydroxypyrimidine sulfate (DDP) (95%) was purchased from Sigma-Aldrich, and a 8.6 mM stock solution was daily prepared by dissolving adequate amounts in ultrapure water containing 200 mM β-mercaptoethanol (β-ME), also provided from Sigma-Aldrich. Ammonia/ammonium chloride buffer was prepared by dissolving ammonium chloride from Panreac (Barcelona, Spain) in ultrapure water and fixing the pH at 10.0 with ammonia (Panreac). Phosphoric acid (85%) was provided by Scharlau (Barcelona, Spain), acetic acid (95.5%) by Romil Chemical LTD (Cambridge, England), and formic acid (98%) by Fluka (Seelze, Germany). Different solutions of pH between 2.9 and 4.0 were prepared by dilution of an adequate volume of concentrated acid in ultrapure water. Methanol (MeOH), HPLC grade, was purchased from Panreac. Ultrapure water was obtained from a Milli-Q water system (Millipore S.A.S., Molsheim, France). Wines analyzed were acquired from local markets and kept at 4 °C, avoiding exposure to direct light. Specifically, red wines (Monasterio de Tentudía, Ribera del Duero, and Merlot), white wines (Rioja Comportillo, Viña Canchal, and Manzanilla), red sweet wines (Vin Santo and Port Tawny), and white sweet wines (Málaga Dulce and Oremus Takaji) were purchased. Most of them are from Spain, with the exception of red sweet wines (from Italy and Portugal) and Oremus Tokaji wine (from Hungary).

2.2. Instrumentation and Software. Chromatographic studies were performed on an Agilent model 1100 LC instrument (Agilent Technologies, Palo Alto, CA, USA), equipped with an online degasser, quaternary pump, manual six-way injection valve, UV−vis diode-array detector, rapid scan fluorescence spectrophotometer detector, and the Chemstation software package to control the instrument, data acquisition, and data analysis. Chromatographic studies and analytical separation were carried out in columns purchased from Agilent. The column temperature was controlled by a coil with recirculating water, in which the temperature was selected through a thermostatic bath. The injection volume was set at 20 μL for the Zorbax-Eclipse XDB C18 column and at 10 μL for columns with minor particle size. The flow rate was 1 mL min^{-1} for Eclipse columns and 0.5 mL min^{-1} for the Poroshell column. Detection was performed with a fluorimetric detector at 450 nm, exciting at 270, 330, and 350 nm.

A Crison MicropH 501 m (Barcelona, Spain), equipped with a combined glass/saturated calomel electrode, was used for pH measurements.

Calibration curves and analytical figures of merit were performed by means of the ACOC program,[32] in MATLAB code.

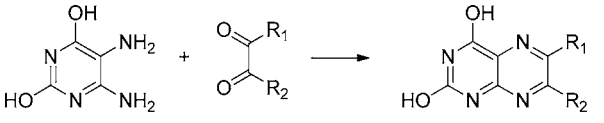
2.3. General Procedure: Calibration Curves. To build the calibration curves, aliquots of each α-dicarbonyl compound in variable concentration were placed in 25 mL volumetric flasks, and 0.125 mL of ammonia/ammonium chloride buffer (0.5 M, pH = 10) and 1.5 mL of 8.6 mM DDP solution containing 200 mM β-ME were added. After 30 min at 60 °C, solutions were cooled in ice water and diluted with 0.4 mM phosphoric acid solution (pH 3.2) up to the mark. Resulting solutions were filtered through a 0.22 μm nylon filter, and aliquots of 10 μL were injected in the chromatographic system. Separation was performed with a Poroshell 120 column, employing a solution of 0.4 mM phosphoric acid solution (pH 3.2)/MeOH (95:5, v/v) (eluent A) and MeOH (eluent B) as mobile phase, with the following gradient mode: 0−5 min, 0% B; 5−13 min, 30% B; 13−13.5 min, 40% B. These conditions were maintained until 25 min, and finally, the eluent B content was decreased to the initial conditions (0% B) and the column was re-equilibrated for 5 min. The eluate was fluorimetrically monitored at 450 nm (exciting at 270, 330, and 350 nm), and peak areas were used as analytical signal. Three replicas of each standard were used. Temperature was fixed at 25 °C, and a flow rate of 0.5 mL min^{-1} was employed.

2.4. Analysis of α-Dicarbonyl Compounds in Wine Samples. Analysis of the α-dicarbonyl compounds in red, white, and sweet wines was carried out by the standard addition method. For each wine sample, adequate volumes were added in a 25 mL volumetric flask. Increasing volumes of a standard mixture of the dicarbonyl compounds were added, and the general procedure was followed for the derivatization step. Separation of derivatives was carried out in a Poroshell 120 column thermostated at 25 °C. A mobile phase composed of 0.4 mM phosphoric acid solution (pH 3.2)/MeOH (95:5, v/v) (eluent A) and MeOH (eluent B) was employed by following the same gradient mode described in section below. Fluorescence excitation/emission wavelengths of 330/450 nm were employed.

3. RESULTS AND DISCUSSION

The first aim of this work is to realize a comparative study of the chromatographic behavior of the lumazinic derivatives from α-dicarbonyl compounds using three different C18 columns. In any case, the focus was to obtain baseline separation of all compounds in the shortest time and with the lowest solvent consumption as possible in order to achieve a simple, a fast, and an environmental friendly method, susceptible of being applied to analysis of these compounds in wine samples.

3.1. Formation of Lumazinic Derivatives. The most extensively applied methods in wine analysis for control of α-dicarbonyl compounds levels are based on reaction with 2,3-diaminobenzene to form quinoxaline derivatives that can be determined by HPLC with UV detection at 313 nm,[22] fluorimetric detection exciting at 350 nm,[33] or GC with a MS or NPD detector.[34] These derivatization reactions need high temperatures and reaction times close to 3 h. In this paper, DDP is proposed as derivatizing reagent in order to simplify the derivatization reaction. Optimization of the conditions for formation of the lumazínic derivatives for Gly and MGly was described in previous work.[20] In this work, use of DDP as derivatizing reagent was expanded to the seven α-dicarbonyl compounds that can be present in wine samples. The scheme of the derivatization reaction is shown in Figure 1.



Gly: $R_1 = R_2 = H$

MGly: $R_1 = H$, $R_2 = CH_3$

DIA: $R_1 = R_2 = CH_3$

2,3-Pen: $R_1 = CH_3$, $R_2 = CH_2CH_3$

PhGly: $R_1 = H$, $R_2 = Ph$

3-DG: $R_1 = H$, $R_2 = -CH_2-(CHOH)_2-CH_2OH$

GS: $R_1 = H$, $R_2 = -(CHOH)_3-CH_2OH$

Figure 1. Derivatization reaction of α-dicarbonyl compounds with 5,6-diamino-2,4-dihydropyrimidine (DDP) to yield the corresponding lumazinic derivatives.

The physicochemical variables that influence the yield and reaction rate, such as pH, temperature, reaction time, and DDP excess, were studied chromatographically by monitoring the derivatization reaction. In accordance with previous studies, the yield of the reaction of α-dicarbonyl compounds with DDP was optimal at pH 10, and this value was fixed in all solutions with 0.125 mL of ammonia/ammonium chloride buffer (0.5 M). Temperature and reaction time are two very important parameters that influence in the DDP−dicarbonyl compound reaction rates. For this reason, a series of standard mixture solutions containing 1.0 μg mL^{-1} GS, 400.0 ng mL^{-1} 3-DG, 100.0 ng mL^{-1} Gly, 100.0 ng mL^{-1} MGly, 100.0 ng mL^{-1} DIA, 120.0 ng mL^{-1} 2,3-Pen, 500.0 ng mL^{-1} PhGly, and DDP solution (7.5×10^{-2} mM) (concentrations enough so that all obtained derivatives provide a good signal, easily measurable, and whose variations are detectable, when the conditions of the reaction are changed) were placed in 25 mL volumetric flasks at pH 10 and incubated at 45, 60, and 80 °C during several heating times in the range 2−60 min. After completing the reaction times, the flasks were cooled in ice water and made to volume with 0.4 mM phosphoric acid (pH 3.2), and aliquots of 10 μL of these solutions were injected in the chromatographic system. For all α-dicarbonyl compounds, except for DIA and PhGly, the peak area of the derivatives increased with temperature and is maintained constant between 60 and 80 °C. The peak area of DIA and PhGly derivatives increased up to 60 °C, and for higher temperatures, the signal decreases. Finally, we selected 60 °C as the optimum heating temperature. With respect to the heating time, the peak area of the seven lumazinic derivatives increased up to 15 min. However, the reaction rate for formation of GS and 3-DG lumazinic derivatives is more dependent on the heating time, and after 60 min, these reactions had not been completed. With the object of not extending the total time of the derivatization reactions, a compromise value of 30 min was selected as optimum.

In the optimized conditions of temperature and reaction time, the DDP/total aldehyde ratio was studied in a range between 10:1 and 70:1. For all compounds a 10:1 ratio was enough to obtain the maxima signal; however, for GS and DIA a 30:1 ratio was necessary, and this relation was chosen as optimum.

Studies carried out showed that in the derivatization conditions DDP is degraded into several products, with the object of minimizing the appearance of degradation products that can interfere in analysis of some of the lumazinic derivatives, and in accordance with previous research[14,18] β-ME is added to the DDP solution. The influence of this reagent in the stabilization of DDP has been studied by preparing DDP solutions (0.8 mM) in the presence of different concentrations of β-ME (200, 400, and 600 mM). Aliquots of each solution were placed in a 25 mL volumetric flask, heated at 60 °C for 30 min at pH 10, diluted with 0.4 mM phosphoric acid (pH = 3.2) until the mark, and injected into the chromatographic system. It can be observed that degradation of DDP was avoided in the same extension, independent of the concentration of β-ME employed. Therefore, a solution of DDP was prepared in the presence in 200 mM of this compound. Figure 2A shows the chromatograms of a DDP solution in the presence and in the absence of 200 mM β-ME, and it can be observed that, in the presence of β-ME, degradation of the reagent is practically avoided and signal decreases.

In Figure 2B, a representative chromatogram from lumazinic derivatives obtained in physicochemical-optimized conditions is shown. As can be seen, all α-dicarbonyl compounds become a single lumazinic derivative, except 2,3-Pen and PhGly, which form two derivatives. For unequivocal identification of the derivatives, a comparison of the retention time of Gly derivative with a reference standard of lumazine was done. A standard solution containing 50 ng mL^{-1} of lumazine was injected in the chromatographic system, in the conditions previously described. As expected, retention time and excitation spectra of both peaks are coincident, and this allows confirmation of formation of the lumazinic derivatives.

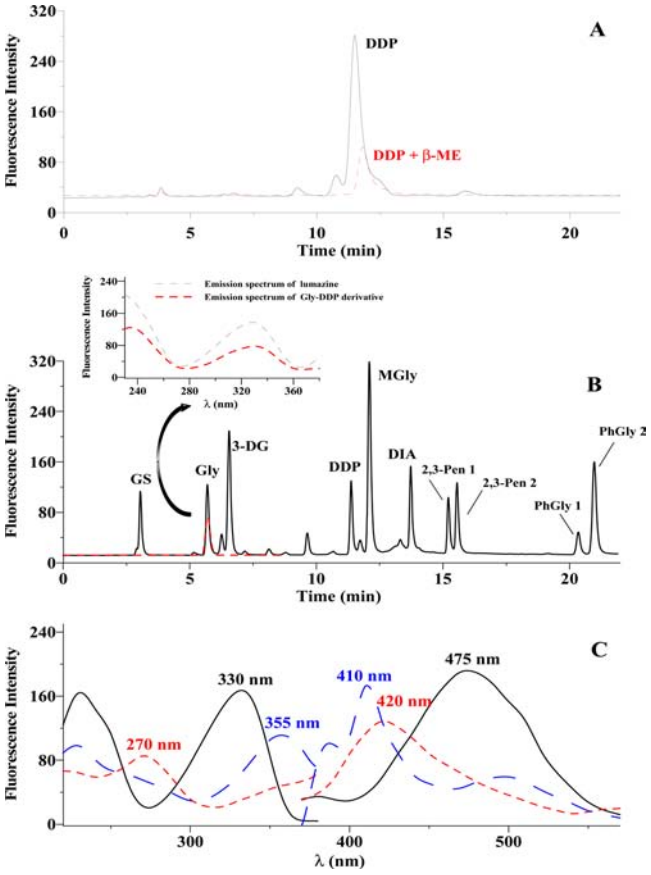

Figure 2. (A) Influence of the presence of β-ME in the degradation process of DDP in the derivatization reaction conditions. Chromatograms correspond to a DDP solution (7.5×10^{-2} mM) in the absence of β-ME (continuous line) and in the presence of 200 mM of β-ME (dashed line). $\lambda_{exc}/\lambda_{em}$ = 330/450 nm. (B) HPLC/FLD chromatograms from a stock standard solution of the α-dicarbonyl compounds in the presence of DDP solution (7.5×10^{-2} mM) at pH 10, derivatized in optimized conditions (heating for 30 min at 60 °C) (continuous line), and of a standard solution of lumazine, 50 ng mL^{-1} (dashed line). $\lambda_{exc}/\lambda_{em}$ = 330/450 nm. [GS] = 1.0 μg mL^{-1}, [3-DG] = 400.0 ng mL^{-1}, [Gly] = 100.0 ng mL^{-1}, [MGly] = 100.0 ng mL^{-1}, [DIA] = 100.0 ng mL^{-1}, [2,3-Pen] = 120.0 ng mL^{-1}, and [PhGly] = 500.0 ng mL^{-1}. (C) Excitation and emission spectra of lumazinic derivatives GS, 3-DG, Gly, MGly, DIA, and 2,3-Pen (—), PhGly 1 (---), and PhGly 2 (———).

Spectral characteristics of all derivatives were studied in order to achieve higher sensitivity in their analysis, and excitation and emission spectra were obtained for each peak (Figure 2C). All of them, except the PhGly derivatives, presented excitation and emission wavelengths characteristics of the lumazines at 330 and 475 nm, respectively. Also, the two derivatives of 2,3-Pen have identical spectral characteristics, with excitation and emission wavelengths at 330 and 475 nm, respectively, and both are formed in similar extension, as can be seen in the chromatogram shown in Figure 2B, where the peak areas of the two derivatives are similar. In the case of the PhGly derivatives, its spectral characteristics are different. Thus, the lumazinic derivative with minor elution time (PhGly 1) presents excitation and emission wavelengths at 270 and 420 nm, respectively, while the other derivative (PhGly 2) shows excitation at 355 nm and emission at 410 nm. On the other hand, in this case formation of one of the derivatives (PhGly 2) is more favorable that the other, probably due to steric impediments.

As a consequence of the different excitation and emission wavelengths of the lumazinic derivatives, a fluorescence detector was programed in multiexcitation mode and each chromatogram was recorded simultaneously exciting at 270, 330, and 350 nm. A wavelength of 450 nm was selected as the emission wavelength as a compromise in order to analyze all compounds in only one run.

3.2. Optimization of Separation and Comparison of Columns Efficiency. With the aim of selecting the more appropriate column for separation of the seven α-dicarbonyl-DDP derivatives, we realized a systematic comparison of three columns assayed. This study was performed in order to develop a simple, reliable, and robust method for efficient separation and quantification of these compounds. In this study, reversed-phase C18 columns with different dimensions and different size and surface particles were tested. The columns used were Zorbax-Eclipse XDB C18 (5.6 μm), Poroshell 120 (2.7 μm), and Zorbax-Eclipse XDB-C18 RRHT (1.8 μm). The most important parameters that influence chromatographic separation, such as mobile phase composition, flow rate, and column temperature, were assayed with each column.

The composition of the mobile phase has a large influence in complete resolution of the derivatives. Due to the analytes differing widely in polarity, isocratic elution is unviable and it was necessary to use a binary gradient. The two solvents employed in the gradient elution were mixtures of acid:MeOH, as solvent A, and MeOH 100% as solvent B. The presence of acid in the mobile phase is essential to complete resolution of the lumazinic derivatives, so the influence of the nature of the acid used in solvent A and the pH of the mobile phase was studied. Acetic, phosphoric, and formic acids were assayed, and the pH was varied between 2.9 and 4.0 for each acid. The behavior of the α-dicarbonyl−DDP derivatives was identical with the three columns assayed, independent of the acid used. In general, the retention times of DIA, 2,3-Pen, and PhGly lumazine derivatives are not affected, and the retention times of the less retained derivatives decreased as the pH increased. Finally, 0.4 mM phosphoric acid (pH 3.2) was selected as the aqueous component of solvent A for the three columns.

Below, the composition of solvent A was optimized for each column by modifying the phosphoric acid (0.4 mM)/MeOH ratio between 99/1 and 99/5, v/v. Also, different gradients with methanol as solvent B were assayed to achieve baseline separation of all derivatives in a time as short as possible. Optimized conditions for each column are summarized in Table 1.

Also, the influence of the temperature in the separation has been studied with the three columns. In general, the capacity factors decreased with increasing temperature for all compounds. It is noticeable that this effect is greater for the less retained compounds and when the mobile phase is 100% aqueous, as can be seen in Figure 3. In gradient mode, as the percentage of methanol increased and the mobile phase viscosity was varying, the effect of temperature in the capacity factors decrease, and the variation in the last four analytes eluted is lower.

Representative chromatograms obtained in the optimized conditions with the three columns assayed, XDB-C18, Poroshell, and XDB-C18 RRHT, are shown in Figure 4. As can be seen, use of a conventional monomeric C18 column results in a lack of complete separation between the peak of the

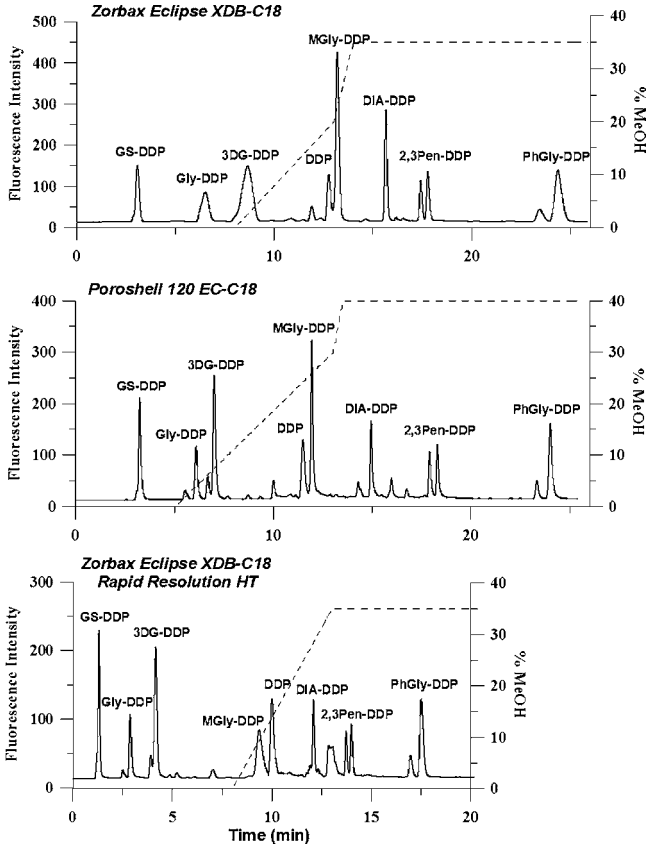

Figure 4. Optimum separation of lumazinic derivatives in the three columns assayed. Dashed lines indicated the gradient program employed. $\lambda_{exc}/\lambda_{em}$ = 330/450 nm.

MGly−DDP derivative and the peak of the DDP reagent. In addition, more polar analytes presented peak tailing, and in general, peak shape was wider than in the other columns. On the other hand, lower analysis time is obtained with the XDB-C18 RRHT column. It is important to remark that elution order of MGly derivative and DDP is inverted in this column. The Poroshell column achieves complete separation of the compounds in 25 min with narrow and symmetric peaks.

Once elution conditions were established, chromatographic parameters (column resolution (R), capacity factor (k'), and theoretical plate number (N)) were calculated to obtain information about the efficiency of each column in the chromatographic separation of the lumazinic derivatives. These parameters have been calculated following eqs 1−3, and the obtained values are summarized in Table 2.

$$R = \frac{1.17(t_{R_2} - t_{R_1})}{(w_{1/2})_1 + (w_{1/2})_2} \quad (1)$$

$$k' = \frac{t_R - t_0}{t_0} \quad (2)$$

$$N = 5.54x(t_R/w_{1/2})^2 \quad (3)$$

t_R is the retention time, t_0 is the dead time, and $w_{1/2}$ is the width of the peak at half height.

Retention time is the most important parameter to know the length of analysis. For all compounds, using the optimized elution conditions, retention times were shorter with the XDB-C1 8 RRHT column than with conventional C18 and Poroshell columns, getting a total scan time of 18 min, against the 25 min for the other two columns. Thus, the column length reduction decreases analysis time, as expected. Retention times of the lumazinic derivatives in the three columns assayed can be seen in Table 2.

Peak resolution describes the degree of separation between two compounds. Usually an R value of 1 is accepted to consider that a separation is satisfactory, but R must be equal to or higher than 1.5 to achieve a baseline resolution. As can be seen in Table 2, better resolution for all compounds is achieved when the separation was carried out with a Poroshell column. It is important to highlight that R has been calculated with respect to the previous peak eluted; thus, in the case of columns XDB-C18 and Poroshell, MGly resolution is referred to its separation from the DDP. However, as the order of elution between DDP and MGly derivative changes in XDB-C18 RRHT, the resolution of MGly is calculated with regard to the 3-DG derivative, with a resolution value of DDP-MGly of 1.4 ± 0.1. In relation to k' values, in the case of the Poroshell column, they are comprised between 0.84 and 12.7, which are near the ideal values (1 and 10),[35] while for XDB-C18 RRHT, k' values are too high (approximately 35 for the last derivative). This is in agreement with the fact that superficially porous particles typically have about one-half to three-quarters the surface area of totally porous particles, resulting in a smaller capacity factor value for columns of core−shell particles in size comprised between 2.5 and 2.7 μm.[36] On the other hand, N values, calculated based on the width of peak at half height, were greater for the Poroshell column in all cases, which indicates more efficient chromatographic separation.

Other aspects like solvent consumption were taken into account. In this way, although the analysis time for the XDB-C18 RRHT column is lower, solvent consumption is higher than with Poroshell (12.5 against 18 mL per run) due to the flow rate employed with this column being one-half.

In order to evaluate the precision of analysis with the three columns, repeatability was assessed by injection of 10 standard solutions, in the optimized conditions, for each column. The RSD from the signal of the peak area was between 1.6% and 7.4% for XDB-C18, 2.4% and 6.3% for XDB-C18 RRHT, and 2.4% and 6.1% for Poroshell. Therefore, significant differences were not found.

In summary, although the XDB-C18 RRHT column has the fastest elution time, resolution was enhanced with the core−shell column. Also, the solvent reduction achieved with this column is a good advantage with the aim of developing a method of analysis less polluting as possible; thus, the Poroshell 120 column was chosen for the following experiments.

3.3. Method Validation: Analytical Parameters. For validation of the method, a calibration curve of each compound was established employing the peak area as analytical signal and using the optimized conditions for the selected Poroshell column (Table 1). The linearity of the method was assessed by preparing calibration standards with concentrations ranging from 10.0 to 600 ng mL^{-1} of GS, from 4.0 to 120.0 ng mL^{-1} of Gly and 3-DG, from 4.0 to 40.0 ng mL^{-1} of MGly and DIA, from 4.0 to 150.0 ng mL^{-1} of PhGly, and from 4.0 to 60.0 ng mL^{-1} of 2,3-Pen. The pH 10 of the derivatization reaction was maintained with ammonia/ammonium chloride buffer, and the concentration of DDP was 0.86 mM, as previously explained in section 2.3. Standard solutions containing all α-dicarbonyl compounds were prepared in triplicate for each concentration level, and the analytical figures of merit were calculated

[a]SD: standard deviation. [b]Limit of detection. [c]Limit of quantification. [d]Expressed as relative standard deviation (% RSD). Standard solution employed containing 300.0 ng mL^{-1} GS, 60.0 ng mL^{-1} Gly, 3-DG, 20.0 ng mL^{-1} MGly, DIA, 75.0 ng mL^{-1} 2,3-Pen, and 30.0 ng mL^{-1} PhGly.

employing the peak areas as analytical signal. The analytical figures of merit obtained for each α-dicarbonyl compound are shown in Table 3. Evaluation of the precision of the optimized method was done by analyzing standard solutions of the α-dicarbonyl compounds in the same day (intraday precision, n = 10) and in consecutive days (interday precision, n = 6). Intraday and interday repeatability values, expressed as relative standard deviation (RSD), are lower than 6.0% and 5.0%, respectively, so they may be considered as a guarantee of the goodness of the proposed method, and use of an internal standard is not required. The limits of detection (LOD) and quantification (LOQ) were calculated as concentrations corresponding to 3 and 10 times the standard deviation of the signal from baseline from chromatograms obtained in intraday precision study. Low values are obtained that are indicative of the high sensitivity of the developed method. Results obtained are summarized in Table 3.

3.4. Quantitative Measurement of α-Dicarbonyl Compounds in Wines. After evaluation and selection of the optimum column for separation of seven α-dicarbonyl compounds, the proposed method was applied to analysis of different red, white, and sweets wines. To carry out quantification of the α-dicarbonyl compounds in wine samples, the influence of the matrix effect over chromatographic

[a]Concentration expressed as μg mL^{-1} ± SD (standard deviation) [b]Aliquot of wine samples: 500 μL for Gly, MGly, DIA and 2,3-Pen, and 120 μL for 3-DG and DIA wine/water (1/50, v/v) for GS and 3-DG. [c]Aliquot of wine samples: 1500 μL wine/water (1/50, v/v) for GS and 3-DG. [d]Aliquot of wine samples: 120 μL for Gly, MGly, DIA and 2,3-Pen, and 50 μL of a solution wine/water (1/50, v/v) for GS and 3-DG.

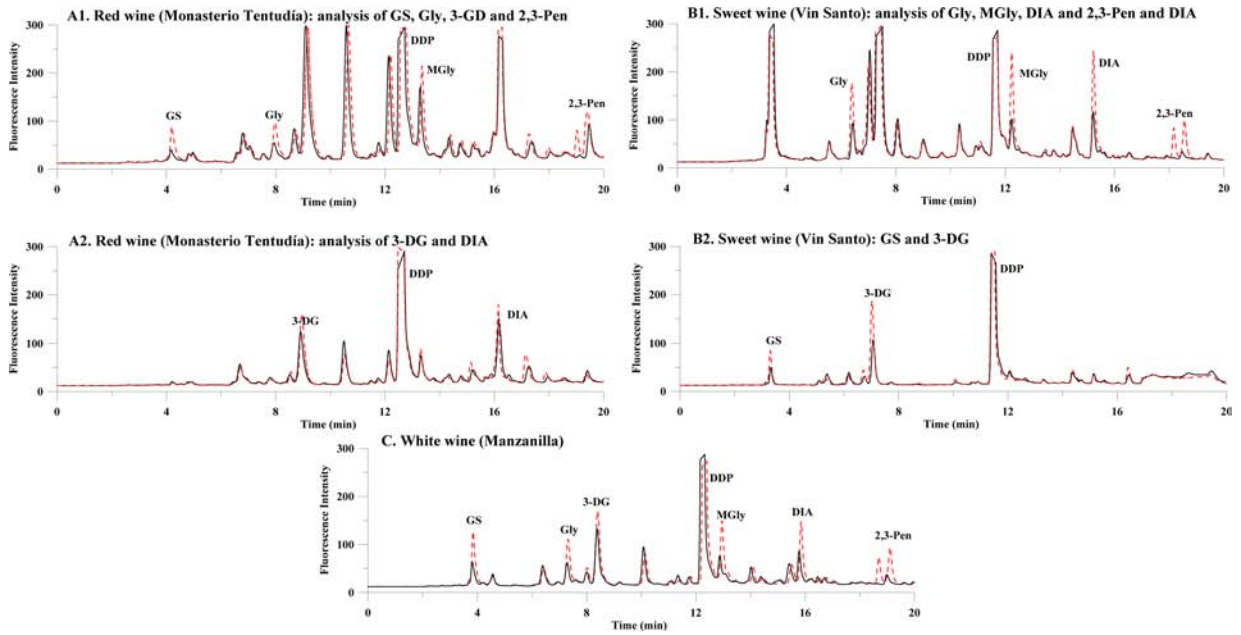

Figure 5. Chromatograms obtained from each type of wine analyzed (continuous line) and from wine samples spiked with 125.0 ng mL^{-1} GS, 60.0 ng mL^{-1} 3-DG, 40.0 ng mL^{-1} Gly, 6.0 ng mL^{-1} MGly, 6.0 ng mL^{-1} DIA, and 40.0 ng mL^{-1} 2,3-Pen (dashed line). (A1) Analysis of GS, Gly, MGly, and 2,3-Pen in red wine (Monasterio Tentudía, 0.50 mL of sample). (A2) Analysis of 3-DG and DIA in red wine (Monasterio Tentudía, 0.12 mL of sample. (B1) Analysis of Gly, MGly, DIA, and 2,3-Pen in sweet wine (Vin Santo, 0.12 mL of sample). (B2) Analysis of GS and 3-DG in sweet wine (Vin Santo, 0.50 mL of a solution wine/water (1/50 v/v)). (C) Analysis of six α-dicarbonyl compounds in white wine (Manzanilla, 1.50 mL of sample). $\lambda_{exc}/\lambda_{em}$ = 330/450 nm.

separation was first evaluated. For this standard addition calibration curves, from each of the α-dicarbonyl compounds in wine samples, were established, and calibration slopes were compared with the corresponding slopes of the external standard calibration plots of each analyte at the 95% confidence level. In all cases, considerable differences were obtained, and these results suggest that there is a matrix effect. As a consequence, calibration curves were constructed using the standard addition method for each of the wines analyzed and used to quantify each analyte in duplicate.

It is important to bear in mind that levels of α-dicarbonyl compounds vary with the type of wine, and for this reason, adequate sample dilutions were optimized for each type of wine analyzed. The volume chosen for each wine is shown in Table 4. The low volumes of samples needed for analysis, in comparison with other published methods, highlight the sensitivity of the proposed method.

Ten wines were analyzed following the methodology described in section 2.4: 3 red wines, 3 white wines, 2 sweet red wines, and 2 sweet white wines. Figure 5 shows an example of chromatograms obtained from each type of wine analyzed, and the results obtained for each α-dicarbonyl are shown in Table 4. Contrary to the literature,[22] PhGly was not detected in any of the different wines analyzed in this study. Also, in all

dx.doi.org/10.1021/jf404180t | J. Agric. Food Chem. 2014, 62, 97−106

samples, only one lumazinic derivative from 2,3-Pen was observed.

To date, the dicarbonyl compound more relevant in wines is DIA, since it has a pronounced butter odor and its presence in wines at high concentrations is undesirable.[8] Depending on the type of wine, the contents of DIA[37,38] ranged from 0.2 to 12 mg L^{-1}. As it can be seen in Table 4, in the samples analyzed in this paper the content of DIA varies between 0.29 and 8.8 mg L^{-1}. It can be observed that in red wines the content is higher than in white wines, in accordance with previous research, and no significant differences were found between not sweet and sweet wines, with the exception of Ribera Duero wine.

With respect to the other α-dicarbonyl compounds with a short chain, concentrations found for Gly and MGly were similar to those previously reported.[33] Values ranged from 1.1 to 1.85 mg L^{-1} for Gly and 0.28 to 1.68 mg L^{-1} for MGly, with the exception of Merlot wine, whose concentration of Gly found was 7.1 mg L^{-1}. Thus, the levels found in Merlot wine are close to the levels found for sweet wines, in which the quantities of Gly and MGly found were higher (between 4.5 and 8.9 mg L^{-1} and 0.9 and 3.2 mg L^{-1} for Gly and MGly, respectively). In all cases the relation Gly/MGly is greater than unity. With respect to the levels of 2,3-Pen, these are similar in all wines analyzed ranging between 0.9 and 5.60 mg L^{-1}, and no appreciable differences were found between sweet and not sweet wines.

On the other hand and with respect to the α-dicarbonyl sugars, 3-DG and GS have been detected in all wines analyzed. In red and white wines, the content of GS varies between 0.4 and 5.2 mg L^{-1} and the 3-DG content between 4.9 and 13.5 mg L^{-1}. In sweet wines, the concentration of both glucosones increases considerably, independent of whether they are red or white, and their concentrations vary between 37 and 261 mg L^{-1}.

Due to the high concentration of glucosones obtained in sweet wines, it was important to check if formation of the α-dicarbonyl compounds from sugars was not favored by the high temperature of the derivatization reaction conditions. Therefore, in sweet wines, the derivatization reaction was performed at room temperature for 2 h and 30 min and aliquots of these samples were analyzed. A comparison of the chromatograms, obtained at room temperature and higher temperature, does not show significant differences. This fact allows us to conclude that the elevated concentrations of glucosones found in sweet wines are related to its high levels of sugars.

Finally, if analyzing the total α-dicarbonyl concentration, it can be observed that no significant variations were found in each type of red or white wine analyzed. However, if we made a comparison between red and white wines, we can confirm that the total α-dicarbonyl concentration is significantly higher in red wines. On the other hand, in sweet wines, a great difference has been found between the wines analyzed, and values of total α-dicarbonyl concentration amounting to 402 mg L^{-1} have been found. In addition, Tokaji wine, which it is a sweet white wine produced with botrytized grapes, contains higher levels of MGly. In spite of this, the total α-dicarbonyl concentration found is lower compared to the other sweet wines analyzed.

In conclusion, all types of columns tested were able to separate the lumazinic derivatives with sufficient resolution and peak symmetry in the optimum chromatographic conditions, although they differed in analysis time and separation efficiency of the derivatives analyzed. The conventional C18 column had the lowest resolution and peaks wider than columns with minor particle size. By comparing the chromatographic behavior of lumazinic derivatives in small particle size columns, it can be observed that although the XDB-C18 RRHT column provides the lowest retention times the best separation efficiency and lowest solvent consumption is achieved with the Poroshell column. For this reason, the comparison study carried out showed that the Poroshell column was most appropriate for analysis of α-dicarbonyl compounds and previous derivatization to lumazines, and this column was selected for their analysis in wine samples. Derivatization reaction time, temperature, and sample volume employed in analysis have considerably decreased with respect to the previous published method. On the other hand, a very sensitive and reproducible method to analyze these compounds in different commercial wine samples has been developed, and no pretreatment of sample is required. The sensitivity of the method is presented as a useful alternative to other methods, even with MS detection, whose instrumentation is more costly and complicated and not available in many laboratories. A comparison between red and white wines shows that the total α-dicarbonyl concentration is significantly higher in red ones. In sweet wines, total amounts up to 400 mg mL^{-1} have been found.

Supporting Information

ABSTRACT: Seeds are complex entities composed of liquids, gels, and solids. NMR spectroscopy is a powerful tool for studying molecular structure but has evolved into two fields, solution and solid state. Comprehensive multiphase (CMP) NMR spectroscopy is capable of liquid-, gel-, and solid-state experiments for studying intact samples where *all organic components* are studied and differentiated in situ. Herein, intact ^{13}C-labeled seeds were studied by a variety of 1D/2D ^{1}H/^{13}C experiments. In the mobile phase, an assortment of metabolites in a single ^{13}C-labeled wheat seed were identified; the gel phase was dominated by triacylglycerides; the semisolid phase was composed largely of carbohydrate biopolymers, and the solid phase was greatly influenced by starchy endosperm signals. Subsequently, the seeds were compared and relative similarities and differences between seed types discussed. This study represents the first application of CMP-NMR to food chemistry and demonstrates its general utility and feasibility for studying intact heterogeneous samples.

KEYWORDS: *multiphase, broccoli, corn, wheat, seeds, NMR spectroscopy, intact sample, in situ analysis, triacylglyceride (TAG)*

INTRODUCTION

Seeds are integral to world nutrition as they not only serve as a direct source of food rich with essential vitamins, fiber, sterols, and antioxidants but carry the potential to be cultivated into fruit- and vegetable-bearing plants.[1−4] Plant sterols have been shown to reduce low-density lipoprotein cholesterol absorption, whereby the structurally analogous sterols compete with cholesterol absorption sites in the intestine.[5] Similarly, high antioxidant intake has demonstrated protective effects against chronic diseases such as cancer, cardiovascular disease, osteoporosis, and diabetes by mitigating the damaging effects related to oxidative stress.[1,2,4] β-Carotene, a precursor to vitamin A, and other antioxidants such as vitamin C are not produced natively by the human body and must be obtained from extrinsic dietary sources, for which fruits and vegetables are naturally abundant.[6,7]

Historically, NMR spectroscopy has evolved into two separate fields, namely, solution-state and solid-state NMR. Seed components can be extracted for solution-state NMR, but this process is destructive and selective toward only a subset of chemicals present. Solid-state NMR can be used to study intact seeds, but in the case of soluble/gel components, the lack of pulse field gradients and a spectrometer lock restrict the type of experiments and information that can be extracted directly. Recently, NMR spectroscopy has been applied in seed analysis for the study of oil and protein composition, but often requires extensive and time-consuming sample preparation.[8,9] One study used wheat seeds that were initially milled into a flour, dissolved in a buffer solution, and centrifuged, and the supernatant was collected prior to NMR analysis.[10] Such methods of sample preparation can be detrimental as they potentially perturb the structure and native chemical and physical interactions that influence analyte kinetics across phase boundaries, which are important for analysis.

The first ^{1}H measurements of intact seeds, in which the oil content was determined for a variety of seeds, were likely performed in 1963.[11] This was followed by the first high-resolution ^{13}C measurements conducted in 1974, whereby the oil composition was measured for a single soybean.[12] Previous

analysis of intact seeds has been performed by high-resolution magic angle spinning (HR-MAS) of canola seeds to determine seed oil composition;[13] cross-polarization (CP)-MAS and HR-MAS to characterize *Arabidopsis*, pea, and lettuce seeds;[14] metabolite profiling to assess conifer seed quality,[15] as well as measuring the moisture content of garden cress seeds.[16] In all cases, although intact seeds were used, only select phases (liquid, gel, or solid) were studied in a given experiment.

Traditional solution-state NMR probes use low-power electronics, a lock channel, and pulsed field gradients and provide excellent line shape but only for dissolved samples. HR-MAS probes were introduced in 1996 and employ magic angle spinning, a magic angle gradient, and susceptibility-matched stators.[17] HR-MAS probes permit the study of swellable and liquid components. However, HR-MAS probes are designed using low-power circuitry; as such, they cannot generate the RF field required for high-power decoupling or cross-polarization, elements essential to the majority of solid-state NMR experiments. Solid-state probes, on the other hand, are designed to generate high RF fields, but as solid-state NMR spectroscopy has been predominantly reserved for the study of true solids, they lack a lock and gradients, which are required for the efficient study of liquid and gel components. Comprehensive multiphase (CMP) NMR, introduced in 2012, incorporates all of the aforementioned aspects, including magic angle spinning, a magic angle gradient, a lock, full susceptibility matching, and solid-state circuitry to permit high power handling. Therefore, it is built to study unaltered samples where *all organic components* can be observed and differentiated in situ, resulting in a universal approach.[18]

The use of separate probes to achieve the same goal is only an option for the most simple, structural studies, where the sample does not change. Even in this case, it is important to stress that in large part, due to independent development of liquid- and solid-state NMR, very few laboratories in the world would have separate liquid, HR-MAS, and solids probes, and even if they did, scheduling all to be available at the same time would be extremely challenging. More importantly, any study involving kinetics transfer between phases (e.g., growth, contaminant sequestration) or changes of one phase into another (for example, soil swelling/drying, feeding phenylalanine to follow lignin formation) will require a CMP probe as such studies are impossible to perform using separate probes. This is discussed in more detail later in this study.

CMP-NMR has been, thus far, used to determine the fate and binding of contaminants in soil.[18,19] Here, we introduce CMP-NMR to applications in food and agriculture. This study focuses on structural information that can be obtained from ^{1}H and ^{13}C CMP-NMR characterization of intact broccoli, corn, and wheat seeds. Wheat and corn were selected as they represent major global crops, whereas broccoli seeds were included as an example of a legume. The different seed types will be compared to each other for relative differences and similarities as well as further considerations of CMP probes (including quantification; need for labeling and future potential) will be discussed toward the end of this study.

Seeds are used here as an example that serves to demonstrate the general applicability of CMP-NMR for the analysis of all organic components in all phases in whole, unaltered samples. CMP-NMR is likely to find widespread application in the agricultural and food sciences due to versatility and ability to provide unsurpassed molecular detail on intact samples. CMP-NMR has potential to understand intact structure, processes that are involved in phase changes (drying, swelling), and molecular interactions (for example, between a herbicide and plant tissue) and, thus, has considerable potential for the analysis of food, soil, sediments, plants, and seeds.

MATERIALS AND METHODS

^{13}C Labeling of the seeds. Uniformly ^{13}C-enriched seeds of broccoli, corn, and wheat (*Brassica oleracea* var. *botrytis* 'Broccoli', *Zea mays*, and *Triticum aestivum*, respectively) were produced in specially designed, airtight, high-irradiance growth chambers[20] (IsoLife, Wageningen, The Netherlands). Plants were grown from ^{13}C-labeled seeds in a closed atmosphere containing 97 atom % $^{13}CO_2$ (from pressurized cylinders; Isotec, Inc., Miamisburg, OH, USA) from the seedling stage until full maturity. Internal wind speed ensured efficient pollination of the corn and wheat. Pollination of broccoli flowers was ensured by combining compatible parent plants and introducing bluebottle flies into the chambers. Mineral nutrients were supplied as Hoagland-type solutions with micronutrients and iron.[21,22] Climate conditions were as follows: irradiance (PPFD), 600 μmol m^{-2} s^{-1} (HPI) during a 16 h day; day/night temperatures, 24/16 °C; relative humidity, 75/85%.

Sample Preparation. Uniformly ^{13}C-labeled (>97% total carbon content) and nonlabeled (<1.2% total carbon content) seeds of broccoli, corn, and wheat (*B. oleracea* var. *botrytis* 'Broccoli', *Z. mays*, and *T. aestivum*, respectively) were used. The whole and intact seeds were placed directly into a 4 mm zirconium rotor and filled with D_2O (Andover, MA, USA) as a lock solvent. The seeds, which contained 6.7 and 6.6, 6.8 and 7.2, and 8.6 and 7.5% water for labeled and nonlabeled wheat, labeled and nonlabeled corn, labeled and nonlabeled broccoli, respectively, were not swollen beforehand. Because the goal of the study was to study seed structure and not the process of germination, 99.8% D_2O was deliberately used because seeds are found to either not germinate or germinate but do not continue to grow afterward when imbibed with D_2O.[23,24] No significant differences were noted over each 24 h acquisition period; all spectra data sets were consistent with each other. In addition, during longer experiments CP-MAS, direct carbon, and 2D NMR the spectra (collected over many hours) will represent the average state of the seeds during that time period and hence give a representative overview of the overall structural state. Seeds remained intact and were not damaged during the spinning process. In the case of corn, which was cut in half to fit into the rotor, the D_2O solvent may have been more likely to leach components from the seed into the aqueous solvent. The goal of this study was only to look at overall structural state; future studies that employ H_2O as the solvent (with an external D_2O lock) and kinetic experiments with high temporal resolution could be used to understand the molecular processes behind germination.

The rotor was sealed using a top insert made from Kel-F, a Kel-F sealing screw, and a Kel-F cap. For wheat, only one seed was used. For broccoli, 2 seeds were used for proton studies and 10 seeds for anything that required carbon to increase sensitivity. Finally, for corn, the seed had to be cut into half due to its size before being placed in the rotor. The nonlabeled equivalents were prepared identically.

1D NMR Spectroscopy. All NMR measurements were performed on a 500 MHz Bruker Avance III spectrometer at a spinning speed of 6666 Hz using a prototype CMP MAS 4 mm $^{1}H-^{13}C-^{19}F-^{2}H$ probe fitted with an actively shielded Z gradient (Bruker BioSpin) at 298 K. All experiments were locked on D_2O, and the lock was maintained for all experiments including the solid-state experiments. Decoupling was used in all 1D and 2D experiments to remove $^{1}H-^{13}C$ coupling from the labeled sample. For low-power experiments *garp* was used for proton observe and *waltz16* for carbon observe. For high-power decoupling *spinal-64* was used for carbon observe.

All ^{1}H NMR spectra were recorded using presaturation for water suppression except for when presaturation utilizing relaxation gradients and echoes (PURGE) was employed.[25] The 90° pulse was calibrated for each sample in the study. A spectral width of 20 ppm was used, 2K scans and 8K time domain points were acquired. T_1 times were measured using the standard inversion recovery approach and the

recycle delay set at 5 times the measured T_1 value. Spectra were processed using a zero-filling factor of 2 and an exponential function corresponding to a line broadening of 2 Hz.

One-dimensional ^{13}C NMR spectra were recorded with a spectral width of 400 ppm using inverse gate decoupling. Scans ranged from 2K to 12K and 16K time domain points. ^{13}C RAMPed-amplitude cross-polarization magic angle spinning (^{13}C RAMP CP-MAS)[26] was acquired with 2K scans, a 1 ms contact time, and a 2 s carbon recycle delay. T_1 times were measured using the standard inversion recovery approach and the recycle delay set at 5 times the measured T_1 value. Spectra were processed using a zero-filling factor of 2 and an exponential function corresponding to a line broadening of 5 Hz (conventional carbon) and 40 Hz (CP-MAS).

Spectral Editing. Diffusion-edited proton and carbon spectra were produced using a bipolar pulse pair longitudinal encode−decode (BPLED) sequence[27] with inverse gated decoupling. Scans were collected using encoding/decoding gradients of 1.8 ms at 50 gauss/cm and a diffusion time of 180 ms. Inverse diffusion edited (IDE) and recovering relaxation losses arising from diffusion editing (RADE) were created via difference from the appropriate controls as previously described.[18] Using CPMG (T_2 filtered) experiments to obtain the liquid phase components, the T_2 delay was rotor synchronized and set at 600 μs and the pulse train was repeated 100 times, yielding a total pulse train length of 120 ms.[18] To remove solid components, two CPMG echoes of 7.5 μs were inserted prior to cross-polarization. During this short period, signals from extremely broad ^{1}H signals (i.e., true crystalline solids) relax (or are not efficiently refocused), whereas signals from more mobile solids remain along the XY plane for subsequent cross-polarization. The approach has been discussed in detail by Courtier-Murias et al.[18] For spectral editing, the spectra were scaled until the dominant component being subtracted was nulled, leaving a difference spectrum containing positive peaks.[18]

2D NMR Spectroscopy. ^{1}H total correlation spectroscopy (TOCSY) spectra were acquired in the phase-sensitive mode, using a mixing sequence with rotor synchronized constant adiabatic WURST-2 pulses within an X_M16 mixing scheme.[28] Scans (128) were collected for each of the 196 increments in the F1 dimension. Data points (2048) were collected in F2 at a mixing time of 120 ms. Both dimensions were processed using sine-squared functions with a $\pi/2$ phase shift and a zero-filling factor of 2. Nuclear Overhauser effect spectroscopy (NOESY) spectra were acquired in phase-sensitive mode, using time proportional phase incrementation. Scans (128) and data points (2048) were collected for each of the 196 increments in the F1 dimension at a mixing time of 300 ms. Both dimensions were processed using sine-squared functions with a $\pi/2$ phase shift and a zero-filling factor of 2. The correlation spectroscopy (COSY) spectra were acquired in non-phase-sensitive mode, using gradients for selection. Scans (128) and data points (2048) were collected for each of the 196 increments in F1. Both dimensions were processed using unshifted sine-squared function, a zero-filling factor of 2, and a magnitude mode for projection.

^{1}H−^{13}C heteronuclear single-quantum coherence (HSQC) spectra were collected in phase-sensitive mode using echo/antiecho-TPPI gradient selection. Scans (128) were collected for each of the 196 increments in the F1 dimension. Data points (2048) were collected in F2 and a 1J ^{1}H−^{13}C of 145 Hz. Both dimensions were processed using sine-squared functions with a $\pi/2$ phase shift and a zero-filling factor of 2. Dipolar assisted rotational resonance (DARR) spectroscopy was acquired using 256 scans for each of 96 increments in F1 and a mixing time of 200 ms. F2 was processed using an exponential function corresponding to 35 Hz line broadening and F1 using a sine-squared function with a $\pi/2$ phase shift. Both dimensions were zero-filled by a factor of 2.

NMR Spectroscopy of Nonlabeled Samples. For nonlabeled samples, only basic 1D ^{13}C spectra and CP-MAS were acquired. Experiments such as diffusion-edited carbon and DARR are very insensitive and time prohibitive on a nonlabeled sample.

Compound Identification. Spectra were calibrated against a range of known compounds in the Bruker Biofluid Reference Compound Database (v 2.0.3). Pattern matching of both 1D and 2D spectra was performed using analysis of mixtures (AMIX, version 3.9.3, Bruker BioSpin) against the Bruker Biofluid Reference Compound Database (v 2.0.0−2.0.3) using a procedure previously developed for complex mixtures.[29] Compounds with a >80% confidence match (from automated searches) were further selected for detailed manual inspection. Only compounds that showed near perfect matches in all spectral regions were retained as assignments. The chemical shifts of the identified compounds were compared with database values (r^2 = 0.99, σ = 0.01). For quantification, spectra were also normalized to total intensity over the 200−0 ppm region in the carbon spectra. The multi-integration tool in AMIX (version 3.9.3, Bruker BioSpin) was used to compare the relative quantity of carbonyl

protein (defined as 190−170 ppm), carbohydrates (defined as 110−50 ppm), lipids/fatty acids (defined as 183−164, 135−121, and 44−3 ppm), and aliphatic proteins (defined as 60−40 ppm).

RESULTS AND DISCUSSION

Comprehensive Multiphase NMR Spectroscopy. In this study a number of spectral editing approaches have been used. These have been discussed in detail by Courtier-Murias et al.[18] Briefly, starting from the most liquid-like through the most solid-like, these experiments can be described as follows. (1) IDE is a difference-based approach that selects molecules that have unrestricted tumbling (i.e., truly dissolved molecules). Here, these components will be referred to as "components with unrestricted diffusion". (2) DE selects molecules with restricted diffusion and will include swollen biopolymers, mobile gels, and smaller molecules that are trapped or sorbed. In this study these components will be referred to as "components with restricted diffusion". There is no clear-cut diffusivity that separates all dissolved molecules from all those with restricted diffusion. Instead, the experiments should be considered as a continuum with the "fast diffusing molecules contained in IDE" and generally "the restricted molecules" being in DE. The strength of the diffusion editing has been developed on standard samples to give the best distinction between truly dissolved molecules from entrapped molecules and gels.[18] (3) RADE is an experiment that compensates for signals that otherwise may be lost through relaxation during diffusion editing. RADE selects semisolid components that may include gels and possibly some very dynamic solids. In this study these components will be referred to as "semisolids". (4) T_2 filtered CP-MAS selects the more mobile "true solids" that may include very rigid gels and solids that exhibit some dynamics. In this study these components will be referred to as "dynamic solids". It is important to note that although no components are missed, some components may be observed twice by ^{1}H RADE and ^{13}C T_2 CP-MAS.[18] (5) Finally, inverse T_2 filtered CP-MAS is a difference approach that selects just the truly rigid solids that show little to no dynamics. In this study these components will be referred to as "rigid solids".

Detailed Analysis of Wheat Seed. *Components with Unrestricted Diffusion (Soluble Components).* A conventional 1D carbon profile of the single ^{13}C-labeled (97 atom %) wheat seed was acquired with low-power *waltz-16* decoupling (Figure 1a). In this experiment carbons from true solid components are strongly attenuated as the lower power decoupling is insufficient to decouple broad proton resonances that are characteristic in solids. As such, the spectrum contained signals from components with and without restricted diffusion and semisolids, but signals from true solids are largely suppressed (Figure 1a). Due to the complex nature of the seeds, the conventional ^{13}C spectrum showed considerable overlap, which was reduced by spectral editing to obtain the IDE spectrum (Figure 1b). IDE shows only molecules that demonstrate unrestricted diffusion in solution. It requires the subtraction of the diffusion-edited spectrum (contains molecules with restricted diffusion) from a reference spectrum (without diffusion weighting, i.e., defocusing/refocusing gradients set to zero power) but otherwise acquired under identical conditions. The IDE spectrum (Figure 1b) emphasized a range of small molecules, but identification from the IDE spectrum alone is challenging. Two-dimensional HSQC correlations provided additional spectral dispersion as well as one-bond ^{1}H−^{13}C connectivity information. Database matching against the AMIX Bruker Bioreference spectral database of the HSQC data along with ^{1}H−^{1}H COSY, ^{1}H−^{1}H TOCSY, and ^{1}H−^{1}H NOESY (see Supporting Information Figure S1 for example COSY and TOCSY data) confirmed a wide range of metabolites present (Figure 1c; see Supporting Information Figure S2 for an expansion of Figure 1c and brief description of each metabolite identified).

After identification from the 2D spectrum, metabolite assignments were transferred to the 1D carbon spectrum (Figure 1a). Major regions can be summarized as follows: carbonyls from proteins and lipids (approximately 190−170 ppm); guanidine group of arginine (159 ppm); conjugated double bonds (135−130 ppm) from triacylglycerides (TAG, see next section); ethylene (sharp signal at 128.1 ppm); anomeric carbons of carbohydrates (90−110 ppm); various overlapping carbohydrate and amino acid signals (90−50 ppm); methanol (56.40 ppm) and amino acids and various metabolites (42−46 ppm including 4-aminobutyric acid, arginine, cadaverine, lysine, ornithine, putrescine) and aliphatics (50−5 ppm, mainly TAG, see next section).

As discussed above, the IDE spectrum (Figure 1b) highlighted the molecules that are most liquid-like or dynamic within the seed. To our knowledge, this is the first report of

dx.doi.org/10.1021/jf4045638 | J. Agric. Food Chem. 2014, 62, 107−115

ethylene, a gas within the seed,[30] detected by NMR spectroscopy. Strong signals from methanol and a range of small sugars dominated, indicating that these are present in a dissolved or dynamic state. Conversely, the aliphatic signals hardly contribute at all to the IDE spectrum and suggest many of these are in a more restricted environment. This will be discussed in the next section.

Components with Restricted Diffusion and Semisolid Components via Diffusion-Based Editing. Diffusion editing encodes the spatial position of a signal at the start of the experiment and decodes it at the end. If the molecule physically changes position during the experiment, it is not refocused and is attenuated. The result is a spectrum that contains signals from molecules that show very slow/no diffusion, such as macromolecules, swollen polymers, and small molecules trapped in an environment that prevents free diffusion.

Figure 2a shows the ^{13}C DE spectrum of the wheat seed. Small signals from carbohydrate were present, indicating that some carbohydrates were present in a restricted diffusion-like state. These could be swollen carbohydrate polymers (for example, starch) or smaller entities sorbed to other larger components. The dominant signals in the DE spectrum arose from triacylglycerides (TAG). The HSQC of the single ^{13}C-labeled wheat seed (Figure 2c) matches extremely well with the ACD/Laboratories HSQC simulation of the generic TAG structure overlaid (Figure 2d). Whereas generic TAG structures clearly dominate the lipid profile, individual TAG molecules could not be distinguished. Detailed assignments are present in Table 1 and are consistent with COSY, TOCSY, NOESY, and

the previous work by Sacco and co-workers.[31] Complete TAG oxidation yields twice the amount of energy that could be generated from protein or carbohydrates.[32] Thus, TAGs are considered highly compact energy reserves and are therefore an efficient way to maximize energy storage within the confines of a seed.[32] Most triglycerides exist as a "solid fat" somewhat analogous to butter; as such, it is logical that TAG within the seeds display restricted diffusion-like properties rather than true liquid or solid properties.

Diffusion editing is a useful experiment to emphasize components with restricted movement. However, the experiment uses a relatively long diffusion delay, which could potentially lead to the loss of signal from very large or semisolid components that exhibit fast relaxation. This rapidly relaxing signal can be fully recovered using an experiment termed RADE, the technicalities of which are discussed by Courtier-Murias and co-workers.[18] In simple terms, RADE accounts for signals from semisolids that otherwise could be missed by diffusion-based spectral editing alone. Figure 2b shows the RADE spectrum for the ^{13}C-labeled wheat seed. The spectrum contains signals from the components that relax extremely quickly and have a semisolid character. As with the spectrum of components with restricted diffusion, there is a strong signature from TAG suggesting that some of the TAG have a semisolid-like character as expected. Other lipid signals may arise from membrane structures within the seed. In addition to the aliphatic species, the RADE spectrum also contains significant carbohydrate signal, indicating strong contribution from carbohydrate polymers. These could arise from the starchy endosperm of wheat seeds[33] as well as cell walls and possibly more flexible components of the seed coat itself. These carbohydrate signals are strongly emphasized by CP-MAS (Figure 3a), which emphasizes the true solid in the seed coat.[34]

Solid Components. The above experiments focused on the unrestricted diffusion (soluble), restricted diffusion, and semisolid components of ^{13}C-labeled seeds. As CMP-NMR probes can handle the high-power RF requirements required for modern solid-state experiments, the solid components of the seeds can also be studied. CP-MAS is an excellent filter for the ^{13}C detection of true solid components.[18] During CP, magnetization is passed from proton on carbon via a strong dipole network. As such, CP is not efficient for dynamic systems (for example, solutions, mobile gels). However, in the true solids static H−C dipoles provide a useful framework for CP and the process is highly efficient. The result is that CP provides a strong bias toward the components in the sample with the most solid-like character. The solid-state NMR spectral profile is shown in Figure 3a and is dominated by starch, cellulose, and hemicellulose signals. Assignments for all peaks have previously been reported[14,35] and are labeled in Figure 3a. Absolute quantification is challenging because of overlap of signals, and additional in-depth research is required to understand how the editing procedure affects quantification. It is unclear how the different editing steps influence absolute quantification; however, it is possible to do relative quantification between the species (see next section) to estimate crude changes or differences. T_2 relaxation editing can be used to further edit the solid components with dynamics from the true solid domains. The proton T_2 filter is utilized prior to CP so that protons in the most solid environment with short T_2 will preferentially relax. This leaves only the resonances from the unrestricted diffusion or semimobile materials (Figure 3c). The most rigid signals with short T_2 can be recovered with spectral subtraction of the T_2-filtered CP-MAS spectrum (dynamic solids) from the regular CP-MAS spectrum (everything), leaving a spectrum containing the most rigid resonances (Figure 3b). For example, the peak for amorphous CH_2 does appear in T_2-filtered CP-MAS (labeled "9" in Figure 3c), demonstrating these chains exhibit motion and likely exist as restricted diffusion/semisolid state. Conversely, the signal labeled "5" (Figure 3b) arose from crystalline cellulose. Specifically, this signal represents the C4 position in crystalline cellulose and is the only signal that can be clearly resolved due to overlap. Crystalline cellulose behaves like a true solid; as such it is strongly emphasized along with the most rigid components (Figure 3b).

Other carbohydrate signals, mainly starch, are prominent in all spectra and come from the starchy endosperm of wheat seeds[33] and from the seed coat.[34] Next to TAG, starch and

dx.doi.org/10.1021/jf4045638 | J. Agric. Food Chem. 2014, 62, 107−115

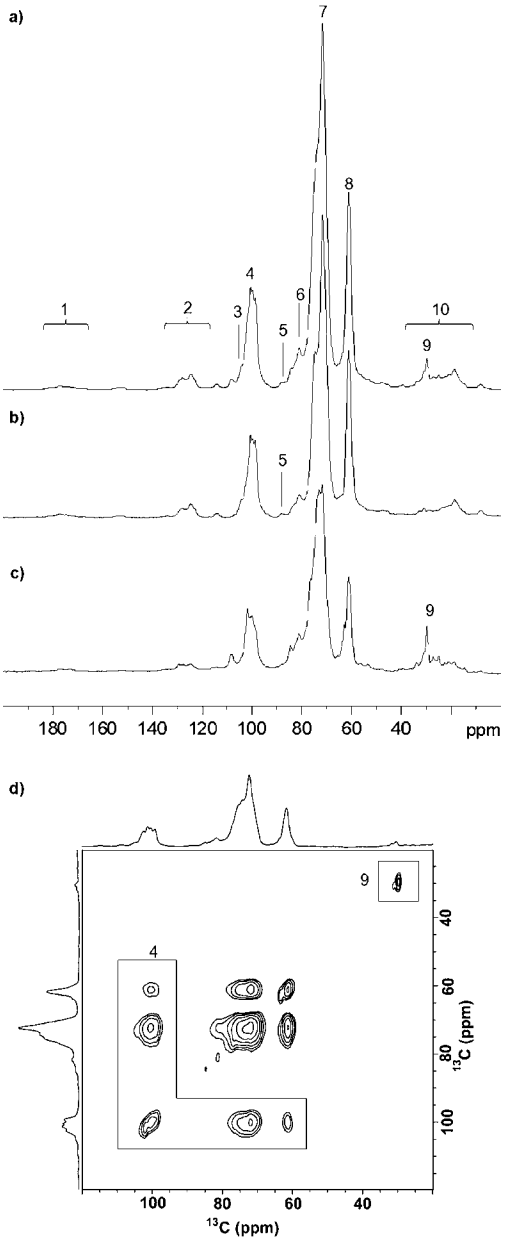

Figure 3. ^{13}C NMR spectra of a single ^{13}C-labeled wheat seed. (a) True solids (by cross-polarization magic angle spinning, CP-MAS). Peaks: 1, carbonyls in lignins, hemicelluloses, and proteins; 2, double bonds (lignins); 3, C1 of cellulose and hemicelluloses; 4, C1 of starch (anomeric carbon); 5, C4 of crystalline cellulose; 6, C4 of amorphous cellulose, hemicelluloses, and/or starch; 7, C2, C3, C5 in celluloses, hemicelluloses, and starch and C6 starch branch points; 8, C6 in celluloses, hemicelluloses, and starch; 9, amorphous CH_2; 10, aliphatic. (b) Spectral editing to emphasize rigid solids. (c) T_2-filtered CP-MAS to emphasize dynamic solids. (d) Dipolar assisted rotational resonance (DARR) to highlight connectivities between carbons for the truly solid components.

storage protein are the main storage reserves of cereal seeds. Higher plants produce starches, which are a critical nutritional source for humans.[36] DARR is able to identify ^{13}C−^{13}C correlations through space (Figure 3d) and is a very useful experiment to confirm and help assign structure. DARR confirms that the signals at 62−73, 62−100, and 73−100 ppm are correlated in the same structure, consistent with that of carbohydrates in general. DARR also confirms that the TAG at 30 ppm and carbonyl at 130 ppm (not shown) each are not correlated to carbohydrate signals.

Comparing Wheat, Broccoli, and Corn Seeds. For unrestricted diffusion (soluble) components (IDE), corn has the most signals in the free carbohydrate area (about 10% more than wheat and 55% more than broccoli, based on integration), with the majority of signals arising from glucose and fructose, which is consistent with the literature (Figure 4c).[37,38] It is important to note that in the case of corn, the seed was cut in half, and it is possible that some of this additional signal intensity from soluble molecules could arise from D_2O leaching components from the exposed interior of the seed. The IDE (unrestricted diffusion (soluble) components, Figure 4b) and DE (restricted diffusion components, Figure 4e) for broccoli looked quite similar, and both were dominated by lipids in large part because of the lower carbohydrate levels compared to the other two species. Broccoli had the highest lipid content (about 10% more than wheat and corn based on integration), and these findings are consistent with trends found in the literature.[39,40] The actual location of these small molecules within the seeds is unclear; previous MRI-based studies have indicated that water has some mobility within the endosperm,[41,42] and it is possible that some of these relatively free molecules are associated with this water. The RADE spectrum (semisolids) of corn and wheat (Figure 4i) emphasized a considerable contribution of carbohydrates.[40] Conversely, broccoli shows very few carbohydrates in the semisolid phase. Note that in wheat, broccoli, and corn the CH_3 signal of lipids (marked with an askterisk (∗) in Figure 4a−f) appeared in the IDE and DE but disappeared in the RADE spectrum. This likely resulted from the local motion of the CH_3 terminal groups that leads to longer relaxation times compared with other parts of the lipid/TAG molecules.

The CP-MAS of broccoli (Figure 4k) was very different from that of wheat (Figure 4j) mainly because it had stronger signals from proteins (about 2.5 times more intense based on integration) and from long chain fatty acyl groups than the wheat spectrum. This is consistent with the literature that lists protein in broccoli seeds to be ∼21 g/100 g[39] and in wheat to be ∼10 g/100 g.[40] The 60−0 ppm region mainly arises from aliphatic amino acids with the strong signals from long-chain aliphatics $(CH_2)_n$ superimposed at ∼30 ppm. α-Carbons from protein resonate in a band from ∼60 to 40 ppm centered at ∼50−55 ppm, and aromatic amino acids add to the aromatic region and are most prominent from 110 to 120 ppm. The carbonyl signals at 190−160 ppm arise from proteins, lignins, lipids, and hemicelluloses. The carbonyls are likely much more intense in the broccoli compared to the wheat (roughly 5.5 times more based on integration) in large part due to the additional protein and oil content.[39,40] The presence of a relatively strong $(CH_2)_n$ superimposed at ∼30 ppm in the broccoli is interesting. This suggests that in the broccoli, at least some of the aliphatic components are more solid-like than in the other seeds. As the characteristic double bonds from TAG are also present (∼125 ppm), it is most likely that the truly solid aliphatic component is a portion of TAG stored in the more solid form when compared to the other seeds. However, it is also possible that some of this additional CH_2 intensity also arises from lipoprotein, free fatty acids, or lipids other than TAG, which are known to be present in seeds.[15,43,44]

Other Considerations. CMP-NMR provides a unique insight into both chemical and physical attributes of molecular structure inside unaltered natural samples. Seeds here were

dx.doi.org/10.1021/jf4045638 | J. Agric. Food Chem. 2014, 62, 107−115

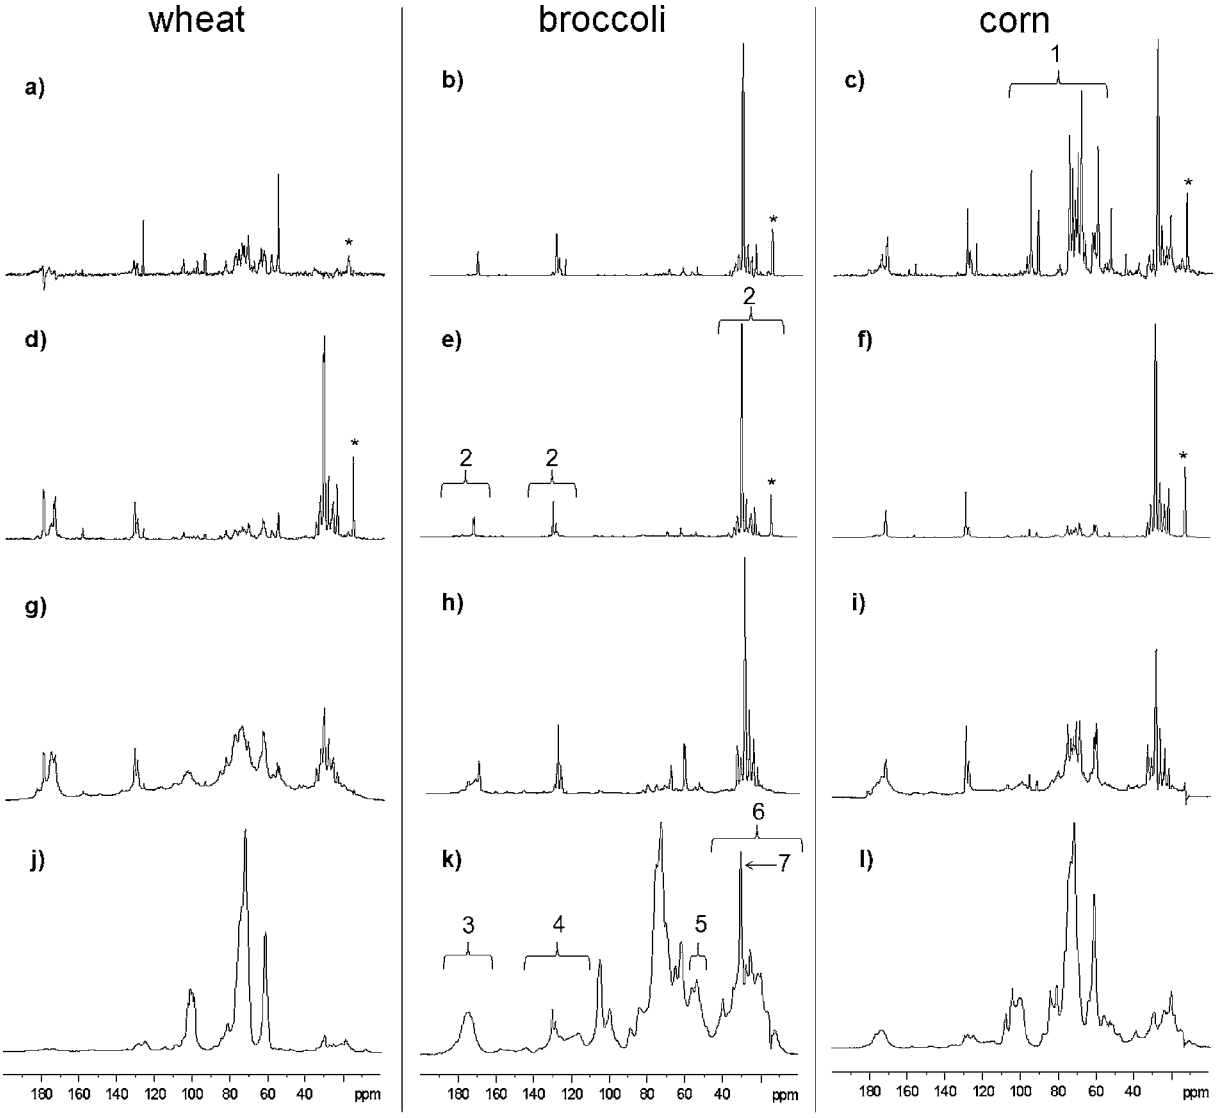

Figure 4. ^{13}C NMR spectra comparing ^{13}C labeled wheat, broccoli, and corn seeds: (a−c) unrestricted diffusion (soluble) components (by inverse diffusion edited, IDE); (d−f) restricted diffusion (by diffusion edited, DE); (g−i) semisolids (by recovering relaxation losses arising from diffusion editing, RADE); (j−l) true solids (by cross-polarization magic angle spinning, CP-MAS). The $-CH_3$ of TAG is marked with an *; 1, dominated by fructose in corn; 2, triacylglycerides; 3, carbonyls (result of increased protein content); 4, aromatic (result of increased protein content); 5, α carbon of amino acids; 6, dominated by aliphatic amino acids; 7, aliphatic $-(CH_2)-$ (dominated by TAG).

used to exemplify the approach to natural samples in general. Isotopic labeling is beneficial but not essential for CMP-NMR. Generally, labeling is necessary when less sensitive multidimensional spectra (for example, DARR in this study) are being obtained to abbreviate spectrometer time with enhanced signal-to-noise ratio. Natural abundance of ^{13}C can be used to acquire NMR spectra but will increase sampling time considerably. The ^{13}C-labeled CP of wheat was performed over a period of 1 h and 43 min for 2K scans (signal-to-noise = 690), whereas the unlabeled equivalent containing ^{13}C at the natural abundance took 16 h and 23 min for 20K scans (signal-to-noise = 69). Comparison of the ^{13}C-labeled spectra to natural abundance spectra are provided in the Supporting Information (Figures S3−S5). In the future, the use of 7 mm rotor diameters will allow ∼4−5 times the sample volume to be introduced, which should substantially increase signal from unlabeled samples and should make similar studies on unlabeled material more feasible. The main drawback of CMP-NMR probes in comparison to a dedicated HR-MAS or solid probe is loss of sensitivity. As discussed by Courtier Murias et al.,[18] the four-channel prototype probe used here suffers from a loss of ∼40% when compared to a two-channel solid probe. This loss mainly arises due to single circuit being quadrupley tuned in the four-channel design. If identical probes could be compared (note, no two-channel CMP-NMR probes have been built to date), it is predicted that the loss in sensitivity would be ∼10−15% (mainly associated with the addition of the gradient coil). Due to the sensitivity losses CMP-NMR probes should be restricted to studies of native sample where the study of the components in their native phase is critical. In such cases the potential for CMP-NMR to provide otherwise inaccessible molecular-level information in situ is considerable. In studies following developmental changes it may be important to study the development of the solid, gel, and liquid components over time. Here it may be important to interleave solid, gel, and liquid NMR experiments and measure not just the phases independently but kinetic transfer between the phases. Such

dx.doi.org/10.1021/jf4045638 | J. Agric. Food Chem. 2014, 62, 107−115

studies would be impossible using two or three separate NMR probes as it takes several hours to change and properly calibrate an NMR probe. Similarly, studies that follow the conversion of a molecule from liquid, to gel, to solid phases (for example, feeding phenylalanine to follow lignin growth or the binding and sequestration of a contaminant) also require the kinetic transfer between phases to be monitored and may find CMP-NMR probes useful in the future. These examples indicate a future potential of CMP-NMR in seed/plant/food research. Finally, as the CMP-NMR probes combine all aspects of solution, HR-MAS, and solids, they provide the potential to develop novel NMR experiments (for example, solids using gradients) to better select and study structure and interaction in situ.

Finally, it is important to note that quantification in complex systems such as seeds is complicated by spectral overlap. Spectral editing can extract molecules in the liquid, gel, semisolid, or solid state, and theoretically if the carbons were detected in exactly the same manner it would be possible to quantify the distribution between the different phases. However, in this study, this has been complicated by the fact CP-MAS was used for solid components, which enhances certain signals more than others, making this comparison inaccurate. Commonly, for quantification in solids, direct polarization magic angle spinning (DP-MAS)[45] would be used. With regard to CMP-NMR, the cross-polarization element was required to select the rigid bonds (i.e., spectral editing to select the solid components), further complicating the issue. It may possible to quantify in the future, but this would require advanced techniques such as spin counting.[46]

Although the focus of this study has been to demonstrate the general applicability of CMP-NMR to the chemical structures of seeds, nonlabeled broccoli seeds were collected after spinning to test if they would germinate. They successfully germinated after being transferred to a Petri dish with a filter paper moist with water. This indicates that the seeds were still alive during spinning, and the potential for monitoring them while germinating the seed exists. CMP-NMR holds potential to provide an unprecedented window into the germination process itself. This avenue opens potential for research in fields such as physiology (germination, vernalization processes), agriculture (seed viability), and food safety (pathogen test, purity). Specifically, applications are possible in selecting viable seeds (current methods are mutagenic, destructive, or time-consuming) or for seed selection breeding programs, which all require detailed yet nondestructive molecular analysis.[47]

ABSTRACT: This study investigated the effect of a 28 day administration of coffee brew on the activity of antioxidant enzymes in rats. After this period of 2.0 mL/day dosages of this beverage, the activities of hepatic superoxide dismutase, catalase, and glutathione peroxidase increased 74.8, 59.4, and 135.2%, respectively, whereas the cytosolic level of Nrf2 increased 131.3%. At the same time, the total antioxidant capacity of the hepatic tissue increased 25.1%, improving the defensive status against oxidative stress. At the end of the experiment, the levels of biomarkers alanine transaminase and aspartate transaminase remained equal to the control group, and no changes were observed in the hepatic histoarchiteture of the animals, suggesting that the liver tissue was not impaired by the exposure to coffee. The changes in enzyme activities and antioxidant capacity were statistically significant ($p < 0.05$), indicating that coffee could be considered an important alternative against oxidative stress and its correlated degenerative diseases.

KEYWORDS: *coffee, hepatic antioxidant enzymes, Nrf2, ORAC, rats*

INTRODUCTION

Chemoprevention has been accepted as one of the most successful strategy to fight cancers. In the past decades, studies have been developed to investigate natural and synthesized substances capable of restraining carcinogenic processes.[1] Some coffee bioactive substances such as phenolic compounds (including chlorogenic acids and phenolic acids released by the hydrolysis of chlorogenic acids), caffeine and other xanthines, Maillard reaction products, and the diterpenes cafestol and kahweol have been evaluated, and most results have suggested that the ingestion of these substances is inversely related to the incidence of liver and colon cancers.[2−7] The degree of roasting also affects coffee antioxidant capacity as it promotes the formation of Maillard reaction products and the partial conversion of trigonelline to *N*-methylpyridinium, both with defensive capacities.[5,7]

In general, a tumor is initiated by a permanent modification of DNA by the action of electrophilic or oxidant species. Once procarcinogens are introduced in organisms, they usually require an enzymatic activation to be converted into highly reactive intermediates that can attack important molecules such as DNA, RNA, and proteins. These enzymatic processes are frequently promoted by phase I enzymes. In opposition, phase II enzymes have the ability to neutralize dangerous species, generating less reactive and more soluble substances that can be eliminated from the organisms.[1,3,6,8,9] Antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx) also play important defensive roles, reducing the levels of dangerous species such as O_2^- (superoxide anion radical), H_2O_2 (hydrogen peroxide), and O_2^{2-} (peroxide anion). This fact decreases the downstream formation of other reactive oxygen species (ROS), neutralizing or reducing their deleterious actions.[2,10] Therefore, considerable efforts have been made to identify substances that can modulate the transcription and increase the activity of these protective enzymes.

Different studies have produced strong evidence that the key point for the transcription of phase II and antioxidant enzymes is the protein nuclear factor-E2-related (Nrf2) factor. Under normal (reducing) condition, Nrf2 remains anchored to its inhibitor cytoplasmic complex Keap1−Nrf2 (Kelch-like ECH-associated protein-1) for its polyubiquitination and subsequent 26S proteasome-mediated degradation. However, under oxidative stress or exposure to inducers, Nrf2 is disrupted from this complex, allowing its translocation to the nucleus of the cells, where it binds to the antioxidant response element (ARE) or electrophile response element (EpRE) present in the promoter region of the mentioned enzymes, increasing their transcription.[3,6,8,9] Keap1 presents a dimeric structure formed through its BTB/POZ (broad-complex, tramtrak, bric-à-brac/pox virus-zinc finger) domains, sequestering one molecule of Nrf2 when thiol groups of the cysteine residues C273 and C288 are reduced (−SH). Oxidative stress and inducers act on these two cysteine residues to form intermolecular disulfides (−S−S−) that cause a conformational change of Keap1, releasing Nrf2 to migrate to the nucleus.[5,9] A post-translational phosphorylation also facilitates Nrf2 to dissociate from Keap1-Nrf2, and this change would be promoted by kinases such as protein kinase C (PKC), phosphatidyl inositol 3-kinase (PI3K), and mitogen-activated protein kinase (MAPK). Advances have accumulated in recent years, but some details still need to be elucidated on the pathway that activates this mechanism.[8,9]

Two studies published experimental evidence that the administration of phenolic acids (gentisic, gallic, ferulic, and *p*-coumaric acids) to rats increased the hepatic and cardiac activities of SOD, CAT, and GPx.[11,12] Simultaneously, these tissues showed higher levels of cytosolic Nrf2 and higher expressions of the mRNA for these enzymes. In both cases, a dose equal to 100 mg/kg of body weight (mg/kg BW) per day of each phenolic acid dissolved in propylene glycol/saline was administered to the animals over 14 days.

Aiming to evaluate the above-mentioned beneficial effect using a natural beverage, we decided to use coffee brew as it contains high levels of phenolic acids found as a family of chlorogenic acids.[13−15] Additionally, high levels of caffeine are also found in coffee brew (from 0.9 to 1.3% w/w dry basis in *Coffea arabica*; from 1.2 to 2.4% w/w dry basis in *Coffea robusta*),[16] and this xanthine has been reported as another bioactive substance capable of modulating antioxidant enzymes.[2,3,6] Another important fact for choosing coffee is that it is one of the most popular nonalcoholic beverages in the world,[2,5,6,17] and the eventual results of this study would have wide application.

In a previous publication,[18] we discussed the effect of a single and small dose of coffee brew (from 0.5 to 2.0 mL) on the activity of hepatic SOD, CAT, and GPx in rats, obtaining increases of 19.1, 22.1, and 25.1%, respectively, in relation to the control group. It was shown that doses containing from 2.0 to 8.0 mg/kg BW phenolic acids promoted measurable beneficial effects. As cited in the present study, besides phenolic acids, other bioactive compounds present in coffee certainly collaborated to achieve this positive answer.[2−6]

Motivated by these encouraging results, we decided to evaluate the effect of a repetitive administration of small doses of coffee brew to rats, (1) measuring the effect of this exposure in the activity of hepatic enzymes SOD, CAT, and GPx and in the cytosolic concentration of Nrf2; (2) evaluating the changes in the antioxidative status of the liver tissue; and (3) identifying any damage to the liver through the quantification of the hepatic biomarkers alanine transaminase (ALT) and aspartate transaminase (AST) together with histological observations.

MATERIALS AND METHODS

Chemicals. Caffeic, ferulic, and *p*-coumaric acids, 5-caffeoylquinic acid (5-CQA), 5-feruloylquinic acid (5-FQA), 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH), 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), tris(hydroxymethyl)-aminomethane hydrochloride (Tris-HCl) buffer, and fluorescein were acquired from Sigma-Aldrich (USA). The commercial kits Ransod and Ransel for SOD and GPx determinations were acquired from Randox Laboratories (UK). Hydrogen peroxide (30%), formic acid, and methanol were acquired from Merck KgaA (Germany). The kits for the determination of AST and ALT were acquired from LabTest Ltd.a. (Brazil). The Western blotting reagents were acquired from Amersham Biosciences (USA).

Coffee Description and Preparation. Medium roast (degree 3) Brazilian coffee (*C. arabica* var. Bourbon blended with 15−30% of *Coffea canephora* var. Robusta) produced in Minas Gerais state (Brazil), packed under vacuum in 500 g aluminized bags with an external cardboard box, was acquired from local stores. Packs were kept under vacuum, at 4 °C (refrigerator) and in the dark to preserve coffee characteristics during the tests. All tests were done using fresh coffee brews prepared with 80 g of coffee powder per liter of mineral water at 90 °C and filtered through paper filter as recommended by the Brazilian Association of Coffee Industry (ABIC).[17]

Animal Characteristics and Treatment. Male rats (*Ratus novergicus* var. Wistar) with 200 ± 10 g of BW were provided by the Animal Facility of the Medical School, University of São Paulo (FM-USP). A total of 12 animals were housed in individual plastic cages for 4 days (adaptation period), with free access to food (purified diet AIN-76) and water. The temperature was kept at 22 ± 2 °C, and the animals were exposed to 12 h light/dark cycles. On day 5, they were randomly distributed in two groups ($n = 6$) and given 2.0 mL of water (group 1) or 2.0 mL of coffee brew (group 2) per day by gavage. After 28 days, the animals were deprived of food for 12 h, anesthetized, and sacrificed by exsanguination (cardiac puncture). The liver tissue was washed with sterile ice-cold 0.9% NaCl solution and immediately frozen in liquid nitrogen. The procedures involving the animals were conducted at the Institute of Tropical Medicine (IMT-USP) in compliance with Brazilian laws and approved by the Committee of Ethics in Research of the IMT-USP under number CEP-IMT-10/07.

Liver Homogenate Preparation. The liver homogenates were prepared as described by Vicente et al.[18] Basically, 1.0 g of washed liver tissues was homogenized with 3 mL of phosphate buffer (0.1 M, pH 7.0) and centrifuged at 1000*g* (20 min at 4 °C); the supernatant was collected and centrifuged at 11200*g* (20 min at 4 °C), and then the supernatant was collected, diluted 1:10 (v/v) with phosphate buffer, and centrifuged at 76900*g* (60 min at 4 °C). The final supernatant was collected and stored at −80 °C in the dark until the end of the analytical determinations (within 48 h of sacrifice). The preparation of the homogenate was done within 2 h of sacrifice.

Instrumentation. The activities of antioxidant enzymes and the biomarkers AST and ALT were determined using a spectrophotometer model 1650 (Shimadzu, Japan). The antioxidant capacity was measured by oxygen radical absorbance capacity (ORAC) using a fluorimeter model FL-55 (Perkin-Elmer, UK). Both instruments were equipped with a 10 mm temperature-controlled cell. Free phenolic acids and caffeine were quantified by high-performance liquid chromatography (HPLC) using an equipment supplied by TSP (USA) and a C18 Microsorb MV column (Varian Inc., USA) with 250 × 4.6 mm (5 μm of particle size). The major chlorogenic acids were quantified by HPLC-DAD-MS using a chromatograph model 1200 SL (Agilent Technologies, USA) equipped with a diode array detector (DAD), a mass spectrophotometer detector (MS), and a Zorbax SB-C18 column (Agilent Technologies, USA) of 50 × 2.1 mm (1.8 μm particle size). The electrophoresis for the Western blotting analysis was developed using a Minive kit (Amersham Biosciences, USA), and the chemiluminescence was measured using an ECL-Plus ImageQuant CAS 4000 (GE Healthcare, USA).

Bioactive Compounds in Coffee Brew. Some of the bioactive substances (caffeic, ferulic, and *p*-coumaric acids) capable of modulating the transcription of antioxidant enzymes are present in coffee as a family of esters called chlorogenic acids formed through different combinations of these hydroxycinnamic acids with quinic acid. Taking into account that both chlorogenic acids and free phenolic acids have been reported as active substances, we decided to measure these two forms. The major chlorogenic acids present in coffee brew were quantified by HPLC-DAD-MS according to the method of Corrêa.[19] This analysis was done by injecting 20 μL of coffee brew, starting with an isocratic elution of 85% of phase A (deionized water with 0.1% of formic acid) and 15% of phase B (methanol) at 0.32 mL/min until 2 min. Between 2 and 6 min, a gradient from 15 to 30% of phase B was developed, ending with second gradient from 30 to 35% of phase B between 6 and 12 min. Operation conditions for MS were ionization voltage, 3000 V; N_2 flow, 12.0 L/min at 30 psig; and temperature, 350 °C. A previous standardization of this method was done (recovery, limit of detection, and limit of quantification),[19] the quantification was performed at 324 nm using external standard curves (five points, triplicate measurements), and the results were expressed in micrograms per milliliter. Because coffee brew does not present free phenolic acids, before the analysis of these substances a previous hydrolysis was done according to the method of Nardini et al.,[20] using 2 N NaOH containing 10 mM EDTA and 1% ascorbic acid to prevent phenolic acid decomposition. Next, these substances were quantified by HPLC as suggested by Kowalski and Wolski,[21] injecting 20 μL of hydrolyzed coffee brew. Water/methanol/acetic acid (75:24:1 v/v) was used as mobile phase at 0.8 mL/min, and the determinations were

done at 323 nm for caffeic and ferulic acids and at 309 nm for *p*-coumaric acid. A previous standardization of this method was done (recovery, limit of detection, and limit of quantification),[15] the quantification was performed using external standard curves (five points, triplicate measurements), and the results were expressed in micrograms per milliliter.

Caffeine is another substance capable of modulating the transcription of antioxidant enzymes, and it was quantified by HPLC as suggested by Vitorino et al.,[22] with small adaptations. Briefly, coffee brew was filtered (0.5 μm), and 20 μL was injected in the HPLC using water/methanol/acetic acid (80:19:1 v/v) as mobile phase at 1.0 mL/min. The wavelength 272 nm was selected for the detection of caffeine. A previous standardization of this method was done, the quantification was performed using external standard curves (five points, triplicate measurements), and the results were expressed in micrograms per milliliter.

Antioxidant Enzyme Activity and ORAC. The activity of SOD was measured by visible spectroscopy (505 nm) according to the method of Woolliams et al.,[23] with small modifications for the use of the kit Ransod.[15] The liver homogenate was diluted 1:20 v/v with phosphate buffer (75 mM, pH 7.4) for this assay. The activity of CAT was determined by ultraviolet spectroscopy (230 nm) using the method described by Aebi.[24] The liver homogenate was diluted 1:5 v/v with phosphate buffer to determine this enzyme. The activity of GPx was also determined by ultraviolet spectroscopy (340 nm) according to the method of Paglia and Valentine,[25] with small modifications for the use of the kit Ransel.[15] The liver homogenate was not diluted for this determination. These enzymatic activities were expressed in units per milligram of protein, micromoles per minute per milligram of protein, and units per milligram of protein, respectively. The quantifications of the proteins for the calculations of the antioxidant enzymes were done in accordance with Bradford[26] using bovine serum albumin (BSA) as standard.

The ORAC assay was developed by fluorescence spectroscopy (excitation, 493 nm; emission, 515 nm) according to the methods of Ou et al.[27] and Prior et al.[28] with small modifications.[15] The liver homogenate was diluted 1:40 v/v with phosphate buffer, and 300 μL of this dilution was used in each test. The results were expressed as micromoles of Trolox equivalent per liter (μmol TE/L).

Hepatic Biomarkers, Histopathological Analysis, and Western Blotting of Nrf2. The hepatic biomarkers AST and ALT were determined as described by Reitman and Frankel,[29] with small modifications for the use of the kits for these enzymes.[15] Both enzymes were determined by visible spectroscopy (505 nm) using a calibration curve (five points, triplicate measurements, from 0 to 200 IU/L).

For the histopathological analysis, a small section of the liver tissue was collected after the sacrifice, washed with sterile ice-cold 0.9% NaCl solution, fixed with 10% formaldehyde (48 h), embedded in liquid paraffin, and sliced (5 μm thick), the paraffin was removed by heat, and the tissue was stained with hematoxylin and eosin dyes (H&E) to be observed under the microscope.[30]

The determination of Nrf2 was done as described by Yeh and Yen[11] with small modifications, using the dye-binding assay proposed by Bradford[26] for the quantification of proteins (BSA as the standard). Briefly, 10 μL of the cytosolic fraction was separated by 10% SDS–polyacrylamide gel electrophoresis (20 V, 300 mA). After the electrophoresis, the proteins were electrotransferred from the gel to a PVDF membrane (25 V, 400 mA) using 25 mM Tris-HCl buffer with 20% of methanol; the membrane was washed with Tris-HCl buffer containing 0.05% (v/v) Tween-20, and free binding sites were blocked for 2 h with defatted dried milk (7% w/v). Next, the membrane was incubated overnight at 4 °C with rabbit polyclonal antibody against Nrf2, washed three times with Tris-HCl buffer, incubated with IgG secondary antibody coupled with horseradish peroxidase for 1 h at room temperature, and washed with Tris-HCl buffer; chemiluminescence was measured. The quantifications were adjusted for the corresponding β-actin level (loading control protein).

Statistical Calculations. Statistical calculations (Kolmogorov–Smirnov and Student's *t* test) were done using the SPSS 16.0 for Windows software package, with a significance level of $p < 0.05$. All tests were done in triplicate, and the results are presented as means ± standard deviations.

RESULTS AND DISCUSSION

Bioactive Compounds in Coffee Brew. As the main purpose of this study was to evaluate the effect of the administration of coffee brew on the activity of antioxidant enzymes, it was important to quantify the levels of the bioactive

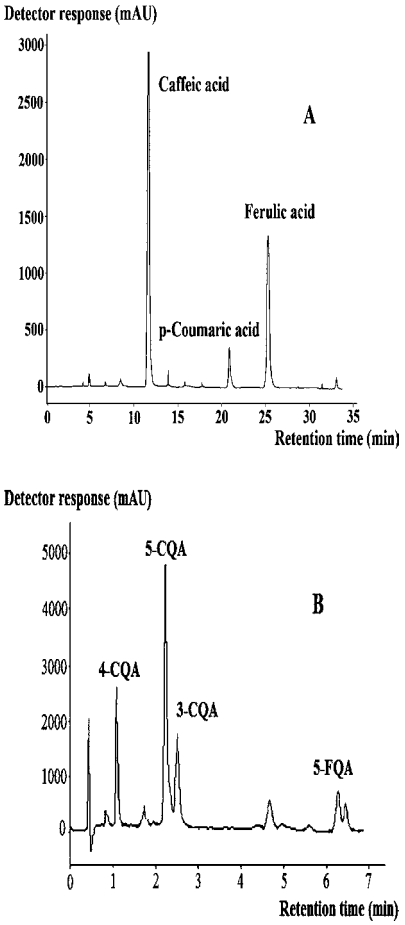

Figure 1. Typical chromatograms obtained during the quantification of free phenolic acids (A) and chlorogenic acids (B) in coffee brew.

substances in this beverage. After the hydrolysis of coffee brew followed by chromatographic tests, a total of 793.3 μg of free phenolic acids/mL of coffee was found (685.1 ± 30.8 μg/mL of caffeic acid, 97.9 ± 8.0 μg/mL of ferulic acid, 10.3 ± 1.3 μg/mL of p-coumaric acid), confirming that this beverage is a rich source of these substances originally present as different chlorogenic acids (Figure 1A). The total concentration of phenolic acids was shown to be 28.7−39.7% lower than the results issued in other publications,[13,14] and these differences could be related to the use of automatic brewing machines in the mentioned studies (longer contact between coffee powder and water). Another possible reason could be the origin of coffee samples. As shown by Farah and Donangelo,[31] the variety Bourbon widely cultivated in Brazil showed the second lowest result for chlorogenic acids among 19 coffees from different origins, probably due to the mild Brazilian climate given that phenolic acids are secondary metabolites produced as a defensive response against stressful environmental conditions.

There is a lot of controversial data regarding whether chlorogenic acids or free phenolic acids are actually absorbed. Some studies affirm that chlorogenic acids are absorbed in the intestine being found intact in plasma and urine.[32,33] However, most publications mention an extensive hydrolysis of chlorogenic acids promoted by esterases in the colon to yield quinic acid and free hydroxycinnamic acids that are rapidly transformed to different derivatives such as glucuronide and sulfate conjugates.[13,34−36] For this reason, the major chlorogenic acids present in coffee brew were quantified (Figure 1B), resulting in 1155.2 μg/mL (1002.3 ± 87.0 μg/mL of 3-, 4-, and 5-CQA, 152.9 ± 10.3 μg/mL of 5-feruloylquinic acid). The results obtained in the present study were similar to the ones issued by Boettler et al.[5] (1040 μg/mL of 5-CQA) and Corrêa[19] (864.0 μg/mL of 3-, 4-, and 5-CQA isomers, 128.1 μg/mL of FQA isomers), all converted to 80 g/L of Brazilian *Arabica* coffee powder. In view of these results, a single dose of 2 mL/day of coffee brew given to rats with 200 g of BW represented approximately 8 mg of phenolic acids/kg of BW per day (or approximately 12 mg of chlorogenic acids/kg of BW per day), which fits the purpose of this study to administer small doses of the active substances.

Caffeine is another bioactive compound present in coffee. The level of this substance was also determined in coffee brew, and an average concentration equal to 728.1 ± 20.5 μg/mL was found. This value was 39.7% lower than the result issued by Natella et al.,[37] and the possible reasons were already discussed (the use of automatic brewing machine and the nature of coffee). This result indicated that 2 mL/day of coffee brew to rats represented approximately 7 mg of caffeine/kg of BW per day, which fits the intention to administer small doses of the bioactive substances.

Antioxidant Enzymes, Nrf2, and Antioxidant Capacity. The activities of antioxidant enzymes in group 1 (control) showed average results equal to 16.3 ± 1.9 U/mg of protein for SOD, 10.1 ± 1.0 μmol/min/mg of protein for CAT, and 16.2 ± 2.4 U/mg of protein for GPx, well-suited to the figures obtained in other studies with similar animal models.[1,11,12,38,39] At the same time, group 2 (coffee) average results were 28.5 U/mg of protein for SOD, 16.1 μmol/min/mg of protein for CAT, and 38.1 U/mg of protein for GPx, showing increases of 74.8, 59.4, and 135.2%, respectively, in relation to the control group (Figure 2). The results of groups 1 and 2 were compared (independent samples), and the differences were statistically significant according to the Student t test ($p < 0.001$ for all enzymes). This finding showed that even a small quantity of a natural beverage containing phenolic acids (released by the hydrolysis of chlorogenic acids in the organism), caffeine, and other unquantified bioactive substances was capable of producing notable changes in the activity of hepatic SOD, CAT, and GPx. As filtered coffee was used, the

dx.doi.org/10.1021/jf401777m | J. Agric. Food Chem. 2014, 62, 116−122

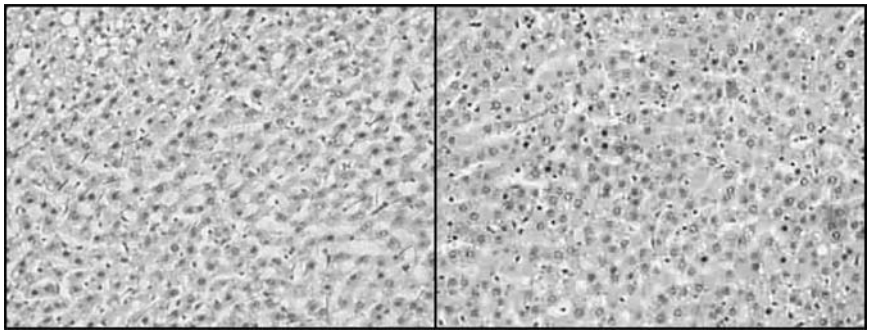

Figure 6. Liver tissues (group 1, left; group 2, right) showing normal architectures and no apparent damage.

contribution of the diterpenes cafestol and kahweol was negligible as they were absorbed by the paper filter.[3]

In a preceding publication, we showed that a single dose of 2.0 mL of coffee brew increased the activities of SOD, CAT, and GPx, but this effect was transitory and the activities started to return to basal levels a couple of hours after the administration.[18] In the present study, even after 12 h of fasting, the enzymatic activities remained much higher than the levels obtained after a single dose. This indicated that a daily ingestion of a small dose of coffee brew produced an accumulative effect that increased and maintained the activities of antioxidant enzymes far above the basal levels.

Another remarkable issue was the concomitant increase in the activities of SOD, CAT, and GPx, also observed in the previous publication using a single dose of coffee.[18] As these enzymes work in a sequential process[10,15] (SOD converts O_2^- to O_2^{2-} or H_2O_2 that is converted to H_2O by CAT or GPx), the simultaneous increases indicate an interesting solution found by evolution to avoid excessive concentration of any dangerous intermediate during hepatic detoxification. Increased levels of SOD could efficiently reduce O_2^- naturally produced in the mitochondrial domain to form O_2^{2-} (or H_2O_2) and subsequently water by the action of CAT and GPx, protecting the cells against the attack of these and other downstream ROS.

Because Nrf2 acts in DNA promoter regions as a direct factor for the transcription of the antioxidant enzymes as well as itself,[3,7−9] it was important to verify if coffee could also affect the concentration and the expression of this protein. The cytosolic level of Nrf2 was measured in groups 1 and 2, showing an increase equal to 131.3% (relative concentrations) in group 2 in relation to group 1 (Figure 3). Increased levels of cytosolic Nrf2 certainly promote the translocation of this protein to the nucleus, activating the transcription of ARE-responsive genes.[3,7−9] These results were compared and indicated a statistically significant difference according to the Student t test ($p < 0.001$). As Nrf2 plays an important role in the transcription of antioxidant enzymes, its increased level certainly collaborated to raise the expression of SOD, CAT, and GPx, resulting in higher activities for these enzymes.

Using the same samples, the total antioxidant capacity of the liver tissue was measured by ORAC. The control group showed an average result equal to 689 ± 34 μmol TE/L, which rose to 862 ± 44 μmol TE/L in group 2 (Figure 4), resulting in a statistically significant difference according to the Student t test ($p < 0.001$). As the ORAC assay measures the total antioxidant capacity of the samples, part of the observed effect must be assigned to the increased activities of the antioxidant enzymes and part to the phenolic compounds present in coffee as they are potent antioxidant molecules through the formation of resonance-stabilized phenoxy radicals.[39] Once more, the accumulative effect already mentioned was observed as a single dose of coffee brew promoted only a small and not statistically significant increase of ORAC ($p = 0.403$).[18]

On the basis of these results it was possible to conclude that a small and repetitive dose of coffee brew was sufficient to modulate the protein Nrf2, increasing the activity of antioxidant enzymes and improving the defensive status against oxidative stress. By comparison of the two studies involving a single dose and repetitive doses of coffee, it was possible to verify an accumulative effect that can be considered a beneficial consequence for coffee drinkers.

Evolution of Body Weight and Changes in Liver Tissue. Next, it was important to verify the occurrence of any damage to the health of the animals. The evolution of body weight is a parameter that could indicate eventual toxicity of coffee. At the beginning of the study, group 1 (control) showed an average weight equal to 203.86 ± 7.00 g, whereas group 2 (coffee) showed an average weight equal to 201.80 ± 6.83 g. These results were compared, and no statistically significant difference was obtained ($p = 0.617$). After the 28 day period, group 1 showed an average value equal to 349.10 ± 10.97 g, whereas group 2 showed 356.66 ± 19.55 g, indicating no statistically significant difference between them ($p = 0.428$). This result suggests that coffee did not present systemic toxicity and did not affect the appetite of the animals or the growing curve.[15]

The levels of the hepatic biomarkers AST and ALT were determined for group 1, showing average results equal to 74.5 ± 5.3 IU/L for AST and 30.2 ± 2.9 IU/L for ALT, compatible with the figures reported in other publications.[1,30,39] Group 2 was evaluated using the same methodology, showing average values equal to 71.5 ± 3.8 IU/L for AST and 27.9 ± 4.0 IU/L for ALT (Figure 5), not statistically different from group 1 according to the Student t test ($p = 0.290$ for AST; $p = 0.284$ for ALT). This finding was an excellent indication that no injury was caused to the liver by a continued exposure to coffee.

To strengthen the previous conclusion, a histopathological analysis of the liver tissue was done. After the preparation of the samples, it was observed that the hepatic histoarchitecture of both groups showed no alterations, presenting normal structures without inflammatory infiltration or necrosis when observed under the microscope (Figure 6). In addition, no fat accumulation in the liver was observed after sacrifice, and the health indicators for both groups (increase of weight, appearance of eyes and skin, physical activity, and response to external stimulus) were identical.

It was possible to conclude that the administration of 2 mL of coffee brew per day to rats greatly increased the cytosolic

levels of Nrf2 and the activity of antioxidant enzymes, improving the defensive status against oxidative stress with no apparent damage to the liver tissue. As a comparison, a human of 70 kg BW would have to consume three to four medium-size cups per day of coffee brew, which means approximately 550 mg of phenolic acids and 500 mg of caffeine.

ABSTRACT: Proanthocyanidins were isolated from fruit stone of Chinese hawthorn (*Crataegus pinnatifida* Bge. var. *major* N.E.Br.). Their structures were analyzed and elucidated by methods of matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) and high performance liquid chromatography electrospray ionization mass spectrometry (HPLC-ESI-MS). The results demonstrated that these compounds are complicated mixtures of homo- and heteropolymers consisting of procyanidin/procyanidin gallate and prodelphinidin. They possessed structural heterogeneity in monomer units, polymer length, and interflavan linkage (A-type and B-type). Their antityrosinase and antioxidant activity were then investigated. The results revealed that they can inhibit tyrosinase activities, including the monophenolase activity and the diphenolase activity. In addition, proanthocyanidins possessed potent antioxidant activity. Our studies revealed that proanthocyanidins isolated from fruit stone of Chinese hawthorn may be applied in food, agriculture, pharmaceutical, and cosmetic industries.

KEYWORDS: *hawthorn proanthocyanidins, structural analysis, MALDI-TOF MS, HPLC-ESI-MS, antityrosinase activity, antioxidant activity*

INTRODUCTION

Proanthocyanidins are polyphenol compounds. They are most commonly found in the plants and have aroused considerable interest and received more and more attention in recent years due to their bioactive functions. These compounds are composed of flavan-3-ol monomer units (Figure 1), which are joined together through C4−C8 or C4−C6 bonds to B-type oligomers and high polymers.[1] When C2 and C7 are linked by an additional ether linkage, these compounds are A-type proanthocyanidins (Figure 1).[2] The structural variability of monomer units, interflavan linkage, and distribution of polymerization degree contribute to the diversity of proanthocyanidins.[2,3] The qualitative and quantitative analysis of these compounds remains very challenging because of their structural diversity and complexity.

In our previous report, proanthocyanidins isolated from stem bark, fruit, and leaf of *Delonix regia* were found with potent tyrosinase inhibitory activity.[4] Tyrosinase (EC 1.14.18.1) is a kind of oxidase that contains copper and possesses two successive catalytic activities: the monophenolase activity (hydroxylation of monophenols to *o*-diphenols) and diphenolase activity (the oxidation of *o*-diphenols to *o*-quinones).[5] It causes melanization in animals and browning in plants.[6,7] In addition, tyrosinase is important in normal developmental processes in insects.[8] This indicates that tyrosinase inhibitors are potential insect control agents as well as whitening agents, food additives, and medicine. Plants are rich in bioactive compounds that have few side effects; thus researchers have shown increasing interest in employing them as a source of tyrosinase inhibitors.[9]

Hawthorn is one of the most popular medicinal and food materials in the world. Its fruits, leaves, bark, and flowers contain significant amounts of phenolic compounds, which exhibit potent antioxidant activity.[10−12] Most of these compounds belonged to proanthocyanidins.[13,14] In addition, Svedström et al. found that oligomeric proanthocyanidins in different tissue of hawthorn range from 2-mers to 6-mers.[15] However, detailed structure information and antityrosinase and antioxidant activity of purified proanthocyanidins extracted from Chinese hawthorn fruit stone have not been reported. Our study primarily aims to provide thorough structural analysis of proanthocyanidins from fruit stone of Chinese hawthorn using reflectron pattern MALDI-TOF MS, linear pattern MALDI-TOF MS, reversed-phase HPLC-ESI/MS, and normal-phase HPLC-ESI/MS analysis. These techniques are initially applied on Chinese hawthorn fruit stone proanthocyanidins to clarify the elementary units, distribution of DP, and type of linkage. The antityrosinase and antioxidant activity information on these compounds are also provided in this study.

obtained from Sigma-Aldrich (St. Louis, Missouri, USA). Mushroom tyrosinase, L-tyrosine, 3,4-dihydroxyphenylalanine, dimethyl sulfoxide, DPPH, ABTS, TPTZ, AAPH, and ascorbic acid, were also obtained from Sigma-Aldrich. The solvents with standard analytical purity were acquired from Sinopharm (Shanghai, China). Acros Organics (New Jersey, USA) is the company that provided the fluorescein and trolox.

Plant Material and Sample Preparation. Hawthorn fruits at commercial maturation were picked on the campus of Jiangxi Normal University (Nanchang, Jiangxi Province, China) in July. Fruit stones were isolated manually and immediately freeze-dried and then were ground to fine powders. The powders were placed at −80 °C before next analysis.

Extraction and Purification of Hawthorn Fruit Stone Proanthocyanidins. The powders (10.0 g) were ultrasonically extracted three times (each 200 mL) with acetone−water (7:3, v/v) solution containing 0.1% ascorbic acid at 25 °C. The acetone was eliminated in a rotary evaporator at 38 °C. Chlorophyll and lipophilic compounds remained in aqueous fraction were eliminated by extracting them with petroleum ether three times (each 150 mL). The remaining aqueous fraction was purified by using chromatography on Sephadex LH-20 column (Pharmacia Biotech, Uppsala, Sweden). Methanol (50% dissolved in water) and 70% acetone (dissolved in water) were used to elute successionally. The latter was freeze-dried to get dry proanthocyanidin powders after the acetone was removed by rotary evaporation. These powders were stored in the refrigerator (−20 °C) prior to structure and activity analysis.

MALDI-TOF MS Analysis of Hawthorn Fruit Stone Proanthocyanidins. Bruker Reflex III instrument (Bruker-Franzen, Bremen, Germany) was used for MALDI-TOF MS analysis. Samples (proanthocyanidins powders) were irradiated at 337 nm with a nitrogen laser. Angiotensin I (M + H 1296.7, monoisotopic) and angiotensin II (M + H 1046.5, monoisotopic) were employed to calibrate mass spectra. Parameters for positive pattern spectra in the reflectron pattern were as follows: accelerating voltage, 20 kV; reflectron voltage, 23.0 kV; delayed extraction voltage, 16.32 kV; lens voltage, 9.45 kV. Parameters for positive pattern spectra in the linear pattern were as follows: accelerating voltage, 20.0 kV; delayed extraction voltage, 16.25 kV; lens voltage, 10.0 kV. DHB was used as the matrix, and Cs^+ was selected as the cationization reagent. Amberlite IRP-64 cation-exchange resin was dissolved in deionized water, which was used to remove ions in the sample and matrix solution. The mixture volumetric ratio of the sample solutions and the matrix solution was 1:3. The final mixed solution (1 μL) was then dripped to the steel target.[16]

Reversed-Phase HPLC-ESI-MS Analysis Followed Thiolysis Reaction. With an Agilent 1200 system (Agilent, Palo Alto, CA, USA) coupled to a QTRAP 3200 (Applied Biosystems, Foster, USA), reversed-phase HPLC-ESI-MS analysis was conducted. The column employed in the analysis was a 250 mm × 4.6 mm i.d., 5 μm, Li-Chrospher 100 RP-18, with a 4 mm × 4 mm i.d. guard column of the same material (Elite, Dalian, China). The linear gradient elution process was performed as follows (two solvents were used as mobile phase, 0.5% trifluoroacetic acid and acetonitrile): 0−45 min, 12−80% acetonitrile; 45−50 min, 80−12% acetonitrile. The flow rate was kept at 1 mL/min, and the chromatogram was detected at 280 nm. In addition, instrument parameters for MS analysis in the negative ion pattern were set as follows: ion spray voltage, 4.5 kV; declustering potential, 50 V; entrance potential, 10 V; curtain gas, 20 psi; source temperature, 400 °C.

Normal-Phase HPLC-ESI-MS Analysis. Analysis was performed on a 250 mm × 4.6 mm i.d., 5 μm Silica Luna (Phenomenex, Darmstadt, Germany). The column temperature was controlled at 35 °C. The HPLC and MS system were the same as reversed-phase HPLC-ESI-MS analysis. Two solvents were used: A = water/acetic acid/methanol/dichloromethane (1:1:7:41, v/v/v/v) and B = water/acetic acid/methanol/dichloromethane (1:1:5:43, v/v/v/v). The linear gradient elution program was as follows: 0−20 min, 0−13.5% B; 20−50 min, 13.5−29.2% B; 50−55 min, 29.2−100% B; 55−60 min, 100% B.[17] Conditions for MS analysis were the same as the reversed-phase HPLC-ESI-MS analysis described previously.

Assay of the Enzyme Activity. Enzyme reaction was performed in compliance with the program of our previous study.[18] L-Tyrosine (2.17 mg/mL) was used as substrate for monophenolase activity assay and 3,4-dihydroxyphenylalanine (1 mg/mL) was used as substrate for diphenolase activity assay. The substrate and tyrosinase were mixed well in the absence or presence of the sample (3 mL reaction system) with different concentrations. The final concentrations of tyrosinase were 33.33 μg/mL for monophenolase activity assay and 6.67 μg/mL for diphenolase activity assay. Their enzyme activities were recorded on a Beckman UD-800 spectrophotometer (Beckman coulter, Pasadena, California, USA) at 475 nm. Lag time (the time for the reaction system reaching steady-state rate) and steady-state rate (a constant rate) were employed to measure the effect of proanthocyanidins on the enzyme activity of monophenolase. The effect of proanthocyanidins on the diphenolase reaction was expressed as percentage.

Fluorescence Analysis. Varian Cary Eclipse fluorescence spectrophotometer was used to record the fluorescence spectra. The reaction system (3 mL) contained 300 μL of mushroom tyrosinase solution, 300 μL of sample solution with different concentrations, and 2.4 mL of sodium phosphate buffer (50 mM, pH 6.8). Excitation wavelength was 290 nm. All the tests were peformed at room temperature.

Determination of Cu^{2+} Chelating Activity. The reaction system (3 mL) contained 100 μL of sample (2 mg/mL) solution, 100 μL of copper sulfate solution with different concentrations (25, 50, 100 μM), and 2.8 mL of sodium phosphate buffer (50 mM, pH 6.8). The mixture was shaken well and kept at 25 °C for 10 min prior to UV−vis analysis.

DPPH Radical Scavenging Activity Assay. DPPH analysis was performed in accordance with the report of Brand-Williams et al.[19] The reaction system was comprised of 0.1 mL of sample solution (dissolved in methanol) and 3 mL of DPPH solution (25 mg/L in methanol). The results were detected at 517 nm after the reaction mixture was shaken well and kept at 25 °C for 30 min. The scavenging effect was determined on the basis of the following equation:

$$\text{DPPH\% inhibition} = [(A_1 - A_2)/A_1] \times 100$$

dx.doi.org/10.1021/jf405385j | J. Agric. Food Chem. 2014, 62, 123−129

where A_1 is the absorbance in the absence of the sample and A_2 represents the absorbance in the presence of the sample. The IC_{50} value (μg/mL) is the sample concentration that caused 50% scavenging.

ABTS Radical Scavenging Activity Assay. ABTS radical scavenging activity was conducted according to the method of Re et al.[20] ABTS solution (7 mM) and potassium persulfate solution (2.45 mM) were mixed and stored in the dark for 16 h to obtain the $ABTS^+$ solution. It was diluted with 80% ethanol to get the $ABTS^+$ working solution. The working solution was detected at 734 nm with an absorbance of 0.700 ± 0.050. Tested sample (0.1 mL) was then mixed with 3.9 mL of $ABTS^+$ working solution. The absorbance was detected on a Beckman UD-800 spectrophotometer (Beckman coulter, Pasadena, California, USA) after incubation for 6 min. The result was expressed as IC_{50} value.

Ferric Reducing Antioxidant Power (FRAP) Assay. The FRAP assay was carried out in compliance with the method described by Benzie and Strain.[21] TPTZ solution (10 mM), ferric chloride solution (20 mM), and sodium acetate buffer (300 mM, pH 3.6) were mixed in a ratio of 1:1:10 to get the FRAP working solution. Sample (0.1 mL) was then added into 3 mL of freshly made working solution. The wavelength for the detection was 593 nm. Reaction mixture was kept at room temperature for 10 min before the detection. FRAP values were expressed as millimoles of ascorbic acid equivalents (AAE) per gram of purified proanthocyanidins.

Oxygen Radical Absorbance Capacity (ORAC) Assay. The ORAC method was performed on the basis of Ou et al.[22] The reaction system (300 μL) included 100 μL (0.33 μM) of fluorescein, 50 μL of extract or Trolox, and 150 μL of AAPH (60 mM). They were shaken well and recorded on a POLARstar Omega (BMG Labtech, Offenburg, Germany) with a 96-well microplate. The detection was performed after that the mixture was kept in 37 °C for 20 min. ORAC value was calculated as micromoles of trolox equivalents per gram of proanthocyanidins (dry weight).

Statistical Analysis. All the enzyme assays were repeated three times. The curves present in the picture were made according to the average value. The data for the antioxidant assay were obtained from three independent determinations, and they were analyzed by one-way analysis of variance. It indicated the significant differences when $p < 0.05$. The software used for the statistical analyses is SPSS 13.0.

RESULTS AND DISCUSSION

MALDI-TOF MS Analysis. Reflectron MALDI-TOF MS spectra of proanthocyanidins extracted from fruit stone of Chinese hawthorn are displayed in Figure 2A,B. Results indicated that hawthorn fruit stone proanthocyanidins exhibit mass spectra with a primary set of peaks with differences of 288 Da. It can be concluded that 288 Da is a mass difference of one catechin/epicatechin. A subset mass 14 Da higher was also found in the spectra (Figure 2A) except the detected mass series mentioned above. They were produced by gallocatechin/epigallocatechin. Additionally, the A-type interflavan linkages of 2 Da less than B-type were also detected in the main set of peaks (Figure 2B). These findings suggested that proanthocyanidins extracted from fruit stone of Chinese hawthorn are composed of procyanidin and prodelphindin. B-type procyanidin dominates. These compounds possess structural heterogeneity in monomer units and interflavan linkage (A-type and B-type). Besides the series of peaks described above, 152 Da mass distances following the main set of peaks were also observed (Figure 2A), which are in line with the addition of one galloyl group at the heterocyclic C-ring.[23] Also, 132 Da mass distances following the main set of peaks were produced by synchronous attachment of two Cs^+ and absence of a proton $[M + 2Cs^+ - H]^+$.[24] Additionally, these compounds had polymer chain length varying from 2-mers to 12-mers, with most intensity in 4-mers.

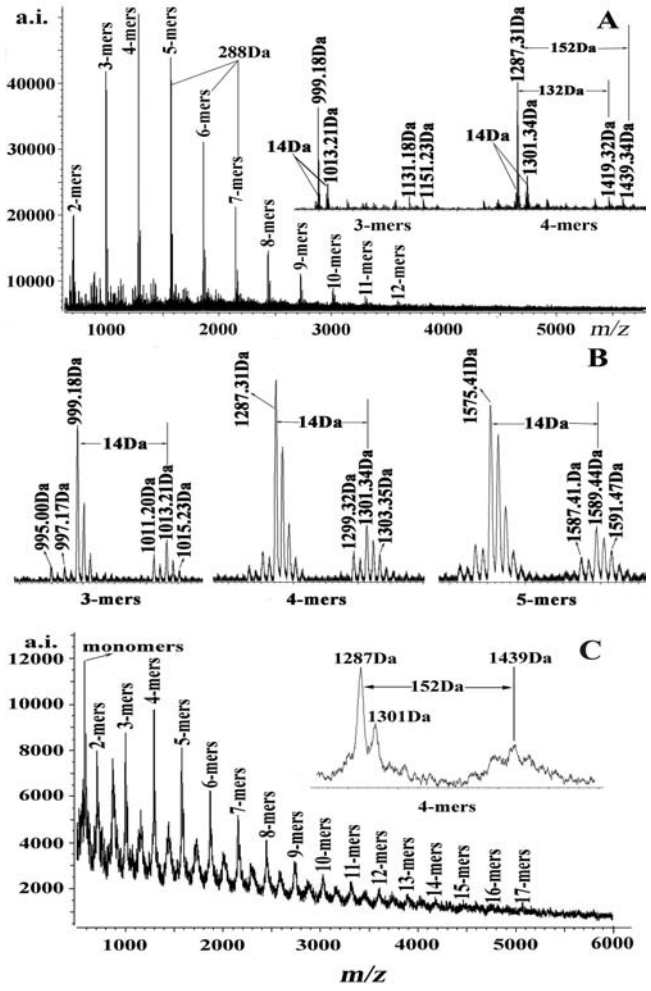

Figure 2. MALDI-TOF mass spectra of Chinese hawthorn fruit stone proanthocyanidins. The *y* axis represents absolute intensity (ai), that is the number of ions of each species that reach the detector.

To detect polymeric proanthocyanidins higher than those shown above, it is necessary to operate the linear pattern MALDI-TOF MS analysis. Figure 2C reveals a series of peaks separated by 288 Da, which are in keeping with the mass difference of one catechin/epicatechin. These compouds had polymer chain length ranging from monomer to 17-mers. In comparison with spectrum obtained from reflectron pattern (Figure 2A), linear pattern (Figure 2C) had weak resolution, but gave detection of mass information in line with higher DP. Linear MALDI-TOF MS analysis revealed the detection of litchi seed proanthocyanidins up to 27-mers.[16] In addition, in our study, proanthocyanidins showed galloyl ester units up to 6-mers in the reflectron pattern, while up to 17-mers in the linear pattern.

Reversed-Phase HPLC-ESI-MS Analyses. Chromatogram of thiolytic degraded proanthocyanidins from fruit stone of Chinese hawthorn is shown in Figure 3A. Results indicated that terminal units are mainly epicatechin (peak 2) and the extension units are primarily epicatechin benzylthioethers (peak 8). In addition, catechin (peak 1) and its benzylthioether (peak 7), catechin gallate (peak 3), and epigallocatechin benzylthioether (peak 5) were detected in Chinese hawthorn fruit stone proanthocyanidins by the thiolysis-HPLC method. Because A-type linkage is stable in the process of thiolytic degradation, the A-type terminal unit would be present in the

dx.doi.org/10.1021/jf405385j | J. Agric. Food Chem. 2014, 62, 123−129

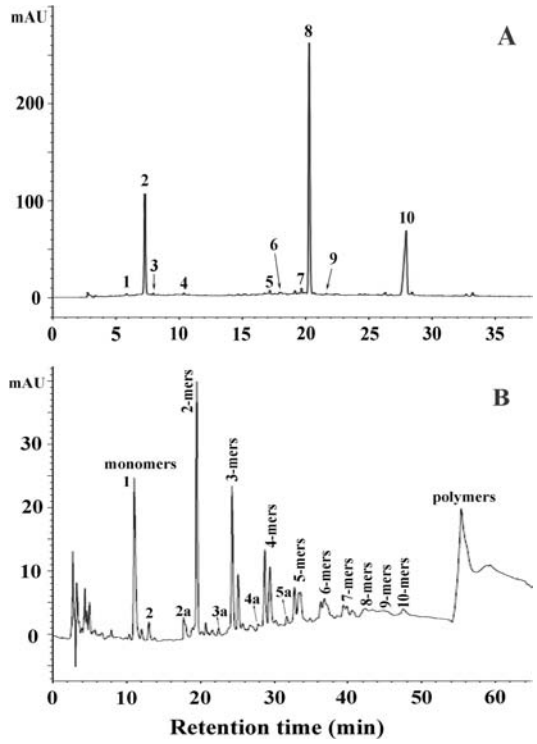

Figure 3. (A) Reversed-phase HPLC-ESI-MS chromatogram of Chinese hawthorn fruit stone proanthocyanidins after thiolytic degradation. Peaks are as follows: 1, catechin (289 Da, $[M - H]^-$); 2, epicatechin (289 Da, $[M - H]^-$); 3, epicatechin gallate (441 Da, $[M - H]^-$); 4, A-type dimer (575 Da, $[M - H]^-$); 5, epigallocatechin benzylthioether (427 Da, $[M - H]^-$); 6, A-type trimer benzylthioether (985 Da, $[M - H]^-$); 7, catechin benzylthioether (411 Da, $[M - H]^-$); 8, epicatechin benzylthioether (411 Da, $[M - H]^-$); 9, A-type dimer benzylthioether (697 Da, $[M - H]^-$); and 10, benzyl mercaptan. (B) Normal-phase HPLC-ESI-MS chromatogram of Chinese hawthorn fruit stone proanthocyanidins. Peaks are as follows: 1, epicatechin (289 Da $[M - H]^-$); 2, catechin (289 Da $[M - H]^-$); 2a, A-type dimer (575 Da $[M - H]^-$); 3a, A-type trimer (863 Da, $[M - H]^-$); 4a, A-type tetramer (1151 Da, $[M - H]^-$) and 5a, A-type pentamer (1439 Da, $[M - H]^-$), respectively.

form of A-type oligomers, while the A-type linkage between the extension units produced an A-type oligomer benzylthioether.[25] Peak 4 was authenticated as A-type dimer. Peaks 6 and 9 were A-type trimer benzylthioether and A-type dimer benzylthioether, respectively. In conclusion, the chromatogram after thiolysis indicated that proanthocyanidins are mainly constituted by the epicatechin unit. In addition, A-type linkage and B-type linkage are both involved in the formation of polymers, with B-type linkage dominating. These results were consistent with the results that achieved by MALDI-TOF MS analysis.

Normal-Phase HPLC-ESI-MS Analyses. Normal-phase HPLC profile of proanthocyanidins from fruit stone of Chinese hawthorn is illustrated in Figure 3B. The result indicated that DP of proanthocyanidins range from monomers to the 10-mers. In the chromatogram, peaks 1 and 2 are epicatechin (289 Da, $[M - H]^-$) and catechin (289 Da, $[M - H]^-$), respectively. Peaks 2a (575 Da $[M - H]^-$), 3a (863 Da, $[M - H]^-$), 4a (1151 Da, $[M - H]^-$), and 5a (1439 Da, $[M - H]^-$) are peaks of 2-mers, 3-mers, 4-mers, and 5-mers with A-type linkage, respectively. HPLC performance implied the precise separation of proanthocyanidins from monomers to 7-mers and the presence of isomers. However, the polymers higher than 10-mers could not be separated and showed a single broad peak at the end of the chromatograms (55.7 min). Our results were similar to the results of Gu et al.[26] and a good supplement of the reversed phase HPLC-ESI-MS analysis.

Effect of Chinese Hawthorn Fruit Stone Proanthocyanidins on the Monophenolase Reaction of Mushroom Tyrosinase. Kinetic courses of L-tyrosine oxidation by mushroom tyrosinase were tested in the presence of different concentrations of hawthorn proanthocyanidins. When L-tyrosine was used as substrate, the monophenolase activity of tyrosinase was assayed in the absence of inhibitor, and it was found that there was a remarkable lag time. The system reached steady-state rate after the lag period (lag time).[27] The steady-state rate of monophenolase activity can be negatively affected by addition of proanthocyanidins from fruit stone of Chinese hawthorn. The steady-state rate decreased in a dose-dependent way following the increase of the inhibitor concentration. When the final concentration of the proanthocyanidins in the system is 166.67 μg/mL, the steady-state rate decreased from 100% to 37.5%. The IC_{50} value was estimated as 37 $\pm$ 0.5 μg/mL for monophenolase activity. However, the corresponding lag time decreased from 94.8 s of the initial state to 47.6 s in the presence of 166.67 μg/mL proanthocyanidins.

In our previous study, the samples lengthened the lag time of the enzyme reaction or had no influence on it.[28] In the present study, however, proanthocyanidins isolated from fruit stone of Chinese hawthorn accelerated the reaction process (decreased the lag time) of the enzyme. To explain this phenomenon, 3,4-dihydroxyphenylalanine, catechin, and epicatechin in different concentrations were added into the enzyme−tyrosine reaction systems (3 mL), and the result showed that all the three compounds can obviously decrease the lag time at a low concentrations. The initial lag time decreased from 277.0 to 140.5, 14.4, and 9.6 s in the presence of 10 μM 3,4-dihydroxyphenylalanine, catechin, and epicatechin, respectively. The results showed that *o*-diphenol could affect the lag period of the monophenolase activity. The presence of *o*-diphenol in the monophenolase reaction system shortens the lag time, because the lag time is the time required to reach the steady *o*-diphenol concentration.[29] These findings further indicated that catechin and epicatechin existing in the extract of fruit stone of Chinese hawthorn are responsible for the particular phenomenon, and the effects of catechin/epicatechin are obviously better than that of 3,4-dihydroxyphenylalanine, which is commonly the substrate of the diphenolase reaction, to shorten the lag period. In summary, proanthocyanidins inhibit monophenolase activity of tyrosinase by reducing its steady-state rate.

Effect of Chinese Hawthorn Fruit Stone Proanthocyanidins on the Diphenolase Reaction of Mushroom Tyrosinase. The substrate for the assay of the diphenolase reaction was 3,4-dihydroxyphenylalanine. The relative activity increased before reaching a maximum (124.6% at 40 μg/mL) and decreased after that as concentration of the samples increased (Figure 4A). When the concentration reached 400 μg/mL, the relative activity decreased to 83.3%.

Gowda et al.[30] found that diphenol can activate diphenolase activity of polyphenol oxidase obtained from field bean (*Dolichos lablab*). Proanthocyanidins isolated from fruit stone of Chinese hawthorn increased diphenolase reaction absorption of tyrosinase in low concentration. To explain the phenomenon, 3,4-dihydroxyphenylalanine was replaced by catechin/epicatechin in 3 mL reaction system. The results indicated that both catechin and epicatechin can be better catalyzed by

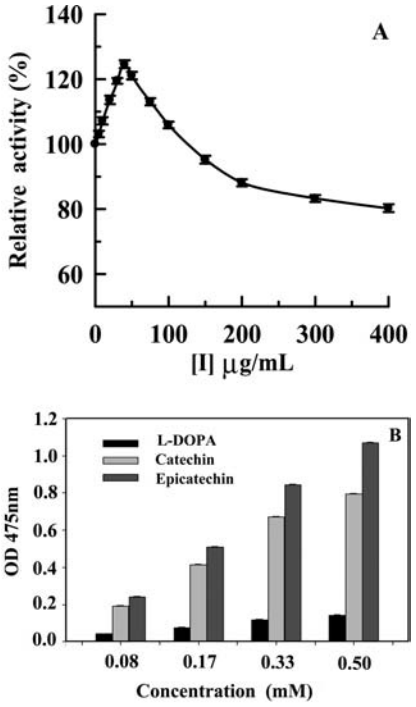

Figure 4. (A) Effects of Chinese hawthorn fruit stone proanthocyanidins on the diphenolase activity of mushroom tyrosinase. [I] represent concentrations of inhibitor. (B) Comparison of diphenolase activity of mushroom tyrosinase after adding 3,4-dihydroxyphenylalanine, catechin, and epicatechin as substrate.

tyrosinase than 3,4-dihydroxyphenylalanine and they are more effective substrates of tyrosinase (Figure 4B). This can be explained because catechin and epicatechin are substrate (3,4-dihydroxyphenylalanine) analogues. The increase of relative activity between 0 and 127 μg/mL is mainly because of the high absorption of products produced from catechin/epicatechin (exist in proanthocyanidins of hawthorn fruit stone) and tyrosinase at 475 nm. However, absorptions were not obvious when hawthorn fruit stone proanthocyanidins were mixed with tyrosinase in the absence of 3,4-dihydroxyphenylalanine. It can be speculated that oligomeric proanthocyanidins, such as dimer and trimer, may combine with tyrosinase and produce absorption at 475 nm. These findings suggested that hawthorn proanthocyanidins may inhibit (not activate) the reaction of 3,4-dihydroxyphenylalanine and tyrosinase by competing for the enzyme.

Fluorescence Emission Spectra of Mushroom Tyrosinase Solution in the Presence of Chinese Hawthorn Fruit Stone Proanthocyanidins with Different Concentrations. Combining capacities with proanthocyanidins of tyrosinase and its conformational alteration were evaluated by measuring the inherent fluorescence intensity of the enzyme in the absence/presence of proanthocyanidins. The fluorescence emission spectrum is recorded from a range of 300−500 nm with excitation wavelength set at 290 nm. As shown in Figure 5, the tyrosinase produces a strong fluorescence emission (337 nm, curve 0), while proanthocyanidins have a peak at 319 nm (curve A). The concentrations of samples for the curves 1−4 are 30, 60, 150, and 300 μg/mL, respectively. The result showed that fluorescence emission intensity reduced markedly with an increasing concentration of proanthocyanidins. The fluorescence intensity decreased from 64.7 to 13.5 (by 79.4%),

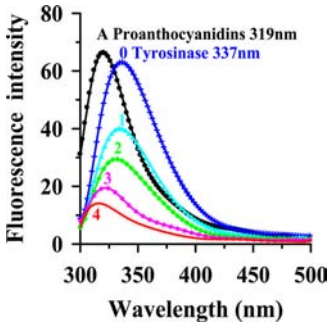

Figure 5. Fluorescence emission spectra of mushroom tyrosinase solution in the presence of Chinese hawthorn fruit stone proanthocyanidins with different concentrations. The concentrations of samples for the curves 0−4 are 0, 30, 60, 150, and 300 μg/mL, respectively. The curve A is fluorescence emission spectra of proanthocyanidins at the concentration of 300 μg/mL.

when the concentration of proanthocyanidins increased from 0 to 0.30 mg/mL. In addition, an obvious blue shift is also present in the spectra. The results indicated that when the proanthocyanidins bind to the enzyme molecule, it can induce the enzyme conformation to change and the enzyme activity to decrease.

Cu^+ Chelating Activity of Proanthocyanidins from Fruit Stone of Chinese Hawthorn. The copper-chelating properties of the proanthocyanidins from fruit stone of Chinese hawthorn were investigated. The increase of Cu(II) concentration to proanthocyanidins solution caused increased absorbance at 280 nm, which shows proanthocyanidins' binding to Cu(II). There is no absorbance difference at 280 nm when Na_2SO_4 is added to the proanthocyanidins solution. The inhibitory effect of proanthocyanidins on the tyrosinase may due to the combining capacity between their −OH group and copper ions in the catalytic center of mushroom tyrosinase. Because the −OH groups of proanthocyanidins present anionic form at pH 6.8, they may interact electrostatically with copper ions.

Determination of Antioxidant Property. Antioxidant activity of proanthocyanidins isolated from fruit stone of Chinese hawthorn was evaluated by DPPH, ABTS, FRAP, and ORAC assays. Figure 6A,B show DPPH and ABTS radical scavenging activities of proanthocyanidins from fruit stone of Chinese hawthorn and ascorbic acid at different concentrations. The results demonstrated that these compounds could eliminate DPPH and ABTS radicals in a dose-dependent manner. The quality of antioxidants was determined by IC_{50} values (antioxidant concentration that reduces the DPPH/ABTS radical by 50%). A much lower value of IC_{50} indicated better antioxidant activity. The proanthocyanidins had potent DPPH (IC_{50} 170.04 ± 5.17 μg/mL) and ABTS (IC_{50} 122.90 ± 1.25 μg/mL) free radical scavenging activity. One thing special is that proanthocyanidins possessed effective ABTS radical scavenging activity that was significantly better than ascorbic acid (140.52 ± 3.40 μg/mL) ($p < 0.05$). Noteworthy, the proanthocyanidins from fruit stone of Chinese hawthorn bleached the DPPH and ABTS radical immediately, which suggests that these compounds could be classified as dynamic antioxidants. Next, FRAP assay was used to measure the antioxidant activity of proanthocyanidins, and the same dose-dependent activity was found (Figure 6C). The FRAP value was calculated to be 5.83 ± 0.04 mmol AAE/g.

dx.doi.org/10.1021/jf405385j | J. Agric. Food Chem. 2014, 62, 123−129

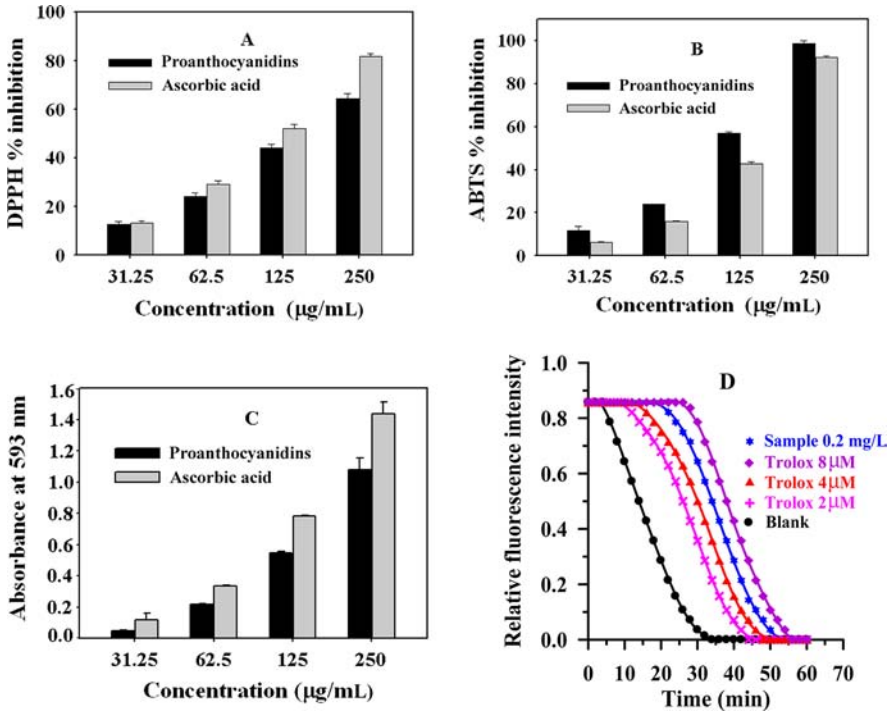

Figure 6. Evaluation of antioxidant activities of Chinese hawthorn fruit stone proanthocyanidins by using (A) DPPH, (B) ABTS, (C) FRAP, and (D) ORAC methods.

Furthermore, ORAC assay was performed. In the presence of antioxidative compounds, fluorescence decay was inhibited, and fluorescence intensity could be measured at 525 nm with excitation wavelength at 485 nm. The scavenging effect of proanthocyanidins against peroxyl radicals is illustrated in Figure 6D. This effect can be calculated from net integrated area under the kinetic curve and compared with that of Trolox. Our results demonstrated that proanthocyanidins scavenge peroxyl radicals effectively; the ORAC value was 29204.40 ± 870.12 μmol Trolox/g proanthocyanidins, measured at the proanthocyanidins concentration of 0.2 mg/L.

The antioxidant activity of proanthocyanidins can be affected by their chemical structure including monomer units, DP, and type of linkage.[31] Hagerman et al.[32] has conducted insightful research on the mechanism of procyanidin as potential antioxidants, the results of which showed that high molecular weight and hydroxyl group play important roles in free radical scavenging. Therefore, it can be speculated that the procyanidin with high DP in hawthorn fruit stone proanthocyanidins is the reason for the potent activity. Antioxidants have broad application prospects, and researchers have done a great deal of work to search for feasible and effective antioxidants. In this study, our results revealed that proanthocyanidins from fruit stone of Chinese hawthorn may be a good resource for further development as an antioxidant.

Revisiting the Prospects of Plastein: Thermal and Simulated Gastric Stability in Relation to the Antioxidative Capacity of Casein Plastein

Chibuike C. Udenigwe,* Sihong Wu, Kiesha Drummond, and Min Gong

Health and Bioproducts Research Laboratory, Department of Environmental Sciences, Faculty of Agriculture, Dalhousie University, Truro, Nova Scotia B2N 5E3, Canada

ABSTRACT: Plastein, a product of protease-induced peptide aggregation, is thought to possess unique physical properties and bioactivity, although its formation, stability, and functional mechanisms remain unclear. This study demonstrates that plastein is formed from bovine casein peptides with Alcalase by hydrophobic and electrostatic interactions and less likely by covalent bonding. The peptide aggregation enhanced the Fe(III) reducing potential and decreased the Fe(II) chelating activity ($p < 0.05$) of casein peptides, but there was no difference in inhibition of Fe-induced linoleic acid peroxidation after plastein reaction. The casein plastein product retained its antioxidative activities after being heated at 100 °C. However, simulated gastric protease treatment with pepsin and pancreatic enzymes resulted in enhanced reducing potential and metal chelation of the casein plastein and reduction of the inhibitory effect on lipid peroxidation. It appears that the plasteins were disintegrated and further hydrolyzed by gastric proteases on the basis of the antioxidative capacity and RP-HPLC profile being similar to those of the casein hydrolysates. Therefore, plastein reaction may not confer metabolic stability or enhance the antioxidative capacity of casein peptides for prospective functional food applications.

KEYWORDS: *plastein, peptide aggregation, antioxidant, bioactive peptide, stability, gastric protease*

INTRODUCTION

Plastein is a product of physical aggregation of peptides catalyzed by proteases at high substrate concentrations. First reported in 1902 by Danilevski and Okuneff, and originally thought to be resynthesized proteins,[1] plasteins are held together mostly by hydrophobic interaction of aggregating peptides.[2] However, the molecular events catalyzed by the protease during plastein formation remain unclear. Currently, plasteins are yet to be applied in the food system, and decades of research explored utilization of its gel-like physical properties in food.[3] Moreover, plastein has prospects for use in delivering desirable amino acids and enhancing the nutritional composition, quality, and health applications of proteins.[4] Furthermore, plastein has been explored for masking the bitterness of protein hydrolysates since hydrophobic amino acid residues that contribute to bitterness are buried within the plastein,[3] possibly limiting their interactions with taste receptors. Recently, a number of studies reported that plastein formation enhances the bioactivity of peptides, particularly their antioxidative and angiotensin-converting enzyme inhibitory activities.[5−7] Consequently, plastein can be explored as a multifunctional peptide-based ingredient for developing functional foods with desirable sensory, physicochemical, and bioactive properties. However, the mechanisms and structural requirements of plastein for enhanced bioactivity are presently not known, although this can be related to the surface property and availability of active functional groups in the peptide aggregates. Moreover, there is a dearth of information on the stability of plastein, which can be susceptible to thermal degradation during food processing and gastric proteolysis during ingestion, potentially leading to loss of structure and bioactivity. The objective of this study was to evaluate the antioxidative property of casein plastein on the basis of the reducing potential, metal chelation, and inhibition of Fe-induced lipid peroxidation with respect to their structural and functional stability against thermal and gastric protease treatments.

MATERIALS AND METHODS

Casein Hydrolysis and Plastein Formation. Casein was prepared by isoelectric precipitation by adjusting commercial skim bovine milk to pH 4.6 using 0.5 M HCl followed by centrifugation at 10000*g* for 15 min and freeze-drying the resulting precipitate. Thereafter, an aqueous suspension of the casein powder (5%, w/v) was heated at 90 °C for 10 min and cooled to 55 °C, followed by addition of protease from *Bacillus licheniformis* ([Alcalase] ≥ 2.4 U/g) at 0.01 g/g of casein to initiate hydrolysis. After 5 h of reaction maintained at 55 °C and pH 8.5 (adjusted by adding 0.5 M NaOH), the mixture was heated at 90 °C for 15 min to inactivate the enzyme, and the resulting product was freeze-dried. The degree of casein hydrolysis (DH) was determined by the *O*-phthaldialdehyde (OPA) method[8] and the average peptide chain length calculated as previously reported.[9] To produce casein plastein, a 40% aqueous suspension of the freeze-dried casein hydrolysates was mixed with 0.01 g of Alcalase/g of hydrolysates at 43 °C for 6 h at pH 6.5. Sample aliquots were withdrawn from the reaction every 1 h to monitor plastein formation and antioxidative activities. After termination of the plastein reaction by heating, the resulting products were freeze-dried and stored at −20 °C for further analysis.

Free Amino Nitrogen Determination. Free amino nitrogen present in the casein hydrolysates and plasteins was analyzed using OPA reagent containing sodium dodecyl sulfate (SDS) and dithiothreitol.[8] The OPA reagent (3 mL) was mixed with a 0.4 mL sample (1 mg/mL), and the absorbance of the solution was measured at 340 nm after 2 min. Serine (0.1 mg/mL) was used as the standard,

and the free amino nitrogen was calculated as milliequiv of serine NH_2/g of protein as previously reported.[8]

Surface Hydrophobicity (S_o). The surface hydrophobicity of the casein hydrolysates and plastein reaction products was determined by the fluorescence method using a hydrophobic probe, 8-anilino-1-naphthalenesulfonic acid, as previously reported.[10] The samples were assayed at concentrations of 0.0009−0.015% with excitation and emission wavelengths of 390 and 470 nm, respectively. The surface hydrophobicity was determined as the slope of the fluorescence vs concentration (%) plot.

Turbidity Measurement. The solution turbidity was measured as reported[9] with modifications. The casein hydrolysates and plasteins were dissolved in deionized water at 3 mg/mL and allowed to stand for 15 min at room temperature followed by vortex mixing. The absorbance of the solution was then measured at 460 nm. The same process was repeated with the samples dissolved in 0.2 M SDS or 2 M NaCl instead of distilled water as previously reported[9] to evaluate the respective roles of hydrophobic and electrostatic interactions during plastein formation.

Sulfhydryl Group Analysis. The total sulfhydryl group concentration of the hydrolysates and plasteins was measured as reported[11] with modifications. Samples (0.5 mL, 10 mg/mL) were mixed with 2 mL of 0.1 M Tris−glycine buffer containing 10 M urea (pH 8.0) and incubated at 40 °C for 30 min. Then 62.5 μL of 5,5′-dithiobis(2-nitrobenzoic acid) (4 mg/mL 0.1 M Tris−glycine buffer, pH 8) was added to the mixture, the resulting mixture was incubated at room temperature for 10 min, and the absorbance was measured at 412 nm. The total sulfhydryl group concentration (μM SH/g of protein) was calculated as $73.53A_{412nm}(D/C)$, where D = the dilution factor and C = the sample concentration.[11]

Antioxidative Assays. Three assays were used to evaluate the antioxidant property of the plasteins. First, the Fe(III) to Fe(II) reducing potential of casein hydrolysates and plasteins was assayed using the potassium ferricyanide method.[12] The samples and glutathione (positive control) were analyzed at 1 mg/mL final concentration, and the reducing potential was expressed as the absorbance at 700 nm. Thereafter, the Fe(II) chelating assay was conducted as previously reported[12] with modifications. Briefly, the 3 mL assay mixture contained 1 mL of peptide solution or EDTA (positive control) at a final concentration of 0.05 mg/mL, 0.05 mL of $FeCl_2$ (2 mM), and 1.85 mL of deionized water. A 0.1 mL solution of 5 mM ferrozine was then added followed by mixing; an equal volume of deionized water was used in the blank assay. The absorbance was then measured at 562 nm and the Fe(II) chelating effect (%) calculated. Last, the assay for inhibition of Fe(II)-induced lipid peroxidation was also conducted as previously reported[13] with modifications. A 70 μL solution of the samples or glutathione (final concentration 0.05 mg/mL) was mixed with 3.2 mL of 0.1 M sodium phosphate buffer containing 1% (v/v) Triton X-100 (pH 7), 50 mM linolenic acid (0.72 mL), and 20 mM $FeCl_2$ (10 μL). The mixture was incubated at 80 °C for 1 h, and a 0.1 mL aliquot was mixed with 75% ethanol (4.5 mL), 30% ammonium thiocyanate (0.1 mL), 1 M HCl (0.2 mL), and 20 mM $FeCl_2$ (0.1 mL in 1 M HCl). The absorbance of the solution was then measured at 500 nm followed by calculation of the inhibition (%) of Fe(II)-induced linoleic acid peroxidation.

Thermal and Gastric Stability. For thermal stability, aqueous solutions of casein hydrolysates and plastein were heated in a water bath (97−100 °C) for 10 min and cooled to room temperature followed by vortex mixing and measurement of the turbidity and antioxidative properties as described earlier. For gastric stability, the casein hydrolysates and plastein samples (50 mg) were mixed with pepsin solution (1 mg/mL in 0.1 M HCl−KCl buffer, pH 2.0) and incubated at 37 °C for 2 h followed by the addition of 1 mL of NaOH to neutralize the solution and inactivate pepsin.[14] Thereafter, 1 mL of pancreatin suspension (3 mg/mL in 0.1 M sodium phosphate buffer, pH 8.0) was added to the mixture, and the resulting mixture was

incubated at 37 °C for 14 h followed by enzyme inactivation at 90 °C for 15 min. The resulting samples were analyzed for free amino group, ferric reducing potential, metal chelation, and inhibition of Fe(II)-induced linoleic acid peroxidation.

Reversed-Phase (RP) HPLC Analysis. Solutions (20 μL) of 5 mg/mL casein hydrolysates and plastein (dissolved in solvent A, 0.05% trifluoracetic acid (TFA) in water) before and after gastric protease treatment were injected into a Waters 515 HPLC system fitted with a Phenomenex C18 column (250 × 4.6 mm, 5 μm). The samples were eluted at a 1 mL/min flow rate using a linear gradient of 0−66% solvent B (0.05% TFA in acetonitrile) for 45 min and then 66−100% for 5 min and equilibration with 100% solvent A for 10 min. The samples and solvents were filtered through 0.2 μm membrane filters prior to analysis, and peptide elution was monitored at 214 nm with a Waters 2487 dual λ absorbance detector fitted to the HPLC equipment.

Statistical Analysis. All data were collected in triplicate and are expressed as the mean ± standard deviation. The statistical significance of difference between treatments was analyzed by one-way analysis of variance and the Holm−Sidak multiple comparison test using SigmaPlot for Windows, version 11.0 (Systat Software, San Jose, CA).

RESULTS AND DISCUSSION

Plasteins are believed to be products of entropy-driven physical aggregation of mostly low molecular size peptides induced by proteases at substrate concentrations often higher than 30% (w/v).[2,3,15−18] Although proteolytic activity is not required, native enzymes are preferred in inducing peptide aggregation during plastein formation.[2] In the present study, Alcalase was used for casein hydrolysis to produce small-chain peptides due to its broad specificity. Extensive proteolysis with the microbial enzyme for 5 h resulted in a 20.4 ± 0.12% degree of casein hydrolysis and a calculated average peptide chain length of 4.9 ± 0.03. The turbidity of the casein peptide solutions was measured at a low concentration (0.3%, w/v) to monitor peptide aggregation induced by the protease during plastein reaction.[9,16] In this study, casein peptide aggregation occurred as observed from the increase in the absorbance value at 460 nm (turbidity) by 45% from 0 to 6 h (CP0−CP6), with the highest increase of 54% observed at 2 h of reaction (CP2) (Figure 1A). These results agree with similar studies that reported an increase in solution turbidity during peptide aggregation.[9,16] Moreover, the plastein reaction resulted in a decrease in free amino nitrogen of the casein peptide solution by 16% after the 6 h reaction, with CP2 showing the lowest value (Figure 1B). A decrease in free amino nitrogen of protein hydrolysates has been reported to occur during plastein formation.[5−7] A possible explanation of the observed changes in free amino nitrogen during peptide aggregation is the enzyme-induced covalent modification of free amino groups, leading to amide bond formation and peptide condensation. However, there is evidence that plastein formation is reversible and that no detectable peptide bonds are formed in casein plasteins.[2,17] An earlier study indicated that blocking the amino and carboxyl groups of peptides reduced the plastein yield,[2] which supports the possible involvement of free amino groups in peptide aggregation during plastein reaction, although the mechanism remains unclear. It is important to note that peptide aggregation did not occur in the absence of the protease. Another possible contributor to peptide aggregation is covalent disulfide bond formation. However, it appears that disulfide linkages are not involved in casein peptide aggregation in this study since the limited sulfhydryl group concentration in the casein hydrolysates did not decrease during plastein reaction (Figure 1C).

Several studies have demonstrated that hydrophobic interaction plays a major role in peptide aggregation.[2,15−17] This was confirmed during casein plastein reaction as the turbidity of the plastein solutions decreased in the presence of a surfactant, SDS (data not shown), which can disrupt hydrophobic interactions in peptide aggregates.[2,16,17] This decrease was highest at 2 h of reaction (CP2), corresponding to the highest turbidity value (Figure 1A) and surface hydrophobicity, S_o (Figure 1D). The peptides' surface hydrophobicity can impact their physiological biomolecular interactions and influence bioactivity especially if hydrophobic interaction with target molecules (e.g., lipids) is required. Apart from CP2, S_o did not change with peptide aggregation during casein plastein formation (Figure 1D). Moreover, considering the phosphates and other charged amino acid species in casein, electrostatic interactions may have also played minor roles in plastein formation as demonstrated by the decreased turbidity of the plastein in a high-ionic-strength NaCl solution (data not shown), which disrupted electrostatic interactions in the casein plastein, similar to previous observations during peptide aggregation.[15−17] On the basis of these data, it is plausible that most of the casein plasteins are held together by noncovalent bonds, especially for the casein plastein product at 2 h (CP2) under our experimental conditions.

Plastein reaction has recently been reported to enhance the bioactivity of peptides including antioxidative properties,[5−7] although there is a dearth of clearly defined mechanisms and structural requirements of the aggregates for the enhanced bioactivity. Results from the present study demonstrate that there is no substantial increase in the physiologically relevant antioxidative properties of casein peptides to justify the additional plastein reaction step. However, there were statistically significant ($p < 0.05$) increases in the ferric reducing potential of the casein plasteins, especially at 2 h (CP2), which enhanced bioactivity by 19% (Figure 2A). In contrast, plastein reaction resulted in a reduced metal (FeII) chelating activity of the casein peptides with up to 42% loss of activity observed in CP3 (Figure 2B). Since the chemical compositions of the casein hydrolysates and plasteins are similar, it appears that molecular rearrangement during aggregation induced the negative effect on bioactivity. Plausibly, the metal chelating residues and phosphates in casein peptides may have participated in stabilizing the plasteins by hydrophobic and electrostatic interactions, respectively, making them unavailable to chelate Fe(II) during the assay. In addition, peptide aggregation during plastein formation did not seem to impact the inhibitory effects of the casein peptides on Fe(II)-induced linoleic acid peroxidation (Figure 2C). It was also observed that the reducing potential of the casein peptides is not related to their total sulfhydryl groups, which is a key electron-donating functionality in peptides. Therefore, the enhanced reducing potential of the plasteins may be due to other antioxidative functionalities of amino acid residues that became proximal and perhaps collectively more reactive within the peptide aggregates. Moreover, the observed inhibitory activities against Fe(II)-induced linoleic acid peroxidation are not exclusively due to their metal chelating effects since there was no correlation between the two antioxidative properties, and a strong metal chelating agent (EDTA) did not inhibit the Fe(II)-catalyzed oxidative process during the assay. Overall, the casein hydrolysates and plasteins competed favorably with equal amounts of the positive controls (EDTA chelated 100% Fe(II) and glutathione inhibited 13% lipid peroxidation) except

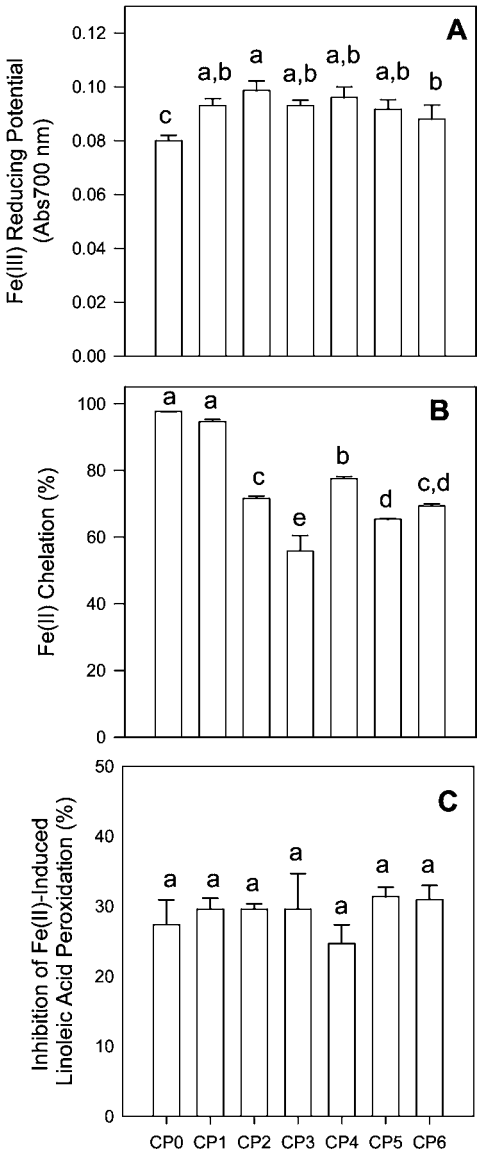

Figure 2. Antioxidative properties of casein hydrolysates (CP0) and plasteins after 1−6 h of reaction (CP1−CP6): (A) Fe(III) reducing potential, (B) Fe(II) chelating activity, and (C) inhibition of Fe(II)-induced linoleic acid peroxidation. in the case of the high reducing potential of glutathione (A_{700nm} = 1.91) due to its substantially higher molar amount of reducing sulfhydryl functionality in the assay compared to that of the casein products.

For decades, an important driver of the need to explore plasteins in food applications has included the modified physicochemical functionality of the peptide aggregates that can purportedly confer unique properties such as molecular stability. However, the mechanism of protease-induced plastein formation remains unclear, and the peptide aggregates have yet to find a major place in food product development. Our study has demonstrated that the intramolecular interactions holding the casein peptides together in the plastein appear stable to heat treatment at 100 °C for 10 min on the basis of the solution turbidity (data not shown). Moreover, the antioxidative properties of the hydrolysates and plasteins were conserved after heat treatment, except that the plastein lost about 8% of its ability to inhibit Fe(II)-induced lipid peroxidation (Table 1). There was also a slight but statistically significant ($p < 0.05$) increase in the ferric reducing potential and metal chelating activity of plastein, indicating possible changes in the noncovalent molecular interactions that exposed functional amino acid residues after heating. That notwithstanding, the same trend was observed for the antioxidative activities of the treated and untreated samples, indicating that the plastein did not have a substantial advantage over the unmodified casein hydrolysates in these model assay systems, which casts doubts on the purported enhanced value and prospective use of casein plasteins in functional food applications.

In contrast, gastric treatment resulted in altered antioxidative activities of the hydrolysates and plastein. The gastric enzymes induced a 4-fold increase in the ferric reducing potential of both samples and enhanced the metal chelating effect of the plastein to a value similar to that of the hydrolysates (Table 1). However, there was loss of over 24% of their inhibitory effects on lipid peroxidation after gastric modification. It appears that the casein hydrolysates and plasteins are similar after gastric treatment on the basis of their similar antioxidative activities (Table 1). Moreover, the HPLC profiles of the casein peptides before and after plastein reaction also appeared similar (Figure 3), indicating limited covalent bond formation induced by the microbial protease during aggregation. This suggests that noncovalent interactions played major roles in casein plastein formation in this study, as earlier suggested using other proteases.[2] Furthermore, simulated gastric protease treatment resulted in further hydrolysis, especially for highly hydrophobic peptides, yielding similar HPLC profiles for the casein hydrolysates and plastein (Figure 3). These data indicate that the aggregated peptides in the plasteins formed by hydrophobic and ionic interactions (and possibly covalent bonds) are not resistant to further gastric proteolysis, similar to peptides in the original casein hydrolysates. A previous study suggested that plastein reaction can confer stability on peptides against further

proteolysis after short-term (up to 30 min) exposure to proteases, including gastric trypsin and pepsin.[7] However, plastein stability may not be guaranteed since the authors' conclusion was based on short-term exposure to proteases and retention of bioactivity and did not consider the peptide aggregate structure or fingerprints, although the authors observed an increase in free amino group postprotease treatment,[7] suggesting susceptibility of the plastein to proteolysis. Gastric metabolic instability of peptides has been a major concern in translating food peptide research due to potential loss of structure and function. However, the present study demonstrated that the overall antioxidative potential of the casein plastein was enhanced as a result of gastric proteolysis, possibly due to further release of cryptic antioxidative peptides. Despite the enhanced bioactivity, the lack of clear distinction in the molecular profile and antioxidative activities of the casein hydrolysates and plastein postmodification by gastric proteases indicates that plastein reaction did not enhance gastric metabolic stability and overall prospects of the casein peptide aggregates.

In conclusion, this study has demonstrated that plastein reaction catalyzed by microbial proteases resulted in the formation of peptide aggregates that are held together mostly by hydrophobic and electrostatic interactions and less likely by covalent bonding. Although plastein reaction enhanced the reducing potential and decreased the metal chelating ability, the overall activity of the casein plastein did not differ substantially from that of the hydrolysates, especially in their effects in inhibiting linoleic acid peroxidation. Despite the thermal stability and retention of antioxidative activities after heating, the structure and bioactivity of casein plastein were modified substantially after simulated gastric treatment. These findings suggest that the aggregates in the plastein product may not improve the metabolic stability of casein peptides in functional food applications.

Maize Genotype and Food Matrix Affect the Provitamin A Carotenoid Bioefficacy from Staple and Carrot-Fortified Feeds in Mongolian Gerbils (*Meriones unguiculatus*)

Supporting Information

ABSTRACT: Biofortification to increase provitamin A carotenoids is an agronomic approach to alleviate vitamin A deficiency. Two studies compared biofortified foods using in vitro and in vivo methods. Study 1 screened maize genotypes (n = 44) using in vitro analysis, which demonstrated decreasing micellarization with increasing provitamin A. Thereafter, seven 50% biofortified maize feeds that hypothesized a one-to-one equivalency between β-cryptoxanthin and β-carotene were fed to Mongolian gerbils. Total liver retinol differed among the maize groups (P = 0.0043). Study 2 assessed provitamin A bioefficacy from 0.5% high-carotene carrots added to 60% staple-food feeds, followed by in vitro screening. Liver retinol was highest in the potato and banana groups, maize group retinol did not differ from baseline, and all treatments differed from control (P < 0.0001). In conclusion, β-cryptoxanthin and β-carotene have similar bioefficacy; meal matrix effects influence provitamin A absorption from carrot; and in vitro micellarization does not predict bioefficacy.

KEYWORDS: *α-retinol, biofortification, carrots, nixtamalization*

INTRODUCTION

Biofortification of staple crops to improve provitamin A carotenoid concentrations is a promising agronomic approach to increase vitamin A (VA) intake in populations. One such crop is maize, which makes up 55−70% of energy intake in countries such as Mexico and Zambia.[1,2] The provitamin A carotenoids, β-carotene (βC), β-cryptoxanthin (βCX), and α-carotene (αC), are present in typical yellow maize in low concentrations[3] and in higher concentrations in biofortified varieties.[4,5] The bioefficacy to make retinol from provitamin A carotenoids in maize was demonstrated by maintaining liver retinol stores of VA-depleted Mongolian gerbils (*Meriones unguiculatus*).[4,6] Furthermore, favorable bioconversion factors, which were more efficient than the Institute of Medicine (IOM) values of 12 μg of βC equivalents to 1 μg of retinol,[7] were measured from single test meals made with biofortified maize in U.S. women[8] and Zimbabwean men.[9]

Several studies have evaluated the effects of the relative carotenoid ratio, food matrices, meal components, and food processing on bioavailability, which is defined as provitamin A carotenoid that is absorbed and available for physiological function. For example, βCX and βC from biofortified maize are equally efficacious at maintaining baseline retinol stores in gerbils.[10] Cooking carotenoid-containing foods increases bioefficacy,[11] and dietary fat in meals increases carotenoid absorption.[12−14] However, carotenoid bioavailability from combined meals prepared with staple crops (biofortified or not) and vegetables, such as carrots and green leaves,[5] has not been determined.

In vitro carotenoid bioaccessibility screening methods (i.e., measuring provitamin A carotenoid released from the food matrix) involve digestion assays and may predict carotenoid bioavailability in vivo.[15−18] The micellarization efficiency (i.e., the fraction of carotenoid transferred from digesta to aqueous fraction) of maize carotenes was higher for porridge than extruded puffs and bread,[17] indicating that wet-cooking enhances bioaccessibility. In vitro digestions have been coupled with Caco-2 cell uptake as a model to screen the relative absorption of carotenoids from micelles with direct proportionality to the amount of provitamin A in cassava.[16] In vitro digestions were used to determine carotenoid bioavailability from vegetables;[19,20] however, it has not been coupled with animal studies to assess the same foods.

Two studies coupled in vitro and in vivo components. Study 1 screened 44 maize genotypes (*Zea mays* sp.) with different βCX to βC ratios. Thereafter, 50% maize feeds, assuming 1:1 rather than the theoretical 2:1 retinol activity equivalency between βCX and βC, were fed to Mongolian gerbils to assess in vivo bioaccessibility and bioconversion to VA, that is, bioefficacy. The hypothesis was that bioaccessibility of provitamin A carotenoids is correlated to concentration when measured by in vitro methods and that βCX will be as bioefficacious as βC in maize at the molar level in vivo. Study 2 assessed the bioefficacy of αC and βC from a small amount of biofortified, high-βC carrots (*Daucus carota* L.) when added to 60% staple-food feeds of gerbils and compared this with in vitro carotenoid bioaccessibility. In prior studies, high-βC carrots

[a]Values are means ± SD, $n \geq 3$ replicates (diet analysis), and $n = 5$ (feed intake and daily theoretical retinol intake). Means in a column without a common capital letter differ. Feed intake and theoretical retinol are per cage ($n = 2$/cage, $n = 10$/treatment group). ND, not detected; NM, not measured; VA+, positive control; VA−, negative control. [b]The limit for detection for carotenoids is <0.001 nmol and that for resistant starch is 0.08%. Assay includes all resistant starch. [c]Daily hypothetical retinol intake assumes 1 mol of β-carotene = 1 mol of β-cryptoxanthin = 1 mol of retinol. [d]Daily theoretical retinol intake assumes 100% bioefficacy (i.e., 1 mol of β-carotene provides 2 mol of retinol and 1 mol of α-carotene or β-cryptoxanthin provides 1 mol of retinol). This calculation (theoretical retinol × feed intake) accounts for losses in provitamin A concentrations over time.

provided an abundant amount of retinol to gerbils.[21] In study 2, the hypothesis was that small amounts of high-βC carrots will be an effective complementary food to maintain liver retinol reserves in gerbils despite potential effects of the combined food matrix.

MATERIALS AND METHODS

Maize and Carrots. Maize genotypes, including lines and synthetics, from the International Maize and Wheat Improvement Center (CIMMYT)/HarvestPlus maize provitamin A biofortification project were grown in Mexico at Agua Fria, Puebla (20°32′ N, 97°28′ W; 110 m above sea level). Ears were harvested and dried, and grain was stored at −20 °C before shipment to the University of Wisconsin (UW)—Madison. Genotypes were selected on the basis of carotenoid profile and contrasting βCX/βC. Carrots from the USDA carrot breeding and genetics program were grown by the University of California Desert Research and Extension Station in sandy, loam soil in October and harvested in March the following year. Carrots were refrigerated at 2 °C until shipped overnight from California to Wisconsin. Upon arrival, they were immediately returned to 2 °C and utilized for feed preparation after freeze-drying. Genotypes used (i.e., HCM and B2327) were selected for high βC concentrations.

In Vitro Digestion, Isolation of Micellarized Fraction, and Analyses. For study 1, maize genotypes ($n = 44$) were prescreened using HPLC (Supplemental Table 1 in the Supporting Information) and in vitro methods.[16,17] From these data, four genotypes were selected along with three others for gerbil study 1. Three genotypes had high βC and four had high βCX concentrations (Table 1). Biofortified maize and feeds from study 2 were weighed (~3 g) in triplicate and subjected to in vitro digestion as described by Thakkar et al.[16] and modified by Kean et al.[17] The method involves an oral phase using α-amylase, a gastric phase with porcine pepsin and pH adjustment with HCl, and an intestinal phase using porcine pancreatin, lipase, and bile extracts to mimic what happens in vivo. After the intestinal phase, the digesta is composed of the fluid and food products. Digesta were transferred to polycarbonate tubes for high-speed centrifugation (10000*g* for 1 h). Aqueous fractions (5−10 mL) were collected and syringe filtered into 15 mL centrifuge tubes, covered with nitrogen, and stored at −80 °C until analysis.[21−23] Digesta and aqueous fractions (3 mL) were placed in glass tubes with internal standard (β-apo-8′-carotenal, 50 μL) and ethanol with 0.1% butylated hydroxytoluene (500 μL). The carotenoids were extracted three times with hexanes (1 mL), pooled, dried under nitrogen, and reconstituted in 100 μL of 50:50 methanol/dichloroethane, and 50 μL was injected into a photodiode array HPLC.

Gerbil Study Designs. For studies 1 and 2, male 34−40-day-old Mongolian gerbils (Charles River Laboratories, Kingston, NY, USA) were group housed (2−3/cage) during VA depletion and treatment (2/cage). During depletion, gerbils were weighed daily for 2 weeks and, thereafter, three times per week. Room temperature and humidity were held constant with a 12 h light/dark cycle. Animal handling procedures were approved by the College of Agriculture and Life Sciences Animal Care and Use Committee at UW—Madison.

For study 1, gerbils ($n = 97$) were fed 50% white maize feed as a wash-out for 5 weeks. A baseline kill ($n = 7$) was performed via exsanguination while the gerbils were under isoflurane anesthesia. Remaining gerbils were divided into nine treatment groups ($n = 10$/group) and fed 50% white (VA− and VA+ groups) or seven orange maize feeds (G1−G7) prepared as published.[6] The feeds were developed by hypothesizing that 1 molecule of βC = 1 molecule of βCX = 1 molecule of retinol from the feed or supplement (Table 1). This contrasts with the theoretical relationship of 0.5 molecule of βC = 1 of molecule βCX = 1 molecule of retinol. Oral supplements,

administered using a positive displacement pipet, consisted of retinyl acetate (VA+ group) or oil only, which was given to groups G1−G7 and the VA− control. The VA+ dose was matched to the nanomoles of βC + βCX consumed from the orange maize on the prior day, and oil doses were matched by volume. Gerbils were fed for 4 weeks and then killed for tissue collection.

For study 2, gerbils (n = 66) were randomly separated into six treatment groups and acclimated to their study treatment by increasing staple amounts by 15% each week during depletion (4 weeks). Feeds ultimately contained 60% white staple food [i.e., potato (PT), rice (RC), banana (BN), or maize (MZ)] + carrot or VA-free feed with (CA) and without (VA−) carrot (Table 2). After depletion, one gerbil from each group (n = 6) was killed to determine initial serum and liver retinol concentrations. During treatment (4 weeks), 0.5% freeze-dried high-βC carrot was added to the staple feeds and the CA group. After treatment, the gerbils were killed, and blood and livers were collected. Blood was centrifuged for 15 min at 2200g in serum separator Vacutainer tubes (Becton Dickinson, Franklin Lakes, NJ, USA). Livers and serum were stored at −80 °C.

Table 2. Composition of Experimental Feeds for Study 2 Designed in Consultation with a Nutritionist at the Feed Supplier (Harlan-Teklad, Madison, WI, USA) That Were Fed to Mongolian Gerbils To Determine Vitamin A Efficacy of High β-Carotene Carrot Mixed with a Variety of Staple Foods

[a]All banana was chopped, freeze-dried, and ground. [b]Vitamin A-free feed was used for both the VA− diet and the 0.5% carrot diet. [c]Fat content was equalized in the feeds as well as nitrogen and energy. [d]Vitamin mix provided the following, mg/kg purified diet: biotin, 0.4; calcium; pantothenate, 66.1; folic acid, 2; inositol, 110.1; menadione, 49.6; niacin, 99.1; p-aminobenzoic acid, 110.1; pyridoxine-HCl, 22; riboflavin, 22; thiamin-HCl, 22; vitamin B12 (0.1% in mannitol), 29.7; ascorbic acid (97.5%), 1016.6.

Feed Preparation for Study 2. Green bananas were purchased from a local grocery store, peeled and sliced, lyophilized for ∼6 days, ground into flour, and kept frozen (−20 °C) until mixed into feeds. Nixtamalized (processed) white maize meal that contained no carotenoids (masa), precooked dehydrated potato flakes (Roundy's), and precooked instant rice (Roundy's) were purchased from a grocery store. Nixtamalization is a common processing method whereby the maize grains are soaked in limewater prior to grinding to improve consistency, increase calcium, reduce phytic acid, and enhance niacin bioavailability from the maize.[24] Potato flakes and rice were ground into fine powders using a Vitamix blender. Basal mixes were formulated for each food item with assistance from a feed nutritionist (Harlan-Teklad, Madison, WI, USA) to provide VA- and carotenoid-free, isoenergetic, and isonitrogenous feeds, which were mixed weekly with 0.5% carrot and stored at −20 °C (Table 2).

Carotenoid, Retinoid, Resistant Starch, and Fiber Analyses. Maize (0.6 g), feeds (0.6 g), and carrots (0.01 g) were analyzed each week in triplicate for carotenoid concentrations using a modified procedure after grinding with a mortar and pestle.[23] Serum preparation followed published methods.[22] Originally, the livers were analyzed for retinyl esters and carotenoids without saponification;[4] however, after initial data analyses, liver retinol was reanalyzed using a saponification procedure to better assess total retinol in study 1 and total α-retinol concentrations in study 2 derived from carrot αC.[22] For liver carotenoids, an unsaponified 5 mL aliquot of the 25 mL liver extract was dried and resuspended in 100 μL of 50:50 methanol/dichloroethane, and 50 μL was injected into an HPLC system as published.[23] Resistant starch and fiber were analyzed using previously published methods.[25,26]

Statistical Analysis and Calculation of Bioconversion Factors. Values are reported as means ± SD. Data were analyzed using the General Linear Model procedure in the Statistical Analysis System (SAS Institute, version 9.2). Outcomes of interest (i.e., gerbil weights, retinol, α-retinol, and carotenoid concentrations) were evaluated using one-way ANOVA, and differences among treatment groups were determined using least significant difference tests. One- and two-tailed t tests were used when appropriate. For calculation of bioconversion factors, the mean total liver retinol of the negative control group was subtracted from each treatment group prior to calculation. In study 1, bioconversion factors were calculated in reference to the retinyl acetate dosed group.[6] In study 2, bioconversion factors were calculated by taking into account the amount of retinol utilized during the treatment period by the negative control group and the amount of provitamin A carotenoids ingested.[27] α < 0.05 was considered significant.

RESULTS

Study 1. *In Vitro Digestion of Maize Genotypes.* Typically, when the βCX to βC ratio was <0.045, micellarized βCX was ≤6%. However, above this parameter, βCX was highly micellarized at all concentrations (Figure 1A). Incorporating all data points resulted in a positive relationship of βCX concentration and micellarization (P = 0.017). After removal of the βCX/βC < 0.045 maize genotypes (n = 6), the slope was not different from zero (P = 0.58). βC micellarization efficiency and total carotenoid micellarized had significant negative relationships with the amount in the maize (Figure 1, panels B and C, respectively, P < 0.0001). At lower βC concentrations, that is, < 5.5 μg/g maize, micellarization was 35.2 ± 12.6%; at concentrations >8.1 μg/g, it was 17.2 ± 6.6% (Figure 1B, P < 0.0001). The total amount of βCX + βC micellarized was stable across genotypes (Figure 1D, r = 0.12, P = 0.45).

Weights and Feed Intakes. Final gerbil body weights (73.0 ± 5.43 g) and liver weights (2.49 ± 0.46 g) were not different among groups. Feed intake differed among groups and therefore affected daily hypothetical and theoretical retinol intake (Table 1). Fiber differed by 1.5% (P = 0.048) and resistant starch by 1% (P < 0.0001) of total dietary content among the feeds (Table 1).

Tissue Concentrations. Serum retinol concentrations did not differ among groups (1.87 ± 0.90 μmol/L, data not shown). Total liver retinol and retinol concentrations differed among groups (Figure 2, P ≤ 0.0043). All biofortified maize groups showed no difference in liver retinol concentration from

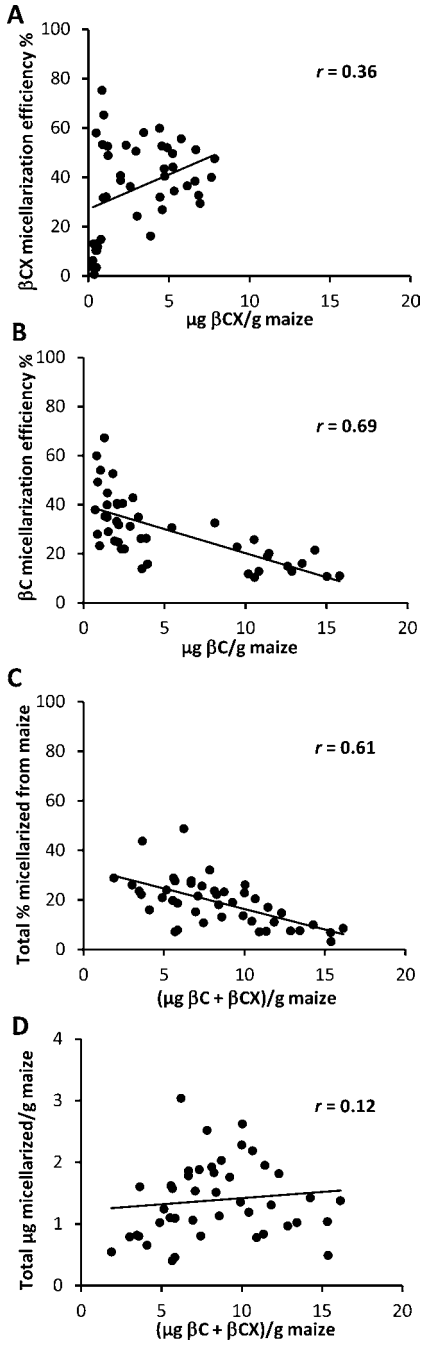

Figure 1. Micellarization efficiencies (concentration in aqueous micellar fraction/concentration in internal digesta × 100%) of provitamin A carotenoids from biofortified maize genotypes in relationship to the amount of the carotenoid, either β-cryptoxanthin (βCX, panel A) or β-carotene (βC, panel B); total percent micellarized [(μg βC + βCX in aqueous micellar fraction)/(μg βC + βCX in maize)] in relationship to (μg βC + βCX) in maize (panel C); total (βC + βCX) micellarized per gram maize in relationship to (μg βC + βCX) in maize (panel D). It is worth noting that the amount of total provitamin A carotenoid micellarized was the same across combined concentrations. Values are means ± SD.

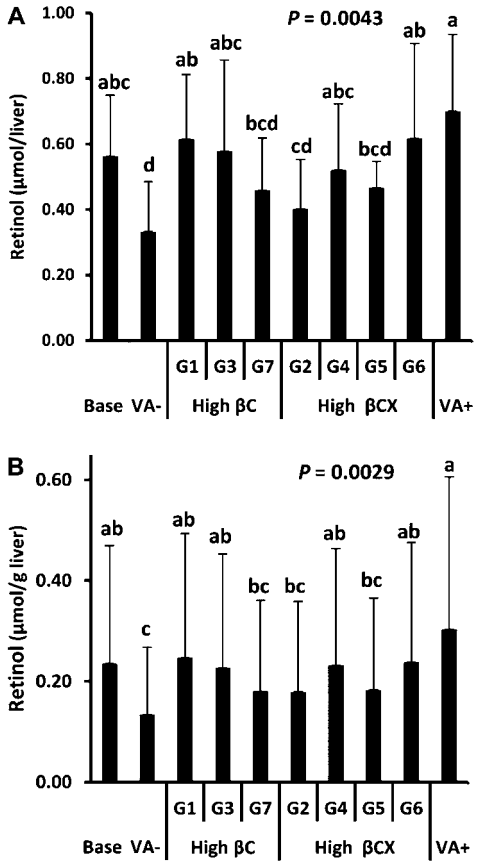

Figure 2. Total liver retinol (A) and retinol concentrations (B) from saponified livers in Mongolian gerbils at baseline after 5 weeks of being fed a vitamin A-free feed (base, n = 7) or fed vitamin A-free (VA−), 50% high β-carotene maize (G1, G3, G7), high β-cryptoxanthin maize (G2, G4, G5, G6), or vitamin A-free feed with daily retinyl acetate doses (VA+) in study 1 (n = 10/group). All other treatment groups received a plain oil dose matched to the VA+ group for 4 weeks. Values are means ± SD.

each other (Figure 2B), and all maize groups maintained baseline concentrations. When corrected for total retinol/liver by multiplying by liver weight, treatment groups differed, but remained similar to baseline. Two of three high-βC maize genotypes achieved liver retinol similar to VA+, whereas the other was not different from VA− (Figure 2A). Two of four high-βCX maize genotypes achieved total liver retinol similar to VA+, whereas the other two were not different from VA− (Figure 2A). When the theoretical retinol intakes (Table 1) are compared between the high-βC and -βCX groups, intakes differed (P = 0.010), but this difference was not reflected in the increase in liver retinol, which supports the hypothesis that βCX is as bioefficacious as βC on a molar level. The bioconversion factors calculated in reference to the VA in oil dose ranged from 1.2 to 6.1 μmol of provitamin A carotenoid to 1 μmol of retinol and did not differ between the high -βC and -βCX maize genotypes (Table 3).

Liver provitamin A carotenoid concentrations reflected those in the feeds and therefore differed (P < 0.0001). Total liver βCX was the same among the four high-βCX groups (0.754 ± 0.285 nmol/liver) and low in the high-βC groups (0.125 ± 0.203 nmol/liver). Although there were slight differences in βC concentrations in the high-βC groups, total liver βC did not differ among high-βC groups (3.21 ± 1.16 nmol/liver) or among the high-βCX groups (1.54 ± 0.53 nmol/liver). Combined βC and βCX concentrations per gram of liver [(nmol βC + nmol βCX)/g liver] did not differ among treatment groups, but total liver carotenoid amounts were different (P = 0.031), with more carotenoids generally found in

Table 3. Bioconversion Factors in Mongolian Gerbils Fed High-β-Carotene or High-β-Cryptoxanthin Maize or 0.5% Freeze-Dried Carrots with Different Staple Food Matrices

	μmol provitamin A/ μmol retinol	μg provitamin A/ μg retinol	IOM reference[a]	% IOM value
Study 1				
high β-carotene				
G1	1.2	2.3	12.0	19
G3	1.5	2.8	12.0	23
G7	3.3	6.3	12.1	52
high β-cryptoxanthin				
G2	6.1	11.8	21.8	54
G4	2.3	4.4	21.5	20
G5	3.3	6.4	20.4	31
G6	1.6	3.0	21.6	14
Study 2				
carrot alone	3.2	6.0	15.1	40
rice matrix	3.0	5.7	15.2	38
potato matrix	2.7	5.1	15.0	34
banana matrix	4.4	8.2	15.3	54
maize matrix	4.6	8.5	15.0	57

[a]The Institute of Medicine (IOM) values[7] were calculated by determining the proportion of β-cryptoxanthin and α-carotene in the diet compared with the β-carotene and multiplying by the IOM values of 12:1 for β-carotene and 24:1 for β-cryptoxanthin and α-carotene.

the high-βC groups than in the high-βCX groups, which supports preferential bioconversion of βCX. Furthermore, the βCX/βC ratio in the feed and liver did not differ in the groups fed high-βC maize, but was much lower in the liver than in the feed in those fed high-βCX maize ($P = 0.0065$).

Study 2. *Carotenoid, Fiber, and Resistant Starch Concentrations and Micellarization.* The concentrations of αC and βC were higher in the BN feed than in other feeds ($P < 0.0001$) due to naturally occurring carotenoids in banana.[11] The theoretical retinol, based on 100% bioefficacy of all feeds (Table 1), exceeded gerbil requirements, which allowed for ample liver storage. Fiber content was lowest in RC feed and highest in the VA-free feeds ($P < 0.0001$). Resistant starch concentration was highest in the BN and RC feeds and lowest in controls ($P < 0.0001$). Micellarization efficiency did not differ or predict findings in vivo (Table 4; $r = 0.02$), where MZ resulted in lower liver retinol concentrations than PT, RC, BN, and CA (Figure 3).

Weights and Intakes. Final gerbil weights were higher in the BN and MZ (74.1 ± 6.2 g) groups than in CA, VA−, and RC groups (68.4 ± 3.0 g, $P = 0.0036$). Liver weights were highest in the PT group (2.61 ± 0.59 g) and lowest in the CA, RC, and BN groups (2.20 ± 0.27 g). Percent liver weight was higher in PT, MZ, and VA− groups (3.46 ± 0.53%) than in the BN group (2.91 ± 0.23%, $P = 0.020$). Feed ($P = 0.024$) and theoretical retinol intakes ($P < 0.0001$) were highest in the BN group and lowest in the RC group (Table 1).

Tissue Concentrations. Serum retinol concentrations did not differ (1.34 ± 0.19 μmol/L, data not shown). Total liver retinol was highest in the PT and BN groups and lowest in VA− (Figure 3A, $P < 0.0001$). Liver retinol concentrations did not differ among the PT, RC, BN, and CA groups, but the MZ group was lower and did not differ from baseline or VA− groups (Figure 3B, $P < 0.0001$). Total liver α-retinol differed (Figure 4A, $P < 0.0001$) and was highest in the BN group, which reflected the higher αC concentration. The MZ group had lower α-retinol than the BN and PT groups, but did not differ from the RC and CA groups. Liver α-retinol concentrations differed (Figure 4B, $P < 0.0001$) and were highest in the BN group followed by PT, RC, and CA groups, which did not differ, and MZ, which was lowest. Bioconversion factors were adjusted for differences in provitamin A carotenoid intakes and ranged from 2.7 μmol of carrot provitamin A from the PT matrix to 4.6 μmol from the MZ matrix, producing 1 μmol of retinol (36 ± 15% of IOM values; Table 3).

Table 4. Micellarization Efficiencies (Aqueous Divided by Digesta Fraction × 100) of α- and β-Carotene from 0.5% Freeze-Dried Carrot Powder Mixed with Staple Foods in Feeds Fed to Mongolian Gerbils in Study 2[a]

component	micelle fraction α-carotene (%)	micelle fraction β-carotene (%)	micelle fraction theoretical retinol (%)
60% potato	6.5 ± 5.0	5.7 ± 3.0	18 ± 5.3
60% rice	12 ± 7.4	13 ± 5.4	37 ± 11
60% banana	26 ± 20	14 ± 14	54 ± 23
60% maize	10. ± 0.2	12 ± 1.0	33 ± 11
carrot only	11 ± 5.0	9.0 ± 5.2	29 ± 8.3

[a]Values are means ± SD, $n = 3$/staple food. Methods were those of Thakkar et al.[16] as modified by Kean et al.[17] No differences in micellarized carotenoids were observed among the feeds ($P > 0.05$).

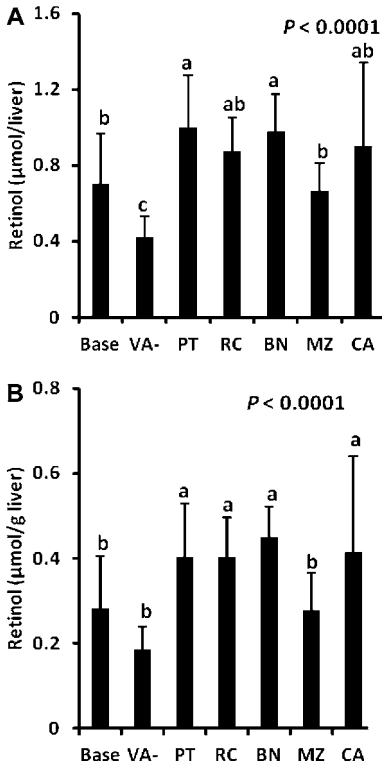

Figure 3. Total liver retinol (A) and retinol concentrations (B) from saponified livers in Mongolian gerbils at baseline after 4 weeks of being fed a vitamin A-free feed (base, $n = 6$) or fed 60% potato (PT), rice (RC), banana (BN), or maize (MZ) with 0.5% high β-carotene carrot or vitamin A-free feed with (CA) or without (VA−) 0.5% high β-carotene carrot for 4 weeks in study 2 ($n = 10$/group). Values are means ± SD.

dx.doi.org/10.1021/jf403548w | J. Agric. Food Chem. 2014, 62, 136−143

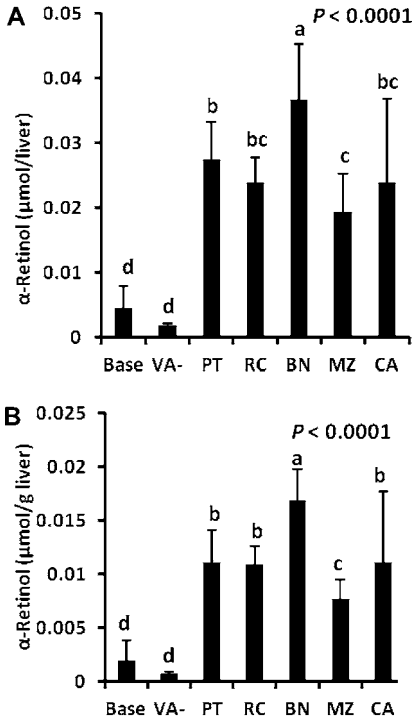

Figure 4. Total liver α-retinol (A) and liver α-retinol concentrations (B) from saponified livers in Mongolian gerbils at baseline after 4 weeks of being fed a vitamin A-free feed (base, n = 6) or fed 60% potato (PT), rice (RC), banana (BN), or maize (MZ) with 0.5% high β-carotene carrot or vitamin A-free feed with (CA) or without (VA−) 0.5% high β-carotene carrot for 4 weeks in study 2 (n = 10/group). Values are means ± SD.

The PT, RC, and BN (8.11 ± 3.27 nmol αC/liver) groups had more αC than the MZ and CA (4.01 ± 2.04 nmol αC/liver) groups (P = 0.0009). Similarly, βC was higher in the PT, RC, and BN (12.8 ± 5.77 nmol βC/liver) groups than in the MZ and CA (6.47 ± 3.41 nmol βC/liver) groups (P = 0.0025). Liver provitamin A carotenoid concentrations did not reflect those in the feeds. The ratio of αC to βC in the feeds (0.35 ± 0.02) was approximately half that in the liver (0.63 ± 0.04) (P < 0.0001), which may reflect preferential cleavage of βC. The ratio in the in vitro micellarized fraction was 0.49 ± 0.16, which is midway between these two ratios.

DISCUSSION

Biofortification of staple and horticultural crops with provitamin A carotenoids is a promising technique to diminish VA deficiency.[28,29] In study 1, percent total carotenoid and βC micellarized were negatively correlated with the total amount of provitamin A carotenoid, but the absolute amount micellarized remained relatively stable and was not related to genotype. βCX was not well-micellarized when concentrations were <0.5 μg/g and βC concentrations were >8 μg/g. Considering the physiochemical properties of micelles, several reasons explain these findings, which were consistent in this study and largely based on maize genotypes with a similar pedigree (entries 17, 19−22, and 27 in Supplemental Table 1 in the Supporting Information). In vitro, βCX likely did not meet a critical concentration needed for micelle incorporation in the genotypes that had a low βCX/βC.[30] Carotenoid interactions are well-documented;[31,32] therefore, the polarity difference between βC and βCX may not have allowed the βCX into the overwhelmingly nonpolar micellar microenvironment formed from the high βC content in these genotypes. Furthermore, the lipid profile differentially affects incorporation of xanthophyll and hydrocarbon carotenoids into micelles.[33] Future studies on maize lines that are close to commercialization should include characterization of the endogenous oil. Study 2 demonstrated good micellarization of αC and βC (6−26%) compared with other studies (0.2−16.7%),[18,31] but perhaps higher variability. This is due to the small amount of carrot added to the feed, which acts more like a fortificant and not an endogenous component, which may lead to higher variability among replicates.

In study 1, gerbil feeds were equalized for total carotenoid content by assuming that 1 mol of βC or βCX would supply 1 mol of retinol; βCX was as good as βC on a molar basis for maintaining VA status, confirming previous studies.[6,10] If 2 βCX/1 βC applied, the high-βC maize should have resulted in 2 times the amount of retinol over the high-βCX maize because of the hypothetical study design. Although the gerbils maintained balance, based on no difference from baseline regardless of feed, differences in liver reserves existed among genotypes. This important finding, not explained by fiber or resistant starch, demonstrates that other factors, such as endogenous interactive nutrients, must be investigated especially among commercial biofortified lines that are being developed and released.[28,34] A recent study in Zambian children showed a genotype effect with biofortified maize intake due to different cooking properties.[35] Furthermore, the current study was able to quantify βCX in the livers of gerbils fed biofortified maize. Although βCX was quantifiable in a study that fed fruits,[36] prior studies with maize did not find quantifiable βCX. Thus, the amounts in the maize likely exceeded gerbil requirements because βCX was absorbed intact and stored.

A review of human studies concluded that the apparent bioavailability of βCX is much higher than that of βC from Western foods.[37] Researchers need to consider resources available and the question being asked when selecting an experimental model. No animal model can replace human studies, but Mongolian gerbils are better predictors of provitamin A bioefficacy than rats or mice.[38] For example, the range of bioconversion factors among the maize genotypes in study 1 was 2.3−11.8 μg of provitamin A carotenoids to 1 μg of retinol, which is similar to the range from single test meals of biofortified maize in young U.S. women (3.9−13.3 μg of βC equivalents to 1 μg of retinol)[8] and Zimbabwean men (1.5−5.3 μg of βC equivalents to 1 μg of retinol).[9]

In study 2, α-retinol, retinol, αC, and βC were quantified. A negative matrix effect occurred on the uptake and storage of αC and βC from carrot and bioconversion to α-retinol and retinol when gerbils consumed 60% nixtamalized MZ feed, which was not found in the in vitro analysis. On the other hand, PT exhibited the least matrix effects. On the basis of the gerbil studies, in vitro digestion, which evaluates carotenoid release from the food matrix and micellarization, did not predict bioefficacy, which is regulated by in vivo processes, such as cellular uptake, bioconversion, and chylomicron packaging and secretion.

In agreement with a prior study in gerbils that were fed high-carotene carrot,[21] as αC increased, αC liver reserves increased; however, in that study, α-retinol was not quantified. Nonetheless, in a subsequent study, αC was as effective as βC in maintaining liver retinol reserves when fed at double the

amount, and quantification of α-retinol implied central cleavage of αC.[22] Bioconversion factors in that study revealed 2 αC to 1 βC, but factors were less efficient than IOM values for supplements.[7,22] In the current study, a small amount of carrot was fed so that the regulatory systems would not be overwhelmed by carotenoids. In the prior carrot study, the group that was fed high-carotene carrots had only 14% more retinol in the liver than the group fed typical orange carrots but had 120% more βC.[21] Although postabsorptive bioconversion occurs,[39] the major site for meeting daily retinol needs is bioconversion at the gut level. The relative amount of carotenoid fed affects bioconversion.[34] In humans and gerbils, extra dietary carotenoid that is not converted to retinol is absorbed and stored, but not currently considered when determining bioavailability. The βC absorbed from biofortified carrot and stored in the liver was 2650% higher in the prior study at 3.3%[21] than the current study at 0.5% of the feed. Carrot intake, in contrast to VA supplements, affects antioxidant capacity of tissues and may support optimal health.[40,41]

The food matrix effect on the uptake of carotenoids from MZ feed was not due to fiber because the CA feed had more fiber. Soluble fiber had no effect on βC efficacy when gerbils were fed orange sweet potato.[14] White maize, as in masa meal, is soaked in limewater (i.e., nixtamalized) to increase some nutrients' bioavailability, and other nutrients are sometimes added, which may have affected the bioavailability of the carrot carotenoids. If nixtamalization, which is widely practiced, does have a negative effect on carotenoid utilization, it needs to be further investigated in biofortifed maize products. The processed maize in this study had a negative impact on the bioconversion factor, which is a similar finding to commercially processed banana.[36] The BN group utilized endogenous carotenoids despite the presence of resistant starch, which is congruent with previous studies[11] and supported by the higher liver α-retinol. All of the mixed feeds maintained or enhanced total liver reserves by the addition of a small amount of carrot as a source of provitamin A carotenoids. As a global measure of bioavailability, the nanomoles/liver of (retinol + α-retinol + βC + αC) was summed after correction for the negative control group and differed among the treatments ($P = 0.05$). PT had the most desirable matrix, endogenous BN carotenoids are bioavailable, and nixtamalized MZ had the least desirable outcome for provitamin A bioefficacy from mixed food.

Determining the many factors that affect carotenoid absorption and utilization from biofortified and mixed foods is important for biofortification and nutrition education efforts to alleviate VA deficiency. Although biofortification of staple crops with provitamin A carotenoids is efficacious, adding a little carrot (and perhaps other high provitamin A fruits and vegetables) to the diet had a greater impact on VA status of the gerbils, which highlights the importance of multipronged approaches to eradicate VA deficiency.

ABSTRACT: The purpose of this study was to complete knowledge on the chemical composition and radical-scavenging activity of olive tree wood. Two new monoterpene glycosides, (−)-oleuropeic acid 6′-*O*-α-D-glucopyranosyl ester (**6a**) and (−)-perillic acid 1′-*O*-β-D-primeverosyl ester (**8**), together with the known compounds (−)-oleuropeic acid (**1**), (−)-olivil (**2**), the aldehydic form of oleuropein aglycone (**3**), (+)-1-hydroxypinoresinol 1-*O*-β-D-glucopyranoside (**4**), (−)-oleuropeic acid 1′-*O*-β-D-glucopyranosyl ester (**5**), (−)-oleuropeic acid 6′-*O*-β-D-glucopyranosyl ester (**6b**), and (−)-olivil 4-*O*-β-D-glucopyranoside (**7**) were isolated from an ethyl acetate extract. The radical scavengers found (**2**−**4** and **7**) were detected and isolated with the help of the online HPLC-DAD-DPPH/ABTS technique. Compounds **2**−**4** and **7** displayed a higher antioxidative effect against the free radical DPPH than the reference BHT and lower than hydroxytyrosol, whereas compounds **1**, **5**, **6a**, **6b**, and **8** showed no activity.

KEYWORDS: *olive tree wood, Olea europaea, agricultural byproducts, online HPLC-DAD-radical-scavenging technique, (−)-oleuropeic acid, (−)-olivil, aldehydic form of oleuropein aglycone, (+)-1-hydroxypinoresinol 1-O-β-D-glucopyranoside, (−)-oleuropeic acid 1′-O-β-D-glucopyranosyl ester, (−)-oleuropeic acid 6′-O-α-D-glucopyranosyl ester, (−)-oleuropeic acid 6′-O-β-D-glucopyranosyl ester, (−)-olivil 4-O-β-D-glucopyranoside, (−)-perillic acid 1′-O-β-D-primeverosyl ester*

INTRODUCTION

Reactive oxygen species (ROS) are widely believed to cause or aggravate several human pathologies such as neurodegenerative diseases, cancer, stroke, and many other ailments.[1] ROS are also the main factor responsible for complete spoilage of lipid-containing foods.[2] For both reasons antioxidants are of great importance nowadays in medicine and in the food industry. In the latter field, some concerns have been expressed about the safety of certain synthetic (artificial) antioxidants commonly used to preserve food, such as *tert*-butylhydroquinone (TBHQ) and *tert*-butyl-4-hydroxyanisole (BHA),[3] which has driven much attention to natural antioxidants and the search of new plant sources containing them. Thus, much work has been done to find interesting sources of potentially safe natural antioxidants in any material of vegetable origin, such as medicinal plants,[4] foods, and drinks,[5] etc., or even in agroindustrial waste materials.[6]

The olive tree (*Olea europaea* L., Oleaceae) is one the most important fruit trees in the Mediterranean countries. The chemical composition of the tree and that of olive oil has been intensively studied for years.[7−9] Among the phytochemicals reported in olive tree, the phenolic compounds constitute an interesting group whose presence has been investigated in practically all parts of the plant: fruits,[10] leaves,[11] stems,[12] bark,[13] wood,[14] stones,[15] and roots.[16] Due to the high interest of phenolic compounds for the food and pharmacy industries great efforts are also being directed toward their recovery from any byproducts and residues generated in olive oil industrial production.[17]

Olive tree wood constitutes a very important agricultural byproduct since large amounts of biomass from pruning are generated every year in all olive oil producing countries. Just in Spain more than 7 million tonnes per year are produced of this biomass, which consists mainly of wood together with leaves and small stems. Olive tree wood is an untapped resource since nowadays it is basically used for house heating in rural areas. For that reason, alternative uses for olive tree wood are being investigated such as a raw material for production of activated carbon,[18] lignin,[19] cellulose pulp,[20] and bioethanol[21] or as a fuel source.[22] However, no information is available on the antioxidant activity of the extracts obtained from this part of the olive tree, with the exception of our previous work.[14,23−25] With the help of HPLC online assay for antioxidants,[26] we detected and isolated the active components of ethyl acetate and ethanol extracts of olive tree wood:[14,24,25] oleuropein, ligustroside, hydroxytyrosol, (+)-cycloolivil, oleuropein-3″-methyl ether, (7″*R*)-7″-ethoxyoleuropein, (7″*S*)-7″-ethoxyoleuropein, (7″*S*)-7″-hydroxyoleuropein, ligustroside 3′-*O*-β-D-glucoside, oleuropein 3′-*O*-β-D-glucoside, jaspolyanoside, jaspolyoside, and isojaspolyoside A (Figure 1). In addition, during the purification work of antioxidants, other compounds which exhibited weak antioxidant activity, such as tyrosol (Figure 1), were also isolated.[24] Two of these compounds, oleuropein and (+)-cycloolivil, were included in a study to determine their

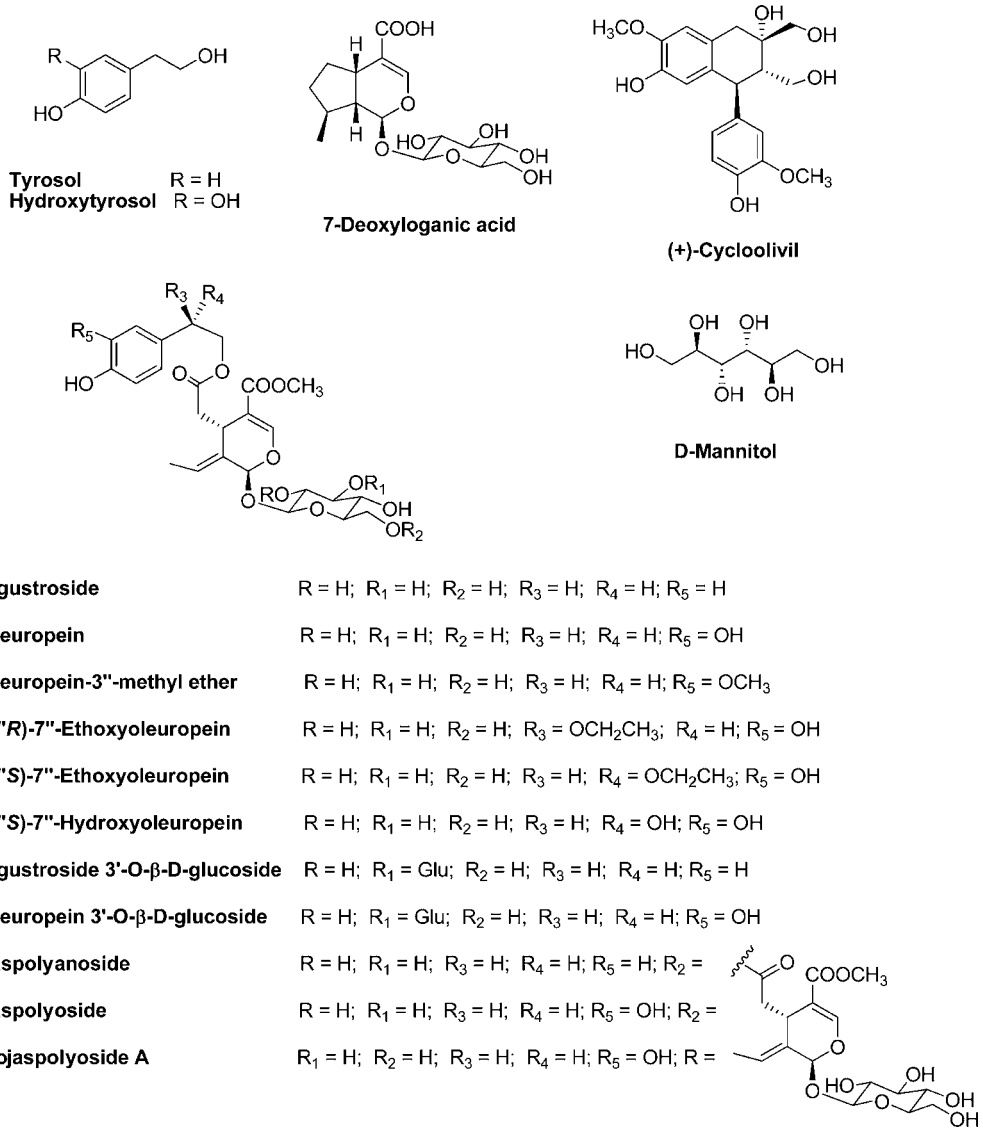

Figure 1. Compounds previously isolated from olive tree wood.[14,24,25,28]

antiplatelet aggregation properties.[27] More recently, a procedure to obtain D-mannitol and elenolic acid from olive tree wood, along with extracts enriched in antioxidants hydroxytyrosol and oleuropein, have been patented by us.[28] Similarly, further work has been reported by others on the composition and applications of fractions obtained from olive tree wood[29−32] and also from the whole byproduct obtained during pruning work on olive grooves.[33−37]

All the work developed on radical scavengers from olive tree wood extracts shows that this agricultural byproduct could become a very interesting source of natural antioxidants, as commercial olive leaf extracts already are,[38] i.e., further research is needed. Thus, in this work, an additional activity-guided isolation of antioxidants from olive tree wood and evaluation of their antioxidant activities are reported. To perform the study, the online HPLC-DAD-DPPH/ABTS technique has been used, since it has demonstrated to be a very useful tool for rapid identification of antioxidants in plant extracts, foods, and beverages.[39,40] This work complements previous studies from our laboratory to give an overall picture of the chemical constituents present in olive tree wood, a renewable source of natural antioxidants rather unknown until a few years ago.

MATERIALS AND METHODS

General Experimental Procedures. Optical rotations ($[\alpha]_D$) were recorded in methanol on a Perkin-Elmer 241 automatic polarimeter (Perkin-Elmer Instruments, Norwalk, CT, USA) in a 10 cm 2 mL cell. UV spectra were obtained in methanol on a Perkin-Elmer Lambda 19 UV/vis/NIR spectrophotometer (Perkin-Elmer Instruments, Norwalk, CT, USA). IR spectra were measured, in liquid films (neat) between KBr plates, on a Perkin-Elmer model 1760X FTIR spectrometer (Perkin-Elmer Instruments, Norwalk, CT, USA). ^{1}H (400 MHz), ^{13}C (100 MHz), and 2D NMR (500 MHz) spectra were taken on Bruker DPX 400 and Bruker AMX 500 spectrometers (Bruker Daltonik GmbH, Rheinstetten, Germany) using CD_3OD as solvent and tetramethylsilane (TMS) as internal reference. When necessary, due to small amounts of samples, NMR spectra were recorded using SHIGEMI tubes (Campro Scientific, The Netherlands) and a Zirconia zircon oxide rotor (Wilmad Labglass, USA). Mass spectra were recorded on two different mass spectrometers: (a) a Hewlett-Packard model HP 5989B mass spectrometer (Agilent Technologies, Santa Clara, CA, USA) using the electron impact ionization method (70 eV), ion source temperature of the MS unit = 250 °C, scan range from m/z 35 to m/z 400 and (b) a Finnigan MAT LCQ ion trap mass spectrometer (Waters Integrity System, Milford, MA, USA) with ESI interface used in both modes, with a capillary temperature of 200 °C and spray voltage of −4.5 kV. High-resolution

mass spectra (HRESIMS) were recorded on a Waters Micromass AutoSpec NT spectrometer (Waters Integrity System, Milford, MA, USA). Silica gel 60 (Merck), particle size 40−63 μm, was used for column chromatography. Silica gel 60 F_{254} precoated aluminum sheets (0.25 mm, Merck) were employed for thin-layer chromatography (TLC). High-performance liquid chromatography (HPLC) analyses were performed by an analytical RP-HPLC (Spherisorb ODS-2 column, 250 mm × 3 mm i.d., 5 μm, Waters Chromatography Division, Milford, MA, USA) on a Waters 600E instrument (Waters Chromatography Division, Milford, MA, USA) equipped with a diode array detector, scan range = 190−800 nm (Waters CapLC 2996 Photodiode Array Detector, Waters Chromatography Division, Milford, MA, USA), and operating at 30 °C. Samples of the extracts were prepared in MeOH at a concentration of 10 mg/mL, and the injection volume was 10 μL. The best separation was obtained with H_2O:CH_3COOH, 99.8:0.2 v/v (solvent A), and CH_3OH:CH_3COOH, 99.8:0.2, v/v (solvent B), at a flow rate of 0.7 mL/min: linear gradient from 20% to 70% B for 55 min and another 10 min to return to the initial conditions. Preparative HPLC separations were performed with a Alltima C18 column (250 mm × 22 mm i.d., 5 μm, Alltech Associates Inc., Deerfield, IL, USA) on a Shimadzu preparative HPLC instrument (Shimadzu, Kyoto, Japan) equipped with a diode array detector, scan range = 190−600 nm (SPD-M10Ap Photodiode Array Detector, Shimadzu, Kyoto, Japan), and a sample collector FRC-10A (Shimadzu, Kyoto, Japan), operating at 30 °C and a flow rate of 12 mL min^{-1}.

Chemicals. Solvents used for extraction and chromatographic separation (dichloromethane, ethyl acetate, ethanol, and chloroform) were glass distilled prior to use. Methanol used for radical-scavenging activity assays was of HPLC grade. Deuterated methanol was used to prepare solutions of purified compounds for NMR analysis. The following reagents were used for radical-scavenging assays: 2,2-diphenyl-1-picrylhydrazyl radical ($DPPH^{\bullet}$) (95%, Sigma-Aldrich Chemie, Steinheim, Germany), 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) (95%, Fluka Chemie, Buchs, Switzerland), potassium persulfate (99%, Sigma-Aldrich Chemie, Steinheim, Germany), NaCl (99%, Panreac, Barcelona, Spain), KH_2PO_4 (99.5%, Riedel de Haën, Seeize, Germany), Na_2HPO_4 (99.5%, Riedel de Haën, Seeize, Germany), KCl (99%, Panreac, Barcelona, Spain), hydroxytyrosol (Extrasynthese, Genay, France), and 2,6-di-*tert*-butyl-hydroxytoluene (BHT) (99%, Sigma-Aldrich Chemie, Steinheim, Germany).

Plant Material. The wood sample of *O. europaea* L. (Picual variety) used in this study was collected from the pruning of a tree growing near the town of Fuensanta (province of Jaén, Spain) in April 2003 and consisted of a single piece of 25 cm diameter and 70 cm length. The sample was stored for 3 months in a dry and dark place at room temperature with passive ventilation prior to extraction. Just before starting the extraction process, the wood piece was scraped in a local sawmill (wood shavings length 3−5 cm, thickness 0.1−0.3 mm).

Extraction and Prefractionation of Olive Wood Extract. Nine individual but identical batches of 250 g of wood chips (9 × 250 g) were extracted successively by maceration during 24 h at room temperature with dichloromethane (9 × 3.5 L) and then for 2 h at reflux with ethyl acetate (9 × 3.5 L). Solvents were evaporated under reduced pressure to give the corresponding dichloromethane (9.2 g) and ethyl acetate (31.2 g) extracts. An aliquot of the ethyl acetate extract (23.4 g) was chromatographed by open column chromatography on silica gel 60 (230 g, 40−63 μm) using $CHCl_3$:EtOH mixtures of increasing polarity. Fractions of 350 mL were collected, monitored by TLC, pooled, and evaporated to give 11 major fractions: C_1 (0.38 g), C_2 (2.75 g), C_3 (3.35 g), C_4 (3.17 g), C_5 (4.98 g), C_6 (4.00 g), C_7 (1.09 g), C_8 (1.17 g), C_9 (0.60 g), C_{10} (1.27 g), and C_{11} (0.20 g).

Activity-Guided Chromatographic Isolation of Antioxidants. Fractions C_1−C_{11} were assessed for their ability to scavenge the DPPH radical by the offline spectrophotometric DPPH assay (calculated as radical-scavenging percentage, RSP) according to the procedure described below. Among all these fractions, the most active ones were C_3, C_5, C_4, and C_6, with RSP values of 91.8%, 90.4%, 76.9%, and 55.6%, respectively. These active fractions were further monitored by online HPLC-DAD-DPPH/ABTS assays to detect the active components present in each fraction according to the procedure described below. Thus, analysis of fraction C_5 revealed that the active constituent was the previously isolated antioxidant oleuropein (Figure 1),[14] and analyses of fractions C_3, C_4, and C_6 showed the presence of some further minor active constituents not reported yet. Accordingly, fraction C_3 (3.3 g) was subjected to silica gel 60 (235 g, 40−63 μm) column chromatography using $CHCl_3$:EtOH mixtures of increasing polarity. Fractions of 50 mL were collected and combined on the basis of TLC into 16 fractions (C_3-I−C_3-XVI). These latter fractions were again monitored by the online assays, which allowed focusing attention

on fractions C_3-VII and C_3-X. Thus, an aliquot of fraction C_3-VII (101 mg) was further chromatographed by preparative RP-HPLC. Separation was carried out with H_2O:CH_3COOH, 99.8:0.2 v/v (solvent A), and CH_3OH:CH_3COOH, 99.8:0.2 v/v (solvent B): isocratic conditions of 25% B for 10 min and then a linear gradient from 25% to 30% B in 10 min yielded pure compound **1**: (−)-oleuropeic acid (10 mg). An aliquot of fraction C_3-X (104 mg) was further chromatographed by preparative RP-HPLC. Separation was carried out with isocratic conditions of 30% B for 25 min yielding pure compound **2**: (−)-olivil (17.3 mg). Fraction C_4 (3.0 g) was subjected to silica gel 60 (177 g, 63−200 μm) column chromatography using $CHCl_3$:EtOH mixtures of increasing polarity. Fractions of 50 mL were collected and combined on the basis of TLC into 20 fractions (C_4-I−C_4-XX). These latter fractions were again monitored by online assays. This allowed focusing attention on fraction C_4-III (10.4 mg), which was identified as pure compound **3**: the aldehydic form of oleuropein aglycone. Fraction C_6 (4.0 g) was fractionated by column chromatography over silica gel 60 (180 g, 40−63 μm) and eluted with $CHCl_3$:EtOH mixtures of increasing polarity. Fractions of 50 mL were collected and combined on the basis of TLC into 13 fractions (C_6-I−C_6-XIII). These latter fractions were again monitored by online assays. This allowed focusing attention on fractions C_6-VIII, C_6-X, and C_6-XII. An aliquot of fraction C_6-VIII (237 mg) was further chromatographed by preparative RP-HPLC. Separation was carried out with a linear gradient from 25% to 40% B in 40 min yielding pure compound **4**: (+)-1-hydroxypinoresinol 1-*O*-β-D-glucopyranoside (5.1 mg). An aliquot of fraction C_6-X (207.2 mg) was further separated by preparative RP-HPLC. Separation was carried out with H_2O:CH_3OH:CH_3COOH, 79.8:20:0.2 v/v (solvent C), and CH_3OH:CH_3COOH, 99.8:0.2 v/v (solvent B); isocratic conditions of 15% B for 5 min and then a linear gradient from 15% to 100% B in 30 min to yield pure compound **5**: (−)-oleuropeic acid 1′-*O*-β-D-glucopyranosyl ester (4.5 mg). Similarly, another aliquot of fraction C_6-X (31.4 mg) was further separated by preparative RP-HPLC with isocratic conditions of 10% B for 60 min to yield a mixture of compounds **6a** ((−)-oleuropeic acid 6′-*O*-α-D-glucopyranosyl ester) and **6b** ((−)-oleuropeic acid 6′-*O*-β-D-glucopyranosyl ester) (8.3 mg). Fraction C_6-XII (1.1 g) was chromatographed on silica gel 60 (172 g, 40−63 μm), eluting with a 90:10 EtOAc:EtOH mixture. Fractions of 30 mL were collected and combined on the basis of TLC into 13 fractions (C_6-XIIa−C_6-XIIm). These latter fractions were again monitored by online assays. This allowed focusing attention on fraction C_6-XIIj. Thus, an aliquot of fraction C_6-XIIj (214.1 mg) was further separated by preparative RP-HPLC with isocratic conditions of 15% B for 10 min and then a linear gradient from 15% to 100% B in 20 min to yield pure compound **7**: (−)-olivil 4-*O*-β-D-glucopyranoside (7.5 mg). Finally, another aliquot of fraction C_6-XIIj (91.8 mg) was further separated by preparative RP-HPLC with a linear gradient from 20% to 70% B in 55 min to yield pure compound **8**: (−)-perillic acid 1′-*O*-β-D-primeverosyl ester (3.5 mg).

Offline Spectrophotometric DPPH Assay. Radical-scavenging activity of chromatographic fractions, purified compounds, and reference compounds was determined spectrophotometrically with the stable DPPH radical.[41] Methanolic solutions (2.4 mL) of DPPH• (~7×10^{-5} M) with an absorbance at 515 nm of 0.80 ± 0.03 AU were mixed with methanolic solutions (1.2 mL) of samples at different concentrations by dissolving the dry samples in methanol. The experiment was carried out in triplicate. Samples were shaken and kept in the dark for 15 min at room temperature, and then the decrease of absorbance was measured at 515 nm.

Radical-scavenging activity of chromatographic fractions, using a concentration of 50 μg/mL, is expressed as radical-scavenging percentage (RSP) and was calculated by the following formula[41]

$$\mathrm{RSP} = \left[\frac{A_B - A_A}{A_B}\right] \times 100$$

where A_B is the absorbance of the blank (t = 0 min) and A_A is the absorbance of tested sample solution (t = 15 min).

Radical-scavenging activity of purified and reference compounds, using different concentrations (4−100 μg/mL), is expressed in terms of the antioxidant concentration (μM) required to decrease the initial DPPH• concentration by 50% (efficient concentration, EC_{50}). The percentage of DPPH• remaining, calculated by the following equation[42]

$$\%\mathrm{DPPH}_{rem} = \frac{[\mathrm{DPPH}]}{[\mathrm{DPPH}]_0} \times 100$$

where [DPPH] is the concentration of DPPH• at the time measured (t = 15 min) and $[DPPH]_0$ is the initial concentration of DPPH• (t = 0 min), was plotted against the sample concentration (μg/mL), a linear or logarithmic regression curve being established in order to calculate the EC_{50}.

Online HPLC-DAD-DPPH/ABTS Assays. Online HPLC radical-scavenging assays of the fractions from the olive tree wood ethyl acetate extract were performed to detect active compounds in complex mixtures.[39] The setup for online assessment of radical-scavenging

dx.doi.org/10.1021/jf403998t | J. Agric. Food Chem. 2014, 62, 144−151

activity consisted of an eluent pump, a photodiode array detector, and a Agilent 1100 Series controller, equipped with a C18 Waters Spherisorb S5 ODS2 (250 × 3 mm, 5 μm) analytical column. Methanolic solutions of fractions were prepared by dilution in methanol at a concentration of 10 mg/mL, and the injection volume was 10 μL. Separation was performed by a linear gradient from 20% to 70% B in 55 min, isocratic hold at 100% B for 5 min, linear gradient from 100% to 20% B in 10 min, and 10 min isocratic hold at 20% B for re-equilibration of the column. After HPLC separation and UV detection, the flow was mixed with a methanolic DPPH$^{\bullet}$ solution or an ABTS$^{\bullet+}$ solution in PBS.[43] Radical solutions were delivered using a Gilson model 302 pump at 0.5 mL/min for both DPPH$^{\bullet}$ and ABTS$^{\bullet+}$ solutions. The reaction between separated compounds and radicals took place in a 3.5 m × 0.25 mm i.d. PEEK reaction coil. The decrease in absorbance was measured at 515 nm for DPPH$^{\bullet}$ and at 414 nm for ABTS$^{\bullet+}$ in an Applied Biosystems UV/vis 759A spectrophotometer equipped with a tungsten lamp.

RESULTS AND DISCUSSION

Isolation of Compounds from the Olive Wood Extract. Olive wood chips were sequentially extracted with dichloromethane and ethyl acetate at room temperature and under reflux conditions, respectively. Dichloromethane extraction (0.4% yield) allowed removing the nonpolar components, which showed low antioxidant activity.[25] The resulting ethyl acetate extract (1.4% yield) was prefractionated by open column chromatography on silica gel, yielding 11 major fractions (C_1−C_{11}). These fractions were assessed for their ability to scavenge the DPPH radical by offline spectrophotometric measurements. This approach was chosen because it is generally known that lipid oxidation is initiated by a free radical attack and due to their simplicity and worldwide acceptance for comparative purposes. Among all these fractions, in terms of DPPH radical-scavenging percentages (RSP), the most active fractions were, in this order, C_3 (14.3% yield), C_5 (21.3% yield), C_4 (13.5% yield), and C_6 (17.1% yield). These active fractions were further monitored by online HPLC-DAD-DPPH/ABTS assays to detect the active components present in each fraction.[14] After a combination of conventional silica gel column chromatography and preparative RP-HPLC the following antioxidants were finally isolated: (−)-olivil (**2**), the aldehydic form of oleuropein aglycone (**3**), (+)-1-hydroxypinoresinol 1-*O*-*β*-D-glucopyranoside (**4**), and (−)-olivil 4-*O*-*β*-D-glucopyranoside (**7**) (Figure 2). In addition, during the purification work of antioxidants, several nonactive compounds, such as (−)-oleuropeic acid (**1**), (−)-oleuropeic acid 1′-*O*-*β*-D-glucopyranosyl ester (**5**), (−)-oleuropeic acid 6′-*O*-*α*-D-glucopyranosyl ester (**6a**), (−)-oleuropeic acid 6′-*O*-*β*-D-glucopyranosyl ester (**6b**), and (−)-perillic acid 1′-*O*-*β*-D-primeverosyl ester (**8**) (Figure 2), were also isolated.

Structure Elucidation of the Isolated Compounds. Compounds **1**−**8** were characterized and identified by UV, IR, MS, HRMS, ^{1}H NMR, ^{13}C NMR, 2D NMR, and specific optical rotation measurements. Spectral and physical data of compounds **1**−**5**, **6b**, and **7** are in agreement with earlier published data: (−)-oleuropeic acid (**1**),[44] (−)-olivil (**2**),[45] the aldehydic form of oleuropein aglycone (**3**),[46] (+)-1-hydroxypinoresinol 1-*O*-*β*-D-glucopyranoside (**4**),[13] (−)-oleuropeic acid 1′-*O*-*β*-D-glucopyranosyl ester (**5**),[44] (−)-oleuropeic acid 6′-*O*-*β*-D-glucopyranosyl ester (**6b**),[44] and (−)-olivil 4-*O*-*β*-D-glucopyranoside (**7**) (Figure 2).[47] Compounds **2**−**4** and **7** have been reported before from other parts of the olive tree. Compounds **1**, **5**, and **6b** have been previously found in the leaves of *Cunila spicata* L.[44] esterified with acylated glucose,

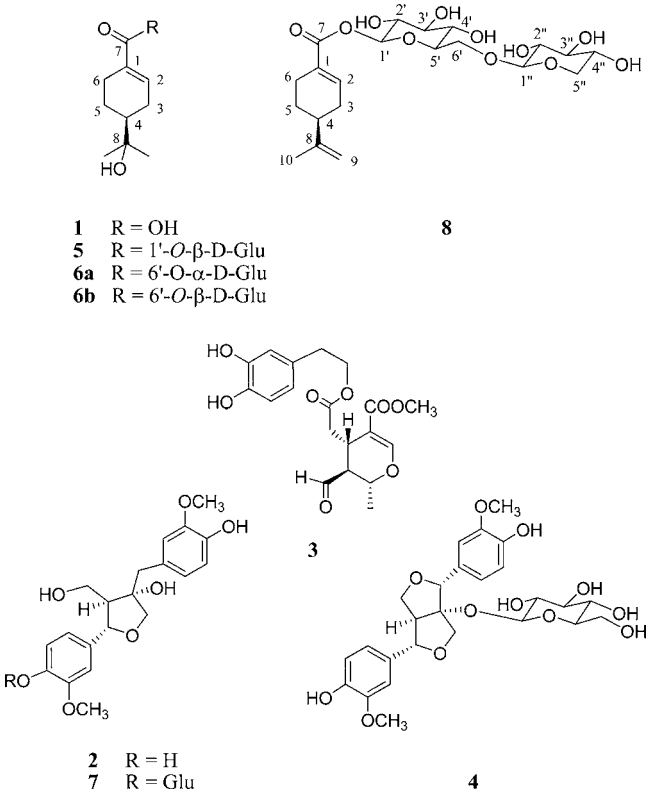

Figure 2. Compounds isolated in this work from an olive tree wood EtOAc extract.

while the methyl ester of compound **1** has been also isolated from *Eucalyptus cypellocarpa* leaves.[48]

Compounds **6a** and **6b** were assigned a molecular formula of $C_{16}H_{26}O_8$ by HRESIMS. They are anomeric glucosides, and their ^{1}H NMR spectrum showed, apart from signals corresponding to two monoterpene aglycone units, similar to that of compound **1**, a set of signals assignable to two glucose moieties; one anomeric proton is centered at 4.44 ppm (1H, d, 7.8 Hz), consistent with the configuration for a *β*-D-glucopyranosyl group, while the other is centered at 5.03 ppm (1H, d, 3.7 Hz), consistent with the configuration for an *α*-D-glucopyranosyl group (Table 1). In the HMBC spectrum, cross peaks between the proton signals H-6′a and H-6′b and the carbon C-7 indicate the linkage of the monoterpene residues and the glucose units. Further cross peaks between the proton signal at *δ* 5.03 (H-1′), from the *α* anomer, and the carbons at *δ* 74.8 (C-3′) and 70.8 (C-5′) and between the proton signal at *δ* 4.44 (H-1′), from the *β* anomer, and the carbons at *δ* 77.9 (C-2′), 76.2 (C-3′), and 75.4 (C-5′) allowed us to assign ^{13}C peaks for each anomer. Accordingly, the structure of compound **6a** was determined to be (−)-oleuropeic acid 6′-*O*-*α*-D-glucopyranosyl ester, while **6b** was determined to be (−)-oleuropeic acid 6′-*O*-*β*-D-glucopyranosyl ester (Figure 2). Integration of anomeric protons in the ^{1}H NMR spectrum indicated an equilibrium mixture of anomers, **6a** and **6b**, with a ratio of 1:1.

Compound **8** was assigned a molecular formula of $C_{21}H_{32}O_{11}$ by HRESIMS. The ^{1}H NMR spectrum (Table 2) showed signals of an isopropenyl moiety [*δ* 1.75 (3H, s), 4.73 (1H, s), and 4.76 (1H, s)], an olefinic proton [*δ* 7.14 (1H, br s)], three methylene groups [*δ* 1.44−2.49 (6H, m)], and a methyne group [*δ* 2.34−2.49 (1H, m)], corresponding to a mono-

dx.doi.org/10.1021/jf403998t | J. Agric. Food Chem. 2014, 62, 144−151

terpene aglycone unit. Additionally, a set of signals assignable to two sugar moieties was observed; one anomeric proton is centered at 4.27 ppm (1H, d, 7.5 Hz), while the other is centered at 5.49 ppm (1H, d, 7.5 Hz), indicating the β configuration for both sugar units. The ^{13}C NMR spectrum showed the presence of an isopropenyl group (a methyl [δ 20.87 (C-10)], a terminal methylene [δ 109.79 (C-9)], and a quaternary carbon [δ 150.02 (C-8)]), three methylene groups [δ 25.41 (C-6), 28.18 (C-5), and 32.27 (C-3)], a methyne carbon [δ 41.36 (C-4)], two olefinic carbons [δ 130.51 (C-1) and 142.50 (C-2)], and a quaternary carbon of an α,β-unsaturated ester [167.26 (C-7)]. The ^{13}C NMR spectrum also showed 11 signals in the sugar region, two of them being anomeric carbons [δ 95.74 (C-1′) and 105.14 (C-1″)]. The two sugars were identified as glucose and xylose. In the HMBC spectrum, cross peaks between the proton signals at δ 5.49 (H-1′) and the carbon at δ 167.26 (C-7) indicate the linkage between the monoterpene residue and the glucose unit. Similarly, cross peaks between the proton signal at δ 4.27 (H-1″) and the carbon at δ 69.42 (C-6′) and between the protons at δ 4.08 (H-6′a) and δ 3.70 (H-6′b) with the carbon at δ 105.14 (C-1″) showed the linkage between the xylose and the glucose units. A glucose and xylose moiety linked via C-6′ → C-1″ is known as the disaccharide primeverose. This linkage explained the upfield shifts observed for the glucose carbons C-1′, C-2′, and C-5′ and the downfield shifts for carbon C-6′. Accordingly, the structure of compound **8** was determined to be (−)-perillic acid 1′-*O*-β-D-primeverosyl ester, which is a new natural product (Figure 2).

Radical-Scavenging Activity of the Isolated Antioxidants. The antioxidant activity of the isolated compounds from olive tree wood was determined with the DPPH radical-scavenging assay and expressed in terms of the antioxidant concentration (μM) required to reduce the initial DPPH$^{\bullet}$ concentration after 15 min by 50% (efficient concentration, EC_{50}). In Table 3, EC_{50} values for the active compounds **2**−**4** and **7** and the reference compounds BHT and hydroxytyrosol are presented as the average of three replicates. The activities of compounds **2**−**4** and **7** were higher than that of reference BHT (505 μM) and lower than that of hydroxytyrosol (39 μM), which was the most active component identified in olive tree wood together to oleuropein (32 μM).[27] Hydroxytyrosol is more active than tyrosol (826 μM),[24] which could be related to the stabilization by delocalization of the *o*-diphenolic moiety present in hydroxytyrosol, since *o*-quinone formation is favored. Thus, the aldehydic form of oleuropein aglycone (**3**) exhibited marked activity; its efficient concentration (45 μM) was just somewhat lower than that of oleuropein (32 μM) and higher than those observed for other secoiridoids, such as jaspolyoside (55 μM), oleuropein 3′-*O*-β-D-glucoside (66 μM), isojaspolyoside A (108 μM), 7″*S*-hydroxyoleuropein (113 μM), oleuropein-3″-methyl ether (170 μM), ligustroside (233 μM), ligustroside 3′-*O*-β-D-glucoside (290 μM), and jaspolyanoside (847 μM), and iridoids, such as 7-deoxyloganic acid (742 μM).[14,27] The lignans (−)-olivil (**2**), (+)-1-hydroxypinoresinol 1-*O*-β-D-glucopyranoside (**4**), and (−)-olivil 4-*O*-β-D-glucopyranoside (**7**) showed EC_{50} values of 176, 164, and 134 μM, respectively. These activities are lower than that observed for lignan (+)-cycloolivil (90 μM).[27] Monoterpenoids **1**, **5**, **6a**, **6b**, and **8** did not show any antioxidant activity.

Table 3. DPPH Radical-Scavenging Activity of the Isolated Active Compounds from Olive Wood Ethyl Acetate Extract, Expressed as Efficient Concentration (EC_{50})

compounds	EC_{50} (μM)[a]
hydroxytyrosol	39
aldehydic form of oleuropein aglycone (**3**)	45
(−)-olivil 4-*O*-β-D-glucopyranoside (**7**)	134
(+)-1-hydroxypinoresinol 1-*O*-β-D-glucopyranoside (**4**)	164
(−)-olivil (**2**)	176
BHT[b]	505

[a] EC_{50} values are means of three replicates, and the RSD is less than 1%. [b] 2,6-Di-*tert*-butyl-4-methylphenol.

In summay, this work completes previous studies on the composition of an ethyl acetate extract from olive tree wood,[14,24,25] as well as their antioxidant activity. On the basis of their chemical structures, the 25 compounds isolated from olive tree wood can be classified into various phytochemical subclasses including simple phenols [hydroxytyrosol, tyrosol], monoterpenoids [(−)-oleuropeic acid (**1**), (−)-oleuropeic acid 1′-*O*-β-D-glucopyranosyl ester (**5**), (−)-oleuropeic acid 6′-*O*-α-D-glucopyranosyl ester (**6a**), (−)-oleuropeic acid 6′-*O*-β-D-glucopyranosyl ester (**6b**), and (−)-perillic acid 1′-*O*-β-D-primeverosyl ester (**8**)], lignans [(+)-cycloolivil, (−)-olivil (**2**), (+)-1-hydroxypinoresinol 1-*O*-β-D-glucopyranoside (**4**), and (−)-olivil 4-*O*-β-D-glucopyranoside (**7**)], iridoids [7-deoxyloganic acid], secoiridoids [ligustroside, oleuropein, the aldehydic form of oleuropein aglycone (**3**), oleuropein-3″-methyl ether, (7″*R*)-7″-ethoxyoleuropein, (7″*S*)-7″-ethoxyoleuropein, (7″*S*)-7″-hydroxyoleuropein, ligustroside 3′-*O*-β-D-glucoside, oleuropein 3′-*O*-β-D-glucoside, jaspolyanoside, jaspolyoside, and isojaspolyoside A], and a sugar alcohol [D-mannitol]. The results obtained here complete the current knowledge of olive tree wood composition and confirm that this agricultural byproduct contains diverse phytochemicals, among which secoiridoids predominate, which in turn could offer interesting potential applications in the food, cosmetic, and pharmaceutical industries.

Identification of IgE-Binding Peptides in Hen Egg Ovalbumin Digested in Vitro with Human and Simulated Gastroduodenal Fluids

Sara Benedé, Iván López-Expósito, Rosina López-Fandiño, and Elena Molina*

Instituto de Investigación en Ciencias de la Alimentación (CIAL), CSIC-UAM, Nicolás Cabrera 9, 28049 Madrid, Spain

Supporting Information

ABSTRACT: The digestibility of the major egg allergen ovalbumin (OVA, Gal d 2) with human and simulated digestive fluids was assessed. Degradation of OVA was faster when treated with human fluids, particularly following duodenal digestion, leading to gastrointestinal digests with lower IgE binding. Gastric digestion with both systems yielded 52 identical cleavage sites and a similar peptide pattern with 47 peptides in common. Subsequent duodenal digestion showed that the human fluid released fewer and shorter peptides. Several high-frequency IgE-binding epitopes were detected among the fragments of molecular mass lower than 3 kDa identified in the digests: OVA (141−154) and OVA (164−176) in the gastrointestinal digests produced with human fluids; and OVA (125−134), OVA (159−172), OVA (141−154), OVA (188−198), OVA (326−336), and OVA (370−385) in the gastrointestinal digests produced with simulated fluids. The high binding frequency of the fragment OVA (370−385), which reacted with 80% of the sera from allergic patients used, was noteworthy.

KEYWORDS: *egg allergy, ovalbumin, in vitro digestion, human digestive fluids, IgE, epitope*

INTRODUCTION

Egg allergy is one of the most frequent food allergies in children below the age of three, with common symptoms frequently involving the skin as well as the gut and, in more severe cases, anaphylaxis.[1] A meta-analysis of double-blind placebo-controlled food challenges confirmed a prevalence of >1.7%,[2] with most children not outgrowing their egg allergy by school age but, instead, showing a long progression to egg allergy resolution.[3]

Ovalbumin (OVA, Gal d 2), the most abundant protein in egg white (up to 54% w/w of the protein content), is considered one of the dominant allergens.[4] It is a phosphoglycoprotein with a molecular mass of 45 kDa, the sequence of which (with 385 amino acids) includes six cysteines, with a single disulfide bond between Cys_{73} and Cys_{120}, a glycosylation site at Asn_{292}, and two phosphorylation sites at Ser_{68} and Ser_{344}. As many other allergenic proteins, OVA partially resists hydrolysis with pepsin and pancreatic enzymes, an aspect that could contribute to its ability to sensitize or elicit allergic reactions.[5]

So far, studies investigating the gastrointestinal stability of OVA have been performed in vitro by the use of enzymes of bovine or porcine origin as part of different digestion models, ranging from simple one-step hydrolyses[6,7] to advanced physiologically relevant systems in which subsequent gastric and duodenal digestions are conducted under conditions that mimic the in vivo processes in infants and adults.[8,9] These latter studies have highlighted the effects that the enzyme to substrate ratio, pH, and concentration of physiological surfactants, such as phospatidylcholine and bile salts, exert on the gastrointestinal stability of OVA and their influence in the resulting immunoreactivity of the digests. However, these relevant parameters regarding digestion, such as enzyme activity, volume of digestive juices secreted, pH, or surfactant level, vary widely among individuals and also with the type and amount of food ingested and the time of the day, making in vivo conditions very difficult to simulate.[10] In addition, human gastrointestinal juices contain complex mixtures of enzymes, which could present either broader or different specificities or vary in their functional parameters with respect to purified commercial enzymes from animal sources.[11] In the present work, the digestibility of OVA using human gastric and duodenal juices was assessed, the peptides released were characterized, and the IgE-binding properties of the most relevant digestion products were evaluated. Digestions were also conducted with simulated fluids for comparative purposes. This allowed the identification of relevant IgE-binding epitopes that resisted digestion in both systems and could contribute to the allergenic potential of the protein.

MATERIALS AND METHODS

Human Digestive Fluids. Human gastric and duodenal fluids were collected by gastroscopy of four different patients without any gastrointestinal pathology at the Hospital Universitario La Paz (Madrid, Spain) after 8 h of fasting. Gastric and duodenal fluids were separately pooled and frozen at −20 °C before use. Pepsin activity of the pooled gastric fluid (pH 2.13) was 728.9 U/mL. Trypsin and chymotrypsin activities of the duodenal fluid (pH 7.8) were 167.2 and 2.8 U/mL, respectively, with a bile salt concentration of 0.7 mM.[12]

Human Sera. Individual serum samples from 22 children with proven allergy to egg white proteins were kindly donated by the Hospital Infanta Sofía (San Sebastián de los Reyes, Madrid, Spain). The diagnosis of IgE-mediated egg allergy was made on the basis of objective symptoms of an acute reaction after egg ingestion, together with evidence of specific IgE antibodies against egg (Table S1 in the

Electrophoresis was performed using Bis-Tris 12% acrylamide gel with reducing agents. Lanes: M, molecular mass marker (Precision Plus Protein standards (Bio Rad), ranging in molecular mass from 10 to 250 kDa; 1, OVA; 2, 60 min gastric digest; 3, gastroduodenal digest (60 min of gastric followed by 30 min of duodenal digestion); 4, gastroduodenal digest (60 min of gastric followed by 60 min of duodenal digestion). ∗, IgE-binding fragment originally present in the human duodenal fluid.

Supporting Information). Serum samples from two nonallergic donors were also used.

In Vitro Digestions. In vitro gastric and duodenal digestions with simulated fluids, based upon the procedure described by Moreno et al.,[13] were performed as described in Benedé et al.,[12] using albumin (EC232-692-7) from chicken egg white grade V (Sigma-Aldrich, St. Louis, MO, USA). Gastric digestions were conducted at pH 2.0 for 60 min at 37 °C, with 182 U/mg OVA of porcine pepsin. Duodenal digestions were conducted on the 60 min gastric digests, readjusted to pH 6.5, and stopped after either 30 or 60 min at 37 °C with Bowman−Birk trypsin−chymotrypsin inhibitor. The final composition of the simulated duodenal mixture was 3.9 mg/mL OVA, 3.3 mg/mL phosphatidylcholine, 7.4 mM bile salts (BS; sodium glycodeoxycholate and sodium taurocholate), 7.6 mM $CaCl_2$, and 20.3 mM Bis-Tris, with pancreatic porcine lipase (24.7 U/mg OVA), pancreatic porcine colipase (1:895 mg/mg OVA), pancreatic bovine trypsin (34.5 U/mg OVA), and pancreatic bovine α-chymotrypsin (0.44 U/mg OVA), all from Sigma-Aldrich.

In vitro protein digestion with human fluids, mimicking gastric and duodenal phases, followed the method of Benedé et al.[12] OVA was mixed with the pool of human gastric fluids at pH 2.1 at a pepsin to OVA ratio of 182 U/mg. After 1 h of incubation at 37 °C, the pH was adjusted to pH 6.5 with 1 M $NaHCO_3$, and the pool of human duodenal fluids was added, so that the enzyme to substrate ratio was 34.5 U/mg trypsin and 0.49 U/mg chymotrypsin. The reaction was stopped after 30 and 60 min with Bowman−Birk trypsin−chymotrypsin inhibitor.

SDS-PAGE Analyses. OVA and its hydrolysates were diluted to 1 mg/mL in sample buffer containing 2% (w/v) SDS and 5% (v/v) β-mercaptoethanol and heated at 95 °C for 4 min. Samples were analyzed on Precast Criterion XT 12% Bis-Tris gels, and electrophoretic separations were carried out at 150 V using XT-MES as running buffer (Bio-Rad, Richmond, CA, USA) in the Criterion cell (Bio-Rad). Gels were stained with Bio-Safe Coomassie G-250 (Bio-Rad).

Western Blotting. After SDS-PAGE separation, the gels (loaded with 50 μL of a 1 mg/mL sample solution) were soaked in transfer buffer (48 mM Tris, 39 mM glycine, 20% methanol, pH 9.2) for 20 min and subjected to semidry transfer in a Trans-Blot SD (Bio-Rad) for 30 min at 18 V. Transfer effectiveness to the membrane was assessed by staining with Ponceau reagent. Western blotting was conducted as explained in Benedé et al.,[12] using pooled sera from six children with egg allergy (patients 7−12, Table S1 in the Supporting Information), diluted 1/50 in Tris buffer saline (50 mM Tris, 150 mM NaCl, pH 7.6, TBS), containing Tween 20 (0.05% v/v) (TBTS) and BSA 0.1% (w/v).

Human IgE Binding by Inhibition ELISA. Human IgE binding of OVA and its digests was assessed by inhibition ELISA as previously reported Jiménez-Saiz et al.,[14] using individual sera from patients 1−6 (Table S1 in the Supporting Information).

Peptide Sequencing by RP-HPLC-MS/MS. RP-HPLC-MS/MS analyses of the digested samples were performed as described in Benedé et al. on an Agilent 1100 HPLC System (Agilent Technologies, Waldbron, Germany) with an RP318 C18 column (250 × 4.6 mm, Bio-Rad). The HPLC system was connected online to an Esquire 3000 quadrupole ion trap (Bruker Daltonik, Bremen, Germany) equipped with an electrospray ionization source. Mass spectra were recorded over the range of m/z 100−3000 for MS spectra. Tandem MS was applied by using a signal threshold of 10000, a window width of 4.0 m/z, and a voltage ramp from 0.3 to 2 V. Using Data Analysis (version 4.0, Bruker), the m/z spectral data were processed and transformed to spectra representing mass values. BioTools (version 3.1, Bruker) was used to process the MS(n) spectra and perform peptide sequencing.

Dot-Blot. Twenty-seven peptides representative of those identified in the in vitro gastroduodenal digests were commercially synthesized (JPT peptide Technologies, Berlin, Germany). Among the peptides selected, those with 8 and 9 amino acids were extended to 10 amino acids with the preceding and following amino acids of the protein chain. Peptides, at a concentration of 1 mM, were diluted 1/3 in TBS. Then, 1 μL of each peptide was spotted onto the membrane and allowed to dry.

The nitrocelullose membranes were conditioned in transfer buffer for 20 min, and 1 μL from each peptide was spotted onto the membrane and allowed to dry. Then, the nitrocellulose membranes were blocked with TBST containing 1% w/v BSA for 60 min and washed with TBST. Immunolabeling with 10 individual serum samples (patients 13−22, Table S1 in the Supporting Information) was conducted as described for the Western blotting experiments.

Ethical Concerns. All human samples in this study have been obtained with written consent of the subjects. The researchers involved in the process handled and used such material sensitively and responsibly. All procedures received ethical approval by CSIC.

RESULTS

In Vitro Digestion of Ovalbumin with Human and Simulated Fluids. Figure 1 shows the SDS-PAGE patterns (Figure 1a,c) and Western blots (Figure 1b,d) of OVA, after being subjected to two-step digestion protocols, mimicking the stomach and duodenal stages, by using human and simulated fluids. In general terms, after 60 min of incubation with human gastric fluid a remarkable amount of OVA remained undigested, whereas the intact protein virtually disappeared following the subsequent duodenal phase (Figure 1a). Gastric and, particularly, duodenal hydrolyses were much faster with

human fluids as compared with simulated fluids, with the appearance of more degradation products after the gastric phase, of ~40, 22, 18, 13, and 5 kDa, and fewer degradation products, within the range from ~25 to 5 kDa, after the duodenal phase (Figure 1a,c). As a result, there was less IgE binding from intact OVA and its 40 kDa fragment following gastroduodenal digestion with human fluids. Remarkably, a strong IgE-binding band of ~21 kDa, which formed during duodenal digestion with simulated fluid, was absent from the corresponding digests produced with human fluid, which, in turn, yielded lower molecular mass immunoreactive degradation products (Figure 1b,d). It should be mentioned that no differences in the degradation patterns were detected when 30 and 60 min of duodenal digestion were compared with either system.

In consonance with these results, inhibition ELISA (Figure 2) showed that the gastric and gastroduodenal digests produced

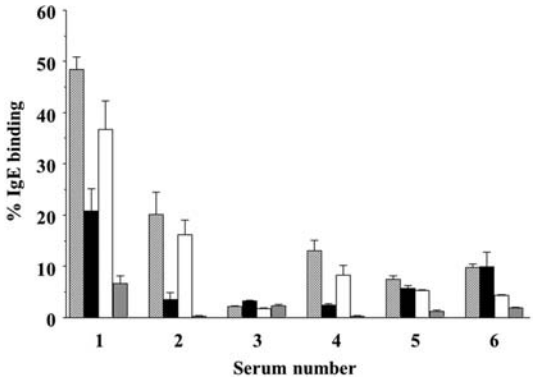

Figure 2. IgE binding of OVA, expressed as percentage of the EC_{50} of the intact protein, as estimated by inhibition ELISA with sera from six allergic patients (patients 1–6, Table S1 in the Supporting Information), after in vitro gastric digestion with simulated (gray dotted bars) and human (black bars) fluids and gastroduodenal digestion with simulated (white bars) and human (gray bars) fluids.

with human fluids exhibited the lowest IgE binding to three individual sera from egg-allergic patients (patients 1, 2, 4, and 5, Table S1 in the Supporting Information). With another two sera (patients 3 and 6, Table S1 in the Supporting Information), IgE reactivities toward the gastric digests produced by both systems were very similar, although the lowest IgE binding always corresponded to the human gastroduodenal digests. No IgE binding to sera from non-allergic donors was detected.

Identification of IgE-Binding Epitopes. Figure 3 shows the sequences of the peptides identified by RP-HPLC/MS-MS in the gastric (60 min) and gastroduodenal (30 min) digests of OVA. No peptides covering the first 50 amino acids of the protein sequence were found in either model. Following gastric digestion with human and simulated fluids, 84 and 118 peptides were identified, respectively, with 47 peptides in common. There were 52 identical pepsin cleavage sites in both systems, including Leu (83, 105, 114, 124, 183, 216, 232, 242, 252, 255, 282, 312, 321, and 365), Glu (70, 108, 143, 202, 248, 266, 274, 336, 340, and 357), Phe (59, 99, 134, 198, 217, and 261), Ala (141, 171, 177, 187, 195, 332, and 345), Met (210, 211, 222, 239, and 241), and Gln (89, 140, 203, and 325). Eighty-one of the 118 sequences identified after gastric hydrolysis with simulated fluid resisted subsequent duodenal hydrolysis, appearing as end products of digestion. Most of the remaining peptides found in the duodenal digests produced with simulated fluid could be products of hydrolysis of the low molecular mass peptides previously released by pepsin action, except for the C-terminal sequence HIATNAVLFFGRCVS, resulting from the trypsin cleavage at Lys369. In addition, in this digestion system, breakdown at the trypsin cleavage sites Lys (55, 92, 226, 228, 277, 279, 286, and 322) and Arg (50, 84, 104, 142, 158, and 276) was detected. Only 47 peptides were identified after gastrointestinal digestion with human fluids. In this case, there were several fragments that could not arise from the peptides previously identified after gastric digestion and, thus, they could derive from the hydrolysis of either intact OVA or the big proteolysis fragments that resisted pepsin hydrolysis. Only six peptides were coincident with those produced with simulated duodenal fluid and, in general terms, the human fluid gave rise to less numerous and shorter peptides. Hydrolysis by trypsin at Lys290 and Arg (50, 158, 284, and 359) was detected (Figure 3 and Table S2 in the Supporting Information).

Twenty-seven peptides, ranging from 10 to 16 amino acids, representative of those found in the gastroduodenal digests with simulated and human fluids were chemically synthesized, and their IgE binding to 10 individual sera from egg-allergic patients was assessed by dot-blot. As shown in Figure 3, all peptides were recognized by, at least, one serum, except for two fragments, OVA (299–308) and (351–360), which did not react with any of the patient's sera employed in the study. A high IgE binding corresponded to the region comprised between positions 125 and 176, because 40–60% of the patients reacted to the synthetic peptides OVA (125–134), OVA (135–144), OVA (141–154), OVA (159–172), and OVA (164–176). The fragments OVA (188–198) and OVA (326–336) were recognized by sera from 60 and 50% of the patients, respectively. The highest IgE binding corresponded to the C-terminal fragment OVA (370–385), which reacted with 80% of the sera.

DISCUSSION

Proteolyses of OVA with human and simulated digestive fluids were compared. The results obtained with simulated gastric fluid agree with previously published information showing that OVA is quite stable to porcine pepsin at an E:S ratio of 182 U/mg and pH 2.0.[9] A digestion pattern with two main degradation products, of 40.1 and 4.1 kDa, has been described,[7,15,16] the first one probably corresponding to the fragment Ala23–Pro385.[9] Moreover, Dupont et al.,[8] using a gastric model under similar conditions (E:S 182 U/mg, pH 2.5) reported, in addition to smaller peptides of ~5400 and 4600 Da, the appearance of digestion products of ~21700 and 17800 Da, which are analogous to those found in the gastric digests produced with human fluid in the present study (Figure 1a). In any case, and although there was intact protein remaining after the gastric phase in both systems, degradation of OVA was faster when digested with human than with simulated fluid (Figure 1a,c), an aspect that was already observed with β-CN.[12] This suggests a more efficient performance of pepsin of human origin despite specificity being similar, as judged by the existence of 52 identical cleavage sites and a similar peptide pattern with 47 peptides in common (Figure 3 and Table S2 in the Supporting Information). It is noteworthy that the in vitro digestion with human gastric juice released peptides with antihypertensive activity that either act as inhibitors of angiotensin-I-converting enzyme or exert a vasodilator action, such as FRADHPFL, YAEERYPIL, YRGGLEPINF, ESSINF, or YQIGL, which were

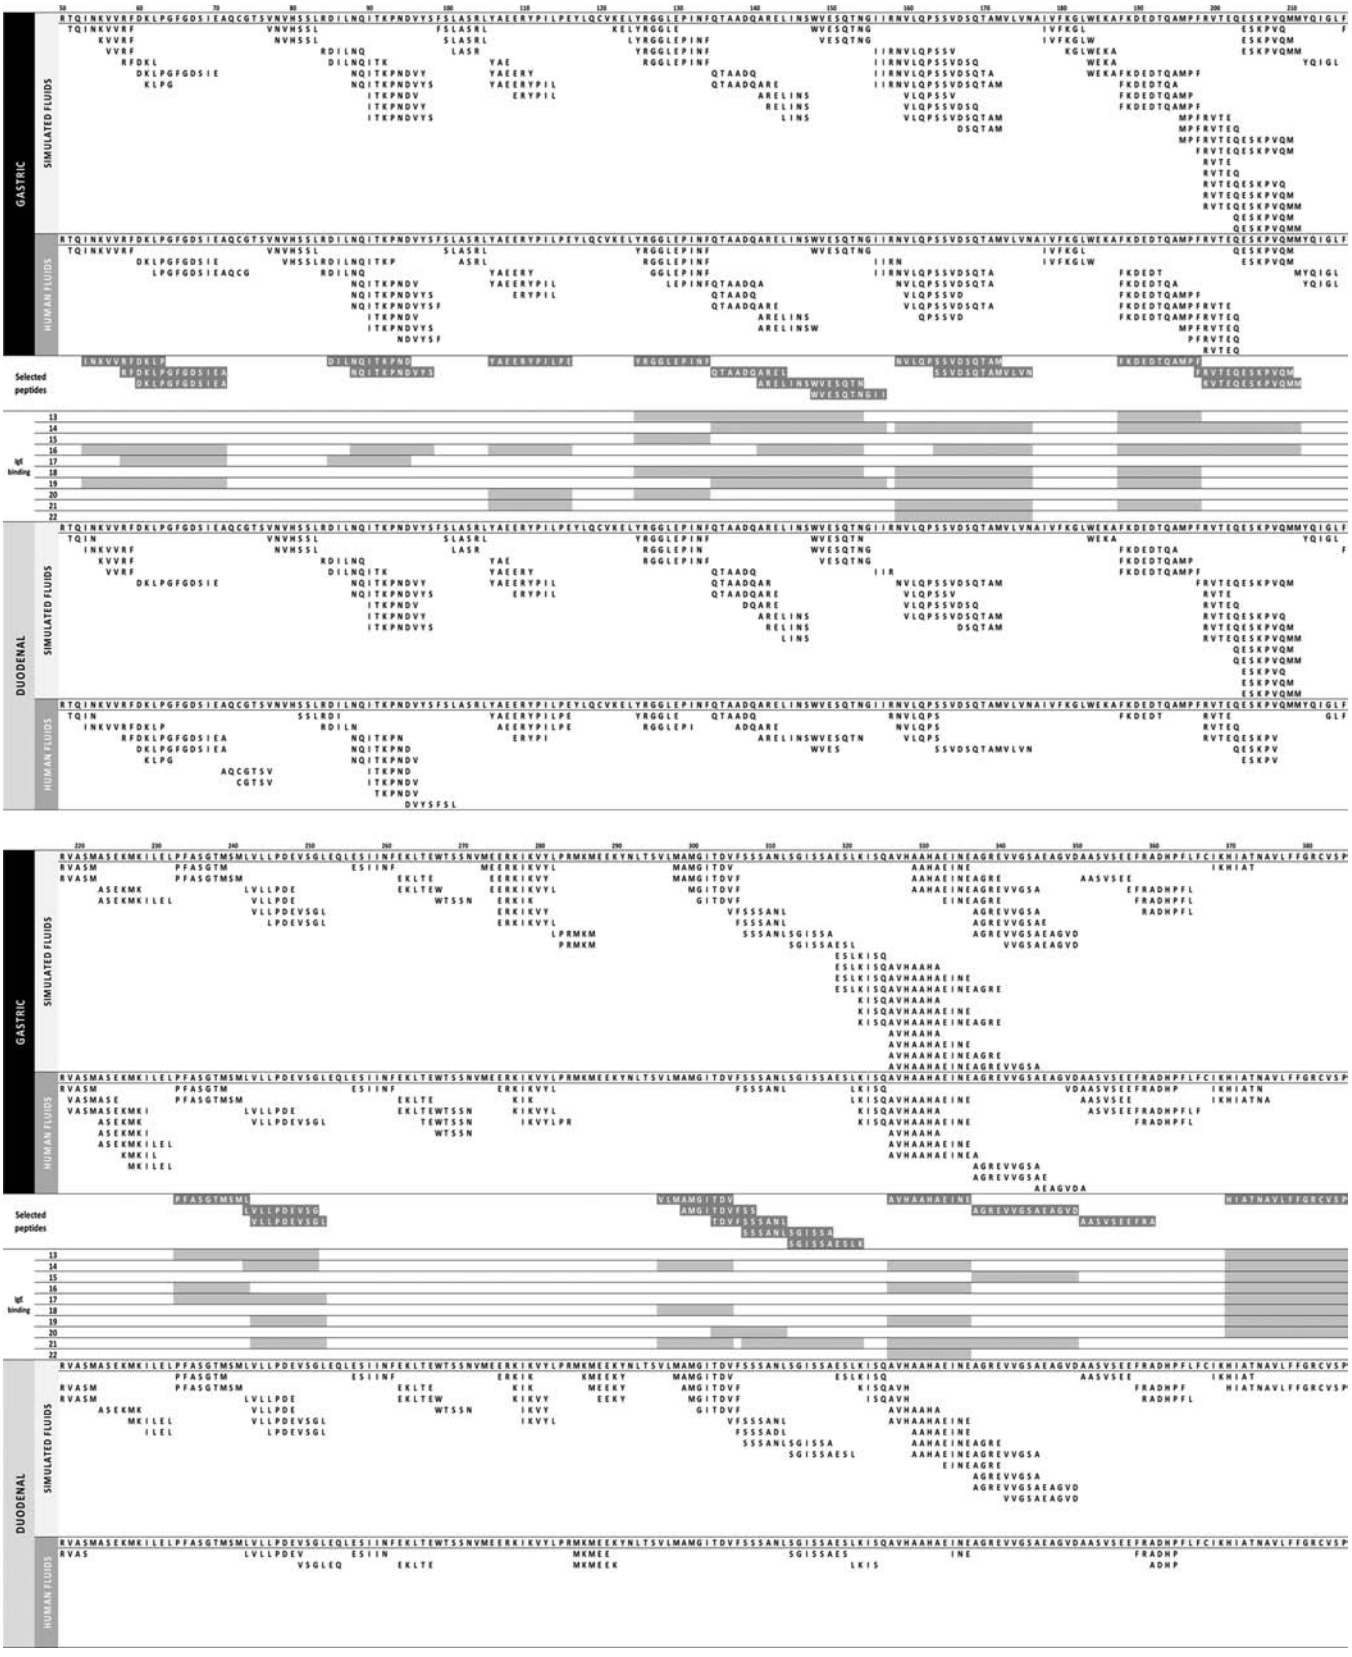

Figure 3. Peptide sequences, identified by RP-HPLC-MS/MS, in the gastric (60 min) and subsequent duodenal digests of OVA (60 min of gastric followed by 30 min of duodenal digestion), and IgE binding, estimated by dot-blot with 10 sera of egg-allergic patients (patients 13−22, Table S1 in the Supporting Information), of 27 synthetic peptides selected within the peptides identified in the simulated digestions.

previously produced from OVA by hydrolysis with porcine pepsin for 3 h and also appeared in the hydrolysates produced with simulated fluid.[17,18]

Following in vitro duodenal hydrolysis with trypsin (E:S 40 U/mg) and chymotrypsin (E:S 0.5 U/mg), the appearance of digestion products of ~20700, 17000, 12500, 10400, and 6500 Da has been described,[8] which could coincide with those formed during duodenal digestion with the simulated fluid in our study (Figure 1c). These degradation products were absent from the gastroduodenal digests produced with human duodenal fluid (Figure 1a), as this caused a much more extensive proteolysis of the gastric digests than the simulated fluid. A difference between both duodenal digestion systems laid in the concentration of BS, which was much lower in the pool of human fluids, probably due to the prolonged fasting that preceded their extraction. It has been found that BS, at the concentration present in the simulated duodenal fluid, which is typical of a fed state, considerably increase the proteolysis of OVA by pancreatic enzymes.[9] However, despite the lower concentration of bile acids in the human duodenal fluid, it promoted very effectively the proteolysis of intact OVA and of the peptides generated from it by pepsin hydrolysis. This could be attributed to differences in the specificity between human trypsin and α-chymotrypsin and their bovine counterparts, as well as to the presence of peptidases in the human pancreatic extracts.[19] In fact, it has been reported that intact OVA and its 40 kDa fragment partially resist hydrolysis by porcine trypsin and chymotrypsin, but they are more readily degraded by an enzyme preparation from the pig pancreas gland that, in addition to both proteases, contains amino and carboxypeptidases.[9] Furthermore, comparison of the peptide patterns produced by both systems showed that in vitro gastroduodenal digestion with human fluids released fewer and shorter peptides, revealing a most extensive liberation of free amino acids from the short fragments previously formed during the gastric phase (Figure 3 and Table S2 in the Supporting Information).

In accordance with the least extensive proteolytic degradation and although there were, as expected, differences in donor's specificity,[20] inhibition ELISA with individual sera from allergic patients revealed a comparatively higher IgE reactivity to the gastroduodenal digests produced with simulated fluids (Figure 2). This is probably because of the presence, in addition to intact OVA and its 40 kDa fragment, of a strong IgE-binding band of ~21 kDa and of other minor immunoreactive degradation products (Figure 1d). This pattern is similar to that previously observed after in vitro digestion of egg white with simulated gastroduodenal fluids that allowed the identification of several IgE-binding fragments with molecular masses in the range of 35−20 kDa, as well as others of 15 and 11 kDa, which derived from the hydrolysis of OVA.[21] The corresponding digests produced with human fluids showed fainter and lower molecular mass IgE-binding degradation products and the virtual absence of intact protein and its high molecular mass fragment (Figure 1b).

In addition, several IgE-binding epitopes were detected among the peptide fragments of molecular mass <3 kDa identified in the digests by RP-HPLC-MS/MS (Figure 3). Considering the binding frequency to human sera of the 27 synthetic peptides that mimicked the products of the gastrointestinal digestion, 4 main areas of the protein were recognized by >40% of the sera from egg-allergic patients: 125−176, 188−198, 326−336, and 370−385.

Within the first one, 125−176, at least five distinct epitopes were found, including OVA (125−134) and OVA (159−172), as well as OVA (141−154) and OVA (164−176), which were present in the gastrointestinal digests produced with simulated and human fluids, respectively. The peptides OVA (188−198) and OVA (326−336), found in the gastrointestinal digests produced with simulated fluids that bound, respectively, 60 and 50% of the sera from allergic patients, are related to previously defined allergenic epitopes. OVA (188−198) partially coincides with one of the five dominant human IgE-binding epitopes described by Mine and Rupa,[20] (38−49, 95−102, 191−200, 243−248, and 251−260), whereas OVA (326−336) is comprised within the fragment 323−339, considered an immunodominant B and T cell epitope.[22] The discovery of this latter epitope gave rise to a transgenic mouse carrying the MHC class II restricted rearranged T cell receptor transgene, Tg(DO11.10)10Dlo, specific for OVA (323−339), broadly used in in vitro studies of T cell differentiation and in vivo studies of tolerance and immune responses.[23] Finally, the C-terminal fragment, OVA (370−385), showed the highest binding frequency, reacting with 80% of the sera. Human IgE binding has been demonstrated to broader areas of the C-terminal region of OVA, such as 301−385[24] and 347−385.[25] On the other hand, the existence of, at least, two epitopes within the shorter fragment OVA (367−385) was implied from a positive basophil stimulation in one allergic patient.[25] Interestingly, the peptide OVA (375−384) was recognized by IgE from orally sensitized BALB/c mice but not from mice submitted to intraperitoneal or subcutaneous immunization,[26] which suggests that, even if it is protected within the native structure (Figure 4), it can be specifically exposed as a result of

Figure 4. Representation of the IgE-binding epitope OVA (370−385) in the 3D structure of the protein obtained from the RCSB Protein Data Bank (PDB ID 1OVA) with the UCSF Chimera package.

digestion. This immunoreactive fragment was present in the gastrointestinal digests produced with simulated fluids, but it could not be found in the gastrointestinal digests produced with human fluids.

In agreement with a previous study comparing the in vitro digestibility of bovine β-casein with human and simulated digestive fluids[12] and despite human fluids leading to a much faster proteolytic degradation, a high degree of similarity within the peptide patterns arising from gastric digestion was detected, which was not so evident following duodenal digestion, likely

because of the presence of active exopeptidases in the human duodenal extract. The accumulation of large degradation fragments and low molecular mass peptides with IgE-binding properties could contribute to the stronger residual IgE-binding capacity of the gastroduodenal digests produced with simulated fluids as compared with those produced with human fluids, although the gastrointestinal digests produced with human fluids also contained IgE-binding epitopes that could play a role in the allergenic potential of OVA. Among the epitopes released, OVA (370−385) seemed to be of special importance, as it was able to bind IgE of 80% of the sera employed in the study. More research is needed to elucidate the biological activity of this fragment.

Production and *in Vitro* Fermentation of Soluble, Non-digestible, Feruloylated Oligo- and Polysaccharides from Maize and Wheat Brans

Junyi Yang, María X. Maldonado-Gómez, Robert W. Hutkins, and Devin J. Rose*

Department of Food Science and Technology, University of Nebraska—Lincoln, Lincoln, Nebraska 68583-0919, United States

Supporting Information

ABSTRACT: High-pressure hydrothermal treatment of cereal bran results in fragmentation of the cell wall, releasing soluble, non-digestible, feruloylated oligo- and polysaccharides (FOPS), which may be beneficial to gut health. The objectives of this study were to (1) determine treatment temperatures for production of FOPS from maize bran and wheat bran and (2) determine the fermentation properties of partially purified FOPS from maize bran and wheat bran. FOPS were produced by heating bran and water (10%, w/v) in a high-pressure stirred reactor until the slurry reached 160−200 °C (in 10 °C increments). Final temperatures of 190 °C for maize bran and 200 °C for wheat bran resulted in the highest release of FOPS (49 and 50% of starting non-starch polysaccharide, respectively). Partial purification with ion exchange and dialysis resulted in a final product containing 63 and 57% total carbohydrate and 49 and 30% FOPS, respectively (other carbohydrate was starch). Following *in vitro* digestion (to remove starch), *in vitro* fermentation revealed that wheat FOPS were more bifidogenic than maize FOPS. However, maize FOPS led to continual production of short-chain fatty acid (SCFA), resulting in the highest SCFA and butyrate production at the end of the fermentation. In addition, maize FOPS showed significantly higher antioxidant activity than wheat FOPS. This study identified a process to produce FOPS from maize bran and wheat bran and showed that, considering the overall beneficial effects, FOPS from maize bran may exhibit enhanced benefits on gut health compared to those of wheat bran.

KEYWORDS: *maize, short-chain fatty acids, butyrate, prebiotic, Bifidobacterium*

INTRODUCTION

The basic structure of arabinoxylan, the predominant non-starch polysaccharide in grains, is a (1,4)-linked β-D-xylopyranosyl backbone substituted at C(O)-2 and/or C(O)-3 with α-L-arabinofuranosyl moieties, some of which are themselves substituted with ferulic acid that can be involved in oxidative cross-linkages with other arabinoxylan chains and other cell-wall components.[1] Beyond these basic structures, arabinoxylan can also contain oligosaccharide side chains comprised of pentose or hexose sugars or uronic acids. Dependent upon botanical source and location within the kernel, arabinoxylan can differ in distributions and types of side chains, molecular weight, ferulate content, and degree of cross-linking.[1,2] Because of its complex nature, arabinoxylan is sometimes referred to as glucuronoarabinoxylan or heteroxylan.[3−5] For simplicity, arabinoxylan will be used in this paper to refer to this complex class of polysaccharides.

Two sources of divergent arabinoxylan structures are those from maize and wheat. Enzymatic or dilute acid degradation accompanied by partial methylation analysis of alkali-solubilized arabinoxylan from maize bran and wheat bran has revealed greater branch density and complexity in maize arabinoxylan compared to that of wheat.[4,6,7]

In its native form, arabinoxylan is mostly insoluble and cross-linked, making it a poorly fermentable substrate for gut bacteria.[8−10] However, partial hydrolysis of arabinoxylan from wheat bran with xylanase releases arabinoxylan oligosaccharides (AXOS), which are highly fermentable in the gut and stimulate the growth of bifidobacteria and other beneficial bacteria.[11] AXOS have also been shown to reduce blood serum triglyceride and cholesterol levels, facilitate diabetic weight loss, and enhance antioxidant capacity in liver.[11]

Arabinoxylan may also be released from its insoluble matrix by autohydrolysis,[12,13] but the structure of the carbohydrates released are different from those released by enzyme. For instance, autohydrolysis breaks down the arabinoxylan into many size pieces ranging from monosaccharides on up to polysaccharides with a degree of polymerization (DP) of 750 or more,[12,13] while enzymatic treatment releases mostly shorter chain oligosaccharides.[14] Additionally, autohydrolysis can release arabinoxylan structures that are resistant to enzymatic hydrolysis, as evidenced by increased yields with autohydrolysis (ca. 50% from maize bran and wheat bran)[12,13] compared to enzymatic release (ca. 30% in wheat bran[10,14] and <3% in maize bran[15]).

Although the fermentation properties of AXOS have been reported extensively,[11] utilization of the soluble, non-digestible, feruloylated oligo- and polysaccharides (FOPS) released by autohydrolytic processing have only been studied in a few instances, and in these cases, the hydrolytic product was further treated with xylanase.[16−18] Because maize bran and wheat bran contain vastly different arabinoxylan structures[4,6,7] and the parent arabinoxylans from these two sources have been shown

to be used very differently by gut bacteria,[8] the objectives of this study were to (1) determine treatment temperatures for production of FOPS from maize bran and wheat bran and (2) determine the fermentation properties of partially purified FOPS from these substrates.

MATERIALS AND METHODS

Safety. The high-pressure processing followed the safety portions of the instrument manual (4848, Parr Instrument Co., Moline, IL). The chemicals used in this study required no special safety considerations.

Production of FOPS. Maize bran was obtained from Bunge Milling (Crete, NE), and wheat bran was obtained from Horizon Mills (Newton, KS) and milled with a cyclone sample mill (UDY, Boulder, CA) equipped with a 1 mm screen. A total of 150 g of milled bran and 1350 mL of water were combined in a 2 L high-pressure reactor (model 4848, Parr, Moline, IL). The slurry was heated to 170, 180, 190, or 200 °C at full power (ca. 4 °C/min) under constant stirring at a speed of 400 rpm. The slurry was then cooled to 80 °C using an internal serpentine cold water cooling coil (ca. 15 min). Following the treatment, the slurries were centrifuged at 10000*g* for 10 min and the supernatant was retained. The supernatant was referred to as the autohydrolysate liquor (Figure 1). Each treatment was performed in duplicate.

Total carbohydrate, total starch, free monosaccharides, free and esterified ferulic acid, furfural, hydroxymethylfurfural (HMF), total starch, and protein were determined in all autohydrolysate liquors (see Compositional Analyses). FOPS were calculated according to the following equation:

$$\text{FOPS}\ (\%) = W_{ara} + W_{xyl} + W_{man} + W_{gal} + W_{glc} + W_{fa}$$

where W_{ara} is total arabinan (%), W_{xyl} is total xylan (%), W_{man} is total mannan (%), W_{gal} is total galactan (%), W_{glc} is total non-starch glucan (%), determined as the difference between the total glucan content after acid hydrolysis and the starch content, and W_{fa} is total esterified ferulate. Autohydrolysate liquors corresponding to treatment temperatures that resulted in the highest release of FOPS were also analyzed for molecular weight distribution and antioxidant activity (see Compositional Analyses).

The autohydrolysate liquors from treatment temperatures corresponding to the highest release of FOPS were pooled and dialyzed (molecular weight cut-off of 500, Spectrum Laboratories, Rancho Dominguez, CA). The retentate was mixed with ion-exchange resin (AG501-X8, Bio-Rad, Hercules, CA) at a rate of 1 g/20 mL and stirred gently overnight. After ion-exchange resin was filtered, the sample was treated under partial vacuum at 80 °C to concentrate the solids and

dx.doi.org/10.1021/jf404305y | J. Agric. Food Chem. 2014, 62, 159−166

remove volatile compounds. The material, referred to as partially purified FOPS, was then freeze-dried and assayed for total carbohydrate, free monosaccharides, free ferulic acid and esterified ferulate, furfural, HMF, starch, protein, antioxidant activity, and molecular weight distribution (see Compositional Analyses).

Fermentation of FOPS. To prepare for fermentation, *in vitro* digestion of partially purified FOPS was performed according to Yang et al.[19] The digested content was dialyzed (molecular weight cut-off of 500). Dialyzed material was freeze-dried and analyzed for total carbohydrate, free monosaccharides, free ferulic acid and esterified ferulate, starch, furfural, HMF, protein, antioxidant activity, and molecular weight distribution (see Compositional Analyses). This material was referred to as digested FOPS.

In vitro fermentation of digested FOPS was performed according to Hartzell et al.,[20] except that the sample size was 70 mg of carbohydrate instead of 100 mg. Fructooligosaccharides (FOS, Beneo, Morris Plains, NJ) were included as a positive control, and tubes containing no substrate were used as blanks. Samples (1 mL each) were taken at predetermined time points and stored at −80 °C. At times 0, 12, and 24 h, samples were assayed for short-chain fatty acid (SCFA), *Bifidobacterium*, and antioxidant activity (see Fermentation Analysis and Compositional Analyses). At other time points, samples were only assayed for SCFA.

Compositional Analyses. Total carbohydrate and free monosaccharides were determined according to Rose et al.[13] Briefly, 1 mL of liquid sample or 30 mg of solid sample were analyzed in tandem for carbohydrate content with or without chemical hydrolysis.[21] With hydrolysis constituted total carbohydrate, and without hydrolysis gave free monosaccharides. Oligo- and polymeric carbohydrates were determined as the differences between total carbohydrate and free monosaccharides.

Free ferulic acid and esterified ferulate were measured using methods described by Yuan et al.[22] and Carole et al.[23] For bran samples, 10 mg of sample was weighed into a tube. If the sample was a liquid (such as autohydrolysate liquors), 0.2 mL of sample was used. If sample was a freeze-dried powder, it was dissolved in water at 3% (w/v) and 0.2 mL of sample was used. Two tubes were prepared for analysis per replicate. To one of the tubes, which represented the total ferulic acid content, 0.2 mL of 0.4 M sodium hydroxide was added. The tube was shaken for 2 h at room temperature, and then 0.3 mL of 0.4 M phosphoric acid was added, followed by 0.2 mL of water. Free ferulic acid was assayed in the other tube in the same manner, except that sodium hydroxide was replaced by water. Each tube was then extracted with 1 mL of ethyl acetate 3 times. The pooled ethyl acetate extracts were evaporated using a partial vacuum, and the extract was dissolved in 2 mL of 50% aqueous methanol. Samples were filtered through a 0.45 μm membrane, and 15 μL was injected into high-performance liquid chromatography (HPLC, 1260, Agilent, Santa Clara, CA) equipped with a C18 column (C-18-4E, Skowa Denko K.K., Tokyo, Japan) and ultraviolet (UV) detector at 320 nm. Elution was performed using the gradient described by Carole et al.[23] Quantification was by means of external calibration with a ferulic acid standard (MP Biomedicals, Solon, OH). Esterified ferulate content was calculated by the difference between the total ferulic acid and the free ferulic acid.

Samples were analyzed for furfural and HMF by means of external calibration with authentic standards (Sigma-Aldrich, St. Louis, MO) following Gomis et al.,[24] except that the mobile phase was 96:4 (v/v) water/acetonitrile rather than 92:8. If the sample was a liquid, it was analyzed directly or after appropriate dilution (in samples containing high furfural or HMF concentration). If the sample was a freeze-dried powder, it was dissolved at 3% (w/v) for analysis.

Total starch was measured in solid samples using a kit (K-TSTA, Megazyme, Bray, Ireland). In liquid samples, the total starch content was measured following the method from Rose et al.[12]

The protein content of solid samples was obtained by a FP528 nitrogen/protein determinator (LECO Corporation, St. Joseph, MI) after using a conversion factor of 6.25 for percent nitrogen to percent protein.[25] In liquid samples, the protein content was measured using the Bradford method with bovine serum albumin (Pierco, Rockford, IL) used to create a standard curve.[26]

To determine the molecular weight distribution, 10 mg of freeze-dried powder was dissolved in 2 mL of water. Samples were filtered through a 0.45 μm membrane, and 100 μL was injected into HPLC (Agilent) equipped with Shodex SB-G, SB-804 HQ, and SB-802 HQ (Skowa Denko K.K., Tokyo, Japan) columns connected in series followed by a refractive index detector (Agilent). The mobile phase was 0.02% sodium azide at 0.5 mL/min. Molecular weight calibration was accomplished by means of external pullulan (P-82, Shodex) and glucooligosaccharide (4-7265, Sigma-Aldrich, St. Louis, MO) standards.

Antioxidant activity was determined using the 1,1-diphenyl-2-picrylhydrazyl (DPPH) and 2,2-azino-bis-3-ethylbenzthiazoline-6-sulfonic acid (ATBS) methods. The DPPH assay was performed by reacting 0.2 mL of appropriately diluted sample with 1 mL of DPPH as described by Sensoy et al.,[27] except that, after incubating for 30 min, the tubes were centrifuged for 10 min at 3000*g* to remove the cloudiness. The ATBS assay was conducted according to Re et al.[28] Antioxidant activity was expressed relative to the antioxidant activity of 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox, Sigma-Adrich, St. Louis, MO).

Fermentation Analysis. Samples taken during fermentation were thawed and centrifuged (10000*g* for 5 min). The supernatant was used for analysis of SCFA after Hartzell et al.[20] and for antioxidant activity (see Compositional Analyses). The pellet was used for analysis of *Bifidobacterium* by quantitative real-time polymerase chain reaction (PCR) as described.[20]

Data Analysis. For autohydrolytic processing, two replications at each temperature were performed. Each replicate was analyzed twice. Differences in chemical compositions were analyzed using analysis of variation (ANOVA) in combination with Fisher's protected least significant difference. The replicates from autohydrolysis were pooled for the *in vitro* fermentation stage. Differences in SCFA production between treatments were analyzed with three replicates using ANOVA with repeated measures followed by Fisher's protected least significant difference using SAS (version 9.2, SAS Institute, Cary, NC). Differences among substrate treatment on the population of *Bifidobacterium* and antioxidant activity were computed using ANOVA in combination with Fisher's protected least significant difference.

RESULTS AND DISCUSSION

Production of FOPS. Maize bran and wheat bran contained high concentrations of total dietary fiber (Table 1), most of which was water-insoluble.[29] Higher ferulic acid content was

observed in maize bran compared to wheat bran. Maize has the highest ferulic acid content among major cereal brans, which exhibits high antioxidant activity and displays potential health benefits.[29]

The composition of the autohydrolysate liquors differed depending upon the treatment temperature (Figure 2A). The

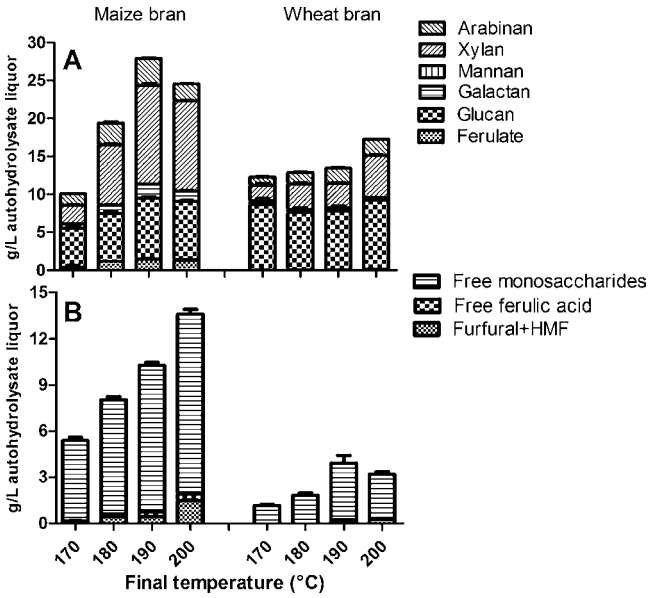

Figure 2. Composition of autohydrolysate liquor upon hydrothermal treatment to selected temperatures: (A) FOPS and (B) non-FOPS material released by autohydrolysis treatment. HMF = hydroxymethylfurfural. Error bars show standard deviation (n = 2). Some error bars were too small to plot.

release of FOPS was increased in autohydrolysate liquor from maize bran as the temperature increased from 170 to 190 °C and then showed a marked decrease from 190 to 200 °C. The highest yield represented 49% of the starting non-starch polysaccharide content and 44% of the initial ferulic acid content. With wheat bran, an increased final temperature resulted in a steady increase in the concentration of FOPS in the autohydrolysate liquor, ultimately releasing 50% of the initial non-starch polysaccharide content and 82% of the ferulic acid content at a final treatment temperature of 200 °C. These yields agree well with the percentage of cell-wall polysaccharides released by hydrothermal treatment of other agricultural byproducts[30] and were substantially higher than the AXOS released by enzymatic hydrolysis.[14] Thus, 190 and 200 °C were selected as the desirable temperatures to release FOPS from maize bran and wheat bran, respectively.

The autohydrolysate liquors also contained high concentrations of non-FOPS material (Figure 2B). The release of arabinose and xylose was largely affected by the treatment temperature, with more arabinose being released (mainly side chain) than xylose (mainly backbone), suggesting that arabinoxylan was partially debranched during autohydrolysis (data not shown). Furfural and HMF increased as the treatment temperature increased. These compounds are one of the thermal degradation compounds of pentoses and hexoses, respectively.[31] Starch and protein were also present in autohydrolysate liquors (10.9−15.3 and 0.180−2.01 g/L, respectively), but the concentration did not vary as a function of the treatment temperature.

Dialysis, ion-exchange, and vacuum concentration were used to partially remove non-FOPS material from autohydrolysate liquors. The partially purified material from maize bran contained a higher percentage of FOPS compared to wheat bran (49 versus 30%, respectively; see Table S1 of the Supporting Information). Nearly 4-fold higher antioxidant activity was observed on partially purified maize FOPS compared to wheat when using ATBS radical; when using DPPH radical, maize FOPS showed 2-fold higher antioxidant activity compared to wheat (see Table S1 of the Supporting Information).

The purification process removed furfural, HMF, and free ferulic acid (i.e., these compounds were not detectable in the partially purified samples; see Table S1 of the Supporting Information). More than 90% of the free monosaccharaides present in autohydrolysate liquors from both maize bran and wheat bran was removed with the partial purification process (see Table S1 of the Supporting Information).

Because the purification process only concentrated oligo- and polysaccharides and removed non-carbohydrate material, there was still substantial starch contamination in the partially purified FOPS preparations (15.5 and 27.1% in maize bran and wheat bran freeze-dried material, respectively; see Table S1 of the Supporting Information). Pretreatments are often employed to remove starch prior to producing FOPS-like materials.[12,13] However, this step was not performed to simplify the production process because it was anticipated that the digestion phase would remove any contaminating starch prior to determining fermentation characteristics.

Partially purified FOPS showed a broad molecular weight distribution, resulting from the fragmentation of arabinoxylan caused by high-pressure hydrothermal treatment. The majority of polymers ranged from 0.24×10^5 to 1.9×10^5 g/mol (data not shown). The presence of high-molecular-weight polymers could have been due to the release of polysaccharides or from the release of oligosaccharides that were covalently linked through diferuloyl groups.

Fermentation of FOPS. Because the partially purified FOPS contained appreciable starch (see Table S1 of the Supporting Information), prior to *in vitro* fermentation, *in vitro* digestion was performed. *In vitro* digestion removed nearly all of the starch and, consequently, increased the percentage of FOPS in the freeze-dried material compared to the partially purified FOPS (see Table S1 of the Supporting Information). The digestion process also resulted in concentrating the ferulate content and, subsequently, increasing the antioxidant activity (see Table S1 of the Supporting Information). Protein decreased after digestion, but a small percentage persisted (2.37 and 3.27% in maize bran and wheat bran samples, respectively). Some of this protein could have been denatured enzymes from the digestion process as well as enzyme-resistant protein from the starting material. The difficulty in completely removing protein from cereal grain materials has been noted previously.[32]

In vitro digestion removed some of the shortest polymers in wheat FOPS (data not shown), suggesting that starch may have been fragmented into small dextrins. However, the digested FOPS contained a similar broad molecular weight distribution compared to before *in vitro* digestion.

In vitro fermentation was performed to determine how FOPS from maize bran and wheat bran were metabolized by fecal bacteria. Wheat FOPS resulted in lower SCFA production at 4 h compared to FOS (included as a positive control), and there

was no significant change in SCFA production after 4 h (Table 2). Maize FOPS also showed low SCFA production relative to FOS at 4 h but brought about continual production of SCFA thereafter, resulting in the highest SCFA production at the end of the fermentation.

The steadily fermentation profile of maize FOPS suggests that fermentation may persist into the distal part of the colon, where protein fermentation otherwise predominates, resulting in the production of toxic compounds, such as ammonia, phenol, indoles, thiols, amines, and sulfides.[34] A greater increase in SCFA production in distal colon may result in protective effects by lowering the pH and inhibiting the fermentation of protein.[33]

The difference in chemical structure between maize and wheat arabinoxylan may be responsible for their different fermentation profiles. As mentioned, maize arabinoxylan contains higher branch density and complexity, coupled with higher levels of esterified ferulic acid compared to wheat arabinoxylan.[4,6,7] Notably, extended fermentation properties for alkali-extracted maize arabinoxylan[8] as well as its hydrolysate[34] have been shown previously. Thus, slow fermentation appears to be an inherent property of maize arabinoxylan, independent of the DP or method of release from the cell-wall matrix.

Individual SCFA production also differed among substrates. After 24 h of fermentation, microbial butyrate production on maize FOPS was significantly higher than that on other substrates (Table 2). Butyrate has been shown to inhibit inflammatory responses by inhibiting activation of nuclear factor κB.[35] Thus, the high butyrate production of maize FOPS may exert potential health benefits compared to the other substrates.[33,35,36] Significantly higher propionate was also observed on maize FOPS compared to wheat FOPS. Propionate may reduce serum lipid as well as the risk of cardiovascular diseases.[37] Propionate has also been shown to have the potential to prevent obesity-related inflammation and associated diseases.[38]

Because the target of many prebiotic studies is to increase *Bifidobacterium*,[33,39] and because AXOS produced by enzyme treatment have been shown to be particularly bifidogenic,[40−42] the shift in *Bifidobacterium* upon FOPS treatment was investigated. Both maize and wheat FOPS showed a significant increase in *Bifidobacterium* compared to the blank and baseline after 12 and 24 h of fermentation, although the increase was not as great as FOS (except for wheat FOPS after 12 h of fermentation; Figure 3). Wheat FOPS exhibited higher bifidogenicity than maize at the end of the fermentation.

These results are contrary to previous reports demonstrating that AXOS can be a more potent bifidogenic substrates than FOS.[40,41] This is likely because FOPS (released by autohydrolysis) contained more complex, higher DP structures compared to AXOS (released by enzyme).[14] The higher branch density and complexity of maize arabinoxylan compared to wheat may account for the lower bifidogenicity of maize FOPS, whereas other bacteria may have greater capacity to use these substrates. For instance, the SCFA data suggest that maize FOPS supported butyrate producers (Table 2). The main butyrate producers in the gut include *Eubacterium rectale*/*Roseburia* spp. and *Faecalibacterium prausnitzii*, which have shown beneficial effects on the gut.[43] Other members of the gut microbiota also contribute to the SCFA pool.

Although the gut is an anaerobic environment, the gut epithelia release reactive oxygen species into the lumen of the gut in response to environmental stresses and, in some cases, even commensal bacteria.[44] Numerous diseases, such as inflammatory bowel diseases and colon cancer, are associated with an imbalance in the gut cellular redox system.[45] When the antioxidant activity in the medium was measured, the potential ability of FOPS to prevent oxidative damage in the gut was investigated.

dx.doi.org/10.1021/jf404305y | J. Agric. Food Chem. 2014, 62, 159−166

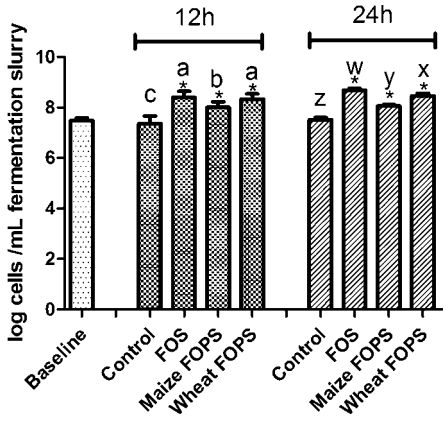

Figure 3. Enumeration of *Bifidobacterium* during *in vitro* fermentation. The baseline represents *Bifidobacterium* in the fecal inoculum before fermentation (0 h). The control represents a sample after fermentation with no added carbohydrate substrate. FOPS = feruloylated oligo- and polysaccharides. FOS = fructooligosaccharides. Bars marked with different letters are significantly different within each time point. (∗) Significantly different from the baseline ($p < 0.05$). $n = 2$ (baseline) or 3 (fermentation samples). Error bars show standard deviation.

As expected, because of the high ferulate content, at 0 h, the highest antioxidant activity was observed on maize FOPS (Figure 4). During fermentation, antioxidant activities changed depending upon the substrate and radical used for the antioxidant assay. On ATBS, the blank and FOS showed decreasing antioxidant activity as fermentation time progressed. The decrease was delayed when wheat FOPS was used, and maize FOPS showed an increase at 12 h before a decrease was experienced. In contrast to ATBS, radical scavenging ability against DPPH increased in all samples, including the blank and FOS, from 0 to 12 h of fermentation, followed by a significant decrease in all samples, except maize FOPS at 24 h.

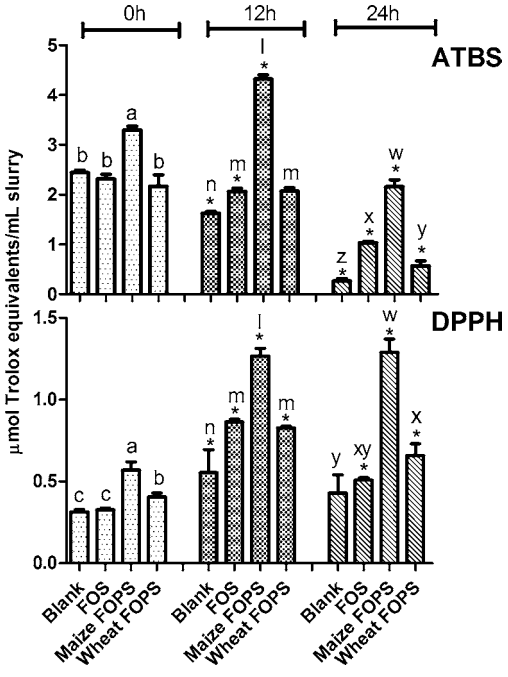

Figure 4. Antioxidant activity of fermentation medium before and after 12 and 24 h *in vitro* fermentation. The blank represents a sample after fermentation with no added carbohydrate substrate. FOPS = feruloylated oligo- and polysaccharides. FOS = fructooligosaccharides. Bars marked with different letters are significantly different within each time point. (∗) Significantly different from the corresponding substrates at the previous time point ($p < 0.05$). $n = 3$. Error bars show standard deviation.

The human microbiota can express several enzymes that are capable of releasing and metabolizing ferulic acid,[46,47] the major antioxidant in FOPS. This has a dramatic effect on biological activity.[46−50] First, gut bacteria probably hydrolyze the ester linkage and release free ferulic acid.[51] This would likely increase the antioxidant activity because free ferulic acid possesses higher antioxidant activity than esterified ferulate.[52] Upon release of the ferulic acid, modification of function groups by microbial enzymes could further affect the antioxidant activity. Metabolism of ferulic acid first involves hydrogenation of the propen-2-oic acid side chain and demethylation of the ring ether[46] to form 3,4-dihydroxyphenylpropionic acid.[46] This compound has been shown to possess higher antioxidant activity than ferulic acid in edible oil systems;[53] however, this compound is only transient and, subsequently, dehydroxylated to 3-hydroxyphenylpropionic acid and, finally, phenylpropionic acid.[46] These conversions likely decrease antioxidant activity.

Other factors not directly related to the bioconversion of ferulic acid may also contribute to changes in antioxidant activity. For instance, higher antioxidant activity has been observed for free ferulic acid in the presence of AXOS compared to without AXOS.[52] As mentioned, ferulic acid is initially de-esterified by the gut microbiota, and this could be analogous to free ferulic acid in the presence of AXOS. As fermentation progresses, however, AXOS are removed from the system by microbial metabolism. Microbial metabolism of AXOS also leads to production of SCFA, which lower the pH and could affect antioxidant activity.[54]

This study identified a high-pressure hydrothermal treatment of cereal bran that resulted in fragmentation of the cell wall. Final temperatures of 190 °C for maize bran and 200 °C for wheat bran resulted in the highest release of FOPS (49 and 50% of initial non-starch polysaccharide, respectively) and esterified ferulic acid (44 and 82% of initial ferulic acid, respectively). Maize FOPS displayed a desirable protracted fermentation profile with higher butyrate production compared to wheat FOPS and FOS. Both maize and wheat FOPS exhibited bifidogenic activity, although weaker than FOS. Maize FOPS exhibited high antioxidant capacity during fermentation that could have beneficial properties *in vivo*. Because FOPS can possibly combine beneficial fermentation properties and antioxidant activities, it may have potential to become a functional food ingredient to promote gut health.

Inhibition of the β-Catenin/Tcf Signaling by Caffeoylquinic Acids in Sweet Potato Leaf through down Regulation of the Tcf-4 Transcription

Junsei Taira,* Masatsugu Uehara, Eito Tsuchida, and Wakana Ohmine

Department of Bioresource Technology, Okinawa National College of Technology, 905 Henoko, Nago City, Okinawa, 905-2192 Japan

ABSTRACT: Sweet potato leaves contain the highest levels of functional polyphenols. In this study the effects of the sweet potato leaf extract and its contents, such as mono (3, 4, and 5)-caffeoylquinic acid (CQA), di-CQA (4,5-diCQA, 3,5-diCQA, and 3,4-diCQA) and caffeic acid (CA), were evaluated on the β-catenin/Tcf-4 signaling in human colorectal cancer HCT116 cells. The extract and the CQA derivatives inhibited the β-catenin/Tcf-4 signaling, and the inhibition of the di-CQA (with two caffeoyl groups) was higher than that of the mono-CQA (one-caffeoyl group) and CA, suggesting that the caffeoyl structure in the presence of a catechol group plays a significant role in interfering with the β-catenin/Tcf-4 signaling. In addition, the CQA derivatives had no effect on the β-catenin protein expression, but all test compounds inhibited the expression of the Tcf-4 transcription, and the inhibition of the di-CQA derivatives was stronger than those of the mono-CQA derivatives as well as the β-catenin/Tcf-4 transcriptional activity. These compounds can modulate the downstream Wnt signaling pathway, suggesting that sweet potato leaves can be a protective food for colorectal cancer.

KEYWORDS: *caffeoylquinic acid, HCT 116 cells, colorectal cancer, β-catenin/Tcf signaling, sweet potato*

INTRODUCTION

Recent studies have demonstrated that sweet potato (*Ipomoea batatas* L.) leaves contain the highest levels of polyphenols compared to other commercial vegetables.[1,2] The leaves were found to be an inhibitor of the growth of colon and stomach cancer cells, leukemia, and viruses[3,4] and to reduce the effects of diabetes in humans.[5] The sweet potato leaves contain phenolic compounds, such as caffeoylquinic acid (CQA) derivatives, a family of esters formed from certain cinnamic acids and quinic acid, including the mono-CQA (chlorogenic acid derivatives) and di-CQA, such as 3,5-diCQA, 3,4-diCQA, and 4,5-diCQA.[6−8] The CQA derivatives are the main sweet potato polyphenols and they have an anti-LDL oxidation activity, DPPH-radical scavenging action, and antimutagen and antitumor activities.[8−11] Colorectal cancer is a human malignance as well as stomach and lung cancer which are causes of human death. The incidence tends to increase due to changing Japanese dietary habits. Recent studies have indicated that in most of the colorectal cancers associated with the aberrant Wnt signaling pathway, the expression of β-catenin plays critical roles in cell proliferation and differentiation. The glycogen synthase kinase (GSK)-3β/Axin complex normally promotes the proteolytic degradation of the β-catenin intracellular signaling molecule. When the β-catenin destruction complex is inhibited, a pool of cytoplasmic β-catenin stabilizes and is able to enter the nucleus and interact with the T-cell factor/lymphoid enhancer-binding factor (Tcf/Lef) family transcription factors to promote a specific gene expression and the signaling is an early progression event in colorectal cancer.[12] In previous studies over the past decade, several naturally occurring dietary compounds, such as flavonoids, curcumin, and the tea polyphenol epigallocatechin-3-gallate (EGCG), have been shown to target intermediates in the Wnt/β-catenin signaling pathway.[13,14] These active compounds have shown antioxidant activity; thus, caffeoylquinic acids will be expected to have a similar activity. This study was designed to confirm whether caffeoylquinic acid derivatives can modulate β-catenin/Tcf-4 signaling.

MATERIALS AND METHODS

Materials. Caffeic acid (CA) and 3-caffeoylquinic acid were obtained from the Wako Pure Chemical Co. (Osaka, Japan). FuGENE 6 as a transfection reagent and the Lucyferase Assay System containing the luciferase substrate and lysis buffer to assess the reporter assay were obtained from the Promega Corporation (CA). Polyclonal anti-β-catenin (mouse monoclonal antibody, BD Biosciences, CA) and Tcf-4 monoclonal antibody (mouse monoclonal antibody, Exalpha Biologicals, Inc., MA) were used to detect the protein expression.

Isolation of CQA Derivatives. The CQA derivatives were isolated from the methanol (MeOH) extract of the sweet potato leaf as previously reported.[8,9] Briefly, the MeOH extract was partitioned between dichloromethane and H_2O (50/50 v/v) and the H_2O fraction was continuously partitioned with n-BuOH. The H_2O fraction was freeze-dried, then separated by HPLC (Agilent 1200, Agilent Technologies, CA) with an ODS-column (COAMOSIL Packed column 5C18-MS-II, 10 I.D. × 250 mm, Nacalai Tesque, Tokyo, Japan), and monitored at 326 nm at the flow rate of 2.0 mL/min at 40 °C. The mobile phase consisting of a formic acid aqueous solution (0.5%) and acetonitrile was carried out by a linear gradient to 2, 45, and 100% for 15, 50, and 60 min, respectively. Each peak of the mono (4 and 5)-CQA and di-CQA, such as 4,5- diCQA, 3,5-diCQA, and 3,4-diCQA, was collected by a fraction collector (Analyte FC, Agilent Technologies). These compounds were used in the β-catenin/Tcf-4

reporter assay and as the standard substances for determining the quantity of the content in the sweet potato leaf extract.

Sample Preparation. The sweet potato leaf powder (1 g) was extracted with distilled water (50 mL) at 85 °C for 45 min. The extract was filtered and then freeze-dried (Tokyo Rikakiki Co. Ltd., Tokyo, Japan). The sample (430.1 mg) dissolved in MQ-water (1 mL) was filtered using a disk filter (0.45 μm, Millipore, MA) and used for the assay and analysis of the contents in the sweet potato leaf.

LC/MS Analysis. The content of each component in the extract of the sweet potato leaves was determined by an LC/MS analysis. The LC/MS (Agilent1200, Agilent Technologies) was carried out using a photodiode array detector and monitored in the operating wavelength range from 210 to 700 nm at the flow rate of 0.80 mL/min on a reversed-phase chromatographic column, YMC-Pack Pro C18 (100 × 4.6 mm I.D., 5 μm particle size, YMC Co., Ltd., Kyoto, Japan) at 40 °C. The mass spectra were measured under the following conditions: ESI negative ion mode; desolvation temperature, 350 °C; desolvation pressure, 35 psi; and desolvation gas flow, 12.01 mL/min (6120 Quadrupole LC/MS spectrometer, Agilent Technologies).

Cell Culture. HCT116 human colon cancer cells (American Type Culture Collection) were cultured in DMEM (Gibco-BRL, Life Technologies, CA) medium (including 10% FBS, 100 U/ml penicillin and 100 μg/mL streptomycin) at 37 °C in a 5% CO_2 atmosphere.

Cell Viability. The cell viability due to treatment with a test sample was examined by an MTT assay as previously reported.[15] Briefly, the cells were seeded at a density of 5.0×10^5 cells/mL and cultured for 24 h with or without the test sample. After the culture, MTT (0.05%) was added to each well and incubated for 3 h, and then the suspension was carefully removed. Extraction with DMSO (50 μL) was measured at 540 nm with the reference at 655 nm using a microplate reader (BIO-RAD model 550, BIO-RAD, CA).

Reporter Assay. The HCT116 cells with or without the test sample were cultured on a 12-well microplate (5×10^5 cells/well) for 24 h the day before being transiently cotransfected in triplicate with Tcf-4 and the β-catenin plasmid using the FuGENE 6 transfection reagent. After 24 h, the cells were washed twice in phosphate-buffered saline (PBS) and lysed in 100 μL of lysis buffer. The lucyferase activity of the lysate cells (50 μL) was assayed with a luciferase substrate, then the chemiluminescence (CL) was measured by a microplate reader (GLOMAX MULTI Detection system, Promega). The protein concentration was determined using a BCA protein assay kit (Thermo Fisher Scientific, Inc., IL).

Western Blot. After stimulation, the cells were washed with PBS and then treated with the lysis buffer. The cellular lysates were centrifuged at 13800*g* for 5 min. The total cellular extracts were separated on SDS-polyacrylamide gels (4−12% SDS-polyacrylamide, Invitrogen, CA) and transferred to a nitrocellulose membrane (iBlot Gel Transfer Mini, Invitrogen) using an iBlot Gel Transfer Device (Invitrogen). The membrane treatment and detection of the protein expression were carried out by manual procedures using an immunodetection system (Invitrogen) while incubated with the polyclonal anti-β-catenin or Tcf-4 overnight at 4 °C.

Statistical Analysis. Data were expressed as mean ± SD. Analysis of data was carried out using one-way analyses of variance (ANOVA) and Tukeỳs method for multiple comparison. Significance $P < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Figure 1 shows the LC−MS chromatogram of the CQA derivatives obtained from the hot-water extract of the sweet potato leaves. It indicated mono-CQA, 5-CQA (24.70 min, 353.0 m/z), 3-CQA (27.19 min, 353.0 m/z), 4-CQA (27.55, 353.0 m/z), CA (27.71 min, 179.1 m/z), and di-CQA, such as 4,5-diCQA (33.62 min, 515.1 m/z), 3,5-diCQA (33.94 min, 515.1 m/z), and 3,4-diCQA (34.89 min, 515.1 m/z). These chemical structures of the CQA derivatives in the sweet potato leaf extract were depicted in Figure 2. Figure 3 shows that the content in the extract and the di-CQA was higher than those of

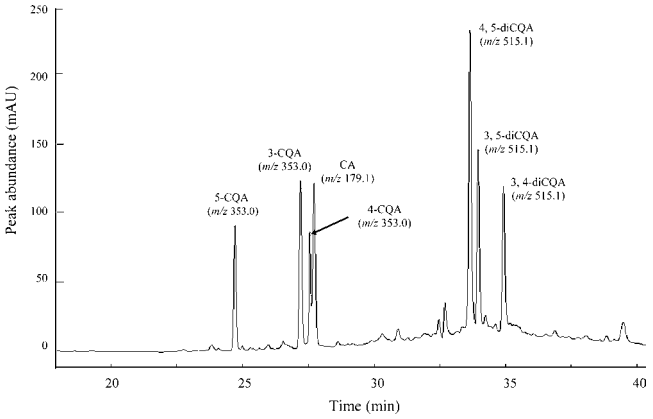

Figure 1. LC/MS chromatogram obtained from the hot-water extract of the sweet potato leaves. The LC/MS was carried out by the analytical condition as shown in the text. Each peak indicated the mono (3, 4, and 5)-caffeoylquinic acid (CQA, m/z = 353.0), di-CQA (4,5-diCQA, 3,5-diCQA, and 3,4-diCQA, m/z = 515.1), and caffeic acid (CA, m/z = 179.1).

the other mono-CQA derivatives and CA, particularly, the 4,5-diCQA had the highest content. Similar results were obtained from the ethanol extract of the sweet potato leaves.[8,9] The CQA derivatives are the antitumor main sweet potato polyphenols and they have DPPH-radical scavenging action, antimutagen, and activities.[10,11] A recent study revealed that the CQA derivatives have an anti-LDL oxidation activity suggesting that they may prevent the development of atherosclerosis caused by the oxidative modification of LDL.[8,9] In previous studies over the past decade, several naturally occurring dietary polyphenols, such as quercetin, EGCG, and curcumin, have been shown to modulate genes in the Wnt/β-catenin signaling pathway.[16−18] Based on the sweet potato leaf extract and the main polyphenol contents, the CQA derivatives were expected to modulate the Wnt/β-catenin signaling pathway; thus, the reporter assay of the test sample was carried out on the β-catenin/Tcf-4 signaling pathway in the human colorectal cancer HCT116 cells. Figure 4 shows the result of the reporter assay by the combination of β-catenin and Tcf-4 plasmid DNAs with or without the test sample. As shown in Figure 4, the chemiluminescence (CL) reporter activity of β-catenin and Tcf-4 transfected in cells increased when compared to Tcf-4 alone. When cells transfected with the β-catenin and Tcf-4 genes were treated with the sweet potato leaf extract, the induction of the CL reporter activity, suppressed in a dose dependent manner (0.22, 1.10, and 2.20 mg/mL). Each compound from the extract also inhibited the CL reporter activity, and the activity of the di-CQA derivatives was higher than those of mono-CQA. The concentration range of these compounds used in the reporter assay did not show any cytotoxicity, indicating that the reduction of the CL reporter activity is due to the interference of the β-catenin/Tcf-4 signaling (Table 1). The antioxidant activity of the phenolic compound is due to the function of the OH group in the molecule, specifically, the presence of a catechol group contributes to the effective radical scavenging activity.[15,19] The CQA derivatives having a catechol group in the caffeoyl structure have an effective antioxidant activity, such as the DPPH-radical scavenging action and the anti LDL-oxidation activity.[7−9] The antioxidant activity of the CQA derivatives was related to the number of caffeoyl groups in the structure, for example, the antioxidant activity is decreasing as follows: tri-CQA, which has three caffeoyl groups, di-CQA

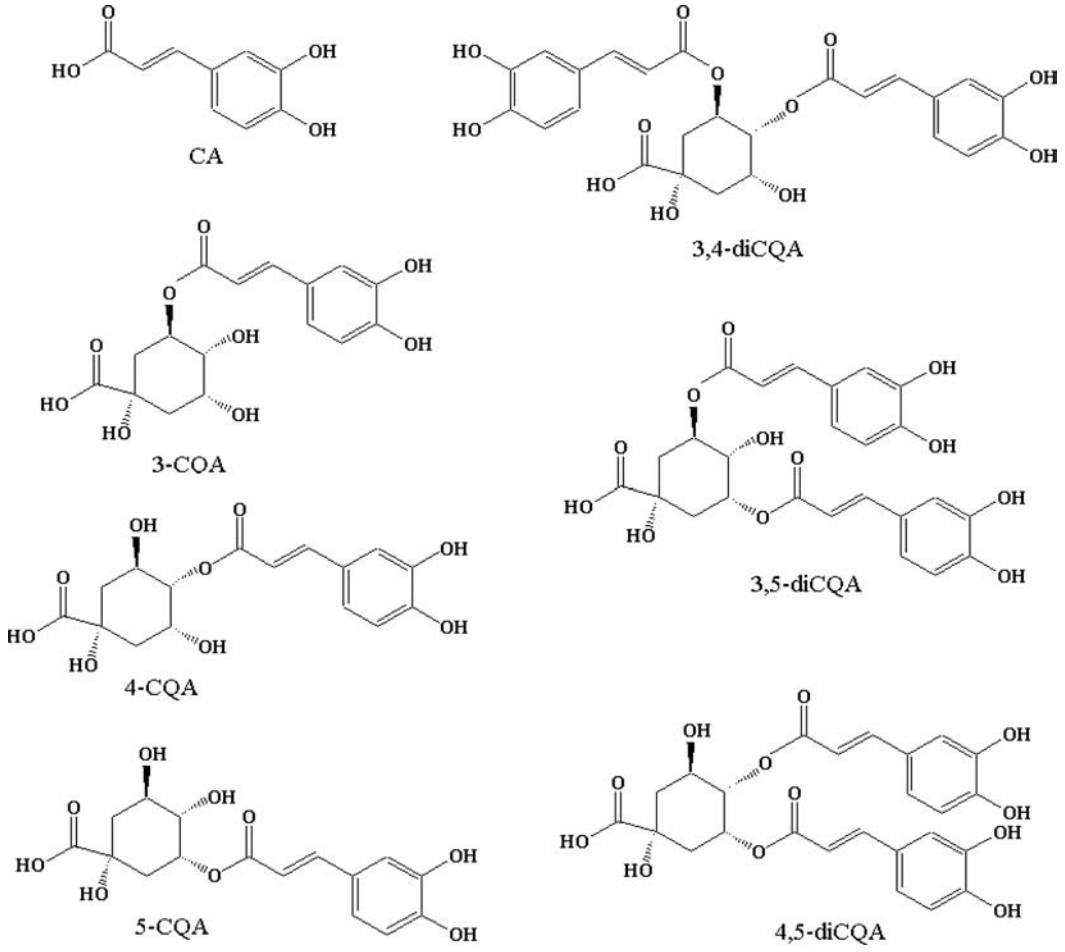

Figure 2. Chemical structures of caffeoylquinic acid (CQA) derivatives including caffeic acid (CA) from sweet potato leaves. The sweet potato leaves were extracted with methanol. The CQA derivatives, except for CA and 3-CQA, were separated from the extract by the procedures shown in the text.

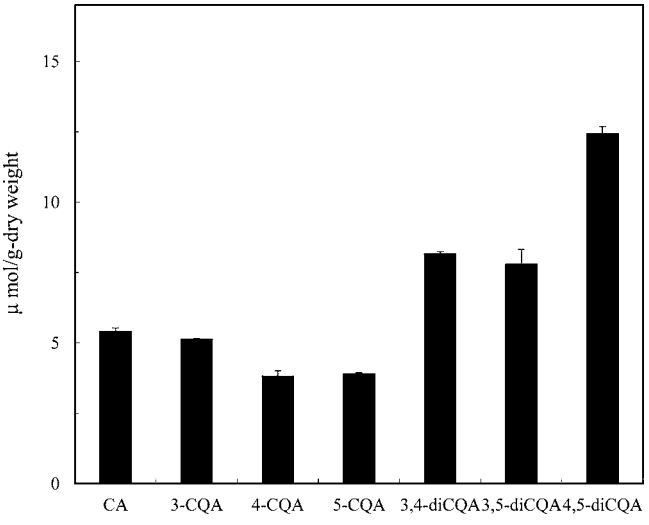

Figure 3. Composition of the CQA derivatives in the sweet potato leaf. The content of each component in the hot-water extract of the sweet potato leaf was determined by an LC/MS analysis using the procedures shown in the text. The content of each compound is expressed as mean ± SD of three experiments.

(with 2 caffeoyl groups) derivatives, and mono-CQA (with one caffeoyl group). The CL reporter activity of the CQA derivatives including CA having a catechol structure similar to that of the antioxidant activity. Quercetin, the major representative of the flavonol subclass of flavonoids, has been shown to be a potent inhibitor of the β-catenin/Tcf signaling in SW480 human colon adenocarcinoma cells. Quercetin also has a catechol function in the A-ring of the molecule.[16] Caffeic acid phenethyl esters, a phenolic component of propolis, having a catechol structure in the molecule inhibited the colorectal cancer cell growth in a dose and time-dependent manner by decreasing the β-catenin.[20,21] Therefore, the caffeoyl structure in the presence of a catechol group of the CQA derivatives may play a functional role in interfering the Wnt/β-catenin signaling pathway.

The cytoplasmic β-catenin levels are normally low through continuous proteasome-mediated degradation by an APC/GSK-3β/Axin complex. When cells receive the Wnt signal, the degradation of β-catenin is inhibited and the levels of β-catenin increase in the cytoplasm and nucleus. Nuclear β-catenin interacts with the transcription factors, such as the Tcf/Lef, and lead to tumor formation and progression.[12] The inhibition of the GSK-3β kinase activity might lead to the onset of the β-catenin/Tcf/Lef-mediated gene transcription, representing a potentially mitogenic stimulus. The molecules, such as GSK-3β, β-catenin, and the transcription factor, and Tcf are the key factors in the Wnt pathway involved in the regulation of the β-catenin homeostasis. In previous studies, it was reported that the naturally occurring dietary compounds inhibited the β-catenin/Tcf-4 transcriptional signaling in the cancer cells. A

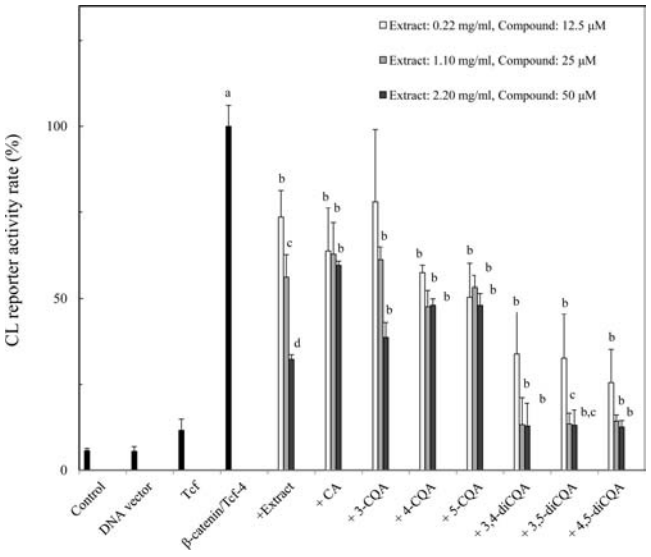

Figure 4. Inhibition of the chemiluminescence reporter activity on β-catenin/Tcf-4 signaling in the HCT116 colorectal cancer cells. The chemiluminescence (CL) of the β-catenin/Tcf-4 signaling in the HCT116 colorectal cancer cells with or without the test sample was measured by the CL reporter assay and indicated as the CL reporter activity rate (%) for the control and β-catenin/Tcf-4 plasmid transfected cells. Data were expressed as mean ± SD of three experiments and groups with different letters are significantly different ($p < 0.05$).

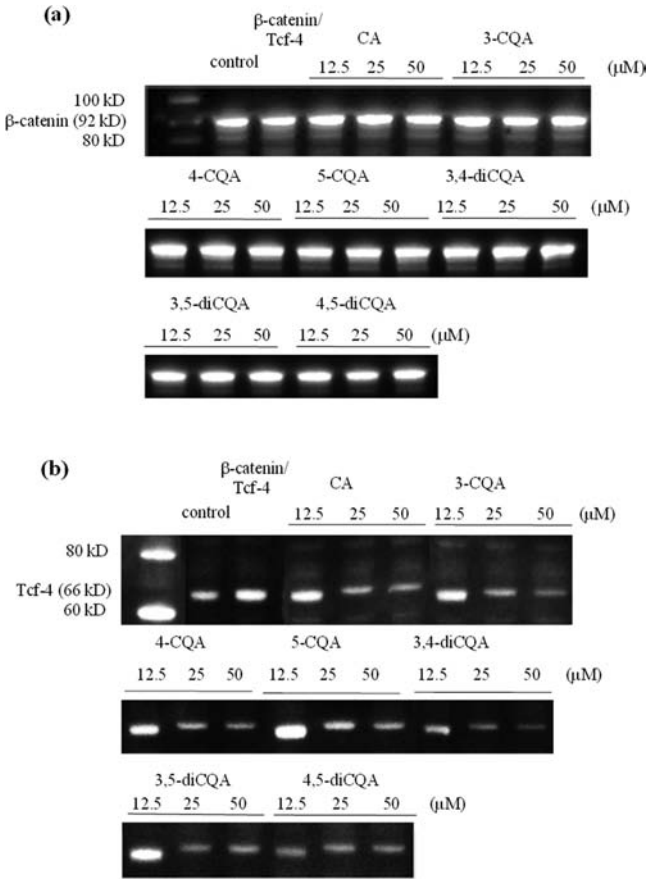

Figure 5. Suppression of the CQA derivatives for the β-catenin and Tcf-4 protein expression in HCT116 colorectal cancer cells. Western blot analysis of protein expression for the β-catenin/Tcf-4 plasmid transfected cells with or without the test sample (12.5, 25, and 50 μM). (a) Effect of the CQA derivatives on β-catenin protein expression and (b) inhibition of the Tcf-4 protein expression. A representative example of two experiments is shown.

polyphenol-rich apple juice extract was found to effectively inhibit the kinase activity of GSK-3β.[22] Curcumin derivative treatment of a variety of colon cancer cell lines reduced in a dose dependent manner the β-catenin transcriptional activity by increasing the degradation of the cytoplasmic β-catenin.[17] EGCG treatment in HEK293 cells inhibited the β-catenin transcriptional activity,[18] and resveratrol also significantly decreased the level of β-catenin in the nucleus of colon cancer cells.[23] In this study, the target molecule by the CQA derivatives in the β-catenin/Tcf-4 signaling was examined in cells transfected with the β-catenin/Tcf-4 plasmid DNAs with or without test compounds (Figure 5). The expression of β-catenin in cells transfected with the β-catenin/Tcf-4 plasmid DNAs was at a level similar to that of the vector alone. As shown in Figure 5a, the CQA derivatives treatment in cells had no effect on the reduction of the β-catenin protein suggesting that the inhibition of the β-catenin/Tcf-4 transcriptional activity is due to the downregulation of the signaling pathway. In the same experiment, the Tcf-4 protein expression in cells transfected with the β-catenin/Tcf-4 plasmid DNAs was greater than that of the vector alone (control). When all of the test compounds were treated at 25 μM in the cells, the production of the Tcf-4 protein was completely suppressed (Figure 5b).

Table 1. Cytotoxicity of Sweet Potato Leaf Extract and the CQA Derivatives in HCT 116 Colorectal Cancer Cells

	cells survival rate (%)[b]

The result clearly indicated that the CQA derivatives targeted the transcription factor Tcf-4 on the Wnt/β-catenin signaling pathway. In previous papers, it was reported that the naturally occurring dietary compounds inhibited the β-catenin/Tcf-4 transcriptional signaling due to modulating the Wnt signaling gene expression. Quercetin inhibits the β-catenin/Tcf-4 signaling in SW480 human colon adenocarcinoma cells by decreasing the levels of β-catenin and Tcf-4 in the nucleus, resulting in a decreased downstream Wnt signaling gene expression of *c-myc*.[16] Curcumin treatment inhibits the mRNA expression of the Wnt target genes *c-myc*, *c-fos*, and *c-jun* in a variety of cancer cells.[24] EGCG reduced the expression of the β-catenin/Tcf-4 signaling target genes *c-jun* and *cyclin D1*.[25,26] Resveratrol decreased the localization of β-catenin in the nucleus due to the expression of *lgs* and *pygol*, the activator of β-catenin in all cell lines.[23] The caffeic acid phenethyl ester significantly suppressed the β-catenin, *c-myc*, and *cyclin D1* protein expression in SW480 cells.[21] The CQA derivatives may have also affected the Wnt target genes, such as the cell cycle prompting genes *c-myc* and *cyclin D1*. In addition, the CQA derivatives may have a potential modulation of the Wnt/β-catenin signaling pathway in various cancer cells. These subjects will be the focus of future research.

In conclusion, this study demonstrated that the edible sweet potato leaf extract and its contents, such as mono (3, 4, and 5)-caffeoylquinic acid (CQA), di-CQA (4,5-diCQA, 3,5-diCQA, and 3,4-diCQA), and caffeic acid (CA), inhibit the β-catenin/Tcf-4 transcriptional activity in HCT116 cells. Particularly, the di-CQA derivatives (with 2 caffeoyl groups) were greater than that of the mono-CQA derivatives (one caffeoyl group) and CA, suggesting that the caffeoyl structure in the presence of a catechol group plays a significant role in the reduction of the β-catenin transcriptional activity. In addition, the compounds targeted the molecular transcription factor Tcf-4 for the inhibition of the β-catenin/Tcf-4 transcriptional activity. Sweet potato leaf containing the β-catenin signaling inhibitor, CQA derivatives, may be a protective diet for colorectal cancer.

ABSTRACT: Looking for antihypertensive mechanisms beyond ACE inhibition, we assessed whether lactoferrin (LF)-derived peptides can act as receptor blockers to inhibit vasoconstriction induced by angiotensin II or endothelin-1. The lactoferricin B (LfcinB)-derived peptide $LfcinB_{20-25}$ (RRWQWR), the low molecular weight LF hydrolysate (LFH < 3 kDa), and two peptides identified in LFH < 3 kDa (LIWKL and RPYL) were tested in ex vivo assays of vasoactive responses. The peptide RPYL was tested in radioligand receptor binding assays. Both LFH < 3 kDa and individual peptides inhibited angiotensin II-induced vasoconstriction. RPYL showed the highest ex vivo inhibitory effect and also inhibited binding of [^{125}I]-(Sar^1,Ile^8)-angiotensin II to AT_1 receptors. By contrast, neither LFH < 3 kDa nor RPYL inhibited endothelin-1 and depolarization-induced vasoconstrictions. In conclusion, LF-derived peptides selectively inhibit angiotensin II-induced vasoconstriction by blocking angiotensin AT_1 receptors. Therefore, inhibition of angiotensin II-induced vasocontriction is suggested as a mechanism contributing along with ACE inhibition to the antihypertensive effect of some LF-derived peptides.

INTRODUCTION

Hypertension is probably the most important modifiable risk factor for cardiovascular disease, and its management includes not only pharmacological treatment but also lifestyle changes including physical activity and dietary habits.[1] The increasing perception about the relationship between food and health is fostering the development of functional foods providing health benefits beyond basic nutrition.[2] Some food proteins contain embedded peptides that once released behave as bioactive peptides with different health-promoting properties including blood pressure lowering effects.[3]

The renin angiotensin system (RAS) is one of the main targets for the treatment of hypertension. Its inhibition at three possible levels, angiotensin-converting enzyme (ACE), upstream renin activity, or downstream angiotensin receptors, is the pharmacological basis for commonly used antihypertensive drugs.[4] ACE inhibition is also the most aimed target for antihypertensive food-derived peptides developed as an alternative to drugs.[5] Although different animal and plant proteins have been used, milk is the main source of antihypertensive ACE-inhibitory peptides reported to date.[6]

In contrast to casein, there was much less information about the potential of milk whey proteins as sources of antihypertensive peptides when some years ago we focused on whey protein lactoferrin (LF)[7] and its well-known functional domain lactoferricin B (LfcinB).[8] First, we have shown that a set of peptides derived from LfcinB had inhibitory effects on in vitro ACE activity and ex vivo angiotensin I-induced ACE-dependent vasoconstriction[9] and were orally effective antihypertensive peptides in spontaneously hypertensive rats (SHRs).[10] With regard to the parent protein, we have reported the inhibitory effects of a LF pepsin hydrolysate (LFH) on ACE activity and ACE-dependent vasoconstriction.[11] Then, we have recently described that the ultrafiltered hydrolysate (LFH < 3 kDa) showed increased inhibitory effect on ACE activity and orally antihypertensive effect in SHRs after both acute[12] and chronic[13] administration. Finally, we have isolated and identified novel non-LfcinB-derived peptides with ACE-inhibitory and antihypertensive properties, which could contribute to the antihypertensive effects of LFH < 3 kDa.[12]

The search for in vitro ACE inhibition is the most common strategy in the selection of potential antihypertensive peptides derived from food proteins. However, it is difficult to establish a

direct relationship between ACE-inhibitory effect in vitro and antihypertensive effect in vivo. On one hand, the in vitro ACE-inhibitory potency of food-derived peptides is around 1000 times lower than that of ACE-inhibitory drugs such as captopril, but there are no substantial differences when their antihypertensive effects are compared.[14] On the other hand, there is no correlation between in vitro and in vivo effects when different individual peptides or protein hydrolysates are compared. To explain these apparent discrepancies, one should take into account both bioavailability issues and mechanisms of action other than ACE inhibition when bioactive peptides are assayed in vivo.[15] Alternative antihypertensive mechanisms reported for food-derived bioactive peptides include short-term vasoactive mechanisms as well as long-term antioxidant and anti-inflammatory mechanisms.[16]

Looking for antihypertensive mechanisms beyond ACE inhibition in milk protein derived bioactive peptides, we have shown that some LfcinB-derived peptides were dual vasopeptidase inhibitors. In addition to ACE, they inhibit endothelin-converting enzyme (ECE), a key enzyme of the endothelin system also involved in vascular tone and blood pressure regulation.[17] We have also reported that orally effective antihypertensive LF hydrolysates may act as dual vasopeptidase (ACE/ECE) or as single ECE inhibitors with different antivasoconstrictor effects depending on the protease used to release bioactive peptides.[18] In the present study, we aimed to assess whether LF-derived peptides, in addition to inhibiting the converting enzymes of the angiotensin and endothelin systems, can act as receptor blockers to inhibit vasoconstriction induced by angiotensin II or endothelin-1. For this purpose, we included in the study the LfcinB-derived peptide $LfcinB_{20-25}$ (RRWQWR), the low molecular weight LF pepsin hydrolysate LFH < 3 kDa, and two peptides identified in LFH < 3 kDa (LIWKL and RPYL), all of them with proven antihypertensive effects in SHRs.

MATERIALS AND METHODS

Materials. Bovine lactoferrin (LF) was provided by FrieslandCampina Domo (Zwolle, The Netherlands). Porcine pepsin, porcine kidney ACE, human endothelin-1 (ET-1), captopril, valsartan, and protease inhibitor cocktail were purchased from Sigma-Aldrich Química (Tres Cantos, Madrid, Spain). Angiotensin II was supplied by Calbiochem Co. (La Jolla, CA, USA), and fluorescent ACE substrate *o*-aminobenzoylglycyl-*p*-nitrophenylalanylproline was from Bachem Feinchemikalien (Bubendorf, Switzerland). [^{125}I]-(Sar^1,Ile^8)-angiotensin II and angiotensin AT_1 receptor (human) membrane preparation were from PerkinElmer, Inc. (Waltham, MA, USA), where membranes were prepared from transfected Chinese hamster ovary cells (cell line CHO-K1).

Peptides ($LfcinB_{20-25}$, LIWKL, and RPYL) were ordered at >95% purity from GenScript Corp. (Piscataway, NJ, USA) where they were synthesized by solid phase methods using *N*-(9-fluorenyl)-methoxycarbonyl (Fmoc) chemistry. $LfcinB_{20-25}$ was acetylated at the N-terminus and amidated at the C-terminus, because such a modified peptide was used in our previous studies showing its vasoactive[9] and antihypertensive[10] effects. Actual peptide purities of supplied batches were 99.8% for $LfcinB_{20-25}$, 97.7% for LIWKL, and 99.5% for RPYL. Stock solutions of each peptide were prepared at 5 mM concentration in Milli-Q water (Millipore Corp., Bedford, MA, USA) and stored at −20 °C. $LfcinB_{20-25}$ (RRWQWR) and LIWKL concentrations were determined on the basis of the extinction coefficient of W residues by measuring the absorbance at 280 nm (ε_{280} = 5600 M^{-1} cm^{-1} for W residue), whereas RPYL concentration was based on the dry weight of the peptide.

A low molecular weight fraction of an LF hydrolysate obtained by enzymatic treatment with pepsin (LFH < 3 kDa) was prepared as described previously,[11,12] and the resulting permeate was freeze-dried and kept at room temperature until use. LFH < 3 kDa was subjected to determination of protein content by the bicinchoninic acid method (BCA; Sigma-Aldrich Química) using BSA as standard and to in vitro assay of ACE-inhibitory potency (IC_{50}) using the method described by Sentandreu and Toldrá[19] as previously reported.[12]

Animal Welfare. Rabbits were housed in temperature-controlled rooms (23 °C) with 12 h light/dark cycles and consumed tap water and standard diet ad libitum. Euthanasia was carried out in accordance with the Spanish legislation on "Protection of Animals used for Experimental and other Scientific Purposes". The study was approved by the Ethics Committee for Animal Welfare of the Hospital 'La Fe' to be carried out in its accredited animal research facility (ES462500001001).

Isolation of Rabbit Carotid Arteries and Preparation of Membrane Microsomal Fraction. Thirty male New Zealand White rabbits (Technology Transferring Center, Polytechnic University of Valencia, Valencia, Spain), weighing 2.5−3 kg, were killed by injection of 25 mg/kg sodium thiopental and 1.5 mL of 10 mM KCl solution through the ear vein. A midline throat incision provided access to both common carotid arteries, which were dissected free and cut into four 4 mm long segments, each one for the ex vivo functional assays in organ bath. On the other hand, the membrane microsomal fraction from carotid arteries was obtained for radioligand binding assays according to the method of Faber et al.[20] with some modifications. Briefly, frozen tissue was pulverized in liquid N_2 and homogenized (500 μL for 100 mg of tissue) in 4 °C buffer (25 mM Tris-HCl, 1 mM EDTA, 2 mM $MgCl_2$, and 100 mM KCl, pH 7.4) plus protease inhibitor cocktail (1% v/v) with an Ultra-Turrax T8 homogenizer (IKA-Werke, Staufen, Germany) at maximal speed (5 × 10 s). All procedures specified below were carried out at 4 °C. The homogenate was subjected to three strokes at 4 W in a Microson XL ultrasonic cell disruptor (Misonix, Farmingdale, NY), treated with 0.6 M KCl for 20 min to remove major contractile proteins, and centrifuged at 1000*g* for 10 min; the supernatant was centrifuged at 10000*g* for 10 min, and again the supernatant ultracentrifuged at 110000*g* for 1 h. The final pellet was resuspended in storage buffer (50 mM Tris-HCl, 0.5 mM EDTA, 10 mM $MgCl_2$, 10% sucrose, pH 7.4, protease inhibitor cocktail) and kept at −80 °C until used. The concentration of the membrane protein was determined by using the bicinchoninic acid method.

Ex Vivo Functional Assays of Vasoactive Responses. The arterial segments were mounted in an organ bath containing Ringer−Locke solution (120 mM NaCl, 5.4 mM KCl, 2.2 mM $CaCl_2$, 1.0 mM $MgCl_2$, 25 mM $NaHCO_3$, and 5.6 mM glucose) for computer-assisted isometric tension recording, as described previously.[9] The contractile capacity of every arterial segment was checked by exposure to 50 mM KCl Ringer−Locke solution (NaCl replaced with an equimolar amount of KCl). Carotid arteries contracting less than 1 g were discarded.

To assess effects on angiotensin receptor-mediated vasoconstriction, every arterial segment was challenged with angiotensin II (1 μM). After washing out, each arterial segment was subjected to one of the following protocols: (i) control, a second challenge to angiotensin II to check for response reproducibility, or (ii) treated, preincubation (20 min) with LFH < 3 kDa (100 μg/mL), one of the LF-derived peptides (20 μM), the ACE-inhibitor drug captopril (0.1 μM), or the angiotensin II AT_1 receptor blocker drug valsartan (10 nM) and a second challenge to angiotensin II to check for their effect on angiotensin II-induced contraction. Concentration-dependent effects were assessed for the LF-derived peptide RPYL (20−200 μM) and valsartan (10−100 nM).

To assess effects on endothelin receptor-mediated vasoconstriction, every arterial segment was challenged with KCl (50 mM). After washing out, each arterial segment was subjected to one of the following protocols: (i) a challenge with endothelin-1 (10 nM) to obtain the control contractile response, or (ii) treated, preincubation (20 min) with LFH < 3 kDa (100 μg/mL), the LF-derived peptide RPYL (20 μM), or the angiotensin II AT_1 receptor blocker drug valsartan (0.1 μM), and a challenge with endothelin-1 to check for their effect on endothelin-1-induced contraction.

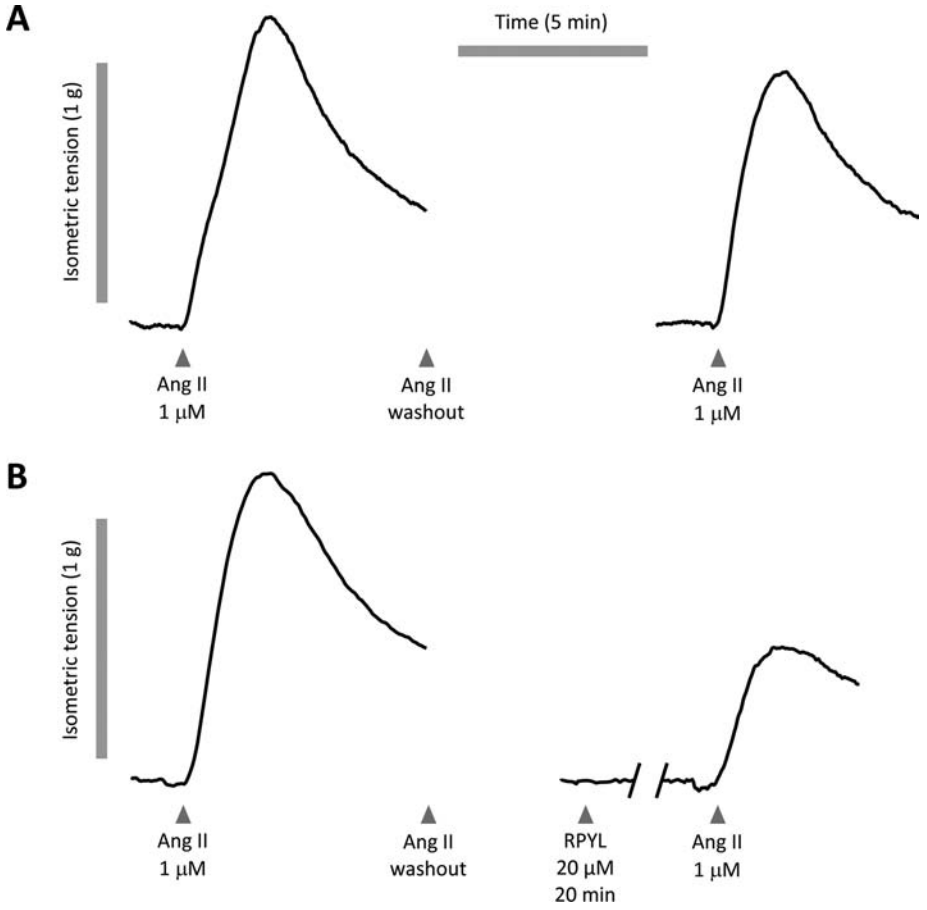

Figure 1. Typical vasoconstrictor effects of angiotensin II (Ang II) in carotid artery segments isolated from New Zealand White rabbits: (A) successive vasoconstrictions to Ang II in control conditions; (B) effect of the LF-derived peptide RPYL on Ang II-induced vasoconstriction.

Finally, some arterial segments were subjected to two successive challenges to 50 mM KCl with or without LFH < 3 kDa (100 μg/mL), the LF-derived peptide RPYL (20 μM), or valsartan (0.1 μM) between to check for nonspecific effects of the treatments on arterial contractile capacity.

Radioligand Receptor Binding Assays. Competition binding assays were carried out with both a membrane preparation containing human angiotensin AT_1 receptor and a membrane microsomal fraction from rabbit carotid artery. The human receptor membrane preparation (0.6 μg protein) was incubated at 27 °C for 60 min in a total volume of 200 μL of assay buffer (50 mM Tris-HCl, 5 mM $MgCl_2$, pH 7.4) with [^{125}I]-(Sar^1,Ile^8)-angiotensin II (0.03 nM) and various concentrations of unlabeled competitors. Experiments were terminated by rapid vacuum filtration through Whatman GF/C fiberglass filters (GE Healthcare Europe GmbH, Barcelona, Spain) presoaked in 0.5% BSA using a Brandel cell harvester (M24R, Valley Research Iberica, Madrid, Spain). The filters were then washed five times with 1 mL of ice-cold 50 mM Tris-HCl buffer (pH 7.4), and the filter-bound radioactivity was measured in a gamma counter (2480 WIZARD, PerkinElmer, Waltham, MA, USA). Nonspecific binding was determined in the presence of 1 μM unlabeled valsartan. Specific binding is defined as total binding minus nonspecific binding. For the rabbit carotid artery membrane preparation, 40 μg of protein and [^{125}I]-(Sar^1,Ile^8)-angiotensin II (0.06 nM) were used instead. A full competition binding assay curve (1 pM−1 μM) was carried out for valsartan, and selected concentrations of RPYL were assayed according to the vasoactive responses in the ex vivo functional assays.

Statistical Analyses. Values are expressed as the mean ± SEM. Unpaired Student's t test was used to assess differences between two groups. Analysis of variance (ANOVA) followed by Student−Newman−Keuls test or Dunnett's test was used for multiple comparisons among more than two groups. P values <0.05 were considered significant. The calculation of IC_{50} values was performed by nonlinear regression analysis. GraphPad Prism software (GraphPad Software Inc., La Jolla, CA, USA) was used.

RESULTS

Lactoferrin-Derived Peptides Inhibit Angiotensin II-Induced Vasoconstriction. Challenge of rabbit carotid arterial segments with a depolarizing solution (50 mM KCl) induced phasic contraction followed by active tone maintained until KCl wash-out. Average active tone amounted to 3424 ± 106 mg in all viable arterial segments included in the study (n = 200).

Angiotensin II (1 μM) induced phasic, transient contractions that were almost completely reproducible in two consecutive challenges to the same arterial segment (Figure 1A). Average contractile response to the second challenge was 82 ± 2% of the first response (n = 30). The inhibitory effects of the different treatments on angiotensin II-induced vasoconstriction were assessed as shown for RPYL in the representative recording of Figure 1B. $LfcinB_{20-25}$ (20 μM), LFH < 3 kDa (100 μg/mL), LIWKL (20 μM), and RPYL (20 μM) produced significant inhibition of angiotensin II-induced vasoconstriction when compared to control vasoconstriction (Figure 2A). The degree of inhibition ranged from 21% response reduction over the control conditions for the weakest $LfcinB_{20-25}$ to 44% response reduction for the strongest RPYL. Figure 2A also shows the lack of effect of the ACE inhibitor captopril (0.1 μM) on angiotensin II-induced vasoconstriction and the significant inhibitory effect of the angiotensin II AT_1 receptor blocker

dx.doi.org/10.1021/jf404616f | J. Agric. Food Chem. 2014, 62, 173−181

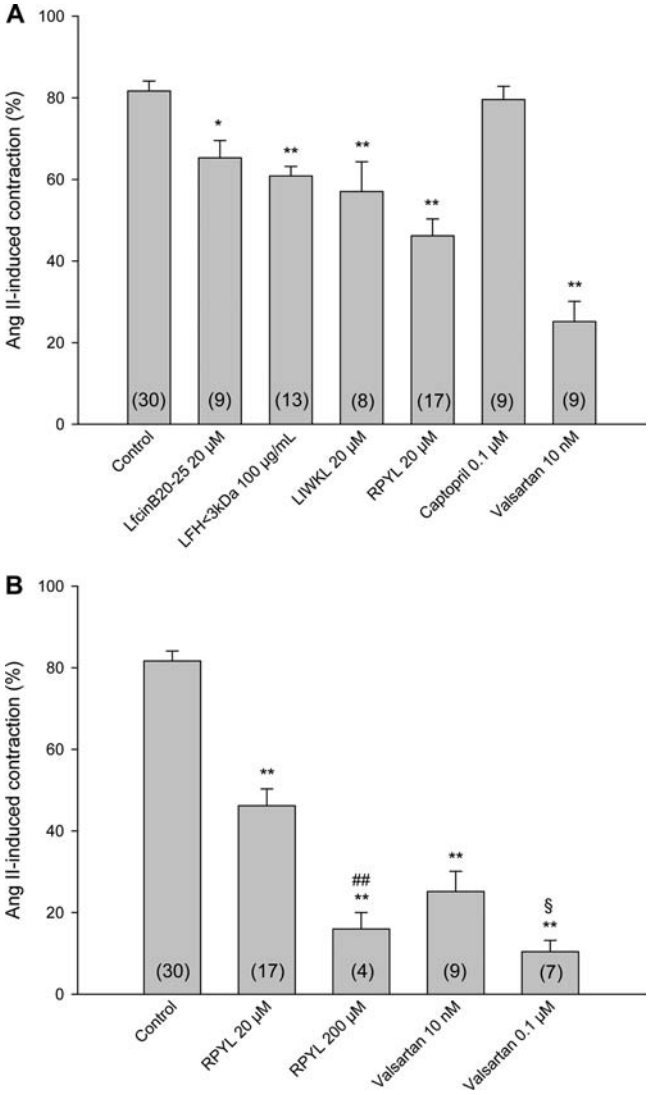

Figure 2. Inhibitory effects of lactoferrin-derived peptides on angiotensin II (Ang II)-induced vasoconstriction in carotid artery segments isolated from New Zealand White rabbits. (A) $LfcinB_{20-25}$, LFH < 3 kDa, the LF-derived peptides LIWKL and RPYL, the ACE-inhibitor captopril, and the Ang II AT_1 receptor blocker valsartan were applied before the second addition of Ang II (1 μM). (B) Concentration-dependent inhibitory effects of RPYL and valsartan on Ang II-induced vasoconstriction. Vasoconstrictor responses are expressed as a percentage of previous Ang II-induced contraction. Data are the mean ± SEM from (n) arterial segments. ∗, $P < 0.05$, and ∗∗, $P < 0.01$, compared with Ang II alone (control), respectively. ##, $P < 0.01$, compared with RPYL (20 μM), and §, $P < 0.05$, compared with valsartan (10 nM).

valsartan (10 nM). Finally, concentration-dependent inhibitory effects on the contractile response to angiotensin II are shown for RPYL (20−200 μM) as well as for valsartan (10−100 nM) (Figure 2B).

Lactoferrin-Derived Peptide RPYL Inhibits Binding of [^{125}I]-(Sar^1,Ile^8)-Angiotensin II to AT_1 Receptors. The competitive angiotensin II AT_1 receptor blocker valsartan (1 pM−1 μM) induced concentration-dependent inhibition of [^{125}I]-(Sar^1,Ile^8)-angiotensin II (0.03 nM) specific binding to human angiotensin AT_1 receptors (Figure 3A) with a calculated IC_{50} value of 0.79 ± 0.15 nM (n = 6). The peptide RPYL (3−300 μM) also induced significant concentration-dependent inhibition of [^{125}I]-(Sar^1,Ile^8)-angiotensin II specific binding to human angiotensin AT_1 receptors (Figure 3B), amounting to 62% binding inhibition at the highest RPYL concentration assayed (300 μM). On the other hand, RPYL (100 μM) also significantly reduced to 38.2 ± 5.0% (n = 3, $P < 0.01$) specific binding of [^{125}I]-(Sar^1,Ile^8)-angiotensin II (0.06 nM) to rabbit carotid artery angiotensin AT_1 receptors.

Lactoferrin-Derived Peptides Do Not Inhibit Endothelin-1 and Depolarization-Induced Vasoconstrictions. Endothelin-1 (10 nM) induced slow contraction (Figure 4A) with maximum effect amounting to 108 ± 5% relative to previous response to KCl, reached at 67 ± 6 min, with a mean slope of 61 ± 7 mg/min (n = 16). The effects of the different treatments on endothelin-1-induced vasoconstriction were assessed as shown for LFH < 3 kDa in the representative recording of Figure 4B. LFH < 3 kDa (100 μg/mL), the peptide RPYL (20 μM), or valsartan (0.1 μM) did not induce significant modification of the contractile response to endothelin-1 (Table 1).

Finally, the effects of some treatments inhibiting angiotensin II-induced vasoconstriction were assayed also against KCl-induced vasoconstriction. In control conditions, the second vasoconstriction to KCl-induced depolarization was 116 ± 2% of the first response in the same arterial segment (n = 19), and the responses to KCl were not significantly different after incubation with LFH < 3 kDa (100 μg/mL), RPYL (20 μM), or valsartan (0.1 μM) (Table 1).

DISCUSSION

We have found that some lactoferrin (LF)-derived antihypertensive peptides inhibit angiotensin II-induced vasoconstriction due to their blocking effect on angiotensin AT_1 receptors. This effect is selective for angiotensin AT_1 receptors as endothelin-1-induced, ET_A receptor-mediated vasoconstriction is not inhibited, and no unspecific effects on depolarization-induced vasoconstriction are shown.

We have previously reported that the low molecular weight LF hydroysate included in this study (LFH < 3 kDa) shows antihypertensive effects in SHRs. Single-dose LFH < 3 kDa induces acute blood pressure reduction in SHRs,[12] and long-term intake attenuates progression of hypertension.[13] LFH < 3 kDa inhibits both in vitro ACE activity[12] and ACE-dependent angiotensin I-induced vasoconstriction.[18] The ACE inhibitory effect of LFH < 3 kDa has been confirmed as an in vivo mechanism for the antihypertensive effect.[13] The present results point to inhibition of angiotensin II-induced vasoconstriction as a potential mechanism also contributing along with ACE inhibition to the antihypertensive effect of the hydrolysate. We have also previously shown that individual peptides embedded in different regions of the LF sequence, either derived from the lactoferricin B domain (LfcinB) or identified in LFH < 3 kDa, are ACE inhibitors and have antihypertensive effects when acutely administered to SHRs.[9,10,12] The present study shows that $LfcinB_{20-25}$ also has a slight inhibitory effect on angiotensin II-induced vasoconstriction. On the other hand, the inhibitory effects of individual peptides such as LIWKL and, to a higher extent, RPYL on angiotensin II-induced vasoconstriction would contribute at least in part to the inhibitory effect of the whole hydrolysate LFH < 3 kDa.

The mechanism involved in the inhibitory effects of LF-derived peptides on angiotensin II-induced vasoconstriction has been further investigated using the most effective peptide

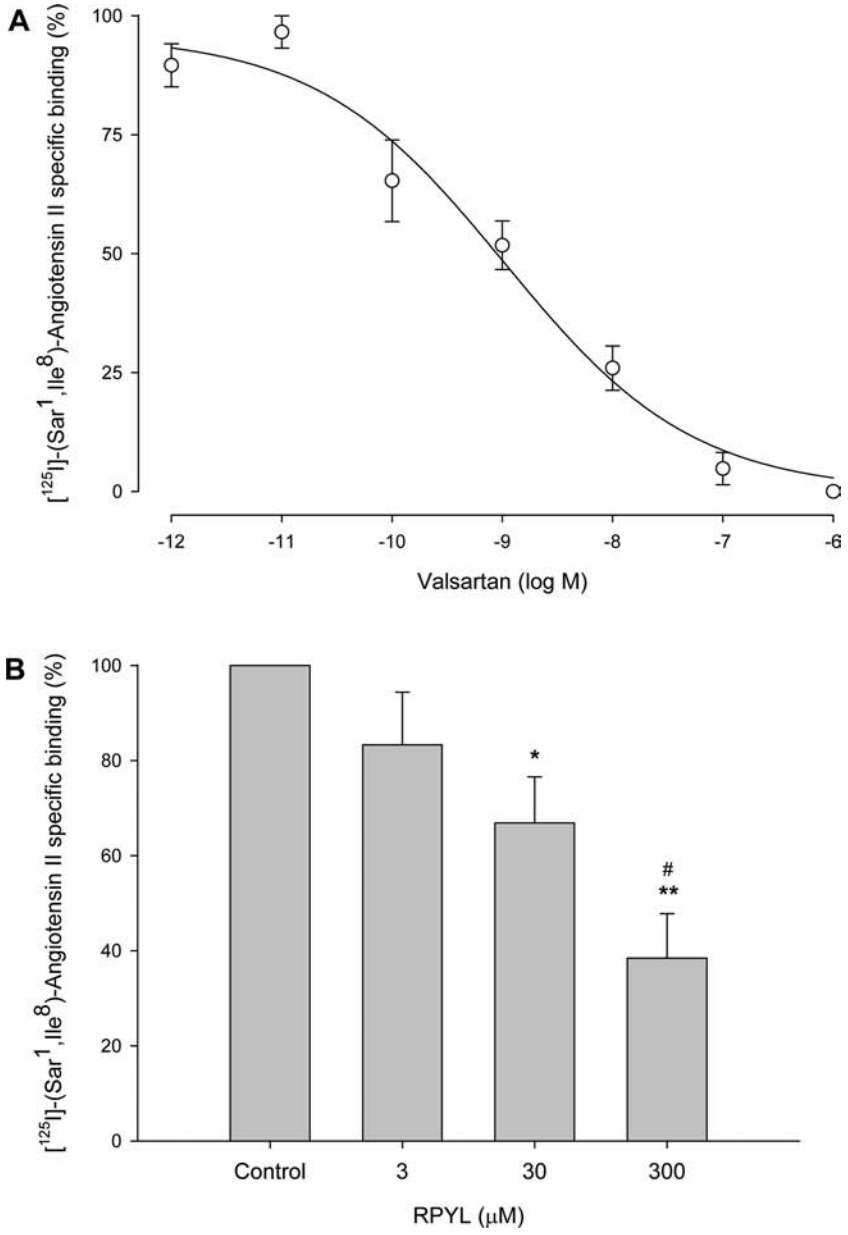

Figure 3. Inhibition of [^{125}I]-(Sar^1,Ile^8)-angiotensin II specific binding to a membrane preparation from CHO-K1 cells expressing the human angiotensin AT$_1$ receptor. Nonspecific binding was 29.3 ± 2.9%, mean ± SEM, from nine independent experiments (each performed in duplicate or triplicate). (A) Sigmoidal curve for concentration-dependent inhibitory effects of the angiotensin II AT$_1$ receptor blocker valsartan. Data are the mean ± SEM from six independent experiments (each performed in duplicate or triplicate). (B) Concentration-dependent inhibitory effects of the LF-derived peptide RPYL. Data are the mean ± SEM from at least three independent experiments (each performed in duplicate or triplicate). ∗, $P < 0.05$, and ∗∗, $P < 0.01$, compared with [^{125}I]-(Sar^1,Ile^8)-angiotensin II alone (control), respectively. #, $P < 0.05$, compared with RPYL (30 μM).

RPYL. Our results show that the inhibitory effect of RPYL on angiotensin II-induced vasoconstriction was concentration-dependent. Moreover, RPYL displaced the binding of [^{125}I]-(Sar^1,Ile^8)-angiotensin II to human angiotensin AT$_1$ receptors also in a concentration-dependent manner. These human recombinant receptors, expressed in transfected Chinese hamster ovary cells, are commonly used for AT$_1$ receptor binding assays both in whole cells[21] and in membrane preparations.[22] Finally, the inhibitory effect of RPYL on [^{125}I]-(Sar^1,Ile^8)-angiotensin II specific binding was confirmed in membranes from rabbit carotid artery, the native tissue used in vasoconstriction experiments. All of these results support an angiotensin AT$_1$ receptor-blocking mechanism for the inhibitory effect of RPYL on angiotensin II-induced vasoconstriction.

Angiotensin receptor blocker (ARB) drugs are a series of chemically related imidazole derivatives used in the clinical setting for hypertension treatment because of their ability to bind to angiotensin AT$_1$ receptors, thereby inhibiting vasoconstriction and other cellular actions of angiotensin II.[23,24] Valsartan, a member of this drug family,[25] has been used in our study as a positive control in both vasoconstriction and binding experiments. At the concentrations used, RPYL was much less potent than valsartan in both experimental settings.

The inhibitory effects of food-derived antihypertensive peptides on angiotensin II-induced vasoconstriction have not been extensively studied, and when studied, no inhibition has been found. Others have reported the lack of effect of the milk-derived tripeptide IPP[26] and the sardine muscle-derived

control	123 ± 7 (12)	nd
BQ-123 (1 µM)[b]	49 ± 3 (8)[c]	

[a]Vasoconstrictor responses are expressed as a percentage of previous KCl-induced contraction. Data are the mean ± SEM from (*n*) arterial segments (nd, not determined). [b]Taken from Fernández-Musoles et al.[17] [c]Significantly different from control, $P < 0.01$. Unpaired Student's *t* test.

dipeptide VY[27] on angiotensin II-induced vasoconstriction. In a previous study with rationally designed heptapeptides, we found that the ACE inhibitor antihypertensive heptapeptide PACEI50 (RKWHFLW) did not modify angiotensin II-induced vasoconstriction.[28] With regard to LF-derived peptides, the crude LF pepsin hydrolysate before ultrafiltration (LFH) did not inhibit angiotensin II-induced vasoconstriction, did not modify blood pressure in SHRs and showed much less inhibitory potency on ACE than LFH < 3 kDa,[11,12] thus indicating that the antihypertensive effects of the LF hydrolysate are due to the bioactive properties of its low molecular weight peptides such as LIWKL and RPYL.

To the best of our knowledge, the present study for the first time shows the ability of antihypertensive bioactive peptides to inhibit angiotensin II-induced vasoconstriction by an angiotensin AT_1 receptor blocking mechanism. With regard to nonpeptide substances, inhibition of angiotensin II-induced vasoconstriction has been reported to underlie the antihypertensive effects of compounds such as nitro-oleic acid, a NO-derived fatty acid,[29] and especially plant extracts used in folk medicine.[30−34] Moreover, proanthocyanidins and alkaloids from some plant extracts are angiotensin AT_1 receptor binding compounds.[21,35,36] On the other hand, inhibitory effects on renin activity, the rate-limiting enzyme upstream of the RAS,[37] have been reported for hemp seed protein hydrolysates,[38] flaxseed protein hydrolysate fractions,[39] and peptides from pea protein hydrolysates,[40] as well as for peptides from a protein hydrolysate of the macroalga *Palmaria palmate*.[41] In most of these cases, inhibitory effects were observed on both renin and

dx.doi.org/10.1021/jf404616f | J. Agric. Food Chem. 2014, 62, 173−181

ACE activities.[38−40] Therefore, bioactive peptides with antihypertensive potential can be multifunctional peptides inhibiting more than one of the RAS steps: generation of angiotensin I from angiotensinogen by renin, generation of vasoactive angiotensin II from angiotensin I by ACE, or activation of the AT_1 receptor by angiotensin II.[37]

The endothelin system, similar to the RAS, is another peptidic system with an increasingly recognized role in blood pressure regulation and hypertension pathophysiology.[42] Of particular relevance in the cardiovascular system, endothelin-1 has powerful vasoconstrictor and pressor properties. The gene product preproendothelin-1 is cleaved by a furin-like endopeptidase to form a biologically inactive intermediate termed big endothelin-1. Next, big ET-1 is cleaved by an endothelin-converting enzyme (ECE) to form endothelin-1, which binds to vascular ET_A receptors to induce vasoconstriction.[43] Both AT_1 and ET_A receptors belong to class 1 of G protein-coupled receptors,[44] and dual-action AT_1 and ET_A receptor antagonists reduce blood pressure in experimental hypertension.[45] Moreover, angiotensin AT_1 receptor binding alkaloids from the root of *Bocconia frutescens* also show weaker binding to endothelin ET_A receptors.[35] Our results show that neither LFH < 3 kDa nor RPYL, the peptide with the highest inhibitory effect on angiotensin II-induced vasoconstriction, modified the vasoconstriction induced by endothelin-1, thus supporting the selective effects of LF-derived peptides on the AT_1 receptor. In a previous study, we reported that LfcinB-derived peptides hinder endothelin-1 generation by inhibiting ECE activity but do not act on downstream ET_A receptors or intracellular signal transduction mechanisms leading to vasoconstriction.[17]

Some considerations have to be made regarding the availability of LF-derived peptides both in the present experiments and in in vivo circumstances. Peptidases are present in the wall of blood vessels, both in the endothelial layer and in the smooth muscle.[46] In addition to ACE[9] and ECE[17] activities previously shown in the isolated rabbit carotid artery used in our ex vivo assays, some other vascular peptidases hydrolyze endogenous vasoactive peptides, thus interfering with their biological effects.[47,48] A possible hydrolytic effect of vascular peptidases on LF-derived peptides during their incubation with the carotid arteries cannot be dismissed. Furthermore, depending on the acid−base nature of their amino acid residues, peptide−peptide ionic interactions can occur to form quite stable noncovalent complexes.[49] In our study, interaction between LF-derived peptides and angiotensin II to form peptide complexes unable to bind to AT_1 receptors has not been assessed. The influence of such a mechanism on the availability of LF-derived peptides and their inhibitory effects on angiotensin II-induced contraction cannot be discarded. Finally, bioavailability of peptides after oral administration is needed to guarantee bioactivity.[14] The few bioavailability studies performed in vivo show the detection of VPP and IPP in plasma in picomolar to nanomolar concentrations[50] with elimination half-lives of about 2 min.[51] The low bioavailability found for most natural peptides raises questions as to whether those peptides lower blood pressure only via an ACE-inhibiting mechanism in blood vessels. Although plasma levels of the peptides were not measured in our studies reporting the antihypertensive effects of orally administered $LfcinB_{20-25}$,[10] LIWKL, and RPYL,[12] we showed RPYL to be particularly resistant to simulated gastrointestinal digestion.[12] Moreover, RPYL and the other LF-derived peptides add their inhibitory effects on angiotensin II effects to ACE inhibition.

In conclusion, LF-derived peptides released from different regions of the protein inhibit angiotensin II-induced vasoconstriction by blocking angiotensin AT_1 receptors. The lack of effects on endothelin-1-induced and ET_A receptor-mediated vasoconstriction as well as on depolarization-induced vasoconstriction points to a selective effect of the peptides. Therefore, inhibition of angiotensin II-induced vasocontriction is suggested as a potential mechanism also contributing along with ACE inhibition to the antihypertensive effect of some LF-derived peptides.

ABSTRACT: This study explored whether chlorogenic acid (CGA) and coffee have protective effects against retinal degeneration. Under hypoxic conditions, the viability of transformed retinal ganglion (RGC-5) cells was significantly reduced by treatment with the nitric oxide (NO) donor *S*-nitroso-*N*-acetylpenicillamine (SNAP). However, pretreatment with CGA attenuated cell death in a concentration-dependent manner. In addition, CGA prevented the up-regulation of apoptotic proteins such as Bad and cleaved caspase-3. Similar beneficial effects of both CGA and coffee extracts were observed in mice that had undergone an optic nerve crush (ONC) procedure. CGA and coffee extract reduced cell death by preventing the down-regulation of Thy-1. Our *in vitro* and *in vivo* studies demonstrated that coffee and its major component, CGA, significantly reduce apoptosis of retinal cells induced by hypoxia and NO, and that coffee consumption may help in preventing retinal degeneration.

KEYWORDS: *coffee, chlorogenic acid, neuroprotection, retinal degeneration, hypoxia, RGC-5, glaucoma*

INTRODUCTION

The retina, a thin layer of tissue on the inside back wall of the eye, contains millions of light-sensitive cells and other nerve cells that receive and organize visual information. Collectively, these cells send visual information to the brain through the optic nerve. The retina is one of the most metabolically active tissues in the body, consuming oxygen more rapidly than any other tissues, including the brain. Therefore, it is susceptible to a variety of diseases caused by oxidative stress, including age-related macular degeneration, diabetic retinopathy, and glaucoma—all of which can lead to partial or complete blindness.[1]

One mechanism of retinal degeneration is hypoxia, a reduction in retinal oxygen supply caused by pathologies such as central retinal artery occlusion, ischemic central retinal vein thrombosis, complications of diabetic eye disease, and some types of glaucoma that cause vascular eye diseases.[2,3] Retinal hypoxia can negatively impact both tissue function and cell viability, and is a potential risk factor for sight-threatening disorders.[4]

Unsurprisingly, there has been great interest in identifying neuroprotective compounds that inhibit hypoxia. Particularly promising in this capacity are natural products and phytochemicals that act as antioxidants and can be taken regularly without causing significant side effects.[5−7]

One important group of neuroprotectants comprises derivatives of chlorogenic acid (CGA). Collectively, these phenolic phytochemicals are known to have hepatoprotective, antibacterial, anti-inflammatory, DNA protective, and anti-cancer activities, among others.[8−13] Several studies have also suggested that the antioxidant properties of CGA make it a powerful neuroprotectant.[14−16]

CGA derivatives are found in a variety of edible plants, including tea, fruits, and vegetables. However, the major source of CGA intake in humans is coffee.[17] CGA is 4−12% of raw coffee, while a 200 mL cup of prepared coffee contains 200 mg of total CGA.[18,19] It has also been reported that part of CGA from foods enters into the blood circulation with relatively high absorption rate (33%) in the small intestine of humans.[20] There are also many reports for the bioavailability and pharmacokinetic profile of CGA after coffee consumption.[21−23] Previous studies by Farah et al. showed that major CGA compounds from green coffee are highly absorbed and metabolized in humans by a different manner throughout the whole gastrointestinal tract.[22]

Coffee consumption appears to decrease the risk of developing chronic diseases such as Parkinson's, prostate cancer, and diabetes.[24−27] It also reduces the extent of cognitive declines associated with aging.[28−30] The latter pattern, in particular, supports the idea that the neuroprotective effects of CGA derivatives stem from their antioxidant activities.

Despite these generally positive results, the effects of coffee consumption on ocular health are not yet clear. In particular, clinical studies on the relationship between coffee consumption and risk of glaucoma have yielded conflicting results.[31,32] Thus, we designed the current study to investigate whether coffee and, in particular, its main polyphenol, CGA has protective effects against the degeneration of retinal ganglion cells (RGC-5), both *in vitro* and *in vivo*.

MATERIALS AND METHODS

Chemicals. Hoechst 33342 and propidium iodide (PI) were purchased from Molecular Probes (Eugene, OR, USA). Fluorogold was purchased from Invitrogen (Carlsbad, CA, USA). Anticleaved caspase-3, anti-Bad, and anti-Thy-1 were purchased from Cell Signaling Technology (Danvers, MA, USA). Anti-β-actin and secondary antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA).

The VECTASHIELD Mounting Medium was purchased from Vector Laboratories (Burlingame, CA, USA). Zoletil and Rumpun were used as anesthesia and purchased from Virbac Laboratories (Fort Worth, TX, USA) and Bayer (Newbury, UK), respectively.

Chlorogenic acid (C3878) and all other chemicals and reagents were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Animals. All animal studies were carried out in a pathogen-free barrier zone at the KIST Gangneung Institute and were done in accordance with the procedure outlined in the Association for Research in Vision and Ophthalmology (ARVO) Statement for the Use of Animals in Ophthalmic and Vision Research. Procedures used in this study were approved by the Animal Care and Use Committee of KIST.

Male ICR mice weighing between 30 and 35 g (5 weeks of age) were used in the present study and were acclimated for at least one week, were caged in groups of five or less, and were fed with a diet of animal chow and water *ad lib.* They were housed at 23 ± 0.5 °C and 10% humidity with a 12 h light-dark cycle.

Preparation of the Crude Extract from Coffee Powder. The coffee sample was obtained from a local supermarket (Colombian roast and ground coffee, Tesco, U.K.). Ground coffee (30.0 g) was refluxed with 70% EtOH (600 mL) three times each for 3 h, and the combined solution was filtered and evaporated under vacuum to give a 70% EtOH extract (9.76 g).

HPLC Analysis. Coffee extract (CE) was analyzed by HPLC to quantify CGA using an Agilent 1200 series system, equipped with a G1379B vacuum degasser, a G1312A binary pump, a G1329A autosampler, a G1316A column oven, and a G1315B DAD detector (Agilent, Palo Alto, CA, USA). The separation was carried out on a Shiseido MGII C-18 column (250 mm × 4.6 mm i.d., 5 μm particle size). The mobile phase consisted of 0.1% TFA in water and acetonitrile (93:7) with a flow rate of 1.0 mL/min during 45 min. The UV detector was set at 330 nm with full spectral scanning from 200 to 400 nm, and the sample injection volume was 10 μL.

A standard solution of CGA (31.25−1000 μg/mL) was prepared in methanol, and 10 μL of each was injected into the HPLC column via the autoinjector. The linearity was evaluated by linear regression analysis, which was calculated by the least-squares regression method. The limit of detection (LOD) and the lower limit of quantification (LOQ) were defined as the minimum concentration at the signal-to-noise ratio (S/N), equal to 3.3 and 10, respectively. The precision, accuracy, and recovery were evaluated by analyzing three different concentrations on the same day and on three different days. All the experiments were carried out in triplicate.

Culture of RGC-5 Cells. RGC-5 cells that are proven to be of mice origin are highly relevant to the study of glaucomatous neurodegeneration and have been previously shown to express ganglion cell markers and ganglion cell-like behavior in culture.[33,34]

To mimic physiological hypoxic stress, RGC-5 cultures were transferred into a closed hypoxic chamber (Billups-Rothenberg Inc., Del Mar, CA, USA) in which the gas levels (1% O_2, 5.13% CO_2, and 93.87% N_2) and temperature (37 °C) were automatically controlled, and they were incubated for 24 h. Under hypoxic conditions, cells were cotreated with *S*-nitroso-*N*-acetylpenicillamine (SNAP), a nitric oxide (NO) donor, with low glucose (5.5 mM) Dulbecco's modified Eagles's medium (DMEM; Gibco, Carlsbad, CA), which mimics physiological normal blood sugar levels *in vivo*. Culture of RGC-5 cells in 96-well plates was analyzed 24 h later for cell viability, and the cells in a 60 mm^2 dish were analyzed 24 h later for Western blot analysis.

Cell Viability. To measure the relative number of living cells, an EZ cytox cell viability assay kit (Daeil Labservice, Seoul, Korea) for a WST-1 assay was used.

The number of living cells in each well was determined by measuring the optical density (OD) at 460 nm with a microplate reader (BioTek Instruments, Winooski, VT, USA). This quantity was expressed relative to the control value.

Microscopic Analysis of Cell Viability by Hoechst 33342 and PI Double Staining. The Hoechst 33342 and PI double staining method was used to determine whether cell death occurred as a result of apoptosis or necrosis.[35] The cells were stained with 8 μM Hoechst 33342 and 1.5 μM PI for 30 min at 37 °C. After being washed twice with serum free media, the cells were imaged using a fluorescence microscope (Olympus, Tokyo, Japan).

Protein Extraction and Western Blot Analysis. The cells were scraped using a cell scraper and centrifuged at 14,000*g* for 10 min. The cell pellets were resuspended in cell lysis buffer [1 M Tris pH 7.4, 2 M NaCl, 1 M EDTA, 10% NP40, 1 × protease inhibitors, 1 mM PMSF] and then incubated on ice for 10 min. The extracted cells were centrifuged at 14,000*g* for 30 min at 4 °C. The supernatant was sonicated, and the total protein concentration was determined using a Bio-Rad Protein Assay kit (Bio-Rad Laboratories, Hercules, CA, USA).

Western blot analysis was performed with the primary antibodies, including anticleaved caspase-3, anti-Bad, anti-Thy-1 (1:1000, Cell Signaling Technology, Beverly, MA, USA), and β-actin (1:3000, Santa Cruz Biotechnology, CA, USA). Secondary antibodies were purchased from Santa Cruz Biotechnology Co. Ltd. (1:3000, Santa Cruz Biotechnology, CA, USA). Immunoreactive bands were detected using enhanced chemiluminescence reagents (Amersham Bioscience, GE Healthcare, U.K.) and were measured via densitometry using a LAS-4000 image reader and Multi Gauge 3.1 software (Fuji Photo Film, Japan).

Histological Analysis. For Hematoxilin and Eosin staining, the enucleated eyes were fixed in 10% formalin for 24 h, embedded in paraffin, and sectioned through an equatorial plane at 4 μm thickness using a HM340E microtome (Walldof, Germany). Four sections (n = 4) were used for analysis.

Hematoxylin solution was added to the retina section (0.1% hematoxylin, 10% ammonium) for 8 min. The sections were then washed three times with distilled water. Bluing reagent (0.2% lithium carbonate solution) was added to the section for 1 min. The sections were quickly rinsed in 95% alcohol, and 1% Eosin Y solution was added to the sections for 1 min. Eosin Y was washed off with 95% alcohol three times, and the sections were cover-slipped with a mounting medium and observed under a light microscope (Olympus, Tokyo, Japan).[36]

For TUNEL staining, the sections were submitted to enzymatic digested with 20 μg/mL of proteinase K for 15 min and then washed with PBS and incubated with 3% hydrogen peroxide in PBS for 5 min at room temperature and twice rinsed in PBS. They were then immersed, incubated with a stock solution of terminal deoxynucleotidyl transferase (TdT) reaction enzyme in a humidified chamber at 37 °C for 1 h, and then washed three times in PBS for 1 min. The sections were subsequently incubated with antidigoxygenin peroxidase conjugate and peroxidase substrate. Histological analysis was performed with a light microscope (Olympus, Tokyo, Japan), allowing us to look for signs of apoptosis (brown staining).

Optic Nerve Crush. Five-week-old ICR mice with a body weight of 30−35 g were used in the study.

Animals were anaesthetized by intraperitoneal injection with a mixture of Zoletil (1.6 μg/g, Verbac Laboratories 06515, France) and Rompun (0.05 μL/g, Bayer), and retinal damage was induced using optic nerve crush (ONC).[37] The optic nerve of the left eye in all treatment groups was exposed by opening the meninges of the optic nerve with the sharp tips of a forceps, followed by blunt dissection. Then the exposed optic nerve was partially crushed 2 mm behind the globe for 10 s with a cross-action calibrated forceps. In each case, a "sham" operation was performed in the same way on the partner eye, but without closing the forceps, to check for any falsifying influence of surgery on the treatment effects. In all cases the retinal blood supply

remained grossly intact, as judged on the basis of a direct ophthalmoscopic inspection. After ONC in mice, CGA or CE was dissolved in PBS, and administered orally at a dose of 10 mg/kg and 30 mg/kg for 2 weeks once a day.

All eyeballs were enucleated immediately after mice were sacrificed, and then fixed for retrograde labeling of retinal ganglion cells (RGCs).

RGC Labeling and Retinal Flat Mount Preparation. Mice were anesthetized by intraperitoneal or intramuscular administration of a mixture of Zoletil (1.6 μg/g, Verbac Laboratories 06515, France) and Rompun (0.05 μL/g, Bayer) 9 days after CGA or CE treatment. The skin over the cranium was incised, and the scalp was exposed. Holes approximately 2 mm in diameter were drilled in the skull 4 mm posterior to the bregma, 1 mm lateral to the midline, with a dentist's drill on both sides of the midline raphe. These positions correspond to the superior colliculi as determined from a stereotactic mouse brain atlas.

The superior colliculi were exposed by gentle aspiration of the overlying occipital cortex. A piece of Gelfoam soaked in a 5% solution of the neurotracer dye Fluorogold (Invitrogen, NY, USA) was directly applied to each superior colliculus. Skull openings were then sealed with a petrolatum-based antibiotic ointment. The overlying skin was sutured and antibiotic ointment applied externally.

Five days after the application of Fluorogold (enough time to allow retrograde uptake of the dye and labeling of the RGC somata), mice were sacrificed by transcardial perfusion with 4% buffered paraformaldehyde (Sigma-Aldrich, St. Louis, MO, USA) while under the same anesthesia as that used for RGC labeling. Eyes were immediately enucleated, and the retinas were detached at the ora serrata and cut with a trephine around the optic nerve head. Four radial relaxing incisions were made and the retinas prepared as flattened whole mounts on silane-coated microscope slides.[38]

Statistical Analysis. The data are expressed as a mean percentage of the control value plus standard error of the mean (SEM). Statistical comparisons were made using a one-way ANOVA followed by a Dunnett's test. Statistical analyses were conducted using GraphPad Prism (version 4.0) (GraphPad, San Diego, CA, USA). Significance was defined as $p < 0.05$.

RESULTS AND DISCUSSION

Cell Viability Following Treatment with SNAP and/or Hypoxia. Under normoxic conditions, we observed no changes in cell viability when RGC-5 cells were treated with SNAP (data not shown). Likewise, the two lowest concentrations of SNAP did not have any noticeable effects on the viability of RGC-5 cells exposed to hypoxic conditions (Figure 1). However, both the 50 and 100 μM treatments resulted in highly significant reductions in viability ($p < 0.001$). The 100 μM treatment had a particularly noticeable effect, causing a 41% reduction of viability. Thus, this is the concentration that was used in the *in vitro* experiments (Figure 1).

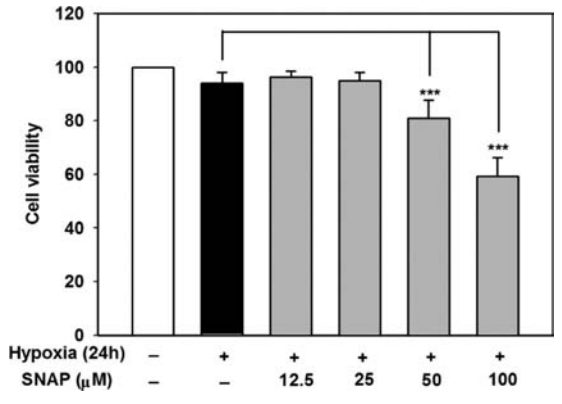

Figure 1. Effects of *S*-nitroso-*N*-acetylpenicillamine (SNAP) on the viability of retinal ganglion (RGC-5) cells cultured under hypoxic conditions for 24 h. Values are presented as means ($n = 6$ independent experiments per treatment); error bars indicate SEM. Triple asterisks (***) indicate $p < 0.001$.

The negative effects of SNAP observed here are similar to those previously reported by Sato et al. (2010).[39] They found that treatment with SNAP under hypoxic conditions resulted from activation of caspase and the formation of superoxide anions and peroxynitrite.[39]

Cell Viability Following Treatment with SNAP and CGA. CGA significantly blunted the negative effect of SNAP on RGC-5 cells (Figure 2). This effect was dose-dependent, with cell viability increased by 72.6%, 92.7%, and 101.6% in response to 25, 50, and 100 μM CGA pretreatments, respectively (all $p <$ 0.001 in comparison with the control; Figure 2A).

The antioxidant *N*-acetylcysteine (NAC) and the NO scavenger 2,4-carboxyphenyl-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (CPTIO) were used as positive controls. Both

(a) Control RGC-5 cells under normoxic conditions. (b) RGC-5 cells under hypoxic conditions. (c) RGC-5 cells treated with 100 μM SNAP under hypoxic conditions. (d–f) RGC-5 cells pretreated with CGA (25, 50, and 100 μM concentrations, respectively) prior to being exposed to 100 μM SNAP under hypoxic conditions. Scale bar =50 μm.

dx.doi.org/10.1021/jf404285v | J. Agric. Food Chem. 2014, 62, 182–191

treatments also significantly reduced the negative impacts of SNAP observed in the untreated controls ($p < 0.05$ for the 2 mM NAC treatment, and $p < 0.001$ for the 100 μM CPTIO treatment; Figure 2A). Previous work has shown that the benefits of CPTIO stem from its suppression of both caspase activation and NO production.[39] CGA has been considered an antioxidant agent; moreover, CGA is a potent inhibitor of NO production by the inhibition of the expression of inflammatory proteins such as COX-2 and iNOS, without cytotoxic effects.[40,41]

The similar viabilities observed in cells treated with CPTIO and CGA treatments suggest that CGA may protect cells by scavenging NO that might otherwise lead to neurodegeneration of RGC-5 cells under hypoxic conditions.

Fluorescence microscopy of Hoechst 33342- and PI-stained cells revealed similar patterns to those produced by the WST-1 assay (Figure 2B). More apoptotic/necrotic cells were observed in cultures treated with SNAP than in control cultures. However, lower levels of cell death were observed in cultures that had been pretreated with CGA; this was particularly noticeable in response to the 100 μM CGA treatment.

Our Western blot analysis showed up-regulation of Bad and cleaved caspase-3 in cells that had been exposed to SNAP under hypoxic conditions, in relation to β-actin of the control (Figure 3). However, this response was noticeably suppressed in cells given a 100 μM CGA pretreatment. A similar pattern was observed in cells treated with CPTIO as a positive control.

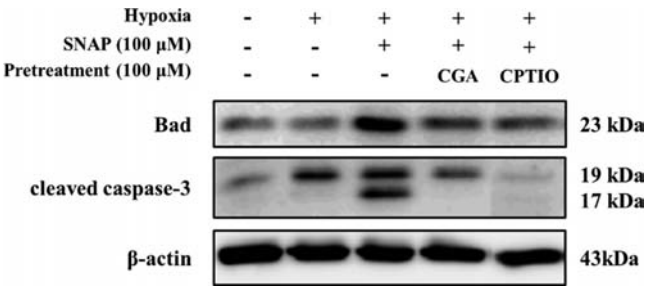

Figure 3. Western blot of apoptotic proteins in RGC-5 cells subjected to 100 μM SNAP for 24 h under hypoxic conditions. The nitric oxide (NO) scavenger 2,4-carboxyphenyl-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (CPTIO) was used as a positive control. Pretreatment with CGA appeared to have antiapoptotic effects on hypoxia and NO-induced down-regulation of both Bad and cleaved caspase-3.

Bad (BCL-2 antagonist of cell death), a pro-apoptotic protein in the BH3 domain-only group,[42] is the key regulator of apoptosis and is, itself, regulated primarily by phosphorylation.[43,44] Bad can be cleaved into a shortened form by caspases, which are cysteine proteases that play an important role in apoptosis.[45−47] When this cleavage occurs, Bad can be a more potent inducer of apoptosis.[46,47] Apoptosis is also facilitated by the activity of caspase-3, which is known to promote neuronal apoptosis.[48,49]

Effects of CGA on Optic Nerve Crush-Induced Retinal Damage in Mouse. ONC is a well-known experimental model for chronic glaucoma. During the procedure, the surgically exposed optic nerve is clamped for several seconds, resulting in both primary RGC death due to the optic nerve injury and secondary death of surrounding, uninjured RGCs.[50]

Results from our histological hematoxylin and eosin staining assay can be seen in Figure 4A. Relative to tissues that underwent no ONC (Figure 4A, a), those that were crushed but received no chemical treatment exhibited a clear thinning of the inner plexiform layer (IPL) (Figure 4A, b). However, this thinning appears to have been inhibited in tissues treated with CGA (Figure 4A, c and d).

In addition to investigating these morphological patterns, we also used TUNEL staining to explore whether CGA could also reduce ganglion cell apoptosis associated with ONC (Figure 4B). Control tissues (Figure 4B, a) had fewer TUNEL-positive cells than those subjected to ONC (Figure 4B, b). As with the hematoxylin and eosin assay, however, we found that the negative effects of ONC were mitigated by treatment with CGA; in this case, there were notably fewer TUNEL-positive cells in the ganglion cell layer (GCL) of tissues treated with CGA (Figure 4B, c and d).

RGC survival was much lower in tissues that had undergone optic nerve crush (ONC) than in controls (Figure 4C, a−d). In tissues that had been treated with CGA, however, RGC survival was markedly higher (Figure 4C, e−h). This was particularly true in tissues that had been dosed with 30 mg/kg of CGA (Figure 4C, g and h). Further, both CGA treatments appeared to prevent the dramatic decrease (52.7%) in Thy-1 protein that occurred in tissues that had undergone ONC (Figure 4D). Thy-1 is a surface glycoprotein expressed uniquely in RGCs; it serves as an early marker of RGC loss in models of retinal damage.[51]

Indeed, 30 mg/kg CGA was similar or more effective for the neuroprotective effects on retinal degeneration than the same concentration of epigallocatechin gallate (EGCG) used as positive control; thus, the patterns reported here strongly suggest that CGA is a powerful neuroprotectant that can prevent retinal cell death.

Previously reported mechanisms for the degeneration by ONC include blockade of axonal transport resulting in inadequate supply of neurotrophic factors, disturbances of intracellular calcium homeostasis, activation of cell death genes, and local excitotoxicity due to uncontrolled activation of NMDA receptors.[52,53] ONC induces apoptotic cascades during which cytochrome *c* is released and both caspases-9 and -3 are subsequently activated.[54,55]

Injury of the optic nerve also causes an inflammatory response involving the release of cytotoxic compounds such as free radicals, NO, and glutamate.[56]

Administration of SNAP under hypoxic conditions has been associated with NO release, causing RGC-5 cell death by decreasing mitochondrial membrane potential, increasing the formation of superoxides, and activating caspases.[39] Thus, our current data suggest that the beneficial effects of CGA on retinal cells, both *in vitro* and *in vivo*, are partly due to its NO scavenging activity.

HPLC Chromatograms of CE and Standardization of CGA in CE. HPLC chromatograms of CE showed a CGA peak retention time at 28.5 min (Figure 5). We observed no interference from other materials in the extract, indicating that the specificity of the method was reliable. The limits of detection (LOD) and limits of quantification (LOQ) for CGA were 7.67 μg/mL and 23.26 μg/mL, respectively (Table 1). Precision is the measure of how close the data values are to each other for a number of measurements under the same analytical conditions and expressed as the % relative standard deviation (%RSD) of each analyte concentration. Our analyses were associated with very low levels of relative standard deviation (RSD: intraday, >2.57%; interday, >2.60%), indicating that our CGA measurements were highly precise (Table 2).

(RGCs) harvested from mice 14 days after optic nerve crush (ONC). Retina from (a) an untreated control mouse, (c) a mouse that underwent ONC only, (e) a mouse that underwent ONC and was treated with 10 mg/kg of CGA, (g) a mouse that underwent ONC and was treated with 30 mg/kg of CGA, and (i) a mouse that underwent ONC and was treated with 30 mg/kg EGCG. Images in the lower row are 100× magnifications of the images above them; scale bars in the upper row represent 500 μm, while scale bars in the lower row represent 100 μm. (k) Quantitative analysis of the survival (%) rate of RGCs 14 days after ONC. Experimental values are expressed as mean SEM. Single asterisks (*) indicate $p < 0.05$; double asterisks (**) indicate $p < 0.01$; triple asterisks (***) indicate $p < 0.001$. (D) Results of Western blot analysis investigating Thy-1 expression in RGCs 14 days after the ONC procedure. Densitometric analysis of Thy-1 levels; data are shown as mean SEM. Single asterisks (*) indicate $p < 0.05$.

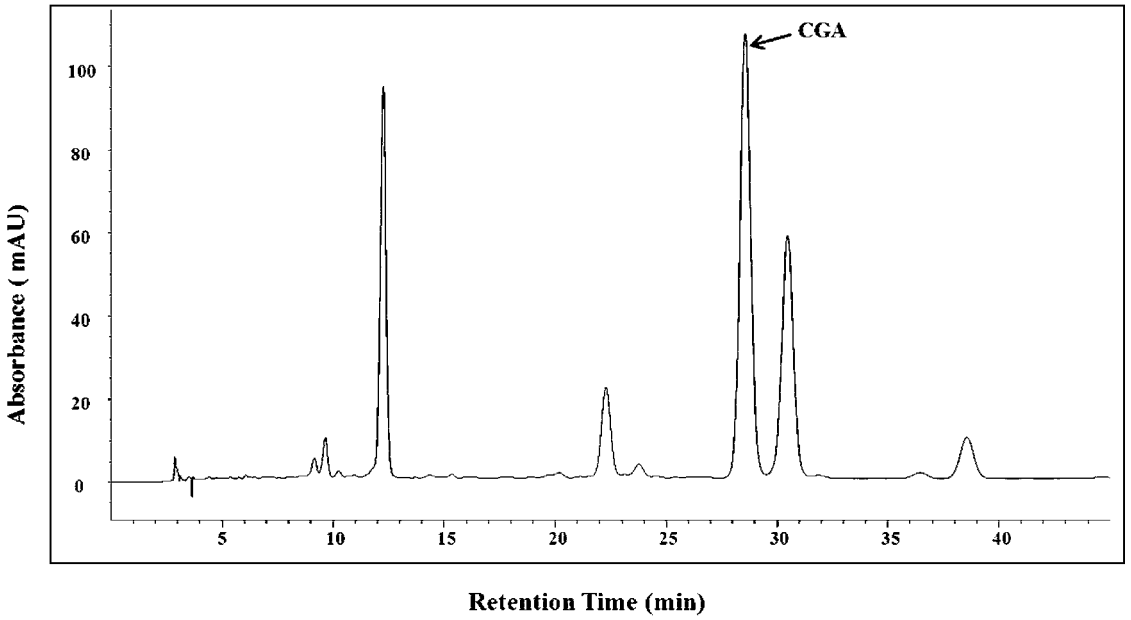

Figure 5. High-performance liquid chromatography analysis of coffee extract (prepared in 70% EtOH); ultraviolet detection was performed at 330 nm. The arrow indicates the peak corresponding to CGA.

Table 1. Calibration Curve, Correlation Coefficients, Limits of Detection (LOD), and Limits of Quantification (LOQ) of CGA

standard sample	range (μg/mL)	slope	intercept	R^2	LOD[a] (μg/mL)	LOQ[a] (μg/mL)
CGA	31.25−1000	24.226	167.56	1.0	7.67	23.26

[a]$n = 3$ replicates.

Table 2. Intra- and Interday Precision and Accuracy for the Determination of CGA

		intraday ($n = 3$)			interday ($n = 3$)		
stand sample	conc (μg/mL)	found conc (μg/mL) ± SD	recovery (%)	%RSD[a]	found conc (μg/mL) ± SD	recovery (%)	%RSD[a]
CGA	61.25	64.42 ± 0.94	103.07	1.46	61.60 ± 1.60	98.56	2.60
	125	126.88 ± 3.06	101.50	2.41	125.28 ± 0.45	100.22	0.36
	250	253.45 ± 6.51	101.38	2.57	246.47 ± 0.40	98.59	0.16

[a]RSD refers to the relative standard deviation.

The accuracy by mean recovery (%) for CGA ranged from 98.56 to 103.07% (Table 2), thus it can be accurately determined by this method from any small changes in the standard sample concentration.[57]

Effects of CE on Optic Nerve Crush-Induced Retinal Damage in Mouse. In addition to investigating the effects of pure CGA on retinal degeneration, we also explored whether CE, a major source of CGA, has similar benefits. As we observed in the CGA activity, lower levels of RGC death were found in control tissues (Figure 6A, a and b) than in those that were crushed but not treated with exogenous compounds (Figure 6A, c and d). In tissues treated with 50 mg/kg of CE, however, cell death was markedly reduced (Figure 6A, i and j). The protective effects of CE occur in a dose-dependent manner (Figure 6A, e−j). Likewise, while the 50 mg/kg CE treatment was associated with a preservation of Thy-1 expression, the 10- and 30 mg/kg CE treatments were less effective than the group of 50 mg/kg CE treatments (Figure 6B).

Based on the HPLC chromatogram of CE, we found 14.7 mg/g of CGA in CE. Although the amount of CGA in CE is less than the reported amount, the group of CE treatment shows similar protective effects with the CGA treatments (Figures 4C and 6A).[19]

Since significant amounts of CGA are metabolized in the human intestine and some phenolic metabolites of coffee are known to possess high antioxidant activity,[58] we expect that the

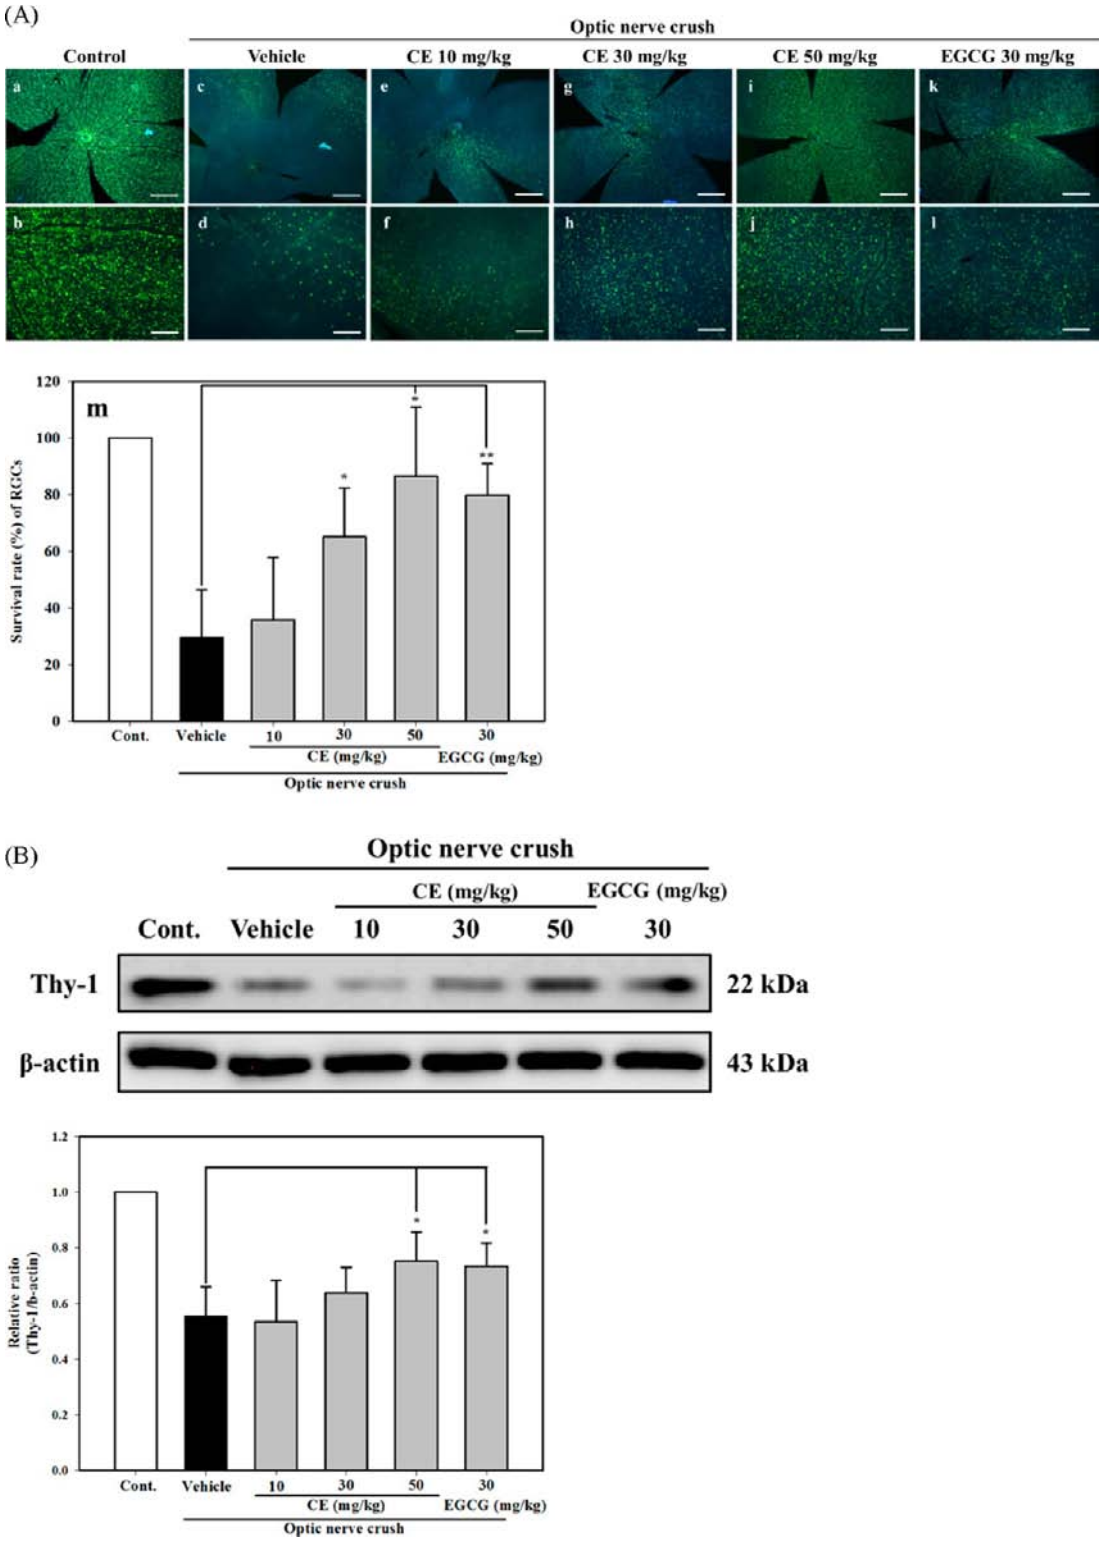

Figure 6. Optic nerve crush (ONC) experiments on the impacts of CE treatment on retinal tissues of mice. (A) Representative micrographs of Fluorogold-labeled tissues from (a) a control, (c) a mouse that underwent ONC, (e) a mouse that underwent ONC and was treated with 10 mg/kg of CE, (g) a mouse that underwent ONC and was treated with 30 mg/kg of CE, (i) a mouse that underwent ONC and was treated with 50 mg/kg of CE, and (k) a mouse that underwent ONC and was treated with 30 mg/kg EGCG. Images in the lower row are 100 × magnifications of the images in the row above them; scale bars in the upper row represent 500 μm, while scale bars in the lower row represent 100 μm. (m) Quantitative analyses of the survival (%) rate of RGCs 14 days after ONC. Experimental values are expressed as mean SEM. Single asterisks (*) indicate $p < 0.05$; double asterisks (**) indicate $p < 0.01$. (B) Results of Western blot analysis investigating Thy-1 expression in RGCs 14 days after the ONC procedure. Densitometric analysis of Thy-1 levels; data are shown as mean SEM. Single asterisks (*) indicate $p < 0.05$.

dx.doi.org/10.1021/jf404285v | J. Agric. Food Chem. 2014, 62, 182−191

additional bioactivities are originated from those metabolites. Therefore, the research on the protective effects of CGA and coffee metabolites on retina is being conducted.

In conclusion, this study shows that CGA and coffee extract are responsible for reduction of the RGC apoptosis induced by hypoxia and NO. Therefore, coffee consumption may provide additional health benefits by preventing retinal degeneration.

ABSTRACT: Many studies have utilized a variety of methods to induce obesity in rodents, but they often received inconsistent results. The present study intended to use resistant maltodextrin (RMD) as a means to investigate the variations in its efficacy on body fat accumulation under the influence of four high-fat (HF) models of 23% or 40% total fat, comprising soybean oil, lard, and/or condensed milk. Results indicated that integrating condensed milk into the diets could help increase diet intake, boost energy intake, increase weight gain, and enhance fat formation. Supplementation of RMD (2.07 g/kg) notably reduced total body fat levels in three HF models, with the exception of a condensed-milk-added 40%-fat diet that may have misrepresented the functions of RMD. The uses of the 23% HF diets, with and without milk, and the milk-free 40% HF diet were therefore recommended as suitable models for antiobesity evaluations of RMD, or other fiber-rich products.

KEYWORDS: *Resistant maltodextrin, body fat, high-fat diet*

INTRODUCTION

Obesity is a medical condition that facilitates the development of metabolic disorders including diabetes, hypertension, and cardiovascular disease.[1] In recent decades, many studies, including human trials and animal tests, have been widely performed to investigate the relationship between dietary lipid absorption and body fat accumulation, in hopes of finding ways to reduce lipid absorption and body weight.[2−4]

To study the mechanisms involved in body fat reduction, obese rodent models are commonly used. A variety of methods have been developed to induce obesity in rodents. For example, obesity could be induced by feeding them fat-enriched, high-sugar, or high-calorie diets. Among these diet choices, a high-fat (HF) diet was commonly used to induce obesity in rodents. A wide range of fat contents, ranging from 10% to 63% (w/w), have been used in different studies, with fat contents around 23% and 40% being the two most frequently used models.[5] Dietary lipid types also varied between animal-derived fats (e.g., lard or beef tallow) and plant oils (e.g., corn or safflower oil) in previous studies. In some studies, a portion of condensed milk or fructose was also added into the HF diets to help induce obesity.[6,7] However, different combinations of fat contents and fat types have been found to induce diversified increases in body fat, ranging from 38% to 169%.[8,9]

In the past few decades, the potential inhibitory effects of many food ingredients on lipid absorption and its accumulation in body have been investigated, but the results have not always been consistent.[8−12] For instance, though green tea (at 1−3 mg/kg per day) has commonly been reported to have body-fat-reducing effects, contradicting results were observed between rats fed a 15%-fat HF diet and those fed a 30%-fat HF diet.[12,13] It was therefore speculated from these studies that different HF feeding models could lead to different outcomes to the assessments of the same ingredient.

New ingredients possessing potential for body fat-reducing effect have been reported in recent years. Resistant maltodextrin (RMD), as one of the candidates, is a type of colorless and tasteless water-soluble fiber, composed of short-chain glucose polymers that are resistant to digestion in the human digestive system. Studies have reported that RMD could delay absorption of carbohydrates, reduce dietary lipid absorption and serum triglyceride level, and suppress elevation of postprandial blood glucose.[14−17] Its high stability against temperature variations and acidic conditions has driven RMD to become a popular water-soluble fiber component in many nutritional supplements.

The present study intends to use RMD as a means to demonstrate and compare the various possible influences of different HF diet compositions on body fat accumulation in rats. In particular, the variations in the efficacy of RMD in different HF dietary models will be accurately evaluated and discussed. Relationships between different HF diets and food intake, body weight, visceral fat, or total body fat will also be addressed.

MATERIALS AND METHODS

Experimental Diets and Design. One hundred and four male Sprague−Dawley rats (6 weeks old) weighing 137 ± 5 g were purchased from the National Laboratory Animal Center (Taipei, Taiwan). The animals were individually housed in stainless steel screen-bottomed cages and placed in a room maintained at 22 ± 2 °C with a 12-h light/dark cycle. After a two-week acclimation period, the rats were divided into eight weight classes of thirteen animals each. The rats in each weight class were randomly assigned to one of the thirteen diet groups, including one normal chow diet (ND), and twelve HF diet experimental groups.

The compositions of the ND diet and twelve high-fat experimental diets are shown in Table 1. All HF diets contained either 23% or 40% (w/w) total fat contents. The HF diet groups included soybean oil and lard, with or without condensed milk. Specifically, the twelve high-fat diets were designed for 4 distinct HF-diet arrangements (namely, 23, 23M, 40, and 40M), each with its own experimental control (-C) group, low-dose treatment (-1xF) group, and high-dose treatment (-2xF) group. In more detail, the twelve HF-diet groups comprised three groups (23-C, 23-1xF, and 23-2xF) receiving 23%-fat diets without condensed milk, three groups (23M-C, 23M-1xF, and 23M-2xF) receiving 23%-fat diets with condensed milk, three groups (40-C, 40-1xF, and 40-2xF) receiving 40%-fat diets without condensed milk, and three groups (40M-C, 40M-1xF, and 40M-2xF) receiving 40%-fat diets with condensed milk. Animals in all -1xF groups received a single dose of RMD (1.03 g/kg body weight) each day, and each animal in the -2xF groups was given a double dose of RMD (2.07 g/kg body weight) every day. The doses of RMD (at 1.03 and 2.07 g/kg) are approximately equivalent to 10 and 20 g/day, respectively, for a 60-kg human. These dose equivalents are in accordance with body surface area calculation as recommended by the U.S. FDA.[18] The actual amounts of RMD supplement for the rats were constantly recalculated every three days to adjust for changes in body weights throughout the test period.

Animals were allowed free access to food and water during the experimental period. Food intake and body weights were recorded daily. At the end of the experimental period, animals were anesthetized by carbon dioxide after fasting for 12 h. After blood samples were drawn from the orbital sinus, the anesthetized rats were sacrificed by exsanguination. The visceral fat pads were immediately excised, blot dried, and weighed. The coats were shaved and the remaining carcasses were then weighed and stored at −20 °C until analysis. The institutional guidelines for the care and use of laboratory animals were carefully followed. This study protocol was approved by the Institutional Animal Care and Use Committee of National Chung Hsing University.

Feed Efficiency. Feed efficiency was determined after 8 weeks on the experiment diets for each rat using the following formula:

$$\text{Feed efficiency} = \text{body weight gained (g)} / \text{food intake (g)} \times 100$$

Measurement of Total Visceral Fat. Total visceral fat was defined as the sum of the mesenteric, epididymal, and perirenal fat depots.[19] All fat along the mesentery starting at the lesser curvature of the stomach and ending at the sigmoid colon was considered mesenteric fat. At sacrifice, the mesenteric, epididymal, and perirenal fat depots were dissected from the rats and weighed before freezing.

$$\text{Visceral fat\%} = \text{total visceral fat (g)} / \text{final body weight (g)} \times 100$$

Measurement of Crude Carcass Fat. For the present study, the carcass was defined as the entire shaved rat torso minus the visceral fat

dx.doi.org/10.1021/jf404809v | J. Agric. Food Chem. 2014, 62, 192−197

Figure 1. Effects of different diet models on visceral fat mass in control groups. (A) Epididymal fat of normal diet (ND) group; (B) peri-renal fat of normal diet (ND) group; (C) epididymal fat of nonmilk 23%-fat control (23-C) group; (D) peri-renal fat of nonmilk 23%-fat control (23-C) group; (E) epididymal fat of milk-containing 23%-fat control (23M-C) group; (F) peri-renal fat of milk-containing 23%-fat control (23M-C) group; (G) epididymal fat of nonmilk 40%-fat control (40-C) group; (H) peri-renal fat of nonmilk 40%-fat control (40-C) group; (I) epididymal fat of milk-containing 40%-fat control (40M-C) group; (J) peri-renal fat of milk-containing 40%-fat control (40M-C) group.

pads removed during sacrifice. Following the method of Janis et al. with slight modifications, rat carcasses were dried at 80 °C for 4 h, followed by drying at 105 °C for another 24 h.[20] Dried carcasses were weighed and ground individually without deboning. Furthermore, fat extractions were performed on all shaved coats and the carcasses. Following the AOAC method with slight modifications, carcass fats were extracted from the dried carcass powder by ether (1:20, w/v), and total crude carcass fats were quantified gravimetrically after evaporating the solvents in the lipid extracts.[21]

$$\text{Carcass fat\%} = \text{crude carcass fat (g)} / \text{final body weight (g)} \times 100$$

Determination of Body Fat Percentage. Total body fat was defined as the sum of total visceral fat and crude carcass fat. Body fat percentage of each rat was therefore calculated using the following formula:

$$\text{Body fat (\%)} = (\text{visceral fat (g)} + \text{crude carcass fat (g)}) / \text{final body weight(g)} \times 100$$

Statistical Analysis. All experiments were performed on groups of eight animals. Data are presented as means ± standard deviation. Numerical data were analyzed with SPSS 19.0 statistics software (Chicago, IL, USA). The significance level was set to $p < 0.05$ (Duncan).

RESULTS

The food intakes, energy intakes, fat intakes, body weight gains, and feed efficiencies of the animals fed the different diets are shown in Table 2. After the acclimation period, there were no differences in the initial body weights (249−280 g) among the thirteen dietary groups. Throughout eight weeks of observation, all animals remained healthy and active. All animals on the four HF control diets (i.e., 23-C, 23M-C, 40-C, and 40M-C) consumed lesser amounts of feed (−5 to −31%) cumulatively than the ND group (1509 g). Feed consumptions for the 40%-fat groups (40-C and 40M-C) were lower than those of the 23%-fat groups (23-C and 23M-C, respectively). Owing to the higher energy density in the 40%-fat diets (Table 1), the actual fat and energy intakes in the 40%-fat groups were significantly higher, demonstrating that the actual energy intake could be a collective consequence of the consumption level and energy density. Furthermore, it was also noted that the incorporation of condensed milk into the HF diets might help increase food intakes. Total energy intakes (6051−6925 kcal) for all six condensed milk-feeding groups were higher than those (5575−5677 kcal) of the other milk-free HF groups.

In terms of the body weight changes during the experimental period, all four HF control groups gained significantly ($p < 0.05$) more weight (133−153%) than the ND group due to higher fat intake in these HF groups. Similarly, the feed efficiencies of the four HF control diets (20.9−25.0) were significantly ($p < 0.05$) higher than that of ND diet (13.0) (Table 2). The results revealed that fat intake and feed efficiency were positively correlated. It seemed that the fat component was a major factor affecting the feed efficiency while both condensed milk and RMD supplementation only led to some slight but consistent decreases in feed efficiencies.

The apparent differences in visceral fat sizes are visually presented in Figure 1. The organs were removed before the measurement of fat mass. The ND control group was shown to have the lowest fat mass in the epididymal and peri-renal area (Figure 1A and B), while all four HF diet control groups had greater fat mass than ND, with the milk-containing 40%-fat diet (40M-C) control group showing the greatest fat mass in the same visceral area (Figure 1I and J). More specifically, Table 3 shows that the visceral accumulations of fat in four HF control groups were all markedly ($p < 0.05$) higher (1.6- to 2.4-fold)

Table 3. Effects of the Administration of RMD on Visceral Fat Percentage[a]

	high-fat controls[b]	RMD treatment groups[c]	
treatment	(without RMD)	low dose (1.03 g/kg bw)	high dose (2.07 g/kg bw)
23% fat	9.9 ± 1.0nx	9.5 ± 0.7xy	8.6 ± 1.0y
23% fat (with condensed milk)	13.5 ± 1.3ox	12.4 ± 1.0x	10.5 ± 0.7y
40% fat	13.0 ± 1.2ox	12.6 ± 1.5x	10.9 ± 1.5y
40% fat (with condensed milk)	15.5 ± 1.7px	15.5 ± 0.9x	15.3 ± 1.0x

[a]Data are expressed as mean ± standard derivation ($n = 8$). [b]The visceral fat percentage of the ND group (6.4 ± 1.4%) was significantly ($p < 0.05$) lower than that of all high-fat controls. Values with different letters (n−p) in the high-fat control column are significantly different (Duncan, $p < 0.05$). [c]Values in the same row with different letters (x−y) are significantly different (Duncan, $p < 0.05$).

than that of the ND group (6.4%). The visceral fats of 40%-fat HF controls (40-C and 40M-C) were significantly ($p < 0.05$) higher than those of the 23%-fat controls (23-C and 23M-C, respectively). The incorporation of condensed milk in both the 23%- and 40%-fat diets led to significant ($p < 0.05$) increases in visceral fat (1.36- and 1.19-fold, respectively) against their corresponding milk-free diets. Furthermore, our results revealed that the administration of RMD at a high dose (2.07 g/kg) could result in significant ($p < 0.05$) reductions in the levels of visceral fat (−13% to −22% against the controls) among different HF models excluding the 40M model.

Moreover, the effects of RMD administration on crude carcass fat (nonvisceral fat) accumulation are demonstrated in Table 4. Similar to the findings in the visceral fat, the carcass fat accumulations in all four HF control groups were significantly ($p < 0.05$) higher (1.67- to 2.0-fold) than that of the ND group (3.3%). Among the four HF controls, the 40%-fat diet with condensed milk was again the most effective model in accumulating fat (6.6%). In the other three models (i.e., 23-C, 23M-C, and 40-C), different amounts of fat consumption (292−417 g) and total energy intakes (5635−6359 kcal) (Table 2) merely led to comparable levels of carcass fat accumulation (5.5% to 5.8%). Nonetheless, administration of RMD at 2.07 g/kg was again able to significantly reduce ($p < 0.05$) the carcass fat (−16% to 28% against the controls) in different HF models, except the 40M model. It was interesting to note that RMD was similarly more effective in reducing the carcass fat in diets without condensed milk. These results reaffirmed that the ability of RMD in reducing fat accumulation was basically affected by dietary compositions such as fat content and condensed milk.

Lastly, the present study also compared total body fat in the animals as a sum of total visceral fat and crude carcass fat. As shown in Figure 2, the total body fat accumulations in all four HF control groups were significantly ($p < 0.05$) higher (1.3- to 2.3-fold) than that of the ND group (9.7%), with a visceral-to-carcass fat ratio of approximately 2:1. Higher levels of body fat ($p < 0.05$) were observed for groups with higher dietary fat consumption as well as with condensed milk. Specifically, the effectiveness of the four HF controls in inducing the accumulations of total body fat was ranked as follows: 40M-C (22.1%) > 23M-C (19.0%) ≥ 40-C (18.8%) > 23-C (15.7%), demonstrating that HF diets with condensed milk could produce greater amounts of body fat than HF diets alone, regardless of fat content. In contrast, the ability of RMD in reducing body fat accumulation declined in the reverse order,

Table 4. Effects of the Administration of RMD on Crude Carcass Fat Percentage[a]

treatment	high fat controls[b] (without RMD)	RMD groups[c] low dose (1.03 g/kg bw)	RMD groups[c] high dose (2.07 g/kg bw)
23% fat	5.8 ± 0.4nx	5.5 ± 0.6x	4.2 ± 0.5y
23% fat (with condensed milk)	5.5 ± 0.5nx	5.2 ± 0.5x	4.6 ± 0.5y
40% fat	5.8 ± 0.5nx	5.6 ± 0.5x	4.7 ± 0.4y

with the 40M diets showing the least body fat reduction after the RMD supplementation.

DISCUSSION

From many in vivo studies on the abilities of various ingredients to affect accumulation of body fat, a multitude of high-fat diets with fat levels between 10 and 63% have been used. Total fat contents of 23% and 40% were chosen for this study based on the prevalence of common fat levels used in previous studies.[5] Condensed milk has also been incorporated into two of the experimental models as an extra palatable component, since such a supplementation was practiced in some high-fat studies, for the purposes of boosting dietary intake and levels of obesity.[5,22] In addition, after comparing the nutrient profiles of the experimental diets to the estimated nutrient requirements, casein was incorporated into the 40 M diet to compensate for the protein content for the maintenance of the rats.

After feeding the rats for eight weeks, the findings in our study agreed with the observations that both the dietary fat level and uses of condensed milk played important roles in total body fat accumulation.[6,14] The consumption of condensed milk was actually found to be associated with higher body fat levels (Table 3), though the 23%-fat (with condensed milk) and 40%-fat groups were found to have similar amounts of visceral fat. Such a connection between palatable dietary component and visceral fat formation has previously been reported in some other studies.[22,23] Therefore, it was inferred that the addition of condensed milk (84.5% carbohydrate) would induce obesity more effectively in rats through improving feed and energy intake, and the combination of condensed milk and high levels of dietary fat might have a concrete effect on boosting the visceral fat accumulation of a 23%-fat diet to a level comparable to that of a milk-free 40%-fat diet.

Kishimoto et al. has suggested that resistant maltodextrin could potentially suppress lipid absorption and promote lipid excretion by inhibiting the decomposition of micelles and the release of fatty acids from micelles in the lipid absorption process.[15] Similarly, our results demonstrated that long-term consumption of RMD at 2.07 g/kg under various high-fat models (excluding the 40% fat diet with condensed milk) could be promising in reducing the body fat effectively ($p < 0.05$) (Figure 2). The works from other authors have also proclaimed the efficacy of resistant maltodextrin on body fat accumulation. In 2004, Okuma and Kishimoto asserted that persistent RMD consumption could significantly decrease body fat ratio and body fat area in obese objects.[17] Later in 2007, Gordon has reported that providing 30 g of RMD to overweight hyperlipidemia patients in addition to their daily regular diet could significantly reduce body fat ratio and the area of visceral and subcutaneous fats, though total weight did not significantly decline, in three months.[24] More recently, Hashizume et al. also recorded that providing metabolic syndrome patients with 27 g of RMD for 12 weeks in addition to their normal diet could significantly decrease waist circumference and visceral fat area.[25] The consistency of these studies reinforced our observations on the efficacy of RMD on body fat reduction.

Nonetheless, our results also suggested that the promotional effects of condensed milk plus high fat (i.e., 40 M groups) might have been too effective in inducing body fat accumulation, which then resulted in the diminishment of the fat-reduction capability of the high dose RMD supplement. In other words, the functions of RMD might be underestimated and misrepresented in a 40%-fat diet model when used with condensed milk. Thus, it should be noted that the 40M diet model might be a nutrient-wise extreme diet, with micronutrient contents close to the minimum limit of daily requirement, for inducing obesity, and thus it should not be considered as an appropriate model for the above-mentioned evaluation of RMD at the present dosages.

In sum, it was concluded from our results that the composition of HF models could affect the consistency of the evaluations of a sample's efficacy for comparison purposes. Both 23%-fat models (with and without condensed milk) and the 40%-fat diet without condensed milk can be considered as suitable experimental models for body fat reduction assessment trials of RMD or other fiber-rich products. However, since the recommended daily total fat intake for adults (ages 19 and older) is between 20 and 35% of dietary calories according to the USDA,[26] having 40% fat in an experimental diet (equivalent to about 67% of dietary calories) is in fact considered extremely high for attempting to mimic the actual dietary patterns of the general population. Thus, when shorter periods of obesity-induction or greater levels of body fat formation were desired, the inclusion of condensed milk in HF diets (around 23% dietary fat) could be considered over milk-free HF diets.

Supporting Information

ABSTRACT: The increased consumption of fish products, as well as the occurrence of exotic fish species in the Mediterranean Sea and in the fish market, has increased the risk of commercial fraud. Furthermore, the great amount of processed seafood products has greatly limited the application of classic identification systems. DNA-based identification allows a clear and unambiguous detection of polymorphisms between species, permitting differentiation and identification of both commercial fraud and introduction of species with potential toxic effects on humans. In this study, a novel DNA-based approach for differentiation of fish species based on pyrosequencing technology has been developed. Raw and processed fish products were tested, and up to 25 species of fish belonging to *Clupeiformes* and *Pleuronectiformes* groups were uniquely and rapidly identified. The proper identification based on short and unique genetic sequence signatures demonstrates that this approach is promising and cost-effective for large-scale surveys.

KEYWORDS: *Clupeiformes, Pleuronectiformes, commercial fraud, fish species identification, pyrosequencing*

INTRODUCTION

The consumption of fish products in Europe has increased in recent decades mainly because of the growing awareness of the importance of a healthy diet and the consequent demand for new sources of healthy food.[1] This factor, in combination with the globalization of the fish markets, has contributed to the introduction of novel fish species in the European fish markets and to an increased risk of commercial and/or sanitary fraud. In this regard, a commercial fraud consists of the illegal substitution of one species with another.[2] These economic corruptions can greatly affect the seafood commerce. Considering an estimated conservative worldwide substitution rate of 10%, the economic losses for worldwide fisheries is about US$ 24 billion/year.[3] For instance, in the case of red snapper (*Lutjanus campechanus*) fraudulent substitutions can account for three-quarters of the fish sold,[4] whereas for fish products sold as Alaska pollock (*Theragra chalcogramma*) more than 80% of the analyzed samples were prepared with species different from the one indicated on the label.[5] In the Mediterranean sea, high levels of market mislabeling were reported in different countries, to quote but a few, hake in Spain and Greece[6] and cod in Italy.[7] Besides the economic impact, these substitutions could also introduce species with potential toxic effects on humans.[8] All these issues combined with the increase in seafood consumption may well explain why it is mandatory to assign a unique market name to a given fish species in order to be unambiguously identified.[1,8] The European Union (EU) regulation 104/2000 imposes that commercial name, method of production (Directive 2200/13/EC), and capture area (EU Commission Regulation No 2065/2001) must be clearly indicated on the product label prior to its submission to the commercial circuit.[9] Despite these regulations, the process of labeling can still have some drawbacks.[10]

Identification of fish species is traditionally based on external morphological features (i.e., body shape, pattern of colors, position of fins, and number); otoliths count and shape analysis are also occasionally used. However, these identification systems are not considered useful or reliable for processed products subject to filleting, beheading, and/or skinning due to the obvious lack of morphological distinct features.[11] In more recent times, methods based on the separation and characterization of specific proteins using electrophoretic techniques, such as isoelectric focusing (IEF),[12] have been officially recognized and adopted to identify and assign species to fish products characterized by poor morphological integrity.[13] Some processing procedures often remove or damage key species signatures, as might be the case for proteins denatured by cooking,[13,14] making identification of species by morphological or protein-based taxonomic means extremely difficult if not impossible. The percentage of processed seafood related to the total seafood consumed in Europe can be relevant, for instance, up to 80% in the German market according to Horstkotte and Rehbein,[15] or to about 50% in Italy (ISMEA, 2007, http://www.ismea.it/flex/cm/pages/ServeBLOB.php/L/IT/IDPagina/2756). Taking these data into account, traditional

morphological and protein-based methods are not sufficient for correct species identification.[8]

The advancement of genomic technologies in recent years has made the DNA-based identification system a new and powerful option to accurately identify the fish species of high commercial value or of those frequently involved in commercial fraud. Generally speaking, this system is based on the presence of species-specific polymorphisms naturally occurring in the genomes.[16] The DNA-based methods present several advantages, such as high sensitivity, high specificity, large scale throughput, and the possibility to apply different types of analyses on the same specimen (e.g., PCR, sequencing, cloning, phylogenetic analysis, etc.). A variety of DNA-based identification approaches have been developed, as reported by refs 13 and 17, mainly based on PCR reaction: PCR-RFLP,[18−20] PCR-SSCP,[21] real time PCR,[22] PCR-RAPD,[23] and PCR-AFLP.[24] Besides the DNA-based approaches, DNA barcoding is the most widely adopted method for species identification.[25,26] Over the past decade, Sanger sequencing technology has become largely available, and at present it is considered one of the best methodologies to overcome the limitations of the morphology-based approach.[8,27−30] Microarray and next generation sequencing (NGS) technology has been also considered but not implemented to date for fish species identification.[11]

A novel and powerful DNA-based technology with a potential for species identification is pyrosequencing.[17,31] Using this technique, short stretches of nucleotides (approximately 30−40 nucleotides in length) downstream from a sequencing primer can be sequenced with high efficiency and accuracy.[32,33]

In this study, we evaluated the application of an alternative and modular technique to the Sanger sequencing (DNA barcoding) based on PCR followed by pyrosequencing for the rapid identification of two groups of fish commonly present in fish markets and frequently involved in commercial fraud. The first group includes species belonging to the genus *Clupeidae* as well as other species potentially used as fraudulent substitutes of *Clupeids*. The second group includes species belonging to the genus *Pleuronectidae* as well as other flat fish, such as *Solea solea*, *Hipoglossus hipoglossus*, etc.

It is interesting to note that products derived from these species are often commercialized as fillets in various forms, for example, fresh, frozen, marinated, salted, or breaded, all of which are unsuitable for morphological means of identification and sometimes even for protein-based species identification. Although pyrosequencing was previously applied for the identification of genetic lineages of *Salmo trutta* species,[34] to date, this is the first application of pyrosequencing-based analysis that aims at the identification of commercial fraud involving fish species.

MATERIALS AND METHODS

Sample Collection and DNA Extraction. One-hundred and sixteen (57 *Clupeiformes* and 59 *Pleuronectiformes*) specimens consisting of whole fishes and processed seafoods were collected from the fish market in Chioggia (Venice, Italy) and from local shops. Scientific and common names of fish species (11 *Clupeiformes* and 15 *Pleuronectiformes*) were assigned following identification by species-specific morphological traits following classification criteria and Sanger sequence DNA analysis; species names are listed in Table 1. DNA was extracted from 25 to 50 mg of fish muscles or processed seafood with the High Pure PCR Template Preparation kit (Roche Diagnostics,

Mannheim, Germany) according to the manufacturer's instructions. Specimens represented the most common product types present on the market in the commerce, such as fresh (skinned, filleted, eviscerated, etc.) or processed products (dried, salted, marinated, smoked, etc.). In detail, the samples analyzed were frozen fillet (59 samples), smoked (7 samples), cooked/precooked (12 samples), whole fresh fish (5 samples), marinated (6 samples), fermented (2 samples), salted in oil (14 samples), and frozen in breadcrumbs fillets (11 samples).

Preliminary Identification. *Morphological Analysis.* The specimens represented by the whole fish (n = 5) included in this study were at first identified by morphological analysis. Whole fish, with intact skin and fins, were identified using the dichotomous keys approach proposed by the FAO and available on the Web site http://www.fao.org/fishery/species/search/en, which refers to specific monographs (ref 35 for the Mediterranean Sea).

Sanger Sequence-Based Identification. All the specimens were identified by using cytochrome c oxidase I (COI) sequence. Briefly, the samples were amplified by using the PCR reaction previously described.[36] Sanger sequencing method was applied on the obtained PCR products. The sequences were generated using the Big Dye Terminator v3.1 cycle sequencing kit (Applied Biosystem, Foster City, CA). The products of the sequencing reactions were cleaned-up using PERFORMA DTR Ultra 96-Well kit (Edge BioSystems, Gaithersburg, MD) and sequenced by using ABI PRISM 3130xl Genetic Analyzer (Applied Biosystem, Foster City, CA). COI sequences obtained were compared to the COI sequences deposited in the GenBank database.

PCR Design and PCR Amplification for Pyrosequencing. Sequences of conserved regions of mitochondrial DNA (mtDNA) from different species present in the public database GenBank were aligned using the software MEGA 5.[37] On the basis of the analysis of the alignment, a set of PCR primers targeting 16S rRNA conserved region (16SForbio 5′-biotin-ACGAGAAGACCCTDTGGAG-3′, 16SRev 5′-TGTTATCCCTAGGGTAACTTG-3′) and a sequencing primer (16Sseq 5′-GTCGCCCCAACCGAAGA-3′) for pyrosequencing were designed. This set of primer was developed to amplify all the commercial species of interest in this study. On the basis of the *in silico* analysis, not all the originated pyrosequences showed the polymorphisms needed to be correctly and uniquely differentiated as in the case of *Cluipeidae*, that is, *Engraulis encrasicolus* and *Engraulis japonicus.* As for *Pleuronectidae*, *Hippoglossoides elassodon*, *Reinhardtius hippoglossoides*, *Limanda limanda*, *Limanda aspera*, *Pleuronectes quadrituberculatus*, *Pleuronectes platessa*, *Platichtys flesus*, and *Lepidopsetta bilineata* were not uniquely identified. Then, two other set of primers targeting different genomic sequences were designed. The first set of primers (Engra JEF 5′-biot- GCAGCCTTCCTTACCTTAAACA-3′ and Engra JER 5′-GTAGGAGGTTTGTGGCGAGAG-3′ for amplification, Engra JES 5′-AGTCACTTGGGTAAGAATC-3′ for sequencing), targeting the NADH dehydrogenase subunit II gene (ND2), allows discrimination of *Engraulis japonicus* from *Engraulis encrasicolus* on the basis of the pyrosequences obtained. The second set (PleuFbio 5′-ATCGCAAACGATGCTTTAG-3′ and PleuRseq1 5′-GGAARAGAAAGTGGAAKGC-3′ for amplification, PleuRseq2 5′-GGAAGAGRAAGTGGAATGC-3′ for sequencing), targeting a portion of the *cytb* gene of the *Pleuronectiformes*, discriminates species of *Hippoglossoides elassodon*, *Reinhardtius hippoglossoides*, *Limanda limanda*, *Limanda aspera*, *Pleuronectes quadrituberculatus*, *Pleuronectes platessa*, *Platichtys flesus*, and *Lepidopsetta bilineata*.

For each set, one of the amplification primer had to be biotinylated according to the pyrosequencing chemistry to allow the purification and selection of the specific fragment in the subsequent procedures.

Amplification of DNA was performed by using a PCR in a 50 μL reaction volume with 5 μL of DNA, 1.5 U AmpliTaq Gold (Roche Diagnostics, Mannheim, Germany), 2 mM $MgCl_2$, 1 mMdNTPs, and 0.5 μM of each specific primer (Eurofins MWG-Operon, Ebersberg, Germany). PCR was performed with the following thermal conditions: 10 min at 95 °C, 40 cycles consisting in 30 s at 95 °C, 30 s at 58 °C, 55 °C, 52 °C respectively for ND2, 16S and cyt B amplification, 30 s at 72 °C, with a final extension of 5 min at 72 °C. The amplified products, 289 bp for 16S, 520bp for cyt B and 291bp for ND2, were analyzed on a 2% agarose gel (Sigma-Aldrich, St. Louis, MO) in TAE buffer with 0.1 μL/mL GelRed (Biotium, Hayward, CA) and visualized under UV illumination.

Pyrosequencing Reaction and Sequence Library. The biotinylated PCR products were purified and prepared for the pyrosequencing reaction according to the manufacturer's instructions (Biotage, Uppsala, Sweden). Briefly, 20 μL of the biotinylated PCR product was immobilized onto 4 μLof Streptavidine-Sepharose (GE Healthcare, Uppsala, Sweden) beads in 40 μL of binding buffer with 20 μL of DEPC water at room temperature for 30 min. Single-stranded DNA was prepared with the PyroMark Vacuum Prep Workstation (Biotage, Uppsala, Sweden). The single-stranded, biotinylated DNA products were hybridized to sequencing primer (final concentrations of 0.5 μM) in a 96-well plate . The reaction was performed in 40 μL of annealing buffer in a sample plate heated at 80 °C for 4 min and then cooled to room temperature for 10 min before being placed into the pyrosequencing instrument. Pyrosequencing was performed using PyroGold reagents according to manufacturer's recommendations. The sequences originated by the analysis were automatically compared with a sequences library containing all the reference sequences of the species of interest in this study. The sequences library was generated, and the analysis was performed using the IdentiFire software (Biotage, Uppsala, Sweden).

For some of the fish species included in this project, sequences of the target genes were not available in the public databases. Those sequences were generated using the classical sequencing protocol (Sanger), added to the library (IdentiFire software), and deposited in a public database (see following section).

This software will assign a score value to each tested sequence, indicating the quality and the affordability of the result. This score is not only based on the sequence homology, but also on the position of any possible mismatch, the quality of the pyrogram, and the intensity of the peaks. Thus, the same number of mismatches may give different scores according to the positions of the polymorphisms along the pyrosequence. Mismatches closer to the 5′-end of the pyrosequences can affect the score value, which can be decreased more than a mismatch close to the 3′-end.

RESULTS

Preliminary Identification. The samples analyzed in this study originated from species belonging to *Clupeiformes* (n = 57) and *Pleuronectiformes* (n = 59) (Table 1).

Sequences obtained by the Sanger method were used as the gold standard for pyrosequences identification. For some of the species analyzed in the present study, the sequence of 16S gene was not available in the public databases, and therefore the newly Sanger-generated 16S sequences were submitted to Genbank [accession numbers: KC461225 (*Alosa falla nilotica*), KC461223, KC461224 (*Alosa fallax lacustris*), and KC461222 (*Sardinella fimbriata*)]. Similarly, *cytb* PCR products from samples of *Lepidopsetta polyxystra* (identified by COI gene Sanger sequence DNA analysis) were submitted to GenBank (Acc numbers: KF007183, KF007184, KF007185).

Pyrosequencing Identification: Experimental Design and Proposed Workflow. In order to correctly and unambiguously identify all the 25 fish species targeted in this study, the entire procedure was divided into two phases (herein, phase 1 and phase 2). Phase 1 was based on the use of one PCR reaction targeting the 16S rRNA gene, followed by the pyrosequencing analysis to identify and differentiate 20 out of the 25 targeted species. For those sequences not uniquely identified in phase 1, two other PCR amplifications followed by pyrosequencing were performed (phase 2), specifically targeting the group of *Clupeiformes* (two species) and the *Pleuronectiformes* (four species). The proposed workflow is schematically illustrated in Figure 1.

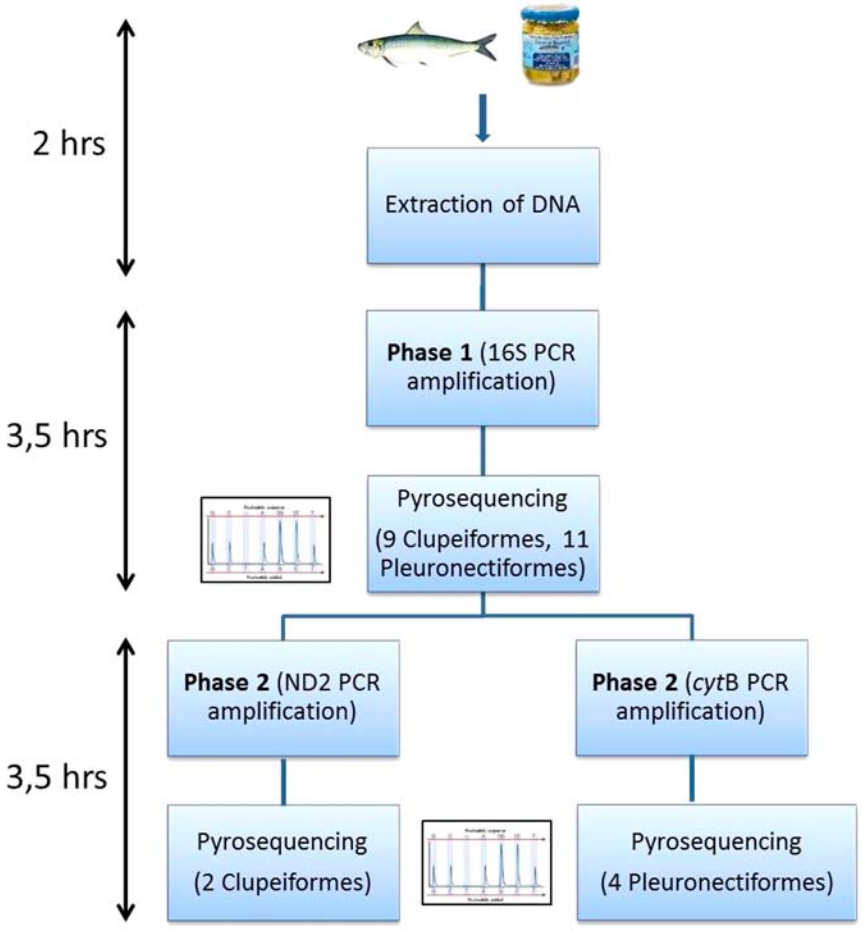

Figure 1. Schematic representation of pyrosequencing workflow. The number of fish species identified throughout the two phases is indicated as well as the analysis turn-around time. Overall, 20 fish species can be identified with this procedure in 3.5 h. The identification of the 25 species targeted in this study is achieved in a maximum time frame of 7 h. It can be reduced if phase 1 and 2 are performed simultaneously.

Phase 1 – Targeting the 16S rRNA Gene. The DNA isolated from all the fresh and processed samples collected in this study was amplified using the PCR targeting the 16S rRNA gene.

The pyrosequencing reaction was able to produce the short sequences, and the subsequent comparison of the query sequences was carried out with the reference sequences in the library database (based on the Identifire software). The results demonstrated that for 20/25 species the 16S rRNA sequences identified correctly and uniquely with a score range in the Identify software between 66.8 and 100 (*Coilia spp, Sardinops sagax, Sprattus sprattus, Sardinella aurita, Sardinella fimbriata, Sardina pilchardus, Clupea harengus, Sardinella jusseu, Alosa spp., Atheresthes stomias, Reinhardtius hippoglossoides, Paralitchthys patagonicus, Eopsetta jordani, Solea solea, Solea senegalensis, Solea lascaris, Synaptura lusitanica, Microchirus azevia, Psettodes belcheri, Arnoglossus spp.*) (Table 1). Some samples were ambiguously identified because of the similarity of their sequences with more than one reference sequences included in the database, as was the case for two samples identified in the *Clupeiformes* group as *Engraulis encrasicolus* and *Engraulis japonicus.* As illustrated in Figure S-1 (Supporting Information), the same score with three different reference sequences, *Engraulis australis*, *Engraulis encrasicolus*, and *Engraulis japonicus* was obtained. Similarly, a unique and precise identification of *Limanda limanda*, *Pleuronectes platessa*, *Platichthys flesus*, and *Lepidopsetta polyxystra* in the *Pleuronctiformes* group was not possible in phase 1 (Figure S-2, Supporting Information).

Phase 2 – Targeting NADH and cyt b Gene. The samples assigned to *Clupeiformes* group but ambiguously identified in phase 1 were tested with a PCR assay targeting the NADH dehydrogenase subunit II gene (ND2). The subsequent pyrosequencing procedure enabled the discrimination between genetic sequences belonging to *Engraulis encrasicolus* and *Engraulis japonicus* and the correct identification of these species with scores ranging from 77.8 to 100 (Figure 2).

The samples assigned to the *Pleuronectiformes* group but ambiguously identified in phase 1 were tested with a distinct PCR targeting the cytochrome *b* (*cyt* b) gene. The sequences obtained allowed the correct and unambiguous identification of four of the previously misclassified species (*Limanda limanda, Pleuronectes platessa, Platichtys flesus, Lepidopsetta polyxystra*), with scores ranging from 79.4 (in the case of *Platichtys flesus*) to 100 (in the case of *Pleuronectes platessa*) (Figure S-3, Supporting Information).

DISCUSSION

The identification of a species substitution using morphological detection or other classical systems (IEF) can fail when processed fish products are considered, since the diagnostic

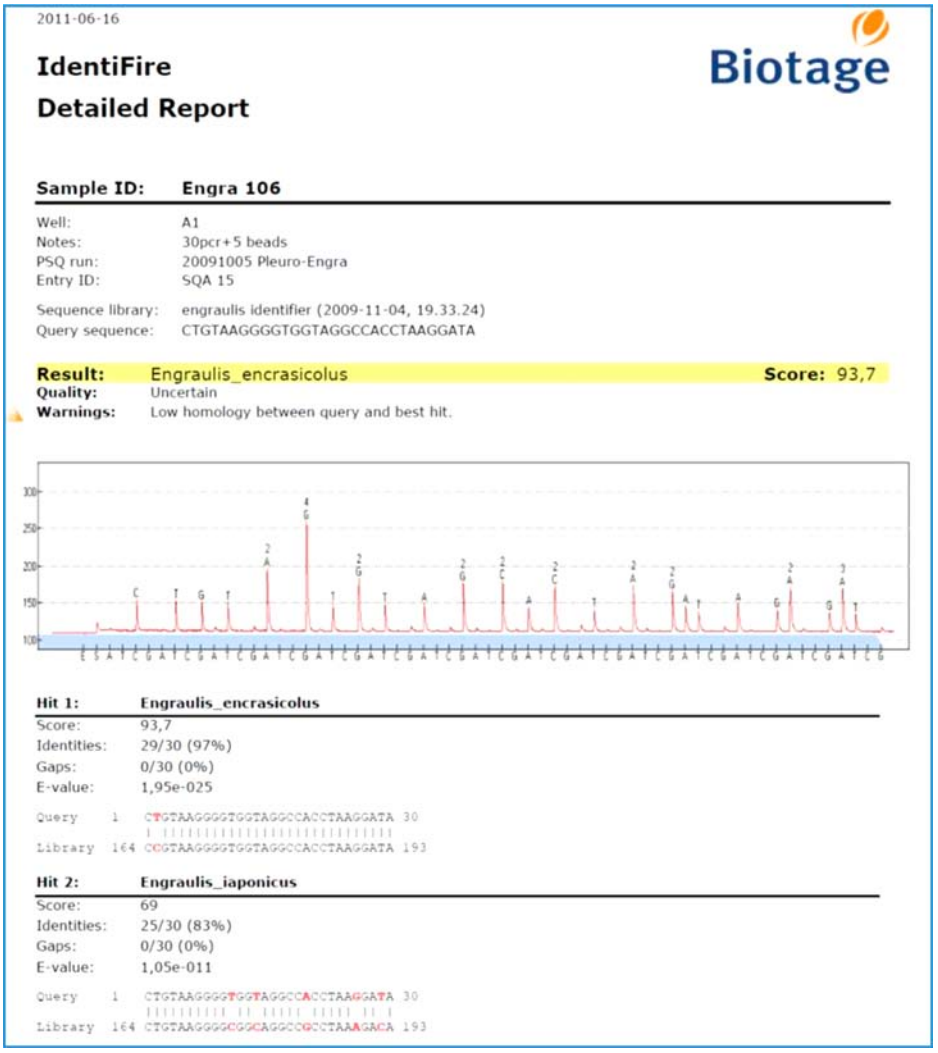

Figure 2. Example of IdentiFire results of the phase 2 discriminating *Engraulis encrasicolus* from *Engraulis japonicus*. The different score assigned indicates a level of polymorphism that enables correct identification.

target can be damaged. In those cases, traditional methods do not always provide satisfactory results.[8]

The selection of the proper DNA target is a crucial point in the DNA-based fish species identification methods. The DNA target should be present in large amounts to ensure it will always be detectable and show a sufficient number of polymorphisms between the species to be unequivocally assigned to a given species.[13] Several genes or genomic sequences satisfy these criteria, but the mtDNA has been widely used because of its particular features: it is present in several copies into the cell (up to 1000 times more than in the nuclear DNA), and it shows more polymorphisms than nuclear DNA because of its faster evolution.[13] Besides this, mtDNA is more stable because of its circular structure that may constitute a crucial advantage in the case of processed seafood, where thermal treatment could reduce the integrity of DNA originating fragments from less than 100 bp up to about 500 bp.[2] Among the mtDNA, some genes have been widely used for fish species identification, especially cytochrome oxidase c subunit 1 (COI), cytochrome *b* (*cytb*), and 16S rRNA.[1,2,11,13,38−44] The 650 base pairs sequence of COI is the main barcode for animal species identification and can discriminate all the commercially available fish species.[45,46] The pyrosequencing technique provides the sequence of a conserved region containing a short stretch of nucleotides (30−40) with a number of polymorphisms sufficient enough to enable differentiation of the species under investigation.

The testing protocol developed in this study is based on three different PCR reactions followed by pyrosequencing analysis and provides a rapid, sensitive, specific, and robust system to identify fish species based on the nucleotide sequence of a specific locus.[34]

The simple workflow schematically illustrated in Figure 1 allowed for an efficient and accurate identification of 25 species (11 *Clupeiformes* and 15 *Pleuronectiformes*), and the analysis detected some of the most important commercial frauds related to these groups of fish that could have a great impact on the market.[47]

The precise and unambiguous discrimination of *Engraulis encrasicolus* (commercially, a high-value species) is relevant in the framework of the official control of commercial fish frauds.[48] *E. encrasicolus* can also be substituted by *Sprattus sprattus*,[49] and this fraud can be clearly identified by the pyrosequencing protocol as well. The lack of available samples belonging to *E.* japonicus in this study did not allow for testing of this species in the laboratory; nevertheless, the *in silico* analysis confirmed the clear DNA discrimination between *E.*

japonicus and *E. encrasicolus* on the basis of the *cyt* b available sequences from public databases.

In *Pleuronectiformes*, *Pleuronectes platessa* and *Solea solea* are the two species that are most widely substituted by various low-value species such as members of the genus *Limanda* and *Lepidopsetta*. The results presented showed that *P. platessa* and *S. solea* can be unambiguously differentiated. It is clear that the identification of species by using sequence data is strongly affected by the availability of reference sequences in public databases.

A major point of interest is that the method developed in this study has proven to be highly efficient on processed fish products as well. As a matter of fact, the DNA from all these samples was amplified and correctly assigned to a given species, indicating that the method developed is not affected by the various processing methods.

As for other barcoding techniques, such as mini-barcoding,[50] one of the advantages of the pyrosequencing protocol is that the relatively small size of the amplified PCR products, less than 520 bp, coupled with the high efficiency and accuracy of this sequencing method for short sequence fragments allows detection of high quality genetic sequences, even in samples where DNA may be partially damaged or degraded by the processing, providing a robust identification system.[2]

It was possible to identify the specimens at the species level in most of the analyzed samples; however, in some cases the identification limited to the Genus level (e.g., *Arnoglossus sp*, *Coilia sp*, and *Alosa sp*) was still considered sufficient for commercial purposes. In those cases, all the members of the genus presented comparable commercial values and/or the same commercial denomination. The analysis in phase 1 can be considered as a primary screening test to identify most of the species of interest being capable to identify 20 species in 3.5 h (Figure 1). Phase 2 analysis acts as a fine-tuned identification step, but both can be performed simultaneously to reduce the turn-around time, if necessary (Figure 1). To make the entire process as fast as possible (i.e., about 3.5 h), all three PCR reactions (phase 1 and 2) can be performed at the same time, and the resulting PCR products can then be analyzed in a single run on the pyrosequencing platform. Furthermore, depending on the species to be investigated (and the correspondent fraud), only one specific PCR could be performed. Indeed, in most cases of mislabeling fraud, only one of the PCR presented was sufficient to identify the species involved. According to this, the system presented can be considered as a modular system, and either phase can be used independently. This reduces the total analysis time to that of a single PCR step.

The classical sequencing system (Sanger method) is a very useful tool to identify fish species, but it still is rather expensive and time-consuming; therefore, its use is not recommended for routine analyses to date.[51] On the basis of the commercial value of the reagents and platform, the cost per sample of PyroMark ID pyrosequencing analysis ranges from 5 to 6 euro (from 480 to 576 euro/96 plate). On the other hand, the cost per sample of the Sanger sequencing system is of about 11 or 12 euro (1056 to 1152 euro/96 plate). Interestingly, the pyrosequencing pipeline is more time-efficient and cheaper than Sanger sequencing. Indeed, pyrosequencing requires only few protocol steps, and the sequence detection is performed in real-time. The additional mandatory steps to be performed in the Sanger protocol, consisting of big-dye terminator sequencing reaction, postreaction purification, and final electrophoresis, prolong the total time of the analysis and increase costs.[50] Conversely, the total cost of the pyrosequencing analysis has decreased since it does not need terminator enzymes and time-consuming purification steps.[52−54]

The newest upgrade to PyroMark platform makes the read-length up to 140 nucleotides (instead of the current 30−40) longer (www.qiagen.com). This improvement could extend the application field of the pyrosequencing technique to a wider target range. In addition, the cost of the new upgraded platform is still lower than the Sanger sequencing platform commercially available making pyrosequencing even cheaper and more powerful.

In conclusion, the analysis of the 30-bp fragment following the sequencing primer enabled the discrimination of 25 fish species in 3.5−7 h, indicating that the fish species identification system based on pyrosequencing analysis is a powerful tool to discriminate the most important cases of commercial fraud regarding *Clupeiformes* and *Pleuronectiformes* groups.

ABSTRACT: The similarities of two major peanut allergens, Ara h 2 and Ara h 6, in molecular size, amino acid sequence, and structure have made it difficult to obtain natural Ara h 6 free of Ara h 2. The objectives of this study were to purify natural Ara h 6 that is essentially free of Ara h 2 and to compare its IgE reactivity and potency in histamine release assays to Ara h 2. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis of the highly purified allergen (<0.01% Ara h 2) revealed a single 14.5 kD band, and the identity of Ara h 6 was confirmed by liquid chromatography−tandem mass spectrometry. Ara h 6 showed a higher seroprevalence in chimeric IgE enzyme-linked immunosorbent assay (n = 54) but a weaker biological activity in basophil histamine release assays than Ara h 2. Purified Ara h 6 will be useful for diagnostic IgE antibody assays as well as molecular and cellular studies to investigate the immunological mechanisms of peanut allergy.

KEYWORDS: *peanut, allergen, IgE reactivity, histamine release*

INTRODUCTION

Peanut allergy is an important food allergy in the United States that affects 1.4% of children and 0.6% of adults.[1,2] In the United Kingdom, approximately 1.8% of children have an allergy to peanut.[3,4] While most children outgrow food allergies to milk, egg, or wheat, allergy to peanut is more persistent and often continues into adulthood.[5] Minute amounts of peanut, as little as 0.4 g, are enough to elicit milder allergic symptoms that include rashes, angioedema, and gastrointestinal symptoms.[5,6] However, peanut is also one of the main triggers of severe anaphylactic reactions that can be fatal.[7]

Currently, 12 peanut allergens have been documented by the World Health Organization (WHO)/International Union of Immunological Societies (IUIS) Allergen Nomenclature committee.[8] Ara h 1 and Ara h 2 have been well-studied and are recognized as major allergens. Ara h 2 has a higher predictive value for diagnosis of clinical peanut allergy than Ara h 1, Ara h 3, Ara h 8, and Ara h 9.[9] Ara h 2 is also more potent than Ara h 1 or Ara h 3 in histamine release assays and skin prick tests.[10−12]

Another peanut allergen, Ara h 6, has recently emerged as an important allergen, which, together with Ara h 2, has been associated with clinical peanut allergy.[13] Ara h 6 has approximately the same seroprevalence as Ara h 2 and thus is considered a major peanut allergen.[13,14] Ara h 6 and Ara h 2 are of similar molecular size; Ara h 2 is 17−19 kDa, and Ara h 6 is 14.5 kDa. Both allergens are 2S albumins that are heat-stable, immunogenic, and resistant to digestion in the gut.[15−17] The nucleotide (and amino acid) sequences of Ara h 2.0101 and Ara h 6.0101 are 50% identical and 58% similar (EMBOSS Needle alignment). The structure of the protease-resistant core of Ara h 6 has previously been determined by nuclear magnetic resonance (NMR), and the folds of this allergenic core were found to be virtually identical to those of Ara h 2.[15] The three-dimensional folds determine the IgE epitopes, which are lost upon unfolding.[18] More recently, the structure of Ara h 2 was determined by X-ray crystallography, and molecular modeling studies predict that half of the residues on the surfaces of both proteins are conserved.[19] These factors contribute to the difficulty in obtaining purified natural Ara h 6 (nAra h 6) that is free of Ara h 2. Ara h 7, the third peanut allergen of the 2S albumin family, also shows sequence homology to Ara h 2 and Ara h 6.[20] However, attempts to identify natural Ara h 7 protein in peanut extracts have failed. Recently, Schmidt et al. found low abundance of natural Ara h 7.0201 and Ara h 7.0202 in peanut extracts after enrichment of the low-molecular-mass peanut proteins.[21]

Highly purified allergens are important for allergen standardization.[22,23] There is extensive variability in allergen composition and potency between different commercially available peanut extracts, including those used for skin prick testing that could lead to misdiagnosis.[24,25] "Component-resolved" or molecular diagnostics is based on measuring IgE antibodies to multiple individual allergens rather than to heterogeneous extracts. The use of molecular diagnostics tends to lower false-positive IgE antibody results caused by the interaction with profilins and cross-reactive carbohydrate

determinants that are present in diverse plant-based food.[26−29] Some birch pollen-allergic patients were found to be cross-sensitized to peanut through cross-reactivity between Bet v 1 and Ara h 8, which are homologous proteins that belong to the PR-10 family.[30] Moreover, pea-allergic patients, who later developed peanut allergy, recognized only Ara h 1 but not Ara h 2 or Ara h 3.[31] Vicilin homologues in pea and peanut (Ara h 1) are the molecular basis for this cross-reactivity. Most peanut-allergic patients that react to Ara h 2 also have IgE against Ara h 6; however, a recent case study reported that Ara h 6 caused severe reactions to peanut in the absence of sensitization to Ara h 2.[32] Thus, it is important to have pure, single-component peanut allergens for accurate diagnosis of peanut allergy.

Our objective in this study was to obtain purified nAra h 6 that is essentially free of Ara h 2 and compare its IgE reactivity and potency in histamine release assays to Ara h 2.

MATERIALS AND METHODS

Purified Natural Ara h 6. Peanut flour was extracted into phosphate-buffered saline (PBS) at pH 7.4 containing 1 M sodium chloride for 2 h at 60 °C. The mixture was centrifuged at 13500*g* for 25 min, and the supernatant was sterile-filtered. Ammonium sulfate precipitation was used to remove contaminating Ara h 1. The 70−100% pellet containing Ara h 6 and Ara h 2 was redissolved in PBS and passed over a 1C4 monoclonal antibody column to remove the contaminating Ara h 2. Size-exclusion chromatography (HiPrep 16/60 Sephacryl S-100 HR, GE Life Sciences, Uppsala, Sweden) was used as a final polishing step. The identity of purified nAra h 6 was confirmed by liquid chromatography−tandem mass spectrometry (LC−MS/MS), and its purity was analyzed by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and silver staining. The concentration of the purified protein was determined by the Advanced Protein Assay (Cytoskeleton, Denver, CO), and the Ara h 2 content was measured using a two-site antibody enzyme-linked immunosorbent assay (ELISA) with monoclonal antibody 1C4 as the capture antibody and rabbit-polyclonal antibody anti-Ara h 2 for detection.[33] Ara h 6 was measured by ELISA using capture monoclonal antibody 3B8 and detection antibody 3E12. Another nAra h 6 preparation available from TNO Quality of Life, Zeist, Netherlands (T-Ara h 6) was tested for comparison.

Sera. Sera for the immunoblotting, chimeric IgE ELISA, and cross-inhibition ELISA were obtained from Bioreclamation, Inc. (East Meadow, NY) (n = 24), which operates in full compliance with the Food and Drug Administration guidelines, the Department of Allergy and Clinical Immunology at Johns Hopkins University (n = 25), and kindly provided by Dr. Peter Heymann, University of Virginia (n = 8). Sera for the Basophil Histamine Release Assay were provided by the Department of Allergy, Asthma, and Clinical Immunology at the University of Colorado (n = 20). All donors signed informed consent and, for minors, assent. Sera were collected with approval from the respective institutions' human investigation committees.

Immunoblotting. IgE reactivity of purified nAra h 6 was compared to natural Ara h 2 (nAra h 2), peanut extract, and T-Ara h 6 by immunoblot using pooled sera from six peanut-allergic patients (≥100 kU/L by chimeric IgE ELISA, PWH6, BR13, BR21, BR22, BR23, and BR24). Proteins loaded at 0.5 mg/mL and separated by SDS−PAGE under non-reducing conditions (20% homogenous, GE Lifesciences, Uppsala, Sweden) were transferred to a polyvinylidene difluoride (PVDF) membrane (Bio-Rad Laboratories, Hercules, CA) by electroblotting. The membrane was blocked with 5% non-fat dry milk in 25 mM Tris, 150 mM NaCl at pH 7.4, and 0.05% Tween-20 for 16 h at 4 °C and then incubated with the pooled sera at a 1:2 dilution in blocking buffer for 2 h at room temperature. Bound IgE was detected with peroxidase-labeled goat anti-human IgE (Kirkegaard and Perry Laboratories, Inc., Gaithersburg, MD) followed by ECL Western Blotting Analysis System (GE Lifesciences, Uppsala, Sweden), which produced a detectable chemiluminescent signal.

Chimeric IgE ELISA. IgE antibody binding to nAra h 6 was compared to IgE binding to T-Ara h 6 and nAra h 2 by a modified chimeric IgE ELISA as described previously.[34−36] Briefly, microtiter plates coated to saturation with one allergen at 0.5 μg/well were incubated with sera from peanut-allergic patients (ImmunoCAP values ranged from 0.45 to >100 kUA/L, with an average of 15.2 ± 21.4 kUA/L; n = 54). Bound IgE antibody was detected using biotinylated goat anti-human IgE (Kierkegaard and Perry, Gaithersburg, MD), followed by streptavidin peroxidase. The intensity of the color developed by 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) was measured at 405 nm. A chimeric anti-Der p 2 antibody, 2B12-IgE, was used to establish a standard curve from 0.4 to 115 U/mL IgE to quantify the bound specific IgE as previously reported.[36] Ara h 6- and Ara h 2-specific IgE for each serum sample were extrapolated from the linear portion of the 2B12−IgE curve. Levels of specific IgE antibody reactive with nAra h 6 and nAra h 2 or T-Ara h 6 were plotted and modeled using linear regression. Pearson correlations were used to analyze the relationship between specific IgE to nAra h 6 and nAra h 2 or T-Ara h 6 in sera of peanut-allergic patients.

Cross-inhibition ELISA. The chimeric IgE ELISA was modified for cross-inhibition assays. Microtiter plates were saturated with nAra h 6 or nAra h 2 at 0.5 μg/well for 16 h at 4 °C.[34] A serum pool of the same sera used in the immunoblot was incubated with increasing concentrations of the inhibitor (either nAra h 6 or nAra h 2) for 1 h prior to performing the assays. The protein concentration of the inhibiting allergen was increased in 10-fold increments from 10 to 10 000 ng/mL. The pooled sera with or without the inhibitor were added to their respective wells and incubated at room temperature for 1 h. Bound IgE was detected as described for the chimeric IgE ELISA. The percent inhibition was calculated on the basis of the optical density at 405 nm. A 0% inhibition was assumed for the wells that had no inhibitor.

Basophil Histamine Release Assay. The stripped basophil histamine release assay was performed as previously described.[37] Briefly, basophil cells were stripped of membrane-bound IgE and sensitized with each serum from peanut-allergic patients (Ara h 6-specific IgE values ranged from 5 to 480 kUA/L, with an average of 87.8 ± 125 kUA/L; n = 20). The cells were then stimulated with increasing concentrations of allergen, and histamine release was measured by fluorometric analysis. Histamine release was expressed as a percentage of the total amount of histamine in the cells determined after lysis of the cells with perchloric acid (100% release). EC_{50} was the allergen concentration required to stimulate 50% of the maximum release. Histamine release dose response curves for nAra h 6 and nAra h 2 were generated for concentrations between 0.001 and 1000 ng/mL.

RESULTS

Protein Characterization. Purified nAra h 6 (lane 4) and T-Ara h 6 (lane 5) migrated as single bands on silver-stained SDS−PAGE at the predicted molecular weight of 14.5 kDa (Figure 1A). The Ara h 6 content was 1.05 mg/mL, while the

(B) Proteins transferred onto a PVDF membrane were probed with sera, and bound IgE was detected with a peroxidase-labeled goat anti-human IgE. Lane M, marker; lane 1, peanut extract; lanes 2 and 3, nAra h 2; lane 4, nAra h 6; and lane 5, T-Ara h 6.

dx.doi.org/10.1021/jf4022509 | J. Agric. Food Chem. 2014, 62, 206−213

concentration of Ara h 2 was less than 0.1 μg/mL (0.01%) as measured by two-site antibody ELISA. The results of LC−MS/MS confirmed the identity of the purified allergen as Ara h 6.0101 with 74.5% sequence coverage (Figure 2).

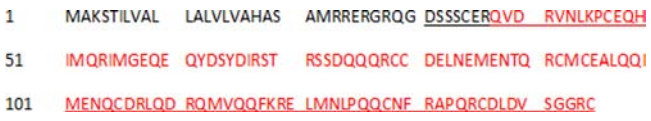

Figure 2. Sequence coverage of purified nAra h 6 with Ara h 6.0101. Underlined red letters indicate identical amino acids between the purified allergen and the published sequence.

IgE Binding Analysis. Immunoblotting demonstrated strong IgE reactivity to nAra h 2 (lanes 2 and 3), nAra h 6 (lanes 4 and 5), and peanut extract (lane 1; Figure 1B). The major allergens, Ara h 1 (63 kDa), Ara h 2 (18−20 kDa), and Ara h 6 can be seen as major bands in the peanut extract. Ara h 2 was not detected in the purified nAra h 6 preparation.

More sera showed IgE binding to nAra h 6 than to nAra h 2 (45 versus 39) using a chimeric IgE ELISA; however, the levels of Ara h 2-specific IgE were on average 13% higher than the levels of Ara h 6-specific IgE. A total of 25 of these patients had higher levels of specific IgE to one allergen but not to the other (Table 1). For example, patient BR1 had 4-fold higher Ara h 2-specific IgE than Ara h 6-specific IgE, while patient BH25 had 5-fold higher Ara h 6-specific IgE than Ara h 2-specific IgE (Table 1). There was a strong quantitative correlation between the levels of specific IgE to nAra h 6 and specific IgE to nAra h 2 ($r = 0.91$; $n = 54$; $p < 0.001$; Figure 3A). The levels of Ara h 6-specific IgE binding to purified nAra h 6 correlated well with the same Ara h 6-specific IgE binding to T-Ara h 6 ($r = 0.98$; $n = 39$; $p < 0.001$; Figure 3B). On average, the IgE binding to the purified nAra h 6 material was 46% higher than that observed interacting with T-Ara h 6.

Results obtained in the cross-inhibition assay indicate that nAra h 2 inhibited IgE allergen binding more effectively than nAra h 6. At 70 ng/mL, Ara h 2 inhibited 50% of IgE−Ara h 2 and IgE−Ara h 6 interactions (Figure 4). However, 600 and 5000 ng/mL of Ara h 6 were required to inhibit 50% IgE binding to Ara h 6 and Ara h 2, respectively.

Biological Activity. Natural Ara h 6 showed less biological activity than nAra h 2 in the basophil histamine release assay (Figure 5). At a concentration of 0.1 μg/mL, Ara h 2 stimulated 50% of the maximum histamine release, while 1 μg/mL of Ara h 6 was required to achieve 50% of maximum histamine release. In general, histamine release was 10% lower for nAra h 6 than nAra h 2 at the same allergen concentration. The dose−response curve of histamine release by nAra h 6 was shifted to the right of the dose response curve for nAra h 2 (Figure 5). On average, histamine release began to plateau at 0.001 μg/mL Ara h 2 and continued an upward trend even to a concentration of 1 μg/mL Ara h 6.

DISCUSSION

Peanut allergy is on the rise, as evidenced by a 1% increase in just over an 11 year period (1997−2008) in the U.S.[2] Traces of peanut can be found in many processed foods, and this poses a danger to peanut-allergic patients because miniscule amounts can trigger an allergic reaction.[6] Previous studies have demonstrated significant variability in the protein content and allergenicity of commercially available peanut extracts.[38] There is a critical need for ultrapure allergens to clarify research results and improve the accuracy of diagnostic tests in an attempt to better understand the mechanisms associated with the induction of allergic diseases. Analysis of single components

allows for more effective dissection of cross-reactivity among structurally similar allergens and aids in identifying the cross-reactive allergen from the allergen that initially elicited the sensitization. For food allergy studies in particular, molecular diagnostics more effectively reveal patterns of sensitization and cross-reactivity among allergenic homologues across food groups.[39]

Ara h 2 has been extensively studied and established as a major allergen, while Ara h 6 has only recently gained interest in peanut allergy research. Ara h 2 and Ara h 6 belong to the 2S albumin family that are characterized by having a stable core formed by four disulfide bridges, which makes these proteins resistant to high-temperature processing and proteolytic digestion.[16,40] The stability of these proteins and their resistance to digestive enzymes in the gut has been identified as major factors contributing to their allergenicity.[15,41] The sequence and structural similarity between Ara h 6 and Ara h 2 has made it difficult to produce nAra h 6 free of nAra h 2.[19] Recombinant Ara h 6 has been produced, but conformational differences between the natural and recombinant forms have yielded recombinant Ara h 6 with low IgE reactivity.[20] More recently, a recombinant Ara h 6 produced in *Pichia pastoris* has shown improved biological potency similar to that of nAra h 6.[42]

Highly purified nAra h 6 has analytically been shown to be free of Ara h 2. Similar to natural Ara h 2, natural Ara h 7 also shares sequence similarity with Ara h 6 and thus may co-purify with Ara h 6. However, natural Ara h 7 has a very low abundance in peanut extracts, which greatly minimizes the risk of contamination.[21]

Purified natural Ara h 6 displayed its own unique immunological activity patterns. While a strong correlation was shown between the relative levels of Ara h 2-specific IgE and Ara h 6-specific IgE, sera from 25 individuals reacted more strongly to one allergen than the other, as reported in previous studies.[16,32,43] Interestingly, only 8 of the 25 tested sera had higher Ara h 2-specific IgE, even though Ara h 2 is the predominantly recognized allergen by peanut-allergic patients.[13]

In our cross-inhibition analyses, Ara h 2 inhibited Ara h 6-specific IgE binding more effectively than Ara h 6 inhibited Ara h 2-specific IgE binding as reported previously.[16] The inhibitory

effect of Ara h 2 may be due to its unique IgE-binding epitopes that are not present in Ara h 6, while Ara h 6 contains IgE-binding epitopes that are also present on Ara h 2.[44] However, we did not achieve complete inhibition of Ara h 6−IgE binding by Ara h 2 even at 10 μg/mL, which suggests that Ara h 6 could have unique IgE-binding epitope(s). This is supportive of the report by Lehmann et al., who performed an enzyme allergosorbent test and found that maximal inhibition by

dx.doi.org/10.1021/jf4022509 | J. Agric. Food Chem. 2014, 62, 206−213

recombinant Ara h 2 and recombinant Ara h 6 was only 70 and 60%, respectively.[15,45]

Ara h 2 consistently induced higher levels of histamine release than Ara h 6 in basophil studies. In general, a 10-fold lower concentration of Ara h 2 than Ara h 6 was required to induce the same amount of histamine release. Similarly, Ara h 2 was recently found to be more potent than Ara h 6 using the RBL SX-38 cells assay, although the magnitude of the difference was less than we report here with the stripped basophil assay.[46] Ara h 2 also elicited a higher magnitude of mediator release at lower concentrations than Ara h 6.[15] However, as the allergen concentration increased, Ara h 6 induced the release of higher percentages of β-hexosaminidase than Ara h 2.[47]

While most published data suggest that Ara h 2 is more potent than Ara h 6, there are exceptions. Ara h 6 had a higher seroprevalence (83.3%) than Ara h 2 (72.2%) in our study that involved testing 54 sera from peanut-allergic patients. In another study, Ara h 6 was shown to produce a stronger Th2 response than Ara h 2 in peripheral blood mononuclear cells of peanut-allergic children.[48] The depletion of Ara h 2 or Ara h 6 alone from crude peanut extract did not cause a significant reduction in the maximal net level of mediator release from SBX-38 cells, but the removal of both allergens decreased effector activity by approximately 20%.[49] Previously, Ara h 2 and Ara h 6 together were shown to be responsible for over 60% of the effector activity.[50] Furthermore, *in vivo* studies using murine models showed that desensitization with the Ara h 2/Ara h 6 mixture and crude peanut extract produced comparable results.[51,52]

Peanut allergy associated with sensitization to storage proteins (Ara h 1, Ara h 2, Ara h 3, Ara h 6, and Ara h 7) presents the most serious form of peanut allergy.[53] While Ara h 1 and Ara h 3 are the most abundant storage proteins in peanut (11−31 and 38−76% of protein content in peanut extracts, respectively), patients with peanut allergy recognize predominantly Ara h 2 and Ara h 6.[13,14,54] Molecular diagnostics have shown that the combined results of IgE reactivity to the two storage proteins Ara h 2 and Ara h 6 yielded the highest diagnostic sensitivity and specificity for detecting clinically evident peanut allergy.[13] By themselves, Ara h 2 and Ara h 6 had high diagnostic sensitivity and specificity compared to Ara h 1 and Ara h 3, but together, the two 2S albumin proteins were able to predict peanut allergy with 98% sensitivity and 85% specificity at a predictive threshold of 0.1 kU/L. The addition of specific IgE tests for other storage proteins, such as Ara h 6, or Ara h1, and Ara h 3, will increase specificity and sensitivity of molecular diagnosis, because not all patients with clinical peanut allergy show sensitization to Ara h 2.[32,53,55] Thus, purified nAra h 6 should be considered an important diagnostic reagent for both *in vitro* and *in vivo* assays that, together with nAra h 2 will improve diagnostic, immunologic, and biologic assays used in the investigation of peanut allergy, T-cell studies, and mouse models of asthma.

Potato and Mushroom Polyphenol Oxidase Activities Are Differently Modulated by Natural Plant Extracts

Supporting Information

ABSTRACT: Enzymatic browning is a major quality issue in fruit and vegetable processing and can be counteracted by different natural inhibitors. Often, model systems containing a single polyphenol oxidase (PPO) are used to screen for new inhibitors. To investigate the impact of the source of PPO on the outcome of such screening, this study compared the effect of 60 plant extracts on the activity of PPO from mushroom (*Agaricus bisporus*, AbPPO) and PPO from potato (*Solanum tuberosum*, StPPO). Some plant extracts had different effects on the two PPOs: an extract that inhibited one PPO could be an activator for the other. As an example of this, the mate (*Ilex paraguariensis*) extract was investigated in more detail. In the presence of mate extract, oxygen consumption by AbPPO was found to be reduced >5-fold compared to a control reaction, whereas that of StPPO was increased >9-fold. RP-UHPLC-MS analysis showed that the mate extract contained a mixture of phenolic compounds and saponins. Upon incubation of mate extract with StPPO, phenolic compounds disappeared completely and saponins remained. Flash chromatography was used to separate saponins and phenolic compounds. It was found that the phenolic fraction was mainly responsible for inhibition of AbPPO and activation of StPPO. Activation of StPPO was probably caused by activation of latent StPPO by chlorogenic acid quinones.

KEYWORDS: *enzymatic browning, tyrosinase, LC-MS, plant extracts, Ilex paraguariensis*

INTRODUCTION

Polyphenol oxidases (PPOs) catalyze enzymatic browning by oxidizing phenolic compounds to their respective *o*-quinones, which subsequently undergo nonenzymatic reactions with each other and other compounds present, resulting in the formation of dark-colored pigments, also referred to as melanins.[1] This phenomenon is a major quality problem in fruit and vegetable processing (e.g., apple, potato, mushroom), but it is also associated with discoloration of shrimps[2] and formation of hyperpigmentation in human skin.[3]

To control enzymatic browning, much research is dedicated to finding natural inhibitors of enzymatic browning.[4−7] In such research, it is important to distinguish between (i) actual PPO inhibitors that prevent the formation of *o*-quinones, (ii) compounds that reduce the *o*-quinones to their *o*-diphenolic precursors (e.g., ascorbic acid[8]), and (iii) compounds that form colorless addition products with *o*-quinones (e.g., cysteine[9]).

Inhibition studies have been conducted on PPOs from a range of sources. Because of its commercial availability, mushroom tyrosinase is often used in model browning systems, both for browning of food products and for skin pigmentation.[10] Little is known on whether results of inhibition studies with one PPO can be extrapolated to another PPO, as most such studies were conducted with a single PPO. To address this issue, we compared the effect of a selection of plant extracts on two different PPOs in the same model system of enzymatic browning. A commercially available mushroom (*Agaricus bisporus*) tyrosinase (AbPPO) and a PPO isolated from potato tubers (*Solanum tuberosum*) (StPPO) were used.

MATERIALS AND METHODS

Materials. Potato (*S. tuberosum* cv. Celino) tubers were obtained from Gemüse Meyer (Twistringen, Germany). Mushroom (*A. bisporus*) tyrosinase, L-3,4-dihydroxyphenylalanine (L-DOPA), chlorogenic acid, and theobromine were obtained from Sigma-Aldrich (St. Louis, MO, USA). Ultrahigh-performance liquid chromatography−mass spectrometry (UHPLC-MS) grade acetonitrile (ACN) was obtained from Biosolve BV (Valkenswaard, The Netherlands), and caffeine was from Boom (Meppel, The Netherlands). Water was prepared using a Milli-Q water purification system (Millipore, Billerica, MA, USA).

Plant Extracts. Commercial, food grade plant extracts (Table 1) were obtained from Frutarom (Wädenswil, Switzerland). The solvents used in the production of the extracts are specified in Table S1 in the Supporting Information.

Purification of Mushroom Tyrosinase. The mushroom tyrosinase was purified by a single gel filtration step.[11] A HiLoad 26/60 Superdex 200 column connected to an Akta Explorer system (GE Healthcare, Uppsala, Sweden) was used. Fifty milligrams of the commercial enzyme (dissolved in 50 mM HEPES buffer, pH 6.8) was loaded and eluted with 50 mM HEPES buffer, pH 6.8, at 4 mL/min. Fractions (5 mL) were collected, and activity was assayed by a spectrophotometric assay: 50 μL of each fraction was combined with 100 μL of 0.8 mM tyrosine in a 96-well plate, and absorbance at 520 nm was monitored in time. Active fractions were pooled and stored at −20 °C until use. Tyrosinase activity was expressed in units (U), according to the suppliers definition (1 U increases the A_{280} by 0.001/

[a]The rate of dopachrome formation relative to the appropriate control (L-DOPA with AbPPO or StPPO and the solvent used to dissolve the plant extract). [b]Biocurcumin was not included in the spectrophotometric assay due to interfering color of the extract.

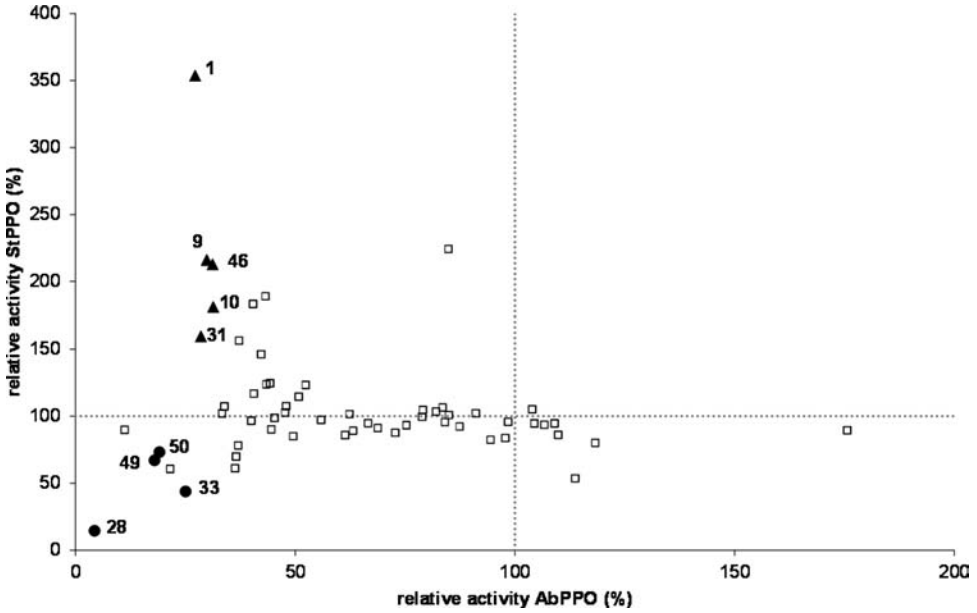

Figure 1. Comparison of the influence of different plant extracts on the conversion of L-DOPA to dopachrome by AbPPO and StPPO. Solid circles indicate extracts that were relatively good inhibitors for both reactions, solid triangles indicate extracts that showed a large difference in inhibition, and open squares indicate all other plant extracts. Numbers refer to Table 1.

min with L-tyrosine as substrate, at pH 6.5 and 25 °C). Purified mushroom tyrosinase is further referred to as AbPPO.

Purification of Potato PPO. One kilogram of potatoes was cooled to 4 °C, washed, and homogenized in 1 L of ice-cold 50 mM HEPES buffer, pH 6.9, containing 1% ascorbic acid and two tablets of protease inhibitor (Complete - EDTA free, Roche Diagnostics GmbH) using a commercial blender. The homogenate was filtered through four layers of cheesecloth, and the filtrate was centrifuged at 13600*g* at 4 °C for 1 h (crude extract, CE). Ammonium sulfate was added to 40% saturation, and the resulting solution was stirred overnight at 4 °C. The precipitate was collected by centrifugation at 13600*g* at 4 °C for 1.5 h and dissolved in a minimal amount of 50 mM HEPES buffer, pH 6.9, containing 1% ascorbic acid. The obtained protein solution was three times dialyzed against 2 L of 50 mM HEPES buffer, pH 6.9, containing 0.1% ascorbic acid and two tablets of the protease inhibitor, after which it was centrifuged at 13600*g* at 4 °C for 30 min.

All subsequent chromatographic steps were performed using an Akta Explorer system (GE Healthcare) at room temperature. The dialyzed protein solution (268 mL) was applied onto a Fast Flow Q-sepharose column (2.6 × 10 cm), pre-equilibrated with 50 mM HEPES buffer, pH 6.9. After a washing with 400 mL of starting buffer, bound protein was eluted using an 800 mL linear gradient of 0−1 M NaCl in the same buffer. The flow rate was 4 mL/min, and 15 mL fractions were collected. Fractions showing maximal PPO activity were pooled and concentrated using a 10 kDa Amicon membrane filter (Millipore) under air pressure.

The concentrated enzyme solution (5 mL) was applied onto a Superdex S-200 column (2.6 × 100 cm) and eluted with 50 mM HEPES buffer, pH 6.9, at a flow rate of 1.5 mL/min. Fractions (5 mL) showing maximal PPO activity were concentrated as described above.

This purification procedure gave an activity yield of 10.6% and resulted in an 11-fold purified enzyme preparation with a specific activity of 5.9 U/mg (Supporting Information Table S2).

Fractionation of Mate Extract. Mate extract was fractionated using a 12 g Reveleris C18 column on a Reveleris flash chromatography system (Grace, Deerfield, IL, USA) operated at 30 mL/min. Twenty milliliters of a 30 g/L solution of mate extract in MQ was applied onto the column. Water acidified with 0.1% (v/v) acetic acid, eluent A, and ACN acidified with 0.1% (v/v) acetic acid, eluent B, were used as eluents. The following elution profile was used: 0−2 min, isocratic on 0% (v/v) B; 2−3 min, linear gradient from 0 to 30% (v/v) B; 3−8 min, isocratic at 30% (v/v) B; 8−13 min, linear gradient from 30 to 100% (v/v) B; 13−15 min, isocratic at 100% (v/v) B. Fractions of 10 mL were collected and pooled on the basis of RP-UHPLC-MS analysis.

Screening of Plant Extracts. Inhibitory activity of plant extracts was assayed using a spectrophotometric assay. Plant extracts (5 g/L) dissolved in either water or dimethyl sulfoxide were diluted (0.16 g/L) into 0.2 mM L-DOPA and 6.5 U/mL AbPPO or 0.4 mM L-DOPA and 0.19 U/mL StPPO in 50 mM HEPES buffer, pH 6.9, in a total volume of 155 μL in a 96-well plate. The absorbance at 520 nm was measured every 20 s for 20 min at 25 °C. The initial rate of color formation (100−240 s) was compared to the appropriate water or dimethyl sulfoxide controls and expressed as relative activity. To ensure that potential competitive inhibition could be observed, substrate concentrations were chosen below the K_m of the two PPOs for L-DOPA.

Oxygen Consumption Measurements. Oxygen consumption of AbPPO or StPPO with selected extracts was measured using an Oxytherm System (Hansatech, Kings Lynn, UK). Incubations with plant extracts or fractionated mate extracts (0.16 g/L) were done with 0.4 mM L-DOPA and 0.19 U/mL StPPO or 0.2 mM L-DOPA and 65 U/mL AbPPO in a total volume of 1 mL of 50 mM HEPES buffer, pH 6.9, at 25 °C. Data acquisition and analysis were performed using Oxygraph Plus software (Hansatech).

RP-UHPLC Analysis. Samples were analyzed on an Accela UHPLC system (Thermo Scientific, San Jose, CA, USA) equipped with a pump, autosampler, and PDA detector. Samples (1 μL) were injected onto a Hypersil Gold column (2.1 × 150 mm, particle size 1.9 μm; Thermo Scientific). Water acidified with 0.1% (v/v) acetic acid, eluent A, and ACN acidified with 0.1% (v/v) acetic acid, eluent B, were used as eluents. The flow rate was 400 μL/min, and the column oven temperature was controlled at 30 °C. The PDA detector was set to measure the range 200−600 nm. The following elution profile was used: 0−1 min, isocratic on 5% (v/v) B; 1−21 min, linear gradient from 5 to 75% (v/v) B; 21−21.1 min, linear gradient from 75 to 100% (v/v) B; 21.1−24 min, isocratic on 100% (v/v) B; 24−24.1 min, linear gradient from 100 to 5% (v/v) B; 24.1−27 min, isocratic on 5% (v/v) B.

Electrospray Ionization Mass Spectrometry (ESI-MS). Mass spectrometric data were obtained by analyzing samples on an LTQ-Velos (Thermo Scientific) equipped with a heated ESI probe coupled to the RP-UHPLC system. Nitrogen was used as sheath gas and auxiliary gas. Data were collected over the m/z range 150−1500. Data-dependent MS^n analysis was performed with a normalized collision energy of 35%. The MS^n fragmentation was performed on the most intense product ion in the MS^{n-1} spectrum. Most settings were optimized via automatic tuning using Tune Plus (Xcalibur 2.1, Thermo Scientific). The system was tuned with a mate extract in negative ionization (NI) mode. The source heater temperature was 45 °C, the transfer tube temperature was 350 °C, and the source voltage was 3.5 kV. Data acquisition and analysis were done with Xcalibur 2.1 (Thermo Scientific).

RESULTS

Screening of Plant Extracts for PPO Inhibitory Activity. The effect of 60 different plant extracts on dopachrome formation by AbPPO and StPPO was compared by expressing the rate of dopachrome formation as activity relative to the appropriate control (L-DOPA with AbPPO or StPPO and the solvent used to dissolve the plant extract) (Table 1). To facilitate this comparison, the relative activities were plotted against each other (Figure 1). From this plot it can be observed that, in general, the StPPO-mediated color formation seemed to be less inhibited than color formation caused by AbPPO. Interestingly, some extracts seemed to inhibit AbPPO, whereas they stimulated StPPO. It should be taken into account that the observed effect on color formation is not necessarily caused by influencing the enzymatic activity. An alternative explanation for an observed inhibition of color formation could be the presence of reducing compounds in the plant extracts, which can either reduce the enzymatically formed *o*-quinone back to the corresponding *o*-diphenol (e.g., ascorbic acid[12]) or combine with the *o*-quinone in an addition product (e.g., cysteine[9] or sulfite[13]). An explanation for enhanced color formation could be the presence of substrates for enzymatic browning in the plant extract itself. To investigate whether enzymatic activity was truly affected, five extracts that showed a large difference in effect on AbPPO and StPPO and four extracts that appeared to be relatively good inhibitors for both the AbPPO and StPPO-mediated color formation were selected for oxygen consumption measurements.

Oxygen Consumption Measurements Discriminate between Inhibition of Color Formation and Enzyme Activity. The four extracts indicated with a circle in Figure 1 (licorice root, pelargonium root, OPC grape seed ActiVin, and NHDC) were used in oxygen consumption measurements to determine whether the observed inhibitory effect on dopachrome formation for both enzymes was caused by inhibition of PPO activity. Biocurcumin was also used in this assay, as the color of this extract was found to interfere with the spectrophotometric assay. The trend of color formation with StPPO being less inhibited than that with AbPPO (Figure 1) was confirmed by oxygen consumption of the two enzymes (Figure 2). Remarkably, the relative oxygen consumption of

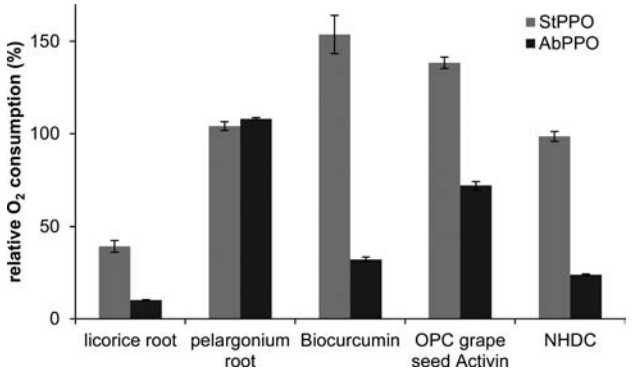

Figure 2. Relative oxygen consumption rates of StPPO and AbPPO with combinations of plant extracts and L-DOPA. Bars represent averages of duplicate determinations; error bars indicate standard deviation.

StPPO in the presence of biocurcumin, grape seed, pelargonium root, and NHDC was 100% or more, whereas the relative color formation with StPPO and these extracts was below 100%. Possibly, the extract contained substrates for StPPO, the oxidation of which did not result in products with an absorption at 520 nm, the wavelength used for the screening assay. If these substrates are preferentially used by StPPO, no color development at 520 nm would be observed, while oxygen consumption occurs. It is unlikely that this effect could be attributed to the presence of reducing compounds in the extracts, as no differences between StPPO and AbPPO would then be expected.

The influence on oxygen consumption of StPPO and AbPPO of five extracts that showed a large difference in their effect on StPPO- and AbPPO-mediated color formation (mate, balm herb, sage leaf, rosemary, and oregano, indicated with triangles in Figure 1) was investigated. Because compounds present in the extracts could potentially be substrates for either of the PPOs, in this way possibly enhancing enzyme activity, incubations of PPO with only plant extract were compared to incubations of PPO, plant extracts, and L-DOPA (Figure 3). The oxygen consumption of StPPO with all of the plant extracts alone was higher than that of the control reaction (StPPO with L-DOPA) used for standardization, indicating that these plant extracts contained either substrates that had a higher affinity for StPPO than L-DOPA or substrates in a considerably higher concentration than the L-DOPA used (0.4 mM). Assuming a molecular weight of 150−300 g/mol for possible substrates in the plant extracts and assuming that these extracts consisted only of substrate, it can be calculated that the maximum theoretical substrate concentration is approximately 0.5−1 mM, with the concentration of plant extracts used in the assay. Balm herb, sage, rosemary, and oregano are all members of the Lamiaceae plant family, which are known to contain a variety of phenolics, including phenolic acids, flavonoids, and phenolic terpenes.[14,15] LC-MS analysis of the extracts used confirmed the presence of a range of compounds, with the most abundant compounds being rosmarinic acid and derivatives of rosmarinic acid (data not shown). The fact that the extracts

Figure 3. Relative oxygen consumption rates of StPPO and AbPPO in the presence of plant extracts alone or combinations of plant extracts and L-DOPA. Oxygen consumption was expressed relative to the control reaction of either StPPO or AbPPO with L-DOPA. Bars represent averages of duplicate determinations; error bars indicate standard deviation.

consisted of multiple components indicated that substrates present in the extracts had higher affinities for StPPO than L-DOPA. The relative activity of AbPPO on the plant extracts alone was lower than the activity on combinations of plant extract and L-DOPA, and activity of both reactions was lower than that of the control reaction (AbPPO with L-DOPA). This indicated that the selected plant extracts effectively reduced the rate of AbPPO-mediated color formation by inhibiting the enzyme. The observation that AbPPO showed some activity on the plant extracts alone indicated that besides inhibitors for AbPPO, the extracts also contained substrates for AbPPO. Furthermore, comparing the activity of StPPO and AbPPO on the plant extracts alone, it can be concluded that the substrates present in the extracts are probably better substrates for StPPO than for AbPPO.

Comparing the effect of the plant extracts in combination with L-DOPA on StPPO to the activity of StPPO on the plant extracts alone, the effect of the mate extract stands out. Whereas the activity of StPPO on the mate extract alone was approximately double that of StPPO on L-DOPA, the activity of StPPO on a combination of L-DOPA and mate extract was >9 times that of StPPO on L-DOPA alone. It seems unlikely that this effect can be attributed only to the presence of substrates in the mate extract. As an example of the contrasting effects a plant extract can have on the activity of different PPOs, the effect of mate extract on StPPO and AbPPO was further investigated.

Mate Extract Accelerates Oxygen Consumption of StPPO, whereas It Inhibits That of AbPPO. The effect of sequential addition of mate extract and L-DOPA to StPPO was compared to a control incubation of StPPO with L-DOPA alone and an incubation of StPPO with L-DOPA and mate extract added simultaneously (Figure 4A). The initial activity of StPPO on mate extract is comparable to that on the combination of mate extract and L-DOPA, both of which are higher than the activity on L-DOPA alone. The activity of StPPO on mate extract alone started to decrease shortly after the beginning of the reaction and eventually leveled off, indicating that the substrates present in mate extract were all converted. When L-DOPA was added after complete conversion of the substrates present in the mate extract, enhanced StPPO activity was still observed. This is an indication that the enhanced oxygen consumption of StPPO with combinations of L-DOPA and mate extract not only is due to supplementation of L-DOPA with additional substrates present in the extract but rather points toward activation of StPPO.

The activity of AbPPO on mate extract was much lower than that of StPPO, and the L-DOPA oxidation rate of AbPPO was lower in the presence of mate extract than without mate extract (Figure 4B). AbPPO was also inhibited upon sequential addition of mate extract and L-DOPA.

These results seemed to indicate that the mate extract used contained one or more activators for StPPO and one or more inhibitors for AbPPO. It is not known whether the same compounds are responsible for the activation of StPPO and the inhibition of AbPPO or whether activators for StPPO are present alongside inhibitors for AbPPO.

Characterization of Mate Extract. To identify the compound(s) responsible for activation of StPPO and inhibition of AbPPO, the composition of the mate extract was characterized on the basis of RP-UHPLC-MS analysis (Figure 5A). Peaks were annotated on the basis of comparison of MS/MS fragmentation with published data (Table 2).[16−18] Two distinct groups of compounds were found, hydroxycinnamic acid conjugates and saponins. Furthermore, quercetin-3-*O*-rutinoside, a glycosylated flavonol, caffeine, and theobromine were found. The hydroxycinnamic acid conjugates were, besides a small amount of feruloylquinic acid, all chlorogenic acid-like compounds, that is, different caffeoyl- and dicaffeoylquinic acid isomers. Chlorogenic acid is a well-known substrate

[a]Peaks were annotated on the basis of MS^2 fragmentation.

for PPO,[19,20] so the presence of these compounds explains the observed activity of StPPO and AbPPO when incubated with mate extract as substrate. Chlorogenic acids are the most abundant phenolic compounds in potato,[21] which might explain the much higher activity of StPPO than AbPPO on the mate extract, considering that chlorogenic acid is likely to be the natural substrate for StPPO. To investigate whether indeed the different chlorogenic acid isomers were used as substrate by PPO, RP-UHPLC-MS analysis of incubations of mate extract with StPPO and AbPPO was done. The MS traces of these samples revealed that the different chlorogenic acids and quercetin-3-*O*-rutinoside were converted, whereas the saponins remained (data not shown). No reaction products of the oxidation of the different substrates were found, whereas the mate extract after incubation with PPO visibly turned brown. This might be explained by the formation of a wide variety of reaction products from the *o*-quinones resulting from PPO oxidation, which individually fall below the detection limit of the RP-UHPLC analysis.

Polar Compounds in Mate Extract Are Responsible for Activation of StPPO. The fact that the saponins remained after PPO activity led to the hypothesis that they might be responsible for the observed activation of StPPO and inhibition of AbPPO. Saponins extracted from *Paris polyphylla* have been

dx.doi.org/10.1021/jf4043375 | J. Agric. Food Chem. 2014, 62, 214−221

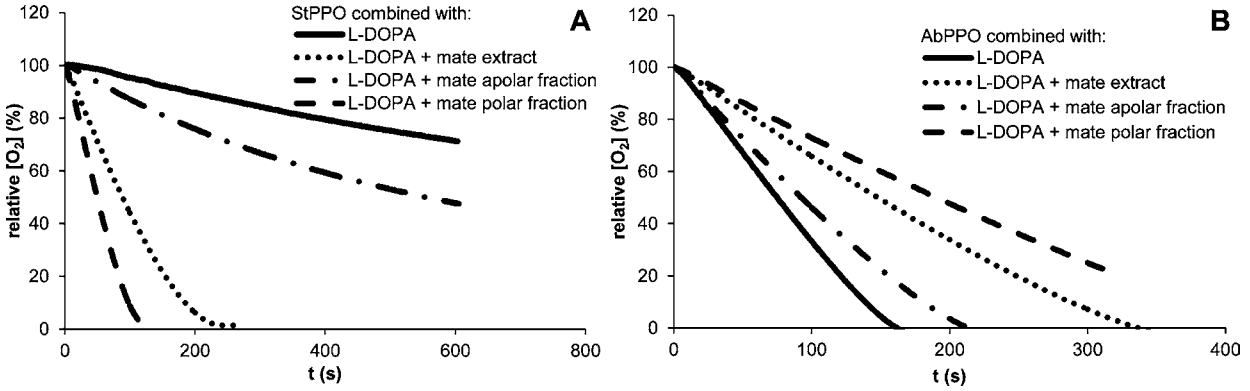

Figure 6. Oxygen consumption in time of incubations of StPPO (A) and AbPPO (B) with L-DOPA (blank) and L-DOPA combined with mate extract, the polar mate fraction, and the apolar mate fraction.

found to inhibit AbPPO.[22] To investigate this, reversed-phase flash chromatography was used to fractionate the mate extract to investigate the effect of the saponins separately from the chlorogenic acid-like compounds. Fractions from flash chromatography were pooled such that a fraction containing mainly chlorogenic acid-like compounds (polar fraction, Figure 5B) and a fraction containing mainly saponins (apolar fraction, Figure 5C) were obtained.

Oxygen consumption measurements with L-DOPA and StPPO in the presence of the apolar or polar mate fraction (Figure 6A) showed that the polar mate fraction seemed to be mainly responsible for activation of StPPO: whereas StPPO was slightly more active in the presence of the apolar mate fraction than with only L-DOPA, activity in the presence of the polar mate fraction was much higher than the blank incubation.

Besides chlorogenic acid-like compounds, caffeine and theobromine were also present in the polar fraction. Whereas the chlorogenic acid-like compounds were converted after incubation with PPO, caffeine and theobromine remained. Experiments with pure caffeine and theobromine showed that they were not responsible for activation of StPPO or inhibition of AbPPO (data not shown). Apparently, the substrates present in the mate extract activated StPPO, also after they had reacted (Figure 4A). To investigate whether the activation of StPPO was indeed due to the chlorogenic acid-like substrates present in the mate extract, StPPO was incubated with pure chlorogenic acid. When oxygen consumption had leveled off, L-DOPA was added. The results obtained were similar to those obtained with mate: oxygen consumption with sequential chlorogenic acid and L-DOPA addition was accelerated compared to a control of StPPO with only L-DOPA (data not shown).

Because of the inhibition of AbPPO by mate, fractionation of the extract indicated that the polar fraction was mainly responsible for inhibition (Figure 6B). In the presence of the apolar mate fraction, oxygen consumption of AbPPO with L-DOPA was comparable to that in the blank reaction, whereas in the presence of the polar fraction the oxygen consumption was decreased compared to that with the blank.

■ DISCUSSION

Our results of screening 60 plant extracts for StPPO and AbPPO inhibitory activity demonstrated that the effect that an extract can have on PPO-catalyzed browning is dependent on the source of PPO. Some extracts showed inhibitory activity toward both PPOs, whereas other extracts inhibited only one PPO or even inhibited one and activated the other PPO. As an example, a mate extract was investigated in more detail, and it was found to be an activator for StPPO and an inhibitor for AbPPO.

Inhibition of PPOs by Plant Extracts. Of 60 plant extracts screened for inhibitory effects on StPPO and AbPPO, 4 were further investigated by measuring their influence on oxygen consumption. Only the extract of licorice root was found to inhibit the activity of both StPPO and AbPPO (Figure 2), indicating that the observed inhibitory effect on color formation of the other extracts was most likely caused by reducing compounds in the extracts. These compounds only prevent formation of color, but do not inhibit enzyme activity.

The inhibitory effect of licorice root on AbPPO has been described before, and several inhibitory (iso)flavonoids and chalcones have been identified.[23−25] Licorice extracts were found to inhibit both mushroom tyrosinase in vitro and melanin formation in cultured human melanocytes.[24] In addition to this, our results demonstrated that licorice also inhibited StPPO. This might indicate that the inhibitors present in licorice are inhibitors with a wide application range.

Activation of StPPO by Mate Extract. When StPPO was incubated with mate extract, oxygen consumption and conversion of substrates present in the extract was observed. Incubation of StPPO with mate extract had an activating effect on L-DOPA oxidation by the enzyme (Figure 4A). Fractionation of the mate extract demonstrated that chlorogenic acid-like compounds were responsible for this activation, which was confirmed by experiments with pure chlorogenic acid. An explanation for the increased StPPO activity observed might be activation of StPPO, which was extracted in a latent state, by *o*-quinones resulting from chlorogenic acid oxidation. Similarly, activation of latent PPO from red clover (*Trifolium pretense*) by *o*-quinones resulting from oxidation of endogenous substrates has been demonstrated.[26] It was proposed that a conformational change of clover PPO occurred through interaction of *o*-quinones with the protein. Conformational changes have been implicated before in the activation of latent plant PPOs. Treatment with surfactants such as SDS, addition of fatty acids, and pH-induced conformational change have been reported to activate plant PPOs, by making the active site more accessible.[27−30] Possibly, interaction of chlorogenic acid quinones with StPPO induced a conformational change, in this way making its active site more accessible.

In conclusion, our results showed that care should be taken when results of inhibitor studies obtained with one specific PPO are generalized to broader food or cosmetic applications.

dx.doi.org/10.1021/jf4043375 | J. Agric. Food Chem. 2014, 62, 214−221

Although screening with a commercially available PPO might be a convenient way to find potential inhibitors, experiments with the target PPO should be done before an inhibitor can be applied in a specific product. Moreover, when a different PPO is used for inhibitor screening than for the final application, potentially useful inhibitors might be overlooked.

Supporting Information

ABSTRACT: The prevalence of food allergy has increased in recent years, and Korean pine vicilin is a potential food allergen. We have previously reported the crystallization of Korean pine vicilin purified from raw pine nut. Here we report the isolation of vicilin mRNA and the crystal structure of Korean pine vicilin at 2.40 Å resolution. The overall structure of pine nut vicilin is similar to the structures of other 7S seed storage proteins and consists of an N-terminal domain and a C-terminal domain. Each assumes a cupin fold, and they are symmetrically related about a pseudodyad axis. Three vicilin molecules form a doughnut-shaped trimer through head-to-tail association. Structure characterization of Korean pine nut vicilin unexpectedly showed that, in its native trimeric state, the vicilin has three copper ligands. Sequence alignments suggested that the copper-coordinating residues were conserved in winter squash, sesame, tomato, and several tree nuts, while they were not conserved in a number of legumes, including peanut and soybean. Additional studies are needed to assess whether the copper-coordinating property of vicilins has a biological function in the relevant plants. The nutritional value of this copper-coordinating protein in tree nuts and other edible seeds may be worth further investigations.

KEYWORDS: *7S vicilin, pine nut, allergen, X-ray crystallography, copper protein*

1. INTRODUCTION

Food allergies have become a major global health concern.[1,2] Most food allergies are triggered by immunoglobulin E (IgE) recognition of food allergens.[3] To date, there is no cure for food allergies, although immunotherapy using a very small amount of food, recombinant allergens, and engineered hypoallergenic proteins is considered promising.[4−7] Peanut and tree nuts account for the majority of fatal and near-fatal food allergy cases in the United States.[8,9] Cross-reactivity exhibited by peanut allergic patients to other tree nuts, legumes, and oil seeds[10,11] poses an additional risk to these patients.

Pines (family Pinaceae, genus *Pinus*) are widely distributed around the world and are among the most important forest trees. One single species, the loblolly pine (*Pinus taeda* L.), provides ∼16% of the world's annual timber supply.[12] Pine woods are also widely used in the pulp and paper industries. The edible seeds of pine trees (pine nuts) have been consumed in Asia and Europe since prehistoric times, and in some regions, people may have survived winters by consuming only pine nuts.[13] About 30 species of pine produce seeds that are large enough for harvesting.[14] Korean pine nuts are extensively harvested in northeastern China. More than 80% of the pine nuts sold in the United States are imported, primarily from China.[15] Pine nuts are considered a delicacy in many of the world's cultures,[14] and they are frequently used in the preparation of bakery products, vegetable dishes, and other foods.[16,17] Pine nuts are also of high nutritional value. Proteins make up as much as 31.6% of the total dry weight of the edible portion of pine nuts.[17,18] Pine nuts contain a considerable number of vitamins (e.g., vitamins A, B1, and B2), potassium, magnesium, copper, and other minerals as well as dietary fiber.[17,19]

Unfortunately, pine nuts, similar to peanuts and other tree nuts, are reported to cause allergic reactions in certain patients,[20,21] although no pine proteins have been officially recognized as allergens by the World Health Organization and International Union of Immunological Societies (WHO/IUIS) Allergen Nomenclature Subcommittee. The 7S vicilin type seed storage proteins belong to the cupin protein superfamily, which also includes the 11S legumins. Both the 7S and 11S proteins in peanut, hazelnut, cashew nut, pistachios, and walnuts are known to be allergens.[22,23] The crystal structures of a few of these allergens have been reported, including Ara h 3[24] and Ara h 1[25,26] from peanut and Pru du 6[27] from almond. Structural studies on a related protein from *Amaranthus hypochondriacus*

were also attempted.[28] To understand the allergenicity of the cupin family of proteins, additional information about the structural properties of the 7S and 11S proteins is needed. In this paper, we describe the cloning of Korean pine vicilin and X-ray crystallographic study of the structure of this potential allergen.

2. MATERIALS AND METHODS

2.1. Plasmid Construction. *2.1.1. Total RNA Extraction.* The 7S vicilin of Korean pine was first purified from pine nut and identified by aligning its N-terminal peptides with the available sequence of vicilin from loblolly pine.[29] To determine the mRNA sequence of Korean pine vicilin, fresh tissues of female flowers and young cones of Korean pine were collected at the Chicago Botanic Garden (Chicago, IL). Total RNA from young Korean pine cones was extracted using the QIAGEN (Valencia, CA) RNeasy Plus Mini Kit according to the manufacturer's protocol with minor modifications. Briefly, 100 mg of fresh tissues/seeds of young cone were ground in liquid nitrogen and collected in a microcentrifuge tube. As soon as the liquid nitrogen evaporated, 450 μL of buffer RLT was added, and the sample was mixed by inversion. RLT and RW1 and RPE mentioned below are proprietary buffers provided by the kit, and their compositions are not described. After centrifugation, the supernatant was transferred to a gDNA Eliminator Mini Spin column and subjected to centrifugation. The flow-through was mixed with 1/2 volume of ethanol and loaded onto an RNeasy Mini Spin column. The column was washed with 700 μL of RW1 buffer and 500 μL of RPE buffer, and the total RNA was eluted with 50 μL of RNase-free water. Two microliter (80 units) of RNaseOUT recombinant ribonuclease inhibitor (Invitrogen, Carlsbad, CA) was added to the sample immediately after elution. Fresh total RNA was used as a template for reverse transcription (RT).

2.1.2. RT and PCR. An Omniscript Reverse Transcription Kit (QIAGEN, Valencia, CA) was used to synthesize cDNAs from the total RNA of various pine tissues. The RT reaction was carried out using a 20-nucleotide poly-dT primer at a 6 μM concentration and 2 μL of the fresh total RNA as the template in a 20 μL RT mixture. The RT reaction was allowed to proceed for 1 h at 37 °C, and the reverse transcriptase was inactivated by incubation at 95 °C for 5 min. The RT product was either used immediately as a template in PCR or stored at −80 °C for further use.

Previously, we reported the purification and biochemical and biophysical characterization of the Korean pine vicilin.[29] N-terminal peptide sequencing of the purified protein indicated that it was similar but not identical to that of loblolly pine.[29] To isolate the mRNA sequence of Korean pine vicilin, PCR primers (atggcttttgtttctttacttacc-attcttc, forward; cgtggagaaactctagt, reverse) were designed on the basis of the loblolly pine vicilin mRNA sequence, and PCR was carried out using Phusion DNA polymerase (New England BioLabs, Ipswich, MA). By blunt end ligation using quick ligase, the PCR product was inserted into a pBluescript SKII vector digested with *Eco*RV to generate pBlue−vicilin. Two colonies were sent to a commercial vender for sequencing, and the resulting mRNA sequence was deposited in GenBank (access ID KF530834).

2.2. Identification of Metal Ligands. A Varian AA 55B atomic absorption spectrophotometer (Agilent Technologies, Santa Clara, CA) was used to determine and quantify possible metal ligands in Korean pine vicilin. An air/acetylene (oxidant/fuel) mixture was used as the flame source. Standard solutions of Cu, Ni, Zn, Mg, Mn, Ca, Fe, and Al ions were prepared fresh for each measurement according to the spectrophotometer manufacturer's instructions and were used for the calibration of the instrument. A vicilin sample of 0.161 mM monomer concentration in Milli-Q H_2O was used for metal content determination.

2.3. Structure Refinement. Korean pine vicilin was purified from raw pine nut and crystallized by the vapor-diffusion method as described previously.[30] X-ray diffraction data were collected at the SER-CAT 22ID beamline at the Advanced Photon Source (APS), Argonne National Laboratory. Data processing with HKL2000[31] and a structure solution by PHASER[32,33] molecular-replacement calculations have been previously reported.[30]

Structure refinement was carried out with REFMAC5[34] implemented in CCP4i[35] and with PHENIX[36] alternated with model building and model improvement using Coot.[37]

The final structure was refined with all data to a 2.40 Å resolution, and the final model was checked by PROCHECK[38] and MolProbity validation.[39] The quality of the structure model was also checked with a shake-and-omit protocol by first introducing random errors up to 0.3 Å to the coordinates of the final refined structure using the program PDSET distributed with CCP4.[35] For each region to be checked, the concerned region of the shaken structure was manually omitted and 20 cycles of restrained refinements were carried out using REFMAC5.[34] This was followed by inspecting the $F_o - F_c$ map together with the final refined structure.

The structure of pine nut vicilin has been submitted to the Protein Data Bank with the accession code 4LEJ. Molecular graphics were prepared using the programs RASMOL,[40] MOLSCRIPT,[41] Raster3D,[42] and Pymol (http://pymol.org/).

3. RESULTS

3.1. Isolation of Korean Pine Vicilin cDNA. To allow characterization of the physicochemical, structural, and immunological properties of Korean pine vicilin, the availability of purified protein is needed. Toward this end, we sought to isolate the vicilin gene and deduce its peptide sequence. The coding sequence of Korean pine vicilin was cloned, sequenced, and deposited in GenBank (KF530834). The coding sequence of vicilin as well as its encoded peptide sequence is shown in the Supporting Information (Figure S1). The signal peptide was determined by comparing the predicted pro-protein with the result of N-terminal sequencing of the native protein purified from mature seeds.[29] The isolation of the coding sequence of pine nut vicilin and production of the recombinant protein can be used in future studies to investigate pine nut allergy and the allergenicity of this protein.

3.2. Structure of Pine Nut Vicilin. The translated peptide sequence from the newly cloned Korean pine vicilin was used for structure refinement. The refined structure gave R/R_{free} values of 0.1924/0.2414 for all data to 2.40 Å (Figure 1 and Table 1). The RMSDs from ideal empirical values[43] were 0.004 Å for the bond lengths and 0.80° for the bond angles, with no main-chain bond length deviating more than 0.05 Å or main-chain bond angle deviating more than 10° from the "ideal" small-molecule values. On the Ramachandran plot calculated with MolProbity validation,[39] all residues were in allowed

Figure 1. Structure of pine vicilin. A vicilin molecule in one asymmetric unit is shown in a ribbon diagram with a rainbow coloring scheme (N-terminal, blue; C-terminal, red). A copper ligand of the protein is shown as a bronze sphere, and the side chains of copper-binding residues are shown as sticks with the CPK coloring scheme.

[a] $R_{merge} = \sum_h\sum_i|I_i(h) - \langle I(h)\rangle|/\sum_h\sum_i I_i(h)$, where $I_i(h)$ and $\langle I(h)\rangle$ are the ith and mean measurements of the intensity of reflection h. [b] $R_{pim} = \sum_h[(1/n - 1)^{1/2}]\sum_i|I_i(h) - \langle I(h)\rangle|/\sum_h\sum_i I_i(h)$, where $I_i(h)$ and $\langle I(h)\rangle$ are the ith and mean measurements of the intensity of reflection h and n is the redundancy of reflection h and was calculated with unmerged intensities using PHENIX merging statistic utilities. [c] $R_{work} = \sum_h||F_o(h)| - |F_c(h)||/\sum_h|F_o(h)|$, where $F_o(h)$ and $F_c(h)$ are the observed and calculated structure factors, respectively. No I/σ cutoff was applied. [d] R_{free} was calculated from 5% of the total data set randomly selected that was not used in the refinement.

regions, and 96.3% of all residues were in favored regions (Table 1). In the final refined structure, there was one vicilin molecule in the crystallographic asymmetric unit with 355 protein residues located in the electron density map. Eight residues at the N-terminal and nine residues at the C-terminal of the mature protein could not be located in the electron density map and were not included in the refined structure. Two flexible loop regions (residues N241−A261 and G342−H355) were also not located in the structure. In addition, the final structure included 30 water molecules, 1 glycerol molecule, 1 phosphate ion, and 1 metal ligand. Flame atomic absorption spectrometry was used to determine the identity of the metal ligand of vicilin. The results indicated that there was one copper ion in each vicilin molecule. No Ni, Zn, Mg, Mn, Ca, Fe, or Al ions could be detected in the sample (data not shown).

The overall structure of pine nut vicilin consists of an N-terminal domain and a C-terminal domain. Each assumes a cupin fold, and the two domains are symmetrically related about a pseudodyad axis. Three vicilin molecules form a doughnut-shaped trimer through head-to-tail association (Figure 2). The structures of several 7S seed storage proteins from other plants have been reported, including adzuki bean (PDB 2EAA), mung bean (PDB 2CV6), soybean (PDB 1UIK and 1IPK), kidney bean (PDB 2PHL), jack bean (PDB 2CAU), and peanut (PDB 3S7I and 3SMH). All these previously reported structures, however, were from legumes, and they did not contain any metal ligands.

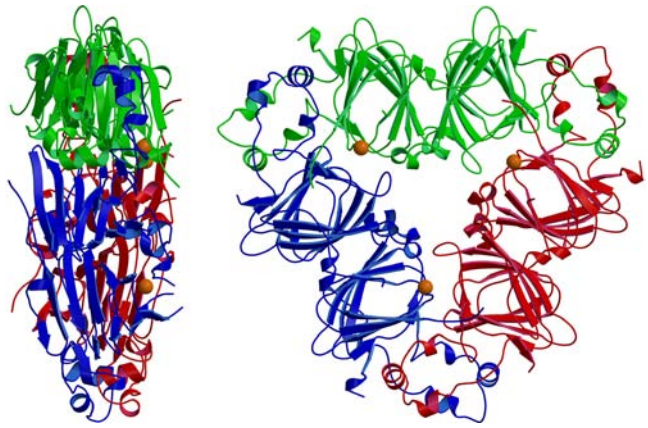

Figure 2. Trimeric structure of pine vicilin. The trimeric vicilins are shown in a ribbon diagram with the monomers colored in cyan, green, and magenta. The trimer is shown in two orthogonal views and with the copper atoms in all three monomers shown in space-fill and colored in bronze.

On the basis of patient serum recognition and LC/MS/MS sequencing of peptides resulting from protease digestion of a 50 kDa protein, *Pinus pinea* (stone pine) vicilin was suggested to be a pine nut allergen.[44] The three peptides identified in that study (ASSEAGEIR, QFLAGK, and FGVPSGHTFY) can be separately aligned with Korean pine vicilin isolated in this study with 100% identity, except for the second peptide, which would align with a sequence of EFLAGK, with one amino acid residue not identical (data not shown). A total of 23 linear IgE epitopes in peanut allergen Ara h 1 were identified, and the smallest IgE-binding sequence was determined to contain six amino acids.[45] When pine vicilin isolated in this study was aligned with Ara h 1 (data not shown), the longest stretch of exact matches contained six residues but did not reside in any of the known linear epitopes of Ara h 1. The second longest match only contained less than 6 amino acids. To date, the allergenicity of food proteins is still poorly understood, and the reliability of using sequence comparison alone to predict protein allergenicity may be questionable. Structural properties may provide clues that contribute to the understanding of the allergenicity of these proteins. Unfortunately, very little information is available regarding conformational IgE epitopes of known allergens. The availability of three-dimensional structures of additional food allergens may help the understanding and mitigation of the allergenicity of food proteins in the future when more information about conformational epitopes is obtained.

3.3. Copper Center in Pine Nut Vicilin. The copper center of pine nut vicilin consists of a cysteine (C338), a tyrosine (Y67), and two histidines (H340 and H379). The sulfur of C338, the ND1 of H340, and the NE2 of H379 form a trigonal planar structure with the copper ion in the center, but slightly away from the plane. The hydroxyl group of Y67 provides the fourth, axial ligand with a longer coordinating distance (Figure 3).

On the basis of the structural and spectroscopic properties of copper proteins, their Cu centers are classified into different types (types I, II, III, Cu_A, Cu_B, and Cu_Z).[46] Modification of the Cu center by protein engineering has also generated a so-called type I and half copper site.[47] Type I copper proteins are also called blue copper proteins because of their strong absorbance at about 600 nm, and they function in electron transfer.[48] This type of Cu center is typically coordinated by two His residues

dx.doi.org/10.1021/jf4039887 | J. Agric. Food Chem. 2014, 62, 222−228

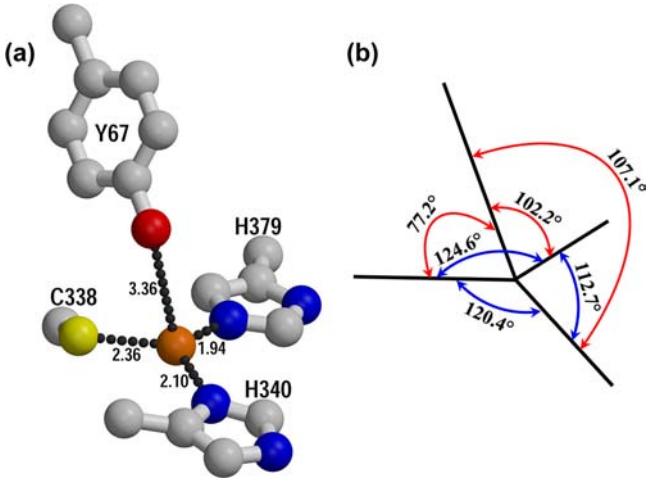

Figure 3. Type II copper center in pine nut vicilin. (a) Ball-and-stick representation of copper coordination in vicilin. The distances (Å) are shown next to the dotted lines between the copper ion and its coordinating residues. Atom colors are gray, red, blue, yellow, and bronze for C, O, N, S, and Cu, respectively. (b) Coordination geometry parameters about the copper. The lines between the copper ion and its coordinating atoms are shown in the same orientation as in (a). The angles formed by two distances connecting the Cu and two of its coordination atoms are shown in degrees.

and a Cys residue in a trigonal planar arrangement with an additional axial Met coordinated, distorting the geometry toward tetrahedral. Type II Cu centers lack the strong, distinctive absorbance at 600 nm and have no evident color. The amino acid coordination and geometries of type II Cu centers are diverse.[49] A typical type II Cu center is coordinated with four His residues in a square pyramidal geometry and is generally considered not to have a Cys ligand.[50] The Cu center in pine nut vicilin has features of both type I and type II Cu sites. Its ligands include the side chain sulfur of a Cys residue, but it was colorless and the absorbance spectra of the protein were featureless in the visible region (data not shown). Unlike in type I proteins where both the His residues bind to the Cu ion through ND1,[51] H379 in Korean pine vicilin interacts with the Cu ion through its NE2. In addition, the distance between the sulfur of C338 and the Cu ion (2.36 Å) is longer than its counterpart in a typical type I copper protein.[52] Thus, it does not fit a type I copper protein, and for now, we will group it in the more divergent type II category.

3.4. Possible Copper Binding in Other Vicilin Orthologues. Free copper ions in the cell can be toxic even at low concentrations, so the ability of certain proteins to bind copper might provide a mechanism to detoxify the cell. It is unclear whether the existence of a copper ligand of the 7S protein is unique to Korean pine. It is also unclear whether this copper center of the vicilin protein has an important biological

Figure 4. Multiple sequence alignments of vicilins from different species. The sequence of Korean pine vicilin isolated in this study was aligned with those of other species identified by a BLAST search of the nonredundant protein sequence (NR) database at NCBI (see the text). The copper-coordinating residues in pine nut vicilin, and the corresponding conserved residues in other vicilins, are shown in red. Only the alignments around the copper-coordinating residues are shown. (a) Vicilins with conserved copper-coordinating residues and a possible copper center. (b) Vicilins without the copper-coordinating residues conserved. These include the 7S proteins for which the crystal structures were reported previously (and for whose structures were solved the PDB access codes were also used to label the sequences).

dx.doi.org/10.1021/jf4039887 | J. Agric. Food Chem. 2014, 62, 222−228

function. To assess whether the copper-binding property is shared by vicilins from other species, ClustalW was used to align available vicilin sequences from different species. The copper-coordinating residues in pine nut are conserved in the 7S seed storage proteins of *Picea glauca* (white spruce, NR accession number CAA44873), *Juglans nigra* (black walnut, AAM54366), *Juglans regia* (English walnut, AAF18269), *Carya illinoinensis* (pecan, ABV49593), *Pistacia vera* (pistachio, ABO36677), *Anacardium occidentale* (cashew, AAM73730), *Corylus avellana* (hazelnut, AAL86739), *Cucurbita maxima* (winter squash, BAA34056), *Sesamum indicum* (sesame, AAK15089), and *Solanum lycopersicum* (tomato, CAP69670). On the other hand, the copper-coordinating residues are not universally conserved in the 7S storage proteins in a number of legumes. These include the 7S proteins in *Vigna angulariz* (adzuki bean, 2EAA_A), *Vigna radiata* var. *radiata* (mung bean, 2CV6_A), *Glycine max* (soybean, 1UIK_A (conglycinin α) and 1IPK_A (conglycinin β)), *Phaseolus vulgaris* (kidney bean, 2PHL_A), *Canavalia ensiformis* (jack bean, 2CAU_A), and *Arachis hypogaea* (peanut, P43238). These residues are also not conserved in the extensively studied model plant *Arabidopsis thaliana* (thale cress, NP_566714). Regardless of whether the copper-coordinating residues are presented or not, many of these vicilins have been identified as food allergens, including Ara h 1 in peanut, Gly m 5 in soybean, Vig r 2 in mung bean, Ses I 3 in sesame, Cor a 11 in hazelnut, Ana o 1 in cashew, Pis v 3 in pistachio, Jug r 2 in English walnut, and Jug n 2 in black walnut. Thus, the presence of a copper center is unlikely to be related to the allergenicity of the 7S proteins.

Multiple sequence alignments of pine nut vicilin and its orthologues with and without the conserved copper coordination residues are shown in parts a and b, respectively, of Figure 4. The alignment of the full sequences of these 7S proteins is shown in the Supporting Information (Figure S2). Copper-coordinating residues are conserved in a large number of seed plants, including conifers and a subset of flowering plants, suggesting that copper is a ligand of vicilin in these species. Copper is an essential trace element in nearly all organisms.[53] As a seed storage protein, besides preserving nitrogen, carbon, and sulfur for the development of young plants, no other biological function for vicilin is known. The identification of pine nut vicilin as a copper protein indicates that it may have a function in copper reservation.

The biological roles of copper include transportation of dioxygen and iron, electron transfer, oxidation of organic substrates and metal ions, and reduction of nitrite, nitrous oxide, an dioxygen.[54] The diverse category of proteins with a type II Cu center also includes peptidylglycine α-hydroxylating monooxygenase whose function requires two copper centers[55] and galactose oxidase whose activity involves a covalently modified tyrosine.[56] To our knowledge, the 7S seed storage protein has not been reported to contain a copper center. The copper center of pine vicilin does not readily reveal a possible biological function. As the copper ion binds to residues from both the N- and C-terminal domains of the protein, it may contribute to the stability of the protein. Future investigations are needed to unveil whether the presence of a copper ligand is required by an unknown catalytic activity of vicilin in pine and other plants. Further studies on whether copper centers exist in the vicilins from other species may result in valuable information and provide insights into the molecular evolution of this seed storage protein and reveal the nutritional value of this type of abundant copper-binding protein in seeds.

Supporting Information

ABSTRACT: Polysaccharide from the seeds of *Plantago asiatica* L. was given via oral administration to mice (0.4 g/kg body weight, 30 days) to observe its effects on mouse nutrient metabolism and colon microbiota. It was found the polysaccharide intake could lower the apparent absorption of lipid. Total triglyceride, cholesterol, and atherogenic index in blood serum with total lipid and cholesterol levels in liver of polysaccharide group mice were all significantly lower than those of the control group ($p < 0.05$). Furthermore, the effect of the polysaccharide intake on mouse colon bacterial communities was investigated. Mice from the polysaccharide group showed a higher colon bacterial diversity than the control group. *Bacteroides* sp., *Eubacterium* sp., butyrate-producing bacteria *Butyrivibrio* sp., and probiotics *Bifidobacterium bifidum*, *Lactobacillus fermentum*, and *Lactobacillus reuteri* in mouse colon were all increased after polysaccharide intake. These indicated that the intake of polysaccharide from *P. asiatica* L. could be beneficial for lipid metabolism and colon microbiota.

KEYWORDS: *Plantago asiatica L., polysaccharide, lipid metabolism, colon microbiota*

INTRODUCTION

In recent years, the influence of polysaccharides on major nutrient (carbohydrate, protein, and lipid) metabolism has been of particular interest because major nutrient metabolism is related to many chronic diseases.[1,2] In addition, the effects of polysaccharide on colon microbiota were also paid much attention because of its benefits for the colon health, which is of more and more concern nowadays.[3] The gut microbiota in colon contact with its host takes part in a great number of metabolic processes.[4] The supply of fermentable carbohydrate is an important factor limiting the growth of bacteria in colon and, as in other environments, bacteria that can transform the available substrates most rapidly will occur in the greatest numbers.[5]

Polysaccharides can be extracted from many kinds of herbal or plant materials. Some *Plantago* plants, such as *Plantago afra* L., *Plantago psyllium* L., *Plantago ovata* Forsk. (isabgul), *Plantago indica* L., and *Plantago major* L., are often used in traditional medicine throughout the world because the soluble fibers in their seeds are able to improve some intestinal functions.[6] Our research group has recently isolated a pure and homogeneous polysaccharide from the seeds of *Plantago asiatica* L. with a molecular mass of 1894 kDa.[7] The polysaccharide was found to be a highly branched heteroxylan, which consisted of a β-1,4-linked Xyl*p* backbone with side chains attached to *O*-2 or *O*-3. The side chains consisted of β-T-linked Xyl*p*, α-T-linked Ara*f*, α-T-linked GlcA*p*, β-Xyl*p*-(1→3)-α-Ara*f*, and α-Ara*f*-(1→3)-β-Xyl*p*, etc.[8] In addition, our recent studies have also shown that this polysaccharide may induce maturation of murine dendrite cells, have antioxidant activity in vitro, promote mouse defecation, increase short-chain fatty acid (SCFA) production in mouse colon and in vitro fermentation, and have some effects on intestinal function in vitro.[9−14] However, the influence of the polysaccharide from *P. asiatica* L. on nutrient metabolism and colon microbiota in mouse has not been studied.

In this study, the effect of the polysaccharide from *P. asiatica* L. on mouse nutrient metabolism was evaluated by determining the apparent absorption of major nutrients, blood serum ingredients, and liver lipid contents. Additionally, the effect of the polysaccharide on mouse colonic bacterial communities was investigated. Amplicons of the V3 variable regions of bacterial 16S rDNA were analyzed by denaturing gradient gel electrophoresis (DGGE), cloning, and sequencing. Furthermore, the relationship between lipid metabolism difference and bacterial community change of mouse after polysaccharide intake was also discussed.

MATERIALS AND METHODS

Materials and Animals. The seeds of *P. asiatica* L. were purchased from Ji'an, Jiangxi, China, and dried in the sun before use. All reagents used were of analytical grade and purchased from Shanghai Chemicals and Reagents Co. (Shanghai, China).

Kunming mice, weighing 20.0 ± 2.0 g [grade II, certificate SCXK (gan) 2006-0001], were purchased from Jiangxi College of Traditional Chinese Medicine, Jiangxi Province, China. All animals used in this study were cared for in accordance with the *Guidelines for the Care and Use of Laboratory Animals* published by the U.S. National Institutes of Health (NIH Publication 85-23, 1996), and all procedures were

Polysaccharide Preparation. Polysaccharide from *P. asiatica* L. seeds was prepared using our published method.[7] Briefly, the seeds of *P. asiatica* L. (50 g) were defatted with 1 L of ethanol at room temperature for 24 h under stirring and then extracted with 500 mL of doubly distilled water at 100 °C for 2 h. The residue was re-extracted. The combined aqueous extract (a highly viscous gel) was centrifuged (4800*g*, 10 min) and prefiltered through a cotton cloth bag. After that, the filtrate was concentrated by a rotary evaporator under reduced pressure at 55 °C to yield *P. asiatica* L. water extract. The filtrate was mixed with 1.5 g/L papain and heated in water at 60 °C for 2 h. The resulting aqueous solution was extensively dialyzed against doubly distilled water for 72 h and precipitated by adding 4 volumes of anhydrous ethanol at 4 °C for 12 h. After centrifugation, the precipitate was washed with anhydrous ethanol, dissolved in water, and lyophilized to yield the polysaccharide.

Animal Experiment Design. Male 6-week-old Kunming mice (20.0 ± 2.0 g) were individually housed in stainless steel cages in a room with controlled temperature (25 ± 0.5 °C), relative humidity (50 ± 5%), and a 12 h/12 h light/dark cycle. All mice were fed the same amount of basal diet (Table 1), which was prepared according to the published formula,[15] and water was provided ad libitum. All mice were randomly divided into two groups: (1, Polysaccharide group) Mice were orally administered polysaccharide at the dose of 0.4 g/kg body weight of mice. The dose for the polysaccharide administration was selected according to our previous research.[11,12] (2, Control group) Mice were given distilled water of the same volume as the mean volume of the polysaccharide groups. Each group had 12 mice, and mice were housed individually. All of the mice were given oral administration of polysaccharide or water at about 9:00 a.m. every day for 30 days. In addition, we determined the body weight of each mouse every day before gavage and changed the volume of the polysaccharide to ensure that the mice were given polysaccharide at the dose of 0.4 g/kg body weight by gavage every day. Throughout the experiment, the animals' general health status and body mass were observed twice daily.

Table 1. Composition of the Basal Diet for Mice

component	g/kg dry weight (DW) basis
corn starch	454
soybean meal	240
sucrose	100
corn oil	60
cellulose	50
gelatinized starch	10
vitamin mixture[a]	10
mineral mixture[b]	76

[a]Containing, in g/kg (DW basis): 0.25 (250000 IU) vitamin A; 0.002 (65000 IU) vitamin D_3; 2 (2000 IU) vitamin E; 0.41 menadinoe; 0.07 folic acid; 1.25 niacin; 0.5 calcium pantothenate; 0.2 riboflavin; 0.25 thiamin; 0.5 pyridoxine; 0.003 cyanocobalamine; 0.025 biotin; 70.0 cholin chloride. [b]Containing, in g/kg (DW basis): 69.6 $CaCO_3$; 313.1 $C_{12}H_{10}Ca_3{\cdot}4H_2O$; 114.6 $CaHPO_4{\cdot}2H_2O$; 222.2 $K_2HPO_4{\cdot}3H_2O$; 126.7 KCl; 78.3 NaCl; 38.9 $MgCO_3$; 35.8 $MgCO_3$; 0.204 $MnSO_4{\cdot}H_2O$; 0.042 KI; 0.515NaF; 0.091 $AlNH_4(SO_4)_2{\cdot}12H_2O$.

At the end of the designated experiment period, feces of the mice were collected individually and used to measure the apparent absorption of major nutrients (carbohydrate, protein, and fat). Blood was drawn from the eyes of the mice, and the serum was isolated by brief centrifugation of the whole blood. After that, the mice were sacrificed, and the liver and colon (with contents) were obtained. Then the colons were aseptically removed immediately and placed on an ice-cold plate and longitudinally opened, and the colon contents were collected. The feces, liver, and colon content were then kept at −20 °C for further analysis.

Measurement of the Apparent Absorption of Major Nutrients (Carbohydrate, Protein, and Lipid). The feeds and freeze-dried feces were crushed and measured for their carbohydrate, crude protein, and crude lipid.[16] The carbohydrate content was determined colorimetrically: To an aliquot of the feed (200 mg) or feces (200 mg) was added 10 mL of a 0.2 M acetate buffer (pH 4.8) and 5 mL of a 0.12% glucoamylase solution (Biochemical Co., Shanghai, China). After the addition of distilled water to give 50 mL of the solution, a few drops of toluene were added, and the mixture was incubated at 37 °C for 24 h. After hydrolysis, the mixture was filtered, and an aliquot of the solution was used for determining the reducing sugar according to the method of Somoyi-Nelson, 0.9 being adopted as the conversion factor to carbohydrate. The crude protein content was determined by titration: An aliquot of the feed (200 mg) or feces (200 mg) was weighed and degraded by H_2SO_4. The nitrogen content was determined using the Kjeldahl method with a Kjeltec TM 8400 instrument (Foss, Denmark), 6.25 being adopted as the conversion factor to protein. The crude lipid content was determined gravimetrically according to the Soxhlet method, using an aliquot of the feed (200 mg) or feces (200 mg). The apparent absorption of major nutrients (carbohydrate, protein, and lipid) was calculated by using the following equation:

$$\text{apparent nutrient absorption (\%)} = [(\text{intake} - \text{excretion})/\text{intake}] \times 100 \quad (1)$$

Measurement of Blood Serum Ingredients and Liver Lipid Contents. Total serum protein, albumin, albumin/globulin ratio, glucose, urea nitrogen, creatinine, triglyceride, total cholesterol, high-density lipoprotein (HDL)-cholesterol, low-density lipoprotein (LDL)-cholesterol, atherogenic index, glutamic oxalacetic transaminase activity (GOT), and glutamic pyruvic transaminase activity (GPT) were determined by using an Automatic Biochemical Analyzer (AU2700, Olympus, Hamburg, Germany). Freeze-dried livers were ground, and the lipids were extracted with chloroform/methanol (2:1, v/v).[17] The total lipid content was quantified gravimetrically, and the total cholesterol and triglycerides were determined by using the Automatic Biochemical Analyzer, whereas phospholipid contents were determined colorimetrically with a determiner assay kit (Jinghao Medix Co., Beijing, China).

Colon Content DNA Extraction and PCR Amplification. To describe bacterial diversity in the mouse colon tract, total DNA was isolated from colon content samples and used as a template for PCR amplification. Amplicons of the V3 regions of bacterial 16S rDNA were analyzed using the DGGE analysis method. Sample DNA extraction (200 mg of frozen colon content for every mouse) was performed by using a QIAamp DNA Stool Mini Kit (QIAGEN, Inc., Shanghai, China), according to the manufacturer's instruction. For DGGE analysis, PCR amplifications with V3 region primers against the 16S rDNA were performed in a 25 μL (total volume) mixture containing 1.2 μL of forward primer with a GC-clamp [primer F338-GC, sequence (5′−3′), CGCCCGCCGCGCGCGGCGGGCGGG-GCGGGGGCACGGGGGGACTCCTACGGGAGGCAGCAG] and 1.2 μL pf reverse primer [primer R518, sequence (5′−3′), ATTACC-GCGGCTGCTGG], 0.5μL of deoxynucleoside triphosphate at a concentration of 10 mM, 2.5 μL of PCR reaction buffer, 0.2 μL of DNA polymerase (5 U/μL), 1.0 μL of DMSO (4%, v/v), 1 μL of DNA template with an appropriate amount, and 17.4 μL of sterile water.[18] PCR amplification was performed with a Biosci PCR system as follows: an initial denaturation of 94 °C for 4 min, followed by 30 cycles of 94 °C for 0.5 min, 56 °C for 0.5 min, and 72 °C for 1 min, and a final elongation at 72 °C for 10 min. Aliquots of 5 μL were analyzed by electrophoresis on an agarose gel (1%) to check the size and amounts of the amplicons.

DGGE Profiling. DGGE was performed with the Bio-Rad DCodeTM system (Bio-Rad Ltd., Hercules, CA, USA). PCR products were loaded onto 1 mm thick 8% (w/v) polyacrylamide (acrylamide/bisacrylamide = 37.5:1) gels containing a 35−65% linear denaturing gradient. TAE buffer (1×, 40 mM Tris-acetate, 1 mM Na-EDTA, pH 8.0) was used as the electrophoresis buffer. The electrophoresis was

initiated by prerunning for 5 min at a voltage of 220 V and subsequently run at a fixed voltage of 85 V for 16 h at 60 °C. The gel was stained with $AgNO_3$ and developed after completion of electrophoresis. The obtained DGGE patterns were subsequently normalized and analyzed with Bio-Rad Quantity One 4.4.0 software. During the processing, the different lanes were defined, background was subtracted, differences in the intensity of the lanes were compensated during normalization, and the correlation matrix was calculated. Clustering was done with Pearson correlation and the unweighted pair group mean average (UPGMA) method.

Identification of DGGE DNA Bands. The bands of interest were excised from the gel using a sterile blade and incubated overnight at 4 °C in Tris−EDTA buffer (pH 8.0) for future sequencing. PCR amplifications of the DNA fragments from the excised gel were carried out according to the same protocols described above with the corresponding primers [forward primer F338, sequence (5′−3′), ACTCCTACGGGAGGCAGCAG; reverse primer R518, sequence (5−3′), ATTACCGCGGCTGCTGG] and 1 μL aliquot of the gel elution.[18] PCR products were excised from a 1.0% agarose gel and purified with a DNA Gel Extraction Kit (Tiangen, China). Isolation of DNA bands from the DGGE gel, cloning of excised bands, and sequence analysis were performed as described by Gong et al.[19] The sequences were submitted to GenBank and the RDP database to determine their most related bacterium. The DNA sequences are available in the GenBank database with accession numbers.

Statistical Analysis. All of the experiments were done in triplicate. Statistical analysis was carried out using SPSS (version 16.0, Chicago, IL, USA). The results were expressed as the mean ± standard deviation and compared using the Tukey test at a 5% confidence level. DGGE banding patterns in each group were digitalized by Quantity One software (Bio-Rad). The intensity and relative position of each DGGE band were determined manually with background subtraction. The intensity of each band was expressed as percentage of the integrated intensity of the entire lane. The matrix of intensity and relative position was analyzed by principal component analysis (PCA) using SPSS software.

RESULTS AND DISCUSSION

General Health Status of Mice. Throughout the experiment period, no noticeable behavioral or activity changes were observed in the mice, and no treatment-related illness or death occurred. The growth of mice appeared normal throughout the experiment period, and no mouse experienced diarrhea or constipation. There was no observable difference in the animals' body mass and hair luster between the polysaccharide-treated group and control group.

Effect of Polysaccharide on Absorption of Major Nutrient of Mice. The apparent absorption of major nutrients (carbohydrate, protein, and lipid) is summarized in Table 2. Although the values for nutrient absorption were all nearly quantitative, there was a significant difference ($p < 0.05$) between the control group (94.8 ± 0.2%) and polysaccharide group (87.4 ± 0.3%) for lipid apparent absorption. This observation suggested that the polysaccharide from *P. asiatica* L. may have had some influence on lowering the absorption of lipid, which was consistent with our previous finding that the polysaccharide from *P. asiatica* L. could inhibit some pancreatic lipase activity and reduce cholesterol available for absorption.[13] The polysaccharide from *P. asiatica* L., which was found to promote mouse defection in our previous study, might also have some effect on promoting cholesterol and lipid excretion.[11] In addition, the polysaccharide was found to increase the propionic acid production in mouse colon, which might influence the lipid metabolism.[12] Furthermore, the polysaccharide from *P. asiatica* L. was found to bind bile acid in vitro,[13] which may also affect the excretion and metabolism of cholesterol and lipid. Other studies showed that some other polysaccharides could enhance the excretion of lipids in feces,[20] which was similar to our results.

Table 2. Effect of Polysaccharide from *P. asiatica* L. on Apparent Absorption of Carbohydrate, Protein, and Lipid in Mice[a]

	apparent absorption (%)	
	control group	polysaccharide group
carbohydrate	99.9 ± 0.0 a	99.6 ± 0.3 a
lipid	94.8 ± 0.2 a	87.4 ± 0.3 b
protein	99.9 ± 0.1 a	99.9 ± 0.1 a

[a]Each value is the mean ± standard deviation ($n = 12$); means in the same row not sharing a common letter are significantly different ($p < 0.05$).

Effect of Polysaccharide on the Characteristics of Blood Serum and Liver Lipid Levels. The characteristics of the blood serum and the liver lipid levels in mice of the polysaccharide group or control group are given in Tables 3 and 4, respectively. There was in general no marked difference in serum chemistry, apart from total triglyceride, total cholesterol, and atherogenic index (Table 3). Total triglyceride, total cholesterol, and atherogenic index in blood serum tended to be lower in the group of mice given oral administration of polysaccharide, with the difference between the control group

Table 3. Effect of Polysaccharide from *P. asiatica* L. on Characteristic Blood Serum Chemistry of Mice[a]

	control group	polysaccharide group
glucose (mmol/L)	6.72 ± 0.51 a	6.56 ± 0.39 a

and the polysaccharide group being significant ($p < 0.05$). Studies have shown that an elevation of serum lipids, especially cholesterol, is one of the most important risk factors leading to coronary heart disease.[21] Thus, the cholesterol-lowering effect of the polysaccharide from *P. asiatica* L. was beneficial for health.

A difference in liver lipid levels was apparent for cholesterol and total lipid (Table 4). The liver cholesterol and total lipid level in mice given oral administration of polysaccharide were both significantly lower ($p < 0.05$) than that of the control group. Thus, the polysaccharide from *P. asiatica* L. appears to play a role in lowering the liver cholesterol level. Some other studies also indicated that polysaccharides present in some food materials could reduce the cholesterol in serum and lipid in liver,[22] which was similar to our results.

In contrast to liver cholesterol level, the liver triglyceride level in mice was not significantly decreased after polysaccharide administration for 30 days (Table 4, $p > 0.05$). We have observed that the polysaccharide intake could significantly lower the serum triglyceride level of mice (Table 3, $p < 0.05$). The influence of the polysaccharide on serum triglyceride level may be faster than its effect on liver triglyceride level because the triglyceride was accumulated in liver and the reducing effect by polysaccharide intake may need more time. However, for cholesterol, the polysaccharide could significantly reduce both the serum and liver cholesterol levels (Tables 3 and 4, $p < 0.05$). Although cholesterol was also accumulated in the liver, the liver cholesterol level was significantly reduced by the polysaccharide intake. This may be because except for the polysaccharide itself, the organic acids, particularly propionate, that are produced by colonic fermentation could also influence the liver cholesterol metabolism.[23] The polysaccharide from *P. asiatica* L. was found to increase the propionic acid production of mouse colon in our previous study.[12] Thus, the effect of the polysaccharide on lowering the liver cholesterol level may be stronger than its effect on lowering the liver triglyceride level.

Effect of Polysaccharide on Mice Colon Microbiota. Diversity indices for the DGGE bacterial profiles (Figure 1A) generated from the 16S rDNA V3 region are shown in Table 5. The richness of the DGGE banding profiles for the polysaccharide group (30.80 ± 3.96) was significantly higher than for the control group (24.60 ± 3.05, $p < 0.05$) after 30 days of administration. In addition, a significant increase was also observed in the Shannon−Wiener index and maximum Shannon−Wiener index for the polysaccharide group relative to the control group ($p < 0.05$). There was no significant difference for the evenness between the polysaccharide group and control group ($p > 0.05$).

The effect of polysaccharide on the bacterial communities after 30 days of oral administration was investigated by PCR-

dx.doi.org/10.1021/jf4040942 | J. Agric. Food Chem. 2014, 62, 229−234

DGGE bacterial profiling and identification of putative bacterial species through sequence analysis of recovered DGGE DNA bands. To compare the predominant bacterial communities between different treatments, PCR amplification of the V3 region of the 16S rRNA gene was carried out with corresponding primers. DGGE banding patterns of the V3 region of colon content of each group are shown in Figure 1A. The influence of polysaccharide intake on bacterial community structure was investigated. DGGE image analysis showed that the bacterial community structure from the colon content samples of the polysaccharide group was similar (Figure 1A) and also grouped together in the UPGMA cluster analysis (Figure 1B). In addition, it could also be seen that the bacterial community structure of colon content from polysaccharide group mice was low in similarity with the control group, which means the influence of polysaccharide intake appeared to be a major factor affecting the community. Furthermore, the PCA scores plot (Figure 1C) was also used to compare the differences between banding patterns of different treatments. In the PCA scores plot, "sit together" demonstrates similarity between samples. As shown in Figure 1C, the banding pattern of the control group was different from that of the polysaccharide group. Because banding patterns were related to the bacterial communities, the above results suggest that the predominant bacterial communities in the colon content of polysaccharide group mice were different from those of the control group mice.

Several numerically dominant bacterial species in the colon content for the polysaccharide group corresponding to the presence of some intense DGGE DNA bands, which were different from the control group, were observed (Figure 1A). To further clarify the differences, bands that showed different percentages of density among groups were sequenced for determining their putative identity of bacteria. The putative identity of bacteria is presented in Table 6, which may suggest their possible role in the utilization of the polysaccharide. As shown in Figure 1A and Table 6, 14 interesting excised bands were identified.

Although bands 1, 3−6, and 8−12 have the same migration in different lanes, higher peak density of bands can be observed in the polysaccharide-treated group than in the control group (Figure 1A). Sequencing results showed that their most related bacteria (bands 9−12) were *Bacteroides* sp. *Bacteroidetes* can degrade polysaccharides and metabolic intermediates. They were also able to produce SCFAs such as acetate, lactate, propionate, and others.[24] Band 1 was closest to butyrate-producing bacteria and affiliated with the family of *Butyrivibrio*. A few species-related bands, 5, 6, and 8, had a closer relationship with probiotics *Bifidobacterium bifidum*, *Lactobacillus fermentum*, and *Lactobacillus reuteri*, respectively. These putative butyrate-producing bacteria or probiotics were observed to increase after polysaccharide intake in this study, similar to these bacteria reported to utilize fibers previously.[25] Bands 3 and 4 were sequenced and identified as belonging to *Eubacterium* sp., which were reported to be very active fermentation bacteria for fiber.[26]

Bands 2, 7, 13, and 14 were sequenced as well (Figure 1A), which had higher peak density in the control group than in the polysaccharide-treated groups. The sequencing results showed that their most related bacteria were *Clostridiales* sp. and *Helicobacter* sp., which are the common commensal bacteria in the colon and not good for health in a large amount.[18] These sequencing results indicated that polysaccharide treatment could decrease *Clostridiales* sp. and *Helicobacter* sp. in the mouse colon microbiota.

On the basis of the banding patterns (Figure 1A) and sequencing results (Table 6), it can be inferred that orally administered polysaccharide could substantially affect the mouse colon microbiota. In addition, some other papers have indicated that the predominant increased species in colon microbiota belong to the genera *Bacteroides*, *Eubacterium*, and *Bifidobacterium* after the supply of fermentable carbohydrates. Many other bacteria also occur in high numbers, including *Lactobacilli* and various anaerobic Gram-positive cocci.[27] Their results were similar to ours.

It was reported that there were some relationships between lipid metabolism difference and bacterial community change. The intestinal microbiota develops an important biochemical activity within the host body by providing additional metabolic functions. Specific components of the commensal microbiota also regulate serum lipids and cholesterol by taking part in metabolism.[28] Some intestinal bacteria could influence lipid metabolism. *Butyrivibrio proteoclasticus*, a butyrate-producing ruminal bacterium, could have some effects on cholesterol and lipid utilization.[29] Lactic acid bacteria and *Bifidobacteria* could remove cholesterol or carry out cholesterol assimilation. For example, *Lactobacillus fermentum* was reported to reduce serum lipids and cholesterol in subjects.[30] Low lipid level was associated with higher *Bifidobacterium* numbers in cecal content in mice.[31] Furthermore, *Eubacterium rectale*, *Bacteroides thetaiotaomicrometer*, and *Bacteroides vulgatus* were also found to be cholesterol-reducing bacteria.[32] Thus, the *Bacteroides* sp., *Eubacterium* sp., *Butyrivibrio proteoclasticus*, *Bifidobacterium bifidum*, *Lactobacillus fermentum*, and *Lactobacillus reuteri*, which were found increased in mouse colon after the intake of polysaccharide *P. asiatica* L., may have some effect on the mouse lipid metabolism in this study.

In addition, some probiotics-related metabolites might also exert beneficial effects on cholesterol and lipid metabolism. Propionic acid was reported to affect the liver cholesterol metabolism.[23] The polysaccharide from *P. asiatica* L. was found to increase the propionic acid production in mice colon in a previous study,[12] which might influence the lipid metabolism. Bile acid was found to be closely related to cholesterol and lipid metabolism; thus, the polysaccharide from *P. asiatica* L., which

was found to bind bile acid in vitro,[13] might also affect cholesterol and lipid metabolism.

Our results showed the effect of polysaccharide from *P. asiatica* L. on mouse lipid metabolism and colon microbiota for the first time. The intake of polysaccharide from *P. asiatica* L. could lower the apparent absorption of lipid and decrease the serum and liver lipid level in mice. Mice from the polysaccharide group showed a higher colon bacterial diversity than the control group. *Bacteroides* sp., *Eubacterium* sp., butyrate-producing bacteria *Butyrivibrio* sp., and probiotics *Bifidobacterium bifidum*, *Lactobacillus fermentum*, and *Lactobacillus reuteri* in mouse colon were all increased after mice were given oral administration of the polysaccharide. These suggested that the intake of polysaccharide from *P. asiatica* L. may be beneficial for lipid metabolism and colon microbiota. The changed colon bacteria may play a role in utilization of the polysaccharide and mouse lipid metabolism, which was also affected by polysaccharide intake.

Identification and Characterization of Dimeric Oxidation Products of *p*-Cymene-2,3-diol Isolated from *Thymus vulgaris* L.

Guido Rainis and Waldemar Ternes*

Department of Analytical Chemistry, Institute of Food Toxicology and Analytical Chemistry, University of Veterinary Medicine Hannover, Foundation, Bischofsholer Damm 15, D-30173 Hannover, Germany

ABSTRACT: The aim of this study was to investigate the oxidation products of *p*-cymene-2,3-diol, a major antioxidative constituent of thyme (*Thymus vulgaris* L.). Although a dimeric form of *p*-cymene-2,3-diol and some derivative substances exhibiting valuable food technological and health-promoting properties have been reported in earlier publications, no obvious correlation has been shown between these substances. A modified HPLC-ESI-MS method made it possible to prove that two dimers, 3,4,3′,4′-tetrahydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl (**1**) and the newly identified 3′,4′-dihydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,4-dione (**2**), are oxidation products of *p*-cymene-2,3-diol. **2** was characterized by the fragmentation pattern determined by multiple mass spectrometry, ^{1}H NMR, ^{13}C NMR, H−H COSY, HSQC, and HMBC. Both biphenyls were also quantitated in freeze-dried thyme as well as in a food matrix spiked with thyme extract. Model experiments using raw and cooked minced pork meat as matrix and sodium nitrite as oxidizing and reduction agent with and without ascorbic acid as protective reagent showed the correlation between food processing and dimer generation.

KEYWORDS: *p-cymene-2,3-diol, Thymus vulgaris L., oxidation products, HPLC, LC-ESI-MS, hydrodistillation*

INTRODUCTION

Members of the botanical family of Lamiaceae (or Labiateae) have been intensively investigated as well-known sources of antioxidant and antimicrobial components, and the best-studied[1−6] genera include *Origanum*, *Rosmarinus*, *Salvia*, and *Thymus*. The most often cultivated and commercially most widespread species of that genus is *Thymus vulgaris* L. (garden or common thyme).[7] Native to the Iberian peninsula, it is traditionally used as a flavoring herb for many dishes in Mediterranean cuisine as well as for medicinal purposes.[7] The main functional constituents of *T. vulgaris* L. are the odorous monoterpene phenols thymol and carvacrol, which have been widely discussed in the literature in regard to their antioxidant,[1,8−11] antimicrobial,[2,10] and anti-inflammatory[10] effects. However, *Thymus citriodorus* L. (lemon thyme), another commonly available species, is reported to contain no carvacrol[12,13] and only small amounts of thymol.[13] Despite the beneficial health effects of thymol and carvacrol, their use as ingredients in food is limited by their strong odorous activity. Whereas thymol and carvacrol have been known for more than 100 years, another important component, *p*-cymene-2,3-diol, was not detected until much later,[14] probably due to the fact that thyme (*T. vulgaris* L.) has mainly been analyzed by means of gas chromatography, as the putative substances of interest, that is, thymol and carvacrol (and, e.g., compounds of essential oils), are volatile. In contrast, the semivolatile *p*-cymene-2,3-diol is hard to determine by gas chromatography; it is much easier to detect with liquid chromatographic methods such as HPLC-DAD.[14,15] *p*-Cymene-2,3-diol is sometimes included[16,17] and sometimes not[18,19] in the literature on the nonvolatile substances of *T. vulgaris* L. Furthermore, only marginal information is available about the formation, chemical behavior due to food processing, and possible oxidation products of *p*-cymene-2,3-diol. In comparison with thymol and carvacrol, *p*-cymene-2,3-diol possesses one additional hydroxyl group on the aromatic ring system and exhibits similar functional properties.[14,15] Thymoquinone has been suggested as a possible oxidation product of thymol and carvacrol.[16,20,21] Furthermore, Nakatani and Miura isolated from the leaves of thyme five biphenyl compounds[22,23] proven to have deodorizing,[22−24] antioxidative,[5,17,24,25] and human platelet aggregation-inhibiting activities.[26] The biphenyls occur in the same fraction as flavonoids and other nonvolatile natural compounds described and analyzed in several newer publications,[16,17,19,27−31] but only two of these[16,17] mention at least one of the biphenyls mentioned above, 3,4,3′,4′-tetrahydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl (**1**),[22] along with other nonvolatile compounds. One further biphenyl described by Nakatani and Miura is assumed to be a dimer of thymoquinone, that is, the quinoid form of **1**, 3,3′-diisopropyl-6,6′-dimethylbiphenyl-1,2,1′,2′-tetraone (**3**).[23] Each of the other three postulated compounds contains one thymol molecule dimerized with one of the following substances: *p*-cymene-2,3-diol (named 3,4,4′-trihydroxy-5,5′-diisopropyl-2,3-dimethylbiphenyl),[22] hydroxy thymoquinone (named 4,4′-dihydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,6-dione),[23] or thymoquinone (named 4′-hydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,4-dione).[23] For better comparability, we have maintained the nomenclature of these substances, which was established by Nakatani and Miura.[22] To date, nothing is known about the formation and content of the biphenyls in commercial thyme in consideration of the fact that it exhibits the various exploitable characteristics mentioned above. There is no clear and coherent information

about the correlation of monomeric and dimeric substances or their formation pathway under experimental or even native conditions. **1** has recently been described as a major antioxidative component of a supercritical CO_2 extract of *T. vulgaris* L. and as a dimer of *p*-cymene-2,3-diol.[16,17] To investigate the potential chemical pathway between *p*-cymene-2,3-diol and its postulated dimeric oxidation products in the nonvolatile part of *T. vulgaris* L., we planned to add supercritical CO_2 extracts of thyme to a minced pork meat matrix to determine the oxidation stability of *p*-cymene-2,3-diol and its dimeric oxidation products. Considering previous results,[16,17] we intended to develop an HPLC-ESI-MS method for chromatographic analysis of *p*-cymene-2,3-diol along with the biphenyls that should also be applicable to minced meat and other food matrices. In consideration of the potentially high amounts of *p*-cymene-2,3-diol and dimeric substances in freeze-dried thyme (and thyme byproducts), the intended results of the present study should facilitate the industrial exploitation of the functional substances of thyme and make it possible to utilize their advantageous properties in specific applications in the future.

MATERIALS AND METHODS

Sample Material. Seedlings of known varieties of common and lemon thyme, *T. vulgaris* L. (variety 'Faustini') and *T. citriodorus* L. (variety 'Silver Queen') were obtained from a local market and grown in a kitchen garden for 3 months in 2012. The leaves were harvested and freeze-dried in June. The *T. vulgaris* L. and *T. citriodorus* L. leaves contained 26.7 and 23.8% dry matter, respectively. Minced, conventionally packaged pork meat was obtained from a local market. A commercial supercritical CO_2 extract of nonspecified *T. vulgaris* L. varieties was obtained from Raps (Kulmbach, Germany).

Chemicals. Water (18 MΩ × cm) was obtained from a water purification system (Millipore, San Jose, CA, USA). Silica gel was obtained from Riedel-de-Haën (Seelze, Germany). The reference standard of *p*-cymene-2,3-diol and diethyl ether were obtained from Sigma-Aldrich (Steinheim, Germany). *p*-Coumaric acid, ascorbic acid, hydrogen peroxide (30%), sodium chloride, and sodium nitrite were obtained from Carl Roth (Karlsruhe, Germany). Three nitrite curing salt formulations were prepared by mixing sodium chloride with 1.0, 3.0, and 6.0% (w/w) sodium nitrite. **1** and **2** (3′,4′-dihydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,4-dione) were isolated from a supercritical CO_2 extract of thyme by means of preparative HPLC as described below. Samples and standards were diluted in methanol (LC-MS grade, Sigma-Aldrich); the ascorbic acid and nitrite curing salt were dissolved in purified water. Acetonitrile (LC-MS grade, Sigma-Aldrich) and purified water (Millipore) were used for chromatographic purposes.

Steam Distillation. Freeze-dried leaves of thyme were ground to a fine powder in an A 11 basic analytical mill (IKA, Staufen, Germany). To remove the volatile substances, approximately 1 g of the powder was steam-treated in a laboratory glass apparatus according to the method of Antonacopoulos[32] until approximately 100 mL of aqueous distillate had been collected. The aqueous distillate containing the volatile substances was discarded. The steam distillation residue was dried at room temperature.

Extraction and Purification. Freeze-dried thyme and the residue from steam distillation were extracted three times with methanol/water (70:30, v/v) for 30 min at room temperature on a magnetic stirrer. The extracts were transferred through a folded filter into a round-bottom flask; the combined extracts concentrated using a rotary evaporator at 50 °C under vacuum and then collected with methanol. The extract was further purified by solid-phase extraction (SPE) applying Chromabond C-18 "Hydra" cartridges (500 mg, Macheray-Nagel, Düren, Germany) conditioned with water. The extract was mixed with water before loading into the cartridge, which had been rinsed with water. The substances were eluted with 5 mL of methanol into a 5 mL volumetric flask, and the flask was filled to volume with methanol. To compare experimental conditions with previously published preparation methods,[22,23] purification by silica gel chromatography was conducted using a glass column half-filled with silica gel and diethyl ether as eluent. Eluted solutions were evaporated to dryness on a rotary evaporator and collected with methanol. All solutions obtained were diluted with methanol for analytical use.

Oxidation Assays. A storage assay was performed on six 1000 mg/L preparations of *p*-cymene-2,3-diol solutions, which were stored at room temperature and constantly stirred in a sealed round-bottom glass flask. Samples were obtained from each assay immediately and after 1, 2, and 6 days of storage. All solutions were purified with Chromabond C-18 Hydra cartridges (500 mg, Macheray-Nagel) as described above and analyzed by HPLC-MS as described below.

Experiments under food-relevant conditions were carried out on a mixture of minced pork meat with a 1.0% (w/w) supercritical CO_2 extract of thyme (containing *p*-cymene-2,3-diol, **1**, and **2**) and 1.0% (w/w) nitrite curing salt mixtures containing either 1.0, 3.0, or 6.0% sodium nitrite (all percentages w/w: 100, 300, and 600 mg/kg of the entire matrix) and with or without 1.0% (w/w) ascorbic acid in a conventional mixer. The mixtures were heated in a closed plastic vessel at 80 °C in a water bath for 30 min. The cooked minced meat was homogenized again, extracted three times with methanol/water (70:30, v/v) with an Ultra-Turrax (IKA, Staufen, Germany), filtered through a folded filter, purified by means of SPE as described above, and analyzed by HPLC-MS as described below.

3 as reference substance was produced by spiking 1 part hydrogen peroxide (30% solution in water) to 9 parts of a highly concentrated standard solution of *p*-cymene-2,3-diol (5000 mg/L), stirring in a clear round-bottom flask for several days at room temperature (no direct sunlight), and subsequent isolation of the resulting **3** by preparative HPLC (as described below).

Preparative HPLC-UV. Preparative chromatography was carried out on a Knauer Smartline 1000 pump connected to a Smartline Manager 5000 and a Knauer 8700 variable-wavelength detector, controlled by EuroChrom 3.05 software (Knauer, Berlin, Germany) on a Knauer IF 2 interface box. A 250 mm Nucleodur C 18 Isis column with an inner diameter (i.d.) of 4.8 mm and a particle size of 5 μm (Macheray Nagel) was used for chromatographic separation. Solvent A was purified water with 0.1% (v/v) acetic acid; solvent B was acetonitrile mixed with 0.1% (v/v) acetic acid. Isocratic separation was achieved with 50% A and 50% B with a flow rate of 1.0 mL/min for 15 min, followed by a washing step with 95% B for 5 min and recalibration to starting conditions for 5 min. Detection was carried out by the Knauer 8700 variable-wavelength detector at 273 nm. The injection volume for the preparative separation of **1**, **2** (both from methanol solution of supercritical CO_2 thyme extract), and the produced **3** (as described above) was 200 μL. Substances were repeatedly collected, purified by means of SPE, and, after removal of the eluent under vacuum, the greasy, dark brown residue (95% purity, estimated by means of NMR and MS data) was weighed out and determined by HPLC-MS.

Analytical HPLC-UV. HPLC-UV was carried out at 273 nm on the same HPLC system as described above. Water with 0.1% acetic acid (solvent A) and acetonitrile mixed with 0.1% acetic acid (solvent B) were used at a flow rate of 1.0 mL/min. The gradient started with 70% A for 2 min, followed by a linear decrease to 50% A within 10 min, then to 10% A within 3 min, back to 70% within 5 min, and then recalibration to starting conditions for 10 min. The injection volume of each sample was 20 μL.

Analytical HPLC-MS. Chromatographic separation was carried out on a Waters 616 gradient pump and a Waters 171 plus autosampler (Waters, Eschborn, Germany) controlled by a Waters 600 controller unit. The interior temperature of the autosampler was set to 10 °C. A Nucleodur C 18 Isis column (150 mm × 2.1 mm i.d.) with a particle size of 5 μm (Macheray-Nagel) was used for chromatographic separation at 20 °C. The temperature was kept stable by means of a column oven (LabSource, Manchester, UK). Water with 0.1% (v/v) acetic acid (solvent A) and acetonitrile with 0.1% (v/v) (solvent B) were used at a flow rate of 0.2 mL/min. The gradient started with 80%

[a]Calibration data confirmed with XCalibur 1.3 software in the range of 0.5−50 mg/L, calculated from quadratic polynomial regression as calibration function of the second degree. [b]Calculated by means of calibration data and Valoo 2.5 software.[32] [c]DIN 32645:2008-11.[31]

A for 10 min, followed by a linear decrease to 70% A within 5 min, then to 50% A in 5 min, which was held for 10 min, followed by an increase to 90% B within 5 min, and held for 5 min (washing step); recalibration to starting conditions was then allowed for 15 min. The injection volume of each sample was 5.0 μL.

The HPLC system was connected with a Finnigan LCQ Classic mass spectrometer (Thermo Scientific, Bonn, Germany) with an electrospray ionization (ESI) source operating in negative ion mode. Mass spectra were recorded in total ion chromatogram (TIC, *m/z* 150−1000) mode during the chromatographic separation and in selected ion monitoring (SIM) mode for quantitation purposes. The instrument was tuned by optimization of *m/z* 327 while a standard solution of 1.0 mg/L **2** was infused directly into the ESI source by a syringe pump with a flow rate of 3.0 μL/min. Tuning parameters were as follows: capillary temperature, 250 °C; sheath gas flow, 60 arbitrary units; and auxiliary gas flow 10, arbitrary units. Automatically set parameters after tuning were as follows: source voltage, 4.5 kV; capillary voltage, 32 V; tube lens offset, 55 V; multipole 1 offset, −3.0 V; multipole 2 offset, −4.5 V; interpole lens voltage, −24 V; trap DC offset voltage, 10 V. Chromatographic and mass spectrometric data were acquired with XCalibur 1.3 software (Thermo Scientific). To obtain structural information, collision-induced fragmentation spectra were recorded using TunePlus 1.3 (Thermo Scientific) software. Preparatively isolated substances were infused by a syringe pump with a flow rate of 3.0 μL/min. Collision energy values were adjusted to between 35 and 41 arbitrary units.

HPLC-ESI-MS Calibration, Method Validation, and Statistical Analysis. Stock solutions of 1000 mg/L were prepared on the basis of the commercially available standard of *p*-cymene-2,3-diol and isolated **2**. The internal standard was *p*-coumaric acid. The concentration of the internal standard in each calibration standard and sample was 5.0 mg/L. Calibration was conducted using XCalibur 1.3 software. The analytical parameters as configured in the software were as follows: Genesis peak detection algorithm with minimum peak height of 3.0 arbitrary units, 5-point-smooth, minimum signal-to-noise ratio (S/N ratio) of 0.5 arbitrary unit, and valley detection with a 20 s expected width. The calibration curve was created with standard amounts of 0.5, 1.0, 2.5, 5.0, 10, 25, and 50 mg/L *p*-cymene-2,3-diol and **2**. To cover a wide range of concentration, quadratic (polynomial) regression and a calibration function of the second order were applied. **1** was quantitated as **2** equivalents (using the calibration standards of **2**). Statistical differences were determined by a paired (two-tailed) Student's *t* test. All statistical tests were conducted at a significance level of $\alpha = 0.05$ ($p < 0.05$). The sensitivity of the HPLC-ESI-MS instrument was evaluated by determining the limits of detection (LOD), quantitation (LOQ), and capability (LOC) by means of the calibration function method according to DIN 32645:2008-11[33] (Table 1). The calibration curves were tested for outliers (Grubbs test). All statistical parameters were calculated using Valoo 2.5 software.[34] Formation/decomposition rates (FDRs) in the matrices were determined by spiking freeze-dried thyme and minced pork meat (raw and cooked) with a *p*-cymene-2,3-diol standard solution containing *p*-cymene-2,3-diol, **1**, and **2**. No interferences were detected due to unwanted coelutions. FDRs were expressed in percentage of untreated standard contents (minus analyte amounts in plain matrix) and of contents after extraction to determine content changes during extraction and processing.

Nuclear Magnetic Resonance Spectroscopy (NMR). ^{1}H NMR (400 MHz), ^{13}C NMR (100 MHz), correlation spectroscopy (H−H COSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) spectra were obtained in deuterated chloroform (**1**, **2**) or deuterated methanol (**3**) with a Bruker DPX 400 MHz NMR spectrometer. The chemical shift of protons and carbons is expressed here as δ values with tetramethylsilane (TMS; δ = 0) as the internal standard.

RESULTS AND DISCUSSION

Identification of 1 and 2 by Means of HPLC-MS and NMR Spectroscopy. As depicted in Figure 1A,B, chromatographic analysis of *p*-cymene-2,3-diol (MW = 166 g/mol, no. II) standard in methanolic solutions by HPLC-ESI-MS in negative ion mode and in TIC mode revealed two additional distinct peaks after storage. These peaks potentially represent the *p*-cymene-2,3-diol oxidation products **1** and **2**, as peaks III and IV have molecular weights consistent with those calculated for **1** (330 g/mol) and **2** (328 g/mol). Considering that *p*-cymene-2,3-diol is very sensitive to oxidation in air, oxidation of *p*-cymene-2,3-diol may already take place in the unharvested

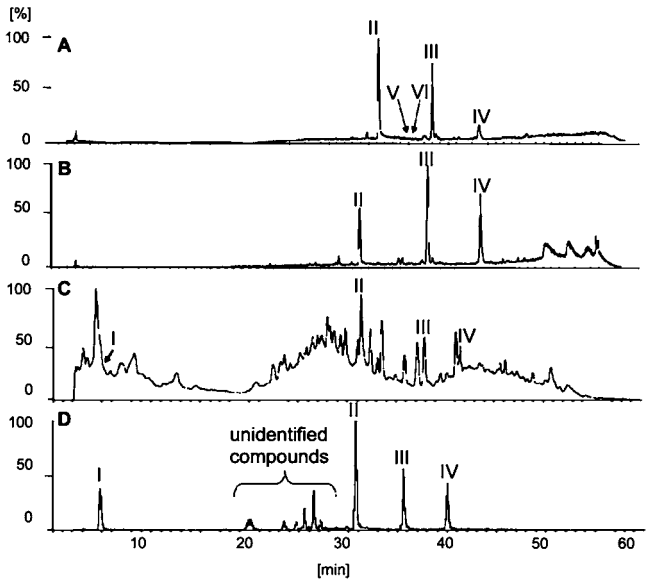

Figure 1. Chromatographic separations in negative ion mode of *p*-coumaric acid (*m/z* 163) (I), *p*-cymene-2,3-diol (*m/z* 165) (II), 3,4,3′,4′-tetrahydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl (**1**, *m/z* 329) (III), and 3′,4′-dihydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,4-dione (**2**, *m/z* 327) (IV). V and VI are approximate retention times for carvacrol (V) and thymol (VI) (neither detectable by means of ESI-MS). (A) Freshly prepared solution of *p*-cymene-2,3-diol commercially available standard (100 mg/L in methanol) in total ion chromatogram (TIC) mode (*m/z* 150−1000); (B) standard solution after 4 days of storage in a glass envelope at room temperature in TIC mode (*m/z* 150−1000); (C) extraction solution of freshly harvested freeze-dried *Thymus vulgaris* L. in TIC mode (*m/z* 150−1000); (D) extraction solution of freshly harvested freeze-dried *T. vulgaris* L. in selected ion monitoring (SIM) mode (*m/z* 163, 165, 327, 329).

thyme plant. The two potential dimeric oxidation products of *p*-cymene-2,3-diol were already present in the freshly prepared *p*-cymene-2,3-diol solution (Figure 1A), but after storage, the signal intensities of those increased, whereas that of *p*-cymene-2,3-diol decreased (Figure 1B). As the dimers have nonvolatile characteristics, they are suitable for examination by HPLC-ESI-MS detection, a technique that is mainly applied for analysis of nonvolatile secondary plant material such as flavonoids and phenolic acids. Because thymol and carvacrol, the major constituents of thyme, are volatile, they cannot be detected by that method and have to be analyzed by means of other detection techniques such as UV−vis or gas chromatography. The expected retention times of thymol and carvacrol as determined by analytical HPLC-UV are shown in Figure 1A (arrows V and VI).

The preparatively isolated substances with m/z 329 ($[M - H^-]$) **1** and m/z 327 ($[M - H^-]$) **2** were identified by means of ESI-MS detection by the characteristic fragmentation pattern (Figures 2 and 3). Due to the negative ion mode setting, the

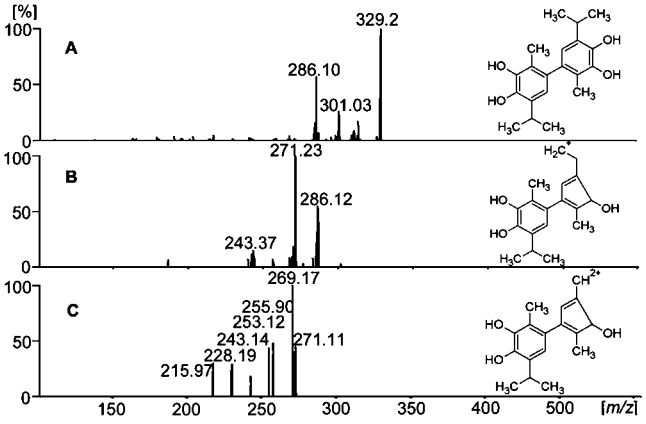

Figure 2. ESI product ion spectrum in negative ion mode ($[M - H]^-$) of **1** m/z 329 (A) and selected daughter ions m/z 286 (B) and m/z 271 (C).

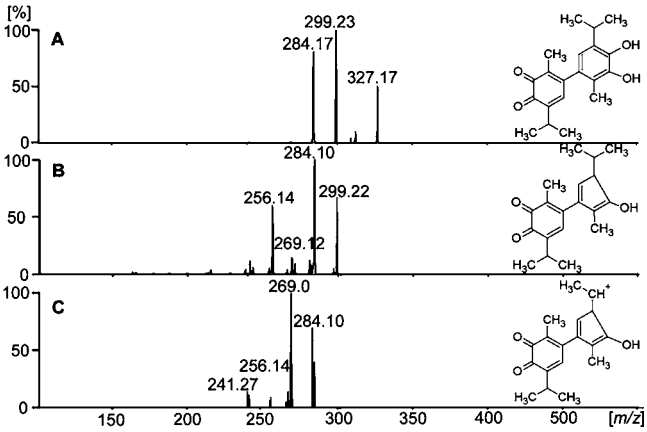

Figure 3. ESI product ion spectrum in negative ion mode ($[M - H]^-$) of m/z 327 (**2**) (A) and selected daughter ions m/z 299 (B) and m/z 284 (C).

base peaks are displayed as $[M - H]^-$. Therefore, the correct molecular weights of the substances are 330 g/mol, which is consistent with the molecular formula of **1**, and 328 g/mol, consistent with that of **2**. Figure 2 shows the fragmentation pattern of **1**: The first fragmentation step resulted in m/z 301 by phenol-characteristic loss of [CO] as reported in the literature on general mass spectrometry,[35] followed by splitting off [CH_3], on the one hand, and loss of [CO], on the other, so that m/z 286 is formed. The ion with m/z 286 can be observed even at the first fragmentation step (Figure 2B), as m/z 301 is very unstable and fragments immediately to m/z 286. In the further fragmentation step (Figure 2B), m/z 286 lost one [CH_3], so that m/z 271 was formed, followed by m/z 256 due to the loss of [CH_3] and by m/z 228 and further loss of [CO] (Figure 2C).

Table 2 shows ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) data as well as results from HMBC of **2** (MW = 328 g/mol), which have not yet been reported in the literature. The ^{1}H NMR spectrum showed the presence of two aromatic protons (singlets at 6.62 and 6.57 ppm), two hydroxyl groups (broad singlets at 5.34 and 5.43 ppm), two isopropyl groups (septets at 3.00 and 3.20 ppm and doublets at 1.13 and 1.29 ppm), and two methyl groups (singlets at 1.78 and 2.15 ppm). Assignment of directly coupling protons was confirmed by H−H COSY. The ^{13}C NMR spectrum exhibited 20 signals, and allocations were confirmed by means of HSQC and HMBC experiments. The HSQC experiment indicated that the ^{13}C NMR signal at 116.63 ppm correlates with the ^{1}H NMR signal at 6.57 ppm and the ^{13}C NMR signal at 138.39 ppm with the ^{1}H NMR signal 6.62 ppm. By means of the HMBC experiment, which shows C−H correlations over multiple bondings, it could also be shown that the ^{1}H NMR signal at 6.62 ppm correlates with the ^{13}C NMR signal at 180.23 ppm assigned to be one of the carbonyl carbons (position 3 or 4). This fact confirms that the ^{1}H NMR signal at 6.62 ppm and the ^{13}C NMR signal at 138.06 ppm correspond to position 6, just as the ^{13}C NMR

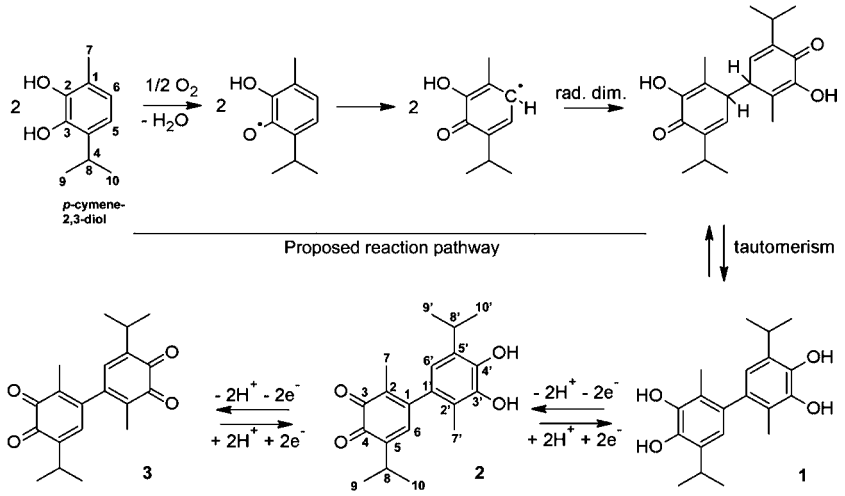

Figure 4. Proposed reaction pathway (upper part) leading to the formation of *p*-cymene-2,3-diol dimeric oxidation products **1**, **2**, and **3** identified by comparing retention times, MS, ^{1}H NMR, and ^{13}C NMR spectra. rad. dim. = radical dimerization.

signal at 180.23 ppm refers to position 4. On the other hand, the ^{1}H NMR signals at 3.20 ppm (isopropyl CH) and 6.57 ppm (aromatic CH) correspond to the ^{13}C NMR signal at 141.22 ppm, which in turn must suggest that this signal refers to position 4′. Thus, all ^{13}C NMR signals could be allocated distinctively. These data therefore prove that the isolated compound with the molecular mass of 328 g/mol has to be 1′,2′-dihydroxy-3,3′-disopropyl-6,6′-dimethylbiphenyl-1,2-dione **2** as depicted in Figures 3 and 4. Although Nakatani and Miura isolated and characterized a dimer with the same molecular weight (328 g/mol), they determined a different structure by NMR experiments,[23] but this was not confirmed in our studies. We were able to identify naturally occurring substances such as flavonoids and phenolic acids, but found no dimeric oxidation products other than **1** and **2**, in methanolic extracts either from steam-treated thyme (Figure 1D) or from the eluent of silica gel chromatography (data not shown). The ^{1}H NMR and ^{13}C NMR data for **1** and **3** correspond with those reported earlier.[22,23] We isolated **1** and **2** from thyme extract by extraction techniques and preparative HPLC as described above. Here, **2** was characterized for the first time as a further oxidation product. On the other hand, we found only traces of **3** in thyme extract (retention time of approximately 50 min), so we isolated it from a standard solution of *p*-cymene-2,3-diol, where it occurred as an oxidation product. **3** was obtained through oxidation of *p*-cymene-2,3-diol and subsequent preparative HPLC. The results are listed below.

*3,4,3′,4′-Tetrahydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl (**1**):* ^{1}H NMR (400 MHz, chloroform-*d*) δ 1.27 (d, 12, J = 7 Hz, CH$\underline{CH_3}$), 1.96 (s, 4 H), 3.15−3.26 (sept, 2, J = 7 Hz, $\underline{CH}CH_3$), 5.39 (bs, 4, OH), 6.59 (s, 2, CH); ^{13}C NMR (100 MHz, chloroform-*d*) δ 12.70 (C-7, C-7′), 22.66 (C-9, C-9′), 22.77 (C-10, C-10′), 27.19 (C-8, C-8′), 119.30 (C-6, C-6′), 119.98 (C-2, C-2′), 131.52 (C-5, C-5′), 134.08 (C-1, C-1′), 139.85 (C-3, C-3′), 141.38 (C-4, C-4′).

*3,3′-Diisopropyl-6,6′-dimethylbiphenyl-1,2,1′,2′-tetraone (**3**):* ^{1}H NMR (400 MHz, methanol-d_4) δ 1.17 (d, 12, J = 7 Hz, CH$\underline{CH_3}$), 1.89 (s, 10, CH_3), 2.91−3.02 (sept, 2, J = 7 Hz, $\underline{CH}CH_3$), 6.69 (s, 2, CH); ^{13}C NMR (100 MHz, methanol-d_4) δ 11.53 (C-7, C-7′), 20.35 (C-9, C-9′, C-10, C-10′), 27.44 (C-8, C-8′), 133.49 (C-1, C-1′) 134.04 (C-6, C-6′) 144.41 (C-2, C-2′), 147.63 (C-5, C-5′), 179.20 (C-4, C-4′), 180.09 (C-3, C-3′).

Assumed Reaction Pathway of *p*-Cymene-2,3-diol, 1, 2, and 3 under Oxidative Conditions. The proposed reaction pathway of *p*-cymene-2,3-diol leading to the formation of the oxidation products **1**, **2**, and **3** shown in Figure 4 was created on the basis of the reaction products identified and general reference literature.[36] It follows a common reaction pathway of phenols. The reaction starts with oxygen-catalyzed radical formation of two *p*-cymene-2,3-diol molecules and loss of two protons (one from each molecule) and then proceeds with electron migration from a hydroxyl group to the unsubstituted *para* carbon atom, forming a quinoid radical transitional state.[36] The resulting radicals form a quinoid dimer, which immediately reacts to its hydrolyzed form, accompanied by intramolecular migration of two protons. That reaction step can be explained as a tautomerism, which is promoted by *para*-substituents on both aromatic parts of the dimer. The resulting product with a molecular weight of 330 g/mol (**1**) has been described in the literature[22,23] (as mentioned above) and can be specified as the dimeric form of *p*-cymene-2,3-diol. By means of further oxidation of one part of the dimeric compound and formation of a stable quinoid structure containing two ortho keto groups, the newly identified **2** is formed with a molecular weight of 328 g/mol followed by the quinoid dimer **3** with a molecular weight of 326 g/mol. We observed that the kinetics of the phenolic dimerization reaction and further oxidation of one aromatic part were very slow at room temperature and without further addition of oxidizing agents. However, HPLC-MS showed that the presence of oxidation reagents such as sodium nitrite in acid medium sped the reactions. These processes can even be observed macroscopically, as a freshly prepared solution of *p*-cymene-2,3-diol changes from clear and colorless to dark brown during a few days of storage at room temperature. This process took place within a few minutes upon heating and addition of oxidizing agents.

Previously, five substances had been reported that were assumed to be dimeric oxidation products of *p*-cymene-2,3-diol and thymol,[22,23] but only two of them (**1** and **3**) could be definitely identified in the present work. One dimer, **2**, was newly identified, as described above. Furthermore, **3** could be identified only on the basis of a highly concentrated standard

[a]Five milliliter elution volume (in methanol) after purification by SPE. [b]Each data point represents the mean of three determinations (n = 3). [c]Each data point represents the mean of four determinations (n = 4). [d]Minced meat was cooked at 80 °C without standard addition and used as plain matrix after cooking. [e]Contents of analytes determined from diluted (5 mL) and nonpurified standard solution. [f]Formation/decomposition rate (FDR) = [content in extract of spiked matrix/(content in utilized standard solution + content in extract of plain matrix)] × 100, expressed in percentage of contents of standard solution plus contents in plain matrix and contents in extracts of spiked matrices to examine content changes during processing.

solution of *p*-cymene-2,3-diol and not in methanolic thyme extract. We detected traces of appropriate masses of the other compounds described here (3,4,4′-trihydroxy-5,5′-diisopropyl-2,3-dimethylbiphenyl, 4,4′-dihydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,6-dione, 4′-hydroxy-5,5′-diisopropyl-2,2′-dimethylbiphenyl-3,4-dione)[22,23] by means of LC-ESI-MS in standard solutions of *p*-cymene-2,3-diol, but we could not identify them in methanolic extracts of freeze-dried thyme. One reason for this may be that the present method of extraction and isolation of the biphenyls differs distinctively from the conditions described in the literature.[22,23] For example, Nakatani and Miura used a preparation technique involving steam distillation and silica gel column chromatography in which multiple further oxidation reactions can take place, which may have resulted in the artificial production of some of the previously characterized structures during isolation that do not naturally occur in large amounts. To test this assumption, we conducted silica gel chromatography with a standard of *p*-cymene-2,3-diol and a freshly prepared extract of freeze-dried thyme for comparison, but our HPLC-ESI-MS method showed that the eluates contained only artifacts of the expected appropriate masses (data not shown). In particular, the three biphenyls deriving from thymol described by Nakatani and Miura[22,23] may be formed under conditions created by the method applied by these authors, which presumably promoted more oxidation purification. The biphenyls characterized in this work (**1** and **2**) are major constituents of thyme extracts; however, the other previously described substance, **3**, as well as the three biphenyls deriving from thymol described by Nakatani and Miura[22,23] were not definitely identified in a thyme extract by means of the current standard HPLC-MS method. As mentioned above, the literature provides no coherent information on this subject: whereas one of the biphenyls described by Nakatani and Miura[22,23] has been reported as being extracted from thyme,[22,23] in a later report it is described as a synthetic compound,[5] so that its natural occurrence in thyme must be considered questionable. Additionally, the possibility of oxygen-coupled dehydrodimers was also considered, but there was no indication of these substances in the chromatographic and mass spectrometric data.

Analytical Method. The method described under Analytical HPLC-MS was developed considering previously reported methods,[16,17] especially for the oxidation products of thyme, but it may be used in further studies for effective analysis of the whole nonvolatile phase of thyme and other natural materials. Validation data including instrumental detection and quantitation limits are given in Table 1. The limits of detection (LOD) and quantitation (LOQ) of **1** and **2** are the same, 0.099 and 0.307 mg/L, whereas those of *p*-cymene-2,3-diol are clearly higher (0.178 and 0.536 mg/L). Table 3 shows the formation/decomposition rates (FDRs) in three matrices: freeze-dried thyme, raw minced meat, and cooked minced meat. Minced meat was used to examine oxidation reactions in a food matrix that is within the scope of subsequent industrial application of the functional oxidation products. The postulated reaction pathway from *p*-cymene-2,3-diol to **1** and **2** can be understood in light of their FDRs. Whereas the amounts of *p*-cymene-2,3-diol decreased, those of **1** first increased and then decreased, and those of **2** increased distinctly in all defined matrices. These facts support the reaction pathway postulated above, as **2** is assumed to be a secondary product of *p*-cymene-2,3-diol and **1**, and oxidation reactions take place intensely during storage. Thus, the FDRs determined for extraction techniques have to be interpreted not only as decreases in amounts due to extraction and purification but also as being due to unavoidable oxidation processes. Therefore, the FDRs specified in Table 3 have to be regarded as an indication for the conversion of *p*-cymene-2,3-diol, **1**, and **2**, and not only as process-related losses of substance. Not surprisingly, the losses of *p*-cymene-2,3-diol and **1** caused by the more complex extraction of raw and cooked minced meat matrix are considerably higher than for freeze-dried thyme, as the oxidation reactions indicated also take place. Therefore,

both losses and conversions have to be regarded as part of a systematic, coherent process.

Amounts of 1 and 2 in *T. vulgaris* L. and *T. citriodorus* L. and Their Hydrodistillation Residues. *p*-Cymene-2,3-diol, **1**, and **2** were found in extracts of freshly harvested, freeze-dried samples of *T. vulgaris* L. (Figure 1C,D) and *T. citriodorus* L. **1** and **2** were determined for the first time in thyme species. As shown in Figure 5, both thyme species contain larger amounts of **1** than of *p*-cymene-2,3-diol and **2**, whereas *T. vulgaris* L. has distinctly higher amounts of all three analytes than *T. citriodorus* L. Thus, **1** and **2** can be assumed to occur in the unharvested plant, where oxidation reactions possibly take place immediately after metabolic production of *p*-cymene-2,3-diol (Figure 5A).

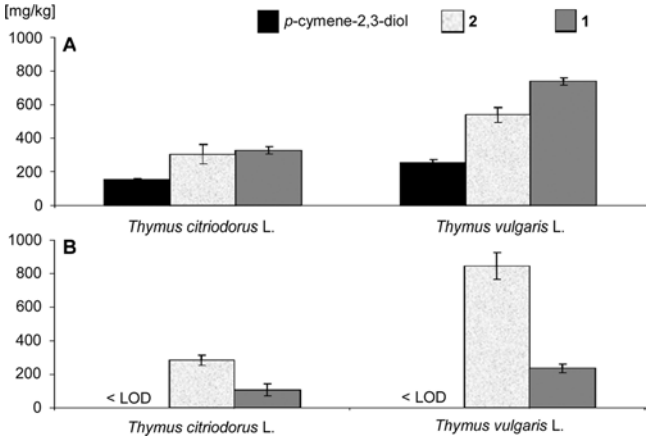

Figure 5. Amounts of *p*-cymene-2,3-diol, **2**, and **1** in freshly harvested, freeze-dried thyme species (A) and of **2** and **1** in hydrodistillation residue of thyme species (B). Each data point represents the mean of three determinations (n = 3) in dry matter.

After immediate hydrodistillation of the samples, the concentration of analytes in the remaining residues (results in dry matter) differed greatly (Figure 5B) from that of freshly harvested, freeze-dried thyme species. The concentration of the semivolatile *p*-cymene-2,3-diol was below the LOD when it was transferred (together with other volatile and semivolatile compounds) into the aqueous distillate, where it could have been identified (data not shown). However, before being transferred, some *p*-cymene-2,3-diol may have been oxidized, resulting in **1**, and total **1** may have been oxidized, resulting in **2**. As **1** and **2** are nonvolatiles, they were therefore predominately found in the residue. Notably, the ratio of **1** and **2** changed after hydrodistillation, after which **2** was the dominant dimer in the residue. This is not surprising, as **2** is suspected of being the oxidation product of **1**; furthermore, hydrodistillation conditions (heat treatment) accelerated the oxidation reactions described above. From these results it can be deduced that the functional biphenyls can be partly formed and enriched by means of a simple hydrodistillation treatment.

Kinetics of *p*-Cymene-2,3-diol in Methanol Solution and Meat Matrix. As proved in preliminary experiments with commercial standards of *p*-cymene-2,3-diol, thymol, and carvacrol, formation of **1** and **2** could be determined only in solutions containing *p*-cymene-2,3-diol and not from those prepared only from thymol or carvacrol, proving that the dimeric oxidation products identified were not formed from the major constituents thymol and carvacrol as reported earlier.[6,22,37] This may be explained by the fact that the half-wave potentials of thymol (+790 mV)[14] and carvacrol (+840 mV)[14] are higher than that of *p*-cymene-2,3-diol (+640 mV),[14] whereas *p*-cymene-2,3-diol is more sensitive to oxidation than thymol and carvacrol. In consideration of the circumstances of the sophisticated sample preparation including steam distillation and silica gel chromatography conducted earlier,[22,23] and the differences in half-wave potentials, the biphenyls including thymol monomers may be formed simply under intensive oxidative conditions. However, our easier and faster purification procedure described above suggests the possibility of milder conditions and less time for possible reactions.

In freshly prepared standard solutions, *p*-cymene-2,3-diol was always accompanied by **1** and **2** (Figure 1A,B). Figure 6 shows a storage experiment with a freshly prepared solution of *p*-cymene-2,3-diol. Storage for 1 day at room temperature under stirring led to significant ($p < 0.05$) degradation of *p*-cymene-2,3-diol and (to a lesser extent) **1**, whereas the **2** concentration increased significantly ($p < 0.05$). During the next 5 days, only marginal changes were observed in concentrations of *p*-cymene-2,3-diol, **1**, and **2**. During storage, the concentration of total analytes (sum of *p*-cymene-2,3-diol, **1**, and **2** contents) decreased successively from 1154 mg/L on the first day to 930 mg/L on the sixth. Therefore, it cannot be excluded that further, unidentified oxidation products were generated in addition to those postulated in the present work.

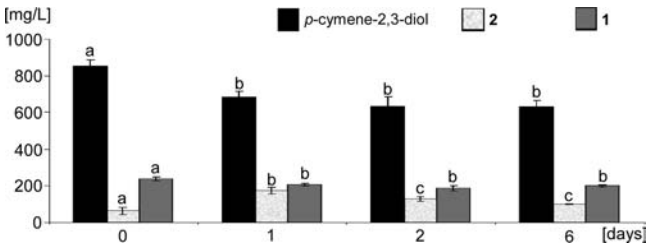

Figure 6. Amounts of *p*-cymene-2,3-diol, **2**, and **1** in freshly prepared solution of commercially available *p*-cymene-2,3-diol after 1, 2, and 6 days of storage. Each data point represents the mean of four determinations (n = 4). Values with the same letter within one data series are not significantly ($p > 0.05$) different between days of storage. Values with the letter "a" are starting values. Values with the letter "b" are significantly distinguished from those with the letters "a" and "c", and values with the letter "c" are significantly distinguished from values with the letters "a" and "b".

In another experiment, supercritical CO_2 thyme extract was added to minced pork meat as a representative food matrix to which the dimers could be supplemented. Figure 7 shows the amounts of *p*-cymene-2,3-diol as well as **1** and **2** after heat treatment: I (raw minced meat) and II (cooked minced meat) are control conditions including raw and cooked matrix with 1.0% (w/w) thyme extract; III, IV, and V contained 1.0% (w/w) nitrite curing agent with 1.0% (III), 3.0% (IV), and 6.0% (V) sodium nitrite (all w/w) as an additional reagent; whereas VI, VII, and VIII contained the same amount of nitrite curing salt (1.0%, w/w) with the same amounts of nitrite (1.0% (VI), 3.0% (VII), and 6.0% (VIII)) and with the addition of 1.0% (w/w) ascorbic acid. The resulting sodium nitrite concentrations in minced meat (100, 300, and 600 mg/kg) were chosen in consideration of the usual additions of sodium nitrite in food processing in accordance with the German food additive law (Zusatzstoff-Zulassungsverordnung, ZZulV), which specifies a maximum of 150 mg/kg sodium nitrite for meat products. To

dx.doi.org/10.1021/jf404193y | J. Agric. Food Chem. 2014, 62, 235−243

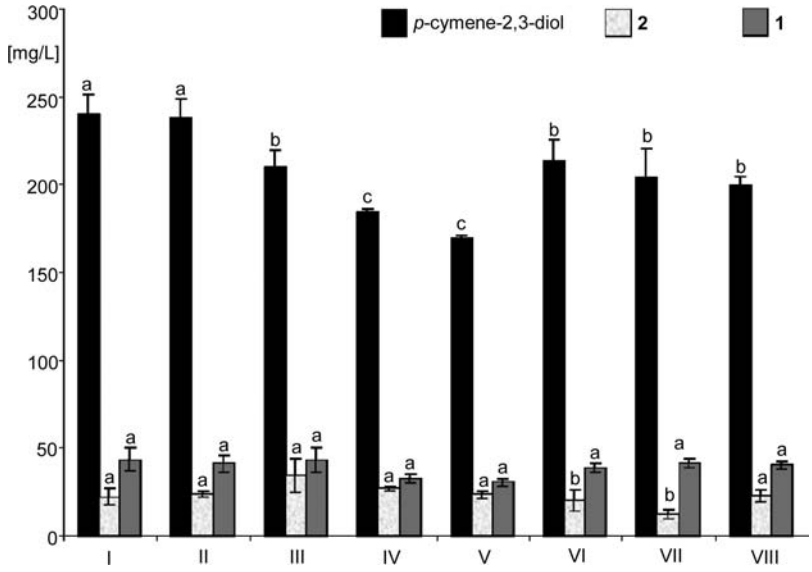

Figure 7. Amounts of *p*-cymene-2,3-diol, **2**, and **1** in minced meat under the following conditions: I, raw with 1% thyme extract; II, cooked with 1% thyme extract; III, cooked with 1% thyme extract and 0.01% sodium nitrite; IV, cooked with 1% thyme extract and 0.03% sodium nitrite; V, cooked with 1% thyme extract and 0.06% sodium nitrite; VI, cooked with 1% thyme extract, 0.01% sodium nitrite, and 1% ascorbic acid; VII, cooked with 1% thyme extract, 0.03% sodium nitrite, and 1% ascorbic acid; VIII, cooked with 1% thyme extract, 0.06% sodium nitrite, and 1% ascorbic acid. All percentages are related to weight of minced meat. Each data point represents the determination of mean of four determinations ($n = 4$). Values with the same letter within one data series are not significantly ($p > 0.05$) different between assays I and VIII. Values with the letter "a" are starting values. Values with the letter "b" are significantly distinguished from those with the letters "a" and "c", and values with the letter "c" are significantly distinguished from those with the letters "a" and "b".

test the efficiency of sodium nitrite as an oxidizing agent, concentrations (300 and 600 mg/kg) were also used that are considerably higher than allowed by law. As shown in Figure 7, cooked minced meat containing thyme extract but without further addition of sodium nitrite (II) showed a significantly ($p < 0.05$) higher amount of *p*-cymene-2,3-diol than samples with 1.0% (III), 3.0% (IV), or 6.0% (V) sodium nitrite (all w/w) after cooking. As described in the previous sections, at room temperature, *p*-cymene-2,3-diol initially reacts slowly to **1** and then to **2** as second step (and finally to **3**). It could be shown that these reactions can be accelerated by heat treatment and oxidizing agents. Assays with further addition of ascorbic acid (VI, VII, and VIII), a well-known antioxidant food preservative, showed that the decrease in *p*-cymene-2,3-diol was significantly ($p < 0.05$) lower than without ascorbic acid (IV and V) due to enhanced degradation of the responsible oxidizing agent, NO_2^-.

As stated above, no other oxidation products of *p*-cymene-2,3-diol were identified in the present work, but a further reaction of **2** and **3** caused by oxidation reagents can be considered possible and must be investigated in future experiments.

In summary, a method for the quantitative HPLC-MS analysis of *p*-cymene-2,3-diol along with its oxidation products has been established that is applicable for meat and other food matrices. This study revealed high contents of **1** and the newly identified **2** in methanol extracts of *T. vulgaris* L., its hydrodistillation residue, and supercritical CO_2 thyme extracts. Large amounts of industrially produced residues from the production of essential oils, that is, industrial waste (by-products), that are usually discarded by producers can now be viewed as potential sources for **1** and above all **2**, if species such as *T. vulgaris* L. are used. In addition, **1** and **2** are characterized by relatively low odorous activity compared with thymol, carvacrol, and other volatile antioxidants and antimicrobials, which constitutes a clear advantage over other sources. For efficient exploitation of the functional substances of thyme and utilization of these advantageous properties, further investigations should be conducted on the possible applicability of these species as a food additive.

ABSTRACT: The utilization of kaempferol and its glycosides in food and pharmaceutical industries could be improved by the formation of inclusion complexes with cyclodextrins at different pH. This study explores the complexation of kaempferol-4′-glucoside with sulfobutyl ether-β-cyclodextrin (SBE-β-CD), hydroxypropyl-β-cyclodextrin (HP-β-CD), and methylated-β-cyclodextrin (M-β-CD) in phosphate buffer solutions of different pH using isothermal titration calorimetry, UV−vis absorption and proton nuclear magnetic resonance spectroscopy at 298.2 K. Experimental results showed that kaempferol-4′-glucoside binds with the three β- cyclodextrins in the same 1:1 stoichiometry. The rank order of stability constants is SBE-β-CD > HP-β-CD > M-β-CD at the same pH level and pH 6.0 > pH 7.4 > pH 9.0 for the same cyclodextrin. The binding of kaempferol-4′-glucoside with the three β-cyclodextrin derivatives is synergistically driven by enthalpy and entropy at pH 6.0 and enthalpy-driven at pH 7.4 and 9.0. The possible inclusion mode was that in the cavity of β-CD is included the planar benzopyranic-4-one part of the kaempferol-4′-glucoside.

INTRODUCTION

Consumption of fruits and vegetables has been consistently associated with a reduced risk of human cancers.[1] Flavonoids are polyphenolic phytochemicals that are ubiquitous in vegetables and fruits. They are components in the human diet and constitute a large group of secondary plant metabolities.[2,3] The average intake of all flavonoids is 23 mg/day.[4] The antioxidant and anti-inflammatory capacities of these natural products are well documented,[5] and many display a cancer fighting potential.[6] As a typical kind of flavonoid, kaempferol (3,4′,5,7-tetrahydroxyflavone) is widely distributed in onion leaves, carrot, and black tea with the contents of 832, 140, and 118 mg/kg of dry weight, respectively.[7] Several biological activities have been attributed to kaempferol, including antioxidant,[8] antiatherogenic activities[9] and anti-inflammatory properties.[10] Significantly, kaempferol inhibits cancer cell growth and angiogenesis and induces cancer cell apoptosis.[11] Kaempferol-4′-glucoside (KG, Figure 1) is a glucosylated form of kaempferol with β-D-glucopyranoside substitution on the 4′ position of the B-ring. Kaempferol and its glycosides are characterized by the presence of hydroxyl groups that can be ionized depending on the working conditions. It was found that the biochemical activity of flavonoids is correlated to the position of these groups and their corresponding p*K*a values.[12] In addition, the type and degree of glycosylation may be important in determining the ability of these compounds to cross the intestinal wall.[13]

In recent years, the food, cosmetic, pharmaceutical, and chemical industries have become increasingly interested in kaempferol and its glycosides due to their health-promoting effects.[14] However, their poor water solubility and sensitivity to external agents such as air, light, and oxidative enzymes severely restrict their bioavailability, formulation, and manipulation in the elaboration of functional foods. However, these limitations can be overcome by the formation of inclusion complexes with cyclodextrins (CDs). β-Cyclodextrin (β-CD) is a cyclic oligosaccharide consisting of seven glucose units connected by α-(1,4) glycoside bonds. This molecular structure confers to β-CD the shape of a truncated cone, with the outer side formed by the secondary hydroxyl groups and the narrow side by the primary hydroxyl groups. This conformation makes β-CD have hydrophobic internal cavity and hydrophilic external surface and form inclusion complexes with various guest molecules

through noncovalent interactions.[15−18] The complexation has many applications in food, cosmetics, and pharmaceutical industries due to the improvement of the solubility, stability, and bioactivity of guest molecules. However, β-CD is unsuitable for parenteral administration due to its low aqueous solubility. A universal solution to this problem is the use of CD derivatives.[19] β-CD derivatives of pharmaceutical interest include hydroxypropyl-β-CD (HP-β-CD), methylated-β-CD (M-β-CD), sulfobutyl ether β-CD (SBE-β-CD), and the so-called branched CDs such as maltosyl-β-CD (G_2-β-CD).

Several papers have been published on the complexation of kaempferol by CDs.[20−25] However, to the best of our knowledge, there is no report about the inclusion complexation between KG and different β-cyclodextrin derivatives. Among various measuring techniques, isothermal titration calorimetry (ITC) is an extremely powerful and highly sensitive technique for the characterization of the interaction mechanisms of CDs with drugs.[26] It has been used with great success in the study of weak interactions from thermodynamic and kinetics points of view. In this work, the complexations of KG with three different cyclodextrins (SBE-β-CD, HP-β-CD, and M-β-CD) in aqueous solutions of different pH were studied using complementary techniques of ITC, UV−vis absorption spectroscopy, and ^{1}H nuclear magnetic resonance spectroscopy (^{1}H NMR). The resulting thermodynamic parameters may promote the application of KG in the food and pharmaceutical industries.

MATERIALS AND METHODS

Materials. Kaempferol-4′-glucoside (KG, purity >98%) was purchased from Shanghai Forever Biotech Ltd., Co. (Shanghai, China). HP-β-CD (average molecular weight =1460), SBE-β-CD (total degree of substitution = 6.8), and M-β-CD (average molecular weight = 1310) were obtained from Aldrich (St. Louis, MO, USA), Shandong Binzhou Zhiyuan Bio-Technology Co., Ltd. (Binzhou, China), and J&K Chemical (Beijing, China), respectively. Dimethyl sulfoxide-d_6 (DMSO), containing 0.03% (v/v) tetra methyl silane (TMS), was from Aldrich (St. Louis, MO, USA). All other reagents were of analytical grade. Deionized and double-distilled water were used throughout the study. All solutions of different pH values (pH 6.0, 7.4 and 9.0) were prepared with 0.05 M phosphate buffer solution (PBS) as solvent. The final concentrations of KG and three β-CD derivatives were adjusted for individual analytical instruments, as detailed below.

Isothermal Titration Calorimetry (ITC). ITC experiments were carried out with a nanowatt scale isothermal titration microcalorimeter supported by Thermal Activity Monitor-2277 (Thermometric, Sweden). The instrument was periodically calibrated either electrically using an internal electric heater or chemically by measuring the dilution enthalpy of a concentrated sucrose solution.[27] The titrant was CD (SBE-β-CD, HP-β-CD, or M-β-CD) at the concentration of 4.0×10^{-3} M in PBS, and all solutions were degassed before each titration. The sample cell and reference cell of the calorimeter were initially loaded with 0.50 mL of KG solution and 0.75 mL of PBS, respectively. The concentration of KG in PBS was 1.0×10^{-3} M. The programmable titration was controlled by Digitam 4.1 software, and the titrant was injected into the stirred sample cell in 30 portions of 15 μL using a 500 μL Hamilton syringe. The interval between two injections was sufficiently long for the signal to return to the baseline. To correct the thermal effect due to mixing and dilution, a control experiment was performed by injecting the β-CD solution into PBS and PBS into the KG solution, respectively. All experiments were performed at a fixed temperature of (298.2 ± 0.1) K and repeated 3-fold.

UV−vis Absorption Spectroscopy. A stock solution of KG (2.0×10^{-5} M) was prepared in PBS and was dissolved by vortexing. An accurately weighed quantity of β-CD (SBE-β-CD, HP-β-CD, or M-β-CD) was dissolved into each specific volume of KG solution to obtain a series of solutions for each kind of the CDs and the largest concentration of the host is 6.0×10^{-3} M. All solution samples were then equilibrated in an electro-heating standing-temperature cultivator maintained at 25 °C for 60 min. Spectra for each of the solution transferred into a quartz cuvette (1 cm × 1 cm × 4 cm) was recorded using a HP 8453 UV−vis spectrophotometer (Hewlett-Packard Company, USA). The temperature was controlled by an externally coupled bath at 25 °C. All experiments were performed in triplicate.

^{1}H Nuclear Magnetic Resonance (NMR) Spectroscopy. ^{1}H NMR spectra were performed on a Varian Mercury Plus 400 MHz nuclear magnetic resonance spectrometer (USA). KG and CDs were dissolved in D_2O in presence of 40% (v/v) deuterated dimethlsulfoxide-d_6 (DMSO) due to the poor solubility of KG in D_2O. TMS was employed as an internal standard.

RESULTS AND DISCUSSION

Calorimetric Characterization of Complexation at Different pH Conditions. ITC is one of the most sensitive methods available for the determination of the stoichiometry (n), equilibrium constant (K_a) and enthalpy change (ΔH°), for host−guest association, based on direct determination of the heat released or taken up during the interaction.

Complex formation between a CD (derivative) and KG can easily reach the equilibrium

$$m\mathrm{CD} + n\mathrm{KG} \rightleftharpoons \mathrm{CD}_m\cdot\mathrm{KG}_n \quad (1)$$

in which m and n = 1, 2, 3. Therefore, there are five possible inclusion models. The experimental association constant K_c can be expressed by equilibrium concentrations

$$K_c = \frac{[\mathrm{CD}_m\cdot\mathrm{KG}_n]}{[\mathrm{CD}]^m[\mathrm{KG}]^n} \quad (2)$$

The total concentration of CDs and KG can be obtained according to the following formulas

$$[\mathrm{CD}]_0 = [\mathrm{CD}] + mK_a[\mathrm{CD}]^m[\mathrm{KG}]^n \quad (3)$$

$$[\mathrm{KG}]_0 = [\mathrm{KG}] + nK_a[\mathrm{CD}]^m[\mathrm{KG}]^n \quad (4)$$

ΔH° and K_a can be obtained by the multinonlinear regression equation analysis with the Ligand Binding program available within the Digitam 4.1 software. By comparing the fitness between the simulation curve and the experiment point, the most reasonable result can be obtained as final result. A representative titration curve is given in Figure 2A. The excellent fit between experimental and calculated points is observed for 1:1 complex formation between the three substituted CDs and KG, as illustrated in Figure 2B. Furthermore, the standard association Gibbs free energy (ΔG°) and the standard association entropy (ΔS°) can be obtained from ΔH° and K_a according to the following thermodynamic formulas:

$$\Delta G^0 = -RT \ln K_a \quad (5)$$

where $K_a = K_c(c^0)^{m+n-1}$, c^0 = 1 mol dm^{-3}

$$\Delta S^0 = (\Delta H^0 - \Delta G^0)/T \quad (6)$$

The calculated association constants as well as the changes in Gibbs free energy, enthalpy, and entropy for the inclusion complexations of SBE-β-CD, HP-β-CD, and M-β-CD with KG are listed in Table 1.

As shown, the K_a values of KG with the three investigated β-CDs evidently decrease with the increase of pH of buffer solution from pH 6.0 to pH 9.0. This result indicates that acidity of buffer aqueous media has strong impact on the

complexation process. Hydroxyl groups of KG molecules are sequentially dissociated into anions with the elevation of pH values. Ionized KG exhibits much weaker binding with CD derivatives due to their enhanced hydrophilic character. Similar results have been observed in many other CD/guest complexation studies.[28] So the controlled release of KG could be achieved by the complexation with β-CD at different pH values. It was also noted that the stability of KG inclusion complexes is in the order SBE-β-CD > HP-β-CD > M-β-CD at the same pH. These differences are due to the variety of substituent group of the three CDs.[29] The hydrophility of the substituent group on the outer surface of SBE-β-CD, HP-β-CD, and M-β-CD decreases successively. The most probable binding mode of native and modified CDs with various guests involves the insertion of the hydrophobic part of the guest molecule into the CD cavity, while the hydrophilic, often charged, group remains outside the rim of the cavity.[30] The main driving forces for complex formation include hydrophobic interactions, electrostatic interactions (ion−ion interaction, ion−dipole interaction, and dipole−dipole interaction), van der Waals force interactions, hydrogen binding and the release of "high energy water" molecules from the cavities of CD to bulk water. Therefore, the binding process is the cooperative effects of the above driving forces. In many cases, hydrophobic interactions are the principal intermolecular weak forces responsible for the formation of stable supramolecular complexes. However, in some cases, where neutral or charged guest molecules and charged CDs mutually interact, strong complexations have been observed.[31,32] In such cases, the improvement in complexation has been associated with additional interaction sites provided by the CD charge. The mode of interaction is presumed to be hydrophobic interaction with the cavity interior along with additional electrostatic interactions between the guest and host molecules. Therefore, electrostatic interactions, including ion-dipole interactions,[33] maybe contribute to the formation of inclusion complexes. The stronger electrostatic interactions between the anions of the outer surface of SBE-β-CD and the hydroxyl groups of KG lead to a stronger complexation. In contrast, the hydrophobic−hydrophilic interactions between the methyl group of the outer surface of M-β-CD and the hydroxyl groups of KG are unfavorable to the complexation process.

The study of ΔH^0 and ΔS^0 obtained from ITC data leads to the determination of the driving force of the interaction. The main factors contributing to the formation of the complexation include release of cavity-bound water, partial destruction of hydration shells and noncovalent interactions (van der Waals, hydrophobic and electrostatic interactions as well as H-bonding).[34] Thermodynamic parameters of complex formation are the result of the competitive equilibrium among the above effects.

The three complexation reactions have negative ΔH^0, indicating that the association is exothermic in the order SBE-β-CD > HP-β-CD > M-β-CD at the same pH levels. The most negative ΔH^0 value for KG/SBE-β-CD complex may be attributed to the strong electrostatic interaction, which is consistent with the conclusion obtained from values of stability constant K_a, since the hydrophobic molecular cavity of the CDs is the same.[33] In addition, for the same CD, the heat released from the complexation increases with increasing pH. This could also be caused by the stronger electrostatic interaction at higher pH values.

The entropy effect is due to the total result of the host−guest combination which includes two opposite effects.[35] The negative contribution to entropy is due to the association of two molecules and the restriction of rotational and translational degrees of freedom, in particular those of the guest molecule. The positive contribution is due to the release of the highly ordered solvent molecules surrounding the host and guest molecules. The strong electrostatic interaction leads to the loss of degree of freedom. Therefore, the entropy change is in the order SBE-β-CD < HP-β-CD < M-β-CD at the same pH level and pH 6.0 > pH 7.4 > pH 9.0 for the same CD.

The differences in the proportion by which the binding entropy and enthalpy contribute to the Gibbs energy reflect the differences in the interaction established between the various CDs and KG molecules. It can be concluded from the above discussion that the binding of KG with the three β-CD derivatives is synergistically driven by enthalpy and entropy ($\Delta H^0 < 0$ and $T\Delta S^0 > 0$) at pH 6.0 and enthalpy-driven ($|\Delta H^0| > |T\Delta S^0|$) at pH 7.4 and 9.0.

UV−vis Absorption Spectroscopy. Figure 3 shows the absorption spectra of KG (2.0×10^{-5} M) in PBS of different pH values in the presence and absence of the three β-CD derivatives at 298.2 K. The higher wavelength band at about 265 nm is related to the $\pi \rightarrow \pi^*$ transition absorbance in the A-ring.[36] As can be seen from Figure 3, the addition of CDs results in a corresponding decrease in the absorbance intensity of KG. Similar reduction in absorption profile was observed upon the inclusion of resveratrol within HP-β-CD,[37] rosmarinic acid within natural and derivative cyclodextrins,[38] puerarin within glucosyl-β-cyclodextrin,[17] and *trans*-ferulic acid within HP-β-CD.[39] According to the symmetry forbidden rule, the $\pi \rightarrow \pi^*$ transition in KG may be less intense in the case of being included inside the cavity of the three β-CD derivatives than of being exposed in the polar solution.[40] SBE-β-CD shows a more pronounced absorbance decrease, probably due to a greater propensity to form inclusion complexes with KG. UV−vis spectra of KG (2.0×10^{-5} M) in the presence of various concentrations of SBE-β-CD at pH 7.4 is illustrated in Figure 4A. As shown, the absorbance intensity of KG gradually decreases with the stepwise addition of SBE-β-CD. The change in the absorption peak strength is characteristic of the interaction of KG with CDs.

Assuming a 1:1 stoichiometry of complex formation between the KG molecule and each of the three investigated β-CDs, the stability constant (K_a) can be obtained from the analysis of the sequential changes of absorption (ΔA) at various CD concentrations by using the modified Benesi−Hildebrand equation[41]

$$\frac{1}{\Delta A} = \frac{1}{K_a \Delta\varepsilon [\mathrm{KG}]_0 [\mathrm{CD}]_0} + \frac{1}{\Delta\varepsilon [\mathrm{KG}]_0} \quad (7)$$

where $[\mathrm{CD}]_0$ and $[\mathrm{KG}]_0$ refer to the total concentration of CD and KG, respectively, $\Delta\varepsilon$ is the change in molar extinction coefficient between the free and associated host, and ΔA denotes the change in absorbance of KG upon stepwise addition of CD. An exemplary double reciprocal Benesi−Hildebrand plot, i.e. plot of $1/\Delta A$ (at 268 nm) versus $1/[\text{SBE-}\beta\text{-CD}]_0$, was constructed and is shown in Figure 4B. The good linearity indicates that the presumed 1:1 stoichiometry of the complex is reasonable. Stability constants of complexation between KG and SBE-β-CD, HP-β-CD, and M-β-CD obtained by the spectroscopic analysis are listed in Table 2. The results show that the general rank order and order of magnitude of stability constants are consistent with those obtained from ITC data. Therefore, the rank order of stability constants is SBE-β-CD > HP-β-CD > M-β-CD.

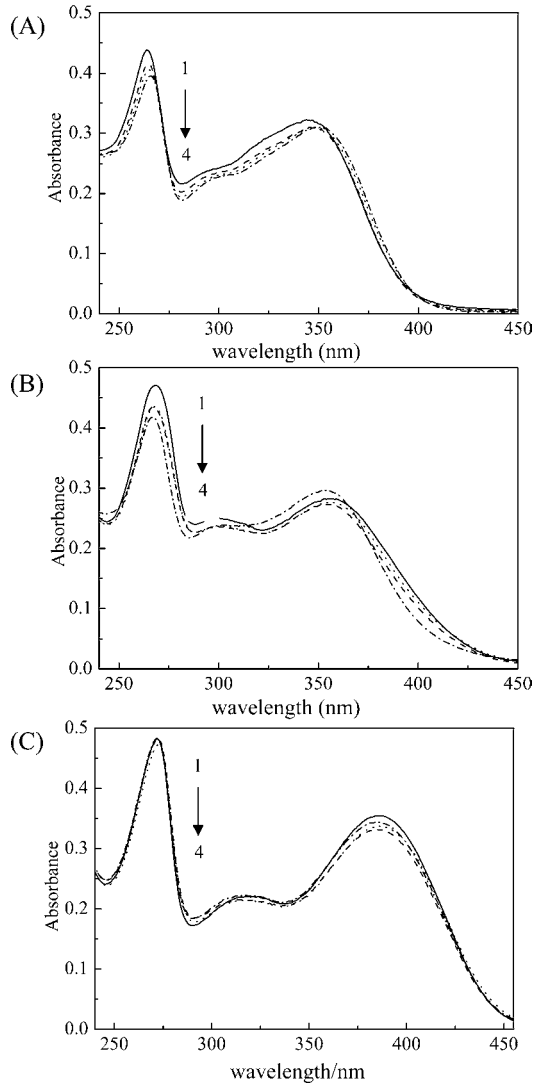

Figure 3. UV−vis spectra of KG (2.0×10^{-5} M) in the absence and presence of different β-CDs (1.0×10^{-3} M) in PBS of different pH values at 298.2 K: (A) pH 6.0, (B) 7.4, and (C) 9.0. Curves 1−4 correspond to KG (——), KG + M-β-CD (− − −), KG + HP-β-CD (· · ·), and KG + SBE-β-CD (− · − ·), respectively.

Characterization of Complexes by NMR. The formation of complexes was also studied by proton nuclear magnetic resonance spectroscopy (^{1}H NMR), where the relative orientation of the guest in the hydrophobic cavity of the host was obtained.[42,43]

The chemical shifts of protons in β-CD derivatives were not reliable for the NMR characterization due to the purity problem, caused by the degree and position of substitution.[44] Thus, only those of the protons in the guest were considered in this presentation. The spectra of ^{1}H NMR of KG in the absence and presence of CDs are presented in Figure 5. The detailed change of the chemical shifts ($\Delta\delta$) calculated for the protons in KG by using eq 8 were shown in Figure 6.

$$\Delta\delta = \delta_{(\text{complexation})} - \delta_{(\text{guest})} \quad (8)$$

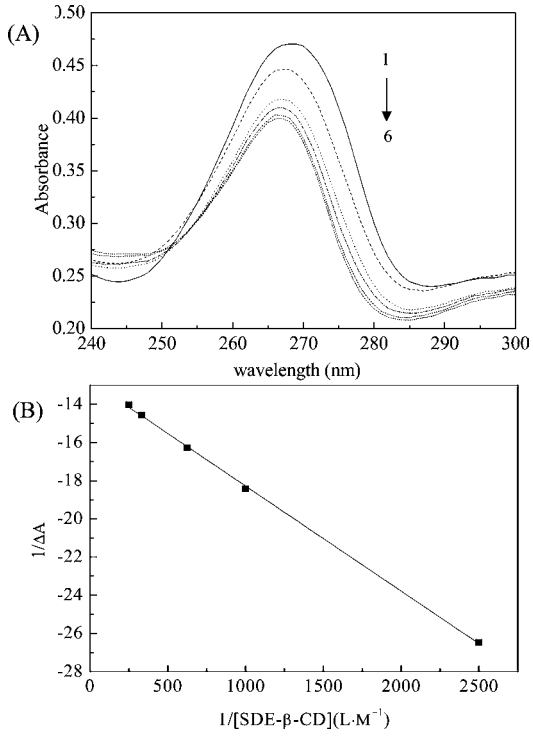

Figure 4. (A) UV−vis spectra of KG in the presence of SBE-β-CD of various concentrations at 298.2 K and pH 7.4. The concentration of KG was 2.0×10^{-5} M, and the concentrations of SBE-β-CD were 0, 0.4, 1.0, 1.6, 3.0, and 4.0×10^{-3} M corresponding to curves 1−6. (B) Double reciprocal plot of the data at 268 nm according to eq 7.

Table 2. Stability Constants of Complexation between Kaempferol-4′-glucoside and SBE-β-CD, HP-β-CD, and M-β-CD Derived from Double Reciprocal Benesi−Hildebrand Plot

	K/(L mol^{-1})		
	SBE-βCD	HP-βCD	M-βCD
pH 6.0	6154 ± 321	5300 ± 158	4722 ± 120
pH 7.4	2322 ± 16	1452 ± 9	1272 ± 10
pH 9.0	2081 ± 72	1304 ± 6	1176 ± 8

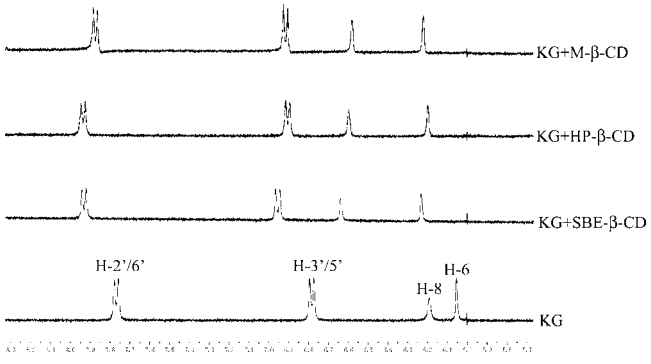

Figure 5. Chemical shifts of aromatic protons of KG in the absence and presence of different β-CDs in D_2O/DMSO (V:V = 6:4) solution.

where $\delta_{(complexation)}$ and $\delta_{(guest)}$ are the ^{1}H chemical shift of associated and free guest, respectively. The final results of $\Delta\delta$ were the average of triplicate values.

Although added DMSO may reduce the binding strength of the KG-β-CD complex, the general trend was revealed by the change of chemical shift.[44] As shown in Figure 6, the presence of CDs caused a downfield shift for all of the protons, which was probably due to their relatively strong interaction with β-CDs. In addition, Figure 6 indicates that the chemical shift change of H8 is the largest. It can therefore be inferred that the most possible binding mode is that the planar benzopyranic-4-one part of KG is included in the cavity of β-CD, as shown in Figure 7. The protrusion of A-ring is hindered due to the steric effect of 5-hydroxyl and 7-hydroxyl of A-ring and the intramolecular hydrogen bonding between 5-hydroxy of A-ring and 4-carbonyl group oxygen of C-ring.

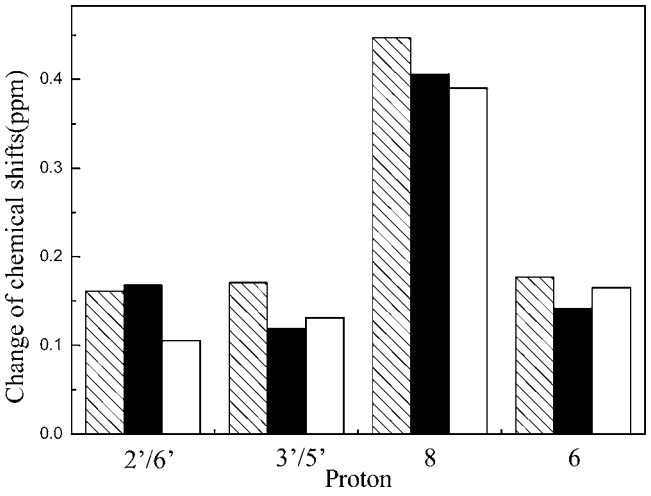

Figure 6. Chemical shifts change of aromatic protons of KG in presence and absence of βCDs in D_2O/DMSO (V: V = 6:4) solution. Cross-hatched bar, SBE-β-CD; black bar, HP-β-CD; white bar, M-β-CD.

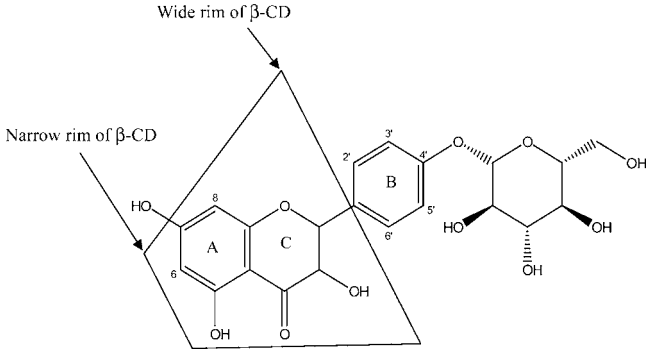

Figure 7. Possible inclusion mode of KG/SBE-β-CD, KG/HP-β-CD, and KG/M-β-CD inclusion complexes.

This binding model has been verified by Yang et al. for the interaction of rutin with β-CD.[45] Rutin (quercetin-3-rhamnosylglucoside) is a natural flavone derivative whose molecular structure is similar to that of KG molecule. It is also found in Figure 6 that the chemical shift change of SBE-β-CD is most prominent among the three β-CD derivatives, indicating that stronger interaction between KG and SBE-β-CD. The results are in good agreement with those of ITC and UV−vis absorption spectra analyses.

ABSTRACT: The analysis of the effect of cultivar and olive leaves addition before the extraction on the different analytical values revealed significant differences ($p < 0.05$) in some parameters, mainly in peroxide value, phenols and tocopherol contents, and oxidative stability. Aroma profiles were also influenced by the different varieties and the addition of different amounts (0% and 3%) of olive leaves. Twenty-three compounds were characterized, representing 86.1−99.2% of the total volatiles. Chétoui cultivar has the highest amount of (*E*)-2-hexenal, followed by Chemlali cultivar, whereas (*E*)-2-hexen-1-ol was the major constituent of Zalmati and crossbreeding Chemlali by Zalmati cultivars. Sensory analysis showed that Chemlali and Chétoui Zarzis possessed a high fruity, bitter, and pungent taste, whereas the Zalmati and crossbreeding Chemlali by Zalmati had a 'green' taste among its attributes. Indeed, the taste panel found an improvement of the oil quality when an amount of olive leaves (3%) added to the olives fruits.

KEYWORDS: *olive leaves, extra-virgin olive oil, volatile compounds, Tunisian cultivars, sensory characteristics, principal component analysis*

INTRODUCTION

Extra-virgin olive oil is a valuable vegetable oil that is produced without any preliminary refining process. It plays a very important role in the agronomy and economy, providing both employment and export revenue. Olive trees in Tunisia cover an area of 1.7 million ha and account for more than 4% of the olive oil produced in the world. Indeed, with an annual production of 170.000 tons, Tunisia is the fourth largest producer and exporter of olive oil in the world.[1] More than 50 different olive oil cultivars exist in Tunisia such as Chemlali, Chétoui, Meski, Chemchali, Oueslati, and Zalmati. However, two important varieties dominate most of the arable land: Chétoui and Chemlali.[2]

In fact, Chemlali is the main cultivated variety, covering 60% of the olive-growing surface, spread from the northeast of the country to the extreme south.[3] In addition, despite its ordinary organoleptic and taste characteristics, olive oil composition is different according to the geographical origin.[4] In contrast, the Chétoui variety can be found mostly in the north of the country. The oil of the latter's cultivar is characterized by high amounts of total phenols and tocopherols.[5] Almost all research studies on Tunisian virgin olive oil have focused on the characterization and improvement of these two varieties.[6] However, the work on other cultivars could be very interesting as it aims at planting new cultivars with a high yield of oil, good quality, and good stability. The minor components and the unsaponifiables are the delicate and the interesting fractions of the lipid matter,[7] rising to about 2% of the total oil weight. They include many chemical compounds such as aliphatic and triterpenic alcohols, sterols, hydrocarbons, volatile compounds, and antioxidants. In fact, olive oil has a special flavor that is generated from a number of volatile molecules present at extremely low concentrations.[8] These molecules mainly include aldehydes, alcohols, ketones, and esters.[9] The main volatile compounds usually found in high sensory quality virgin olive oil are produced from polyunsaturated fatty acids through the cascade of reactions collectively called the lipoxygenase (LOX) pathway.[10−12] Many positive attributes and sensory defects in olive oil can be associated with volatile compounds. The absence of sensory defects is necessary for the olive oil to be classified as EVOO.[13] Cultivar type influences the formation of volatile compounds in oil and is an important factor for determining the final olive oil quality.

Olive leaves are one of the farming byproducts of the olive groove and are considered as a cheap raw material that can be used as a useful source of highly added value products,[14] particularly phenolic compounds[15] exhibiting a strong protective effect against oils oxidation.[16,17] On the other hand, the addition of olive leaves during the oil extraction process could cause mechanical problems associated with the flow of olive paste. Moreover, the presence of leaves before olive fruits extraction may further enhance the flavor and did not distort the aroma of such oils. Di Giovacchino et al.[18] suggested that the analyses of the volatile components of the oil, in fact, show no newly formed substances or considerable

changes in the majority of volatile components. An exception is a noticeable increase in the trans-2-hexenal, hexanal content, and some alcohols, such as cis-3-hexenol, trans-2-hexenol, and 1-hexanol.This increase could be explained by release of chloroplasts from crushing olive leaves.[18]

In this context, we intend to study if the addition of olive leaves before the extraction process of olive oil introduces a favorable effect on the chemical composition and quality of olive oils of two widespread olive cultivars (Chemlali and Chétoui) of Zalmati cultivar and for the first time a new cultivar obtained by crossbreeding Chemlali by Zalmati. Different lots with over mature olives and with increasing quantities of olive leaves (0% to 3%) of the four samples were processed. The extracted olive oils were characterized for several quality parameters, oxidative stability (through Rancimat method), fatty acids composition, tocopherols, volatile compounds, and sensory analyses.

MATERIALS AND METHODS

Olive Origin. Monovarietal virgin olive oil samples were obtained from four Tunisian olive varieties: Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati, which were harvested in Zarzis, (south of Tunisian) during two crop seasons (2011/2012 and 2012/2013). In order to eliminate the influence of maturation state on olive oil quality, the ripening degree was the same for the four studied olive samples (maturation indices were 6.07, 6.14, 6.88, and 6.86 for Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati cv., respectively). The olive samples were collected from the olive trees in triplicate from orchards in the same neighborhood carried out with the same cultural practices. The olive ripening index (RI) was determined according to the method developed in ref 19, on the basis of the evaluation of the olive skin and pulp colors. RI values range from 0 (100% intense green skin) to 7 (100% purple flesh and black skin).

Chemicals. Methanol, hexane, acetone, acetic acid, and cyclohexane HPLC-grade solvents were purchased from Riedel-deHaen (Switzerland). The solvents were of appropriate purity. Double distilled water was used in the HPLC mobile phase. Folin−Ciocalteu reagent was obtained from Fluka (Switzerland).

Oil Extraction. After harvesting, samples of Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati olives were transported the same day to the laboratory to be transformed into oil within 24 h. For each olive sample, fruits were processed and olive oil was obtained using a two-phase centrifugation: about 1.5−2 kg of olives from each sample were crushed with a hammer crusher, and the paste mixed at a temperature of about 27 °C for 30 min, centrifuged in a decanter (3500 rpm for 3 min) without the addition of warm water and then transferred into dark glass bottles, and stored at 4 °C until analysis.

Analytical Methods. *Quality Indices Determinations.* The determination of acidity (given as % of oleic acid), peroxide value (PV) (meqO_2/kg of oil) were carried out following the analytical methods described by the International Olive Council.[20]

Fatty Acid Methyl Ester Analysis. The fatty acid composition of the oils was determined by gas chromatography (GC) as fatty acid methyl esters (FAMEs). FAMEs were prepared by saponification/methylation with sodium methylate according to the EEC Reg 2568/91.[21] A chromatographic analysis was performed in a SHIMADZU set 17 A Series II gas chromatography using a capillary column (stabilwax, Restek, length 50 m, internal diameter 0.32 mm, and film thickness 0.25 μm). The column temperature was isothermal at 180 °C, and the injector and detector temperatures were 230 and 250 °C, respectively. Fatty acids have been identified by comparing retention times with standard compounds, palmitic (16:0), hypogeic (16:1(n − 9)) + palmitoleic (16:1(n − 7)), heptadecanoic (C17:0), heptadecenoic (C17:1n-8), stearic (18:0), (Z)-vaccenic (18:1(n − 7)) + oleic (18:1(n − 9)), linoleic (18:2), linolenic (18:3), arachidic (20:0), and gondoïc (C20:1(n − 9)) behenic (22:0) and lignoceric (24:0) acids they have been expressed as percentages of fatty acid methyl esters.

Tocopherol Determination. HPLC analysis for α-tocopherol was performed with an Agilent (1100) Series HPLC (Hewlett-Packard, Waldbronn, Germany) apparatus. Detection was performed at 290 nm for α-tocopherol. The column was C-18, 4.6 × 250 mm, particle size 5 μm, shim-pack, VP-ODS, Shimadzu, Kyoto, Japan. The elution solvents used were A (2% acetic acid in water), B (methanol), C (acetonitrile), and D (isopropanol). The samples were eluted according to the following gradient: 95% A/5% B in 2 min; 60% A/10% B/30% C in 8 min; 25% B/75% C in 22 min, and this percentage was maintained for 10 min; 40% C/60% D in 10 min; and this percentage was maintained for 15 min; 25% B/75% C in 2 min, and finally, 95% A/5% B in 3 min. Flow rate was 1 mL/min and run time was 70 min. The run was performed at 32 °C. The sample injection volume was 20 μL. The identification of α-tocopherol was achieved by comparing its retention time values with a standard.[22] The α-tocopherol content was determined by diluting approximately 1100 mg of olive oil in 1 mL of n-hexane and analyzing the sample solution by HPLC. Besides, the concentrations of α-tocopherol were calculated by integrating peak areas of the samples and the calibration curve of the α-tocopherol standard. Then, acceptable linearity was achieved in the range 300−1100 mg kg^{-1} (y = 1.30x, R^2 = 0.899).

Analysis of Phenolic Compound. *Extraction of Phenolic Fraction from Olive Oil.* The phenols containing extracts were obtained following the procedure of Mraicha et al.,[23] with some modification. Briefly, the oil sample (4 g) was added to 2 mL of n-hexane and 4 mL of a methanol/water (60:40, v/v) solution in a 20 mL centrifuge tube. After vigorous mixing, they were centrifuged for 3 min. The hydroalcoholic phase was collected, and the hexane phase was re-extracted twice with 4 mL of methanol/water (60:40, v/v) solution each time. Finally, the hydroalcoholic fractions were combined, washed with 4 mL of n-hexane to remove the residual oil, then concentrated and dried by evaporative centrifuge in vacuum at 35 °C.

Determination of Total Phenols. The determination of the total phenolic compounds was performed by means of the Folin−Ciocalteau reagent using the method that was described by Bouaziz et al.[3] The total phenols content was expressed as milligrams of gallic acid (GA) equivalents per kilogram of oil (y = 0.011x, R^2 = 0.990).

Volatile Compound Analyses. *Extraction.* Solid-phase microextraction was used as a technique for headspace sampling of virgin olive oils. Supelco SPME devices coated with polydimethylsiloxane (PDMS, 100 μm) were used to sample the headspace of 2 mL of olive oil inserted into a 5-mL glass septum vial and allowed to equilibrate for 30 min at 22 ± 1 °C. After the equilibration time, the fiber was exposed to the headspace for 50 min. Extraction temperature and times were optimized in previous studies.[24]

Identification. GC analyses were performed using a HP-5890 series II instrument equipped with a DB-5 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness), working with the following temperature program: 60 °C for 10 min, ramp of 5 °C min 1 to 220 °C; injector and detector temperatures, 250 °C; carrier gas, helium (1 mL min^{-1}); detector FID; splitless injection. The components were identified by the comparison of their retention times with those of pure authentic standards and by means of their linear retention indices (LRI) relative to the series of n-hydrocarbons. GC−EIMS analyses were performed using a Varian CP 3800 gas-chromatograph equipped with a DB-5 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thicknesses) and a Varian Saturn 2000 ion trap mass detector. Analytical conditions were as follows: injector and transfer line temperature at 250 and 240 °C, respectively; oven temperature was programmed from 60 to 240 °C at 3 °C min^{-1}; carrier gas, helium at 1 mL min^{-1}; splitless injection. The identification of the constituents was based on the comparison of the retention times with those of authentic samples, comparing their LRI relative to the series of n-hydrocarbons, and on computer matching against commercial (NIST 98 and ADAMS) and homemade library mass spectra built from pure substances and components of known oils and MS literature data.[25] Moreover, the molecular weights of all the

identification substances were confirmed by GC-CI-MS, using MeOH as CI ionizing gas.[26]

Determination of Oxidative Stability by Rancimat Method. The oil samples (5.0 g) were heated in a Rancimat equipment at 120 °C (Metrohm Ltd., Herisau, Switzerland), with a continuous air flow of 20 L/h passing through the samples. The conductivity cells were filled with 60 mL of deionized water. The time needed (hours) for the appearance of a sudden water conductivity rise, caused by the adsorption of volatiles derived from oil oxidation, was registered as the induction time.

Sensory Assessment. Sensory evaluation was carried out by a panel composed by eight judges who were fully trained in the evaluation of virgin olive oil (VOO) according to the official methods of the International Olive Oil Council (IOOC).[20]

Statistical Analysis. The results were expressed as mean ± standard deviation (SD) of three measurements for the analytical determination. Significant differences between the values of all parameters were determined at $p < 0.05$ according to the one way ANOVA: Student−Newman−Keuls test, using SPSS Statistics 17.0 for Windows (SPSS Inc., 2008).

Nonstandardized principal component analysis (PCA) was applied to show the effect of addition of olive leaves (3%) on the quality of different varieties of olive oils from Zarzis region according to all the parameters investigated, using the Varimax rotation with Kaiser Normalization. The PCA type was Pearson (n), the biplot type was correlation biplot and the coefficient was automatic. PCA plots were performed using XLSTAT software for Windows (v.2013.2.03, Addinsoft, NY, U.S.A.).

RESULTS AND DISCUSSION

Quality Indices. Table 1 shows the physicochemical quality parameters of olive oils from the studied cultivars with different olive leaves amounts (0% and 3%) added before the extraction process.

The free fatty acid content is an important quality factor and has been extensively used as a traditional criterion for classifying olive oil in various commercial grades.[27] The free fatty acids of oils produced from the four olive varieties extracted with different percentages of olive leaves (Table 1) did not exceed the upper limits of 0.8% established by the COI norm, and they all corresponded to the extra-virgin olive oil class.[28] The addition of olive leaves (3%) to all studied samples before the extraction of olive oil did not significantly ($p > 0.05$) change the free acidity in these samples except for the Zalmati and crossbreeding Chemlali by Zalmati samples ($p < 0.05$). Compared to the results obtained by Malheiro et al.[29] and Di-Giovacchino et al.[8] for the other cultivar, our free acidity values are lower. Malheiro et al.[29] have reported that the addition of olive leaves may also increase the presence of lipolytic enzymes which consequently entails an increase in the free acidity, explaining the observed increments in this parameter.

The peroxide values (PV) evaluate the hydroperoxide content and offer a measure of lipid oxidation.[30] In the studied oils, the PV ranged between 9.00 and 16.63 meq O_2 kg^{-1}, resulting in values lower than the maximum indicated by the EEC Regulations.[31] The highest PV was observed in the oil from crossbreeding Chemlali by Zalmati oil (13.15 and 16.63 meq O_2 kg^{-1}, respectively for 0% and 3% of added leaves). While, the lowest ones were detected in the Chemlali olive oils, it tends to 9.00 without the addition of olive leaves and 11.50 meq O_2 kg^{-1} with the addition of 3% of olive leaves. Concerning the Chétoui and Zalmati varieties, they showed intermediate PV, comprised between 12.75 to 15.45 and 11.00 to 13.50 meq O_2/kg in the olive oils with added leaves at 0% and 3%, respectively. As observed, the varietal selection of

[a]SFA: saturated fatty acids. MUFA: monounsaturated fatty acids. PUFA: polyunsaturated fatty acids. UFA: unsaturated fatty acids. Each value represents the mean of three determinations ($n = 3$) and three independent experiments. Different symbols (*, **) within the same line indicate significant differences ($p < 0.05$) between 0 and 3% percents of olive leaves for each variety. Different lower-case letters (a, b) within the same line indicate significant differences ($p < 0.05$) for the same percentage of olive leaves between the different varieties.

dx.doi.org/10.1021/jf404395x | J. Agric. Food Chem. 2014, 62, 251−263

olives and addition of olive leaves before the extraction of olive oils induce significant ($p < 0.05$) increases in all the peroxide values. These results are in agreement with those obtained by Di Giovacchino et al.[8] and Malheiro et al.[29]

Fatty Acid Profile. As shown in Table 2, many fatty acids were detected in the extra-virgin olive oils of the studied varieties extracted with different percentages of olive leaves. As expected, the most abundant one in all the samples was oleic acid (C18:1), followed by palmitic (C16:0) and linoleic acids (C18:2), while palmitoleic, stearic, linolenic, and arachidic acids were present in small amounts, independently of the percentage of olive leaves added. The four EVOO showed a fatty acid composition (Table 2) in compliance with the established limits[31] and variety-depending ranges. Oleic acid, the major monounsaturated fatty acid, also showed a wide variability depending on the varieties. Chemlali Zarzis had the highest percentage of oleic acid which did not follow any tendency with the increasing quantity of olive leaves added ($p > 0.05$), varying from 67.84% to 67.88% (samples with 0% and 3% of leaves, respectively). While Zalmati Zarzis and crossbreeding Chemlali by Zalmati Zarzis showed the lowest values in the oleic acid varying from 58.75% to 58.98% and 55.73% to 56.41% for samples with 0% and 3% of added leaves, respectively. Chétoui Zarzis had a good value of C18:1, which remained almost the same for 0% and 3% of added leaves before the extraction process of olive oil (64.77% to 64.50%, respectively). Palmitic acid (C16:0) is the major saturated fatty acid in olive oil; its content was not influenced by the amount of the added leaves ($p > 0.05$), but it was instead strongly affected by the cultivar ($p < 0.05$). The highest percentage was observed in crossbreeding Chemlali by Zalmati oils (18.34 to 18.13 for samples with 0% and 3% of added leaves, respectively), whereas the lowest values were present in Chétoui oil (11.00% and 10.90% for samples with 0% and 3% of added leaves, respectively). Concerning linoleic acid, crossbreeding Chemlali by Zalmati oil samples had the highest mean values (19.47% and 19.22% for samples with 0% and 3% of added leaves, respectively) whereas the lowest one was found in Chemlali Zarzis (from 8.76 to 9.07% in the olive oils without addition of olive leaves to 3% of added leaves). The Chétoui and Zalmati varieties presented intermediate percentages, comprised between 18.76 and 19.11% and between 17.26 and 17.23% in samples with 0% and 3% of added leaves, respectively. The percentages of the other fatty acids, including palmitoleic (C16:1), stearic (C18:0), linolenic (C18:3) and arachidic (C20:0) acids, vary from one olive oil to another, but the amounts were quite small. The levels of these fatty acids in the various tested oils were close to those required by the IOOC (2011).[31] The percentages of saturated, monounsaturated and polyunsaturated fatty acids and the oleic acid/linoleic acid ratio (O/L) in the studied olive oils were also evaluated. It was observed that crossbreeding Chemlali by Zalmati oil was the richest in total saturated fatty acids (SFA) (21.27% and 21.11% from oil samples with 0% to 3% of added leaves, respectively) essentially due to its high content in palmitic acid, which represents the major acid of the SFA fraction.

With respect to the total monounsaturated fatty acids (MUFA), Chemlali Zarzis olive oil contained the highest percentage (70.21%) because of its high content in oleic acid. Crossbreeding Chemlali by Zalmati olive oil was the richest in total polyunsaturated fatty acids (20.09%) because of its high contents in linoleic acid, representing the major fatty acid component of that fraction. The oleic acid/linoleic acid ratio varied between 2.86 and 7.74% according to the varieties. This ratio can be useful to characterize olive cultivars and have a relationship with stability.[32] We can then claim that fatty acid composition may be an important factor to identify the monovarietal olive oils. Notably, the percentages of the fatty acids did not follow any tendency with the increasing quantity of the added olive leaves.[29]

Total Phenols. Olive oil usually contains considerable amounts of phenolic compounds. The four varieties showed different amounts of total phenols (Table 1). The highest content of these components was detected in Zalmati olive oil, with 343.61 to 355.00 ppm with 0% and 3% of added leaves, respectively, while the lowest amount was recorded for Chemlali olive oil (101.07 and 122.14 for 0% and 3% of added leaves, respectively). The effect of the cultivar on these compounds is obvious. These results are in agreement with those obtained by Issaoui et al.[33] Moreover, the data in Table 1 show that the total phenols contents (ppm) of oils oils increase slightly but significantly ($p < 0.05$) when the different percentages of leaves were added to olives. This is due to the fact that the concentration of the phenolic compounds (glycosides) of leaves is similar to that in olive flesh. Moreover, the phenolic substances are present in leaves as glycosides, soluble in water but not in oil.[8]

Total Tocopherols Content. Tocopherols constitute the lipophilic antioxidant fraction and are well-known for their effective inhibition of lipid oxidation in all vegetable oils. The tocopherols content in these four Tunisian olive oil samples (Table 1) extracted with olive leaves can be considered as medium−high (comprised between 109.71 and 254.74 ppm). Chemlali and Chétoui olive oils showed the highest values of tocopherol (254.49 to 234.53 ppm and 274.14 to 254.74 ppm for 0% and 3% of added leaves, respectively), whereas Zalmati and crossbreeding Chemlali by Zalmati oils contained the lowest levels of these compounds (126.40 to 109.71 ppm and 135.44 to 128.74 ppm for 0% and 3% of added leaves, respectively). Notably, the tocopherol level is highly variety-dependent. These results are in agreement with those previously reported, which showed that tocopherols contents vary between cultivars.[34] Indeed, the contents of tocopherols presented a slight difference but also significant ($p < 0.05$) between the olive oils without addition of leaves and those up to 3% of the added leaves. In addition, these observations are in agreement with the research studies of Malheiro et al.[29]

Oil Stability. The oxidative stability of EVOO measured by Rancimat test (at 120 °C) showed that the induction time varied according to the cultivar. The highest level was attributed to the cultivar Chétoui Zarzis (from 8.85 to 8.18 h samples with 0% and 3% of added leaves, respectively). The different induction times of all the samples are probably due to the combination of fatty acid composition, and in particular to the relatively low content of polyunsaturated fatty acids, expressed by the O/L ratio. Furthermore, the effect of various pro/antioxidants present in the oils should not be neglected.[35,36] Chemlali Zarzis olive oils presented intermediate values, varying between 6.21 and 5.53 h with 0% and 3% of added leaves. Zalmati and crossbreeding Chemlali by Zalmati oil seem to have a lower stability value that does not exceed 5.10 h for both oils extracted with different percentages of olive leaves. Indeed, the results showed that the addition of leaves also did slightly but significantly ($p < 0.05$) affect the induction time. Furthermore, our results are in agreement with those obtained by Di-Giovacchino et al.[8] On the contrary, Malheiro et al.[29]

[a]LRI, linear retention index.

have reported that the induction times are clearly associated with changes induced in the composition of olive oils due to leaves addition, namely by the extraction of antioxidative components into the olive oils.

Aroma Profiles. The characteristic and the unique flavor of extra-virgin olive oil, in particular, its green and fruity attributes depends on many volatile compounds.[13,6,37] The concentration and odors threshold of volatile compounds, whether major or minor, are crucial to extra-virgin olive oil quality. Table 3 displays the compounds identified in the volatile fractions of the oils obtained from the four varieties of *Olea europaea L.* (Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati) extracted with different percentages of olive leaves using SPME-GC/MS. It proves that the virgin olive oil headspace consists of a complex mixture of 23 compounds, representing 86.1−99.2% of the total volatile compounds. Moreover, 17 unknown minor volatile compounds detected in olive oils samples were presented in Table 4. These results indicate that olive oil volatile compounds accumulate differently, according to the cultivar kind and the increase of the percentage of olive leaves. The present results are in agreement with other studies, such as Ouni et al.[38] Commonly, each volatile compound is characterized by an odor threshold. So, even if different fruits have similar qualitative compositions, the aroma could considerably vary when the relative proportions in olive leaves are different. The detected compounds can be divided into four chief chemical groups: aldehydes, alcohols, esters, and terpene hydrocarbons (monoand sesquiterpenes). Their main aromatic notes can be classified as green, fruity, bitter, pungent, and fatty.[39] In detail, within the main chemical groups, we have identified seven alcohols (34.8−78.1% of total volatile fraction), five aldehydes (5.4−37.3%), three esters (0−18.9%), two monoterpenes (0−7.3%), and four sesquiterpenes (2−7.7%). On the contrary, a ketone fraction was not identified

[a]LRI, linear retention index.

in all the studied oils, indicating an extremely low content or activity of alcohol acetyl transferase.[40]

Aldehydes and alcohols were the main chemical classes detected in the analyzed oils (Table 3). Indeed, alcohols in olive oil are connected to positive sensory characteristics: olive fruity, other fruits, green, and aromatic. However, since they have higher threshold values, they also have a lower sensory significance than aldehydes.[41] Besides, alcohols were the most abundant volatile compounds in these studied oils, ranging between a minimum of 57.70% and 60.60% in 0 and 3% of the added leaves samples for oils produced from Chemlali Zarzis to a maximum of 64.10% to 78.10% for 0 and 3% of leaves for oil produced from Zalmati Zarzis cultivars, with the exception of Chétoui olive oil processed with 0% and 3% leaves, which showed the highest percentages of aldehydes (31.60% and 37.30% of the total aroma, respectively). The difference between cultivars became much stronger when considering the highest levels of esters observed in Chétoui and Chemlali olive oil (18.90% to 18.10% and 12.50% to 18.10% for 0% to 3% of leaves, respectively). These results therefore indicate that the level of ester was strongly affected by the leaves added to the olives.

The major components of the volatile fraction of extra-virgin oils were the C6 compounds, which derive from the cascade of enzymatic reactions starting with the formation by lipoxygenase action (LOX pathway occurring during the crushing of olive fruit and the malaxation of paste), of 13-hydroperoxides from linoleic and linolenic acids.[11,12,39] The different accumulations of metabolites from the lipoxygenase cascade were highly dependent on the levels of enzymes involved, the extraction conditions, the variety, the storage time, and the degree of ripening of olives.[6] Their quantitative composition basically changed according to the cultivar. However, some modifications of the concentration of C6 compounds from the LOX pathways should be attributed to the addition of olive leaves before the extraction of olive oil. The chemical compositions of all Tunisian olive oil headspaces showed that C6 aldehydes (hexanal and (*E*)-2-hexenal) were the most abundant compounds. Chétoui cultivars had the highest amount of (*E*)-2-hexenal (27.90% and 32.60% for 0% to 3% of added leaves, respectively) followed by Chemlali Zarzis (9.60% and 12.60% for 0% to 3% of leaves added, respectively), while Zalmati Zarzis registered the lowest amounts of this compound, (0% and 5.20% from 0% to 3% of added leaves, respectively). Interestingly, this compound was not detected at all in crossbreeding Chemlali by Zalmati Zarzis. Therefore, we can affirm that the analysis of aroma matrix showed similarities between Zalmati and crossbreeding Chemlali by Zalmati Zarzis. These results agree with previous findings suggesting that monovarietal VOO could be distinguished by their (*E*)-2-hexenal content. Moreover, the amount of hexanal that confer apple and green fruity attributes[38] was lower and varied between 0% for crossbreeding Chemlali by Zalmati and 4.70% in Chétoui olives oil samples with 3% of added leaves. According to Brkic Bubola et al.[42] a low hexanal/(*E*)-2-hexenal ratio indicates better quality and lower oxidation degree of the oil. Zalmati and crossbreeding Chemlali by Zalmati oils had no influence on these two aldehydes nor on its ratio, and it can be concluded that oxidative changes in the oils did not occur with 0% and 3% of the added leaves. In Chemlali and Chétoui oils, the hexanal/(*E*)-2-hexenal ratio was very low due to the low hexanal content and the high levels of (*E*)-2-hexenal. Indeed, Di-Giovacchino et al.[42] stated that the taste panel found a quality improvement in oil when the percentage of leaves added to olives was increased, even though there was a slight decrease in the evaluation of the oil obtained from olives containing 5% leaves. This result can be explained by the increase in the content of hexanal, an unpleasant to the taste aldehyde. Therefore, when evaluating olive oil quality, the importance to

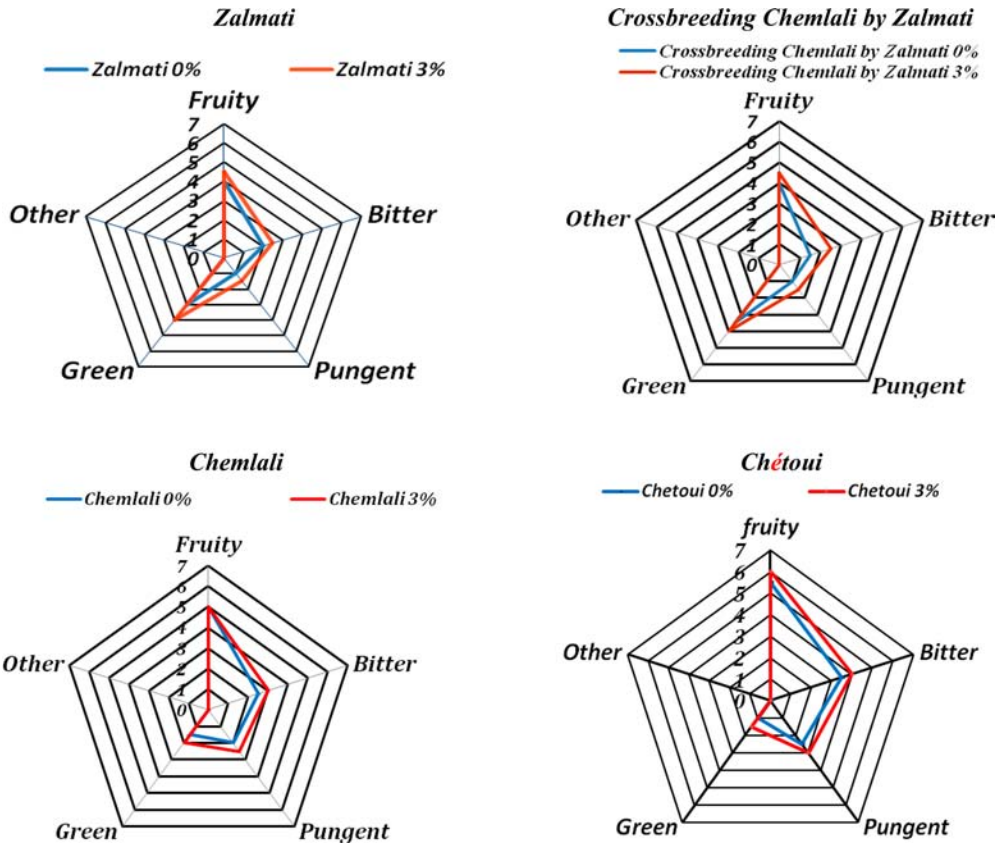

Figure 1. Sensory spider plot of extra-virgin olive oils for the Tunisian olive cultivars: Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati from Zarzis region extracted with different percentages (0 and 3%) of olive leaves.

study the ratio between hexanal and (*E*)-2-hexenal content was confirmed.

In the volatile alcohols component of the oil, no newly formed substances or considerable changes in the majority of volatile components was proven. An exception is a noticeable increase in some C6 alcohols, such as (*E*)-2-hexenol. The role of this compound in the flavor of olive oil is not clear. In fact, in the literature, only very few papers[25] have reported the presence of this compound, which could play a very important role in the fragrance of this valuable food. The highest percentage of this volatile fraction was detected in Zalmati and crossbreeding Chemlali by Zalmati oils. Such an increase could be explained by the method of olive leaves crushing (30.0% to 58.0% and 35.20% to 45.40% in 0% and 3% of added leaves added, respectively). The same observation is true in the case of Chemlali Zarzis. It has been shown that the enzymatic conversion of 13-L-hydroperoxides from linoleic and linolenic acids to the corresponding alcohols occurs primarily in the lamellae of chloroplasts.[18] Thus, we can estimate that the overall amounts of C6 aldehydes were clearly higher than the sum of C6 alcohols in Chétoui samples, as reported for virgin olive oil analyzed by others variety. Nevertheless, in Chemlali, Zalmati and crossbreeding Chemlali by Zalmati oils, the sums of C6 alcohols was generally higher than those of C6-aldehydes. However, Baccouri et al.[6] have shown that, in Chétoui oils, the sum of C6-alcohols was generally higher than that of C6-aldehydes. These results may be explained by the differential activity of the alcohol dehydrogenase (ADH) enzyme, which reduces the C6-aldehydic compounds to the corresponding alcohols due, among genetic factors, also to the region of growing of the plants.[43] Indeed, the Chétoui cultivar studied in this research work grows in the south of the country, while the samples studied by Baccouri et al.[6] have been harvested in the north.

1-Hexyl acetate and (*Z*)-3-hexenyl acetate, which contribute to the elicitation of pleasant fruity perceptions, are present in the aroma of all the studied olive oil samples, but they are minor components when compared with aldehydes or alcohols. These esters are synthesized by alcohol acetyl transferase (AAT) within the LOX pathway. Moreover, the absence of esters in the varieties Zalmati and crossbreeding Chemlali by Zalmati also point out the absence of alcohol acetyl transferase (AAT) activity in the olive oils compared with Chemlali and Chétoui varieties (6.40% to 6.70% and 6.30% to 9.60% with 0 and 3% leaves).

Several terpene hydrocarbons (mono- and sesquiterpenes) were detected in all the analyzed samples. Most of them were minor compounds of the volatile fraction not derived from fatty acid transformations. However, even if they occur in EVOO below their olfactory threshold they may provide useful quality markers. It is important to note that the main sesquiterpene (*E*,*E*)-α-farnesene a tetraun-saturated acyclic sesquiterpene, detected in all the oils was more abundant in Chétoui olive oil (4.60% to 5.30% for 0% and 3% of the added leaves, respectively) than in crossbreeding Chemlali by Zalmati olive oils (0.80% and 3% for 0% to 3% of added leaves, respectively). Zalmati and Chemlali olive oil had similar percentage to crossbreeding Chemlali by Zalmati olive oils with 3% of added leaves. α-Copaene is a monounsaturated sesquiterpene that has already been detected in Tunisian oils, mainly in those obtained from olives of the Oueslati variety.[44] The addition of 0−3% olives leaves seemed to slightly influence the contents of α-

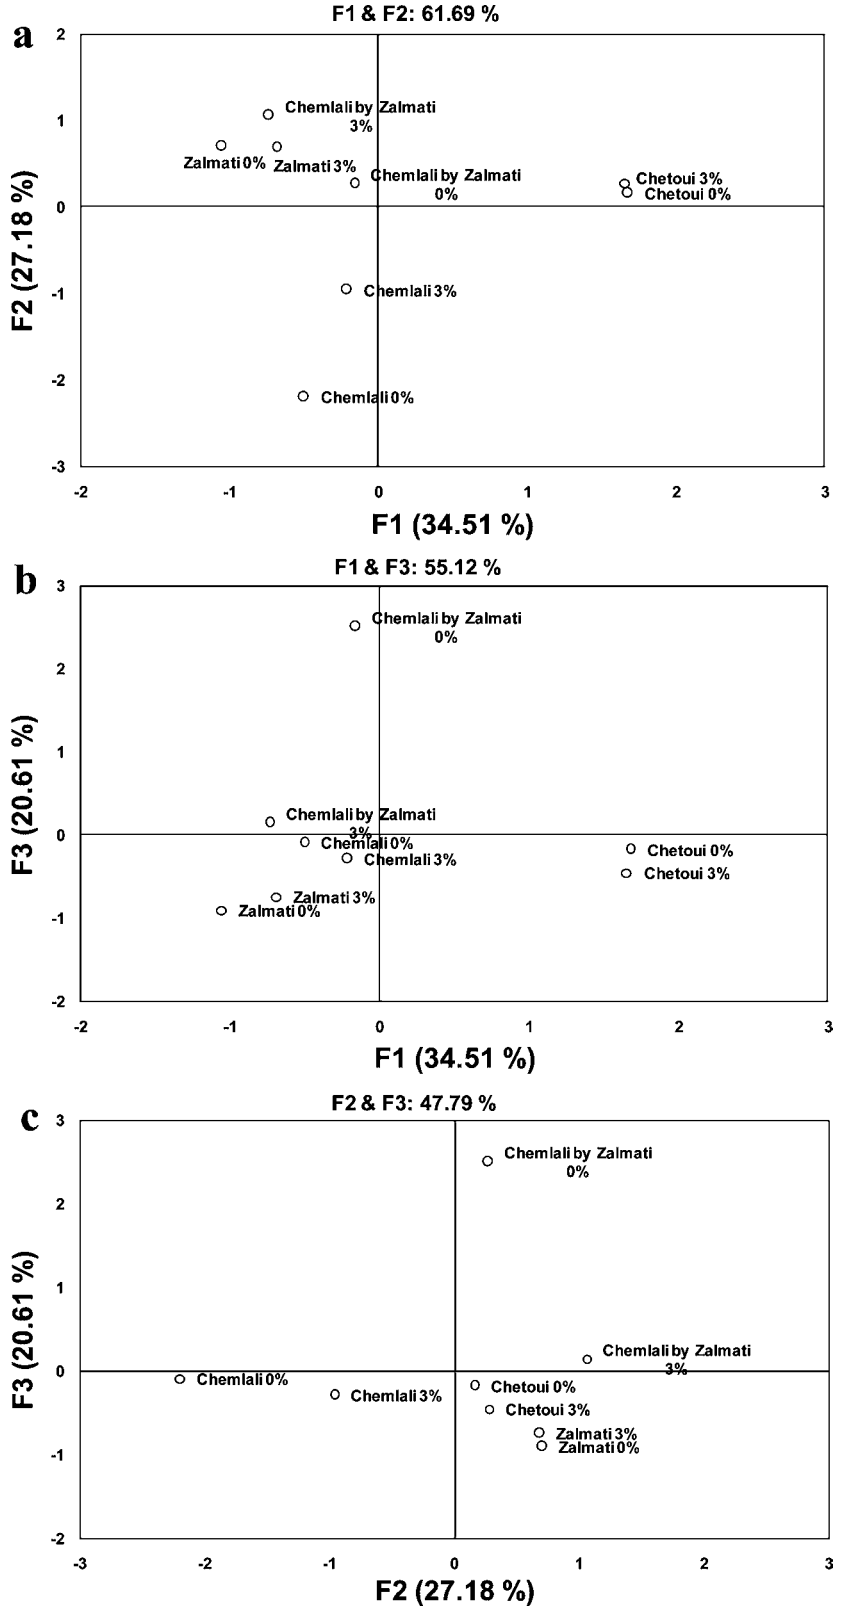

Figure 3. (a, b, and c) Principal components analysis based on all the analyses performed for the four olive oil varieties extracted with and without addition of olive leaves (3%).

copaene as also reported by Vichi et al.[45] Furthermore, this chemical was not detected in Chemlali, Zalmati, and cross-breeding Chemlali by Zalmati. It was only detected in low percentages in Chétoui olives oil (Table 3). These results are in agreement with those of Cecchi et al.,[46] which showed that terpene hydrocarbons show a large variability that depend on the olives variety.

dx.doi.org/10.1021/jf404395x | J. Agric. Food Chem. 2014, 62, 251−263

Sensory Analysis. Chemlali, Chétoui, Zalmati, and crossbreeding Chemlali by Zalmati cv, growing in Zarzis location, gave extra-virgin olive oils that are endowed with four positive descriptors: fruity, green, bitter, and pungent (Figure 1). The eight olive oils samples with and without the addition of olive leaves also showed the absence of any defects and had the typical fruity flavor preferred by consumers. Chemlali and Chétoui olive oils from Zarzis location were bitter and pungent, but very fruity. This result can be explained by the increase in the content of C6-compounds, especially the aldehydes, as reported by Angerosa.[13] This class of compounds is usually characterized by intense sensory descriptions associated with fruity and bitter sensory notes.[47] On the contrary, Zalmati and crossbreeding Chemlali by Zalmati oils from Zarzis were less bitter and pungent and acquired well-balanced fruity and green tastes probably due to the presence of C6-alcohols such as (*E*)-2-hexen-1-ol.[41]

On the other hand, in contrast to what is postulated by Angerosa,[13] incorporating leaves in concentrations of about 0−3% prior crushing, enhances the flavor of the oils from overripe fruits and improves their quality. The aroma is not distorted and tasters perceive higher intensities of green fruity, pungent and bitter taste. In fact, the analysis of the volatile compounds did not show any newly formed substances but a noticeable increase in C6 aldehydes (hexanal and (*E*)-2-hexenal) and C6-alcohols ((*E*)-2-hexen-1-ol), which are in good agreement with the results of the organoleptic evaluation.

Chemometric Analysis. PCA was used in exploratory analysis to characterize the effect of addition of olive leaves (3%) on the components of the extra-virgin olive oils from different varieties of Zarzis region, before the extraction process. PCA was applied to the data set of all performed analyses of EVOOs using the Varimax rotation with Kaiser Normalization, and three factors were selected justifying 82.30% of total variance (F1, 34.51%; F2, 27.18%; and F3, 20.61%) (Figures 2 and 3). Regarding these factors, the different varieties (enriched and unenriched oils with 3% of olive leaves) could be discriminated on the PCA diagrams (Figure 3a, b, and c). According to Figures 2(a, b) and 3(a, b), Chétoui and crossbreeding Chemlali by Zalmati varieties were related to the axe F1 which was dominated after the Varimax rotation by the following variables: oxidative stability, total tocopherols, C14:0, C16:0, C16:1($n-7$) + C16:1($n-9$), C17:0, C17:1($n-8$), C20:1($n-9$), (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, α-copaene, (*Z*)-β-farnesene, and (*E*,*E*)-α-farnesene.

According to Figures 2(a, c) and 3(a, c), Chemlali variety was related to the F2 axe which was dominated after the Varimax rotation by the following variables: peroxide value, total phenols, C18:0, C18:1($n-7$) + C18:1($n-9$), C18:2($n-6$)($n-9$), C18:3($n-3$)($n-6$)($n-9$), C20:0, C22:0, C24:0, 2-decanol, 1-hexyl acetate, and (*E*)-β-ocimene. Indeed, F2 clearly showed the effect of the enrichment of Chemlali oil with 3% of olive leaves, which is consistent with the results of mean comparison (Student−Newman−Keuls test).

Finally, Zalmati variety was related to the axe F3 according to Figures 2(b, c) and 3(b, c), which was dominated after the Varimax rotation by the following variables: free fatty acids, hexanal, (*E*)-2-nonenal, (*E*)-2-octen-1-ol, (*E*)-2-nonen-1-ol, *n*-dodecane, *n*-tetradecane, limonene and valencene.

In conclusion, our results confirm that olive oil quality is cultivar dependent. Hence, fatty acid compositions are useful for distinguishing the monovarietal olive oils belonging to particular cultivars, in which Chemlali and Chétoui oils showed the best fatty acid composition compared to that of Zalmati and crossbreeding Chemlali by Zalmati (lowest palmitic acid and the highest oleic acid). Concerning the leaves addition prior the fruits extraction process, it induces significant increases ($p < 0.05$) mainly in peroxide value and phenols and tocopherols contents, as well as oxidative stability. In addition, the application of SPME to the analysis of extra-virgin olive oil headspace allowed the detection of significant differences in the proportions of volatile constituents from oils of different varieties and the addition of olive leaves prior the fruits extraction processes. Evidently, the addition of 3% of olive leaves promoted the increase in C6 compounds specially the hexanal, (*E*)-2-hexanal and (*E*)-2-hexan-1-ol. Finally, the results obtained provide information on the performance of the studied Tunisian cultivars. The studied olive oils showed chemical profiles corresponding to extra-virgin olive oil category (high quality) and good sensory attributes highly appreciated by the consumers.

ABSTRACT: A large amount of (*all-E*)-lycopene was successfully purified from tomato paste using an improved method that included a procedure to wash crystalline powder with acetone. The total yield of the pure (*all-E*) form was at least 30%. The melting point of (*all-E*)-lycopene was determined to be 176.35 °C by differential scanning calorimetry (DSC) measurements. Bathochromic shifts were observed in the absorption maxima of all solvents tested (at most a 36 nm shift for λ_2 in carbon disulfide, as was observed in hexane) and were accompanied by absorbance decreases, namely, a hypochromic effect, showing a higher correlation between the position and the intensity of the main absorption bands. This bathochromic shift was dependent upon the polarizability of the solvent rather than its polarity. The structure of (*all-E*)-lycopene in $CDCl_3$ and C_6D_6 was identified on the basis of one- and two-dimensional nuclear magnetic resonance (NMR) spectra, including ^1H and ^{13}C NMR, homonuclear correlation spectroscopy ($^1H-^1H$ COSY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond connectivity (HMBC). The rate constants of the decrease in (*all-E*)-lycopene with hexane and benzene were calculated to be 3.19×10^{-5} and 3.55×10^{-5} s^{-1}, respectively. The equilibrium constants between (*all-E*) and (13*Z*) isomers were estimated to be 0.29 in hexane and 0.31 in benzene, respectively, from the point at which the amount of (13*Z*)-lycopene reached its maximum.

KEYWORDS: *lycopene, purification, tomatoes, spectrum analysis, thermal isomerization, density functional theory*

INTRODUCTION

Lycopene is a well-known carotenoid found abundantly in vegetables and fruits with a red color, such as tomatoes, red carrots,[1] watermelons, and gac (*Momordica cochinchinensis*),[2] as well as in microorganisms, such as *Dunaliella salina*,[3] *Chlorella* spp.,[4,5] and *Blakeslea trispora*.[6,7] Lycopene, like other carotenoids, is responsible for the characteristic bright color of these organisms and plays a protective role against oxidative stress.[8−10] The natural benefits of lycopene have been applied not only to food and dietary supplements as edible colorants and antioxidants but also to medical approaches to cancer and arteriosclerosis prevention,[11−13] taking advantage of its physiological properties and biocompatibility. These useful functions of lycopene, the molecular formula of which is $C_{40}H_{56}$, have been attributed to its chemical structure containing many unsaturated bonds, in which 11 double bonds are conjugated (Figure 1), and more effectively allow for the absorption of relatively long-wavelength light and quench singlet oxygen. Therefore, many researchers have studied this useful pigment and published excellent reports from the middle of the 20th century.[14−19] However, these studies were performed with lycopenes prepared from different origins and with different purification degrees, which may lead to a misunderstanding because of different values for basic physicochemical properties.

Although most of the lycopenes are known to be present in the (*all-E*) configuration in tomatoes and other vegetables, 71 kinds of (*Z*) isomers are theoretically possible.[20] However, bioavailability of the (*Z*) isomers of lycopene by lymph-cannulated ferrets[21] and a human intestinal cell model[22] was shown to be significantly greater than that of the (*all-E*) isomer. Therefore, an efficient method to improve the isomerization of (*all-E*) to the (*Z*) configuration is desired, with isomerization kinetics only being investigated in unpurified mixtures.[23,24]

Under these circumstances, we performed an extraction of (*all-E*)-lycopene with higher purity from a tomato paste and determined its physical and chemical properties, including some spectrophotometric measurements. The isomerization of lycopene by a heating apparatus was also investigated by chromatography. The results of our study give new criteria for the identification of lycopene and contribute to the fundamental chemistry of this carotenoid in the food science and technology field.

MATERIALS AND METHODS

Reagents. All reagents and solvents used were analytical-grade, except for methanol, which was high-performance liquid chromatography (HPLC)-grade (Sigma-Aldrich, St. Louis, MO), and were used without any further purification.

Extraction and Purification of (*all-E*)-Lycopene. All procedures were performed at room temperature, unless otherwise indicated. A total of 500 mL of dichloromethane was added to 50 g of tomato paste (Kagome Co., Ltd., Tokyo, Japan; lycopene content, 8−12 g/kg) in an Erlenmeyer flask, and the mixture was stirred for 60 min in darkness. The organic layer was separated with a separatory funnel, and repetitive extraction was performed on the resulting suspension by the same volume of dichloromethane. The solvent was evaporated on a rotary evaporator under a vacuum (170 mmHg) at 25 °C for 30 min. The crude extract (345 mg) containing lycopene was dissolved in 15

mL of benzene at 60 °C within 10 min and recrystallized at 4 °C for 4 h under shading. The resulting crystals were collected by suction filtration on a Kiriyama funnel (number 5B filter paper), rinsed with 100 mL of acetone, and dried *in vacuo*: 188 mg of fine red crystalline powder, with a melting point (mp) of 176.35 °C [differential scanning calorimetry (DSC)]; HPLC, ≥99.3%; ultraviolet/visible (UV/vis), Table 1; infrared (IR) (KBr), Table 2; nuclear magnetic resonance (NMR), Table 3; high-resolution mass spectrometry−fast atom bombardment (HRMS−FAB) (*m*/*z*) [M + H] $^+$ calcd for $C_{40}H_{57}$, 537.4460; found, 537.4418.

Thermal Isomerization of Lycopene. Purified (*all-E*)-lycopene dissolved in 100 mL of organic solvent (hexane, 9.76 μM; benzene, 198 μM) was transferred into a three-neck flask equipped with a mechanical stirrer, a reflux condenser, and a gas inlet tube. The isomerization of lycopene was conducted at 50 °C with an oil bath in darkness under an argon stream. The reaction mixtures were sampled at intervals, and the contents of the lycopene isomers were analyzed by reversed-phase HPLC. The recoveries of the total lycopene isomers with hexane and benzene during the sampling periods were estimated to be 87.5 and 61.9%, respectively, by the HPLC method.

UV−Vis, Fourier Transform Infrared (FTIR), Mass, and NMR Spectroscopic Analyses. UV−vis spectra of the purified lycopene were measured in organic solvents over a scanning range of 200−600 nm, and the λ maxima of the compounds were determined. Spectra were recorded with a Hitachi U-2910 spectrophotometer (Tokyo, Japan).

IR spectra were obtained by JASCO FT/IR 4100 (Tokyo) using the KBr disc in the range of 4000−400 cm^{-1}.

The HRMS of (*all-E*)-lycopene was recorded in the positive-ion mode by FAB+ on a JEOL JMS-700T instrument (Tokyo), using 3-nitrobenzyl alcohol as the matrix.

NMR spectra of (*all-E*)-lycopene were recorded using a JEOL JMN-LA400 FT 400 NMR spectrometer at 400 MHz (^{1}H) and 100 MHz (^{13}C). Chemical shifts were recorded as the δ value (ppm) using tetramethylsilane (TMS) as an internal standard. Spectra were observed on $CDCl_3$ and benzene-d_6 (C_6D_6).

DSC. The melting point of purified (*all-E*)-lycopene was determined by DSC using a DSC-60A system (Shimadzu, Kyoto, Japan). DSC measurements were performed with aluminum sample pans and empty reference pans. Both the sample and reference were scanned at a heating rate of 5 K/min from 303 to 473 K under a nitrogen atmosphere with a flow rate of 50 mL/min. The mass of the sample was 7 mg. All measurements were performed in triplicate.

[a] ^{1}H and ^{13}C NMR were recorded at 400 and 100 MHz, respectively. s, singlet; d, doublet; dd, doublet of doublets; and m, multiplet.

HPLC Analysis. Reversed-phase HPLC analysis with a photodiode array detector (SPD-M10AVP, Shimadzu, Kyoto, Japan) was performed under the following conditions: column, YMC Carotenoid (250 × 4.6 mm inner diameter, 5 μm particles, YMC, Kyoto, Japan); solvent A, methanol/methyl *tert*-butyl ether (MTBE)/ H_2O (75:15:10, v/v/v); solvent B, methanol/MTBE/H_2O (7:90:3, v/v/v); gradient, started with 100% eluent A and ended with 100% eluent B over a period of 35 min; flow rate, 3.0 mL/min; and column temperature, 22 °C. A typical chromatogram of the lycopene isomers was obtained with a retention time and absorption maxima at (13*Z*)-lycopene [24.6 min; 440.0, 465.0, and 496.5 nm; and (*Z*) peak[25] at 361 nm with a relative intensity of 59.2% D_B/D_{II}], (9*Z*)-lycopene [27.6 min; 441.0, 467.0, and 497.5 nm; and (*Z*) peak at 361 nm with 13.7% D_B/D_{II}], (*all-E*)-lycopene (31.9 min; 445.0, 472.5, and 503.5 nm); and (5*Z*)-lycopene (32.6 min; 445.0, 472.0, and 503.5 nm). The quantification of all lycopenes was performed by peak area integration at 470 nm, showing a reliable approximation for the analysis of isomers.[26,27]

Computational Analysis. *Ab initio* and density functional theory (DFT) calculations on the infrared spectrum of (*all-E*)-lycopene were performed with Gaussian 03 software using the B3LYP functional and 6-31G(*d*) basis set.

RESULTS AND DISCUSSION

Physical Properties of (*all-E*)-Lycopene. In this study, a large amount of (*all-E*)-lycopene was successfully purified from tomato samples without laborious chromatographic procedures.[28,29] This improved method included a procedure to wash crystalline powder with acetone, in which the solubility of (*all-E*)-lycopene was low (ca. 0.75 mg/mL).[30] The total yield of the pure (*all-E*) form (purity ≥ 99.3% by HPLC) was at least 30% when the lycopene content of the tomato paste was considered. The DSC curve for the purified lycopene showed two possible melting points of 170.66 and 176.35 °C. The lower value may be attributed to the (*Z*)-lycopenes, which arose from the (*all-E*) form because of the heating process. The content of the (*all-E*) form was reduced to 61.6% by reversed-phase HPLC for

dx.doi.org/10.1021/jf404497k | J. Agric. Food Chem. 2014, 62, 264−269

lycopene samples after the DSC measurement. The melting point of (*all-E*)-lycopene was then determined to be 176.35 °C, which was consistent with the value obtained by Manchand et al.[18]

Lycopene has an electron spectrum characterized by 11 conjugated double bonds, which geometrically impose a linear and highly planar structure. In hexane, (*all-E*)-lycopene showed strong absorption maxima at 502.5, 471.0, and 444.0 nm with molar extinction coefficients estimated as 168×10^3, 182×10^3, and 118×10^3 (Table 1), corresponding to vibrational transition energies of 0−0, 0−1, and 0−2, respectively. The peak at approximately 360 nm, the so-called (*Z*) peak,[25,31] was not observed in this sample.

Furthermore, absorption maxima and molar extinction coefficients with (*all-E*)-lycopene were measured in various organic solvents to investigate the solvent effect on the electronic spectrum of the molecule (Table 1). All values for the maxima (λ_2) of the fine structure in this study were also consistent with the calculated values according to an empirical rule.[32−34] The values (λ_1, λ_2, and λ_3) listed in this table were plotted as a function of wavelength in Figure 2A. From these

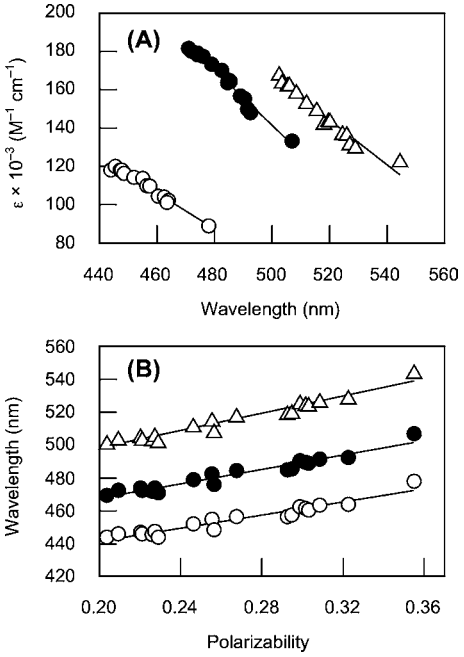

Figure 2. Relationships (A) between the absorption maxima and molar extinction coefficients of (*all-E*)-lycopene in various solvents and (B) between the polarizabilities of the solvents and the absorption maxima. The values of (○) λ_1, (●) λ_2, and (△) λ_3 are from Table 1. Polarizability of the solvent is calculated as follows: $(n^2 - 1)/(n^2 + 2)$, where *n* is the refractive index of the solvent.[39]

results, bathochromic shifts in the absorption maxima were observed in all solvents tested (at most a 36 nm shift for λ_2 in carbon disulfide, as was observed in hexane) and were accompanied by absorbance decreases, namely, a hypochromic effect, showing a higher correlation between the position and the intensity of the main absorption bands. Although many studies suggested that the bathochromic shift had been independently reported previously,[35,36] the highly purified (*all-E*)-lycopene had first enabled a discussion of the solvent effect on this carotenoid. This bathochromic shift depends upon the polarizability of the solvent because of high correlation between them (Figure 2B)[37] rather than its polarity (data not shown). This is the first report showing the solvent effect on the electron spectra of (*all-E*)-lycopene, because this was difficult to evaluate before as a result of samples having different purification grades with different origins. This finding contributes to the fundamental chemistry of carotenoids and will be a new criterion for the identification and evaluation of lycopene in agriculture, food, and medical fields.

The IR spectrum of (*all-E*)-lycopene was measured, and characteristic absorptions were shown in Table 2, along with those calculated by the Gaussian program. Observed and calculated values from C−H and C═C stretches and C−H out-of-plane attributed to the alkene as well as other origins were consistent with each other. This computational estimation with high fidelity may depend upon the restriction of the molecular motion of lycopene caused by the 11 conjugated double bonds. Therefore, these observations will facilitate an evaluation of the relative free energy of (*Z*) isomer lycopenes, which may be contained in foods or originate from heat-induced isomerization.

NMR Assignment of (*all-E*)-Lycopene. The structure of (*all-E*)-lycopene has been identified on the basis of one- and two-dimensional NMR spectra, including ^{1}H and ^{13}C NMR, homonuclear correlation spectroscopy (^{1}H−^{1}H COSY), heteronuclear multiple-quantum coherence (HMQC), and heteronuclear multiple-bond connectivity (HMBC). Chemical shifts for proton and carbon signals of the (*all-E*)-lycopene in this work were good accordance with those of the synthetic (*all-E*)-lycopene[38] (Table 3). Spectral data on (*all-E*)-lycopene in $CDCl_3$ were also independently reported by different literature;[40−42] however, some values reported were not consistent among the previous studies, e.g., for the coupling constants of protons H−C(11), H−C(11′) and the chemical-shift value of carbon atoms C(14), C(14′). In our study with thoroughly purified lycopene, the coupling constant values between H−C(11), H−C(11′) and H−C(10), H−C(10′) and between H−C(11), H−C(11′) and H−C(12), H−C(12′) were measured as 11.4 and 14.9 Hz, respectively. The chemical shift for C(14), C(14′) could be assigned to the signal observed at 132.64 ppm by the HMQC experiment, and refinement of the NMR signal assignment of (*all-E*)-lycopene was then achieved in $CDCl_3$.

Measurements were subsequently performed in another solvent, C_6D_6, in expectation of NMR signal charts distinct from those obtained in $CDCl_3$ because of differences in their physical properties, such as polarity, resonance, and viscosity. Proton and ^{13}C signals in C_6D_6 were preliminarily assigned by the results obtained in $CDCl_3$ and ascertained by ^{1}H homonuclear decoupling and the nuclear Overhauser effect difference (NOE-dif) experiments in addition to the above two-dimensional measurements. As shown in Table 3, chemical shifts in methyl protons between H−C(19), H−C(19′) and H−C(20), H−C(20′) were discriminated in C_6D_6 at 1.925 and 1.876 ppm, respectively (Table 3), whereas these signals appeared as a singlet at 1.968 ppm in $CDCl_3$ (this study and refs 40 and 41). Furthermore, the coupling system between H−C(14), H−C(14′) and H−C(15), H−C(15′) could be analyzed in C_6D_6, whereas their corresponding signals in $CDCl_3$ overlapped with H−C(8), H−C(8′) and H−C(11), H−C(11′), respectively, and were assigned to a multiplet. The observed spin signal occurred in the AA′BB′-type system, to which similar coupling was assigned in some carotenoids, such as prolycopene and (9*Z*,9′*Z*)-7,8,7′,8′-tetrahydrolycopene,[38,43]

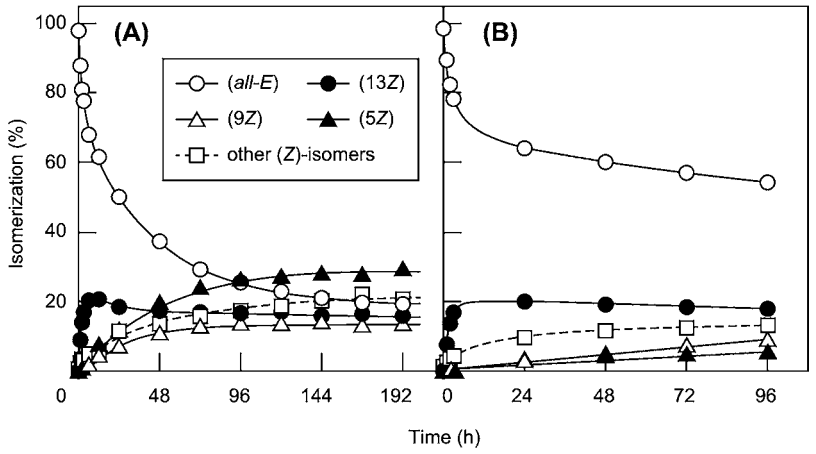

Figure 3. Isomerization of (*all-E*)-lycopene to (*Z*) isomers in (A) hexane and (B) benzene at 50 °C. Changes in the content percentage of (○) (*all-E*)-, (●) (13*Z*)-, (△) (9*Z*)-, and (▲) (5*Z*)-lycopene, as well as the other (*Z*) isomers (□), are presented with regard to the total amount of lycopenes resulting at each point of sampling.

and the full assignment of ^{1}H and ^{13}C signals was then given in Table 3. The unambiguous determination attained in this study will also help to analyze the (*Z*) isomers occurring in natural sources and those generated from the isomerization of (*all-E*)-lycopene by a heating process.

Thermal Isomerization of (*all-E*)-Lycopene. The isomerization of (*all-E*)-lycopene to (*Z*) isomers was investigated in hexane and benzene at 50 °C. The contents of (*all-E*)-lycopene rapidly decreased within a few hours in both solvents at this temperature and reached less than 20% for hexane and 55% for benzene during the test periods (Figure 3). Corresponding to the decrease in (*all-E*)-lycopene, (13*Z*)-lycopene emerged as the first (*Z*) isomer observed, and the content of the isomer gradually decreased after reaching its maximum of ca. 20% at 10 h. These decreases reflect the regeneration of (*all-E*)-lycopene and subsequent isomerization to other (*Z*) forms. The generation rates for (9*Z*) and (5*Z*) isomers were different in both solvents, and this may have led to the selective enrichment of a desirable isomer by taking advantage of the solvent effect.

The rate constants for the isomerization of lycopenes were then investigated on approximation to the one-order reaction.[44,45] The rate constants of the decrease in (*all-E*)-lycopene with hexane and benzene were calculated as 3.19×10^{-5} and 3.55×10^{-5} s^{-1}, respectively. It is necessary to evaluate the main kinetic parameters of lycopene isomerization in such a complex system that several equilibrium states can coexist. At the very early stage of these reactions, the reaction rate for the formation of (13*Z*)-lycopene overcome that of other isomers, which indicated that the reduction rate of (*all-E*)-lycopene could be approximate to the production rate of (13*Z*) isomer. The values obtained with lycopene were shown to be greater than those of the corresponding (13*Z*)-*β*-carotene and its derivative at 64 °C, apart from (15*Z*)-lycopene, which could not be observed in our or other studies.[44] According to the above approximation, the equilibrium constants between (*all-E*) and (13*Z*) isomers were estimated to be 0.29 in hexane and 0.31 in benzene, respectively, from the point at which the amount of (13*Z*)-lycopene reached its maximum.

Fundamental data for (*all-E*)-lycopene were obtained in the present study using an extremely purified extract from tomato paste, which provided a new insight into the spectroscopic and geometrical properties of lycopene. Moreover, the obtained thermal information of (*E*–*Z*) isomerization will contribute not only to the efficient production of (*Z*)-lycopenes that may give many benefits to human wellness but also to the identification of chemical and physical properties of the (*Z*) isomers.

Supporting Information

ABSTRACT: Most known allergenic proteins in rice (*Oryza sativa*) seed belong to the Tryp_alpha_amyl family (PF00234), but the sequence characterization and the evolution of the allergenic Tryp_alpha_amyl family members in plants have not been fully investigated. In this study, two specific motifs were found besides the common alpha-amylase inhibitors (AAI) domain from the allergenic Tryp_alpha_amyl family members in rice seeds (trRSAs). To understand the evolution and functional importance of the Tryp_alpha_amy1 family and the specific motifs for the allergenic one, a BLAST search identified 75 homologous proteins of trRSAs (trHAs) from 22 plant species including main crops such as rice, maize (*Zea mays*), wheat (*Triticum aestivum*), and sorghum (*Sorghum bicolor*) from all available sequences in the public databases. Statistical analysis showed that the allergenicity of trHAs is closely associated with these two motifs with high number of cysteine residues (p value = 0.00026), and the trHAs with and without the two motifs were clustered into separate clades, respectively. Furthermore, significant difference was observed on the secondary and tertiary structures of allergenic and nonallergenic trHAs. In addition, expression analysis showed that trHA-encoding genes of purple false brome (*Brachypodium distachyon*), barrel medic (*Medicago truncatula*), rice, and sorghum are dominantly expressed in seeds. This work provides insight into the understanding of the properties of allergens in the Tryp_alpha_amyl family and is helpful for allergy therapy.

KEYWORDS: *rice seed allergen, allergenic protein, Tryp_alpha_amyl family, evolution of trHAs, allergen-specific characteristics*

INTRODUCTION

Allergy is a major health problem frequently caused by allergens, which are recognized by the immune system and induce type-I hypersensitivity reaction in atopic individuals.[1] Common allergens in our daily lives are mainly proteins from plants including crops.[2] It has been reported that several proteins in wheat (*Triticum aestivum*), rice (*Oryza sativa*), soybean (*Glycine max*), peanut (*Arachis hypogaea*), and maize (*Zea mays*) can cause allergic responses in susceptible individuals.[3−6] Most of the plant food allergens that have been identified are proteins belonging to a few protein families and superfamilies, among which the Tryp_alpha_amyl family (pfam: PF00234) is the most widespread group, accounting for 16.88% of plant food allergens.[7]

The Tryp_alpha_amyl family includes plant lipid transfer proteins (LTP), seed storage proteins, and trypsin-alpha amylase inhibitors, and they share the alpha-amylase inhibitors (AAI) domain with a similar structure.[8−11] Pru p 3 (*Prunus persica*) and Cor a 8 (*Corylus chinensis*) were shown to be allergenic plant LTPs.[12,13] The structure of 7−9 kDa monomeric LTPs contains a hydrophobic tunnel formed by four disulfide bonds.[14,15] Some of the seed storage proteins such as Ber e 1 (*Bertholletia excelsa*) and Ses i 2 (*Sesamum indicum*) were shown to trigger allergy in hypersensitive patients.[16,17] Typical 2S albumin, a major group of storage proteins of the Tryp_alpha_amyl family, contains four disulfide bonds that link two polypeptide chains, forming a heterodimeric protein complex.[18] Trypsin-alpha amylase inhibitors such as Hor v 15 and Sec c 1 from barley (*Hordeum vulgare*) and rye (*Secale cereal*) also have been reported as allergenic multimers that contain four disulfide bonds.[19−22] Furthermore, studies showed that the Tryp_alpha_amyl family allergenic proteins are rich in cysteine and form three-dimensional structures with α-helices.[7,23,24]

In rice seeds, eight proteins, Os07g11320.1, Os07g11330.1, Os07g11360.1, Os07g11380.1, Os07g11380.2, Os07g11410.1, Os07g11510.1, and Os08g09250.1, have been reported as allergens because of their IgE-binding activity.[4,25−29] Particularly, seven of these seed allergens belong to the Tryp_alpha_amyl protein family, indicating that the Tryp_alpha_amyl protein family might play an important role in the allergenicity of plant foods. However, the genome-wide characterization and evolutionary analysis of the allergenic Tryp_alpha_amyl family members in plants have not been fully investigated.

In this study, we characterized the sequence features of trRSAs, rice seed allergens belonging to the Tryp_alpha_amyl family, and in silico identified the homologous proteins of trRSAs (trHAs) in all organisms with available genome sequence. In addition, the structures related to allergenicity of these trHAs were analyzed, and their evolutionary relationship

was also performed. Finally, the expression profiles were also discussed.

MATERIALS AND METHODS

Motif Identification and Annotation. The MEME tool (version 4.8.1) was used to elucidate conserved motifs among all rice proteins of the Tryp_alpha_amyl family.[30] To check whether trHAs contain the trRSAs-specific motifs, the FIMO tool (version 4.8.1) was used with a *p* value threshold of 0.001.[31] The sequence logo of motifs was retrieved from the output of MEME results and confirmed by WebLogo3.[32]

Homology Search and Tree Building. To search a comprehensive and nonredundant set of trHA homologues, the BLAST program was performed.[33] First, trRSAs' sequences were used for BLASTP in the nr (nonredundant protein sequences) database (organism: rice) of NCBI (National Center for Biotechnology Information) and MSU-RGAP (Rice Genome Annotation Project, release 7) protein sequences. Each obtained sequence was then used as the query sequence to perform TBLASTN in the following databases: NCBI nucleotide collection (nt), TAIR (The *Arabidopsis* Information Resource), Phytozome genome (version 8.0), and genomic databases in JGI (Joint Genome Institute). The algorithm parameters were set to be default. The redundant sequences within species with >95% identity were removed from our data set. The remaining sequences with *E* values below 1×10^{-4} were combined in our data set. To confirm the sequences we obtained, the amino acid sequences were searched using Pfam,[34] and the ones that were not included in the Tryp_alpha_amyl family (PF00234) were excluded from further analyses.

ClustalX2 was used for multiple sequence alignments with the default parameters, and Muscle was used to recheck the result.[35,36] The alignment was then adjusted manually by GeneDoc software.[37] A neighbor-joining (NJ) tree was constructed with the aligned trHAs protein sequences using MEGA (version 5) with the following parameters: poisson correction, pairwise deletion, and bootstrap (1000 replicates; random seed).[38] The views of the tree were constructed by interactive Tree Of Life (iTOL).[39]

Allergen Prediction Approaches. The allergen in trHAs was predicted using the criterion defined by FAO/WHO (Food and Agriculture Organization of the United Nations/World Health Organization) Codex alimentarius and SVM-AAC (Support Vector Machine–Amino Acid Composition).[40,41] The FAO/WHO criterion of exact match of a stretch of 8 or more amino acids was used in this study, because the evaluation showed that this level could ensure high sensitivity and specificity.[42] To study whether the allergenicity of trHAs is related to specific motifs significantly, one statistical method, Fisher's exact test, was performed by R.[43]

Expression Pattern Analysis. The expression data of rice trHAs were collected from RiceGE (Rice Functional Genomics Database) of SIGnAL (Salk Institute Genomic Analysis Laboratory, http://signal.salk.edu/) and SeedGeneDB (http://ibi.cqupt.edu.cn/sgdb/index.php), which integrated the raw array data from GEO (Gene Expression Omnibus). The corresponding data of trHAs of purple false brome (*Brachypodium distachyon*), barrel medic (*Medicago truncatula*), and sorghum (*Sorghum bicolor*) were collected from GEO (GSE10055, GSE10151, GSE36689, GSE30249, and GSE33391).

Statistical Analysis and 3D Structure Modeling. The instability index, GRAVY (grand average of hydropathicity), and amino acid composition of all trHAs were analyzed by ProtParam,[44] and the 3D structure of trHAs was modeled by SWISS-MODEL.[45] To understand the role of disulfide bonds in allergenic trHAs, Fisher's exact test was performed on trHAs in the number of sulfur atoms. For amino acid composition, a permutation test was used to analyze the statistical significance of the amounts of cysteine in allergenic trHAs, with random sampling 10000 times.[46] The Wilcoxon test was used on the differential analysis of secondary structure and cysteine enrichment analysis.[47] All of the *p* values of multiple tests in this study were corrected using the Benjamini–Hochberg procedure.[48]

RESULTS AND DISCUSSION

Sequence Characterization of Rice trRSAs. Previously seven proteins including Os07g11320.1, Os07g11330.1, Os07g11360.1, Os07g11380.1, Os07g11380.2, Os07g11410.1, and Os07g11510.1 from rice were identified as allergenic proteins within the Tryp_alpha_amyl family (trRSAs).[4,25] These *trRSA* genes are all localized on chromosome 7 (Table 1) and expressed dominantly in seeds, particularly in mature seeds, from the available microarray data (http://signal.salk.edu/cgi-bin/RiceGE) (Supplemental Figure 1). To study the sequence differences and conservation between trRSAs and other rice proteins in Tryp_alpha_amly family, we obtained a total of 114 rice proteins belonging to the Tryp_alpha_amyl family from RGAP (Rice Genome Annotation Project, http://

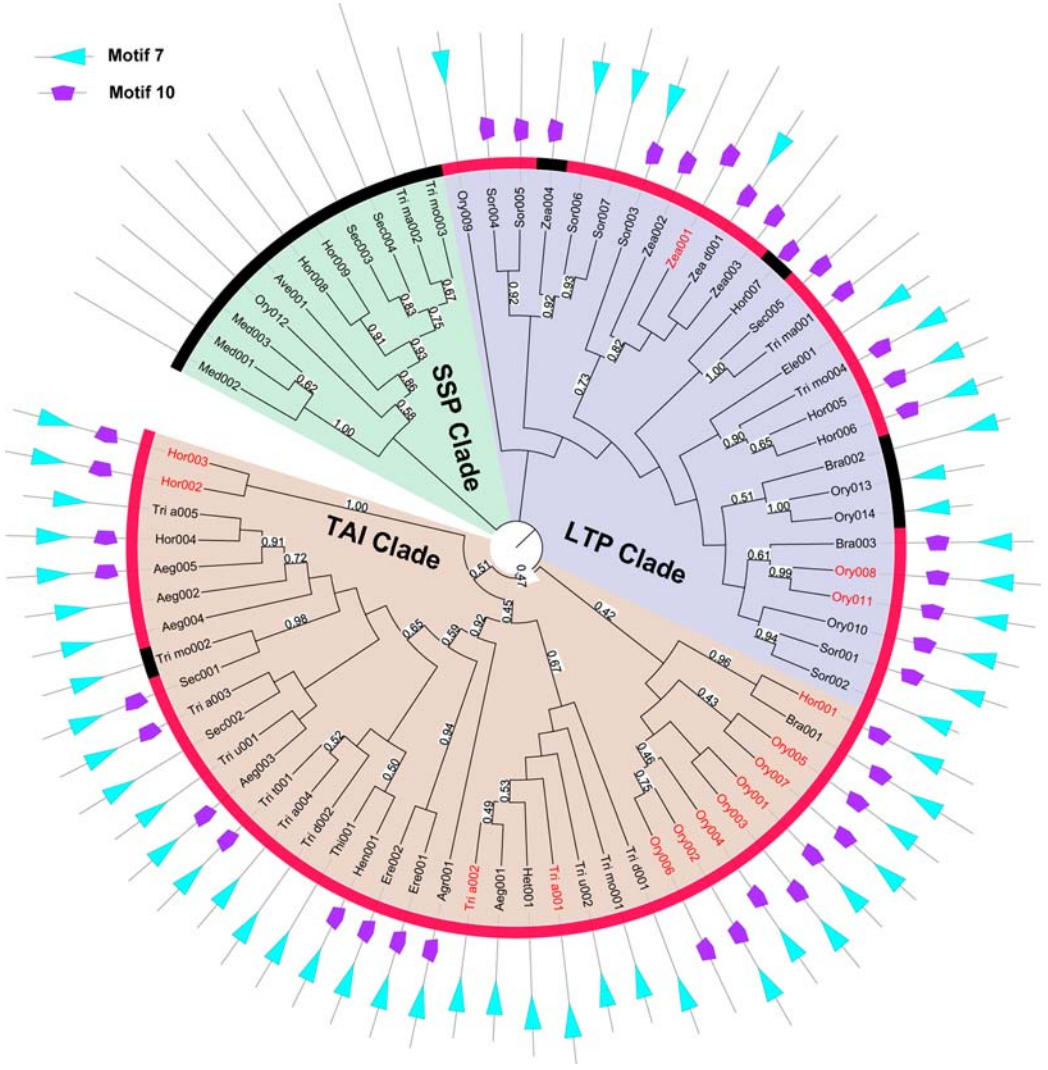

Figure 1. Phylogenetic tree of trHAs. 75 trHAs (see Supplemental Table 2) are grouped into three clades shaded in different colors. Bootstrap values are indicated in the branches of different clades. The color strip represents the putative allergenicity of each trHA: red identifies the trHAs predicted as allergen; black identifies the trHAs predicted as nonallergens. The outer domain architecture represents the existence of motif 7 and motif 10 and the relative length of each trHA.

rice.plantbiology.msu.edu/index.shtml) (Supplemental Table 1).

To characterize the sequence of these rice proteins of the Tryp_alpha_amyl family and explore the relationship among them, we searched the dominant motifs in these 114 proteins using MEME (with the parameters of $6 \leq$ width ≤ 50 and maximum number of motifs = 15)[49] and performed phylogenetic analysis using MEGA.[38] For conciseness of the display, we renamed all of the proteins in abbreviations containing the family domain name and the sequential number (Supplemental Table 1). As shown in Supplemental Figure 2, the seven known allergenic trRSAs were grouped into a specific subclade highlighted with red branches, and motif 7 having a length of 41 amino acids and motif 10 with 29 amino acids were found to be enriched among these trRSAs (Supplemental Figure 2). Thus, we proposed that the two specific motifs might be critical for the allergenicity of these proteins, and further analyses were performed to verify this point.

Phylogenetic Analysis of trHAs in Plants. To understand more trHAs from other organisms, we used the seven known rice trRSAs as BLASTP queries against all species with available genome sequences. We observed 75 putative trHAs encoded by 74 genes from 22 plant species, in which there were 21 grass species and barrel medic. This result suggests that trHAs might originate after the divergence of grass species; alternatively, the ancestors of trHAs may be lost in many other species during evolution. Similarly, all trHAs were renamed in abbreviations using the species name and the sequential number (Supplemental Table 2). To analyze the evolutionary relationship of the *trHA* genes, a NJ phylogenetic tree was generated through the multiple sequence alignments of the trHAs sequences using 1000 replicates (Figure 1).

As illustrated in Figure 1, these 75 trHAs were grouped into three clades: the seed storage protein (SSP) clade, the lipid transfer protein (LTP) clade, and the trypsin-alpha amylase inhibitor (TAI) clade named on the functional annotation. The SSP clade contained 11 members from 7 species: 3 from barrel medic, 1 from rice, 1 from wild oat (*Avena fatua*), 2 from barley, 2 from rye, 1 from *Triticum macha*, and 1 from einkorn wheat (*Triticum monococcum*) (Supplemental Table 3). Among them, Ory012 (LOC_Os05g41970.1) was identified as a 2S albumin seed storage protein, and the other 10 trHAs have

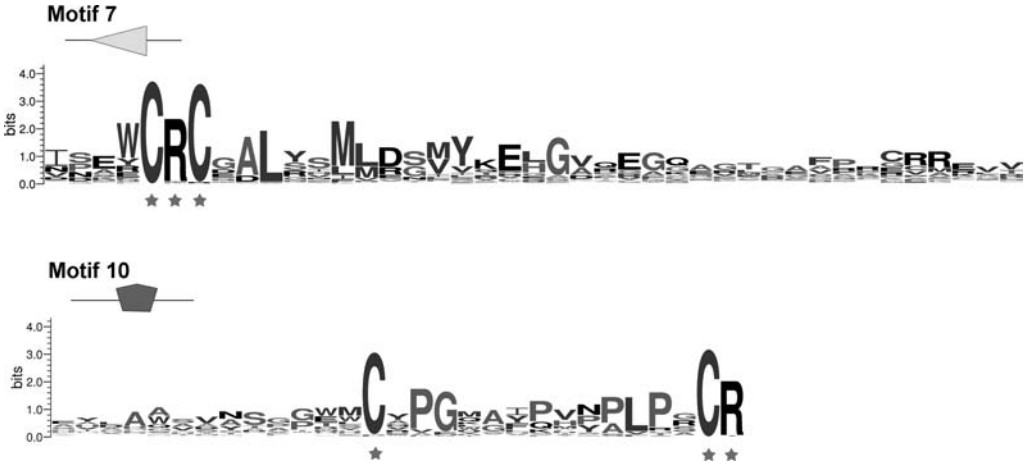

Figure 2. Analysis of conserved amino acid residues of motifs 7 and 10 in trHAs. Motifs are represented by position-specific probability matrices that specify the probability of each possible letter appearing at each possible position in an occurrence of the motif. The total height of the stack is the information content of that position in the motif in bits. The height of the individual letters in a stack is the probability of the letter at that position multiplied by the total information content of the stack. The bigger characters indicate the higher conserved residues by the alignment of motif sequences in trHAs. Highly conservative sites are marked with a star (★).

been reported as homologues of Ory012.[50] The LTP clade consisted of 27 trHAs from 10 species including rice, sorghum, purple false brome, barley, *Triticum macha*, einkorn wheat, finger millet (*Eleusine coracana*), rye, *Zea diploperennis*, and maize (Supplemental Table 3). An allergen from maize (Zea m 14, Zea001) in the LTP clade has been described as a LTP,[51,52] and six LTPs from rice named Ory008−Ory011, Ory013, and Ory014 are in this clade.[53] The third clade contained 37 trHAs from 15 species including rice, wheat, barley, goatgrass (*Aegilops*), einkorn wheat, rye, red wild einkorn (*Triticum urartu*), *Triticum timopheevii* subsp. *Armeniacum*, emmer wheat (*Triticum dicoccoides*), *Thinopyrum bessarabicum*, *Henrardia persica*, *Eremopyrum bonaepartis*, *Agropyron desertorum*, *Heteranthelium piliferum*, and purple false brome (Supplemental Table 3). Likewise, we called the third clade the trypsin-alpha amylase inhibitor clade because it had 7 rice trHAs and 11 wheat trHAs defined as trypsin-alpha amylase inhibitor (Figure 1).[19,26]

Figure 1 shows that all members of barrel medic were grouped into one subclade in the SSP clade and that all members of another subclade in the SSP clade were from Triticeae except one from rice. All trHAs in the LTP and TAI clades were from only monocot grasses (Figure 1). In addition, trHAs of Andropogoneae (sorghum, *Zea diploperennis*, and maize) were observed only in the LTP clade.

To analyze the evolution of the two motifs, motif 7 and motif 10, and their association with allergenicity in plants, we investigated their distribution in all trHAs shown in Figure 1. Interestingly, the trHAs with none of motif 7 and 10 were grouped into one clade (SSP clade, including a subclade of barrel medic members), whereas the trHAs containing motif 7 and/or motif 10 were clustered into the LTP and TAI clades (Figure 1).

Allergenic Analysis of trHAs in Plants. Among the 75 trHAs, 13 members including 7 rice trRSAs, 3 barley trHAs, 2 wheat trHAs, and 1 maize trHA have been reported as allergens (Supplemental Table 3).[3,26,51,54−56] To understand the allergenicity of all trHAs, we scanned each by allergen prediction approaches. One way is recommended by the FAO/WHO criteria by matching eight or more continuous amino acids with known allergens.[42] Another prediction method is SVM-AAC for measuring the false-positive rate (FDR).[41] We considered the candidates to be allergenic trHAs when they were identified as allergens by both of the two approaches. As shown in Figure 1, 58 trHAs were predicted as allergens (color strip, colored in red) and 17 trHAs were nonallergens (color strip, colored in black). All 13 reported allergenic trHAs were included in the putative allergens by prediction (Figure 1, red leaves).

From Figure 1, we observed that the trHAs in the SSP clade were all predicted as nonallergens, whereas most of the trHAs in the LTP and TAI clades were predicted as allergens (color strip). Specifically, all candidates containing neither motif 7 nor motif 10 were identified as nonallergens and 90.63% (58/64) of the members with motif 7 and/or motif 10 as putative allergens. To further investigate whether these two motifs are associated with trHAs' allergenicity, we compared the prediction results of trHAs with none of the two motifs to other trHAs, and the results showed the significant correlation between allergenicity and the existence of one or both motif 7 and motif 10 (Fisher's exact test, p value = 0.00026), suggesting that motifs 7 and 10 are involved in allergenicity.

Structure Analysis in Plant trHAs. *Enrichment of Cysteine Residues.* To further characterize the sequence features of motifs 7 and 10, we did alignment analysis of the trHAs containing motifs 7 and 10, respectively, and three consensus sites for motif 7 (5-C, 6-R, 7-C) and three for motif 10 (14-C, 28-C, 29-R) were observed (Figure 2, Supplemental Figure 3). Given that cysteines are the main conserved amino acids in these two motifs of trHAs, we analyzed the amino acid preferences of trHAs by comparing the amino acid compositions of trHAs with Swiss-Prot proteins to understand the importance of these cysteine residues. Here, the definition of amino acid composition is the percentage of each amino acid in a protein. As shown in Figure 3A, the amount of cysteine was significantly enriched in trHAs (permutation test, p value < 0.0001). As disulfide bonds are a typical feature for allergens in the Tryp_alpha_amyl family,[14,18] we further analyzed the distribution of sulfur atoms among trHAs and observed that the putative allergenic trHAs had more sulfur atoms than those of nonallergenic ones (Wilcoxon test, p value = 1.768×10^{-9}) (Figure 3B).

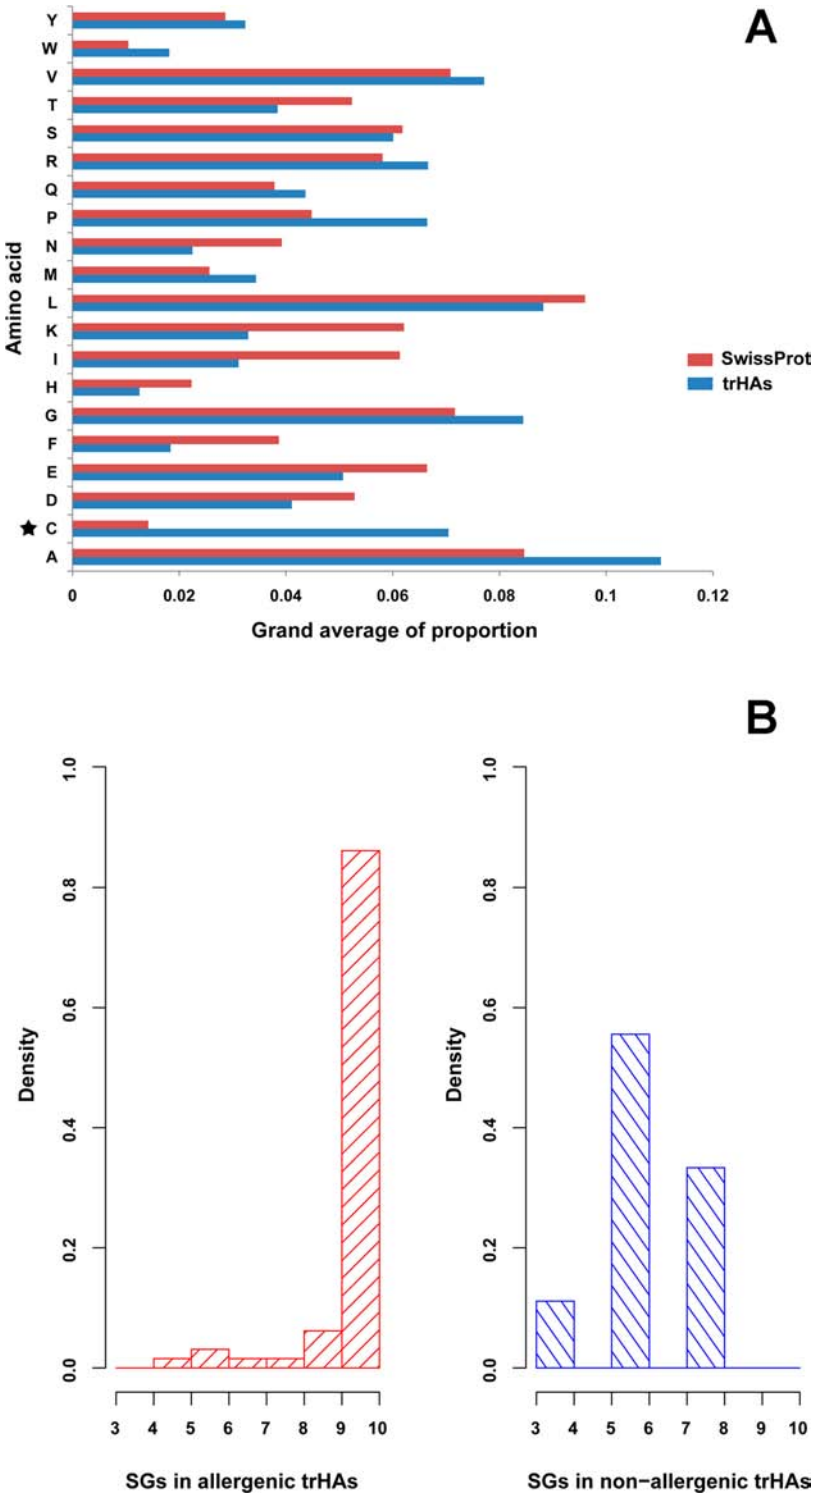

Figure 3. Comparison of amino acid composition of trHAs with the proteins in Swiss-Prot database. (A) The horizontal axis is the proportion of each amino acid in protein sequence, and the letters beside the vertical axis represent the 20 amino acids. Statistical results show significance on the amount of cysteine in trHAs (permutation test, p value < 0.0001), which is marked by a star (★). (B) Comparison of the number of sulfur atoms (labeled SG) of allergenic trHAs and nonallergenic trHAs (Wilcoxon test, p value = 1.768×10^{-9}).

Secondary Structure. We also analyzed the secondary structure of trHAs, which is associated with the protein's stability and function.[12,57] Generally, the secondary structure assignments of protein by DSSP are grouped into eight types including H (α helix), B (residue in isolated beta-bridge), E (extended strand, participates in beta ladder), G (3-helix, 3/10 helix), I (5 helix, pi helix), T (hydrogen bonded turn), S (bend), and blank (loop or irregular).[58] Our analysis data showed that the average percentage of H content in both putative allergenic and nonallergenic trHAs was the highest, which accounted for 40.75 and 48.43%, respectively, followed by the blank, T, and S, whereas the average percentages of B, E and G were much lower, and no I was observed in any trHAs (Figure 4). We made statistical analysis about the difference of

Figure 4. Preference of the secondary structure in trHAs. The types of secondary structure are from DSSP including H (α helix), B (residue in isolated beta-bridge), E (extended strand, participates in beta ladder), G (3-helix, 3/10 helix), I (5 helix, pi helix), T (hydrogen-bonded turn), S (bend), and blank (loop or irregular, represented as C here). The bottom table in this figure gives the p values of Wilcoxon tests showing the degree of variance of each secondary structure type between putative allergenic and nonallergenic trHAs.

each secondary structure of putative allergenic and non-allergenic trHAs. The results showed a significant difference in the compositions of H, B, E, and T between the two groups (Figure 4, Wilcoxon test). Specifically, nonallergenic trHAs contained more H-type secondary structure than those of allergenic ones with a p value of 0.0032. On the contrary, the contents of B, E, and T in the allergens are higher than in the nonallergens, and the corresponding p values are 0.0043, 0.0014, and 0.019, respectively (Figure 4).

3D Structure and Allergenicity. Three-dimensional (3D) structure is closely related to a protein's function.[59] To find the correlation of the characteristics of 3D structure with allergenicity of plant trHAs, we analyzed the 3D structure for all trHAs.[60] Analysis of the 3D structures of four representative trHAs randomly selected from four distinct groups, three allergenic trHAs groups containing both motifs 7 and 10, motif 7 only, motif 10 only, and one group of nonallergenic trHAs without any motif 7 or motif 10, revealed that allergenic trHAs were different from nonallergenic trHAs in 3D structure (Figure 5). The allergenic trHAs seemed more likely to have four alpha-helix and at least four disulfide bonds than nonallergenic trHAs (Fisher's exact test, p value = 1.259×10^{-5}) (Figure 5). Supportively, the trHAs with and without motif 7/10 were separated into different clusters by root mean square deviation (RMSD) analysis (Supplemental Figure 4A). Furthermore, analysis of the physicochemical properties also showed a distinct difference between the trHAs with and without specific motifs in grand average of hydropathicity (GRAVY). Specially, the GRAVY of most trHAs containing neither of the two motifs was below −0.2, whereas the figure for trHAs containing any/both of the specific motifs was > −0.2 (Supplemental Figure 4B), suggesting that the two specific motifs may increase the ability of hydropathicity.

Expression Patterns of trHAs of Purple False Brome, Barrel Medic, Rice, and Sorghum. To further understand the biological role of trHAs, we analyzed their expression patterns using the available information of purple false brome,

barrel medic, rice, and sorghum. Expression data of rice *trHA* genes from SIGnAL, and *trHA* genes of purple false brome, barrel medic, and sorghum from GEO (Figure 6) showed that

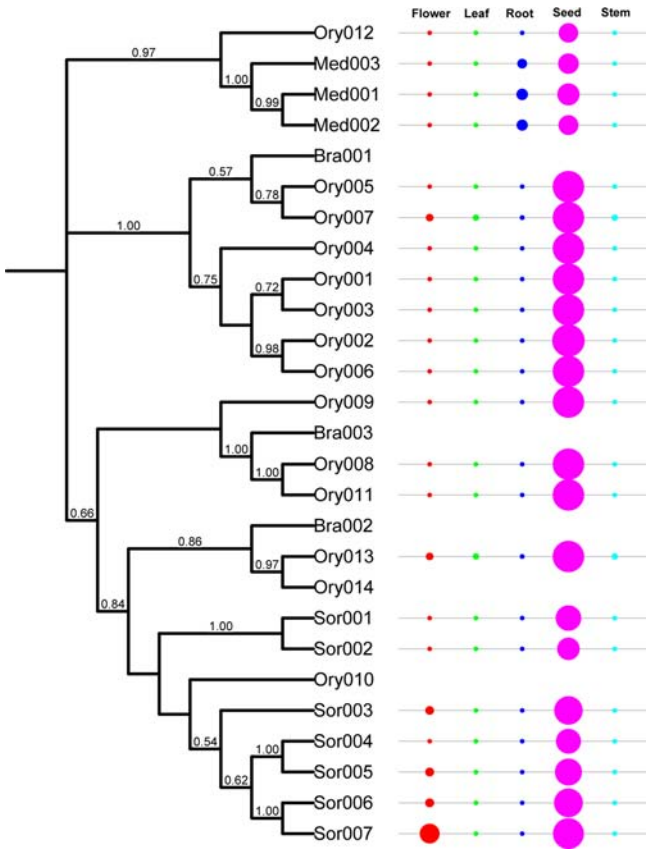

Figure 6. Expression patterns of trHAs in four species: expression pattern represented by solid circles in five tissues, that is, flower, leaf, root, seed, and stem. The area of the circle indicates the expression level, and higher expression level is indicated by a larger area.

trHA genes were preferentially expressed in seeds, suggesting that the trHAs have conserved transcriptional regulation in grass seeds. Supportively, previous papers showed the expression of rice trRSAs in maturing seeds.[4,25−29] Interestingly, trHAs of barrel medic had a higher expression in root than the other three species, suggesting that trHAs may be involved in root development processes in barrel medic (Figures 1 and 6).

Supporting Information

ABSTRACT: The effectiveness of grape seed extract (GSE) encapsulated in liposomes to inhibit the formation of heterocyclic aromatic amines (HAA) during frying of beef patties was assessed. All liposomal systems were prepared by high pressure homogenization at 22 500 psi. A total of six samples (rapeseed oil (control), GSE at 0.1% and 0.2%, and GSE-containing liposomes with 1%, 2%, and 5% soy lecithin) were investigated. MeIQx (2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline), PhIP (2-amino-1-methyl-6-phenylimidazo[4,5*b*]pyridine), Norharman, and Harman were found after the marinade application and frying. PhIP concentrations decreased upon marination with GSE (0.1%) and GSE-containing liposomes (1% and 5%) ($p < 0.05$). MeIQx contents decreased in all samples compared to the oil control ($p < 0.01$) while no effect on β-carboline formation was observed. Results are in contrast to previous studies that had shown that liposomal encapsulation may enhance effectiveness of polyphenols to inhibit radical reactions. A mechanistic model was proposed to explain the observed differences.

KEYWORDS: *liposomes, grape seed extract, heterocyclic aromatic amines, phenolic compounds, beef patties*

INTRODUCTION

Diet plays a vital role in maintaining human health, and many studies have been carried out that demonstrate a cause and effect relationship between diet and disease, especially if harmful substances are present in food. Heterocyclic aromatic amines (HAA) are such compounds, as they have been shown to exhibit carcinogenic and mutagenic activities. They are formed in meat and fish when cooked at high temperatures (≥150 °C).[1,2] HAA are classified into two groups based on the temperatures that are prevalent during their formation. HAA formed at temperatures between 100 °C and 300 °C are known as "thermic HAA", IQ type, or aminoimidazoazaarenes (AIA) while HAA produced at higher temperatures (>300 °C) are known as "pyrolytic HAA" or non-IQ type.[3] Their concentration has been found to depend on meat type, cooking parameters (duration, temperature, equipment, and methods), pH, water activity, creatine concentration, amount, and type of carbohydrates, as well as free amino acid content.[4] Several studies have demonstrated the progressive decrease of HAA in the presence of compounds with antioxidant activity, such as vitamin E, fruit extracts, plant extracts, carotenoids, spices, beer, wine, and polyphenols.[5−8]

A wide variety of polyphenols exist in nature, with compounds exhibiting significant antioxidant activities thereby inhibiting radical reactions. Moreover, they have been found to display beneficial physiological functions, such as, for example, anticarcinogenic activity.[9] These potent antioxidants, however, can lose their efficacy when subjected to high temperatures or exposed to oxygen or light-sources. To improve their stability and also control release, researchers have worked on a rational design of encapsulation systems that are compatible with the application matrix and enable protection from degradation.[10,11] Such encapsulation approaches have shown to not only improve chemical stability but also to alleviate unpleasant taste or flavor and improve the compounds' in vivo and in vitro bioavailabilities.[12] Different studies have demonstrated that the activity of polyphenols in particular may be maintained and/or enhanced by encapsulation.[13]

Microencapsulation can be performed by different techniques, such as spray drying, spray chilling, fluidized bed coating, extrusion coating, coacervation, inclusion complexation, centrifugal extrusion, rotational suspension separation, and liposome entrapment.[14] The latter method involves the use of lipid bilayer vesicles that enclose aqueous compartments, allowing in principal the conveyance of a wide variety of molecules having different polarities. Recent studies have shown that liposomes are particularly well suited to carry bioactive compounds of an amphiphilic nature.[15] Liposomal encapsulation, therefore, is a powerful technological tool that can be helpful in producing high-quality foods. The controlled delivery of bioactive compounds can lead to an enhanced absorption of such molecules and to food systems that are more stable having extended shelf-lives.[16−18]

The polyphenols in grape seed extract (GSE) consist mainly of flavonoids, including gallic acid, monomeric flavan-3-ols catechin, epicatechin, gallocatechin, epigallocatechin, and epicatechin 3-*O*-gallate, and procyanidin dimers and trimers and the more highly polymerized procyanidin.[19] Such compounds, when encapsulated in liposomes, have shown to be predominately localized in the bilayer membrane, and only a small part of the substances are found in the inner

compartment of the liposomes.[20] In model systems these capsules have proven to be highly effective in inhibiting radical reactions.[21] However, only a few studies have been conducted that have investigated their functionalities in complex foods such as, for example, meats and meat products.

The aim of this work was to evaluate the efficiency of the encapsulation of polyphenols from GSE in liposomes and to assess their functionality with respect to HAA formation in fried beef patties after marination. We hypothesized that liposomal-entrapped GSE may have a higher inhibitory effect on the formation of HAA, as liposomes provide large surfaces which can readily interact with the meat compounds that generate HAA. Moreover, liposomes could facilitate a burst release upon heating, which might be beneficial to inhibit the initial stages of the propagating reaction.

MATERIALS AND METHODS

Materials. Soy lecithin (Lipoid S75) was provided by Lipoid (Ludwigshafen, Germany). The contents of phosphatidylcholine, phosphatidylethanolamine, and lysophosphatidylcholine were 69.3%, 9.8%, and 2.1%, respectively, according to the company's specifications. The concentration of the antioxidant DL-α-tocopherol was 0.18%, and the fresh lecithin standard had a maximal peroxide value specification of 3 mequiv O_2/kg (1.5 mmol O_2/kg). The grape seed extract (GSE; *Vitis vinifera L.*) had a procyanidins content of ≥30% (calculated as cyanidin chloride) and a total content of polyphenols of ≥40% (calculated as anhydrous gallic acid) according to the manufacturer's specification; GSE was provided by the Martin Bauer Group Plantextrakt GmbH & Co.KG. (Vestenbergsgreuth, Germany). SephadexG50, Triton X100, gallic acid, sodium acetate, acetic acid, hydrochloric acid, ammonium hydroxide solution, sodium hydroxide, and Folin−Ciocalteu reagent were purchased from Sigma-Aldrich (St. Louis, MO). Ethyl acetate, toluene, methanol, acetonitrile (HPLC grade), triethylamine, and orthophosphoric acid (20%) were supplied by Merck (Darmstadt, Germany). A silica column, propylsulfonic acid (PRS) (500 mg), and C18 (500 mg and 100 mg) solid-phase extraction (SPE) cartridges were purchased from Varian (Palo Alto, CA). The HAA standards IQ, IQx, MeIQ, MeIQx, 4,8-DiMeIQx, 7,8-DiMeIQx, PhIP, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2, AαC, and MeAαC were obtained from Toronto Research Chemicals (Toronto, Ontario, Canada). Norharman and harman were supplied by Sigma-Aldrich (St. Louis, MO). The standards were used to prepare a mixed stock standard solution with final concentration of 19.7, 22.8, 21.3, 13.6, 12.9, 12.5, 9.6, 6.5, 5.9, 7.4, 9.4, 5.3, 5.0, 4.9, and 4.1 ng in 100 μL of methanol, respectively (concentrations of HAA in order as described above). All stock solutions were corrected by means of the extinction coefficient.[22] Caffeine was used as an internal standard at a concentration of 2.5 μg/mL in ultrapure water and methanol (1:1, v/v).

Preparation of Liposomes. Liposomes were prepared with different percentages of soy lecithin (1%, 2%, and 5%). Soy lecithin was dispersed in an acetate buffer system (0.25 mol/L, pH 3.8) containing GSE at 0.1% and 0.2%. The GSE-containing buffer system was prepared in ultrapure water and filtered with a folded cellulose filter (Whatman-VWR, Darmstadt, Germany). The GSE solution had been characterized in an earlier study by LC/MS/MS,[23] by a method suggested by Maier et al.[19] The main components of the filtered extract were procyanidin B1 (19.3 mg/g), (+)-catechin (19.1 mg/g), (−)-epicatechin (10.3 mg/g), procyanidin B2 (5.3 mg/g), gallic acid (2.6 mg/g), and (−)-epicatechin gallate (2.1 mg/g). Galloylated dimeric procyanidin and dimeric procyanidins were also found by HPLC-ESI-MS/MS.[19] The mixture was predispersed using a magnetic stirrer overnight and was passed five times through a high-pressure homogenizer consisting of a diamond chamber at 22 500 psi (M110-EH-30, Microfluidics International Cooperation, Newton, MA) to form finely dispersed liposomes incorporating GSE.

Zeta Potential and Average Particle Diameter Measurements of Liposomes. Liposomal charge and z-average particle diameter were determined by dynamic light-scattering (Zetasizer Nano ZS, model ZEN3600, Malvern Instruments, Malvern, UK) at 25 °C. The samples were diluted approximately nine times with the acetate buffer (0.25 mol/L, pH 3.8) and transferred into cuvettes for size determination (DTS1060, Malvern Instruments). The instrument measures the size of particles by determining their Brownian motion at a backscattering angle of 173°. The charge of particles is determined by applying an oscillating electric field and measuring the electrophoretic mobility of particles via light scattering. The z-average particle size and zeta potential were determined immediately after liposome preparation and throughout the four weeks of storage. For each sample, the measurement was repeated twice at 25 °C.

Determination of Total Phenolic Compounds by Folin−Ciocalteu Assay. Two GSE solutions (0.1% and 0.2%) were prepared by dissolving the dried GSE in acetate buffer (pH 3.8 ± 0.2; 0.25 M), stirring for 30 min, and filtering with folded filters. The amount of phenolic compounds was determined in the extract and in the liposomes after encapsulation and after gel filtration according to the Folin−Ciocalteu assay.[24] Liposomes were deliberately destabilized by adding 3 mL of 15 wt % Triton X100 to the samples for the determination of polyphenols in bilayers. The spectrophotometric measurements were carried out at 720 nm, after a 60-min reaction. The results were expressed as milligrams of gallic acid per gram of extract. The encapsulation efficiency of liposomes containing extract was calculated by the amount of total polyphenols of liposomes containing GSE after gel filtration and treatment with the surfactant Triton X-100 divided by the concentration of total polyphenols treated with Triton X-100.

Preparation of Samples and Pan-Frying Trials. Deep-frozen beef patties were obtained from Salomon Hitburger (Grossostheim, Germany). A total of 72 deep-frozen beef patties (62.5 g, 112 × 105 mm, thickness 10 mm) were marinated with 10 g of marinade solution ($n = 6$ for each experimental treatment). As controls, a treatment marinated with rapeseed oil and two treatments marinated with 0.1% and 0.2% unencapsulated (free) GSE were used. Liposomal treatments consisted of solutions containing 1%, 2%, and 5% of soy lecithin and two different GSE concentrations (0.1% and 0.2%) (Table 1). The

dx.doi.org/10.1021/jf4035332 | J. Agric. Food Chem. 2014, 62, 279−287

marination time was 3 h at 8 °C. The marinated beef patties were fried on a double contact grill (Nevada, Neumarker, Hemer, Germany) and heated at 220 °C for 2 min 40 s, as previously described by Gibis et.[6] The core temperature was monitored using a data logger (Therm 3280-8M, Ahlborn, Holzkirchen, Germany). Meat samples were stored under vacuum conditions in the freezer (−18 °C) until analysis. All measurements were repeated at least three times using two replicates. Means and standard deviations were calculated from these measurements with Excel (Microsoft, Redmond, VA).

Determination of HAA. Concentrations of 15 polar and nonpolar HAA were determined using a modified HPLC method[25] based on the method described by Gross and Grueter.[26] Briefly, crushed patties were homogenized with 1 M sodium hydroxide solution. Two homogenates were spiked with 100 μL of the standard mixture. Diatomaceous earth was added and mixed to each of the four equivalent homogenates. HAA were extracted from the patties by multiple solid-phase extractions. HAA were eluted with an ethyl acetate solution containing 5% toluene (100 mL) and adsorbed onto a coupled preconditioned cation exchanger PRS cartridge which had been preconditioned with a mixture of ethyl acetate and 5% toluene. After the PRS cartridge had been dried and washed with 0.01 M HCl solution, the nonpolar HAA were eluted with 15 mL of a mixture of 0.01 M HCl:methanol (2:3, v/v). The nonpolar fraction was purified, first by being adsorbed onto a C18 cartridge (500 mg). After a cleaning step with ultrapure water and drying, the nonpolar HAA were eluted with a 1.2 mL of methanol:ammonia (25%) mixture (90:10, v/v) into a vial. After drying, the eluate was redissolved in 100 μL of caffeine solution (internal standard). The polar HAA were eluted from the PRS cartridges with 20 mL of 0.5 M ammonia acetate solution (pH 8.5) and adsorbed onto a coupled C18 cartridge that had been conditioned with methanol for cleanup. After washing with ultrapure water (2 mL) and drying, the polar HAA were eluted with a 0.8 mL of methanol:ammonia (25%) mixture (90:10, v/v), dried under nitrogen, and redissolved in 100 μL of caffeine solution (internal standard). A Gynkotek HPLC-system (Gynkotek, Germering, Germany) with a M480 pump, a Gina 50 autosampler, a degasser (DG 1310 S) connected to a fluorescence detector (RF 1002), and a diode array detector (UVD 320) were used for the analytical determination of HAA. The system was equipped with a Gynkosoft chromatography data software (version 5.50). HAA were analyzed using a TSK-gel ODS-80TM 250−4.6 mm, 5 μm analytical column (Tosoh Bioscience, Stuttgart, Germany) and a Supelguard LC-18-DB guard column (Supelco, Bellefonte, PA). The injection volume was 60 μL. The mobile phase contained 10 mM triethylamine adjusted with phosphoric acid to pH 3.2 as eluent A, 10 mM triethylamine adjusted to pH 3.6 as eluent B, and acetonitrile as eluent C. HAA were separated with the following gradient program: 82−75% A, 10% B, and 8−15% C from 0 to 10 min; 0% A, 85−75% B, and 15−25% C from 10 to 20 min; 0% A, 75−55% B, and 25−45% C from 20 to 29 min; 0−82% A, 55−10% B, and 45−8% C from 29 to 33 min; 82−15% A, 10% B, and 8−75% C from 33 to 35 min. The flow rate was 1 mL/min. The mobile phase with 75% C was run for 4 min to recover the HPLC column. The HPLC system was then reset to its original starting conditions and equilibrated for 10 min. UV-detection was carried out at 258 nm, and a 3D-field was used for spectral plots at 200−360 nm. The fluorescence detector (ex/em) was adjusted to 360/450 nm at 0 min, 300/440 nm at 14 min, 265/410 nm at 22 min, 305/390 nm at 24 min, 265/410 nm at 25.5 min, and 335/410 nm at 28 min. The peaks of HAA, norharman, and harman were identified by comparing their retention times and UV-spectra with those of the corresponding standards. Quantification was performed with an external calibration (norharman, harman) or standard addition using a single point in duplicate (MeIQx, PhIP) (two samples and two standard mixture spiked samples). The limit of detection (LOD) was 0.017−0.03 ng/g for UV and 0.002−0.015 ng/g for fluorescence detection.[27]

Statistical Method. All data for the concentrations of HAA, the diameter of liposomes, and the ratio of shell volume to total liposome volume were subjected to the Shapiro−Wilk test to assess whether the data was normally distributed. If the data were normally distributed, the values would be analyzed using an analysis of variance with the procedure GLM and the Tukey test ($\alpha = 0.05$ and/or $\alpha = 0.01$) of SAS program version 9.3 (SAS Institute Inc., Cary, NC). If the data was not normally distributed, a nonparametric test (Kruskal−Wallis test, $\alpha = 0.05$) would be used to determine differences. The coefficients of determination (R^2) were calculated (SAS program) for the particle diameter of liposomes, as well as for the ratio of GSE to lecithin concentration.

RESULTS AND DISCUSSION

Determination of Liposomal Stability. The diameter of each liposomal preparation, with and without extract, was measured immediately after production and during storage for four consecutive weeks. Figure 1A−C shows that the diameters of the liposomes without extract were significantly smaller than those of liposomes with GSE. The 5% lecithin liposomes had the smallest z-average particle diameter when compared to the 1% and 2% trials. The differences in z-average diameter between the control (without extract) and liposomes with

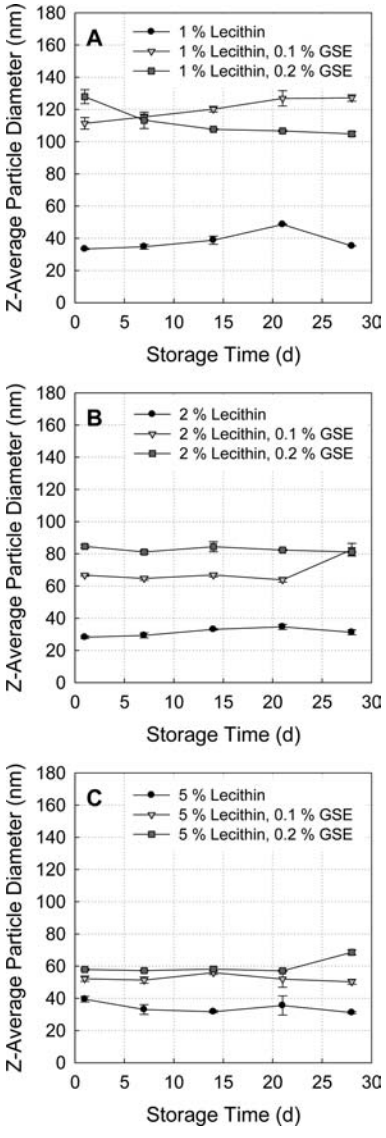

Figure 1. Evaluation of z-average particle diameter of liposomal solutions with different lecithin (1−5%) and GSE (0−0.2%) concentrations, during storage (0−28 days) ($n = 8$). (A) 1% lecithin, (B) 2% lecithin, (C) 5% lecithin.

dx.doi.org/10.1021/jf4035332 | J. Agric. Food Chem. 2014, 62, 279−287

extract suggest that the polyphenolic compounds had been incorporated into the liposomal bilayer, because liposomes with extract were larger than liposomes without it (3-, 2.5-, and 1.6-fold for the 1%, 2%, and 5% trials with 0.2% GSE, respectively). Particle diameters remained virtually unchanged during the four weeks of storage, an indication of the good stability of the liposomal preparations (Figure 1A–C).

The ratio of GSE content to lecithin had a linear, positive correlation (R^2 = 0.97, p < 0.001) to the particle diameter (Figure 2). The largest particle diameter had a ratio of 20%

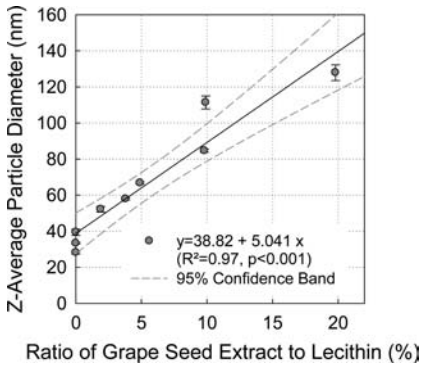

Figure 2. z-Average particle diameter as a function of the ratio of content of GSE to lecithin concentration (0–20%) (n = 8).

GSE in the liposomal lecithin at 1% liposomes containing 0.2% GSE. The correlation shown in Figure 2 confirms that higher ratios of GSE led to liposomes having higher z-average particle diameters. It was not possible to encapsulate more than 20% of GSE because at higher concentrations, large GSE–lecithin aggregates were formed that rapidly developed a sediment layer at the bottom of the sample container. Such sediment-containing solutions could not be processed with the microfluidizer, i.e., the aggregates blocked the homogenization valve. In Figure 3, the zeta potential of liposomes containing GSE concentrations ranging from 0% to 0.2% is depicted as a function of storage time. The zeta potential decreased on average about −14 mV for 0.1% GSE and −9 mV for 0.2% GSE. Similar results had been reported in an earlier study, where liposomes containing GSE had a more negative surface charge with respect to the controls.[21] The zeta potential slightly decreased in all liposomal systems during storage (Figure 3).

Determination of Total Phenolic Compounds by Folin–Ciocalteu Assay. The analysis of the polyphenolic content using the Folin–Ciocalteu assay confirmed that most of the polyphenolic compounds had been incorporated in liposomes (Figure 4). The mean encapsulation efficiency for all liposomal systems containing GSE was 94% ± 14.9%. For example, the amount of unbound polyphenols was particularly low in liposomes containing 5% lecithin, suggesting that the ratio of GSE to lecithin affected the amount being encapsulated (Table 2). The fact that higher ratios of GSE to lecithin resulted in higher amounts of phenols being present in liposomes is in agreement with results from a prior study.[21] To gain more insight into the distribution of polyphenols between the liposomal membrane and the interior, the volume of the inner compartment of liposomes and thus the concentration of GSE there can be calculated by considering the ratio of shell to total volume of liposomes V_{shell}/V_{total} (eq 2) (Table 2).

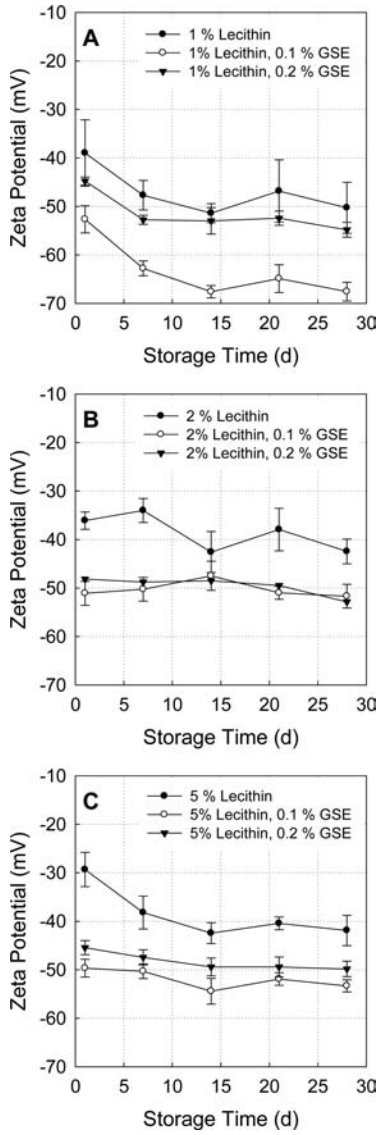

Figure 3. Zeta potential of the liposomes containing GSE as a function of storage time (0–28 days) (n = 8). (A) liposomes 2% containing 0–0.2% GSE, (B) liposomes 5% containing 0–0.2% GSE.

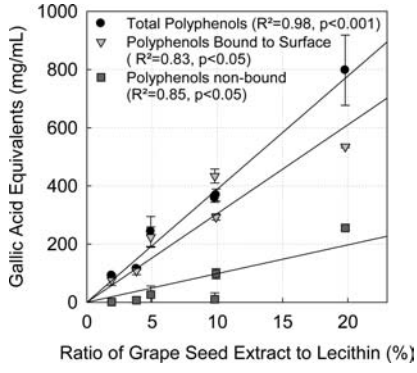

Figure 4. Concentration of phenolic compounds (calculated as gallic acid equivalents) in liposomal solution, as a function of the ratio of GSE to lecithin content (0–20%) (n = 4).

$$\frac{V_{shell}}{V_{total}} = \frac{\frac{4}{3}\pi {r_2}^3 - \frac{4}{3}\pi(r_2 - \Delta r)^3}{\frac{4}{3}\pi {r_2}^3} \quad (1)$$

[a]lip. = liposomes, lec. = lecithin, and GSE = grape seed extract. Means with different letters are significantly different.

$$\frac{V_{shell}}{V_{total}} = 1 - \frac{(r_2 - \Delta r)^3}{r_2^3} \quad (2)$$

with r_2 being the mean radius after microfluidization. A shell thickness of 44.5 Å ± 0.3 Å for unilamellar 1,2-dimyristoyl-phosphatidylcholine vesicles of approximately 4 nm (Δr) has been reported for small unilamillar vesicular liposomes containing a single bilayer.[28,29] The ratio of the core volume to the total volume thus increased from 37% to 82% in liposomes containing extract (Table 2). Consequently, at higher loading capacities of GSE where lipsomes have larger particle diameters, GSE is increasingly located in the interior of liposomes rather than in the membrane, simply due to spatial constraints (Figure 2).

Effect on the Formation of HAA in Fried Beef Patties. The effectiveness of application of liposomal-encapsulated GSE on beef patties on weight loss and formation of HAA was assessed. The weight loss of patties during frying was determined as the weight difference of the beef patties before and after frying. The internal temperature was continually monitored by using a data logger, and it was around 72 °C at the end of the frying process. The mean weight loss of the patties was between 29.3% and 34.9% for the different batches, with an overall standard deviation of 2.7%. The results of the weight loss measurements showed that all patties were subjected to similar frying conditions.

In the polar fraction of HAA method, the two most important polar HAA (MeIQx and PhIP) were identified. The HPLC-chromatograms are shown in Figure S1 in Supporting Information. The concentrations of PhIP were quantified using the higher sensitively fluorescence detection. β-Carbolines norharman and harman were found in the nonpolar fraction (data not shown). The average recoveries for HAA were 61% for MeIQx, 47% for PhIP, and 55% for norharman and harman, which confirms the high efficiency of the method used for such substances. These recoveries are similar to those reported in other studies.[27]

Table 3 shows the content of HAA in fried beef patties. The most predominant HAA found in the beef samples for the polar fractions was MeIQx. Generally, the content of polyphenols had an inhibiting effect on the formation of MeIQx during frying of beef. In comparison to control samples (marinated with rapeseed oil), a significant decrease of MeIQx ($p < 0.01$) was observed with respect to all other samples. However, no significant differences were found between different experimental treatments marinated with liposomes and liposomal-encapsulated GSE (Table 3). In contrast, significant differences were detected in the MeIQx concentration in the control trial, in particular between the samples marinated with rapeseed oil and those marinated with pure GSE. The concentration of extract (0.1% and 0.2%) did not have an impact on the formation of MeIQx. However, significant differences were detected between the control treatment (marinated with rapeseed oil), and the encapsulation trials (1%, 2%, and 5% of soy lecithin) regardless of the soy lecithin percentage. The MeIOx concentration was approximately 1.6-fold higher in the sample marinated with rapeseed oil than in samples marinated with liposomal-encapsulated GSE solution.

Various studies have demonstrated the positive effect exerted by molecules with antioxidant activity on the inhibition of HAA formation, with a particular focus on the inhibition of formation of MeIQx.[30,31] The marination of meats with barbeque sauces,

dx.doi.org/10.1021/jf4035332 | J. Agric. Food Chem. 2014, 62, 279–287

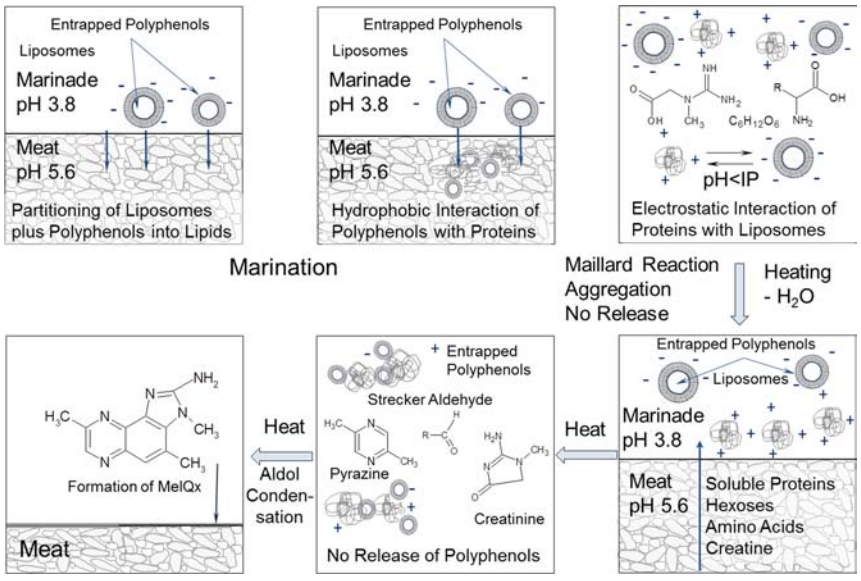

Figure 5. Schematic overview of HAA formation (e.g., MeIQx) and the proposed mechanism with possible interactions between the marinade consisting of liposome-entrapped GSE and the meat matrix.

mixtures of spices, red wine, beer, or plant extracts before frying mostly led to a reduction in the HAA content.[5−7,25,32−34] Similarly in the present study, an inhibitory effect on formation of HAA was found when compounds with antioxidant activities were used to marinate the beef patties. However, liposomal encapsulation of GSE did not lead to a significant improvement in the inhibition of the HAA formation compared to the use of free GSE. Complex interplays take place that depend on oil/lipid type and concentration. For example, authors reported an increasing effect of oxidized oil on the formation of HAA after different storage times.[35,36]

These somewhat disappointing results with respect to MeIQx may be due to the formation mechanism of polar amines, which are generated by the reaction of hexose and amino acids via Maillard and Strecker degradation reactions, whereby the free radical intermediate form of pyridines and pyrazines will react with creatine.[37,38] The apparent positive impact on the diminution of polar MeIQx may not be solely due to the action of the polyphenols but may be attributed to an antioxidant effect exerted by soy lecithin, which contained 0.18% DL-α-tocopherols, according to its specification. Therefore, approximately 4−8 mg of polyphenolic compounds and 0.2−0.9 mg of α-tocopherols were calculated per patty marinated with GSE-entrapped liposomes.

With PhIP, a different behavior was observed compared to that of the other polar HAA. No differences at a level of significance of $p = 0.01$ were found between the control and samples treated with GSE, regardless of the polyphenol concentration. In other words, an antioxidant effect from the polyphenolic compounds was not evident. A significant decrease of PhIP was detected in the trials with liposomes prepared with 5% of soy lecithin that contained 0.1% GSE ($p < 0.05$). Nevertheless, no systematic correlation between the concentration of PhIP and the GSE content in liposomes could be established.

A significant increase of norharman compared to the rapeseed oil control was observed after marination with 0.2% pure extract, and 2% and 5% liposomes containing 0.2% GSE. The β-carboline norharman levels varied between 8.9 and 11.9 ng/g, except for the 5% liposomes containing 0.1% GSE (Table 3). Harman concentration ranged from 3.3 to 5.7 ng/g. The β-carboline harman generally increased with GSE content with results being significantly different for samples marinated with 2% liposomes containing GSE. These results are similar to those reported in an earlier study, where β-carbolines increased with the addition of GSE.[23] The concentration of norharman and harman are comparable to those reported by Totsuka et al.[39] One can conclude from these results that the use of GSE is somewhat detrimental to the formation of β-carbolines norharman and harman and that the application form (encapsulated or free) does not affect the β-carboline levels. This may be related to the formation mechanism of norharman and harman, which does not involve a free radical action and, for this reason, cannot be inhibited by the addition of antioxidants such as polyphenols.[37] In the formation pathway of these compounds, tryptophan has been identified as their precursor, whereas glucose enhances norharman formation. In aqueous model systems containing creatine, glucose, and various single amino acids, norharman and harman were formed in mixtures containing isoleucine, arginine, phenylalanine, and tryptophan, and this mixture combined with tyrosine generated norharman upon heating at 180 °C for 10 min. [40] When iron (Fe^{2+}) and copper (Cu^{2+}) were added to a model system, norharman was generated even at temperatures as low as 40 °C.[40]

Mechanistic Insights. The fact that entrapped GSE polyphenols in liposomes had no additional inhibitory effect on the formation of MeIQx and PhIP is somewhat surprising, considering that liposomal-encapsulated polyphenols have previously been found to improve inhibition of, for example, lipid oxidation in model systems.[21] Moreover, in another study, the use of a different encapsulation system, a water-in-oil marinade with GSE being encapsulated in water droplets suspended in an oil phase, was found to significantly reduce formation of the mutagenic compounds MeIQx and PhIP compared to water-in-oil marinade without extract.[23] There, the water-in-oil marinade contained 0.2−0.8% GSE (pH 5.6) and had been applied before frying of beef patties. In consequence, the content of MeIQx and PhIP decreased by approximately 57% and 90%, respectively.[23]

dx.doi.org/10.1021/jf4035332 | J. Agric. Food Chem. 2014, 62, 279−287

The observed differences between the results in this study and the results of the above cited former studies may be due to a variety of physical mechanisms that are influenced by the structure and physical properties of the encapsulation system used and its interaction with the application matrix (Figure 5):

(i) Diffusion and partitioning behavior: Liposomes containing GSE had a very small particle size and a hydrophilic surface and thus were water-soluble. Thus similar to free GSE, once applied on the surface of the meat matrix, they are able to rapidly diffuse into the interior of the meat matrix. Once in the interior, they are effectively unable to inhibit the formation reaction of HAA that occurs mostly at the surface where high temperatures are prevalent. This is notably different from the above-described water-in-oil system, which is hydrophobic and has much larger particle sizes. There, water droplets containing GSE are enclosed by an oil matrix and are thus mostly present at the surface of the meat product. The heating may lead to an evaporation of the internal water droplets, which in turn leads to a release of the polyphenols able to inhibit the reaction.

(ii) Interaction behavior: The encapsulation of GSE in liposomes may have also not prevented the polyphenols from interacting with dissolved proteins in the meat matrix. During grinding, some of the proteins are solubilized, leading to a characteristic binding of meat and fat particles in ground beef patties. Studies have shown that the interaction of both phosphatidylcholine liposomes and polyphenols with dissolved proteins generally leads to the formation of protein−polyphenol[41] and liposomes−protein complexes,[42] respectively, rendering polyphenols unable to effectively inhibit radical reactions. These interactions may be driven by hydrophobic as well as electrostatic interactions, the latter being due to the fact that both the liposomes and the free GSE were negatively charged (Figure 3) while the surface charge of meat proteins at the pH of the buffered marinade of 3.8 was below the isoelectric point and therefore positively charged. The former may be due to the fact that most proteins possess significant surface hydrophobicities, and because GSE was bound mostly to the surface or was part of the liposomal membrane, an interaction may readily occur. This would again be noticeably different from the functionality of a water-in-oil emulsion, in which the polyphenols are protected from interaction with proteins by the oil phase that surrounds the internal water droplets containing the GSE.

Finally, the formation of PhIP differs from the formation of MeIQx. On the basis of literature studies, while glucose does not seem to be a necessary precursor when using dry heating in a model system, it may however enhance or inhibit the formation of PhIP.[43] In a model system with only phenylalanine and creatinine as precursors, the Strecker aldehyde phenylacetaldehyde is initially formed. In a second step an aldol condensation of the aldehyde with creatinine and subsequent dehydration takes place. The products of the addition as well as the condensation product were identified in the model system and in heated meat.[44]

Our working hypothesis that a liposomal encapsulation may inhibit HAA formation due to the increased surface of the liposomes was therefore not supported by the data obtained. In fact, the system proved to be ineffective with results being analogous to those of trials with free GSE. However, the study led to new mechanistic insights that should help to more effectively and rationally design encapsulation systems for antioxidants. A functional encapsulation system for polyphenols must not only be able to contain high contents of the active ingredient such as for example the polyphenol, but it must be designed such that is ensures that high concentrations of an active compound are present at the required site of release. If the reaction takes place at the surface of a product, then the generation of small particles that are compatible with the properties of the food matrix may not be ideal. Rather, larger particles with a certain "incompatibility", preventing a migration into the matrix, should be manufactured. In contrast, if the reaction takes place in the interior of the matrix, small carriers that are compatible with the matrix may be well suited to influence the reaction. This study therefore should be helpful to food manufacturers to better understand chemical or physical interactions in complex food matrixes (such as meat), by means of encapsulated active compounds as well as the encapsulating material.

ABSTRACT: Dispositions of deoxynivalenol (DON) in rats and chickens were investigated, using a radiotracer method coupled with a novel γ-accurate radioisotope counting (γ-ARC) radio-high-performance liquid chromatography ion trap time-of-flight tandem mass spectrometry (radio-HPLC-IT-TOF-MS/MS) system. 3β-^{3}H-DON was chemically synthesized and orally administrated to both sexes of rats and chickens as single or multiple doses. The results showed that DON was widely distributed and quickly eliminated in all tissues. The highest concentration was found in the gastrointestinal tract at 6 h post-administration. Substantially lower levels were detected in the kidney, liver, heart, lung, spleen, and brain. Three new metabolites were identified tentatively as 10-deoxynivalenol-sulfonate, 10-deepoxy-deoxynivalenol (DOM-1)-sulfonate, and deoxynivalenol-3α-sulfate. Deoxynivalenol-3α-sulfate was a major metabolite in chickens, while the major forms in rats were DOM-1 and DON. Additionally, a higher excretion rate in urine was observed in female rats than in male rats. The differences in metabolite profiles and excretion rates, which suggested diverse ways to detoxify, may relate to the different tolerances in different genders or species.

KEYWORDS: *metabolism, disposition, deoxynivalenol, tritium labeled*

INTRODUCTION

Deoxynivalenol [DON (Figure 1)], one of the primary trichothecene toxins produced by *Fusarium culmorum* and *Fusarium graminearum* species, is a widespread contaminant in grains, such as wheat, barley, oat, and maize. The presence of DON in grains is considered as an important limit for economic benefits in the livestock industry. It reduces feed intake, body weight, and reproductive capacities of food-producing animals while increases disease incidence and, thus, leads to significant economic losses.[1] Upon consumption of DON-contaminated grains or food products, it is known to trigger a wide range of disorders in humans and animals, including vomiting, diarrhea, and gastroenteritis, by targeting ribosome and endoplasmic reticulum (ER), ultimately leading to inhibition of protein synthesis.[2,3] Because of these mycotoxicosis, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) has recently set the limit of group provisional maximum tolerable daily intake (PMTDI) of DON for 1 μg kg^{-1} of body weight (bw) day^{-1}.[4]

Previous studies revealed that DON was widely distributed and rapidly excreted in rats and chickens. Following a single oral administration of 10 mg/kg of bw of [^{14}C] DON to rats, DON was detectable in the gastrointestinal tract, liver, testes, prostate, seminal vesicles, and heart, with negligible radioactivity retained in the above tissues in 96 h. Excretion in the urine and feces accounts for 25 and 64%, respectively, of the administered dose.[5] In chickens, after a single dose of 2.2 mg of [^{14}C] DON per bird, radioactivity was detectable in all tissues, including the gastrointestinal tract, liver, spleen, heart, kidney, fat, and brain in 3 h, and 78.6 ± 21% was excreted within 24 h.[6] DON can be extensively metabolized mainly into deepoxy-deoxynivalenol [DOM-1 (Figure 1)] and DON conjugates.[7] Using unlabeled DON, DOM-1 was identified in rat feces by gas chromatography−mass spectrometry (GC−MS) and shown later to be a major form in rat excreta.[5,8] After *in vitro* incubation with the contents of large intestines or intestinal microbes of chickens, DON was completely converted into DOM-1.[9,10] Glucuronide conjugations appear to be important phase II metabolites in rats, swine, sheep, cows, and humans, including DOM-1-glucuronide and three DON-glucuronide conjugates.[7,11,12] One of the major glucuronide conjugations, DON-3α-glucuronide, could be a biomarker for monitoring DON exposure in human urine.[13] Additionally, minor DON sulfate conjugation was also found, which involved 2% of the recovered dose in sheep urine, following intravenous administration.[14]

Although research on metabolism, distribution, and excretion of DON in rodent and poultry has been partially performed, information on *in vivo* metabolism of DON in poultry is still limited. The gender differences in metabolism, distribution, and excretion were not investigated in rats or any other species. In

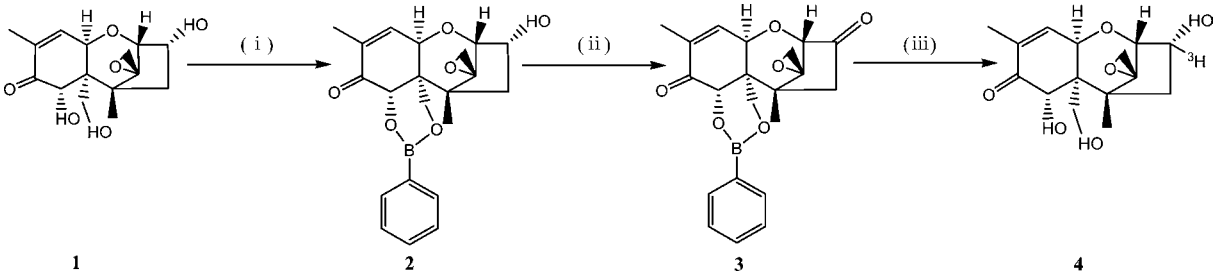

Figure 2. Synthesis of [3β-^{3}H] DON: (i) 1.1 equiv phenylboronic acid, acetone, reflux, 10 h, (ii) Swern oxidation, CH_2Cl_2, −80 °C, 15 min, and (iii) 1/4 equiv NaB^3H_4, isopropanol, room temperature, 30 min.

this study, a comparison study on metabolism, distribution, and excretion of DON in both sexes of rats and chickens was investigated by a radiotracer method, coupled with a novel γ-accurate radioisotope counting (γ-ARC) radio-high-performance liquid chromatography mass spectrometry (radio-HPLC-MS) system. The γ-ARC radio detector was specifically designed for enhanced sensitivity of radioactivity and online radioisotope detection. The full understanding of the dispositions of DON in both sexes of rodents and poultry would provide basis data of DON for future food safety evaluation and toxicological research.

MATERIALS AND METHODS

Chemicals. DON for the animal experiment was produced according to the method by Altpeter and Posselt.[15] DON and DOM-1 for structure confirmation were commercially purchased from Sigma-Aldrich Co. (St. Louis, MO). NaB^3H_4 (500 mCi/mmol) was from American Radiolabeled Chemicals, Inc. (St. Louis, MO). Phenylboronic acid (>98%) and oxayl chloride (>98%) were provided by Aladdin, Inc. (Shanghai, China). Other organic solvents were of analytical grade and from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China).

Tritium-Labeled DON. Tritium-labeled DON (3β-^{3}H-DON) was prepared using a modified method, as illustrated in Figure 2.[16] Briefly, the mixture of DON (**1**) and phenylboronic acid in dry acetone was refluxed for 4 h to give the 7,15-dihydroxyl-protected product (**2**), followed by Swern oxidation to afford a 3-keto-DON-7,15-phenylboronic acid ester (**3**). After reduction with NaB^3H_4 in isopropanol, 3β-^{3}H-DON (**4**) was obtained in moderate yields. Further purification of DON was conducted using model 2695 HPLC with a 2996 detector (Waters, Milford, MA). The separation procedure was performed on a 150 × 21.5 mm inner diameter, 10 μm, Venusil XBP-18 column (Agela Techonologies, Inc., Tianjin, China), eluting with MeOH/water (1:4, v/v) at a flow rate of 5 mL/min at 30 °C. Fractions containing pure ^{3}H-DON were pooled and concentrated under nitrogen, then subjected to a freeze-drying procedure, and finally dissolved in absolute EtOH to afford 110 mCi of 3β-^{3}H-DON (22% yield) with a radiochemical purity of 99%.

Subjects. Wistar rats (8 weeks, 200 ± 10 g) were supplied by the Hubei Provincial Center for Disease Control and Prevention (Wuhan, China). Avian broilers (4 weeks, 1.5 ± 0.3 kg) were from Charoen Pokphand Group (Hubei, China). After routine immunization, both species were placed in all-stainless-steel metabolism cages and fasted overnight with free access to DON-free feed and water. A constant environmental temperature of 25 ± 2 °C was maintained with a relative humidity of 55 ± 5% and 12 h light/dark cycle. All experimental procedures were conducted in accordance with the guidelines of the Committee on the Care and Use of Laboratory Animals of China (permit number SYXK 2007-0044).

Instrumentation. The γ-ARC radio-HPLC-MS system consisted of an online isotope detector system (γ-ARC 2.0, AIM Research Co., Hockessin, DE), an ion trap time-of-flight mass spectrometry (IT-TOF-MS) instrument and high-performance liquid chromatography (HPLC). The online isotope detector (γ-ARC) is fitted with a 750 μL flow cell and a splitter (600-PO10-06). The IT-TOF-MS instrument is equipped with an orthogonal spray electrospray ionization (ESI) source (Shimadzu Corp., Kyoto, Japan), while the HPLC system (Shimadzu Corp., Kyoto, Japan) contains a solvent delivery pump (LC-20AD), an autosampler (SIL-20AC), a DGU-20A3 degasser, a photodiode array detector (PDA, SPD-M20A), a communication base module (CBM-20A), and a column oven (CTO-20AC). This γ-ARC detector uses dynamic flow counting technologies to accurately detect and quantitate radioisotopes and is controlled by LC Solutions software (Shimadzu Corp., Kyoto, Japan). A liquid scintillation counter, Tri-Carb 2900TR, includes a quench standards set, which contains the same amount of nuclide with varying amounts of quenching agent (PerkinElmer, Waltham, MA).

Dosing and Sample Collection. *Excretion and Metabolism of [^{3}H] DON.* Animals were divided into three dose groups (0.5 and 2.5 mg/kg of bw dose rat group and 2.5 mg/kg of bw dose chicken group), with males (n = 3) and females (n = 3) in each group. On the basis of the dose levels, a single dose of [^{3}H] DON (1.1 mCi/mg) was administered orally. The excreta were collected 6, 12, and every 24 h thereafter (24, 48, 72, 96 h, etc.) after administration until radioactivity was no longer detectable in urine or feces. Each feces sample was homogenized in an equal amount of MeOH/water (50:50, v/v), while each urine sample was divided into two parts and stored at −20 °C prior to total radioactivity determination and metabolite profiling.

Distribution and Depletion of [^{3}H] DON. Three groups of animals, including two rat groups and one chicken group (each group with 15 males and 15 females), were given [^{3}H] DON for 5 days. In accordance with the excretion and metabolism tests, rats were dosed 0.5 and 2.5 mg kg^{-1} of bw day^{-1}, respectively, and chickens received 2.5 mg kg^{-1} of bw day^{-1}. According to the above excretion rate of

dx.doi.org/10.1021/jf4047946 | J. Agric. Food Chem. 2014, 62, 288−296

DON in these animals, rats were sacrificed at 6, 24, 48, 72, and 96 h after dosing, while chickens were sacrificed at 6, 12, 24, 48, and 72 h. The following samples were obtained from both rats and chicken: gastrointestinal tract, plasma, bile, brain, heart, liver, kidney, lung, spleen, pancreas, urinary bladder, ovary/testis, adipose, muscle, and skin. Above tissues were thoroughly rinsed with phosphate-buffered saline (PBS) to avoid external blood contamination and stored at −20 °C prior to analysis.

Determination of Total Radioactivity and Radioactivity Profiles. Radioactivity was determined on Tri-Carb 2900TR, with samples mixed with 10 mL Ultima Gold scintillation cocktail (PerkinElmer, Waltham, MA) and counted for 5 min unless 2σ of 0.4% was reached. An external standard quench curve was used to correct for differences in counting efficiency and calculate disintegrations per minute (dpm), where dpm = counts per minute (cpm)/efficiency. Urine (200 μL), plasma (200 μL), and bile (10 μL) were directly mixed with Ultima Gold scintillation cocktail and counted on Tri-Carb 2900TR. Air-dried feces (190−210 mg) were powdered and burned in oxygen in an autosampler oxidizer (PerkinElmer, Waltham, MA) to generate ^3H_2O by combustion before analysis. Individual tissues (190−210 mg) were dissolved in a 2 mL tissue Solvable solubilizer (PerkinElmer, Waltham, MA) in unquenched standard vials for 12 h. A total of 0.2 mL of 30% H_2O_2 was added dropwise with swirling to bleach. After standing for 10 min at ambient temperature, samples were warmed to 37 °C for 15 min to decompose peroxides and, thus, minimize chemiluminescence. Quantification of radioactivity in HPLC elutes was performed on the γ-ARC detector, using a dynamic flow mode at a flow of 1.0 mL/min. A linear relationship exists between cpm (X), obtained from the γ-ARC detector, and dpm (Y) from Tri-Carb 2900TR: $Y = 4.37X + 175.93$ ($r = 0.997$).

Metabolite Profiling. The Strata-X column (Phenomenex, Torrance, CA) was conditioned with 2 mL of MeOH followed by 2 mL of H_2O. A total of 0.4 mL of urine sample was diluted with 1.5 mL of 2% phosphoric acid in 10 mM ammonium acetate, mixed, and applied to the preconditioned Strata-X column. After washing with 2 mL of 0.1% phosphoric acid, followed by 2 mL of 5% aqueous ammonia in MeOH, the eluate was concentrated under nitrogen at 50 °C, followed by reconstitution with 0.1 mL of mobile phase (10% MeOH, containing 5 mM ammonium acetate). A total of 2 g of the homogenized feces was extracted twice with an equal volume of MeOH and centrifuged at 8000 rpm at 25 °C for 10 min. The combined extracts were concentrated under nitrogen at 50 °C, followed by reconstitution with a mobile phase up to 0.1 mL. Recovery was determined by detection of radioactivity in an equal amount of samples before and after above procedures on Tri-Carb 2900TR. The chromatographic separation was performed on a 150 × 2.1 mm inner diameter, 5 μm, Thermo Hypersil Gold (Thermo Fisher Scientific, Inc., Waltham, MA) using a linear gradient at a flow rate of 0.2 mL/min at 40 °C. The mobile phases were 5 mmol/L ammonium acetate (A) and MeOH (B). The gradient was programmed as follows: 0−30 min, 1−20% B; 30−50 min, 20% B; 50−52 min, 20−95% B; 52−53 min, 95−1% B; and 53−60 min, 1% B. A total of 20 μL of sample was injected each time. The eluate from the chromatographic separation was divided into two portions. The portion for metabolic quantification was applied to a γ-ARC 2.0, and the rest was analyzed and identified by ion trap time-of-flight tandem mass spectrometry (IT-TOF-MS/MS). To obtain the abundant signal for the product ion scan, mass spectrometric analysis was carried out on a full-scan mass spectrometer, operated in both positive and negative modes with a mass range of m/z 150−650. The MS/MS spectra were produced by collision-induced dissociation (CID) of the selected precursor ions using argon as the collision gas with a relative energy of 50%. Prior to data acquisition, external mass calibration was carried out using a direct infusion of reference standards from 50 to 2000 Da, including 0.25 mL/L trifluoroacetic acid and 0.1 g/L sodium hydroxide. Mass errors (5 mDa) were allowed after calibration.

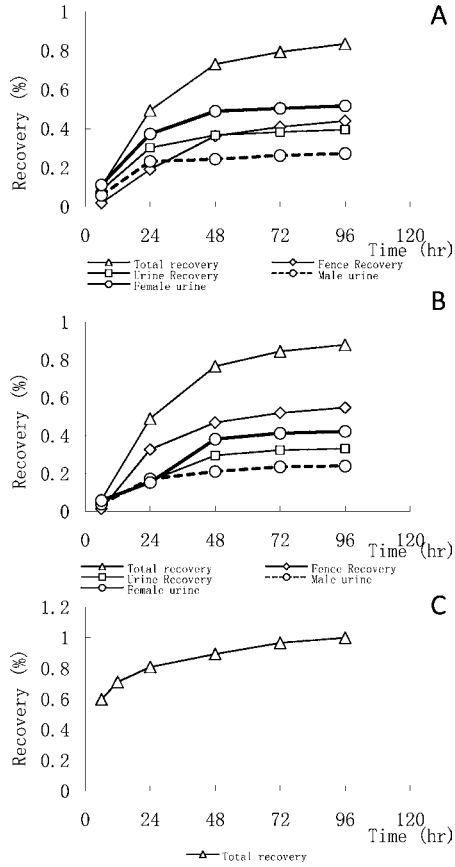

Figure 3. Mean cumulative excretion of total radioactivity in rat and chicken excreta: (A) 0.5 mg/kg of bw rat group, (B) 2.5 mg/kg of bw rat group, and (C) 2.5 mg/kg of bw chicken group.

RESULTS AND DISCUSSION

Synthesis of the Tritium-Labeled DON. Tritium-labeled DON was partially synthesized from DON via a three-step route. Protection of 7,15-dihydroxyl groups with phenylboronic acid and oxidation of the secondary hydroxyl of compound **2** to the 3-ketone derivative (**3**) were preceded smoothly in good yields as reported earlier.[17,18] Afterward, tritiated sodium borohydride was used for reduction of the 3-keto group, and tritium was introduced to DON with high specific radioactivity. A previous study on the synthesis of [^{3}H] T-2 toxin revealed a mixture of 3α- and 3β-hydroxyl epimeric products in a ratio of 4:1.[16] In this study, the absence of a 4β-hydroxyl group in 3-keto DON has resulted in a unique 3α-hydroxyl product when reduced with $NaBH_4$; no β epimer was found. The stereoselectivity and regioselectivity of this reduction of compound **3** with $NaBH_4$ have been described previously.[19] Thus, the desired compound 3β-^{3}H-DON was obtained. To ascertain the "exchange risk" of radioactive samples quantitatively, total radioactivity in plasma and urine was measured on Tri-Carb 2900TR before and after freeze-drying. Because no tritiated water was formed, the "exchange risk" could be ignored[20] (data not shown).

Excretion of the Radioactivity. DON was rapidly eliminated in rats and chickens. In rats, 73.08 ± 11.92% (n = 6; 0.5 mg/kg of bw) and 76.63 ± 8.91% (n = 6; 2.5 mg/kg of bw) of the radioactive dose were recovered from urine and feces in 48 h. By 96 h, they were accumulated to 87.99 ± 10.30% (n = 3; 0.5 mg/kg of bw) and 83.44 ± 7.88% (n = 3; 2.5 mg/kg of bw), respectively. In chickens, 80.90 ± 6.24% (n =

[a]The terminal slope (β) for determining the elimination constant (K_e) and half-life ($t_{1/2}$) of tissues was calculated by linear regression analysis using points by WinNonlin Enterprise, version 5.2.1. [b]ND = not detectable. [c]— = not determined.

3; 2.5 mg/kg of bw) of the radioactive dose was recovered in 24 h and accumulated to 94.52 ± 3.59% (n = 6) in 72 h from excreta (Figure 3). The urine radioactivity excretion rate was 39.51 ± 13.41% (n = 6) of the radioactive dose in the 0.5 mg/kg of bw group and reduced to 33.12 ± 10.31% (n = 6) in the 2.5 mg/kg of bw group. Significant differences in the dose- and sex-dependent excretions were found in rats. For female rats, urine radioactivity excretion rates were 57.13 ± 1.18% (0.5 mg/kg of bw; n = 3) and 42.26 ± 3.07% (2.5 mg/kg of bw; n = 3), while for males, they were 27.29 ± 0.67 and 23.97 ± 2.26%, respectively. This difference in the urine excretion rate may relate to the previous report that the female rats were less sensitive than male rats in response to DON.[21]

Distribution and Depletion of Total Radioactivity in Tissues. After DON was administered to rats and chickens for 5 days, the animal body weight, urine volume, feces weight, and general appearance of the animals were not affected, except for a slight reduction in food intake in rats at the high dosage. The concentrations of the DON-related substance in the tissues at each time point was shown in Tables 1−3. The terminal slope (β) for determining the elimination constant (K_e) and half-life ($t_{1/2}$) of tissues was calculated by linear regression analysis using points by WinNonlin Enterprise, version 5.2.1. DON was widely distributed in 6 h and quickly depleted in all tissues from rats and chickens. In rats, the highest concentration of radioactivity was detected at 6 h post-administration in the gastrointestinal tract at 5226.2 and 834.4 μg/kg, which declined to 50.3 and 10.6 μg/kg in 48 h, for the 2.5 and 0.5 mg/kg of bw groups, respectively; substantially lower levels were detected in the kidney, liver, heart, lung, spleen, and brain. In the 0.5 mg/

kg of bw group in rats, the radioactivity in the plasma, muscle, fat, and adrenals was not detectable at 24 h, while at 96 h after administration, the radioactivity was not detectable in most tissues, except the large intestine and ovary. Nevertheless, in the 2.5 mg/kg of bw group in rats, at 96 h after administration, the radioactivity can be detected at very low levels (<20 μg/kg) in most of the tissues, except the plasma and adrenals. In chickens, the radioactivity was eliminated even faster. The highest concentration was also found at 6 h post-administration in the gastrointestinal tract at 1928.7 μg/kg, and it declined to 225 μg/kg in 24 h. At 72 h after administration, radioactivity was detectable in the gastrointestinal tract only and the concentrations were less than 50 μg/kg. Initially, higher specific radioactivity in the gastrointestinal tract appeared to undergo fast, with $t_{1/2}$ ranging from 8.3 to 20.7 h. Estimated clearance rates for radioactivity varied slightly among the various tissues examined, with the elimination half-life values occurring between 6 and 34 h. The gastrointestinal tract, the first barrier against food contaminants, is highly sensitive to mycotoxins, especially DON. Moreover, the results of the distribution showed that DON could be detected in the brain, which suggested that DON or its metabolites may deliver across the blood−brain barrier in rats and chickens.

Structural Determination of Identified Ions. *DON (MD5) and DOM-1 (MD6).* As shown in Table 4, MD5 (t_R = 18.8 min) gave a deprotonated ion $[M + CH_3COO - H]^-$ and its molecular formula was deduced as $C_{15}H_{20}O_6$. A product ion scanning spectrum provided its characteristic fragment ions at m/z 295 $[M - H]^-$, 265 $[M - H - 30]^-$, 247 $[M - H - 48]^-$, and 217 $[M - H - 78]^-$, suggesting that it was the parent product (DON). The molecular form of metabolite MD6 (t_R = 27.5 min) was calculated as $C_{15}H_{20}O_5$ by IT-TOF-MS ($[M + CH_3COO - H]^-$). The difference of the 16 Da mass between m/z 339 and 355 indicated the neutral loss of oxygen based on DON. Its major product ions were m/z 279 $[M - H]^-$, 261 $[M - H - 18]^-$, 249 $[M - H - 30]^-$, and 231 $[M - H - 48]^-$, suggesting that it was DOM-1, a de-epoxy product of DON. The structures of those two compounds were confirmed by comparison of their retention times and MS/MS spectra on liquid chromatography−mass spectrometry (LC−MS) to the standards.

dx.doi.org/10.1021/jf4047946 | J. Agric. Food Chem. 2014, 62, 288−296

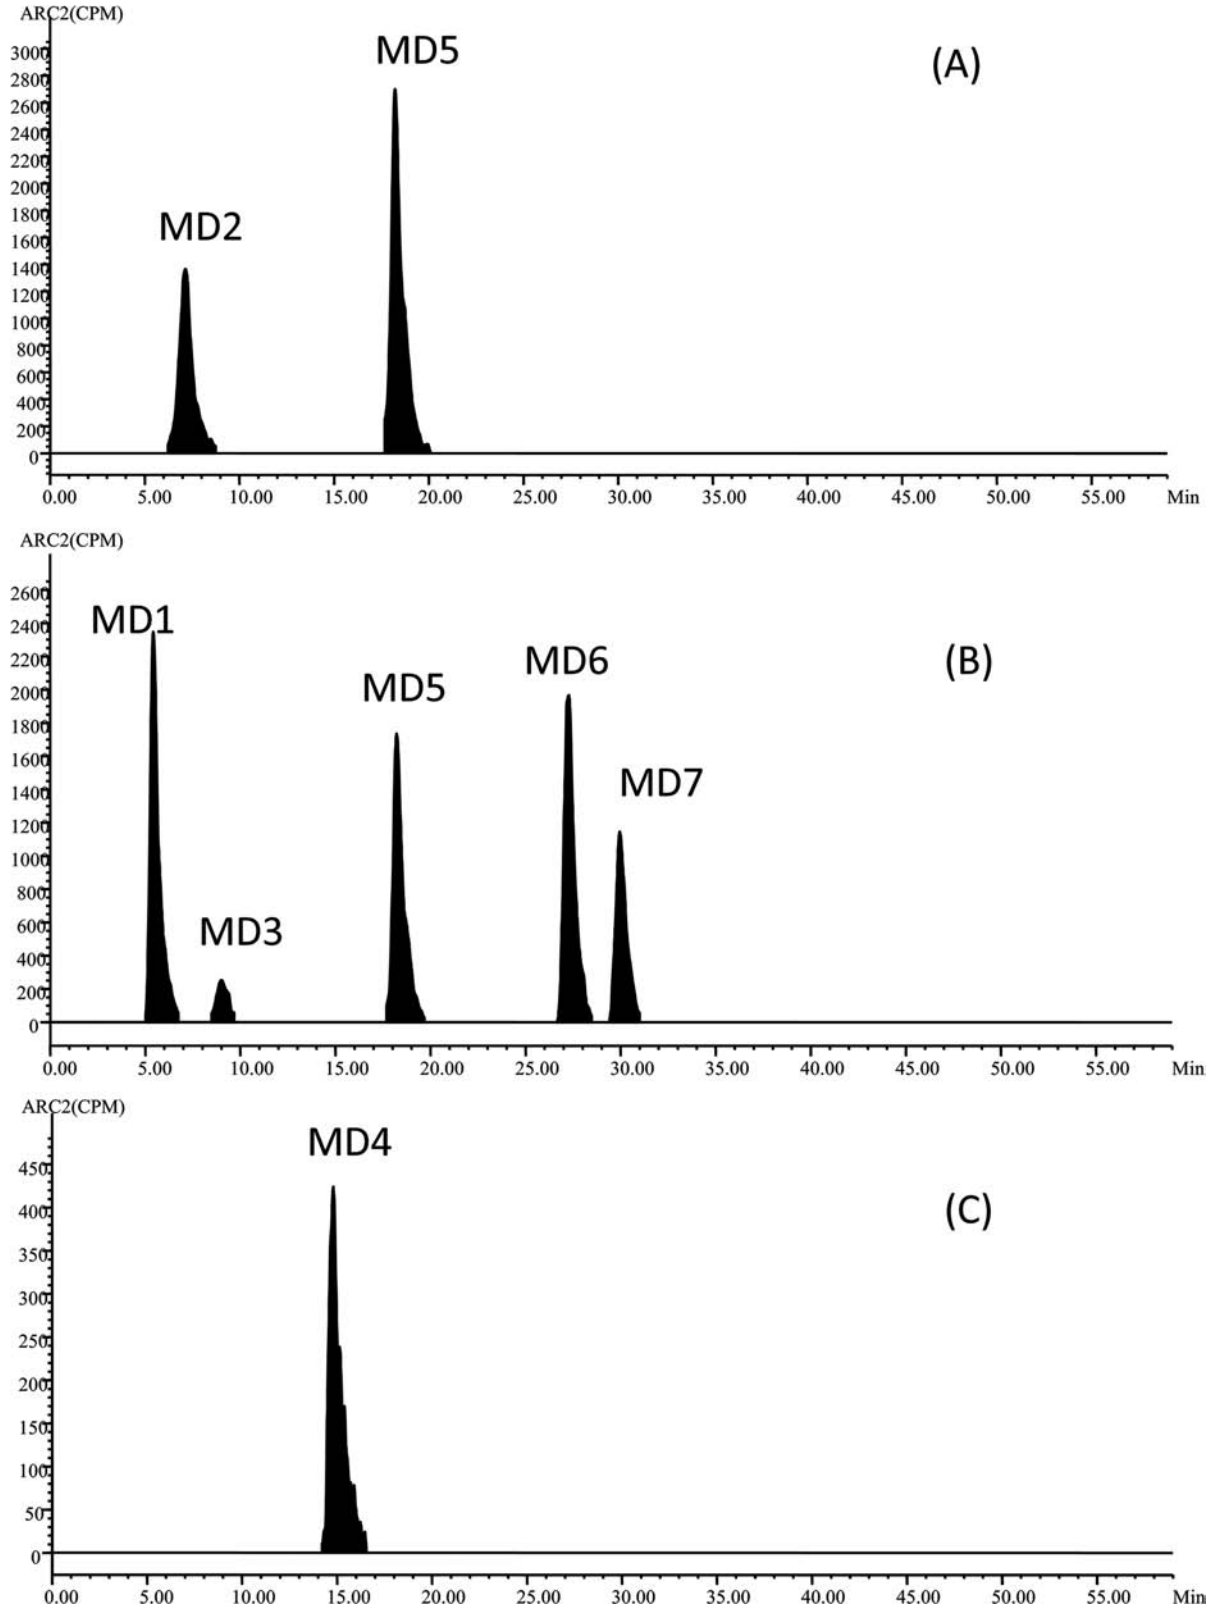

Figure 4. Representative radio-HPLC chromatograms of excreta from [^{3}H]-DON-treated animals: (A) 0−6 h urine from [^{3}H]-DON-treated rats, (B) 6−24 h feces extracts from [^{3}H]-DON-treated rats, and (C) 0−48 h excreta from [^{3}H]-DON-treated chickens.

MD2 and MD4 (3α-Hydroxy Conjugates). Metabolites MD2 and MD4 were expected for phase II metabolites, because the skeleton was identical with DON according to the MS/MS fragments (Figure 5A). MD2 (t_R = 7.5 min) gave a $[M - H]^-$ molecule. The product ion spectrum of MD2 displayed a fragment ion at m/z 411, 265, 247, 217, and 175. The mass loss of 206 Da (176 + 30 Da) and the fragment ion m/z 175 indicated that it is a DON-3α-glucuronide conjugate. MD4 (t_R = 12.3 min) showed a $[M - H]^-$ molecule with a series of product ions at m/z 345, 327, 265, 247, 229, and 217.

dx.doi.org/10.1021/jf4047946 | J. Agric. Food Chem. 2014, 62, 288−296

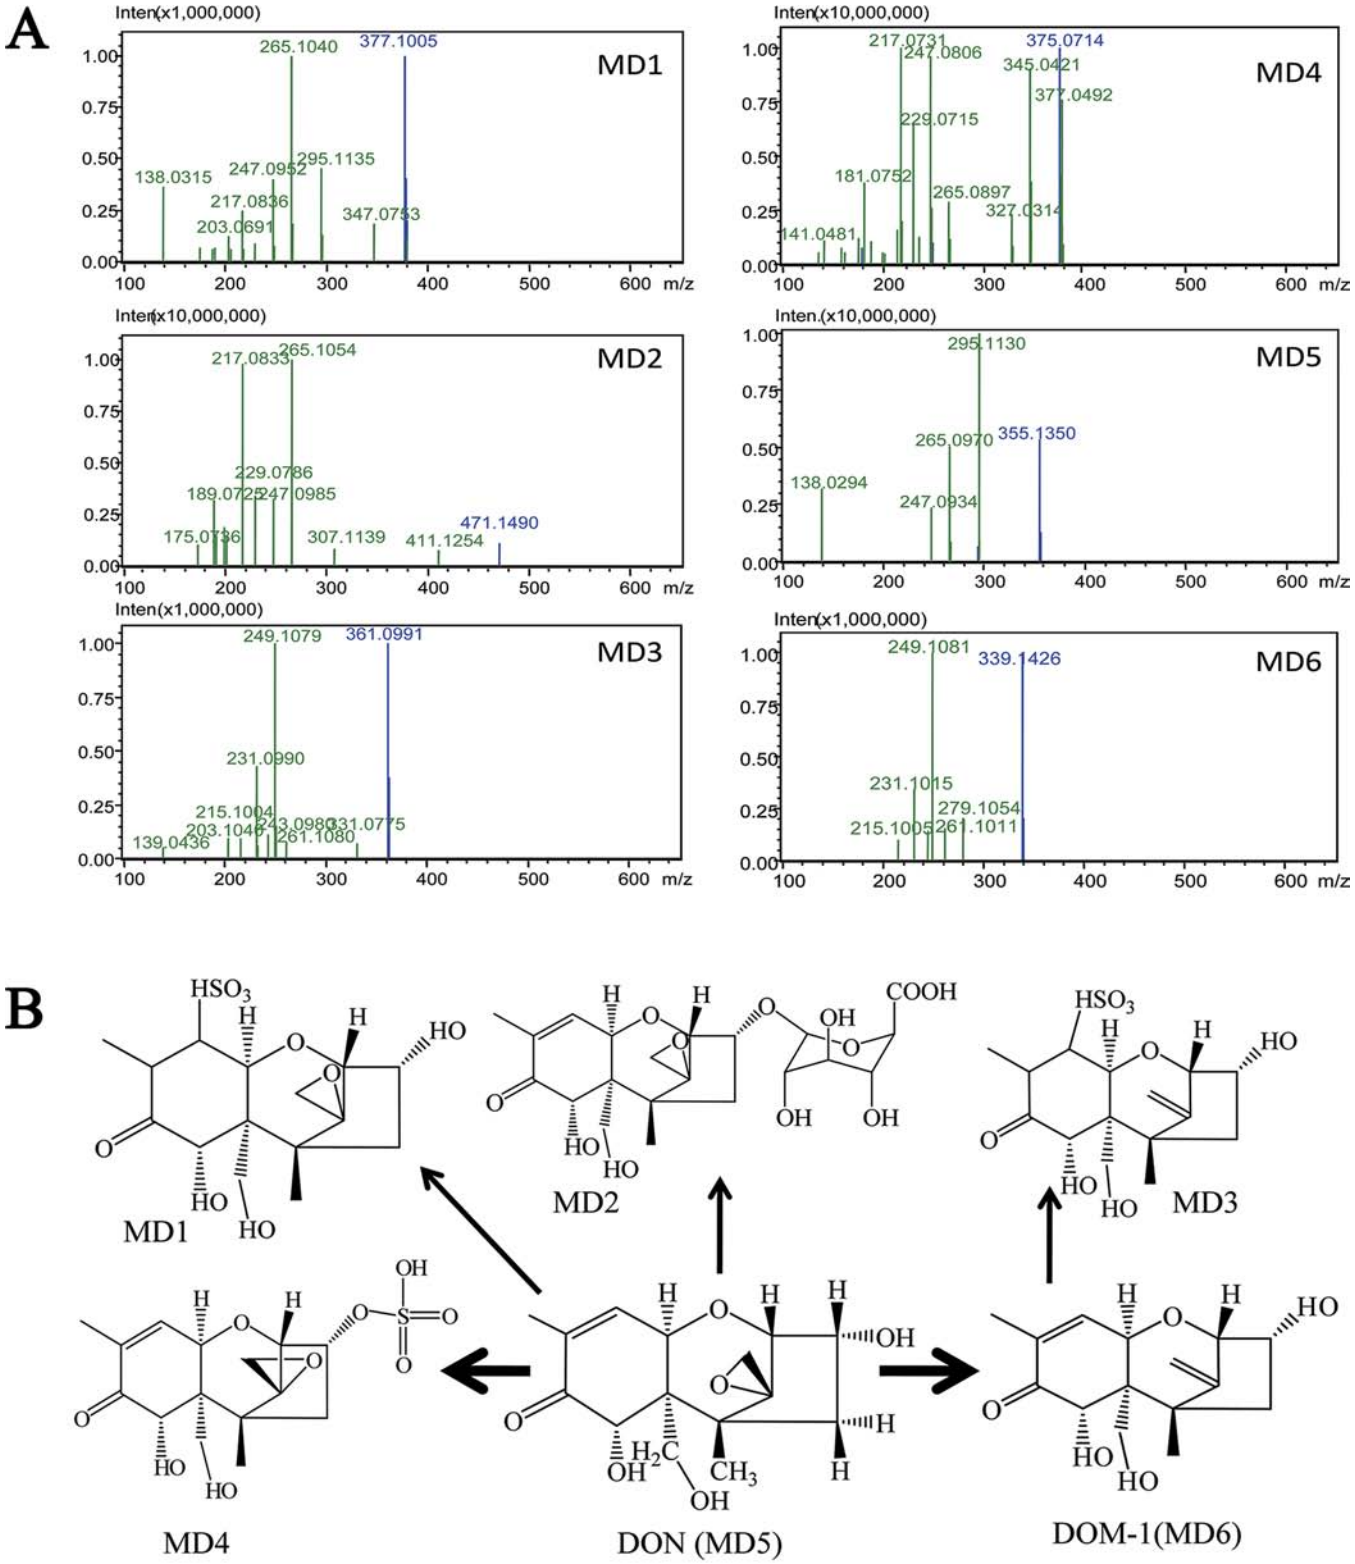

Figure 5. MS and MS^2 of the metabolites of DON and the potential metabolism pathway in the excreta of rats and chickens. (A) MS and MS^2 of the identified metabolites. (B) Structure of the identified metabolites and the potential metabolism pathway.

Subsequent neutral loss of 80 Da from fragment ions m/z 345 and 327 yielded fragment ions at m/z 265 and 247, respectively, which is a specific signature for sulfate conjugates. The product ion at m/z 345 because of the loss of 30 Da ($-CH_2O$) indicated that the sulfate is conjugated at the 3α-hydroxy position. For deoxynivalenol-sulfate, first reported in sheep urine,[14] the details of structural elucidation are missing. Here, the fragmentation patterns (m/z 345, 327, 265, 247, and 217) in MS/MS confirmed that the sulfate was conjugated with a 3α-hydroxyl group.

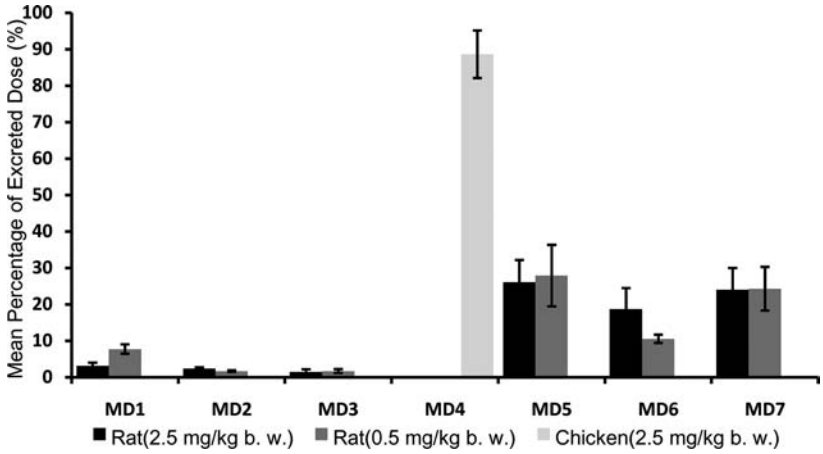

Figure 6. Total excretion of metabolites from rats and chickens (n = 6) 0−96 h after single-dose administration [means ± standard deviation (SD)].

MD1 and MD3 (Sulfonate Acid Conjugates). Two new metabolites, MD1 (t_R = 5.6 min) and MD3 (t_R = 9.2 min), were found in radiometric HPLC (Figure 4B). MD1 gave a $[M - H]^-$ molecule in IT-TOF-MS, and its molecular formulas was deduced as $C_{15}H_{22}O_9S$ (Table 4). Its mass fragments (m/z 295 $[M - H - 82]^-$, 265 $[M - H - 82 - 30]^-$, 247 $[M - H - 82 - 48]^-$, 217 $[M - H - 82 - 78]^-$, and 138 $[M - H - 82 - 157]^-$) were identical to those of DON. The mass neutral loss of 82 Da was deduced as H_2SO_3 (calculated 81.9725) by IT-TOF-MS (Figure 5A). The keto group or the 9,10 double bond of DON could potentially undergo an addition with H_2SO_3, which suggested that MD1 was generated from a rare sulfonation metabolic pathway. Further comparison of MS fragmentation patterns and retention time of MD1 with 10-deoxynivalenol-sulfonate, a reference substance that was synthesized on the basis of the protocol by Beyer et al.,[22] confirmed that it was 10-deoxynivalenol-sulfonate. Similarly, MD3 (m/z 361, 331, 279, 249, 261, and 231) was proposed to be 10-DOM-1-sulfonate.

Profiles of Excreted Metabolites. The radioactivity in excreta was completely recovered, as the recovery efficiencies were 98.7 ± 2.4% in rat urine, 96.1 ± 3.6% in rat feces, 99.6 ± 4.1% in chicken excreta. Seven peaks were observed in HPLC radiochromatograms (Figure 4), and six of them were identified as deoxynivalenol-sulfonate, DON-3α-glucuronide, DOM-1-sulfonate, deoxynivalenol-3α-sulfate, DON, and DOM-1. An unexpected metabolite (MD7), which was found in rat urine and feces, was not identified because of its weak ion response in this high-performance liquid chromatography ion trap time-of-flight tandem mass spectrometry (HPLC-IT-TOF-MS/MS) system. In rats, deoxynivalenol-sulfonate, DON-3α-glucuronide, DOM-1-sulfonate, DOM-1, and DON were detected in both dose groups and both genders. DON existed in all samples, while DOM-1 was detected in urine and feces after 24 h post-administration, DON-3α-glucuronide was found only in urine during 0−6 h after dosing, and deoxynivalenol-sulfonate and DOM-1-sulfonate were found only in feces after 24 h post-administration. In chickens, the toxin residue mainly existed in the form of deoxynivalenol-3α-sulfate and DON but DOM-1, deoxynivalenol-sulfonate, DOM-1-sulfonate, and DON-glucuronide were not detectable. In total, the new metabolites, deoxynivalenol-sulfonate and DOM-1-sulfonate, comprised 10% or less of the total radioactivity, while DON-3α-glucuronide involved 2% of the radioactivity. The major compounds, DON, DOM-1, and MD7, accounted for 27.89 ± 8.44, 10.55 ± 1.14, and 24.28 ± 5.99% of the original dose in the 2.5 mg/kg of bw rat group and 26.08 ± 6.09, 18.73 ± 5.74, and 24.02 ± 5.96% in the 0.5 mg/kg of bw rat group, respectively (Figure 6). The new metabolite deoxynivalenol-3α-sulfate, a major metabolite in chickens, accounted for about 88.63 ± 6.53% of the dose. This O-sulfate conjugation was considered to be a detoxification or deactivation pathway.[23] The specific capability of chicken to biotransform DON to deoxynivalenol-sulfate effectively seems to be a rational reason why poultry is less sensitive than rodents to the toxin DON.[24]

A rare sulfonation metabolic pathway, which led to new [M + 82] metabolites of DON and DOM-1 in rats, was found for the first time. Earlier studies have reported that a few chemicals can be converted into [M + 82] metabolites in rats, such as (*R*)-(+)-menthofuran, gambogic acid, and xanthohumol.[25−27] These compounds, including DON, containing an α,β-unsaturated carbonyl group, might result in this biotransformaition *in vivo*. To date, these metabolites were not identified in chicken and swine. It seems that it is a specific metabolic pathway for rats. Although the enzymes involved in this metabolic pathway were not clear, several hypotheses were proposed. One possible mechanism involves an addition of glutathione (GSH) to the unsaturated ketoaldehyde, followed by further metabolism to give the sulfonic acid conjugates.[25] Thus, it can be hypothesized that, if *in vivo* reversibility of the GSH adduct of DON could occur, it could represent a mechanism for DON delivering and regenerating to the toxicological target. The addition of GSH to the double bond of DON was found in wheat, for which nuclear magnetic resonance (NMR) evidence was provided, most likely a 1,4 addition of α,β-unsaturated ketones.[28] In that case, the proposed structures of the sulfonates, the GSH conjugate-processing products, were 10-deoxynivalenol-sulfonate and 10-DOM-1-sulfonate. Alternatively, it might also result from microbial metabolism. However, the action of gut flora was not to catalyze the sulfonation directly but to transform inorganic sulfate to sulfite. The sulfur-containing chemical substance reacted with DON from bile excretion by a well-known Michael addition reaction. In any case, it is a detoxification or deactivation pathway, because the increased polarity of deoxynivalenol-sulfonate is associated with fast excretion of the molecule.[17]

In summary, the metabolism, distribution, and excretion of DON in rats and chicken were investigated in the present study. DON and its metabolites were quickly distributed to the entire body and eliminated from all tissues. Gender and species

dx.doi.org/10.1021/jf4047946 | J. Agric. Food Chem. 2014, 62, 288−296

appear to play a role in the excretion rate and metabolic pathway. In addition, to some known metabolites, sulfate-conjugated DON and sulfones were identified as important detoxification routes in chickens and rats. This quick elimination and extensive detoxification of DON in chicken strongly suggested that DON residues from poultry meat would probably be non-toxic to humans, as long as these poultry were exposed to feeds contaminated with a low level of DON 24 h before sacrifice. Metabolites in other species need to be established *in vivo*, as indicated by different metabolism profiles in chickens and rats from this study.

Supporting Information

ABSTRACT: A novel water-soluble chitosan oligosaccharide (COS) derivative, chitosan oligosaccharide/kojic acid grafts assigned as COS/KA, was prepared by using the selective partial alkylation of *N*-benzylidene COS and chlorokojic acid in the presence of dimethyl sulfoxide (DMSO) and pyridine (Py). The derivative was characterized by UV−vis spectroscopy, FTIR, ^{1}H NMR, TGA, SEM, and XRD techniques, which showed that the alkylation reaction took place at the C-6 and C-3 positions of COS. The results showed that the degree of substitution (DS) for COS/KA was from 0.38 to 1.21, and the product exhibited an excellent solubility in organic solvents and distilled water. The antibacterial results indicated that the antibacterial activity of COS/KA was strengthened relative to COS with the increase of DS for *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger* and *Saccharomyces cerevisiae*. These findings provide important supports for developing new antibacterial agents and expand the scope of application of COS in the food industry.

KEYWORDS: *chitosan oligosaccharide, kojic acid, antimicrobial activity*

INTRODUCTION

Many researchers have focused on chitosan as a source of potential bioactive material during the past few decades. However, it has several drawbacks for its utilization in biological applications, including poor solubility and absorption under physiological conditions.[1] Unlike chitosan, chitosan oligosaccharide (COS), the hydrolyzed product of chitosan, is a mixture of oligomers of β-1,4-linked D-glucosamine residues that have better biocompatibility and solubility due to their shorter chain lengths and free amino groups in D-glucosamine units.[2] Many of the biological activities reported for COS, such as antifungal,[3,4] antibacterial,[5] and antitumor,[6] are dependent on their physicochemical properties, which allow COS to be considered as a potential novel functional food ingredient, particularly in the preparation of low-calorie foods.[7] Recently, it has been shown that COS and its derivatives exert antimicrobial effects against different groups of microorganisms such as bacteria, fungi, and yeast.[7] Therefore, it has also been used as an antibacterial agent and additive to improve the shelf life of food products.[8] There are three types of reactive functional groups present in COS (an amino group as well as both primary and secondary alcoholic OH groups at the C-2, C-3, and C-6 positions, respectively), which can be readily subjected to chemical derivatization, allowing its antibacterial activity to be increased.[9] However, the antibacterial activity of COS is low, and chemical modification may lead to enhancement of its antibacterial activity.

Kojic acid (KA), 2-hydroxymethyl-5-hydroxy-4*H*-pyran-4-one, which is an organic acid, is a metabolic compound produced by several species of economically valuable fungi, such as *Aspergillus*, *Acetobacter*, and *Penicillium*.[10] At present, kojic acid and its derivatives have drawn attention because they have been shown to possess various bioactivities such as antimicrobial and antiviral,[11] anti-inflammatory,[12] antitumor,[13] antidiabetic,[14] and skin-whitening activities.[15] Recently, methods for the synthesis of various kojic acid derivatives, such as kojic acid esters kojic acid laureate and kojic acid dipalmitate, have been reported in many studies.[16,17] Moreover, kojic acid provides a promising skeleton for development of new more potent derivatives such as chlorokojic acid (2-chloromethyl-5-hydroxy-4*H*-pyran-4-one), which is a good ligand for the nucleophilic and electrophilic substitution reaction depending on the reagent type and can inhibit *Aeromonas aerogenes*, *Micrococcus pyogenes* var. *aureus*, *Salmonella typhosa*, *Penicillium digitalum*, *Russula nigricans*, and *Saccharomyces cerevisiae* growth.[10] Marwaha and co-workers reported that organomercury(II) complexes of kojic acid and maltol demonstrated greater antibacterial activity than kojic acid.[18] Nevertheless, at present, there is little information available regarding the synthesis of COS/KA graft complexes and their antibacterial activity.

Both COS and kojic acid are good natural food preservatives for improving food quality and safety. Herein we report the preparation of a derivative of COS, *N*-benzylidene COS, by alkylation with chlorokojic acid. The chemical structure and physical properties of products were characterized by UV−vis spectroscopy, FTIR, ^{1}H NMR, TGA, SEM, and XRD techniques. Besides, the solubility and the antibacterial activity against *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger*, and *Saccharomyces cerevisiae* were also studied. These two chemical groups are expected to supplement each other for their antibacterial activity in the preparation of new effective and environmentally friendly biocides.

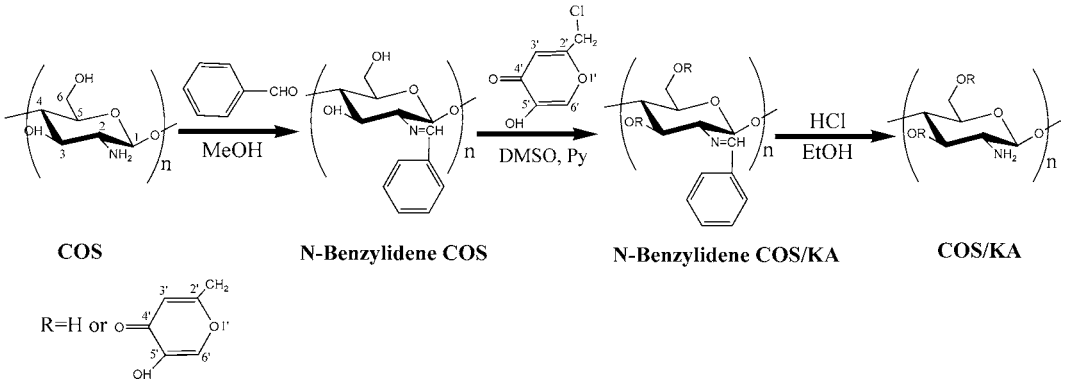

Figure 1. Reaction scheme for the synthesis of COS/KA.

MATERIALS AND METHODS

Materials. Chitosan oligosaccharide (MW = 1 kDa), with a degree of deacetylation of 90%, was made from crab shell and obtained from Zhejiang Jinke Biochemical Co. Ltd. (Zhejiang, China). Kojic acid (2-hydroxymethyl-5-hydroxy-4*H*-pyran-4-one) was purchased from Wuhan Weisheng Biochemical Co. Ltd. (Hubei, China). Chlorokojic acid (2-chloromethyl-5-hydroxy-4*H*-pyran-4-one) was prepared by the reaction of kojic acid with thionyl chloride in chloroform according to the method of Uher and Hudecová.[19] Chlorination of the 2-hydroxymethyl moiety of kojic acid using thionyl chloride at room temperature produced chlorokojic acid, with the ring alcoholic OH being unaffected. Dimethyl sulfoxide (DMSO), deuterium oxide (D_2O), pyridine, and benzaldehyde were purchased from Sigma-Aldrich (St. Louis, MO, USA). *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger*, and *Saccharomyces cerevisiae* used for the antibacterial assay were provided by the School of Food Science and Technology of Jiangnan University. All of the reagents used were of a highly pure grade and were used without further purification, and deionized water was used for all reagent solutions.

Synthesis of Chitosan Oligosaccharides/Kojic Acid (COS/KA). Three chitosan oligosaccharide/kojic acid grafts designated COS/KA1−3 were prepared by the reaction of *N*-benzylidene COS with chlorokojic acid in DMSO and pyridine (Py) (Figure 1). Reaction conditions are summarized in Supplemental Table 1 of the Supporting Information. COS (ca. 6 g) was dissolved in 70 mL of 1% acetic acid and diluted with 120 mL of methanol. Then 6 mL of benzaldehyde was slowly added into the COS solution over 30 min to obtain *N*-benzylidene COS, and the reaction was conducted at 60 °C for 12 h to protect amino groups of COS as Schiff base. After the reaction was completed, the reaction mixture was filtered using a sintered glass filter, and the residue was washed three times sequentially with ethanol and water to remove unreacted benzaldehyde and finally freeze-dried for 24 h. Chlorokojic acid (2.16−1.07 mol) was dissolved in DMSO. By stirring, *N*-benzylidene COS (1 mol) was added to this solution, and then Py was added dropwise at room temperature. Both *N*-benzylidene COS and chlorokojic acid dissolved completely in DMSO, so the reaction was homogeneous in this case. The reaction mixtures were stirred at different temperatures for 6 h and cooled to room temperature. Then an excess of acetone was poured into the DMSO solution, and the product was precipitated. The solid was recovered by filtration, washed repeatedly with acetone, Soxhlet-extracted with ethanol for 24 h, and finally oven-dried at 40 °C for 16 h to obtain *N*-benzylidene COS/KA. Then, the *N*-benzylidene COS/KA was suspended in 1000 mL of 0.25 mol/L hydrochloric acid solution at room temperature for 12 h, followed by filtration and three washings with ethanol and water, respectively, and oven-dried at 60 °C for 12 h to obtain the product.

UV−Vis Spectroscopy. UV−vis absorption spectra of 0.2% (w/v) solutions were obtained using a UV1000 spectrophotometer (Techcomp Ltd., China) in the spectral region of 190−600 nm and with a beam width of 2 nm.

FTIR Spectroscopy. Fourier transform infrared (FTIR) spectrum was recorded on a Nicolet NexuS470 instrument (Nicolet Instrument, Thermo Co., Madison, WI, USA). Samples were prepared as KBr pellet and scanned against a blank KBr pellet background at wavenumber range 4000−400 cm^{-1} with resolution of 4.0 cm^{-1}.

^{1}H NMR Spectroscopy. ^{1}H NMR spectra were obtained on a Bruker AV400 MHz (Bruker, Rneinstetten, Germany). Samples were dissolved in D_2O with tetramethylsilane (TMS) as internal standard.

Thermogravimetric Analysis (TGA). The TGA for the samples was performed on a Mettler Toledo TGA/SDTA851 thermogravimeter (Zurich, Switzerland) at the heating rate of 10 °C/min under N_2 atmosphere in the temperature range of 25−500 °C. STARe software (version 9.01) was used to analyze the thermal stability of the samples.

X-ray Diffraction (XRD). Crystallinity measurements were made using a Bruker D8 Advance diffractometer with an area detector operating at a voltage of 40 kV and a current of 50 mA at Cu Kα radiation of k = 0.154 nm. The scanning rate was 2°/min, and the scanning scope was set from 5° to 80° at room temperature.

Scanning Electron Microscopy (SEM). The morphological characteristics of COS and KA1−3 were checked using SEM (Hitachi S-4800, Hitachi Co., Japan). The samples were attached to SEM stubs using two-sided adhesive tape and spray-coated with gold powder (<10 nm) to improve the conductivity of the surface.

Solubility Test. The solutions of COS, KA, and COS/KA 1−3 were evaluated at a concentration of 5 mg/mL in different solvents including distilled water, anhydrous ethanol, acetone, diethyl ether, ethyl acetate, and glacial acetic acid at room temperature (25 °C).

Antimicrobial Activity. The antibacterial activities of the COS, KA, and COS/KA1−3 were tested using a modified colony counting method on bacteria selected for their resistance to common antimicrobial agents. A representative microbe colony was picked off with a wire loop, placed in nutrient broth, and then incubated at 37 °C overnight. By dilution with sterile normal saline (0.9%) solution, the cultures of *Staphylococcus aureus* and *Escherichia coli* containing 10^7 CFU/mL were prepared and used for the antibacterial test. The bacterial suspension (0.1 mL) was inoculated under aseptic condition into 10 mL of liquid peptone medium containing COS, KA, and COS/KA1−3. Each sample contained test materials at a concentration of 1.0, 1.25, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0, 6.0, or 8.0 mg/mL, whereas a blank without test materials was prepared for comparison. All of the samples were incubated at 37 °C under constant agitation. During incubation, 0.1 mL of each suspension was taken to determine the bacteria count by serial dilution with triplicate plating on agar plates. Then the plates were taken out of the incubator, and the inhibitory activity was calculated.

The inhibitory activity (I) was calculated using eq 1 and expressed as percentage:

$$I\ (\%) = N_1 - N_2/N_1 \times 100 \quad (1)$$

N_1 is the initial cell number (CFU/mL), and N_2 is the cell number after treatment (CFU/mL).

In the determination of the inhibition rate of COS, KA, and COS/KA1−3 on the growth of *Aspergillus niger* and *Saccharomyces cerevisiae* by the same method, the differences were that all of the samples were incubated at 28 °C under constant agitation. The cultures were filtered, the pellet was washed with distilled water and dried at 80 °C to constant weight, and then measured the dry cell weight and the inhibitory activity were calculated.

The inhibitory activity (I) was calculated using eq 2 and expressed as percentage:

$$I(\%) = W_1 - W_2/W_1 \times 100 \quad (2)$$

W_1 is the dry cell weight of *Aspergillus niger* and *Saccharomyces cerevisiae* in the control culture medium, and W_2 is the dry cell weight of *Aspergillus niger* and *Saccharomyces cerevisiae* in the COS, KA, and COS/KA1−3 culture medium, respectively.

The 50% inhibitory concentrations (IC_{50}) against microorganisms were determined for COS, KA, and COS/KA1−3. Fitting of the data was performed by linear regression using the concentration versus percent inhibition. The calculated IC_{50} was submitted to analysis of variance, and the means were compared by the Tukey test ($p \leq 0.05$) using SPSS 20.0.

RESULTS AND DISCUSSION

UV−Vis Spectroscopy Analysis of COS/KA. In the UV−vis spectra of COS, KA, and COS/KA1−3 (Supporting Information, Supplemental Figure 1), broad absorption bands between 200 and 300 nm were observed for all five samples. On the basis of the data reported in the published literature, the broad absorption band of COS might be ascribed to the C═O group.[20] In the UV spectrum of KA, obvious absorption peaks appeared at 219 and 273 nm, ,whereas the UV−vis absorption spectra of COS/KA1−3 obtained at different reaction conditions were quite similar to each other. Two absorption bands of COS/KA1−3 at 207 and 271 nm indicated the presence of a 5-hydroxypyranone group. These bands were assigned to intraligand n→π^* and $\pi\rightarrow\pi^*$ transitions of the chromophoric C═O group,[18,21] indicating that KA had been substituted onto the COS.

FTIR Spectroscopy Analysis of COS/KA. FTIR spectroscopy of COS and COS/KA1−3 is shown in Figure2. From the FTIR spectrum of COS, a characteristic peak at 3422.36 cm^{-1} appeared, and this can be attributed to the −NH and −OH group stretching vibration, as well as inter- and extramolecular hydrogen bonding of COS molecules. The weak band at 2923.83 cm^{-1} was attributed to the −CH− stretch of COS. The characteristic peaks at 1628.76, 1519.37, and 1322.79 cm^{-1} were assigned to the carbonyl stretching $\nu_{C=O}$ (amide I), amine bending δ_{N-H} (amide II), and amide three absorption band of COS, respectively. The absorption band at 1155.97 cm^{-1} was the asymmetric stretching of the C−O−C bridge. In addition, the adsorption band at 1071.52 and 1034.16 cm^{-1} corresponded to the involved skeletal vibration of the C−O stretching and the band at 890.44 cm^{-1} had been assigned to the β (1→4) glycoside linkage. The FTIR spectra of the COS/KA1−3 samples were quite similar to each other. The intense band at 1216.72 cm^{-1} and the shoulder at 911.09 cm^{-1} were broadened and shifted from the corresponding features of chlorokojic acid that could be due to covalent bonding of the kojic acid residues onto the COS.[18] Compared with the NH_2 characteristic absorption band of COS and the absorption band of COS/KA1−3, the characteristic peak at 1519.37 cm^{-1} for the NH_2 group is present in both COS and COS/KA1−3, but the absorption peaks at 1030 and 1074 cm^{-1}, which were attributed to ν_{C-O} of C6−OH and C3−OH of COS, respectively, were substantially weakened. These results indicate that the alkylation reaction mainly occurred not on the amine group but on the alcoholic OH groups of COS.

^{1}HNMR Spectroscopy Analysis of COS/KA. The ^{1}HNMR spectra of COS and COS/KA1 in D_2O solvent are shown in Figure 3. In Figure 3A, the peak at 1.98 ppm existed because of the presence of $-CH_3$ of the N-alkylated glucosamine residue. A singlet at 2.98 ppm was assigned to H_2 of glucosamine and N-acetylated GlcN, and multiplets from 3.24 to 3.94 ppm corresponded to H_3, H_4, H_5, and H_6 of the methine protons of glucosamine and N-acetylated glucosamine.

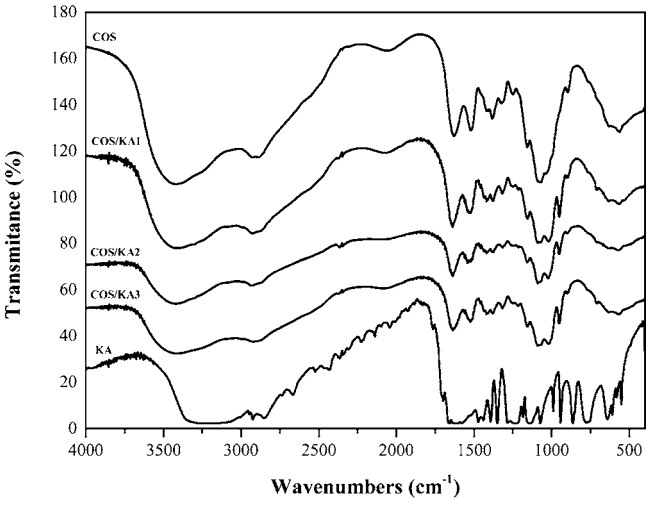

Figure 2. FTIR spectra of COS, KA, and COA/KA1−3.

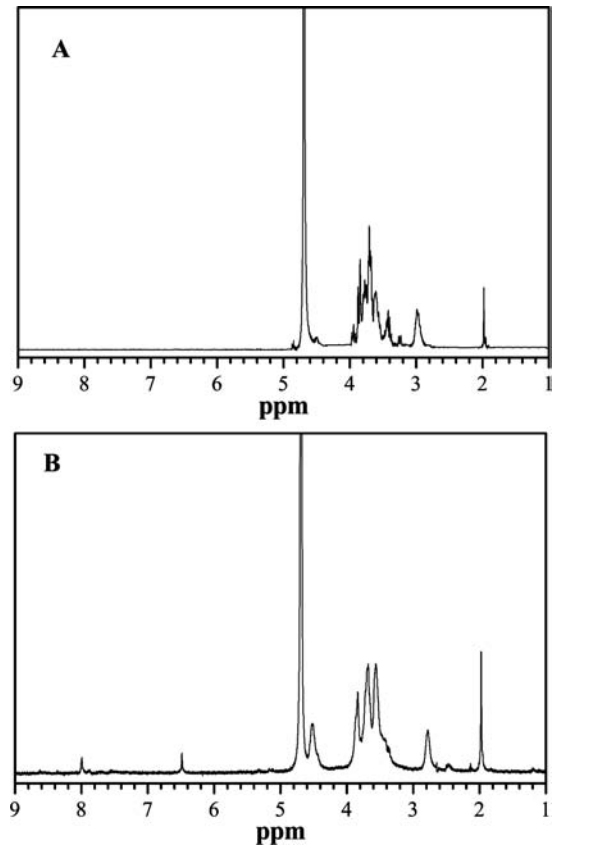

Figure 3. ^{1}H NMR spectrum of COS (A) and COS/KA1 (B).

dx.doi.org/10.1021/jf404026f | J. Agric. Food Chem. 2014, 62, 297−303

The peak at 4.5 ppm was attributed to H_1 of glucosamine, N-acetylated glucosamine. The solvent proton resonates at 4.7 ppm.[22,23] For the ^{1}H NMR spectrum of COS/KA1, the signals of COS protons at 1.98 and 2.98 and from 3.24 to 3.94 ppm did not change significantly their chemical shifts. In Figure 3B, signals of the newly formed three resonance signals appeared at 4.19 (CH_2), 6.59 (H-3′), and 8.07 (H-6′) ppm. These new peaks were assigned to the protons of kojic acid residues bound to the polysaccharide.[10,11] In free kojic acid, the signals due to CH_2, H-3′, and H-6′ have been reported in 4.52, 6.45, and 7.92 ppm regions, respectively.[18] Therefore, compared with kojic acid the signals of aromatic proton H-3′ and H-6′ in COS/KA1 were upfield shifted by 0.14 and 0.15 ppm, respectively, whereas the CH_2 signal was downfield shifted by 0.33 ppm. Hence, the observed shifts confirm that the kojic acid moiety is bound to COS via the CH_2 group.

COS contains two hydroxyl groups in every monosaccharide residue and potentially is able to undergo many reactions of alcohols. One of the most common reactions of alcohols is etherification, which takes place between OH groups of alcohols or between an OH group of an alcohol and a halogen group of an alkyl halide.[24] Aromatic protons of the 4-pyrone ring are much less sensitive to the chlorine substitution than the methylene protons. Hence, the KA moiety is covalently bound to GlcN of COS via the CH_2 group.

TGA of COS/KA. TGA and the first derivative of weight loss (DTG) have been widely used to evaluate the thermal properties of materials and to show the mechanism by which a material loses weight as a result of controlled heating.[25] Figure 4 shows the TGA and DTG curves of COS and COS/KA1−3. Despite some differences in terms of the presence of bound water and residual mass, similar profiles in the curves of mass loss were observed. Both COS and COS/KA1−3 involved two steps of weight loss. In the case of COS, the first stage of weight loss of about 10% between 30 and 100 °C was observed corresponding to the water content. The weight loss of about 47% in the second step was attributed to a complex process including degradation of saccharide rings and disintegration of macromolecule chains in the sample. It had a rapid decomposition between 150 and 320 °C, reaching its peak temperature at 214 °C. As for COS/KA1−3, the first stage, with weight loss of about 6% before 100 °C, was ascribed to the volatile low molecular products and water. The second event, approximately from 160 to 350 °C, refers to a complex process including dehydration of the saccharide rings, depolymerization, and decomposition of the alkylated units of the polymer with weight loss of about 50%.[26] COS/KA1, COS/KA2, and COS/KA3 had similar curves, which showed a maximum degradation temperature (T_{max}) at about 198 °C. This indicates that they have similar thermal stabilities. The T_{max} values of COS and COS/KA1−3 were about 214 and 198 °C, respectively. It was suggested that the thermal stability of COS/KA1−3 decreased compared with COS, which might be attributed to the disruption of crystalline structure. For COS a slight change in crystalline structure could cause significant alteration in thermal stability.[27]

XRD Analysis of COS/KA. The XRD patterns of COS and COS/KA1 are presented in Figure 5. The COS exhibited two peaks at around $2\theta = 11°$ and $2\theta = 21°$, respectively, characteristic of crystallinity of COS, as has been shown previously.[27,28] In contrast, the peak at $2\theta = 11°$ completely disappeared in COS/KA1, and the peak at $2\theta = 21°$ was wider and weaker, indicating that COS/KA1 was considerably more amorphous than COS.

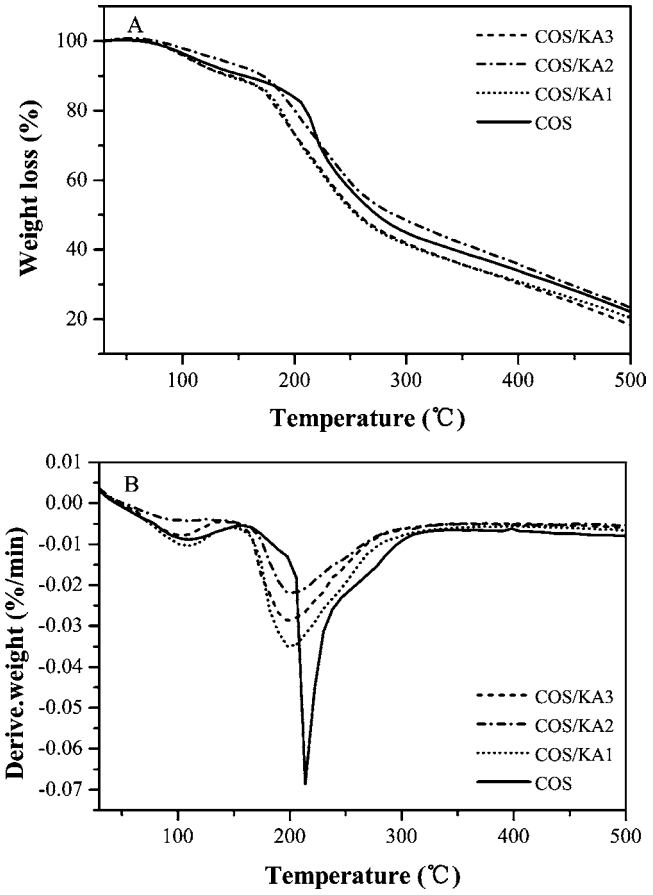

Figure 4. Thermogravimetric curves of COS (solid) and the modified COS: COS/KA1 (short dot), COS/KA2 (short dash dot), COS/KA3 (short dash).

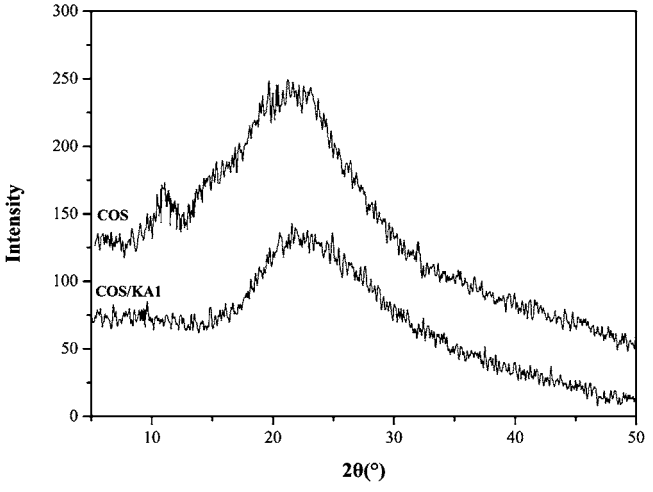

Figure 5. XRD patterns of COS and COS/KA1.

SEM Analysis of COS/KA. Surface morphological studies of COS and COS/KA1 have been investigated using SEM (Supporting Information, Supplemental Figure 2). Because the SEM images of COS/KA1−3 were quite similar, only the image of COS/KA1 is presented here for comparison with COS. The SEM image of COS shows a smooth surface and a more or less spherical shape, because there is stronger

dx.doi.org/10.1021/jf404026f | J. Agric. Food Chem. 2014, 62, 297−303

interaction between the COS molecules, whereas the particles of COS/KA1 were observed to be in the form of irregular flakes and the surfaces of COS/KA1 had many indentations. This could be attributed to effects of drying rate. High drying rates, associated with small particles, usually led to rapid wall solidification, and thus dent smoothing cannot occur.[29] This indicated that the alkylate reaction changed the fiber's microstructure and surface morphology.

Solubility Test of COS/KA. The solubilities of COS, KA, and COS/KA1−3 were investigated in various solvents (Supporting Information, Supplemental Table 1). The results showed that COS did not dissolve in the acetone and diethyl ether, but did dissolve in the other four solvents (distilled water, anhydrous ethanol, ethyl acetate, and glacial acetic acid). KA has better solubility compared with COS. However, COS/KA1−3 could be dissolved in all of the solvents except acetone. In these solvents, COS/KA1−3 showed improved solubility as compared with COS. This can be explained by the contribution of decreased crystallinity confirmed by XRD and TGA.

COS/KA1−3 with different DS values were synthesized by adjusting the molar ratio of chlorokojic acid to COS and the reaction temperature. The DS of derivatives increased when the molar ratio of chlorokojic acid to COS was increased and decreased when the reaction temperature was increased. This might be due to the introduction of a 5-hydroxypyranone group, which disturbed the formation of the ordered structure of COS and hindered the formation of inter- and intramolecular hydrogen bonds. Hence, it was helpful to dissolve.[18]

Antimicrobial Activity Assessment. The antimicrobial effect of chitosans has been reported to be dependent on MW[2,30] and degree of deacetylation,[31] which suggested that chitosans and highly deacetylated COS were more effective at inhibiting the growth of *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger*, and *Saccharomyces cerevisiae* than COS with low deacetylation. The COS used in this study was highly deacetylated (90%). The antibacterial activities of COS, KA, and COS/KA1−3 against *Staphylococcus aureus*, *Escherichia coli*, *Saccharomyces cerevisiae*, and *Aspergillus niger* are shown in Table 1. At tested conditions, COS/KA1−3 could inhibit the growth of all four tested microorganisms, whereas COS and KA could not inhibit *Aspergillus niger*. The result indicated no noticeable antimicrobial activity when COS and KA were tested against *Aspergillus niger* at concentrations up to 8.0 mg/mL. However, COS/KA1−3 markedly inhibited growth of *Aspergillus niger* with IC_{50} values ranging from 2.15 and 2.46 mg/mL. *Aspergillus niger* belongs to the fungus category, whereas the fungal cell wall contains chitosan. Therefore, *Aspergillus niger* has a certain resistance to the antifungal performance of chitosan.[32] However, COS/KA1−3 showed an excellent antifungal activity and expanded the antimicrobial spectrum.

Table 1. Antimicrobial Activity of COS, KA, and COS/KA1-3 against *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger*, and *Saccharomyces cerevisiae*

	IC_{50} (mg/mL)				
	COS	KA	COS/KA1	COS/KA2	COS/KA3
Staphylococcus aureus	6.30	6.63	1.04	1.15	1.24
Escherichia coli	7.39	6.04	1.23	1.38	1.58
Saccharomyces cerevisiae	7.37	7.58	1.56	1.63	1.75
Aspergillus niger			2.15	2.37	2.46

It can be observed that the antimicrobial activities of COS/KA1−3 were enhanced with increasing of DS. COS/KA1 (DS = 1.21) displayed the highest antibacterial activity followed by COS/KA2 (DS = 1.13) and COS/KA3 (DS = 0.38) against the four microorganisms with IC_{50} values from 1.04 to 2.15 mg/mL, from 1.15 to 2.37 mg/mL, and from 1.24 to 2.46 mg/mL, respectively. However, COS and KA possessed a weaker antimicrobial activity (IC_{50} from 6.30 to 7.58 mg/mL) compared to COS/KA1−3. The IC_{50} values of COS/KA against antimicrobial activities were 3−7 times lower than those of KA and COS. Hence, the introduction of a 5-hydroxypyranone group to the COS chain greatly enhanced the antimicrobial activity of the COS/KA.

There were also some differences in the inhibition activity against *Staphylococcus aureus* and *Escherichia coli* for COS, KA, and COS/KA1−3. Both COS and COS/KA1−3 showed higher activity against *Staphylococcus aureus* (IC_{50} = 6.30, 1.04−1.24 mg/mL) than against *Escherichia coli* (IC_{50} = 7.39, 1.23−1.58 mg/mL). On the contrary, KA showed higher activity against *Escherichia coli* (IC_{50} = 6.04 mg/mL) than against *Staphylococcus aureus* (IC_{50} = 6.63 mg/mL). This result accorded with the previous studies[33,34] and may be attributed to their different cell walls. The cell wall of Gram-positive bacteria (*Staphylococcus aureus*) is fully composed of peptide polyglycogen. The peptidoglycan layer is composed of networks with plenty of pores, which allow COS and COS/KA molecules to come into the cell without difficulty and allow more rapid absorption of COS and COS/KA into the cell. However, the cell wall of Gram-negative bacteria (*Escherichia coli*) is made up of a thin membrane of peptide polyglycogen and an outer membrane constituted of lipopolysaccharide, lipoprotein, and phospholipids. Because of the complicated bilayer cell structure, the outer membrane is a potential barrier against COS and COS/KA molecules. Therefore, the samples have different effects on the two kinds of bacteria.

As discussed above, the probable antimicrobial mechanisms of COS/KA are suggested as being, on one hand, the positive charge of the amino group at the C-2 in the glucosamine monomer of COS/KA allows interactions with negatively charged microbial cell membranes that lead to the leakage of intracellular constituents. On the other hand, the 5-hydroxypyranone group was introduced along the molecular chain, which can form complexes with various metal ions. The hydroxyl group at the carbon 5 position acting as a weak acid is capable of forming salts with a few metals such as sodium, zinc, copper, calcium, nickel, and cadmium, which is important in cell membranes. The catechol groups readily interact with phospholipids of the cell membrane subsequently disrupting the microbial membrane and may also denature proteins. Hence, we can deduce that COS/KA showed a synergistic effect against four microorganisms. More work is needed to confirm this hypothesis.

In this study, the COS/KA derivatives with different DS values from 0.38 to1.21 were successfully prepared by alkylation reaction of chitosan oligosaccharide and chlorokojic acid in the presence of DMSO and Py. The product was characterized by UV, FTIR, and ^{1}H NMR, and XRD confirmed that the amino groups of COS reacted with chlorokojic acid to form the alkylate chitosan. TGA showed that the thermal stability of COS/KA was lower than that of COS. COS/KA exhibited an excellent solubility in organic solvents and distilled water. The

antimicrobial activity of COS was significantly enhanced by the kojic acid derivative of COS, and it increased with DS for *Staphylococcus aureus*, *Escherichia coli*, *Aspergillus niger*, and *Saccharomyces cerevisiae*. Thus, COS/KA may have potential as an antimicrobial agent in food applications. However, more biological studies are needed to understand their mechanisms of action, to improve their activity by other modifications of those molecules, and to determine their safety for food applications.

Screening for the Presence of Patulin in Molded Fresh Produce and Evaluation of Its Stability in the Production of Tomato Products

Evelien Van de Perre, Liesbeth Jacxsens, Wendy Van Der Hauwaert, Ine Haesaert, and Bruno De Meulenaer*

NutriFOODchem Unit, Department of Food Safety and Food Quality, Faculty of Bioscience Engineering, Ghent University, Coupure Links 653, 9000 Ghent, Belgium

ABSTRACT: A screening for the presence of patulin in molded fresh produce was conducted. Patulin was present in 11% of the sweet bell peppers and in 8% of the soft red fruits, but not in onions. Patulin was also found in tomatoes, but could not be detected in derived tomato products. When the production process of tomato concentrates was simulated, none of the evaluated hypotheses could however explain a complete degradation of patulin. It was thus concluded that the tomato varieties used for further processing are probably less susceptible to infestation by patulin-producing molds compared to tomatoes used for the fresh market. This was confirmed by screening for patulin throughout the production process of tomato concentrate, gazpacho, and salmorejo in three different countries; all 191 samples were negative for patulin. Therefore, it can be concluded that no health risk can be associated with derived tomato products considering this particular mycotoxin.

KEYWORDS: *patulin, tomato products, UPLC, stability of mycotoxins*

INTRODUCTION

Patulin is a well-known mycotoxin in several fruits, especially in apple and apple-derived products such as apple juice, cider, or apple puree.[1−5] It is also found in other fruits or fruit-derived products such as blueberry, cranberry, raspberry syrup, and grape juice.[6−8] When contaminated fruits are used as raw material for the manufacture of derived products, the final product is likely to be contaminated as well, because patulin is not readily degraded during the processing of fruits.[9] Different treatments during the production process can have an influence on the final patulin concentration in the product. In apple juices it is shown that an average loss of patulin of 39% is obtained for conventional clarification.[10] A study on the effect of heat treatments showed that as the heating and evaporation time increased, the concentration of patulin in apple juice samples decreased.[11]

Patulin is produced by more than 60 fungal species, of which *Penicillium expansum* is the most important.[4] Growth of the fungi on fruits occurs mainly if the surface tissue of the fruit is damaged and is thus mostly a postharvest problem.[12,13] In contrast to its original description as an antibiotic, patulin can cause symptoms of acute and chronic toxicity and has teratogenic properties.[14] After absorption in the gastrointestinal tract, patulin degrades quickly before reaching other tissues.[15] The International Agency for Research on Cancer (IARC) concluded that there is inadequate evidence that patulin is carcinogenic in animals.[16] The "no observable effect level" (NOEL) was set at 43 μg/kg bw/ay and a provisional maximum tolerable daily intake (PMTDI) of 0.4 μg/kg bw was established.[17] The maximum permitted level of patulin in apples and derived products in Europe is 50 μg/kg, and that in baby food is 10 μg/kg. [18] Thus, the presence of patulin in fruits and derived products is a potential and relevant food-related health risk, especially for vulnerable consumers.[5,19] The structural formula of patulin is given in Figure 1.

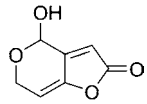

Figure 1. Structural formula of patulin.

The first objective of this study was to evaluate the presence of patulin in molded vegetable and fruit matrices other than previously reported (i.e., tomatoes, onions, sweet bell peppers, soft red fruits (small berries such as strawberries, blueberries, blackberries, red currants, and raspberries) and derived tomato products). After the observation that patulin was found in fresh molded tomatoes, but was absent in derived tomato products, hypotheses linked to the potential degradation of patulin during tomato processing were evaluated, under both laboratory and industrial conditions.

MATERIALS AND METHODS

Reagents and Chemicals for Patulin Analysis. Ethyl acetate (pa), ultrapure water, and acetic acid (99−100%) (pa) were purchased from ChemLab, Zedelgem, Belgium. Perchloric acid 70% and acetonitrile were bought from Fisher Scientific, Aalst, Belgium, and patulin was obtained from Sigma, Diegem, Belgium. A stock standard solution of patulin was prepared by dissolving 5 mg of patulin in 25 mL of ethyl acetate. The working standards were further prepared by making dilutions in water at pH 4. Standards were kept at −28 °C. Ascorbic acid, malic acid, and citric acid were bought from ChemLab. L-Glutamate (sodium salt) was bought from Fluka, Diegem, Belgium, and aspartate (sodium salt) was purchased from Merck, Overijse, Belgium.

Analyses for Patulin and Screening of Molded Products and Derived Tomato Products. *Molded Tomatoes, Bell Peppers, and Onions.* To evaluate the method for screening of patulin, the protocol described by Sanzani et al.[20] was adapted. Potato dextrose agar (PDA) Petri plates (Oxoid, Drongen, Belgium) were inoculated with *P. expansum* MUM 00.01 and incubated for 10 days at 25 °C. Three different types of samples were taken to evaluate which contained the highest patulin concentration: only fungi/mycelium (1 cm^2), only agar (1 cm^2), and combination of fungi and agar (1 cm^3). This procedure was conducted in triplicate. Results showed that when fungi were taken together with some agar (up to 1 cm^3), the highest peak of patulin was obtained. Therefore, it was decided to take a piece of fungus combined with a piece of the molded matrix for the screening. Because the objective was to evaluate the possible presence of patulin producing molds, this qualitative method proved to be sufficient.

A 1 cm^2 piece of fungus together with 1 cm depth of product was put into a Falcon tube together with 3 mL of acidified water (pH adjusted to 4 with pure acetic acid). This was centrifuged for 10 min at 9000*g*, filtered through a 0.45 μm syringe filter, and analyzed by HPLC-UV (Thermo, Aalst, Belgium). The results were expressed as present/absent and are qualitative. This method allowed an easy screening to determine the presence of patulin-producing molds on the molded products (i.e., tomatoes, sweet bell peppers, and onions).

Molded Soft Red Fruits and Derived Tomato Products. Patulin was extracted from frozen soft red fruits and derived tomato products by adding 2 mL of ethyl acetate to 1 g of homogenized sample. After vortexing, it was mixed using a rotary shaker for 1 h. The mixture was centrifuged during 10 min at 9000*g*. A volume of 750 μL of extract was transferred into Eppendorf tubes, dried under a gentle stream of nitrogen, and reconstituted in 750 μL of water pH 4. After vortexing and sonication, the reconstituted extract was filtered through a 0.45 μm syringe filter and analyzed by UPLC (Dionex, Aalst, Belgium). This method is quantitative, and the results are expressed as micrograms patulin per kilogram product.

Instrumental Parameters. The HPLC was a Varian Vista 5500 (Thermo). It was equipped with a Rheodyne model 7125 six-way injector with a 20 μL loop. The column used was a 250 mm × 4.6 mm i.d., 5 μm, Inertsil 5 ODS-2 stainless steel (Varian, Diegem, Belgium) column. As a mobile phase acetonitrile/0.0175% perchloric acid in water (7/93, v/v) was used at 1 mL/min. After 13 min, a change was made to 90% acetonitrile to elute interfering compounds from the extract. After 15 min, there was again a shift to acetonitrile/0.0175% perchloric acid in water (7:93, v/v). The column and guard column were maintained at 36 °C during the HPLC analysis. Detection was carried at 276 nm, and run time was 38 min.

UPLC separation was achieved on an Ultimate 3000 RS system (Dionex), consisting of a vacuum degasser, quaternary pump, cooled autosampler, and column oven (30 °C) and equipped with a 150 × 2.1 mm i.d., 2.2 μm, Acclaim RSLC 120 C18 column (Dionex). As a mobile phase acetonitrile/perchloric acid in water (0.0175%) (7/93, v/v) was used at 0.5 mL/min. After 5 min, a change was made to 90% acetonitrile to elute polluting compounds from the extract. After 6.6 min, there was again a shift to acetonitrile/0.0175% perchloric acid in water (7:93, v/v). The column was maintained at 30 °C during the UPLC analysis. Detection was carried out at 276 nm by a diode array detector, and run time was 10 min.

Validation of the Quantitative Method for Determining Patulin in Molded Soft Red Fruits and Derived Tomato Products. The analytical method was validated by spiking fresh soft red fruit (strawberry, red currant, blackberry, and blueberry) that had been homogenized to a juice and tomato concentrates with patulin (0.1, 0.5, 1, and 1.5 μg/mL). This procedure was done in duplicate. After spiking with patulin, the samples were mixed for 1 h using a rotary shaker to allow equilibration with the matrix. The total recovery (TR) was calculated as described by Sulyok et al.:[21]

$$\mathrm{TR}\ (\%) = 100 \times \text{slope } b/\text{slope } a$$

a is the slope of spiked pure solvents, and b is the slope of the calibration curve from blank extracts spiked before extraction. The LOD and LOQ were determined using the equations

$$\mathrm{LOD} = 3s_{\mathrm{bl}}/S$$

where s_{bl} is the standard error of the intercept and S the slope of the respective calibration curve) and

$$\mathrm{LOQ} = 3\mathrm{LOD}$$

Evaluation of the Stability of Patulin in the Production Process of Tomato-Derived Products. *Binding of Patulin with Compounds Present in the Tomato Matrix.* Fresh tomatoes were visually checked for the absence of molds and then mixed to prepare a tomato juice using a blender. The tomato juice was spiked with three patulin concentrations (0.5, 1.0, and 1.5 μg/mL) and left between 0 and 5 days at 4 °C before the extraction procedure was begun. This was done in duplicate.

Influence of Ascorbic Acid (Vitamin C) and Free Amino Acids on the Stability of Patulin. Different tomato simulants were made to investigate the influence of vitamin C on patulin. Tomato juice was first analyzed for the presence of free amino acids[22] and vitamin C.[23] On the basis of these results, the formulation of the tomato simulants was made to evaluate the effect of vitamin C and amino acids on the stability of patulin during the heating process of the production of tomato concentrate. The simulant was made by adding citric acid and malic acid (respectively 9 and 4% on dry matter (DM) (5% DM in tomato)) and vitamin C (0.14 g/5 g DM) to water. The same was done without the addition of vitamin C but with the addition of amino acids glutamate (0.07 g/5 g DM) and aspartate (0.02 g/5 g DM). These amino acids proved to be the two dominant amino acids representing, respectively, 63 and 21% of the total free amino acids present in tomatoes. To simulate the production process of tomato concentrate, the simulants were thickened from 5 to 12% DM using a rotary evaporator (100 °C) (Heidolph, Schwabach, Germany). Each experiment was done in duplicate and analyzed for patulin using the previously presented extraction procedure.

Influence of the Heating Process on the Stability of Patulin. Tomatoes, visually checked for the absence of molds, were inoculated with *P. expansum* MUM 00.01 and incubated at 25 °C for 2 weeks. After homogenization, the sample was preheated in a warm water bath at 95 °C for 30 min and then put on a rotary evaporator at 77 °C for 20 min, thus simulating the cold break procedure. This was done in quintuplicate. Samples were taken before preheating, after preheating, after 10 min of evaporation, and at the end (20 min of evaporation). Samples were analyzed for patulin using the previously presented extraction procedure.

Sampling in Industrial Production Process of Derived Tomato Products. Samples were taken from the field stage through the end product at different companies producing tomato concentrate (in Spain, Portugal, and Poland), salmorejo (Spain), and gazpacho (Spain). The type and number of samples that were analyzed for patulin were molded tomatoes in the field (preharvest) (n = 49), molded tomatoes entering the factory (postharvest) (n = 36), skin and seeds (removed from process) (n = 17), intermediate products (n = 61), and end products (i.e., concentrates, gazpacho, and salmorejo) (n = 28).

Data Evaluation. Prevalence data of patulin for each type of fresh produce and each country were expressed, and the standard deviation of a sample proportion was calculated with eq 1

$$s_p = \sqrt{\frac{p(1-p)}{n}} \tag{1}$$

with p the proportion of positive samples and n the number of samples tested.[24] Statistics were performed with Excel (2007).

RESULTS AND DISCUSSION

Development and Validation of the Quantitative Method for Analyzing Patulin in Molded Soft Red Fruits and Derived Tomato Products. Because the molded soft red fruits were liquid after defrosting, the described qualitative method could not be used to screen for the presence of patulin and thus for patulin-producing molds in these samples.

spiked concen on day 0 (μg/mL of patulin)	recovery[a] ± SD (%)		
	day 0	day 1	day 5
0.5	108.4 ± 11.4a	82.2 ± 8.5b	80.9 ± 5.8b
1	95.1 ± 0.2a	73.7 ± 0.4b	79.4 ± 1.1b
1.5	85.9 ± 1.5a	67.6 ± 3.4b	7.9 ± 1.8b

[a]Different letters indicate significant difference within the same concentration..

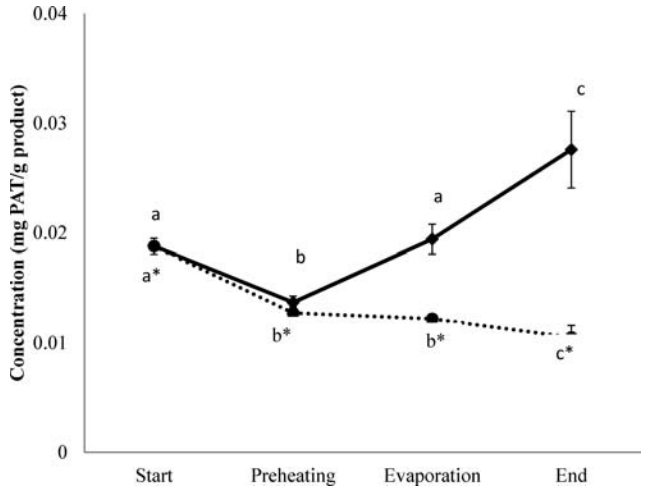

Figure 3. Evolution of patulin concentration in tomatoes throughout the production process of concentrated tomatoes: (solid line) patulin concentration on total product (mg patulin/g tomato product) (mean ± SD, n = 5; a, b, and c are significantly different); (dotted line) patulin concentration on dry matter content; (a*, b*, and c* are significantly different. Start, juice molded tomatoes; preheating = 95 °C, 30 min, evaporation = 77 °C, 10 min, and end = final product tomato concentrate (77 °C, 10 min).

Therefore, a more complex method was used to detect patulin. All derived tomato products were also screened with this method.

Patulin standards were analyzed at different levels (0.1, 0.5, 1, and 1.5 μg/mL). The linearity was assessed by plotting the peak area versus the patulin concentration, resulting in a good linearity with R^2 > 0.99. The RSD values obtained at different levels were 3.9% for 1.5 μg/mL and 4.7% for 0.1 μg/mL (n = 10; two repetitions over 5 days). The recovery of patulin in the different matrices was 96.5 ± 11.0% for tomato concentrate, 77.5 ± 7.4% for blueberry, 76.1 ± 12% for red currant, 76.4 ± 8.6% for strawberry, and 71.1 ± 6.8% for blackberry. A good recovery above 70% was achieved for all matrices. The recovery for tomato concentrate was higher than the recoveries for soft red fruit. A LOD of 13 μg/kg and a LOQ of 39 μg/kg were obtained. These are below the maximum permitted level of 50 μg patulin/kg in apples and derived products in Europe.[18]

Screening for Patulin in Molded Products. In total, 44 molded sweet bell peppers, 61 molded onions, 50 molded soft red fruits, and 158 molded tomatoes were screened for the presence of patulin. The results of the screening are shown in Figure 2. In molded onions no patulin was found. Patulin was present in 16.7% of the molded sweet bell peppers from Belgium (n = 30, Sp = standard deviation of a sample proportion = 6.8%) and in none of the molded sweet bell peppers from India (n = 14). Currently, in the literature there is no information on patulin occurrence in sweet bell peppers available. It is reported that after inoculation with *P. expansum*, patulin was found in sweet bell peppers, but not in onions.[23] Up to 8% of the molded soft red fruits were contaminated with patulin (n = 50, Sp = 3.8%). Frank[23] also mentioned the occurrence of patulin on strawberries after inoculation with patulin-producing molds. Additionally, patulin was present in 11% of molded tomatoes (n = 158, Sp = 2.5%). Fourteen percent of the tomatoes from the Belgian market were positive for patulin (n = 107, Sp = 3.4%), and patulin was present in 7.4% of the molded tomatoes from the Spanish market (n = 27, Sp = 5%). So far, no information on the presence of patulin in molded tomatoes is available in the literature. Because of the high number of tomatoes contaminated with patulin, it was decided to screen further for the presence of patulin in derived tomato products, because they form a higher risk for exposure to patulin for consumers than the molded tomatoes, which are not likely to be consumed as such.

Screening for Patulin in Derived Tomato Products. In total, 173 derived tomato samples (purees, concentrates, juices, dried tomatoes, soups) were screened for patulin (from Belgium (n = 114), Spain (n = 13), South Africa (n = 13), Brazil (n = 7), Egypt (n = 16), Cyprus (n = 7), and Finland (n = 5)) by applying the qualitative screening method. Although 11% of the molded fresh tomato samples were positive for patulin, none of the derived tomato samples tested positive (173 samples < LOD). At the moment there is no reported knowledge on the presence of patulin in processed tomato products. A study in Brazil analyzed 48 samples of tomato pulp after processing, and no patulin was found in any of the samples.[24] The Ministry of Agriculture, Fisheries and Food (MAFF) of the United Kingdom analyzed 26 samples of tomato products, and none of the samples were contaminated with patulin.[25] In view of the fact that patulin was found in 11% of the molded fresh tomatoes, and none was found in the derived tomato products, different hypotheses on the behavior and stability of patulin throughout the production process of tomato products were evaluated.

Evaluation of the Stability of Patulin in Tomato Product Production Processes. *Binding of Patulin with Compounds Present in the Tomato Matrix.* In a first experiment the possibility of patulin binding with compounds from the tomato matrix was evaluated. Previously, it was shown

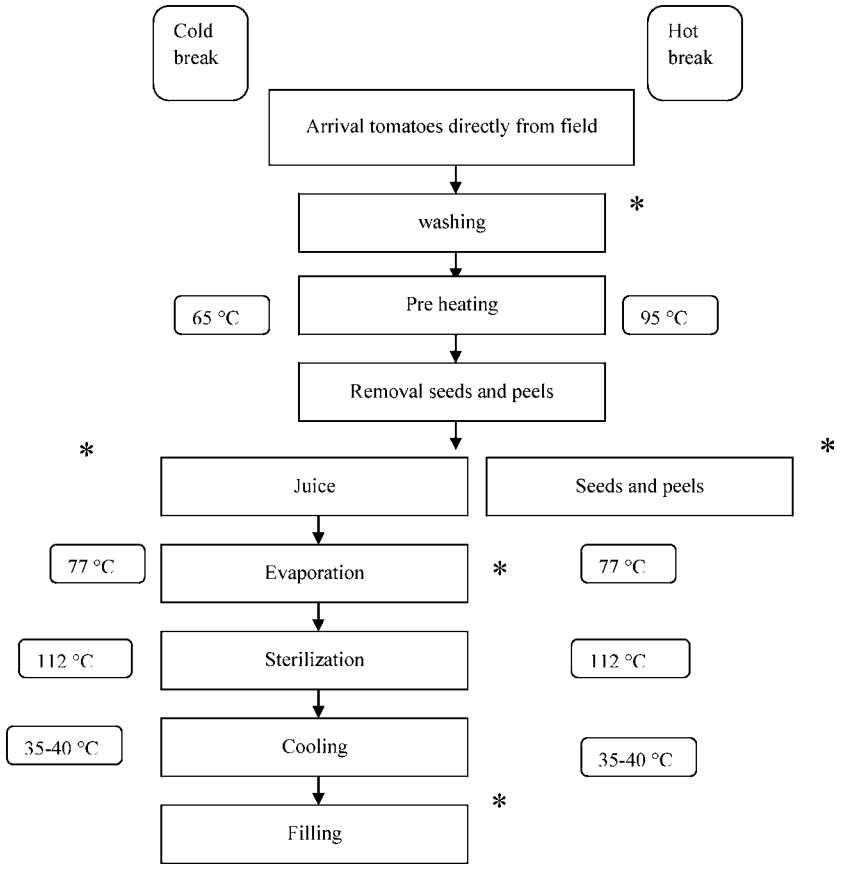

Figure 4. Flowchart of derived tomato product production process and indication of sampling in various steps (sampling is indicated by ∗).

that the clarification process reduced significantly the concentration of patulin in apple juice.[26] Moreover, a study on patulin in apple juices showed that patulin was able to bind with the solid particles of cloudy apple juice, probably due to binding with proteins.[27] It has been reported before that patulin is able to bind with thiol groups from small molecules such as amino acids.[13] Therefore, a spiking experiment with patulin was performed on laboratory-made tomato juice. The tomato juice was spiked with three patulin concentrations and left during 0−5 days at 4 °C before the extraction procedure was begun. As can be seen in Table 1, a reduction of patulin of 18−26% was observed after 1 day. After 5 days, no further significant reduction was observed. These results reveal that patulin is binding only partially to compounds in the tomato matrix, probably with proteins or free amino acids, and remains available for detection.

Influence of Ascorbic Acid and Free Amino Acids on the Stability of Patulin during the Heating Process of the Production of Tomato Concentrate. In a second experiment the influence of specific tomato matrix compounds on the stability of patulin during the production process of tomato concentrate was investigated. Therefore, different tomato simulants were made and spiked with three concentrations of patulin. The simulants were subsequently heated using a rotary evaporator (20 min, 95 °C), mimicking the tomato concentration process. The results showed that the heating process did not induce the binding of patulin with the amino acids evaluated (recovery of 88.3 ± 15%). On the other hand, the average recovery of patulin in the simulant to which vitamin C was added (59.9 ± 9.2%) was significantly lower than the average recovery of patulin in the simulant with only amino acids ($p = 0.027 < 0.05$). This confirms previous findings that ascorbic acid reduces the concentration of patulin.[28−32] In one study the addition of ascorbic acid reduced the presence of patulin by 30% after 34 days at acidic conditions in an aqueous juice-like model system.[30]

Overall Influence of the Production Process on the Stability of Patulin in Tomatoes. In a third experiment, the impact of the whole production process of tomato concentrates on the stability of patulin in a tomato matrix was evaluated on a laboratory scale. Figure 3 shows the evolution of the patulin concentration as a function of the different steps in the production of tomato concentrate. The full line shows that the patulin concentration decreased 27% after preheating (30 min at 95 °C), whereas after 20 min in the rotary evaporator, the concentration of patulin was increased by 47% compared to the original concentration. However, this increase was due to the concentration process of the tomato juice. To investigate the effect of the heating treatments on patulin alone, the evaporation of water was thus taken into account. By doing so, a decrease of the patulin content by 44% is observed in the final product, mainly due to a decrease after the preheating (30 min at 95 °C). Overall, however, the observed absence of patulin in the derived tomato products cannot be explained by the impact of the production process on patulin. In the literature it is shown that patulin is relatively heat stable, confirming our results.[10,28] Therefore, a screening for patulin in products taken during the industrial production process of tomato concentrates, gazpacho, and salmorejo was performed in various production countries.

Screening of Patulin during the Production Process of Tomato Concentrate, Gazpacho, and Salmorejo. Samples

dx.doi.org/10.1021/jf404192n | J. Agric. Food Chem. 2014, 62, 304−309

were taken from the field until the end product in the production process of tomato concentrates in different companies in producing regions in Spain, Portugal, and Poland, gazpacho (Spain), and salmorejo (Spain). Figure 4 gives a flowchart of the production process and shows the steps in the production process where samples were collected. None of the samples tested positive for patulin. The products tested were molded tomatoes in the field (preharvest) (n = 49), molded tomatoes entering the factory (postharvest) (n = 36), skin and seeds (removed from the process) (n = 17), intermediate products (n = 61), and end products (i.e., concentrates, gazpacho, and salmorejo) (n = 28). Agronomics at the different fields in Spain and Portugal, where the tomatoes for further production are cultivated, confirmed the observation that the tomatoes in the field are not infected by *P. expansum*, hence supporting the findings about the absence of patulin in the derived tomato products. However, to confirm and in particular explain this observation, extra studies have to be performed, for example, with a genetic approach. It is currently not clear why tomatoes for the fresh market are clearly more susceptible for infestation with patulin-producing molds, whereas tomatoes that are further processed are not. It is striking though that the dry matter content of the different tomatoes is significantly different: 0.5−0.6% dry matter for the tomatoes of the fresh market versus 3−4% dry matter for the tomatoes that are used for further processing. Interestingly, Konstantinou et al.[33] observed that the susceptibility to *P. expansum* was negatively correlated to the fruit firmness. In addition, *P. expansum* is a postharvest problem, whereas the tomatoes used for further processing are stored for no longer than 48 h after harvesting before further processing. However, it cannot be excluded that other factors are involved in the observed differences in the vulnerability to mold infestation.

Fresh tomatoes, soft red fruits, and sweet bell peppers in the fresh market are likely to be contaminated with patulin upon mold infestation. Remarkably, no patulin was found in processed tomato products, although it was shown that patulin is not likely to be completely degraded during processing. It could be concluded that the tomato varieties used for further processing are not vulnerable to infestation by patulin-producing molds and thus that patulin is not a relevant safety risk in processed tomato products although it is in molded fresh tomatoes.

ABSTRACT: Acrylamide formation in sweetpotato French fries (SPFF) is likely a potential health concern as there is an increasing demand for good-quality fries from carotene-rich sweetpotatoes (SP). This is the first report on acrylamide formation in SPFF as affected by processing methods. Acrylamide levels in SPFF from untreated SP strips fried at 165 °C for 2, 3, and 5 min were 124.9, 255.5, and 452.0 ng/g fresh weight, which were reduced by about 7 times to 16.3, 36.9, and 58.3 ng/g, respectively, when the strips were subjected to processing that included water blanching and soaking in 0.5% sodium acid pyrophosphate before frying. An additional step of strip soaking in 0.4% calcium chloride solution before par-frying increased the calcium content from 0.2 to 0.8 mg/g and decreased the acrylamide levels to 6.3, 17.6, and 35.4 ng/g, respectively. SPFF with acrylamide level of <100 ng/g or several times lower than that of white potato French fries can be obtained by integrating processing treatments commonly used in the food industry.

KEYWORDS: *sweet potatoes, Ipomoea batatas, sugars, asparagine, acrylamide French fries*

INTRODUCTION

Consumer demands for French fries processed from orange-fleshed sweetpotatoes (SP) as a carotene-rich food have increased in recent years.[1] In response to the increasing market demand, many food companies have thus ventured into commercial production of sweetpotato French fries (SPFF). For commercial success, the product should be of consistent quality regardless of root storage duration. Our previous studies demonstrated that consistent quality SPFF can be produced year round from SP roots stored under appropriate conditions. SPFF have relatively low fat content, 10% fresh weight (fw), and high carotene content, 10 mg/100 g fw.[2] However, aside from quality, acrylamide formation in SPFF can be a potential health concern.

Acrylamide is potentially carcinogenic in humans, and its formation is found to be associated with the Maillard reaction in thermally processed foods. Free amino acids, especially asparagine and reducing sugars, are the most important precursors for the acrylamide formation that occurs during the heat processing of foods.[3] Various studies on acrylamide intake indicated that French fries and potato chips (referred to as potato crisps in the United Kingdom and some other places), bread and bakery products, coffee, and breakfast cereals are the main sources of dietary acrylamide exposure.[4,5] French fries containing less than a proposed value of 100 μg/kg are recommended for reducing the dietary acrylamide intake.[6]

Numerous studies have been conducted to determine factors affecting its formation and to develop possible mitigation strategies to limit acrylamide levels in various foods, especially fried potato products.[7−11] The mitigation strategies include lowering reducing sugars and free asparagine in the raw materials through potato cultivar selection, application of appropriate agronomical practices, control of storage conditions (>8 °C), and tuber reconditioning for reduction of reducing sugars before processing.[12−14] Processing strategies recommended for reducing acrylamide formation in potato French fries include having the appropriate shape and size of potato cuts, that is, surface to volume ratio,[15] blanching temperature and time,[16] and soaking in water containing various additives or processing aids including calcium and sodium acid pyrophosphate (SAPP).[10] The effects of frying time, temperature, and oil type on acrylamide formation in fried potato products have been studied in detail.[8,10] Gökmen and others[17] reported a linear relationship between frying time and acrylamide content in potato French fries and an exponential increase with increased frying temperature between 150 and 190 °C. A frying model was developed for a close estimate of acrylamide content in potato French fries as a function of reducing sugar level, strip thickness, frying time, and temperature.[18]

For SPFF, several studies have been reported on the effects of SP cultivars, postharvest handling, processing treatments, and frying conditions on product quality.[2,19−23] However, limited information is available on acrylamide content in SP fries and other SP processed products. Therefore, research in this area would be beneficial to SP processors in delivering good-quality SPFF with low acrylamide levels to the consumers. We report, hereto, the effect of processing treatment and frying time on acrylamide formation in SPFF. To our knowledge, this is the first study on acrylamide

formation in SPFF as affected by common practices of French fry processing.

MATERIALS AND METHODS

Chemicals. Food grade chemicals, namely, SAPP and anhydrous calcium chloride ($CaCl_2$), were purchased from Spectrum Chemical MFG Corp. (Gardena, CA, USA) and Tetra Chemicals (Woodlands, TX, USA), respectively. High-pressure liquid chromatography (HPLC) grade methanol (99.9%) was purchased from Sigma-Aldrich (St. Louis, MO, USA). Water used for HPLC analysis was purified with a deionized water system (Pure Water Solutions, Hillsborough, NC, USA). Cellobiose and asparagine standards were obtained from Sigma-Aldrich (St. Louis, MO, USA). Acrylamide (>99%) was purchased from Sigma-Aldrich (Diesenhofen, Germany). Potassium hexacyanoferrate, zinc sulfate, and formic acid (98%) were obtained from Merck (Darmstadt, Germany). Carrez I solution was prepared by dissolving 15 g of potassium hexacyanoferrate in 100 mL of water, and Carrez II solution was prepared by dissolving 30 g of zinc sulfate in 100 mL of water. The Oasis MCX solid phase extraction (SPE) cartridges (30 mg, 1 mL) were obtained from Waters Corp. (Berkshire, UK). All other chemicals were of analytical grade (Fisher Scientific, Suwannee, GA, USA).

Sweetpotato Cultivar and French Fry Processing. Orange-fleshed SP (cv. Covington) was grown at the experimental fields of the Sweetpotato Breeding Program (Clinton, NC, USA), North Carolina State University. The harvested roots were cured at 30 °C and 85−90% relative humidity for 7 days and stored at 13−16 °C and 80−90% relative humidity for 4 months prior to sampling for the experiments.

Sweetpotatoes were washed, peeled, and cut into 0.9 × 0.9 cm strips using a manual French fry cutter (model 29, Vollrath, Bloomfield, IN, USA). Strips were trimmed by hand to a uniform length of 9 cm and divided into three batches, one for each processing treatment. For treatment 1 (Trt 1), strips were not subjected to any soaking or blanching treatments. Strips were cut and fried as commonly practiced for home preparation of French fries. A par-frying step was included in Trt 1 for parallel comparison with the other treatments in this study. For treatment 2 (Trt 2), samples were blanched in tap water at 95 ± 2 °C for 3 min using a steam-jacketed kettle. Immediately after blanching, the strips were drained and soaked in 0.5% SAPP at 62 ± 1 °C for 10 min followed by soaking in tap water at 21 ± 1 °C for 10 min. The strips were then drained, placed on a stainless steel rack, and partially air-dried at 65 ± 5 °C for 10 min to obtain up to 10−15% weight loss using a 1600 W food dehydrator (model D-14, The Sausage Maker Inc., Buffalo, NY, USA). For treatment 3 (Trt 3), the materials were processed as described in Trt 2 with an additional step of soaking the blanched SAPP-treated strips in 0.4% $CaCl_2$ at 62 ± 1 °C for 10 min before air-drying. All strips (120 g) were par-fried at 165 °C for 1 min in 22 L of canola oil in an electric fryer (1ER50 Series, Vuncan-Hart Co., Louisville, KY, USA) and drained on absorbent paper towels. This frying temperature is 10 °C lower than the maximum frying temperature recommended by the European Food Safety Authority for white potato French fries.[24] Due to the high reducing sugar content in SP, frying temperatures above 170 °C as commonly applied in potato French fries[8,11] would produce SPFF with an undesirable brown color. Par-fried strips were cooled to room temperature, covered, and frozen at −20 °C. Final frying was also done in canola oil at 165 °C for 2, 3, and 5 min.

Sample Preparation for Chemical Analyses. Samples were collected at each processing step and stored at −20 °C for analyses of dry matter, asparagine, calcium, and sugar contents. For calcium and acrylamide determination, the collected samples were dried for 24 h in a convection oven at 50 ± 1 °C and pulverized using a Mr. Coffee precision coffee grinder (Sunbeam, Boca Raton, FL, USA). Raw SP strips were freeze-dried for several days using a VirTis Genesis 25XL freeze-dryer (Gadiner, NY, USA), operated at −35 to −40 °C, and pulverized as other samples. The dry matter content of all samples was determined by using the oven method at 100 °C for 24 h.

Quantitation of Sugars. Duplicate specimens (5 g) from each frozen sample were ground in 15 mL of boiling 80% ethanol with a Tekmar tissuemizer (type SDT-1810; Tekmar Co., Cincinnati, OH, USA) and centrifuged at 5000 rpm for 10 min. Each sample was extracted two more times with 15 mL of 80% ethanol, and the combined supernatants were brought to 50 mL and filtered with a 0.25 μm syringe filter. Sugars were analyzed using a Shimadzu HPLC system equipped with a SIL-20AC HT autosampler, DGU-20a_3 degasser, LC 20AD pump, CTO-20A column oven, and CBM-20A controller hooked to an Antec Leyden model Decade II electrochemical detector in the pulsed mode using a gold electrode and LabSoultions/LC Solution Acquisition software (Shimadzu Corp., Kyoto, Japan). Sugar separation (glucose, fructose, sucrose, and maltose) was achieved by a 250 × 4 mm CarboPac-PA1 column attached to a 50 × 4 mm CarboPac guard column (Thermo Scientific, Waltham, MA, USA). The eluent was 0.15 N NaOH at a flow rate of 1 mL/min and temperature of 30 °C. An internal standard of cellobiose was used for peak area quantitation of the separated sugars.[25] All standard curves had a goodness of fit coefficient of at least 0.99 with the intercept being set to zero.

Quantitation of Asparagine. Free asparagine was analyzed by HPLC using the method described by Palazoğlu and Gökmen[26] with minor modifications. Duplicate specimens (5 g) from each frozen sample were ground in 25 mL of cold deionized water using a Tekmar tissuemizer (type SDT-1810) for 2 min. An additional 20 mL of cold water was used to rinse the dispersion probe, and the extraction was continued for 5 min with occasional shaking. The suspension was then centrifuged at 5000 rpm and 10 °C for 10 min, and the extract was adjusted to a final volume of 50 mL with cold water. Asparagine was converted to its 9-fluorenylmethylchloroformate (FMOC) by mixing 0.8 mL of the extract with 0.1 mL of 50 mM borate buffer, pH 10, and 0.1 mL of derivatizing agent (2 mg/mL FMOC-Cl reagent in acetonitrile) for 2 min. Hexane was added to remove the excess FMOC-Cl reagent after derivatization. This step was repeated three times to ensure the removal of the unused fluorescent reagent. Aliquots were taken for injection into a Thermo Finnigan HPLC system equipped with a fluorescent detector FL3000 set at 265/340 nm and ChromQuest data acquisition software (Thermo Electron Corp., San Jose, CA, USA). A Zorbax Eclipse Plus C8 column (150 × 4.6 mm, 5 μm) was used, and the fluorescent compound was eluted at a flow rate of 1 mL/min and 25 °C by mixtures of 50 mM sodium acetate buffer (A) and acetonitrile (B) with the following gradient: from 100 to 75% A from 0 to 10 min, from 75 to 55% A from 10 to 17 min, from 55 to 0% A from 17 to 25 min, then to 100% A in 5 min, and equilibrated for 37 min. Asparagine was calculated on the basis of an external standard with a range from 0.05 to 0.2 mM.

Quantitation of Calcium. Samples of SP strips and SPFF were oven-dried at 100 °C for 24 h and ground into powders. Calcium analysis was conducted at the Analytical Spectroscopy Service Laboratory, North Carolina State University, Raleigh, NC, USA. Duplicate specimens (1 g) from each sample were subjected to acid digestion into liquid and diluted further before analysis for calcium concentration using an inductively coupled plasma atomic emission spectromery (Perkin-Elmer Optima 2000DV, Boston, MA, USA).

Quantitation of Acrylamide Formation. All par-fried and finish-fried SP samples were dried at 50 °C for 24 h and ground into fine powder for acrylamide analysis as previously described.[26,27] Sample (1 g) was extracted with 20 mL of 10 mM formic acid in three stages (10, 5, and 5 mL). The coextracted colloids were precipitated with Carrez I and Carrez II reagents. Fat was separated by means of cold centrifugation (0 °C) at 5000 rpm for 10 min. The extract was cleaned up using a cation-exchanger SPE cartridge to remove positive charged coextractives, which may interfere during the mass spectrometric detection of acrylamide. The clear extract was eluted through a preconditioned Oasis MCX cartridge at a rate of 1 drop/s. After the first seven to eight drops had been discarded, the remaining drops were collected and filtered through a 0.45 μm nylon filter prior to analysis.

The samples were analyzed by using a Waters Acquity UPLC system coupled to a TQ detector operated in ESI(+) mode. Chromatographic separations were performed on an Acquity UPLC HSS T3 column using 10 mM formic acid with 0.5% methanol as

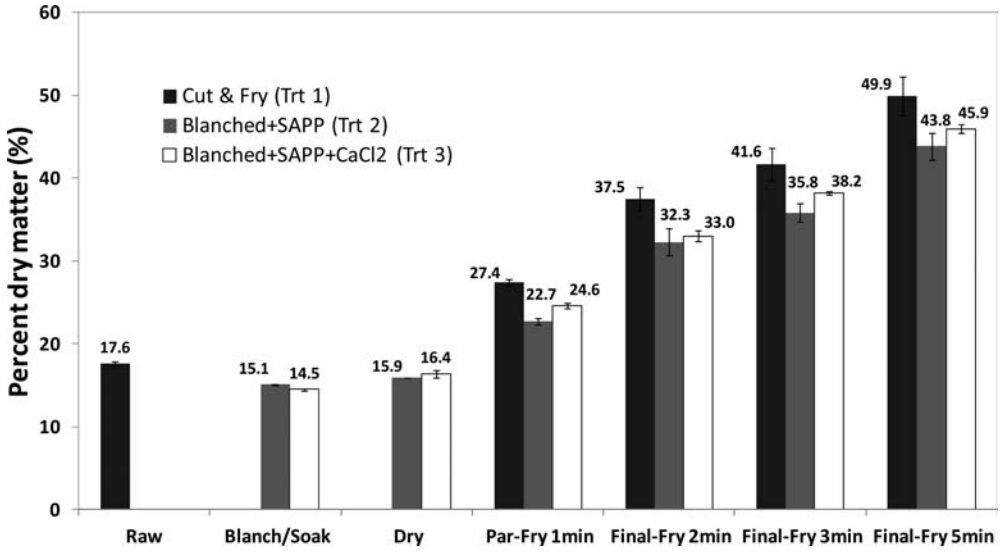

Figure 1. Dry matter content of SP strips at different processing stages.

Figure 2. Typical samples of SP French fry processing: (a) blanched SP strips; (b) par-fried, 165 °C; (c) final frying, 165 °C, 3 min.

mobile phase at the flow rate of 0.3 mL/min. The column was equilibrated at 40 °C, and a Waters Acquity FTN autosampler was held at 10 °C during the analysis. The electrospray source had the following settings: capillary voltage, 0.75 kV; cone voltage, 21 V; extractor voltage, 4 V; source temperature, 120 °C; desolvation temperature, 450 °C; desolvation gas (nitrogen) flow, 900 L/h. Acrylamide was identified by MRM of two channels. Collision gas (argon) had the flow of 0.25 mL/min. The precursor ion $[M + H]^+$ 72 was fragmented, and product ions 55 (collision energy = 9 V) and 44 (collision energy = 12 V) were monitored. The dwell time was 0.2 s for all MRM transitions. Concentration of acrylamide was calculated by means of an external calibration curve built in a range between 1 and 20 ng/mL (1, 2, 5, 10, and 20 ng/mL).

Statistical Analysis. The experiment was conducted with two replicates in a completely randomized design with a covariate. Two samples per replicate were taken for analysis. The General Linear Model procedure in the Statistical Analysis System (SAS, v. 9.2, SAS Institute Inc., Cary, NC, USA) was used to compute the statistical interferences. Group differences were evaluated using t tests with $p < 0.05$ considered to be a statistically significant difference. Means were compared with Duncan's multiple-range test with $\alpha = 0.05$.

RESULTS AND DISCUSSION

Dry Matter, Sugar, and Free Asparagine Contents. The dry matter content of the orange-fleshed SP such as the Covington cultivar used in this study is about 20% after harvest.[28] Respiration and metabolism during storage decreased the dry matter content of raw SP used in this study to 17.6%. Soluble solid leaching out during blanching further decreased the dry matter content to 14.5−15.1% in Trts 2 and 3 (Figure 1). Partial drying of SP strips before par-frying resulted in increases of dry matter content by 5.6−13.6%, which were in accordance with previous studies.[22] The final-fried samples that were fried for 2, 3, and 5 min at 165 °C had dry matter contents of 32.3−49.9% (Figure 1). With the results on dry matter content in Figure 1, all of the fresh weight (fw) data can be converted into dry weight (dw) basis for comparison with information from other studies. For commercial potato French fries, white potato tubers with dry matter content of 20−24% are preferred,[29] and after final-frying, a good-quality product should have residual moisture in the range of 38−45 or 55−62% dry matter.[11,15] After blanching and soaking, potato strips are usually subjected to partial drying to remove surface water, increasing dry matter content, shortening frying time, and consequently reducing acrylamide formation.[17] The SP French fries from all three treatments in this study had lower dry matter contents than commercial potato French fries and a softer creamy texture in the interior. The typical appearances of blanched, par-fried, and final French fry samples of the orange-fleshed SP are shown in Figure 2.

As the name implies, raw SP have a much higher sugar content than white potatoes. The sugar levels of the SP samples from different stages of the three SPFF processing schemes are shown in Figure 3. Raw strips had high concentrations of glucose, 10.22 ± 0.22 mg/g fw (1.0%); fructose, 8.09 ± 0.04 mg/g (0.8%); and sucrose, 41.91 ± 0.63 mg/g (4.2%). The total reducing sugar (sum of glucose and fructose) content was 18.31 mg/g fw (1.8%). This was 9- and 3.6-fold higher than the maximum levels of 0.2 and 0.5% reducing sugar content in white potato cultivars, which was set for limiting the browning color and acrylamide formation in the industrial processing of potato chips and French fries, respectively.[25,29]

Blanching and soaking in water or $CaCl_2$ solution decreased glucose, fructose, and sucrose contents to 0.9, 0.6, and 3.5%,

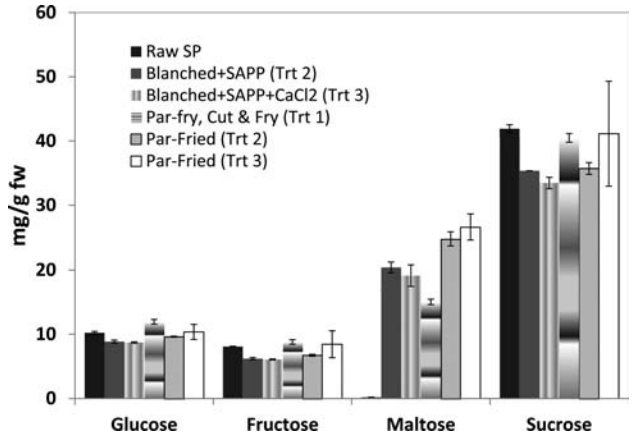

Figure 3. Effects of processing treatments and par-frying on sugar profiles of SP samples.

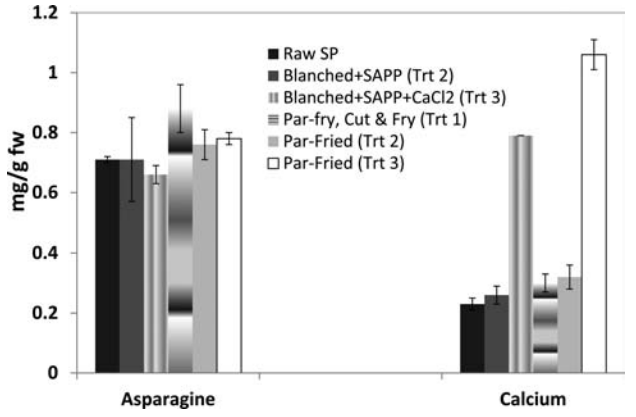

Figure 4. Asparagine and calcium contents in the raw, blanched, and par-fried SP samples.

respectively, accounting for about a 17% reduction of sugar levels in the raw SP strips. This amount of sugar leaching was much lower than the 85% decrease of reducing sugars due to water blanching of potato strips reported by Mestdagh and others.[16] Raw SP strips had negligible maltose content (0.19 ± 0.01 mg/g), which was significantly increased in the blanched and par-fried samples of all three treatments (Figure 3). The starch−maltose conversion during heating is due to hydrolysis of gelatinized starch by endogenous amylases in SP roots.[30,31] The par-fried SP samples of the cut and fry process (Trt 1) had a maltose content of 15.05 ± 0.42 mg/g (Figure 3). This maltose level was lower than the levels of the blanching and soaking treatments, which were 24.86 ± 1.11 mg/g for Trt 2 and 26.66 ± 1.98 mg/g for Trt 3. The differences can be attributed to direct application of the raw SP strips in Trt 1 to the high frying temperature and shorter time (165 °C, 1 min), which were less suitable for amylase hydrolysis of gelatinized starch into maltose as compared to blanching conditions (95 °C, 3 min). The sugar levels, except maltose, were not significantly changed by par-frying ($p > 0.05$). In the final-fried samples, the contents of total reducing sugars (sum of glucose, fructose, maltose) were 50.21−59.93 mg/g (5.02−5.99%) and sucrose levels were 52.34−70.55 mg/g (5.2−7.0%) (Table 1); these compounds provide the natural sweetness and unique flavor of SPFF as compared to white potato French fries.[23]

The asparagine content among the SP samples was found to be from 0.66 to 0.88 mg/g fw (Figure 4), which was at the low end of a range of 0.5−4.2 mg/g fw reported for eight SP varieties harvested in different years in Japan.[32] Lim and others[33] recently reported an asparagine content of 1.97 mg/g dw, equivalent to 0.68 mg/g fw of a purple-fleshed SP cultivar. The concentrations of asparagine in SP are thus much lower than the levels of 1.5−17.7 mg/g fw reported for various white potato cultivars.[13,34,35] Asparagine is the most abundant free amino acid in white potato tubers, accounting for approximately 30% of the total amino acid pool.[13] On a molar basis, asparagine concentration was about 3.7 and 5.6 times higher than that of glucose and fructose, respectively. Therefore, in white potatoes, asparagine has not been considered as a limiting factor in the Maillard reactions and acrylamide formation is mainly governed by reducing sugars during frying of potato products.[11,36] On the contrary, the amount of total reducing sugars in SP was 25 times more than that of asparagine, suggesting that asparagine is likely a limiting factor in acrylamide formation during frying of SP strips. Okuno and others[37] reported a high correlation ($R^2 = 0.803$) between free asparagine content in 15 SP varieties and acrylamide levels of 5 mm thick root slices fried in soybean oil for 4 min at 197 °C. However, there was no significant correlation between acrylamide formation with either glucose or fructose concentration in the fried crisps. In cereals such as wheat, in which the

sugar concentrations are relatively higher as compared with free amino acids, the asparagine level can be a limiting factor in acrylamide formation. Selection of wheat cultivars and growing conditions for low asparagine content is among the recommended practices in mitigating acrylamide formation in heated wheat products.[38]

Processing Treatments and Acrylamide Formation. The cut and fry process without par-frying is one of the common methods for home preparations of French fries. In this study, a par-frying step was inserted in Trt 1 for comparison with the processing effects in Trts 2 and 3. The acrylamide concentration in the par-fried SP strips of the cut-fry process was 10.7 ng/g, which linearly increased to 125−452 ng/g on a fresh weight basis (Figure 5) and 324−874 ng/g on a dry

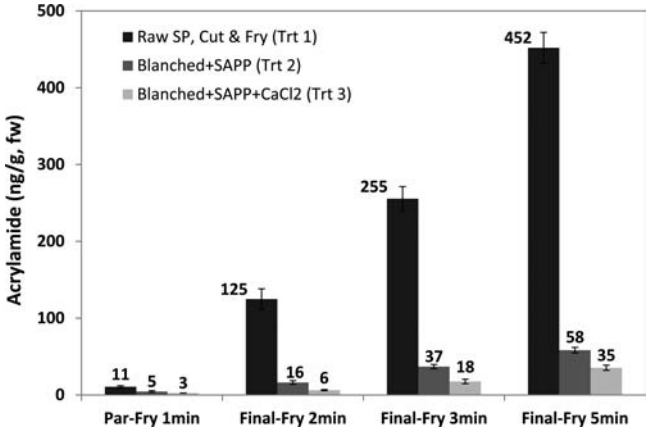

Figure 5. Acrylamide levels in sweetpotato French fries (ng/g fresh weight).

weight basis during final frying at 165 °C for 2, 3, and 5 min. The linear relationship between acrylamide formation and frying time was in accordance with the previous studies on white potato French fries.[18] The acrylamide levels obtained for the nonblanched SPFF samples (Trt 1) (Figure 5) were within the 50−1823 ng/g range of acrylamide content in white potato French fries from various commercial varieties and breeding lines.[34] Acrylamide levels up to 2970 ng/g were reported for home preparation of white potato French fries from potato varieties with wide variations in reducing sugars, 0.015−0.788% fw.[35] Mestdagh and others[16] found an acrylamide level of 833 ng/g from unblanched strips of a potato variety having low reducing sugars (0.061%) fried at 180 °C for 5 min. Commercial white potato French fries in Canada had acrylamide levels that fluctuated from 60 to 1800 ng/g.[34] Acrylamide data gathered from food monitoring in 2007−2010 by the European Food Safety Authority indicated a range of 277−356 μg/kg in white potato French fries.[39,40]

Unlike white potato French fries, information on acrylamide levels in fried SP products is very limited. Acrylamide levels up to 3000 ng/g were formed in 0.5 cm thick root slices of different SP varieties fried at 197 °C for 4 min.[37] The type of vegetable oil and the number of batches fried consecutively in the same oil affect acrylamide formation. The levels of acrylamide varied from 296 to 2019 ng/g in fried chips of a SP cultivar, which were deep-fried in different vegetable oils for 10 consecutive frying sessions, 2 min each at 180 °C.[32] On the basis of the regression of the browning index and the acrylamide content among the fried and roasted food items from different roots and tubers in Africa, the fried SP had the highest estimated acrylamide formation of 1043 ng/g.[41] Sweetpotato fries with acrylamide content of 136.3−366.1 ng/g were among the acrylamide survey of traditional snacks in Thailand.[42]

The results presented in Figure 5 demonstrate the beneficial effect of blanching and soaking SP strips in 0.5% SAPP (pH 4.4) to reduce acrylamide formation in SPFF. Blanching and soaking SP strips in SAPP as described in Trt 2 significantly ($p < 0.05$) reduced the acrylamide content to levels of 16, 37, and 58 ng/g in the final SPFF fried for 2, 3, and 5 min, respectively. The reductions were equivalent to 85−87% on fw (Figure 5) and 83−85% on dw (based on the dry matter content in Figure 1), as compared to the SPFF samples of the cut and fry process (Trt 1). Leaching out of the acrylamide precursors, reducing sugars and asparagines (Figures 3 and 4) contributed to the acrylamide reduction in the SPFF samples. It has been demonstrated that acrylamide formation mainly occurred at the surface of the white potato French fries.[6] Therefore, any processing treatments that result in decreasing the levels of reducing sugars and asparagine on the strip surface would be effective strategies in mitigating acrylamide formation. Further studies need to be conducted to determine the blanching and soaking effects on chemical components at the outer layers of SP strips and acrylamide formation in SPFF. Blanching is commonly practiced in the industrial processing of white potato French fries to inactivate oxidases associated with enzymatic browning and to develop a layer of gelatinized starch, which reduces oil absorption and improves the texture of the fried products. Acrylamide content in potato French fries was reduced from 833 ng/g in the unblanched treatment to 365 ng/g or 56% reduction and to 254 ng/g or 70% reduction by blanching white potato strips in tap water and industrially used blanching water before frying, respectively.[16]

Soaking the potato cuts in acidic solutions, for example, SAPP, citric acids, and other organic acids to reduce darkening has also been reported as a effective way to reduce acrylamide formation in white potato French fries.[10] The SAPP treatment has also been applied in processing of various SP products including purees, chips, and French fries.[23,31] Measurements of pH on the surface of SP strips was performed using a flat electrode of a pH meter (Accumet electrode 13-620-299, Fisher Scientific Accumet AR50). The results showed that the water-blanched SP strips had a pH of 6.2, which was decreased to 5.2 after soaking in 0.5% SAPP for 10 min at 65 °C. Jung and others[43] reported that soaking the potato cuts in citric acid and other organic acid has a mitigating effect by protonating asparagine amino groups at low pH and preventing the formation of Schiff bases, intermediates in the Maillard reaction and acrylamide formation.

Soaking the blanched SAPP-treated strips in 0.4% $CaCl_2$ solution (Trt 3) further decreased the acrylamide levels to 6, 18, and 35 ng/g in the final SPFF fried for 2, 3, and 5 min, respectively (Figure 5). These reductions were equivalent to 40−62% on fresh weight and 42−62% on dry weight as compared to the SPFF samples with no $CaCl_2$ (Trt 2). Therefore, the combined effects of water blanching and soaking SP strips in SAPP and $CaCl_2$ resulted in 92−95% reduction of acrylamide formation in the final frying of SPFF. Soaking the blanched SP strips in 0.4% $CaCl_2$ resulted in a 3.4-fold increase in calcium content (Figure 4). Calcium content in the potato strips after soaking was not always measured in previous studies on acrylamide formation in potato French fries.[9,10] Gökmen and Senyuva[9] reported that dipping potato strips in 0.1 M

$CaCl_2$ solution inhibited the acrylamide formation by up to 95% during frying. In the same mechanism, Kalita and Javanty[44] reported that soaking the potato strips in 0.001, 0.01, and 0.1 M vanadyl sulfate solutions before frying can reduce acrylamide formation by 30.3, 53.3, and 89.3%, respectively. It was postulated that cations such as Na^+, Ca^{2+}, and VO^{+2} could interact with asparagine and prevent the Schiff base reaction involved in acrylamide formation.

In summary, blanching the SP strips and using processing aids and additives, such as SAPP and $CaCl_2$, were effective in reducing acrylamide formation in SP French fries. These processing treatments, especially blanching and SAPP soaking, have been widely used in SP processing and unlikely affected SPFF sensory quality. Overall acceptability scores of SPFF prepared with these treatments were rated >6.0 on a nine-point hedonic scale as reported in previous studies.[2,23] Unlike white potatoes, SP contain low asparagine and high reducing sugar levels, and therefore asparagine is likely a limiting factor in acrylamide formation in SP fried products. Acrylamide formation in SPFF linearly increased with frying time. SPFF with acrylamide levels of <100 ng/g or several times lower than those of regular white potato French fries can be obtained by integrating processing treatments commonly used in the food industry.

Minor Groove Binding of the Food Colorant Carmoisine to DNA: Spectroscopic and Calorimetric Characterization Studies

Anirban Basu and Gopinatha Suresh Kumar*

Biophysical Chemistry Laboratory, Chemistry Division, CSIR–Indian Institute of Chemical Biology, Kolkata 700 032, India

ABSTRACT: The interaction of the food additive carmoisine with herring testes DNA was studied by multifaceted biophysical techniques. Carmoisine exhibited hypochromic effects in absorbance, whereas in fluorescence the intensity enhanced upon complexation with DNA. Energy transfer from the DNA base pairs to carmoisine molecules occurred upon complexation. A groove binding model of interaction was envisaged for carmoisine–DNA complexation from 4′,6-diamidino-2-phenylindole (DAPI) and Hoechst displacement studies. The binding of carmoisine stabilized the DNA structure against thermal denaturation. The binding induced moderate conformational perturbations in the B-form structure of DNA. The binding affinity (10^4 M^{-1}) values, calculated from absorbance and fluorescence data, and calorimetry titrations were in close agreement with each other. The binding was characterized to be exothermic and favored by small negative enthalpic and large positive entropic contributions. Salt-dependent calorimetric studies revealed that the binding reaction was dominated by nonpolyelectrolytic forces. The negative heat capacity value suggested the role of hydrophobic effect in the interaction.

KEYWORDS: *carmoisine, DNA binding, groove binder, thermodynamics*

INTRODUCTION

Food colorants, either natural or synthetic, are widely used to enhance the aesthetic appeal of food. Azo dyes constitute one such class of synthetic organic colorants, which are extensively used in the food, textile, paper, cosmetics, agrochemical, and pharmaceutical industries.[1] Carmoisine (Figure 1) is a synthetic

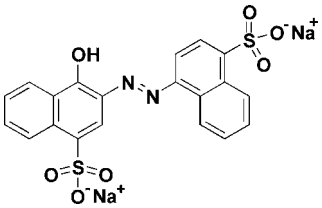

Figure 1. Molecular structure of carmoisine.

azo food dye. It is also known as Azorubine, Food Red 3, Azorubin S, Brillant carmoisine O, Acid Red 14, and C.I. 14720. It usually exists as a disodium salt and is obtained as a red to maroon powder. It has been employed for heat treatment of food after fermentation. It has E number E122 and is found in a number of food items such as blancmange, marzipan, Swiss roll, jams, preserves, yogurts, jellies, breadcrumbs, and cheesecake mixes. Carmoisine is also used as a colorant in oraldene mouthwash.[2] Owing to the presence of an azo group, carmoisine can be reduced in organisms to an aromatic amine, which is highly sensitizing.[2] Sulfanylic acid is the main metabolite of carmoisine that has been reported to date.[3] Carmoisine exercised histopathological effects on the hepatic and renal tissues of rats, which were indicated by vacuolation, swelling, necrosis, and pyknosis of their cells.[4] Histopathological studies revealed that carmoisine induced brown pigment deposition in the portal tracts and Van Küpffer cells of the liver and kidney.[5] The response was dependent not only on dose, age, gender, nutritional status, and genetic factors but also on long-term exposure to low doses.[2,6] It was recently reported that carmoisine can affect adversely and alter biochemical markers in vital organs even at low doses.[2] Significant increase in ALT, AST, ALP, urea, creatinine, total protein, and albumin in the serum of rats dosed with carmoisine have been observed. These changes were found to be more pronounced at higher doses.[2] Amin et al. reported that carmoisine induced changes in the hepatic and renal parameters, and induced oxidative stress by formation of free radicals at higher doses.[2] In the light of the above health hazards, much more safety assessment of carmoisine is essential and the use of this synthetic azo food dye should be thoroughly checked by laws, regulations, and acceptable daily intake (ADI) values.[7]

Deoxyribonucleic acid (DNA) is the key genetic substance that encodes the genetic instructions used in the development and functioning of all known living organisms. It is the carrier of hereditary information and promotes the biological synthesis of proteins and enzymes through replication and transcription.[7,8] DNA is most often the prime cellular target for natural and synthetic organic materials. In anticancer therapy specific interaction of organic molecules with genomic DNA may be exploited in preventing retrieval of further information, thereby leading to the arrest of cell division. Noninvasive therapeutic action of organic molecules may also involve photosensitization leading to energy transfer from a photoexcited molecule to molecular oxygen, generating a singlet state that may directly or indirectly damage the cellular DNA.[9] Hazardous organic materials, such as dyes, heavy metals, and pesticides, that enter into the biological system by inhalation, ingestion, or absorption through the skin can interact with

DNA directly or indirectly in vivo, which may alter the DNA morphology and bring about DNA damage, thereby adversely affecting its function and genetic expression.[7,10] A few studies on the interaction of synthetic azo dyes with DNA have been undertaken.[11,12] The results suggested a groove binding model for these azo dyes and proposed that these colorants had a toxic potential to DNA in vitro.[11,12] Hence, studies on the interaction of carmoisine with DNA are of great significance as they could provide useful insights into the toxicological aspects of the dye. A preliminary spectroscopic investigation on carmoisine–DNA binding has been reported,[11] but detailed aspects on the mode, mechanism, affinity, and energetics of its DNA binding are still obscure. Therefore, in this study we present the outcome of our detailed investigation on the binding of carmoisine to DNA from multifaceted biophysical studies.

MATERIALS AND METHODS

Materials. Herring testes DNA (HT DNA, Type XIV, 41 mol % GC), carmoisine (disodium 4-hydroxy-3-[(4-sulfo-1-naphthalenyl)-azo]-1-naphthalenesulfonate, ~98% purity), bisbenzimide (Hoechst 33258, ≥98% purity), and 4′,6-diamidino-2-phenylindole (DAPI, ≥98% purity) were purchased from Sigma-Aldrich Corp. (St. Louis, MO, USA). DNA was purified by phenol extraction and ethanol precipitation. DNA samples were sonicated to uniform size of about 280 ± 50 base pairs in a Labsonic sonicator (B. Brown, Germany) and were dialyzed under sterile conditions at 5 °C into the experimental buffer. The DNA exhibited characteristic ultraviolet absorption spectrum with an A_{260}/A_{280} ratio between 1.88 and 1.92 and an A_{260}/A_{230} ratio between 2.12 and 2.22. Concentration of the DNA was determined spectrophotometrically using a molar extinction coefficient value of 13200 M^{-1} cm^{-1} expressed in terms of base pairs. The nativeness of the DNA sample was confirmed from optical melting studies in which a sharp cooperative melting profile with about 40% hyperchromicity was observed. Carmoisine was highly soluble in aqueous buffer and hence its solution was freshly prepared and kept protected in the dark to prevent any light-induced photochemical changes. All of the buffer salts and other reagents were of analytical grade. All experiments were performed in filtered 10 mM citrate–phosphate (CP) buffer, pH 7.0, containing 5 mM Na_2HPO_4 prepared in deionized and triple-distilled water. The pH of the buffer solution was adjusted with citric acid.

Absorbance and Fluorescence Spectral Titrations. The absorption spectral titrations were performed at 20 ± 0.5 °C on a Jasco V660 unit (Jasco International Co. Ltd., Hachioji, Japan) equipped with a thermoelectrically controlled cell holder and temperature controller in matched quartz cuvettes of 1 cm path length, following generally the methods standardized in our laboratory and reported earlier.[13,14] Steady state fluorescence measurements were performed on a Shimadzu RF-5301PC fluorometer in fluorescence-free quartz cuvettes of 1 cm path length as described previously.[13,15] The excitation wavelength for carmoisine was 324 nm. All of the measurements were carried out under conditions of stirring and keeping excitation and emission band passes of 10 nm. The sample temperature of the fluorometer was maintained at 20 ± 1.0 °C using an Eylea Uni Cool U55 water bath (Tokyo Rikakikai Co. Ltd., Tokyo, Japan).

Estimation of the Binding Parameters. The spectral titration data were analyzed by employing the Benesi–Hildebrand plot.[16] The apparent equilibrium constant (K_{BH}) was measured using the relationship

$$\frac{1}{\Delta A} = \frac{1}{\Delta A_{max}} + \frac{1}{K_{BH}(\Delta A_{max})} \times \frac{1}{[M]} \quad (1)$$

where ΔA is the change in absorbance or fluorescence intensity at a given wavelength and [M] is the concentration of DNA. By plotting the reciprocal of the difference in absorbance or fluorescence intensity against the reciprocal of DNA concentration, the Benesi–Hildebrand association constant (K_{BH}) for the carmoisine–DNA association was calculated from the ratio of the intercept to the slope.[16]

Quantum Efficiency Measurements. The quantum efficiency (Q) of DNA binding to carmoisine is defined as the energy transferred from the DNA to carmoisine upon association and is determined from the ratio of the quantum efficiency of carmoisine bound to DNA (q_b) to the quantum efficiency of free carmoisine (q_f). It is calculated using the equation[17]

$$Q = \frac{q_b}{q_f} = \frac{I_b \varepsilon_f}{I_f \varepsilon_b} \quad (2)$$

where ε_f and ε_b represent the molar extinction coefficients of the free and DNA-bound carmoisine and I_b and I_f are the fluorescence intensities of complexed and free ligands, respectively. The quantum efficiency was determined according to a procedure reported earlier.[18]

Measurement of Energy Transfer. Energy transfer from DNA base pairs to the bound carmoisine was measured from the excitation spectra of the complexes in the wavelength range of 220–310 nm.[19−21] Excitation spectra were recorded at the emission maximum of carmoisine. The ratio $Q = q_b/q_f$, where q_b and q_f are the quantum efficiencies of bound and free carmoisine, respectively, was calculated for each wavelength using eq 2. A plot of the ratio Q_i/Q_{310} against wavelength was constructed. The wavelength of 310 nm was selected as the normalization wavelength owing to the negligible absorbance of DNA here.

Determination of the Binding Stoichiometry: Job Plot Analysis. The continuous variation method of Job was employed to determine the binding stoichiometry from fluorescence spectroscopy.[22,23] The fluorescence signal was recorded for solutions having the concentrations of both DNA and carmoisine varied while the sum of their concentrations was kept constant. The difference in fluorescence intensity (ΔF) in the absence and presence of DNA was plotted as a function of the input mol fraction of carmoisine. In the resulting plot the break point corresponded to the mole fraction of bound carmoisine in the complex. The stoichiometry was obtained in terms of DNA–carmoisine $[(1 - \chi_{carmoisine})/\chi_{carmoisine}]$, where $\chi_{carmoisine}$ denotes the mole fraction of carmoisine. The results reported are averages of three experiments.

Minor Groove Displacement Assay. Two well-known minor groove binders, DAPI and Hoechst 33258, were used to perform the minor groove displacement assays as reported earlier.[24−26] In a typical experiment, the changes in the emission spectra of DAPI and Hoechst complexed with the DNA were monitored upon addition of increasing concentrations of carmoisine at room temperature.

Hydrodynamic Studies. Viscometry studies were performed using a Cannon–Manning semimicrodilution viscometer type 75 (Cannon Instruments Co., State College, PA, USA) submerged vertically in a constant-temperature water bath (Cannon Instruments Co.) maintained at 20 ± 0.5 °C; 750 μL of the DNA solution was placed in the viscometer, and aliquots of concentrated carmoisine solution were added directly into the viscometer to obtain increasing D/P [carmoisine/DNA molar ratio] values. The two solutions were mixed thoroughly by gently bubbling dry nitrogen gas through the viscometer. Flow times of DNA alone and DNA complexed with different ratios of carmoisine were measured in triplicate with an accuracy of ±0.01 s using a Casio model HS-30W electronic stop watch (Casio Computer Co. Ltd., Japan), and the relative specific viscosity (η'_{sp}/η_{sp}) was determined using the equation

$$\eta'_{sp}/\eta_{sp} = \{(t_{complex} - t_0)/t_0\}/\{(t_{control} - t_0)/t_0\} \quad (3)$$

as reported.[14] In eq 3 η'_{sp} and η_{sp} are the specific viscosity of DNA in the presence and absence of carmoisne, $t_{control}$ and $t_{complex}$ are the average efflux times of DNA alone and carmoisine–DNA complex, and t_0 is average efflux time for the buffer.

Circular Dichroism (CD) Studies. CD spectra were recorded on a PC-controlled Jasco J815 unit (Jasco International Co. Ltd.) equipped with a temperature controller and thermal programmer model PFD 425L/15 in rectangular quartz cuvettes of 1 cm path length at 20 ± 0.5 °C as reported earlier.[27] Each spectrum was averaged from five

successive scans at a scan rate of 100 nm/min using a bandwidth of 1 nm at a sensitivity of 100 millidegree and was baseline corrected and smoothed within permissible limits using the built-in Jasco software. The molar ellipticity values $[\theta]$ are expressed in terms of DNA base pairs.

Optical Melting and Differential Scanning Calorimetry Studies. Thermal melting profiles of carmoisine−DNA complexes were measured on a Shimadzu Pharmaspec 1700 spectrophotometer equipped with a Peltier-controlled TMSPC-8 model accessory (Shimadzu Corp.). In a typical melting experiment, DNA samples were mixed with carmoisine and diluted into the degassed buffer in the micro-optical eight-chambered cuvette of 1 cm path length. The temperature of the microcell accessory was raised at a heating rate of 0.5 °C, monitoring the absorbance change at 260 nm. The midpoint of the transition profiles obtained from the maxima of the first-derivative plots gave the melting temperature (T_m).

Excess heat capacities as a function of temperature were measured on a Microcal VP-differential scanning calorimeter (DSC) (MicroCal, Inc., Northampton, MA, USA) as described previously.[28] In a series of DSC scans, both the calorimeter cells were loaded at first with the buffer, equilibrated at 35 °C for 15 min, and scanned from 35 to 95 °C at a rate of 50 °C/h. The buffer scans were repeated until a reproducible baseline was obtained (noise specification <0.5 μcal/°C and repeatability specification <1.3 μcal/°C). Once a steady baseline was achieved, on cooling, the sample cell was rinsed with the experimental buffer, loaded with the DNA sample followed by the DNA−carmoisine complex, and scanned in the same range. Each experiment was repeated twice with separate fillings. The DSC thermograms of excess heat capacity versus temperature were analyzed with Origin 7.0 software. The area under the experimental heat capacity (C_p°) curves was used to calculate the calorimetric transition enthalpy (ΔH_{cal}) by employing the equation

$$\Delta H_{cal} = \int C_p^\circ \, dT \tag{4}$$

where T is the absolute scale temperature in kelvins. This calorimetrically determined enthalpy being model-independent is unrelated to the nature of the transition. The temperature at which excess heat capacity reaches a maximum defines the transition temperature (T_m). The model-dependent van't Hoff enthalpy (ΔH_v) was obtained by shape analysis of the calorimetric data, and the cooperativity factor was obtained from the ratio of ΔH_{cal} and ΔH_v. Temperature calibration of the DSC unit was performed using the built-in calibration heaters of the unit.

Isothermal Titration Calorimetry (ITC). ITC experiments were performed on a MicroCal VP-ITC microcalorimeter (MicroCal, Inc.). Instrument control, data acquisition, and analysis were carried out using the dedicated Origin 7.0 software provided with the unit as described previously.[14,18] In a typical ITC experiment, aliquots of 10 μL of degassed DNA solution were injected from a rotating syringe (stirring speed = 290 rpm) into the isothermal sample chamber containing carmoisine solution (1.4235 mL). This protocol enabled us to keep a low concentration of carmoisine in the calorimeter cell, thereby preventing the possibility of aggregation of the dye. The reference cell was filled with degassed deionized water. Corresponding control experiments to determine the heat of dilution of the injectant were performed. The area under each heat burst curve was determined by integration using Origin 7.0 software. The heat associated with each DNA−buffer mixing was subtracted from the corresponding heat of carmoisine−DNA reaction to obtain the heat of carmoisine−DNA binding. The heat of dilution for injecting the buffer alone into the carmoisine solution was found to be negligible. The resulting corrected injection heats were plotted as a function of the molar ratio. The experimental data were fitted using a nonlinear least-squares minimization algorithm to one site binding to obtain the binding affinity (K), binding stoichiometry (N), and standard molar enthalpy

dx.doi.org/10.1021/jf404960n | J. Agric. Food Chem. 2014, 62, 317−326

of binding ($\Delta H°$). The standard molar binding Gibbs energy ($\Delta G°$) was calculated from standard relationship

$$\Delta G° = -RT \ln K \quad (5)$$

where R signifies the universal gas constant (1.9872041 cal K^{-1} mol^{-1}) and the entropic contribution ($T\Delta S°$) was obtained from the relationship

$$T\Delta S° = \Delta H° - \Delta G° \quad (6)$$

RESULTS AND DISCUSSION

Absorbance and Fluorescence Spectral Studies. Carmoisine has a characteristic absorption spectrum in the 200−700 nm region with three well-defined intense peaks with maxima around 216, 324, and 515 nm, respectively (Figure 2A). The interaction of carmoisine with DNA was monitored in the 300−700 nm region, where the absorbance of DNA is negligible. The absorption spectra of carmoisine exhibited 24% hypochromicity at 515 nm upon addition of increasing concentrations of DNA, revealing strong intermolecular association (Figure 2B). Such spectral changes have often been attributed to a strong interaction between the π electron cloud of the interacting ligand and the DNA base pairs.[11,29,30]

Carmoisine exhibited an emission maximum at 427 nm upon excitation at 324 nm. The interaction was studied by titrating a constant concentration of carmoisine with increasing concentrations of DNA. In the presence of increasing concentrations of DNA, enhancement of the fluorescence intensity of carmoisine was observed without any noticeable shift in the emission maximum (Figure 3A). This enhancement of the fluorescence intensity upon binding to DNA suggested an effective interaction of the bound carmoisine molecules with the DNA base pairs. This also indicated the location of the bound carmoisine molecules to be in a hydrophobic environment.

Evaluation of Binding Affinity Values. The spectral data obtained from absorbance and fluorescence titration studies were used to construct Benesi−Hildebrand plots to determine the apparent equilibrium constant (K_{BH}) for carmoisine−DNA complexation. The ratio of the intercept to slope afforded the apparent equilibrium constant as described earlier as per eq 1. From spectrophotometry, the magnitude of the apparent equilibrium constant was deduced to be 2.88×10^4 M^{-1}. Similarly, from spectrofluorometry the value of K_{BH} was estimated to be 2.41×10^4 M^{-1}. It can be seen that these two values, obtained from spectrophotometry and spectrofluorometry, were in very close agreement with each other.

Measurement of Quantum Efficiency and Energy Transfer. The quantum efficiency (Q) of a DNA binding ligand gives a measure of the energy transferred from the DNA to the bound ligand upon complexation and is calculated from the ratio of the quantum efficiency of the ligand bound to the nucleic acid (q_b) to the quantum efficiency of the free ligand (q_f). Determination of quantum efficiency (Q) further testifies to the strong binding of carmoisine to DNA. A plot of ΔAbs versus the inverse of the DNA concentration gave an exponential plot (not shown) from which a quantum efficiency value of 1.883 was determined for the complexation of carmoisine with DNA, which indicates enhancement of the energy of the bound carmoisine. $Q > 1$ is indicative of enhancement of fluorescence intensity and greater retention of fluorescence energy by the bound carmoisine molecules due to shielding within the binding site from quenching by the solvent.[17,18]

Energy transfer from the DNA base pairs to carmoisine upon complexation can serve as an evidence for strong intermolecular association. In Figure 3B the variation of Q_λ/Q_{310} with wavelength for the complexation of carmoisine with DNA is presented. An enhancement in the quantum yield is observed in the 230−290 nm region with maximum around 262 nm, which is the characteristic DNA absorbing region. The increase in quantum yield suggested that the DNA−carmoisine complexation resulted in significant energy transfer from the DNA base pairs to the carmoisine molecules.

Determination of the Binding Stoichiometry by Job Plot. The stoichiometry of the complexation was determined independently by continuous variation analysis (Job plot) in fluorescence.[22,23] At constant temperature, the fluorescence intensity was monitored for solutions in which the concentrations of both DNA and carmoisine were varied while the sum of their concentrations was kept constant. The plot of the difference in fluorescence intensity (ΔF) at 427 nm versus the mole fractions of carmoisine revealed a single binding mode for carmoisine−DNA complexation. The intersection of least-squares fitted lines at $\chi_{carmoisine} = 0.192$ corresponds to a stoichiometry value (number of DNA base pairs bound per carmoisine molecule) of 4.21 base pairs for the carmoisine−DNA complexation.

Minor Groove Displacement Assay. DAPI is a well-known minor groove binder having a fluorescence intensity that is enhanced upon complexation with DNA.[24,25] In the presence of another minor groove binding ligand, there would be competition between the new probe and DAPI for binding to the DNA, thereby leading to a decrease in the fluorescence intensity of the DAPI−DNA complex. Such competitive binding assay enables the location of the binding site of the new ligand. A pronounced decrease (~76%) in the fluorescence intensity of the DAPI−DNA complex was observed upon the addition of carmoisine (Figure 4A). This quenching in the

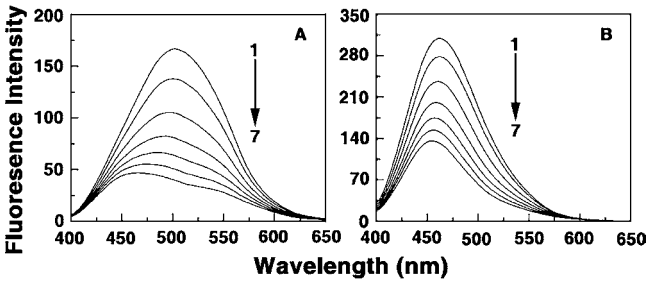

Figure 4. Changes in the fluorescence emission spectra of (A) DAPI−DNA and (B) Hoechst−DNA complexes (curve 1) upon addition of increasing concentration of carmoisine (curves 2−7). The excitation and emission band passes were fixed at 3 nm.

fluorescence intensity suggested that carmoisine has the ability to displace DAPI from the minor grooves of the DNA. Therefore, carmoisine is most likely to be a minor groove binder of DNA.

Hoechst 33258, 2-(4-hydroxyphenyl)-5-[5-(4-methylpiperazine-1-yl)benzimidazo-2-yl]bezimidazole, a synthetic *N*-methylpiperazine derivative, is another classical DNA minor groove binder with specificity for A-T-rich sequences.[26,31−36] The fluorescence intensity of Hoechst 33258 enhances significantly on binding to DNA.[37] The displacement of DNA-bound Hoechst molecules by a new ligand competing for the same sites on the DNA may be reflected as a decrease in the

dx.doi.org/10.1021/jf404960n | J. Agric. Food Chem. 2014, 62, 317−326

fluorescence intensity of the Hoechst−DNA complex upon addition of the competing ligand. The fluorescence spectral changes of Hoechst−DNA complex upon addition of increasing concentration of carmoisine are shown in Figure 4B. The decrease (∼57%) in the fluorescence intensity of DNA-bound Hoechst 33258 in the presence of carmoisine confirms that carmoisine is also an A-T-specific minor groove binder.

Hydrodynamic Studies. In another assay we checked the intercalation ability of carmoisine. The viscosity of a rod-like DNA enhances upon intercalation of ligands to accommodate the stacked molecules between the base pairs. This leads to an increase in the helix contour length of the DNA.[38] Very minor alterations in relative viscosity occur for ligands binding to the grooves of DNA. To prove the mode of binding, the viscosity of DNA in the presence and absence of carmoisine was measured in terms of flow time, which was obtained as an average of four readings. The viscosity of the DNA solution was estimated in the presence of increasing concentrations of carmoisine, and the change in the relative viscosities with increasing D/P values was calculated. The relative viscosities of the DNA solution, determined employing eq 3 (vide supra), showed only marginal alterations in the presence of carmoisine. Such minor changes in relative viscosity rule out intercalation and may be correlated to a groove binding model.[11,26]

Circular Dichroism Studies. The DNA in its B conformation exhibits a positive band at around 278 nm (due to base stacking) and a negative band at around 245 nm (due to polynucleotide helicity).[39] Intercalative binding results in an increase in the molar ellipticity of the positive bands due to the stacking interaction of the intercalator between the base pairs of DNA.[40] However, the groove binders generally do not cause significant unwinding of the DNA base pairs.[41] Figure 5 depicts

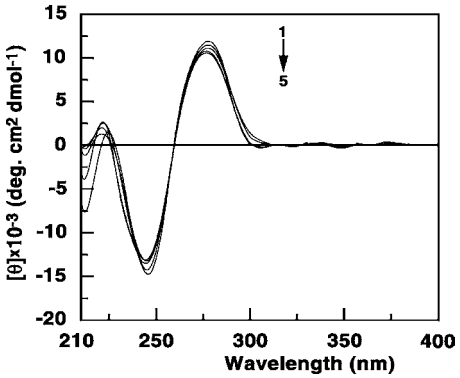

Figure 5. Circular dichroism spectra of DNA (curve 1) treated with increasing concentrations of carmoisine (curves 2−5).

the CD spectra of DNA in the absence and in the presence of increasing concentrations of carmoisine in the 210−450 nm region. A moderate decrease in the positive band upon addition of carmoisine was observed with no change in the band shape or induction of new bands. Besides, minor perturbations in the negative CD band at 245 nm were also evident. Thus, no significant conformational change or unwinding of the DNA base pairs or formation of any altered form of DNA were observed upon the addition of carmoisine, indicating that it most likely binds in the minor groove.[26] The decrease in the positive CD band of DNA in the presence of carmoisine may be attributed to a transition from the extended double-helix form to a more compact Ψ-structure form.[42] Small molecules having achiral chromophores do not exhibit any CD spectra, but on binding to the chiral DNA double helix, the ligand can acquire an induced CD signal. The sign and magnitude of the induced CD spectra are governed by the binding mode, DNA sequence, depth of intercalation, and orientation of the transition dipoles of the ligand.[43] However, carmoisine did not exhibit any induced CD spectra upon complexation with DNA in the studied wavelength region.

Optical Melting and Differential Scanning Calorimetry Results. The ability of carmoisine to enhance the stability of the double-stranded DNA against strand separation was studied by optical melting and by DSC experiments. Under the experimental conditions, native DNA melted cooperatively at 65.0 °C without any hysteresis. The binding of carmoisine enhanced the thermal stability of DNA against strand separation. Under saturating conditions, the melting temperature of DNA increased to around 71.5 °C. A ΔT_m value of about 6.5 °C was obtained for carmoisine−DNA complexation. The optical melting profiles of native DNA and DNA complexed with carmoisine are presented in Figure 6A. This enhancement in the melting temperature further substantiates the binding of carmoisine to double-stranded DNA.

DSC studies also showed identical stabilization of the double-stranded DNA by carmoisine against strand separation (Figure 6B). ΔH_{cal} is the sum total of endothermic contributions, such as the disruption of hydrogen bonds[44] and exothermic contributions such as the breakup of hydrophobic interactions.[45] It is model independent and is not governed by the nature of the transition. This also holds true for the van't Hoff enthalpy (ΔH_v).[46] The ratio $\Delta H_v/\Delta H_{cal} > 1$ gives a measure of the average number of DNA base pairs that melt as a single thermodynamic entity,and tends to suggest a significantly populated intermediate state.[47] The data obtained from the helix melting experiments were used to evaluate the binding constant (K_{obs}) of the DNA association at 20 °C using the equation derived by Crothers[48] as described in detail earlier:[9,14,49]

$$1/T_m^{\circ} - 1/T_m = (R/n\Delta H_{wc}) \ln(1 + K_{T_m}\alpha) \quad (7)$$

T_m° is the optical melting temperature of the DNA in the absence of carmoisine, T_m is the melting temperature in the presence of saturating amounts of carmoisine, ΔH_{wc} is the enthalpy of DNA melting, R is the universal gas constant (1.9872041 cal K^{-1} mol^{-1}), K_{T_m} is the drug binding constant at the T_m, α is the free drug activity, which may be estimated by half of the total drug concentration, and n is the site size of the drug binding. The calculated apparent binding constant at the melting temperature can be extrapolated to a reference temperature (say 293.15 K) using the standard relationship

$$\partial[\ln(K_{obs})]/\partial(1/T) = -(\Delta H_b/R) \quad (8)$$

where K_{obs} is the drug binding constant at the reference temperature T (in kelvin) and ΔH_b is the standard molar binding enthalpy, which was directly determined from the ITC experiment. The data obtained from the helix melting experiments are collated in Table 1. The magnitude of the binding constant (K_{obs}) for carmoisine−DNA complexation from the helix melting experiments was deduced to be 2.91×10^4 M^{-1}. This value is of the same order and in close agreement with that obtained from the spectroscopic studies.

DNA + carmoisine	71.5	71.4	6.50	10.07	90.30	2.74	2.91

[a]Melting stabilization of DNA in the presence of saturating amounts of carmoisine. ΔH_{cal} is the calorimetric enthalpy, ΔH_v is the van't Hoff enthalpy, K_{T_m} is the binding constant at the melting temperature, and K_{obs} is the carmoisine binding constant at 20 °C determined using equations described in the text. ΔH_{cal} and ΔH_v were obtained from the DSC data.

Elucidating the Thermodynamics of the Interaction. Thermodynamic analysis of the complexation of a ligand to a biomacromolecule provides valuable insights into the molecular forces governing the complexation. Here we present a detailed calorimetric studies on the interaction of carmoisine and DNA. Figure 7A presents the representative primary data from the isothermal calorimetric titration of DNA into a solution of carmoisine at 293.15 K. It can be seen from the plot of power versus time that the binding reaction was characterized by exothermic heats. The integrated heat data after correction of heat of dilution showed only one monophasic binding; hence, it was fitted to a single-site model. This was also based on the results of the Job plot analysis, which revealed a single binding mode for carmoisine–DNA complexation. The binding affinity value obtained from ITC was $(2.62 \pm 0.06) \times 10^4$ M^{-1} and is in very close agreement with the value calculated from spectroscopic studies. The binding of carmoisine to DNA was driven by a positive standard molar entropic contribution of 5.695 kcal/mol and a negative standard molar enthalpic contribution of −0.235 kcal/mol. Thus, the binding reaction was dominated by large positive entropy changes and relatively small negative enthalpy changes. This strong positive entropy term is suggestive of the disruption and release of DNA-bound water molecules, and the negative enthalpy term originates from noncovalent interactions such as stacking.[50,51] The standard molar Gibbs energy for carmoisine–DNA complexation was estimated to be −5.93 ± 0.06 kcal/mol. The overall binding affinity and the binding site size values obtained from ITC analysis (Table 2) are in excellent agreement with the affinity values and the stoichiometry values derived from spectroscopy studies. These values are also comparable to those evaluated from the thermal melting data.

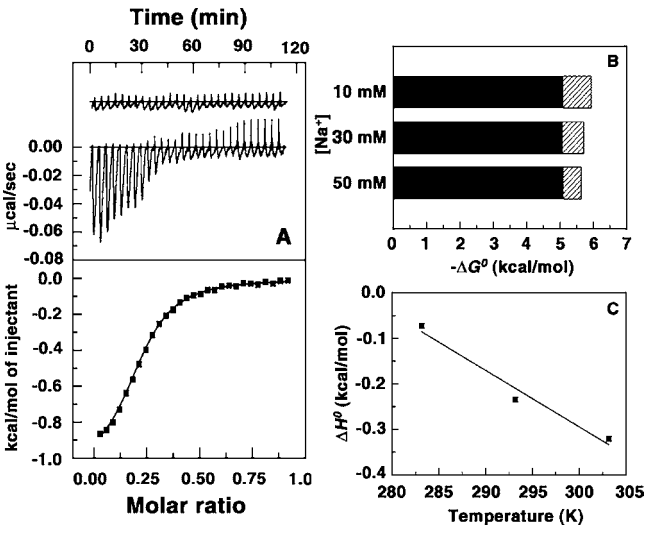

Figure 7. (A) ITC profiles for the complexation of carmoisine with DNA. The top panel represents the raw data for sequential injection of DNA into carmoisine solution, and the bottom panel shows the integrated heat data after correction of heat of dilution against molar ratio of DNA/carmoisine. The data points (■) were fitted to a one-site model, and the solid line represents the best fit data. Experiments were performed at 293.15 K. (B) Partitioned polyelectrolytic ($\Delta G°_{pe}$) (shaded) and nonpolyelectrolytic ($\Delta G°_t$) (black) contributions to the binding Gibbs energy at different [Na^+]. (C) Plot of variation of $\Delta H°$ (■) with temperature for carmoisine–DNA complexation.

Influence of Ionic Strength of the Medium on Binding and Parsing of the Standard Molar Gibbs Energy Change. The analysis of carmoisine–DNA complexation in the salt concentration range 10–50 mM Na^+ in conjunction with van't Hoff analysis revealed the contributions from polyelectrolytic and nonpolyelectrolytic forces. A relationship between the binding constant (K) and Na^+ ion concentration has been given by Record and co-workers[52]

$$\partial \log(K)/\partial \log([Na^+]) = -z\varphi \quad (9)$$

dx.doi.org/10.1021/jf404960n | J. Agric. Food Chem. 2014, 62, 317–326

Table 2. Thermodynamic Parameters for the Association of Carmoisine with DNA from ITC at Different Salt Concentrations[a]

	$[Na^+]$ (mM)	$K \times 10^{-4}$ (M^{-1})	n	ΔH° (kcal/mol)	$T\Delta S^\circ$ (kcal/mol)	ΔG° (kcal/mol)	ΔG°_t (cal/(mol K))	ΔG°_{pe} (kcal/mol)
carmoisine	10	2.62 ± 0.06	4.55 ± 0.02	−0.235 ± 0.009	5.695	−5.93 ± 0.06	−5.08	−0.85
	30	1.80 ± 0.05	3.66 ± 0.01	−0.214 ± 0.007	5.496	−5.71 ± 0.03	−5.07	−0.64
	50	1.59 ± 0.04	4.92 ± 0.01	−0.211 ± 0.006	5.429	−5.64 ± 0.02	−5.09	−0.55

[a]All of the data in this table are derived from ITC experiments conducted at different $[Na^+]$, pH 7.0, and are the average of four determinations. K and ΔH° values were determined from ITC profiles fitting to Origin 7.0 software as described in the text. The values of ΔG° and $T\Delta S^\circ$ were determined using the equations $\Delta G^\circ = -RT \ln K$ and $T\Delta S^\circ = \Delta H^\circ - \Delta G^\circ$. ΔG°_t and ΔG°_{pe} are the Gibbs energy contributions from the nonpolyelectrolytic and polyelectrolytic forces, respectively. All of the ITC profiles were fitted to a model of single binding. Uncertainties correspond to regression standard errors.

Table 3. Thermodynamic Parameters for the Association of the Carmoisine with DNA from ITC at Different Temperatures[a]

temperature (T) (K)	$K \times 10^{-4}$ (M^{-1})	n	ΔH° (kcal/mol)	$T\Delta S^\circ$ (kcal/mol)	ΔG° (kcal/mol)	ΔC_p^0 (cal/(mol K))	ΔG°_{hyd} (kcal/mol)
283.15	3.27 ± 0.06	5.41 ± 0.03	−0.073 ± 0.004	5.777	−5.85 ± 0.06		
293.15	2.62 ± 0.06	4.55 ± 0.02	−0.235 ± 0.009	5.695	−5.93 ± 0.06	−12.4	−0.99
303.15	1.32 ± 0.03	4.56 ± 0.02	−0.321 ± 0.009	5.399	−5.72 ± 0.04		

[a]All of the data in this table are derived from the ITC experiments and are the average of four determinations. T denotes the temperatures studied. K, the binding affinity and ΔH°, the enthalpy change, were determined from ITC profiles fitting to Origin 7.0 software as described in the text. The values of ΔG°, Gibbs energy change, and $T\Delta S^\circ$, the entropy contribution, were determined using the equations $\Delta G^\circ = -RT \ln K$ and $T\Delta S^\circ = \Delta H^\circ - \Delta G^\circ$. ΔG°_{hyd} is the Gibbs energy contribution from the hydrophobic transfer of binding of the analogs and ΔC_p^0 denotes the heat capacity changes. All of the ITC profiles were fit to a model of single binding sites. Uncertainties correspond to regression standard errors.

where z is the apparent charge of the bound ligand and φ is the fraction of sodium ions bound per DNA phosphate group. With increasing $[Na^+]$ from 10 to 50 mM, the binding affinity reduced from $(2.62 \pm 0.06) \times 10^4$ to $(1.59 \pm 0.04) \times 10^4$ M^{-1}. However, the binding stoichiometry varied only marginally. The slope of the plot of log K versus log $[Na^+]$ yielded a value of −0.315. With increasing salt conditions, the negative enthalpy and positive entropy values decreased in magnitude. The binding Gibbs energies of the complexation reduced by about 0.29 kcal mol^{-1} (in absolute values) with changing salt concentration from 10 to 50 mM (Table 2). There are contributions from various physical factors to the total binding Gibbs energy for a ligand−DNA reaction, and a better understanding of the energetics of the complexation can be achieved from detailed partitioning of the binding Gibbs energy. From the dependence of K on $[Na^+]$, the observed binding Gibbs energy can be partitioned between the polyelectrolytic (ΔG°_{pe}) and nonpolyelectrolytic (ΔG°_t) components. The uncharged molecules can also have polyelectrolytic contribution owing to separation of phosphates that reduces the extent of counterion condensation that releases cations.[53−55] The contribution to the binding Gibbs energy from the electrostatic forces (polyelectrolytic) is given by the standard relationship[56,57]

$$\Delta G^\circ_{pe} = -z\varphi RT \ln([Na^+]) \quad (10)$$

where $z\varphi$ is the slope of the van't Hoff plot. At 10, 30, and 50 mM $[Na^+]$, the value of ΔG°_{pe} has been calculated to be −0.85, −0.64, and −0.55 kcal mol^{-1}, respectively, which accounts for about 14, 11, and 10% of the total binding Gibbs energy. The ΔG°_{pe} contains contribution from an enthalpic term, originating from the coulombic interaction of the solute molecules with the counterions present in solution, and an entropic term, arising from the disruption of the ion atmosphere upon complexation of carmoisine. A graphical representation of the partitioning of the binding Gibbs energy between polyelectrolytic (ΔG°_{pe}) and nonpolyelectrolytic (ΔG°_t) components is depicted in Figure 7B. It can be seen that the ΔG°_{pe} contribution decreased with increasing $[Na^+]$, whereas ΔG°_t had large magnitude in all cases and remained almost invariant with change in salt concentration (Table 2). The ΔG°_t term originates from noncovalent molecular interactions such as H-bonding, hydrophobic contacts, van der Waals forces, and $\pi-\pi$ stacking between the aromatic rings of carmoisine and the DNA base pairs.

Temperature-Dependent Isothermal Titration Calorimetry: Determination of Heat Capacity Changes. To obtain insight about the nature of forces driving the interaction, ITC experiments were performed in the temperature range of 283.15−303.15 K. The constant-pressure heat capacity change (ΔC_p^0) was determined by employing the standard relationship

$$\Delta C_p^0 = \partial \Delta H^\circ / \partial T \quad (11)$$

Heat capacity change data can lend valuable information about the type and magnitude of forces governing the complexation phenomenon. The thermodynamic quantities deduced from ITC experiments conducted at three temperatures, namely, 283.15, 293.15, and 303.15 K, are depicted in Table 3. The binding constant of the reaction decreased from $(3.27 \pm 0.06) \times 10^4$ to $(2.62 \pm 0.06) \times 10^4$ M^{-1} when the temperature was raised from 283.15 to 293.15 K. An additional rise in temperature from 293.15 to 303.15 K further reduced the K value to $(1.32 \pm 0.03) \times 10^4$ M^{-1}. Furthermore, there were remarkable changes in the enthalpy and entropy contributions; while the ΔH° values increased, the $T\Delta S^\circ$ values decreased (Table 3). Variation of the ΔH° with temperature can provide information on the heat capacity changes (ΔC_p^0). The observed enthalpy change (ΔH°) varied linearly within the experimental temperature range, suggesting that there is no measurable shift in the preexisting equilibrium between the conformational states of DNA. The variation of ΔH° with temperature afforded a ΔC_p^0 value of −12.40 cal K^{-1} mol^{-1} (Figure 7C). The finite value of ΔC_p^0 indicated temperature dependence of the enthalpy change. Furthermore, change in solvent-accessible surface area has also been revealed to be a significant component of ΔC_p^0.[58−60] Besides, the change in the structured water like the water of hydrophobic hydration as well as the transfer of nonpolar groups into the DNA grooves may also

dx.doi.org/10.1021/jf404960n | J. Agric. Food Chem. 2014, 62, 317−326

result in the release of water, which can contribute a negative term to the ΔC_p^0. The negative ΔC_p^0 value observed here for carmoisine−DNA complexation indicated that the binding is specific and accompanied by burial of nonpolar surface area.[51,58,59] Furthermore, this suggested the involvement of a significant hydrophobic component in the complexation process. ΔG°_{hyd}; the Gibbs energy contribution for the hydrophobic transfer step was calculated from the relationship $\Delta G^\circ_{hyd} = (80 \pm 10) \times \Delta C_p^0$, given by Record et al.[61] The value of ΔG°_{hyd} for carmoisine−DNA complexation was found to be −0.99 kcal mol^{-1}.

This study delineates the structural and thermodynamic aspects of the binding of the food colorant carmoisine to DNA through multifaceted spectroscopic and calorimetric studies. The thermodynamics of the binding reaction correlated well with the structural aspects, thereby enabling a complete and unambiguous understanding of the interaction profile. Carmoisine exhibited hypochromic shift absorbance, and its fluorescence intensity enhanced upon complexation with DNA. The magnitude of the association constant calculated from the Benesi−Hildebrand analysis of the absorption and fluorescence data was of the order 10^4 M^{-1}. Helix melting studies revealed that carmoisine enhanced the thermal stability of DNA by about 6.5 °C. Job plot analysis revealed a single binding mode for carmoisine−DNA complexation. The quantum efficiency value provided evidence for energy transfer from the DNA base pairs to carmoisine. CD studies showed that carmoisine induced moderate conformational perturbations in the secondary structure of DNA. DAPI and Hoechst displacement assay revealed a groove binding model for carmoisine−-DNA complexation. The energetics of the interaction showed that the binding was predominantly entropy driven with a smaller but favorable enthalpy term, which enhanced significantly with temperature. The strong positive entropic terms suggested the disruption and release of DNA-bound water molecules by carmoisine. Salt-dependent ITC studies showed that the contribution from the nonelectrostatic forces to the binding Gibbs energy was clearly dominant and accounted for about 85−90% of the total binding Gibbs energy. The negative heat capacity change observed here can be attributed to the involvement of dominant hydrophobic forces in the complexation process, corroborating the low polyelectrolytic contribution to the binding Gibbs energy. This study presents for the first time a complete structural and thermodynamic profile of the minor groove interaction of carmoisine with double-stranded DNA that further advances our knowledge of the interaction of small molecules with DNA that may be useful for assessing the toxicological effects of this important food additive.

ABSTRACT: One attractive strategy to discover more active and/or crop-selective herbicides is to make structural changes to currently registered compounds. This strategy is especially appealing for those compounds with limited herbicide resistance and whose chemistry is accompanied with transgenic tools to enable herbicide tolerance in crop plants. Bromoxynil is a photosystem II (PSII) inhibitor registered for control of broadleaf weeds in several agronomic and specialty crops. Recently at the University of Tennessee—Knoxville several analogues of bromoxynil were synthesized including a previously synthesized pyridine (2,6-dibromo-5-hydroxypyridine-2-carbonitrile sodium salt), a novel pyrimidine (4,6-dibromo-5-hydroxypyrimidine-2-carbonitrile sodium salt), and a novel pyridine *N*-oxide (2,6-dibromo-1-oxidopyridin-1-ium-4-carbonitrile). These new analogues of bromoxynil were also evaluated for their herbicidal activity on soybean (*Glycine max*), cotton (*Gossypium hirsutum*), redroot pigweed (*Amaranthus retroflexus*), velvetleaf (*Abutilon theophrasti*), large crabgrass (*Digitaria sanguinalis*), and pitted morningglory (*Ipomoea lacunose*) when applied at 0.28 kg ha^{-1}. A second study was conducted on a glyphosate-resistant weed (*Amaranthus palmeri*) with the compounds being applied at 0.56 kg ha^{-1}. Although all compounds were believed to inhibit PSII by binding in the quinone binding pocket of D1, the pyridine and pyridine-*N*-oxide analogues were clearly more potent than bromoxynil on *Amaranthus retroflexus*. However, application of the pyrimidine herbicide resulted in the least injury to all species tested. These variations in efficacy were investigated using molecular docking simulations, which indicate that the pyridine analogue may form a stronger hydrogen bond in the pocket of the D1 protein than the original bromoxynil. A pyridine analogue was able to control the glyphosate-resistant *Amaranthus palmeri* with >80% efficacy. The pyridine analogues of bromoxynil showed potential to have a different weed control spectrum compared to bromoxynil. A pyridine analogue of bromoxynil synthesized in this research controlled several weed species greater than bromoxynil itself, potentially due to enhanced binding within the PSII binding pocket. Future research should compare this analogue to bromoxynil using optimized formulations at higher application rates.

KEYWORDS: *bromoxynil, herbicide resistance, glyphosate resistance, Palmer amaranth*

INTRODUCTION

No new herbicidal mode of action has been incorporated into weed management strategies in over 20 years.[1] Prior to 1991 a new mode of action was introduced to the market approximately every three years. The dearth of novel herbicidal modes of action has led to selection pressure for herbicide-resistant weed biotypes in many different cropping systems. Currently, over 400 weedy biotypes exist that are resistant to at least one herbicide active ingredient.[2] To that end, optimization of molecules with the potential to either provide new modes of action or target established sites where resistance is not problematic is important for the future of weed management.[3,4]

A known target site with the potential to be exploited further is the plastoquinone binding site (Q_B) of the photosystem II (PSII) reaction center. PSII consists of multiple protein subunits and acts as a water:quinol oxidoreductase in all oxygenic organisms including cyanobacteria, algae, and plants. Upon illumination, the reaction center primary donor P680 becomes excited to a singlet state, where it then rapidly undergoes charge separation. P680 chlorophyll donates an electron to a proximal pheophytin (Ph) molecule, which leads to the formation of a $P680^{\bullet+}Ph^{\bullet-}$ radical pair. The occurrence of the radical pair is brief, as an electron is transferred from the Ph anion to the nonmobile plastoquinone electron acceptor Q_A to form the $P680^{\bullet+}Q_A{}^{\bullet-}$ radical.[6,7] Subsequently, an electron is transferred to Q_B via several intermediates. $P680^+$ is then rereduced by extracting an electron from Tyr_{161} of the D1 protein, which leads to the formation of a $TyrZ^{\bullet}(H^+)Q_A{}^{\bullet}$ radical pair.[8,9] This cation is then stabilized by the Mn_4Ca cluster in the oxygen-evolving complex, which upon further illumination extracts four electrons from two H_2O molecules to evolve O_2. On the other side of the membrane the electron is transferred from Q_A to Q_B via the nonheme Fe. After accepting

two electrons Q_B is converted to plastoquinol and released from the D1 binding pocket.[5]

Generally, PSII-inhibiting herbicides bind at the exchangeable Q_B site of the D1 protein in the PSII reaction center.[10−14] Binding of these herbicides displaces plastoquinone at the Q_B site; thus, the less mobile Q_A is unable to be oxidized. This leads to a charge recombination pathway resulting in the formation of triple chlorophyll and singlet oxygen species, which causes lipid peroxidation and general oxidative stress.[5,15] However, PSII inhibitors can interact with different portions of this binding pocket of the D1 protein. On the basis of simulation modeling and D1 mutant studies, phenolic herbicides such as bromoxynil and ioxynil form hydrogen bonds with His_{215} in the D1 protein, whereas it is believed that triazines and ureas do not form a hydrogen bond at this residue; rather they form a hydrogen bond at Ser_{264} of the D1 protein.[16,17]

Currently, there are approximately 70 weedy biotypes that are resistant to triazine herbicides, and many of the biotypes contain a Ser to Gly_{264} mutation.[2,18] Comparatively, only one weedy biotype is resistant to phenolic herbicides, and the mechanism of resistance is metabolism based.[2] Also, weedy biotypes containing the Gly_{264} mutation are hypersensitive to phenolic herbicides.[19,20] Resistance to phenolic herbicides is less likely to occur for two reasons: (1) bromoxynil and ioxynil typically have limited residual soil activity when compared to triazine herbicides; thus, there is less selection pressure on the seed bank for resistant biotypes[21,22]; and (2) $Hist_{215}$ and three other histidine residues form hydrogen bonds with the nonheme iron. This amino acid residue is more conserved than Ser_{264}; thus, resistance is less likely to occur due to target site mutations.

Physiologically, the interaction of His_{215} with phenolic herbicides could be exploited further with analogues of different electronegative properties because of the proximity of phenolic herbicides to Q_A.[16] Essentially, a molecular bridge forms between Q_A, His_{214} of the D2 protein, the nonheme iron, His_{215} of the D1 protein, and Q_B. The CO group on bromoxynil, which is deprotonated at physiological pH, forms a stronger hydrogen bond with the NH imidazole group on His_{215} than plastoquinone.[16] The tighter bond coupled with slightly different electron density characteristics of the herbicide likely affects the conformation of the Q_A−His_{214}−iron−His_{215}−Q_B system. Specifically, the hydrogen bond strength of the Q_A CO group and the imidazole NH group off His_{214} is likely altered.[23] Subsequently, the redox potential of Q_A is reduced, which leads to a charge recombination that favors $P680^+pPheo^-$, ultimately leading to a triplet chlorophyll state. Evaluation of analogues of phenolic herbicides is warranted given how important the Q_A−His_{214}−iron−His_{215}−Q_B molecular bridge is in PSII. In particular, heterocyclic[24] analogues (cyclic structures containing atoms other than carbon) of the phenolic herbicides would be interesting candidates for evaluation because of the potential impact that a ring structure with different electronegative properties would have on the π electron system of the molecular bridge, Q_B binding site, and redox potential of Q_A.

Bromoxynil is an ideal phenolic PSII inhibitor for structural modification because of its current significance to the marketplace, limited environmental impact due to rapid degradation in the soil, and effectiveness when applied postemergence (POST) for control of many problematic broadleaf weeds including pitted morningglory.[25,26] Bromoxynil is labeled for use in alfalfa (*Medicago sativa*), cereals, corn (*Zea mays*), flax (*Linum usitatissimum*), mint (*Mentha spicata*), garlic (*Allium sativum*), and onions (*Allium cepa*).[22] Commercially, bromoxynil is formulated as an ester to help penetrate the hydrophobic cuticle of weeds. Subsequently, the herbicide is then hydrolyzed by plant enzymes to a free acid molecule.[27] Typically, bromoxynil absorption is greater in shoots than in roots because bromoxynil is conjugated in the soil and does not translocate as easily to leaves.[28,29]

An understanding of bromoxynil's impact on plant physiology, availability of the target crystal structure of the D1 protein, and bromoxynil's importance to weed management make bromoxynil an interesting compound for optimization. Research was conducted to evaluate novel heterocyclic analogues of bromoxynil synthesized on site for crop tolerance and weed control. Further analysis was performed by simulating the interaction of bromoxynil analogues in the binding pocket.

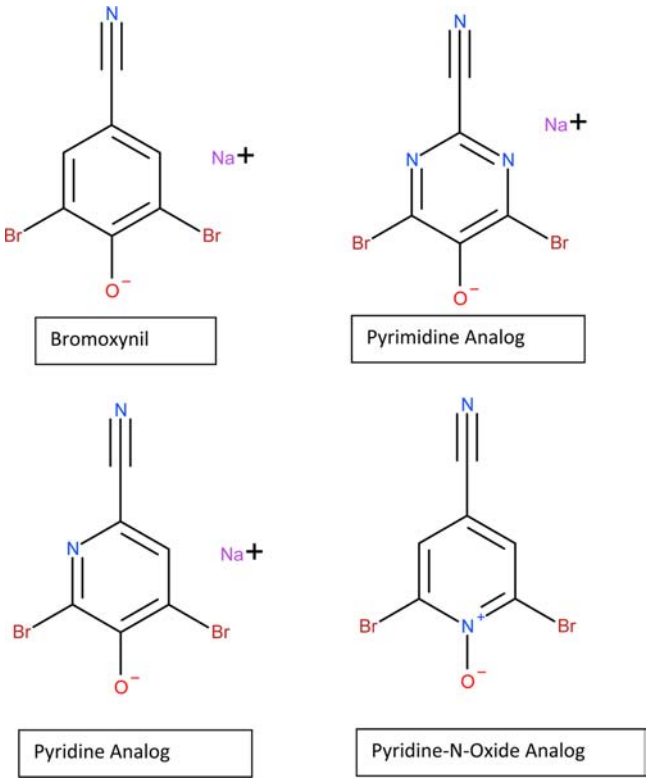

Figure 1. Chemical structures of bromoxynil and the heterocyclic analogues synthesized and tested at the University of Tennessee (Knoxville, TN, USA) during 2012 and 2013.

MATERIALS AND METHODS

Compound Synthesis (Figure 1). A 3,5-dibromo-4-hydroxybenzonitrile bromoxynil salt (bromoxynil, Figure 2) compound was synthesized following procedures from Gulbenk and Ruetman.[30] A total of 300 mg of 4-hydroxybenzonitrile, 1500 mg of sodium bromate, and 2050 mg of sodium bromide was dissolved in 15 mL of deionized water in a 250 mL round-bottom flask with a magnetic stir bar. Subsequently, the flask was capped with a rubber stopper and vented with a nitrogen balloon while 6 mL of concentrated hydrochloric acid (HCl) was slowly added to the reaction with a syringe over a period of 10 min. The flask was kept over a magnetic stir plate for 24 h at 20 °C. Finally, the solution was subjected to vacuum rotary evaporation

(Buchi R-114. Nine Buchi Labortechnik AG, Flawil, Switzerland). Structural conformation was determined by direct analysis in real time (DART) HR mass spectrometry MS (m/z): 276.91 (found). A 2,4-dibromo-6-cyano-5-pyridin-3-olate sodium salt (pyridine) was also brominated using the same technique using 5-hydroxypyridine-2-carbonitrile starting material (pyridine; Figure 3). Structural

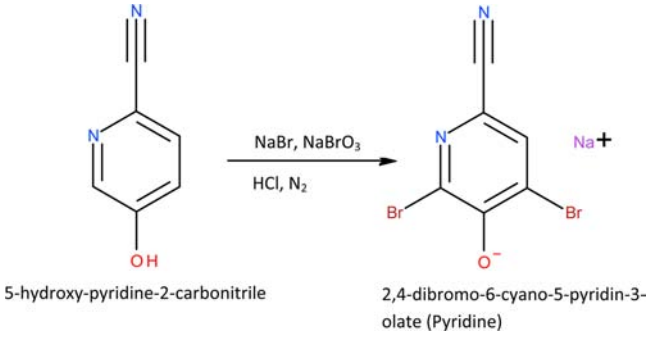

Figure 3. Synthesis of 2,4-dibromo-6-cyano-5-pyridin-3-olate (pyridine) evaluated in greenhouse trials at the University of Tennessee (Knoxville, TN, USA) during 2012 and 2013.

conformation was determined by DART HR mass spectrometry MS (m/z): 277.9 (found). However, because 5-hydroxypyridine-2-carbonitrile is more electrophilic than 4-hydroxybenzonitrile, fewer equivalencies of sodium bromate (753 mg) and sodium bromide (1028 mg) were required to make pyridine.

The first time step of the synthesis of 4,6-dibromo-2-cyanopyrimidin-5-olate sodium salt (pyrimidine; Figure 4) required 300 mg of 5-benzyloxypyrimidine-2-carbonitrile (Waterstone Techology, St. Carmel, IN, USA), which was dissolved in 20 mL of acetic acid and mixed with 30 mg of a 10% carbon palladium catalyst (Strem Chemicals, Newburyport, MA, USA) in a 250 mL round-bottom flask with a magnetic stir bar. Subsequently, the flask was capped and vented with hydrogen gas and reacted over a magnetic stir plate for 36 h at 20 °C. After 36 h, the solution was poured onto a Celite filter aid (Fisher Scientific, Fair Lawn, NJ, USA) covered Büchner funnel connected to an aspirator. The liquid phase was subjected to vacuum rotary evaporation and then dried under a high vacuum for 24 h. The structure of 5-hydroxypyrimidine-2-carbonitrile was confirmed by DART HR mass spectrometry (m/z): 121.1 (found). Next, 600 mg of sodium bromate and 900 mg of sodium bromide were dissolved in 15 mL of deionized water with 250 mg of 5-hydroxypyrimidine-2-carbonitrile in a 250 mL round-bottom flask with magnetic stir bar. Subsequently, the flask was capped with a rubber stopper and vented with a nitrogen balloon while 6 mL of HCl was slowly added to the reaction with a syringe over 10 min. The flask was kept over a magnetic stir plate for 24 h at 20 °C. The solution was then subjected to vacuum rotary evaporation. The structure of 4,6-dibromo-2-cyanopyrimidin-5-olate sodium was confirmed by DART HR mass spectrometry MS (m/z): 278.89 (found).

Synthesis of 2,6-dibromo-1-oxidopyridin-1-ium-4-carbonitrile (pyridine-*N*-oxide; Figure 5) required a different bromination technique. Bromination of pyridine at the 2- and 6-positions within the ring structure of pyridine is difficult and requires drastic conditions that typically involve high pressure and vapor phase reactions at temperatures >500 °C.[24] However, displacement of chlorine with bromine at the 2,6-positions on pyridine had previously been performed under less drastic conditions.[31] To avoid vapor phase reactions, 213 mg of 2,6-dichloro-4-pyridinecarbonitrile was dissolved in 10 mL of acetic acid in a capped 250 mL three-neck round-bottom flask with a magnetic stir bar vented with a nitrogen balloon. The flask was attached to a condenser and an addition funnel in a hot oil bath at 103 °C over a magnetic stir plate. A total volume of 2 mL of hydrobromic acid was added to the solution through the addition funnel over a period of 5 min. After 9 h, 2.9 mL of phosphorus

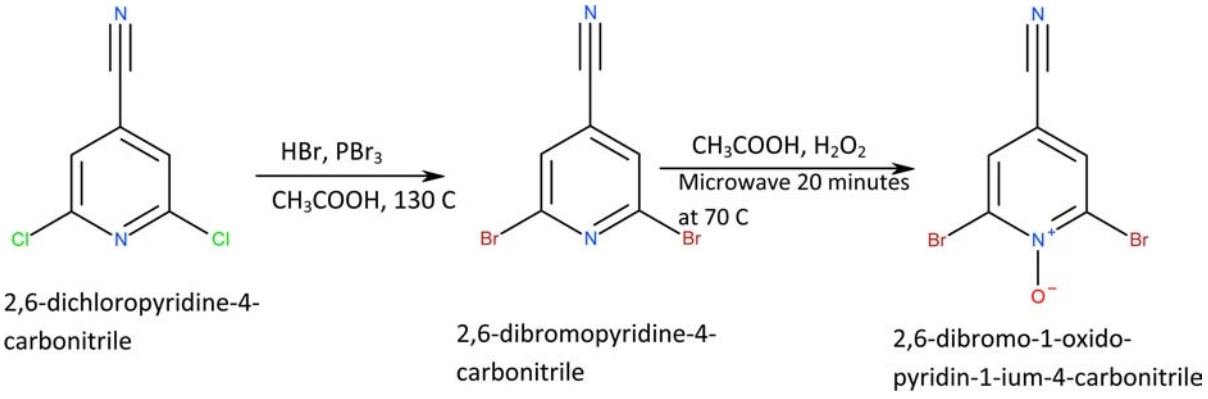

Figure 5. Synthesis of 2,6-dibromo-1-oxidopyridin-1-ium-4-carbonitrile (pyridine-*N*-oxide) evaluated in greenhouse trials at the University of Tennessee (Knoxville, TN, USA) during 2012 and 2013.

tribromide was added to the reaction with a syringe over 45 min and the reaction continued for an additional 16 h at 130 °C. The product of this reaction was a red solution that was cooled in an ice bath and diluted with 20 mL of dichloromethane and 40 mL of deionized water. The phases were mixed in a separation funnel, and the organic layer was extracted and subjected to vacuum rotary evaporation. The structure of the product, 2,6-dibromopyridine-4-carbonitrile, was confirmed through DART HR mass spectrometry MS (m/z): 272.5 (found). A total of 200 mg of 2,6-dibromopyridine-4-carbonitrile was then dissolved in 3 mL of glacial acetic acid and 1.5 mL of 30% hydrogen peroxide. The reaction mixture was exposed to 70 W of microwave irradiation for 20 min at normal absorption using a Biotage Initiator robot (Biotage, Kungsgatan, Sweden) following a protocol by Khrustalev et al.[32] Next, 15 mL of deionized water was added to the final solution and later removed using vacuum rotary evaporation. The product, 2,6-dibromo-1-oxidopyridin-1-ium-4-carbonitrile (pyridine-*N*-oxide), was confirmed using DART HR mass spectrometry MS (m/z): 277.6 (found).

All mass spectrometry analyses were conducted at the Mass Spectrometry Center located in the Department of Chemistry at the University of Tennessee. The DART analyses were performed using a JEOL AccuTOF-D time-of-flight (TOF) mass spectrometer with a DART ionization source from JEOL USA, Inc. (Peabody, MA, USA). Mass spectrometry solutions were prepared with methanol.

Weed and Crop Response Greenhouse Study. To evaluate the crop tolerance and weed control efficacy of synthesized bromoxynil analogues (bromoxynil, pyridine, pyrimidine, and pyridine-9*N*-oxide), an array of crops and weeds were propagated at the University of Tennessee Plant Science Greenhouse (Knoxville, TN, USA; 35.946471 latitude, 83.938558 longitude) including soybean, cotton, redroot pigweed, velvetleaf, large crabgrass, and pitted morningglory. All plants were grown in plastic 10.2 × 10.2 cm circular pots (Dillen Products/Myers Industries, Inc., Middlefield, OH, USA) containing peat-based growing media (ProMix BX Mycorrhizae, Premier Tech Horticulture, Quakertown, PA, USA) and treated 10 days after seeding. The experiment was conducted from Octboer 6 until 30, 2012, and repeated from November 14 until December 8, 2012. During both experimental runs the average air temperature in the climate-controlled greenhouse was 23 °C, whereas the lowest/highest air temperatures recorded were 20/30 °C. Mean daytime light levels during this period were 280 μmol m^{-2} s^{-1}. Irrigation was supplied through an overhead mist system and was withheld for 24 h after experimental herbicide application to ensure adequate time for foliar absorption of the experimental herbicides.

The compounds were applied POST at a rate of 0.28 kg ha^{-1}. This rate was chosen because it is the lowest labeled rate of bromoxynil recommended for weed control.[22] Additionally, the quantities of the analogues for use in studies were limited given that the yields of the aforementioned synthesis processes ranged from 20 to 35%. All compounds were dissolved in a mixture of acetone (3 mL) and deionized water (32 mL) and agitated using a (CL-18) sonicator (Fisher Scientific International Inc., Hampton, NH, USA) prior to application. Subsequently, the solutions were mixed with 0.1% nonionic surfactant. The solutions were then applied to the plants using an enclosed spray chamber (Generation III track sprayer; DeVries 10 Manufacturing, Hollandale, MN, USA) in deionized water carrier at 215 L ha^{-1} with an 8004 EVS nozzle (Teejet, Wheaton, IL, USA).

Visual percent plant injury ratings were recorded 7 days after treatment (DAT), whereas dry aboveground biomass was recorded 14 days after treatment. Aboveground biomass was harvested from every plant and oven-dried (Thelco 130D laboratory oven, Precision Scientific) at 65 °C for 3 days and weighed. Chlorophyll fluorescence (F_V/F_M) was recorded 10 DAT from soybean using a pulse-modulated fluorometer (OS1-FL, Opti-Sciences, Inc., Hudson, NH, USA).

Glyphosate Resistant Palmer Amaranth (*Amaranthus palmeri*) Greenhouse Study. A second study was conducted to evaluate bromoxynil, pyridine, pyrimidine, and pyridine-*N*-oxide for control of glyphosate-resistant Palmer amaranth (gift from Dr. Chad Brommer, BASF Research Triangle Park, NC, USA) from February 20 to March 13, 2013. Potting medium and irrigation conditions in the greenhouse were the same as previously described for the weed and crop response greenhouse study. The application rate in this study was increased to 0.56 kg ha^{-1} considering that these compounds imparted minimal injury to Palmer amaranth when applied at 0.28 kg ha^{-1} in prior experiments.

Statistical Analysis. All experiments were conducted in a completely randomized design (CRD) with three replications. All data were subjected to analysis of variance (ANOVA), and means were separated using Fisher's protected LSD at α = 0.05 in SAS (SAS Institute v. 9.2, Cary, NC, USA). Percent visual injury ratings were arscine transformed prior to analysis. Interpretations were not different from nontransformed data. Thus, nontransformed percent visual ratings are presented for clarity.

Docking Calculations. A crystal structure of the D1 and D2 proteins was extracted from the PSII complex of *Thermosynechococcus elongatus* at 2.9 Å resolution (Protein Data Bank entry 3BZ1)[33] and incorporated into the Molecular Operating Environment (MOE, 2012.10; Chemical Computing Group Inc., Montreal, QC, Canada) program. Structural optimization was performed on the Q_B binding site to include the nonheme iron, the four surrounding histidine ligands (D1-Hist$_{215}$, D1-His$_{272}$, D2-His$_{214}$, and D2-His$_{268}$), and the D1 residues of the QB binding site that consisted of Met$_{214}$, Leu$_{218}$, Val$_{219}$, Tyr$_{246}$, Ile$_{248}$, Ala $_{251}$, His$_{252}$, Phe$_{255}$, Ser$_{264}$, Phe$_{265}$, and Leu $_{271}$). The bromoxynil compounds were constructed in MOE; subsequently, Amber forcefield was used to optimize molecular mechanics.[34] Geometry optimization and energy minimization were applied to the system containing bromoxynil and the 3BZI protein. Bromoxynil was then inserted proximal to the binding pocket, and docking simulations were performed. Heterocyclic analogues were substituted for bromoxynil, and docking simulations were repeated with the analogues. To simulate physiological pH conditions, the CO group

from all compounds was deprotonated. The simulation distance between herbicide and target amino acids in the binding pocket was transcribed in Symx Draw (version 4.0, Accelrys Inc., San Diego, CA, USA) to enhance visual clarity.

RESULTS AND DISCUSSION

Weed and Crop Response. No treatment-by-experimental run interactions were detected in percent injury or aboveground biomass data; therefore, data from both runs were combined.

Application of bromoxynil resulted in >35% injury to soybean, cotton, and pitted morningglory (Table 1). However, when bromoxynil was applied to velvetleaf, redroot pigweed, or large crabgrass, injury measured <25% (Table 1).

Different trends were observed with applications of heterocyclic bromoxynil analogues. Applications of the pyridines (pyridine and pyridine-*N*-oxide) generally injured all plant species more than pyrimidine. Injury ratings were similar when pyridine and pyridine-*N*-oxide were compared; however, applications of pyridine-*N*-oxide resulted in more injury to pitted morningglory and cotton than pyridine (Table 1). This response was especially pronounced following treatment to cotton, where application of pyridine-*N*-oxide resulted in 38% injury whereas application of pyridine resulted in only 16% injury. Interestingly, pyridine and pyridine-*N*-oxide were also more injurious to redroot pigweed when compared to bromoxynil. None of the herbicides injured large crabgrass >13%.

Generally, aboveground biomass data supported visual assessments of plant injury (Table 2). However, pyridine reduced velvetleaf aboveground biomass more than bromoxynil, which caused greater visual injury than pyridine. Technical grade material was applied in our research, and volatility in the spray chamber may have limited the effectiveness of the compound. Commercially formulated herbicides often have emulsifiers, detergents, wetting agents, and other surfactants that improve herbicide efficacy.[35]

Pyridine reduced photosynthetic efficiency more than any other treatment (Table 3.). Analysis of F_V/F_M data did not always correlate with visual ratings. For example, pyridine reduced PSII efficiency significantly more than pyridine-*N*-oxide; however, pyridine-*N*-oxide generally induced more phytotoxicity than pyridine (Tables 2 and 3). Pyrimidine did not reduce F_V/F_M significantly more than the nontreated check.

Table 3. Impact of Compounds Applied to Soybeans at 0.28 kg ai ha^{-1} on F_V/F_M Values Taken 10 Days after Treatment

treatment	F_V/F_M[a]
bromoxynil	0.456 b
pyridine	0.222 c
pyrimidine	0.671 a
pyridine-*N*-oxide	0.456 b
nontreated	0.804 a

[a]Means within a column followed by the same letter are not significantly different according to Fisher's protected least significant difference test at the 0.05 level.

The most interesting trend observed in the weed and crop response study was the ability of the pyridine analogues (pyridine and pyridine-*N*-oxide) to inflict greater phytotoxicity on redroot pigweed than bromoxynil. Although the redroot pigweed injury observed in this study would not be considered acceptable, the potential impact on weed management that the pyridine herbicides would have when applied as a formulated product at higher rates is intriguing.

Glyphosate-Resistant Palmer Amaranth Study. Applications of bromoxynil and pyridine all injured glyphosate-resistant Palmer amaranth >80% (Table 4). Although it cannot be determined statistically, it appeared that doubling the application rate to 0.56 kg ha^{-1} in this study greatly improved

Table 4. Glyphosate-Resistant Palmer Amaranth (*Amaranthus palmeri*) Injury and Aboveground Biomass following Applications of Bromoxynil and the Heterocyclic Analogues of Bromoxynil at 0.56 kg ai ha^{-1} in a Greenhouse Experiment Conducted in Knoxville, TN, USA, in 2013[a]

treatment	injury[b,c] (%)	aboveground biomass[c,d]
bromoxynil	87 a	0.18 cd
pyridine	83 a	0.08 d
pyrimidine	25 b	0.41 b
pyridine-*N*-oxide	25 b	0.30 bc
nontreated		0.80 a

[a]Injury and aboveground biomass data were collected 7 and 14 days after treatment, respectively. [b]Injury was evaluated visually on a 0 (no injury) to 100% (complete kill) scale relative to the nontreated check. [c]Means within a column followed by the same letter are not significantly different according to Fisher's protected least significant difference test at the 0.05 level. [d]Aboveground biomass was harvested from every plant and oven-dried at 65 C for 3 days and weighed.

the efficacy of bromoxynil and pyridine against pigweed species. Application of pyrimidine and pyridine-*N*-oxide injured glyphosate-resistant Palmer amaranth ~25%. This response was surprising considering the level of redroot pigweed injury observed with pyridine-*N*-oxide in the weed and crop tolerance study (Table 1). Whereas pyridine-*N*-oxide reduced glyphosate-resistant Palmer amaranth aboveground biomass more than pyrimidine, reductions in aboveground biomass were less than with bromoxynil and pyridine (Table 4). Glyphosate-resistant Palmer amaranth biotypes typically exhibit increased transcription of EPSP-synthase.[36] Therefore, increased expression of cytochrome-P450s, glutathione-*S*-transferases, and altered ABC-transporters in Palmer amaranth are likely not responsible for the decreased effectiveness of pyridine-*N*-oxide in this study.

Docking Simulations. Bromoxynil docking in our research was similar to work done by Takahashi et al.[16] Interestingly, the distance of the hydrogen bond between the CO group from the pyridine and the D1 His_{215} was closer than was observed with bromoxynil (Figure 6). This may explain why pyridine performed better than bromoxynil in the weed and crop response study. However, pyridine is supposedly less injurious to broadleaf crops as described by Gullbenk and Ruetman.[30] The decreased susceptibility of broadleaf crops to pyridine may be due to metabolism. The pyrimidine analogue was inverted in the binding pocket relative to the other compounds tested, and the CN group formed a hydrogen bond with His_{215} during the simulation. Hydrogen bonding with a CN group is typically weaker when compared to a CO group; additionally, the bond distance was greater in the pyrimidine simulation than in the pyridine simulation. This could explain why pyridine resulted in more injury than pyrimidine during our greenhouse trials. Pyrimidine did not form a strong hydrogen bond with His_{215}. Different parameters likely need to be applied to the environment to account for the unique properties of a pyridine-*N*-oxide bromoxynil analogue. An alternative simulation performed with pyridine-*N*-oxide showed that the oxyanion interacted with the hydrogen backbone of His_{215} as opposed to the imidazole ring. Additionally, a hydrogen bond formed between the ring of pyridine-*N*-oxide and the sulfur atom on Met_{214}. The presence of a cation at the QB binding site may influence the π electron system of the Q_A–His_{214}–Iron–His_{215}–Q_B bridge, which is interesting information that could be used to design future compounds.

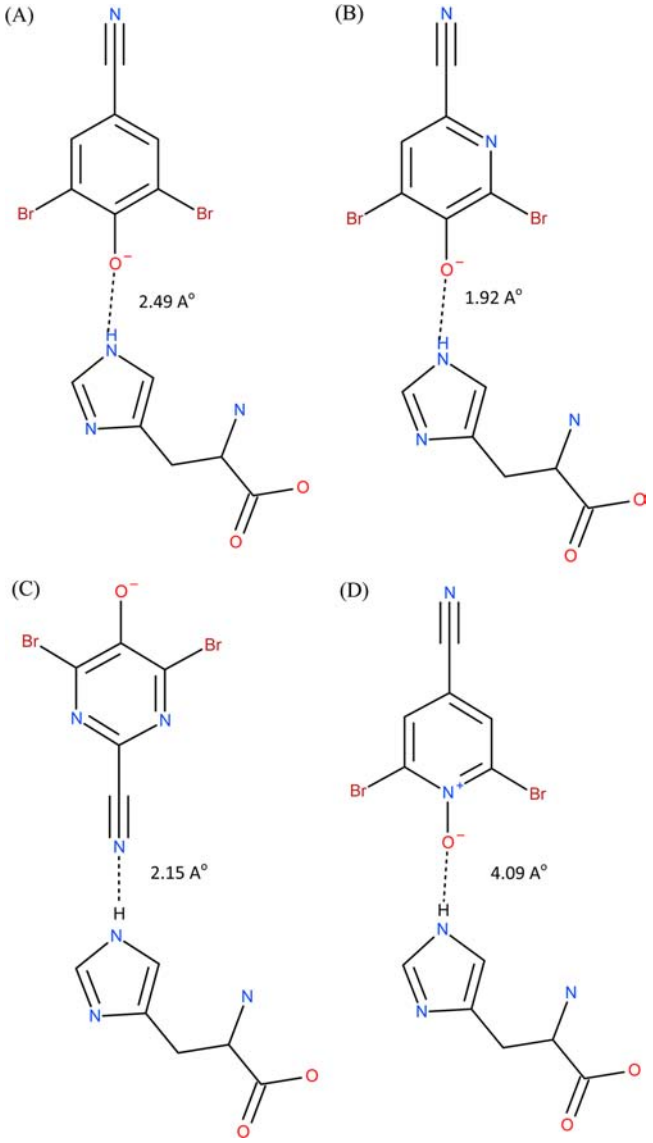

Figure 6. Docking simulations of bromoxynil and heterocyclic analogues (A) bromoxynil, (B) pyridine, (C) pyrimidine, and (D) pyridine-*N*-oxide. The hydrogen bond distance between the ligand and $histidine_{215}$ is in angstroms (A°).

Structure–Activity Relationship. The primary metabolite of bromoxynil in nonsusceptible plants and microbial soil systems results from the hydrolysis of the nitrile group to a carboxylic acid or amide.[37,38] Additionally, replacement of the bromines with hydroxyl groups results in a less herbicidal metabolite.[8,37] This hydroxylation reaction involves the formation of a hydroxide anion, which then initiates an S_N2 reaction by attacking the meta-positioned carbons on bromoxynil. An electron pair is then donated to bromine, which leaves the ring and forms a Br^- ion. Pyridine and pyrimidine analogues are less electron dense compared to bromoxynil and would be more susceptible to hydroxylation and other nucleophilic attacks. If hydroxylation of bromine is the metabolic mechanism that results in decreased efficacy of bromoxynil, then pyrimidine would be the most readily metabolized analogue tested because it is the most electrophilic. This theory is supported by the results of the greenhouse trials as well as what was observed in the docking calculations. Pyrimidine did not bind as strongly to His_{215} in the binding

dx.doi.org/10.1021/jf404209d | J. Agric. Food Chem. 2014, 62, 329–336

pocket as bromoxynil or pyridine and is likely easier to metabolize, thus reducing weed and crop injury. Pyridine formed a stronger hydrogen bond with His_{215} in the binding pocket compared to bromoxynil; however, it is likely metabolized more easily than bromoxynil, and thus did not significantly injure all plants more than bromoxynil. As mentioned earlier, the pyridine-*N*-oxide analogue is similar to bromoxynil with regard to electrophilicity and therefore may not be as easily hydroxylated as the pyridine and pyrimidine analogues. Interestingly, application of pyridine-*N*-oxide resulted in greater redroot pigweed control than bromoxynil with less damage to cotton and soybean. Alternatively, the structure of pyridine-*N*-oxide may be altered by metabolism in both crop and weed species, resulting in greater herbicidal activity. This scenario could be possible because the docking simulations indicated that pyridine-*N*-oxide hydrogen bond distance with His_{215} was not optimal.

Evaluating the stability of pyridine-*N*-oxide, synthesizing ester analogues of pyridine and pyrimidine, and optimizing formulations for all of these compounds would be important for further characterizing the potential of these heterocyclic bromoxynil analogues as new herbicides. The ability of the nonformulated pyridine herbicides to inflict significant damage to multiple weed species necessitates evaluating these compounds within multiple formulations. Additionally, evaluating the safety of the heterocyclic compounds on *bxn* crops would be of interest. The *bxn* trait consists of a nitrilase gene that detoxifies bromoxynil by converting the nitrile group into a carboxylic acid.[39] Cotton containing this trait may be safely sprayed with bromoxynil. The effectiveness of pyridine on glyphosate-resistant Palmer amaranth and the potential safety of the compounds in *bxn* plants may provide a new tool for farmers to manage cropping systems where glyphosate-resistant weeds are problematic.

Supporting Information

ABSTRACT: *Ralstonia solanacearum* (Rs) and *Clavibacter michiganensis* subsp. *sepedonicus* (Cms) are the bacterial causal agents of potato brown and ring rot, respectively, and are included in the A2 list of quarantine pathogens in Europe. Identification by GC-MS analysis of volatile organic compounds from Rs or Cms cultured on different nutrient media was performed. GC-MS and PTR-MS analysis were carried out also on unwounded potato tubers infected with the same pathogens. Infected tubers were produced by experimental inoculations of the plants. In in vitro experiments, Rs or Cms emitted volatile compounds, part of which were specific disease markers of potato (2-propanol and 3-methylbutanoic acid), mainly originating from bacterial metabolism (i.e., amino acid degradation, carbohydrate and fatty acid oxidation). In potato tubers, pathogen metabolism modified the volatile compound pattern emitted from healthy samples. Both bacteria seem to accelerate metabolic processes ongoing in potatoes and, in the case of Rs, disease markers (1-hepten-3-ol, 3,6-dimethyl-3-octanone, 3-ethyl-3-methylpentane, 1-chloroctane, and benzothiazole) were identified.

KEYWORDS: *Ralstonia solanacearum, Clavibacter michiganensis subsp. sepedonicus, volatile compounds*

INTRODUCTION

Brown rot and ring rot caused by bacteria *Ralstonia solanacearum* race 3 biovar 2 (Rs) and *Clavibacter michiganensis* subsp. *sepedonicus* (Cms), respectively, are among the most severe potato diseases worldwide. Rs occurs mostly in Solanaceous plants (e.g., *Capsicum* spp., eggplant, potato, and tomato) and many weeds and wild plants,[1] and it is spread wordwide.[2,3] Cms has a host range restricted to potato, tomato, eggplant, and some Solanaceous weeds; it occurs in northern America, northeastern Europe, and Asia. Both bacteria are included in the A2 list of quarantine pathogens in Europe and are subject to EU directives (2006/63/EC and 2006/56/EC for Rs and Cms, respectively). Tuber internal symptoms of potato brown rot (see symptoms shown in Table 1) are discoloration and decay localized at vascular ring and a bacterial slime oozing from the area until the complete destruction of tubers.[4] When tubers, infected with potato ring rot, are cut and squeezed, a cheesy cream comes out from the vascular ring; as the infection develops, destruction of vascular tissue occurs and cracks appear on the tuber surface.[5] The absence of internal symptoms does not exclude the absence of the pathogens (latent infections).

It is well-known that both microorganisms and plants emit volatile compounds, some of which may have odors that are characteristic of the species. As reported in Turner and Magan,[6] the microbial species, as well as the type of culture media and growth time, may influence the amount and pattern of volatile compounds that are produced. In case these compounds are formed in the presence of pathogens, they can be used as markers for their presence. No studies about the volatile molecules emitted from bacterial cultures of Rs and Cms are reported in the literature.

Potato flavor has been extensively studied due to its importance in nutrition: volatile compounds predominantly include aldehydes, alcohols, ketones, acids, esters, hydrocarbons, amines, furans, and sulfur compounds. The pattern and the number of volatile components obtained from potatoes can be quite different, depending on whether potatoes are raw or cooked and the cooking method used to prepare them.[7] All studies reported in the literature on raw potato flavor are conducted on sliced or peeled tubers to favor smell diffusion.

Fungi, prokaryotes (bacteria and mollicutes), parasitic plants, viruses and viroids, nematodes, and protozoa can modify the volatile pattern emitted from diseased species.[8] Potatoes inoculated with *Pectobacterium carotovorum* ssp. *carotovorum* and *P. carotovorum* ssp. *atrosepticum*,[9,10] *Phytophthora infestans*, *Pythium ultimum*, and *Botrytis cinerea*,[11,12] and *Fusarium sambucinum*[13] produce volatile molecules that can be considered markers of infection. Potatoes used for these studies have been wounded before the experimental inoculation. Stinson et al.[14] found that potatoes infected with Rs and Cms emit molecules associated with disease: 3-methyl-2-pentanone has been indentified as a marker of ring rot, and the variation of peak intensity of short-chain alcohols and ketones is indicative of brown rot disease. In this study, potatoes were at the final stage of

infection when the whole tuber rots away; at this stage, other secondary microorganisms such as *Fusarium* sp. and *Erwinia* spp. or other saprophytic microrganisms can contribute to the degradation of the tuber tissues[15,16] and can affect the visual symptom analysis, making difficult the discrimination of brown and ring rot from other tuber rots.

The present work describes part of the results of the Q-Detect project performed in the EU's seventh Framework Program (FP7); its aim was to develop reliable detection methods for quarantine pests and pathogens to be used by National Plant Protection Organizations (NPPO) and Inspection Services also through the detection of volatile organic compounds emitted from diseased species.

The work was focused on detection of brown rot and ring rot of potato, by the identification of volatile markers or specific fingerprints of the diseases using gas chromatography and proton transfer reaction coupled with mass spectrometry (GC-MS and PTR-MS) analysis. For the first time, volatile compounds emitted from (i) bacterial cultures of Rs and Cms (in vitro assays) and (ii) unwounded potatoes (in vivo assays) without external disease symptoms and with a low disease severity (to avoid cross-contaminations due to the presence of other secondary microorganisms) were investigated.

MATERIALS AND METHODS

Chemicals. Reference compounds were injected, when available, to confirm identification of volatile compounds detected. Methanol, acetaldehyde, 2-propanone, 2-propanol, 2-butanone, propanoic acid, 3-methylbutanal, 2-methylpropanoic acid, toluene, dimethyl disulfide, 3-methylbutanoic acid, benzaldehyde, methyl 2-methylbutanoate, benzothiazole, and 1-hepten-3-ol were purchased as pure or analytical standards from Sigma-Aldrich Co. LLC (USA). Reference volatile concentration for GC-MS analysis was 100 μM.

Bacterial Strains. The virulent strains IPV-BO 5836 of Rs and IPV-BO 7695 of Cms were routinely grown on tetrazolium (TZ)[17] and yeast dextrose calcium carbonate (YDC)[18] media at 27.0 ± 0.1 °C for 72−96 h, respectively. The IPV-BO 5836 (Mazzucchi and Traversa, unpublished data) and IPV-BO 7695 (Mazzucchi and Mucini, unpublished data) strains were isolated from potato tubers.

In Vitro Assays. *Rs and Cms in Solid Media.* Preliminary studies were carried out to identify volatile compounds produced by the metabolism of Rs and Cms cultured on specific substrates chosen as a model for their growth. The Rs and Cms strains were streaked on agar media such as TZ, "*levure*" peptone glucose (LPG),[19] potato dextrose (PDA; Difco, Becton, Dickinson and Co., USA), and PD prepared using peeled potato tubers,[20] referred to hereafter as natural PD (NPD). The plates were incubated at 27.0 ± 0.1 °C for appropriate time durations, based on the growth rate on each specific solid medium: 5 days for Rs on TZ-agar (TZA; Cms was not cultured on TZA); 2 days on LPG-agar (LPGA), 11 days on PDA, and 12 days on NPD-agar (NPDA) for both Rs and Cms. Agar media without pathogens have been used as a negative control. All experiments were carried out in duplicate.

Rs and Cms in Liquid Media. To follow the development of volatile compounds as a function of bacterial growth, time course studies were performed on broth cultures of the pathogens. RS or Cms bacterial strains were inoculated in TZ (only Rs), LPG, PD, and NPD broths to obtain an initial suspension (time point = 0 h) of ca. 10^6 CFU mL^{-1} for each pathogen; sterile deionized water (SDW) was added as a negative control. The inoculated broths were incubated in a rotary incubator at 27.0 ± 0.1 °C at 80 rpm. At days 2 and 7, 1 mL of suspension was collected, and 10-fold dilutions of the suspension were plated (10 μL drops) on LPGA and incubated at 27.0 ± 0.1 °C. Each suspension concentration was determined by counting the number of Rs and Cms colonies grown after 3 and 5 days of incubation, respectively, when by a naked eye each single colony was visible. Experiments were carried out in duplicate.

In Vivo Assays. Infected potatoes were obtained by experimental inoculations with both bacterial pathogens in potato plants; cultivars 'Spunta' and 'Kennebec' were chosen as sensitive hosts and inoculated with Rs and Cms, respectively.

Rs and Cms Experimental Inoculations. For Rs, ca. 100 potato plants were grown in the field following standard agronomical procedures; within the end of blooming time (after 2 months from the tuber seeding), 30 μL of water suspension containing the pathogen (ca. 10^9 CFU mL^{-1}) was experimentally injected into a wound made at the stem (one-third to two-thirds of the total stems). Cms was inoculated in two distinct phenological phases (seed and third−fourth-leaf stage) to increase the disease incidence and the spectrum of variability of the disease severity in the daughter tubers. Half of the total plants were experimentally inoculated at the seed stage (around 50 potato tubers) by injection of 180 μL of pathogen water suspension (ca. 10^9 CFU mL^{-1}) in a well, made at the heal end. The inoculated tubers were then placed in a dark chamber at 95% humidity for 48 h and then left for an additional 24 h at 23 ± 1 °C to dry the tubers. The next day the inoculated tubers were seeded in the field. The remaining plants (about fifty) were experimentally inoculated at the stem in the third−fourth-leaf stage (two-thirds of the total stems) following the procedure used for Rs inoculation. SDW was employed as a negative control.

At approximately 4 months after the inoculation, the tubers from experimental fields were harvested and stored in a dark climatic chamber at 4 ± 1 °C. Negative controls and tubers inoculated with the pathogens were harvested and stored separately to avoid cross-contaminations. At storing temperature, Rs just survives,[3,4,21] whereas Cms decreases its activity.[5,22] Before volatile compound analysis, to promote the reactivation and, indeed, the bacterial growth of both pathogens, the tubers were left at room temperature from 1 to 10 days.

Volatile Compounds Headspace Sampling for GC-MS Analysis. Volatile compounds analysis on in vitro samples were performed on slices of medium with the grown Rs and Cms strains, which were placed in glass tubes sealed with Teflon caps (Figure 1a). A slice of medium without the pathogen was used as a negative control. Unwounded tubers (healthy or Rs/Cms experimentally inoculated) without external visible symptoms of diseases, were placed in 500 mL jars, and the jars were filled to volume and sealed with Teflon caps (Figure 1b). Due to the low intensity of measured signals, analysis was carried out on pooled tubers. Eight pooled Rs-diseased samples with 4 healthy samples as control, and 10 pooled Cms-diseased samples with 5 control samples were analyzed.

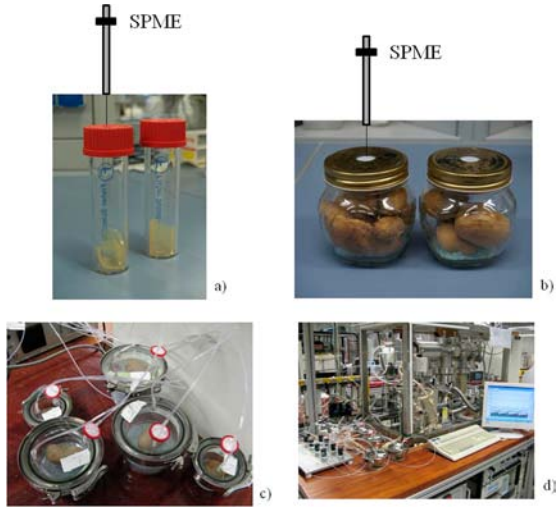

Figure 1. In vitro and in vivo sample preparation for GC-MS analysis: (a) slices of Rs or Cms cultured agar medium in glass tubes and (b) unwounded potato tubers infected with Rs or Cms in jars. Both container types were sealed with a Teflon cap. CAR/PDMS (Supelco) SPME fibers were used for headspace sampling. In vivo sample preparation for PTR-MS analysis is reported in (c), where single potato tubers were placed in glass cuvettes and flushed with 2 L h^{-1} air for headspace analysis. Panel d shows a view of the PTR-MS instrument measuring low molecular weight volatile compounds from tubers placed in glass cuvettes.

Detection of volatile compounds emitted from in vivo or in vitro samples was performed by sampling the headspace with solid phase microextraction (SPME) fibers. Supelco 75 μm carboxen/polydimethylsiloxane fibers were used to monitor gases emitted from Rs or Cms cultures and infected potatoes. SPME fibers were exposed for 24 h to headspace of in vitro solid media and in vivo samples and for 30 min to headspace of broth samples.

After GC-MS analysis, tubers have been examined by visual analysis of symptoms on the vascular ring and by bacterial strain reisolation and identification.

GC-MS Analyses. Volatile compounds adsorbed by SPME fibers from in vitro and in vivo samples were thermally desorbed in the GC injector (kept at 250 °C) of a Finnigan Mat ion trap gas chromatograph GC-MS (Thermo Fisher Scientific, USA) and analyzed for the masses. Transfer line and source temperatures were kept at 250 and 200 °C, respectively. Mass spectra were recorded with a 1 s scan time in the m/z range from 20 to 350 using electronic ionization (ionization energy, 70 eV) as a source. The carrier gas was helium (pressure, 35 kPa). Chromatographic separation was performed on a fused-silica bonded-phase capillary column Supelco SPB-5 poly (5% diphenyl/95% dimethylsiloxane) 30 × 0.32 mm; 0.25 mm film thickness (Sigma-Aldrich Co. LLC, USA). Volatile compounds were separated by applying the following GC oven temperature program: 40 °C for 3 min, raised at 3 °C min^{-1} to 130 °C, raised at 10 °C min^{-1} to 260 °C, and held at 260 °C for 10 min. The identification of volatile compounds was achieved by comparing their mass spectra with the mass database stored in the National Institute of Standards and Technology U.S. Government library (NIST, 1998).

Quantitative analysis of detected volatiles emitted by in vitro samples was done by integration of peak area, whereas, for in vivo samples, by area normalization to sample weight. Data were statistically processed using the semimaximal dispersion (maximal error) or the standard deviation.

Volatile Compound Headspace Sampling for PTR-MS Analysis. Potato tubers experimentally inoculated with Rs (18 samples) and Cms (23 samples) and controls (mocked or healthy, 18 tubers as Rs and 23 tubers as Cms control) were shipped from Bologna (Italy) and stored in the refrigerator at Radboud University, Nijmegen (The Netherlands). A few hours before the PTR-MS measurements, they were kept in the laboratory at 20 °C. A single unwounded potato was placed in a leaktight glass cuvette and flushed with 2 L h^{-1} hydrocarbon-free air (Figure 1c). An automatic valve system was used to connect up to five cuvettes to the PTR-MS (Figure 1d) in alternate sequences of 30 min.[23] After the volatile compound analyses, the samples were returned to the Bologna laboratory for establishment of the symptomatic and asymptomatic features by expert visual inspection.

PTR-MS Analysis. PTR-MS analysis was carried out with a custom-built mass spectrometer at the Trace Gas Research Group at the Radboud University, Nijmegen (The Netherlands). A detailed description of the instrument has been given elsewhere.[24,25] Trace quantities of volatile compounds are sampled directly, and those having proton affinity (PA) greater than that of water (PA = 691 kJ mol^{-1}) undergo ion−molecule reactions by receiving a proton from the hydronium cation, H_3O^+. The protonated compounds are mass filtered with a quadrupole mass spectrometer and quantified by a secondary electron multiplier as mass to charge ratio, m/z. The calibration was performed with different concentrations ranging from 0.035 to 1 ppmv (parts per million volume) obtained from a reference mixture of 1 ± 0.05 ppmv (of methanol (m/z 33), acetaldehyde (m/z 45), 2-propanone (m/z 59), isoprene (m/z 69), benzene (m/z 79), toluene (m/z 93), m-xylene (m/z 107), and α-pinene (m/z 137) in nitrogen dilution gas (Linde, Dieren, The Netherlands).

Symptom Analysis. After GC-MS and PTR-MS analyses, each tuber was cut in half, and the disease symptoms on the vascular ring were visually analyzed and photographed: to better evaluate the disease severity, a phytopathometric class ladder was built (Table 1).

Bacterial Pathogen Reisolation and Identification. *Sample Processing.* After the symptom visual analysis, from each tuber, at the

[a]Specific markers of Rs and Cms are highlighted in bold. Methods used to confirm volatile compound detected are also reported. [b]MS, identification by comparison with NIST mass spectrum; RS, identification by injection of reference standards.

heal end, a core was crushed in 2 mL of SDW and left to settle. After 15 min, 1.5 mL of extract was collected to carry out microbiological and molecular assays.

Reisolation and Identification of the Pathogen. Each core extract was centrifuged for 20 min at 10000*g* at 4 ± 1 °C; the pellet was resuspended in 1 mL of SDW, and 50 μL of resuspension was inoculated on SMSA agar(for Rs, as specified in the EU Directives) and YDC or NCP-88 (for Cms, EU Directives) agar and incubated at 27 ± 1 °C from 3 to 7 days to isolate Rs and Cms pathogens. The Rs-like and Cms-like colonies were purified on appropriate media and identified with pathogenicity test (EU Directives).

Molecular Assays. The remaining 950 μL resuspended pellet was used for DNA extraction using a DNeasy Plant Mini Kit (Qiagen, Germany). The DNA was then stored at −20 °C for PCR assays. The protocols of Seal et al.[26] and Pastrik et al.[27] were followed for PCR assays to identify Rs and Cms, respectively (EU Directives). The PCR method of Pastrik et al.[27] was slightly modified, and the use of the endogenous control primers was avoided to increase the sensitivity of the assay.

RESULTS AND DISCUSSION

GC-MS Analysis. *In Vitro Assays.* Volatile compounds emitted from bacterial cultures of Rs or Cms grown on different media (TZA, LPGA, PDA, and NPDA) were detected by SPME-GC-MS analysis (Table 2). These media were chosen to study the metabolism of Rs or Cms in matrices less complex than that represented by potato tuber. PDA and NPDA were chosen to

simulate a simplified potato substrate. Depending on media characteristics, volatile compound analysis was done when the single colonies have shown their typical morphology on agar media: after 5 days for Rs grown on TZA, and after 2, 11, and 12 days for Rs or Cms grown on LPGA, PDA, and NPDA, respectively (EU Directives). Because no data about the incubation time on PDA and NPDA (these media are basically used as standard in mycology but not in bacteriology) are reported in EU Directives, the required time to evaluate the morphology of a typical colony was deduced by visual analysis of Rs or Cms cultured plates.

The microorganism activity in cultured media was related to the increase of volatile compound concentration in comparison with that of uncultured media. Indeed, although samples were prepared in sterile conditions and hermetically sealed, the occurrence of volatile compounds released by the substrate incubated at 27 °C could not be avoided.

In Table 2, only volatile compounds emitted in amounts significantly different from the control or detected in cultured agar media are reported. Volatile compounds emitted from the metabolic activity of the two pathogens were broadly similar, and only minor differences were observed.

Dimethyl disulfide (DMDS) was the main volatile compound metabolized by Rs on TZA. Cms was not cultured on this medium that is typical for Rs, and it is also not recommended because of its slow growth rate.

A mixture of polysulfides (DMDS and dimethyl trisulfide) was produced by Rs on LPGA along with 2-propanone and methyl 2-methylbutanoate. 2-Propanone, DMDS, and methyl 2-methylbutanoate were markers for Rs on LPGA, whereas dimethyl trisulfide was a degradation product detected in uncultured LPGA, the concentration of which increased in the presence of pathogen. Considering the slow growth of Cms with respect to Rs, only a few molecules were identified as markers of pathogen presence: 3-methylbutanal was a compound characteristic of the Cms metabolism on LPGA, and an increase of dimethyl trisulfide concentration was revealed in comparison with the control.

Volatile compound pattern of Rs metabolism on PDA was more complex than that observed on the other agar media as highlighted from the number of volatile compounds detected (Table 2 and Figure S1 in the Supporting Information). Among these, 3-methylbutanoic acid, propanoic acid, methyl 2-methylbutanoate, and an unknown compound with m/z 84 were detected only in Rs cultured on PDA. Moreover, the metabolic activity of Rs pathogen on PDA was related to the increase of 2-butanone, 2-furancarboxaldehyde, and styrene concentrations. 2-Propanol and 3-methylbutanoic acid were markers of Cms metabolism cultured on PDA. The pathogen favored also the increase of 2-methylpropanoic acid, an unknown compound with m/z 86, and benzaldehyde concentrations.

No disease markers and no variations of volatile compound concentration were detected in Rs cultured on NPDA. On the contrary, similar to what was observed on PDA, the metabolism of Cms on NPDA was related to the variation of 2-propanol, 2-methylpropanoic acid, and 2-hydroxy-3-pentanone concentrations (Figure S2 in the Supporting Information). 3-Methylbutanoic acid was also detected but with a concentration too low to be taken into consideration as a disease marker on NPDA.

All volatile compounds detected seemingly come from degradation reactions of amino acids.[28−33] The short-chain alcohols, acids, aldehydes, and ketones detected are known as degradation products of carbohydrates.[7] As far as methyl 2-methylbutanoate is concerned, it can be produced by oxidation of very long chain unsaturated fatty acids.[34]

Time Course Study on in Vitro Samples. The distribution of volatile compounds emitted from bacteria kept for 2 and 7 days at 27 ± 1 °C in liquid suspensions was analyzed in relation with time. Time course studies were carried out in a time range arbitrarily chosen but adequate to allow the growth of the two bacterial pathogens. In general, the presence of water coupled with shaking increases the bacterial growth speed with respect to that in agar media. In our experimental conditions, the pathogen growth was maximal at day 2 in all bacterium−broth systems with the exception of Rs suspended in NPD broth, in which even after 7 days, the bacterium kept growing (data not shown). For Cms in both LPG and NPD broths, the death phase was observed at day 7. No bacterial growth was observed in PD broth for both Rs and Cms within 7 days as confirmed by SPME-GC-MS analysis, which did not reveal differences between inoculated samples and controls (data not shown). As shown in Table 3, Rs growth rate in different broths calculated at 2 days increased in the order TZ ≥ LPG ≫ NPD, whereas for Cms inoculated in LPG and NPD broths the growth rates were comparable. Rs growth rate in LPG broth doubled that of Cms in the same liquid medium; in NPD broth, on the contrary, the Rs growth rate was significantly lower than that of Cms (3 and 20 generation number × 10^{-5} min^{-1} for Rs and Cms, respectively).

Table 3. Number of Cells Generated and Growth Rate Calculated at Day 2 for Rs or Cms in Different Liquid Media

	substrate					
	generation no.			growth rate (generation no.× 10^{-5} min^{-1})		
bacterial pathogen	TZ	LPG	NPD	TZ	LPG	NPD
Rs	14	13	0.8	49	45	3
Cms		6	6		20	20

As was already observed for Rs cultured in TZA, dimethyl disulfide was the marker of Rs metabolism in TZ broth: after 7 days, its concentration increased 5 times compared with that at day 2 (data reported in the Supporting Information, Figure S3). In Figure 2, volatile compounds emitted during the Rs and Cms bacterial growth in LPG broth are reported. The pattern of detected volatile compounds was different for Rs and Cms because the growth rates of the two bacteria in LPG broth were different (the growth rate of Rs doubled that of Cms, Table 3). The increase of toluene concentration after 2 days from inoculation of Rs in LPG broth along with the emission of DMDS confirmed the bacterial growth. Similar to what it was observed for methyl 2-methylbutanoate, also toluene can be considered a product of long-chain unsaturated fatty acid oxidation.[34]

As expected, for Cms at day 0, control and inoculated broths produced similar volatile compound patterns. After 2 days and more markedly at day 7, concentrations of 2-methylpropanal and 3-methylbutanal (both derived from amino acid Strecker degradation) considerably decreased in the inoculated samples in contrast with what has been observed in LPGA medium. After 7 days, the Cms growth curve achieved the death phase and the decrease of volatile compounds concentrations could be due reasonably to the reduction of living cell number that metabolized the substrate. At this stage, volatile compound distribution differences were observed between inoculated and control samples: the concentration of dimethyl disulfide and an

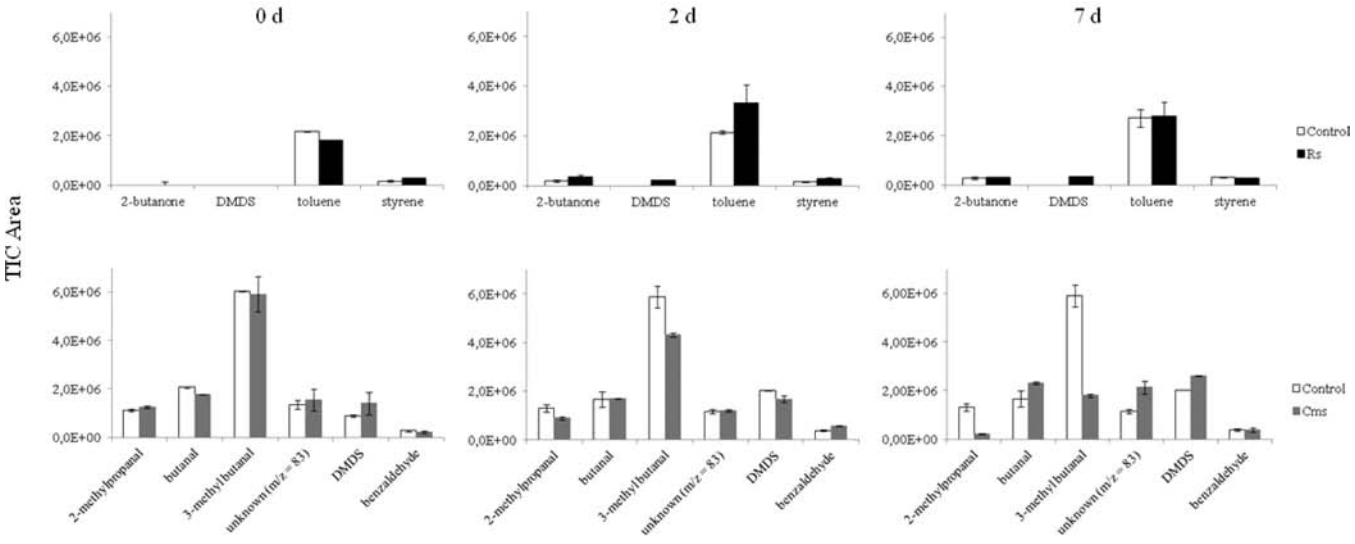

Figure 2. Volatile compounds emission from Rs or Cms cultured in LPG broth after 0, 2, and 7 days of growth. Volatile compounds emitted from uncultured LPG broth samples are reported as a control (mean of two replicates; semimaximal dispersions in vertical bars). TIC, total ion current; DMDS, dimethyl disulfide.

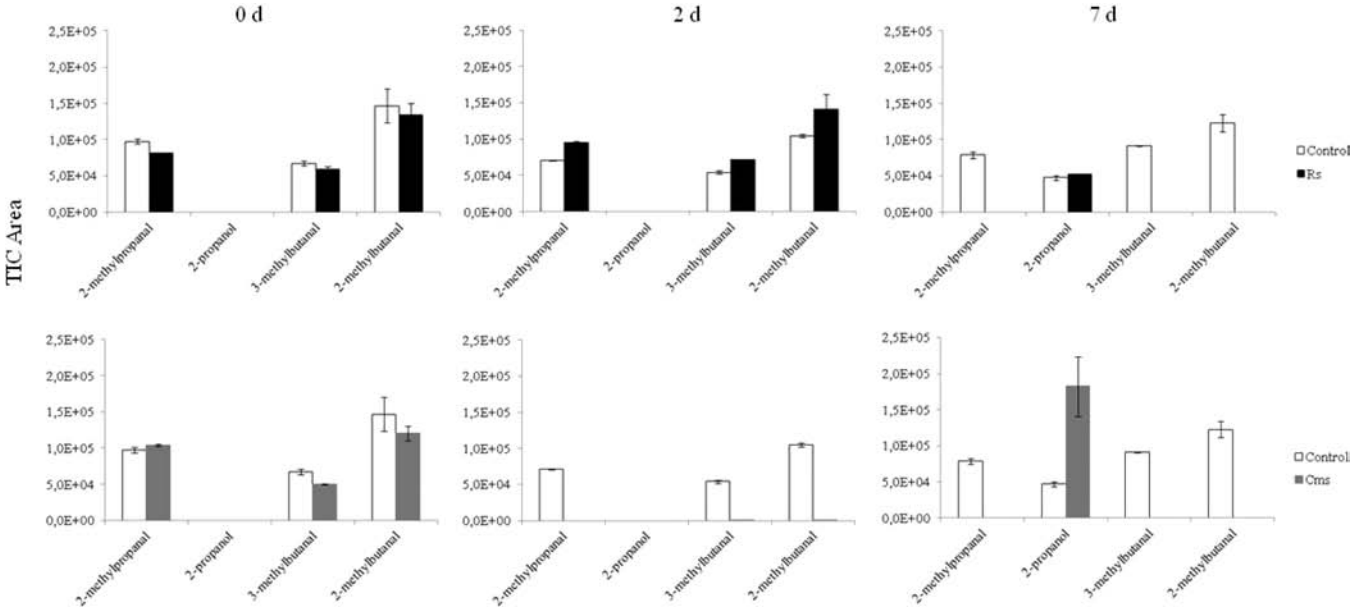

Figure 3. Volatile compound emission from Rs or Cms cultured on NPD broth after 0, 2, and 7 days of growth. Volatile compounds emitted from uncultured NPD broth samples are reported as a control (mean of two replicates; semimaximal dispersions in vertical bars). TIC, total ion current.

unknown molecule (m/z 83) in the Cms−LPG broth system increased compared to the control.

The volatile compound pattern detected in the headspace of Rs or Cms inoculated in NPD broths was very similar (Figure 3) but different from the patterns observed on NPDA media. A mixture of methyl-aldehydes containing three or four carbon atoms were detected in both inoculated and control samples, whereas a mixture of methyl-carboxylic acids containing three or four carbon atoms were identified in Cms cultured on NPDA (no disease markers and no variation of volatile compound concentration were detected in Rs cultured on the same medium). Slight differences (i.e., an increase of 2-methylpropanal, 3-methylbutanal, and 2-methylbutanal concentrations) were observed after 2 days in Rs−NPD broth system compared with control sample. After 7 days, the metabolism of Rs in NPD broth changed: the mixture of aldehydes disappeared, and 2-propanol was the only volatile compound to be detected. For the Cms−NPD system, after 2 days, negligible volatile compound amounts were detected and, after 7 days, 2-propanol was the only identified volatile. The concentration of 2-propanol in the presence of Cms in NPD broth was about 3 times higher than that measured in Rs−NPD sample due to the higher growth rate of Cms (20 and 3×10^{-5} generation number min^{-1} for Cms and Rs, respectively).

The different pattern of volatile compounds detected depends on pathogen growth rate as well as chemical composition of the substrate. The large amount of dimethyl disulfide released by Rs−TZ solid and liquid media samples might derive from casamino acids present in TZ composition (BD Biosciences, USA), which contains cystine (derived from cysteine oxidation). LPG contains Bacto Peptone (BD Biosciences, USA), an enzymatic digest of animal proteins that can contain traces of

Total ion current (TIC) relative abundance (peak area normalized to sample weight) of (a) 3-methylbutanoic acid (m/z 102), 2,2,3,4-tetramethylpentane (m/z 128), 2,3,4-trimethylhexane/4-methyloctane (m/z 128), and 4-methyl-2-propyl-1-pentanol (m/z 144) detected in Rs infected potato samples and (b) 2-propanol (m/z 60), 3-methyl-3-buten-2-one (m/z 84), and toluene (m/z 92) in Cms samples. (Abundances lower than 10^3 are not reported.)

fatty acids, the oxidation of which produces toluene. Both PD and NPD contain potato derivatives such as starch, sugar, protein, minerals, and glycoalkaloids. Solanine and chaconine glycoalkaloids are usually found concentrated in potato peel, and thus they can be present in commercial PD, but they can be insignificant in NPD, extracted from peeled potatoes. As has been already reported for fungi,[35] these toxic compounds could have an inhibitory effect on bacteria, which explains the slow Rs and Cms growth in PD broth. The yeast extract contained in LPG and the carbohydrates naturally present in potato (i.e., PD and NPD media) might explain the formation of carbohydrate degradation products. On the basis of these considerations, it was possible to explain the occurrence of volatile compounds produced by the degradation of amino acids and fatty acids (detected in the first two days) and of carbohydrates (detected at day 7): note that the final degradation products as CO_2 and H_2O were not detected because they are not retained and separated from the GC column used.

dx.doi.org/10.1021/jf403436t | J. Agric. Food Chem. 2014, 62, 337−347

In Vivo Assays. Infected tubers produced under field conditions by Rs or Cms experimental inoculations were analyzed by SPME-GC-MS to identify markers of brown and ring rot diseases and compared with those identified in in vitro assays.

Harvested tubers showed a high percentage of disease incidence but not all were symptomatic: 78 and 91% of tubers were found infected by Rs and Cms, respectively, 49 and 46% of which showed the typical tuber symptoms of brown and ring rot. Among the symptomatic tubers, the severity of diseases was variable, and the evaluation of the disease severity of the tuber vascular ring (Table 1) assigned the lowest value to healthy potatoes and to the class of infected but asymptomatic tubers (latently infected) and was rated 0 (zero). The remaining classes were rated between 1 and 5 according to five levels of disease severity (from "very low" to "very high" level) as shown by the pictures reported in Table 1. At the highest level of the phytopathometric scale (corresponding to class 5), symptoms of the tubers were ascribed to Rs or Cms as well as to other secondary microorganisms as *Fusarium* sp. and *Erwinia* spp. that contributed to the degradation of potato tissues.[15,16,36] All samples analyzed were composed for the most part by tubers belonging to class 1 or 2. Moreover, all Rs-infected and 50% of Cms-infected samples contained at least one tuber with medium or high symptom level (class 3 or 4).

Chromatograms and corresponding mass spectra were collected (Figure S4) for infected and control samples kept at room temperature for different times.

Some significant differences, which increase with the reactivation time, could be observed in the GC-MS chromatograms of Rs-infected potato samples with respect to controls (see the Supporting Information, Figure S5 (left), and Table 2): 1-hepten-3-ol (m/z 114), 3,6-dimethyl-3-octanone (m/z 156), 3-ethyl-3-methylpentane (m/z 142), 1-chloroctane (m/z 148), and benzothiazole (m/z 135) were identified as markers of brown rot disease (their presence in diseased samples was confirmed for about 50% analyzed samples). In addition, the presence of symptoms of brown rot disease seemed to be related to the increase of relative intensities of the peaks assigned to 3-methylbutanoic acid (m/z 102), 2,2,3,4-tetramethylpentane (m/z 128), 2,3,4-trimethylhexane/4-methyloctane (m/z 128), or 4-methyl-2-propyl-1-pentanol (m/z 144) (Table 2). The collected chromatograms showed variations of the relative intensity of peaks in the entire acquisition range (peaks with m/z 158 and 186 attributable to 2-propyl-1-heptanol and 2-ethyl-1-decanol, respectively, showed the most evident variations but the frequency of appearance was <25%).

The average abundance and appearance frequency of 3-methylbutanoic acid, 2,2,3,4-tetramethylpentane, 2,3,4-trimethylhexane/4-methyloctane, and 4-methyl-2-propyl-1-pentanol are reported in Table 4: these volatile compounds were detected both in control and Rs-diseased samples with a frequency percentage of about 75 and 63%, respectively, even if their average abundance was slightly lower in the control samples than in diseased ones. Their relative abundances (peak area normalized to sample weight) are reported in Figure 4a. Samples named Control3-10d, Rs4-10d, and Rs5-10d were kept at 25 °C for 10 days before GC-MS analyses. Generally, volatile compound emission normalized to sample weight was higher from the diseased samples than controls and seemed to depend on the reactivation time duration, as clearly shown in volatile compounds composition emitted from Rs4-10d and Rs5-10d samples. For these samples, an increase of 2,2,3,4-tetramethylpentane and the corresponding disappearance of 3-methylbutanoic acid were observed. Disease severity analysis revealed that the samples contained tubers with medium to high symptom level (class ≥3).

No specific markers of ring rot have been identified after GC-MS analysis of Cms-diseased samples kept for 1 day at room temperature, but an increase of the relative intensity of two peaks, which were identified as 2-propanol (m/z 60) and 3-methyl-3-buten-2-one (m/z 84), in diseased samples was observed (see Supporting Information, Figure S5 (right), and Table 2). Further analyses performed on Cms suspected diseased samples showed significant intensity variations of the peak assigned to toluene (m/z 92). Different from what has been observed in Rs samples, volatile compound production of Cms-diseased samples did not seem related to the time of bacterial reactivation (data not shown) as a confirmation of the different biology of the two pathogens.[3,5,21,22]

The average abundance and appearance frequency of volatile compounds detected are reported in Table 4. The appearance frequency was low (30, 50, and 20% of total analyzed samples for 2-propanol, 3-methyl-3-buten-2-one, and toluene, respectively), but the differences between the average abundances of control and diseased samples were significant. The trend was confirmed by the relative abundances of the volatile compounds normalized to each sample weight (Figure 4b): 2-propanol and toluene allowed discrimination between healthy and Cms-diseased samples.

The 2-propanol and 3-methylbutanoic acid were already identified as markers of Cms metabolism in cultured agar media PDA and NPDA; 3-methylbutanoic acid was also a marker of Rs metabolism in PDA. The similarity between potato tubers and PDA in terms of chemical composition can explain the detection of the same volatile compounds. However, potato is a matrix more complex than PDA, especially for the presence of unwounded peel, which creates a barrier between the tuber internal part and the environment. Peel reduces the potato smell diffusion and, at the same time, adsorbs on its surface odors from the environment such as soil or fungi smell, making very complex the detection of possible diseases markers due to the presence of these interfering volatile compounds. To minimize this effect, potato tubers used in our study have been gently brushed to remove residues of soil and possible spores of saprophytic fungi. Moreover, the absence of external disease symptoms and low disease severity in assayed tubers were responsible for the limited production of volatile compounds characteristic of brown and ring rot diseases. An attempt to identify brown and ring rot markers by GC-MS analysis has been made by Stinson et al.[14] Unfortunately, these results are not comparable with those reported in the present paper because they used potatoes with clear disease symptoms (comparable with our class 5 symptom level, Table 1), whereas in our study potato tubers belonging to the lower classes were used. Moreover, a comparison between the two analytical approaches is not allowed as Stinson et al.[14] did not report details of GC-MS analysis. Similarly, in a recent review[7] on volatile compounds emitted from raw potatoes, tubers have been analyzed after peeling and for this reason the results cannot fit with our findings.

Volatile compounds detected in our bacterial cultures are organic compounds usually produced in the main metabolic processes. On the contrary, in potato samples, with the exception of 2-propanol and 3-methylbutanoic acid, volatile compounds from the metabolism of Rs or Cms were mostly identified as branched-chain alkanes and alcohols with a C atom number >5.

No data are available in the literature to explain the formation of these products. Likely, they might be carbohydrate degradation intermediates, more complex than volatiles with three or four carbon atoms detected in bacterial cultures. As far as the detection of other volatile compounds is concerned, benzothiazole is a degradation product of S-containing amino acid and toluene, as previously reported, along with detected ketones are products of fatty acid degradation. 2-Propanol, toluene, and benzothiazole were also detected in the headspace of tubers infected with *Phytophthora infestans* and *Fusarium solani* var. *coeruleum*.[37] In our case infected tubers were chosen to avoid contamination due to other saprophytic organisms such as *Fusarium* spp. and *Pectobacterium* spp: moreover, the presence of *Phytophthora infestans* in tubers used for this study was excluded.

PTR-MS in Vivo Analysis. PTR-MS is a useful tool for real-time monitoring of low molecular mass volatile compound emissions, such as ethanol, methanol, propanol, and 2-propanone. Most of these volatile compounds are not in the range of the compounds measured with GC-MS.

High levels of several m/z were measured in diseased samples of Rs and Cms as compared to the controls; their abundance is given in Table 5.

Identification of the measured m/z is not straightforward, as PTR-MS cannot distinguish between product ions with the same mass. However, previous experimental determinations in similar conditions as used here (e.g., E/N = 120 V cm^2, where E is the electric field strength expressed as V cm^{-1} and N is the density of the neutral molecules expressed as molecule number cm^{-3} in the reaction chamber); reaction chamber pressure (2 mbar) together with the isotopic ratio analysis[38] allows assignment of several compounds such as methanol (m/z 33), acetaldehyde (m/z 45), ethanol (m/z 47), 2-propanone (m/z 59), dimethyl sulfide (DMS, m/z 63), and dimethyl disulfide (DMDS, m/z 95). Possible candidates or their major fragment for the ions measured are indicated in Table 5. Two of them, with m/z 43 and 93, were specific to Cms-diseased tubers and were attributed to 2-propanol and toluene, respectively, as confirmed by GC-MS analysis in this study. For some of the remaining compounds the most probable candidates were indicated on the basis of the literature.

Most of the volatile compounds were common for tubers infected with Rs as well as for those infected with Cms. 2-Butanone and sulfur-containing compounds (DMS and DMDS) were identified only in Rs-diseased tubers (DMDS was also the marker of Rs presence in TZ and LPG solid and liquid media). Ethanol and toluene were mainly produced by the Cms-diseased samples with symptomatic characteristics of class 3 or higher (identified after the measurements). These volatile compounds could be considered specific markers for Rs and Cms infection, respectively.

The PTR-MS analysis provided a profile of low molecular mass volatile compounds complementary to the GC-MS analysis. However, 2-butanone, dimethyl disulfide, ethanol, ethyl acetate, acetaldehyde, and 2-propanone were also found in the headspace of potatoes inoculated with *Pectobacterium carotovorum* ssp. *carotovorum* and *atrosepticum*.[9,39] Hexanal and traces of toluene and acetic acid were reported from tubers inoculated with *Phytophthora infestans* and *Fusarium solani* var. *coeruleum*.[37]

In conclusion, GC-MS and PTR-MS techniques allowed recognition of potato tubers infected by Rs or Cms through the identification of specific disease markers: 1-hepten-3-ol, 3,6-dimethyl-3-octanone, 3-ethyl-3-methylpentane, 1-chloroctane, and benzothiazole were markers of potato brown rot, whereas 2-propanol and toluene were markers of potato ring rot. The techniques provided also a promising alternative to the molecular assays.

Within the framework of the development of innovative and rapid techniques for the detection of quarantine pathogens to be used by National Plant Protection Organizations and Inspection Services in the European Union, these findings represent the first step toward the realization of plant pathogen noninvasive diagnostic methods alternative to the standard methods reported in EU Directives, which require costly and time-consuming microbiological, serological, and molecular assays.

Further studies will be addressed to the volatile compound detection by electronic nose due to the importance of accelerating potato disease analysis.

ABSTRACT: A primary component to human health risk assessments required by the U.S. Environmental Protection Agency in the registration of pesticides is an estimation of concentrations in surface drinking water predicted by environmental models. The assumptions used in the current regulatory modeling approach are designed to be "conservative", resulting in higher predicted pesticide concentrations than would actually occur in the environment. This paper compiles previously reported modeling and monitoring comparisons and shows that current regulatory modeling methods result in predictions that universally exceed observed concentrations from the upper end of their distributions. In 50% of the modeling/monitoring comparisons, model predictions were more than 229 times greater than the observations, while, in 25% of the comparisons, model predictions were more than 4500 times greater than the observations. The causes for these overpredictions are identified, followed by suggestions for alternative modeling approaches that would result in predictions of pesticide concentrations closer to those observed.

KEYWORDS: *pesticide, modeling, monitoring, surface water, water supply*

INTRODUCTION

Regulation of agricultural pesticides use in the Unites States is required to be protective of both human health and the environment. The U.S. Environmental Protection Agency (EPA) assesses the risk of a particular pesticide use to human health from all nonoccupational sources by determining an estimated drinking water concentration (EDWC) of the pesticide, generally using simulation models, and combining this with other possible routes of exposure (food and residential sources) for comparison against human health effects metrics (the pesticide toxicity). Occupational exposure is assessed under a separate paradigm. The aggregate exposure is compared with effects data so that the risk manager may make an informed decision based on the risk characterization. The EDWC is often the determining factor in a risk assessment, and the accurate estimations of exposure are worthy of evaluation and improvements as technology and available data improve. EDWCs are calculated for both groundwater and surface water, with the higher of the two values representing the exposure level in the risk assessment. While challenges exist in the determination of groundwater and surface water EDWCs, this paper will focus on surface water. Surface water EDWCs can be determined from direct monitoring of raw and finished water in surface water supplies (for already registered products), modeling the pesticide fate and transport in surface drinking water using established regulatory tools or refined tools, or a combination of the two approaches. While extensive monitoring of pesticide residues in drinking water systems has occurred in the US over the past few decades, the need to calculate EDWCs for certain types of water systems and pesticides lacking more extensive monitoring records (especially limited and new use products) will continue. For this reason, modeling of pesticide EDWCs is the most common approach taken when conducting risk assessments; however, the usefulness of existing monitoring programs should not be ignored in their ability to validate the regulatory process and modeling predictions made by the EPA.

Current Regulatory Modeling Approach. In pesticide registration review, the U.S. EPA follows a tiered risk assessment process that applies more conservative aquatic exposure modeling methods for estimating pesticide EDWCs at the lower tiers and only applies more complex, refined modeling approaches for those pesticides that have not passed the risk assessment at the lower tiers. The Tier 1 modeling approach (designed to be most conservative) uses EPA's FIRST model,[1] and because most pesticides fail this initial tier, a Tier 2 assessment is often required. In a Tier 2 assessment, the EPA requires that a standard modeling approach utilizing the Pesticide Root Zone Model (PRZM) field scale hydrologic model[2] and the Exposure Analysis Modeling System (EXAMS) receiving water model[3] be followed when estimating pesticide EDWCs for the purpose of product registration. Refinements including Percent Crop Area (PCA) adjustments to the assumption of 100% cropping are within the Tier 2 guidance, but other refinements are limited. Registrants have at times submitted more complex modeling approaches that incorporate site specific environmental conditions (e.g., soil and weather), probabilistic methods (e.g., Monte Carlo simulation), specialized models, spatial analysis of model input parameters, and monitoring data as a Tier 3 and Tier 4 assessment to further refine exposure predictions.[4] US EPA acceptance of Tier 3 and

Tier 4 has been limited, so in practice, exposure modeling beyond the screening level assessment provided in Tier 2 is rarely conducted, making the Tier 2 modeling results the most relevant for comparison with monitoring data.

The modeling results reported on in this study were generated using the Tier 2 modeling approaches that were prescribed by the EPA at the time the studies were conducted. The Tier 2 approach simulates daily concentrations of a pesticide in an "Index Reservoir" over a 30-year period. The Index Reservoir was characterized by the US EPA as being "designed to mimic drinking water reservoirs in the central Midwest known to be highly vulnerable to contamination from pesticides used in agriculture".[5] This Index Reservoir and its associated watershed is based on the Shipman Reservoir in Illinois. The Shipman Reservoir covers approximately 5.3 ha, has a mean depth of 2.7 m, and has a watershed that drains approximately 172.8 ha. These geometric characteristics result in a drainage area to normal capacity ratio (DA/NC) of 12, which is higher than approximately 90% of drinking water reservoirs.[5] Because higher DA/NC ratios lead to higher pesticide exposure vulnerability, the geometric characteristics of the Index Reservoir place it on the high end (90th percentile) of vulnerability.

The use of Shipman Reservoir to represent the Index Reservoir scenario for estimating EDWCs was designed to be conservative; therefore, the predicted pesticide concentrations are expected to be higher than would be found in most drinking water reservoirs.[6] Another important input assumption when applying the Index Reservoir scenario to calculate EDWCs is the percent cropped area (PCA) adjustment factor. A PCA adjustment factor is necessary because, for watersheds greater than a few hectares in size, the percentage of the watershed being cropped will be less than 100%. The PCA is a critical input assumption to the Index Reservoir modeling approach because it dictates the fraction of the reservoir watershed that will be treated with the pesticide under evaluation. The US EPA has recently developed updated guidance on how PCA adjustment factors should be determined for major crop and crop groups for both national and regional assessments.[7] This guidance provides recommendations of national and regional PCA values for major crops, for combinations of major crops, and for all agriculture, as well as a prescribed methodology for choosing the appropriate PCA value for a given pesticide use pattern scenario. While this recent guidance supersedes the approaches to PCA calculation that were effective at the time when several of the modeling studies in this report were conducted, the differences in PCA values between current and past guidance are small relative to the magnitude of the modeled versus monitoring data concentrations. Furthermore, the recommended PCA values in the most recent guidance are generally higher than the previously guidance, making the current model predictions more conservative than past analogous predictions. The national maximum PCAs for the major crops that were recommended for use during the period between 2000 and 2012[8] and the current post-2012 guidance are shown in Table 1.

The only legal constraints on pesticide use are the conditions for use placed on a product label. These conditions (for agricultural products, the application rates and timing on specific crops) are what EPA uses as a basis for modeling exposure, focusing on what could occur as opposed to what actually occurs or is likely to occur. Following the EPA modeling approach, the PCA and subsequently the fraction of the watershed treated with pesticide are constant for all pesticides that are labeled for use on a particular crop, regardless of the relative market share of individual products or the prevalence of actual use. Additionally, it is assumed that application of the pesticide is made over the entire cropped area in the watershed on the same day. The assumption that the entire cropped area is treated on the same day is likely to be more accurate for very small watersheds and low acreage crops consisting of a few fields under the management of few farmers, but it quickly becomes less realistic as the watershed size increases or for high acreage crops (due to farmer equipment constraints or pest and weed management strategies). Misrepresentation of actual product use spatially and temporally can have a significant impact on EDWCs. In order for models to successfully predict pesticide concentrations that can realistically be expected to occur under high vulnerability conditions, the product use assumptions must reflect reality. A comparison of modeling results with monitoring data will give an indication of model performance but also how well assumptions used for input values reflect actual conditions.

Table 1. Comparison of National Percent Cropped Area (PCA) Adjustment Factors for Major Crops from US EPA Guidance during 2000−2012 and Updated Guidance for 2012−Present

crop	max percent cropped area (2000−2012)	max percent cropped area (2012−current)
corn	0.46	0.61
soybeans	0.41	0.57
wheat	0.56	0.38
cotton	0.2	0.33
all agricultural land	0.87	0.91

Comparing Modeling to Monitoring Data. Making comparisons of water quality modeling results and monitoring data is a common activity used in model calibration and validation. Often times, these comparisons are not straightforward due to monitoring frequency and sampling methods relative to the modeling data.

One common comparison approach is to perform time series analysis where monitoring data and modeling results are evaluated over specific time periods (typically daily) where the two co-occur. A time series analysis can also occur based on longer duration time steps (monthly or annually) where both the monitoring and modeling data are aggregated over the duration being assessed. Obtaining an accurate assessment of model performance from time series analysis can be challenging in pesticide simulation modeling due to the uncertainties in pesticide application timing and subsequent transport to receiving waters. These uncertainties make the quantification of differences between model and monitoring data difficult, because the time series goodness of fit statistics are very sensitive to small timing errors in the model. The difficulty in applying time series comparison methods is even more difficult in situations where the number of monitoring samples is small compared to the number of model predictions. In situations where pesticide application timing is very well understood and monitoring data is more abundant, a time series analysis can be a meaningful approach for assessing the performance of pesticide concentration simulations. Another approach for comparing modeling and monitoring data is to perform statistical comparisons of the probability distributions of the two data sets. This type of approach places less emphasis on

assessing the model's ability to match temporal signals in the monitoring data and, instead, looks to assess the model's ability to predict concentration magnitude and frequency. This approach is particularly appropriate for pesticides where the specific temporal use patterns are often highly uncertain and where the monitoring data may not be able to capture the details of day to day temporal variability.

When making comparisons between modeling and monitoring data, the uncertainties inherent in both need to be considered. Uncertainties in modeling arise from the identification of model parameters, measured model inputs, and the underlying conceptual model and model structure. Uncertainties in model parameters have long been recognized in pesticide exposure modeling, and parameter space sampling techniques, such as Monte Carlo Analysis, Latin Hypercube Sampling, and Deterministic Equivalent Modeling Method (DEMM), have been used to address them.[9−12] Unfortunately, techniques such as Monte Carlo analysis often do not include errors and uncertainties in model inputs, such as weather and pesticide application timing, which can often be as or more important as many model parameters included in a probabilistic approach. Often times, model uncertainty is reduced by the refinement of model parameters accomplished through calibration with monitoring data.

Uncertainty in monitoring data used to calibrate and validate hydrologic and water quality models is also well acknowledged, and can lead to poor identification of model parameters. Efforts to quantify this uncertainty and development of tools to aid in the comparison of monitoring data with model data have been developed[13,14] and may be used to improve model calibration. Techniques for quantification of uncertainties associated with a conceptual model and model structure are not commonly applied to water quality models with a static form used in pesticide exposure modeling; however, the existence of these uncertainties should be acknowledged.

One of the greatest sources of uncertainty associated with monitoring data is the potential bias in the monitoring data resulting from low sampling frequency. Arguments can be made that infrequent sampling at regular intervals in a monitoring program can sometimes miss the peaks in concentration which are important in the determination of EDWCs for use in risk assessments. While this argument cannot be disputed, the question of the sampling frequency required to enable accurate prediction of the "true" distribution in concentration levels remains a topic of interest and continued investigation. Crawford[15] evaluated the sampling frequency required to accurately predict various exceedance probabilities of annual maximum concentrations. Crawford found that required sampling frequency was dependent upon watershed size and the exceedance probability being detected. For example, the median annual concentration in water bodies draining lager watersheds (e.g., 16,400 km^2) can be estimated sufficiently by sampling 7 times per year. For the 95th percentile annual concentrations (5% exceedance probability) on smaller watersheds (90−250 km^2), a sampling frequency of 10 times per month during the runoff season following pesticide applications was required. In addition, Mosquin et al.[16] presented an approach for estimating higher percentile (lower exceedance probability) pesticide concentrations in surface drinking water from monitoring data sets of various frequencies. In addition, they provided estimates of the number of samples required to derive confidence bounds for the upper percentiles of concentration distributions. For example, an effective sample size of 59−69 can provide the estimates for the 95th percentile concentrations with sufficient statistical confidence (e.g., 95%), and increasing the sample size to 212 reduces the relative standard error to 30% or below. Other recent work has sought to quantify the potential bias in the estimates of higher percentile pesticide concentrations based on nondaily monitoring data.[17,18] These studies have suggested that bias factors (defined as the 95th percentile of the ratios of a true concentration end point derived from daily monitoring data to the corresponding estimate from nondaily sampling) increase as monitoring frequency decreases and as the desired averaging interval decreases in duration (i.e., the bias factor increases if estimating maximum versus 14-day average). Chen et al.[18] found an average bias factor of 2.4 when using 7-day sampling interval data to estimate an annual peak value, and Hetrick[17] found bias factors averaging 1.79 for estimating peaks from 4-day sampling data or 8.35 when using 28-day sampling data. The development of bias factors for estimating higher percentile pesticide concentrations from monitoring data of various sampling frequencies provides an important basis for the comparisons between modeling results and monitoring data obtained from nondaily sampling studies. While the development of methods for using monitoring data in statistical estimation of higher percentile pesticide concentrations will continue, modeling tools will always be required when assessing EDWCs for newly registered crop protection products.

The question of if and by how much pesticide EDWCs derived from the standard regulatory modeling approach overestimate actual pesticide concentrations in drinking water has long been one of considerable interest. Several authors have published comparisons of modeling and monitoring data within the past ten years.[19−24] These studies (and others) have determined that the regulatory modeling based EDWCs consistently overpredict the concentrations of pesticides found in surface drinking water monitoring data sets. As was stated, the US EPA's modeling approach is understandably designed to be conservative; however, the magnitude of the gap between modeled and observed pesticide concentrations in surface drinking water should be fully understood so that the modeling results can be applied more appropriately in the context of better understood certainty/uncertainty of the modeled estimates. This paper brings together a collection of previously published comparisons between monitoring data and regulatory modeling-based EDWCs, with the objective of evaluating how accurately the regulatory modeling approach being used by the U.S. EPA reflects what has been observed in monitoring studies. In combining data from multiple past studies, the analysis contained in this paper is based on the most comprehensive set of data on the subject to date. A secondary objective of this paper is to identify the possible factors leading to the overprediction of EDWCs following the current modeling approach and to propose alternative assumptions and methods that produce results closer to observed values of pesticide concentrations in surface drinking water.

MATERIALS AND METHODS

This comparison of modeling and monitoring data of pesticide concentrations focused on modeled EDWCs derived from standard US EPA Tier 2 regulatory modeling and monitoring data covering a wide range of water body types (flowing and nonflowing) and sizes. A preliminary literature review on the subjects of pesticide modeling and monitoring identified 179 documents from peer reviewed journal

articles, technical reports, conference proceedings and presentations, and Web sites. This initial bibliography was then screened to identify the studies that contained explicit comparisons between Tier 2 PRZM/EXAMS modeling results and monitoring data. This screening resulted in seven studies from which the data for evaluation were compiled. All the monitoring and modeling results reported in each of the seven studies selected were designed to select either the maximum or a higher percentile monitoring data concentration for comparison with the modeled values (which were generally the 1 in 10 year annual maximum values used in regulatory risk assessments). The discussion that follows and footnotes to the individual data tables will provide the information concerning each of the data sources and describe the methodology for the modeling/monitoring data comparisons made in this report.

Data Sources. The data sets, and descriptions of the source studies they came from, are provided in this section. First was the paper by Jones.[19] This study reported on four pesticides that were part of targeted monitoring studies that sought to identify community drinking water systems (CWS) that were in locations most vulnerable to potential exposure to each individual pesticide. The study included between 5 and 28 CWS for each pesticide, with between 233 and 2120 samples of raw water and between 30 and 306 samples of finished water (total samples per pesticide ranging from 263 to 2426). The sampling associated with these studies lasted between 2 and 3 years and included weekly or biweekly sampling frequency during and after the application season. The study compared both daily maximum concentrations and annual average concentrations. A summary of the data compiled from this study is provided in Table 2. In Table 2, the highest modeled concentrations represent the highest daily maximum value based on 30-year simulations of all multiple crop scenarios simulated for the pesticide shown. The highest monitoring concentration represents the highest of finished water over the duration of the study (2 to 3 years).

Table 2. Summary of Modeling and Monitoring Data from Jones[17]

pesticide	highest modeled conc[e] (μg/L)	max monitoring conc (μg/L)	EDWC duration	tot samples[f]
aldicarb[a]	17	0.68	acute (daily max)	2426
bromoxynil[b]	11	0.38	acute (daily max)	543
carbaryl[c]	745	0.16	acute (daily max)	2369
ethoprophos[d]	127	0.012	acute (daily max)	263
aldicarb[a]	5.8	0.07	chronic (annual avg)	2426
bromoxynil[b]	0.2	0.01	chronic (annual avg)	543
carbaryl[c]	31	0.005	chronic (annual avg)	2369
ethoprophos[d]	13	<0.003	chronic (annual avg)	263

[a]Includes 28 sites monitored for 3 years with weekly sampling during application season. [b]Includes 16 sites monitored for 2 years with biweekly sampling during application season. [c]Includes 20 sites monitored for 3 years with weekly sampling during application season. [d]Includes 5 sites monitored for 3 years with weekly sampling during application season. [e]Modeling conducted by EPA and represents 90th percentile annual maximum; for bromoxynil, value represents the average of annual maxima. [f]Raw water plus finished water samples.

The second source of data by Jackson et al.[20] examined 25 different pesticides, making predictions of EDWCs following the standard EPA PRZM/EXAMS regulatory modeling approach and comparing those results with monitoring data collected in the study of water supply reservoirs conducted by the US Geological Survey (USGS) and the US EPA.[25] The USGS study monitored 12 reservoirs over a period of one to two years (1999−2000) extending geographically across 12 different states, from California to New York . The reservoirs selected focused on small reservoirs with high pesticide use, and were thus highly vulnerable to elevated pesticide concentrations. A sampling strategy was designed to be able to estimate higher percentile (90th, 95th, and 99th percentile) with high confidence. The strategy was derived from an evaluation of a 2-year record of daily pesticide concentrations from Perry Lake reservoir in Kansas, and PRZM/EXAMS simulations. Three different sampling schemes were developed (11, 26, and 37 times per year), each of which focused samples during the pesticide application season. One of the 12 reservoirs received the highest sampling frequency (37 times per year), four reservoirs received the middle frequency (26 times per year), and seven received the lower frequency sampling, resulting in 537 to 551 samples per pesticide. In addition to data from the 2-year reservoir monitoring study, Jackson et al.[20] also presented monitoring data from the USGS National Water Quality Assessment (NAWQA) program as an additional data set for comparison. The NAWQA data set analysis included a longer record of water quality sampling (1992−2004) and a larger total number of samples for each pesticide, ranging from 105 to 23,726. The NAWQA sampling locations are not specifically targeted as sites having a high vulnerability to pesticide exposure, but rather represent a cross section of agricultural, developed, and mixed land use watersheds spread geographically across the United States. Sampling for NAWQA is generally conducted on a biweekly basis. One of the primary objectives of the NAQWA program is to monitor trends in surface water quality. A summary of the PRZM/EXAMS modeling and the monitoring results from the USGS reservoir monitoring and the NAWQA database analysis is provided in Table 3. The highest modeling concentration reported is the highest 90th percentile annual maximum concentration (from the 30-year PRZM/EXAMS simulations) simulated from one or more crop scenarios. The 90th percentile annual maximum concentrations are calculated by first determining the maximum concentration in each simulation year and then ranking those annual maximum concentrations and calculating the 90th percentile of those values. The data presented for the reservoir monitoring program represents the maximum concentration detected, while the data from the NAWQA program is the 95th percentile of the collection of samples. Although these two monitoring data sets are not equivalent, the additional NAWQA data provide a valuable comparison with both the modeled concentrations and the reservoir data.

A conference presentation by Hertl et al.[21] also compared modeling results following the EPA PRZM/EXAMS regulatory modeling approach with monitoring data from the USGS reservoir monitoring program.[19] This study evaluated several pesticides in addition to the Jackson et al.[20] study and also looked at both acute (short-term) and chronic (long-term) concentrations. The acute concentrations were represented by the maximum individual sample values, and the chronic concentrations were calculated as the 95th percentile of the time weighted annual average. In addition, the monitoring data evaluated in the Hertl et al.[21] study represented only the raw water samples, whereas the Jackson et al. paper included finished water as well, with a total number of samples per pesticide ranging from 312 to 323. For the vast majority of the pesticides analyzed, the raw water samples had higher concentrations than the finished water samples (highlighting another area of conservatism in the regulatory approach). These data are summarized in Table 4.

The most recent report reviewed that compared monitoring data to regulatory model simulation results was prepared by the US EPA.[7] The purpose of this report was to present an updated methodology for selecting appropriate PCA adjustment factors based on analysis of the most recent land use and cropping data sets. In addition to presenting the updated methodology, the report also showed monitoring data comparisons of the regulatory modeling simulations using the new PCA adjustment factors. In addition, the report included monitoring data from multiple sources (some were the same as those used in the earlier studies described) compiled over the past 20 years. These monitoring data sets included the following: USGS monitoring data from community water systems presented in *Concentration Data for*

[a]Modeled values represent 90th percentile of annual maxima. [b]Data presented in Jackson et al. (2005) was graphical. Specific values reported were extracted directly from Bloomquist et al. (2001). [c]Includes 12 sites monitored for 1 to 2 years with 11 to 37 samples per year, focused during application season (up to every 3 days for 1 month). [d]No detections occurred in sampling. Value represents detection limit. [e]Values preceded by "<" were below the level of quantification for the analytical method. [f]Raw water plus finished water samples.

Anthropogenic Organic Compounds in Ground Water, Surface Water, and Finished Water of Selected Community Water Systems in the United States, 2002–05 (http://pubs.usgs.gov/ds/2007/268/); USGS NAWQA surface water data (http://infotrek.er.usgs.gov/nawqa_queries/); the USDA's Pesticide Data Program (PDP); the California Department of Pesticide Regulation's Surface Water database (http://www.cdpr.ca.gov/docs/emon/surfwtr/surfdata.htm); and data obtained from crop-specific monitoring studies submitted to EPA. The comparisons in Echeverria et al.[7] represent the most current implementation of EPA's regulatory modeling approach as well as the most comprehensive compilation of monitoring data comparison. These data comparisons from the EPA report are summarized in Table 5. The highest modeling concentration shown represents the 1 in 10 year peak, or 90th percentile annual maximum concentration (see footnote earlier in this section). The total number of samples per pesticide was not provided in the EPA report; however, given that NAWQA was one of the sources, the number of samples likely well exceeded 1000 for many of the pesticides.

The four studies presented thus far accounted for the majority of the modeling results monitoring data comparisons. Three other studies provided additional comparisons of regulatory modeling results with monitoring data. The first study focused on the fungicide vinclozolin and its use on golf courses.[22] In this study, 10 CWS watersheds with high numbers of golf courses were monitored for over a two year period for vinclozolin. The second study assessed the herbicide oxadiazon, which is also used on turf.[23] In this study, three community water systems were monitored for a period of three years. The third study was an analysis of fungicide iprodione use on turf and included its degradate product, 3,5-DCA.[24] This study compared monitoring data of finished water collected over three years from three different CWS with regulatory modeling predictions. The modeling and monitoring data from these three studies, including the total number of monitoring samples (ranging from 480 to 639), are presented in Table 6.

Data Compilation and Analysis. The modeling/monitoring data comparison from the seven studies presented in Tables 2–6 were combined for an assessment of the modeled data overprediction in surface water EDWCs. For the Jackson et al.[20] study, only the monitoring data from the USGS reservoir study was included for the combined comparison. This was done because, for all pesticides, the monitoring data from the USGS reservoir monitoring found greater concentrations than the 95th percentile data from the NAWQA analysis. There were a total of 85 modeling/monitoring data points for evaluation. These 85 data points included 68 acute and 17 chronic EDWC concentrations spread over 52 different pesticides (52 acute and 15 chronic). The overprediction in the modeled concentration was calculated as the ratio of modeled concentration to monitored concentration. The results of this analysis follow.

RESULTS AND DISCUSSION

Analysis of Modeling and Monitoring Data Comparisons. All monitoring and modeling data comparisons from the seven studies compiled are shown in Figure 1a. The 85 data points are sorted from highest modeled concentration to lowest modeled concentration. Figure 1b shows only the 25 data points with the lowest modeled concentrations. The modeled concentrations ranged from a high value of 1350 μg/L (for tebuthiuron acute concentration) to a low value of 0.2 μg/L (for bromoxynil chronic concentration). The median modeled concentration was 32.5 μg/L (for bentazon, acute concentration), which had an associated monitoring concentration 2 orders of magnitude lower at 0.344 μg/L. In total, 96.5% of the

[a]Vinclozolin data from Jackson et al. (2010); oxadiazon data from Nandihalli et al. (2010); iprodione and 3,5-DCA data from Jones (2012). [b]Includes 3 sites monitored for 3 years with weekly/biweekly sampling. [c]Includes 10 sites monitored for 3 years with biweekly sampling for first 6 months, then monthly. [d]Modeled values represent 90th percentile of annual maxima. [e]Raw water plus finished water samples.

modeled concentrations were greater than 1 μg/L, while the monitoring data values were greater than 1 μg/L only 10.6% of the time. In all 85 comparisons, the monitoring data were lower than the modeling data.

The magnitude of the overprediction by the modeling results was quantified by calculating the ratio of the modeling concentration to the monitoring concentration. These ratios are plotted from low to high in Figure 2 using percentiles calculated from the Weibull plotting position. In addition, the 85 data points were split into acute and chronic comparisons. Based on the population of all 85 data points, the range in overprediction is from 1.5 to 85,041, with the median overprediction greater than 2 orders of magnitude (229×). More than 90% of the comparisons had a model overprediction of greater than 1 order of magnitude (10×). For one-third of all comparisons, the overprediction by the modeling results was greater than 1000×. When comparing the distribution of model overprediction for acute versus chronic EDWCs, the distributions are very similar between from the 30th through 90th percentiles. Below the 30th percentile, the chronic EDWC overpredictions are somewhat higher than the acute overpredictions. The smallest overprediction in the chronic EDWCs

dx.doi.org/10.1021/jf4036996 | J. Agric. Food Chem. 2014, 62, 348−359

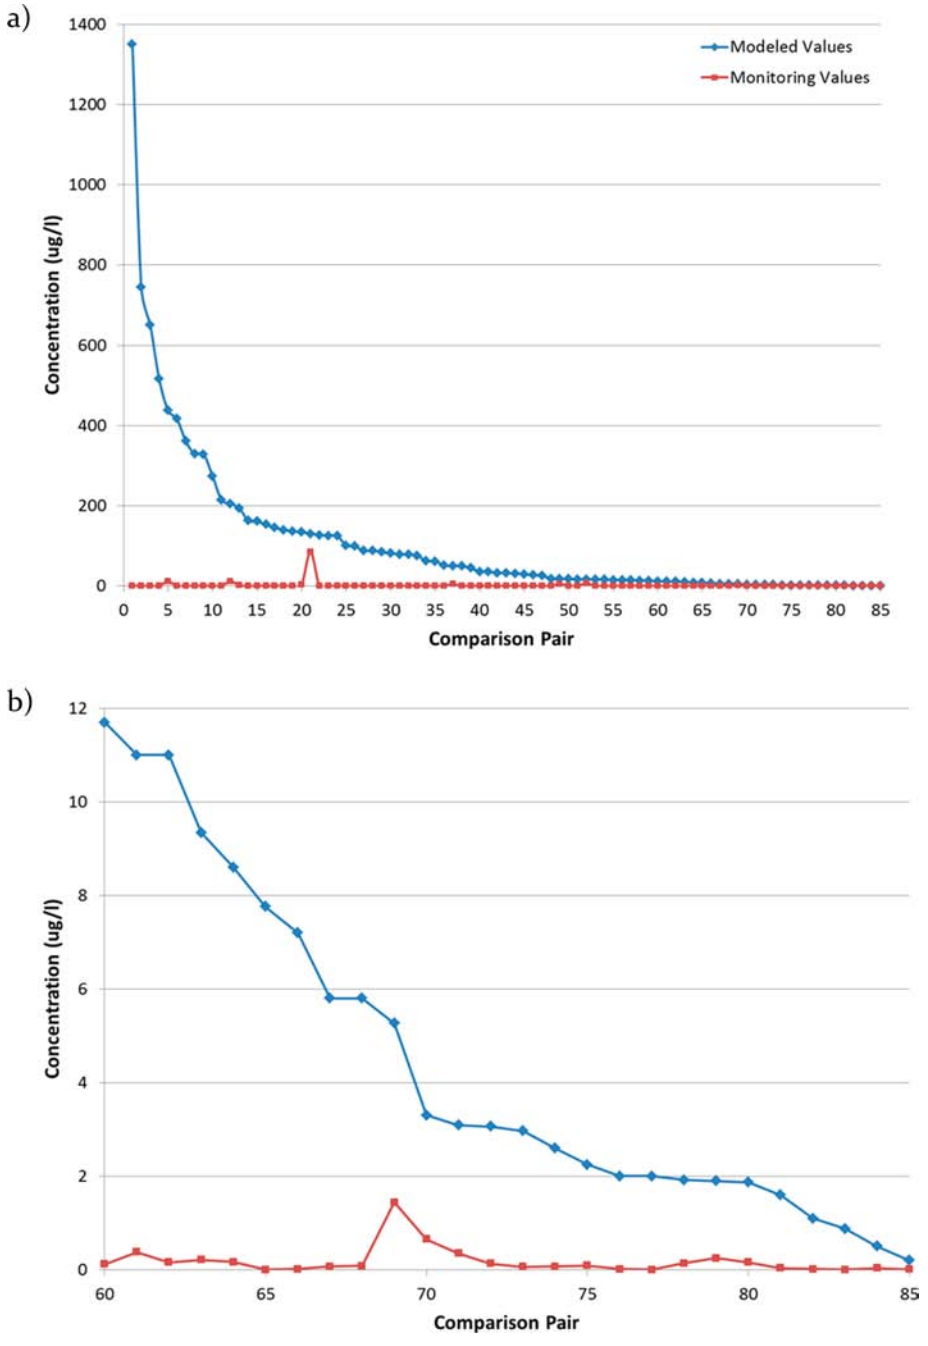

Figure 1. (a) Comparison of modeled and monitoring data concentrations for all pesticides, all data points. (b) Comparison of modeled and monitoring data concentrations for all pesticides, low concentration data points.

was 20× while the smallest acute overprediction was 1.16×. This suggests that, even as the regulatory modeling approach results in peak concentrations that are too high, the persistence of elevated concentrations that it predicts can lead to more significant overprediction of longer duration concentrations. This persistence of high concentrations may be in part due to the underestimation of inflows and outflows associated with the index reservoir assumptions.

The overprediction ratios by pesticide for the acute EDWC comparisons are shown in Figure 3. The average (arithmetic mean) was calculated for those pesticides (e.g., atrazine) where multiple comparisons of modeling and monitoring data were available. In the figure, (I) indicates an insecticide, (H) indicates a herbicide, (F) indicates a fungicide, (F,D) indicates a fungicide degradate, and (N) represents a nematocide. Based on the data in Figure 3, there are a few trends to note. First, three of the pesticides in the top ten highest overprediction ratios were fungicides or associated degradates, while no fungicides occurred among the lowest ten ratios. In addition, two of the pesticides in the top ten lowest overprediction ratios (acetochlor and atrazine) are among the top 5 highest use pesticides in the US in 2007.[26] Of the ten pesticides with the highest overprediction ratios shown in Figure 3, none of them were among the 25 pesticides with the highest use in the US in 2007. While the data available concerning actual pesticides use associated with each modeling/monitoring data comparison are limited at best, the comparison trend demonstrates a

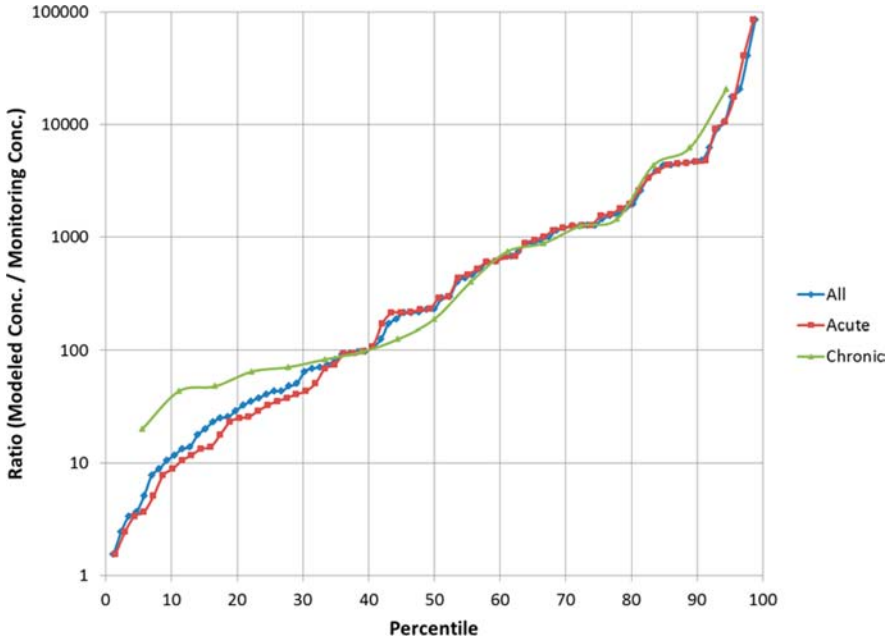

Figure 2. Overprediction ratios of EDWCs for acute, chronic, and all predictions pooled together.

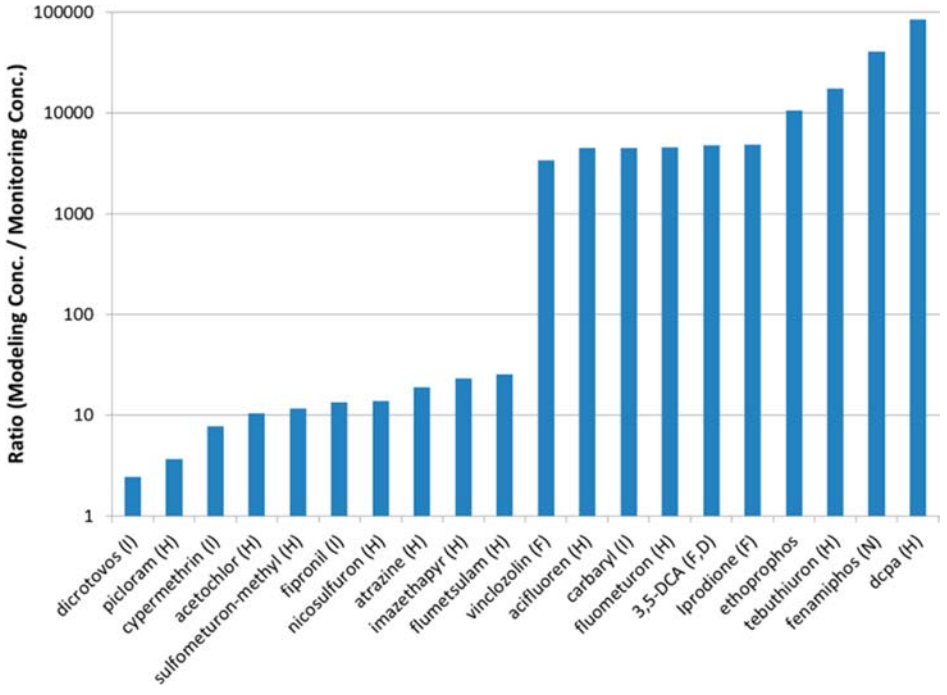

Figure 3. Top 10 and bottom 10 acute overprediction ratios of EDWCs by pesticide.

correlation between lower use pesticides and higher overprediction ratios.

Factors Affecting Model Comparisons with Monitoring Data. It must be acknowledged that the comparisons between the modeled EDWCs and monitoring data are not, and cannot be, absolutely equivalent comparisons, as the regulatory modeling was not conducted on a site-specific basis under monitoring watershed conditions (e.g., specific weather or soil characteristics). They were run under the generic Index Reservoir standard setting. One aspect of the monitoring data sets that is different than the modeling data is the sampling interval. The modeling data EDWCs are based on daily predictions, whereas the monitoring data sets are based on different prescribed sampling intervals. As has been discussed, the data sets cited in this paper all had annual sampling frequency in the range of once every 3-days to biweekly samples during the high runoff season. Although these nondaily sampling frequencies might have missed the true maximum concentration in a particular year, the annual mean (chronic end point) and/or the 90th percentiles (acute) concentrations over the many sites and years (up to 20 years) should provide sufficient statistical power for estimating these end points based on Crawford[15] and Mosquin et al.[16] Recall that Crawford[15] found that seven samples per year was sufficient to estimate median annual concentrations for larger watersheds, and 95th percentile annual maximum concentrations could be con-

dx.doi.org/10.1021/jf4036996 | J. Agric. Food Chem. 2014, 62, 348−359

fidently estimated with ten samples per month (every three days) during the runoff season. The sampling frequency in the monitoring studies contained in this report all exceeded the frequency required for estimates of annual mean concentrations (chronic), and several met or approached the frequency required to estimate the 95th percentile annual concentration (a level requiring more frequent sampling than the standard 90th percentile annual acute concentration). In addition, research concerning the bias factors between the true peak concentrations and peak concentrations[17,18] inferred from a nondaily sampling scheme indicated a weekly based sampling scheme could likely underestimate peak concentrations by a factor of 2.4 on average, whereas a 28-day sampling scheme could underestimate peak concentrations by a factor of 8.35 on average. The monitoring programs evaluated in the comparisons contained in this study included targeted monitoring (designed to sample high vulnerability sites), with weekly or sometimes more frequent sampling (sampling information is provided as footnotes associated with each data table and earlier in the text). A monitoring bias factor of around 3x is very small compared to the median model overprediction of 280x reported in the studies evaluated here.

A second aspect of the modeling data that differs from the monitoring data is the length of the model simulation compared to the monitoring sampling period. Model simulations for Tier 2 regulatory modeling are run for 30 years in order to account for climate variability. Although some of the monitoring data sets included in this study included longer periods of record (>10 years), such as some sources included in Echeverria et al.,[7] many were based on durations of two to three years.[19−24] If these monitoring studies were each considering only a single site, one might conclude that the shorter duration of the monitoring data would be expected to show potentially lower peak pesticide concentrations compared to a model simulation representative of a 30-year weather time series (with greater extremes). In the case of the studies presented in this report, this conclusion would not be valid, because all of the studies evaluated multiple sites throughout the monitoring period, effectively multiplying the number of sample years by the number of sites. For example, in the Jones study,[19] individual pesticide monitoring ranged from five sites for three years (15 effective site-years) to 28 sites for three years (56 effective site-years). The USGS targeted reservoir monitoring program,[25] which was used in model comparisons in several studies,[20,21] intensively monitored 12 sites for two years (24 effective site-years). By including multiple sites monitoring for the same pesticide, the potential for a low bias in the monitoring data due to having less climate variability than a 30-year modeling period is likely to be low. This can also be supported by the statistical work of Crawford[15] and Mosquin et al.,[16] who have shown that nondaily sampling data sets over many sites and years (up to 20 years in our cited data) should provide sufficient statistical power for estimating the annual mean (chronic end point) and/or the 90th (acute) concentrations. Recall that Mosquin et al.[16] found that an effective sample size of 212 is sufficient to estimate the 95th percentile concentrations with a relative error of 30% or less for a target population of monitoring. As can be seen in reviewing Tables 2−6, the total number of samples per pesticide used to compare with model results ranged from a minimum of 263 samples for ethoprophos (Table 2) to 23,736 samples in the case of the NAWQA atrazine data (Table 3), with most pesticides having greater than 500 samples. These findings suggest that the sample sizes in the monitoring data sets evaluated in this study are large enough to allow meaningful estimation of both chronic (annual mean) and acute (90th percentile) concentrations.

Framework for More Accurate Modeling of Drinking Water Exposures. This study included comparisons of modeling results generated by using standard EPA regulatory practices with monitoring data dating back to 2002,[21] continuing up through a comprehensive assessment compiled by the US EPA using that latest parametrization methodology.[7] Each of these studies concludes that, to varying degrees, the regulatory modeling approach overpredicts drinking water EDWCs. While overprediction by the modeling approach is consistent with the regulatory objective of protecting human health, the degree of overprediction identified in this study (median of nearly 280×) suggests that for most pesticides the current modeling approach may have unrealistically predicted a higher potential health risk than actually exists. Evaluation of the current modeling approach is thus warranted, including a critical review of the inputs and assumptions in the current approach that are responsible for the significant overprediction of EDWCs.

Many of the assumptions leading to the large overpredictions have been identified by the authors of previous publications on the subject. Hertl et al.[21] mention several factors leading to the overprediction, foremost among them being the overrepresentation of pesticide use in the Index Reservoir watershed. Even though a PCA adjustment factor is applied to lower the effective fraction of the Index Reservoir watershed receiving pesticide application, this PCA is based on a conservative estimate of crop extent and does not take into consideration information on actual pesticide use. The assumption that 100% of a given crop is applied across the whole watershed with the same pesticide under consideration at the maximum labeled rate (as is the assumption in regulatory modeling) is never true in reality, and for many pesticides with small market share, it is a gross overestimate of actual use. Hertl et al.[21] goes on to mention issues associated with the appropriateness of the PRZM/EXAMS model scale compared to the scale it is being used to simulate. PRZM is a single field model which is being used to simulate the hydrochemical behavior of a heterogeneous watershed. The PRZM model cannot account for watershed scale attenuation and the effects of interaction between adjacent landscape units (such as vegetated and/or riparian buffers) which have been shown to significantly reduce off-field transport of pesticides.[27] Furthermore, the issue of scale is a key factor in the assumptions of pesticide spray drift contributions to EDWCs in the index reservoir modeling scenario, which assumes that all treated fields are adjacent to water bodies contributing to the reservoir and that those water bodies are always downwind of the field treated with pesticide; an assumption that is physically an impossibility. Other factors contributing to the regulatory modeling overprediction include the compounding of conservative assumptions such as the following: selection of only a single representative but runoff vulnerable soil and the interpretation of product labels assuming the maximum rates at the minimum intervals to all fields within a watershed on the same day. The chemical specific environmental fate parameters chosen as inputs to the models are selected with each parameter individually representing the upper 90th of sample values for that parameter's data set. Collectively, however, combining these parameter values creates a vulnerability scenario much higher

than the 90th. Other authors[19,20] have identified similar factors contributing to regulatory model overprediction, with Jackson et al.[20] proposing a correction factor based on the total pesticide applied in the model simulation.

The authors of this paper support the suggestions by previous authors on the subject regarding the causes for overprediction in the regulatory modeling approach that are most responsible for model overprediction. There are several other factors that deserve mentioning and reinforcement. First, as stated in the Introduction, the Index Reservoir scenario is based on CWS with a very low drainage area to normal capacity ratio (DA/NC), and according to the EPA,[5] 90% of surface drinking water reservoirs will have higher DA/NC ratios. This issue of CWS watershed characteristics becomes even more relevant in the context of drinking water supplies located along flowing water bodies, where the characteristics of pesticide concentrations are very different than static water supply reservoirs. The use of a high vulnerability static water body to represent pesticide exposure potential in a broad range of both static and flowing water bodies does not capture the variability in these types of drinking water supplies. Second, while the overrepresentation of pesticide use has already been discussed, another related problem is the implicit assumption that all fields in a watershed receive the pesticide application at the same time. This assumption is inappropriate for even the smallest sized watersheds that can support an adequate drinking water supply (such as the 172.8 ha Shipman Reservoir) and has greater invalidity as the size of the CWS watershed increases and the variability of agronomic practices of multiple farms contributes to a broad range in pesticide application dates. Accounting for the variability in application timing when modeling pesticide fate and transport at the watershed scale has been shown to have a significant effect on predicted concentrations in flowing water bodies.[28,29] We have discussed the many factors that are contributing to the unrealistically high estimates of drinking water concentrations of pesticides using the current regulatory modeling approach. Refined approaches to applying the current Tier 2 models, as well as methods for applying alternative models, already exist and have shown promise in their ability to accurately predict pesticide residues in surface water.

These alternative modeling approaches include both newly developed tools as well as models with a longer history. The US EPA is currently working on developing updated modeling tools, such as the Surface Water Calculator (Young, 2013)[30] and the Spatial Aquatic Model,[31] that may be able to address some of the shortcomings of the current modeling approach. The Surface Water Calculator (SWC) is expected to include a replacement to the EXAMS receiving water model called the Variable Volume Water Model (VVWM) which will allow for simulation of dynamic water volumes and a wider range in hydrologic conditions. The Spatial Aquatic Model (SAM) is being designed to simulate both static and flowing water bodies draining a watershed with heterogeneous land use and soils. In addition to US EPA efforts to improve the accepted regulatory modeling tools, several other models reported in the scientific literature have been shown to perform well at the prediction of pesticides in complex watersheds that are typical of surface drinking water systems. The United States Geological Survey Watershed Regressions for Pesticides (WARP) model[32] was designed to predict annual atrazine concentration percentiles in flowing water bodies across the US. The WARP model was shown by both Jones[19] and Jackson et al.[22] to predict pesticide concentrations closer to monitoring data than the standard Index Reservoir modeling method. The WARP model was originally developed based on a statistical analysis of atrazine monitoring data and has since been adopted for use with other pesticides through incorporation of a surface water mobility index.[33] The strength of the WARP model is that it was built on robust monitoring data sets; however, because it is not physically based, it is unable to provide important functions such as the simulation of alternative Best Management Practices. This model also has limited testing on pesticides for target crops with a smaller geographic extent than corn.

Promising opportunities for developing a modeling approach that addresses the shortcomings in the current regulatory modeling method reside in the application of exiting watershed scale models that have a proven ability to accurately represent the hydrochemical processes that are necessary for pesticide fate and transport prediction. These tools could easily work into the current regulatory process as a higher tier refinement and could be utilized to simulate either additional representative scenarios or individual drinking water−watersheds of specific concern. One of the most widely used watershed scale models is the Soil and Water Assessment Tool (SWAT) developed and maintained by the United States Department of Agriculture.[34] SWAT is a watershed-scale, continuous, physically based, semidistributed model that has been used in a broad range of hydrologic and water quality applications.[35] One of SWAT's strengths is its ability to simulate the water quality impact of alternative management practices, including tillage practices, buffers and grassed waterways, and pesticide application practices. The use of the SWAT model in the simulation of pesticide transport at the watershed scale has been reported in the literature since at least 2005, and SWAT was recently selected from a pool of 36 models as one of the most appropriate for watershed-scale simulation of pesticides.[36] Pesticide transport modeling with SWAT has included assessments of pesticides in both static and flowing water bodies. Winchell et al.[28] and Peranginangin et al.[37] developed and evaluated a SWAT modeling methodology which focused on identifying a parametrization approach that takes advantage of intelligent use of data in place of extensive site-specific calibration for use in aquatic pesticide concentration predictions in complex watersheds. Another watershed-scale modeling approach based on the PRZM model is the PRZM-Hybrid modeling method described by Snyder et al.[38] and in reports by Miller and colleagues.[29,39] The PRZM-Hybrid approach utilizes spatially explicit high-resolution NEXRAD radar rainfall data, additional meteorology data, field-scale soil properties from the US national SSURGO database, and spatially explicit land use data as input data to model daily watershed runoff concentrations. Both the SWAT and PRZM-Hybrid models are designed for simulation of complex, spatially heterogeneous watersheds and could be readily adapted to serve the purposes of modeling EDWCs for the purposes of human exposure risk assessments. In order for either of these models to generate accurate pesticide concentration predictions when compared to monitoring data, a good understanding of pesticide use information needs to be incorporated. If used in a regulatory context, the models have the ability to represent more complex and realistic hydrology, soil, weather, and application technologies than is possible with the models currently used by EPA. USEPA scientists and pesticide registrants have evaluated the use of watershed modeling

approaches in the past,[40] and because many of the tools have matured, a similar effort should be explored again.

Regardless of the model platform, achieving more realistic model predictions of EDWCs will require incorporating accurate assumptions on pesticide use intensity (i.e., pounds of pesticide per acre of watershed) into the regulatory modeling framework. The current assumption that any pesticide evaluated is applied to 100% of the maximum possible extent defined by its label is overly conservative for even the most widely used pesticides. This implausible assumption is the driving factor leading to the common occurrence of 3 to 5 orders of magnitude model overpredictions of EDWCs that were shown in Figure 2. Strong evidence to support the incorporation of realistic pesticide use assumptions in watershed scale modeling is found in recent studies where WARP (which explicitly accounts for pesticide use intensity) was shown to much more closely match monitoring data than the current regulatory modeling approach.[19,22] Information and techniques similar to those used by the USGS in their recently released national pesticide use maps[41] could serve as the foundation for more realistic use estimates but may require additional scale adjustments to be representative of small watersheds.

The data compiled in this paper represents the most complete collection to date of pesticide modeling and monitoring data. The accuracy of the concentration predictions made by the current regulatory modeling approach was shown to be poor, with significant overprediction common. Some of the primary reasons for this overprediction were discussed, including the regulatory modeling assumptions of pesticide use, a lack of application timing variability, reservoir and watershed geometry, and missing spatial heterogeneity of the watershed. In order for many of these shortcomings to be addressed, a watershed scale modeling approach will need to be adopted and databases of more accurate pesticide use information will need to be compiled. Several existing watershed modeling approaches were proposed, each of which has already shown promise in predicting pesticide concentrations in watersheds of similar size and complexity to typical CWS watersheds. A suggested next step is to take a closer look at several of the watershed scale models introduced in this discussion and determine which ones best fit the needs of regulatory modeling and result in more accurate predictions of EDWCs.

ABSTRACT: In this study, the enantioselective bioaccumulation of epoxiconazole enantiomers in tubifex (Oligochaeta, Tubificida) was investigated in two uptake pathways. A sensitive and rapid chiral method was developed for the determination of epoxiconazole enantiomers in tubifex and soil based on high-performance liquid chromatography coupled with triple-quadrupole mass spectrometry (HPLC-MS/MS). In the spiked-water or spiked-soil treatments, enantioselective bioaccumulation of epoxiconazole in tubifex was obersved. For spiked-water treatment, (−)-epoxiconazole accumulated in tubifex to a greater extent than (+)-epoxiconazole, leading to enrichments with a composition (−) > (+). However, for spiked-soil treatment, the enantioselectivity in tubifex was reversed with a preferential accumulation of (+)-epoxiconazole. Calculated accumulation factors (AFs) indicated that epoxiconazole in spiked-water treatment had higher bioaccumulation potential than that in spiked-soil treatment. The results from the spiked-soil treatment also revealed that the dissipation of epoxiconazole in soil was enantioselective, and tubifex has positive effects on epoxiconazole diffusion from soil to overlying water.

KEYWORDS: *epoxiconazole, tubifex, enantioselectivity, bioaccumulation*

INTRODUCTION

Epoxiconazole is a broad-spectrum triazole fungicide and extensively used worldwide to control diseases caused by fungi, such as Ascomycetes, Basidiomycetes, and Deuteromycetes, in cereals, sugar beet, peanuts, oilseed rape, apple, and ornamentals.[1] It is also used to regulate plant growth by acting as an inhibitor of C-14 demethylase in sterol biosynthesis. Epoxiconazole also plays an important role in the formation of ergosterol, a component of fungal cell membrane.[2] This fungicide, which is widely used on wheat, sugar beet, triticale, barley, and oat,[3] persists in soil and aquatic sediment.[4,5] Hence, epoxiconazole in sediment may lead to serious noxious effects on benthic organisms that use sediment as food resources and living environments. After prolonged repeated applications, epoxiconazole could enter into fresh-water circulations. Therefore, the influence of epoxiconazole on the aquatic ecosystem should be investigated.

Epoxiconazole, *cis*-1-{[3-(2-chlorophenyl)-2-(4-fluorophenyl)oxiranyl]ethyl}-1*H*-1,2,4-triazole, was first produced by BASF Corp. in 1993.[6] It consists of two chiral centers in its molecular structure and therefore presents two diastereoisomers with four stereoisomers. However, present commercial epoxiconazole pesticide contains only a pair of enantiomers with 2*R*,3*S*- and 2*S*, 3*R*-configurations.[7] The chemical structures and molecular weights (MWs) of four epoxiconazole stereoisomers are shown in Figure 1. Thus, epoxiconazole is a member of the chiral pesticide family. Organic pesticides play a crucial role in agricultural protection, and among these pesticides, >25% are chiral compounds with at least two mirror-image enantiomers.[8] However, most of the currently used chiral pesticides are produced and released into the environment as racemates. Theoretically, enantiomers have identical physical and chemical properties, as well as abiotic degradation rates,[9] whereas their individual toxicities, biological activities, and microbial degradation rates have been shown to differ.[9−13] Thus, the mechanism, exposure, and effect of each enantiomer should be evaluated when the risk of chiral pesticides to human and wildlife populations is assessed.[13] This necessity has led to extensive research on the enantioselectivity of chiral compounds. Several studies have

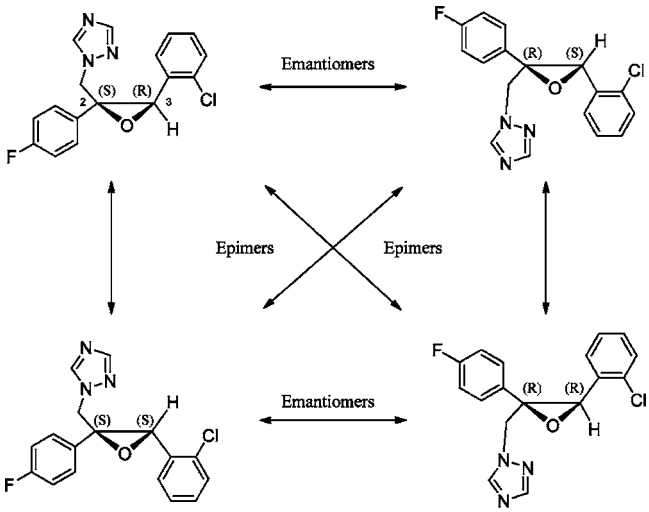

Figure 1. Structures of epoxiconazole stereoisomers. The present commercial product refers to the *cis*-stereoisomers with 2*S*,3*R* and 2*R*,3*S* configurations.

shown that enantiomers of epoxiconazole behave differently during biodegradation in the environment.[14] Liang et al.[6] reported that the dissipation of epoxiconazole enantiomers in grape is enantioselective with relative enrichment of (+)-epoxiconazole, and an enantioselective dissipation also occurred in soil with preferential degradation of the (−)-form under field condition. However, other aspects such as enantioselective bioaccumulation of epoxiconazole in tubifex have not been investigated.

Tubifex is a cosmopolitan freshwater oligochaete (Tubificidea). It forms an important link in aquatic food chains.[15,16] Given their endobenthic lifestyle, this oligochaete is in intimate contact with the solid phase and the pore water of the sediment.[16] In addition, this worm ingests the substrates and utilizes adhering micro-organisms and detrital material.[17,18] Tubifex is widely cultured as a fish food.[19] Therefore, it is prone to transfer sediment-associated contaminants to higher trophic levels. Thus, tubifex plays an important role in the aquatic ecosystem and has been designated as a representative freshwater benthic infauna for aquatic system bioassays. Several studies have chosen tubifex to study bioaccumulation and sediment toxicity.[20−23] However, data on enantioselective bioaccumulation of epoxiconazole enantiomers in *Tubifex tubifex* have not been reported.

The differences in the bioaccumulation behavior of the two enantiomers of epoxiconazole in tubifex were investigated in the present study. Effective methods for the extraction, purification, and detection by high-performance liquid chromatography coupled with triple-quadrupole mass spectrometry (HPLC-MS/MS) have been developed to study epoxiconazole enantiomers in tubifex tissue under laboratory conditions. We compared the effect of two different contamination sources, spiked water and spiked soil, on the bioaccumulation of epoxiconazole. The results showed that bioaccumulations of epoxiconazole were both enantioselective in the two contamination treatments. Additionally, we evaluated the effects of tubifex on the diffusion and dissipation of epoxiconazole.

MATERIALS AND METHODS

Chemicals and Reagents. Reference standards of *rac*-epoxiconazole (98.4%) were purchased from Shanghai Pesticide Research Institute (Shanghai, China). Acetone, formic acid, methanol, *n*-hexane, and ethyl acetate were of analytical grade and purchased from Beijing Chemical Reagent Co. Ltd. (Beijing, China). Acetonitrile was of HPLC grade and purchased from J. T. Baker (Phillipsburg, NJ, USA). The Florisil solid phase extraction (SPE) cartridges (500 mg/6 mL) were obtained from Agela Technologies (Tianjin, China) and conditioned with 5 mL of acetone/*n*-hexane (1:3, v/v) ether before use.

Worms and Soil Collection. *T. tubifex* was obtained from Beijing Xiyuan Flower Market (Beijing, China). The worms were maintained in 2 L plastic tanks containing uncontaminated soil and deionized water at 21 ± 1 °C under 12 h light/12 h darkness. The water was continuously aerated, 75% of which was replaced weekly. The worms were fed TetraMin Flakes (Tetra Werke, Melle, Germany) weekly. For the experiments, adult *T. tubifex* (aged 5−7 weeks) were used. Prior to the introduction of worms into the treatments, tubifex worms were allowed to live in the uncontaminated environment for 1 week to acclimate.

The experimental substrate was terrestrial soil collected from Baiwang Forest National Park northwest of Beijing, China. No detectable epoxiconazole was found at detectable levels in this soil. After the superficial layer of 1−2 cm was removed, the soil was collected to a depth of 10 cm, sieved through a 500 μm mesh, air-dried at room temperature, and stored in the dark until use within a few days. Physicochemical properties of the soil were as follows: organic carbon (OC), 4.28 ± 1.05%; moisture content (MC), 1.37%; clay, 4.31 ± 0.02%; sand, 58.42 ± 0.25%; silt, 37.19 ± 0.22%; and pH, 8.2 ± 0.2.

Soil Handling and Spiking. To disperse the test substance epoxiconazole homogeneously within the 100 g dry weight of soil, we performed a stepwise dilution spike procedure.[24] First, racemic epoxiconazole was dissolved in acetone to make a stock solution at a concentration of 1000 mg/L. Then, 0.1 mL of acetone solution was added dropwise into the dry soil (100 g) while the mixture was continuously mixed manually for approximately 5 min with a stainless steel laboratory spoon, yielding a nominal epoxiconazole concentration of 1 mg/kg_{dwt}. The spiked soil was left in a fume cupboard for >12 h. After complete evaporation of the solvent, the contaminated soil (100 g dry weight) was transferred to a 500 mL beaker and rehydrated with 100 mL of deionized water. The height of the bottom substrate was 2−3 cm, and the overlying water was 2−3 cm. The test vessels were incubated for a 24 h equilibration period. Prior to tubifex addition, four 50 mL samples of wet soil were weighed, dried at room temperature until the weight became stable, and then reweighed to estimate the moisture content.

Bioassay Procedure. To examine the influence of different uptake pathways of epoxiconazole on the total bioaccumulation in tubifex, two types of uptake kinetics were examined resulting from the spiked-water and spiked-soil treatments. The first scenario was designated {+Tub +water}, in which epoxiconazole was accumulated from spiked water. For each individual experiment, acclimated tubifex (10 g) were placed into beakers (21 beakers, 7 sampling points, and triplicates for one sampling point), and the spiking solutions were prepared by adding epoxiconazole dissolved in acetone to deionized water to obtain a final concentration of 1 mg/L. After an exposure period (0.5, 1, 3, 5, 7, 10, and 14 days), the living worms were removed from the beaker, gently passed through a 500 μm sieve to a clean pan, and then washed three times with deionized water. Finally, the peripheral water of the worm samples was dried using absorbent paper, and samples were weighed before storage at −20 °C, and the worm sample for extraction was 5 g. In the present study, only the uptake from the aqueous phase was studied for 14 days of exposure, and this treatment was performed in semistatic conditions with daily water renewal.

The second scenario, which consisted of tubifex, water, and spiked soil, was designated {+Tub+soil}, in which epoxiconazole was accumulated from overlying water, pore water, and ingestion of soil particles. Acclimated tubifex (10 g) were added to the test beaker containing unspiked water and spiked soil (21 beakers, 7 sampling points, and triplicates for one sampling point). For the {+Tub+soil} treatment, test organisms, overlying water, and soil were also sampled after an exposure period (1, 3, 5, 7, 10, 14, and 20 days). At each sample point, overlying water was gently poured and initially sampled. Then, the beakers were placed on ice for 2 h, during which the tubifex worms climbed to the soil surface and intertwined slowly together. At this moment, worm aggregation was sampled with forceps and rinsed in deionized water. Water on the surface of the worms was carefully dried by absorbent paper. Soil samples, overlying water, and tubifex sampled from each beaker were weighed and frozen at −20 °C.

To compare with the second scenario, a separate experiment (negative control), which was designated {−Tub+soil}, that used only water and spiked soil, was performed (21 beakers, 7 sampling points, and triplicates for one sampling point). The sampling times were also 1, 3, 5, 7, 10, 14, and 20 days. At these sampling points, overlying water and aliquots of 3.15 g of soil (based on dry weight) were removed from each beaker and transferred into 50 mL plastic centrifuge tube for extraction and analysis.

For the {+Tub+soil} and {−Tub+soil} treatments, the test beakers were weighed daily, and the loss of water resulting from evaporation was compensated for by adding deionized water. All beakers were cultured in a dark environmental chamber, and temperature was controlled to 20 ± 2 °C. The treatment beakers were arranged in a randomized block design.

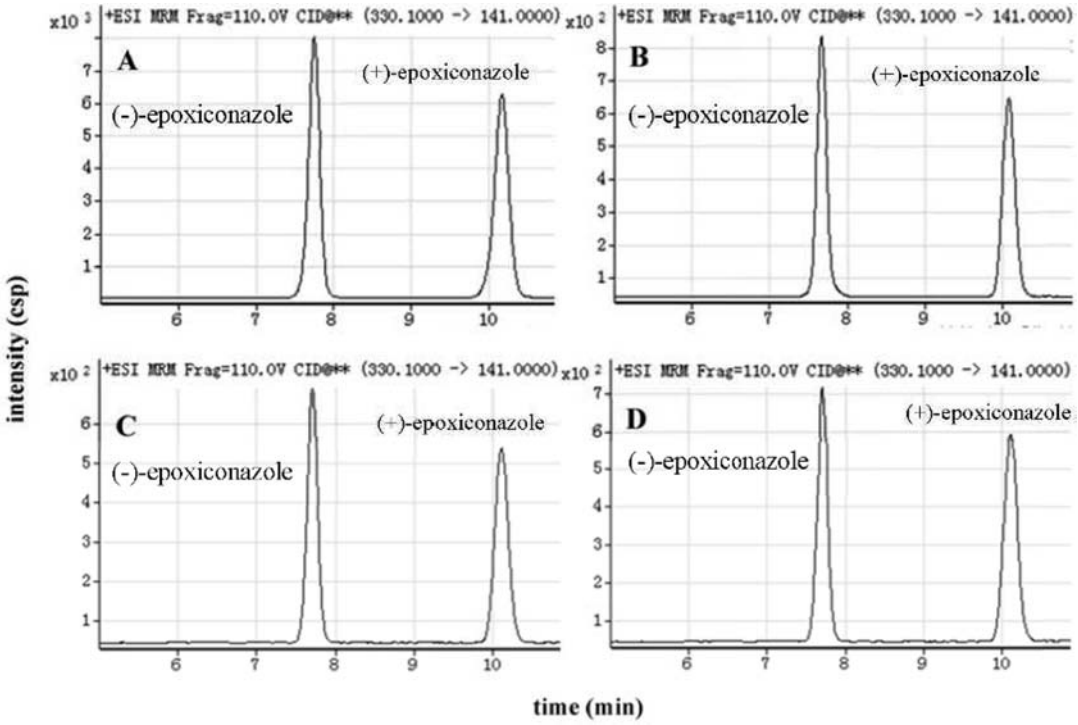

Figure 2. Chromatograms of (A) standard solution at 1 mg/L, (B) overlying water spiked at 0.1 mg/L, (C) soil spiked at 0.1 mg/L, and (D) tubifex spiked at 0.1 mg/L.

Sample Extraction. The water and overlying water samples (5 mL) were extracted by 10 mL of acetone/ethyl acetate (1:3, v/v) in glass separatory funnels after removal of the solid matter by vacuum filtration. This extraction was repeated twice using fresh solvent. The combined solvent phase was filtered through 5 g of anhydrous sodium sulfate for dehydration, transferred to a pear-shaped flask, and then evaporated to dryness at 35 °C by a vacuum rotary vaporator. The dry extract was redissolved to 1 mL with methanol for analysis on HPLC-MS/MS.

The wet soil samples were extracted by acetone/ethyl (1:3, v/v) acetate, and interfering substances were cleaned up by Florisil SPE (500 mg) on a cartridge (6 mL). Briefly, soil samples (5 g wet weight per sample), 20 mL of acetone/ethyl (1:3, v/v) acetate, and 2 g of anhydrous sodium sulfate were added to a 50 mL polypropylene centrifuge tube. The tube was capped, vortex-mixed for 3 min, and centrifuged at 3500 rpm for 5 min. The extract was filtered through 5 g of anhydrous sodium sulfate for dehydration and transferred to a pear-shaped flask. The remaining part was re-extracted following the same extraction step. Then, the combined extract was concentrated to dryness on a vacuum rotary evaporator at 35 °C. The SPE cartridge was preconditioned by elution with 5 mL of acetone followed by 5 mL of *n*-hexane and equilibrated with 10 mL of acetone/*n*-hexane (1:4, v/v). The sample of dry extract was recovered in 3 mL of 20% acetone in *n*-hexane, and then the solution was passed through the SPE cartridge. The cartridge was eluted with an additional 7 mL of acetone/*n*-hexane (1:4, v/v). The eluates were combined with the loading eluates. The combined 10 mL of eluates was collected in a glass tube, evaporated to dryness under a stream of nitrogen, and diluted to 1 mL with methanol after passage through a filter membrane (pore size = 0.45 μm).

The tubifex samples were thawed for about 15 min at room temperature. Then, 20 mL of acetone/ethyl (1:3, v/v) acetate was added to a 50 mL polypropylene centrifuge tube containing 5 g of worms. The mixture was homogenized with an Ultra-Turrax T18 homogenizer for 30 s, vortex-mixed for 5 min, and then separated by centrifugation at 3500 rpm for 5 min. The upper organic phase was passed through a funnel with about 5 g of anhydrous sodium sulfate to a pear-shaped flask. The extraction was repeated two more times. The combined extracts were evaporated to dryness at 35 °C and reconstituted in 5 mL of acetonitrile. Then 5 mL of *n*-hexane was added for liquid−liquid partition to extract most of the lipid, and this procedure was repeated three times. The upper layer of *n*-hexane was discarded, and the acetonitrile layer was evaporated to dryness by a vacuum rotary evaporator. The purification process was similar to that of the soil samples described above.

Chemical Analysis. A chiral liquid chromatograph coupled with a tandem mass spectrometer was used to determine the concentrations of epoxiconazole enantiomers in the samples. The liquid chromatograph was an Agilent 1200 HPLC system equipped with a G1322A degasser, a G1311A quatpump, a G1316B column compartment, a G1329A autosampler, and a 100 μL sample loop. Stereoselective separation was performed on a new highly efficient chiral column [Phenomenex LuxCellulose-1 column, 250 × 4.6 mm (i.d.)] packed with a chiral stationary phase of cellulose tris(3,5-dimethylphenylcarbamate). The mobile phase consisted of a mixture of acetonitrile/water/formic acid (5:95:0.1, v/v/v) at flow rate of 0.5 mL/min. Chromatographic separation was conducted at a temperature of 30 °C. The injection volume was maintained at 5 μL. According to a previous paper,[25] the enantiomeric elution order of epoxiconazole on the Lux Cellulose-1 column was (−)-isomer first and (+)-isomer second with acetonitrile/water as mobile phase at an optical rotation detection wavelength of 426 nm.

An Agilent 6460 triple-quadrupole mass spectrometer equipped with an electrospray ionization source was used for MS/MS analysis (Agilent, USA). The analyses were performed in the positive mode with a 3500 V capillary voltage, 110 V fragmentor, and a 350 °C dry gas temperature. An 11 L/h dry gas flow was used. The nebulizer gas was 99.95% nitrogen with a pressure of 40 psi, and the collision gas was 99.999% nitrogen. The transitions of precursor ion (m/z 330.1) to production (m/z 121 and 141) of epoxiconazole were detected with multiple reaction monitoring (MRM) in positive ion (ESI+) mode. The collision energies for m/z 121 and 141 were 10 and 14 V, respectively, ,and the ion m/z 141 was used for quantification. Masshunter (Agilent, USA) software was used to collect and analyze the data obtained.

The linear regression equations and the correlation coefficients of each stereoisomer were obtained from the peak area ratio plotted

Table 1. Summary Recoveries for Epoxiconazole Stereoisomers in Overlying Water, Soil and Tubifex

		overlying water		soil		tubifex	
compound	spiked level (mg/kg)	av recovery (%, n = 3)	RSD	av recovery (%, n = 3)	RSD	av recovery (%, n = 3)	RSD
(−)-epoxiconazole	0.05	89.2	4.8	83.6	4.2	84.6	8.3
	0.5	86.0	5.6	80.3	4.9	83.1	4.2
	2.5	88.3	8.2	78.2	6.8	88.5	6.4
(+)-epoxiconazole	0.05	92.4	5.2	81.4	7.8	90.2	5.9
	0.5	89.3	7.6	85.7	6.9	85.8	7.8
	2.5	95.2	9.3	88.2	5.4	88.7	9.6

against its respective concentration (0.01−10 mg/L). Calibration curves were generated by plotting peak area versus the concentration of each enantiomer. The relative standard deviation (RSD) was calculated at the standard range. The standard curves for (−)- and (+)-enationmers showed excellent linearity in the range of 0.01−10 mg/L of each enatiomer (n = 3). For (−)-epoxiconazole, $y = 114043x + 23890$, $R^2 = 0.9973$; for (+)-epoxiconazole, $y = 129131x + 24593$, $R^2 = 0.9963$. The precisions of peak areas at the six concentration levels were also good with RSDs of 0.4−0.8% for (−)-epoxiconazole and 0.1−0.8% for (+)-epoxiconazole.

A series of blank samples fortified *rac*-epoxiconazole at 0.1, 1, and 5 mg/kg were determined immediately after fortification into the overlying water, soil, and tubifex tissue. In this work, the LC-MS/MS method was successfully developed to analyze epoxiconazole stereoisomers in water, soil, and tubifex samples. As shown in Figure 2, two stereoisomers were baseline separated. There were no interference peaks eluted at the same retention times as those of the stereoisomers. Table 1 shows the fortified results of epoxiconazole stereoisomers in water, soil, and tubifex samples. Thus, recovery rates and their standard error were acceptable. The LOQs and LODs for both stereoisomers in overlying water were found to be 0.005 and 0.001 mg/kg, and those in soil and tubifex tissue were both 0.03 and 0.006 mg/kg.

Data Analysis. The enantiomer fraction (EF) was used to measure the enantioselectivity behavior of epoxiconazole in our experiment. The EF values ranged from 0 to 1, with EF = 0.5 representing the racemic mixture. EF was expressed as

$$\mathrm{EF} = \text{peak area of } (-)/[(-) + (+)]$$

where (−) is the first eluted chromatograph peak of (−)-epoxiconazole and (+) is the second eluted peak of (+)-epoxiconazole.

Data presented correspond to mean ± standard deviation of three independent experiments (n = 3). Statistical analysis for the enantioselectivity of epoxiconazole enantiomers was performed using SPSS 18.0. A one-sample t test was used to compare the means of the EF values in tubifex and sediment samples with EF = 0.5. The concentrations and accumulation factors (AFs) of the two enantiomers of epoxiconazole were analyzed using one-way ANOVA, and a pairwise multiple-comparison procedure (S−N−K test) was used to compare results at $P < 0.05$.

RESULTS AND DISCUSSION

Enantioselective Bioaccumulation in Spiked-Water Treatment. For the spiked-water treatment ({+Tub+water}), in which water was the only supply of living environment and the worm can accumulate contamination via a single skin exposure, concentrations of the two enantiomers of epoxiconazole in tubifex tissue were detected. The typical LC-MS/MS chromatograms in tubifex obtained from this treatment at different times are shown in Figure 3A,B. Figure 4 shows the bioaccumulation concentrations of each enantiomer of epoxiconazole in tubifex samples under this treatment. On the seventh day, the concentrations of the two enantiomers reached the highest levels. Then, a significant decrease in concentrations was observed between 7 and 10 days of exposure, which could be the metabolism and excretion of epoxiconazole caused by the self-detoxification of tubifex. At the end of exposure, the concentrations tended toward a steady state. Additionally, Figure 4 also shows a clearly greater bioaccumulation of (−)-epoxiconazole than of (+)-epoxiconazole. The EF values in tubifex tissue were calculated and are shown in Figure 5. A one-sample t test was performed to compare the means of the EF values in tubifex with EF = 0.5, and the result showed that the EF values significantly deviated from 0.5 ($P < 0.005$). Therefore, the bioaccumulation of epoxiconazole in tubifex tissue under this treatment was enantioselective.

In this study, AF was used to express the bioaccumulation of epoxiconazole enantiomers in tubifex tissue. AF is a function of the relative sorptive capacities of the organism versus the surrounding environment. It is often used to compare the body burden of an organism with the degree of contamination in the water. The following definition is used here:

$$\mathrm{AF} = C_{\mathrm{worm}}/C_{\mathrm{water}}$$

C_{worm} and C_{water} are concentrations of epoxiconazole enantiomers in tubifex and water, respectively. The AF value at each sampling point was plotted against time. The AF values of (−)-enantiomer were larger than those of (+)-enantiomer, indicating that the (−)-enantiomer was preferentially accumulated over the (+)-enantiomer in tubifex tissue, and a significant difference was observed between the two enantiomers (Figure 4). Thus, the bioaccumulation of epoxiconazole in tubifex tissue exposure was enantioselective.

Enantioselective Dissipation of Epoxiconazole in Soil. In general, the residues of both enantiomers of epoxiconazole decreased with prolonged time in the {+Tub+soil} and {−Tub +soil} treatments (Figure 6). For worm-free treatment, the dissipation kinetics of (−)-epoxiconazole and (+)-epoxiconazole in soil followed first-order kinetics with $R^2 = 0.96$ and 0.98, respectively. The first-order kinetic equations were $C(t) = 0.4615e^{-0.063t}$ and $C(t) = 0.4781e^{-0.051t}$, respectively, where $C(t)$ was the concentration at time t (days). The corresponding half-life was calculated as $t_{1/2} = \ln 2/k = 0.693/k$, where k is the dissipation rate constant. The (−)-epoxiconazole and (+)-epoxiconazole had half-lives of 11.0 and 13.6 days in soil, respectively, resulting in relative enrichment of the (+)-form in soil (Figure 3C,D). For the worm-present treatment, the dissipation kinetics of (−)-epoxiconazole and (+)-epoxiconazole in soil also followed first-order kinetics with $R^2 = 0.92$ and 0.93, respectively, and the first-order kinetic equations were $C(t) = 0.3854e^{-0.105t}$ and $C(t) = 0.4217e^{-0.079t}$, respectively. The half-lives of (−)- and (+)-epoxiconazole were 6.6 and 9.2 days in soil, respectively, resulting in preferential dissipation of the (−)-form in soil (Figure 3E,F). Therefore, enantioseletive

dx.doi.org/10.1021/jf403996g | J. Agric. Food Chem. 2014, 62, 360−367

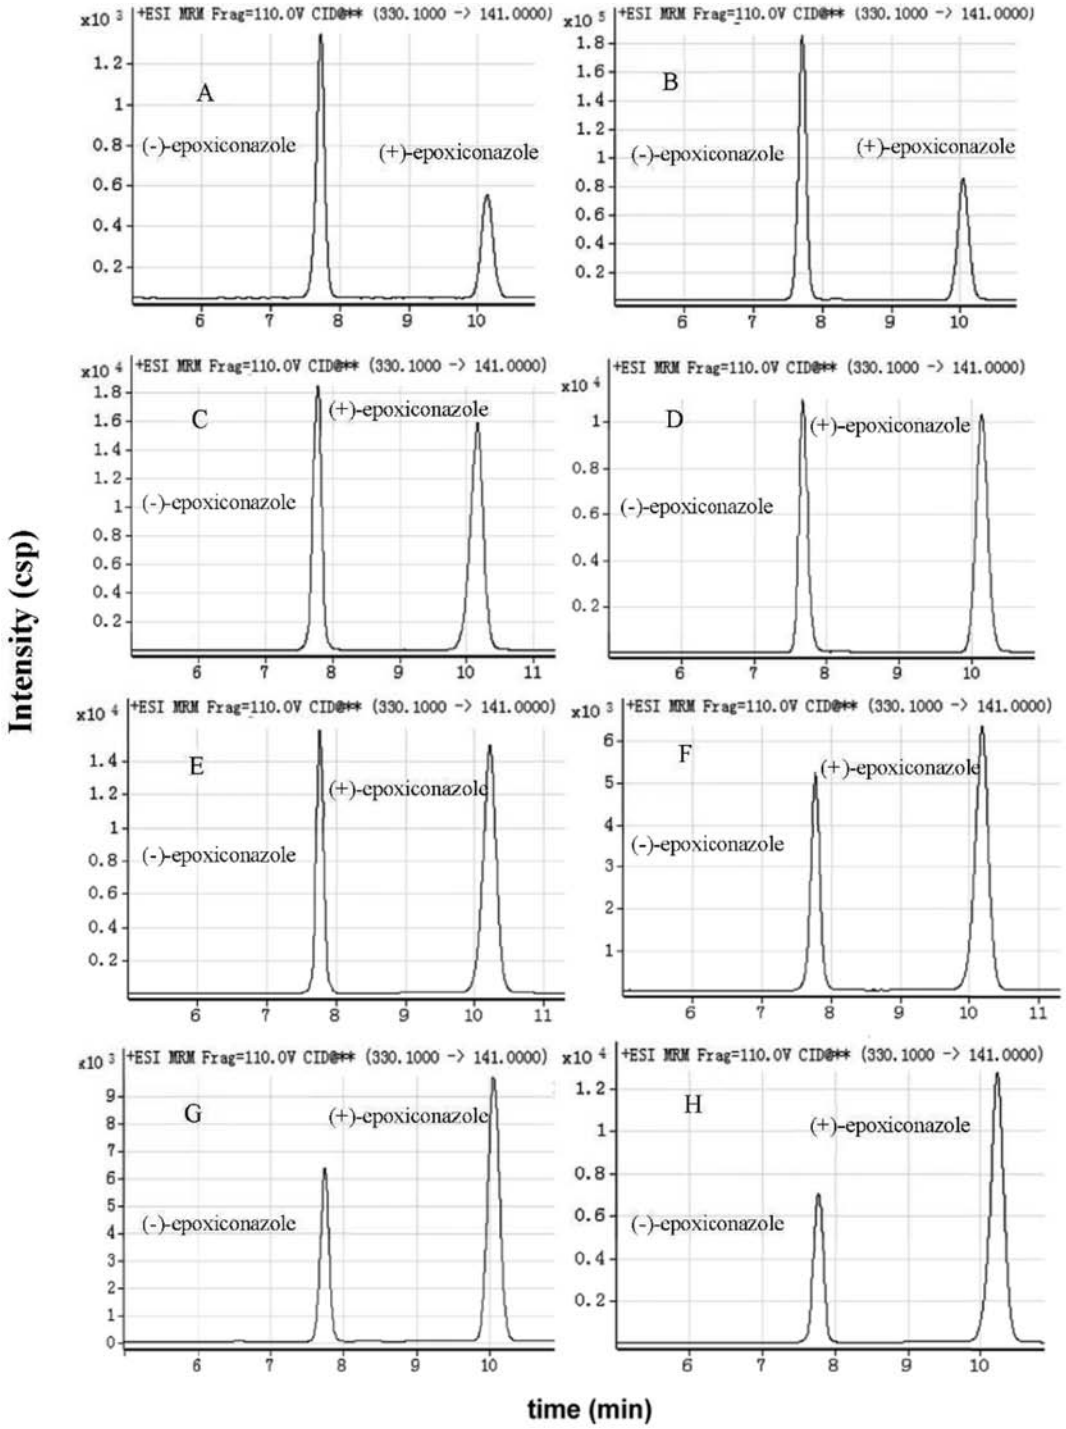

Figure 3. Typical chromatograms of extracts from water in {+Tub+water} treatment after 0.5 days (A) and 7 days (B), extracts from soil in {−Tub +soil} treatment after 1 day (C) and 14 days (D), extracts from soil in {+Tub+soil} treatment after 1 day (E) and 14 days (F), and extracts from tubifex in {+Tub+soil} treatment after 1 day (G) and 14 days (H).

behaviors were detected in the dissipation of the epoxiconazole in soil. During the whole 20-day exposure, the concentrations of the two enantiomers of epoxiconazole in soil under worm-present conditions were lower than those under worm-free conditions. Hence, epoxiconazole had lower persistence in soil with the existence of tubifex. In other words, tubifex could play an important role in remediation of contaminated soil.

Enantioselective Bioaccumulation in Spiked-Soil Treatment. For the {+Tub+soil} treatment, in which soil was the initial contamination source and tubifex can accumulate epoxiconazole via skin and ingestion exposure routes, concentrations of epoxiconazole enantiomers in tubifex tissue, overlying water, and spiked soil were evaluated. Figure 7 shows the bioaccumulation curves of the two enantiomers of epoxiconazole in tubifex tissue. Both concentrations of the two enantiomers of epoxiconazole in tubifex tissue persistently increased from days 1 to 5. After a 5 day decline, concentrations increased again and reached steady state as the duration of exposure increased. A significant difference between the two enantiomers was observed during the whole uptake period. The

concentrations of (+)-enantiomer in tubifex tissues were higher than those of (−)-enantiomer, resulting in relative enrichment of the (+)-epoxiconazole (Figure 3G,H). The EF values of epoxiconazole changed with time as shown in Figure 8. A one-

sample *t* test between the EF values of epoxiconazole in tubifex and EF = 0.5 yielded a *P* value of 0.001. These results showed that enantioselective bioaccumulation of epoxiconazole in tubifex occurred. For this treatment ({+Tub+soil}), the AF was defined as

$$AF = C_{worm}/C_{soil}$$

where concentrations of epoxiconazole enantiomers in tubifex and soil were expressed as C_{worm} and C_{soil}, respectively. The AF values versus the duration of exposure are plotted in Figure 8. On the basis of the S−N−K test, a significant difference between the AF values of the two enantiomers was observed, and the (+)-enantiomer was preferentially accumulated over the (−)-enantiomer in tubifex tissue. According to Figures 5 and 8, we found that the direction of the enantioselectivity

dx.doi.org/10.1021/jf403996g | J. Agric. Food Chem. 2014, 62, 360−367

varied with incubation conditions. Epoxiconazole was found to be enriched in the (−)-enantiomer in spiked-water treatment. However, enantioselectivity reversal in spiked-soil treatment was observed, resulting in concentrations enriched in (+)-enantiomer. Furthermore, the AF values in spiked-soil treatment were lower than those in spiked-water treatment during the whole exposure period. These interesting phenomena may have resulted from the different uptake pathways of the two treatments. For the spiked-water treatment, the accumulation activities of tubifex are absorbed merely through the epidermis. For spiked-soil treatment, bioaccumulation of epoxiconazole in tubifex may have occurred through ingestion of the soil particles and exposure in overlying water or pore water. Hence, the relative bioaccumulation capacities and bioaccumulation enantioselectivity of epoxiconazole in tubifex are related to the different chiral environments that play a role in the uptake of epoxiconazole.

Influence of Bioturbation. Bioturbation is caused by the activity of animal species living at the surface and/or within the sediment superficial layers.[26,27] Previous studies have investigated the effects of freshwater infaunal invertebrates on sediment transport and solute composition.[27−32] Bioturbation was found to induce a significant release of some xenobiotics from the sediment to the overlying waters. In this study, the concentrations of epoxiconazole enantiomers in overlying water for {+Tub+soil} and {−Tub+soil} treatments were detected. Data from Figure 9 illustrate that the concentrations of

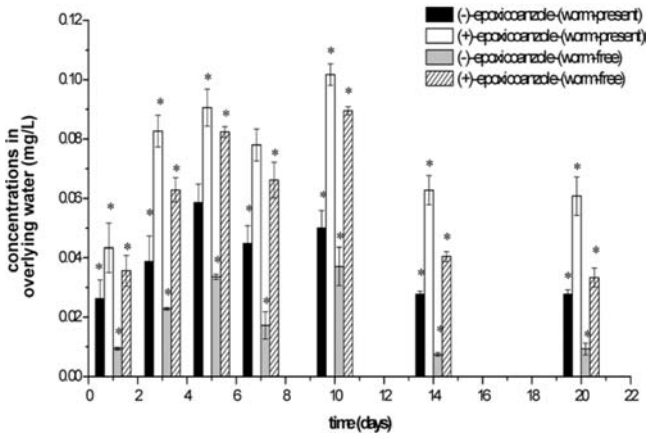

Figure 9. Concentrations of epoxiconazole in the overlying water (bars are standard error). ∗ indicates significant difference between the two enantiomers at the same time point ($P < 0.05$, S−N−K test).

(+)-epoxiconazole in overlying water samples in the two treatments were higher than those of (−)-epoxiconazole. Furthermore, the results also indicated that the concentrations of the two enantiomers in worm-present experiments were higher than those in worm-free experiments. This phenomenon could have been explained by the traversal of epoxiconazole to the spiked soil into the overlying water by simple diffusion processes in the worm-free treatment. However, for the worm-present treatment, epoxiconazole could pass through the spiked soil into the overlying water by two processes, diffusion and bioturbation. Thus, bioturbation has a positive effect on epoxiconazole diffusion from soil to overlying water.

ABSTRACT: *Rumex dentatus* L. is a problematic weed of wheat. Bioassay-directed isolation of culture filtrates of a plant pathogenic fungus *Drechslera australiensis* gave holadysenterine as the main herbicidal constituent against this weed of wheat. Leaf disc bioassay showed that herbicidal activity of holadysenterine was comparable to that of synthetic herbicide 2,4-D. This is the first report of this herbicidal compound from the genus *Drechslera*.

KEYWORDS: *Drechslera australiensis, leaf disc bioassay, natural herbicides, Rumex dentatus, weed of wheat*

INTRODUCTION

Rumex dentatus L. (family Polygonaceae) is a broad-leaf densely populated weed of wheat (*Triticum aestivum* L.) fields.[1,2] It is an extremely competitive annual herb that causes remarkable reduction in the yield of wheat.[3,4] Besides, the weed is also known for its allelopathic activity.[5] Anjum and Bajwa[3] reported 83% reduction in grain yield of wheat due to *R. dentatus* infestation. To control this weed, use of chemical herbicides is on the increase to boost up crop productivity.[6,7] However, we are now facing new challenges regarding weed control, especially emergence of resistance in weeds to herbicides[8] and concerns about herbicide effects in food, soil, groundwater, and atmosphere.[9,10] Because of these ill effects of herbicides coupled with increasing demand for organic farming in the world, isolation of new herbicides from natural sources is gaining importance.[11,12] Use of natural herbicidal constituents from microbes is one of the alternative strategies to manage the weeds.[13,14]

There have been many successful attempts to control weeds by metabolites of fungi of genus *Drechslera*.[15−17] Some bioactive compounds have been isolated from some species of this genus and proposed as potent natural herbicides.[18−20] Kastanias and Chrysayi-Tokousbalides[21] isolated macrodiolide (8*R*,16*R*)-(−)-pyrenophorin (8,16-dimethyl-1,9-dioxa-cyclohexadeca-3,11-diene-2,5,10,13-tetraone) from cultures of *Drechslera avenae* (Eidam) Shoem. The isolated compound inhibited seed germination of wild oats (*Avena fatua* L.). Another herbicidal compound drazepinone was identified from culture filtrates of *Drechslera siccans* (Drechsler) Shoemaker.[15] Evidente et al.[17] isolated a number of herbicidal metabolites from culture filtrate of *D. gigantea* Heald & Wolf including ophiobolin A that proved to be a potent herbicide against several grass and dicotyledonous weeds including *Avena ludoviciana* Dur., *Phalaris canariensis* L., *Chenopodium album* L., and *Sonchus oleraceus* L. Ophiobolin A proved to be the most potent phytotoxin as compared to the other related compounds. Preliminary investigations on culture filtrates of some species of *Drechslera* from Pakistan, namely *D. australiensis*, *D. hawaiiensis*, *D. biseptata*, and *D. holmii*, revealed their herbicidal activity against some problematic weeds of wheat and *Parthenium hysterophorus*.[22−24] However, detailed studies regarding isolation of herbicidal compounds from Pakistani *Drechslera* species are lacking. Therefore, the present study was carried out to identify the herbicidal constituents present in culture filtrates of *D. australiensis*.

MATERIALS AND METHODS

Preparation of Culture Filtrates of the Test Fungus. Culture of *D. australiensis* was procured from Fungal Culture Bank of Pakistan, Institute of Agricultural Sciences, University of the Punjab, Lahore, Pakistan. M-1-D growth medium was prepared by following the procedure described by Evidente et al.[17] First, 100 mL of medium was poured in 500 mL conical flasks and autoclaved. These flasks were then inoculated with actively growing culture discs of *D. australiensis* and incubated at 25 ± 2 °C in an incubator. After 28 days of incubation, cultures were filtered through muslin cloth, centrifuged, and finally filtered through Whatman filter paper no. 1. to get crude fungal culture filtrates free of fungal mycelia and spores.

Organic Solvent Extraction. A total of 4 L of crude fungal culture filtrate of *D. australiensis* was collected and evaporated (45 °C) to yield 1.5 L of concentrated filtrate. Four organic solvents, viz. *n*-hexane, chloroform, ethyl acetate, and *n*-butanol, were successively used for extraction. These organic solvents were used in order of their increasing polarity. The organic solvent phases were collected and evaporated under vacuum in a rotary evaporator to yield crude organic fractions.[25]

Bioassays with Crude Organic Fractions. Bioassays with crude organic fractions were carried out following procedure described by Sarpeleh et al.[26] with some modifications. Seeds of *R. dentatus* were sown in plastic pots under natural environmental conditions. Young leaves from 30-day-old plants were detached, and discs of 1 cm diameter were cut with the help of a cork borer. These leaf discs were

placed on glass slides and punctured with the help of a fine needle. Glass slides were placed in a Petri plate on a filter paper wetted with 2 mL of sterilized distilled water.

Then 4 mg of each of the four crude fractions were dissolved in 100 μL of dimethylsulfoxide (DMSO). Final volume of each fraction was raised to 1.0 mL with distilled water to prepare a stock solution of 4 mg mL^{-1} concentration. The stock solution was serially double diluted by adding distilled water to prepare lower concentrations of 2, 1, ..., 0.0625 mg mL^{-1}. Droplets of 15 μL of each of the seven concentrations were applied on the punctured leaf discs surfaces. Ten leaf discs of the test weed species were used for each concentration. For blank control treatments, 100 μL of DMSO were dissolved in distilled water to prepare a 1.0 mL mixture and subsequent lower concentrations were made by double diluting it with distilled water. Petri plates were incubated at 25 °C under continuous fluorescent light in a growth room. Symptoms regarding appearance of necrotic spot and discoloration of leaf discs were observed after 72 h. Color scale 0–3 and necrotic spot scale 4–10 were used for comparisons following Mahoney et al.[27] with some modifications.

10 = necrotic spot ≤ 6 > 5 mm

Isolation of Compounds through Chromatographic Techniques. Crude chloroform fraction of culture filtrate of *D. australiensis* were selected for thin layer chromatography (TLC) analysis followed by separation of compounds through preparative thin layer chromatography (PTLC) and reversed phase high performance liquid chromatography.

A thin strip of aluminum foil backed TLC was used as chromatogram. First, 5 mg of crude chloroform fraction was taken in an Eppendorf tube and was dissolved in 1 mL of methanol. Then 10 mL of solvent (chloroform, ethyl acetate, and *n*-hexane) in a 10:6:84 ratio was used to elute the mixture of compounds spotted on chromatogram strip. Spots were located under UV transilluminator, both at short and long wavelengths as well as visualized by spraying ceric sulfate solution accompanied by heating with heat gun. Retention factor (R_f) value for each spot was calculated using the formula:

$$R_f = \frac{\text{distance traveled by component}}{\text{distance traveled by the solvent}}$$

Six fractions, namely **A** (R_f 0.096), **B** (R_f 0.130), **C** (R_f 0.170), **D** (R_f 0.269), **E** (R_f 0.480), and **F** (R_f 0.576), were isolated from chloroform fraction.

TLC fractions were further purified by preparative thin layer chromatography (PTLC). For preparative thin layer chromatography, precoated silica gel GF-254 preparative plates (20 cm × 20 cm, 0.5 mm thick, E-Merck) were used. Solvent system was same as in TLC. When developed with the solvent, the compounds separated in horizontal bands. These bands were scraped from the plates and eluted with methanol. Soluble compounds were carefully collected separately in another vial through filtration and were evaporated at 40 °C to dryness and weighed.

Compounds separated through PTLC were further subjected to reversed phase high performance liquid chromatography. For elution, acetonitrile (HPLC grade) with 0.1% formic acid was added and deionized water with 0.1% formic acid was used as solvent system. Gradient elution was employed with initial ratio of acetonitrile and deionized water as 10:90 with an increasing ratio of acetonitrile to water as 100:0. Fractions containing purified compounds were collected in glass vials, and solvent was evaporated under continuous currents of clean air at room temperature.

Bioassays with Purified Chromatographic Fractions. Bioassays with purified chromatographic fractions were generally carried out using the same method as was adopted in case of crude organic fractions. Stock solutions of 2 mg mL^{-1} of the various purified isolated constituents were prepared by dissolving 2 mg of the compound in 50 μL of DMSO and raised the volume to 1.0 mL by adding distilled water. Lower concentrations of 1, 0.5, ..., 0.03125 mg mL^{-1} were prepared by serially double diluting the stock solutions. In total, seven concentrations were made with distilled water viz. 2, 1, 0.5, 0.25, 0.125, 0.0625, and 0.03125 mg mL^{-1}. A set of blank control treatments with different concentrations of DMSO corresponding to DMSO concentration in various treatments of pure compounds was also included. Different concentrations of a known herbicidal compound 2,4-D (2,4- dichlorophenoxyacetic acid) were also included as positive control to compare with efficacy of the isolated compounds. Symptoms regarding appearance of necrotic spots and discoloration of leaf discs were observed after 72 h.

Spectroscopic Analyses. Structural elucidation by 1D and 2D NMR techniques of only the most active compounds was carried out. Less bioactive compounds were not subjected to mass spectroscopy because their bioactivity was far too low as compared to synthetic herbicide in use.

Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded in CD_3OD using TMS as internal standard at 600 MHz on Bruker AM-500 nuclear magnetic resonance spectrometers. The ^{13}C

[a]Color scale: 0 = no change; 1 = light discoloration; 2 = moderate discoloration; 3 = severe discoloration. [b]NS = necrotic spot. Necrotic spot scale: 4 = no necrotic spot; 5 = necrotic spot ≤ 1 mm; 6 = necrotic spot ≤ 2 > 1 mm; 7 = necrotic spot ≤ 3 > 2 mm; 8 = necrotic spot ≤ 4 > 3 mm; 9 = necrotic spot ≤ 5 > 4 mm; 10 = necrotic spot ≤ 6 > 5 mm.

NMR spectra were recorded in CD_3OD at 125 MHz on the same instrument.

EIMS spectra were recorded on a Finnigan MAT 311 with MASSPEC data system.

RESULTS AND DISCUSSION

Bioassays with Crude Organic Fractions. Positive reaction showing necrotic spots was recorded on punctured *R. dentatus* leaf discs surfaces. The chloroform fraction produced the most prominent necrotic spots followed by the ethyl acetate fraction. A 1.0 mg mL^{-1} concentration of crude chloroform fraction produced necrotic spot, while ethyl acetate fraction produced necrotic spots at a minimum concentration of 2.0 mg mL^{-1}. *n*-Hexane and *n*-butanol fractions did not produce any necrotic spot. Severe discoloration was also observed in the case of bioassays that performed well. In the case of the chloroform fraction, severe discoloration was observed due to 0.25 mg mL^{-1} and higher concentrations. In the case of the ethyl acetate fraction, severe discoloration was observed only at the highest concentration of 4.0 mg mL^{-1}. In the case of *n*-hexane and *n*-butanol fractions, discoloration was not much pronounced. Leaf sections treated with DMSO as a positive control exhibited only light discoloration (Table 1).

Bioassays with Purified Chromatographic Fractions. In these bioassays, out of six purified chromatographic fractions from crude chloroform fraction of culture filtrate of *D. australiensis*, four, viz. **A**, **C**, **D**, and **F**, were found effective in producing necrotic spot on leaf discs of *R. dentatus*. Among these, **A** and **F** were found to be the most herbicidal and produced necrotic spots on leaf discs surfaces at a minimum concentration of 0.5 mg mL^{-1}. Fraction **C** was found active at a minimum concentration of 1.0 mg mL^{-1}, while fraction **D** was found active at the highest concentration of 2.0 mg mL^{-1}. Chromatographic fractions **B** and **E** did not produce any necrotic spots. In the case of bioassays performed with reference compound 2,4-D, maximum bioactivity was observed at minimum concentration of 0.25 mg mL^{-1}. Discoloration of leaf discs was also observed to a variable extent in all the treatments. Fraction **C** and **F** induced severe discoloration at a concentration of 2.0 mg mL^{-1}. In contrast, only light discoloration was observed in case of 2,4-D, even at the highest concentration of 2.0 mg mL^{-1} (Table 2).

Spectroscopic Data of the Isolated Compound. Chromatographic fraction **F** exhibited the highest herbicidal activity, therefore, spectroscopic analysis of only this compound was carried out. Chromatographic fraction **F** was identified as compound **1** (Figure 1).

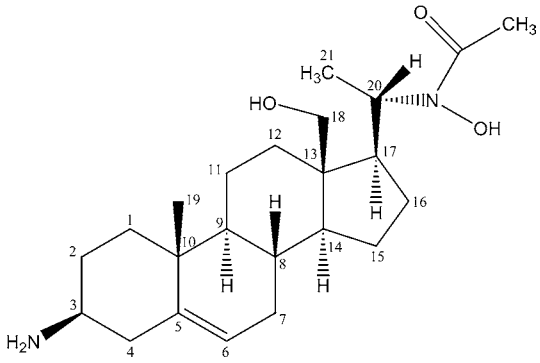

Figure 1. Chemical structure of holadysenterine.

Compound 1. Holadysenterine. Colorless amorphous powder; $[\alpha]_D^{28}$ −14.6° (*c* = 1.0, MeOH); mp 219.5–220.5 °C. EIMS *m*/*z*: $[M]^+$ 390 (2.0), 317 (4.5), 354 (3.5), 307 (60), 289 (22), 278 (65), 154 (25), 136 (54), 115 (48), 107 (50), 85 (100). HREIMS *m*/*z*: $[M]^+$ 390.3030 (calcd for $C_{23}H_{38}N_2O_3$ 390.3083). ^{1}H NMR (CD_3OD, 600 MHz) δ_H: 1.19 (1H, m, H-1), 1.33 (1H, m, H-1), 1.35 (1H, m, H-2), 1.44 (1H, m, H-2), 2.99 (1H, brm, H-3), 5.44 (brs 1H, m, H-6), 1.84 (2H, m, H-12), 1.33 (1H, m, H-17), 4.01 (1H, d, *J* = 10.9, H-18), 3.70 (1H, d, *J* = 10.9), 1.29 (s, 3H, H-19), 3.45 (1H, m, H-20), 1.38 (1H, d, *J* = 7.1 H-21), 2.01 (s, 3H, CO-Me).

Compound **1** (holadysenterine) was isolated as amorphous solid from the chloroform extraction. Molecular formula was obtained by HREIMS, showing a peak at *m*/*z* 390.3030 for $C_{23}H_{38}N_2O_3$ showing six degrees of unsaturation in the compound. Four unsaturations were accounted for by a tetracyclic pregnane type skeleton, and two were due to the endocyclic double bond and was due to the carboxyl function. The UV spectrum was inconclusive. Inspection of ^{1}H NMR spectrum of compound **1** showed olefinic proton at δ 5.44 (1H, br singlet). The spectra showed two doublets at δ 3.70 (1H, d, *J* = 10.9 Hz) assignable to the hydroxyl methylene protons. At δ 2.99 and 3.45, two broad multiplets were observed and were assigned to the H-3α and 20β, respectively. Two methyl singlets were observed at δ 1.29 and δ 2.0, while at δ 1.38 a

dx.doi.org/10.1021/jf403860b | J. Agric. Food Chem. 2014, 62, 368–372

characteristic methyl doublet was observed having J = 7.1 Hz. The downfield shift of methyl group at δ 2.0 indicated the presence of acetamide functionality in the molecule. A solvent exchangeable proton singlet due to *N*-hydroxy was observed at δ 4.98,[28] indicated its attachment at amine side chain functionality. EIMS spectrum gave peaks at m/z 317 [M + H − CH_3CONOH]+ (−C−N bond cleavage), 289 [M + H − $C_4H_8NO_2$]+ (C17−C20 bond cleavage) and 278 [M + H − $C_5H_8NO_2$]+ (C13−C17 and C16−C17 bond cleavage). This proves the attachment of a hydroxyl methyl group at the amine center. On the basis of this evidence and comparison with the literature data, compound **1** was assigned as (20*S*)-20 acetylhydroxylamine,3β-amino,13β-hydroxymethylenepregn-5-ene and named previously as holadysenterine.[29] Because of a lack of amount, ^{13}C spectrum was unpredictable, however, some 2D NMR spectra (HMBC, ^{1}H−^{1}H COSY) were showing some signals of ^{13}C and from which final structure of compound **1** was concluded.

In earlier studies, some herbicidal constituents have been isolated from other species of *Drechslera*. The culture of *Drechslera siccans* (Drechsler) Shoemaker is also reported to yield a phytotoxin named as 6,8-dihydroxy-3-(2′-hydroxypropyl) isocoumarin (de-*o*-methyldiaporthin). Phytotoxicity of this compound has been estimated in terms of necrotic spot area when tested on *Avena sativa*, *Echinochloa crus-galli*, and *Amaranthus spinosus*.[30] Capio et al.[20] isolated two phytotoxic compounds, namely cytochalasin B and dihydrocytochalasins, from extracts of dried mycelia and liquid culture filtrates of *Drechslera wirreganensis* Wallwork, Lichon & Sivan and *D. campanulata* (Lév.) B. Sutton. Similarly, another metabolite namely drazepinone with broad spectrum herbicidal activity has been isolated from *Drechslera siccans*.[15] The present study concludes that herbicidal activity of culture filtrates of *D. australiensis* is mostly due to holadysenterine.
